

Interventional Cardiology

Principles and Practice

Second Edition

Edited by

George D. Dangas, MD, PhD, FACC, FSCAI, FESC, FAHA

Professor of Medicine
Director, Cardiovascular Innovation
Mount Sinai Medical Center
New York, NY
USA

Carlo Di Mario, MD, PhD, FRCP, FACC, FSCAI, FESC

Consultant Cardiologist
Royal Brompton Hospital
Professor of Clinical Cardiology
National Heart & Lung Institute Imperial College London
London
UK

Nicholas N. Kipshidze, MD, PhD, FACC, FESC, FSCAI

Professor of Medicine and Surgery
Consultant Cardiologist
N. Kipshidze Central University Hospital
Tbilisi, Georgia
Director,
New York Cardiovascular Research,
New York, NY
USA

Associate Editors

Peter Barlis and Tayo Addo

Foreword by

Patrick W. Serruys, MD, PhD

WILEY Blackwell

Designations used by companies to distinguish their products are often claimed as trademarks. All brand names and product names used in this book are trade names, service marks, trademarks or registered trademarks of their respective owners. The publisher is not associated with any product or vendor mentioned in this book. It is sold on the understanding that the publisher is not engaged in rendering professional services. If professional advice or other expert assistance is required, the services of a competent professional should be sought.

The contents of this work are intended to further general scientific research, understanding, and discussion only and are not intended and should not be relied upon as recommending or promoting a specific method, diagnosis, or treatment by health science practitioners for any particular patient. The publisher and the author make no representations or warranties with respect to the accuracy or completeness of the contents of this work and specifically disclaim all warranties, including without limitation any implied warranties of fitness for a particular purpose. In view of ongoing research, equipment modifications, changes in governmental regulations, and the constant flow of information relating to the use of medicines, equipment, and devices, the reader is urged to review and evaluate the information provided in the package insert or instructions for each medicine, equipment, or device for, among other things, any changes in the instructions or indication of usage and for added warnings and precautions. Readers should consult with a specialist where appropriate. The fact that an organization or Website is referred to in this work as a citation and/or a potential source of further information does not mean that the author or the publisher endorses the information the organization or Website may provide or recommendations it may make. Further, readers should be aware that Internet Websites listed in this work may have changed or disappeared between when this work was written and when it is read. No warranty may be created or extended by any promotional statements for this work. Neither the publisher nor the author shall be liable for any damages arising herefrom.

Library of Congress Cataloging-in-Publication Data

Names: Dangas, George D., editor. | Di Mario, Carlo, editor. | Kipshidze, Nicholas N., editor.

Title: Interventional cardiology : principles and practice / edited by George D. Dangas, Carlo Di Mario, Nicholas N. Kipshidze ; foreword by Patrick W. Serruys.

Other titles: Interventional cardiology (Di Mario)

Description: Second edition. | Chichester, West Sussex ; Ames, Iowa : John Wiley & Sons, Inc., 2017. | Includes bibliographical references and index.

Identifiers: LCCN 2016018228 (print) | LCCN 2016018438 (ebook) | ISBN 9781118976036 (cloth) | ISBN 9781118975930 (pdf) | ISBN 9781118976067 (epub)

Subjects: | MESH: Cardiovascular Diseases--therapy | Cardiac Surgical Procedures | Cardiovascular Diseases--diagnosis

Classification: LCC RD598 (print) | LCC RD598 (ebook) | NLM WG 166 | DDC 617.4/12--dc23

LC record available at <https://lcn.loc.gov/2016018228>

A catalogue record for this book is available from the British Library.

Wiley also publishes its books in a variety of electronic formats. Some content that appears in print may not be available in electronic books.

Contents

About the Companion Website vi
Contributors vii
Foreword xvi
Preface xvii
Acknowledgments xviii

Part I Principles and Techniques 1

Section I Basic Knowledge 3

- 1 Atherogenesis and Inflammation 3
Umair Hayat, Vikas Thondapu, Tim Tsay, and Peter Barlis
- 2 The Essentials of Femoral Vascular Access and Closure 17
Ted Feldman and Mohammad Sarraf
- 3 Radial Artery, Alternative Arm Access, and Related Techniques 27
Thomas J. Ford, Martin K.C. Ng, Vikas Thondapu, and Peter Barlis
- 4 Optimal Angiographic Views for Coronary Angioplasty 34
Gioel Gabrio Secco and Carlo Di Mario
- 5 Material Selection 44
Sahil A. Parikh, Michele Pighi, and Carlo Di Mario

Section II Imaging and Physiology 59

- 6 Physiologic Assessment in the Cardiac Catheterization Laboratory: CFR, FFR, iFR, and Beyond 59
Sukhjinder Nijjer and Justin Davies
- 7 Intravascular Ultrasound and Virtual Histology: Principles, Image Interpretation, and Clinical Applications 71
Adriano Caixeta, Akiko Maehara, and Gary S. Mintz
- 8 Optical Coherence Tomography, Near-Infrared Spectroscopy, and Near-Infrared Fluorescence Molecular Imaging 91
Ismail Dogu Kilic, Roberta Serdoz, Enrico Fabris, Farouc Amin Jaffer, and Carlo Di Mario
- 9 Complementary Imaging Techniques: Multislice Computed Tomography of Coronary Arteries 107
Omosalewa O. Lalude, Francesca Pugliese, Pim J. de Feyter, and Stamatios Lerakis
- 10 Cardiovascular Magnetic Resonance Imaging 126
Omosalewa O. Lalude and Stamatios Lerakis

Section III PCI in Different Clinical Settings 138

- 11 Stable Coronary Artery Disease 138
Abhiram Prasad and Bernard J. Gersh

- 12 PCI Strategies in Acute Coronary Syndromes without ST Segment Elevation (NSTEMI) 148
Georgios E. Christakopoulos, Subhash Banerjee, and Emmanouil S. Brilakis

- 13 Primary and Rescue PCI in Acute Myocardial Infarction and Elements of Myocardial Conditioning 155
Tayo Addo, Neil Swanson, and Anthony Gershlick

- 14 The Management of Cardiogenic Shock and Hemodynamic Support Devices and Techniques 163
Bimmer E.P.M. Claessen, Dagmar Ouweneel, and José P.S. Henriques

Section IV PCI in Different Lesion Types 168

- 15 Percutaneous Coronary Intervention in Unprotected Left Main 168
Gill Louise Buchanan, Alaide Chieffo, and Antonio Colombo

- 16 Bifurcation Lesion Stenting 175
Yves Louvard, Thierry Lefevre, Bernard Chevalier, and Philippe Garot

- 17 Risk Stratification Approach to Multivessel Coronary Artery Disease 185
Davide Capodanno and Corrado Tamburino

- 18 Chronic Total Coronary Occlusion 190
Gerald S. Werner and Emmanouil S. Brilakis

- 19 Percutaneous Coronary Intervention of Arterial and Vein Grafts 201
Bimmer E.P.M. Claessen, José P.S. Henriques, and George D. Dangas

- 20 Interventional Approach in Small Vessel, Diffuse, and Tortuous Coronary Artery Disease 205
Robert Pyo

- 21 In-Stent Restenosis in New Generation DES Era 213
Marco G. Mennuni and Patrizia Presbitero

Section V Special Techniques and Complications 224

- 22 Laser, Rotational, and Orbital Coronary Atherectomy 224
Kaleab N. Asrress, Peter O'Kane, Robert Pyo, and Simon R. Redwood

- 23 Thrombus-Containing Lesions 233
Giovanni Luigi De Maria and Adrian P. Banning

- 24 Specialized Balloons in Percutaneous Coronary Intervention: Cutting, Scoring, Gliding, and Drug-Eluting Balloons 244
Bimmer E.P.M. Claessen, José P.S. Henriques, and George D. Dangas

- 25** Coronary Artery Dissections, Perforations, and the No-Reflow Phenomenon 248
Adriano Caixeta, Luiz Fernando Ybarra, Azeem Latib, Flavio Airoidi, Roxana Mehran, and George D. Dangas
- 26** Access Site Complications 267
Jose M. Wiley, Fernando Pastor, and Cristina Sanina
- 27** Renal Insufficiency and the Impact of Contrast Agents 274
Michael Donahue and Carlo Briguori
- 28** Radiation Management in Interventional Cardiology 282
Stephen Balter and Charles E. Chambers
- 29** Concepts of Cell Therapy and Myocardial Regeneration 290
Kevin O'Gallagher, Zoë Astroulakis, Alex Sirker, and Jonathan M. Hill

Section VI Clinical Trials in Coronary Heart Disease 296

- 30** Statistical Essentials in the Design and Analysis of Clinical Trials 296
Usman Baber and Stuart J. Pocock
- 31** Historical Perspective of Sirolimus and Paclitaxel-Eluting Stent Clinical Studies 301
Adriano Caixeta, Leonardo Guimarães, Philippe G n reux, and George D. Dangas
- 32** Cobalt-Chromium Everolimus-Eluting Stents 313
Vikas Thondapu, Yoshinobu Onuma, Bimmer E.P.M. Claessen, Patrick W. Serruys, and Peter Barlis
- 33** Platinum-Chromium Everolimus-Eluting Stents 326
Vikas Thondapu, Bimmer E.P.M. Claessen, George D. Dangas, Patrick W. Serruys, and Peter Barlis
- 34** Bioresorbable Stents 335
Gianluca Caiazzo, Alessio Mattesini, Ciro Indolfi, and Carlo Di Mario
- 35** The Biolimus Stent Family 344
Anna Franzone, Raffaele Piccolo, and Stephan Windecker
- 36** The Biotronik Stent Family 360
Anna Franzone, Raffaele Piccolo, and Stephan Windecker
- 37** Novel Drug-Eluting Stent Systems 368
J. Ribamar Costa, Jr., Adriano Caixeta, and Alexandre A.C. Abizaid

Part II Interventional Pharmacology 377

Section I Fundamentals of Interventional Pharmacology 379

- 38** Basics of Antiplatelet and Anticoagulant Therapy for Cardiovascular Disease 379
Piera Capranzano and Dominick J. Angiolillo
- 39** Balance of Ischemia and Bleeding in Selecting Antithrombotic Regimens 389
Bimmer E.P.M. Claessen and Jos  P.S. Henriques

Section II Pharmacological Agents 397

- 40** Oral Antiplatelet Agents in PCI 397
Jonathan A. Batty, Joseph R. Dunford, George D. Dangas, and Vijay Kunadian
- 41** Parenteral Anticoagulant Agents in PCI 408
Piera Capranzano, Corrado Tamburino, and George D. Dangas

- 42** Parenteral Antiplatelet Agents in PCI 415
Piera Capranzano, Giuseppe Gargiulo, and Corrado Tamburino
- 43** Role of Parenteral Agents in PCI for Stable Patients 421
Joanna Ghobrial, David A. Burke, and Duane S. Pinto
- 44** Vasoactive and Antiarrhythmic Drugs During PCI 432
Bimmer E.P.M. Claessen and Jos  P.S. Henriques
- 45** The Optimal Duration of Dual Antiplatelet Therapy After PCI 436
Mikkel Malby Schoos, Roxana Mehran, and George D. Dangas
- 46** Triple Antiplatelet Therapy and Combinations with Oral Anticoagulants After PCI 443
Jonathan A. Batty, Joseph R. Dunford, Roxana Mehran, and Vijay Kunadian

Section III Pharmacological Testing 453

- 47** Peri-procedural Platelet Function Testing in Risk Stratification and Clinical Decision Making 453
Paul A. Gurbel, Fang Liu, Gailing Chen, and Udaya S. Tantry
- 48** Genetics and Pharmacogenetics in Interventional Cardiology 459
Hillary Johnston-Cox, Johan L.M. Bj rkegren, and Jason C. Kovacic
- 49** Monitoring and Reversal of Anticoagulation and Antiplatelet Agents 469
Gregory W. Yost and Steven R. Steinhubl

Part III Hypertension and Structural Heart Disease 485

Section I Systemic and Pulmonary Hypertension 487

- 50** Right Heart Catheterization and Pulmonary Hemodynamics 487
P. Christian Schulze
- 51** Treatment of Pulmonary Embolism: Medical, Surgical, and Percutaneous 491
Ian del Conde and Barry T. Katzen
- 52** Renal Denervation for Resistant Hypertension 499
Hitesh C. Patel, Carl Hayward, Sebastian Ewen, and Felix Mahfoud

Section II Structural Heart Interventions 507

- 53** Antithrombotic Strategies in Valvular and Structural Heart Disease Interventions 507
Mikkel Malby Schoos, Davide Capodanno, and George D. Dangas
- 54** Alcohol Septal Ablation for Hypertrophic Obstructive Cardiomyopathy 517
Amir-Ali Fassa, George D. Dangas, and Ulrich Sigwart
- 55** Left Atrial Appendage Exclusion 525
Jorge G. Panizo and Jacob S. Koruth
- 56** Cryptogenic Stroke, Patent Foramen Ovale, and ASD Closure 530
Barry Love

- 57** Paravalvular Leak Closure and Ventricular Septal Defect Closure 540
Saurabh Sanon, Mackram F. Eleid, Allison K. Cabalka, and Charanjit S. Rihal

Section III Valvular Heart Disease Interventions 546

- 58** Aortic Valvuloplasty and Large-Bore Percutaneous Arterial Access 546
Matthew I. Tomey, Annapoorna S. Kini, Samin K. Sharma, and Jason C. Kovacic
- 59** Transfemoral Aortic Valve Implantation: Preparation, Implantation, and Complications 558
Brandon M. Jones, Samir R. Kapadia, Amar Krishnaswamy, Stephanie Mick, and E. Murat Tuzcu
- 60** Transthoracic Aortic Valve Implantation 569
Giuseppe Bruschi, Kaleab N. Asrress, Paola Colombo, and Vinayak N. Bapat
- 61** New Aortic Valve Technologies 575
Dimytri Alexandre Siqueira and Alexandre A.C. Abizaid
- 62** Transseptal Puncture 582
Alec Vahanian, Dominique Himbert, Fabrice Extramiana, Gregory Ducrocq, and Eric Brochet
- 63** Principles of Carpentier's Reconstructive Surgery in Degenerative Mitral Valve Disease 592
Farzan Filsoufi and Alain Carpentier
- 64** Mitral Valve Repair: MitraClip and Emerging Techniques 599
Ted Feldman, Mohammad Sarraf, Mayra Guerrero, and Francesco Maisano
- 65** Balloon Mitral Valvuloplasty 606
C.N. Manjunath, Nagaraja Moorthy, and Upendra Kaul
- 66** Pulmonary Artery and Valve Catheter-Based Interventions 619
Kasey Chaszczewski, Damien Kenny, and Ziyad M. Hijazi
- 67** Imaging for Planning and Guidance for Structural Heart Interventions 629
Ankit Parikh and Stamatios Lerakis

Part IV Vascular Disease for the Interventionalist 641

Section I Cerebrovascular Disease 643

- 68** Acute Stroke Intervention 643
Stefan C. Bertog, Iris Q. Grunwald, Anna Luisa Kühn, Laura Vaskelyte, Ilona Hofmann, Sameer Gafoor, Markus Reinartz, Predrag Matic, and Horst Sievert
- 69** Carotid Artery Angioplasty and Stenting 653
Alberto Cremonesi, Shane Gieowarsingh, and Fausto Castriota

- 70** Cerebral Aneurysms: Diagnosis, Indications, and Strategies for Endovascular Treatment 671
Gyula Gál

Section II Aorta and Branch Diseases 677

- 71** Management of Acute Aortic Syndromes 677
Christoph A. Nienaber and Rachel E. Clough
- 72** Thoracic Endovascular Aortic Aneurysm Repair 687
Paul S. Lajos and Michael L. Marin
- 73** Endovascular Aortic Aneurysm Repair 692
William Beckerman, Paul S. Lajos, and Peter L. Faries
- 74** Acute and Chronic Mesenteric Ischemia 698
Robert J. Rosen, Amit Jain, and Jennifer Drury
- 75** Renal Artery Interventions 705
Mark Shipeng Yu, Kun Xiang, Steven T. Haller, and Christopher J. Cooper
- 76** Revascularization for Arteries in the Pelvis 713
Femi Philip and Jason H. Rogers

Section III Peripheral Arterial Disease 721

- 77** Iliac Interventions 721
Manish Taneja and Apoorva Gogna
- 78** Superficial Femoral Artery Interventions 726
Cristina Sanina, Pedro R. Cox-Alomar, Prakash Krishnan, and Jose M. Wiley
- 79** Popliteal Artery Interventions 733
Karthik Gujja, Gopi Pudukollu, Vishal Kapur, and Prakash Krishnan
- 80** Below the Knee Interventions in Critical Limb Ischemia 738
Karthik Gujja, Katarzyna Nasiadko, Arthur Tarricone, and Prakash Krishnan
- 81** Subclavian, Vertebral, and Upper Extremity Vascular Disease 748
Ian Del Conde, Cristina Sanina, and Jose M. Wiley

Section IV Venous Disease/Interventions 754

- 82** Antithrombotic Strategies in Endovascular Interventions: Current Status and Future Directions 754
Mehdi H. Shishehbor
- 83** Chronic Venous Insufficiency 759
Karthik Gujja, Cristina Sanina, and Jose M. Wiley
- 84** Cardiac Vein Anatomy and Transcoronary Sinus Catheter Interventions in Myocardial Ischemia 768
Werner Mohl, Levente Molnár, and Béla Merkely

Index 776

About the Companion Website

Don't forget to visit the companion website for this book:

www.wiley.com/go/dangas/cardiology

There you will find valuable material designed to enhance your learning, including:

- 19 procedural videos illustrating key procedures
- More than 400 interactive multiple choice questions

Scan this QR code to visit the companion website:

Contributors

Alexandre A.C. Abizaïd, MD, PhD

Director, Invasive Cardiology Department
Instituto Dante Pazzanese de Cardiologia (IDPC);
Hospital do Coração—Associação do Sanatório Sírio (HCor);
Hospital Israelita Albert Einstein
São Paulo, Brazil

Tayo Addo, MD

Associate Professor of Medicine
University of Texas Southwestern Medical Center
Dallas, TX, USA

Flavio Airoidi, MD

Director
Interventional Cardiology Unit
IRCCS Multimedica
Sesto San Giovanni, Italy

Dominick J. Angiolillo, MD, PhD

Department of Medicine, Division of Cardiology
University of Florida College of Medicine—Jacksonville
Jacksonville, FL, USA

Kaleab N. Asrress, MA, PhD, MRCP

Department of Cardiology
St. Thomas' Hospital;
King's College London British Heart Foundation Centre of
Excellence
The Rayne Institute, St. Thomas' Hospital
London, UK

Zoë Astroulakis, MBBS, MRCP, PhD

Consultant in Interventional Cardiology
Department of Cardiology, St George's Hospital
London, UK

Usman Baber, MD, MS

Director of Clinical Biometrics
Cardiovascular Institute Assistant Professor of Medicine
Icahn School of Medicine at Mount Sinai
New York, NY, USA

Stephen Balter, PhD

Professor of Radiology and Medicine
Columbia University Medical Center
New York, NY, USA

Subhash Banerjee, MD

Chief of Cardiology
VA North Texas Health Care System;
Professor of Medicine
University of Texas Southwestern Medical Center
Dallas, TX, USA

Adrian P. Banning, MBBS, MD, FRCP, FESC

Consultant Cardiologist
Oxford Heart Centre, Oxford University Hospitals
John Radcliffe Hospital
Oxford, UK

Vinayak N. Bapat, MBBS, MS, FRCS.CTh

Department of Cardiology and Cardiothoracic Surgery
St Thomas' Hospital;
King's College London British Heart Foundation Centre of Excellence
The Rayne Institute, St. Thomas' Hospital
London, UK

Peter Barlis, MBBS, MPH, PHD, FACC, FESC, FRACP

Professor of Medicine
Faculty of Medicine, Dentistry & Health Sciences
The University of Melbourne
Victoria, Australia

Jonathan A. Batty, BSc, MBChB

Institute of Cellular Medicine
Newcastle University;
The Royal Victoria Infirmary
Newcastle upon Tyne NHS Foundation Trust
Newcastle upon Tyne, UK

William Beckerman, MD

Resident in Vascular Surgery
Division of Vascular Surgery
Icahn School of Medicine at Mount Sinai
New York, NY, USA

Stefan C. Bertog, MD

CardioVascular Center Frankfurt
Frankfurt, Germany

Johan L.M. Björkegren, MD, PhD

The Zena and Michael A. Wiener Cardiovascular Institute
and the Department of Genetics & Genomic Sciences
Institute of Genomics and Multiscale Biology
Icahn School of Medicine at Mount Sinai
New York, NY, USA

Carlo Briguori, MD, PhD, FACC, FSCAI

Chief of Interventional Cardiology
Laboratory of Interventional Cardiology and Department of Cardiology
Clinica Mediterranea
Naples, Italy

Emmanouil S. Brilakis, MD, PhD

Minneapolis Heart Institute
Minneapolis, MN, USA;
Professor of Medicine
University of Texas Southwestern Medical Center
Dallas VA Medical Center
Dallas, TX, USA

Eric Brochet, MD

Cardiologist
Echocardiography Laboratory
Department of Cardiology
Hôpital Bichat-Claude Bernard
Paris, France

Giuseppe Bruschi, MD, FESC

Department of Cardiology and Cardiothoracic Surgery
Niguarda Ca' Granda Hospital
Milan, Italy

Gill Louise Buchanan, MBChB

Department of Cardiology
North Cumbria University NHS Trust
Carlisle, UK

David A. Burke, MD

Division of Cardiovascular Medicine, Department of Medicine
Beth Israel Deaconess Medical Center
Harvard Medical School
Boston, MA, USA

Allison K. Cabalka, MD

Division of Pediatric Cardiology
Mayo Clinic College of Medicine
Rochester, MN, USA

Gianluca Caiazzo, MD, PhD

Division of Cardiology, Department of Medical and Surgical Sciences
Magna Graecia University
Catanzaro, Italy;
National Institute of Health Research (NIHR)
Royal Brompton & Harefield NHS Foundation Trust
London, UK

Adriano Caixeta, MD, PhD

Interventional Cardiologist
Hospital Israelita Albert Einstein;
Professor of Medicine
Universidade Federal de São Paulo,
São Paulo, Brazil

Davide Capodanno, MD, PhD

Associate Professor of Cardiology
University of Catania;
Interventional Cardiologist
Ferrarotto Hospital
Catania, Italy

Piera Capranzano, MD

Cardiovascular Department
Ferrarotto Hospital, University of Catania
Catania, Italy

Alain Carpentier, MD, PhD

Hôpital Européen Georges-Pompidou
Paris, France

Fausto Castriota, MD

Maria Cecilia Hospital
GVM Care & Research
Cotignola, Italy

Charles E. Chambers, MD

Professor of Medicine and Radiology
Penn State Hershey Medical Center
Hershey, PA, USA

Kasey Chaszczewski, MD

Rush University Medical Center
Chicago, IL, USA

Gailing Chen, MD

Sinai Center for Thrombosis Research
Cardiac Catheterization Laboratory
Baltimore, MD, USA

Bernard Chevalier, FESC

Institut Cardiovasculaire Paris Sud
Hôpital Privé Jacques Cartier, Massy;
Hôpital Privé Claude Galien
Quincy, France

Alaide Chieffo, MD

Consultant Interventional Cardiologist
Interventional Cardiology Unit
San Raffaele Scientific Hospital
Milan, Italy

Georgios E. Christakopoulos, MD

Research Fellow
VA North Texas Health Care System;
University of Texas Southwestern Medical Center
Dallas, TX, USA

Bimmer E.P.M. Claessen, MD, PhD

Department of Cardiology
Academic Medical Center—University of Amsterdam
Amsterdam, The Netherlands

Rachel E. Clough, MD

University Heart Center Rostock
Department of Internal Medicine
Cardiology, Pulmonology, Intensive Care Medicine
Rostock School of Medicine
Rostock, Germany

Antonio Colombo, MD

Interventional Cardiology Unit
San Raffaele Scientific Hospital
Milan, Italy

Paola Colombo, MD, PhD

Department of Cardiology and Cardiothoracic Surgery
Niguarda Ca' Granda Hospital
Milan, Italy

Christopher J. Cooper, MD

Department of Medicine, Cardiovascular Medicine
University of Toledo
Toledo, OH, USA

J. Ribamar Costa, Jr., PhD

Chief of the Medical Section of Coronary Intervention of the Instituto Dante
Pazzanese de Cardiologia (IDPC);
Hospital do Coração—Associação do Sanatório Sírio (HCor)
São Paulo, Brazil

Pedro R. Cox-Alomar, MD, MPH, FACC

Interventional Cardiology Fellow
Division of Cardiology
University of Florida College of Medicine
UF Health Medical Center
Jacksonville, FL, USA

Alberto Cremonesi, MD

Maria Cecilia Hospital
GVM Care & Research
Cotignola, Italy

George D. Dangas, MD, PhD, FACC, FSCAI, FESC, FAHA

Professor of Medicine
Director, Cardiovascular Innovation
Department of Cardiology
Mount Sinai Medical Center
New York, NY
USA

Justin Davies, BSc, MBBS, MRCP, PhD

Imperial College London
London, UK

Giovanni Luigi De Maria, MD

Oxford Heart Centre, Oxford University Hospitals
John Radcliffe Hospital
Oxford, UK

Ian del Conde, MD, FACC

Miami Cardiac and Vascular Institute
Miami, FL, USA

Carlo Di Mario, MD, PhD, FRCP, FACC, FSCAI, FESC

Consultant Cardiologist
National Institute of Health Research (NIHR)
Royal Brompton & Harefield NHS Foundation Trust, London;
Professor of Clinical Cardiology
National Heart & Lung Institute Imperial College London
London, UK

Michael Donahue, MD

Interventional Cardiologist
Laboratory of Interventional Cardiology and Department of Cardiology
Clinica Mediterranea
Naples, Italy

Jennifer Drury

Physician Assistant
Lenox Hill Heart and Vascular Institute
New York, NY
USA

Gregory Ducrocq, MD

Hôpital Bichat-Claude Bernard
Paris, France

Joseph R. Dunford, MRes

Institute of Cellular Medicine
Newcastle University
Newcastle upon Tyne, UK

Mackram F. Eleid, MD

Division of Cardiovascular Diseases
Mayo Clinic College of Medicine
Rochester, MN, USA

Sebastian Ewen, MD

Klinik für Innere Medizin III
Universitätsklinikum des Saarlandes
Homburg-Saar, Germany

Fabrice Extramiana, MD

Hôpital Bichat-Claude Bernard
Paris, France

Enrico Fabris, MD

Interventional Cardiologist
National Institute of Health Research (NIHR)
Royal Brompton & Harefield NHS Foundation Trust, London;
NHLI Imperial College London
London, UK;
Cardiovascular Department
Ospedali Riuniti and University of Trieste
Trieste, Italy

Peter L. Faries, MD, FACS

The Franz W. Sichel Professor of Surgery
Chief, Division of Vascular Surgery
Professor of Surgery & Radiology
Icahn School of Medicine at Mount Sinai
New York, NY, USA

Amir-Ali Fassa, MD

La Tour Hospital
Geneva, Switzerland

Ted Feldman, MD, FESC, FACC, MSCAI

Director, Cardiac Catheterization Laboratories
Evanston Hospital
NorthShore University HealthSystem
Evanston, IL, USA

Pim J. de Feyter, MD, PhD, FESC, FACC

Professor of Cardiac Imaging
Departments of Cardiology and Radiology
Erasmus MC University Medical Center
Rotterdam, The Netherlands

Farzan Filsoufi, MD

Professor
Department of Cardiovascular Surgery
Icahn School of Medicine at Mount Sinai
New York, NY
USA

Thomas J. Ford, MBChB

Department of Cardiology
St. George Hospital;
Faculty of Medicine
University of New South Wales
Sydney, New South Wales
Australia

Anna Franzone, MD

Department of Cardiology
Bern University Hospital
Bern, Switzerland

Sameer Gafoor, MD

CardioVascular Center Frankfurt
Frankfurt, Germany;
Swedish Medical Center
Seattle, WA, USA

Gyula Gál, MD

Department of Radiology, Section of Neuroradiology
Odense University Hospital
Odense, Denmark

Giuseppe Gargiulo, MD

Cardiovascular Department
Ferrarotto Hospital
University of Catania
Catania, Italy

Philippe Garot, FESC

Institut Cardiovasculaire Paris Sud
Hôpital Privé Jacques Cartier, Massy;
Hôpital Privé Claude Galien
Quincy, France

Philippe G n reux, MD

Clinical Instructor
Division of Cardiology
Center for Interventional Vascular Therapy
Columbia University Medical Center
New York, NY, USA

Bernard J. Gersh, MBChB, DPhil, FACC

Professor of Medicine
Mayo Clinic and Mayo Clinic College of Medicine
Rochester, MN, USA

Anthony Gershlick, MBBS, BSc, FRCP

University of Leicester
Leicester, UK

Joanna Ghobrial, MD, MS

Division of Cardiovascular Medicine
Department of Medicine
Beth Israel Deaconess Medical Center
Harvard Medical School
Boston, MA, USA

Shane Gieowarsingh, MBBS, MET

Maria Cecilia Hospital
GVM Care & Research
Cotignola, Italy

Apoorva Gogna, MBBS, FRCR

Consultant, Interventional Radiology
Singapore General Hospital
Singapore

Iris Q. Grunwald, MD, PhD

Post Graduate Medical Institute
Anglia Ruskin University
Chelmsford, UK;
Southend University Hospital
Southend-on-Sea, UK

Mayra Guerrero, MD, FACC, FSCAI

NorthShore University HealthSystem
Evanston, IL, USA

Leonardo Guimar es, MD

Interventional Cardiologist
Hospital Israelita Albert Einstein;
Universidade Federal de S o Paulo
S o Paulo, Brazil

Karthik Gujja, MD, MPH

Assistant Professor of Medicine
Icahn School of Medicine at Mount Sinai;
Assistant Director of Endovascular Fellowship
The Zeta and Michael A. Weiner Cardiovascular Institute
Icahn School of Medicine at Mount Sinai
New York, NY, USA

Paul A. Gurbel, MD

Director, Inova Center for Thrombosis
Research and Drug Development
Inova Heart and Vascular Institute
Falls Church, VA, USA

Steven T. Haller, PhD

Department of Medicine
Cardiovascular Medicine
University of Toledo
Toledo, OH, USA

Umair Hayat

Melbourne Medical School
Faculty of Medicine, Dentistry and Health Sciences
The University of Melbourne
Victoria, Australia

Carl Hayward, MB, BChir, MRCP, MA

Cardiology Research Fellow
National Institute of Health Research (NIHR)
Royal Brompton & Harefield NHS Foundation Trust
London, UK

Jos  P.S. Henriques, MD, PhD

Department of Cardiology
Academic Medical Center—University of Amsterdam
Amsterdam, The Netherlands

Ziyad M. Hijazi, MD, MPH, MSCAI

Professor of Pediatrics
Weill Cornell Medicine
Chair, Department of Pediatrics
Sidra Medical and Research Center
Doha, Qatar

Jonathan M. Hill, MD

Department of Cardiology
King's College Hospital NHS Foundation Trust
London, UK

Dominique Himbert, MD

Cardiologist
Department of Cardiology

Foreword

The development of interventional cardiology has followed the evolutionary trend of internal medicine. After World War II and during the latter part of the twentieth century, the number of subspecialties in the field of Internal Medicine exploded. The “Great Internal Medicine” became Cardiology, Pneumonology, Gastroenterology, Endocrinology, and so on.

Interventional cardiology was originally created by Andreas Grüntzig when, for the first time in a conscious patient, he applied the technique of percutaneous transluminal angioplasty: the whole intervention consisted of “inflating” a balloon inside the narrowed section of a coronary artery. It took almost two decades to diversify the approach of the percutaneous treatment of coronary artery disease with devices such as directional atherectomy, rotational atherectomy, and stenting.

The ground-breaking work in congenital treatment, the first pulmonary balloon angioplasty, the first closure of an atrial septum defect, almost went unnoticed by the “mature” interventional cardiologist. It was not until Alain Cribier’s pioneering work that the field of adult valvular intervention ushered in the specialty of interventional cardiology outside the coronary arteries.

In the 1990s the term TCT was coined (transcatheter treatment) and this further evolved into the concept of percutaneous coronary intervention (PCI), which today englobes and comprises intracranial treatment, carotid treatment, aortic arch reconstruction, descending aorta, femoral, popliteal, pedal artery, most of the congenital abnormalities including ASD, VSD, patent ductus arteriosus, and also left atrial appendage and most recently the extraordinary explosion of devices to treat aortic stenosis, aortic regurgitation, and mitral valve stenosis ... as well as others such as the alcoholization of the interventricular septum in hypertrophic cardiomyopathy.

As a consequence of this diversification, we see highly specialized doctors in interventional cardiology, who dedicate their time to total chronic occlusion, bifurcation, aortic stenosis with TAVR, mitral clips, mitral valve replacement, and so on.

What is striking is that the development of a highly specialized subspecialty requires an in-depth knowledge of very specific details to efficiently and safely perform these interventions. For instance, the transseptal punctures for left appendage closure or clip implantation are quite different and necessitate 3D imaging online with precise measurement in 3D dimension of the site of the puncture, which has to be a few millimeters below, above, at the back, in the front of the septum, and so on. Thus, the new generation gets involved in a very granular analysis of the syndromes, techniques, type of lesion, and type of imaging, and may, at some point, lose the “helicopter view of the field.” Therefore we must commend the editors of the second edition of the *Interventional Cardiology* for having a very broad and wide description of the field, which is an increasingly challenging endeavor.

It would be easy to be laudative about the content. It is apparent that all the authors have done their utmost to cover the field. It is always very challenging to start and maintain a so-called “textbook.” In my personal experience as an editor/co-editor of 42 (text) books; I can frankly say that a textbook in the field is a most exacting activity, in the sense that only a few great names have been able to repeat the experience multiple times during their lifetime and their textbook became such a historical entity that the baton was taken up by other people.

So once more I can only congratulate the editors for having conceived, constructed, and finalized the expanded second edition of this textbook. A textbook is a matter of endurance and repetition, and while it might be easy to criticize the content, the real question is this: will these three magnificent editors be able to continue the work of updating their textbook throughout their careers, because that’s what really gives a sense of purpose to a textbook. I sincerely hope that they will.

Patrick W. Serruys, MD, PhD
January 2016

Preface

There is no doubt that our specialty has been expanding in every direction at a fast pace in recent years. Just in the 5 years since publication of the first edition of *Interventional Cardiology*, almost its entire content has been revised extensively. The updated edition includes not only current data and critical new information on the most important subjects, but also introduces new subspecialties that have been developing in the intervening years. Additionally, specialists from other areas of medicine and surgery are taking part in the treatment of patients with interventional, percutaneous, minimally invasive methods and techniques. The technological advances are vast and highlight the overall growth of cardiovascular interventions.

In this edition, we have been fortunate to have a group of internationally recognized authorities in many fields contributing chapters describing the use of these techniques in a wide range of cardiovascular diseases.

Accordingly, we have expanded considerably the second edition of this textbook to cover four major sections: coronary interventions, interventional pharmacology, structural heart interventions, and endovascular therapy. We believe that the reader will find this approach useful and practical. Each section includes key subjects presented in an organized way: starting with the pathophysiological background and relevant pathology, followed by mechanisms of

treatment, device description, procedural techniques, follow-up care, risks, contraindications, and complications, where applicable. The inclusion of multiple choice questions with each online chapter allows both self-assessment as well as completion of accredited learning hours.

The modular presentation of this textbook, both as a printed book, and as an e-book CD-ROM or web-based program reflects the efforts of the publisher and the editors to reach out to many generations of physicians in training. The evolution of specialty certification and recertification has indeed made life learning a reality in our era. Therefore, the present textbook must also fulfill the quest to approach the new and tech-savvy learner, those ahead of an initial certification examination, those in advanced clinical practice who need practical instruction for a certain specialized subject, as well as those who have been practicing for a long time and need to refresh their knowledge with or without a recertification examination ahead of them. We have tried our best, and we certainly hope the reader will concur.

*George D. Dangas
Carlo Di Mario
Nicholas N. Kipshidze*

Acknowledgments

In a time when interventional cardiology has become too complex to be mastered by one or even three individuals, we decided to involve the best scholars in the field to cover the various topics of this book: without their help we could not have achieved this final result.

Our masters have taught us more than to push catheters. They made us love our profession and love teaching: we are delighted that many of them also contributed to this textbook.

Our Fellows have told us with their questions and doubts that not everything can be found in the many existing textbooks and the Internet. They inspired us to embark on this endeavor and

acted as a continuous source of inspiration to draw enough attention to practical details.

Finally, we have neglected our spouses and children to spend long hours in front of a computer screen. We are confident that our wives already understand us and we hope one day our children will see this textbook on the shelves of the family library, read some pages, and forgive us.

*George D. Dangas

PART I

Principles and Techniques

CHAPTER 1

Atherogenesis and Inflammation

Umair Hayat¹, Vikas Thondapu¹, Tim Tsay¹, and Peter Barlis²

¹Melbourne Medical School, The University of Melbourne, Australia

²The University of Melbourne, Australia

Atherosclerosis and its clinical consequences are the leading cause of death in Western nations [1]. Several factors have been implicated in the evolution, progression, and destabilization of atherosclerotic plaque highlighting its multifaceted nature. Atherosclerosis, now considered a chronic inflammatory disease, begins at a young age and progresses slowly for decades [2–4]. The clinical symptoms of atheroma occur in adults and usually involve plaque rupture and thrombosis [5–7].

While several advances have helped curb some of the complications resulting from atherosclerosis, this disease still represents an ongoing challenge with several new insights raising optimism that help to improve clinical outcomes is at hand. This chapter reviews the pathogenesis of atherosclerosis and the inflammatory cascades leading to plaque progression and destabilization. New coronary imaging modalities and developments in computer modeling are critiqued as tools to help improve the understanding of cardiovascular diseases.

Pathogenesis of atherosclerosis

Atherosclerosis is an inflammatory fibro-proliferative process in which plaque forms in the intima, bringing about stenosis or thrombosis and hence ischemia [8–10]. Though the exact initiator of plaque formation remains unknown, there is a general consensus that the triggering episode is endothelial damage, which could be caused by factors such as cigarette smoke toxins, hypertension, or immune injury [4,11–15]. Damaged cells become more permeable, ultimately causing subendothelial macrophages to consume circulating low density lipoproteins (LDL) which are altered in the intima to induce further endothelial damage [8,9,16]. More macrophages are then recruited, after which they remain in the intima as lipid-rich foam cells [9,10,17–19]. Meanwhile, in an attempt to restore endothelial function, smooth muscle cells migrate from the media to the intima to proliferate and generate a connective tissue matrix to cap the lipid core, further thickening the lesion [8,19,20]. Plaques enlarge as the process becomes chronic, classified as stable or unstable (Figures 1.1 and 1.2), either of which can lead to clinical sequelae [8,17,21].

Clinical features

The first indication of coronary artery disease (CAD) may be sudden death, or patients can present with silent ischemia, stable angina, or an acute coronary syndrome (ACS) [22]. ACSs comprise a range of syndromes resulting from atherosclerotic plaque disruption or rupture and are divided into unstable angina (UA), non-ST-elevation myocardial infarction (NSTEMI), and ST-elevation myocardial infarction (STEMI) [21,23,24]. An unstable plaque, characterized by a large lipid core covered by a thin and unstable fibrous cap, is prone to rupture [21,25–27]. The sudden rupture can cause thrombus formation, in turn leading to ACS (Figure 1.2) [26,28,29]. Conversely, a stable plaque has a thick fibrous cap which is not easily ruptured (Figure 1.1), causing the chronic condition of stable angina through episodes of ischemia experienced upon physical exertion [25,27,30].

Consequences of atherosclerosis

The risk of major thrombotic and thromboembolic complications of atherosclerosis appears to be related more to the stability of atheromatous plaques than to the extent of disease [31,32]. Stable angina is associated with smooth fibrous coronary artery plaques (stable plaque), whereas unstable angina, acute myocardial infarction (AMI), and sudden cardiac death are almost invariably associated with destabilization of plaques [29]. Similarly, in patients with carotid artery atherosclerotic disease, plaque irregularity and rupture are closely associated with cerebral ischemic events, and patients with irregular or ulcerated plaque demonstrate a higher risk of ischemic stroke irrespective of the degree of luminal stenosis [33].

Much attention has been placed on trying to identify plaques at high risk of disruption leading to thrombosis. Such “vulnerable plaques” have also been areas of intense research using novel intracoronary imaging modalities: optical coherence tomography (OCT) [6,29]. OCT offers the advantages over intravascular ultrasound or angiography of ultra-high resolution and superiority in imaging the vessel wall and lumen interface [34–36].

Figure 1.1 Stable atherosclerotic plaque characterized by the presence of a low inflammatory infiltrate. This type of lesion is constituted by a lipid core (extracellular lipid, cholesterol crystals, and necrotic debris) covered by a *thick* fibrous cap consisting principally of smooth muscle cells (SMC) in a collagenous–proteoglycan matrix, with varying degrees of infiltration by macrophages and T lymphocytes. HDL, high density lipoprotein.

Figure 1.2 Unstable atherosclerotic plaque characterized by the presence of a *thin* fibrous cap rich in inflammatory macrophagic foam cells and T lymphocytes. Rupture of the fibrous cap at the shoulder region has resulted in thrombus formation.

Considerable data exist to sustain the hypothesis that several morphologic and molecular markers identifying unstable plaques could be expressed during plaque vulnerability. As shown by a number of anatomical and clinical studies, these vulnerable plaques are more often associated with rupture and thrombosis than stable plaques covered by a thin fibrous cap and show an extensive inflammatory infiltrate [28,37].

Unlike the stable plaque that shows a chronic inflammatory infiltrate, the vulnerable and ruptured plaque is characterized by features of acute inflammation [37,38]. There are a large number of studies showing that “active” inflammation mainly involves T lymphocytes and macrophages which are activated toward a pathway of inflammatory response, secrete cytokines and lytic enzymes which in turn cause thinning of the fibrous cap, predisposing to plaque rupture. Recent research has furnished new insight into the molecular mechanisms that cause transition from a stable to an unstable phase of atherosclerosis and points to inflammation as the playmaker in the events leading to plaque destabilization and suggest that alterations in shear stress may also play a pivotal part [39,40].

A current challenge is to identify morphological and molecular markers able to discriminate stable plaques from vulnerable ones allowing the stratification of “high risk” patients for acute cardiac and cerebrovascular events before clinical syndromes develop. Bearing this aim in mind, this chapter focuses on cellular and molecular mechanisms affecting plaque progression and serum markers correlated to plaque inflammation.

Insights from coronary imaging

Traditionally, coronary angiography has been the gold standard to detect extent and severity of CAD. These findings form the foundation of the interventionist’s clinical decision-making process and whether to proceed to percutaneous therapy. It is widely acknowledged, however, that angiography has several limitations. First, it maintains a relatively low image resolution. Second, it represents a luminogram of the artery and stenosis. Therefore little detail is provided as to the composition of the underlying plaque causing the stenosis and, finally, it is a 2D imaging method used to assess what are complex 3D structures.

Intravascular ultrasound

Intravascular ultrasound (IVUS) utilizes ultrasound waves that reflect off vascular tissues to yield real-time images [41,42]. While angiography only portrays a luminal silhouette [41], IVUS, with a resolution of 100–150 μm , captures details not retrievable with angiography—cross-sections of the lumen and vessel wall, even a differentiation of its layers [43–46]. Thus, IVUS enables study of the atherosclerotic process through the visualization of plaque in the vessel wall [41,47–49]. Indeed, the technology has demonstrated a greater prevalence of atherosclerosis than initially claimed with angiography [44].

Optical coherence tomography

OCT, the optical analog of IVUS, employs the reflection of near-infrared (NIR) light instead of sound. Initially applied in ophthalmology, advancement in the technology has now enabled OCT to capture non-transparent tissues such as coronary vessels [50,51]. OCT offers real-time, *in vivo* and *in situ* cross-sectional imaging of vascular structures with a resolution 10-fold that of IVUS (15 μm versus 150 μm) and a penetration depth similar to that of histology [34,43,50–53].

By virtue of its superior resolution, OCT can provide near-histological analysis of atherosclerotic plaques in real time (Figure 1.3). OCT definition of thin cap fibroatheroma (TCFA) follows the findings of autopsy studies of sudden death patients that had revealed the presence of fibrous caps <65 μm in the majority of plaques that had ruptured. These thin ruptured caps were also found to have an infiltrate of macrophages [54]. Whereas OCT is well placed in precisely defining the thinness of fibrous cap, macrophage infiltration seen as punctate, signal-rich spots at the junction of fibrous cap and lipid pool has been described less consistently. Previous autopsy studies had also shown that plaque rupture, erosion, and calcified nodules were the three leading underlying mechanisms for luminal thrombosis with a frequency of 65%, 30%, and 5%, respectively [25]. In recent years OCT has enabled this type of information to be obtained *in vivo* and has confirmed similar prevalence of plaque morphologies in patients presenting with STEMI and NSTEMI [55].

Plaque rupture on OCT is identified by a clear-cut disruption in the signal-rich thin fibrous cap overlying a signal-poor necrotic core resulting in extrusion of highly thrombogenic material into the lumen. Plaque erosion on the other hand is identified by the presence of luminal thrombus adjacent to a plaque that has an irregular but intact, thicker fibrous cap. Such plaques are mostly devoid of necrotic core. Calcified nodules are the least common etiology in ACS and are less well defined. They are recognized by sharp nodules protruding into the lumen causing discontinuation of the fibrous cap (Figure 1.4).

In patients with stable CAD, coronary imaging can provide lesion level information and help to show the changes in plaque microstructure in response to pharmacotherapies. Kataoka *et al.* [56] evaluated 293 and 122 lipid and fibrous plaques in 280 stable statin-treated patients with CAD and reported that patients with LDL-C levels <50 mg/dL were less likely to have lipid plaques, and had more features of plaque stability such as thicker fibrous caps and smaller lipid arcs.

The vulnerable plaque

Atherosclerotic lesions, according to the classification of the American Heart Association modified by Virmani *et al.* [29], are divided in two groups: (i) non-atherosclerotic intimal lesions and (ii) progressive atherosclerotic lesions which include stable, vulnerable, and thrombotic plaques.

The different pathologic characterization of atherosclerotic lesions largely depends on the thickness of the fibrous cap and its grade of inflammatory infiltrate, which is in turn largely constituted by macrophages and activated T lymphocytes. Typically, the accumulating plaque burden is initially accommodated by an adaptive positive remodeling with expansion of the vessel external elastic lamina and minimal changes in lumen size [57,58]. The plaque contains monocyte-derived macrophages, smooth muscle cells, and T lymphocytes. Interaction between these cells types and the connective tissue appears to determine the development and progression of the plaque itself, including important complications such as thrombosis and rupture.

The lesions classified as vulnerable or TCFA identify a plaque prone to rupture and thrombosis characterized by a large necrotic core containing numerous cholesterol clefts. The overlying cap is thin and rich in inflammatory cells, macrophages, and T lymphocytes with few smooth muscle cells [28,29,59]. Burke *et al.* [54] identified a cut-off value for cap thickness of 65 μm to define a vulnerable coronary plaque. Despite the predominant hypothesis

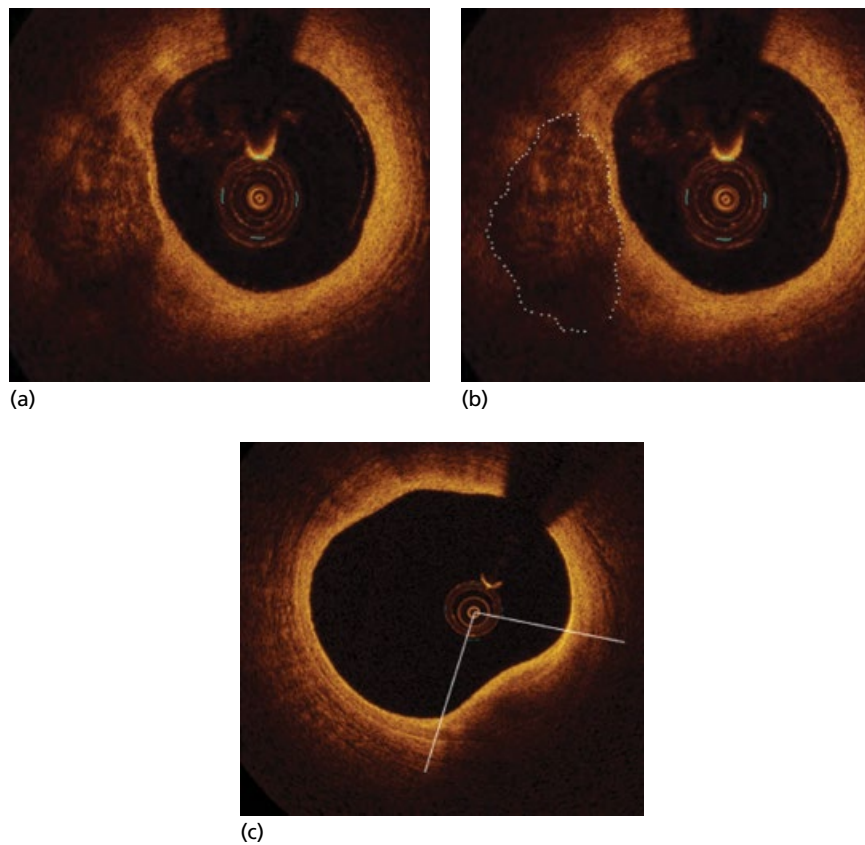

Figure 1.3 Stable coronary plaques seen on optical coherence tomography (OCT). (a) Calcified plaque is seen at 7- to 10 o'clock position. It is characterized by sharply delineated borders and heterogeneous core. (b) Calcified plaque is outlined with white dotted line. (c) Lipid-rich plaque marked by white lines. It is characterized by dark, signal-poor core with ill-defined margins and a bright thick fibrous cap ($>65\ \mu\text{m}$). As the light rapidly attenuates through the necrotic core, OCT cannot be used to measure the depth of such plaques.

Figure 1.4 Unstable coronary plaques seen on OCT. (a) Plaque erosion: intact fibrous cap with irregular luminal surface and superficial calcium. (b) Plaque rupture with luminal thrombus. At the 11 o'clock position a thin cap fibro-atheroma (TCFA) is seen (fibrous cap thickness measured $40\ \mu\text{m}$, marked with small white bar).

focusing on the responsibility of a specific vulnerable atherosclerotic plaque rupture [5,7] for acute coronary syndromes, some pathophysiologic, clinical, and angiographic observations seem to suggest the possibility that the principal cause of coronary instability is not to be found in the vulnerability of a single atherosclerotic plaque, but in the presence of multiple vulnerable plaques in the

entire coronary tree, correlated with the presence of a diffuse inflammatory process [37,38,60,61].

Within this context, recent angiographic studies have demonstrated the presence of multiple vulnerable atheromatous plaques in patients with unstable angina [20,62] and in those affected by transmural myocardial infarction [61]. Recently, by means of flow

cytometry Spagnoli *et al.* [38] have demonstrated the presence of an activated and multicentric inflammatory infiltrate in the coronary vessels of individuals who died of AMI. Similar results have been obtained by Buffon *et al.* [60], who, through the determination of the neutrophil myeloperoxidase activity, have proved the presence of a diffuse inflammation in the coronary vessels in individuals affected by unstable angina. These results have been confirmed by a morphological study which demonstrated the presence of a high inflammatory infiltrate constituted by macrophages and T lymphocytes activated in the whole coronary tree, also present in the stable plaques of individuals who died of AMI. These plaques showed a two- to fourfold higher inflammatory infiltrate than aged-matched individuals dying from non-cardiac causes with chronic stable angina (SA) or without clinical cardiac history (CTRL), respectively [37]. Moreover, it has also been demonstrated that activated T lymphocytes infiltrate the myocardium both in the peri-infarcted area and in remote unaffected myocardial regions in patients who died of a first myocardial infarction [63].

The simultaneous occurrence of diffuse coronary and myocardial inflammation in these patients further supports the concept that both coronary and myocardial vulnerabilities concur in the pathogenesis of fatal AMI.

AMI—at least associated with unfavorable prognosis—is therefore likely to be the consequence of a diffuse “active” chronic inflammatory process which determines the destabilization of both the entire coronary tree and the whole myocardium, not only the part of it affected by infarction. The causes of the diffuse inflammation associated with myocardial infarction are scarcely known. The presence of activated T lymphocytes suggests the “*in situ*” presence of an antigenic stimulus which triggers adaptive immunity.

Role of inflammation in the natural history of atherosclerosis

Inception of the plaque

Endothelium injury has been proposed to be an early and clinically relevant pathophysiologic event in the atherosclerotic process [4,32]. Patients with endothelial dysfunction have an increased risk for future cardiovascular events including stroke [64]. Endothelial dysfunction was described as the ignition step in atherogenesis. From this point on, an inflammatory response leads to the development of the plaque.

Endothelial damage can be caused by physical and chemical forces, by infective agents or by oxidized LDL (ox-LDL). Dysfunctional endothelium expresses P-selectin (stimulation by agonists such as thrombin) and E-selectin (induced by IL-1 or TNF- α). Expression of intercellular adhesion molecule-1 (ICAM-1) both by macrophages and endothelium and vascular adhesion molecule-1 (VCAM-1) by endothelial cells is induced by inflammatory cytokines such as interleukin-1 (IL-1), tumor necrosis factor-1 (TNF- α), and γ -interferon (IFN γ).

Monocytes recalled in the subintimal space ingest lipoproteins and morph into macrophages. These generate reactive oxygen species (ROS), which convert ox-LDL into highly oxidized LDL. Macrophages upload ox-LDL via scavenger receptors until foam cells form. Foam cells with leukocytes migrate at the site of damage and generate the fatty streak. The loss of biologic activity of endothelium determines nitric oxide (NO) reduction together with increased expression of prothrombotic factors, proinflammatory adhesion molecules cytokines, and chemotactic factors. Cytokines may decrease NO bioavailability increasing the production of ROS. ROS

reduces NO activity both directly, reacting with endothelial cells, and indirectly via oxidative modification of eNOS or guanylyl cyclase [65]. Low NO bioavailability can upregulate VCAM-1 in the endothelial cell layer that binds monocytes and lymphocytes in the first step of invasion of the vascular wall, via induction of nuclear factor κ B (NF κ B) expression [66]. In addition, NO inhibits leukocyte adhesion [67] and NO reduction results in induction of monocyte chemotactic protein-1 (MCP-1) expression which recruits monocytes [68]. NO is in a sensitive balance with endothelin-1 (ET-1) regulating vascular tone [69]. Plasma ET-1 concentrations are increased in patients with advanced atherosclerosis and correlate with the severity of the disease [70,71]. In addition to its vasoconstrictor activity, ET-1 also promotes leukocyte adhesion [72] and thrombus formation [73]. Dysfunctional endothelium expresses P-selectin (stimulation by agonists such as thrombin) and E-selectin (induced by IL-1 or TNF- α) [74]. The expression of both ICAM-1 by macrophages and endothelium, and VCAM-1 by endothelial cells is induced by inflammatory cytokines such as IL-1, TNF- α , and IFN γ . Endothelial cells also produce monocyte chemotactic protein-1 (MCP-1), monocyte colony-stimulating factor, and IL-6 which further amplify the inflammatory cascade [75]. IL-6 production by smooth muscle cells represents the main stimulus for C-reactive protein (CRP) production [3]. Recent evidence suggests that CRP may contribute to the proinflammatory state of the plaque both mediating recruitment of monocytes and stimulating monocytes to release IL-1, IL-6, and TNF- α [76]. The damaged endothelium allows the passage of lipids into the subendothelial space. Fatty streaks represent the first step in the atherosclerotic process.

