Atherosclerotic cardiovascular disease comprises coronary artery disease (CAD), cerebrovascular disease, and peripheral artery disease (PAD). CAD manifestations include stable CAD and acute coronary syndromes (ACS), which embrace a spectrum of clinical presentations, ranging from unstable angina to non-ST-elevation myocardial infarction (NSTEMI), and ST-elevation MI (STEMI). The common pathophysiologic processes of these cardiovascular disease conditions and their clinical manifestations consist in atherosclerotic plaque progression, thrombosis, or embolization. Mural thrombus formation is the consequence either of the spontaneous disruption of an atherosclerotic plaque as in the setting of an ACS or of iatrogenic endothelial denudation as in the setting of a percutaneous coronary intervention (PCI) [1]. Indeed, spontaneous or iatrogenic erosion of the endothelial surface or rupture of atherosclerotic plaque triggers platelet and coagulation activation, leading to arterial thrombosis, which blocks blood flow and oxygen supply (ischemia) in the affected arteries [1,2]. The mechanisms of arterial thrombosis require a close interplay between platelets, endothelium, coagulation factors, and the extracellular matrix of the vessel wall. In particular, arterial thrombosis comprises three basic pathways: (i) platelet adhesion, activation, and aggregation; (ii) blood coagulation with fibrin formation; and (iii) fibrinolysis. This chapter reviews the pathophysiology of the arterial thrombosis cascade and provides a general overview of current and novel antiplatelet and anticoagulant agents.

Role of platelets and coagulation factors in thrombus formation

Platelet-activated thrombus formation proceeds in three stages:

- 1 An initiation phase involving platelet adhesion;
- 2 An extension phase including activation, additional recruitment, and aggregation of platelets; and
- 3 A perpetuation phase characterized by continued platelet stimulation and stabilization of clots [1,3].

Under physiologic conditions, endothelial cells exhibit anti-thrombotic properties. The endothelial discontinuity of endothelial barrier exposes the subendothelial layer, which contains thrombogenic components, such as collagen, von Willebrand factor (vWF), and other molecules (e.g., fibronectin), which bind to platelet receptors, inducing platelet adhesion [3,4]. This latter is mainly mediated by interaction between the glycoprotein (GP) Ib/V/IX receptor complex on the platelet surface to vWF, which is required for initiation of platelet adhesion under high shear rate conditions, and GP VI and Ia to collagen at sites of vascular injury [4]. These interactions allow the arrest and activation of adherent platelets (Figure 38.1) [5].

Platelet activation and aggregation in the extension phase can be induced by multiple pathways (Figure 38.2) [5–7]. When activated platelets adhere to sites of vascular injury, the local platelet-activating factors help to recruit additional circulating platelets to extend and stabilize the plug [4]. These platelet-activating factors include adenosine diphosphate (ADP), thromboxane A₂ (TXA₂), serotonin, collagen, and thrombin [6]. ADP is one of the most important mediators of thrombosis. Platelets express two ADP-specific purinergic receptors: P2Y₁ and P2Y₁₂ [8]. Activation of the P2Y₁ receptor leads to signaling events that initiate a weak and transient phase of platelet aggregation [8]. In contrast, activation of the P2Y₁₂ receptor results in activation of the GPIIb/IIIa receptor, granule release, amplification of platelet aggregation, and stabilization of the platelet aggregate [8]. TXA₂ is a key platelet agonist, which derived from arachidonic acid through conversion by cyclooxygenase-1 (COX-1) and thromboxane synthase [9]. The binding of these agonists to their respective receptors ultimately activates the GP IIb/IIIa receptor, which promotes the interaction of adjacent platelets through fibrinogen (Figure 38.2) [7]. The perpetuation phase of thrombus formation is mediated by cell–cell, contact-dependent mechanisms, mostly intermediated by vWF under high shear stress conditions, which lead to changes in platelet morphology, expression of pro-coagulant and pro-inflammatory activities, and platelet aggregation [6].

Figure 38.1 Platelet adhesion, activation, and aggregation. The interaction between glycoprotein (GP) Ib and von Willebrand factor (vWF) mediates platelets tethering, enabling subsequent interaction between GP VI and collagen. This triggers the shift of integrins to a high-affinity state and the release of adenosine diphosphate (ADP) and thromboxane A₂ (TXA₂) which bind to the P2Y₁₂ and TP receptors, respectively. Tissue factor (TF) locally triggers thrombin formation, which contributes to platelet activation via binding to the platelet protease activated receptor (PAR-1). Figure 38.2 The platelet activation pathways and the coagulation cascade. Major platelet activation pathways are those stimulated by TXA₂, ADP, and thrombin. These agonists bind and activate their respective receptors, which in turn stimulate the activation of associated G-proteins, ultimately activating GP IIb/IIIa and promoting the interaction of adjacent platelets within the clot. In addition to its role in platelet activation, thrombin generated through the activity of the coagulation cascade or by the prothrombinase complex (factor Xa–factor Va) on the surface of activated platelets converts fibrinogen to fibrin, which adds stability to the growing plug. TP, thromboxane receptor; vWF, von Willebrand factor. Source: Adapted from Angiolillo *et al.* 2013 [7]. Reproduced with permission of Springer.

The platelet clot is stabilized by fibrin derived from the coagulation cascade (Figure 38.2) [7]. Initiation of blood coagulation occurs mainly through tissue factor (TF), a membrane GP that following vessel wall injury becomes exposed to circulating blood and forms a complex with the zymogen factor VIIa [10]. The TF-factor VIIa complex activates factor X into factor Xa and factor IX into factor IXa (extrinsic pathway) [10]. Generated factor Xa initially converts limited amounts of prothrombin into thrombin (factor IIa) sufficient to activate factors VIII, V, and XI, thus amplifying the coagulation process. In addition, thrombin activates platelets triggering coagulation on the platelet surface, through complex formation between factor IXa and its cofactor factor VIIIa (intrinsic tenasease complex), where factor IX is activated to factor IXa by factor XIa via the intrinsic pathway [11]. Thus, Factors IXa and Xa represent points of convergence for the intrinsic and extrinsic pathways. Finally, factor Xa in complex with its cofactor factor Va (prothrombinase complex) activates prothrombin to thrombin ultimately resulting in the formation of a fibrin clot (Figure 38.2).

Thrombin is a very potent platelet agonist that activates platelets at extremely low concentrations (lower than those required for its anticoagulant effect; Figure 38.2) [12,13]. Thrombin-mediated platelet activation contributes to pathologic thrombosis, but pre-clinical studies suggest it may not be required for protective hemostasis [12–16]. Thrombin-mediated cleavage of fibrinogen into fibrin is more important for hemostasis than thrombin-mediated platelet activation [17]. Thrombin activates platelets by binding protease-activated receptor-1 (PAR-1) on the platelet surface, leading to several processes that enhance thrombus formation (Figure 38.2) [17,18].

Overview of antiplatelet agents for atherosclerotic diseases

Aspirin

Aspirin (ASA) permanently inactivate platelet COX-1, blocking the production of TXA₂ [19]. ASA is rapidly absorbed in the stomach and upper intestine. Peak plasma levels occur 30–40 minutes after ASA ingestion, and platelet inhibition is evident by 1 hour. In contrast, it can take up to 3–4 hours to reach peak plasma levels after the administration of enteric-coated ASA. ASA is the cornerstone of oral antiplatelet therapy for the prevention of atherothrombotic events [19]. Indeed, several large-scale clinical trials and meta-analyses have consistently demonstrated the benefit of ASA in significantly reducing fatal and non-fatal recurrent ischemic events in patients with a large spectrum of atherosclerotic disease manifestations [20]. Although ASA is recommended for secondary prevention in all patients who have experienced ischemic cerebrovascular events or ACS and/or undergoing PCI, it is associated with limitations [21,22]. These include a dose-dependent increased risk for bleeding and residual morbidity and mortality higher than those for more recently developed antiplatelet agents when used as monotherapy in different clinical settings [23]. In addition to clinical observations, measurements of platelet aggregation, activation, and bleeding time have suggested a wide interpatient variability in response to a given dose of ASA, and the decreased responsiveness is associated with a higher risk for atherothrombotic events [24].

P2Y₁₂ ADP receptor antagonists

These agents include currently available thienopyridines (ticlopidine, clopidogrel, and prasugrel), and a cyclopentyltriazolopyrimidine (ticagrelor), as well as several compounds in late development (cangrelor) (Table 38.1) [5,25]. These drugs exert their clinical benefit by selectively inhibiting ADP-induced platelet aggregation.

Clopidogrel, a second-generation thienopyridine, has largely replaced ticlopidine, a first-generation thienopyridine, because of its better safety profile and its ability to yield a more rapid antiplatelet effect through the administration of a loading dose [26,27]. The safety and efficacy of clopidogrel has been evaluated in several clinical trials, which have been performed in patients with different manifestations of atherothrombotic disease, including CAD, cerebrovascular disease, and PAD [28–35]. Reduction in the risk of ischemic events observed in trials of clopidogrel plus ASA in patients with ACS and/or undergoing PCI have led to the use of dual antiplatelet therapy as standard-of-care therapy in these patient populations [21,22]. However, dual antiplatelet therapy has been associated with increased bleeding risk. A large amount of evidence has demonstrated a wide variability of response to clopidogrel [36]. Importantly, inadequate inhibition of the ADP platelet-activation pathway increases risk for thrombotic events [36].

Prasugrel is a third-generation thienopyridine, which, as with clopidogrel, is orally administered as a prodrug, needing conversion to an active metabolite to irreversibly block the P2Y₁₂ receptor [37]. However, prasugrel is more efficiently metabolized than clopidogrel, reaching higher concentrations of its active metabolite more rapidly, resulting in faster onset of action, enhanced platelet inhibition, and lower interindividual response variability, even when compared with higher loading (600 mg) and maintenance doses (150 mg) of clopidogrel [37–39]. Prasugrel has been compared with clopidogrel in the TRITON-TIMI 38 trial in patients with ACS undergoing PCI, providing lower ischemic events, driven by a reduction in myocardial infarction (MI), and higher bleeding complications, but with a more favorable net clinical benefit [40]. Prasugrel was also compared with clopidogrel in the large spectrum of medically managed ACS patients in the TRILOGY-ACS trial, but failed to show superiority [41]. Prasugrel (60 mg loading dose and 10 mg/day maintenance dose) is currently approved for the prevention of atherothrombotic events in patients with ACS undergoing PCI. In patients with NSTEMI, prasugrel has to be given after coronary anatomy is known in patients undergoing PCI, as pretreatment with this drug did not reduce the 30-day rate of major ischemic events but increased the rate of major bleeding [42]. Contraindications to prasugrel include prior cerebrovascular events (CVA), high bleeding risk, and hypersensitivity. Dose modulation (prasugrel 5 mg) is suggested in older and low-weight patients.

Ticagrelor is a direct-acting oral agent, which provides higher and a more consistent degree of platelet inhibition than clopidogrel, and more rapid time to maximal platelet inhibition [43]. Several studies consistently showed that ticagrelor, in addition to antagonizing the P2Y₁₂ receptor, inhibits the cellular uptake of adenosine. The adenosine-mediated mode of action contributes to several specific effects of ticagrelor, including increase in coronary blood flow, improved endothelial function, reduced mortality in

Table 38.1 Properties of current and emerging P2Y₁₂ ADP receptor antagonists.

Agent	Class	Mechanism of action	Mode of administration	Frequency of maintenance dose administration	Approval/development status
Ticlopidine	Thienopyridine (first generation)	Pro-drug, irreversible	Oral	Daily	Approved 1991
Clopidogrel	Thienopyridine (second generation)	Pro-drug, irreversible	Oral	Daily	Approved 1997
Prasugrel	Thienopyridine (third generation)	Pro-drug, irreversible	Oral	Daily	Approved 2009
Ticagrelor	Cyclopentyltriazolopyrimidine	Direct-acting, reversible	Oral	Twice daily	Approved 2011
Cangrelor	ATP analog	Direct-acting, reversible	IV	n/a	Phase 3 CHAMPION-PLATFORM and CHAMPION-PCI trials terminated 2009; CHAMPION-PHOENIX terminated 2013
Elinogrel	Quinazolidinedione	Direct-acting, reversible	IV and oral	Twice Daily	Phase 2 trials terminated

Source: Angiolillo DJ, et al. 2010 [5]. Reproduced with permission of the Japanese Circulation Society.

patients with ACS, increased incidence of ventricular pauses and of dyspnea, and increased creatinine levels [44]. Ticagrelor has been compared with clopidogrel in patients with ACS, both invasively and medically managed, in the PLATO trial, and was found to have superior efficacy, including lower cardiovascular mortality. Although overall major bleeding events were not increased, ticagrelor was associated with increased risk of spontaneous bleeding and higher rates of fatal intracranial hemorrhages [45]. Ticagrelor (180 mg loading dose and 90 mg twice daily maintenance dose) is currently approved for the prevention of atherothrombotic events in patients with ACS managed invasively or medically with no prior hemorrhagic stroke. Other contraindications include patients at high risk for bleeding, severe hepatic impairment, and hypersensitivity. There are several ongoing trials investigating ticagrelor in multiple therapeutic areas (e.g., secondary prevention, PAD, CVA, diabetes).

Cangrelor is a direct-acting, intravenously administered, highly selective P2Y₁₂ antagonist, with a short half-life (~2.6 minutes) [46]. It provides, in a dose-dependent manner, near-complete inhibition of ADP-induced platelet aggregation, with rapid onset and offset of action leading to recovery of platelet function within ~30–60 minutes after discontinuation [46]. Cangrelor has been compared with clopidogrel in three large-scale randomized trials in patients undergoing PCI, mostly for ACS. The first two trials (CHAMPION-PCI and PLATFORM), differing in the timing of study treatment start, failed to show any significant difference between the two treatments in ischemic events, probably in part because of a difficult adjudication of peri-procedural MI [47,48]. The recent CHAMPION-PHOENIX trial, using a more stringent definition of peri-procedural MI, has shown that cangrelor compared with clopidogrel significantly reduced ischemic events at 48 hours in about 11,000 patients undergoing PCI, including patients with stable CAD and ACS [49]. A pooled

analysis of patient-level data from the three cangrelor trials, cangrelor compared with control (clopidogrel or placebo) reduced PCI peri-procedural thrombotic complications, at the expense of increased bleeding [50]. The pharmacologic profiles of cangrelor make it an attractive strategy for bridging therapy of patients on dual antiplatelet therapy who are scheduled for surgery. The BRIDGE trial compared cangrelor (0.75 µg/kg/min) with placebo for at least 48 hours, with the study drug discontinued ~1–6 hours before surgery, in patients with ACS (n = 210) on a thienopyridine scheduled for cardiac surgery [51]. Cangrelor compared with placebo was shown to consistently achieve and maintain adequate platelet inhibition at levels known to be associated with a low risk of thrombotic events, at the price of an increase in minor bleeding [51].

Glycoprotein IIb/IIIa inhibitors

GP IIb/IIIa inhibitors interfere with platelet cross-linking and clot formation, by competing with fibrinogen and vWF for GP IIb/IIIa binding [4]. GP inhibitors are only intravenously administered within the hospital setting in patients with ACS undergoing PCI and are not used in the long-term care of patients with atherothrombotic disease. Investigations of oral GP inhibitors have been halted as a result of negative results from several large trials. The three parenteral GP inhibitors in clinical use are abciximab, eptifibatid, and tirofiban.

Abciximab is a monoclonal antibody with a rapid onset and a short plasma half-life (<10 minutes) [52]. However, because of its high binding affinity for the receptor, it has a biologic half-life of 12–24 hours. An estimated 30% of GP IIb/IIIa receptors are still occupied by abciximab 8 days after completion of infusion [52]. The efficacy and safety of abciximab in patients undergoing PCI, including primary PCI for STEMI, have been evaluated in several trials, predating the use of clopidogrel [53–56]. Overall, these

trials have shown that abciximab significantly improved PCI outcomes [53–56]. When abciximab was compared with placebo in patients undergoing PCI and receiving pretreatment (>2 hours) with clopidogrel 600 mg, additional benefits associated with abciximab were found only in high-risk patients with non-ST-elevation (NSTEMI) ACS with elevated levels of troponin, but not in those at low to intermediate risk undergoing elective PCI [57,58]. These observations suggest that when adequate inhibition of ADP-induced platelet aggregation is achieved, GP inhibitors should be restricted to high-risk ACS patients with positive cardiac markers. The issue of whether abciximab remains beneficial after adequate clopidogrel loading was tested also in patients (n=800) with STEMI in the BRAVE 3 trial, showing no benefits in terms of infarct size prior to discharge [59]. However, the infarct size 30 days after primary PCI for anterior STEMI was reduced by the use of an intracoronary bolus of abciximab in the INFUSE-MI trial [60].

Eptifibatid is a small, reversible, and highly selective, synthetic heptapeptide with a rapid onset, a short plasma half-life (mean 1 hour), and a renal clearance accounting for 40% of total body clearance [52]. Recovery of platelet aggregation occurs within 2–4 hours after infusion discontinuation. Several randomized clinical trials have shown the efficacy and safety of eptifibatid in patients with NSTEMI-ACS or undergoing PCI [61–63]. The EARLY-ACS trial demonstrated that upstream administration of eptifibatid versus provisional eptifibatid after angiography resulted in similar 30-day rates of ischemic complications during PCI in patients with NSTEMI-ACS [64]. Major and minor bleeding events were significantly higher with early eptifibatid versus delayed eptifibatid [64]. Overall, these findings do not support the use of upstream rather than selective downstream GP inhibitors in patients with ACS undergoing PCI.

Tirofiban is a non-peptide, tyrosine-derived, highly selective inhibitor associated with a rapid onset, a short plasma half-life (about 2 hours), and a renal clearance in that range of 25–50% [52]. The efficacy and safety of tirofiban in patients with ACS/PCI have been investigated in several trials [65,66].

Phosphodiesterase inhibitors

Cilostazol is indicated for symptomatic relief of intermittent claudication from PAD and does not have an indication for treatment of patients with CAD although it has been studied extensively in adjunct to aspirin and clopidogrel. Cilostazol is an inhibitor of phosphodiesterase type III with both antiplatelet and vasodilatory effects [67] and is associated with more potent platelet inhibitory effects when added to aspirin and clopidogrel [68]. During PCI, cilostazol added to aspirin and clopidogrel (“triple therapy”) was associated with a significantly reduced risk of stent thrombosis, angiographic restenosis, and clinical ischemic events without increased bleeding risk when compared with aspirin plus clopidogrel, especially among patients with diabetes [69]. An FDA warning indicates that cilostazol should be avoided in patients with congestive heart disease of any severity because of an increased mortality risk. Cilostazol is also frequently associated with headache, palpitations, and diarrhea.

Dipyridamole selectively inhibits the cyclic guanosine monophosphate (cGMP) phosphodiesterase type V enzyme, thus augmenting the antiplatelet effects of the NO–cGMP signaling pathway [70]. In a large ESPS II trial, dipyridamole with or without ASA effectively prevented stroke recurrence [71]. The

ESPRIT trial demonstrated that dipyridamole plus ASA versus ASA alone may not only provide protection against stroke recurrence but also against MI or death from vascular causes [72]. Results of the PROFESSION trial showed that there was no significant difference in the risk of fatal or disabling stroke in patients receiving dipyridamole plus ASA when compared with clopidogrel [73].

PAR-1 antagonists

PAR-1 inhibitors block the binding of thrombin to PAR-1, thus inhibiting thrombin-induced platelet activation and aggregation. Preclinical observations showed PAR-1 receptor inhibition does not interfere with thrombin-mediated fibrin generation which is essential for hemostasis [14]. Two PAR-1 inhibitors are under clinical development for the prevention of arterial thrombosis: vorapaxar and atopaxar [74].

Vorapaxar is a highly selective, orally active, potent and competitive PAR-1 antagonist. Phase 1 and 2 studies have shown that adding vorapaxar to ASA plus clopidogrel does not significantly increase bleeding, but may have the potential for reducing ischemic events. These results set the rationale for two large-scale phase 3 trials: the TRACER and TRA 2°P-TIMI 50 [75,76]. The TRACER trial randomized 12,944 high-risk patients with NSTEMI ACS, mostly already on dual antiplatelet therapy, to vorapaxar or placebo, but was halted prematurely because of a lack of reduction in overall ischemic events and a significant increase in the risk of major bleeding, including intracranial hemorrhage, in the investigational arm [75]. In the TRA 2°P-TIMI 50 trial, vorapaxar (2.5 mg/day) compared with placebo significantly reduced ischemic events, at the cost of increased moderate or severe bleeding, including intracranial hemorrhage, in patients (n=26,449) with a history of MI, ischemic stroke, or PAD [76]. Notably, after an interim analysis, the data and safety monitoring board recommended discontinuation of vorapaxar in patients with a history of stroke, because of an unacceptable risk of intracranial hemorrhage without an improvement in major vascular events, including ischemic stroke, as also shown by a subsequent subanalysis [77]. In contrast, another pre-specified subanalysis of the TRA 2°P-TIMI 50 showed that in patients with a history of MI, vorapaxar reduced ischemic events but increased the risk of moderate or severe bleeding [78]. Also, patients with PAD experienced less acute limb ischemia and peripheral arterial revascularization with vorapaxar, despite the higher risk of bleeding [79].

Clinical development of atopaxar is still in the early stage. Two phase 2 studies, LANCELOT-ACS and LANCELOT-CAD, have suggested a good safety profile of the drug in patients with ACS and CAD, respectively [80,81]. However, the highest doses of atopaxar compared with placebo were more commonly associated with QTc prolongation and transient liver enzymes elevation. Phase 3 investigations are not currently ongoing for atopaxar.

A meta-analysis of eight phase 2 and 3 trials of PAR-1 antagonists in patients (n=41,647) with CAD highlighted a higher risk of major bleeding, including intracranial hemorrhage, with the novel agents over placebo, paralleled by a significantly lower risk of MI, which was consistently noted in studies of vorapaxar and atopaxar [82]. Interestingly, a significant interaction was found between bleeding with PAR-1 antagonists and the use of P2Y₁₂ inhibitors, suggesting that future studies on these novel agents in patients not receiving a P2Y₁₂ inhibitor or studies versus P2Y₁₂ inhibitors on a background of ASA therapy might be considered.

Other novel antiplatelet agents

Other agents are targeted to inhibit TXA_2 -induced platelet activation mediated by TP receptors [83]. The rationale for the development of TP receptor antagonists (e.g., terutroban) is that platelets continue to be exposed to TXA_2 despite complete COX-1 blockade using ASA. Preclinical and clinical studies are currently ongoing for this family of platelet inhibitors as well as for other targets, including those targeted to inhibit serotonin and collagen receptors.

Overview of anticoagulant agents for atherosclerotic diseases

Anticoagulants are classified according to the target coagulation enzyme that is being inhibited (e.g., anti-factor IIa or antithrombins; anti-factor Xa; anti-factor IXa; Figure 38.3) [84]. They are further categorized based on whether inhibitory effects are direct or indirect (warranting a co-factor).

Thrombin inhibitors

Indirect thrombin inhibitors

Indirect thrombin inhibitors include unfractionated heparin (UFH) and low molecular weight heparins (LMWH). Thrombin has an active site and two exosites, one of which—exosite 1—binds to its fibrin substrate, orientating it toward the active site. UFH binds to exosite 2 on thrombin and also to antithrombin, forming a ternary complex, which is necessary for the inhibition of thrombin by antithrombin [85]. In contrast to thrombin inhibition, inactivation of factor Xa does not require the formation of the ternary complex. The ratio of anti-Xa to anti-IIa activity for UFH is equal to 1. LMWH derived from the fragmentation or the depolymerization of heparin by chemical or enzymatic process. Because most LMWH chains are not sufficiently long to form the ternary complex necessary for the inactivation of thrombin, their action is mainly directed against factor Xa, thereby the ratio of anti-IIa to anti-Xa activity varies from 1.9 to 3.8 (enoxaparin) [86].

The pharmacologic properties of UFH and LMWH are compared in Table 38.2. UFH has important limitations because of quite variable pharmacokinetic and pharmacodynamic profiles, significant non-specific protease binding, the inability to inhibit fibrin-bound thrombin, the prothrombotic effect on platelet activation and aggregation and, finally, the life-threatening risk of heparin-induced thrombocytopenia (HIT). Although to a less extent, part of these limitations are also associated with LMWH.

UFH and LMWH are routinely used in interventional practice as the standard anticoagulation for the treatment of patients with ACS and in the PCI setting [20,21]. In these populations, LMWH when compared with UFH has been found associated with a better overall efficacy profile and similar safety, while being more practical as, unlike UFH, it does not require anticoagulation monitoring and dose adjustment.

Direct thrombin inhibitors

Direct thrombin inhibitors (DTI) directly inhibit soluble and clot-bound thrombin without depending on antithrombin for anticoagulant activity. Indeed, they are physically small molecules that do not interact with exosite 2 but bind directly to the active site of thrombin and inhibit all its proteolytic activity without the need for antithrombin as an intermediary molecule. They have high specificity and potency for thrombin inhibition, and do not promote platelet aggregation. Given their potential benefits over heparins, parenteral DTIs have undergone extensive appraisal in patients with ACS or HIT, and those undergoing PCI. Three parenteral agents are currently available for clinical use in these populations: recombinant hirudin (lepirudin), argatroban, and bivalirudin [87]. The oral agent dabigatran, while approved for clinical use as a replacement for warfarin in patients with atrial fibrillation (AF), clinical investigation has been halted in the setting of ACS after the very high bleeding rates observed in adjunct to dual antiplatelet therapy in the phase 2 RE-DEEM trial [88].

Lepirudin is a peptide that binds to the catalytic site and exosite 1 of thrombin with very high affinity. It has a half-life of 80 minutes

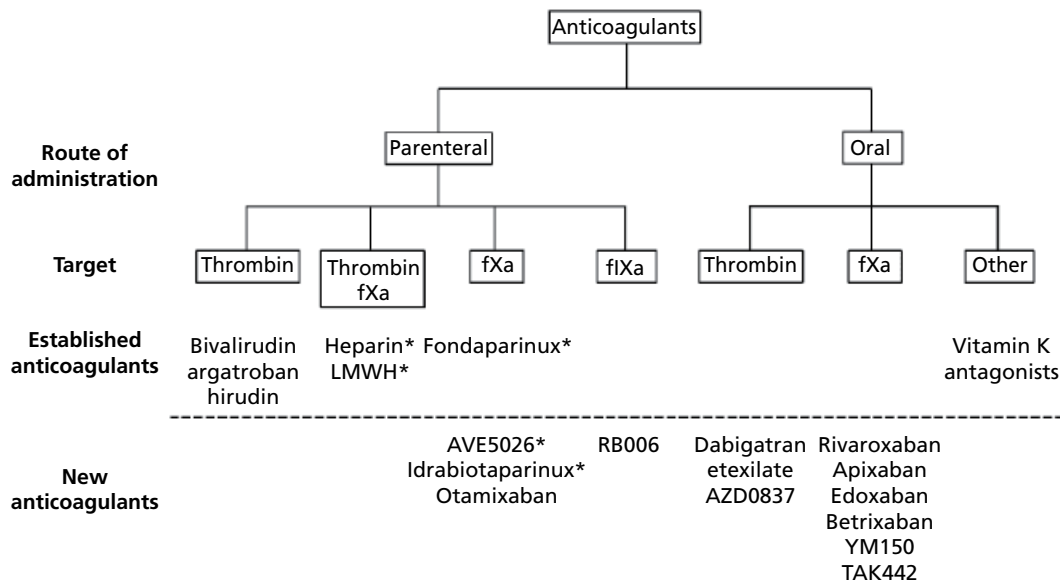

Figure 38.3 Established and new anticoagulants classified according to the target coagulation enzyme that is being inhibited. *Subcutaneously administered. Source: Eikelboom and Weitz 2010 [84]. Reproduced with permission of Wolters Kluwer Health.

Table 38.2 Comparison of pharmacologic properties of current anticoagulants.

Property	UFH	LMWH	Fondaparinux	Bivalirudin
Predictability in pharmacologic profile	–	++	+++	+++

Rebound of thrombin generation after discontinuation	+++	+	–	–
Inhibition of bound thrombin	–	–	–	+++
Neutralization by platelet factor 4	+++	+	+	+
Inhibition of thrombin generation	+	++	++	+++

LMWH, low molecular weight heparin; UFH, unfractionated heparin.

and is cleared primarily by the kidneys. It is approved for treatment of patients with HIT. No studies have evaluated the role of lepirudin in contemporary PCI.

Argatroban is a synthetic peptide competitive inhibitor of thrombin, binding to a site near the catalytic site [87]. It has a short half-life (45 minutes) and is mainly metabolized by the liver, requiring dose adjustment in patients with hepatic dysfunction. It is approved for treatment of patients with HIT. A few small studies have evaluated the effects of argatroban during PCI, and it is approved in this setting as an alternative anticoagulant only in patients with HIT [21].

Bivalirudin (hirulog-1) is a 20-amino acid polypeptide and is a synthetic version of hirudin that binds to the catalytic site and exosite 1 of thrombin. This binding is reversible and is associated with the cleavage near the amino-terminal of bivalirudin by thrombin itself [89]. When bivalirudin is cleaved, the bond between exosite 1 and the amino-terminal of the bivalirudin segment is weakened, leading to the dissociation and to restoration of normal thrombin activity [89]. Bivalirudin has a half-life of 25 minutes, which is prolonged by renal insufficiency, and is primarily cleared via proteolysis, with renal excretion accounting for <20% of its degradation. The pharmacologic properties of bivalirudin compared with those of heparins are listed in Table 38.2.

Bivalirudin is currently the only DTI that has been extensively evaluated in several powered clinical trials with respect to its use in coronary intervention in patients with stable CAD and in those with ACS, including NSTEMI and STEMI [90–95]. Multicenter trials on bivalirudin are consistent in showing that bivalirudin compared with heparin plus GP inhibitors is associated with comparable ischemic outcomes and reduced major bleeding. Bivalirudin is currently approved for use during PCI as an alternative to UFH and in patients with HIT.

Factor Xa inhibitors

Indirect factor Xa inhibitors

Fondaparinux is the prototype of the indirect factor Xa inhibitor. Other agents are variants of fondaparinux and include idraparinux, idrabiotaparinux, and SR123781A. All these agents are

subcutaneously administered. Only fondaparinux has been investigated in the setting of ACS/PCI.

Fondaparinux, a synthetic analog of the antithrombin-binding pentasaccharide sequence found in heparin, binds to antithrombin with very high specificity, enhancing the ability of antithrombin to neutralize factor Xa and hence the formation of thrombin. Fondaparinux has almost complete bioavailability after subcutaneous injection with rapid absorption, achieving a steady state after 3–4 daily doses. Its plasma half-life of approximately 17 hours allows once-daily administration at fixed dosages. It has a highly predictable anticoagulant effect and thus there is no need for laboratory monitoring. The pharmacologic properties of fondaparinux compared with those of heparins are listed in Table 38.2.

The efficacy and safety of fondaparinux (2.5 mg/day SC) compared to heparin were tested in patients with ACS [96–98]. In the NSTEMI-ACS population, fondaparinux was associated with superior net clinical benefit compared to enoxaparin [96–98]. In patients with STEMI, fondaparinux compared to UFH reduced the combined endpoint of death/MI in patients treated with thrombolysis, while those who underwent primary PCI had no significant benefit with fondaparinux [98]. Of concern, patients who underwent primary PCI with fondaparinux had more catheter-related thrombi, more coronary complications, and a trend toward higher death/MI compared to UFH. Fondaparinux is recommended for patients with NSTEMI-ACS in whom an early conservative or a delayed invasive strategy of management is considered and for STEMI patients receiving fibrinolytic therapy. Fondaparinux should not be used in patients with acute STEMI undergoing primary PCI. Despite guideline recommendations for the use of fondaparinux in ACS, fondaparinux is not approved for such use by the FDA in the USA.

Direct factor Xa inhibitors

Direct factor Xa inhibitors include parenteral agents, such as DX9065a and otamixaban, and several orally active drugs, including rivaroxaban, apixaban, edoxaban, darexaban, LY517717, and betrixaban. Only otamixaban, rivaroxaban, and apixaban have advanced to phase 3 clinical investigation in the setting of ACS/PCI.

Otamixaban is an intravenous, direct, reversible, selective inhibitor of factor Xa. It has an initial half-life of 30 minutes and rapid on–off anticoagulant activity. It is mainly cleared unchanged via the biliary system with no significant renal excretion (<25%), suggesting no need for dose modification in patients with renal insufficiency. Because of its predictable pharmacodynamics there is no need for anticoagulation monitoring. The SEPIA-ACS1 TIMI 42 trial showed a marked reduction in death/MI and similar bleeding rates with otamixaban at mid-range doses, compared with UFH plus eptifibatide [99]. These positive findings set the rationale for the investigation of otamixaban in phase 3 TAO randomized, double-blind, triple-dummy trial, in which otamixaban did not reduce the rate of ischemic events compared with UFH plus eptifibatide, but did increase bleeding in patients with NSTEMI ACS to be treated with dual oral antiplatelet therapy and an invasive strategy [100].

Rivaroxaban is an orally active oxazolidone derivative, which acts by directly and selectively inhibiting both free factor Xa and factor Xa bound in the prothrombinase complex. Rivaroxaban has a rapid and predictable anticoagulant effect with no need for dose adjustment or routine laboratory monitoring. The half-life is 9–13 hours and renal elimination accounts for 33%. It is approved for stroke prevention in patients with AF. A recent phase 3 trial (ATLAS ACS 2-TIMI 51) has evaluated rivaroxaban (2.5 or 5.0 mg twice daily) versus placebo on top of low-dose ASA (75–100 mg/day), with or without a thienopyridine, in 15,526 patients with ACS [101]. Rivaroxaban reduced the incidence of ischemic outcomes at the cost of increased bleeding. The 2.5 mg twice daily dose had the better risk–benefit balance, because of a lower bleeding risk than the 5 mg twice daily dose, with significant mortality reduction [101].

Apixaban is a potent direct inhibitor of both free and prothrombin-bound factor Xa, has a minimal affinity for factor IIa, a half-life of 8–15 hours, and is mainly eliminated via the fecal route (~75%). It is approved for stroke prevention in patients with AF. A recent phase 3 trial, APPRAISE-2, has evaluated apixaban 5 mg twice daily versus placebo on top of standard antiplatelet therapy in high-risk ACS patients [102]. The trial was stopped prematurely after recruiting 7392 of the preplanned 10,800 patients because an interim analysis showed that the increase of major bleeding with apixaban, including increases in fatal and intracranial bleeding, was not counterbalanced by the expected decrease in recurrent ischemic events compared with placebo. Importantly, the decrease in ischemic events was offset by an increase in bleeding both in patients taking only ASA and in those on dual antiplatelet therapy.

Other anticoagulants under clinical development

Investigations are ongoing on novel anticoagulants using recombinant proteins that are directed at the initiation of coagulation targeting tissue factor or factor VII. Another novel anticoagulant approach involves using RNA aptamer technology to target targeting coagulation factors (e.g., factor IXa). The advantage of this approach is the ability to initiate rapid anticoagulation that can be reversed immediately with a complementary RNA strand. The clinical safety and pharmacodynamic profiles of REG1, consisting of RB006 (drug), an injectable synthetic RNA aptamer that specifically binds and inhibits factor IXa, and RB007 (antidote), a complementary oligonucleotide that neutralizes the effect of RB006, have been evaluated in phase 1b and 2b studies in patients with stable CAD or ACS undergoing PCI and receiving standard antiplatelet therapy. In the phase 2b RADAR trial, the REG1 System with reversal from

50% to 100% compared to UFH or LMWH reduced major bleeding and ischemic events in 640 patients with ACS undergoing cardiac catheterization [103]. A large-scale phase 3 clinical investigation comparing REG1 with bivalirudin was interrupted because of serious adverse events related to allergic reactions.

Conclusions

Arterial thrombus formation is the common pathophysiologic process of different cardiovascular disease manifestations. Platelets and coagulation factors are key in this process. Identification of key targets within the platelet and coagulation cascade has been pivotal for the development of strategies aimed to reduce ischemic recurrences. Although recent advances in the field have yielded a greater reduction in ischemic events though their ability to achieve more potent blockade thrombotic processes, this has come at an increased risk of bleeding complications. Indeed, the future of antithrombotic therapies will rely on identifying treatment strategies that are able to find a fine balance between ischemic and bleeding risk. Emerging treatment regimens will represent a step forward toward reaching these goals.

Key points

- Arterial thrombus formation is the common pathophysiologic process of different cardiovascular disease manifestations. Platelets and coagulation factors are pivotal in this process.
- Key targets within the platelet and coagulation cascade have been identified for the development of pharmacologic strategies aimed to reduce ischemic events.
- Recently developed antiplatelet agents have yielded a greater reduction in ischemic events but associated with an increased risk of bleeding, especially in specific subgroups.
- Recently developed anticoagulant agents have more favorable pharmacologic properties and better safety and efficacy profile.
- New antithrombotic strategies are under development with the aim to find an optimal balance between ischemic and bleeding risk.

Disclosures

Dominick J. Angiolillo received payment as an individual for: (i) consulting fee or honorarium from Bristol Myers Squibb, Sanofi-Aventis, Eli Lilly, Daiichi-Sankyo, The Medicines Company, AstraZeneca, Merck, Abbott Vascular, and PLx Pharma; (ii) participation in review activities from Celonova, Johnson & Johnson, St. Jude, and Sunovion; (iii) institutional payments for grants from Bristol Myers Squibb, Sanofi-Aventis, Glaxo Smith Kline, Eli Lilly, Daiichi-Sankyo, The Medicines Company, AstraZeneca. Piera Capranzano has no conflicts of interest.

Balance of Ischemia and Bleeding in Selecting Antithrombotic Regimens

Bimmer E.P.M. Claessen and José P.S. Henriques

Department of Cardiology, Academic Medical Center – University of Amsterdam, Amsterdam, The Netherlands

In the USA, coronary revascularization by percutaneous coronary intervention (PCI) is performed over 1 million times annually [1]. However, PCI has only been associated with improved clinical outcomes when performed for acute coronary syndromes (ACS) [2,3]. In patients with stable coronary artery disease, there is an ongoing debate concerning the clinical usefulness of PCI. Although PCI is strongly associated with relief of anginal complaints and a reduction in the need for medication [4], no study to date has shown an improvement in terms of hard clinical endpoints (i.e., cardiac or all-cause mortality). Therefore, minimizing the number of ischemic and bleeding complications after PCI is an important priority for interventional cardiologists.

Rates of adverse outcomes after PCI vary widely. In general, adverse outcomes are more common after PCI for ACS compared with elective PCI. Moreover, rates of ischemic and bleeding complications tend to be lower in the selected patient populations of randomized clinical trials compared with unselected cohorts in observational studies. In this chapter, we aim to provide pharmacologic treatment strategies to optimize the safety and efficacy of PCI by minimizing the risk of ischemic and bleeding outcomes.

Definitions of the most common ischemic and bleeding outcomes

Uniform definitions of ischemic and bleeding complications of PCI are needed to adequately evaluate its safety and efficacy. However, there was a large variability in these definitions until as recently as 2007. In that year, an Academic Research Consortium (ARC) proposed definitions for a number of ischemic events which have subsequently been adopted across the world and are now being used in clinical research and practice [5]. Definitions of myocardial infarction (MI), restenosis, and stent thrombosis as proposed by the ARC are shown in Table 39.1. No definition for stroke was provided by the ARC; however, a useful definition was utilized in the HORIZONS-AMI (harmonizing outcomes with revascularization and stents in acute myocardial infarction) trial: “An acute neurologic deficit resulting in death or lasting for more than 24 hours, as classified by a physician, with supporting information, including brain images and neurologic/neurosurgical evaluation” [6].

Prior to 2011, when standardized bleeding definitions were proposed by the Bleeding Academic Research Consortium (BARC), a

wide variety of different definitions for bleeding were used such as thrombolysis in myocardial infarction (TIMI) [7], global utilization of streptokinase and Tpa for occluded arteries (GUSTO) [8], global registry of acute coronary events (GRACE) [9], CRUSADE [10], and many others. The BARC proposed an objective, hierarchically graded classification for bleeding which is shown in Box 39.1. A growing number of randomized clinical trials and observational studies have adopted this bleeding definition, mostly reporting only BARC bleeding ≥ 3 .

Outcomes after ischemic or bleeding complications

Both ischemic and bleeding complications are associated with an increased risk of mortality after PCI. A patient-pooled meta-analysis of three randomized trials comparing bivalirudin and heparin in PCI (n = 17,034) reported a hazard ratio for mortality of 4.2 and 2.9 after TIMI major bleeding and MI, respectively [11]. This study also showed that not all types of bleeding have similar effects on mortality as there was no increased risk of mortality after bleeding defined as a hematoma ≥ 5 cm at the arterial access site. This finding has also been reported by a number of other studies [12–14]. Interestingly, mortality is increased not only within the first 30 days after a bleeding event, but also thereafter. In contrast, some studies have suggested that MI is only associated with increased mortality within the first 30 days after the event [13]. The BARC bleeding definition has been validated in a patient-pooled analysis of six randomized trials of patients undergoing PCI [15]. BARC class ≥ 2 bleeding occurred in 9.9% of patients, and was associated with an increased 1-year mortality with an adjusted hazard ratio of 2.72. A retrospective analysis in over 2000 patients from an observational study in a large European tertiary care hospital indicated that the BARC bleeding classification can be used to identify STEMI patients at risk of 1-year mortality [16].

It remains unclear how a bleeding event contributes to an increased risk of mortality even beyond the first month after the event itself. A number of studies have reported suboptimal medical therapy in patients with bleeding events such as beta-blocker and statin therapy or a reduction in the use of antiplatelet agents, as has been reported in the PREMIER (prospective registry evaluating myocardial infarction: events and recovery) registry [17,18]. However, patient frailty and comorbidity have also been implicated as causal factors relating bleeding with an increased risk of mortality.

Table 39.1 Definitions of myocardial infarction, restenosis, and stent thrombosis.

Classification	Biomarker criteria	Additional criteria
Myocardial infarction		
Peri-procedural MI PCI	Troponin >3 times URL or CKMB >3 times URL	Baseline value <URL
Peri-procedural MI CABG	Troponin >5 times URL or CKMB >5 times URL	Baseline value <URL and any of the following: new pathologic Q waves± or LBBB, new native or graft vessel occlusion, imaging evidence of loss of viable myocardium
Spontaneous	Troponin >URL or CKMB >URL	
Sudden death	Death before biomarkers obtained or before expected to be elevated	Symptoms suggestive of ischemia and any of the following: new ST elevation or LBBB, documented thrombus by angiography or autopsy
Reinfarction	Stable or decreasing values on two samples and 20% increase 3–6 hours after second sample	If biomarkers increasing or peak not reached then insufficient data to diagnose recurrent MI
Angiographic restenosis		
Diameter stenosis of ≥50%		
Clinical restenosis		
Diameter stenosis of ≥50% and one of the following		
<ol style="list-style-type: none"> 1. A positive history of recurrent angina pectoris, presumably related to the target vessel 2. Objective signs of ischemia at rest (ECG changes) or during exercise test (or equivalent), presumably related to the target vessel 3. Abnormal results of any invasive functional diagnostic test (e.g., coronary flow velocity reserve, fractional flow reserve <0.80; IVUS minimum cross-sectional area under 4 mm² (and <6.0 mm² for left main stem) 4. A TLR with a diameter stenosis ≥70% even in the absence of the above-mentioned ischemic signs or symptoms 		
Stent thrombosis		
<i>Definite stent thrombosis:</i>		
Angiographic confirmation of stent thrombosis		
The presence of a thrombus that originates in the stent or in the segment 5 mm proximal or distal to the stent and at least one of the following within a 48-hour time window		
<ul style="list-style-type: none"> • Acute onset of ischemic symptoms at rest • New ischemic ECG changes that suggest acute ischemia • Typical rise and fall in cardiac biomarkers 		
Pathologic confirmation of stent thrombosis		
<ul style="list-style-type: none"> • Evidence of recent thrombus within the stent determined at autopsy or via examination of tissue retrieved following thrombectomy 		
<i>Probable stent thrombosis</i>		
Any unexplained death within the first 30 days		
Irrespective of the time after the index procedure, any MI that is related to documented acute ischemia in the territory of stent thrombosis and in the absence of any other obvious cause		
<i>Possible stent thrombosis</i>		
Any unexplained death from 30 days after intracoronary stenting		

CABG, coronary artery bypass graft surgery; CKMB, creatine kinase MB; ECG, electrocardiogram; IVUS, intravascular ultrasound; LBBB, left bundle branch block; MI, myocardial infarction; PCI, percutaneous coronary intervention; TLR, target lesion revascularization; URL, upper range limit.

Box 39.1 Bleeding definition according to the Bleeding Academic Research Consortium.

Type 0: no bleeding

Type 1: bleeding that is not actionable and does not cause the patient to seek unscheduled performance of studies, hospitalization, or treatment by a healthcare professional; includes episodes leading to self-discontinuation of medical therapy by the patient without consulting a healthcare professional

Type 2: any overt, actionable sign of hemorrhage (e.g., more bleeding than would be expected for a clinical circumstance, including bleeding found by imaging alone) that does not fit the criteria for type 3, 4, or 5 but does meet at least one of the following criteria: (1) requiring non-surgical, medical intervention by a healthcare professional, (2) leading to hospitalization or increased level of care, or (3) prompting evaluation

Type 3a: Overt bleeding plus hemoglobin drop of 3 to <5 g/dL (provided hemoglobin drop is related to bleed)

Any transfusion with overt bleeding

Type 3b: Overt bleeding plus hemoglobin drop ≥ 5 g/dL (provided hemoglobin drop is related to bleed)

Cardiac tamponade

Bleeding requiring surgical intervention for control (excluding dental/nasal/skin/hemorrhoid)

Bleeding requiring intravenous vasoactive agents

Type 3c: Intracranial hemorrhage (does not include microbleeds or hemorrhagic transformation, does include intraspinal)

Subcategories confirmed by autopsy or imaging or lumbar puncture

Intraocular bleed compromising vision

Type 4: CABG-related bleeding

Perioperative intracranial bleeding within 48 h

Reoperation after closure of sternotomy for the purpose of controlling bleeding

Transfusion of ≥ 5 IU whole blood or packed red blood cells within a 48-hour period

Chest tube output ≥ 2 L within a 24-hour period

Type 5: Fatal bleeding

Type 5a: Probable fatal bleeding; no autopsy or imaging confirmation but clinically suspicious

Type 5b: Definite fatal bleeding; overt bleeding or autopsy or imaging confirmation

CABG, coronary artery bypass graft surgery.

Stent thrombosis (ST) is a dreaded complication of intracoronary stenting and is associated with high rates of morbidity and mortality [19–21]. Recent studies have suggested that the timing of the ST event (e.g., in-hospital vs. out-of-hospital, or early vs. late/very late) is correlated with the risk of mortality. Early stent thrombosis or stent thrombosis occurring in-hospital has been associated with worse clinical outcome than late/very late stent thrombosis [19,22,23].

Methods to assess the risk of ischemic and bleeding complications

Risk factors for ischemic and bleeding complications are known to overlap. A number of risk scores have been developed to individualize risk stratification for patients undergoing PCI. Pocock *et al.* [24] investigated predictors of bleeding and MI in 13,819 patients with ACS undergoing an early invasive strategy randomized to heparin plus a glycoprotein IIb/IIIa inhibitor (GPI), bivalirudin plus a GPI, or bivalirudin monotherapy. Predictors of both MI and bleeding included older age, ST-segment deviation ≥ 1 mm at baseline. Moreover, three predictors for MI were identified: elevated baseline cardiac biomarkers, family history of coronary artery disease, and a history of a prior MI. Finally, predictors of bleeding were female sex, baseline anemia, use of heparin plus a GPI compared with bivalirudin monotherapy, elevated baseline serum creatinine, elevated baseline white blood cell count, no history of a prior PCI, prior stroke, and treatment with heparin plus routine upstream GPI compared with deferred selective GPI use. Therefore, estimating an individual patient's risk to develop ischemic complications and bleeding complications permits personalized clinical decision making.

Currently, a large number of risk scores exist for MI, mortality, ST, and bleeding that can be used to assess the risk profile of an individual patient. The GRACE [25] and TIMI risk scores for non-ST segment elevation acute coronary syndromes [26] and for ST-segment myocardial infarction (STEMI) [27] can be easily accessed on the internet and are widely used in clinical practice to assess the risk of ischemic events. Additionally, Table 39.2 shows a risk score that can be used to predict the risk of stent thrombosis in patients with STEMI undergoing primary PCI with stent placement [28].

Two bleeding risk scores that are particularly useful in clinical practice are the REPLACE2/ACUITY/HORIZONS-AMI PCI bleeding risk score [11], and the HAS-BLED risk score, which can be useful in patients already treated with warfarin for atrial fibrillation [29]. Table 39.3 shows the variables of which these risk scores are composed.

Pharmacologic strategies to reduce ischemic and bleeding complications

Antithrombotic therapies

Antithrombotic therapy in PCI is focused on minimizing thrombotic complications while limiting the number of bleeding events. Figure 39.1 shows an overview of currently available antithrombotic drugs. At present, unfractionated heparin and bivalirudin (a direct thrombin inhibitor) are the most widely used antithrombotic drugs during PCI. A number of studies have shown a reduction in bleeding with bivalirudin compared with unfractionated heparin (with or without a GPI) [11,30–32]. Moreover, some studies have reported increased survival with bivalirudin

Table 39.2 Integer-based risk score for 1-year definite/probable stent thrombosis in patients with acute coronary syndromes.

Variable	Integer assignment for stent thrombosis		Risk score	Calculation
Type of acute coronary syndrome	NSTE-ACS w/o ST changes +1	NSTE-ACS with ST deviation +2		STEMI +4
Current smoker	Yes: +1			No: +0
Insulin-treated diabetes mellitus	Yes: +2			No: +0
History of PCI	Yes: +1			No: +0
Baseline platelet count	<250 K/ μ L: +0	250 K/ μ L–400 K/ μ L: +1		>400 K/ μ L: +2
Absence of early (pre-PCI) heparin *	Yes: +1			No: 0
Aneurysm or ulceration	Yes: +2			No: 0
Baseline TIMI flow grade 0/1	Yes: +1			No: 0
Final TIMI flow grade under 3	Yes: +1			No: 0
Number of vessels treated	1 vessel: +0	2 vessels: +1		3 vessels: +2

NSTE-ACS, non-ST-segment elevation acute coronary syndrome; PCI, percutaneous coronary intervention; TIMI, thrombolysis in myocardial infarction.

*Includes parenteral heparin or low molecular weight heparin.

monotherapy compared with heparin with or without a GPI [33–35]. Cavender and Sabatine [36] recently conducted a meta-analysis of 33,958 patients undergoing PCI from 16 randomized controlled trials comparing bivalirudin and heparin (with or without a GPI). This study showed that a bivalirudin-based anticoagulation regimen increased the risk of MI (risk ratio [RR] 1.09, 95% confidence interval [CI] 1.01–1.17; $p=0.02$) and ST (RR 1.38, 95% CI 1.09–1.74; $p=0.007$). Overall, bivalirudin significantly reduced the incidence of bleeding events (RR 0.62, 95% CI 0.49–0.78; $p<0.0001$). However, this reduction in bleeding was limited to trials comparing bivalirudin with provisional GPI use with heparin with protocol mandated GPI use (RR 0.53, 95% CI 0.47–0.61; $p<0.0001$), with no significant reductions in trials comparing bivalirudin with provisional GPI use and heparin with provisional GPI use (RR 0.78, 95% CI 0.51–1.19; $p=0.25$) and trials comparing bivalirudin and heparin both with protocol mandated GPI use (RR 1.07, 95% CI 0.87–1.31; $p=0.53$).

Fondaparinux, a pentasaccharide factor Xa inhibitor, was compared with unfractionated heparin in patients with STEMI in the 12,092-patient OASIS-6 (organization to assess strategies in acute ischemic syndromes) randomized trial [37]. In this trial, fondaparinux was associated with a reduction in death or reinfarction at 3–6 months' follow-up. However, this benefit was limited to patients not undergoing primary PCI. In patients undergoing PCI there was a higher rate of guiding catheter thrombosis and more coronary complications such as abrupt coronary artery closure, no reflow, dissection, or perforation. Therefore current guidelines state that fondaparinux should not be used as the sole anticoagulant to support PCI. The addition of an anticoagulant with anti-IIa activity is advised [38].

Antiplatelet therapy

Aspirin and P2Y₁₂ inhibitors

An aspirin loading dose of 325 mg orally or 500 mg intravenously is administered before PCI. There is no consensus on the optimal

dose of aspirin after PCI. However, a number of studies have shown a reduction in major bleeding when using a low maintenance dose of aspirin (i.e., <100 mg/day) [39–41]. This finding may be explained by the fact that doses of as little as 50 mg aspirin can sufficiently block the enzyme cyclo-oxygenase 1 (COX 1) in platelets to prevent platelet aggregation [42]. Higher doses of aspirin can increase the risk of developing gastrointestinal bleeding by inhibiting COX 1 in gastric mucosal cells which inhibits the production of protective prostaglandins [43].

Clopidogrel, prasugrel, and ticagrelor inhibit platelet activation by antagonizing the adenosine diphosphate receptor P2Y₁₂. Clopidogrel and prasugrel irreversibly inhibit P2Y₁₂ while its inhibition by ticagrelor is reversible. Current guidelines recommend a loading dose of either 600 mg clopidogrel, 60 mg prasugrel, or 180 mg ticagrelor before PCI [38]. After balloon angioplasty alone or bare metal stent (BMS) implantation P2Y₁₂ inhibitors should be continued for 1 month. After drug-eluting stent (DES) implantation P2Y₁₂ inhibitors should be continued for at least 12 months according to US guidelines and for 6 months according to European guidelines [38,44]. Therefore, BMS implantation may be preferred in patients at high risk of bleeding or likely not to be compliant.

Both prasugrel and ticagrelor have been associated with improved clinical outcomes as compared with clopidogrel [45,46]. Clopidogrel is a prodrug that requires transformation by cytochrome P-450 (CYP) enzymes to establish its antiplatelet effect. Variability in CYP activity by common polymorphisms resulting in a reduced function have been associated with reduced circulating levels of the active metabolite of clopidogrel, diminished platelet inhibition, and a higher rate of ST [47]. Prasugrel also requires conversion to an active metabolite to act as an antiplatelet agent. However, prasugrel inhibits platelet aggregation faster, more consistently, and to a greater extent than clopidogrel in patients undergoing PCI [48]. Prasugrel was compared with clopidogrel in the large randomized TRITON-TIMI 38 (trial to assess improvement in therapeutic outcomes by optimizing platelet inhibition

Table 39.3 The REPLACE-2/ACUITY/HORIZONS-AMI PCI bleeding risk score and the HAS-BLED bleeding risk score in patients with atrial fibrillation.

(a) REPLACE-2/ACUITY/HORIZONS-AMI PCI bleeding risk score							
Serum creatinine (mg/dL)	<1.0 [0]	1.0-<1.2 [+2]	1.2-<1.4 [+4]	1.4-<1.6 [+6]	1.6-<1.8 [+8]	1.8-<2.0 [+10]	≥2.0 [+12]
Age (years)	<50 [0]	50-59 [+3]		60-69 [+6]		70-79[+9]	≥80 [+13]
Gender	Female [+5]						
White blood cell count (*10 ⁹)	<10 [0]	10-<12 [+1]	12-<14 [+2]	14-<16 [+4]	16-<18 [+5]	18-<20 [+6]	≥20 [+8]
Presentation	Normal biomarkers (elective and NSTEMI) [0]		NSTEMI- raised biomarkers [+3]			STEMI [+6]	
Current cigarette smoker	Yes [+4]						
Antithrombotic medications	Heparin + GPI [0]				Bivalirudin monotherapy [-6]		
(b) HAS-BLED risk score							
Hypertension	+1						
Abnormal renal and liver function	+1 (for each)						
Stroke	+1						
Bleeding	+1						
Labile INR	+1						
Elderly	+1						
Drugs or alcohol	+1 (for each)						

ACUITY, Acute catheterization and urgent intervention triage strategy trial; HORIZONS-AMI, Harmonizing outcomes with revascularization and stents in acute myocardial infarction; INR, international normalized ratio; NSTEMI, non ST-segment elevation myocardial infarction; PCI, percutaneous coronary intervention; REPLACE-2, randomized evaluation of PCI linking angiomas to reduced clinical events 2; STEMI, ST-segment elevation myocardial infarction.

with prasugrel – thrombolysis in myocardial infarction) trial [48]. In this moderate–high risk ACS population, prasugrel was associated with a reduction in MI, urgent revascularization, and ST. However, prasugrel was associated with an excess in (fatal) bleeding. Subgroup analyses of TRITON TIMI 38 have suggested an increased benefit of prasugrel in diabetic patients and patients with STEMI undergoing PCI [49,50]. Prasugrel is contraindicated in patients with a history of prior stroke or transient ischemic attack, and is only recommended in patients >75 years if they have diabetes mellitus or a history of a prior MI.

Ticagrelor is not a prodrug but rather a direct-acting reversible P2Y₁₂ inhibitor. It is dosed twice daily whereas clopidogrel and prasugrel are dosed once daily. The 18,624 patient PLATO (platelet inhibition and patient outcomes) trial comparing ticagrelor with clopidogrel in patients with ACS showed a reduction in death from vascular causes (ticagrelor group 4.0% vs. clopidogrel group 5.1%; $p < 0.001$) and death from any cause (ticagrelor group 4.5% vs.

clopidogrel group 5.9%; $p < 0.001$). Moreover, definite/probable stent thrombosis (2.2% vs. 2.9%) and MI (5.8% vs. 6.9%; $p = 0.005$) were lower in patients randomized to treatment with ticagrelor [45]. There were no differences in the rate of overall major bleeding. However, there was a higher rate of non-coronary artery bypass graft (CABG) related major bleeding with ticagrelor (4.5% vs. 3.8%). In patients undergoing PCI, the beneficial effects of ticagrelor were consistent with the overall results in the PLATO trial [51,52]. A post hoc analysis of the PLATO trial investigating patients with chronic kidney disease has suggested that ticagrelor compared with clopidogrel significantly reduces ischemic end-points and mortality with similar rates of major bleeding [53].

Glycoprotein IIb/IIIa inhibitors

In the current era of dual antiplatelet therapy the role of GPIs is unclear, as most trials of GPIs in PCI were performed before the introduction of dual antiplatelet therapy. GPIs such as

Parenteral anticoagulants	Enteral anticoagulants
<i>Xa/IIa inhibitors:</i>	<i>Direct thrombin inhibitors:</i>
Unfractionated heparin	Dabigatran
Enoxaparin	<i>Xa inhibitors:</i>
<i>Xa inhibitors:</i>	Rivaroxaban
Foundaparinux	Apixaban
Otamixaban	Edoxaban
<i>Direct thrombin inhibitors:</i>	Rivaroxaban
Argatroban	
Bivalirudin	
Hirudin	
Parenteral antiplatelet agents	Enteral antiplatelet agents
<i>COX-I inhibitor:</i>	<i>COX-I inhibitor:</i>
IV aspirin (Aspegic)	Aspirin
<i>Glycoprotein IIb/IIIa inhibitors:</i>	<i>P2Y12 antagonists:</i>
Eptifibatide	Clopidogrel
Tirofiban	Prasugrel
Abciximab	Ticagrelor
<i>P2Y12 antagonists:</i>	<i>PAR-1 antagonists:</i>
Cangrelor	Vorapaxar

eptifibatide, tirofiban, and abciximab are intravenous antiplatelet agents that antagonize platelet aggregation by inhibiting the glycoprotein IIb/IIIa receptor. GPIs have been associated with an increased risk of bleeding and their use may therefore best be limited to patients not at high risk of developing bleeding complications [31,54]. Clinical trials in patients undergoing elective PCI pretreated with P2Y12 inhibitors have not shown any benefit of GPIs [55,56]. In patients with unstable angina or non-ST elevation ACS, GPIs may be associated with a reduction in ischemic outcomes [57]. Finally, in patients with STEMI the use of GPIs is generally limited to patients with large anterior MI or a large thrombus burden who have a high risk of ischemic events and a low risk of bleeding events. Moreover, bolus administration of GPIs can be considered as a bailout strategy in patients with a high risk of ischemic events but also a high risk of bleeding.

New oral anticoagulants after PCI

Novel oral anticoagulant drugs are also being investigated after PCI. The ATLAS ACS-TIMI 51 (Anti-Xa therapy to lower cardiovascular events in addition to standard therapy in subjects with acute coronary syndrome – thrombolysis in myocardial infarction) trial showed a reduction in death from cardiovascular causes, MI, or stroke in patients with a recent ACS with the addition of twice-daily 2.5 mg of the novel oral Xa inhibitor rivaroxaban [58]. The results of additional randomized clinical trials evaluating the use of oral anticoagulant drugs after PCI are eagerly awaited.

Figure 39.1 Overview of currently available antithrombotic drugs.

<p>Low bleeding risk, low ischemic risk Preloading with: Aspirin and clopidogrel Anticoagulant therapy: Bivalirudin or unfractionated heparin Antithrombotic therapy at discharge: Aspirin, clopidogrel</p>	<p>Low bleeding risk, high ischemic risk Preloading with: Aspirin and prasugrel or ticagrelor* Anticoagulant therapy: Heparin plus a glycoprotein IIb/IIIa inhibitor Bivalirudin Antithrombotic therapy at discharge: Aspirin, prasugrel or ticagrelor, consider low-dose rivaroxaban</p>

Figure 39.2 Algorithm suggesting antithrombotic strategies according to bleeding and ischemic risk.

Conclusions and recommendations for clinical practice

In general, a more aggressive anticoagulant regime will be associated with a reduction in ischemic events at the cost of an increased risk of bleeding. It is therefore paramount that all patients undergoing PCI should be evaluated for risk of bleeding. Patients at a low risk of bleeding will derive benefit from more aggressive antithrombotic therapy. However, patients at a high risk of bleeding will benefit from selective use of antithrombotic agents. On the other hand, the risk of developing ischemic complications should also be assessed, as patients undergoing PCI for ACS may benefit from more effective antithrombotic therapy (especially in STEMI) [38].

Figure 39.2 shows a treatment algorithm suggesting antithrombotic therapeutic options in patients undergoing PCI according to their bleeding and ischemic risks. Many new antithrombotic drugs are still being investigated and there is a large variety of antithrombotic drugs currently available, allowing extensive pharmacologic personalization (Figure 39.1).

In addition to acting as the immediate effector of primary hemostasis, platelets are a critical mediator of atherothrombosis, following atherosclerotic plaque rupture in coronary artery disease (CAD). Oral antiplatelet therapy (APT) is a critical therapeutic strategy in the prevention and management of acute coronary syndrome (ACS; comprising non-ST-elevation ACS (NSTEMI) and ST-elevation myocardial infarction (STEMI)), and as an adjunct in percutaneous coronary intervention (PCI) [1,2]. The objectives of APT pharmacotherapy in PCI are twofold: (i) to mitigate the sequelae of iatrogenic plaque rupture in angioplasty or stenting; and (ii) to reduce the risk of intravascular and in-stent thrombus formation [3].

Oral antiplatelet agents recommended in the contexts of ACS and PCI operate by one of two major mechanisms: (i) inhibition of prostaglandin synthesis via cyclo-oxygenase isoform 1 antagonism (COX-1; e.g., aspirin); or (ii) inhibition of platelet aggregation, via adenosine diphosphate (ADP) P2Y₁₂-receptor antagonism (e.g., ticlopidine, clopidogrel, prasugrel, and ticagrelor). Although other classes of agent have been evaluated in clinical trials, dual antiplatelet therapy (DAPT) with aspirin and a P2Y₁₂-receptor antagonist remains the evidence-based mainstay of oral antiplatelet therapy in PCI. However, despite the benefits of this strategy, a considerable number of patients experience adverse, recurrent, peri- and post-procedural ischemic and atherothrombotic complications (e.g., reinfarction and stent thrombosis) [4–8]. As such, significant room for further optimization of antiplatelet therapy exists.

In general, greater potency platelet inhibition efficaciously translates into reduced risk of atherothrombotic and ischemic events, but at the expense of greater risks of bleeding. Indeed, even minor bleeding episodes can lead to non-compliance with therapy. As such, all decisions regarding the selection of APT must be in close collaboration with the patient; striving to achieve an optimal balance between safety and efficacy, maximizing prevention of ischemia and minimizing risk of hemorrhage.

The aim of this chapter is to summarize the clinical evidence regarding the optimization of oral antiplatelet therapy for patients undergoing PCI. It will consider the evolution of antiplatelet therapy as an adjunct to PCI, and explore emerging antiplatelet agents presently undergoing clinical development. The role of

peri-procedural intravenous antiplatelet therapy, and combinations of antiplatelet and anticoagulant agents, is outside the scope of this review, and is considered elsewhere.

Methods

A series of structured searches of major biomedical databases (PubMed, Medline, Embase, and Web of Science) were performed on October 20, 2014, using the key terms “antiplatelet,” “percutaneous coronary intervention,” “acute coronary syndrome,” “platelet function,” “platelet reactivity,” and “pharmacogenetics.” Only articles published in English, between 1950 and 2014, were included. This is a synthesis of available clinical data regarding oral antiplatelet therapy during PCI.

Background

Platelet activation: pathophysiology and pharmacotherapeutic targets

During intra-arterial thrombosis, platelets become activated as a sequela of rupture, fissure, or erosion of a vulnerable, mural atherosclerotic plaque. The recruitment of platelets to the site of rupture results from complex interactions between specific platelet cell-surface receptors (e.g., platelet glycoprotein VI) and exogenous substrates (e.g., collagen, von Willebrand factor), which expose acidic phospholipids and induce conformational change in the platelet surface membrane. Following adhesion to the vessel wall, platelet-platelet aggregation occurs via synergistic adenosine diphosphate (ADP; P2Y₁, and P2Y₁₂) and glycoprotein (GP) IIb/IIIa receptor-mediated binding. Degranulation of a cocktail of pro-inflammatory mediators occurs, releasing thromboxane A₂ (TxA₂) and ADP, triggering further platelet activation and aggregation. The exposure of acidic phospholipids activates the coagulation cascade; thrombin-mediated cleavage of fibrinogen to insoluble fibrin culminates in the formation of an occlusive thrombus. Thrombin also interacts with platelets at protease-activated receptors (e.g., PAR-1), enhancing degranulation, and perpetuating further activation. Thus, the platelet is a complex structure, with numerous pharmacologic antithrombotic targets (Figure 40.1).

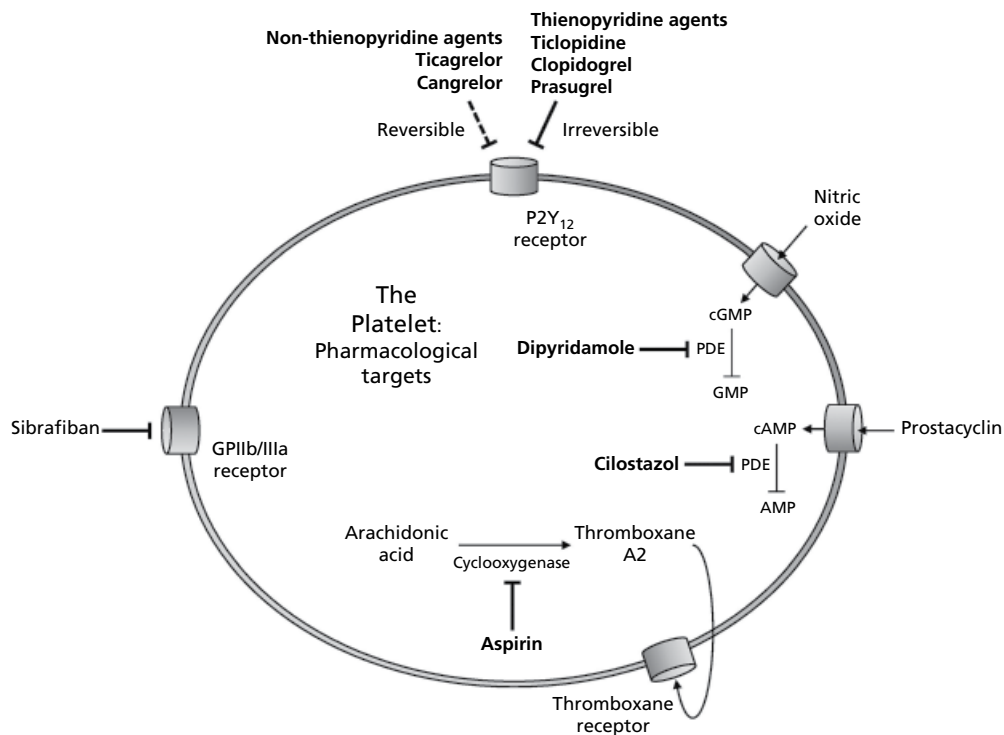

Figure 40.1 A simplified representation of the platelet and selected targets of oral antithrombotic agents.

Oral antiplatelet agents: pharmacology

Antiplatelet agents act via the inhibition of platelet recruitment, adhesion, aggregation, or activation. Aspirin is a ubiquitous, irreversible, non-specific inhibitor of COX, abrogating the downstream synthesis of TxA_2 from arachidonic acid, via selective acetylation of a serine residue at position 529. TxA_2 induces changes in platelet shape and enhances recruitment and aggregation, via binding to thromboxane and prostaglandin endoperoxide (TP) receptors. The thienopyridine-class agents (ticlopidine, clopidogrel, and prasugrel; first, second, and third generation, respectively) act via irreversible platelet ADP P2Y_{12} -receptor antagonism. Although both P2Y_1 and P2Y_{12} cause aggregation, P2Y_{12} -mediated activation is the principal pathway. The thienopyridines are prodrugs; clopidogrel undergoes hepatic activation via a double-oxidation process mediated by the hepatic cytochrome (CYP) P450 system (predominantly CYP2C19) to an active metabolite, which inhibits the ADP P2Y_{12} receptor for the lifespan of the platelet (7–10 days). Prasugrel has distinct pharmacokinetic advantages over clopidogrel: it undergoes more efficient hepatic biotransformation into the active form (with a single oxidation stage), has a more rapid onset of action, and demonstrates reduced variability in response, even compared to high-dose clopidogrel [9]. The non-thienopyridine, cyclopentyl-triazolopyrimidine agent ticagrelor is a reversible ADP P2Y_{12} -receptor antagonist, at an allosteric binding site. Unlike the thienopyridines, ticagrelor is administered in active form, and thus has a rapid onset of action, producing potent and consistent platelet inhibition. However, as ticagrelor has a plasma half-life of 8–12 hours, twice daily dosing is required (c.f. the previous agents, for which once daily dosing is sufficient). Additional oral antiplatelet drugs include sibrifiban, which acts to inhibit the GP IIb/IIIa receptor, and cilostazol, a selective phosphodiesterase-3 (PDE-3) inhibitor, which increases cyclic adenosine monophosphate (cAMP), leading to protein kinase

A (PKA) activation and inhibition of platelet aggregation. Novel oral antiplatelet agents under development include antagonists of the TxA_2 and PAR-1 pathways.

Oral antiplatelet therapy and PCI

Since the first demonstration of human coronary angioplasty in 1978 [10], interventional cardiology techniques, equipment, peri- and post-procedural care has evolved significantly, leading to major improvements in therapeutic outcomes. Most significantly in the context of this chapter, the pharmacotherapy recommended during PCI has undergone many incremental and beneficial iterations. Antiplatelet therapy has emerged as a critical determinant of outcome following PCI, in both the management of stable CAD, and ACS. However, significant questions remain unanswered regarding the optimal agent(s), combination, and dosing regimen in oral antiplatelet therapy.

Aspirin (acetylsalicylic acid, ASA)

The role of aspirin in all patients with (or at high risk of) cardiovascular disease, is well defined. Evidence-based guidelines universally advocate that such patients should routinely and indefinitely receive low-dose (75–100 mg) aspirin, after an initial loading dose of 300–325 mg, in ACS [1,2]. A meta-analysis by the Antithrombotic Trialists' Collaboration of 287 studies of aspirin therapy in high-risk patients with cardiovascular disease (including over 135,000 patients) definitively established the benefits of such therapy; aspirin therapy reduced incidences of death, myocardial infarction (MI), and stroke by 25% [11]. However, a dose-dependent risk for (specifically, upper gastrointestinal) bleeding, with no bearing on efficacy, was observed. Thus, aspirin is routinely given to all patients with CAD, and was assumed to

equally benefit those undergoing, and not undergoing, an invasive management strategy.

Early evidence regarding the benefits of aspirin in the specific context of coronary revascularization arose from ISIS-2, a double-blind, randomized, two-by-two factorial, placebo-controlled trial, which evaluated the effect of aspirin as an adjunct to thrombolysis (streptokinase) in the management of acute MI. This study, which randomized 17,187 patients, demonstrated that 1 month of aspirin, given alone or in combination with revascularization therapy, significantly improved outcome [12,13]. Contemporaneous insight into optimal aspirin dosing emerged from the CURRENT/OASIS-7 trial, in which 25,087 patients with ACS undergoing angiography were randomized to receive either open-label high (300–325 mg/day) versus low (75–100 mg/day, after initial 300 mg) dose aspirin for a month, in addition to high or standard dose of clopidogrel [14]. Although no differences between high and low dose aspirin were observed in overall efficacy (4.2% vs. 4.4%, hazard ratio (HR) 0.97, 95% confidence intervals (CI) 0.86–1.09; $p=0.61$) or hemorrhage (2.3% vs. 2.3%, HR 0.99, 95% CI 0.84–1.17; $p=0.90$), the high dose aspirin treatment was non-significantly associated with gastrointestinal bleeding (0.38% vs. 0.24%; $p=0.051$) at 30 days. Further, a sub-study of the HORIZONS-AMI trial followed-up 2851 patients with STEMI who underwent primary PCI [15]. Of these, 2289 were discharged on low dose aspirin (≤ 200 mg/day) and 562 on high dose aspirin (>200 mg). Patients receiving high dose aspirin were more likely to have multiple cardiovascular risk factors and, accordingly, had greater 3-year rates of major adverse cardiovascular events (MACE) and significant bleeding. However, multivariate analysis demonstrated that high dose aspirin was significantly associated with a greater rate of major bleeding (HR 2.80, 95% CI 1.31–5.99; $p=0.008$) but not MACE. These data demonstrate that after an appropriate loading dose prior to PCI (300 mg), which efficaciously improves peri-procedural outcomes, a low dose regimen (75 mg/day) is most appropriate for the long-term secondary prevention of cardiovascular events.

Subsequently, studies have established an association between poor responsiveness to aspirin (high on-aspirin platelet reactivity), and adverse outcomes peri- and post-PCI [16]. In studies that utilize robust COX-1-specific assays (e.g., serum TxA_2 quantification), the prevalence of the resistant phenotype is less than 5% of aspirin-treated patients [16]. A recent registry study of on-aspirin platelet reactivity, ISAR-ASPI, which quantified platelet function in 7090 PCI-treated patients, observed that high on-aspirin platelet reactivity was associated with a significantly increased risk of all-cause mortality or stent thrombosis at 30 days (2.5% vs. 1.1%, odds ratio (OR) 2.24, 95% CI 1.50–3.36) and 1-year (6.2% vs. 3.7%, OR 1.78, 95% CI 1.39–2.27; $p<0.0001$) compared to those with normal platelet reactivity [17]. However, a major cause of apparent “aspirin resistance,” and a major confounder, is poor patient compliance. Additional factors implicated include genetic polymorphism (e.g., in COX-1), and drug–drug interactions (e.g., with ibuprofen). These resistance phenotypes may require evaluation during post-PCI follow-up, in order to ensure treatment compliance and optimize lifelong aspirin dosing.

Thienopyridine P2Y₁₂ receptor antagonists

Ticlopidine

Dual antiplatelet therapy with ticlopidine and aspirin emerged as the standard of care after PCI in the mid-1990s, as a result of a number of trials demonstrating the superiority of this combination over aspirin monotherapy [18,19], and other available antithrombotic

agents [19–22]. The addition of 250 mg ticlopidine twice daily was associated with fewer thrombotic and hemorrhagic complications. However, as a result of the delayed onset of action of ticlopidine, several days were required to achieve full antiplatelet effects, limiting immediate efficacy in ACS [23].

Clopidogrel

Following regulatory approval, clopidogrel rapidly superseded ticlopidine as the second antiplatelet of choice in PCI, as a result of a faster onset of action via administration of a loading dose [24]. The favorable safety profile of clopidogrel was first demonstrated in the CLASSICS trial, which randomized 1020 patients to receive 325 mg/day aspirin, and either: (i) 300 mg clopidogrel loading dose, followed by a 75 mg maintenance dose, (ii) 75 mg/day clopidogrel, or (iii) 250 mg twice daily dose of ticlopidine [25]. The primary endpoint was a composite of major bleeding complications, other significant side effects, or discontinuation of the study drug. At 28 days' follow-up, 4.6% clopidogrel-treated versus 9.1% ticlopidine-treated patients satisfied criteria for this endpoint (relative risk (RR) 0.50, 95% CI 0.31–0.81; $p=0.005$). The overall rate of MACE (cardiac death, MI, target lesion revascularization) remained comparable between groups (1.2 vs. 0.9 vs. 1.5 for groups (i), (ii), and (iii), respectively; p = not significant). However, CLASSICS randomized patients post-PCI; further studies were required to ascertain the effects of pretreatment clopidogrel.

Subsequent trials definitively demonstrated the incremental benefit of clopidogrel pretreatment, in reducing MACE during PCI, in ACS and stable angina [4–8]. First, the CURE trial randomized 12,562 patients in double-blind fashion to receive clopidogrel (300 mg pretreatment loading dose; 75 mg maintenance dose) or placebo [4]. A total of 2658 of these patients had NSTEMI and underwent PCI as part of the PCI-CURE sub-study [26]. The primary endpoint was a composite of cardiovascular death, MI, and target vessel revascularization, within 30 days of PCI. This endpoint was reached in 4.5% and 6.4% in the clopidogrel-treated and placebo-treated groups, respectively (RR 0.70, 95% CI 0.50–0.97; $p=0.03$). This reduction in MACE was maintained to 9 months' follow-up ($p=0.002$), with no differences in major bleeding ($p=0.64$). This demonstrated that pretreatment with clopidogrel improved outcomes for invasively managed patients with NSTEMI, without significant risks of bleeding.

Further trials were performed to optimize the clopidogrel dosing regimen. The ARMYDA-2 trial randomized 255 patients scheduled to undergo PCI to receive either a 600 or 300 mg loading dose, given 4–8 hours pre-procedure [27]. At 30 days, the primary endpoint (death, MI, or target vessel revascularization) occurred in 4% and 12% of patients in the high and low-loading dose groups, respectively ($p=0.041$). Multivariate analysis demonstrated a 50% risk reduction in MI associated with the high-loading dose (OR 0.48, 95% CI 0.15–0.97; $p=0.044$). All safety endpoints (including bleeding) were similar between the two groups. Thus, this small trial indicated that a 600-mg loading dose was safe, and offered greater efficacy, compared to the conventional 300-mg loading dose, in patients undergoing PCI. The aforementioned CURRENT/OASIS-7 study also evaluated a high dose clopidogrel regimen (600 mg loading dose; 150 mg/day maintenance dose post-PCI days 2–7; 75 mg maintenance dose) versus the standard dose regimen, in ACS patients ($n=25,087$), treated conservatively and invasively [14,28]. Overall, the efficacy of the high dose and conventional regimens was equivalent, with similar 30-day MACE rate (4.2% vs. 4.4%,

HR 0.94, 95% CI 0.83–1.06; $p=0.30$), but increased major bleeding (1.7% vs. 1.3%, HR 1.26, 95% CI 1.03–1.54; $p=0.03$). In prespecified subgroup analysis of invasively managed patients ($n=17,263$), the high dose regimen led to fewer MACE (3.9 vs. 4.5, HR 0.86, 95% CI 0.74–0.99; $p=0.039$), but greater major bleeding (1.6% vs. 1.1%; HR 1.41, 95% CI 1.09–1.83; $p=0.009$).

Additional trials offered insight into the optimal timing of clopidogrel pre-treatment. CREDO randomized 2116 patients (scheduled for elective PCI) to receive 300 mg clopidogrel loading dose, or placebo, 3–24 hours pre-PCI, and 75 mg maintenance dose thereafter [5,29]. At 1 year, clopidogrel was associated with a significant reduction in the primary endpoint (composite of death, MI, stroke, and target vessel revascularization; RR 0.73, 95% CI 0.66–0.96; $p=0.02$). Clopidogrel administration more than 6 hours pre-procedure (but not thereafter) was associated with significant benefit. Clopidogrel was not associated with a greater risk of major bleeding (8.8% vs. 6.7%; $p=0.07$). Further to this, ARMYDA-5 PRELOAD evaluated the safety and efficacy of in-catheterization laboratory 600 mg pre-treatment, versus routine 6-hour pre-treatment, in 409 patients (39% with ACS) [30]. The primary endpoint was 30-day incidence of MACE. ARMYDA-5 PRELOAD demonstrated non-inferiority in primary endpoint between the pre-treatment and in-laboratory arms (8.8% vs. 10.3%; $p=0.72$), with no increased risk of hemorrhage (5.4 vs. 7.8; $p=0.42$). However, patients in the in-laboratory group demonstrated greater platelet reactivity at PCI, and 2 hours post-procedure ($p=0.043$). Thus, an in-laboratory strategy was non-inferior to conventional pre-treatment—where unavoidable, high dose in-laboratory administration is a safe alternative. In the context of primary PCI for STEMI, the randomized CIPAMI trial evaluated the administration of clopidogrel in the pre-hospital phase of care [31]. Although terminated prematurely as a result of slow recruitment, CIPAMI reported a trend toward improved outcomes in the pre-hospital treatment group.

A meta-analysis of randomized and observational data has appraised the effect of pre-treatment with clopidogrel (vs. placebo, in addition to aspirin) on subsequent mortality and bleeding, in 37,814 patients undergoing PCI [32]. Clopidogrel pre-treatment was associated with improvements in the risk of MACE (OR 0.77, 95% CI 0.66–0.89; $p<0.001$) but without translation into improved mortality (OR 0.80, 95% CI 0.57–1.11). No differences were reported in major hemorrhage (OR 1.18, 95% CI 0.57–1.11). Although this analysis was limited by substantial interstudy heterogeneity (indications for PCI included stable and unstable angina, NSTEMI, and STEMI), the results suggest an inconsistent treatment effect exists across the spectrum of CAD presentations. The benefits of clopidogrel pre-treatment were greater with increasing severity of CAD (i.e., STEMI > NSTEMI > unstable angina > stable angina). Indeed, the authors report that clopidogrel pre-treatment did not improve outcomes in stable angina, and troublingly, was associated with a greater bleeding risk. A further meta-analysis by this group appraises the risks and benefits associated of thienopyridines pre-treatment in the context of 32,383 patients with NSTEMI (55% underwent PCI) [33]. Pre-treatment was associated with reduced MACE (OR 0.84, 95% CI 0.72–0.98; $p=0.02$), driven by the inclusion of CURE and CREDO, but did not translate into improvements in mortality (OR 0.90, 95% CI 0.75–1.07; $p=0.24$). No differences in MACE or mortality were observed in the subpopulation undergoing PCI. Significant excess bleeding (30–45%) was observed in all patients (OR 1.32, 95% CI 1.16–1.49; $p<0.0001$). Although these analyses included

clopidogrel and prasugrel, analysis stratified by agent, or limited to randomized trial evidence, did not alter the findings.

Optimization of clopidogrel therapy

Despite the benefits of clopidogrel in the context of PCI, a significant number of patients experience recurrent, adverse, peri- and post-procedural atherothrombotic complications, as a result of high on-treatment platelet reactivity [4–8]. This is hypothesized, in part, to be caused by the wide inter-individual variability in responsiveness to clopidogrel: a significant proportion of clopidogrel-treated patients have suboptimal inhibition of platelet function. The prevalence of this resistance phenotype ranges from 5% to 40%, dependent on the definition of resistance, platelet function assay, clopidogrel dosing regimen, and study population. One mechanism conferring inadequate clopidogrel responsiveness is the presence of loss-of-function alleles at the CYP2C19 locus; lack of expression of the CYP2C19 enzyme, and poor activation of clopidogrel [34]. Concomitant administration of agents that repress CYP2C19 activity (e.g., omeprazole) can also contribute to the resistance phenotype [35]. Indeed, these observations have prompted several regulatory agencies to issue warnings regarding the use of clopidogrel in such individuals. However, whether high PR represents a risk marker, or modifiable risk factor, remains a matter of contentious debate.

Several major studies have explored this issue, including GRAVITAS, which evaluated high-dose clopidogrel, in 2214 patients with stable CAD or NSTEMI undergoing PCI, with high on-clopidogrel PR [36]. Patients were randomized to high-dose (600 mg loading dose, 150 mg/day dose) or standard-dose clopidogrel (300 mg loading dose, 75 mg/day dose). At 6 months' follow-up, no differences in efficacy or safety endpoints were noted, differential clopidogrel dosing based on PR had no impact on clinical outcomes. In a further study, 429 ACS patients undergoing PCI with poor response to a 600-mg clopidogrel loading dose were randomized to receive either standard therapy, or up to three additional 600 mg clopidogrel loading doses, guided by PR, prior to PCI [37]. The authors observed that the rate of MACE was significantly lower in the PR-guided group than the control group (0.5 vs. 8.9%; $p<0.001$), with no difference in bleeding rates (2.8% vs. 3.7%; $p=0.80$), suggesting that PR-guided loading can be advantageous in the management of the clopidogrel resistance phenotype. The TRIGGER-PCI study specifically targeted higher potency thienopyridine pharmacotherapy to patients with the clopidogrel resistance phenotype [38]. Despite the pharmacodynamic superiority of the alternative agent, TRIGGER-PCI was stopped prematurely due to futility. The event rate was lower than predicted in both groups. The clinical utility of this strategy could not be determined.

In addition, trials have evaluated genotype-based dosing regimens. Most notably, the ELEVATE-TIMI-56 trial randomized 333 patients with stable CAD to receive CYP2C19 genotype-guided clopidogrel dosing regimens. Although this strategy successfully enabled patients with loss-of-function alleles to achieve levels of PR comparable to wild-type patients, this study was not powered to report clinical outcomes. Indeed, well-powered trials have thus far been performed in the context of PCI.

Thus, despite significant efforts, to date, differential dosing strategies, based on PR or pharmacogenetic testing, have had no beneficial impact on hard, clinical endpoints, in appropriately controlled, powered, randomized, and blinded trials. However, the development of greater potency P2Y₁₂-receptor antagonists, with less inter-individual variation, has proven highly fruitful.

Prasugrel

The third generation thienopyridine, prasugrel, has distinct pharmacokinetic advantages over clopidogrel: it has a more rapid onset of action, and demonstrates reduced variability in response. TRITON-TIMI-38 randomized 13,608 clopidogrel-naïve patients with moderate–high risk ACS undergoing PCI to receive either prasugrel (60 mg loading dose, 10 mg/day maintenance dose) or clopidogrel (300 mg loading dose, 70 mg maintenance dose) [39]. Randomization occurred following ascertainment of coronary anatomy, with the exception of patients undergoing primary PCI for STEMI. At 15 months' follow-up, the primary endpoint (composite of cardiovascular death, non-fatal MI, or stroke) occurred in 9.9% of prasugrel-treated and 12.1% of clopidogrel-treated patients (HR 0.81, 95% CI 0.73–0.90; $p < 0.001$), driven by non-fatal MI (40% of which were peri-procedural) and stent thrombosis (HR 0.48, 95% CI 0.36–0.84; $p < 0.0001$) [39,40]. This benefit was also observed at 30 days, and was independent of stent type. However, this was offset by a significant risk of major (2.4% vs. 1.8%, HR 1.32, 95% CI 1.03–1.68; $p = 0.03$) and fatal bleeding (0.4% vs. 0.1%, HR 4.19, 95% CI 1.58–11.11; $p = 0.002$) in the prasugrel-treated and clopidogrel-treated groups, respectively [39,41]. Pre-specified analysis demonstrated that prasugrel was associated with net benefit, despite bleeding risks ($p = 0.004$). Certain subgroups experienced greater benefits, including those with STEMI, and with diabetes mellitus, for whom the benefits far outweighed the risk of bleeding [42,43]. Conversely, no net benefit was observed in patients aged ≥ 75 years, weighing less than 60 kg, and with previous history of stroke or transient ischemic attack (TIA).

ACCOAST is the only placebo-controlled trial of prasugrel pre-treatment; randomizing 4033 NSTEMI patients (69% of whom underwent PCI) to receive 30 mg prasugrel, or placebo [44]. A supplementary 30-mg pre-PCI dose was administered following diagnostic angiography in the pre-treatment group, and 60 mg of prasugrel given to the placebo group. Pre-treatment was not associated with a reduced risk of MACE (HR 1.02, 95% CI 0.84–1.25; $p = 0.81$), although a higher rate of major bleeding was observed (HR 1.90, 95% CI 1.19–3.02; $p = 0.006$). Indeed, this rate of bleeding exceeding the a priori defined threshold, and the study was halted during enrolment.

Observational studies have also been undertaken to evaluate real-world prasugrel outcomes. Koshy *et al.* [45] recently reported a retrospective case series of 1688 primary PCI-treated patients with STEMI, who received pre-treatment with aspirin plus clopidogrel ($n = 866$) or prasugrel ($n = 822$) [45]. Patients were excluded if aged ≥ 75 years, weighed < 60 kg or had active bleeding, cerebrovascular disease, or hepatic impairment. No differences were reported in the frequency of in-hospital bleeding complications, unadjusted in-hospital, 30-day or 1-year mortality, in prasugrel and clopidogrel-treated patients. Covariate-adjusted analysis demonstrated an association between prasugrel and reduced mortality at 1 year (HR 0.47, 95% CI 0.25–0.88; $p = 0.018$). However, several limitations of this study suggest caution in the interpretation of these findings, including the highly selected, retrospective population.

Recently, methodologically superior registry data has emerged, prospectively following 23,994 clopidogrel-treated and 2142 prasugrel-treated patients undergoing PCI [46]. Prasugrel was primarily used in patients with STEMI, without hemorrhagic risk factors. In patients presenting with ACS, lower mortality was observed in prasugrel-treated than the clopidogrel-treated patients; however, mortality remained equivocal in those undergoing elective angiography and PCI. In-hospital bleeding complications occurred less

frequently in prasugrel-treated than clopidogrel-treated patients. These data suggest that when prasugrel is used in appropriately selected patients (i.e., those with ACS) and avoided in patients with characteristics indicating increased risk of hemorrhage, mortality and bleeding rates are acceptably low for both agents. These studies indicate that although prasugrel has a role in specific groups of high risk ACS patients, it should be used with caution in patients for whom the risks outweigh benefits.

Non-thienopyridine P2Y₁₂ receptor antagonists

Ticagrelor

The development of ticagrelor was impelled by the need for an agent that overcomes the limitations of the thienopyridines—the slow onset and wide inter-individual variability of clopidogrel, and the adverse safety profile of prasugrel. Preclinical and early phase clinical studies demonstrated that ticagrelor is characterized by rapid, extensive, and consistent antiplatelet activity, with favorable bleeding risks.

The landmark PLATO trial randomized 18,624 ACS patients to receive ticagrelor (180 mg loading dose, 90 mg twice daily maintenance dose) or clopidogrel (300–600 mg loading dose, 75 mg/day maintenance dose) [47]. Patients with moderate–high risk ACS received an additional, blinded loading dose of clopidogrel (total loading dose 600 mg) or placebo. In contrast to TRITON-TIMI-38, randomization occurred before angiography, and non-clopidogrel-naïve patients were eligible. At 12 months, ticagrelor significantly reduced the primary endpoint (cardiovascular death, non-fatal MI, or stroke; 9.8% vs. 11.7%, HR 0.84, 95% CI 0.77–0.92; $p < 0.0001$), driven by reductions in cardiovascular mortality (4.0% vs. 5.1%, HR 0.79, 95% CI 0.69–0.91; $p = 0.001$), non-fatal MI (5.8% vs. 6.9%, HR 0.84, 95% CI 0.75–0.95; $p = 0.005$) and stent thrombosis (2.2% vs. 3.0%, HR 0.73, 95% CI 0.57–0.94; $p = 0.014$). Overall, no difference in bleeding was observed in ticagrelor-treated and clopidogrel-treated patients (11.6% vs. 11.2%, HR 1.04; $p = 0.43$). However, major bleeding was significantly higher in ticagrelor-treated patients (2.8% vs. 2.2%; $p = 0.03$; by TIMI criteria), including fatal intracranial hemorrhage (0.1% vs. 0.01%; $p = 0.02$), but not all-cause fatal bleeding (0.3% vs. 0.3%; $p = 0.66$). The absolute rate of major bleeding was similar to that in TRITON-TIMI-38. Several PLATO subgroup analyses demonstrate consistency of the benefits of ticagrelor in patients undergoing (i) coronary artery bypass graft surgery [48], (ii) planned PCI [49] and (iii) non-invasive, medical management [50]. Unlike prasugrel in TRITON-TIMI-38, there were no patient subgroups for which there was an excess frequency of bleeding, including those with cerebrovascular disease, or aged ≥ 75 years. However, several non-hematologic, off-target effects were observed; associated with discontinuation of the study drug including: (i) ventricular pauses, (ii) dyspnea, and (iii) elevated serum creatinine and uric acid. Although precise mechanisms remain to be definitively elucidated, these effects have not been proven to have any other demonstrable clinical impact. Additionally, subgroup analysis demonstrated worse outcomes in North American ticagrelor-treated patients, associated with the use of high dose daily aspirin (> 100 mg) [51]. As such, the use of aspirin doses lower than 100 mg are recommended.

PLATO did not evaluate the use of a pre-treatment strategy compared with delayed administration; all patients received pre-treatment, irrespective of the intended (i.e., invasive or non-invasive) strategy. As such, the recently reported ATLANTIC study offers further insight on the optimal timing of administration; randomizing 1862 patients with STEMI in double-blind fashion to receive

either pre-hospital or in-laboratory ticagrelor [52]. ATLANTIC recruited patients with ongoing STEMI of duration less than 6 hours; the median time difference between the two treatment arms (pre-hospital or in-hospital) was 31 minutes. No difference was observed in the proportion of patients achieving $\geq 70\%$ resolution of ST-elevation prior to PCI, or TIMI flow grade 3 in the infarct-related artery at angiography. Thirty-day MACE rates did not significantly differ between the treatment arms, although the rate of stent thrombosis was lower in the pre-hospital group than the in-hospital group (0 vs. 0.8% at 24 hours, 0.2% vs. 1.2% at 30 days). The frequency of major bleeding was low and equivocal. Thus, administering ticagrelor in the pre-hospital setting does not improve outcomes (or increase risk) for patients with STEMI.

Until recently, there has existed a paucity of evidence regarding the long-term efficacy of treatment with ticagrelor post-MI and post-PCI. The multicenter PEGASUS-TIMI 54 trial randomized 21,162 patients (17,568 of whom had undergone previous PCI; 83.0%), 1–3 years post-MI, to receive ticagrelor 90 mg twice daily (high dose), ticagrelor 60 mg twice daily (low dose), or placebo, in addition to low dose aspirin, in double-blind fashion [53]. The primary efficacy endpoint (composite of cardiovascular death, MI, or stroke) was reduced in both the 90 and 60 mg groups, versus placebo (90 mg twice daily: HR 0.85, 0.75–0.96; $p=0.008$; 60 mg twice daily: HR 0.84, 0.74–0.95; $p=0.004$). However, there was no difference in the primary endpoint when comparing the low and high dose groups ($p=NS$). Patients receiving the low and high dose ticagrelor had a 2.3- and 2.7-fold greater risk of clinically significant bleeding, and a 3.0- and 3.7-fold greater need for transfusion, respectively, compared with placebo (all $p < 0.001$). As such, the authors conclude that the long-term administration of 60 mg twice daily ticagrelor can offer the most attractive risk–benefit profile, in addition to low dose aspirin, following MI. Thus, the long-term administration of ticagrelor post-PCI, in carefully selected patients, offers significant improvements in patient outcomes.

Other oral antiplatelet agents

Despite significant progress in the development of oral antiplatelet agents as adjuncts to PCI, success has been far from universal. In particular, the development of the oral glycoprotein IIb/IIIa inhibitors has been fraught with difficulty: xemilofiban, orbofiban, and sibrifiban have all undergone extensive placebo-controlled phase 3 clinical trials in CAD [54–56]. Each of these trials failed to report benefits, and suggested increased off-target mortality associated with such therapy.

Other oral APT agents have received approval for clinical use in various clinical settings—including cilostazol, dipyridamol, and pentoxifylline—but are not indicated in PCI, because of an insufficient evidence of benefit. Several novel agents, targeting different pathways in the thrombotic pathway, are currently in development. These have emerged in response to the shortcomings of current APT, which include: (i) no available TxA_2 pathway inhibitor apart from aspirin, to which a significant proportion of patients are allergic, cannot tolerate, or demonstrate inadequate responses; and (ii) the slow offset of $P2Y_{12}$ -receptor antagonists, an issue in patients with hemorrhagic complications.

Direct inhibition of the TxA_2 pathway poses several advantages over upstream COX-1 inhibition, including more potent platelet inhibition (via antagonism of endoperoxides at their receptors, or TxA_2 synthase) and less off-target effects (e.g., gastric mucosal erosion). TxA_2 inhibitors under development include picotamide, ridogrel, terutroban, ramatroban, EV077, and NCX4016. Although

TxA_2 inhibition remains a promising strategy, of the agents that have undergone clinical testing against aspirin (picotamide, ridogrel, terutroban), results have largely been underwhelming [57–59]. Elinogrel, a direct-acting, reversible ADP $P2Y_{12}$ -receptor antagonist, available in both intravenous and oral forms, provides potent platelet inhibition, with rapid onset and offset of action [60]. Despite demonstrating early promise in preclinical and early clinical studies, a phase 2 trial of elinogrel as an adjunct to PCI demonstrated an unacceptable bleeding risk compared with clopidogrel (INNOVATE-PCI; HR 1.98, 95% CI 1.10–3.57) [61]. As a result, the development of elinogrel was terminated prior to phase 3 trials, in 2012.

Another potential avenue of antiplatelet therapy is inhibition of platelet PAR-1, which interacts with thrombin. Two candidate compounds are currently undergoing development; vorapaxar (which has undergone phase 3 trials) and atopaxar (which has undergone phase 2 trials). Two large-scale phase 3 trials of vorapaxar, TRACER and TRA 2°P-TIMI-50 both report that the agent is efficacious in preventing MACE, but at the expense of significant bleeding [62,63]. Indeed, both trials were terminated prematurely because of an unacceptable risk of hemorrhage. Phase 2 trials (LANCLOT-ACS, LANCELOT-CAD, and J-LANCELOT) demonstrated the favorable safety profile of atopaxar with regard to bleeding risk, in patients with both ACS and stable CAD [64–66]. However, other side effects (dose-related QTc prolongation, hepatic transaminase elevation) were observed. Although phase 3 trials are required to provide definitive answers, none are planned at present.

Additional potential oral agents in early, preclinical development, include nitric oxide donors (LA419, LA846), prostaglandin E receptor 3 (DG-041), and serotonin receptor antagonists (APD791). Further preclinical testing is required before the applications of these agents become apparent.

Clinical guidelines: oral antiplatelet therapy in PCI

Evidence-based clinical guidelines advise clinicians regarding the optimal antiplatelet pharmacotherapy in patients undergoing PCI. The latest European Society of Cardiology (ESC) and European Association for Cardiothoracic Surgery (EACTS) guidelines stratify optimal APT by indication for PCI: (i) stable CAD, (ii) NSTEMI, and (iii) STEMI (Table 40.1) [1]. In all indications for PCI, a 150–300 mg loading dose of aspirin, followed by 75–100 mg life-long daily maintenance dose, is recommended.

In PCI for stable CAD, 300–600 mg clopidogrel loading dose, followed by 75 mg/day, should be administered. Although no evidence of benefit exists for systematic clopidogrel preloading before diagnostic coronary angiography in stable CAD [32], a loading dose of 600 mg is recommended in patients scheduled for elective PCI if coronary anatomy has been pre-established. In PCI for NSTEMI, DAPT is recommended with a potent $P2Y_{12}$ -receptor antagonist; either prasugrel (60 mg loading and 10 mg/day maintenance dose), ticagrelor (180 mg loading and 90 mg twice daily maintenance dose) or, when these are contraindicated or not available, clopidogrel (600 mg loading and 150 mg/day maintenance dose). In PCI for STEMI, DAPT with a potent $P2Y_{12}$ -receptor antagonist is also recommended; either prasugrel (60 mg loading and 10 mg/day maintenance dose), or ticagrelor (180 mg loading and 90 mg twice daily maintenance dose). However, caution against the use of these agents is advised in patients with cerebrovascular disease, or moderate-to-severe hepatic impairment—clopidogrel (600 mg loading and

Table 40.1 Summary of current European (ESC/EACTS) guidelines regarding the use of oral antiplatelet agents in percutaneous coronary intervention (PCI).

Indication for PCI	Oral antiplatelet	Recommendations	Class	Level
Stable CAD	Aspirin	Indicated prior to elective stenting	I	B
		Pre-treatment with 150–300 mg loading dose if not on maintenance dose	I	C
		Life-long aspirin therapy recommended	I	A
	Clopidogrel	Treatment with 600 mg loading dose once anatomy known, and PCI is planned. Preferably ≥ 2 hours pre-procedure	I	A
		Consider pretreatment in patients at high probability for significant CAD	IIb	C
		In patients on 75 mg maintenance therapy, a new loading dose of 600 mg may be considered, once PCI is planned	IIb	C
		600 mg loading dose, 75 mg/day maintenance dose is recommended for elective stenting	I	A
		Continue for at least 1 month after BMS implantation	I	A
		Continue for at least 6 months after DES implantation	I	B
		Shorter duration (<6 months) can be considered after DES implantation for patients at high risk of bleeding	IIb	A
Longer duration (>6 months) can be considered in patients at high ischemic risk and low bleeding risk	IIb	C		
Non-ST-elevation ACS	Aspirin	Recommended in all patients without contraindications. 150–300 mg loading dose, 75–100 mg/day maintenance dose. To be continued indefinitely	I	A
	Prasugrel	60 mg loading dose, 10 mg/day maintenance dose, for patients in whom coronary anatomy is known and who are proceeding to PCI. Contraindicated in patients with prior TIA/stroke. Not recommended in patients >75 years of age. Consider lower maintenance dose in patients weighing <60 kg. Continue for 12 months, unless contraindications exist (excess bleeding risk)	I	B
	Ticagrelor	180 mg loading dose, 90 mg twice daily maintenance, for patients at moderate–high risk of ischemic events, regardless of initial treatment strategy including those pretreated with clopidogrel, if no contraindication. Continue for 12 months, unless contraindications exist (excess bleeding risk)	I	B
	Clopidogrel	600 mg loading dose, 75 mg/day dose, only when prasugrel or ticagrelor are not available or are contraindicated. Continue for 12 months, unless contraindications exist (excess bleeding risk)	I	B
ST-elevation MI	Aspirin	Recommended in all patients without contraindications. 150–300 mg loading dose, 75–100 mg/day maintenance dose. To be continued indefinitely	I	A
	Prasugrel	60 mg loading dose at first medical contact, 10 mg/day maintenance dose, unless contraindication. Contraindicated in patients with prior TIA/stroke. Not recommended in patients >75 years of age. Consider lower maintenance dose in patients weighing <60 kg. Continue for 12 months, unless contraindications exist (excess bleeding risk)	I	B
	Ticagrelor	180 mg loading dose at first medical contact, 90 mg twice daily maintenance, unless contraindication. Continue for 12 months, unless contraindications exist (excess bleeding risk)	I	B
	Clopidogrel	600 mg loading dose at first medical contact, 75 mg daily dose, only when prasugrel or ticagrelor are not available or are contraindicated. Continue for 12 months, unless contraindications exist (excess bleeding risk)	I	B

Table 40.2 Summary of current North American (ACC/AHA/SCAI) guidelines regarding the use of oral antiplatelet agents in PCI.

Indication for PCI	Oral antiplatelet	Recommendations	Class	Level
ACS	Aspirin	Patients already taking daily aspirin therapy should take 81–325 mg before PCI	I	B
		Patients not on aspirin therapy should be given a loading dose of 325 mg before PCI	I	B
		After PCI, use of aspirin should be continued indefinitely	I	A
		After PCI, aspirin 81 mg/day should be used in preference to higher maintenance doses	IIa	B
	Clopidogrel	A loading dose of 600 mg of clopidogrel should be considered	I	B
		The clopidogrel loading dose for patients undergoing PCI post-fibrinolysis therapy should be: (i) 300 mg within 24 hours; or (ii) 600 mg >24 hours after receiving fibrinolysis	I	C
		In patients receiving a stent (either BMS or DES) during PCI, clopidogrel 75 mg/day should be given for at least 12 months	I	B
		If the risk of morbidity from bleeding outweighs the anticipated benefit afforded by a recommended duration of clopidogrel therapy after stent implantation, earlier discontinuation (e.g., <12 months) of clopidogrel inhibitor therapy is reasonable	IIa	C
	Prasugrel	A loading dose of 60 mg prasugrel should be considered	I	B
		In patients receiving a stent (either BMS or DES) during PCI, prasugrel 10 mg/day should be given for at least 12 months	I	B
		If the risk of morbidity from bleeding outweighs the anticipated benefit afforded by a recommended duration of prasugrel therapy after stent implantation, earlier discontinuation (e.g., <12 months) of prasugrel inhibitor therapy is reasonable	IIa	C
		Prasugrel should not be administered to patients with a prior history of stroke or transient ischemic attack	III	B
Ticagrelor	A loading dose of 180 mg ticagrelor should be considered	I	B	
	In patients receiving a stent (either BMS or DES) during PCI, ticagrelor 90 mg twice daily should be given for at least 12 months	I	B	
	If the risk of morbidity from bleeding outweighs the anticipated benefit afforded by a recommended duration of clopidogrel therapy after stent implantation, earlier discontinuation (e.g., <12 months) of ticagrelor inhibitor therapy is reasonable	IIa	C	
Non-ACS	Aspirin	Patients already taking daily aspirin therapy should take 81–325 mg before PCI	I	B
		Patients not on aspirin therapy should be given a loading dose of 325 mg before PCI	I	B
		After PCI, use of aspirin should be continued indefinitely	I	A
	Clopidogrel	A loading dose of 600 mg clopidogrel should be considered	I	B
		In patients receiving a stent (either BMS or DES) during PCI, clopidogrel should be given for a minimum of 1 month; ideally up to 12 months (unless bleeding risk increased—then it should be given for a minimum of 2 weeks)	I	B
	Prasugrel	If the risk of morbidity from bleeding outweighs the anticipated benefit afforded by a recommended duration of prasugrel therapy after stent implantation, earlier discontinuation (e.g., <12 months) of prasugrel inhibitor therapy is reasonable	IIa	C
		Prasugrel should not be administered to patients with a prior history of stroke or transient ischemic attack	III	B
	Ticagrelor	If the risk of morbidity from bleeding outweighs the anticipated benefit afforded by a recommended duration of clopidogrel therapy after stent implantation, earlier discontinuation (e.g., <12 months) of ticagrelor inhibitor therapy is reasonable	IIa	C

150 mg/day maintenance dose) should be substituted. In addition, all patients should be instructed not to prematurely discontinue oral APT without first consulting a physician, because of increased risks of recurrent MI and stent thrombosis [67].

The most recent American College of Cardiology (ACC) and American Heart Association (AHA) guidelines (Table 40.2) advocate broadly similar regimens [2]. An aspirin loading dose of 325 mg for aspirin-naïve patients, or 81–325 mg for patients previously receiving daily aspirin, is recommended, with low dose aspirin advocated indefinitely. Patients should also receive a loading dose of a P2Y₁₂-receptor antagonist; recommended options include: (i) clopidogrel (600 mg; ACS and non-ACS patients), (ii) prasugrel (60 mg; ACS patients), or ticagrelor (180 mg; ACS patients). Patients should be counseled on the need for, and risk of, DAPT in advance of stent placement, and alternatives pursued (i.e., balloon angioplasty) if patients are unwilling or unable to comply for the recommended duration. The guidelines advocate a holistic assessment of potential benefits and harms (thrombotic vs. bleeding risks), and pragmatic adjustment of the post-PCI antiplatelet regimen, accordingly.

Future perspectives

Despite significant progress, a number of questions remain unanswered regarding the optimization of oral antiplatelet therapy during PCI. Perhaps most importantly: how much scope remains for the further improvement of oral antiplatelet therapy in PCI, given the current status of such therapy, and recent improvements in intravenous antiplatelet agents (e.g., GP IIb/IIIa inhibitors, direct thrombin inhibitors). Insight from the PARIS registry, which prospectively studied 5018 patients undergoing PCI indicated that MACE following cessation of DAPT depend on the clinical circumstances of discontinuation, and attenuate over time [67]. Approximately half of all premature discontinuations within 2 years of PCI was physician-advised, and did not result in adverse outcomes. However, disruptions in antiplatelet therapy or non-compliance were associated with a significantly increased risk of MACE, which attenuated after 30 days. Surprisingly, the overall contribution of DAPT cessation was small—indeed, most MACE occurred while patients were receiving optimal DAPT (74%; 8.5% of overall study population). Although patients received mainly aspirin and clopidogrel DAPT, improvements in antiplatelet regimens may still yield improved outcomes in a large number of patients for whom existing therapy is ineffectual.

Despite a number of placebo- and clopidogrel-controlled studies, the relative efficacy and safety of prasugrel and ticagrelor remains uncertain: head-to-head comparisons, in prospective, randomized studies, are required. In the interim, subgroup and meta-analysis represents approaches by which these strategies can be indirectly compared, in different settings. A further concern is that of cost; the newer, more potent P2Y₁₂ inhibitors remain on-patent, and are thus greatly more expensive than clopidogrel, which has recently become available in a generic, inexpensive formulation in most countries. However, as the patents for prasugrel and ticagrelor expire in 2017 and 2018, respectively, generic forms could soon become available.

Conclusions

The evolution of antiplatelet strategies has yielded incremental improvements in peri- and post-PCI outcomes, as a direct result of demonstration of safety and efficacy in methodologically robust

randomized clinical trials and prospective registries. However, despite notable advances and best-available antiplatelet regimens, a proportion of patients continue to experience adverse outcomes; both ischemic and from bleeding risks. As such, decisions regarding antiplatelet therapy must be patient-centered; holistically appraising the potential benefits and risks inherent with such treatment. Further optimization of present antiplatelet pharmacotherapeutic regimens, and the development of novel oral antiplatelet agents targeting novel pathways in the thrombotic pathway, will surely continue to improve outcomes following PCI.

Parenteral Anticoagulant Agents in PCI

Piera Capranzano¹, Corrado Tamburino¹, and George D. Dangas²

¹ Cardiovascular Department, Ferrarotto Hospital, University of Catania, Catania, Italy

² Department of Cardiology, Mount Sinai Medical Center, New York, NY, USA

Unfractionated heparin (UFH) has been the mainstay of anticoagulation in ischemic coronary disease for over a quarter of a century. However, pharmacologic treatment options have expanded rapidly over the past decade with the advent of low molecular weight heparins (LMWH), direct thrombin inhibitors, and factor Xa inhibitors. Discrete bodies of evidence have emerged to support the use of each of these agents across the spectrum of urgent or elective percutaneous coronary intervention (PCI). This chapter examines the data on the use of available anticoagulants in the setting of PCI for the different clinical presentations of coronary artery disease (CAD), and makes summary recommendations for best clinical practice.

Heparin

Structure and function

Heparin was fortuitously isolated from dog liver in 1916. Its structure was elucidated 20 years later at approximately the same time as it was introduced into clinical practice. UFH is a sulfated glycosaminoglycan composed of alternating uronate and glucosamine units that contain straight chain mucopolysaccharides of highly variable length. This complex heterogeneous substance has a molecular weight ranging 3–30 kDa with a mean of 15 kDa.

Heparin functions as an indirect thrombin inhibitor, exerting its effects through the endogenous serine protease antithrombin (AT) III (Table 41.1). As AT complexes with heparin it undergoes a conformational change, accelerating its enzymatic activity by 1000× to 4000×. This results in the rapid inhibition of factor IIA (thrombin), factor Xa, and, to a lesser extent, factors IXa and XIa (Figure 41.1). Heparin requires a specific pentasaccharide motif for AT binding and polysaccharide chains of at least 18 units of length for thrombin inactivation (ternary complex formation with AT and thrombin).

Guidelines recommendation

Despite the advent of new pharmacologic therapies and intracoronary interventions, UFH remains the standard of care for preventing thrombus formation and propagation in the setting of PCI. Indeed, it has a Class I indication for the use in PCI across the entire spectrum of clinical presentations of CAD, including stable CAD, non-ST-elevation acute coronary syndrome (NSTEMI-ACS), and ST-elevation myocardial infarction (STEMI) [1–3].

Dosing recommendation

Because of marked variability in UFH bioavailability, monitoring of its anticoagulant effect is required. Before PCI with no planned use of a glycoprotein IIb/IIIa inhibitor (GPI), UFH is administered as a 70–100 IU/kg bolus, to achieve a target activated clotting time (ACT) of 250–300 s for HemoTec and 300–350 s for Hemochron. If GPI use is planned, a 50–70 IU/kg bolus to achieve an ACT of 200–250 s is recommended. In patients with ACS, UFH can be initiated at presentation at an initial bolus of 60–70 IU/kg with a maximum of 5000 IU, followed by an initial infusion of 12–15 IU/kg/h, to a maximum of 1000 IU/h, maintaining an activated partial thromboplastin time (aPTT) level of 50–75 s, corresponding to 1.5–2.5 times the upper limit of normal. This narrow therapeutic window is due to the increased risk of bleeding complications, without further antithrombotic benefits at the higher aPTT values. In patients receiving prior UFH, at the time of PCI an additional UFH bolus is administered as needed (e.g., 2000–5000 IU) to achieve the ACT target level.

Heparin can be discontinued at the end of the PCI with few exceptions (left ventricular aneurysm and/or thrombus, atrial fibrillation, prolonged bed rest, deferred sheath removal).

Reversal

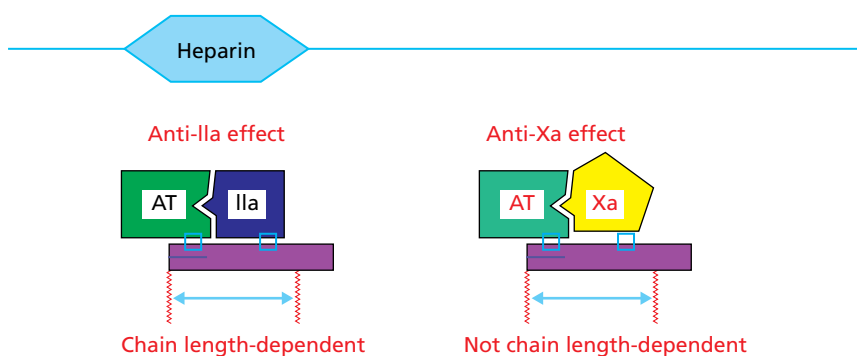

In the event of bleeding complications the anti-IIa effects of UFH can be reversed by the administration of protamine sulfate. Protamine should be given as a slow intravenous (IV) infusion administration of 1 mg protamine/100 units remaining circulating heparin. Patients should not receive a protamine bolus of >25–50 mg. Indeed, excessive protamine administration can lead to paradoxical anticoagulation. Those who have been previously exposed to protamine, including diabetic patients receiving insulin, have a 1% risk of a hypersensitivity or anaphylactic reaction.

Limitations

The use of UFH has a number of limitations (Table 41.1). Indeed, heparin is unable to bind clot-bound thrombin or factor Xa bound to platelets in the prothrombinase complex. It does bind non-specifically to platelets, macrophages, and endothelial cells, and can activate platelet function. These phenomena theoretically reduce the ischemic efficacy of heparin. Heparin also binds to cells and plasma proteins resulting in a variable dose–response relationship leading to

Table 41.1 Comparison of antithrombotic agents.

Heparin	Enoxaparin	Direct thrombin inhibitors
<ul style="list-style-type: none"> • Indirect thrombin inhibitor • Non-specific binding to: <ul style="list-style-type: none"> ◦ Serine proteases ◦ Endothelial cells • Reduced effect in ACS <ul style="list-style-type: none"> ◦ Inhibited by PF-4 ◦ Clot-bound thrombin • Causes platelet aggregation • Non-linear pharmacokinetics • Risk of HIT 	<ul style="list-style-type: none"> • Indirect thrombin inhibitor • Less non-specific binding than UFH • Reduced effect in ACS <ul style="list-style-type: none"> ◦ Compared to UFH, markedly less inhibition by PF-4 ◦ Clot-bound thrombin • Causes much less platelet aggregation than UFH • Predictable anticoagulation • Markedly reduced risk of HIT 	<ul style="list-style-type: none"> • Do not require a cofactor • Not inhibited by PF-4 or anti-heparin proteins • Effective against clot-bound thrombin • No platelet aggregation • Predictable anticoagulation • No thrombocytopenia

**Figure 41.1** Schematic depiction of the anti-IIa and anti-Xa activities of unfractionated heparin (UFH).

a narrow therapeutic window, and to several side effects. Indeed, its interaction with platelet factor 4 can result in the production of antibodies that lead to heparin-induced thrombocytopenia (HIT). The XLM fraction (or “extra large” material >8 kDa heparin contains) also contributes to an increased risk of hemorrhagic complications.

Heparin-induced thrombocytopenia

As many as 20% of patients receiving UFH experience thrombocytopenia and/or >50% drop in their platelet count 48 hours after initiation of therapy. This thrombocytopenia is often benign, usually normalized even with continued heparin therapy, and is often referred to as HIT type 1.

In 0.2–0.3% of individuals receiving heparin, platelet counts will drop precipitously (thrombocytopenia with median count 60,000/ μ L, >50% drop in initial platelet count) after 4–10 days after initiation of heparin and will not reverse. Thrombocytopenia is often associated with thrombotic and rarely with hemorrhagic complications. This serious disorder is referred to as HIT type 2 (HIT-2). Rapid-onset HIT-2 occurs <24 hours after the initiation of heparin and is seen in the setting of previous heparin exposure within 3–4 months. Occasionally, thrombocytopenia can occur within days or weeks after cessation of heparin (delayed-onset HIT).

HIT-2 results from immunoglobulins G and M (IgG and IgM) antibody formation against a neoepitope created by the heparin–PF4 complex. Antibody formation leads to platelet consumption and often thrombosis; antibodies can also mediate heparin-induced skin necrosis. The heparin–PF4–antibody complex can bind platelet Fc- γ -RIIA, leading to platelet activation, PF4 release, and further propagation of platelet activation. The same complex can bind microvascular endothelial cells, leading to the release of platelet secretagogues and

adhesion molecules. Furthermore, the heparin–PF4–antibody complex can interact with monocytes to cause the release of tissue factor.

Thrombosis occurs in up to 75–90% of patients with HIT-2 and more commonly occurs in the venous (deep venous thrombosis/pulmonary embolism, gangrene, cerebral sinus thrombosis) as opposed to the arterial (myocardial infarction, stroke, acute limb ischemia, mesenteric ischemia) circulation.

HIT-2 is a clinical diagnosis but is aided by laboratory testing. Many hospitals use enzyme-linked immunosorbent assay (ELISA) to detect antibodies to the heparin–PF4 complex. This test is highly sensitive (>90–95% sensitivity) but much less specific (75–85% specificity) for HIT-2. Serotonin release and heparin-induced platelet aggregation have also been utilized to aid in making a diagnosis.

The first step in the treatment of HIT-2 is the immediate cessation of all heparin therapy including subcutaneous heparin and heparin flushes. Direct thrombin inhibitors (DTI), discussed later, are used to prevent primary or recurrent thrombosis. If a patient has thrombocytopenia but not thrombosis, a DTI is continued until the platelet count normalizes. Observation is reasonable if the patient is at high risk for bleeding but bear in mind that the patient is still at risk for thrombosis. If a patient requires ongoing anticoagulation for thrombosis or comorbidities (atrial fibrillation, mechanical valve) then a DTI is continued and overlapped for at least 5 days with warfarin therapy. Warfarin should be continued for 2–3 months or 3–6 months in the absence and in the presence of thrombosis, respectively. Heparin can be reintroduced for short periods of time (i.e., during cardiac surgery) in patients with history of HIT-2 (>4 months) who are clear of antibodies because the assumption is it would take approximately 3 days to mount an anamnestic response to repeated exposure.

Table 41.2 Comparison of low molecular weight heparins.

	Median molecular weight	Anti-Xa IU/mg	Anti-IIa IU/mg	Xa/IIa
Enoxaparin	4800	104	32	3.3
Dalteparin	5000	122	60	2.0
Nadroparin	4500	94	31	3.0
Tinzaparin	4500	90	50	1.8
Clivarine	3900	130	40	3.3

Low molecular weight heparin

Structure and function

Low molecular weight heparin is produced through the enzymatic or chemical (nitrous acid, alkaline) degradation of UFH. These processes result in smaller molecules containing shorter polysaccharide chains (Table 41.2). The molecular weight of LMWH ranges 2–9 kDa with an average of 4–5 kDa (Table 41.2). LMWH has a few theoretical advantages over UFH (Table 41.1). LMWH still acts through AT, but because many of its chains contain <18 monosaccharides they cannot form a ternary complex with AT and thrombin; therefore LMWH has preferential anti-Xa effect as opposed to antithrombin activity. LMWH has a complete bioavailability after subcutaneous administration, longer than twice the half-life of UFH (4.5–7 hours for enoxaparin) and a predictable dose–response relationship, not requiring anticoagulation monitoring (Table 41.1). LMWH incurs much less non-specific binding and therefore presents a lower risk of HIT-2 and results in less platelet activation than with UFH. LMWH is cleared predominantly by the kidneys but also by the reticulo-endothelial system. This becomes important for dosing in renal failure. Enoxaparin is the best studied LMWH for ischemic prophylaxis in CAD.

Enoxaparin in PCI for stable coronary artery disease

The role of enoxaparin in elective PCI for stable disease has been evaluated in the STEEPLE open-label trial which randomized 3528 patients to either IV enoxaparin 0.5 or 0.75 mg/kg or UFH [4]. The primary endpoint of non-CABG-related bleeding over 48 hours was significantly reduced for the lower dose (0.5 mg/kg) but not the higher dose (0.75 mg/kg) group. Major bleeding was significantly reduced in both enoxaparin groups, with similar efficacy compared with UFH. Enoxaparin provided more predictable anticoagulation. The enoxaparin low-dose arm was stopped prematurely because of a non-significant trend toward excess mortality not related to ischaemic events and not confirmed at 1 year of follow-up.

Based on this trial, enoxaparin should be considered as an alternative to UFH for elective PCI in patients with stable CAD according to European (Class IIa, B) and US (Class IIb, B) guidelines, respectively [1,5].

Enoxaparin in PCI for non-ST-elevation acute coronary syndrome

The SYNERGY study evaluated the safety and efficacy of enoxaparin within the context of an early invasive strategy in 10,027 patients with high risk ACS. Patients received either open-label enoxaparin (1 mg/kg) or UFH until anticoagulation was no longer required as judged by the patient's treating physician [6]. The majority of patients received contemporary pharmacologic therapy including

aspirin (95%), thienopyridines (66%), and GPI (57%). Most patients (92%) underwent coronary angiography, 47% underwent PCI, and 19% bypass surgery. For those undergoing PCI who were assigned to enoxaparin, if the last enoxaparin dose was given <8 hours prior to the procedure no additional drug was given. If the last enoxaparin dose was given >8 hours prior to PCI an additional enoxaparin bolus of 0.3 mg/kg was administered prior PCI. Seventy-five percent of trial patients received antithrombin therapy prior to randomization. The enoxaparin group met non-inferiority criteria with respect to the primary efficacy composite endpoint of 30-day all-cause death or non-fatal myocardial infarction (MI). No significant differences were observed for ischemic events during PCI including abrupt closure, threatened abrupt closure, unsuccessful PCI, or emergency bypass surgery. There was a modest significant increase in bleeding complications with enoxaparin. However, a relative advantage of enoxaparin emerged when therapy crossovers were censored.

Based on this trial, enoxaparin should be considered for PCI in patients with NSTEMI-ACS pre-treated with subcutaneous enoxaparin according to European (Class IIa, B) and US (Class IIb, B) guidelines (Table 41.3) [1,2]. Crossover of UFH and LMWH is not recommended.

Enoxaparin in primary PCI for ST-elevation myocardial infarction

Enoxaparin (0.5 mg/kg intravenous bolus) was compared with UFH in the setting of primary PCI only in the ATOLL randomized, open-label trial, including 910 patients [7]. The 30-day primary

Table 41.3 European and US guidelines indications for the use of parenteral anticoagulant agents for percutaneous coronary intervention (PCI) in the setting of acute coronary syndrome.

	Enoxaparin		UFH		Bivalirudin	
NSTEMI-ACS (EU 2014) [1]	IIa*	B	I	C	I	A
NSTEMI-ACS (US 2011) [2]	IIb*	B	I	C	I	B
STEMI (EU 2014) [1]	IIa	B	I	C	IIa	A
STEMI (US 2013) [3]	–	–	I	C	I	B

* Enoxaparin should be considered for PCI in patients pre-treated with subcutaneous enoxaparin. Crossover of UFH and LMWH is not recommended. NSTEMI-ACS: non-ST-Elevation acute coronary syndrome; STEMI: ST-Elevation myocardial infarction; UFH: unfractionated heparin.

composite endpoint of death, complication of MI, procedural failure, or major bleeding was not significantly reduced in the enoxaparin arm. There was no signal of higher incidence of bleeding from use of enoxaparin over UFH. In the per-protocol analysis of the ATOLL trial—pertinent to more than 87% of the study population—enoxaparin was superior to UFH in reducing the primary endpoint, and also mortality and major bleedings, contributing to the improvement of the net clinical benefit [8].

Based on this trial, enoxaparin with or without GPI should be considered as an alternative to UFH for primary PCI in patients with STEMI according to the European guidelines (Class IIa, B; Table 41.3) [1]. There are no specific recommendations for the use of enoxaparin in the setting of primary PCI for STEMI in the US guidelines. According to these latter guidelines enoxaparin is recommended in Class I A as adjunctive antithrombotic therapy to support reperfusion in patients with STEMI treated with fibrinolytic therapy [3].

Dosing recommendations

In patients who have not received prior anticoagulant therapy a 0.5–0.75 mg/kg IV bolus is given before PCI. For prior treatment with enoxaparin, if the last subcutaneous dose was administered 8 hours earlier or if less than two therapeutic doses of enoxaparin have been administered, an additional intravenous dose of enoxaparin 0.3 mg/kg is given before PCI.

Enoxaparin dosage should be reduced to 1 mg/kg once daily in patients with a creatinine clearance <30 L/min and is contraindicated in dialysis. Also caution should be used when treating the elderly and patients at both extremes of the weight spectrum for fear of an unreliable dose–response and an increased risk of bleeding.

Protamine can reverse the anti-IIa effect of the higher molecular weight components of heparin but does not completely reverse the drug's anti-Xa activity. Protamine administered as 1 mg/100 units of circulating LMWH can reduce clinical bleeding. The dose should be reduced if LMWH was given >8 hours before the bleeding event.

Limitations of LMWH

LMWH can cause HIT-2, although the incidence is markedly decreased compared to UFH therapy. LMWH is also associated with bleeding complications without an ideal option for reversal, although protamine can inhibit anti-IIA effects.

Direct thrombin inhibitors

Direct thrombin inhibitors are small molecules that can bind and inactivate both circulating and clot-bound thrombin (Table 41.1). DTI do not interact with plasma proteins or cells; therefore DTI do not activate platelets and do not cause HIT. In fact, they are used for the treatment of HIT. DTI have a much more predictable dose response than UFH. The three available DTI are L-hirudin (lepirudin), argatroban, and bivalirudin.

Hirudin was initially isolated from *Hirudo medicinalis*, the medicinal leech, and was identified as an antithrombotic agent in 1884. Hirudin is a bivalent protein that binds irreversibly to thrombin. It is renally cleared and is relatively contraindicated in patients with renal insufficiency. Production of anti-hirudin antibodies is relatively common and can affect dosing, but there is only a 0.015% incidence of anaphylaxis with L-hirudin exposure and a 0.016% incidence with re-exposure.

Argatroban is a small, monovalent DTI that binds reversibly to thrombin. It has a half-life of 50 minutes and is hepatically cleared.

Argatroban is relatively contraindicated in patients with liver dysfunction. Argatroban is not immunogenic.

Bivalirudin is a bivalent 20 amino acid protein that reversibly inhibits thrombin. It has a half-life of 25 minutes and is cleared predominantly through proteolytic cleavage, with renal excretion accounting for <20% of its degradation. Bivalirudin is not immunogenic.

No studies have evaluated the role of lepirudin in contemporary PCI. A few small studies have evaluated the effects of argatroban during PCI, and it is approved in this setting as an alternative anticoagulant only in patients with HIT. Lepirudin and argatroban are approved only for the treatment of HIT. Bivalirudin can also be used in patients with HIT. Bivalirudin is currently the only DTI that has been extensively evaluated in several powered clinical trials with respect to its use in PCI across the broad spectrum of CAD [9].

Bivalirudin in PCI for stable coronary artery disease

ISAR-REACT-3 was the only randomized trial to compare bivalirudin (bolus 0.75 mg/kg; infusion 1.75 mg/kg/h) with UFH (140 IU/kg) in 4570 patients pre-treated with clopidogrel [10]. The trial showed similar net clinical outcomes (primary endpoint) between bivalirudin and UFH, with an excess of major bleeding in the UFH group, which could be attributable to the UFH dosage being higher than recommended. In the ISAR-REACT 3A trial the use of a reduced UFH bolus of 100 IU/kg in 2505 patients led to no differences between bivalirudin and UFH in terms of major bleeding, with a trend toward less ischemic events in the UFH arm [11]. In view of the ISAR-REACT 3 and 3A results with a trend toward a lower risk of MI, anticoagulation with UFH remains the standard anticoagulant treatment for elective PCI. According to the European guidelines, bivalirudin should be considered in place of UFH during elective PCI in patients at high-risk for bleeding (Class IIa, B) [3].

Bivalirudin in PCI for non-ST-elevation acute coronary syndrome

ACUITY was the first large-scale randomized trial to assess the use of bivalirudin as an alternative to UFH for anticoagulation in the contemporary treatment of NSTEMI-ACS [12]. It was found that 13,819 moderate to high risk patients with NSTEMI-ACS managed with contemporary pharmacotherapy and undergoing an early invasive strategy were randomized to UFH or enoxaparin plus planned GPI, bivalirudin plus planned GPI, or bivalirudin monotherapy. Therapy with GPI was randomized to downstream (in the catheterization laboratory) or upstream administration. Bivalirudin was started before angiography with an IV bolus of 0.1 mg/kg and an infusion of 0.25 mg/kg/h, followed before PCI by an additional IV bolus of 0.5 mg/kg and infusion of 1.75 mg/kg/h. The drug was stopped after PCI. Ninety-nine percent of patients underwent angiography within 19.6 hours following admission. Pre-treatment with clopidogrel was left to the discretion of the treating physician. Only 56% of patients received PCI through the femoral access, 11% received CABG, and 33% received medical therapy. Bivalirudin monotherapy met non-inferiority criteria with respect to the primary ischemic endpoint at 30 days (death, MI, or unplanned revascularization), with a significantly lower rate of major bleeding. Therefore, the 30-day net clinical outcome was significantly better with bivalirudin alone than with heparin plus GPI. Notably, this bivalirudin advantage was confirmed at 1-year follow-up and was not related to the timing of GPI administration (upstream or downstream).

In the ACUITY trial, major bleeding was an independent predictor of mortality at 30 days and 1 year [13,14]. Subgroup analysis suggested that while lack of clopidogrel pre-treatment did not affect the ischemic outcome for the two groups receiving GPI, it resulted in a significant increase in the ischemic endpoint for those receiving bivalirudin monotherapy.

The ACUITY PCI subanalysis analyzed outcomes for the 7789 patients in the PCI subgroup [15]. There was no difference in the primary ischemic endpoint or stent thrombosis, but bivalirudin monotherapy was associated with a significant reduction in major bleeding, minor bleeding, and transfusion requirements.

The safety and efficacy of bivalirudin monotherapy versus UFH plus GPI in NSTEMI-ACS patients undergoing PCI through the femoral access and pre-treated with clopidogrel were assessed in the more recent ISAR-REACT 4 trial [16]. At the time of PCI, patients in the bivalirudin group received a bolus dose of bivalirudin 0.75 mg/kg, followed by an infusion of 1.75 mg/kg/h for the duration of the procedure. Compared with ACUITY, the ISAR-REACT 4 trial:

- 1 Included only high risk patients with positive biomarkers undergoing PCI, whereas ACUITY also included patients with unstable angina;
- 2 UFH was the only heparin used in the control arm, whereas in ACUITY the use of enoxaparin was allowed in the heparin plus GPI arm;
- 3 GPIs were administered only after the guidewire had crossed the lesion, whereas in ACUITY patients assigned to heparin plus GPIs or bivalirudin plus GPIs were randomly assigned, in a two-by-two factorial design, to upstream or downstream treatment with GPIs);
- 4 Abciximab was the only GPI used in the control arm, whereas in ACUITY the use of tirofiban or eptifibatid was permitted;
- 5 Clopidogrel 600 mg was given before any study drug, whereas in ACUITY the initial dose and timing of clopidogrel were left to the discretion of the investigator;
- 6 The definition of major bleeding was less sensitive.

In the ISAR-REACT 4 trial the primary endpoint of death, recurrent MI, urgent target vessel revascularization, or major bleeding within 30 days was similar, but bivalirudin was associated with significantly less major bleeding, with the biggest difference between the two groups being in the access site bleeding.

Based on this latter trial, in the most recent 2014 European guidelines on myocardial revascularization, bivalirudin (0.75 mg/kg bolus, followed by 1.75 mg/kg/hour for up to 4 hours after the procedure) is recommended as alternative to UFH plus GPI during PCI in patients with NSTEMI-ACS (Class I A) [1], while UFH is recommended as anticoagulant for PCI in patients with NSTEMI-ACS, if patients cannot receive bivalirudin (Class I C; Table 41.4) [1]. Differently, in the most recent 2014 US guidelines on NSTEMI-ACS, there is no preference for one anticoagulation agent and both bivalirudin and UFH are indicated as anticoagulation options for PCI in NSTEMI-ACS in Class I B and I C, respectively, reflecting the higher number of evidences on bivalirudin (Table 41.3) [2]. According to the US guidelines, in patients with NSTEMI-ACS undergoing PCI who are at high risk of bleeding, it is reasonable to use bivalirudin monotherapy in preference to the combination of UFH and GPI (Class IIa B) [2].

Bivalirudin in primary PCI for ST-elevation myocardial infarction

The HORIZONS-AMI was the first large, multicenter, open-label trial, which randomized 3602 patients with STEMI undergoing primary PCI (93%) through the femoral access to bivalirudin or

UFH plus planned GPI [17]. Bivalirudin was stopped at the end of PCI. This landmark trial showed that bivalirudin plus provisional GPI compared with UFH plus routine GPIs reduced major bleeding and the combined endpoint of all-cause death, reinfarction, repeat revascularization, definite stent thrombosis, stroke, or major bleeding both at 30 days and 1 year. In addition, bivalirudin was associated with improved overall and cardiac survival at 30 days and up to 3 years [18]. However, there was a higher incidence of acute stent thrombosis during the first 24 hours in the bivalirudin group (1.3% vs. 0.3%; $p=0.001$), with no difference in stent thrombosis at 30 days. Pre-randomization use of UFH bolus and 600 mg clopidogrel loading dose were independent predictors of lower risk of acute and subacute stent thrombosis.

The EUROMAX multicenter, open-label trial compared outcomes of bivalirudin with UFH in STEMI patients ($n=2218$) managed in a more contemporary practice setting, including prehospital initiation of study treatment in all patients, use of prasugrel and ticagrelor (59%) and radial artery access (47%) [19]. Planned GPI use was optional in both groups: in the bivalirudin arm upstream GPI (3.9%) was recommended only in the presence of a large thrombus, while in the UFH arm (58.5%) was left to the operator's preference. The GPI bailout use occurred in 7.9% and 25.4%, in the bivalirudin and UFH arms, respectively. Differently from the HORIZONS-AMI trial, infusion of bivalirudin was to be continued for at least 4 hours after PCI, either at the higher dose used during PCI (1.75 mg/kg/h) or at the lower maintenance dose (0.25 mg/kg/h). The primary composite of death or major bleeding was significantly reduced by bivalirudin, driven by a significant reduction in major bleeding. However, the risk of acute stent thrombosis remained higher with bivalirudin (1.1% vs. 0.2%; $p=0.007$). In a EUROMAX subanalysis, bivalirudin and UFH were compared according to the mode of GPI administration (routine [$n=649$] vs. bailout [$n=460$]) in the heparin arm [20]. The benefit of bivalirudin, driven by major bleeding reduction, was evident in both comparisons, versus heparin plus routine GPI, and versus heparin plus bailout GPI [20]. Similar to the main study, stent thrombosis was more frequent with bivalirudin, irrespective of GPI mode of use [20]. Although pre-specified, the conclusion of this subanalysis should be regarded only as hypothesis generating. Another subanalysis assessed the impact on outcomes of the bivalirudin infusion dose after PCI. The prolonged infusion of bivalirudin at the higher dose given during PCI (1.75 mg/kg/h) was associated with a rate of acute stent thrombosis (0.4%) similar to that in the UFH arm (0.2%) with or without GPI. Acute stent thrombosis was higher (1.6%) in the group continuing bivalirudin infusion at reduced dose (0.25 mg/kg/h) [21]. Major bleeding was lower with bivalirudin than with UFH, irrespective of the post-PCI infusion dose [21].

The HEAT-PPCI was a single-center study that challenged the benefit of bivalirudin in terms of reduced bleeding and improved net clinical outcomes [22]. Differently from previous bivalirudin trials, the HEAT-PPCI trial compared bivalirudin ($n=905$) with UFH alone ($n=907$), without routine use of GPI in the setting of primary PCI for STEMI. Indeed, GPIs were allowed only for bailout use in both treatment groups. Bivalirudin infusion was stopped at the end of PCI. Prasugrel and ticagrelor were used in about 90% of patients; radial access was used in 80%, and GPI were given to 13% and 15% of patients treated with bivalirudin and UFH, respectively. The 30-day primary composite endpoint of all-cause mortality, cerebrovascular accidents, recurrent infarction, urgent target vessel revascularization was significantly higher with bivalirudin, mostly driven by higher early MI. Definite or probable stent thrombosis,

mostly acute, was significantly higher with bivalirudin (3.4% vs. 0.9%; $p=0.001$). In disagreement with the other trials, there were no differences in major and minor bleeding between bivalirudin and UFH. The main concerns that have been raised in HEAT-PPCI include its open-label, single-center design and a possible underdosing of bivalirudin.

Additional data on the comparative effectiveness of bivalirudin and UFH, with or without GPI in the setting of primary PCI, have been recently provided by the BRIGHT multicenter, open-label trial, which randomized Chinese patients with acute MI (90% STEMI) to bivalirudin alone ($n=735$), UFH alone ($n=729$), or UFH plus tirofiban ($n=730$) [23]. Among patients treated with bivalirudin, a post-procedure infusion at the PCI dose of 1.75 mg/kg/h was administered for a median of 180 minutes (IQR 148–240 minutes). The radial access was used in about 79% of patients. Net adverse clinical events at 30 days were lower in the bivalirudin group than both heparin groups, driven by reduction in major bleeding and no differences between treatments in the 30-day rates of major adverse cardiac or cerebral events. Moreover, there were no differences in 30-day stent thrombosis (0.6% in the bivalirudin, 0.9% in the heparin alone, and 0.7% in the heparin plus tirofiban group; $p=0.77$) or in acute (<24 hour) stent thrombosis (0.3% in each group). Patients treated with UFH alone had similar ischemic outcomes compared with those treated with UFH plus tirofiban. At the 1-year follow-up, the results remained similar.

Based on the recent EUROMAX and HEAT-PCI trials casting doubts on the superior safety and efficacy balance of bivalirudin as compared with heparin plus GPI, the most recent 2014 European guidelines on myocardial revascularization have downgraded the recommendation for the use of bivalirudin in primary PCI for STEMI from Class I A to Class IIa A, while UFH is indicated in Class I C (Table 41.3) [1]. The recommended bivalirudin dosage is 0.75 mg/kg IV bolus followed by IV infusion of 1.75 mg/kg/h for up to 4 hours after the procedure [1]. This latter dose regimen seems effective and safe, with no excess in stent thrombosis and reduced bleeding compared to heparin with or without GPI, as demonstrated in the BRIGHT trial, which was published after the European guidelines release. In the most recent 2013 US guidelines on STEMI, both bivalirudin and UFH are indicated as anticoagulation options for primary PCI in Class I B and I C, respectively, reflecting the greater amount of evidence on bivalirudin (Table 41.3) [3]. These latter guidelines have been released before EUROMAX, HEAT-PCI, and BRIGHT trials and are based on the HORIZONS-AMI findings.

Factor Xa inhibitors

Factor Xa inhibitors are the most refined and lowest molecular weight heparin. They contain a pentasaccharide sequence that specifically binds factor Xa. Fondaparinux, the most well-studied and widely used of these agents, is a 1.7 kDa synthetic pentasaccharide that rapidly and reversibly binds AT, inducing a conformational change that accelerates AT–Xa interactions by >300-fold. Fondaparinux can be administered in a fixed dose (2.5 mg for creatinine clearance >30 L/minute) with no need for weight-based adjustment or routine monitoring. This drug does not significantly interact with any cells or other plasma proteins, and therefore does not affect platelet function or cause HIT.

In NSTEMI-ACS, fondaparinux with lower bleeding leads to lower 30-day mortality compared with enoxaparin and for this reason is the agent of choice for anticoagulation in this settings [24].

Because of higher catheter-related thrombosis, fondaparinux is not recommended for PCI, and the adjunctive use of UFH at the time of PCI in NSTEMI-ACS is recommended [25]. The addition of low or standard UFH dose at the time of PCI does not increase bleeding; low dose UFH was not superior to standard ACT-guided UFH dosing [25].

In patients with STEMI fondaparinux reduced death and MI in patients treated with thrombolysis, but increased ischemic events in primary PCI compared with UFH and thus is not recommended in this latter setting [26].

Interactive multiple choice questions are available for this chapter on www.wiley.com/go/dangas/cardiology

Parenteral Antiplatelet Agents in PCI

Piera Capranzano, Giuseppe Gargiulo, and Corrado Tamburino

Cardiovascular Department, Ferrarotto Hospital, University of Catania, Catania, Italy

Percutaneous coronary intervention (PCI) has a central role in the management of patients with stable or unstable coronary artery disease. To maintain the immediate results of PCI and prevent complications and recurrence of thrombotic events, inhibition of platelet activity is essential. Parenteral antiplatelet agents include glycoprotein IIb/IIIa inhibitors (GPI) and cangrelor, which is a reversible inhibitor of the platelet adenosine diphosphate receptor (P2Y₁₂). These agents have a useful pharmacologic profile because of their ability to reach rapid antiplatelet effect and overcome the limitations of oral antiplatelet agents.

This chapter examines the contemporary evidence on the use of parenteral antiplatelet agents in PCI, reporting current recommendations for best clinical practice [1–3].

Glycoprotein IIb/IIIa inhibitors

The IIb/IIIa integrin receptor on the surface of platelets binds preferentially to collagen and fibrinogen as well as fibronectin, vitronectin, and von Willebrand factor. IIb/IIIa activation triggers the final common pathway of platelet aggregation: fibrinogen cross-linking of platelets. Activation of the receptor also fosters platelet adhesion to the vascular endothelial surface. GPI abrogate the effects of the IIb/IIIa receptor on platelet aggregation and adhesion through reversible or irreversible inhibition (Figure 42.1). Three GPIs are commercially available: abciximab, eptifibatide, and tirofiban (Table 42.1).

Abciximab

This is a chimeric murine-human monoclonal antibody that consists of the Fab fragment of a murine glycoprotein IIb/IIIa antibody fused the constant region of human IgG. Abciximab binds to platelets with high affinity and irreversibly. It is a long-acting agent (>48 hours) but its effects are readily reversed with platelet transfusions. Abciximab has a rapid onset of action, a half-life of 30 minutes, and causes complete platelet inhibition within 2 hours of administration. Abciximab is eliminated by protease degradation. Patients sometimes produce anti-chimeric antibodies; however, hypersensitivity/anaphylactic reactions to abciximab are rare. Abciximab should be dosed as a bolus of 0.25 mg/kg followed by 0.125 µg/kg/min infusion (maximum

10 µg/min) which can be continued for 12 hours after PCI. There is no adjustment for renal insufficiency.

Eptifibatide

This is a non-immunogenic cyclic heptapeptide that reversibly inhibits the platelet IIb/IIIa receptor as a competitive inhibitor of the fibrinogen-binding site. Eptifibatide contains an active pharmacophore derived from barbourin, the primary component of southeastern pigmy rattlesnake poison. This agent is short acting (2–4 hours) and its effects are not reversible with platelet transfusions. Eptifibatide has a rapid onset, a half-life 2.5 hours, and causes high-level platelet inhibition within 2 hours of administration. Eptifibatide is cleared predominantly by the kidneys and should be dosed with caution in patients with renal insufficiency (infusion should be reduced by half if creatinine clearance is <50 mL/min and should be avoided in patients on hemodialysis). Eptifibatide should be dosed with a bolus of 180 µg/kg over 1–2 minutes, a second bolus of 180 µg/kg 10 minutes later, and an infusion of 2 µg/kg/min.

In the BRIEF-PCI trial, a single bolus dose plus a truncated infusion (<2 hours) of eptifibatide was used in low risk patients undergoing PCI and was found to have a similar incidence of death, myocardial infarction (MI), and target vessel revascularization (TVR), but with less incidence of major bleeding [4]. Accordingly, a recent retrospective study demonstrated that the catheterization laboratory-only regimen compared with prolonged infusion after PCI was associated with reduced bleeding complication in the absence of differences in death and MI [5].

Tirofiban

This is a reversible non-peptide GPI that acts as a competitive inhibitor of the fibrinogen-binding site. This agent is short acting (2–4 hours) and its effects are not reversible with platelet transfusions. When using tirofiban and eptifibatide approximately 4 hours are needed for the effects to wear off. Tirofiban is slower in onset than the other two GPIs, has a half-life of 2 hours, and causes high-level platelet inhibition within 2 hours of administration. Tirofiban is recommended for patients with STEMI at a high bolus dose of 25 µg/kg IV, then 0.15 µg/kg/min infusion. The bolus and infusion should be reduced by 50% in patients with a creatinine clearance of <30 mL/min.

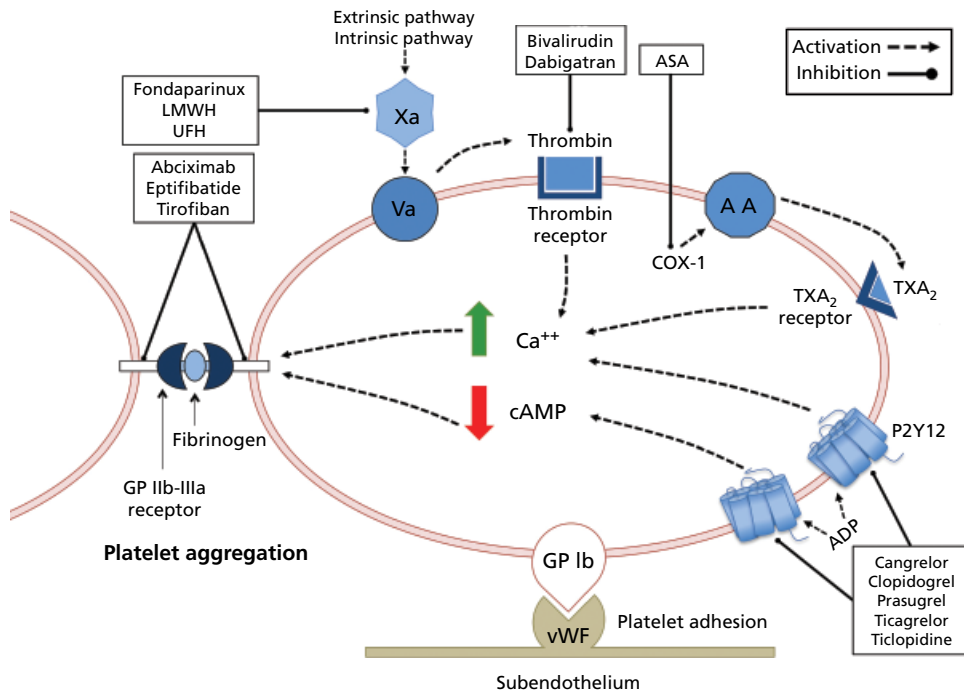

Figure 42.1 Platelet activation pathway and site of action of antiplatelet agents. AA, arachidonic acid; ADP, adenosine diphosphate; cAMP, cyclic adenosine monophosphate; ASA, acetylsalicylic acid (aspirin); COX-1, cyclo-oxygenase-1; GP, glycoprotein; LMWH, low molecular weight heparin; TXA₂, thromboxane A₂; UFH, unfractionated heparin; vWF, von Willebrand factor.

Table 42.1 Basic pharmacologic characteristics of glycoprotein IIb/IIIa inhibitors (GPI).

	Abciximab	Eptifibatide	Tirofiban
Type	Fab fragment of chimeric human-murine monoclonal antibody	Synthetic cyclic heptapeptide	Synthetic non-peptide
Molecular weight	Large molecule (47,515 Da)	Small molecule (832 Da)	Small molecule (496 Da)
Plasma half-life	10–30 minutes	2.5–2.8 hours	1.2–2 hours
Receptor binding	Minutes	Seconds	Seconds
Elimination route	Spleen	Renal 75%	Renal 65%; biliary 25%

Stable coronary artery disease

The evidence emerging from major clinical trials did not show additional benefit by administering GPI after a loading dose of 600 mg clopidogrel [6–8]. Therefore, in the setting of elective PCI, GPI are not recommended except for “bailout” situations (intraprocedural thrombus formation, slow-flow, threatened vessel closure) in which they could be considered (Class IIa, level C of recommendation), as there is anecdotal experience suggesting potential benefits in these settings [1].

Non-ST-segment elevation acute coronary syndrome

Some older trials before the era of dual antiplatelet therapy showed that patients undergoing PCI experienced lower ischemic events, mainly driven by reduction in MI when receiving adequately dosed GPI combined with unfractionated heparin (UFH) instead of UFH alone [1,9]. Interestingly, the ISAR-REACT 2 trial, showed that the benefit in terms of composite primary endpoint (death, MI, or urgent TVR within 30 days) related to GPI use for PCI was still present even if clopidogrel pretreatment at loading dose of 600 mg was given in patients with NSTEMI, but not in those with unstable angina [10]. In the ACUTY trial, the combination of UFH plus GPI was compared with bivalirudin alone (with bailout GPI in 7.4%), demonstrating a significant benefit in terms of the composite of ischemic and bleeding complications (11.7% vs. 10.1% at 30 days; p = 0.02), mainly driven by decrease in major bleeding (5.7% vs. 3.0%; p < 0.001) [11]. Notably, this bivalirudin advantage was confirmed at 1-year follow-up and was not related to the timing of GPI administration (upstream or downstream) [12]. In the latter trial, approximately 40% of the patients did not have elevated cardiac biomarkers, and more than 40% did not undergo PCI. The combination UFH plus abciximab was compared with bivalirudin alone in patients with NSTEMI undergoing PCI in the ISAR-REACT 4 trial [13]. In this latter study, no benefits have emerged in the primary composite endpoint (death, recurrent MI, urgent TVR, or major bleeding within 30 days), but significantly more major bleeding events were observed in the GPI group than in the bivalirudin group (4.6% vs. 2.6%; p = 0.02).

The use of upstream eptifibatide with or without clopidogrel pretreatment compared with downstream provisional eptifibatide in the EARLY-ACS trial was related to increased bleeding in the absence of ischemic benefits in patients with NSTEMI-ACS [14].

Finally, in the TRITON-TIMI 38 trial, ischemic and bleeding events of prasugrel versus clopidogrel were not influenced by GPI use: (i) the significant reduction of cardiovascular death, MI, or stroke by using prasugrel instead of clopidogrel remained significant in patients receiving GPI ($n=7414$, 54.5% of overall study population) as was in patients not receiving GPI (p for interaction=0.83); (ii) TIMI major or minor bleeding did not differ significantly between prasugrel and clopidogrel groups, irrespective of GPI use (p for interaction=0.19) [15]. These data led to the following guidelines recommendations [1,2].

- European guidelines (on myocardial revascularization 2014):
 - 1 Current evidence does not support an additional benefit of routine upstream use of GPI in patients with NSTEMI-ACS undergoing coronary angiography (Class III, level A);
 - 2 GPI should be considered in bailout or thrombotic complications (Class IIa, level C);
- US guidelines (on NSTEMI-ACS management 2014):
 - 1 GPI use (abciximab, double-bolus eptifibatid or high-dose bolus tirofiban) is useful at the time of PCI in the case of NSTEMI-ACS with high-risk features (e.g., elevated troponin) but without adequate pre-treatment with clopidogrel or ticagrelor (Class I, level A);
 - 2 GPI use in upstream can be considered in patients treated with an early invasive strategy and dual antiplatelet therapy with intermediate/high risk features (e.g., positive troponin) (Class IIb, level B); and
 - 3 GPI use at the time of PCI could be reasonable in patients with NSTEMI-ACS and high-risk features (e.g., elevated troponin) treated with UFH and adequately pretreated with clopidogrel (Class IIa, level B). This latter recommendation should be reserved for those patients without high risk of bleeding complications and does not include prasugrel or ticagrelor because there are still insufficient data to make specific recommendations.

ST-segment elevation myocardial infarction

In the era before pre-loading with thienopyridines, several studies have shown that GPI, mainly abciximab, added to UFH in patients with STEMI treated with primary PCI is associated with improved outcomes [16–19]. In order to test if the early upstream administration of abciximab would improve outcomes compared with intracatheterization laboratory administration, in the FINESSE trial [20], 2452 patients with STEMI undergoing primary PCI were randomly assigned to: (i) early upstream (at first medical contact) abciximab plus half-dose reteplase (combination-facilitated PCI); (ii) early upstream abciximab alone (abciximab-facilitated PCI), or (iii) abciximab administered immediately before the primary PCI. No significant differences emerged among the three groups in the primary endpoint (composite of all-cause death, ventricular fibrillation occurring more than 48 hours after randomization, cardiogenic shock, and congestive heart failure during the first 90 days after randomization; $p=0.55$) and in 90-day mortality ($p=0.49$). Importantly, subgroup analyses showed a survival benefit with the use of abciximab in patients presenting within 4 hours of symptom onset to non-PCI hospitals and requiring transfer for primary PCI [21].

In the On-TIME-2 trial including 936 patients with STEMI with a median time from onset of symptoms to diagnosis of 76 minutes, high-bolus dose tirofiban started during the pre-hospital phase and continued for up to 18 hours after the procedure provided significant improvements in surrogate markers of reperfusion

(ST-segment resolution) compared with placebo (only provisional use of tirofiban in catheterization laboratory) [22]. With upstream tirofiban, there was also a reduction in the composite secondary endpoint of death, recurrent MI, urgent TVR, and thrombotic bailout, although the difference was mainly caused by a decrease in the thrombotic bailout. These latter data were pooled together with those on 414 patients enrolled during the On-TIME-2 open-label run-in phase, comparing tirofiban with no tirofiban [23]. This protocol pre-specified pooled analysis of the two study phases showed that the rate of major adverse cardiac events at 30 days was significantly reduced by systematic high dose tirofiban versus no tirofiban or placebo, with also reduced mortality, in the absence of significant increase of major bleeding. Unfortunately, it was not clear if the benefits in On-TIME-2 were related to upstream versus downstream administration or related to systematic versus provisional administration. The differences of results between FINESSE and On-TIME-2 that should be considered are that the time from symptom onset to GPI administration was much shorter in On-TIME-2 [24], and, furthermore, in the FINESSE trial only a few patients were recruited by the ambulance system and only 40% of patients were transferred for PCI from centers without catheterization laboratories. The issue of whether abciximab remains beneficial after adequate clopidogrel loading was tested also in patients ($n=800$) with STEMI in the BRAVE 3 trial, showing no benefits in terms of infarct size prior to discharge [25]. However, the infarct size 30 days after primary PCI for anterior STEMI was reduced by the systematic use of an intracoronary bolus of abciximab in the INFUSE-MI trial [26]. Therefore, there is no definitive answer regarding the current role of routine use of GPI in primary PCI, particularly when prasugrel or ticagrelor is used, and the value of starting upstream of PCI remains uncertain.

Finally, several studies have assessed the administration of abciximab as an intracoronary instead of intravenous bolus. Despite some small studies suggesting potential benefits of the intracoronary route, these observations were not confirmed in large randomized trials and in a recent meta-analysis pooling results of five randomized trials [27,28].

On this background the following guideline recommendations were set [1,3]:

- European guidelines (on myocardial revascularization 2014) [1]:
 - 1 Upstream use of GPI (versus in-lab use) can be considered only in high risk patients undergoing transfer for primary PCI (Class IIb, level B);
 - 2 In-lab use is reasonable for angiographic evidence of large thrombus, slow- or no-reflow, and other thrombotic complications as bailout therapy (Class IIa, level C), although this has not been tested in randomized trials.
- US guidelines (on STEMI management 2013) [3]:
 - 1 It is reasonable to begin treatment with an intravenous GPI such as abciximab (level of evidence A), high-bolus-dose tirofiban (level of evidence B), or double-bolus eptifibatid (level of evidence B) at the time of primary PCI (with or without stenting or clopidogrel pretreatment) in selected patients with STEMI who are receiving UFH (Class IIa).
 - 2 It may be reasonable to administer intravenous GPI in the pre-catheterization laboratory setting (e.g., ambulance, emergency department) to patients with STEMI for whom primary PCI is intended (Class IIb, level B of recommendation).
 - 3 It may be reasonable to administer intracoronary abciximab to patients with STEMI undergoing primary PCI (Class IIb, level B of recommendation).

Cangrelor

Cangrelor is an intravenous reversible P2Y₁₂ inhibitor. Chemically known as N-2-methylthio-ethyl-2-(3,3,3-trifluoropropylthio)-5'-adenyl acid, it is an analogue of adenosine triphosphate (ATP), the natural antagonist of the P2Y₁₂ receptor. It is dephosphorylated to the nucleoside and its primary metabolite is essentially inactive. It is characterized by a potent, predictable inhibition of ADP-induced inhibition of platelet aggregation that is virtually immediate (when administered as a bolus) and rapidly reversible. Cangrelor achieves almost complete and immediate inhibition of ADP-induced platelet aggregation when administered as a bolus of 30 µg/kg, and continuous infusion sustains the high degree of inhibition. The plasma half-life is approximately 3–5 minutes and platelet function is

restored within 1 hour after cessation of infusion. Notably, cangrelor is not characterized by a significant renal or hepatic metabolism, a relevant difference when compared with oral P2Y₁₂ inhibitors that can be particularly attractive in the acute setting.

While the pivotal trials showed a satisfactory rate of major bleeding side effects, the highly potent cangrelor did not demonstrate a significant impact on adverse cardiac events. The initial promising results obtained in phase 2 studies have led the foundation for cangrelor phase 3 program, CHAMPION (Cangrelor versus standard tHerapy to Achieve optimal Management of Platelet InhibitiON). This program originally consisted of two randomized 1 : 1, double-blind, double-dummy trials: CHAMPION PCI and CHAMPION PLATFORM (Table 42.2) [29,30]. These trials tested

Table 42.2 Cangrelor phase 3 trials.

	CHAMPION PLATFORM	CHAMPION PCI	CHAMPION PHOENIX	BRIDGE
Number of patients	5295 (modified ITT)	8877 (ITT)	10,942 (modified ITT)	210
Patients included	Requiring PCI (with or without stent) in elective or ACS excluding STEMI and P2Y12 naive	Requiring PCI (with or without stent) in patients with ACS. Previous daily use of clopidogrel 75 mg allowed	Requiring either urgent or elective PCI and P2Y12 naive	ACS or treated with a coronary stent and receiving a thienopyridine awaiting CABG
Cangrelor protocol	30 µg/kg IV bolus and 4 µg/kg/minute IV infusion	30 µg/kg IV bolus and 4 µg/kg/minute IV infusion	30 µg/kg IV bolus and 4 µg/kg/minute IV infusion	Infusion of 0.75 µg/kg/minute IV on the basis of a stage I dose-finding study in 10 patients
Duration of treatment	Minimum infusion of 2 h and a maximum of 4 h, followed by clopidogrel 600 mg	Infusion at least 2 h or the duration of PCI, and a maximum of 4 h followed by clopidogrel 600 mg	Infusion at least 2 h or the duration of PCI, and a maximum of 4 h followed by clopidogrel 600 mg	Thienopyridines were stopped (clopidogrel 5 days before CABG, prasugrel 7 days) and cangrelor or placebo was administered for at least 48 h which was discontinued 1–6 h before CABG
Comparator	Clopidogrel 600 mg loading dose (end of PCI)	Clopidogrel 600 mg loading dose (before PCI)	Clopidogrel 300 or 600 mg loading dose (before PCI)	Placebo
Primary endpoint	Composite of death, MI, or IDR at 48 h	Composite of death from any cause, MI, or IDR at 48 h	Composite of death, MI, IDR, or ST at 48 h	Platelet reactivity assessed daily
Safety endpoint	Bleeding events at 48 h (single events and categorized events [ACUITY, GUSTO, TIMI criteria])	Bleeding events at 48 h (single events and categorized events [ACUITY, GUSTO, TIMI criteria])	Major/minor non-CABG related hemorrhage by clinically relevant criteria at 48 h (TIMI, GUSTO, others); Incidence of blood product transfusion until 48 h, categorized according to relationship with CABG	Excessive CABG surgery-related bleeding
Notes	Enrollment was stopped when a 70% interim analysis concluded that the trial would be unlikely to show superiority for the primary endpoint	Enrollment was stopped when a 70% interim analysis concluded that the trial would be unlikely to show superiority for the primary endpoint		

ACS, acute coronary syndromes; CABG, coronary artery bypass graft; IDR, ischemia-driven revascularization; ITT, intention-to-treat; MI, myocardial infarction; PCI, percutaneous coronary interventions; PRU, P2Y12 reaction unit; ST, stent thrombosis; STEMI, ST-segment elevation myocardial infarction.

the hypothesis that cangrelor, given during PCI, could reduce thrombotic events compared to clopidogrel administered at the beginning or at the end of PCI respectively, with an acceptable safety profile. The phase 3 CHAMPION-PCI and CHAMPION-PLATFORM trials compared cangrelor with clopidogrel 600 mg in patients with ACS scheduled for PCI, with the timing of the clopidogrel dose being the major difference between the trials. Both trials were prematurely discontinued because of insufficient evidence of the clinical effectiveness of cangrelor. However, there were reductions in stent thrombosis and death from any cause. Furthermore, the lack of overall demonstrable clinical benefit of cangrelor could be related to the definition of MI used, which made it difficult to adjudicate early ischemic events. The definition of MI used in CHAMPION PCI and PLATFORM did require biomarkers elevation but clinical judgment was applied to interpreting the relationship to the PCI or to the index event; that definition preceded the last update of universal definition of MI. According to the original definition, the presence of stable or falling biomarkers at the time of PCI was not required to define PCI-related MI endpoint. Two independent analyses of the CHAMPION dataset retrospectively applied the universal MI definition and consistently indicated a reduced number of PCI-related MI events and more favorable treatment effects for cangrelor.

On this background, the CHAMPION-PHOENIX study was designed with a careful evaluation of the MI definition [31]. Differing from the two previous studies, the CHAMPION-PHOENIX trial had the following characteristics: (i) the definition of MI as endpoint; (ii) the comparator arm was clopidogrel 300 or 600 mg, at the investigator's discretion; (iii) the primary endpoint was the composite of death, MI, ischemia-driven revascularization, or stent thrombosis (including intraprocedural) at 48 hours; and (iv) the population of interest was restricted to clopidogrel-naïve patients. The definition of MI used in PHOENIX was based on the Second Universal definition of MI for all types of MI but PCI-related (type 4a) MI, where this definition was expanded to include some elements (like angiographic complications) that were later included in the Third Universal MI definition. In PHOENIX PCI-related MI could be assessed using cardiac biomarkers only if troponin pre-PCI was normal or elevated but stable or falling according to at least two samples over 6 hours. As learned from CHAMPION PCI and PLATFORM, great emphasis was placed on an accurate assessment of baseline status: in PHOENIX, 98% of the enrolled patients had at least two troponin values before PCI. Patients with NSTEMI-ACS, with one or no biomarker assessment available or increasing biomarkers before PCI required additional evidence of MI. By definition, PCI-related MI was not adjudicated in patients with STEMI as entry diagnosis.

CHAMPION-PHOENIX (Table 42.2) was a randomized, double-blind, double-dummy trial that compared cangrelor with clopidogrel in 11,145 patients who had not previously received a P2Y₁₂ antagonist and required PCI, including patients with stable angina and ACS (with or without ST-segment elevation). The primary efficacy endpoint was a composite of death, MI, ischemia-driven revascularization, or stent thrombosis at 48 hours after randomization. The rate of the primary efficacy endpoint was lower in the cangrelor group than in the clopidogrel group (4.7% vs. 5.9%; $p=0.005$), driven by the reduction in the rate of acute periprocedural MI and by a reduced rate of stent thrombosis (0.8% vs. 1.4%; $p=0.01$). The benefit from cangrelor was consistent across several pre-specified subgroups, except for diabetic patients, who represented 27.8% of the global population ($p=0.26$). The rate of

the primary safety endpoint was 0.16% in the cangrelor group versus 0.11% in the clopidogrel group ($p=0.44$). Overall, the data suggest a promising role for cangrelor, particularly for patients with ACS who could benefit from its pharmacologic rapidity in the onset–offset of action. However, future studies are needed to determine the optimal way to transition ACS PCI patients from cangrelor to prasugrel or ticagrelor; such patients represented only 43% of patients recruited in the CHAMPION-PHOENIX trial. The pre-specified pooled analysis of patient-level data from the three cangrelor trials confirmed the lower rates of PCI peri-procedural thrombotic complications (3.8% for cangrelor vs. 4.7% for control; $p=0.0007$) and of stent thrombosis (0.5% vs. 0.8%; $p=0.0008$) with no difference in major bleeding [32].

Because of its rapid on–off effect, cangrelor also has potential as a bridging agent in patients requiring surgery, by adequately preventing ischemic events while allowing rapid restoration of platelet function on therapy discontinuation in the event of bleeding. The BRIDGE study evaluated the efficacy of this strategy for patients taking clopidogrel who were scheduled for surgery (Table 42.2) [33]. A total of 210 patients taking thienopyridines for ACS or after stent placement, who were awaiting coronary artery bypass grafting (CABG), had their thienopyridine stopped and were then randomized to either cangrelor (0.75 µg/kg/min) or placebo for at least 48 hours. The study drug was discontinued 1–6 hours before CABG surgery. Patients randomized to cangrelor had lower levels of platelet reactivity throughout the treatment period compared with placebo. There was no significant difference in major bleeding prior to CABG surgery, although minor bleeding episodes were numerically higher with cangrelor. With the use of a surrogate endpoint (platelet reactivity as the primary endpoint) the findings of this trial must be interpreted with caution. However, it demonstrates the potential role of cangrelor in this not rare clinical setting.

Specific guidelines recommendations on the use of cangrelor are not available yet. Cangrelor has been approved in Europe for the reduction of thrombotic cardiovascular events in adult patients with coronary artery disease undergoing PCI who have not received an oral P2Y₁₂ inhibitor prior to the PCI procedure and in whom oral therapy with P2Y₁₂ inhibitors is not feasible or desirable. Recently, the FDA recommended approval for cangrelor for human use in the USA.

Interactive multiple choice questions are available for this chapter on www.wiley.com/go/dangas/cardiology

Role of Parenteral Agents in PCI for Stable Patients

Joanna Ghobrial, David A. Burke, and Duane S. Pinto

Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, MA, USA

Optimal anticoagulation has proven to be a key component in the management of patients undergoing percutaneous coronary intervention (PCI). There has been a considerable evolution in the pharmacotherapy of PCI since the early days of balloon angioplasty. Medications with variable modes of action are used to reduce complications by inhibiting thrombin formation, platelet activation, and platelet aggregation. These medications have targeted different portions of the coagulation cascade, and newer synthetic agents have been developed to specifically target factor Xa or thrombin in an attempt to minimize ischemic and bleeding complications, goals that are often at odds with one another.

The principal aims of pharmacotherapy during PCI are to avoid the adverse consequences related to iatrogenic plaque rupture from balloon inflation or stent deployment after PCI and to reduce the risk of thrombus formation on intravascular PCI equipment during the procedure. Growing evidence supports use of a variety of agents in the setting of stable ischemic heart disease, unstable angina, non-ST-elevation myocardial infarction (NSTEMI), and ST-elevation myocardial infarction (STEMI).

Most data involving newer antithrombotic drugs focus on their use in acute coronary syndromes (ACS). However, the main aims of this review are to summarize the agents available for anticoagulation during elective PCI, to outline their mode of action, and to review the evidence supporting their use.

Antiplatelet therapy using glycoprotein IIb/IIIa inhibition

Platelet adherence to abnormal surfaces and aggregate is mediated by surface membrane glycoprotein receptors which are expressed in increasing numbers with platelet activation and are potential targets for antiplatelet therapies. The platelet glycoprotein IIb/IIIa receptor has a central role in platelet aggregation and so forms an attractive target for therapy.

Abciximab, tirofiban, and eptifibatide are currently available for clinical use. Abciximab is a monoclonal antibody directed against the glycoprotein receptor, while tirofiban and eptifibatide are high affinity non-antibody receptor inhibitors. The use of intravenous glycoprotein IIb/IIIa inhibitors (GPI) has been studied in patients with ACS and those undergoing intracoronary stent implantation and has been associated with improved outcomes (Figure 43.1).

The use of GPI among patients who are undergoing PCI depends upon on the clinical setting of PCI and patient risk for ischemic complications. The utility of GPI in “elective” PCI has been evaluated in the EPIC, EPILOG, and EPISTENT trials for abciximab [1–5], IMPACT-II and ESPRIT trials for eptifibatide [6,7], and the ADVANCE and TOPSTAR trials for tirofiban (Table 43.2) [8,9]. These trials were completed before the routine use of stents in patients undergoing PCI and before the use of clopidogrel prior to and/or at high dose before PCI and before development of more potent oral antiplatelet agents. The incremental benefit of GPI in patients pretreated with aspirin and clopidogrel was addressed in the ISAR-REACT series of randomized placebo-controlled trials. Among patients undergoing elective PCI, considered low to intermediate risk for ischemic complications, the ISAR-REACT trial found no benefit for GPI at 30 days or in subsequent follow-up at 1 year in patients who had received clopidogrel (600 mg) at least 2 hours prior to the procedure [10]. The same lack of benefit was apparent for GPI in a subgroup analysis of lower risk patients from the ESPRIT trial [11]. However, there is evidence that GPI did provide benefit among patients with ACS and high risk patients undergoing elective procedures who were pretreated with clopidogrel [10,12,13].

Based on available data, many operators limit use of GPI in elective PCI to those patients considered higher risk, or to those who have not already received appropriate pretreatment with antiplatelet therapy, those who have a suboptimal angiographic result or angiographic complications during the procedure, so-called bailout. There is marked variation in opinion regarding the optimal duration of GPI infusion following PCI.

Abciximab

Abciximab is the Fab fragment of the chimeric human-murine monoclonal antibody 7E3. With intravenous bolus, plasma concentrations decrease rapidly with an initial half-life of less than 10 minutes and second phase half-life of 30 minutes, likely related to rapid binding to the platelet glycoprotein receptor. At highest dose, 80% of platelet GP receptors are occupied in 2 hours, and platelet aggregation is completely inhibited. Upon cessation, free plasma concentrations rapidly fall over the first 6 hours, then at a slower rate.

When initially studied in ACS, patients invariably underwent angioplasty without stenting and thienopyridine therapy was not used.

Figure 43.1 Glycoprotein IIb/IIIa inhibitors in percutaneous coronary interventions. The composite endpoint is the risk of death, non-fatal myocardial infarction, or urgent revascularization at 30 days. * Indicates statistical significance at $p < 0.05$. In EPIC, the abciximab bolus plus infusion group was compared with the placebo group. In EPILOG, the abciximab plus low dose heparin and the abciximab plus standard dose heparin groups were combined. In IMPACT-II, the low and high dose eptifibatide groups were combined. In EPISTENT, the stent plus abciximab group was compared with the stent plus placebo group. CIs, confidence intervals; GP, glycoprotein; RRR, relative risk reduction. Source: Sabatine MS, Jang I. The use of glycoprotein IIb/IIIa inhibitors in patients with coronary artery disease. *Am J Med* 2000; **109**(3): 224–237. Copyright 2000 Elsevier.

A number of randomized trials were performed and in a subsequent meta-analysis including over 5400 patients from the EPIC [1–3], EPILOG [4,14], RAPPORT [15], EPISTENT [5], and CAPTURE [16–20] studies who received percutaneous transluminal coronary angioplasty (PTCA), abciximab significantly reduced 30-day mortality and reinfarction (hazard ratio 0.52, 95% CI 0.41–0.65) [21]. A meta-analysis looking at patients with STEMI who underwent PCI with stenting with abciximab or placebo included the RAPPORT [15], ADMIRAL [22,23], ISAR REACT-2 [24], CADILLAC [25], and ACE studies [26]. Abciximab showed a significant reduction in mortality at 30 days (2.4% vs. 3.4% with placebo) and at 6–12 months (4.4% vs. 6.2%), with no increased bleeding seen in these patients [27].

In terms of patients with stable coronary heart disease undergoing PCI, the following trials evaluated outcomes comparing abciximab with placebo in predominantly stable patients and came to differing conclusions.

The EPILOG study examined a lower risk group of patients including approximately 30% with stable ischemia, and patients with unstable angina and ECG changes or acute myocardial infarction (MI) in the previous 24 hours were excluded. The trial randomized 2792 patients to undergo emergent or elective PCI with abciximab and either standard or low dose heparin versus placebo with standard dose heparin. The trial was terminated early at the first interim analysis for reaching its efficacy endpoint (death, MI, or urgent revascularization) at 30 days with greater than 50% relative reduction in both abciximab arms, standard and low dose heparin (composite event rates of 5.4% and 5.2%, respectively) compared with placebo (composite event rate of 11.7%). There was no difference in major bleeding between the groups [4]. Subsequently, the EPISTENT trial randomized 2399 patients undergoing elective (approximately 40%) or emergent PCI to stenting

alone, stenting with abciximab, or PTCA with abciximab [28,29]. All patients who received a stent were given aspirin and ticlopidine. Adverse events (death, MI, and urgent revascularization) at 30 days (10.8%, 5.3%, and 6.9%) and 6 months (11.4%, 5.6%, and 7.8%) were significantly lower in the abciximab groups, with the difference largely driven by reduced death and NSTEMI.

Conversely, the ISAR-REACT study consisted of 2159 patients with stable coronary artery disease undergoing PCI with stenting and treated with aspirin and thienopyridine, who were randomized to abciximab or placebo. The 30-day major adverse cardiac events (MACE) rates between abciximab and placebo were the same (both 4%), and major bleeding complications were comparable [10]. In the ISAR-REACT 2 trial, abciximab administration, among high risk patients with NSTEMI among receiving clopidogrel with a 600-mg loading dose, was associated with a lower incidence of death, MI, or urgent revascularization (8.9% vs. 11.9%, RR 0.75, 95% CI 0.58–0.97; $p = 0.03$), but the benefit was confined to those who with elevated troponin (13.1% vs. 18.3%, RR 0.71, 95% CI 0.54–0.95; $p = 0.02$) compared with those who had normal troponin level (4.6% vs. 4.6%, RR 0.99, 95% CI 0.56–1.76; $p = 0.98$) [13].

Tirofiban

Stable patients undergoing PCI were evaluated in the ADVANCE trial which aimed to assess the potential benefit of using a higher dose of tirofiban than had been used in trials assessing the drug in the setting of ACS (RESTORE, PRISM, and PRISM-PLUS trials) [30–32]. A total of 202 patients, pretreated with thienopyridines, were randomized to high dose bolus tirofiban (25 $\mu\text{g}/\text{kg}/3$ min, and infusion of 0.15 $\mu\text{g}/\text{kg}/\text{min}$ for 24–48 hours) or to placebo [8]. At 6 months, adverse events (death, MI, target vessel revascularization (TVR), or bailout GPI) was significantly less frequent with tirofiban (20% vs. 35%, hazard ratio 0.51, 95% CI 0.29–0.88; $p = 0.01$),

a difference driven by the incidence of MI and bailout GPI in the placebo group. In subgroup analysis, the benefit of tirofiban was significant among patients with ACS but not among those with stable angina.