Evolving fibro-atheromatous plaque

The atheroma evolution is modulated by innate and adaptive immune responses [3,77,78]. The most important receptors for innate immunity in atherothrombosis are the scavenger receptors and the toll-like receptors (TLRs) [79]. Adaptive immunity is much more specific than innate immunity but may take several days or even weeks to become fully mobilized. It involves an organized immune response leading to generation of T- and B-cell receptors and immunoglobulins, which can recognize foreign antigens [80].

Stable plaque

Macrophages take up lipid deposited in the intima via a number of receptors, including scavenger receptor-A, and CD36. Deregulated uptake of modified LDL through scavenger receptors leads to cholesterol accumulation and “foam cell” formation. The lipid laden macrophages (foam cells) forming the fatty streak secrete proinflammatory cytokines that amplify the local inflammatory response in the lesion, matrix metalloproteinases (MMPs), tissue factor into the local matrix, as well as growth factors, which stimulate the smooth muscle replication responsible for lesion growth. Macrophages colony-stimulating factor (M-CSF) acts as the main stimulator in this process, next to granulocyte-macrophage stimulating factor (MGM-CSF) and IL-2 for lymphocytes [81]. Lymphocytes enter the intima by binding adhesion molecules: VCAM-1, P-selectin, ICAM-1, MCP-1 (CCL2), IL-8 (CxCL8) [75]. Such infiltrate constituted mainly by CD4⁺ T lymphocytes recognize antigens bound to MHC class II molecules involved in antigen presentation to T lymphocytes thus provoking an immune response [2]. The major histocompatibility complex molecules (MHC II) are expressed by endothelial cells, macrophages, and vascular smooth muscle cells in proximity to activated T lymphocytes in the atherosclerotic plaque. Proinflammatory cytokines manage a central transcriptional control

point mainly mediated by NF κ B. Macrophage/foam cells produce cytokines that activate neighboring smooth-muscle cells (SMCs), resulting in extracellular matrix production [2].

Repeated inflammatory stimuli induce foam cells to secrete growth factors that induce proliferation and migration of SMCs into the intima. The continuous influx of cells in the subintimal space convert the fatty streak in a more complex and advanced lesion in which inflammatory cells (monocytes/macrophages, lymphocytes), SMCs, necrotic debris mainly resulting from cell death, ox-LDL elicit a chronic inflammatory response by adoptive immune system. SMCs form a thick fibrous cap that cover the necrotic core and avoid the exposition of thrombogenic material to the bloodstream. The volume of lesion grows and protrudes into the arterial lumen causing variable degrees of lumen stenosis. These lesions are advanced complicated “stable” atherosclerotic lesions, asymptomatic and often unrecognized [82,83].

Vulnerable plaque: a shift toward Th1 pattern

Early phases of the plaque development are characterized by an acute innate immune response against exogenous (infectious) and endogenous non-infectious stimuli. Specific antigens activate adaptive immune system leading to proliferation of T and B cells. A first burst of activation might occur in regional lymph nodes by dendritic cells (DCs) trafficking from the plaque to the lymph node. Subsequent cycles of activation can be sustained by interaction of activated/memory T cells re-entering in the plaque by selective binding to endothelial cell surface adhesion molecules with plaque macrophages expressing MHC class II molecules. In this phase of the atherogenic process the selective recruitment of a specific subtype of CD4⁺ cells play a major part in determining the future development of the lesion. Two subtypes of CD4⁺ cells have a juxtaposed role: Th1 and Th2 cells [84].

Th1 cells secreting proinflammatory cytokines, such as IFN γ , promote macrophage activation, inflammation, and atherosclerosis, whereas Th2 cells (cytokine pattern IL-4, IL-5, and IL-10) mediate antibody production and generally have anti-inflammatory and antiatherogenic effects [64]. Therefore the switch to a selective recruitment of Th1 lymphocyte represents a key point toward plaque vulnerability and disruption. T cells in the plaque may encounter antigens such as ox-LDL. Moreover, T-cell response can be triggered by heat shock proteins of endogenous or microbial origin [85]. It is still unknown why the initial inflammatory response becomes a chronic inflammatory condition. However, when the plaque micro-environment triggers the selective recruitment and activation of Th1 cells they in turn determine a potent inflammatory cascade.

The combination of IFN γ and TNF- α upregulates the expression of fractalkine (CX3CL1) [86]. IL-1 and TNF α -activated endothelium express also fractalkine (membrane bound form) which directly mediates the capture and adhesion of CX3CR1 expressing leukocytes providing a further pathway for leukocyte activation [87]. This cytokine network promotes the development of the Th1 pathway which is strongly proinflammatory and induces macrophage activation, superoxide production, and protease activity.

Role of inflammation as vulnerability factor

Homeostasis of plaque “microenvironment” (i.e., the balance between cell migration and cell proliferation, extracellular matrix production and degradation, macrophages and lymphocytes interplay) appears strictly related to the transition of a stable plaque into a vulnerable one.

A limited number of T cells, following the Th1 pathway, initiates the production of large amounts of molecules downstream in the cytokine cascade orchestrating the transition from the stable to unstable plaque [77,88].

Within the plaque, inflammatory cells such as foam cells and monocyte-derived macrophages are induced to produce matrix-degrading enzymes, cytokines, and growth factors strictly implicated in extracellular matrix homeostasis. In particular, cytokines such as IFN γ suppress collagen synthesis, a major component of the fibrous cap [75]. Moreover, infiltration of mononuclear cells results in release of proteases which causes plaque disruption [89]. The production of ROS within the atherosclerotic plaque has important implications for its structural integrity [65]. Deregulated oxidant production has the potential to promote the elaboration and activation of matrix degrading enzymes in the fibrous cap of the plaque. Moreover, impaired NO function coupled with oxidative excess can activate MMPs [90], namely MMP-2 and MMP-9, which weaken the fibrous cap. Another mechanism that can determine the thinning of the fibrous cap is the apoptosis of smooth muscle cells. In fact, there is evidence for extensive apoptosis of SMCs within the cap of advanced atherosclerosis, as well as those cultured from plaques [32,91].

A very important role, not yet well studied, is that of dendritic cells, namely cells specialized in antigen presentation with a key role in the induction of primary immune response and in the regulation of T-lymphocyte differentiation, as well as in mechanisms of central and peripheral tolerance aiming at the elimination of T lymphocytes that are potentially self-reactive toward self-antigens [92,93]. A characteristic of dendritic cells is also the ability to polarize T-cell responses toward a T-helper phenotype (Th1) in response to bacterial antigens. Molecules expressed by activated T lymphocytes, like CD40L, OX40, stimulate the release from dendritic cells of chemokines (fractalkines) able to attract other lymphocytes toward the inflammation site, amplifying the immune response [94].

Patients with ACS are characterized by the expansion of an unusual subset of T cells, CD4⁺CD28^{null} T cells, with functional activities that predispose for vascular injury [95,96]. CD4⁺CD28^{null} T cells are a population of lymphocytes rarely found in healthy individuals. Disease-associated expansions of these cells have been reported in inflammatory disorders such as rheumatoid arthritis. CD4⁺CD28^{null} T cells are characterized by their ability to produce high amounts of IFN γ [96]. Equally importantly, CD4⁺CD28^{null} T cells have been distinguished from classic Th cells by virtue of their ability to function as cytotoxic effector cells. Possible targets in the plaque are SMCs and endothelial cells, as recently shown [97]. *In vivo*, CD4⁺CD28^{null} cells have a tendency to proliferate with the frequent emergence of oligoclonality, raising the possibility of continuous antigenic stimulation, as it is the case in certain autoimmune disorders and in chronic infections. The demonstration of oligoclonality within the CD4⁺CD28^{null} T-cell subsets and sharing of T-cell receptor sequences in expanded T-cell clones of patients with ACS strongly support the notion that these cells have expanded and are activated in response to a common antigenic challenge [98]. CD4⁺CD28^{null} T cells are long-lived cells. Clonality and longevity of these cells are associated with defects in apoptotic pathways [99]. Moreover, CD28 is relevant for the expansion of naïve T cells, thus the absence of this molecule contributes to the senescence of lymphocytes. The excessive expansion of a pool of senescent T lymphocytes might compromise the efficacy of the immune responses direct against exogenous antigens as well as determinate autoimmune responses.

Recently, a subpopulation of T CD4⁺ cells, expressing IL-2 receptor, CD25 membrane marker, has been pointed out. Such lymphocytes represent 7–10% of T CD4⁺ cells and their homeostasis is due to some co-stimulatory molecules, such as CD28 receptor expressed by T cells and B7 molecules expressed by dendritic cells [100]. The current knowledge of the role of this specific subset of T cells in human atherogenesis is still incomplete, even though a very recent study carried out on mice has demonstrated an antiatherogenic effect of T CD4⁺CD25⁺ cells [101].

Th1 cells and T regulatory 1 cells have been demonstrated to play opposite roles in rupture of atherosclerotic lesion. The role of novel subset of T regulatory cells, known as CD4⁺CD25⁺Foxp3⁺ T cells, has been recently studied in CAD. Han *et al.* [102] found that the reduction of CD4⁺CD25⁺Foxp3⁺ T lymphocytes was consistent with the expansion of Th1 cells in patients with unstable CAD. The reversed development between CD4⁺CD25⁺ Tregs and Th1 cells might contribute to plaque destabilization.

Serum markers correlated to plaque inflammation

In recent years, a number of studies have correlated different serologic biomarkers with cardiovascular disease [4,103] leading to a rapid increase in the number of biomarkers available (Table 1.1). These biomarkers are useful in that they can identify a population at risk of an acute ischemic event and detect the presence of so-called vulnerable plaques and/or vulnerable patients [104,105]. Ideally, a biomarker must have certain characteristics to be a potential predictor of incident or prevalent vascular disease. Measurements have to be reproducible in multiple independent samples, the method for determination should be standardized, variability controlled, and the sensitivity and specificity should be good. In addition, the biomarker should be independent from other established risk markers, substantively improve the prediction of risk with established risk factors, be associated with cardiovascular events in multiple population cohorts and clinical trials, and the cost of the assays has to be acceptable. Finally, to be clinically useful a biomarker should correctly reflect the underlying biological process associated with plaque burden and progression.

Traditional biomarkers for cardiovascular risk include LDL cholesterol and glucose. However, 50% of heart attacks and strokes occur in individuals who have normal LDL cholesterol, and 20% of major adverse events occur in patients with no accepted risk factors [106]. Therefore, in light of changing atherosclerotic models, vulnerable blood may be better described as blood that has an increased level of activity of plasma determinants of plaque progression and rupture.

In this context, proposed biomarkers fall into nine general categories: inflammatory markers, markers for oxidative stress, markers of plaque erosion and thrombosis, lipid-associated markers, markers of endothelial dysfunction, metabolic markers, markers of neovascularization, and genetic markers. The last six biomarker categories are not treated in this chapter but only listed in Table 1.1. Some of these markers may indeed reflect the natural history of atherosclerotic plaque growth and may not be directly related to an increased risk of cardiovascular events. On the contrary, other markers are more related to complex plaque morphological features and may reflect an active process within the plaque which is in turn related to the onset of local complications and onset of acute clinical events.

However, it is important to emphasize that, in any individual patient, it is not yet clear how these biomarkers relate to quantitative

risk of major adverse cardiovascular events. The best outcomes may be achieved by a panel of markers that will capture all of the different processes involved in plaque progression and plaque rupture, and that will enable clinicians to quantify an individual patient's true cardiovascular risk. In all likelihood, a combination of genetic (representing heredity) and serum markers (representing the net interaction between heredity and environment) will ultimately be the ones that should be utilized in primary prevention. Finally, different non-invasive and invasive imaging techniques may be coupled with biomarkers detection to increase the specificity, sensitivity, and overall predictive value of each potential diagnostic technique.

Markers of inflammation

Markers of inflammation include CRP, inflammatory cytokines soluble CD40L (sCD40L), soluble vascular adhesion molecules (sVCAM), and TNF.

CRP is a circulating pentraxin that has a major role in the human innate immune response [107] and provides a stable plasma biomarker for low grade systemic inflammation. CRP is produced predominantly in the liver as part of the acute phase response. However, CRP is also expressed in SMCs within diseased atherosclerotic arteries [108] and has been implicated in multiple aspects of atherogenesis and plaque vulnerability, including expression of adhesion molecules, induction of NO, altered complement function, and inhibition of intrinsic fibrinolysis [109]. CRP is considered to be an independent predictor of unfavorable cardiovascular events in patients with atherosclerotic disease. Beyond the ability of CRP to predict risk among both primary and secondary prevention patients, interest in it has increased with the recognition that statin-induced reduction of CRP is associated with less progression in adverse cardiovascular events that is independent of the lipid-associated changes [110] and that the efficacy of statin therapy may be related to the underlying level of vascular inflammation as detected by high-sensitivity CRP (hs-CRP). Among patients with stable angina and established CAD, plasma levels of hs-CRP have consistently been shown associated with recurrent risk of cardiovascular events [111,112]. Similarly, during acute coronary ischemia, levels of hs-CRP are predictive of high vascular risk even if troponin levels are non-detectable, suggesting that inflammation is associated with plaque vulnerability even in the absence of detectable myocardial necrosis [113,114]. Despite these data, the most relevant use of hs-CRP remains in the setting of primary prevention. To date, over two dozen large-scale prospective studies have shown baseline levels of hs-CRP to independently predict future myocardial infarction, stroke, cardiovascular death, and incidence of peripheral arterial disease [115,116]. Moreover, eight major prospective studies have had adequate power to evaluate hs-CRP after adjustment for all Framingham covariates, and all have confirmed the independence of hs-CRP [117]. Despite this evidence, it is important to recognize that there remain no firm data to date that lowering CRP levels per se will lower vascular risk. Further, as with other biomarkers of inflammation, it remains controversial whether CRP has a direct causal role in atherogenesis [118], and ongoing work with targeted CRP-lowering agents are required to fully test this hypothesis. However, the clinical utility of hs-CRP has been well established, and on the basis of data available through 2002, the Centers for Disease Control and Prevention and the American Heart Association endorsed the use of hs-CRP as an adjunct to global risk prediction, particularly among those at "intermediate risk" [119]. Data available since 2002 strongly reinforce these recommendations and suggest

Table 1.1 Serologic markers of vulnerable plaque/patient.

Reflecting metabolic and immune disorders	Reflecting hypercoagulability	Reflecting complex atherosclerotic plaque
Abnormal lipoprotein profile (i.e., high LDL, low HDL, lipoprotein [a], etc.)	Markers of blood hypercoagulability (i.e., fibrinogen, D-dimer, factor V Leiden)	<i>Morphology/structure</i>
Non-specific markers of inflammation (hs-CRP, CD40L, ICAM-1, VCAM, leukocytosis and other immuno-related serologic markers which may not be specific for atherosclerosis and plaque inflammation)	Increased platelet activation and aggregation (i.e., gene polymorphism of platelet glycoproteins IIb/IIIa, Ia/IIa, and Ib/IX)	<ul style="list-style-type: none"> • Cap thickness • Lipid core size • Percentage stenosis • Remodeling (positive vs. negative) • Color (yellow, red) • Collagen content vs. lipid content • Calcification burden and pattern • Shear stress
Serum markers of metabolic syndrome (diabetes or hypertriglyceridemia)	Increased coagulation factors (i.e., clotting of factors V, VII, VIII, XIII, von Willebrand factor)	<i>Activity/function</i>
Specific markers of immune activation (i.e., anti-LDL antibody, anti-HSP antibody)	Decreased anticoagulation factors (i.e., proteins S and C, thrombomodulin, antithrombin III)	<ul style="list-style-type: none"> • Plaque inflammation (macrophage density, rate of monocyte and activated T-cell infiltration) • Endothelial denudation or dysfunction (local nitric oxide production, anti/procoagulation properties of the endothelium) • Plaque oxidative stress • Superficial platelet aggregation and fibrin deposition • Rate of apoptosis (apoptosis protein markers, microsatellite) • Angiogenesis, leaking vasa vasorum, intraplaque hemorrhage • Matrix metalloproteinases (MMP-2, -3, -9) • Microbial antigens (<i>Chlamydia pneumoniae</i>)
Markers of lipid peroxidation (i.e., ox-LDL and ox-HDL)	Decreased endogenous fibrinolysis activity (i.e., reduced tissue plasminogen activator, increased type I PAI, PAI polymorphisms)	Temperature
Homocysteine	Prothrombin mutation (i.e., G20210A)	<i>Pan arterial</i>
PAPP-A	Thrombogenic factors (i.e., anticardiolipin antibodies, thrombocytosis, sickle cell disease, diabetes, hypercholesterolemia)	<ul style="list-style-type: none"> • Transcoronary gradient of vulnerability biomarkers • Total calcium burden • Total coronary vasoreactivity • Total arterial plaque burden (intima media thickness)
Circulating apoptosis markers (i.e., Fas/Fas ligand)	Transient hypercoagulability (i.e., smoking, dehydration, infection)	
ADMA/DDAH/		
Circulating NEFA		

ADMA, asymmetric dimethylarginine; CRP, C-reactive protein; DDAH, dimethylarginine dimethylaminohydrolase; HDL, high density lipoprotein; HSP, heat shock protein; ICAM, intercellular adhesion molecule; LDL, low density lipoprotein; NEFA, non-esterified fatty acids; PAI, plasminogen activator; PAPP-A, pregnancy-associated plasma protein A; VCAM, vascular adhesion molecule.

expansion to lower risk groups, as well as those taking statin therapy. Perhaps most importantly, data for hs-CRP provides evidence that biomarkers beyond those traditionally used for vascular risk detection and monitoring can have important clinical roles in prevention and treatment.

Cellular adhesion molecules can be considered potential markers of vulnerability because such molecules are activated by inflammatory cytokines and then released by the endothelium [120]. These molecules represent the one available marker to assess endothelial activation and vascular inflammation. The Physicians' Health Study evaluated more than 14,000 healthy subjects and demonstrated ICAM-1 expression positive correlation with cardiovascular risk and showed that subjects in the higher quartile of ICAM-1 expression showed 1.8 times higher risk than subjects in the lower quartile [121]. Furthermore, soluble ICAM-1 and VCAM-1 levels showed a positive correlation with atherosclerosis disease burden [122]. IL-6 is expressed during the early phases of inflammation and it is the principal stimulus for CRP liver production. In addition, CD40 ligand, a molecule expressed on cellular membrane, is a TNF α homologue which stimulates activated

macrophages proteolytic substances production [123]. CD40 and CD40L have been found on platelets and several other cell types in functional-bound and soluble (sCD40L) forms. Although many platelet-derived factors have been identified, recent evidence suggests that CD40L is actively involved in the pathogenesis of ACS. CD40L drives the inflammatory response through the interaction between CD40L on activated platelets and the CD40 receptor on endothelial cells. Such interactions facilitate increased expression of adhesion molecules on the surface of endothelial cells and release of various stimulatory chemokines. These events, in turn, facilitate activation of circulating monocytes as a trigger of atherosclerosis. Beyond known proinflammatory and thrombotic properties of CD40L, experimental evidence suggests that CD40L-induced platelet activation leads to the production of reactive oxygen and nitrogen species, which are able to prevent endothelial cell migration and angiogenesis [124]. As a consequence of inhibiting endothelial cell recovery, the risk of subsequent coronary events may be greater. Clinical studies have supported the involvement of CD40L in ACS and the prognostic value in ACS populations. Levels of sCD40L have been shown to be an independent predictor of

adverse cardiovascular events after ACS [125], with increased levels portending a worse prognosis [126]. Importantly, specific therapeutic strategies have shown to be beneficial in reducing risk associated with sCD40L [127]. IL-18 is a proinflammatory cytokine mostly produced by monocytes and macrophages, which acts synergistically with IL-12 [105]. Both these interleukines are expressed in the atherosclerotic plaque and they stimulate IFN γ induction which, in its turn, inhibits collagen synthesis, preventing a thick fibrous cap formation and facilitating plaque destabilization. Mallat *et al.* [128] examined 40 stable and unstable atherosclerotic plaques obtained from patients undergoing carotid endarterectomy and highlighted how IL-18 expression was higher in macrophages and endothelial cells extracted from unstable rather than stable lesions and it correlated with clinical (symptomatic plaques) and pathological (ulceration) signs of vulnerability.

Pregnancy-associated plasma protein-A (PAPP-A) is a high molecular weight, zinc-binding metalloproteinase, typically measured in women's blood during pregnancy and later found in macrophages and SMCs inside unstable coronary atherosclerotic plaques. This protease cleaves the bond between insulin like growth factor-1 (IGF-1) and its specific inhibitor (IGFBP-4 e IGFBP-5), increasing free IGF-1 levels. IGF-1 is important for monocytes-macrophages chemotaxis and activation in the atherosclerotic lesion, with consequent proinflammatory cytokine and proteolytic enzyme release, and stimulates endothelial cell migration and organizational behavior with consequent neoangiogenesis. Hence, IGF-1 represents one of the most important mediators in the transformation of a stable lesion into an unstable one [129]. Bayes-Genis *et al.* [130] demonstrated that PAPP-A is more often expressed in the serum of patients with acute coronary syndromes (UA, MI), than subjects presenting with SA. In particular, PAPP-A serum levels >10 mIU/L recognize patient vulnerability with a specificity of 78% and a sensitivity of 89%. It has also been demonstrated that PAPP-A histological expression is higher in complex, vulnerable/ruptured carotid plaques than stable lesions [131]. As PAPP-A serum levels can be easily measured today by means of enzyme-linked immunosorbent assay (ELISA), this protease could represent an easily quantifiable marker of vulnerability, with a reproducible method, allowing the identification of a patient subgroup with a high cerebrovascular risk before its clinical manifestation.

Jaffer *et al.* [132] have published a detailed review on different techniques for detection of vulnerable plaque based on several biomarkers that have been implemented in recent years. In this context, plaques with active inflammation can be identified directly by extensive macrophage accumulation [133]. Possible intravascular diagnostic techniques [134] based on inflammatory infiltration determination within the plaque include thermography [135], contrast-enhanced MRI [136], fluorodeoxyglucose positron emission tomography [137], and immunoscintigraphy [138]. In addition, non-invasive techniques include MRI with superparamagnetic iron oxide [139,140] and gadolinium fluorine compounds [141,142].

Oxidative stress markers

Oxidative stress has a very important role in atherogenesis. Evidence shows that activation of vascular oxidative enzymes leads to lipid oxidation, foam cell formation, expression of vascular adhesion molecules and chemokines, and ultimately atherogenesis. Myeloperoxidase (MPO) is a heme peroxidase that is present in and secreted by activated phagocytes at sites of inflammation. MPO can generate several reactive, oxidatively derived intermediates, all mediated through a reaction with hydrogen peroxide, to induce oxidative damage to cells and tissues [143]. Oxidation products

from MPO are found at significantly increased rates (up to 100-fold higher than circulating LDL) on LDL isolated from atherosclerotic lesions [144] and lead to accelerated foam cell formation through nitrated apoB-100 on LDL and uptake by scavenger receptors [145]. Accumulating evidence suggests that MPO may have a causal role in plaque vulnerability [146]. Sugiyama *et al.* [147] showed that advanced ruptured human atherosclerotic plaques, derived from patients with sudden cardiac death, strongly expressed MPO at sites of plaque rupture, in superficial erosions and in the lipid core, whereas fatty streaks exhibited little MPO expression. In addition, MPO macrophage expression and HOCl were highly co-localized immunochemically in culprit lesions of these patients. Several inflammatory triggers, such as cholesterol crystals and CD40 ligand, induced release of MPO and HOCl production from MPO-positive macrophages *in vitro*. Consistent with the potential role for MPO in the atherosclerotic process, genetic polymorphisms resulting in MPO deficiency or diminished activity are associated with lower cardiovascular risk, although the generalizability of these findings is uncertain [148]. In parallel with the effects of MPO on nitric oxide, LDL oxidation, and presence within ruptured plaques, several recent clinical studies have suggested that MPO levels can provide diagnostic and prognostic data in endothelial function, angiographically determined CAD, and ACSs. In a case-control study of 175 patients with angiographically determined CAD, Zhang *et al.* [149] showed that the highest quartiles of both blood and leukocyte MPO levels were associated with odds ratios of 11.9 and 20.4, respectively, for the presence of CAD compared with the lowest quartiles. Brennan *et al.* [150] obtained MPO levels in the emergency department in 604 patients presenting with chest pain but no initial evidence of myocardial infarction, and showed that MPO levels predicted the in-hospital development of myocardial infarction, independent of other markers of inflammation, such as CRP. In addition, they showed that MPO levels were strong predictors of death, myocardial infarction, and revascularization 6 months after the initial event. Current data suggest that MPO can serve as both a marker of disease, providing independent information on diagnosis and prognosis of patients with chest pain, and also as a potential marker for assessment of plaque progression and destabilization at the time of acute ischemia.

Biomechanical stress as a trigger for plaque progression and rupture

Despite the exposure of the entire coronary tree to the *systemic* risk factors and inflammation, spatial distribution of atherosclerotic plaques is often a *focal* phenomenon [151]. Vascular endothelium is subjected to complex mechanical stresses resulting from its 3D geometry, vessel curvatures, and cardiac motion. These mechanical strains in combination with fluid frictional forces or shear stress gradients inside the arteries can lead to a number of structural and humoral changes in endothelial cells [39,152]. High wall shear stress (>15 dyne/cm²) has been found to induce endothelial quiescence and an atheroprotective gene expression profile, whereas low shear stress (<4 dyne/cm²) stimulates an atherogenic phenotype [152]. It has been shown that the plaques and wall thickenings are localized mostly on the outer wall of one or both daughter vessels at bifurcations and along the inner wall of curved segments [151]. In the Prediction study, Stone *et al.* [153] studied the natural history of plaques in 506 patients with ACS treated with percutaneous coronary intervention, and used reconstructed coronary models from angiography and IVUS. A total of 74% patients had follow-up studies at 6–10 months to relate the effects of local hemodynamic milieu on plaque changes. Authors reported that decrease in lumen area

Figure 1.5 Neointimal hyperplasia seen on OCT. (a) Neointimal hyperplasia inside the stent. A uniform layer of neointima is seen covering the stent struts (white arrows) from the 12 to 4 o'clock position. Remainder of the stent circumference is covered by an irregular, very thick tissue layer containing dark, signal-poor core consistent with lipid pool and signal-rich, thick fibrous cap. (b) Lipid/necrotic core in the neointimal plaque is highlighted in yellow.

was independently predicted by baseline large plaque burden and low endothelial shear stress [153]. Other investigators have reported that high wall shear stress is associated with transformation of plaques into high risk phenotypes prone to instability and rupture [154,155].

Neointimal hyperplasia

The neointimal tissue inside the stents is subject to similar atherogenic forces as the native vessels [156,157]. Neointimal hyperplasia is the development of atherosclerosis within this neointima. Histologically, it is recognized by the presence of clusters of lipid-laden foamy macrophages within the neointima with or without necrotic core formation [157,158]. On OCT it is seen as areas of heterogeneous appearance within the neointima with low-intensity lipid-laden regions or well demarcated calcification within stents (Figure 1.5) [159,160]. Although the exact pathogenesis of this phenomenon is yet to be proven, inflammation and endothelial dysfunction have been shown to have a fundamental role [157,158,161]. It has been reported in autopsy and *in vivo* imaging studies that neointimal hyperplasia occurs at an earlier stage and with higher frequency in DES than BMS [157,162]. It is thought to be one important mechanism for late stent failure including in-stent restenosis and very late stent thrombosis [156,158,163].

Future challenges in the treatment of vulnerable plaques

With the concept of “vulnerable” plaque not nearly as straightforward as once thought, there are challenges to creating a therapeutic strategy for assessing the risk of rupture of vulnerable plaques in asymptomatic patients.

First, there must be an ability to identify the vulnerable plaque with non-invasive or invasive techniques. It has been demonstrated that coronary plaque composition can be studied with invasive and non-invasive imaging techniques, allowing real-time analysis and *in vivo* plaque characterization including the identification of TCFA. However, the severity of the inflammatory infiltration of the cap, which certainly has a major role in plaque disruption, cannot be accurately evaluated even with the most advanced *in vivo* imaging techniques. Moreover, dynamic plaque changes, such as abrupt

intra-plaque hemorrhages from vasa vasorum which may be fundamental in predicting the potentiality of a plaque to rupture, will be extremely difficult to identify with real-time imaging techniques. Nevertheless, some promising work has been done in this regard in the SECURITT trial introducing the concept of sealing the non-obstructive, high risk IVUS and OCT-derived TCFA, using a dedicated nitinol self-expanding vShield device. Authors reported an interesting observation of neocap formation in the shielded plaques with an increase in the average cap thickness from $48 \pm 12 \mu\text{m}$ at baseline to $201 \pm 168 \mu\text{m}$ at 6 months' follow-up [164]. It is hoped that this study may provide the foundation for larger scale trials in future.

A second challenge is that a lesion-specific approach requires that the number of vulnerable plaques in each patient needs to be known and the number of such lesions need to be limited. That is not the case, however. Several pathological studies indicate the presence of multiple “lipid-rich” vulnerable plaques in patients dying after ACS or with sudden coronary death [37,61]. Further complicating the issue, coronary occlusion and myocardial infarction usually evolve from mild to moderate stenosis—68% of the time, according to an analysis of data from different studies.

The third and fourth challenge is that the natural history of the vulnerable plaque (with respect to incidence of acute events) has to be documented in patients treated with patient-specific systemic therapy, and the approach has to be proven to significantly reduce the incidence of future events relative to its natural history. At this time, neither is documented nor proved.

Fifth, we believe that at the current stage it is not possible to know which vulnerable plaques will never rupture. Although we suspect it is the vast majority of them, we may have to shift to a more appropriate therapeutic target. In addition, targeting not only the vulnerable plaque but also the vulnerable blood (prone to thrombosis) and/or vulnerable myocardium (prone to life-threatening arrhythmia) may be also important to reduce the risk of fatal events.

Conclusions

Atherosclerosis is now recognized as a diffuse and chronic inflammatory disorder involving vascular, metabolic, and immune system with various local and systemic manifestations. A composite

vulnerability index score comprising the total burden of atherosclerosis and vulnerable plaques in the coronary, carotid, aorta, and femoral arteries, together with blood vulnerability factors, should be the ideal method of risk stratification. Obviously, such index is hard to achieve with today's tools. A future challenge is to identify patients at high risk of acute vascular events before clinical syndromes develop. At present, aside from imaging modalities such as IVUS, virtual histology, magnetic resonance, and local Raman spectroscopy that could help to identify vulnerable plaques, highly sensitive inflammatory circulating markers such as hsCRP, cytokines, PAPP-A, pentraxin-3, LpPLA2 are currently the best candidates for diffuse active plaque detection. In order to achieve this aim a coordinated effort is needed to promote the application of the most promising tools and to develop new screening and diagnostic techniques to identify the vulnerable patient.

Interactive multiple choice questions are available for this chapter on www.wiley.com/go/dangas/cardiology

The Essentials of Femoral Vascular Access and Closure

Ted Feldman and Mohammad Sarraf

NorthShore University HealthSystem, Evanston, IL, USA

While we are often preoccupied with the coronary and cardiac complications of catheterization and intervention, it is femoral access complications that occur more frequently, and which are certainly more recognized and remembered by patients. The incidence of local vascular complications that are considered major, as defined by the need for prolonged hospitalization, transfusion, or vascular surgery, ranges between 1% and 1.5% in diagnostic catheterization procedures, and typically between 3% and 5% in interventional procedures. More recently, refinements in techniques and antithrombotic regimens have reduced femoral vascular complications in interventional procedures to 2–3%, but they still remain frequent adverse events [1–3]. Risk factors for vascular complications include advanced age, female gender, low body surface area (BSA), aggressive antithrombin or antiplatelet agent use (e.g. GP IIb/IIIa inhibitors), emergent procedures, vascular disease, vessel size, sheath size, and puncture location [1,4]. The subjects of femoral access and management of femoral puncture after sheath removal are of vital importance in cardiac catheterizations and interventions, especially in patients with high risk of complications.

Femoral access

Anatomy

A good understanding of some key features of the local anatomy is essential for both optimal access and ideal management of the puncture site. Careful attention to access and careful evaluation of the access site are fundamental to reduce sheath insertion trauma and lead to uncomplicated sheath removal and the safe use of vascular closure devices.

It is important to puncture at the level of the common femoral artery. This allows compression of the vessel against the femoral head at the time of sheath removal. Punctures below the common femoral arterial bifurcation (hence in the profunda femoris or the superficial femoral artery) are over soft tissue and are difficult to compress (Figures 2.1 and 2.2). Such punctures have been shown to be associated with increased risk of pseudoaneurysms and arteriovenous fistula formation [5,6]. Punctures above the inguinal ligament (hence in the external iliac artery) are in the retroperitoneal space which also represents an incompressible space. Such high punctures are associated with increased risk of retroperitoneal bleeding [6–8].

Landmarks on fluoroscopy are useful for identifying the position of the common femoral artery. About 75–80% of the common femoral bifurcation is at or below the inferior border of the femoral head and 95% is at or below the mid femoral head [5,9]. While the inguinal ligament is not visualized under fluoroscopy, the deep circumflex iliac artery is commonly used as a surrogate marker of the upper border of the common femoral artery because it is the last arterial branch of the external iliac artery before the external iliac courses under the inguinal ligament and becomes the common femoral artery (Figure 2.1). The deep circumflex iliac artery arises from the lateral aspect of the external iliac artery nearly opposite the origin of the inferior epigastric artery. It ascends obliquely laterally behind the inguinal ligament, contained in a fibrous sheath formed by the junction of the transversalis fascia and iliac fascia, to the anterior superior iliac spine. Puncture above the most inferior border of the course of the deep circumflex iliac artery has been associated with increased risk of retroperitoneal hemorrhage. This landmark is above the most superior border of the acetabulum in most patients [6].

Puncture technique

The basic technique of arterial access has changed very little since it was initially introduced by Seldinger [10]. Puncture of the common femoral artery is basically unchanged, save that the original concept used a through and through puncture and withdrawal of needle into the arterial lumen, while our current approach ideally punctures only the anterior surface of the femoral artery.

However, the technique can be substantially improved by using fluoroscopy of bony landmarks to identify the likely course of the common femoral artery followed by confirmation with femoral angiography after sheath insertion [11]. A point of entry into the common femoral artery at the mid femoral head or slightly above is ideal. The femoral skin crease, which is a very commonly used landmark for puncture, is distal to the common femoral bifurcation in 72% of cases [12]. Generally speaking, younger patients have a mid femoral head location relatively close or slightly above the femoral crease. Older patients have a femoral head significantly above the femoral crease, since the crease tends to sag with age. Obese patients may have two or sometimes even three femoral creases.

Figure 2.1 Femoral artery angiogram taken after sheath insertion. The sheath has been inserted into the superficial femoral artery (SFA). The profunda femoris or deep femoral artery is labeled PF. The sheath terminates in the common femoral artery (CFA). The arrow denotes the lower margin of the curve of the deep circumflex iliac artery. This lower border of the curve courses along the inguinal ligament. Punctures above this landmark are usually adjacent to the retroperitoneal space and poses a high risk for bleeding complications.

Figure 2.2 Bilateral femoral artery angiograms. On the left panel, a line is drawn through the level of the mid femoral head. This is normally an ideal location for puncture. In this case, however, the femoral artery bifurcation is above the mid femoral head and the sheath can be seen entering the deep femoral artery. The right panel shows the left femoral angiogram. A line is drawn at the level of the top of the femoral head, showing a remarkably high bifurcation in this patient. Even though the sheath insertion on this side is just below the top of the femoral head, it is also in the deep femoral artery. Although this puncture is compressible over the femoral head, the branch is relatively smaller than the common femoral artery and less well suited for use of closure devices.

Figure 2.3 (a) shows a fluoroscopic image recorded prior to puncture. The 18 g thin wall needle has been laid on the skin at the point of anticipated femoral puncture based on palpation. The arrow shows the tip of the needle. Fluoroscopy demonstrates that the needle is at the lower border of the femoral head. This is an ideal location for skin entry as the needle will puncture the femoral artery superior to this point. (b) shows the needle advanced until the pulsation of the femoral artery is felt to be transmitted through the needle. The arrow shows the position of the needle. This is just below the mid femoral head and is an ideal “landing zone” for puncture. The majority of patients’ femoral artery bifurcation will be below this point and the probability of common femoral artery entry is high. The arrowhead pointing upward shows the location of the skin crease. In (c) sheath angiography demonstrates that the entry point is in the common femoral artery above the line of the mid femoral head. This is higher than ideal but represents a good entry point for the sheath. Just above the sheath entry site, the U-shaped branch of the external iliac artery denotes the location of the inguinal ligament and the division between the common femoral artery and the retroperitoneal iliac vessel. This branch is the deep circumflex iliac artery.

The technique of puncture requires multiple small steps to be optimized. Before local anesthesia is given, a clamp or needle can be laid at the point where the pulse is most easily felt, just above the femoral crease. Fluoroscopy can be used to locate the position of the needle relative to the center of the femoral head (Figure 2.3). Local anesthesia can thus be given accordingly. After local anesthesia is given, the needle is advanced to a point just above the arterial wall,

using palpation as a guide. At this point, it is useful to fluoroscope the location of the needle once again. This is the last chance to adjust the puncture to enter the common femoral artery in the ideal landing zone. This method is not often adhered to, but in the long run is very worthwhile and justifies the few seconds of extra time at the beginning of the procedure. Meanwhile, this is also the time to observe the behavior of the needle that is placed close to the femoral

artery. If the needle is moving up and down, it is indirect evidence of puncturing the anterior wall of the common femoral artery. However, if the needle is moving side to side, it is indirect evidence of puncturing the lateral or medial side of the common femoral artery. Therefore, the operator can still adjust the angle of attack to the femoral artery.

Once the sheath has been inserted, a sheath angiogram should be performed. Using an AP projection best preserves the relationship between the puncture site and the lower border of the inferior epigastric artery, but may have overlap of the femoral bifurcation. A 20° ipsilateral angulation of the image intensifier will expose the entry point of the sheath, as well as the femoral bifurcation [6]. It can thus be determined whether the common femoral artery has in fact been entered, and whether there is atherosclerosis, calcification, or angulation of the puncture site. It is our practice to obtain the sheath angiogram at the beginning of the procedure, so that decisions about closure and sometimes anticoagulation can be made before the procedure is performed. If the sheath has been inserted into the branch vessels below the bifurcation, this will often have an impact on ultimate sheath size, for example in the setting of bifurcation or chronic total occlusion intervention, and can impact the choice of anticoagulation. When the puncture is above the most inferior border of the inferior epigastric artery, it is likely that the retroperitoneal space has been entered with the sheath. In this instance, an option is to defer intervention until a later time. Full anticoagulation with the sheath in this location greatly increases the risk of retroperitoneal bleeding, which is one of the worst and more difficult local complications to manage.

Ultrasound guided femoral access

Ultrasound guided vascular access has gained attention by catheterization laboratories for arterial access, especially for large bore vascular access. The main advantage of ultrasound guided access is to identify the anatomy of the vessels and the relationship between the artery and the vein. Ultrasound guided access helps to select the puncture site more precisely. The major landmarks should be identified by conventional fluoroscopy. By using a sterile plastic cover, the probe is positioned over the point of maximal pulsation to scan the femoral artery and vein. The scanning should start from the point of maximal pulse with cranial to caudal movement of the probe perpendicular to the skin until the bifurcation site is accurately identified. The appearance of femoral artery is a pulsatile circle, with thicker and more prominent delineation of the arterial walls. Sometimes, the calcification of the vessels or plaques inside the artery can be identified, which helps to avoid entering these areas. Identification of femoral artery versus vein is easily achieved by gentle pressure with the vascular probe; the artery is not compressible and the pulsations become more apparent. It is noteworthy that pulsation of the vessels can be misleading in patients with severe tricuspid regurgitation. The artery should be imaged in the center of the image, and the needle should be gently approached. The reverberation artifact of the needle helps to identify the path of the needle to the artery. When the needle enters the artery, the rest of the procedure follows the standard procedure for vascular access. Sometimes, the vein runs medial and posterior to the artery. Using ultrasound can occasionally be useful to avoid entering artery before venous access and prevent other complications such as arteriovenous fistulae.

Femoral access closure

Manual compression

Manual compression has been the standard for sheath removal for decades. Classically, after diagnostic catheterizations the technique involves sheath removal after normalization of the activated clotting time (ACT) to <160–180 seconds and direct digital pressures with fingers positioned over the arterial puncture site and one to two fingerbreadths more proximally. The manual pressure should be applied with enough force to allow for a faint palpable distal pulse. Pressure is held for 10–15 minutes, during which hemostasis should be achieved, after which the patient is kept under bed rest for 4–6 hours.

The use of larger arterial sheaths, more intensive anticoagulation, and antiplatelet regimens associated with coronary and cardiac interventions have led to the need for more prolonged direct pressure to achieve hemostasis and more prolonged bed rest prior to ambulation. A variety of mechanical manual compression aids, such as the Femostop (Radi Medical System, Sweden) and Compressar C-clamp (Advanced Vascular Dynamics, Portland, OR), have been developed to relieve the requirement for staff to physically apply prolonged direct digital pressure. A number of studies have compared such devices with direct manual pressure, with most studies finding lower vascular complications with mechanical compression devices [13–15] although a small study (90 subjects) found better results with direct manual pressure [16].

Clamp devices provide compression without the need to have someone using direct manual pressure. While clamps may be less demanding on personnel, they do not obviate the need for careful supervision of the compression process. If clamps are applied with too much pressure or left in place for too long, they can result in arterial or venous thrombosis. If applied without adequate pressure, bleeding can result. The Femostop (RADI Medical) uses an inflatable bubble to apply pressure to the puncture site. This is our preferred device for compression in fully anticoagulated patients with failed suture closure or large caliber arterial or venous sheaths. The bubble is clear, so the puncture site can be observed directly. The pressure is regulated with a blood pressure cuff bulb. Near systolic pressure (usually 10 mm less than systolic blood pressure) can be applied for 15–30 minutes, and then the pressure can be decreased 10–15 mmHg every 10–20 minutes.

Even with interventional procedures, there have been some remarkable experiences with ambulation as early as 2 hours after simple manual compression. With the use of bivalirudin, in a study of 100 patients, after a mean manual compression time of 13 minutes, patients were able to ambulate at a mean duration of 2 hours and 23 minutes after sheath removal [17]. Even using heparin, there are various studies suggesting ability to ambulate after 2 hours. Using a regime of a standard heparin dose of 5000 IU and 6 Fr guiding catheters, two studies involving 359 and 907 patients were able to have sheaths removed immediately, with a mean compression time of around 10 minutes and successful early ambulation within 2 hours with no significant excess in puncture site complications [18,19]. A study with more aggressive anticoagulation (ACT to 300 seconds) and subsequent sheath removal when ACT is less than 150 seconds showed no difference in site complications between patients ambulating at 2 hours compared to 4 or 6 hours. In this latter study, there are also similar results in a subgroup of patients who received GP IIb/IIIa inhibitors [20]. Thus, manual compression is clearly an acceptable form of puncture site management in all patients.

Table 2.1 Types of closure devices.

	Manufacturer	CE Mark	US Approval	Status
Plugs

Mynx	Access Closure	+	+	

Vascular closure devices

A variety of vascular closure devices have been developed to enhance vascular closure without need for prolonged compression. These are deployed at the conclusion of the cardiac catheterization procedure and can be used despite an elevated ACT. Closure devices are classified into four major categories: sutures, plugs, glues, and topical patches (Table 2.1). The current FDA-approved devices in most common use in the USA are the AngioSeal (Datascope Inc), Perclose, ProStar, and StarClose (Abbott Vascular, Redwood City CA). Hemostatic patches are also approved for use in the USA (Figure 2.4).

AngioSeal

The AngioSeal device consists of a rectangular absorbable copolymeric anchor deployed intravascularly against the arterial wall which is attached by an absorbable Dexon traction suture to an extravascular collagen plug applied to the outside of the arterial wall. The AngioSeal assembly consists of a carrier system with the anchor, collagen plug, and traction suture compacted at the distal end. There is a delivery sheath with a modified locator dilator which identifies when the sheath is intravascular. After cardiac catheterization, the working sheath is changed over to the AngioSeal delivery sheath. Once the delivery sheath is intravascular, as indicated by pulsatile flow in the arteriotomy locator system of the dilator, the dilator and wire are removed. The carrier is then advanced into the sheath, locks in place with the sheath, and then the entire assembly is withdrawn until resistance is felt. This indicates apposition of the anchor on the luminal arterial wall. Further withdrawal releases the collagen plug on the external surface of the artery, followed by a tamper tube. The

Figure 2.4 Use of vascular closure approaches in the United States.

tamper tube is used to compress the plug over the wire, followed by removal of the tamper tube and cutting of the suture, which are external to the patient. Currently, the AngioSeal is available in two sizes: 6 and 8 Fr. Deployment success rates ranged from 92% to 98%, and hemostasis success ranged from 84% to 97% [21].

Perclose

The Perclose device is a suture-mediated system which has undergone a steady evolution which included the Techstar device, Closer S 6 Fr, and the current ProGlide 6 Fr system. It incorporates two

needles in the proximal compartment of the device and a catheter that houses the suture (Figure 2.5). The working sheath is exchanged over a wire for the Perclose device. The device is advanced until return of pulsatile blood in the locator, indicating appropriate intravascular placement. A lever is pulled to open the “feet,” and the device is withdrawn until resistance is felt, indicating apposition of the foot processes and suture catch plates against the inner vessel wall. A plunger is depressed, forcing the needles through the outer vessel wall into the suture catch plates. The catch plates are attached to the ends of the suture. Retraction of the plunger withdraws the needles and the attached sutures through the skin. With the current ProGlide system, the device incorporates a non-absorbable polypropylene monofilament with pre-tied knot that is tightened and the vascular access site closed using a pusher device. One significant advantage of the Perclose system is to maintain access to the vessel during deploying the device by using the guidewire before

withdrawing the device. Therefore the wire can be reintroduced via the device after the needle and suture deployment, and the wire removed after confirmation of adequate hemostasis. This feature is unique among the closure approaches. In most series, the device is successfully deployed in 89–100%, with hemostasis success seen in 86–99%. The Prostar device is a Perclose-based suture mediated device, which allows for closure of larger arteriotomy. It comes in 8 or 10 Fr and can incorporate one or two sutures (associated with two or four needles, respectively).

StarClose

StarClose is a device that applies a 4-mm low profile nitinol clip entirely on the external surface of the artery with no permanent intravascular component (Figures 2.6 and 2.7). The tines of the clip grasp the arterial tissue and close the arteriotomy in a purse string fashion. The device consists of the clip applicator and a proprietary

Figure 2.5 The Perclose ProGlide device is used to deliver sutures through the puncture to close the arteriotomy site. The small insets of the upper left of the figure show feet that are opened inside the artery, and the mechanism by which needles are driven from the handle of the device into the feet to capture the sutures. The sutures are then withdrawn using the needles, and a pre-tied knot is pushed through the skin to the top of the arteriotomy site on the outside of the artery.

Figure 2.6 The StarClose device is delivered through a special sheath provided with the device. After the device is loaded into the artery, nitinol wings are opened within the artery and pulled back to capture the inner arterial wall. The clip device, shown on the left part of the figure, is then advanced to the outside surface of the artery. When a clip is fired, it inverts and the tines of the clip capture the arteriotomy and force it closed. This device is unique in that what is left behind is entirely extra-arterial.

Figure 2.7 Femoral angiogram 1 year after closure with the StarClose device. The arrowhead on the left shows the device, and on the right contrast injection demonstrates the insertion site of the re-puncture. The device is entirely extravascular.

6 Fr sheath. After conclusion of cardiac catheterization, the working sheath is changed over a wire to the proprietary sheath, with further blunt dissection during the process to ease subsequent advancement of the 12 Fr clip applicator through the skin and subcutaneous tissue. The clip applicator has a vessel locator, which is inserted into the sheath, until the clip applicator snaps into the sheath. A button is depressed which deploys small flexible nitinol wings at the end of the vessel locator, inside the artery. The entire assembly is withdrawn until resistance is felt, indicating apposition of the wings against the inner vessel wall. The sliding element with the attached clip is then depressed splitting the sheath and applies the clip to the arterial wall at the end of the assembly. At this stage, it is very important to ensure that the skin does not block the “splitter.” It is reasonable therefore to nick the skin after the proprietary sheath is placed. The procedure is completed by release of the clip using a button “trigger.” In the CLIP trial, which compared the StarClose with manual compression, device success was 87%, with no difference in complications between the groups [22].

Exoseal, Femoseal

Exoseal (Cordis, Bridgewater, NJ) is a passive closure device that consists of deployment of a polyglycolic acid plug (absorbed within 90 days) over the arteriotomy site for hemostasis. The system is delivered through 5–7 Fr sheaths. The minimum diameter of the femoral artery is 5 mm for closure. Time to achieve hemostasis and ambulation appears to be lower than with manual compression. Access through the same site requires a delay of at least 30 days.

Femoseal (St. Jude Medical Systems, Uppsala, Sweden) comprises a bioabsorbable polymer anchor plate that remains inside the artery and an outer disk. After procedural sheath removal, the anchor seal is deployed within the artery while the outer locking disk is placed on the outer wall of the artery. The arteriotomy is sandwiched between the two disks and held together by a bioabsorbable multifilament.

Hemostatic patches

Hemostatic patches were originally designed for military purposes to achieve temporary arterial hemostasis in the battlefield. The mechanisms of action include causing vasoconstriction, creation of a positively charged environment, which attracts negatively charged

red blood cells and platelets, or direct promotion of rapid coagulation [23–25]. Available patches include: Syvek Patch using poly-N-glucosamine (Marine Polymer Technologies, Danvers, MA); Neptune pad using calcium alginate (Biotronik, Bulach, Switzerland); Closure PAD (Medtronic, Santa Rosa, CA); Chito-Seal using chitosan gel (Abbott Vascular, Redwood, CA); SafeSeal using a microporous polysaccharide (Possis Medical, Minneapolis MN, formerly Stasys Patch, St. Jude Medical, St. Paul, MN); and D-Stat Dry using thrombin (Vascular Solutions, Minneapolis, MN) (Table 2.1) [23].

Hemostatic patches allow sheath removal in anticoagulated patients, with ACT as high as 300 seconds [24]. Studies on hemostatic patches have generally demonstrated shorter time to hemostasis and ambulation. However, a period of manual compression is generally required and may be longer than the recommended compression times from manufacturers [25–27]. It is likely a combination of both hemostatic properties of the patch and manual compression that leads to hemostasis. There are no consistent data demonstrating reduction in vascular complications with the use of hemostatic patches over manual compression. Neither the Syvek patch nor Chito-Seal has been shown to reduce vascular complications over manual compression in a review of cases registered with the American College of Cardiology-National Cardiovascular Data Registry (ACC-NCDR) [28]. D-Stat Dry used after diagnostic procedures reduced vascular complications compared to manual compression in a series utilizing a historical control [25], but no direct comparisons have been performed. As the complication rate from vascular puncture in general appears to be declining with time, direct comparisons are necessary to clearly demonstrate decreased complication rates using these patches [4]. There are now several other patches available.

Evidence-based issues for vascular closure devices

The design goals of active vascular closure devices (as replacement of manual compression for management of femoral arterial sheath removal) would include reduction in hemostasis and ambulation times with associated improved patient comfort and reduction in hemorrhagic vascular complications. As experience with this family of devices has grown it is clear that hemostasis and ambulation times can be decreased, but the reduction of vascular complications has not been as well shown. There are real concerns for the potential to increase rare but serious complications such as infection, arterial occlusion, distal embolization, and arterial wall injury with pseudoaneurysm. In addition, bleeding complications, should they occur, could potentially be more severe than seen with manual compression because manual compression requires normalization of ACT prior to sheath removal while vascular closure devices can be deployed at elevated ACT [4]. In a review of case series of AngioSeal and Perclose, the reported incidence of such complications include: infection 0.6%; pseudoaneurysm or arteriovenous fistula 0.6–1%; and occlusion or embolism 0.2–0.4% [21]. In a review of 4 years of cardiac catheterizations and interventions at the Mayo Clinic between 2000 and 2003, during which vascular closure devices were used in 1662 patients, the incidence of device-related infection was 0.24% [29].

There are numerous randomized and non-randomized comparisons of vascular closure devices and manual compression. There is significant heterogeneity between the trials in inclusion criteria and definitions of outcomes. Three meta-analyses have reviewed the studies involving collagen plug devices (AngioSeal and VasoSeal) and suture devices (Perclose) [28,30]. Use of vascular closure

devices is associated with significant reductions in time to hemostasis (by 17 minutes), time to ambulation (by up to 11 hours) and time to discharge (by 0.6 days) [31]. However, in these analyses in both diagnostic and interventional settings, there is no substantial difference (benefits or harms) in vascular complications by the vascular closure devices, except for the VasoSeal device, which has been associated with increased vascular complications in two of the meta-analyses [30,32]. There are a number of limitations to assessing the relative rates of complications with manual compression and vascular closure devices. First, some trials have required femoral angiography, and higher risk patients may be eliminated from the trials, because of small caliber femoral vessels, atherosclerosis of the puncture site, or calcification. In addition, many of the trials have rigorous protocol specifications for the manner in which the closure devices are used, but generally give no guidance regarding manual compression methods, which can be highly variable. In some institutions, there are sheath removal teams who become quite expert at sheath removal, manual compression, and puncture site management. It is difficult to make comparisons between these programs and lower volume programs, or programs where new trainees are relegated to the task of sheath removal and manual compression.

The largest registry study of femoral hemostasis comes from the ACC-NCDR [33]. From this registry, the outcomes of 166,680 patients who underwent diagnostic and interventional cardiac catheterizations in 2001 were evaluated, with suture devices used in 25,495 cases, collagen-plug devices used in 28,160 cases, while the rest underwent manual compression. In the overall multivariate analysis, use of collagen plug devices was associated with reduced bleeding in diagnostic catheterization (odds ratio 0.68) and both types of closure devices were associated with reduced risk of pseudoaneurysm formation in diagnostic and interventional procedures (odds ratio 0.46–0.52). It is possible that among individual operators who develop special expertise with a particular closure device, there is potential to achieve improved success rates with lower complication rate [34].