A small study of 96 patients, the TOPSTAR (The Effect of Additional Temporary Glycoprotein IIb/IIIa Receptor Inhibition on Troponin Release in Elective Percutaneous Coronary Interventions after Pre-treatment with Aspirin and Clopidogrel) trial, was a randomized, double-blind, placebo-controlled study, and the first to observe that additional inhibition of platelet aggregation by tirofiban with aspirin and clopidogrel reduced periprocedural troponin release and the composite endpoint (death, MI, and TVR) after 9 months (2.3% with tirofiban vs. 13.0% with placebo; $p < 0.05$) [9].

Eptifibatide

Eptifibatide is a heptapeptide of the glycoprotein IIb/IIIa receptor that inhibits platelet aggregation. The plasma half-life is 10–15 minutes, and it is predominantly renally excreted (75%) with the remainder via hepatic pathways (25%) (Table 43.1).

Over 4000 patients were enrolled in the IMPACT-II (Integrilin to Minimize Platelet Aggregation and Coronary Thrombosis-II) study (59% with stable coronary disease), which randomized patients to either placebo or one of two doses of eptifibatide [7]. At 30 days, there was no significant difference in the MACE rates between the groups, and eptifibatide did not increase rates of major bleeding or transfusion. By a treatment-received analysis, the lower dose regimen produced a significant reduction in the composite endpoint (11.6% vs. 9.1%; $p = 0.035$), with reduced rates of abrupt closure and ischemic events at 30 days, but the higher dose produced a less substantial reduction (11.6% vs. 10.0%; $p = 0.18$). The investigators believed that the doses studied appeared to be at the lower end of the efficacy–response curve, and that further investigation was needed.

The ESPRIT trial randomly assigned 2064 patients to placebo or eptifibatide immediately prior to elective PCI [6]. The trial was terminated prematurely because eptifibatide reduced the primary endpoint (48-hour death, MI, urgent revascularization, or bailout GPI) by 37% (6.6% vs. 10.5%; $p = 0.0015$).

The INSTANT trial attempted to examine the benefit of added eptifibatide to heparin versus heparin alone in stable patients undergoing complex PCI; however, the trial was stopped early because of slow enrollment and because it lacked statistical power, but there were favorable trends in the primary endpoint of abnormal post PCI creatine kinase-MB (CK-MB) (41% in eptifibatide and heparin group vs. 55% in the heparin alone group, RR 0.74; $p = 0.169$) [33] suggesting that further larger studies are warranted.

Comparisons between agents

The TARGET study was designed to test whether tirofiban was not inferior to abciximab in patients undergoing elective PCI, but demonstrated that tirofiban offered less protection from major ischemic events than did abciximab (30-day MACE 7.6% with tirofiban vs. 6.0% abciximab, HR 1.26, 95% CI 1.01–1.57; $p = 0.038$) [34]. The inferiority of tirofiban was thought to be the result of an inadequate bolus regimen.

The TENACITY (Tirofiban Evaluation of Novel Dosing Versus Abciximab with Clopidogrel and Inhibition of Thrombin) trial sought to investigate a high dose tirofiban bolus regimen and randomized patients undergoing elective PCI to abciximab or tirofiban,

with all patients receiving aspirin and clopidogrel. Patients were additionally randomized to either unfractionated heparin (UFH) or bivalirudin. The planned enrollment of 8000 only reached 383 patients as a result of financial reasons. Results from this small group suggested that further study is warranted (30-day MACE, 8.8% with abciximab vs. 6.9% with tirofiban) [35].

A meta-analysis of eight prospective trials evaluating 14,644 patients undergoing PCI compared abciximab, tirofiban, and eptifibatide. Certain differences were noted between the agents, but these trials compared each drug with placebo so conclusions regarding comparative effectiveness is limited, especially because these trials largely included patients treated with PTCA only or those who did not receive thienopyridine treatment [36].

Unfractionated heparin

The most commonly used antithrombin agent for PCI has been UFH. UFH has been the gold standard for many years in the treatment of patients undergoing PCI because of its ease of administration, rapid onset, easily measurable efficacy (monitored by activated clotting time; ACT), and reversibility. It is a heterogeneous mixture of glycosaminoglycans of varying lengths with a high affinity for antithrombin. The antithrombin activity of UFH is dependent on antithrombin activation, which subsequently inactivates thrombin, and so UFH is considered an indirect antithrombin agent.

Elimination of UFH is initially through rapid metabolism within the endothelial cells and macrophages (zero-order kinetics), and then by a slower renal clearance (first-order kinetics). Plasma half-life is dependent on the dosage administered but is of the order of 1 hour at doses of 100 unit/kg. If necessary, the effects can be reversed with protamine sulfate.

UFH remains the mainstay anticoagulant worldwide in patients undergoing PCI. Despite its common use, there have been no prospective randomized comparisons demonstrating efficacy compared with placebo for obvious reasons, and the current dosing regimens are empiric because clinical experience and anecdotal evidence demonstrate clearly the need for some degree of anticoagulation with balloon and stent-mediated vascular wall injury. In a pooled analysis of data from randomized clinical trials utilizing UFH only, there was a gradient of benefit associated with increasing degrees of anticoagulation. At ACT levels >350 seconds there was an association with fewer ischemic events, although bleeding rates increased [37]. The STEEPLE (Safety and Efficacy of Intravenous Enoxaparin in Elective Percutaneous Coronary Intervention: An International Randomized Evaluation) Study [38] noted that bleeding increased significantly with ACT values >325 seconds, but ischemic events also increased when the ACT value was <325 seconds [38]. Available data do not support the use of prolonged heparin infusions after PCI where an excess in bleeding events and accompanying increase in the length of stay without a reduction in ischemic events has been observed with this approach.

Anticoagulation using UFH monotherapy appears insufficient to optimally protect against ischemic events such as peri-procedural MI in patients with ACS. Aggressive antiplatelet therapy is thought to prevent against embolization of platelet aggregates formed as a result of platelet activation induced by UFH. The use of high dose clopidogrel or GPI in elective PCI, or the use of both in patients with ACS undergoing PCI reduces peri-procedural ischemic complications with UFH [6,8,28].

The high ACT levels utilized in early studies are no longer thought to be required given the high prevalence of stent usage and

Table 43.1 Overview and dosing for antithrombin agents.

	Dose	Half-life	Clinical condition	Note	Trials
Heparins					
Unfractionated heparin	60IU/kg IV bolus and 12IU/kg infusion adjusted to maintain PTT 50–70 s Intermittent bolus dosing during PCI to maintain ACT >200–250 with GPI and >250–300 s for HemoTec or 300–350 s for Hemochron without GPI		Stable IHD UA NSTEMI conservative and invasive STEMI	Contraindicated with HIT Avoid switching to LMWH Continue if planned CABG Can use with fibrinolytic therapy though enoxaparin and fondaparinux superior	6 small randomized studies vs. placebo
Enoxaparin	1 mg/kg SQ twice daily up to 100 mg/dose For PCI, additional 0.3 mg/mg IV dose if last SQ dose >8 h or <2 doses administered but prior therapy administered With fibrinolysis and age >75 years, 30 mg IV followed 15 min later by 1 mg/kg subcutaneously every 12 h until hospital discharge for a maximum of 8 days. For age >75 years, eliminate IV bolus and reduce maintenance to 0.75 mg subcutaneously twice daily and if CrCl <30 mL/min reduce subcutaneous dose frequency to daily irrespective of age	4.5 h	Stable IHD UA NSTEMI STEMI fibrinolysis	Reduce dose (1 mg/kg every 24h) with renal failure (CrCl <30 mL/min) Avoid switch to UFH Avoid if CABG <24 h Discontinue 12–24 h before CABG and dose with UFH	ESSENCE/ TIMI-11B SYNERGY ACUTE-II INTERACT A to Z EXTRACT-TIMI 25
Dalteparin	120 IU/kg subcutaneously every 12 h (maximum 10,000 IU twice daily)	Approx 2–5 h	IV GPI planned: target ACT 200 s using UFH No IV GPI planned: target ACT 250–300 s for HemoTec; 300–350 s for Hemochron using UFH		FRISC FRIC
Glycoprotein IIb/IIIa inhibitors					
Abciximab	For PCI, 0.25 mg/kg IV bolus administered 10–60 min prior to PCI, followed by infusion of 0.125 µg/kg/min (max 10 µg/min) for 12 h	Approx 30 min	UA NSTEMI STEMI	No dose adjustment for renal or hepatic impairment	EPIC EPILOG RAPPORT EPISTENT CAPTURE RAPPORT ADMIRAL ISAR-REACT ISAR-2 CADILLAC
Tirofiban	(Off-label) for PCI: loading dose 25 µg/kg IV over 3 min at time of procedure. Infusion 0.15 µg/kg/min continued for 18–24 h UANSTEMI: initial rate 0.4 µg/kg/min IV for 30 min, then continued at 0.1 µg/kg/min. Dosing through procedure and for 12–24 h post-intervention	Approx 2 h	UA/NSTEMI in combination with heparin STEMI (off-label) Elective PCI (off-label)	Reduce dose to 50% normal rate with renal failure (CrCl <30 mL/min)	ADVANCE TOPSTAR

Eptifibatid	PCI: bolus 180 µg/kg IV immediately before PCI, with infusion 2 µg/kg/min. Second bolus 180 µg/kg 10 min after first bolus. Infusion for 18–24 h. Shorter infusion durations can be considered for non-emergent PCI in patients adequately pretreated with clopidogrel	Approx 2.5 h	Stable IHD UA NSTEMI STEMI in combination with UFH	Heparin infusion after PCI is discouraged Discontinue >2–4 h before CABG Use with caution in renal impairment. Dialysis is a contraindication to use	ESPRIT IMPACT-II
Direct thrombin inhibitors					
Bivalirudin	0.1 mg/kg IV bolus then 0.25 mg/kg/h IV 0.75 mg/kg IV bolus then 1.75 mg/kg/h for PCI if no prior antithrombotic therapy administered	Approx 25 min	Stable IHD UA NSTEMI invasive STEMI	Reduced with renal failure (0.25 mg/kg/h IV for hemodialysis) Caution with GFR <30 mL/h Discontinue bivalirudin 3 h before CABG and dose with UFH	HAS ACUITY REPLACE-2 ISAR-REACT-3 ISAR-REACT-4 HORIZONS-AMI EUROMAX NAPLES-III BRIGHT HEAT-PPCI
Argatroban	350 µg/kg IV over 3–5 min then 25 µg/kg/min for PCI	Approx 50 min	Use in PCI in patients with HIT	Caution with hepatic impairment	
Factor XA inhibitors					
Fondaparinux	2.5 mg/day subcutaneously With fibrinolysis, 2.5 IV followed 2.5 mg/day until hospital discharge for a maximum of 8 days	17–21 h	Medical UA/NSTEMI conservative STEMI fibrinolysis	Contraindicated with renal failure (CrCl <30 mL/min) Significantly lower incidence of HIT compared with heparins Discontinue enoxaparin 12–24 h before CABG and dose with UFH	OASIS-5 OASIS-6 PENTUA
Rivaroxaban	Dose used in ATLAS ACS-TIMI 51 trial were 2.5 mg or 5 mg twice daily	5–9 h	Not approved for ACS or PCI in the USA	Caution with hepatic impairment	ATLAS 2 ACS-TIMI 51

ACS, acute coronary syndrome; ACT, activated clotting time; CABG, coronary artery bypass grafting; CrCl, creatinine clearance; GFR, glomerular filtration rate; GPI, glycoprotein IIa/IIIb inhibitor; HIT, heparin-induced thrombocytopenia; IHD, ischemic heart disease; LMWH, low molecular weight heparin; NSTEMI, non-ST-elevation myocardial infarction; PCI, percutaneous coronary intervention; PTT, partial thromboplastin time; STEMI, ST-elevation myocardial infarction; UA, unstable angina; UFH, unfractionated heparin.

antiplatelet medications, nearly eliminating the complication of abrupt closure [39]. The optimal dosing regimen is not defined, but most practitioners utilize regimens of 40–60 IU/kg for goal ACT of >225 seconds when GPI is used and a goal ACT of >300 seconds when UFH is used alone (Table 43.1). A prospective single center trial of elective transfemoral PCI with low dose heparin at 40 IU/kg in 300 patients pretreated with aspirin and 600 mg clopidogrel showed low ischemic and bleeding complications [40], but a randomized trial has yet to be performed. The optimal dosing regimen with new oral antiplatelet agents, prasugrel and ticagrelor, also remains a matter of debate given variable times of pretreatment and the lack of supportive outcomes studies.

During PCI, major limitations of UFH include the narrow therapeutic window, unpredictable individual antithrombin response across patient populations and disease states, platelet activation, and an inability to bind to clot-bound thrombin. The latter is protected from inhibition by the heparin–antithrombin complex serving to propagate thrombus even while heparin is being administered, and it can act as a nidus for further thrombin activation upon discontinuation of heparin. There is also a risk of heparin-induced thrombocytopenia (HIT) and thrombosis syndrome (HITTS) [41]. The latter is rare in the setting of elective PCI, but can be seen with repeated exposures [42]. To address these limitations, other agents have been developed.

Low molecular weight heparins

Low molecular weight heparins (LMWH) are produced by chemical and enzymatic depolymerization of UFH resulting in fragments with a mean molecular weight of 3000–5000 Da. Specifically, these agents have a greater activity against factor Xa than against thrombin, a uniform and predictable anticoagulation action and lower incidence of HIT, addressing some of the limitations of UFH. LMWHs have a longer half-life than UFH, and clearance is by renal excretion. In patients with severe renal dysfunction (creatinine clearance <30 mL/min), the dosage is typically halved. Because it has greater anti-Xa activity, LMWH dosing cannot be reliably adjusted using the ACT (Table 43.1).

The most studied of the LMWHs is enoxaparin. An observational study of 803 patients with ACS treated with a twice daily dose of 1 mg/kg enoxaparin subcutaneously showed that 30-day mortality was closely linked with anti-Xa levels [43]. This study served as the basis of dosing for subsequent PCI studies where anti-Xa levels >0.5 IU/mL are considered therapeutic for enoxaparin [44]. However, anti-Xa levels are not commonly measured during PCI, though they are sometimes measured in medically treated patients.

One aspect of enoxaparin use is that the drug can be administered parenterally or subcutaneously. The subcutaneous route has been used for initial medical management of ACS [45] and the parenteral route is used for PCI [44,46].

Experience with enoxaparin in PCI included a series of studies performed by the National Investigators Collaborating on Enoxaparin (NICE) group. The NICE-1 registry consisted of 828 patients receiving intravenous enoxaparin before coronary intervention at time of elective or urgent PCI. All patients received aspirin, and clopidogrel pretreatment at that time was left to operator discretion. The composite endpoint of death, MI, and urgent revascularization at 30 days was seen in 7.7%, with MI in 5.4% [47].

NICE-4 evaluated PCI with enoxaparin and compared these patients with historic data from the EPILOG and EPISTENT studies where UFH and a GPI (abciximab) were used. NICE-4 adopted

a protocol where 818 patients received enoxaparin 0.75 mg/kg and abciximab 0.25 mg/kg bolus followed by 0.125 µg/kg/min infusion. The 30-day composite endpoint of death, MI, or urgent revascularization occurred in 6.8%, suggesting that enoxaparin can confer a similar efficacy and safety to UFH when used with abciximab [47].

The SYNERGY (Superior Yield of the New Strategy of Enoxaparin, Revascularization and Glycoprotein IIb/IIIa Inhibitors) trial randomized 10,027 patients with ACS to either subcutaneous enoxaparin or intravenous UFH. Enoxaparin proved non-inferior to UFH with the primary endpoint of death or MI at 30 days. For PCI, there was no difference in rates of unsuccessful PCI, abrupt closure, or emergency coronary artery bypass grafting (CABG) between groups. There was a significantly higher rate of thrombolysis in myocardial infarction (TIMI) major bleeding among patients receiving enoxaparin, but no significant difference in the rate of GUSTO severe bleeding, TIMI minor bleeding, or blood transfusions between enoxaparin or UFH groups [46]. The SYNERGY data were not blinded and there was significant crossover between UFH and enoxaparin; an occurrence associated with worse bleeding outcomes compared with no crossover.

Though not the primary intent of the study, the EXTRACT-TIMI-25 (Enoxaparin and Thrombolysis Reperfusion for Acute Myocardial Infarction Treatment, Thrombolysis in MI-Study 25) reported on the role of enoxaparin for elective PCI after STEMI. PCI occurred at a median of 109–122 hours following fibrinolysis [48]. The 2272 patients on enoxaparin undergoing PCI had a significant reduction in 30-day death or MI (10.7% vs. 13.8%; $p=0.001$) without an increase in TIMI major bleeding, providing indirect evidence that enoxaparin is superior to UFH in reducing ischemic complications during STEMI and for elective PCI after fibrinolysis.

The CRUISE trial randomized 261 patients undergoing elective or urgent PCI to intravenous enoxaparin 1 mg/kg or UFH, with all patients also receiving eptifibatide. There was no difference in bleeding complications or angiographic complications (6.3% vs. 6.2%; $p=NS$) during the procedure, and no differences in ischemic endpoints at 48 hours or 30 days.

The STEEPLE trial evaluated 3528 patients with PCI who were randomized to enoxaparin (0.5 or 0.75 mg/kg) or UFH adjusted according to ACT, and stratified according to the use or non-use of GPI [44]. GPI and thienopyridines were used in 40% and 95% of patients, respectively, and 16% of cases required multivessel intervention. The lowest rate of non-CABG-related bleeding at 48 hours was seen in the 0.5 mg/kg enoxaparin arm (5.9% vs. 8.5%; $p=0.01$), but the 0.75 mg/kg enoxaparin dose was not significantly different (6.5% vs. 8.5%; $p=0.051$). Patients in the 0.5 mg/kg group achieved a therapeutic level of anticoagulation 78.8% of the time compared with 91.8% in the 0.75 mg/kg group. Only 19.7% of patients in the UFH arm achieved therapeutic anticoagulation ($p<0.001$ for either enoxaparin dose vs. UFH) [22]. The trial was not large enough to provide a definitive comparison of efficacy in prevention of ischemic events.

A meta-analysis of 13 trials comparing intravenous LMWH with UFH showed that a strategy of intravenous LMWH was associated with significant reduction in major bleeding (odds ratio 0.57, 95% CI 0.40–0.82), with no difference in death, MI, or TVR [49]. Overall, the use of intravenous enoxaparin during elective PCI is associated with a better safety profile than weight-adjusted UFH with no additional risk of ischemic events. The possibility of improved outcomes compared with UFH among patients undergoing elective PCI with aggressive intravenous or oral antiplatelet

therapy remains unproven. Coupled with an inability to easily monitor therapeutic levels during PCI, complex dosing regimens, and the need for dose adjustment among patients with impaired renal function, enoxaparin is not frequently utilized during elective PCI.

Dalteparin

Supportive data for the LMWH dalteparin are limited. While dalteparin was utilized in 2457 patients undergoing PCI in ACS, the subjection of this study was comparing an early invasive to conservative approach to PCI in ACS rather than a comparison of anticoagulation strategies [50]. Use of dalteparin in elective PCI has not been adequately studied. A dose-ranging study of 107 patients with all patients receiving aspirin and abciximab led to early unblinding of the study and the decision to terminate the lower dose 40 unit/kg arm. The composite endpoint of death, MI, and urgent revascularization was observed in 15.5% of patients, and major bleeding and transfusion each occurred in 2.8% of patients. Despite the fact that the study was inadequately powered to evaluate the agent fully in this setting, the high clinical event rates resulted in limited uptake.

Fondaparinux

In the attempt to overcome the limitations of the heparins, newer agents have been developed to specifically inhibit factor Xa. Fondaparinux, a pentasaccharide, is a synthetic indirect inhibitor of factor Xa that mimics the action of heparin through its interaction with antithrombin. Its half-life is approximately 20 hours, allowing once daily dosing. Action upstream from thrombin in the coagulation cascade is an attractive feature during PCI, and HIT is extremely rare [51]. It is contraindicated with renal insufficiency because of primarily renal excretion (Table 43.1).

Phase 2 experience proved promising with fondaparinux during PCI in the ASPIRE study (Arixtra Study in Percutaneous Coronary Intervention: A Randomized Evaluation) which randomized 350 patients undergoing elective or urgent PCI to two doses intravenously (2.5 and 5.0 mg) or weight-adjusted UFH. There was no difference compared with UFH in terms of total bleeding (7.7% UFH vs. 6.4% fondaparinux; $p=0.61$) and the composite of MACE (death, MI, urgent TVR, or use of bailout GPI) (6.0% UFH vs. 6.0% fondaparinux; $p=0.97$) [51].

The OASIS-5 (Organization to Assess Strategies in Acute Ischemic Syndromes) trial was the only study to evaluate patients undergoing PCI. Over 20,000 patients with ACS were randomized to enoxaparin or fondaparinux. There were no differences in ischemic complications, but there was benefit in respect of bleeding events with fondaparinux as compared with the LMWH (enoxaparin 8.8% vs. fondaparinux 3.3%; $p<0.001$). A substantial number of patients received UFH in both arms of the trial, and the protocol was actually modified during the course of the study to ensure use of UFH with fondaparinux because of a significantly higher rate of catheter-related thrombosis (enoxaparin 0.5% vs. fondaparinux 1.3%; $p=0.001$). The concerns of the study were corroborated in the subsequent OASIS-6 trial in patients with STEMI. Primary PCI with fondaparinux resulted in significantly higher 30-day mortality and reinfarction than in patients with UFH [52]. As a result, guidelines recommend the addition of agents with activity against factor IIa during PCI in patients treated with fondaparinux. As such, this medication is suggested for use among patients being treated medically for ACS and has a limited role in elective PCI (Table 43.2).

Direct antithrombin agents

The most studied direct thrombin inhibitor in PCI is bivalirudin. It is a small molecule, consisting of 20 amino acids, and is a bivalent synthetic direct thrombin inhibitor. It binds directly to thrombin in both its fluid phase and also its clot-bound form, unlike heparin-based drugs, which bind only to free (unbound) thrombin. Bivalirudin inactivates thrombin directly and does not require laboratory monitoring to assess effect. Half-life is approximately 25 minutes and it does not cause HIT. Thrombin-induced platelet aggregation is essentially obliterated by bivalirudin (Table 43.1).

There is a large body of evidence in support of bivalirudin use in patients with ACS, including those with unstable angina, NSTEMI, and STEMI [53–59]. In the ACUITY trial [56], bivalirudin monotherapy in an early invasive PCI strategy in patients with unstable angina and NSTEMI provided superior 30-day clinical outcomes compared with a heparin and GPI regimen, and ACUITY scale major bleeding was reduced by 47% with bivalirudin at 30 days (3.0% vs. 5.7%, RR 0.53, 95% CI 0.43–0.65; $p<0.001$) [56]. HORIZONS-AMI, one of the largest trial assessing bivalirudin in STEMI, reported a mortality benefit at 30 days in the bivalirudin monotherapy group compared with a heparin plus GPI strategy (cardiac death 1.8% vs. 2.9%; $p=0.03$; all cause mortality 2.1% vs. 3.1%; $p=0.047$). The 30-day rate of net adverse clinical events including a lower rate of major bleeding was lower with bivalirudin alone (4.9% vs. 8.3%, RR 0.60; $p<0.001$) [56].

Bivalirudin use in ACS has recently become a controversial topic in light of the HEAT-PPCI trial, a randomized controlled trial, where 1812 patients undergoing emergency PCI received either bivalirudin or heparin, with similar rate of use of GPI in both arms (13% and 15%, respectively). The primary efficacy endpoint (all-cause mortality, cerebrovascular accident, reinfarction, target lesion revascularization) occurred in 8.7% of the bivalirudin group and 5.7% of the heparin group (absolute risk difference 3.0%; $p=0.01$), and the primary safety outcome (major bleeding) occurred in 3.5% of the bivalirudin group and 3.1% in the heparin group, showing that heparin monotherapy relative to bivalirudin monotherapy reduced ischemic events with no difference in major bleeding [60].

Stent thrombosis associated with bivalirudin treatment has been noted now in several trials including HORIZONS-AMI, HEAT-PPCI, and EUROMAX [55]; this effect was mitigated in the BRIGHT trial where they used a prolonged infusion of bivalirudin post PCI of approximately 4 hours. In BRIGHT, 2194 patients with acute MI were randomized to bivalirudin, heparin alone, or heparin with tirofiban. Primary endpoint (death, MI, TVR, stroke, any bleeding at 30 days) occurred in 8.8% of the bivalirudin group, 13.2% of the heparin only group, and 17% of the heparin and tirofiban group ($p<0.001$); this difference was driven completely by the reduction in bleeding complications, with no difference in MACE [61].

In patients with stable coronary disease undergoing elective PCI, there have been two randomized trials supporting the use of bivalirudin. The REPLACE-2 (Randomized Evaluation of PCI Linking Angiomax to Reduced Clinical Events-2) study was a multicenter, double-blind, triple dummy randomized trial in patients with a low to moderate risk for ischemic complications undergoing PCI (56% elective cases). Patients were randomized to heparin with planned GPI (abciximab, or eptifibatide) or bivalirudin with provisional GPI. At 30 days, there was no significant difference in MACE (death, MI, urgent revascularization, or major bleeding) between the groups (9.2% in bivalirudin group vs. 10.0% in heparin plus GPI). In-hospital major bleeding rates were significantly reduced by bivalirudin (2.4% vs. 4.1%; $p<0.001$).

Table 43.2 Recommendations for antithrombin use.

	Recommendation	Class of recommendation	Level of evidence	Guideline
Unfractionated heparin	UFH should not be given to patients already receiving therapeutic subcutaneous enoxaparin	III (Harm)	B	PCI
	For patients with UA/NSTEMI in whom an initial conservative strategy is selected, enoxaparin or fondaparinux is preferable to UFH as anticoagulant therapy, unless CABG is planned within 24 h	IIa	B	UA/ NSTEMI
	For patients with UA/NSTEMI who are managed conservatively and do not develop an indication for catheterization continue UFH for 48 h if managed without PCI or CABG; otherwise discontinue	I	A	UA/ NSTEMI
Enoxaparin	For PCI, additional 0.3 mg/mg IV dose if last SQ dose >8–12 h or <2 doses administered	I	B	PCI
	PCI with enoxaparin can be reasonable in patients either treated with “upstream” subcutaneous enoxaparin for UA/NSTEMI or who have not received prior antithrombin therapy and are administered IV enoxaparin at the time of PCI	IIa	B	PCI
	For patients with UA/NSTEMI in whom an initial conservative strategy is selected, enoxaparin or fondaparinux is preferable to UFH as anticoagulant therapy, unless CABG is planned within 24 h	I	A	UA/ NSTEMI
	Continue enoxaparin for duration of hospitalization, up to 8 days, if given before diagnostic angiography and no PCI or CABG	I	A	UA/ NSTEMI
Bivalirudin	For patients undergoing PCI, bivalirudin is useful as an anticoagulant with or without prior treatment with UFH	I	B	PCI
	Either discontinue bivalirudin or continue at 0.25 mg/kg/h for up to 72 h at the physician’s discretion if given before diagnostic angiography and no PCI or CABG	I	B	UA/ NSTEMI
	With HIT, it is recommended that bivalirudin or argatroban be used to replace UFH	I	B	PCI
Fondaparinux	Fondaparinux should not be used as the sole anticoagulant to support PCI	III (Harm)	C	PCI
	For UA/NSTEMI patients in whom an initial conservative strategy is selected, enoxaparin or fondaparinux is preferable to UFH as anticoagulant therapy, unless CABG is planned within 24 h	I	A	UA/ NSTEMI
	Continue fondaparinux for duration of hospitalization, up to 8 days, if given before diagnostic angiography and no PCI or CABG	I	A	UA/ NSTEMI
	With a conservative strategy, in those patients who have an increased risk of bleeding, fondaparinux is preferable	I	B	UA/ NSTEMI
Argatroban	With HIT, it is recommended that bivalirudin or argatroban be used to replace UFH	I	B	PCI
Glycoprotein IIb/IIIa inhibitors	Elective PCI patients treated with UFH and not pretreated with clopidogrel, GPI can be used (abciximab, double-bolus eptifibatide, or high-bolus dose of tirofiban)	IIa	B	PCI
	If pretreated with clopidogrel, in elective patients using UFH, the level of evidence is less compelling	IIb	B	PCI

The ISAR-REACT-3 (Intracoronary Stenting and Anti-thrombotic Regimen – Rapid Early Action for Coronary Treatment) trial evaluated 4570 troponin-negative patients treated with aspirin and clopidogrel (600 mg loading dose) at least 2 hours prior to planned PCI. Patients were randomized to 140 IU/kg UFH or bivalirudin in what was a placebo-controlled trial. The primary endpoint of MACE at 30 days (death, MI, urgent TVR, or major bleeding) was not different (UFH 8.7% vs. bivalirudin 8.3%, RR 0.94, 95% CI 0.77–1.15; $p=0.57$). There was a significant reduction in major bleeding (4.6% vs. 3.1%; $p=0.008$) and minor bleeding (9.9% vs. 6.8%; $p=0.001$) with bivalirudin, but one criticism is that UFH dosing was higher than used in contemporary practice [58,62]. Thus, the patients in the UFH arm may have had higher bleeding rates, resulting in the apparent advantage for bivalirudin.

The NAPLES-III trial showed no difference between bivalirudin and UFH use in elective PCI in patients with high bleeding risk. The study randomized 837 patients with stable and unstable angina and high predicted risk of bleeding to receiving either bivalirudin or heparin therapy (WITHOUT concomitant GPI) during elective transfemoral PCI. The primary endpoint of in-hospital bleeding was similar between the bivalirudin and heparin arms (3.3% vs. 2.6%; $p=0.54$). Clinical endpoints at 30 days were also similar between the two arms with regard to MACE (6.5% vs. 4.3%; $p=0.17$), death (2.4% vs. 1.4%), MI (0.2% vs. 0%), stent thrombosis (0.5% vs. 0.5%), and 1 year outcomes were likewise similar. The use of dual antiplatelet therapy (DAPT) was not clarified in this trial [63]. Notably, heparin dosing in NAPLES-III was similar current practice at 70 IU/kg, rather than the higher dose of 140 IU/kg used in ISAR-REACT 3.

A 2014 meta-analysis, including data from 16 trials with 33,958 patients, including elective PCI reported an increase in the risk of MACE with bivalirudin-based regimens compared with heparin-based regimens (risk ratio 1.09; $p=0.02$), which was largely driven by increases in MI and revascularization. Bivalirudin increased the risk of stent thrombosis (risk ratio 1.38; $p=0.0074$). Furthermore, while bivalirudin lowered the risk of major bleeding, this varied largely depending on whether GPI were used with heparin (risk ratio 0.53; $p<0.0001$) or provisionally planned in both arms (risk ratio 0.78, $p=0.25$; risk ratio 1.07, $p=0.53$) [64]. Needless to say, there are a wide array of varying of protocols and patients included in this meta-analysis, which limits its applicability.

Taken together, these trials indicate that bivalirudin is a reasonable alternative to UFH alone or in combination with GPI in patients undergoing elective PCI, especially in patients with high bleeding risk. However, there is a consistent signal in ACS trials of acute stent thrombosis associated with bivalirudin use which may be mitigated by prolonging the infusion or more potent platelet inhibition, issues that warrant further study.

Other agents

Argatroban is a direct thrombin inhibitor approved by the Food and Drug Administration (FDA) in 2000 for use in prophylaxis or treatment of thrombosis in patients with HIT. In 2002, it was approved for use during PCI in patients who have HIT or are at risk of developing it. It is given intravenously, has a half-life of 50 minutes, and is metabolized in the liver. It can be used in the setting of renal failure, but not in those with significant hepatic dysfunction (Table 43.1). Another direct thrombin inhibitor, lepirudin, had been available for HIT patients. A business decision was made by

the manufacturer to discontinue production of this agent in May 2012. More evidence is still needed to clarify the role of novel oral anticoagulants such as rivaroxaban, dabigatran, and apixaban in elective PCI.

Intravenous antiplatelet therapy

Until recently, glycoprotein IIb/IIIa receptor antagonists were the only intravenous antiplatelet medications approved for use in the USA until cangrelor was approved in June 2015. Cangrelor is an intravenous P2Y₁₂ receptor antagonist with near immediate effect. It has a half-life of 2.6–3.3 minutes, and normal platelet function is restored within 1 hour of discontinuation. The medication was evaluated in a series of trials. The Cangrelor versus Standard Therapy to Achieve Optimal Management of Platelet Inhibition (CHAMPION)-PCI and CHAMPION-PLATFORM studies yielded disappointing results. The two trials were stopped prematurely, after interim analyses indicated that demonstration of a benefit for the primary endpoint would be unlikely [65,66]. Secondary endpoints, from the CHAMPION-PLATFORM trial, indicated that PCI patients receiving cangrelor had fewer stent thromboses compared with delayed administration of clopidogrel. As such, the CHAMPION-PHOENIX trial was designed comparing cangrelor at the time of PCI to clopidogrel administration after PCI [67]. In approximately 11,000 patients undergoing PCI, the primary endpoint of all-cause mortality, MI, ischemia-driven revascularization, or stent thrombosis at 48 hours was lower with cangrelor than clopidogrel (4.7% vs. 5.9%, OR 0.78, 95% CI 0.66–0.93; $p=0.005$). This difference was largely attributable to a difference in the rate of stent thrombosis at 48 hours (0.8% vs. 1.4%, OR 0.62, 95% CI 0.43–0.90; $p=0.01$), of which most were intraprocedural stent thromboses (0.6% vs. 1.0%, OR 0.65, 95% CI 0.42–0.99; $p=0.04$). These differences persisted to 30 days. ACUITY major bleeding was more frequent with cangrelor (4.3% vs. 2.5%, OR 1.72, 95% CI 1.39–2.13; $p<0.001$). Cangrelor is approved for PCI amongst patients who have not received GPI or adequate pretreatment with oral antiplatelet medications.

Conclusions

Anticoagulation strategies have rapidly evolved over recent decades and numerous agents are now available. An improved understanding of the coagulation cascade and the interplay between thrombin and platelet activation has led to the development of agents specifically targeting key components of the coagulation cascade. Along with improvements in PCI technique, expanded use of these agents has led to impressive reductions in ischemic outcomes and more recently in bleeding events. While the magnitude of benefit of these agents in clinical trials over UFH is smaller or non-existent in elective PCI compared with PCI in ACS, there are certainly a number of patients at high bleeding risk or who have contraindications to UFH and can benefit from these agents.

The mainstay for anticoagulation in PCI for patients with stable disease remains UFH, with selective use of additional intravenous or oral antiplatelet agents, but LMWH and direct thrombin inhibitors, either alone or in combination with heparins, have a variety of benefits. Whether more aggressive DAPT, especially prasugrel, ticagrelor, or cangrelor, improves ischemic outcomes with UFH, LMWH, or bivalirudin without an increase in bleeding complications remains unknown and whether the benefits demonstrated in patients with ACS can be generalized to stable patients remains a

Key points

- Despite significant improvements, it remains important to select anticoagulant agents carefully in the percutaneous treatment of coronary disease with the dual goal of decreasing ischemic events and minimizing bleeding complications.
- In the “elective” population, glycoprotein IIb/IIIa receptor inhibitors tend to be reserved for higher risk patients, for those not adequately pretreated with thienopyridines, or for those with a suboptimal procedural outcome.
- Unfractionated heparin (UFH) continues to be a mainstay in the elective PCI population because of its ease of use, simple monitoring, and reversibility.
- Enoxaparin has been shown to have reduced bleeding outcomes, with comparable ischemic events to UFH in patients undergoing PCI, but the inability to easily monitor the level of anticoagulation has limited its use.
- Bivalirudin is a reasonable alternative to UFH, especially in patients with high bleeding risk.

matter of debate. Finally, personalizing the optimal antithrombin in combination with the optimal antiplatelet agent for a patient based on individual hematologic, genetic, angiographic, and comorbid factors has the potential to improve outcomes dramatically but remains an enormously challenging task for future investigation.

Vasoactive and Antiarrhythmic Drugs During PCI

Bimmer E.P.M. Claessen and José P.S. Henriques

Department of Cardiology, Academic Medical Center – University of Amsterdam, Amsterdam, The Netherlands

Patients undergoing percutaneous coronary intervention (PCI) are administered a large variety of pharmacologic agents during this procedure. In addition to antithrombotic drugs to minimize the risk of thrombotic complications of the mechanical intervention performed during PCI, patients are sometimes administered sedatives, analgesics, vasodilators, antiarrhythmic agents, vasopressors, and inotropes. Sedative and analgesic drugs are used to increase patient well-being during the procedure. Vasodilators can be administered for a variety of indications, for example to facilitate standardized and accurate vessel size measurements, treatment of the no-reflow phenomenon after PCI, treatment of arterial spasm during PCI, or inducing maximal hyperemia to facilitate measurement of fractional flow reserve (FFR). Antiarrhythmic drugs are indicated for recurrent ventricular fibrillation, ventricular tachycardia, or to prevent ventricular extrasystoles during ventriculography. Moreover, several drugs should be interrupted before coronary angiography or PCI such as metformin, diuretics, and angiotensin converting enzyme (ACE) inhibitors.

Vasodilators during PCI

Vasodilators are used during PCI to treat arterial or coronary spasm or no-reflow, to accurately assess the diameter of coronary arteries before stent implantation, or to induce hyperemia during invasive coronary physiology measurements. Nitroglycerine, verapamil, and adenosine are frequently used during PCI to achieve vasodilatation. Nitroglycerin was discovered by Asciano Sobrero in 1847, who first noted a violent headache after administering a small quantity of nitroglycerine on his tongue [1]. He also discovered its explosive properties and was badly scarred on the face after a nitroglycerine explosion. Nitroglycerine (glycerine trinitrate) is an organic nitrate that releases nitric oxide (NO) through an enzymatic reaction [2]. Nitroglycerine causes vasodilatation without a reduction in blood pressure in doses up to 200 µg. However, when doses exceeding 250 µg are administered, hypotension can result without a further increase in coronary vasodilatation [3]. Direct NO donors such as nitroprusside and molsidomine release NO directly without the need for activation by molecular metabolism [4,5].

Verapamil, a calcium channel blocker, is a class IV antiarrhythmic agent according to the Vaughan Williams classification. Verapamil

has negative chronotropic effects by decreasing the electrical impulse conduction in the atrioventricular (AV) node, where there is a high concentration of calcium channels [6]. By blocking calcium channels in the smooth muscle of coronary arteries, verapamil also induces vasodilatation [7]. Because of the different mechanisms by which verapamil and nitroglycerin cause coronary artery vasodilatation, they are often combined and administered together as an intracoronary “cocktail.” Because of its negative chronotropic properties, verapamil is contraindicated in patients with severe bradycardia. Furthermore, verapamil is contraindicated in patients with left ventricular dysfunction because of its negative inotropic properties. Diltiazem, another calcium channel blocker, has stronger vasodilating and weaker negative chronotropic effects than verapamil [8].

Adenosine is a purine nucleoside that can bind to purinergic receptors in different cell types. Vasodilatation results by binding to adenosine type 2A (A_{2a}) receptors in vascular smooth muscle cells. Moreover, adenosine inhibits calcium entry into the cell through L-type calcium channels which are present in vascular smooth muscle cells and also in the sinoatrial and the AV nodes resulting in negative chronotropic and dromotropic effects [9]. Adenosine is used to induce hyperemia to accurately assess the severity of intermediate coronary artery stenoses by FFR [10]. Adenosine can be administered by both intracoronary or intravenous infusion.

Vasodilators in the treatment of no-reflow

The no-reflow phenomenon is caused by vasospasm and downstream embolization of debris during PCI or suboptimal reperfusion of an infarct artery attributed to endothelial injury in addition to embolization and vasospasm [11]. Most studies investigating the utility of vasoactive drugs to treat or prevent no-reflow have been conducted in the setting of PCI for acute coronary syndromes (ACS). A recent meta-analysis of 3821 patients from 10 randomized controlled trials undergoing PCI for ACS investigated whether adjunct therapy with adenosine was associated with a reduction in no-reflow and subsequently clinical outcomes [12]. Compared with placebo, adenosine was significantly associated with a reduction of post-procedural no-reflow with an odds ratio of 0.25 (95% confidence interval 0.08–0.73; *p* = 0.01). However, adenosine failed to reduce mortality, reinfarction, symptoms of heart failure, and

ST-segment resolution. Nicorandil and nitroprusside have also been associated with improved coronary flow [13,14], again without a benefit in terms of hard clinical endpoints. Therefore, these agents are not commonly used in everyday clinical practice. The administration of an intracoronary vasodilator to treat PCI-related no-reflow carries a Class IIa recommendation with a level of evidence B in the current interventional guidelines [11].

Vasodilators in the treatment of arterial spasm

Vascular access is associated with fewer bleeding complications when compared with the femoral approach and is rapidly becoming the standard of care for coronary angiography and percutaneous PCI [15]. However, radial artery spasm (RAS) causes reduced success rates and patient discomfort during cardiac catheterization via the radial approach in approximately 10% of patients [16]. Risk factors for the development of RAS include smaller diameter radial arteries, female gender, larger sheath size, and operator inexperience [17]. RAS can be prevented and treated by using intra-arterial nitroglycerin or a cocktail of vasodilating agents (i.e., 100 µg nitroglycerine with 1.25 mg verapamil) [18].

Antiarrhythmic drugs in PCI

Ischemia or pain during PCI results in an increased sympathoadrenal tone that can induce a rise in heart rate, blood pressure, and myocardial contractility, resulting in increased oxygen demand. Beta-blockers decrease myocardial oxygen demand by lowering heart rate and blood pressure [19]. A number of animal studies have shown that the administration of beta-blockers can reduce myocardial injury in animal models of myocardial infarction [20,21]. Moreover, clinical studies established that the administration of intracoronary beta-blockers during PCI may reduce adverse clinical events and myocardial injury after PCI [22–24]. For example, the METOCARD-CNIC (the effect of metoprolol in cardioprotection during an acute myocardial infarction) trial randomized 270 consecutive patients with an anterior ST-elevation myocardial infarction (STEMI) to treatment with intravenous metoprolol or nothing before reperfusion [25]. The investigators showed a significant reduction in infarct size, assessed by magnetic resonance imaging (MRI) at 5–7 days after the infarction. Currently, larger clinical trials powered for clinical endpoints are being conducted that investigate whether the promising results of early metoprolol administration before reperfusion in patients with STEMI can be confirmed.

Other antiarrhythmic drugs are sporadically used during PCI. Lidocaine is not only used as a local anesthetic, but also acts as a Class Ib antiarrhythmic drug, blocking the rapid influx of sodium ions during the depolarization of cardiac myocytes. Class Ib antiarrhythmics primarily affect the His–Purkinje system and are used to treat ventricular tachycardias. Ventricular extrasystoles occur frequently during left ventriculography. Sporadically, sustained ventricular

tachycardia ensues. A bolus of intravenous lidocaine can be injected to stop ventricular tachycardia.

Peri-procedural sedation

During PCI, peri-procedural sedation is sometimes applied to achieve a minimally depressed state of consciousness without compromising the airway and by allowing the patient to respond to verbal comments [26]. Usually, benzodiazepines are used to achieve conscious sedation. Benzodiazepines such as oxazepam, midazolam, and diazepam have sedative, hypnotic, muscle relaxant, and anxiolytic effects by selectively enhancing the inhibitory activity of gamma-aminobutyric acid (GABA) by binding to the benzodiazepine site of the GABA_A receptor in the central nervous system [27]. Anterograde amnesia can sometimes be a welcome side effect of benzodiazepines, causing patients to forget any unpleasantness during the procedure.

A potential complication when using procedural sedation is the possibility that a level of sedation deeper than desired is induced. For this reason, current guidelines recommend that level of consciousness, respiratory rate, blood pressure, and oxygen saturation should be monitored [11]. Additionally, catheterization laboratories should be outfitted with oxygen and suction ports and a resuscitation cart. Other, less frequently used drugs used for peri-procedural sedation include the opioid fentanyl, and the hypnotic propofol [11]. Table 44.1 shows an overview of commonly used short-acting drugs used in peri-procedural sedation.

Which drugs should be discontinued before PCI?

Contrast-induced acute kidney injury (CI-AKI) can result as a side effect of using contrast agents in PCI and is associated with prolonged hospital stay. CI-AKI is an infrequent complication in non-diabetic patients with normal renal function (~2%) [28]. However, CI-AKI has been reported to occur in up to 50% of patients with diabetic nephropathy and a mean serum creatinine of 5.9 mg/dL [29]. An association between CI-AKI and an increased incidence of myocardial infarction, target vessel revascularization, and death after PCI has been reported [30,31]. Although the mechanism causing CI-AKI is currently incompletely understood, direct cytotoxicity of iodinated contrast agents and disturbances in renal hemodynamics have been identified to be contributing factors (Table 44.2) [32].

Patients undergoing PCI will often use medication that is associated with an increased risk of CI-AKI such as diuretics, non-steroidal anti-inflammatory drugs (NSAIDs), and angiotensin-converting enzyme inhibitors (ACEI), angiotensin II receptor blockers, and direct renin inhibitors. These drugs may cause prerenal kidney insufficiency and are routinely discontinued 24–48 hours prior to

Table 44.1 Overview of short-acting drugs used in peri-procedural sedation.

Class	Drugs	Effects	Onset (min)	Duration (min)	Reversal agents
Benzodiazepines	Midazolam	Sedative, anxiolytic	2–3	45–60	Flumazenil
Opioids	Fentanyl	Analgesic	3–5	30–60	Anexate
Other	Propofol	Sedative, anxiolytic	<1	5–15	None

Table 44.2 Drugs that should be stopped prior to PCI.

Class	Drugs	Reason to discontinue
Diuretics	Furosemide, bumetanide, hydrochlorothiazide, chlorthalidone	Can cause prerenal kidney injury
Angiotensin-converting enzyme inhibitors	Captopril, enalapril, ramipril, lisinopril	Can cause prerenal kidney injury
Angiotensin II receptor blockers	Valsartan, candesartan, irbesartan	Can cause prerenal kidney injury
Direct renin inhibitors	Aliskiren	Can cause prerenal kidney injury
Non-steroidal anti-inflammatory drugs	Ibuprofen, diclofenac, naproxen	Can cause prerenal kidney injury
Aminoglycoside antibiotics	Gentamicin, amikacin, tobramycin	Nephrotoxicity by inhibiting protein synthesis in renal cells. Nephrotoxicity is increased in patients with liver failure
Biguanides	Metformin	Increased risk of lactate acidosis

PCI and restarted after 24–48 hours after PCI. However, no clinical trials have investigated whether discontinuation of ACEI or diuretics is associated with reduction in CI-AKI and subsequently a reduction in clinical outcome. Interestingly, it was once thought that prophylactic treatment with diuretics during PCI could prevent CI-AKI by inducing and maintaining diuresis and blocking of the oxygen-demanding active ionic transport processes in the loop of Henle. Solomon *et al.* [33] randomized 78 patients with chronic renal insufficiency who underwent cardiac angiography to receive saline alone, saline plus mannitol, or saline plus furosemide during a period of 12 hours before and 12 hours after angiography. The incidence of CI-AKI, defined as a rise in serum creatinine of 0.5 mg/dL within 48 hours after angiography, was 11%, 28%, and 40% in the saline, mannitol, and furosemide groups, respectively ($p=0.05$). Prehydration with saline became the standard of care after the publication of this landmark trial.

Metformin, an antidiabetic agent from the class of biguanides, is associated with the incidence of potentially lethal lactate acidosis [34]. The risk of lactate acidosis is increased in patients with acute renal insufficiency, therefore metformin is usually discontinued 24–38 hours after PCI and restarted 48 hours after the procedure after renal function has been assessed.

High-dose statin treatment to reduce the risk of peri-procedural MI

Peri-procedural myocardial injury, assessed by a rise in cardiac biomarkers after PCI, remains a common complication. Pretreatment with high doses of hydroxymethyl-glutaryl-CoA reductase inhibitors, commonly known as statins, is known to reduce the incidence of peri-procedural myocardial injury. A study by Pasceri *et al.* [35] randomized 153 patients with chronic stable angina undergoing elective PCI to pretreatment with atorvastatin 40 mg once daily versus placebo. In this study, the detection of cardiac biomarkers above the upper limit of normal was significantly reduced with statin pretreatment compared with placebo (20% vs. 48% for troponin I; $p=0.0004$). A single loading dose of 80 mg atorvastatin or 40 mg rosuvastatin has also been found to reduce peri-procedural myocardial injury [36,37].

A small number of other studies and meta-analyses have confirmed the protective effects of statin pretreatment before PCI [38,39]. The exact mechanism by which statins reduce peri-procedural myocardial injury is not well understood. These effects of statins occur before significant lipid lowering has occurred, therefore it is hypothesized that pleiotropic effects of statins such as anti-inflammatory effects, a reduction in oxidative stress, or improvement of endothelial function are involved.

Vasopressors and inotropes during PCI

Vasopressors and inotropes are sometimes used to treat patients who are hemodynamically unstable during PCI in whom short- or medium-term recovery is expected. Many of the vasopressors and inotropes are a member of the family of catecholamines. These catecholamines, such as adrenaline, noradrenaline, dopamine, dobutamine, isoproterenol, and phenylephrine, act by stimulating alfa- or beta-adrenergic receptors. Simply put, beta-receptor stimulation results in positive chronotropy, positive inotropy, and vasodilatation. Alfa-adrenergic stimulation results in vasoconstriction. As vasodilatation by agents with primarily beta-adrenergic receptor stimulating properties can cause blood pressure to fall, inotropes such as noradrenaline (with predominantly alfa-adrenergic activity) and phenylephrine (selective alfa-adrenergic activity) are often used in combination with vasopressors. Important complications of catecholamines include tachycardias, both supraventricular and ventricular [40]. Finally, stress dose glucocorticoids (cortisol 100 mg every 8 hours intravenously) should be considered in refractory hypotension and in patients thought to be at risk for adrenal insufficiency under stress (e.g., those on high maintenance dose of oral steroids).

Conclusions

A large number of adjunct drugs are used during PCI for a variety of indications. The use of a variety of sedative, vasoactive, antiarrhythmic, vasopressive, inotropic, and risk-factor modifying drugs during PCI are sometimes used. Moreover, some types of drugs

must be temporarily stopped when performing PCI. Decision on which adjunct drugs to use during PCI and which drugs to stop during PCI should be made carefully, and should be tailored to the specific needs of individual patients.

The Optimal Duration of Dual Antiplatelet Therapy After PCI

Rationale and evolution behind dual antiplatelet therapy after stent implantation

The first coronary angioplasty was performed in 1977. It was soon realized that occlusion and restenosis were the most common reasons for transluminal balloon angioplasty to fail to provide long-term benefit and an intravascular mechanical support was therefore developed with the aim of preventing restenosis and sudden closure. Almost a decade later, in 1986, following the first implantation of a coronary stent, its usefulness was promptly established in a case series published in the *New England Journal of Medicine* in 1987 [1]. However, in this very first report, the risk of thrombotic stent occlusion was described. In early clinical trials, around 1990, the rate of stent thrombosis was approaching 20% [2], which led to the adoption of anticoagulant (heparin followed by oral warfarin) and antiplatelet regimens including oral aspirin and dipyridamole. The incorporation of this antithrombotic strategy was subsequently tested in randomized clinical trials in the mid-1990s, comparing stent implantation with balloon angioplasty, and demonstrated a reduced risk of acute and subacute stent thrombosis of approximately 3.5% [3,4]. In 1998, Leon *et al.* [5] published a landmark trial establishing that in comparison with aspirin alone and the combination of aspirin and warfarin, a treatment strategy with aspirin and ticlopidine resulted in a lower rate of stent thrombosis, although there were more hemorrhagic complications than with aspirin alone at 30 days' follow-up. This regimen of a thienopyridine derivative added to aspirin has been the mainstay of antiplatelet therapy after coronary stenting ever since and introduced the concept of dual antiplatelet therapy (DAPT) in patients undergoing percutaneous coronary intervention (PCI). In 2001, the CURE trial tested another thienopyridine derivative, clopidogrel, on top of aspirin, and lately new P2Y₁₂ inhibitors have been introduced—prasugrel [6] in 2007 and ticagrelor [7] in 2009—which have further improved the outcome of DAPT regimens in patients with stents.

In parallel with the evolution of the DAPT regimen, stent technology has matured from bare metal stents (BMS) over first generation to now second generation drug-eluting stents (DES)

and improvements in stent technology have direct implications for the clinical strategy of DAPT.

Longstanding controversy about the safety of first generation DES, because of their delayed stent strut neointimalization preventing restenosis but promoting thrombosis on the exposed stent struts compared to BMS, was fueled by concerns of late (beyond 30 days) and very late (beyond 1 year) stent thrombosis (ST) in patients discontinuing DAPT [8–11], and annual accrual rates of ST events up to 4 years [12].

In comparison with older platforms, second generation DES differ by a stent platform of a cobalt-chromium or platinum-chromium alloy which enables thinner strut configurations, rendering the stent more deliverable. Newer generation DES also have improved polymer technology with enhanced drug deliverability which generates less vascular inflammatory response and more rapid vessel healing by faster endothelial coverage of stent struts, as well as less vessel remodeling, persistent fibrin and platelet deposition, and premature neoatherosclerosis [13]. Consequently, trials investigating second generation DES have consistently shown lower rates of target lesion revascularization (TLR), myocardial infarction (MI), and ST than first generation DES [14,15].

Early cessation of DAPT has been known to increase the risk of thrombotic events after PCI with first generation DES [16]; however, randomized studies suggest that shorter durations are safe with newer stent platforms. Faster vessel healing after stent implantation results in a decreased need for antithrombotic protection. Recently, strategies with DAPT of only 3 months' duration have proven successful [17].

The use of newer generation DES has rapidly increased and is currently implanted in approximately 85% of patients undergoing PCI. In a nationwide cohort study from Sweden, the use of newer generation DES increased from 10% in 2009 to 85% in 2012. In the meantime, the use of BMS decreased from 50% in 2007 to 15% in 2012, while the use of older generation DES decreased from 50% in 2007 to 0.1% in 2012 [18].

This constantly evolving stent technology affects international guidelines on myocardial revascularization, which have recently been altered with regard to the relevant antiplatelet therapy after implantation of second generation DES.

International guidelines on the duration of dual antiplatelet therapy

In patients with stable coronary artery disease, the latest European guidelines on myocardial revascularization released by the European Society of Cardiology and the European Association for Cardio-Thoracic Surgery (ESC/EACTS) recommend DAPT for at least 1 month after BMS implantation and 6 months after DES implantation. Shorter DAPT duration (<6 months) can be considered in patients at high risk of bleeding. Furthermore, lifelong single antiplatelet therapy (usually aspirin) is indicated. Finally, DAPT can be used for longer than 6 months in patients with high ischemic risk and low bleeding risk.

In patients with acute coronary syndrome (ACS) undergoing PCI, the ESC/EACTS guidelines recommend that a P2Y₁₂ inhibitor is maintained over 12 months in addition to aspirin, unless there are contraindications such as excessive risk of bleeding. Treatment options are prasugrel (60 mg loading dose, 10 mg/day) and ticagrelor (180 mg loading dose, 90 mg twice daily) clopidogrel (600 mg loading dose, 75 mg/day) should only be used when prasugrel or ticagrelor are not available or are contraindicated [19].

The American guidelines differ in that they do not differentiate the duration of DAPT according to ACS presentation in patients with stents and generally suggest longer DAPT duration than the ESC/EACTS. The latest ACCF/AHA/SCAI guidelines recommend DAPT to be continued for up to 12 months in non-invasively treated patients with non-ST segment elevation (NSTE) ACS and for at least 12 months in all ACS and non-ACS patients undergoing PCI with DES [20,21].

The interest of the shortest possible DAPT regimen lies primarily in the optimal balance between preventing ischemic events after PCI and avoiding the bleeding complications inherent to antiplatelet treatment. Two landmark trials have provided solid evidence that the occurrence of major bleeding after PCI increases mortality. In both the HORIZONS-AMI (The Harmonizing Outcomes with Revascularization and Stents in Acute Myocardial Infarction) [22] and OASIS-5 (Organization for the Assessment of Strategies for Ischemic Syndromes) [23] trials, the ischemic endpoints between the treatment groups were similar but major bleeding differed significantly, resulting in a mortality benefit associated with reduced bleeding. Since then, several other substudies in cohorts originating from randomized clinical trials have confirmed that major bleeding is a powerful independent predictor of short and long-term mortality [24,25]. Short DAPT regimens that do not compromise the ischemic protective benefit will also provide substantial savings in healthcare expenses.

Trials behind the guidelines for best evidence-based clinical practice

Seminal trials have delineated the current recommendations on DAPT in patients with and without ACS [26–30]. The Clopidogrel for the Reduction of Events During Observation (CREDO) trial evaluated the benefit of long-term (12-month) treatment with the addition of clopidogrel to aspirin after elective PCI (65% had a recent MI or unstable angina) and found a significant 27% relative reduction in the combined risk of death, MI, or stroke in the clopidogrel group [30].

The Clopidogrel in Unstable Angina to Prevent Recurrent Events (CURE) trial enrolled ACS patients without ST-segment elevation to receive clopidogrel on top of aspirin for 3–12 months; the mean

duration of treatment was 9 months. The primary outcome, a composite of death from cardiovascular causes, non-fatal MI, or stroke, was relatively reduced at 20%. This benefit was driven by fewer MI in the clopidogrel group, while there was no isolated effect on cardiovascular death, and this came at the price of a 1.3-fold increased risk of major bleeding [26].

In the CURE-PCI trial, which investigated patients with ACS undergoing PCI and receiving aspirin, the addition of clopidogrel pretreatment followed by an 8-month regimen led to a 31% reduction in cardiovascular death or MI compared with placebo. There was no isolated effect on mortality [28].

The CLARITY-TIMI 28 trial (Addition of Clopidogrel to Aspirin and Fibrinolytic Therapy for Myocardial Infarction with ST-Segment Elevation) demonstrated that the addition of clopidogrel improved the patency rate of the infarct-related artery and reduced ischemic complications at 30 days' follow-up in patients with STEMI and who were treated with aspirin and a standard fibrinolytic regimen [29].

The COMMIT trial demonstrated that in patients with acute MI, clopidogrel added to aspirin during hospital admission and up to 4 weeks after the index event reduced both mortality and major vascular events in hospital. In both trials, bleeding was not increased [27].

In the context of these guideline referenced trials, the American recommendation of DAPT for at least 12 months in patients with ACS undergoing PCI might seem arbitrary, as none of these trials specifically investigated the recommended 12 month DAPT duration in an exclusive ACS population. Meanwhile, this recommendation has been sustained for over a decade because of repeated reports of early DAPT discontinuation and ACS predicting late coronary stent thrombosis [8,9,31].

Conversely, the latest European guidelines on DAPT duration after implanting second generation stents in patients with stable coronary artery disease recommend a 6-month DAPT duration [19], demonstrating the current controversy of differing needs for antiplatelet therapy for patients with ACS and those without the condition.

Parallels of stent technology evolution and shorter DAPT regimen

Randomized controlled trials (RCT) suggest that shorter durations of DAPT are safe with newer stent platforms. In a recent meta-analysis, the clinical impact of extended DAPT duration >12 months versus short DAPT duration (6 months) in all-comer PCI with predominantly second generation DES did not reduce ischemic events, but increased major bleeding [32], lending support to previous findings in patients with first generation DES [33,34].

This ongoing area of controversy was recently tested by Vahrenhorst *et al.* [35] in a prospective cohort of 56,440 unselected new-onset and clopidogrel-naïve patients with ACS (40% STEMI) from the SWEDEHART registry, predominantly treated with BMS. In extensively adjusted analyses, DAPT >6 months was associated with a 25% lower risk of all-cause death, stroke, or reinfarction but more bleeding at 1 year compared with treatment for 6 months. Only event-free patients within the first 6 months were considered. The demographics illustrated how contemporary treatment decisions are steered by patient comorbidities such as previous PCI, insulin-treated diabetes, stent type, count and length, as well as atrial fibrillation, anticoagulant treatment, and bleeding risk. This study indicated that DAPT for >6 months in patients with ACS reduces ischemic endpoints irrespective of patient characteristics, supporting the current guidelines for ACS treatment [35].

These results have to be interpreted in the light of two pivotal studies that were conducted in primarily non-ACS patients treated with first generation stents, showing that the vast majority (up to 80%) of definite or probable ST occur in the first 6 months after DES implantation and, additionally, the median time interval from thienopyridine therapy discontinuation to ST increases from several days to several months after the first 6 months, weakening the idea of a direct relationship between DAPT cessation and the occurrence of ST beyond 6 months after PCI [33,36].

DAPT cessation is traditionally classified using a binary, on-off approach that ignores the clinical reasons and underlying context in which antiplatelet treatment is discontinued. An alternative approach was recently offered by the PARIS (Patterns of Non-adherence to Anti-platelet Regimens In Stented Patients) trial, classifying DAPT cessation according to the clinical circumstance of DAPT withdrawal, which directly influenced adverse cardiac outcome after stenting and was related to whether the patient discontinued therapy by physician recommendation, interrupted for surgery, or disrupted because of non-adherence or bleeding [37].

It is likely that the optimal duration of DAPT is the dependent on patient's risk profile. To date, specific recommendations on DAPT duration according to risk subset have not been given in international guidelines; however, contemporary clinical practice undoubtedly modifies duration of DAPT after PCI by risk profile assessment based on patient demographics and procedural characteristics.

High risk patients

The clinical practice of extended DAPT duration in high risk patients is based on landmark studies such as the CHARISMA (Clopidogrel for High Atherothrombotic Risk and Ischemic Stabilization, Management, and Avoidance) and CAPRIE (Clopidogrel versus Aspirin in Patients at Risk of Ischaemic Events) trials, in which only the subset of patients enrolled based on previously documented coronary or peripheral atherosclerotic artery disease derived benefit of extended clopidogrel in terms of a reduction in the composite of MI, stroke, or death from cardiovascular causes [38,39]. In addition, Eisenstein *et al.* [40] showed in a large observational study that event-free patients at 6 and 12 months post PCI landmark analyses benefited from extended DAPT at up to 2 years' follow-up.

In a more contemporary setting, the PEGASUS-TIMI 54 study investigated the efficacy and safety of ticagrelor beyond 1 year after MI. In a double-blind 1 : 1 : 1 fashion, 21,162 patients who had had an MI 1–3 years earlier, were randomly assigned to ticagrelor at a dose of 90 mg twice daily, ticagrelor at a dose of 60 mg twice daily, or placebo. All the patients were to receive low-dose aspirin and were followed for a median of 33 months. The treatment with ticagrelor in both doses significantly reduced the risk of cardiovascular death, MI, or stroke but increased the risk of major bleeding [41].

This message was recently expanded to non-high risk patients: the DAPT (Dual Antiplatelet Therapy) study enrolled all-comer patients after they had undergone a coronary stent procedure in which a first generation DES was placed in over 30% of subjects. After 12 months of treatment with a thienopyridine drug (clopidogrel or prasugrel) and aspirin, patients were randomly assigned to continue receiving thienopyridine treatment or to receive placebo for another 18 months. In almost 10,000 patients, DAPT beyond 1 year significantly reduced the risks of ST and major cardiovascular and cerebrovascular events but was associated with an increased risk of bleeding [42].

This is disputed in a randomized controlled trial by Lee *et al.* [43], who reported that in event-free patients at 12 months after PCI, predominantly with first generation DES (65%), an additional 24 months of DAPT versus aspirin alone did not reduce the risk of the composite endpoint of death from cardiac causes, MI, or stroke.

The RESET Trial (REal Safety and Efficacy of 3-month dual antiplatelet Therapy following Endeavor zotarolimus-eluting stent implantation) [44] randomly assigned study participants to receive either the Endeavour zotarolimus stent followed by 3 months of DAPT or another currently available DES followed by 12 months of DAPT. The Endeavour zotarolimus + 3-month DAPT regimen was non-inferior to the standard therapy with respect to cardiovascular death, MI, stent thrombosis, TVR, or bleeding at 1 year. Importantly, there was no positive interaction for treatment effect by predefined subgroups, being diabetes mellitus (DM) but also >65 years of age, gender, ACS, congestive heart failure, stent length, multivessel disease, and vessel diameter, all factors considered characteristics defining a high risk patient profile. These results indicate that in patients treated with second generation DES, DAPT duration is not influenced by risk profile, although the combined endpoint of ischemic and bleeding outcome and the limited power of the subgroup analyses have to be kept in mind.

Nevertheless, the Prolonging Dual Antiplatelet Treatment After Grading Stent-Induced Intimal Hyperplasia Study (PRODIGY) confirmed the RESET results. A regimen of 24 months of clopidogrel therapy in patients who had received a balanced mixture of DES and BMS was not more effective than a 6-month clopidogrel regimen in reducing the composite of death from any cause, MI, or stroke [45]. Again, these results were found to be consistent across risk subgroups of age (>65 years), ACS, and DM.

Baber *et al.* [46] recently showed that associations between either chronic kidney disease (CKD) or DM alone and high residual platelet reactivity were attenuated after covariate adjustment while the odds for platelet reactivity associated with both CKD and DM remained significant with an approximate 2.5-fold increased risk. Consequently, the presence of both CKD and DM seem to confer a synergistic impact on residual platelet reactivity when compared with either condition alone.

Whether more potent platelet inhibitors improve outcomes among patients with risk factors is controversial and warrants investigation.

In a prespecified subgroup analysis of the PCI-CURE trial [21], the addition of clopidogrel to aspirin in patients with NSTEMI-ACS undergoing PCI significantly reduced cardiovascular death or MI in non-diabetic patients but had no beneficial effect in patients with diabetes. This finding could lead to the speculation that clopidogrel does not provide sufficient ischemic protection in patients with DM. In a prespecified substudy of the TRITON-TIMI 38 trial [6], subjects with DM had a greater reduction in recurrent MI than patients without DM when treated with prasugrel compared to clopidogrel, without an observed increase in major bleeding. This implies that patients with DM could benefit from the more intensive antiplatelet effect provided by prasugrel [47]. Angiolillo *et al.* [48] confirmed these findings in patients with type 2 DM and CAD. Standard-dose prasugrel was associated with greater platelet inhibition during both the loading and maintenance periods when compared with double-dose clopidogrel [22]. Conversely, in the PLATO trial, ticagrelor reduced ischemic events in patients with ACS in comparison with clopidogrel, irrespective of diabetic status, glycemic control, and insulin treatment [15]. Recently, a small, single center, open-label study randomized 100 patients with DM

and undergoing PCI for an ACS to receive either prasugrel or ticagrelor. Platelet reactivity assessed between 6 and 18 hours post-loading dose with ticagrelor showed significantly lower platelet reactivity than prasugrel. Whether this signal of higher potency of ticagrelor could translate into a clinical benefit is unknown [23].

Hence, the clinical necessity of intensified platelet inhibition in patients with DM remains unclear and beneficial effects might be specific to the various P2Y₁₂ compounds. Alternatively, the different findings of prasugrel and ticagrelor in diabetic populations could relate to variations in patient profiles. In fact, a recent clinical report suggests that higher on-treatment platelet reactivity is prevalent among obese patients, although the signal was confined to those who also had the metabolic syndrome [24]. Whether an increased body mass index (BMI) by itself is associated with platelet reactivity is controversial [25].

The matter of prolonged DAPT duration might be summarized as it was stated in the conclusion of a recent meta-analysis. Findings were that short DAPT duration had overall lower rates of bleeding yet higher rates of ST compared with longer DAPT duration, with the latter effect being significantly attenuated with the use of second generation DES. There was a trend of higher all-cause mortality, which was numerically higher with longer DAPT durations but without reaching statistical significance. Prolonging DAPT therefore requires careful assessment of the trade-off between ischemic and bleeding complications [49]. The recent DAPT study offers some insight into the mechanisms of increased all-cause mortality with longer duration of DAPT [42]. While there was no significant difference between the randomized treatments (thienopyridine vs. placebo for 18 months after 1 year of treatment with clopidogrel or prasugrel and aspirin after DES) with respect to severe bleeding (GUSTO criteria) or with respect to fatal bleeding, non-cardiovascular death was increased with prolonged DAPT treatment, in part explained by bleeding related non-cardiovascular deaths caused by trauma [42].

DAPT duration in patients in need of surgery

The length of a planned DAPT regimen after PCI can influence or in some cases even postpone or inhibit other treatments needed by the patient.

Surgery is a frequent cause of DAPT cessation in patients following PCI, with approximately 5% of patients with stents undergoing cardiac or non-cardiac surgery within the first year of PCI [50–52]. Surgery is associated with platelet activation [53] and coronary artery thrombus is a likely mechanism of peri-operative MI [54], which in turn is the most common major vascular complication after surgery and independently associated with 30-day mortality [55–57].

Nevertheless, there is ongoing controversy over the optimal timing and peri-operative strategy of oral antiplatelet treatment in patients undergoing both cardiac and non-cardiac surgery. Currently, the ACCF/AHA/SCAI (American College of Cardiology Foundation/American Heart Association/Society for Cardiac Angiography and Interventions) guidelines regarding revascularization before non-cardiac surgery hold a IIa benefit > risk recommendation (level of evidence B) for balloon angioplasty or BMS implantation followed by 4–6 weeks of DAPT [20]. This grace period after BMS implantation relates to the increased thrombogenicity in the immediate postoperative phase, inherent to the prothrombotic effect of surgery. In the earlier days of coronary

angioplasty with BMS, catastrophic outcomes of very elevated rates of death and MI, with ST accounting for most of the fatal events, were reported when patients underwent surgery within the first 2–5 weeks [58,59], a timeframe that corresponds accurately with the 4-week period of vascular healing with complete stent strut coverage after BMS implantation [60]. Since then, studies conducted in patients with first generation DES showed that non-cardiac surgery within the first year after PCI was an independent predictor of adverse ischemic events. Rates were higher when surgery was performed within 6 months of PCI but stabilized thereafter [61,62], which, in comparison to BMS, was most likely a function of the delayed vessel healing because of the antiproliferative drugs eluted and the polymer coating in first generation DES implants [8,9,13].

Parallel results from recent stent trials indicate that a 3-month grace period after PCI with second generation DES implantation is probably advisable before recommending interruption of DAPT for surgery [17,63].

In the event of surgery, guidelines hold a Class IIa recommendation for discontinuation of DAPT, with continuous aspirin treatment if possible and restart of P2Y₁₂ inhibitors in the immediate postoperative period. However, the level of evidence in support of this recommendation is scarce (level C), with the limited data available relying on expert consensus [20]. The recent results from the large RCT POISE-2 (PeriOperative ISchemic Evaluation-2) have questioned this clinical practice, as the administration of aspirin (100 mg/day after a 200-mg loading dose) before non-cardiac surgery and throughout the early post-surgical period had no significant effect on the rate of a composite of death or non-fatal MI but increased the risk of major bleeding [64]. The American Society of Regional Anesthesia Guidelines for peri-operative management of patients on antiplatelet therapy even recommends that all elective surgery after DES implantation should be postponed for 12 months [65]. Therefore, a tendency exists toward BMS implantation if surgery is planned. In the event that elective surgery can be postponed for 3 months, these guideline precautions might be unnecessary and possibly even disadvantageous as the patient will not benefit from the lower revascularization rates of second generation DES over BMS [15].

Atrial fibrillation

It is estimated that 5–7% of patients undergoing PCI have atrial fibrillation (AF) [6]. Warfarin has been the standard of care for several decades and has been considered superior to DAPT in preventing stroke and thromboembolism in patients with AF who do not undergo PCI [7]. Conversely, in patients in need of PCI, DAPT with aspirin and thienopyridine has been shown to be more beneficial in preventing ST than oral anticoagulation alone [66].

The current AHA guidelines on AF for patients undergoing PCI are non-specific as they recommend “BMS may be considered to minimize the required duration of DAPT” and “It may be reasonable to use clopidogrel concurrently with OAC but without ASA” [67]. One European and one North American recent consensus paper state that triple therapy (TT) with warfarin, aspirin, and thienopyridine should be preferred for patients with AF undergoing PCI with stenting and CHADS₂ > 1 [68,69]. The length of triple therapy in these patients is dependent on stent type and the assessment of ischemic and bleeding risk. After BMS implantation, TT should be limited to 1 month, 3 months after limus stents, and 6 months after paclitaxel stents. For DES, warfarin plus either clopidogrel or aspirin (100 mg) with concomitant proton pump

inhibitor treatment should be continued for up to 12 months after PCI. Hereafter warfarin alone should be continued lifelong. It is well recognized that the benefits of TT come with a significant bleeding risk (threefold increase compared to warfarin monotherapy; fivefold increase compared to DAPT), which further increases with longer durations of TT [70,71]. In patients with high bleeding risk, the recommendation is to avoid DES altogether. However, with the recent results from pooled analyses from the RESULTE programs considering zotarolimus stents [63], the recommendation of avoiding DES implantation in patients with AF could be obsolete with the latest generation scaffolds and polymer coatings.

These consensus statements have recently been challenged by the WOEST trial which found that in patients undergoing PCI and on an anticoagulant (69% indication AF, 88% CHADS₂>1), the use of clopidogrel without aspirin was associated with a significant reduction in bleeding complications and no increase in the rate of thrombotic events compared to TT [72]. These results were confirmed by a recent Danish nationwide retrospective study based on dispensed drug prescriptions in patients with AF hospitalized with an MI and/or undergoing PCI, in whom oral anticoagulants and clopidogrel was equal or better than TT on both benefit and safety outcomes [73].

Future directives

Several large RCTs studying the duration of DAPT after PCI are currently enrolling. The Ticagrelor With Aspirin or Alone in High-Risk Patients After Coronary Intervention (TWILIGHT) trial has the primary objective to determine in 9000 patients undergoing PCI the impact of antiplatelet monotherapy with ticagrelor alone versus DAPT with ticagrelor plus aspirin for 12 months in reducing clinically relevant bleeding (efficacy) among high risk patients undergoing PCI who have completed a 3-month course of aspirin plus ticagrelor (NCT02270242). An upcoming trial is the Short Duration of Dual antiplatelet Therapy With Synergy II Stent in Patients Older Than 75 Years Undergoing Percutaneous Coronary Revascularization (SENIOR) study in patients with stable angina, silent ischemia (1 month DAPT), or ACS (6 months DAPT) (NCT02099617).

Finding the right balance in patients with AF undergoing PCI, which minimizes bleeding risk and maintains anti-ischemic efficacy, remains a complex and controversial clinical dilemma in these unique patients. The arrival of novel antiplatelet agents and anticoagulants on the scene has led to an exponential increase in the combinations that can be employed by clinicians in real-life situations. At present, four approved oral anticoagulant options for AF (vitamin K antagonist, dabigatran, rivaroxaban, and apixaban) and edoxaban (imminent approval awaited), as well as four commonly used oral antiplatelet options (aspirin, clopidogrel, ticagrelor, prasugrel). There is little evidence on this topic and currently the PIONEER-AF trial is enrolling patients with AF undergoing PCI, randomizing participants to rivaroxaban 2.5 mg twice daily+one P2Y₁₂ inhibitor, rivaroxaban 15 mg once daily+one P2Y₁₂ inhibitor, or vitamin K antagonist (VKA)+one P2Y₁₂ inhibitor and aspirin (PIONEER-AF; NCT01830543), with an inclusion period projected to run until July 2015. A trial with dabigatran (RE-DUAL PCI) is on the horizon, planning to randomize participants to either Pradaxa 110 mg twice daily+APT, Pradaxa 150 mg twice daily+APT or VKA+DAPT. The sheer number of combinations means that the best APT and anticoagulant combination and duration based on solid randomized data will not be known for many years.

Interactive multiple choice questions are available for this chapter on www.wiley.com/go/dangas/cardiology

Dual antiplatelet therapy (DAPT), comprising aspirin and a P2Y₁₂-receptor antagonist, is recommended following stent implantation during percutaneous coronary intervention (PCI), by European [1,2] and North American [3,4] guidelines. Although DAPT efficaciously improves peri- and post-procedural outcomes, a significant proportion of patients experience stent thrombosis, reinfarction, and cardiac-related death [5]. In order to further improve patient outcomes, several studies have been conducted to determine the efficacy and safety of administering a further antithrombotic agent, such as an anticoagulant or an additional antiplatelet agent. However, such antithrombotic regimens can lead to an increased risk of bleeding. There remains a great deal of heterogeneity between studies, and so the clinical utility of such therapies is still debated.

Up to 10% of patients undergoing PCI also have a prior indication for long-term oral anticoagulation (OAC), such as atrial fibrillation (AF) or a mechanical heart valve *in situ*. This proportion is set to rise markedly, because of the increasing prevalence of comorbidity, AF, and valvular heart disease; a sequela of population aging [6–11]. Although vitamin K antagonists (VKAs; e.g., warfarin) remain the mainstay of OAC, novel non-vitamin K antagonist oral anticoagulants (NOACs; e.g., apixaban, rivaroxaban and dabigatran) have been developed with potentially advantageous pharmacologic properties and improved safety profiles [12]. Conventional wisdom has held that co-administration of DAPT and OAC (triple antithrombotic therapy; TATT) significantly reduces thromboembolic events, at the expense of increased major bleeding. Because of the narrow margin between the risks and benefits of triple therapy regimens, it is imperative that such strategies are evidence-based and patient-centered, and balance the thromboembolic and hemorrhagic risk factors of the patient [13]. Recent randomized and observational evidence has emerged to offer insight into the net benefits and risks of this strategy, in the settings of PCI and acute coronary syndrome (ACS), and has led to changes to best practice guidelines [14,15].

This chapter reviews the safety and efficacy of triple antiplatelet and antithrombotic regimens, following PCI. It examines the preliminary data regarding novel oral anticoagulants, summarizes the latest evidence-based clinical guidelines, and addresses questions

that remain unanswered regarding the optimal clinical use of such antithrombotic regimens.

Methods

A series of structured searches of major biomedical databases (PubMed, Medline, Embase, and Web of Science) were performed, using the key terms; “triple therapy,” “percutaneous coronary intervention,” “stent implantation,” “antiplatelet,” “anticoagulation,” and “novel anticoagulant agents.” Only articles published in English, between 1950 and 2014, were included. This is a synthesis of all available clinical data regarding TATT following PCI.

Platelet activation and the pathophysiology of arterial thrombosis

The primary trigger of intra-arterial thrombosis is rupture of a vulnerable atherosclerotic plaque, which develops from the progressive accumulation of lipid-laden macrophages in the arterial wall. Following rupture, platelet recruitment occurs via the interaction of cell-surface receptors (e.g., glycoprotein VI) with collagen and von Willebrand factor. Following platelet adhesion to the vessel wall, adenosine diphosphate (ADP; P2Y₁ and P2Y₁₂) and glycoprotein IIb/IIIa (GP IIb/IIIa) receptor-mediated binding of additional platelets occurs, causing aggregation. Degranulation of a cocktail of pro-inflammatory mediators from the platelet releases thromboxane A₂ (TxA₂) and adenosine diphosphate (ADP) which, in turn, propagate further activation. Simultaneously, tissue factor exposed from the denuded plaque activates the clotting cascade via the extrinsic pathway, activating factor VII. This sequentially activates factor X, V, and the final common pathway, activating thrombin. Thrombin cleaves soluble fibrinogen to fibrin monomers, which polymerize to form an insoluble meshwork in which platelets and red blood cells become trapped and so a thrombus is formed. Thrombin interacts with platelets at protease-activated receptors (e.g., PAR-1) to further enhance degranulation, perpetuating further platelet activation. Thus, arterial thrombosis is dependent on activation of both platelets and the clotting cascade; pharmacotherapeutic strategies targeting these pathways are critical in preventing adverse outcomes following PCI.

Mechanisms of antithrombotic pharmacotherapy

Antithrombotic drugs are classified in two main categories: (i) antiplatelet agents, which act via inhibition of platelet recruitment, adhesion, aggregation, or activation, and (ii) anticoagulant agents, which act via inhibition of critical components of the coagulation cascade. Aspirin is a ubiquitous, irreversible, non-specific inhibitor of cyclo-oxygenase (COX), abrogating downstream TxA_2 production; clopidogrel, prasugrel, and ticagrelor act via antagonism of the ADP P2Y_{12} receptor. The traditional anticoagulants, such as warfarin, reduce vitamin K-dependent clotting factor (II, VII, IX, and X) synthesis, via inhibition of vitamin K epoxide reductase subunit C1 (VKORC1). This impairs both the intrinsic and extrinsic clotting pathways. The NOACs directly act on critical components of the final common pathway of the coagulation cascade: apixaban, rivaroxaban, and edoxaban inhibit free/platelet-bound factor Xa (as opposed to low molecular weight heparins and fondaparinux, which bind to Xa via antithrombin III). Dabigatran directly inhibits free/platelet-bound thrombin, abrogating the conversion of fibrinogen to fibrin.

Triple antiplatelet therapy following PCI Phosphodiesterase-3 inhibitors

Many randomized trials have evaluated the benefits and risks of cilostazol in addition to DAPT following PCI. The largest study randomized 1212 patients to receive either DAPT alone (aspirin and clopidogrel), or with the addition of cilostazol [16]. The addition of cilostazol reduced the composite endpoint of major adverse cardiovascular events (MACE; cardiac death, non-fatal myocardial infarction, stroke, or target vessel revascularization; 0.3 vs. 15.1%; $p=0.01$), without increasing the risk of major bleeding (0.0 vs. 0.2%; $p=0.50$). To date, 10 further randomized controlled trials have assessed the incremental benefits of cilostazol, randomizing 5096 patients to receive either DAPT (aspirin and clopidogrel) or triple antiplatelet therapy (TAPT; aspirin, clopidogrel, and cilostazol) following PCI [16–25]. Although the sample size of individual trials is relatively low ($n=84$ –1212 patients), with many reporting equivocal results, meta-analysis demonstrates that cilostazol reduces MACE (odds ratio [OR] 0.56, 95% confidence intervals [CI] 0.47–0.68; $p<0.00001$), without increasing bleeding (OR 1.42, 95% CI 0.52–3.85; $p=0.49$) [26–29].

Registry studies of cilostazol-treated patients have provided additional insights. The DECREASE registry ($n=3099$) evaluated DAPT (aspirin and clopidogrel) versus TAPT (aspirin, clopidogrel, and cilostazol), reporting that TAPT was associated with reduced risk of subsequent MI (hazard ratio [HR] 0.23, 95% CI 0.08–0.70; $p=0.01$) and stent thrombosis (HR 0.14, 95% CI 0.04–0.52; $p=0.004$), with no differences in major hemorrhage (HR 0.97, 95% CI 0.44–2.12; $p=0.94$) at 12 months [30]. However, no difference in mortality was observed (HR 0.76, 95% CI 0.40–1.45; $p=0.41$). The COBIS-II registry ($n=2756$) evaluated TAPT versus DAPT in patients with coronary bifurcation lesions [31]. Although patients who received TAPT had more cardiovascular comorbidities, there were no significant differences in DAPT versus TAPT in terms of MI, stent thrombosis, mortality, or bleeding complications.

Despite these promising results, a study by Yang *et al.* [32] demonstrated that DAPT regimens containing the third-generation thienopyridine prasugrel induced superior platelet inhibition compared to a TAPT regimen of aspirin, clopidogrel, and cilostazol (VerifyNow- P2Y_{12} assay; 72.1 ± 12.2 vs. 57.5 ± 23.5 , respectively; $p=0.020$) [32]. Although clinical data are not presented, this

highlights the complexity associated with comparing permutations of antiplatelet agents in higher order regimens. A subsequent meta-analysis, which indirectly compares the efficacy of different DAPT regimens with cilostazol-containing TAPT, reports that TAPT significantly reduced MACE rate, compared with prasugrel- and ticagrelor-based DAPT (prasugrel: OR 0.70, 95% CI 0.56–0.87; $p=0.0012$; ticagrelor: OR 0.67, 95% CI 0.55–0.83; $p=0.0003$) [29]. Furthermore, TAPT with cilostazol did not increase the frequency of major bleeding (OR 1.42, 95% CI 0.52–3.85; $p=0.49$) or overall bleeding (OR 1.16, 95% CI: 0.79–1.69; $p=0.45$).

Glycoprotein IIb/IIIa inhibitors

The oral platelet GP IIb/IIIa inhibitors xemilofiban, orbofiban, and sibrafiban have undergone extensive phase 3 clinical trials [33–35]. The placebo-controlled EXCITE trial evaluated xemilofiban 10 and 20 mg, administered three times daily for 2 weeks, followed by twice-daily dosing, for up to 6 months following PCI, in 7232 patients [33]. All patients received aspirin therapy; patients receiving stents in the placebo group also received the first generation P2Y_{12} -receptor antagonist, ticlopidine. This trial failed to achieve reductions in its primary endpoint (a composite of death, recurrent MI, and revascularization), demonstrating no benefit of xemilofiban at 6 months at a 10 mg (HR 1.03, 95% CI 0.86–1.23; $p=0.82$) or 20 mg (HR 0.94, 95% CI 0.78–1.13; $p=0.36$) dose. The OPUS-TIMI 16 trial randomized 10,302 patients presenting with ACS to either 50 mg orbofiban twice daily for 6 months, 50 mg orbofiban twice daily for 30 days followed by 30 mg twice daily for 5 months, or placebo [34]. All patients received aspirin therapy; placebo-treated patients receiving stents received ticlopidine. OPUS-TIMI was halted prematurely because of significantly increased mortality in the orbofiban arm (5.1 vs. 3.7% in the 50/30 mg orofiban-treated vs. placebo-treated group; $p=0.008$). Bleeding was dose-dependently higher in orofiban-treated patients, occurring in 2.0%, 3.7%, and 4.5% in the placebo, 50/30, and 50/50 groups, respectively ($p<0.0001$). The SYMPHONY trial studied weight-creatinine-individualized sibrafiban therapy versus aspirin in 9233 ACS patients [35]. The primary endpoint (death, reinfarction, or severe ischemia) did not differ between aspirin, low, or high dose sibrafiban-treated patients, but major bleeding was more common in sibrafiban-treated patients (OR 1.34, 95% CI 1.05–1.71) compared to aspirin alone. Enrolment of second SYMPHONY, comparing low dose sibrafiban with aspirin, high dose sibrafiban without aspirin, or aspirin alone, was terminated prematurely, following analysis of SYMPHONY [36]. In those randomized (6671 of a planned 9000 patients) a major bleeding risk was also observed in sibrafiban-treated patients.

Each phase 3 oral GP IIb/IIIa inhibitor trial reported significant harms associated with such therapy. Subsequent meta-analysis confirmed this phenomenon, demonstrating significant excess mortality, regardless of aspirin co-administration or dosage [37]. However, trials of intravenous GP IIb/IIIa inhibitors (abciximab, eptifibatide, and tirofiban) demonstrate significant benefits as adjuncts to PCI during the management of ACS, and stable CAD [38,39]. The unfavorable safety profile of oral agents precluded their usage in clinical practice.

Antiplatelet combinations with oral anticoagulants following PCI

Vitamin K antagonists

Although the beneficial effects of warfarin in reducing mortality and preventing reinfarction post-MI have been ascertained in several placebo-controlled, randomized studies, these predate the

widespread implementation of mechanical reperfusion strategies and DAPT, and as such have uncertain relevance to contemporary practice [40,41]. In the context of multiagent regimens, a large meta-analysis demonstrated that there was no mortality benefit associated with the routine co-administration of warfarin and DAPT versus DAPT alone (OR 1.20, 95% CI 0.63–2.27; $p=0.56$); reductions in the incidence of ischemic events (OR 0.29, 95% CI 0.15–0.58; $p=0.0004$) were counterbalanced by a twofold increased risk of bleeding (OR 2.00, 95% CI 1.41–2.83; $p<0.0001$) [42]. The use of OACs in combination with DAPT for specific, high risk patient groups, such as those with comorbid AF and *in situ* mechanical heart valves, is further evaluated in this chapter.

Non-vitamin K antagonist oral anticoagulants

Direct thrombin inhibitors

Impelled by the advent of NOACs, renewed interest has emerged in routine combination antithrombotic therapy following PCI [43]. However, phase 3 clinical trials exploring the use of NOACs in AF systematically excluded patients with recent stent implantation, and conversely, recent trials of ACS management have excluded patients on novel anticoagulants. The placebo-controlled, dose-escalation RE-DEEM study randomized 1861 patients with ACS to receive standard DAPT (aspirin and clopidogrel, or another thienopyridine) alone, or with dabigatran, following PCI [44]. Patients were randomized to receive placebo or dabigatran 50, 75, 110, or 150 mg (each twice daily). Although the study was not adequately powered to assess efficacy, because of multiple-group comparisons and the small event rates within each group (1.7–3.8%), it was able to detect differences in major bleeding (the primary study outcome). A dose-dependent relationship with bleeding risk was robustly observed in dabigatran-treated patients, compared with placebo-treated controls (50 mg: HR 1.77, 95% CI 0.70–4.50; 75 mg: HR 2.17, 95% CI 0.88–5.31; 110 mg: HR 3.92, 95% CI 1.72–8.95; and 150 mg: HR 4.27, 95% CI 1.86–9.81), with equivocal antithrombotic benefit.

Direct factor Xa inhibitors

The APPRAISE study randomized 1715 patients with ST-elevation or non-ST-elevation MI to evaluate the incremental effects of apixaban in addition to DAPT [45]. Patients received placebo or apixaban 2.5 mg (twice daily), 10 mg (once daily), 10 mg (twice daily), or 20 mg (once daily). The high dose groups (20 mg/day) were later discontinued, following early reports of excessive clinically significant bleeding among patients receiving these regimens (7.8% and 7.3% of patients administered 10 mg twice daily and 20 mg once daily, respectively). Among patients receiving the lower dose regimens, the risk of clinically significant bleeding remained greater than that of placebo-treated controls (2.5 mg twice daily: HR 1.78, 95% CI 0.91–3.48; $p=0.09$; 10 mg once daily: HR 2.45, 95% CI 1.31–4.61; $p=0.005$). The apixaban-treated groups experienced a reduced rate of further cardiovascular events compared to the placebo-treated group (2.5 mg twice daily: HR 0.73, 95% CI 0.19–0.56; 10 mg once daily: HR 0.61, 95% CI 0.04–0.65). However, the observed increase in bleeding risk was more pronounced, and reductions in ischemic events less evident, in patients taking aspirin plus clopidogrel, compared to those taking aspirin alone. Subsequently, the APPRAISE-2 trial was prematurely terminated following recruitment of 7392 (of target enrolment of 10,848) patients, randomized to receive 5 mg twice daily apixaban (based on the optimal dosing profile identified in APPRAISE) or placebo, in

addition to aspirin and a P2Y₁₂-receptor antagonist [46]. Significant increases in major bleeding were observed with apixaban treatment compared to the control group (HR 2.59, 95% CI 1.50–4.46; $p=0.001$). During apixaban therapy, a greater number of these episodes were intracranial or fatal, compared to placebo. No differences in the rates of MACE were observed (7.9 vs. 7.5%, respectively; $p=0.51$), at 8 months' follow-up. These data indicate that the use of apixaban, even at the 5 mg dose determined in APPRAISE to offer the greatest risk–benefit profile, increased major hemorrhage, without reducing incident cardiovascular events. Although the authors suggest the inclusion of patients with extensive comorbidities, such as advanced age, diabetes mellitus, heart failure, and renal impairment, could have increased the rate of bleeding, these factors were distributed equally throughout both groups, and should not have deleteriously impacted upon outcomes.

The ATLAS-ACS-TIMI 46 study aimed to identify the optimal dosage regimen of rivaroxaban, in ACS patients receiving aspirin with or without a thienopyridine [47]. This trial randomized 3491 patients (2730 on DAPT) to either receive placebo, or rivaroxaban at daily doses of 5, 10, 15, and 20 mg, administered in a single or divided doses. This study reported a daily dose-dependent, increased risk of clinically significant bleeding with rivaroxaban versus placebo (5 mg: HR 2.21, 95% CI 1.25–3.91; 10 mg: HR 3.35, 95% CI 2.31–4.87; 15 mg: HR 3.60, 95% CI 2.32–5.58; and 20 mg: HR 5.06, 95% CI 3.45–7.42; $p<0.0001$). However, rivaroxaban treatment efficaciously reduced mortality and MACE, compared with placebo (doses combined: HR 0.69, 95% CI 0.50–0.96; $p=0.027$). Twice daily rivaroxaban 2.5 and 5 mg achieved the optimum balance between minimization of bleeding risk, and maximization of benefit. The phase III ATLAS-ACS-2-TIMI-51 study then randomized 15,526 patients to either placebo, twice daily rivaroxaban 2.5 or 5 mg (in addition to aspirin and a thienopyridine) [48]. At 13 months' follow-up, rivaroxaban therapy reduced the risk of a composite endpoint of MI, stroke, and death (doses combined: HR 0.84, 95% CI 0.74–0.96; $p=0.008$), with greater risk reductions amongst those receiving twice daily 5 mg compared with twice daily 2.5 mg dosage (8.8% vs. 9.1%). Although rivaroxaban was associated with an increased risk of major bleeding (doses combined: HR 3.96, 95% CI 2.46–6.38; $p<0.001$), fatal hemorrhage remained equal (HR 1.19, 95% CI 0.54–2.59; $p=0.66$). Thus, rivaroxaban may represent a useful adjunct to DAPT following PCI.

Although development was later discontinued, the efficacy of darexaban was evaluated in a multicenter, double-blind, randomized trial, RUBY-1 [49]. This trial randomized 1279 patients with ACS to receive one of six darexaban regimens (10–60 mg/day, in once-only or divided dose regimens) or placebo, in addition to DAPT. At 6 weeks' follow-up, darexaban was associated a significant dose-dependent risk of bleeding (overall HR 2.28, 95% CI 1.13–4.60; $p=0.022$). Although underpowered to definitively provide insight into clinical efficacy, no differences in mortality or adverse cardiac events were noted between the darexaban and placebo-treated groups.

A meta-analysis of seven phase 2 and 3 studies of NOACs in ACS ($n=30,866$; 26,731 on DAPT) demonstrates that the addition of a NOAC to standard therapy, as indicated, reduced the incidence of MACE (HR 0.87, 95% CI 0.80–0.95), but doubled the risk of significant bleeding (HR 2.34, 95% CI 2.06–2.66) [50]. The analyses were robust; with low interstudy heterogeneity, and equivalent outcomes when limited to phase 3 studies. Thus, the results of this meta-analysis, in line with the individual trials, demonstrate that while NOACs

can offer incremental efficacy over DAPT regimens, this may be outweighed by associated excess bleeding.

Achieving improved outcomes following PCI: a role for a third agent?

At present, insufficient evidence of an acceptable risk–benefit balance exists to recommend the routine use of a third antithrombotic agent in the post-PCI setting [1,3,4,51]. The addition of cilostazol to present TAPT regimens may be associated with improved outcomes, particularly for patients known to be at high risk of recurrent adverse events following PCI [52,53]. However, limited evidence of benefits on absolute endpoints and uncertain efficacy in comparison to contemporary DAPT regimens have precluded the inclusion of cilostazol in guidelines. Although the use of intravenous GP IIb/IIIa inhibitors has become the standard of care for certain patients during revascularization, the adverse safety profile of oral agents precludes their further development as adjunct to DAPT. The routine administration of OACs with DAPT remains controversial; any antithrombotic benefits of VKAs are counterbalanced by increased risk of hemorrhage and pragmatic limitations associated with maintaining therapeutic anticoagulation. Although early evidence suggests NOACs can reduce the risk of post-procedure adverse cardiovascular events, a significant risk of bleeding, high cost, and difficulties in reversal limits routine administration. As such, DAPT remains the mainstay of treatment following ACS. The routine use of additional antithrombotic agents poses significant risks, without proven benefit. Antithrombotic regimens should be reserved for specific cases, in which there is proven clinical benefit.

Triple antithrombotic therapy following PCI with prior indications for OAC Vitamin K antagonists

As a consequence of population aging, an increasing number of patients presenting for PCI have comorbid indications for long-term OAC, such as AF, *in situ* mechanical heart valves, or intramural thrombus [54]. However, in AF, it remains challenging to identify patients who would benefit from long-term OAC. The CHADS₂ (congestive heart failure, hypertension, age over 75 years, diabetes mellitus, and transient ischemic attack or stroke) and CHA₂DS₂-VASc (CHAADS₂ factors, vascular disease, age over 65 years, and female sex) tools aid clinicians in making recommendations regarding the appropriateness of OAC [55,56]. Each factor scores one, apart from those indicated with subscript characters. A CHADS₂ or CHA₂DS₂-VASc score ≥ 1 should prompt consideration of OAC (antithromboembolic benefits outweigh risk of hemorrhage). The HAS-BLED (hypertension, abnormal renal/liver function, stroke, bleeding predisposition, labile international normalized ratio [INR], elderly, and drug history) score is used to ascertain bleeding risk; scores ≥ 3 indicate high risk of bleeding, and suggest caution when considering OAC [57]. HAS-BLED also has clinical utility in combination with antithrombotic regimens, predicting bleeding risk with moderate accuracy during combination antithrombotic pharmacotherapy. The development and validation of further scores may better guide decisions regarding the use of novel antithrombotic regimens following PCI.

For patients who have prior indications for both OAC and undergo PCI, the most common therapeutic regimen consists of warfarin, aspirin, and a thienopyridine (OAC + DAPT). However, is

such a strategy rigorously evidence-based? A retrospective, nationwide study (n=11,480), demonstrates that patients treated with warfarin, aspirin, and clopidogrel are at increased risk of spontaneous (and fatal) hemorrhage, compared to patients treated with DAPT alone (10.2 vs. 3.2; p=0.01) [58]. Outcomes are compared in patients treated with: (i) all agents (n=1,495), (ii) warfarin plus either aspirin (n=1,310) or clopidogrel (n=527), (iii) aspirin and clopidogrel (n=3144), and (iv) antiplatelet or anticoagulant monotherapy (n=5004). Patients receiving OAC + DAPT had high rates of clinically significant bleeding during the first 30 days (22.6 per 100 patient-years), reducing over 2 months (20.2), to approximately half at 3 months (10.7), indicating no safe therapeutic window exists. The bleeding risk in patients receiving DAPT + OAC remained greater than a single antiplatelet agent and OAC, at 3 months (HR 1.47, 95% CI 1.04–2.08) and 1 year (HR 1.36, 95% CI 0.95–1.95). Notably, no significant difference in thromboembolic risk was observed for DAPT + OAC versus a single antiplatelet agent and OAC (HR 1.15, 95% CI 0.95–1.40), calling into question the use of multiple antiplatelet agents. The findings of multiple, small, observational studies with regard to bleeding risk are in agreement. Rogacka *et al.* [59] also noted that amongst patients receiving DAPT + OAC following PCI (n=127), most bleeding (67%) occurs within the first month. The AVIATOR registry prospectively followed 425 patients with AF receiving PCI because of ACS. On discharge, patients received OAC + DAPT (n=185), or DAPT (n=240; aspirin and clopidogrel) [60]. At 1 year, the risk of MACE was similar in both groups (14% vs. 16%, HR 0.90; p=0.78), although the risk of bleeding was greater in those receiving OAC + DAPT (13% vs. 6%; HR 2.05; p=0.03). Yu *et al.* [61] report a contemporary cohort of n=367 patients with AF undergoing drug-eluting stent implantation; 154 received OAC + DAPT, 213 received DAPT alone. At 2 years, the OAC + DAPT group experienced a greater rate of major bleeding (16.7% vs. 4.6%; p < 0.001), without significant increases in MACE (22.1% vs. 17.7%; p=0.31).

Although informative observational studies are limited by selection bias, and the lack of a control group, precluding definitive conclusions regarding the safety and efficacy of triple antithrombotic therapy in patients at risk of thromboembolism, further interventional studies were required. The seminal WOEST trial randomized 573 patients receiving OAC and undergoing PCI, to receive either clopidogrel alone, or with aspirin, in addition to their pre-existing VKA, using an open-label design [62]. PCI was primarily elective; drug-eluting stents were used in 65% of cases. AF (with CHADS₂ ≥ 1) was the most frequent indication for anticoagulation. At 1 year, bleeding was significantly less in patients receiving OAC plus clopidogrel, compared with those receiving OAC + DAPT (HR 0.36, 95% CI 0.26–0.50; p < 0.0001). Although inadequately powered to demonstrate non-inferiority, the absolute MACE rate was lower with OAC plus clopidogrel versus OAC + DAPT (11.1% vs. 17.6%, HR 0.60, 95% CI 0.38–0.94; p=0.025). Thus, the removal of aspirin significantly reduces the risk of bleeding by more than 50%, without increases in MACE. The authors hypothesize that inhibition of thrombin (factor IIa; a powerful platelet activator) with VKA OACs, and the P2Y₁₂ receptor (which has a major role in amplifying the effects of TxA₂) with clopidogrel, reduces the importance of COX inhibition in the protection against thromboembolic events.

The findings of WOEST were supported by the observational data in the Danish National Registry, which included 12,165 patients with AF, receiving multiple antithrombotic regimens following PCI [63]. At 1 year, no increased risk of MACE was observed for OAC plus clopidogrel in comparison to OAC + DAPT (HR 0.69,

95% CI 0.48–1.00), OAC plus aspirin (HR 0.96, 95% CI 0.77–1.19) or aspirin plus clopidogrel (HR 1.17, 95% CI 0.96–1.42), supporting the notion that OAC plus clopidogrel reduces MACE to an equivalent extent as OAC+DAPT. The bleeding risk for OAC plus clopidogrel was lower than for OAC+DAPT, albeit non-significantly (HR 0.78, 95% CI 0.55–1.12). There was a similar rate of all-cause mortality in OAC plus clopidogrel and OAC+DAPT, but greater rates for OAC plus aspirin, and DAPT alone. Thus, the Danish registry is the second major study to suggest the lack of efficacy of aspirin in antithrombotic regimens with OAC and clopidogrel.

Further observational studies have confirmed the safety and efficacy of OAC plus clopidogrel following PCI in patients with AF. Seivani *et al.* [64] report a registry of 221 patients receiving prior OAC and different antithrombotic regimens, following drug-eluting stent implantation. Patients received 6–12 months of clopidogrel therapy, followed by OAC monotherapy alone. The combination of OAC and clopidogrel was safe and efficacious; however, a sharp rise in MACE following clopidogrel cessation was noted, particularly in patients with sub-therapeutic anticoagulation. More recently, the non-randomized prospective AFCAS registry followed 975 patients

receiving DAPT, OAC+DAPT and OAC plus clopidogrel, in order to evaluate clinical safety and efficacy [65]. However, at 1 year, no significant intergroup differences in terms of occurrence of MACE, or frequency of bleeding, in both crude and propensity score-adjusted analysis, were observed.

Further insights into the risks associated with the inclusion of aspirin arose from the CORONOR registry, which prospectively enrolled 4184 patients with stable CAD, with no MI or revascularization for 1 year before enrolment [66]. Although the majority received antiplatelet monotherapy (n=2798), a significant proportion received DAPT (aspirin and clopidogrel; n=861) or an OAC (n=461). Among these, 342 patients received VKA and an antiplatelet agent (aspirin, n=308; clopidogrel, n=34). At 2 years, the use of a VKA was not associated with significantly increased risk of bleeding (HR 1.69, 95% CI 0.39–7.30); however, this was highly significant in those receiving aspirin concomitantly (HR 7.30, 95% CI 3.91–13). This study extends the insights of WOEST into the excess risk associated with the inclusion of aspirin in multiple antithrombotic regimens. Figure 46.1 summarizes the evidence regarding combinations of antithrombotic agents, in patients with AF undergoing PCI.

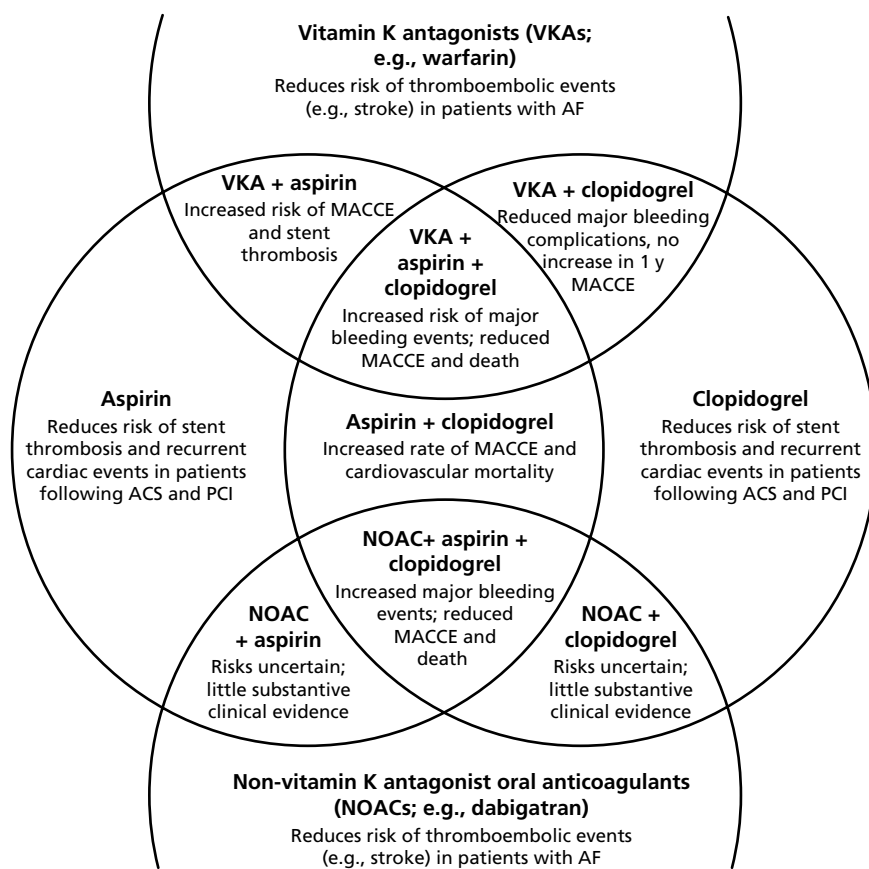

Figure 46.1 A summary of the risks and benefits of different combinations of antithrombotic agents for patients with indications for both oral anticoagulation and dual antiplatelet therapy. For patients with AF whom undergo PCI, the number of possible combinations of antiplatelet agents is significant. This modified Venn diagram briefly summarizes the clinical evidence regarding each regimen. Antithrombotic combinations for patients with indications for an anticoagulant following PCI for ACS recommended by the ESC/ACC are dependent on bleeding and stroke risk, but include initial triple antithrombotic therapy with OAC (VKA or NOAC) + aspirin + clopidogrel, followed by OAC (VKA or NOAC) + clopidogrel (for up to 12 months post-procedure), and life-long OAC (VKA or NOAC). AF, atrial fibrillation; MACCE, major adverse cardiac and cerebrovascular events; MI, myocardial infarction; NOAC, non-vitamin K antagonist oral anticoagulants; OAC, oral anticoagulants; PCI, percutaneous coronary intervention; VKA, vitamin K antagonists; y, year.

Until recently, significant uncertainty prevailed regarding the optimal length for OAC+DAPT therapy following stent implantation. The recent ISAR-TRIPLE trial randomized 614 patients to either a 6-week or 6-month OAC+DAPT therapy regimen, following drug-eluting stent implantation [67]. Aspirin and OAC were continued indefinitely; only the duration of clopidogrel therapy changed. At 9 months' follow-up, no difference was noted in composite clinical outcomes between groups (9.8% vs. 8.8%, HR 1.14, 95% CI 0.68–1.91; $p=0.63$). Thus, shortening the duration of OAC+DAPT neither reduced major bleeding ($p=0.44$), nor increased the incidence of ischemic events ($p=0.87$), and appears safe.

Non-vitamin K antagonist oral anticoagulants

Given the non-inferior clinical efficacy, favorable safety profile, and numerous pragmatic benefits of NOACs, co-administration with DAPT could represent an advantage over VKAs among patients requiring triple antithrombotic therapy. Several studies explored the role of the NOACs in this context. The RE-LY trial evaluated 18,113 patients with AF who were administered either warfarin (according to INR), or dabigatran (110 or 150 mg, twice daily) [68]. *Post hoc* subgroup analysis of patients co-administered antiplatelet therapy at baseline ($n=6952$) has been performed. Of these, 5789 received aspirin monotherapy, 351 received clopidogrel monotherapy, and 812 received DAPT [69]. Patients receiving concurrent low dose dabigatran and antiplatelet agents had a reduced risk of bleeding, compared with patients administered warfarin and antiplatelet agents (HR 0.82, 95% CI 0.67–1.00), despite a similar risk of cerebrovascular and systemic embolism (HR 0.93, 95% CI 0.70–1.25). Patients receiving high dose dabigatran were at similar risk of bleeding and embolism compared with warfarin (HR 0.93, 95% CI 0.76–1.12 and HR 0.80, 95% CI 0.59–1.08, respectively). This suggests that low dose dabigatran represents an alternative therapeutic option to warfarin, with equivocal thromboembolic benefits, and reduced bleeding risk.

In the ATLAS studies, and the first APPRAISE trial, an indication for ongoing anticoagulation was amongst the exclusion criteria, and so the safety of apixaban and rivaroxaban was not evaluated amongst patients with AF; however, the doses used in these studies were previously demonstrated to provide effective thromboprophylaxis for patients with AF [70,71], suggesting that in this setting TATT with these drugs could have a role. However, further study is clearly needed.

Clinical guidelines: DAPT in combination with OAC in AF

European Joint Society guidelines address issues associated with managing patients with AF who require treatment for ACS [72,73]. These provide detailed recommendations on the evidence-based optimal management strategy, based on the nature of the stent used during PCI, and achieving an equilibrium between risk factors associated with bleeding, reinfarction, stent thrombosis, and adverse cardiac, cerebrovascular, and thromboembolic events. Updated in 2014 (Table 46.1) [73] to reflect the clinical evidence that has emerged since the 2010 version [72], these guidelines emphasize formal assessment of hemorrhagic risk (i.e., using the HAS-BLED score) and stroke risk ($\text{CHA}_2\text{DS}_2\text{-VAS}_c$), and vary depending on the setting of PCI (stable CAD or ACS). For example, in patients with a low baseline bleeding risk (HAS-BLED 0–2), and significant risk of stroke ($\text{CHA}_2\text{DS}_2\text{-VAS}_c \geq 2$), undergoing elective PCI, at least 4 weeks (and no longer than 6 months) of OAC + DAPT,

followed by OAC and clopidogrel alone until 12 months post-procedure, and lifelong OAC thereafter. These guidelines no longer differ between drug-eluting and bare metal stents. Furthermore, European ACS guidelines [1,2] do not advocate routine post-procedural oral anticoagulant therapy, except when a specific indication exists (AF, mechanical valve, or left ventricular thrombus). In such patients, the guidelines advocate that triple antithrombotic therapy should be continued for the minimal possible time (to reduce bleeding risk), until stent endothelialization is complete. Importantly, while long-term OAC is to be used in conjunction with DAPT, the target INR should be reduced, to 2.0–2.5. For patients at high risk of gastrointestinal bleeds, gastric protection (i.e., a proton pump inhibitor) should be initiated.

North American guidelines are largely in line with their European counterparts [74,75]. Updated in 2014, guidance from the American Joint Societies regarding PCI in patients with AF advocate consideration of BMS implantation to minimize the duration of OAC+DAPT. For patients at high risk of stroke ($\text{CHA}_2\text{DS}_2\text{-VAS}_c \geq 2$), the use of OAC+DAPT is advocated for either 1 or 3–6 months, depending on the type of the stent, followed by an OAC and clopidogrel (but without aspirin) until 12 months post-procedure. Following 12 months of antiplatelet therapy, antiplatelet therapy should be stopped, and OAC continued, as required. If the stroke risk is low ($\text{CHA}_2\text{DS}_2\text{-VAS}_c 0\text{--}1$) DAPT is recommended for 12 months, before returning to regular AF treatment. The target INR should remain at 2.0–3.0 (Table 46.2).

Though the European and American guidelines differ in how they stratify patients for antithrombotic therapy (European by bleeding and stroke risk, and clinical setting of PCI; American by stroke risk and the nature of the implanted stent), both recommend a role for triple therapy in certain patient subgroups, in the early period following PCI. Although no robust guidelines exist regarding the role of triple anticoagulant therapy for other indications (i.e., mechanical valve prostheses, intramural thrombus, or DVT) the AF guidelines should translate to such cases, as bleeding risk remains clinically determinable.

Unanswered questions and future perspectives

A significant number of questions remain unanswered considering the efficacy of TAPT and the use of OAC following PCI. Many of the trials occurred before contemporary proton pump inhibitor (PPI) therapy was routinely recommended as the standard of care with DAPT, efficaciously reducing major gastrointestinal bleeding [76]. Although studies have reported that combining the PPI omeprazole and clopidogrel can lead to diminished antiplatelet efficacy, via impairment of the formation of the active metabolite of clopidogrel, this has not had reported clinical consequences [77,78]. The COGENT trial randomized 3873 75 mg clopidogrel-treated ACS patients to receive either omeprazole 20 mg or placebo [79]. The addition of omeprazole proved superior to placebo in reducing the rate of overt gastrointestinal bleeding (HR 0.13, 95% CI 0.03–0.56; $p=0.001$), with no significant differences in the risk of adverse cardiovascular events (HR 0.99, 95% CI 0.68–1.44; $p=0.96$). Subsequent reports have advocated that PPI should be encouraged during multiple antiplatelet pharmacotherapy [78]. Indeed, such therapy can abrogate the risk of bleeding that has thus far precluded the addition of additional antithrombotic agents to DAPT regimens; further study, both in the form of new trials and post hoc analysis of completed trials, is warranted.

Table 46.1 2014 ESC guidelines for the recommended antithrombotic strategies following PCI in patients with AF a moderate to high stroke risk.

Bleeding risk (HAS-BLED)	Stroke risk (CHA ₂ DS ₂ -VAS _c)	Clinical setting	Treatment recommendation	Evidence class/level
Low or moderate (0–2)	Moderate (1 in males)	Stable CAD	≥4 weeks (≤6 months): OAC + aspirin + clopidogrel Up to 12 months: OAC + clopidogrel (or aspirin) Lifelong: OAC	Ila / C Ilb / C I / B
	High (≥2)	Stable CAD	≥ 4 weeks (≤6 months): OAC + aspirin + clopidogrel Up to 12 months: OAC + clopidogrel (or aspirin) Lifelong: OAC	Ila / C Ilb / C I / B
	Moderate (1 in males)	ACS	6 months: OAC + aspirin + clopidogrel Up to 12 months: OAC + clopidogrel (or aspirin) Lifelong: OAC	Ila / C Ilb / C I / B
	High (≥2)	ACS	6 months: OAC + aspirin + clopidogrel Up to 12 months: OAC + clopidogrel (or aspirin) Lifelong: OAC	Ila / C Ilb / C I / B
High (≥3)	Moderate (1 in males)	Stable CAD	12 months: OAC + clopidogrel Lifelong: OAC	Ila / C I / B
	High (≥2)	Stable CAD	4 weeks: OAC + aspirin + clopidogrel Up to 12 months: OAC + clopidogrel (or aspirin) Lifelong: OAC	Ila / C Ilb / C I / B
	Moderate (1 in males)	ACS	4 weeks: OAC + aspirin + clopidogrel Up to 12 months: OAC + clopidogrel (or aspirin) Lifelong: OAC	Ila / C Ilb / C I / B
	High (≥2)	ACS	4 weeks: OAC + aspirin + clopidogrel Up to 12 months: OAC + clopidogrel (or aspirin) Lifelong: OAC	Ila / C Ilb / C I / B

No differentiation in guidelines regarding whether OAC is preferentially a VKA or NOAC. If warfarin is the OAC of choice, INR should be maintained at 2.0–2.5 while on DAPT, and 2.0–3.0 otherwise. NOACs should be administered at the lower tested dose in AF (dabigatran 110 mg twice daily, rivaroxaban 15 mg once daily, or apixaban 2.5 mg twice daily). PPI should be considered in all patients. Newer generation drug-eluting stents are preferred over bare metal stents in patients at low baseline bleeding risk.

ACS, acute coronary syndrome; AF, atrial fibrillation; CAD, coronary artery disease; DAPT, dual antiplatelet therapy; ESC, European Society of Cardiology; INR, international normalized ratio; NOAC, non-vitamin K antagonist oral anticoagulant; OAC, oral anticoagulant agent; PCI, percutaneous coronary intervention; VKA, vitamin K antagonist.

Patients with AF requiring PCI tend to be of advanced age, and have high rates of comorbidity. Many are octogenarians, a group that is frequently under-represented (or actively excluded from) randomized trials of antiplatelet and triple therapy. As such, it is uncertain whether present guidelines can be safely applied to this group. By definition, such patients will have a high CHA₂DS₂-VAS_c score, in addition to a greater risk of bleeding when administered OACs. In this group, the importance of even minor bleeding should not be underestimated—even minor and non-clinically significant bleeds can lead to poor compliance with, and discontinuation of, therapy, with the potential for catastrophic thrombotic and thromboembolic complications. Thus, in addition to the routine inclusion of older patients in future studies, specific evaluation of approaches to the management of this challenging group are required.

Many further studies exploring the risks and benefits of triple antithrombotic therapy following PCI are presently ongoing with

objectives relevant to this chapter, include the PIONEER AF-PCI, RE-DUAL PCI, MUSICA-2, and LASER studies. The PIONEER AF-PCI (NCT01830543) study is designed to evaluate rivaroxaban at two separate doses versus vitamin K antagonist anticoagulants, in addition to antiplatelet monotherapy, or various DAPT combinations. The projected enrolment is n = 2,169, and the study is scheduled for completion in 2016. Similarly, the multicenter RE-DUAL PCI study (NCT02164864) is designed to compare dabigatran at two dosage levels, plus a single, non-aspirin oral antiplatelet versus warfarin plus DAPT, in patients with AF undergoing PCI. The trial has an a priori defined primary endpoint of death, MI, and stroke, hopes to recruit 8520 patients, and is expected to complete in 2017. The MUSICA-2 trial (NCT01141153) is a smaller study, investigating the safety and efficacy of the triple antithrombotic regimen of the vitamin K antagonist acenocoumarol, in addition to aspirin and clopidogrel in 304 patients, expected to report in 2016. A further

Table 46.2 2012 ACCP guidelines for the recommended antithrombotic strategies following PCI in patients with AF.

Stroke risk (CHADS ₂)	Stent type	Treatment recommendation	Evidence class/level
High (≥2)	BMS	4 weeks: OAC + aspirin + clopidogrel Up to 12 months: OAT + clopidogrel Lifelong: OAT	IIa / C IIb / C I / B
	DES	3–6 months: OAT + aspirin + clopidogrel (depending on stent type) Up to 12 months: OAT + clopidogrel Lifelong: OAT	IIa / C IIb / C I / B
	None	Up to 12 months: OAT + clopidogrel Lifelong: OAT	IIb / C I / B
Low (0–1)	BMS or DES	Up to 12 months: aspirin + clopidogrel Lifelong: OAT or aspirin + clopidogrel, as indicated	IIb / C I / B
	None	Up to 12 months: aspirin + clopidogrel Lifelong: OAT or aspirin + clopidogrel, as indicated	IIb / C I / B

BMS, bare metal stent; DES, drug-eluting stent; OAT, oral anticoagulant agent.

OAT may be a VKA or NOAC, depending on clinical factors.

ongoing, non-randomized, observational study, the prospective, multicenter LASER (NCT00865163) registry, with nested case-control design, is following 2000 patients following PCI; half have prior indications for VKAs, half do not. It is hoped that the results of the LASER registry will offer insight into the rates of clinically relevant bleeding events associated with anticoagulation in contemporary PCI.

Conclusions

Despite numerous robust randomized controlled trials and meta-analyses, the safety of triple antiplatelet and antithrombotic therapy remains controversial. Although the evidence of clinical benefit is insufficient to advocate the routine use of such regimens following PCI or ACS, patients at high risk of further thrombotic or thromboembolic events could stand to benefit from these high intensity treatment regimens. Novel anticoagulant agents demonstrate significant promise in providing additional protection against recurrent infarction and stent thrombosis, with safety profiles non-inferior to traditional oral anticoagulants. It remains conceivable that these agents offer the greatest balance of risk and benefit in high risk patients, although further prospective evaluation is required. Whenever higher order antithrombotic agents are to be combined, careful elucidation and consideration of bleeding risk must be weighed up against the potential benefits of such therapy.

Myocardial infarction (MI) and stent thrombosis are catastrophic events that occur in patients with coronary artery disease (CAD) undergoing percutaneous coronary intervention (PCI). Overwhelming evidence exists that thrombus generation resulting from platelet activation and aggregation at the sites of plaque rupture is the primary process involved in the occurrence of the latter clinical events. Although thromboxane A₂ and adenosine diphosphate (ADP) act synergistically during platelet aggregation, the ADP-P2Y₁₂ receptor interaction has a central role in sustaining the activation of glycoprotein IIb/IIIa receptors by amplifying the response to agonists. P2Y₁₂ activation also modulates platelet procoagulant activity, P-selectin expression, and inflammation (Figure 47.1) [1].

The clinical efficacy of dual antiplatelet therapy (DAPT) of aspirin and a P2Y₁₂ receptor blocker in preventing MI and stent thrombosis has been demonstrated in a wide range of high risk CAD patients [1]. However, clopidogrel therapy, the most widely used P2Y₁₂ receptor blocker, is associated with widely variable pharmacodynamic response where approximately one in three clopidogrel-treated patients will have high platelet reactivity (HPR). The HPR measured peri-procedurally has been strongly linked to PCI ischemic event occurrence in observational studies of thousands of patients. Despite the fundamental importance of unblocked P2Y₁₂ receptors in the genesis of thrombosis, the clear demonstration of clopidogrel non-responsiveness, and their strong link to increased post-PCI ischemic risk, cardiologists largely do not determine platelet function in their high risk patients treated with clopidogrel. In comparison to the objective assessments and adjustments frequently made during treatment with most other cardiovascular drugs, this “non-selective” or “one-size-fits-all” approach to clopidogrel, the most widely used P2Y₁₂ inhibitor to prevent a catastrophic thrombotic event occurrence, is paradoxical [1–3].

There has been a long-term reluctance to assess platelet function because of the potential introduction of artifacts by laboratory methods, incomplete reflection of the actual *in vivo* thrombotic process, and failure to establish unequivocally a causal relation between the results of the test and thrombotic event occurrence [4]. In the last decade, the understanding of platelet receptor physiology has markedly improved, more potent P2Y₁₂ receptor blockers which

can overcome some of the limitations of clopidogrel have been developed, and cheaper generic clopidogrel is available. In addition, more user-friendly platelet function assays which can reliably determine the antiplatelet effect of P2Y₁₂ receptor blockers have stimulated great interest in therapy monitoring and personalized therapy [5,6].

Initial evidence for HPR to ADP as a risk factor

In 2003, the response variability and resistance of clopidogrel was first demonstrated using conventional platelet aggregometry and flow cytometry studies in patients undergoing PCI who had received a 300-mg loading dose followed by 75 mg/day maintenance dose of clopidogrel [7]. Since then, numerous similar observations using various assays to measure ADP-induced platelet reactivity have been made in subsequent studies involving thousands of PCI patients, which indicate clopidogrel non-responsiveness where a substantial percentage of patients (up to 35%) exhibit either negligible or no antiplatelet response to clopidogrel [5,6].

Most translational research studies linking ADP-induced platelet aggregation during clopidogrel administration to clinical outcomes were performed in patients undergoing PCI. Barragan *et al.* [8] reported an association between post-treatment P2Y₁₂ reactivity measured by vasodilator-stimulated phosphoprotein phosphorylation (VASP-P) assay and the occurrence of stent thrombosis in a case-control study of PCI patients. Matetzky *et al.* [9] observed that patients undergoing primary PCI for ST-segment elevation myocardial infarction (STEMI) who were in the lowest quartile of clopidogrel responsiveness (measured by aggregometry) had the highest rates of ischemic events during follow-up.

Given the interindividual variability in baseline ADP-induced platelet aggregation, the measurement of clopidogrel responsiveness (absolute or relative changes in platelet aggregation from baseline) may overestimate ischemic risk in non-responders with low pre-treatment reactivity as well as underestimating risk in responders who remain with high platelet reactivity after treatment [10,11]. Therefore, the absolute level of platelet reactivity during treatment

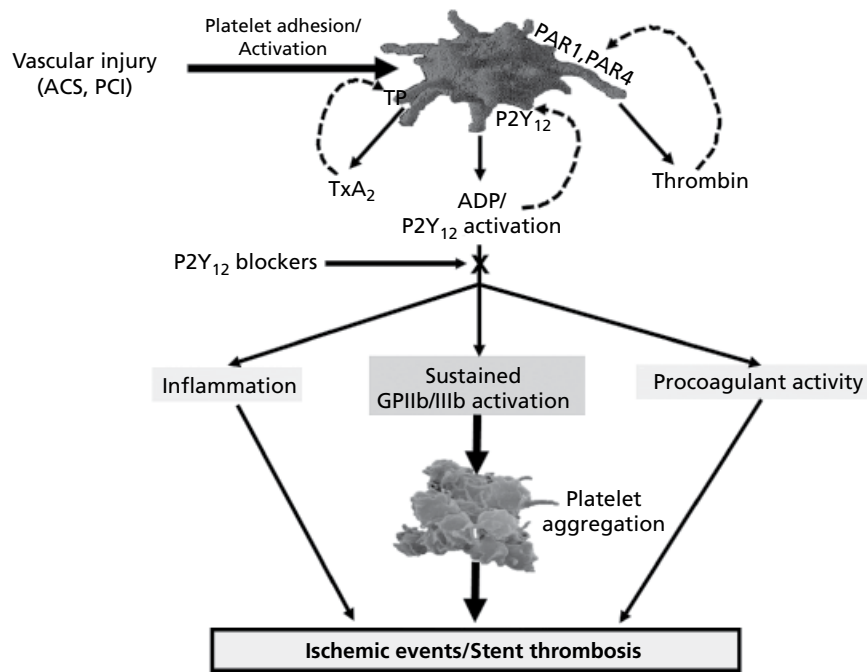

Figure 47.1 Central role of ADP-P2Y₁₂ interaction in platelet aggregation and ischemic event occurrence during percutaneous coronary intervention.

(i.e., on-treatment platelet reactivity) has been proposed as a better measure of thrombotic risk than responsiveness to clopidogrel. Subsequent studies based on aggregometry demonstrated that a threshold of ~50% maximal peri-procedural aggregation (20 μmol ADP) was strongly associated with 6-month ischemic event occurrence; ~40% aggregation (20 μmol ADP) was associated with stent thrombosis occurrence and ~46% pre-procedural platelet aggregation (5 μmol ADP) among patients before stenting was associated with 24 month post-PCI ischemic event occurrence [12–14]. Using the VerifyNow P2Y₁₂ assay, it was demonstrated that patients with post-treatment reactivity ≥235 PRU (upper quartile) had significantly higher rates of cardiovascular death (2.8% vs. 0%; $p=0.04$) and stent thrombosis (4.6% vs. 0%; $p=0.004$) [15]. Low responders as indicated by upper quintile (~416 AU*min) using the Multiplate analyzer, had a significantly higher risk of definite stent thrombosis and a higher mortality rate within 30 days compared with normal responders [16]. These initial studies stimulated a great interest in platelet function testing (PFT) in patients undergoing PCI during DAPT in identifying patients at high risk for recurrent ischemic event occurrences.

HPR cut-off values defined by receiver operating characteristic curve analysis

Receiver operating characteristic (ROC) curve analysis was used to define a threshold or cut-point of on-treatment platelet reactivity associated with the optimal combination of sensitivity and specificity to identify thrombotic and/or ischemic risk. A consensus statement was proposed with HPR cut-off values based on ROC curve analysis for various platelet function assays [5,6].

In a time-dependent covariate Cox regression analysis of on-treatment platelet reactivity in the GRAVITAS (Gauging Responsiveness with A VerifyNow assay—Impact on Thrombosis And Safety) study ($n=2214$), HPR defined as a P2Y₁₂ reaction units (PRU) <208 was an independent predictor of event-free survival at 60 days (hazard ratio

[HR] 0.23; $p=0.047$) and strongly trended to be an independent predictor at 6 months (HR 0.54; $p=0.06$) [17]. In the multinational prospective registry study ADAPT-DES (Assessment of Dual AntiPlatelet Therapy with Drug-Eluting Stents) involving >8500 patients (~50% of patients with ACS), 43% of patients met the criteria of HPR (>208 PRU) and PRU >208 was independently associated with an ~4.0, 1.5, and 1.8-fold increase in the risk of definite or probable stent thrombosis at 0–30 days (HR 3.90, 95% confidence interval [CI] 1.90–8.00; $p<0.0001$), 30 days to 1 year (HR 1.55, 95% CI 0.76–3.18; $p=0.23$), and 2 years (HR 1.84; $p=0.009$), respectively. PRU >208 identified the risk for definite or probable stent thrombosis in 35% of patients [18,19]. The relationship between HPR and ischemic event occurrences was more pronounced in patients with ACS than patients with stable CAD (adjusted HR 2.60, $p<0.005$ and HR 1.44, $p=0.47$, respectively). Finally, in a recent meta-analysis of 20 observational studies comprising a total of 9187 PCI patients, HPR (>208 PRU) was demonstrated to be a strong predictor of myocardial infarction, stent thrombosis, and the composite endpoint of reported ischemic events (odds ratio [OR] 3.0, 4.1, and 4.9, respectively; $p<0.00001$ for all cases) [20].

Randomized trials of platelet function testing

In the GRAVITAS trial, primarily stable and low risk PCI patients with HPR (≥230 PRU) were randomized to 75 mg/day standard or 150 mg/day high clopidogrel dosing. High dose clopidogrel treatment was ineffective in reducing 6-month composite ischemic event occurrence and there was an unexpectedly low event rate (2.3%) in both groups [21]. The pharmacodynamic effect of high dose clopidogrel was relatively modest (~40% of the patients still had HPR) and unlikely to influence clinical outcomes in an overall low risk population [22]. In support of this hypothesis, in the ELEVATE-TIMI 51 trial, up to 225 mg/day clopidogrel dose was required to overcome HPR [23].

In the TRIGGER-PCI trial, the effects of a more potent active arm (prasugrel) compared with standard dose clopidogrel in low risk patients with HPR (>208 PRU) undergoing non-urgent PCI was investigated [24]. This trial was prematurely terminated because of a very low incidence of cardiovascular events. Finally, in the ARCTIC study, 2440 low risk patients (27% NST-ACS vs. 73% patients with stable CAD) scheduled for planned coronary stenting were randomly assigned to a strategy of platelet-function monitoring and drug adjustment or to a conventional strategy without monitoring. In the monitoring arm, one-third of patients had HPR (>235 PRU or <15% inhibition) before stent implantation and 80% of these patients received additional clopidogrel loading dose for PCI while only 2.3% received prasugrel loading doses. The primary endpoint was not different in the monitoring arm compared to the conventional arm (34.6% vs. 31.1%, HR 1.13; $p = 0.10$) [25]. In total, these recent studies that included low risk patients undergoing PCI with low event rates demonstrate that high dose clopidogrel is not an optimal strategy to overcome HPR and suggest that future personalized antiplatelet therapy trials should focus on enrolling high risk patients undergoing PCI and treating patients with HPR with prasugrel or ticagrelor. In addition, potent P2Y₁₂ receptor blocker should be administered as soon as possible—even before PCI—to prevent early events.

While the results of the latter three randomized trials were negative, smaller studies have suggested that the PFT-directed approach may be effective with proper implementation. In two small multicenter studies, a strategy of tailoring incremental loading doses of clopidogrel to reduce on-treatment platelet reactivity below the HPR cut-off based on the VASP-P before PCI was associated with significantly reduced adverse event occurrence, including early stent thrombosis without increasing thrombolysis in myocardial infarction (TIMI) major or minor bleeding [26,27]. Similarly, two other studies have suggested that the selective administration of a glycoprotein IIb/IIIa receptor inhibitor to patients undergoing elective PCI who were identified as poor responders to acetylsalicylic acid or clopidogrel was effective in reducing both 30-day and 1-year post-PCI ischemic events without increasing bleeding rates [28,29]. In a recent study, Aradi *et al.* [30] demonstrated that patients with ACS undergoing successful PCI and identified as having HPR during clopidogrel therapy using the multiplate device and switching to prasugrel exhibited reduced thrombotic and bleeding events to a level similar to that of those without HPR treated with clopidogrel.

A meta-analysis of nine randomized trials demonstrated a significant reduction in cardiovascular mortality and stent thrombosis in HPR patients when intensified antiplatelet therapy was used [31]. Of interest, the benefit was mostly observed in high risk patients, suggesting that other factors, including demographic, clinical, and angiographic factors, must also be taken into consideration to identify the patients at greatest risk. For this purpose, recent studies have suggested that adding clinical variables and genotype to platelet reactivity measurements (a combined risk factor) could improve risk prediction [32,33].

Relation between low on-treatment platelet reactivity and bleeding: the therapeutic window concept

In addition to the upper threshold for ischemic risk (i.e., HPR), small translational research studies have suggested a relation between low on-treatment platelet reactivity (LPR) with bleeding

(Table 47.1) [34–40]. Unlike arterial ischemic events that are mainly platelet-centric, the underlying mechanisms of bleeding during PCI are more complex and heterogeneous in origin. The role that platelet function has in these different types of bleeding might vary, and it might be related to the extent of impaired hemostatic potential and possibly a higher degree of platelet inhibition. The concept of a “therapeutic window” of P2Y₁₂ receptor reactivity associated with both ischemic event occurrence (upper threshold, HPR) and bleeding risk (lower threshold, LPR) has been proposed [41]. Based on observational studies, various cut-offs for HPR and LPR are presented in Table 47.2 [35,37,38,40]. These cut-offs could be used in future studies of personalized antiplatelet therapy. This approach is more meaningful while titrating the dose of more potent P2Y₁₂ receptor blockers that are known to be associated with increased incidences of bleeding.

Relation of platelet reactivity to bleeding during surgery

In patients undergoing coronary artery bypass grafting (CABG), withdrawal of a P2Y₁₂ receptor blocker treatment for 5–7 days is recommended by the guidelines to avoid excessive peri-operative bleeding by allowing platelet function recovery [42,43]. As clopidogrel therapy is associated with response variability and non-responsiveness, it was suggested that an objective measurement of the antiplatelet effect of clopidogrel before surgery can obviate the need for the recommended waiting period in a substantial percentage of patients. In support of this hypothesis, in the prospective Time Based Strategy to Reduce Clopidogrel Associated Bleeding During CABG (TARGET CABG) study, clopidogrel response was measured by thrombelastography with platelet mapping and surgery was scheduled with no delay in those with ADP-induced maximum amplitude (MA_{ADP}) >50 mm, within 3–5 days in those with $MA_{ADP} = 35$ –50 mm, and after 5 days in those with $MA_{ADP} < 35$ mm. This study demonstrated that stratifying clopidogrel-treated patients to specific waiting periods based on a preoperative assessment of clopidogrel response resulted in similar peri-operative bleeding compared to clopidogrel-naïve patients undergoing elective first time on-pump CABG [44]. Despite the absence of evidence from a large-scale prospective trial, in the 2012 Society of Thoracic Surgeons Guideline for cardiovascular surgeons, it was stated that “For patients on dual antiplatelet therapy, it is reasonable to make decisions about surgical delay based on tests of platelet inhibition rather than arbitrary use of a specified period of surgical delay. Class IIa (Level B)” [45].

HPR in patients with STEMI during prasugrel and ticagrelor therapy

An accumulating body of data suggests that drug absorption in patients with ACS is impaired, particularly in patients with STEMI. Impaired bioavailability of clopidogrel in patients with STEMI, resulting in suboptimal platelet inhibition compared with healthy controls, has been demonstrated [46]. In a recent prospective, single-blind study, 55 STEMI patients undergoing PCI were randomized to either ticagrelor or prasugrel; platelet reactivity measured by VerifyNow did not differ significantly between ticagrelor and prasugrel therapy at 1 hour. However, HPR at 2 hours persisted in a significant percentage of patients in both groups and again differ from the findings in stable, non-PCI patients where the frequency of high on-treatment platelet reactivity

Table 47.1 Relation between platelet function measurement and bleeding in patients treated with PCI.

Study	Patients (n) and P2Y ₁₂ treatment	Platelet function test(s)	Bleeding criteria	Outcome
Cuisset <i>et al.</i> [34]	NSTE-ACS (n = 597), clopidogrel	LTA preheparin ADP-induced aggregation and VASP-PRI	Non-CABG, TIMI major and minor	<40% aggregation associated with higher risk of 30 days post-discharge bleeding
Sibbing <i>et al.</i> [35]	PCI (n = 2533) clopidogrel	Multiplate analyzer, ADP-induced aggregation	Procedure-related non-CABG TIMI major bleeding	<19 AU/min associated with 3.5× bleeding
Mokhtar <i>et al.</i> [36]	PCI (n = 346) Clopidogrel, retrospective analysis	VASP Assay	Non-CABG TIMI minor and major	Low on treatment PRI independent predictor of bleedings
Gurbel <i>et al.</i> [37]	PCI (n = 225) clopidogrel	MA-ADP TEG platelet mapping assay		≤31 MA-ADP associated with post-PCI bleeding
Campo <i>et al.</i> [38]	PCI (n = 300), Clopidogrel	VerifyNow P2Y ₁₂ assay	TIMI bleeding	<85 PRU was associated with bleeding events >238 PRU was associated with ischemic events

Bonello <i>et al.</i> [40]	ACS patients undergoing PCI (n = 301) prasugrel	VASP Assay	Major and minor TIMI bleeding	VASP-PRI <16% associated with major bleedings

ADP, adenosine diphosphate; AU, arbitrary aggregation units; CAD, coronary artery disease; DAPT, dual antiplatelet therapy; DES, drug-eluting stent; LTA, light transmittance aggregometry; MA, maximum amplitude; NSTE-ACS, non-ST-segment elevation acute coronary syndrome; PA, platelet aggregation; PCI, percutaneous coronary intervention; TIMI, thrombolysis in myocardial infarction.

Table 47.2 Platelet reactivity cut-off associated with ischemic and bleeding events (therapeutic window).

	Cut-off associated with ischemic event occurrences	Cut-off associated with bleeding event occurrences [ref]
VerifyNow P2Y ₁₂ Assay (PRU)	>208	<85 [18,38]
Multiplate Analyzer ADP-induced aggregation (AU)	>46	<19 [35]
Vasodilator Stimulated Phosphoprotein Phosphorylation-Platelet Reactivity Index (%)	≥50%	<16% [40]
Thrombelastography Platelet Mapping Assay ADP-induced Platelet-fibrin clot strength (mm)	>47	<31 [37]

was negligible [47]. In another study of 50 patients with STEMI undergoing primary PCI on bivalirudin monotherapy, patients were randomly treated with 60 mg prasugrel loading dose or 180 mg ticagrelor loading dose. Both prasugrel and ticagrelor therapy was only effective in inhibiting platelet reactivity in ~50% of patients at 2 hours. At least 4 hours were required to achieve effective platelet inhibition in ~80% of patients. Interestingly, morphine use was associated with a delayed activity of both agents [48]. In a subsequent study of healthy volunteers, morphine use was associated with delayed clopidogrel absorption and reduced clopidogrel active metabolite levels which were accom-

panied by delayed maximum platelet inhibition (up to 4 hours) [49]. At this time, the clinical significance of HPR in patients with STEMI during prasugrel or ticagrelor therapy is unknown.

Conclusions

Currently, there is conclusive pharmacodynamic evidence that clopidogrel has a suboptimal effect in a substantial proportion of patients and HPR is strongly associated with poorer clinical outcomes in high risk clopidogrel-treated patients who have undergone PCI. Most of the studies linking HPR to thrombotic event occur-

rence have employed a peri-procedural platelet reactivity measurement. HPR may be most predictive of event occurrence in high risk patients. Recent data indicate that prasugrel and ticagrelor therapy is also associated with non-responsiveness, particularly soon after stenting in high risk patients (although <10%). The primary goal of PFT is to identify the patient who is suboptimally responsive and to adjust therapy accordingly to reduce the risk for the catastrophic events of MI and stent thrombosis. Genotyping predicts who is at risk of being suboptimally responsive but does not replace PFT.

Recent prospective, randomized trials have failed to demonstrate that personalized antiplatelet therapy based on platelet function is effective in reducing ischemic event occurrences. It should be acknowledged that randomized trials of personalized antiplatelet therapy are associated with major limitations, such as the enrollment of low risk patients, which resulted in low event rates and lack of power—and the use of high dose clopidogrel, which is not an optimal strategy to overcome HPR and to improve clinical outcomes. Therefore, the results of these randomized trials should not be used to refute the utility of PFT or personalized antiplatelet therapy strategies.

Treatment with more potent P2Y₁₂ receptor blockers, such as prasugrel and ticagrelor, is associated with faster and greater platelet inhibition than clopidogrel therapy and is a credible alternative strategy to overcome HPR during clopidogrel therapy. Therefore, a reasonable strategy is to assess platelet function in high risk clopidogrel-treated patients (e.g., patients with current or prior ACS, a history of stent thrombosis and target vessel revascularization, poor left ventricular function, multivessel stenting, complex anatomy (bifurcation, long, small stents), high body mass index, diabetes mellitus, and patients co-treated with proton pump inhibitors) and use of more potent P2Y₁₂ receptor therapy selectively in the patient with HPR. Unselected therapy with the new P2Y₁₂ receptor blockers is associated with increased bleeding. It is also important to note that clopidogrel results in an adequate P2Y₁₂ receptor inhibition in about two-thirds of the patients undergoing PCI. Selectively treating these patients with generic clopidogrel rather than treating all patients with new and potent P2Y₁₂ inhibitors might provide significant cost savings.

Moreover, rather than ischemic events alone, both ischemic and bleeding events (net clinical outcome) should be considered as a primary composite endpoint. This will not only increase the event rate, but also improve overall clinical outcome in the presence of more potent P2Y₁₂ receptor blocker therapies that are known to be associated with increased bleeding events. It is crucial to capture early events that are platelet-centric and that are significantly influenced by improved treatment strategies. It was also suggested that serial PFT can facilitate the modification of treatment strategies over time and improve net clinical outcomes. Currently, two large-scale studies of personalized antiplatelet therapy (ANTARCTIC [NCT01538446] and TROPICAL-ACS [NCT01959451]) are under way.

In the absence of evidence from a superiority trial, at this time we must rely on the guidelines and the existing observational data while fully keeping in mind the role that platelet physiology has in catastrophic event occurrence in the stented patient. Finally, it is not practical and wise to ignore the strong evidence that:

- 1 HPR is associated with post-PCI ischemic event occurrences;
- 2 User-friendly and reliable assays are available to assess platelet function;
- 3 More potent P2Y₁₂ receptor blockers are available to overcome HPR in 35% of patients;

- 4 Nearly 65% of patients without HPR can be optimally treated with less expensive generic clopidogrel; and
- 5 Excessive bleeding can be avoided and net clinical outcome can be improved by utilizing serial PFT in patients treated with the more potent P2Y₁₂ receptor blockers.

The therapeutic window concept for the P2Y₁₂ receptor blocker therapy can facilitate the balance between reducing ischemic events and avoiding bleeding events, thereby improving net clinical outcome. PFT can have a role to monitor: (i) efficacy when clopidogrel is the chosen therapy; and (ii) safety of the long-term use of new, more potent drugs, especially in low risk patients and in patients with high bleeding risk. Finally, platelet reactivity should not be regarded as an absolute and sole prognostic marker, instead platelet reactivity should be evaluated in combination with demographic variables associated with risk, the time of platelet reactivity testing with respect to the time of PCI and the presence of ACS.

Genetics and Pharmacogenetics in Interventional Cardiology

Hillary Johnston-Cox, Johan L.M. Björkegren, and Jason C. Kovacic

Icahn School of Medicine at Mount Sinai, New York, NY, USA

Heritability accounts for the number of observed differences in a disease trait because of inherited genetic differences between people. While other mechanisms like epigenetic modification of deoxyribonucleic acid (DNA) likely also contribute to inheritance, most inherited differences are thought to be carried by changes to the nucleotide DNA sequence (i.e., A, T, C, and G; Figure 48.1). Although environmental and genetic influences were initially thought to be independent factors contributing to disease, it is now appreciated that the interaction of genetic and environmental factors is a major element contributing to an ultimate clinical disease phenotype such as coronary artery disease (CAD). As we elaborate later, it now appears that the absence or presence of environmental factors, such as presence of smoking or lack of exercise, can determine if a genetic factor will contribute to the pathogenesis of disease. As becomes evident in this chapter, the redirecting of our scientific efforts toward understanding aspects of CAD, such as the biologic intersection point of genetics–genomics and environmental influences using systems genetics, is potentially of very high yield in terms of advancing our understanding of the causality of this disease. This chapter focuses on reviewing the genetics of CAD as relevant to interventional cardiology, discussing limitations to genomewide association studies (GWAS) and the knowledge gained so far, and finally proposing future directions for identifying the presently unknown genetic aspects of CAD and how this knowledge might be useful in the clinic and catheterization laboratory.

Initial focus on human genetics: rare single-gene disorders

The heritability of traits that are passed between generations is thought to be predominantly carried in DNA, manifested as alterations in DNA that include single nucleotide polymorphisms (SNPs), deletions, insertions, and copy number variants. A component of heritability that is independent of DNA [1,2] can be mediated via epigenetic mechanisms that generally involve changes in either the methylation status of DNA or in histone changes that impact DNA transcription [3]. However, epigenetic mechanisms are beyond the scope of this chapter.

Rare single-gene disorders generally arise by a single change in a DNA coding region that typically follows a known pattern

of inheritance (Mendelian inheritance) between generations. Common inheritance patterns for single-gene disorders include autosomal dominant, autosomal recessive, and X-chromosome-linked inheritance. However, not all carriers of a single-gene variant that is associated with a Mendelian disorder will develop that disease, thus penetrance (the proportion of persons carrying a mutation or genetic change that develop the clinical disease) is generally <100%. Penetrance is also a time-dependent component of disease development. For example, in cystic fibrosis (CF) and Huntington's disease (HD), these two diseases are generally 100% penetrant; CF presents in infancy and HD presents generally in late adulthood. Other single-gene disorders, like the *BRCA1* gene, have “incomplete penetrance” (<100% of persons carrying the disease-causing *BRCA1* gene develop the relevant diseases) and a lifetime penetrance risk, suggesting that there are other elements of risk including environmental and other genetic predispositions that contribute to the development of the disease. This also suggests that there are resistance variants that protect individuals from developing single-gene disorders [4], which is relevant when risk stratifying patients for management and addressing preventative measures for a disease. As further defining features of single-gene disorders and in contrast to CAD, although the penetrance of many single-gene disorders is high, the occurrence of these disorders is less than 1% in the general population. Furthermore, the frequency and phenotypic expression of these genes varies in different populations as a result of differences in genetic ancestry in those communities.

Through the study of “classic” disease phenotypes that arise with single-gene disorders and their patterns of inheritance, initial DNA-based pedigree and linkage studies were first used to understand causative variants for rare disorders showing Mendelian inheritance [5]. In summary, these techniques involve very careful clinical phenotyping of family members, and then searching for DNA changes that are apparent in the affected versus non-affected family members. The first single-gene cardiovascular disorder to be extensively studied using these techniques was familial hypertrophic cardiomyopathy, with the subsequent discovery of the missense mutation within the cardiac beta-myosin heavy chain gene. Following this, other genetic mutations for many other generally single-gene cardiovascular disorders were identified, including long QT syndrome, dilated cardiomyopathy, Wolf–Parkinson–White

Figure 48.1 Overview of differing approaches of genomewide association studies (GWAS) versus systems genetics. Fundamentally, GWAS begins with an analysis of DNA and then attempts to define molecular processes. Systems genetics begins by studying genomic activity measures reflecting disease-relevant molecular processes (e.g., RNA or protein levels) to understand biologic disease networks that ultimately permit DNA-level changes driving these processes to be revealed.

syndrome, Brugada syndrome, and arrhythmogenic right ventricular dysplasia. Subsequent studies of other rare single-gene disorders led to the identification of mutated genes including those involved in familial hypercholesterolemia, such as mutations in the low density lipoprotein receptor (LDL-R).

While these approaches used to study single-gene disorders were highly successful and opened the door to our understanding of the genetic basis of disease, this type of approach for common complex disorders such as CAD and atherosclerosis is not broad enough to encompass the relevant biologic processes and multiple causative genes involved in the pathogenesis of these diseases [6].

Realm of GWAS: understanding the genetics of common complex disorders

Unlike single-gene disorders like those discussed above, the genetics of CAD is fundamentally more complex. CAD is one of many “polygenic” or “common complex disorders.” Unlike single-gene disorders which are rare, run in families, and are also highly heritable (i.e., they are genetically driven by typically one or only a few genes), the etiology of common complex disorders typically involves significant contributions from both genetic and environmental risk factors and their interactions. As a consequence, complex disorders are far more prevalent in the community (“common”), and are not limited to specific families. Furthermore, unlike single-gene disorders where the effect of each disease-causing genetic alteration is typically quite large, in common complex disorders the effect of each disease-relevant genetic alteration is only minimal to modest, and there are typically also many genetic alterations implicated in disease pathogenesis. Other examples of common complex disorders are diabetes, obesity, hypertension, and stroke.

The widespread prevalence and diversity of risk factors of the common complex diseases made linkage analysis of family pedigrees (as applied to single-gene disorders) inappropriate to study CAD. In addition, from the outset of investigations there was a notion that common complex disorders are driven by many genetic factors, each with weaker effects. As a consequence, a research tool allowing for the analysis of a multitude of genetic markers in thousands of individuals in the general population across families in case-control association studies was proposed to better study common complex

disorders; this was the beginning of the era of genomewide association studies (GWAS) [7]. In summary, GWAS design involves collecting large numbers of subjects with the disease (“cases”) and controls without the disease and then looking for changes in DNA that are present in the cases and not the controls. Ideally, cases and controls are matched for as many non-disease-related features as possible (age, gender, race/ethnicity, and other comorbidities).

The study of CAD using GWAS first began in the Wellcome Trust Case Control Consortium, which identified the famous 9p21 locus that is associated with CAD [7–9]. Since this initial study, 153 suggestive DNA variants have been identified with GWAS, with 50 being replicated in meta-analyses of GWAS datasets [10]. These variants are prevalent in the general population but the observed effect of the variants is weak, with each conferring a minimal to modest average increase in relative risk of ~18% [7]. The ability of this approach to identify numerous genetic markers and isolate many previously unknown disease-causing genes is impressive and notable. Nevertheless, the 153 CAD-associated variants that have been identified by GWAS are responsible for only approximately 10.6% of the genetic variation of CAD in the general population [10]. Indeed, not only for CAD but for most other complex diseases, about 90% of their heritability is not explained by loci identified so far by GWAS, despite including very large GWAS sample sizes [10].

To place this information in context, it is important to also appreciate the overall contribution of the traditional risk factors versus genetics to the development of CAD. Seminal studies performed several decades ago defined that the genetic variance in CAD is 40–60% [11]. In other words, heritable factors are thought to account for about 50% of the likelihood of developing CAD, with the remaining ~50% of risk thought to be attributable to environmental and lifestyle-related risk factors such as smoking, sedentary lifestyle, obesity, salt intake, diet, and other factors. Therefore, with 50% heritability, the 153 loci identified by the GWAS explain ~5% of the overall likelihood of developing CAD (Figure 48.2). Accordingly, further study regarding independent genetic risk factors and how they are influenced by environmental factors to contribute to CAD heritability is warranted [12].

The development of more complete DNA sequencing techniques, such as whole exome/whole genome sequencing (WES/WGS) generally applied to case-control cohorts as in GWAS, could be used as a tool to identify additional rare risk variants that might have more

Figure 48.2 Current understanding of coronary artery disease (CAD). While traditional risk factors likely account for ~50% of the likelihood of developing CAD and ~5% is attributable to known CAD risk loci, approximately 45% of the likelihood of developing CAD is thought to be caused by currently unknown genetic factors: the “missing heritability” of CAD.

effect on heritability [13]. Preliminary findings from WES indicate, however, that the number of SNPs in coding regions (i.e., exomes) that potentially contribute to some fraction of the missing heritability of CAD is sparse. The lack of coding region SNPs associated with CAD, as discussed in more detail later, underscores the notion indicated from studies like ENCODE that risk SNPs identified by GWAS are largely situated in regulatory regions of the genome rather than in protein-coding regions [14]. Nevertheless, the next section specifically evaluates CAD and the role for genes identified in GWAS so far, and we argue that it is likely that these genes belong to a group of genes that are mostly important at specific intervals in the protracted course of the pathogenesis of CAD. We argue that those identified by GWAS might not necessarily be involved in the final culmination of CAD leading to clinical events. Thus, we believe complementary approaches beyond GWAS will be required to explain the full heritability of CAD and particularly to explain the occurrence of clinical events.

Identification and characterization of genetic risk variants for CAD and MI

Since the discovery in 2007 of the 9p21 CAD risk variant using GWAS [9,15], initial efforts focused on increasing sample sizes, defining new variants, and then replicating and confirming these findings [16]. Eventually, in order to detect risk variants with low frequency and minimal effect, large collaborative groups were founded to provide for larger sample sizes, one of which being the Coronary Artery Disease Genome-Wide Replication and Meta-Analysis (CARDIoGRAM). This meta-analysis confirmed 10 previously described risk variants as well as the identification of 13 new risk variants for CAD [17–19]. These genetic risk variants for CAD are common but with a relative risk that is usually minimal to moderate. The currently known CAD genetic risk variants are presented in Table 48.1.

Of the genetic risk variants identified for CAD, 35 of the 50 act through currently unknown mechanisms and many of these are in non-coding DNA regions, suggesting that there are several pathways that contribute to the pathogenesis of CAD that have yet to be

described. Other genetic variants have been linked to established risk factors for CAD, including those involved in lipid metabolism, such as variants related to LDL cholesterol, lipoprotein-a, apolipoprotein-B, LDL-R, apolipoprotein-E, and ABCG5. A new variant not previously associated with LDL-C includes a SNP associated with Sortilin1 (SORT1), which is thought to modulate LDL-C secretion [20]. In addition, the discovery of the PCSK9 variant has led to the development of novel agents to reduce LDL cholesterol levels (PCSK9 inhibitors) that are now in advanced stages of clinical testing [21,22].

As a relevant aspect of CAD and myocardial infarction (MI), an MI is typically caused by an occlusive thrombus that is superimposed on an atherosclerotic plaque. The acute rupture of this plaque is what precipitates the formation of a thrombus. However, the presence of CAD is the result of typically decades of slow progression of this disease process. Importantly therefore, the biology of plaque development and acute plaque rupture with thrombus formation are distinct, and consequently the genetic variants contributing to thrombus formation are distinct from those that contribute to the protracted development of atherosclerosis. The variant 9p21 is associated with both processes but likely mostly accounted for in CAD [23,24]. However, it is particularly notable that the only genetic risk variant currently associated with MI is the ABO blood group locus [24]. Multiple studies have suggested and confirmed an association between the ABO blood groups at locus 9q34.2 and MI, including CARDIoGRAM, which demonstrated an increased risk of 20% for MI with A and B risk variants [19]. Blood groups A and B encode for a protein that transfers a carbohydrate on von Willebrand factor (alpha-1-3-N-acetylgalactosaminyltransferase); this results in a prolonged half-life of von Willebrand factor with predisposition to coronary thrombosis and subsequent MI [25]. In the Nurse’s Health Study, the blood group A or B was associated with a 10% increased frequency of MI, the combination of A and B blood groups increased the risk to 20% [26]. Clearly, much remains to be understood regarding the molecular mechanisms whereby these risk loci promote CAD.

Relevance of CAD pathogenesis and clinical manifestations from a genetics perspective

It is becoming increasingly clear that the development of atherosclerotic lesions and CAD is profoundly influenced by genetic factors. While atherosclerotic biology is comprehensively covered in other chapters of this book, here we very briefly summarize what we perceive to be the key aspects related to atherosclerosis and CAD as relevant to genetic factors.

Atherosclerotic lesion development within the coronary vessels generally follows a sigmoidal-shaped (S-shaped) model, with the caveat that the late stage of atherosclerosis with plaque development and progression can be variable and include further rapid progression [27,28]. In detail, studies in both humans and mice have supported the notion that atherosclerosis develops over a long period of time, but with a period of rapid progression before a later final period of generally slowed growth [29–32]. Plaque development is initiated by retention of circulating plasma lipoproteins, predominantly LDL, at sites in the vasculature that are regions of turbulent blood flow. Some LDL particles remain within the subendothelial space and are modified by redox processes. The endothelium is activated by oxidized LDL via the expression of adhesion molecules,

leading to transendothelial migration of leukocytes (predominantly monocytes). Within the subendothelial space and the intima, monocytes differentiate into macrophages. These macrophages uptake oxidized LDL particles, initiating foam cell formation, a key process of atherosclerosis. The accumulation of foam cells in the intima manifests as the appearance of fatty streaks on histologic examination. Aggregation of multiple foam cells leads to formation of small atherosclerotic plaques with well-defined borders [32].

The second phase of atherosclerosis involves the rapid expansion of the small plaques across the arterial wall and into the lumen of the blood vessel, leading to compromise of blood flow. Through the use of ^{14}C dating of human plaques, this rapid phase is thought to occur less than 10 years prior to clinical symptoms [30].

The third and final stage can be variable. In about 30% of the cases, rapid progression of lesions occurs over 12 months to a fibroatheroma, with encapsulation of the lipid-rich core by a thin or thick cap. The most unstable lesions are the thin-cap atheromas that lead to an acute MI. In the span of 12 months, 75% of thin-cap fibroatheromas stabilize, while 5% of the thick-cap atheromas will develop high risk features [28,33]. The rupture of a complex plaque is influenced by an interplay of multiple factors including: extent and degree of necrosis of the deposited lipid core mediated by proliferating macrophages within the plaque area; the de novo migration/emigration of monocytes; extent of luminal stenosis; plaque burden; vessel remodeling into the lumen of the vessel; and the thickness of the fibrous cap [34]. An occlusive thrombus leads to reduced perfusion of the myocardium which results in an acute coronary syndrome or sudden cardiac death.

Specific limitations of GWAS and presently identified CAD risk loci

While the achievements regarding the genetics of CAD thus far using GWAS cannot be gainsaid, there are several inherent limitations to the GWAS study design that we believe are responsible for skewing the nature of the genetic loci identified. This idea is supported by three conventions underlying development and phenotypic expression of complex diseases: shifting environments, time, and case-control overlap.

Shifting environments

The DNA code in each individual is established at conception. Therefore, DNA variants that function independent of environmental factors are most likely to reach significance in a GWAS because these are not reliant on any specific environmental factor to be present for their effect to become manifest. On the other hand, DNA variants that are dependent on environmental stimuli or factors are unlikely to reach the same significance in a GWAS because the additional element of the requisite environmental influence is needed, which may or may not occur in a given individual. The context-dependent or environmentally influenced risk modifiers of genetic risk in CAD include lifestyle factors such as smoking, diet, salt intake, and sedentary lifestyle, or coexisting comorbidities including obesity, diabetes, hypertension, and inflammatory driven diseases. Other risk factors include environmental pollution and highly stressful events [35,36], but these are even harder to account for in an individual patient. However, environmental factors that decide whether a genetic factor will influence CAD development or not can also be local in a given tissue. As an example, fatty liver can induce a number of genes in the liver that influence the genetic risk of CAD which are absent or insignificant in the normal liver. Such

context-dependent or environmentally influenced genetic factors may be identifiable in GWAS datasets, but current analytic approaches have failed to do so [37]. In summary, genetic variants modifying gene expression in CAD that are dependent on environmental contexts is a phenomenon that has been confirmed to be common and strong experimentally [38–41]. The reanalysis of GWAS datasets seeking to identify such context-dependent variants is potentially a very fruitful line of investigation which several groups are now actively pursuing.

Time

DNA variants involved in the regulation of disease processes over a long period of time (and which remain operative despite changing environmental and other influences) are more likely to reach genomewide significance in GWAS in comparison to those that regulate processes over a short period of time. Therefore, the DNA variants that are found to have genomewide significance in GWAS are most likely to be implicated in the early phase of disease pathogenesis where the initial growth phase is slow and spread over more time in comparison to the rapid growth phase or late phases. The pathogenesis of early CAD is likely driven more by genetic predisposition in comparison to the later stages of the disease and is less likely to be influenced by the factors that likely drive later stages of the disease, including diabetes, obesity, and different inflammatory states. The later stages of the disease are also more complex given that there are generally additional disease processes acting in parallel across organ systems (i.e., CAD includes the liver and pancreas in diabetes, adipose stores in obesity or systemic immune modulation). Late modulators of disease are complex and involve multiple systemic cofactors that are related to environmental or stimulus-dependent DNA variants that are unlikely to be of genomewide significance in a GWAS.

Case-control overlap

In the control populations sampled in GWAS studies for common complex disorders such as CAD, who did not have clinically manifest CAD or MI, it is inevitable that many had subclinical atherosclerotic disease and CAD. Therefore, using a GWAS study design, the power to detect subtle variants associated with CAD was almost certainly eroded because of the inclusion of persons with significant but subclinical CAD in the control population. In the absence of rigorous screening methods such as angiography, which is clearly impractical when recruiting many thousands of healthy controls as required for GWAS, it is impossible to exclude this confounding effect.

These limitations to the GWAS design, namely case-control overlap, lack of accounting for environmental factors, and bias toward genetic variants with a protracted period of effect, have implications for how we interpret the CAD risk alleles identified using GWAS. For example, because the GWAS design favors the identification of genes that have a role during early CAD development, these early phase genes are likely to be best suited to develop preventative measures for patients with these loci in addition to the development of disease therapies targeted toward inhibiting early disease development. A key limitation of identifying genes that are involved early in disease pathogenesis includes not being able to identify risk factors for secondary prevention and lack of development of therapies targeted toward the later, more rapidly progressive phases of CAD implicated in clinical manifestations such as MI and stroke.

Analysis of the validated genes linked to the CAD GWAS loci (Table 48.1) further confirms this outlook [10]. Of the 50 genes

identified, 10 are involved in regulating lipid levels, including high density lipoprotein and triglycerides (Table 48.1) [7]. Circulating lipids have a major role in early atherosclerosis development; this supports the notion that targeting of the loci identified in GWAS would be most useful in primary prevention, also supported by data demonstrating that LDL lowering leads to regression of atherosclerosis more significantly in early than in advanced lesions [29]. Other CAD risk loci identified so far include genes related to hypertension (Table 48.1), which contributes to early endothelial cell activation and with hypertension having little impact on disease progression in the later phases of atherosclerosis. Indeed, most of CAD-associated loci identified by GWAS have been implicated in early CAD development with the exception of the ABO locus (Table 48.1), highlighting that context- and environmental-dependent variants and those operative late in the disease process are likely to be under-represented.

Integration of GWAS findings into future models of disease: systems genetics to identify networks mediating pathogenesis of disease and key regulatory pathways

Given the complexity of CAD and that GWAS tends to identify genes and loci associated with the early phases of disease development, the next question that arises is how to best identify later phase genetic loci that are dependent on environmental contexts and that

are activated over a shorter course of time. Systems genetics is rapidly coming to the forefront as a potential solution to this issue [42–45]. Systems genetics works to identify key drivers of disease through the use of network models of interacting molecular pathways by integrating the analyses of both DNA and genomic (e.g., RNA, protein) datasets. Systems genetics data can be enriched by integration with GWAS datasets, and then ultimately used to identify and characterize DNA variants that contribute to the pathogenesis of late phases of complex diseases. The expectation is that systems genetics will also facilitate the development of diagnostic tools and the identification of new treatment targets for these complex diseases, with the goal of prevention of further remodeling and perhaps regression of current disease.

For common complex diseases such as CAD, the mere isolated effect of the individual genetic variants and/or genes as identified by GWAS does not explain the intrinsic complexity of the molecular disease processes. These diseases have polygenic regulation that involves the interaction of multiple genes within a complex and dynamic biologic network. These types of networks are sparse, with most genes (denoted as nodes) having a limited number of interactions with other genes (edges), with a small number of highly interconnected nodes acting as hubs given their multiple interactions (Figure 48.3) [46]. By studying measures of gene activity and creating network models of disease, systems genetics can identify these highly interconnected nodes [47]. Particularly important nodes can be considered as key drivers of any given disease process. By applying these approaches and the development of new technologies for screening genomes and studying genomic activity, and the

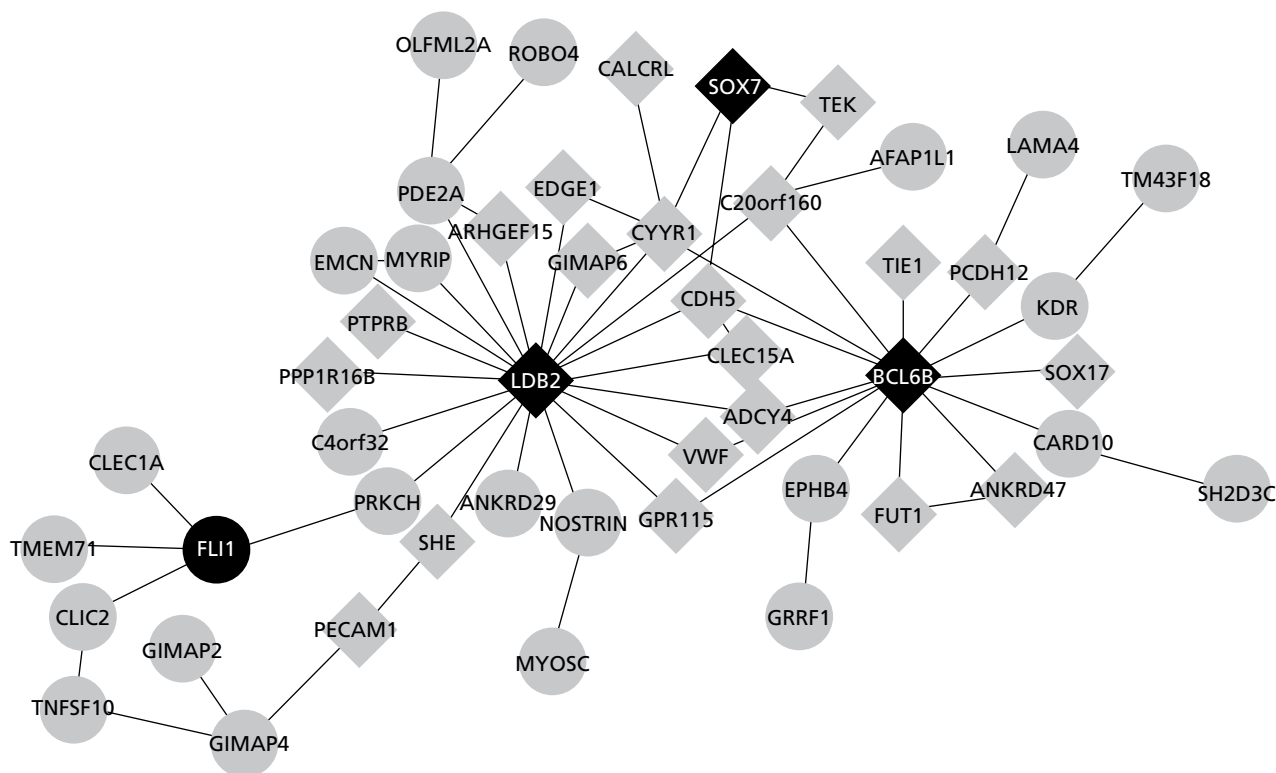

Figure 48.3 CAD regulatory network. This CAD regulatory network was identified by the team in the STAGE study. Regulatory genes are shown in black. Of these, Lim-domain binding 2 (LDB2) was found to be a high-hierarchy regulator of the transendothelial migration of leukocytes (TEML) pathway in atherosclerosis development, with a functional LDB2 variant (eQTL rs 10939673) linked to an increased risk for CAD [6,92]. Source: Hagg *et al.* 2009 [6]. Reproduced under the Creative Commons Attribution (CC BY) license.

advancement of computational analysis of growing datasets, we now appear poised for the large-scale application of system genetics to biology, medicine, and healthcare.

An example of this includes the STAGE (Stockholm Atherosclerosis Gene Expression) [6] and STARNET (Stockholm-Tartu Atherosclerosis Reverse Network Engineering Task) studies (Figure 48.3). With STAGE as the pilot forerunner study, STARNET is a landmark genetics-of-RNA-expression study comprising 925 CAD cases who had coronary artery bypass graft surgery and 207 controls without CAD who had open-thorax surgery. Each subject underwent DNA sampling, clinical characterization, angiographic assessment of CAD burden, and RNA isolation from up to nine CAD-relevant tissues: atherosclerotic (aorta) and non-atherosclerotic (internal mammary artery) arterial wall, liver, abdominal and subcutaneous fat, skeletal muscle, whole blood, and macrophages and foam cells differentiated from primary monocytes *in vitro*. RNA from these samples was then sequenced and extensive expression datasets were generated. The utility of these datasets includes: (i) to identify causal regulatory factors that potentially drive molecular mechanisms behind disease processes made possible through the study of multiple tissues involved in the pathogenesis of CAD; and (ii) to identify DNA variants that are involved in controlling gene expression in these networks. Furthermore, as these studies are primarily based on RNA expression data reflecting both genetic and environmental influences, this type of approach should permit the study of complex diseases in the later stages of disease pathogenesis, where the regulatory factors are more likely to be dependent on environmental contexts, including multiorgan cross-regulation. The STAGE/STARNET dataset can be used to identify expression quantitative trait loci (eQTLs) in CAD [48–52]; eQTLs are generally DNA variants, usually SNPs, that regulate gene expression levels. eQTLs are determined by linking the alleles of SNPs discovered by genotyping patient's DNA with gene expression levels from the different tissues. Thus, SNP alleles can be associated with different gene expression levels of tissues and can be identified as eQTLs. It is expected that this approach will help elucidate the large fraction of unknown heritability behind complex diseases and contribute to the development of novel molecular diagnostics and individually tailored therapies in healthcare.

Pharmacogenomics and interventional cardiology

Clopidogrel pharmacogenetics

Moving away from the genetics of CAD and to other relevant situations in the catheterization laboratory where pharmacogenetics has a key role, in recent times a large amount of data has emerged to highlight the importance that genetic influences have in the individual response to clopidogrel therapy. Indeed, despite the fact that clopidogrel remains the current cornerstone of antiplatelet therapy for patients undergoing percutaneous coronary intervention (PCI) for stable CAD, approximately 4–30% of patients do not respond adequately to this agent [53,54]. This is supported by pharmacologic studies that demonstrated *ex vivo* ADP-stimulated platelet reactivity (a surrogate marker of clopidogrel response) varies substantially in patient populations treated with clopidogrel [53,55]. Patients who have undergone recent stent implantation who receive clopidogrel and who exhibit high on-treatment platelet reactivity (HTPR) are more likely to develop a recurrent adverse clinical event [56]. While several clinical and demographic factors affect clopidogrel efficacy, the contribution of these factors is relatively modest

[57]. However, genetic studies have revealed several SNPs that significantly influence clopidogrel response. Specifically, genetic variants in genes responsible for clopidogrel transport and bioavailability (ATP-binding cassette subfamily B member 1 (*ABCB1*) [58–63], hepatic metabolism (CYP enzymes) [64–66], paraoxonase 1 (*PON1*) [67–70], carboxylesterase 1 (*CES1*) [71,72], and receptor interaction/activation (*P2Y12*) [73–75]) have been shown to have a role in clopidogrel pharmacodynamics, pharmacokinetics, and subsequent cardiovascular event rates. While it is possible to perform testing for these genetic variants, at present such testing has not been shown to be clinically efficacious and is currently given a IIb recommendation (level of evidence C) by the AHA/ACC, with the comment: “Genotyping for a CYP2C19 loss of function variant in patients with UA/NSTEMI (or, after ACS and with PCI) on P2Y12 receptor inhibitor therapy might be considered if results of testing may alter management” [76]. The TAILOR-PCI study is a multisite, prospective, randomized study that is currently recruiting patients and which seeks to use genetic testing for the *2 and *3 CYP2C19 alleles to determine whether choosing clopidogrel versus ticagrelor based on these genotype data will influence major adverse cardiovascular events. It is hoped that this study will give definitive proof as to whether genetic testing for likely responsiveness to clopidogrel has a role in the care of patients post-PCI requiring antiplatelet therapy.

Warfarin pharmacogenetics

Warfarin is widely used for the treatment and prevention of thromboembolic diseases, but is characterized by its narrow therapeutic index, individual variability in response, high rates of adverse events, and requirement for cautious patient selection and frequent adjustment for therapeutic dosing [77–79]. Standard dosing for warfarin is 2–6 mg/day; however, the effective daily dose varies from 0.5 to more than 30 mg in the general population. Subtherapeutic dosing results in a risk of failing to control blood clotting, whereas supratherapeutic dosing can lead to excessive and uncontrolled bleeding. Genetic polymorphisms of a number of enzymes involved in the mechanism of action and pharmacokinetics of warfarin have been demonstrated to be pivotal in determining the individual variability in response to warfarin therapy. Those studied include polymorphisms of *VKORC1* and *CYP2C9* [80–84], as well as genes that indirectly influence warfarin anticoagulation: *GGCX* [85], *CALU* [86], and *PROC* [87]. Of these, *VKORC1* polymorphisms account for approximately 25% of the variability in warfarin dosage and many studies have consistently shown that *VKORC1* genotype is the single biggest predictor of warfarin dose [88]. Those that carry the 1173 T/T allele of *VKORC1* require approximately 30–50% less warfarin daily dose than patients with wild-type 1173 C/C allele, while polymorphisms in the coding regions of *VKORC1* lead to varying degrees of drug resistance. Patients who carry the *CYP2C9**2 and -*3 alleles have a reduced capacity for metabolizing (S)-warfarin, resulting in supratherapeutic levels. However, variability in warfarin efficacy is a complex issue that involves more than just the genotypes of *CYP2C9* and *VKORC1*. Other factors, including age, gender, diet, drugs, and BMI, contribute another 20% (reviewed in [89,90]). Beyond these factors, there still exist further unidentified factors that account for almost 50% of variability of response to warfarin. Potentially, this complexity in the genetics and other factors that influence warfarin efficacy led to the failure of the much anticipated COAG study to find a benefit of genetic testing to aid in the initial choice of warfarin dose [91]. In the COAG study, over 1000 patients who were

being initiated on warfarin were assigned to receive an initial dose using an algorithm based on genotype plus clinical data versus clinical data only. Unfortunately, genotype-guided warfarin dosing did not improve anticoagulation control during the first 4 weeks of therapy and at the current time there is no clinical indication for such testing. Nevertheless, although the newer novel oral anticoagulant medications have rapidly displaced warfarin as the agent of choice in eligible patients, the continued need for warfarin in specific patient subsets and its far lower cost appear to support further studies to identify important networks responsible for variability in drug response. These data would potentially help in improving therapeutic response, reduce adverse effects, and assist in reducing overall healthcare costs.

Conclusions

GWAS have played a critical part in identifying risk variants that partially explain the heritability of common complex diseases such as atherosclerosis and CAD. These risk variants have facilitated the identification of new molecular pathways that are involved in the pathogenesis of disease. However, the GWAS design appears to have limitations, and in particular it likely overlooks context-dependent risk variants (i.e., those that only exert risk when a specific environmental stimulus or factor is also present). These environment or context-dependent factors are likely to be most influential during the later and complex stages of common complex disease development and are therefore thought to exert a significant effect on molecular processes that are active in short timeframes during the later stages of CAD, such as the events in the weeks leading up to plaque rupture and MI. As we move into a new era of genetic studies where systems genetics assumes a major role in our investigative approach, further study of disease-causing networks is expected to uncover key biologic pathways involved in the pathobiology of common complex diseases, including CAD. In turn, it is anticipated that our improved understanding of these causal disease networks will permit the development of improved diagnostic tools, enhanced risk stratification, and novel therapeutic applications. Specific to the catheterization laboratory, as we unravel the causal molecular pathways that promote CAD and adverse vascular remodeling, it is certainly possible that novel stent platforms and adjunctive pharmacotherapies will also be developed which leverage this improved genetic and biologic knowledge.

Monitoring and Reversal of Anticoagulation and Antiplatelet Agents

Gregory W. Yost¹ and Steven R. Steinhubl²

¹ Geisinger Medical Center, Danville, PA, USA

² Scripps Translational Science Institute, San Diego, CA, USA

Closure of a coronary vessel has been the biggest concern with performing interventions since the beginnings of percutaneous transluminal coronary angioplasty (PTCA). Thrombosis remains a prominent concern despite the advances in percutaneous coronary intervention (PCI), especially with stenting. Thrombogenic potential exists in a newly placed stent until there is complete endothelialization [1], after ~28 days for bare metal stent and longer for drug-eluting stents because of delayed neointimal proliferation [2,3]. There is extensive clinical evidence that the use of antithrombotic therapy lowers the risk of vessel closure during and after PCI. Anticoagulation and dual antiplatelet therapy with stent placement is a standard of treatment with Class I indication according to current practice guidelines [4]. Anticoagulation has been used since before the stent era and, although not as rigorously studied as antiplatelets in PCI, it remains a routine part of therapy for two major reasons: preventing arterial thrombus formation and reducing thrombogenicity of catheters and guidewires used during the invasive procedures [5].