What then are the advantages of vascular closure devices? Unquestionably, the complete avoidance of compression with immediate hemostasis and early ambulation improves patient satisfaction [35]. This alone can justify the use of these devices in many cases. However, with no clear difference in complication rates, possibly the strongest benefit may be an early (same-day) discharge of patients after percutaneous coronary intervention that could result from early ambulation [4,36]. Over the past 5 years, major vascular complications have decreased among patients undergoing percutaneous coronary intervention in the Northern New England Cardiovascular Disease Study Group. In their database, with 36,631 patients undergoing percutaneous coronary intervention, arterial complications decreased from 3.37% in 2002 to 1.98% in 2006 [30]. Whether this reflects more careful attention to needle puncture and sheath insertion, improved management of anticoagulation, better manual compression, or optimized use of closure devices cannot be ascertained without a randomized trial. Such a trial would require such a large population that is unlikely ever to be performed.

Vascular closure devices shorten the time to hemostasis and ambulation, compared with manual compression, but the aggregate of reports are mixed regarding the potential for closure devices to increase or decrease the risk of vascular complications. In a recent study of patients undergoing diagnostic coronary angiogram with a 6 Fr system, the vascular closure devices were not inferior to manual pressure. There were no increased risks of vascular

complications; however, it is important to note that in this study the patients did not undergo any coronary interventions so the results should be considered in the context of diagnostic angiography. This study compared FemoSeal (St Jude Medical) with ExoSeal (Cordis). ExoSeal is not frequently used in the USA, and FemoSeal is only currently available in Europe [37].

Preclosure for large arterial sheaths

Large bore arterial sheaths (12–14 Fr) can be required for certain interventions such as retrograde balloon aortic valvuloplasty or, more recently, retrograde transcatheter aortic valve replacement (14–24 Fr). Such large bore arterial sheaths are historically associated with need for prolonged compression to achieve hemostasis, prolonged bed rest prior to mobilization (up to 12–24 hours in certain cases), and high risk of recurrent bleeding and need for transfusion. Transfusion rates after manual compression following balloon aortic valvuloplasty have been in the range of 25%. Preclosure is a technique using the Perclose or ProStar device to “preload” the suture around the puncture site prior to access with the large bore sheath to allow for subsequent suture closure at removal of the large arterial sheath. After puncture, a standard 6–8 Fr sheath is inserted and subsequently exchanged over the wire to introduce a Perclose or ProStar device. Deployment of the needle is performed with the standard manner to preload the suture around the arteriotomy. The suture is not tightened. A wire is reintroduced into the device over which an exchange is made with the subsequent large bore arterial sheath. At completion of the procedure requiring the large bore sheath, the sheath is removed and closure performed by tightening of the preloaded sutures. With this technique, a 6-Fr Perclose system had been successful in closing 12 Fr arteriotomies and a 10 Fr ProStar system had been successful in closing 14 Fr arteriotomies. In a non-randomized comparison, this technique had been successful in significantly reducing length of hospital stay and almost eliminating the need for blood transfusions after retrograde arterial balloon aortic valvuloplasty [38,39]. Although there are no commercially available closure devices for larger than 14 Fr sheath size, most operators have adopted approaches to utilize preclosure. Several novel devices for large vessel closure are under development. There are mainly three approaches of new technology to manage percutaneous closure following large bore vascular access: suture-based, suture and plug/sealant, and ipsilateral/contralateral graft placement. There are a number of products under investigation that are not available on the market yet.

Arterial access management for transcatheter aortic valvular replacement

In our catheterization laboratory, we use a standard approach for patients requiring transcatheter aortic valvular replacement (TAVR). This approach starts before the patient comes to the catheterization laboratory by meticulous attention to the aorto-iliac and femoral artery anatomy on pre-TAVR CT angiography. Understanding the location of calcifications of these vessels, tortuosity, diameter, and the presence of prior bypass grafts and/or stents is invaluable. The location of femoral bifurcations relative to the femoral head can be assessed.

We start the procedure with the contralateral access site (non-TAVR sheath) using a micropuncture needle with iterative usage of fluoroscopy. After placing a 7-Fr sheath in the contralateral artery, a JR4 or internal mammary artery catheter is used to cross into the ipsilateral common iliac artery with a wire (J tipped guidewire, angled glide wire, Wholly wire). The tip of the catheter is placed in

the terminal portion of the ipsilateral external iliac artery and a cine angiogram of the ipsilateral common femoral artery is performed. A V18 guidewire is passed through the crossover catheter across the distal abdominal aortic bifurcation to the terminal segment of superficial femoral artery on the side in which the large caliber TAVR sheath will be placed. This wire is used for a possible usage of crossover balloon technique should major vascular complications occur with the TAVR sheath [40,41]. Ultrasound guidance is used as the preferred method for vascular access in some centers. It has the advantage of showing areas of calcification as well as the level of the femoral bifurcation, and better insures a puncture of the anterior wall of the common femoral artery.

At this point the ipsilateral common femoral artery is punctured for the TAVR sheath. The crossover angiogram is used as a road-map for micropuncture. An injection through the crossover catheter can be used to verify the entry point of the needle in the common femoral artery (Figure 2.8). If we are not satisfied with the location of the femoral access, we withdraw the microcatheter and hold pressure for several minutes. Some operators prefer a pigtail from the contralateral access site. The terminal circle of the pigtail is placed over the target puncture site of the femoral head en face, to be used as a target for ipsilateral femoral access. A regular J tipped guidewire is placed in the microcatheter, and the microcatheter is removed. A 6 or 7 Fr dilator is placed over the wire to enlarge the arteriotomy prior to preclosure. Some operators recommend dissecting the subcutaneous tissue before 7 Fr dilator is removed for easier access to the vessel wall. Next we use two ProGlide devices for preclosure of the arteriotomy, the first placed at the 10 o'clock position and the second device at 2 o'clock. After the second ProGlide device is deployed a stiff Amplatz guidewire is passed through the second ProGlide. An alternative to ProGlide device is using one or two ProStar closure devices.

Serial dilatation of the arteriotomy is not necessary, because most TAVR devices currently require 1420 Fr arterial sheaths. We sometimes use a 14 Fr dilator (and sometimes a 14 Fr sheath) before inserting the TAVR sheath. After completion of TAVR procedure, an Amplatz Superstiff or Extrastiff wire is placed through the TAVR sheath. The first operator ties down the arteriotomy with the first ProGlide closure device with a knot pusher, while the second

operator carefully removes the TAVR sheath over the guidewire. An immediate assessment of the bleeding is a direct indication of the success of the closure device. Frequently, the first preclosure device successfully closes the arteriotomy with minimal bleeding. Subsequently, by using the knot pusher, the second preclosure knot is pushed down over the wire. Until this point, the wire is still left in place in case homeostasis is not achieved. In some cases, a third or sometimes even fourth ProGlide closure device may be necessary. When homeostasis is achieved, the wire can be removed and both knots tied down again by the knot pushers. We always perform a final femoral angiogram with digital subtraction via contralateral access, with either a pigtail above the aortic bifurcation, or via a catheter over the crossover wire. This latter approach requires placing a Toughy connector on the hub end of the catheter. If there is any contrast extravasation or stenosis of the access site, it can be managed with a crossover balloon (Figure 2.9). If the results are satisfactory, the V18 wire is removed and the contralateral femoral artery is closed.

The crossover balloon technique can also be used just before withdrawal of TAVR sheath under a controlled and safe environment. The TAVR sheath is withdrawn to the common femoral artery over the stiff wire. Using a peripheral 8–10 mm balloon over the 0.018 inch crossover wire, the balloon is placed in the terminal segment of the external iliac artery or proximal segment of the common femoral artery inflated to 1–2 atm. This creates proximal control and hemostasis with a non-traumatic occlusion of the vessel during sheath removal and knot delivery.

Large bore venous sheath management

Currently, the most common indications for using large sheaths in the common femoral vein are shunt closure, left atrial appendage occlusion, paravalvular leak closure, and MitraClip. Some devices such as percutaneous left ventricular assist devices can also require large access to the venous system; however, more frequently, patients who require percutaneous left ventricular assist devices may have to leave the catheterization laboratory with the device in place, in which case there is a long delay before sheath removal and closure devices should not be used because of the high risk of infection.

Figure 2.8 Left panel: The white arrow shows the tip of a left internal mammary artery catheter that has been passed from the left femoral artery access over the top of the aortic bifurcation and into the right external iliac artery. This crossover catheter is used for angiography and delivery of a protective crossover wire. Right panel: Micropuncture needle having entered the right common femoral artery at the level of the white arrow. A micropuncture wire can be seen going retrograde in the right iliac and femoral system. Injection through the crossover catheter demonstrates the entry point of the micropuncture needle in the common femoral artery.

Figure 2.9 Following the completion of the procedure, crossover angiography can be used to assess the adequacy of femoral closure. (a) Needle entry at the beginning of the procedure. The entry point of the needle is in the lower one-third of the femoral head, below the lower border of the inferior epigastric artery and above the bifurcation of the common femoral artery, in the ideal landing zone for sheath insertion. (b) Extravasation of contrast after percutaneous closure of the large sheath entry point. The black arrow shows the contrast extravasation. The dotted white arrow shows course of a 0.018 inch crossover wire. The angiogram was taken with a pigtail positioned at the distal aorta above the iliac bifurcation. (c) A balloon passed over the crossover wire and inflated at 2 atm at the site of contrast extravasation and bleeding. (d) Complete sealing of the artery at the closure site. The contrast injection was through the shaft of the balloon catheter, around the 0.018 inch wire, via a Toughy connector on the back end of the balloon catheter.

The strategy for managing large sheaths in the venous system is easier than for arterial punctures because of the lower pressure of the venous system. After the access is carefully obtained by a regular 18-gauge needle, we place a 7 Fr dilator in the vein. Blunt dissection of subcutaneous tissue facilitates delivery of larger sheaths. The sheath is inserted in the standard manner. After completion of the procedure, we use a “figure of 8” suture for hemostasis. For this technique, we use a 0 silk suture and we start from the distal edge of the access site, below the insertion of the sheath through the skin. The orientation of the needle entry can be either from medial to lateral or vice versa. When the needle is withdrawn from the skin, we use the same needle on the more proximal segment of the sheath, superior to the sheath insertion, with same the same direction of passage (medial to lateral or vice versa). After cutting off the needle, we take one end of the suture line and wrap around the other end three times, and finally tie down over the skin, while the sheath is still through the skin. The first operator keeps active force on the suture over the sheath as the second operator removes the sheath from the skin. Finally, the reinforcing knots will be placed. Very rarely do we see any ongoing oozing from the venous access site by using this simple and cost-effective technique [42].

Conclusions

Proper management of femoral access is vital in reducing the femoral vascular adverse events, which are the most common complications in cardiac catheterizations and interventions. Refinements in

antithrombotic and antiplatelet regimens, and reductions in access size have reduced ambulation times and the risks of complications. Vascular closure devices have further significantly improved hemostasis and ambulation times, and current data suggest they are mostly safe. However, there is no unequivocal evidence to suggest they reduce vascular complications in either diagnostic or interventional subgroups. Experience and expertise with whichever technique for femoral access site management one chooses are the best ways to minimize complications.

Just as important as management of vascular closure, careful attention to obtaining vascular access is important. Careful assessment of bony landmarks by fluoroscopy prior to femoral access will maximize the chance of sheath insertion into the common femoral artery with reductions in complications. Similarly, routine femoral angiography after femoral access to confirm sheath position is useful not only for assessing suitability of applications of vascular closure device, but also for assessing the risks of bleeding with use of antithrombotics which can affect interventional decision making. Femoral vascular access and closure approaches have been greatly refined by the demands of TAVR, with CT assessment for procedure planning, the use of micro-puncture and ultrasound, and crossover techniques.

The last decade has seen a paradigm shift in access site practice with an extraordinary uptake of radial artery access for both coronary angiography and interventional cardiac procedures [1]. While we are most often concerned about the coronary and cardiac complications of catheterization and intervention, vascular access complications are more common and carry prognostic importance for patients. The benefits of the radial artery as an access site for catheterization is primarily because of its superficial compressible location allowing early effective hemostasis and mobilization. The uptake of transradial access (TRA) is a triumph of contemporary evidence-based medicine as multiple large trials have challenged previous dogma about TRA causing increased risk of stroke and hand ischemia [2].

Rationale for transradial access

Ischemic complications of percutaneous coronary intervention (PCI) have reduced over time through developments in anticoagulants, antiplatelet therapy, and coronary stents coupled with procedural improvements [3]. Non-ischemic complications of PCI have increasingly been the focus of attention—namely those involving vascular access and bleeding. TRA reduces vascular access complications allowing early ambulation, improved comfort, reduced bleeding risk, shorter hospital stay, and reduced cost [4]. While the definition of major bleeding varies widely, access site hematomas large enough to require transfusion are inexorably linked to worse short-term and long-term clinical outcomes and this relationship is thought to be causal [5,6]. Pharmacological developments that result in reduced bleeding complications have been associated with reductions in mortality [7]. If the relationship between bleeding and mortality is causal, any method of reducing bleeding, including procedural advances, will also reduce mortality. This hypothesis was supported by a subgroup analysis of the multicenter randomized RIVAL study of radial vs. femoral PCI in acute coronary syndrome (ACS) showing a reduction in primary outcome (death, myocardial infarction, stroke, or major bleeding) in the highest volume radial centers and in patients with ST-elevation myocardial infarction [8]. The MATRIX study is the largest trial to date (n = 8404) comparing radial with femoral access for PCI in patients

with ACS. Radial artery PCI reduced the rate of net adverse clinical event (death, myocardial infarction, stroke, or major bleeding) by 17% (9.8% vs. 11.7% of patients; 0.83, 0.73–0.96; p = 0.0092) [9]. Mortality was reduced with radial PCI by 28% (1.6% vs. 2.2% of patients; 0.72, 0.53–0.99; p = 0.045). This is consistent with the updated meta-analysis of all trials, which shows highly significant benefits of radial access in a population with ACS for major adverse cardiac events (MACE) by 14% (6.0% vs. 7.0% of patients; 0.86, 0.77–0.95; p = 0.0051) and mortality by 28% (1.8% vs. 2.5%; 0.72, 0.6–0.88; p = 0.0011) [9].

Radial anatomy

Arterial supply to the upper limb begins as the axillary artery before it reaches the lower border of teres major becoming the brachial artery—the main blood arterial supply to the arm. This bifurcates 1–2 cm distal to the intercondylar line of the humerus (proximal border of the antecubital fossa) into the radial and ulnar arteries (Figure 3.1).

Preprocedural considerations

There are several relative contraindications to TRA (Box 3.1). The modified Allen's test is often performed prior to TRA to demonstrate patency of ulnopalmar arches because of the theoretical risk of hand ischemia in the event of radial artery occlusion (RAO). The generous redundant vascularization of the hand by the radial, ulnar, and interosseous arteries provides excellent protection against digital ischemia which is almost never seen even in instances of RAO after catheterization [10]. The test involves compression of both the radial and ulnar arteries while blood is expelled from the hand by forced fist clenching. After opening the hand, ulnar artery compression is released and the amount of time to achieve maximal palmar blush is measured. "Normal" response times vary but a common contemporary definition regards within 5 seconds as normal, 6–10 seconds as intermediate, and greater than 10 seconds as abnormal [11]. Plethysmography using a thumb pulse oximeter trace can be used to increase objectivity and diagnostic accuracy of the test (Barbeau test) [12].

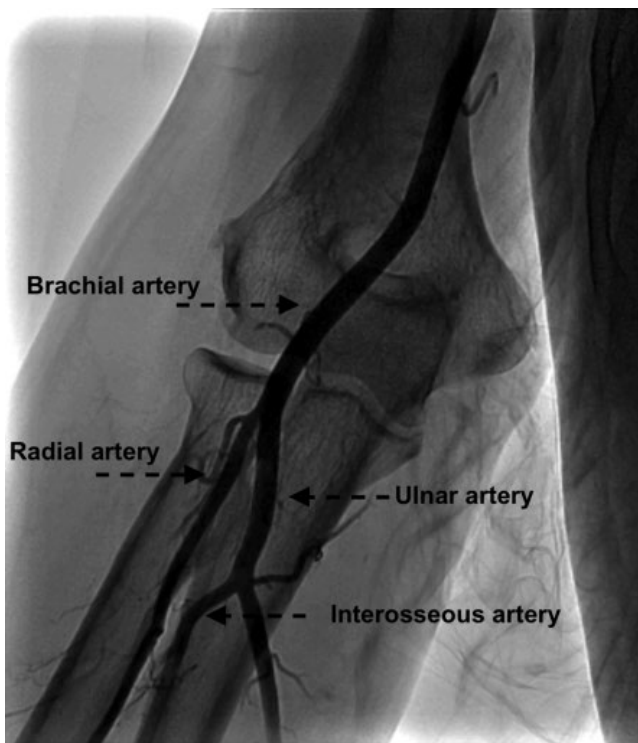

Figure 3.1 The forearm and hand benefit from a dual blood supply resulting from the radioulnar anastomosis in the hand via superficial and deep palmar arches.

Box 3.1 Transradial approach—relative contraindications

Absent radial pulse
 Severe vasospastic disease (e.g., Raynaud's, CREST)
 Arteriovenous fistula for dialysis (current or planned)
 Requirement for radial artery aortocoronary bypass conduit

CREST, syndrome of calcinosis, Raynaud's phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasia.

The ability of these tests to reliably predict those at significant risk of ischemic hand complications is hotly debated [13–15]. There are only a few isolated case reports of distal hand ischemia and gangrene following TRA and these patients often had normal Allen's tests and were most likely caused by distal embolization [16,17]. The paradigm is shifting away from testing ulnar artery patency, with solid clinical evidence supporting the safety of TRA across the full spectrum of Allen's test results [11]. Almost one-quarter of operators worldwide now forgo assessment of ulnopalmar arterial supply prior to TRA while high-volume radial centers in the UK have shown this approach to be safe and without ischemic sequelae [18,19].

Right vs. left radial approach

The right-sided controls in the catheterization laboratory lend themselves to a right radial approach, which is generally preferred by both patient and operator [13]. Nevertheless, the left radial approach (LRA) can offer a favorable approach because of direct

takeoff of the left subclavian artery from the aortic arch, providing better guide support akin to the femoral approach [20]. In shorter elderly patients, the LRA approach may be favorable with less subclavian tortuosity easing catheter passage into the aorta. LRA has recently been shown to be as effective as the right radial with an improved radiation safety profile to the operator [21]. Other considerations for LRA include bypass graft studies involving angiography of the left internal mammary artery and possible future need for a bypass conduit from the non-dominant hand. Importantly, in patients with previous bypass surgery LRA coronary angiography is a feasible alternative but is associated with increased contrast use, procedure time, and operator radiation exposure compared with transfemoral angiography [22].

Ulnar and brachial approach

Ulnar artery access has been used as a feasible alternative for coronary angiography and PCI, although compared with first-line TRA it is inferior with increased crossover rates to TRA. Nevertheless, in terms of access complications it was comparable to radial including comparable rates of large hematomas with no cases of ulnar nerve damage or hand ischemia [23]. The path of the ulnar artery is deeper and less centered over bone and thus does not lend itself to compressive hemostasis as readily as the radial. The brachial approach is usually reserved as a third or fourth line access site because of higher risk of major access complications than TRA: thrombosis, dissections, and median nerve injury [24].

Gaining radial access

Careful vessel palpation and planning is key to successfully gaining access and minimizing inherent risk of spasm with multiple punctures. The artery should be punctured 1–2 cm proximal to the radial styloid in order to avoid the tortuous distal radial artery and its smaller branches. Repeat procedures or attempts can be performed more proximally if required. A small quantity of 2% lidocaine is useful for anesthetic and can be mixed with a small amount of subcutaneous nitroglycerin in patients whose pulse is low volume. There are two main techniques for arterial puncture: a traditional Seldinger technique (“through-and-through” puncture) and a modified Seldinger technique (“anterior only” puncture). In the traditional Seldinger technique a needle with an overlying Teflon-coated cannula sheath is used to puncture the artery at approximately 30°. A flash of blood indicates anterior arterial wall puncture, and the needle is advanced through the posterior radial artery wall. After removal of the needle, a 0.021-inch guidewire is placed in the hub of the Teflon cannula and the entire system is withdrawn backwards until pulsatile flow occurs into the hub of the Teflon cannula indicating luminal cannula sheath position. The guidewire can be advanced and subsequently the hydrophilic introducer sheath inserted over the guidewire.

The modified Seldinger technique uses a short 21-gauge bore needle with an anterior-only puncture technique. After puncture of the anterior wall of the radial artery, a 0.021-inch guidewire is advanced into the artery allowing removal of the needle and sheathing over the guidewire.

An elegant randomized trial showed the traditional Seldinger technique (double wall puncture) to be a more reliable way to obtain radial artery access with greater success rates, shorter procedure time, and shorter time to gain access. Importantly, there were

no differences in procedure-related complications such as radial hematoma or radial artery obstruction [25].

Navigating common anatomic problems

While various anomalies in radial, brachial, and axillary arterial circulation are common, knowledge of just three major anatomic variations is important as they determine most radial procedural failures [26]. With experience these can often be negotiated; however, where this is not possible the asymmetrical nature of forearm vasculature leaves contralateral radial access and the femoral approach as equally plausible options [27].

High radial–ulna bifurcation (“high take-off”)

High-origin radial arteries (defined by their origin above the antecubital fossa) are the most commonly encountered radial artery anomaly, occurring in 7% of patients undergoing radial angiography. These present problems during angiography because of their small caliber and often tortuous course making them prone to spasm. Nevertheless, in experienced hands (and with frequent use of 5 Fr catheters and hydrophilic wires) the procedure can be completed transradially in over 95% of cases [26].

Radial artery loops

This is the most common cause of transradial failure for experienced radial operators [28]. Radial artery loops involve a retrograde loop in the radial artery proximally toward the brachial bifurcation before heading down to the forearm. Navigating the loop is made more challenging by the invariable association with a recurrent (accessory) radial artery, which typically is a small caliber vessel with a straight path up the arm from the apex of the loop. After defining the loop with angiography, small loops can often be navigated with a coronary wire or a soft-tipped hydrophilic wire looped into the brachial artery. Wire passage alone can straighten the loop; alternatively, a buddy wire or small caliber catheter can be exchanged allowing passage of a 0.035-inch wire with gentle traction allowing the loop to be straightened and permitting the procedure to be completed in over two-thirds of cases (Figure 3.2) [28].

Tortuous radial arteries

Radial tortuosity defined by the presence of a bend of more than 90° in the contour of the vessel occurs in around 2% of cases and is often associated with severe spasm [29]. With any resistance to wire passage, the vessel should be mapped using angiography and these angulated segments can usually be crossed using a hydrophilic or coronary wire in the majority of cases. Balloon assisted tracking (BAT) can be used facilitating non-traumatic navigation through challenging anatomic situations including severe tortuosity, resistant spasm, small caliber radial artery, and complex loops. In this technique, an inflated percutaneous transluminal coronary angioplasty (PTCA) balloon is partially protruded through the distal end of a guide (or diagnostic catheter) and deployed at 6 atmospheres. The entire assembly is then advanced over a non-traumatic PTCA guidewire and steered through the challenging segment [30].

Other barriers

After navigation to the subclavian artery, two further barriers to TRA include a tortuous subclavian system or a distal insertion of the subclavian into aorta (arteria lusoria). Risk factors for subclavian

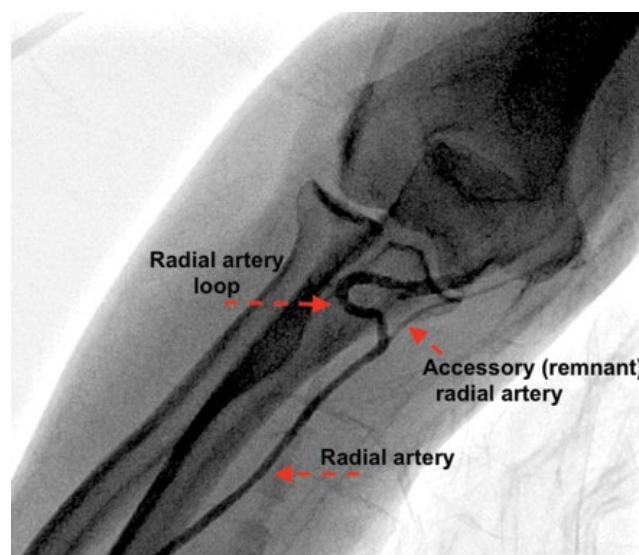

Figure 3.2 Radial artery loop with typical appearance of accessory radial artery from apex of loop.

Figure 3.3 Retroesophageal right subclavian artery (RORSA). Note subclavian insertion into distal aortic arch in a young patient with acute ST elevation myocardial infarction.

tortuosity include hypertension, female gender, older age, smoker, short stature, and high body mass index [31]. A deep breath held in inspiration normally facilitates a straightening of the passage into the ascending aorta allowing correct catheter orientation in the ascending aorta. In very rare cases (0.29%), the right subclavian artery enters very distally into the aortic arch or descending aorta. While it is technically feasible to negotiate the retroesophageal right subclavian artery (RORSA; Figure 3.3), early identification of this issue with conversion to an alternative access site is advised to avoid unnecessarily long procedures with excessive radiation exposure [32].

Complications of transradial access

Spasm

The radial artery is a muscular small-caliber vessel allowing only limited clearance for catheter passage. Resultant mechanical friction combined with circulating catecholamines can trigger α_1 -adrenoreceptors leading to arterial vasospasm. Catheters can become difficult to manipulate and torque potentially abetting more spasm (Table 3.1). This phenomenon occurs in around 15% of cases but the incidence varies widely (2–30%) according to center and definition used [33]. While spasm is usually painful for both the patient and operator, its incidence is reduced with increasing operator experience [34], adequate procedural sedation (opiate/antiemetic) [35], and administration of a “spasmolytic cocktail” after sheath insertion [35,36]. This usually consists of a combination of calcium channel blockers (e.g., verapamil 2.5–5 mg) and/or nitrates (e.g., nitroglycerin 0.1–0.4 mg) given directly into the radial artery sheath. Intravascular imaging studies show the luminal area increases by 44% after 3 mg intra-arterial verapamil with only a moderate blood pressure reduction and no significant change in heart rate [37]. Intra-arterial lidocaine should be avoided as it causes paradoxical vasoconstriction [38]. Intra-arterial heparin administration may be painful so can either be given intravenously, or it can be given intra-arterially with the “cocktail” after dilution with saline or blood from the sheath to reduce arterial irritation and burning.

Table 3.1 Complications of transradial access.

Common	Uncommon
Spasm	Arterial injury (dissection/perforation/eversion/laceration)
Hematoma (forearm)	Compartment syndrome
Radial artery occlusion	Catheter entrapment
	Transient vocal cord paralysis
	Atheroembolism/thromboembolism

Hematoma

Unlike bleeding from femoral access, hematoma formation in the forearm is usually visible during the procedure and very seldom requires a blood transfusion [10]. Forearm hematomas can be classified according to the EASY classification by Bertrand: Grades I and II relate to puncture site bleeding whereas Grades III and IV relate to intramuscular bleeding (Figure 3.4) [39]. TRA is rarely associated with severe access-related bleeding complications;

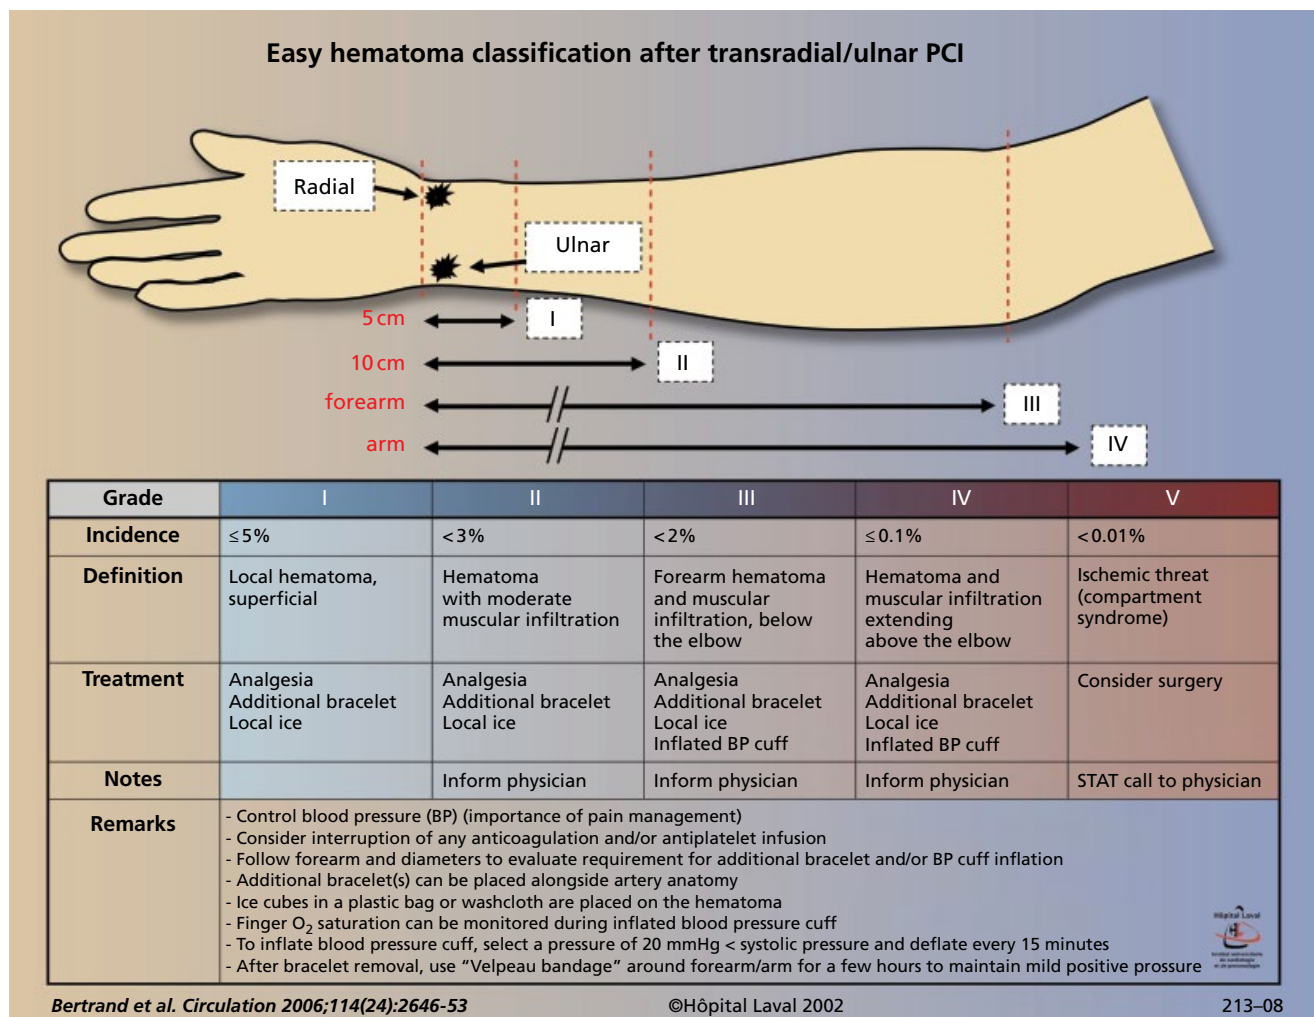

Figure 3.4 Transradial hematoma classification system. Source: Bertrand 2010 [39]. Reproduced with permission of John Wiley & Sons.

however, their prompt identification allows targeted therapy at the point of pain or swelling including BP cuff inflation at 20 mmHg below the systolic pressure for 15 minutes to stop bleeding and reduce forearm pressure.

Compartment syndrome

This limb-threatening emergency is fortunately extremely rare (incidence <0.01%) [40]. It usually relates to hematoma formation but can occur in its absence [41]. Characterized by forearm pain and swelling, disastrous sequelae can usually be avoided by prompt recognition and cessation of local bleeding by [42]:

- 1 Cessation of anticoagulants (and/or reversal)
- 2 Pain and blood pressure control
- 3 Transient external compression (BP cuff).

Artery dissection or perforation

In the absence of wire resistance in the arm, systematic fluoroscopy is not necessary until the subclavian artery is reached. It should be commenced prior to entering the brachiocephalic artery to avoid inadvertent wiring of the right carotid, vertebral, or distal mammary artery. Where wire resistance is encountered, angiography should allow the operator to identify and often overcome the problem. If the wire is pushed against resistance, vessel dissection

or perforation can ensue. Brachial or radial artery perforation is rare (incidence around 0.05%) while angiographic images may be dramatic, rather than aborting the procedure the literature supports careful attempts to recross with a soft angioplasty wire (0.014 inch) [10]. Once crossed, guide catheters can be used to complete the PCI while the catheter will usually seal the dissection or perforation. This avoids the potential for large hematoma formation and compartment syndrome which may ensue if the procedure is aborted (Figure 3.5) [29].

This important complication of transradial access occurs in approximately 5% of cases [24,43,44]. For the anatomic reasons already described, RAO is almost always clinically silent. Nevertheless, patency of the artery is important for future TRA, while the radial artery can also be used as a hemodialysis fistula or bypass conduit, hence operators should consider the significance of this complication for each individual patient. The reported incidence varies according to the method used to detect RAO; however, the use of periprocedural anticoagulation with heparin or its analogues significantly reduces its occurrence [45]. Smaller diameter sheaths and catheters with careful hemostasis techniques are also protective against occlusion [46]. Up to half of early occlusions spontaneously recanalize within 1 month [47].

Figure 3.5 (a) Guidewire induced perforation of radial access. (b) A soft tip 0.014-inch percutaneous transluminal coronary angioplasty (PTCA) guidewire crossed the perforated segment (arrow). (c) Successful use of balloon assisted tracking (BAT) technique to navigate a 6 Fr guide catheter through the perforated segment (arrow). (d) Post procedure injection revealed proper sealing of perforation and no extravasation. System. Source: Patel *et al.* 2013 [29]. Reproduced with permission of John Wiley & Sons.

Table 3.2 Common diagnostic and guide catheter shapes for TRA.

Universal diagnostic	Diagnostic	Universal guide	Guide (left)	Guide (right)
Tiger II (Tig)	Judkins left 3.5	IKARI left	EBU/XB 3.5	Judkins right 4.0
Kimny	Judkins right 4.0	MAC 30/30	Judkins left	Amplatz right
Jacky		Kimny	Amplatz left	Amplatz left
			IKARI left	IKARI right

Techniques for radial artery hemostasis

There are many similar devices developed to achieve hemostasis following TRA catheterization. The crux of most designs is a band around the wrist enabling discrete pressure over the radial artery while ulnar flow is left unimpeded. The TR band (Terumo, Tokyo, Japan) is a transparent band allowing puncture site visualization while air is titrated into a sack compressing the radial artery. It compares favorably in a non-randomized comparison with the HemoBand (HemoBand, Portland, OR), the latter associated with higher rates of RAO (7.2% vs. 3.2% at 30 days; $p=0.04$) [48]. If compression is too aggressive, a no-flow state occurs and is the biggest predictor of subsequent RAO [47]. The technique of “patent hemostasis” to preserve antegrade flow is the preferred method of radial artery closure. RAO is minimized by using either plethysmography (Barbeau test) or mean arterial pressure (via TR band attached to sphygmomanometer) to achieve hemostasis while preserving antegrade flow [46,49].

Basic catheter selection

There are an increasing number of catheters specifically designed for radial access (Table 3.2); however, the majority of operators worldwide still prefer standard femoral shapes for TRA procedures [13]. When compared with the femoral approach, a shorter curve of the Judkins left catheter 3.5 is preferable and often requires more manipulation from the radial approach. The 0.035-inch wire may be advanced into the cusp of interest to direct the catheter; subsequently the wire can be kept inside the catheter tip to facilitate torquing and prevent the catheter curling back up the aorta. Gentle advancement with counter-clockwise rotation can assist in selectively engaging the left main ostium with a Judkins left catheter. A J-wire should be used to change to the Judkins right coronary catheter; a long length exchange J-wire should be used to keep the position in the ascending aorta in cases with significant subclavian or aortic tortuosity. Technique to engage the right coronary artery with a Judkins right catheter is similar to the femoral approach where withdrawal occurs with clockwise torque.

One advantage of TRA is the opportunity to use a universal catheter shape incorporating end and side holes facilitating left and right coronary angiography and left ventriculography with a single catheter. The Tiger II catheter (Terumo, Sommerset, NJ) is the most commonly used universal catheter shape; however, the Kimny (Boston Scientific, Natick, MA) and other similar designs are in use [13]. Caveats of the universal catheter approach include the learning curve from traditional femoral shapes, potential for non-coaxial engagement, poor artery opacification, “deep-throating” coronary arteries with inherent risk of ostial trauma and vessel dissection. Potential benefits include reduction in catheter exchanges, spasm, and procedure time, particularly beneficial in the setting of ST-elevation myocardial infarction (STEMI).

Common guides for TRA left coronary angiography include EBU/XB 3/3.5/4, while right coronary guides include JR4, AL0.75/1. For most angioplasties, 6 Fr equipment is sufficient; however, where two stent techniques or large thrombectomy devices are required a 7-Fr approach can be used utilizing sheathless guiding catheters. These feature combined hydrophilic coating with inner dimensions larger than 7 Fr but smaller outer profile than a conventional 6 Fr introducer sheath. They are useful in patients with severe spasm and those with small arteries enabling complex transradial PCI that would not be feasible using conventional techniques.

Conclusions

The access site is a major determinant of successful angiography and PCI as well as a predictor of procedural complications. Radial access has evolved over the last three decades to emerge as the safest access site with clear advantages over the femoral approach. There is a weight of clinical evidence supporting TRA for physician-oriented hard clinical endpoints including bleeding, vascular complications, and MACE. For the authors’ patients, TRA is preferred with better functional outcomes allowing early mobilization and discharge. For hospitals and governments there are cost-saving implications. The exponential rise of TRA is clear and here to stay.

Optimal Angiographic Views for Coronary Angioplasty

Gioel Gabrio Secco¹ and Carlo Di Mario²

¹ Santi Antonio e Biagio e Cesare Arrigo Hospital, Alessandria, Italy

² National Institute of Health Research (NIHR), Royal Brompton & Harefield NHS Foundation Trust, London, and National Heart & Lung Institute, Imperial College London, UK

Angiography has been the keystone tool to assess coronary anatomy, leading to the development of largely applied revascularization techniques such as coronary artery bypass graft (CABG) and percutaneous coronary intervention (PCI). When CABG was the only revascularization strategy, the main scope of angiography was to detect the presence of significant stenosis and to provide information on vessel distality and contrast run-off. There was no need to be parsimonious with contrast because no further angiographic procedures were being planned. However, with the development of PCI, angiography has become far more important. In addition to clearly demonstrating the entire length of all epicardial arteries, the focus is to identify the anatomy of the lesion including its extension and the relationship with side branch vessels in order to allow correct planning of the revascularization strategy. The number of views and contrast use is restricted to the minimum required in anticipation of further contrast requirement during intervention. Therefore, angioplasty-focused projections should be favored in view of standard acquisitions, carefully selecting the more informative views in order to avoid foreshortening or overlapping of the diseased vessels.

The main limitation of angiography is that it can only provide a limited analysis of lumen profile without providing in-depth information about vessel wall characteristics or the composition of coronary lesions. New intracoronary imaging techniques have been developed to overcome these limitations. Intravascular ultrasound (IVUS) was the first intracoronary imaging modality introduced in interventional cardiology in the early 1990s, followed more than a decade after by optical coherence tomography (OCT), a near-infrared light-based technology. The use of ultrasound reflectance and near-infrared light allows IVUS and OCT to provide information about intravascular anatomy with a level of detail far exceeding that achieved from conventional angiography.

Catheter selection

Since the first human cardiac catheterization, performed by Forssmann in 1929, access site approach and angioplasty equipment have undergone considerable evolution. Miniaturization and refinement of materials have been among the most important goals, allowing interventionalists to perform more complex procedures and resolving most of the percutaneous limitations. The size of sheath, catheter, balloon, and stent delivery systems has been dramatically

reduced in the last few years. From 9 French (Fr) devices used by Gruentzig in the late 1970s [1], now most PCI can be safely performed with a 6 Fr guiding catheter [1]. Contemporary diagnostic catheters are preshaped to facilitate intubation of the coronary ostia, in most cases with only minimal catheter manipulation. These smaller catheters appear of particular interest in the “transradial era” where transradial PCI has emerged as a gold standard in many centers replacing the transfemoral route in daily practice. The lack of back-up support offered by smaller catheters can be partially compensated by extra-stiff wires for the cannulation of the ostium and the use of extra-support guidewire or “mother and child” systems during the intervention. Moreover, the flexible tips facilitate the deep intubation of the target vessel and reduce the risk of vessel damage. Access site, sizing of the ascending aorta, and origin and take off of the target artery strictly condition the selection of the ideal curve for the catheter.

Left coronary

Judkins curve catheters are used most widely. Judkins left (JL) 4 would suit the anatomy of most patients although downsizing to JL3.5 may be required in patients with a smaller diameter aorta such as women. If the aortic root is dilated, JL4.5, JL5, or even JL6 with longer secondary curves may be required. Selective intubation can be encountered when there is a short left main stem (LMS) or separate origin of the left anterior descending (LAD) and circumflex (Cx) arteries, which may necessitate selecting a catheter with an upwards pointing tip (e.g., JL3.5) for intubation of the LAD and a more horizontal tip (e.g., JL4) for intubation of the Cx.

Right coronary

The take off of the right coronary artery (RCA) varies more than the left. A Judkins right (JR) 4 curve is most often used successfully. High anterior origin of the RCA may necessitate the use of an Amplatz right or left curve if a JR is unsuccessful.

Radial approach

The same curves suit most patients during left radial intervention, while a 0.5 downsizing of the left curve (e.g., to JL3.5 if JL4 would have been suitable from the femoral approach) is generally required when using the right arm. A Barbeau, Tiger, or Ikari catheter suitable for both the left and right coronaries can also be used from the right radial approach.

Coronary intubation

The left anterior oblique (LAO) view is most useful for intubation of the left and right coronary arteries, because the left and right coronary sinuses are maximally separated and there is minimal overlap between the ostia and the coronary sinuses (Figure 4.1). For intubation of the left system the J-wire is advanced up to just above the aortic leaflets. The catheter is advanced over the wire and when the tip nears the aortic sinuses the J-wire is withdrawn to allow it to approach close to or intubate the coronary ostium. Slow J-wire withdrawal is recommended to avoid the catheter tip flicking into the ostium which can cause dissection, plaque dislodgement, or spasm, and also to avoid sucking air into the proximal catheter hub. The right coronary is intubated by advancing the JR catheter over the J-wire until the tip is just above the aortic leaflets. The wire is then withdrawn into the distal catheter to facilitate manipulation. Gentle counterclockwise rotation aiming the catheter tip toward the left with concomitant withdrawal is usually required. Gentle movements are emphasized to avoid sudden or deep intubation, which can precipitate spasm. Before proceeding to inject dye the pressure trace is checked. The pressure trace can be damped or ventricularized indicating the possibility of ostial right or LMS disease, spasm, complete occlusion of a non-dominant RCA, or that the catheter tip is abutting the vessel wall. Forceful contrast injection during any of these scenarios could result in dissection or plaque dislodgement. Contrast injection with an occlusive catheter with contrast remaining at the end of the injection, for instance holding up into the conus branch, should also be avoided because this can precipitate ventricular fibrillation. Spasm can be reversed with intracoronary nitrate, for example isosorbide dinitrate (ISDN) 100–200 µg. Rapid

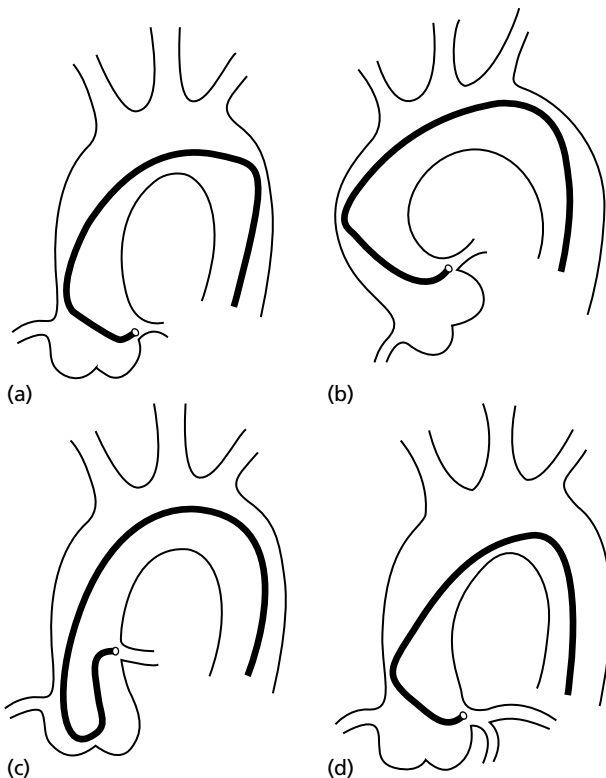

Figure 4.1 Guiding catheter selection for left coronary artery. (a) Normal: JL4. (b) Dilated root: JL5, VL4, GL4, EBU. (c) Superior origin: AL3, VL4, GL4, EBU, Champ. (d) Short left main: JL4 short tip, JL3.5.

but gentle catheter withdrawal is indicated until the coronary ostium is extubated or the pressure trace normalizes. A small dose of intracoronary nitrate can be required to counteract any coronary vasospasm (e.g., ISDN 100–500 µg depending on the blood pressure). On occasion, smaller (e.g., 5F or 4F) catheters are required to avoid damping caused by spasm in hyper-reactive arteries or when there is ostial plaque.

The active support offered by deep intubation is frequently used also during interventions. However, this technique presents several relative limitations. The obstruction of flow during deep cannulation can induce severe ischemia, not always prevented by the presence of side holes [2]. Moreover, there is a potential risk of air embolism because of aspiration of air through the Y-connector while the catheter is damped inside the artery with a low back pressure. In any case, if the guide catheter is advanced coaxial with gentle rotation over the rail offered by a previously inserted wire and balloon, the risk of vessel damage is extremely low. A balloon can also be inflated at low pressure in the artery to stabilize the system while pushing the guiding catheter.

Diagnostic angiography

Left-sided views

The first view is chosen to identify LMS disease. Either a post-anterior (PA) view with minimal angulation to the right to project the catheter tip off the spine or a LAO caudal (the so-called spider) view, are used most often. At least three to four perpendicular views are required to visualize the left coronary tree (Table 4.1 shows the most widely used combinations of views). In many patients these views would suffice, potentially even when proceeding immediately to angioplasty. However, because of variations in patient anatomy such as increased overlap caused by prominent tortuosity, displacement, or rotation of the heart axis in the chest (e.g., when there is normal anatomic variation, chest wall deformity, previous cardiothoracic surgery, or lung pathology), modification of views or additional views are sometimes required. When a lesion is identified, additional views can be indicated depending on how well the affected coronary segment has been visualized (Table 4.2).

Right-sided views

Two perpendicular views are advocated for the RCA, usually LAO and right anterior oblique (RAO). However, it is frequently impossible to exclude disease at or beyond the crux without an additional view with cranial angulation (e.g., PA cranial or LAO cranial).

Lesion-specific approach

Optimal views for each coronary segment

Views that reliably demonstrate the full length of each coronary segment while minimizing foreshortening and overlap for the left coronary arteries are shown in Figures 4.2 and 4.3(a). However, because of the wild degree of variation in human anatomy there are no views that will in all cases demonstrate clearly a lesion in a particular coronary segment. An example of a patient where the lesion was only clearly demonstrated after further adjustment of the gantry to unusual angles is shown in Figure 4.4.

Left main stem

Lesions in the ostium or mid segment of the LMS are often best seen in the anteroposterior (AP) cranial view. The straight AP view with only slight rightward angulation to project the catheter tip off

AP, anteroposterior; LAD, left anterior descending; LAO, left anterior oblique; LCX, left circumflex; LIMA, left internal mammary artery; OM, obtuse marginal; PDA, posterior descending artery; PLV, posterior left ventricular; RAO, right anterior oblique; RCA, right coronary artery.

the spine is sometimes advocated but may not be optimal because the ostium of the LMS can be projected over the left coronary sinus. The ostium of the LMS can also be seen clearly in an LAO caudal view (30–50° left; 25–40° caudal), which will also demonstrate the mid LMS and can sometimes be the only view to clearly separate the LMS bifurcation. In this view, also known as the “spider view,” the picture can be grainy and of poor quality particularly when angulation is steep and in obese patients. The image can be optimized by positioning the LMS in the center of the field and reducing image contrast by blanking the field from the 12 o’clock to the 3 o’clock position. A small test injection before acquisition is sensible because a more horizontal axis of the heart can require steeper caudal angulation and occasionally overlap at the LMS bifurcation can be separated by rotating more steeply to the left or toward AP caudal.

Left anterior descending

Separation of the bifurcation of the LMS in the LAO caudal view also shows the ostium of the LAD clearly as well as the proximal LAD and frequently also the origin of the first diagonal. For these reasons the LAO caudal view is useful for wiring the proximal LAD

or for stent positioning at the ostium of the LAD, but if possible it should be avoided as a working view because X-ray attenuation caused by the highly angled projection through the spine results in higher X-ray doses. Working views for the LAD ostium include RAO caudal and RAO cranial, although in the latter more than 30° of rightward angulation are sometimes required to move the circumflex off the region of interest. Although the RAO cranial view can clearly demonstrate lesions in the proximal and mid LAD this is not the ideal working view because steep >40° rightward angulation is required to eliminate overlap with diagonals and wide diaphragmatic excursion during breathing causes highly variable contrast ratio in the field of view. Simply moving the gantry from AP to AP cranial elongates the proximal LAD and separates the diagonals to the right of the screen. A rightward tilt of <5° may be required to separate the proximal segment from the spine and the catheter in order to produce an excellent standard working view for the proximal and mid LAD unaffected by movement of the diaphragm. For diagnostic purposes, the ostia of the diagonals may be better seen in the LAO cranial view. However, LAO cranial is seldom used as a working view because a deep breath hold is

Table 4.2 Popular view combinations for diagnostic angiography with benefits and limitations of each view.

View	Good for visualizing	Limitations
Combination 1		
AP (5–10° RAO)	LMS (ostium and main shaft)	Overlap on LMS bifurcation and sometimes LMS ostium with left coronary sinus
Lateral	Mid and distal LAD, mid Cx	Potentially high radiation dose to operator, usually limited view of proximal LAD, patient's arms need to be above head to visualize posterior arteries, often overlap diagonals/LAD
RAO cranial	Proximal and mid LAD, distal Cx	Test injections can be required to adjust angulation to ensure diagonals are above LAD, overlap with dominant Cx, and position of the diaphragm
RAO caudal	Circumflex and distal LAD	
Combination 2		
LAO caudal	LMS bifurcation, proximal LAD and proximal circumflex	Potentially a higher radiation dose to the patient, poor quality images sometimes in large patients
LAO cranial	Mid LAD, origin of diagonals, proximal and mid Cx	Patient required to hold in inspiration during acquisition to elongate the proximal LAD
AP cranial	Proximal and mid LAD, distal Cx	Steep cranial angulation required can be a problem for patients with cervical spine fixation
RAO caudal	Circumflex and distal LAD, sometimes LAD ostium	

AP, anteroposterior; Cx, circumflex; LAD, left anterior descending; LAO, left anterior oblique; LMS, left main stem; RAO, right anterior oblique.

Figure 4.2 Guiding catheter selection for right coronary artery. (a) Normal: JR4. (b) Inferior orientation: modified right Amplatz. (c) Anterior origin (right cusp): Multipurpose. (d) Shepherd's crook: Arani 75°, Champ. (e) Superior origin: MAC, Champ, Multipurpose. (f) Dilated root: AL2.

required to reduce foreshortening and reduce projection of the diaphragm over the proximal and mid LAD. The body habitus of some patients also requires steep leftward angulation to project the LAD off the spine. An alternative but much less frequently used working view for lesions in the proximal and mid LAD is the left lateral. If the only vessel of interest is the LAD it is not necessary to ask patients to remove their arms from the field of view by keeping them above their heads, as this requirement is often uncomfortable and can be impossible for the elderly and patients with arthritis or old shoulder injuries.

Panning is usually required in the RAO cranial and LAO cranial views to demonstrate the distal LAD. Smooth slow panning allows

Figure 4.3 Ikari catheters for radial approach. (a) Ikari left. (b) Ikari right. Curve A to fit angle of brachiocephalic artery; straight portion B to generate strong back-up force supported by opposite site of the aorta wall.

the X-ray generator to adjust automatically to changes in X-ray attenuation. The lateral view is a good alternative for demonstrating the distal LAD around the apex but can also require controlled movement of the table during the acquisition toward the floor and/or in the direction of the head. The RAO caudal view can include the distal LAD without the requirement for table movement or being affected by diaphragmatic movement.

Circumflex

The circumflex ostium can be clearly seen together with the LMS bifurcation in the LAO caudal view. Occasionally, eccentric ostial lesions not clearly seen in other views can be delineated in the RAO cranial view although steep angulation may be required. The RAO caudal is the most useful diagnostic view for the circumflex and can clearly define lesions in the ostium, proximal, and mid vessel as well as the bifurcations and obtuse marginals. To obtain a working view with improved image quality by eliminating overlap with the diaphragm and reduced X-ray attenuation the view can be modified to AP caudal with only 10–15° rightward angulation.

The proximal and mid circumflex territory can also be viewed in the left lateral. A drawback of this view is that the patient has to remove their arms from the field of view by elevation above their head. Even young patients without arthritis can find this difficult to maintain for prolonged periods. Additional caudal angulation can be required to reduce overlap with marginal vessels. RAO or LAO with cranial angulation can be required to view lesions in the distal circumflex when the RAO caudal is suboptimal. If the circumflex is dominant, the LAO cranial or AP cranial views may open up the distal bifurcation and elongate the posterior descending artery (PDA).

Figure 4.4 Optimal angiographic views for specific segments of the left anterior descending artery are indicated with a green tick mark. Some views that may be useful but are not generally recommended are indicated with an orange tick mark and inadequate views with a red cross.

Right coronary artery

Views that reliably demonstrate the full length of each coronary segment while minimizing foreshortening and overlap for the RCA are shown in Figure 4.3. Usually, the only two views required to demonstrate lesions in the proximal, mid, and distal RCA are LAO and RAO, because of the absence of side branches in these segments. Ostial lesions in the RCA are often detected in LAO but can be significantly foreshortened in this view. If stent placement is being considered, finding the least foreshortened segment can facilitate accurate positioning at ostium. The ostial segment and proximal RCA often lay perpendicular to the X-ray beam in the AP cranial and LAO caudal views, despite variation in the origin of the RCA toward anterior or posterior. The lateral view with cranial angulation can identify occasional highly eccentric ostial lesions not clearly seen in other views. The lateral view can also occasionally help to better delineate lesions in a highly tortuous mid RCA or when right ventricular branches overlap the main vessel.

The distal RCA, PDA, and posterior left ventricular (PLV) branches lie posterior to the heart and require cranial angulation (in LAO) or caudal angulation (in RAO or AP) to be visualized without overlap. Many operators routinely include a third view, either AP cranial or LAO cranial, in addition to LAO and RAO as standard during diagnostic imaging.

Vein grafts

An operative report describing graft number and insertions is imperative to reduce the chances of missing a graft as well as to reduce fluoroscopy dose and procedure time spent hunting for an unknown number of grafts. An aortogram can be helpful for graft localization, potentially saving time and contrast, but it is not a panacea, because grafts can sometimes opacify only if the pigtail catheter is positioned at the level of the graft origin, if at all, when the take off is vertical and/or flow is slow. The insertions of vein grafts can vary substantially, in particular after redo bypass surgery. A rule of thumb is that the aorto-ostial insertions of vein grafts to the left coronary system tend to arise lower and more anterior for grafts to an anterior artery (e.g., LAD) and progressively more superior and leftward as the insertion site moves more toward left lateral (e.g., diagonal, intermediate, obtuse marginal, AV circumflex). In the RAO view, left-sided grafts can be intubated by pointing the catheter toward the right of the screen. Right-sided grafts can be found in LAO by dragging the catheter pointing to the left of the screen along the ascending aorta starting above the RCA ostium. A patent graft with slow flow may only partially opacify and thus appear occluded if intubated with a catheter tip that is angulated toward the wall of the graft, for example vertical origin of vein grafts to the RCA intubated with a JR catheter. In these instances a coaxially aligned catheter, for example a multipurpose or right coronary bypass (RCB) catheter for a right-sided graft and a multipurpose or left coronary bypass (LCB) for left-sided grafts, should be used to clarify whether or not a graft is occluded. The views are selected according to the native coronary segment where the graft inserts. Two perpendicular views are required.

Left internal mammary artery grafts

The left internal mammary artery (LIMA) graft is usually prognostically the most important. Selective intubation of the LIMA with demonstration of the entire length of the graft and native vessel including any lesions and collateral supply is the standard. The origin of the left subclavian artery is usually engaged in the AP view.

An 0.035-inch J-wire is used to lead before the catheter is advanced over it to reduce the risk of trauma to the vessels. If difficulty is encountered with an abnormal aortic arch, severe tortuosity, or stenosis the following steps can be tried: intubation of the left subclavian may be easier in the LAO view; making use of non-selective contrast injections to delineate the anatomy; using a JR rather than an internal mammary artery (IMA) catheter to engage the left subclavian and exchanging it via a 300-cm J-wire for an IMA catheter if necessary once the catheter is beyond the origin of the LIMA; and making use of a 0.035-inch steerable hydrophilic J-wire if extreme tortuosity is preventing passage of the standard J-wire. Once the catheter tip is near the ostium of the LIMA, the AP view is most useful for engagement. If the JR catheter tip appears too horizontal during gentle withdrawal or too short to engage the ostium of the LIMA, an IMA catheter can be used or sometimes the even more acute hook of a Bartorelli-Cozzi (BC) catheter. Before contrast injection—including test injections—it is important to remember to check that the pressure tracing does not indicate wedging of the catheter tip against the vessel wall. If selective intubation via the femoral route proves elusive despite multiple attempts, the left radial route can offer a safer alternative. A drawback of the left radial route is that right internal mammary artery (RIMA) grafts cannot be engaged, although successful intubation of the LIMA via the right radial route has been previously described [3]. The first angiographic view for the LIMA requires panning from origin to the distal LAD. The views that best show the insertions are RAO cranial and left lateral. Collateral filling of other vessels should also be documented. Intubation to the diaphragm of a pedicle RIMA graft follows the same principles as for the LIMA, but with even greater care in view of the close proximity of the right internal carotid artery.

Coronary variants

Aberrant coronary anatomy occurs infrequently and the prevalence of <1.3% is remarkably consistent in different series of patients attending for angiography [4]. Some anomalies are easy to identify, such as abnormal origin of RCA (Figure 4.5) but others can be more subtle, such as anomalous non-dominant circumflex (Figure 4.6). The culprit lesion can be missed if the aberrant anatomy is not identified (Figures 4.7 and 4.8). Systematic review to identify areas of the myocardium for which a vascular supply has not been demonstrated is helpful in this respect and also for identifying occlusions (Figure 4.8). Once it is known which vessel is anomalous, a review of the images can identify ghosting of the vessel. If there are no clues as to the origin, a systematic search starting with the most common variant is required. The diagnostic catheter shape needs to be changed as required to reach the wall of the aortic root in the area of interest. The most common coronary anomaly is an absent LMS. A slightly smaller curve catheter is required to intubate the LAD selectively (e.g., JL3.5 if JL4 preferentially and exclusively intubates the Cx). The Cx arising from the right coronary sinus can often be cannulated using the JR4 catheter, but a steep take off can require a multipurpose catheter whereas a posterior or high anterior origin can require an AR or AL shape. If the RCA arises from the left side separately from the LMS an AL1 or multipurpose catheter is most likely to be successful.

Once the anomalous coronary vessel has been intubated the standard views are often sufficient for the mid and distal vessel if the heart has a normal position and orientation (Figures 4.2 and 4.3), while the views for the proximal vessel and ostium may need to be modified depending on the origin and course.

Figure 4.5 This 80-year-old obese female was admitted for angiography following a recent worsening of angina. She had a previous history of myocardial infarction. Preceding this presentation her angina symptoms had been stable for many years and were not previously investigated with angiography. A coronary ostium could not be engaged at the left aortic sinus. The left anterior descending (LAD), circumflex, and right coronary arteries originated from a single right-sided ostium. The right coronary artery (RCA) (black arrows, a–d) was occluded distally. The left anterior descending (LAD) (white arrows, a–c) was critically stenosed proximal to a large diagonal and the circumflex (gray arrows, b–d) was critically stenosed mid course. The catheter partially obscures the LAD in (a) and the circumflex in (d).

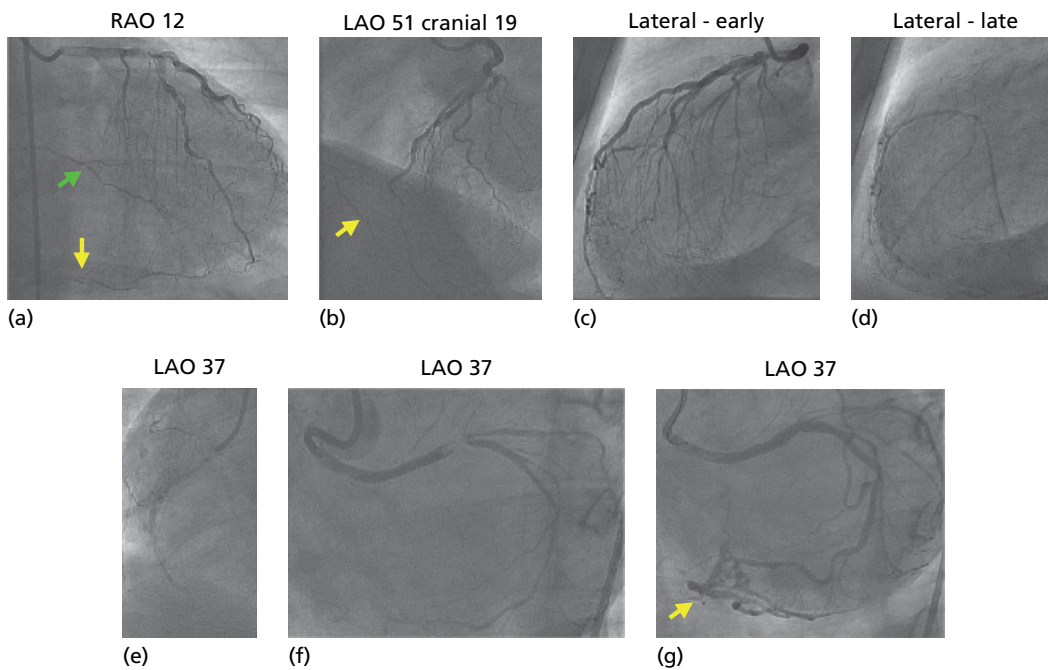

Figure 4.6 These views were taken during primary angioplasty performed in a 41-year-old male who presented with an acute inferolateral myocardial infarction. No antegrade perfusion was evident in the circumflex territory (a to d), although retrograde collaterals to an obtuse marginal branch were seen in some views (green arrow, a). The right coronary artery (RCA) was occluded and filled retrogradely via the left anterior descending (LAD) (yellow arrow, a and b; d and e). The culprit lesion was in an aberrant circumflex arising from the right sinus (f). Following aspiration thrombectomy and stent deployment it was evident that the aberrant circumflex provided the principal collateral supply to a chronically occluded dominant RCA (yellow arrow, g).

After stenting

(f)

Figure 4.8 This 47-year-old male with known coronary disease presented with deteriorating angina and reversible ischemia in the anterior territory on perfusion imaging. Conventional views (a–c) raised suspicion of a lesion in the left anterior descending (LAD) ostium due to haziness (a) but were limited by overlap at the ostium of the LAD due to unusual tortuosity (a). Unusual modification including a steep spider view and a lateral view with cranial angulation were required to delineate the lesion (d, e). The final angiographic result is shown after stenting (f).

Chronic total occlusion

Chronic total occlusions (CTO) affect almost 20–30% of patients with coronary artery disease undergoing angiography [5,6]. Recent advancement in materials such as guidewires, microcatheters, and crossing devices has increased the success rate of CTO percutaneous recanalization from 50–60% [7,8] to 70–80% [9–11], with peaks above 90% for a few highly specialized centers [12–14]. The lack of a general consensus regarding the usefulness of CTO recanalization together with the difficulty of the procedure have partially affected the development of CTO-PCI in daily practice. Two large registries in the USA addressed the benefit of CTO recanalization procedure on long-term survival leading to conflicting results, negative in the first [15] and positive only for LAD recanalization in the other [16]. However, they both included patients treated with plain balloon angioplasty alone suffering from a high percentage of re-occlusion. More recent studies, conducted in the drug-eluting stent (DES) era, showed that successful recanalization is associated with improved long-term survival and reduced need for surgical revascularization at follow-up compared with failed CTO procedure. Moreover, it has been recently shown that successful recanalization provided a significant improvement in quality of life, with less physical activity limitation, rarer angina episodes, and higher treatment satisfaction when compared with patients with failed procedure [17]. These positive findings have led to a rapid increase in percutaneous CTO procedures. However, when approaching these complex interventions the selection of the correct angiographic views, especially during retrograde recanalization, is pivotal.

The correct imaging of a coronary occlusion requires acquisitions in multiple views and the acquisition must be prolonged enough to visualize the distal segments eventually filled by collaterals. A dual injection performed using low magnification, so that the entire coronary tree is visualized, is generally recommended. The injections should be performed at the beginning of the procedure because wire and catheter advancement might impair the ipsilateral collateral flow, thus resulting in a collateral or preferential collateral shift to the retrograde collaterals. Moreover, initial careful evaluation of the collaterals provides important information in choosing the most appropriate one and alerts the operator to the risk for ischemia and hemodynamic or electrical instability if the collateral becomes occluded [18]. Coronary collaterals are a network of nascent microvessels, which, in case of coronary occlusion, grow in favor of a viable distal myocardium. The most widely used method to assess coronary collaterals is angiography using the view with the least foreshortening of the collateral connection. Collaterals' anatomic pathways are generally summarized in four categories: septal, intra-arterial (bridging), epicardial with proximal take off (atrial branches), and epicardial with distal take off [19]. The size of the collateral connection (CC) diameter is classified according to Werner *et al.*: CC0, no continuous connection between donor and recipient artery; CC1, continuous, threadlike connection; and CC2, continuous, small side branch-like size of the collateral through its course [20].

The treatment of CTO often involves the X-ray gantry being maintained in one working view, with occasional rotation in an

orthogonal and equally fixed view, so the same skin and body segments are therefore exposed to the majority of the radiation dose. Given that, a careful evaluation of radiation-induced skin injury should be performed and the most recent recommendation from the EuroCTO consensus document should be strictly followed [21].

Multi-slice computed tomography can provide additional information regarding the plaque characterization, tortuosity, and length of the occluded artery. Moreover, 3D reconstruction integrated with 2D angiographic images during CTO intervention helps identify the best projection giving a directional guide for the missing angiographic segment [22].

Ventriculography

Knowledge of ventricular function is essential to interpreting the clinical relevance of coronary disease and planning appropriate treatment. Many patients have a contemporary assessment of left ventricular function by non-invasive testing, which provides similar or superior definition of the left ventricular cavity volume and global and regional wall motion, with the advantage that most of them can also dynamically study wall thickness and tissue characteristics (echocardiography, magnetic resonance imaging, nuclear imaging, and multidetector CT), when attending for coronary angiography [23]. These modalities provide more information on the function and morphology of the left ventricle than conventional ventriculography and can obviate the need for further assessment. Ventriculography should be performed in the catheter laboratory if left ventricular function has not been assessed recently. The RAO view is standard, although an additional LAO view could be considered if assessment of the postero-lateral wall, usually supplied by the circumflex, is likely to influence management.

Legend has it that the first coronary angioplasty balloons were made by Andreas Gruentzig and his wife in a kitchen. They were very bulky, difficult to position as there was no guidewire lumen, and too compliant to safely expand resistant lesions in coronary arteries. Further understanding and development in manufacturing techniques and evolution of materials have reduced the profile of angioplasty balloons while increasing their robustness, deliverability, reliability, and safety profile. Similarly, workhorse guidewires have been developed with improvements in torque and force transmission while having more durable and less traumatic but shapeable tips. Specialty guidewires have been developed for the treatment of specific lesion types including chronic total occlusions. A wide range of guide catheters, guidewires, and angioplasty balloons are now available, and continue to evolve to overcome variations in anatomy, changes in vascular access, and evolution in technique. The appropriate selection and safe and optimal use of these devices can reduce procedural time and increase procedural success and safety with hopes of improving clinical outcomes.

Guide catheter selection

Functional design of modern guide catheters

Guide catheters permit safe intubation of the coronary ostia, accurate hemodynamic monitoring, injection of contrast, and passage of guidewires, balloons, and stents. The clinical, anatomic, and angiographic scenario must be considered when selecting the size, shape, and length of a guide catheter. Modern catheters have a soft tip to reduce the risk of vessel trauma during intubation or manipulation. The wall consists of an outer layer which retains a predefined curve and increases shaft stiffness to provide backup support during intervention, a middle layer of wire braid to increase kink resistance, improve torque transmission, and shaft radiopacity, and a smooth lubricated inner layer to facilitate the transit of equipment. Guide catheters have thinner walls than diagnostic catheters to increase inner lumen size and can be easily damaged by excessive rotation (Table 5.1).

When difficulty is encountered in engaging the coronary ostia, one must first consider whether the guide catheter shape is appropriate. The use of a supportive 0.035 inch guidewire within the catheter can facilitate manipulation. Similarly, deep inspiration by the patient can facilitate coronary intubation. In the case of excessive vascular tortuosity or calcification, the use of a peripheral

sheath long enough to straighten the most tortuous arterial segments can improve guide catheter maneuverability. The optimal view for left and right coronary intubation is the left anterior oblique because in most patients it offers the least superimposition of the coronary ostia with the left and right aortic sinuses.

Size requirements

The advantages and disadvantages of smaller and larger catheter sizes are listed in Table 5.2. Routine angioplasty using 5 French (Fr) guiding catheters may be ideal when direct stenting is planned, but not all stents are deliverable through a 5 Fr guide and most bifurcation techniques are not applicable [1]. The general standard is a 6 Fr (2.00 mm external diameter) guide catheter which permits radial access, allows active engagement (“deep seat”), accommodates two modern rapid exchange balloons or a 1.50 or 1.75 mm rotational atherectomy burr, and uses less contrast than larger catheter diameters. For bifurcation techniques requiring the simultaneous insertion of two stents (Crush, V stenting), 7 Fr (2.33 mm diameter) guides are required. These are necessary for advanced techniques that require two over the wire (OTW) catheters and facilitate the insertion of rotational atherectomy burrs greater than 1.75 mm. For rotational atherectomy burrs greater than 2.0 mm in diameter and complex techniques requiring multiple wires, balloons, and/or stents, 8 Fr (2.66 mm diameter) guides are used. The use of guide catheters greater than 8 Fr is extremely rare in contemporary coronary intervention.

Shape selection

Selection of guide catheter shape is critical to allow positioning of the catheter coaxially with the proximal segment of the artery, to reduce the risk of catheter-induced vessel trauma, and optimize support during intervention. When selecting the shape of the catheter, the following factors should be considered: the curve and fit of the diagnostic catheter; size of the aortic root; origin and take off of the artery; location and complexity of the lesion; and the devices likely to be utilized during intervention.

Shape selection for the left coronary system

Shapes for commonly used guide catheters for the left coronary system are shown in Figure 5.1. The curve sizes of different shapes have been largely standardized and the comparable curve sizes used most commonly are shown in Table 5.3.

Table 5.1 Guide catheter inner lumen size by manufacturer and outer lumen size.

Guide/manufacturer	Inner lumen (in)	Outer lumen size (French)			
		5	6	7	8
Launcher/Medtronic		0.058	0.071	0.081	0.090
Vista Brite Tip/Cordis		0.056	0.070	0.078	0.088
Mach1/Boston Scientific		NA	0.070	0.081	0.091
Viking/Guidant Abbott		NA	0.068	0.078	0.091
Wiseguide/Boston Scientific		NA	0.066	0.076	0.086

Table 5.2 The advantages and disadvantages of smaller versus larger catheter diameters have to be weighed when selecting catheter size.

Smaller diameter	Larger diameter
Advantages	
Smaller puncture	Increased torque
Small vessel access	Increased support
Less traumatic radial access	Improved visualization
Allows deeper engagement without significant damping	Allows two balloon/stent strategy
Disadvantages	
Less torque	Larger puncture: increased access site trauma /recovery time
Reduced visualization	Pressure damping
Less support	Increased contrast use
Difficult or impossible to use two balloon/stent strategy	

For the left coronary artery, catheters with a smaller curve will point upward and selectively engage to left anterior descending (LAD) and a larger curve will selectively engage and provide better support for the circumflex. The tip of Amplatz Left (AL) guides tend to point downward and are useful to selectively engage the circumflex in situations where there is a short or absent left main.

The shape of the guide catheter is an important component of the backup or support system that allows delivery of devices to the target lesion. Changing the guide catheter to improve support in the middle of a procedure can be problematic, and therefore careful consideration of guide support prior to intervention is critical. It is also important to appreciate that selection of a guide with optimal backup may obviate the need for stiffer wires or balloons, with a corresponding reduction in cost and procedure time. Although Judkins Left (JL) curves are commonly used for diagnostic intervention, these guide shapes provide less support than “backup” guides which provide contralateral aortic wall

support such as the XB, EBU-, or Q-type curves. Because of the secondary curve on the JL, the tip may be withdrawn from the coronary ostium when resistance is encountered. XB/EBU/Q/Voda or similar curves provide comparatively more support with minimally increased risk of damage to the coronary ostia. AL curves are required in certain situations, but should only be used by experienced operators in view of the increased risk of iatrogenic dissection. Techniques to obtain support other than the passive support allowed by the guide catheter shape are discussed later in this chapter.

Shape selection for the right coronary system

Shapes and sizes of commonly used guide catheters for the right coronary system are shown in Figure 5.2. The take off of the right coronary artery tends to vary more than that of the left coronary. If the take off is transverse, the most commonly used guide would probably be a Judkins Right (JR) 4. With a superiorly directed take off, a JR, Hockeystick, EBU-R, or Amplatz R or L are more suitable. Inferiorly directed take offs can be cannulated with a multipurpose or SLS catheter. Although the JR shape does not provide much active support, the guide can often be actively engaged more deeply to augment support if required via “deep seating” by advancing and clockwise rotating the guide.

Length

The standard length of a coronary guide catheter is 100 cm. Occasionally, shorter lengths (85 or 90 cm) are required to reach for distal lesions (e.g., lesions reached via the left internal mammary artery (LIMA), sequential saphenous vein grafts (SVGs), or retrograde approach to chronic total occlusions (CTO)). Longer lengths (110–115 cm) are required for unusually tall patients or severely tortuous aorto-iliac vessels. The use of a long sheath and of longer balloon catheters (>145 cm) has partially overcome this problem but stent delivery catheters remain 135 cm.

Side holes or not?

Side holes help to maintain coronary perfusion when there is the likelihood of ostial obstruction by the guide catheter that results in pressure dampening. This can occur when using a larger guide caliber, in the presence of aorto-ostial disease, non-coaxial engagement, and in small caliber arteries encountered in smaller patients. Side holes can reduce contrast opacification of the arteries with a consequent reduction in image quality and increased overall contrast dye utilization. The persistence of aortic pressure morphology can mask severe catheter-induced pressure dampening which is of

Figure 5.1 Shapes of a selection of guide catheters for the left coronary system.

Table 5.3 Comparability of curve sizes for different shapes of left sided guide catheters.

	AL (Amplatz) Curve	CLS or XB Curve	JL (Judkins Left) Curve	Q Curve	VL (Voda Left) Curve
Normal	AL 1	XB 4.0 or 3.5	JL 4	Q 4	VL 4
Dilated	AL 2	XB 4.0 or 4.5	JL 4.5	Q 4.5	VL 5
Narrow	AL 0.75	XB 3.0 or 3.5	JL 3.5	Q 3.5	VL 3

importance for measuring fractional flow reserve and may not always protect from hydraulically induced vessel dissection [2].

Variation in access site

The same guide catheters can be used for transradial access as well as transfemoral access. Dedicated transradial guide catheters include the Barbeau, Ikari, and brachial/radial curves. Such curves can be used for access to either the left or right coronary system and provide support against the contralateral aortic wall (Figure 5.3).

Vein grafts

Both right- and left-sided vein grafts with a transverse origin can often be cannulated with a JR4 guide catheter; however, guide support can be suboptimal. If the vein graft points downwards (inferior or vertical such as often for right coronary artery (RCA) grafts), coaxial engagement may be difficult with a JR guide. A multipurpose or RCB guide is usually coaxially aligned when the take off is inferior and would also offer good support if required. Left-sided vein grafts lesions can also often be attempted with a JR guide or, if more support is needed, with an Amplatz or Hockeystick guide catheter. If the ascending aorta is large or dilated, a guide with a more pronounced secondary curve is frequently required such as the left coronary bypass (LCB) or an Amplatz shape may be selected.

Left and right internal mammary arteries

Although the LIMA can often be reached with a JR guide, the more acute primary angle and longer tip of an internal mammary artery (IMA) guide may be required. Short-tip hook-shaped IMA catheters can occasionally be required to intubate a very steep take off angle. Sometimes, because of subclavian stenosis or extreme tortuosity, the IMA can only be selectively cannulated via the left radial approach.

Gastroepiploic artery grafts

In an attempt to simulate the longevity of IMA grafts and overcome the problem of reaching the distal RCA, the gastroepiploic artery (GEA) is sometimes used as an *in situ* graft to the posterior or inferior surface of the heart (RCA, posterior descending artery, posterior left ventricular) [3]. The GEA can be cannulated using catheters designed for abdominal vascular intervention such as Cobra or Simmons catheters [4]. The celiac trunk is accessed from the abdominal aorta in the direction of the common hepatic artery (the other branch being the splenic artery) (Figure 5.4). The gastroduodenal artery arises in an inferior direction and gives off the pancreaticoduodenal branch beyond which it becomes the GEA, which passes through the diaphragm to reach the inferior wall of the heart (Figure 5.4). Anastomotic stenoses require percutaneous treatment [5].

Support

Complex anatomic situations including tortuosity, calcification, or diffuse atherosclerosis frequently require escalating degrees of backup support. The components of the “backup” support intrinsic to an angioplasty system includes the guide catheter, guidewire(s), and balloon(s) in the target artery. The components can be changed individually or in combination as demanded by the difficulties that are encountered. Hybrid strategies using more complex wire and/or balloon-based techniques are sometimes required to overcome more challenging anatomy.

Guide catheter support

The role of shape selection has been discussed. Guide catheter support is either passive or active. Passive support is provided by a large diameter catheter positioned optimally in the coronary ostium

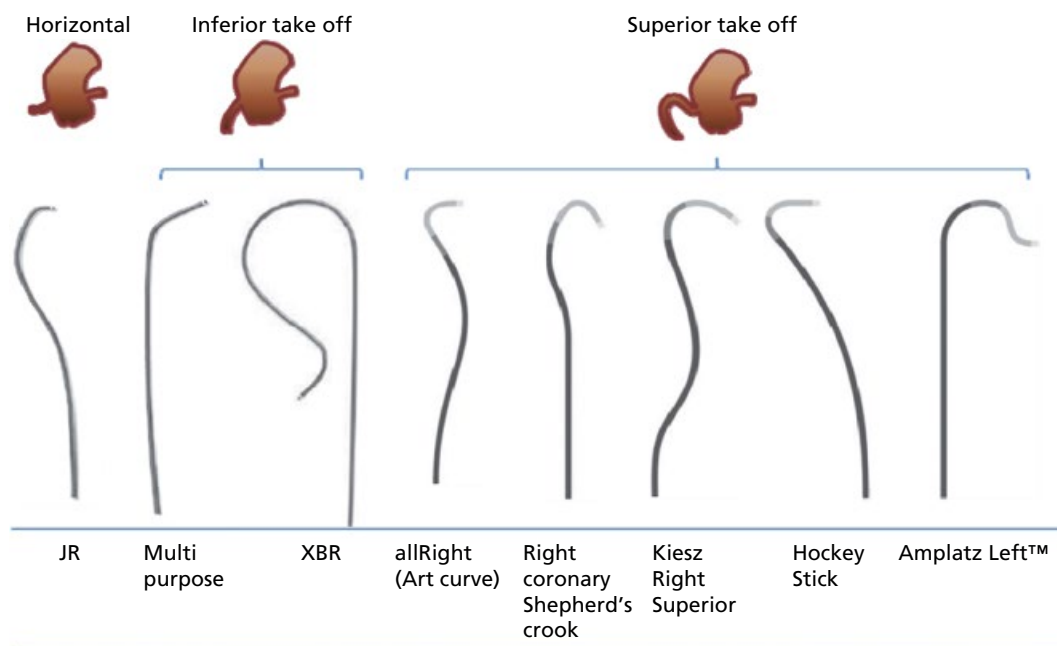

Figure 5.2 Shapes of commonly used guide catheters for the right coronary system.

Figure 5.3 The Barbeau and radial/brachial curve catheters can be used via the radial route and have a “one size fits all” design for intervention to either the left or right coronary systems. (Diagram courtesy of Cordis International.)

whereas active support is provided by judiciously advancing a small diameter catheter to deeply intubate an epicardial artery.

Passive support

Although 6 Fr guide catheters are successfully used for most cases of angioplasty, larger catheters are required when complex lesions are encountered such as bifurcation stenting or CTO [6] (Figure 5.5).

Active support

Guide catheters smaller than 6 Fr can be advanced over the guide-wire and balloon catheter shaft to sub-selectively engage the proximal or mid segment of an artery (Figure 5.5). This technique is also referred to as active engagement or “deep seating” of the guide catheter. The risk of damage to the artery can be minimized by ensuring that the catheter is advanced coaxially over a balloon already inside the vessel. Stabilization of the system while advancing the guide catheter is sometimes required and can be achieved by inflating a balloon within the artery. When considering the use of active support, it is important to bear in mind that deep engagement of large arteries can cause profound ischemia. The use of side holes may not prevent and may even delay detection of catheter-induced ischemia. A further risk is that of air embolism following aspiration through the Y-connector while the back pressure in the guide catheter is reduced as a result of damping inside the artery. Despite these risks,

for a skilled operator capable of rapidly advancing and withdrawing catheters, active support offers an efficient solution in most cases.

Hybrid support

Several additional strategies have been described based upon the concept of inserting an additional device, wire, balloon, or other catheter specifically to augment support when active and/or passive support of the guide catheter proves insufficient (Figure 5.6).

Wire support

The buddy wire technique refers to the passage of a second or third guidewire distal to a target lesion to provide additional support for delivery of angioplasty equipment. This is a commonly used strategy for crossing difficult lesions with a balloon or a stent [7]. The additional wire provides a rail that facilitates advancement across calcification, tortuosity, or recently deployed stents. The wire facilitates active engagement of the guide catheter and can straighten tortuosity when a supportive wire is used. This technique is also the first essential step for the distal anchor balloon technique. Although it can at first appear to be counterintuitive, advancing an additional wire into a branch that lies proximal to the target lesion may increase support only slightly, but sufficiently to allow passage of a balloon, stent, or additional wire along the first wire into the tortuous distal vessel (Figure 5.6) [8].

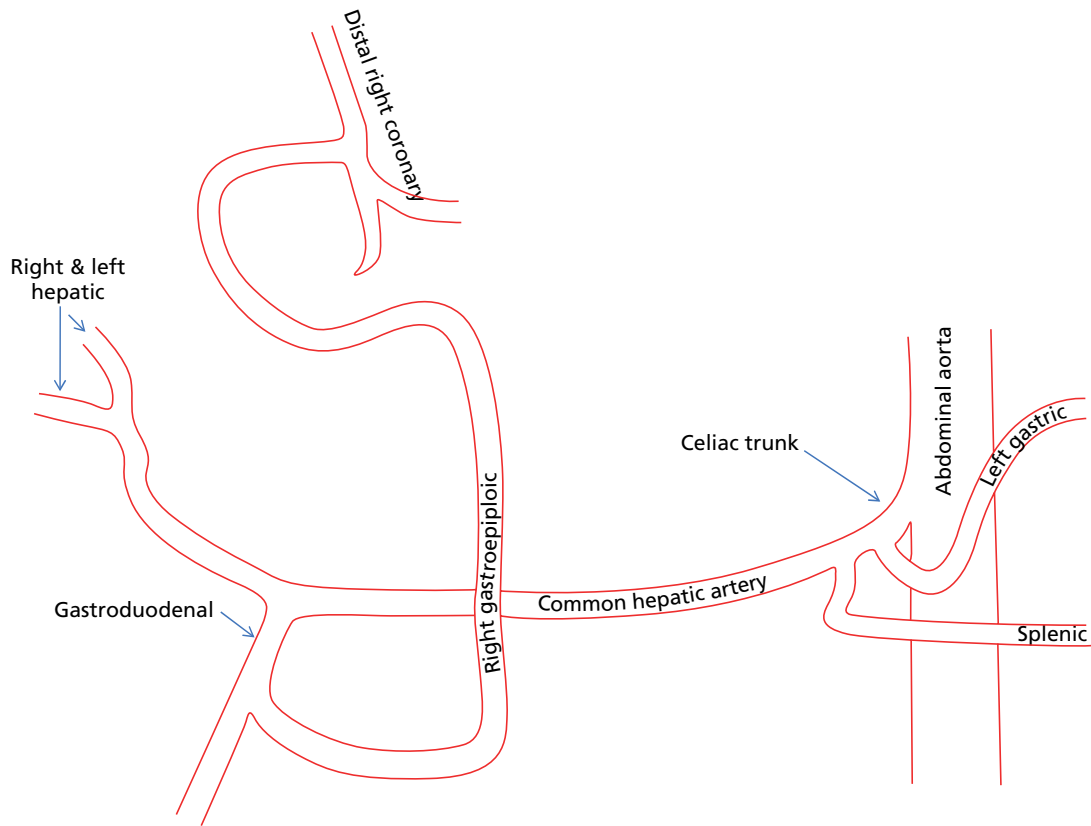

Figure 5.4 Vascular anatomy of a pedicle graft of the right gastroepiploic artery to right coronary artery.

Figure 5.5 Approaches to increase guide catheter support for treating complex lesions.

The risks of deep engagement or the delays and potential difficulties of upgrading the guide catheter can then be avoided. A floppy, steerable wire can advance easily and be exchanged using an OTW catheter for a wire with a supportive shaft but soft flexible tip. The use of stiff hydrophilic wires as a “buddy wire” is discouraged because of the risk of perforation. Occasionally, if support from the guide and an additional wire still proves insufficient, additional techniques are needed and are delineated subsequently.

Anchor balloon technique

Inflation of an adequately sized balloon at low pressure (3–6 atmospheres) in a proximal branch can augment support by anchoring the guide catheter to the vessel and the branch (Figure 5.6) [9]. Low inflation pressures are essential to reduce the risk of dissection or damage to a small right ventricular branch or diagonal/marginal branch. In these branches, ischemia resulting from prolonged inflation is well tolerated. The technique is mostly used in treating CTO and requires a large guide catheter.

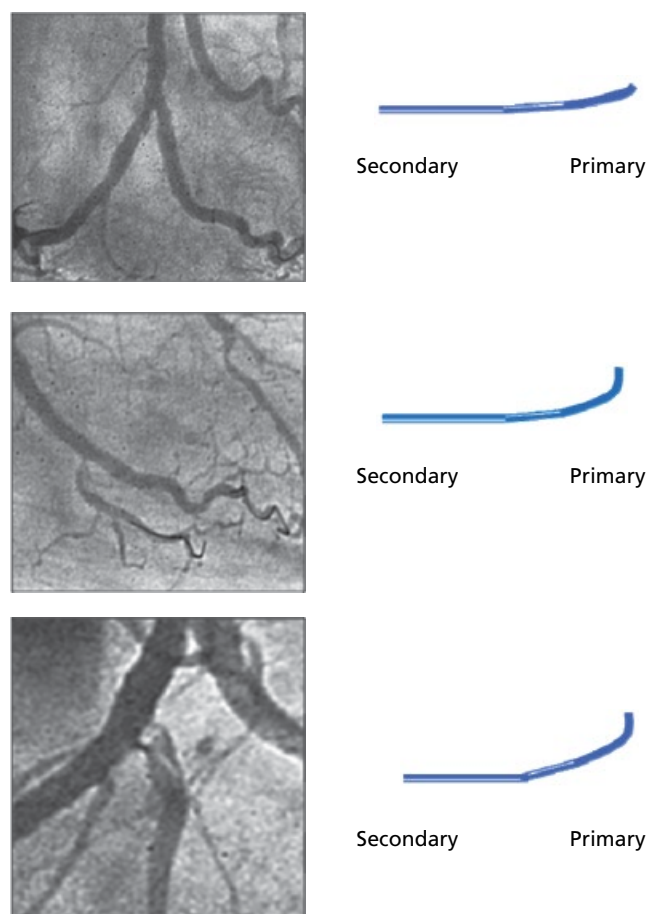

Figure 5.6 “Intraluminal” hybrid support techniques that can be used to substantially augment guide catheter support when treating complex lesions.

Another strategy that can be tried when a buddy wire does not resolve problems in tracking a stent to a target lesion because of tortuosity or calcification of the proximal segment, is to advance over the buddy wire a balloon optimally sized to match the diameter of the distal vessel (Figure 5.6). The balloon is positioned distal to the lesion and inflated at low pressure allowing enough space for the stent to be fully advanced across the target stenosis. It is imperative to remember that the distal anchoring balloon must be deflated and removed before the stent is deployed. In addition to providing extra support, the shaft of the distal balloon also acts as a rail to facilitate stent advancement. The operator needs to be experienced enough to anticipate when the force required may detach the stent from the balloon. Additional strategies can then be considered such as the need for better lesion preparation or the insertion of a sub-selectively engaged guiding catheter around the most tortuous segment, using the guide already in place or a 5 Fr in 6 or 7 Fr strategy as outlined in the next section (Figure 5.5).

Adjunctive techniques

Double coaxial guiding catheter technique (also known as mother-child)

By placing one guide catheter inside another, the advantages of the passive support provided by a large guide catheter are combined with the ability to actively engage the smaller catheter into the target vessel (Figure 5.5) [10]. Compatibility of different guide catheter lengths and

diameter is a limiting factor. Mainly a 6 Fr, 110 cm long “child” guide catheter is combined within an 85 or 90 cm 7 or 8 Fr “mother” guide catheter. A greater difference between the lengths of the “mother” and “child” catheters, however, enables more flexibility because it permits further advancement of the “child” catheter into the artery. The “mother” catheter shape is selected to cannulate the ostium of the target vessel and is inserted first. In contrast, a straight “child” catheter, with a soft atraumatic tip, is desirable. If an unusual shape is required for the “mother” catheter that is not available in a short length, the solution is to cut the distal end of a 100 cm guiding catheter of the selected shape and insert within it a smaller valved sheath. Leakage from an insufficiently tight seal can affect the quality of contrast injections. A further risk is the potential for air trapping within the sheath and subsequent inadvertent intracoronary air embolism.

This is an advanced technique that has been used for treating CTO, but may very occasionally also be useful in other situations where a very high level of backup is required, such as when one encounters extreme coronary tortuosity often combined with calcification. It may also be useful for example when a 7 or 8 Fr guide is too large to engage ostial disease or a critically diseased vessel and other situations where deep engagement of the guide is undesirable. The smaller guide can then be engaged into the vessel ostium, whereas the larger guide adds passive backup to the system. Relative adjustments of the positions of the two guide tips can help to achieve optimal orientation of the tip of the “daughter” catheter.

When using this technique care has to be taken not to damage the proximal arterial segment.

Guide catheter extensions

Over the past few years technology evolution has allowed the introduction of new devices, called guide catheter (GC) extensions, specially designed to address the problem of support in the treatment of unfavorable tortuous coronary anatomy and complex, heavily calcified, and often distally located lesions, which otherwise may have been considered unsuitable for percutaneous coronary intervention (PCI). GC extensions include early OTW devices such as 5 Fr-in-6 Fr Heartrail II® and 4 Fr-in-6 Fr Kiwami® catheters (Terumo, Tokyo, Japan), and more recent rapid exchange GuideLiner® (Vascular Solutions, Maple Grove, MN, USA) and Guidezilla™ (Boston Scientific, Marlborough, MA, USA).

The Heartrail II® “five-in-six catheter system” comprises a flexible-tipped, long (120 cm) 5 Fr catheter advanced through a standard 6 Fr guiding catheter to deeply intubate the target vessel. This system uses the target vessel itself to provide the extra backup support required for stent delivery. Furthermore, the absence of a primary curve and the flexibility of its tip permit the “child” catheter to remain coaxial with the target vessel, thereby minimizing the risk of catheter-induced coronary dissection. Use of this system has been shown to be useful in the treatment of CTO cases where such increased backup support is important. However, its use requires removal of the Y-connector, making the procedure more demanding [11].

Kiwami® 4 Fr-in-6 Fr catheter measures 120 cm, 1.43 mm (outer diameter) 1.27 mm (inner diameter); the inner layer is coated with polytetrafluoroethylene (PTFE) and the surface is coated with a hydrophilic surface up to 15 cm from the tip of the catheter. The back-stream prevention valve (Terumo) is connected to the guide catheter of 6 or 7 Fr. The conventional Y-connector is attached to Kiwami® (child) which was inserted in the 6 or 7 Fr (mother) catheter. Because the effective length of Kiwami® is 120 cm, the projected length from the mother catheter differs depending on the length of mother catheter used [12]. While the 4 Fr-in-6 Fr Kiwami® catheter probably is the most deliverable among the GC extensions, it has the smallest lumen (0.050 inch) and has the highest risk of air embolism [13].

The GuideLiner® catheter is a coaxial device mimicking the “mother-child” technique. The device is mounted on a monorail system, which extends the guide catheter and enables deep intubation of the coronary artery to achieve extra support and improve coaxial alignment. It has a distal end of 20 cm, consisting of a flexible extension with a radiopaque marker situated 2.7 mm from the tip and a coaxial exchange system 20 cm from the tip, joined to a 125 cm compact metal hypotube by means of a ring (“collar”, made of metal in the first version and replaced by a lubricious polymer in the V2 version), which can be deployed through the existing Y-adapter for rapid exchange delivery. The device is available in three sizes: 5-in-6 (0.056 inch internal diameter (ID)), 6-in-7 (0.062 inch ID), and 7-in-8 (0.071 inch ID). Its monorail design permits rapid exchange and offers important advantages over its predecessors, the “five-in-six mother and child” catheters Heartrail II®, which had a coaxial system that made their utilization more demanding [11]. Furthermore, rapid exchange helps with deployment through the existing hemostatic valve without extending the guiding catheter length, and so does not limit the useable length of balloons and wires. De Man *et al.* [14], published results from the Twente GuideLiner Registry identifying three primary indications for the use of the device: improvement of back-up and facilitated stent delivery (59%), more selective contrast injection (13%), and

improvement of alignment of the guide (29%). Moreover, they found a device and procedural success rate of 93% and 91%, respectively, without major complications and a small incidence of minor complications (3%). The safety and efficacy of utilizing the GuideLiner monorail catheter to treat complex lesions was confirmed in a recent experience published by Chang *et al.* showing good performance of the device in the settings of bypass graft intervention, bifurcation lesions, and chronic total occlusions. On the basis of the presented data, the authors suggested the following tips and tricks for a safe and effective use of this device:

- In case of non-coaxial alignment of the coronary ostium and extreme proximal vessel tortuosity (e.g., the “shepherd’s crook”), a balloon inflated distally can be used to “attract” the GuideLiner and facilitate intubation of the coronary artery.
- The placement of a balloon that can also be used for lesion predilatation (i.e., matching the diameter of the target artery or slightly undersized) prior to intubation with the GuideLiner is always recommended (to improve support and to reduce the chance of damaging the ostium and the proximal vessel by acting as centering rail).
- The positioning of the transition zone of the GuideLiner in a straight part of the descending aorta rather than at the aortic arch, typically by gently withdrawing and rotating the GuideLiner helps in avoiding occasional difficulties in the advancement of coronary stents across the rapid exchange transition zone. This problem was solved, in the last version of the device GuideLiner catheter (V2), by replacing the metal transition zone with a lubricious polymer.

The most recent GC extension available on the market is the Guidezilla™. The device is mounted on a monorail system, which extends the guide catheter and enables deep intubation of the coronary artery. It is made of a distal end of 25 cm covered by a hydrophilic polymer, joined to a 120-cm compact metal hypotube. The distal flexible extension consists of a pair radiopaque markers, the first situated 2 mm from the tip and the second 3 mm from the transition collar. The device is available in one size 5-in-6 and compatible with guide catheter ≥ 6 Fr.

Guidewire selection

Guidewires are required to cross the target lesion and to provide support for the delivery of balloons, stents, and other devices while at the same time minimizing the risk of vessel trauma. A guidewire needs to be steerable, visible, flexible, lubricious, and supportive. There is no single wire that has the perfect combination of these characteristics for all situations. Variation in guidewire components have produced a wide range of wires. Wire selection depends on which characteristics are thought to optimally facilitate angioplasty for a given clinical and angiographic scenario.

Guidewires typically come in two basic lengths ranging from 180–195 cm for rapid exchange (Rx) use to 300 cm for OTW use. They consist of a central core of stainless steel or nitinol alloy that makes up the proximal section of the wire, approximately 145 cm long, and which tapers toward a distal tip, a distal section measuring 35–40 cm has a further outer covering of either a fine coil spring consisting of tungsten, platinum or stainless steel, or a polymer coating loaded with a material such as tungsten to improve radiopacity, and the tip often has a lubricious coating that is either hydrophobic or hydrophilic (Figure 5.7). Using stainless steel as the core material improves the steerability and torque control, but steel wires can be deformed by tortuosity and cannot be reshaped. A nitinol core also offers excellent torque control, but the wire will retain its shape and can be reshaped if deformed. Increasing the

Figure 5.7 Components of guidewire design.

Figure 5.8 The components of a rapid exchange balloon catheter.

core diameter increases shaft support (Figure 5.8). There is often a short transition zone between the tapered distal segment whereas some wires have a very gradually tapering central core, which tends to track better around tortuous anatomy and prolapse less when there is extreme angulation (Figure 5.8). Features of the functional design of guidewires are listed in Table 5.4. Guidewires can be classified into general purpose or “workhorse” and dedicated wires (Table 5.5).

Workhorse guidewires typically possess soft tips, but the amount of shaft support varies (Table 5.5). Although some wires have preshaped tips, the tip stiffness can be increased by heating during the preshaping process so the angle may not match the anatomy. Guidewire shaping can be achieved in many ways including curling the shaping ribbon of the wire over the side of the introducer needle, advancing the wire through the introducer tip and bending it gently outside of the introducer needle tip, or curling it with a finger. It does not matter which method is used to

shape the wire tip, provided that it is done without damaging the wire. As a result, preshaping rarely offers an advantage except perhaps for polymer-coated wires, which can be difficult to shape, or in the case of certain CTO wires. When shaping the tip of a wire, the primary curve should match the greatest angle to be negotiated, whereas the secondary curve is chosen to match the size of the vessel (Figure 5.9).

Hydrophilic wires are not recommended as a first choice for general purpose use, because the highly lubricious tip can easily slip beneath a plaque and create a dissection during insertion. These wires also have a higher tendency to migrate distally and increase the risk of perforation, give less tactile feedback, and have lower visibility. Highly tortuous vessels require a flexible lubricious wire in the first instance (e.g., BMW Universal, WhisperMS, Choice floppy), which can then be exchanged via an OTW balloon for a more supportive wire (e.g., Choice extra support, Mailman, Ironman, Grand Slam, Platinum Plus). When

Table 5.4 The selection of a guidewire depends on the characteristics required to deal with lesion complexity or particular vessel characteristics. The characteristics of guidewires can be altered by modifying specific components during the production process.

Flexibility	Flexible wires can better negotiate severe tortuosity or angulation without deformation	Shaft core material (nitinol offers greater flexibility and shape retention), core thickness (thinner core = more flexible)
Support	Improved equipment delivery when hampered by angulation, tortuosity, lesion severity, calcification	Shaft core material, core thickness
Steerability is a function of:		
• torque transmission	1 : 1 transmission of torque to the tip is the ideal	Core materials are chosen for having good torque transmission, which is also improved by a thicker core with more gradual distal taper
• tip shape ability	Importance increases as lesion complexity increases	Nitinol is more difficult to shape, but can be reshaped; steel is easier to shape but can be ruined by being deformed
Lubricity	Can ease wire passage in tight, calcified, severely tortuous lesions	Tip or distal segment coating with silicon, hydrophilic coating, or polymer coating: “plastic jacketed” wires are the most lubricious but also the most dangerous; when combined with a stiff tip long dissections can be inadvertently created: <ul style="list-style-type: none"> • hydrophilic requires water for activation • hydrophobic does not require water for activation, allows feedback from distal tip so that excessive friction when creating a subintimal dissection or going below stent struts can be detected
Tendency to prolapse	Can be important when negotiating angles >75°	A gradually tapering core with a smooth transition toward the tip improves support and tracking around bends; abrupt tapers and floppy cores are more likely to prolapse
Visibility	The level of visibility becomes more important in obese patients or when angled working views are required	Lubricious polymer-coated nitinol wires can be difficult to see, platinum, steel, or tungsten markers at distal tip
Tactile feedback	Provides the operator with essential non-visual information, allows “palpation” of the lesion at the distal wire tip	Hydrophilic wires provide poor tactile feedback; hydrophobic wires provide more feedback
Tip stiffness	A soft gentle tip is essential for all “workhorse” wires; to reduce the risk of vessel trauma; stiffer tips are required for dedicated CTO wires	More gradual distal taper, distal core material (e.g., high tensile steel)

additional support is required, guidewires can be exchanged for those with greater shaft support if required or, more frequently, a second wire can be placed alongside the initial wire to facilitate equipment passage. This so-called “buddy” wire can behave as an additional as previously discussed.

The handling characteristics of different wires vary substantially and even the same wire can have a very different “feel” under different circumstances. For example, wires frequently perform differently and offer different tactile feedback in more complex lesion subsets including those with diffuse disease with heavy calcification or angulation. Inexperienced operators often progress more confidently by becoming familiar with one

workhorse wire used for most cases. Nitinol wires are more forgiving and can be reshaped. An important principle is never to push when the wire bends or buckles, but rather to withdraw and rotate before gently re-advancing it. Learning how to exchange a wire using OTW balloons or microcatheters is an essential skill before tackling complex lesions. More complex angioplasty will also provide an opportunity to gain familiarity with an expanded range of wires.

Dedicated wires for treating CTO have stiffer tips. Tip stiffness is measured in grams of forward pressure required to flex the tip. Specialty wires are listed in Table 5.5 and are discussed in other chapters. Over the last two decades, technologies used for

Figure 5.9 Distal tip styles and components contributing to the crossing profile of balloon catheters.

CTO recanalization have emerged with the production of wires specially developed to satisfy the demands of operators involved in this challenging field. The development of new interventional recanalization techniques has been followed by a concomitant increase in the number of specialized wires, mostly produced by Asahi (Asahi Intecc, Japan) for specific applications:

- Drilling technique (Miracle family)
- Penetration technique (Conquest family)
- Sliding technique (Fielder family)
- Deflection and rotation techniques (Gaia family).

In particular, the development over the last 5 years of the new Sion (Sion, Sion Blue, and Sion Black, Asahi Intecc, Japan) and Gaia wire families (first, second, and third, Asahi Intecc, Japan) have expanded the interventional toolbox for CTO. The Sion wire is currently the gold standard for epicardial collateral tracking, because of its unique trackability which enables the wire to follow most collateral bends. Using this innovative wire, epicardial connections are successfully utilized in almost 35% of retrograde cases in contemporary series from Japan [15,16]. It uses a composite core technology that includes multiple wire components to enhance durability and torque transmission. The tip of the wire can be shaped and successfully retain its shape through collateral tracking. This technology allowed the introduction in contemporary CTO practice of new interventional strategies such as the septal “surfing” technique, which utilizes septal collateral connections between the left and right coronary arteries. A polymer jacketed soft guidewire, traditionally the Fielder FC wire and more recently the Sion Black wire with composite core technology, is advanced to the septal branch supported by a microcatheter. The wire is steered toward the septal branch and kept in constant motion, forward and backward, in an

attempt to engage the distal true lumen of the occluded epicardial artery. Septal “surfing” is the norm for investigating septal connections and is further reviewed elsewhere in this book. While wire “exits” or microperforations occur frequently, they rarely result in clinical sequelae. Nevertheless, because of technical complexity, septal surfing should only be used by operators considerably experienced in the retrograde approach.

Gaia wires also feature the composite core technology. They present a unique trackability and 1/1 guidewire motion. These wires allowed a new approach to the manipulation of a CTO, with the “rotation and deflection” principle, representing a breakthrough in these complex lesions. The wires are preshaped and do not lose their shape while being rotated through the body of the occlusion. Their application remains primarily in the complex CTO subset.

Balloon catheters

Balloon catheters remain an important tool in interventional cardiology despite the advent of adjunctive devices such as stents. When Gruentzig first introduced coronary angioplasty balloons, the correct choice of balloon diameter and length, compliance, pressure, and duration of inflation were the key ingredients for a successful PCI and reflected the experience and quality of individual operators. However, in today’s era of direct stent deployment, sometimes without pre- or post-dilatation, high quality angioplasty technique has been minimized. Nevertheless, the experienced operator recognizes that balloon angioplasty confers not only important acute gain, but also assists in estimation of lesion diameter and length for the selection of stents, can facilitate exchange after wire

Figure 5.10 Support can be increased by increasing core diameter.

crossing (OTW), and holding the guide catheter in place when greater support is required (anchor balloon in side branches or proximal–distal to the lesion in the main vessel). Moreover, with the advent of drug-coated balloons, angioplasty balloons are again able to deliver more than acute gain from vessel dilatation, but also deliver adjunctive pharmacotherapy to mitigate neointimal hyperplasia and reduce restenosis.

Anatomy of a balloon catheter

The anatomy of an angioplasty balloon from proximal to distal consists of a hub, a proximal shaft, and a distal shaft. It has a cylindrical body with proximal and distal conical tapers and a distal tip (Figure 5.10). Early balloon catheters had a fixed wire proximal to the balloon, as dual lumen catheters were typically bulky and difficult to advance into the coronary circulation. Contemporary balloon catheters are dual lumen with separate ports for the guidewire and balloon inflation. OTW balloons have a lumen for the guidewire extending along the length of the catheter, a feature very useful and sometimes essential for procedures requiring wire exchange without re-wiring a vessel such as in the treatment of CTO, crossing of very tortuous lesions, advancement of poorly steerable wires such as those for rotational atherectomy. The principle of the Monorail or rapid exchange technique is that the wire lumen is limited to a short segment (20–30 cm) at the distal tip which allows the rapid exchange of balloons with no need for long wires or wire extensions. The shaft of the catheter only contains a lumen for balloon inflation and deflation (i.e., can be thinner) and often consists of a reinforced hollow metal tube providing great pushability. OTW balloons are typically touted for their superior support but require two operators for optimal control, whereas monorail systems dominate the market and permit a single operator to control all devices.

The parameters considered when selecting a balloon are balloon diameter, length, and compliance, although occasionally the shaft diameter, length, and crossing profile are also important considerations (e.g., bifurcation techniques using smaller bore guides, retrograde recanalization of CTO, very tall patients, extreme tortuosity, or target lesion distance from the access site as in peripheral vascular interventions).

Balloon diameter is normally selected to match the vessel size with balloon to artery ratios of 1 : 1 in general. Vessel size can be measured using quantitative coronary angiography (QCA)

or intravascular imaging such as intravascular ultrasound (IVUS) or optical coherence tomography (OCT). Aiming for a balloon to reference vessel ratio of 0.9 : 1.1 is typical. For predilatation, “undersizing” may be acceptable whereas for postdilatation balloon to vessel ratios are typically $>1 : 1$. For long tapering lesions, the diameter of the vessel at the distal end of the segment to be dilated is typically used as the reference vessel diameter for balloon selection. An appropriately sized balloon for postdilatation is a critical step to achieve better expansion and apposition when the initial balloon deployment fails, despite the high pressures allowed by modern stent delivery balloons, to fully expand the stent.

Balloon length is selected depending upon lesion and stent length. Especially after the introduction of drug eluting stents when the principle is to avoid injuring segments that will not be covered by stents, a situation known as geographic miss, smaller balloons tend to be used for predilatation, just aiming to create a passage for stent insertion and exclude the presence of truly undilatable lesions [8]. Postdilatation balloons should be shorter than the stent and short balloons are recommended for postdilatating resistant lesions.

The first angioplasty balloons were composed of flexible polyvinyl chloride (PVC), a material characterized by great compliance. Subsequent generations were made of cross-linked polyethylene, polyethylene terephthalate (PET), nylon, Pebax, and polyurethane. Most modern balloons allow controlled limited expansion, burst resistance up to high pressure, and have a low crossing profile. The tip style (tapering, length, flexibility) varies substantially among different balloons, and is one of the factors contributing to a successful crossing (Figure 5.11). Compliant balloons show a linear increase in diameter with increasing inflation pressure whereas the diameter increase tends to plateau in semi- or non-compliant balloons until reaching the rated burst pressure. More compliant balloons have a limited pressure range whereas non-compliant balloons have a limited diameter range and are useful for treating resistant lesions requiring high pressure inflation or postdilatation. Semi-compliant balloons fall between these two extremes and tend to be multipurpose “workhorse” balloons. Familiarity with the compliance charts of balloons is necessary to reduce the risk

of trauma to the healthy vessel or of exceeding the vessel elasticity and induce dramatic vessel ruptures. Terms encountered on these charts include the following:

- 1 Nominal: the pressure at which the balloon reaches its nominal diameter (diameter on the label);
- 2 Rated burst pressure: the pressure below which *in vitro* testing has shown that 99.9% of the balloons will not burst with 95% confidence;
- 3 Mean burst pressure: the mathematical mean pressure at which a balloon bursts.