Since PTCA was first described [6,7], and the breakthrough studies on the role of stents [8,9], the evolution in anticoagulation and antiplatelet therapy used during PCI has led to reductions in periprocedural ischemic events and stent thrombosis [10]. There is a significant trade-off with higher risk of major and minor bleeding when using greater combinations and doses of anticoagulation and antiplatelet for protection against thrombogenic and embolic events [11]. This chapter describes each of the commonly used antiplatelet and anticoagulants used at time of PCI with specific focus on drug monitoring and reversal, if applicable.

Anticoagulants

Exposure of clotting factors to disrupted endothelium, catheters, and guidewires predisposes to thrombosis during catheterization. Anticoagulation therapy is used to minimize thrombus propagation on the endovascular surface and formation of new thrombi from PCI equipment use [5,12]. Ideal anticoagulation would effectively prevent thrombus formation, have low risk of bleeding, a safe monitoring profile, short duration of effect (half-life), and could be

reversed if necessary. Anticoagulants used during PCI include unfractionated heparin (UFH), low molecular weight heparin (LMWH), direct thrombin inhibitors, and indirect factor Xa inhibitors (Table 49.1) [12,13].

Unfractionated heparin

Thrombus propagation occurs when thrombin is produced on the surface of activated platelets, converting fibrinogen to fibrin. Fibrin is cross-linked with factor XIIIa reinforcing platelet aggregation and culminating in clot formation. Heparin combines with antithrombin to indirectly inactivate thrombin, factors Xa, and intrinsic pathway factors XIIa, XIa, and IXa [14,15]. UFH has been proven to be beneficial in the treatment of unstable angina or myocardial infarction (MI; not treated with thrombolytic therapy) [16–18]. While anticoagulants have been shown to inactivate von Willebrand factor there may be differences between anticoagulants in curbing its release. Enoxaparin lessens the release more than UFH. This can be important in patients with unstable angina when there may be an early rise of von Willebrand factor. This early release of von Willebrand factor is associated with worse outcomes [19,20].

Use of intravenous (IV) UFH given before PCI to prevent intracoronary thrombosis was started at the time of the very first percutaneous intervention by Andreas Gruntzig and has remained the gold standard through the current age of routine stenting and use of dual antiplatelets [5]. In the early phases of PTCA the vessel closure rate during or after dilatation was 2–11% [21]. Use of UFH lowered these rates but there remained a risk for closure because there was no clear consensus for proper dosing. Changes in heparin dosing recommendations and the increasing use of radial artery access have reduced the incidence of ischemia and bleeding events when UFH is used in preference to alternative anticoagulants [12,22]. Unfractionated heparin remains the most commonly used anticoagulant despite the availability of newer medications.

Despite UFH being the most widely used anticoagulant there are several limitations to its use beyond the risk of bleeding seen in all anticoagulants. UFH has a less predictable pharmacologic profile.

This article updates Yost GW, Steinhubl SR, Monitoring and reversal of anticoagulation and antiplatelets. *Interventional Cardiology Clinics* 2013; 4: 643–663, with permission of the publisher.

Table 49.1 Types and properties of common anticoagulant agents.

	Mechanism of action	Onset of action (half-life)	Method of monitoring	Recommended point-of-care test	Reversal for bleeding
UFH	Inactivates thrombin, factors IXa, Xa, XIa, XIIa	Immediate, IV (dose, dependent, 30–90 min)	aPTT	ACT	Protamine sulfate (1 mg per 100 units UFH)
LMWH	Inactivates thrombin (less affinity) and factor Xa (higher affinity)	Immediate, IV 3–5 hours, SQ (3–6 hours)	Anti-factor Xa level	None	Partial with protamine sulfate (1 mg per 100 anti-Xa units or 1 mg per 1 mg enoxaparin)
Bivalirudin	Transiently inhibits thrombin	<5 minutes, IV (25 minutes, longer with renal failure)	ACT	ACT	None*
Argatroban	Reversibly inhibits thrombin	Immediate, IV (30–60 minutes)	aPTT	ACT	None*
Fondaparinux	Inactivates factor Xa	2 hours, SQ (17–21 hours)	Anti-factor Xa	None	None*

ACT, activated clotting time; aPTT, activated partial thromboplastin time; IV, intravenous; LMWH, low molecular weight heparin; SQ, subcutaneous; UFH, unfractionated heparin.

* Recombinant factor VIIa can be used to help reduce bleeding.

Several of the heparin-binding proteins are acute phase reactants which typically become elevated in the setting of unstable angina or MI. Studies have confirmed that thrombin bound to fibrin is protected from inactivation by heparin [23]. Additionally, there is decreased affinity of antithrombin III when factor Xa is bound to phospholipid surfaces within a prothrombinase complex which accounts for the variable effect with UFH [24,25]. There may even be a prothrombotic risk (outside of heparin-induced thrombocytopenia) because of its weaker control of von Willebrand factor, possibility of rebound thrombin generation after its discontinuation, and platelet activation and enhanced aggregation with therapeutic concentrations of UFH [19,20,26]. Because of its unpredictability UFH needs close continual monitoring, especially while being used during PCI.

Monitoring

Monitoring of UFH is typically with activated partial thromboplastin time (aPTT). There are variations in response to heparin amongst different commercial aPTT reagents [27]. Another problem is that aPTT becomes prolonged when heparin concentrations exceed 1 U/mL [25]. This is typically the case during coronary artery bypass surgery and PCI when very high doses of heparin are utilized. Monitoring is performed in these cases by using activated clotting time (ACT). Earlier studies in the aspirin-only era identified a narrow therapeutic window for UFH and that lower ACT levels could be associated with higher incidence of ischemia [28–30]. One meta-analysis identified an optimal ACT range of 350–375 in patients undergoing PCI. This was associated with a 6.6% ischemic event rate defined by the composite endpoint of death, MI, or urgent revascularization at 7 days. The relative risk reduction in ischemic events at 7 days was 34% with these higher levels of ACT. The lowest level of bleeding (8.6%) was observed in the range of 325–350 seconds, and it progressively increased to 12.4% at 350–375 s. There was a substantial increase in bleeding events when ACT values exceeded 400 s [31]. In contrast, a subanalysis from the more recent STEEPLE trial suggested that an ACT of 325 s was the

optimal target when balancing risk with benefits. This paralleled similar findings from a meta-analysis carried out by Brener *et al.* [32] showing no further protection against ischemic events but a greater bleeding risk with higher ACT levels. This holds true especially in the modern era of PCI when P2Y₁₂ and glycoprotein IIb/IIIa (GP IIb/IIIa) inhibitors are frequently used. Based on these results, lower ACT levels to the low 200 s are not associated with lower incidences of ischemia but higher ACT levels and weight indexed dosing of UFH can lead to more bleeding [32,33].

It is important to recognize the different models for measuring ACT levels can have different results [34]. The 2011 PCI guidelines recommend an ACT level of 200–250 s following an initial UFH bolus of 50–70 U/kg when GP IIb-IIIa inhibitors are used. ACT levels of 250–300 s (for HemoTec device) or 300–350 s (for Hemochron device) following an initial bolus of 70–100 U/kg UFH are the goals when not using glycoprotein inhibitors [4].

Reversal

Heparin has a relatively short half-life; however, it has a non-linear response when used at therapeutic doses. The half-life of heparin increases from ≈ 30 minutes after an intravenous (IV) bolus of 25 U/kg to 60 minutes with an IV bolus of 100 U/kg and 150 minutes with a bolus of 400 U/kg [15]. Intravenous protamine sulfate can be used when immediate reversal of heparin is needed. One milligram (mg) of protamine sulfate will neutralize 100 units of heparin (e.g., 50 mg protamine sulfate should be given for heparin IV bolus of 5000 units). When a patient is on continuous heparin infusion, only the preceding 1–2 hours of heparin needs to be considered for dosing of protamine sulfate because of the short half-life of heparin (e.g., 25 mg protamine sulfate given to neutralize heparin at 1200 units/hour for the past 2 hours). Slow infusion of protamine can reduce the chances of bradycardia, hypotension (no faster than 20 mg/minute and no more than 50 mg in any 10-minute period). The aPTT should normalize after administration of protamine. As protamine is derived from fish sperm, patients with allergic reactions to fish can be pretreated with corticosteroids and/or antihistamines [35–37].

Low molecular weight heparin (enoxaparin)

Low molecular weight heparin (3000–5000 Daltons) is produced by chemical or enzymatic depolymerization of UFH (weight ranges 3000–30,000 Da) [38]. This change in molecular weight and size creates several important differences between UFH and LMWH. Heparin has a unique pentasaccharide sequence allowing it to bind to antithrombin, causing a conformational change and inactivating factor Xa. A ternary complex must be formed to inactivate thrombin—heparin binding to antithrombin and thrombin. This complex can only be formed by pentasaccharide chains consisting of 18 saccharide units. UFH is composed of at least 18 saccharide units; however, LMWH typically has shorter chain units. This creates an important difference in that LMWH has a much higher affinity for factor Xa than UFH which has equal activity against factor Xa and thrombin. Even enoxaparin and other LMWHs (e.g., dalteparin, tinzaparin) differ in size resulting in differing ratios of anti-Xa to thrombin effect: enoxaparin has a ratio of 4 : 1 and dalteparin has a ratio of 2 : 6 [12,25,37,39–41]. Enoxaparin is the most studied and currently the only recommended LMWH for use during PCI.

LMWH has a more predictable anticoagulant profile and can be given intravenously or subcutaneously in fixed or weight-adjusted doses without routine monitoring (renal insufficiency, obesity, and children are exceptions) [35]. Less binding of LMWH to plasma proteins is a major reason for this which establishes better bioavailability, longer half-life, and dose independent clearance [23,37,42]. LMWH reduces the risk of bleeding because it causes less vessel wall permeability, less platelet activation, less susceptibility to inactivation by platelet factor 4, and less risk of heparin-induced thrombocytopenia (HIT) than UFH [42,43], although clinical data supporting this are inconclusive.

Further exploration of using LMWH rather than UFH for patients with acute coronary syndrome (ACS) during PCI was because of its potentially better predictability and less harmful effects. Gurfinkel *et al.* [44] first noted a decrease in rates of silent ischemia, recurrent angina, revascularization, and minor bleeding in the group that received LMWH and aspirin versus UFH and aspirin when used for treatment of unstable angina. The FRIC trial found no significant differences between LMWH and UFH when used for treatment of unstable angina or non-Q wave MI [45]. Several other studies showed support for LMWH over UFH. TIMI 11B and ESSENCE separately showed superiority of enoxaparin over UFH in reducing endpoints of death, non-fatal MI, and urgent revascularization when used for treatment of unstable angina and non-ST elevation myocardial infarction (NSTEMI). A meta-analysis of the two studies showed persistence of lower endpoints through 43 days. There was a significant increase in minor bleeding but not for major bleeding rates [46–48]. The SYNERGY trial showed enoxaparin was not inferior to UFH but may have a slightly increased risk of bleeding. However, there were a non-negligible number of patients who crossed over to the other antithrombotic agent, confounding the interpretation of the results. The study concluded that despite an increase in bleeding, enoxaparin is likely superior when used as initial first-line therapy without changing to UFH [49]. Crossing over or giving additional UFH after initially treating with enoxaparin should be avoided as supported by the STACKENOX trial [50].

The STEEPLE trial compared the use of enoxaparin with UFH and GP IIb/IIIa inhibitors in patients undergoing elective PCI. Results showed enoxaparin (compared to UFH) had a significant increase in achieving target anticoagulation levels and bleeding

rates were similar to or lower than those with UFH (depending on dose used at time of elective PCI) [51]. This further supports the better bioavailability and predictability of LMWH over UFH without the need for close monitoring [19]. Use of intravenous enoxaparin in combination with glycoprotein inhibitors was shown to be a safe alternative to UFH when used during PCI in the NICE 1 and NICE 4 studies (dosed at 1 and 0.75 mg/kg, respectively). NICE 3 showed the combination can also be used safely as initial anticoagulation for ACS and continued during the transition to the catheterization laboratory for PCI [43,52]. Bhatt *et al.* [53] performed a randomized study comparing enoxaparin with GP IIb/IIIa inhibitors versus UFH with GP IIb/IIIa inhibitors. The results showed no significant difference in bleeding and enoxaparin was no less efficacious than UFH when used during urgent or elective PCI. A meta-analysis of 13 studies carried out by Dumaine *et al.* [54] showed that use of LMWH was associated with less major bleeding and no differences in endpoint of death and MI when compared to UFH. There may also be less incidence of bleeding associated with sheath removal [53,55].

Monitoring

Despite the safe findings demonstrated in previous trials using LMWH and GP IIb/IIIa inhibitors, there remains concern over monitoring therapeutic levels of anticoagulation especially in select populations (i.e., elderly, obesity, renal failure). Because LMWH has minimal effect on thrombin it has only a modest effect on aPTT levels. Unlike UFH, where ACT is the standard for monitoring during cardiac catheterization, LMWH does not significantly prolong ACT levels and cannot be reliably used during PCI [56,57]. Measuring anti-factor Xa levels most accurately reflect LMWH levels because of its predominant anti-factor Xa activity [58]. Peak anti-factor Xa levels occur 3–5 hours after a subcutaneous dose of LMWH but are longer in patients with renal insufficiency [37]. An optimal anti-factor Xa level has not been clearly defined; however, a therapeutic range of 0.5–1.8 IU/mL has been suggested based on several studies [52,59–62]. The standard anti-factor Xa activity laboratory study is not a method that can be readily used at the time of a catheterization procedure. In this scenario, a point of care test (POCT) can be useful to determine if a patient is therapeutically anticoagulated at the time of PCI [63]. Several POCT methods have been developed for this purpose but are not widely used clinically.

Previously, the Rapidpoint ENOX test was used to determine appropriate therapeutic ranges of anticoagulation specifically for enoxaparin but this test was never commercially available [64,65]. The Heptest is a clotting assay that is sensitive to both low molecular compounds with exclusive anti-factor Xa activity as well as agents affecting anti-factor IIa. Its correlation with both assays makes it useful when needed to monitor LMWH as well as UFH [58]. HEMONOX clotting time (CT) is a POCT used to monitor LMWH. An observational study by Roubey *et al.* [63] showed good correlation between HEMONOX CT and anti-Xa activity levels in two treatment groups at time of PCI: enoxaparin plus GP IIb/IIIa inhibitor and enoxaparin alone. Prior to administration of enoxaparin, the baseline levels of HEMONOX CT <100 s correlated with an undetectable anti-Xa level. The HEMONOX CT and anti-Xa levels showed similar increasing levels at 5 minutes and peak levels at 10 minutes. There was less of an increase in both HEMONOX CT and anti-Xa levels in the enoxaparin plus GP IIb/IIIa group versus the enoxaparin alone group. The HEMONOX CT for patients receiving enoxaparin alone was 257 ± 95 s (130–431 s) versus 207 ± 74 s (104–386 s) in patients receiving enoxaparin plus GP IIb/

IIIa inhibitors. This corresponded with peak anti-Xa levels of 0.86 ± 0.11 (0.69–1.14) U/mL for enoxaparin alone group and 0.78 ± 0.12 (0.61–1.10) U/mL for the enoxaparin plus GP IIb/IIIa group. Despite the corresponding lower levels in presence of GP IIb/IIIa, the anti-Xa levels remained within the recommended therapeutic ranges of 0.6–1.8 U/mL at time of PCI. There were similar decreases in HEMONOX CT and anti-Xa levels at 30 and 60 minutes following administration of enoxaparin in both treatment groups. Although this was a small observational study, the significant correlation between HEMONOX CT and anti-Xa levels during PCI support its potential use as a POCT for enoxaparin [63].

Monitoring is not indicated in all situations but may be warranted in certain populations that may be at higher risk of bleeding (e.g., increased age, history of gastrointestinal bleeding, renal insufficiency) [58]. The clearance of LMWH's anti-Xa effect is largely correlated with creatinine clearance and its decreased clearance poses greater risk for major bleeding events [66]. Monitoring and dosing of different LMWH agents in obese patients have been studied. Anti-factor Xa activity levels increased to appropriate levels when administered based on body weight up to 144 kg for enoxaparin, 190 kg for dalteparin, and 165 kg for tinzaparin [37]. Until there is a universally accepted recommendation for monitoring, the guidelines advocate additional dosing of LMWH before PCI to be dependent on timing of the most recent dose. No additional anticoagulation therapy is needed if the last dose of enoxaparin was less than 8 hours prior to PCI. If the last dose of enoxaparin was 8–12 hours prior to PCI, a 0.3 mg/kg bolus of IV enoxaparin at time of PCI is recommended. If the last dose of enoxaparin was more than 12 hours prior to PCI then conventional anticoagulation therapy is advised [67].

Reversal

The half-life of LMWH is 3–6 hours after subcutaneous administration but is longer in patients with kidney disease. A major concern for most clinicians in using LMWH is that there is no proven reversal agent. Protamine sulfate only partially reverses the effects of LMWH because while it neutralizes the anti-factor IIa activity, it has little to no effect on the anti-Xa activity [68]. When immediate reversal is needed, it is generally recommended to give 1 mg protamine sulfate per 100 anti-Xa units of LMWH given in the last 8 hours (where 1 mg enoxaparin equals 100 anti-Xa units). A second dose of 0.5 mg protamine sulfate per 100 anti-Xa units (or per 1 mg enoxaparin administered) can be given if bleeding continues. The maximum single dose of protamine sulfate is 50 mg [69].

Pentasaccharides (fondaparinux)

Fondaparinux is a synthetic derivative of the natural pentasaccharide sequence found in heparin. This works through antithrombin to inhibit factor Xa with greater specificity than UFH and LMWH. Fondaparinux does not directly inhibit thrombin because it is a short molecule and unable to form a bridging complex between antithrombin and thrombin. Fondaparinux is subcutaneously injected, reaches peak levels in 2 hours, and is excreted in urine with a half-life of 17 hours in a younger population and ~21 hours in the elderly. Like LMWH, fondaparinux has less binding to other plasma proteins as seen with UFH. It is typically administered once daily without monitoring because of its long half-life, bioavailability, and predictable anticoagulant response. It is contraindicated in renal insufficiency (creatinine clearance less than 30 mL/min) [13,35,37].

Several studies have supported fondaparinux as a safe and effective alternative for anticoagulation in setting of ACS and PCI.

The PENTALYSE study revealed that administration of pentasaccharide inhibiting factor Xa with alteplase can be as safe and effective at revascularizing as UFH with alteplase in patients with STEMI. There were similar coronary patency rates seen by angiography after 90 minutes but a trend toward lower re-occlusions in the culprit coronary artery and less revascularizations after 5–7 days [70]. The PENTUA study suggested that fondaparinux has similar safety and efficacy to enoxaparin when used for treatment of ACS without ST-elevation and not undergoing revascularization within 48 hours. This study showed no significant dose responses between different doses of fondaparinux (2.5, 4, 8, and 12 mg once daily). There were no significant differences in fondaparinux plasma concentrations between groups with primary endpoints (i.e., death, MI, and recurrent ischemia) and those without primary endpoints. Similarly, non-significant differences in plasma concentrations were seen in groups with bleeding versus those without bleeding. The lowest primary event rate was seen in the fondaparinux 2.5 mg dose group. Also, no major bleeding events occurred in the fondaparinux 2.5 mg and enoxaparin groups [71]. OASIS 5 held up the notion that fondaparinux was non-inferior to enoxaparin in the subsequent 9 day endpoint outcomes of death, MI, and refractory ischemia when used for treatment of high risk unstable angina or NSTEMI. Fondaparinux was superior to enoxaparin in respect to significant reductions in major bleeding at 9 days, deaths at 30 days, and deaths at 180 days [72]. The results from the ASPIRE study showed fondaparinux was just as efficacious and safe as using UFH for patients undergoing elective or urgent PCI, regardless whether or not a GP IIb/IIIa inhibitor was being used. In this trial, fondaparinux was given in 2.5 or 5 mg doses. There were no significant differences in bleeding complications between the two doses but there was a trend for lower incidences with the 2.5 mg dose. The procedural success rate was high in all groups with a slightly better percentage in the higher dose fondaparinux group: 96.3% for UFH; 96.5% for fondaparinux 2.5 mg; and 98.4% for fondaparinux 5 mg [73]. In patients with STEMI treated conservatively and not undergoing PCI, OASIS 6 showed reductions in death and recurrent infarction without increased risk of bleeding events when using fondaparinux compared to UFH [74].

Further pooled analysis into OASIS 5 and 6 trials supported the net clinical outcomes favoring fondaparinux over heparin therapies, which was mainly driven by reduction in bleeding events. Despite this positive finding there was higher rate of catheter-related thrombosis in OASIS 5 and likewise in OASIS 6 when fondaparinux was not used with UFH. OASIS 6 study showed a significantly higher 30-day rate of death or reinfarction when fondaparinux is used alone during primary PCI as part of therapy for STEMI, compared with the UFH group. This risk of catheter-related thrombus with fondaparinux was minimized without an increase in major bleeding when UFH (50–60 IU/kg) was given in the catheterization laboratory immediately before PCI [75]. Based on these findings, current guidelines recommend use of additional agents with activity against factor IIa when using fondaparinux for primary PCI [4].

Monitoring

Monitoring for fondaparinux is not routinely recommended. A fondaparinux specific anti-Xa assay can be used when needed but there is no clearly established therapeutic range, unlike LMWH. Peak steady state when using therapeutic doses of fondaparinux (e.g., 7.5 mg) should be 1.20–1.26 mg/L 3 hours after dosing [37]. Currently, there is no point of care test available for use during PCI [13].

Reversal

Despite the reductions in major bleeding rates identified in previous trials, there remains a concern for bleeding complications because of its long half-life. Fondaparinux does not bind to protamine sulfate, unlike UFH and LMWH [37]. Recombinant factor VIIa is recommended for uncontrolled bleeding attributed to fondaparinux. Recombinant factor VIIa is able to overcome thrombin inhibition by fondaparinux and has been shown to normalize the prolongation of aPTT and prothrombin time (PT) [76].

Direct thrombin inhibitors (bivalirudin, argatroban)

Use of direct thrombin inhibitors has shown benefit in preventing ischemic complications from PCI [77,78]. Direct thrombin inhibitors do not require antithrombin as a cofactor, unlike UFH, LMWH, and fondaparinux. Direct thrombin inhibitors are able to directly inhibit both circulating thrombin and clot-bound thrombin. They are also more predictable than heparins because they do not activate platelets (thus not neutralized by platelet factor 4 when platelets are activated) and do not bind to plasma proteins [79]. Without platelet activation there is no interaction with platelet factor 4, thus eliminating the possibility of immune-mediated heparin-induced thrombocytopenia (HIT). This makes direct thrombin inhibitors a safe alternative to heparin for PCI in patients with HIT [80]. The direct thrombin inhibitors currently available for use during PCI are bivalirudin and argatroban.

Bivalirudin

Bivalirudin is a synthetic analogue of hirudin that is slowly cleaved by thrombin and only transiently inhibits thrombin. Its quick onset of action achieving therapeutic ACT within 5 minutes and a short half-life of approximately 25 minutes contribute to its safe profile with lower risk of bleeding, making it attractive for use during PCI [79,81]. Bivalirudin has been extensively studied since its development. Studies have shown reduced incidences of bleeding compared with heparin when used as treatment with a thrombolytic agent for acute MI and unstable angina. After proving that it was a safe alternative to heparin in the setting of balloon angioplasty it was later suggested to lower ischemic complications in addition to a lower risk of bleeding [77,78,82–84]. These initial studies of bivalirudin were carried out in the era before use of GP IIb/IIIa inhibitors. The REPLACE-2 trial tested the safety and efficacy of using bivalirudin compared to heparin with planned use of GP IIb/IIIa inhibitors during PCI. The results showed that bivalirudin was non-inferior to heparin plus a GP IIb/IIIa antagonist with significantly less bleeding in the bivalirudin group. The secondary triple composite endpoint of death, MI, or urgent revascularization was non-significantly lower in the heparin plus GP IIb/IIIa group [85]. ISAR-REACT 4 trial showed similar rates of death, MI, or revascularization between bivalirudin and heparin plus GP IIb/IIIa inhibitor groups when used during PCI in patients with NSTEMI. However, the outcomes showed an increased risk of bleeding in the heparin plus GP IIb/IIIa inhibitor group [86]. The ACUTY investigators studied the outcomes of treating moderate to high risk ACS patients. Groups were divided as follows: UFH or enoxaparin with GP IIb/IIIa inhibitor; bivalirudin with GP IIb/IIIa inhibitor; or bivalirudin alone. Results showed bivalirudin had similar rates of ischemia whether or not it was used with GP IIb/IIIa inhibitors but had significantly lower rates of bleeding when used alone when compared with the heparin (or enoxaparin) plus GP IIb/IIIa

inhibitor group [87]. This was further expanded on by the HORIZONS-AMI trial investigators who compared outcomes of patients with STEMI treated with either bivalirudin alone or heparin plus GP IIb/IIIa inhibitors. Interestingly, there was a higher rate of stent thrombosis within 24 hours (1.3% vs. 0.3%; $p < 0.001$) but significantly reduced 30-day mortality (2.1% vs. 3.1%, $P = 0.047$) in the bivalirudin arm. The reduced 30-day event rate was largely because of the significantly lower rate of major bleeding with bivalirudin than heparin plus GP IIb/IIIa inhibitors (4.9% vs. 8.3%; $p < 0.001$) [88]. These studies were carried out in the era mostly using a femoral artery approach and were limited in almost exclusively comparing bivalirudin alone with heparin plus a GP IIb/IIIa antagonist but never with UFH alone. Several more recent studies have attempted to overcome this limitation. The radial artery approach has been increasingly used and is associated with less risk of bleeding, while dual oral antiplatelet therapy has become routine, diminishing the antithrombotic benefit of GP IIb/IIIa antagonists. A recent large randomized trial in a primary PCI STEMI population compared UFH alone with bivalirudin and found heparin alone was better at reducing ischemic events, including stent thrombosis, with no difference in bleeding complications [22].

Monitoring

Bivalirudin can typically be given immediately prior to PCI with 0.75 mg/kg IV bolus then 1.75 mg/kg/hour continuous infusion. It is renally excreted; however, no adjustments need to be made until creatinine clearance (CrCl) is less than 30. If the CrCl is 10–29 mL/minute then the infusion rate should be decreased to 1 mg/kg/hour; and decreased to 0.25 mg/kg/hour if the patient is on hemodialysis. This can be continued for up to 4 hours after the PCI procedure at the discretion of the physician [89]. Bivalirudin can cause elevations in multiple coagulation assays: aPTT, PT, INR, and ACT. Routine monitoring is not required with use of bivalirudin but can be performed with ACT. In REPLACE-2, the median ACT 5 minutes after a bolus infusion (0.75 mg/kg) followed by continuous infusion (1.75 mg/kg/hr) was 358 s. If ACT is < 225 s after first bolus, then an additional bivalirudin bolus of 0.3 mg/kg should be given. If ACT is > 225 s, then no further monitoring is required as infusion dose should maintain appropriate ACT levels. Because of the short half-life of bivalirudin (~25 minutes), an ACT is also not required before sheath removal [85,89,90].

Argatroban

Argatroban is a small, synthetically derived, direct thrombin inhibitor that reversibly binds to the active site of thrombin. It is metabolized through the liver and has a half-life of approximately 45 minutes [81]. Use of argatroban in combination with thrombolytic therapy compared with heparin with thrombolytic therapy has shown better rates of TIMI III flow on angiography at 90 minutes. Despite potentially better TIMI III flow rates there have been no differences in total mortality, recurrent MI, revascularization, or ischemic stroke. There was a non-significant lower incidence of bleeding in the argatroban group [91].

The prospective ARG-E04 trial tested three different doses of argatroban in comparison with UFH during PCI. In this study, argatroban rapidly and consistently achieved sufficient ACT prolongation to allow for shortened time to initiate PCI compared with patients receiving UFH (ACT target parameter of 250 s used for anticoagulation). There were no significant differences in angiographic success rates, composite endpoints (death, MI, or revascularization), or incidence of bleeding. This study proved that

argatroban dose-dependently achieved ACT prolongation more effectively than UFH in patients undergoing elective PCI with dual antiplatelet therapy (aspirin and clopidogrel). Importantly, this study provides evidence that argatroban has a predictable anticoagulant effect and can be used in patients undergoing PCI with dual antiplatelet therapy (only studied with aspirin and clopidogrel). Particular settings where argatroban may be most attractive is in patients with HIT or renal dysfunction when undergoing PCI [80,92].

Monitoring

Like bivalirudin, argatroban can cause elevations in multiple monitoring assays: aPTT, PT, ACT, and ecarin clotting time (ECA-T) which is sensitive only to direct thrombin inhibitors. There seems to be a consistent dose-effect relationship with using argatroban, regardless of the assay used. In contrast to UFH, argatroban causes a faster response in all coagulation parameters—quicker rise after initiation and normalization after stopping medication. ACT is the most appropriate method for monitoring the effect of argatroban in patients undergoing PCI [93].

Argatroban is given intravenously with bolus dose of 350 µg/kg followed by initial infusion rate of 25 µg/kg/minute. ACT should be checked within 10 minutes and can proceed with PCI if ACT >300 s. If ACT <300 s, give an additional 150 µg/kg bolus and increase the infusion rate to 30 µg/kg/minute. If ACT >450 s, decrease the infusion rate to 15 µg/kg/minute. An ACT level should be obtained within 10 minutes after any change to the infusion rate of argatroban [94].

Reversal of direct thrombin inhibitors (bivalirudin, argatroban)

There are no specific reversal agents available for direct thrombin inhibitors. In normal healthy subjects with normal kidney function, coagulation times will return to normal within 1 hour of discontinuing the infusion. Recombinant factor VIIa can reduce some of the bleeding effect from these agents. Hemodialysis can remove approximately 25% of bivalirudin or argatroban [37].

Antiplatelets

Platelets have a key role in arterial thrombotic events. Once normal endothelium is compromised, platelet adhesion, activation, and aggregation lead to thrombus formation. Adhesion of platelets to the site of vessel wall injury occurs via von Willebrand factor and other glycoprotein cell receptors (GP Ib/IX/V, GP IV, GP VI, GP Ia/IIa). Platelet activation occurs following adhesion which initiates further activation of surrounding platelets through secretion of platelet granules from agonists (adenosine diphosphate, collagen, thrombin), synthesis of thromboxane A₂, and increased expression of activated GP IIb/IIIa receptors on the platelet surface. The activation also facilitates binding of factors Va and VIIIa. Platelet aggregation occurs via fibrinogen acting as a bridge between GP IIb/IIIa receptors on neighboring platelets. Platelet aggregation leads to formation of a platelet plug which is further anchored by fibrin mesh developed from the coagulation cascade [14,95]. This important cascade of events leads to the serious complications of MI and stroke. Steps of the cascade can be interrupted by different classes of antiplatelet agents in order to minimize the risk of arterial thrombosis. Aspirin irreversibly inhibits the production of thromboxane A₂ by acetylation of cyclo-oxygenase-1 (COX-1). This reduces platelet activation and recruitment to the site of injury. Thienopyridines (ticlopidine, clopidogrel, prasugrel) and other adenosine diphosphate

(ADP) antagonists (ticagrelor, cangrelor) inhibit the P2Y₁₂ receptor, a key ADP receptor on the platelet surface. Ticlopidine, clopidogrel, and prasugrel irreversibly inhibit P2Y₁₂, whereas ticagrelor and cangrelor are reversible inhibitors of P2Y₁₂. GP IIb/IIIa inhibitors (abciximab, eptifibatide, tirofiban) inhibit platelet aggregation by preventing fibrinogen and von Willebrand factor from binding to activated GP IIb/IIIa [35]. Antiplatelet therapy is the standard of care, not only in patients undergoing PCI, but also in the acute and long-term management of ACS (Table 49.2) [95–97].

Aspirin

Aspirin (ASA) has long been recognized for its protective effect of thrombotic occlusive events and its importance in reducing incidence of death, MI, and stroke as seen in the large meta-analysis carried out by the Antithrombotic Trialists' Collaboration [98]. ASA has also been shown to significantly decrease mortalities in the setting of acute STEMI and severe cardiovascular complications in patients undergoing PCI. Since the benefit of ASA has been widely established, it is now the standard of therapy in clinical practice and routine background therapy when studying possible additive benefits of other agents used in treatment of ACS or during PCI [14].

Several studies have attempted to define the "optimal" dose of ASA. A dose of 75 mg achieves complete inactivation of COX-1 [35]. When comparing ASA 75 mg/day with high doses up to 1500 mg/day there has been no proven benefit but rather there is increased risk of bleeding (particularly gastrointestinal). There is less conclusive evidence on the benefit of doses less than 75 mg [99–101]. In situations where an immediate antithrombotic event is needed (i.e., ACS, ischemic stroke), a higher dose of aspirin (160–325 mg) should be given as either a chewed pill, solution, or even intravenously where available. Current PCI guidelines recommend giving ASA 325 mg at least 2 hours and preferably 24 hours prior to PCI [4,98]. Low doses of ASA (75–150 mg/day) are recommended for long-term prevention of vascular events in high risk patients with less risk of bleeding events [102].

Monitoring

Although not routinely utilized in the clinical setting, multiple methods of monitoring platelet function have been developed over time. These monitoring methods have been developed and studied in the setting of ASA therapy and in the evaluation of bleeding diatheses without antiplatelet therapy. Ideally, platelet monitoring assays would identify whether a patient who had an occlusive event (MI or ischemic stroke) while on ASA therapy was caused by treatment failure or treatment resistance, or prospectively identify the risk of a patient developing severe bleeding, especially in the setting of surgery.

The bleeding time was the initial and is still the only *in vivo* test of platelet function. Initially developed as a measure of bleeding diatheses and the influence of platelet count, but after decades of broad clinical use it was subsequently found not to be predictive of clinical bleeding in the setting of surgery or antiplatelet therapy [103]. Several point-of-care antiplatelet assays have been developed and studied in research settings; however, similar to bleeding time, there has been no clinical evidence that shows the clinical benefit of these monitoring methods. Light transmittance aggregometry (LTA) is the historic gold standard of platelet function testing which has shown a significantly higher risk of thrombotic events in patients with increased aggregation in the setting of ASA therapy. However, this test is labor intensive and technically demanding,

Table 49.2 Types and properties of common antiplatelet agents.

Mechanism of action	Time of onset (half-life)	Recommended point-of-care test	Platelet function test available	Reversal for bleeding
Aspirin Irreversibly inhibits COX-1,2 and thromboxane-A2	1–2 hours (~3 hours for doses up to 325 mg)	None	LTA	Platelets, Desmopressin
Clopidogrel Thienopyridine; Irreversibly blocks P2Y12 receptor	20–30% platelet inhibition at 6 hours; 300–600 mg (6 hours); 50–60% platelet inhibition at 5–7 days, 50–100 mg	None	LTA, VerifyNow®, ImpactR®, TEG®, VASP, Multiplate	Platelets, Desmopressin
Prasugrel	<30 minutes, 60 mg (7 hours)	None	LTA, VerifyNow®, ImpactR®, TEG®, VASP, Multiplate	Platelets, Desmopressin
Ticagrelor Non-thienopyridine; reversibly inhibiting P2Y12 receptors	41% platelet inhibition <30 minutes, 180 mg (6–12 hours)	None	LTA, VerifyNow®, ImpactR®, TEG®, VASP, Multiplate	Platelets, Desmopressin
Cangrelor	Rapid onset (3–6 minutes)	None	LTA, VerifyNow®, ImpactR®, TEG®, VASP, Multiplate	Platelets, Desmopressin
Abciximab Near irreversible, GP IIb/IIIa inhibition	<10 minutes (15–30 minutes)	None	LTA, VerifyNow®, PFA-100®	Platelets, Desmopressin
Eptifibatid Reversible GP IIb/IIIa inhibition	<60 minutes (2–3 hours)	None	LTA, VerifyNow®, PFA-100®	Hemodialysis, Platelets, Desmopressin
Tirofiban Reversible GP IIb/IIIa inhibition	<30 minutes (1.5–2 hours)	None	LTA, VerifyNow®, PFA-100®	Hemodialysis, Platelets, Desmopressin

COX, cyclo-oxygenase; GP, glycoprotein; LTA, light transmission aggregometry; PFA-100®, platelet function analyzer; VASP, vasodilator-stimulated phosphoprotein phosphorylation.

preventing its routine application in clinical practice. Simpler, point-of-care devices such as the VerifyNow aspirin assay have been developed and shown to correlate well with LTA. Studies using the VerifyNow aspirin assay found that patients with elevated platelet agglutination while receiving ASA had higher elevations of cardiac biomarkers (CK-MB, troponin I) when undergoing elective PCI. Unlike the LTA, the VerifyNow aspirin assay has less processing time and is easier to use. Despite these findings, there have been no studies to suggest change of therapy, based on point-of-care ASA assays, would have a benefit on clinical outcomes or cost efficiency [95,104,105].

Reversal

The antiplatelet effect of ASA lasts 5–10 days. Rarely does the antiplatelet effect of aspirin need to be reversed, with the exception of intracranial bleeding. However, if bleeding from aspirin needs to be reversed immediately, platelet concentrate can be administered, although banked platelets are also functionally diminished. Desmopressin, or DDAVP, can also be used to correct the antiplatelet effect of aspirin. Dosing is similar when used for hemophilia or von Willebrand disease: 0.3 µg/kg in 100 mL infused over 30 minutes [69].

P2Y₁₂ inhibitors (clopidogrel, prasugrel, ticagrelor, cangrelor)

Inhibiting P2Y₁₂ receptors for ADP provide additional antiplatelet therapy to ASA. Some studies suggest even synergistic platelet inhibition provides enhanced protection from thrombotic complications during PCI. The role of dual antiplatelet therapy beyond the setting of PCI is less clear and may be agent specific [100].

Clopidogrel received FDA approval in 1998 following the results of the CAPRIE trial which compared ASA only with clopidogrel alone. The clopidogrel group of patients had a statistically significant ($p=0.043$) lower risk of MI, ischemic stroke, or vascular death (9.8%) compared with the ASA group (10.7%). This study showed that clopidogrel is a safe and effective alternative to aspirin [106]. The CURE Trial was the first large-scale prospective trial of dual antiplatelet therapy versus ASA alone which found that when used for patients with unstable angina or NSTEMI, clopidogrel plus ASA reduces ischemic events relative to ASA, regardless of whether invasive or non-invasive therapy. There was a higher incidence of major bleeding events, with an increased risk of CABG-related bleeding limited to those who underwent surgery sooner than 5 days after discontinuing clopidogrel. The subanalysis of the PCI cohort, PCI-CURE, showed that ASA with clopidogrel pretreatment (median 6 days) followed by long-term therapy after PCI had a 31% reduction in cardiovascular death or MI at 30 days and 9 months ($p=0.002$) when compared to no pretreatment and short-term dual therapy (4 weeks after PCI). There was no significant difference in major bleeding between the groups [107]. The CREDO trial studied the benefits of pretreatment and long-term treatment (1 year) with clopidogrel and ASA in the setting of non-urgent PCI. The results showed a 26.9% relative risk reduction for combined incidence of death, MI, or stroke ($p=0.02$) at 1 year, although only a trend toward benefit at 30 days as a result of pretreatment [96]. A post hoc analysis of the results suggested that a longer interval between the loading dose of clopidogrel and PCI can further reduce peri-procedural thrombotic events. Patients receiving 300 mg clopidogrel at least 10–12 hours prior to PCI experienced a significant reduction in the combined 30-day endpoint [108]. Giving a loading dose of 600 mg clopidogrel to patients undergoing PCI raises the plasma

concentration of the clopidogrel-active metabolite and causes greater suppression of ADP-induced platelet aggregation. Further aggregation suppression was not significant with doses higher than 600 mg (i.e., 900 mg) [109]. Using a loading dose of 600 mg prior to PCI in comparison with 300 mg showed a significant reduction in the primary endpoints of death, MI, and target vessel revascularization at 30 days (4% vs. 12%, respectively; $p=0.041$). The 600 mg loading dose was associated with a lower incidence of periprocedural MI (OR 0.48, 95% CI 0.15–0.97; $p=0.044$) [110,111].

Use of clopidogrel in setting of acute STEMI treated with a primary non-invasive strategy gained acceptance following the results of CLARITY-TIMI 28 and COMMIT trials [112,113]. Patients with STEMI initially treated with a thrombolytic who then received clopidogrel prior to PCI showed reductions in death, recurrent MI, and stroke without increased bleeding [114]. The CURRENT-OASIS 7 trial was a large multicenter international study that showed benefit of using a double dose of clopidogrel for 7 days starting with a loading dose of 600 mg followed by 150 mg in comparison to the standard dose of 300 mg loading dose then 75 mg/day. There was a lower incidence in the primary outcomes of cardiovascular death, MI, or stroke when using a double dose of clopidogrel versus the standard dose (3.9% vs. 4.5%, respectively; adjusted HR 0.74–0.99; $p=0.039$). Lower incidence of MI was the main reason for this difference as there were similar rates of cardiovascular deaths and stroke between the two groups. Stent thrombosis was also much lower in the double dose group [115]. The GRAVITAS trial showed that a prolonged course of double dose clopidogrel at 150 mg/day versus 75 mg/day had no reduction in cardiovascular death, MI, or stent thrombosis even in patients with high platelet reactivity [116].

Prasugrel is a new thienopyridine proven to be beneficial in the treatment of patients with ACS undergoing PCI. Similar to clopidogrel, prasugrel irreversibly binds to the P2Y₁₂ receptor. Prasugrel is rapidly absorbed and nearly completely activated. In contrast, clopidogrel is more slowly absorbed and only ~15% undergoes metabolic activation [35]. The quick onset of action for prasugrel makes it attractive to use at the time of PCI, especially in the setting of ACS. Prasugrel 60 mg achieves high levels of platelet inhibition by 30 minutes as opposed to clopidogrel 300 and 600 mg doses which require 4–6 hours. The duration of platelet inhibition for both clopidogrel and prasugrel lasts for at least 5–7 days because of its irreversible binding of P2Y₁₂ receptors [117–119]. In patients with ACS scheduled to undergo PCI, TRITON-TIMI 38 proved prasugrel to be superior in both loading and maintenance doses (60 and 10 mg) to clopidogrel (300 and 75 mg) in preventing death, MI, ischemic stroke, urgent revascularization, and stent thrombosis (9.9% vs. 12.1%, hazard ratio 0.81; $p<0.001$). There was a significantly higher risk of major bleeding, specifically in patients aged >75 years, weight <60 kg, or with a history of stroke or TIA. The overall benefit with prasugrel is strengthened after excluding these patients (HR 0.74, 95% CI 0.66–0.84; $p<0.001$) [120–122].

Ticagrelor is a novel, non-thienopyridine, reversible P2Y₁₂ inhibitor that has a rapid onset of action within 30 minutes to peak platelet inhibition within 2 hours. Because of its reversible receptor binding properties, ticagrelor has a short half-life of 6–12 hours and requires twice daily dosing [117]. The PLATO investigators showed superiority of ticagrelor compared with clopidogrel in patients with ACS with or without STEMI, all on a background of ASA. Patients in the ticagrelor group had significantly lower rates of death from vascular causes, MI, or stroke without an increase in the rate of major bleeding. The benefits were evident at 30 days and

persisted at 1-year follow-up [123]. Early administration of ticagrelor (pre-hospital vs. in-hospital) prior to PCI has been shown to be safe and to reduce the incidence of stent thrombosis at 24 hours and 30 days [124].

Cangrelor is an intravenously administered non-thienopyridine that reversibly inhibits the P2Y₁₂ receptor, achieving high levels of platelet inhibition *in vitro* and *ex vivo*. It is notable for its very rapid onset of action and short half-life (3–6 minutes) [125]. Normalization of platelet function occurs within 60 minutes after discontinuing cangrelor. Prior large-scale randomized trials did not find cangrelor to be superior to placebo or clopidogrel 600 mg when used in patients with ACS or stable angina when given prior to PCI in terms of reducing composite endpoints (death, MI, or revascularization) [126,127]. More recently, a study has shown promise in the use of cangrelor when compared with clopidogrel loading doses at time of PCI for stable angina, ACS without ST-segment elevation, or STEMI. Patients receiving cangrelor had lower composite endpoint rates of death from any cause, MI, revascularization, or stent thrombosis at 48 hours (4.7% vs. 5.9%, OR 0.78, 95% CI 0.66–0.93; $p=0.005$) with peri-procedural MI driving most of the benefit. There was a non-significant increase in bleeding with cangrelor by some definitions [128]. Cangrelor is potentially an alternative agent in patients unable to take or adequately absorb enteral medications; however, at this time it is not commercially available.

Current guideline recommendations are to give a loading dose of a P2Y₁₂ inhibitor (i.e., clopidogrel 600 mg, prasugrel 60 mg, ticagrelor 180 mg) prior to PCI in ACS and non-ACS settings followed by maintenance dual antiplatelet therapy with ASA and a P2Y₁₂ inhibitor (clopidogrel 75 mg/day, prasugrel 10 mg/day, ticagrelor 90 mg twice daily) for at least 1 month after bare metal stent placement and at least 1 year after drug-eluting stent placement [4,129].

Monitoring

Tailored antiplatelet therapy based on platelet reactivity and responsiveness has been theorized to potentially improve outcomes. One theory regarding the concern of antiplatelet resistance is that there is actual platelet hyper-reactivity in the setting of the acute thrombotic event, although whether it is a cause or effect is not clear [130]. Several studies using the VerifyNow P2Y₁₂ assay have shown a correlation between higher platelet reactivity based on the assay and adverse cardiovascular outcomes including death [131]. The GRAVITAS trial aimed to evaluate whether tailoring clopidogrel after PCI would improve outcomes based on point-of-care platelet function assays but found no improvement in outcomes with higher dose antiplatelet therapy based on higher platelet reactivity [116]. Similarly, the ARCTIC trial found no differences in major adverse cardiac events (MACE) when antiplatelet therapy was tailored both before and after stent placement based on platelet function monitoring using the VerifyNow P2Y₁₂ assay (Accumetrics Corporation, San Diego, CA, USA) compared with standard treatment without monitoring [132]. The vasodilator-stimulated phosphoprotein (VASP) phosphorylation analysis is highly specific for P2Y₁₂ inhibitors showing strong correlation between platelet reactivity and clinical outcomes but it is not useful as a point-of-care method during PCI [133,134]. Another method of monitoring is using multiple electrode platelet aggregometry with the Multiplate analyzer (Roche, Basel, Switzerland). A study using the Multiplate point-of-care method was able to show a strong correlation amongst patients considered poor responders to clopidogrel (evident by higher platelet reactivity) with higher incidence of stent thrombosis [135]. Further, a study used the Multiplate analyzer to adjust antiplatelet

therapy in patients 12–36 hours after PCI and who were pretreated with clopidogrel. Patients found to have high platelet reactivity based on Multiplate analyzer results were randomized to either prasugrel or higher dose clopidogrel. This tailoring of therapy showed not only significantly more platelet inhibition, but lower incidence of death, MI, stent thrombosis, or stroke in the prasugrel group compared with the high dose clopidogrel group. The prasugrel group had a similarly lower risk than patients without high platelet reactivity. There was also less bleeding when switched to prasugrel [136]. Despite efforts made to identify an accurate and reliable point-of-care assay for P2Y₁₂ inhibitors at time of PCI and for tailored antiplatelet therapy, there is insufficient evidence that point-of-care platelet function testing for P2Y₁₂ inhibitors would be beneficial [137,138]. The ongoing TROPICAL-ACS trial, with an anticipated enrollment of 2600 using the Multiplate analyzer, will be one of the largest and definitive studies of the potential benefit of tailored antiplatelet therapy based on monitoring [139].

Reversing P2Y₁₂ antagonists

Bleeding while on dual antiplatelet therapy remains a difficult situation to manage. Patients who have undergone recent stent implantation are still at high risk of stent thrombosis until complete endothelialization occurs. Besides cangrelor, all P2Y₁₂ antagonists require days off therapy before platelet function is normalized. If the decision is made to reverse bleeding induced by P2Y₁₂ inhibitors, it is recommended to administer platelet concentrate. Desmopressin (DDAVP) can also be used to correct the effect on platelet aggregation [69].

Glycoprotein IIb/IIIa inhibitors (abciximab, eptifibatide, tirofiban)

Vessel trauma by PCI can lead to adhesion, followed by activation and aggregation of platelets. GP IIb/IIIa inhibitors offer additional protection from thrombus formation by preventing platelet aggregation and reducing risk of intracoronary thrombosis [140]. Currently, three GP IIb/IIIa inhibitors are available for use during PCI: abciximab, eptifibatide, and tirofiban. These agents block fibrinogen from binding to GP IIb/IIIa receptors. Meta-analysis of GP IIb/IIIa inhibitors during PCI has shown a 30-day mortality benefit in addition to fewer incidences of non-fatal MI and urgent repeat revascularizations. The strongest data supporting the use of GP IIb/IIIa inhibitors comes from trials studying abciximab [141]. The EPILOG and EPISTENT trials demonstrated sustained benefits in these endpoints up to 1 year whereas EPIC reported benefit at 3 years [10,142–144]. Select populations especially experience a protective effect during PCI with GP IIb/IIIa inhibitors: high risk ACS, diabetic patients, and those with chronic kidney disease [145].

The first developed GP IIb/IIIa inhibitor, abciximab, is a human-murine chimeric monoclonal antibody with high affinity for GP IIb/IIIa receptors leading to near-irreversible inhibition, although its plasma half-life is short. Approximately 50% platelet inhibition remains 24 hours after discontinuing abciximab. The EPIC trial first showed its clinical benefit during PCI with a 35% reduction in rate of primary endpoints (death from any cause, non-fatal MI, CABG, or repeat PCI for acute ischemia; placement of intra-aortic balloon pump to relieve refractory ischemia); a 10% reduction was observed after abciximab bolus alone [142,146]. The breakthrough trials EPIC, EPILOG, and EPISTENT demonstrated that treatment with abciximab and UFH (abciximab continued after procedure) was superior to UFH alone in reducing major adverse cardiac

events following PCI without significant differences in bleeding complications between the treatment groups [142–144].

Abciximab administration can improve outcomes in PCI for patients with STEMI. The ADMIRAL trial randomized patients to receive abciximab plus stenting or placebo plus stenting for treatment of STEMI. Abciximab improved coronary patency and left ventricular function with fewer incidences of reinfarction and recurrent ischemia. Although not statistically significant, there remained a mortality benefit from 30 days to 3 years after PCI treatment of STEMI in patients who received abciximab. In this 3-year follow-up period there was a 30% relative risk reduction of the composite endpoint of death and MI [147]. The CADILLAC trial randomized 2082 patients presenting with STEMI to treatment groups of balloon angioplasty alone, balloon angioplasty plus abciximab, stenting alone, or stenting plus abciximab. Use of abciximab showed significant improvements ($p < 0.001$) in the primary composite endpoint of death, reinfarction, stroke, and ischemia-driven target vessel revascularization. The endpoint occurrences were balloon angioplasty alone 20%, balloon angioplasty plus abciximab 16.5%, bare metal stent alone 11.5%, and bare metal stent plus abciximab 10.2%. These endpoints were mainly driven by revascularization as there were no significant differences between the groups treated with stents in terms of rates of death, stroke, or reinfarction [148]. Antonucci *et al.* [149] similarly demonstrated a reduction in composite endpoint of death, reinfarction, target vessel revascularization, and stroke at 1 month when comparing bare metal stent plus abciximab to bare metal stent alone (4.5% vs. 10.5%, respectively; $p = 0.023$). There was also smaller infarct size on technetium-99m sestamibi scintigraphy at 1 month. Abciximab is recommended for STEMI and high risk patients undergoing PCI. Abciximab is not recommended for low risk patients or non-invasive treatment for ACS [150,151].

There has been less convincing evidence for eptifibatide and tirofiban. Both are smaller molecules than abciximab. Eptifibatide is a synthetic heptapeptide (<1000 Da) that reversibly binds to a beta subunit of GP IIb/IIIa receptor, causing platelet inhibition correlating to the plasma level of the drug. It is metabolized by the kidneys with half-life of ~2–3 hours. Tirofiban is a tyrosine derivative non-peptide that is metabolized by the biliary system (30–40%) and primarily excreted by the kidneys (60–70%). Tirofiban half-life is ~1.5–2 hours [152].

The IMPACT-II trial randomized patients undergoing elective, urgent, or emergency PCI to one of three treatment arms: placebo, eptifibatide 135 µg/kg bolus followed by 0.5 µg/kg/min infusion, or eptifibatide 135 µg/kg bolus followed by 0.75 µg/kg/min infusion. There was no significant difference between the eptifibatide groups compared with placebo in the composite endpoint of death, MI, unplanned surgical or repeat percutaneous revascularization, or coronary stent implantation for abrupt closure. Additionally, there was no difference in outcomes between the eptifibatide groups [153]. It has been hypothesized that the doses used in this trial may have been insufficient to provide adequate platelet inhibition [14]. The PURSUIT trial investigators used higher doses of eptifibatide in patients with ACS, but without STEMI. Those patients undergoing early PCI (<72 hours) treated with eptifibatide 180 µg/kg bolus followed by 2.0 µg/kg/min infusion had a significantly lower 30-day composite endpoint of death or non-fatal MI than the placebo group (11.6% vs. 16.7%; $p = 0.01$) [154]. The ESPRIT trial randomized 2064 patients undergoing PCI to receive a high dose regimen of eptifibatide or placebo. The eptifibatide group received two boluses of 180 µg/kg administered 10 minutes apart followed by 2.0 µg/kg/

min infusion for 18–24 hours. Both groups also received ASA, heparin, and a thienopyridine as part of standard therapy. The primary endpoint was composite of death, MI, urgent target vessel revascularization, and thrombotic bailout GP IIb/IIIa inhibitor therapy within 48 hours after randomization. The trial was terminated early because of significant efficacy findings: primary endpoint reduced from 10.5% in placebo group to 6.6% in eptifibatide group ($p = 0.0015$). Although not frequent, major bleeding occurred more often in the eptifibatide group (1.3% vs. 0.4%; $p = 0.027$). This trial proved that pretreatment with eptifibatide as a GP IIb/IIIa inhibitor significantly reduces ischemic complications during PCI [155], and provided the recommended eptifibatide dosing in current guidelines for patients undergoing PCI treated with UFH [4].

Tirofiban showed a non-significant trend toward reduced endpoints of death, MI, revascularization in the balloon angioplasty-based RESTORE trial; however, there was also higher rates of major bleeding than with placebo [156]. Later, the PRISM-PLUS investigators demonstrated greater efficacy in patients with ACS treated with UFH plus tirofiban over UFH alone. The endpoint of death, MI, or refractory ischemia was reduced from 17.9% in the UFH alone group to 12.9% in the UFH plus tirofiban at 30 days ($p = 0.004$). Subgroup analysis of patients who underwent PCI provided further evidence that the combination of tirofiban with UFH compared with UFH alone reduced the endpoint incidence from 15.3% to 8.8% (risk ratio 0.55, CI 95% 0.32–0.94) [157]. In the TARGET trial, tirofiban was compared head-to-head against abciximab in a non-inferiority trial in ~5000 patients undergoing PCI. Surprisingly, tirofiban was found to be inferior to abciximab [158]. Subsequent studies suggested that the dose of tirofiban studied in TARGET was too low. Smaller trials have studied higher doses with encouraging results [159]. Current PCI guidelines recommend administration of GP IIb/IIIa inhibitors with UFH in patients with high risk ACS when not treated with bivalirudin and not adequately pretreated with a thienopyridine [4].

Monitoring

Although the GP IIb/IIIa inhibitors are beneficial during PCI, there is a narrow therapeutic window. Earlier studies on GP IIb/IIIa inhibitors showed higher risk of bleeding and thrombocytopenia (especially with abciximab). There is variability amongst GP IIb/IIIa inhibitors as a result of pharmacologic differences. For example, the plasma level of eptifibatide correlates closely with platelet inhibition, whereas abciximab does not provide good correlation because it has high affinity to the receptors and is cleared rapidly from plasma [160]. This brings up the important question as to how to best tailor GP IIb/IIIa therapy, not only during PCI, but also for the return of normal platelet function. The theoretical benefit of tailored therapy based on monitoring is met with the real-life limitations such as technical experience, expensive equipment, and transferring what is found *in vitro* to the clinical situation. It remains to be proven whether an assay can provide the most reliable results and be translated into clinical practice [161].

Light transmission aggregometry has historically been the gold standard of platelet function testing. Although it is based on the fibrinogen–GP IIb/IIIa aggregation, its poor reproducibility between laboratories, long sampling time, and labor-intensive requirements make it less appealing during PCI.

The best study to date correlating the efficiency of platelet inhibition through GP IIb/IIIa inhibitors with clinical outcomes was the GOLD multicenter study. This study used the point-of-care Ultegra-rapid platelet function assay (RPFA), known as the

VerifyNow assay. The VerifyNow assay provides a quick and simple means of monitoring GP IIb/IIIa inhibitors with results that correlate well with aggregometry and receptor-binding assays [162]. In this study, 485 patients were evaluated for the primary endpoint of MACE: death, MI, or urgent target vessel revascularization in hospital or within 7 days of PCI. The predominant GP IIb/IIIa inhibitor used was abciximab (84%), others received tirofiban (9%) or eptifibatid (7%). The dosing regimens for each medication were based on previously described trials showing potential benefit of their use in PCI. Platelet inhibition was achieved at high percentages in the initial 10 minutes ($96 \pm 9\%$), 1 hour ($95 \pm 8\%$), and 8 hours ($91 \pm 11\%$) after initiating therapy. However, at 24 hours the mean inhibition decreased to $73 \pm 20\%$ with wide variability. The patients in the lowest quartile of platelet inhibition ($<95\%$) at 10 minutes after GP IIb/IIIa bolus had a substantially higher incidence (14.4%) of MACE compared with those with $>95\%$ platelet inhibition (6.4%; $p = 0.006$). This study confirmed higher incidences of MACE are associated with lower levels of platelet inhibition but was not designed to demonstrate that altering therapy to achieve higher levels of inhibition improved outcomes. The study did not find a correlation between the level of platelet inhibition and major bleeding complications when using the point-of-care assay. However, an increased procedural ACT correlated with major bleeding [163,164].

Reversing GP IIb/IIIa inhibitors

Platelet monitoring for return to normal function is helpful in non-emergent situations; however, immediate reversal is warranted when major bleeding occurs or emergency CABG is needed. The pharmacodynamics of each GP IIb/IIIa inhibitor affect how they can be reversed in emergent situations. No direct antidote is available for any of the three available GP IIb/IIIa receptor antagonists.

Despite the long dissociation half-life from GP IIb/IIIa receptors of abciximab (up to 6–12 hours), it has a short plasma half-life (15–30 minutes) meaning that little of the medication remains in the plasma once discontinued. Platelet transfusion after discontinuing abciximab decreases the platelet receptor occupancy which is related to platelet function inhibition. Platelet transfusion leads to redistribution of abciximab from platelets saturated with the medication to transfused cells. This causes a “dilution” of bound GP IIb/IIIa receptors by abciximab with little hemostatic defect [165,166]. In addition to platelet transfusion, administration of desmopressin (DDAVP) can also have an additive effect in normalizing platelet function following GP IIb/IIIa inhibition [99].

Platelet transfusion is ineffective for the smaller molecule GP IIb/IIIa inhibitors (i.e., eptifibatid and tirofiban) because of their high plasma levels. The pharmacokinetic effect is dose dependent. The biologic half-life is ~ 2.5 hours for these agents based on the adjusted dosing for CrCl [146]. Reversal of the antiplatelet effect from eptifibatid and tirofiban occurs within 2–4 hours after discontinuation. It is typically considered safe to proceed with surgical procedure after the allotted time [166]. In patients with advanced renal insufficiency, where the time to reversal may be longer, hemodialysis can hasten the reversal of platelet inhibition induced by these agents [167,168].

Conclusions

Anticoagulation and antiplatelet therapy have been extensively studied since their inception. While certain agents have advantages and disadvantages relative to others, there will likely never be a “one

size fits all” medication. Therapies require tailoring based on the unique needs of the patient. This holds true during PCI where certain presentations or pre-existing comorbidities make one anticoagulant or antiplatelet agent better than another. It is important not only to understand which therapies are available but when one is preferable over another, what are their unique limitations, and what other tools are needed to achieve optimal use of the medication. Understanding how to monitor (if possible) the therapy and how to manage emergency situations (major bleeding) is as crucial as the technical skills required during PCI.

PART III

Hypertension and Structural Heart Disease

CHAPTER 50

Right Heart Catheterization and Pulmonary Hemodynamics

P. Christian Schulze

Friedrich-Schiller-University Jena, Jena, Germany

Right heart catheterization using floating catheters allows the analysis of right atrial, right ventricular, pulmonary artery, and pulmonary capillary wedge pressures, determination of cardiac output using the Fick principle, and thermodilution and analysis of blood oxygenation levels. Further, detailed screening for cardiac shunts and structural defects can be performed.

Risks during flotation catheter placement, invasive hemodynamics, and subsequent monitoring are very low. Most common are insertion-site hematomas. Central cardiac complications are extremely rare. Temporary cardiac arrhythmias during the procedure are common and usually self-terminating. When placed for long-term monitoring, line infection and sepsis can develop.

Balloon flotation catheters

Balloon flotation catheters are the established intravascular monitoring devices for the assessment of right heart (RH) function and hemodynamics. There are various types of balloon flotation catheter, which are all characterized by a soft, flexible, fluoroscopically visible structure with an inflatable balloon at the distal tip (Figure 50.1). The balloon allows floating of the device with the bloodstream from the right atrium into the right ventricle and further into the pulmonary artery. Thermistors allow thermodilution cardiac output measurements to be obtained. Further, through pressure sensors, cardiac pressures can be monitored. Internal lumens allow blood collections for Fick cardiac output measurements and shunt analysis.

Technique

Placement of flotation catheters can be performed through the internal jugular vein, most commonly on the right side, but other central sites including the left neck and through the subclavian veins are possible access sites. Further, peripheral right or left femoral vein access, in particular during standard left heart catheterization procedures, and through the brachial veins are common access sites. However, femoral access is limited by the inability of the patient to move and has been associated with higher rate of infections and site complications such as bleeding.

Standard placement technique follows a modified Seldinger technique. A 21-gauge guide needle is used to find and access the vein. Using the guide needle, a larger needle is used to enter the vein followed by advancement of a short guidewire. The needles are removed and a 7-Fr sheath is introduced into the vessel with an internal dilator. The dilator is then removed with the placement wire and stable blood flow through the lateral port confirmed followed by flushing of the sheath and the ports. With the sheath in place, the balloon flotation catheter is advanced into the vein and advanced by around 20 cm. At this point, the balloon is inflated allowing easy advancement of the balloon tip into the right atrium for measurement of right atrial pressure. Attention should be paid to the curvature of the catheter which is designed to be advanced from the neck with a tip pointing toward the left to facilitate crossing of the tricuspid valve from the right atrium. With further advancement, the tricuspid valve is crossed and the balloon placed in the right ventricle for pressure analysis. At this point, the catheter has to be redirected to point upwards with clockwise rotation and advancement into the right ventricular outflow track for crossing through the pulmonic valve into the main pulmonary artery. Once placed in the pulmonary artery, the catheter can be further advanced into a distal pulmonary artery and into the wedge position. Most commonly, the catheter floats into the right pulmonary artery and distally into a segmental artery in the right middle or lower lobe.

During the advancement of the catheter, deep inspiration maneuvers can be used to facilitate the movement of the balloon via the increased cardiac return and pulmonary flow during inspiration. If unable to move the balloon tip from a distal position in the right ventricle, which is more common during procedures from the femoral access sites because of the preformed structure and curving, a conventional 0.035-inch guidewire can be used to stabilize the catheter. An alternative technique for advancing the flotation catheter is by forming a loop in the right atrium with a lateral pointing of the balloon tip. With further advancement, the tip will point downwards and can be moved through the tricuspid valve into the right ventricle.

Placement of the flotation catheter in the cardiac chambers has to be confirmed by changes in specific waveforms and pressures

Figure 50.1 Swan–Ganz catheter with inflated balloon at the distal tip.

(Figure 50.2). Once a stable wedge position has been reached and the measurement has been achieved, the balloon should be deflated and the catheter be retracted by several inches for stable placement in the larger branches of the pulmonary artery to avoid accidental perforation. Prolonged positioning in the wedge position is to be avoided. Removal of the catheter requires deflation of the balloon, which has to be confirmed before retraction.

Pulmonary hemodynamics

Normal cardiac and pulmonary hemodynamics

Normal pulmonary hemodynamics are shown in Table 50.1 and illustrated in Figure 50.2. Cardiac and pulmonary hemodynamics are directly related to cardiac venous return and preload. Respiratory variation in inspiration with decreased intrathoracic pressure and increase venous return and in expiration with increased intrathoracic pressures and reduced venous return play an important part in the definition of cardiac pressures, filling, and hemodynamics. Of note, in intubated patients, these hemodynamics are reversed because of the positive end-expiratory pressures and respiratory dynamics associated with positive pressure ventilation. Normal cardiac filling pressures and hemodynamics with normal cardiac output are associated with central venous mixed saturations of >65%. Cardiac output can be calculated by the formula according to Fick:

$$CO = \text{oxygen consumption} / \text{Hg}(\text{g/dL}) \times 1.34 \times (\text{arterial O}_2 \text{ saturation} - \text{mixed venous O}_2 \text{ saturation})$$

(Hg – hemoglobin; O₂ – oxygen). Cardiac index is cardiac output corrected for body surface area (BSA):

$$CI = CO / \text{BSA}.$$

An important parameter of cardiopulmonary hemodynamics is systemic and pulmonary vascular resistance. Systemic vascular resistance (SVR) is calculated as follows:

$$SVR = (\text{mean arterial blood pressure} - \text{RA pressure}) / \text{cardiac output}.$$

SVR is found elevated in circumstances of increased vascular tone such as in hypertension and decompensated heart failure.

Pulmonary vascular resistance (PVR) is defined as:

$$PVR = (\text{mean PAP} - \text{PCWP}) / \text{cardiac output}.$$

Elevated PCR is a marker of lung disease and is found to be fixed and non-reversible in interstitial lung diseases, chronic obstructive pulmonary disease (COPD), and several forms of pulmonary hypertension. Reversible increases in PVR are typical for pulmonary hypertension caused by left heart failure or elevated filling pressures from volume overload. Pharmacologic testing for these changes are described later.

Heart failure and low cardiac output

The main indication for the analysis of cardiac filling pressures and hemodynamics is the suspicion of a low cardiac output state in the setting of heart failure with dilated or ischemic cardiomyopathy, valvular heart disease, and to diagnose cardiac or pulmonary causes of shortness of breath and fatigue. A low cardiac output state is characterized as cardiac output below normal (CO <4L/min or CI <2L/min/m² BSA). Associated filling pressures can be elevated, normal, or low depending on the fluid status of the patient. The MVO₂ is typically decreased leading to the diagnosis of a low cardiac output state. The Fick formula for calculation of cardiac output allows a more reliable method than the thermodilution method which can be affected by severe tricuspid regurgitation, not uncommon in severe heart failure.

Left heart failure

Central hemodynamics in patients with isolated left heart failure are characterized primarily by elevated left-sided filling pressures with notable increases in pulmonary capillary wedge pressure (PCPW) with or without elevated pulmonary arterial pressures (PAPs). Reduced cardiac output is shown by reduced MVO₂. Severe left heart failure induces all changes of right heart failure caused by increased right-sided filling pressures from impaired flow and the associated volume overload of the right ventricle.

Right heart failure

Right heart failure is most commonly a secondary phenomenon of left heart failure. Isolated right heart failure can occur acutely after right ventricular infarction and, rarely, caused by genetic right ventricular cardiomyopathies. Further, it occurs in 30–35% of patients following implantation of a left ventricular assist device because of the inability of the right ventricle to respond to the increased preload following surgery. Hemodynamics are characterized by increased right atrial pressures (>8 mmHg) with inappropriately “normal” or elevated pulmonary artery pressures.

Pulmonary hypertension

Pulmonary hypertension is defined as a mean pulmonary artery pressure of >25 mmHg. Many clinicians consider a mPAP of 21–24 mmHg as borderline pulmonary hypertension. The underlying type of pulmonary hypertension (WHO 1–5) defines the associated cardiac filling pressures. Group 1 PH (pulmonary arterial hypertension) is characterized by normal capillary wedge pressures (<15 mmHg) while group 2 PH (pulmonary hypertension with left heart disease) is defined by the presence of elevated capillary wedge pressures (>25 mmHg).

Shunt diagnostics

Cardiac shunt diagnostics is based on changes in the oxygen saturation caused by the mixture of oxygen-rich blood after lung passage with oxygen-depleted blood from the periphery. At any point,

Figure 50.2 Normal hemodynamics.

Table 50.1 Normal and pathologic cardiac hemodynamics and filling pressures.

	Right atrium	Right ventricle	Pulmonary artery	Pulmonary capillary wedge pressure	MVO ₂
Normal	<5	<30/5	<30/10 (<25)	<12	>65
Pulmonary hypertension	Normal or elevated	Normal or elevated	>25	Normal or elevated	Normal or reduced
Left heart failure	Normal or elevated	Normal or elevated	Normal or elevated	>15	Reduced
Right heart failure	>5–8	“Normal” or elevated	“Normal” or elevated	Normal	Normal or reduced

All pressures are in mmHg.

MVO₂, mixed venous oxygen saturation.

blood samples can be collected through the internal lumen of the catheter. Typically, sampling occurs in the superior vena cava, the inferior vena cava, the right atrium and ventricle at various positions as needed to specify positions of suspected defects, in the main as well as the left and right pulmonary artery.

Pharmacologic drug testing

Pharmacologic drug testing is a standard procedure in the catheterization laboratory and allows the characterization of elevated filling pressures, definition of right heart or left heart failure, and the definition of pulmonary hypertension as a primary or secondary phenomenon.

Inotropic drug testing using PDE5 inhibitors such as milrinone or beta-adrenergic stimulation using dobutamine is performed to test the contractile response in patients with reduced ejection

fraction and reduced cardiac output. A continuous infusion of the drug with continuous measurement of cardiac filling pressures and central oxygen saturations (MVO₂) are performed. Many centers define a positive response as an increase in cardiac output by >20% or a decrease in PCWP by >20%. Typical protocols allow increased doses of inotropes every 3–5 minutes with a full set of hemodynamics and MVO₂. Of note, cardiac hemodynamics might not change immediately, in particular in the setting of biventricular failure and volume overload, and a positive response might require testing not only acutely in the catheterization laboratory but also retesting after 24 hours.

Another role for pharmacologic drug testing is in the characterization of abnormal pulmonary artery pressure, elevated transpulmonary gradients (TPG), and increased PVR. This is of utmost importance for the evaluation of patients before heart transplantation as an increased TPG and PVR has been associated with the occurrence of right ventricular failure and increased morbidity and

Figure 50.3 Right heart catheterization and pharmacologic drug testing for the assessment of pulmonary hypertension. With continuous infusion of sodium nitroprusside (50 µg/mL/min), pulmonary artery pressure decreased from 50/18 to 26/7 mmHg. Pulmonary capillary wedge pressure (PCWP) remained stable at 7–9 mmHg. Note the v-waves at baseline which resolved in response to vasodilator infusion.

mortality after heart transplantation. Standard right heart catheterization is used as a first step. In the normotensive patient in the setting of elevated PCWP and increased PAP, pulmonary and systemic vasodilators can safely be tested. Most established is short-term infusion of sodium nitroprusside (nipride) with subsequent decrease in SVR and PVR as a result of the direct vasodilatory effect of nitric oxide on vascular smooth muscle cells. After baseline measurements, the dosage of sodium nitroprusside is increased stepwise from 25 µg/L/min by 25 µg/mL/min steps as illustrated in Figure 50.3. A positive response is defined as a decrease in PVR by >20%.

Invasive hemodynamics and cardiac filling pressure measurements are helpful in the characterization of patients with pulmonary hypertension for their response to pulmonary vasodilators and supplemental oxygen. A standard test involves a baseline right heart catheterization with definition of cardiac filling pressures and hemodynamics. High dose nasal oxygen is first applied to the

patient and the direct pulmonary vasodilatory response is assessed after 3–5 minutes using a full set of cardiac hemodynamics and systemic oxygen saturation measurements. In patients with normal PCWP, pure pulmonary vasodilators such as inhaled nitric oxide, epoprostenol (flolane), or iloprost (ventaxis) can be tested. Of note, such testing is contraindicated in patients with elevated PCWP because of the risk of inducing pulmonary edema caused by poor left heart function leading to worsening of pulmonary congestion. The response is monitored by continuous assessment of pulmonary artery pressure and repeated measurements of cardiac output. A positive response is defined as a decrease of mean PAP by >10 mmHg to reach an absolute value of 40 mmHg or lower.

Treatment of Pulmonary Embolism: Medical, Surgical, and Percutaneous

Ian del Conde and Barry T. Katzen

Miami Cardiac and Vascular Institute, Miami, FL, USA

Pulmonary embolism (PE) presents in a continuum of severity that spans from incidentally discovered subsegmental PE to massive PE resulting in cardiogenic shock and death. The main cause of death in patients with large PE is right ventricular failure, cardiogenic shock, and refractory hypoxemia. Therefore, rapid recanalization of the pulmonary arteries is the ultimate goal of all therapies for acute PE, regardless if pharmacologic (anticoagulation or systemic fibrinolysis), surgical, or catheter-based.

Risk stratification and patient selection

All patients presenting with PE should be risk-stratified with the goal of: (i) identifying patients who are at high risk of dying if they do not receive treatment with thrombolysis or surgical embolectomy; and (ii) identifying patients who are likely to develop chronic thromboembolic pulmonary hypertension (CTEPH). Whereas a number of well-validated risk stratification tools help identify patients at increased risk of death or clinical deterioration from PE, identifying patients who are more likely to develop CTEPH is more challenging. CTEPH occurs in 2–4% of patients after acute PE, and is mostly diagnosed in patients who are in their forties [1,2]. Recurrent PE, larger perfusion defects, and younger age at presentation appear to be some of the strongest predictors for the development of CTEPH [3]. Whether thrombolysis (systemic or catheter-based) or thrombectomy decrease the risk of developing CTEPH is not known, but there are small studies that suggest that aggressive revascularization of the pulmonary arteries in large PEs is associated with lower pulmonary pressures than in patients who receive anticoagulation therapy alone [4].

There are three main risk categories in patients with PE [5,6]. Each category carries a specific definition and has important implications regarding prognosis and treatment considerations:

- 1 Massive PE:** PE that results in persistent hypotension (systolic blood pressure <90 mmHg for over 15 minutes), vasopressor requirement, or in profound bradycardia (heart rate <40 b.p.m.). The short-term mortality in these patients can be as high as 50–65%.
- 2 Submassive PE:** diagnosed in patients with acute PE who have a normal blood pressure, but who have evidence of right ventricular (RV) dysfunction, which can be detected on physical examination, cardiac biomarkers, electrocardiography (ECG),

echocardiography, and chest computed tomography (CT) [6,7]. Patients are usually tachycardic, with an elevated jugular venous pressure. If the RV is significantly dilated, a right parasternal heave can be palpated. ECG findings of acute PE with RV strain include sinus tachycardia, incomplete or complete right bundle-branch block, T-wave inversions in leads V1 through V4, and the combination of an S wave in lead I, Q wave in lead III, and T-wave inversion in lead III (S1Q3T3).

Normotensive patients with acute PE who have any of the following factors at presentation are at increased risk of death and clinical deterioration: (i) RV systolic dysfunction, usually determined by echocardiography; (ii) RV dilatation, which can be demonstrated either by echocardiography or chest CT angiography, (iii) elevated plasma levels of brain natriuretic peptide (BNP) or N-terminal pro-BNP (NT-ProBNP); or (iv) evidence of myocardial injury, as assessed by elevated levels of troponin T and I [8–11]. Although patients with submassive PE have in-hospital mortality rates of around 2–3%, which is much lower than that of patients with massive PE [7,12], they are at increased risk of death or escalation of therapy (e.g., need for endotracheal intubation, cardiopulmonary resuscitation, thrombolysis). Consequently, these patients are often considered for thrombolysis.

RV dilatation is defined as the right ventricular diameter to left ventricular diameter ratio greater than 0.9 [13–15]. This ratio can be measured by echocardiography in the apical four-chamber view, measuring the maximal ventricular diameters at end-diastole. More commonly, however, the measurement is made on PE-protocol chest CT angiography. The RV/LV short-axis diameters are measured at the valvular plane. Maximal ventricular diameters are obtained by measuring the distance between the free ventricular wall and the interventricular septum, perpendicular to the septum. When making the RV measurements, contrast within the LV should be seen. Non-gated, axial images are sufficient for the accurate measurement of the maximal ventricular diameters, and reformatted four-chamber views are not required [16].

- 3 Low-risk PE:** patients with no high-risk features (i.e., normotensive with no evidence of RV dilatation or dysfunction, and with normal levels of pro-BNP and troponin I or T) have low mortality rates and generally do well with anticoagulation alone [17,18].

Therapies for acute PE

Patients with low-risk PE who have no contraindications to anticoagulation should be treated with anticoagulation alone [17,18]. Patients with massive PE are at high risk of death and should be considered for emergent systemic intravenous thrombolysis, which can be quickly administered in the emergency room or a hospital ward. Surgical embolectomy can also be considered if it can be performed quickly. Most contemporary catheter-based therapies take at least a few hours to achieve meaningful revascularization of the pulmonary arteries, and are therefore generally not the preferred strategy for most patients with massive PE who are hemodynamically unstable. Whether patients with submassive PE should be managed with anticoagulation alone, systemic thrombolysis, or catheter-based thrombolysis is still being hotly debated. Patients with submassive PE with a low or acceptable bleeding risk, and with evidence of severe RV dysfunction or myonecrosis can benefit from catheter-based therapies or even systemic thrombolysis. Surgical embolectomy is almost never performed in hemodynamically stable patients.

Medical therapy

Anticoagulation

Anticoagulation therapy remains a cornerstone in the management of patients with acute PE. Patients who have no low-risk PE can be considered for initial treatment with one of the new oral anticoagulants, potentially avoiding the need for initial parenteral heparin or low molecular weight heparins (LMWH). The preferred parenteral options for therapeutic anticoagulation include LMWH or fondaparinux [17]. For patients with end-stage renal disease, unfractionated heparin is an option. If heparin-induced thrombocytopenia is suspected, argatroban or bivalirudin can be used. If the patient is being considered for systemic or catheter-based thrombolysis, a short-acting intravenous anticoagulant, such as unfractionated heparin, is preferred because it can be discontinued and reversed rapidly. Short-acting intravenous anticoagulants should also be considered in patients with acute PE who are at high risk of bleeding (e.g., in the early postoperative period).

The new oral anticoagulants, including the factor Xa antagonists, rivaroxaban, apixaban and edoxaban, and the direct thrombin inhibitor, dabigatran, have now been studied in approximately 27,000 patients with venous thromboembolism (VTE) enrolled in phase 3 clinical trials [19–24]. These agents have similar efficacy to

standard anticoagulation (initial heparin/LMWH bridge to a vitamin K antagonist), but are associated with fewer bleeding complications, including a ~45–55% reduction in the risk of fatal bleeding or intracranial hemorrhage [25,26]. Another significant advantage of the new oral anticoagulants is that in contrast to coumadin, they are not cumbersome to take: all of these agents use fixed dosing and monitoring is not required; there are no significant food–drug interactions, and they have fewer drug–drug interactions than vitamin K antagonists. Table 51.1 summarizes the basic pharmacologic properties and FDA-approved doses for these drugs.

Systemic thrombolysis

The only FDA-approved fibrinolytic drug for the treatment of acute PE is recombinant tissue plasminogen activator (rt-PA, or alteplase). The standard, FDA-approved dose of rt-PA consists of a 100-mg intravenous infusion over 2 hours. Systemic thrombolysis is the first-line therapy in patients with massive PE and cardiovascular collapse, who have no contraindications to fibrinolysis, because it can be administered without significant delay, which may not be the case for interventional or surgical therapies. Table 51.2 lists absolute and relative contraindications to thrombolysis.

The main evidence derived from a randomized controlled trial to support thrombolysis in patients with massive PE comes from a very small trial in which patients with acute PE, hypotension, and heart failure were randomized to pharmacologic thrombolysis with 1,500,000 IU streptokinase infused in 1 hour followed by heparin, or to heparin alone [27]. The trial was stopped after the first eight patients were enrolled. All patients in the anticoagulation-alone arm died from heart failure whereas all patients in the thrombolysis group survived. Consistent with these findings, a meta-analysis of five trials suggested that systemic thrombolytic therapy in patients with massive PE resulted in a 55% reduction in the risk of death or recurrent PE (9.4% vs. 19.0%; odds ratio 0.45) compared with heparin alone [28]. Based on these data, it is generally accepted that patients with massive PE should be considered for emergent thrombolysis or revascularization of the pulmonary arteries, either surgically or through a catheter-based procedure [6,29,30]. The ninth American College of Chest Physicians (ACCP) and the American Heart Association (AHA) / American College of Cardiology (ACC) guidelines give a Class 2 C (very weak recommendation) and IIa (weight of evidence/opinion is in favor of usefulness) recommendations, respectively, to thrombolysis in massive PE [6,17]. The weak strength of these recommendations

Table 51.1 Novel oral anticoagulants for the treatment of acute venous thromboembolism.

Drug	Mechanism of action	Approved dose*	Half-life	Renal excretion	Pivotal VTE trials [ref]
Dabigatran etexilate	Direct thrombin inhibitor	CrCl >30 mL/min: 150 mg PO BID after 5–10 days of initial parenteral anticoagulation	12–17 hours	85%	RECOVER I and II [23,24]
Rivaroxaban	Direct factor Xa inhibitor	15 mg PO BID x 21 days with food, then 20 mg/day PO	5–13 hours	33%	EINSTEIN [21,22]
Apixaban	Direct factor Xa inhibitor	10 mg PO BID for 7 days, then 5 mg PO BID	9–14 hours	27%	AMPLIFY [19]
Edoxaban	Direct factor Xa inhibitor	60 mg PO once daily after 5–10 days of initial parenteral anticoagulation [†]	9–10 hours	50%	HOKUSAI-VTE [20]

BID, twice daily; CrCl, creatinine clearance; PO, per os (orally); VTE, venous thromboembolism.

* Dose approved by the US Food and Drug Administration for the treatment of acute venous thromboembolism.

[†] Edoxaban dose reduction: 30 mg once daily in patients with CrCl 15–50 mL/min, weight ≤60 kg, or if taking certain concomitant P-GP inhibitor medications.

is a reflection of the absence of high quality data (e.g., large randomized controlled clinical trials) to guide management in these patients rather than evidence of marginal clinical benefit.

Systemic thrombolysis in patients with submassive PE has also been studied. In the MAPPET study, 256 patients with submassive PE were randomized to alteplase plus heparin, or heparin plus placebo [12]. The primary endpoint, consisting of in-hospital death or clinical deterioration that required escalation of therapy (defined as need for catecholamine infusion, secondary thrombolysis, endotracheal intubation, cardiopulmonary resuscitation, or surgical or

catheter thrombectomy) was significantly reduced and the patient to receive thrombolysis, from 24.6% (heparin plus placebo) to 11% (alteplase plus heparin) ($p=0.006$). However, most of this benefit was driven not by decreased mortality, but by decreased rates of escalation of therapy. Although rates of major bleeding were higher in the thrombolysis group (3.6% vs. 0.8%), there was only one case of fatal bleeding and no cases of hemorrhagic stroke in patients treated with thrombolysis. More recently, in the PEITHO trial, 1006 patients with submassive PE were randomized to the fibrinolytic drug, tenecteplase, or placebo [31]. All patients received therapeutic anticoagulation with heparin. Death or hemodynamic decompensation (the primary outcome) occurred in 13 of 506 patients (2.6%) in the tenecteplase group compared with 28 of 499 (5.6%) in the placebo group, representing a 66% risk reduction ($p=0.02$). Similar to MAPPET [12], thrombolysis had no effect on mortality, and the difference in the primary outcome was primarily driven by lower rates of hemodynamic decompensation. These findings support the premise that rapid recanalization of the pulmonary arteries in submassive PE results in decreased hemodynamic decompensation. However, the cost of these benefits was a substantial increase in the risk of major bleeding, including hemorrhagic stroke (11.5% of patients who received tenecteplase experienced major bleeding, compared to 2.4% in the placebo group). Intracranial hemorrhage occurred in 2% of patients who received tenecteplase and 0.2% of patients who received placebo. The current ACCP and AHA/ACC guidelines give a Class 2C and IIB (usefulness/efficacy is less well established) recommendations, respectively, to the use of thrombolysis in patients with submassive PE [6,17].

Table 51.2 Contraindications to systemic thrombolysis.

Absolute	Relative
Any intracranial hemorrhage	TIA in the preceding 6 months Oral anticoagulation
Known intracranial lesions that predispose to bleeding (e.g., malignancy, aneurysms, or arteriovenous malformations)	Pregnancy of first postpartum week Non-compressible puncture sites
Ischemic stroke in the previous 3 months	Traumatic resuscitation Uncontrolled hypertension (SBP >180 mmHg)
Major trauma or surgery in the preceding 3 weeks	Advanced liver disease
Active bleeding	Age >75 years Infective endocarditis Active peptic ulcer

SBP, systolic blood pressure; TIA, transient ischemic attack.

Surgical embolectomy

Surgical embolectomy is a safe and effective technique in the treatment of acute PE when performed by an experienced cardiothoracic surgeon (Figure 51.1). Surgical embolectomy requires a median sternotomy and cardiopulmonary bypass. Although different surgical techniques have been described, an incision into the main pulmonary artery is usually made, allowing thrombus to be

Figure 51.1 Surgical embolectomy. The patient presented with massive pulmonary embolus (PE), with persistent hypotension. (a) Chest CT angiogram demonstrated a large, almost occlusive saddle embolus, with a severely dilated right ventricle. The patient underwent surgical embolectomy. (b) Large emboli (up to 10 cm in length) were retrieved. (c) Postoperative CT angiogram showed minimal residual emboli. removed. The incision can be extended into the distal pulmonary arteries when necessary. The degree of revascularization of the pulmonary arteries that can be achieved surgically is generally much more significant than with catheter therapies. Surgical embolectomy is most effective in patients with large central or saddle pulmonary emboli. Peri-operative mortality for patients undergoing surgical embolectomy has declined over the last two decades. Survival rates among patients with massive PE treated with surgical embolectomy have been reported to be as high as 75–86% [32,33].

Catheter-based therapies

Contemporary catheter-based treatment of acute PE offers significant versatility which can be advantageous for tailoring therapy to the individual patient. Techniques are based primarily on mechanical removal or fragmentation of the thrombus or a hybrid approach (pharmacomechanical therapy) which combines a mechanical approach with local thrombolysis. The mechanical component allows rapid recanalization of the pulmonary artery and increases exposure of the thrombus to the fibrinolytic agent. The pharmacologic component allows a steady reduction in thrombus burden via a longer catheter-delivered infusion of a fibrinolytic agent at a dosage that is typically a fraction of that used in systemic thrombolysis. An important principle is that in contrast to catheter-directed thrombectomy in other vascular territories (e.g., coronary arteries, lower extremities, or vascular grafts), interventional treatment of PE should be aimed at improving hemodynamic status rather than obtaining optimal angiographic results. Revascularization of the pulmonary arteries with contemporary devices and techniques is somewhat limited, and generally requires several hours. Therefore, catheter-based techniques are generally used in patients with submassive PE rather than in hemodynamically unstable patients.

Catheter-directed thrombolysis

In catheter-directed thrombolysis access is usually obtained through a femoral vein or the right internal jugular vein. A multi-holed infusion catheter is advanced into the pulmonary artery.

The catheter tip is positioned within or just proximal to the embolus. Although there are no standardized thrombolytic infusion protocols, common regimens include alteplase 0.5–1.0 mg/hour over a period of 12–24 hours. If two (i.e., bilateral) catheters are used, the dose in each of the catheters is halved. Typical total doses of alteplase are 20–30 mg over 24 hours. Whether anticoagulation should be continued during the infusion of the fibrinolytic agent is a matter of some debate. Most interventionalists hold full-dose anticoagulation during fibrinolysis, and instead infuse a reduced dose of heparin (e.g., 300–500 U/hour) through the sidearm of the access sheath. In otherwise young and healthy patients deemed at very low risk of bleeding, and who have significant thrombus burden, full-dose anticoagulation with a short-acting drug (e.g., unfractionated heparin) can be continued during the infusion of the fibrinolytic. Some interventionalists follow fibrinogen levels during the infusion of the fibrinolytic because it has been suggested (though not conclusively demonstrated) that significant drops in fibrinogen levels predict bleeding complications. Fibrinogen levels are determined at baseline, and then at 4–6 hour intervals. If the fibrinogen levels fall to 30–40% of their level at baseline (or an absolute level <100–150 mg/dL), then the dose of the fibrinolytic infusion rate can be reduced.

Ultrasound-assisted thrombolysis

The EkoSonic Endovascular System (EKOS Corporation, Bothell, WA, USA) (Figures 51.2 and 51.3) is the only catheter at this time to have been cleared by the Food and Drug Administration (FDA) for use in treating patients with acute PE. The device consists of two endovascular devices: an Intelligent Drug Delivery Catheter (IDDC), which is a 5.2 Fr multi-lumen infusion catheter, and a MicroSonic Device (MSD) containing several evenly spaced ultrasound transducers positioned along the treatment zone. The EkoSonic device is capable of simultaneously infusing a fibrinolytic drug within the pulmonary artery, and of emitting low-power, high-frequency (2.2 MHz) ultrasound that “loosens” the thrombus, increasing penetration of the fibrinolytic drug into the

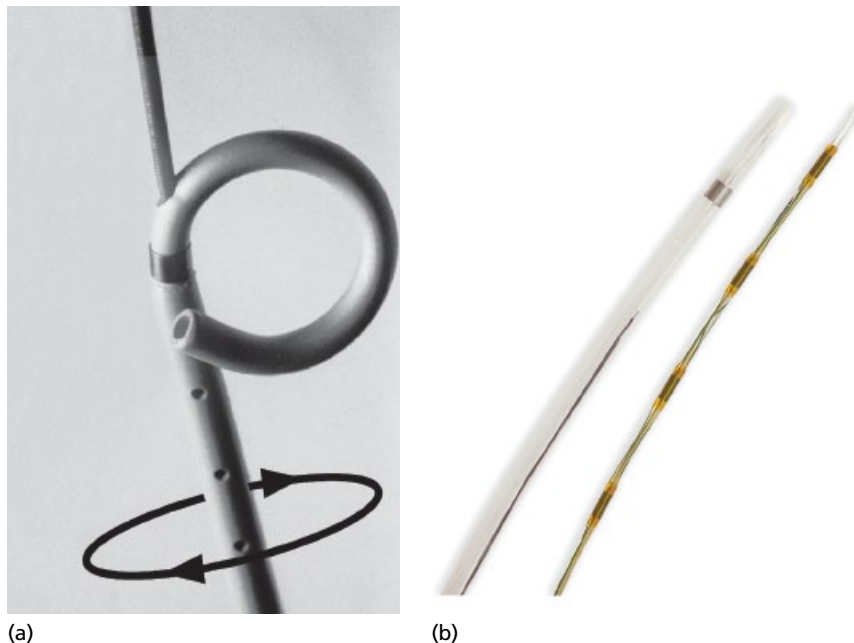

Figure 51.2 (a) Rotatable pigtail catheter. (b) EkoSonic Endovascular System. See text for details.

Figure 51.3 Catheter-based therapy for a patient with submassive PE. (a) Saddle embolus extending into the bilateral main pulmonary arteries (arrows). (b) Marked right ventricular (RV) dilatation (asterisk) with a RV : LV ratio of 1.7. (c) Pulmonary angiogram shows a large filling defect within the right pulmonary artery. (d) An EkoSonic catheter was placed in the bilateral pulmonary arteries. Tissue plasminogen activator (tPA) was infused at a rate of 0.5 mg/hour through each catheter for approximately 12 hours.

thrombus, and (theoretically) accelerating thrombolysis. This is one of the best studied modern devices for the catheter-based treatment of acute PE. The SEATTLE-II trial was a prospective, single arm trial that evaluated the efficacy and safety of the EkoSonic catheter to reverse right ventricular dilatation on chest CT angiography in 150 patients presenting acute PE with an RV : LV ratio ≥ 0.9 [34]. Of enrolled patients, 79% had submassive PE, while 20.7% met criteria for massive PE. The alteplase dose protocol was 1 mg/hour for 24 hours with the use of a unilateral catheter, and 1 mg/hour/catheter for 12 hours in patients receiving bilateral catheters. Successful device placement was achieved in 97.5% of patients. The mean total dose of alteplase administered was approximately 24 mg. At 48 hours, there was a 30% decrease in the RV : LV ratio, from 1.55 pre-procedure, to 1.13 ($p < 0.0001$). Similarly, pulmonary artery systolic pressures dropped from 51 mmHg pre-procedure to 37 mmHg at 48 hours. Major bleeding was experienced by 11.4% of patients within 30 days, but there were no cases of intracranial hemorrhage.

Suction embolectomy

The AngioVac System (AngioVac, Vortex Medical, MA, USA) is a suction device that allows the suction of intravascular material (e.g., thrombus, myxoma, and vegetation) while maintaining extracorporeal circulation. This option can be attractive in patients with large central PE [35], or those who are ineligible for thrombolysis. The system consists of two components: the AngioVac Cannula catheter, and the AngioVac Circuit (Figure 51.4). The 25-Fr catheter has a balloon-expandable funnel at the tip that functions as a cannula. The catheter can be advanced percutaneously or through a surgical cutdown, usually through groin access, although some interventionalists have used this system through the right internal jugular vein. An adjustable amount of suction (up to 80 mmHg) is applied at the cannula to suction the unwanted material; blood is filtered and then returned via another sheath to a contralateral large peripheral vein. The Circuit system has features of a cardiopulmonary bypass circuit and requires a trained perfusionist for its operation. The limited flexibility and maneuverability of the 25-Fr

Figure 51.4 The AngioVac System. Unwanted intravascular material is aspirated with the AngioVac cannula. Blood is filtered, and then reinfused into a large peripheral vein.

catheter is an important limitation of this system in the treatment of patients with PE.

Right ventricular assist device

Although experience with right ventricular assist devices (RVAD) for the treatment of massive PE is extremely limited, there are case reports that suggest they can be a life-saving intervention in carefully selected cases. As opposed to extracorporeal membrane oxygenation (ECMO), which bypasses the entire pulmonary circulation, RVAD only bypasses the RV. RVADs can be placed surgically, or percutaneously. In at least one recent case report of a 48-year-old patient with acute massive PE and persistent cardiogenic shock, bypassing the acutely failing RV, but not the pulmonary circulation, with a percutaneous RVAD stabilized the patient and led to a full recovery [36,37].

Rotatable pigtail catheter

This is an early technique in catheter-directed therapies for PE [4,38,39]. A high-torque 5-Fr pigtail catheter is advanced over the wire and wedged within the thrombus. The catheter has a radiopaque tip, 10 side holes, and an oval side hole in the outer tangential plane of the loop that allows straight passage of the guidewire (Figure 51.2). Once positioned within the thrombus, the loop is rapidly spun around the axis formed by the catheter and guidewire, fragmenting the thrombus. This is a purely mechanical form of thrombolysis which can be considered in patients with massive or submassive PE, with contraindications to pharmacologic thrombolysis, and who are not candidates for other surgical or catheter-based therapies.

Aspirex

The Aspirex device (Straub Medical, Wangs, Switzerland) has three components: the catheter (usually 6, 8, or 10 Fr), a control unit, and an electric motor (drive). At the tip of the catheter there is a helix-like driveshaft inside the catheter tubing, creating negative pressure that allows thrombus aspiration through a distal aspiration port. Although the device has been extensively tested in animals, and there are a numerous published small case series that suggest its efficacy and safety, it has not been approved by the FDA, and is not available in the USA.

Rheolytic thrombectomy (AngioJet)

The AngioJet device (Medrad Interventional, PA, USA) consists of a double-lumen catheter that generates high-pressure saline jets at the catheter tip, creating a vacuum that allows thrombus aspiration. There are numerous reports of the development of severe bradyarrhythmias (including high-degree AV block and asystole) and death developing within seconds of activating the system [40–42]. These concerns have prompted the FDA to issue a black-box warning regarding intrapulmonary interventions with the AngioJet system.

Inferior vena cava filters

The only indication for an inferior vena cava (IVC) filter use in patients with acute PE that all major societies agree with is in patients who have contraindications to anticoagulation (AHA/ACC class I recommendation, level of evidence B). Other more controversial indications include patients with acute PE who have poor cardiopulmonary reserve and who are deemed to be at high

risk of death if they develop another PE (Class IIb recommendation, level of evidence C). Most patients with massive or submassive PE fall into this category. In a recent analysis from a Nationwide Inpatient Sample that included over 2 million patients who were discharged with a diagnosis of PE, IVC filter use was associated with lower in-hospital mortality in patients with massive PE, and in stable PE patients who underwent thrombolysis [43]. IVC filter placement has been shown to reduce the incidence of recurrent PE, but not to lower long-term mortality. IVC filters do not prevent continued thrombus formation, and can increase the risk of deep venous thrombosis. Patients who receive removable IVC filters should be re-evaluated periodically for retrieval of the filter as soon as deemed safe.

Conclusions

All patients with acute PE should be risk-stratified as soon as the diagnosis of PE is made. Patients who meet criteria for massive PE should receive systemic thrombolysis, unless there are any contraindications. Surgical embolectomy is also an option if it can be performed quickly. Because revascularization of the pulmonary arteries with catheter-based therapies generally takes at least a few hours, these strategies are rarely used in hemodynamically unstable patients. However, catheter-based therapies should be considered in patients with submassive PE who do not have increased bleeding risk, especially if there is evidence of significant RV dilatation or dysfunction, or myonecrosis. Currently, there are no standard protocols for catheter-based therapies for PE, and the strength of recommendations for this strategy are overall weak. The catheter or device used is usually determined by institutional experience and resources. The strongest indication for IVC filter use is in patients with acute PE who are ineligible for anticoagulation. However, selected patients with submassive or massive PE can also benefit from placement of a retrievable IVC filter, even if they are candidates for anticoagulation.

Hypertension is a common condition with an estimated 1 billion individuals affected worldwide [1]. In 2010, it was the leading single risk factor for mortality and accounted for 9.4 million deaths worldwide [2]. Worryingly, its prevalence is increasing and it is estimated that over the next two decades hypertension will affect approximately half of the world's population [1].

A meta-analysis of almost 1 million patients confirmed a linear relationship between blood pressure and vascular mortality [3]. This linear dose–response relationship serves to remind us that not only are those patients with higher blood pressure at greater risk of cardiovascular events, but also that any reduction in blood pressure will help reduce this risk. Indeed, a 2-mmHg reduction in systolic blood pressure is expected to reduce stroke mortality by 10% [3].

Despite an awareness of hypertension and its harmful consequences being described in texts dating back to ancient China (2600 BC), effective therapies were not first reported until the 1900s [4]. Two therapeutic options were available: the low sodium Kempner diet and surgical sympathectomy. Though sometimes efficacious, neither was well tolerated by patients and both fell out of favor in the 1950s when the first effective antihypertensive medications were developed [4].

Therapeutic options have progressed since then. The most recent international guidelines on the management of hypertension (from the European Society of Cardiology) [5], suggest that following diagnosis patients should implement lifestyle changes which include sodium restriction, moderation of alcohol consumption, dietary changes, weight reduction, regular physical exercise, and smoking cessation. In conjunction with this, medications are also required and currently the available classes of antihypertensives include: angiotensin-converting enzyme inhibitors, angiotensin II receptor antagonists, calcium-channel blockers, and diuretics. Further treatment strategies include aldosterone-receptor antagonists, adrenoreceptor (α or β) blockers, and centrally acting agents.

Resistant hypertension

Amongst treated hypertensive patients, only 50% will achieve adequate control [4]. Those who do not are either not compliant with medications, are under-medicated, or are misdiagnosed and have white coat hypertension [6]. Up to 20% of patients with

uncontrolled hypertension develop secondary (and thereby potentially curable) forms of hypertension [7]. Those that remain are classified as having resistant hypertension, defined as blood pressure consistently $>140/90$ mmHg despite compliance with at least three classes of antihypertensives (one of which is a diuretic) at maximally tolerated doses [6].

The resistant hypertension cohort tends to have a longer duration of hypertension, greater end-organ damage, and a greater mortality rate than non-resistant hypertensive patients [6]. As such, this high-risk patient group would benefit from intensive treatment. However, the evidence-base guiding management of resistant hypertension is sparse; there are fewer than 10 randomized, controlled, and blinded studies involving patients with resistant hypertension. There has been resurgence of interest in the management of this condition driven by the development of novel non-pharmacologic therapies. In this chapter, we review one of these therapies, renal denervation, and summarize its journey from bench to bedside.

Rationale of targeting the renal sympathetic nervous system

An important factor underlying several forms of hypertension is an elevated level of sympathetic nerve activity. Neurogenic control of blood pressure is evidenced by the increase in blood pressure in patients with hypertension when waking up, coincident with the morning surge in sympathetic activity [8]. The role of the sympathetic nervous system in hypertension has further been conclusively demonstrated in animal and human studies using complementary techniques [9,10]. A dose–response relationship has been demonstrated, in that those individuals with higher blood pressure also display evidence of greater sympathetic activation [11]. It is the sympathetic efferents and sensory afferents of the kidney that are particularly important for the development and progression of hypertension [12].

Sympathetic nerve fibres originating from the brainstem supply the renal vasculature, tubules, and juxtaglomerular apparatus via the thoracic sympathetic ganglia (T10–12) [13]. Activation of the nerves at each of these sites is associated with reduced renal blood flow, salt and water retention, and activation of the renin–angiotensin–aldosterone

system, which all promote hypertension [13]. Furthermore, afferent nerves originating predominantly from the renal pelvic wall travel to the brain and contralateral kidney via the dorsal root ganglia. The role of these nerves in hypertension is less well defined. Animal studies have demonstrated that electrical stimulation of these afferent nerves can produce sympathetic activation and augment blood pressure, though contradictory findings have also been published [14]. There is some evidence that sensory signals from the kidney can augment whole body sympathetic tone thereby not only activating renal efferents, but also efferent fibres to the heart and peripheral vasculature [15]. In animal models of hypertension, surgical denervation of the renal sympathetics (afferent and efferent) significantly reduces blood pressure [16].

However, the relationship between blood pressure and the sympathetic nervous system is complex and is not the panacea for blood pressure control. First, using the noradrenaline spillover technique it has been shown that the sympathetic nervous system in hypertensive patients is most activated in those aged 20–39 years and that with increasing age this effect attenuates [17]. This suggests that in the majority of patients with hypertension (i.e., those older than 40 years), the renal sympathetic nervous system is not as important a target. Second, hypertension is not always neurogenic in origin (e.g., patients have secondary causes of hypertension). Finally, even less is known about the role of the sympathetic nervous system in those with resistant hypertension and interestingly there is some evidence to suggest that sympathetic activity in resistant hypertension could be related to prescribed drugs, notably diuretics and vasodilators [8]. Others have shown that the level of sympathetic activity in patients with resistant hypertension is similar to healthy non-hypertensive elderly individuals [8].

Surgical sympathetic denervation

Prior to the advent of effective antihypertensive medications, patients with malignant hypertension (hypertension with papilledema) had a mortality rate of 100% at 5 years [4]. There was already data in that era to suggest that the sympathetic nerves were important for the genesis of hypertension and it was in this climate that surgeons were spurred to perform sympathectomies for hypertension.

The surgical technique involved either a selective renal sympathectomy (renal decapsulation or cautery/transection of the renal sympathetic nerve) or a non-selective ganglionectomy. Large series of patients with severe hypertension, including individuals with end-organ damage, experienced a reduction of BP accompanied by an improvement of mortality after sympathetic splanchnicectomy [18–20]. Interestingly, an improvement of mortality was also observed in patients who did not exhibit a meaningful BP reduction [19,20]. Responses to this therapy were variable and frequently there was a constellation of associated non-desirable autonomic side effects [18]. With the development of the first antihypertensive medications, surgical denervation was removed from the physician's armoury as a treatment for hypertension.

More recently, the value of surgical denervation has been realized in a sub-selected group of patients within renal transplant medicine. In patients who remain hypertensive after renal transplantation, native nephrectomy (which involves interruption of the renal sympathetic nerves) has been shown to improve blood pressure control and improve allograft perfusion by attenuating the heightened neurohumoral activation from the diseased kidneys [21].

Percutaneous denervation

With the maturation of percutaneous intervention and radiofrequency ablation for the treatment of cardiac arrhythmias, it was not a large theoretical leap to conceive a device and technique to ablate the renal sympathetic nerves. To take this step, an understanding of the anatomic relationship between the lumen of the renal artery and the sympathetic nerves is required, as is an understanding of the effect of radiofrequency energy on the tissue around the ablation catheter tip.

Anatomy of the renal sympathetic nerves

Initial work in human cadavers lent support to the feasibility of renal denervation using ablation through the renal artery lumen. These data suggested that over 90% of the renal nerves (afferents and efferents) were located circumferentially within 2 mm of the lumen wall of the renal artery in the adventitia, making them amenable to disruption with ablation [22].

This work has since been surpassed by Sakakura and colleagues who performed a human autopsy study with key differences: they examined a larger number of individuals and nerves (20 patients with 10,320 nerves vs. 5 patients with 956 nerves); they used a perfusion-fixed technique under physiologic pressure; and histologic analysis was performed of the whole peri-renal tissue as opposed to the first 2.5 mm of peri-vascular tissue [23]. They demonstrated that while there was a greater density of nerves in the proximal and mid segment of the renal artery, the nerves in the distal segment were closer to the renal artery lumen and hence more accessible to ablation. In a small subset they also found that there was no difference in nerve anatomy between hypertensive and non-hypertensive subjects.

Accessory renal arteries were also shown to be associated with sympathetic nerves. They confirmed that renal arteries are surrounded by both afferent and efferent nerves, though the latter are more numerous. In contrast to the earlier work they discovered that 28% of the sympathetic nerves are more than 4 mm away from the artery lumen, suggesting that a significant proportion of nerves are not accessible to current ablation technology (Figure 52.1). What remains unknown is the proportion of nerves that need to be interrupted to produce physiologic changes and clinical benefit.

Ablation catheter technology and the biophysics of ablation

There are six CE marked renal denervation catheters commercially available (Table 52.1). Five deliver radiofrequency energy (RF) while the other uses ultrasound. RF and ultrasound are forms of energy that exist on the electromagnetic spectrum. Both techniques lead to tissue damage through a process of resistive heating as consequence of energy being deposited in the area of interest (ablation is not synonymous with cautery). As the target tissue heats up, this then conducts heat to the surrounding tissues leading to expansion of the ablation lesion [24].

Ablation lesion size is determined by the power and duration of energy delivery, tissue contact of the catheter (this is important for RF only) and electrode cooling/tissue temperature [24]. As such, it cannot be assumed that each of the available catheters creates comparable lesions. The duration of energy delivery for each catheter varies between 10 to 120 seconds, but is usually less than 2 minutes per application. The latest generation multi-electrode catheters enable all electrodes to be activated simultaneously thereby reducing overall procedure time and radiation exposure. Cooling of the lumen wall is an important feature of ablation as this enables greater

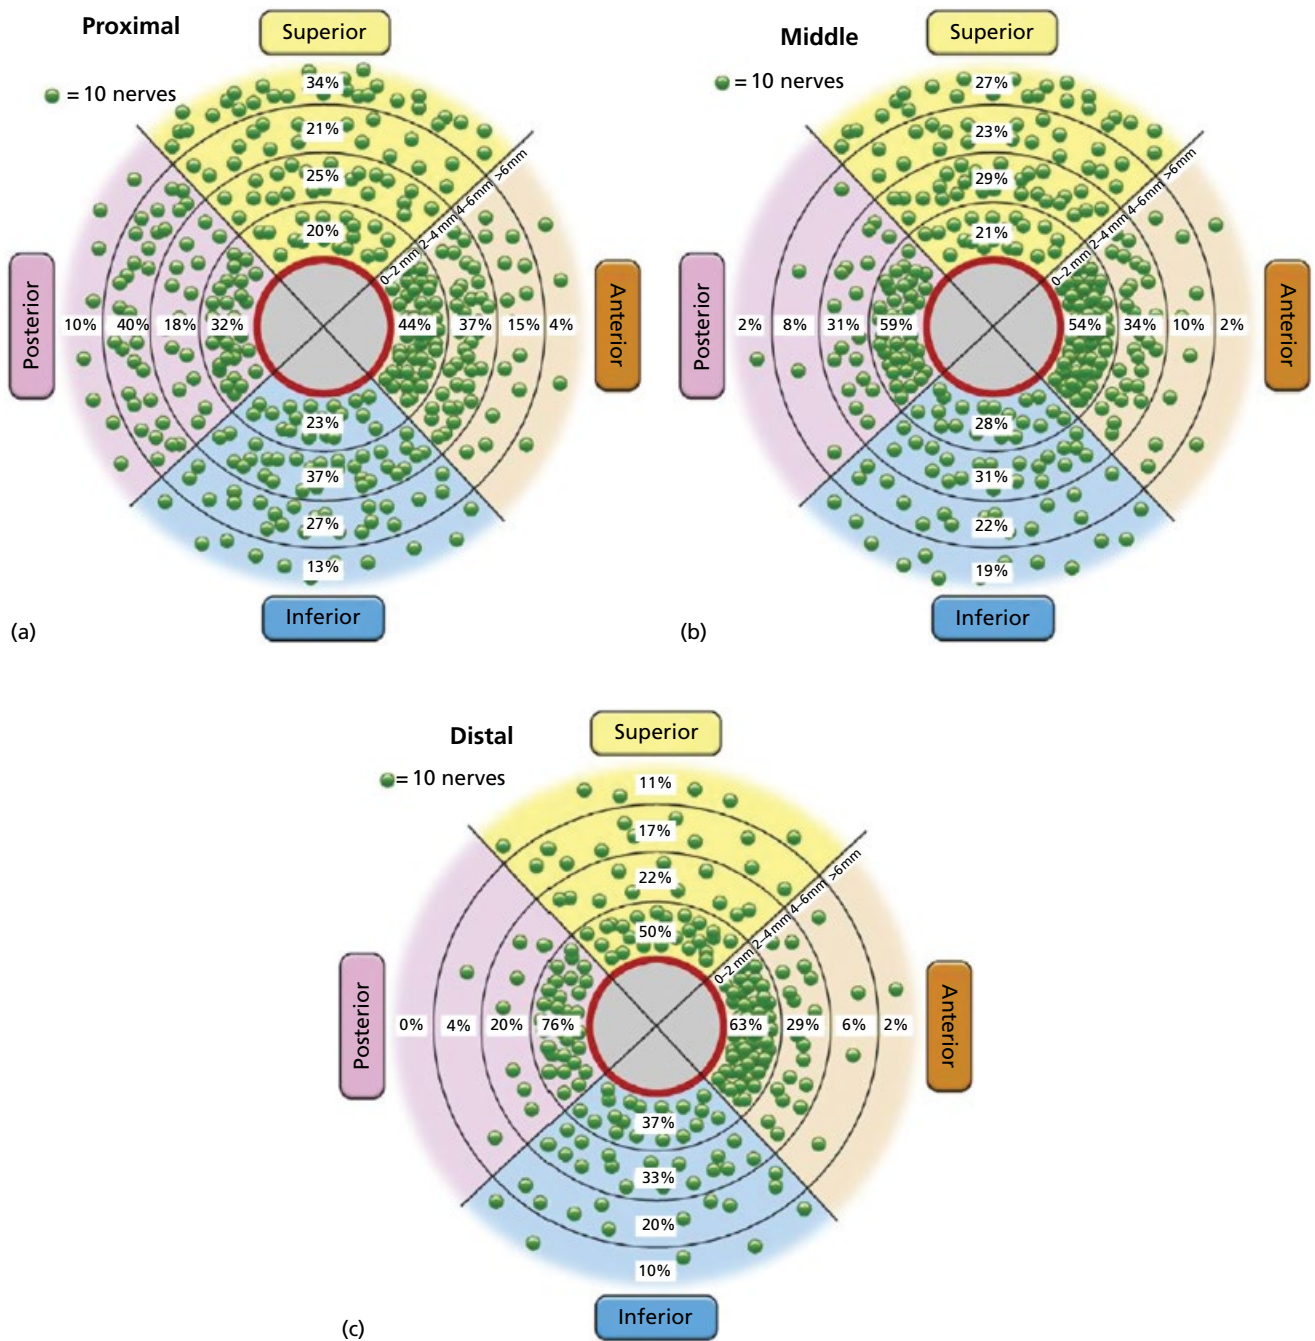

Figure 52.1 The distribution and density of renal nerves in the proximal (a), middle (b), and distal (c) portion of the renal artery. Each green dot represents 10 nerves. Source: Mahfoud F, *et al.* 2014 [44]. Copyright 2014 Elsevier.

energy deposition along with reduced surface damage. The current catheter systems rely either on renal artery blood flow or irrigation to cool the endothelial surface of the artery. Although each system is tested on large mammals as part of the approval process, the results of these investigations are not widely available making it difficult to compare the depth of lesion created by each technology. A recent case report of a postmortem of a 36-year-old woman who had undergone renal denervation showed that the ablation did not extend further than 2 mm from the lumen [25].

Trial evidence

The first-in-man experience of renal denervation therapy was reported in the pilot study, SYMPPLICITY HTN I, which used the Medtronic single electrode Flex catheter [26]. A series of safety measures were built into this pilot study. First, all participants were at the severe end of the spectrum of resistant hypertension with entry criteria mandating a systolic blood pressure of 160 mmHg or greater. Second, the first 10 patients underwent a staged procedure with the first procedure treating one renal artery followed by a

Table 52.1 The currently available renal denervation catheters with CE mark.

Catheter	Energy	Electrode	Balloon (sizes)	Cooling	Lesion	Ablation T	Max power (W)	Size (Fr)	OTW

second procedure a month later to treat the other kidney. A third angiogram was performed 2 weeks after the second procedure. The renal arteries were assessed once more at 6 months with a magnetic resonance angiogram. Following the original publication ($n=88$), the study was extended and data are now available for 111 patients with 3-year follow-up [27].

There were no major safety concerns from this pilot study and at 1-month follow-up there was a 21/10 mmHg reduction in office blood pressure. The patients who completed 3 years' follow-up displayed a further reduction in blood pressure at 32/14 mmHg below baseline. The results of this trial must be interpreted within the constraints of first-in-man study design: a single-arm, open labeled trial that ultimately should be viewed as showing no evidence of undue harm and a strong signal for efficacy. Similar first-in-man studies have reported efficacy and safety with the other catheter designs [28,29].

This was followed-up by two more SYMPLICITY studies in which the same catheter system was used. SYMPLICITY HTN-2 was a multicenter, randomized, open label trial [30]. Fifty-two patients were allocated to renal denervation and 54 were allocated to control (usual medical therapy; there was no sham procedure). At 6 months there was a significant reduction in blood pressure in the active arm by 32/12 mmHg on office readings, whereas there was a small increase in blood pressure in the control arm of 1/0 mmHg. In a subset of 20 patients who underwent ambulatory blood pressure monitoring the blood pressure reduction in the active arm was more modest at 11/7 mmHg and there was a small, statistically insignificant, reduction in the control arm of 3/1 mmHg.

These results captured the imagination of both interventionalists and hypertension specialists alike. Renal denervation for resistant hypertension was offered on an individual patient basis in Europe, Asia, and Australasia. The findings of the majority of the subsequently published reports echoed the impressive blood pressure effects seen in the first two SYMPLICITY trials.

However, the absence of a blinded sham procedure in the control arm raised theoretical concerns about bias and the reliability of these studies [31]. An additional concern about the conduct of these studies was the absence of ambulatory blood pressure monitoring to exclude white coat hypertension. A European study in 346 patients with uncontrolled hypertension undergoing renal denervation addressed the concern about white coat hypertension by using ambulatory monitoring to dichotomize patients into true resistant hypertension (both office and ambulatory measures elevated, $n=303$) and pseudoresistant hypertension (office measurement elevated but ambulatory measures normal, $n=43$) [32]. Renal denervation was performed on both groups and although there was a similar reduction in office blood pressure measurements in both, only the true resistant cohort demonstrated a reduction in ambulatory measures.

The US Food and Drug Administration required that a further trial be conducted before endorsing renal denervation as a licensed therapy for resistant hypertension. To this end, the SYMPLICITY HTN-3 trial was launched which is, to date, the only trial of renal denervation with a sham-control and a blinded design [33]. It was performed across 88 centers in the USA. Ambulatory blood pressure monitoring was mandated not only to exclude white coat hypertension at screening, but also to assess response to therapy as a secondary endpoint.

SYMPLICITY HTN-3 randomized 535 patients, making it to date the largest single trial conducted in this field. In the renal denervation group, the office systolic blood pressure dropped significantly at

6 months by 14 mmHg and the ambulatory systolic blood pressure by 7 mmHg. However, these falls were not significantly different from the large blood pressure reductions observed in the sham arm. In sub-group analysis there was a signal that the denervation was more effective in Caucasians than African-Americans. As a consequence of the findings of SYMPLICITY HTN-3 the clinical role of renal denervation in the treatment of resistant hypertension has been challenged. Proponents of renal denervation and the authors themselves have raised concerns that the procedural performance in the three trials may not have been equivalent as the operators in SYMPLICITY HTN-3 were less experienced with the technique. Indeed, only 26 of 111 interventionalists in SYMPLICITY HTN-3 had performed five or more renal denervations. In a *post hoc* multivariate analysis of the blood pressure response in the trial, number of ablation attempts was associated with a greater blood pressure drop.

The majority of the trial data of renal denervation in resistant hypertension is based upon the Symplicity Flex catheter system, which was first on the market. Newer catheter systems have evolved to provide complete circumferential ablations and work is still ongoing to determine if renal denervation using different technologies is effective.

The procedure

Patient selection

According to the current European Hypertension Guidelines, renal denervation represents a last resort treatment option for patients with resistant hypertension, in whom medical therapy fails to control blood pressure values $<160/<110$ mmHg. Those centers that wish to perform renal denervation (currently in a research context) ought to embrace a multidisciplinary team approach for each patient. A dedicated hypertension specialist should be involved in their management [5].

The renal denervation trials specified certain anatomic features as exclusion criteria, though there have been reports of the procedure being safely performed even in the presence of some of these:

- 1 The renal arteries ought to be greater than 4 mm in diameter to accommodate the ablation catheter and minimize complications.
- 2 The presence of any accessory or polar arteries must be sought.
- 3 A length of at least 20 mm of renal artery must be available for ablation prior to any branches.
- 4 Significant renal artery stenosis or fibromuscular dysplasia is a contraindication to the procedure.

Computerized tomography, magnetic resonance angiography, or renal duplex ultrasound of the renal arteries and kidneys are the preferred imaging modalities to determine this anatomy as they allow complete visualization of the vessels, which is not always feasible with ultrasound. In particular they can identify accessory arteries (these are arteries that enter the kidney via the hilum alongside the main renal artery) and polar arteries (which enter the kidney away from the hilum; Figure 52.2). Accessory arteries are found in 20% of the general population. Furthermore, cross-sectional imaging can identify branches of the main renal artery that supply important other organs (adrenal gland, testes, ovaries), whose ostia should not be put at risk.

Patients with renal artery stents have been excluded from renal denervation trials. However, there are reports of ablations being performed to the renal artery wall distal to a stent [34]. It is likely that ablation will be ineffective in segments, which have stents *in situ*, but appears to be safe and effective when performed distal to stented segments [35].

Figure 52.2 Magnetic resonance angiography of the renal arteries. Polar arteries to the right kidney are highlighted with blue arrows. An accessory artery entering at the hilum is highlighted with a red arrow.

Estimated glomerular filtration rate ought to be greater than 45 mL/min/1.73 m². While it may be feasible to perform the procedure when the renal function is worse, this is not recommended outside of a clinical trial and in cooperation with a nephrologist as part of a multidisciplinary team.

Patient preparation

When ablation is applied to the renal artery lumen, nociceptors are stimulated resulting in visceral pain. General anesthesia is rarely required but analgesia (morphine and/or fentanyl) and sedation (midazolam) are mandatory. To reduce the risk of gastric aspiration the patient should be in a fasting state.

As shown on optical coherence tomography, renal denervation can induce thrombus formation at ablation sites [36]. Heparin should therefore be administered during the procedure and titrated to maintain the activated clotting time (ACT) >250 s. It is also suggested that antiplatelet agents (e.g., acetylsalicylic acid 75–100 mg/day) should be administered for 4 weeks following the procedure to further reduce the risk of thrombus (though there is no definitive trial evidence for this recommendation).

As for all procedures using contrast medium, it is advisable to withhold certain medications that can increase the risk of contrast nephropathy. These include metformin, non-steroidal anti-inflammatory drugs, and inhibitors of the renin–angiotensin–aldosterone system. Pre-hydration with intravenous fluid is also recommended. Centers that have performed renal denervation in patients with an estimated glomerular filtration rate <30 mL/min/1.73 m² have used carbon dioxide angiography to reduce the risk of contrast nephropathy, though this is not widely available.

Vascular access and renal angiogram

Continuous monitoring of heart rate, blood pressure, and oxygen saturation is mandatory after administration of analgesics and sedatives. Currently, Terumo's Iberis system and Recor's Paradise system can be deployed via the radial artery but all other systems require femoral arterial access (Table 52.1). The size of femoral sheath depends on the type of catheter used and can vary from 5 to 8 Fr. The first step of the intervention (in patients with preserved renal function) is to obtain angiographic images of the renal artery with an automated aortogram (to identify accessory arteries and

origin of each artery). Typically, 30 mL of contrast at 20 mL/s is delivered by an autoinjector. The tip of the pigtail is positioned at the level of the L1 vertebra (using the 12th rib as a landmark) and an image is acquired in the anteroposterior (AP) plane. A selective angiogram of each target artery is then acquired to confirm suitability for ablation and exclusion of significant renal artery stenosis. Intra-arterial nitrates are helpful to dilate the renal artery fully. The usual choice of guiding catheter is either the internal mammary guide (IMA) or the renal double curve (RDC1). For femoral approach cases it is important to remember to use the shorter length catheters. For radial approach, long multipurpose or steerable guiding catheters are ideal. At the end of the procedure the sheath can be removed and the puncture site either manually compressed or an appropriate closure device used.

Ablation

Ablation is preferentially applied in a helical pattern (as opposed to circumferentially in one cross-sectional plane) to ensure as many branches of the sympathetic nerves are targeted as possible but minimizing the risk of inducing renal artery stenosis. This is particularly important with the single electrode catheters (Medtronic Flex and Terumo Iberis) as this pattern is created by the operator whereas the multi-electrode systems create this pattern automatically with a single ablation. The Paradise system, which utilizes ultrasound energy, is the only system that applies energy in a circular pattern.

The power output (Watts) of each catheter system is adjusted automatically by proprietary algorithms built into the generators and is predominately determined by sensed impedance (Ohms), electrode temperature (°C) and rate of temperature increase. Cell death occurs instantly at 50°C [24]. For effective and safe ablation, target tissue temperature should be 60–80°C. A gradual decline in impedance (5–20%) suggests good tissue contact and position. A rapid decline suggests loss of tissue contact, whereas a rapid increase might indicate coagulum formation. Some generators terminate the ablation prematurely if these parameters are detected.

Certain practical pointers are important with all of the ablation systems. First, proper electrode contact with the vessel wall is important with RF energy [24]. This can be assessed using fluoroscopy and the detection of appropriate impedance readings. Second, the catheter position should be stable and this can be confirmed with both fluoroscopy and the presence of stable impedance measurements (variations <20 Ohms). To improve stability and vessel apposition some of the systems provide rotation and flexion control (Flex, Iberis), some require balloon inflation (Vessix, Paradise), while others have a preformed spiral or basket design (Spyral, EnligHTN). Third, ablations should be performed in the distal main artery first followed by further ablations as the catheter is withdrawn and rotated to a new more proximal segment. This is mandatory with the single electrode systems (Flex, Iberis, at least four ablations per artery) and suggested for the other multi-electrode systems.

When this procedure was first pioneered in humans it was suggested that the last ablation should be applied close to the renal artery origin in a superior position. The histology data do not entirely support this assertion and suggest that the nerve density is greater proximally and ventrally but the nerves are closer to the lumen distally [23]. Theoretically, one would assume that the more unique sites at which energy can be safely delivered, the greater the probability of interruption of the sympathetic nerves.

A major limitation of renal denervation remains the lack of intraprocedural markers of efficacy, thus remaining an entirely

anatomically driven procedure. Blood pressure and heart rate response to renal sympathetic nerve stimulation before and after denervation are a potential method to assess efficacy of the procedure. There are some preliminary human [37] and animal data [38] to suggest that there is a dampened blood pressure and heart rate response to renal nerve stimulation after successful denervation.

Complications

Early complications of the procedure include those of any angiographic or ablation procedure: vascular access site damage; infection; skin burns; and contrast nephropathy. It is important to perform a selective renal artery angiogram at the end of the procedure. Spasm or edema of treated renal arteries is considered normal and should resolve within hours of ablation. There is a risk of renal artery dissection or rupture either caused by trauma from the renal denervation catheter, guidewires, or the ablation itself. This would be identified during the procedure and hence could be promptly treated with angioplasty and stenting (bare or covered).

There are case reports to suggest that renal denervation can induce renal artery stenosis, especially if the procedure is performed adjacent to existing plaque [39]. However, this is an uncommon complication with an incidence estimated to be <1%. Evidence from trial and registry data does not suggest that renal denervation accelerates renal dysfunction. However, patients who undergo renal denervation should be followed up long term and in those who display worsening renal function, rebound hypertension or episodes of acute heart failure, iatrogenic renal artery stenosis should be excluded. In addition to renal artery stenosis another cause of rebound hypertension is regeneration and reconnection of the renal sympathetic nerves, which has been shown to occur in animal models [40].

Unlike surgical sympathectomy for hypertension, which commonly resulted in profound orthostatic dysfunction or chronotropic incompetence, there is no evidence to suggest that percutaneous denervation is associated with these adverse effects [41,42].

The future

Renal denervation remains a relatively safe procedure, but there remain questions to be answered as to its efficacy, which can only be achieved by well-designed and well-conducted trials. Useful lines of enquiry include:

- 1 What percentage of renal nerves need to be ablated to show clinical benefit?
- 2 Are the newer multi-electrode catheters more effective in causing denervation but as safe?
- 3 How can success of renal sympathetic denervation be confirmed during the procedure?
- 4 Should patients be selected for the procedure on the basis of an elevated blood pressure *and* evidence of an elevated sympathetic nerve activity?

So far, renal denervation has been investigated predominantly in patients with resistant hypertension, a condition characterized by high cardiovascular morbidity and mortality. However, renal denervation could be particularly beneficial in other conditions associated with high sympathetic activity. There have already been some early studies investigating its role in heart failure [43] and atrial fibrillation [37]. More studies are needed to understand the role of this interesting treatment approach in different disease states.

Antithrombotic Strategies in Valvular and Structural Heart Disease Interventions

³Department of Cardiology, Mount Sinai Medical Center, New York, NY, USA

Intervention for valvular and structural heart disease is an exponentially growing field within interventional cardiology. Transcatheter therapies for both valvular and congenital heart disease imply the introduction of large and potentially thrombogenic instruments through the venous or arterial system to the site of the intervention, as well as the implantation of devices that require time for full endothelialization. In addition, a proportion of these patients have a greater propensity for hemodynamic compromise, which increases the risk of ischemic stroke. For these reasons, the use of antithrombotic drugs for reducing the risk of stroke, systemic embolism, or valve/device thrombosis in the early and mid-term period is key to achieving successful procedural results and improving the overall outcomes of transcatheter procedures. However, drugs and regimens for antiplatelet and anticoagulant therapy for valvular and structural interventions are mostly empirical in daily practice and typically administered at the operator's discretion. The objectives of this chapter are: (i) to review the current evidence supporting the rationale for antithrombotic management of patients undergoing transcatheter aortic valve implantation (TAVI), percutaneous mitral valve repair with the Mitraclip system, patent foramen ovale (PFO), atrial septal defect (ASD) closure, and left atrial appendage closure (LAAC); (ii) to describe common strategies for managing antiplatelet and anticoagulant therapy in patients with valvular and structural heart disease undergoing transcatheter procedures; and (iii) to provide insights on future directions and research lines in this field.

Embolic stroke and thrombosis in valvular and structural transcatheter interventions

Embolic stroke is one of the most feared complications of interventional catheter procedures, being associated not only with increased acute mortality, but also with increased morbidity and physical disability.

Transcatheter aortic valve implantation

Cerebral silent embolic events have been reported post-TAVI by magnetic resonance imaging (MRI) in 68–84% of cases (Figure 53.1) [1–5]. Intriguingly, however, the vast majority of

lesions had no remaining signal in follow-up MRI and cognitive function stayed unaffected [4]. On a more clinical level, randomized controlled trials (Table 53.1) and most registries report stroke rates after transcatheter aortic valve replacement (TAVR) in the range of 2–6% at 30 days' follow-up. A weighted meta-analysis of 53 studies including a total of 10,037 patients estimated the incidence of peri-procedural stroke and subsequent outcomes in patients undergoing transfemoral, transapical, or trans-subclavian TAVI. Pooled rates of stroke within 24 hours and 30 days were $1.5 \pm 1.4\%$ and $3.3 \pm 1.8\%$, and six of every seven stroke events were classified as major strokes. Not surprisingly, patients who experienced a stroke also experienced a 3.5-fold increased risk of mortality at 30 days ($25.5 \pm 21.9\%$ vs. $6.9 \pm 4.2\%$) [6]. Similarly, another weighted meta-analysis using Valve Academic Research Consortium (VARC) definitions reported a 3.2% (95% confidence interval (CI) 2.1–4.8%) risk of major stroke at 30 days [7]. Of note, the incidence of stroke peaks within 2 days, but continues slightly afterwards, reflecting the high baseline risk of patients who are currently referred for TAVI (Figure 53.2) [8]. Valve thrombosis is estimated at a non-negligible weighted rate of 1.2% (95% CI 0.3–2.2%) [7].

MitraClip

In the EVEREST II (Endovascular Valve Edge-to-Edge Repair Study), the only randomized trial to date reporting data of MitraClip versus surgical mitral repair or replacement, two strokes occurred within 30 days in the interventional arm (1.1% vs. 2.1% in the surgical arm; $p=0.89$) [9]. Observational series with different baseline case-mix reported major strokes in 0–2.6% of cases [10–15]. A weighted meta-analysis could meaningfully increase the precision of this risk estimate, given the small number of patients enrolled in the studies, mostly reflecting the early experience of single institutions with percutaneous mitral valve repair. In the EVEREST II trial, clip thrombosis was uncommon, being detected in 1 of 184 cases (0.5%). However, a recent large national registry from Germany described an in-hospital stroke incidence of 0.4%, but an additional 1% transient ischemic attack (TIA) and a 0.3% systemic embolism rate, yielding an almost 2% occurrence of potential thromboembolic events [16].

Figure 53.1 New cerebral ischemic lesions post-transcatheter aortic valve implantation (TAVI) as detected by magnetic resonance imaging.

Patent foramen ovale and atrial septal defect closure

The options for secondary prevention of cryptogenic embolism in patients with PFO are administration of antithrombotic medications or percutaneous closure of the PFO. Whether closure is superior to medical therapy is still unsettled, as recent results of a multinational trial investigating closure of a PFO for secondary prevention of cryptogenic embolism did not result in a significant reduction in the risk of recurrent embolic events or death as compared with medical therapy, although there was a non-significant numerical benefit of device closure and the study was possibly underpowered [17].

Data on peri-procedural stroke as the consequence of percutaneous closure of a PFO or an ASD cannot be easily disconnected from the underlying risk of recurrent stroke owing to suboptimal sealing of the shunt area or cerebrovascular embolism from alternative sources. In addition, closure devices differ in terms of thrombogenicity and the incidence of new-onset conditions at high embolic potential, including atrial fibrillation [18–22]. In 499 patients from the Amplatzer PFO closure device arm of the RESPECT (Randomized Evaluation of Recurrent Stroke Comparing PFO Closure to Established Current Standard of Care Treatment) trial, one ischemic stroke (0.2%) occurred 1 week post-implant and another one 5 months post-implant with finding of severe shunting related to previously undiagnosed sinus venosus defect, requiring surgical closure [22]. No thrombus was detected on any implanted device. In observational series, thromboembolic events while on antiplatelet treatment have been reported in 1.6–8.2% of patients within 1 year after PFO closure [23–29]. Also, many cases of device thrombosis have been reported within the first months after ASD device implantation, with an incidence of up to 7%, depending on the device [30,31].

Conversely, in the trial by Meier *et al.* [17], where endpoint adjudication was performed blinded to the study group assignments (medical therapy vs. device closure), stroke (0.5%), TIA (2.5%), and systemic embolism incidence (0%) remained numerically lower than in medically treated patients and the incidence curves only diverged late (after 6 months post-procedure). The likelihood of a substantial procedure-related thromboembolism occurrence is therefore controversial.

Left atrial appendage closure

In patients with non-valvular atrial fibrillation and absolute contraindications to anticoagulation therapy, LACC with the WATCHMAN or AMPLATZER device is an emergent interventional treatment

option to reduce the risk of cardiac thromboembolisms [32–34]. Procedure-related stroke rates were 1.1% and 0.7% in the PROTECT AF [33] and PREVAIL [34] trials, respectively. Preliminary results in small series suggest that the risk of device thrombosis is very low. Urena *et al.* [32] reported on patients having the AMPLATZER Cardiac Plug device implanted followed by dual or single antiplatelet therapy and showed a low rate of embolic and bleeding events after a mean follow-up of 20 months.

Pathophysiology of stroke and systemic embolism in valvular and structural transcatheter interventions

Not surprisingly, embolism of thrombotic material is more commonly detected in left heart catheterization procedures, which require advancing the catheter through the aorta, thus increasing the risk of embolization by scraping of aortic plaques with subsequent direct embolization of debris to the brain. Indeed, scraping of aortic plaques occurs more commonly with large catheters, such as those employed for TAVI. Embolic stroke also theoretically occurs in the setting of right heart catheterization in patients with PFO or ASD, or following transeptal puncture in patients undergoing Mitraclip implantation.

Transcatheter aortic valve implantation

The time distribution of strokes is inherently correlated to the underlying pathophysiology. Strokes occurring in the acute (<24 hours) and sub-acute early (<30 days) post-TAVR period are strongly related to procedural factors, whereas late events (1–12 months) are mostly connected to patient and disease factors [35].

Pathophysiologic mechanisms of early stroke after TAVR

Van Mieghem *et al.* [36] recently examined the histopathology of embolic debris captured in an embolic protection device following TAVR. Macroscopic debris was found in 30 (75%) patients and, out of those, 27% had amorphous calcium or valve tissue likely to originate from degenerated aortic leaflets, and 43% had evidence of collagenous tissue coming from either the valve or the aortic wall. Importantly, about half (55%) of patients had thrombotic tissue debris.

Several pathophysiologic mechanisms account for this macroscopic debris. First, the aortic arch is recognized as a source of embolic material. In fact, retrograde progression of atheroma from

N/A, not applicable; TAVR, transcatheter aortic valve replacement; TIA, transient ischemic attack; Tx, therapy.

Figure 53.2 Stroke incidence is estimated to be $\approx 5.5\%$ at 30 days and $\approx 8\text{--}9\%$ at 1 year, based on the PARTNER and the CoreValve programs. Approximately half of the strokes at 30 days occur within the first 24 hours, amounting to 2.5–3% from days 2–30. Additionally, the large majority ($>75\%$) of strokes within 1 year occur in the first 6 months, amounting to additional $\sim 3.5\%$ in the period 1–6 months [80]. The symbols mark the cumulative incidence at the given time point based on landmark trials. The clear circle indicates the cumulative incidence of the background population (2% per year in patients over 80 years of age) and the dotted line the monthly stroke incidence rate (0.17%) of the background population based on the European epidemiologic study by Truelsen *et al.* [81] and the stroke incidence meta-analysis by Russo *et al.* [82].

the descending aorta to the arch has been shown to correlate significantly with presence of cardiovascular risk factors and advanced age, conditions that are frequently encountered in patients referred for TAVI [37]. Retrograde crossing of a stenotic aortic valve during diagnostic catheterization results in new focal cerebral lesions in 22% of patients [38].

Second, initial balloon aortic valvuloplasty (BAV) not only results in the fracture of valvular tissue leading to embolism of overlying calcium deposits, but also increases the risk of thrombotic complications. Stenotic valves host large amounts of localized tissue factor and thrombin covered by vascular endothelium. BAV, by means of endothelial denudation and fracture of the valve, exposes these factors to blood circulation, which in turn triggers coagulation cascades and platelet activation resulting in increased inflammation and recurrent thrombogenicity [39]. Therefore, thromboemboli can arise from the bioprosthesis before endothelialization is complete. Aggregation of platelet and fibrin has been known to occur on valve leaflet within a few hours after implantation [8]. It has been suggested that the balloon expandable valve produces emboli during positioning of the valve on the annulus, whereas the self-expanding valve does so during valve deployment, as manifested by simultaneous transcranial Doppler studies [40,41].

Furthermore, the interaction of the newly deployed stent valve with the aortic annulus over the displaced natural valve can cause additional embolic debris. Additional possible mechanisms are prosthetic valve surface exposure, flow turbulence, and exposure of stents struts to the circulation [42]. Blood stasis in the perivalvular space “outside” the metallic stent of a undersized or underexpanded prosthetic valve, where the irregularly crushed native aortic valve cusps persist, could also generate thrombi with subsequent events.

Given these pathoanatomic considerations mainly related to the aortic arch, the choice of the arterial access has a pivotal role in the determination of embolic risk with the potential advantage of non-transfemoral approaches. The transapical approach offers an option in patients hosting a high degree of aortic atheroma with potential reduction of the risk caused by aorta manipulation and anterograde valve access. The transapical access has previously been associated with the lowest risk [6]. However, the transapical approach is limited by the risk of air embolisms, given the large catheter used and the direct communication of the left ventricle to the external air space [43] and the transapical approach is considered the more invasive procedure. Furthermore, no differences in the rates of in-hospital stroke were noted in a propensity-matched comparison between the subclavian and transfemoral access from the Italian registry of the self-expanding Medtronic CoreValve (Medtronic Inc., Minneapolis, MN, USA; 2.1% vs. 2.1%; $p = 0.99$) [44]. Spurring the controversy are results showing that despite propensity matching, peripheral artery disease, a marker of more advanced and extended atherosclerosis, was still more prevalent in patients from the Italian CoreValve registry treated via the subclavian approach than those treated transfemorally (85% vs. 21%; $p < 0.0001$) and therefore the advantages of non-transfemoral accesses in this kind of comparison are likely underestimated. Variables that are more specifically linked with the TAVI procedure include device manipulation in the arch, the possibility to dislocate plaque or calcium particles while crossing the native valve, and the act of deploying/post-dilating the prosthesis. A transcranial Doppler study during TAVI showed that the majority of procedural embolic events occurred during balloon valvuloplasty, manipulation of catheters across the aortic valve, and valve implantation [45]. Differences in

the risk of stroke could be theoretically attributable to different mechanisms of valve deployment (self-expanding vs. balloon-expandable) and characteristics of the available systems. There are currently no conclusive data suggesting differences in the stroke rate of the two types of valves. Ideally, this hypothesis should be investigated in the setting of a large head-to-head randomized comparison. In a propensity-matched comparison of the self-expanding Medtronic CoreValve and the balloon-expandable Edwards SAPIEN/SAPIEN XT (Edwards Lifesciences, Irvine, CA, USA) transcatheter heart valves from the PRAGMATIC Plus (Pooled-Rotterdam-Milano-Toulouse In Collaboration) initiative, the rates of stroke were numerically higher with the CoreValve system but did not significantly differ at 30 days, likely as the reflection of the small sample size (2.9% vs. 1.0%, odds ratio [OR] 3.06, 95% CI 0.61–15.35; $p=0.17$) [46]. In contrast, the recent randomized CHOICE trial showed a numerical difference in stroke incidence at 30 days between the balloon and self-expandable valves (5.8% vs. 2.6%; $p=0.33$) [47]. Although these results are based on small event numbers and the result of chance, they could point to another potential, yet unconfirmed, mechanism of ischemic injury during TAVR. Hypoperfusion could occur during BAV and balloon expandable valve deployment because of repeated rapid ventricular pacing which is necessary for positioning and deployment resulting in transiently reduced cardiac output. This technique could therefore induce ischemia to watershed areas localized in the border zones between the territories of two major arteries in the brain, where cerebral blood flow can be additionally impaired as a result of decreased washout of dislodged microemboli [48]. These mechanisms are particularly likely in the elderly population of patients undergoing TAVI.

Finally, operator's experience plays a major part. This includes a meticulous technique and proper management of antiplatelet and anticoagulant therapy. A list of potential explanations for the risk of stroke in patients undergoing TAVI is shown in Table 53.2.

Pathophysiologic mechanisms of late stroke after TAVR

There is a range of other explanations for peri-procedural stroke in TAVI patients. First, elderly patients present with a higher prevalence of comorbidities of embolic potential, such as hypertension, atrial fibrillation, and carotid stenosis, which is why the stroke risk 6 months after TAVR is believed to approach the basis risk of the age-matched background population. New onset atrial fibrillation (NOAF) is a common complication after cardiac surgery with inflammatory factors acting as mediators. Patients undergoing TAVR are mainly octogenarians, representing a population with an even higher baseline risk for NOAF because of diastolic dysfunction and left atrium enlargement as a consequence of aortic stenosis [49]. Instrumentation during the TAVR procedure is another likely mechanism of NOAF. The increased prevalence of atrial fibrillation after TAVR is a likely cause of the elevated stroke risk during the first 6 months after TAVR.

Mitraclip

Embolic stroke is uncommon in the setting of right heart catheterization. However, blood clots can form in and around catheters inside the venous system in patients who are not adequately anticoagulated. The execution of a trans-septal puncture during the procedure determines a transient direct communication between the venous and the arterial circulation, thereby creating the premises of paradoxical embolism. Reasons for clot formation vary according to host factors, catheter characteristics, cannulation site, and

Table 53.2 Stroke determinants in patients undergoing transcatheter aortic valve implantation (TAVI).

antithrombotic prophylaxis. Right and left heart thromboemboli in the setting of Mitraclip procedures rarely include thrombi that may develop within the cardiac chambers on injured endothelium and implanted devices.

Patent foramen ovale and atrial septal defect closure

Adding to thrombotic mechanisms described earlier for the Mitraclip procedure, transcatheter closure of PFO has been shown to induce significant activation of the coagulation system, which reaches maximal levels 7 days after device deployment, gradually returning to baseline by day 90 [50]. However, implantation of the device does not seem to be associated with any increase in platelet activation in aspirin-treated patients. These findings are similar to those obtained after transcatheter closure of ASD [51].

Antithrombotic strategies in patients undergoing valvular and structural percutaneous interventions

The approach to antithrombotic prophylaxis against valve or device-related thromboembolic complications in valvular and structural transcatheter intervention is currently empiric. Disadvantages of antithrombotic therapy include the risk of bleeding, especially in elderly patients like those undergoing valvular procedures [52].

Transcatheter aortic valve implantation

Pre- and intraprocedural antithrombotic treatment

Antithrombotic treatment is believed to be a cornerstone for the prevention of ischemic strokes during and post-TAVR. Albeit

Table 53.3 Recommendations for antithrombotic agents and strategies after transcatheter aortic valve replacement (TAVR).

	ACC/AHA/STS [77]	ESC [78]	CCS statement [62]	ACCP [55]
Procedural	Unfractionated heparin Goal ACT: 300s Reversal with protamine recommended			
Post-procedural	Aspirin 81 mg indefinitely Clopidogrel 75 mg for 3–6 months If VKA indicated, no clopidogrel	ASA or clopidogrel indefinitely ASA and clopidogrel early after TAVI If VKA indicated, no antiplatelet therapy	Indefinite low-dose aspirin + P2Y ₁₂ for 1–3 months If OAC is indicated, avoid triple Tx unless definite indication exists	Aspirin (50–100 mg/day) + clopidogrel (75 mg/day) over VKA for 3 months

TAVR procedures have been performed for more than a decade, little is known about optimal antiplatelet and anticoagulation therapy. There is no consensus on the optimal duration of dual antiplatelet therapy after TAVI and current recommendations for antithrombotic agents and strategies for TAVR (Table 53.3) and are not based on large controlled randomized studies. Thus, there is an unmet need for better antithrombotic therapies given the fact that the incidence of major stroke has not declined significantly over time.

Intraprocedural anticoagulation with weight-adjusted unfractionated heparin (UFH) has been a well-established standard of care in all major published registries of TAVI, although clinical practice regarding dosing is variable. In the PARTNER trial, heparin was used for procedural anticoagulation (5000 IE bolus loading dose) with a target of activated clotting time (ACT) >250 s, whereas guidelines recommend a target time of 300 s. Using UFH and protamine sulfate to reverse the anticoagulant effect at the end of the procedure has the advantage of being intuitive, relatively economical, and broadly familiar in the interventional and surgical setting. On the downside, this approach suffers from ample variability in pharmacokinetics and pharmacodynamics of heparin, resulting in wide interindividual response. In addition, late anticoagulant effects of heparin, which dissociates from cells and proteins, and protamine, with rebound bleeding, have been described. Finally, rapid reversal of anticoagulation can lead to prothrombotic rebound with detrimental clinical consequences. (Clinical research in this area of TAVR is described in the section on Future directions.)

Similarly, dual antiplatelet therapy (loading dose, maintaining dose, duration) after TAVR has not been explicitly defined. For example, the PARTNER (Placement of Aortic Transcatheter Valves) trial recommendations were 75–100 mg/day aspirin, a 300 mg clopidogrel loading dose and 75 mg/day for 6 months following TAVR [53]. In the large FRANCE-2 (French Aortic National CoreValve and Edwards) registry [54], patients were on aspirin (≤ 160 mg/day) and clopidogrel (300 mg loading dose, then 75 mg/day) before the procedure and aspirin alone after 1 month of dual therapy. In general, it seems that most centers adopt a strategy of low-dose aspirin and a short to intermediate period with a thienopyridine. The American College of Chest Physicians (ACCP) practice guidelines for antithrombotic and thrombolytic therapy in

valvular heart disease support this strategy, but with a low grade of recommendation and level of evidence [55]. The recommendations for antithrombotic agents and strategies in patients undergoing TAVR are summarized in Table 53.3.

Post-procedural antithrombotic treatment

The underlying rationale for adding clopidogrel to aspirin derives from the initial TAVI experience, when extracorporeal bypass for hemodynamic support was used during the procedure. Grube *et al.* [56] observed two cases of prolonged and severe post-procedural thrombocytopenia in patients who were not treated with clopidogrel, likely as the reflection of platelet activation processes and consumption. TAVI is now performed mostly under local anesthesia and/or light sedation with no need for extracorporeal circulatory support, and very infrequent cases of mild and transient thrombocytopenia have been reported [57]. The need for a course of dual antiplatelet therapy is theoretically supported by the delay of time needed for incorporation of the prosthesis within the aortic wall for neointimal tissue growth and endothelialization. This process begins with early fibrin deposition, linked to inflammatory response and foreign body reactions. Three months later, smooth muscle cells and endothelial cells replace fibrin [58]. While these findings derive from histopathologic studies of CoreValve explants, clinical evidence for the benefit of dual antiplatelet therapy after TAVI remains elusive. Clopidogrel loading dose or treatment duration or are not specifically defined in guidelines, and lately the general usefulness of clopidogrel on top of aspirin in TAVR patients has been questioned [59,60]. In two studies comparing DAPT with mono-antiplatelet therapy (aspirin or clopidogrel), dual antiplatelet therapy did not reduce the incidence of new strokes but was associated with a significantly higher rate of major and life-threatening bleeding complications.

Ussia *et al.* [59] reported in a small single center study on 79 patients randomized to either dual antiplatelet therapy with a 300-mg loading dose of clopidogrel on the day before TAVI followed by a 3-month maintenance dose of 75 mg/day on a background of aspirin 100 mg or aspirin alone. The primary efficacy endpoint, a composite of major cardiac and cerebrovascular events, including overall mortality, myocardial infarction, major stroke, urgent or emergency conversion to surgery, or life-threatening bleeding, occurred with a similar frequency between the two groups both

at 30 days (13% vs. 15%; $p=0.71$) and 6 months (18% vs. 15%; $p=0.85$). There were no differences in VARC-defined major and minor bleeding between the two strategies. Although limited by the small sample size, this study does not seem to support a strategy of short-term adjunctive use of clopidogrel added to aspirin after TAVI. These findings were essentially confirmed by Durand *et al.* [60] in a recent prospective observational study. As it is unclear whether thrombi produced during and after TAVR are of platelet or thrombin-based origin, the latter does not favor clopidogrel as an effective agent in these patients and more investigations are needed.

Controversy also exists for patients with a history of pre-existing atrial fibrillation. There is no consensus or evidence from trials regarding treatment with triple therapy, warfarin with one antiplatelet or warfarin alone, although American and Canadian guidelines discourage the use of triple therapy (Table 53.3) [61,62].

In a recent report, serial imaging of bioprosthetic aortic valves implanted either surgically or with a TAVR procedure were found to exhibit leaflet thrombosis in 15–20% which was associated with leaflet motion abnormality and less frequently with adverse neurologic events and disappeared with oral anticoagulation [63]. This finding concurs with an earlier report of successful treatment of bioprosthetic valve thrombosis with anticoagulation [64]. These observations have increased the medical awareness around this phenomenon and has initiated the clinical investigation on leaflet thrombosis, leaflet motion imaging, and their possible relationship with neurological overt or silent abnormalities. This field is expected to evolve over the following years.

MitraClip

The manufacturer leaves antithrombotic management of Mitraclip to the discretion of the operator, because of a lack of specific investigations comparing different treatment strategies after percutaneous mitral valve repair. Indicatively, in the EVEREST II trial, patients were treated with heparin during the procedure, and a combination of aspirin (at a dose of 325 mg/day) for 6 months and clopidogrel (at a dose of 75 mg/day) for 30 days after the procedure. While no definite device thrombosis was identified in the EVEREST trial, several cases of large thrombus formation after Mitraclip procedure in clinical practice have been reported. Bekeredian *et al.* [65] published a case report on thrombus in the posterolateral wall of the left atrium and on the right atrial side of the septum on day 5 after Mitraclip implantation, and the authors reported a note of caution on the need for a course of anticoagulation in patients undergoing percutaneous mitral valve repair. Hamm *et al.* [66] reported a 3-week post-procedural cardioembolic stroke caused by thrombus formation on the MitraClip, despite the patient receiving dual platelet therapy. Overall, evidence on peri-procedural antithrombotic regimens is very sparse, but Alsidawi and Effat [67] recently published a set of recommendations; however, these can neither be interpreted as a consensus paper nor as guidelines. They state that patients not being treated with antiplatelets should be started on aspirin 325 mg and clopidogrel 75 mg immediately after the procedure for 6 months to 1 year. Anticoagulation should be interrupted at least 5 days before the procedure. Only patients with high risk for thrombosis (previous mitral valve prosthesis, caged-ball or tilting disc aortic valve, stroke, TIA or venous thromboembolism within 6 months, CHADS₂ ≥ 5, rheumatic valvular heart disease, or severe thrombophilia) should be bridged regardless of their risk of bleeding. The management of patients with moderate risk for thrombosis should be individualized depending on their bleeding risk and informed decision. Heparin should be bolused

right after successful trans-septal puncture (ACT around 250) and bivalirudin is not recommended. Patients in whom anticoagulation was interrupted before the procedure should be started back on their anticoagulation regimen. If needed, heparin infusion can be started 6 hours after the access sheath is removed. Post-procedural anticoagulation is currently not recommended if no other indication for anticoagulation exists; however, the above case reports call for more studies addressing this issue and caution is warranted.

Patent foramen ovale and atrial septal defect closure

There are no studies on the most appropriate antithrombotic therapy after transcatheter closure of PFO/ASD, and the choice of antithrombotic drugs after these procedures has been empirically determined, with aspirin as the agent most frequently used. In the CLOSURE-1 (A Prospective, Multicenter, Randomized Controlled Trial to Evaluate the Safety and Efficacy of the STARFlex® Septal Closure System Versus Best Medical Therapy in Patients With a Stroke and/or Transient Ischemic Attack Due to Presumed Paradoxical Embolism Through a Patent Foramen Ovale) trial, after PFO closure with the StarFlex device, all patients were given a standard antiplatelet regimen including clopidogrel (75 mg/day) for 6 months, and aspirin (81–325 mg/day) for 2 years. Experimental studies have demonstrated that the Amplatzer PFO occluder is partially endothelialized 1 month after implantation and completely covered by neoendothelial cells at 3 months [68]. Thus, the first weeks after PFO closure constitute a vulnerable window with newer devices, in which the closure system is potentially more thrombogenic [69,70]. Remarkably, most of the patients who experience device thrombosis are receiving antiplatelet treatment, and most of them are successfully treated with heparin or warfarin. Therefore, some operators advocate short-term anticoagulation (1–3 months) after PFO/ASD closure. Once device endothelialization is completed and no residual shunt is observed, anticoagulant treatment is then switched to antiplatelet therapy or no antithrombotic treatment.

Left atrial appendage closure

In order to prevent to prevent large thrombus formation on the device during its endothelialization, patients were treated with warfarin and aspirin (81 mg) for 45 days after implantation, in both the PROTECT AF and PREVAIL trials [32,34]. Furthermore, these study designs dictated that if the 45-day transesophageal echocardiography documented either complete closure of the left atrial appendage, or if residual peri-device flow was <5 mm in width and there was no definite visible large thrombus on the device, warfarin was discontinued. After discontinuation of warfarin, only clopidogrel 75 mg/day and aspirin 81–325 mg/day were prescribed until the 6-month follow-up visit, at which time clopidogrel was discontinued and aspirin alone was continued indefinitely.

Future directions and conclusions

Bivalirudin is a direct selective inhibitor of the activated coagulation factor II (thrombin). Direct thrombin inhibitors have some advantages over the heparins, such as lack of dependence on plasma protein, which results in a more predictable response and makes them very attractive for use in populations at high risk of bleeding (Table 53.4). Bivalirudin was shown to be efficacious in BAV patients in the BRAVO (Effect of Bivalirudin on Aortic Valve Intervention Outcomes) trial [71]. Bivalirudin is evaluated for its assumed beneficial bleeding profile but concerns over reversibility

Table 53.4 Pharmacologic properties of heparin and bivalirudin.

	UFH	Bivalirudin
Bioavailability (%)	35	100
Action independent of antithrombin III	No	Yes
Non-specific protease binding	Yes	No
Predictable PK-PD	No	Yes
Inhibits fibrin-bound thrombin	No	Yes
Activates/aggregates platelet	Yes	No
Half-life (minutes)	60–90	25

PK-PD, pharmacokinetic–pharmacodynamic; UFH, unfractionated heparin.

of its activity exist in the case of life-threatening bleeding/vascular complications. Additionally, it is a strictly procedural agent (parenteral administration) which can only impact acute events.

Bivalirudin was recently evaluated against procedural heparin during TAVR in the BRAVO 2/3 (Effect of Bivalirudin on Aortic Valve Intervention Outcomes 2/3) trial, which is an ongoing international, multicenter, open-label, randomized controlled trial of bivalirudin in patients undergoing transfemoral TAVI. A total of 802 patients were randomly assigned to either standard dosing of bivalirudin (bolus 0.75 mg/kg plus infusion) or UFH (targeting an activated coagulation time ≥ 250 s) as control (UFH with possible protamine reversal). Use of antiplatelet agents pre-, during, and post-procedure, and possibly oral anticoagulants post-procedure, will be according to the sites' standard practice. The primary endpoint was major bleeding defined as Bleeding Academic Research Consortium (BARC) type ≥ 3 at 48 hours or hospital discharge, whichever occurred first [72]. Based on the final results of the BRAVO3 trial [73], direct thrombin inhibition with bivalirudin during TAVI did not significantly reduce major bleeding at 48 hours and was found non-inferior to heparin with respect to the net adverse clinical event rate at 30-days post-TAVI. Despite the absence of an immediate antidote (which was a safety concern for this approach early on), rates of adverse events were in fact arithmetically lower with bivalirudin. This indicated that the percent of anticoagulant reversal in case of life-threatening complications does not have an overwhelming clinical impact. If one takes into account the cost of bivalirudin, heparin (with possible reversal with heparin) remains the main anticoagulant for TAVI. Anticoagulation with bivalirudin is safe and feasible in patients who undergo TAVI and cannot receive heparin. Further research with antithrombin agents is expected to evolve in this field.

The clustering of thromboembolic risk factors in TAVI populations such as renal failure (10%), atrial fibrillation (40%), severe chronic obstructive pulmonary disease (15%), coronary artery disease (70%), peripheral vascular disease (30%), and moderate to severe mitral regurgitation (30%), implies that long-term anticoagulation therapy (beyond 12 months) after TAVR is of value. Whether such a strategy would provide benefit is currently unknown [74].

Importantly however, >50% of post-procedural strokes are of a likely thromboembolic nature. To that end, the prescription of a mid-term (up to 6–12 months) anticoagulation therapy might have

a significant role in the reduction of subacute and late strokes [75]. Currently, anticoagulation treatment after TAVI is only recommended if other indications for anticoagulation exist.

Triple therapy after TAVI should be avoided in those patient cohorts with a high inherent bleeding risk. Furthermore, data show no difference in stroke rates in mono-antiplatelet versus dual antiplatelet therapy, and the combination of one oral anticoagulant with one antiplatelet has recently shown better safety results without excess ischemic events in comparison to triple therapy in patients with atrial fibrillation [76]. The exact regimen and duration remain to be determined in a prospective manner. Modifiable risk factors of late strokes such as hypertension, diabetes, dyslipidemia, and smoking, should undergo aggressive treatment attempts. The pharmacology-oriented guidelines of the TAVI field are expected to evolve over time based on evidence generated from trials [77,78].

A number of relatively novel antiplatelet (i.e., prasugrel, ticagrelor) and anticoagulant (dabigatran, rivaroxaban, apixaban) agents have recently entered the cardiologist's armamentarium in Europe and the USA. None of these drugs is currently approved from European or US regulatory agencies for antithrombotic management of patients undergoing valvular or structural percutaneous intervention. Randomized clinical trials remain the most appropriate setting to establish the safety and efficacy of a drug for any novel indication. Several studies for patients undergoing TAVI are underway. The currently enrolling POPular-TAVI trial investigates 1000 patients divided in two cohorts, one with (cohort A) and one without (cohort B) a pre-existing oral anticoagulation indication (atrial fibrillation, previous systemic embolism, mitral valve prosthesis) (NCT02247128). Patients in cohort A are randomized to aspirin monotherapy versus aspirin + clopidogrel and patients in cohort B are randomized to oral anticoagulation vs. oral anticoagulation + clopidogrel. Another ongoing trial is the ARTE study (n = 300), which randomizes TAVI patients to aspirin monotherapy versus DAPT for at least 6 months (NCT01559298).

The safety and efficacy of the current approach for TAVI, Mitraclip implantation, and PFO/ASD closure, mostly using a short to intermediate term combination of aspirin and clopidogrel after the procedure, and UFH during the procedure, has never been prospectively investigated in a randomized clinical trial. Therefore, at present, the apparent superiority of any antithrombotic approach over another remains speculative. Research questions include which antiplatelet anticoagulant agents to use after valvular and structural interventions, when they should be administered, at which doses, and for how long. Careful and tailored risk–benefit assessment is needed for any antithrombotic combination in patients undergoing valvular or structural transcatheter interventions [79].

Alcohol Septal Ablation for Hypertrophic Obstructive Cardiomyopathy

Amir-Ali Fassa¹, George D. Dangas², and Ulrich Sigwart³

¹La Tour Hospital, Geneva, Switzerland

²Department of Cardiology, Mount Sinai Medical Center, New York, NY, USA

³Geneva University Hospitals, Geneva, Switzerland

Left-ventricular outflow tract obstruction is seen in approximately 25% of patients with hypertrophic cardiomyopathy under resting conditions, and is an independent predictor of poor prognosis [1,2]. Although negative inotropic drugs can efficiently alleviate symptoms in many cases, 5–10% of patients with hypertrophic obstructive cardiomyopathy (HOCM) remain refractory to drug therapy [3]. Surgical myectomy (also known as the Morrow operation) has been performed since the 1960s, and has been shown to reduce outflow gradients. Nevertheless, some patients are not regarded as favorable candidates for this major intervention because of factors such as advanced age, concomitant medical conditions, or previous cardiac surgery [4,5]. In 1994, a catheter treatment (known under a variety of abbreviations listed in Box 54.1) using absolute alcohol to induce a localized myocardial infarction to the interventricular septum was introduced as an alternative to surgery [6]. Alcohol-induced septal branch ablation had been previously described for therapy of ventricular tachycardia [7]. This technique was applied to HOCM after clinical observations of improvement in a patient with septal hypertrophy who developed an anterior myocardial infarction and also the transient reduction in left-ventricular outflow pressure gradients observed with temporary septal artery balloon occlusion. Since its introduction, there has been growing enthusiasm for this technique. Indeed, over 800 procedures were performed during the first 5 years [8], and the number to date is probably more than 5000 [9,10]. Although initially confined to Europe and North America, this technique is now being performed worldwide [11].

Selection of patients

Patient selection for alcohol septal ablation (ASA) should be based on a careful individual evaluation of the clinical symptoms, associated comorbidities, and echocardiographic and angiographic parameters [5,9,12]. The primary indications for the procedure are New York Heart Association (NYHA) or Canadian Cardiovascular Score (CCS) Class III or IV symptoms despite adequately tolerated drug therapy with a documented left ventricular outflow tract (LVOT) gradient variably defined as ≥ 50 mmHg at rest or after

exercise, or >30 mmHg at rest or ≥ 60 mmHg under stress. Likewise, selected patients with advanced NYHA or CCS Class II symptoms (e.g., those with syncope and severe pre-syncope) and a resting gradient >50 mmHg or >30 mmHg at rest and ≥ 100 mmHg with stress can also be considered for the procedure (Box 54.2). However, a septal wall thickness <18 mm should be taken as a contraindication for ASA because of the risk of septal perforation.

Mechanisms of treatment efficacy

In HOCM, obstruction is caused by protrusion of the hypertrophied interventricular septum into the outflow tract and by systolic anterior movement of the mitral valve due to a Venturi phenomenon and a drag effect [5,13].

ASA induces a well-demarcated subaortic necrosis, corresponding to approximately 10% of the post-ablation total left ventricle mass (or 31% of the septal myocardial mass), as assessed by various imaging techniques (such as single-photon emission computed tomography, positron emission tomography, and contrast-enhanced magnetic resonance imaging) [14–18]. However, with the use of smaller ethanol doses nowadays, septal necrosis is probably less.

The hemodynamic response to the induced reduction of septal myocardium is usually triphasic [5,19]. Immediately after ASA, there is a marked reduction of the LVOT gradient. Proposed mechanisms involved in the acute benefit are improvement in left ventricular relaxation and compliance via a reduction in regional asynchrony, resulting in an increase in left ventricular passive filling and a reduction in left atrial size and left ventricular ejection force [20–23]. This initial relief is usually followed during the following days by a rise of the LVOT gradient to about 50% of the pre-procedure level, possibly in relation to some degree of recovery from stunning or to edema caused by the infarct, which subsequently disappears [19,24]. Finally, within the following weeks to months, there is a new decrease in LVOT gradient back to the post-ablation level. It is believed that long-term benefit results from the creation of localized septal infarction and scarring, which increase LVOT diameter as a result of septal thinning and “therapeutic remodeling” [14,20,25,26]. The overall effect is an increase in left ventricular

Box 54.1 Common abbreviations for alcohol septal ablation.

ASA	Alcohol septal ablation
ASR	Alcohol septal reduction
NSMR	Non-surgical myocardial reduction
NSRT	Non-surgical septal reduction therapy
PTSMA	Percutaneous transluminal septal myocardial ablation
TAA	Transcoronary alcohol ablation
TASH	Transcoronary ablation of septal hypertrophy

Box 54.2 Criteria for selection of patients for alcohol septal ablation.

- Symptoms refractory to adequate tolerated drug therapy
- NYHA or CCS Class III or IV with a resting gradient of >30 mmHg or ≥60 mmHg under stress or ≥50 mmHg at rest and/or with provocation
- NYHA or CCS Class II in selected patients (e.g., those with syncope or severe pre-syncope) with a resting gradient >50 mmHg or >30 mmHg at rest and ≥100 mmHg with stress
- Basal septal wall thickness ≥18 mm
- Adequately sized septal perforator supplying the area of the systolic anterior motion-septum contact
- High risk of surgical morbidity and mortality
- Absence of concomitant cardiac disease requiring surgery (such as extensive coronary artery disease that would be treated surgically, organic valvular disease, morphologic abnormalities of the mitral valve and papillary muscles)

CCS, Canadian Cardiovascular Society; NYHA, New York Heart Association.

size, a decrease in left ventricular mass and hypertrophy [15,25,26], and alteration of septal activation, resulting in incoordination of contraction [27]. The regression of hypertrophy in areas remote from the basal septum after ASA indicates that myocardial hypertrophy in HOCM is in part afterload dependent and is not entirely caused by the genetic defect [25,26]. Furthermore, changes in diastolic function resulting from ASA also seem to contribute to long-term improvement in hemodynamics [28]. This effect might be brought about by more favorable relaxation as well as a reduction in left ventricular stiffness secondary to regression of hypertrophy [22,23,25,29,30], decrease in interstitial collagen, and expression of tumor-necrosis factor [31].

The technique

Assessment of outflow gradient

Although some centers only measure the gradient non-invasively using echocardiography, most operators use hemodynamic measurement of outflow gradient during the procedure to confirm the gradient. A 5 Fr pigtail or multipurpose catheter with side holes situated close to the tip can be used to measure pre-stenotic pressure. Many operators prefer to introduce the catheter retrogradely via a contralateral femoral arterial puncture, rather than perform trans-septal puncture with a Brockenbrough catheter as described initially [6]. It is essential to place the catheter close to the apex particularly in cases with mid-ventricular hypertrophy. A J-wire is sometimes used to advance the catheter further toward the apex. Attention should be paid to avoid entrapment in the myocardium, as this can exaggerate the gradient. This is achieved by injecting a small volume of contrast via the catheter, and checking for proper clearance of the dye.

A 7 or 8 Fr guiding catheter (e.g., short tip Judkins type which allows deep intubation of the vessel if necessary) is placed in the ascending aorta to measure the post-stenotic pressure. A 6 Fr catheter can cause excessive pressure damping with concomitant use of a balloon catheter required for alcohol injection later during the procedure, and should therefore not be used. After exclusion of a valvular gradient, the peak-to-peak intraventricular gradient should be measured at rest, during isoproterenol infusion, and after extrasystoles (Figure 54.1). Isoproterenol infusion is particularly useful to reveal a gradient in sedated patients and can be administered by diluting 200 µg in 50 mL saline, with injection of a bolus of 1–3 mL followed by additional boluses until a heart rate of 100–120 b.p.m. is reached.

In order to ensure backup pacing in the advent of complete atrio-ventricular (AV) block, a temporary pacing wire should be placed in the right ventricle. If extrasystoles are not observed spontaneously, the pacing wire may also serve to measure the post-extrasystolic gradient by programmed stimulation (with coupling intervals of approximately 370 ms). Any beta-blocker therapy should be discontinued because of the increased risk of heart block and also in order to assess the underlying outflow gradient optimally.

Placement and testing of the balloon catheter

An angiogram of the left coronary artery is performed (Figure 54.2a). Milking of the septal perforators that supply the hypertrophied segments, which is often observed, is a good indicator for identifying the target vessel. Placing the guidewire in the septal branch can occasionally be challenging because of a steep take-off angle. It can be helpful to pre-shape the guidewire with two angles through a needle as shown in Figure 54.3 (rather than a curve). A floppy guidewire should be tried first, and advanced distally into the septal perforator in order to ensure stability. Stiffer guidewires (intermediate, or in rare cases a standard wire) are sometimes needed to make the balloon go through steep angles. Exceptionally, a 4 Fr catheter with a sharp angle (e.g., an internal mammary catheter) can be used as an inner catheter to pre-select septal branches with extremely steep takeoffs for placing the 0.014-inch guidewire. Nonetheless, catheters should be manipulated with extreme caution to avoid dissection. Ultimately, another balloon catheter can also be briefly inflated just distally to the septal branch, and the 0.014-inch guidewire bounced off into the targeted vessel.

The targeted septal branch should have a diameter of at least 1.5 mm. After administration of intravenous heparin, the shortest available balloon catheter (a 10 × 2 mm balloon is suitable for most cases) is placed as proximally as possible in a stable position. The balloon should be adapted to the dimension of the vessel and slightly oversized (usually 2–3 mm). Although balloons dedicated to this procedure have been developed, standard angioplasty balloons can be used. If there is early proximal branching of the septal perforator, a very short balloon (5 mm) can be used. Consequently, the guiding catheter should be positioned more deeply to give more support for the balloon catheter and avoid recoil during injection. The balloon should be inflated with a pressure of 4–6 bar, and proper positioning should be verified by injection of contrast agent into the left coronary artery (Figure 54.2b), and then distally via the lumen of the balloon catheter using about 1 mL dye (Figure 54.2c). Absence of retrograde leakage and stability of balloon position (especially with shorter balloons) should be verified cautiously. A key point is to inject the contrast *forcefully* via the inflated balloon catheter when testing for stability. In addition, the extent of

Figure 54.1 Hemodynamic monitoring with a resting peak-to-peak gradient of 100 mmHg and a post extrasystolic gradient of approximately 170 mmHg.

myocardium supplied by the septal branch and shunting of flow to non-targeted regions can also be analyzed, preferably using two different projections. The injection of contrast agent also increases ischemia to the territory of the septal branch. The outflow gradient should be monitored constantly, and within 5 minutes of balloon occlusion, a drop in the resting gradient by >30 mmHg or the post-extrasystolic gradient by >50 mmHg should be observed. In a significant proportion of patients, these criteria are not met [30]. Nowadays most operators prefer echocardiographic criteria using echo contrast to delineate the target area. If necessary, the balloon catheter can be positioned in another septal branch. The target vessel occasionally originates from an intermediate or diagonal branch [32], or from the posterior descending artery in case of a dominant right coronary artery [12].

Guidance by myocardial contrast echocardiography (MCE) has proved to be particularly useful, and can influence the interventional strategy in 15–20% of cases either by changing the target vessel or aborting the procedure. In addition, MCE allows increased success

rates despite reduced infarct size, which in turn reduces complications [20,32]. Before injecting alcohol, 1–2 mL echo contrast (e.g., Sonovue®, Levovist®, Optison®, Albutex®) is injected via the inflated balloon catheter under transthoracic echocardiography in the apical four- and five-chamber views (Figure 54.4a). This will ascertain whether the opacified myocardium is adjacent to the region where the anterior mitral leaflet comes into contact with the septum, and allows withholding of alcohol administration where there is a sub-optimal perfusion pattern, such as if the right side of the interventricular septum is predominantly opacified [33]. This technique also allows the delineation of the infarct zone and rules out any retrograde leakage or involvement of myocardium distant from the expected target region such as the ventricular free wall or papillary muscles [16,32,34]. With echo contrast volumes of more than 1 mL, transcapillary leakage of the contrast medium into the ventricles occurs, more often the right than the left (Figure 54.4b). When echo contrast is not available, echocardiography can also be performed by using agitated regular contrast dye injection in the septal

Figure 54.2 Angiography of the left coronary artery (a). Right anterior oblique view (b). Balloon catheter inflated and placed in the first septal branch over a 0.014-inch guidewire (c). Contrast medium is injected via the balloon catheter to confirm the absence of retrograde leakage (d). Angiogram after alcohol injection. Note that the first septal branch is patent.

Figure 54.3 Pre-shaping the 0.014-inch guidewire with two angles through a blunt needle (left) and positioning of the guidewire in a septal branch (right).

perforator via the occluded balloon catheter. Furthermore, contrast dye injections through the inflated balloon should not be carried out before echographic imaging (e.g., when testing for balloon stability), as this can opacify the myocardium and make interpretation of the images more difficult during subsequent injections.

Alcohol injection

Once the septal perforator is deemed suitable and the balloon position is stable without any retrograde spilling, 0.7–3 mL 96% alcohol is injected through the inflated balloon catheter. Before

this, analgesia can be administered for pain control. The volume injected depends on the dimension of the vessel and the volume of the targeted myocardium. The speed of delivery is subject to debate, as the alcohol may be either injected slowly over 1–5 minutes or as a bolus. We prefer the latter technique, as this allows more efficient dissipation of the alcohol over a larger volume of myocardium and avoids preferential streaming to a single region. However, it can be argued that slow injection allows for longer contact of the alcohol with the myocardium (for instance, by initially inducing capillary leakage which subsequently allows more alcohol extravasations into the interstitial tissue). Nonetheless, recent animal studies have shown that it is not the speed of alcohol injection, but the amount of alcohol injected that determines the resultant infarct size [35,36]. Therefore, during recent years, there has been a tendency to reduce the volume of alcohol injected to a maximum of 2 mL [14,30,37], which reduces complications. During injection, the electrocardiogram should be closely monitored, and the injection aborted if AV block develops. The balloon should remain inflated during at least 5 minutes in order to enhance contact of alcohol with the tissue and avoid reflux into the left anterior descending artery. Angiography of the left coronary artery should be repeated following balloon deflation in order to confirm patency of the left anterior descending artery (Figure 54.2d). The target septal vessel is not necessarily occluded, although flow usually appears sluggish. It is not

Figure 54.4 (a) Apical four-chamber echocardiogram showing the hypertrophied septum (b). Injection of echo contrast via the occluded balloon catheter positioned in the first septal perforator, with opacification of the basal septum (arrow). Note the presence of echo contrast (asterisks) within both ventricles due to transcapillary passage (c). After alcohol injection, the area of necrosis becomes echodense (arrow).

known whether this has any impact on treatment efficacy. Echocardiographically, the injection of alcohol results in a marked contrast effect, which is much stronger than currently available echo contrast agents (Figure 54.4c).

The hemodynamic objective is a decrease of the gradient to <10 mmHg at rest in patients with resting gradients >30 mmHg, or a decrease by >50% of a significant provokable gradient [12]. If there is a significant residual gradient after a period of 5–10 minutes following the last injection, a new alcohol injection can be attempted by placing the balloon more proximally inside the same septal branch, or using a shorter balloon if branches of the septal perforator were occluded by the balloon inflation during the first injection. Alternatively, a second septal perforator can be targeted using the same procedure as for the first branch. Most patients require one target perforator branch only, especially since the advent of MCE. Furthermore, a residual gradient of <30 mmHg is often acceptable, as it has been shown that outflow gradient can further decrease over time [19]. Some operators therefore prefer a “one vessel per session” approach, and it is still unclear whether more than a single septal perforator should be targeted initially.

Post-procedural management

Vascular sheaths can be removed after normalization of coagulation parameters. Heparin at therapeutic levels does not need to be pursued after the procedure. Furthermore, all patients should receive aspirin (e.g., 100 mg/day) before the procedure, which should be continued for 1 month to prevent mural thrombosis resulting from the infarct. Creatinine kinase (CK) levels should be assessed every 4 hours in order to measure peak values. Peak rises are commonly in the range of 750–1500 U/L. Patients should be observed in the coronary care unit for 48 hours, with removal of the transvenous pacemaker at the end of this period in the absence of AV block. The patient can then be transferred to a monitored step-down unit for the remainder of the hospital stay (which is usually 1 day). Inotropic and chronotropic therapy, especially beta-blockers, can be resumed—possibly at lower doses—if there are no significant bradyarrhythmias [12].

Treatment efficacy

Although no randomized controlled trial comparing ASA with surgical myectomy has been performed, the general consensus is that in centers with appropriate expertise, operative risks, hemodynamic benefits, and initial symptomatic benefits are broadly comparable with either technique [38]. Evidence from non-randomized trials also indicate that ASA is similar to myectomy with respect to hemodynamic and functional improvement [39–41]. Pooled results of published studies on ASA show acute reductions in mean resting LVOT gradients from 65 to 17 mmHg and mean post-extrasystolic gradients from 125 to 53 mmHg, with persistence of the reduction after 12 months (16 and 32 mmHg, respectively) [42]. In addition, there is a significant improvement at 12 months of functional class (NYHA Class 2.9–1.2, CCS 1.9–0.4), peak oxygen consumption (17.8–23.6 mL/kg/min), and exercise capacity (86.2–122.8 W). Procedure success is achieved in 89% of cases. Repeat procedures despite initial success are required because of recurring gradient and symptoms in 7% of patients. Reported predictors of procedural failure are total peak CK <1300 U/L and immediate residual LVOT gradient \geq 25 mmHg [43].

Adverse events

Early mortality (occurring during or up to 30 days after the procedure) is low, with a mean value of 1.5% reported [42], which is similar to that for surgical myectomy. Causes of early mortality include left anterior descending dissection, ventricular fibrillation, cardiac tamponade, cardiogenic shock, and pulmonary embolism. Late all-cause mortality is reported at 0.5%, the most frequent causes being sudden cardiac death, pulmonary embolism, congestive heart failure, and other non-cardiac causes. Other reported adverse events include coronary dissection and spasm (1.8% and 1.4%, respectively), stroke (1.1%), and pericardial effusion (0.6%).

Spontaneous ventricular fibrillation in the immediate peri-procedural period is not frequent (2.2%), and sustained ventricular tachycardia is extremely rare (only three cases reported in current literature) [42,44].

The most frequent complication of ASA is complete AV block requiring permanent pacemaker implantation. Occurrence of acute

complete AV block during the procedure varies between 21% and 70% of patients [45–49]. Yet there is recovery of AV conduction in most cases (41–100%) before leaving the catheterization laboratory, and in two-thirds of patients within the first 3 days [46,47]. Disappearance of procedural complete AV block has been reported as late as 13 days after the procedure [46]. Delayed complete AV block can also develop later during hospitalization in patients without previous procedural complete AV block or as a recurrence after recovery from acute complete AV block. Depending on the definition used, delayed complete AV block occurs in 1–25% of cases, after a mean period of 36 hours post-procedure, and usually requires permanent pacemaker implantation because of persistence of the conduction defect [47,49]. The block can appear sometimes as late as 96 hours after the procedure [50]. It is thought that transient procedural conduction abnormalities are likely caused by the acute effects of alcohol on the myocardium and conduction system (ischemia, edema, and inflammation), while permanent conduction abnormalities are probably caused by necrosis, scarring and, possibly, remodeling [47]. Ultimately, around 10% of patients require permanent pacemaker implantation after ASA [42].

Several studies have sought to determine predictors of development of delayed complete AV block, with conflicting results [43,47,49,51]. Overall, the most consistent predictors of subsequent permanent pacing implantation appear to be baseline left bundle branch block (LBBB), baseline first-degree AV block, and procedural complete AV block [43,47–49,51]. Some authors suggest elective permanent pacemaker implantation prior to ASA in patients with baseline LBBB [48]. Furthermore, an earlier study showed that use of MCE limits infarct size and reduces the need for permanent pacemaker implantation from 17% to 7%, subsequently leading to widespread use of MCE during ASA [45]. Other parameters reported as significant predictors of complete AV block development are new intraventricular conduction defects, pre- or post-procedure prolongation of QRS duration, retrograde AV nodal block (assessed by simultaneous electrophysiologic investigation), advanced age, female gender, bolus injection of alcohol, and injection of more than one septal artery. However, none of these parameters were systematically confirmed across different studies [43,47–49,51]. Based on several of these predictors, some groups have elaborated specific management strategies based on risk of complete AV block occurrence [48,49]. We and others implant a pacemaker if the block persists for >48–72 hours, although AV conduction recovers in many patients with longer observation [43].

New right bundle branch block (RBBB) is seen approximately in half of patients [42]. This finding is not surprising, because the right bundle is a discrete structure that is vascularized by septal branches from the left anterior coronary artery in 90% of patients, whereas the left bundle is fan-like and receives a dual blood supply from perforator branches of both the left anterior descending and posterior descending arteries. The left conduction system can nevertheless be involved, and new left anterior fascicular block is reported in 6% of procedures [42]. Furthermore, a cardiac magnetic resonance study reported a greater left ventricular mass reduction following ASA in patients who developed new RBBB compared with those without RBB [52].

Despite the creation of a septal infarct, new Q-waves in the septal leads are rarely seen after ASA. Baseline Q waves even tend to disappear following the procedure [53].

In patients with permanent pacemakers undergoing ASA, loss of capture occurs if the ventricular lead is placed near the septum

[54]. Increasing pacing to maximum output during the first days following the procedure might therefore be prudent in these patients.

Finally, although concern has been raised about creation of an arrhythmogenic substrate by ASA [10,55], there is currently no evidence that indicates an increase in incidence of ventricular arrhythmias or sudden death during follow-up, as assessed by serial electrophysiologic studies before and after the procedure [30,56] or by analysis of implantable cardioverter-defibrillator intervention rate [57].

Future directions

Since the original description in 1995, the procedure has undergone several modifications and improvements that have led to optimization of the results and minimization of complications, most importantly through the reduction of the effective dose of alcohol and the use of MCE. Recently, use of intracardiac echocardiography has been described as a way to provide continuous imaging of the treated segment of the septum during the whole procedure [58,59]. Facilitation of septal artery cannulation by magnetic navigation has also been reported [60]. Other novelties include use of polyvinyl alcohol foam particles, absorbable gelatin sponge, or septal coil embolization as alternatives to alcohol, which can further reduce the incidence of complete heart block [61–63]. Finally, reduction of septum by radiofrequency catheter ablation and cryoablation are currently under investigation [64,65].

Clinical investigation and expert consensus documents have produced more clinical outcomes data regarding this interventional procedure and have attempted to put in perspective the other two ways to approach hypertrophic cardiomyopathy: conservative medical therapy and surgical myectomy. The importance of a comprehensive evaluation with clinical, imaging, genetics, interventional and surgeon specialists has become widely accepted and the arrhythmic risk of all these patients warrants additional evaluation with electrophysiology point of view. Reviewing these data, we deduce that different types of patients are treated with different therapeutic approaches and none of the studies employed prospective randomization. Therefore, the nature of the observations does not allow a fair comparison among the three treatment strategies [66–70].

Conclusions

Although surgical myectomy has set the standard of therapy for drug-resistant HOCM, ASA is an alternative that may be considered in many patients. Data indicate that functional and hemodynamic success is high and similar to that of surgery, with the advantage that it may be performed in patients in whom major surgery is considered unsuitable. Benefits in comparison to myectomy also include shorter hospital stay, minimum pain, and avoidance of complications associated with surgery and cardiopulmonary bypass. Nevertheless, ASA has an important learning curve, with potentially serious complications, the most frequent of which is complete AV block requiring permanent pacemaker implantation in approximately 10% of patients. Although these rates are declining with continuing experience, the advent of imaging techniques such as MCE and use of lower alcohol doses, the procedure should be performed only by experienced operators and on carefully selected patients.

Left Atrial Appendage Exclusion

Jorge G. Panizo and Jacob S. Koruth

Helmshley Electrophysiology Center, Mount Sinai Hospital, New York, NY, USA

The relationship between thromboembolic events and atrial fibrillation (AF) has been convincingly established in numerous studies [1,2]. Prevention of these embolic events has traditionally been based on chronic oral anticoagulation with either warfarin or one of the newer oral anticoagulant agents (NOAC) [3]. The left atrial appendage (LAA) has been identified to be the site of thrombus formation in most patients in this setting [4]. Based on this, percutaneous and/or surgical exclusion of the LAA has been demonstrated to be an effective approach to reduce the thromboembolic risk associated with AF.

Surgical LAA exclusion has been performed for many decades as part of cardiac surgical procedures like mitral valve surgery. However, this approach is limited by complications such as peri-operative stroke and/or bleeding, incomplete LAA closure, laceration, and so on. Because of its invasive nature and the morbidity associated with surgical exclusion, non-surgical approaches have gained considerable momentum. This chapter provides an overview primarily addressing catheter-based devices that are currently available or being investigated for LAA exclusion. Most of these are designed to obstruct the LAA orifice mechanically from the endocardial aspect (e.g., Watchman and Amplatzer cardiac plug; endocardial devices). The Lariat procedure, however, uses a combined endo-epicardial access to suture ligate the base of the LAA from its epicardial aspect (epicardial device). The chapter includes a general description of implant technique, procedural tips, and recommendations post-implantation.

Indication for LAA exclusion

Endocardial devices

The only endocardial device approved in the USA is the Watchman device which is indicated for patients at risk for embolic events (CHA₂DS-VASC₂ > 1) who have been deemed to be suitable for anticoagulation *and* have an appropriate rationale to seek a non-pharmacologic alternative:

- History of major or recurrent bleeding on anticoagulation therapy;
- High risk of major bleeding secondary to trauma related to lifestyle, occupation, frequent falls or fall risk, where the benefits of anticoagulation outweigh the risk of major bleeding; and
- Inability to maintain a stable INR or comply with INR monitoring (and unable to take a NOAC).

The reader should note that these are the only approved indications that are supported by randomized data [5].

However, endocardial devices may be also considered as *options* for certain other patients. One must keep in mind that these indications are not approved in the USA, are not supported by randomized data but are derived from observational studies, and involve the use of antiplatelet agents that themselves carry a significant bleeding risk:

- Patients with absolute contraindications to anticoagulation such as history of a significant bleeding event such as intracranial or life-threatening bleed, the source of which cannot be eliminated;
- Increased bleeding risk: HAS-BLED score ≥ 3 ;
- Requiring prolonged triple therapy (aspirin, clopidogrel, and warfarin/NOAC) such as patients with AF with recent coronary stenting [6];
- Conditions such as chronic inflammatory bowel disease, thrombocytopenia, or cancer that increase bleeding risk (not reflected by HAS-BLED score).

Epicardial devices

This approach is currently only available using the Lariat device. The typical patient offered this approach has an absolute contraindication to anticoagulation. Outside the USA, if dual antiplatelet therapy is allowable, endocardial devices are still often used; however, if antiplatelet therapy is also contraindicated then this remains the only available option.

Endocardial devices: design and technical details

Watchman LAA Occlusion device

The Watchman device (Boston Scientific, Natick, MA, USA) (Figure 55.1a) is a nitinol-nickel and titanium alloy based device with 10 active fixation anchors around its perimeter frame designed to engage the LAA wall. The nitinol frame expands radially to maintain its position within the LAA. In addition, it has a membranous cap made of polyethylene terephthalate that functions as a filter to block emboli from exiting the LAA. It is available in five different sizes: 21, 24, 27, 30, and 33 mm. The Watchman device is supported by evidence that includes nearly 6000 patient-years of

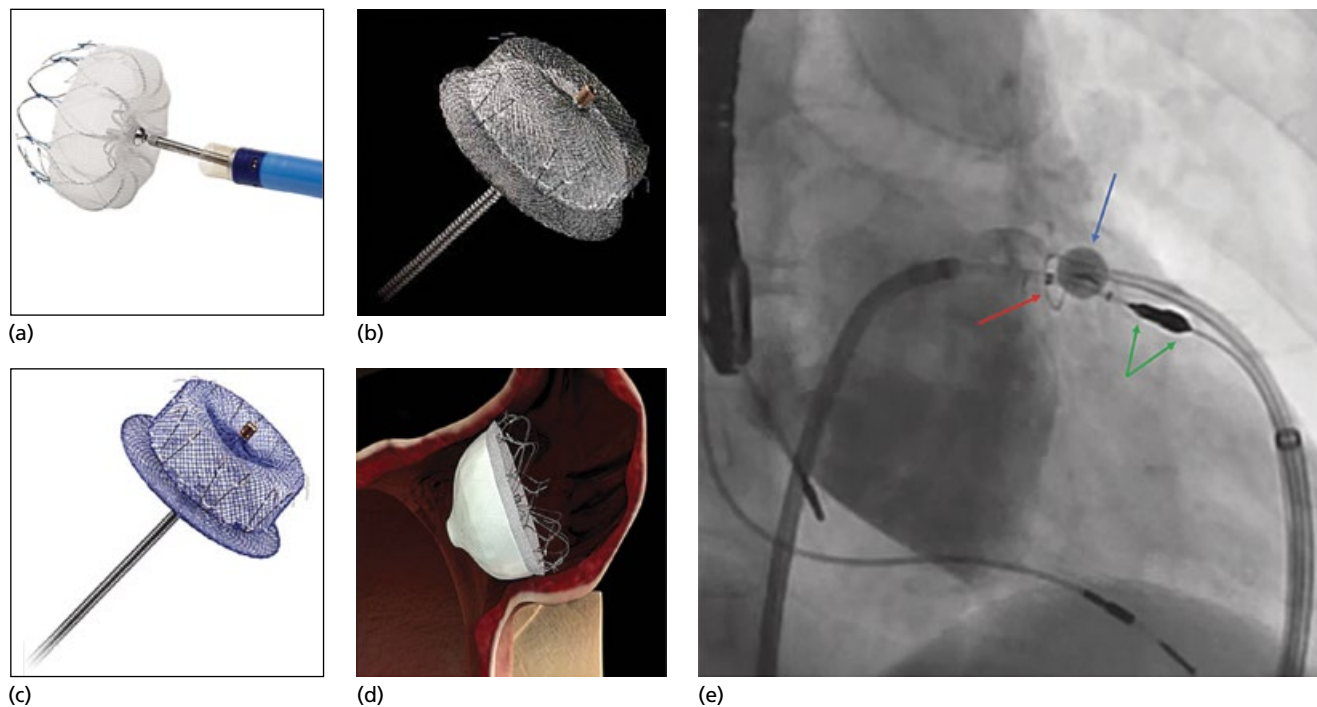

Figure 55.1 (a) Watchman device. (b) Amplatzer Cardiac Plug. (c) Amulet device. (d) WaveCrest device. (e) Fluoroscopic image of left atrial appendage (LAA) closure using the Lariat device: endo- and epicardial magnet-tipped are connected from both sides of LAA apex (green arrows); the endocardial balloon is seen inflated at the level of the LAA ostium (blue arrow) and the epicardial suture is seen as it is tightened around the LAA ostium (red arrow). The left atrium can be seen outlined by iodinated contrast. Sources: (a) Boston Scientific. Reproduced with permission. (b) St. Jude Medical, Cardiology Division. Reproduced with permission. follow-up and is currently the only device approved by the US Food and Drug Administration for LAA exclusion [5,7–9].

Amplatzer Cardiac Plug

The first generation of the Amplatzer Cardiac Plug (ACP 1) device (St. Jude Medical, Minneapolis, MN, USA) consists of a self-expandable cylindrical nitinol “lobe” connected to a nitinol “disk” by a short flexible waist that facilitates positioning and conformation to different LAA shapes (Figure 55.1b). This design was made for sealing the body and ostium of the LAA, respectively. Unlike the Watchman, its length is shorter than its diameter which has advantages for certain LAA shapes [10].

The new generation Amplatzer Cardiac Plug (ACP 2, Amulet device; Figure 55.1c) is designed to accommodate the highly variable anatomy of the LAA and reduce complications [11]. It is available in eight sizes ranging from 16 to 34 mm and has a bigger proximal lobe, a longer waist, recessed proximal end screw, and more stabilizing wires than older models.

WaveCrest LAA Occlusion system

The WaveCrest system (Coherex Medical, Salt Lake City, UT, USA) is a nitinol structure without any exposed metal (Figure 55.1d). Its independent fixation anchors are separately actionable and radially positioned to stabilize the device once the right position is attained. The current generation offers three sizes: 22, 27, and 32 mm. It has been designed for more proximal placement and provides an alternative for very short LAAs.

Procedural aspects for implantation

In the following section we describe the implantation technique primarily of the Watchman and ACP devices. Implantation is typically performed under general anesthesia, based on the need for continuous use of transesophageal echocardiography (TEE) and the potential risk of tamponade or device embolization from inadvertent patient movement during the procedure. Operators should be prepared to identify and treat complications such as cardiac tamponade, air, and device embolism, and so on. Developing protocols for the management of these, including the availability of emergent cardiac surgical backup, are necessary. Fluoroscopy and continuous TEE assessment by an experienced echocardiographer are required. Invasive arterial pressure monitoring is optional.

Imaging

Initially, the echocardiographer rules out thrombus within the left atrium (LA) and LAA. Once the decision to proceed with the implant is made, unilateral femoral venous access is obtained. Although pre-procedural imaging (CT/MRI) can be useful, intra-procedural TEE assessment is usually sufficient. In general, the Watchman and ACP are sized such that they are 15–20% larger than the diameter of the landing zone within the LAA to allow for stable positioning. The most useful TEE views to assess LAA anatomy are the mid-esophageal views at 0°, 45°, 90°, and 135° (Figure 55.2) [12].

The following measurements are usually obtained:

- **LAA ostium:** this measurement is taken from the level of the left circumflex artery to a point 1 cm from the tip of the left superior

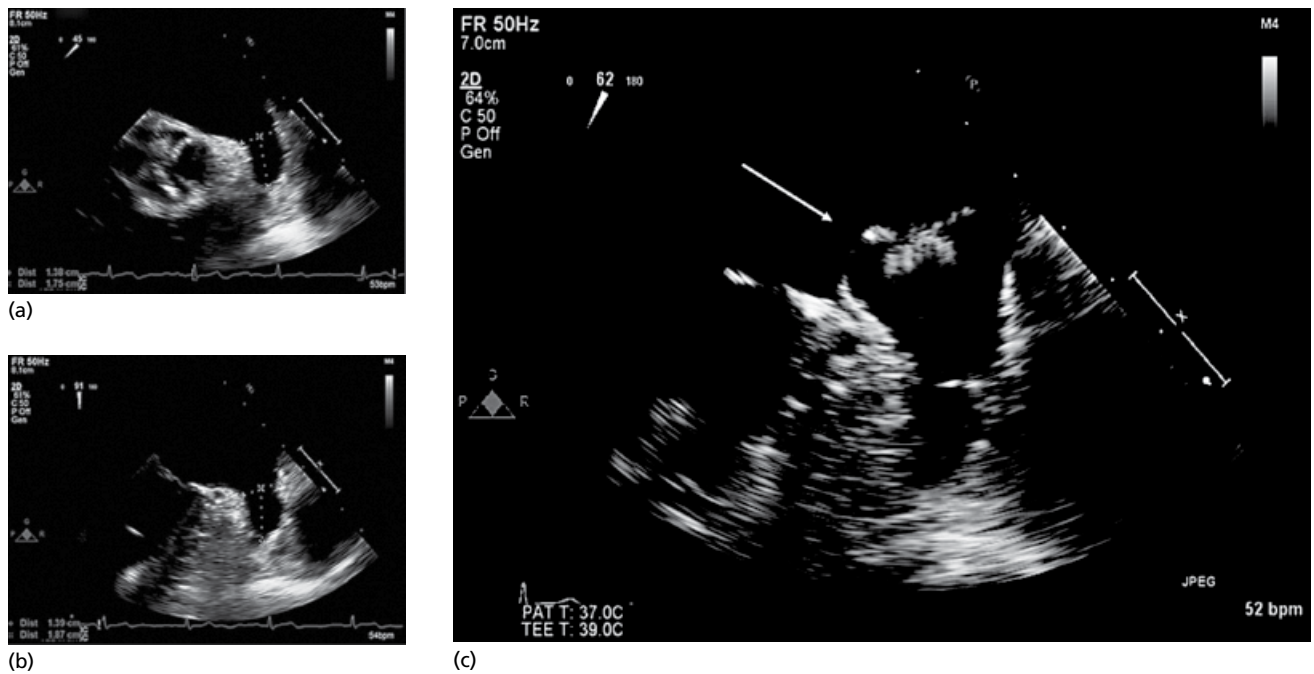

Figure 55.2 (a) LAA measurements in the standard transesophageal echocardiography (TEE) view at 45° and 90° (b). (c) TEE image showing a Watchman device already implanted in the LAA (white arrow).

pulmonary vein limbus (0° view) or from the mitral annulus to a point 1 cm from the limbus (45°, 90°, and 135° views). The Watchman can be implanted if the maximum LAA ostium measures between 17 and 31 mm. The ACP1 device is restricted to ostia less than 29 mm. For larger diameters, the Amulet device is a reasonable alternative.

- **Depth:** measured from the ostial line to LAA apex. A depth that is smaller than the width of the ostium can result in unstable positioning of some devices. In this situation the WaveCrest device is an alternative.

Transeptal access

Anticoagulation with heparin to achieve activated clotting times of 250–300 seconds is required. Access is then obtained under fluoroscopic and/or TEE guidance. It is very important to perform the septal puncture in the inferior portion of the posterior septum, as this allows for direct alignment of the delivery sheath with the LAA. A suboptimal puncture often forces the operator to perform unnecessary manipulation of the delivery sheath during device deployment increasing the risk of potential complications. LA pressures are obtained and if <10 mmHg infusing saline avoids underestimation of LAA size. Device specific sheaths are then placed within the LA for device delivery.

LAA angiography

An adequate outline of LAA is essential to visualize the landing zone. This is usually performed by placing a 4–6 Fr pigtail catheter within the LAA. The best fluoroscopic views to visualize the landing zone for the Watchman is right anterior oblique (RAO) 30° with 30° caudal angulation; for the ACP and WaveCrest devices, RAO with 30° cranial angulation is most useful.

Sizing and positioning

The size of the Watchman device chosen should be 15–20% larger than the diameter of the landing zone within the LAA to prevent dislodgement. For the Watchman device, there are three radio-opaque marker bands on the access sheath that serve as additional guides to assess the depth of the LAA. The Watchman device should be avoided if the LAA depth is less than the device diameter and/or LAA ostium is <17 or >31 mm. For ACP devices, ACP1 must be avoided if the landing zone diameter is >29 mm and/or LAA depth <10 mm. The Amulet must be avoided if the landing zone diameter is >31 mm and/or LAA depth <7.5 mm. The device is typically upsized by 3–5 mm for ACP1 and 2–4 mm for the Amulet (based on landing zone/neck of LAA). Finally, the WaveCrest was designed to cover LAA ostia between 18 and 30 mm.

Deployment

Once angiography is performed, the pigtail catheter is used as a non-traumatic rail over which the delivery sheath is advanced into the LAA. From this point onwards, the patient can be made apneic (if under general anesthesia) as this minimizes the risk of trauma to the LAA wall by the sheath device. Generous “back-bleeding” from the sheath and maintaining “fluid–fluid” connection while loading the device into the delivery sheath are critical for reducing the risk of air embolism.

For the Watchman, once the constrained device is inserted all the way to the tip of the access sheath, the sheath is retracted so that the device is exposed within the LAA resulting in deployment. This is confirmed by TEE imaging. For the ACP, the delivery sheath is placed 1.5 cm within the LAA and the “lobe” of the device is delivered by retracting the sheath followed by deployment of the “disk”

upon retracting the sheath further. Following deployment, respiration can be resumed if apnea was used.

Confirmation and release

Watchman release criteria:

- 1 *Position*: the plane of the maximum diameter should be at or just distal to the LAA ostium. If it too distal within the LAA, partial/full recapture may be required for repositioning.
- 2 *Anchor*: a fluoroscopic “tug test” is performed to demonstrate proper anchoring.
- 3 *Size*: the widest plane of the device should be compressed to 80–92% of its original size. This confirms the correct choice of size.
- 4 *Seal*: ensure that all LAA lobes are distal to the device and confirm that there is complete occlusion of the LAA ostium. Color Doppler is used to detect leaks. Partial or full recapture can be performed until residual jets are minimized.

ACP release criteria:

- 1 Proper alignment and adequate compression of the lobe. Absence of compression suggests proximal position or undersizing.
- 2 Lobe position (at least two-thirds) distal to left circumflex artery on TEE.
- 3 Slight concave shape of disk.
- 4 Separation of the disk from the lobe.

Once all criteria are met and there is no leak noted on TEE, the device can be released. A gentle tug test is occasionally used to establish stability.

The Lariat system: a combined endocardial–epicardial approach

The Lariat system (SentreHeart, Redwood City, CA, USA) involves obtaining epicardial access followed by placing an epicardial suture that is then tightened around the base of the LAA, excluding it from the LA. This system combines trans-septal access (endocardial) followed by the placement of a magnet-tipped 0.025-inch wire within the LAA apex. This magnetically connects itself with a second magnet-tipped epicardial wire introduced on to the epicardial aspect of the LAA apex (Figure 55.1e). The endocardial wire has a compliant 15-mm balloon that when inflated allows identification of the LAA os. A lasso suture is then delivered over the connected wire and then ligated at the LAA os. LAA closure is confirmed by TEE and the pre-tied suture is released. TEE is performed in follow-up to demonstrate absence of any LA–LAA communication.

The Lariat can be considered as an alternative when LAA diameters are too large for either Watchman or ACP devices (although the upper limit for Lariat is 40 mm). However, this approach is contraindicated in patients with prior heart surgery because of the presence of pericardial adhesions. This device should also be avoided in patients with superiorly oriented LAA or if the LAA apex is behind the pulmonary artery. The existing literature provides little insight into its effectiveness as an approach to reducing stroke or its safety relative to other approaches [13].

Post-implantation consideration and follow-up

Endocardial devices

After femoral venous sheath removal, adequate hemostasis can be obtained by manual compression or by placing a subcutaneous non-absorbable figure-of-eight stitch around the tract of the sheath

[14]. The “stitch” approach allows for adequate hemostasis by bringing the subcutaneous tissue together over the vein puncture site. Patients should be observed overnight and it is especially important that nursing staff are familiar with identifying complications that are known to occur with these procedures. Transthoracic echocardiogram (TTE) is often performed to rule out pericardial effusion prior to discharge, although this may not be necessary in experienced centers.

Anticoagulation considerations

For the Watchman device, warfarin is continued post-procedurally (INR 2.0–3.0) along with aspirin 81–100 mg/day.

After 6 weeks, a TEE is performed to confirm exclusion of the LAA:

- (i) Complete occlusion or (ii) residual leak less than 5 mm wide: warfarin can be stopped and replaced with clopidogrel 75 mg/day with increase in dose of aspirin to 300–325 mg/day. This dual antiplatelet therapy (DAT) should be continued for a total of 6 months. Thereafter, long-term aspirin at 300–325 mg is recommended.
- (iii) Leak greater than 5 mm in width or (iv) presence of thrombus over the device: the patient should be maintained on warfarin and return in 4–6 weeks for repeat imaging.

The Watchman was approved for clinical use in the USA on the basis of continued use of warfarin after device implantation and the above protocols are followed in clinical practice. However, the ASAP trial [15] investigated the use of 1–6 months of DAT— aspirin and clopidogrel daily— followed by long-term aspirin only, as an alternative to the warfarin strategy. This study demonstrated that the Watchman could be safely implanted without peri-procedural warfarin therapy with an acceptable ischemic stroke rate of 1.7% (compared to 2.2% stroke rate seen in the PROTECT-AF trial). This strategy, although not supported by randomized data, has a role in some specific clinical situations.

The ACP devices have a low thrombogenicity profile and 6 months of DAT without concomitant oral anticoagulant therapy is thought to be sufficient [16,17]. Of note, although many successful implants have been performed outside the USA using this strategy, there are no randomized data available.

Other considerations

Given that endocardial devices are prosthetic materials placed within the circulatory system, endocarditis prophylaxis for the 6 months following implantation should be prescribed when indicated. Continuing prophylaxis beyond this point is left to the physician's discretion.

Epicardial devices (Lariat)

With regards to epicardial access, a pigtail catheter is placed within the pericardial space for drainage overnight prior to removal. It is mandatory to perform a TTE before discharge to rule out pericardial effusion.

Anticoagulation considerations

Although this is typically performed in patients who cannot receive antiplatelet or anticoagulation therapy, in practice there is a marked heterogeneity in the use of these agents. Continuation of agents when possible is a reasonable strategy to prevent acute post-procedural thrombus formation [18].

Areas for future research

Except for the Watchman device, none of the other devices have been evaluated by randomized controlled trials and device-specific trials are needed to allow the use of these devices clinically with confidence. Although comparisons with warfarin have been made, further studies evaluating LAA closure techniques against NOACs are needed. In addition, enhancements in delivery techniques, device design, and device thrombogenicity will ultimately lead to improved efficacy and safety of this approach to stroke prevention.

Interactive multiple choice questions are available for this chapter on www.wiley.com/go/dangas/cardiology

Cryptogenic Stroke, Patent Foramen Ovale, and ASD Closure

Barry Love

Mount Sinai Medical Center, New York, NY, USA

Excluding bicuspid aortic valve, atrial septal defect (ASD) is the most common congenital defect first recognized in adulthood while a patent foramen ovale (PFO) is found in 20–30% of normal adults. Hemodynamically significant ASDs should be closed to treat symptoms and to prevent the sequelae of long-term left-to-right shunt. Most ASDs are of the secundum type and 80–90% can be closed percutaneously [1] with equivalent safety and efficacy to surgery in the properly selected patient [2,3]. PFO closure is more controversial. PFOs can be closed as secondary prevention after a stroke or transient ischemic attack (TIA) although the effectiveness of this strategy remains an area of controversy.

Types of ASD and PFO

The most common type of ASD is the ostium secundum type. Ostium secundum (or simply secundum) ASDs are defects that result from excessive resorption of septum primum during development. The “secundum” refers not to the septum, but to this being the second hole that is seen in the septum during development.

Ostium primum ASD is less common. It results as a failure of the growing septum primum to reach the AV valves and is a persistence of the first hole to be seen in the septum. Ostium primum ASD is always associated with a defect in the AV valves and is found more commonly in patients with Down syndrome. These defects cannot be closed percutaneously as the defect is contiguous with the AV valves. Other types of atrial septal defects including sinus venosus ASD and sinoseptal defects are much less common, and are not amenable to percutaneous closure.

The foramen ovale is the flap valve that persists between septum secundum to the right and septum primum to the left. Normally, the two septae fuse in the months and years after birth; however, in 20–30% of adults, the potential “trapdoor” remains. The distance that septum primum extends beyond the inferior limit of septum secundum is referred to as the tunnel, which can be quite long. Redundancy of septum primum is called an atrial septal aneurysm defined as excursion of >1 cm. Septum secundum is sometimes quite thickened (lipomatous) in older adults.

Cryptogenic stroke and its relation to PFO

Ischemic stroke is common. In older adults, the etiology is usually attributed to carotid stenosis, intracranial stenosis associated with hypertension, and cardioembolic from atrial fibrillation. Typical risk factors include age, hypertension, smoking, hypercholesterolemia, and family history.

In younger patients without these factors, stroke is much less common and the usual mechanism is referred to as cryptogenic. In patients with cryptogenic stroke, especially those younger than 55 years, a patent foramen ovale is found more often than is found in the general population (~40% compared with 20–30% in the general population) [4,5]. There is presumptive evidence that small venous thromboemboli that would be harmlessly filtered out in the lungs can pass from the right atrium to the left atrium and then pass unfiltered to the brain causing transient ischemic attack or stroke.

In a patient without a prior history of stroke or TIA and the presence of a PFO, there is generally no indication for PFO closure. The risk of a first neurologic event with a PFO is extremely low and cannot be shown to be higher than the baseline risk [6]. However, in a patient who has had a prior stroke or TIA and also has a PFO, the data suggest a risk of 1–5% per year of recurrent stroke [7]. The risk appears to be on the higher end of the range (3–5% per year) for those who have an atrial septal aneurysm in addition to the PFO [7]. In those patients, secondary prevention becomes an important goal.

To date, there have been three large randomized clinical trials, none of which showed a statistically benefit to PFO closure over medical therapy alone. Having said that, there were significant issues with these trials that may have masked a true benefit to the therapy of PFO closure in young patients with cryptogenic stroke and PFO.

The first randomized controlled trial was the Closure I trial which randomized over 900 patients with stroke or TIA to PFO closure using the Cardioseal occluder against medical therapy with warfarin or antiplatelet therapy [8]. There was not a statistically significant difference in outcome of device closure patients versus

either medical arm and no difference between coumadin and antiplatelet therapy; however, the medical therapy arm was not randomized. The major criticism of this trial was poor patient selection in that it was felt in retrospect that many patients with other causes of stroke and TIA were not properly screened out of enrollment, leading to a higher incidence of stroke than expected in both treatment arms and lack of treatment efficacy for PFO closure.

The PC trial, published in March 2013, was a multinational, multicenter trial that randomized 414 patients with PFO and stroke, TIA, or peripheral embolization to medical therapy or device closure with an Amplatzer PFO occluder. Over 4 years, a recurrent event occurred in 3.4% of the closure group and 5.2% of the medically treated group (hazard ratio (HR) 0.62; $p=0.34$). [9]. The study had difficulty enrolling especially because PFO closure was being practiced extensively outside the USA and was underpowered to detect a difference.

Published simultaneously with the PC trial was the most rigorous trial to date, the RESPECT trial comparing the Amplatzer PFO Occluder to medical therapy (warfarin or antiplatelet therapy) in patients with stroke (not TIA) [10]. The RESPECT trial enrolled 980 patients randomized 1 : 1 and completion of the trial occurred after 25 stroke events. Entry criteria were more rigorous than Closure I and the mean age of the patients was 45.9 years. In the intention-to-treat analysis over the course of the trial, there were 16 strokes in the medical therapy group and 9 in the closure group equaling a 51% risk reduction of device therapy but the p value of this difference was only 0.08 – not quite reaching statistical significance. However, on further analysis, three of the patients in the closure group did not have a device in place at the time of their stroke. When those three patients were excluded and the data analyzed on an “as-treated” basis, the risk reduction increased to 73% ($p=0.007$). Subgroup analysis shows an even stronger benefit to closure in patients with atrial septal aneurysm, substantial shunt on bubble study, and to those treated with antiplatelet therapy versus anticoagulation. The risk of PFO closure was low with a 2.4% incidence of procedure-related events and a 2% incidence of device-related events—none fatal.

Based on these data, the trial sponsor (St. Jude Medical) has submitted an application to the FDA for the Amplatzer PFO occluder for secondary prevention of stroke in patients with PFO. However, despite the data being published for more than 2 years, the FDA has yet to make a determination. The significance of the study results are debated in the medical literature [11,12]. PFO closure is being performed outside the USA using various occluders, and in the USA off-label using the Amplatzer™ Cribiform Septal Occluder, and also with the Gore® Helex® Occluder/Cardioform. A third randomized trial is underway comparing the Gore Helex/Cardioform Occluder to medical therapy but enrollment has been difficult.

Our practice has been to offer PFO closure to patients with PFO and cryptogenic stroke after a full disclosure of the state of the science and discussion of the small risk of the procedure. The usual patient is between 18 and 60 years of age with a PFO demonstrated by transesophageal echocardiography (TEE), with positive bubble study, and a prior stroke or TIA with no other cause demonstrated. The stroke work-up is ideally undertaken in partnership with a stroke neurologist to exclude other etiologies for stroke that will not be helped by PFO closure.

The presence of an atrial septal aneurysm and strongly positive bubble study makes the case for closure more compelling and, in our opinion, a reasonable option for patients. There is certainly

no benefit to having a PFO, and so the arguments against closure are the risk of the procedure (low), and the cost. Insurance coverage for off-label PFO closure has been variable in the USA, with some insurers outright refusing to cover the procedure and others willing to pay for the procedure based on the available data.

A rare indication for PFO closure absent stroke or TIA is the patient with orthodeoxia-platypnea syndrome as a result of right to left flow at the atrial septal defect. This unusual circumstance can be seen following a pulmonary lobectomy in a patient with a PFO. In this instance, upright positioning directs the inferior vena cava (IVC) flow across the PFO resulting in significant right to left shunt and desaturation (orthodeoxia) and shortness of breath (platypnea) in the upright position. These patients have a very large bubble shunt seen on echocardiography – worse in the upright position. PFO closure in these patients is curative [13].

Patients with PFO closed for secondary stroke/TIA prevention have reported an improvement or even cure of recurrent migraine symptoms that were present prior to closure. Patients with migraine and aura are more likely to have a PFO (40–60%) than found in the general population (20–30%) [14]. Despite initial enthusiasm, only a single trial of prospective studies to assess PFO closure as a therapy for recurrent migraine in patients without stroke or TIA has been completed, with disappointing results [15].

Atrial septal defect

Physiology

Although ASD is usually diagnosed in childhood, it is also the most commonly diagnosed congenital condition in adulthood (excluding bicuspid aortic valve). It is not uncommon to see an adult patient with a significant ASD with only subtle physical examination findings. In addition, flow across an ASD is dependent on the *relative* diastolic compliances between the right and left ventricles. With increasing age, the left ventricle becomes less compliant, increasing the flow across an ASD that had otherwise gone undetected. Symptoms of shortness of breath on exertion can start to appear in middle age onwards as a result of the increased flow. Atrial fibrillation as a result of chronic left and right atrial stretch from volume starts to be seen in the fourth and fifth decade onwards.

Indications for closure

ASDs that have a shunt fraction of $\geq 1.5 : 1$ should be closed as these have been shown to be enough of a hemodynamic burden to increase the risk of right heart failure, arrhythmias (mainly atrial fibrillation), and pulmonary hypertension (PAH) with time [16]. In addition, exercise capacity is increased in patients undergoing closure for hemodynamically significant ASD [17]. Severe PAH, especially in a younger patient, is a relative contraindication to closure and can hasten their demise. Advanced PAH therapy should be considered and these patients should be managed in conjunction with an experienced PAH center. Some benefit from ASD closure if they respond to treatment [18]. Milder pulmonary hypertension in older patients ($< \frac{1}{2}$ systemic pressure) is common and usually improves with closure as pressure = flow/resistance. When the flow across the pulmonary bed is reduced, the corresponding pressure will decrease as well.

The size of an ASD in the adult that can lead to a significant shunt is usually one that is larger than 6 mm. Smaller ASDs in the adult are not associated with enough left to right shunt to warrant closure on a hemodynamic basis.

Figure 56.1 Atrial septum defect (ASD) rims. Atrial septum as viewed from the right atrial surface. The rim that is usually deficient to some degree is the antero-superior or aortic rim. Large defects often have limited inferior vena cava (IVC) rim for a distance and are called IVC confluent.

ASD transcatheter closure: patient selection

For patients with ASD, a TEE showing a secundum ASD and right ventricular dilatation is required. Further anatomic information can be obtained with a pre-procedural TEE but this step can also be obtained at the time of closure if the transthoracic images are good. A good device candidate is one where the defect is large enough to warrant closure, but not so large as to make closure unlikely to be successful. The usual “window” where this falls is a defect of 6–26 mm in diameter. The occluder size needed for closure will be several millimeters larger than the static dimension measured on echocardiography. Smaller than 6 mm is unlikely to require closure and larger than 26 mm becomes less likely that a device will be able to close the defect without embolization. The largest ASD occluder is a 40-mm Amplatzer Septal Occluder (38 mm in the USA); however, devices this large are rarely used and are best limited to centers with extensive ASD closure experience. There is always discussion about adequacy of atrial septal “rims” for closure (Figure 56.1). The minimum rim is frequently quoted as 5 mm; however, in practice, many patients have deficiency especially of the anterior rim and can have a successful implantation provided the remainder of the rims are adequate and the device is not oversized [19].

Closure of ASD and PFO

In 1995, the Amplatzer Septal Occluder was first introduced for human study for closure of atrial septal defect and gained CE mark in 1998 and FDA approval in 2001. The Gore Helix Occluder was FDA approved in 2006 and has been recently supplanted by the newer Gore Cardioform Occluder that was FDA approved in 2015. Gore has ceased manufacturing the Helix occluder since mid 2015. There are no devices yet approved for PFO closure in the USA.

The Amplatzer Septal Occluder (ASO) is made from a winding of nitinol wire creating two disks and a central waist with polyester

fabric disks sewn into the mesh to create an occluding surface. This device was the first approved device to close ASDs and gained widespread popularity owing to its simple design, ease of use, and excellent closure characteristics. The device is sized according to the central waist ranging from 4 to 40 mm (38 mm in the USA) (Table 56.1).

The Amplatzer Cribiform Septal Occluder is a modified version of the ASO designed to close multifenestrated atrial septal defects. This occluder is different from the ASO in that the central waist is narrow and closure relies on the disks of the occluder. The Cribiform occluder is available in four sizes: 18, 25, 30, and 35 mm which corresponds to the size of the disks. The cribiform occluder is very similar to the PFO occluder used in the RESPECT study; however, the PFO occluder has a uniform 18 mm left atrial disk and the right atrial disk is 18, 25, or 35 mm in diameter. Owing to the design, the cribiform occluder is most used for off-label PFO closure in the USA.

The Gore Helix occluder is a winding of a nitinol wire frame with a Goretex (ePTFE) bag that, when extruded from the delivery catheter, creates two disks of equal size. Unlike the Amplatzer, the device size refers to the size of the disks. The device sizes are available from 15 to 35 mm in 5-mm increments. The Helix occluder has been supplanted by the newly approved Gore Septal Occluder (renamed the Gore Cardioform). The Cardioform is a multilobed nitinol frame with a Goretex bag. The device is superior to the Helix in that the multilobed design is more rigid and less prone to embolization. The simple delivery handle system is also an improvement over the clumsy push-pull technique needed for the Helix. The Cardioform is available in sizes from 15 to 30 mm in 5-mm increments with a recommended 1.7 : 1 sizing ratio also making the device best suited to small and medium-sized defects up to 17 mm.

Contraindications to ASD and PFO closure

The usual considerations of active infection or left atrial thrombus would preclude patients from a closure procedure. Defects other than PFO or secundum ASD cannot be closed with current device technology. The presence of a temporary IVC filter is sometimes encountered in patients undergoing PFO closure. Venography should be undertaken in those patients to ensure that there is not a large thrombus on the filter that could be dislodged with paradoxical embolization. Congenitally interrupted IVC with azygous continuation is rarely encountered but makes closure from the femoral approach impossible. Transhepatic access for closure or an superior vena cava (SVC) approach could be attempted by experienced operators in settings where the IVC approach is contraindicated.

Technique

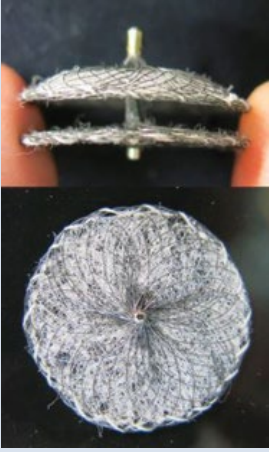

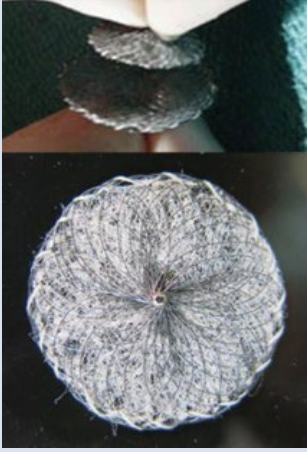

ASD and PFO closure are similar. We will begin the discussion with the elements that are common to both and diverge for the differences.

Premedication

Aspirin 81 mg is usually started 3–5 days beforehand. For patients with aspirin sensitivity, clopidogrel 75 mg/dly can be used instead.

Femoral venous access provides the preferred angle for ASD and PFO closure. ASD and PFO closure is difficult from the SVC approach owing to the sharp angle needed to cross back from right atrium to left atrium with a relatively large, stiff sheath. Arterial access is not usually performed unless concomitant coronary angiography is required. For patients >50 years of age in whom

there is a large ASD and risk of device embolization, we perform coronary angiography routinely prior to attempting ASD closure in case surgery is required.

For atrial septal defect, a right heart catheterization is performed to assess cardiac pressures and shunt fraction. For PFO, unless there are other issues, we usually do not assess hemodynamics.

Heparinization is achieved with 100 U/kg heparin to a maximum of 5000 units with an activated clotting time (ACT) goal of ≥ 250 s.

Imaging for ASD and PFO closure

Single plane fluoroscopy is sufficient for ASD and PFO closure and echocardiographic imaging is required for both.

TEE is most commonly used for ASD closure, while intracardiac echocardiography (ICE) is a good alternative for PFO closure and also for smaller ASDs. For TEE, the echocardiographer or anesthesiologist will be an indispensable ally in assessment of the atrial septum, device selection, and assessment of device positioning across the atrial septum. Two-dimensional imaging is usually better than three-dimensional imaging for assessing defect size and rims (Figure 56.2).

For ICE, the interventionalist usually also interprets the images. The advantage of ICE is that the procedure can be performed with minimal sedation without the use of anesthesia and with a faster post-procedure recovery. TEE generally provides a better view of the atrial septum and we prefer this imaging for larger ASDs. ICE probes are disposable and cost in the range of \$2500 each. There are companies that will resterilize used probes and sell them back (usually at about half the cost of a new probe) for up to three times of use.

Intracardiac echocardiography

Two ICE imaging systems are available: Seimens AcuNav and St Jude Viewflex. The Siemens probes are available in 8 and 10 Fr and the St. Jude catheter needs a 10 Fr introducer. Unlike intravascular ultrasound (IVUS), ICE has a “forward looking” array rather than a circumferential array to give a two-dimensional view of the anatomy. Both ICE probes have handles that allow for two degrees of freedom of movement of the tip—forward and backward in the plane of the array and side-to-side—and also have color Doppler for assessment of flow. Access for the additional catheter is usually performed in the same femoral vein as access for the catheterization a few millimeters inferior to the first needle entry.

The ICE catheter is advanced to the right atrium. Often this needs to be done under fluoroscopy as the catheter tends to “snag” in venous tributaries and patients complain of back pain when it occurs. The atrial septum is best viewed by retroflexing the catheter and turning the catheter clockwise past the aorta to view the septum in a “long axis” view (Figure 56.2, Aa). The foramen ovale is seen in this view. Color Doppler interrogation can be performed to assess for ASD and the catheter should be rotated clockwise and counterclockwise to “sweep” the atrial septum for ASD. The catheter can then be further retroflexed and rotated rightward to view the septum in a “short axis” view (Figure 56.2, Bb). The aortic rim of tissue is best viewed in this plane to assess for deficiency. The ASD should be measured in both planes. For patients with PFO, a bubble study can be performed at this point to assess for right to left bubble shunt. The patient can be instructed to perform a Valsalva to bring out right to left shunt not observable at rest.

Figure 56.2 Intracardiac echocardiogram and corresponding fluoroscopic images during patent foramen ovale (PFO) closure. Note that unlike transesophageal echocardiography, the right atrium (RA) is the closest chamber to the probe. A: ICE catheter in RA retroflexed to view atrial septum in long axis (a). B: ICE catheter further retroflexed and turned clockwise to view atrial septum in short axis (b). C: Crossing PFO with multipurpose catheter and Magic Torque wire. Note that wire crosses the septum at the level of the catheter imaging the PFO. The wire tip is in the left atrial appendage (c) wire crossing PFO. D: Following placement of a 25 mm Amplatzer™ Cribriform Occluder, the device is visualized in the long-axis with ICE (d).

Once the defect is crossed and closure is underway, the septum can be viewed as the left atrial disk contacts the septum and after the right atrial disk is formed. Final device position and a post-procedure color Doppler interrogation for ASD or bubble study for PFO can then be performed (Figure 56.2, Dd).

ASD and PFO closure procedure

After access and interrogation of the atrial septum with ICE or TEE, the ASD/PFO is crossed in preparation for closure. The easiest catheter and wire combination in our experience is a 6 Fr Multipurpose catheter and a 0.035–260 cm Magic Torque wire (Boston Scientific). The advantage of this wire is that it is very directable, the floppy tip avoids damage to cardiac structures, and the relatively stiff shaft can be used as the guidewire over which the delivery sheath is advanced for PFO closure without the need to exchange guidewires. The multipurpose catheter is positioned in the lower one-third of the right atrium and the tip is directed to the patient's left and then turned clockwise. Clockwise rotation points the tip posteriorly where the atrial septum lies. The atrial septum is probed with the wire and entry to the left atrium is confirmed when the wire crosses to the left of the spine without ventricular ectopy. If ventricular ectopy is encountered, the wire is in the right ventricle and needs to be withdrawn and probing continued more posteriorly (more clockwise rotation of the catheter). One "trick" that can be used to help cross the PFO/ASD is that with ICE or TEE, the ultrasound array that is imaging the PFO/ASD must be at the same superior/inferior location as the PFO for the imaging. Under fluoroscopy, the array can be visualized and probing aimed at that level (Figure 56.2, Cc). In our experience, the ultrasound image itself is not particularly helpful in probing for the defect as the part of the wire that is seen tantalizingly near to the defect may be the shaft and not the tip.

Once the PFO/ASD is crossed, the tip of the wire will often lie in the left atrial appendage (LAA) (Figure 56.2, C) The wire is seen to be at the left upper heart border, and usually curls back to the LA. This is not a good wire position as the thin LAA can be perforated with a wire or the device delivery system. It is best to have wire position in a left pulmonary vein. This is accomplished by advancing the MP catheter over the wire to the middle of the spine, withdrawing the wire, turning clockwise (posterior), and probing for the pulmonary vein. The wire will pass beyond the heart border when it is in a left pulmonary vein.

Some advocate a trans-septal puncture to close PFOs with a long tunnel. In order to perform a trans-septal puncture, septum primum needs to be entered quite a bit more inferior than normal or the trans-septal needle will just ride up the septum and cross the PFO. A device placed lower in the septum may not then adequately close the PFO. In our experience, we have only rarely needed to consider a trans-septal puncture to adequately close a PFO. For long tunnels, the Amplatzer Cribiform Occluder is better at closing the defect than the Gore occluders.

ASD sizing

The ASD is first sized by TEE or ICE in the static dimension in orthogonal planes and the rims are assessed. The retroaortic rim is usually this most important and is most often deficient (i.e., less

than 5 mm). If the rim is deficient for only a small distance, then device implantation is probably safe. A large distance of "bare" aorta, however, with no rim should alert the implanter to use caution in device selection and consider avoiding the Amplatzer Septal Occluder because of the risk of device erosion. Balloon-sizing the defect is important in device selection in all but the smallest of ASDs. A 24 or 34 mm compliant sizing balloon (St. Jude Medical) is used for this purpose. The initial guidewire used to cross the ASD is exchanged for an Amplatzer Super Stiff Guidewire (Boston Scientific) with a short (2 cm) floppy tip with the tip placed in a left pulmonary vein. The balloon is inflated under fluoroscopy using dilute contrast (20% contrast, 80% saline) across the ASD until there is no longer flow seen crossing the defect under echocardiography (the so called "stop-flow" diameter). At this point, a small indentation or "waist" is seen fluoroscopically on the balloon (Figure 56.3d) A short cine run is taken and a note made of the exact amount of volume remaining in the syringe used to inflate the balloon. The balloon is then deflated and removed. The balloon is then reinflated outside the body to the same volume stopping at the same point where stop-flow point was encountered. A sizing plate (St. Jude Medical) can then be used to compare the indentation on the balloon seen fluoroscopically with a similar indentation formed when the balloon is placed through varying sizes on a sizing plate. When the same amount of indentation is found, this is the "stop-flow" diameter. This size can also be calculated from the cine image using the marker bands for sizing and it can also be performed by echocardiography; however, we find these two methods to be less reliable than the sizing plate method.

ASD device selection

If the stop-flow diameter is up to 17 mm, both the Gore Cardioform or Amplatzer Septal Defect Occluder can be considered. Larger defects are only suitable for the Amplatzer Septal Occluder. Practically speaking, even the largest Cardioform is much less likely to deploy satisfactorily if the stop-flow is larger than 15 mm.

If there is minimal retroaortic rim, the Cardioform may be advantageous in reducing the risk of device erosion (Figure 56.3a). However, from a practical standpoint, device erosion has been reported mainly for Amplatzer occluder sizes >18 mm and so the risk reduction for the Gore occluder may be overstated.

For Amplatzer sizing, a device at, or 1–2 mm larger than the stop-flow diameter is chosen, keeping in mind that the central waist is the labeled diameter for the Amplatzer occluders. For the Gore Cardioform Occluder, a device at least 1.7× and preferably 2× the the stop-flow diameter is chosen. In our experience, almost all adults with an ASD suitable for the Cardioform occluder receive the 30 mm occluder.

PFO device selection

Although some advocate balloon-sizing for PFO closure, in our experience this has not proved helpful or necessary. The vast majority of PFOs are closed with a 25 mm Amplatzer Cribiform Occluder, or a 20 or 25 mm Helex or Cardioform Occluder. For a very aneurysmal septum, we find a 30 mm Amplatzer Cribiform Occluder is better at stabilizing more of the septum.

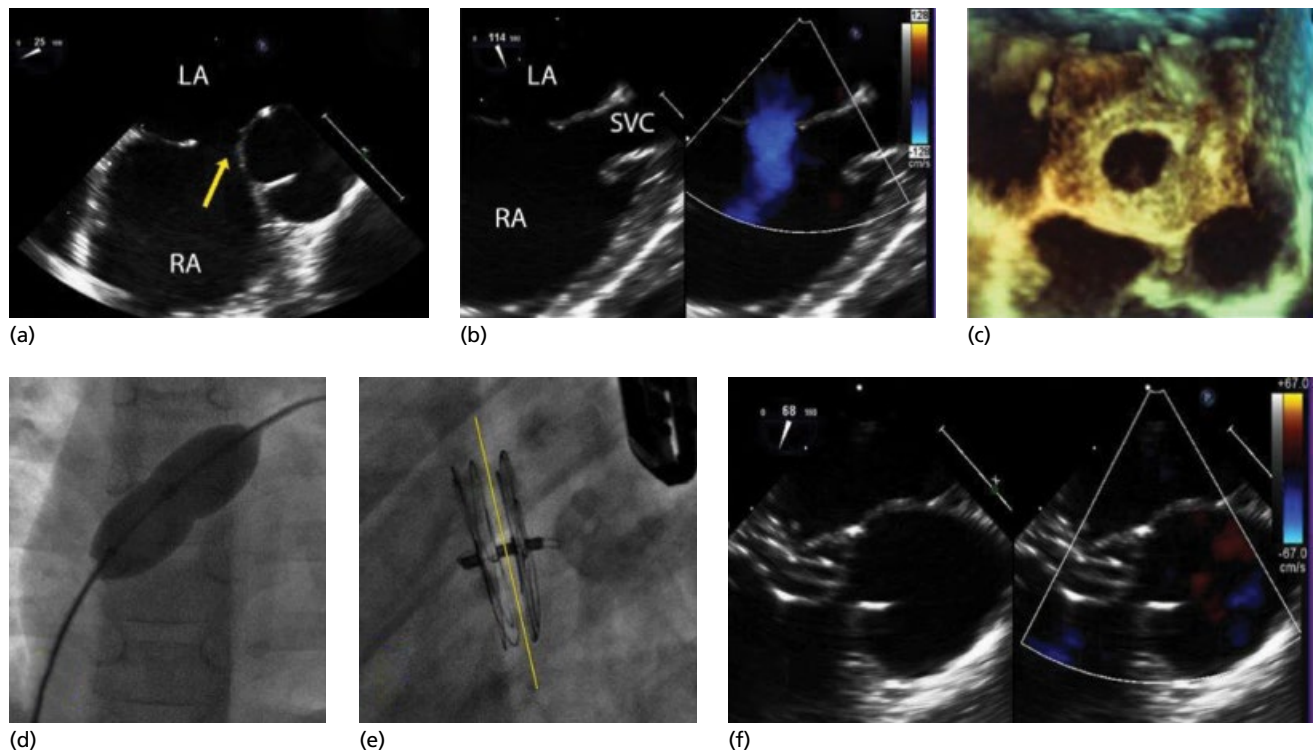

Figure 56.3 ASD closure with a Gore® Cardioform. (a) TEE short axis view of the ASD showing 12 mm defect in that plane with minimal retroaortic rim (arrow). (b) TEE long axis view of the septum showing also 12 mm defect in the orthogonal plane. Note the relatively short distance as well to the superior vena cava (SVC). (c) 3D TEE from the left atrial view showing the ASD. Although the 3D image confirms that the ASD is circular, the relationship to the other cardiac structures is not well seen in 3D. (d) Balloon-sizing of the ASD showing a 15 mm “stop-flow” diameter. (e) Following device release the 30 mm Gore Cardioform Occluder is viewed in a steep LAO view. Note the separation of the disks when the LA and RA disks are on their respective sides (yellow line). (f) TEE post-device release shows good device position and no residual color flow across the ASD.

Device delivery

Amplatzer Cribiform and Amplatzer Septal Occluder

The Amplatzer devices use a long sheath as part of the delivery system. For all sizes of the Cribiform, an 8 Fr delivery system is acceptable. For the Septal occluder, delivery systems ranging 7–12 Fr are used depending on the size of the device. The device is screwed on to the delivery cable that has been put through the loader. Care is taken not to screw the device on too tight on the cable otherwise release can prove challenging. The device is then withdrawn into the loader submerged in a bowl of saline. The device is advanced just to the tip of the loader. Any residual air is flushed from the loader by squeezing about 20 mL saline through the side port of the loader while tapping the loader to disengage any bubbles.

The short sheath is then removed and the delivery sheath passed over the wire. The long sheath positioned in the left atrium over the wire with the dilator approaching but not entering the left pulmonary vein. The sheath is then advanced off the dilator to the tip. The wire and dilator are then removed. The next step is critical. Especially in a spontaneously breathing patient (i.e., when using ICE instead of TEE), the left atrial pressure in young patients without left-sided disease often phasically dips below 0 mmHg—especially if the patient is snoring. If care is not taken, a large air embolism can be entrained through the long sheath into the left atrium with potentially catastrophic results. A minor air embolism is usually noted by ST elevation in the inferior leads because of embolization to the right coronary artery. If that occurs, administration of 100% oxygen and elevation of the

systemic arterial pressure with vasoconstrictors usually resolves the issue within a few minutes. To avoid this problem, the tip of the sheath should be covered with a finger immediately once the dilator is removed and a syringe attached quickly to the hub. To remove any air in the sheath, 10–20 mL of freely aspirated blood should be withdrawn. The loader is then connected to the hub while continually flushing saline through the loader to ensure a “bubble-free” connection.

The device is advanced to the tip of the delivery sheath by advancing the delivery cable. The delivery sheath is pulled back to the middle of the left atrium and the left atrial disk is then delivered by pushing the device out of the sheath. The entire apparatus is then withdrawn until the left atrial disk is opposed to the septum. This is felt by gentle resistance on the delivery cable and also by visualizing the left atrial disk against the septum on the echocardiogram. The delivery cable is then held fixed against the table and the sheath is withdrawn uncovering the central waist and right atrial disk in the case of a Septal occluder or just the right atrial disk in the case of a Cribiform occluder. The delivery cable is then advanced to form the right atrial disk against the septum. A gentle push–pull of the delivery cable ensures that the device is correctly opposed to the septum. If the device is not in a good position, the device can be recaptured into the delivery sheath and delivery reattempted. If the device is recaptured in the right atrium, the delivery sheath is sufficiently curved to allow crossing of the atrial septum with the device at the tip of the delivery sheath; however, this should be performed very cautiously as inadvertent cardiac perforation could occur if not at the atrial septum.

The device position is re-evaluated by echocardiography and if both disks are on the correct side of the septum and there is no deformation of the aorta by the device, the device can be released. This is accomplished by counterclockwise unscrewing of the delivery cable using the torque tool on the back of the delivery cable. Once the device releases from the delivery cable, it will reorient on the septum as the torque from the delivery cable is removed.

Larger ASDs can be difficult to close because the leading edge of the left atrial disk tends to cross over to the right of the aortic rim as the device is withdrawn against the septum. In that instance, one can try to deploy the central waist and right atrial disk more leftward but that often results in the entire device deploying on the left atrial side. Multiple attempts at deployment and recapturing the device are sometimes required. There have been many techniques described to overcome this difficulty; however, the most reliable in our experience has been the right upper pulmonary vein technique. After the left atrial disk is deployed, the delivery system is rotated clockwise until the left atrial disk orients in a horizontal plane. At that moment, the left atrial disk is in the mouth of the right upper pulmonary vein. The device is withdrawn until resistance is felt on the septum and the central waist and right atrial disk are deployed. The device will usually “snap” into position across the atrial septum with this maneuver.

Cardioform

The Cardioform device is first prepared outside the body by submerging the occluder in saline, flushing the delivery system, and then withdrawing the device inside the catheter. The delivery catheter for all sizes is 9 Fr but a 12 Fr sheath is necessary to pass the delivery system with the use of a guidewire. We find this most advantageous and the small increase in sheath size is not problematic. The delivery system is then advanced to the middle of the left atrium over the guidewire and the wire is then withdrawn. The left atrial disk is then formed with a simple forward motion of the slider until the left atrial disk is completely formed. The delivery catheter is then withdrawn against the septum and the right atrial disk is formed by completing the forward motion of the slider. A gentle push–pull of the delivery catheter can be performed to ensure stable position against the atrial septum. The device is evaluated by ultrasound and good position with each disk on the correct side of the atrial septum is ensured. If the device is not in satisfactory position, the device can be recaptured by simply retracting the slider and the process can be repeated.

When the device is in good position, the lock loop is set by pinching and sliding the release mechanism. The device usually reorients a fair bit on the atrial septum when the tension of the delivery system is removed. The frontal camera should be moved to a steep LAO to see both left and right atrial disks perpendicular to each other. When the device is in a good position, a straight line can be drawn between the disks that does not cross any of the “petals” of the frame (Figure 56.3, E). If this cannot be done, one needs to suspect that the device is not in a good position across the septum and consideration should be given to removing the device and reattempting placement with a new occluder.

When the lock loop is set and device position is satisfactory, the retrieval cord is removed by lifting up the red retrieval cord handle and applying gentle smooth traction on the cord. This needs to be done gently as too much force risks dislodging the device. Once the retrieval cord is removed, the delivery system can be removed from the body. A final examination of the device is performed with echocardiography (Figure 56.3f).

Once the lock loop is set, device placement is committed. However, the device can still be removed if needed at this point using the retrieval cord. To do this, the outer sheath as part of the delivery system is unscrewed, and the device is withdrawn into the sheath. Care needs to be taken with the maneuver as the device is being held by only the retrieval cord. Overly aggressive pulling can break this safety cable making device removal more complex, necessitating a snare and a larger sheath and risking embolization.

Completing the procedure

The device is reassessed using echocardiographic imaging and a final bubble study performed if the indication was PFO closure. The delivery sheath and ICE probe are removed and the sheaths are removed. Hemostasis is obtained with manual pressure. We do not reverse heparin as it can lead to thrombosis on the device. As the access is venous only, hemostasis usually takes just a few minutes. The tracking forms for device implantation need to be completed and returned to the manufacturer as required by the FDA.

Adverse events

Serious adverse events are reported in 0.3–0.5% of all implants [20,21]. Of these, perforation/tamponade and embolization predominate. Device embolization generally occurs during the procedure or within the first 12 hours post-procedure. If the device embolizes to the aorta or pulmonary artery, transcatheter retrieval is feasible. To retrieve an embolized device, the screw (Amplatzer) or end (Hexel or Cardioform) needs to be firmly grasped using a snare, and the device withdrawn into a sheath at least 2 Fr sizes larger than the size used to place the device. The device should be fully withdrawn into a long sheath prior to pulling the device through the heart. If the device is lodged in the right or left ventricle, it is inadvisable to attempt catheter removal as this risks tearing the chordae of the tricuspid or mitral valve. This is then best left to the surgeon to remove and close the defect at the same time.

Other rare risks of device closure include endocarditis, stroke, thrombus on the device, air embolism, and device erosion. The risk of erosion has been reported only with the Amplatzer occluder and occurs in 1–3/1000 implants [22]. Device oversizing has been implicated as risk factor as has implantation with retroaortic rim <2 mm. The risk of “insufficient rim,” however, has not been clearly established and at least 40% of secundum ASDs have some measure of deficient rim. This has therefore been labeled a “warning” and not a contraindication for device placement. We feel that careful assessment of the aorta is indicated after device placement and if the device appears to impinge on the aorta, we consider device removal and either reattempting with a smaller device or abandoning the procedure. Device erosion usually occurs within the first few months after closure but late reports of erosion beyond a year have been known to occur. If a patient complains of chest pain following ASD closure, they should be evaluated by echocardiography. If a new pericardial effusion is present, consideration should be given to an erosion event and cardiac surgical consultation obtained promptly.

Arrhythmias—mainly atrial fibrillation—occurs in about 0.5% of patients [2]. Older age is a risk factor. Patients with longstanding shunt from ASD are at risk for atrial fibrillation. Once established, atrial fibrillation will not be improved by ASD closure. In some patients, we have referred for ablation or left atrial appendage occlusion prior to ASD closure.

Headaches are seen in some patients following closure with the Amplatzer Septal Occluder. This seems to occur more frequently in patients with a history of migraine. It is felt to be caused by platelet activation and changing the antiplatelet regimen to clopidogrel from aspirin seems to resolve the symptoms promptly in most patients [23].

There are rare reports of patients experiencing persistent symptoms of chest pain, palpitations, and shortness of breath following Amplatzer Septal Occluder implantation that are thought to be a result of nickel allergy [24]. In some patients, symptoms improve following surgical explant. This phenomenon is very rare, however, compared with the prevalence of nickel sensitivity in the general population (~8%) and we do not routinely test for nickel sensitivity prior to implantation.

Aftercare

Patients undergoing PFO or small ASD closure are usually discharged the same day, whereas we keep patients with larger ASDs overnight to assess for embolization with a transthoracic echocardiogram the following morning. Outpatient follow-up visits with a transthoracic echocardiogram are recommended at 1 week, 1 month, 6 months, and then yearly thereafter. Because the risk of erosion is low and no known methods are able to predict this in follow-up, we feel that unless there are ongoing concerns, follow-up can be generally discontinued after a year and patients instructed that if they experience cardiac symptoms they should be re-evaluated.

Antiplatelet therapy for ASD and PFO closure (aspirin 81 mg or clopidogrel 75 mg) is continued for 6 months until the device is fully endothelialized. At this point, antiplatelet therapy is stopped for ASD patients. However, for PFO patients, we feel that continuing ASA 81 mg/day is a reasonable recommendation based on a “belt and suspenders” approach—that is, some of the strokes that occur in patients undergoing PFO closure are related to other factors and aspirin is helpful to decrease the risk of recurrent events in those patients.

Endocarditis prophylaxis is recommended for dental visits for 6 months following device placement and can then be discontinued. For practical purposes, we recommend that patients avoid routine dental work for 6 months.

The devices are all MRI compatible.

Future directions

The FDA are to decide in the near future if the RESPECT data warrants a device-specific approval for PFO closure in cryptogenic stroke. The Gore REDUCE trial will complete enrollment as another randomized trial comparing device with medical closure in the management of cryptogenic stroke and TIA. New devices continue to be developed to improve on closing larger ASDs while minimizing the risk of complications. Gore currently has a next generation Cardioform in development with self-centering properties to allow larger defects to be closed. Without a PFO market, companies are wary of investing significant resources in new ASD closure designs as the risks are high and the rewards are limited given the smaller population of patients with ASD than with other diseases.

Transcatheter paravalvular leak closure

Upon long-term follow-up after prosthetic valve replacement, up to 17% of prosthetic mitral valves and 10% of prosthetic aortic valves develop peri-prosthetic regurgitation [1–3]. Furthermore, the incidence of moderate or severe peri-prosthetic regurgitation after transcatheter aortic valve replacement has been reported to range from 15% to 20% [4]. While most such patients remain asymptomatic, at least in the short term, 1–3% eventually develop symptoms necessitating intervention [5,6]. Because the underlying anatomic substrate that predisposes to development of peri-prosthetic regurgitation remains, and because re-operation carries significant morbidity and mortality, transcatheter closure of peri-prosthetic regurgitation becomes an attractive treatment option. This chapter discusses the fundamental principles of paravalvular regurgitation evaluation and percutaneous closure.

Pathophysiology

The most common etiologies implicated in the development of paravalvular regurgitation include:

- 1 Underlying tissue friability resulting from senescence, prior endocarditis, or a systemic inflammatory condition with or without corticosteroid use;
 - 2 Extensive annular calcification, especially asymmetric calcification; and
 - 3 Previous valvular surgery (multiple valvular re-do procedures) [7,8].
- Technical aspects of the surgical procedure, such as suture technique and shape of the implant used, are also known to be associated with development of paravalvular regurgitation. While early development of paravalvular regurgitation is usually related to the relative shape of the implant compared with the annulus and underlying annular calcification, later development of paravalvular regurgitation is usually related to tissue friability and suture dehiscence.

Clinical features

Mild paravalvular regurgitation can often be asymptomatic; however, more severe degrees of paravalvular regurgitation can present with signs and symptoms of congestive heart failure. In some cases, even modest volume paravalvular regurgitation can lead to profound symptoms of heart failure because of regurgitation into a non-compliant chamber, either left atrium (LA) or left ventricle (LV). Patients also develop hemolysis from shear stress on red

blood cells (RBCs), and present with fatigue, conjunctival and palmar crease pallor, jaundice, hematuria, and petechiae. Patients with aortic paravalvular regurgitation can present with a diastolic decrescendo murmur over the left sternal border, and patients with mitral paravalvular regurgitation often present with a pansystolic murmur over the mitral area with radiation incumbent on the direction of the major jet. Other classic signs of congestive heart failure can also occur, including elevated jugular venous pressure (JVP), dependent edema, orthopnea, paroxysmal nocturnal dyspnea, and cardiac cachexia.

Diagnostic evaluation

Laboratory findings

Basic laboratory testing should be performed to assess presence, severity, and mechanism of anemia including markers of hemolysis. These should include hemoglobin, hematocrit, reticulocyte count, mean corpuscular volume, reticulocyte count, haptoglobin, lactate dehydrogenase, iron, folic acid, total and direct bilirubin, and peripheral smear examination for the presence of schistocytes. The following findings typically suggest hemolysis: undetectable haptoglobin level, lactate dehydrogenase >500 units, >1% schistocytes on peripheral smear, and >5% reticulocytes.

Imaging

Transthoracic echocardiography (TTE) is usually the first line imaging modality to detect paravalvular regurgitation. While anterior aortic paravalvular regurgitation is easily detected using this modality, detection of posterior leaks is often hampered because of acoustic shadowing from prosthetic valves. Furthermore, the phenomenon of “garden-hosing” which is caused when a strong color flow Doppler signal emanates from a small defect and fans out to occupy a relatively small left ventricular outflow tract, makes accurate assessment of the severity of the paravalvular regurgitation by color flow difficult. Real-time three-dimensional transesophageal echocardiography (TEE) overcomes some of these challenges and allows accurate detection of the location and severity of paravalvular regurgitation. This modality is particularly useful for mitral paravalvular regurgitation. Intracardiac imaging, although not commonly used, can assist with procedural imaging, especially posteriorly located aortic paravalvular regurgitation which can be imaged using an intracardiac imaging catheter positioned in the

right ventricular outflow tract. Aortography can allow accurate assessment of the severity of aortic paravalvular regurgitation in the absence of intravalvular regurgitation. EKG-gated cardiac computed tomography with volume-rendering reconstruction provides invaluable information for peri-procedural planning including accurate detection of paravalvular defect location, shape, and size. It also allows identification of orthogonal angles of AP and lateral imaging intensifiers that would facilitate crossing the paravalvular defect.

Localization

Aortic paravalvular regurgitation is typically localized using the transthoracic aortic short axis view and identifying the regurgitation in relation to one of six sectors each equaling 60°, based on position on the valve leaflets. This is then correlated with a corresponding position on the left anterior oblique (LAO) caudal view. The echocardiographic view of the valve is known to be rotated clockwise by 120° compared with the fluoroscopic LAO caudal view.

In our practice, mitral paravalvular regurgitation localization is performed using a triangulation system utilizing the following landmarks: the anteriorly located aortic valve, the anterolaterally located left atrial appendage, and the medially located atrial septum. Others recommend using a clock face system to localize the paravalvular regurgitation.

These nomenclature systems allow accurate and effective communication between the echocardiographer and structuralist, which is essential to the success of transcatheter paravalvular leak occlusion.

Transcatheter paravalvular regurgitation occlusion

Indications

The recent American College of Cardiology/American Heart Association guidelines for the management of valvular heart disease give percutaneous repair of paravalvular prosthetic valve regurgitation a Class IIa indication for patients with intractable hemolysis or New York Heart Association (NYHA) class III or IV heart failure who are at high risk for surgery and have anatomic features suitable for catheter-based therapy, when performed in centers with expertise in this procedure [9]. The common indications for transcatheter paravalvular regurgitation occlusion include:

- 1 Clinically and/or hemodynamically significant paravalvular regurgitation as evidenced by symptoms and signs of congestive heart failure or hemolytic anemia;
- 2 Stable prosthetic valve function; and
- 3 Defect size involving less than one-quarter valve circumference.

Contraindications include active infection or endocarditis, and unstable prosthesis and regurgitation involving more than one-third of the circumference of the prosthetic annulus.

Devices

Currently, there are no FDA-approved devices for paravalvular leak occlusion. Amplatzer™ Vascular Plug (AVP; AVP II, or IV), Amplatzer™ Duct Occluder, Amplatzer™ Septal Occluder, and Amplatzer™ Muscular VSD Occluder (all manufactured by St. Jude Medical, St. Paul, MN, USA) have been used to occlude paravalvular leaks. We recommend using the AVP II or AVP IV because these devices have a finer and softer nitinol mesh that lowers incidence of hemolysis compared with the other devices. The AVP III has an oblong cross-sectional shape that is particularly suited for paravalvular leak occlusion; this device is available in Europe but not in the USA.

With any device, extreme care must be taken to avoid interference with prosthetic valve leaflet motion or interaction with surrounding structures prior to device deployment.

Techniques

Aortic transcatheter paravalvular regurgitation occlusion

We recommend approaching aortic paravalvular defects using a retrograde aortic approach. For most anteriorly located defects, TTE is sufficient to guide the procedure. This also allows the use of moderate sedation, as opposed to general anesthesia, which is required for prolonged TEE procedural guidance. Posteriorly located defects often require TEE guidance, or intracardiac imaging (ICE) from the right ventricular outflow tract. The fluoroscopy gantries are oriented to visualize the sewing ring on its side on the right anterior oblique (RAO) view and en face on the LAO caudal view. We utilize a “5-in-6” telescoping, coaxial catheter system (125 cm 5 Fr multipurpose diagnostic coronary catheter inside a 6 Fr 100 cm multipurpose guiding catheter) and a 0.035-inch stiff angled glide wire to cannulate the defect. Alternatively, in larger aortic roots, an AL1 catheter can be used to provide directionality to the guidewire. Once the defect is cannulated the 5 Fr multipurpose catheter is used to cross the defect followed by the 6 Fr multipurpose guide. An exchange length 0.032-inch Amplatz Extra-stiff guidewire (Cook Medical, Bloomington, IN, USA) with a pre-formed LV curve is then positioned in the LV (the anchor wire technique; Figure 57.1a). Alternatively, the stiff angled glide wire can be extruded out through the native/bioprosthetic aortic valve and snared in the ascending aorta to be exteriorized via the contralateral femoral artery forming a stable arterio-arterial rail (modified anchor wire technique). Care must be taken to closely monitor hemodynamics while using this technique, because hemodynamically significant aortic regurgitation can develop secondary to the rail. For smaller defects necessitating deployment of a single closure device this may not be required; however, for planned deployment of multiple devices either an anchor wire or formation of a rail becomes necessary. Once the anchor wire or arterio-arterial rail is in place the guiding catheter can be replaced with a 90 cm Cook Flexor Shuttle sheath to facilitate device delivery. Knowledge of the compatibility of combinations of catheters, wires, and closure devices is crucial to ensure success.

Mitral transcatheter paravalvular regurgitation occlusion

An antegrade transvenous trans-septal approach is commonly used for mitral paravalvular defects; however, retrograde aortic and LV apical approaches are necessary when cannulation of the defect is unsuccessful using the former approach. This might occur in the case of medial defects, which can be challenging to cannulate because of proximity to the interatrial septum. TEE guidance and general anesthesia are essential. Gantry setup is similar to that described for aortic paravalvular leaks. TEE and fluoroscopic guidance is used for trans-septal puncture. For medial defects a posterior location of interatrial puncture with the superior-inferior plane at the level of the defect is recommended as this provides the ability to maneuver catheters toward the defect along the mitral annular plane. After obtaining access to the LA, the interatrial septum is dilated using an Inoue dilator and an 8.5 or 11 Fr Agilis NxT Steerable guiding catheter (St. Jude Medical, St. Paul, MN, USA) is introduced over an Inoue wire into the LA. Meticulous care is required to maintain an activated clotting time ≥ 300 s to avoid development of thrombosis. A 5-in-6 telescoping catheter system and exchange length 0.032-inch stiff angled glide wire are used

Figure 57.1 (a) Transcatheter aortic paravalvular leak closure. Top left: LV anchor wire (arrow) through an aortic paravalvular defect. Top right, bottom left: right anterior oblique and left anterior oblique views of nested Amplatzer vascular plugs with anchor wire in place. Bottom right: Amplatzer vascular plugs ready for deployment, yet still attached to their delivery cables. (b) Transcatheter mitral paravalvular leak closure. Top left: Agilis catheter with telescoping catheters, and a still angled Glide wire cannulated through a mitral paravalvular defect. Top right: arrow demonstrates the modified anchor wire technique (arteriovenous loop). Bottom left: an Amplatzer vascular plug being deployed with arteriovenous loop in place. Bottom right: deployed Amplatzer vascular plug.

through the Agilis catheter to cannulate the defect. The 5 and 6 Fr multipurpose catheters are then sequentially advanced into the LV. Depending on the size of the defect one or more devices are required, and can be deployed as described in the subsequent sections.

Sequential deployment technique using the Anchor wire

An 0.032-inch exchange length extrastiff Amplatz guidewire with an LV curve is carefully positioned in the LV and the multipurpose guide is replaced by a appropriately sized Cook Flexor Shuttle Sheath in the LV. Once the first closure device has been successfully deployed, the Shuttle sheath is removed over the guidewire and then reloaded on to the guidewire, leaving the device cable outside of the sheath to facilitate delivery of additional devices using the same sequence. This allows sequential deployment of multiple devices without losing access to the LV.

Sequential deployment technique using an arteriovenous rail or transapical rail (modified Anchor wire)

When additional support is required, the hydrophilic guidewire can be snared in the ascending aorta and exteriorized (Figure 57.1b). An appropriately sized Flexor Shuttle sheath is used as described earlier. With the arteriovenous guidewire rail in position, the first closure device can be placed through the shuttle sheath alongside the existing exteriorized guidewire rail. The Shuttle sheath is then removed and reloaded over the arteriovenous rail, leaving the device delivery cable outside the sheath. Multiple devices can be placed using this sequence while maintaining complete control on wire tension, and allowing device delivery at the end of the

procedure. An attractive aspect of this technique is the ability to reverse course and remove all devices at the very end of the procedure.

Simultaneous deployment technique (double wire technique)

In this technique two or more 0.032-inch Amplatz ExtraStiff Guide Wires are used to make LV loops through the 6 Fr guiding catheter. A large 20 Fr venous sheath is often used. The guiding catheter is removed over the guidewires and two separate 5-in-6 catheter systems are loaded on the guidewires and advanced into the ventricle. The 5 Fr diagnostic catheters are then removed and the 6 Fr guides are used to deploy devices simultaneously.

Complications

Procedural complications include bleeding (5.2%), prosthetic leaflet impingement (4%), device embolization (<1%), and need for emergency surgery (0.9%). Thirty-day complication rates have been described by our group at 8.7% (sudden and unexplained death 1.7%; stroke 2.6%; emergency surgery 0.9%; bleeding 5.2%) [10].

Follow-up

We recommend close follow-up of the patient to monitor resolution of hemolysis and/or heart failure symptoms. No additional antiplatelet or anticoagulation therapy is necessary from the standpoint of the occluder device(s) placed. Serial screening imaging with TTE is recommended during follow-up visits to assess residual paravalvular regurgitation.

Conclusions

In high surgical risk patients with hemolysis or heart failure symptoms secondary to paravalvular regurgitation, transcatheter paravalvular leak occlusion has emerged as a promising and effective therapy when performed in centers with experienced operators.

Transcatheter VSD closure

Ventricular septal defects (VSD) can be divided into congenital (comprising up to 20% of congenital heart defects) and acquired etiologies resulting from either myocardial infarct or post-surgical changes. VSDs are classified as muscular, peri-membranous, or supracristal according to their location within the interventricular septum. Among congenital causes, peri-membranous VSD are the most common (70%) whereas pure muscular VSDs account for 15% and supracristal 5% of congenital VSDs. Catheter VSD closure is indicated for heart failure symptoms, left heart chamber enlargement/volume overload, and previous endocarditis [11]. In the setting of left heart chamber enlargement, VSD closure can prevent the development of pulmonary hypertension, ventricular dysfunction, aortic regurgitation, and arrhythmias. While surgical closure is considered the gold standard treatment, it may be associated with morbidity and mortality, prompting development of less invasive percutaneous transcatheter techniques. Since the first percutaneous VSD closure was performed in 1988 [12], improvements in technique including smaller sheath size and availability of newer dedicated Amplatzer (St. Jude Medical, St. Paul, MN, USA) devices, transcatheter VSD closure has become an increasingly safe and effective procedure.

Patient selection

Transcatheter VSD closure is an especially attractive option in patients with increased surgical risk, multiple previous surgical interventions, “Swiss cheese” type VSDs where multiple defects are present, and poorly accessible muscular VSDs. Anatomic characteristics that favor transcatheter VSD closure over surgical closure include defect location that is remote from the tricuspid valve and aorta, in order to minimize device interference with these structures [11].

Important exclusion criteria to transcatheter VSD closure include:

- 1 Presence of other cardiac lesion requiring surgical repair;
- 2 Irreversible pulmonary vascular disease (pulmonary vascular resistance index $>6-8$ WU/m²);
- 3 Contraindication to antiplatelet therapy;
- 4 Uncontrolled infection; and
- 5 Anatomic features that make transcatheter closure unfavorable (concomitant subaortic rim <2 mm from peri-membranous VSD, close proximity to tricuspid valve).

Procedural techniques

Several devices are available for transcatheter VSD closure including the muscular Amplatzer VSD occluder, membranous Amplatzer VSD occluder (not available in the USA), ASD Amplatzer occluder. Amplatzer ASD and VSD occluder devices are made of self-expanding nitinol, consisting of two umbrellas and middle “waist.” Polyester fabric inserts aid in closing the defect by providing a foundation for tissue growth over the device after deployment. Maximum umbrella size for the 18 mm muscular VSD occluder is 26 mm, 54 mm for the 28 mm ASD occluder, and 32 mm for the

24 mm Amplatzer muscular post-infarct VSD occluder. Devices are secured to a delivery cable and inserted into a delivery sheath ranging 6–10 Fr in size. Device sizes are selected based on two-dimensional echocardiographic measurements; generally the waist of the device should be 1–2 mm larger than the defect size (Table 57.1). Longer waist lengths are required as interventricular septum thickness increases, for instance in adults. Additionally, post-myocardial infarction VSD closure requires longer device waists because of the unique nature of these defects.

Pre-procedural antibiotic prophylaxis (typically, intravenous cefazolin) is administered as well as aspirin (325 mg) and intravenous heparin (100 U/kg). In many patients, the procedure can be performed using conscious sedation. Patients who are better suited for general anesthesia are those in which TEE use is planned, internal jugular vein access is used for device delivery, or in the setting of post-myocardial infarction VSD.

VSD closure

Femoral arterial access is performed with insertion of a 6 Fr sheath and either femoral venous or internal jugular (IJ) venous access obtained with a 7 Fr sheath depending on the planned approach for closure. Femoral access is usually preferred for defects in the more superior portion of the septum (i.e., membranous) whereas IJ more commonly used for other locations. If ICE is planned, an additional 10 Fr sheath is placed in the femoral vein. The VSD is then crossed retrogradely from the LV using fluoroscopic and echocardiographic guidance (TTE, TEE, or ICE) with either a diagnostic right Judkins or a multipurpose catheter and an exchange-length stiff angled guidewire. After the defect is crossed, the wire is typically advanced into the pulmonary artery (PA). A balloon-tipped end-hole catheter is then used to cross the tricuspid valve from the right side with the balloon inflated, in order to avoid entrapment of the chordal apparatus during later placement of the device. This catheter is advanced into the PA and an exchange length guidewire is positioned through the end-hole catheter over which the guide for the snare is positioned. The glide wire is then snared and exteriorized through the venous access site, establishing an arteriovenous rail. If desired, a sizing balloon can be used to help in the assessment of the VSD size by stop-flow method and to delineate the VSD boundaries more accurately; however, echocardiographic guidance is sufficient in most cases (Figure 57.2).

The appropriate sized delivery sheath is then advanced through the venous access site, over the wire rail, into the LV (if one elects to leave the wire rail in place during device delivery a larger sheath will be needed). The wire and dilator are then removed and the loaded device is advanced through the sheath, across the defect, and into the LV. The device is then extruded from the sheath into the LV until the left-sided umbrella is expanded, being careful not to deploy the device into the mitral apparatus. The delivery catheter is then drawn back into the right ventricle until the left-sided umbrella is against the septum, as guided by fluoroscopic and echocardiographic imaging. Finally, the right-sided umbrella is released by withdrawing the sheath, thus covering the defect. The device is then tested for stability by gentle pulling and pushing under fluoroscopic and echocardiographic guidance. Doppler color-flow is used to determine the presence and degree of residual shunting as well as potential interference with surrounding structures such as the tricuspid and aortic valves. Once device position is determined to be stable and there is a significant reduction in shunt (\leq mild residual shunt), the device is released.

Table 57.1 Transcatheter ventricular septal defect (VSD) closure devices.

Device	Device size/waist diameter (mm)	Disc diameter (mm)	Waist length (mm)	Min. sheath size (Fr)

Figure 57.2 Transcatheter ventricular septal defect (VSD) closure. Top left: left anterior oblique left ventricle (LV) angiogram demonstrating muscular VSD with communication from left to right ventricle (arrow). Top right: an arteriovenous rail from femoral artery to internal jugular vein is established. Bottom left: muscular VSD device prior to release with LV angiogram showing no residual shunting. Bottom right: device is released with stable position and minimal residual shunt.

Efficacy and complications

Procedural success rates for transcatheter closure are approximately 90–95% for congenital and post-surgical peri-membranous and muscular defects. Complete VSD closure is achieved in 40–50% of patients immediately post-procedure and 80–90% at 1 year [13]. Residual shunting is usually trivial or mild in degree, with <1% of patients having severe residual shunt requiring surgery [13]. Complications have been reported in up to 10% of patients, including 3–4% risk of rhythm and conduction disturbances, <1% risk of device embolism, <1% risk of major vascular complications, <1% of infection, development of new aortic or tricuspid regurgitation (3–6% of patients, usual of trivial or mild degree), hypotension, and blood loss [13,14].

In contrast, closure of post-infarct VSD has a much lower success rate, in part because of the tendency of the defect to grow over time because of ongoing necrosis and the critically ill state of such patients. Closure performed in the acute setting is associated with a significantly less successful longer term result. While initial procedural success can be as high as 86% [15], the procedural complication rate is 41% including major residual shunting, left ventricular rupture, and device embolization. When cardiogenic shock is present at baseline, despite an 80% procedural success rate, long-term mortality is 93%, reflecting the extreme critical illness present in this population.

Conclusions

Transcatheter VSD closure has emerged as an effective and safe treatment in selected patients with appropriate indications. Advances in catheter-based techniques, imaging, and device technology continue to expand the use of percutaneous transcatheter VSD closure.

Aortic Valvuloplasty and Large-Bore Percutaneous Arterial Access

Matthew I. Tomey, Annapoorna S. Kini, Samin K. Sharma, and Jason C. Kovacic

The Zena and Michael A. Wiener Cardiovascular Institute, and The Marie-Josée and Henry R. Kravis Cardiovascular Health Center, Icahn School of Medicine at Mount Sinai, New York, NY, USA

Near-abolition of rheumatic heart disease in developed countries has transformed the demography of aortic stenosis (AS), which today results primarily from age-associated calcific degeneration [1]. Once common in the sixth decade of life, onset of AS today occurs most commonly in the eighth decade of life. Among older adults, AS is common, with moderate or severe valvular AS documented in 2.8% of US adults over age 75 [2]. Accordingly, with aging of the population [3], incidence is rising.

In the absence of aortic valve replacement (AVR), symptomatic severe AS portends a high risk of mortality that has remained largely unchanged despite advances in medical therapy [4–6]. And yet, with shift in the onset of AS to later years of life, its natural history has been transposed to an age with greater burdens of frailty and medical comorbidities, complicating management. Before the recent advent of transcatheter AVR (TAVR), only half of older adults with severe AS would ever visit a cardiothoracic surgeon, and fewer still would ultimately undergo AVR. Common reasons for this gap included advanced age, comorbidities, high operative risk, perceived lack of symptoms, and refusal by patients or family members [7]. TAVR today offers a lifesaving option for many patients at high or extreme risk for surgical AVR [8–10], and an emerging alternative for those at intermediate risk [10a].

Percutaneous balloon aortic valvuloplasty (BAV) is a minimally invasive structural intervention for management of symptomatic severe valvular AS which emerged in the 1980s, first used in children with congenital AS [11] and subsequently in adults with bicuspid aortic valve disease, rheumatic heart disease, and calcific AS [12,13]. The technique found particular application among patients who were too ill to undergo surgery [14]. With a minimally invasive approach, it was possible to achieve immediate reduction in the transvalvular aortic gradient, increase in calculated aortic valve area, and often improvement in left ventricular function [15–17]. Enthusiasm for these acute benefits and accompanying symptom relief [18] was tempered, however, by recognition of their lack of durability. Three-quarters of patients exhibit hemodynamic evidence of restenosis at 6-month follow-up after BAV [19–21], and indeed, reductions in transvalvular gradient can begin to regress within days after the procedure [22]. Correspondingly, BAV has

been found to yield no benefit for event-free or actuarial survival above and beyond that expected with medical management of AS alone [23,24]. With appreciation that BAV, though less invasive than surgery, was not without risk [25], the procedure was largely dismissed as a standard treatment for symptomatic severe AS, and rather relegated to the roles of palliation in selected cases or occasional temporization prior to surgical AVR [26].

TAVR has disrupted the field of AS management, however, and accordingly, BAV is receiving a second look [27]. The TAVR movement has renewed attention to the many patients with AS previously deprived of intervention because of advanced age or comorbidities. Implementation of percutaneous transfemoral TAVR has required teaching and learning skills shared with BAV and, in particular, techniques for safe large-bore femoral arterial access and closure. Indications for BAV have emerged before and during the TAVR procedure. In several centers, the introduction of a TAVR program brought with it an increase in utilization of BAV [28,29]. This chapter provides a comprehensive reassessment of BAV and large-bore arterial access for adult patients with calcific AS in the era of TAVR.

Basic principles and mechanisms of action

Broadly, BAV entails large-bore vascular access, typically via the femoral artery; placement of a stiff guidewire across the aortic valve; delivery of a non-compliant balloon over the guidewire to the level of the aortic valve; balloon inflation; device removal; and arteriotomy closure. For each element, there exist specialized equipment, essential technique, and opportunities for failure and complications.

Inflation and deflation of a non-compliant balloon placed properly across the stenosed aortic valve produces an immediate increase in valvular effective orifice area via three major mechanisms: fracture of calcium deposits, rupture of commissural fusion, and, to a lesser degree, stretch of valve and annular tissue [13,30–32]. This increase in effective orifice area, typically 50% above baseline upon immediate reassessment [33], confers an acute reduction in transvalvular pressure gradient and left ventricular afterload. Accordingly, immediately post-BAV, patients characteristically

experience a fall in left ventricular peak systolic pressure, left ventricular end-diastolic pressure, and pulmonary capillary wedge pressure. Correction of afterload mismatch [34] can be associated with an increase in calculated cardiac output and improvement in left ventricular ejection fraction, particularly among those with left ventricular systolic dysfunction at baseline [17,33]. In the absence of a change in stroke volume, improvement in left ventricular performance can be evident in a decrease in ejection time, particularly in the later decelerative phase of systole [35]. Additional salutary effects of BAV include attenuation of sympathetic nervous system and renin-angiotensin-aldosterone system activation and mitigation of hemostatic dyscrasias associated with AS, typified by shearing of von Willebrand factor multimers [36,37].

Effects of BAV on aortic valve area, hemodynamics, and left ventricular performance are short-lived. Regression begins quickly: within 2–4 days after BAV patients can expect a 20% increase in mean and peak instantaneous pressure gradient, with 80% of patients experiencing a rise in peak instantaneous pressure gradient of at least 10% [22]. This rebound in pressure gradient can be explained in part by a small but measurable increase in stroke volume via reduction in afterload mismatch. Inflammation and fibrosis of the valve following traumatic injury mediate a structural remodeling response that also contributes to restenosis. In the early weeks following BAV, there is evidence of hemorrhage and inflammation at sites of calcium fracture, with a neutrophilic predominance [38]. By 2 months, microfractures persist but with a transition in associated inflammation to a heavier infiltrate of lymphocytes, plasma cells, granulation, and mesenchymal tissue [38]. In the months that follow, the acute inflammatory response gives way to mesenchymal cell proliferation, hyalinization, myxoid change, and dystrophic calcification and scarring [39]. By 6 months, approximately half of patients experience restenosis back to their baseline level of valvular stenosis [18,40,41].

Indications and evidence for use

Although TAVR has inspired re-examination of BAV, the essential transience of the benefits of BAV remains unchanged, and this informs contemporary indications for its use. In older patients with calcific AS, the primary indication for BAV is to provide temporary relief of transvalvular pressure gradient and symptoms in well-selected patients in anticipation of definitive therapy with surgical AVR or TAVR. Current American College of Cardiology (ACC)/American Heart Association (AHA) guidelines issue a single recommendation for BAV: “Percutaneous aortic balloon dilation may be considered as a bridge to surgical AVR or TAVR in patients with severe symptomatic AS” (Class IIb, level of evidence C) [42].

In clinical practice, this “bridging” role has been applied in several scenarios. For patients acutely ill with symptomatic, severe AS who are too unstable to undergo either surgical AVR or TAVR, BAV facilitates partial recovery en route to subsequent definitive therapy [28,29,43]. In other patients with symptomatic, severe AS, particularly those with evidence of a low cardiac output, low left ventricular ejection fraction, and/or low transvalvular gradient, BAV serves a diagnostic purpose to assess the likelihood of improved left ventricular performance in response to afterload reduction. In certain patients requiring urgent surgery, BAV is sometimes used as a short-term measure with intent to reduce the cardiovascular risk of non-cardiac surgery [44–47]. High quality evidence for this approach is lacking and current guidelines do not endorse it [42]. Finally, in patients who cannot undergo either

surgical AVR or TAVR, BAV remains useful as a palliative measure for temporary symptom relief in select patients. Among inoperable patients randomized to standard therapy in the Placement of Aortic Transcatheter Valves (PARTNER) trial, the 73% of patients who underwent BAV post-randomization enjoyed a significant improvement in quality of life at 30 days that was sustained to 6 months but gone by 1 year [43].

As a new role for BAV, it has become an integral step during TAVR in many centers. The purpose of performing BAV as the step immediately prior to the deployment of a percutaneous valve during TAVR is to ensure the aortic valve leaflets open adequately to permit the passage of the valve across the calcified and disease aortic valve apparatus. However, this indication for BAV continues to evolve as the crossing and deployment profiles of the various TAVR valves improves. Typically, operator preference has a significant role in the decision to perform BAV immediately prior to valve deployment during TAVR.

In children and young adults with congenital AS, BAV maintains an important role. As discussion of BAV in the young exceeds the scope of this chapter, we direct our readers elsewhere for further review [48].

Patient selection and contraindications to BAV

In appreciation of both the temporary benefits and the significant risks of BAV, contemplation of the procedure must obey the principle of *primum non nocere*. The assessment of benefits and risks is inherently individualized. It is nonetheless important to highlight a few relative if not absolute contraindications to BAV: moderate to severe valvular aortic insufficiency; lack of a safe means for percutaneous vascular access and closure; eligibility for primary surgical AVR or TAVR; and, conversely, lack of likelihood to benefit from mechanical relief of AS.

Analysis of the TAVR experience has made apparent a subset of patients with symptomatic, severe AS who do not benefit from correction of AS, even by AVR. At 1 year follow-up of the PARTNER trial, 30% of inoperable patients assigned to TAVR were dead, and half were either dead or devoid of even moderate improvement in functional status or quality of life [8,49]. Clinical predictors of increased risk in the setting of severe AS are presented in Box 58.1 [50].

A final word of caution is warranted concerning risks and benefits of repeated BAV. Given the predictable eventual recurrence of

Box 58.1 Adverse prognostic indicators for balloon aortic valvuloplasty

- Severe left ventricular dysfunction, as evidenced by low flow (stroke volume index <35 mL/m²), low gradient (resting mean gradient <20 mmHg), and/or low ejection fraction with lack of contractile reserve (increase in stroke volume ≥20%) on dobutamine stress echocardiography [51]
- Severe myocardial fibrosis, as assessed by cardiac magnetic resonance imaging [52]
- Severe concurrent mitral [53,54] or tricuspid [55] valve regurgitation
- Severe pulmonary hypertension [56]
- Severe liver, kidney, or lung disease, particularly when associated with oxygen dependence
- Severe elevation in global risk scores such as the Society for Thoracic Surgeons risk score (>15%) [57] and the logistic EuroSCORE [58]
- Geriatric factors, including frailty, malnutrition, impaired cognition, mood disturbance, social isolation, disability, impaired mobility, fall tendency, and polypharmacy [59–61]

stenosis and symptoms after initial BAV, in selected surviving patients with symptomatic, severe AS, repeated BAV can be considered. It is important to recognize that hemodynamic benefits of repeat BAV may be more modest than those achieved with initial balloon dilatation [43], and durability of benefits may be reduced [62]. For a given patient, the probability of experiencing a serious complication of BAV increases with repeated exposure to the procedure. Risks are particularly elevated on the third and fourth occasions [62].

Approach to the procedure

BAV, like its descendant TAVR, can be accomplished either via an antegrade or retrograde approach, described as the direction in which the balloon crosses the aortic valve relative to the direction of blood flow.

An *antegrade approach*, in which the balloon approaches the valve via the left ventricle, can be accomplished either via left ventricular apical access or via venous access with accompanying trans-septal or caval–aortic [63] puncture. The major advantage of an antegrade approach is avoidance of the arterial system, which is affected by a substantial and sometimes prohibitive burden of atherosclerosis in many candidates (Table 58.1). Transvenous access, in particular, offers the putative advantage of reduced access site bleeding and vascular complications in association with large-bore vascular access. A transvenous approach was indeed used for the first case of TAVR in humans [64]. Transapical access, which was studied in the context of TAVR in the PARTNER trial [8,9], offers the added advantages of a shorter distance from the access point to the aortic valve, avoidance of the aortic arch with the device, coaxial wire positioning across the aortic valve, and secure access site closure under direct visualization, at the expense of a mini-thoracotomy [65]. Somewhat surprisingly, expected benefits of the transapical approach for stroke avoidance were not observed in the PARTNER trial. Potential explanations include residual

confounding from vasculopathy influencing selection for the transapical approach in the PARTNER trial [66] and the likelihood that many if not all intraprocedural strokes during TAVR occur during device positioning and deployment at the level of the aortic valve, irrespective of approach [67]. Importantly, while antegrade BAV is still performed in association with antegrade TAVR, given the more invasive nature of this approach it is difficult to conceive of any situation in which antegrade BAV would be performed as a stand-alone procedure in the current era. The remainder of this chapter exclusively considers the retrograde approach.

A *retrograde approach* has been traditionally favored for BAV. In this approach, access is obtained via a large artery (typically, the common femoral artery), and equipment is advanced over guidewires to the left heart via retrograde passage through the aorta. In most cases, transfemoral access permits a totally percutaneous approach. Challenges particular to the transfemoral retrograde approach include risks of vascular complications, bleeding, often tortuous aortoiliac anatomy, and a long distance from the access point to the aortic valve (70–100 cm), creating opportunities for wire bias, slack, and non-coaxial device positioning across the aortic valve [65]. In the following sections, we discuss the optimal approach to large-bore arterial access and retrograde percutaneous transfemoral BAV, acknowledging that there exist inter-institutional and inter-operator differences in technique, preference, and style.

Large-bore arterial access

Safe femoral arterial access is a fundamental step in BAV and TAVR, with important implications for procedural success, safety, and patient satisfaction. Indeed, there are numerous other indications for large-bore percutaneous arterial access in the modern catheterization laboratory, such as left ventricular hemodynamic support devices [72,73]. The techniques described are equally applicable across all of these applications.

Percentages reflect investigator-reported rates of disease at baseline per study definitions.

ACC, American College of Cardiology; CAD, coronary artery disease; CVD, cerebrovascular disease or stroke; PAD, peripheral artery disease; PARTNER, Placement of Aortic Transcatheter Valves; STS, Society of Thoracic Surgeons; TVT, transcatheter valve therapy.

Successful arterial access provides a sufficiently large channel to permit both insertion and removal of necessary devices such as a BAV balloon; an unobstructed pathway from the access point to the aortic annulus and heart; an “exit strategy” for safe closure and hemostasis at procedure conclusion; and minimization of pain, bleeding, and vascular complications. With effective percutaneous access and closure, a patient can be mobilized within hours of BAV, or even TAVR, with little to show other than a small incision and a bandage.

Candidates for large-bore arterial access, however, often represent a particularly vulnerable subset of patients with severe AS with a disproportionate burden of frailty, comorbidity, and instability, limiting tolerance for complications. The femoral and iliac arteries are commonly affected by atherosclerosis, as shown in Table 58.1, with associated tortuosity, calcification, and luminal narrowing. Sheaths required for BAV are large, ranging from 9 to 12 Fr (3–4 mm) in diameter, while access for TAVR requires access from 14 up to 22–24 Fr. Vascular complications of BAV remain common, affecting 5–10% of patients in the TAVR era [74]. The stakes of vascular complications are high. In patients undergoing transcatheter aortic valve interventions including BAV, major vascular complications are associated with higher rates of bleeding, transfusion, renal failure, and mortality [74,75]. Accordingly, meticulous planning and technique for femoral arterial access and closure for BAV and TAVR are required.

Access planning

Increasingly, computed tomography angiography (CTA) is performed prior to contemplating large bore arterial access for the purpose of access planning. This exercise is mandatory prior to arterial access for TAVR. Selected recent recommendations for this imaging from the Society for Cardiovascular Computed Tomography [76] are presented in Box 58.2. When CTA is available, it is essential that the primary operator responsible for access reviews the primary imaging data in advance of the procedure. Nevertheless, in many cases, a comprehensive, appropriately protocolled CTA may not be available at the time of BAV. Attention should be paid in these cases to iliofemoral angiography performed in the context of cardiac catheterization.

Key observations on pre-procedure CTA, if available, and prior iliofemoral angiography include the size, tortuosity, plaque burden, and calcification of the left and right iliac and femoral arteries.

Special note should be made of the location of the common femoral bifurcation, particular areas of heavy plaque or calcification, anomalies and anatomic variants, and any evidence of vascular injury or soft tissue pathology secondary to prior procedures. Based on these observations, the operator should form a strategy for the laterality, precise cranio-caudal position, and caliber of the femoral arteriotomy.

Sheath selection

Sheath sizes appropriate for transfemoral BAV range in caliber 9–22 Fr, with requirements that vary based on balloon selection (Table 58.2). Sheath selection for TAVR is dependent on the valve being implanted, and ranges 14–22 Fr. As mentioned, there are three principal factors to consider in terms of suitability of vascular access for large-bore sheath insertion: minimum diameter, tortuosity, and degree of calcification. While not the only factor to be considered, experience with TAVR has demonstrated the danger of sheath oversizing. A sheath-to-femoral artery ratio exceeding 1.05 predicts increased risks of not only vascular complications but also short-term mortality [77].

In addition to sheath caliber, it is important to tailor sheath length to vascular anatomy. For most patients, standard short sheaths measuring 10–12 cm in length are sufficient to provide secure arterial access and support for BAV. In selected patients with significant iliofemoral plaque, calcification, or tortuosity, a longer sheath is desired to facilitate torque control and smooth device advancement and retrieval. A 25 cm sheath is usually adequate to bypass the iliac arteries, whereas a 45–55 cm sheath will typically terminate comfortably in the descending thoracic aorta. In rare cases with extreme aortoiliac tortuosity, longer sheaths are considered. For TAVR, in most cases using a percutaneous transfemoral approach, a 25–40 cm sheath is used which terminates in the mid-descending aorta.

Pre-closure

Successful use of a percutaneous suture-mediated closure device dramatically simplifies large-bore arterial access site management. In published observational data, the use of a percutaneous suture-mediated closure “pre-close” technique has been associated with improved vascular and bleeding outcomes. In the Effect of Bivalirudin on Aortic Valve Intervention Outcomes (BRAVO)

Box 58.2 Recommendations for use of CTA in TAVR access planning

- CTA should be performed in the evaluation process of patients who are under consideration for TAVR unless there is a contraindication
- CTA datasets should be interpreted jointly with a member of the TAVR procedural team or reviewed with the operator before the procedure
- Slice thickness should be ≤ 1.0 mm
- Imaging of the aorta and peripheral vessels should extend from the aortic arch (and preferably subclavian artery) to below the groin
- Imaging of the abdominal aorta and peripheral vessels does not need to be ECG gated
- CTA examinations should be performed with iodinated contrast medium. Contrast agent exposure can be an issue in patients who are often of advanced age and may have renal impairment. Contrast reduction and adherence to protocols for prevention of contrast-induced nephropathy is recommended
- Qualitative assessment of vascular tortuosity should be performed
- Qualitative assessment of vascular calcification should be performed
- Consideration to varied thresholds of vessel size (sheath : femoral artery ratio) should be contemplated, depending on the presence and extent of vascular calcification
- The left ventricle should be evaluated for the presence of thrombus and, if a transapical access route is planned, for geometry and position of the apex
- The entire aorta should be imaged and evaluated, unless a transapical access is planned
- Severe elongation and kinking of the aorta, dissection, and obstructions caused by thrombus or other material should be reported

CTA, computed tomography angiography; ECG, electrocardiogram; TAVR, transcatheter aortic valve replacement.

registry of 428 patients undergoing BAV between 2005 and 2011, patients treated with pre-closure technique ($n=269$) experienced a significantly lower rate of not only major bleeding (5.6% vs. 14.5%; $p=0.01$), but also a composite of major bleeding, myocardial infarction, stroke, and all-cause mortality (10% vs. 24.5%; $p<0.001$) [78]. It is important when interpreting such observational data to acknowledge the influence of atherosclerotic disease burden on patient eligibility for vascular closure device use and likelihood of device success.

Anterior wall calcification and vascular fibrosis are key predictors of closure device failure [79]. In addition to providing a plausible explanation for an increase in closure device failure, local access site bleeding, and vascular complications [56], iliofemoral atherosclerosis

has been shown to predict incident cardiovascular events attributable to other vascular beds [80].

Pre-closure technique can be accomplished using either of two commercially available suture-mediated closure systems marketed by Abbott Vascular (Redwood, CA, USA): Prostar® XL and Perclose ProGlide®. Both systems can be used for primary closure at the conclusion of a transfemoral procedure (“post-closure”), with the Prostar XL device indicated for closure of arteriotomies of 8.5–10 Fr and the Perclose ProGlide device indicated for closure of arteriotomies of 5–8 Fr. With a pre-closure technique, sutures are partially deployed prior to maximal dilatation of the arteriotomy, permitting more certain grasping of peri-arteriotomy arterial tissue and the ability to close larger holes. For closure of

very large arteriotomies, multiple devices can be used in conjunction. In published literature, a single Prostar XL device has been used successfully to pre-close arteriotomies as large as 18 or 19 Fr, and a pair of devices has been used successfully to close arteriotomies measuring 22 or 24 Fr in the context of TAVR [81]. With the Perclose ProGlide device, a combination of two devices can be used to close arteriotomies measuring 8.5–24 Fr. In our practice, we have observed that pre-closure with a single Perclose ProGlide device can sometimes be adequate to achieve closure of 9 or 10 Fr arteriotomies.

One study has compared the Prostar XL with Perclose ProGlide devices for the purpose of pre-closure prior to TAVR. In the multicenter retrospective CLOSURE device IN TRANSfemoral aORTic vaLve implantation (CONTROL) study, which included 3138 patients undergoing percutaneous transfemoral TAVR, propensity-matched comparison of 944 patients assigned to pre-closure with either device revealed a significant excess of major vascular complications in Prostar XL-treated patients (7.4% vs. 1.9%; $p < 0.001$) [82]. Additionally, Prostar XL-treated patients experienced higher rates of major bleeding and acute kidney injury and had longer hospital stays. Differences in outcomes between the two devices perhaps reflect differences in device design. Whereas the Prostar XL delivers four needles on each end of two sutures, all delivered simultaneously outward from the arterial lumen, the Perclose ProGlide delivers two needles on each end of one suture, with two devices typically deployed in sequence via a cross-hair approach [82]. Failure of the Prostar XL is total, whereas one of two Perclose ProGlide sutures can accomplish partial or even complete success.

It is clear that experience matters. There is a demonstrable learning curve with percutaneous suture-mediated closure systems, with success rates improving from 85% to over 95% in seasoned operators [81]. When performed by experienced operators, percutaneous suture-mediated closure is furthermore associated with substantial reduction in total and major vascular complications, including iliac complications, and shorter stays in the intensive care unit after TAVR [81]. We strongly advocate that operators in training gain experience with use of a percutaneous suture-mediated closure system of choice in cases with smaller arteriotomies prior to application in BAV or TAVR.

The above data have been progressively incorporated in contemporary practice, and our perception is that most operators now prefer pre-closure with Perclose ProGlide devices. For illustration of the steps in device use, readers are encouraged to view a manufacturer video demonstrating recommended technique which is freely available online (<http://www.abbottvascular.com/us/video/proglide-lhc-video.html>).

Pre-closure with Perclose ProGlide®

As a critical first step, pre-procedure review of available iliofemoral imaging data is mandatory. While for TAVR iliofemoral assessment is primarily performed by CTA, for BAV CTA data may not be available, in which case the operator must rely on careful examination of the groin and iliofemoral anatomy by inspection, palpation, and fluoroscopic assessment. A prior history of multiple catheterizations via the right femoral artery should also be considered, which typically leads to scarring of the arterial access site which makes pre-closure more challenging. In this case a left femoral approach can be preferable. If a CTA is available, it is essential to pay close attention to the common femoral arteries, to identify vascular diameter and areas of calcification, the site of the bifurcation

of the common femoral artery, and to relate these data to bony landmarks such as the femoral head that can then be used as a reference for accurate arteriotomy.

On inspection, identify the inguinal crease and make note of any superficial scars, wounds, and fungal infections that could interfere with access. On palpation, identify the inguinal ligament and the point of maximal impulse of the femoral arterial pulse, scanning cranially and caudally, paying attention to areas of a diffuse or split impulse, which may reflect the bifurcation of the femoral artery into its superficial and deep branches. If the pulse is diminished or absent, be suspicious of significant aortoiliac atherosclerosis. It is important also to recognize qualities of the soft tissue overlying the femoral artery, such as scarring and depth of adipose tissue, which can impede delivery of larger sheaths or percutaneous sutures. On fluoroscopic assessment, evaluate the appearance of the unopacified femoral artery in the anteroposterior projection with particular attention to zones of dense calcification. Real-time fluoroscopy during left–right rotation of the camera provides additional three-dimensional perspective of vascular calcification, in particular permitting recognition of anterior wall calcium. A radio-opaque object such as a hemostat can be placed at this time to mark a desired location for arterial puncture.

Given the frailty and hemodynamic tenuousness of many patients undergoing large-bore arterial access, aim to use minimal necessary doses of parenteral anxiolytics and narcotics, instead favoring thorough local anesthesia, typically with 1% lidocaine. Next proceed with arterial puncture. Many techniques are possible here, and typically the “optimal” technique for any individual operator will be closely related to what they usually perform for small-bore access. A popular approach is to initial “micro-access” using a 21-gauge needle and compatible wire, then confirming position by contrast injection through a 1–2 Fr microsheath. An anterior wall puncture of the common femoral artery in an area of minimal calcification and plaque is required to permit pre-closure technique. Accordingly, in the event of a suboptimal puncture, it is easy to remove the microsheath and abort the arteriotomy, obtain manual hemostasis, and reattempt access. Once satisfactory arteriotomy is achieved, exchange the micro-access system for an 0.035-inch wire and proceed with pre-closure.

Other popular techniques for accurate arteriotomy include first accessing the contralateral common femoral artery and then placing a small catheter in the ipsilateral external iliac artery and then performing an angiogram to precisely delineate the ideal access point on the desired side for the large-bore sheath. As a variation on this, 4–5 Fr pigtail catheter can be placed from the contralateral common femoral artery into the precise position in the ipsilateral common femoral artery that is desirable to access (guided by contrast injections and angiography through the pigtail as needed), with the operator then accessing the ipsilateral common femoral artery under fluoroscopy by aiming the tip the arteriotomy needle directly at the center of the pigtail.

Once suitable ipsilateral access has been initially secured by any of these techniques, to facilitate successful pre-closure and subsequent large sheath delivery, it is advantageous to prepare the tissue track by blunt dissection. This can be performed before or after arterial puncture. The optimal tissue track should be large enough to accommodate the main sheath without being unnecessarily broad; free of clots, fat, skin tags, and fibrinous strands; and straight. Serpentine tracks significantly increase the difficulty of sheath insertion and closure.

Next advance a first Perclose ProGlide device over the 0.035-inch guidewire into the femoral artery until pulsatile flow is

observed from the device's marker lumen. Next, rotate the device 30–45° clockwise prior to deploying its suture in usual fashion. Then lower the footplate and withdraw the device, harvesting the sutures and re-establishing wire access to the vessel. It is important at this point to secure the lock and rail ends of the suture using a hemostat, taking care to avoid any tension in the suture (which would prematurely tighten the knot). Repeat the process using a second Perclose ProGlide device, instead rotating the device 30–45° counterclockwise prior to deploying the suture. If a single device is used, this can be deployed at 0°. Following pre-closure, access is re-established using an 0.035-inch guidewire. In a stepwise fashion, sequentially dilate the tissue track and arteriotomy from 8 Fr up to the desired sheath size (usually using only one or perhaps two dilation size increments) and finally insert the main sheath.

Contralateral safety wire

While less commonly used now because of decreasing TAVR sheath sizes, an optional technique is to deliver a “safety wire” from the contralateral common femoral artery down the ipsilateral iliofemoral arterial system. Typically, a stiff 0.018-inch guidewire is used for this purpose, which is performed using standard iliac crossover techniques. The wire is delivered down to the ipsilateral distal superficial femoral or proximal popliteal artery, and remains in place throughout the entire procedure. The safety wire can be delivered prior to pre-closure, with a small risk of entanglement in the Perclose sutures, or after pre-close, with the possibility of some difficulty navigating around the sheath and Perclose sutures that will then be in place in the ipsilateral common femoral artery. This safety wire provides secure access to the true lumen of the access vessel, and can be used to deliver an adjunctive balloon for inflation in the external iliac artery or at the arteriotomy site to assist with access site closure. In the advent of iliofemoral dissection, rupture, or perforation, a safety wire can be a lifesaving method to deliver a covered stent or other device. In contemporary practice, a safety wire is rarely if ever used for stand-alone BAV, but is typically still used for larger TAVR sheaths.

Performing balloon aortic valvuloplasty

Prior to proceeding with BAV, if not previously performed, it is advisable to perform a comprehensive right and left heart catheterization in the standard fashion, including hemodynamic assessment and coronary angiography. Aortography is also performed in the left anterior oblique 30° projection to assess baseline severity of aortic insufficiency.

Anticoagulation during BAV

Anticoagulation is indicated during BAV to reduce risk of procedure-related thrombosis and arterial thromboembolism. This is usually with a low dose of unfractionated heparin or bivalirudin – typically, half the dose that would normally be administered for coronary intervention.

Historically, the preference during BAV was to use unfractionated heparin, with variable application of protamine at procedure conclusion for reversal of anticoagulation. Recently, there has been interest in using bivalirudin as an alternative to heparin for BAV and TAVR. Putative advantages of bivalirudin include predictable anticoagulant effect, avoidance of heparin-induced thrombocytopenia, and a proven track record of bleeding avoidance in the

setting of percutaneous coronary intervention [83]. Potential disadvantages include irreversibility, reliance on renal clearance, and cost. To date, no randomized trials have compared the two agents for use in BAV. In the Effect of Bivalirudin on Aortic Valve Intervention Outcomes (BRAVO) registry, which retrospectively studied 427 patients undergoing BAV at two high-volume centers, patients receiving bivalirudin (n = 223; 52.2%) experienced a lower rate of major bleeding (4.9% vs. 13.2%; p = 0.003) that remained significant after multivariate analysis [84]. Observed reduction in bleeding was driven by both access site related bleeding (3.6% vs. 7.8%; p = 0.06) and non-access site related bleeding (1.3% vs. 5.4%; p = 0.02), which included pericardial bleeding. Stroke was rare, with two major strokes documented in the heparin group and none in the bivalirudin group.

Crossing the aortic valve

Multiple techniques are available for crossing the aortic valve. Often preferred is an Amplatz right 2 (AR2) catheter with careful advance of a stiff, straight-tipped hydrophilic guide wire in the left anterior oblique projection. For different aortic configurations, other catheters may be preferable to optimize alignment of wire advance with the axis of the aortic annulus. For dilated aortic roots, an Amplatz left 1 catheter may be more appropriate. A to-and-fro motion of the catheter tip with the cardiac cycle can indicate alignment of the catheter with the turbulent jet of left ventricular outflow and improved likelihood of success. If wire crossing is unsuccessful after 2–3 minutes, it is usual to withdraw and clean the wire and flush the catheter prior to reattempt.

Once the wire crosses the aortic valve into the left ventricle, extreme care must be taken. Excessive advance of the slippery, sharp, stiff hydrophilic wire can easily perforate the left ventricle, precipitating pericardial hemorrhage and cardiac tamponade [85]. Mechanical irritation of the often hypertrophied left ventricular myocardium can precipitate ventricular tachyarrhythmias, poorly tolerated in the setting of severe AS. Once intracavitary position is confirmed, the hydrophilic wire is carefully exchanged for the soft-tipped catheter and removed.

Wires

After measuring and recording the transaortic valve pressure gradient, the next step is to exchange the catheter for a stiff wire to support BAV. This can either be done directly, or by first placing an exchange-length soft wire and changing the AR2 catheter for a pigtail catheter, and then introducing the stiff wire via the pigtail. The latter two-step approach is preferable for operators less experienced in handling the very stiff wires required for BAV and TAVR that can also perforate the ventricle.

Several wires are suitable to support BAV, such as the J-tipped Amplatz Extra Stiff, the straight 1 cm floppy tip Amplatz Super Stiff™, and Lunderquist® wires (all from Cook Medical, Bloomington, IN, USA), in progressive order of increasing stiffness and support. If there are no mitigating factors such as vascular tortuosity, it is usually advisable to use the least stiff wire from among these options. Some of these wires require shaping prior to use, in which case either a pigtail bend (for the Amplatz Super Stiff), or a larger V-shaped bend (for the Amplatz Extra Stiff) are usually created. Appropriate positioning of this wire at the left ventricular apex is essential to minimize the risk of lacerating the ventricle during the procedure. Exchange and replacement of the stiff wire using a pigtail catheter can help to ensure central wire positioning, free from the mitral apparatus.

Figure 58.1 Valvuloplasty balloon sizes and corresponding cross-sectional area.

BAV balloons

A selection of BAV balloons is presented in Table 58.2. Balloons vary with respect to length and size; shape, with some balloons featuring a central “waist”; profile and associated sheath size requirement; speed of inflation and deflation; radiographic markers for placement; materials; and compliance. Choice of a specific balloon for an individual patient is influenced by annular size, availability, operator comfort, and limitations on safe sheath sizing.

With respect to balloon sizing, it is advisable to favor a balloon to aortic annulus diameter ratio of $<1 : 1$. Typically, most operators use an initial size range of 18–23 Fr for most patients. It is important to also note that whereas balloons expand to become circular in cross-section (Figure 58.1), the aortic annulus is rarely circular but is usually elliptical [86,87]. Annular size tends to be smaller in women [87] and larger in patients with bicuspid aortic valves [88]. In patients with very severe AS or heavy calcification of the valve apparatus, initial inflation with a balloon sized 1 : 1 with the aortic annulus may not be feasible or safe.

Balloons used in aortic valvuloplasty, sized with respect to diameter in millimeters, expand to become circular in cross-section, with a corresponding area equal to π times the radius squared. As discussed later, the feared complication of BAV, especially if performed as a stand-alone procedure not in association with TAVR, is severe aortic regurgitation. This concern means it is always advisable to be conservative in balloon selection for BAV. Sequential dilatation with a larger balloon is always an option, in which case it is possible to assess the degree of aortic regurgitation and ensure there has been no increase, prior to upsizing to a large balloon.

Pacing

Rapid ventricular pacing (at 180–200 b.p.m.) at the time of balloon inflation acutely decreases stroke volume and cardiac motion. This facilitates precise balloon placement and reduces likelihood of balloon slippage or to-and-fro movement. To the extent that such to-and-fro motion can transform the balloon and wire into a spear and a saw, avoidance of this motion might reduce likelihood of ventricular perforation, pericardial hemorrhage, and cardiac tamponade during BAV. Whether rapid ventricular pacing should be performed routinely is controversial, with uncertainty about its deleterious hemodynamic effects and limited data concerning safety and efficacy [89]. In published observational literature [90], rapid ventricular pacing was helpful in balloon placement and safe even in high risk BAV patients. In order to minimize any added ischemic insult, it is important to minimize the duration of pacing. To accomplish this, close teamwork between operators and trained laboratory technical staff is essential.

Procedural conclusion

Following balloon inflation and deflation, the balloon is withdrawn from the body. Hemodynamic measurements are repeated to assess interval change in aortic valve gradient and area, and aortography is

repeated to assess interval change in aortic regurgitation. Close monitoring is essential during this time, as new onset hypotension can be indicative of one of several life-threatening complications. If the patient remains stable and the result is acceptable, it is appropriate to proceed to arteriotomy closure. If a significant gradient remains, it is possible to consider repeat BAV using a larger balloon. In the decision to use a second, larger balloon, it is critical to weigh the potential risks, which of course increase with larger balloon size, against the benefits. For many frail elderly patients undergoing BAV as a stand-alone palliative or temporizing procedure, the risk often outweighs the possible benefit. While an “acceptable” result from stand-alone BAV varies according to the patient and their indication to undergo the procedure, typically a reduction in peak gradient by 50–70% is considered successful. Attempting to achieve a more substantial reduction in aortic gradient is unrealistic and potentially dangerous.

Arteriotomy closure and troubleshooting

If pre-closure technique was successful, the pre-deployed sutures can then be used to close the arteriotomy. Usually during TAVR, but rarely for BAV due to smaller sheath sizes and lack of contralateral access, the large-bore sheath is first retracted to the external iliac artery, and digital subtraction angiography (DSA) of the ipsilateral common and external iliac arteries is performed to ensure no arterial perforation or dissection. If there is no vascular injury, at this time the stiff wire is usually swapped for a softer wire, because withdrawing the stiff wire used for BAV/TAVR (especially if it has a large loop at the end) through the arteriotomy can damage the femoral artery. If a safety wire was placed, a conservatively sized peripheral balloon can be inflated in the distal external iliac artery to decrease flow. As the large-bore access sheath is removed from the body, the Perclose sutures are tightened in sequence, in the same order in which they were initially deployed. A guidewire can be left in place during this step, maintaining access to the vessel and allowing reinsertion of a hemostatic sheath in the event that suture-mediated closure is unsuccessful. Again, if a safety wire was placed, a low pressure inflation at the arteriotomy site is usually performed to aid with hemostasis. If contralateral access was obtained, a final DSA is then performed, and the procedure completed. Often, despite successful pre-closure, 5–15 minutes of additional manual groin compression is needed to achieve complete hemostasis.

For BAV using up to 12 Fr sheaths, if pre-closure fails and there was no contralateral access, sustained manual compression is usually attempted to obtain hemostasis. If pre-closure fails with larger sheath sizes where there is typically contralateral access, sustained balloon inflation at the arteriotomy site is performed. Ideally, this is via the safety wire that was placed at the beginning of the procedure. If a safety wire was not placed, then it may be necessary to consider wiring across the arteriotomy site from the contralateral femoral access site. Technically, this can range from being relatively simple if the issue is an unacceptable residual stenosis of the large-bore access arteriotomy, to exceptionally challenging if there is a complex dissection, perforation, avulsion or significant hemorrhage from the large-bore arteriotomy site. Obviously, if any of these more serious complications arise, more advanced salvage techniques such as covered stent placement are required. If covered stent placement is needed, this is best performed on the ipsilateral wire for common and external iliac complications, but for major complications at the large-bore arteriotomy site, a wire

from the contralateral side is required. Complex iliac anatomy (calcification, stenosis, tortuosity) in BAV/TAVR patients can add significant procedural challenge to the management of any vascular complication.

Complications of BAV and their management

Complications are common and can be life-threatening. A list of key complications of BAV is presented in Table 58.3, with frequencies as reported in the recent BRAVO registry [84].

Vascular complications are a particular concern, and patients having BAV or TAVR are at heightened risk because of comorbid atherosclerosis and large-bore sheaths. Valve Academic Research Consortium criteria for major and minor vascular complications are presented in Box 58.3.

Structural complications particular to BAV merit special consideration. Acute reduction in left ventricular afterload can induce development of a dynamic intracavitary gradient, particularly in patients with left ventricular hypertrophy, small chamber size, and any pre-existing left ventricular outflow tract obstruction. Arterial pressure recordings can reveal hypotension and new onset of a spike-and-dome waveform. In rare cases, reported chiefly in the setting of TAVR [92], this can manifest fulminantly as cardiovascular collapse, earning the appellation of “suicide left ventricle.” Management consists of volume resuscitation and pure vasopressors (e.g., phenylephrine) without beta-adrenergic agonist properties.

Acute aortic insufficiency (~1%) [93] is a devastating complication of BAV which is best avoided by careful patient selection and balloon sizing. Clinical manifestations of acute aortic insufficiency include hypotension, a widened pulse pressure, flash pulmonary edema, cardiovascular collapse and arrest usually with pulseless electrical activity. Left ventricular pressure recordings show a steep rise in left ventricular diastolic pressure, equaling aortic diastolic pressure prior to end-diastole in the setting of severe aortic regurgitation. By contrast aortography, severe aortic insufficiency is evidenced by instantaneous opacification of the left ventricle. Acute management, complicated by coexisting AS, consists of diuretics, arterial vasodilators, fast ventricular pacing, and surgical consultation if appropriate.

Patients with very severe AS and associated extensive aortic annular calcification are at risk for annular rupture (0.3%) [93]. Extreme caution is warranted in these cases. This catastrophic, rare complication of BAV is rapidly fatal, and the prognosis of emergent cardiac surgery is poor.

Cardiac perforation results in pericardial hemorrhage and cardiac tamponade (0.3–1.2%) [84,93]. Causes of perforation include the temporary venous pacing wire, the hydrophilic wire used to cross the aortic valve, the stiff wire used to support BAV, and the balloon itself. Clinical presentation can be insidious as blood gradually accumulates in the pericardium, not becoming clinically manifest as hypotension until several minutes later. Fluoroscopy reveals a pericardial shadow. Echocardiography confirms the diagnosis of pericardial effusion and can show evidence of tamponade physiology. Treatment is emergent pericardiocentesis and discontinuation of anticoagulation with protamine administration if heparin was

Table 58.3 Complications of balloon aortic valvuloplasty.

Complication	Frequency (%)
Mortality (in-hospital)	6
Bleeding:	
Major (BARC 3, 4, or 5)	9
Minor (BARC 1 or 2)	4
Vascular complications:	
Major	2
Minor	5
Acute kidney injury	10
Myocardial infarction	3
Major stroke	0.5

Frequencies reflect reported event rates as adjudicated according to VARC and BARC criteria in the Effect of Bivalirudin on Aortic Valve Intervention Outcomes (BRAVO) registry [84]. BARC, Bleeding Academic Research Consortium; VARC, Valve Academic Research Consortium.

Box 58.3 Vascular access site and access-related complications

Major vascular complications:

- Any thoracic aortic dissection
- Access site or access-related vascular injury (dissection, stenosis, perforation, rupture, arteriovenous fistula, pseudoaneurysm, hematoma, irreversible nerve injury, or compartment syndrome) leading to either death, need for significant blood transfusions (≥ 4 U), unplanned percutaneous or surgical intervention, or irreversible end-organ damage (e.g., hypogastric artery occlusion causing visceral ischemia or spinal artery injury causing neurologic impairment)
- Distal embolization (non-cerebral) from a vascular source requiring surgery or resulting in amputation or irreversible end-organ damage

Minor vascular complications:

- Access site or access-related vascular injury (dissection, stenosis, perforation, rupture, arteriovenous fistula or pseudoaneurysms requiring compression or thrombin injection therapy, or hematomas requiring transfusion of ≥ 2 but, 4 U) *not* requiring unplanned percutaneous or surgical intervention and *not* resulting in irreversible end-organ damage
- Distal embolization treated with embolectomy and/or thrombectomy and *not* resulting in amputation or irreversible end-organ damage
- Failure of percutaneous access site closure resulting in interventional (e.g., stent graft) or surgical correction and not associated with death, need for significant blood transfusions (≥ 4 U), or irreversible end-organ damage

Current definitions according to the Valve Academic Research Consortium.

used. Depending on the site and size of perforation, bleeding sometimes ceases spontaneously; in other cases, limited cardiac surgery with patch placement is required to obtain hemostasis.

Conclusions, recommendations, and future directions

The advent of TAVR has renewed interest in BAV and reminded us of its limitations. For patients once untreated for a deadly disease, BAV offers a minimally invasive option for temporary mechanical relief of severe AS and its symptoms. Yet, while minimally invasive, BAV still exposes patients to mortal risks. Though alleviating symptoms, BAV confers no durable benefit for longevity. Patients considering palliative BAV must still ask: “Am I willing to risk death for a chance at an improved quality of life?” For some, the answer is yes. Honest, open, patient-centered conversations are mandatory to establish a plan of care tailored to an individual. For many patients under consideration for BAV, adjunctive consultation with palliative care services are useful to facilitate broader conversations about goals of care.

Recognition of the persistently high rates of major complications of BAV reminds us of the need for further improvement in safety. Opportunities for improvement include research and development of lower profile balloon systems with smaller sheath requirements; atraumatic wires to cross the valve and support BAV; and bleeding avoidance strategies, including closure devices and different anti-coagulant regimens.

Finally, as TAVR matures, miniaturizes, and streamlines, the question becomes: are there any remaining candidates for stand-alone BAV, or is the only appropriate mechanical treatment for severe AS an AVR? We foresee a continuing role for BAV for some time to come but predict that accessibility and availability of TAVR will only continue to increase.

Calcific aortic stenosis is an increasingly common problem in developed countries, with an estimated prevalence of 2–4% among adults over 65 years old [1]. After the onset of symptoms, severe aortic stenosis is associated with a median survival of approximately 2 years without intervention [2]. Surgical aortic valve replacement (SAVR) has long been the standard of care for managing symptomatic aortic stenosis in the absence of significant comorbidities [3]. Unfortunately, in practice, at least 30% of such patients do not undergo SAVR because of risk factors that are felt to put them at prohibitive surgical risk [4]. Initially, attempts to manage inoperable patients with balloon aortic valvuloplasty (BAV) showed short-term improvement in symptoms, but a high rate of stenosis recurrence and no improvement in survival [5]. Similarly, medical therapy has not been shown to significantly impact the disease process. Therefore, there continued to be a great need for novel therapies to treat patients without surgical options for aortic valve replacement. The result was the development of transcatheter aortic valve replacement (TAVR), which was first performed in a human patient by Cribier *et al.* in 2002 [6].

Several pivotal trials were subsequently conducted to study the safety and efficacy of TAVR [7–10]. Because of the success of these clinical trials, TAVR has become an established therapy for inoperable and high-risk patients with severe aortic stenosis, shown excellent safety in certain intermediate risk populations, and grown from a technologic standpoint to include multiple valve designs, vascular access approaches, and unique procedural considerations (Figure 59.1) [11]. Generally speaking, TAVR has been divided into procedures that can be performed through adequate peripheral vascular access (most commonly from the femoral artery), and those requiring direct access to the thoracic cavity, either through the left ventricle (LV) apex via a mini-thoracotomy (transapical) or through the ascending aorta via a mini-sternotomy (transaortic). For specific patients in whom neither the transfemoral nor traditional chest access approaches are considered feasible, operators have successfully implanted the valve using access at the subclavian artery, axillary artery, carotid artery, or femoral vein (via a transeptal or transcaval approach). This chapter discusses the steps required to evaluate a patient for transfemoral (TF) TAVR, outlines the interventional technique for performing both balloon-expandable and self-expandable TAVR, and discusses the identification and management of procedural complications.

Indications and candidacy for TAVR

Currently, TAVR is indicated for inoperable and high-risk patients with symptomatic, severe aortic stenosis, as determined by the existing guidelines on management of valvular heart disease [3]. In the USA, the Edwards SAPIEN-XT and S3 (Edwards Life Sciences, Inc., Irvine, CA, USA) balloon expandable valves and the Medtronic self-expanding CoreValve® and Evolute-R® (Medtronic, Inc., Minneapolis, MN, USA) are currently approved by the Food and Drug Administration (FDA) for commercial use. In Europe, there are additional devices that have obtained the Conformité Européenne (CE) mark of approval. As the technology grows, the populations in whom it is appropriate to offer TAVR continues to evolve, and recently published studies involve patients that are at intermediate surgical risk [12]. Currently, TAVR with the Medtronic, self-expanding CoreValve is also an approved strategy for patients with severe, bioprosthetic valve degeneration, commonly referred to as “valve-in-valve TAVR.” TAVR is not currently approved for patients with severe aortic regurgitation without stenosis. The lack of appropriate devices for a frequently non-calcified aortic valve and large annulus will need to be resolved before this technique can be widely applied to pure aortic regurgitation cases.

The most essential aspect of evaluating a patient for TAVR is the heart team approach, which focuses on a multidisciplinary assessment of each patient with the collaboration of cardiac surgeons, interventional cardiologists, imaging specialists, other experts from different disciplines, nurses, and other support staff. A careful assessment of comorbid conditions, both cardiovascular and non-cardiovascular, is important in determining each patient's risk for a traditional surgical valve replacement (SAVR), and evaluation by a cardiac surgeon experienced in SAVR is a requirement to determine surgical risk category. Traditionally, these categories have been defined as low, intermediate, high, and extreme (not suitable for SAVR or “inoperable”). While the Society of Thoracic Surgeons (STS) risk calculator has often been used to set more quantifiable ranges for each of these categories, especially in the setting of randomized clinical trials, there are certain factors that are not accounted for in the established surgical risk calculators that have an especially large impact on surgical candidacy. These factors include the presence of a porcelain aorta (evaluated by chest CT), chest wall deformities, severe lung disease (evaluated by pulmonary function

tests), cirrhosis, prior radiation to the chest, prior bypass graft anatomy complicating re-do sternotomy, or significant frailty [13]. Thus, the heart team approach is absolutely essential to ensure that the best possible options are made available to each individual patient.

Contraindications to TAVR

In some situations, despite elevated surgical risk, TAVR is not the most appropriate option. TAVR is often a less appropriate option for patients with multivalvular disease requiring additional surgical replacement and/or repair, concomitant aortopathy, concomitant significant coronary artery disease not amenable to PCI, no or minimally calcified aortic valve disease in which the device may be less secure, and in some congenitally malformed valves. When the annulus is too small or too large to accommodate a transcatheter device, surgery is sometimes the only option. Finally, in some instances it is clear that the patient's symptoms and life expectancy are limited by factors outside of their severe AS, and it is important not to offer a procedure that is unlikely to improve functional status or survival. It is inappropriate to offer TAVR to individuals

with a severely limited life expectancy because of non-cardiac, comorbid conditions [13].

Evaluating the patient for transfemoral TAVR

The most common route for TAVR is via the common femoral artery, termed the transfemoral (TF) approach. Other options include the transapical (TA) approach which is performed via a small left anterior thoracotomy, passing the catheter through the apex of the LV, and the transaortic (TAo) approach which is commonly performed via a partial sternotomy, allowing direct access to the ascending aorta (discussed separately). Some operators perform the TAo approach via right thoracotomy or manubriotomy.

TF-TAVR has the obvious benefit of being minimally invasive by obviating the need for sternotomy or thoracotomy, and in many cases can be completed using local anesthesia and conscious sedation. The primary requirement for TF candidacy is adequate iliofemoral artery access. Many patients with calcific AS also possess significant peripheral arterial disease, and a careful evaluation of

*Based on manufacturer labeling where available. In practice, most valves that require an 18 Fr sheath can be placed through a minimal luminal diameter of 6 mm, and with the 14 Fr S3 sheath, as low as 5 mm, but individual practices differ.

the arterial anatomy is essential. Fortunately, there have been significant improvements in the size of the delivery sheaths needed for TAVR from the first generation devices to the present day, and in the recently completed PARTNER II continued access registry involving the Edwards S3 valve, 84% of high-risk patients and 89% of intermediate risk patients were able to undergo TAVR via the TF approach.

All patients being considered for TAVR should undergo a contrast enhanced computed tomography (CT) scan of the chest, abdomen, and pelvis. The chest CT should be gated (images acquired at the same point in the cardiac cycle to limit artifact) to accurately determine the size of the aortic annulus, which dictates the size of the valve that the patient requires. The annulus is rarely a circular structure but frequently elliptical, so valve sizing based on single-diameter echocardiographic measurements can lead to significant error. Gaining a precise measurement of the aortic annulus is very important in reducing valve undersizing which is a significant risk factor for paravalvular regurgitation, and CT has been shown to reduce the degree of undersizing when compared with transthoracic or transesophageal echocardiography [14,15]. Tomographic

assessment of the aortic root is also important to evaluate the distance between the annulus and the coronary artery ostia.

After obtaining the CT of the chest, imaging is continued through the abdomen and pelvis to evaluate the iliofemoral anatomy. The required iliofemoral diameter is dependent on the type and size of valve that is used. Table 59.1 shows the various available valve designs, sizes, corresponding sheath sizes, and minimal luminal diameter needed to accommodate the vascular sheath. The decision regarding adequate iliofemoral access is comprehensive and must take into account not only the size of the artery, but the presence of calcification, whether the calcification is circumferential, and the presence of significant tortuosity. Calcific arteries are less compliant and pose a higher risk for vascular complications, especially when the luminal diameter is borderline and calcification is circumferential [16].

When renal function is deemed insufficient to tolerate a normal contrast CT, alternative ways to obtain the required information must be considered. One such strategy is to obtain annular measurements by cardiac magnetic resonance imaging (MRI) or three-dimensional transesophageal echocardiography (3D-TEE), and

subsequently obtain a CT of the abdomen and pelvis by direct intra-aortic injection of 10–15 mL contrast via a pigtail catheter. The pigtail catheter is placed and positioned under fluoroscopy via the common femoral artery in the cardiac catheterization laboratory, and the patient is then transported to the CT scanner for a direct, arterial contrast CT, which can be performed with minimal contrast.

Alternative vascular access has been an area of significant investigation as some patients have significant iliofemoral disease and are at prohibitive risk for TAO or TA TAVR. The subclavian and axillary arteries have been utilized in small groups of patients receiving the Edwards SAPIEN and Medtronic CoreValve devices, and appear both safe and feasible [17–19]. The carotid artery has also been used in small series of patients [20]. A venous, transseptal approach has been reported in small series as well, involving passage of the device from the femoral vein to the right atrium, across the intra-atrial septum, into the LV, and across the valve in an antegrade fashion [21,22]. Finally, a transcaval approach has been described that involves gaining access to the femoral vein, and crossing from the inferior vena cava (IVC) to the descending aorta in the abdomen [23]. A closure device is then used to repair the arteriovenous fistula that is created at the conclusion of the procedure.

Management of cardiovascular comorbidities pre-TAVR

Patients with senile, calcific aortic stenosis often have coexisting coronary artery disease, and commonly require concomitant coronary artery bypass grafting at the time of surgical AVR. In patients who are selected to undergo TAVR, similar efforts to achieve revascularization prior to the valve procedure are also important to consider. The impact of unrevascularized coronary artery disease on outcomes after TAVR has been difficult to quantify, however, as this is typically an exclusion criteria for clinical trials and retrospective analysis has its inherent biases. One prospective registry study considered the pre-TAVR SYNTAX score (and for patients who were revascularized the residual SYNTAX score), and showed that the severity of CAD prior to TAVR was associated with an increase in cardiovascular mortality [24]. In general, severe stenosis in the presence of symptoms or large areas of ischemia that are amenable to percutaneous coronary intervention (PCI) should be considered for PCI prior to TAVR. However, chronic occlusions, especially those with adequate collateral flow, are permissible to be approached less aggressively, but each case must be considered individually. Finally, in our experience, conservative management of certain asymptomatic but angiographically evident stenoses did not compromise the success of TAVR.

Carotid artery disease is also commonly found in patients with severe aortic stenosis, and must be carefully considered prior to TAVR. When severe carotid artery stenosis is discovered, particularly if the patient is symptomatic, carotid artery stenting (CAS) or carotid endarterectomy (CEA) should be considered [25]. Intermediate lesions must be considered on a case-by-case basis, but situations in which carotid intervention would be especially important to consider prior to TAVR include patients with complete occlusion of the contralateral internal carotid artery (unprotected carotid stenosis), or patients who are likely to have a prolonged period of hypotension or hemodynamic instability during TAVR.

Electrical conduction system abnormalities must also be considered, especially as they relate to LV function and the selection of balloon-expandable versus self-expandable TAVR devices. Patients with symptomatic LV dysfunction and significant left bundle-branch block (LBBB) need to be evaluated for cardiac resynchronization therapy either before or after TAVR. It is important not to overlook the possibility of a LBBB cardiomyopathy superimposed upon a decline in LV function from valvular heart disease. Also, a proportion of patients undergoing TAVR develop additional AV conduction disease during or after the procedure. This is more common with self-expanding valves, but irrelevant in patients who are already pacemaker dependent.

Certainly, it is important to optimize a patient's hemodynamic status prior to any invasive procedure, and in more tenuous patients, Swan–Ganz catheter guided management to ensure adequate optimization of pre-load and after-load in the days leading up to TAVR can be important. Optimal management of non-cardiovascular comorbid conditions is often equally important including chronic obstructive pulmonary disease (COPD), chronic kidney disease, and diabetes mellitus.

Interventional technique for TF-TAVR

There can be considerable variation from institution to institution with regard to the facilities, personnel, and equipment that are involved in the procedure. While most hospitals perform TAVR in a “hybrid” suite that has the capability to be used as a catheterization laboratory as well as an operating room, some perform the procedure in a dedicated cardiac catheterization suite. While TF-TAVR does not routinely require surgical access to the thorax, it is prudent to be prepared for any potential complications that would require emergency thoracotomy or sternotomy and cardiopulmonary bypass, and many institutions complete a full surgical preparation of the chest in the unlikely event that conversion to an open heart procedure is required [26]. Additionally, at most institutions the procedure is performed with the active participation of both interventional cardiologists and cardiac surgeons for similar reasons.

A decision must next be made with regard to the type of anesthesia used. During the early experience, it was almost universally accepted that patients be placed under general anesthesia during TF-TAVR to allow for careful cardiopulmonary monitoring and to more easily facilitate continuous TEE during the procedure. As the procedure has become more refined, however, and with the significant reductions in paravalvular leak (PVL) seen with newer generation devices, there has been less need for intra-procedural TEE, although the impact of this strategy on PVL-related outcomes is still unknown. Also, some patients undergoing TF-TAVR have significant lung disease that makes endotracheal intubation undesirable. As a result, many institutions have transitioned to performing selected procedures under conscious sedation with excellent results [27,28]. That said, there are clear benefits to the involvement of anesthesiologists during TAVR, and rapid access to both general anesthesia and TEE is essential in case they are needed.

The following workflow describes the routine procedural steps in our institution. Once the patient is prepared and appropriate sedation administered, the next step is to obtain vascular access for the procedure. One arterial sheath is placed in the common femoral artery at the location where the TAVR sheath will eventually be placed. This should be on the side with the most favorable anatomy as determined by pre-op evaluation. Given that this site will need to accommodate the largest arterial access sheath, exact placement of

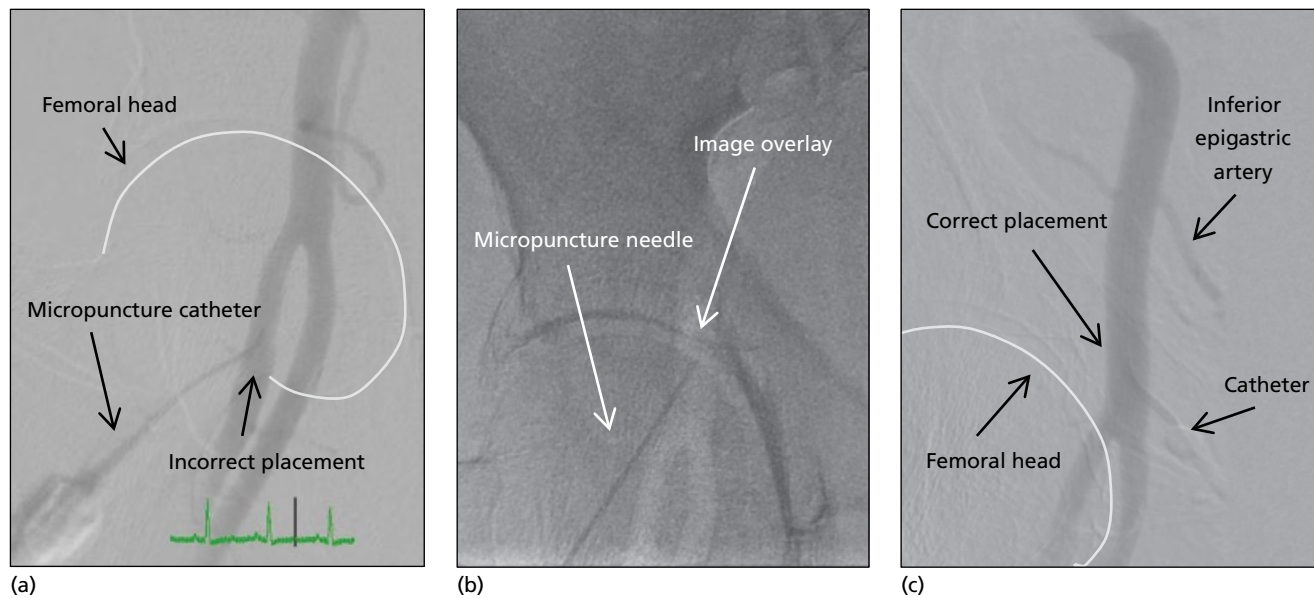

Figure 59.2 Technique for confirming correct femoral arteriotomy site by fluoroscopy. In this example, the femoral artery bifurcation is much higher than usual, above the mid-femoral head. The initial arteriotomy was found to be incorrectly placed in the superficial femoral artery (a). The micropuncture sheath was therefore removed and access re-attempted under fluoroscopy with image overlay (b). Correct placement is achieved and confirmed to be located above the bifurcation and below the inferior epigastric artery (c).

the needle stick is essential. One way to ensure the correct placement of the arteriotomy is to confirm the relationship between the femoral artery bifurcation and the femoral head by either pre-op CT or angiography, and then gain access to the artery with fluoroscopic guidance utilizing a micropuncture needle. Alternatively, using ultrasound guidance to identify the bifurcation can also be very useful. These strategies ensure that the artery is accessed at the desired location, which can be confirmed by a small injection of diluted contrast through the micropuncture sheath, best visualized with digital subtraction angiography (DSA) in an ipsilateral projection of approximately 40° which shows the femoral artery bifurcation (Figure 59.2). Once the correct arteriotomy location is confirmed, the micropuncture sheath is exchanged for a short 5 Fr sheath. Contralateral arterial access is obtained in a similar manner, and this sheath is used to place a 5 Fr pigtail catheter in the aortic root for angiography during valve position/deployment. While this can instead be placed from a radial approach, we prefer the femoral arterial access so that endovascular repair of any delivery sheath complications can be accomplished. Venous access is obtained with a sheath large enough to accommodate a temporary pacemaker wire. If desired, a second venous access can be used for a pulmonary artery (Swan-Ganz) catheter, although this is usually performed from the neck if necessary.

Once the appropriate arterial and venous access has been obtained, the next step is preclosure of the TAVR sheath site. This is accomplished by sequentially deploying two Perclose ProGlide® (Abbott Vascular, Minneapolis, MN, USA) suture-mediated closure systems at the 10 and 2-o'clock positions. This stepwise process requires the replacement of the wire to hold arterial position during each sheath and Perclose exchange. The Perclose strings are then pulled gently away and secured with a clamp on the adjacent drape, taking care not to lock the knot. The ProStar XL (Abbott Vascular) system can also be used for preclosure of the arteriotomy, although this has become less common. The use of preclosure devices has

reduced the need for surgical cutdown and primary repair in the vast majority of cases [29,30]. Surgical cutdown can still be considered in cases of extreme calcification around the puncture site or the presence of aorto-femoral grafting, and when necessary, an axillary or femoral graft can be utilized.

Next, a temporary pacemaker wire is placed into the right ventricle (RV) apex and appropriate capture is tested at a rate of 180–220 beats per minute. When the risk for permanent pacemaker is high, a screw-in lead from the internal jugular vein may be preferred. The high incidence of conduction system abnormalities after CoreValve placement must be considered, and at our institution it is routine to place an active fixation temporary pacemaker wire that is left in place for 72 hours after the procedure. In cases where the patient has a pre-existing permanent pacemaker, a passive fixation wire can be used peri-procedurally for more modest RV pacing (rate in the 100–120 range) if necessary to assist with CoreValve deployment or for rapid RV pacing if valve post-dilation is necessary.

Intravenous heparin is then administered to achieve a therapeutic activated clotting time (ACT) >300 seconds, and the TAVR sheath is carefully upsized over a stiff wire (e.g., Lunderquist). A 5–6 Fr angled pigtail catheter is advanced to the non-coronary cusp, and the fluoroscopic projection demonstrating the perpendicular annular plane is established, and all three inferior margins precisely superimposed [31]. The valve is then crossed utilizing a 5-Fr Amplatz left-1 (AL-1) diagnostic catheter and a 0.035-inch straight-tip guidewire. Care should be taken not to cross through the mitral subvalvular apparatus. After advancing the AL-1 into the LV, it is exchanged for a pigtail catheter to record simultaneous pressure measurements across the aortic valve. Next, an Amplatz Extra-stiff 0.035-inch guidewire is shaped with a large curve at the distal end, and the belly of the curve is placed carefully into the apex of the LV. When placing a CoreValve, an Amplatz Super Stiff™ guidewire is utilized (rather than the Extra-Stiff) to obtain additional support for stabilizing the position of the delivery system. However,

it is felt that the Super Stiff guidewire can bias the delivery system of the SAPIEN devices too far to the posterior aortic wall or hold back the prosthetic valve leaflet after deployment (causing valvular aortic regurgitation).

BAV is often performed at this point with the intent of preparing the native valve to accommodate the prosthesis. As device technology has progressed, however, BAV has been utilized with decreasing frequency in balloon expandable TAVR, and is not commonly used with self-expandable valves. Finally, the prosthetic valve is loaded onto the delivery device, and advanced into the aortic position, coaxial to the annulus. The device should be positioned at the appropriate height, taking the annular anatomy and position of the coronary ostia into account. Both root angiography and TEE (when utilized) can be used to position the valve. The balloon-expandable valves are typically positioned with the lower third of the device in the annulus and the remainder of the device above the valve level. The technique for positioning of the CoreValve involves placing the device slightly lower in the left ventricular outflow tract (LVOT) and then withdrawing the device to the desired height.

When ready to implant the balloon expandable valve, respirations are held, rapid pacing from the temporary pacemaker wire is initiated, and the valve is deployed under fluoroscopy (Figure 59.3a, b). It is important to deflate the balloon completely prior to the cessation of RV pacing so the valve does not become dislodged as the balloon is ejected. Comparatively, the self-expandable valve does not require rapid pacing, but often a rate of 100–110 bpm is used to decrease the cardiac output modestly. The valve is then unsheathed starting with the LVOT portion, withdrawn to the desired height in the annulus, and fully deployed (Figure 59.3c–f). The position and function of all valves should then be evaluated angiographically, echocardiographically, and hemodynamically. If the valve is positioned too high or too low, a second valve can be considered if needed. Post-dilatation of an underexpanded valve can be done when there is significant peri-valvular regurgitation, or a second valve can be deployed within the first. While the balloon-expandable SAPIEN valves cannot be moved once deployed, the CoreValve can be partially deployed and pulled back slightly if needed. This is because of the unsheathing mechanism involved in deploying the CoreValve, but once partially unsheathed, the device cannot be resheathed to be recovered. Some newer generation devices including the Boston Scientific Lotus and the Direct Flow Medical valve have the advantage of being fully retrievable. The Medtronic Evolut R system, an iteration of the CoreValve, is retrievable when it is partially, but not fully, deployed.

When the procedure is considered complete, the access sheath is removed, and the pre-closure devices secured. It is important to maintain wire position during closure in the event that one of the sutures fails. Also, proximal balloon occlusion of the iliac artery via the contralateral arterial access can assist in preventing blood loss during sheath removal and suture securement. A final angiographic picture through the contralateral arterial access can confirm the absence of occult bleeding or other vascular complications prior to removal of the smaller arterial sheath.

Valve designs that have the CE mark for use in Europe, and are under investigation but not currently approved for use by the US FDA, include the self-expandable Portico valve (St. Jude Medical, St. Paul, Minnesota, MN, USA), and the uniquely designed Lotus Valve (Boston Scientific) and Direct Flow Valve (Direct Flow Medical, Santa Rosa, CA, USA).

Complications of TF-TAVR

There are a number of peri-procedural and post-procedural complications that must be considered in patients undergoing TAVR. The Valve Academic Research Consortium (VARC-2) has outlined criteria to standardize the definitions for these complications in clinical practice and in the setting of outcomes adjudication for clinical trials [13]. Procedural complications have become less common in more contemporary series, likely because of a combination of device improvements and operator experience. Complications lead to significant morbidity, mortality, and account for approximately 25% on non-implant-related hospital costs associated with TAVR [32]. Complications that are particularly important to consider in patients undergoing TAVR include vascular and access site complications, bleeding, stroke, conduction system disease, cardiac tamponade, annular rupture, peri-valvular aortic regurgitation, and device malpositioning or embolization (Table 59.2).

The most common complications of TF-TAVR relate to issues with the vascular access site. Vascular complications can be as simple as VARC-2 minor bleeding, but given the relatively large sheaths that are required, more serious complications such as rupture, dissection, or occlusion sometimes occur. Major vascular complications have been reported in up to 16% of patients undergoing TF-TAVR, but appear to be significantly declining, occurring in only 8% of the non-randomized continued access registry patients in the PARTNER trial, and <6% of TF patients in the PARTNER II trial using the S3 valve [33,34]. Vascular complications are more common in patients with calcific, small caliber, or tortuous arteries. When severe bleeding is identified, an endovascular balloon can be inflated to achieve temporary hemostasis, or a covered stent placed. Minor bleeding at the arteriotomy or venipuncture site can usually be controlled by applying external pressure. In cases where there is ongoing bleeding after the pre-closure sutures are tightened, another Perclose or an Angio-Seal device (St. Jude Medical) can be advanced over the wire and subsequently deployed to help close the residual hole.

Late bleeding complications can also occur after TAVR, which was seen with an incidence of 5.9% and at a median of 132 days in the PARTNER cohort/registries [35]. The cause of late bleeding was most commonly found to be gastrointestinal complications (40.8%), neurologic complications (15.5%), or traumatic falls (7.8%), and were more common in patients with low baseline hemoglobin, atrial fibrillation or flutter, moderate or severe paravalvular leak, or larger LV mass. Bleeding has been defined in the VARC-2 document as either minor, major (associated with a drop in hemoglobin ≥ 3 g/dL or requiring ≥ 2 units of whole blood/RBC transfusion), or life-threatening (drop in hemoglobin > 5 g/dL or > 4 units transfusion, involving a critical organ, leading to shock requiring surgery or vasopressors, or fatal) [13].

Stroke is an uncommon but dreaded complication of any cardiovascular procedure. While the initial results of the PARTNER 1A and 1B randomized cohorts raised concern for an elevated risk of stroke with TAVR compared with SAVR or medical therapy, more recent studies have shown significant improvements, and no elevated risk with TAVR compared with surgery [7,10]. Most neurologic events associated with TAVR are felt to be embolic in nature, and the 30-day incidence of clinical stroke or TIA in a large meta-analysis of 10,037 TAVR patients was $3.3 \pm 1.8\%$ [36]. Studies utilizing diffusion weighted MRI, however, have shown a high incidence of subclinical events in both TAVR and SAVR patients, so there has been considerable focus on finding strategies to protect the cerebral vasculature [37]. Much of this focus has been

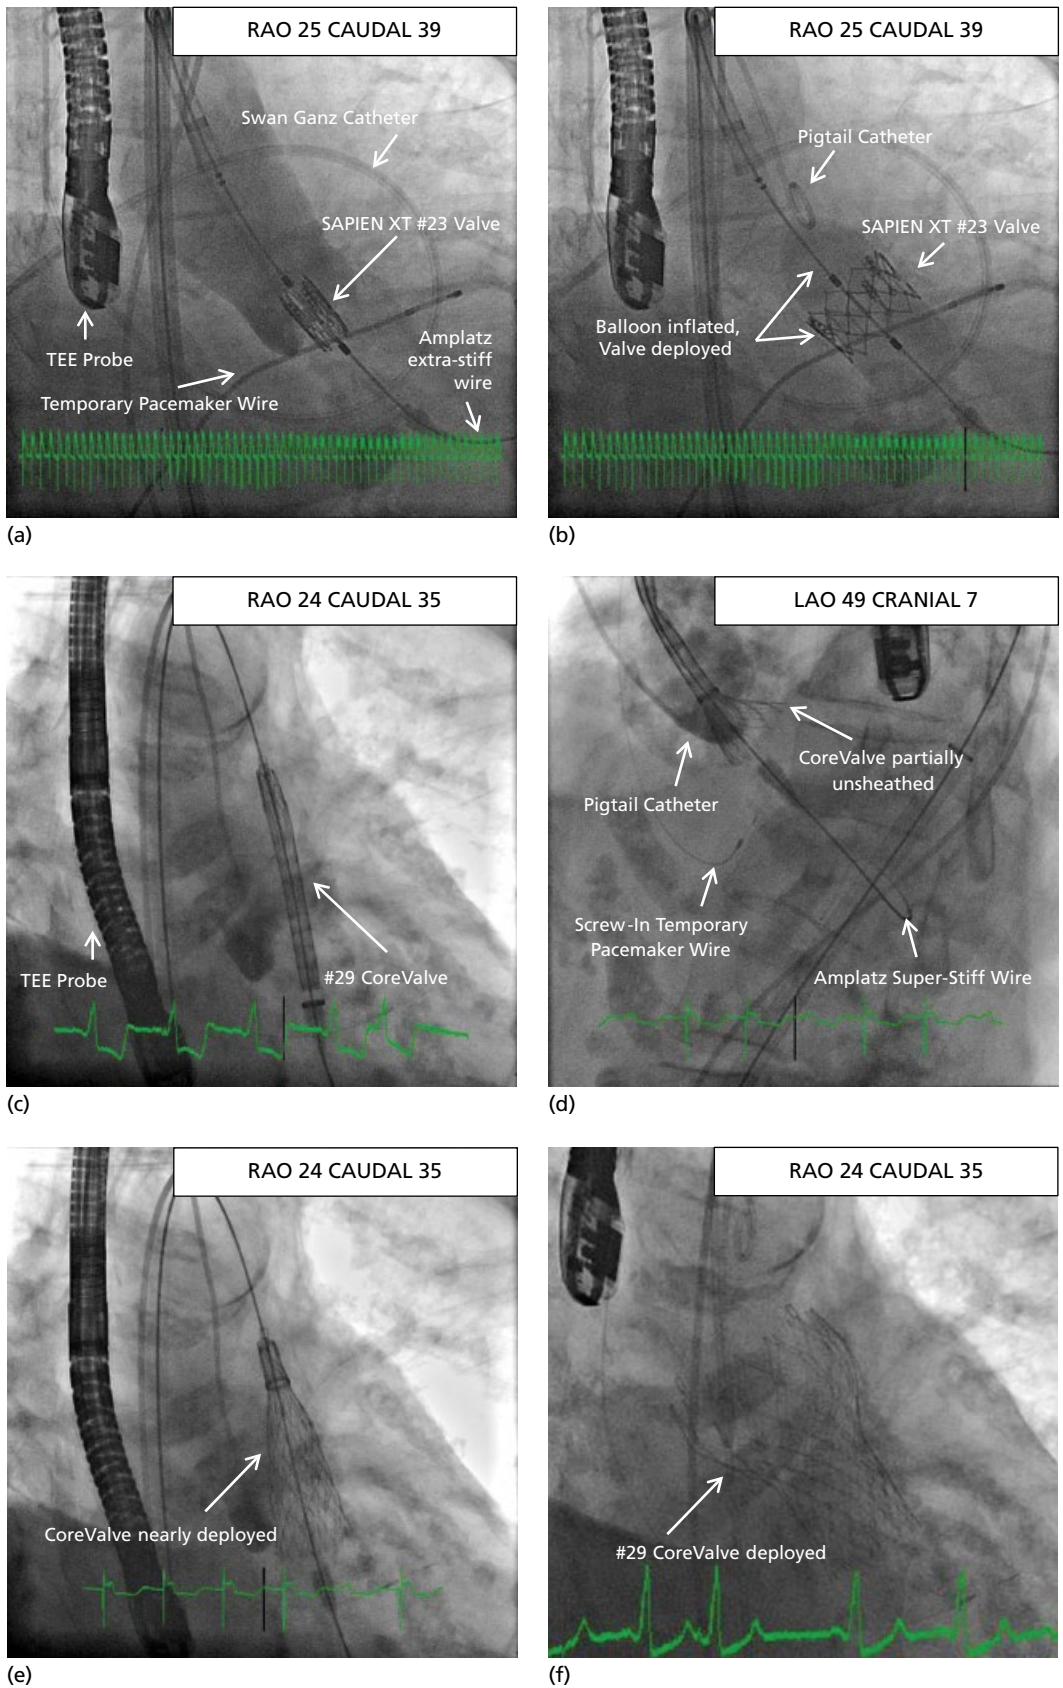

Figure 59.3 Positioning and deployment of the SAPIEN XT (a, b) and CoreValve (c–f) TAVR devices.

Table 59.2 Complications of transcatheter aortic valve replacement (TAVR).

Complication	Risk factors	Ways to mitigate/resolve
Vascular complications	Small femoral artery luminal diameter Calcified arteries, especially circumferential	Careful pre-procedural planning and evaluation of arterial access Confirm correct femoral artery placement (above bifurcation, below inferior epigastric) prior to large sheath dilatation Pre-closure of the arteriotomy site Iliac angiography at conclusion of the case Prompt endovascular or surgical repair of vascular injuries
Stroke	Older age, female, prior cerebrovascular or peripheral vascular disease, diabetes, hypertension, prior cardiac surgery Need for balloon post-dilatation No clear differences in TAVR route or device design Post-TAVR atrial fibrillation	Appropriate heparinization during procedure Appropriate pharmacologic treatment post-procedure Anticoagulation when needed for atrial fibrillation Minimize unnecessary manipulations of the device in the aortic root Cerebral embolic protection devices (under investigation) Alternative antiplatelet and anticoagulant regimens (under investigation)
Conduction system disease	Pre-existing conduction system disease Pre-existing right bundle branch block Valve oversizing Low valve implantation Self-expandable devices Calcified annulus	Consider active fixation, temporary pacemaker for high-risk cases and for self-expandable devices Carefully monitor patients post-procedure for conduction system disease Permanent pacemaker implantation when indicated Limit device oversizing (must be weighed against risk of paravalvular regurgitation)
Cardiac tamponade	Temporary pacemaker perforation Guidewire perforation Annular rupture during BAV or valve deployment (more common in oversized valves, calcified annulus, with post-dilatation, and with balloon-expandable valves)	Careful wire management Limit device oversizing (must be weighed against risk of paravalvular regurgitation) Prompt diagnosis and management in the setting of hemodynamic instability Consider self-expanding device (less risk of annular rupture) for severely calcified annulus
Aortic regurgitation	Asymmetric, calcified annulus Device undersizing	Annular sizing and valve measurement by multidetector CT, cardiac MRI, or 3D transesophageal echocardiogram rather than single dimension sizing by 2D transthoracic echocardiogram Post-dilatation or placement of a second valve (must be weighed against risk of stroke or annular rupture) Central regurgitation requires placement of a second valve if not resolving
Valve malpositioning or embolization	Deployment of the valve too high or too low Valve undersizing	Careful pre-procedural evaluation including annular size, and distance from annulus to coronary ostia Prompt intervention for coronary artery ostial occlusion with PCI or CABG

BAV, balloon aortic valvuloplasty; CABG, coronary artery bypass grafting; CT, computed tomography; MRI, magnetic resonance imaging; PCI, percutaneous coronary intervention.

turned to the study of embolic protection devices, of which there have been several systems under investigation including the Claret Sentinel Cerebral Protection System, and the Triguard Cerebral Protection Device (Figure 59.4). Further studies are also underway to evaluate the optimal anticoagulant strategies for TAVR. Current guidelines support the use of procedural heparin, then aspirin (50–100 mg/day) plus clopidogrel (75 mg/day) for 3 months after

TAVR followed by aspirin monotherapy (Grade 2C) [13,38]. Ongoing trials are studying the use of bivalirudin compared with unfractionated heparin, the use of the vitamin K antagonist acenocoumarol after TAVR, and the use of dual antiplatelet therapy versus aspirin alone.

Conduction system disturbances can also occur after TAVR, sometimes resulting in the need for permanent pacemaker

implantation (PPI). The mechanism for conduction abnormalities is thought to be mechanical compression of the conductive tissues, and the left bundle is particularly vulnerable. Thus, pre-existing RBBB is significantly associated with the need for PPI after TAVR, as is lower implantation of the prosthesis in the LVOT, calcified annulus, or a significantly oversized prosthesis [39,40]. Perhaps the strongest association with the need for post-TAVR PPI is the use of a self-expanding prosthesis. In the GARY registry, there was a significantly higher incidence of PPI with the Medtronic CoreValve (25.2%) than the Edwards SAPIEN device (5.0%). At our institution, we maintain an active fixation temporary pacemaker for 72 hours after CoreValve placement for this reason. When needed, pacemaker implantation has no adverse associations with short or long-term outcomes in TAVR patients, and is protective against unexpected death [41].

Cardiac tamponade is a rare complication of TF-TAVR. This can occur because of RV perforation from a temporary pacemaker wire, LV perforation from guidewires used to cross the aortic valve or support the TAVR device, or from annular rupture. Annular rupture is rare, but has been reported in 1% of TAVR procedures, and contained asymptomatic rupture may occur more frequently without detection [42]. Rupture can occur at the supra-annular, intra-annular, or sub-annular level, and sometimes involves multiple levels of the annulus and aortic root. Injury can occur during balloon pre-dilatation of the aortic valve, prosthetic valve deployment, or post-dilatation to reduce paravalvular leak. Annular rupture is not typically observed in self-expanding valves, unless post-dilatation is required. Rupture occurs more frequently when the valve is oversized $\geq 20\%$ and when the LVOT is calcified and subsequently less compliant [43]. Rupture often leads to immediate hemodynamic instability from tamponade, but presentation can sometimes be delayed or even occult in a contained rupture or hematoma. Generally, the presence of a hemopericardium should lead to suspicion for annular rupture, which can be confirmed by echocardiography or aortic root angiography. Treatment of less severe situations involve pericardial drainage and careful observation, but many cases will require emergency cardiopulmonary bypass and surgical correction. The mortality in patients who undergo open heart surgery because of annular rupture is very high at approximately 50%, and the outcome in patients who are observed more conservatively is not known [42].

Paravalvular aortic regurgitation after TAVR has also been extensively studied. There is a higher incidence of aortic regurgitation after TAVR than surgical AVR, which is not surprising considering that the prosthesis must be expanded to fit in an asymmetric annulus which is often heavily calcified. Several studies have shown an increase in mortality among patients with moderate or severe aortic regurgitation after TAVR, and even mild aortic regurgitation can be associated with worse outcomes [44,45]. When significant aortic regurgitation is identified at the time of TAVR, additional balloon inflation of the valve can be attempted to reduce paravalvular leak, although this can predispose to an increase in central regurgitation if the valve is over-distended. In some cases, a second valve is placed inside the first valve in attempts to reduce the severity of regurgitation. Unfortunately, both of these techniques are associated with a small, but not insignificant, increase in the risk of further embolic stroke, or injury to the annulus or conduction system. Fortunately, however, newer TAVR device designs have been specifically designed to reduce the incidence of paravalvular regurgitation. For example, the direct-flow valve is designed with two inflatable cuffs on the superior and inferior aspect of the valve apparatus that attempt to create a tighter seal between valve and annulus. Similarly, the Edwards S3 valve is designed with a skirt on the outer aspect of the inferior portion of the prosthesis. It is to be hoped that, with these and other technologic advances, there will be a significant reduction in aortic regurgitation after TAVR in the future. It remains to be seen whether these reductions in aortic regurgitation will correlate with similar improvements in clinical outcomes.

Conclusions

TAVR is an exciting therapy for patients with severe, symptomatic aortic stenosis who are at elevated risk for surgery, and the technology continues to evolve to include new valve designs, vascular access strategies, lower profile devices, and adjunctive methods to reduce the risk of procedural complications. It is to be hoped that, with these efforts, cardiologists and cardiac surgeons will be increasingly empowered to offer the best possible strategy for aortic valve therapy to each individual patient, as the burden of calcific aortic stenosis continues to grow among our aging population.

Case study

The patient is an 85-year-old male who is referred for evaluation of severe aortic stenosis. He has a past medical history of hypertension, coronary artery disease with three-vessel bypass surgery 10 years ago, chronic kidney disease with a baseline creatinine of 2.2 g/dL (GFR 26 mL/min/1.73 m²), mild COPD due to a remote history of smoking, and insulin-dependent diabetes mellitus. He has progressive dyspnea on exertion with New York Heart Association Class III symptoms. One year ago he was able to walk 2 miles at a slow pace approximately three times per week, but currently he is unable to walk for more than 10 minutes without having to stop to catch his breath. He also notes difficulty with breathing while sleeping at night and requires three pillows to prop up his head. He denies chest pain either at rest or on exertion.

The physical examination is notable for an elderly-appearing man who is well developed and with no labored breathing at rest. There is no distention of the jugular veins and no carotid bruits. The lungs are clear to auscultation bilaterally except for faint bibasilar crackles on inspiration. The heart sounds are regular with a III/VI systolic murmur that is late peaking. The abdomen is soft and non-tender without organomegaly. The extremities are notable for 2/2 bilateral radial and pedal pulses without pitting edema.

A transthoracic echocardiogram is obtained and reveals normal left ventricular size with a mildly reduced left ventricular

ejection fraction of 45%, mild mitral and tricuspid regurgitation, and severe aortic stenosis with a peak/mean gradient of 76/46 mmHg, and calculated aortic valve area of 0.76 cm².

The patient undergoes a left heart catheterization showing severe, native coronary artery disease, but patent bypass grafts to the left anterior descending, first obtuse marginal, and posterior descending arteries. Due to his baseline renal dysfunction, a cardiac MRI is carried out to evaluate annular size, and found to be 24 mm in average diameter. A CT scan with direct arterial contrast injection via a pigtail catheter is completed and the minimal luminal diameter of the left iliofemoral system is 6 mm and the right iliofemoral system is 9 mm with mild bilateral calcification.

The patient is evaluated by the heart team including a cardiac surgeon and an interventional cardiologist and it is determined that he is at high risk for re-do open heart surgery for aortic valve replacement with a calculated STS score of 9.4% for risk of mortality. It is determined that the patient is an appropriate candidate for transfemoral TAVR, and the patient undergoes implantation of a commercially available, 26 mm Edwards SAPIEN XT valve via the right femoral artery. After the procedure, the patient has no apparent complications, begins ambulating slowly on post-procedure day 1, and is discharged from the hospital on post-TAVR day 3.

Since the feasibility demonstrated by Cribier *et al* [1,2], transcatheter aortic valve implantation (TAVI) has become an established treatment in patients with calcified aortic stenosis who are inoperable or at high risk for conventional aortic valve replacement [3]. Multiple transcatheter heart valve (THV) types are now available for implantation either commercially or as a part of a trial [4–7]. The first two THVs to be commercially available, the Edwards SAPIEN THV valve (Edwards Lifesciences, Irvine, CA, USA) and the CoreValve ReValving System (Medtronic, Minneapolis, MN, USA), were initially implanted via either transfemoral (TF) or transapical (TA) routes [6,8,9]. This was because of the nature of the device design and the dedicated delivery systems. Subsequently, with the focus on minimizing patient morbidity and mortality, alternative access routes were developed: subclavian (TS) and transaortic (TAo). These two approaches have been shown to lower morbidity and mortality associated with a TA approach [10–14]. Further, they were also useful when the THV could only be delivered in a retrograde manner, for example the CoreValve. An important observation in earlier studies and ongoing registries is the high incidence of access site complications which directly impact on mortality, and 1 year survival [5,7]. This highlights the critical importance of access site choice in order to reduce morbidity and mortality, particularly as we move into treating medium and lower risk patients. This chapter describes the indications, patient selection, and planning for the TAo approach, and specific technical approaches and tips and tricks for some of the commercially available valve technologies, which are important in ensuring optimal outcomes.

Indications for transaortic access

During the inception of TAVI and its subsequent development, TF and TA approaches were the only available access routes, with TF as the default and TA if this was not possible. TAo was first performed several years later [11,15]. Excellent outcomes were demonstrated in extremely high-risk patients unsuitable for TF or TA—those with poor respiratory function, poor ventricular function, and frail patients [16,17]—with the relative ease of the procedure leading to increased utilization of the TAo approach. This trend was seen even prior to dedicated purpose-made

delivery systems. When these became available with subsequent CE mark for the CoreValve and SAPIEN systems, making the procedure even more straightforward, it became the preferred route over TA in many centers. It was also preferred over TF in patients with mobile atheroma or large atherosclerotic burden in the aortic arch when operators wanted to avoid instrumentation in these areas with its risk of embolization.

Patient selection

Appropriateness for TAVI should be discussed by a “heart team,” and where patients are deemed suitable, a discussion of the optimal strategy and approach should also constitute an integral part of the discussion. When considering suitability for TAo the key consideration is the landing zone which is the area on the ascending aorta where the purse-strings are placed to perform a TAVI. This area should be free of calcium, should allow perpendicular placement of the TAVI device within the aortic annulus, and should be a minimum distance away from the annulus to allow complete deployment of the TAVI device [16]. In re-operations, a computed tomography (CT) scan and angiography should be used to determine suitability, which includes proximity to the innominate vein and/or aorta to the sternum. In cases of prior coronary artery bypass graft (CABG), it is important to assess the position of patent grafts, particularly the left internal mammary artery (LIMA). If the LIMA does lie in the midline, or when the right internal mammary artery crosses the midline, there is a danger of injuring these grafts if a mini-sternotomy is performed. In this situation, TAo should be performed via a right anterior thoracotomy.

TAo TAVI approaches

Exposure of the ascending aorta can be carried out either through a mini-sternotomy or through a right anterior thoracotomy. Hybrid procedures can be carried out via a full sternotomy:

- *Mini-sternotomy* involves a J-upper sternotomy through the second or third right intercostal space or a T-sternotomy through the second intercostal space (Figure 60.1a, b). This has the advantages over a right anterior thoracotomy of familiarity for surgeons and the ability to keep the pleural space intact.

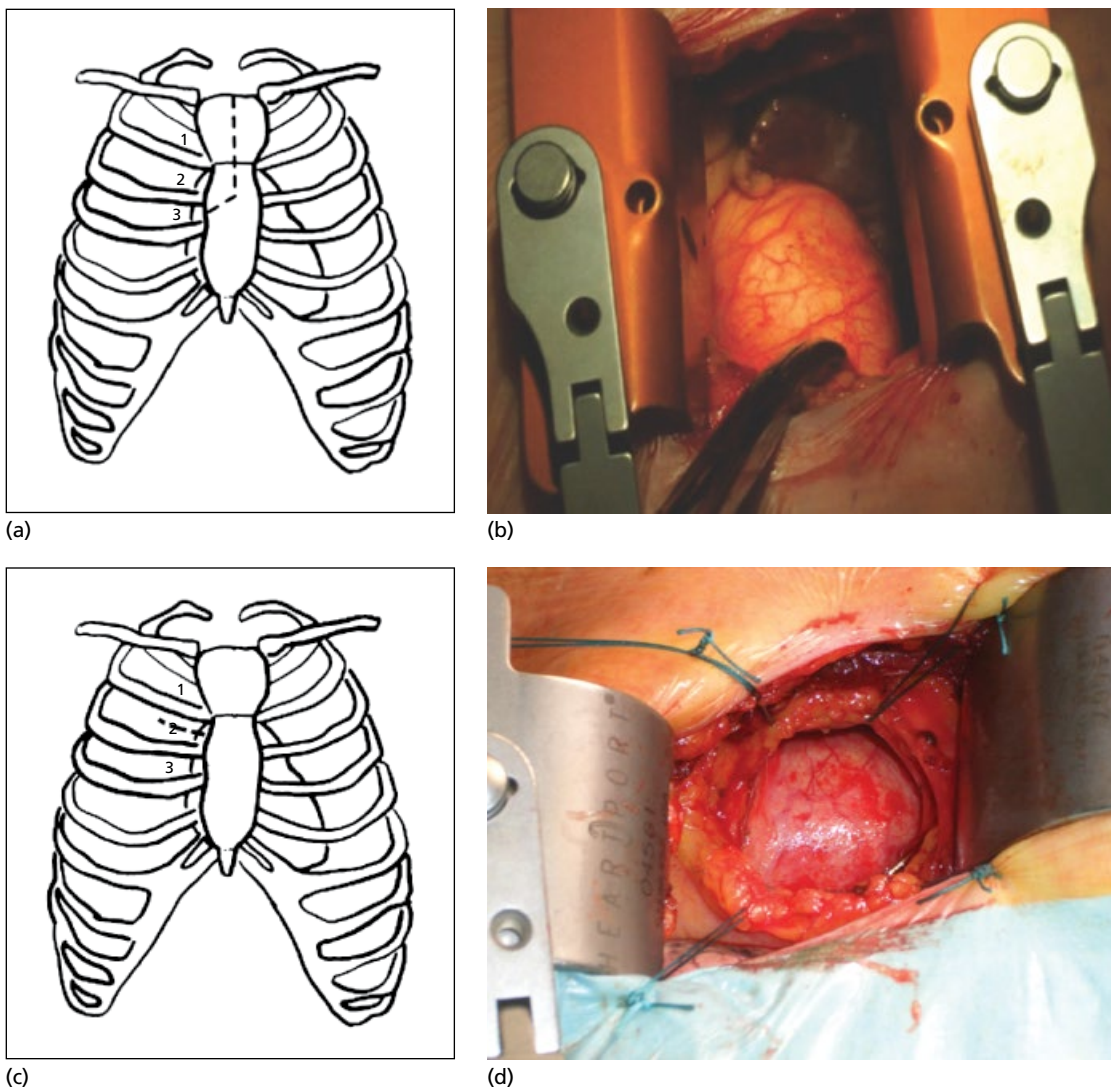

Figure 60.1 Sternotomy and thoracotomy site and operative view. (a) Exposure is obtained via a mini-sternotomy through a second or third right intercostal space. The dotted line shows the access schematic. (b) Operative exposure with metal marker at the site of purse-string. (c) Exposure is obtained via a right anterior mini-thoracotomy in second intercostal space. The dotted line shows the access schematic. (d) Operative exposure of ascending aorta through right thoracotomy.