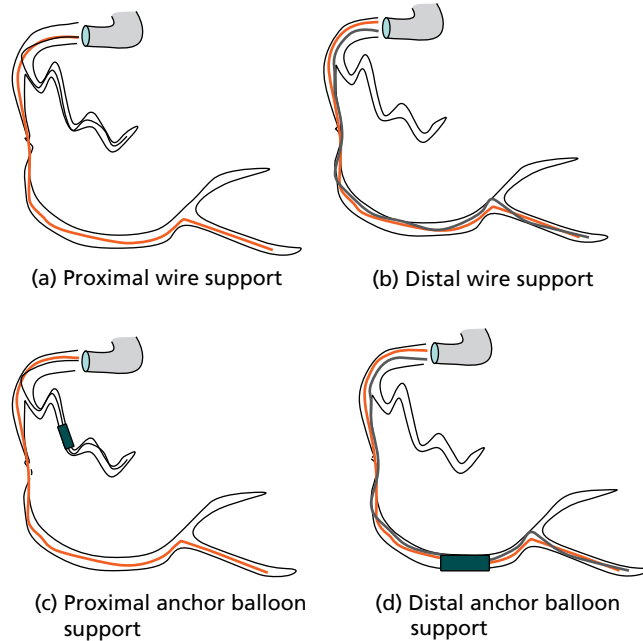

Figure 5.11 The primary curve is shaped to fit the tightest angle to be wired and the secondary curve to reflect vessel size.

Wall stress within a cylindrical balloon can be represented by the following equations:

$$\sigma_{\text{radial}} = pd/2t$$

$$\sigma_{\text{axial}} = pd/4t$$

where σ_{radial} = radial stress, σ_{axial} = axial or longitudinal stress, p = pressure, d = diameter, and t = wall thickness. It can be seen that wall stress is linearly proportional to diameter which means that higher dilatation pressure is possible with smaller diameter balloons. Furthermore, axial stress is half of radial stress which means that balloon rupture is usually longitudinal rather than circumferential and therefore less likely to result in vessel trauma.

Balloons have proximal and distal radiopaque markers to allow positioning (one central marker for some small diameter balloons). Rewrap refers to the ability of the balloon to regain its original folded state following deflation. Deflation and rewrapping can take time when large and long balloons are used. Rewrapping is essential to allow safe withdrawal of the balloon into the catheter. Stent deployment balloons tend to rewrap less well, have more variable expansion characteristics, and should ideally not be used for post-dilatation. Balloon catheters may also be used to augment support when treating complex lesions.

The past decade has heralded the development of several specialty balloons including cutting balloons, focal force balloons, and drug-coated balloons (Figure 5.12) with specific applications for each type of balloon.

The cutting balloon is marketed by Boston Scientific (Malborough, MA, USA) as the “Flextome.” The balloon has three blades equally spaced about its circumference which come into contact with the arterial wall and score the vessel wall. The balloon is specifically indicated for discrete lesions with resistance to conventional balloon angioplasty without heavy calcification. This balloon is frequently used to dilate highly resistant lesions, particularly fibrotic lesions.

Focal force balloons such as the Angiosculpt (Spectranetics, Inc, Colorado Springs, CO, USA) and the Chocolate (TriReme Medical,

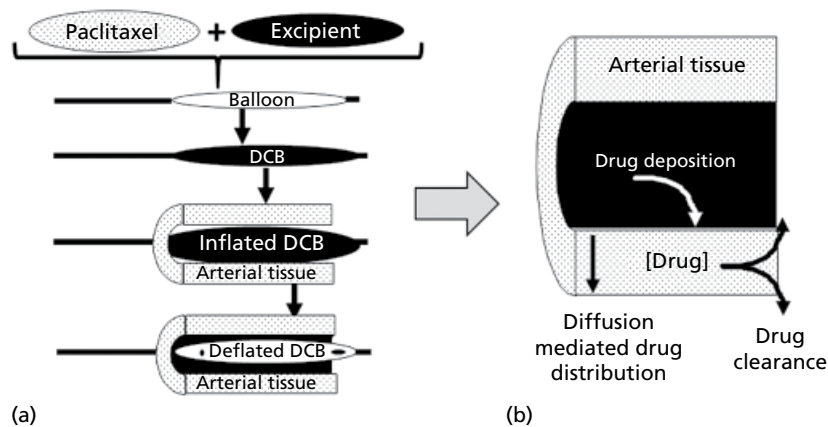

Figure 5.12 Drug-coated balloons and arterial drug delivery: mechanism of action. (a) Drug-coated balloons are comprised of a drug such as paclitaxel admixed with an excipient that helps bind the drug to an angioplasty balloon catheter. When the balloon is inflated, the bonds between the drug and excipient and the balloon are broken depositing a layer of drug and excipient on to the arterial surface. (b) Endovascular drug administration results in adluminal drug entering arterial tissue via diffusion mediated transport. The balance between the steady state diffusion mediated drug distribution and drug clearance results in the ultimate arterial drug concentration. This drug concentration is directly related to the efficacy of the drug.

Pleasanton, CA, USA) have recently established a niche in the market for treatment of resistant lesions. The Angiosculpt is a non-compliant balloon with three nitinol wires or elements spiraling from the tip to the shaft transition. The function and application is similar to a cutting balloon; however, the degree of vascular injury imparted is thought to be less than the Flextome balloon. Developed for both coronary and peripheral vascular applications, the Angiosculpt is similarly used in highly resistant lesions when conventional balloons are unable to dilate the vessel. Another focal force balloon is the Chocolate balloon which is a traditional semi-compliant balloon within a nitinol cage. When the balloon is inflated, the cage restrains the balloon expansion, and the balloon protrudes from between the struts of the nitinol cage applying focal pressure to discrete areas of the plaque. Theoretically, this will result in more controlled plaque fracture. These balloons are frequently applied in vessels where stenting is inadvisable (side branches) or not possible (small vessels). Lesion preparation is felt to also be better with focal force balloons [17].

Conclusions

A good operator will have a thorough knowledge of the advantages and limitations of each specific piece of equipment, familiarity with their specific characteristics and modalities of use, and a preparedness to change to an alternative strategy or strategies if required.

CHAPTER 6

Physiologic Assessment in the Cardiac Catheterization Laboratory: CFR, FFR, iFR, and Beyond

Sukhjinder Nijjer¹ and Justin Davies²

¹Hammersmith Hospital, Imperial College Healthcare NHS Trust, London, UK

²Imperial College London, London, UK

Coronary angiography is the current gold standard in quantifying the presence of epicardial coronary disease but has well-known limitations driven by the difficulties of assessing three-dimensional structures using two-dimensional approaches.

Although intravascular imaging provides insight into the levels of atheroma in a coronary artery, there is a disconnect between stenosis appearance and the flow limitation it imposes. Physiologic interrogation provides not only determination of flow limitation, but stratification of risk and the potential value from revascularization. Conceptually, physiologic assessment should improve outcomes by focusing revascularization where the gain is greatest.

Measuring coronary flow remains the ultimate aim of all physiologic parameters, including those that estimate flow based by measuring pressure only.

This chapter reviews the basic principles of coronary physiology and their clinical application in the cardiac catheterization laboratory. Specifically, CFR, FFR, iFR, and IMR are discussed in detail.

Impact of a stenosis upon coronary flow

Every coronary stenosis imposes a degree of resistance to flow in the epicardial vessel. Coronary autoregulation, working through a variety of paracrine and neural factors, responds by microcirculatory vasodilatation. This maintains normal resting coronary flow up to a stenosis diameter of 85%, at the expense of distal coronary pressure (Figure 6.1) [1]. Distal pressure falls as a result of kinetic energy loss from viscous friction, turbulence, and flow separation across the stenosis, producing a resting trans-stenotic pressure gradient which increases with increasing stenosis severity (Figure 6.2). The degree of gradient at rest is therefore a marker of the physiologic impact of the stenosis upon the microcirculation.

Because of limitations in pressure wire technology, with bulky catheters with low fidelity cycle averaged traces, it was not practically possible to make detailed assessment of stenosis significance under resting conditions. Instead, hyperemia was sought, with the aim to increase flow and therefore increase the measurable gradient across a given stenosis to more easily distinguish mild, moderate,

and severe stenoses. Typically, adenosine, ATP, papaverine, or balloon occlusion can be used to induce varying degrees of hyperemia. This reduces microcirculatory resistance and increases coronary flow but does so in a non-uniform manner. Trivial and mild stenoses demonstrate the greatest increase in flow in response to hyperemic stimulus. With stenoses over 30% a reduction in hyperemic flow is observed while a more marked reduction is evident in stenoses over 50% (Figure 6.1).

As stenoses cause natural microcirculatory vasodilatation, the vasodilator reserve, which is the capacity to respond to a hyperemic stimulus by increasing flow, falls with increasing stenosis severity. It follows that severe stenoses that genuinely limit flow will have an impaired response to hyperemia and with increasing severity there is less additional gain in the gradient observed above that evident at rest.

The degree of pressure loss or gradient observed with these stenoses will be dependent upon the geometry of the stenosis; if turbulence is minimal, flow can escalate significantly with little pressure loss. If turbulence predominates, pressure loss is exacerbated even if flow is increasing significantly and there is no true “flow limitation.” In long lesions, a great deal of resistance can cause considerable pressure loss alongside a failure to increase flow in response to hyperemia.

For each stenosis, coronary flow and pressure have a curvilinear relationship in which curve steepness is directly related to stenosis severity (Figure 6.3). The greater stenosis severity, the greater the imposition on trans-stenotic flow and the larger the detectible pressure gradient. In such stenoses, trivial increases in flow over the resting state are expected with a considerable resting pressure gradient. In milder stenoses, resting gradients can be small but become larger if the trans-stenotic flow is increased considerably. It follows that such stenoses are non-flow-limiting despite the detectible pressure gradient.

The capacity to increase flow is a marker of microcirculatory function in the absence of epicardial disease, or a combined marker of epicardial and microcirculatory resistance when a stenosis is present. If flow can be made to increase significantly across a stenosis, then it is likely that microcirculatory function must be intact even if

not entirely normal. Microcirculatory vasodilatation is related to size of the tissue bed and the demand placed. If vasodilatation cannot compensate for the stenosis, distal flow diminishes and ischemia under resting conditions would result.

Fundamentals of practical physiologic assessment

Physiologic assessment requires the use of adequately sized guiding catheters to engage the vessel of interest. Catheters of 6 Fr are suitable. Caution is required to ensure there is no damping of the pressure signal after engagement, because this will compromise all measurements. Catheters with side holes should be avoided; although the side hole can improve the appearance of the pressure trace, there remains a relative ostial obstruction. In the event of pressure damping or the presence of important ostial disease, it is appropriate to perform measurements with the guiding catheter disengaged. However, this obviates the possibility of using intracoronary vasodilators or injectants for thermodilution.

Figure 6.1 Behavior of resting and hyperemic flow in relation to stenosis severity. Resting flow is remarkably preserved despite worsening stenosis severity—up to 85% diameter stenosis by formal measurement. Hyperemic flow starts falling when stenoses are 30% but falls significantly once stenoses are 50%. Source: Adapted from Gould *et al.* 1974 [1].

Figure 6.2 The flow of blood across a coronary stenosis. Pressure gradients across stenoses are due to both viscous and separation losses. Pressure is lost owing to viscous friction along the stenosis (Poiseuille’s law). Flow also accelerates as it passes through the narrowed segment, causing pressure loss as pressure is converted into kinetic energy (Bernoulli’s law). Flow separation and the formation of eddies prevent complete pressure recovery at the exit of the stenosis. Measurement of intracoronary hemodynamics includes proximal perfusion pressure (P_a), coronary pressure and flow velocity distal to the stenosis (P_d and V_d , respectively), and the venous pressure (P_v), which is typically assumed to be negligible. ΔP is the difference between P_d and P_a . Normal diameter (D_n), stenosis diameter (D_s), proximal velocity (V_n), and stenosis velocity (V_s) are indicated. Source: Reprinted by permission from Macmillan Publishers Ltd: *Nat Rev Cardiol*, van de Hoef TP, *et al.* Fractional flow reserve as a surrogate for inducible myocardial ischaemia, 10, 439–452, copyright 2013.

Essential to all invasive coronary physiologic assessment is the use of heparin to prevent thrombosis upon the wire; typically 70–100 IU/kg is administered before any wires are placed.

A further essential step is to provide adequate intracoronary nitrates (200–300 μg). Nitrates do *not* create a long-lasting hyperemic

Figure 6.3 The curvilinear relationship between pressure and flow is unique for each stenosis. Pressure drop across a stenosis is determined by $\Delta P = Fv + Sv^2$ (where F is friction losses and S is separation losses). This produces curvilinear relationship unique to any stenosis; the steepness of the curve reflects the severity of the lesion (e.g., reference vessel, stenosis A, B, C). Increasing the flow velocity across a stenosis will alter the pressure gradient observed. In stenosis A, there is a large resting pressure gradient that is accentuated during hyperemia with little increase in flow. In stenosis B, increasing the concentration of hyperemic agent (depicted as arrows) will increase flow velocity to generate a larger gradient; as resting flow is unchanged, CFR and FFR will move in opposite directions. In even milder stenoses, such as A, large escalations of flow velocity from a relatively low resting value could create a large pressure gradient; in these situations, pressure does not reflect the change in flow. Source: Adapted by permission from Macmillan Publishers Ltd: *Nat Rev Cardiol*, van de Hoef TP, *et al.* Fractional flow reserve as a surrogate for inducible myocardial ischaemia, 10, 439–452, copyright 2013.

effect but remove wire-related and guide-related vessel spasm and ensure epicardial resistance is minimized. This enables accurate physiologic assessment; readings without nitrates should be repeated, as even a small degree of distal wire spasm will raise distal coronary pressure while more proximal spasm will make distal assessment appear worse.

Hyperemia

Hyperemia is believed to occur in two stages. Agents primarily achieve maximal hyperemia through their vasodilator action on microvascular smooth muscle cells (an endothelium-independent response). The resultant increase in blood flow is thought to stimulate shear stress-induced endothelial nitric oxide release, which promotes further vasodilatation of the microcirculation (flow-mediated dilatation) and increase in blood flow (an endothelium-dependent response). Therefore the response to hyperemic agents will integrate a change in coronary blood flow and microvascular function but alone cannot distinguish between components.

Non-specific agents such as adenosine and papaverine are commonly used to induce maximal hyperemia for assessment of indices such as coronary flow reserve (CFR), fractional flow reserve (FFR), and index of microcirculatory resistance (IMR). The dose of adenosine is accepted as 140 $\mu\text{g}/\text{kg}/\text{min}$ when given as a central venous infusion (e.g., femoral vein); ATP can be given as an alternative. The hyperemic effect is typically observed after 30 seconds and infusions should continue for 1–2 minutes to observe for stable hyperemia. Side effects include relative hypotension, a central chest discomfort or burning, dyspnea, and bronchospasm. It should be avoided in patients with severe brittle asthma. Short-lived atrioventricular conduction delay is frequent. It is common to seek peripheral veins to avoid additional femoral venous puncture; there are data to support this approach but hyperemia can become more variable with a longer time course [2].

For intracoronary dosing, clinical practice remains variable. Early validation work was performed using considerably lower doses than found in clinical practice today. Accepted intracoronary doses of adenosine or ATP are 80–120 μg in the left coronary system and 40 μg in right coronary artery; these typically produce

hyperemia lasting 5–10 seconds [3]. Caution is required in ensuring pressure ports are closed to ensure appropriate pressure traces can be recorded.

Papaverine is an alternative intracoronary agent that achieves a longer lasting hyperemia of 30–60 seconds which permits pullback assessments at the cost of transient QT prolongation and rare trigger ventricular tachycardia or torsade de pointes [3]. It is typically used when adenosine is not available (15–20 mg in the left coronary artery; 10–12 mg in the right coronary artery) [3].

Newer alternatives include regadenoson, a selective A_{2A} receptor agonist which has been approved for use in myocardial perfusion imaging. Given as a single bolus into a peripheral vein using a weight-unadjusted dose (400 μg over 10 seconds), regadenoson achieves a peak flow velocity after 1 minute and declines thereafter [4]. However, the duration of hyperemia is very variable among patients, making pullback and multi-vessel assessment unreliable and inconsistent. Side effects include adenosine-like effects with hypotension, chest discomfort, and flushing. Third-degree heart block has also occurred.

Alternatives to achieve increased flow include the use of contrast—which in some settings can have a similar effect to that of other intracoronary hyperemic agents [5]. Caution is required as the hyperemic effect is variable between injections, very short-lived, and can contribute to considerable contrast burden. Furthermore, it remains unclear what the threshold for treatment should be; small studies have limited power to determine cut-offs while larger ones are not helpful if different types and volumes of contrast are used. As the hyperemia is submaximal, changing volumes can lead to different pressure ratios and uncertainty.

Coronary flow reserve and relative CFR

The concept of CFR is to compare the flow at rest with that measured under hyperemia. CFR is derived from the ratio of steady state maximal hyperemic flow to resting flow in a given artery [6]. Conceptually simple, CFR can be measured invasively using intracoronary wires capable of measuring coronary flow velocity (using a piezo-electric Doppler; Figure 6.4) or apply thermodilution

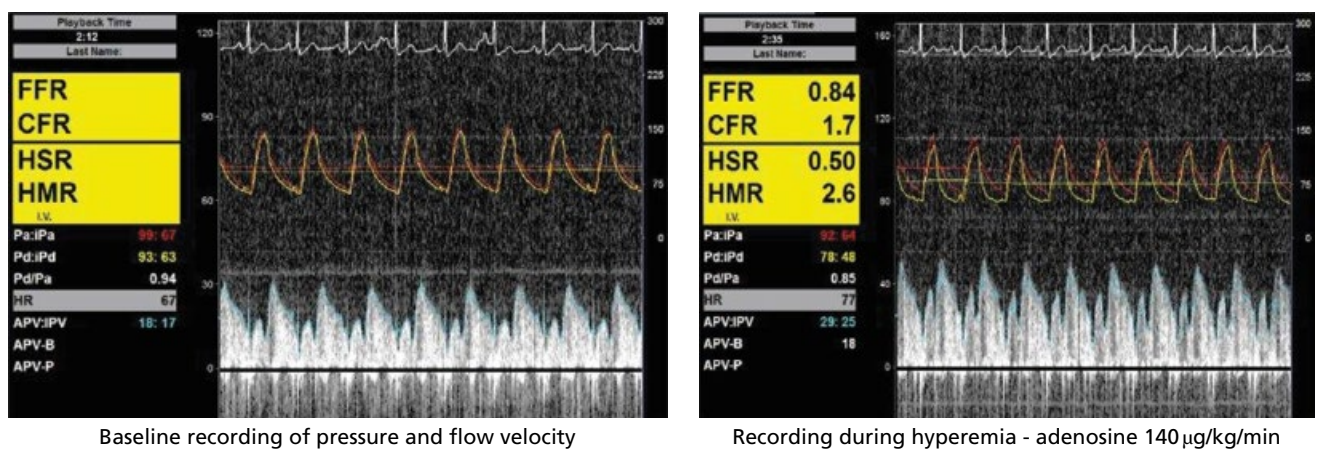

Figure 6.4 Physiologic interrogation in the catheter laboratory. Left panel shows baseline data at rest. There is trivial resting gradient (Pd/Pa 0.94). Note the spectral Doppler trace has the majority of flow in diastole; also note the digital tracking has been optimized to avoid extraneous noise. Right panel shows data after hyperemia. CFR is calculated as the ratio of average peak velocity (APV) at maximal hyperemia to baseline. In this case, FFR and HSR are negative suggesting no significant limitation on flow; CFR is low—which will be partly caused by the stenosis and partly caused by microvascular disease.

principles (using wires with a thermistor). It can also be measured during non-invasive testing using positron emission tomography (PET) derived quantification of regional myocardial blood flow or by transthoracic echocardiographic assessment of coronary blood flow. Comparison with non-invasive functional imaging techniques has shown that a CFR <2.0 strongly correlates with ischemia in the subtended territory [7]. Extensive prognostic data that strongly suggest that events are low if flow can elevate greater than twice that measurable at rest [8].

Relative CFR (rCFR) indexes the CFR value of the interrogated vessel by that of a normal unobstructed reference vessel in the same patient, provided that at least one vessel is available [6]. Accordingly, a normal rCFR is between 0.65 and 1.0. An important limitation is that of potential collateralization between coronary territories in the presence of a severe stenosis can alter the values. As vasodilators cause indiscriminate microcirculatory vasodilatation, then flow in the reference vessel can be significantly higher than if the stenosis in the neighboring territory was absent. Consequently, the CFR in the reference vessel may be supra-normal, causing overestimation of the significance of the stenosed territory. Alternatively, an inadequate hyperemic response in the “reference” territory would lead to underestimation of the importance of the stenosed vessel.

Practical approaches to measuring CFR

CFR is calculated using either Doppler flow velocity or thermodilution. Doppler flow velocity traces are acquired using a piezoelectric tipped guidewire to elicit spectral traces; average peak flow velocity (APV) is determined by digital tracking (Figure 6.4) and CFR is computed using the ratio of APV at rest and hyperemia. Epicardial resistance must be stabilized using intracoronary nitrates, ensuring a constant surface area which allows flow velocity to be directly proportional to flow.

Added care and attention is required to ensure the flow sensor is coaxial within the vessel. Not only must the Doppler signal be dense, but the automated digital tracing around the Doppler flow velocity signal must also be fully optimized. Inadequate tracking will impair CFR calculation and any phasic analysis. When stenoses are highly obstructive, acquisition of high quality traces is challenging.

The principle of thermodilution is based upon the concept that transit time of an intracoronary injectate, derived from a thermodilution curve, is inversely proportional to flow [2]. CFR can therefore be derived as the ratio of the mean transit time of an intracoronary injectate at baseline and maximal hyperemia. Dedicated pressure wires with a temperature sensor can detect the transit time of a handheld 3–4 mL intracoronary injectate of room temperature saline [9–11]. The shaft of this wire, on which the temperature-dependent electrical resistance is monitored, acts as a proximal thermistor. The distal pressure sensor also allows simultaneous high fidelity temperature measurements. Multiple injectants are typically performed to take an averaged thermodilution curve. Thermodilution techniques require for a standardized volume of injectant, given at a standard speed and force, followed by a standard flush time. Changing these parameters can lead to subtle changes in the thermodilution patterns observed. The need to inject means intravenous hyperemia is required.

Clinical interpretation of CFR

In the absence of an epicardial stenosis, CFR is a measure of microvascular reserve and the capacity to respond to an exogenous vasodilator. In the presence of an epicardial stenosis, CFR provides a marker of flow obstruction; values below 2 are considered flow

limiting. When used alone, CFR cannot estimate the relative contribution of microvascular dysfunction and epicardial stenosis because it inherently combines both. CFR may be used alongside another hyperemic index such as FFR; however, there may be similar concern that inadequate hyperemia can lead to misclassification of stenosis significance. Discrepancy between FFR and CFR occurs in 30–60% of cases. Typically, the pressure-based index has been considered correct since the availability of FAME study data, although alternative explanations should be considered as pressure is being used to estimate flow.

When CFR is low, and FFR is above the treatment threshold, it can be interpreted that there is a non-flow limiting stenosis with microvascular dysfunction. However, as FFR is reliant upon achieving adequate hyperemia, then a non-significant value may not be accurate. In this case, alternative hyperemic approaches should be sought: papaverine may overcome resistance to adenosine. Alternatively, a resting index such as the instantaneous wave-free ratio (iFR) may help. Since the resting index relies upon the natural response of the circulation to the stenosis it is not reliant on the response to the exogenous agent. A truly significant stenosis will cause resting pressure loss even if the response to a hyperemic agent is incomplete. If the iFR is positive, then it suggests, together with the low CFR, that the flow limitation is genuine and that a high FFR is caused by a lack of microcirculatory response to adenosine. If the iFR is negative, it suggests that the epicardial resistance offered by the stenosis is small and predominantly microvascular disease is present.

An alternative discrepancy is that CFR may be high, suggesting there is no difficulty in escalating flow when required, while FFR may be strongly significant, suggesting a flow limitation. This situation occurs because high flow velocities across even trivial stenoses can generate turbulence and energy loss that is detectable as pressure loss, despite the capacity to increase flow. Should a resting index such as iFR be negative, it suggests little impact of the epicardial stenosis. Alternatively, a combined pressure and flow velocity parameter such as the hyperemic stenosis resistance (HSR) may help (Figures 6.4 and 6.5).

Hyperemic stenosis resistance and basal stenosis resistance

The pressure–flow velocity relationships of a stenosis can be described by the gradient of the curve and this is encapsulated by HSR and basal stenosis resistance (BSR). Both measures use the translesional pressure gradient and index it by the flow velocity distal to the stenosis (Pa-Pd/flow velocity) [12]. HSR is measured under hyperemic conditions, while BSR is measured at rest; application of both enable elucidation of the relative contributions of epicardial and microvascular resistance to impaired coronary flow. Both are accurate surrogates for myocardial ischemia [12–14]. Stenoses with hyperemic resistance over 0.80 mmHg/cm/s or resting resistance over 0.66 mmHg/cm/s are likely to be causing ischemia [13,14].

As both HSR and BSR include both pressure and flow measurements, the difficulties posed by CFR or FFR measurement are resolved. High flow situations causing pressure loss due to Bernoulli's principle are readily detected; similarly microvascular disease limiting flow increases without epicardial limitation can be determined.

The specific value of these parameters is that they remove the likelihood of false positive pressure gradients that can occur when

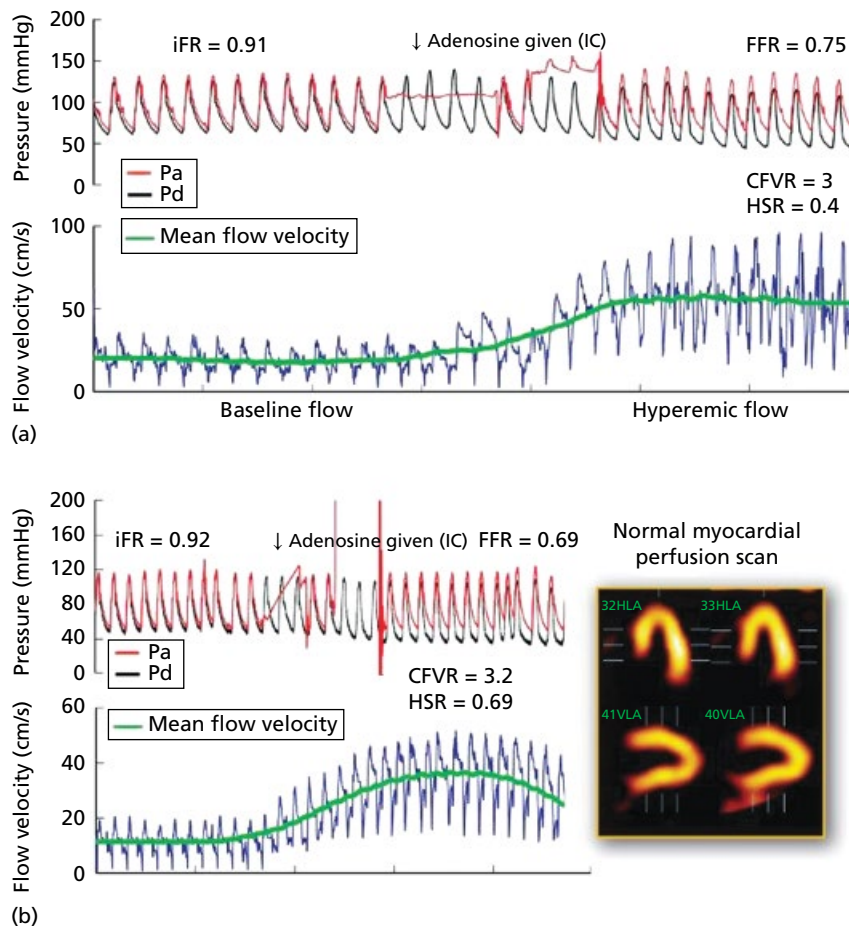

Figure 6.5 Examples of cases in which low FFR values are generated by high magnitudes of hyperemic flow. In both cases, baseline instantaneous wave-free ratio (iFR), coronary flow velocity reserve (CFVR), and hyperemic stenosis resistance index (HSR) were normal, indicating a mild, not flow-limiting stenosis. In (b) a SPECT myocardial perfusion scan also confirms the absence of myocardial ischemia. In these cases, hyperemic pressure is not reflecting flow and is not representative of ischemia. Source: Petraco *et al.* 2014 [39]. Reproduced with permission of Wolters Kluwer Health.

coronary flow increases significantly across an otherwise mild non-flow-limiting stenosis. As predicted by the curvilinear relationship between pressure and flow, even a trivial narrowing can generate a considerable pressure gradient if the flow increases dramatically and this can occur particularly in proximal lesions in vessels subtending a large territory (such as the left anterior descending; LAD) with a microcirculation that is particularly responsive to exogenous vasodilators (Figure 6.5). First, the large response to a vasodilator suggests there is considerable vasodilatory reserve within the microcirculation which has not had to adapt to flow-limiting stenosis. Second, the fact that flow can elevate significantly across the stenosis suggests it cannot be flow limiting. Using a pressure-only index, under conditions of hyperemia, a large gradient manifest in this manner (“false positive”) would be indistinguishable from a “true positive” value. By measuring both the gradient and the actual flow, both HSR and BSR resolve this difficulty and give a highly accurate representation of the significance of a stenosis.

In modern clinical practice, HSR and BSR can be acquired using a combined pressure and flow velocity guidewire, which features both a pressure sensor and a piezo-electric crystal capable of measuring Doppler flow velocity. As with CFR, optimized flow

signals are required and familiarity with wire handling. Advances in the commercially available consoles can facilitate use of these parameters but, until then, HSR and BSR remain in the research domain.

Fractional flow reserve

Fractional flow reserve (FFR) is a reference standard for coronary physiology in the catheter laboratory. It is used routinely in clinical practice and is supported by a large volume of research data. FFR, as a concept, is defined as the maximum myocardial blood flow in the presence of an epicardial stenosis divided by the theoretical maximum flow in the absence of a stenosis (maximum flow when the vessel is normal) in a given artery [1–3,15]. In clinical practice, FFR does not measure flow, instead measuring intracoronary pressure [15]. As pressure and flow are not linearly related, a direct relationship can only be inferred if coronary microcirculatory resistance is constant (and minimal) as is theoretically the case during maximal arteriolar vasodilatation [15]. Hyperemic agents such as adenosine, papaverine, ATP, or regadenoson are used to reduce resistance and increase coronary flow, thereby magnifying a trans-stenotic pressure gradient that is often present at rest [15]. FFR is therefore

defined in the catheter laboratory as a ratio of the distal and proximal coronary pressures (P_d/P_a) during stable hyperemia averaged over 3–5 complete cardiac cycles.

When administering vasodilators, it is appropriate to observe the change in the P_d/P_a ratio as it may fluctuate before settling during a period of stable hyperemia [16]. When using short-lived intracoronary vasodilators, the lowest P_d/P_a ratio achieved can be used. Caution should be exercised when relying upon automated device calculation, as the lowest value may be spurious, such as calculated during arterial port opening, an ectopic beat, or a cardiac pause [15].

Conceptually, a vessel with FFR of 0.80 has 80% of the blood flow it should have if the stenosis was absent. Theoretically, if a stenosis was removed from that vessel, the FFR should be 1.0. For FFR to be correct the resistance imposed by the microcirculation and any collaterals must be entirely stable and flow across the stenosis maximal. If higher flow across the stenosis can be achieved, or if the microcirculation resistance can be lower, then the severity of the stenosis will be underestimated and the calculated value of FFR will be overestimated (e.g., 0.85 when it should be 0.76).

Consideration of right atrial pressure

Outflow of blood from capillaries into the venous circulation contributes to resistance; and this was accounted for by the original definition of FFR ($FFR_{myo} = P_d - P_v / P_a - P_v$) [17]. To simplify FFR and its increase adoption, venous pressure is typically assumed to be zero. If zero, P_v can be removed from the equations calculating FFR. However, typical venous pressures of 2–8 mmHg are reported during hyperemia and patients with cardiac impairment can have higher values [18]. The implications are that stenosis severity may be underestimated, particularly if venous pressure is elevated [19]. While the effects may be diluted in population samples, for individual patients the effects and the change in categorization can be marked and measurement of right atrial pressure should be considered.

Stenosis-specific assessment

In modern practice, FFR_{myo} (total flow through the myocardial bed, including collateral flow) and FFR_{cor} (quantification of flow limitation caused by stenosis) are considered the same. FFR_{cor}

requires coronary wedge pressure (P_w)—measured during balloon occlusion of a stenosis—to estimate the flow contribution from collateral vessels. $P_d - P_w / P_a - P_w$ is required for FFR to provide stenosis specific information, and it is known that the simplified FFR_{myo} underestimates FFR_{corr} [17,20]. However, for practical reasons when assessing an intermediate stenosis the risks of balloon inflation may be undesirable, and therefore a balloon occlusion measurement is rarely performed.

Thresholds for significance and evidence to support

A cut-off FFR value of <0.75 across an epicardial stenosis is accepted to be indicative of myocardial ischemia. There is a close correlation between $FFR <0.75$ and different non-invasive indices of reversible myocardial ischemia [21]. While there may be discrepancy with individual functional tests, when multiple tests are performed agreement is more likely; early work suggests $FFR \leq 0.75$ detects 97% of ischemia [21]. Meta-analytical work suggests the match with non-invasive testing is typically 70% [22]. The DEFER study demonstrated it was clinically safe to defer revascularization with FFR values over 0.75, although the study was small and the number of points in the intermediate range even smaller [9].

FFR values over 0.80 have over 90% sensitivity of excluding ischemia. The FAME and FAME II studies both used a 0.80 threshold, ostensibly to ensure potentially ischemic stenoses were not missed. FAME randomized patients to either FFR-guided revascularization in multivessel disease or an angiographic approach where all stenoses $\geq 50\%$ were stented; FFR reduced the number and length of stents placed and reduced the number of lesions considered significant (Figure 6.6) [10]. This led to an improvement in composite outcomes of death, myocardial infarction (MI), and repeat revascularization [10]. FAME II randomized those patients with confirmed $FFR \leq 0.80$ to PCI with optimal medical therapy or optimal medical therapy alone. Two-year follow-up suggested the composite of death, non-fatal MI, and revascularization was significantly lower with PCI than medical therapy when peri-procedural events were excluded, although the majority of the events were urgent revascularization and the trial was stopped early which could overestimate the benefits (Figure 6.6) [11].

Figure 6.6 Results of FAME and FAME II studies. FAME randomized patients with multivessel disease to a FFR or angiographic guided approach; stenoses with $FFR >0.80$ were deferred. FAME II randomized patients with a stenosis found to have an $FFR \leq 0.80$ to PCI with optimal medical therapy (OMT) or to OMT alone.

Therefore, it is typical for revascularization to be offered when stenoses have $\text{FFR} \leq 0.75$, while deferral is more likely when $\text{FFR} > 0.80$. For values in the “gray zone” (between 0.75 and 0.80), clinical judgment is required, combining knowledge of the patient’s clinical presentation, other investigations, and the impact of natural variability [23]. It is common practice to give additional doses of hyperemic agent when values are close to the threshold: higher doses can give confidence that maximal hyperemia has been achieved, but as flow is not being directly measured, caution is required because some changes can result from the hemodynamic disturbance of higher doses.

An area of great potential remains the use of FFR during routine clinical angiography rather than at the time of coronary intervention. Greater utility can be gained by performing multivessel physiologic assessment at the time of angiography to objectively delineate the clinical significance of any coronary atheroma. Studies suggest there could be significant changes in medical decision making with the additional information [24,25].

Clinical technique for assessment of FFR

FFR is measured using pressure-tipped guidewires (pressure wire) [3]. The pressure wire is introduced through a standard guiding catheter and positioned distal to the coronary stenosis being investigated under fluoroscopic guidance. Prior to passing the wire past the stenosis, effort should be made to ensure that the distal pressure trace (Pd) is equalized or “normalization” with aortic pressure trace

(Pa) at the origin of the vessel (left main stem or osmium of the right coronary artery) (Figure 6.7). If ostial stenosis is suspected, the wire will require normalization in the aorta. Measurements should be made with the needle-introducer fully closed to avoid minor pressure drift. Once the wire is passed past the stenosis, it is recommended that sensor is at least 2–3 vessel diameters away from the stenosis to reduce the impact of pressure recovery phenomena. Pd and Pa traces are displayed continuously, and either intravenous or intracoronary hyperemic vasodilator should be administered; FFR is then taken during a period of stability.

When there is diffuse disease, it is possible to move the pressure wire backwards by applying gentle traction to bring the sensor to the vessel osmium. This permits estimation of areas of large pressure drops if performed while continuous hyperemia is achieved—most easily with an intravenous infusion of adenosine.

The sensor should always be returned to the vessel ostium after assessment to exclude the presence of significant pressure wire or hemodynamic system drift which would make the measurement unreliable. Values of drift over 2 mmHg suggest the measurement should be repeated.

Caution is required when there are large hemodynamic shifts in aortic pressures caused by central adenosine infusions. Large falls in proximal aortic pressure cannot account for a significant proportion of the change in distal coronary pressure and can alter the FFR results. Caution should be taken to ensure ratios are calculated during stable hyperemia to match the original validation work. In some

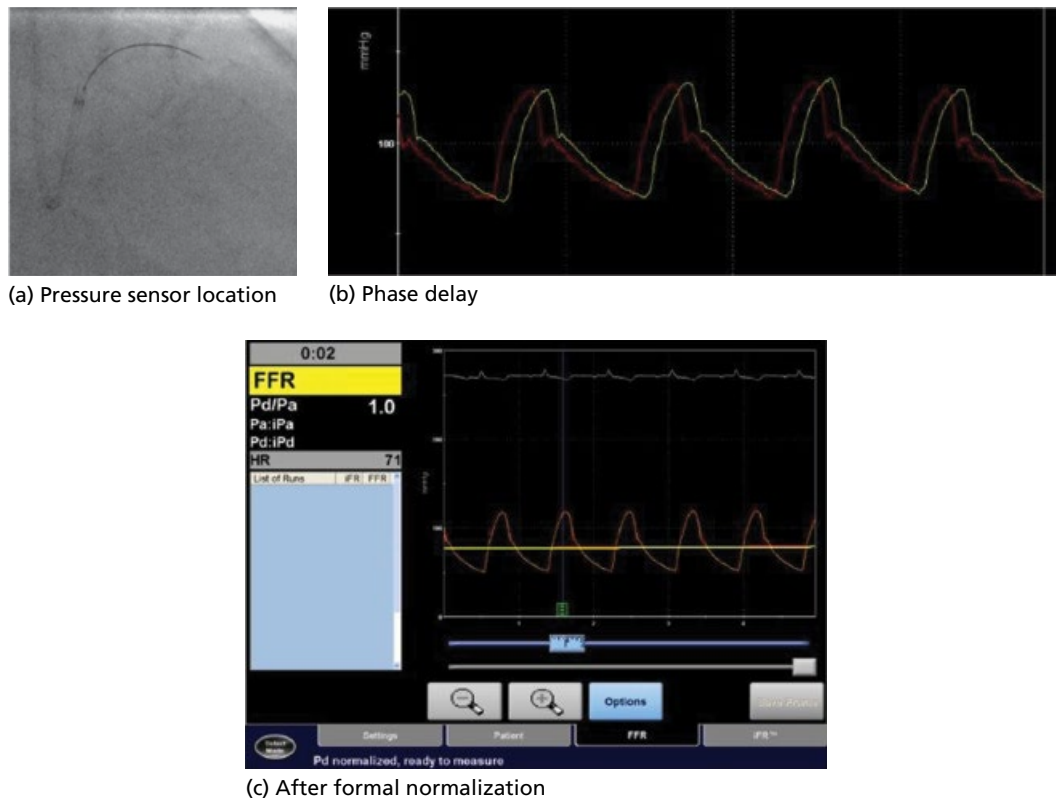

Figure 6.7 Active and phasic normalization. (a) The pressure wire sensor should be normalized at the ostium of the vessel. For most pressure wires the sensor is at the junction of the radiopaque marker. (b) There is a phase delay between proximal aortic pressure (Pa, red) and distal wire pressure (Pd, yellow); while the Pd/Pa ratio over the whole cycle is 1.0, during the wave-free period in diastole, the ratio is an erroneous 1.08 at the ostium. Therefore any measurements taken would be erroneous. (c) After the formal normalization process, the Pd and Pa are now aligned.

situations, the lowest FFR value can occur during the initial peak hyperemic phase causing a change in classification of stenosis significance [15]. Prolonged intravenous infusions of adenosine can cause paradoxical vasoconstriction of the microcirculation and the whole trace should be observed for a reliable value [26,27].

Clinical applications of FFR

FFR has been widely assessed in a number of different settings to assist clinical decision making. There are clinical studies utilizing FFR for the assessment of left main stem disease [28,29], side branch vessels, and for guiding surgical graft placement [30]. There remains limited data for the use of FFR within surgical grafts [31]. FFR has been used in patients with acute coronary syndromes with reasonable reproducibility, despite concerns that the microvasculature is not optimally responsive to adenosine shortly after infarction.

A number of studies have sought to correlate intravascular ultrasound (IVUS) or optical coherence tomography (OCT) parameters with FFR. Overall, the thresholds determined will be dependent upon the underlying population and the distribution of the FFRs studied. Although this avenue of research remains attractive to those wishing to minimize vessel instrumentation, tools, intracoronary imaging, and physiology offer complementary not mutually exclusive information to aid clinical decisions.

Instantaneous wave-free ratio

The instantaneous wave-free ratio (iFR) is a resting index of stenosis severity that quantifies the impact a stenosis upon the coronary circulation [32]. A pressure-only index, it is measured during the wave-free period in diastole. The wave-free period was determined using wave-intensity analysis, and is a period where the conflicting forces that control blood flow are quiescent, and microcirculatory resistance is at its lowest compared to whole cardiac cycle. As such, pressure and flow are linearly related over the wave-free period, enabling a resting pressure index to assess stenosis severity without the need of an exogenous vasodilator [32,33].

iFR is calculated in the same manner as FFR or other pressure-based approaches. Once the pressure sensor beyond the stenosis in question, iFR can be calculated as a single heart beat calculation, or an average over five heart beats. Initial commercial systems have required ECG monitoring to determine the correct phase in the cardiac cycle, but newer pressure-only algorithms remove this need.

The wave-free period is not significantly affected by beat-to-beat variability or atrial arrhythmias. Heart rates typical for performing physiologic assessment (40–130 bpm). Algorithms within the commercial consoles are capable of excluding inappropriate beats with a wide variability.

iFR can be plotted throughout the vessel during gentle pressure wire pullback to identify focal and diffuse disease throughout the vessel. The degree of information observed will depend partly upon the speed of pullback; 20–30 seconds typically suffices. As this information is acquired at rest, the degree of flow interaction that can occur between multiple stenoses during hyperemia is minimized [34]. This provides an additional advantage of an iFR-pullback approach, because it becomes possible to predict the hemodynamic effect of removing a stenosis (Figure 6.8) [35]. The residual resting gradients typically remain the same after coronary intervention because resting flow velocity changes little. In contrast, hyperemic pullbacks, while they can identify areas of high pressure gradient, cannot predict the hemodynamic impact of stenting because hyperemic pressure gradients change after the removal of a stenosis. This

novel additional information can facilitate a more physiologically guided coronary intervention than hitherto possible.

It is also possible to measure iFR during administration of a vasodilator such as adenosine. While this has consistently produced lower iFR values, many even lower than FFR, because the stability of resistance is unchanged there is no significant incremental diagnostic yield. It appears the information available at rest is sufficient. If used, a much lower threshold (0.66 for ischemia) must also be applied.

iFR in clinical trials

iFR has been compared with FFR in a number of studies, notably the ADVISE family of studies [32,36,37]. The degree of classification match is strongly dependent upon the distribution of lesions included with clinical cohorts demonstrating 80–88% match. The limit of match is driven by the capacity for FFR to match itself when repeated. This varies according to the technique and analysis route chosen but can be as much as 15% change in classification match when FFR is close to its threshold. When compared with third party markers of ischemia, including HSR, CFR, SPECT, and PET imaging, iFR and FFR are equal in their capacity to detect ischemia (Figure 6.9) [33,38–41].

Clinical outcome studies are underway in very large randomized controlled trials: DEFINE-FLAIR and the iFR-Swedeheart studies will compare clinical outcomes when patients undergo revascularization based upon either iFR or FFR.

Practical considerations of iFR measurement

When performing resting physiologic assessment, a rigorous standardized approach is necessary, encapsulated by the “3Ns”: nitrates, normalize, and no touch.

First is to administer intracoronary nitrates. Nitrates are required for all physiologic assessment to stabilize epicardial resistance, since the introduction of the pressure wire will cause a highly variable degree of spasm not always evident upon angiography. Typically, 300 μg is sufficient and this should be administered as soon as the guiding catheter is engaged, before the pressure wire is passed into the vessel. If time has elapsed between the last administration and a recording, it is usual to re-administer the nitrate. Nitrates do not cause significant or long-lived hyperemia; any increase in flow has returned to baseline within 30 seconds.

Second, “normalization” of the pressure wire at the vessel ostium is strongly recommended prior to passing the wire into the vessel in question. This should be performed with the introducer needle removed. Active normalization will not only ensure the pressure ratios are 1.0, but also ensure there is no time delay between proximal and distal pressure tracings. This is pertinent for phasic pressure analysis such as iFR, as time offsets will generate incorrect calculation (Figure 6.7).

Third, once the wire has been positioned in the location for measurement, there should be no further touching of the pressure wire. For optimal resting assessment, additional contrast injections should be avoided just prior to measurement of the index. If a contrast injection is necessary, it would be appropriate to wait 20 seconds to allow the impact of submaximal hyperemia to subside.

In the post-PCI state, either after ballooning or stenting, resting flow states have typically resumed by the time the balloon is withdrawn and the catheters have been flushed. In practical terms, there is no delay in the time required to make a resting measurement.

Other concerns that patient anxiety or conscious state affect resting measurements has not been found in practice. The ADVISE family of studies were all performed in typical patients attending the catheter laboratory without a specific protocol for sedation.

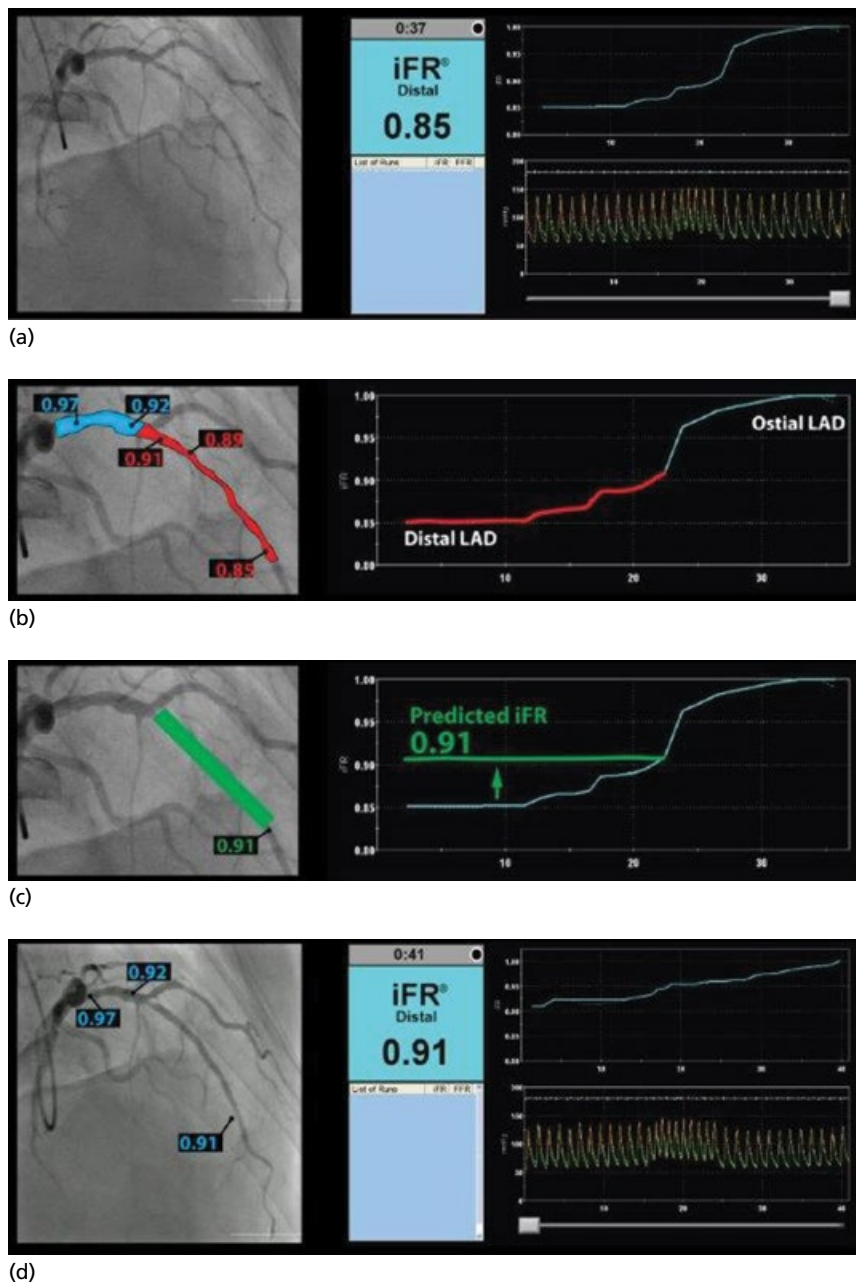

Figure 6.8 iFR pullback can be used to predict post-PCI iFR values. (a) The left anterior descending (LAD) has a moderate proximal stenosis and a long segment of moderate-to-severe disease. iFR is positive for ischemia. (b) The live beat-to-beat iFR-pullback suggests the proximal stenosis contributes 0.05 iFR units while the mid-vessel disease is 0.06. (c) Removing the mid-vessel disease is predicted to give an iFR of 0.91, above the treatment threshold. (d) Repeat iFR post-stenting the mid-vessel disease confirms an iFR of 0.91; pullback shows that proximal disease continues to contribute 0.05 pressure drop and can be deferred.

iFR has attraction in simplifying stenosis assessment by removing the absolute need for a vasodilator. This likely reduces cost, time, and patient discomfort from vasodilators. There is potential use in patients who cannot be given a vasodilator, such as those with allergy, severe airways disease, or with conditions that cannot tolerate hypotension—including aortic stenosis. Multivessel assessment and physiologically planned coronary intervention with assessment after intervention provide further potential scenarios.

Assessment of coronary microvascular function

The functional state of the coronary microcirculation has a strong prognostic role [4] and assessment of coronary microvascular function can assist in risk stratification of patients. Current approaches rely upon indirect assessment of the microcirculation: assessing a change in coronary flow in response to a specific agonist that evokes differential microvascular responses. Agonists are either endothelium-dependent (requiring an intact endothelium to

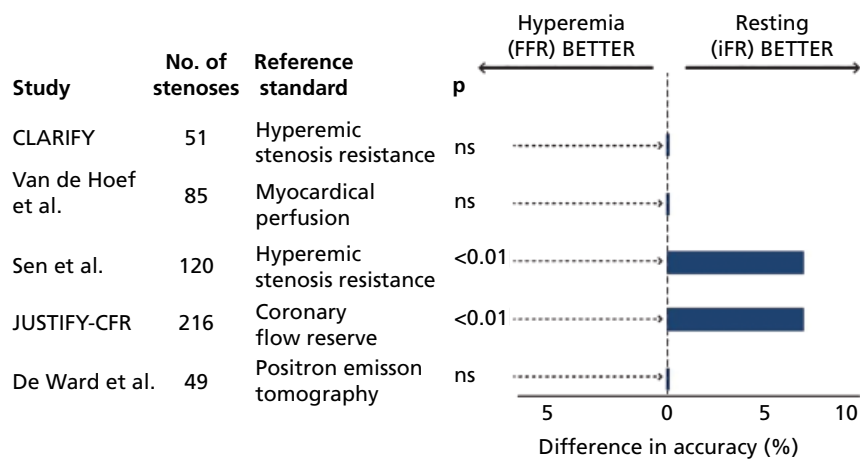

Figure 6.9 iFR and FFR compared with ischaemic parameters. Adenosine-free instantaneous wave-free ratio (iFR) has equivalent diagnostic accuracy to adenosine-mediated fractional flow reserve (FFR). In multiple studies where both parameters are compared to a third-party parameter of ischemia, including the gold standard of positron emission tomography (PET), there is no difference in the accuracy of either pressure index to detect ischemia.

function, such as acetylcholine, substance P, and bradykinin) or endothelium-independent (such as nitrate and nitroprusside) [42]. The level of change in coronary blood flow in response to a given agonist is inversely proportional to the functional state of the microcirculation.

Research approaches to assessing coronary microvascular function

The basic principle requires determination of blood flow in response to a microvascular agonist. Flow can be derived from the product of the cross-sectional area of the vessel and the average velocity of the fluid within: $\text{flow} = (\pi D^2/4) \times (0.5 \times \text{APV})$, where D is the diameter of the vessel measured using quantitative coronary angiography and APV is the average peak velocity measured using a Doppler guidewire. Vessel diameter measurements should be rigorously performed, over a 5-mm segment approximately 2.5 mm distal to the Doppler sensor. Following acquisition of baseline coronary flow, measurements should be repeated after delivery of the agonist, either as a continuous infusion through a guiding catheter together with an infusion pump or as an intracoronary bolus. The change in flow can be quantified as percentage change compared with baseline or hyperemic flow. The potential for error, from diameter measurements or inadequate flow velocity envelopes, is significant and care is required.

IMR: a clinical tool to assess microvascular function

IMR measures the resistance of coronary microvascular vessels and is derived from application of Ohm's law (that the potential difference across an ideal conductor is proportional to the current through the conductor) [43]. By neglecting the influence of venous pressure, IMR is determined by dividing hyperemic distal coronary pressure (P_d) by hyperemic flow; since it is typically derived using thermodilution techniques, it is readily calculated by the product of P_d with transit time (T_{mn}) under hyperemia [43]. A brisk injectant of 3 mL saline at room temperature should be used to determine transit times under maximal hyperemia, typically achieved using intravenous adenosine infusions (Figure 6.10).

Figure 6.10 IMR calculation. A combined pressure–temperature guidewire is used to obtain mean P_d and mean distal coronary blood flow (based on the principles of thermodilution in response to a 3 mL handheld intracoronary injection of room temperature saline). IMR is derived from the ratio of mean P_d (green circle) and mean distal coronary flow at maximal hyperemia. Distal coronary flow is inversely proportional to the mean transit time (T_{mn}) of the injectate. Therefore $\text{IMR} = P_d : 1/T_{mn} = P_d \times T_{mn}$.