- *Right anterior thoracotomy* is usually performed through the right second intercostal space, although the first right intercostal space is also an option (Figure 60.1c, d). This is not a bone-cutting incision and therefore has its benefits, particularly if the patient has undergone a previous sternotomy. In general, patients tolerate this better than a rib-spreading incision in terms of overall recovery.

Although technical considerations, particularly anatomy of bypass grafts, should dictate the choice of TAO approach, in the absence of contraindications this should be based on which is likely to be technically easier: a right anterior thoracotomy is easier if the aorta is to the right side and not very far from the rib cage, and a mini-sternotomy is easier if the aorta is in the midline or deeper. These can be assessed with CT. In general, patients with poor lung function do better with a mini-sternotomy as the pleura are kept intact. In patients with chest wall deformities, the choice is

governed by the position of the aorta. If a mini-sternotomy is not feasible and a right anterior thoracotomy is potentially technically difficult, an approach where that might help is by inserting a double lumen endotracheal tube to collapse the right lung for a short duration, which allows easier access to the aorta by shifting the mediastinum to the right.

Procedural considerations

General considerations for all devices

The surgical techniques and details of the procedure have been well described in previous publications [16,18]. The setup of the operating space should be either a mirror image of the TA procedure or a TF procedure through the aorta, which makes it easier to adapt from the routine setup. A dedicated room setup is essential for the success of the procedure. If there is doubt in terms of access, use a

Figure 60.2 Site of aortic access and purse-string position. (a) The TAO zone or the ideal site for purse-string is evaluated on multislice computed tomography; this varies slightly depending on the valve and delivery system. (b) Aortogram identifying the valve deployment view as well as confirm the distance between the aortic annulus and site of purse-string (at least 6 cm) and evaluate implant trajectory.

mini-sternotomy, as this gives the operator more control. Re-confirmation of the site of the purse-string should be made by fluoroscopy before they are placed to evaluate distance from aortic annulus and implant trajectory (Figure 60.2). A suture ring or bumper should be used to stabilize the sheath. A Seldinger technique should be used to cannulate the aorta. If the aorta is thin, a small knife can be preferred to insert the sheath. The wire position should be similar to that for the TF approach, with a large loop in the left ventricle free of kinks with the tip free to avoid trauma.

The TAO approach is now a well-established approach and can essentially be used for any TAVI device that can be implanted through a TF approach. A large body of experience exists in the TAO approach for SAPIEN and CoreValve, and there is emerging experience for other devices including the Engager (Medtronic, Minneapolis, MN, USA), Lotus (Boston Scientific, Natick, MA, USA), and Direct Flow (Direct Flow Medical Inc., Santa Rosa, CA, USA).

Edwards SAPIEN XT and SAPIEN 3

Several groups have reported on their experience with implanting the SAPIEN XT and more recently SAPIEN 3 (Edwards LifeSciences) via a TAO approach. The largest XT series comprised 83 patients with unfavorable peripheral access by Hayashida *et al.* [19]. All procedures were performed with the Ascendra 2 or older generations of the Ascendra system (Edwards LifeSciences), which did not have a nose cone. Device success rate was 92.6%, paravalvular leak $\geq 2/4$ was seen in 7.4%, conversion to open chest surgery was required in 5.3% (three aortic dissections, one valve migration, and one left main stem occlusion), and 30-day mortality was 7.4%. Lardizabal *et al.* [20] published a single-center series of 44 patients who underwent SAPIEN TAVI via TAO, and compared them with a non-randomized cohort who underwent TA from the same institution. Results showed equivalent 30-day combined safety endpoints, but significantly lower rate of major bleeding and vascular

complications, as well as intensive care stay in the TAO group. Published literature on the SAPIEN 3 is limited but a small number of procedures were performed in the initial CE mark study [21].

CoreValve

Following the first clinical procedure this approach was developed at the Niguarda Ca' Granda hospital in Milan [11,12,18]. Since then multiple single center and multicenter experiences have been reported [22]. The largest series of CoreValve direct aortic implantation was presented by Bruschi *et al.* at the 46th annual ANMCO meeting [23]. The EURyDICE Registry: EUROpean Direct Aortic Corevalve Experience, is a multicenter experience that comprises patients treated in 20 centers in nine countries in Europe and in Israel, between June 2008 and January 2014. A total of 519 cases have been collected. Mean age of the population was 81.3 ± 6.3 years, 48% were female, mean logistic EuroSCORE was 25.8 ± 15.8 ; 429 patients were in New York Heart Association (NYHA) Class \geq III (83%). Peripheral vasculopathy was the principal exclusion criterion from transfemoral TAVI and was present in 330 patients (64%); 306 patients had coronary artery disease (59%) and 109 patients had undergone previous coronary artery bypass surgery. TAVI procedure was performed in 224 of cases (43%) through a right anterior mini-thoracotomy in the second intercostal space or via an upper hemi-sternotomy in the other 295 patients. A size 29 mm CoreValve was implanted in 228 patients (44%). Procedural success was achieved in 509 patients (98%). Four patients required a second valve implanted and two patients had more than moderate paravalvular regurgitation; 30-day mortality was 8%. Seven patients experienced stroke (1.4%) and 72 patients (14%) required a new permanent pacemaker; 93% of patients had aortic regurgitation $< 2+/4+$. Median postoperative hospitalization was 9 days. Low access site complications and low stroke rate were two obvious highlights of these data.

Engager

The Engager™ aortic valve bioprosthesis (Medtronic, Inc., Minneapolis, MN, USA) consists of bovine pericardium mounted in a self-expanding nitinol frame. The stents consist of a main frame and a support frame. The control arms of the support frame are designed to be placed into the sinus of the aortic root and capture the native leaflets to aim to achieve an anatomically correct position in a defined height of implantation to minimize the risk of coronary obstruction, with a valve design that is also intended to minimize paravalvular regurgitation. The prosthesis is available in two sizes (23 and 26 mm) covering annulus diameters of 21–27 mm. The delivery system is 29 Fr with a 32 Fr crossing profile.

The Engager bioprosthesis has been evaluated in first-in-man, feasibility studies, as well as a European pivotal trial [24–26]. All of the published literature has been for the TA access, but Bapat *et al.* (personal communication) have successfully implanted this device TAO, with excellent procedural and short- to medium-term outcomes. This demonstrates that the TAO procedure remains robust despite larger sheath sizes.

Direct Flow

The Direct Flow Medical TAVI (Direct Flow Medical Inc., Santa Rosa, CA, USA) is the first aortic transcatheter valve device that is not based on a metallic frame technology. The Direct Flow is a bovine pericardial valve with an expandable Dacron polyester double ring design containing non-compliant angioplasty balloon technology. The upper (aortic) and lower (ventricular) ring balloons, interconnected by a tubular bridging system, can be pressurized independently through position-fill lumens. This inflatable and deflatable support structure allows precise positioning, retrieval, and assessment of valve performance before final fixation with a durable polymer. An 18-Fr sheath is used for all valve sizes. Early clinical results have shown excellent short-term results with 99% freedom from all-cause mortality at 30 days in the Prospective Multicenter Evaluation Direct Flow Study [27].

The first instance of Direct Flow TAVI made through a right anterior mini-thoracotomy was reported by Bruschi *et al.* [28], in a 78-year-old patient affected by severe aortic stenosis and severe peripheral vasculopathy, who had previously undergone CABG with bilateral mammary artery grafts. The standard technique to implant the device by “inner curve technique” was modified to treat this patient, where pulling on the portion directed to the outer side of the aorta was done before realigning the device at the annulus “outer curve technique.” The conclusions to be drawn from this are that with Direct Flow it is possible to perform a direct aortic approach even if the distance between the entry site and aortic annulus is <5 cm, (i.e., due to right mammary course), and that the angle between the sheath and ascending aorta is not a problem with Direct Flow. So, differently from other TAVI devices, it should be possible to choose any entry site on the ascending aorta, because coaxial alignment of the device is independent from entry site and perfect Direct Flow implantation is obtained by pulling on the three positioning wires.

Lotus

Lotus Valve (Boston Scientific) is a second-generation transcatheter heart valve device with two unique features: it is repositionable and retrievable, and it has an adaptive seal to reduce paravalvular leak.

It is implanted using a dedicated TF delivery system, which has a “pre-curve” to accommodate the curve of the aortic arch. Early clinical results have shown excellent short-term results [29]. First-in-man implantation of this device by TAO has been reported by Bapat *et al.* [30]. The valve is delivered using a delivery system, which is introduced through a dedicated sheath (20 or 22 Fr outer diameter). As the pre-curve in the delivery system, which was designed to facilitate a TF approach, cannot be overcome with any available sheath, it is important to choose an ideal site of the aortic puncture so as to achieve a coaxial placement of the Lotus valve. The site chosen should be at least 7 cm from the aortic annulus and on the anterior wall of the ascending aorta. For SAPIEN and CoreValve, the preferred site of the purse-string would be a lateral portion of the aorta to get a coaxial alignment of the device to the annulus but for the Lotus, because of the pre-curve, the purse-string should be placed anterior or slightly to the left of the ascending aorta. Amongst the currently available sheaths, we found that the Ascendra sheath (Edwards Life Sciences) was optimal as it has internal (tip) and external distance markers and it is not hydrophilic. A fluoroscopic marker at the tip for the delivery system is important as it allows the operator to visualize how far the tip is in the aorta and its relationship with the delivery system so as to allow complete expansion of the device and avoid pop-out. This is particularly important for Lotus deployment as the sheath tends to move inwards in the first half of the deployment and outwards during the latter.

TAo: comparison with other approaches

Across the world, the TA approach remains the default non-TF approach, and the majority of data available are therefore for TA compared with TF. There are no randomized data comparing TA with TF, but virtually all studies report better outcomes in those undergoing TF, but this is largely because of the higher underlying risk and comorbidities of patients who undergo TA. However, there are identifiable features of the TA approach that increase risk:

- 1 Access site problems, including apical rupture and delayed pseudoaneurysm formation [31,32];
- 2 Interference with postoperative respiratory dynamics because of thoracotomy;
- 3 Effects of left ventricular function because of the disruption and suturing of the left ventricular apex [33].

A TAO approach can potentially overcome each of these issues. There is no surgical interference of cardiac structures—the ventricular cavity—and mitral valve; it avoids the arch, which potentially reduces the risk of stroke. A mini-sternotomy without accessing the pericardial cavities provides the best non-TF option in those with poor respiratory function. Indeed, its advantages over a full sternotomy are well described, including reduced postoperative FiO₂ requirement, pain, and lengths of intensive care and hospital stay [34]. There are also technical aspects including improved tactile feedback because of the proximity to the aortic annulus as well as an ability to perform hybrid procedures.

Contraindications

The only contraindications for this approach are a complete porcelain aorta where there is presence of calcium in the TAO zone, although the advent of cardiac CT technology has shown that this is quite a rare occurrence, and when the ascending aorta is not accessible as a result of anatomic deformity of the chest wall.

Rare types of access for high risk inoperable TAVI

As described earlier, TA access was part of the first large TAVI trial because of an anatomically intuitive direct cardiac exposure with a minimally extensive lateral thoracotomy [35–37]. However, it was realized that this approach and the patients selected for it had many inherent limitations: the severe calcification of the arterial system (“porcelain ascending aorta”) or otherwise extensive subocclusive disease of the aorta, the subclavian and the iliac arteries, frail status, severe kyphoscoliosis, possible injury to the coronaries during apex suturing, suboptimal apex hemostasis because of frail myocardium, stroke, and infection [9,31–33,37]. Notably, the valve delivery, positioning, and implantation was the least complicated part of this entire procedure. Although dedicated valve delivery equipment has been made available, most of these risks are related to unfavorable patient comorbidities; hence, this type of access was reserved only for patients completely unsuitable for any alternative. Research initiatives to develop minimally invasive or even percutaneous closure devices/techniques for the left ventricular apex have been incomplete thus far. Accordingly, TA access TAVI remains currently feasible but with an ever-shrinking clinical application.

Another type of “heroic” TAVI access has been developed in response to the high complication rate of TA TAVI. Again, patients without any feasible aortic, subclavian, or iliofemoral access for TAVI are the target patient population. Transcaval abdominal aortic access has been described [38] and can be performed after a careful anatomic plan has been developed based on the CT aortography review [39]. Adequate access through either one of the iliofemoral veins and the inferior vena cava is available for the TAVI delivery system. The “tricky” part in planning this procedure is to identify an area of the abdominal aorta appropriate to receive the large-bore device at an area adjacent to the cava (because a transseptal needle would be used to obtain wire access from the cava to the aorta) and away from important arterial branches in such a way that the aorto-caval communication can be sealed with an intracardiac closure device before sheath retrieval following successful TAVI. However, there are still patients for whom this approach cannot be performed as a result of “porcelain” abdominal aorta or other extreme anatomic unsuitability.

Such high risk patients can be approached with antegrade trans-mitral access [40] provided that the angle of mitral and aortic annulus is not extremely sharp and the left ventricular cavity is of sufficient size to allow passage of the bulky TAVI delivery system without myocardial rupture or ripping of the anterior mitral valve leaflet (both imminently fatal complications). Notably, this was the very first way TAVI was implanted but was quickly abandoned because of the frequency of these two major complications.

Interestingly, transcarotid TAVI delivery [41] has also been described in high risk TAVI candidates who are obviously inoperable otherwise and have no other mode of access.

Conclusions

The TAo approach using the majority of the currently available TAVI devices is feasible and safe. It is less invasive than the TA approach, provides an access route that is considerably more familiar to cardiac surgeons which improves the learning curve, and provides the option of performing hybrid procedures. Although randomized head-to-head comparisons with TA have not yet been published, the available data suggest more favorable outcomes for TAo. Dedicated delivery options for the newer devices should

make what is already a very straightforward procedure even easier, resulting in shorter procedure times as well as improved outcomes.

³Hospital Israelita Albert Einstein, São Paulo, Brazil

First performed in 2002 [1], transcatheter aortic valve replacement (TAVR) allows implantation of a prosthetic heart valve within the diseased native aortic valve without the need for open heart surgery and cardiopulmonary bypass, offering an established therapeutic option to elderly patients considered at high surgical risk or with contraindications to surgery. Despite the excellent outcomes observed with the balloon-expandable devices SAPIEN™/SAPIEN XT™ (Edwards Lifesciences, Irvine, CA, USA) [2,3] and with the self-expandable system Medtronic CoreValve® (Medtronic, Minneapolis, MN, USA) [4], the first devices approved globally, the occurrence of adverse events such as paravalvular regurgitation, valve malpositioning, vascular complications, and conduction disorders need to be addressed in order to further improve the prognosis of high risk patients with aortic stenosis and potentially expand the indications of TAVR to lower risk individuals.

Development of newly transcatheter aortic bioprosthesis is aimed to facilitate the procedure and underscores the need to: (i) reduce delivery catheter diameter, preventing vascular complications; (ii) to ensure accurate annular positioning, allowing the retrieval, recapture, and re-implantation of the device in cases of prosthesis misplacement; and (iii) to incorporate innovative design features that reduce the occurrence of paravalvular leaks, conduction disturbances, and coronary occlusion. Currently, some different percutaneous aortic valves—“second-generation TAVR devices”—are commercially available in Europe and others are gaining early clinical evaluation [5,6]. In this chapter, the unique features and the initial clinical results of new aortic valve technologies are reviewed.

SAPIEN 3

The balloon-expandable SAPIEN 3 transcatheter heart valve system™ (Edwards Lifesciences Inc.) has several new features intended to ensure a more precise implantation and to reduce the occurrence of paravalvular leak and vascular complications [5,6]. The SAPIEN 3™ (S3) valve is composed of modified bovine pericardial tissue leaflets sutured in a cobalt-chromium stent design, which permitted a further downsizing in profile (Figure 61.1a). Like the SAPIEN XT™ (Edwards Lifesciences Inc.) device, the inflow of the S3 is covered by an internal polyethylene terephthalate (PET) skirt; an

additional outer PET sealing cuff was incorporated to prevent paravalvular regurgitation. Four sizes are available (20, 23, 26, and 29 mm), covering annulus sizes between 16 and 28 mm.

The new transfemoral delivery system is called Commander™ (Figure 61.1b) and has a smaller profile (14 Fr) and a higher flexibility than the previous NovaFlex™ delivery catheter (Edwards Lifesciences Inc.). Therefore, navigation through tortuosities is facilitated and the S3 can be positioned more coaxial to the native valve in challenging anatomies, such as horizontal aorta. A complementary wheel has been added in the delivery handle, and the height of the implant can be adjusted precisely, providing accurate and more reproducible valve positioning and further preventing paravalvular leak, conduction disturbances, and permanent pacemaker need. During balloon inflation, the stent frame of the crimped valve foreshortens predominantly from below, so this movement should be anticipated when positioning the device.

The S3 system is compatible with a 14 Fr expandable eSheath™ (Edwards Lifesciences Inc.), which transiently expands as the prosthesis passes through the sheath. With the improved profile, the incidence of vascular and hemorrhagic complications is reduced, and a broader proportion of patients can be treated by transfemoral access (a minimum vessel diameter of 5.5 mm iliofemoral arteries is required). The profile of the transapical Edwards Certitude delivery system™ (Edwards Lifesciences Inc.) has also been downsized to 18 Fr (for S3 23–26 mm) and 21 Fr (S3 29 mm).

In the first-in-human experience with the SAPIEN 3™, 15 patients with symptomatic, severe aortic stenosis were treated by transfemoral approach [7]. All the devices were successfully implanted, and the aortic valve area and the mean transaortic gradient improved from 0.7 ± 0.2 to 1.5 ± 0.2 cm² ($p < 0.001$) and from 42.2 ± 10.3 to 11.9 ± 5.3 mmHg ($p < 0.001$), respectively. None of the patients had moderate or severe paravalvular aortic regurgitation. In the PARTNER II S3 trial, 1076 patients considered intermediate risk for surgical aortic valve replacement and 583 patients deemed high risk or inoperable were treated with the SAPIEN 3™ valve [8]. In the high risk cohort, the mortality rate at 30 days was 2.2% and the stroke occurred in 1.5% of patients; the rate of moderate–severe aortic regurgitation was 2.9%. For the intermediate risk patients, all-cause mortality was 1.1%, and 2.6% had a stroke at 30 days; the rate of moderate and severe paravalvular regurgitation was 4.2% in this cohort.

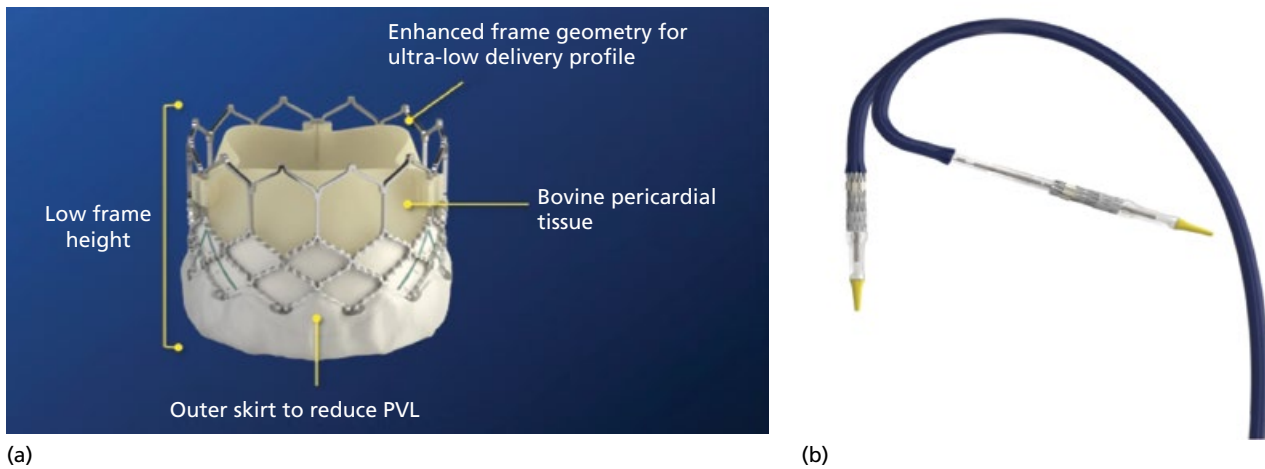

Figure 61.1 (a) SAPIEN 3: composed of bovine pericardial tissue leaflets in a cobalt-chromium stent design; the inflow has an outer sealing cuff to prevent paravalvular regurgitation. CoreValve Evolut R

The major improvements of the new Medtronic CoreValve system—CoreValve Evolut R™ (Medtronic, Minneapolis, MN, USA) were developed to provide stable and controlled deployment of the prosthesis at the desired level of the aortic annulus and to prevent paravalvular regurgitation, making the procedure more predictable [9]. The fully repositioning and recapture properties enables accurate positioning and minimizes the risks of paravalvular leakage, mitral anterior leaflet compromise, valve embolization, and conduction disturbances requiring permanent pacemaker. Although several other features of the previous CoreValve™ system (like the self-expanding nitinol stent frame, the porcine leaflets, and the supra-annular functioning of the valve leaflets) have been preserved, the distal inflow portion has been redesigned for an extended pericardial skirt, further reducing the risk of paravalvular aortic regurgitation (Figure 61.2a). The outflow portion is 10 mm shorter than the previous version, aimed to optimize fit in angulated anatomy. The Evolut R™ is available in four sizes (23, 26, 29, and 31 mm), covering aortic

annuli from 18 to 30 mm. The new delivery system (Enveo R™) guarantees a rapid, precise interaction between deployment knob rotation and prosthesis unsheathing and resheathing (Figure 61.2b). It has a reinforced nitinol capsule for resheathing and an integrated sheath, mounted in the catheter and named InLine™. The InLine™ sheath has a 14 Fr profile (true outer 18 Fr), which allows for a sheathless procedure, further reducing the rate of vascular complications.

Initial clinical outcomes for CoreValve Evolut R system™ were reported in a first-in-man experience, multicenter study with 60 patients [10]. Transfemoral access was possible in all but one patient (98.3%) and a correct valve position with one device in place was achieved in 98.3%. All resheathing and recapture attempts (22 in 15 patients) were performed safely and successfully. Post-dilatation was required in 21.7% of cases, and mean aortic gradient decreased from 49.1 mmHg at baseline to 8.1 mmHg post-procedure; moderate or severe aortic regurgitation were observed in 3.4% of patients at 30 days. No incidents of death or stroke were observed at 30 days, and the pacemaker rate was 11.7%.

Lotus™ valve system

The Lotus™ valve system (Boston Scientific, Natick, MA, USA) [11] is designed to ensure a precise positioning, minimizing paravalvular regurgitation. The valve is comprised of bovine pericardial leaflets within a braided, single nitinol wire in a self-expanding frame. A radio-opaque marker is located centrally in the frame to aid in positioning. The valve frame is surrounded in its inflow (ventricular) portion by an outer sleeve membrane (Adaptative Seal™), which can potentially occupy remaining gaps between the valve and aortic annulus, thus preventing paravalvular aortic regurgitation (Figure 61.3a). Inside its delivery catheter, the Lotus™ valve is stretched to 70 mm length, and shortens to approximately 19 mm after deployment. It is available in three sizes (23, 25, and 27 mm), which permits the treatment of patients with aortic annulus from 19 to 27 mm. The valve is pre-attached to the delivery system and is deployed in a controlled mechanical fashion, which enables proper leaflets function early in the expansion phase—mitigating hemodynamic instability during this part of the procedure—and allows for helpful evaluation of positioning and performance before final release (Figure 61.3b). In cases of significant paravalvular leakage, coronary compromised or severe conduction disturbances, the special property of resheathing the Lotus™ valve permits repositioning and retrievable maneuvers. The delivery system of the Lotus™ has a 18–20 French size, is pre-curved, and covered with a hydrophilic coating, which ensures a better trackability in diseased and tortuous vessels and for adjustment to the angulation of the aortic arch.

Successful implantation of the Lotus valve was first reported in Germany in 2007 [12]. After refinement of the initial design, the valve underwent clinical testing. In the REPRIS I trial and feasibility study to assess the acute safety and performance of the Lotus™ valve, 11 high-surgical risk patients with symptomatic, severe aortic stenosis were treated [13]. In all patients, the valve was successfully deployed in the first attempt. Partial resheathing was required and successfully performed in four patients; none required full retrieval. A successful implantation without residual gradient and major adverse cardiovascular or cerebrovascular events was achieved in nine patients (82%), with no in-hospital major adverse cardiac and coronary events (MACCE) in 10 patients. One patient suffered a major stroke and other patient had a mean gradient above 20 mmHg at discharge. The hemodynamic performance of the Lotus™ valve was sustained: mean aortic gradient decreased from 53.9 ± 20.9 mmHg at baseline to 15.4 ± 4.6 mmHg ($p < 0.001$) at 1 year and valve area increased from 0.7 ± 0.2 to 1.5 ± 0.2 cm² ($p < 0.001$). After adjudication by an independent core laboratory, paravalvular aortic regurgitation was mild ($n=2$), trivial ($n=1$), or absent ($n=8$) as assessed by echocardiography. Four patients (36.3%) required a permanent pacemaker post-procedure.

In the prospective, single-arm, multicenter REPRIS II trial, 120 patients considered to be at high surgical risk by a heart team were selected [14]. The valve was successfully implanted using transfemoral access in all patients; complications such as valve embolization, ectopic valve deployment, or additional valve implantation were not observed. All required attempts of repositioning ($n=26$) and retrieval ($n=6$) the valve were successful; 34 patients (28.6%) received a permanent pacemaker. The primary device performance endpoint (30-day mean pressure gradient by echocardiography) was met, and the mean gradient improved from 46.4 ± 15.0 to 11.5 ± 5.2 mmHg; mean effective orifice area increased from 0.7 ± 0.2 to 1.7 ± 0.4 cm² post-procedure. At 30 days, the mortality rate was 4.2% and major stroke occurred in

1.7%. Only one (1.0%) patient had moderate paravalvular regurgitation, and none had a severe paravalvular leak. The ongoing REPRIS III is a randomized, multicenter, controlled trial that aims to assess the safety and effectiveness of the Lotus system, as compared to the self-expandable CoreValve™; more than 1000 patients were expected to be enrolled in 60 centers.

ACURATE valve system

The Symetis Acurate™ transcatheter valve (Symetis SA, Ecublens, Switzerland) is a self-expanding nitinol device, with supra-annular porcine leaflets and a unique stent architecture [15]. The stent frame is divided into three parts, released in sequential steps from the aorta to left ventricle (Figure 61.4):

- 1 The “upper crown” is first deployed in a subcoronary position and provides fixation to the annulus, capturing the native leaflets and reducing the occurrence of coronary obstruction.
- 2 Three aortic stabilization arches, designed for self-alignment and coaxiality, are then released and prevent tilting of the device during deployment; up to this point the valve can still be repositioned and retrieved.
- 3 The “lower crown” has good radial force and after unsheathing, protrudes minimally in the left ventricular outflow tract, which favorably impacts post-procedure pacemaker rate.

The upper crown is fenestrated, and the stent body and lower crown have internal and external pericardial skirts, also preventing paravalvular leak. The Acurate valve™ is available in three sizes, covering aortic annulus sizes from 21 to 27 mm (ACURATE™ S 21–23 mm, M 23–25 mm, and L 25–27 mm).

In a multicenter post-market study, 250 high risk, elderly patients with severe aortic stenosis were treated with the ACURATE TA™ (transapical) bioprosthesis (Symetis SA, Ecublens, Switzerland) [16]. Mean STS and logistic Euroscore were $8.0 \pm 5.9\%$ and $22.3 \pm 12.7\%$, respectively. The procedural success rate was 98% ($n=245$) with two valve-in-valve procedures and three conversions to open-heart surgery. Moderate paravalvular regurgitation was detected in 2.3% of patients, and none had a severe aortic regurgitation. A new pacemaker implantation was required in 10% of patients and 30-day mortality rate was 6.8%. Well-grounded in the ACURATE TA™ experience, a transfemoral version of the device was developed: ACURATE Neo™ (Symetis SA, Ecublens, Switzerland). The ACURATE Neo™ has a very flexible delivery catheter compatible with a 18 Fr sheath. The first-in-man trial enrolled 20 patients in Brazil and Germany between February and August 2012 [15]. Patients were 84.8 ± 4.5 years old with a mean logistic EuroSCORE of $26.5 \pm 8.0\%$. The procedural success was 95% ($n=19$) and one patient had to be treated with a valve-in-valve procedure because of low (too ventricular) placement. The effective orifice area improved from 0.7 to 1.8 cm² and all except one patient have more-than-mild paravalvular regurgitation. The pacemaker rate was 10% ($n=2$).

Direct Flow

The Direct Flow™ transcatheter heart valve (Direct Flow Medical Inc., Santa Rosa, California, USA) differs from the other new aortic valve technologies already in clinical use, as it consists in a non-metallic, trileaflet bovine pericardial valve attached to an inflatable, polyester fabric cuff [5,6]. Two circular balloons—one proximal (aortic) and the other distal (ventricular)—were connected by vertical tubular supports and inflated independently and sequentially with a solidified polymer that hardens the non-metallic frame,

encircling the annulus and anchoring the bioprosthesis at the annular level (Figure 61.5). The device is fully repositionable and retrievable through the introducer prior to final deployment, allowing for accurate and controlled deployment to ensure perfect

sealing and reduced risk of paravalvular aortic regurgitation. Other technical advantages of the Direct Flow™ system includes its flexibility due to the non-metallic design, an important feature in tortuous anatomies; maintenance of hemodynamic stability throughout the

Figure 61.5 The Direct Flow Medical® Transcatheter Aortic Valve consists of a trileaflet bovine pericardial valve attached to a non-metallic, inflatable, polyester fabric cuff. Image used with permission of Direct Flow Medical.

deployment, because transaortic blood flow is preserved and rapid pacing is not required during positioning and implantation; and, finally, the inflatable polyester cuff conforms to the native aortic annulus, minimizing further the risk of paravalvular regurgitation. The Direct Flow™ bioprosthesis is available in four sizes (23, 25, 27, and 29 mm), for aortic annulus sizes between 19 and 28 mm. The delivery system is 18 Fr-compatible for all valve sizes.

The safety and efficacy of Direct Flow Medical system™ were evaluated in a prospective, multicenter, non-randomized trial with 100 high surgical risk patients with severe aortic stenosis [17]. All procedures were performed transfemorally, and all patients underwent balloon valvuloplasty before valve implantation to ensure expansion of the stenotic leaflets and annulus; the mean time for valve positioning, assessment, and deployment was 14 minutes. Freedom from all-cause mortality at 30 days (the pre-specified primary endpoint) was 99%, and overall device success was 93%. The mean aortic valve gradient decreased from 45.9 ± 9.6 to 12.6 ± 7.1 mmHg post-procedure, and the effective orifice area increased from 0.65 ± 0.18 cm² at baseline to 1.50 ± 0.56 cm² at 30 days. Total aortic regurgitation was mild or less in 98.6%, and no patient had severe aortic regurgitation. Paravalvular regurgitation was

none in 70.3%, mild in 28.4%, and moderate in 1 (1.4%). Stroke rate was 2.7%, and 16% required a new, permanent pacemaker.

Because of the non-metallic design, concerns about durability and recoil of the Direct Flow Medical valve™ have been raised. So far, 2-year data from the very first patients ($n = 16$)—treated with an older version of the device—revealed that there were no changes in the position, diameter, or orifice area of the prosthesis over time with no evidence of recoil, as assessed by multislice computed tomography. Hemodynamic performance were also stable by echocardiography, with absent and mild aortic regurgitation in 73% and 27% of patients, respectively [18].

Engager

The Medtronic Engager™ aortic bioprosthesis (Medtronic Inc.) is designed for a transapical, antegrade approach and combines a self-expanding nitinol frame and bovine pericardium trileaflets [5,6,19]. The nitinol stent consists of a central frame, which houses the leaflets, and a support frame, with control arms designed to stabilize the device in the sinuses of Valsalva, obtain anatomic orientation and positioning. The prosthesis has a polyester sleeve sutured to the main frame to reduce the risk of paravalvular regurgitation (Figure 61.6). The Engager™ is available in two sizes, 23 and 26 mm, for an annulus range between 21 and 27 mm. The first step of the implantation procedure consists in locating the support arms into the sinuses of Valsalva. Correct subcoronary positioning is mandatory, and should be verified by angiography. Repositioning (if necessary with recapture of the support arms) could be performed at this stage. The commissural posts are then released, and final deployment is ideally performed under rapid ventricular pacing for stability and accuracy of positioning.

The Engager™ underwent first-in-man implantation in 2008 [19]. The feasibility study with the new Engager® system was conducted in 10 patients at high risk for surgery (mean age 82.5 ± 3.6 years, mean logistic EuroSCORE $24.6 \pm 13.6\%$). Implantation was successful in all patients, and no complications related to the device were reported. Aortic regurgitation caused by paravalvular leakage was absent or trivial (\leq grade 1) in the majority (90%) of patients, and two required permanent pacemaker implantation for complete atrioventricular block.

Figure 61.6 Medtronic Engager™ bioprosthesis. Designed for a transapical approach, is composed by a self-expanding nitinol frame, bovine pericardium trileaflets, and a polyester sleeve to reduce the risk of paravalvular regurgitation. Image used with permission by Medtronic ©2016. Note added in proof: The Engager bioprosthesis has been discontinued.

In a published, interim analysis of the multicenter Engager® CE pivotal trial, 61 patients with mean age of 81.9 years and mean logistic EuroSCORE of 18.9% were selected. Overall device success, defined by modified VARC criteria, was achieved in 94.3%, without conversions to surgery, second valve implantation, device malposition, aortic annular rupture, or coronary obstruction. All-cause mortality was 9.9% at 30 days and 16.9% at 6 months. Mean aortic valve gradient improved from 43.7 ± 16.7 to 11.5 ± 5.0 mmHg at 30 days, and there was no paravalvular regurgitation greater than mild through 6 months [20].

Portico

The Portico™ valve (St. Jude Medical, USA) consists of bovine pericardial tissue mounted on a nitinol, self-expandable stent (Figure 61.7). Although similar in appearance to the CoreValve™, the Portico™ prosthesis has several and distinct features aimed at reducing potential complications:

- 1 The inflow portion is covered by a porcine pericardium cuff designed to minimize paravalvular leaks.
- 2 The leaflets are located lower on the support frame, minimizing device protrusion into the left ventricular outflow tract and therefore conduction disturbances.
- 3 The valve is resheathable and can be repositioned before deployment, provided the stent has not been fully released.
- 4 A large stent cell design guarantees easier access to coronaries and results in a low crimped profile; the large cell area also potentially minimizes the risk of paravalvular leak by allowing valve tissue to conform around calcific nodules at the annulus.

The valve uses Linx® anti-calcification technology [21].

In the first-in-man experience, the Portico™ valve was implanted in 10 patients with severe aortic stenosis using transfemoral access [22]. Device implantation was successful in all patients. Prosthesis recapture and repositioning was required in four patients, and one patient underwent a second transcatheter valve implantation because of intermittent prosthetic leaflet dysfunction. Mean transaortic gradient decreased from 44.9 ± 16.7 to 10.9 ± 3.8 mmHg ($p < 0.001$), and valve area increased from 0.6 ± 0.1 to 1.3 ± 0.2 cm² ($p < 0.001$). Moderate paravalvular regurgitation was detected in one patient (10%). No major strokes, major vascular complications, major bleeds, need of permanent

Figure 61.7 Portico™ valve. Bovine pericardial tissue mounted on a nitinol, self-expandable stent, with inflow portion covered by a porcine pericardium cuff to minimize paravalvular leaks. pacemaker, or deaths were reported. The feasibility of transapical implantation of the Portico® valve has been investigated in Canada and Europe [23]. A total of seven cases were successfully performed, with procedure successes in 100% according to VARC II definition. Paravalvular regurgitation was mild or trace in all patients. The 24 Fr delivery system used is one of the smallest used for transapical access, and could, in particular, be safer in patients with left ventricular dysfunction.

JenaValve

The JenaValve® prosthesis (JenaValve Technology GmbH, Munich, Germany) consists of a porcine root valve mounted on a low profile, self-expanding nitinol frame [5,6,24]. Initially a transapical-only system, which included a sheathless 32 Fr delivery catheter (Cathlete; JenaValve Technology GmbH), the prosthesis is available in three sizes (23, 25, and 27 mm), covering aortic valve annuli from 21 to 27 mm. The self-expanding stent has three feelers, which should be placed in the left, right, and non-coronary cusps before deployment (Figure 61.8). The purpose is to position the commissures of the prosthesis precisely on the commissures of the native aortic valve. After the feelers have been placed in the correct orientation, the catheter is pulled back up until a tactile feedback indicates the contact of the feelers with the proper cusps; the lower part of the JenaValve® is then released. Rapid pacing is not required during prosthesis positioning, and hemodynamic flow is maintained during prosthesis placement. Patients' native valve leaflets are hence clipped between the feelers and the base of the prosthesis. This clipping mechanism firmly anchors the prosthesis independently of the amount of calcium at the aortic annulus or leaflets, providing active fixation and resistance to migration. At this point the bioprosthesis is competent and functioning but still repositionable and retrievable. After releasing the base, the last step in deployment is the opening of the upper part of the nitinol frame. Because of the clipping mechanism, the JenaValve® is the only transcatheter heart valve with a CE

Figure 61.8 JenaValve prosthesis. Composed of porcine root valve mounted on a low-profile, self-expanding nitinol frame, it has three feelers to be placed in the native aortic cusps before deployment. Image used with permission of JenaValve Technology, Inc.

Mark indication for symptomatic, severe pure aortic regurgitation. A transfemoral concept has been presented.

The safety and efficacy of transapical implantation of the JenaValve[®] were evaluated in two multicenter, prospective trials [25]. In the first trial, 67 patients with severe aortic stenosis considered high-risk surgical candidates (mean age 83.1 ± 3.9 years, mean logistic EuroSCORE $28.4 \pm 6.5\%$) underwent transapical implantation of the device. The procedural success rate was 89.6% (60/67 patients). Mortality at 30 days was 7.6%, and conversion to open heart surgery was required in four patients (6%). Stroke occurred in two patients (3%), and permanent pacemaker implantation was necessary in eight patients (12%). After the procedure, patients had a reduction in mean transvalvular gradient (40.6 ± 15.9 to 10.0 ± 7.2 mmHg) and an increase in valve area (0.7 ± 0.2 to 1.7 ± 0.6 cm², respectively). None of the treated patients had moderate to severe (>grade 2+) paravalvular aortic regurgitation. In the second trial, 31 patients with severe aortic regurgitation considered high-risk surgical candidates (mean age 73.8 ± 9.7 years, mean logistic EuroSCORE $23.6 \pm 14.5\%$) underwent transapical implantation of the device [26]. The procedural success rate was 96.8% (30/31 patients). Mortality at 30 days was 12.9%, and no conversion to open heart surgery was required. No stroke occurred, and permanent pacemaker implantation was necessary in two patients (6.4%). After the procedure, mean transvalvular gradient was low (7.9 ± 4.0 mmHg), and none of the treated patients had moderate or worse paravalvular aortic regurgitation. More recently, clinical and valve performance results from a multicenter, prospective post-market registry including both aortic stenosis and aortic regurgitation patients have been reported.

Conclusions

TAVI has become a feasible and effective therapeutic option for inoperable or high surgical risk patients with severe aortic stenosis. Despite the impressive and positive clinical results with the first-generation devices, there are many challenges to be addressed for further improvement in outcomes and, potentially, to expand the indications to lower risk patients. New valve technologies are characterized by repositionable and/or retrievable properties, lower profile, and innovative features designed to prevent complications such as paravalvular leaks, vascular complications, and conduction disturbances. Further studies are necessary to evaluate if the theoretical benefits of the second-generation valves will result in better clinical outcomes.

Transseptal Puncture

Alec Vahanian, Dominique Himbert, Fabrice Extramiana, Gregory Ducrocq, and Eric Brochet

Hôpital Bichat-Claude Bernard, Paris, France

Transseptal catheterization (TS) remains an integral yet specialized technique for interventional cardiologists and electrophysiologists. It was introduced in the late 1950s [1]. Initially seldom used, mostly because of lack of experience and trepidation, this relatively complex technique has had a revival with the introduction of new percutaneous electrophysiologic and structural, especially valvular, interventions (Box 62.1) [2–8].

This chapter describes the technical aspects of the procedure, including guidance by imaging, then addresses the specific aspects related to specific interventions performed for which TS is the first step.

Training

The presence of a learning curve has been well described [2,3]. Thus, training in transseptal catheterizations involves the acquisition of specialist skills [9]. However, currently there are no specific data regarding the minimum numbers needed for initial training and maintenance of competency.

Physicians performing transseptal catheterization must have a good knowledge of the pathoanatomy of the heart, hemodynamics, and echocardiography. Interventionists must be able to recognize and manage complications such as tamponade and stroke. Training in transseptal catheterization is expected to derive benefit from simulator training before clinical training during specific courses on the technique [10].

Echocardiographic guidance

Echocardiographic examination performed before TS catheterization must carefully look for abnormalities of the interatrial septum such as very thick septum, calcifications, aneurysmal deformation, and presence of a patent foramen ovale, which should be taken into account when performing the procedure. In addition, the presence of even mild to moderate pericardial effusion should be described in the echocardiography report in order to serve as a comparator if hemopericardium is suspected during the procedure.

The goal of the guidance of TS puncture is to puncture the fossa ovalis which is composed mainly of thin and fibrous tissue and is the easiest and safest part of the septum for a standard puncture. In valve disease, the position of the fossa ovalis can be altered because, when the LA is enlarged, the fossa ovalis tends to be displaced inferiorly.

Both transesophageal echocardiography (TEE) and intracardiac echocardiography (ICE) provide excellent imaging of the interatrial septum, which is useful to guide the orientation of the catheter and needle in the fossa ovale, to show proper positioning and tenting of the septum, and monitor the crossing of the septum. Drawbacks of echocardiographic guidance are the need for anesthesia, or at least analgesia, in most patients when TEE is performed; the cost of the devices and the need for a second femoral access are the drawbacks for ICE. The recent introduction of real time 3D TEE further improves imaging of the septum [11,12].

During electrophysiologic interventions or percutaneous mitral balloon commissurotomy, in experienced teams, echocardiographic guidance, using either TEE or ICE, is restricted to patients in whom there are anticipated difficulties, such as severe thoracic deformity, or when unexpected difficulties occur. ICE is widely used in the USA as demonstrated by the fact that approximately 50% of the experts involved in the 2007 consensus statement on atrial fibrillation ablation routinely used ICE to facilitate the transseptal procedure or to guide catheter ablation [18]. TEE guidance is mandatory for the technical steps needed after transseptal catheterization in most structural interventions and is therefore systematically used in such procedures. It is also a useful adjunct in the early part of the operator's experience. Effective echocardiographic guidance requires specialized training for the echocardiographer, without which may result in a false impression of security. Finally, successful echocardiographic guidance requires good understanding and collaboration between the interventionist and the echocardiographer, as well as the use of similar definitions, to optimize the performance of the procedure.

Transthoracic echocardiographic (TTE) guidance is seldom used because it is difficult to perform at the same time as fluoroscopic imaging. However, it could be helpful in experienced hands.

Finally, isolated case reports have described the feasibility of transseptal puncture on echocardiographic guidance alone, without fluoroscopy, in emergency cases [13]. However, this approach cannot be recommended at the present time.

Equipment

The Brockenbrough needle is the most commonly used transseptal needle, which is 70 cm long, has a curved tip, and tapers distally. A hub arrow on the proximal part indicates the direction of the needle. The stylet inside the needle should be removed before use [14].

The most commonly used catheters comprise a dilator and a sheath, and are 8 Fr [15]. This allows the introduction of another catheter, such as a floating balloon, in the left atrium (LA) after penetration and withdrawal of the dilator (Figure 62.1). A variety of dilator shapes are available in order to adapt to the requirements of the procedure. The most commonly used are the Mullins sheath or the St. Jude SL 0 or SL 1 sheaths. The conventional Mullins sheath is advised when aiming to cross the mitral valve using another catheter. The St. Jude type devices are advisable when catheterization of the superior pulmonary vein is planned for mitral clip or left atrial appendage closure, for example (Figure 62.2).

Box 62.1 Indications for transseptal puncture during interventional procedures

Structural interventions:

- Percutaneous mitral balloon commissurotomy
- Percutaneous edge-to-edge mitral repair
- Antegrade aortic balloon valvuloplasty
- Transcatheter aortic valve implantation
- Patent foramen ovale closure
- Percutaneous occlusion of the left atrial appendage

Electrophysiologic studies and catheter ablation:

- Left-sided accessory pathways
- Pulmonary vein ablation for paroxysmal atrial fibrillation
- Left atrial tachycardia
- Atypical left atrial flutters
- Left ventricular tachycardia

Circulatory support:

- Percutaneous left ventricular assist device

Before performing transseptal catheterization, it is necessary to carefully check: (i) that the proximal arrow is aligned with the needle tip, and (ii) to measure the distance (in fingers) between the proximal part of the catheter and the proximal arrow when the tip of the needle is advanced to lie just inside the dilator to avoid inadvertent puncture during manipulation (Figure 62.3).

Procedure

Before starting the procedure, the patient must be lying flat for better anatomic landmarks. This could be difficult in emergency cases such as pulmonary edema, which requires a semi-supine position. In such cases, the procedure should only be performed by an experienced operator.

A 5 Fr pigtail should be positioned retrogradely from the femoral artery to the right aortic coronary sinus for identification of the aorta and systemic pressure monitoring. However, left heart catheterization can be omitted by experienced operators, but is useful otherwise when only fluoroscopic guidance is used.

Percutaneous venous access is via a puncture of the right femoral vein as this offers a direct approach from the inferior vena cava

Figure 62.2 Different shapes of dilator and sheaths used for transseptal catheterization. 1. This curved shape enables catheterization of the left ventricle afterward through the mitral valve. 2. The straighter shape facilitates the catheterization of the upper pulmonary vein, which is useful during MitraClip or left atrial occlusion procedures.

Figure 62.3 Measurements of the landmarks between needle and catheter. Measurement of the distance between the proximal of the needle arrow and the proximal part of the catheter (a) necessary to position the needle just inside the catheter (b).

Figure 62.4 Procedure I: Positioning in antero-posterior view. (a) Pigtail catheter placed on the aortic cusps. The dilator is advanced into the superior vena cava. (b) The guidewire is removed. (c) The needle is advanced through the dilator. Courtesy of Professor A. Cribier.

to the interatrial septum at the fossa ovalis. If right access is not possible, left femoral access can be attempted but this renders the procedure more difficult, and can be painful for the patient and lead to a vagal reaction. In very rare cases, transseptal catheterization has been performed using a transjugular or transhepatic approach [16].

A 0.032–0.035-inch J-tipped guidewire is advanced into the superior vena cava, up to the origin of the left innominate vein, in anteroposterior view. It is important to avoid forcing the guidewire into the right atrial appendage, as this is a fragile structure. The catheter is advanced over the guidewire into the superior vena cava and the guidewire is removed (Figure 62.4).

The Brockenbrough needle is connected to a pressure line, which is continuously flushed, and inserted into the dilator just inside the

distal end under fluoroscopic guidance and using the predetermined measurement. The needle is allowed to rotate freely while being advanced. If resistance is felt, the proximal hub arrow should be gently rotated until the needle can be advanced without resistance. In the very rare cases where difficulties persist, it could be helpful to push the needle over a 0.0014 angioplasty guidewire. This latter modification seems more useful than the stylet provided with the needle.

When the needle reaches the desired position inside the catheter the flush is stopped and pressure is continuously monitored. From then on, it is necessary to hold the needle and the catheter firmly and to move them as a unit. Initially, the tip of the catheter is orientated toward the right shoulder of the patient in anteroposterior view. Then, under continuous fluoroscopic and pressure monitoring, both the catheter and needle are withdrawn downward and rotated counterclockwise until contact with the septum is felt.

Other techniques initially orientate the catheter toward the left shoulder (innominate vein) and perform a clockwise rotation. In such cases, when the system is withdrawn three sequential bumps can be felt representing (i) the right atrium–superior vena cava junction; (ii) movement over the ascending aorta of which pulsations can be felt; and (iii) the passage over the limbus to enter the fossa ovalis. Whatever method is used, the proximal arrow and the tip of the needle have a posteromedial position of 4–6 o'clock, looking from bottom to top in anteroposterior view (Figure 62.5). The angle is chosen according to the size of the LA (4 o'clock in normal size; up to 6 o'clock in a large atrium).

The selection of an adequate puncture site varies according to the imaging modality used for its guidance. If the procedure is fluoroscopy guided, in anteroposterior view, the correct position of the tip of the needle is usually mid-way between the pigtail and the right atrial border in the horizontal axis and slightly below the horizontal line at the level of the pigtail. It is recommended that a complementary view is used to provide further information on the orientation of the needle in the anteroposterior axis before puncturing the septum (Figures 62.6 and 62.7). This could be a lateral view with a target zone at the mid-part of the line between the pigtail and the spina, or right anterior oblique 30° with a target zone vertically in the middle of the line between the pigtail and the spina and below a horizontal line at the level of the pigtail. With both methods, the puncture site is posterior and inferior to the aortic plane.

(a)

(b)

Figure 62.5 Procedure II: Positioning of the needle. (a) The catheter and the needle are moved as a unit, keeping in mind the predetermined distance necessary to avoid protrusion of the needle out of the catheter. (b) The needle is rotated so that the arrow is oriented to 5 o'clock (red arrow).

If the TS is guided by echocardiography (Figure 62.8), three two-dimensional TEE planes are sequentially used to define the preferred puncture site precisely [11]:

- 1 Short axis view at the base (30–50°) which allows for anterior–posterior orientation;
- 2 Long axis view (bicaval) at 90–120° which allows for superior–inferior orientation;
- 3 Four-chamber view (0°) is used to determine the correct height above the mitral valve which is mandatory when performing the MitraClip and other mitral procedures.

The position of the TS needle can be identified by a tent-like doming of the interatrial septum toward the LA (tenting; Figure 62.9). Successful crossing of the septum is confirmed by the abrupt loss of tenting. Three-dimensional X-plane imaging facilitates the TS puncture by presenting a short and a long axis view simultaneously, thus providing anteroposterior and superior–inferior orientation in a single view.

Figure 62.6 Procedure III: Reaching the fossa ovale. The catheter and needle are moved downward to the fossa ovale. Courtesy of Dr. S. Shaw.

When using ICE imaging, tenting of the interatrial septum should be identified in the long axis view and clear visualization of the point of maximal tenting should be obtained before puncturing. Relationship with the aortic root can be obtained by counterclockwise rotation of the ICE catheter. Confirmation of the location of the ICE catheter in the LA can be obtained by injection of non-agitated saline or contrast during ICE imaging or the presence of a left-to-right shunt with color Doppler. In addition to visual guidance, it is important to feel a sensation of more or less elastic resistance through the catheter, which happens in most cases.

If the previous stage is successfully performed, the catheter may pass into the LA without puncture by the needle which is shown by the LA pressure recording. This can occur in cases with patent foramen ovale but also in its absence [17]. If this is the case, the catheter and the needle are gently pushed without resistance and the needle is withdrawn.

However, in most cases it is necessary to puncture the septum. The needle is gently advanced. Entry into the LA is indicated by changes in pressure tracing. If no changes are perceived this can be a result of:

- 1 Problems with pressure recording, or problems with the permeability of the needle. In the latter case, as opposed to forceful flushing, it is recommended to gently aspirate blood, which will be red if the needle is in the LA.
- 2 If the position seems adequate, but there is still resistance to penetration, it may be because of a thick or fibrous septum, especially in children or in patients with previous cardiac surgery, or a “receding septum” feeling, which can be because of an aneurysm of the septum requiring the application of additional pressure.
- 3 Incorrect positioning which requires re-puncture at another site. In such cases, the catheter and needle should not be re-advanced upward, and the maneuver should be restarted.

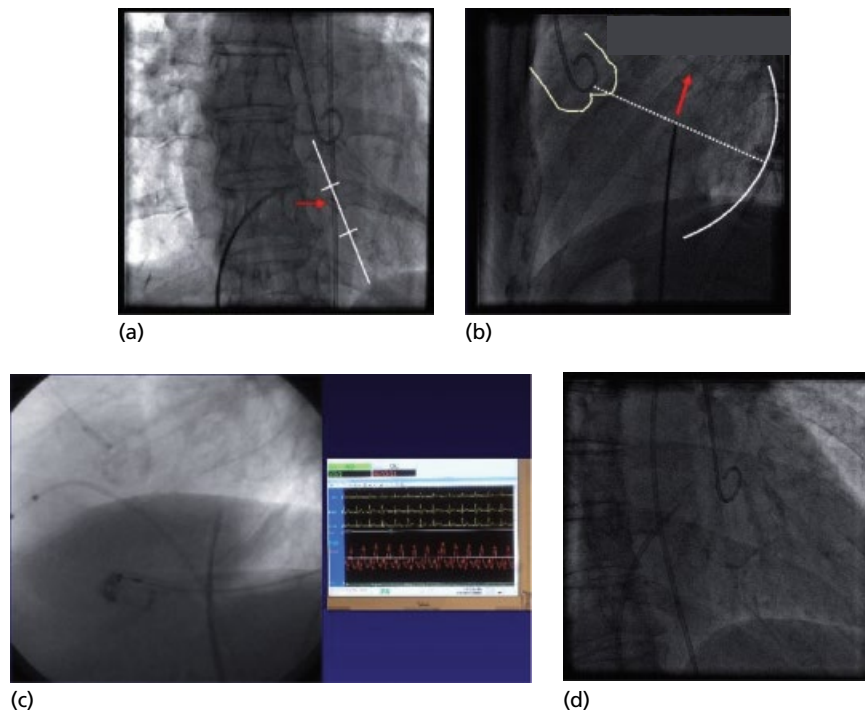

Figure 62.7 Procedure IV: Transseptal puncture. (a) Antero-posterior view. The catheter and needle are at the level of the fossa ovalis, below and lateral to the pigtail. (b) Lateral view. The catheter and needle are below and posterior to the pigtail catheter. (c) The needle is advanced and left atrial pressure is obtained. Courtesy of Professor A. Cribier. (d) The position of the puncture in right anterior oblique 30° is also inferior and posterior to the aortic cusps.

Figure 62.8 Guidance of transseptal puncture by echocardiography. Transesophageal echocardiographic views. 1: Bicaval view shows the position: superior directed toward the superior vena cava versus inferior toward the inferior vena cava. 2: Short axis view: anterior directed toward the aorta versus posterior. 3: Four-chamber view: low, close to the atrioventricular plane versus high at a distance.

The entire system is withdrawn into the inferior vena cava, the needle is withdrawn, and the J-tipped guidewire is advanced through the catheter and repositioned in the superior vena cava. The catheter should be advanced into the LA only when assurance is obtained that the needle has crossed the septum.

Before advancing the catheter it is recommended to return to the anteroposterior view, which provides a better view of the borders of the LA, to avoid damage to the neighboring structures (i.e., LA wall, left atrial appendage, or pulmonary veins when using fluoroscopic guidance only).

Before moving forward it is necessary to be sure that the X-ray table is fixed and will not move during the following maneuvers. It is now even more important to move the needle and the catheter as a unit because the needle is protruding into the LA. Continuous pressure is applied with the right hand at the proximal part of the needle while the left hand holds the catheter at the groin and provides counter-resistance if necessary.

When both the needle and the catheter have crossed the septum, the needle is withdrawn. The LA pressure is then recorded. It is necessary to ensure that both the needle and the catheter have crossed the septum before removing the needle because too early removal of the needle can lead to backward movement of the catheter into the RA. When using a dilator and a sheath after crossing of the septum, the needle is withdrawn into the dilator. The dilator and the sheath are then advanced into the LA. The needle and the dilator are removed and the sheath is carefully flushed before connection to the pressure line.

Heparin, usually with a target activated clotting time (ACT) of 250–300 s, is given when the catheter is securely positioned in the LA.

Specificities in transseptal puncture

Anatomic variations

Large right or left atrium

In patients with enlarged atrial cavities the ideal puncture site is slightly below this line but not too posteriorly. It should be stressed

(a)

(b)

Figure 62.9 Transesophageal echocardiography showing the tenting of the interatrial septum during the septal puncture. (a) 2D echo; (b) 3D echo.

that a too posterior puncture, outside the borders of the fossa ovale, should be avoided in order to avoid a perforation into the pericardial space between the two atria. In such cases, the convexity of the septum as a result of LA enlargement can cause catheter slippage and, thus, can impede adequate contact with the septum. In addition, in patients with severely enlarged RA it is useful to slightly bend the needle at 10 cm from the tip to facilitate contact with the septum.

Resistant septum

This can occur in re-do interventions [18], either after cardiac surgery or multiple electrophysiologic interventions or in older patients, after thoracic radiation. If resistance to crossing the septum with the needle occurs, pressure must be continuously applied until crossing has been achieved. If crossing is still not possible, it may be useful to introduce an inverted exchange angioplasty 0.014 guidewire into the needle [19]. A more sophisticated variant is the SafeSept® wire (Pressure Products, San Pedro, CA, USA) where a 0.014 coronary guidewire is advanced through the TS needle lumen

and as soon as the wire enters the LA it takes a J shape to avoid damaging the LA wall [20]. Recent alternatives have been developed using radiofrequency, which does not require mechanical force [21,22]; this can be carried out using dedicated catheters such as the Baylis (Baylis Medical, Montreal, Canada). However, radiofrequency can also be used by a standard electrocautery generator via the TS needle, brief pulses being applied to the hub of the TS needle by direct contact [23].

If the needle can cross but not the catheter, it may be useful to introduce an exchange angioplasty 0.018 guidewire into the needle (Steelcore, Abbott Vascular) up to the superior pulmonary vein and use it as support for both the needle and the catheter. If this maneuver fails, an exchange angioplasty 0.014 guidewire can be introduced into the needle, to withdraw both the needle and the catheter and insert an angioplasty balloon (2 mm) to dilate the septum before re-advancing the transseptal catheter over this guidewire [24]. This latter technique is difficult and not always successful. Finally, it can be necessary to re-do the puncture at another site, as the first attempt was likely not at the fossa but at a thicker part of the septum.

Subsequent interventional procedure

Percutaneous mitral commissurotomy

When performing the Inoue technique the preferred site for the transseptal puncture is usually in the lower part of the fossa ovale if the LA is severely enlarged. However, if crossing the mitral valve is not possible using this puncture location, it can be necessary to re-do the transseptal puncture in a slightly higher position and more posteriorly [5].

Percutaneous mitral valve repair or replacement

The most common mitral valve repair technique used today is the edge-to-edge technique using the MitraClip. The transseptal puncture is performed under echocardiographic guidance, which is subsequently necessary for the performance of the procedure [25]. The determination of the optimal puncture site is of major importance for a MitraClip procedure.

The puncture must be performed in the superior–posterior part of the fossa ovalis and at an adequate distance from the mitral valve (Figure 62.10). The optimal height above the mitral valve differs for primary and secondary mitral regurgitation (MR). In cases with primary MR the puncture site should be 4–5 cm above the mitral annulus, thus providing enough space to maneuver the delivery system adequately within the LA. In patients with secondary MR, important valve tethering results most often in a shift in position of the line of coaptation to below the mitral annulus. Subsequently, TS puncture needs to be lower, approximately 3.5 cm above the annular plane or 4–4.5 cm above the coaptation of both leaflets in order to be able to advance the catheter more deeply into the LA.

An inadequate puncture site will lead to the following complications: aortic hugging if the puncture is too anterior, for example through a patent foramen ovale; inability to cross the mitral valve in a too high puncture; inability to pull back the clip and tether the leaflets after a too low puncture; and, finally, risk of perforation if the puncture is too posterior.

The stability of the position of the needle should be carefully checked before pushing the sheath over the needle. For this purpose the use of radiofrequency energy could be a useful adjunct by avoiding the potential slippage of the needle while applying force to cross the septum.

Figure 62.10 Optimal location of the transseptal puncture site in selected structural interventions: Mitraclip, left atrial occlusion using the Watchman or Amplatzer devices. Ant, anterior; Ao, aorta; AV, aortic valve; IVC, inferior vena cava; PV, pulmonary veins; 4 ch, four-chamber view; SAX, short axis view.

There are no precise recommendations concerning the transseptal technique for other mitral interventions such as “valve-in-a-valve” or “valve-in-a-ring” or direct annuloplasty because the number of cases performed is still limited [8,26]. As a general rule, the TS puncture for these procedures shares most of the characteristics of that used for the MitraClip technique (i.e., a superior and posterior puncture in order to allow for sufficient maneuverability in the LA and crossing of the mitral valve).

Left atrial appendage closure

Transseptal puncture is also the first step of the percutaneous left atrial closure techniques. Here again the location of the transseptal puncture is important and somewhat dependent on the particular characteristics of the device to be implanted in order to facilitate coaxial alignment and reduce the risk of complications such as tamponade or embolization. When using the Watchman device, the ideal location is in the middle portion of the posterior fossa which allows a coaxial engagement of the appendage. The TS puncture is ideally slightly more anterior and inferior with the Amplatzer device (Figure 62.10).

Patent foramen ovale closure

The presence of a long funnel-shaped patent foramen ovale is challenging for the placement of most closure devices. A TS puncture of the most cephalad aspect of the septum primum at the level of the fossa ovalis allows placement of the device which can then “sandwich” both the septum primum and secundum and effectively close the tunnel [27].

Electrophysiology

Interventional electrophysiologists have used TS since the 1980s as an alternative or complementary approach to the retro-aortic route to ablate left-sided accessory pathways. However, the spread of the technique in the electrophysiology laboratory has followed the development of left atrial ablation to treat atrial fibrillation.

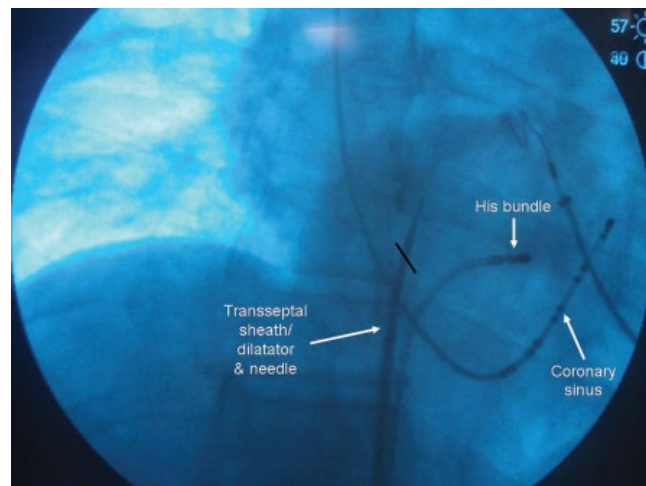

Figure 62.11 Transseptal catheterization in electrophysiologic interventions: electrophysiology and ablation catheters as landmarks. Catheter position during the transseptal puncture. RAO 30° view. The black line indicates the position of the fossa ovalis.

The techniques of TS have similarities whether used in the electrophysiology laboratory or in the hemodynamic or structural intervention laboratory but some specific features deserve to be emphasized [3,4,18,22,28–31]. Specific features of TS in the electrophysiology laboratory include the following.

- 1 Electrophysiology and ablation catheters as landmarks** The position of the His bundle indicates the level of the most inferior aspect of the non-coronary cusp. The catheter placed in the coronary sinus provides information on coronary sinus ostium location as well as on the position of the lower portion of the mitral annulus. On a 30° right anterior oblique view, the fossa ovalis is located midway between the His bundle and the right atrial posterior wall on the anterior–posterior axis and below or at the level of the His bundle on the superior–inferior axis (Figure 62.11).
- 2 The double transseptal technique** In most cases, more than one catheter is used for left atrial ablation. This is done using either a double TS puncture or a single puncture. In the former, a guidewire is placed in the left superior pulmonary vein through the first sheath and dilator which are then pulled back into the right atria. Next, the ablation catheter (through a second sheath) is positioned (under fluoroscopy and/or TEE or ICE) in the fossa ovalis and pushed into the left atria following the guidewire direction. Finally, the first sheath and dilator are pushed over the wire into the LA (Figure 62.12). An alternative method for the double transseptal technique with a single puncture has also been described [32].
- 3 Resistant septum in cases of re-do procedure and thrombotic issues** have been addressed earlier.

Circulatory support

Transseptal catheterization can also be used during percutaneous left ventricular assist device implantation.

The Tandem Heart (Cardiac Assist Technologies Inc., Pittsburg, PA, USA) is a transseptal left atrial to femoral arterial assist device that provides left heart bypass designed for short-term circulatory support. The inflow transseptal cannula is a 21 Fr polyurethane catheter with a large end hole and 14 side holes to facilitate left atrial decompression [33].

Figure 62.12 Transseptal catheterization in electrophysiologic interventions: the double transseptal technique. (a) Guidewire in the left superior pulmonary vein and ablation catheter on the right side of the transseptal puncture. (b) Guidewire in the left superior pulmonary and ablation catheter in the right superior pulmonary vein. (c) Ablation catheter in the right superior pulmonary vein and lasso catheter at the ostium of the left superior pulmonary vein.

Table 62.1 Complications of transseptal catheterization.

* Catheter ablation of atrial fibrillation.

[†] Related to transseptal puncture.

Transseptal catheterization can also be used to unload the LA in patients with persisting pulmonary edema after implantation of a femoro-femoral Extra-Corporeal Membrane Oxygenator.

Complications

Although generally safe, transseptal catheterization is associated with an incidence of complications, albeit low, if performed carefully following the rules described earlier (Table 62.1) [2,3,30,31,34–37]. The failure rate is usually 1–2% and fatality is the exception.

Heart perforation related to transseptal puncture concerns the free wall of the RA, LA, left atrial appendage, or a puncture going from the RA to the LA via the pericardium, or the aorta. It mostly occurs when the operator is less experienced. Unfavorable patient characteristics such as severe atrial enlargement or thoracic deformity also increase risk. Perforation of the heart can result in mild pericardial effusion without clinical consequences, but hemopericardium usually has immediate clinical consequences resulting in tamponade. Its incidence is around 1% but can be as high as 4% in centers with limited experience. It should always be suspected as a potential cause when hypotension occurs during transseptal catheterization. The potential consequences of this complication necessitate the immediate availability of echocardiography whenever transseptal catheterization is performed.

Puncture of the aorta by the needle only is usually without consequences when it is recognized immediately by pressure monitoring. It

requires close monitoring and avoidance of heparin administration. On the other hand, advancement of the catheter in such cases can lead to massive hemopericardium. If hemopericardium is suspected, echocardiography should be performed urgently before deterioration occurs. Hemopericardium requires immediate pericardiocentesis, ideally performed under echocardiographic guidance after reversal of anticoagulation if already given. In most cases, hemopericardium from transseptal catheterization can be managed by pericardiocentesis, especially when it results from a puncture by the transseptal needle only. If this is successful, the planned procedure can then be continued but the patient should be closely monitored.

Embolism can be caused by a pre-existing thrombus, usually in the left atrial appendage, or one developed during the procedure. The TS puncture in itself is seldom responsible for this complication which is mostly related to the lengthy procedures performed afterwards [38]. Cerebral embolism usually results in stroke. Less frequently, coronary embolism leads to transient ST segment elevation. The treatment of cerebral embolism should be in collaboration with a stroke center. Cerebral imaging should be performed on an emergency basis to rule out hemorrhage, then intra-arterial fibrinolytic therapy should be administered early in the absence of contraindications.

In the case of persistent ST segment elevation, coronary angiography should be performed. ST segment elevation in the inferior leads accompanied by diaphoresis, hypotension, and chest discomfort with normal coronary angiogram has been occasionally

observed after transseptal catheterization as is also the case after other intracardiac manipulations. They can be neutrally mediated as a Bezold–Jarish-like reflex and are responsive to atropine [37]. In the very rare cases where a coronary occlusion is present, coronary angioplasty can be performed, while thrombo-aspiration could be an appealing alternative. Inferior vena cava perforation and retroperitoneal hematoma could be the consequences of pushing the needle extruded from the catheter during its positioning in the vena cava.

Atrial tachyarrhythmias are possible but are rare and usually transient. Persistent interatrial shunts are not observed after the performance of transseptal catheterization in isolation.

Contraindications

To avoid these complications, any of the following contraindications must be eliminated. The performance of TEE is recommended in the days just preceding transseptal catheterization to disclose left atrial thrombosis as the technique is contraindicated in patients with a thrombus floating in the LA cavity or on the atrial septum. No consensus has been reached regarding patients with thrombosis in the LA appendage. In such cases, TS can only be indicated in patients who are candidates for urgent intervention but not surgery, or if intervention is not required urgently and when oral anticoagulation can be given for at least 2 months, and new TEE shows the thrombus has disappeared. LA myxoma also constitutes a contraindication.

TS should not be performed in patients with bleeding disorders, especially caused by too high anticoagulation (INR >1.5), in particular in patients who have not undergone previous cardiac operation. When intravenous heparin is used, it should be discontinued 4 hours before and can be restarted 2 hours after the procedure. This rule has been recently challenged in two circumstances where the risk of thrombosis resulting from the withdrawal of anticoagulation in lengthy procedures was felt to be superior to that of bleeding: (i) in MitraClip implantation when it is performed by experienced operators under TEE it is possible to perform TS with an INR >2 [39]; (ii) the same opinion is shared by electrophysiologists planning TS before atrial fibrillation (AF) ablation because of the long duration of the procedure, the presence of AF, and the thrombotic effect of radiofrequency lesion, clotting in the left atria and/or on the TS sheath and ensuing stroke are always feared. Hence, most echocardiography centers now perform TS and catheter ablation of AF without warfarin discontinuation and with heparin on top of vitamin K antagonists, which reduces the occurrence of peri-procedural stroke and minor bleeding complications. During AF ablation procedures, heparin is administered prior to or immediately following TS and adjusted to achieve an ACT of 300–400 s throughout the procedure [28,38].

Thoracic deformity, such as cyphoscoliosis, is a contraindication if severe. In practice, the level of acceptable deformity depends on operator experience and the availability of echocardiographic guidance.

Complex congenital diseases are also considered contraindicated because of the altered anatomic landmarks.

Transseptal catheterization can be performed in dextrocardia by experienced operators using left femoral access, inversion of the X-ray image, and echocardiographic guidance [40].

Obstruction of the vena cava is a classic contraindication for femoral access but membranous obstruction of the vena cava can be dilated. The presence of a filter in the vena cava is not an absolute contraindication if it is permeable.

Another contraindication is agenesis of the vena cava associated with azygos return. This latter condition should be diagnosed by X-ray before the procedure or, if during the procedure the catheter has an unusually posterior position behind the heart, confirmed by venous angiography in the RA [41]. In such circumstances TS can be performed using a transjugular approach if absolutely necessary.

Presence of an interatrial patch [24], or even atrial septal occluder [42], is not an absolute contraindication but may render the crossing of the interatrial septum difficult.

Conclusions

Transseptal catheterization has had a revival since it is the first step for several structural interventions as well as in interventional electrophysiology. Imaging guidance by echocardiography has considerably eased the performance of the procedure. However, it remains a demanding procedure and requires specific expertise. A stepwise and cautious technique is the key to limiting complications. It is hoped that further refinements in the technique will result from the evaluation of new technologies and better guidance by multi-imaging modalities.

Principles of Carpentier's Reconstructive Surgery in Degenerative Mitral Valve Disease

Farzan Filsoufi¹ and Alain Carpentier²

¹Icahn School of Medicine at Mount Sinai, New York, NY, USA

²Hôpital Européen, Georges-Pompidou, Paris, France

Degenerative mitral valve disease has become the predominant cause of mitral regurgitation (MR) in developed countries during the last four decades mainly because of the eradication of rheumatic fever and the aging population. Several confusing terminologies (myxomatous valve disease, mitral valve prolapse, floppy valve, flail leaflet, and so on) have been used in the literature to describe degenerative mitral valve disease. The understanding of valve pathology is facilitated by the use of the “pathophysiologic triad” [1].

Pathophysiology and functional classification

The pathophysiologic triad is composed of etiology (cause of the disease), valve lesions (resulting from the disease), and valve dysfunction (resulting from the lesion) [1]. These distinctions are relevant because long-term prognosis depends on etiology, whereas treatment strategy and surgical techniques depend on valve dysfunctions and lesions, respectively (Table 63.1).

Carpentier's functional classification is used to describe the mechanism of MR (Figure 63.1) [1]. This classification is based on the opening and closing motions of the mitral leaflets. Patients with type I dysfunction have normal leaflet motion. MR in these patients is caused by annular dilatation or leaflet perforation.

There is increased leaflet motion in patients with type II dysfunction with the free edge of the leaflet overriding the plane of the annulus during systole (leaflet prolapse). The most common lesions responsible for type II dysfunction are chordae elongation or rupture, and papillary muscle elongation or rupture. Patients with degenerative mitral valve regurgitation often present with type II dysfunction.

Patients with type IIIa dysfunction have a restricted leaflet motion during both diastole and systole. The most common lesions are leaflet thickening and/or retraction, chordae thickening and/or shortening or fusion, and commissural fusion. MR is most often associated with some degrees of mitral stenosis. The most common corresponding etiologies are rheumatic valve disease, mitral calcification, and carcinoid valve disease.

The mechanism of MR in type IIIb dysfunction is restricted leaflet motion during systole. Left ventricular enlargement with

apical papillary muscle displacement causes this type of valve dysfunction. The two most frequent etiologies are ischemic and dilated cardiomyopathy.

The functional classification is further refined by the introduction of segmental analysis which allows the precise localization of leaflet dysfunction, which is of critical importance while performing reconstructive surgery [2].

The mitral valve is separated into eight segments (Figure 63.2). Anterolateral and posteromedial commissures are two segments. Two indentations on the posterior leaflet divide this structure into three anatomically individualized scallops. The three scallops of the posterior leaflet are identified as P1 (anterior scallop), P2 (middle scallop), and P3 (posterior scallop). The three corresponding segments of the anterior leaflet are A1 (anterior segment), A2 (middle segment), and A3 (posterior segment).

Application of pathophysiologic triad in patients with degenerative mitral valve disease

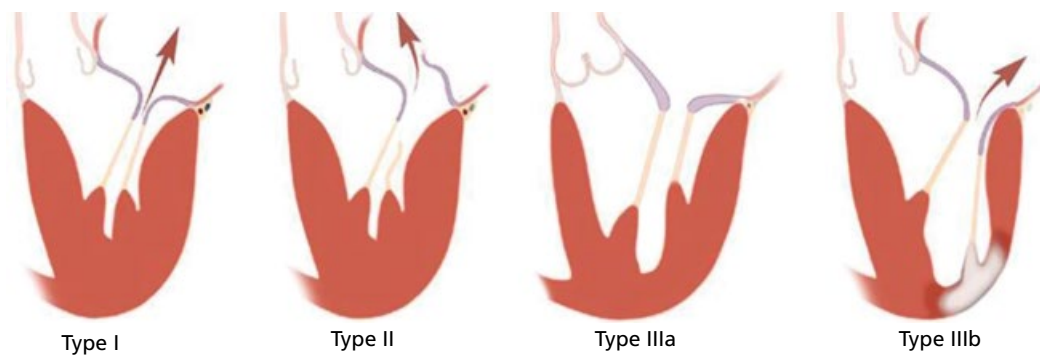

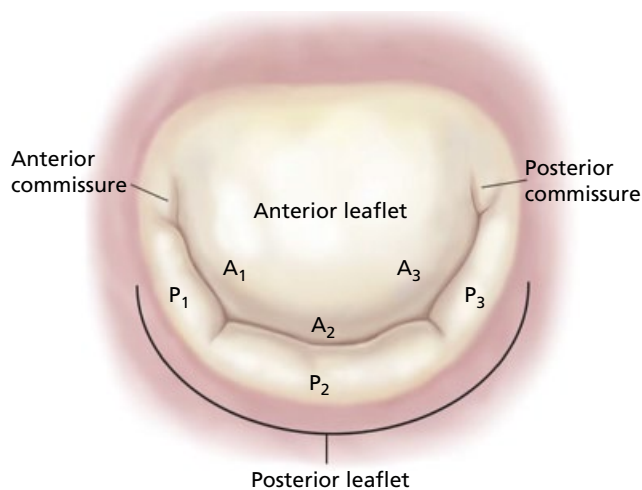

Etiologies of degenerative mitral disease include Barlow's disease and fibroelastic deficiency. Marfan's disease, the third etiology, is encountered in a minority of patients. In about 10–20% of patients, although the valve displays some pathologic features compatible with either Barlow's disease or fibroelastic deficiency, it is difficult to determine the exact etiology, leading our group to suggest the concept of “spectrum of degenerative mitral valve disease.” The mechanism of MR is often leaflet prolapse (type II dysfunction) resulting from chordae rupture or elongation. Barlow's disease is the most common condition affecting up to 5% of the population whereas fibroelastic deficiency is observed with increasing frequency as the age of the population increases.

Barlow's disease

Barlow's disease appears early in life, and patients typically have a long history of a systolic murmur [3,4]. Most patients who require surgery for MR are referred for surgery in their fourth or fifth decades of life. The valve is billowing with typically thick leaflets and with marked excess tissue (Figure 63.3a). The chordae are thickened, elongated, and may be ruptured. Papillary muscles are also

Table 63.1 Pathophysiologic triad.

Dysfunction	Lesions	Etiology
Type I Normal leaflet motion	Annular dilatation Leaflet perforation/tear	Dilated cardiomyopathy Endocarditis
Type II Excess leaflet motion (leaflet prolapse)	Elongation/rupture chordae Elongation/rupture of papillary muscle	Degenerative valve disease Fibroelastic deficiency Barlow's disease Marfan disease Endocarditis Trauma Ischemic cardiomyopathy
Type IIIa Restricted leaflet motion (Diastole and Systole)	Leaflet thickening/retraction Leaflet calcification Chordal thickening/retraction/fusion Commissural fusion	Rheumatic heart disease Carcinoid heart disease
Type IIIb Restricted leaflet motion (Systole)	Left ventricular dilatation/aneurysm Papillary muscle displacement Chordae tethering	Ischemic/Dilated cardiomyopathy

occasionally elongated. The annulus is dilated and sometimes calcified. Most patients with Barlow's valve present with the prolapse of multiple segments of the valve. Bileaflet prolapse is present in about 30% of patients. Histologically, there is extensive myxoid degeneration with destruction of the normal three-layer leaflet tissue architecture.

Fibroelastic deficiency

Fibroelastic deficiency is most common in elderly patients (>65 years) with a relatively short history of MR [4]. Valve analysis typically shows transparent leaflets with no excess tissue except in the prolapsing segment, and elongated, thin, frail, and often ruptured chordae (Figure 63.3b). The annulus is often dilated, and may be calcified. Most these patients present with isolated P2 prolapse. An important feature of fibroelastic deficiency is the development of secondary lesions at the level of prolapsing segment with myxoid degeneration, excess tissue, and leaflet thickening which may entertain the confusion with the diagnosis of Barlow's disease on echocardiography or histologic analysis.

(a)

(b)

Figure 63.3 (a) Barlow's disease. (b) Fibroelastic deficiency.

Marfan's disease

Marfan's disease with MR is characterized by excess leaflet tissue, which can be thickened (without myxoid degeneration), and a dilated annulus that is rarely calcified [5].

Surgical indications

In patients with degenerative mitral disease, the very low operative mortality (less than 0.5%) and morbidity combined with the excellent long-term results of mitral valve reconstruction have considerably modified the indications of surgery during the last decade.

Several variables such as clinical symptoms, atrial fibrillation, severity of MR, left ventricular ejection fraction, left ventricular end-systolic diameter, pulmonary hypertension, and the overall surgical risk profile (age, comorbid factors) should be taken into consideration for decision-making with regard to the indications of surgery.

All symptomatic patients with moderate to severe MR should be referred for surgical intervention. It is preferable to operate on patients early in their symptomatic course, as long-term survival following mitral valve reconstruction is less favorable in patients with New York Heart Association Class III or IV symptoms or left ventricular ejection fraction <60%. It is important to stress that

in patients with degenerative mitral disease with New York Heart Association Class I or II and ejection fraction >60%, the life expectancy following mitral valve reconstruction is similar to that of an age- and gender-matched general population. As Carpentier stated, "following valvular reconstruction most patients with degenerative valve disease are cured for the rest of their lives."

Patients with mild to moderate degrees of MR in the presence of symptoms will often be found to have increased MR or inadequate increase in ejection fraction on stress echocardiography and should also be considered for surgical treatment.

Asymptomatic patients with left ventricular dilatation (left ventricular end-systolic diameter >45 mm), decreased ejection fraction (<60%), atrial fibrillation or pulmonary hypertension (pulmonary artery systolic pressure >50 mmHg at rest or >60 mmHg with exercise) should also be referred for elective mitral valve surgery. When following patients with asymptomatic moderate to severe MR, one should pay particular attention to serial ejection fraction, as a drop to <60% confers poorer long-term survival even with successful mitral valve reconstruction.

The decision to refer or accept an asymptomatic patient for mitral valve surgery should also take into consideration one important factor, which is the likelihood of valve reconstruction

which depends mainly on: (i) the etiology of MR (Barlow's disease vs. fibroelastic deficiency); and (ii) surgeon's skill and experience in valve reconstruction. For example, patients with Barlow's disease and bileaflet prolapse, which often require a complex operative procedure, should be referred to centers where reconstructive surgery can be performed with a great certainty.

Principles of mitral valve surgery

Perioperative management

Standard techniques of monitoring (e.g., arterial line, central venous access, Foley catheter) are used in patients undergoing mitral valve reconstructive surgery. A Swan-Ganz catheter should be placed in cases of complex mitral valve reconstructive surgery, multivalve surgery, combined mitral and coronary artery bypass grafting (CABG) surgery, and in patients with increased operative risk (e.g., left ventricular dysfunction, pulmonary hypertension, reoperation). Initially, a transesophageal echocardiography (TEE) should be performed in all patients. TEE is important to determine the mechanism and severity of MR, to assess left ventricular function, quality of reconstruction, and de-airing of the cardiac cavities at the completion of the procedure. An external defibrillator is placed in reoperation and minimally invasive approaches. A double lumen endotracheal tube is necessary in right thoracotomy incisions [6]. An epiaortic scanning of the ascending aorta is recommended in elderly patients with associated atherosclerotic risk factors, and those undergoing a combined mitral valve and CABG surgery prior to arterial cannulation.

Surgical incisions and cardiopulmonary bypass

A small skin incision and a midline sternotomy remain the most commonly performed surgical approach in mitral valve reconstructive surgery. It provides an excellent access to all cardiac structures allowing for central cannulation using the ascending aorta and the superior and inferior vena cava.

Mini-invasive, direct vision mitral surgery is performed through the partial upper or lower hemisternotomy. A 6 cm skin incision is performed in both cases. The sternum is partially divided from the sternal notch to the left fourth intercostal space (upper hemisternotomy) and from the xyphoid to the second right intercostal space (lower hemisternotomy) [7]. Central arterial and venous cannulations are often possible with these approaches. Video-directed [8] and robotic mitral valve surgeries are performed through a right mini-thoracotomy at the fourth intercostal space.

Multiport access is obtained by additional keyhole incisions. Peripheral vessels are used to initiate cardiopulmonary bypass. Additional adjunctive techniques such as port access instrumentation, CO₂ insufflation, and vacuum-assisted venous drainage are frequently used to facilitate these surgical procedures.

Myocardial protection is achieved with intermittent antegrade or a combined antegrade and retrograde administration of high potassium cold blood cardioplegia. Further myocardial protection can be obtained by moderate systemic hypothermia at 28–30°C. The myocardial temperature should be assessed continuously during the procedure and maintained below 15°C. If it exceeds 15°, additional administration of cardioplegic solution is necessary.

Mitral valve exposure and intraoperative valve analysis

Perfect exposition of the mitral valve is essential before undertaking mitral valve reconstructive surgery. We favor the interatrial approach through the Sondergaard's groove. The interatrial groove is incised and the two atria are dissected and divided up to the fossa ovalis. This dissection exposes the roof of the left atrium, which is opened close to the mitral valve [2]. In patients with a small left atrium, the inferior extension of the left atrial incision between the right inferior pulmonary vein and inferior vena cava optimizes the mitral valve exposure.

The entire mitral valve apparatus must be carefully examined to confirm the mechanism of MR, to assess the feasibility of reconstruction, and to plan the exact operative strategy. The endocardium of the left atrium is examined for jet lesions, which indicate opposite leaflet prolapse. The mitral annulus is examined to assess the severity of annular dilatation, and the presence and extent of calcification. The valvular apparatus is examined with a nerve hook in order to assess the severity and the extent of leaflet prolapse according to the segmental valve analysis [2]. The anterior paracommissural scallop of the posterior leaflet (P1) is often intact and rarely prolapsing in patients with degenerative disease. The P1 segment constitutes the reference point [2]. Applying traction to the free edge of other valvular segments and comparing them to P1 determines the severity and the extent of leaflet prolapse.

Fundamentals of mitral valve reconstructive surgery

The goals of reconstructive surgery are preservation or restoration of normal leaflet motion, creation of a large surface of coaptation, and stabilization of the entire annulus with a remodeling annuloplasty (Figure 63.4) [1]. Current surgical techniques allow surgeons to perform reconstructive surgery in almost all patients

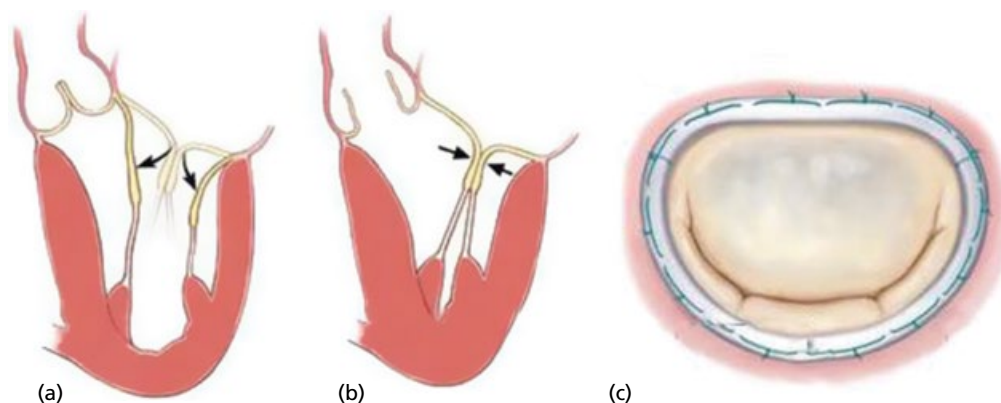

Figure 63.4 Principles of reconstructive surgery. Source: Carpentier A, et al. 2010 [14]. Copyright 2010 Saunders/Elsevier.

with degenerative mitral disease, provided that these guidelines are followed carefully.

Posterior leaflet prolapse

Limited posterior leaflet prolapse is best treated by a triangular resection. Extensive posterior leaflet prolapse is treated by a quadrangular resection of the prolapsed area. Stay sutures are placed around the normal chordae in order to determine the prolapsed area. The prolapsed segment is then removed by performing a perpendicular incision from the free edge toward the annulus, resecting a quadrangular portion of the leaflet. Plication sutures are placed along the posterior annulus in the resected area. Finally, direct sutures of the leaflet remnants restore valve continuity without tension (Figure 63.5).

When excessive posterior leaflet tissue is present, such as in Barlow's disease, it is important to reduce the height of the posterior leaflet to less than 15 mm to prevent postoperative systolic anterior motion (SAM) [9]. A sliding leaflet technique is performed following quadrangular resection. The P1 and P3 segments are detached from the annulus; compression sutures are then placed in the posterior segment of the annulus. A sliding plasty of the P1 and P3 segments is performed and the gap between the two scallops is closed with interrupted sutures. In Barlow's valve with significant excess tissue of posterior leaflet, an additional triangular resection at the base of P1 and P3 may be necessary prior to proceeding with the sliding leaflet plasty.

Sliding plasty is also indicated if a large segment of the posterior leaflet is resected. Plication of a large segment of the posterior

annulus must be avoided because of the increased risk of circumflex artery kinking.

Anterior leaflet prolapse

Several techniques are described to correct anterior leaflet prolapse depending upon the extent of the prolapse and the lesions responsible (chordae elongation versus rupture).

Triangular resection

Limited prolapse of the anterior leaflet with excess tissue can be treated by a small triangular resection of the prolapsed area followed by direct closure with interrupted monofilament sutures. The triangular resection must not be extended to the body of the anterior leaflet and should not involve more than 10% of the anterior leaflet surface area. Large resection of the anterior leaflet distorts the geometry and reduces the coaptation area. In addition, it compromises leaflet mobility considerably and is incriminated as a risk factor for repair failure.

Chordae transposition

Chordae transposition from the secondary position to the free margin of the anterior leaflet is the most preferable technique. A strong and normal secondary chordae adjacent to the prolapsing area is identified. This chordae is detached at 2 mm from its origin on the body of the anterior leaflet. If the chordae is cut at its base, this will likely cause leaflet perforation. It is then attached to the free margin of the anterior leaflet in the prolapsed area with a figure-of-eight suture. In case of a large prolapsed area, several secondary chordae

Figure 63.5 Posterior leaflet quadrangular resection with annular plication. Source: Carpentier A, et al. 2010 [14]. Copyright 2010 Saunders/Elsevier.

should be transferred to the free margin with a maximum 5 mm interval between two adjacent chordae.

In the absence of normal secondary chordae, chordae transposition from the posterior leaflet to the anterior leaflet should be considered. If marginal chordae of the posterior segment opposite to the prolapsed area of the anterior leaflet is normal, it can be used for chordae transposition. A small segment of the posterior leaflet with its marginal chordae is detached and then reattached to the free margin of the anterior leaflet at the site of prolapse. Interrupted sutures are used to close the defect in the posterior leaflet.

If these two techniques can not be applied, the use of artificial chordae is a valuable alternative.

Papillary muscle sliding plasty

This technique is convenient for anterior leaflet prolapse caused by elongation (<5 mm) of multiple chordae arising from a papillary muscle. The portion of the papillary muscle supporting the elongated chordae is split longitudinally and re-sutured to the other portion at a lower level. This downward displacement of papillary muscle corrects leaflet prolapse.

Papillary muscle shortening

Papillary muscle elongation or chordae elongation involving a group of chordae can also be treated by papillary muscle shortening. A triangular wedge at the base of the papillary muscle is resected. This defect is then closed by direct suture resulting in a reduced height of the papillary muscle and correction of chordae length. Papillary muscle shortening not only corrects the leaflet prolapse, but also reduces considerably the billowing of the leaflet body. This procedure is typically indicated in Barlow's disease with bileaflet prolapse.

Commissural prolapse

Commissural prolapse is best treated by resection of the prolapsed area followed by annular plication (limited prolapse) or sliding plasty of the paracommissural area (extensive prolapse) (e.g., A1 and P1 sliding plasty for anterolateral commissural prolapse). Additional inverting sutures should be placed in the newly created commissure in order to avoid residual minimal regurgitation. Occasionally, a patient presents with a papillary muscle with two heads. The rupture of one head can lead to commissural prolapse, which can be corrected by reattachment of the latter to the remnant papillary muscle. If extensive commissural and paracommissural prolapse resulting from chordae elongation are present, papillary muscle sliding plasty or papillary muscle shortening are valuable alternative options.

Remodeling ring annuloplasty

In patients with a normal mitral valve, the ratio between anteroposterior (septolateral) and transverse diameter of the mitral annulus is 3 : 4 during systole. This ratio is inverted in patients with degenerative mitral valve disease and annular dilatation [1]. The remodeling ring annuloplasty restores the physiologic ratio with maximal orifice area during systole. Therefore the prosthetic ring restores not only the size, but also the shape of the annulus. Remodeling annuloplasty provides increased leaflet coaptation area without causing any valvular stenosis. Furthermore, it prevents late annular dilatation and preserves leaflet mobility. Appropriate ring sizing is based on the intercommissural distance and the surface area of the anterior leaflet, measured with an obturator (Figure 63.6). If the surgeon hesitates between two sizes, in patients with degenerative

Figure 63.6 Ring selection based on sizing of the mitral valve: (i) measure of inter-commissural distance, (ii) measure of the anterior leaflet surface area.

valve disease the selection of the greater size is recommended in most instances [2]. In Barlow's valve, the typical size of the prosthetic ring is 36–40 mm [10]. The choice of a too small ring increases significantly the risk of post-repair SAM [11].

Sutures are placed circumferentially through the mitral annulus. These sutures are equally spaced in the area between the two commissures and the corresponding segment of the selected prosthetic ring. In the remaining portion of the annulus, the spacing is set to conform the annulus to the shape and size of the prosthetic ring. When the ring sutures are tied, the ring reshapes the annulus in its normal systolic position.

Saline test and post bypass TEE

The quality of the repair must be evaluated at the completion of the reconstruction and before tying the ring to the annulus with a saline test. Saline is injected into the ventricular cavity through the mitral valve with a syringe while the aortic root is vented to prevent air emboli into the coronary arteries. A symmetric line of coaptation, parallel to the posterior aspect of the annulus, and at distance from the left ventricular outflow tract (3/4 to 1/4 ratio of anterior to posterior leaflet) indicates a satisfactory result. An asymmetrical line of coaptation indicates the presence of residual leaflet prolapse or restricted leaflet motion, which must be corrected. If the posterior leaflet occupies half or more of the orifice area its height should be reduced (less than 15 mm) to minimize the risk of SAM. Two hooks should also be used to determine the length of the coaptation which is ideally greater than 10 mm. At the completion of cardiopulmonary bypass, the quality of reconstruction is assessed by TEE. This examination should carefully evaluate leaflet motion, the competency of the valve and rule out the presence of post-valvuloplasty SAM in patients with excess leaflet tissue. In the presence of residual regurgitation, TEE is crucial to determine the severity and the mechanism of regurgitation which can justify a second look. No patient should leave the operating room with more than 1+ residual MR. In patients with $\geq 2+$ MR, a second bypass run is necessary to reanalyze the valve and correct a residual valvular dysfunction.

Results

Patients with degenerative mitral valve disease are the most suitable for reconstructive surgery [12–14]. Operative mortality in this group of patients is less than 0.5% in experienced centers [10] with a repair rate of near 100% [13]. In patients with severe MR, reconstructive surgery should be carried out before the occurrence of clinical symptoms, atrial fibrillation, pulmonary hypertension, and left ventricular dysfunction or enlargement.

The long-term survival of patients with preserved left ventricular function following reconstructive surgery is similar to that of an age and gender-matched population.

Our group was among the first to publish the very long-term results (>20 years) of mitral reconstructive surgery [12]. This observational study, which consisted of 162 consecutive patients operated on between 1970 and 1984, was mostly composed of patients with degenerative disease (90%). The main mechanism of MR was type II dysfunction in 152 (94%) patients. Posterior, anterior, and bileaflet prolapse were present in 93 (61%), 28 (19%), and 31 (20%) patients, respectively. All patients underwent annuloplasty; valve resection was done in 126 patients, and shortening or transposition of the chordae in 46 patients. The linearized rate of reoperation was 0.4% per patient year. Freedom from reoperation was 97%, 86%, and 83%

for posterior, anterior, and bileaflet prolapse, respectively, at 20 years (Figure 63.7). The increased rate of early reoperation in the anterior leaflet prolapse group was attributed to technical failure. The widespread use of intraoperative TEE and improved surgical techniques (chordae transposition) have most likely contributed in reducing the incidence of early failure in the last two decades. However, the freedom from reoperation was unchanged at 10, 20, and 25 years of follow-up. These excellent and stable results confirm the predictability and durability of mitral valve reconstruction in degenerative disease. Today, reconstructive valve surgery allows patients to enjoy a normal life and to be cured for the rest of their life [14].

Mitral Valve Repair: MitraClip and Emerging Techniques

Ted Feldman¹, Mohammad Sarraf¹, Mayra Guerrero¹, and Francesco Maisano²

¹NorthShore University HealthSystem, Evanston, IL, USA

²University Hospital Zurich, Zurich, Switzerland

Percutaneous mitral valve repair has emerged as an alternative to surgery for patients with significant symptomatic mitral regurgitation (MR) and prohibitive risk for surgical mitral repair or replacement. The first MR surgical treatment concept to be adapted for percutaneous use was the double-orifice or edge-to-edge repair [1]. The surgical technique was developed in the early 1990s [2]. The free edges of the mitral leaflets are sewn together along the coaptation surface of the mid segments of the anterior and posterior mitral leaflets to create a double orifice valve. This technique was used initially for patients with focal anterior leaflet mitral prolapse [3]. The initial description of the surgical technique specifically suggested that “the concept introduced by this type of repair can open the perspective of percutaneous correction of MR.”

Percutaneous mitral leaflet repair with MitraClip

The edge-to-edge repair concept led to the development of the MitraClip [4]. This device replicates the surgical repair by mechanically grasping the mitral leaflet free edges. The device is introduced into the left atrium via transseptal puncture, positioned and opened above the mitral leaflets, passed beyond the leaflets tips into the left ventricle (LV), and then slowly pulled back toward the atrium to grasp the leaflets (Figure 64.1). The clip is then closed to create a double orifice valve, and the effect on reduction of MR is assessed. The MitraClip can be reopened and repositioned, or removed completely, up to the point that it is released.

The MitraClip system consists of three major components: a 24-Fr steerable guiding catheter, the clip delivery system (CDS), and the MitraClip device. The CDS has a steering mechanism for the clip and controls to manage the opening and closing of the clip, the lock, and the “gripper,” which is a barbed element to help affix the mitral leaflets to the clip arms. The clip is covered in polyester fabric. The deployment is completely reversible and it is possible to grasp the mitral leaflets and ultimately choose to release them and remove the clip safely when needed (Figures 64.2 and 64.3).

The first procedures were carried out in July 2003. After demonstrating feasibility in the EVEREST I trial [5], the MitraClip was evaluated in a randomized trial comparing the MitraClip with conventional surgery for patients deemed good surgical candidates, EVEREST II

(Figure 64.4) [6]. The majority of the patients randomized in the EVEREST II trial were patients with degenerative mitral regurgitation (DMR). About one-fourth had functional MR (FMR).

At 1 year of follow-up, the major findings of EVEREST II trial were that the MitraClip was less successful at reducing MR than surgery, but led to similar improvements in favorable LV remodeling and clinical outcomes including functional class and quality of life scores. Subgroup analysis showed that the patients who derived the greatest improvement with MitraClip were older, had FMR, and had poor LV function. This latter finding has contributed to the broader use of the MitraClip in this clinical setting in global practice, and the subsequent development of the EVEREST REALISM Registry. In the first 6 months after MitraClip therapy in the EVEREST II trial, almost 20% of patients required surgery. Almost half of these were because of initially unsuccessful procedures with an inability to either implant a clip successfully, or inadequate reduction in MR. Almost 9% of these patients who had single leaflet detachment from the MitraClip device. In this instance, a single leaflet is noted to have escaped from the clips typically at the 30-day follow-up visit. No occurrences of complete embolization occurred in this experience. Single leaflet detachment was not associated with clinical events, but obviously led to a failure to reduce MR adequately. After the initial 6-month period, when the early procedure failures are noted, comparisons of MitraClip and surgery in the EVEREST II randomized trial show equivalent outcomes in terms of reoperation, mortality, and LV remodeling.

At 5 years, the outcomes from the MitraClip therapy in EVEREST II trial are remarkably stable [7]. The durability of LV remodeling and stability of the mitral annular dimensions suggest that after initially successful therapy, the procedure results are durable for at least 5 years.

It has been recognized that during this randomized trial, many patients who might have benefited from MitraClip had too high surgical risk to be enrolled. This led to a high risk registry [8]. Ultimately, 351 high risk patients were prospectively enrolled [9].

The global experience with MitraClip in the ensuing decade of experience has witnessed a dramatic improvement in acute procedure success with rates approaching 100%. In addition, single leaflet detachment now occurs in about only 1% of patients. Thus, most of the failures seen in the first 6 months in EVEREST II would not occur in current practice.

Figure 64.1 Fluoroscopic images of a MitraClip procedure. (a) A single MitraClip has been advanced into the left ventricle beyond the mitral leaflets. The open clip will be pulled back to grasp the leaflets, and then released. (b) After placement of the first clip a second clip is placed. (c) Release of the second clip. (d) Final appearance of two clips. Note the transesophageal echocardiography (TEE) probe in all of the images. Two clips are placed on the mitral leaflets in about half of cases, and one clip in half.

Figure 64.2 The MitraClip System. (a) The partially open MitraClip device is shown without its fabric covering. A fine wire runs through the barbed “grippers,” which is used to raise the grippers. (b) The device in closed configuration. (c) The MitraClip is attached to the clip delivery system (CDS), which protrudes from the steerable guide catheter. (d) Control knobs allow deflection of the guide and CDS to steer the system through the left atrium and position the MitraClip above the mitral orifice. Source: Feldman T, Young A. *J Am Coll Cardiol* 2014; **63**: 2057–2068.

Figure 64.3 To introduce the clip, the Clip Delivery System (CDS) is advanced through the guide into the left atrium (left). Under echocardiographic and fluoroscopic guidance, the clip is aligned perpendicular to the valve plane, with the clip arms perpendicular to the line of coaptation. It is then advanced into the left and then slowly retracted to grasp the leaflets (right). The clip is closed (right, inset), and if reduction of mitral regurgitation is satisfactory, it is released. Figure 64.4 A recent review highlights the procedural safety of MitraClip leaflet repair. In a meta-analysis including over 3000 patients from 21 studies, 30-day outcomes for high risk patients showed low morbidity and mortality. Source: Philip F, *et al.* 2014 [10]. Reproduced with permission of John Wiley & Sons.

One of the striking findings from the EVEREST II trial is the safety of the MitraClip procedure. The procedure can be performed with remarkable hemodynamic stability, despite the fact that a large caliber device is manipulated in the mitral apparatus of the beating heart. In the randomized EVEREST II comparison with surgery, the MitraClip procedure was, as anticipated, significantly safer. There was virtually no procedure mortality, and the most frequent event was bleeding from the access site. Recent global experience with the device in high-risk patients has reinforced the safety profile of the therapy. Recent meta-analysis in over 3000 patients with an estimated STS risk of 10% or greater showed a 30-day mortality of only 3.3%, and a stroke rate of 1.1% within 30 days [10]. In the EVEREST REALISM high risk DMR subset, the actual 30-day mortality was 6.3% compared to a predicted mortality for this patient group with multiple comorbidities of >13% [11]. In the meta-analysis, the number of ICU days and

hospital stay were significantly shorter than in matched surgical patients. In fact, in the contemporary experience with the therapy, over 85% of patients are typically discharged directly to home without need for rehabilitation or an extended hospital stay, despite significant age and comorbidities [12].

MitraClip has been widely used internationally since CE Mark approval in 2008, based on the EVEREST I feasibility trial. The path to FDA approval has been significantly more protracted. Approval ultimately came from a subanalysis of the REALISM High Risk Registry. Of the 351 patients in the registry, a total of 127 patients were thought to have both prohibitive risk for surgery and DMR as the underlying etiology for their MR. These patients were selected by a panel of cardiovascular surgeons who felt that they had prohibitive risk for mitral valve surgery. The resultant population had a mean age of 82 years and a STS mortality risk of 13%. They had multiple comorbidities including coronary artery disease in 73%, prior cardiovascular surgery in 48%, atrial fibrillation in 71%, diabetes in 30%, and moderate to severe renal disease in 28%. Despite this very aged and complex population, the average hospital length of stay was only 2.9 days. Eighty-seven percent of these patients were discharged directly home. The safety of the procedure was reflected in a 30-day observed mortality of 6.3%, which is significantly lower when compared with the predicted mortality of 13.2%. The most important finding from this analysis was a reduction in hospitalizations for heart failure in the year after MitraClip therapy compared to the year prior, with a 73% decrease in the re-hospitalization rate (Figure 64.5). This led to the FDA approval of the MitraClip system in October 2013. The indication for use of the MitraClip delivery system is for the “percutaneous reduction of significant symptomatic MR due to primary abnormality of the mitral apparatus (degenerative MR) in patients who have been determined to have a prohibitive risk for mitral valve surgery by a heart team, which includes a cardiac surgeon experienced in mitral valve surgery and a cardiologist experienced in mitral valve disease, and in whom existent comorbidities would not preclude the expected benefit from reduction of the MR.” The approved indication is thus for prohibitive surgical risk patients with DMR. In the first year after approval of the device in the USA, about 800 procedures were performed at almost 70 sites.

Figure 64.5 Heart failure hospitalizations were reduced by 73% after MitraClip, comparing the year prior with the year after treatment. Source: Lim DS, Reynolds MR, Feldman T, et al. 2014 [11].

While the labeled indication for use in the USA is for DMR, the preponderance of global use of the MitraClip is among patients who have FMR. As FMR is a disease of the LV, most commonly in high surgical risk patients and often associated with ischemic LV dysfunction, treating the FMR without addressing the underlying LV dysfunction might not have a favorable impact on mortality. The benefit in this setting has yet to be shown in randomized trials. Observational and retrospective surgical series have shown mixed results from mitral repair. There has been favorable LV remodeling in some studies, but also high rates of recurrent MR and no impact on mortality. In addition, the commercial international experience with MitraClip for FMR has been accrued without a systematic approach for patient selection. Therefore, the reports on this experience are from heterogeneous groups, including mixed etiologies and widely varied levels of LV systolic function. The EVEREST II randomized trial subgroup analysis showed the best outcomes in patients with older age, poor LV function, and functional MR. This might have driven the preponderance of use in this setting in clinical practice. Nonetheless, the benefit of MitraClip compared with optimal medical therapy including cardiac resynchronization therapy has not been studied in a randomized clinical trial. For this reason, the FDA has not approved its use in this setting.

The benefit of the MitraClip in patients with FMR is being evaluated in the Clinical Outcomes Assessment of the MitraClip Percutaneous Therapy for High Surgical Risk Patients (COAPT) trial in the USA. The COAPT trial will randomize 430 patients in a 1:1 comparison of MitraClip with guideline-directed medical therapy. The safety endpoint is the composite of death, stroke, worsening renal function, left ventricular assist device (LVAD) implant, or heart transplant at 12 months. The primary effectiveness endpoint is recurrent heart failure hospitalizations. Enrollment started in 2013 and is currently ongoing.

Percutaneous indirect and direct annuloplasty

While the MitraClip therapy has been used in more than 18,000 patients worldwide, several other percutaneous repair technologies are at an earlier stage of development. Currently, approaches that

include direct and indirect annuloplasty make up the other entrants into the percutaneous mitral repair field. Indirect annuloplasty can be accomplished with the Carillon Mitral Contour System (Cardiac Dimensions, Inc., Kirkland, Washington, USA). This is the next most frequently used mitral repair technology after MitraClip. Indirect annuloplasty is performed via device placement in the coronary sinus. The device is a wire structure made of nitinol. One of the most attractive features of this approach is the ease of use. A 9-Fr guide catheter is placed in the coronary sinus via internal jugular venous access. A left coronary catheter is used for monitoring of the left coronary system for potential circumflex branch compression during device insertion. Transesophageal echocardiogram is utilized to assess the effect of device cinching on MR during the procedure. The distal anchor is released in the distal coronary sinus, and then the guide catheter is pulled back to cinch the coronary sinus and shorten the posterior annular circumference. Assessments of coronary circulation and reductions in MR can be made at that point. If the results appear satisfactory, the device can be released (Figure 64.6).

Two prospective registries, TITAN I and II, have been evaluated [13]. The findings suggest significant reductions in indices of MR severity, and improvements in LV chamber dimensions and clinical parameters such as New York Heart Association (NYHA) Functional Class and 6 minute walk test. One of the concerns with this device is compression of the circumflex coronary branches, because the coronary sinus frequently crosses over these vessels [14]. While this limited the therapy during early experience, it appears that in most cases the position of the device can be adjusted to relieve coronary compression. Among patients with functional MR, approximately 90% are good candidates for this therapy based on their anatomy. A unique observation with Carillon in the TITAN trials is progressive improvements in MR reduction and LV chamber dimensions over the first year after device implantation, with associated improvement in clinical status. This observation needs to be verified in a larger trial. There have been no direct comparisons of Carillon with MitraClip, but overall the reductions in MR and improvements in clinical status with Carillon seem similar to the outcomes seen with MitraClip.

Several technologies implant a device directly into the mitral annulus to reduce the annulus circumference. Access to the annulus can be either antegrade through transseptal puncture or retrograde through the aortic valve and LV.

The Mitralign Percutaneous Annuloplasty System (Mitralign, Tewksbury, MA, USA) is predicated on surgical annular suture plication [15]. A deflectable transaortic catheter is advanced to the LV and used to deliver pledgeted anchors through the posterior annulus (Figure 64.7). These anchors can be tethered together resulting in a segmental posterior annuloplasty to shorten the annulus up to 17 mm. In 15 patients treated in a phase 1 trial, the 1-year results demonstrated at least 1+ MR reduction that was associated with improved NYHA function class and reduction in tenting area and depth. A CE approval trail has completed enrollment and is awaiting follow-up.

The Accucinch system (Guided Delivery Systems, Santa Clara, CA, USA) is based on suture annuloplasty. A retrograde femoral arterial approach to gain access to the LV aspect of the mitral annulus is used. A catheter is placed under the posterior mitral leaflet next to the anterior trigone, adjacent to the annular tissue beneath the valve (Figure 64.8). Using this catheter, up to 20 anchors can be placed from the anterior to posterior commissures along the posterior mitral annulus. These anchors are connected

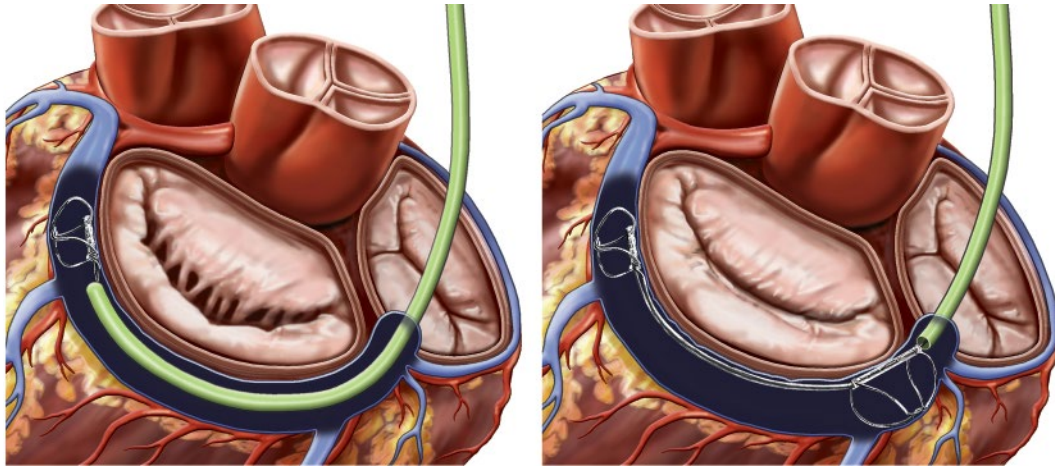

Figure 64.6 Coronary sinus annuloplasty: the Cardiac Dimensions Carillon Device: The guide catheter is introduced through jugular venous access. The device is delivered in the distal coronary sinus and the distal anchor is released (left), and then the guide catheter is pulled back to release the proximal anchor in the coronary sinus ostium. The wireform, made of nitinol wire, after release in the coronary sinus (right). Cinching of the mitral annulus results in compression of the septal–lateral dimension and thus the regurgitant orifice. Source: Feldman T, Young A. *J Am Coll Cardiol* 2014; **63**: 2057–2068. Artwork by Craig Skaggs.

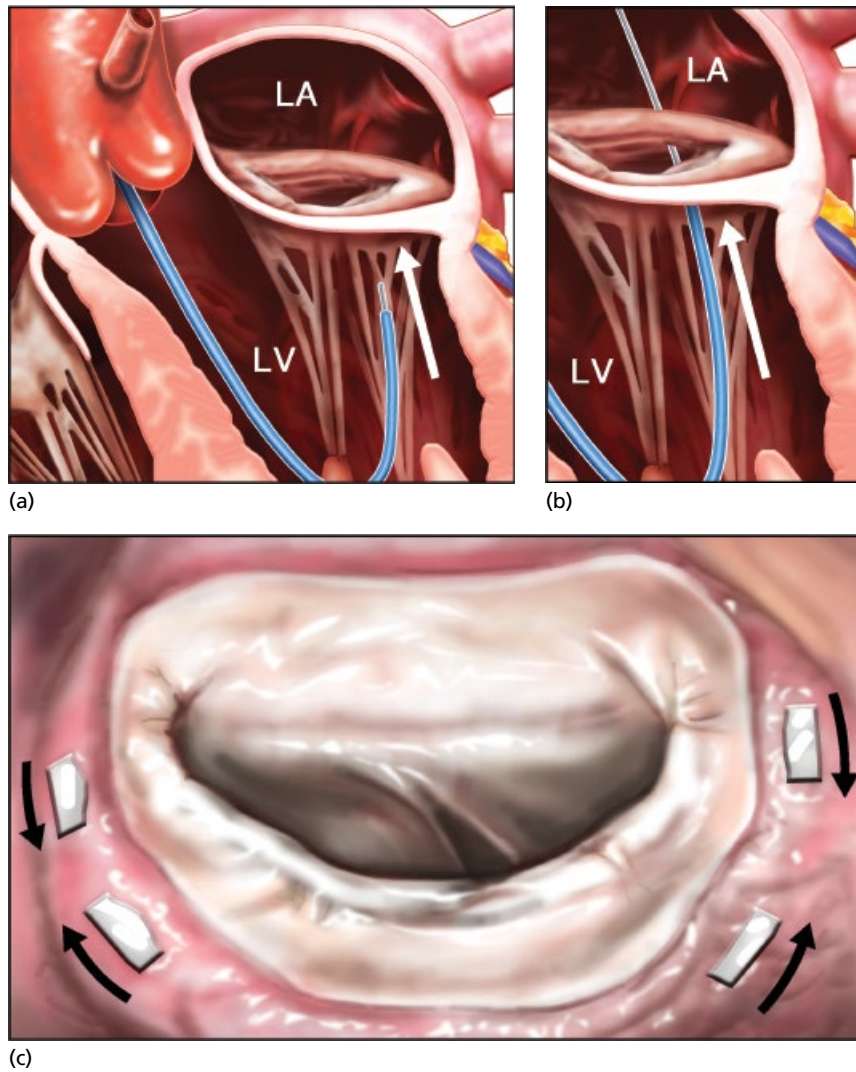

Figure 64.7 Mitralign annular plication: (a) shows the retrograde guide catheter in the LV, with the distal catheter tip under the mitral annulus, behind the posterior leaflet (arrow). A wire has been passed from the left ventricle (LV) through the annulus and into the left atrium (LA) in (b). Two pairs of wires are used to place pledgets near both commissures, shown from the left atrial side in (c). The pledgets are drawn together (arrows) to decrease the mitral annular circumference. Source: Feldman T, Young A. *J Am Coll Cardiol* 2014; **63**: 2057–2068. Artwork by Craig Skaggs.

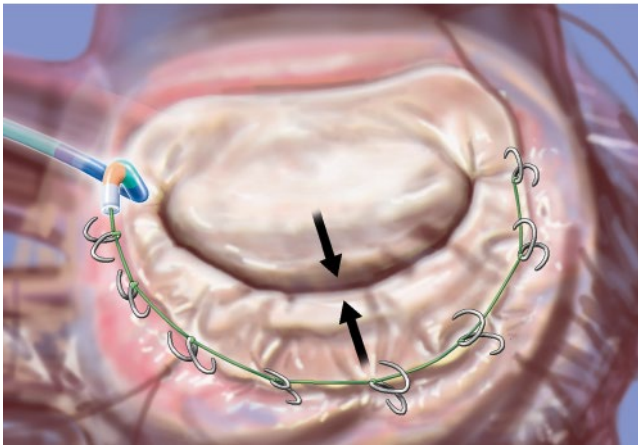

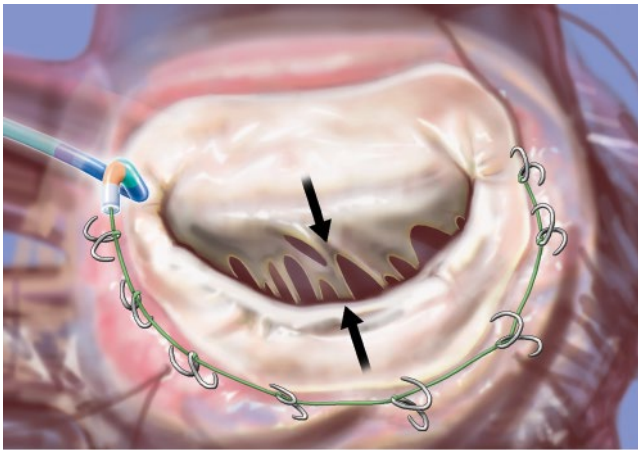

Figure 64.8 Direct annuloplasty: the Guided Delivery Systems Accucinch device is delivered through retrograde catheterization of the left ventricle (top). The arrows highlight the separation of the leaflet edges, which define the regurgitant orifice. Anchors are placed in the posterior mitral annulus and connected with a “drawstring” to cinch the annular circumference. When the cord is tightened the basilar myocardium and annulus draw the mitral leaflets together to decrease the regurgitant orifice (bottom). Source: Feldman T, Young A. *J Am Coll Cardiol* 2014; **63**: 2057–2068. Artwork by Craig Skaggs.

by a suture that can plicate the annulus to reduce the mitral annular circumference and MR.

The Cardioband (Valtech, Or Yehuda, Israel) most closely resembles a surgical annuloplasty ring [16]. It utilizes transeptal percutaneous placement of a series of small corkscrew anchors on the atrial side of the left atrium by transesophageal echocardiogram. The anchors are connected by a Dacron sleeve that can be subsequently tensioned and reduce the mitral annular circumference (Figure 64.9). Preclinical studies in a swine model have shown excellent outcomes in short term and up to 90 days. Early results in patients are promising and a CE approval trial is underway.

Another developing technique is chordal replacement. This is challenging to accomplish by completely percutaneous methods, and early work has been via LV apical access during a beating heart surgery [17,18].

Transcatheter mitral valve replacement

Transcatheter mitral valve replacement (TMVR) as a therapy for FMR is also developing, with several different devices having first in human experience in the last 2 years. The effort to develop TMVR is just beginning, with the total number of treated patients in low double-digits at the time of this writing. Early experience with valve-in-valve implants of transcatheter aortic valve replacement (TAVR) devices for degenerated mitral bioprosthetic valves and native calcific mitral stenosis have demonstrated proof of concept for TMVR [19,20]. The obvious appeal of replacement is the elimination of residual MR and the potential for recurrence of MR that is common with percutaneous repair devices. The challenges facing development of these devices include larger area and asymmetrical “D” shape of the mitral valve, lack of calcium for anchoring, and more complicated delivery route compared to TAVR. The large mitral area and annulus diameter necessitates bulkier, larger profile devices. Anchoring requires special valve frame features dedicated to the purpose. Delivery in the early development has been mostly transapical, with the hope that transeptal delivery will eventually be most frequent. The question is often asked: will transcatheter mitral replacement eliminate the need for repair approaches? Transcatheter mitral repair and replacement interventions will become complementary solutions to accommodate the variability of the disease. Algorithms for patient-specific approach

(a)

(b)

will evolve as outcomes in the several patient subpopulations become available. Imaging screening and guidance will have a fundamental role in determining the relative role of these procedures in the future.

Interactive multiple choice questions are available for this chapter on www.wiley.com/go/dangas/cardiology

Balloon Mitral Valvuloplasty

C.N. Manjunath¹, Nagaraja Moorthy¹, and Upendra Kaul²

¹Sri Jayadeva Institute of Cardiovascular Sciences and Research, Bangalore, India

²Fortis Escorts Heart Institute, New Delhi, India

Although the prevalence of rheumatic fever has greatly decreased in the Western world, mitral stenosis (MS) still results in significant morbidity and mortality especially in developing countries. Rheumatic heart disease is responsible for valvular MS in nearly almost all cases. MS occurs when stenosis of the valve occurs from leaflet thickening, commissural fusion (Figure 65.1), and chordal shortening or fusion restricting blood flow from the left atrium to the left ventricle during diastole. This ultimately results in increased pulmonary capillary wedge pressure, an elevated pulmonary vascular resistance, and right ventricular dysfunction. Echocardiography has a major role in decision-making for MS, allowing confirmation of diagnosis, quantification of stenosis severity and its hemodynamic consequences, and guides management options.

Anatomic considerations

The mitral valve (MV) apparatus is a complex structure consisting of annulus fibrosus, mitral leaflets, chordae tendinae, papillary muscles, and the posterior wall of the left ventricle. All these components should be considered functionally as a single unit, because derangements of any one can affect overall MV performance.

The normal mitral valve area (MVA) is 4.0–6.0 cm². An MVA of >1.5 cm² usually does not produce symptoms. As the severity of MS increases, cardiac output becomes subnormal at rest and fails to increase during exercise. This is the main reason for considering MS significant when MVA is ≤1.5 cm². When the MVA is reduced to 1.5 cm² or less, symptoms become severe and complications develop.

Balloon mitral valvuloplasty

Historical aspect

The treatment of MS has been revolutionized since the development of balloon mitral valvuloplasty (BMV). In 1982, Kanji Inoue, a Japanese cardiac surgeon, first developed the idea that a degenerated mitral valve could be inflated using a balloon with differential compliance [1]. In India, Lock *et al.* [2] first reported the use of a cylindrical balloon for mitral valvuloplasty. Subsequently, the idea of a double-balloon technique was introduced from Saudi Arabia [3] as a potential alternative method for balloon commissurotomy. The double balloon

technique requires that two guidewires be positioned in the left ventricular apex, through which two floating balloon catheters are then advanced across the mitral valve orifice. However, the double-balloon technique is technically more demanding and thus often requires a longer procedure time, which can lead to inadvertent complications. The guidewire positioned in the left ventricular apex sometimes induces perforation of the apex, leading to cardiac tamponade. Therefore, Inoue's single-balloon technique has become the most popular method for performing BMV in most parts of the world. The mechanism of BMV is the same as the already abandoned closed mitral commissurotomy [4]. Pathologic studies have disclosed that the main mechanism of successful BMV is a split of the commissures. Before 1984, when Inoue *et al.* [1] first described the clinical application of percutaneous BMV, surgical mitral commissurotomy was the preferred option for patients who had severe MS. Since its introduction, percutaneous mitral commissurotomy has demonstrated good immediate and mid-term results [5,6] and has replaced surgical mitral commissurotomy as the preferred treatment of rheumatic MS in appropriate candidates.

Indications and recommendations for percutaneous balloon mitral valvuloplasty

Indications for BMV have been formulated by the American College of Cardiology (ACC) and the American Heart Association (AHA) [7,8].

Class I recommendations

- 1 BMV is recommended for symptomatic patients with severe MS (mitral valve area ≤1.5 cm², stage D) and favorable valve morphology in the absence of left atrial thrombus or moderate–severe mitral regurgitation (MR) (level of evidence A).
- 2 BMV is effective for asymptomatic patients with moderate or severe MS and valve morphology that is favorable for BMV who have pulmonary hypertension (pulmonary artery systolic pressure greater than 50 mmHg at rest or greater than 60 mmHg with exercise) in the absence of left atrial thrombus or moderate to severe MR (level of evidence C).

Figure 65.1 (a) Transthoracic 2D; and (b) 3D echocardiogram showing thickened mitral valve with bicommissural fusion giving “fish-mouth” appearance.

Class IIa recommendations

- 1 BMV is reasonable for asymptomatic patients with very severe MS (mitral valve area $\leq 1.0 \text{ cm}^2$, stage C) and favorable valve morphology in the absence of left atrial thrombus or moderate–severe MR (level of evidence C).

Class IIb recommendations

- 1 BMV can be considered for asymptomatic patients with severe MS (mitral valve area $\leq 1.5 \text{ cm}^2$, stage C) and valve morphology favorable for BMV in the absence of left atrial thrombus or moderate–severe MR who have new onset of atrial fibrillation (AF) (level of evidence C).
- 2 BMV can be considered for symptomatic patients with MVA greater than 1.5 cm^2 if there is evidence of hemodynamically significant MS based on pulmonary artery wedge pressure greater than 25 mmHg or mean mitral valve gradient greater than 15 mmHg during exercise (level of evidence C).
- 3 BMV can be considered for severely symptomatic patients (NYHA Class III–IV) with severe MS (mitral valve area $\leq 1.5 \text{ cm}^2$, stage D) who have a suboptimal valve anatomy and who are not candidates for surgery or at high risk for surgery (level of evidence C).

Contraindications

The following are contraindications for BMV (i.e., Class III recommendations).

- 1 BMV is not indicated for patients with mild MS (level of evidence C).
- 2 BMV should not be performed in patients with moderate–severe MR or left atrial body thrombus, bicommissural calcium (level of evidence C). However, using a modified over-the-wire technique, BMV can be safely carried out in patients with types Ia, Ib, and II or LA/LAA thrombus after 8–10 weeks of anticoagulation.

Peri-procedural care

Preprocedural planning

Physical examination is an important initial step in assessing the pliability of the valve. Accentuation of the first heart sound (S1) occurs when the mitral valve leaflets are pliable. Marked calcification or thickening of the mitral valve leaflets reduces the amplitude

of S1, probably because of diminished motion of the leaflets. The opening snap of the mitral valve is caused by a sudden tensing of the valve leaflets after the valve cusps have completed their opening excursion. It is most readily audible at the apex; if present, it indicates that the mitral valve has at least some mobility.

The likelihood of hemodynamic benefit and the risk of complications with BMV are predicted by the morphologic features of the valve leaflets and subvalvular structures. With rigid, thickened valves that exhibit extensive subvalvular fibrosis and calcification, results will be suboptimal [7].

Role of echocardiography in BMV: valve assessment and case selection

Echocardiography is the primary modality of evaluation for patients who are planned for BMV. It is essential for the preprocedural evaluation of patients, case selection, intraprocedural monitoring, and the post-procedural assessment and follow-up (Box 65.1). The primary aim of echocardiographic assessment is to find the suitable valve for BMV and identify high risk echocardiographic features that may result in complications. The echocardiographic scoring system developed by Wilkins *et al.* [9] is useful for estimating likely outcomes of BMV (Table 65.1).

In this system, points are given for leaflet mobility, valve thickening, subvalvular thickening, and valvular calcification. The final score is determined by adding the points for each of the components (maximum, 16 points). A score of 8 or lower is usually associated with excellent immediate and long-term results for BMV, whereas scores higher than 8 are associated with less impressive results, including the risk of development of MR. However, in our institution, 30–35% patients undergoing BMV have Wilkins scores of 8–12, and this group of patients have optimal immediate and long-term results with comparable complications.

An important factor in determining the suitability of the valve for BMV is the presence of commissural calcification, assessed by means of a two-dimensional echocardiography in short-axis view. The presence or absence of severe calcification of one or both commissures is an independent determinant of near-term success during the procedure, as well as long-term outcome [10]. In asymmetric involvement of the commissures, in which one commissure is heavily fibrosed or calcified, splitting can occur in the opposite commissure. However, calcification of both commissures is considered

as absolute contraindication for BMV as it poses increased risk of leaflet tear. The presence of predominant subvalvular fibrosis and calcification results in suboptimal results from BMV because it is unclear that balloon dilatation is able to split chordal fusion.

Several echocardiographic scoring systems have been proposed as a guide to the selection of patients for BMV. Although studies using these methods have been shown to correlate with the immediate results, no single parameter is able to predict success or complications independently. Therefore, these criteria should be used only as a guide to the severity of the individual morphologic variables of the mitral valve.

BMV is now the procedure of choice for selected MS patients. Optimally, a team comprising an interventionalist and a cardiac imaging expert collaborates during the preprocedural and peri-

procedural assessment. Targeted echocardiography not only is critical to the selection of candidates for BMV but also can be of great value in guiding the procedure and assessing the results [11]. Simultaneous echocardiography (transthoracic, transesophageal, or intracardiac echocardiography) directly illustrates the relation of the catheter to myocardial structures.

In patients whose anatomy is distorted by an enlarged LA or kyphoscoliosis, echocardiography can be used to ensure that the catheter crosses the atrial septum at the level of the fossa ovalis. Catheter crossing elsewhere can give rise to complications, and through the muscular portion of the septum can result in difficult manipulation of the balloon catheter into left ventricle. Echocardiography is useful for directing the catheter across the mitral valve; the balloon initially tends to position itself toward the lateral annulus in the left atrium. Finally, hemodynamic evaluation of the transmitral gradient and the severity of MR is easily performed by means of Doppler echocardiography [11].

Box 65.1 Role of two-dimensional Doppler echocardiography in the evaluation of patients undergoing balloon mitral valvotomy.

Preprocedural evaluation:

- Severity of valve disease
- Mitral valve gradient
- Mitral valve area
- Severity of mitral regurgitation
- Left atrial/LA appendage thrombus
- Subvalvular apparatus
- Valvular/commissural calcification
- Interatrial septal bulge/aneurysm
- Associated other valvular disease
- Preprocedural pulmonary artery pressure and right ventricular function

During balloon mitral valvotomy:

- Assistance in transseptal puncture
- Changes in valve area or gradient
- Changes in mitral regurgitation
- Complications (pericardial effusion, tamponade, atrial septal defect, etc.)

Post-procedural follow-up and long-term results:

- Restenosis
- Changes in mitral regurgitation grade
- Residual atrial septal defects
- Pulmonary artery pressure
- Ventricular size and function
- Progress of other valve disease

Patient preparation

Usually, BMV is carried out with the patient under local anaesthesia and moderate sedation. The patient remains in the supine position during the procedure.

Techniques

Approach

Retrograde (transarterial) and antegrade (transvenous) approaches to BMV have been described. The retrograde approach eliminates the risk of atrial septal defect but carries a risk of potential arterial damage; because of its complexity, it has now been largely abandoned [12]. Currently, the antegrade approach with transseptal catheterization is more widely used. It is usually performed through the femoral vein or, exceptionally, through the jugular vein [13].

Choice of technique

Double-balloon technique

In this approach, after transseptal catheterization, a balloon-tipped catheter is advanced into the left ventricle. One or two exchange guidewires are advanced through the lumen of the balloon-tipped

Table 65.1 Echocardiography scoring system (Wilkins score) to predict outcome of mitral balloon valvuloplasty.

Grade	Mobility	Thickening	Calcification	Subvalvular thickening
1	Highly mobile valve with only leaflet tips restricted	Leaflets near normal in thickness (4–5 mm)	A single area of increased echo brightness	Minimal thickening just below the mitral leaflets
2	Leaflet mid and base portions have normal mobility	Midleaflets normal, considerable thickening of margins (5–8 mm)	Scattered areas of brightness confined to leaflet margins	Thickening of chordal structures extending to one-third of the chordal length
3	Valve continues to move forward in diastole, mainly from the base	Thickening extending through the entire leaflet (5–8 mm)	Brightness extending into the mid-portions of the leaflets	Thickening extended to distal third of the chords
4	No or minimal forward movement of the leaflets in diastole	Considerable thickening of all leaflet tissue (>8–10 mm)	Extensive brightness throughout much of the leaflet tissue	Extensive thickening and shortening of all chordal structures extending down to the papillary muscles

The total score is the sum of the four items and ranges between 4 and 16.

catheter and positioned in the apex of the left ventricle or, less frequently, in the ascending aorta.

The balloon-tipped catheter is withdrawn over the guidewires, and the interatrial septum is dilated with the use of a peripheral angioplasty balloon (6–8 mm in diameter). Finally, the valvotomy balloons (15–20 mm in diameter) are advanced over the guidewires and positioned across the mitral valve and dilated [12].

Multitrack technique

Bonhoeffer *et al.* [14] have described the use of the multitrack system, which is a refinement of the double-balloon technique that employs a monorail system requiring only one guidewire. This technique allows easier dilatation than the standard technique; however, clinical experience with the multitrack system is still limited.

Metallic commissurotomy

Cribier *et al.* [15] introduced the metallic commissurotomy in the 1990s. This procedure is as efficacious as balloon commissurotomy, but it is more demanding on the operator than the Inoue technique and appears to carry a higher risk of pericardial effusion and tamponade as a consequence of the presence of a stiff guidewire in the left ventricle. The potential advantage of the procedure is its cost-effectiveness.

Inoue balloon technique

The Inoue balloon technique, first described in 1984 [1], is still the most commonly employed technique today. Wide experience has now been acquired by a number of groups worldwide. In developing countries, Inoue prototype Accura Balloon (Vascular Concepts) is routinely used with comparable success rates.

Vascular access

A 7 Fr sheath is inserted in the right femoral vein for transseptal access; a 5 Fr sheath is placed in the right or left femoral artery for left heart catheterization. Two pressure transducers are required for simultaneous left atrial, left ventricular pressures. A pigtail catheter is placed in the aortic root (left/non-coronary sinus), and aortic pressures are obtained.

Transseptal puncture

Transseptal catheterization is a vital component of BMV. The goal of transseptal catheterization is to cross from the right atrium to the left atrium through the fossa ovalis. Puncture of the fossa ovalis itself is safe; the danger of the transseptal approach lies in the possibility that the needle and catheter will puncture an adjacent structure (e.g., the coronary sinus, the posterior wall of the right atrium, or the aortic root). To minimize the risk of complications, the operator must have a detailed knowledge of the regional anatomy of the atrial septum.

Equipment for septal puncture Essential instruments include a pre-shaped transseptal sheath with introducer (Mullins sheath) and a pre-shaped transseptal puncture needle (Brockenbrough needle).

Landmarks for septal puncture Transseptal puncture is usually carried out under fluoroscopic guidance. There are certain fluoroscopic landmarks that are used to identify the location of fossa ovalis. The pigtail marks the location of aortic valve. In anteroposterior view, the fossa ovalis lies inferior and medial to the aortic valve. To select the optimal transseptal puncture site, two imaginary lines are drawn: (i) the vertical midline; and (ii) the horizontal M line. The point of intersection of vertical “midline” and horizontal “M line” locates the site of septal puncture.

As seen in Figure 65.2a, a horizontal line is drawn from the tip of the pigtail catheter placed in the non-coronary sinus of the aortic root and the lateral border of the left atrium. The vertical line drawn from the midpoint of this line is the *vertical midline*. The *horizontal M line* is the line crossing the center of the mitral annulus. It is derived from a diastolic stop frame of diagnostic left ventriculography obtained in right anterior oblique (RAO) 30° projection (Figure 65.2b). The plane of the mitral annulus is obtained by joining fulcrum points of the mitral valve. From the midpoint of this line, a horizontal line is drawn toward the vertebral body. This is referenced to a vertebral body. The ideal puncture site is the intersection of the vertical midline and the M line. Usually, the intersection point will be half to one vertebral body below the horizontal line drawn from the aortic root in the vertical midline.

In most institutions the septal puncture is carried out in left anterior oblique (LAO) 40°, or in left lateral projection as shown in Figure 65.2c. In these projections the ideal septal puncture site corresponds to the midpoint between the pigtail catheter placed in aortic sinus and the spine. The position should also be confirmed in RAO 30° projection (Figure 65.2d).

The procedural technique (see Video 65.1)

The procedure is always performed via a femoral approach with a 8–9 Fr sheath in the femoral vein and a 5 Fr sheath in the femoral artery, with the patient under light sedation. After bolus administration of 1000 U heparin, right heart catheterization is performed. The Mullins sheath is advanced over a 0.032-inch guidewire into the superior vena cava, preferably into left innominate vein. The pigtail catheter is placed in the aortic root in the non-coronary cusp. A standard Brockenbrough needle is then advanced into the Mullins sheath about 2–3 cm short of the tip. It is useful to keep a finger between the base of the Brockenbrough needle and hub of the Mullins sheath to prevent inadvertent advancement of the needle. While most operators attach a 2 mL contrast-filled syringe, preferable with a Luer lock, it is also possible to attach the needle to a pressure transducer. The entire assembly of the Mullins sheath with the needle is then gradually withdrawn in the AP projection under fluoroscopy into the right atrium, taking care that the Brockenbrough needle points at the 4 o'clock position. The assembly first descends from the superior vena cava into the right atrium and then along the thick part of the interatrial septum. The entire assembly is then withdrawn slowly until it reaches the level of the aortic valve. During this manoeuvre, care is taken that needle continues to point at 4 o'clock position. It is then gradually withdrawn further below the level of the aortic valve about half to one vertebral space, to lie along the interatrial septum at the expected location of the fossa ovalis. The position of the needle is then confirmed in RAO 30°, LAO 45° or dead lateral.

In RAO 30°, the interatrial septum is generally enface and the needle tip should point away from the operator, and also the needle should lie posterior and inferior to the plane of the aorta. In the lateral view, the needle should be facing posteriorly toward the spine and should be halfway from pigtail to spine. The needle should not be too low. The position of the needle needs to be confirmed in all three views for a safe and optimal septal puncture. Transesophageal (TEE) or intracardiac echocardiography (ICE) can be useful in identifying the anatomic location of the interatrial septum relative to the right atrium. The septal indentation by Brockenbrough needle guides the intended site of septal puncture. Echocardiography also helps in early detection of complications such as pericardial effusion, perforation, and tamponade. However, in the authors' institution, TEE/ICE is not routinely used during

Figure 65.2 Fluoroscopic landmarks for septal puncture. (a) An imaginary horizontal line is drawn from point T to point L where the line intersects the lateral border of the left atrium. The dotted vertical line crossing the midpoint between T and L is the midline. (b) The M line is obtained using the left ventriculogram with a stop frame RAO view. The target site for septal puncture is located at the intersecting point of the vertical midline and the horizontal M line. (c) Fluoroscopic landmark for septal puncture in LAO projection and (d) in RAO projection.

septal puncture. Transthoracic echocardiography is sufficient in majority of patients with good echo window to guide and confirm site of septal puncture and to recognize early tamponade. A gentle probing in this area may often permit left atrium entry through the stretched fossa ovalis without an actual need for needle puncture.

Successful entry into the left atrium should be confirmed both by recording a left atrial pressure waveform and by withdrawing oxygenated blood or by demonstrating the typical fluoroscopic appearance of the left atrium during a small contrast injection through the needle. Once the catheter is safely placed in the left atrium, heparin (usually 100 U/kg) is administered for anticoagulation. Anticoagulation time is monitored during the procedures to maintain appropriate levels of anticoagulation. Box 65.2 summarizes the steps of the septal puncture procedure.

Dilatation of interatrial septal puncture site

After advancing the Brockenbrough needle, a coiled-tip guidewire is placed into the left atrium through the Brockenbrough sheath. The septal dilator (14 Fr polyethylene tube with a thinner tip 70 cm in length) is advanced over the coiled-tip wire to facilitate the entry of an Inoue balloon catheter.

Box 65.2 Steps of septal puncture

- Step 1 Mullins sheath with Brockenbrough needle positioned in superior vena cava. Pigtail catheter positioned in aorta at the level of aortic valve
- Step 2 Mullins sheath with Brockenbrough needle withdrawn into the right atrium to lie half to one vertebra below the level of the pigtail catheter in AP projection
- Step 3 Brockenbrough needle rotated to 4–5 o'clock position. Optimal position confirmed in AP, RAO, and lateral/LAO projection. (Refer above described fluoroscopic landmarks)
- Step 4 Left atrial (LA) entry by probing around fossa ovalis site with tip of Mullins sheath or septal puncture performed by protruding the Brockenbrough needle slightly beyond the Mullins sheath
- Step 5 Confirm left atrial entry by withdrawal of oxygenated blood, pressure recording showing LA pressure tracing and by contrast injection into LA chamber

Selection of balloon catheter

The most commonly used balloon catheters during BMV are the triple lumen Inoue balloon catheter (Toray International America Inc.) and the double lumen Accura balloon catheter (Vascular Concepts, Halstead, UK). Both Accura and Inoue mitral valvotomy

balloons are effective in providing relief from hemodynamically significant MS in terms of gain in valve area and reduction in transmitral gradient. Both have similar procedural success and complication rates, restenosis, and follow-up events at 1 year [16,17]. A balloon catheter system for accomplishing BMV consists of the following devices: Inoue/Accura balloon catheter, metallic stiffening cannula (18 gauge, 80 cm in length) for stretching and stiffening the Inoue balloon catheter, guidewire for BMV (0.028 inches in diameter, 180 cm in length), dilator (14 Fr polyethylene tube with a thinner tip 70 cm in length) for dilating the puncture site of the femoral vein and atrial septum, and a stylet (wire with J-shaped tip, 0.038 inches in diameter, 80 cm in length) for directing the Inoue balloon toward the mitral orifice.

The balloon diameter size is chosen on the basis of the patient's weight, height, and body surface area. Most commonly, the reference size of the balloon is calculated according to Hung's formula [18]: the patient's height (in cm) is rounded to the nearest zero and divided by 10 and 10 added to the ratio to yield the reference size (in mm), for example, if the patient's height is 158 cm, then reference diameter will be $160/10 + 10 = 26$ mm.

In case of pliable, non-calcified valves with mitral regurgitation of $\leq 1+$, a balloon catheter with a nominal reference size calculated according to Hung's formula can be used. In contrast in patients with high risk features of developing severe MR (valvular calcification, severe subvalvular stenosis, and non-pliable valves), a balloon catheter two size smaller than reference size is selected. However, after each dilatation, echocardiography should be reviewed for new appearance of significant MR or worsening of pre-existing MR before the next inflation.

At the authors' institution, initial inflation is carried out at 2 mm less than the reference diameter and size is upgraded after carefully assessing hemodynamics and MR. The balloon catheter upsizing should be *guided, graded, and gated* to achieve optimal results.

Crossing the mitral valve

In the next step, the Inoue/Accura balloon catheter is advanced over the coiled-tip wire. Once the balloon catheter has crossed the interatrial septum, the catheter should be placed in the left atrium so that the catheter forms a loop with the tip facing toward the mitral valve orifice. Several techniques are described for entering mitral valve: (i) vertical method, (ii) direct method, (iii) sliding method, (iv) posterior loop method, and (v) modified over-the-wire technique. The stylet is inserted in the balloon catheter, and the stylet is given 2–3 anticlockwise rotations so that the balloon catheter with stylet is moved together toward the mitral valve orifice. In RAO view, the deflated Inoue balloon catheter is advanced until the tip of the catheter has crossed the mitral valve into the left ventricle. Once the balloon is close to the valve, a bobbing movement or "woodpecking sign" of the balloon can be observed. Once the balloon catheter is across the valve orifice, a fall in the aortic pressure may be noticed. ECG showing ventricular ectopic indicates that the balloon is in the left ventricle.

Once the balloon catheter has been inserted into the left ventricle, the distal portion of the balloon is inflated with contrast media (diluted 1 : 1) using a specially graduated syringe. The catheter is then pulled until resistance is felt when the balloon catheter aligns across the mitral valve. Once this happens, inflate the balloon fully to expand the proximal part of the balloon. The valve will be stretched and the commissures will give way. Figure 65.3 shows a step-by-step demonstration of the BMV procedure.

During inflation of the balloon, the appearance of a deformed distal balloon (balloon impasse sign/balloon compression sign) suggests entrapment in the subvalvular apparatus as shown in Figure 65.4. In this situation, further inflation should not be performed and the balloon should be repositioned to a location that is more proximal to the mitral orifice to avoid trauma to the subvalvular apparatus.

After each dilatation, the operator should obtain the left atrial pressure through the middle port of the Inoue catheter and the left ventricular pressure through the pigtail catheter simultaneously. If the pressure gradient between the left atrial pressure and the simultaneously obtained left ventricular pressure does not decrease, the balloon size is increased in 1-mm increments until the pressure gradient decreases or substantial worsening of mitral regurgitation occurs. In addition, two-dimensional echocardiographic observations are performed after each dilatation. To assess mitral valve orifice area after each dilatation, planimetry of the valve orifice with two-dimensional echocardiography should be adopted rather than the pressure half-time method on continuous Doppler waveform, because pressure half-time-derived orifice area might be inaccurate in this acute setting [19].

If one of the three following events is encountered—decrease in the pressure gradient between the left atrium and the left ventricle, occurrence of significant mitral regurgitation, or substantial splitting of the commissure—further dilatation is not performed (Box 65.3; Figure 65.5) [20].

BMV in difficult scenarios

BMV in LA/LAA clot

Left atrial thrombus occurs in 3–13% of patients with MS and its presence is generally considered as a contraindication for BMV. Systemic embolization occurs in 0.3–0.8% of patients during or shortly after the procedure and represents a potentially devastating complication. TEE is recommended before the procedure to determine the presence of left atrial thrombus, with specific attention paid to the left atrial appendage. If a thrombus is found, 3 months of anticoagulation with warfarin can result in resolution of the thrombus.

Left atrial thrombus in patients with MS has long been regarded as a contraindication for BMV. In selected patients with MS with left atrial thrombus (types Ia, Ib, and IIa) (Figure 65.6) [21], BMV can be performed safely with the modified over-the-wire technique (Figure 65.7) [22]. Systemic thromboembolism, technical failures, and other complications are very rare when performed by experienced operators.

Our modification of the over-the-wire technique is safe, effective, and does not require any additional accessories. Using this technique, BMV can be performed, even in difficult cases wherein the conventional method of crossing the mitral valve has failed. This technique involves direct positioning of a coiled Inoue wire into the left ventricle through the Mullin sheath followed by introduction of an Inoue catheter over the wire as illustrated in Figure 65.7.

BMV in giant left atrium/interatrial septal aneurysm

The size of the left atrium with or without interatrial septal (IAS) aneurysm has been noted to have a significant influence on outcome as in patients with large left atria, technical difficulties can be encountered in performing the transseptal puncture and crossing the MV orifice. In such situations increasing the curvature of the Brockenbrough needle or probing around the fossa ovalis assists in safe septal puncture. When difficulty is encountered in crossing

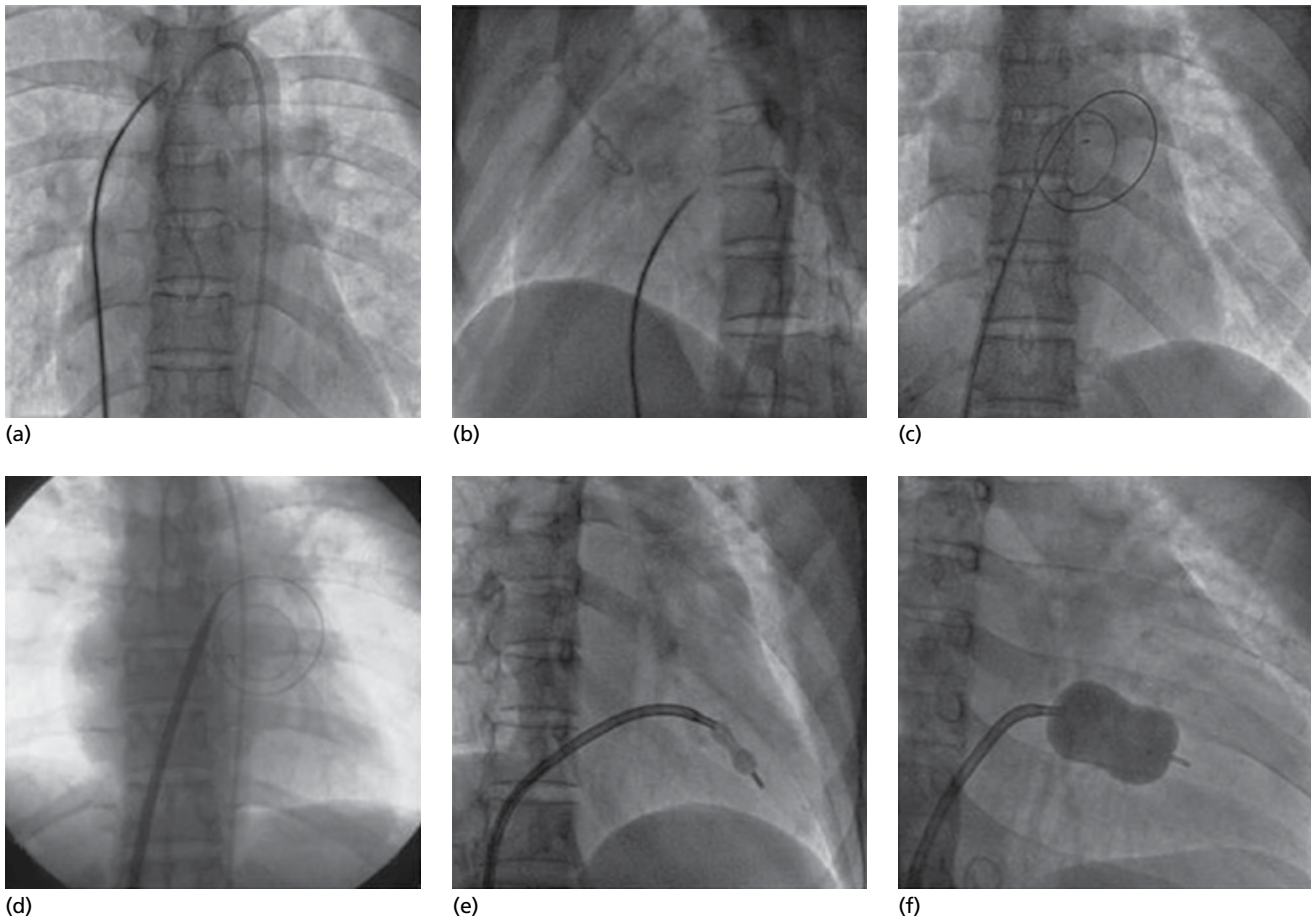

Figure 65.3 Salient steps of balloon mitral valvuloplasty (BMV). (a) Pigtail catheter in aorta; (b) septal puncture using Brockenbrough needle; (c) coiled wire in LA after septal puncture; (d) septal dilatation with 14 Fr dilator; (e) Inoue balloon LA entry assisted with stylet; (f) fully inflated Inoue balloon across mitral valve.

Figure 65.4 Distorted shape of Inoue balloon inside left ventricle showing impasse sign (a) and compression sign (b) suggestive of severe submitral stenosis.

Box 65.3 Definition of successful balloon mitral valvuloplasty

- 1 $\geq 50\%$ increase in the mitral valve area
- 2 Increase in mitral valve area to $\geq 1.5 \text{ cm}^2$
- 3 Significant fall in left atrial pressure and transmitral gradient (Figure 65.5)
- 4 Mitral regurgitation not more than Grade II
- 5 At least one of the commissures is split
- 6 No major complications

Figure 65.5 The images depict simultaneous tracings of pulmonary capillary wedge pressure and left ventricular pressure in a patient with mitral stenosis before and after valvuloplasty. The preprocedural peak transmitral gradient was 24 mmHg and end diastolic gradient was 14 mmHg; post-procedural peak gradient was 4 mmHg and end diastolic gradient was 1 mmHg.

the mitral valve, either changing the shape of the stylet, reverse loop entry, modified over-the-wire technique (Figure 65.7), balloon flotation catheter-assisted entry, or deliberate low septal puncture methods can be used to enter the left ventricle.

BMV in severe subvalvular disease

In severe submitral stenosis, balloon entry into left ventricle can be difficult. Severe subvalvular stenosis can affect immediate procedural results as well as increase the incidence of acute severe MR. Severe subvalvular stenosis also causes difficulty in entering the Inoue balloon into the left ventricle. In such situations, predilating and releasing submitral apparatus stenosis using peripheral angioplasty balloon (short length balloons with 6–8 mm in diameter) facilitates subsequent entry of a 12 Fr Inoue balloon catheter. This can be achieved either through an antegrade or retrograde approach. However, utmost care should be taken not to cause chordal or papillary muscle rupture.

BMV in IVC interruption/IVC anomalies through IJV approach

In the vast majority of patients, BMV can be successfully performed using femoral venous access; however, certain congenital or acquired anomalies of the inferior vena cava (IVC) or iliofemoral veins preclude this option and necessitate the use of alternative access

routes. The transjugular approach to transseptal BMV is a useful alternative in patients with venous anomalies that preclude the conventional femoral venous approach. Landmarks for septal puncture are derived from Inoue's angiographic method in frontal projection. Alternatively, levophase injection of pulmonary arteriogram can be utilized to delineate the interatrial septum. The appropriate site of septal puncture is 2 cm below the left atrial roof. Deliberate high atrial puncture facilitates balloon crossing into the left ventricle in jugular approach. However, very high puncture should be avoided because it is associated with high incidence of cardiac tamponade. If the septal puncture is low or at fossa ovalis, the over-the-wire technique can be helpful in delivering the balloon through the mitral valve orifice. Other than a Inoue balloon, a single balloon technique can be applied for mitral valve dilatation. The procedure-related complications, including cardiac tamponade, emergency surgery, acute severe MR, and embolization, are similar to the transfemoral approach. However, the transjugular approach is technically challenging but can be considered as an alternative to the femoral approach when the anatomic variations warrant it.

BMV in juvenile mitral stenosis

In comparison with adults, children and adolescents with rheumatic mitral stenosis more often have severe pulmonary hypertension and very high transmitral gradient but less often have atrial fibrillation

and left atrial dilatation. Although the mitral valves in these younger patients are typically more pliable, with less calcification and lower echocardiographic scores than in older populations [23,24] we frequently encounter young patients with mitral stenosis who have severe subvalvular disease and grossly thickened leaflets, indicative of the fulminant course of the disease in this population.

Careful attention to procedural details—use of a balloon diameter smaller than the typically recommended size, stepwise increases in balloon diameter, meticulous pressure gradient measurement, and watch for MR after each dilatation—is important in these young patients. BMV in young patients is effective, safe, and provides better immediate results than in adults particularly with regard to acute complications. Although indexed MVA was larger than in adults, freedom from restenosis and from clinical events at 10 years was no different from adult populations [25].

BMV in pregnancy

The majority of patients with moderate to severe MS worsen during pregnancy because of increased intravascular volume and increases in heart rate. Symptoms occur in 25% of patients, become apparent by 20 weeks' gestation, and aggravate at the time of labor and delivery. Without intervention, maternal mortality is significantly higher (6.8%) for those in NYHA Classes III and IV, particularly during labor and delivery [26]. Optimal timing of BMV is the end of the second trimester or the beginning of the third trimester during which radiation risk to the fetus is negligible.

BMV should be performed by experienced operators with abdominal and pelvic shielding and with minimum radiation exposure and should be avoided during the first trimester. With these precautions, BMV can be safely performed in pregnancy. Esteves *et al.* [27] reported optimal immediate and long-term results in pregnant patients who underwent BMV during the second trimester of their pregnancy.

Complications of BMV

Most of the adverse complications relevant to this procedure occur during the procedure (i.e., during the process of interatrial septum puncture, manipulation of the Inoue balloon catheter in the left atrium, and commissurotomy of the mitral valve by Inoue balloon catheter). Major complications with regard to the Brockenbrough

puncture are related to penetration of the Brockenbrough needle into the adjacent structure (i.e., ascending aorta and the post-atrium pericardial space). Procedural mortality is in the range of 0–3% in most series. Table 65.2 lists complications during BMV.

Pericardial effusion and tamponade

The most common serious complication is hemopericardium, with an incidence of 0–2.0% [28]. When hemopericardium or rupture into the space surrounding the aortic root occurs, protamine sulfate should be administered to promote spontaneous hemostasis unless urgent surgical intervention is necessary.

Although relatively rare, unintended perforation by the tip of the Inoue catheter or guidewires while being manipulated in the cardiac chambers might occur in the left atrial appendage, the pulmonary veins, or the left ventricular apex because of the vulnerability of these structures.

When hemopericardium or rupture into the space surrounding the aortic root occurs, protamine sulfate should be administered to promote spontaneous hemostasis unless urgent surgical intervention is necessary.

Acute mitral regurgitation

An increase in mitral regurgitation is another possible complication after commissurotomy; however, in most cases, the degree of mitral regurgitation slightly increases after BMV without requiring surgical intervention. The mechanism of the increase or new appearance of mitral regurgitation is reported to be excessive tearing of the commissure(s) or the posterior/anterior leaflet at non-commissural part, incomplete closure of a calcified leaflet, and localized rupture of the subvalvular apparatus. The mechanism of post-BMV mitral regurgitation is reported to be closely related to long-term prognosis. Severe mitral regurgitation is relatively rare, with a frequency ranging from 1.3% to 19% in different series [29–32]. Surgical findings [29,33] suggest that this complication is related to non-commissural tearing of the posterior or anterior leaflet and chordal rupture. Additionally, with significant asymmetric commissural calcification, the non-calcified commissure can tear, causing severe MR.

The incidence of acute severe MR following BMV in our study is 1.3% [29]. Clinically, hypotension and hypoxia are the predominant manifestations of acute severe MR. Anterior mitral leaflet tear is the most common cause for severe MR (Figure 65.8). The severity of submitral disease which is underestimated by 2D-TTE appears to

Table 65.2 Complications during balloon mitral valvuloplasty

Complications	Incidence (%)	Management
Pericardial effusion/tamponade	0.5–12.0	1. Pericardiocentesis 2. Reversal of heparin with protamine 3. Autotransfusion 4. BMV through second puncture to reduce LA pressure 5. Surgical closure of perforation when conservative strategy fails
Acute severe MR requiring surgery	0.9–2.0	Early MVR, preferably within 24 hours, is recommended for optimal outcome
Acute embolism or stroke	0.5–5.0	Conservative management ? Intra-arterial lysis
Residual atrial septal defect	At 48 hours: 60–70 At 6 months: 8–10	Conservative in almost all cases

BMV, balloon mitral valvuloplasty; LA, left atrium; MR, mitral regurgitation; MVR, mitral valve replacement.

Figure 65.8 Transthoracic echocardiography showing post BMV anterior mitral leaflet tear and severe mitral regurgitation.

be one of the important risk factors predisposing to severe MR. A strategy of early MVR, preferably within 24 hours of onset of severe MR, is recommended for optimal outcome.

Stroke and embolism

Detachment of undetected microthrombi in the left atrium or left atrial appendage by the catheter or guidewire tip can occasionally occur. To avoid these mechanical complications, gentle manipulation of the guidewires and catheters are required, and the Inoue catheter should be formed using the stylet, with the tip of the catheter properly directed toward the mitral valve orifice.

The frequency of embolic events related to mitral valvuloplasty is in the range of 0.5–5.0%. On rare occasions, such events cause of permanent severe disability and even death. In view of the severe potential consequences of this complication, it is critical for the operators to take all possible precautions to prevent it.

Residual atrial septal defect

The frequency of atrial septal defects after mitral valvuloplasty is in the range of 10–90% in different series. These are typically small and restrictive shunts. Significant right-to-left shunts occur on rare occasions in patients who had pulmonary hypertension and elevated right heart pressures. In our study [34], incidence of residual atrial septal defect within 48 hour of percutaneous transmitral commissurotomy (PTMC) by TEE color flow Doppler imaging is 66.5%. These defects are hemodynamically significant only in 4.3% of patients. Surrogate markers of elevated left atrial pressures do not determine the development of atrial septal defect after PTMC. Most of the defects close spontaneously and a residual defect is observed in 8.7% patients at 6 months.

Results of BMV

Immediate results

The binary endpoint of immediate procedural success is most often a final valve area $>1.50\text{ cm}^2$ without moderate or severe mitral regurgitation. After BMV, mitral valve area approximately

doubles in most successful cases. Mitral valve anatomy as assessed by two-dimensional echocardiography is a strong predictor of the immediate results of BMV. The previously described Wilkins score has a discriminant cut-off point of 8 according to analyses of the immediate results of BMV. Whatever echocardiographic scoring system is used, older age, smaller valve area, previous commissurotomy, or baseline mitral regurgitation should be considered as potential predictors for poor immediate outcome with a similar predictive strength as valve calcification [30]. In clinical practice, young patients (<50 years) with favorable valve anatomy have usually shown particularly good immediate results [35,36].

Long-term results

Most patients with initial procedural success report significant functional improvement. When immediate results are suboptimal, the patient's functional status does not improve or improves only transiently.

The best results of BMV are observed in young patients who have MS with favorable anatomic characteristics (i.e., pliable non-calcified valves and moderate impairment of the subvalvular apparatus). Published series from India and Tunisia have clearly demonstrated the safety and efficacy of BMV in such patients [37,38]. After BMV, at least 90% of patients are alive without intervention on the mitral valve and with few or no symptoms 5–7 years after the procedure. Randomized trials conducted in these young populations show that 3- and 7-year results after BMV are as good as those obtained with open-heart commissurotomy and better than those with closed-heart commissurotomy.

Suboptimal immediate results lead to relatively early intervention, which explains the presence of an early drop in event-free survival rates after the procedure. Post-BMV mitral restenosis is defined as a valve area $<1.5\text{ cm}^2$ or a $>50\%$ loss of the initial gain in valve area [39]. The incidence of restenosis after a successful procedure ranges from 2% to 40% in different studies, at time intervals ranging from 3 to 10 years. Reportedly, the freedom from restenosis rates were 85% at 5 years, 70% at 10 years, and 44% at 15 years and were significantly higher (i.e., 92% at 5 years,

85% at 10 years, and 65% at 15 years) for patients with optimal morphology [40,41]. Depending on the anatomy, restenosis can be treated either with repeat MBV or with surgical mitral valve replacement. Repeat BMV should be proposed as first-line therapy if the patient had symptoms related to MS and showed only mild mitral regurgitation based on the observational evidence that the mechanism of mitral restenosis is primarily commissural refusion.

Conclusions

Although the incidence of rheumatic fever and the prevalence of rheumatic heart disease as sequelae are decreasing in most Asian countries, a small but substantial occurrence of rheumatic MS exists in Asia. Since its introduction, percutaneous mitral commissurotomy has demonstrated good immediate and mid-term results and has replaced surgical mitral commissurotomy as the preferred treatment of rheumatic MS in appropriate candidates. Adequate understanding of indications, BMV procedures, complications, and assessment of results are key factors.

Advancement within interventional cardiology hinges upon the continued development of less invasive procedures that aim to achieve the same efficacy as primary surgical repair. This continuous pursuit, obstacle identification, and further innovation is perhaps best exemplified by the progressive advancement of pulmonary artery and valve-based interventions.

Pulmonary artery and pulmonary valve stenosis are common features of many forms of congenital heart disease. Each results in the elevation of right ventricular pressure, right ventricular hypertrophy, and eventually right ventricular dilatation and failure. Previously, surgical valvotomy had been the sole option to relieve these forms of obstruction. However, the development of pulmonary balloon valvuloplasty, over three decades ago, provided an alternative that avoided cardiopulmonary bypass and has now replaced surgical repair as the preferred intervention.

Yet it is essential to recognize that valvuloplasty is not without its own disadvantages. It is understood that in relieving stenosis the dilatation inherently causes damage to the valve leaflets and can result in a degree of pulmonary regurgitation. Previously, a significant degree of pulmonary regurgitation was deemed an expected and acceptable outcome of the procedure. Such was also the case for patients with tetralogy of Fallot who had undergone transannular patching. However, as significantly more patients are surviving and thriving to adulthood, the resultant consequences have become more apparent and in turn less acceptable. Now these patients require further intervention to address the right ventricular overload, ventricular dysfunction, and ventricular arrhythmias caused by their pulmonary regurgitation. Until just over a decade ago, surgical reintervention had remained the sole treatment option available. However, the advent of transcatheter pulmonary valve replacement (TPVR) has become a realistic alternative.

This chapter details the indications, complications, and outcomes of the primary catheter-based interventions of the right ventricular outflow tract, the pulmonary valve, and the pulmonary arteries.

Balloon pulmonary artery angioplasty

Pulmonary artery stenosis occurs both as a feature of congenital heart disease as well as a sequela of its repair. Typically, congenital pulmonary artery stenosis occurs in conjunction with pulmonary

valve stenosis, ventricular septal defects, and tetralogy of Fallot. There is also a well-established association with multiple genetic syndromes including Williams syndrome, Noonan syndrome, Alagille syndrome, and Ehlers–Danlos syndrome.

Alternatively, acquired stenosis occurs as a result of scarring at sites of surgical intervention. Some of the most common sites are at the point of conduit insertion, along the surgical connection of an aortopulmonary shunt, following arterial switch operation for transposition of the great arteries, and after placement of pulmonary bands to control excessive pulmonary blood flow [1].

Indications

Branch pulmonary artery stenosis is the most common indication for balloon angioplasty in pediatric patients. Angioplasty can acutely relieve significant areas of stenosis; however, there are high rates of recurrence in these stenotic regions [2]. Therefore, balloon angioplasty without stent implantation is typically reserved for severe stenosis in very small patients who require prompt intervention or patients with complex arterial anatomy. More satisfactory results can be obtained with the use of cutting balloons.

The primary indications for angioplasty in patients with stenosis based on recent pediatric interventional guidelines are:

- Measurable gradient greater than 20–30 mmHg across the stenosis;
- Right ventricular pressure greater than 50% systemic;
- Evidence of right ventricular failure; and
- Relative flow discrepancy of less than 35%/65% between lungs [3].

While these criteria appear clear and succinct there are frequently difficulties in assessing the gradient across stenotic segments. In some patient cohorts, particularly those with Glenn and Fontan physiology, significant pressure gradients do not exist and therefore angiographic assessment of the relative narrowing is also important. Three-dimensional rotational angiography can prove beneficial in achieving a complete evaluation of the vessel diameter and thus guiding intervention [4].

Procedural technique

Access is typically achieved through the femoral vein and a guide-wire is then advanced through the right heart into the pulmonary arteries, and beyond the area of stenosis. Angiography and accurate vessel measurements can be performed prior to this or following

good wire placement with a multitrack catheter. The chosen balloon catheter should be approximately 3–4 times the diameter of the stenotic vessel but not more than 2 mm greater than the diameter of the adjacent normal vessel. In order to achieve a successful dilatation there must be a degree of tearing of the intima of the vessel. For this reason, it is imperative to inflate to a high enough pressure to remove the waist, as lesser pressures are associated with a significantly higher rate of recurrence [2,5].

Generally, a longer sheath is advisable when using cutting balloons. The microtomes of the device score the vessel wall and in doing so disrupt the fibrous connections contributing to stenosis and can cause damage to surrounding structures when removed. The cutting balloon diameter should not exceed the normal vessel diameter in order to minimize risk for vessel rupture [6,7]. In larger children with severe localized stenosis the cutting balloon diameter can be smaller than the normal vessel diameter and can be followed with a high pressure balloon for maximum effect. Each balloon dilatation attempt should be followed by angiography to ensure there is no vessel wall damage.

Complications

Typically, the pulmonary arteries are extremely compliant vessels and are able to tolerate dilatation to greater than three times their stenotic diameter. As previously noted, though, successful dilatation hinges on causing controlled damage to the intima of the vessels. Segments of stenosis, both congenital and iatrogenic, represent areas of abnormal tissue that are inherently less compliant and therefore at increased risk of rupture. Pulmonary vessel rupture can cause a hemothorax and, depending on the severity of the injury and bleeding, can lead to death [8].

Outcomes

Balloon angioplasty typically results in excellent acute improvement with up to a 50% increase in vessel diameter and a 50% decrease in gradient. However, because of the high frequency of restenosis, balloon angioplasty alone often does not provide long-term benefit without the use of an endovascular stent [4,8].

A multicenter prospective randomized trial comparing the use of high-pressure balloon dilatation with cutting balloon devices found the latter to demonstrate superior efficacy. In each case, an attempt was made to dilate the vessel using a low-pressure balloon (<8 atm). In the event this did not eliminate the waist (71% of attempts), either cutting balloon deployment followed by repeat low-pressure balloon dilatation or high-pressure balloon dilatation (15–22 atm) was performed. Cutting balloon dilatation resulted in an improvement in vessel diameter by 85% compared with only 52% in the high-pressure arm [7]. There were no serious adverse events and the authors concluded that cutting balloon therapy is more effective than high-pressure balloon angioplasty for pulmonary artery stenosis not responsive to low pressure balloons.

Pulmonary artery endovascular stenting

Indications

The primary indications for endovascular stent placement are the same as those for pulmonary artery balloon angioplasty with the addition that balloon angioplasty alone has not or likely will not provide an adequate response. Ideal stent placement occurs when the child's vessels are large enough to accommodate a stent with adult-sized potential, which is usually not feasible in neonates and small infants. Thus, endovascular stenting in these patients

should be reserved for patients requiring urgent intervention when angioplasty, including the use of cutting balloons, has not provided adequate relief.

Procedural technique

Venous access is achieved in a similar fashion to balloon angioplasty and a catheter is advanced to the pulmonary arteries. Good wire position is vital and, once achieved, a long sheath is advanced across the stenosis to ensure the stent will pass freely across the stenosis. Stent advancement without the use of a long sheath has been described in smaller children [9]; however, there is a risk of the stent migrating from the balloon during advancement with this approach. Adequate stent crimping over an appropriate-sized balloon can mitigate against stent movement off the balloon when advancing through the longer sheath. When the stent is in correct position, as confirmed by angiograms through the side-arm of the long sheath, the delivery sheath is fully retracted from the balloon, the balloon is inflated, and the stent is fixed within the vessel. This technique is utilized to deliver single, tandem, or bifurcating stents.

Unlike balloon angioplasty, dilatation beyond the desired vessel diameter is typically unnecessary, as the stent will provide the required support upon deflation of the delivery balloon. Similarly, pre-dilatation of the stenotic region is typically unnecessary except for a few specific circumstances. The primary indication for pre-dilatation is that the degree of stenosis is so significant that the sheath and delivery catheter cannot be advanced beyond the affected area [3].

Small patients, refractory to balloon angioplasty, are challenging because the smaller caliber of their vessels may not tolerate the necessary larger, stiffer catheters. In this circumstance the use of a pre-mounted stent can be preferable as it precludes the need for a longer sheath and provides a significant degree of flexibility [10]. An evolving number of lower profile pre-mounted stents that are dilatation to 5–18 mm are now available and are very attractive for use in this circumstance [11,12].

Complications

The implantation of endovascular stents requires larger, stiffer guidewires and delivery systems, thus increasing the risk for vascular damage. Damage to the intima may be reduced as there is more support for the vessel wall with less need for over-dilatation and hence less risk for artery rupture [13]. Either way, it is advisable to have a covered stent available for use should arterial damage be encountered.

Many of the primary complications associated with endovascular stent placement focus on stent migration and poor positioning following placement. In the event that the stent is improperly sized, the stent can undergo embolization in a retrograde fashion to the main pulmonary artery or the right ventricle [13].

Outcomes

The outcomes of stent implantation for pulmonary artery stenosis have been quite good. Significant restenosis of single vessel pulmonary artery stents occurs in less than 7% of patients [13]. There are typically two primary mechanisms by which restenosis of the vessel occurs. The first is the continued growth of the patient and their vasculature as the stent itself remains fixed. In these cases, redilatation of the stent has proven to be safe and effectively reduces the gradient [14]. The second is intimal hyperplasia, particularly at the edges of stents or areas of overlap. The rates of restenosis secondary to intimal hyperplasia have declined with continued experience and

associated attempts to avoid stent overlap and severe angulation between the vessel wall and stent [15].

Pulmonary artery stenting has also proven effective in adults with congenital heart disease. Typically, these patients require bilateral or multiple stents. One retrospective study demonstrated a reduction in mean systolic gradient from 24 to 3 mmHg [16].

Balloon pulmonary valvuloplasty

Pulmonary valvular stenosis is a common feature of a wide array of congenital heart diseases which can present in a plethora of fashions. Patients with mild to moderate obstruction often remain asymptomatic until adolescence at which point they begin to develop exercise intolerance, as their right ventricular output can no longer compensate for their increased demands. Occasionally, mild–moderate stenosis improves through childhood and does not require intervention. Alternatively, critical pulmonary stenosis causes significant cyanosis in the neonatal period, and patients are dependent upon a patent ductus arteriosus to provide adequate pulmonary blood flow. Regardless of the severity of the obstruction, balloon valvuloplasty has become the treatment of choice for valvular pulmonary stenosis [17].

Indications

Balloon pulmonary valvuloplasty is indicated for any symptomatic patient following diagnosis of valvar stenosis. Timing is particularly important for neonates with critical stenosis as these patients are typically maintained on prostaglandin infusions to ensure patency of the ductus arteriosus.

Indications for intervention in asymptomatic patients are customarily guided by their degree of obstruction on echocardiogram or resting gradients across the valve during diagnostic catheterization. Typically, a peak instantaneous gradient of 40 mmHg or right ventricular systolic pressures greater than 50% systemic on echocardiogram serve as sufficient criteria to pursue intervention [18].

It is important to note that transcatheter valvotomy and valvuloplasty are contraindicated in patients with right ventricle dependent coronary circulation, in the setting of pulmonary atresia with intact ventricular septum, as these patients have been noted to have significantly higher mortality [19].

Procedural technique

Following assessment of the pressure gradient and right ventricular angiography to evaluate the annular diameter, a guidewire is placed into one of the branch pulmonary arteries. An appropriately sized balloon catheter is placed over the wire and advanced to the mid-point of the valvular obstruction. The balloon is fully inflated, assessing for disappearance of the waist. Following dilatation, the gradient across the valve should be reassessed, with success considered improvement to less than 30 mmHg.

Generally accepted recommendations advocate the use of devices with a balloon to annulus ratio of 1.2–1.4 : 1 in children [3,20]. Inflation of the balloon effectively separates the inappropriately fused valve cusps, thus reducing the degree of stenosis. However, by rupturing the fused cusps, the procedure also inherently places the patient at risk of developing or worsening valvular regurgitation. To minimize the risk and degree of regurgitation, certain groups have recommended balloon selection with a ratio closer to 1.2–1.25 [21]. In neonates with critical pulmonary stenosis, a balloon to annulus ratio closer to 1 : 1 may be preferable.

Balloon pulmonary valvuloplasty has also been effectively utilized in adult patients. Balloon diameter selection is more challenging in adults, as there are significantly fewer data available. Best available data suggest that balloon diameter approximately 1 mm larger than the annulus is effective [22,23]. In larger patients, achieving a balloon diameter of this size with conventional balloons has often necessitated the use of double and triple balloon techniques. However, the introduction of Inoue balloons has provided an effective alternative, permitting single balloon dilatation [23].

Complications

Pulmonary artery tears, rupture of tricuspid valve papillary muscles, and right ventricular outflow tract rupture have all been documented; however, all have decreased significantly in frequency with continued experience and improvement in device technology.

Hypertrophy of the infundibulum is a common response to pulmonary stenosis. Therefore, not unexpectedly, the incidence of infundibular obstruction following the procedure remains high, occurring in approximately 30% of cases [24]. With time, the hypertrophy decreases and the degree of obstruction abates. However, if the gradient across the right ventricular outflow tract (RVOT) is greater than 50 mmHg acutely following intervention, patients transiently require beta-blockade to augment right ventricular output [24].

Outcomes

Large studies of pulmonary valvuloplasty have routinely demonstrated effective relief of pulmonary stenosis. A study of 533 patients found that of those with normal valve morphology, 85% maintained a gradient <36 mmHg and were free from reintervention during a median follow-up of 33 months. Results were less impressive for patients found to have dysplastic valve morphology, with only 65% demonstrating a similar outcome [25]. These findings have been consistent across studies and have been notably less successful in patients with Noonan syndrome who classically exhibit thickened, dysplastic valve leaflets. However, given the relative low rate of severe complications compared with surgical repair, valvuloplasty is still typically attempted [26].

Expansion of the balloon across the patient's annulus intrinsically increases the risk of developing pulmonary regurgitation with an incidence of 10–40% [27]. A study of 41 patients who had undergone balloon valvuloplasty for isolated valvar pulmonary stenosis utilized cardiac magnetic resonance imaging (MRI) and exercise testing to assess the degree and effect of valvar insufficiency at a median follow-up of 13 years. Based on cardiac MRI findings, 34% of patient had a regurgitant fraction >15%, 10% of patients had a fraction >30%, and 5% with a fraction >40%. This study excluded individuals with other forms of congenital heart disease, those with residual valvar stenosis, and those requiring interim valve replacements. However, it suggests that while valvar insufficiency following balloon dilatation is prevalent and more likely when larger balloon to annulus ratios are used, the frequency of severe regurgitation may not be as high as previously assumed [28].

Right ventricular outflow tract stenting

Neonates with tetralogy of Fallot present a unique challenge as they classically demonstrate an anterior and cephalad deviation of their infundibular septum, producing a muscular subvalvar narrowing. Combined with infundibular hypertrophy, this can result in severe RVOT obstruction. These patients will inevitably require definitive

surgical repair; however, delaying surgical intervention until the patient is 3–4 months of age has been associated with improved clinical outcomes [29]. Therefore, the goal of immediate therapy is to reduce the patient's obstruction, improve pulmonary blood flow, and in turn stimulate catch-up growth of their hypoplastic pulmonary arteries.

In those patients with severe RVOT obstruction, options to restore adequate pulmonary artery blood flow include a systemic to pulmonary artery (modified Blalock–Taussig) shunt or a complete neonatal repair. A review of the Society of Thoracic Surgeons Database revealed that both are associated with relatively high mortality rates, 6.2% and 7.8%, respectively, during the first month of life [29]. Stenting of the RVOT can provide a significant reduction in cyanosis and allow time for pulmonary artery growth prior to surgical repair.

Indications

RVOT stenting is indicated in patients with severely narrowed RVOT causing profound desaturations and in those requiring continuous prostaglandin infusion to maintain adequate pulmonary blood flow. At this time there are no consensus guidelines that establish criteria for intervention.

Procedural technique

Biplane angiography of the right ventricle is utilized to better define the patient's underlying anatomy and extent of RVOT obstruction. Pre-dilatation of the pulmonary valve with balloon valvuloplasty can be performed to improve ease of access across the valve. The use of a guidewire with markers is helpful given the likelihood of foreshortening in standard angiographic projections leading to potential underestimation of the length of obstruction. Either a pre-mounted coronary or peripheral vascular stent can be deployed depending on the patient's size. Peripheral vascular stents provide the benefit of potential for progressive dilatation as the child grows, whereas the maximal diameter of coronary stents is inherently limited.

Ideally, the stent is not placed across the pulmonary valve so as to avoid or minimize pulmonary regurgitation. However, in the event this is not possible relief of RVOT obstruction is preferable. Placement of a stent across the pulmonic valve produces the same physiology as a non-valved right ventricle to pulmonary artery conduit, which is generally well tolerated prior to definitive surgical repair. In the event that the stent does not cross the pulmonary valve, simultaneous balloon valvuloplasty addresses the fact that obstruction is typically seen at multiple levels of the right ventricle.

Complications

RVOT stenting carries with it a risk profile similar to other stent-related interventions. Specifically, patients can experience perforation of the pulmonary artery or RVOT with associated hemopericardium, cardiac tamponade, and death. Another significant risk is the dislodgement of the stent with possible embolization. For this reason close attention should be paid to appropriately sizing the device prior to deployment. Finally, RVOT stenting carries the theoretical risk of coronary compression and thus this must be considered when evaluating these patients.

Of note, multiple small to medium-sized case studies have demonstrated complication rates less than those associated with a Blalock–Taussig shunt [30–32], therefore suggesting that RVOT stenting should be considered the preferred first step in palliation.

Outcomes

Effective stenting of the RVOT in neonates with significant desaturations has demonstrated significant improvement in oxygen saturation, pulmonary blood flow, pulmonary artery growth, and delay to definitive surgical repair. A study of 55 patients demonstrated a median improvement in oxygen saturation of 20% following intervention and the ability to remove all but one patient (11 of 12) from continuous prostaglandin infusion [30]. Perhaps even more importantly, given the implications for surgical repair, is that stenting improved median pulmonary artery Z scores by 2 [30,31]. Subsequent surgical repair has not been shown to be associated with significant morbidity as a consequence of the pre-existing stent.

Transcatheter pulmonary valve implantation

As detailed throughout this chapter there are a multitude of congenital and acquired abnormalities of the pulmonary valve, which eventually necessitate surgical replacement of the valve. The three types of valves typically utilized for surgical replacement are homografts from cadavers, valved conduits, or bioprosthetic valves implanted directly in the RVOT [3], the choice of which is dictated by the patient's size and the nature of the RVOT disease. In each case, the typical mechanism of non-native valve failure is caused by progressive stenosis of the valve with or without concomitant insufficiency. The primary mechanisms contributing to failure are a combination of external compression, internal calcification, development of fibrotic intimal peel, and patient outgrowth [33]. The combination of these factors necessitates reintervention of conduits in about 25% of smaller patients by approximately 4–5 years after homograft placement [34]. In an effort to address this, balloon dilatation of the conduit has been performed, but has demonstrated minimal improvement in the long-term utility of the conduit [35]. Following this failure, RVOT stent implantation across the valve was employed, thus reducing the degree of stenosis but permitting free regurgitation. This strategy has been shown to postpone surgical repair [36]; however, it places the patient at significant risk of right ventricular dilatation and progressive failure. Most recently, the development of a pulmonary valve that can be deployed via catheterization has effectively produced a reduction in both stenosis and regurgitation across the valve. In doing so, tPVR has reduced right ventricular pressures, improved biventricular function, and reduced arrhythmogenic electrical remodeling, thus becoming the therapy of choice for repair of stenotic RVOT conduits. With evolving technology, tPVR may also soon compete with surgical valve replacement for chronic severe native outflow regurgitation.

Indications

Given the relatively recent development and utilization of tPVR, precise indications for and timing of intervention have yet to be firmly established. Theoretically, ideal timing is prior to the point at which replacement of a competent valve can no longer re-establish normalization of ventricular volumes and function. Consensus guidelines for intervention in pediatric cardiac disease advocate use in patients with a right ventricle to pulmonary conduit and associated moderate to severe pulmonary regurgitation or stenosis, provided the patient meets inclusion and exclusion criteria for the available valve (Melody™; Medtronic, Minneapolis, MN, USA and SAPIEN™; Edwards Lifesciences LLC, Irvine, CA, USA) [3]. The Melody trial also included a mean RVOT gradient of ≥ 35 mmHg as

an indication to intervene [37]. As a source of comparison, surgical guidelines suggest that surgical replacement is typically indicated for patients with a right ventricular end diastolic volume (RVEDV) greater than 150 mL/m² on cardiac MRI [38]. These guidelines reflect the different cohort of patients with predominant pulmonary regurgitation that are usually assessed for surgical valve replacement. In each case, cardiac MRI provides accurate assessments of ventricular volumes, function, and regurgitant fraction. However, MRI is time-consuming, uncomfortable for patients, and may require sedation in young patients with tenuous ventricular function.

As a result of these disadvantages of cardiac MRI, the US Melody clinical trial investigated the reliability and accuracy of right heart evaluation via echocardiography and the results were striking. Assessment of RVOT obstruction with Doppler echocardiography correlates closely with gradient evaluation by catheterization and three-point severity scale assessment of valve regurgitation was consistent with cardiac MRI derived regurgitant fraction. Perhaps most notably, patients with an indexed apical diastolic area >30 cm²/m² by echocardiography correlated extremely well with patients with RVEDV >160 mL/m² by cardiac MRI. These results suggest that echocardiography, a significantly less cumbersome imaging modality, can be utilized as a screening modality for tPVR candidates [37]. The primary limitations of echocardiography in this setting are that it does not provide detailed imaging of the RVOT and branch pulmonary arteries, assessment of the degree of conduit calcification, or adequate evaluation of the relationship of coronary arteries to the conduit. However, in this setting cardiac computed tomography (CT) has the capacity to provide superior temporal and spatial resolution than cardiac MRI for these indices.

In addition to the degree of conduit dysfunction and right ventricular dysfunction, increased propensity for arrhythmia also guides intervention with tPVR. Significant pulmonary valve regurgitation that results in right ventricular dilatation also produces a significant degree of electrical remodeling and in turn an increased propensity for ventricular arrhythmias. A 10-year follow-up demonstrated that a prolonged QRS duration >180ms is associated with a 42-fold increased risk of developing sustained ventricular tachycardia and a 2.2-fold increased risk of sudden cardiac death [39]. With resolution of significant pulmonary regurgitation, tPVR has been demonstrated to reduce QRS duration [40], and in doing so reduce the risk of ventricular arrhythmia and sudden cardiac death.

Procedural technique

Prior to intervention it is imperative to assess the proximity of the coronary vessels to the RVOT, as coronary compression is a well-documented complication reported in approximately 4% of cases [41]. Once this relationship is established, pre-stenting of the conduit should be performed. Pre-stenting of the conduit serves to minimize the degree of residual stenosis as well as decrease the rate of stent fracture, seen predominantly with the Melody valve [42].

Once coronary assessment and pre-stenting is completed, tPVR proceeds with one of two currently available valves. Delivery of each valve requires a delivery sheath that is at least 22 Fr, although refinements in SAPIEN valve technology and delivery sheaths for transcatheter aortic valve replacement can benefit those requiring tPVR. The significant sheath size requirement has precluded the use of transfemoral access in smaller patients (typically <30 kg). In such cases, access through the internal jugular vein or via a right ventricular free wall approach can be utilized [43].

The Melody valve is a bovine jugular vein sewn inside a Cheatham-Platinum stent that is hand-cripped onto a balloon-in-balloon angioplasty balloon catheter. The valve's companion delivery system, the Ensemble delivery system, and Melody valve are introduced into the access vein and advanced to the RVOT. When proper placement has been achieved, the inner and then outer balloon system are inflated, thus securing the valve in place (Figure 66.1). Alternatively, the SAPIEN valve is formed from an arrangement of three bovine pericardial leaflets sewn inside a stainless steel stent. The valve is crimped onto the delivery balloon by a crimper and then advanced in a similar fashion. In both cases, wire position and stiffness are vital to creating enough, but not too much, support to advance the large and stiff valve system around the right heart.

The newer Edwards valve, SAPIEN XT, made of cobalt chromium, and new delivery catheter, NovaFlex, can be inserted via a larger 18–20 Fr expandable sheath (eSheath).

Complications

The complications associated with tPVR can be divided into those seen peri-procedurally and those seen commonly at follow-up. First, conduit rupture has been documented as a consequence of balloon dilatation of the homograft during pre-stenting [44]. Such cases typically occur as a consequence of dilatation of severely calcified homografts with significantly reduced compliance, although the exact mechanisms are unclear and hence deciphering a risk profile for each patient has not been possible to date. Balloon dilatation of the RVOT is essential to assess for potential coronary artery compression. This assessment is often one of the subtlest yet most important aspects of the procedure, as one must decide how aggressive to be in relation to ruling out coronary compression. In either case, it is imperative to have covered stents available to address potential conduit rupture [45].

Following deployment of the new valve, patients may demonstrate valve dislodgement and resultant device embolization. The valve typically embolizes in a retrograde fashion to the right ventricle where percutaneous retrieval is possible though technically challenging. In the event percutaneous retrieval is not feasible, the stent must then be retrieved surgically [46]. Finally, coronary artery compression is a complication that can be avoided with adequate pre-intervention surveillance. The importance of monitoring is reiterated by the fact that US Melody cohort study demonstrated that 4.4% of included patients demonstrated unfavorable coronary anatomy [47].

Following intervention, the most common complication and indication for reintervention is stent fracture. The incidence of stent fracture with the Melody valve has been quite significant, with documented incidence as high as 22% [44,47]. Stent fracture can result in the recurrence of significant RVOT obstruction and resultant elevation in right ventricular pressures. However, a more recent study with a pre-stenting of 95% demonstrated a stent fracture rate of less than 5% [48], suggesting that this measure is able to significantly reduce this troubling complication. Endocarditis, particularly with the Melody valve, is also a concern. Close observation of the true rates of endocarditis is warranted.

Outcomes

Post-procedural evaluation of both the Melody and SAPIEN valves has demonstrated significant reduction in indicators of pulmonary valve dysfunction with low rates of morbidity and valve failure. Lurz *et al.* [44] demonstrated improvement in right ventricle to pulmonary artery gradient from a mean of 37 to 17 mmHg and right ventricle systolic pressure from 63 to 45 mmHg with the use of the

Figure 66.1 Fluoroscopic images demonstrating implantation of Melody® valve (Antero-posterior view, capital letters; lateral views, lowercase). A: Angiography distal to the bioprosthetic valve demonstrates some RVOT narrowing with concomitant pulmonary regurgitation. B: Delivery and (C) balloon inflation of pre-stent, followed by (D) angiography without evidence of damage to RVOT. E: Delivery and (F) balloon inflation of the Melody valve within the pre-stented RVOT. G: Appropriate positioning of the Melody valve, and (H) final angiography without evidence of pulmonary regurgitation. Coronary angiography was performed prior to pre-stenting and demonstrated remote take-off and course of the left coronary artery. Compression is deemed to be less likely in the setting of a pre-existing bioprosthesis.

Melody valve [44]. McElhinney *et al.* [47] demonstrated similar results of tPVR with Melody valve with mean gradient reduction from 28.1 to 12.7 mmHg, and right ventricle systolic pressure reduction from 61.6 to 47.2 mmHg. Investigation of the SAPIEN

valve has yielded comparable results with an effective reduction of gradient from 27 to 12 mmHg [49].

At this time direct comparisons between surgical valve revision and tPVR are not available; however, tPVR outcomes have demonstrated

low valve failure rates. As further experience is gained the incidence of adverse events continues to decline and has been cited at approximately 5% [44,47]. Similarly, mean freedom from reintervention at 1 year had been documented as high as 94% [47] and as high as 70% at 70 months [44].

The future

Although tPVR is evolving into an acceptable alternative to surgery, much uncertainty exists as longer term data are lacking. It appears that initial benefits on right ventricular remodeling occur within the first 6 months with limited further changes in RVEDV or ejection fraction as measured by MRI at 1 year [50]. However, this is likely to mirror surgical data, and concerns should be targeted less toward continued right ventricle remodeling than valve and stent durability. There is every reason to believe that valve durability will be at least as good as surgical valve replacement, as reports have demonstrated pulmonary regurgitant fractions $\geq 30\%$ at 1 year in 7% of surgical valve replacement patients [38]. However, it may be difficult to recruit patients into a randomized clinical trial to prove this considering patient preference for tPVR. A recent meta-analysis of PVR after tetralogy of Fallot repair in 3118 patients from 48 studies revealed pooled 5-year re-replacement of the pulmonary valve of 4.9% [51] and mirroring this in the shorter

term must be a targeted goal. Although risk factors for re-intervention are being identified [52], the exact pathologic mechanisms of valve degeneration in a host of different conduits have only been postulated on through case reports [53]. One attractive option with tPVR is the potential for further valve replacement with the valve-in-valve technique, extending the number of repeat percutaneous valve replacements to an as yet undefined number [54].

Strategies for the future should be threefold: The first should be consolidating and improving upon current techniques to minimize procedural risk and simplify follow-up protocols thus reducing cost, which is not inconsiderable [55,56], and inconvenience to the patient. Intracardiac echocardiography has provided excellent imaging of valve function in the acute phase confirming valve competency, which can be otherwise distorted by catheters required for post-deployment angiography and can provide more accurate post-deployment assessment of valve function.

The second endeavor should be aimed at further valve development to extend technology to those with native RVOTs. Although deployment of balloon expandable stents in native out-flow tracts is evolving with larger valve systems, SAPIEN XT is available in 29mm, and has been deployed in the pulmonary position [57], it is likely a self-expanding system will gain wider clinical acceptance. Clinical reports of a new valve sewn into a self-expanding nitinol frame have been described (Figure 66.2) [58];

(a)

(c)

Figure 66.2 Self-expanding Medtronic Atlas valve and delivery system, currently being developed for native RVOT implantation. (a) Valve as viewed from short axis; (b) being loaded into delivery system; and (c) completely loaded and ready for delivery.

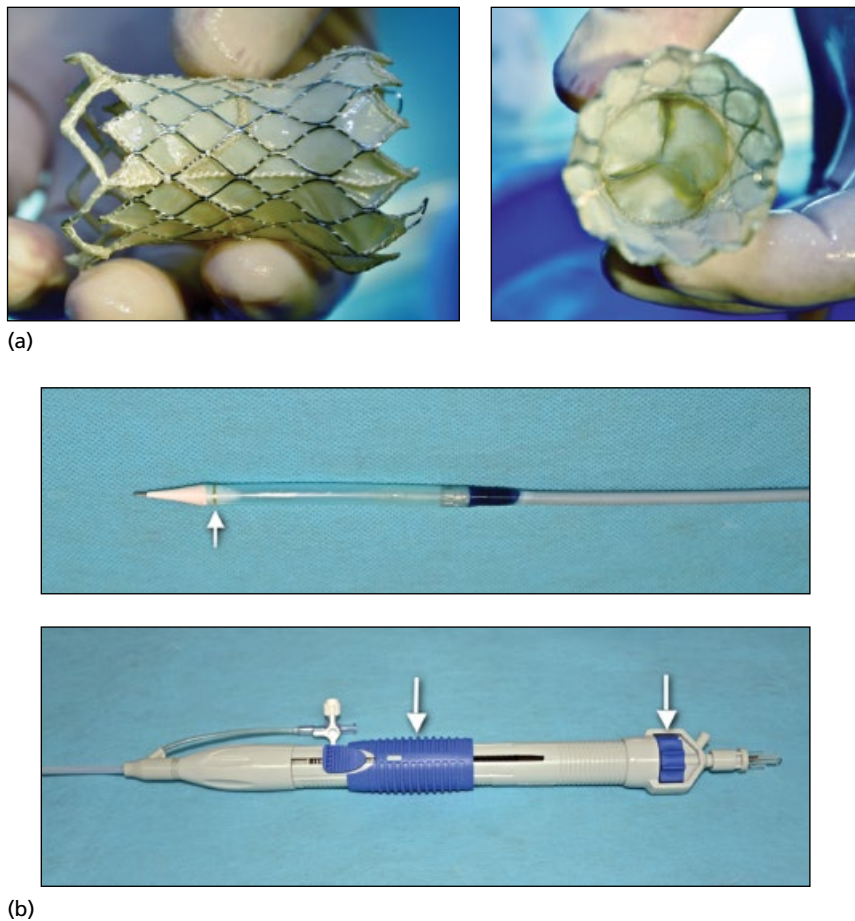

Figure 66.3 (a) Venus P valve viewed from long (left) and short axis (right). Note the flared, uncovered distal aspect of the valve which serves to anchor the device and decrease the likelihood of migration. (b) Venus P valve delivery system. Note the tapered distal end of the delivery system (top). The proximal end of the delivery system (bottom) has a controlled release handle which allows both slow and fast valve deployment.

however, applicability of this technology over the anatomic and dynamic variability that exists within the RVOT [59] remains questionable and further modifications may be necessary. The outcomes of a small feasibility trial in 20 patients using this valve are awaited. Other self-expanding valve systems are in development.

The Venus Pulmonary Valve (Venus Medtech, Shanghai, China) is a self-expandable nitinol multilevel support frame with a tri-leaflet porcine pericardial tissue valve (Figure 66.3a) with a 19–24Fr delivery catheter (Figure 66.3b). The entire stent is covered, except the distal cells, by porcine pericardial tissue. A flared uncovered outflow end secures anchoring at the distal (pulmonary artery bifurcation) end with radio-opaque markers indicating the distal anchoring position and the valve location. The proximal end is also flared but covered allowing conformability within the dilated RVOT. Stent valve diameters range from 24–36 mm (in 2-mm increments) with each diameter available in 25 and 30 mm straight sections lengths. Early clinical experience is promising with excellent early valve function and right ventricle remodeling reported [60].

The last endeavor should be to merge these approaches with tissue engineering technologies to provide living autologous valve

replacements with regenerative and growth potential. This approach has been described in an animal model [61], and although representing the longer term goal of valve replacement, this may be some way off as yet.

Imaging for Planning and Guidance for Structural Heart Interventions

Ankit Parikh and Stamatios Lerakis

Emory University School of Medicine, Atlanta, GA, USA

The field of structural heart interventions is one that is expanding at an exponential pace. The role of the interventional echocardiographer and/or cardiac imaging specialist has become increasingly important to assist with the planning and guidance of these interventions. This chapter discusses the general role of imaging and specific role of echocardiography as an adjunct for selected structural heart interventions. As more types of interventions and devices become available, the role of the imager will continue to grow and develop. While imaging technology continues to improve in parallel with interventional techniques, it remains crucially important to understand the limitations of available imaging modalities. The interventional echocardiographer and imaging specialist have an important role in anticipating when imaging may be suboptimal and communicating this information to the interventional team.

Transcatheter aortic valve replacement

Transcatheter aortic valve replacement (TAVR) has become an alternative to surgery in patients with severe aortic stenosis (AS) who are inoperable or at high risk for surgical aortic valve replacement. Imaging is important to support TAVR procedures and assess potential complications. The determination of AS severity and the indications for intervention are discussed in recent guidelines [1,2]. Several excellent comprehensive reviews on the role of imaging during TAVR have also been recently published [3–7].

Knowing the planned procedural access site is an important initial consideration for the imager. Potential access sites include transfemoral, transapical, transcaval, transaortic, or transcarotid approaches. Basic knowledge about these approaches is important and can help the imager anticipate some of the information that will be needed during the procedure. For example, if a transapical approach is chosen, the imager can be asked to assist with localization of an optimal apical site for access and identification of any abnormalities such as apical thrombi that can result in significant complications.

Another important initial consideration involves the type of valve. The role of the imager may be different during cases in which a balloon-expandable valve is chosen compared to cases in which a self-expanding valve is chosen. Additionally, the anticipated complications are different for different types of valves. The current

balloon-expandable valves include the second-generation SAPIEN XT and the third-generation SAPIEN 3 (Edwards Lifesciences, Irvine, CA, USA) [3,4]. The SAPIEN XT is composed of three bovine pericardial leaflets mounted on a cobalt chromium stent. The valve is deployed by delivering it to the desired site crimped over a balloon, and the balloon is then inflated to expand the valve (Figure 67.1). A fabric skirt mounted inside of the valve stent below the leaflets allows the valve to seal at the aortic annulus. There are three available sizes: 23, 26, and 29 mm. It is important to note that not all aortic annuli come in three sizes, and cases will often be encountered in which the annular size falls outside of the ideal range. Important aspects of valve sizing are discussed further later. The SAPIEN 3 requires a smaller delivery system and also has an outer skirt designed to attempt to reduce paravalvular leak (PVL), which remains one of the major complications of TAVR. The evaluation of PVL is also discussed later. The SAPIEN 3 also has a 20 mm valve size that allows for a wider range of annular dimensions to be considered for intervention. The CoreValve (Medtronic, Minneapolis, MN, USA) is a porcine pericardial valve mounted within a self-expanding nitinol frame [3,4]. A skirt is also mounted within the frame. As the valve is unsheathed, it deploys on its own, and the outflow end of the valve sits in the ascending aorta (Figure 67.2). It is available in four sizes: 23, 26, 29, and 31 mm.

When choosing the appropriate valve size, the most important measurement is the annular plane at the level of the hinge points (the lowest point of attachment of the three native aortic valve cusps) [4]. Because the annulus is often asymmetric and oval, echocardiographic measurement is challenging. The standard two-dimensional (2D) transthoracic echocardiographic (TTE) parasternal long-axis view is used to measure left ventricular outflow tract (LVOT) dimension for the calculation of aortic valve area by the continuity equation. However, this view is insufficient on its own for TAVR valve sizing. It is currently recommended to use either three-dimensional (3D) transesophageal echocardiography (TEE), computed tomography (CT), or both. With 3D TEE, annular sizing can be accomplished by rotating the planar views to cut through the aortic valve hinge points at the widest orthogonal dimensions of the aortic annulus. The resulting short-axis image can be used to either directly planimeter annular dimensions and area or indirectly obtain this information by marking off the annular hinge points on the corresponding long-axis planes at end-systole

Figure 67.1 Two-dimensional transesophageal echocardiographic views demonstrating deployment of a balloon-expandable valve. (a) The stent frame crimped around the balloon. (b) The balloon in the process of expansion. (c) The balloon fully expanded. (d) The final result, with the balloon pulled back and the valve fully deployed.

Figure 67.2 Two-dimensional transesophageal echocardiographic views demonstrating deployment of a self-expanding valve; the valve frame expands on its own (from left to right) as it is unsheathed.

[4]. If the indirect method is used, the points along the annulus are marked off and the echocardiographic software package then calculates annular dimensions and area (Figure 67.3). Because of the lower frame rate of 3D imaging than 2D imaging, it can be challenging to determine the occurrence of end-systole; the exact instant of end-systole often falls between two consecutive frames. In part because of this limitation, and because of the more invasive nature of TEE, CT has been used at many centers as an alternate

method to calculate annular dimensions and area. With CT, the annular plane is identified in a similar fashion, by identifying the hinge points and then identifying the appropriate transaxial slice. Annular sizing with indirect planimetry on 3D TEE closely approximates that of CT and predicts mild or greater PVL with equivalent accuracy [8].

Ranges of annular area that correspond to available valve sizes have been published for both balloon-expandable and self-expanding

Figure 67.3 With three-dimensional transesophageal echocardiographic imaging, two orthogonal long-axis planes can be identified after a full volume is obtained (green and red panels). The hinge points are marked off on these two panels and the results are shown on the short-axis image (blue panel). The software then calculates annular dimensions and area.

valves [4]. Valves can be oversized compared to the native aortic annulus to ensure stable seating and minimize PVL. However, oversizing by >20% of aortic annular area is associated with a greater risk of rupture [9]. In contrast, valve undersizing can impact both PVL severity and transvalvular hemodynamic performance. In some cases, when the annular size falls in between two of the available valve size ranges, the interventionalist needs to consider intentional under-expansion of a larger valve, although again this can impact valve hemodynamics and performance.

Additional important observations must be made during the initial work-up to determine TAVR candidacy. These observations are made at each anatomic level, from the LVOT to the aortic sinotubular junction and beyond [4]. When assessing the LVOT, the imager should note the presence of marked basal septal hypertrophy. This is related to compensatory hypertrophy secondary to pressure overload in AS. Additionally, a sigmoid-shaped septum is often observed in older individuals. Marked basal septal hypertrophy can complicate the TAVR procedure by impeding the ability of the interventionalist to maintain coaxiality of the valve delivery system. As discussed further later, maintenance of coaxiality of the valve delivery system is an important component of valve positioning and deployment. Another important complication that can be observed during cases in which the septum is hypertrophied and hyperdynamic is post-procedural LVOT obstruction and mitral regurgitation (MR) from systolic anterior motion of the anterior mitral valve (MV) leaflet. In contrast, a thin septum can increase the risk of iatrogenic ventricular septal defect, and a calcified septum can increase the risk of post-deployment PVL and of annular rupture [4].

The native aortic valve leaflets must also be assessed for bulky calcification [4]. Not only can significant calcification impact valve deployment and seating, it can also lead to complications such as PVL, coronary occlusion (by displacement of calcium into the ostium of a coronary artery), or aortic trauma (annular or root perforation, rupture, hematoma, or dissection). Procedural results can be worse in patients with native bicuspid aortic valve disease, although this remains an area of active research [4].

Above the aortic valve, it is important to assess the sinuses of Valsalva, sinotubular junction, and the positions of the coronary ostia [4]. Occlusion of the left main coronary artery is more common than occlusion of the right coronary artery, and this is usually

caused by displacement of a calcified nodule or a calcified native valve leaflet. Both TEE and CT can be used to measure coronary height above the annulus, and coronary patency can be monitored during the procedure both echocardiographically and angiographically [4]. It is also important to note the presence of plaques in the aortic arch and descending aorta, as these can impact the procedural approach, particularly if catheters will be directed retrogradely up the aorta.

After determining that a patient is a reasonable candidate for TAVR, it is important to consider the most appropriate intraprocedural imaging modality. While fluoroscopy and angiography remain the primary imaging tools used by the interventional cardiologist during the procedure, echocardiography has a very important adjunctive role in monitoring valve delivery and deployment as well as assessing for post-deployment complications. The choice of TTE versus TEE as the main echocardiographic adjunct to intraprocedural fluoroscopy and angiography remains an area of intense debate [10]. While TEE is most commonly used as the complementary imaging modality to fluoroscopy and angiography during the procedure, TTE is an acceptable alternative in transfemoral cases when the use of conscious sedation is planned as opposed to general anesthesia [11]. When deciding whether to choose TTE over TEE for intraprocedural guidance, it is important to consider the adequacy and quality of pre-procedural TTE images. Difficulties with obtaining adequate acoustic windows are likely to be exacerbated during the procedure, as are difficulties with visualization because of acoustic shadowing or artifacts. It is important for the interventional echocardiographer or advanced cardiac imaging specialist to convey to the interventionalist when imaging difficulties and suboptimal image quality are anticipated intraprocedurally based on the pre-procedural assessment. Useful TTE views include the parasternal long-axis and short-axis views as well as the apical five-chamber and three-chamber views. Useful TEE views include the mid-esophageal long-axis (110–130°) and short-axis (30–50°) views as well as the deep transgastric view (120°) looking upward at the LVOT and aortic prosthesis from a more inferior position.

Balloon aortic valvuloplasty (BAV) can be performed prior to TAVR to increase cusp exertion and to confirm annular sizing (Figure 67.4) [4]. BAV can also be useful to predict calcium displacement during final valve deployment and assure adequate coronary artery perfusion during balloon inflation [4]. Complications

Figure 67.4 Two-dimensional transesophageal echocardiographic view of a balloon being inflated during balloon aortic valvuloplasty.

Figure 67.5 Two-dimensional transesophageal echocardiographic view of a valve stent frame that has been crimped around a balloon and is in the process of being positioned. The yellow arrows mark the edge of the stent frame, while the green arrows mark the edge of the balloon. Sometimes it can be difficult to differentiate the stent frame from the balloon.

of BAV include acute coronary occlusion, severe aortic regurgitation, or aortic trauma with the possibility of resultant cardiac tamponade.

Prior to deployment of a balloon-expandable valve, the echocardiographer must consider the coaxiality of the stent frame with the aortic annulus as well as the position of the edges of the stent frame with the aortic leaflets [4]. While maintaining coaxiality is very important, it is often difficult for the interventional cardiologist to obtain a perfect alignment. However, small deviations from a perfectly coaxial alignment will often correct themselves as the valve is being expanded. Prior to balloon expansion, the distal edge of the stent frame should cover the native leaflets but remain below the sinotubular junction and coronary ostia (Figure 67.5). Differentiation of the crimped stent from the underlying balloon can sometimes be difficult despite concerted efforts to tilt and rotate the ultrasound probe, especially in cases with poor acoustic

windows or significant acoustic shadowing. Options for better differentiation include reducing the echocardiographic gain or using live 3D imaging, if available [4]. Correlation with fluoroscopy and angiography can also increase confidence in appropriate stent frame positioning prior to valve deployment. Compared with the deployment of a balloon-expandable valve, the deployment of a self-expanding valve is a more gradual procedure, and fluoroscopy plays the primary part during procedural deployment as the valve is unsheathed. Echocardiography can assist in the diagnosis of deployment-related complications, such as PVL.

Echocardiography perhaps has its most critical role in assessing procedural complications after valve deployment. There are a number of observations that must be made to provide the interventional team with an integrated and comprehensive determination of procedural success. Many of these post-deployment observations rely on a combination of 2D and color Doppler imaging. Spectral Doppler can also be employed to assess valve hemodynamic function and gradients. It is often useful to correlate this information with invasive hemodynamic measurements obtained by the interventional cardiologist.

Initial observations include stent positioning, shape, and leaflet motion [4]. Leaflets that appear to open completely are unlikely to be associated with hemodynamically significant prosthetic valve stenosis. However, this qualitative information on valve opening and closing can be compared with quantitative determination of gradients by continuous wave Doppler. It can be more difficult to measure gradients across the valve with TEE than with TTE, as it is often more difficult to obtain adequate the deep transgastric views on TEE compared to the apical views obtained from the transthoracic approach. The ultrasound beam should be aligned as parallel as possible to the direction of blood flow to obtain the most accurate assessment of gradients across the valve.

A global assessment of left and right ventricular function should be made post-deployment, and new regional wall motion abnormalities should be noted [4]. A change in cardiac function can reflect consequences of rapid pacing used during balloon inflation, which can result in low forward cardiac output, with resultant hypotension and ischemia. A change in ventricular function can also result from coronary occlusion, and thus it is also important to assess for coronary patency post-deployment, as discussed earlier [4]. Coronary patency can be assessed with 2D imaging, and coronary arterial flow can be confirmed using color Doppler. This information can be correlated to that observed with post-deployment angiography, with power injection of contrast into the aortic root.

Other important observations include assessing the LVOT for obstruction, evaluating the function of the other cardiac valves, assessing the aortic annulus and root for signs of iatrogenic trauma, and evaluating for any rapidly accumulating pericardial effusion. LVOT obstruction can be seen in cases of basal septal hypertrophy and can be exacerbated by increased circulating catecholamines and relative hypovolemia [4]. Worsening MR can be a result of systolic anterior motion of the anterior mitral valve leaflet, or it could reflect damage to the mitral valve apparatus during the procedure [4]. If iatrogenic, the MR may be associated with chordal rupture or a flail MV leaflet. Additionally, the possibility of ischemic MR must be considered if the MR is observed in conjunction with new wall motion abnormalities after rapid pacing or after coronary occlusion. Iatrogenic ventricular septal defect can also be seen if the septum is perforated by the delivery apparatus. Dreaded aortic complications include rupture, dissection, and hematoma. Aortic trauma can be related to deployment itself or can be related to the

displacement of sharp, bulky calcium into the aortic root during the procedure. If there is concern for aortic pathology post-deployment, it is important to correlate the appearance of the aortic root with that observed on pre-deployment images. Pericardial effusion can be caused by aortic perforation or rupture, or it can be related to cardiac chamber perforation from the right ventricular pacing wire or from the valve deployment apparatus. A rapidly accumulating pericardial effusion in a pericardial sac unaccustomed to such an effusion can result in potentially fatal cardiac tamponade. Comparison to pre-deployment images is critically important when assessing for progression of a pericardial effusion, especially if an effusion was present at the start of the procedure.

Echocardiography also has a major role in assessing the presence and severity of post-deployment PVL (Figures 67.6 and 67.7). In many cases this ends up being the primary component of the post-deployment assessment. Moderate or severe PVL is common after TAVR, with an incidence of approximately 14% at 30 days in the PARTNER trial [12]. This complication was far more common than

similar degrees of PVL after surgical aortic valve replacement. PVL has been shown to be an independent predictor of mortality after the procedure, and even mild PVL was associated with an increased risk of mortality in the PARTNER trial [12,13], though this finding remains controversial, as other studies have not found a similar association between mild or trace PVL and mortality [14]. The development of PVL after TAVR can be related to annular issues, such as significant calcification, or it may be related to technical and device-related issues, such as valve undersizing or maldeployment [14,15]. While valve oversizing can reduce the risk of significant PVL, it can increase the risk of annular rupture, coronary artery occlusion, and arrhythmic complications [14,16].

The assessment of PVL severity is not straightforward. Shielding and reverberations from the valvular frame or from the native calcified root that can obscure visualization can occur. In addition, the regurgitant orifices tend to be crescentic and irregular, leading to eccentric regurgitant jets that can be difficult to quantify [14,15]. Several guidelines regarding the grading of PVL severity have been published [1,3,7,17,18]. Semi-quantitative parameters include regurgitant jet width as a percentage of LVOT width and diastolic flow reversal in the proximal descending aorta. Quantitative parameters include regurgitant volume, regurgitant fraction, and effective regurgitant orifice area. A criterion about which there has been some disagreement has been the circumferential extent of the regurgitant jet expressed as a percentage of the aortic annular circumference on the short-axis view (either the transthoracic parasternal short-axis view or the transesophageal mid-esophageal short-axis view at 30–50°; Figure 67.8). While earlier publications endorse using a cut-off of >20% for severe PVL [3,18], more recent publications suggest a cut-off of >30% for severe PVL [7,17]. There is acknowledgment that this criterion is not well-validated and may overestimate PVL severity compared to quantitative Doppler echocardiography [17]. Because of the difficulty in characterizing PVL severity solely based on echocardiographic assessment, cardiovascular magnetic resonance (CMR) imaging has emerged as an alternate option [19]. Compared with CMR, the circumferential extent of PVL visualized echocardiographically in short-axis tends to overestimate PVL severity [20]. A regurgitant fraction >20%, as calculated by CMR, has been associated with a higher incidence of adverse events after TAVR [21].

While there are no universally established guidelines for the management of PVL after TAVR, potential intraprocedural options include balloon post-dilatation, valve repositioning by snaring, valve-in-valve replacement, or surgical conversion [14,15,22–24]. In patients with chronic PVL after TAVR, transcatheter device closure is an option [25,26]. Echocardiography is an important adjunct to these percutaneous closure procedures. TEE is generally the preferred imaging modality in this setting [3], although the use of intracardiac echocardiography has also been reported [27]. 3D TEE can also be used to demonstrate the irregular crescentic shape of the defect or defects and assist with accurate defect sizing [3]. The interventional echocardiographer must be cautious to avoid overdiagnosing areas of echocardiographic dropout as paravalvular defects; the addition of color Doppler can be helpful in avoiding this pitfall. The echocardiographer can assist the interventional cardiologist in following the passage of the guidewire and catheter through the defect [3], although the interventional cardiologist can also use hemodynamic, fluoroscopic, and contrast-based angiographic data for this purpose. Subsequently, the echocardiographer can assure proper positioning of the selected closure device, proper seating of the device, and assess for residual regurgitation after device

Figure 67.6 Two-dimensional transthoracic echocardiographic view demonstrating significant paravalvular leak after balloon-expandable valve deployment (yellow arrow).

Figure 67.7 Two-dimensional transesophageal echocardiographic view demonstrating significant paravalvular leak after self-expandable valve deployment (yellow arrow).

Figure 67.8 The left panel demonstrates severe paravalvular regurgitation visualized in short-axis. In the right panel, the left ventricular outflow tract area is traced in green and the regurgitant flow is traced in yellow. Note that the yellow tracings cover >30% of the circumferential extent of the left ventricular outflow tract. Also note the presence of multiple jets as well as the irregular crescentic shape of the regurgitant orifices.

Figure 67.9 Deployment of two vascular plugs for correction of paravalvular leak (yellow arrows).

closure (Figure 67.9). It is important to ensure that device closure of a defect does not result in deterioration of prosthetic valve function; this undesired outcome would most commonly be caused by hindering of prosthetic leaflet motion by the closure device. When the defect is large or multiple defects exist, multiple closure devices may be required. Even when device closure results in hemodynamic improvement of the degree of regurgitation, it is possible for small amounts of residual regurgitation to result in significant hemolysis [3]. As with the index TAVR procedure, the echocardiographer must remain aware of the litany of potential complications that occur during repeat aortic valve intervention, as previously discussed.

Percutaneous mitral valve repair

Percutaneous MV repair has emerged as a therapeutic option for patients with significant symptomatic MR who are deemed to be too high risk for surgery or who have had previous cardiac surgeries. The current device used for percutaneous MV repair is the MitraClip (Abbott Vascular, Santa Clara, CA, USA). The preferred imaging modality to support percutaneous MV repair is TEE using a combination of 2D and 3D imaging; the procedure is typically performed under general anesthesia with endotracheal intubation, obviating the discomfort to the patient associated with prolonged TEE imaging. The role of the echocardiographer in pre-procedural planning, intraprocedural guidance, and post-procedural follow-up

of percutaneous MV repair cannot be understated. While the following discussion is centered on percutaneous MV repair, it is important to note that the echocardiographic techniques used for procedural guidance can also be applied to other MV interventions, such as percutaneous closure of a paraprosthesis defect to correct significant paraprosthesis regurgitation (Figure 67.10).

The MitraClip is a polyester fabric-covered cobalt-chromium implant which has two arms that can be opened and closed, as well as a steerable guiding mechanism [3]. The design of the MitraClip is intended to replicate the double MV orifice created using the surgical Alferi edge-to-edge repair [28]. The device is delivered to the right atrium via a femoral venous approach and then across the interatrial septum to the left atrium via transseptal puncture. By

aligning the device perpendicular to the line of coaptation between the involved leaflet segments, the goal is to grasp the involved leaflets and cinch them together with the clip mechanism, thus apposing the leaflets and reducing the degree of MR. The device has been used successfully in selected patients with either degenerative or functional MR [29]. In patients with flail MR, the flail gap, or gap between the flail leaflet and normal leaflet, should ideally be <10 mm wide, and the width of the flail segment or scallop should ideally be <15 mm [3]. Measurement of the flail gap is usually easily performed with 2D TEE imaging, while measurement of the flail width sometimes requires 3D imaging of the involved scallop. In functional MR that is secondary to left ventricular dysfunction, the length of leaflet tissue available for coaptation should ideally

Figure 67.10 Three-dimensional transesophageal echocardiographic imaging of a bioprosthetic mitral valve in a patient with significant paraprosthesis regurgitation. (a) Three defects (yellow arrows), all of which are confirmed by the addition of color Doppler (b). The most prominent regurgitant jet originates from the defect at the 6 o'clock position. (c) A catheter crossing the largest defect after transseptal puncture. (d) The final result with deployment of four closure devices. AV, aortic valve; LAA, left atrial appendage.

be ≥ 2 mm in length and the depth from the mitral annular insertion points to the actual point of coaptation should ideally be ≤ 11 mm [3]. Determination of the severity of MR in the pre-procedural setting incorporates a number of observations, including the structure of the mitral apparatus, left atrial and left ventricular size and function, regurgitant jet area and vena contracta width by color Doppler, effective regurgitant orifice area (EROA) by the proximal isovelocity surface area (PISA) method, flow quantification by pulsed wave Doppler, jet profile by continuous wave Doppler, the peak mitral E velocity on the mitral inflow profile, and the pulmonary venous flow profiles by pulsed wave Doppler [1,30]. It is also useful to note the pre-procedural gradient across the mitral valve, as creation of the double orifice can increase the gradient across the valve significantly. It is important to understand that no single parameter in isolation can completely characterize MR severity, and a comprehensive evaluation is required in the pre-procedural setting in order to determine MR severity and procedural feasibility. It is also important to understand that the severity of MR can vary with loading conditions, and the assessment of severity can differ when the patient is ambulatory compared to when the patient is sedated under general anesthesia. As such, a focused re-evaluation is often warranted in the early procedural stages to determine if there have been any significant changes in perceived MR severity.

During transseptal puncture, the bicaval view at 90° can help the interventional cardiologist locate the tip of the transseptal catheter. The echocardiographer should assess for “tenting” of the interatrial septum to localize the point of planned septal puncture (Figure 67.11). The mid-esophageal short-axis ($30\text{--}50^\circ$) and four-chamber (0°) views can be used to determine where the tenting point is in relation to other structures such as the aortic annulus and the mitral annular insertion points. Ideally, the tenting should be observed about 3.5–4.0 cm above the insertion point of the mitral valve leaflets prior to leaflet puncture [3].

After transseptal puncture, the echocardiographer assists the interventional cardiologist with proper delivery of the device [3].

This often requires a combination of 2D and 3D TEE imaging, and the echocardiographer must be prepared to quickly switch back and forth between 2D and 3D. It is often very helpful use biplane echocardiographic imaging to be able to simultaneously visualize the location of the device in two different orthogonal views (Figure 67.12). In the mid-esophageal bicommissural view ($55\text{--}75^\circ$), the medial edge of the mitral annulus will typically be oriented on the left side of the echocardiographic image, in close proximity to the interventricular septum, while the lateral edge of the mitral annulus will typically be oriented on the right side of the image, in close proximity to the left atrial appendage. In the mid-esophageal long-axis view ($110\text{--}130^\circ$), the posterior edge of the mitral annulus will typically be oriented on the left side of the image and the anterior edge will be oriented on the left side of the image, in close proximity to the aortic valve and annulus. The ridge of tissue between the aortic and mitral valves (the aortic–mitral curtain) is often a useful landmark on 3D TEE imaging, as it should be placed at the top of the screen in the “surgeon’s view” looking down at the mitral valve from the left atrium (Figure 67.13). In this 3D view, the left atrial appendage will be on the left side of the screen at the 9 o’clock position and the aortic valve will be at the top of the screen at the 12 o’clock position. The anterior MV leaflet will be toward the top of the screen and posterior MV leaflet will be toward the bottom. The orientation of the scallops progresses from A1 to A3 or P1 to P3 in a left to right (lateral to medial) direction. By using a combination of 2D and 3D TEE imaging, the echocardiographer can facilitate guidance of the device into the proper position above the largest regurgitant orifice and perpendicular to the line of coaptation (Figure 67.14). Opening the arms of the device while in the left atrium can facilitate this alignment, but the arms should be closed when the MV is crossed and the device is situated in the left ventricle.

Leaflet grasping is performed in the “grasping view,” which is essentially the mid-esophageal long-axis view between 110° and 130° ; occasionally angles higher than 130° are required to adequately

Figure 67.11 Two-dimensional transesophageal echocardiographic imaging of a transseptal puncture. The tenting of the interatrial septum is clearly visualized in the left panel (yellow arrow). The right panel demonstrates the measurement of the tenting height above the mitral annular insertion points. An imaginary line is drawn from the tenting point across the left atrium, parallel to the line connecting the mitral annular insertion points; a parallel line connecting these two is then drawn and measured (red lines). The green line shows the distance from the tenting point to the actual leaflet coaptation. The difference in distance between the green line and the red line represents the coaptation depth.

Figure 67.12 Biplane echocardiographic images without (left panel) and with (right panel) superimposed color Doppler, demonstrating the device in both the medial–lateral orientation (left side of both panels) and posterior–anterior orientation (right side of both panels). The right side of both panels demonstrates the mid-esophageal long-axis grasping view used to determine if the leaflets have been appropriately cinched by the device.

Figure 67.13 Three-dimensional transesophageal echocardiographic “surgeon’s view” of the mitral valve as seen from the perspective of the left atrium. The aortic valve (AV) and aortic–mitral curtain (AMC) are aligned at the 12 o’clock position, and the left atrial appendage (LAA) is at the 9 o’clock position. The scallops of the anterior mitral leaflet are labeled A1–A3, and those of the posterior mitral leaflet are labeled P1–P3.

visualize the MV leaflets in relation to the arms of the device, which have now been opened as the device is pulled back from the left ventricle toward the left atrium. Biplane echocardiographic imaging can be very useful at this point to ensure that the medial–lateral orientation of the device remains stable while the device is advanced. The key is to ensure that both leaflets have been grasped by the grippers of the device; this can often be one of the more challenging aspects of intraprocedural imaging (Figure 67.15). 3D imaging can be used to help determine if a double orifice has been formed (Figure 67.16). In the mid-esophageal bicommissural view, the medial orifice will be on the left and the lateral orifice will be on the right. If either leaflet has not been captured, or if it is unclear if both leaflets have been captured, the arms can be reopened and repeat grasps can be attempted. Once it is clear that both leaflets have been grasped, the

Figure 67.14 Three-dimensional transesophageal echocardiographic view of the device being aligned toward the mitral valve. Note that the device is perpendicular to the line of coaptation between the anterior and posterior leaflets.

echocardiographer should perform a focused evaluation using color Doppler to determine residual MR severity, continuous wave Doppler to determine the medial and lateral gradients in order to exclude hemodynamically significant mitral stenosis, and pulsed wave Doppler of the pulmonary venous flow profiles to determine if there has been improvement in the degree of systolic flow reversal or blunting. Correlation with invasively obtained hemodynamics by the interventionalist can be useful; these include mean left atrial pressure and left atrial V-wave height pre- and post-deployment. If there is still significant residual MR, the decision must be made whether to deploy the first clip and prepare a second clip for deployment or to release the leaflets and attempt to regrasp at a more favorable position. It is not uncommon for a second clip to be required, and on occasion even a third clip is required. However, with each additional clip, it becomes increasingly important to exclude hemodynamically significant gradients across the valve.

Figure 67.15 Two-dimensional transesophageal echocardiographic grasping view with the posterior leaflet on the left side of the image and the anterior leaflet on the right side of the image. Note the appearance of the mitral valve leaflets within the grippers of the device (yellow arrows).

Figure 67.16 Double orifice seen at the conclusion of the procedure. The clip has apposed A2 and P2 in this case.

There are a number of potential complications of the procedure that can be imaged by TEE: chamber perforation with subsequent pericardial effusion formation; clip dehiscence after initial deployment; or leaflet or chordal trauma related to the device itself [3]. Post-procedural follow-up becomes challenging in that some of the traditional measurements described for quantifying native MR severity [1,30] are no longer validated for quantifying MR severity post-percutaneous MV repair. For example, flow quantification by pulsed wave Doppler becomes limited by the fact that there are now two pathways for flow to enter from the left atrium into the left ventricle [3]. Additionally, the calculation of EROA by the PISA method has not been validated in this setting, nor has it been

validated for the multiple regurgitant jets that can exist after clip deployment [3]. In this sense, pulmonary venous flow profiles take on added significance as surrogates for invasively measured hemodynamics.

Conclusions

The role of the structural imager in collaboration with the interventional cardiology team continues to grow and evolve. As imaging modalities continue to improve and new techniques become available, the structural imager will become even more integral to the function of the structural heart team. A thorough understanding of the views and techniques used will help the imager apply these principles to a number of novel interventions that become available in the future.

Background and evidence

Stroke remains the third leading cause of death and leading cause of disability in the USA and Europe [1]. Preventive and interventional strategies should be a high priority. In this context, interventional therapies for stroke prevention have gained momentum in the last two decades and become accepted treatment strategies in a number of countries. Carotid stenting has been demonstrated equivalent to carotid endarterectomy in suitable patients [2,3], patent foramen ovale closure has recently been shown to be effective for secondary prevention in patients with cryptogenic stroke [4], and left atrial appendage closure was superior to anticoagulation with warfarin at longer term follow-up in the largest randomized trial examining left atrial appendage closure published to date [5]. Moreover, to those involved in acute stroke intervention, based on personal experience of dramatic neurologic recovery (in selected patients) after timely culprit vessel revascularization, the merit of acute stroke intervention has been obvious. However, results of earlier randomized trials, with first generation devices, examining the efficacy of acute stroke intervention were mixed [6–8]. Importantly, with the publication of five recent randomized controlled acute stroke trials showing superiority of thromboembolectomy in addition to usual care (thrombolysis) versus usual care alone, interventional therapy has the potential to revolutionize acute stroke therapy in a similar manner as percutaneous coronary intervention has for treatment of acute myocardial infarction.

It is undisputed that thrombolysis significantly improves neurologic outcomes in acute stroke. It is widely available and can be administered rapidly in most hospitals. Based mainly on the National Institute of Neurological Disorders and Stroke (NINDS) recombinant tissue plasminogen activator (rt-PA) trial [9], in the absence of contraindications, rt-PA (0.9 mg/kg body weight; maximum 90 mg, with 10% administered as a bolus followed by the remainder over 60 minutes without concomitant antiplatelet or anticoagulant therapy) is a recommended treatment for patients who present less than 4.5 hours after stroke onset. In the NINDS trial, patients treated with thrombolysis within 3 hours of stroke

onset were 30% more likely to have minimal or no disability at 3-month follow-up than patients in the control group [9]. Subsequently, based on the results of the ECASS III randomized controlled trial [10], the therapeutic window for intravenous thrombolysis was extended to 4.5 hours. Nevertheless, thrombolysis is accompanied by a number of shortcomings. First, only a very small number (<5%) of patients are eligible for thrombolysis based on late presentation or contraindications. Second, culprit vessel recanalization rates are lower than those observed after thrombolysis in acute myocardial infarction. For example, acute vessel patency rates are $\geq 70\%$ after thrombolysis for acute myocardial infarction with second-generation lytics [11] compared to 34% after thrombolysis for acute stroke [12]. The reason for the lower vessel patency rates may be the mechanism of initial vessel closure. Whereas in acute myocardial infarction the underlying mechanism is plaque rupture causing *in situ* thrombus formation, the overwhelming majority of strokes are caused by more heterogeneous embolic material from the carotid artery or aortic arch (including atherosclerotic debris with or without superimposed thrombus) or heart that may not respond well to thrombolysis. Moreover, the re-occlusion rate of intracerebral vessels is high. For example, in one study of patients who underwent thrombolysis in the setting of a middle cerebral artery (MCA) occlusion in the M1/M2 segment, the re-occlusion rate after initial recanalization was 34% [13]. Third, reperfusion into the injured brain tissue, in conjunction with a thrombolytic state, can lead to intracranial hemorrhage causing neurologic status deterioration in 6.8–8.8% of patients (treated with lytics) [9,14], thereby limiting the benefit of therapy. It is therefore not surprising that the likelihood of death and major disability remains high (>50%), despite administration of intravenous thrombolytic therapy [9,14,15].

In an effort to maximize thrombolytic effect in the culprit vessel while minimizing bleeding, intra-arterial thrombolysis with rt-PA was extensively studied.

In the Prolyse in Acute Cerebral Thromboembolism 1 (PROACT-1) (n=26) [16], PROACT-2 (n=180) [17], and the Middle Cerebral Artery Embolism Local Fibrinolytic Trial (MELT)

(n = 114) [18], intra-arterial lytic therapy administered to patients with MCA occlusions in conjunction with intravenous heparin was compared with intravenous heparin only. Several observations are worth mentioning. Though the stroke vessel patency rates (defined as TIMI II–III in PROACT-1 and TIMI I–III in PROACT-2) were higher after intra-arterial lysis (58% vs. 14%, 66% vs. 18% in PROACT-1 and 2), brisk, TIMI III, flow was seen in a minority of patients (18% in PROACT-2). High doses of intravenous heparin (100 IU/kg loading dose followed by 1000 IU/hour) together with intra-arterial thrombolysis resulted in unacceptably high intracranial hemorrhage rates in PROACT-1 (70% in the lytic arm versus 20% in the control arm receiving intravenous heparin only) leading to heparin dose adjustment (2000 IU bolus followed by 500 IU/hour) for the remainder of PROACT-1 and 2. In PROACT-2, significantly more patients (40% vs. 25%; $p = 0.045$) achieved excellent neurologic outcomes (modified Rankin score ≤ 1) with no difference in mortality. Though in MELT there was no difference in the primary endpoint (modified Rankin score of ≤ 2), significantly more patients (42% vs. 23%) experienced an excellent neurologic recovery (defined as modified Rankin score of ≤ 1) after intra-arterial lysis (predefined endpoint) with no difference in mortality.

Data comparing intra-arterial with intravenous lytic therapy are limited. In a non-randomized study of 112 patients exhibiting a hyperdense media sign consistent with an MCA occlusion comparing intra-arterial lytic therapy (within 6 hours of symptom onset) with intravenous thrombolysis (within 3 hours of stroke onset), a favorable neurologic outcome was seen in significantly more patients after intra-arterial lysis (53% with modified Rankin score of ≤ 2 versus 23%; $p < 0.001$) despite a shorter mean time to treatment administration with intravenous compared with intra-arterial thrombolysis (156 vs. 244 minutes) with significantly lower mortality (5% vs. 23%) in the group treated with intra-arterial thrombolysis [19]. In the Interventional Management of Stroke trial (IMS) I, 80 patients were assigned to reduced-dose intravenous lytic therapy (0.6 mg/kg bodyweight; maximum 60 mg) with 15% administered as a bolus followed by 85% over 60 minutes followed by cerebral angiography and intra-arterial lytic administration (up to 22 mg over a 2-hour period) if residual thromboembolic material was seen [20]. Results were compared with historical controls from the NINDS-rt-PA trial. With this strategy, 62% of patients received intra-arterial lytic therapy. At follow-up, 43% of patients were left with a favorable neurologic outcome (modified Ranking score of ≤ 2) compared with 39% and 28% in the historical NINDS trial population treated with and without lytics, respectively, with no difference in intracranial hemorrhage rates. Of note, similar to aforementioned studies, brisk, TIMI III occurred in only a minority of patients (11%). In IMS-II [21], a study with similar design as IMS-I, 81 patients received the same dose of intravenous lytics followed by angiography and intra-arterial lytics if residual thromboembolic material was seen in addition to low energy ultrasound application at the site of thromboembolic material via the EKOS (EKOS Corporation, Bothell, WA, USA) microinfusion catheter with favorable neurologic outcome in 46% of patients and no increase in intracranial hemorrhage.

In summary, though in selected patients intra-arterial lytic therapy appears to be superior to anticoagulation with heparin only, data are limited and virtually no data are available comparing a strategy using intravenous lytics with intra-arterial lytics as first line therapy. Even with intra-arterial lytic therapy, brisk, TIMI III flow is the exception rather than the rule. In an analogy to mechanical coronary reperfusion for acute ST-segment elevation myocardial infarction, an important observation appears to characterize most

studies. The degree of neurologic recovery and mortality correlates closely with infarct or stroke vessel patency. For example, in a meta-analysis of 53 studies examining data from 2066 patients who underwent cerebral angiography within 24 hours of therapy, spontaneous recanalization was observed in only 24%, 46% of patients after intravenous and 63% after intra-arterial thrombolysis [22]. Favorable neurologic recovery occurred in 58% of patients whose target vessel recanalized versus 25% when the target vessel remained occluded. Likewise, mortality was 42% in patients without and 12% in patients with successful target vessel recanalization. Furthermore, those vessels in which occlusion causes the most devastating neurologic consequences (internal carotid, carotid T, proximal MCA, or basilar artery) are typically least likely to recanalized after thrombolysis.

The recognition of the importance of early stroke vessel recanalization and the limitations encountered by thrombolytic therapy fostered the pursuit of mechanical thromboembolism. A number of thromboembolism devices have been studied. Initial enthusiasm was dampened by the announcement of the results of three trials in 2013, all of which did not show harm, but failed to demonstrate the expected benefit of mechanical thromboembolism compared to intravenous thrombolysis. The IMS-III trial was designed to randomize 900 patients to endovascular therapy in addition to conventional intravenous thrombolytic therapy versus conventional thrombolytic therapy alone but was stopped after enrollment of 656 patients demonstrated no additional benefit of endovascular therapy (primary endpoint of modified Rankin ≤ 2 , 41% with endovascular therapy in addition to intravenous thrombolysis and 39% with conventional intravenous thrombolysis alone) [6]. There was also no difference in mortality or intracranial hemorrhage rates. Several shortcomings deserve attention. First, major (large) vessel occlusion was documented in less than 50% of patients. Second, the time delay from intravenous thrombolytic administration to percutaneous mechanical therapy was long (equal to or greater than 2 hours). Third, the rate of recanalization with brisk flow in the stroke related vessel (TICI IIB–III) was low (40%).

MR-RESCUE was a small (n = 68) randomized trial of endovascular therapy in addition to intravenous thrombolysis versus intravenous thrombolysis only [7]. The main goal of this trial was evaluation of endovascular therapy efficacy depending on the size of the penumbra assessed by pre-intervention imaging. At the conclusion of this trial there was no difference in neurologic outcome, death, or intracranial hemorrhage. The absence of efficacy was demonstrated regardless of the size of the penumbra. Though large vessel occlusion was documented prior to intervention by magnetic resonance tomography, similar to IMS-III, time to treatment was long (mean time from stroke symptom onset to therapy equal to or greater than 6 hours) and successful recanalization rate low (TICI IIB–III, 27%).

Finally, in SYNTHESIS Expansion, 362 patients were randomized to receive intravenous thrombolysis versus endovascular therapy (the overwhelming majority of whom received intra-arterial lytics) [8]. Compared with conventional intravenous thrombolysis, there was no difference in the rate of favorable neurologic outcome, death, or intracranial hemorrhage. Though the times to treatment were shorter than in the latter two trials (3.75 hours in the endovascular therapy group vs. 2.75 hours in the intravenous thrombolysis group), large vessel occlusion was again not confirmed prior to study inclusion. Of note, only 56 patients underwent mechanical thromboembolism. Hence, this trial should be considered mainly a comparison of intra-arterial versus intravenous thrombolysis rather than an evaluation of the merit of mechanical thromboembolism.

In summary, the aforementioned three trials should be interpreted keeping in mind the long treatment delays, inconsistent documentation of large vessel occlusion prior to inclusion, the lack of modern thrombectomy devices, the overall low recanalization rates, not to mention the small number of patients enrolled in each facility (0.8–3.6). The majority of devices used for thromboembolism in the mechanical arm were wire manipulation alone, the outdated first generation Merci Retriever (Stryker, Fremont, CA, USA) which worked by the principle of entrapment and retrieval via a Spiral and the Penumbra System (Penumbra, Alameda, CA, USA) using aspiration for thromboembolism. Though these devices have been shown to achieve recanalization rates superior to historical controls of conventional intravenous thrombolysis in small single-arm studies [23–26], their clinical efficacy has never been shown in randomized trials comparing the specific device with intravenous thrombolysis. Newer generation devices, particularly stent retrievers, were used in only 0–13% of patients in the interventional groups [6–8].

Stent retrievers are small, self-expanding stents with ultrafine stent struts delivered and expanded into the thrombus/embolus engulfing the thrombus/embolus within the stent struts. Deployment alone frequently establishes some degree of flow accompanied by improvement in neurologic status. The stent is non-detachable. Instead, in its expanded form, it is pulled back into the guide catheter or sheath while maintaining suction through the balloon-tipped guide catheter or sheath with the balloon inflated, preventing dislodgement of thromboembolic material into the cerebral circulation during retrieval. Removal of an expanded stent seems counterintuitive to operators accustomed to percutaneous coronary interventions during acute myocardial infarction. However, the main aspect (apart from the low profile and excellent flexibility) that allows safe retrieval of a deployed stent retriever from the intracranial circulation is the common absence of underlying atherosclerotic plaque or stenosis at the site of the cerebral vessel occlusion. Several registries and one randomized trial comparing results using a stent retriever (Solitaire, Medtronic, Dublin, Ireland) with prior older generation mechanical clot/embolus removal devices demonstrated more rapid reperfusion and higher vessel patency rates and better clinical outcomes after use of the stent retriever [27–30]. These findings promoted the conduction of a number of randomized trials that were recently published and are likely to change the landscape of acute stroke therapy.

The Multicenter Randomized Clinical Trial of Endovascular Treatment for Acute Ischemic Stroke in the Netherlands (MR CLEAN) was a multicenter trial randomizing patients (NIHSS score of ≥ 2 , $n=500$) with an acute distal internal carotid, MCA (M1/M2 segment) or anterior cerebral artery (A2/A2 segment) occlusion to endovascular therapy (mechanical thrombectomy, intra-arterial lysis or both) in addition to intravenous thrombolysis or intravenous thrombolysis alone [31]. Importantly, the overwhelming majority (82%) of patients were treated using stent retrievers. Treatment was open label but endpoint evaluation was performed in a blinded manner. Duration from symptom onset to administration of intravenous thrombolysis was equivalent in both treatment groups (85 minutes in the control arm versus 87 minutes in the endovascular therapy group) and median time from stroke onset to access site puncture was 260 minutes. The primary endpoint, modified Rankin score of ≤ 2 at 90 days, was achieved in 33% of patients in the endovascular therapy group versus 19% in the control group (significant 13% absolute difference in favorable outcome, adjusted OR 2.2, 05% CI 1.39–3.38). All other endpoints favored endovascular therapy. The 5–7 day NIHSS score was 2.9

points lower in the endovascular therapy as was the infarct volume (by 19 mL). Importantly, no residual occlusion was seen in 75% of patients on computed tomography (CT) angiography 24 hours after treatment in patients treated endovascularly compared with only 33% in patients treated conventionally. There was no significant difference in mortality or rate of intracranial hemorrhage. It was noted that, at 90 days' follow-up, 5.6% of patients who underwent endovascular therapy had exhibited signs of stroke in a different cerebral vascular territory than the initial stroke compared with only 0.4% in the control group. In summary, MR CLEAN demonstrated superiority of endovascular therapy in addition to conventional therapy compared with conventional therapy alone when administered within 6 hours of stroke onset without causing excess mortality or intracranial hemorrhage.

The design of the Endovascular Treatment for Small Core and Anterior Circulation Proximal Occlusion with Emphasis on Minimizing CT to Recanalization Times (ESCAPE) trial [32] was similar to MR CLEAN. Patients with acute stroke in the carotid T, M1, or M1 equivalent distribution confirmed on CT angiography and small infarct core based on the Alberta Stroke Early Computed Tomography (ASPECT) score of 6–10 were assigned randomly to endovascular therapy (intra-arterial lytic therapy, mechanical thrombectomy with stent-retrievers, or both) in addition to intravenous thrombolysis or thrombolysis alone. The planned enrollment was 500 patients but the trial was terminated early (after 316 patients) as a result of demonstrated efficacy. In the endovascular treatment group stent retrievers were used in 86% of patients. The primary endpoint, odds ratio of improving the modified Rankin score by 1 point at 90 days favored endovascular therapy (OR 2.5, 95% CI 1.7–3.8). In addition, the median 90-day modified Rankin score was 2 after endovascular therapy compared with 4 after conventional therapy, the likelihood of functional independence 53% versus 29%, and the 90-day mortality was significantly lower favoring intervention with no difference in intracranial hemorrhage. The median duration from CT scan and stroke symptom onset to reperfusion was very short (84 and 241 minutes, respectively). These results confirmed findings described by MR CLEAN trial investigators and emphasized the possibility and importance of short symptom onset to recanalization times.

The Extending the Time for Thrombolysis in Emergency Neurological Deficits—Intra-Arterial (EXTEND-IA) trial randomized acute stroke patients to intravenous thrombolysis or endovascular therapy using the Solitaire Flow Restoration Stent Retriever in addition to intravenous thrombolysis [33]. Intravenous therapy needed to be administered within 4.5 hours of stroke onset. Vascular access needed to be established within 6 hours of symptom onset and an infarct core of <70 mL with residual salvageable brain tissue on CT angiography was required for inclusion. Enrollment of 100 patients was planned, but the trial was stopped early (after 70 patients) due to efficacy. Similar to ESCAPE, the median time from symptom onset to vascular access was short (210 minutes). Three-day neurologic recovery was significantly more common after endovascular therapy (80% vs. 37%). Ninety-day functional independence (modified Rankin ≤ 2) occurred in 71% of patients in the endovascular therapy group compared with 40% in the conventional therapy group ($p=0.01$). There was no difference in mortality or symptomatic intracranial hemorrhage. Though embolization into a territory different from the initial stroke was observed in 6% patients, this was not clinically apparent.

The Solitaire with the Intention for Thrombectomy as Primary Endovascular Treatment (SWIFT PRIME) [34] trial was also stopped prior to planned enrollment because of proof of efficacy.

At trial termination, 196 patients with acute stroke in the anterior circulation (internal carotid, T-occlusion or MCA occlusion) were randomized to conventional intravenous thrombolysis or mechanical thrombectomy using the Solitaire stent retriever (Medtronic, Dublin, Ireland) (successfully deployed in 89%) in addition to intravenous thrombolysis. Time from stroke onset to groin puncture (224 minutes) and from stroke onset to stent deployment (252 minutes) was very short. Substantial or complete reperfusion occurred in 88% of patients treated with the stent retriever and clinical efficacy was superior in patients who underwent endovascular therapy in addition to thrombolysis compared with patients who were treated with conventional thrombolysis only, reflected by lower modified Rankin scores in the interventional group as well as a higher percentage of patients who reached a low modified Rankin score of ≤ 2 (60% versus 35%; $p < 0.001$). There was no difference in mortality or symptomatic intracranial hemorrhage.

In the Randomized Trial of Revascularization with Solitaire FR Device versus Best Medical Therapy in the Treatment of Acute Stroke Due to Anterior Circulation Large Vessel Occlusion Presenting within Eight Hours of Symptom Onset (REVASCAT), 206 patients with acute anterior circulation stroke were randomized to undergo intravenous thrombolysis alone (when eligible) versus mechanical thrombectomy with the Solitaire stent retriever in addition to venous thrombolysis if treatment was feasible within 8 hours of symptom onset and infarct area not large by neuroimaging [35]. The trial was stopped early given the superior neurologic outcome with endovascular therapy and publication of aforementioned trials demonstrating superiority of endovascular therapy in addition to intravenous thrombolysis over conventional intravenous thrombolysis alone. Stroke onset to reperfusion time in the group undergoing endovascular therapy was 355 minutes. Stent retrievers were used in 95% of the interventional group. Significantly more patients (44%) experienced a favorable neurologic outcome in the endovascular treatment group than the control group (28%). Similar to all four other trials, there was no difference in intracranial hemorrhage or mortality.

A recent meta-analysis of eight randomized trials, totaling 2423 patients, showed that endovascular thrombectomy was associated with improved functional outcomes (modified Rankin Scale 0–2, odds ratio 1.56, 95% CI 1.32–1.85; $p < 0.00001$). There was a tendency toward decreased mortality (odds ratio 0.84, 95% CI 0.67–1.05; $p = 0.12$), and symptomatic intracerebral hemorrhage was not increased (odds ratio 1.03, 95% CI 0.71–1.49; $p = 0.88$) compared with best medical management alone. The odds ratio for a favorable functional outcome increased to 2.23 (95% CI 1.77–2.81; $p < 0.00001$) when newer generation thrombectomy devices were used in greater than 50% of the cases in each trial. The meta-analysis demonstrates clear evidence for improvement in functional independence with endovascular thrombectomy, compared with standard medical care, suggesting that endovascular thrombectomy should be considered the standard effective treatment alongside thrombolysis in eligible patients [36].

Acute stroke therapy: practical aspects

Clinical examination

A neurologic examination should be performed according to the National Institute of Health Stroke Scale (NIHSS). Precise and fast assessment of the NIHSS score requires experience and should be

Box 68.1 Contraindications for systemic lytic therapy

- Intracerebral hemorrhage suspected or present on CT or MR imaging
- Initial CT demonstrates evidence for tissue necrosis in more than one-third of the middle cerebral artery territory
- History of intracranial hemorrhage
- Presence of an arteriovenous malformation or large partially thrombosed aneurysm
- Uncontrolled hypertension (BP >185/110 mmHg)
- Profound hyperglycemia
- History of Alzheimer's dementia
- Unknown stroke duration (e.g., patient woke up with symptoms)
- Stroke symptom onset >6 hours (relative contraindication)
- Recent stroke (within 3 months)
- Recent major surgery (<4 weeks)
- Recent gastrointestinal bleeding (<4 weeks)
- INR >1.7
- Thrombocytopenia (<100,000 cells/mL)

practiced under non-acute circumstances. An excellent resource for demonstration of NIHSS stroke scale assessment is found at the following link: <https://www.youtube.com/watch?v=x4bjXqtn6k> (NIH stroke scale training parts 1–4). The presence of a severe headache is rare in ischemic strokes [37] and should alert one to the possibility of intracranial hemorrhage. Similarly, neck pain in conjunction with a neurologic deficit should raise suspicion for carotid or vertebral artery dissection. Severe back pain, particularly if accompanied by a pulse deficit, can be a symptom of acute aortic dissection. Involvement of cranial vessels by the dissection can cause neurologic deficits by hypoperfusion. In the latter case, thrombolytic therapy or anticoagulation is contraindicated. Heart murmurs, fever, and constitutional symptoms in the setting of a neurologic defect can be symptoms of infectious endocarditis under which circumstances the administration of anticoagulation or thrombolysis can lead to neurologic deterioration because of hemorrhagic transformation of embolic strokes. Importantly, for the purpose of intravenous lytic administration, a brief history focusing on contraindications to lytic therapy (Box 68.1) should be performed. It is important to note that the presence of contraindications to lytic therapy does not preclude performance of endovascular therapy. Though the clinical benefit of stent retrievers has been demonstrated mainly in patients treated with intravenous thrombolysis, some stroke centers perform mechanical thromboembolectomy without prior lytic therapy and in the absence of systemic anticoagulation, provided continuous flush solution maintains clot-free catheters and sheaths.

Imaging

At the minimum, a non-contrast CT-scan should be performed to rule out intracerebral hemorrhage and stroke mimics (e.g., space occupying lesions). The Alberta stroke program early CT score (ASPECTS) quantitatively evaluates the core of ischemia on CT scans. ASPECTS is a topographic scoring system that divides the MCA territory of the brain that is affected by ischemic damage into 10 areas of interest. It is a strong predictor of both functional outcome and adverse events following treatment. Recently, the CE marked e-ASPECTS software has been developed to automate the ASPECTS scoring system for ischemic stroke patients. In a meta-analysis of the four studies that presented stratified ASPECTS data for mRS (ESCAPE, MR CLEAN, REVASCAT, and SWIFT PRIME), it was demonstrated that endovascular stroke treatment improved

functional independence compared with best medical treatment in patients with high baseline ASPECTS (OR 2.10, 95% CI 1.61–2.73; $p < 0.00001$) [36]. Mechanical thrombectomy also improved functional independence with moderate baseline ASPECTS (OR 2.04, 95% CI 1.25–3.32; $p = 0.004$). There was no evidence of benefit of endovascular stroke treatment in patients with low baseline ASPECTS (OR 1.09, 95% CI 0.14–8.46; $p = 0.93$) but only 28 patients were included in this analysis because MR CLEAN was the only study that incorporated this group of patients in their trial. Overall, these results suggest that patients with baseline ASPECTS >4 benefit from endovascular stroke treatment. ASPECTS is recommended by the American Society of Neuroradiology, American Heart Association/American Stroke Association, European Stroke Organization, and the Canadian Stroke best practice.

Most centers have the capability of performing CT angiography, requiring minimal additional time. This allows localization of the occluded vessel and can facilitate the intervention by obviating the need for cerebral angiography of non-target vessels. Moreover, it can identify collateral circulation and clot length. Assessment of the presence and size of cerebral parenchymal damage guides candidacy for intravenous or intra-arterial therapy. MR or CT perfusion imaging allows the identification and quantification of the ischemic penumbra (ischemic, yet viable tissue at risk that may be salvaged by timely reperfusion) guiding further therapy, especially in wake-up strokes or presentations with onset of symptoms >4.5 hours. Mobile CT scanners or flat panel CT in the catheterization laboratory and intensive care units (or even ambulance) accelerates treatment decisions [38,39].

Laboratory tests

A complete blood count, partial thromboplastin time (pTT), prothrombin time, serum creatinine, electrolytes and glucose levels should be obtained upon patient arrival in the emergency department. To shorten potential delays, portable point of care laboratory systems that allow measurement of these parameters at the site of imaging or in the emergency department have been shown to be useful [40].

Cerebral angiography

Considerable debate surrounds the topic of whether the patient should be sedated or undergo general anesthesia. This depends on cooperation of the patient and comfort level of the operator. Absence of sedation or general anesthesia allows continued neurologic assessment during the intervention but occasionally makes invasive imaging and maneuvering of equipment more challenging because of patient movement. In addition, the patient can experience severe pain during clot extraction. In any case, stroke should be treated as “cerebral resuscitation” and an anesthetic team should be instantly available. Importantly, any drop in blood pressure during intubation should be avoided to optimize the reserve of collaterals.

With rare exceptions, femoral access is obtained. Use of a micro-puncture system and fluoroscopic or ultrasound guidance facilitates single front wall common femoral artery puncture. Though a 6 Fr sheath can be used, in most cases a long 8 Fr balloon guide, allowing extra support, is preferable. Arch aortography using a 5 or 6 Fr pigtail catheter in 40° left anterior oblique angulation (10–15 mL contrast with digital subtraction imaging) is usually not necessary. A type I arch is the most favorable configuration with all cranial vessels (the innominate artery, left common carotid, and left subclavian artery) originating from the arch in one single plane with the outer curvature of the aortic arch. Type II (the innominate artery originates

between the outer and inner curvature of the aortic arch) and III (the innominate artery originates below the inner curvature of the aortic arch) arches are more difficult to navigate.

Attention should also be directed to the ostia, tortuosity, and presence of disease in the proximal arch vessels. The most common arch configuration is a separate take-off (from right to left) of the innominate artery, left common carotid and left subclavian artery ($\sim 70\%$) followed by a common origin of the innominate and left common carotid artery ($\sim 20\%$), origin of the left common carotid from the innominate artery (“bovine arch”) ($\sim 7\%$), separate take-off of the left vertebral artery from the aortic arch and (0.5%), and separate take-off of the right subclavian artery from the arch distal to the left subclavian artery coursing posterior to the esophagus toward the right upper extremity (rare). With a straightforward arch configuration, all arch vessels can usually be engaged with a 5 Fr SIMS, H1, or vertebral catheter. A road map can be superimposed on fluoroscopic imaging to help direct the wire and catheter. A hydrophilic (0.035-inch) guidewire (e.g., angled Glide wire, Terumo, Tokyo, Japan) is advanced into the desired location to help track the diagnostic catheter. For angiography of the anterior circulation, the wire is advanced into the internal carotid artery, provided this vessel is not stenosed or occluded. Alternatively, it can be left in the distal common carotid artery and the diagnostic catheter advanced over the wire into the common carotid artery for angiography. First, angiography of the carotid bifurcation and proximal internal carotid artery is performed in a 30° ipsilateral oblique and lateral views (additional views; for example with caudal angulation or contralateral oblique views, can be obtained if initial images do not adequately demonstrate the proximal internal carotid). Cerebral angiography of the anterior circulation is performed in lateral and postero-anterior cranial ($10\text{--}15^\circ$) views. Usually, injection of 2–4 mL contrast is sufficient for opacification. The stump of large vessel occlusions can usually be identified without difficulty (Video 68.1; Figure 68.1). However, in some cases, rotational angiography can be useful to identify vessel cut-off otherwise masked by overlapping branches (Video 68.7). Visualization of the cerebral veins and collaterals is important and this requires prolonged imaging and inclusion of the entire skull. For the posterior circulation, the wire can be positioned into the axillary artery and the diagnostic catheter advanced over the wire proximal to the vertebral artery ostium and non-selective angiography of the proximal vertebral artery can then be performed. Subsequently, the wire can be directed into the vertebral artery and the catheter tracked for engagement and angiography. It is often easier to cannulate the left vertebral artery first as this is the easier one to negotiate. The best views for the vertebral circulation are contralateral oblique for the segment from the origin to the location where the vertebral artery enters the first transverse foramen of C5 or C6 (V1 segment), ipsilateral oblique (alternatively, posteroanterior and lateral) for the segment between the first and last transverse foramen (V2 segment) as well as for the segment between the last transverse foramen and the foramen magnum (V3 segment), and lateral and postero-anterior cranial ($\sim 40^\circ$) for the intracranial vertebral segment (V4 segment), basilar artery, and posterior cerebral arteries. When encountering a difficult arch, arch vessel cannulation requires the use of a Simmons or Vitek catheter. These catheters are shaped such that, after delivery over a J-tipped 0.035-inch guidewire into the ascending thoracic aorta and withdrawal of the wire, the catheter is configured in the aortic arch and the vessel is cannulated by catheter withdrawal and rotation. Only when the

Figure 68.1 Angiography demonstrating an acute thromboembolic occlusion of the right middle cerebral artery (see also Video 68.1).

catheter is straightened will it be possible to advance a 0.035-inch hydrophilic guidewire into the respective vessels. Even if the occluded vessel is known from CT angiography, it may be important to have information on the contralateral flow and anterior and posterior circulation, as there might be collaterals via the circle of Willis. This can have favorable prognostic value.

Intervention (example of an acute middle cerebral artery occlusion intervention illustrated in Videos 68.1–68.13 and Figures 68.1–68.11)

For clot extraction, currently, a stent retriever is most commonly used. Within the diagnostic catheter, a hydrophilic guidewire (e.g., angled Glide wire) is advanced into the carotid artery and the diagnostic catheter tracked over the wire. If necessary, the Glide wire is then exchanged for a stiffer (e.g., Amplatz Stiff, Cook Medical, Bloomington, IN, USA) wire, providing sufficient support to advance the sheath and guide catheter into the common carotid artery. If there is no significant carotid stenosis, the sheath or, preferably, balloon-tipped guide catheter (e.g., Cello balloon guide catheter, eV3, Irvine, CA, USA) can be advanced (over a guidewire) into the internal carotid artery to allow closer position to the thrombus or embolus. If a balloon-tipped guide catheter is not available it becomes even more important to generously aspirate through the guide catheter/sheath during stent retriever retraction into the guide or sheath. A long distal access catheter (Neuron, Penumbra Inc., Alameda, CA, USA; DAC, Concentric Medical, Mountain View, CA, USA; Fargo, Balt, Montmorency, France) can give extra stability. For interventions in the vertebrobasilar or posterior cerebral circulation a 6 Fr sheath is positioned into the vertebral artery using a hydrophilic 0.035-inch wire.

When advancing a microwire into the cerebral vessels, it is important to respect and avoid small branches (e.g., lenticostriate arteries). Some operators prefer off-label use of a coronary 0.014-inch guidewire (e.g., Whisper wire, Abbott Vascular, Redwood City, CA, USA; or ChoicePT wire, Boston Scientific, Marlborough, MA,

Figure 68.2 The microcatheter has been advanced over the 0.14-inch wire into the inferior branch of the right middle cerebral artery distal to the distal end of the occlusion, followed by a microcatheter. Subsequently, the wire has been removed and a Solitaire stent retriever (Medtronic, Dublin, Ireland) advanced into the microcatheter with the distal markers at the tip of the microcatheter.

Figure 68.3 The Solitaire stent retriever (Medtronic, Dublin, Ireland) has been deployed (see also Video 68.2) by microcatheter retraction while maintaining Solitaire position. This causes partial flow restoration (see also Video 68.3).

USA), others prefer dedicated wires for the cerebral circulation (e.g., 0.014-inch Synchro microwire, Stryker, Kalamazoo, MI, USA; or Transcend wire, Boston Scientific, or 0.014-inch). An attempt should be made to position the distal wire tip beyond the occlusion as far as safely possible and, optimally, in a larger segment or branch (Video 68.8; Figure 68.8). Advancing the wire in the tortuous cerebral vasculature can be challenging. Tracking the wire with a microcatheter (e.g., Rebar 18 or 27™, Covidien, Dublin, Ireland, Prowler select plus Cordis, Hialeah, FL, USA; or Excelsior XT 27, Stryker

Figure 68.4 The balloon of the balloon-tipped guide catheter has been inflated (see also Video 68.4).

Figure 68.6 Angiography demonstrates flow restoration in the inferior branch of the right middle cerebral artery (see also Video 68.6).

Figure 68.5 During balloon inflation and while applying continuous suction via the guide catheter, the Solitaire stent retriever (Medtronic, Dublin, Ireland) in its deployed state and the microcatheter are removed as a unit (see also Video 68.5). The captured thrombotic material can be seen entrapped in the stent retriever after removal from the guide catheter.

Figure 68.7 There is residual thrombus in the superior branch of the right middle cerebral artery (see also Video 68.7).

can provide better support and torque transmission. Occasionally, crossing the occlusion with the wire alone causes some improvement in flow. The microcatheter should be positioned with the tip distal (preferably 1–1.5 cm) to the thrombus or embolus (Video 68.9; Figure 68.9). Some operators proceed with removal of the wire and

gentle injection of a very small amount (0.5–1.0 mL) of contrast via the microcatheter to assure intravascular position and to outline the cerebral vasculature distal to the occlusion (Video 68.9; Figure 68.9); however, this carries the risk of dislodgement of distal fragments of the clot. Once intravascular position is confirmed, a Solitaire stent retriever is advanced through the microcatheter into the culprit vessel such that the distal marker aligns with the distal tip of the microcatheter (Video 68.10). The Solitaire stent retriever is available in four sizes: 4X15, 4X20, 6X20, and 6X30 mm. The 4 mm Solitaire can be used for 2.0–4.0 mm vessel diameters and the 6 mm device for 3.0–5.5 mm vessel diameters. If a Rebar microcatheter is used, the Rebar 18 is recommended for deployment of the 4 mm and the 27 (slightly larger inner diameter; 0.027 vs. 0.021 inch) for deployment of the 6 mm device. The microcatheter is

Figure 68.8 The superior branch of the right middle cerebral artery is wired (see also Video 68.8) and a microcatheter advanced over the wire into the superior branch of the right middle cerebral artery.

Figure 68.10 The Solitaire stent retriever (Medtronic, Dublin, Ireland) has been advanced to the tip of the microcatheter (see also Video 68.10) and is deployed by removal of the microcatheter while maintaining Solitaire position (see also Video 68.11). Deployment causes restoration of flow in the superior branch of the right middle cerebral artery (see also Video 68.12).

Figure 68.9 The wire has been removed and a small amount of contrast is injected into the superior branch of the right middle cerebral artery confirming intraluminal position of the microcatheter (see also Video 68.9).

Figure 68.11 The stent retriever has been removed and angiography now demonstrates brisk flow in both inferior and superior branch of the right middle cerebral artery (see also Video 68.13).

then slowly removed while maintaining stent retriever position, thereby allowing the stent to expand (Video 68.2 and Video 68.11). Depending on the instructions for use, some operators leave the stent in expanded shape at the site of the thrombus or embolus for several (2–5) minutes. This maneuver alone sometimes re-establishes some degree of cerebral flow (Video 68.12; Figures 68.3 and 68.10) and can be accompanied by neurologic improvement. Subsequently, the expanded stent and microcatheter are removed as a unit and pulled back into the guide catheter or sheath (Video 68.5). If the guide catheter is balloon tipped, the balloon should be inflated and continuous suction applied during removal and until the stent

retriever exits the proximal end of the catheter (Video 68.4; Figure 68.4). If a balloon-tipped guide cannot be used, carotid flow can be interrupted by external manual compression during stent retriever removal while applying suction to the guide or catheter. Angiography is repeated to assess whether reperfusion has occurred. If not, or incomplete (Video 68.7; Figure 68.7), the culprit vessel is rewired, a microcatheter advanced with the distal tip distal to the thrombus, and the previously used stent retriever can be re-advanced and deployed in the thrombus in a similar fashion as described earlier.

The optimal antiplatelet, anticoagulant, or thrombolytic strategy remains to be determined. It is worth mentioning that in all randomized

trials demonstrating the efficacy of stent retrievers in acute stroke therapy, intravenous thrombolytic therapy had been initiated in most patients prior to proceeding with endovascular therapy. Some centers do not use thrombolytic therapy when the patient can be transferred directly to the catheterization laboratory from the emergency department or CT scanner without delay once a stroke with sufficient deficit is identified that warrants endovascular therapy. However, the merit and safety of this approach remain to be determined. If thrombolytic therapy was not administered immediately before endovascular therapy, administration of low dose intravenous heparin (e.g., 25–40 IU/kg) can be considered.

Regardless of the thrombolytic strategy, given that routine intravenous heparin may not be used or used at low dose and/or antiplatelet therapy are not administered before or during the procedure, meticulous attention to continuous heparinized saline flush via the side arm of a Y-connector attached to the microcatheter and the side arm of the guide catheter is of paramount importance to avoid catheter-associated thrombus formation. Purposeful omission of intraprocedural intravenous heparin or oral/intravenous antiplatelet agents is counterintuitive to those performing coronary interventions but reduces the risk of intracranial hemorrhage.

Complications

Intracranial hemorrhage is, by far, the most devastating complication. Risk factors include age, delayed reperfusion, use of anticoagulant or antiplatelet therapy in addition to lytics, lytic dosage, hyperglycemia, and size of the perfusion defect [41]. The incidence of intracerebral hemorrhage after endovascular stroke therapy is often overestimated because of the misinterpretation of contrast used for the intervention. Symptomatic intracranial hemorrhage occurs in approximately 10% of patients in most larger trials using intra-arterial thrombolysis [42–45]. However, in most recent trials using stent retrievers for mechanical reperfusion, the incidence of symptomatic intracranial hemorrhage is lower at 1–7.7%. In case of intracranial hemorrhage it should be known that most thrombolytic agents are not reversible but relatively short acting. If concomitant heparin is used, the administration of protamine is recommended (1 mg/100 IU heparin administered, maximal dose 50 mg). If glycoprotein IIb/IIIa inhibitors are used, platelet transfusions can be considered. Meticulous technique during wiring avoiding small perforator branches and careful attention to blood pressure control after reperfusion may help reduce the likelihood of hemorrhagic complication. Nevertheless, hemorrhagic transformation can occur even in the absence of any endovascular, thrombolytic, or anticoagulant therapy and can be related to breakdown of the blood–brain barrier caused by parenchymal necrosis. Hence, it should be recognized that the occurrence of intracerebral hemorrhage does not necessarily imply a problem with procedural technique or patient management.

Conclusions

In the past 20 years two important milestones have been reached in the treatment of acute stroke, intravenous thrombolysis and, more recently, mechanical thrombectomy using stent retrievers. Intravenous thrombolysis, though proven effective in large randomized controlled trials, has a number of shortcomings, most importantly, the low rate of stroke vessel recanalization and functional neurologic recovery particularly in large vessel occlusions that cause the most dramatic neurologic deficits. Routine

mechanical thrombectomy with stent retrievers, in addition to intravenous thrombolysis, if performed in a timely manner by experienced operators, has the advantage of substantially improving stroke vessel patency and neurologic outcome in large vessel occlusions of the anterior circulation without increasing the rate of intracranial hemorrhage or mortality. Under optimal conditions, this should be available to patients at most locations 24/7, similar to systems offering prompt percutaneous coronary interventions to patients with acute ST-segment elevation myocardial infarctions. To accomplish this, a sufficient number of centers with acute stroke management systems in place with an adequate number of well-trained physicians capable of cerebral thromboembolism are needed.

Carotid Artery Angioplasty and Stenting

Alberto Cremonesi, Shane Gieowarsingh, and Fausto Castriota

Maria Cecilia Hospital, GVM Care and Research, Cotignola, Italy

Stroke has been acknowledged as the third leading cause of death, subsequent to heart disease and cancer, in industrialized nations [1]. In the last decades, there has been unprecedented investment at national levels to develop the quality of services for heart disease and cancer leading to an improvement in patient survival. Recently, the focus has changed toward advancing the management of stroke patients, as it is recognized with an aging population the burden of this disease because of its high mortality, major disability, and dependence [2]. For this reason, it is vital that the more mature approach to the prevention and treatment at different levels in the pathogenesis and manifestation of this disease is pursued further by all concerned.

Ten to fifteen percent of all ischemic strokes originate from an atherosclerotic plaque at the level of the internal carotid artery (ICA). Carotid endarterectomy (CEA) has been shown to be efficacious in the long-term prevention of stroke for both symptomatic and asymptomatic patients with severe obstructive carotid disease [3–6]. Despite the controversial design and results of randomized trials comparing it with CEA, carotid angioplasty and stenting (CAS) is still a promising field because of its potential as a complementary therapy for patients who are considered high risk for CEA; and as an alternative, less invasive and effective revascularization procedure for a large subset of patients.

Background

The main goal of carotid intervention is the prevention of stroke, in particular disabling stroke. Following the application of surgical endarterectomy for treating carotid bifurcation disease in the 1950s, it was not until 40 years later that level 1 evidence from large randomized trials for its efficacy was established. Although there have been significant developments in pharmacotherapy for vascular disease over the last 30 years, the stroke prevention benefit has not been established specifically for patients with high-grade carotid stenosis [7,8]. CAS was developed to meet a need for a less-invasive revascularization strategy for patients considered high risk for surgical revascularization. The rapid advancement in endovascular technologies and techniques has resulted in the evolution of CAS to a refined technique with great potential to be applied to routine carotid revascularization practice.

Currently, controversy exists as to whether CAS should be accepted as an alternative to CEA. To answer this question there have been a few randomized trials comparing the therapies [9–15]; however, some have been hampered by difficulties with enrollment, results have been conflicting, many criticisms have been levied against trial designs and the required level of operator endovascular experience, and hence a clear consensus cannot be established. It is to be hoped that ongoing large randomized trials (SPACE-2; ACST-2; CREST-2; and ACT-1) [16,17] will address this uncertainty. Over the last decade single-center and multicenter case series and registry data have been published providing valuable evidence for the effectiveness of this therapy in both the short and medium term. Nonetheless, arising from these discussions and debates one thing is clear: to move forward toward the goal of stroke prevention, these procedures must be performed by high level and well-trained operators, preferable at high-volume CAS centers.

Important concepts and considerations

Tailored approach

To achieve a high level of procedural success the multifactorial CAS strategy involves a *tailored approach* in the application of endovascular devices and techniques to specific patients with specific lesions and vascular anatomies. This requires an in-depth knowledge of neuroassessment, carotid plaque characteristics, vascular anatomy, and technical features of endovascular materials: guiding catheters and sheaths, guidewires, embolic protection devices (EPDs), balloons and carotid stents. Following the experience gained in this field since 1997, with over 3000 procedures, our group strongly believes that each device has special characteristics and should be used in predefined indications.

Stent intrinsic antiembolic property

The major source of complications is distal embolization, either intraprocedural or post-procedural. For effective reduction of intraprocedural risk great emphasis is placed on the use of EPDs. An important concept to consider is the view that in the presence of an EPD, the type of stent implanted may not significantly impact on the risk of intraprocedural complications but subsequently plays a vital part in preventing neurologic events resulting from plaque

prolapse. It is appreciated that whereas in open surgical techniques the atheroma and thrombus burden are excised, the stent-protected angioplasty technique compacts this material to the wall, retaining it with its supporting scaffolding and wall-coverage properties. The stent cell geometry thus has an *intrinsic antiembolic property* influencing the risk of plaque prolapse and distal embolization during the 24-hour post-procedural and recuperative period until re-endothelialization is complete.

Safe CAS and protected procedure

The interventionalist *safe CAS and protected procedure* concept should encompass the idea that two protection positions should be implemented in practice. In addition to the use of high-tech devices to contain plaque (stents) or capture and remove embolic debris (EPDs), the implementation of the tailored philosophy to the entire management strategy from appropriate patient and lesion selection to meticulous device choice and interventional techniques is essential. An important element of this concept is the recognition of high-risk cases for CAS dependent primarily on the skill of the interventional vascular specialist. This is considerably more relevant in this field than other areas of percutaneous interventions.

Clinical governance and regulation

Establishment of standard operating procedures is critical to a successful CAS program. This is based on informed consent and patient choice, and effective clinical governance including consideration of setting up a prospective registry as a measure of quality assurance. This approach should be performed as part of a local institutional review board approved protocol with dispassionate oversight and assessment by an independent neurologist. This *regulation* must be emphasized because of the need to always be critical of our management to improve patient care.

Measurement of early outcomes and complications

In order to determine the safety of what we do in our clinical practice, *early outcomes and complications* should be analyzed in a focused manner. Several factors influence the 30-day risk of transient ischemic attack (TIA), stroke, and death: patient characteristics such as age and neurologic symptom status; and operational variables such as operator experience, aortic arch and carotid anatomy, plaque characteristics, stent technology, and type of EPD employed. If complications are recorded with no discrimination of time distribution, analysis of this cumulative data may not be useful to determine in detail the relevance of specified variables and can be misleading because of the heavy weight of confounding variables. Hence, we recommend documentation and analysis of adverse events within specified time periods: the intraprocedural period (those occurring after the beginning of the procedure to the time point when the patient leave the procedure room); the 24-hour post-procedural period (from the time point when the patient leaves the procedure room to 24-hours post-procedure); and the subsequent recuperative period of up to 30 days [18]. For a complete register of each adverse event, it should also be categorized according to its distribution: (i) access site complications; (ii) confined to the target vessel complications (arterial occlusion, severe vasospasm, dissection); (iii) organ-specific complications (neurologic, cardiovascular, respiratory, gastrointestinal, renal, and liver); and (iv) systemic complications (allergic and anaphylactoid reaction, septicemia, idiosyncratic reaction to drugs). These tools allow prospective and retrospective analyses of each event [18].

Table 69.1 High surgical risk criteria.

Clinical criteria	Anatomic criteria
1 Age >75 years	1 High cervical lesion
2 CCS Class 3–4 or unstable angina	2 Tandem lesions >70%
3 NYHA Class III–IV	3 CEA restenosis
4 LVEF <35%	4 Contralateral ICA occlusion
5 MI <6 weeks	5 Hostile neck (prior irradiation, tracheostomy, radical neck dissection)
6 Multivessel coronary artery disease	6 Cervical immobility
7 Severe pulmonary disease	
8 Severe renal impairment	
9 Contralateral cranial nerve injury	

CCS, Canadian Cardiovascular Society; CEA, carotid endarterectomy; ICA, internal carotid artery; LVEF, left ventricular ejection fraction; MI, myocardial infarction; NYHA, New York Heart Association.

Box 69.1 Challenges for carotid angioplasty and stenting (CAS)

- 1 Tortuous iliac vessels
- 2 Bovine or type III aortic arch
- 3 Calcified and irregular aortic arch
- 4 Tortuous supra-aortic vessels
- 5 Long irregular dishomogeneous plaque
- 6 Highly calcified carotid lesions

Indications and contraindications

The indication for carotid intervention includes a symptomatic patient with an angiographic stenosis of $\geq 50\%$ (i.e., a lesion-related neurologic event in the preceding 66 months), and an asymptomatic patient with an angiographic stenosis of $\geq 80\%$. The specific absolute contraindication for elective CAS is floating thrombus in the carotid artery. Standard relative contraindications to endovascular techniques would apply. The potential factors for considering a patient high risk for CEA, because of medical comorbidities or anatomic factors, thus indicating an endovascular approach, are shown in Table 69.1. Box 69.1 provides some insight into the issues that can prove challenging or increase the risk of the stenting procedure.

Carotid plaque characteristics

The evaluation of carotid plaque profile should describe, in addition to degree stenosis and vessel dimensions, both the length of disease and the morphologic features that predict plaque complexity and embolization risk (“vulnerable plaque”).

Both long lesions and clinically unstable plaques (i.e., recurrent TIAs) define a high-risk lesion subset, because of high plaque burden and inflammatory activation, respectively. Indeed, Krapf *et al.* [19] reported, using diffusion-weighted MRI, that the risk of new cerebral ischemic lesions after CAS was related to the length of the lesion, and Aronow *et al.* [20] described preprocedural leukocyte count to be associated with increased microembolization during CAS.

A study analyzing 200 CEA specimens showed that plaque phenotype correlated with embolization risk, where “vulnerable plaques” characterized by a large lipid pool covered by a thin fibrous cap were more prone to perioperative microembolization than fibrous plaques [21]. These vulnerable plaques are less echogenic, described as “soft-lesions,” and this pattern can be quantified by the Grey scale median (GSM) method. In the ICAROS study [22], the risk of CAS-related stroke was 7.1% in lesions with GSM <25 and 1.5% in lesions with GSM >25.

Therefore clinical, biochemical, and morphologic data should be assessed and integrated to predict the embolic risk of a specific carotid lesion in order to plan the tailored approach to intervention.

Vascular anatomy

Complete and standardized assessment of the patient’s vascular profile is achieved by evaluating all vascular beds involved in CAS procedure according to the Five Arterial Zones classification. The angiographic analyses of the “aortic arch,” “proximal vessel,” “stenting segment,” “distal vessel,” and “cerebral vessel” zones predicts the procedural technical difficulties allowing the operator to choose suitable techniques and materials according to the most relevant anatomic aspects [23–25]. The Five Arterial Zones procedural anatomic classification is shown in Figure 69.1 and the theoretical correlation between each zone and the basic procedural steps of CAS procedure is described in Figure 69.2. This classification stresses the need for a

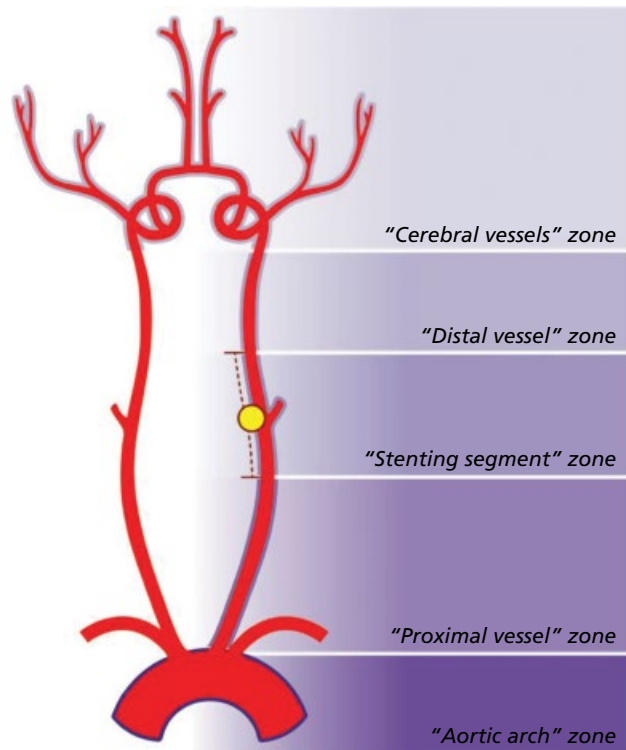

Figure 69.1 Schematic application of the “five arterial zones” classification system. The carotid lesion is represented by the yellow ball and the “stenting segment” limits by the red dashes. full anatomic evaluation, from the traditional aortic arch type (Figure 69.3) to the cerebral vessels pattern (Figure 69.4).

Cerebral protection devices

Carotid lesions contain friable, ulcerated plaque and thrombotic material that can embolize during an intervention as shown in histopathologic analysis [26] and transcranial Doppler studies [27]. Embolic particles can be classified as either macroemboli (>100 μm) or microemboli (<100 μm). Macroemboli, especially >200 μm , are usually associated with clinical events; however, the effects of microembolization are not well known and can include subtle changes in neurocognitive function. Despite advanced stenting techniques and dual antiplatelet therapy, embolization invariably occurs. A reduction of the Doppler-defined embolic load by an EPD has been shown [28], and preliminary results indicate that with the routine use of such devices the results of CAS are comparable with the best surgical series [29,30].

Protected CAS: clinical results

There has been no randomized trial comparing the efficacy of protected with unprotected CAS and it is difficult to imagine that such a study will ever be conducted on a significant number of patients. Recent literature data shed some light:

- Visible debris was documented in 60% of cases of filter-protected CAS by Sprouse *et al.* [31], and in 66.8% by our group [32].
- In the German registry [33], protected CAS was associated with a significantly lower rate of ipsilateral stroke (1.7% vs. 4.1%; $p=0.007$).
- Our group reported a 79% reduction in the rate of embolic complications with protected CAS [34].
- In the early phase of the EVA-3S study, unprotected CAS was associated with a 3.9 times higher stroke rate at 30 days than protected CAS [35].
- A 2003 review of the global registry found that the rates of stroke and death were 5.2% for unprotected CAS and 2.2% for protected CAS [36].
- Kastrup *et al.* [29], in a systematic review of the literature regarding the early outcome of CAS with and without EPD, analyzed studies published between 1990 and 2002 (2537 unprotected CAS and 896 protected CAS procedures); the combined 30-day stroke and death rates were 5.5% and 1.8%, respectively ($p<0.001$).

On the basis of this review, EPDs appear to reduce thromboembolic complications during CAS.

Distal protection devices

Distal protection devices work by interrupting or filtering blood flow by positioning the device distal to the lesion in a straight portion of the ICA (landing zone). The first system utilized an occlusion balloon, but nowadays filters are usually employed because they are less complex and perhaps more intuitive to use. Filters entrap debris of medium to large size, generally particles >100 μm . Filter performance can be summed up in crossing profile and capturing capability. Crossing profile is an important characteristic justified by the fact that the wire and the filter, constrained in the delivery system, must pass the lesion without detaching friable material. Capturing capability is dependent on membrane pore size and adequate wall apposition of the filter.

CAS BASIC STEPS	Accessing CCA/BCT	Proximal EPD selection and delivery	Distal EPD selection and delivery	Lesion pre-dilatation	Stent selection and delivery
	GC/LS removal	Proximal EPD retrieval	Distal EPD retrieval	Lesion (Stent) post-dilatation	Stenting Stent delivery system retrieval
"Cerebral vessels" zone	0	+++	0	0	0
"Distal vessel" zone	0	0	+++	0	0
"Stenting segment" zone	0	++	++	+++	+++
"Proximal vessel" zone	+++	+++	+	+	++
"Aortic arch" zone	+++	+++	+	+	++

Figure 69.2 Theoretical impact of the “five arterial zones” classification system on the technical evaluation of the basic carotid angioplasty and stenting (CAS) steps. The technical evaluation of CAS was divided into: (1) accessing and stabilising the system (guiding catheter, long-sheath or proximal EPD) in the CCA/BCT; (2) selection, deployment, and retrieval of proximal EPD; (3) selection, deployment, and retrieval of distal EPD; (4) lesion pre- and post-dilatation; and (5) stent selection, delivery, and deployment. 0: no influence; +: little influence; ++: moderate influence; +++: strong influence; BCT: brachiocephalic trunk; CAS: carotid artery stenting; CCA: common carotid artery; EPD: embolic protection devices; GC: guiding catheter; LS: long-sheath. Source: de Campos Martins EC, *et al.* 2012 [24], p. 614. Reproduced with permission of Europa Digital & Publishing.

Figure 69.3 Aortic arch anatomy classified as types 1, 2, and 3 with increasing levels of complexity for catheter engagement and provision of support for intervention. The red and white dashed lines point the outer and inner aortic arch curvatures, respectively. The brachiocephalic trunk origin (BCT) is represented in each figure. In aortic arch type 1 the origin of the BCT is at the level of the outer curve of the aortic arch; in type 2 the BCT originates between the levels of the outer and inner curve of the aortic arch, and in type 3 the BCT originates below the level of the inner curve of the aortic arch.

Limitations of distal protection devices

The distal occlusion balloon shares with filters, especially in tight stenoses, the limitation of unprotected crossing of the lesion in order to deploy the device. Filters are not effective in trapping microemboli, as they are limited by pore size. In tortuous or large distal ICA

anatomy, incomplete wall apposition can allow even macroemboli to bypass the system. In addition, debris can be dislodged during the recapture phase (squeezing effect). The distal occlusion balloon, despite being able to block microemboli by occluding the ICA, can lead to embolization via collaterals from the external carotid artery

Figure 69.4 (a) Right AP intracranial angiogram. The outlined arrow shows the right internal carotid artery (ICA). The black arrow points to the anterior cerebral artery leading to the pericallosal artery (black arrowhead). The middle cerebral artery is shown by the white arrow and its branches (white arrowhead). (b) Right lateral intracranial angiogram. The outlined arrow shows the right ICA. The black arrowhead shows the pericallosal artery. The middle cerebral and anterior cerebral arteries are not well individualized in this projection.

(ECA) to the middle cerebral artery. Moreover, about 5–8% of patients develop clamping intolerance to the interruption of cerebral perfusion [37]. Additionally, both systems can be a source of embolism because of intimal damage at the landing zone.

Proximal protection devices

Proximal protection devices work by interrupting or reversing blood flow in the ICA. They offer the advantage of crossing the lesion under protection and blocking both macro- and micro-emboli. Moreover, navigation of the device in the distal ICA is not required, thus reducing the risk of intimal damage, spasm, or dissection. There are two such devices: the Mo.Ma and NeuroProtection systems.

Mo.Ma™ (Medtronic)

The Mo.Ma system consists of a 9 Fr sheath (8 Fr in the new system) with an effective working channel of 6 and 5 Fr, respectively, and two independently inflatable balloons placed at a distance of 7.2 cm. The distal balloon occludes the ECA up to a diameter of 6 mm and the proximal balloon occludes the common carotid artery (CCA) up to a diameter of 13 mm, thus preventing antegrade flow from the CCA and retrograde flow from the ECA. The lesion can be crossed and treated under protection. Following post-dilatation, three 20-mL syringes of blood are actively aspirated and checked for debris before deflating the balloons. Insertion of the system via a 9–10 Fr sheath is advisable in order to allow arterial pressure monitoring via the femoral sheath side-arm throughout the procedure.

NeuroProtection System™ (NPS) (Gore)

The NeuroProtection System, derived from the Parodi antiembolic system (PAES) (ArteriA), allows continuous passive ICA flow reversal through endovascular clamping of the CCA by inflating a

balloon located at the tip of a 9 Fr compatible delivery system/sheath and of the ECA by inflating an independent balloon catheter advanced into the ECA via the sheath. The system allows connection to the contralateral femoral vein, and flow reversal of blood from the contralateral cerebral circulation via the circle of Willis, down the ICA, and through the sheath into the venous system. A filter (pore size 180 μm) collects debris before the blood re-enters the venous system. Then the lesion can be crossed and treated under protection. After each stage, particularly those associated with the greatest risk of embolization, 10 mL blood is actively aspirated and at the end of the procedure balloons are deflated while active suction is applied to retrieve any particle contiguous to the balloon occluder. The effective working channel of the assembled system is 6 Fr. Manufacturing of this particular system has ceased during the past 2 years, owing to the global limitation of carotid stenting procedures.

Proximal protection during CAS: clinical data

The available clinical experience is from five multicenter registries: EMPiRE trial (354 patients – including lead-in and continued access patients with the use of GORE flow reversal system) [38]; ARMOUR trial (262 pivotal plus lead-in patients with the use of MO.MA system) [39]; multicenter single-arm European trial (121 patients with the use of GORE flow reversal system) [40]; two prospective registries (157 patients with the MO.MA system and 233 patients using MO.MA and GORE flow reversal system) [41,42]; and one large-scale single center registry (1270 patients with the MO.MA system) [43], which have been summarized in a meta-analysis [44]. Among 2397 patients, the 30-day rate of composite stroke, myocardial infarction (MI), or death was 2.25%. Stroke, MI, and death were encountered in 1.71%, 0.02%, and 0.40%, respectively. Age and diabetic status were found to be the only significant

independent risk predictors; however, total stroke rates remained below 2.6% in all subgroups, including symptomatic octogenarians. Other variables including gender, symptomatic status and contralateral carotid occlusion, were not found to be independent risk predictors. The authors speculate the potential benefits of proximal occlusion devices over distal protection devices were the result of two main factors: first, proximal protection allows neuroprotection throughout all phases of the procedure, transcranial Doppler studies have demonstrated that proximal protection is associated with fewer micro embolic signals (MES) during initial wire crossing when compared with distal protection [45,46], and, second, proximal protection devices are able to capture particulate debris with high efficiency [47]. Distal filter are known to face difficulty in capturing small particles (40–120 mL) [48,49]. Because of limitations in broad expansion of CAS, innovation in the area of proximal protection equipment has ceased.

New developments in cerebral protection

ENROUTE Neuroprotection System (Silk Road Medical)

The ENROUTE Neuroprotection System is a novel flow reversal system consisting of two sheaths, one surgically placed in the CCA (initial portion) via a transcarotid approach connected to a transfemoral percutaneous venous line. The procedure represents a combined surgical and endovascular approach to carotid revascularization. An in-line flow regulator allows the operator to modify the flow through the circuit from high flow up to temporary flow cessation. The carotid sheath is placed in the ipsilateral CCA via a surgical incision above the clavicle. The venous sheath is inserted percutaneously into the femoral vein. The arterial and venous return sheaths are connected by the flow line, which creates an arteriovenous shunt. Following the proximal protection concept, the flow reversal is induced prior to any lesion manipulation by occluding the carotid artery proximally to the carotid sheath resulting in pressure gradient. The ipsilateral ECA does not need to be occluded with this system, as it is the case with other proximal embolic protection devices. The main advantage of this system is the avoidance of aortic arch manipulation associated to robust proximal embolic protection. Disadvantages of the system include the requirement of a disease-free portion of CCA at the site of surgical incision.

The PROOF study was a first-in-man, single-arm feasibility study using the ENROUTE™ Neuroprotection System in 44 patients who were candidates for carotid artery revascularization. The primary endpoints were major stroke, MI, or death from the index procedure up to 30 days. Procedural microembolization was studied in a subgroup by performing diffusion-weighted magnetic resonance imaging (DW-MRI) pre and post-procedure. One minor contralateral stroke was reported at 30 days in a patient who was free of lesions on pre and post-procedural DW-MRI scans. There were no MIs or cranial nerve injuries [50]. A subset of 31 patients underwent DW-MRI of brain within 72 hours preprocedure and 24–48 hours post-procedure. Five patients had new white lesions (16.1%). This represents the lowest DW-MRI rate of any carotid stenting strategy to date.

The ROADSTER trial is an ongoing prospective, single-arm, multicenter investigational device exemption clinical trial of the ENROUTE Neuroprotection System (Silk Road Medical Inc. Sunnyvale, CA, USA) in conjunction with all commercially available carotid artery stents, approved by the Food and Drug Administration (FDA), used for revascularization in patients with carotid artery disease who were considered to represent a high risk for carotid endarterectomy. The trial has recently completed

enrollment to target with 141 pivotal patients. The primary endpoint, a composite of stroke, death, and MI will be compared with an objective performance criterion based on the results from the CREATE trial and will be presented to the FDA for device approval.

Limitations of proximal protection devices

The drawbacks of proximal protection devices include their large size, clamping intolerance, and the impossibility of their use with severe disease of the ECA or CCA. Contralateral ICA occlusion is not necessarily a contraindication in the presence of a functional circle of Willis with adequate flow from the vertebral system.

The need for large femoral sheaths can preclude use in patients with severe peripheral disease and could be associated with an increase in access site complications. Nevertheless, with the first version of the Mo.Ma device (10 Fr), in the PRIAMUS registry, the rate of local complications was 4.1%, none requiring surgical repair or blood transfusions. Higher complication rates were reported by Rabe *et al.* [51] with the PAES, but, given the current availability of 8–9 Fr size for the Mo.Ma and 9 Fr for the NPS device, it is reasonable to expect a low rate of clinically significant access site complications.

Clamping intolerance occurs in up to 8% of patients and is generally associated with severe contralateral disease or poorly developed cerebral collateral circulation. An intraprocedural parameter predictive of intolerance is represented by a backpressure <40 mmHg occlusion [44]. Another key factor is overall clamping time, which has progressively shortened with increased experience (for the Mo.Ma system from 10 minutes in the study of Diederich *et al.* [52] to 5 minutes in the PRIAMUS registry [53], with a parallel decline in the rate of clamping intolerance from 12% to about 6%). The same holds true for the PAES/NPS device, as the rate of clamping intolerance dropped from 8% in 2001 to 3% in 2005 [54]. However, clamping intolerance has not been associated with higher major adverse coronary and cardiac events (MACCE), even in the presence of contralateral occlusion [44], and it does not represent an absolute contraindication to carry on the procedure. Indeed, three strategies can be adopted: hurry up in order to restore perfusion as soon as possible; positioning under protection a distal filter and then deflating the balloons (“seatbelt and airbag” technique); perform a step-by-step procedure in which the balloons are inflated and deflated at each procedural step.

When to use proximal or distal protection and potential complications

Large studies comparing proximal with distal protection are lacking, so device selection should be based on the tailored approach. In challenging anatomies, with angulated ICA-CCA take-off and/or lack of a suitable ICA landing zone, proximal protection should be strongly recommended. The same holds true for lesions with high embolic risk, because proximal protection devices seem to be more effective than filter systems in avoiding distal embolization. The most frequent complications with distal protection devices are spasm and slow flow with an incidence of up to 3.6% and 7.2%, respectively [55]. In our experience a gentle approach as well as the use of a soft-tipped filter wire minimized the frequency of this problem. Slow flow occurs when the filter pores are partially or completely occluded with debris and disappears following removal of the filter. Dissections at the landing zone have been described in 0.5–0.9% of cases [30,56]. Device retrieval occasionally poses a problem and it is here that the torqueability of a guiding catheter can help change the attitude of the system allowing the retrieval sheath to cross the stent. Other maneuvers include turning the

patient's head or using a buddy wire. Complications related to proximal protection devices are mostly related to intolerance. In the recently completed Mo.Ma registry [57], intolerance was observed in 7.1% of patients; in 1.9% intermittent balloon deflation was necessary to complete the procedure, and in 0.6% a distal filter was positioned. All patients completed the procedure without in-hospital or 30-day neurologic complications.

Self-expanding carotid stents

Structural and functional characteristics

Braided-mesh stent

The first self-expanding stent dedicated to carotid application was the cobalt alloy braided-mesh frame which is highly flexible with acceptable radial strength. The frame is compressible and constrained within a sheath: a spring-like action allows it to expand as the sheath is withdrawn during deployment. Advantages include a small and flexible delivery system, a small free-cell area with high scaffolding and wall-coverage properties (plaque covering) and adaptability to the changing diameter across the bifurcation. However, it tends to straighten the vessel and has an unpredictable foreshortening during deployment.

Nitinol stents

The second group of self-expanding stents is represented by a nitinol structure (nickel-titanium alloy). The thermal expansion properties of nitinol characterize these devices and when exposed to body temperature they expand to the predetermined shape and size. Most are obtained from a tube of nitinol which is laser-cut to create a frame comprised of sequential aligned annular rings interconnected in a helical fashion. Another frame is the flat-sheet nitinol-roll closed-cell design. An advantage of the nitinol stents is minimal foreshortening on deployment.

Nitinol stents, for simplicity, can be categorized as an open cell, closed cell, and hybrid designs, with either a cylindrical or tapered shape. The open-cell designs tend to have a larger free-cell area than

the closed-cell designs. The advantages of open-cell stents include high conformability and flexibility, and high vessel-wall adaptability. Disadvantages include moderate scaffolding and wall-coverage properties, and stent-strut malalignment in complex carotid lesions. The closed-cell stents have high scaffolding and wall-coverage properties but are disadvantaged by stiffness with poor conformability and flexibility. The semi-quantitative comparison of functional differences among stent designs are shown in Table 69.2. Hybrid nitinol stents can be characterized by a hybrid solution of open cells in the distal and proximal segments in order to enhance flexibility and adaptability, and a closed-cell design in the middle to obtain the appropriate scaffolding and wall coverage to prevent plaque prolapse (Figure 69.5). No study has definitively determined if an open, closed, or hybrid stent has a definite superiority in all lesions. Closed-cell design stents allow less plaque protrusion but also cause more arterial straightening and distal vessel kinking. The opposite effects are evident with open-cell design stents. Stent choice in a specific patient should be based on clinical judgment regarding which of the two concerns is more applicable in the individual case.

Is there a logical scheme for stent selection?

Different stent designs demonstrate functional equivalence when used in uncomplicated scenarios: simple supra-aortic anatomies, straight carotid bifurcations, and stable fibrous plaques. However, frequently the operator has to face challenging situations requiring a move toward a tailored approach. Table 69.3 shows a functional categorization where cobalt-alloy braided-mesh stents are the first choice when the greatest need is to achieve reliable plaque coverage and long-acting plaque prolapse prevention because of the constant radial force property (soft and long non-homogeneous lesions are very prone to distal embolization). Bosiers *et al* [58] demonstrated a clear benefit in favor of stent scaffolding and wall coverage for reducing post-procedural neurologic complications for symptomatic patients (unstable risky plaque). When the main technical challenge is represented by the carotid bifurcation and

plaque complexity (severely angled lesions, plaque ulceration), or the main goal is to maintain the original anatomy/course of a very tortuous vessel, the in-vessel flexibility and the wall–plaque conformability of nitinol open-cell stents are unmatched. Nitinol closed-cell stents represent a great technical solution for focal concentric lesions, especially if resistant or calcified: in such a clinical

subset the functional key point is the outward radial force exerted by the stent over time.

New developments in carotid stents
Double-layer mesh stent technology

The RoadSaver™ carotid stent (Terumo, Japan) is a self-expanding, double layer, micromesh scaffold compatible with a 0.014-inch guide wire and 7 Fr guiding catheter/6 Fr long sheath (Figure 69.6). The external nitinol mesh layer enables a flexible scaffold that can accommodate tortuous anatomy and allow for adequate strut apposition while the internal nitinol micromesh—the cell size is extremely small (0.381 mm²)—allows an increased plaque coverage, a characteristic that should be beneficial in terms of post-procedural embolic protection by very tight plaque coverage (Figure 69.7). The stent diameter currently available is in the range 5–10 mm while the length cover ranges from 20 up to 50 mm in 10-mm intervals. The promise of this technology is to achieve improved plaque coverage thanks to the internal micromesh that captures the prolapsing tissue, while the flexible external layer provides great adaptation to the vessel anatomy, thus reducing the rate of acute malapposition. It remains to be demonstrated whether this interesting concept will translate into a reduction of ischemic neurologic events associated with CAS; no such study can provide definitive evidence thus far.

Step-by-step technique of carotid stenting

Clinical protocol

Pre-medication

Dual antiplatelet therapy with aspirin and clopidogrel, ideally initiated 5 days before the procedure; and continued for at least 30 days, at which time clopidogrel is usually discontinued.

Pre-procedure investigations

- Carotid duplex scan, CTA/MRA scan.
- Independent neurologic evaluation.

General procedural measures

- Head restraint and no sedation, with neuroevaluation during procedure by simple communication and movement parameters.
- Standard monitoring of vital parameters.
- Heparin IV 70IU/Kg (activated clotting time 250–300 seconds).

Technique

Vascular access

Femoral access is recommended, but in the presence of extreme tortuosity or occlusion of the iliac arteries the radial or brachial approach is feasible; however, consideration needs to be given to the compatibility of the materials in planning the intervention. Generally, the right CCA is approached from the left arm and vice versa, but in reality it is determined by the distance between the origins of the supra-aortic trunks.

Figure 69.7 Optimal coherence tomography assessment of a RoadSaver™ stent showing no significant prolapse of plaque and good wall apposition. The white arrows point to the stent meshes.

Baseline angiographic evaluation

In the absence of a CTA/MRA scan, aortic arch angiography is undertaken with a pigtail catheter (30–45° LAO) to visualize the origin of the supra-aortic vessels. Selective cannulation of the target vessel is performed to evaluate the carotid bifurcation in at least two orthogonal projections, demonstrating the maximum severity of the lesion and adequate separation of the ICA from the ECA, in both digitally subtracted and regular formats. The RAO view is helpful to separate the division of the brachiocephalic trunk into the subclavian artery and CCA. It is mandatory to perform an intracranial angiogram which may reveal an unexpected arteriovenous malformation or for comparative assessment with the post-intervention angiogram in the event of embolization. Four-vessel angiography is indicated only where the complexity of the case recommends it as mandatory, such as establishing the adequacy of the collateral circulation and the function of the circle of Willis when considering endovascular clamping in the presence of contralateral ICA occlusion.

Common carotid engagement

Obtaining a safe and stable engagement of the CCA is one of the most important technical aspects to the CAS procedure. Two standard techniques are described outlining the most commonly used materials in our laboratory.

Guiding-catheter engagement

- A 90–100 cm 8 Fr guiding catheter is chosen according to the aortic arch configuration:
- For simple anatomy, a 40° angled soft-tip catheter is advanced to the mid-CCA over a soft-angled 0.035-inch standard hydrophilic wire positioned just below the bifurcation.
- For complex anatomy an angulated guide such as a “hockey stick” curve catheter is advanced into the proximal CCA.
- The introduction of two, or possibly three, 0.035-inch wires in order to advance the catheter in the presence of an unstable situation is feasible. Another option is the placement of a 0.014-inch wire in the ECA for increased stability during the intervention.

- The great advantage of this technique is steerability but it is critical to be cognizant of the risk of scraping the aortic arch during manipulation with the attendant risk of embolization. This can be avoided by meticulous technique, executed by gentle, small, and slow movements; always advancing under rotation and with the right orientation of the catheter using the wire to engage the artery. Of course, a drawback of this strategy is the large femoral access with the attendant risk of complications.

Sheath placement

- A 100 cm 5 Fr JR4 guiding-catheter is advanced over a soft-angled 0.035-inch standard hydrophilic wire into the CCA. The use of a guiding catheter allows contrast injection with a 0.035-inch wire. The same can be achieved with a 6 Fr Vitek or Berenstein type catheter according to anatomic suitability.
- Following an angiogram delineating the bifurcation, the hydrophilic wire is advanced into the ECA and positioned in a distal branch avoiding the lingual artery. The guiding catheter is then advanced deeply into the ECA in a stable position, and if added support is needed a 0.018-inch wire may also be accommodated. The standard 0.035-inch wire is exchanged for a long 260–300 cm 0.035-inch support wire.
- The guiding catheter is then withdrawn and a guiding sheath is advanced to the mid-CCA over the support wire. In our practice the Mo.Ma device, which incorporates the functional aspect of a proximal protection device into a shuttle sheath, is applied and its respective aspects are advanced into the ECA and CCA.
- The advantage of this technique is its safety but it is less steerable and with a tortuous CCA kinks can result or existing tortuous loops can be exaggerated and displaced cephalad. In addition, with significant disease in the proximal CCA or an occluded ECA this technique is not feasible.

EPD management

Managing the EPD in a safe and expeditious manner is one of the key points to successful CAS and several issues are discussed in the relevant sections.

Pre-dilatation

Pre-dilatation is reserved for very tight lesions, heavily calcified lesions, or stenoses with a high tendency to recoil such as long fibrotic lesions. This is usually undertaken with a low profile coronary balloon in the range of 2.5–4.0 mm diameter and 20–30 mm length, and inflated at nominal pressure to minimize the risk of embolization. Consideration should be given to using a cutting balloon for heavily calcified lesions, usually with a diameter of 3.5–4.0 mm and inflated at moderate pressure (8 atm). Our group reported on the use of this application in 111 patients with severe highly calcific *de novo* disease with a procedural technical success rate of 100% [59,60]. The combined all stroke and death rate at 30 days follow-up was 0.9%, with one major stroke. Pretreatment with 0.5–1 mg intravenous atropine is required at this stage and/or post-dilatation phase. Large doses of atropine are avoided in the elderly, as this can result in confusion and make accurate neurologic assessment difficult.

Stent deployment

The unconstrained diameter of the self-expanding stent should be 1–2 mm larger than the reference vessel diameter in order to obtain a stable position and a reliable wall apposition. Usually, we recom-

mend to stent from “angiographically normal-to-normal” vessel. In the presence of challenging anatomy it is helpful when bringing up materials across the arch is to view the stability of the guide in an LAO view. When deploying the stent, release at least 5 mm of the stent distally and wait for it to expand and stabilize against the wall before releasing the remainder of the stent. If the distal edge lands into a tortuous segment injury can result. It is prudent to be aware that tortuous segments are not straightened by a stent but are simply displaced cephalad and can be exaggerated. Speed and minimum use of devices across the lesion are not negligible keys for successful CAS.

Post-dilatation

Post-dilatation is always a critical step as the greatest amounts of emboli are released in this phase. To minimize the embolic load we recommend:

- Balloons no larger than 5.5 mm in diameter;
- Inflating to nominal pressure;
- Accepting a 10–15% residual stenosis;
- Persistent flow via the struts into an ulcer does not require further dilatation; and
- If the ECA becomes occluded, recanalization should be attempted only if the patient is symptomatic (jaw or facial pain) and in such a case it may be sufficient to restore only TIMI II flow.

Final angiographic evaluation

Following EPD removal, final angiograms are acquired in the same baseline projections. If a distal protection device was used the landing zone has to be checked carefully, particularly if the ICA is tortuous, to exclude any spasm or dissection. Ipsilateral intracranial angiography should be routinely acquired.

Vascular access site management

General access site management should apply and take into account that an early ambulation and discharge can counteract the activated carotid sinus reflex and the occasionally observed post-procedural hypotension.

Case histories

The following cases were selected to illustrate the tailored approach to CAS.

Case 1: Technical issues related to the stenting segment: short and soft plaque associated with complex anatomy (Figure 69.8)

Technical issues

- Vessel tortuosity is challenging for distal EPDs and necessitates a stent with good conformability to respect the original vessel anatomy; and the mismatch between the ICA and CCA requires a tapered design.
- Soft, highly embologenic plaque needs a stent with high scaffolding properties.

“Tailored” CAS strategy

- Proximal EPDs avoid the risk of unprotected crossing of the lesion and tortuous segment with a distal device.
- The stent provides good conformability because of the open cells at the distal and proximal parts; the closed cells in the middle part afford adequate scaffolding and the tapered design suitably adjusts to the vessel mismatch.

Figure 69.8 Stenting segment complexity: (a) Short and high-grade lesion in right ICA with significant “soft” component identified by duplex scan. (b) Contrast injection through the Mo.Ma device after flow blockage “roadmap.” (c) Stent 7/10 x 40 mm positioning. (d) Stent deployed: distal edge diameter showed by white arrows, proximal edge diameter showed by black arrow. (e) Post-dilatation with a 5.5/20 mm balloon. (f) Final result: the closed-cell segment is shown by the full arrow and the outline arrows show the open-cell segments.

Case 2: Technical issues related to the proximal vessel zone: challenging supra-aortic anatomy (Figure 69.9)

Technical issues

- Marked tortuosity of the brachiocephalic trunk and CCA, in addition to posing a challenge to engagement makes it difficult to establish good support to complete the intervention.

“Tailored” CAS strategy

- Use of multiple wires to engage the CCA and maintain stability; in addition to the use of a soft-tip guiding catheter are key strategies.
- Also, the choice of a highly deliverable stent is crucial.

Case 3: Technical issues related to stenting segment: long ulcerated lesion (Figure 69.10)

Technical issues

- A long irregular lesion with severe ulcerations poses a high embologenic risk. In addition, crossing of the lesion with a wire affixed to a filter is risky.

“Tailored” CAS strategy

- The Spider filter (eV3) allows the choice of an independent 0.014-inch wire to gently cross the lesion.
- Carotid stent provides high scaffolding and long-acting plaque prolapse prevention until the ulcerations are obliterated. As the

Figure 69.9 Proximal vessel zone complexity: (a) Arch angiogram shows marked tortuosity of the supra-aortic vessels. (b) A 0.035-inch hydrophilic wire placed in the right subclavian artery (full arrow) stabilizes the 40° 8 Fr guide in order to advance a 0.014-inch wire to the external carotid artery (ECA; outline arrow). (c) Then the 0.035-inch wire is brought up into the common carotid artery (CCA) followed by another 0.035-inch wire (arrowhead). With this support the guide can be safely advanced into the CCA. (d) A filter is positioned in the distal ICA with the 0.014-inch wire in the ECA providing extra support. (e) Carotid Wallstent (Boston Scientific) positioning. (f) Final result after post-dilatation.

ICA is aligned to the CCA the tendency of this stent to straighten the vessel does not pose a problem in this case.

Case 4: Technical issues related to the proximal vessel zone: very large CCA > 10 mm and consequent vessel mismatch (Figure 69.11)

Technical issues and “tailored” CAS strategy

The very large CCA and vessel mismatch requires the right stent, which can be sized 12 mm in diameter. In addition, availability in a tapered shape would be suitable for the vessel size mismatch.

Case 5: Technical issues related to the cerebral vessel zone: arteriovenous malformation (Figure 69.12)

A patient awaiting aortic valve surgery attended for intervention to an asymptomatic right ICA stenosis. Unexpectedly, intracranial angiography revealed an arteriovenous malformation (AVM)

feeding off from the right anterior cerebral circulation. Our neurosurgical colleagues were consulted and, based on the possibility that stenting will increase the perfusion pressure to the AVM thus risking a hemorrhagic complication, a decision was made to manage the patient conservatively until further assessment and treatment of the AVM. This case illustrates the value of obtaining an intracranial angiogram when planning CAS, and emphasizes the importance of teamwork and consultation of colleagues in a safe CAS practice.

Carotid stenting complications

Bradycardia and hypotension

Transient sinus bradycardia or asystole are relatively common responses during balloon dilatation at the carotid bifurcation and pretreatment with atropine is preventative. This is less commonly observed in treating restenosis after CEA where the receptors have

Figure 69.10 Stenting segment zone complexity. (a) Long ulcerated lesion involving the left ICA and distal CCA. (b) Cerebral angiogram shows a dominant left hemisphere with visualization of both anterior cerebral arteries (full arrows) and the anterior communicating artery (circle). (c) Confirmation of good wall apposition of filter (circle). (d) Suboptimal wall apposition of 9/40 mm stent. (e) Post-dilatation with a 5.5/20 mm balloon. (f) Final result showing good stent expansion. The concept to cover from angiographically normal-to-normal segments is illustrated. The persistent ulcerations will be excluded by in 2–3 weeks.

been denervated by surgical dissection. Hypotension from stimulation of the baroreceptors from both balloon dilatation and the persisting stretch of the self-expanding stent is not uncommon and is usually managed by adequate intravascular volume expansion, but with heavily calcified lesions can be more pronounced and require small doses of intravenous vasopressors such as 0.5 mg metaraminol. Continued hemodynamic monitoring in the 24-hour post-procedural period is crucial. Severe sustained hypotension can require dopamine infusion, but it is important not to overlook other potential causes of

hypotension such as retroperitoneal hemorrhage. Hypotension should be corrected expeditiously in the presence of contralateral ICA occlusion, intracranial stenoses, vertebrobasilar disease, and pre-procedural cerebral ischemia secondary to an embolic event.

Carotid artery spasm

Spasm of the distal ICA following filter deployment usually resolves spontaneously within several minutes after removal. A flow-limiting spasm could be a potential hazard in the presence of contralateral

Figure 69.11 Stenting segment zone complexity. (a) Short and severe lesion of right ICA with an enormous CCA. (b) Confirmation of good filter wall apposition. (c) Stent positioning 8/12 x 40 mm. (d) Stent aspect after deployment, noting the struts in the CCA. (e) Post-dilatation with 5.5/20 mm balloon. (f) Final result.

ICA occlusion and/or incomplete circle of Willis. Intra-arterial administration of 100–400 μ g nitroglycerin, once blood pressure allows, through the guiding catheter generally aids in resolution of the spasm. Recalcitrant spasm usually responds to low-pressure balloon angioplasty (≤ 2 atm).

Distal embolization

Symptomatic distal embolization is the most important complication but the extensive use of EPDs has reduced this to a rare event (0.4–1.5%). The predisposing factors are shown in Box 69.2. It is essential to monitor the patient's neurologic status after every step of the procedure. If a significant change appears and persists, gen-

eral patient care should be instituted with emphasis on maintaining normal blood pressure and intravascular volume status, stabilizing heart rate, and maintaining a viable airway with oxygen administration. If the patient becomes agitated and especially if the airway is compromised, the assistance of an anesthesiologist should be utilized. Whenever possible the procedure should be concluded quickly and intracranial angiography undertaken. The most likely sites are the distal ICA and the middle cerebral artery including its branches. Large vessel occlusion is easy to detect, but embolism in the smaller branches requires careful scrutiny utilizing the preprocedural angiogram. An attempt should be made to recanalize an occluded large vessel as soon as possible (balloon angioplasty,

Figure 69.12 Cerebral vessel zone complexity. (a) Focal right ICA stenosis. (b–e) show the intracranial angiogram revealing an arteriovenous malformation.

thrombolytic agents, IIb/IIIa inhibitors). For a symptomatic small branch occlusion, adequate hydration, blood pressure, and anticoagulation should be ensured.

Intracranial hemorrhage

Cerebral hemorrhage is a life-threatening complication, though rare. Sudden loss of consciousness preceded by severe headache in the absence of vessel occlusion should alert the operator. A more subtle feature is signs of a localized expanding phenomenon on angiography. Once suspected, anticoagulation should be reversed and an emergency CT scan performed. Cerebral hemorrhage has been associated with a combination of excessive anticoagulation, poorly controlled hypertension, aggressive attempts at intracranial

neurovascular rescue, presence of a vulnerable berry aneurysm, or CAS in the presence of a recent ischemic stroke (less than 3 weeks).

Hyperperfusion syndrome

The hyperperfusion syndrome is related to long-standing hypoperfusion that results in impaired autoregulation of the microcirculation; thus following revascularization the increased perfusion pressure overwhelms the ability of the dilated arterioles to constrict. This is a rare complication manifested as ipsilateral headache, nausea, confusion, neurologic deficits, focal seizures, and intracranial hemorrhage; typically occurring in patients with severe carotid stenosis and poor collateral circulation, such as with occlusion of the contralateral ICA or underdeveloped circle of Willis. In addition,

Box 69.2 Considered factors increasing risk of embolization.

- 1 Inadequate pre-treatment with antiplatelet therapy
- 2 Inadequate anticoagulation
- 3 Prolonged attempts to engage common carotid artery in challenging anatomies
- 4 Soft plaque
- 5 Aggressive guidewire manipulation
- 6 Aggressive balloon dilatation pre- or post-stent implantation
- 7 Forceful crossing of a heavily calcified plaque with a high-profile stent

bilateral carotid stenting during the same sitting can contribute. Contrary to the surgical hyperperfusion syndrome where symptoms develop within a few days, the endovascular hyperperfusion syndrome develops during or in the immediate post-procedural period. This is likely related to heparin administration, dual antiplatelet agents, and the previous use of glycoprotein IIb/IIIa antagonists which is no longer recommended. Meticulous control of anticoagulation and blood pressure in predisposed patients is critical to prevention.

Contrast encephalopathy

Contrast encephalopathy is very rare and is a transient neurologic syndrome mostly related to a prolonged procedure where a large volume of contrast is used. Neurologic deficit with marked contrast enhancement “staining” in the basal ganglion and the cortex can develop, but without brain abnormalities on CT. No abnormalities on intracranial angiography are detected. Because the contrast medium does not cross the blood–brain barrier, this phenomenon can be caused by both a fine particulate embolization and excessive local contrast. Patients typically recover completely within 24 hours without permanent neurologic deficit.

Carotid dissection

Carotid dissection is a rare complication, predisposed by severe tortuosity and poor control of filter position or use of a distal balloon occlusion device. Post-dilatation of the distal stent edge within the ICA and aggressive manipulation of the guiding catheter in the CCA are also risky. Management options include balloon angioplasty, additional stent implantation, or a conservative strategy dependent on severity and flow.

Carotid perforation

Carotid perforation is an extremely rare event predisposed by oversizing the post-dilatation balloon or aggressive dilatation. Prolonged balloon inflation or a covered stent can be considered to manage the situation.

Acute stent thrombosis

Acute stent thrombosis is a remarkably rare event. Dual antiplatelet therapy has been demonstrated to lower the rate of stent thrombosis and peri-procedural embolic events. In addition, good stenting techniques can have a positive role. As a general rule, based mostly on common sense, we treat patients referred for non-atherosclerotic lesions or with suboptimal results with dual antiplatelet agents indefinitely.

Restenosis

The restenosis rate after CAS is remarkably low. Recently, Setacci *et al.* [61] reported on one of the largest assessments undertaken which showed an intrastent restenosis (>70%) rate of 2.7%.

Tailored approach to CAS: scientific evidence

Only a few published data are available regarding the potential impact of technical features of stents and EPDs on CAS clinical outcome. In 2009, our group published the tailored CASE Registry [62], which involved 1380 patients (1523 procedures) from April 1999 to September 2007 who were managed with mandatory neuroprotection and a tailored approach to intervention. A wide range of stents and EPDs were used. The primary endpoint was the cumulative incidence of all strokes and deaths at 30 days. The secondary endpoint was a composite of the primary endpoint plus cumulative incidence of all strokes or stroke-related deaths up to September 30, 2007. CAS success was 99.6% and the 30-day all-stroke/death rate was 1.5% (minor stroke 11, 0.7%; major stroke 8, 0.5%; death 5, 0.3%). Regarding symptomatic patients this risk was 2.7% versus 1.2% for asymptomatic patients ($p=0.042$). Symptomatic octogenarians had a higher risk than other groups (OR 3.9, 95% CI 1.06–14.0): asymptomatic ≤ 79 1.2%, asymptomatic ≥ 80 1.2%, symptomatic ≤ 79 2.3%, and symptomatic ≥ 80 4.5%. The results from this large cohort demonstrate that carotid stenting for all-comers in a “real-world” setting, based on the tripod of expert operators, “tailored approach” and mandatory neuroprotection, is safe and efficacious, and durable in the long-term prevention of stroke.

In a previous study [32], we analyzed the embolic events in depth with regard to their temporal distribution during and after the procedure (Figure 69.13). It was clear that with a tailored approach procedural embolic complications were limited to TIAs, and embolic neurologic events (minor and major strokes) occurred invariably within the 24-hour post-procedural and recuperative periods up to 30 days’ follow-up. It is a reasonable hypothesis that there was a partial stent-frame failure: despite the routine application of selected stents, advanced protection techniques, and combined antiplatelet therapy, we were able to protect the procedure but not the patient over time.

Owing to the early identification of high risk anatomy for carotid endarterectomy [63], the level of carotid lesion with respect to bony “obstacles” to surgical access for proximal and distal vessel control has been used for case selection for carotid stenting. High carotid bifurcation above the mandibular angle is a reason to avoid surgery, as is a high petrous segment lesion (most appropriately treated by neuroradiology techniques) and the proximal common carotid location. The latter can at times also preclude any type of embolic protection device because of the absence of an adequate landing zone and the risk versus benefit of its performance should be carefully evaluated.

Early clinical evidence also substantiated that balloon expandable stents are unsuitable for the treatment of carotid bifurcation disease [64]. Finally, contrast media-specific reactions that simulate neurologic injury should also be considered [65].

Future directions

Carotid stenting, although it has become a mature technique regularly applied with excellent outcomes in high volume centers by expert operators, is still struggling to find the consensus of the scientific community. Inadequate requirements in terms of operator endovascular experience, potentially leading to an increased adverse event rate related to both insufficient technical skills and inadequate patient selection, has been proposed as the central reason for the unfavorable outcomes related to CAS. In this scenario,

Figure 69.13 Temporal-distribution of CAS adverse embolic events.

one thing is clear: the need for highly trained operators. The *tailored approach* has been emphasized as the key to achieving a safe practice, a concept that, in its essence, requires from the operators a solid theoretical and practical learning curve on dedicated endovascular materials and techniques. Emerging technologies and further innovations pursuing stroke prevention will probably allow operators to address safer carotid endovascular revascularization only in the more general context of serious research protocols and formal training programs.

The entire field of carotid revascularization (via stenting or endarterectomy) for asymptomatic, highly stenotic disease has received heavy criticism from the clinical neurology community because of the tremendous progress of medical therapy in this area, in comparison to the era of the original randomized trials. In other words, neurologists question the window of clinical benefit with revascularization can be sufficiently large to justify the procedure when compared with state-of-the-art therapy with thienopyridine antiplatelet treatment (e.g., clopidogrel), plus high intensity statins (e.g., rosuvastatin, atorvastatin) and improved systemic arterial pressure control over time. At the same time, improved techniques have rendered both stenting and endarterectomy safer than in earlier eras. Accordingly, a prospective randomized trial (with NIH funding support) is underway to compare revascularization (either stent or endarterectomy) or not on a common background of state-of-the-art intense medical therapy in patients with asymptomatic highly stenotic carotid bifurcation disease.

Acknowledgments

We thank the entire organization of Maria Cecilia Hospital and Gruppo Villa Maria Care and Research for their support in the development of the carotid stenting program. Special thanks to Dr. Estêvão Carvalho de Campos Martins and Dr. Caterina Cavazza for their contribution to this chapter.

Cerebral Aneurysms: Diagnosis, Indications, and Strategies for Endovascular Treatment

Gyula Gál

Odense University Hospital, Odense, Denmark

Cerebral aneurysms are located under the arachnoid membrane, and can be classified as ruptured, causing life-threatening hemorrhage, or unruptured (elective). The latter can be further classified as symptomatic, mainly due to the mass effect, or asymptomatic, also called incidental. The diagnosis of a ruptured aneurysm is an emergency angiography in the acute phase, as soon as possible after the bleeding, followed by the treatment, surgical or endovascular. If the latter, it should be carried out in the same session, if possible, to prevent rebleeding, which can have disastrous consequences.

The indication for treatment of a ruptured aneurysm is absolute, because it is a life-saving procedure. According to the results of the ISAT [1], endovascular treatment had significant lower risk for adverse effects than surgical clipping, which is why this has become the method of choice since the publication of the results in *The Lancet*, 2002.

There is a wide variety of indications and treatment strategies for elective aneurysms, depending on factors like size, shape, location, age, and whether they are symptomatic.

Intracranial aneurysms are located outside of the arachnoid membrane, intra-, or extradural, mainly on the cavernous portion of the internal carotid artery (ICA), in the cavernous sinus (CS), and rarely on the petrous portion of the ICA. If asymptomatic, there are no indications to treat them, because they cannot bleed into the subarachnoid space, but if large they can cause cranial nerve palsy (III, IV, or VI) beginning with diplopia, hearing loss (VIII), or—if ruptured—a direct carotico-cavernous fistula (CCF) with similar symptoms, plus bruit. In these cases, endovascular treatment is indicated.

Diagnosis

Ruptured aneurysms

The first and most important step in the diagnosis of a ruptured aneurysm is the correct evaluation of the clinical signs and symptoms, which start with sudden, intense headache, often followed by nausea and vomiting. The pain can be so intense that the patient becomes unconscious for a short period or longer. Clinical examination can reveal nuchal rigidity. The next step in the diagnosis is a cranial computed tomography (CT) scan, which can detect the hemorrhage, which is most often subarachnoid, but can be

intraventricular, intracerebral, and rarely even subdural, or a combination of these. CT shows the thickness of the clot, which is one of the predictors of clinical outcome. The blood distribution can localize the likely source of the bleeding, especially if a hematoma surrounds the aneurysm. With negative CT findings, lumbar puncture (LP) should then be performed, to confirm or rule out small intrathecal bleeding, so-called warning leak that can be undetected on CT, or—when several days have passed after the ictus—to evaluate blood degradation products in the cerebrospinal fluid, which can confirm subacute bleeding up to 3 weeks prior to the examination. If subarachnoid hemorrhage (SAH) has been confirmed, “four-vessel” digital subtraction angiography (DSA) should be the next step, ideally under general anesthesia, to evaluate the cerebral circulation, in order to reveal the bleeding source, further classify its shape and configuration, and assess the collateral circulation. Rotational angiography with three-dimensional reconstruction (3DRA) of the aneurysm is essential, in order to obtain accurate measurements and define the exact anatomy of the sack and the neck in relation to the parent artery and to decide the best therapeutic option. In significant bleed but negative angiogram, the patient should be kept in hospital and DSA repeated after 10–14 days, to reveal aneurysm that might have been thrombosed or a blood blister-like aneurysm, which were undetectable at the time of the initial angiogram.

Elective aneurysms

Following intravenous injection of iodine-based contrast material, CT can readily visualize the intracranial vessels. As the method is quick, cheap, and can accurately demonstrate intracranial space-occupying processes, a large number of these examinations are performed in every X-ray unit equipped with a CT scanner, for many different indications, often including headache, even without neurologic symptoms, because it can rule out severe pathologic processes, like tumors. The vast majority of these examinations do not demonstrate any pathologic findings, but can reveal cerebral aneurysms as incidental findings. As every physician—and also many patients—is aware of how dangerous these aneurysms can be if ruptured, many of these findings will lead to referrals to neurosurgical centers, to evaluate whether that particular aneurysm needs further medical attention. In the author’s praxis, serving a catchment area of approximately 2 million people, the evaluation of these incidental

aneurysms takes a couple of hours every week, within a frame of a neurovascular conference, involving one senior interventional neuroradiologist, and at least one senior and some younger vascular neurosurgeons.

With the evolving development of technology, like the introduction of spiral and multislice CT, examination time has decreased significantly, and a complete examination of the cerebral vessels, CT angiography (CTA), can nowadays be performed in 10–15 seconds. As this is a non-invasive method, it is routinely used to evaluate the cerebral circulation if an incidental aneurysm has been detected. Also, in a patient with a ruptured aneurysm associated with a hematoma that requires surgical evacuation, a good quality CTA can replace the DSA, giving the neurosurgeon immediate information to be able to clip the aneurysm safely during evacuation, without waiting for DSA to be performed, to minimize the time the brain tissue is subjected to high intracranial pressure.

Everything that has been mentioned about CT and CTA is also valid for magnetic resonance imaging (MRI, or nowadays just MR) and magnetic resonance angiography (MRA). This technology can distinguish the intracranial tissues even more accurately than CT, without the need for ionizing radiation. Imaging of the cerebral vessels with MRA is easy if the patient can cooperate (i.e., keep still for several minutes). It can be performed without intravenous contrast, which is why it has become the method of choice as a screening procedure for cerebral aneurysms during the last two decades. Both CTA and MRA can depict aneurysms in the range of 1 mm, which is sufficient for the diagnosis of unruptured aneurysms. MRA is also utilized as follow-up examination of aneurysms treated by endovascular means, and as serial follow-up of untreated aneurysms to detect progress of their size.

Indications for endovascular treatment

Ruptured aneurysms

This is a very serious condition that kills 30% of patients before they reach the hospital. All patients surviving the first bleed have a significant risk for early rebleeding that is highest in the first hours following the initial bleed, successively diminishing over the weeks. According to the natural history, rebleeding would kill an additional 10–15% of untreated patients within the first months. According to Kassell *et al.* [2], based on the clinical outcome of 3521 patients with ruptured cerebral aneurysms, early surgery is no more hazardous than delayed surgery, and eliminates the risk of rebleeding, which is the major cause of mortality. This result prompted neurosurgeons to perform surgical intervention—clipping—as soon as possible following the bleeding. The same conclusion is valid for endovascular treatment as well. In the author's institution, endovascular treatment of eligible patients with ruptured aneurysm is performed on the day of admission, if the procedure can be started before 8 pm at latest, unless there is evidence of rebleeding. In case of the latter, the treatment is performed during the night as well, to prevent repeated rebleeding, which can be fatal.

Elective aneurysms

Incidental aneurysms <7 mm in the anterior circulation

Following the publication of the ISUIA [3], which assessed 4060 patients, stating that the risk for rupture of an incidental cerebral aneurysm located in the anterior circulation, measuring less than 7 mm is very low, while treatment of elective aneurysms carries a significant risk, which often exceeds the risk of rupture according to the natural history, a scientific debate among neurologists,

neurosurgeons, and interventional neuroradiologists has taken place, questioning the validity of the conclusions in the era of modern endovascular therapy, because the risk–benefit calculation of the treatment was based mostly on surgical clipping: 1917 versus 451 endovascular procedures. Worldwide clinical experience could not verify the low rupture risk of these aneurysms, which is why the results of the study have not been fully implemented into clinical practice. The established clinical routine in most of the high volume institutions, where both neurosurgical clipping and endovascular treatment are available—including the author's—is that all referred cases are discussed in scheduled neurovascular conferences, where the decision whether or not the treatment—be it surgical or endovascular—should be offered to a patient is made, taking into consideration the patient's age, general health condition, and following a careful analysis of the location and configuration of the aneurysm.

Incidental aneurysms >7 mm in the anterior and all sizes in the posterior circulation

According to the same study [3], the natural history of these aneurysms showed that the risk of rupture was significantly higher in the posterior circulation, including posterior communicating aneurysms, and increased with size. However, the risk associated with the repair in the study—again, mainly based on surgical clipping—often equalled or exceeded these rates. As the study was published in 2003, analyzing the data based mainly on surgical clipping performed roughly 20 years ago has no relevance for current practice, in the author's opinion. The indication for endovascular treatment of these aneurysms with the tools available now is valid, because it can eliminate the risk of bleeding, with a reasonably low risk associated with the treatment.

Coincidental aneurysms

This is a special group of aneurysms, discovered during DSA of a patient with bleeding from another aneurysm or arteriovenous malformation (AVM). Clinical experience shows that aneurysms associated with other ruptured aneurysms have higher risk for bleeding than “pure” incidental aneurysms, which is why the indication for endovascular treatment of them is also stronger. For that reason, in the author's institution, these aneurysms are treated, either in the same session as the presumed ruptured one, if the patient is in good clinical condition and the treatment is technically easy to perform without the need for platelet inhibitors, or at the scheduled follow-up of the ruptured aneurysm, usually 9 months after treatment, or earlier, depending on clinical judgment.

Unruptured aneurysms associated with AVMs—flow-related aneurysms—have a different natural history, with a similar or lower rupture rate to pure incidental aneurysms, which is why the indication for and optimal timing of endovascular treatment is dependent on the strategy regarding the AVM. If the AVM is ruptured, and the patient is eligible for the treatment, it has to be treated first. Following successful treatment of that—by endovascular, surgical or radiation therapy, or the combination of these—the aneurysm(s) may shrink or disappear. Follow-up angiography 2 years after completed treatment (5 years after radiation therapy) can usually give relevant information about these flow-related aneurysms to decide whether they need further medical attention.

Symptomatic aneurysms

These aneurysms are usually large (15–25 mm) or giant (>25 mm), and patients can present with pain caused by their mass effect, compressing the dura mater, cranial nerves and other neural structures,

and they can cause visual disturbances, motor weakness/hemiparesis, sensory loss, and epileptic seizures. The symptoms are mainly related to the location of the aneurysm, but because of their size, they can be partially thrombosed, and patients can also present with transient ischemic attack(s) (TIA) in the vascular territory downstream of the aneurysm. As a result of these disabling symptoms, endovascular treatment is indicated even if the aneurysm is outside of the subarachnoid space, but if it is within, the indication is very strong, because the risk for rupture of these aneurysms in the subarachnoid space is high, and, if ruptured, the treatment—endovascular or surgical—is technically difficult and associated with high risk, which is why subacute, prophylactic endovascular treatment is strongly recommended to prevent rupture.

Strategies for endovascular treatment

Historical background

The first surgical clipping of an intracranial aneurysm was performed by Dandy in 1937. With this operation, he set the direction for aneurysm surgery for the following 70 years.

The first report of endovascular treatment of intracranial aneurysms was published in 1974, by Serbinenko [4], who described navigation of balloon-tipped microcatheters in the intracranial vessels, performing temporary and—by detachment of the balloon—permanent occlusion and subsequently the application of the same technique also for intracranial aneurysms. This was a sensational scientific communication, and the method was taken up within a short time by several highly skilled interventional neuroradiologists worldwide. During the following 17 years, balloon occlusion of the aneurysmal sac or the parent artery to redirect the flow from the aneurysm was the only endovascular therapeutic option for aneurysms unsuitable for clipping. However, the results were disappointing, with high morbidity and mortality rates.

In 1991, a report describing a totally new concept was published by Guglielmi *et al.* [5], who introduced a detachable, soft platinum coil, Guglielmi Detachable Coil (GDC) into 15 experimental saccular aneurysms, created on the carotid artery in a swine model. The platinum coil was soldered to a stainless steel wire. Applying low positive direct current on the wire thrombosed the aneurysms, which was interpreted by the authors as happening due to the attraction of the negatively charged white and red blood cells, platelets, and fibrinogen to the positively charged coil, which was subsequently detached by the electric current (electrolysis). Follow-up angiograms obtained 2–6 months post-embolization confirmed permanent occlusion of the aneurysms as well as patency of the parent artery in all cases. This experimental work is considered to be the starting point of modern endovascular treatment of intracranial aneurysms.

The first human experience with this new device, published by the same group from the UCLA [6], in the same issue of the same journal, described successful endovascular occlusion of 15 intracranial, saccular aneurysms, 8 of them ruptured, all of them considered as having high risk for surgical clipping. Following this initial success, endovascular treatment of intracranial aneurysms with detachable coils soon became an important part of interventional neuroradiology, and after the publication of the results of the ISAT [1], it was considered as the first line treatment option for ruptured aneurysms.

During the following 24 years, many new devices and techniques were developed to improve the angiographic and clinical results of patients with intracranial aneurysms, treated by endovascular

means. The most important was probably the remodeling technique, introduced by Moret *et al.* [7]. Utilizing this technique, aneurysms with an unfavorable neck to dome ratio can also be treated with coils that are placed while a non-detachable balloon is temporarily inflated in front of the neck of the aneurysm, to force the coil to remain in the sac. A new technique that has been developed in the late 1990s is stent-assisted coiling, utilizing first balloon-expandable coronary stents, later self-expandable “neuro” stents that act as a scaffold to support the coils at the neck of the aneurysm.

The first self-expandable, braided intracranial stent with a tight mesh, the Leo (Balt) was developed in 2002. Based on this technology, the first flow diverter, the SILK (Balt) was introduced in 2007. The next step in the same direction was the introduction of intrasaccular flow diverters in 2010 (Luna, Nfocus Medical, Palo Alto, CA, USA and WEB, Sequent Medical, Aliso Viejo, CA, USA) utilizing similar technology. In 2013, a new neck-bridging device, the PulseRider (Pulsar Vascular, San Jose, CA, USA) was introduced, for the treatment of wide neck aneurysms at a bifurcation. This is a self-expanding nitinol implant, which acts as a scaffold, supporting the coils at the neck.

General considerations

Placement of foreign bodies, like catheters, guidewires, or any kind of embolic agent into a blood vessel will induce platelet aggregation on its surface, which can cause thromboembolic complications, which can have severe consequences in the cerebral vessels. To prevent neurologic deficit, the use of drugs with anticoagulant effects, like heparin or platelet inhibitors, is mandatory in most interventional neuroradiology procedures. On the other hand, ruptured aneurysms are prone to rebleed, which is why premedication with platelet inhibitors is contraindicated in the acute phase following the rupture. This means that some of the recently developed tools, like stents and flow diverters, should only be utilized if adequate treatment cannot be performed with other adjunctive devices or methods, such as surgery.

In the following section, the currently available devices are briefly introduced, highlighting the pros and cons of their use, followed by treatment strategies for ruptured and elective aneurysms. As a comprehensive description of all available tools and methods is beyond the scope of this chapter, focus is placed on the most frequently used devices, based on the author's experience with endovascular treatment of >3000 cerebral aneurysms during the last 20 years.

Tools

To reach aneurysms located on the intracranial vessels, it is necessary to use *guiding catheters*, (sometimes also long sheaths), to support the navigation and placement of *microcatheters* steered by *microguidewires*. To occlude them, we need embolic agents, like *detachable coils*; adjunctive devices, like *balloons*, *stents*, and *intraluminal or intrasaccular flow diverters*.

Guiding catheters In the majority of cases, endovascular treatment of cerebral aneurysm can be performed with a microcatheter—and a balloon, if necessary—through an ordinary 6 Fr (1 Fr = 1/3 mm) 100 cm long, multipurpose tip, guiding catheter, like the Envoy (Codman Neuro, Raynham, MA, USA) which can be navigated via a short femoral sheath, over a Terumo 0.035-inch guidewire with hydrophilic coating (Terumo, Tokyo, Japan) into the ICA or vertebral artery, and its tip placed at the desired level (highest possible without provoking vasospasm or intimal lesion). The tip is soft enough to be placed up to the petrous portion of the ICA, while the

shaft is stiff enough to support the navigation of a microcatheter and a balloon with moderate tortuosity distal to the tip. In case of significant tortuosity, a 6 Fr, long femoral sheath—NeuronMax 80/90 cm (Penumbra, Alameda, CA, USA), IVA 80 (Balt), Destination 90 cm (Terumo)—is placed over a 0.035-inch, stiff exchange-guidewire (Terumo) to the proximal ICA or vertebral artery, and a 6 Fr, 105–115 cm long, soft-tip, guiding catheter—Fargomax (Balt), Benchmark (Penumbra)—is navigated over the guidewire or the microcatheter/microguidewire up to the highest possible level the tortuosity permits, up to the cavernous portion of the ICA or to the intracranial portion of the vertebral artery, followed by careful coaxial navigation of the long sheath to a higher position, if necessary, to get enough support for the microcatheter and the balloon, if chosen.

Microcatheters The majority of coils can be delivered through the 0.010-inch microcatheters, which actually have an inner diameter of 0.0165-inch. These are 150 cm long, braided with hydrophilic coating to diminish the friction between the microcatheter and the microguidewire or coil. They have different degrees of suppleness, with a more rigid proximal and an extra soft distal portion, with radio-opaque markers at the tip and 3 cm proximal to that, to match the detachment marker on the coil, in order to be able to safely detach the coils in the sac, even if the detachment point is obscured by the previously placed coils. The tip should be shaped under steam or hot air, according to the anatomy of that particular aneurysm and the parent artery. Alternatively, pre-shaped microcatheters can be used. The author's preferred microcatheter is the Excelsior SL 10 (Stryker, Kalamazoo, MI, USA) with straight tip, due to its shapeability, trackability over 0.014-inch microguidewires, stability of the tip in the sac and the microcatheter in the parent artery, and support to the coil during the packing of the sac. All sizes of coils, manufactured by other companies too, can be delivered through this microcatheter, except one, recently introduced, the Penumbra (Penumbra), which has a diameter that is double that of the other coils, thus a volume that is four times greater than the others of the same length, and consequently needs a larger microcatheter, the PX Slim (Penumbra), with an inner diameter of 0.025-inch. Using this microcatheter and a remodeling balloon in the same guiding catheter requires a larger inner diameter, which is why, in the author's institution, it is usually performed through a NeuronMax (Penumbra), which has softer tip than the other long sheaths, which is why it can be placed higher. Flow diverters, some intracranial stents, and neck-bridging devices also need larger microcatheters, in the range of 0.021–0.035-inch, and consequently stronger support, which is why utilizing long sheaths is essential.

Microguidewires Most microcatheters used in the cerebral vessels can be navigated on 0.014-inch microguidewires. These are 200 cm long. Their tip should be easily shapeable—and reshapeable—to facilitate the navigation and placement of the microcatheter into the aneurysm, and they should ideally retain this shape. Furthermore, the distal portion, especially the tip, should be very soft, so as not to rupture the wall of the aneurysm or the parent artery. One of the most valuable 0.014-inch microguidewires is the Traxcess (Microvention, Tustin, CA, USA), which has a 40 cm long, 0.012-inch distal portion, with a 3 cm long radio-opaque tip that is extra soft, and can help to detect the position of the tip of the microcatheter between the previously placed coils. Another great advantage of this microguidewire is that it can easily be extended at the

proximal end, which is why exchange of microcatheters can easily be done leaving the tip in the same position.

Coils Since the introduction of the GDC in 1991, when only two groups of coils with different thickness from the same company were available, the market has been continuously growing, and nowadays there are a plethora of coils to choose from, produced by many companies. This does not mean that all endovascular therapists have to have detailed knowledge of, and experience with all of them. However, it is essential to know some basic properties.

All types of coils used in the endovascular treatment of cerebral aneurysms should be soft enough not to provoke rupture of the aneurysm while packing them, because they obviously have to touch the wall of the sac during treatment. To achieve that, they are made of platinum, a very soft metal, with a thin primary wire as the basic component which builds up a secondary wire that has two-, or three-dimensional memory shape, and different degrees of softness. They are chosen according to the size and the shape of the aneurysm. They are retrievable, thus can be repositioned in the sac, to fit its shape, and also replaced should the size be wrong. For small aneurysms, <3 mm, the softest available small sizes should be chosen, while the larger ones can be packed with coils of successively incremental thickness, diameters, and lengths, according to the physician's choice and experience. There are hundreds of different types of coils, with lengths from 1 to 70 cm, diameters from 1 to 25 mm, and thicknesses of 0.010 to 0.020-inch. Interestingly, a thick coil is not necessarily more rigid than a thin one, because of its complex structure. Some coils have firm three-dimensional memory shape, making them suitable to place in aneurysms with wide necks, even without adjunctive devices.

Use of remodeling balloons This has several advantages and practically no disadvantages, which is why its regular use, especially treating ruptured aneurysms, is beneficial for the patient. Aneurysms are vulnerable, especially the ruptured ones. Touching their wall with a microguidewire and/or a microcatheter or coil can provoke bleeding, which is why the procedure should be carried out very carefully. Should a rupture occur, inflating the balloon at the neck of the aneurysm can be life-saving, because it can seal the sac, and give at least 5 minutes to reverse the effect of the heparin with IV protamine sulfate—usually slow injection of 50 mg is sufficient—and quickly packing the aneurysm with coils, until the rupture site is occluded. The other advantage is that the inflated balloon can keep the tip of the microcatheter in the desired position, which can add to the safety of the procedure, especially when treating small aneurysms, where the tip should be at the neck, or just outside of it, to avoid direct contact with the wall of the aneurysm. Furthermore, the balloon can help to achieve higher packing density, which is the most important factor to avoid recurrence [8].

The following balloons are the most frequently used: Hyperglide, Hyperform (Medtronic, Dublin, Ireland), Copernic, Eclipse (Balt, Montmorency, France), Transform (Stryker), Scepter (Microvention, Tustin, CA, USA). The first five have a single lumen, and their tips are sealed by the microguidewire when it is pushed through that, so that they can be inflated via a rotatory valve, with a mixture of contrast material—containing 300 mg iodine/mL—and saline, 2 : 1. In the Medtronic balloons, a 0.010-inch microguidewire will fit, in the Balt balloons a 0.012-inch, while in the Transform and Scepter a 0.014-inch, making navigation easier and the position of the balloon more steady for working with the larger wires. Furthermore, the Scepter has a double lumen, making it unique, because having

reached the desired position, the microguidewire can be removed, and embolic tools like coils, small stents, and also fluid embolic agents or spasmolytic drugs can be delivered, while the balloon remains inflated. The same balloons can be used in the endovascular treatment of vasospasm, which is, next to rebleeding, the most devastating complication of SAH.

Stents All modern intracranial stents are self-expandable. The main purpose of their use is to support coils treating wide necked aneurysms, but sometimes also to slowly dilate stenotic vessels. There are two major groups.

1 Laser-cut stents, made of nitinol, with two different designs:

- a** *Open-cell*: Neuroform EZ (Stryker), available in diameters of 2.5–4.5 mm (in increments of 0.5 mm), and lengths of 10–30 mm; and
- b** *Closed-cell*: Enterprise (Codman), available in diameter 4.5 mm, which can be placed in vessels 2–4.5 mm diameter, and lengths of 14, 22, 28, and 37 mm.

The Neuroform needs a 0.027-inch microcatheter while the Enterprise can be delivered through a 0.021-inch, thus can reach more distal targets. Both have radio-opaque markers at the ends, low metal surface coverage (MSC), high porosity, and low pore density, thus no significant flow diverting -effect, but have been able to assist in the treatment of wide necked aneurysms for >10 years, and still have a role in endovascular treatment of aneurysms that need double stenting.

2 Braided stents, woven of nitinol wires that are loosely connected to each other, which allows for optimal vessel wall apposition and easy passage of the microcatheter through the stent mesh. Four devices are available: the LVIS & LVIS Jr. (Microvention), which can be placed in vessels of 2.5–5.5 mm in diameter and lengths of 14–34 mm, and the Leo + & Leo + Baby (Balt), which can be placed in vessels of 1.5–6.5 mm in diameter, and lengths of 8–80 mm. The Jr. and the Baby can be delivered through 0.0165-inch microcatheters, while the larger ones need from 0.021 up to 0.028-inch for the largest Leo. The LVIS has markers at the ends, while the Leo has two platinum filaments along the stent, for enhanced visibility on fluoroscopy. All have flared ends, for improved stability in the vessel. The Balt stents have a significant flow diverting effect, which, in the author's experience, has contributed to excellent long-term angiographic results in >100 cerebral aneurysms.

Flow diverters These are tightly woven devices, with high MSC, pore density, and low porosity. The aim is to achieve reduction and stagnation of the intra-aneurysmal flow, which will promote thrombosis and aneurysm occlusion without the need for coils. They can be divided into two groups:

1 Intraluminal flow diverters, deployed in the parent artery. These are stent-like devices, braided of wires of nitinol, (SILK, Balt; p64, Phenox, Bochum, Germany; FRED, Microvention); or cobalt-chromium (PED, Medtronic; Surpass, Stryker). They represent a paradigm shift in endovascular treatment of cerebral aneurysms, replacing coil embolization of aneurysms with endovascular repair, which is a fundamentally different approach. All of them are highly thrombogenic, which is why premedication with platelet inhibitors is mandatory. The SILK covers 1.5–5.8 mm diameter vessels, and can, up to 4.5 mm diameter be delivered through a 0.021-inch microcatheter, while the two largest sizes need a 0.025-inch microcatheter. The PED covers 2–5 mm diameter, the FRED 3–5.5 mm diameter, the Surpass 2–5 mm diameter, with appropriate lengths, and all of these need a 0.027-inch microcatheter for delivery. Currently, all of them are

partially retrievable, and one, the p64, can be fully deployed and then detached at the discretion of the treating physician. The clinical experience with the SILK and PED is significant, with more than 10,000 patients treated with each, including long-term follow-up. The results are excellent, with a complication rate <5%. The author's medium-term experience with the FRED is excellent, with the p64 is good, and with the Surpass is limited.

2 Intracascular flow diverters are deployed into the aneurysm. These are spherical implants, braided of nitinol wires, and, due to the microbraid technique, have higher MSC and pore density than the intraluminal flow diverters, thus can induce rapid thrombosis of the aneurysm. As these devices are placed in the aneurysm, platelet inhibition is not mandatory, which is why they can be also used in ruptured aneurysms. Currently, only one of the initially introduced two devices is available, the Woven EndoBridge, WEB (Sequent Medical, Aliso Viejo, CA, USA). The original version was double layered, while the latest two versions are monolayered. The available devices are 4–11 mm in diameter, delivered through the VIA microcatheter, with an inner diameter of 0.021–0.033-inch. The large size of the microcatheter is a disadvantage of the system. Several initial clinical reports were promising, but a recently published paper [9] showed 36% residual aneurysms and 57% neck remnants at mid-term follow-up, which is why the long-term efficacy and safety of the device needs to be further analyzed.

PulseRider Utilizing this new neck-bridging device, wide necked—up to 10 mm—aneurysms can be treated with coils. It has an open cell frame, with significant less metal in the parent artery than double stenting. It can be deployed through a 0.021-inch microcatheter, followed by placement of a coil-delivery microcatheter into the sac through its mesh at the neck, and coil occlusion of the sac. The author has treated 15 cases, and the initial results are promising, but the overall clinical experience with this device is still limited.

Treatment strategies

Ruptured aneurysm approach Occlusion of ruptured aneurysms has to happen quickly and safely. The goal of the treatment is to prevent rebleeding, which is the most feared complication in the acute phase. In the author's institution, following the evaluation of the angiographic findings of a ruptured aneurysm, including the 3DRA, a short neurovascular conference between a senior interventional neuroradiologist and neurosurgeon, or a neurosurgeon on call is organized, to discuss the best treatment option for the patient. Based on the relevant information about the patient's clinical status, and the analysis of the angiographic findings, the decision for surgical or endovascular treatment is taken in consensus. If endovascular treatment is chosen, the senior interventional neuroradiologist decides the strategy for the procedure, which must include the following steps:

- 1** Analysis of the access route, tortuosity, to assess whether high placement of a guiding catheter, possibly supported by a long sheath, is necessary to reach the target.
- 2** Further analysis of the angiography, to assess whether the remodeling technique is necessary or feasible to occlude the aneurysm safely. The optimal working projection should visualize the neck and its relation to the parent artery, allowing safe occlusion of the sac, without interfering with the flow in the parent artery. If biplane equipment is available, the other working projection should be perpendicular to the first, to fully exploit the advantage of this technology.

Independently from the above decisions, a bolus dose of intravenous (IV) heparin should be given at the start of the procedure, to protect the patient from thromboembolic complications. In the author's praxis, 5000 International Unit (IU) is the average bolus dose, which can be higher or lower, depending on the patient's body weight. Both the guiding catheter and the microcatheter should be flushed with isotonic NaCl solution, which is ideally heparinized. In the author's experience, 5000 IU/L in all flushing fluids is usually enough to keep the activated clotting time (ACT) at the desired level: 250–300 seconds. The ACT should be measured 15–20 minutes after the bolus dose was given, and regularly once per hour during the whole procedure.

Aneurysms with reasonable dome:neck ratio can be occluded with coils, without balloon remodeling, depending on the physician's experience. Coil placement should be performed on a high quality road-map. The first coil should have the largest possible diameter the sac can accommodate, to fill the peripheral portion of that, covering also the neck area. The following coils should be smaller and shorter, depending on the remaining space in the sac, which can readily be visualized with a short DSA if or when necessary. All coils should be delivered carefully, but the first and the last are the most critical ones for the risk of peri-procedural rupture. Ruptured aneurysms should be fully occluded, to avoid rebleeding. However, it is better to accept a small neck remnant than to provoke bleeding or thromboembolic complications with aggressive packing. Following the finishing DSA in the working projection(s), a final angiogram in standard projections should be performed and compared with the initial one, to detect early signs of thromboembolic complications.

Elective aneurysm approach According to existing experience with the currently available tools described earlier, endovascular treatment of elective aneurysms is feasible, safe, and the results are predictable. Utilizing flow diverters and braided stents, alone or in combination with coils, makes the procedure safer, because tight packing of the sac is no longer necessary, and has been made easier, knowing that these potent tools will facilitate endovascular repair after the completed treatment. Thromboembolic complications can be prevented by platelet inhibitors. However, rigorous routines regarding the measurement of the effect of these drugs must be established, because >25% of the population is a non- or low

responder to clopidogrel, which has to be addressed. On the other hand, utilizing these drugs is potentially dangerous for the patient, because a periprocedural rupture can cause life-threatening bleeding. For that reason, endovascular treatment of these aneurysms should only be performed by specialists properly trained in neuro-interventional procedures, with significant experience to handle both expected and unforeseen complications. The risk:benefit ratio associated with the endovascular treatment of each patient with elective aneurysm has to be individually analyzed with the neurovascular team, followed by careful selection of the best treatment option, based on the experience of the endovascular therapist.

Management of Acute Aortic Syndromes

Christoph A. Nienaber and Rachel E. Clough

University Heart Center Rostock, Rostock, Germany

The concept of an acute aortic syndrome (AAS) summarizes conditions with high risk of rupture, identification of patients with aortic pain, and expedites early implementation of definitive treatment. These conditions include acute aortic dissection, intramural hematoma (IMH), and penetrating aortic ulcer (PAU), with a common denominator of a disrupted media layer (Figure 71.1). Aortic dissection has the highest incidence (62–88%) followed by IMH (10–30%) and PAU (2–8%) [1–3]. AAS is also an important differential to be considered along with acute coronary syndrome (ACS), pulmonary embolism (PE), and pneumothorax. AAS has a relatively low annual incidence compared with acute coronary syndrome, but a high rate of mortality [4]. It is the most frequently fatal condition in the spectrum of patients presenting with chest pain [5]. Besides clinical symptoms contemporary imaging techniques have contributed to understanding of the evolution, natural history, and diagnosis of AAS.

Epidemiology

The estimated incidence of aortic dissection of 2.6–3.5 cases per 100,000 persons per year [6] is likely to be underestimated as it is underreported because of death prior to hospital admission; 22% of thoracic aneurysm and dissection are diagnosed at autopsy [7] and frequently missed *in vivo* [8]. Approximately 65% of patients are male, with an average age of 65 years [9]. Systemic hypertension is most common and found in 72%; other risk factors include atherosclerosis, a history of prior cardiac surgery, known aortic aneurysm, and a family history of AAS [3]. The epidemiology of aortic dissection is different in young patients (<40 years of age) frequently including Marfan's syndrome and other connective tissue diseases. Recent data suggest an increasing incidence to 4.3 cases per 100,000 persons per year as a result of improved diagnostic testing. There is overlap within AAS, with PAU acting as an entry site for dissection, or IMH evolving to aortic dissection and increasing incidence with age [10].

Conditions in the context of AAS

Gender and age

Men are at higher risk for dissection with an age-adjusted incidence of 5.2 per 100,000 per year and 2.2 per 100,000 per year in women [7]. Two-thirds of dissection patients are males consistent in both

Stanford type A and B [9–13]. The ratio is similar for IMH whereas the proportion of men with PAU appears to be slightly lower than women [14,15].

A sex-based comparison suggests that women are older than men at the onset of aortic dissection (mean age 67 years for women and 60 years for men) [12]. A greater proportion of women have delayed diagnosis and treatment, with 40% hospitalized more than 24 hours after dissection onset. Interestingly, clinical signs at onset seem to differ between men and women; altered consciousness and congestive heart failure, as well as periaortic hematoma and pericardial or pleural effusions, are more common in women, whereas abrupt onset of pain, pulse deficits, and a widened mediastinum are more common in men [12]. The average age at onset of dissection type A and B is 61 years and 66 years, respectively [4,9,10,16]. However, it is important to keep in mind that AAS occurs at a much younger age in patients with connective tissue disorders than in sporadic cases.

Pregnancy

Pregnancy has been considered a risk factor for thoracic aortic disease (TAD) while considered an artifact of “selective reporting” and “markedly overstated” [17]. Subsequently, data from the International Registry of Aortic Dissection (IRAD) showed a substantial proportion of women develop TAD during the first four decades during or shortly after pregnancy [12,18]. Whereas 0.6% of women with TAD were pregnant when their dissection occurred, nearly 13% of TAD in women aged <40 years occurred peripartum. By striking contrast, the Swedish national birth registry from 1987 to 2007 reported that 62% of female patients with TAD who were aged ≤40 years were pregnant [19]. The incidence of TAD among pregnant women under 40 years was 1.39 per 100,000 women per year, compared to 0.06 per 100,000 women per year under 40 who were not pregnant [19]. These estimates translated to a 23-fold greater risk of TAD for pregnant women than for non-pregnant women in this age group. However, this study did not account for the potential impact of other risk factors, such as Marfan's syndrome, and so this is inconclusive.