IMR correlates significantly with true microcirculatory resistance measured in an open-chested pig model. In the presence of an epicardial stenosis, coronary wedge pressure should be included in the calculation ($\text{IMR} = P_a \times \text{hyperemic mean transit time} \times [(P_d - P_w)/(P_a - P_w)]$); this is particularly important in significant stenoses with an $\text{FFR} \leq 0.60$ where the likelihood of collateral flow is high. Mathematical derivation of P_w is also possible based upon the statistical relationship between FFR_{corr} and FFR_{myo} ; IMR can therefore be calculated as:

$$\text{IMR}_{\text{calc}} = P_a \times T_{mn} \text{Hyp} \times \left(1.35 \times P_d / P_a - 0.32\right) [20].$$

No threshold has been formally accepted and IMR can be considered a relative rather than absolute index. However, values below 25 have been found in two small healthy populations with normal

angiographic appearance to vessels [44]. After ST-segment elevation myocardial infarction (STEMI), patients with high IMR values (>40) are more likely to have raised cardiac enzymes, less cardiac recovery on non-invasive imaging, and evidence of microvascular obstruction on magnetic resonance imaging [45]. Values below 40 are associated with lower rates of death or rehospitalization for congestive heart failure or death alone. Active research is seeking adjunctive approaches to minimize microvascular dysfunction during STEMI and after elective intervention in stable patients as assessed by IMR. There may also be utility in using high IMR values to diagnose microvascular dysfunction as the cause of angina in patients with otherwise normal appearing coronary vessels.

Intravascular Ultrasound and Virtual Histology: Principles, Image Interpretation, and Clinical Applications

Adriano Caixeta¹, Akiko Maehara², and Gary S. Mintz²

¹Hospital Israelita Albert Einstein; Universidade Federal de São Paulo, São Paulo, Brazil

²Columbia University Medical Center and the Cardiovascular Research Foundation, New York, NY, USA

Medical uses of ultrasound came shortly after the end of World War II. However, real-time ultrasound imaging originated in the late 1960s and early 1970s when Bom *et al.* [1] pioneered the development of linear array transducers for use in the cardiovascular system. The first two-dimensional catheter imaging system was designed in 1972 using a solid-state transducer array of 32 elements arranged radially at the tip of a 9 Fr catheter [2]. By the late 1980s, Yock *et al.* [3,4] had successfully miniaturized a single-transducer system that could be placed within coronary arteries. Ever since, intravascular ultrasound (IVUS) has become an increasingly important catheter-based imaging technology providing both practical guidance for percutaneous coronary interventions (PCI) as well as many different clinical and research insights [5–10].

Coronary angiography has numerous limitations, including foreshortening and vessel overlap, high inter- and intra-observer variability when assessing lesion severity, and provides no details of plaque burden or composition. Conversely, IVUS directly images the atheroma within the vessel wall, allowing reproducible measurement of plaque size, distribution, and to some extent its composition. The application of IVUS as a prognostic tool and to guide coronary intervention is well established. IVUS has also provided new insights into the efficacy and safety of drug-eluting stent (DES). Thus, IVUS has been established as the method of choice for the serial assessment of atherosclerotic plaque burden in progression–regression trials.

Recent advances in IVUS technology permit identification of plaque composition and morphology using computed-assisted analysis of raw radiofrequency signal (e.g., virtual histology; VH). Several studies have emerged correlating these newer IVUS approaches with patient outcomes in a variety of clinical scenarios. This chapter reviews the rationale, technique, and interpretation of grayscale IVUS and VH imaging in diagnostic and therapeutic applications.

Principles of IVUS imaging

Ultrasound is acoustic energy with a frequency above human hearing. The highest frequency that the human ear can detect is approximately 20 thousand cycles per second (20,000 Hz). This is where the sonic range ends and where the ultrasonic range begins. In medical imaging, high-frequency acoustic energy is the range of

millions of cycles per second (megahertz; MHz). Current IVUS catheters used in the coronary arteries have frequencies ranging 20–45 MHz and 100–200 μm axial resolution [11].

IVUS supplements angiography by providing a tomographic perspective of lumen geometry and vessel wall structure. The equipment required to perform intracoronary ultrasound consists of a catheter incorporating a miniaturized transducer and a console to reconstruct the images. The IVUS transducer converts electrical energy into acoustical energy through a piezo-electric (pressure-electric) crystalline material that expands and contracts to produce sound waves when electrically excited (i.e., a series of pulse/echo sequences or vectors). After reflection from tissue, part of the ultrasound energy returns to the transducer; the transducer then generates an electrical impulse that is converted into moving pictures [12]. All materials in the body reflect sound waves. Sound waves bounce back at various intervals depending on the type of material and the distance from the transducer. It is the variation in reflective sound waves that creates the ultrasound image on the console.

The intensity of reflected (or backscattered) ultrasound depends on a number of variables including the intensity of the transmitted signal, the attenuation of the signal by the tissue, the distance from the transducer to the target, the angle of the signal relative to the target, and the density of the tissue [5]. Several clinically relevant properties of the ultrasound image—such as the resolution, depth of penetration, and attenuation of the acoustic—are dependent on the geometric and frequency properties of the transducer. The higher the center frequency, the better the axial resolution, but the lower the depth of penetration. For coronary imaging, because the transducer is close to the vessel wall, high ultrasound frequencies are used that are centered at 20–40 MHz. The use of high ultrasound frequencies provides axial resolution between 80 and 120 μm and lateral resolution (dependent on imaging depth and beam shape) between 200 and 500 μm [5].

Equipment for IVUS examination

Two different transducer designs are commonly used yielding comparable information: mechanically rotated and electronically activated phased-array. Mechanical probes use a drive cable to rotate a single-element transducer at the tip of the catheter at 1800 rpm.

At approximately 1° increments, the transducer sends and receives ultrasound signals providing 256 individual radial scan lines for each image. The mechanical transducer has the advantage of a simple design, greater signal-to-noise ratio, and higher temporal and spatial resolution. In electronic systems, multiple tiny transducer elements in an annular array are activated sequentially to generate the cross-sectional image [5,12].

The IVUS console contains numerous imaging controls such as zoom, gain, TGC (time-gain-compensation), gamma curves, compression and reject, and others. With both systems, still frames and video images can be digitally archived on local storage memory or a remote server using DICOM format.

Imaging artifacts

Artifacts often appear in images generated by contemporary IVUS devices and can interfere in imaging interpretation and measurements.

Ring-down

Ring-down artifacts usually appear as a series of parallel bands or halos of variables thickness surrounding the catheter obscuring near field imaging. Phased-array systems tend to have more ring-down artifacts (Figure 7.1).

Non-uniform rotational distortion

Non-uniform rotational distortion (NURD) arises from frictional forces to the rotating elements in mechanical catheters. NURD creates stretched or compacted portions of the images. Because accurate reconstruction of IVUS two-dimensional images is dependent on uniform rotation of the catheter, non-uniform rotation can create errors during IVUS measurements (Figure 7.1) [13]. For practical propose the mean lumen area tends to increase as the degree of distortion increases [14]. NURD artifacts can also occur because of bends in the catheter driveshaft or in the presence of acute bends in the artery.

Reverberations

Strong spatial tissue heterogeneity creates acoustic noise and pulse reverberations—multiple echoes reaching the transducer before the next pulse transmission to give rise to multiple copies of the

anatomy (Figure 7.1). Reverberation artifacts are more common from strong echoreflectors such as stents, guidewires, guiding catheters, and calcium (especially after rotational atherectomy).

Other artifacts

A few other artifacts can also interfere in IVUS interpretation; *side lobes* and *ghost* artifacts also generated from strong echoreflectors such as calcium and stent metal [5]. In longitudinal or L-mode display, catheter motion artifacts during the pullback results in a “saw tooth” appearance (Figure 7.2).

Catheter position also has an important role in image quality. Off-axis position of the catheter can alter vessel geometry in an elliptical fashion to mislead the operator to overestimate the lumen and vessel area [15]. Axial (antegrade–retrograde) movement of the IVUS probe during the cardiac cycle scrambles consecutive image slices that can have implications for three-dimensional reconstruction and attempts to assess coronary artery compliance [16].

Image acquisition and presentation

Two important consensus documents have been published: Standards for the acquisition, measurement, and reporting of IVUS studies: a report of the American College of Cardiology Task Force on Clinical Expert Consensus Documents [12] and the Study Group on Intracoronary Imaging of the Working Group of Coronary Circulation and the Subgroup on Intravascular Ultrasound of the Working Group of Echocardiography of the European Society of Cardiology [17].

IVUS is displayed as a tomographic cross-sectional view. A longitudinal view (L-mode or long-view) can be also displayed, but this should be done only when using motorized transducer pullback. Longitudinal representation of IVUS images is useful for lengths measurements, for interpolation of shadowed deep arterial structures (i.e., external elastic membrane behind calcium or stent metal).

There are advantages and disadvantages to using manual or motorized pullback; however, motorized pullback is usually preferable. Using motorized transducer pullback allows assessment of lesion length, volumetric measurements, consistent and systematic IVUS image acquisition among different operators, and uniform and reproducible image acquisition for multicenter and serial studies [18,19].

Figure 7.1 Three examples of artifacts. In (a), ring-down artifacts in an electronic-array system image, near-field bright halos (arrows) close to the face of the catheter can obscure the area immediately adjacent to the catheter. In (b), non-uniform rotation distortion (NURD) occurs only with mechanical systems. Part of the image is expanded causing deformation of the image in its circumferential view—the image appears elliptical (arrows). In (c), reverberations are repetitive echoes of the same structure. This is an example of reverberations from calcium. The arcs of calcium are indicated by the arrows **a**, and the false structures (reverberations) are indicated by arrows **b**.

In standard image acquisition after anticoagulation and intracoronary nitroglycerin administration, the IVUS catheter should be placed distal to the segment of interest (at least 10 mm of distal reference), and a continuous pullback to the aorta should be recorded. The preferred pullback speed is 0.5 mm/s.

Figure 7.2 Longitudinal image reconstruction (or L-mode) is shown. There is excessive motion of the transducer **a** relative to the artery, causing zigzag or sawtooth appearance (white arrows). This artifact is more of a problem with the right and circumflex arteries, because of the wide atrioventricular groove movement between systole and diastole.

Normal artery morphology

The ultrasound appearance of normal human arteries *in vitro* and *in vivo* has been reported [3,7,20–22]. In muscular arteries such as the coronary tree there are three layers: intima, media, and adventitia. Normal intima thickness increases with age, from a single endothelial cell at birth to a mean of 60 μm at 5 years to 220–250 μm at 30–40 years of age [23]. The definition of abnormal intimal thickness by IVUS is still controversial; in general, the threshold of “normal intimal thickness” is <300 μm (0.3 mm). The innermost layer of the intima is relatively echogenic compared with the lumen and media and displayed on the screen as a single bright concentric echo. The lower ultrasound reflectance of the media is due to its homogeneous smooth muscle cells distribution and smaller amounts of collagen, elastic tissue, and proteoglycans. The thickness of media histologically averages 200 μm , but medial thinning occurs in the presence of atherosclerosis [24]. In advanced atherosclerotic disease, the media may not appear as a distinct layer around the full circumference of the vessel; media thickness of coronary arteries is inversely related to lesion thickness [25]. The intima–media border is poorly defined because the intimal layer reflects ultrasound more strongly than the media. Conversely, the media–adventitia border, consistent with the location of the external elastic membrane (EEM), is accurately defined because a step-up in echo reflectivity occurs without *blooming*. The outermost layer, the adventitia, is composed of collagen and elastic tissue; it is 300–500 μm thick. The outer border of the adventitia is also indistinct due to echo reflectivity similar to the surrounding peri-adventitial tissues [13,21]. Therefore, the normal coronary artery is either (i) “mono-layered” in cases of intimal thickness <100 μm because of a 40 MHz IVUS catheter resolution is less than 100 μm ; or (ii) “three-layered” to include a bright echo from the intima, a dark zone from the media, and bright surrounding echoes from the adventitia (Figure 7.3).

Figure 7.3 Normal coronary artery morphology in cross-sectional view. In the magnified image on the right, the bright inner layer (intima), middle echolucent zone (media), and outer bright layer (adventitia) are representative of the “three-layered” appearance of intravascular ultrasound (IVUS). In the magnified image on the left, only the outer bright adventitial layer is representative of the “mono-layered” appearance.

Quantitative analysis

In non-stented lesions there are two strong acoustic interfaces that are well visualized by ultrasound: the leading edge of the intima and the outer border of the media (or media–adventitia junction). Therefore, two cross-sectional area (CSA) measurements can be defined by IVUS: the lumen CSA and the media–adventitia CSA (or EEM CSA). The atheroma or plaque&media (P&M) complex is calculated as EEM minus lumen; the media cannot be measured as a distinct structure. Thus, complete quantification of a non-stented lesion is possible by tracing the EEM and lumen areas of the proximal reference, lesion, and distal reference; calculating derived measures (minimum and maximum EEM and lumen diameters, P&M area and thickness, and plaque burden; P&M divided by EEM); and measuring lesion length (distance between the proximal and distal reference) (Figure 7.4).

In stented vessels, the stent forms a third measurable structure (stent CSA). It appears as bright points along the circumference of the vessel. Complete quantification of a stented lesion is possible by tracing the EEM and lumen areas of the proximal and distal reference and the EEM, lumen, and stent areas of the stented lesion; calculating derived measures (minimum and maximum EEM, stent, and lumen diameters; peri-stent P&M area and thickness; and intra-stent intimal hyperplasia [IH, area and %IH]); and measuring stent length. With the use of motorized pullback, area measurements can be added to calculate volumes using Simpson's formula.

Qualitative analysis

Grayscale IVUS has some ability to differentiate plaque composition based on different echorefectivity of the tissue. Atherosclerotic plaques are rarely homogeneous and contain a mixture of plaque components with different impedance (density). A standard approach is to compare the echointensity or “brightness” of the plaque to the surrounding adventitia that is used as a reference. Three basic types of lesions are distinguished according to plaque echogenicity: (i) “soft” or hypoechoic plaque does not reflect much ultrasound and appears dark with less echointensity compared to the adventitia (Figure 7.5); (ii) fibrous; and (iii) calcific plaques are characterized by equal or greater intensity than the adventitia. A plaque that is not so reflective as to cause shadowing is labeled “hard” or hyperechoic and is composed primarily of fibrous tissue (Figure 7.5). The presence of acoustic shadowing along with the brightest echoes and reverberations are characteristic of the presence of calcification (Figure 7.5).

Intimal hyperplasia due to in-stent restenosis often appears to have low echogenicity depending, in part, on age and adjunct therapies (i.e., brachytherapy) (Figure 7.6).

The identification of thrombus is difficult by IVUS. It may appear as lobulated hypoechoic mass within the lumen, scintillating echoes, a distinct interface between the presumed thrombus imaging and underlying plaque, and blood flow through the thrombus (Figure 7.7).

Figure 7.4 IVUS measurements pre-intervention in a non-stented artery. The proximal and distal reference and minimum lumen area (MLA) of the lesion are shown. The IVUS study is shown in duplicate: one unlabeled and one highlighted with lines to illustrate quantitative analysis. The dashed line highlights each external elastic membrane cross-sectional area (EEM CSA), and the solid line indicates each lumen interface (lumen CSA). The minimal lumen cross-sectional area (lumen CSA) at the lesion site is 2.1 mm². Between the EEM CSA and lumen CSA, the atheroma or plaque&media (P&M) complex is calculated.

Figure 7.5 A pure soft or hypoechoic plaque is uncommon because atherosclerotic plaques are rarely homogeneous. (a) shows an example of a predominantly soft plaque—a thin fibrous cap (small arrows) and lipid core underlying it; the plaque is less bright than the adventitia **a**. In (b), fibrous plaque or hyperechoic plaque is shown. Hyperechoic plaque is as bright as or brighter than the adventitia **a** without shadowing. In this eccentric plaque, the thickness of the media behind the thickest part of the plaque **b** is an artifact caused by attenuation of the beam as it passes through the hyperechoic plaque. In reality, the media becomes thinner with increasing atherosclerosis. Note that the media behind the thinnest part of the plaque is also thinner—without artifacts. (c) shows superficial calcium—defined as calcium **a** that is closer to the intima than it is to the adventitia. Calcium shadows the deeper arterial structures; in this case, the arc of calcification is $\sim 180^\circ$.

Figure 7.6 This patient presented with diffuse in-stent restenosis (white arrow on angiogram). Neointimal tissue is packed around the IVUS catheter at **a** and **b**, where the maximum amount of intimal hyperplasia occurs. There is also stent malapposition proximally (white arrows). Comparison of IVUS and angiography

Coronary angiography depicts the coronary anatomy as a longitudinal silhouette of the lumen. Conversely, IVUS with its tomographic perspective directly images the lumen, atheroma, and the vessel wall. Coronary angiography significantly underestimates the presence, severity, and extent of atherosclerosis compared to IVUS [19,26,27]. Furthermore, IVUS routinely shows significant atherosclerosis in angiographically “normal” segments in patients undergoing PCI [28]. This phenomenon may be explained by three major factors: (i) coronary atherosclerosis is often diffusely distributed involving long segments of the vessel containing no truly normal reference segment for comparison; (ii) complex atherosclerotic plaques are not appreciated by the two-dimensional “silhouette”; and (iii), most importantly, the presence of arterial wall remodeling [12]. In some circumstances diffuse, concentric, and symmetrical coronary disease can affect the entire length of

the vessel resulting in an angiographic appearance of a small artery with minimal luminal narrowing.

Coronary artery remodeling

Arterial remodeling of the vessel wall at the site of coronary plaques was originally described from necropsy examinations by Glagov *et al.* [29] and later validated *in vivo* by IVUS imaging [30]. “Positive,” “outward,” or “expansive” remodeling is defined as an increased in arterial dimensions; and “negative,” “inward,” or “constrictive” remodeling is defined as a smaller arterial dimension. Positive remodeling occurs as a compensatory increase in local vessel size in response to increasing plaque burden, especially during early stages of atherosclerosis [31]. An absolute reduction in lumen dimensions typically does not occur until the lesion occupies, on average, an estimated 40–50% of the area within the EEM (40–50% plaque burden) [29]. Conversely, negative remodeling has been

Figure 7.7 An unstable plaque before (white arrow in a) and after balloon angioplasty (b). A new post-balloon angioplasty filling defect at the origin of the acute marginal branch is shown (white arrow in b). Pre-intervention IVUS (c) shows a lobulated and penduculated thrombus **a** and a distinct interface with the underlying vessel wall **b**. Post-balloon angioplasty IVUS (d) shows the thrombus **c** that has embolized into the acute marginal branch **d**. Source: Mintz 2005 [5]. Reproduced with permission of Taylor & Francis.

implicated in the development of native significant stenosis in the absence of plaque accumulation (Figure 7.8) [32,33].

A number of definitions of remodeling have been proposed and published [12,30–36]. One definition compares the lesion EEM CSA to the average of the proximal+distal reference EEM CSA; positive remodeling is an index >1.0 and negative remodeling <1.0 . A second definition defines positive remodeling as a lesion EEM greater than the proximal reference EEM, intermediate remodeling as a lesion EEM between the proximal and distal reference EEM, and negative remodeling as a lesion EEM less than the distal reference EEM. Using a third definition, arterial remodeling has been calculated by a remodeling index (lesion/reference EEM); positive remodeling is an index >1.05 , intermediate remodeling is an index of 0.95 – 1.05 , and negative remodeling is an index <0.95 .

It is important to note that all of these remodeling definitions are based on a comparison of the reference EEM and lesion EEM. Accordingly, because both reference and lesion sites may have undergone quantitative changes in EEM during the atherosclerotic process, the evidence of remodeling derived from this index is relative and indirect. It depends on the definition of the reference, and the classification of an individual lesion depends on the definition used.

More recently, Inaba *et al.* [37], have reported a novel concept of remodeling, in which positive (RI >1.0) and negative (RI <0.88) lesion site remodeling was associated with unanticipated non-culprit lesion major adverse cardiac events in the PROSPECT study.

Unstable lesions

In patients with acute coronary syndromes, culprit lesions more frequently exhibit positive remodeling and a large plaque area; conversely, patients with a stable clinical presentation more frequently show negative remodeling and a smaller plaque area [34]. Echolucent plaques are also more common in unstable than in stable patients. In addition, unstable lesions have less calcium than stable lesions; and when present, calcific deposits in unstable lesions are small, focal, and deep [38]. Plaque ruptures can occur with varying clinical presentations although they are more often associated with acute coronary syndromes (Figure 7.9) [39]. Multiple ruptured plaques have been reported in patients with acute coronary syndromes; their prevalence, however, is the subject of controversy [40,41]. Typical IVUS features of acute myocardial infarction include plaque rupture, thrombus, positive remodeling, attenuated plaque, spotty calcification, and thin-cap fibroatheroma (Figure 7.10) [42].

Attenuated plaque is defined as hypochoic or mixed atheroma with deep ultrasound attenuation without calcification or very dense fibrous plaque. Wu *et al.* [43] reported that 78% of the patients with acute myocardial infarction had attenuated plaques in the Harmonizing Outcomes With Revascularization and Stents in Acute Myocardial Infarction (HORIZONS-AMI) trial. Lee *et al.* [44] documented that attenuated plaque was observed in 39.6% of patients with ST-segment elevation myocardial infarction (STEMI) and 17.6% of those with non-ST-segment elevation myocardial

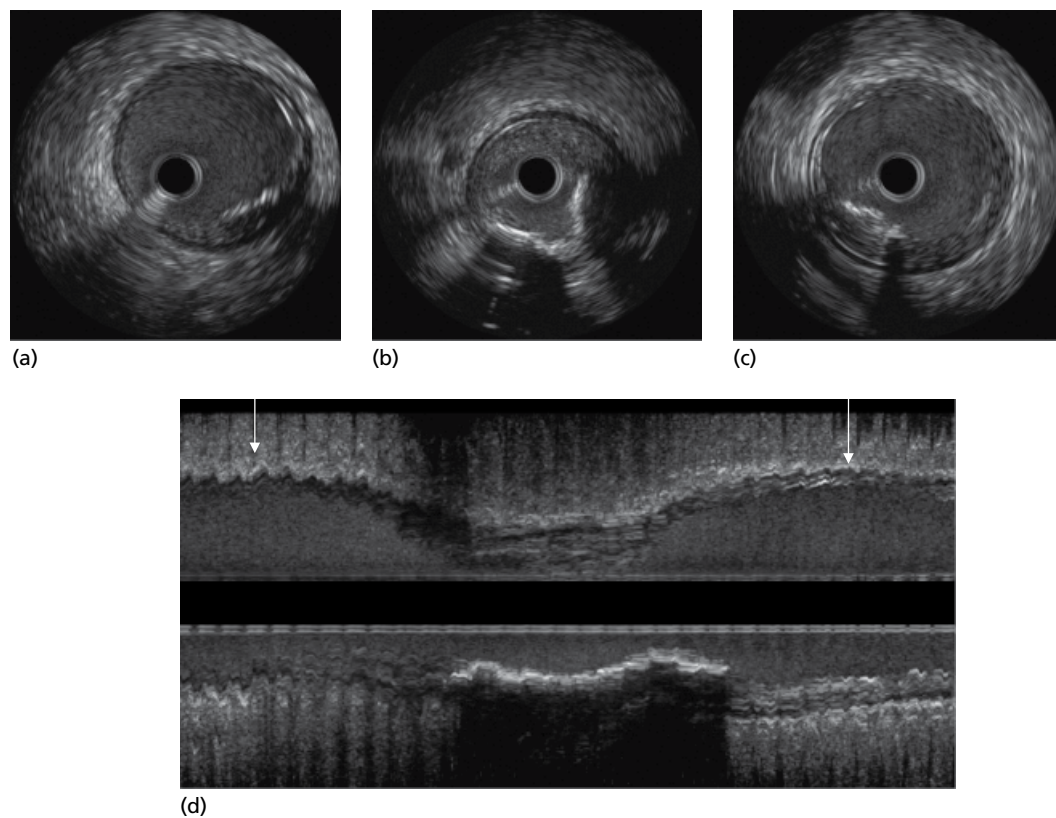

Figure 7.8 An eccentric, calcific, and small plaque accumulation leading to negative remodeling. (a) and (c) refer to proximal and distal vessel references and their respective longitudinal views (white arrows in d). In (b) notice how the vessel cross-sectional area (or EEM) is smaller than both the proximal and distal vessels. The longitudinal view depicts clearly the artery shrinkage at the lesion site.

Figure 7.9 This patient presented with an acute coronary syndrome and a complex right coronary lesion (white arrows) and disrupted plaque by IVUS. The IVUS imaging run shows the residual fibrous cap **a**, the evacuated plaque cavity **b**, and the true lumen containing the catheter **c**.

infarction (NSTEMI). Plaque ruptures and attenuated plaques are considered to be unstable and have been identified in both culprit and non-culprit lesions of patients with (STEMI) [45]. Histopathologically, the vast majority of attenuated plaques correspond to either a fibroatheroma with a necrotic core or pathologic intimal thickening with a lipid pool; almost all segments with superficial echo attenuation indicated the presence of a fibroatheroma with an advanced necrotic core [46]. Most importantly,

attenuated plaque has been associated with the occurrence of microvascular obstruction after primary PCI [47], no-reflow phenomenon [43], and with late acquired stent malapposition in patients with STEMI [48].

Intermediate lesions and left main coronary artery disease

Coronary angiography underestimates stenosis severity most markedly in arteries with a 50–75% plaque burden and in patients with multivessel disease [27,49]. In patients with stable coronary artery disease, fractional flow reserve (FFR) is the well-established physiologic index to assess the functional significance of a coronary stenosis. Recent studies have used $FFR \leq 0.80$ as the optimal cut-off point to guide revascularization [50,51], and have reported correlation between FFR values and anatomic parameters (specially minimum lumen area; MLA) derived from IVUS or optical coherence tomography (OCT) [52–59]. Of the IVUS-derived measurements, MLA cut-off values to predict FFR had been widely reported [60]. The correlation between MLA cut-off points and ischemic FFR threshold ranged from 2.0 to 3.9 mm² in non-left main coronary artery (LMCA) intermediate stenosis and from 4.5 to 5.9 mm² in LMCA stenosis [60]. The FIRST (Fractional Flow Reserve and Intravascular Ultrasound Relationship) study, based on a multicenter, prospective registry in the USA and Europe proposed 3.07 mm² as a best cut-off value to define the presence of myocardial ischemia [58]. In the largest sample-size and international multicenter study with 822 patients (881 lesions), Han *et al.* [59] found that best cut-off value of IVUS-MLA to define the functional

Figure 7.10 This patient presented with STEMI. Note a severe lesion in the angiogram after manual thrombectomy. The corresponding IVUS image shows the ruptured plaque cavity (a). Distal to the plaque rupture on the angiogram (b) is an echo-attenuated plaque; attenuation is defined as shadowing or attenuation of the ultrasound signal (loss of echoes) in the absence of calcification. Also note positive remodeling. Normal reference vessel with three-layer aspect (c).

significance ($\text{FFR} < 0.8$) to be 2.75 mm^2 , further subgroup analysis showed that ethnicity influenced on the cut-off value of MLA, it was 2.75 mm^2 in Asians and 3.0 mm^2 in Westerners. A meta-analysis of 11 studies comparing IVUS-MLA with FFR for assessment of intermediate lesions showed that the weighted overall mean MLA cut-off was 2.61 mm^2 in non-LMCA and 5.35 mm^2 in LMCA to predict a functional stenosis [61].

LMCA atherosclerosis is often underestimated by coronary angiography. Several studies have showed that a very high percentage of patients with angiographically normal LMCA have disease by IVUS [62–64]. Conversely, only that half of angiographically ambiguous LMCA stenosis had a significant stenosis, especially in ostial lesions [65]. The main reasons for the discrepancy between angiography and IVUS are the following: (i) diffuse atherosclerotic plaque involvement may lead to a lack of a normal reference segment; (ii) a short LMCA makes identification of a normal reference segment difficult; (iii) the presence of arterial remodeling; (iv) the correlation between angiography and necropsy or IVUS appears to be better in non-LMCA lesions possibly because of unique geometric issues in the LMCA [66]; and (v) significant inter- and intraobserver variability in the angiographic assessment of LMCA disease [67], especially in ostium location [68].

Other unusual lesion morphology

During coronary angiography it is common to encounter unusual appearing lesions that elude accurate characterization despite thorough examination using multiple radiographic projections. The use of IVUS allows accurate characterization of unusual morphology: filling defects, aneurysms, and spontaneous dissections. While most filling defects are true thrombi, a small percentage are highly calcified plaque (Figure 7.11) or even calcified nodules, an unusual form of vulnerable plaque.

In an IVUS analysis of 77 angiographically diagnosed aneurysms, 27% were true aneurysms (Figure 7.12), 4% were pseudo-aneurysms (Figure 7.13), 16% were complex plaques, and 53% were normal arterial segments adjacent to stenoses [59].

By IVUS, a spontaneous dissection appears as a medial dissection with an intramural hematoma occupying some or all of the dissected false lumen without identifiable intimal tears and without a communication between the true and false lumens, typically in a non-atherosclerotic artery.

In-stent neoatherosclerosis has been recently described as an important mechanism of late stent failure (i.e., restenosis and stent thrombosis). The development of neoatherosclerosis appears to occur more frequently and much earlier following DES than bare

Figure 7.11 Diagnostic IVUS was performed to assess this angiographic filling defect at the proximal right coronary artery (white arrow in the angiogram). The IVUS imaging run begins at the ostium **a** of the right coronary artery to beyond the filling defect **b**. Note the calcification (white arrow in the IVUS) without lumen compromise. metal stent (BMS) implantation. Importantly, fibrous cap thickness negatively correlates with follow-up time, especially after DES [69].

Guidance for stent implantation

Stent sizing

Pre-interventional IVUS is performed to assess stenosis severity and plaque composition and distribution, measure reference vessel size, and measure lesion length. As a result, stent size can be chosen more accurately than solely by angiography. There are a number of paradigms that can be used. Stent size can be selected by identifying the maximum reference *lumen* diameter (proximal or distal to the lesion); it results in stent upsizing without an increase in complications. At the other extreme, stents can be sized to the “true vessel,”

“media-to-media,” or mid-wall dimensions to reflect the amount of angiographically silent disease and, in most cases, the extent of positive remodeling, not just vessel size. Typically, this measurement will be larger than reference *lumen* reference and, thus, should be used only by experienced operators who understand its limitations.

IVUS measures lesion length more accurately than angiography because IVUS eliminates foreshortening, vessel tortuosity, or bend points.

Stent expansion and malapposition

IVUS studies have shown that lumen enlargement after stent implantation is a combination of vessel expansion and plaque redistribution/embolization, not plaque compression [70–72]. Plaque

reduction in patients with acute coronary syndromes is attributed to plaque or thrombus embolization. Intrusion or prolapse of plaque through the stent mesh into the lumen is more common in acute coronary syndromes and in saphenous vein graft lesions. Importantly, after stent implantation there is a significant residual plaque burden behind the stent struts that almost always measures 50–75% at the center of the lesion. Thus, the stent CSA always looks smaller than the EEM even when the stent is fully expanded.

Apposition refers to the contact between the stent struts to the arterial wall. Incomplete stent apposition is defined as one or more

struts clearly separated from vessel wall with evidence of blood speckles behind the strut (Figure 7.14). There is no conclusive evidence suggesting that isolated acute incomplete stent apposition (in the absence of concomitant underexpansion) is associated with adverse clinical outcomes. The incidence of post-procedural incomplete stent apposition with DES has been reported comparable to that with BMS, ranging from 7.0% to 16.2% [73,74].

IVUS-guided stent implantation and predictors of restenosis and thrombosis

The two main uses of IVUS are to insure optimal stent expansion (stent CSA) and full coverage of the lesion (especially with DES implantation). In the majority of pre-DES studies, IVUS use optimized stent expansion; and the initially larger minimum stent area (MSA) achieved was associated with a lower restenosis rate [75–83]. In a meta-analysis by Parise *et al.* [84] evaluating 2193 patients from five randomized studies, IVUS guidance was associated with a significantly larger post-procedure angiographic minimum lumen diameter (MLD), and was also associated with a significantly lower rate of 6-month angiographic restenosis, a significant reduction in the revascularization rate, and overall major adverse cardiac events.

At the introduction of DES, the importance of optimal stent deployment was initially underestimated. Suboptimal stent expansion with both BMS and DES was a risk factor for restenosis and target vessel revascularization, but also for stent thrombosis [85–88]. Roy *et al.* [89] reported that IVUS guidance during DES implantation had the potential to reduce both DES thrombosis and the need for repeat revascularization. In this study, 884 patients undergoing IVUS-guided DES implantation were compared with 884 propensity-score matched patients undergoing DES implantation with angiographic guidance alone. At 30 days and at 12 months, a lower rate of definite stent thrombosis using the ARC definition was seen in the IVUS-guided group (0.5% vs. 1.4%; $p=0.046$) and (0.7% vs. 2.0%; $p=0.014$), respectively. At 1 year, target lesion revascularization (TLR) was also lower in the IVUS-guided group (5.1% vs. 7.2%; $p=0.07$). A multicenter MAIN-COMPARE registry of LMCA interventions showed that in 201 matched pairs of the overall population, patients treated with IVUS-guided DES implantation had better 3-year survival than patients in whom IVUS was not used to guide LMCA DES implantation (4.7% vs. 16.0%, log-rank $p=0.048$). Finally, a recent meta-analysis of outcomes after IVUS-guided vs. angiography-guided DES implantation in 26,503 patients enrolled in three randomized trials and 14 observational studies,

Figure 7.13 This patient underwent a previous directional coronary atherectomy of a lesion, in the left anterior descending artery, during which the artery was perforated. Follow-up catheterization showed both restenosis and a large aneurysm on angiography. The IVUS shows the body of the aneurysm **a** and the eccentric proximal restenotic lesion **b**. Notice that the adventitia stops at the point of transition from the vessel to the aneurysm **c**, indicating loss of vessel wall integrity and making this, in fact, a pseudoaneurysm. Source: Mintz 2005 [5]. Reproduced with permission of Taylor & Francis.

Figure 7.14 Acute stent malapposition. Notice the space between the stent strut and the intima and the blood speckle behind the stent struts **a**. Five stent struts are malapposed (white arrows). Because of stent malapposition, the stent area (9.4 mm^2) is smaller than the lumen area (14.4 mm^2). The post-stent implantation IVUS image is shown in duplicate.

demonstrated that IVUS-guided PCI was associated with a significantly lower risk of TLR (odds ratio (OR) 0.81, 95% CI 0.66–1.00; $p=0.046$). In addition, the risk of death (OR 0.61, 95% CI 0.48–0.79; $p < 0.001$), MI (OR 0.57, 95% CI 0.44–0.75; $p < 0.001$), and stent thrombosis (OR 0.59, 95% CI 0.47–0.75; $p < 0.001$) were also decreased [90].

Complications

IVUS has a higher sensitivity than angiography in identifying complications that can occur during PCI. Angiography tends to underestimate the presence and extent of dissection. Stent edge dissections are common because the junction between stent metal and reference segment tissue is a site of compliance mismatch. Edge dissections are more common when the stent ends in a reference segment that contains: (i) both plaque and normal vessel wall; or (ii) both calcific (or hard) and soft plaque elements (Figure 7.15). Dissection may not be visible by IVUS if the true lumen is severely stenotic and the ultrasound catheter presses the flap against the arterial wall or if the dissection occurs behind a calcified plaque that prevents accurate morphologic definition. In general, the treatment of coronary dissection with stent implantation depends on the combination of angiographic assessment, flow assessment, and signs or symptoms of ischemia, and residual IVUS MLA. Treatment of dissections

should be based on IVUS findings when they show evidence: (i) reduced lumen dimensions below the threshold for an optimum result; (ii) impingement of the dissection flap on the IVUS catheter; (iii) mobility; and (iv) increased length. In general, minor edge dissections should not be treated unless they result in lumen compromise; the vast majority have healed when imaged at follow-up.

Intramural hematoma is a variant of dissection. Blood accumulates in the medial space; the EEM expands outward, and the internal elastic membrane is pushed inward to cause lumen compromise. Intramural hematomas are typically hyperechoic and crescent-shaped, with straightening of the internal elastic membrane [91]. In general, an intramural hematoma should be treated because of the propensity for propagation and lumen compromise.

Coronary perforation and rupture usually occurs with over-aggressive and/or oversized balloon dilatation although it can occur with a guidewire and stenting as well. In general, there are three distinct IVUS morphologic patterns indicating arterial rupture: (i) free blood speckle outside the EEM (Figure 7.16); (ii) extramural hematoma—an accumulation of blood outside the EEM; and (iii) less common, a new peri-adventitial echolucent interface representing contrast extravasation [3]. Acute management includes conservative strategy of monitoring to prolonged balloon inflations, covered stents, and surgery.

Figure 7.15 This patient presented with proximal edge dissection after coronary stenting. (a) depicts the proximal reference segment, which contains mild plaque. (e) shows the stent. Notice the tear into the lumen (arrow) and the dissection reaching the medial layer of the vessel (b, c, and d).

Figure 7.16 This patient presented with in-stent restenosis. After balloon dilatation, coronary perforation with myocardial contrast extravasation occurred, as seen by angiography (arrows). On IVUS, notice the small vessel with stenting at a distal site (image e) and the medial and adventitial discontinuation at the site of perforation (images b, c, and d, and arrows). Notice also an accumulation of blood outside the EEM **a**. One stent graft was implanted prior to IVUS assessment (image a), followed by an additional stent graft after IVUS assessment.

Serial IVUS studies of restenosis

Restenosis

Serial IVUS studies have shown that the main mechanism of restenosis in non-stented arteries is negative arterial remodeling (decrease in EEM area), not intimal hyperplasia [33]. Conversely, in-stent restenosis is primarily due to neointimal proliferation, not chronic stent recoil. By IVUS, %IH (IH volume divided by stent volume) has been shown to be consistent for each stent type. DES reduce restenosis by reducing IH from an average of 30% in BMS [92] to 3–5% in sirolimus-eluting stents (SES) [93,94], to 8–13% in polymer-based paclitaxel-eluting stents [95], 16% in zotarolimus-eluting stents [96], and to 6% in everolimus-eluting stents [97].

Stent underexpansion is a common finding in restenotic stents. It is the result of poor expansion at implantation, not chronic stent recoil. In an analysis of over 1000 patients with BMS restenosis, 15% had a MSA <4.5 mm² and 25% had a MSA of 4.5–6.0 mm². In addition, in 4.5% there were technical and mechanical complications of stent implantation that contributed to the restenosis. Examples of mechanical complications have included (i) missing the lesion (e.g., an aorto-ostial stenosis); (ii) stent “crush” (Figure 7.17); (iii) having the stent stripped off the balloon during the implantation procedure; or (iv) DES fracture (Figures 7.18 and 7.19) [98,99].

Acquired late stent malapposition

Late stent malapposition (LSM) is usually caused by regional vessel positive remodeling (Figure 7.20). LSM has been reported in 4–5% after BMS implantation [74,100]. Studies have suggested a higher incidence of LSM after DES (especially after first-generation DES) [101–105].

Hong *et al.* [74] showed *in vivo* that BMS implantation during primary PCI was an independent predictor of late incomplete stent apposition (ISA), but it was not linked to increased rates of adverse events at 3-year follow-up. Hoffmann *et al.* [103] studied the impact of LSM after SES implantation on 4-year clinical events. This pooled IVUS analysis from three randomized trials comparing SES with BMS showed that LSM at follow-up was more common after SES than after BMS (25% vs. 8.3%; $p=0.001$); however, major adverse cardiac event free survival at 4 years was identical for those with and without LSM (11.1% vs. 16.3%, $p=0.48$), and LSM was not a predictor for target lesion revascularization, target vessel failure, or late stent thrombosis during the 4-year follow-up period in either patient group.

Conversely, others have suggested that LSM can contribute to late stent thrombosis [106,107]. Cook *et al.* [107] studied 13 patients presenting with very late stent thrombosis (>1 year) after DES implantation and compared them with 144 control patients who did not experience stent thrombosis. Compared with DES controls,

Figure 7.17 Stent crush at the right coronary artery detected at IVUS follow-up. Two stents have been implanted with a gap between them **a**. The proximal edge of the second stent has been crushed as shown on IVUS (arrows) but not on angiography.

Figure 7.18 This patient presented with restenosis at follow-up after Cypher™ stent implantation in the right coronary artery (arrows on angiogram). Note the stent fracture with acquired transection on fluoroscopy. On IVUS, all stent struts are seen at proximal and distal references, whereas at the fracture site only one stent strut is seen (arrow).

Figure 7.19 Stent fracture by coronary CT angiography and IVUS (arrows) at the ostial right coronary artery 1 year after Xience V everolimus-eluting stent.

Figure 7.20 This patient underwent sirolimus-eluting stent (Cypher™) implantation in a right coronary stenosis. The final angiogram is shown in (a) and (b). At follow-up (c and d), there was a proximal and focal angiographic aneurysm (white arrows). Final (post-stent implantation) IVUS image is shown in (e), and the follow-up IVUS image is shown in (f). Note the late stent malapposition (a and b). At the site of maximum stent malapposition (b), there has been an increase in EEM CSA from 17.8 to 28.9 mm². The stent CSA (8.8 mm²) and the peri-stent P&M (8.9 mm²) have not changed. Source: Mintz GS, Weissman NJ. Intravascular ultrasound in the drug-eluting stent era. *J Am Coll Cardiol* 2006; **48**(3): 421–429.

patients with very late stent thrombosis had longer lesions and stents, more stents per lesion, and more stent overlap. Vessel cross-sectional area was significantly larger for the in-stent segment (28.6 ± 11.9 vs. 20.1 ± 6.7 mm²; $p=0.03$) in very late stent thrombosis patients compared with DES controls, denoting evidence of positive arterial remodeling. Although IVUS was not performed at stent implantation in any patients of either group, incomplete stent apposition was more frequent (77% vs. 12%, $p < 0.001$) and maximal incomplete stent apposition area was larger (8.3 ± 7.5 vs. 4.0 ± 3.8 mm²; $p=0.03$) in patients with very late stent thrombosis compared with controls. Guagliumi *et al.* [108] demonstrated by combined IVUS and OCT assessments that the presence and magnitude of incomplete stent apposition were significantly higher in patients with DES thrombosis than in those without. Alfonso *et al.* [109] also identified ISA in patients with ST using IVUS and OCT (ISA was identified in 40% and 47% of patients, respectively). Kang *et al.* [110] performed OCT imaging in 33 patients with very late ST and found that in the DES group, 52% and 64% had ISA and thrombi, respectively, whereas no patients presented with ISA in the BMS group.

Flow disturbances and risk of delayed strut coverage both increase with incomplete stent apposition, especially with detachment distance >100 μ m; suggesting a role of ISA in the pathogenesis of late stent thrombosis. Nevertheless, based on these studies with conflicting data, it is still speculative as to how to treat patients with IVUS or OCT findings of LSM.

Blood-free environment obtained during OCT image acquisition along with its higher axial resolution provides a sharper delineation of the stent–lumen interface compared with IVUS [105]. Several studies demonstrated that OCT is superior to IVUS in detecting ISA. Yet, OCT allows a cross-sectional and longitudinal level of assessment of strut-level analysis, which enables the diagnosis and quantification of ISA in each individual strut—and IVUS does not. Although IVUS and OCT complement each other in the identification and characterization of ISA, OCT should be preferred in clinical practice, especially in an era of bioresorbable vascular scaffold (BVS) (Figure 7.21).

Virtual histology and IVUS radiofrequency

The major limitation of IVUS is its limited spatial resolution (axial resolution of 100–200 μ m and a lateral resolution of 250 μ m). Although it can visualize deep structures, IVUS is not a suitable imaging modality for detecting thin fibrous cap that is one of the main components of vulnerable plaques (TCFA). Grayscale IVUS not only accurately assesses plaque composition, but atherosclerotic plaques in most cases have a complex and heterogeneous composition consisting of a mixture of plaque components [111]. These limitations have been partially overcome by analysis of the IVUS acoustic signal before demodulation and scan conversion. There are three modalities currently available: virtual histology IVUS (VH-IVUS, Volcano Therapeutics, Rancho Cordova, CA, USA), iMAP-IVUS

Figure 7.21 This patient underwent Absorb bioresorbable vascular scaffold implantation in proximal left anterior descending (LAD) and first diagonal. Co-registered images by optical coherence tomography (OCT) and IVUS after device implantation; OCT shows mild incomplete scaffold malapposition and dissection behind the strut at 8 o'clock (C); IVUS was unable to identify.

(Boston Scientific, Santa Clara, CA, USA), and integrated backscatter IVUS (IB-IVUS, YD, Nara, Japan).

To date, only VH-IVUS has been commercialized in the USA, utilizing a spectral radiofrequency analysis of the backscattered ultrasound signal with a classification algorithm developed from *ex vivo* coronary datasets [112]. The reported accuracies are 91% for calcified regions, 93% for fibrofatty regions, 90% for necrotic regions, and 90% for fibrous regions. VH-IVUS classified tissue as fibrous tissue (dark green), fibrofatty tissue (light green), necrotic core (red), and dense calcium (white) and lesions as pathologic intimal thickening (PIT), fibrotic, fibrocalcific, thick-cap fibroatheroma (ThFA), or thin-cap fibroatheromas (TCFA) (Figure 7.22) [113,114].

VH-IVUS data are collected with a 20-MHz, 2.9 Fr phased-array transducer catheter (Eagle Eye™ Gold, Volcano Therapeutics, Rancho Cordova, CA, USA) that acquires IVUS data that are ECG-gated.

The potential value of VH-IVUS-derived plaque types in the prediction of future adverse coronary events was evaluated in the Providing Regional Observations to Study Predictors of Events in the Coronary Tree (PROSPECT) study [115]. This 697 patients study demonstrated that non-culprit lesions associated with

recurrent events were more likely than those not associated with recurrent events to be characterized by a plaque burden of $\geq 70\%$, a minimal luminal area of $\leq 4.0 \text{ mm}^2$, or to be classified as TCFA. Conversely, non-fibroatheroma lesions were clinically stable and were rarely associated with clinical events during 3 years of follow-up [116]. In the VIVA study, Calvert *et al.* [117] analyzed 170 patients who were prospectively enrolled and underwent three-vessel VH-IVUS pre-PCI and also post-PCI in the culprit vessel. Non-culprit lesion factors associated with non-restenotic major adverse cardiac events (MACE) included VH-TCFA and plaque burden $>70\%$. In addition, VH-TCFA, plaque burden $>70\%$, and MLA $<4 \text{ mm}^2$ were associated with total MACE. Thus, as shown in the PROSPECT and VIVA studies, prospective identification and characterization of atherosclerotic non-culprit lesions in the coronary arteries is feasible with VH-IVUS and is predictive of adverse cardiovascular future events.

Plaque composition detected by VH-IVUS was also associated with the occurrence of distal embolization after PCI. Several studies showed a relationship between the amount of necrotic core and distal embolization [118].

Another commercially available system (outside of the USA) is the iMAP software, which uses a 40-MHz single rotational

Figure 7.21 (Continued)

Figure 7.22 Five types of phenotypes documented by virtual histology IVUS (VH-IVUS). From left to right, thin cap fibroatheroma (TCFA), thick cap fibroatheroma (ThCFA), pathologic intimal thickening (PIT) and fibrocalcific plaques.

transducer (Atlantis™ SR Pro, Boston Scientific) to obtain the radiofrequency signal. iMAP uses a pattern recognition algorithm on the spectra that were obtained from fast Fourier transformation of the backscattered signals. *Ex vivo* validation demonstrated accu-

cies at the highest level of confidence as: 97%, 98%, 95%, and 98% for necrotic, lipidic, fibrotic, and calcified regions, respectively (Figure 7.23) [119]. Preliminary study by our group has shown that the software can appropriately identify TCFA in patients with acute

Figure 7.23 Various types of plaque composition (a–h). (a) plaques tissue composition by iMAP. Fibrotic tissue (green) and necrotic core (red) are the main tissue component (ThCFA), in which necrotic core represents 27% of total area of the plaque. (b) necrotic core abutting to the lumen with superficial calcification (from 8 to 10 o'clock; TCFA). (c) ThCFA with calcification at 3 o'clock. (d) necrotic core and fibrotic tissue. (e) mild atherosclerosis with calcification (blue). (g) and (h) Fibroatheromas.

myocardial infarction. However, it is limited by the wire artifact, which overestimates the tissue component of the necrotic core [120]. A prospective natural history study of vulnerable atherosclerotic plaque using iMAP is lacking.

Integrated backscatter (IB) analysis is another tissue classification scheme based on radiofrequency analysis of the reflected ultrasound signal. Comparison of IB-IVUS to histopathology demonstrated that the sensitivity of IB-IVUS for characterizing lipid pool, fibrosis, and calcification was 84%, 94%, and 100%, respectively, with specificity of 97%, 84%, and 100%, respectively. This system has been also shown capable to identify TFCA, and potentially be used to identify lesions with an elevated risk of myocardial infarction after PCI [121,122].

Conclusions

Grayscale IVUS provides (i) high quality, tomographic imaging of the lumen, the atheroma, and the vessel wall; (ii) incremental and more detailed qualitative and quantitative information than coronary angiography; (iii) practical guidance for percutaneous coronary intervention; and (iv) many clinical and research insights. IVUS has become an important part of DES studies, representing an effective way to understand the mechanisms, effects, and complications of stent technology. Grayscale IVUS may not accurately assess plaque composition. Variations of the traditional grayscale IVUS technique permit more detailed tissue characterization of atherosclerotic plaques. The most commonly technique used is referred to as VH-IVUS, which is based upon the radiofrequency analysis of the backscattered ultrasound signal. Development of novel techniques, including IVUS and near-infrared spectroscopy has great potential to improve our current ability to identify plaques at higher risk of rupture.

Optical coherence tomography

Intravascular optical coherence tomography (OCT) has emerged in recent years. This technology, originally described in the early 1990s by David Huang, was first applied in the field of ophthalmology [1] and named OCT by James Fujimoto. In 1996, Brezinski *et al.* [2] published on the possibility of imaging coronary arteries with an OCT device. Subsequent advances in OCT technology enabled faster image acquisition rates, sufficient for its *in vivo* application in humans.

OCT is a high-resolution imaging technology that employs a bandwidth in the near-infrared spectrum with wavelengths ranging from 1250 to 1350 nm to probe micrometer-scale structures in combination with advanced fiber-optics to create images. The light that illuminates the vessel is absorbed and backscattered, or reflected, by the structures in tissue at different degrees, and images are formed by measuring the magnitude and time delay of a reflected backscattered light signal in a manner analogous to intravascular ultrasound (IVUS) [3]. The speed of light (3×10^8 m/s) is several orders of magnitude faster than that of sound (1.5×10^3 m/s), and in OCT an interferometer is used to transmit the reflected light signal [4]. The interferometer shares the light source in two arms: a reference arm and a sample arm, which is directed toward the tissue. The images are created comparing the back-reflected optical signal from the two arms (interference signal). Compared with IVUS, OCT offers a 10 times higher image resolution (with an axial resolution of 10–20 μm); however, this high resolution is at the expense of reduced penetration depth into tissue and the need to create a transient blood-free field of view during imaging acquisition. The tissue penetration is limited to 1–3 mm compared to 4–8 mm achieved by IVUS.

OCT system

Early commercially available versions of the technology used time domain (TD) detection, while the second generation systems using Fourier domain (FD) has significantly improved the signal-to-noise ratio and allows high speed pullbacks with faster acquisition [5].

Time domain OCT

The M2/M2x TD-OCT Imaging System (ImageWire™ LightLab Imaging Inc., Westford, MA, USA) was the first commercially available OCT system. The first generation OCT (ImageWire™ and M2/3 OCT system; LightLab Imaging Inc.) incorporated an OCT imaging wire and an over-the-wire occlusion balloon. The OCT imaging wire had a maximum outer diameter of 0.019 inch (with a standard 0.014 inch radiolucent coiled tip) and contained a single-mode fiber-optic core within a translucent sheath. An over-the-wire low-pressure occlusion balloon with distal flush ports was used to infuse saline at approximately 0.5 mL/s to selectively displace blood during acquisition [6]. Attempts were made to switch to a non-occlusive technique for OCT image acquisition using a flexible catheter with a short monorail distal lumen, injecting manually or via a power injector through the guiding catheter. Because of the slow speed of acquisition, the automatic pullback speed had to be set between 1.0 and 3.0 mm/s, with cross-sectional images being acquired at up to 20 frames/s resulting in 7 frames/mm or pitch of 142 μm [6]; however, maximal pullback length under 20–30 mm, the maximal duration that flushing can be expected to last, was inadequate for routine use.

Fourier domain OCT

Fourier domain OCT (FD-OCT) (Dragonfly Duo™ St. Jude/LightLab Imaging Inc., and Fastview Terumo, Lunawave®) is the new generation of OCT systems which enables rapid imaging of the coronary arteries without occlusive acquisition. There are two types of FD-OCT; spectral domain OCT (SD-OCT), which relies on a broadband light source, and a spectrometer as a detector. In the latter, the light source is a wavelength-swept laser and receiver comprises single-element photodiodes. A frequency shifter is typically used to resolve otherwise degenerate positive and negative depths to the reference arm path length. These systems are also referred to as frequency domain OCT, optical frequency domain imaging (OFDI) [7]. Because of its fast acquisition mode, FD-OCT systems can acquire images of long segments maintaining good longitudinal resolution during short injections.

Table 8.1 Comparison of optical coherence tomography systems.

	IVUS	TD-OCT	FD-OCT (St. Jude)	OFDI (Terumo)
Energy wave	Ultrasound	Near-infrared	Near-infrared	Near-infrared
Wavelegh (μm)	35–80	1.3	1.3	1.3
Axial resolution (μm)	100–150	15–20	10–15	10–20
Lateral resolution (μm)	150–300	25–40	20–30	20
Tissue penetration (mm)	4–8	1.5–2	1.5–2	1–2
Frame rate (frames/s)	30	20	180	158
Pullback speed (mm/s)	0.5–2	1–3	18–36	Up to 40

FD, Fourier domain; IVUS, intravenous ultrasound; OCT, optical coherence tomography; OFDI, optical frequency domain imaging; TD, time domain.

The optical probe is integrated into a short monorail catheter that can be advanced in the coronary artery over any conventional 0.014 inch guide wire. The catheter profile varies from 2.4 to 3.2 Fr and are compatible with 6 Fr guiding catheters (in fact, these catheters can be inserted through 5 Fr guiding catheters as well, but then the speed of contrast flushing is often inadequate). The position and number of the radiopaque markers varies among different systems. During imaging, the optical fiber probe is pulled along the catheter sheath. The FD-OCT frame rate is typically 100 frames/s, with a pullback speed of 20 mm/s, achieving 5 frames/mm or a frame pitch of 200 μm. Newer systems acquiring data at 180 frames/s markedly enabled high-speed acquisitions, adequate for 3D reconstruction, of up to 10 cm and this image segment length, sufficient for complete assessment of most vessels. However, in spite of claims of better axial resolution, the tissue penetration remains limited to 0.5–2.0 mm. Currently, available commercial systems for clinical use are the St. Jude/LightLab Imaging Inc., Westford, MA, USA and Lunawave Terumo, Tokyo, Japan. A summary of the characteristics of the OCT systems is shown in Table 8.1.