A recent expert consensus document recommended that women with Marfan's syndrome and an aortic root diameter >4 cm carry a 10% risk of TAD during pregnancy, versus a 1% risk of TAD or other major cardiac complications for women with Marfan's

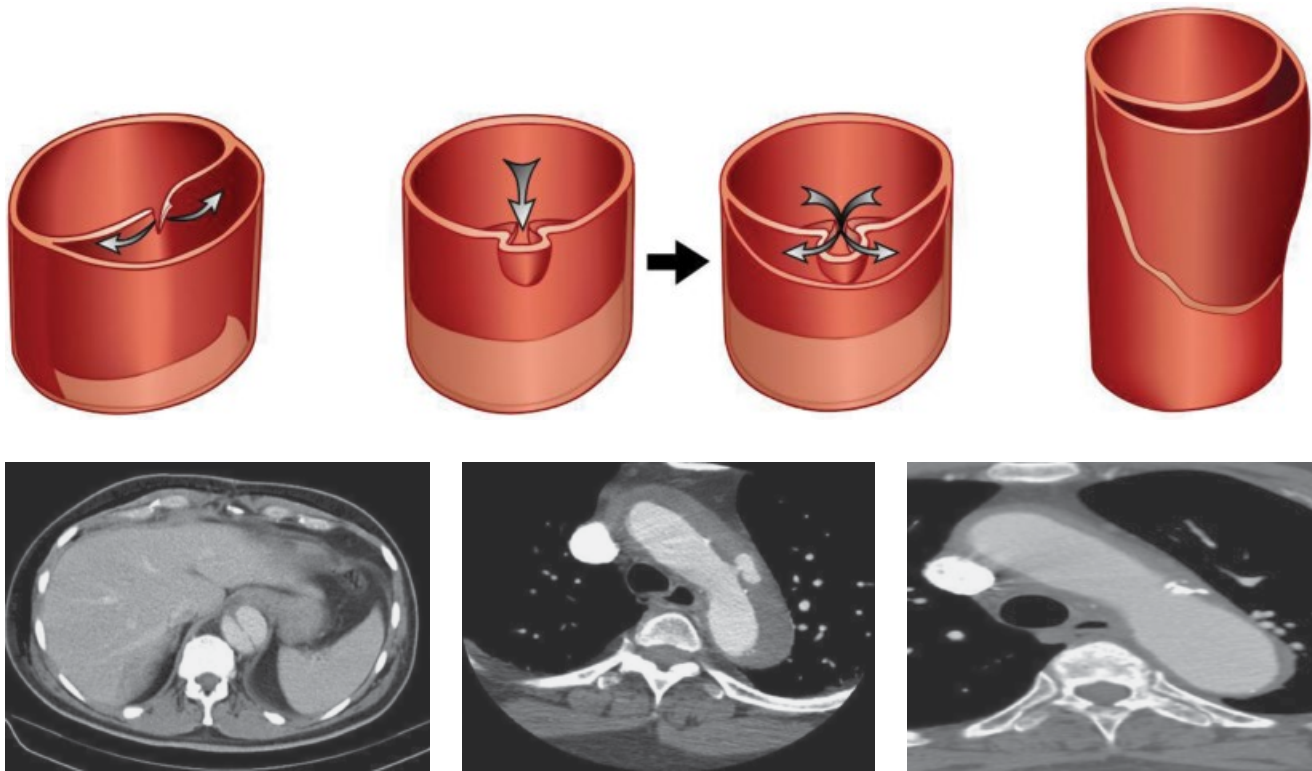

Figure 71.1 Schematic illustration and tomographic imaging display of all constituents of acute aortic syndrome with full dissection, penetrating aortic ulcer, and intramural hematoma (from left to right).

syndrome and an aortic root diameter <4 cm; in women with aortic root diameters ≥ 4.5 cm, elective aortic root replacement before pregnancy lowers the risk of TAD in pregnancy [20]. In pregnant women who develop TAD, more than two-thirds have type A TAD, and fewer than one-third have type B TAD [21–23]. Of pregnancy-related cases of TAD, $\geq 60\%$ occur prepartum, usually after 24 weeks' gestation, whereas $\leq 40\%$ occur after delivery [23]. Aortic complications during pregnancy are associated with maternal mortality of up to 11%, and the incidence of maternal death is 0.4 per 100,000 women per year [19,22,24]. Fetal mortality tends to be around 33% [22].

Drug use

US centers have reported that 10% of TAD is related to cocaine use [25,26]. However, only five individuals in IRAD, equivalent to $<0.5\%$, have used cocaine before dissection [26–28]. Early mortality associated with cocaine-related TAD is similar to non-cocaine-related TAD, although late mortality appears to be higher in cocaine users [25–27]. Amphetamine use is also associated with an 3.3-fold risk of TAD [29]; sildenafil could also be associated with TAD [30,31]. However, although a temporal relationship might exist, other risk factors such as hypertension, smoking, or bicuspid aortic valve could have caused both of these TAD cases.

Genetics and clinical manifestations of AAS

Congenital cardiovascular defects (bicuspid aortic valve, aortic coarctation, and annuloaortic ectasia), syndromic conditions (Marfan's syndrome, Loeys–Dietz syndrome, Ehlers–Danlos

syndrome), non-syndromic conditions (ACTA2), and genetic variants such as single nucleotide polymorphisms have been linked to development of AAS and acute aortic dissection [32,33]. Marfan's syndrome is an autosomal dominant connective tissue disorder caused by mutations in the fibrillin 1 (*FBN1*) gene. Loeys–Dietz syndrome is caused by mutations in the genes that encode the TGF- β type 1 and 2 receptors (*TGFBR1* and *TGFBR2*), which can lead to an increase in TGF- β signaling. Both syndromes frequently present with acute aortic symptoms [34,35]. Differential expression of elastin assembly genes predispose to structural failure in aortic dissection; such changes were associated with diminished fibulin-1 and enhanced MMP-9 levels [36]. Fibulin-1 exhibits distinct interactions with collagen IV which is down-regulated in aortic dissection (Table 71.1) [37].

The symptoms of an IMH and PAU are similar to classic aortic dissection (Table 71.2) and differentiation between these aortic conditions is difficult. The differential exclusion of cardiac and pulmonary causes of chest pain by myocardial enzyme and D-dimer blood tests, electrocardiogram (ECG), and imaging is essential; but 20% of patients with AAS show non-specific ST-T segment changes [3], prompting urgent CT and transesophageal echocardiographic (TEE) imaging [38,39]. Pain is the most common presenting symptom in 84%, independent of age, sex, or other associated clinical features [6,40]. Pain radiating to the neck, throat, and/or jaw indicates the involvement of the ascending aorta, particularly when associated with the murmur of aortic regurgitation, pulse differentials, or signs of tamponade; conversely, pain in the back or abdomen indicates dissection of the descending aorta. Pericardial effusion occurs in 8%, syncope in 4%, and circulatory shock in 3% [34,41–43].

Table 71.2 Clinical symptoms associated with acute aortic syndromes.

Acute syndrome arising from	Presenting features	Other characteristics
Type A dissection	Syncope Tamponade Severe chest pain	Aortic insufficiency Collapse Pulse differential Myocardial ischemia Neurological signs
Type B dissection	Severe chest or back pain Migrating pain Distal pulse differential	High blood pressure Renal insufficiency Claudication Distal malperfusion
Leaking thoracic aneurysm	Diffuse pain in back or chest Rapid deterioration of hemodynamics Paleness Exsanguination	Rapidly increasing diameter of TAA Sudden death within 1 hour
Intramural hematoma	Chest or back pain Tamponade*	High blood pressure Rarely any malperfusion
Penetrating ulcer	Painless or low intensity pain Pain located in back or abdomen	High blood pressure Collapse with perforation
Traumatic dissection or rupture	Deceleration trauma Severe pain Pulse differential Syncope Exsanguination Tamponade*	Stable at low blood pressure Rapid pulse prior to exsanguination

* Rare in proximal intramural hematoma.

Diagnostic pathways

Non-invasive imaging in emergency department ensures early diagnosis of even subtle forms of AAS; half of patients with clinical suspicion of AAS have normal findings on chest X-ray, and only

30% have a widened mediastinum. CT echocardiography and magnetic resonance (MR) imaging all have excellent accuracy and have become preferred diagnostic options (Table 71.2). The hemodynamic instability and local expertise often determine the

primary modality with computed tomography (CT) in 62%; TEE in 32%, and MRI in 1%.

Computed tomography

The investigation of choice for the presence of AAS is CT scanning. Unenhanced scans should be included to provide information regarding the presence of IMH or any mediastinal bleeding [44]. A combined unenhanced and contrast-enhanced CT has a sensitivity of 95% and specificity of 87–100% for detection of AAS [45]. Triple rule-out CT protocols are being used to differentiate between different causes of chest pain such as AAS, ACS, and PE. Post-acquisition reformatting of images by multiplanar reconstruction and maximum intensity projection are useful to improve detection and characterization of AAS [46]. Disadvantages are nephrotoxic contrast medium and exposure to ionizing radiation.

Surface echocardiography

The sensitivity and specificity for type A and B dissection is 78–100% and 31–55%, respectively [47]. Moreover, tamponade, aortic regurgitation, and wall motion abnormalities are clearly identified. In contrast to both CT and MR technology, modern ultrasound equipment is mobile and TEE acquisition can be performed at the bedside for unstable cases with sensitivity and specificity of 99% and 89%, respectively, and a negative predictive accuracy of 99% for AAS [45,48,49]. It does not provide any information below the diaphragm and has limited views of the proximal arch because of interposition of the air-filled trachea and main bronchus. While it detects valve regurgitation and pericardial effusion, it is not suited for surveillance. During thoracic endovascular aortic repair (TEVAR), TEE emerged as a powerful tool to quality control the TEVAR procedure [50–52]. Yet, intravascular ultrasound may emerge as a useful adjunct to guide endovascular procedures.

Magnetic resonance imaging

MR imaging is a highly accurate, non-invasive imaging modality, with a sensitivity and specificity in the range of 95–88% and 94–98%, respectively [53]. However, the MR environment is not

Table 71.4 Biomarkers in aortic dissection.

compatible with life support and monitoring equipment required for critically ill patients. Thus, MRI is reserved for serial follow-up studies in patients with an anticipated long surveillance. Contrast-enhanced MR imaging with intravenous gadolinium has emerged as a standard (Table 71.3) [54].

Serologic markers

Currently, there are no reliable biomarkers diagnostic of AAS, although a number of markers have been suggested: smooth muscle proteins, soluble elastin fragments, fibrin degradation products, myosin heavy chain, and creatine kinase BB isoforms [36,39,55]. Elevated D-dimers in the clinical context of suspected AAS should prompt urgent further investigation. S100A12 has also been recently proposed as a marker of thoracic aortic dissection [56]. Myocardial markers of ischemia should be requested to help in the differential diagnosis. Elevated C-reactive protein (CRP) has been associated with adverse outcomes in patients with aortic dissection and IMH [57,58]. While a series of conceptually promising biomarkers are under study, only a few have been shown to be useful (Table 71.4).

Initial medical management of aortic dissection

Initial management of AAS is directed at limiting propagation by control of blood pressure over time. Reduction in pulse pressure with a target systolic pressure of 100–120 mmHg and a heart rate of 60–80 beats per minute to maintain sufficient end-organ perfusion is a priority. Intravenous beta-blockade is suggested as first-line therapy, although often multiple agents are required. Appropriate triage and image sharing is important if transfer to a specialized aortic center is considered [59].

Acute aortic dissection

The proximal aorta has highest risk of dissection because of steepest fluctuations in pressure. The proximal entry tear can occur at any point although it is frequently found in the ascending aorta (an area of great hydraulic stress) or in the proximal segment of descending

thoracic aorta. It is not uncommon to find one or more re-entry tears allowing communication between the true and false lumen throughout the descending thoracic aorta and abdominal aorta. Over time, the false lumen of the dissection can undergo expansion with aneurysmal degeneration, which can eventually lead to aortic rupture.

Classification systems

Acute aortic dissection can be classified *anatomically* according to either the site of the intimal tear and extent of the dissection, or the part of the aorta affected (Figure 71.2). Dissections can also be classified *temporally* into acute and chronic phases; the acute phase with

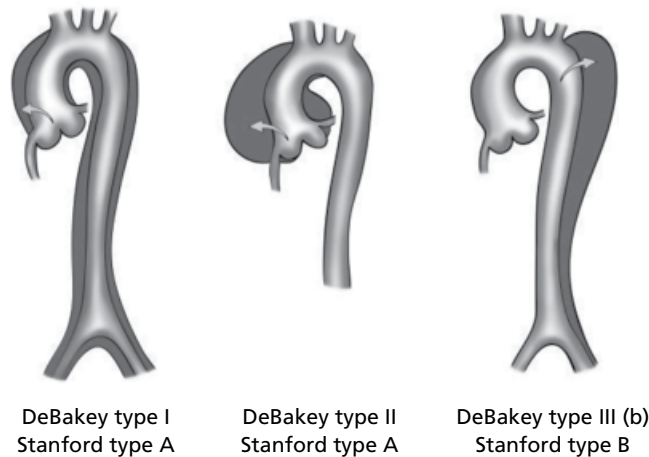

Figure 71.2 Standard classification system of aortic dissection with focus on anatomic involvement and prognosis.

higher inherent mortality is defined as <14 days from the onset of symptoms and chronic beyond this period [60]. This classification system has recently been redesigned into four time domains: hyperacute (<24 hours); acute (2–7 days); subacute (8–30 days); and chronic (>30 days) (Figure 71.3) [61]. Additionally, dissections are typically classified as *complicated* or *uncomplicated*. Complicated dissections involve those with malperfusion, rupture or impending rupture, refractory hypertension, continued pain, expansion >1 cm/year, or an overall aortic diameter of >5.5 cm [62]. Approximately 30% of type B dissections are considered complicated at initial presentation and are associated with an increased early risk of death [63]. Despite advances in non-invasive diagnosis of aortic dissection and in therapy, up to 28–55% of patients die without an *in vivo* diagnosis. The incidence of in-hospital complications is higher with type A than type B dissection with a mortality of nearly 24% at day 1, 29% at day 2, 44% at day 7, and 50% after 2 weeks [4]. Less than 10% of untreated patients with proximal aortic dissection live for 1 year, and almost all die within 10 years. Acute aortic dissection of the descending aorta is less frequently lethal. In the absence of obvious complications, survival rates are 89% at 1 month, 84% at 1 year, and 80% at 5 years [4,64].

Predictors of outcome

Among patients with type B aortic dissection, >60% of deaths are caused by rupture of the false lumen. Continued patency of the false lumen leads to aneurysmal dilatation while false lumen thrombosis is predictor of false lumen stability [65]. However, false lumen thrombosis has shown an inconsistent association with survival; partial thrombosis tends to predict post-discharge mortality compared with complete thrombosis or no thrombosis. It was suggested that thrombus in the distal false lumen could impede outflow, resulting in aneurysmal expansion and rupture [66,67].

Figure 71.3 The International Registry of Aortic Dissection (IRAD) classification system of aortic dissection with focus on the time domain. Survival in the early phase is lowest with open surgical management.

Visceral branches which arise from the false lumen, re-entry tears and a maximum diameter of the false lumen in the abdominal aorta are risk factors for incomplete thrombosis of the false lumen [68]. In addition, refractory pain or hypertension, and age ≥ 70 years were predictors of in-hospital mortality (OR 3.3 and 5.1, respectively) [69], while a large proximal entry tear identifies high risk patients [70]. Patient-specific simulation tools are being developed to analyze hemodynamics in aortic dissection with focus on velocity, stroke volume, and helicity of blood flow by four-dimensional phase contrast MR (4D PC-MR) imaging (Figure 71.4) [71,72].

Treatment of type A dissection

The mainstay of treatment in acute type A aortic dissection is open resection preventing lethal complications such as aortic rupture, stroke, visceral ischemia, cardiac tamponade, and circulatory failure. During surgery the aorta is reconstructed with interposition of synthetic graft and reimplantation of the coronary arteries and restoration of aortic valve competence. Operative mortality for ascending aortic dissections varies widely between 10% and 35%, but clearly below the mortality of medical therapy [73]. Endovascular

treatment for type A dissection has been reported in highly selected cases and remains under development [74–76].

Treatment of type B dissection

Recent data suggest significant differences with respect to in-hospital death stratified by type of treatment for patients with acute type B aortic dissection. IRAD reported an in-hospital mortality of 32% for those treated with surgery, and 10% for patients managed with medical therapy alone [4]. With 90% of patients surviving to hospital discharge, medical management constitutes the current standard of care for stable, clinically silent patients [77]. Conversely, open surgical replacement of dissected aorta has recently been abandoned because of the risk of left posterolateral thoracotomy in conjunction with single-lung ventilation, full heparinization, cardiopulmonary bypass, profound hypothermia, cerebrospinal fluid drainage, and circulatory arrest [78,79]. Data from IRAD, however, suggest a significant mortality rate for complicated type B dissection over the last 5 years, and an in-hospital mortality of 17% with open surgery [4], or even higher in presence of renal or mesenteric ischemia at 50–88%, respectively [80,81].

Figure 71.4 Functional imaging in aortic dissection; the upper row shows a two-dimensional magnetic resonance (MR) image after injection of gadolinium (left) with compromised true lumen and an expanded false lumen with partial thrombosis in the setting of chronic type B aortic dissection; the corresponding four-dimensional MR image identifies areas of highest flow turbulence and pulse pressure (right). The lower row reveals on transactional positron emission tomography (PET) image enhanced local ^{18}F -FDG-uptake in areas of inflammation and impending rupture (left) that can be stabilized by thoracic endovascular aortic repair (TEVAR) and induced remodeling of the dissected aorta.

Figure 71.5 Angiographic documentation of distal malperfusion before (a) and after TEVAR (b) of the proximal descending thoracic aorta in complicated type B dissection; three-dimensional CT reconstruction of the same dissection before (c) and after PETTICOAT TEVAR (d) to prevent an evolution to irreversible changes and false lumen expansion in the chronic state of 3 years post-dissection (e).

Endovascular management

The feasibility of TEVAR for aortic dissection has been established since 1999 as an alternative to high-risk open surgical treatment in patients with complicated type B aortic dissection. A recent report using Medicare data suggests that 25% of type B dissection repairs are now treated endovascularly, with lower mortality and morbidity rates compared with open repair [82]. A meta-analysis revealed an in-hospital mortality of 9%, stroke in 3.1%, paraplegia in 1.9%, conversion to type A dissection in 2%, bowel infarction in 0.9%, and major amputation in 0.2% [83].

The INSTEAD and ADSORB trials were designed to investigate the role of TEVAR in uncomplicated type B aortic dissection; 5-year results of INSTEAD-XL trial showed a reduction in aortic-related death and disease progression with endovascular repair and optimum medical therapy compared with optimum medical therapy alone [84], while ADSORB demonstrated better aortic remodeling in the TEVAR group. If further remodeling of the aorta is required a bare metal stent can help, known as the PETTICOAT concept (Figure 71.5) [85]. Patients treated in the acute setting are prone to aortic growth, particularly of the abdominal aorta [86,87].

Intramural hematoma

IMH is identified as a contained intramural hemorrhage in absence of a detectable intimal tear (Figure 71.1) [45]. IMH also occurs as a result of blunt trauma [88]. Complications of IMH are common, with progression to complete dissection in 28–47%, and aneurysm or rupture in 20–45% of patients [88,89]. IMH of the ascending aorta is often complicated by pericardial effusion, pleural effusion, and aortic insufficiency and needs surgical repair. Patients with IMH tend to be older and there is a higher incidence in male patients [45]. Similar to Stanford, type A IMH involves the ascending aorta and Stanford B IMH does not involve the ascending aorta

[3,90]. There is controversy regarding the natural history of IMH in North America and Europe compared with Japan and Korea. The incidence of IMH from Western centers was 6% (58/1010), versus an incidence in Eastern series of 28.3% and 29% [45,91,92]. While in Western populations IMH is similar to dissection, oriental patients seem to be more stable [93,94]. In a recent Japanese series, early and late progression was 30% and 10%, respectively [91]; in a Korean registry $\geq 80\%$ of patients were treated medically [3] and survived [95,96].

Treatment

Western centers reported early mortality with surgery of 8% versus 55% with medical treatment and recommend open repair in proximal IMH [44,97–99]. Conversely, type A patients from Asia showed no difference in early mortality between surgical (10.1%) and medical strategies (14.4%) [100]. Other Asian studies have found high rates of progression in patients treated medically, with a mortality rate of 32%, prompting these authors to recommend surgical resection for these patients [101]. Immediate surgery resulted in a 14.3% mortality, whereas mortality was 7.1% in those undergoing delayed surgery; in those awaiting surgery, 33% of type A IMHs converted to aortic dissection (none within the first 72 hours) [102].

Predictors of disease progression

Development of ulcer-like projections during follow-up of IMH has been reported to be a predictor of poor prognosis [103,104]. These lesions can progress to both localized dissection and aneurysmal dilatation, with complications occurring more commonly in proximal than in distal IMH. Other predictors of disease progression in IMH include age >70 years, cardiac tamponade, maximum hematoma thickness of ≥ 10 mm, and an aortic diameter ≥ 50 mm for type A [91,103].

Penetrating aortic ulcer

PAU is a painful ulceration in the aortic wall caused by rupture of the intima allowing blood through the internal elastic lamina, with pseudoaneurysm formation over time or rupture [89]. Patients are at risk of rupture, even at a normal aortic diameter. PAU has the highest incidence of rupture of all constituents of AAS with rates of up to 42% [105], and occurs in older men with lesions of 4–30 mm in depth and 2–25 mm in diameter [106]. PAU occurs more frequently in the descending, but rarely in the ascending aorta [107,108]. The typical patient is elderly, hypertensive, with a history of tobacco abuse, presenting with chest or back pain, but no signs of aortic regurgitation or malperfusion; asymptomatic patients can also be found and 27.8% of cases were associated with a saccular aneurysm, while 14% were associated with IMH [109].

Predictors of disease progression

Recurrent or refractory pain is considered to be one of the most important clinical symptoms in determining the appropriateness of intervention. Predictors of progression include sustained or recurrent pain ($p < 0.0001$), increasing pleural effusion ($p = 0.0003$), and both the diameter ($p = 0.004$) and depth ($p = 0.003$). PAU involving the ascending aorta is considered to be associated with a high risk of rupture and requires emergency or urgent intervention. Computational fluid-structure analysis may demonstrate structural fragility of the PAU wall [110].

Treatment

Urgent surgical repair is recommended for type A lesions although the majority of patients with PAU may not be suitable for conventional surgery. Type B PAU represents an ideal target for TEVAR due to segmental and well-localized wall pathology, particularly in a patient population with multiple comorbidities [106,111].

Outlook and conclusions

Survival of patients with AAS is 81% at 1 year and 63% at 5 years [112]. Medical therapy including beta-blockers is needed to minimize aortic wall stress in all patients, and serial imaging to detect signs of progression should be performed annually. Each case should be referred and discussed at a multidisciplinary meeting to consider patient age, general life expectancy, and fitness for either open surgery or TEVAR. After TEVAR, secondary aortic interventions are common and should prompt long-term surveillance [113]. Grouping various aortic conditions into the entity of AAS offers a structured early identification of patients at risk [114–116]. Nonetheless, optimal management of patients with AAS remains challenging. The advent of minimally invasive endovascular techniques has shifted the treatment paradigm with treatment no longer limited to open surgery or best medical therapy alone. The current challenge is to determine the patient population best suited for active (open or endovascular) treatment rather than just best medical therapy to ensure individualized optimal care.

Thoracic Endovascular Aortic Aneurysm Repair

Paul S. Lajos and Michael L. Marin

Icahn School of Medicine at Mount Sinai, New York, NY, USA

Thoracic aortic aneurysms and their complications have been noted since antiquity [1–3] with Paré in 1572 speculating on a direct link with syphilis [2]. The principle of proximal ligation of aneurysms was originally described by Anel in 1710 [4] and surgical replacement of descending thoracic aortic aneurysms using an aortic homograft was reported by Lam and Aram in 1951 with the patient expiring three months later [5]. In 1953, Bahnson presented his series of repairs by lateral resection and aortorrhaphy [6] and later the same year DeBakey and Cooley described the first successful replacement of a descending thoracic aortic aneurysm using a prosthetic graft [7]. In 1951, Cooley performed what appeared to be the first open repair of an aortic arch aneurysm by cross-clamping and oversewing [8].

Today, open thoracic aortic aneurysm (TAA) repair while highly studied and optimized [11] still remains a more morbid repair than its open abdominal counterpart. Open repair of TAAs has been associated with significant morbidity and mortality according to Stevens and Farber [9], who reviewed 1600 patients undergoing elective open repair for descending TAAs with mean 30-day mortality of 9.2% and a range of 4.4–31%. The National Inpatient Sample Administrative Database reports an operative mortality of 10% for all descending TAAs [10]. From Baylor, a high volume center, a series reports 387 patients undergoing repair of TAAs with a paraplegia rate of 2.6%, stroke rate of 1.8%, renal failure 7.5%, and mortality 4.4% [11].

Dake performed the first thoracic endovascular aortic aneurysm repair (TEVAR) in 1994 [12]. TEVAR has revolutionized the treatment of this highly morbid condition into a durable and minimally invasive treatment. The Food and Drug Administration (FDA) approved the first commercially available stent graft for thoracic aortic aneurysms in 2005, the W.L. Gore TAG endograft (Flagstaff, AZ, USA), and in 2008 both the Cook Zenith TX2 (Bloomington, IN, USA) [13] and Medtronic Talent (Santa Rosa, CA, USA) became commercially available. Currently, there are four thoracic grafts commercially available in the USA: W.L. Gore C-TAG (Flagstaff, AZ, USA); Medtronic Valiant (Santa Rosa, CA, USA); Cook TX2 (Bloomington, IN, USA); and Bolton Relay (Sunrise, FL, USA).

TEVAR remains a preferred technique because of its minimally invasive approach, ease of application and deployment, shorter operating times, reduced blood loss, and decreased morbidity and mortality, and length of stay. Devices have continued to evolve since

the introduction of smaller access sheaths, hydrophilic coatings, and smaller delivery and deployment systems. TEVAR is a safe and effective therapy for different aortic pathologies leading to promising long-term results, with patients with acute type B aortic dissections, aneurysms, and traumatic ruptures seeming to benefit the most [14].

Demographics

Among all aortic aneurysms, 60% are located in the abdominal aorta and 20% in the thoracic or thoracoabdominal aorta. Of those 20%, 40% are confined to the ascending aorta, 15% to the arch, 35% to the upper thoracic, and 10% to the lower distal thoracic aorta [15].

TAAs have an incidence of 6 per 100,000 patient-years with a rupture risk of 3.5–5 per 100,000 patient-years with an overall 5-year rupture risk of 20% [16]. The natural history of TAAs is progressive expansion leading to rupture, which is usually fatal. Aneurysm growth is strongly related to maximal diameter and this increases exponentially with aneurysm size [16–18]. Risk of rupture is seven times higher in women than men and is directly related to diameter >6 cm [19]. Thoracoabdominal aortic aneurysms, on the other hand, have an 80% 1-year risk of rupture when ≥ 8 cm [20].

Etiology

The majority of TAAs are the result of medial degeneration within the wall of the aorta. Medial degeneration or previously cystic medial necrosis is a complex combination of hemodynamic forces, genetic factors, and matrix metalloproteinases (MMPs). The end product is breakdown of extracellular matrix and smooth muscle within the aortic wall. While the majority of TAAs are secondary to medial degeneration, 20–50% are believed to have arisen from an area of previous aortic dissection [15–18].

TAAs and thoracic aortic dissections are classified as syndromic, familial, or sporadic. Syndromic consist of less than 5% and arise from a collection of clinical manifestations of Marfan's, Ehler-Danlos type IV, or Loeys-Dietz syndromes. Endografting is generally not recommended in this group due to continued aortic dilation.

Marfan's syndrome (MFS) is a connective tissue disorder with an autosomal dominant inheritance pattern with an incidence of 1 in 10,000 individuals. MFS displays varying physical traits including dolichostenomelia, arachnodactyly, ectopia lentis, and thoracic

aortic aneurysm and dissection. The defect is in the fibrillin (*FBN1*) gene [21,22].

Loeys–Dietz syndrome (LDS) manifests in very young patients with bifid uvula or cleft palate, hypertelorism, craniosynostosis, and as aneurysms or dissections in abdominal or thoracic aorta with missense mutations in transforming growth factor B1 and B2 receptors and in *TGFBR2* or *TGFBR1* genes [23].

Ehler–Danlos IV (EDS) manifests as tissue fragility of skin and joints, internal organs, and blood vessels with type IV as rupture or dissection in medium-sized vessels of chest and abdomen as opposed to the aorta, which is in contradistinction to MFS. Its incidence is 1 in 50,000 individuals with a mutation in the *COL3A1* gene, which encodes for type III collagen.

Familial TAAs comprise roughly 15–20% and roughly 80% are sporadic in etiology and about 15–20% have a first degree relative with a TAA [17]. These cluster in families but do not have an association with a connective tissue disorder like MFS, EDS, or LDS. The Familial TAAs are inherited as an autosomal dominant disorder and patients generally present at a younger age than with the sporadic form and have an association with a bicuspid aortic valve or patent ductus arteriosus. Primary genes associated with this are *ACTA2*, *TGFBR2*, and *MYH11*.

Indications

Surgical intervention is advised in the presence of symptoms, rapid dilatation, and compression of adjacent thoracic or abdominal structures, rupture, and diameter ranging 5–7 cm depending on age, associated risks, and medical comorbidities.

Open repair of TAA and thoracoabdominal aortic aneurysm (TAAA) confers significant morbidity and measurable mortality, potential blood loss, and physiologic stresses to heart and lungs. TEVAR offers less potential blood loss, preservation of forward blood flow, avoidance of aortic cross-clamping and cardiac stress; and avoidance of potential morbidity as related to thoracotomy and laparotomy. Advances in stent graft technology and newer generation devices, debranching techniques to extend landing zones, and percutaneous access have increased potential cases suitable for TEVAR to 70–80%. Anesthesia can be performed under local, regional, or general anesthetic. Cardiac stability is improved and spinal chord ischemia, length of stay, and duration of postoperative recovery all are diminished.

Diagnostic imaging

Duplex ultrasound

Duplex ultrasound is not routinely useful because of air in the thoracic cavity generating poor image quality. However, it is important in assessing size and quality of access vessels, such as iliac, femoral, carotid, and left subclavian arteries.

Computed tomography

Computed tomography remains the gold standard for preoperative imaging. Post-imaging processing using specific vascular protocols allows three-dimensional rendering and simulations or angiography for accurate measurements in graft sizing useful for case planning. Utilizing large numbers of axial slices and combination with multiplanar reconstructions can provide computed tomographic angiography. Extent and nature of aortic disease and iliac disease, location and size diameters, and quality can be obtained and measured for stent graft repair. CT scan can delineate calcifications, intramural thrombus, access vessel sizing, and architecture. Potential disadvantages for CT include contrast load and radiation exposure.

Angiography

Conventional diagnostic angiography has been largely replaced by CT angiography but may be appropriate for the measurement of questionable landing zones and assessment of potential side branches. Three-dimensional angiography is also helpful as rotational angiography on newer fixed mounted units. Angiography has the disadvantage of being invasive and requiring intra-arterial contrast.

Magnetic resonance

MR angiography is performed with intravenously injected paramagnetic contrast (i.e., gadolinium) or has the advantage of being performed without contrast in some scanners. High performance systems can chase a single contrast bolus throughout the body for MRA but generally requires a long period of time (e.g., 45 minutes) for image acquisition. MRA may not be possible in some patients because of the extended period of time needed and images are affected by motion artifact.

Transesophageal echocardiography

Transesophageal echocardiography can provide short and long-axis images of the descending thoracic aorta to the level of the stomach to assess aortic atherosclerosis. It can be helpful especially in dissections for locating intimal re-entry tears in the dissected TAA. Benefits include lack of contrast load; quality of imaging is operator dependent and is not readily available in some centers.

Anatomic requirements

Thoracic stent grafts were originally designed as modified designs of abdominal endografts. Thoracic pathology requires significant constraints and challenges including the requirement to conform to the curve of the aortic arch to gain accurate and secure fixation. These requirements have led to significant challenges including tortuous aortas, limited proximal and distal landing zones, and pathologies.

Successful anatomic requirements for successful TEVAR include proximal landing zone diameter needing to be <40 mm; adequate proximal landing zone length of 20 mm on the lesser curve of the aortic arch; at least 15 mm of normal aorta required for distal landing zone; landing zone cannot potentially have an acutely angled arch and cannot form a tight circumferential seal. The proximal stent graft can cover the left subclavian artery with arm ischemia reported to be quite low [24]. The role of subclavian artery transposition or common carotid to subclavian bypass is controversial with some evidence of spinal chord ischemia and posterior circulation compromise being higher in patients who do not undergo prior revascularization [25]. Tortuosity of the descending thoracic aorta can cause difficulties with endograft placement and fixation although newer generation devices have improved tracking and flexibility and less kinking possibilities [26]. If distally more landing zone is required it may necessitate taking the TEVAR graft to the abdominal aorta and potentially cover or snorkel some of the larger visceral vessels (i.e., celiac, superior mesenteric artery, and/or renals) or perform surgical debranching. There are reports of covering the celiac artery to increase distal landing zones; however, this must be carried out in the setting of adequate superior mesenteric artery perfusion [27]. Access vessels remain an important consideration as calcified and tortuous iliac arteries can be a contraindication with a minimum iliac diameter of 7 mm being the necessary to accommodate most commercially available devices (Box 72.1).

Evidence to support TEVAR

TEVAR has been used successfully in all aortic pathologies, both emergent and elective including aortic transection, aneurysmal disease, and dissection.

The European Collaborators on Stent/Graft Techniques for Aortic Aneurysm (EUROSTAR) and UK Thoracic Registries reported a multicenter series of 443 patients undergoing TEVAR for degenerative aneurysm, dissection, false aneurysm, and traumatic injuries [28]. Technical success was 87%. Left subclavian artery coverage occurred in 17% with 50% undergoing revascularization. Thirty-day mortality was 10% in TAA group (5.7% for elective and 27.9% for emergent procedures). Cumulative survival was 80% with a 1% late rupture rate.

In a study by Bavaria *et al.* [29], the randomized trial that led to the approval of the Gore TAG device showed that with good anatomy TEVAR can be performed with lower mortality than open

surgery (2.1% vs. 11.7%); less spinal chord ischemia (3% vs. 14%); less renal failure (1% vs. 13%); and less respiratory insufficiency (4% vs. 20%). However, access-related complications were more common in the TEVAR group.

The INSTEAD XL trial (INvestigation of STent grafts in patients with type B aortic dissection), a randomized clinical trial completed in Europe, in uncomplicated type B aortic dissections, initially at 1 year did not show a mortality benefit to TEVAR [30]. Their 5-year follow-up showed an aorta-specific survival benefit in patients treated with TEVAR versus medical therapy of 6.9% versus 19.3%, respectively in risk of aorta-specific mortality, as well as less progression of disease of 27.0% versus 46.1%, respectively [30].

In a complicated aortic dissection trial (branch vessel malperfusion, impending rupture, aortic diameter ≥ 40 mm, rapid aortic expansion, and persistent pain or hypertension despite maximum medical therapy) using Cook proximal TX2 thoracic stent grafts and distal bare metal dissection stents (Zenith Dissection Endovascular System; Cook Medical, Bloomington, IN, USA), 10 centers enrolled 40 patients in acute, subacute, and chronic aortic dissections. The overall mean time from symptom onset to treatment was 20 days (range 0–78 days). Seven combinations of stent grafts and dissection stents were used, and all devices were successfully deployed and patent. The 30-day mortality rate was 5% (2 of 40) with two deaths occurring after 30 days, leading to a 1-year survival rate of 90%. Thirty-day morbidity included stroke in 7.5%; transient ischemic attack in 2.5%; paraplegia in 2.5%; retrograde dissection in 5%; and renal failure in 12.5%. Four patients (10%) underwent secondary interventions within 1 year. Favorable aortic remodeling was observed during the course of follow-up, indicated by an increase in the

Box 72.1 Indications for operation

- Penetrating aortic ulcer
- Rapid dilatation
- Compression
- Rupture
- Dissection
- Blunt thoracic trauma
- Twice size of distal aortic arch
- Size 5–7 cm

Case study

A 73-year-old male presented to an outside hospital with acute sudden back and chest pain. He had a history of coronary artery disease with prior placed stents and hypertension. Chest CT angiogram revealed a focal penetrating ulcer at distal transverse

aortic arch with aneurysmal dilatation at the aortopulmonary window and intramural aortic hematoma extending into the arch and descending thoracic aorta (Figure 72.1). He was started on beta-blocker therapy with control of his blood pressure;

Figure 72.1 (a) Preoperative CT scan showing aneurysmal dilatation (arrow) with intra aortic hematoma. (b) Three-dimensional rendering of thoracic arch showing intramural hematoma at aortopulmonary window (arrow).

however, his back pain persisted despite optimal medical therapy. On day 7 he underwent repeat imaging which revealed unchanged intramural aortic hematoma with penetrating ulcer and aneurysmal dilatation (Figure 72.1).

Due to the close proximity of the left subclavian artery with a questionable proximal landing zone, he underwent thoracic

Figure 72.2 Preoperative thoracic aortogram demonstrating aneurysmal dilatation at the distal transverse aortic arch with an exact 2 cm proximal landing zone in a relatively straight segment of the distal arch.

arch aortogram. Diagnostic arch aortogram confirmed location of aneurysm exactly 2 cm from the distal left subclavian artery to the arch aneurysm (Figure 72.2).

The following day he underwent an ultrasound-assisted left transfemoral placement of percutaneous conformable Gore TAG endoprosthesis (W.L. Gore, Flagstaff, AZ, USA) through the left groin via the Preclose Proglide (Abbott Laboratories, Redwood City, CA, USA). The patient had resolution of his back pain and follow up CT scan revealed complete exclusion of his penetrating ulcer (Figure 72.3).

Figure 72.3 Postoperative time resolved MRA showing placement of thoracic endograft with complete exclusion of aortic aneurysm.

true lumen size and a decrease in the false lumen size along the dissected aorta, with completely thrombosed thoracic false lumen observed in 31% of patients at 12 months as compared to 0% at baseline [31].

In an aortic transection meta-analysis, Tang *et al.* [32] reviewed 370 patients treated with TEVAR and 329 patients managed with open surgery. Technical success rates were similar between groups; however, mortality was significantly lower in the TEVAR group (7.6% vs. 15.2%) as were rates of paraplegia (0% vs. 5.6%) and stroke (0.85% vs. 5.3%). The most common procedure-related complications for each technique were iliac artery injury during TEVAR and recurrent laryngeal nerve injury after open surgery. Their study showed a significant reduction in mortality, paraplegia, and stroke rates in patients who undergo TEVAR versus open repair.

Conclusions

In closing, TEVAR can be performed safely and effectively in appropriate patients. Attention to access vessel size and quality and appropriate proximal and distal landing zones in the thoracic aorta are paramount to successful long-term outcomes. Strong reliance on preoperative high-quality CT scan will help aid in diagnostic workup and appropriate case planning.

Endovascular Aortic Aneurysm Repair

William Beckerman, Paul S. Lajos, and Peter L. Faries

Icahn School of Medicine at Mount Sinai, New York, NY, USA

The first open repair of an abdominal aortic aneurysm (AAA) was performed by Charles Dubost in 1951 at the Hôpital Broussais in Paris using a cadaveric arterial graft, a technique later brought to the USA by Cooley and DeBakey [1,2]. Another major advancement occurred in 1978 when Cooley developed a double-velour Dacron graft that quickly became the standard graft for open AAA repair [3]. Despite decades of experience with open aneurysm repair that continue to this day, open surgical repair has meant longer recovery times, even with decreased perioperative mortality rates that have fallen to between 1% and 7% [4,5].

In 1991, Parodi's placement of a balloon-expandable stent graft delivered endovascularly under fluoroscopy to treat AAA ushered in a new era in vascular surgery [6]. This technology was soon adopted worldwide and the first two endovascular devices, Guidant's Ancure and Medtronic's AneuRx, gained regulatory approval from the US Food and Drug Administration (FDA) in 1999 [7]. By 2006, endovascular aneurysm repair (EVAR) overtook open repair as the most common elective treatment for AAA [8]. At the time of this publication, there are currently six FDA-approved abdominal aortic stent grafts commercially available in the USA: Cook Zenith (Bloomington, IN, USA); Endologix AFX (Irvine, CA, USA); Gore Excluder (Flagstaff, AZ, USA); Lombard Aorfix (Irvine, CA, USA); Medtronic Endurant (Santa Rosa, CA, USA); and the Trivascular Ovation (Santa Rosa, CA, USA).

Since its initial use over two decades ago, the prevalence of EVAR to treat AAA has been increasing steadily, validated by a number of randomized controlled studies showing decreased perioperative mortality and non-inferior long-term mortality versus traditional open surgery in addition to obvious benefits including decreased length of stay [9–11]. Smaller delivery sizes and access sheaths have evolved in EVARs now being able to be performed entirely percutaneously (PEVAR), expanding the scope of interventionalists who can perform the procedure.

Demographics

AAAs are responsible for approximately 13,000 deaths annually in the USA and are the fifteenth leading cause of death overall and the tenth leading cause of death in men above the age of 55 [12,13]. AAA primarily affects adults over the age of 50 (and increases with increasing age), with men affected 2–6 times more frequently than

women and 5 times more commonly in patients with a smoking history. Other risk factors for AAA include Caucasian race, a family history of AAA, the presence of other large aneurysms, and atherosclerosis [14,15]. The incidence of AAA is 3.5–6.5 per 1000 person-years in males with a reported incidence of rupture of 1–21 per 100,000 person-years [16–18]. Aneurysm rupture carries a particularly poor prognosis, with an overall mortality of 78%, with the majority of those deaths occurring before the patient presents to a medical center. Incidence of rupture increases exponentially with increasing aneurysm diameter, with an estimated rupture risk of approximately 30–50% per year for those aneurysms >8 cm. Among all aortic aneurysms, 60% are distributed in the abdominal aorta with the vast majority involving the infrarenal aorta and only 5–15% involving the aorta above the renal arteries [19].

Etiology

AAAs are typically the result of chronic loss of vascular structural proteins and subsequent decrease in aortic wall strength [20]. While atherosclerosis is a risk factor for AAA, atherosclerosis alone does not cause AAA. Atherosclerosis is limited to changes in the inner layers of the aorta whereas AAA is transmural involving loss of elastin and smooth muscle and abnormal collagen remodeling. Circulating markers of inflammation including C-reactive protein (CRP) and interleukins (especially interleukin-6) are both associated with aneurysm formation. This chronic inflammation is thought to degrade elastin and collagen in the aortic wall through the work of proteases, including plasmin, matrix metalloproteinases (MMPs), and cathepsins S and K from endothelial and smooth muscle cells and inflammatory cells in the media and adventitia.

Connective tissue disorders, including Marfan's syndrome, Loeys–Dietz syndrome, and Ehler–Danlos type IV have all been implicated in AAA formation. Inflammatory aneurysms, which comprise approximately 5% of all AAAs, are a distinct entity involving notable aortic wall thickening with increased vascularity and elevated erythrocyte sedimentation levels [21].

The natural history of AAA typically involves an increase in AAA diameter of approximately 0.3 cm/year, with larger aneurysms tending to grow faster than smaller ones, and active smoking increasing aneurysm growth as well as risk of rupture [22].

Indications

EVAR is indicated as treatment for symptomatic AAA (e.g., limb ischemia, thromboembolic events, abdominal, back or flank pain), inflammatory AAA (characterized by chronic abdominal pain, weight loss, and elevated erythrocyte sedimentation rate), or ruptured AAA. EVAR is also indicated as prophylactic treatment to prevent aneurysm rupture in the case of rapidly expanding AAA (generally described as aneurysm growth >0.5 cm in 6 months or >1 cm in 1 year), or for AAA greater than 5.5 cm in maximum diameter (with some proposing >5 cm in low operative risk females) [23,24]. Coexisting AAA in association with aneurysms of the iliac arteries would also prompt EVAR.

In the preoperative evaluation of a patient for elective EVAR, risk of aneurysm rupture and associated morbidity and mortality must be weighed against operative risk. Perioperative mortality from EVAR ranges from 4% in some population studies to less than 1% at centers of excellence [25]. While a thorough workup involving cardiovascular testing should be performed for all elective cases, the decreased blood loss, avoidance of aortic cross-clamping, decreased procedure time and postoperative recovery and increased options for anesthesia (including general, local, moderate sedation, and spinal anesthesia) all increase the range of patients who can be successfully treated at lower perioperative risk than conventional open operative repair [26].

Ruptured AAA

EVAR is increasingly being used to treat ruptured AAA [27]. The largest randomized clinical trial, Immediate Management of the Patient with Rupture: Open versus Endovascular Repair (IMPROVE), was a multicenter trial out of the UK and Canada that attempted to examine this treatment in real-world conditions [28]. A total of 613 patients with suspicion of ruptured AAA but prior to imaging were randomized into endovascular or open repair groups. While there was no difference in 30-day mortality between the two groups as initially randomized, of the patients treated with the different modalities, mortality was significantly lower in the EVAR group (25%) than the open repair group (38%). Additionally, more patients were discharged directly to home in the EVAR group (94% vs. 77%). It is also interesting to note that of the 266 patients starting out in the endovascular arm of the study, 174 (64%) were deemed to have suitable anatomy for EVAR.

Ideally, a patient being considered for EVAR for ruptured AAA should be hemodynamically stable with preoperative CT imaging to determine suitability for EVAR [28]. If not feasible, an aortic occlusion balloon can be inflated to stabilize the patient. The same basic anatomic criteria for elective EVAR hold true for ruptured EVAR. Absolute contraindications are an infrarenal aortic neck diameter >32 mm (as the largest diameter device on the market is 36 mm and approximately 10% oversizing needs to be considered) or an infrarenal aortic neck length <7 mm (to avoid covering the renal arteries while maintaining aortic wall apposition). Heavily calcified or thrombus-filled aortic necks, angulated aortic necks ($>60^\circ$), small iliac arteries (<7 mm) are all relative contraindications [29,30].

Special preoperative considerations for ruptured EVAR versus elective EVAR include permissive hypotension (aiming for goal systolic blood pressure of 80–100 mmHg), resuscitation with blood products as opposed to crystalloid fluids (as well as alerting the blood bank to the potential need for massive transfusion protocol), and avoidance of spinal or epidural anesthesia both for time considerations as well as their effect on blood pressure [28,31].

Diagnostic imaging

Duplex ultrasound

Abdominal B-mode ultrasound is the most frequently used screening modality to look for AAA. Indeed, for patients in the USA, Medicare covers a one-time screening for those with a family history of AAA and men aged 65–75 years who have smoked at least 100 cigarettes in their lifetime [32]. Ultrasound is both inexpensive as well as non-invasive; however, it may be associated with decreased accuracy and higher interobserver variability [33]. Visualization of the suprarenal aorta and iliac arteries is often difficult, especially in patients with larger body habitus, and the ability to predict impending rupture is not usually possible. It is the preferred method to diagnose and monitor AAA until they become suitably sized for operative treatment as well as for postoperative monitoring for endoleaks.

Computed tomography angiography

Computed tomographic angiography (CTA) requires exposure to radiation as well as intravenous contrast material; however, in spite of this it remains the primary imaging modality for diagnosis as well as for pre-operative planning. It has greater accuracy and less interobserver variability when compared with ultrasound [34]. Three-dimensional reconstruction of CTA with centerline measurements has been valuable for greater accuracy in measurements and for visualizing the complete vasculature from the aortic arch down to the access vessels. It is also the best modality for defining the quality of the patient's vessels including thrombus and calcifications. Given the rapid image acquisition speed of CTA, stable patients presenting with ruptured AAA can be considered for immediate preoperative case planning to treat these patients endovascularly (REVAR).

Rotational angiography

Conventional diagnostic angiography has been largely replaced by CT angiography; however, the use of on-table rotational angiography as a primary imaging modality in the event of ruptures is being studied. It appears to be limited in clarity as well as field size (when attempting to visualize both iliac arteries and access vessels) when compared with CTA but can be effective in detecting endoleaks intraoperatively. Angiography also has the disadvantage of being invasive and requiring intra-arterial contrast [35].

Magnetic resonance

Magnetic resonance imaging (MRI) and magnetic resonance angiography (MRA) both offer radiation-free alternatives to CT and conventional angiography for AAA imaging. Disadvantages include high cost, long acquisition time (making it less tolerated in claustrophobic patients), poor visualization of calcified plaque and lower spatial resolution, and sensitivity to motion artifact. While use of gadolinium paramagnetic contrast makes it a reasonable imaging modality for patients with allergies to traditional intravenous contrast, it is not a benign alternative for patients with renal insufficiency because of increased risk of potentially fatal nephrogenic sclerosing fibrosis [36].

Anatomic requirements

Standard EVAR has a number of anatomic requirements that are roughly similar amongst the various stent-graft devices. That being said, each stent-graft model has its own instructions for use (IFU) outlining more specific device detail about the exact anatomic

parameters and limitations that should be met for optimal outcomes. Traditionally, however, EVAR requires healthy points of apposition (known as landing zones) at the proximal and distal fixation points of the stent-graft as well as healthy access vessels to deliver the device safely into the aorta [29]. Furthermore, excessive tortuosity, especially of the infrarenal aorta has been associated with poorer outcomes with associated graft failure and endoleaks. As a rough guide, IFU for most EVAR devices specify an infrarenal aortic neck diameter between 16 and 32 mm and a landing zone of at least 10 mm of healthy infrarenal aorta with less than 60° of angulation. The iliac arteries should have >10 mm of length to land the distal aspect of the device with a diameter between 8 and 25 mm to accommodate most commercially available grafts. Heavily calcified vessels or vessels with extensive thrombus both make device apposition more challenging [30].

For patients with suboptimal anatomy or aneurysms encroaching on or involving the visceral or renal arteries, a number of methods and device modifications have been developed to ensure adequate graft fixation. Utilizing smaller parallel stent grafts into visceral or renal arteries, it is possible to maintain perfusion in these vessels in a technique known as snorkeling (or chimneying) [37]. More recently, fenestrated EVAR (FEVAR), a preordered and patient-specific manufactured aortic stent graft with cutouts for visceral and renal vessels, is being used as a newer alternative to snorkeling in patients with more difficult anatomy [38]. Branched devices, with a smaller stent-graft sutured onto the main device to preserve flow to a branch artery (such as a renal or hypogastric artery) are also in development and being used at select centers in the USA at time of publication.

It is common for the aneurysmal disease in the aorta to extend into the iliac arteries. In cases where it is not possible to find healthy landing zone proximal to the takeoff of the hypogastric artery, it may be necessary to embolize one, or even both (in a staged fashion) hypogastric arteries in order to extend the iliac artery landing zone distally beyond the hypogastric artery. This can be accomplished in a retrograde fashion from the ipsilateral femoral side or an antegrade fashion from either the contralateral femoral side or from superiorly via brachial or even radial artery access. These larger vessels usually require either embolization plugs such as the St. Jude Amplatzer (Saint Paul, MN, USA), embolization coils, or a combination of the two [39]. Often, the inferior mesenteric artery (IMA) is not visualized on pre-operative imaging because of thrombosis from the aneurysm sac. When the IMA is patent and visualized on flush angiography, some centers report decreased endoleak rates and increased sac shrinkage with embolization prior to stent graft placement [40]. Similar to the hypogastric artery, the IMA is a fairly large vessel, and embolization coils or microcoils are typically needed to achieve complete thrombosis of the artery. The rationale behind these embolizations is to prevent endoleaks, discussed later in this chapter.

Access vessels remain an important consideration as calcified and tortuous iliac arteries may be a contraindication and a minimum iliac diameter of 7 mm necessary to accommodate most commercially available devices

EVAR devices

The initial aortic stent grafts were simple tubular devices, constructed by marrying available stents to a Dacron tube graft [6]. This was soon followed by the 1993 development of the bifurcated aortobiiliac stent graft which became the prototype for most devices

Table 73.1 FDA-approved endovascular aneurysm repair (EVAR) devices.

Device	Device diameter (mm)	Main body sheath size (Fr)	Fixation
Cook Zenith	22–36	18–22	Suprarenal barbed stents
Endologix AFX	22–34	17	Suprarenal stents, anatomic seating at aortic bifurcation
Gore Excluder	23–31	18–20	Infrarenal barbs
Lombard Aorfix	24–31	22	Infrarenal barbs
Medtronic Endurant	23–36	18–20	Suprarenal barbed stents
Trivascular Ovation	20–34	14–15	Suprarenal barbed stents, infrarenal polymer-filled rings

that followed [41]. The current FDA-approved devices all fit this basic bifurcated design; however, differences do exist between approved devices (Table 73.1). The Cook Zenith, Gore Excluder, Lombard Aorfix, and Medtronic Endurant are all modular devices with woven polyester (Zenith, Aorfix, Endurant) or ePTFE (Excluder) graft material supported by the stent. Infrarenal fixation is accomplished by means of either suprarenal barbed stents in the case of the Zenith and Endurant or by barbs or hooks at the infrarenal edge of the stent graft in the case of the Aorfix and Excluder. The Ovation is unique in eschewing a traditional stent material for most of the main body, using polymer-sealing rings to create wall apposition but maintaining traditional iliac limbs. The Endologix AFX is unique in two ways: both in its passive fixation with its flow divider seated at the aortic bifurcation as well as its graft fabric lying on the outside surface of the stents. These latter two devices both utilize suprarenal fixation stents for additional protection against migration. Selection of device is at the discretion of the operator; to date there have been no randomized controlled trials comparing EVAR devices with each other [42].

Endoleaks

Blood flow in the aneurysm sac after stent graft deployment is known as an endoleak. This continued filling of the aneurysm sac can lead to aneurysm rupture in the post-EVAR patient. There are five distinct types of endoleaks that will be discussed in brief here [43].

A type I endoleak is defined as persistent blood flow into the aneurysm sac from around the stent graft proximally (type IA, typically around the main body) or distally (type IB, typically around an iliac limb). As these are considered antegrade, high-pressure leaks, type I endoleaks are usually repaired whenever discovered, be it on post-EVAR completion angiogram or surveillance CTA. This usually entails extension of the graft with either a cuff proximally or iliac extension limb distally. Type II endoleaks involve persistent

filling of the aneurysm sac from retrograde blood flow of side branches, typically the inferior mesenteric artery or lumbar branches. These are considered low pressure, and frequently resolve up to 80% of the time without any need for intervention. As such, these are typically only treated (often making use of microcatheters, embolization coils and/or N-butyl cyanoacrylate glue) when there is enlargement of the aneurysm sac on surveillance CTA [44].

Type III endoleaks describe blood flow into the aneurysm sac through a tear in the graft fabric or from component separation. Similar to the type I endoleak, these are considered high-pressure antegrade leaks and are treated whenever seen, usually by stent graft re-lining.

Type IV endoleaks involve filling of the aneurysm sac through the graft fabric caused by porosity, not rips or tears. These are sometimes noted within the first 30 days of graft implantation before resolution, but are seen less frequently with newer stent grafts compared with earlier models.

Finally, type V endoleaks are due to “endotension,” described as elevated sac pressure or sac enlargement without a demonstrated leak. The cause is thought to be either an undetected type I–IV endoleak or by pressure transmitted through thrombus. Re-lining with proximal or distal extension is the most common intervention for this endoleak, with complete operative explant being reserved for the most recalcitrant cases.

Evidence to support EVAR

EVAR has been validated as an effective treatment for abdominal aortic aneurysms in a number of randomized controlled trials, including the DREAM, the OVER, and EVAR 1 trials.

The Dutch Randomized Endovascular Aneurysm Management (DREAM) trial was a 2004 study that randomly assigned 351 patients with >5 cm AAA and suitable anatomy to either open or endovascular aneurysm repair. Thirty-day and 2-year aneurysm-related mortality were both significantly lower in the EVAR group (1.2% vs. 4.6% and 2.1% vs. 5.7%, respectively), the difference entirely a result of increased perioperative mortality in the open repair. All-cause mortality, however, equalized at 1 year postoperatively and stayed equivalent until the longest follow-up of 6 years (68.9% in the EVAR group vs. 69.9% in the open group). There were greater rates of reintervention (29.6% in EVAR vs. 18.1% in open) but fewer moderate and severe systemic complications (11.7% vs. 26.4%) for EVAR compared with open repair, respectively [10].

The Endovascular Aneurysm Repair Versus Open Repair in Patients With AAA (EVAR 1) trial was a randomized controlled

trial involving 1252 patients, with exactly half ($n=626$) divided to receive open repair and half to receive EVAR. The perioperative (30-day) mortality was significantly less for EVAR (1.8% vs. 4.3%), but no significant differences were seen in overall mortality. Similar to DREAM, graft-related complications and rates of reintervention occurred more frequently with EVAR [9].

The Open Versus Endovascular Repair (OVER) trial was a Veterans Affairs multicenter study involving 881 veterans with AAA >5.0 cm, AAA with iliac aneurysm of diameter ≥ 3.0 cm, or a AAA diameter of ≥ 4.5 cm with rapid enlargement (>0.5 cm growth over 6 months or 1.0 cm in 1 year) randomized to either open AAA repair or EVAR. Overall mortality was similar between groups over 9 years of follow-up (7.0% EVAR vs. 9.8% open repair) with an increased but not statistically significant difference in aneurysm rupture in the EVAR group. Not surprisingly, EVAR was also associated with shorter procedure times (2.9 vs. 3.7 hours), shorter intensive care unit stay (1 vs. 4 days), and shorter hospital lengths of stay (3 vs. 7 days) [11].

While there have been no randomized controlled trials in the USA comparing EVAR with open repair for ruptured or symptomatic AAA, a systematic review of 23 observational studies involving 7040 patients with symptomatic or ruptured AAA was performed including 6300 open and 740 endovascular repairs, all on an urgent or emergent basis. Emergent EVAR was associated with a significantly reduced perioperative (30-day) mortality risk relative to open repair (pooled odds ratio [OR] 0.62, 95% CI 0.52–0.75) [45].

Conclusions

EVAR has proven to be a safe and effective procedure for treating AAAs in appropriate patients. All-cause perioperative mortality, as well as AAA-related mortality at short- and intermediate-term follow-up, are lower in patients undergoing endovascular stent graft placement versus open surgery in randomized trials. However, this was associated with higher repeat intervention rate in the endovascular group noted at intermediate follow-up. Long-term survival appears to converge between the two groups, as it is dominated by the natural history of severe cardiovascular disease [46,47].

As in all procedures, patient selection is paramount and preoperative case planning with CT angiography is mandatory for successful outcomes. Advancements in EVAR technology including lower device profiles and increasing use of parallel grafts and fenestrated EVAR should increase the potential candidates for EVAR in the future.

Case study

A 50-year-old male presented with known infrarenal AAA incidentally revealed on screening ultrasound. He had a strong family history for aneurysm as his father died of a ruptured AAA. Serial CT scan showed progression to 5 cm over the course of 6 months. He was electively sized for repair (Figure 73.1).

He was sized for Endologix AFX bifurcated main body and suprarenal proximal aortic extension cuff lying below the lowest renal artery (left). He underwent percutaneous placement of the device utilizing the Abbott Perclose Proglide (Abbott Laboratories, Abbott Park, IL, USA) for his femoral access.

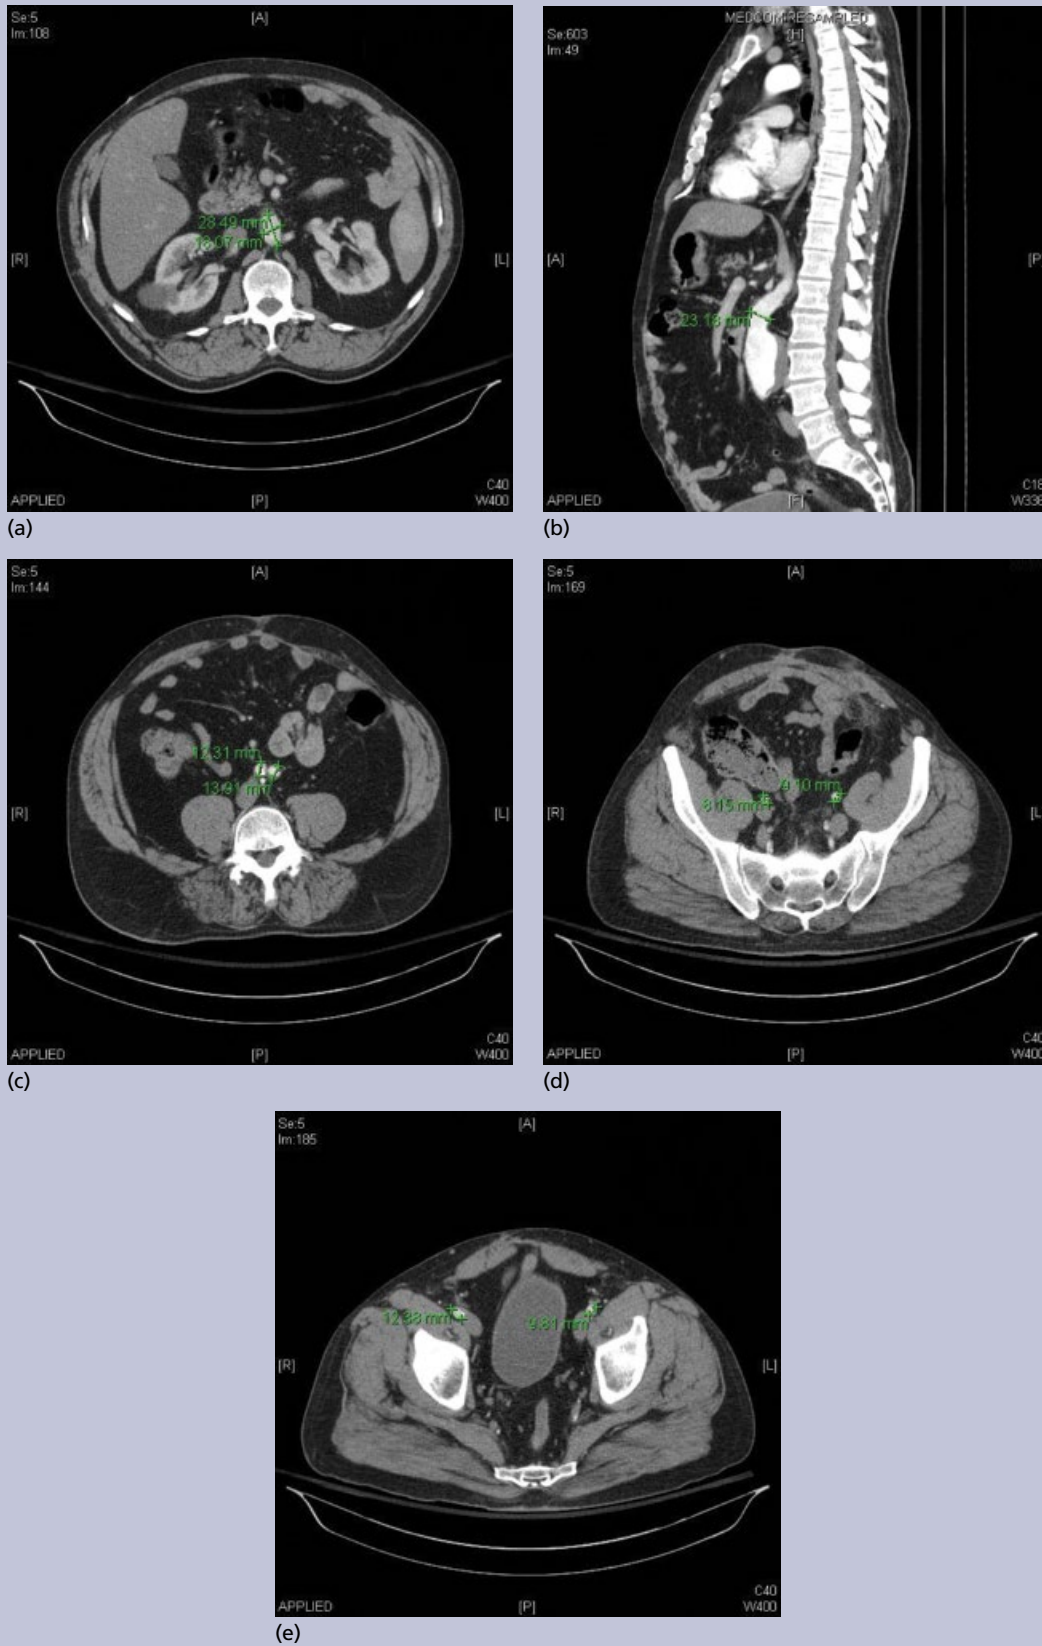

Figure 73.1 (a) Cross-sectional and (b) sagittal CT scan views showing adequate iliac arteries with appropriate vessel diameters and favorable anatomy for endovascular aneurysm repair (EVAR). (c,d,e) Sizing of common and mid and distal external iliac arteries showing adequate access vessels to accommodate EVAR device.

Acute and Chronic Mesenteric Ischemia

Robert J. Rosen, Amit Jain, and Jennifer Drury

Lenox Hill Heart and Vascular Institute, New York, NY, USA

Mesenteric ischemia is a relatively uncommon but potentially catastrophic clinical problem [1]. Acute mesenteric ischemia (AMI) is a true emergency which can rapidly progress to fatal intestinal gangrene if there is a delay in its diagnosis and subsequent management [2,3]. Chronic mesenteric ischemia (CMI) has more insidious presentation and is usually encountered in patients with widespread atherosclerotic vascular disease. The classic presentation of CMI, abdominal angina, is characterized by postprandial abdominal pain and weight loss secondary to “food fear” [4]. In spite of the similar anatomic location of the pathophysiology in both acute and chronic forms of mesenteric ischemia, the difference in their clinical presentation and management mandate separate consideration of these conditions.

Acute mesenteric ischemia

AMI is most commonly associated with acute occlusion of the superior mesenteric artery, either embolic or thrombotic (Figure 74.1). Most emboli originate in the heart secondary to atrial fibrillation, myocardial ischemia, valvular heart disease, left ventricular aneurysm, or extensive atherosclerotic aortic disease. Acute obstruction can also be seen in the setting of aortic dissection or as a complication of aortic surgery or endovascular interventions. While embolic disease is generally considered the most frequent cause of acute ischemia, *in situ* mesenteric thrombosis was actually found to be a more frequent cause of AMI in several recent reviews [2,5–7]. The sudden onset of generalized abdominal pain with pre-existing symptoms of CMI (intestinal angina, weight loss) suggests acute thrombosis of advanced atherosclerotic lesions in the mesenteric vasculature. Cholesterol crystal embolization can also cause AMI and should be suspected in an elderly person with widespread atherosclerotic vascular disease who has severe abdominal pain, out of proportion to their physical examination, hours after a recent diagnostic or therapeutic catheter-based vascular intervention [8]. Cutaneous mottling of the trunk and lower extremities often accompanies this scenario.

As mortality secondary to AMI increases exponentially once transmural necrosis of bowel sets in, it is of paramount importance to make the correct diagnosis early and intervene as quickly as possible [2]. Irreversible transmural necrosis of the bowel wall can

develop in 6–12 hours, depending on the level of arterial occlusion, the presence of collateral flow, and the patient's overall circulatory status. A high clinical suspicion is the key, as diagnosis is often delayed because of non-specific clinical findings. Abdominal pain is of sudden onset and severe but is generally not localized early on. Localization of this pain with peritoneal signs suggests transmural necrosis of bowel. Physical examination is usually unremarkable with occasional abdominal distension and diarrhea, which may become bloody as time progresses secondary to mucosal sloughing. Laboratory findings are non-specific and include an elevated white blood cell (WBC) count, lactic acidosis (highly sensitive but relatively non-specific), and increased serum amylase levels in about half of these patients [2,3,5,9]. More recent experimental studies have suggested the possible value of tests including serum alpha-glutathione S-transferase (alpha-GST) and cobalt albumin binding assay (CABA) [10,11].

Imaging studies should include plain films of the abdomen which can demonstrate an ileus or gasless abdomen. When findings such as air in the bowel wall (pneumatosis intestinalis), mucosal edema (“thumbprinting”), free air under the diaphragm or air in the portal system are identified, the ischemia is well advanced and the mortality rate is very high. Computed tomography (CT) scans will show these findings at a much earlier stage, while CT angiography will often demonstrate the actual site of vascular compromise as well as revealing any associated pathology such as aortic dissection [12]. A recent study evaluating the accuracy of biphasic mesenteric multidetector CT angiography in mesenteric ischemia showed a positive predictive value of 100% and a negative predictive value of 94% [13].

In spite of the accuracy of CT imaging techniques, selective angiography remains the gold standard for making the diagnosis of acute intestinal ischemia, providing specific information on the location of the obstruction as well as the presence of residual flow through either the superior mesenteric artery (SMA) or collateral pathways. The angiographic study should be started by performing flush aortography in the anteroposterior (AP) and lateral projections, as it is essential to evaluate the origins of the celiac and mesenteric arteries, the most frequent sites of atherosclerotic disease. The aortogram can also show other sites of embolization (especially in the spleen or kidneys), as well as demonstrating the

Figure 74.1 AP selective superior mesenteric artery (SMA) study (a) and lateral (b) aortogram demonstrating acute embolic occlusion (arrow) of SMA with distal reconstitution of branches. Lateral aortogram should be performed initially to visualize the SMA origin and prevent distal embolization.

status of the inferior mesenteric and hypogastric arteries. Selective studies are then performed, using prolonged injections of contrast with imaging of the arterial, mucosal, and portal phases. Having a catheter in place also provides access for initiating endovascular treatment, including thrombolysis, vasodilator infusions, and stenting. Previously, catheter-based intervention has been infrequently used to treat AMI, as reflected in the American Gastroenterological Association (AGA) guidelines which generally recommended laparotomy after the diagnosis was confirmed [14].

Thrombolysis, both pharmacologic and mechanical, has been reported in some series when there has been early diagnosis [15,16]. The time required for complete lysis may not always be available, as the window for restoring the blood flow is limited and the potential risk of distal embolization is high. Thrombolytic therapy should only be considered when the diagnosis has been made within 8 hours of the onset of abdominal pain, and should not be used when there is evidence of gastrointestinal bleeding or transmural infarction. The most common lytic agent used is tissue plasminogen activator (tPA), which is infused selectively into the occluded artery (nearly always the SMA) with or without an initial bolus of the drug. If, after 4 hours of initiating the infusion, there is no evidence of significant clot lysis, or if there is evidence of thrombus progression or clinical deterioration, the infusion should be stopped and an open surgical approach initiated. The use of endovascular interventions for AMI is on the rise [5,7,17] and has been even proposed by some authors to be the primary treatment modality given its reduced complications and improved outcomes [12].

In the setting of acute thrombosis of an atherosclerotic plaque, Wyers *et al.* [18] recently reported a hybrid approach to retrograde open SMA stenting (ROMS) in AMI during the emergency laparotomy to assess and resect non-viable bowel if necessary. They proposed local thromboendarterectomy of the SMA inferior to the transverse colon mesentery and a patch angioplasty. This was followed by a retrograde cannulation of the SMA and stenting of the proximal lesion.

Non-occlusive mesenteric ischemia (NOMI) is sometimes encountered in critically ill patients as one of the manifestations of

Figure 74.2 SMA angiogram in non-occlusive mesenteric ischemia (NOMI) associated with shock state. Note the irregular areas of segmental vasoconstriction.

a shock state. The patient may be so ill that diagnosis is delayed until it is too late for treatment. The patient is generally in a low flow state secondary to cardiogenic shock or septic shock and is often on a high dose vasopressor agent. A high index of suspicion in any patient who develops abdominal pain in the suggested clinical settings leads to the diagnosis which is most often confirmed by endoscopy and contrast angiography. Angiography will typically show diffuse or irregular vasoconstriction (Figure 74.2) in the mesenteric circulation and the treatment is primarily directed at improving the overall hemodynamic status of the patient. Catheter directed intra-arterial infusion of vasodilator drugs into the SMA, particularly papaverine, has been used to improve flow to the intestine in this setting [19,20].

Mesenteric venous thrombosis (MVT), particularly of the superior mesenteric vein (SMV), is a rare cause of bowel ischemia. Presentation is similar to other causes of AMI but with a more insidious onset of diffuse abdominal pain progressing over a few days with or without nausea, vomiting or diarrhea and can progress to signs of localized peritonitis with eventual transmural bowel necrosis [21]. Direct injury, hypercoagulable states (particularly factor V Leiden, protein C, protein S, antiphospholipid antibodies, prothrombin gene mutation), dehydration, sepsis, laparoscopic surgery, and portal venous congestion secondary to cirrhosis or congestive heart failure (CHF) are the usual risk factors [22,23]. An increasing number of MVT have been recently reported after laparoscopic bariatric surgeries [24,25]. Diagnosis is usually made by the radiologist on the contrast CT scan performed for abdominal pain or by the surgeon intraoperatively at the time of bowel resection. MVT usually extends into the portal and splenic venous trunks. Systemic anticoagulation with bowel rest and parenteral nutrition is treatment of choice for patients without peritonitis.

Patients with persistent symptoms or deterioration while on anticoagulation benefit from endovascular thrombolysis with or without stenting of the portomesenteric axis to maintain flow [26,27]. Compared with systemic anticoagulation, early mechanical or pharmacologic thrombolysis of acute porto-mesenteric venous thrombosis via transjugular or percutaneous transhepatic approach prevents progression of bowel ischemia in the short term and in the long term prevents development of portal hypertension [27].

Acute aortic dissection involving the abdominal aorta can cause malperfusion syndrome and AMI when the dissection flap causes either a dynamic or static obstruction of the visceral arterial origins. CT or magnetic resonance (MR) angiograms are crucial in making a diagnosis. Surgical repair of the proximal intimal tear is the most effective treatment for type A dissection [28]. Endovascular treatment of acute complicated type B dissection with malperfusion syndrome has a low morbidity and mortality compared to open repair and can now be considered the therapy of choice [28–30]. This involves covering the proximal site of aortic intimal tear via stent graft, re-expansion of true aortic lumen with or without a stent, obliteration of false lumen, and restoration of flow to the distal aorta and all its branches. In some cases of aortic dissection, distal reperfusion involves stenting of the visceral branches and endovascular fenestration of the aortic septum. Percutaneous fenestration can be achieved with either a re-entry needle or the stiff end of the 0.014-inch wire followed by balloon angioplasty to 12–15 mm. Open surgical approach to malperfusion syndrome is by direct resection of the dissecting septum with direct repair of the ostia of visceral vessels.

Vasculitis affecting small and medium size vessels is a rare cause of mesenteric ischemia [31]. Polyarteritis nodosa, Buerger's disease, systemic lupus erythematosus, and Behçet's disease can involve mesenteric vessels, causing small bowel ischemia leading to mucosal sloughing, bleeding, or transmural necrosis and gangrene. Takayasu's disease affects the visceral aorta and causes narrowing of major branches with eventual fibrosis and scarring which can lead to thrombosis and extensive mesenteric ischemia.

Chronic mesenteric ischemia

CMI is nearly always the result of atherosclerotic stenosis or occlusion of the SMA. The prevalence of asymptomatic mesenteric artery stenosis—peak systolic velocity (PSV) >200 cm/s for celiac and >270 cm/s for SMA—can be as high as 17.5 % in the elderly population [32]. The typical presentation consists of postprandial abdominal pain, progressing to “food fear,” and eventually leading to weight loss, which is often dramatic [4]. These patients very often go through a prolonged series of diagnostic studies to rule out other common gastrointestinal disorders before the correct diagnosis of CMI is considered, as the initial symptoms are non-specific and can mimic so many other disorders. CMI is more common in women, and there is invariably a history of extensive atherosclerotic vascular disease. While the gastrointestinal tract is normally supplied by three vascular trunks (celiac, SMA, and inferior mesenteric artery; IMA), extensive collateralization between them allows the body to compensate for a significant degree of occlusive disease. Occlusion or stenosis of the celiac trunk is actually fairly common, either caused by atherosclerosis or extrinsic compression by the arcuate ligament of the diaphragm (median arcuate ligament syndrome, discussed later). Isolated celiac arterial disease, either stenosis or occlusion, is nearly always asymptomatic because of extensive collateralization from the SMA, primarily via the gastroduodenal

Figure 74.3 Celiac arteriogram shows occlusion of SMA at its origin with reconstitution via gastroduodenal artery collaterals. Celiac occlusions are common and usually asymptomatic. SMA occlusions are much more likely to be associated with visceral ischemia.

arcade [32]. Similarly, the much smaller IMA commonly becomes occluded as a result of infrarenal aortic atherosclerotic disease or aneurysm formation and this is also generally asymptomatic because of the collaterals from the SMA and hypogastric circulation. The SMA, conversely, is the critical vessel for maintaining visceral flow and its occlusion is nearly always clinically significant (Figure 74.3).

Aside from the history and obvious cachexia, there are few specific clinical findings to suggest the diagnosis. Abdominal bruits, while considered a classic physical finding, are often appreciated retrospectively after the diagnosis has been made. With the widespread availability of CT and MR angiography, the diagnosis can now be made earlier than in the past, when angiography was required [33]. Color flow Doppler imaging is now being used increasingly as a cost-effective and non-invasive modality to diagnose mesenteric arterial stenosis. Currently, catheter angiography is performed primarily to confirm the diagnosis, allow treatment planning, and in selected cases to carry out endovascular intervention. Involvement of the SMA by atherosclerosis is fairly stereotypical and is nearly always confined to its origin and proximal few centimeters of the vessel with normal distal anatomy. The involvement resembles that found in the renal artery in that the process is an extension of the aortic wall disease into the ostium of the vessel. This localized nature of the disease makes it suitable for both surgical and endovascular treatments. The choice of treatment is somewhat controversial at present, with each approach having strong advocates.

Median arcuate ligament (MAL) syndrome, the existence of which is still challenged by several authors, is the postprandial pain complex, weight loss and abdominal bruit associated with dynamic obstruction of celiac artery trunk by the fibers of median arcuate ligament. Elevated PSV at end expiration on duplex ultrasound may point to a diagnosis [34]. CT angiography can show the relationship

of the narrow portion of the celiac artery to the diaphragm and also highlight post-stenotic dilation [35]. Recently, minimally invasive combined modality of treatment via both laparoscopic release of MAL and endovascular treatment of the celiac artery have been proposed [36]. Late follow-up in one of the largest case series reported a 76% freedom from symptoms in those treated with both celiac decompression and revascularization versus only 53% in those treated with decompression alone [37]. Angioplasty alone as a treatment of MAL syndrome has been associated with failures [38–40]. It has also been theorized that the symptoms may be secondary to compression of the celiac ganglion, which is located on top of the celiac artery, and relief of symptoms can occur with celiac ganglion block [41].

The primary issues in the treatment of CMI concern the morbidity and mortality of the initial procedure and durability of the results. Traditionally, open surgical repair has been the standard for CMI. Open revascularizations are durable with a 81–92% symptom-free survival at 3–5 year follow-up [42–46]. The disadvantages of open repair are higher morbidity (20–30%) and mortality (4–15%) with prolonged hospitalization [42–44,46].

The last two decades have seen an increasing trend toward endovascular management of CMI (Figure 74.4) as the first line of

intervention [47,48]. Several retrospective studies from high volume centers comparing their open with endovascular results for CMI have shown a similar incidence of in-hospital morbidity and mortality [17,49,50]. However, a few others have noted similar mortality but higher morbidity with open repair [43]. In the analysis of the Nationwide Inpatient Sample, the mortality was lower after percutaneous transluminal angioplasty/stent compared to open bypass in CMI (3.7% vs. 13%; $p < 0.01$) [48].

In a recent review of such retrospective studies comparing open with endovascular repair [45], overall results were comparable between the two modes of treatment in terms of technical success (100% vs. 95%) and immediate pain relief (93% vs. 88%). Endovascular repair has the advantage of decreased short-term morbidity but the disadvantage of decreased long-term primary patency compared with open repair (58% vs. 90% at 1 year [49]; 27% vs. 66% at 3 years [17]; and 41% vs. 88% at 5 years [43]).

Brown *et al.* [51] compared their mesenteric stenting group with an open surgical group and concluded that stent patients had lower perioperative major morbidity and shorter hospital and ICU length of stay; however, stent patients were 7 times more likely to develop restenosis, 4 times more likely to develop recurrent symptoms, and 15 times more likely to undergo reintervention.

Figure 74.4 Patient with symptoms of chronic visceral ischemia. (a) AP aortogram shows what appears to be patent SMA. (b) Oblique view demonstrates severe ostial stenosis of SMA. (c) Selective SMA study shows the proximal stenosis more clearly. (d) Post placement of stent with resolution of stenosis. No effort is made to match the caliber of the post-stenotic dilatation.

Endovascular therapy for CMI offers the advantage of early recovery, less short-term morbidity and shorter length of stay in hospital; despite high recurrence and re-intervention rates it may be the ideal option in a patient with severe comorbidities and short life expectancy or poor functional status. Open repair, on the other hand, has excellent durability and should be considered the best treatment for a patient fit for surgery and with lesions not amenable to endovascular repair.

Technical considerations

Once the diagnosis of visceral ischemia is suspected, abdominal angiography should be performed. The SMA is by far the most critical of the three visceral trunks and because of its size and anatomic alignment with the aorta it is the vessel most frequently involved by embolus. The study should begin with a flush aortogram using a pigtail catheter in AP and lateral projections to identify the origins and proximal segments of the celiac and superior mesenteric arteries. Starting with selective catheterizations risks showering proximal emboli distally, which might turn a simple embolectomy into a case of multiple distal occlusions that cannot be salvaged. As a rule, acute thrombosis of a pre-existing stenosis of the SMA will present as an ostial or proximal occlusion, as the plaque is usually an aortic process extending into the origin of the vessel. An acute embolus, on the contrary, is typically cardiac in origin and more often lodges in the SMA beyond a few centimeters from its ostium, usually at the origin of the middle colic artery. Even in the presence of an acute embolic occlusion, angiography will nearly always demonstrate some distal reconstitution of mesenteric branches. Once it has been determined that the ostium is free of thrombus, a selective catheter (Cobra 2 or Sos) can be used to study the SMA in order to demonstrate the extent of occlusion, the site of reconstitution, as well as evidence of any other process such as a low-flow state (non-occlusive mesenteric ischemia), or mesenteric venous thrombosis. In general, if the patient is an operative candidate, operative embolectomy should be carried out immediately and the viability of the bowel can be assessed at the same time.

However, if the lesion is deemed amenable to endovascular treatment, the short sheath is then replaced by a long sheath (Shuttle, Raabe, Ansel) and advanced as close to the lesion as possible. The diseased segment of the artery is crossed with a steerable but atraumatic wire which is then exchanged for a more supportive wire which will enable balloon and stent placement. There has been a general trend toward the use of coronary type wires (0.016 or 0.018 diameter), balloons, and stents instead of standard guidewires (0.035 or 0.038) because of decreased trauma and better tracking. In terms of stent selection, precise placement and superior radial strength have favored the use of balloon expandable rather than self-expanding stents in the visceral circulation. As these are generally ostial lesions, it is important to extend the stent slightly into the aortic lumen in order to prevent plaque progression and stent occlusion. Embolic protection devices have been recommended by some authors but are not at present used in most institutions performing visceral stenting. They are somewhat problematic to use in ostial lesions, and if they are positioned in the hepatic artery there is a risk of spasm or dissection of this unusually delicate vessel.

Some authors routinely use an upper extremity approach (radial, brachial, axillary) for visceral stenting because of the acute angle of take-off of the visceral trunks. In our institution, we generally start with a femoral approach, which provides more catheter control and

shorter systems. Only on occasion is a change to an upper extremity approach necessary.

In a review of endovascular treatment of CMI from the Cleveland Clinic [52], most of the stents placed in mesenteric vessels were balloon expandable (91.5%) and had a mean diameter of 6.5 ± 2.2 mm, and the average length was 18.8 ± 6.4 mm. No difference was noted in the patency rates irrespective of the stent type, size, number, or the vessel treated. Oderich *et al.* [53], in their experience from the Mayo Clinic, used balloon-expandable stent in 98% of patients with a large profile system in 52% and femoral access in 68% versus brachial approach in 32% of patients.

Drug-eluting stents (DES) can prove useful by blocking cellular proliferation and reducing intimal hyperplasia in the treated vessel. The stent diameter of currently available DES is generally too small (<5 mm) for use in the mesenteric arteries.

Tallarita *et al.* [54], from the Mayo Clinic, used covered stents in four patients to treat in-stent restenosis and reported no restenosis in any of these patients as compared with a 50% second restenosis rate in those treated with PTA or bare metal stents. Erdoes *et al.* [55] recently reported a superior primary patency for covered stent versus bare metal stent at 18 months as 86% vs. 34%.

Controversy persists as to whether a single vessel intervention is better than multivessel treatment. While a few studies have shown equivalent outcomes after single and multiple vessel revascularization [42,46], better long-term patency and symptom-free survival of open revascularization has been attributed to a multivessel intervention. Van Petersen *et al.* [45] summarized the outcomes from eight recent studies comparing open with endovascular repair showing that both primary patency and freedom from recurrent symptoms were better with open surgical interventions than endovascular interventions. Similar differences have been observed in other studies [17] with proposal to improve durability of endovascular treatment by two-vessel revascularization.

Post-procedure follow-up

There are no established guidelines for follow-up of patients who had endovascular repair of their mesenteric circulation. Given the high restenosis rate and reasonable success of repeat interventions it is imperative that a close follow-up is maintained. Although duplex ultrasound is not as accurate in stented vessels as in native arteries it does offer an inexpensive and easily available non-invasive objective tool to follow these patients. At our institution we routinely study patients with duplex ultrasound at 1, 3, and 6 month intervals. Duplex ultrasound velocity criteria for detecting native SMA and celiac arterial stenosis or occlusion are highly variable. Various authors have different criteria ranging from a PSV ≤ 275 cm/s to 400 cm/s in the SMA for >70% stenosis and ≤ 200 cm/s to 320 cm/s in the celiac artery for >70% stenosis [56,57]. A few others rely on end diastolic velocities of >45 cm/s for a >50% stenosis of the SMA and >55 cm/s for a >50% stenosis of the celiac artery [58,59]. There is a tendency toward higher velocities in stented celiac artery/SMA in comparison to native arteries [60] and these criteria of the native SMA cannot be applied to a previously stented SMA as they overestimate the lesions [61]. Any significant change in the PSV is then followed up with a contrast imaging study to assess the situation and plan further interventions if needed (Figure 74.5). Sudden recurrence of abdominal pain can be the earliest sign of stent thrombosis. Hence, patient education is of paramount importance and they are explicitly instructed to seek urgent medical care if they experience any abdominal symptoms.

Figure 74.5 Follow-up CT angiogram 6 months after SMA stent demonstrates early intimal hyperplasia, a frequent problem in visceral stenting. Note that the celiac is severely stenotic at its origin.

Complications

Mesenteric vascular interventions can potentially cause mesenteric arterial dissection, thrombosis, distal embolization, stent dislodgment, or vessel perforation with resulting bowel ischemia or bleeding with mesenteric hematoma. Oderich *et al.* [53], in a review of 156 patients and 173 mesenteric stents, reported an overall morbidity of 15% and mortality of 2.5% with a 7% incidence of mesenteric artery complications during angioplasty and stent placement. They noted that factors associated with complications were use of large profile devices, non-visualization of the wire tip in the main SMA trunk, mesenteric occlusion, severe calcification, and lesion length >30 mm. Use of an embolic protection device was recommended for high risk lesions [62]. Antiplatelet therapy started before the procedure also decreased the risk of embolization and thrombosis. A recent analysis of the national inpatient sample by Schermerhorn *et al.* [48] showed a mortality of 3.7% for the percutaneous interventions compared to 13% after open repairs. On a mean follow-up of 29 months, Tallarita *et al.* [54] reported a 36% in-stent restenosis rate defined by duplex PSV >330 cm/s and angiographic stenosis of >60%.

Conclusions

Mesenteric ischemia is a relatively uncommon condition, but one where delayed diagnosis and intervention can be deadly. The condition is clearly divided into acute and chronic presentations. AMI is an extreme emergency, as delayed diagnosis and treatment will rapidly lead to intestinal infarction and high mortality. The most common cause of AMI is embolization from a cardiac source, while less commonly it can occur in the setting of acute thrombosis of a chronic atherosclerotic lesion, acute aortic dissection, or iatrogenically. Most embolic occlusions are handled surgically, as the window for restoration of mesenteric flow is short and embolectomy is a fairly straightforward undertaking. There has been an increasing use of endovascular techniques, but their role in the acute setting remains unclear.

CMI can present insidiously, and its manifestations frequently mimic other abdominal conditions so that diagnosis is often delayed. The hallmarks of the condition include postprandial pain, weight loss, and “food fear,” and it is generally encountered in patients with known widespread atherosclerotic disease. The diagnosis can usually be made by CT or MR angiography and confirmed by catheter angiography. The optimal type of intervention remains controversial, with advocates of both endovascular and open surgical revascularization. Stenting can be performed safely with minimal morbidity; however, open surgical reconstruction has indisputably better long-term patency, at least at present.

Renal Artery Interventions

Mark Shipeng Yu, Kun Xiang, Steven T. Haller, and Christopher J. Cooper

University of Toledo, Toledo, OH, USA

Renal artery stenosis

Renal artery stenosis (RAS) is narrowing of the renal arteries, most often occurring in the main renal artery. Many etiologies are responsible for RAS, including atherosclerosis, fibromuscular dysplasia (FMD), vasculitis, congenital abnormalities, aneurysm, William's syndrome, trauma, arteriovenous malformations or fistulas, thromboemboli, extrinsic compression, radiation, and neurofibromatosis. Atherosclerosis, which accounts for approximately 90% of cases, and FMD, which is present in up to 10% of cases, are the most common etiologies. Atherosclerotic renal artery stenosis (ARAS) is caused by atherosclerotic plaque in the renal artery wall and is a chronic inflammatory process affected by multiple factors. In many individuals with ARAS, the plaques appear to be extension of aortic plaque into the ostium of the renal artery. In contrast, FMD is a non-inflammatory arterial wall dysplasia causing RAS.

RAS has been underrecognized clinically in the past. With the increasing use of non-invasive diagnostic imaging techniques such as duplex ultrasonography, computed tomography (CT) angiography, and magnetic resonance angiography [1] and increased awareness of ischemic renal disease, the diagnosis of RAS has become increasingly common. ARAS was found in about 7% of the general population older than 65 years of age when a very liberal duplex peak systolic velocity threshold of 1.8 m/s was used during community screening [2]. The prevalence of ARAS in patients with comorbidities is even higher, reaching 20% in patients with hypertension and diabetes, 25% in patients with peripheral vascular disease, and has been reported to be as high as 54% in those with congestive heart failure [3].

Natural history and clinical outcomes

ARAS can progress anatomically at the atherosclerotic lesion or in association with declining kidney function in a minority of individuals. In the pre-statin era, progression to occlusion occurred in 6% [2] to 39% [3] in patients with stenosis >60% [2] to >75% [3]; however, with appropriate medical therapy this risk is likely overstated. Several conditions have been associated with renal artery disease progression, including severity of disease and comorbid conditions such as diabetes and hypertension [4].

ARAS causes ischemic nephropathy in some individuals. Ischemic nephropathy is defined as renal dysfunction resulting from stenosis of a main renal artery [4]. ARAS has been estimated to be the cause of end-stage renal disease (ESRD) in approximately 15% of patients over age 50 who begin dialysis [5]. Chronic ischemia produces inflammation, tubulosclerosis, fibrosis, thickening of Bowman's capsule, intrarenal arterial medial thickening, and atrophy in the kidney [6]. The possible mechanisms of renal fibrosis caused by a hemodynamically significant RAS include microvascular damage, endothelial and epithelial factors, activation of renin-angiotensin-aldosterone system with subsequent vasoconstriction [7], and CD40 signaling within the proximal tubule leading to interstitial fibrosis [8].

RAS is also a potential cause of secondary hypertension, and can be present in as many as 5% of individuals with hypertension. Activation of renin-angiotensin-aldosterone systems and increased sympathetic nerve output contribute to the elevated blood pressure [9]. Patients with RAS and hypertension can be resistant to medical therapy and some develop early complications including left ventricular hypertrophy, heart failure, and renal failure.

Patients with ARAS are at high risk for fatal and non-fatal cardiovascular and renal events. It was found that ARAS is an independent predictor for mortality in patients undergoing diagnostic coronary angiography [10] and in patients with peripheral arterial disease [11]. The risk ratio (versus age-matched controls) was 3.3 for overall mortality and 5.7 for cardiovascular mortality in a cohort of patients with RAS lesions exceeding 50% [12]. The annual mortality rate in patients with ARAS was 16.3% in a Medicare analysis and was three times higher than Medicare patients without ARAS [13]. However, it is not apparent whether this relationship is attributable to the RAS per se, or whether RAS is simply a marker for more diffuse atherosclerosis.

Additionally, a strong relationship has been identified between chronic kidney disease and mortality in patients undergoing stent revascularization [14]. Patients with ARAS are 6–28 times more likely to die of a cardiovascular event than ESRD [1,15]. However, if a patient with ARAS develops ESRD and requires dialysis, the annual mortality rate approaches 36% [16]. The underlying mechanisms connecting loss of kidney function with increased mortality and non-fatal cardiovascular and renal events are not fully clear.

The possible answers are activation of the renin–angiotensin–aldosterone and sympathetic nervous systems, associated renal insufficiency, concomitant atherosclerosis in other vascular beds, and activation/alteration of other neuroendocrine systems [17].

FMD occurs mainly in middle-aged females and involves the mid to distal renal artery and other arterial vasculatures (e.g., carotid arteries, external iliac arteries, coronary arteries, and mesenteric arteries). Most patients with FMD are asymptomatic, but resistant secondary hypertension in young patients is the most common clinical presentation. FMD can cause loss of renal mass in up to 63% of patients [18], but it rarely causes loss of renal function. Stenosis progression occurs in a minority of patients with FMD [18]; however, progression to occlusion is rare. FMD predisposes to dissection and aneurysm because of the dysplasia of arterial walls.

Indications for screening

Currently, there is controversy regarding the appropriate use of screening for the detection of RAS. In younger individuals with unexplained hypertension, screening for FMD is often warranted as identification of FMD can lead to a hypertension cure with balloon angioplasty. However, in older individuals who might be suspected as having ARAS, the value of screening is less certain. With several convincingly negative trials for revascularization of ARAS, the role for screening is under debate. The most recent American College of Cardiology/American Heart Association (ACC/AHA) guideline on peripheral arterial diseases published in 2013 suggested screening renal arterial disease with diagnostic studies for several clinical situations [19]. However, these recommendations predate the results of the CORAL study. As a result it may be reasonable to limit screening for ARAS to patients with suspected RAS who have clearly failed management with aggressive medical therapy.

Class I indications:

- Onset of hypertension with age <30 years old (level of evidence B);
- Onset of severe hypertension after the age of 55 years (level of evidence B);
- Certain clinical characteristics: (i) accelerated hypertension (sudden and persistent worsening of previously controlled hypertension); (ii) resistant hypertension; and (iii) malignant hypertension (hypertension with acute end-organ damage) (level of evidence C);
- New azotemia or worsening renal function after the administration of an angiotensin-converting enzyme (ACE) inhibitor or an angiotensin receptor blocker (ARB) (level of evidence B);
- Unexplained atrophic kidney or a discrepancy in size between two kidneys of >1.5 cm (level of evidence B);
- Sudden unexplained pulmonary edema, especially with azotemia (level of evidence B).

Class IIa indications Unexplained renal failure, including starting dialysis or renal transplantation (level of evidence B).

Class IIb indications Multiple vessel coronary artery disease without evidence of peripheral arterial disease at the time or unexplained congestive heart failure or refractory angina (level of evidence C).

Diagnosis

Duplex ultrasonography, computed tomographic angiography (CT angiography, or CTA), and magnetic resonance angiography (MRA) are recommended by guideline as screening tests to establish

the diagnosis of RAS [19]. When these tests are inconclusive and clinical suspicion is high, catheter angiography is the next step [19]. Captopril test, captopril renal scintigraphy, and selective renal vein renin measurement are not recommended as screening tests to establish the diagnosis [19]. Duplex ultrasonography is the most cost-effective study, although it is dependent on the technician's proficiency and experience in the procedure. In a high-volume and experienced center, duplex ultrasonography is the preferred method of screening. CTA has better resolution than MRA, but CTA carries risk of contrast nephrotoxicity and ionizing radiation. MRA with gadolinium contrast cannot be used in patients with advanced chronic kidney disease and patients with certain devices, because of electromagnetic interference.

Duplex ultrasonography

Duplex ultrasonography has a sensitivity of 75–98% and specificity of 87–100% for RAS, and 67% sensitivity in identifying accessory renal arteries [20]. Duplex can evaluate the artery anatomy, blood flow velocity and waveform, and kidney size. The peak systolic velocity (PSV) should be measured at the origin, proximal portion, at the mid aspect, near the helium, and at any site of color aliasing or suspected stenosis [21]. Doppler waveforms should be recorded within the stenosis and distal to the stenosis. If there are accessory renal arteries, the PSV should be measured. The aortic PSV is used to calculate the ratio of the PSV in the renal artery to the aorta at the level of renal artery. Many Doppler velocity criteria have been proposed to diagnose RAS. The most commonly accepted diagnostic criteria for RAS by duplex ultrasound are listed in Table 75.1 [2,20]. In clinical practice a PSV of 180 cm/s is sensitive at the expense of poor specificity. This high sensitivity threshold is appropriate for the purpose of screening but because of poor specificity it should not be used to confirm the diagnosis. For confirmation, a velocity of >300 cm/s is more useful [22].

Color Doppler interrogation of the segmental or interlobar arteries within the kidney can provide additional clues of RAS. A significant stenosis delays the systolic rise in the arteries distal to the stenosis, shown as tardus parvus waveform [23]. The significant stenosis (e.g., >60%) will also cause slowing (<3 m/s²) or absence of the early systolic peak or notch at the beginning of systole in the intrarenal segmental and interlobar arteries [23]. The time from the start of the systolic upstroke to the first peak is the systolic acceleration time, with >0.07 s indicating main RAS >60%. The renal arterial resistive index (RI) is calculated with the following formula:

$$RI = \frac{(\text{peak systolic velocity} - \text{end diastolic velocity})}{\text{peak systolic velocity}}$$

Duplex ultrasound evaluation after a renal artery stent procedure should include recording a PSV in the proximal renal artery, within the stent, and distal to the stent [21]. The diagnostic criteria for in-stent restenosis vary among clinicians, from criteria same as native RAS in Table 75.1, to a higher velocity (e.g., >225 cm/s [24], >280 cm/s [25]), or a renal : aortic ratio >4.5 [25]).

Computed tomographic angiography

CTA has a sensitivity of 94% and specificity of 60–90% in detection of ARAS [26,27]. The better spatial resolution of CTA than MRA enables it to detect small accessory renal arteries. The specificity of CTA is not as efficient as MRA. However, CTA can be used in patients who are claustrophobic, intolerant of long time positioning, and have a non-MRI-friendly implanted device. Because CTA

Table 75.1 Diagnosis criteria of renal artery stenosis by duplex ultrasound.

Stenosis severity percentage	Peak systolic velocity (PSV)	Renal : aortic ratio (RAR)	Post-stenotic turbulence
<60%	>180 cm/s	<3.5	No
>60%	>180 cm/s	>3.5	Yes
Total occlusion	None	Not available	Not available

sees the thickness of the vessel wall, and positive remodeling occurs commonly in atherosclerosis, simply measuring the degree of narrowing at the stenosis can overestimate the severity of the lesion. A more reliable strategy is to compare the degree of narrowing at the stenosis to the caliber of the more distal renal artery, after any post-stenotic dilatation. Extensive calcification in the renal artery and adjacent aorta can be a challenge for CTA image interpretation. CTA also cannot be used in patients with significantly impaired kidney function because of the risk of contrast-induced nephropathy, unless the benefit outweighs the risk.

Magnetic resonance angiography

MRA has a sensitivity of 93% and specificity of 91% for ARAS [26]. MRA has better specificity than CTA. MRA also offers the benefit of avoiding iodinated contrast and radiation exposure. But MRA cannot be used in advanced chronic kidney disease because of the risk of systemic fibrosis from accumulated gadolinium-based contrast medium used in MRA. It is also not used in patients with non-MRI-friendly devices and who are claustrophobic.

Catheter angiography

Renal angiography, typically using the digital subtraction technique, provides the most accurate diagnosis when non-invasive studies are inconclusive and clinical suspicion is high. With angiography, the visual estimation of diameter reduction compared to the reference vessel is used for stenosis severity evaluation (e.g., 60%, 70%, and 80% stenosis, etc.). Angiography can also evaluate the anatomy of the renal vasculature including the intrarenal vessels and accessory renal arteries, and the gross anatomy of the kidney. While ARAS most often (about 90% cases) presents as ostial stenosis, FMD often presents uniquely on angiography as a “string of beads.”

However, of concern has been the practice of performing selective catheter angiography for the detection of RAS using preformed catheters to engage the renal artery. Often excellent image quality can be obtained with aortography, performed at the level of the renal arteries, using modest volumes of contrast (10–15 mL per injection). This strategy is superior to selective angiography for the following reasons:

- Avoids aortic scraping that can lead to atheroembolization;
- More often identifies origins of renal arteries, when multiple arteries are present;
- Permits thoughtful catheter selection if selective angiography becomes necessary; and
- Often results in lower total contrast dosing.

Translesional pressure gradient, pressure ratio of distal renal artery to aorta, and renal fractional flow reserve

Several additional parameters can be measured at the time of angiography. The translesional pressure gradient can be measured across the stenosis, comparing aortic pressure with pressure in the renal artery after the stenosis. The most reliable method uses an

0.014-inch pressure sensing guidewire as catheter-based gradients can grossly overestimate lesion severity [28].

Most stenoses that are truly >80% stenosis by angiography will have a pressure gradient [1]. For 60–80% lesions, it is considered hemodynamically significant if the peak systolic translesional pressure gradient is >20 mmHg [1]. The ratio of peak systolic pressure distal to the lesion over peak systolic aortic pressure at the renal artery level is called renal : aorta pressure ratio. A ratio of <0.9 is associated with increased renin production and the stenosis of this type is considered as hemodynamically significant [21,29]; however, these data were derived from acute ischemia experiments and may not be as relevant in the setting of chronic ischemia. The renal fractional flow reserve (FFR) has been studied during angiography using intrarenal papaverine and an FFR <0.8 is considered as severe stenosis [29]. Recently, the renal FFR has been correlated with residual plaque volume and clinical outcome [30]. These parameters (e.g., visual estimation of stenosis severity, translesional pressure gradient, and FFR) were shown to correlate with each other in some studies [29], but not in others [30].

In individuals with FMD, translesional pressure gradients are often extremely helpful in clinically differentiating “cosmetic” FMD (stenosis without hemodynamic significance) from those that are functionally significant. Furthermore, repeating pressure gradients after each balloon angioplasty provides an objective tool to indicate when the lesion has been adequately dilated and the webs are sufficiently disrupted to allow normal blood flow and pressure. Importantly, though, there are no trials that show whether treatment of patients with ARAS with some threshold for stenosis severity (pressure gradient, angiographic percent stenosis, renal FFR) results in improved clinical outcome when comparing patients managed medically with those undergoing revascularization.

Treatment options for ARAS

While balloon angioplasty is the standard interventional treatment for FMD, for ARAS there has been considerable debate over the past several decades about which treatment modality is better when considering medical therapy versus stenting. Fortunately, several recent clinical trials provide more evidence about this choice.

Three randomized trials have been completed that directly compared medical therapy alone with medical therapy with stenting: the Cardiovascular Outcomes in Renal Atherosclerotic Lesions (CORAL) trial, the trial of STent placement and blood pressure and lipid-lowering for the prevention of progression of renal dysfunction caused by Atherosclerotic ostial stenosis of the Renal artery (STAR), and the Angioplasty and Stenting for Renal Artery Lesions (ASTRAL) trial [1,31,32]. The STAR trial [32] was a randomized study that tested whether stenting could reduce by 50% the proportion of patients that experienced a 20% decline in GFR. The authors of STAR concluded that “confidence bounds are compatible with both efficacy and harm, so the finding is inconclusive.”

The ASTRAL trial [31] enrolled 806 patients but failed to demonstrate an improvement in the primary endpoint, slope of reciprocal creatinine (-0.0713×10^{-3} vs. -0.13×10^{-3} $\mu\text{m/L/year}$; $p=0.06$). This difference was neither statistically nor clinically significant, as were the findings of the secondary analyses from ASTRAL.

The most recent trial, Cardiovascular Outcomes in Renal Atherosclerotic Lesions trial (CORAL) [1] published in 2014, was designed to compare optimal medical therapy alone with stenting with optimal medical therapy, with a primary endpoint of the occurrence of major cardiovascular or renal events. This was defined as a composite of death from cardiovascular or renal causes, stroke, myocardial infarction, hospitalization for congestive heart failure, progressive renal insufficiency, or the need for permanent renal replacement therapy. In CORAL, 947 patients with ARAS and either hypertension or chronic kidney disease were randomized into two groups: optimal medical therapy (ARB, atorvastatin, and an antiplatelet agent, with or without thiazide or amlodipine), or optimal medical therapy with stenting. There was no significant difference in the occurrence of the primary composite endpoint, or any of its individual components, between the stent group and medical therapy-only group, and no difference in all-cause mortality. Systolic blood pressure was modestly lower in the stent group than in the medical therapy-only group (-2.3 mmHg; 95% CI -4.4 to -0.2 mmHg; $p=0.03$), and the difference persisted throughout the follow-up period. The CORAL study showed that, when added to a background of high-quality medical therapy, contemporary renal artery stenting provides no incremental benefit for patients with ARAS. Thus, it is clear that optimal medical therapy without stenting is the preferred management strategy for the majority of people with ARAS.

Stenting in specific populations with ARAS

Several studies suggest that stenting can improve kidney function in patients with stenosis affecting all of the kidney parenchyma; however, CORAL showed no clinical advantage in this subgroup with global renal ischemia. A study by Watson *et al.* [33] focused on patients with progressive, but not severe, chronic renal insufficiency and with global high-grade stenosis. Renal artery stenting was performed in 33 patients who displayed a serum creatinine >1.5 mg/dL (mean 2.1 mg/dL), and found an improvement in the rate of loss of GFR, when compared with the rate of loss prior to the procedure. An additional study found favorable responses to revascularization for patients with ARAS and rapidly declining kidney function [34]. However, as stated earlier, when compared with a contemporary group of individuals managed medically, there is no evidence that stenting improves kidney function more than medical therapy alone.

In a single center, observational study in patients with ARAS presenting with “flash pulmonary edema,” a term for acute heart failure, revascularization reduced mortality (HR 0.4, 95% CI 0.2–0.9; $p=0.01$), but did not affect cardiovascular event or ESRD rates [35]. This observation is confounded significantly though by significant age differences between the medical therapy and revascularized subjects. The small observational studies have described cohorts of patients with RAS with acute heart failure that appeared to benefit from renal artery revascularization [36,37]. In general terms these cohorts demonstrated that 75% of subjects undergoing revascularization had no further episodes after treatment [36,37]. Whether similar results would be seen with medical therapy is not known.

There have been efforts in developing predictors that can identify subgroups of patients who will benefit from revascularization.

As assessed by MRI, a high ratio of renal parenchymal volume to single-kidney GFR was reported to be an indicator of improvement in GFR after revascularization in a study of 50 patients [38]. High blood oxygen level-dependent (BOLD) MRI signal to single kidney isotopic GFR has been shown to be a predictor for improvement of renal function after revascularization in a clinical study of 28 patients [39]. Pre-intervention brain natriuretic peptide (BNP) levels of >80 pg/mL were reported to be predictive of a response to revascularization in a study of 27 patients [40]; however, this finding was not replicated when it was tested in a larger cohort of individuals [41]. On the other hand, a renal resistance index of more than 80 by duplex Doppler ultrasound was reported to be an indicator of unresponsiveness to revascularization [42]; yet again the finding was not replicated in subsequent studies [43,44]. More data are needed to draw a convincing conclusion.

Medical therapy of ARAS

The ultimate goal of ARAS treatment is the reduction of mortality (mainly cardiovascular and renal mortality) and morbidity (adverse cardiovascular and renal events), and prevention of complications. Medical therapy is the cornerstone of care for patients with ARAS. There are unfortunately few comparative data between different regimens of medical therapy. Clearly, anti-atherosclerotic therapies are indicated, such as lipid-lowering agents, especially statins. Antiplatelet therapy, diabetes management, and hypertension medications are all indicated in patients with ARAS. Lifestyle modification is also important such as smoking cessation, exercise, and weight reduction. Previously it was advised that ACE/ARBs should be avoided in this setting; however, data suggest the risk to be low [45,46]. ACEI/ARB treatment in observational studies is associated with a significant mortality and morbidity benefit in patients with ARAS [47]; however, it is also associated with a slightly elevated risk of acute renal failure. The usage of ACEI/ARB should be considered for all patients with ARAS. Smoking is not only a cardiovascular risk factor, it is also a risk factor for chronic kidney disease and can increase the risk of nephropathy progression [48]. All patients with cardiovascular disease or cardiovascular disease equivalents are high-risk for adverse cardiovascular events. Importantly, with optimal medical treatment of ARAS, the mortality rate can be decreased, at least in the setting of cohorts selected for participation in clinical trials, as shown by the ASTRAL trial (average annual mortality rate of 8%) [31] and the more recent CORAL trial (average annual mortality rate of 4%) [1]. Details of medical therapy can be found in a recent review [49].

Indications for endovascular intervention (revascularization)

Recently published guidelines for renal artery revascularization, according to current AHA/ACC guidelines published in 2013, are listed here [19]. As more evidence becomes available, the guidelines will be modified as many of these subgroups of patients with ARAS were not benefited in the recently completed randomized trials. We believe that the strongest rationale for revascularization in the atherosclerotic patient is for those infrequent individuals with severe renal stenosis and advanced chronic kidney disease who are faced with the choice of an attempt at revascularization or instituting renal replacement therapy in the near future. However, this is not an evidence-based recommendation but is grounded in clinical experience.

- Asymptomatic patients with bilateral or solitary kidney with a hemodynamically significant RAS (level of evidence C);
- Resistant, accelerated, or malignant hypertension with hemodynamically significant RAS, or hypertension with unilateral

unexplained small kidney or intolerance to medications (level of evidence B);

- Progressive chronic kidney disease with bilateral or solitary functioning kidney and with RAS (level of evidence B), or with unilateral RAS (level of evidence C);
- Recurrent, unexplained congestive heart failure or sudden, unexplained pulmonary edema in patients with hemodynamically significant RAS (level of evidence B);
- Unstable angina in patients with hemodynamically significant RAS (level of evidence B).

Contraindications for endovascular intervention

The commonly accepted contraindications for percutaneous transluminal renal angioplasty include the following:

- A non-functioning kidney, generally <8 cm pole-to-pole length;
- Limited life expectancy;
- Generally poor surgical or endovascular intervention candidate;
- Pregnancy; and
- Non-compliance with medical therapy.

Technical aspects of renal endovascular intervention for renal artery stenosis

The direct goal of renal artery intervention is to obtain the optimal patency of the artery while minimizing the risk of atheroembolization, renal artery dissection, and other complications. We first describe the techniques for stenting ostial ARAS, as these are the most common. This type of lesion involves the ostium of renal artery at its origin from the aorta.

Arterial access

Common femoral arterial access site is most commonly used. Radial or brachial artery access site should be considered for antegrade approach if the takeoff of the renal artery is sharply downward angulated or in the presence of severe bilateral aortoiliac disease and/or tortuosity. In the presence of an aortic aneurysm, the angulation of the renal artery could favor upper or lower extremity access. Similarly, if a renal artery has been covered by a stent during an aortic procedure, careful selection of access and willingness to change access sites may be the difference between a successful and unsuccessful procedure. A longer sheath (e.g., 23 cm rather than 11 cm) should be considered for tortuous arteries.

Renal artery angiography

Abdominal aortography prior to stenting should be performed to identify the local anatomy, including the severity and location of aortic pathology, location of the renal ostia, the extent of the ostial stenosis, the angulation of the renal artery takeoff from the abdominal aorta, accessory renal arteries, and the presence of aneurysms and calcification. A shallow left anterior oblique projection is often the best angle view for identifying both the right and left renal ostia. If CTA or MRA images are available the angulation of the ostia can be more precisely estimated. Prior to the first selective renal angiography, active aspiration of 10 mL blood via a Y-connector or passive back-bleeding can be performed to clean debris from the guiding catheter to reduce the risk of embolism.

Engagement of guide catheter

Anticoagulation should be started after sheath insertion. Indirect engagement of the renal artery ostium using the guide catheter is preferred over direct engagement of the renal ostium because of the

higher risk of renal artery complications associated with direct engagement (e.g., dissection, atheroembolism, artery abrupt closure, and aortic injury). Indirect engagement of the renal ostium can be achieved through two kinds of approaches: the “exchange technique” or the “no touch” technique.

For the exchange technique, after renal angiography a 4-Fr diagnostic catheter is inserted through the sheath and used to engage the renal ostium gently. The soft small diagnostic catheter carries a lower risk of atheroembolization and dissection than the stiffer guiding catheter. After engagement of the diagnostic catheter in the renal artery ostium, a guidewire, 0.014 or 0.018 inch, is introduced into the main renal artery through the diagnostic catheter. The guide is then advanced over the wire and diagnostic catheter, after which the diagnostic catheter is removed leaving the guidewire in place.

For the “no touch technique”, a 0.035-inch J-tip guidewire is placed above the ostium and the guide catheter is introduced in close proximity to the renal artery ostium over the J-tip guidewire. Then the guidewire is retracted to allow the guide catheter to assume its angled shape. The tip of the guidewire is against the aortic wall above the renal artery ostium. The opening of the guide catheter is then adjusted gently to align the opening of the guide catheter with the ostium of renal artery. A 0.014-inch wire is introduced through the guide catheter and engaged into the distal renal artery, after which the J-tip guidewire is removed, leaving 0.014-inch wire in the renal artery. An 0.014-inch wire is compatible with most stent platforms and distal protection devices. Hydrophilic wires should generally be avoided because of the higher risk of renal parenchymal perforation.

A 6-Fr guiding catheter is most often used and its shape should reflect the angle between renal artery and the aorta with consideration of other characteristics of local anatomy. A variety of guiding catheter configurations are available (e.g., “hockey stick,” renal double curve, internal mammary artery, right Judkins, and right Amplatz). Our current “workhorse” shape for most renal interventions is the IMA or internal mammary shape. The “hockey stick” guide catheter can be used for radial or brachial approach.

Percutaneous renal transluminal angioplasty

Balloon angioplasty is the treatment of choice for FMD and can be used for predilatation and sizing of the renal artery prior to stent placement. With FMD, balloon angioplasty is the treatment of choice and the goal is to tear the webs in the renal artery thus minimizing the pressure drop-off across the area of involvement. Balloon angioplasty can be performed with a 0.014 inch pressure-sensing guidewire in place that allows the success of each dilatation to be ascertained. Generally, the balloon size in FMD is matched to vessel size; however, at times it may be necessary to slightly oversize the balloon to achieve the desired result. When this is done great care should be taken for symptoms of pending arterial rupture or dissection, heralded as back pain, at which time the balloon is gently deflated. Generally, stenting should be avoided, if at all possible, when treating FMD. The stent is an unnecessary expense and young patients especially can suffer from the consequence of metal stent fatigue or corrosion over the patient’s lifetime, resulting in device fracture and restenosis. In atherosclerotic stenoses, predilatation is achieved through a balloon with a slightly smaller diameter than the reference vessel.

Percutaneous renal stenting

The atherosclerotic renal artery often recoils after angioplasty resulting in restenosis, so stenting is a better approach to maintain the patency of the artery. Balloon expandable stents are favored

over self-expanding stents because of the lack of precision associated with the latter stents. Balloon expandable stents are sized 1:1 with the reference vessel diameter, not the post-stenotic dilated segment. Stent length should be as short as possible while being long enough to completely cover the entire lesion. Using the shortest stent possible that allows complete lesion coverage can be helpful because the renal artery displaces dynamically during the respiratory cycle and longer stents are subject to greater stress and potentially fracture risk.

The stent should be positioned with 1 mm protruding into the aorta, in order to completely cover the arterial ostium. An ostial stent, the ArchStent™ (Ostial Corporation, Mountainview, CA, USA), enables rapid and precise placement of the stent for ostial lesions. It uses a dual-balloon delivery system, with a locator balloon stopping at the ostium for visually confirming the right position. The second balloon inflation results in stent placement. Further inflation of the locator balloon results in flaring of the proximal stent end and full ostial coverage. Another stent device developed to help stenting ostial lesions is the Ostial Pro stent positioning system (Ostial Solutions, Kalamazoo, MI, USA).

After proper positioning of the stent, the balloon is inflated to its nominal diameter to achieve a 1 : 1 ratio with the diameter of the reference vessel. Inadequate stent expansion results in high rates of restenosis; thus, it is important to further dilate the stent if it appears to be underdeployed initially. Larger balloons with higher inflation pressure can be utilized to further dilate an underexpanded stent. Caution, though, should be exercised in trying to maximize stent diameter. Specifically, when the patient experiences back pain during balloon inflation, this can be the only warning sign before main renal artery rupture or perforation. Should this complication occur, placement of a covered stent is clearly indicated if the perforation of the renal artery is not promptly sealed with balloon inflation. Importantly, in order to adequately stabilize the patient it may be necessary to place a larger diameter balloon, inflated to low pressure (1–2 atmospheres), to adequately seal the vessel. A final selective angiogram should be performed to assess the stent position, exclude dissection, perforation and spasm, and the renal parenchymal blush to exclude atheroembolism.

The “kissing balloon technique” can be utilized for the renal arteries with same origin without a common trunk or in the presence of a short main trunk. This technique can be carried out in two ways. The first utilizes a single guiding catheter through which two wires and two balloons are introduced by femoral access route. However, this technique is limited by the relatively large diameter of the stents and their delivery balloons, making this impractical for lesions of the main renal arteries that require stents of 5 mm diameter or larger. The other strategy utilizes two guiding catheters, two wires, and two balloons with one guiding catheter through femoral access and the other guiding catheter through radial or brachial access. In the latter approach, it is far easier if ipsilateral vascular access is used (i.e., right arm and right leg as an example).

For a short common renal trunk, two balloons can be placed in the trunk, extending into each renal artery branch respectively. After predilation, a stent with appropriate length is placed in the trunk over one of the wires and then two balloons are inflated within the stent to deploy the stent within the trunk and into two renal artery branches. When this is done caution should be used in selecting balloon size.

Stenting other types of renal artery stenosis

Atherosclerotic plaques not involving the ostium cause RAS within the trunk, or distal RAS. The optimum intervention on these lesions is not as clear. Angioplasty is preferred by some interventional physicians and angioplasty with stenting is preferred by others. If angioplasty results in suboptimal result, stenting is then needed. Self-expanding stents oversized by 1 mm over the reference vessel can be useful because of their flexibility and better fracture resistance compared with balloon-expandable stents, as there is significant bending stress on the stent within the mid renal artery during cardiorespiratory motion [50,51].

For vasculitis-caused RAS, the actual technical procedure is the same as the procedure for ARAS. However, there is no conclusive preference for angioplasty or stenting if endovascular intervention is warranted. A recent retrospective study suggested superiority of angioplasty over stenting for Takayasu’s disease [52]. Regardless of which endovascular procedure is chosen, perioperative appropriate medical treatment of the underlying pathophysiologic disease process (e.g., immunosuppression) is required for better clinical outcome [53].

Distal protection devices to prevent atheroembolization

The atherosclerotic plaque burden associated with ARAS is quite high, although much of this risk resides in the aorta. It is intuitive to imagine the debris shattered from the fractured plaques going distally in the renal artery resulting in parenchymal inflammation and impaired kidney function. The debris is often observed when an embolic protection device is used [54]. These devices are unlikely to catch 100% of the debris but decrease the debris burden. The question to ask is the risk–benefit ratio. The distal protection device was shown to be beneficial in improving or stabilizing the renal function by several authors [55,56]. The combination of a distal filter protection device and abciximab was shown to protect kidney function after atherosclerotic renal artery stenting [54]. The risks of using these devices include increased case complexity and time, renal artery spasm, and dissection. Use of a distal protection device is sometimes not feasible for short renal arteries simply because there is no room to deploy the protection device.

Peri-interventional care

Aspirin (81–325 mg) should be started at least 1 day before the intervention and continued for life. Clopidogrel (75 mg) is used for at least 4 weeks after stenting by most interventional physicians, although there has been no study yet to validate the benefit. Anticoagulation is not needed after intervention. As described earlier, abciximab was shown to protect kidney function after atherosclerotic renal artery stenting over the short term when used in combination with an embolic protection device [54]. Blood pressure medications should not be held on the day of the procedure and should be continued after the procedure. Overnight observation is suggested for monitoring blood pressure, adjusting blood pressure medications, and monitoring for complications. Intravenous hydration can be used prior and after the contrast exposure to prevent contrast-induced acute kidney injury.

Duplex ultrasound is useful 1 month after discharge to establish the baseline characteristics for comparison with later imaging. Follow-up by duplex ultrasound is recommended at 6 and 12 months, or if kidney function declines, to evaluate renal stent patency.

Complications and management

The most common complications in renal artery intervention are vascular access-related, including local hematoma (~5%), retro-peritoneal hematoma, pseudoaneurysm, arteriovenous fistula, blood vessel and nerve injury.

Atheroemboli can happen during catheter manipulations in the aorta, resulting from disruption of plaques or thrombi on the aortic wall. This risk can be heightened in the presence of highly atherosclerotic aortas or with aneurysms. Every effort should be made to minimize the manipulation, and especially scraping, of catheters along the aortic wall. Embolism can also occur because of plaque disruption during predilatation, stenting, and post-dilatation within the renal artery. Distal embolic protection devices can be utilized; however, their utility is still uncertain.

Renal artery dissection can occur during the procedure, especially during catheter engagement or during stenting. The “exchange technique” and “no touch technique” are useful. In all cases, gentle engagement is preferred. Bailout stent placement can be used to treat the dissection. Aortic wall dissection can also occur. Stenting and conservative treatment are the usual modality of treatment.

Renal artery perforation is a severe complication that is somewhat unpredictable. It can be associated with guidewire injury or over expansion of a lesion. Some patients have back pain as their warning sign; when this is experienced the balloon should be deflated and repeat imaging performed. When the patient experiences acute back pain during balloon inflation it is safer to err on the side of underexpansion and risk of restenosis than it is to err on the side of a “perfect result” and vessel rupture. Hemodynamic instability may or may not occur. Prolonged balloon inflation, use of covered stent, or, rarely, surgical intervention are required.

Wire perforation of the renal parenchyma also occurs at low frequency and, if not addressed, can result in severe hemorrhage and loss of the kidney. The kidney is more sensitive to perforation than the heart or lower extremity, especially when hydrophilic guidewires are used. To avoid perforation, meticulously track the distal position of the wire during the entirety of the procedure. Should perforation occur, immediate treatment using an embolic strategy (coils, foam, glue, etc.) is likely required.

In-stent restenosis and management

The restenosis rate after renal artery stenting ranges from 10% to 40% [57–60], with higher rates in smaller diameter renal arteries (<4.5 mm) [61] and lower rates in larger diameter arteries (5–7 mm) [60]. Risk factors for atherosclerosis, including smoking and diabetes, contribute to the development of in-stent restenosis [62]. Duplex ultrasound monitoring after initial stent placement can be useful to monitor for the development of restenosis, especially if patients have recurrent clinical problems such as resistant hypertension or worsening kidney function. In-stent stenosis is suspected when the duplex ultrasonography demonstrates an in-stent velocity >200 cm/s and a peak systolic velocity ratio (renal:aortic) >3.5 [63].

Various methods have been used to treat renal artery in-stent stenosis successfully, including balloon angioplasty [59,64], bare-metal [57,59] or drug (paclitaxel) eluting stent placement [59,65,66], covered stent [65], or endovascular brachytherapy [67]. However, the optimum strategy to prevent recurrent restenosis remains unknown [59]. Although sirolimus-eluting stent was suggested to be effective in maintaining long-term patency by one study [68], a subsequent study suggested that use of a sirolimus-eluting stent is associated with a high restenosis rate in treating renal artery

in-stent restenosis [69]. Aggressive risk factor management including diabetes control, smoke cessation, hypertension control, and use of aspirin and statins is recommended [49].

Revascularization for Arteries in the Pelvis

Femi Philip and Jason H. Rogers

University of California, Davis Medical Center, Sacramento, CA, USA

Normal erectile function is a complex neurovascular event that requires neurochemical stimulation and end-organ response for the initiation and maintenance of erection. Erectile dysfunction (ED) is a common medical problem affecting over 50% of men between the ages of 45–75 years [1]. There are currently over 150 million men worldwide with ED and this number is projected to increase to 322 million by 2025, the majority of the increase being in developing countries mirroring the increase in cardiovascular risk factors in these societies [2]. The etiology of ED is multifactorial but a vasculogenic cause either coexists with or has a dominant role underlying this disorder in over 40% of cases. Vasculogenic etiologies include endothelial dysfunction with impaired smooth muscle relaxation, arterial insufficiency caused by proximal atherosclerotic stenosis, or venous insufficiency because of inability to trap blood in the corpus cavernosa because of venous leak. The exact frequency distribution of these etiologies in patients with ED remains poorly defined. Coronary artery disease and ED share many cardiovascular risk factors such as age, diabetes, hypertension, hyperlipidemia, and tobacco use [3]. Erectile dysfunction is also an emerging risk factor for the development of antecedent symptomatic coronary artery disease and adverse cardiovascular events [4].

The current therapy for ED uses pharmacologic agents such as phosphodiesterase-5 inhibitors (PDE5i) that increase penile arterial blood flow and improve endothelial function. However, a large proportion of patients (~50%) have a poor response to these agents or have a contraindication to their use and are relegated to the use of vacuum constrictor devices, intrapenile injection of prostaglandins, or implantation of a penile prosthesis [5,6]. There is currently evidence documenting the presence of angiographically severe penile arterial inflow (PAI) disease in a significant proportion of older patients with ED [7]. Clinical trials have reported some limited efficacy in erectile function after percutaneous intervention on vascular stenosis related to PAI. Despite these data, penile arterial revascularization remains investigational to date and is currently not recommended by the American Urological Association [6].

A novel minimally invasive approach targeting PAI disease may prove to be a safe and effective treatment strategy for ED related to impaired arterial inflow. This chapter reviews the normal penile arterial blood supply, describes the angiographic anatomy in ED, and critically discusses the available literature on microsurgical and endovascular techniques to treat vasculogenic ED.

Penile arterial blood supply and anatomy

Normal penile vascular anatomy

The abdominal aorta bifurcates into the right and left common iliac artery. The common iliac bifurcates into the internal and external iliac arteries. The internal iliac artery passes downward to the upper margin of the greater sciatic foramen where it divides into anterior and posterior branches. The anterior division provides the majority of blood supply to the pelvic and reproductive organs including the internal pudendal artery. The posterior division provides arterial supply to the gluteal and lumbosacral musculoskeleton via the ilio-lumbar, lateral sacral, and superior gluteal arteries (Figure 76.1). Any artery proximal to the internal pudendal artery (IPA) can be considered an erectile-related artery (ERA) and stenosis could lead to ED because of arterial insufficiency. As the vast majority of penile inflow is normally carried through the bilateral IPAs, the focus of discussion will be on the IPA and its anatomic variations.

The IPA is the smaller of the two terminal branches of the anterior trunk of the internal iliac artery. This artery passes outward along the lower border of the greater sciatic foramen, and emerges from the pelvis across the ischial spine and re-enters the perineum through the lesser sciatic foramen. The artery then passes along the lateral wall of the ischioanal fossa and in between the fascial layers of the urogenital diaphragm along with the pudendal nerve (Alcock's canal) and terminates by forming the common penile artery which then divides into the bulbocavernosal, deep cavernosal, and dorsal arteries of the penis. The IPA has multiple branches: inferior rectal artery, perineal artery, artery of the urethral bulb, urethral arteries, and the cavernosal and dorsal arteries in the penis (Figure 76.2). The inferior rectal artery arises above the ischial tuberosity and supplies the muscles and integument of the anal region. The perineal artery provides several posterior scrotal branches that are distributed to the skin. The artery of the urethral bulb and the urethral artery are short blood vessels that supply the urethral bulb, the posterior part of the corpus cavernosum, and the glans penis. The cavernosal arteries of the penis run bilaterally forward in the center of the corpus cavernosa, to which its branches are distributed and there are communicating branches between the cavernosal arteries. The dorsal artery of the penis ascends between the crus penis and the pubic symphysis and runs

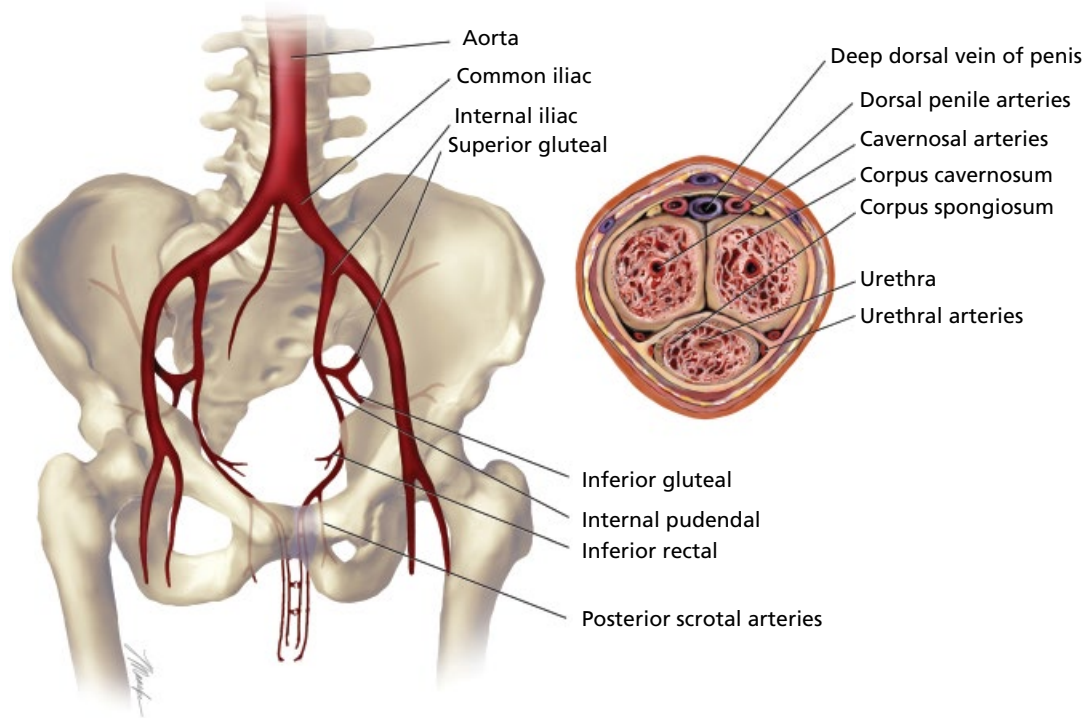

Figure 76.1 Normal pelvic arterial blood supply. A schematic view of the pelvis showing the most common arterial anatomy.

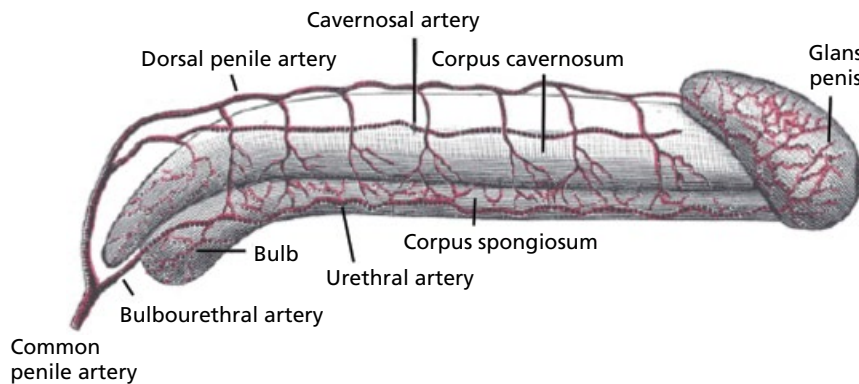

Figure 76.2 Penile arterial blood supply.

forward on the dorsum of the penis to the glans, where it divides into two branches, which supply the glans and prepuce.

Common anatomic variations in penile arterial anatomy

The most frequent anatomic variation occurs when the IPA ends as the artery of the urethral bulb or less frequently the perineal artery. In these cases, the dorsal and deep arteries of the penis are derived from an accessory pudendal artery. These accessory arteries originate from the external iliac, obturator, vesical, and femoral arteries, and in some men constitute the dominant or only arterial supply to the corpus cavernosum. Accessory pudendal arteries are identified in up to 70% of cadaveric studies, and 7–14% by radiographic studies. These anatomic aspects are essential to consider when planning an endovascular strategy. Yamaki *et al.* [7] studied 645 pelvic halves from Japanese cadavers and proposed a classification for the branching patterns of the internal iliac artery consisting of four groups (detailed in

Figure 76.3). The most common branching patterns involve the IPA originating either as the first branch, terminal branch, or trifurcating branch of the inferior division of the internal iliac artery.

Angiographic studies in erectile dysfunction

Leriche [8] first described the association between ED and occlusive disease in the aorta in 1923. This was caused by the presence of aorto-iliac occlusion resulting in lower extremity ischemia and PAI insufficiency. This association remained unexplored until 1969 when it was noted that 70% of the men with aorto-iliac occlusion had impotence [9]. In the same year, relief of impotence after bilateral endarterectomy of occluded internal iliac arteries was reported [10]. There was still no firm evidence that organic disease was responsible for impotence until 1973 when

Figure 76.3 The branching pattern of the internal iliac artery, as classified by Adachi and modified by Yamaki. Group A: The internal pudendal artery is a terminal branch of the inferior division of the internal iliac artery after the inferior gluteal and superior gluteal arteries. Group B: The internal pudendal artery is the first branch of the inferior division of the internal iliac artery. Group C: The inferior division of the internal iliac artery trifurcates into internal pudendal artery, superior and inferior gluteal arteries. Group D: The internal pudendal artery is the second branch after the inferior gluteal artery is given off. I, inferior gluteal artery; S, superior gluteal artery; P, internal pudendal artery; U, umbilical artery.

angiographic and histologic data suggested the coexistence of severe arterial disease in patients with impotence [11]. This was again confirmed in 1978 with the angiographic demonstration of the presence of arterial inflow disease in patients with ED [12]. These observations came in parallel with the evolution of conventional angiography. At the time, angiography was limited to visualization of the aorta and iliac vessels and more selective techniques to visualize smaller caliber vessels like the internal pudendal and penile arteries were not possible. Visualization of the smaller caliber penile vessels was possible with the use of retrograde phallo-arteriography. With this technique, 30 males with ED had translumbar aortography followed by puncture of the dorsal artery of the penis and contrast administration followed by radiographic image acquisition [13]. This technique was the first study to demonstrate severe disease or occlusion of the vessels supplying the cavernosal bodies in patients with ED.

To date there have been 10 studies assessing penile arterial blood flow in 629 patients with ED (Table 76.1) [14–23]. Collectively, these studies show a high incidence of PAI disease that ranges between 37–79% with an average incidence of 76%. The proportion of patients with arterial inflow disease may be overestimated as the majority of patients included in these studies have concurrent symptomatic coronary or peripheral vascular disease as opposed to the larger majority of patients without such comorbidities with ED. The atherosclerotic process affecting the IPA is diffuse and often involves the ostial or proximal segments of the vessels in 56% of cases and the distal segments of the vessel (small penile vessels) in over 60% [19,24]. There is also multisegment disease and this feature is often seen in older patients or those with diabetes mellitus although the numbers of patients studied in the literature are small and poorly documented.

Previous studies have also identified a considerable anatomic variation with the IPA. The IPA arises as a gluteopudendal trunk from the inferior gluteal artery in 70% of patients or as an independent branch from the anterior division of the internal iliac artery in 30% [17]. While this makes identification of the vessel more challenging, the location and origin of the IPA relative to the internal iliac artery can also influence erectile function, as there is some evidence that in Japanese men this plays a part as a cause for ED but the broader implications of this recent finding is currently unknown [25]. Accessory pudendal arteries arise in up to 21% of patients and originate as an independent branch from the obturator artery, remnant of the urachal artery, and superior division of

the internal iliac artery [19]. It is therefore critical to consider angiography as the current gold standard for evaluation of penile arterial blood supply.

The angiographer must perform a quality angiogram, otherwise angiography can be misleading, resulting in both false positive and false negative diagnosis. Important considerations include: inclusion of both the large pelvic and the distal vessels, location of the source of blood flow to cavernosal arteries using direct cannulation of the pudendal or accessory pudendal artery, and recognizing variant arterial anatomy. Finally, it is essential to place the anatomic information obtained during angiography within the context of functional assessments of penile blood flow obtained via Doppler ultrasound examination during pharmacologic induction of erection to exclude venous leak. It is not known if arterial revascularization of patients with venous leak will result in improvement of erectile function, but venous leak should theoretically limit the efficacy of any improvement in arterial inflow.

Penile arterial revascularization: surgical and endovascular approaches

Surgical approach to penile arterial revascularization

Michal *et al.* [26] reported the first penile arterial revascularization in 1973, by anastomosis of the inferior epigastric artery (IEGA) to the corpus cavernosum which was successful in the short term but resulted in cavernosal smooth muscle fibrosis leading to thrombosis of the graft in the long term. The Michal II procedure was then popularized, where the IEGA was anastomosed in an end-to-side fashion to the dorsal penile artery [27]. Hauri [28] proposed direct arterial anastomosis of the IEGA to the dorsal artery but, in addition, incorporating the deep dorsal vein into the anastomosis (arterialization). In principle, arterialization of the dorsal vein would improve arterial flow to the corpora cavernosa in a retrograde manner via the emissary veins. Virag *et al.* [29] described a procedure in which the IEGA was anastomosed directly to the deep dorsal vein, introducing the concept of venous arterialization. In theory, these modifications improve inflow while reducing venous outflow. In concept, these procedures can be attractive not only in men with pure arteriogenic ED, but also those with a venogenic component. However, these procedures are rarely performed given the limited experience and the associated morbidity and mortality from the operation.

Thirty-one studies have been performed to evaluate these surgical techniques and those included in the American Urologic

Table 76.1 Penile arterial inflow studies in erectile dysfunction.

Study	n	Anatomic variations of internal pudendal and accessory arteries	Location of stenosis
Michal 1978 [11]	30	N/A	100% cavernosal arteries
Herman 1978 [15]	35	N/A	100% IPA disease
Struyven 1979 [16]	14	N/A	50% IPA disease
Huguet 1981 [17]	200	85% from ILA, 65% from gluteopudendal artery	Not described
Buvat 1981 [18]	29	N/A	37% proximal IPA 48% distal disease (perineal and cavernous arteries)
Bruhlman 1981 [19]	24	Accessory pudendal artery from superior vesical, urachal and obturator arteries	71% IPA 24% mid-segment of the IPA 59% bilateral IPA 100% deep and dorsal arteries of the penis
Gary 1982 [21]	73	21% had accessory pudendal arteries, of these 14% were unilateral and 7% were bilateral	44% ILA or proximal IPA 44% distal IPA or cavernosal arteries
Nessi 1987 [20]	44	N/A	79% IPA 20% occlusion of the IPA or bilateral disease 52% with single vessel occlusion or multiple lesions in a single vessel
Valji 1988 [22]	57	N/A	19% ILA 70% IPA 40% distal disease 56% intrapenile disease
Rosen 1990 [23]	170	N/A	Cavernosal arteries in the majority
Rogers 2010 [14]	10	N/A	90% IPA
Total*	629		IPA disease: 144/259 (56%) Small vessel disease: 274/459 (59%)

ED, erectile dysfunction; ILA, internal iliac artery; IPA, internal pudendal artery; N/A, not available.

*Patients from Huguet *et al.* and Rosen *et al.* studies were excluded from the total numbers due to lack of data regarding degree and location of stenosis of the IPA and cavernosal arteries.

Association (AUA) position statement are listed in Table 76.2. One of the largest contemporary retrospective series is that of Kawanishi where 51 men with vasculogenic ED had comprehensive assessments of ED which included intracavernosal pharmacologic erection tests, penile duplex Doppler, and digital subtraction angiography [30]. The etiology of the arterial lesions was blunt perineal trauma in 33 and unknown in 35. Either the Hauri or Furlow–Fischer procedure (IEGA to deep dorsal vein but circumflex collaterals are preserved and dorsal venous valves are not disrupted) was used for penile revascularization. The patency of the neoarterial blood flow was assessed objectively by color flow duplex Doppler. A significant improvement in penile blood flow was noted and was sustained in approximately 70% of the patients [31]. Of the 31 publications on penile revascularization surgery

reviewed by the AUA, only four reports for a total of 50 patients met the peer review criteria set by these guidelines. These reports document a success rate of 36–91% [5]. The most important limitation of the current surgical literature is that patients who underwent these operations generally had blunt trauma without atherosclerosis. Furthermore, surgery was associated with a wide range of complications that included penile parasthesia and retrograde ejaculation (a reflection of the pelvic nerve damage). Because of these findings, the AUA considers vascular reconstructive approaches to ED experimental, with revascularization reserved for patients with trauma who have focal lesions without any evidence of vascular disease. These procedures provided a conceptual framework for consideration of endovascular therapies in treating this problem.

Table 76.2 Outcomes of penile revascularization surgery.

Study	n	Procedure	Follow-up (months)	Overall intercourse success rates (%)
Jarow 1997 [36]	11	DDVA	50	92
Lukkarinen 1997 [37]	24	Hauri F-F	Not described	72
Manning 1998 [38]	62	Virag Hauri	41	54
Manning 1998 [38]	42	DDVA	Not described	57
Kawanishi 2000 [30]	18	DA Hauri F-F	32	94
Sarramon 1997 [39]	114	DA DDVA	17	63
Sarramon 2001 [40]	38	DDVA	61	N/A
Vardi 2002 [5]	61	N/A	60	N/A
Kawanishi 2004 [31]	51	Hauri	36–60	85.6

DA, dorsal arterialization; DDVA, dorsal artery to deep vein anastomosis; F-F, Furlow–Fisher technique, arterialization of a dorsal vein segment (after ligating its proximal and distal ends including its circumflex branches); Hauri, three-vessel anastomosis with side-to-side between the dorsal artery and vein, covered by a spatulated inferior epigastric artery; Virag, deep dorsal vein arterialization using the retrograde approach from the emissary veins.

Endovascular approach to penile arterial revascularization

The current experience with transluminal angioplasty or stenting for the treatment of ED is very limited and detailed in Table 76.3. Almost all endovascular studies to date focused on large vessel inflow disease (common and internal iliac arteries). There are only limited case reports of transcatheter means of excluding pelvic venous insufficiency but not venous leak related to the penile emissary veins. Additionally, the duration of follow-up and methods in many of the published literature are lacking.

More recently, the ZEN trial (Zotarolimus-Eluting Peripheral Stent System for the Treatment of Erectile Dysfunction in Males with Suboptimal Response to PDE5 Inhibitors) has evaluated the role of endovascular intervention in patients with drug refractory ED. The study addressed many of the limitations associated with previous literature. A total of 30 patients (out of 383 subjects screened) with ED were enrolled. Procedural success was 100% with no major adverse events through follow-up. The primary feasibility endpoint at 6 months was achieved by 59.3% of intention-to-treat subjects and 69.6% of per-protocol subjects. Duplex ultrasound peak systolic velocity of the cavernosal arteries increased from baseline by 14.4 ± 10.7 cm/s at 30 days and 22.5 ± 23.7 cm/s at 6 months. Angiographic binary restenosis was reported in 11 (34.4%) of 32 lesions.

The ZEN trial clearly demonstrated the feasibility and safety of stenting atherosclerotic IPA lesions in highly selected subjects. Many subjects (but not all) reported subjective improvement in erectile function after these procedures, and there were concomitant increases in penile flow as determined by duplex ultrasound. Angiographic follow-up demonstrated no stent fractures and

reasonable binary patency considering the first-in-man use of a drug-eluting stent (DES) in a new vascular bed. Although the ZEN trial demonstrated safe and feasible stenting of the IPA in selected patients, most patients screened for this trial did not qualify and the main reasons for exclusion were: (i) excessive or insufficient angiographic disease; (ii) lack of arterial insufficiency by duplex; or (iii) venous leak. Additionally, a higher binary restenosis rate at 6 months (34%) highlights the unknowns in applying DES to the pelvic vasculature. Furthermore, the mechanism by which clinical improvement in erectile function persisted at 6 months despite angiographic binary restenosis in one-third of subjects remains unknown. Given these considerations, the authors concluded that the results of the ZEN trial precluded widespread use for the treatment of PAI [47].

Given the anatomic variations and the degree of diffuse disease noted in the ZEN Trial, Wang *et al.* performed the Pelvic Revascularisation For arteriogenic EreCtile dysfunction (PERFECT-1) study. They used CT angiography to assess the safety and feasibility of catheter-based therapy for isolated penile artery stenoses in patients with erectile dysfunction. Twenty-five patients with ED and isolated penile artery stenoses (unilateral stenosis $\geq 70\%$ or bilateral stenoses $\geq 50\%$) identified by pelvic computed tomographic angiography were enrolled. A total of 20 patients (mean age 61 years; range 48–79 years) underwent balloon angioplasty. Three patients had bilateral penile artery stenoses. Procedural success was achieved in all 23 penile arteries, with an average balloon size of 1.6 mm (range 1.00–2.25 mm). The average International Index for Erectile Function-5 (IIEF-5) score improved from 10.0 ± 5.2 at baseline to 15.2 ± 6.7 ($p < 0.001$) at 1 month and 15.2 ± 6.3 ($p < 0.001$) at 6 months. Clinical success

Table 76.3 Endovascular treatment of erectile dysfunction.

Study	n	Angiographic stenosis	Technique	Follow-up	Success rate
Castaneda-Zunga 1982 [41]	2	Internal iliac	PTA	18 months	2/2 (100%)
Van Unnik 1984 [42]	1	External iliac	PTA	N/A	1/1 (100%)
Goldwasser 1985 [43]	1	Internal iliac	N/A	N/A	1/1 (100%)
Dewar 1985 [44]	30	70% aorto-iliac 47% internal iliac	PTA	N/A	10/33 (33%)
Angelini 1985 [45]	5	100% internal iliac	PTA	2–18 months	4/5 (80%)
Valji 1988 [22]	3	N/A	PTA	N/A	N/A
Urigo 1994 [46]*	23	65% internal iliac 13% internal pudendal	N/A	N/A	15/23 (65%) 3/3 (100%)
Rogers 2011 [47]	30	100% internal pudendal	PTA and drug- eluting stents	3 months	68.2% had improvement in IIEF score >4 points

IIEF, International Index on Erectile Function; N/A, not available; PTA, percutaneous transluminal balloon angioplasty.

*In this study, 65% of patients with internal iliac artery had improvement in erectile function, while all patients with pudendal artery disease had successful outcomes.

(change in the IIEF-5 score ≥ 4 or normalization of erectile function; IIEF-5 ≥ 22) was achieved in 15 (75%), 13 (65%), and 12 (60%) patients at 1, 3, and 6 months, respectively. Despite lack of angiographic follow-up or the use of a control group in this study, the authors concluded that penile artery angioplasty is safe and can achieve clinically significant improvement in erectile function in 60% of patients with ED and isolated penile artery stenosis [48].

Endovascular therapy for PAI is currently limited to a few studies showing modest benefit. This therapy should be reserved for a very select population of patients who have been evaluated by a multidisciplinary team for all potential causes of ED, and who have true PAI with anatomically suitable vessels for interventions after both functional assessment and invasive angiographic or computed tomographic imaging.

Patient selection and work-up

Patients at risk for atherosclerosis or with established coronary artery disease or peripheral vascular disease can be screened for the presence of vascular ED using a five-question subset of the IIEF questionnaire [32]. This is a validated, multidimensional, self-administered questionnaire used for the assessment of ED and treatment outcomes in clinical studies. The whole questionnaire consists of five separate response domains of sexual function: erectile function (questions 1–5, with a possible score of 25); orgasmic function (questions 9 and 10; possible score of 0–10), sexual desire (questions 11 and 12; possible score of 0–10); intercourse satisfaction (questions 6–8; possible score of 0–15); and overall satisfaction (questions 13 and 14; possible score of 2–10). A subset of five

questions are the Sexual Health Inventory for Men (SHIM, or IIEF-5) which assesses erectile function by rating each question on a scale of 1 (almost never or never) to 5 (almost always or always). A score of 0 indicates no attempt at sexual intercourse [33]. A score of less than 17 is considered consistent with severe ED. These patients should be referred to an urologist who specializes in ED who can perform a focused examination to exclude other causes such as Peyronie's disease (distortion of the architecture of the penis that does not allow intercourse irrespective of arterial supply). Additional blood tests such as testosterone levels, thyroid stimulating hormone (TSH), and prostate specific antigen (PSA) should also be obtained. If these are normal, the patient should be referred for duplex ultrasonography with cavernosal injection for measurements of systolic and diastolic penile blood flow. A peak systolic velocity (PSV) consistently exceeding 25 cm/s within 5 minutes of intracavernous injection will rule out PAI disease, while a PSV less than 25 cm/s has a sensitivity of 100% and a specificity of 95% in patients with abnormal pudendal angiography [34,35]. A persistent end-diastolic flow velocity (EDV) (>5 cm/s) accompanied by quick detumescence after stimulation is consistent with venogenic impotence (venous leak through the emissary veins) and the patient is unlikely to benefit from restoration of arterial inflow. Venogenic impotence occurs when there is incompetence of the venous drainage of the penis resulting in failure of engorgement of the cavernosal bodies leading to impotence. Patients with ED should be referred to urology or sexual medicine clinics and a duplex ultrasound should be considered to assess for PAI. If they fail current medical therapy and have evidence of PAI with no venous leak then they may be considered suitable candidates for PAI restoration.

Angiographic technique

Various unpublished methods are used for angiographic evaluation of the pelvic penile blood flow. We propose the following step-by-step angiographic guide for adequate visualization of PAI.

- 1 A Foley catheter is placed in the bladder and the penis is stretched and taped to the contralateral thigh when selective angiography of internal iliac and pudendal artery is performed. Consider gonadal shielding as per institutional radiation safety standards.
- 2 Femoral arterial access is obtained. An AP conventional pelvic angiography is performed after placement of a pigtail catheter above the aortic bifurcation and digital subtraction angiography with iliofemoral run-off is conducted (Figure 76.4). This allows an assessment of distal aorta, common and proximal internal iliac arteries. Additionally, it serves as a roadmap to locate the origin of the IPA or accessory vessels.
- 3 A 4 or 5 Fr diagnostic low profile catheter is then placed in the ostium of the internal iliac artery and selective angiography is performed. The origin of the vessel is best seen in the ipsilateral cranial oblique projection (20–30°). The mid and distal aspect of the vessel is best seen in ipsilateral oblique (20–30°) with mild caudal angulation 10–20° as shown in Figure 76.5a. The penis is positioned pointing to the contralateral side of injection to allow visualization of run-off into the penile vessels.
- 4 Penile vasodilatation may be necessary prior to angiography and can be accomplished by intracavernosal injection of 15 µg prostaglandin E1. This serves to relax the cavernosal musculature and augments blood flow, vessel caliber, and markedly improves angiographic quality. This is especially useful when the anatomy is not clearly demarcated and the functional significance of a stenosis is uncertain.
- 5 Interventional therapy is frequently performed using 0.014-inch wires and coronary balloons and DES. It is important to have one-to-one sizing of the vessel with no oversizing of the vessel (Figure 76.5b).

Conclusions

ED and PAI disease coexists with a high frequency (~76%). Patients who have ED without psychogenic or organic cause should be referred for Doppler ultrasound examinations in collaboration with a urologist. While there is limited experience using contemporary endovascular therapies for this indication, this avenue promises to be an exciting and evolving field that is slowly gaining momentum in the context of the recent emerging evidence for benefit with minimal risk. Future randomized trials should fully evaluate the role of endovascular therapy for ED.

Interactive multiple choice questions are available for this chapter on www.wiley.com/go/dangas/cardiology

Iliac Interventions

Manish Taneja¹ and Apoorva Gogna²

¹Interventional Radiology, Raffles Hospital, Singapore

²Interventional Radiology Centre, Department of Diagnostic Radiology, Singapore General Hospital, Singapore

Approximately one-third of peripheral arterial occlusive disease (PAOD) affects the aorto-iliac segment in Western populations [1]. The prevalence of PAOD is reported to be 16% in patients aged 60–69, rising to 34% in those aged over 70 years [2]. While the TransAtlantic Inter-Society Consensus (TASC-II) guidelines [3], published in 2007, recommend endovascular treatment for type A and B lesions, the accumulation of experience, and improvements in equipment (lower profile wires and balloons, re-entry devices) and imaging have rapidly allowed TASC-II C and even D lesions to be successfully treated using endovascular means.

There is evidence for percutaneous coronary intervention (PCI) to be considered first line therapy even for complex and long aorto-iliac stenoses and occlusions [4] and hence many authors now advise a far more aggressive PCI approach than the original TASC-II treatment recommendations. In fact, the March 2015 Society of Vascular Surgery guidelines [5] recommend PCI as first line treatment in all aorto-iliac occlusive disease (AIOD) classes, and reserve surgery only for failed PCI and severe disease in presence of aortic aneurysms. This recommendation is further strengthened by studies showing that PCI does not preclude further surgical options in AIOD [6].

In a diseased vessel that is not completely occluded, the true lumen is still visible, hence there is usually no need to cross a blind segment and usually no acute blood clots are present. The TASC-II D subtype comprises lesions of greatly varying technical complexity for PCI because both long segment occlusions and multifocal stenoses are included. In practical terms, it is more useful to separate chronic total occlusions (CTO), acute occlusions, and stenoses because they each present unique challenges for PCI. Here we discuss the current recommended treatment guidelines for these categories and other special subsets.

Clinical presentation and diagnosis

Patients with AIOD typically present with symptoms of chronic limb ischemia although acute on chronic presentations are also occasionally seen.

Acute limb ischemia (ALI) is defined as sudden reduction of limb perfusion, usually within 14 days, which threatens limb viability. In the AIOD territory, acute presentations usually relate to graft or stent thrombosis, *in situ* thrombosis of a diseased segment, and,

less likely, occlusion by an acute embolus. Acute and subacute (less than 30 days) occlusions should first be considered for surgical treatment, although pharmacomechanical lysis options are available. Caution is needed because of the large amount of thrombus load which increases the risk of distal embolization, and, concurrently, the treatment chosen should be expedient to prevent irreversible tissue necrosis and reperfusion syndrome. ALI is covered in greater detail elsewhere in the book.

Chronic limb ischemia (CLI) tends to present in an insidious fashion but is far more common than ALI. Severity can be classified using the Rutherford [7] and Fontaine scales, and ranges from asymptomatic subclinical disease to gangrene.

Claudication caused by stenosis results from the inability of the vessel segment to increase demand-related blood flow to the muscle during times of increased activity (e.g., walking). Patients report pain or fatigue during walking which is relieved with rest, gait disturbances, and reductions in walking speed. This can greatly impair patients' quality of life. Conservative treatment with supervised progressive walking programs and medial therapy (e.g., cilostazol) should be attempted first for several months. Endovascular treatment can be offered to patients who fail or are unsuitable for conservative therapy.

Critical limb ischemia refers to rest pain and tissue loss (ulceration, gangrene) when blood flow is insufficient to even meet the resting metabolic tissue requirement. Typically, rest pain is relieved partially by gravity dependent positioning of the limb below the level of the heart (e.g., sitting position or hanging the leg over the side of the bed).

On physical examination, a bruit over the lower abdomen and/or a weak or absent femoral pulse can be detected. The lower extremities should be examined for signs of ischemia. The ankle-brachial index (ABI) is a quick measurement of the overall perfusion at the level of the distal extremity but is unable to quantify the extent and severity of disease in each segment of the lower limb.

Arterial imaging can be performed using non-invasive (ultrasound, CT, or MR angiography) or invasive (catheter angiography, pressure gradients, intravascular ultrasound) methods; the latter usually combined with treatment.

Ultrasound remains the cornerstone of preoperative imaging because it offers cheap, high resolution, real-time information

about the anatomy and flow dynamics of the vessel segment. However, imaging of the aorto-iliac segments is difficult with ultrasound alone because of interference by overlying bowel loops and reduced signal with increasing depth. Abnormal waveforms (i.e., loss of the normal triphasic waveform) at the groin does raise suspicion of inflow disease in the AIOD, but can also result from distal disease. We find preoperative imaging of this segment with CT or MR angiography very useful to define the extent and nature of the occlusion. Non-contrast MR angiography techniques are possible for patients with contraindications to intravenous gadolinium-based contrast (typically, patients with advanced renal failure).

Percutaneous intervention

AIOD lesions can be approached using one or more of four main access ports: ipsilateral common femoral artery, contralateral common femoral artery (CFA), upper limb artery (e.g., brachial or radial), or ipsilateral distal artery (e.g., popliteal). The choice depends on the location of the primary lesion, associated lesions en route to the lesion, and size of instruments desired to be conveyed to the treatment site. In practical terms, the femoral retrograde access is most commonly used. Ipsilateral approaches offer better vis-a-tergo and torque hence improving maneuverability of the catheter or wire. Conversely, the contralateral antegrade access allows crossing in the direction of flow, and allows better imaging to be performed showing the proximal and distal reconstituted segments. Realistically, both groins should be prepared for every intervention to allow change of access site if needed.

For non-CTO lesions, a single contralateral CFA access can be sufficient to treat the aorto-iliac and infra-inguinal disease. For origin or bifurcation lesions, bilateral access is often required (see section on bifurcation lesions). For CTOs, ipsilateral and contralateral or arm access facilitates definition of extent of disease and lesion crossing. In rare cases, popliteal access is chosen to traverse long contiguous CTOs of the iliac and femoral segments.

Premedication with oral aspirin is normally given, with some authors adding oral clopidogrel. Intravenous heparin is typically given according to body weight (70 units/kg), to achieve activated clotting times of 220–250 s. Post-stenting, aspirin should be continued lifelong, while thienopyridines such as clopidogrel or prasugrel are given for at least 1 month [8].

The choice of wire platform and balloon for angioplasty is very much operator dependent, and no consensus exists as to the ideal strategy. We tend to use the 0.014-inch platform for most cases because it allows larger 0.018-inch platform and even 0.035-inch platform balloons to advance over the wire. When more support is needed, we then exchange for larger platform wires after initial dilatation.

Some authors recommend predilatation with a balloon sized about 2 mm smaller than the native vessel diameter [9,10], to prevent distal embolization; others recommend primary stenting for the same purpose.

Aorto-iliac stenoses

The Cardiovascular and Interventional Radiological Society of Europe (CIRSE) guidelines [4] on AIOD, published in 2012, recommend PCI as first line for TASC-II A–C due to low morbidity and mortality, and over 90% technical success (class 1 recommendation, level of evidence C).

Studies comparing PCI with open surgical treatments for AIOD have shown approximately equivalent patency, limb salvage, and overall survival rates, yet lower morbidity and mortality than surgical reconstruction [6,10,11].

Kashyap *et al.* [6] provided a detailed comparison of PCI versus open surgery. They observed worse post-PCI patency rates in younger patients. Conversely, worse post-surgery patency was noted in diabetics and presence of poor runoff to the lower extremity. A small diameter aorta also appears to perform poorly post open bypass [12].

Indes *et al.* [2] reviewed all patients who underwent open and endovascular procedures within the HCUP-NIS (a large American inpatient database of over 8 million hospital stays per year) within the 2004–2007 period, and reported an overall inpatient complication rate of 16% in the PCI group compared to 25% in the open surgical group ($p < 0.001$). Further, average length of stay was 2.2 days versus 5.8 days, while total inpatient cost was \$13,661 versus \$17,161, both in favor of PCI ($p < 0.05$).

Sachwani *et al.* [10] reviewed patients (January 2000 to December 2011) with symptomatic (intermittent claudication 69%; rest pain 19%; and toe gangrene 15%) iliac occlusions who underwent PCI ($n = 100$ patients) or aorto-bifemoral graft bypass ($n = 101$ patients). Open bypass was preferred for patients with long segment common iliac artery (CIA) or external iliac artery (EIA) occlusions with heavy calcifications and infra-inguinal disease and also patients with previous failed PCI/stent interventions, and small diameter vessels. While the primary patency rate after 72 months was higher in the surgical group (91% vs. 73%; $p = 0.01$), the secondary patency rate was not significantly different. Target lesion revascularization (TLR) in the PCI group involved catheter-directed thrombolysis, restenting, and balloon angioplasty. TLR in the bypass group required open thrombectomy or catheter-directed thrombolysis. The authors also observed a trend favoring PCI over bypass toward the latter half of their study period, attributed to increasing experience and availability of technical aids.

Chronic totally occlusive lesions

The PCI procedure in a chronic total occlusion can be technically challenging. Ultrasound, fluoroscopic, or roadmap guidance can be helpful to puncture a pulseless femoral artery [10]. Bilateral femoral artery, and in some cases brachial access may be needed to provide both antegrade and retrograde imaging and wiring. The tram-track calcifications of an occluded vessel are often very helpful during wire crossing, and should be viewed in orthogonal planes on high quality angiography equipment.

Many authors recommend the use of an angled catheter (e.g., 5 Fr Kumpe, Cook Inc., Bloomington, IN, USA) and a 0.035-inch hydrophilic wire (Glidewire, Terumo Medical, Japan). Alternatively, low profile support microcatheters (CXI, Cook Inc.) and 0.014-inch weighted CTO wires (e.g., Winn 40, 80, Abbott Medical) can be used. A combined antegrade and retrograde approach can be very useful in limiting the subintimal dissection to the affected segment, and assisting in re-entry. Often, the catheter can be “selected” from the contralateral access, thereby alleviating the need for an expensive snare device.

Re-entry devices such as Outback (Cordis Johnson & Johnson), Frontrunner (Cordis), and Pioneer IVUS catheter (Medtronic) have been used in only a minority of cases in several large series [10], suggesting that the simple and cost-effective wire and catheter technique suffices in the majority of patients. This has also been our experience, where re-entry devices are required in less than 5% of

cases (unpublished data). The re-entry device serves to direct a wire in the subintimal plane back into the patent true lumen beyond the distal cap of the occlusion.

Jongkind *et al.* [13] published a systematic review of PCI for TASC C and D subtype AIOD in 2010 based on 19 studies (n = 1711 patients) published between the years 2000 and 2009 which fit the systematic review criteria. PCI with or without combined surgical techniques for the aorto-iliac and outflow were used, and primary stenting with bare metal stents (BMS) or stent grafts performed in most studies. Technical success was 86–100%, improvement in clinical outcome 83–100%, morbidity 3–45% (comprising access site hematoma, distal embolization, arterial dissection, pseudoaneurysms, or rupture). Primary and assisted patency rates were 70–97%, 88–100% at 1 year, respectively and 60–86%, 80–98% at 4 or 5 years, respectively.

Stents: covered and uncovered

Overall primary patency of stents is 85–95% at 1 year, 70–85% at 3 years, and 55–75% at 5 years [10,14–16]. The CFA is an area of high biomechanical stress, considered by many as a “no-stent area,” and is traditionally a surgical lesion. This is contributed by a relatively easy surgical exposure of the EIA for endarterectomy, compared to the aorto-iliac and infra-inguinal segments. Lesions extending from the EIA into the CFA have hence been approached in a combined fashion (e.g., stent implantation with femoral patch plasty).

The severity of AIOD has a bearing on stent selection. Kudo *et al.* reported worse outcomes (increased risk for recurrent disease) after stenting for TASC-II C and D compared to A and B [17]; however, Sixt *et al.* [18] reported comparable primary patency rates at 1 year of 98–100% irrespective of TASC-II lesion type.

Suero *et al.* [19] performed a retrospective analysis of 99 consecutive patients with claudication (n = 70) and critical limb ischemia (n = 29) treated for occlusive EIA disease. The mean lesion length was 42.2 mm. Balloon angioplasty alone was used in seven limbs and stenting with self-expanding (n = 65), balloon expandable (n = 24), or covered stents (n = 12) in 101 lesions.

The recent STAG trial [15] (stents vs. angioplasty for the treatment of iliac artery occlusions) compared primary stenting and balloon angioplasty for symptomatic iliac artery occlusions of up to 8 cm in length (n = 112 patients). It showed no difference between the two groups in primary and secondary patency of the iliac segment; however, stenting was associated with improved technical success and reduced procedure complications.

Lesion length also appears to correlate to stent patency. While there is no universal definition of a long AIOD lesion, 100 mm appears to be the cut-off favored by most authors. A 2014 study (for TASC B–D lesions) by Benetis *et al.* showed a significant difference in patency rates for stents greater versus those less than 61 mm: 1 and 2 year patency rates of 90.6% and 86.6% versus 67.7% and 60.2%, respectively, in favour of the shorter stents [20].

Primary stenting (without predilatation) versus stenting after initial balloon angioplasty remains an unresolved issue. Primary stenting of the affected segment (without predilatation) has been considered by several authors as a strategy to reduce embolization, by trapping clot/atheroma between the stent and vessel wall. Further, primary stenting can result in less neointimal hyperplasia.

The issue of primary versus selective stenting for iliac stenoses has been much debated. In 1998, Tetteroo *et al.* [21] published results of a randomized trial comparing primary stenting (n = 143 patients) with angioplasty with selective stenting (n = 136 patients)

for patients presenting with intermittent claudication. They found no difference in short- and long-term outcomes between the groups, including technical success, quality of life, 2-year patency, and reintervention rates. They concluded that the latter option (selective stenting) should be used because of its lower overall cost. However, note that this trial mainly focused on TASC A and B lesions.

Conversely, Bosiers *et al.* [22] reported subgroup analysis of TASC A and B lesions treated under the BRAVISSIMO study and concluded that primary stenting is the preferred option for TASC A/B lesions, with a 12 month primary patency of 94% for TASC A, and 96.5% for TASC B lesions (p = ns).

Ye *et al.* [14] performed a meta-analysis of studies reported between 2000 and 2010 (16 articles, n = 958 patients) for TASC C and D lesions, and demonstrated 1-year primary patency rates of 92.1% for primary stenting and 82.9% for selective stenting although not statistically significant.

Bechter-Hugl *et al.* [1] studied outcomes of primary stenting for symptomatic iliac occlusions, and found 1, 3, 5, and 7 year primary patency rates of 90.3%, 77.2%, 60.2%, and 46.4% for women, and 89.9%, 71.1%, 63.6%, and 59.7% for men, respectively (p = ns). However, on subgroup analysis, younger age was found to adversely affect outcomes: restenosis rates were 23.9% in men and 22.1% in women older than 63.5 years, and 32.1% in men and 49.1% in women younger than 63.5 years, respectively (p < 0.05).

Other factors limiting stent patency are the quality of the distal runoff, critical limb ischemia (as opposed to claudication), diabetes, and subintimal recanalization [14].

Balloon expandable stents are made of cobalt-chromium or stainless steel. In the iliac segment, the patency of both types of stents appears equivalent; however, there are some practical differences. Balloon expandable stents tend to be more difficult to maneuver through tortuous or calcified vessels as they are much stiffer. Their maximum available length is also about 8 cm for this reason. When advanced without a long sheath (“bare-back”), there is a tendency for the stent to get caught on calcific plaque and slip off the balloon. However, the balloon stent deployment is very accurate as there is no tendency for the stent to “jump” during deployment—hence these are good for placement “flush” with the origin of the contralateral common iliac, or the internal iliac artery.

Self-expandable stents are usually made of nickel-titanium alloy (nitinol). The available lengths are much longer (up to 150 cm) in diameters of 6–10 mm. As the stent is much more flexible, it can be advanced through calcified or tortuous vessels more easily. As it comes constrained within a sheath, there is no tendency for the stent to dislodge. However, it does tend to “jump” forward during initial deployment, although improvements in delivery systems have minimized this.

COBEST [23] was a prospective, randomized, multicenter, controlled trial in severe AIOD (n = 125 patients, 168 iliac arteries), with patients randomly assigned to receive balloon-expandable BMS (varied) or balloon-expandable stent grafts (Advanta V12, Atrium Medical). The covered stent group was more likely to remain free of binary restenosis and occlusions, particularly for TASC C and D lesions. The ongoing randomized, prospective, double-blind DISCOVER trial [24] should provide further guidance in this issue.

Our preference is to use self-expanding stents, generally 7–10 mm diameter in the common iliac segment, and 5–8 mm in the EIA, depending on the native diameter of the vessel. Others have reported preference for balloon expanded stents in the CIA segment, because of more accurate placement. We always review the

patient's previous cross-sectional imaging (CT, MRI) as this can be very useful in estimating the native diameter of the diseased vessel prior to angiography for accurate stent sizing.

Bifurcation lesions

Reconstruction of the aorto-iliac bifurcation with “kissing” angioplasty and/or stenting represents a special category because of the added complexity. Bilateral femoral, and sometimes brachial, access is required for simultaneous antegrade/retrograde access, and placement of balloons and stents. Both self-expanding or balloon expandable stents can be used, but the same type should be implanted in bilateral ostial iliac locations. However, certain lesions can be heavily calcific or heavily fibrotic in a way that may obviate the use of self-expanding stents because of their lower radial force; such cases are better targeted with balloon expandable stents. When a deep dissection or localized perforation is feared, a covered stent should be utilized.

Kissing stents should be deployed simultaneously, and extended 0.5–1.5 cm into the distal aorta. The covered endovascular reconstruction of aortic bifurcation (CERAB) technique uses three balloon expanded covered stents to reconstruct the aortic bifurcation for TASC-II C and D lesions.

Complications

Complication rate from the literature is 7–20% overall [9,10,15,25], with expectedly worse outcomes for more severe cases. A meta-analysis [14] reported overall mortality rate of 2.9% and morbidity rate of 15.3% for AIOD PCI (for TASC C and D lesions). Typical complications include groin hematomas, arteriovenous fistulas, pseudoaneurysms, and acute stent thrombosis (about 3% overall). Distal embolization from fragmentation of clot and atheroma occurs in up to 5% [9,10] and can be treated in most cases with aspiration thrombectomy using a long guiding catheter.

The most feared complication of AIOD PCI is iliac artery rupture, reported in 1.73% (range 0.2–3.4%) of patients [4,10]. Because of the high volume flow in the iliac segment (over 200 mL/minute at rest) and the surrounding potential space which can accommodate a large blood volume, catastrophic bleeding can occur rapidly if undiagnosed. Maintaining wire access and early detection is critical. A range of stent grafts should be maintained in the procedure suite for this purpose. In the interim, balloon tamponade should be performed using low pressure inflation of an angioplasty balloon, typically the same balloon that was used for angioplasty prior to rupture. Reversal of heparin with intravenous protamine sulfate (typically, 10 mg for every 1000 units heparin given, up to maximum of 50 mg protamine), blood transfusion, and ICU monitoring may be indicated.

For stent thrombosis, anticoagulant therapy regimens are essential, and comprise combinations of low molecular weight heparin until discharge from hospital, lifelong oral aspirin (81–325 mg/day), and clopidogrel 75 mg/day.

Open surgical repair studies report significantly higher rates of cardiac arrest, hematoma, blood transfusion requirements, respiratory complications, post operative infections, and seroma formation [2].

Conclusions

There is little doubt that in this day and age, AIOD can be managed through an endovascular approach because of comparable long-term results, a relatively low barrier to re-treatment even for

recurrent disease, and preservation of surgical option if all else fails. Primary stenting remains an area of some controversy because although medium-term results are good and somewhat better than angioplasty alone, the downside of leaving permanent metal behind should be weighed, especially for younger, active patients.

In the USA, peripheral arterial disease (PAD) affects 8–12 million people. Almost 20% of the population older than 70 years of age has signs or symptoms of PAD [1–3]. Intermittent claudication (IC), defined as pain in the muscles of the leg with ambulation, is the earliest and most frequent presenting symptom in patients with lower extremity PAD. As the disease progresses in severity patients experience pain at rest, especially when the legs are elevated in bed at night, which is relieved by dependency. Although claudication symptoms are typically localized in the calf or the thigh, “rest pain” is characteristically present in the foot. In the late stages of PAD, tissue hypoperfusion progresses to ischemic ulceration and gangrene, and major amputation is eventually required in more than one-third of these patients [4]. For patients with IC, approximately 20% have progressive symptoms and 1–2% develop critical limb ischemia (CLI) within 5 years with a 1-year mortality rate of about 20% in several series [5–7].

The femoral-popliteal segment is the most commonly involved compartment among atherosclerotic PAD [8] comprising around 60% of PAD lesions [9,10]. Femoral-popliteal lesions are usually long and have varying degrees of calcification with most of these lesions being TransAtlantic Inter-Society Consensus (TASC) C and D lesions [11,12]. Endovascular techniques and strategies have rapidly evolved over the past decade and have become the initial strategy for most femoral-popliteal lesions. Even in complex lesions, such as in patients who present with CLI, the endovascular approach is the preferred choice in most cases.

Endovascular interventions

The last few years have seen an increase in the use of percutaneous interventions for superficial femoral artery disease in the setting of symptomatic PAD. Proponents of endovascular therapy cite two contentions to justify continued use of these modalities. The first is that the decrease in durability is offset by the less invasive nature of endovascular interventions and resultant decrease in morbidity. The second reason is that it is infrequent for a patient to have clinical or angiographic worsening upon failure of an endovascular intervention and so interventions can be repeated if they fail [7].

The following endovascular techniques have been used for recanalization of the superficial femoral arteries:

- Balloon angioplasty (percutaneous transluminal angioplasty; PTA);
- Bare metal stents;
- Drug-eluting stent placement;
- Drug-eluting balloon angioplasty;
- Cryotherapy;
- Atherectomy.

Balloon angioplasty

The main advantages of balloon angioplasty (PTA) are its low complication rate of 0.5–4%, high technical success rates approaching 90% even in long occlusions (Figure 78.1a–d), and good clinical outcomes [11,13]. Conventionally, PTA has been the mainstay therapy for revascularization in aorto-iliac, femoro-popliteal, and below-the-knee arteries, and in many interventional centers PTA still is the first and most frequently used endovascular therapy [14].

Several trials have compared medical therapy, endovascular intervention, and surgery in symptomatic patients with disease in the superficial femoral artery (SFA). A meta-analysis that compared exercise therapy with PTA in patients with IC reported at 3 months’ follow-up, the ankle-brachial index (ABI) was significantly improved in the angioplasty group but not in the exercise group with similar quality of life outcomes [15]. A cost-effective analysis between endovascular therapy, PTA, surgery, and exercise alone showed that endovascular therapies were more effective than exercise alone, and the cost-effectiveness ratio was within the generally accepted range [16].

Despite advances in endovascular technologies, long-term patency rates of femoral-popliteal interventions are poor when compared with iliac interventions [17,18]. PTA of the SFA has a high rate of technical success, but target lesion revascularization (TLR) and target vessel revascularization (TVR) remains high at 30–80% at 6 months [19], especially in total occlusions and longer diseased segments. Failure rates can be as high as 70% at 1 year in long lesions [20,21].

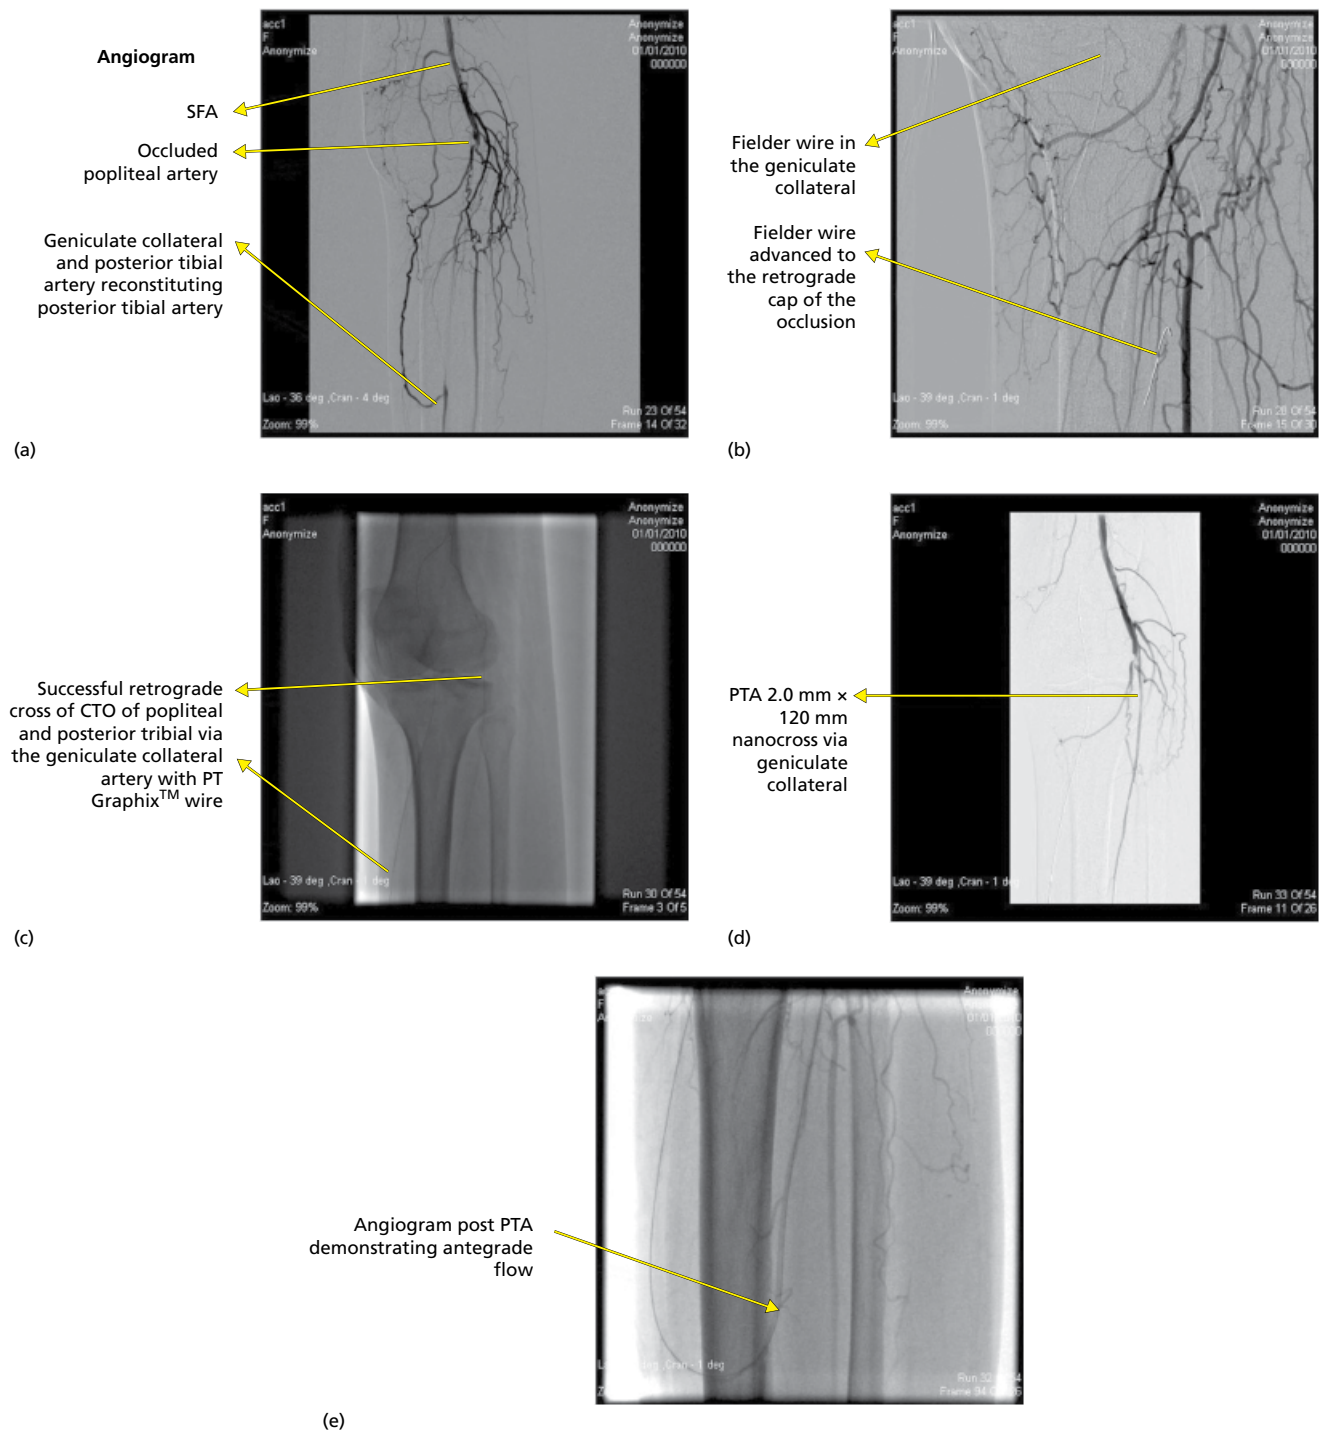

Figure 78.1 Percutaneous transluminal angioplasty (PTA) of occluded distal popliteal artery via infrapopliteal retrograde transc collateral approach: (a) occluded distal popliteal artery with reconstitution in the posterior tibialis artery; (b) 0.014-inch wire in the posterior tibialis artery via geniculate collaterals; (c) retrograde recanalization of distal popliteal artery; (d) PTA distal popliteal artery via retrograde approach; (e) post-PTA angiogram.

Moreover, there is no evidence to support the superiority of endovascular treatment over saphenous vein bypass for SFA disease. However, there is a single multicenter prospective randomized study, the Bypass Versus Angioplasty in Severe Ischemia of the Leg (BASIL) trial, which investigated the difference between angioplasty and open surgical repair for infrainguinal PAD and CLI in 452 patients and

concluded that there was no difference in the primary outcome of 6-month amputation-free survival between the two treatment modalities [22]. However, the updated results with 3- to 7-year follow-up showed that while bypass surgery using veins as conduits offered the best long-term amputation-free survival, balloon angioplasty appeared to be superior to a polytetrafluoroethylene bypass procedure [23].

Bare metal stents

Stent placement for femoral popliteal disease has gained progressive attention. However, there is no level 1 evidence for primary stenting in this segment. Several studies have shown mixed results, although the preponderance of the data do not support primary stenting in all cases. Stents avoid the problems of early elastic recoil, residual stenosis, and flow-limiting dissection after PTA and can thus be used for the treatment of long and complex lesions, even in heavily calcified arteries [17].

Several randomized controlled trials have compared PTA with self-expanding nitinol stents in femoral-popliteal segment. The Femoral Artery Stenting Trial (FAST) compared PTA with primary stenting in short superficial femoral lesions (<50 mm) and showed no statistically significant difference between the two treatment modalities in the primary endpoint of ultrasound-assessed binary restenosis at 12 months [18]. Moreover, no statistically significant differences were seen in TLR, improvement in resting ABI, and improvement by at least 1 Rutherford category of peripheral arterial disease.

For longer lesions (>50 mm) randomized trials of PTA versus primary stenting have shown the benefit of stenting over PTA. In the ABSOLUTE trial [17], 104 patients with severe claudication or chronic limb ischemia caused by stenosis or occlusion of the superficial femoral artery were randomly assigned to undergo primary stent implantation or angioplasty. The results revealed that at 6 months the rate of restenosis on angiography was 24% in the stent group and 43% in the angioplasty group ($p = 0.05$); at 12 months the rates on duplex ultrasonography were 37% and 63%, respectively ($p = 0.01$). Patients in the stent group were able to walk significantly further on a treadmill at 6 and 12 months than those in the angioplasty group. Data reported after 2 years sustained the morphologic benefit and showed a trend toward clinical benefit of stents for longer lesions [24]. In the RESLIENT trial, a total of 206 patients from 24 centers in the USA and Europe with obstructive lesions of the superficial femoral artery and proximal popliteal artery presenting with intermittent claudication were randomized to implantation of nitinol stents or PTA [25]. The mean total lesion length was 71 mm for the stent group and 64 mm for the angioplasty group. At 12 months, freedom from TLV was 87.3% for the stent group and 45.1% for the angioplasty group ($p < 0.0001$). Duplex ultrasound-derived primary patency at 12 months was better for the stent group (81.3% vs. 36.7%; $p < 0.0001$). In the 3-year follow-up, freedom from TLR at 3 years was significantly better in the stent group (75.5% vs. 41.8%; $p < 0.0001$), as was clinical success (63.2% vs. 17.9%; $p < 0.0001$) [26].

Drug-eluting stents

The proven efficacy of drug-coated stents in the treatment of coronary artery disease gave rise to the notion that they might have a better patency than bare-metal stent (BMS) in patients with PAD. Metallic stents with good radial strength obliterate recoil and manage dissections, but in-stent restenosis remains the Achilles heel, especially in patients with CLI and those with poor infrapopliteal arterial run-off [27,28]. The 12-month primary patency rates of BMS in the SFA range between 50% and 65% [29,30]. Other factors contributing to poor patency are stent fracture and vessel kinking at the adductor's canal and popliteal segment. The former is caused by internal and external rotation, compression and expansion; the latter is secondary to high flexion forces. With the advent of drug-eluting stents (DES) the panorama appears to be changing, although

the first multicenter randomized double blind trial of DES versus BMS, the Sirolimus-Coated Cordis Self-expandable Stent (SIROCCO), did not yield positive results, showing lack of significant difference in restenosis between groups [31]. The most recent Zilver PTX study demonstrated appreciable clinical efficacy in symptomatic femoropopliteal disease patients [32]. This study was a prospective, multinational, randomized controlled trial that compared the Zilver PTX stent with PTA and provisional BMS placement. Results showed that the primary DES group demonstrated significantly superior 2-year event-free survival (86.6% vs. 77.9%; $p = 0.02$) and primary patency (74.8% vs. 26.5%; $p < 0.01$). In addition, the provisional DES group exhibited superior 2-year primary patency compared with the provisional BMS group (83.4% vs. 64.1%; $p < 0.01$) and achieved higher sustained clinical benefit (83.9% vs. 68.4%; $p = 0.05$). Two-year freedom from TLR with primary DES placement was 80.5% in the single-arm study and 86.6% in the randomized controlled trial. However, the trial was criticized for treating only short lesions, thus not representing real-world experience.

Drug-eluting balloons

Drug-coated balloons (DCBs) are an attractive alternative to DES as they can deliver an antiproliferative agent, which ameliorates the process of neointimal proliferation and leaves no stent behind. There are three key features in the use of DCBs [33]. First, vessel preparation (PTA utilizing a non-coated undersized balloon) followed with a DCB to facilitate even distribution of the drug. Second, the antiproliferative preferred agent is paclitaxel, as it tends to stay in the local microenvironment, thus increasing its inhibitory effects on intimal cell proliferation. Third, the preferred delivery system is a hydrophilic spacer, which can deliver the drug in a very short time frame with minimal loss into the systemic circulation. Prolonged drug elution is not necessary to obtain sustained inhibition of intimal hyperplasia [34]. Nonetheless, delivery of the antiproliferative drug during the most active phase of neointimal proliferation should be enough to decrease restenosis.

Several trials have paved the way for the use of DCBs in PAD. The THUNDER trial (Local Taxane with Short Exposure for Reduction of Restenosis in Distal Arteries) was the first human trial of DCB in non-coronary arteries [35]. It was a multicenter study with a three-way randomization protocol consisting of 154 patients with severe disease or total occlusion of the femoropopliteal segment. The first group was treated with a paclitaxel-coated balloon, the second group was treated with a standard uncoated balloon and the third group was treated with an uncoated balloon with paclitaxel dissolved in iopromide contrast medium. The mean lesion length was 7.4 cm. The primary endpoint was 6-month angiographic late lumen loss (LLL). The paclitaxel-coated balloon group had a marked reduction in LLL (0.4 ± 1.2 mm vs. 1.7 ± 1.8 mm vs. 2.2 ± 1.6 mm; $p < 0.001$) when compared with the other two groups. TLR at 6 months was reduced in the paclitaxel-coated balloon when compared with the standard uncoated balloon (4% vs. 29%; $p = 0.001$). These favorable DCB effects were sustained at 24-month follow-up. Also, at 5 years, the decrease in LLL persisted [36]. However, TLR rates were not statistically different from the group of uncoated balloon with paclitaxel dissolved in contrast medium (4% vs. 29%; $p = 0.41$).

The FEMPAC (femoral paclitaxel) trial [37] randomized 87 patients in a 1 : 1 fashion between standard uncoated balloon and paclitaxel-coated balloon. Femoropopliteal lesions were short in

length (5.7 vs. 6.1 cm). Results were similar to THUNDER trial. At 6-month follow-up, the primary endpoint of LLL was significantly lower in the DCB group (0.5 ± 1.1 mm versus 1.0 ± 1.1 mm; $p = 0.031$). Similarly, TLR rates were lower in the DCB group (6.7% vs. 33%; $p = 0.002$). These results were sustained at 18 months. There was significant improvement in Rutherford class, but there was no significant difference in ABI. These multicenter trials were limited to relatively short, non-complex femoropopliteal lesions, heterogeneous study subjects, unconventional endpoints, angiographic follow-up limited to only 6 months, and small sample sizes.

The Lutonix Paclitaxel-Coated Balloon for the Prevention of Femoropopliteal Restenosis (LEVANT 1) trial [38] was a prospective, multicenter, randomized study, which evaluated the safety of paclitaxel-coated MOXY balloon. A total of 101 patients with de novo and restenotic femoropopliteal lesions with CLI were randomized to paclitaxel-coated balloon (49 patients) or standard uncoated balloon (52 patients). The lesion lengths were 80.8 and 80.2 mm (varied from 4 to 15 cm). The primary endpoint of LLL at 6 months was significantly lower in the DCB group (0.46 vs. 1.09 mm; $p = 0.016$). In subgroup analysis, the DCB group showed significant reduction in LLL when compared with those patients who underwent PTA with an uncoated balloon. Also, the DCB group continued to demonstrate a reduction in LLL when compared with those patients who underwent stenting (26 patients) because of failed PTA (however, the trial was underpowered to conclude that there is a statistical difference between the stent and DCB groups). Composite 24-month major adverse events were lower in the DCB group (39%) than the non-DCB group (46%). These trials demonstrated that incomplete balloon expansion and geographic miss resulted in a significant decrease in primary patency and TLR rates at 12 months [39].

The Paclitaxel-coated Balloons in Femoral Indication to Defeat Restenosis (PACIFIER) trial [40] was a prospective, multicenter, randomized controlled single-blinded study, which enrolled 85 patients with 91 femoropopliteal lesions (44 were treated with the In.Pact Pacific DCB and 47 with standard uncoated balloon). The mean lesion length was 70 mm in the DCB group and 66 mm in the standard uncoated balloon group. The study met its primary endpoint (reduction in LLL at 6 months) where the In.Pact Pacific DCB balloon group had significant reduction in LLL at 6 months (-0.01 vs. 0.65 mm; $p = 0.0014$). Also, the DCB group had better TLR rates at 6 months (7.3% versus 22%; $p = 0.06$). In a subgroup analysis, the benefits of DCB with regards to LLL were seen irrespective of the lesion type or its length. At 12 months, the DCB group had fewer adverse events (death, amputation, or TLR) than the standard uncoated balloon group (7.1% vs. 34.9%; $p = 0.003$). A meta-analysis [41] of the THUNDER, FEMPAC, LEVANT I, and PACIFIER trials showed improved results with DCBs at a median follow-up of 10.3 months (significant reduction in TLR, LLL, and angiographic restenosis without an increase in adverse events).

Some of the more recent trials such as IN.PACT SFA I (European arm) and II (US arm) [42] are ongoing multicenter randomized studies. These trials intend to assess the safety and efficacy of the Admiral DCB in femoropopliteal lesions. Preliminary 12 month results of 331 patients randomized in a 2 : 1 fashion (220 in the DCB group and 111 in the standard balloon PTA group) across Europe (150 patients) and the USA (181 patients) showed that the DCB group did better ($p < 0.001$) than the standard uncoated balloon group in terms of primary patency (82.2% vs. 52.4%; primary endpoint), clinically driven TLR (2.4% vs. 20.6%), primary sustained clinical improvement (upgrade in Rutherford classification ≥ 1 class

in amputation- and TVR-free surviving patients), primary safety endpoint (freedom from 30-day device- and procedure-related death, target limb major amputation, and clinically driven TVR through 12 months), and MACE (death, clinically driven TVR, target limb major amputation, and thrombosis). The Drug-Eluting Balloon Evaluation for Lower Limb Multilevel Treatment (DEBELLUM) study [43] was a prospective, randomized, single center study that enrolled 50 patients with femoropopliteal (75.4%) and below-the-knee lesions. Twenty-five patients were randomized to be treated with the In.Pact Admiral DCB and 25 patients to be treated with a standard uncoated balloon. LLL at 6 months was better in the DCB group than in the standard uncoated balloon group. BIOLUX P-I was an international, multicenter, randomized controlled trial [44] that evaluated the safety and efficacy of the Paseo-18 Lux paclitaxel-coated balloon (30 patients) compared with standard uncoated balloon (30 patients). The DCB group showed a significant reduction in LLL when compared with the standard uncoated balloon group at 6 months. The overall major adverse event rate did not differ in both groups. The DCB group showed a slightly better outcome with regards to Rutherford class. The DEFINITIVE AR study was a European multicenter, prospective, randomized trial that evaluated the effectiveness of DCBs in heavily calcified lesions. Patients were randomized to directional atherectomy followed by paclitaxel-coated Cotavance balloon versus paclitaxel-coated Cotavance balloon alone. The 30-day preliminary results [45] showed significant higher technical success in the directional atherectomy followed by paclitaxel-coated Cotavance balloon arm than the paclitaxel-coated Cotavance balloon alone.

Cryotherapy

Cryoplasty therapy (cold balloon angioplasty) has been used as an effective primary strategy for limiting the incidence of dissection, vessel recoil, and subsequent intimal hyperplasia and restenosis associated with the endovascular dilatation of atherosclerotic lesions in the peripheral vasculature [46–50]. Specialized cryoplasty balloon catheters, approved by the US Food and Drug Administration (FDA), are inflated not with the standard mixture of saline solution and contrast medium but rather with nitrous oxide, which causes the plaque in the artery to freeze at -10°C . Previous scientific studies have shown that this process results in weakening of the plaque, uniform vessel dilatation, alteration of elastin fibers to reduce vessel wall recoil while collagen fibers remain unperturbed and capable of maintaining architectural integrity [51,52], and induction of smooth muscle cell apoptosis which is associated with reduced neointima formation and reduced subsequent restenosis [53].

Studies involving cryoplasty have conflicting results with patency rates and need for re-intervention. Diaz *et al.* [54], in a 3-year analysis of re-intervention-free survival between cryoplasty versus conventional angioplasty in femoropopliteal arterial recanalization, demonstrated good immediate success rates with lower stent placement rates. However, during the 3-year follow-up, patency rates tended to equalize between the two modalities. A multicenter registry of 102 patients demonstrated a high degree of acute angiographic success with a low frequency of TLR. The patency rate observed compared favorably with that previously documented with conventional angioplasty [50]. The COBRA trial was a prospective, multicenter, randomized controlled clinical trial of diabetic patients to investigate whether post-dilatation of superficial femoral artery nitinol self-expanding stents using a cryoplasty

balloon reduces restenosis compared to a conventional balloon. The key finding of this study was that, for patients with diabetes mellitus who underwent SFA stenting using self-expanding stents, post-dilatation using cryoplasty significantly reduced the 12-month in-stent restenosis rates compared to post-dilatation using a conventional balloon [55]. However, the benefit of cryoplasty over conventional angioplasty cannot be established, as the number of randomized controlled trials is small.

Atherectomy

Atherectomy devices are designed to debulk and remove atherosclerotic plaque by cutting, pulverizing, or shaving with catheter-deliverable blades. The development of the SilverHawk excisional atherectomy catheter (EV3, Minneapolis, MN, USA) has renewed interest in directional atherectomy, a technique that has historically been associated with high restenosis rates in the coronary and peripheral vasculature [56,57]. Like the excimer laser, excisional atherectomy offers the theoretical advantage, compared to PTA and stent implantation, of eliminating stretch injury on arterial walls, limiting acute dissection (and the need for adjunctive stenting) and elastic recoil, and thereby potentially reducing post-procedure inflammation and the rate of restenosis. Both rotational and orbital atherectomy share a niche on calcific lesions. Excimer laser has gained FDA approval for femoropopliteal in-stent restenosis (ISR) [58].

Directional atherectomy

Directional atherectomy involves the resection of the atherosclerotic plaque with a cutting device in the longitudinal plane [59]. Two devices are approved by the FDA for directional atherectomy: the SilverHawk™ (Covidien, Plymouth MN, USA) and the TurboHawk™ (Covidien, Plymouth MN, USA). The recent published DEFINITIVE LE trial is the largest multicenter study that evaluated the intermediate and long-term effectiveness of stand-alone SilverHawk™/TurboHawk™ Plaque Excision Systems for endovascular treatment of PAD in the femoropopliteal and tibial-peroneal arteries [60]. Its primary endpoints were patency at 1 year in claudicants and freedom of unplanned amputation at 1 year in CLI patients. A total of 800 patients were studied. More than half were diabetic and 66% of the lesions were located in the femoropopliteal segment. Final results revealed 78% patency rate in all claudicants and 71% in CLI patients with a 95% of freedom of amputation. The major limitations of the trial were lack of randomization and follow-up after 12 months.

Rotational atherectomy

The Pathway PV system (Pathway Medical, Kirkland, WA, USA) has a unique feature compared to other rotational atherectomy devices. The ability to remove the atherectomized plaque material through aspiration ports reduces the risk of obstructing the microvasculature and avoids increasing erythrocyte degradation products, especially in patients with impaired renal function. High-speed rotational devices without aspiration capabilities increase these degradation products, such as haptoglobin and potassium, which can result in life-threatening cardiac arrhythmias [61]. Additionally, the aspiration feature of the catheter allows the device to be used in lesions containing both occlusive material, including solid, even calcified plaque and fresh thrombus. Potentially, the Pathway PV can be used as a thrombectomy device in subacute and acute vessel occlusions.

Zeller *et al.* [62] reported results on a prospective non-randomized multicenter trial using a rotational atherectomy system with

aspiration capabilities. In this study, a 99% technical success rate was achieved using the Pathway PV Atherectomy System in 210 infra-inguinal cases. Adjunctive balloon angioplasty was performed in 59% and stenting in 7%. Primary and secondary patency rates at 1 year were 61.8% and 81.3%. The 1-year limb salvage rate was 100%. These patency rates are similar to SilverHawk study cohorts.

Orbital atherectomy

The Diamondback 360° Orbital atherectomy System (CSI, St. Paul, MN, USA) uses a plaque ablation catheter. This has an abrasive eccentrically shaped crown with a diamond-coated surface which rotates and creates lumen enlargement by plaque abrasion. Orbital atherectomy appears to have some similarities to mechanical rotational atherectomy (Rotablator) (Boston Scientific, Natick, MA, USA).

Analysis of the CONFIRM registries found that high rates of success in subjects with PAD were equally favorable in men and women. Overall final residual stenosis in the CONFIRM registries was 10% and was actually lower in female patients than in male patients. These findings are in agreement with the OASIS trial, a multicenter, prospective, non-randomized registry of 124 patients (33% women) who underwent orbital atherectomy for the treatment of infrapopliteal lesions. The OASIS trial demonstrated a high success rate (90.1% patients had final diameter stenosis \leq 30%) and a low rate of major adverse events at 6 months (10.4%) [63]. Korabathina *et al.* [64] enrolled 98 patients (54% women) in a single-arm registry database of patients with infra-inguinal lesions treated with OAS. They showed a low rate of major adverse events at 30 days (2.2%) and an overall favorable safety profile.

Excimer laser-assisted angioplasty

Continuous wave laser were evaluated and abandoned for peripheral interventions in the late 1980s because of the high complication rate caused by thermal damage to surrounding tissue [65]. In contrast, excimer laser angioplasty (ELA) of the leg arteries has been used commercially in Europe since 1994 [66]. The 308 nm excimer laser utilizes flexible fiber optic catheters to deliver intense short duration pulses of ultraviolet (UV) energy. The advantages of pulsed UV energy lies in the short penetration depth of 50 μ m and its ability to break molecular bonds directly by a photochemical process, instead of a thermal one. Excimer laser catheters remove a tissue layer of about 10 μ m with each pulse of energy. Tissue is vaporized only on contact without a consequent rise in temperature to surrounding tissue.

The multicenter Laser Atherectomy for Critical Ischemia (LACI) trial of excimer laser-assisted angioplasty treated 423 lesions (41% SFA, 15% popliteal, 41% infrapopliteal) in 155 limbs (91% with at least one occlusion) of 145 patients with CLI (Rutherford categories 4–6, 69% with tissue loss, 66% diabetics) who were determined to be poor candidates for surgical revascularization. Procedural success (defined as $<$ 50% residual stenosis in all treated lesions) was achieved in 85% of the treated limbs [67,68]. The median total length of treated artery per limb was 11.0 cm. Procedural complications in 12% of the treated limbs included major dissection (4%), acute thrombus formation (3%), distal embolization (3%), and perforation (2%). The excimer procedure was followed with adjunctive balloon angioplasty in 96% of the limbs. Stents (mainly bare nitinol) were placed adjunctively in 61% of the SFA lesions, 38% of the popliteal lesions, and 16% of the tibial lesions. Mean lesion stenosis (by visual estimate) was decreased from 92% at baseline to 55% after laser debulking and to 18% at final assessment. At 6-month follow-up, limb salvage was achieved in 110 (92%) of 119 surviving patients

(118 of 127 limbs; 93%); 56% of ischemic ulcers had healed completely [67]. Despite treating a very unfavorable patient cohort, excimer laser assisted angioplasty achieved limb salvage comparable to the gold standard of bypass surgery. Following the LACI protocol, a single-center US registry and a five-center Belgian trial achieved comparable outcomes with the device [69,70].

More recently, the EXCITE ISR study is the first trial conducted under an IDE to support to gain FDA indication for femoropopliteal ISR. The trial was stopped at 250 enrolled patients after successful primary endpoint analysis. ELA + PTA demonstrated better procedural success with a significant reduction in procedural complications and post-treatment stenosis than PTA alone. The primary safety and efficacy endpoints established superiority of ELA + PTA compared to PTA alone [58].

The future

Finally, the concept of biodegradable stents is promising and enticing. The fact that we can achieve the delivery of the antiproliferative drug, prevent acute recoil and negative remodeling with the disappearance of the stent when the process of neointimal proliferation halts is an attractive concept. Recently, a multicenter, non-randomized registry evaluating the efficacy and safety of a biodegradable (REMEDY) stent demonstrated a primary patency of 71% and TLR of 22% [71].

Popliteal Artery Interventions

Karthik Gujja¹, Gopi Punukollu², Vishal Kapur¹, and Prakash Krishnan¹

¹The Zena and Michael A. Weiner Cardiovascular Institute, Icahn School of Medicine at Mount Sinai, New York, NY, USA

²Lenox Hill Hospital (North Shore LIJ), New York, NY, USA

Peripheral arterial disease (PAD) is defined as an obstructive arterial disease of the lower extremities that reduces arterial flow during exercise or, in advanced stages, at rest [1]. It affects 8–12 million people in the USA with many of these cases related to popliteal artery (PA) occlusive disease. As superficial femoral artery (SFA) and PA diseases are often grouped together in medical literature, the number of PAD cases involving just the PA is unknown [2]. PAD is one of the major manifestations of systemic atherosclerosis, advancing to critical limb ischemia (CLI) in 1–2% of patients with PAD who are 50 years of age or older [3]. CLI is a complex, multifactorial disease leading to a high risk of morbidity and mortality. The American College of Cardiology/American Heart Association (ACC/AHA) practice guidelines suggest that patients with CLI have a 25% 1-year cardiovascular mortality, a 25% 1-year amputation rate, and a 50% rate of being alive with two limbs 1 year after diagnosis [3]. Duplex ultrasound is valuable in determining candidates for intervention with the ankle-brachial systolic pressure index (ABI) being 95% sensitive and almost 100% specific for PAD [1]. An ABI of less than 0.4 correlates to a 5-year survival of only 44% compared with 90% for those patients with an ABI greater than 0.85 [1]. CLI involving the PA is a situation that requires prompt diagnosis and treatment to preserve the ischemic limb by establishing inflow to the tibial and the pedal vessels. More than 100,000 peripheral arterial reconstructive operations and 50,000 lower limb amputations for lower extremity ischemia are performed in the USA each year [3,4].

Interventions for popliteal artery disease

Patients with PAD often have multiple medical comorbidities requiring an array of drugs, conservative management, and invasive therapies. If the patient is a surgical candidate and there is sufficient venous conduit, surgical bypass with autogenous veins has historically been the first-line revascularization therapy involving the middle and the distal PA [2]. According to the most recently released TASC II recommendations, lesions involving either the PA or common femoral artery are classified as class D lesions and are strongly recommended for surgery [5]. However, open surgery is not always possible because of prohibiting comorbidities, unsuitable venous conduit, or lack of an adequate distal artery for revascularization [6]. The use of “minimally” invasive endovascular therapies as

surgical alternatives has opened up a new realm of treatments for PA lesions and the patency and long-term clinical outcomes from these endovascular treatments must be considered [2].

Balloon angioplasty

Several options exist for minimally invasive therapy of arterial lesions with balloon angioplasty (PTA), with or without stenting, being the most widely accepted endovascular option with high patency rates and low levels of restenosis [7]. PTA of PA lesions is effective at acutely restoring flow but restenosis occurs in 40–60% of patients within 1 year, leading to therapeutic failure and reintervention [8]. Drug-coated balloon (DCB) have been developed to increase the patency of PA angioplasty and reduce restenosis, thereby decreasing the need for reintervention in comparison with traditional PTA [9]. The IN.PACT SFA trial was a prospective, multicenter, single-blinded, randomized controlled trial assessing the safety and efficacy of the IN.PACT Admiral DCB. It showed significantly better patency (82.2%) at 12 months when compared with traditional PTA (52.4%) [9]. These outcomes are in concordance with multiple other trials showing a favorable primary patency of DCB versus PTA at 1 and 2 years [8,10,11]. The Micari *et al.* [10] multicenter registry showed a patency of 83.7% at 1 year and 72.4% at 2 years. The LEVANT 1 trial showed a DCB primary patency of 67% at 1 year and 57% at 2 years when compared with PTA [8]. The ILLUMINATE trial showed the Stellarex DCB primary patency of 89.5% at 1 year and 80.3% at 2 years (Figure 79.1) [11].

Stenting

Overall, stenting is not routinely performed in PA PAD because of the anatomic location of the PA and the fact that it is not contained within a muscular compartment which leaves it exposed to compression, torsion, and elongation [4,12]. The mobility of the knee joint further presents the potential for external stent fractures, which are associated with stent restenosis or re-occlusions in about two-thirds of cases [12,13]. Stenting was first introduced to femoropopliteal occlusive therapy when balloon expandable stainless steel stents were used to treat short lesions [14]. Then the application of self-expanding nitinol technology added to treatment options with better patency rates in longer lesions compared with

Figure 79.1 The 1- and 2-year primary patency rates reported in first-in-human studies for various paclitaxel drug-coated balloons [8,10,11].

earlier metal stents but restenosis remained a major issue [14]. A meta-analysis review was completed by Mwipatayi *et al.* [15] to compare the short- and long-term results of primary stenting and angioplasty of femoropopliteal occlusive disease. In the stent implantation group, the 12 month primary patency rates varied from 63% to 90%, and 24 month primary patency ranged from 46% to 87% [15]. The 12 month primary patency rates following balloon angioplasty alone ranged from 45% to 84.2% and at 24 months it varied from 25% to 77.2% [15]. These results and that of various other trials suggest that stent placement in the femoropopliteal occlusive disease has some limitations and more research needs to be done to determine the patency rate when compared with angioplasty alone [14–18]. A recent randomized, multicenter trial, the Endovascular Treatment of Atherosclerotic Popliteal Artery Lesions–Balloon Angioplasty Versus Primary Stenting (ETAP) study, investigated the 1- and 2-year results of primary nitinol stent placement in comparison with PTA in true PA lesions beyond the proximal (P1) segment [19,20]. ETAP revealed equivalent patency at 1 year and possibility of a shift toward higher patency rates in favor of primary stenting at 2 years [18–20].

More promising results have been seen with the development of the Supera helical interwoven nitinol stent which has superior radial strength, fracture resistance, and flexibility when compared with the traditional laser-cut nitinol stents [13]. In a single-center study PA stenting with the Supera@ system proved to be safe and effective, with high patency rates and no stent fractures [13,21]. The primary stent patency rates at 6 and 12 months were $94.6 \pm 2.3\%$ and $87.7 \pm 3.7\%$, respectively [21]. Despite the challenging clinical conditions of PA occlusive disease, a good clinical effect of treatment with the Supera@ stent has also been demonstrated with the ABI increasing from 0.58 ± 0.16 preoperative to 0.87 ± 0.14 postoperative [21,22].

Stent placement still remains controversial; however, as drug-eluting technology is becoming more popular the potential for successful use of drug-eluting stents (DES) in the treatment of femoropopliteal artery disease exists although data are limited regarding this. In the Zilver PTX randomized trial DES were

suggested to increase the patency of lesions and reduce the risk of restenosis [2]. The Zilver PTX trial has added to our knowledge of DES with the outcome being a 83.1% primary patency at 12 months with the use of paclitaxel-eluting stents in comparison with standard balloon angioplasty and bare metal stents in femoropopliteal disease [23]. The 2-year follow-up from the Silver PTX trial further supported the safety and effectiveness of paclitaxel-eluting stents in patients with femoropopliteal artery disease, including the long-term superiority of the DES to PTA and to provisional BMS placement [24]. The 2-year primary patency rate was 74.8% for the primary DES group and 26.5% for the long-term PTA subgroup [24]. These data are encouraging and have shown great potential with the opportunity for more studies comparing endovascular interventions in the treatment of PAD.

Adjunctive endovascular technologies

Emerging adjunctive therapies or alternatives to traditional PTA aim to prevent restenosis and include atherectomy to remove atherosclerotic plaque by debulking; brachytherapy to inhibit cellular proliferation by using ionizing radiation; and cryoplasty to induce smooth cell apoptosis and reduce intimal dissection/damage by cold-induced alteration of the arteriosclerotic plaque [4,25]. These and other technologic advancements are rapidly emerging and outpacing clinical trial data to support their efficacy [4]. These technologies may prove a potential solution to the problem of long-term patency and restenosis of femoropopliteal disease following PTA. The 3-year primary patency rates have been reported as a low 50% for PTA and first-generation stents [26].

Atherectomy

The mechanical atherectomy devices are designed to improve the vessel lumen and flow by debulking and removing atherosclerotic plaque with a rotating blade that captures the plaque in a catheter housing and requires intermittent emptying [2]. Currently available technologies for this therapy include orbital, laser, directional, and rotational atherectomy. The benefit of these atherectomy devices is potential avoidance of trauma to the vessel wall such as tears and stretches caused by popliteal artery PTA [27]. The study by Semaan *et al.* [28] compared atherectomy with angioplasty alone in the popliteal artery lesions and found a higher technical success rate with atherectomy. However, there are complications with all these debulking technologies including an increased distal embolization rate when compared with traditional PTA, which has the low rate of less than 1% embolization [26]. A large prospective registry of 1029 patients evaluated the embolization rate during percutaneous lower extremity interventions of 2137 lesions and found the overall embolization rate to be 1.6% with the Jetstream and Diamondback atherectomy devices having a 22% rate, the Silverhawk atherectomy device having a 1.9% rate, and laser atherectomy having a 3.6% embolic rate [26]. More large randomized controlled trials are needed to identify if atherectomy will be a benefit over standard PTA with or without stenting (Figure 79.2) [4].

Popliteal aneurysms

A popliteal aneurysm is the dilatation of the popliteal artery to a diameter of 1.5 cm or 1.5 times the size of the normal proximal artery which results in weakness of the artery [29,30]. The aneurysm progressively dilates and if left untreated it increases the risk

Figure 79.2 (a) Left popliteal artery chronic total occlusion. (b) Left popliteal artery post-intervention (post-atherectomy and PTA).

of thrombosis or embolization leading to CLI with an amputation rate of around 15% [31,32]. Although rare in the general population, occurring at an incidence of less than 0.1%, they are the second most common peripheral aneurysm at about 70% [33]. Popliteal artery aneurysms (PAAs) are more common in men than women (20 : 1 ratio), the incidence increases with age, and approximately half are bilateral [30].

The goal of PAA repair is to eliminate the aneurysm from the circulation to maintain perfusion to the lower extremity. Symptomatic patients can present with claudication and the consensus is that all symptomatic PAAs should be repaired regardless of size [30]. Asymptomatic PAAs are recommended to be treated if the aneurysm diameter is greater than 2 cm, mural thrombus is present, or the patient has poor runoff [30]. The current gold standard of PAA repair is saphenous vein bypass grafting either via open surgery or endovascular approach [30,32]. Open surgical repair is by various operation techniques with the two most popular approaches being the medial approach where the patient is supine and the posterior approach where the patient is in prone position [30]. Both approaches provide comparable results concerning primary patency rates and open surgical repair delivers reproducible therapeutic success [32]. Open surgery for PAAs is marked by low perioperative mortality and morbidity and provides excellent long-term results [34].

Endovascular techniques have been increasingly used with the rationale of low complication rates, shortened length of hospital stay, and long-term patency rates presumed similar to those following open surgical repair; however, current evidence is lacking prospective randomized trials [35–39]. A high standard for endovascular popliteal aneurysm repair (EPAR) has been found to match open popliteal aneurysm repair (OPAR) procedures in which the primary patency rate was 90% with a freedom from reintervention rate of 70% at 10 postoperative years (Figure 79.3) [34]. However, a non-randomized multicentered study found relatively equivalent primary patency rates (73% for EPAR, 64% for OPAR) and freedom from reintervention rates (75% and 72%, respectively) at a mean

Figure 79.3 (a) Left popliteal artery aneurysm. (b) Left popliteal artery stent (resolved aneurysm post-stent).

surveillance period of 31 ± 28 months [38]. Further, the largest meta-analysis on this topic to date is based on 652 cases and the results suggest that patient outcomes after endovascular repair are equal to open surgical repair, and that endovascular technique appears to be a viable alternative to open surgery [39]. EPAR appears to be safe and efficient when compared with OPAR; nevertheless, current evidence on endovascular repair is limited and further research is necessary to draw firm conclusions [39]. The greatest benefit of endovascular stent grafting is for patients with high preoperative risk for surgery and multiple medical comorbidities [37]. The definitive evidence on the comparison of endovascular repair with open surgical repair of popliteal artery aneurysms remains inconclusive (Figure 79.4) [34–39].

Figure 79.4 (a) Left popliteal artery focal aneurysm (prior vein patch aneurysm). (b) Left popliteal artery stent (resolved aneurysm post-stent).

Conclusions

As the population ages, it is anticipated that the prevalence of peripheral vascular disease will increase. Endovascular therapies are improving the safety and effectiveness of percutaneous revascularization in the treatment of PAD with a high success rate; however, long femoropopliteal lesions still represent one of the major challenges of endovascular therapy [6]. The use of endovascular repair increased more than threefold, bypass surgery decreased 42%, and the amputation rate decreased by 29% [18]. Today, most interventionalists treat PA disease with PTA when there is clear indication and, when possible, surgical bypass as the gold standard [2]. Percutaneous procedures and new technologic advancements such as DEB, DES, and atherectomy devices continue to replace open surgery with the challenge being to ensure relevant studies are being carried out to collect definitive data to support these therapeutic measures in the treatment and prevention of PAD [2]. Further, cost-effectiveness data must be considered to accommodate economic considerations and provide cost conscious care while avoiding limb amputation and mortality.

Below the Knee Interventions in Critical Limb Ischemia

Karthik Gujja, Katarzyna Nasiadko, Arthur Tarricone, and Prakash Krishnan

Icahn School of Medicine at Mount Sinai, New York, NY, USA

Background

Peripheral arterial disease (PAD) of the lower extremities is one of the major manifestations of systemic atherosclerosis affecting 8–12 million people. The disorder affects both men and women equally with the risk of PAD increasing two- to threefold for every 10-year increase in age after 40 years and is highly associated with cardiovascular risk factors such as cigarette smoking, diabetes mellitus, hyperlipidemia, and hypertension [1]. The two most important risk factors are diabetes mellitus and smoking, each being associated with a three- to fourfold increase in the risk for PAD [1].

The Rutherford classification is the current industry standard for reports dealing with severity of PAD with categories 4–6 characterizing critical limb ischemia (CLI) on the basis of persistent rest pain with or without ongoing degree of tissue loss in the presence of PAD (Table 80.1) [2].

CLI represents the most severe clinical manifestation of lower extremity PAD and is defined as “greater than 2 weeks of rest pain, ulcers, or tissue loss attributed to arterial occlusive disease” [3]. CLI occurs when arterial lesions impair blood flow to such an extent that the nutritive requirements of the tissues cannot be met. Multiple tests have been devised to confirm the diagnosis of CLI, assess foot perfusion, and predict wound healing (Box 80.1) [3]. The diagnosis of CLI can be confirmed with measurement of an ankle-brachial index (ABI) or toe systolic pressure, with an ankle pressure of ≤ 50 mmHg or a toe pressure of ≤ 30 mmHg suggesting CLI.

CLI develops in approximately 1% of patients with PAD each year and is expected to grow in developed countries as the prevalence of diabetes increases with the World Health Organization (WHO) projecting that diabetes will be the seventh leading cause of death by 2030. Patients diagnosed with CLI have a high cardiovascular morbidity and mortality, high risk of major amputation, and experience poor physical function and quality of life [4]. The goals of treatment for CLI are relieving ischemic pain, healing ulcers, preventing limb loss, improving patient function and quality of life, and prolonging survival [4]. Prompt surgical or endovascular revascularization to achieve a straight-line flow to the foot to promote wound healing is currently recommended for limb salvage in CLI, as “nearly 40% of patients with CLI will progress to amputation within 6 months in the absence of revascularization” [5]. Partial revascularization of iliac or femoropopliteal arteries alone is usually insufficient to heal advanced leg ulcers or gangrene.

Evaluation of the lower extremity arterial system

To assess the lower extremity arteries, it is necessary to understand the arterial anatomy of the lower extremity. The clinician must know the branches of the lower extremity arterial system and the areas of the limb they supply. The angiosome concept highlights five distinct three-dimensional blocks of tissue fed by source arteries and that guiding revascularization to the wound site by restoring flow to the corresponding ischemic angiosome improves wound healing and higher amputation-free rates (Figure 80.1) [6].

To identify the ischemic area and anatomically characterize the disease, non-invasive imaging with duplex ultrasonography, computed tomography angiography (CTA), or magnetic resonance angiography (MRA) can be utilized to help determine the interventional options [5]. Further, potency of the iliac and common femoral arteries is of practical importance because it will determine whether the optimal strategy is via an ipsilateral antegrade or contralateral retrograde common femoral approach [7].

The choice of preprocedural imaging depends on the patient and is based on the advantages and disadvantages of each particular method. The evaluating physician should be fully aware of all revascularization options to select the most appropriate intervention that takes into consideration the goals of therapy, risk–benefits ratios, patient comorbidities, and life expectancy [8]. Box 80.2 lists indications and contraindications of endovascular management for below-the-knee (BTK) arterial occlusive disease [7]. For some patients, primary amputation is the only option.

Approach to BTK intervention

To standardize evaluation of the extent of disease in the lower extremity vessels, a working group was created to devise a classification scheme based on anatomic extent, morphologic assessment, and location of lesions within the vascular system. This group, comprising experts from the USA and Europe, developed the Transatlantic Inter-Society Consensus (TASC) classification strategy and made recommendations regarding appropriate management and therapy for different lesions [1]. The recommendations vary by the location and extent of the lesion (Box 80.3) [7].

Generally, in BTK or infrapopliteal (IP) lesions classified as TASC A or B, endovascular revascularization is preferred, while in

Table 80.1 Rutherford classification of peripheral artery disease and critical limb ischemia [2].

Grade	Category	Clinical description	Objective description
	0	Asymptomatic	Normal treadmill or reactive hyperemia test
I	1	Mild intermittent claudication	Treadmill exercise limited to 5 min; ankle pressure after exercise >50 mmHg but at least 20 mmHg lower than at rest
I	2	Moderate intermittent claudication	Between Rutherford 1 and 3 disease
I	3	Severe intermittent claudication	Treadmill exercise limited to <5 min; ankle pressure after exercise <50 mmHg
II	4	Ischemic rest pain	Resting ankle pressure <40 mmHg and/or great toe pressure <30 mmHg; pulse volume recording barely pulsatile or flat
III	5	Minor tissue loss: non healing ulcer, focal gangrene with diffuse pedal ischemia	Resting ankle pressure <60 mmHg and/or great toe pressure <30 mmHg; pulse volume recording barely pulsatile or flat
III	6	Major tissue loss: extending above transmetatarsal level, functional foot no longer salvageable	Resting ankle pressure <60 mmHg and/or great toe pressure <30 mmHg; pulse volume recording barely pulsatile or flat

Box 80.1 Features of critical limb ischemia [3]

Physical examination

- Dry skin, thickened nails, loss of hair, loss of subcutaneous fat or muscle atrophy
- Coolness to palpation
- Decreased or absent pulses
- Elevation pallor or dependent rubor
- Non-healing wound or ulcer, especially over bony prominences, distally, and on the plantar surface of the foot

Non-invasive vascular laboratory

- Ankle-brachial index ≤ 0.4
- Ankle systolic pressure ≤ 50 mmHg
- Toe systolic pressure ≤ 30 mmHg
- Measures of skin microcirculation
- Capillary density ≤ 20 mm²
- Absent reactive hyperemia on capillary microscopy
- TcPO₂ <10 mmHg

TASC D lesions, surgical vein bypass is recommended. In TASC C lesions, surgical revascularization is the preferred treatment in good-risk patients while considering the patient's comorbidities and preferences, as well as the operator's success rates. However, in the absence of a suitable vein and/or adequate distal runoff vessels, and in high-risk surgical patients, endovascular treatment represents the only valid therapeutic option of CLI [7].

There is no level I evidence to support the superiority of endovascular treatment over saphenous vein bypass for infrainguinal or IP disease. However, a multicenter prospective randomized study, the Bypass Versus Angioplasty in Severe Ischemia of the Leg (BASIL) trial, investigated the difference between endovascular (balloon angioplasty) and open surgical treatment for infrainguinal PAD and CLI. The study randomized 452 patients with severe limb ischemia to surgical bypass first or angioplasty-first strategy. The BASIL trial indicated that patients presenting with CLI caused by infrainguinal atherosclerosis who are suitable for both treatments could be treated with either method with no difference in the primary outcome of

6-month amputation-free survival between the two treatment modalities [9]. Angioplasty alone was clinically equivalent to the "gold standard" of surgical bypass in the treatment of CLI, unless the individual's life expectancy was greater than 2 years [10]. The updated results with 3–7 year follow-up concluded that bypass surgery with vein offers the best long-term amputation-free survival, but balloon angioplasty appears to be superior to a polytetrafluoroethylene bypass procedure (Figure 80.2). The most recent American College of Cardiology/American Heart Association (ACC/AHA) guidelines for the management of PAD are consistent with recommendations made by the BASIL trial investigators (Box 80.4) [11]. Overall, an individualized approach is the best treatment strategy and most specialists initially pursue an endovascular intervention if it seems feasible. This is because bypass surgery is associated with greater mortality and morbidity, with the potential for hospital readmission, prolonged ulcer healing, wound complications, and graft failure leading to reoperation [2]. In a study that used the National Surgical Quality Improvement Program database, the 30-day composite mortality/major morbidity rate of infrainguinal bypass surgery was as high as 19.5%, which made the authors conclude that "stringent indications for infra-inguinal bypass surgery should be maintained when considering the method of lower extremity revascularization" [12].

Endovascular management of below the knee critical limb ischemia

Infrainguinal distal bypass surgery has long been considered the gold standard treatment for CLI but a great number of patients are not eligible because of various underlying comorbidities commonly present in the CLI population or the absence of suitable vein conduits and/or patent non-diseased distal run-off vessels [13]. Moreover, there has been a push in modern CLI treatment towards a more "endovascular first" rationale, especially in patients with a life expectancy of <2 years [13]. Several options exist for endovascular therapy of arterial lesions BTK (Table 80.2) [11]. The minimally invasive nature of these endovascular procedures results in very low morbidity, mortality, and complication rates.

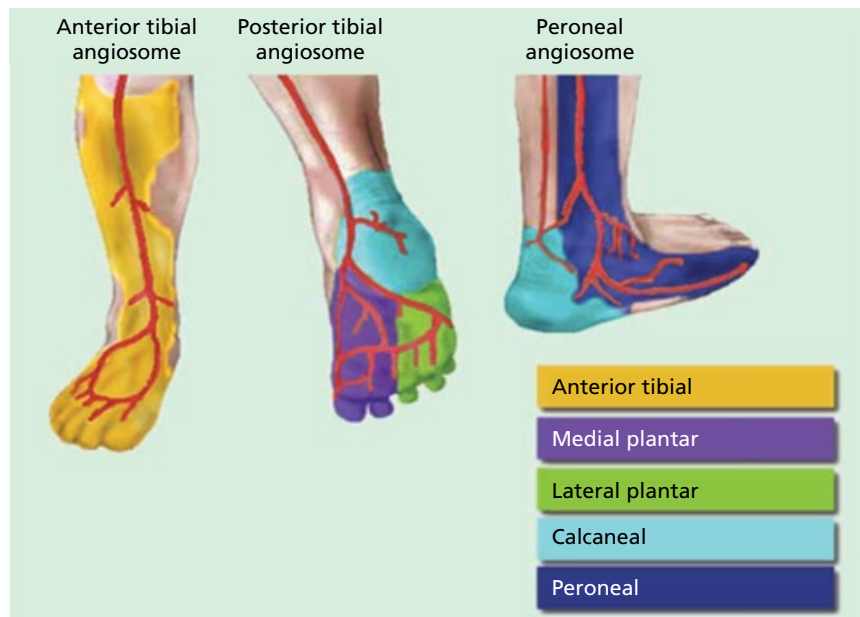

Figure 80.1 The angiosome concept. Five territories supplied by three arteries and their branches [6].

Box 80.2 Indications and contraindications of endovascular management for below-the-knee arterial occlusive disease [7]

Indications

- Critical limb ischemia: rest pain (Rutherford category 4) or non-healing ulcer/gangrene
- Significant flow-limiting stenosis of the anastomoses or outflow vessels in failing below-the-knee femoropopliteal or distal tibial bypass grafts

Absolute contraindications

- Medically unstable patients
- Life-threatening infected (wet) gangrene or/and life-threatening osteomyelitis of the target limb unless it is used to enable a more limited amputation
- Uncorrectable bleeding disorders
- Absent runoff vessels to and in the distal foot

Relative contraindications

- Pregnancy
- Inability of the patient to lie flat and immobile
- Critically ill elderly patients with impaired mobility and dementia
- Buerger disease
- Impaired renal function (EGFR <30 mL/min/1.73 m²)

Box 80.3 Transatlantic Inter-Society Consensus (TASC) classification of morphologic stratification of below the knee lesions

TASC type A

- Single stenosis shorter than 1 cm in the tibial or peroneal vessels

TASC type B

- Multiple focal stenosis of the tibial or peroneal vessel, each less than 1 cm in length
- One or two focal stenosis, each less than 1 cm long at the tibial trifurcation
- Short tibial or peroneal stenosis in conjunction with femoropopliteal PTA

TASC type C

- Stenosis 1–4 cm in length
- Occlusions 1–2 cm in length of the tibial or peroneal vessels
- Extensive stenosis of the tibial trifurcation

TASC type D

- Tibial or peroneal occlusions longer than 2 cm
- Diffusely diseased tibial or peroneal vessels

Percutaneous transluminal angioplasty

At present, balloon angioplasty, also known as percutaneous transluminal angioplasty (PTA), is the primary technique to consider in endovascular treatment of BTK occlusive disease with success rates of IP PTA reported to be as high as 80–100% [7]. Procedural success is defined as the re-establishment of direct “in-line” pulsatile flow to the foot through at least one IP artery [13]. An example of a successful PTA is seen in Figure 80.3.

PTA access

The site and direction of the arterial access depend on the inflow status [7]. In non-obese patients without iliac, common femoral artery (CFA), or very proximal superficial femoral artery (SFA)

lesions, a direct antegrade puncture is preferable because it offers superior agility and trackability of the materials to cross hard, calcified distal occlusions, while it allows easier catheter and guidewire maneuvers [7]. With the standard antegrade percutaneous approach, procedural failure can be up to 20% often relating to long chronic total occlusions (CTOs), wall calcifications, and diffuse involvement of the pedal arteries, compromising distal run-off at the foot level, after trivial recanalization [14].

In patients where the antegrade approach has failed, various retrograde techniques can be used as the ultimate resort for limb salvage. The options for retrograde pedal approach are different, such as retrograde–antegrade recanalization (pedal–plantar loop

Figure 80.2 Results of Bypass Versus Angioplasty in Severe Ischemia of the Leg (BASIL) trial [9].

Box 80.4 Recommendations for critical limb ischemia: endovascular and open surgical treatment for limb salvage [11]

- The recommendations for CLI for patients with limb-threatening lower extremity ischemia and an estimated life expectancy of 2 years or less or in patients in whom an autogenous vein conduit is not available, balloon angioplasty is reasonable to perform when possible as the initial procedure to improve distal blood flow (level of evidence B)
- The recommendations for CLI for patients with limb-threatening ischemia and an estimated life expectancy of more than 2 years, bypass surgery, when possible and when an autogenous vein conduit is available, is reasonable to perform as the initial treatment to improve distal blood flow (level of evidence B)

technique or transcatheter recanalization), which combines retrograde and integrate arterial recanalization using a single entry site, retrograde percutaneous distal access at different locations (pedal or plantar arteries), or advanced access (tarsal branches, transplanter arch, or digital access) [14]. The SAFARI technique, originally described by Spinosa *et al.* [15], involves a “combination” approach of antegrade and retrograde access in patients whose lesions cannot be addressed in standard fashion. Each approach has advantages and disadvantages, and the success rate is largely dependent upon physician experience (Box 80.5).

Pedal access technique

Transpedal access also requires operator experience but the technique can have a short learning curve.

Ultrasound guided

Using handheld duplex ultrasound can help to locate the tibiopedal vessels. The pedal vessels are usually accessed under local anesthesia with a 4 or 5 Fr microaccess needle. The most commonly accessed pedal arteries are the dorsalis pedis artery, followed by the

Table 80.2 Options for interventional treatment of lower extremity arterial disease [11].

Treatment	12 month patency (%)	Notes
Angioplasty with critical limb ischemia	40–60	TASC A and B lesions
Cryoplasty	70	Lesions <8 cm and minimal calcification
Cutting balloon angioplasty	No data	
Laser	60–80	Assisted angioplasty
Mechanical atherectomy	80	30% assisted angioplasty
Stent	60–80	TASC A and B lesions
Drug-eluting stent	80–100	Decreases to 60% at 2 years
Covered stent	60–80	TASC A and B lesions
Brachytherapy	60–80	Difficult application

posterior tibial artery and peroneal artery. However, the peroneal artery’s course lies on the interosseous ligament, and manual pressure for hemostasis can prove cumbersome. Operator familiarity with the ultrasound is important and is a short learning curve. Usually, pedal arteries are accompanied by dual pedal veins, which make accessing the vein much easier, and make the arterial access cumbersome. Compressing the pedal access site with the ultrasound probe slightly will collapse the veins thereby making arterial access easier and precise. A handheld duplex ultrasound can

Figure 80.3 An example of a successful percutaneous transluminal angioplasty (PTA): (a) before PTA; (b) after PTA.

Box 80.5 Summary of percutaneous transluminal angioplasty (PTA) access methods

Contralateral access

- Can be obtained but balloon's shaft length and catheter length can limit the ability to reaching distal tibiopedal lesions
- Loss of ability of the crossing wire to carry torque, which affects pushability
- Device deliverability can pose a challenge because of tortuosity and length limit

Antegrade femoral access

- Increases the ability to cross tibiopedal lesions because of the ability for pushability, deliverability, and availability of catheters, wires with adequate support for catheter crossing
- Antegrade femoral access requires operator experience because the risk of multiple punctures resulting in hematoma is high
- Antegrade puncture can also cause difficulty in access management, especially in obese patients

Retrograde pedal access

- By this method you can attain optimal result especially when combined with a contralateral approach (SAFARI technique)
- Limitations are dissection during access and possible vessel closure

provide an image of the pedal artery in both short and long axis; short axis is easy to puncture with the needle and changing to the long-axis view to introduce the wire is the preferred approach.

Fluoroscopy guided

Approach to transpedal access includes road mapping or image overlay especially with orthogonal angles. However, this method can be difficult if the patient moves or if there is table movement, and it also requires the use of additional contrast. This method requires operator expertise because the puncture must be made at a 90° angle to the flow. Exposure of fingers to radiation is also a concern here.

Access site procedure

An attempt must be made to achieve access with the first puncture to prevent spasm, and if the puncture is through and through, slow withdrawal of the needle will facilitate access with a micropuncture

guidewire. The access wire should be advanced only to the occluded segment of the pedal artery to prevent vessel dissection. Dilator placement over the wire will facilitate placement of a micropuncture sheath or a catheter directly. Regular access sheaths should not be introduced into the vessel as this can cause spasm and occlusion of the vessel.

To prevent clotting and vessel spasm use nitroglycerin, a small dose of heparin, and verapamil. A 0.014–0.018 inch wire can be advanced via micropuncture sheath. Additional support can be achieved with a 0.018-inch support catheter. This method allows crossing of lesions and subsequent insertion of the wire into a sheath from femoral access or the snaring of the pedal wire from the top. Further delivery of balloons and stents can be performed via the femoral approach (SAFARI technique). The pedal sheath and the catheters can be removed and manual pressure held. Dedicated micropuncture pedal access sets are available in 4 and 5 Fr outer diameters. We recommend no sheaths be placed via pedal access site except micropuncture sheath.

Access site hemostasis

Usually, manual compression is the preferred approach and can achieve adequate hemostasis without hematoma unless the puncture is high. Use of transradial band has been adopted by certain operators but patient discomfort, outflow obstruction, and band misfit in obese patients especially are drawbacks.

Modified angioplasty techniques

Among the drawbacks of balloon angioplasty remains the potential of a suboptimal acute outcome because of elastic recoil and/or flow-limiting dissection resulting in technical failure and/or progressive vascular restenosis with relapse of clinical symptomatology [13]. In order to cope with the imminent technical failure of balloon angioplasty, modified angioplasty techniques have been used [13].

Stents

BTK stent placement has been historically used in limited fashion and mostly for failed initial angioplasty although primary stenting is being heavily evaluated as a first-line consideration [16]. In 2004, the first study to investigate primary below-knee stent-supported angioplasty (BKSSA) for restoring straight in-line arterial flow in patients with CLI demonstrated its clinical and hemodynamic efficacy and safety [17]. The study found that BKSSA is associated with a high rate of angiographic success, minimal major adverse events (MAEs; defined as death, stroke, myocardial infarction (MI), renal failure, retroperitoneal bleed, unplanned tibial/pedal bypass, major infection, compartment syndrome, acute renal failure, or need for procedure-related transfusion), and short hospital stay, even in the elderly patient with multiple comorbidities [17].

Bare metal stents

Stent placement for IP disease has gained progressive attention. However, there is no level I evidence for primary stenting in IP arterial disease. Several studies have shown mixed results, although the preponderance of the data do not support primary stenting in all cases of CLI. Randon *et al.* [18] reported on a prospective randomized trial that compared PTA alone with primary stenting for IP lesions. The authors randomized a total of 38 limbs in 35 patients to PTA (n = 22) or stenting (n = 16). Thirty-six limbs had occlusions

and 20 had stenosis. They found no statistically significant difference in primary or secondary patency, limb salvage, or survival between the two groups at 12 months. This study was limited by small sample size, but is the setter for the trend with no worse outcomes reported for primary stenting.

On the same theme, Brodmann *et al.* [19] performed a randomized trial in patients with CLI in the setting of IP disease. They randomized 54 patients; 33 to PTA, and 21 to primary stenting with balloon-expandable bare metal stents (BMS). Seventy-five percent of patients had clinical improvement (81% in the PTA group and 65% in the stent group). Primary patency at 12 months was 48.1% with PTA and 35.3% with stents, with a secondary patency of 70% and 53%, respectively [19]. None of the differences were statistically significant. This study was also limited by the small size and failed to show a benefit of primary stenting over PTA alone.

Donas *et al.* [20] reported on a series of 53 high-risk patients with CLI treated with IP arterial stent placements as bailout after suboptimal angioplasty. The authors used self-expanding nitinol stents for all interventions. They treated 30 stenoses and 23 occlusions with a mean lesion length of 5.5 ± 1.9 cm. Their mean follow-up was 24.1 months. They reported 98.1% technical success with 75.5% 2-year cumulative primary patency. Freedom from amputation was reported at 88.7% with secondary patency of 88%. They also showed that proximal lesions had significantly better patency than distal crural lesions (83.3% vs. 65.2%) and that there was no difference in patency between stenosis and occlusions [20]. Their conclusion was that IP stent placement is a durable bailout treatment option in high-risk CLI patients with suboptimal angioplasty.

Drug-eluting stents

The proven efficacy of drug-coated stents in the treatment of coronary artery disease gave rise to the notion that they might have a better patency than BMS in small IP vessels. Siablis *et al.* [21] conducted a non-randomized, prospective, single-center study of the Cypher sirolimus-eluting balloon-expandable coronary stent (SES) versus a conventional balloon-expandable BMS (Evolution, Spiral Force, Tsunami, or Zeus) employed for bailout after IP PTA (65 lesions in 41 IP arteries) for CLI (Rutherford categories 4–6). Indications for bailout stenting (29 patients in each treatment group) were elastic recoil, flow-limiting dissection, or residual stenosis >30% after the initial PTA. Technical success was 96.6% in the BMS group versus 100.0% in the SES group. At 1 year, primary patency by intra-arterial DSA (86.4% vs. 40.5%) was still significantly higher and binary in-stent restenosis (36.7% vs. 78.6%) and in-segment restenosis (59.1% vs. 9%) were still significantly lower for the SES group. The SES was associated with significantly fewer cumulative target lesion revascularization (TLR) at 6 months (4.0% vs. 17.0%) and at 1 year (9.1% vs. 26.2%). At 1 year, the differences between the two groups in rates of mortality (13.8% for SES vs. 10.3% for BMS), minor amputations (10.3% for SES vs. 17.2% for BMS), and limb salvage (100% for SES vs. 96% for BMS) were not significant.

Scheinert *et al.* [22] treated 60 consecutive patients with IP artery obstructions under a protocol of primary implantation of SES or BMS into tibial and peroneal arteries. Inclusion criteria for this prospective registry were Rutherford category 3–6 and >70% diameter stenosis of the target lesion; maximum allowable lesion length was 30 mm, and only patients with lesions treatable with a single stent could be enrolled. Thirty patients (83.3% diabetics)

received balloon-expandable Cypher stents, while 30 other patients (76.6% diabetics) received uncoated BMS (Bx Sonic). In 21 cases, inflow lesions in the femoral and/or popliteal arteries required treatment prior to the BTK intervention. At follow-up (mean 9.3 months for the SES patients, mean 9.8 months for the BMS patients), the cumulative rate of MAEs was 10.0% for the SES patients versus 46.6% for the BMS patients. The rates of major amputation, bypass surgery, and TLR were all 0% for the SES patients and 10.0%, 0%, and 23.3%, respectively, for the BMS patients. There were three deaths in the SES group and four deaths in the BMS group. On angiographic follow-up of 24 SES patients, no relevant obstructions were seen, while in the BMS group, the rate of binary restenosis was 39.1%; the mean degree of in-stent restenosis was $1.8\% \pm 4.8\%$ for the SES patients versus $53.0\% \pm 40.9\%$ for the BMS patients. Hence, drug-coated stents achieve significantly higher primary and secondary patency than BMS for focal IP artery lesions.

In the PReventing Amputations using Drug eluting Stents (PaRADISE) trial 106 patients (118 limbs) were treated with 228 DES. The number of stents per limb was 1.9 ± 0.9 , and 35% of limbs received overlapping DES (length of 60 ± 13 mm). There were no procedural deaths, and 96% of patients were discharged within 24 hours. The 3-year cumulative incidence of amputation was $6\% \pm 2\%$, survival was $71\% \pm 5\%$, and amputation-free-survival was $68\% \pm 5\%$. TLR occurred in 15% of patients, and repeat angiography in 35% of patients revealed a binary restenosis in 12% [17]. In the YUKON Drug-Eluting Stent Below the Knee-Randomized Double-Blind Study, the trial included 161 patients with mean target lesion length of 31 ± 9 mm. Thirty-five (23.3%) patients died during a mean follow-up period of 1016 ± 132 days. The event-free survival rate was 65.8% in the SES group and 44.6% in the BMS group (log-rank $p = 0.02$). Amputation rates were 2.6% and 12.2% ($p = 0.03$), and target vessel revascularization rates were 9.2% and 20% ($p = 0.06$), respectively [21]. The Destiny trial and Achilles study showed similar results as the prior two studies and showed the importance of DES in IP lesions for patency rates. Advances in DES could be field changing [23].

The use of balloon-expandable BMS as well as drug-eluting stents (DES) in BTK lesions are endovascular technologies with the promise of significant inhibition of vessel restenosis and improved clinical outcomes [16]. Patency and limb salvage rates are all quite similar in the short term, with limb salvage rates higher in general versus vessel patency rates (70–100% vs. 60–80% at 1 year) [16]. However, bailout DES achieves superior long-term primary patency rates compared with bailout BMS. Balloon expandable BMS were found to improve the initial technical success rates of BTK endovascular treatment but did not result in satisfactory long-term results mainly because of the phenomenon of in-stent restenosis [13]. Restenosis remains the leading unresolved issue following every kind of endovascular treatment and is mainly attributed to the continuous mechanical irritation caused by the metal stent mesh, resulting in the inflammatory–proliferative response of the vessel wall, subsequent intimal hyperplasia, negative remodeling, and finally restenosis [13].

Drug-coated balloons

Drug-coated balloon (DCB) technology has emerged as a potential answer to the limitations presented by the utilization of DES and is based on the combination of balloon angioplasty and local, single-dose, cytostatic drug delivery, without the permanent implantation of an endovascular device, with the aim to lower restenosis rates

[13]. An advantage of DCB technology is the superior drug dose fixed on the balloon's surface compared with the dose on the surface of DES, potentially resulting in higher dose delivery to the target vessel [13]. There are a variety of diverse DCB catheters available for IP use and although they all use the same type of drug (paclitaxel) and dosage (3 µg/mm), the coating technology is completely different [24]. More recently, bioabsorbable variations are being investigated and short-term results are anticipated in the near future [16].

Cryoplasty, peripheral cutting balloon, and AngioSculpt Scoring Balloon

Studies investigating the use of PTA with adjunctive therapies such as cryoplasty, peripheral cutting balloon, and AngioSculpt Scoring Balloon provide more meaningful and current information regarding the role of PTA.

Cryoplasty

Cryoplasty (cold balloon angioplasty) combines the pressure of angioplasty with cold energy by delivering nitrous oxide to inflate a non-compliant balloon [1]. Cryoplasty using the PolarCath Peripheral Dilatation System (Boston Scientific Corporation) has an FDA indication for treating stenotic lesions in the peripheral vasculature (iliac, femoral, popliteal, IP, renal, and subclavian arteries) among other indications [16]. During inflation of the balloon, within a separate lumen in the balloon catheter, liquid nitrous oxide is converted to gas thereby cooling the surface of the balloon to -10°C [16]. The theoretical mechanisms of action involve altered plaque response, reduced elastic recoil, and induction of apoptosis within the endothelium, thereby reducing the rate of restenosis. Cryoplasty has been used as an effective primary strategy for limiting the incidence of dissection, vessel recoil, and subsequent intimal hyperplasia and restenosis associated with the endovascular dilatation of atherosclerotic lesions in the peripheral vasculature [25].

The BTK Chill Trial, examining the use of primary cryoplasty for BTK occlusive disease in patients with CLI, included 108 patients involving 111 limbs with 115 target IP lesions. The primary endpoints were acute technical success (ability to achieve ≤50% residual stenosis and continuous inline flow to the foot) and absence of major amputation of the target limb in 6 months. Acute technical success was achieved in 108 (97.3%) of treated limbs, and major amputation at 6 months was avoided in 85 of 91 patients (93.4%) [25]. The study group concluded that cryoplasty therapy was safe and effective in treating IP disease, providing excellent results and a high rate of limb salvage in patients with CLI [26].

Peripheral cutting balloon

In cutting balloon angioplasty, the balloon contains three or four sharp microtomes fixed longitudinally about the outer surface of a non-compliant balloon [1]. Radial expansion of the balloon results in longitudinal incisions in the plaque, thereby relieving hoop stress in the arterial wall [1]. Use of the peripheral cutting balloon for BTK intervention has been described as an effective alternative for IP lesions with significant calcification and/or resistance to standard PTA [16]. A single institution study of its use in the IP segment found the technical success rate was 80% which improved to 100% when adjunctive stenting was included [1].

AngioSculpt Scoring Balloon

The AngioSculpt Scoring Balloon is a semicompliant balloon with a flexible nitinol-scoring element that scores the target lesion with the intended effect of a more uniform and precise outcome [16].

Atherectomy

The mechanical atherectomy device removes plaque with a rotating blade and captures the plaque in a catheter housing which requires intermittent emptying [1]. The use of atherectomy in the IP segment has been largely based on the idea that “debulking” or “lesion prep” will provide a more acceptable acute and more durable angioplasty or stenting result. Numerous registries and single-center studies have been published, but these have the inherent weaknesses of studies of this design, namely, there are no randomized or comparative data.

Most physicians use atherectomy as an adjunct to PTA or stenting and it has become more widespread in the last several years with the development of devices such as the Silver Hawk Plaque Excision System (Plymouth, MN, USA), the Diamondback 360Orbital Atherectomy System (St. Paul, MN, USA), the CLiRPath Turbo Elite laser catheter (Colorado Springs, CO, USA), and the Jetstream Atherectomy Catheter (Kirkland, WA, USA) [13]. The Silver Hawk Plaque Excision System is an excisional atherectomy device with a rotating carbide atherotome that is able to capture the plaque in the nose cone of the device and remove it. The Diamondback 360Orbital Atherectomy System is based on the idea of differential “sanding” of complex and calcified plaque, using centrifugal force to orbit a diamond-encrusted crown within the vessel to create a more compliant vessel for adjunctive PTA or stenting. The OASIS trial was a multicenter, non-randomized, prospective registry evaluating the safety and efficacy of the Diamondback device. The CLiRPath Turbo Elite laser catheter uses an excimer (excited dimer) laser that generates 308-nm pulsed ultraviolet light to “photoablate” plaque, thereby creating a channel to perform additional intervention [16].

Excisional atherectomy

Atherectomy devices are designed to debulk and remove atherosclerotic plaque by cutting, pulverizing, or shaving with catheter-deliverable blades. The development of the Silver Hawk excisional atherectomy catheter (Minneapolis, MN, USA) has occasioned some renewed interest in directional atherectomy, a technique that has historically been associated with high restenosis rates in the coronary and peripheral vasculature [27]. Like the excimer laser, excisional atherectomy offers the theoretical advantage, compared to PTA and stent implantation, of eliminating stretch injury on arterial walls, limiting acute dissection (and the need for adjunctive stenting) and elastic recoil, and thereby potentially reducing post-procedure inflammation and the rate of restenosis. Kandzari *et al.* [28] used the device to treat 160 lesions (40% IP, mean length ATK 74 mm, mean length BTK 51 mm; 34% total occlusions, 80% moderate to severe calcification) in 69 patients with severe CLI (Rutherford categories 5–6, 78% diabetics, 55% with ≤1 patent runoff vessel) at seven different sites. Residual diameter stenosis after the procedure was <50% in all but one of the procedures; adjunctive angioplasty was employed without stent placement in 11% of the procedures, and stents were placed in 6%. There were no reported instances of perforation or embolization and only one instance of abrupt closure. The 6-month rate of major adverse events was 23%, reflecting the significant comorbidity of the patient group. There

was no morphologic measurement of restenosis reported; the rate of TLR was 4%. Through 6-month follow-up, there were no unplanned amputations; in 82% of patients amputation was either less extensive than initially planned or avoided altogether.

Zeller *et al.* [29] reported outcomes through 2 years for SilverHawk treatment of 49 BTK lesions (mean length 46 mm, mean diameter stenosis 89%; 22% total occlusions, 18% in-stent restenosis) in 36 patients (53% with CLI, 61% diabetics). Predilatation was required for 33% of the lesions. Post-atherectomy angioplasty was performed for 38% of the lesions, and 4% required stent implantation as a result of dissection. Mean residual stenosis, which was 12% following the atherectomy, was reduced to 8% following any adjunctive therapy; residual stenosis $\leq 30\%$ was achieved in 98% of lesions. The mean ABI increased significantly from 0.48 ± 0.39 to 0.81 ± 0.10 ($p < 0.05$) before discharge and remained improved during follow-up. Primary and secondary patency rates ($< 70\%$ restenosis by duplex ultrasound and/or angiography) were 67% and 91% after 1 year and 60% and 80% after 24 months. The rate of restenosis was significantly lower for lesions < 50 mm in length versus those ≥ 50 mm (25.8% vs. 44.4%; $p < 0.05$).

Many have suggested that stenosis in the IP arteries can be treated by atherectomy without predilatation, while occlusions should be predilated with an undersized balloon to ensure that the wire crosses the occlusion intraluminally. It is strongly advised against the use of atherectomy in cases in which the occlusion was crossed subintimally because of the potential for perforation.

Excimer laser-assisted angioplasty

Continuous wave laser were evaluated and abandoned for peripheral interventions in the late 1980s because of the high complication rate caused by thermal damage to surrounding tissue [30]. In contrast, excimer laser angioplasty of the leg arteries has been practiced commercially in Europe since 1994 [31]. The 308 nm excimer laser utilizes flexible fiberoptic catheters to deliver intense, short duration pulses of ultraviolet (UV) energy. The advantages of pulsed UV energy lies in the short penetration depth of 50 μm and its ability to break molecular bonds directly, by a photochemical instead of thermal process. Excimer laser catheters remove a tissue layer of about 10 μm with each pulse of energy. Tissue is vaporized only on contact without a consequent rise in temperature to surrounding tissue.

The multicenter Laser Atherectomy for Critical Ischemia (LACI) trial of excimer laser-assisted angioplasty treated 423 lesions (41% SFA, 15% popliteal, 41% IP) in 155 limbs (91% with at least one occlusion) of 145 patients with CLI (Rutherford categories 4–6, 69% with tissue loss, 66% diabetics) who were determined to be poor candidates for surgical revascularization. Procedural success (defined as $< 50\%$ residual stenosis in all treated lesions) was achieved in 85% of the treated limbs [32]. The median total length of treated artery per limb was 11.0 cm. Procedural complications, occurring in 12% of the treated limbs, included major dissection (4%), acute thrombus formation (3%), distal embolization (3%), and perforation (2%). The excimer procedure was followed with adjunctive balloon angioplasty in 96% of the limbs. Stents (mainly bare nitinol) were placed adjunctively in 61% of the SFA lesions, 38% of the popliteal lesions, and 16% of the tibial lesions. Mean lesion stenosis (by visual estimate) was decreased from 92% at baseline to 55% after laser debulking and to 18% at final assessment. At 6-month follow-up, limb salvage was achieved in 110 of 119 (92%) surviving patients (118 of 127 limbs; 93%); 56% of

ischemic ulcers had healed completely [33]. Despite treating a very unfavorable patient cohort, excimer laser-assisted angioplasty achieved limb salvage comparable to the gold standard of bypass surgery. Following the LACI protocol, a single-center US registry and a five-center Belgian trial achieved comparable outcomes with the device [34,35].

Rotational atherectomy with aspiration

The Pathway PV system (Kirkland, WA, USA) has a unique feature compared to other rotational atherectomy devices. The ability to remove the atherectomized plaque material through aspiration ports reduces the risk of obstructing the microvasculature and avoids increasing erythrocyte degradation products, especially in patients with impaired renal function. High-speed rotational devices without aspiration capabilities increase these degradation products, such as haptoglobin and potassium, which can result in life-threatening cardiac arrhythmias [36]. Additionally, the aspiration feature of the catheter allows the device to be used in lesions containing both occlusive material, including solid, even calcified plaque and fresh thrombus. Potentially, the Pathway PV can be used as a thrombectomy device in subacute and acute vessel occlusions.

Zeller *et al.* [29] reported results on a prospective non-randomized multicenter trial using a rotational atherectomy system with aspiration capabilities. In this study, a 99% technical success rate was achieved using the Pathway PV Atherectomy System in 210 infrainguinal cases. Adjunctive balloon angioplasty was performed in 59% and stenting in 7%. Primary and secondary patency rates at 1 year were 61.8% and 81.3%, respectively. The 1-year limb salvage rate was 100%. These patency rates are similar to the Silver Hawk study cohorts.

Orbital atherectomy

The Diamondback 360 Orbital Atherectomy System (St. Paul, MN, USA) uses a plaque ablation catheter. This has an abrasive eccentrically shaped crown with a diamond-coated surface, which rotates and creates lumen enlargement by plaque abrasion. Orbital atherectomy appears to have some similarities to mechanical rotational atherectomy (Rotablator, Natick, MA, USA). However, the Rotablator has greater limitations with respect to device size and lumen enlargement. Although the efficiency of lumen enlargement is 92% for Rotablator (a 2-mm burr will create a lumen diameter of 1.8 mm) [37], it is greater than 175% for orbital atherectomy.

A prospective, non-randomized, multicenter registry examined the safety and 6-month outcomes of 124 patients IP disease and either CLI or claudication. A total of 90.1% of patients achieved the primary outcome of $< 30\%$ final diameter stenosis and no major amputations at 6 months (2.4% minor amputations). Adjunctive angioplasty was performed in 39.3% and stenting in 2.5% of lesions [38].

Complications of endovascular procedures

As with open vascular surgery procedures, the potential for life and limb-threatening complications can occur with endovascular procedures. The number of endovascular procedures being performed is increasing rapidly and so complications of procedures are being encountered with increasing frequency [1]. Immediate complications occurring during or shortly after IP endovascular procedures are reported in 2–10% of cases [8]. As all vascular punctures cause

injury to a vessel access site, complications can occur including chronic pain, hematoma, pseudoaneurysms, AV fistula, vessels thrombosis, vessel rupture, embolization, and dissection. Up to 1% of all patients revascularized will develop a graft infection secondarily to wound breakdown with a 15% mortality rate and 40% incidence of major limb loss [39]. Postoperative lymphedema is considered an important factor in prolonging incisional healing and patient discomfort [39]. To help limit complications constant technologic advancements are being made in catheter and wire construction so the best selection of specific tools is used. Imaging technology is optimized to improve diagnostic accuracy and therapeutic precision.

Conclusions

CLI is a complex multifactorial disease and encompasses the most extreme end of the PAD spectrum leading to significant morbidity and mortality [24]. Preventing amputation in CLI is arguably the most important goal and is predicated on the ability to restore and maintain straight line tibial arterial flow to the foot. Favorably, as the management of patient with CLI evolves, the number of major limb amputation rates will continue to decline significantly.

Historically, bypass surgery with autogenous veins for flow restoration has been the first-line revascularization therapy for CLI; however, advances in endovascular techniques and device technology has changed the treatment paradigm [40]. Angioplasty has become the first-line intervention for patients with BTK CLI with lower morbidity and mortality than surgical treatments, which should be considered for more complex anatomic lesions of BTK vessels or in patients with endovascular failure and persisting clinical symptoms of CLI [41]. Despite extensive research into interventional modalities for treatment of lower extremity atherosclerotic disease, all treatments are associated with some degree of recurrence and an inability to achieve long-term patency [1]. Things to look out for in the future of BTK interventions include bioabsorbable platforms as better biocompatibility is important to reduce the need for long-term antiplatelet therapy and reduce the risk of thrombosis [23].

Subclavian and upper extremity arterial disease

Epidemiology

Upper extremity vascular diseases are significantly less common than those involving the lower extremities. Nevertheless, they are important because of the potentially disabling effects on arm and hand function. Upper extremity vascular disease can be conceptually divided into “large-artery” disease involving the inflow arteries, such as the subclavian and axillary arteries, or “small-artery” disease involving the arteries distal to the wrist. While the list of occupational factors and medical conditions associated with small-artery disease is long and heterogeneous [1], the causes of upper extremity large-artery disease is more limited and includes atherosclerosis of the subclavian artery; arteritis (giant cell or Takayasu’s arteritis); thoracic outlet syndrome; and radiation arteritis. Fibromuscular dysplasia (FMD) rarely occurs in the inflow arteries of the upper extremity and causes occlusive disease [2]. Use of drugs causing vasospasm, such as ergotamine, cocaine, and amphetamines, can cause intense upper extremity arterial vasospasm. Embolism from a proximal source, including the ascending aorta and cardiac sources of embolism, must be considered in patients presenting with acute thrombotic occlusion on the arteries in the upper extremity, especially if the disease is unilateral.

Causes of subclavian and upper extremity arterial disease

Atherosclerosis

Hemodynamically significant atherosclerosis is 20 times less common in the upper extremities than the lower extremities. When atherosclerosis causes a hemodynamically significant stenosis in the upper extremity, it is almost always localized to the proximal subclavian artery; atherosclerosis distal to the subclavian artery is very uncommon [3].

Takayasu’s arteritis and giant cell arteritis

Takayasu’s arteritis (TA) and giant cell arteritis (GCA) are granulomatous arteritides that can involve the aorta and its major branches [4].

Takayasu’s arteritis has higher prevalence rates in Asian countries, including Japan, Korea, India, and China, than in Western countries [5]. Most patients present in their third decade, and are usually female. Constitutional symptoms, such as fatigue or low-grade

fevers, are present in up to 40% of patients [6]. However, TA can be an incidental finding given that up to 20% of patients are asymptomatic. The most common vascular symptom in TA is arm claudication, occurring in 60% of patients, reflecting disease predilection for the aortic arch vessels [7,8]. TA should be suspected in any young (age <40 years) patient presenting with evidence of arterial stenosis or occlusion despite the absence of traditional cardiovascular risk factors, with no history of drug abuse (especially cocaine and amphetamines), and who have no evidence of an underlying prothrombotic state (e.g., antiphospholipid antibody syndrome) or causes of accelerated atherosclerosis. Importantly, serum markers of systemic inflammation, such as erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP), can be normal in up to 50% of patients, even in those with active disease.

Elevated plasma levels of interleukin-6 have been found to closely correlate with disease activity, and can be useful clinically for monitoring and treatment adjustments in patients with TA [9]. In TA, vessel wall inflammation results in stenosis, occlusion, and potentially secondary thrombosis in involved arteries. The innominate and subclavian arteries are most frequently involved, followed by the aorta, common carotids, and renal arteries. Aneurysms develop as a long-term sequela of TA, with higher prevalence rates in Asian countries. In terms of treatment, glucocorticoids are the mainstay of treatment in TA, with resolution of symptoms in 25–100% of patients.

Giant cell arteritis is a relatively common arteritis that usually affects individuals older than 50 years, with a mean age of 70 years, and a female : male ratio of 2 : 1 [10]. Constitutional symptoms are common, and are often the reason why patients seek medical attention. Polymyalgia rheumatic (PMR), which is closely linked to GCA, is seen in up to 40% of patients with GCA and is characterized by symmetrical, proximal aching; morning stiffness, bursitis, and tenosynovitis. Headache is common in GCA, and tends to be localized to the temporal areas, where the temporal arteries can be quite tender. Vision loss is one of the most feared complications of CGA, and is caused by ischemia of the optic nerve. Approximately 15% of patients develop arterial occlusive disease of the large arteries of the upper extremities. Although upper extremity stenoses typically occur in the subclavian and axillary arteries, brachial artery stenoses also occur. Exclusion of atherosclerotic disease, which is also common in this patient population, is an essential step

in the management of these patients. Similar to TA, a normal ESR or CRP does not rule out the possibility of GCA. However, the diagnosis should ideally be confirmed by temporal artery biopsy. In terms of treatment, GCA is extremely sensitive to steroids.

Thoracic outlet syndrome

Thoracic outlet syndrome (TOS) refers to the extrinsic compression of the subclavian artery, subclavian vein, and/or brachial plexus, as these course through the *scalene triangle*, formed by the first rib, the clavicle, the scalenus medius muscle, and the costoclavicular ligament. The type of TOS depends on the structure that is compressed: arterial TOS results from compression of the subclavian artery, venous TOS from compression of the subclavian vein, and neurogenic TOS from compression of the brachial plexus. Neurogenic TOS is by far the most common form of TOS; patients typically present with paresthesias, weakness, or pain in the hand, arm, or shoulder. Raynaud's phenomenon and cold hands are often seen. Patients with venous or arterial TOS usually have a history of repetitive physical exertion using their upper extremities (e.g., baseball pitcher, weightlifting). Patients with venous TOS (also called Paget-Schroetter syndrome) present with arm swelling. Patients with arterial TOS (the least common form of TOS) present with arm claudication, or hand/digit ischemia from distal embolization.

The evaluation of patients with suspected TOS includes measurement of bilateral brachial blood pressures, as well as pulse examination or pulse volume recordings with provocative maneuvers, such as the Adson and EAST (external rotation and abduction stress test) maneuver. Plain X-rays are useful for the evaluation of cervical ribs. Cross-sectional imaging studies, such as CT angiography or MR angiography, are often used, as well as electromyography and nerve conduction tests for the evaluation of neurogenic TOS.

Radiation

Although overall uncommon, radiation-induced arterial injury is a well-documented complication in patients with a history of previous head and neck or mediastinal radiation. The pattern of radiation arteritis depends on the time period elapsed since radiation therapy. Early disease (<5 years since irradiation) is often caused by endothelial injury and mural thrombus. Late disease (usually 10 years or more following irradiation) is caused by fibrotic occlusion of the artery or accelerated atherosclerosis. In radiation-induced arteritis, stenoses or occlusions tend to be caused by smooth vessel narrowing. Calcification and fibrosis often predominates in the wall of the artery that was in closest proximity to the radiation source.

Diagnostic evaluation

History and physical examination

All patients with upper extremity arterial disease should have a detailed cardiovascular history taken. Especially important aspects that should be covered in the patient's history include:

- Description of the symptoms, whether their onset was insidious or acute, unilateral or bilateral, persistent or intermittent, history of Raynaud's, and the presence of ulceration;
- Relevant comorbidities, such as autoimmune disorders, cardiovascular risk factors, prothrombotic states;
- Tobacco use;
- Drugs and medications, especially argot alkaloids, chemotherapeutic agents, cocaine, amphetamines;
- Occupational exposures, including those associated with TOS, vibration injury; and

- Relevant review of symptoms, especially those suggestive of an underlying rheumatologic or autoimmune disorder, or a prothrombotic state.

The upper extremity exam should focus on:

- Inspection: changes that may uncover an underlying connective tissue disorder (e.g., CREST syndrome), distal embolization to a digit (e.g., digit pallor, or discoloration), and the presence of ulceration.
- The subclavian, axillary, brachial ulnar, and radial pulses should all be carefully noted and compared with the contralateral side. An Allen's test should be performed. If TOS is suspected, provocative maneuvers should be elicited while palpating the radial pulse.

Non-invasive and invasive studies

Non-invasive vascular testing can be broadly classified as: (i) functional (or physiologic) studies that provide information on the hemodynamic effects of arterial occlusive disease in the upper extremity, and (ii) anatomic studies that provide detailed information about the location and other physical characteristics related to the occlusive disease. The presence and extent of upper extremity ischemia can be gauged through physiologic studies, which include the wrist-brachial index (WBI), pulse volume recordings (PVRs), and digit photoplethysmography (PPG). CT and MR angiography provide anatomic data. Duplex ultrasonography provides anatomic as well as hemodynamic information.

The WBI is the ratio of the systolic blood pressure measured at the wrist to the pressure measured at the brachial artery, and indicates the presence of occlusive lesions between the brachial arteries and distal radial and ulnar arteries. A WBI is reported for each arm. A WBI <0.7 is considered abnormal. Instead of measuring the pressure at the wrist (i.e., distal radial or ulnar artery), the ratio can be obtained between the finger pressure and the brachial pressure, resulting in a finger-to-brachial pressure index (FIBI). An FIBI <0.7 is considered abnormal.

Similar to the lower extremities, PVR tracings can be obtained in the upper extremities [11]. Cuffs are placed in the upper arms, forearms, and wrists. Systolic blood pressures are obtained by Doppler at each level (Figure 81.1a). Systolic pressures are compared with adjoining levels in the ipsilateral limb, as well as with the contralateral one. A blood pressure differential that exceeds 15–20 mmHg is suggestive of the presence of significant occlusive disease proximal to that level. PVRs depict changes in the volume of the limb during arterial pulsations. A normal PVR waveform is similar to the waveform seen with intra-arterial blood pressure tracings, and consists of a rapid systolic upstroke, a rapid initial downstroke, a prominent diastolic notch, and smooth late equalization in the remainder of diastole. When a PVR waveform is deteriorated (or blunted), occlusive disease in a proximal segment should be suspected. With severe disease, the waveforms ultimately become flat or non-pulsatile. If PVR waveforms in both upper arms are severely dampened, a cardiac etiology, including severe aortic stenosis, should be considered.

Ten-digit PPG should be part of a complete upper extremity non-invasive arterial evaluation. PPGs are performed by placing a strapped sensor in the distal end of each finger to measure changes in blood flow. Finger PPG tracings should be obtained with the patient as warm as possible. A normal finger PPG tracing consists of a rapid upstroke, sharp systolic peak with reflected wave. With decreased blood flow, for example as seen with a proximal severe stenosis or vasospasm, the waveforms become dampened, with low amplitude, and may even flatline (Figure 81.1b).

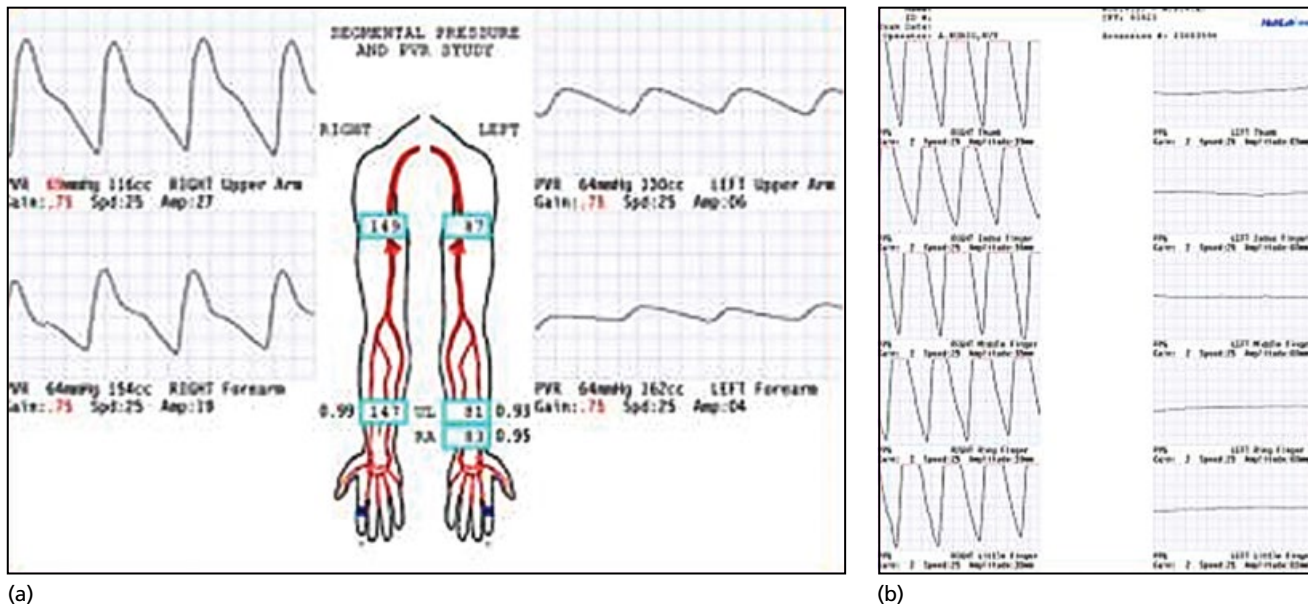

Figure 81.1 (a) Bilateral upper extremity wrist-brachial indices, pulse volume recordings (PVR), and segmental pressures. A significant brachial pressure differential is noted. PVR waveforms on the right are normal, with brisk upstrokes and dichrotic notches. Left upper and lower arm PVR waveforms are markedly blunted, suggesting disease proximal to the brachial artery. (b) Finger photoplethysmography (PPG) tracings are normal on the right, and severely blunted on the left.

Maneuvers for the thoracic outlet syndrome

These maneuvers are used to evaluate patients suspected of having arterial TOS. In each of the maneuvers, the radial artery is palpated. With a positive test, the amplitude of the pulse is decreased. It should be mentioned that there are a significant number of false positive results, as occlusion of the subclavian artery can be elicited by forceful TOS maneuvers, even in healthy individuals without TOS.

- **Adson's test:** the patient sits upright, takes a deep breath in, looks upward, and turns his head to the affected side.
- **EAST maneuver:** The patient is asked to extend his/her arms, externally rotated and behind the head. The patient makes fists repeatedly for 3 minutes. Radial pulses are felt at the end of the test.
- **Military position:** shoulders are thrust downward and backwards maximally.

Duplex ultrasonography

Normal Doppler signals in the upper extremity should be triphasic. A change from triphasic to biphasic can be significant; however, in some patients biphasic flow patterns are normal. Monophasic waveforms with prominent diastolic flow are always abnormal and are usually seen distal to severe stenosis or occlusion. Waveforms in areas of severe stenosis often demonstrate high velocities and spectral broadening, reflecting turbulent blood flow. If the ratio between the velocity at the area of stenosis and the velocity in the proximal arterial segment is >4 , a 75–99% stenosis is suspected (Figure 81.2).

Computer tomography and magnetic resonance angiography

CT angiography (CTA) and magnetic resonance angiography (MRA) have become among the most valuable non-invasive imaging modalities for the assessment of upper extremity vascular diseases. The vessel wall can be well visualized, aiding in the diagnosis

of large-vessel vasculitis, such as TA. Modern reconstruction packages allow the three-dimensional presentation of volumetric information, which can be of significant value in vascular interpretation. These modalities are most useful for the visualization of the proximal larger arteries of the upper extremities. Their value is more limited in the visualization of the small distal arteries of the arm and hand. PVRs can be measured instead of feeling the radial pulsations by physical examination alone.

Catheter-based angiography

Catheter-based angiography should be reserved for patients who may require an endovascular intervention, or to those in whom the architecture and morphology of the distal arm, hand, and digit arteries must be investigated, for example, in a case of small-vessel arterial occlusive disease (Figure 81.3).

Treatment

Medical management

The treatment of GCA is often initiated on the basis of clinical suspicion. Most patients respond to prednisone 60 mg/day within 3–5 days. Patients with immediately threatening symptoms, such as visual loss, should be treated with pulsed intravenous methylprednisolone 1000 mg/day for 3 days. Low dose aspirin should be started, provided that there are no contraindications, to reduce the risk of associated ischemic complications such as vision loss.

Most patients with TA require immunosuppressive agents, initially begun as prednisone 1 mg/kg/day for 1–3 months [12]. If remission and improvement of the disease is not evident, the addition of cytotoxic agents such as methotrexate, azathioprine, cyclophosphamide, or mycophenolate mofetil can be effective. The latter is shown to achieve 90% clinical resolution of symptoms in patients for whom conventional medical therapy has failed [13].

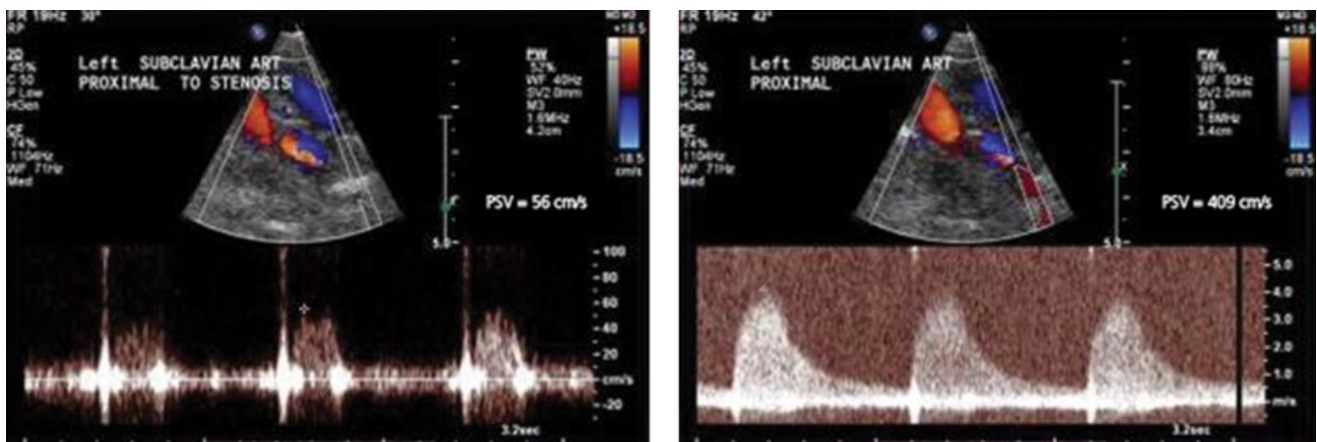

Figure 81.2 Same patient as Figure 81.1. A significant velocity shift is seen in the left subclavian vein, associated with monophasic waveforms. These findings indicate the presence of a severe (75–99%) stenosis.

Figure 81.3 Same patient as Figure 81.1. Angiogram of the aortic arch and its branches shows severe stenosis in the proximal left subclavian artery.

Surgical management

Surgical management of GCA and TA is reserved for when the disease is quiescent. Indications for arterial reconstruction include lesions that produce hemispheric cerebral symptoms, rest pain, effort fatigue, embolism, vertebral–subclavian steal syndrome, or coronary ischemia as a result of subclavian–coronary steal syndrome in patients who have undergone internal mammary to coronary bypass.

Surgical options can be performed through the chest or neck for patients with subclavian and upper extremity occlusive disease. Selection of surgical option depends on the location, extent, presenting symptoms, and patient comorbidities. The three most common reconstruction procedures are carotid–subclavian bypass, carotid–subclavian transposition, and aorto-innominate/aorto-carotid bypass.

In patients with venous TOS, surgical decompression of the thoracic outlet is indicated; however, the timing of surgical decompression is controversial. Some groups use decompression within 3–6 months with interim use of oral anticoagulation [14]. The surgical treatment of arterial TOS is indicated in all symptomatic patients with ischemia and in those who are asymptomatic but have aneurysmal degeneration. Surgical decompression consists of resection of a cervical rib followed by either primary repair of the diseased subclavian artery or replacement bypass with a prosthetic conduit. In patients with neurogenic TOS, 70% will respond to physical therapy for

8 weeks. Patients who fail to achieve symptomatic improvement may require surgical management [15].

Endovascular management

Percutaneous repair of the subclavian artery has shown excellent initial success in comparison with surgical options. However, long-term durability favors surgical revascularization. A femoral approach is usually adequate. Unfractionated heparin should be administered prior to selective catheter engagement to prevent thrombus from forming and embolization. Non-selective angiography in a 45° left anterior oblique (LAO) projection is usually performed with a pigtail catheter in the ascending aorta. Selective catheterization of the supra-aortic vessels is usually achieved with a JR4, Headhunter, or angled Glide catheter. The diseased vessel is commonly crossed with either a non-hydrophilic or a hydrophilic 0.035-inch wire. In the case of crossing the lesion with a hydrophilic wire, it is then exchanged for a 0.035-inch non-hydrophilic wire. The diagnostic catheter is then exchanged for a long 6–7 Fr 90 cm sheath, or alternatively can be telescoped over the diagnostic catheter until it reaches the subclavian artery proximal to the diseased segment. Selective angiography with a non-inflated predilatation balloon matched to the reference vessel size is performed in two views: LAO 40° to position the balloon in the ostium, and a contralateral cranial view to determine the proximity of the distal end of the balloon to the origin of the vertebral artery. After predilatation, the sheath is telescoped over the balloon and exchanged for a

balloon expandable or self-expandable stent for ostial or non-ostial lesions, respectively. The stent is unsheathed and deployment is carried out using the two views previously described. Post-angioplasty angiography is performed, after which the equipment is removed.

In the case of TOS, those presenting with acute subclavian-axillary venous thrombosis, catheter-directed thrombolysis is the preferred initial management strategy. If started within 14 days of symptom onset, the likelihood of success is good when combined with thoracic outlet decompression [16].

Vertebral artery disease

Epidemiology and clinical presentation

Approximately 80% of strokes are ischemic in origin. However, one in four ischemic strokes occur in the posterior circulation [17]. Patients with symptomatic vertebrobasilar insufficiency (VBI) have a 25–40% incidence of vertebral artery stenosis (VAS) [18]. However, symptoms of vertebrobasilar ischemia such as dizziness, ataxia, visual disturbances, and motor sensory deficit are rare. It is well known that ligation of one of two vertebral arteries is well tolerated in humans [19,20]. Even though atherosclerotic occlusive disease of both vertebral arteries is the most common culprit, other combinations of innominate, carotid, or subclavian artery stenosis can compromise the posterior circulation and elicit symptoms of vertebrobasilar insufficiency.

The prognosis for patients with atherosclerotic occlusion of the VBS is poor, with 80–100% mortality [21]. Symptomatic VBI carries a 5–11% incidence of stroke or death at 1 year [22,23]. Transient ischemic attacks (TIA) resulting from extracranial VAS are associated with a stroke rate of 30% at 5 years [24].

Treatment

The initial treatment consists of antithrombotic and antiplatelet therapy. However, there is lack of evidence supporting the use of these drugs for this disease or comparing these drugs with other treatment options [25,26]. If symptoms continue despite maximal medical therapy, an arch and four-vessel angiography, CTA or magnetic MRA is indicated [24].

Three surgical techniques to revascularize one vertebral artery in bilateral symptomatic disease have been described: transection of the vertebral artery above the stenosis and re-implantation into the ipsilateral subclavian or carotid artery; vertebral artery endarterectomy; or vein patch angioplasty. These approaches carry significant morbidity [27]. In one series by Berguer *et al.* [28], 174 patients undergoing proximal vertebral artery reconstruction had no in-hospital death but reported complications: recurrent laryngeal nerve palsy 2%; Horner's syndrome 15%; lymphocele 4%; chylothorax 0.5%; and acute thrombosis 1%. Secondary patency rates were 95% and 91% at 5 and 10 years, respectively. Seventy-five patients undergoing reconstruction of the distal vertebral artery had a mortality of 4% and an immediate graft thrombosis rate of 8%. Secondary patency rates for distal vertebral reconstruction were 87% and 82% at 5 and 10 years, respectively. Other reports quote a combined morbidity and mortality rate of VAS of 10–20% and have dampened enthusiasm for this option [29].

The first reported successful treatment of the vertebrobasilar system by intraoperative percutaneous transluminal angioplasty (PTA) was by Sundt *et al.* in 1980 [30]. As the most common location for VAS is at or near its origin from the subclavian artery, considerable recoil often accompanies PTA alone. Endoluminal stenting of the vertebral artery lesion is an attractive approach,

Figure 81.4 (a) Right vertebral artery angiogram demonstrates severe ostial stenosis (95%). (b) After balloon angioplasty and stent placement, there is a 0% residual stenosis when compared with the reference vessel diameter.

which has proven safety, efficacy, and durability as evidenced by low recurrence rates (Figure 81.4).

Endovascular technique

The femoral approach is the most common access site. Patients should receive aspirin 325 mg/day and clopidogrel 75 mg/day. After arterial access they should receive of anticoagulation with 5000–10,000 units unfractionated heparin. Selective catheterization of the vertebral artery is performed using a 6 Fr Judkins Right-4, internal mammary artery or multipurpose catheter. The diagnostic catheter is then exchanged for a 6–8 Fr multipurpose guide catheter, or a long 6–7 Fr 90 cm sheath can be telescoped over the diagnostic catheter until it reaches close to the ostium of the vertebral artery. A 0.014-inch wire is then advanced into the artery and advanced distally, avoiding advancing past the end of the distal portion (V4) of the vertebral artery (Figure 81.5). Distal embolic protection devices are seldom used because of severe spasm of the vertebral artery. A balloon matched to the reference size is then advanced to the lesion for predilatation, followed by a balloon expandable stent. Post-deployment angiography is performed to include the posterior intracranial circulation. No sedation is used during the procedure and continuous neurologic monitoring is performed.

Vertebral artery trauma and dissection

Over 80% of unilateral vertebral artery traumatic injuries are asymptomatic. Patients may present with VBI, posterior headache, or neck pain. Those with bilateral vertebral artery injuries may present with more severe symptoms. The grade of injury to the vertebral artery does not correlate with its associated risk of stroke or death, which remains at approximately 20% and 8%, respectively.

All patients with traumatic vertebral artery injury, regardless of their symptomatic status, should undergo anticoagulation with unfractionated heparin followed by warfarin, if there are no contraindications, and serial neurologic examination to monitor for progression. Embolic stroke is the major cause of morbidity and mortality in patients with vertebral artery dissection. The treatment of dissection is for the most part conservative. Most dissections heal spontaneously and the associated aneurysms never rupture and only rarely cause delayed ischemic symptoms. Surgical treatment of

Figure 81.5 Vertebral artery segments: V1 is the most proximal segment prior to entering its bony canal at the C6 transverse process; V2 is the segment within the intraosseous canal; V3 is the extracranial segment between C2 and the base of the skull; and V4 is intracranial. Source: Image courtesy of Dr. Christina Sanina.

dissections consisting of an *in situ* interposition graft of extracranial–intracranial bypass is indicated only for those patients with persistent symptoms refractory to maximal medical therapy who are not candidates for endovascular treatment.

Antithrombotic Strategies in Endovascular Interventions: Current Status and Future Directions

Mehdi H. Shishehbor

Heart & Vascular Institute, Cleveland Clinic, Cleveland, OH, USA

Peripheral artery disease (PAD) affects the cerebral circulation and extracranial vessels, the aorta, great vessels, mesenteric and renal arteries, and the lower extremities. In recent years the number of endovascular procedures to treat this condition have significantly increased; however, despite this, little level 1 evidence is available regarding the role of antithrombotic therapy in patients undergoing these endovascular procedures. The current practice in this regard is heterogeneous and has been mainly driven by data from coronary artery disease and percutaneous coronary intervention (PCI). This chapter discusses the role of antithrombotic agents for endovascular intervention.

Pathophysiology

Thrombosis has a significant role in morbidity and mortality associated with cardiovascular, cerebrovascular, and peripheral artery disease. In addition to inflammation and atherosclerosis, hemostatic factors also have a role in the pathogenesis of PAD. For example, plasma fibrinogen and cross-linked fibrin degradation products have been shown to be elevated in patients with claudication compared to controls [1–4]. Furthermore, individuals with PAD have elevated levels of thrombin–antithrombin III complex, D-dimer, von Willebrand factor (vWF), tissue plasminogen activator antigen, plasminogen activator inhibitor-1 levels, C-reactive protein, and prothrombin fragments 1 and 2 [1–4]. It has been suggested that these hemostatic factors are associated with PAD, its progression, and clinical events such as restenosis.

Endovascular intervention has been shown to activate platelets and the inflammatory cascade, possibly resulting in thrombosis and restenosis. Thrombin has been linked to restenosis by activation of thrombin receptors on the smooth muscle cells, macrophages, fibroblasts, and endothelial cells [5–9]. For example, among patients with severe in-stent restenosis, thrombelastometry-derived value coagulation time was significantly shorter than that of patients without restenosis [10]. Furthermore, high levels of plasma heparin factor II, an inhibitor of thrombin action, has been associated with reduced incidence of in-stent restenosis [11].

Platelets are important mediators of atherosclerosis and thrombosis [12]. During endovascular intervention platelets are activated and exposed to collagen and vWF [13]. Through activation of

integrin receptors an array of inflammatory and prothrombotic mediators such as ADP, thromboxane A_2 (TxA_2), and thrombin are released [13], which will then result in further platelet activation [14]. Ultimately, rapid recruitment and activation of platelets leads to thrombus formation manifesting as stroke, acute limb ischemia, restenosis, and graft failure.

Aspirin

Aspirin is an irreversible inhibitor of prostaglandin H-synthase, which inhibits the actions of thromboxane [15]. It is a cyclooxygenase 1 (COX-1) selective inhibitor resulting in impaired synthesis of TxA_2 . The role of aspirin in cardiovascular disease has been well established; however, controversy exists as to whether aspirin could have a net clinical benefit in patients with peripheral vascular disease. A recent meta-analysis of 18 trials with 5269 patients with PAD revealed a reduction in cardiovascular events (adjusted hazard ratio 0.88, 95% CI 0.76–1.04); however, this was not statistically significant [16]. Importantly, no significant reduction in all-cause or cardiovascular mortality was identified [16]. The current American College of Cardiology/American Heart Association (ACC/AHA) guidelines have give a class I indication for the use of aspirin in patients with PAD [17]. Limited data are available on the impact of aspirin post-endovascular intervention; however, the combination of aspirin and dipyridamole has been shown to reduce recurrent obstruction after endovascular angioplasty for up to 12 months [18–20]. Importantly, high dose aspirin had no advantage over low dose therapy in these trials and was associated with significant gastrointestinal symptoms [18–20].

While the current guidelines continue to support the use of aspirin for prevention of cardiovascular endpoints in patients with PAD, few studies have shown benefit with low dose aspirin and the combination of aspirin and dipyridamole has failed to show a significant reduction in reocclusion after lower extremity percutaneous transluminal angioplasty (PTA) [18–20]. Early epidemiologic studies such as the Physicians' Health Study revealed a significant reduction in the rate of lower extremity revascularization with the use of low dose aspirin in men [21]. However, in the current era of stents and other advanced therapies there is no level 1 evidence that chronic aspirin therapy results in better patency, lower rates of

in-stent restenosis, or better limb-associated outcomes. However, it is likely that aspirin has cardiovascular advantages in patients with PAD.

Ticlopidine

A first generation ADP receptor antagonist, ticlopidine is no longer available in the USA. This ADP receptor antagonist inhibitor is of P2Y₁₂ subtype. The two main drugs in this class are ticlopidine and clopidogrel. Early data in patients undergoing PCI showed encouraging results with ticlopidine; however, the Clopidogrel ASpirin Stent International Cooperative Study (CLASSIC) trial compared ticlopidine with clopidogrel and showed much better safety and efficacy profiles with clopidogrel [22].

There are no data from randomized trials with ticlopidine in patients undergoing endovascular intervention. However, ticlopidine has been shown to be superior to aspirin for maintaining vein graft patency [23] but the combination of aspirin plus ticlopidine was not shown to be superior to aspirin alone in maintaining graft patency in the CASPAR trial [24].

Clopidogrel

An ADP receptor antagonist, clopidogrel has the most clinical data for prevention of thrombosis after aspirin. There is a significant body of evidence supporting the use of clopidogrel in patients undergoing PCI and in those presenting with acute coronary syndrome [25–28]. However, the data for the use of clopidogrel in patients with PAD to prevent cardiovascular endpoint remain controversial. The first signal showing potential benefit with clopidogrel in patients with PAD was derived from the Clopidogrel versus Aspirin in Patients at Risk of Ischemic Events (CAPRIE) study (Figure 82.1) [29,30]. In this study, an 8.7% relative risk reduction was seen with clopidogrel compared to aspirin alone and the benefit was mostly seen in those with symptomatic PAD (Figure 82.2). Unfortunately, the Clopidogrel and Aspirin in the Management of Peripheral Endovascular Revascularization (CAMPER) trial was withdrawn because of lack of enrollment. Another trial that evaluated the role of clopidogrel for primary and secondary prevention was Clopidogrel for High Atherothrombotic Risk and Ischemic

Stabilization Management and Avoidance (CHARISMA) trial [31]. A total of 15,063 patients were randomized to clopidogrel plus aspirin or aspirin alone. In the overall population, dual antiplatelet therapy was not superior to aspirin alone for preventing cardiovascular death, stroke, and myocardial infarction (MI) [31]. However, in a subgroup analysis, in those with established cardiovascular disease, dual antiplatelet therapy resulted in a 12.5% significant relative risk reduction. Importantly, dual antiplatelet therapy was associated with a higher risk of bleeding compared to aspirin alone (Table 82.1). Despite the overwhelming data in support of dual antiplatelet therapy for acute coronary syndrome and PCI, currently there are few data to support its use for endovascular intervention. The current ACC/AHA guidelines recommend clopidogrel as monotherapy for those individuals who cannot tolerate aspirin; however, dual antiplatelet therapy is not recommended [17].

Despite these recommendations there are variable treatment approaches for patients undergoing endovascular intervention. A recent survey revealed variable treatment duration and a mix of approaches [32]. Most operators treat patients with dual antiplatelet after most endovascular interventions; however, the duration of dual antiplatelet therapy is variable [32].

Other ADP receptor antagonists

Newer antiplatelet therapies have recently been developed to address some of the limitations of clopidogrel: platelet resistance, longer onset of action, and modest degree of platelet inhibition [12]. Of these, ticagrelor and prasugrel have received US Food and Drug Administration (FDA) approval for PCI. Ticagrelor is a cyclopentyl triazolopyrimidine that directly and reversibly inhibits the P2Y₁₂ receptor. Prasugrel is a prodrug whose active metabolites irreversibly bind to P2Y₁₂ receptors. However, few data are available for their use in patients with PAD or in those undergoing endovascular intervention. The EUCLID trial will examine the role of ticagrelor versus clopidogrel monotherapy for patients with PAD. This trial allows enrollment of patients who are 30 days post-endovascular or surgical revascularization; therefore, data from this trial should help guide antiplatelet therapy for patients with PAD with or without revascularization. The trial has reached full enrollment and the results are anticipated to be released in 2016.

Dipyridamole

Dipyridamole is an inhibitor of the cAMP phosphodiesterase and cyclic GMP phosphodiesterase type V enzyme. It is also a potent inhibitor of adenosine deaminase resulting in increased concentrations of adenosine. In a recent Cochrane meta-analysis of six randomized trials with a total of 356 patients, the combination therapy failed to prevent 6 month reocclusion (fixed effect odds ratio 0.69, 95% CI 0.44–1.10; $p=0.12$) [33].

Vorapaxar

Vorapaxar is a novel antiplatelet agent that selectively inhibits the cellular action of thrombin through antagonism of PAR-1. It has been evaluated for use for secondary prevention in patients with prior history of MI, ischemic stroke, or PAD; however, after 2 years those with ischemic stroke were excluded because of increased risk of intracranial hemorrhage. The study showed some benefit for the composite endpoint of cardiovascular death, MI, stroke, or recurrent ischemia leading to revascularization; however, this was associated with increased risk of bleeding. A subgroup analysis of 3787 patients with PAD did show a reduction in acute limb ischemia and peripheral revascularization; however, no difference in cardiovascular death, MI, or stroke was observed [34]. Given the limited data with this agent, its use is currently limited in the USA.

Low molecular weight heparins

Peri-interventional treatment with low molecular weight heparin (LMWH) has been shown to be superior to unfractionated heparin in femoropopliteal obstructions [35]. However, long-term therapy (for 3 months) with dalteparin failed to reduce femoropopliteal occlusions after PTA [36]. LMWH is used as a bridge in those requiring endovascular procedures but also have a strong indication for anticoagulation.

Glycoprotein IIb/IIIa receptor antagonists

Glycoprotein IIb/IIIa receptor antagonists prevent binding of fibrinogen to the platelet and hence prevent fibrinogen cross-linking. A significant body of literature for their use in the setting of PCI is available; however, over time their use has declined significantly. They have a very limited role during endovascular intervention and are rarely used.

Three clinical trials compared the rates of patency for abciximab with placebo and one trial compared abciximab plus urokinase with urokinase alone [37–40]. The results from these trials were mixed. Duda *et al.* [40] showed no significant advantage with abciximab at 24 hours and 3 months; however, another trial found better patency at 24 hours and 3 months [39]. Overall, there appeared to be higher rates of bleeding with abciximab. Because of limited efficacy, potential cost, and risk of bleeding, abciximab is rarely used as an adjunct to endovascular procedures.

Vitamin K antagonist

Vitamin K antagonist (VKA) has been compared with aspirin plus dipyridamole for better patency. A pooled comparison of two trials showed no benefit with VKA at 1, 3, 6, and 12 months [41,42]. Tan *et al.* [43] conducted a randomized trial comparing clopidogrel plus aspirin with LMWK and coumadin. No statistically significant differences were noted between the two groups at 1, 6, and 12 months for patency. As expected, those treated with LMWH followed by warfarin had higher bleeding complications [43]. The combination of VKA and suloctidil also was not superior to VKA alone [44]. Similarly, VKA was compared with ticlopidine in 197 patients. VKA was not superior to ticlopidine in preventing primary occlusion; however, it was associated with more side effects. Overall, the use of VKA is reserved for select patients with clinical events and hypercoagulable state and in those with recurrent lower extremity graft occlusion.

Cilostazol

Cilostazol is a phosphodiesterase inhibitor with therapeutic focus on cAMP. It is a potent inhibitor of platelet aggregation and is a direct arterial vasodilator. It is the only approved pharmacologic therapy to increase walking distance in patients with claudication. There is also some evidence to support its use for prevention of restenosis in patients undergoing coronary stenting; however, data for use in the lower extremities are less convincing [45–47]. Iida *et al.* [48] conducted a randomized clinical trial of 127 patients with de novo femoropopliteal lesions in which cilostazol plus aspirin showed a high rate of patency at 12, 24, and 36 months compared with ticlopidine plus aspirin. Similarly, in a retrospective analysis, cilostazol therapy showed better primary patency rates than the ticlopidine group [49].

Bivalirudin

Bivalirudin is a thrombin-specific anticoagulant mainly used to treat patients with heparin-induced thrombocytopenia (HIT) and in those undergoing PCI and has been considered for selective endovascular procedures [50]. It can be associated with fewer bleeding and vascular complications than heparin; however, no level 1 data in this regard are available. In a small registry from four institutions no adverse events were reported, with 100% procedural success rate. Bivalirudin has also been evaluated in the setting of endovascular abdominal aneurysm repair (EVAR). Overall, bivalirudin was found to be a safe and feasible alternative to unfractionated heparin in patients undergoing EVAR [51]. In retrospective studies bivalirudin has also been shown to be safe and effective compared to heparin alone in patients undergoing carotid artery stenting [52]. A number of other smaller registries and single-center studies have evaluated the role of bivalirudin in different endovascular settings. These reports have been presented at various national and international meetings but they have yet to be published in peer reviewed journals. However, given the cost and lack of level 1 evidence for better safety and efficacy compared with unfractionated heparin, its use has been limited to select centers and in those with allergic reaction to heparin (HIT).

Conclusions

Despite technical advances and increasing rates of endovascular procedures, limited level 1 evidence is available with regards to antithrombotic therapy in this setting. Most operators use some form of anticoagulation during the procedure and continue antiplatelet therapy thereafter; however, little evidence exists to support this approach. Luckily, the field of antiplatelet and anticoagulant therapies is evolving rapidly with newer agents such as vorapaxar, novel antiplatelet drugs like ticagrelor and prasugrel, and antithrombotic agents like rivaroxaban, eliquis, and dabigatran. In the future, specific therapies for patients with PAD and critical limb ischemia should become available.

Chronic venous disease is an important source of morbidity in Western Europe and the USA. Varicose veins are a common manifestation of chronic venous insufficiency and affect approximately 25% of adults in the Western hemisphere, where prevalence varies greatly by geographic area. The reported incidence of chronic venous insufficiency varies from around 1–40% in women and around 1–17% in men. Estimates for varicose veins are higher; around 1–73% in women and 2–56% in men [1]. These reported ranges reflect differences in the population distribution of risk factors, accuracy in the application of diagnostic criteria, and the quality and availability of medical diagnostic and treatment resources. Various risk factors are responsible for these incidences: older age, pregnancy (especially multiple), family history of venous disease, female gender, obesity, and occupations that result in significant orthostasis from prolonged standing [2]. Venous insufficiency is most often associated with great saphenous vein (GSV) reflux, but can also be present in the small saphenous vein (SSV) or perforator veins.

Historically, the treatment has been surgery, with high ligation and stripping, combined with phlebectomies. Such treatment efficiently reduces symptoms, improves quality of life (QOL), and reduces the rate of reoperation. However, the operation can occasionally be associated with significant postoperative morbidity, including bleeding, groin infection, thrombophlebitis, and saphenous nerve damage. However, major complications are rare based on the current available data. Conventional surgery is expensive as it is often performed in hospital using general or regional anesthesia.

In the past decade, alternative treatments such as endovenous laser ablation (EVLA), radiofrequency ablation (RFA), and ultrasound-guided foam sclerotherapy have gained popularity. Performed as office-based procedures using tumescent local anesthesia, the new minimally invasive techniques have been shown in numerous studies to obliterate the affected vein, eliminate reflux, and improve symptoms safely and effectively [3].

Predisposing factors

Age and gender

The prevalence of varicose veins in women is approximately twice that in men [4]. Advanced age has also been determined to be a risk factor [5]. Varicose veins have an estimated prevalence of 5–30% in

the adult population, with a female to male predominance of 3 : 1, although a more recent study supports a higher male prevalence [6]. The Edinburgh Vein Study screened 1566 subjects for venous reflux and found chronic venous insufficiency (CVI) in 9.4% of men and 6.6% of women. After age adjustment, the prevalence increased with age (21.2% in men >50 years old, and 12.0% in women >50 years old) [7]. The Tampere study investigated a large cohort of 3284 men and 3590 women with varicose veins and showed a prevalence of 18% and 42%, respectively. The overall prevalence of varicose veins at ages 40, 50, and 60 years was 22%, 35%, and 41%, respectively [8].

Pregnancy

Multiparity has been shown to be a major predisposing factor for development of varicose veins and part of its increase in prevalence has been attributed to female gender. In the Tampere study, the prevalence of varicose veins in women with 0, 1, 2, 3, and 4 or more pregnancies was 32%, 38%, 43%, 48%, and 59%, respectively [8]. The exact mechanism of pregnancy-induced venous insufficiency is not fully understood. It has been attributed to both hydrostatic and hormonal effects. Pressure of the gravid uterus on the pelvic vasculature is associated with lower extremity venous hypertension, venous distention, and valve rupture. High serum estradiol levels have been shown by Ciardullo *et al.* [9] to increase venous distensibility and varicose vein formation in menopausal women. The saphenous veins have been shown to contain estrogen and progesterone receptors that may enable the estradiol-rich hormonal state of pregnancy to exert a similar effect.

Hereditary

A positive family history of varicose veins is associated with a significantly increased risk of development of varicose veins. A study conducted in Japan showed that 42% of women with varicose veins reported a positive family history compared with 14% without the disease [10]. Various genetic predispositions have been linked to development of varicose veins. Downregulation of the desmuslin gene affecting the smooth muscle cells in the saphenous vein wall, thrombomodulin mutation (1208/1209 TT deletion) caused by varicose vein formation via deep vein thrombosis, expression of structural genes regulating the extracellular matrix (ECM), cytoskeletal proteins, and myofibroblasts have all been shown to be

associated with increased risk. Certain mutations have been linked to a variety of syndromes, including Klippel–Trenaunay syndrome (translocation involving chromosome 8q22.3 and 14q13; cutaneous capillary malformations, t tissues), lymphedema distichiasis syndrome (*FOXC2* mutation; extra eyelashes from meibomian glands, varicose veins, congenital heart defects, vertebral anomalies, extradural cysts, ptosis, and cleft palate), cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL; heterozygous mutation, -1279G>T), Chuvash polycythemia (autosomal recessive disorder caused by homozygous mutation of the von Hippel–Lindau gene [598>T] on chromosome 3p25), and other genes have been associated with poor wound healing causing venous ulceration (*FL3A1* gene: factor XIII deficiency, *HFE* gene mutation, *FGFR-2* [SNP 2451AG] mRNA instability, *MMP-12* [SNP 82AA]; functional change predisposing to ulcer) [11].

Lifestyle

Sedentary work and prolonged standing at work are independent risk factors for development of venous insufficiency [12]. In the Tampere study, the prevalence of varicose veins in standing versus sitting workers was 36% and 27%, respectively. The Edinburgh Vein Study has also shown predisposition of varicose veins in patients whose work involved prolonged standing.

Body habitus

Epidemiologic studies have shown that varicose veins are more common in female patients with increased body mass index (BMI) (especially >30 kg/m²). It has been assumed that subcutaneous deposition of adipose and fibrous tissue disrupts the cutaneous venous network, impairs drainage, and promotes stasis. The Edinburgh Vein Study supported the findings that increased BMI in women is a risk factor. Callam *et al.* [2], in his epidemiologic review series, reached similar conclusions.

Pathogenesis

Several theories have been proposed for the causal basis of CVI. There are two universally accepted theories: (i) primary valvular incompetence and (ii) primary congenital vein wall weakness.

Primary valvular incompetence is the oldest theory and was postulated by Sir William Harvey in 1628. It states that varicose veins develop as a sequela of central valvular incompetence related to paucity or atrophy of its valves. It causes venous hypertension in the vein segment below, which in turn damages adjacent peripheral valves and propagates varicose transformation in a central-to-peripheral direction. This theory conflicts with the fact that valves are strong structures capable of withstanding pressures of 200 mmHg without leakage or degenerative changes in leaflets and that varicose veins can occur below or between competent valves [13]. The primary vein wall weakness theory states that varicose veins develop from a defect in vein wall integrity rather than from a problem within the valves. The components of a normal vein wall include collagen matrix that provides strength, elastic fibers that provide compliance, and three smooth muscle layers (circular media surrounded by longitudinal intimal and adventitial layers) that control vascular tone. Histologic studies show that compared with normal veins, varicose veins show proliferation of the collagen matrix with disruption and distortion of the muscle fiber layers. In the most diseased areas, the muscle layer is completely disrupted, leaving only elastic tissue and collagen as the sole components of the vein wall. This histologic alteration in turn causes loss of

contractility, sagging of the muscular grid, and vessel dilatation in response to venous hypertension. The characteristic serpigino appearance of varicose veins reflects segments of dilatation interspersed between segments of normal vein [14].

Various factors influence the development of CVI: venous stasis, venous hypertension, fibrin cuff, water hammer effect, and leukocyte trapping.

Venous stasis

This concept suggests that stagnant accumulation of blood in tortuous, non-functioning, dilated skin veins results in subsequent tissue anoxia and cell death leading to skin changes and ulceration. Arteriovenous fistulae in limbs with varicosities have also been attributed to low oxygen content and CVI skin changes [15].

Venous hypertension

This concept has been attributed to muscle pump dysfunction and venous ulceration. It has been hypothesized that venous hydrostatic pressure is equal in the deep and superficial venous systems both at rest and in the erect position. During calf muscle contraction, the pressure in the deep veins increases more than in the superficial veins. However, valve closure prevents the pressure from being transmitted to the superficial veins. In contrast, pump dysfunction or valvular incompetence causes venous pressure to be transmitted to the superficial veins leading to CVI symptoms and ulceration [16–19].

Fibrin cuff

Pericapillary fibrin cuff has been associated with restriction of oxygen diffusion across the vessel wall leading to edema and dermatosclerotic skin changes. Pericapillary fibrin cuffs may act as a barrier, a marker for endothelial cell damage, or as part of an overall mechanism of macromolecular leakage and trapping [20].

Water hammer effect

This theory is the most widespread pathogenesis of CVI. It contends that reflux is mainly transmitted to the superficial veins through perforators. Studies by Raju and Fredericks have shown that this effect explains and correlates with most venous ulceration cases. At rest 20–25% of patients might have normal ambulatory venous pressure; nonetheless, Valsalva-induced venous hypertension transmits pressure, resulting in skin changes and ulceration [18,21].

Leukocyte trapping

The concept of leukocyte trapping was described very early and explains most of the CVI symptoms. Because of stasis and venous pressure changes, margination of the white cells occurs resulting in capillary plugging with further tissue hypoxia and damage. These cells also activate free radicals and cytokine (interleukin-1, tumor necrosis factor) release, resulting in tissue damage and apoptosis [22]. Unifying concepts of leukocyte trapping and venous hypertension have also been proposed [16].

Clinical manifestations

CVI manifests at different stages. At first it can present as telangiectasia or reticular veins and advance to more complicated stages such as skin fibrosis and venous ulceration. The main clinical features of CVI are leg pain, leg edema, varicose veins, and cutaneous changes. Various pathogenic mechanisms produce different clinical manifestations (incompetent valves as varicose veins, venous obstruction as

leg edema, and pump dysfunction as either symptom). Varicose veins are dilated superficial veins that become progressively more tortuous and large. They are prone to develop bouts of superficial thrombophlebitis. Edema begins in the perimalleolar region but later ascends causing leg edema with dependent accumulation of fluid. The leg pain or discomfort is described as heaviness or aching after prolonged standing and is relieved by elevation of the leg. Edema produces pain by increasing intracompartmental and subcutaneous volume and pressure. Tenderness along varicose veins is in the result of venous distention. Obstruction of the deep venous system can lead to venous claudication, or intense leg cramping with ambulation. Cutaneous changes include skin hyperpigmentation with hemosiderin deposition and eczematous dermatitis. Fibrosis also develops in the dermis and subcutaneous tissue (lipodermatosclerosis).

There is an increased risk of cellulitis, leg ulceration, and delayed wound healing. Longstanding CVI can also lead to the development of lymphedema, representing a combined disease process [23]. Several tools have been described to assess the severity of CVI and also monitor the effects of therapy. The CEAP (clinical, etiology, anatomic, pathophysiology) classification was the initial module developed by an international consensus conference to provide a basis for uniformity in reporting, diagnosing, and treating CVI. The CEAP classification takes into account all the diagnostic variables of CVI. In 2004, the CEAP revised consensus refined the class definitions and improved reproducibility of physician observations (Box 83.1; Table 83.1) [24–26]. Because of limitations of the CEAP clinical classification in delineating categories, a venous severity score was developed to complement the CEAP classification. The venous clinical severity score consists of 10 attributes (pain, varicose veins, venous edema, skin pigmentation, inflammation, induration, number of ulcers, duration of ulcers, size of ulcers, and compressive therapy) with four grades (absent, mild, moderate,

Box 83.1 Advanced CEAP classification

Superficial veins

- 1 Telangiectasias/reticular veins
- 2 GSV above knee
- 3 GSV below knee
- 4 Lesser saphenous vein
- 5 Non-saphenous veins

Deep veins

- 6 Inferior vena cava
- 7 Common iliac vein
- 8 Internal iliac vein
- 9 External iliac vein
- 10 Pelvic: gonadal, broad ligament veins, other
- 11 Common femoral vein
- 12 Deep femoral vein
- 13 Femoral vein
- 14 Popliteal vein
- 15 Crural: anterior tibial, posterior tibial, peroneal veins (all paired)
- 16 Muscular: gastrocnemial, soleal veins, other

Perforating veins

- 17 Thigh
- 18 Calf

This classification is the same as the basic classification with the addition that any of 18 named venous segments can be used as locators for venous disorders.

Table 83.1 CEAP classification for chronic venous disorders

Clinical classification	
C0	No visible or palpable signs of venous disease
C1	Telangiectasias, reticular veins, malleolar flares
C2	Varicose veins
C3	Edema without skin changes
C4	Skin changes attribute to venous disease (e.g., pigmentation, venous eczema, lipodermatosclerosis)
C4a	Pigmentation or eczema
C4b	Lipodermatosclerosis or atrophie blanche
C5	Skin changes as defined earlier with healed ulceration
C6	Skin changes as defined earlier with active ulceration
S	Symptomatic, including ache, pain, tightness, skin irritation, heaviness, and muscle cramps, and other complaints attributable to venous dysfunction
A	Asymptomatic
Causal classification	
Ec	Congenital
Ep	Primary
Es	Secondary (post-thrombotic)
En	No venous cause identified
Anatomic classification	
As	Superficial veins
Ap	Perforator veins
Ad	Deep veins
An	No venous location identified
Pathophysiologic classification	
Pr	Reflux
Po	Obstruction
Pr,o	Reflux and obstruction
Pn	No venous pathophysiology identifiable

Therapy can alter the clinical category of chronic venous disease. Limbs should therefore be reclassified after any form of medical or surgical treatment. Source: Adapted from Eklof B, *et al.* 2004 [25]. Copyright 2004 Elsevier.

severe). The venous anatomic segmental score assigns a numerical value to segments of the venous system in the lower extremity that account for both reflux and obstruction (Table 83.2) [27,28].

The venous disability score comes from the ability to perform normal activities of daily living with or without compressive stockings. The venous severity score has been mainly shown to be useful in evaluating the response to treatment [29]. The REVAS classification identifies patients with recurrent varices after surgery. In conjunction with the CEAP classification, it adds valuable information in evaluating patients with chronic venous disease after surgery [30].

QOL and economic impact

The impact of venous insufficiency on QOL was investigated by the Venous Insufficiency Epidemiologic and Economical Study (VEINES), an international survey. In VEINES, 65.2% of subjects with varicose veins had additional venous disease processes (edema, skin changes, ulceration), and both physical and mental QOL scores concomitant with the severity of their venous disease [31]. In the most severe cases, those in which venous ulceration was present, the QOL rating was worse than with chronic lung disease, back pain, or arthritis [32]. The VEINES study has two components: a QOL assessment (VEINES-QOL), which

Table 83.2 Revised venous clinical severity score.

Attribute	None: 0	Mild: 1	Moderate: 2	Severe: 3
Pain or other discomfort (i.e., aching, heaviness, fatigue, soreness, burning) Presumes venous origin	N/A	Occasional pain or other discomfort (not restricting regular daily activities)	Daily pain or other discomfort (interfering with but not preventing regular daily activities)	Daily pain or discomfort (limits most regular daily activities)
Varicose veins Varicose veins must be ≥ 3 mm in diameter to qualify in the standing position	N/A	Few: scattered (i.e., isolated branch varicosities or clusters) Also includes corona phlebectatica (ankle flare)	Confined to calf or thigh	Involves calf and thigh
Venous edema Presumes venous origin	N/A	Limited to foot and ankle area	Extends above ankle but below knee	Extends to knee and above
Skin pigmentation Presumes venous origin Does not include focal pigmentation over varicose veins or pigmentation caused by other chronic diseases (i.e., vasculitis purpura)	None or focal	Limited to perimalleolar area	Diffuse over lower third of calf	Wider distribution above lower third of calf
Inflammation More than just recent pigmentation (i.e., erythema, cellulitis, venous eczema, dermatitis)	N/A	Limited to perimalleolar area	Diffuse over lower third of calf	Wider distribution above lower third of calf
Induration Presumes venous origin of secondary skin and subcutaneous changes (i.e., chronic edema with fibrosis, hypodermatitis). Includes white atrophy and lipodermatosclerosis	N/A	Limited to perimalleolar area	Diffuse over lower third of calf	Wider distribution above lower third of calf
Active ulcer number	0	1	2	3
Active ulcer duration (longest active)	N/A	<3 months	>3 months but <1 year	Not healed for >1 year
Active ulcer size (largest active)	N/A	Diameter <2 cm	Diameter 2–6 cm	Diameter >6 cm
Use of compression therapy	Not used	Intermittent use of stockings	Wears stockings most days	Full compliance: stockings

estimates disease effect; and a symptoms questionnaire, which measures symptoms prevalence (VEINES-Sym). Other assessment programs used in clinical practice to assess the impact of CVI on QOL are the Aberdeen Varicose Vein Questionnaire (AVVQ), Charing Cross Venous Ulcer Questionnaire (CXVUQ), and Specific Quality of Life and Outcomes Response–Venous (SQOR-V) questionnaire [33,34].

Diagnosis

Multiple modalities have shown benefit in diagnosing the cause of CVI. Physical examination is the most important one. A thorough physical examination is usually enough to diagnose CVI. It also provides guidance during therapy.

Physical examination

Physical examination involves inspection of the skin for signs of CVI. Skin changes such as hyperpigmentation, stasis dermatitis, atrophic blanche (white scarring at the site of previous ulcerations with a paucity of capillaries), or lipodermatosclerosis are frequently seen. Varicose veins follow the path of superficial vein insufficiency [23]. Tenderness is almost always observed along the varicose veins. Skin edema is usually pitting, unless chronic edema makes the skin brawny and difficult to examine. Venous ulcerations are most common along the medial supramalleolar area at the site of a major perforator vein of high hydrostatic pressure. The classic tourniquet or Trendelenburg test can be performed at the bedside to help distinguish between deep and superficial reflux. The test is performed with the patient lying down to empty the lower extremity veins. The upright posture is then resumed after applying a tourniquet or using manual compression at various levels. In the presence of superficial disease the varicose veins remain collapsed if compression is distal to the point of reflux. With deep (or combined) venous insufficiency, the varicose veins appear despite the use of the tourniquet or manual compression. Although useful to help determine the distribution of venous insufficiency, this test does not help to determine the extent or severity of disease or to provide information about the cause [35].

Duplex imaging

Doppler is an important tool in diagnosing CVI and monitoring therapy. The goal of duplex imaging is to identify any obstruction or reflux in the deep veins, look for any presence of deep vein thrombosis, diagnose reflux in the superficial veins (great saphenous vein, perforator vein, and small saphenous vein), and localize branch varicose veins and perforator veins. Low-frequency transducers (2–3 MHz) are usually used to evaluate the iliac veins and inferior vena cava. High-frequency transducers (5–10 MHz) are used to evaluate lower extremity veins. Reflux thresholds for deep veins are greater than 1000 ms, superficial veins greater than 500 ms, and for perforators greater than 350 ms [36,37]. The most common site for reflux is the confluence of the GSV and common femoral vein, contributing to 65% of all cases, in a review of 2036 patients [38]. However, duplex has a weak correlation with the severity of the disease. Physical examination and duplex scan can guide most therapy. Venous compressibility complemented with flow characteristics are key elements in excluding thrombosis. The use of a cuff inflation deflation method with rapid cuff deflation in the standing position is preferred to induce reflux [39].

Plethysmography

Photoplethysmography (PPG) can be used to establish a diagnosis of CVI [38]. Relative changes in blood volume in the dermis of the limb can be determined by measuring the backscatter of light emitted from a diode with a photosensor. The venous refill time is the time required for the PPG tracing to return to 90% of the baseline after cessation of calf contraction. A venous refill time less than 18–20 s, depending on the patient's position during the study, indicates CVI. A venous refill time greater than 20 s suggests normal venous filling. The use of a tourniquet or low-pressure cuff allows superficial disease to be distinguished from deep venous disease. Refill time depends on several factors, including the volume of reflux and the vessel diameter. This technique has been used to assess emptying of the venous system during calf muscle contraction and venous outflow. PPG can provide an assessment of the overall physiologic function of the venous system, but is most useful in determining the absence or presence of disease [40,41].

Air plethysmography (APG) has the ability to measure each potential component of the pathophysiologic mechanisms of CVI: reflux, obstruction, and muscle pump dysfunction. Venous outflow is assessed during rapid cuff deflation on an elevated limb that has a proximal venous occlusion cuff applied. The outflow fraction at 1 s (or venous outflow at 1 s expressed as a percentage of the total venous volume) is the primary parameter used to evaluate the adequacy of outflow. A normal venous filling index is less than 2 mL/s, whereas higher levels (>4–7 mL/s) have been found to correlate with the severity of CVI. Complications of CVI, such as ulceration, have been shown to correlate with the severity of reflux assessed with the venous filling index and ejection capacity [42,43].

Computed tomography and magnetic resonance venography

Used in identifying more rare and complex causes of CVI, computed tomography (CT) is an important tool in recognizing thromboembolic disease in the proximal veins, whereas magnetic resonance venography has a major role in determining the age of thrombus. CVI syndromes such as May–Thurner syndrome, Paget–Schroetter syndrome, nutcracker syndrome, pelvic congestion syndrome, venous malformations, and atrioventricular malformations can be diagnosed effectively with these advanced imaging techniques [44,45].

Treatment

Initial treatment: behavioral measures and compression garments

Conservative measures have been proposed to reduce symptoms caused by CVI and prevent secondary complications and progression of disease. Behavioral measures such as elevating the legs to minimize edema and reducing intra-abdominal pressure should be advocated. The use of compressive stockings is the mainstay of conservative management. The Bisgaard regimen has been proposed for the healing of venous ulcers. This regimen has four components: patient education, foot elevation, elastic compression garments, and evaluation subsequently with CEAP classification. Non-elastic ambulatory below-knee compression aggressively counters the impact of reflux from venous pump failure.

Compression therapy is used for venous leg ulcers and can decrease blood vessel diameter and pressure, preventing blood from flowing backwards [46,47]. Compression is also used to decrease release of inflammatory cytokines, reduce capillary leak,

prevent swelling, and delay clotting by decreasing activation of thrombin and increasing that of plasmin. Compression is applied using elastic bandages or boots specifically designed for the purpose. It is not clear whether non-elastic systems are better than multilayer elastic ones. Patients should wear as much compression as it is comfortable. The type of dressing applied beneath the compression does not seem to matter, and hydrocolloid has not been shown to be superior to simple low-adherent dressings. The use of graded elastic compressive stockings (with 20–50 mmHg of tension) is well established in the treatment of CVI. Treatment with 30–40 mmHg compression stockings results in significant improvement in pain, swelling, skin pigmentation, activity, and overall well-being as long as a compliance of 70–80% is achieved [48]. In patients with venous ulcers, graded compression stockings and other compressive bandage modalities are effective in both healing and preventing recurrences of ulcers. With a structured regimen of compression therapy, 93% of patients with venous ulcers can achieve complete healing at a mean of 5.3 months. Compression stockings have been shown to reduce residual volume fraction, an indicator of improvement in the calf muscle pump function, and to reduce reflux in vein segments [49].

Failure of conservative therapy

Symptomatic patients who fail conservative therapy should be followed closely. These patients should have venous duplex studies and/or APG if conservative therapy fails or if there is any progression of symptoms in CEAP class. Further treatment is based on the results of non-invasive studies and specific treatment is based on severity of disease, with CEAP clinical classes 4–6 often requiring invasive treatment. Referral to a vascular specialist should be made for patients with CEAP classes 4–6 (and probably for CEAP class 3 with extensive edema). These patients with uncorrected advanced CVI are at risk for ulceration, recurrent ulceration, and non-healing venous ulcers with progression to infection and lymphedema.

Non-invasive study: venous reflux disease

Superficial venous reflux

Various therapies have been used for superficial venous reflux including cool-touch laser, RFA ablation, venous sclerotherapy, ligation, and phlebectomy.

Cool-touch laser

The first procedure to replace ligation and stripping of the GSV was radiofrequency-mediated thermal ablation. Long-term experience with cool-touch endovenous laser ablation showed that tissue water within the vein wall has a specific target chromophore of 1320-nm laser and the presence or absence of red blood cells within the vessels is unimportant. Water is the main component in the walls of a vein; they are composed mainly of water and collagen. The chromophore for the 1.32-mm or 1320-nm wavelength laser is water. This wavelength penetrates as deep as 500 mm in tissue. This provides a safety margin by reducing the risks of penetration of laser energy beyond the vein wall. For even greater control of energy distribution, the 1320-nm CTEV is coupled with an automatic pullback device that can retract the fiber at a rate of 0.5, 1, or 2 mm/s [50]. Endovenous laser treatments at 810, 940, and 980 nm are designed to produce endothelial and vein wall shrinkage by non-specific heating of the vessel [51]. This non-specific heating is accomplished by creating a superheated coagulum at the fiber tip or by the heating of hemoglobin within

red blood cells to create steam bubbles at extremely high temperatures. Without the presence of blood in the vein, such as an experimental situation in which the vein is filled with saline, laser-induced vessel wall injury is confined to the site of direct laser impact. By contrast, blood-filled veins show extensive thermal damage even in remote areas from the laser fiber, including the vein wall opposite to the laser impact. In the absence of blood, the situation is even worse; the areas of vein wall injury or burning result in intense postoperative pain and early recanalization of the treated vein. More importantly, superheating of hemoglobin leads to high temperatures (often higher than 1200 °C), which results in vein perforations, hematoma, and postoperative pain [52].

RFA therapy

Few studies have shown the superiority of RFA compared with EVLA in terms of pain, bruising, and postprocedure recovery, with GSV occlusion rates being comparable. The LARA study was a randomized control trial conducted to determine whether RFA of the GSV is associated with less pain and bruising than EVLA in 87 leg interventions [53]. In the bilateral group, RFA resulted in significantly less pain than EVLA on days 2–11 after surgery. RFA also resulted in significantly less bruising than EVLA on days 3–9. There were no significant differences in mean postoperative pain, bruising, and activity scores in the unilateral group. Both RFA and EVLA resulted in occlusion rates of 95% at 10 days after surgery [54]. The RECOVERY study randomized 87 veins in 69 patients to Closure FAST or 980-nm EVLA treatment of the GSV. It was a multicenter, prospective, randomized, single-blinded trial, performed at five American sites and one European site. All scores referable to pain, ecchymosis, and tenderness were statistically lower in the Closure FAST group at 48 hours, 1 week, and 2 weeks. Minor complications were more prevalent in the EVLA group ($p < 0.0210$); there were no major complications. Venous clinical severity scores and QOL measures were statistically lower in the Closure FAST group at 48 hours, 1 week, and 2 weeks. Radiofrequency thermal ablation was significantly superior to EVLA as measured by a comprehensive array of postprocedure recovery and QOL parameters [55]. The EVOLVeS trial studied the clinical outcomes of rates of recurrent varicosities, neovascularization, ultrasonography changes of the GSV, and QOL changes in patients undergoing RFA, ligation, or vein stripping. Two-year clinical results of radiofrequency obliteration are at least equal to those after high ligation and stripping of the GSV [56].

Venous sclerotherapy

This treatment modality is used for obliterating telangiectasias, varicose veins, and venous segments with reflux. Sclerotherapy can be used as a primary treatment or in conjunction with surgical procedures in the correction of CVI. Sclerotherapy is indicated for a variety of conditions including spider veins (<1 mm), venous lakes, varicose veins of 1–4 mm in diameter, bleeding varicosities, and small cavernous hemangiomas (vascular malformation). The terminal interruption of reflux source technique involves blocking off the veins that drain the ulcer bed using Sotradecol or Polidocanol foam, administered under ultrasonography guidance [57]. Patients with CVI need to be evaluated for surgical treatment if they have a non-healing ulcer refractory to conservative and minimally invasive therapy resulting in delayed healing, recurrent varicose veins, CVI with disabling symptoms, persistent discomfort refractory to other therapy, non-compliant patients with conservative therapy, and to complement therapy with conservative measures.

Ligation and venous phlebectomy

Surgical ligation of the GSV has been shown to improve symptoms in patient with CEAP classes 2–6. GSV removal with high ligation of the sapheno-femoral junction has long been considered the standard treatment for patients with significant venous reflux, non-healing ulcers, and symptomatic patients with concomitant deep venous reflux [58]. Transilluminated power phlebectomy (or TriVex) is a new surgical technique that uses tumescent dissection, transillumination, and powered phlebectomy. A prospective randomized controlled trial of 141 patients comparing conventional with powered phlebectomy has shown a trend toward reduced operating time in extensive varicosities, and significantly fewer incisions. There was no difference in nerve injury, bruising, and cosmetic score during follow-up [59]. The ESCHAR study evaluated around 500 patients with venous ulcer and reflux of superficial and deep venous systems and randomized them to either conventional saphenous vein surgery with compression or to compression alone. The study showed a significant reduction in ulcer recurrence at 12 months in favor of surgery with compression compared with compression alone (12% vs. 28%) [60]. A follow-up study to observe the improvement in perforating vein incompetence included 261 patients from the ESCHAR trial. Surgical correction of superficial reflux was shown to abolish incompetence in some calf perforators but also helped wound healing and reflux symptoms by preventing development of new perforator incompetence [61].

Deep venous reflux

Valve reconstruction surgery and valvuloplasty

CVI has been shown to be partially attributable to venous valve injury and incompetence. Venous valve reconstruction of the deep vein valves has been performed in selected patients with advanced CVI who have recurrent ulceration with severe and disabling symptoms [62]. Open valve surgery was initially performed to repair the femoral vein valve but subsequently transcommissural valvuloplasty was developed for venous repair. Venous valvuloplasty has been shown to provide 59% competency and 63% ulcer-free recurrence at 30 months. Complications from valvuloplasty include bleeding (because patients need to remain anticoagulated), deep venous thrombosis, pulmonary embolism, ulcer recurrence, and wound infections [63]. This procedure is reserved for selected patients refractory to other therapies. Valve replacements and transposition procedures have been attempted successfully when native valves have post-thrombotic valve destruction (not amenable to valvuloplasty). Valve transposition has been performed with the axillary vein valve, profunda femoris valve, or cryopreserved valve allografts. Cryopreserved vein valve allografts have also been shown to have early thrombosis, poor patency and competency, as well as high patient morbidity, precluding their use as a primary intervention [64].

Perforator reflux

Subfascial endoscopic perforator surgery

Perforator vein incompetence has been proposed as a cause for CVI. Some surgical options have been proposed for the treatment of incompetent perforators, including subfascial endoscopic perforator surgery (SEPS). This procedure involves ligation of the incompetent perforator veins by gaining access from a remote site on the leg that is away from the treatment area and is free of lipodermatosclerosis or ulcers. The North American Study Group performed a study with 146 patients showing cumulative ulcer healing at 1 year of 88% (median time to healing was 54 days). Ablation of superficial venous

reflux combined with lack of deep venous obstruction predicted ulcer healing ($p < 0.05$). Clinical score improved from 8.93 to 3.98 at the last follow-up ($p < 0.0001$). Cumulative ulcer recurrence at 1 year was 16% and at 2 years was 28% (standard error, $< 10\%$). Post-thrombotic limbs had a higher 2-year cumulative recurrence rate (46%) than did those limbs with primary valvular incompetence (20%; $p < 0.05$) [65]. The interruption of perforators with ablation of superficial venous reflux is effective in decreasing the symptoms of CVI and in earlier healing of ulcers. SEPS in conjunction with vein ablation showed better ulcer healing and improvement in clinical severity score [66].

Non-invasive study: chronic venous flow obstruction

May–Thurner syndrome

Endovascular therapy in the treatment of CVI has become increasingly important to restore outflow of the venous system and provide relief of obstruction. Approximately 10–30% of patients with severe CVI can be diagnosed with a significant abnormality in venous outflow involving iliac vein segments that contributes to persistent symptoms. Before endovascular therapy, iliac vein stenosis and obstruction causing CVI was treated with surgical procedures such as cross-femoral venous bypass or iliac vein reconstructions with prosthetic materials. Because of the success of venous stenting, surgical venous bypass is infrequently performed. In a large single-center series of 429 patients with CVI and outflow obstruction, iliac vein stenting resulted in significant clinical improvement: 50% of patients were completely relieved of pain and 33% experienced complete resolution of edema. Furthermore, 55% of patients with venous ulcers experienced complete healing of their ulcers. Patency of iliac vein stents is good, with a primary patency of 75% at 3 years. Close follow-up is mandatory to ensure that stent patency is maintained. Also early intervention is necessary in patients with recurrent symptoms that indicate in-stent restenosis, which occurs in approximately 23% of patients [67,68].

Chronic axillary–subclavian vein thrombosis or Paget–Schroetter syndrome

The pathogenesis of chronic axillary–subclavian thrombosis is associated with anatomic abnormalities at the thoracic outlet (cervical rib, congenital bands, hypertrophy of scalenus tendons, and abnormal insertion of the costoclavicular ligament) and repetitive trauma of the endothelium of the subclavian vein during activity of the upper extremities. The narrow costoclavicular space leads to compression and restricted mobility of the vein resulting in venous stasis. The repetitive endothelial trauma leads to intimal hyperplasia, inflammation, and fibrosis, resulting in venous webs, extensive collateral formation, and perivenular fibrosis worsening the stasis and costoclavicular crowding. Clinically, axillary–subclavian thrombosis preferentially involves the dominant arm and presents with swelling and discomfort of the arm. Other symptoms include heaviness and rubor of the arm with cyanotic, dilated, and visible veins across the shoulder and upper arm. The onset is usually acute or subacute but rarely can present with chronic symptoms. Most patients associate the onset with activities that involve vigorous and sustained upper extremity movements as well as outstretched arm. Complications include pulmonary embolism, post-thrombotic syndrome, and recurrent thrombosis. Despite the classic clinical presentation, the diagnosis of axillary–subclavian thrombosis should be confirmed initially with compression duplex ultrasonography

followed, as needed, with more specific and sensitive tests (e.g., radionuclide, magnetic resonance, computed tomographic venography, or invasive contrast venography). Management of axillary–subclavian thrombosis primarily includes catheter-directed thrombolysis and thoracic outlet decompression (resection of the first rib, division of the scalenus muscles and the costoclavicular ligament) with or without venoplasty/venous bypass. The best surgical approach to achieve thoracic outlet decompression is still debatable and excellent results are reported with both transaxillary and anterior, or sub-clavicular, approaches. Early and aggressive treatment includes optimal surgical strategy to prevent recurrent thrombosis and patient disability. Long-term anticoagulation can be reasonable in patients with coexistent thrombophilia and suboptimal surgical results [69].

Non-invasive study: muscle pump dysfunction

Abnormalities in the calf and foot muscle pumps have a significant role in the pathophysiology of CVI. Graded exercise programs have been used in an effort to rehabilitate the muscle pump and improve CVI symptoms. In a small controlled study, 31 patients with CEAP class 4–6 CVI were randomized to structured calf muscle exercise or routine daily activities. Venous hemodynamics were assessed with duplex ultrasonography, APG, and muscle strength assessed with a dynamometer. After 6 months, patients receiving a calf muscle exercise regimen had normalized their calf muscle pump function parameters but experienced no change in the amount of reflux or severity scores. Padberg *et al.* [70] concluded that structured exercise to re-establish calf muscle pump function in CVI can prove beneficial as a supplemental therapy to medical and surgical treatment in advanced disease.

Cardiac Vein Anatomy and Transcoronary Sinus Catheter Interventions in Myocardial Ischemia

Werner Mohl¹, Levente Molnár², and Béla Merkely²

¹Department of Cardiac Surgery, Medical University of Vienna, Vienna, Austria

²Semmelweis University, Budapest, Hungary

Aims of transcoronary sinus interventions

There is no better way to reach compromised ischemic microcirculation or no reflow zones after initial reperfusion in primary percutaneous coronary intervention (PCI) than with transcoronary sinus interventions (trans-CSI). Since the historical clinical series from Claude Beck reversing flow in the coronary circulation, at least partially, as a means to treat diffuse coronary artery disease, several therapeutic concepts have been formulated to use the “back door of the heart” to effectively reduce disease burden. Demographic changes in coronary artery disease, but also in heart failure, with more complex lesions, advanced comorbidities, and state of the art interventional technologies increase the need for trans-CSI.

In cardiac surgery, the ease of inserting catheters transatrially, the acceptance of retrograde cardioplegia, decades ago allowed cardioprotection for more than 2 hours of complex cardiac surgery without interfering with the surgical approach and undoing the tight relationship between the duration of global ischemic arrest and patient outcome. A different success story is resynchronization therapy enabled by using cardiac veins to reach left ventricular myocardium to adapt contractility dynamics and reduce dyssynchrony and therefore the burden of heart failure.

For today’s interventional cardiologist the advent of more complex lesions and the inherent invisible barrier of current treatment options in coronary artery disease demand innovative alternatives to reduce the amount of compromised microcirculation in acute coronary syndromes (ACS). But trans-CSI span their potential from preventing ischemia in elective cases (i.e., total coronary occlusion) to treating high risk patients with diffuse coronary artery disease and ischemic cardiomyopathies. Even the clinical potential of retroinfusion cardioprotective molecules and regenerative cells are currently under clinical scrutiny [1].

For the interventional cardiologist, trans-CSI became more important for the treatment of microvascular obstruction, no reflow zones, and to enhance and support the healing process of myocardial infarcts. From the many historical concepts of retrograde coronary sinus procedures this chapter focuses on a short overview of procedures that became clinically relevant or are still in clinical use. In addition, the following chapter highlights the clinical potential of a particular coronary sinus intervention, pressure controlled intermittent coronary sinus occlusion (PICSO),

which has proven validity in inducing myocardial salvage and apparently has the potential to regenerate the failing heart.

Anatomy of cardiac veins

To understand the clinical potential of trans-CSI one has to study the special features of the anatomy and pathophysiology of the cardiac venous system. Unlike the coronary arteries and the plethora of knowledge in the field of coronary circulation, cardiac veins are relatively neglected and knowledge about their role in structure and function is sparse. The anatomy of cardiac veins and their nomenclature was described by von Lüdinghausen [2]. Seventy-five percent of venous drainage is collected in the coronary sinus. Most parts of the left ventricle, excluding the upper septum, drain into the coronary sinus; however, most parts of the right ventricle drain via so-called lesser veins into both atria and ventricles. Thebesian veins or direct connections of the venous vasculature into the ventricles were described several centuries ago [3,4]. Although controversial, it stimulated knowledge of the anatomy of cardiac veins and their importance for the coronary circulation. In fact, the venous circulation outnumbers coronary arteries by far and creates a dense meshwork of interconnected channels allowing perfect access to the most important functional parts (i.e., anterior and lateral aspects of the left heart). The proximity between cardiac veins accessible for transcoronary sinus catheter interventions and coronary arteries, as well as the distance between mitral annulus and the great cardiac vein, shows the limitations to some of the methods used to correct structural and functional heart disease. Good reviews of the clinical assessment using CT scans of cardiac veins and their relationship to other anatomic landmarks have recently been published [5–7].

In contrast to trans-CSI for treating structural heart disease as transcoronary sinus mitral annuloplasty, functional modifications such as electrode deployment and radiofrequency ablation also involve the limiting factor of the proximity of the circumflex artery and the importance of reaching left ventricular excitable myocardium to fully explore the potential of resynchronization therapy.

For the use of trans-CSI in interventional cardiology, especially the deployment of catheters, the “silent zone” of the great cardiac vein is important [8]. “Silent zone” means that no additional branching veins enter the collecting chamber of the coronary sinus. Studies on the nomenclature of cardiac veins as well as all important parameters such as distances, angles, and landmarks of the coronary sinus

Figure 84.1 Late phase of a normal coronary arteriogram in two plans. Note the silent zone of the coronary sinus (great cardiac vein). This is the portion the catheter for transcoronary sinus interventions has to be positioned to achieve optimal redistribution of flow toward the deprived myocardium.

anatomy to catheterize the coronary sinus successfully are collected in the Coronary Sinus Library (www.coronarysinus.com), which contains the reprinted versions of proceedings of several seminars and symposia on myocardial protection via the coronary sinus held in the late 1980s [9–11].

The silent zone of the coronary sinus visualized in the late phase of the coronary arteriogram is depicted in Figure 84.1. The ideal place for a therapeutic catheter such as a PICSO catheter is between the stars in the angiogram. Stability of the catheter might be difficult because there is an enormous outward back pressure of venous blood and it requires special catheter technology to hold the catheter in place and to reduce the risk of catheter dislodgement.

In the majority of cases the coronary sinus is a tapered structure of about 4 cm in length from its entrance into the right atrium. The “silent zone” begins after inflow of the posterior interventricular vein until the first branches of the marginal veins. A variable structure of venous valves can hinder the catheterization of the coronary sinus. The width of the coronary sinus varies in patients with normal pressures in the right atrium from 6 to 18 mm² with a median of about 8–10 mm². In patients with increased prohormone of brain natriuretic peptide (proBNP) and manifest right heart failure, diameters can even increase in size. Unlike the coronary sinus orifice with its endocardial quality and embedded nerve endings, the great cardiac vein's surface is covered with endothelial layers. Reflexes such as hypotension and bradycardia have been described in the past by Muers and Sleight [12] as potential hazards of coronary sinus occlusion techniques.

Pathophysiologic background of transcoronary sinus interventions

Microvasculature and salvage

Allowing basal metabolism in deprived zones during ischemia and reopening “no reflow” zones in the center of reperfused myocardium remains an important challenge in today's treatment of

acute coronary artery syndromes. For this purpose it is important to redistribute venous flow like a sloughing wavefront into underperfused microcirculation, expand the vasculature, and by reverting this flow entraining toxic metabolites and cellular debris, thus reopening avenues for arterial inflow via collaterals in border zones [13–15]. PICSO, as it reverses venous flow during coronary sinus occlusion and washes out edema during the release phase, is a feasible intervention accessing the deprived microcirculation [16].

In a series of experimental and clinical studies, myocardial salvage was established as a dose-dependent treatment during pressure controlled intermittent obstruction of coronary venous outflow. In a meta-analysis, Syeda [17] was able to substantiate significant myocardial salvage in different experimental settings and animal models of about 30%. About the same magnitude of myocardial salvage was found in experimental infarction by Jacobs in the early reperfusion period and this has been corroborated in a few clinical series even using primary PCI and modern technology showing the same potential in reducing infarct size [18–20].

The first application of PICSO in ACS was in combination with lysis therapy and, although now outdated and not today's standard of care, showed the way to important discoveries. As already shown in experiments by Miyazaki *et al.* [21], the duration between onset of intravenous lysis and culprit lesion reopening through clot lysis was significantly shorter in the PICSO group [20]. The second important conclusion is based on the 5-year follow-up of these patients. Even after correction for differences in residual stenosis 30 days after treatment with PICSO in ACS and also correcting for differences in the duration of pain onset to reperfusion, there was a significant 96% reduction for reinfarction and 86% reduction in major adverse coronary events (MACE) over the 5 year follow-up in the PICSO-treated group, which heralded a paradigm change in the perception of trans-CSI and the beginning of an alternative in regeneration research [20].

Resynchronization therapy

The breakthrough in trans-CSI occurred at the advent of resynchronization therapy. The ability to improve heart failure with a relatively simple intervention and the chance to reach the left ventricle via a venous access was attractive. Biventricular pacing when applied to current guidelines show superiority in survival and quality of life and has been accepted by clinicians as well as patients [21,22]. Although coronary sinus catheterization is similar to interventional cardiology, the majority of cases are performed via the left subclavian vein. The ability to find an excitable myocardial space in the vicinity of a penetrable coronary vein correcting dyssynchrony is sometimes difficult and requires additional technology [23,24]. In spite of unquestionable successes of this therapy there is still room for innovations and to improve patient groups as non-responders. For this purpose, biomarkers sampled from the coronary sinus as well as other parameters are currently under investigation to improve outcome [25–27].

Mitral annulus modifications

In the quest to find minimal invasive techniques to improve heart failure and mitral insufficiency, the assumed proximity between coronary sinus and mitral valve annulus stimulated the development of several percutaneous cinching devices positioned into the coronary sinus. Enthusiasm for these devices have been hampered recently by lack of clinical efficiency. The obvious distance between the coronary sinus and the mitral valve, especially near the posteromedial commissure where most valve pathologies develop, as well as difficulties in device development and safety, reduced early enthusiasm for this procedure. In addition, cinching devices are in danger of compressing the crossing circumflex branch of the left coronary artery, thus generating iatrogenic myocardial infarction [28–32]. Today, these procedures are less often used clinically and will soon vanish from the clinical arena.

Regenerative potential of transcatheter sinus interventions

The vast meshwork of coronary venous microcirculation is not only important for revascularization procedures using the transcatheter sinus access to deprived myocardial perfusion zones, but also for substance exchange and recently encountered stimulation of innate developmental pathways to initiate structural regeneration. Long-term follow-up in patients treated with PICSO prompted a paradigm change in trans-CSI. Puzzled by the obvious long-term effect of PICSO inexplicable by myocardial salvage and its confounding parameters, several experimental fundamental studies have been performed. Weigel *et al.* [33] showed in a porcine model that according to the clinical findings a causative gene expression was enhanced in the tissue of treated animals. Two important molecules—HO-hemoxygenase and vascular endothelial growth factor (VEGF) gene expression—increased significantly in remote and also partly in border and infarct zones. As HO-hemoxygenase is not only a vasoactive substance that might act during the acute collateralization of the border zone, but also an anti-atherosclerotic and cardioprotective molecule supposed to be a causative element in preventing restenosis and in risk reduction of MACE and reinfarction. The observed absolute risk reduction resulting from PICSO was 29% (95% confidence interval 10.1–73.7%; $p=0.001$). This means, in 100 patient-years, an estimated number of at least 10 events (obtained from the lower confidence limit) can be prevented by PICSO. The number needed to treat was 3.4 (95% CI 1.38–9.90), or, put another way, treating 3.4 patients by PICSO would on average save one MACE per year. Recalculation

counting MACE events only during the first year of follow-up resulted in a higher absolute rate reduction of 51.2%, but at the same time in a wider confidence interval (–1.2% to +131%; $p=0.059$), caused by the considerably lower number of events. This result indicates that PICSO may be more beneficial during the first year of follow-up than afterwards. Because of these unexpected results we went back to the drawing board and tried to envision the cause of long-term effects and decipher changes in the molecular healing cascade after myocardial infarction. We therefore looked at the similarities between cardiac development and innate regenerative processes in the adult heart and formulated the hypothesis of “embryonic recall” [34–36]. Miyasaka found that micro-RNA are expressed in rodents during and after the first heart beat, meaning that the hemodynamic force of the flowing blood and actual pulsations are acting via mechanotransduction on the endocardium, producing a burst of developmental signals. There is an obvious analogy here to PICSO acting on venous endothelium (Figure 84.2). Ongoing analysis of PICSO in adult patients with severe heart failure and cardiac resynchronization therapy (CRT) plus/minus PICSO is evidently supporting the hypothetical considerations. Deciphering the clinical potential of PICSO in heart failure patients will open up completely new horizons in cardiac regeneration beyond cellular therapy.

How to access jeopardized myocardium Expertise necessary to use transcatheter sinus catheter interventions

The anatomy of the coronary sinus in regard to venous access needs special requirements of catheter systems as well as the expertise of the interventionalist. Wang *et al.* [24] recently reported on a steerable catheter system facilitating coronary sinus cannulation under ECG guidance reducing access and procedure time. As the orifice of the coronary sinus is not in the same plane as the inferior cava, one has to rotate the tip back and to the right upwards to obtain good access via the femoral vein.

The ultimate goal in considering the potential success of transcatheter sinus interventions, one may ask when the device manufacturer will come up with a low profile, steerable, and blind (i.e., ECG guidance) catheter system allowing access via brachial veins or at least uncomplicated subclavian, jugular access. Figure 84.3 shows that even in patients with ACS, access as well as adjunct therapy like PICSO can be applied without losing procedure time.

Current transcatheter sinus catheter interventions in myocardial jeopardy PICSO

Transcatheter sinus catheter interventions developed from historic arterial retroperfusion techniques. A comprehensive review on past and present procedures and their background and clinical potential show the uniqueness of PICSO among trans-CSI with two independent principles. The first is the redistribution of flow and subsequent washout with its dose-dependent salvage potential. The second is its threshold dependent mode of action based on the developed pulsatility and backflow of venous blood in cardiac veins initiating molecular responses through mechanotransduction in venous endothelium reiterating developmental processes [37–39]. First-in-man study of PICSO dates back to the 1980s and was performed during the early reperfusion period in patients undergoing

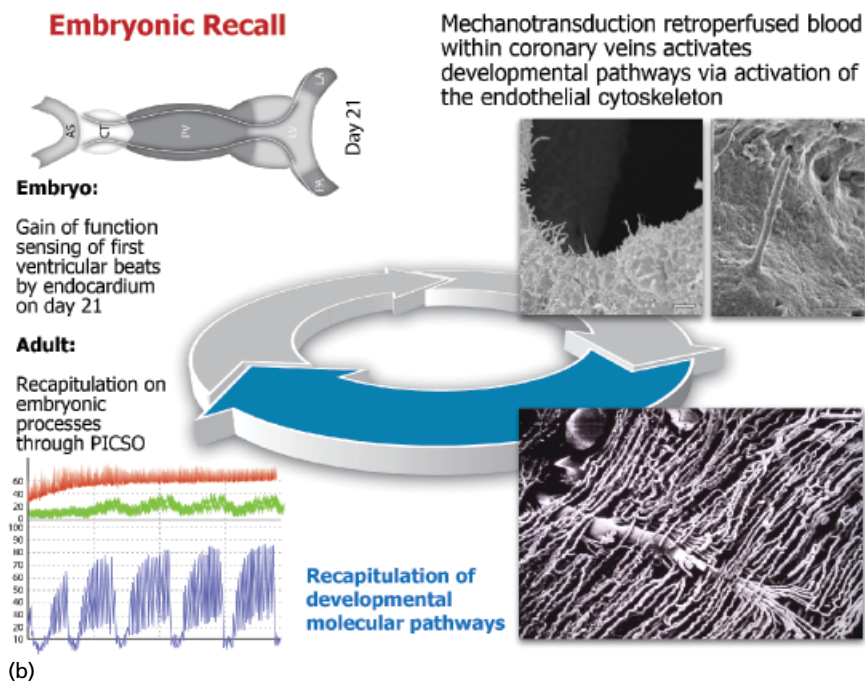

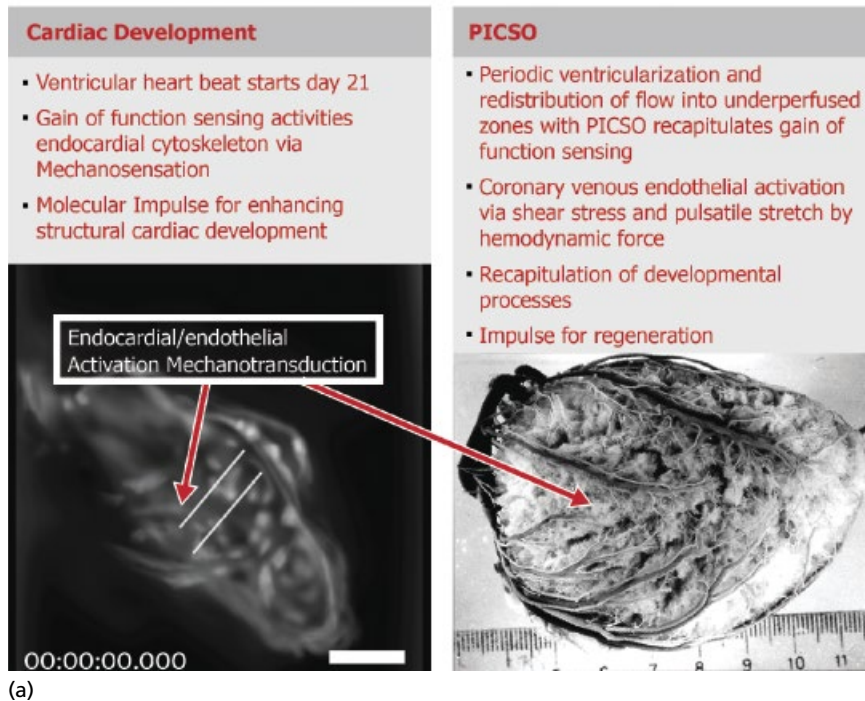

Embryonic recall: Recapitulation of dormant developmental processes

Figure 84.2 The hypothesis of “embryonic recall.” Note the analogy of pressure and flow activating endocardium during development as soon as the heart tube starts to beat with the pulsations in the microcirculation during pressure controlled intermittent coronary sinus occlusion (PICSO) (a). The PICSO tracing with temporarily increased pressures in cardiac veins are depicted (b).

coronary artery bypass grafting. Results showed an improvement in regional wall motion in severely depressed myocardium as well as a trend toward, but an insignificant, improvement in clinical outcomes after 30 days (fewer catecholamines, fewer postoperative infections, shorter intubation time, etc.) [40].

In interventional cardiology, relief of ischemic burden and consequences of reperfusion injury are of utmost importance. PICSO in

ACS has recently been applied in ST-segment elevation myocardial infarction (STEMI) as well as non-STEMI (NSTEMI) patients using the new technology. Noteworthy, however, is the effect that the hemodynamic sloughing blood wave reduces the no reflow zone, the obstructed microcirculation after primary PCI, and induces washout and apparently enhances even decomposition of occluding clots in coronary arteries thus improving prognosis in this patient group [19,20].

Figure 84.3 Timetable of a typical PICSO study in a patient. Note that the timing of catheterization does not interfere with arterial reopening. PICSO application is timed according to the PICSO quantity an empiric parameter claiming to fully evolve the PICSO benefit.

Figure 84.4 PICSO catheter in place in a patient undergoing PCI and PICSO (see also Videos 84.1, 84.2, and 84.3).

A first-in-man study using state of the art technology and automated pressure control was performed by Van de Hoef *et al.* [41] and showed feasibility and anti-ischemic effects in elective patients undergoing PCI. Present state-of-the-art application of PICSO in patients with ACS and primary PCI (PPCI) show the feasibility of this method. As seen in Video 84.1, the catheter is positioned in the silent zone of the coronary sinus and temporary occlusion there-

fore enables redistribution of flow into the reperfused zone. In Video 84.2, the screen of the PICSO controller/pump system is shown illustrating the pressure increase in the venous circulation according to PICSO. Video 84.3 shows the balloon inflation during the PICSO procedure and PPCI (Figures 84.3 and 84.4; Videos 84.1, 84.2, and 84.3). Of importance is the pressure control which is based on an algorithm tested in a series of experiments analyzing

the amount of blood retroperfused during balloon occlusion and the forward flow during balloon deflation showing a net washout phenomenon implying that more fluid and potentially edema is transported out of the myocardium [16,42]. Pressure control is also important because we found in our first-in-man studies a direct relationship between rise time of coronary sinus pressure increase and coronary flow (i.e., there is a sharp increase in pressure amplitudes and a shortening of the rise time when coronary artery bypass grafts are opened). It becomes evident that unphysiologic obstruction of venous circulation beyond the plateau of pressure peaks can increase impedance to arterial inflow. This effect underscores the necessity of present automatic pressure control as depicted in the video (Videos 84.2 and 84.3).

What can be expected from PICSO application in ACS in PPCI? Although current data analysis relies only on one historic clinical study and an additional trial with only a small number of treated patients using new technology and automated pressure control, there are anti-ischemic effects and almost certainly the same salvage potential as in experimental infarction, which however have to be proven by a large propensity-matched trial to establish clinical significance. Using the gold standard for salvage imaging, however, has one severe confounding factor in addition when studying PICSO patients. In experimental infarction, the area at risk is measured before the start of the therapy, which is impracticable in patients with ACS. Therefore the area at risk is measured on day 3 or 4 using the area with increased water content. As PICSO not only induces washout, but also reduces the perfusion deficit by supporting vasodilatation in border zones, the area at risk in PICSO patients will be smaller and therefore also the calculable salvage effect. In our opinion, evidence on the clinical significance of PICSO has to take this into account and it will be necessary to develop a special algorithm between PICSO quantity, or dose, and ultimate infarct size as well as microvascular obstruction, which also can be measured with MRI [14–17]. Another important effect is the coronary sinus pressure dynamics over the time of PICSO application. In our experience, during myocardial infarction and ischemia, coronary sinus pressure increases over time, because of improvement of nutritive flow and subsequently myocardial performance. However, this is not the case in early reperfusion with its temporal hyperemic flow response. Coronary sinus pressure dynamics during early reperfusion after primary PCI in patients show a gradual decline in amplitudes as well as an increase in rise time. This might be caused, as Khattab *et al.* [43] showed in porcine experiments, by two independent factors: first, the effect of opening up the obstructed microcirculation as additional space to fill retrogradely (and therefore longer rise times); and, second, the temporary hyperemic response in early reperfusion reducing the pressure amplitude at the end of the application. Especially in patients with low ejection fraction and large infarcts with low mean arterial pressure, coronary sinus pressure might even fail to increase substantially because of the reduced driving force of myocardial contraction and low coronary venous flow (which is predictive for outcome) which may limit the efficiency of PICSO [44]. However, in a case report on a PICSO application in acute shock patients presented by A. Colombo and his group, myocardial contraction was markedly improved within hours in no-option patients with otherwise failed cardiac support (personal communication and report at EuroPCR 2016).

In all therapies aiming to reduce infarct size and to induce salvage, clinical endpoints and outcome are of enormous

importance. Long-term 5-year follow-up in PICSO studies is only available for historic data and their positive interaction on restenosis, reinfarction, and MACE have to be corroborated with modern technology in primary PCI and analyzed in larger propensity-matched trials, but one can also expect interesting results in registries of PICSO in STEMI and NSTEMI and even heart failure patients [20]. Recently another important application of PICSO has shown promising results: patients with elective PCI in need of cardiac support may benefit from PICSO since this intervention reduces the ischemic burden and clears the microcirculation from debris produced by the coronary intervention.

Banai stent

A different approach is the Banai stent as permanent throttle in the great cardiac vein as a means to reduce chronic angina in high risk patients with diffuse coronary artery disease. There are clinical data supporting this notion in a limited number of patients and Konigstein recently published long-term follow-up data on this intervention. However, there is controversy between the Banai stent concept and scientific considerations on temporal or permanent pressure elevation in cardiac veins [45–48]. The ease of the concept and the potential benefit may develop the application of this technology.

Retroinfusion (cells and gene therapy)

Retroinfusion of cells and molecules have been tried by several groups with high efficacy. Tuma *et al.* [1] showed that even in clinical studies the retrograde access is superior to other more sophisticated or invasive methods like transcoronary artery and myocardial delivery. First, the access to deprived myocardium and diffuse coronaries is an attractive alternative and principles of substrate exchange and the role of venous endothelium might be of importance for success [49–52].

Conclusions and future directions

Demographic changes in patients with more and more complex comorbidities and older age are the imperative to develop new standards in patient care. Based on the special anatomy and pathophysiology of cardiac veins, the options for trans-CSI to develop into a standard of care are enormous. There are several facts supporting the rise of these procedures. In the past, coronary sinus access was troubled by the lack of expertise of interventionists, the paucity of supporting clinical evidence, and shortcomings in interventional technology. Especially in the emergency settings of acute ischemia, the unquestioned evidence of time-dependent myocardial salvage in coronary revascularization procedures made it almost impossible to apply these methods clinically despite supporting evidence of improved long-term outcome. Today the situation has changed drastically. Modern imaging techniques have shown that for all trials to achieve timely reperfusion microcirculatory obstruction persists and that additional methods beyond salvage appear essential. Stem cell transplantation reopened the window of adjunct therapies even days after the acute event. This stimulated research on reperfusion injury and infarct healing as well as therapeutic concepts. Concomitantly, the formation of heart teams for engaging structural heart disease and the success story of resynchronization therapy increased the expertise to catheterize the coronary sinus. Dedicated knowledge focusing on transcoronary

sinus catheter interventions are currently supplying the necessary technology and equipment. It is therefore plausible that technologies like PICSO ameliorating the ischemic burden and claiming to regenerate and recover the heart will develop into a standard of care procedure.