Post-processing and interpretation of Z-offset

Calibrating the system is an important phase of the OCT imaging, which is critical for accurate measurements. Although semi-automated calibration is standard with currently available systems, calibration can still be incorrect because of failed automated calibration, incorrect manual adjustment, or changes in length of the optic fiber caused by bending of the imaging wire and proximity to the vessel wall [8]. The Z-offset is a manually adjustable image calibration, critical for accurate measurements. It is the zero-point setting of the system that corrects the difference in the optical measurement between the sample and reference arms. The catheter diameter acts a reference for optimal Z-offset determination within an image frame, aligning the marks to the outer surface of the catheter. Typically, calibration is made before starting image acquisition and repeated before the automatic measurement process is started.

Artifacts

Interpretation of OCT data and their application in clinical situations is limited by image artifacts (Figure 8.1). Knowledge of these artifacts can be used to guide the operator to a better interpretation of the OCT images.

Shadowing Dense objects such as guidewires, metallic stent struts (Figure 8.1a), blood or lipid-laden macrophage accumulations rapidly attenuate or completely obstruct the OCT signal, leading to a loss of signal and no visualization behind them. Compensation algorithms attempt to reduce shadowing and improve signal from the deepest tissues [9].

Residual blood Blood contamination usually results from inadequate flushing and can be prevented by using power injection through a pump at a speed greater than the maximal coronary flow (typically, 4–6 mL/s in the left coronary and 2–4 mL/s for the right coronary artery). Residual red blood cells disturb the OCT light beam, reducing the visibility and brightness of the vessel wall (Figure 8.1b); blood swirling along the vessel wall can be mistaken for thrombus.

Motion artifacts Physiologic phenomena such as cardiac motion, vessel pulsatility, or, to a lesser extent, catheter movement and respiratory movements are associated with beam scanning or movement of the operator's hand (Figure 8.1c). "Sew-up" artifacts appear as a result of rapid vessel movement during imaging, but they are less prominent than in the much slower IVUS pullbacks and have become clinically irrelevant at the high pullback speeds of the newest OCT systems.

Non-uniform rotational distortion Imaging modalities that use a mechanically rotated endoscopic probe to scan an artery often suffer from image degradation caused by a variation in the rotational speed of rotating optical components during image acquisition [10]. This occurs in the presence of acute angulations, tight hemostatic valve, kinking of the imaging sheath, a defective catheter, or while the catheter crosses a tight stenosis.

Saturation artifact These occur when the signal from a highly reflective surface exceeds the dynamic range of the detector (Figure 8.1d). The shape of signal appears distorted as linear streaks of high and low intensities along the axial direction. Stent struts and guidewires are the most common structures to cause this artifact.

Tangential signal dropout If the imaging beam strikes the tissue with a near parallel angle, a signal-poor area with diffuse borders, covered by a thin signal-rich layer arises (Figure 8.1e), and mimics a lipid-rich plaque with a fibrous cap [11].

Figure 8.1 Frequent artifacts in optical coherence tomography imaging. (a) Shadowing of guidewire (asterisk) and stent struts. (b) Residual blood. (c) Motion artifact. (d) Saturation artifact. (e) Tangential signal drop-out artifact. Please note that this artifact cause a signal-rich area overlying a signal-poor region in an area of adaptive intimal thickening. (f) Bubble in the catheter causes a shadow on the vessel wall (arrow). (g) Multiple reflections. (h) Fold-over artifact.

Blooming artifact The intense signal generated by the reflection of light causes the appearance of a bright reflector maximized and dispersed along the axial direction [12]. This is most commonly caused by stent struts, which appear thicker. Unlike IVUS where the leading edge is the point used for measurements, the true edge of the strut lies somewhere in the *middle* of the blooming and this should be used in measuring the distance strut wall.

Bubble artifact These occur as a result of air bubbles in the catheter sheath. Bubbles also form in the silicon lubricant used to reduce friction between the sheath and the revolving optic fiber in TD-OCT systems [13]. Bubbles can attenuate the signal along a region of the vessel wall, and images with this artifact are unsuitable for tissue characterization (Figure 8.1f).

Multiple reflections This artifact is caused by the reflected surface of some catheters creating one or more circular line within the image (Figure 8.1g).

Strut orientation artifacts When the OCT catheter resides close to a stented artery wall, imaging metal coronary stents deployed appear as a bending of stent struts toward the imaging catheter. This so-called sunflower effect occurs when the catheter occupies an eccentric position within the vessel lumen and the struts appear as a straight line, perpendicular to the imaging light beam and obliquely oriented to the luminal wall [14]. This artifact can cause misclassification of apposed struts as malapposed. Bioabsorbable vascular scaffolds (BVS) are not susceptible to this artifact.

Fold-over artifact This artifact is more specific to FD-OCT systems. It occurs when the vessel is larger than the ranging depth, thus it is typically observed in large vessels or side branches.

Consequently, the vessel might appear to be folded over in the image (Figure 8.1h).

Normal coronary vessel anatomy

With the exception of the left main stem, coronary arteries are muscular arteries and are histologically organized into three layers. The intima consists of a lining layer of endothelial cells supported by a subendothelial layer [15], which is exceedingly thin at birth and grows progressively with age, eventually reaching OCT resolution limits [16]. In OCT, the intima can be visualized as a signal-rich luminal layer. The intima thickens with age, and nearly all adult coronaries display an extent of intimal thickening [17]. There is no established cut-off for the identification of pathologic intimal thickening; however, some authors use, rather arbitrarily, a cut-off of 300 μm to identify intimal thickening, and above 600 μm for pathologic intimal thickening in the absence of a lipid pool or calcified region >1 quadrant [18]. The medial layer is a signal-poor region isolated from the intimal layer by an internal elastic membrane and from the adventitia by an external elastic membrane. Occasionally, these layers can be visualized as highly backscattering structures at the intima-media and media-adventitia borders [12]. The adventitia is recognized as a heterogeneous high signal outer layer.

Plaque characterization

Atherosclerotic plaque components can be categorized by utilizing various optical properties of different tissues (Figure 8.2). Fibrous plaques are identified as homogenous, highly backscattering, low attenuation lesions. However, as emitted light is absorbed by lipids (low backscattering), which leads to a high level of posterior signal attenuation, plaques appear as poor signal regions with poor delineation. Calcifications are also regions of low backscatter (signal poor), but let light filter rather than absorb it, so that they maintain

Figure 8.2 Plaque characterization with optical coherence tomography. (a) Normal coronary anatomy organized in three layers. (b) Lipid-rich plaque; note possible macrophage accumulations around 3 o'clock. (c) Lipid-rich plaque in a saphenous vein graft. (d) Fibrous plaque. (e) Calcification extending deep into the vessel wall between 4 and 11 o'clock. Outer border of the calcification cannot be delineated. (f) Calcification between 12 and 4 o'clock. (g) Thrombus protruding into the lumen. (h) Neovascularization (arrows).

well-delineated external borders. However, differentiation of signal-poor areas is not always straightforward and calcium can be misinterpreted as lipids, particularly if the calcification is situated deep in the vessel wall.

An early *ex vivo* study established a sensitivity and specificity ranging 71–79% and 97–98% for fibrous plaques, 95–96% and 97% for fibro-calcific plaques, and 90–94% and 90–92% for lipid-rich plaques with low inter-observer and intra-observer variability [19]. However, other studies showed conflicting results. For instance, in an OCT study, only 45% of atheromas were identified, with higher identification percentages in fibro-calcific and fibrous plaques of 68% and 83%, respectively [20]. Misinterpretation in this study was mainly caused by low OCT signal penetration, which precluded the detection of lipid pools or calcium behind thick fibrous caps and by misclassification of calcium deposits for lipid pools and vice versa [20]. Furthermore, artifacts such as superficial shadowing and tangential signal dropout can produce images with signal-poor regions covered by a thin signal rich layer mimicking thin-cap fibroatheromas (TCFA) [11]. Rather than relying only on subjective visual interpretations, algorithms based on the optical attenuation coefficient to classify plaques quantitatively have been proposed; however, as yet, these algorithms are not sufficiently robust to be used in the clinical setting [21].

OCT imaging can also demonstrate thrombi as protrusions or floating masses. Red and white thrombi can be identified via the differences in attenuation intensity, with red thrombi showing high attenuation and complete wall shadowing and white thrombi appearing as low attenuation intraluminal masses or layers [22].

Vulnerable plaque assessment

Imaging in acute coronary syndromes (ACS) includes ruptured plaques and histomorphologic features that can be detected by OCT (superficial lipids, fibrous cap thickness as well the presence of macrophages and neovascularization). Accurate *in vivo* detection of plaque components permits the detection of plaques at high risk of rupture. However, the limited penetration depth of OCT precludes the evaluation of remodeling as well as the calculation of plaque burden.

A semi-quantitative definition of the presence of superficial lipids in ≥ 2 quadrants is used to describe lipid-rich plaques in OCT studies [23]. However, low penetration depth prevents accurate evaluation of the lipid core thickness.

Pathologic studies reported that ruptured plaques harbor a thin fibrous cap being $<65 \mu\text{m}$ in 95% of ruptured plaques [24]. Using OCT, the fibrous cap can be detected as a high signal homogeneous band covering the lipid-rich core. OCT was shown to provide accurate measurement of fibrous cap thickness (FCT) *ex vivo* [25]; previous studies demonstrated thinner fibrous caps in patients with ACS [23,26]. However, there is no established *in vivo* OCT “clinically important” cut-off for defining “thin” fibrous caps; current thresholds are obtained from histopathologic studies, raising concerns regarding possible tissue shrinkage during pathologic preparation [27]. A study that aimed to evaluate the relationship between FCT and plaque rupture *in vivo* found that in 95% of ruptured plaques, the thinnest FCT was $<80 \mu\text{m}$ and so the investigators proposed this value as an alternative *in vivo* threshold [28].

The progression of atherosclerosis and plaque vulnerability is critically affected by macrophages. Their accretion in atherosclerotic

plaques can be identified as high signal regions appearing either distinct or confluent punctate visually. With dedicated software, OCT-derived indices can be used to identify macrophages [29]. Nonetheless, macrophages should only be considered in the presence of a fibroatheroma, because there have not yet been any studies to confirm macrophages on normal vessel walls or intimal hyperplasia [12]. In addition, high speckle from microcalcifications or cholesterol crystals can also appear similar to macrophages [30].

Plaque neovascularization is considered as a feature of vulnerable plaques. These microvessels are inherently fragile and leaky, giving rise to local extravasation of plasma proteins and erythrocytes [31]. OCT reveals these vessels as small black holes in the atherosclerotic plaque [32]. The presence of these microchannels is associated with vulnerable features such as thin fibrous cap and positive remodeling [33]. In a larger study, similar results were reproduced only in culprit lesions of patients with ACS, not in non-culprit lesions of patients with ACS or in stable patients [34]. Another study found no difference in the prevalence of microchannels in ACS and non-ACS patients; however, the closest distance from the lumen to the microchannel was shorter in ACS subjects than in non-ACS [35].

OCT imaging over time can provide insights and therapeutic strategies for plaque stabilization. In an initial study, patients on preceding statin therapy were found to have a reduced incidence of ruptured plaques and a trend toward thicker fibrous caps [36]. The influence of statins on fibrous caps was further investigated in a study of 40 patients with previous myocardial infarction. FCT was found to increase in both the statin and control group over time, but more so in the statin group [37]; this was confirmed elsewhere [38]. Recently, atorvastatin therapy at 20 mg/day provided a greater increase in FCT than 5 mg [39]. In an additional study, despite comparable reduction in total cholesterol and low density lipoprotein cholesterol levels with statin therapy in ACS patients, non-culprit lesions *without* neovascularization showed greater increase in fibrous cap thickness than lesions *with* neovascularization at a 6–12 months' follow-up [40]. These important insights into the operative mechanism of statins reveal qualitative arterial wall changes

explaining stabilization without significant modification of angiographic lumen dimensions and only minimal volumetric plaque changes by IVUS [41–43].

Acute coronary syndromes

The presence of a disrupted fibrous cap alongside a cavity describes plaque rupture. Plaque rupture can be observed in a variety of clinical scenarios. One study revealed that plaque rupture, TCFA, and red thrombus are more frequent in patients with ST-elevation myocardial infarction (STEMI). Additionally, the size of the ruptured cavities was greater and an aperture opposite to the flow direction was more frequent in patients with STEMI [44]. OCT also showed differences in the morphology of ruptured plaques in non-STEMI and asymptomatic coronary artery disease (CAD) [45]. Pathologic studies suggest that ruptures do not necessarily lead to ACS, and ruptures can heal and cause plaque progression. Using OCT, healed plaques can be identified as multiple layers of different optical densities overlying a large necrotic core [46].

Although plaque rupture is the most common cause of ACS, more than 20–30% of events are caused by plaque erosion, or with the presence of superficial often protruding calcific nodules shown on OCT (Figure 8.3). Indeed, OCT can detect the presence or absence of plaque disruption and categorize plaque morphology *in vivo* [47] and the characterization of these plaques could aid in the derivation of alternative treatment strategies [48].

Percutaneous coronary intervention

Angiography has been used as the gold standard to evaluate the presence, location, and severity of CAD; however, it is an analysis limited to the vessel lumen and has obvious drawbacks without offering direct information on the characteristics and composition of the coronary lesions. The widespread application of a non-occlusive technique using monorail OCT catheters, the high pullback speed allowed by newer generation FD-OCT systems, and the availability of semi-automatic measurements have made OCT a

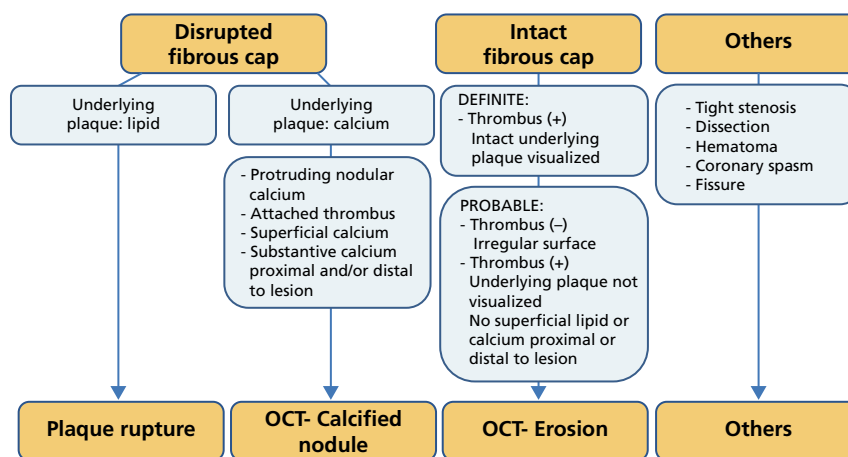

Figure 8.3 Plaque classification algorithm by optical coherence tomography (OCT). Plaque rupture is defined as the presence of fibrous cap discontinuity with a clear cavity formed inside the plaque. Definite OCT erosion is identified by the presence of attached thrombus overlying an intact and visualized plaque, whereas probable OCT erosion is defined by: (i) luminal surface irregularity at the culprit lesion in the absence of thrombus; or (ii) attenuation of underlying plaque by thrombus without superficial lipid or calcification immediately proximal or distal to the site of thrombus. The OCT calcified nodule is defined when fibrous cap disruption is detected over a calcified plaque characterized by protruding calcification, superficial calcium, and the presence of substantive calcium proximal and/or distal to the lesion. (f) Intimal coverage of malapposed struts (arrow). (g) Neointimal hyperplasia. (h) In-stent restenosis. (i) Bioabsorbable vascular scaffold (BVS). Note BVS struts are transparent to light. (j) BVS in the follow-up.

potential alternative for guidance of percutaneous coronary interventions (PCI), overcoming drawbacks of coronary angiography and avoiding the difficulties in interpretation and quantitation of IVUS (Figure 8.4). However, it is very important to understand that OCT and IVUS are not interchangeable intravascular techniques and that they have advantages, limitations, and differences in the way the procedure is guided via online measurements during the PCI procedure.

Because of the sharp delineation of lumen contours, OCT easily provides automatic lumen measurements. Accurate measurement of the reference lumen dimensions allows for optimal stent diameter selection, while the precise identification of the longitudinal extent of the atherosclerotic plaque facilitates selection of the most appropriate stent length and landing zones. The visualization of stent expansion permits optimization with high pressure post-dilatation, in the case of focal underexpansion readily demonstrated in the online lumen profile maps of modern OCT systems. In a recent study, which compared FD-OCT, IVUS, and quantitative coronary angiography [49], the mean minimum lumen diameter measured by quantitative coronary angiography (QCA) was smaller than by OCT, which was smaller than that by IVUS, a result consistent with a previous report [50]. Using a phantom model, investigators showed that mean lumen area (MLA) according to FD-OCT was equal to the actual lumen area of the phantom model while IVUS overestimated the lumen area and was less reproducible than FD-OCT. In addition to cross-sectional measurements, FD-OCT also provides accurate longitudinal measurements [51]. The main difference with IVUS, however, is the inability of OCT to measure the media-to-media diameter in most cases, with the rare exception of some distal reference segments with very small plaque burden and vessel diameter.

OCT-guided coronary intervention

Only a few studies have investigated the role of OCT guidance in PCI. Repeated examinations with OCT can be safely used to guide stent selection and improve stent expansion and apposition [52].

After full lesion predilatation, OCT pullback imaging suggested proceeding directly with stenting in 48% while in 52% advised further treatment. Out of the 207 pullback imaging after stenting, 14% suggested new stent implantation because of dissection or residual stenosis and 31% suggested further optimization with high pressure or larger sized balloon. A multicenter trial compared the outcomes of an angiographic-guided strategy with an OCT-guided strategy in 670 patients [53]; OCT disclosed adverse features requiring further interventions in 35%. OCT guidance was associated with a significantly lower risk of cardiac death or myocardial infarction at 1 year, even after adjustment of important potential confounders. However, further investigations are needed to confirm whether the use of OCT improves clinical outcomes.

Apposition and malapposition

Strut apposition is a part of optimal stent deployment criteria and is defined as the contact of the stent struts with the arterial wall. Conversely, malapposition is defined as lack of strut-wall contact. However, OCT detection of malapposition requires recognition that *only the leading edge* of the metallic stent strut is visible with OCT, therefore stent strut and polymer thickness for each type of drug-eluting stent (DES) should be considered in assessing malapposition. Incomplete strut apposition is defined as a strut-wall distance greater than the strut thickness (metal plus polymer) with the addition of a correction factor, most often $\sim 15\mu\text{m}$ (usually ranging between 10 and $20\mu\text{m}$, up to $30\mu\text{m}$ taking into account the axial resolution of the current OCT systems) [54]. Unlike metallic stents, BVS are transparent to light, therefore the abluminal border of the struts can be easily identified and incomplete strut apposition can simply be established as the presence of struts separated from the underlying vessel wall [55].

However, the clinical implications of stent malapposition remain controversial. Ultrasound studies found conflicting results in the correlation between stent malapposition and adverse clinical events [56–58]. According to a recent OCT analysis of 356 coronary

lesions that received a DES, acute stent malapposition was observed in 62% of lesions, approximately half of them being located within the stent edges [59]. Severe diameter stenosis, calcified lesions, and long stents were independent predictors of acute stent malapposition. Acute stent malapposition with a volume $>2.56 \text{ mm}^3$ differentiated malapposition that persisted at follow-up from stent malapposition that resolved. Moreover, in this study, long-term clinical outcomes of late stent malapposition detected by OCT were favorable [59]. However, segments with acute incomplete strut apposition have higher risk of delayed coverage than well-apposed segments. Acute incomplete strut apposition size (estimated as volume or maximum distance per strut) was an independent predictor of persistence of incomplete strut apposition and of delayed healing at follow-up in 66 stents of different designs [60]. Strut malapposition can cause turbulent blood flow, which in turn can trigger platelet activation and thrombosis. In fact, incomplete strut apposition in addition to delayed neointimal healing of the stent and incomplete endothelialization of the struts is a common morphologic finding in fatal cases of late and very late stent thrombosis [57,61–63]. However, biological and mechanical factors (including levels of circulating endothelial progenitor cells or regional shear stress) can also have a role in neointimal healing and differences in percentage coverage cannot always entirely explain clinically overt stent thrombosis [63].

Tissue protrusion

In OCT, plaque protrusion is characterized by a smooth surface and no signal attenuation, and thrombus protrusion by irregular surface and significant signal attenuation. Tissue protrusion is more frequently observed in the culprit lesions of acute coronary syndromes, as unstable lesions contain soft lipid tissue and thrombi; its clinical significance of tissue protrusion is not clear.

Vascular injury: dissections

OCT is a very sensitive tool in detecting micro-dissections and subclinical dissections [64]. Dissections occur more frequently when the plaque at the edge of the stent is fibro-calcific or lipid-rich than when is fibrous [65]. Nevertheless, currently there is no evidence that subclinical dissections carry adverse prognostic implications [66].

Guidance of complex lesion treatment

Bifurcations represent complex coronary lesions with high rates of acute and late stent failure. Knowing the reference diameter of the vessel distal and proximal to the side branch is critical in correct sizing of the stent and post-dilatation balloon. In both simple (one stent) or complex strategies of bifurcation stenting, OCT showed that the rate of malapposed struts is significantly higher at the side branch ostium than in the vessel side opposite to the ostium [67]. In a series of 45 lesions, OCT showed the persistence of malapposition was as high as 43%, despite consistent use of kissing balloon dilatation and proximal optimization technique [68]. The overall rate of malapposed struts was significantly higher in the lesions treated with angiography-guided than in those undergoing OCT-guided PCI [68].

The position where the guidewire re-crosses the stent struts into the side branch (i.e., proximal, mid, or distal cell) has been demonstrated to be one of the most important factors for strut apposition in the side branch ostium after balloon dilatation. Crossing to the side branch through a proximal cell provides no scaffolding of the side branch ostium and leaves many struts unapposed near the carina, reducing the strut-free side branch ostial area and current

recommendations suggest attempting to re-cross the wire through the most distal cell of the main vessel stent in order to efficiently open a stent at the side branch ostium [69]. The feasibility and effectiveness of OCT-guided stent re-crossing compared with angiography guidance has been evaluated in a 52 patients [70]; the OCT-guided group showed a significantly lower number of malapposed stent struts, especially in the quadrants toward the side branch ostium (9 vs. 42%; $p < 0.0001$).

Three-dimensional (3D) reconstruction of OCT images is also potentially useful to assess the spatial aspect of bifurcation stenting [71–75] and using 3D-OCT reconstruction, the side branch guidewire can be easily tracked. The clinical application of high quality off-line 3D-OCT to optimize side branch opening by identifying the configuration of overhanging struts in front of the side branch ostium according to the presence of the link between hoops at the carina and the appropriate distal cell for the re-crossing position has been evaluated in 22 patients [76]. This study showed that 3D-OCT confirmation of the re-crossing into the jailed side branch is feasible during PCI and helps to achieve distal rewiring and favorable stent positioning against the side branch ostium, leading to reduction in incomplete strut apposition and potentially better clinical outcomes [76]. Finally, OCT has also been used to assess the procedural success of new bifurcation stenting (i.e., dedicated side branch stents) [77].

For other complex lesions, such as chronic total occlusions, after recanalization OCT can assess extent of calcific and fibrotic changes and detect the presence of subintimal wire positions, distal dissections, and double channels.

Assessment at follow-up

The possibility to detect tissue coverage and neointima formation in DES over time is one of the most important current research applications of OCT studies investigating the underlying mechanisms implicated in stent failure, such as stent thrombosis, in-stent restenosis, and neoatherosclerosis; delayed neointimal healing has been considered a possible underlying substrate of fatal stent thrombosis [61,78]. The percentage of uncovered stent struts represented the best morphometric predictor of late DES thrombosis and the risk increases with the percentage of uncovered stent struts per section [61].

An important caveat is the inability of OCT to detect thin layers of neointima below its axial resolution and to differentiate between neointima (smooth muscle cells and matrix) and other pathologic components such as fibrin or thrombus. The latter becomes an issue at very early phases after stenting, when the prevalence of struts covered by fibrin is high. Thus, DES are completely covered with fibrin, rather than a neointima, 1–3 days after implantation, but the low discriminative power of OCT results in false coverage rates of 45–76% [79]. Moreover, fibrin coverage might persist longer with DES. The analysis of optical density might aid discriminating between neointima and fibrin [79,80]. However, as the greatest interest is to assess intimal coverage at late follow-up, when the prevalence of fibrin-covered struts is low, the practical impact of this limitation is minimal. Significant differences exist in stent strut coverage and apposition between various DES at 3–12 months post implantation and this could explain the different clinical results obtained with second generation compared with first generation DES [81]. This is possibly due to the thickness and biocompatibility of the polymer that could be responsible for triggering inflammatory reactions or the different strut thickness and cell design. The analysis of strut coverage by OCT has contributed to a better

understanding of the vascular healing process after BVS implantation showing its unique potential in vascular repair, such as late lumen enlargement and plaque media reduction [82,83].

In-stent restenosis and neoatherosclerosis

OCT offers data concerning the underlying pathophysiology that contributes to in-stent restenosis (ISR), such as stent underexpansion, strut fracture, and strut distribution. OCT is additionally capable of assessing the specific lumen shape and neointimal tissue. Yet, because of reduced tissue penetration of OCT, plaque behind the stent struts is poorly visualized [84]. OCT accurately measures the percentage of neointimal volume obstruction, which is conventionally evaluated with IVUS to portray any neointimal hyperplasia inside the stents, and has become a standard in trials assessing the efficacy and safety of novel stents [85].

Various ISR tissue patterns have been defined based on optical homogeneity (homogenous, heterogeneous, and layered), restenotic tissue backscatter (high, low), visibility of microvessels, lumen shape (regular, irregular), and the existence of intraluminal components [86]. Bare metal stents are associated with homogenous patterns, whereas DES are typically associated with heterogeneous patterns [87,88]. Furthermore, hyperplastic tissue evolution into neoatherosclerosis can be evaluated by OCT; this is important, because there has been emerging data claiming the relevance of late de novo neoatherosclerosis in late ISR or thrombosis [89,90].

In ISR, OCT can also be used to precisely follow the irregular lumen contour after cutting balloon and to guide cutting balloon sizing. In particular, OCT can confirm if cutting balloons have scored the plaque up to the stent at multiple points, which greatly facilitates extrusion and lumen expansion. This is possible because metal struts are powerful enough light reflectors to be visualized through very thick plaques. Through an OCT-guided cutting balloon strategy, intimal hyperplasia was reduced from 69% to 25% in the minimal lumen area segment allowing better preparation for stent deployment or drug-eluting balloon dilatation [54].

Bioabsorbable vascular scaffolds

Bioabsorbable drug-eluting scaffolds have emerged as a potential major breakthrough for treatment of symptomatic coronary artery lesions showing unique potential in vascular repair with restoration of vasomotion, reduction of plaque thickness, and compensatory late lumen enlargement. OCT has been used since the first implants of BVS to study the vessel wall response [82,83] and the timing of the resorption process [91]. Unlike metallic stents which are powerful light reflectors and induce posterior shadowing and blooming artifacts on the vessel surface, polymeric struts of BVS are transparent to the light so that scaffold integrity, apposition to the underlying wall, and changes in the strut characteristics over time can be easily studied. OCT has been used to compare the acute performance of this new device with that of second-generation DES in the treatment of complex coronary artery disease in a real-world setting [92], as well as device-specific complications, such as BVS rupture.

Near-infrared spectroscopy

Atherosclerotic plaque formation is the consequence of inflammation and extracellular matrix formation as well as cholesterol deposition in the vasculature. This process involves the retention of highly atherogenic lipoproteins in the intima of the arterial wall. These lipoproteins accumulate and are modified further deep in the abluminal part of the intima. Altered lipids attract proteolytic

enzyme-producing macrophages to their site, which engulf the lipids and leave behind a soft and unstable core that is highly abundant in foam cells and lipids [31]. Cholesterol, whether esterified or unesterified, forms the major part of the lipid core. Histologic studies as well as studies with intravascular imaging have depicted the association of the presence of lipid-laden plaques with the risk of an ACS and increased peri-interventional complications. The ability to detect lipid-rich plaques in patients is therefore of great clinical significance.

Near-infrared spectroscopy (NIRS) is widely used in many disciplines to identify the chemical composition of unknown substances. It utilizes the absorbance and reflectance of near-infrared light from an illuminated targeted area to derive the presence of the target substance. This method is a simple quick technique that provides multiconstituent analysis, and requires no sample preparation or manipulation with hazardous agents [93]. Studies have documented the ability of NIRS to accurately identify lipid-core atherosclerotic plaques in animal models or autopsy specimens and finally, after *in vivo* and *ex vivo* validation studies [94,95], the intraluminal spectroscopy catheter was developed and marketed.

System description

Initially, intracoronary NIRS was developed as an independent imaging modality, but a major drawback was the inability to provide spatial orientation to match the lipid content alongside the plaque distribution. However, current co-registered NIRS-IVUS catheters (TVC Imaging System, InfraReDx Inc, Burlington, MA, USA) provide data regarding both the vessel structure and the plaque composition.

After completion of an automatic pullback, data are processed displaying a two-dimensional map of the vessel, revealing the probability of the presence of a lipid core plaque (LCP), with the pullback position in millimeters on the x-axis and the circumferential position on the y-axis. This display is known as the “chemogram.” For each pixel of 0.1 mm and 1°, length and angle respectively, the lipid core probability is calculated from the spectral data collected and semi-quantitatively coded on a color scale from 0 for red and to 1 for yellow. Whenever a pixel lacks sufficient data, for instance the guidewire is shadowing, the pixel appears black.

The block chemogram, also created from the NIRS images, combines the results for each 2-mm section of the artery to create a “virtual block” that summarizes and reflects the probability of LCP intervals. The numeric value of each block produced is the 90th percentile of all pixel values obtained in the corresponding 2-mm section of the artery in the chemogram. Here, the red coloration indicates a low probability of an LCP, whereas yellow coloration determines a higher probability of an LCP, alongside the intensity of the color reflecting the amount of cholesterol present. In isolation, the block chemogram specifically adapts a four-color scale method of analysis (red ($p < 0.57$), orange ($0.57 \leq p < 0.84$), tan ($0.84 \leq p < 0.98$) and yellow ($p \geq 0.98$)) that reflects the probability of the existence of an LCP in each 2-mm block of pullback which aids the overall visual interpretation. Spectral data are paired with corresponding IVUS frames, overall displayed as a ring around the IVUS image. The lipid core burden index (LCBI) measures the portion of pixels that exceed an LCP probability of 0.6, in all viable pixels within the scanned region, multiplied by 1000. This is a quantitative measure of the intensity of yellow pixels present on the chemogram. The LCBI values vary from 0 to 1000 and the maximum value of LCBI for any of the 4-mm segments along the analyzed segment is defined as the $\max LCBI_{4mm}$.

Potential clinical uses

Determination of high-risk plaque

The necrotic core region has an abundance of lipid deposition and lacks mechanical stability because of the degradation of fibrous tissue and disappearance of cells. The size of the necrotic core has been significantly associated with the likelihood of plaque rupture. In a previous pathologic study of aortic plaques, ulceration and thrombosis were characteristic of plaques with >40% of their volume occupied by extracellular lipids [96]. As the lipid core increases plaque vulnerability, the NIRS can potentially be used to identify high risk plaques (Figure 8.5). It has been shown that the target lesions responsible for ACS were in most cases lipid-rich plaques; additionally, patients with ACS commonly harbored remote, non-target lipid-rich plaques [97]. In another study in patients with STEMI, $\text{maxLCBI}_{4\text{mm}} > 400$ in NIRS accurately distinguished culprit from non-culprit segments within the artery and from the lipid-rich plaque-free autopsy histology segments [98]. In a recently published prospective observational study, NIRS imaging was performed in a non-culprit coronary artery in 203 patients referred for angiography due to stable angina pectoris or ACS. It was shown that the 1-year cumulative incidence of a cardiovascular event in patients with an LCBI equal to or above the median value (43.0) was significantly higher than those with an LCBI value below the median [99].

Prevention of peri-procedural myocardial infarction and optimizing interventions Peri-procedural myocardial infarction can be related to distal embolization of LCP component, contents, and/or intracoronary thrombus. In a sub-study of COLOR (Chemometric Observation of Lipid Core Plaques of Interest in Native Coronary Arteries) registry, the cardiac biomarkers in 62 stable patients undergoing stenting were evaluated. Findings revealed that 7 out of 14 (50%) patients with a $\text{maxLCBI}_{4\text{mm}} \geq 500$ developed peri-procedural

myocardial infarction in comparison with the occurrence of this in only 2 out of 48 (4.2%) patients with a $\text{maxLCBI}_{4\text{mm}} < 500$ [100]. In a study by Raghunathan *et al.* [101], in which a creatinine kinase-MB increase >3 times the upper normal limit was observed in 27% of patients with a ≥ 1 yellow block as opposed to none of the patients without a yellow block within the stented lesion. Similarly, in the CANARY (Coronary Assessment by Near-infrared of Atherosclerotic Rupture-prone Yellow) trial, patients with peri-interventional myocardial infarction had higher $\text{maxLCBI}_{4\text{mm}}$ than patients without MI [102]. However, preventive measures for this situation remain uncertain. The use of a distal emboli protection device frequently resulted in embolized material retrieval during intervention in a small group of patients with LCP [103]; however, there was no benefit of this adjunctive treatment in the randomized CANARY trial.

A prospective use of NIRS in catheterization laboratories is in stent sizing to ensure adequate lesion coverage. Visual evaluation of lesions by angiography occasionally lack accuracy and using NIRS, Dixon *et al.* [104] demonstrated that in 16% of the lesions assessed in their study, the LCP extended beyond the angiographic margins of the initial target lesion. Therefore, together with the information provided by IVUS, NIRS data can be used for determining the size and length of the artery to be stented.

Guiding the effects of treatment The effects of current or novel agents that modify plaque composition can be evaluated using NIRS, because it is able to assess the lipid content over time. The YELLOW trial recruited patients with multivessel CAD undergoing PCI. After NIRS and IVUS baseline assessment, patients were randomized to either rosuvastatin 40 mg/day versus the standard of care lipid-lowering therapy. After 7 weeks of short-term intensive statin therapy, a significant reduction in the lipid content was found when measured via $\text{maxLCBI}_{4\text{mm}}$ [105].

Figure 8.5 A 39-year-old man was admitted with unstable angina. Angiography showed significant lesions in right and left anterior descending arteries. After post-dilatation, near-infrared spectroscopy–intravenous ultrasound (NIRS-IVUS) imaging was performed, which revealed lipid core plaque in the mid- and distal left anterior descending (LAD) (b and c). Proximal segments were relatively disease free (a). Right coronary artery (RCA) also harbored lipid core plaques.

Figure 8.6 Intravascular near-infrared fluorescence molecular imaging of plaque inflammation integrated with exactly co-registered OCT. A dual-modal near-infrared fluorescence (NIRF) OCT catheter was evaluated in inflammatory atherosclerosis in the rabbit aorta, a vessel of similar caliber to the human coronary artery. Twenty-four hours after an intravenous injection of Prosense VM110, a NIRF molecular imaging agent that reports on cathepsin protease activity in atheroma, *in vivo* intravascular NIRF-OCT was performed. NIRF revealed augmented protease activity in OCT-defined atheroma, with substantial inflammation heterogeneity seen across atheroma (a,d). The OCT catheter is seen in the middle of the image; the NIRF signal intensity (representing quantitative protease inflammatory activity) is represented by a color scale bar mapped on to the luminal border. The NIRF-OCT findings were confirmed by histology (H&E, middle column b and e), and cathepsin B immunohistochemistry (right column, c and f). Source: Yoo *et al.* 2011 [110]. Reproduced with permission of Nature Publishing Group.

Ongoing trials

The prospective multicenter PROSPECT II trial aims to collect the post-PCI NIRS/IVUS data of patients with ACS and evaluate the prognostic value of LCBI >400 to evaluate in the 2-year follow-up. The Lipid-Rich Plaque Study will enroll 9000 patients presenting for a coronary angiography where an IVUS and/or NIRS evaluation is planned or could be added as part of a clinically indicated evaluation. Here, the primary outcome to be investigated is the prediction of the non-culprit lesion-related major adverse cardiac events. The IBIS-3 study aims to test the effect of high-dose rosuvastatin in improving the plaque composition of non-intervened coronary arteries as well as the progression of their necrotic core volume assessed with VH-IVUS and NIRS.

Near-infrared fluorescence molecular imaging

A limitation of current intravascular imaging approaches such as OCT or IVUS is the inability to assess specific biologic processes in the coronary arteries of living subjects. Molecular imaging is a relatively new field that aims to image specific molecules and cells involved in the pathogenesis of vascular disease, including macrophages, endothelial cell adhesion molecules, fibrin, and coagulation

factor XIII activity [106,107]. Molecular imaging requires injectable targeted imaging agents that bind a specific molecular or internalized within a cell. These agents can then be detected by an appropriate hardware imaging system, including positron-emission tomography (PET), magnetic resonance imaging (MRI), single-photon emission tomography (SPECT), ultrasound and, more recently, fluorescence imaging systems.

While PET and MRI molecular imaging approaches appear promising for large arterial beds (e.g., carotids, peripheral arteries), the smaller size of the coronary arteries dictates an intravascular-based imaging approach to achieve sufficient sensitivity and resolution. To meet this need, optical-based imaging using near-infrared fluorescence (NIRF) has evolved to serve as a promising coronary artery-targeted intravascular imaging platform. The NIR window (650–900 nm) is advantageous for fluorescence imaging as this window exhibits reduced blood absorption and scattering, and reduced background tissue autofluorescence, which serves to increase the ability to detect NIRF molecular imaging agents *in vivo*.

Over the past 7 years, several intravascular NIRF systems have been engineered, including a one-dimensional wire spectroscopic-based system, a standalone two-dimensional imaging system, and most recently, a combined NIRF-OCT imaging system [108–110]. These preclinical investigations provided the first

demonstrations that inflammatory protease activity in atheroma, and fibrin deposition on stents, could be specifically imaged *in vivo* in the aorta of rabbits, which have a similar dimension to human coronary arteries. The most recent NIRF-OCT system has the further advantage of providing simultaneous anatomic information that is precisely co-registered with NIRF molecular information, which further allows quantitative NIRF imaging (Figure 8.6). Similarly to NIRF-OCT, a NIRF-IVUS catheter has been developed but has not been tested *in vivo* through blood yet [111].

Clinical translation

NIRF-OCT imaging system Recently, investigators performed the first human coronary imaging studies of patients using a clinically approved NIRF-OCT catheter [112]. While this catheter was used to detect plaque NIR autofluorescence, or NIRAF (no imaging agent was injected), the ability to safely acquired NIRF-OCT

images is a major step forward in realizing intracoronary molecular imaging.

NIRF molecular imaging agents In addition to having a clinically approved catheter, clinical NIRF molecular imaging agents will be required. A promising candidate is indocyanine green (ICG), an amphiphilic molecule that has been FDA-approved for decades to study cardiac, hepatic, and retinal blood flow. In 2011, Vinegoni *et al.* [113] showed that ICG can unexpectedly target plaque macrophages and plaque lipid, and thus could be useful for clinical intracoronary NIRF molecular imaging of vulnerable plaques. This finding was recently confirmed by others [114], and recently in human carotid atheroma patients [115]. Beyond ICG, many targeted NIRF agents are expected to be available for arterial disease in the future, driven primarily by the field of cancer NIRF molecular imaging [116].

Case Study

A 61-year-old man with a history of hypercholesterolemia presents with typical chest pain on exertion. Diagnostic angiogram showed a chronic total occlusion of the right coronary artery (RCA), in addition to critical stenoses in left circumflex (LCx), obtuse marginal (OM), and mid portion of the left anterior descending (Figure 8.7). The operator decided to proceed with coronary intervention.

He started with predilatating LCx with a 2.0×20 mm percutaneous transluminal coronary angioplasty (PTCA) balloon, into the OM1. Lesions were, then, covered by a 2.5×28 mm bioresorbable vascular scaffold (BVS), which post-dilated with a 3.0×8 mm necrotic coreballoon in the proximal part. Angiogram showed excellent results (Figure 8.8). The operator decided to perform an optical coherence tomography (OCT) imaging to better evaluate the results with BVS. However, OCT reveals malapposed struts in the proximal

part of the scaffold (Figure 8.9), which was corrected with further post-dilatation and confirmed by a second OCT pullback (Figure 8.10).

He then proceeded with the LAD intervention and implanted a 3.0×28 mm BVS. This was post-dilated by a 3.0×8 mm necrotic coreballoon at high atmospheres. Angiogram showed good results (Figure 8.11). He, again, performed an OCT pullback. Despite good angiographic results, OCT revealed a distal edge dissection, which was treated by implanting another BVS (Figure 8.12). Moreover, although blood clearance was insufficient in the proximal part, underexpansion of the BVS was evident in this segment. A second post-dilatation was performed using a 3.5×8 mm necrotic coreballoon.

Patient was discharged the following day without complications. Chronic total occlusion of the RCA was successfully opened in a staged procedure.

Figure 8.7 Angiogram of the left coronary system showed critical stenoses (arrows). The right coronary was totally occluded.

Figure 8.8 Angiogram of the LCx after intervention.

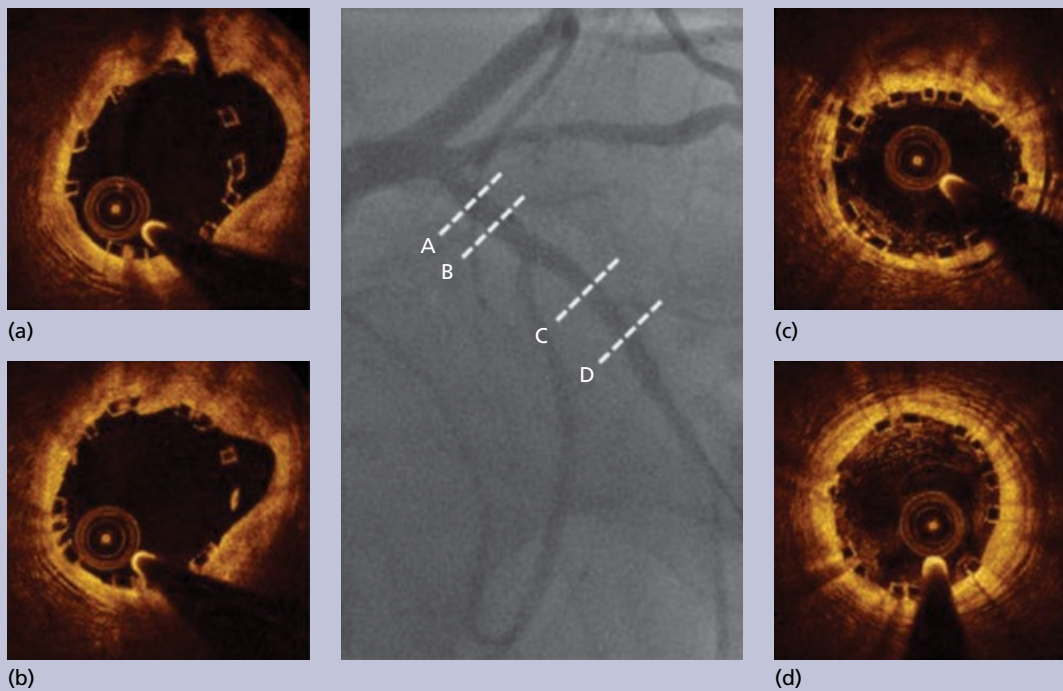

Figure 8.9 OCT showed malapposed struts in the proximal part.

Discussion

Angiography remains for the gold standard in the treatment of coronary artery disease. However, it provides limited information on the degree and extent of atherosclerosis and falls short in stent assessment. On the other hand, optical coherence tomography provides high-resolution cross-sectional images, offering additional information such as plaque characteristics, lumen

measurements, strut apposition and stent expansion, presence of edge dissections.

In this case, the operator preferred an OCT imaging to optimize the results after implantation of BVS. Unlike metallic stents, which are powerful light reflectors and induce posterior shadowing and blooming artifacts on the vessel surface, polymeric struts of BVS are transparent to the light so that scaffold

Figure 8.10 Control pullback showed apposed struts.

Figure 8.11 Angiogram after post-dilatation of the BVS.

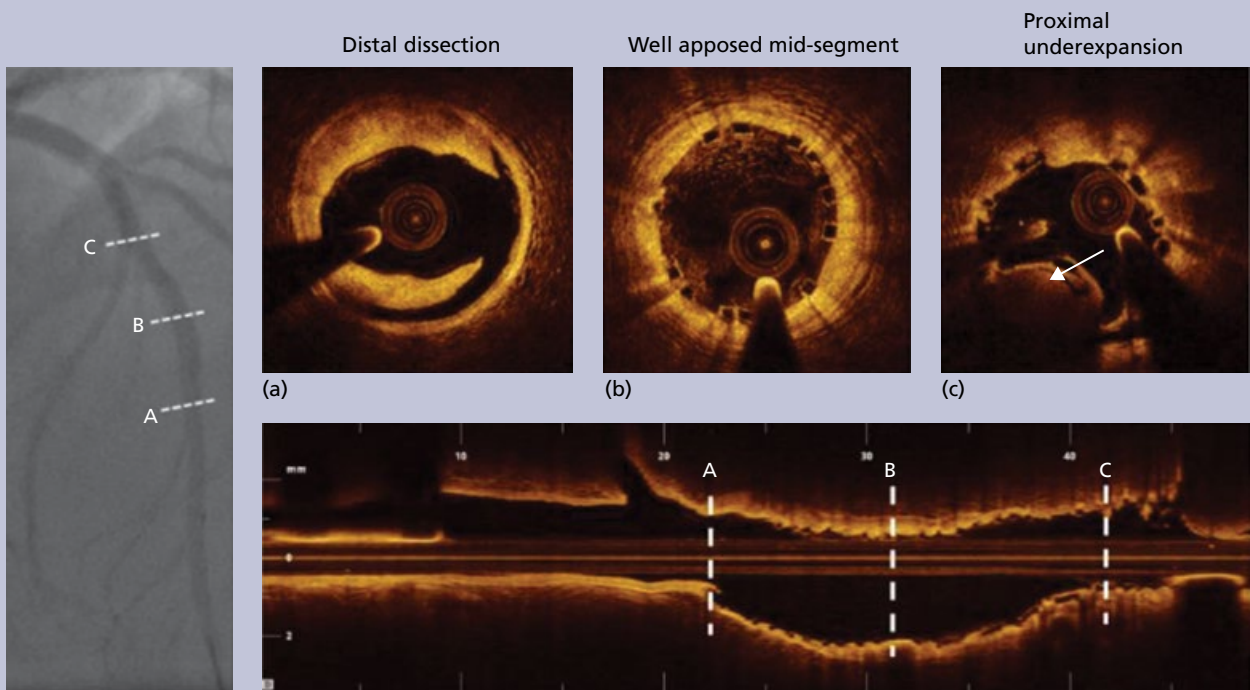

Figure 8.12 Struts were well apposed along the vessel. However, OCT revealed an edge dissection at the distal end. Moreover, BVS was underexpanded in the proximal part of the scaffold. Arrow indicates the blood artifact; note the signal attenuation.

integrity, apposition to the underlying wall, and changes in the strut characteristics over time can be easily studied. Despite conflicting results, some data suggest strut malapposition might be related to stent thrombosis. Similarly, stent underexpansion is a potential cause of stent failure. Dissections usually appear at the stent edges, but most dissections are too small to be detected by

angiography. On the contrary, OCT is a sensitive tool in detecting dissections because of its high resolution. Prognostic significance of edge dissections, currently, remains to be clarified.

This case clearly illustrates OCT's help in recognizing stent malapposition, stent underexpansion, and edge dissections, which can be present despite good angiographic results.

³ Emory University School of Medicine and Georgia Institute of Technology, Atlanta, GA, USA

The introduction of 4-slice computed tomography (CT) in 2000 was followed by rapid and revolutionary advances in multislice computed tomography (MSCT) technology. Currently, 64-MSCT and dual-source computed tomography (DSCT) are considered state-of-the-art for cardiac MSCT imaging with 320-slice systems also emerging in clinical practice.

Non contrast-enhanced MSCT scans allow visualization of cardiac and coronary artery calcification. After intravenous injection of iodinated contrast agent, MSCT can delineate cardiac chambers, great cardiac vessels, and coronary arteries (Figure 9.1).

The evaluation of general cardiac morphology is usually performed by echocardiography and/or magnetic resonance imaging (MRI) without the need for contrast injection or radiation exposure. Nevertheless, MSCT can be clinically helpful in a variety of situations, including the need for cross-sectional imaging in the event of inconclusive findings at echocardiography or in patients with pacemakers or other devices precluding MRI. Importantly, the main clinical focus of MSCT in cardiac imaging is the evaluation of the coronary arteries.

Coronary MSCT angiography—technique

Basic principles

In MSCT scanners, the X-rays are generated by an X-ray tube mounted on a rotating gantry. The patient is centered within the bore of the gantry such that the array of detectors is positioned to record incident photons after they have traversed the patient. MSCT differs from single detector CT principally by the design of the detector array, which allows the acquisition of multiple adjacent sections simultaneously.

MSCT systems have two principal modes of scanning (Figure 9.2). The first mode is *sequential* scanning, also known as “step-and-shoot,” in which the table is advanced in a step-wise fashion. In this mode, the X-rays are generated during an imaging window positioned at a predetermined offset from the R wave (prospective ECG triggering; Figure 9.2a) while the table is stationary. The diastolic phase of the cardiac cycle is usually chosen because cardiac motion is reduced in diastole. Sequential scanning is the current mode for measuring coronary calcium at most centers using MSCT.

The second mode is *spiral* or helical scanning, in which the table moves continuously at a fixed speed relative to the gantry rotation.

The ECG trace of the patient is recorded during the scan. After data acquisition, the optimal reconstruction window is chosen among all available time positions to minimize motion artifacts (retrospective ECG gating; Figure 9.2b). Spiral scanning is the current mode for performing coronary MSCT angiography because it allows flexibility in the position of reconstruction windows, which is helpful to ensure the least motion artifacts. However, spiral scanning is associated with a higher X-ray radiation exposure than sequential scanning.

In order to reduce radiation exposure in spiral scanning, the X-ray tube current can be modulated prospectively: guided by the ECG, the full output occurs only during an interval of the cardiac cycle which will be used for image reconstruction (e.g. diastole), whereas the X-ray output will be reduced during the remaining cardiac cycle (Figure 9.2b).

Temporal resolution is the time for acquiring the data needed for the reconstruction of one image. Temporal resolution depends primarily on gantry rotation time. In particular, because reconstruction of MSCT images requires data acquired over half gantry rotation (180°), temporal resolution equals half of the gantry rotation time (Figure 9.3a). The latest development to improve temporal resolution and omit the need to lower patients’ heart rates by pre-medication has been the introduction of MSCT scanners with two X-ray sources acquiring different projections simultaneously [1]. In DSCT, the two X-ray sources are mounted at an angle of 90°, therefore temporal resolution is equal to a quarter of the gantry rotation time (i.e., $330/4 = 83$ ms) (Figures 9.3b and 9.4).

Coronary arteries have a diameter of 2–4 mm in their proximal tract and taper distally, therefore high *spatial resolution* is another prerequisite for MSCT coronary imaging. Spatial resolution of MSCT on the transverse plane (x, y) is 0.4×0.4 mm². Spatial resolution along patient’s longitudinal axis (z-axis) is determined mainly by the individual detector width, which varies between 0.5 and 0.625 mm depending on the manufacturer. These features permit reconstruction of high quality images with similar sub-millimeter resolution along the x, y, and z axes. Although catheter angiography has a bi-dimensional spatial resolution of 0.2×0.2 mm², a major advantage of MSCT over catheter angiography is the ability to perform multi-planar reconstructed images. An overview of major image parameters, patient preparation, and contrast administration in catheter angiography, 64-MSCT, and DSCT is given in Table 9.1.

Figure 9.1 Axial images provide four-chamber views of the heart without (a) and with (b) injection of contrast agent. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle; void arrow, right coronary artery; arrow, mild calcification of the mitral valve.

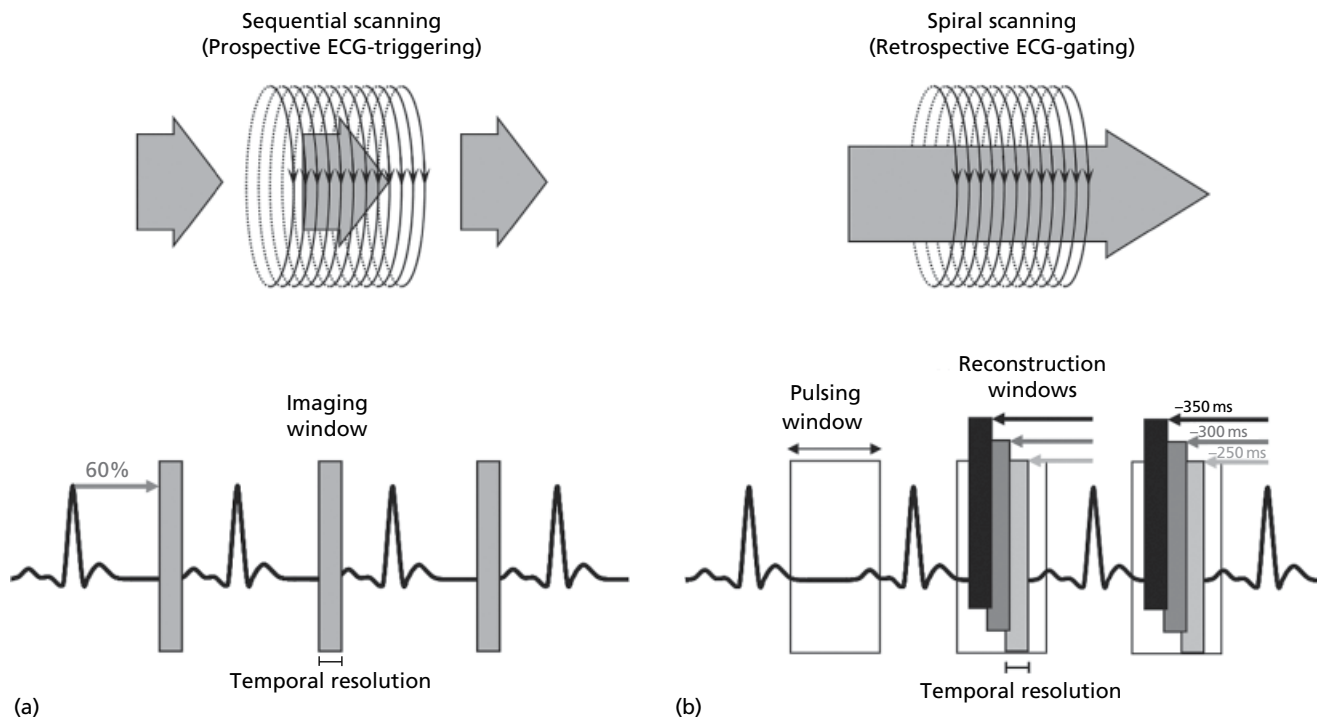

Figure 9.2 In sequential scanning, data for one axial slice are acquired, after which the table is advanced to the next position (a). Sequential scan protocols use prospective ECG-triggering to synchronize the data acquisition to cardiac motion. Based on the measured duration of previous heart cycles, the scan of one slice is initiated at a pre-specified moment after the R-wave. Diastole is commonly chosen to ensure the least motion artifacts (e.g., 60% of the previous R-R interval). Spiral scanners acquire data continuously and record the patient's ECG while the table moves at a constant speed (b). Images are reconstructed using retrospective ECG-gating. This mode is more flexible to minimize motion artifacts because reconstruction window can be positioned arbitrarily within the R-R interval. If X-ray tube modulation is used, the full output occurs only during an interval of the cardiac cycle (pulsing window) which can eventually be used for image reconstruction.

Contrast enhancement

Good contrast enhancement in coronary arteries is essential for the detection of atherosclerotic changes and luminal stenosis. An iodine flow in the range of 1.2–2 g/s is recommended [2]. This can be achieved by either injecting low concentration contrast material at high flow rates or by injection of high concentration contrast material at lower flow rates. However, it is standard practice to inject contrast

agent at rates of at least 5 mL/s. Total contrast volume is determined by contrast injection rate multiplied by the scan time required to cover the heart. Typical injection volumes are in the range 60–100 mL. Dual injection (i.e., iodinated contrast followed by saline, 30–50 mL) is recommended for MSCT of the heart. Saline is helpful to avoid dense opacification of the right cardiac chambers and consequent artifacts which might limit the interpretation of the right coronary artery.

Figure 9.3 Reconstruction of multislice computed tomography (MSCT) images (a) uses data acquired over 180°, thus temporal resolution equals half of the gantry rotation time. Because the shortest gantry rotation time currently achievable by a 64-MSCT scanner is 330 ms, the corresponding temporal resolution is 165 ms. Temporal resolution corresponds to the width of reconstruction window. In dual-source computed tomography (DSCT) (b), two X-ray sources and two corresponding detector arrays are mounted at an angle of 90°, therefore only 90° rotation is needed to provide data from 180°. In DSCT, temporal resolution is equal to a quarter of the gantry rotation time (i.e., $330/4 = 83$ ms).

Image post-processing

With image post-processing, the source axial images are modified and made useful for the observer [3] (Figure 9.5). With isotropic resolution, multiplanar reformats (MPR) and maximum intensity projections (MIP) along the course of the coronary arteries are the routinely methods for assessment of coronaries from MSCT datasets. Three-dimensional volume rendering technique (VRT) provides a helpful overview, for example in cases of complex anatomy such as coronary artery bypass grafts (CABG) or anomalous coronary arteries [4]. However, axial images may be best for the detection of coronary stenoses.

Typical artifacts

It is important to recognize a few typical MSCT artifacts that may lead to image misinterpretation. Motion artifacts typically blur the contours of the heart and coronary arteries (Figure 9.6). Inconsistent triggering or arrhythmias will lead to misalignment of adjacent image stacks. Partial voluming occurs when a pixel (i.e., smallest portion of an image) contains more than one type of tissue. In this setting, the attenuation value assigned to the pixel is the weighted average of the different attenuation values. Thus, when a pixel is only partially filled by a structure of very high attenuation (e.g., metal or bone), a high CT number is assigned to the complete pixel, which will thus appear bright on the image. This may lead

to overestimation of the size of high-attenuation objects (e.g., coronary calcifications and stents) (Figure 9.7).

Coronary MSCT angiography—clinical applications

Stenosis detection

Although conventional coronary angiography is still regarded as the reference standard for the detection and quantification of coronary artery stenosis, there are situations where sufficient information can be acquired by a non-invasive technique with benefits in terms of cost, patient risk, and discomfort.

Since 1999, when the first studies on MSCT coronary angiography were published, the development of MSCT technology has been tremendous. Numerous studies [5–21] have compared the accuracy of MSCT in the detection of coronary artery stenosis with invasive coronary angiography (Table 9.2). While sensitivity and specificity remained similar comparing 16-MSCT and 64-MSCT, 64-MSCT and DSCT became more robust for imaging the coronaries: in the segmental analysis, a decrease was shown for the number of coronary segments that had to be excluded due to insufficient image quality (Figure 9.8; Table 9.2) [22]. Importantly, in the per-patient analysis, which is clinically relevant because it explores the ability of MSCT to identify patients with or without

Figure 9.4 MSCT images display the average cardiac motion over the reconstruction window. A 165 mm-wide reconstruction window (A1–A3) averages MSCT views obtained during 180° gantry rotation. This is the reconstruction algorithm employed in 64-MSCT. An 83 mm-wide reconstruction window (B1–B3) averages MSCT views obtained (by two detector arrays) during 90° gantry rotation. This is the reconstruction algorithm employed in DSCT. Reconstruction using 180° data (A2) might improve image contrast when compared to reconstruction using 90° data (B2) because more MSCT views are averaged for the reconstruction of the same image (gross arrow = LAD). However, a wider reconstruction window worsens temporal resolution and can cause more blurring (A3) than the use of the narrowest reconstruction window (B3) (thin arrow = RCA).

significant coronary artery disease (CAD), the negative predictive value was consistently found to be high, in the range 92–100% (Table 9.2). These findings led to the hypothesis that a normal MSCT obviates the need for invasive angiography in properly selected clinical circumstances. The reported positive predictive values were lower, indicating the tendency of MSCT to overestimate the severity of disease in comparison to invasive coronary angiography. Especially in the presence of coronary calcifications and residual motion in the dataset, MSCT is presently limited to accurately grade lesion severity (percentage of stenosis). However,

Table 9.1 Overview of image parameters, patient preparation, and contrast administration.

	Catheter angiography	64-MSCT	DSCT

DSCT, dual-source computed tomography; MSCT, multislice computed tomography.

MSCT has a notably high sensitivity and negative predictive value for the detection of significant CAD, thus it may be well suited to clinical situations in which exclusion of CAD is of paramount concern (e.g., in patients with low to intermediate pretest likelihood of disease) [23]. The evolving indications of MSCT of the heart, with emphasis on the evaluation of coronary arteries, are shown in Table 9.3.

Bifurcations and ostial lesions

The angiographic evaluation of bifurcation lesions can be hindered by projectional foreshortening, vessel overlap, and insufficient vessel opacification; for these reasons, the assessment of the side branch ostium can be particularly challenging. Errors in diagnosis can lead to consequences for patient management: when CABG surgery is the treatment of choice, underestimation of a side branch lesion can result in the side branch not being grafted; when percutaneous coronary intervention (PCI) is preferred, detailed anatomic information permits selection of the optimal intervention strategy. Moreover, conventional angiography does not provide sufficient information on the plaque burden at the level of the bifurcation. In the presence of a high plaque burden, initial treatment of both the main and side branches (e.g., crush or culottes techniques) should be preferred over main branch stenting first followed by provisional balloon angioplasty (with or without stenting) of the side branch.

(a)

(b)

(c)

(d)

(e)

Figure 9.5 (a) (1–12): The basic information of MSCT is the axial images (a1–a12). Scrolling through them in the cranial to caudal direction shows any structure in the axial plane. The scan starts at the level of the tracheal bifurcation (a1) therefore the main bronchi (asterisks), the ascending aorta (A) and pulmonary artery (PA) are shown. As we scroll caudally, the origin of the left main coronary artery (a2, curved arrow) and its trifurcation (a3) into left anterior descending artery (gross arrow), circumflex artery (open arrow), and intermediate branch (IMB) are seen. The left anterior descending artery (a3–a12, gross arrow) courses along the superior interventricular groove and can be followed down to the apex of the heart. A diagonal branch is also seen (a4–a6, gross arrowhead). The left circumflex artery (a3–a5, open arrow) courses in the left atrioventricular groove and gives an obtuse marginal branch (a6–a8, open arrowhead). The proximal right coronary artery (a6, thin arrow) has a short horizontal course. Then the vessel courses caudally (a7–a9, thin arrow) in the right atrio-ventricular groove. The inferior inter-ventricular groove contains the posterior descending artery (a12, thin arrow). (A, aorta; asterisks, main bronchi; C, cava; CS, coronary sinus; IMB, intermediate branch; iPV, inferior pulmonary veins; L, liver; LA, left atrium; LV, left ventricle; PA, pulmonary artery; RA, right atrium; Rap, right appendage; RV, right ventricle; RVOT, right ventricular outflow tract; sPV, superior pulmonary veins.) (b–e) Axial images are reconstructed to form a volume. Post-processing is performed on this volume dataset. Multiplanar reconstructions (b) cut this volume according to planes arbitrarily tilted in any orientation. When the cut plane is not flat but curved, the result is a curved multiplanar reconstruction (c, d). This image is a flattened representation of the curved plane (d). Maximum intensity projection is an algorithm that visualizes only the structures with the highest attenuation along the observation line (c). Volume rendering (e) displays the volume based on the density of the structures. Color attribution is arbitrary; therefore the appearance will change when the operator changes the colors of the algorithm.

Figure 9.6 Typical artifacts in cardiac MSCT (a) include motion artifacts (b) and stack misalignment resulting from heart rate variations or slight arrhythmia (c). Whereas motion artifacts cause blurring (B), images within a misaligned stack are not blurred (C).

Figure 9.7 Volume rendered image (a), curved maximum intensity projection (b), and multiplanar reconstruction (c) show a calcified plaque (arrow) located in the left anterior descending (LAD) just proximal to the origin of a septal branch (S). The size of structures with high X-ray attenuation such as calcifications is overestimated in MSCT due to partial voluming. This calcification superimposes most of the coronary artery lumen. The conventional angiogram (d) shows a normal LAD. LCx, left circumflex.

Van Mieghem *et al.* [24] compared MSCT with conventional angiography for the detection and classification of coronary bifurcation lesions. In keeping with the available literature on non-bifurcation lesions, they reported 96% sensitivity, 97% specificity, 63% positive predictive value, and 99% negative predictive value for the detection of bifurcation lesions (Figure 9.9). MSCT was found to be accurate also in classifying bifurcation lesions according to the Medina classification system [25]. Furthermore, thanks to the three-dimensional nature of MSCT data, the bifurcation angle between the main vessel and the side branch could be measured accurately. In situations where both branches needed to be stented, information regarding the bifurcation angle was used to support the choice of the stenting technique.

The visualization of ostial lesions (Figure 9.10) can be affected by projectional limitations in conventional angiography. Occasionally, ostial lesions can be masked by the engagement of the catheter tip beyond the lesion. At a pre-interventional stage, MSCT can provide information on three-dimensional anatomy of ostial lesions and vessel take-off angle [26].

Chronic total occlusion

In the diagnostic work-up of patients with chronically occluded coronary arteries, MSCT can add important information to conventional angiography. Measurement of the length of the occluded segment, which has long been identified as a predictor of failed PCI, can be limited in conventional angiography by foreshortening, calibration limitations, and lack of collateral filling (Figure 9.11). Conversely, MSCT is a three-dimensional technique that allows reliable length measurement of coronary segments. Likewise, MSCT permits the evaluation of the proximal entry port, the severity of calcification (Figure 9.12), and the delineation of occlusion trajectory. Therefore, MSCT improves the ability to predict the success rate of PCI. Mollet *et al.* [27] found that a blunt entry point, an occlusion length >15 mm, and severe calcification, all determined by MSCT, were independent predictors of procedural failure.

Table 9.2 Detection of coronary stenosis—diagnostic performance of MSCT vs. conventional angiography.

Stents

Coronary stents are notoriously difficult to assess by MSCT. Partial voluming artifacts enlarge the apparent size of the stent; this is particularly disturbing in smaller stents, where the in-stent lumen might be completely obscured, and in overlapping and bifurcation stents due to an excess of metal. As demonstrated *in vitro*, types of metal and strut thickness also have an important role for in-stent lumen assessability [28]; generally, stents with thinner struts (e.g., 0.14 mm) are less problematic than stents with thicker struts (e.g., 0.15 mm and above).

In the evaluation of coronary stents, the finding of contrast-enhancement distal to the stent is not foolproof for stent patency, because collateral pathways may fill the vessel retrograde; if the stent is being evaluated for the presence of non-occlusive in-stent restenosis, direct visualization of the in-stent lumen becomes the mandatory criterion.

Technical requirements for coronary stent imaging are 64-slice MSCT scanners with thin detectors in order to optimize spatial resolution and decrease partial voluming. High temporal resolution is also important because high density artifacts are exacerbated by the presence of residual motion in the MSCT dataset [29].

Clinical studies compared different generations of MSCT scanners with conventional angiography for the detection of in-stent restenosis, defined as $\geq 50\%$ luminal narrowing (Table 9.4). Studies performed using 16-MSCT [30], 40-MSCT [31], and 64-MSCT [32–34] reported promising results with variable percentages of non-assessable stents. Using DSCT [35], the percentage of non-assessable stents was found to be low; whereas the diagnostic performance did not vary significantly between different stent configurations (i.e., single stents vs. overlapping/bifurcation stenting), the results were influenced importantly by the stent diameter. In particular, the ability of DSCT to exclude with certainty in-stent

restenosis in stents with diameters ≤ 2.75 mm was significantly lower than that observed in larger stents.

Ideally, the stent type and diameter are known prior to the scan, therefore in-stent lumen assessability in a particular patient could be predicted from the available *in vitro* and *in vivo* data. However, MSCT was shown to have a constantly high negative predictive value, therefore it may be useful in patients with clinical symptoms but low pre-test probability for in-stent restenosis.

Stent implantation in the left main (LM) and proximal left anterior descending/circumflex (LAD/Cx) provides a suitable scenario for the use of MSCT in the detection of in-stent restenosis. This is mainly because of the relatively large size of stents implanted in the LM and proximal LAD/CX; moreover, this part of the coronary tree is relatively protected from motion artifacts. Although CABG surgery is still recommended in patients with LM disease, PCI is increasingly performed on the unprotected LM coronary artery in the drug-eluting stent (DES) era. However, in-stent restenosis still occurs with DES and can cause fatal myocardial infarction or sudden death [36], therefore surveillance with routinely angiography 6 months after PCI for LM stem is highly recommended [37]. A study by Van Mieghem *et al.* [38] showed that MSCT was safe and reliable in excluding in-stent restenosis in patients with LM and proximal LAD/CX stents; this study suggested that MSCT might be an acceptable first-line alternative to conventional angiography for the follow-up of patients after unprotected LM stenting.

MSCT also visualizes the configuration of bifurcation/overlapping stents (Figure 9.13) and the position of stents implanted in ostial lesions. Tissue prolapses, stent malapposition, and underexpansion are generally not clearly visualized by MSCT. It is conceivable that stents with thinner struts, absorbable and non-metallic stents (Figure 9.14) will be less affected by high density artifacts; the introduction of these new devices might increase the utility of MSCT in patients after PCI.

Coronary artery bypass grafts

General issues

Patients with prior CABG surgery usually present with comorbidity and have a higher prevalence of valve disease and ventricular dysfunction than non-CABG patients. They have a higher incidence of complications during invasive procedures, including

Table 9.3 Evolving indications of MSCT of the heart with emphasis on the evaluation of coronary arteries [23].

Detection of CAD in symptomatic patients
1. Intermediate pre-test probability of CAD + equivocal ECG/unable to exercise
2. Equivocal exercise tests, perfusion imaging, stress echo
3. Evaluation of coronary arteries in patients with heart failure of new onset to assess etiology
Coronary anomalies
Exclusion of CAD prior to cardiac valve surgery/major non-cardiac surgery
Patients with recurrent chest pain after PCI with low probability of in-stent restenosis and large stents (≥ 3 mm)
Coronary artery bypass grafts
Acute chest pain
1. Non-ST segment elevation and initial troponin negative
2. Intermediate probability of aortic dissection/aneurysm, pulmonary emboli, obstructive CAD (triple rule out)

Figure 9.8 Curved multiplanar reconstructions of the left main (LM) and LAD arteries obtained in three different patients with 16-MSCT (a), 64-MSCT (b), and DSCT (c) show progressive improvement in image quality. All the patients had heart rates during the scan of 62–65 bpm.

Figure 9.9 The DSCCT multiplanar reconstruction (a) shows a proximal bifurcation lesion (arrows) in the left anterior descending (LAD) artery, also seen on the curved multiplanar reconstructions of the LAD (c) and diagonal branch (e). The lesion is confirmed by the conventional angiogram (f). According to the Medina classification system (b), the lesion involves proximal main branch and side branch whereas the distal main branch is unremarkable (1,0,1). The lesion is not clearly detectable in the volume rendered image (e); distally to the bifurcation, the LAD has intramyocardial course (d) (arrowheads).

cardiac catheterization, and can therefore benefit from non-invasive coronary angiography performed by MSCT.

Generally, bypass grafts are well visualized by MSCT because of their large diameter, limited calcification, and relative immobility. However, surgical opaque material, such as vascular clips, sternal wires, and graft orifice indicators, hinder the evaluability of coronary grafts (Figure 9.15).

Clinical performance and limitations

64-MSCT permits the evaluation of graft patency with a sensitivity approaching 100% in both arterial and venous grafts and without exclusion of grafts because of insufficient image quality (Table 9.5) [39–42]. However, ischemic symptoms in patients after CABG surgery can be caused by obstruction of bypass grafts or by disease progression in native coronary arteries. Comprehensive evaluation

(a)

(c)

Figure 9.10 The volume rendered view after removal of the right atrium (a), axial image (b), and curved multiplanar reconstruction (c) demonstrate an ostial lesion of the right coronary artery (RCA).

post-CABG surgery should also include the native coronary tree; assessment of the native coronary arteries can be difficult in these patients owing to the diffuse nature of the disease and the presence of severe calcifications [39].

Valve disease

Whereas the visualization of the tricuspid and pulmonary valves is generally inconsistent, the mitral and aortic valves can reliably be depicted in contrast-enhanced MSCT scans. While MSCT

(a)

(b)

(c)

Figure 9.11 Occlusion of the RCA (open arrowheads) is demonstrated by the conventional angiogram (a), DSCT multiplanar reconstruction (b), and curved multiplanar reconstruction (c) of the vessel. The distal patent RCA is not sharply visualized on the angiogram (a). The multiplanar reconstruction (b) and curved multiplanar reconstruction (c) of the RCA permit better visualization of the distal patent vessel (solid arrowheads) and thus of the actual occlusion length. Asterisks: right ventricular branch.

cannot provide measurements of transvalvular flow and pressure gradients, dynamic imaging of the open and closed valve is possible (Figure 9.16). For the normal and stenotic aortic valve, recent studies have demonstrated the ability of MSCT to measure the orifice area with close correlation to transesophageal echocardiography and invasive assessment of the aortic orifice area [43,44]. However, in the setting of severely calcified stenosis, measurements of the opening area by CT may become unreliable. Non-enhanced CT scans can be used to quantify aortic valve calcium [45].

Figure 9.12 Occlusion of the proximal LAD (arrowheads) is demonstrated by the DSCT maximum intensity projection image (a) and conventional angiogram (b). The DSCT cross sections (c-f), obtained as indicated in (a), provide information on the severity of lesion calcification. Bulky calcifications are present proximally to the occlusion (c), at the level of the stump (d) and more distally (f).

Coronary anomalies

It can sometimes be difficult during invasive coronary angiography to define the origin and course of anomalous coronary arteries. MSCT is extremely reliable for visualizing the origin and course of anomalous coronary vessels and is well suited for investigating patients with known or suspected congenital coronary artery anomalies. MSCT permits morphologic analysis with very high resolution; moreover, this technique is not restricted by “echo windows” or by implanted devices such as pacemakers or implantable cardioverter defibrillators, which are frequently encountered in patients with congenital heart disease. The introduction of whole-heart 320-row CT, which reduces radiation exposure from intensive overscanning and overranging, makes this technique particularly attractive in women and younger age groups [46].

Recent clinical trials of CT coronary angiography

SCOT-HEART trial

CT coronary angiography in patients with suspected angina due to coronary heart disease (SCOT-HEART): an open-label, parallel-group, multicenter trial, is the first trial to assess the clinical impact of the addition of CT angiography (CTA) in patients presenting with suspected angina due to coronary heart disease (CHD) in the outpatient setting [47]. Previous trials have focused

on assessing the accuracy and comparability of CTA for the identification of CHD [48–50] and the evaluation of low–intermediate risk patients with chest pain in emergency departments [51–53]. This prospective, parallel group trial included patients aged 18–75 years referred for the assessment of suspected angina due to CHD from 12 centers across Scotland. The final analysis included 4146 patients randomized to standard care plus CTA or standard care alone. Some 47% of subjects had a baseline diagnosis of CHD and 36% a diagnosis of angina due to coronary heart disease. At 6 weeks, CTA reclassified the diagnosis of CHD in 558 (27%) of subjects assigned to CTA compared with 1% assigned to standard care and the diagnosis of angina due to CHD in 481 (23%) of subjects assigned to CTA compared with 1% to standard care ($p < 0.001$ for both).

The certainty (relative risk [RR] 2.56, 95% CI 2.33–2.79; $p < 0.0001$) and frequency (RR 1.09, CI 1.02–1.17; $p = 0.0172$) of the diagnosis of CHD increased with CTA compared with standard care. However, the certainty increased (RR 1.79, CI 1.62–1.96; $p < 0.0001$) and frequency appeared to decrease (RR 0.93, CI 0.85–1.02; $p = 0.1289$) for the diagnosis of angina due to CHD. This changed planned investigations (12% vs. 1%; $p < 0.0001$) and treatments (27% vs. 5%; $p < 0.0001$) but did not affect 6-week symptom severity or subsequent admittances to hospital for chest pain. After 1.7 years, CTA was associated with a 38% reduction in fatal and non-fatal myocardial infarction (26% vs. 42%, HR 0.62, 95% CI 0.38–1.01; $p = 0.0527$), but this was not significant.

NPV, negative predictive value; PPV, positive predictive value.

*Only one stent available, without in-stent restenosis.

In summary, CTA helped clarify the diagnosis and target interventions with a trend toward lower risk of myocardial infarction in this outpatient cohort with suspected angina due to CHD.

PROMISE trial

Outcomes of anatomic versus functional testing for coronary artery disease: the prospective multicenter imaging study for evaluation of chest pain (PROMISE) trial is the largest outcome study in cardiovascular imaging to date [54]. The trial

randomized 10,003 symptomatic mostly intermediate-risk outpatients (mean age 60.8 years, 52.7% women, 87.7% with chest pain or dyspnea on exertion) without CAD to a strategy of initial anatomic testing with CTA or to functional testing (exercise electrocardiography, nuclear stress testing, or stress echocardiography). Additional inclusion criteria were an age of more than 54 years (in men) or more than 64 years (in women) or an age of 45–54 years (in men) or 50–64 years (in women) with at least one cardiac risk factor (diabetes, peripheral arterial

Figure 9.13 The DSCT axial image (a), its magnification (a'), the cross-sectional views (b, c) and the diagram (e) show the typical appearance of the crush stenting technique, characterized by three layers of metal crushed against the ostium of the side branch. The DSCT cross-section obtained at the level of the carina (B) and the curved multiplanar reconstruction of the diagonal branch (g) demonstrate in-stent restenosis in the diagonal branch stent (arrow). The LAD (main branch) is patent (f). The conventional angiogram (d) confirms the findings.

Figure 9.14 The DSCT multiplanar reconstruction (a) and its magnification (a') show a bioabsorbable stent placed in the LCx artery. The stent is radiolucent with radiopaque markers at the stent edges.

Figure 9.15 In a patient after coronary artery bypass graft surgery, the DSCT volume rendered image (a) and the curved multiplanar reconstruction (b) show patency of the left internal mammary artery graft and of the anastomosis of the graft onto the LAD. Notice the hyper-dense appearance of the surgical clips.

disease, cerebrovascular disease, current or past tobacco use, hypertension, or dyslipidemia).

Over a median follow-up period of 25 months, a primary endpoint event (death from any cause, myocardial infarction, hospitalization for unstable angina, and major complication of cardiovascular procedures or tests) occurred in 164 of 4996 patients in the CTA group (3.3%) and in 151 of 5007 (3.0%) in the functional testing group (adjusted hazard ratio 1.04; 95% CI 0.83–1.29; $p = 0.75$). At 12 months, the risk of death or non-fatal myocardial infarction was marginally lower in the CTA group than in the functional testing group (hazard ratio 0.66; 95% CI 0.44–1.00; $p = 0.049$).

CTA was associated with fewer catheterizations showing no obstructive CAD than was functional testing (3.4% vs. 4.3%; $p = 0.02$), although more patients in the CTA group underwent catheterization within 90 days after randomization (12.2% vs. 8.1%). Revascularization was performed within 90 days after randomization in 311 of 4996 patients (6.2%) in the CTA group compared with 158 of 5007 (3.2%) in the functional testing group ($p < 0.001$), including 72 and 38 patients, respectively, who underwent CABG. The median cumulative radiation exposure per patient was lower in the CTA group than in the functional testing group (10.0 vs. 11.3 mSv), but 32.6% of the patients in the

functional testing group had no exposure, so the overall exposure was higher in the CTA group (mean 12.0 vs. 10.1 mSv; $p < 0.001$).

In an economic sub-analysis there were no significant differences between the strategies in costs in that patient population over 3 years [55]. The costs per person for CTA were slightly more than costs for functional testing: \$279 at 3 months, \$358 at 12 months \$388 at 24 months and \$694 at 36 months. The jump in cost between 24 and 36 months was attributed to some outlier costs for non-cardiovascular care and increased revascularization in the CTA group.

In summary, in symptomatic patients with suspected CAD who required non-invasive testing, a strategy of initial CTA, as compared with functional testing, did not improve clinical outcomes over a median follow-up of 2 years. CTA remains a good initial testing option given the similarity in outcomes and costs to functional testing.

PLATFORM trial

A prospective trial recently evaluated the role of CTA with incorporation of CTA-based calculation of fractional flow reserve (CTA/FFR) of possibly significant lesions [56]. This prospective, randomized multicenter trial found significantly lower rate of

Figure 9.16 The MSCT multiplanar images were obtained in two different patients (A and B) parallel to the aortic valve. Images in the upper row (a1, b1) were obtained during diastole. Images in the lower row (a2, b2) were obtained in systole. In patient A, the cusps adapt during diastole (a1) and open during systole (a2); the aortic valve is normal. In patient B, aortic cusps are thickened and calcified (b1, b2). Opening is incomplete during systole (b2); the patient has aortic valve stenosis.

(futile) invasive coronary angiography in the group randomized to CTA/FFR imaging compared with control. However, this trial did not evaluate whether imaging with CTA alone versus CTA/FFR might have produced similar results.

The last three recent trials provide supporting evidence that coronary CTA should be incorporated in the testing armamentarium for evaluating patients with chest pain and possible coronary artery disease. The trials confirm the high clinical value of

CTA in identifying high risk plaque and determining the existence and severity of coronary stenosis which can lead to alteration of treatment strategies with the potential to improve clinical outcomes of symptomatic patients. Notably, both confirmation but also exclusion of anatomic coronary disease can be of clinical importance in patient care because initiation of proper therapy (in the former case) or the avoidance of futile and potentially dangerous approaches (in the latter case). There is no doubt that

Case study

A 44-year-old woman was seen in the outpatient cardiology clinic for vague left-sided chest pain sometimes aggravated by exertion. She has a history of mixed hyperlipidemia, depression, and morbid obesity (weight 264 lb, BMI 46.8) with a 40 lb weight gain in the last 5 years. Her baseline ECG was normal (Figure 9.17a).

An exercise echocardiogram was performed. She exercised for 6 minutes achieving a workload of 6 METs and 92% of the maximum predicted heart rate. The blood pressure response was hypertensive and there were equivocal ST changes with runs of ventricular bigeminy and symptoms of chest pain/shortness of breath during stress. There was augmentation of the left ventricular ejection fraction (LVEF) from 60% to 80% and no stress-induced wall motion abnormalities. Single vessel or distal vessel coronary artery disease could not be excluded.

A positron-emission tomography (PET) scan was planned. However, a pharmacologic single-photon emission CT (SPECT) study was performed with regadenoson. A moderate sized reversible anterior/anterolateral defect of moderate intensity was noted (Figure 9.17b). The LVEF was 60% at rest and >60% post-stress.

Cardiac catheterization was performed for possible ischemia on the SPECT study. Coronary angiography was performed which revealed an anomalous single coronary artery arising from the right coronary cusp giving rise to the left anterior descending (LAD) and left circumflex (LCx) arteries. There was no apparent angiographic stenosis of any other arteries although the LAD appeared small and could not be selectively engaged. A left ventriculogram revealed normal LV systolic function with an estimated LVEF of 60%. A coronary CTA was recommended for assessment of the course of the LAD and LCx arteries.

A multidetector CT coronary angiogram was obtained using retrospective ECG-gating after coronary vasodilatation with 0.4 mg of sublingual nitroglycerin. A single coronary artery arising from the right coronary cusp was seen (Figure 9.17c). The single coronary artery gives rise to the LAD, LCx, and right coronary (RCA) arteries and there was no stenosis of any of the arteries. The LAD follows a pre-pulmonic course and the left circumflex a retroaortic course (Figure 9.17d). The calcium score was zero. The LVEF was 81%.

This case illustrates the utility of coronary CTA in the assessment of chest pain in low to intermediate risk patients and for

(a)

the evaluation of the origin, course, and patency of suspected anomalous coronary arteries. It would have been reasonable to proceed directly to coronary CTA after the equivocal stress echocardiogram instead of performing another functional stress test and the invasive coronary angiogram could also have been

avoided. The basal anterior/anterolateral reversible defect was likely related to breast attenuation which was also seen on the raw projection images. Breast attenuation artifacts are common in obese women on SPECT studies and a PET study would have been a better choice as previously planned.

CTA imaging with and without functional lesion assessment should be the subject of future clinical trials.

Cardiovascular Magnetic Resonance Imaging

Omosalewa O. Lalude¹ and Stamatios Lerakis²

¹Memorial Healthcare System, Hollywood, FL, USA

²Emory University School of Medicine and Georgia Institute of Technology, Atlanta, GA, USA

In the last 15–20 years, cardiac magnetic resonance (CMR) has emerged as a useful non-invasive tool for the complete assessment of cardiovascular morphology and function in the absence of ionizing radiation. Although other imaging modalities such as echocardiography, nuclear imaging, and computed tomography (CT) are available for the assessment of cardiovascular pathology, CMR has imaging sequences that can be manipulated to generate varying degrees of soft-tissue contrast for cardiac tissue characterization. Coupled with this, is the excellent spatial (1–2 mm in-plane resolution), temporal (50 ms or better), and contrast resolutions which allow for routine assessment of cardiac function and blood flow [1,2]. Sequences involving the administration of gadolinium-based contrast agents (GBCAs) also allow for the assessment of myocardial perfusion, viability, and various myopericardial diseases.

The main limitations of CMR are inability to image very large or claustrophobic patients, the long scan time of 20–45 minutes and the risk of nephrogenic systemic fibrosis from gadolinium contrast in patients with impaired renal function (GFR <30 mL/min). The limitations notwithstanding, the ability of CMR to provide comprehensive evaluations of cardiovascular morphology, function, and pathology makes it an attractive tool for the assessment of patients undergoing cardiac interventional procedures and for the planning of such interventions. It is therefore imperative that the interventional cardiologist be familiar with the applications of CMR in this regard. This chapter provides a concise overview of the techniques for the CMR imaging, the applications of these techniques, and the use of CMR in the planning of interventional procedures.

CMR technical concepts

Image generation

CMR is based on the detection of the magnetic spin direction of protons from water and fat in the body. The human body is composed of ~70% water and water is formed from two hydrogen atoms and one oxygen atom. The hydrogen atom has a single proton in its nucleus and each proton functions as a molecular magnet within the magnetic field of the MRI scanner [3]. The intrinsic angular momentum of each proton results in rotation (or precession) around the longitudinal axis of the scanner's magnetic field. This is referred to as "spin." Application of radiofrequency (RF) energy at a flip angle to this axis with the precessing (Lamor) frequency tips the

proton spins toward the transverse plane generating a magnetization that emits a coherent oscillating signal that decays in amplitude and coherence with time. The decay of amplitude (T1 relaxation) and coherence (T2 relaxation) is unique to each tissue and generates energy which is measured by properly oriented receiver coils [1,4]. Using spatial modulation of the magnetic field strength, the received MR signal is spatially encoded for image generation. Parameters such as the flip angle, the time between the applications of successive RF pulses to generate a transverse magnetization (repetition time, TR), and the time at which the signal is measured after the excitation (TE) can be altered to generate images that highlight a specific type of soft-tissue contrast (i.e., T-1 weighted, T-2 weighted, or proton-density weighted) [1].

CMR techniques

There are multiple CMR sequences that can provide morphologic, cine, perfusion, viability, and velocity-encoded flow images. Morphologic black blood images for excellent depiction of myocardial structure and the relationship of the great vessels are typically performed with single-shot (i.e., static) double inversion recovery fast spin-echo techniques (Double-IR FSE) and half-Fourier acquisition turbo spin-echo (HASTE). A fat saturation prepulse can be applied if necessary and the images are obtained from fast acquisitions every other heartbeat and do not require a breath hold. Segmented (i.e., from several heart beats) FSE images are acquired when higher spatial resolution and improved T1 or T2-weighting are required for the characterization of cardiac masses [5].

Bright blood morphologic imaging was previously performed with gradient-recalled echo (GRE) pulse sequences but steady state free precession (SSFP) sequences have resulted in improved imaging. SSFP sequences are not dependent on the inflow effects of blood but on the T2/T1 ratio of the tissue being imaged and provide high intrinsic contrast between the blood and myocardium [6]. They are similar to HASTE sequences in that they do not require a breath hold and are a form of single-shot imaging. They are useful for the evaluation of intraluminal abnormalities as in aortic dissection or for the localization of pulmonary veins [5]. The SSFP technique can be used to produce cine images in which multiple images are obtained in the same slice location in rapid succession during different phases of the cardiac cycle and displayed as a continuous movie loop. The standard acquisition is a segmented retrospectively

gated acquisition in which data are acquired throughout the cardiac cycle and “time stamped” to allow assignment to the proper cardiac phase. Cine imaging allows evaluation of ventricular wall motion, wall thickening, measurement of chamber sizes, and assessment of valvular morphology and function.

Cardiac tagging is a widely available technique that produces a deformable reference grid that allows visualization and quantification of regional heterogeneity in myocardial contraction in the setting of coronary artery disease (CAD) and non-ischemic cardiomyopathy [7–10]. It is also very useful for assessing the motion of the myocardium relative to the pericardium. Displacement encoding with stimulated echo (DENSE) is a tissue tracking variant that overcomes some of the limitations of tagging by allowing direct visualization of myocardial displacement and tracking of myocardial displacement on a pixel basis [3].

Tissue characterization is a unique feature of CMR. It uses the characteristics of proton relaxation (i.e., the relaxation times T1, T2, and T2*) to characterize myocardial or vascular tissue. T1 images are often used for contrast-enhanced studies while T2 and T2* imaging have mostly been used in non-contrast approaches. For example, within the myocardium, T2-weighted CMR imaging is sensitive to regional or global increases of myocardial water content as with acute transplant rejection, acute myocarditis, and acute myocardial infarction. T2* relaxation times are significantly altered by the myocardial iron content and their quantification provides an excellent marker for iron overload [2]. Pixelwise T1 and T2 maps whereby an estimate of T1/T2 is encoded in the intensity of each pixel allows for quantification of the parameter of interest. This permits establishment of normal ranges and the assignment of colors for simplification of visual interpretation [11–13].

Perfusion imaging for the assessment of myocardial blood flow and ischemia is performed at rest and with a pharmacologic vasodilator stress agent such as adenosine or regadenoson. T1-weighted GRE images are acquired every heart beat in diastole to study the first pass kinetics of GBCAs. Usually, 3–4 myocardial slices (depending on heart rate) are obtained to ensure adequate ventricular coverage and temporal resolution. T1-weighting is accentuated for accurate depiction of GBCAs which substantially shorten the T1 of the myocardium causing an increase in signal intensity. Signal intensity (SI) correlates with contrast concentration and analysis can be performed in a qualitatively or quantitatively. Most frequently, a trained observer qualitatively examines the myocardium for low signal or hypoperfusion relative to normally perfused segments. In delayed enhancement (DE) or late gadolinium enhancement (LGE) CMR, the differential distribution volume of GBCAs and T1 difference between necrotic or fibrotic and normal myocardium is exploited to generate contrast on an inversion recovery (IR) T1-weighted GRE sequence. The inversion delay is chosen such that normal myocardium is “nulled” (zero SI) and appears very dark while necrotic or fibrotic myocardium appears bright (Figure 10.1). This is a consequence of the loss of cell membrane integrity and interstitial edema associated with infarction that increases the volume of distribution of GBCAs in the extracellular space [14,15]. In addition, reduction in functional capillary density alters the contrast kinetics of GBCAs such that washout from infarcted myocardium occurs at a much slower rate than from normal myocardium [15]. Areas of prior infarction will have higher concentrations of contrast on DE images 5–10 minutes after intravenous administration of GBCAs. LGE due to ischemic heart disease is typically sub-endocardial but may be extensive and transmural. Left ventricular (LV) epicardial and midwall patterns of LGE are associated with

Figure 10.1 (a) Two-chamber view showing high signal intensity (SI) transmural late gadolinium enhancement (LGE) of the entire anterior wall, apex, and inferior wall with an apical thrombus (white arrow). (b) Four-chamber view showing high SI transmural delayed enhancement (DE) of the septum, apex and apical lateral walls with underlying thrombus (white arrow). (c, d) Mid and distal short axis slices of the left ventricle showing delayed transmural enhancement of the anterior, septal, and inferior walls. Patient was a 37-year-old man who had an ST-segment elevation MI and received percutaneous intervention (PCI) to the left anterior descending (LAD) artery. He had a previous PCI to the obtuse marginal branch of the circumflex and the right coronary artery (RCA) is found to be occluded at that time. The study was performed for heart failure evaluation. Also note the four chamber dilatation and surrounding pericardial effusion. The circumflex artery territory is viable but there is no viable myocardium in the LAD and RCA territories.

infectious and inflammatory conditions such as myocarditis and sarcoidosis. In cardiac amyloidosis, molecular binding to amyloid protein and very rapid washout of GBCAs from blood results in extensive uptake in myocardial tissue. Single-shot LGE imaging using a long inversion time (~600 ms) is useful for detecting thrombi and can be obtained 2–5 minutes post contrast [5,16,17].

Blood flow can be quantified by phase contrast velocity mapping (PCVM) using velocity-encoded sequences. Velocity-encoding phase shifts result from the sequential application of bipolar magnetic field gradients of opposite polarity. The first gradient produces a phase shift that is reversed by the second pulse such that stationary spins will have no net phase at the end of the sequence. However, flowing spins will acquire a net phase change dependent on velocity in the direction of the flow-encoding gradients [18]. The maximum velocity encoded by the sequence is termed the Venc

and should be set at a value just above the anticipated velocities to be measured to avoid aliasing. Aliasing results in artifactual reduction of measured flow while a Venc setting that is too high leads to increased noise or inaccuracy of flow or velocity measurement [5]. Two sets of data are obtained. The magnitude data provide the map of protons within the slice, giving the conventional cross-sectional image. The other set of data obtained is the phase data. This dataset provides a map of the velocity of the protons within the slice. The intensity of a pixel in a phase image reflects the velocity of the protons within that pixel. Evaluation of the intensity of a region of pixels provides quantitative data reflecting the flow of blood through a portion of the heart or artery [18].

Contrast enhanced MR angiography (CE-MRA) is most often performed using thin-section T1-weighted spoiled GRE image acquisitions during the arterial passage of intravenously administered contrast [5,19]. Multiple thin slices are obtained in a 3D volumetric technique and then assembled into maximum intensity projection (MIP) and volume rendered images. Multiplanar review, which allows visualization of the vessel in cross-section and evaluation of vessel walls, can also be performed. The thoracic aorta is usually imaged in the axial or sagittal plane. An oblique sagittal “candy cane” view which reduces the thickness of the imaging slab can be used to minimize breath hold time. Sequences can be performed with electrocardiographic (ECG) gating and imaging in diastole to avoid image degradation in the aortic root from cardiac motion. Abdominal, pelvic, and lower extremity runoff studies are usually obtained in the coronal plane and are well accepted for comprehensive evaluation of the vasculature in patients likely to require revascularization [20,21]. MRA for the evaluation of renal artery stenosis in comparison with digital subtraction angiography has also been well validated [22].

The visualization of coronary arteries on MR has been a longstanding challenge because of the complexities of imaging small, tortuous vessels at high spatial resolution. This is further compounded by the fact that coronary arteries are only stationary for brief periods of the cardiac cycle. The most successful techniques for imaging coronary arteries utilize navigator echo-based cardiac-gated techniques to minimize respiratory motion [23,24]. A high spatial resolution 3D GRE volume covering the proximal and mid coronary arteries is acquired in mid-diastole when coronary blood flow is maximized. The sequence is time consuming and the distal coronary segments are not well visualized. Thus, the major utility of this technique is for assessing the origins and to a limited degree the course of the coronary arteries.

Patient preparation and MRI safety

Although CMR is generally considered safe, there are three main categories of safety concerns: potential projectiles in the MR scanner room, implanted cardiovascular devices, and issues related to contrast administration.

The first step in the preparation of a patient is screening to ensure that there are no major contraindications such as implanted cerebrovascular clips, cochlear implants, ocular metallic fragments, neural stimulators, or insulin pumps. At most institutions, MRIs are not performed in patients with cardiac pacemakers or implantable cardioverter defibrillator (ICD) because of the potential risk and of device malfunction, excessive device or lead heating, or induction of currents within the leads. In addition, the wires and generator can sometimes be associated with significant artifact and other imaging modalities have to be considered. Recent reports, however,

suggest that CMR can be performed safely in patients with pacemakers and ICDs manufactured after 2000 if the benefits are deemed to outweigh the risks [25,26]. Consultation with a Pacemaker/ICD expert or electrophysiologist is recommended prior to CMR imaging [26]. Most coronary and peripheral stents are safe for CMR, even immediately after implantation, as are many nitinol-based devices, such as septal/left atrial appendage occluders and prosthetic valves [2]. If there is any doubt as to the safety of a device, further enquiry should be made, a CMR safety or physics expert may be consulted or an alternative procedure can be performed. GBCAs should not be administered patients with acute or chronic severe renal insufficiency (i.e., GFR <30 mL/min) who are at increased risk for nephrogenic systemic fibrosis or nephrogenic fibrosing dermopathy (NSF/NFD) [27] and pregnant patients.

The patient is then briefed on what to expect throughout the study and instructed on breath holding as most sequences are performed on end-expiration and require 5–10 second breath-holds. Informed consent is usually obtained for contrast and stress CMR studies. A 20-gauge intravenous catheter is placed in an arm vein for the administration of the contrast agent. A second intravenous line is placed in the contralateral arm if a pharmacologic stress agent is to be administered. Vector cardiographic chest leads are placed for ECG gating and respiratory monitoring can be achieved by attaching a bellows-type belt around the patient's waist. The phased array cardiac receiver coil is then placed on the precordium. Brachial cuff pressure and digital pulse oximetry is periodically measured for stress CMR or studies requiring sedation for claustrophobia. Patients undergoing CMR stress imaging with adenosine or regadenoson should avoid caffeine-containing substances for 12–24 hours before the test. Although anaphylactic reactions to GBCAs are rare [2], patients with prior documented reactions should be premedicated with steroids and antihistamines 12–24 hours prior to the scan.

Applications of CMR

Heart failure

Rest CMR is useful for the initial evaluation of cardiac structure and function for newly suspected or potential heart failure (HF): patients with new symptoms or signs of HF, prior to or during the use of cardiotoxic chemotherapy in patients without prior LV function assessment, in patients with familial or genetic dilated cardiomyopathies, in adult congenital heart disease, and in patients with acute myocardial infarction (AUC imaging in HF 2013). In the evaluation of ischemic etiology, stress/rest CMR can be performed in patients with or without angina or ischemic equivalent. After ischemic etiology is determined, in patients with mild–severe LV dysfunction, LV ejection fraction 30–49% and suitable coronary anatomy for revascularization, viability evaluation can be performed using stress/rest or rest CMR. CMR can also be used to determine candidacy for ICD or cardiac resynchronization therapy (CRT) and for pre-procedure planning (i.e., assessment of fibrosis, intracoronary thrombus, and coronary vein variations) [28].

CMR offers more accurate assessment of function and morphology than most other imaging modalities, providing reliable volumetric data with high diagnostic image quality in nearly all patients. High precision and avoidance of ionizing radiation allows CMR to be used in serial evaluations of patients with heart failure to assess response to medical therapy to follow disease progression. Cine SSFP sequences are used to visualize and quantify global left and right atrial and ventricular systolic function relative to reference

datasets for normal subjects. Regional biventricular function can be assessed qualitatively and quantitatively by myocardial tagging. LV diastolic function parameters such as the mitral inflow and pulmonary vein flow patterns as well as tissue velocity and strain and strain rates can be obtained similar to echocardiography. The distribution of scarring on LGE allows for accurate discrimination of ischemic from non-ischemic cardiomyopathies [29]. Non-ischemic etiologies of heart failure either do not have detectable scars or have a non-subendocardial distribution that is very distinct from ischemic subendocardial to transmural patterns. In hypertrophic cardiomyopathy (HCM), the LGE is typically found in hypertrophied regions and in the interventricular septum close to the right ventricular (RV) insertion areas [30,31]. In dilated cardiomyopathy, a mid-myocardial stripe of septal fibrosis is more typical and is of strong prognostic value [32]. In patients with acute heart failure, T2-weighted CMR may be useful to detect myocardial inflammation due to acute myocarditis [33,34]. In cardiac iron overload, quantification of T2* relaxation times have proven useful for estimating intramyocardial iron content [35].

Coronary artery evaluation

CMR has evolved over the past 10–15 years as an important diagnostic modality for coronary anomalies and coronary artery aneurysms despite the limitations previously highlighted in the section on imaging techniques [23,36]. Coronary anomalies are rare (~1% of the general population [37]) and usually benign. Congenital coronary anomalies in which the anomalous segment courses between the aorta and pulmonary artery are a well-recognized cause of myocardial ischemia and sudden cardiac death, especially among young adults [38,39]. CMR is also very helpful for visualizing the course of coronaries especially when intramural segments are present [2]. Most acquired coronary aneurysms arise as sequelae of mucocutaneous lymph node syndrome (Kawasaki's disease) and are associated with short and long-term morbidity and mortality [40]. These aneurysms have been accurately identified and characterized on CMR [41,42].

In specialized academic centers, CMR has proven useful for the discrimination of multivessel CAD which is helpful in patients with a dilated cardiomyopathy and no clinical history of myocardial infarction. Focal stenosis usually appears as signal attenuation. An international multicenter, free-breathing, 3D volume targeted CMR study of patients without prior angiography showed a high sensitivity (100%) and specificity (85%) with high negative predictive value (100%) for the identification of left main and multivessel CAD ($\geq 50\%$ diameter stenosis) by quantitative angiography [24]. The study was not as predictive for single vessel CAD. Whole heart SSFP coronary CMR methods appear to be as accurate as free breathing methods and can be useful for heavily calcified vessels which cause blooming artifacts on CT [43]. However, the evaluation of coronary stents is limited by local signal void/image artifacts that are dependent on stent material and CMR sequence. In comparison with the native coronary arteries, reverse saphenous vein and internal mammary artery grafts are relatively easy to image because of their minimal motion during the cardiac and respiratory cycles and the larger lumen of reverse saphenous vein grafts. Coronary CMR bypass graft assessment is limited by local signal loss/artifact caused by implanted metallic objects (hemostatic clips, stainless steel graft markers, sternal wires, prosthetic valves or rings, and graft stents). The assessment of grafts has shown good correlation with quantitative X-ray angiography for both graft occlusion and stenosis. This resulted in a sensitivity and specificity of 61% (25/41 grafts) and

91% (114/125 grafts), respectively, for conventional gradient-echo CMR in detecting occlusions in grafts or recipient vessels. A sensitivity of 75% and specificity of 91% was found for grafts alone. The sensitivity and specificity for graft stenosis ($\geq 50\%$; sensitivity) were 82–91% and 60–62%, respectively [44]. Saphenous vein and internal mammary bypass graft CMR has also been combined with rest and adenosine stress graft flow assessment with good results [44].

Ischemic heart disease

The combination of CMR stress perfusion, function, and LGE allows the use of CMR as a primary form of testing for: (i) identifying ischemic heart disease (IHD) in patients who have resting ECG abnormalities or are unable to exercise; or (ii) determining patients who are appropriate candidates for interventional procedures; and (iii) defining the distribution of large vessel CAD in candidates for interventional procedures [2].

Myocardial ischemia and perfusion Dobutamine stress (DS) CMR is useful for the assessment of inducible ischemia by the qualitative or quantitative (CMR tagging) evaluation of wall motion with increasing doses of dobutamine similar to DS echocardiography. Assessment of LV wall motion after low-dose dobutamine in patients with resting akinetic LV wall segments is useful for identifying patients who will develop improvement in LV systolic function after coronary arterial revascularization [2]. GRE DS CMR has high accuracy for detecting ischemia mainly because of the excellent LV endocardial visualization throughout the studies even at high heart rates and can be very useful for patients with poor echocardiographic windows [45,46]. On a meta-analysis of stress-functional CMR studies, stress-induced wall motion abnormality imaging demonstrated a sensitivity of 83% and specificity of 86% and perfusion imaging demonstrated a sensitivity of 91% and specificity of 81% on a patient level [47]. Abnormalities observed during DS or perfusion CMR have been shown to be independent predictors of adverse cardiac events [48]. Three-year event-free survival was reported at 99.2% for patients with normal DS or stress perfusion CMR and 83.5% for those with abnormal studies. Ischemia on DS or stress perfusion CMR was predictive of cardiac events over the 3-year period with hazard ratios of 5.4 and 12.5, respectively, on univariate analysis and 10.6 and 4.72, respectively, on multivariate analysis [48].

Myocardial infarction and viability The spatial extent of LGE correlates with the distribution of myocyte necrosis in the early period following infarction and that of collagenous scar seen at 8 weeks [49–51], whereas in regions of the heart subjected to reversible injury, the retention of contrast does not occur. When compared with SPECT, LGE is more reliable in detecting subendocardial scar [52,53] in a study of patients evaluated for ischemic heart disease. Border zones of infarcts which contain healthy and necrotic myocytes have intermediate intensity LGE between normal and infarcted tissue and have been associated with the development of ventricular arrhythmias [54]. Areas of microvascular obstruction or “no-reflow” are areas of hypoenhancement surrounded by areas of scar with LGE and represent areas of severe capillary damage that do not allow penetration of contrast even after 10 minutes after contrast injection. These areas of non-viable tissue are usually seen in the 7–10 days post myocardial infarction (MI) and portend a worse prognosis (i.e., marker for post-MI complications and greater predictor of MACE than LGE infarct size) [55].

Myocarditis and non-ischemic cardiomyopathies

Acute viral myocarditis

CMR is considered to be the most versatile and powerful tool in the diagnosis of myocarditis. CMR should be performed when there are new or persisting symptoms (dyspnea, palpitations, effort intolerance, malaise or chest pain) suggestive of myocarditis; plus evidence of recent or ongoing myocardial injury (ventricular dysfunction, new or persisting ECG abnormalities or elevated troponin); plus suspected viral etiology (history of recent systemic viral illness or previous myocarditis, absence of risk factors for CAD/age <35 years, symptoms not explained by coronary stenosis on angiogram or recent negative stress test) [34]. The Lake Louise CMR diagnostic criteria developed by an expert consensus group is as follows. In the appropriate clinical setting, CMR findings are consistent with myocardial inflammation if at least two of the following criteria are present: regional or global myocardial SI increase in T2-weighted images; increased global myocardial early gadolinium enhancement (EGE) ratio between myocardium and skeletal muscle in gadolinium-enhanced T1-weighted images; and at least one focal lesion with non-ischemic regional distribution in inversion recovery LGE T1-weighted images [34]. Studies using combined (any two of three) criteria demonstrate high specificity (89–96%), accuracy (73–85%), and positive predictive value (88–95%) for the CMR diagnosis of myocarditis [56,57]. New native and post-contrast T1 mapping techniques with extracellular volume quantification improve the diagnostic criteria of CMR compared with the Lake Louise criteria [58,59].

CMR is useful for the diagnosis of various cardiomyopathies allowing for appropriate therapy and prognostication. CMR is considered to identify the etiology of cardiac dysfunction and heart failure including: (i) evaluation of dilated cardiomyopathy in the setting of normal coronary arteries; (ii) patients with positive cardiac enzymes without obstructive atherosclerosis on angiography; (iii) patients suspected of amyloidosis or other infiltrative diseases; (iv) HCM; (v) arrhythmogenic RV cardiomyopathy (ARVC); or (vi) syncope or ventricular arrhythmia [2].

Dilated cardiomyopathy

Progressive LV dilatation, LV systolic dysfunction, and regional mid-wall myocardial fibrosis associated with dilated cardiomyopathy can be evaluated by CMR. Fibrosis on LGE has been associated with adverse cardiac events [32] and focal interventricular mid-wall septal fibrosis has been linked to ventricular arrhythmias [60].

Stress (Takotsubo) cardiomyopathy

Stress cardiomyopathy (SC) is acute reversible LV dysfunction following a stressful event with a classic appearance of apical ballooning and hypercontractile basal segments. Other variants with mid or basal LV hypocontraction or RV involvement have also been described. This condition has typically been diagnosed on the basis of history, the ECG, cardiac enzyme profile, contraction pattern on echocardiography or ventriculography, and the absence of significant CAD on coronary angiography. CMR is uniquely suited for the evaluation of patients with SC because it allows for accurate visualization of regional wall motion abnormalities, precise quantification of LV and RV function, and assessment of concomitant abnormalities (e.g., pericardial and pleural effusion, LV and RV thrombi). CMR imaging also provides markers for reversible (inflammation, ischemic edema) and irreversible (necrosis/fibrosis) injury, which may be particularly important to verify SC and exclude similar diseases such as acute MI or myocarditis. On a retrospective study of

SC, myocardial edema with a distinct transmural, midventricular to apical distribution matching the distribution of LV dysfunction was observed. [61]. In the same study, there was no LGE at the threshold normally set for myocardial infarction of five standard deviations above remote myocardium. Also, of the patients who underwent the three CMR protocol requirements for the Lake Louise consensus criteria for myocarditis, 67% were positive for acute myocardial inflammation, with increased values for the T2 SI ratio and the EGE ratio during the acute phase [61].

Non-compaction cardiomyopathy

Non-compaction cardiomyopathy is characterized by a thin compacted myocardium in the mid and apical segments of the LV associated with regional dilatation, dysfunction, and hypertrabeculation. On CMR, an end-diastolic ratio of the non-compacted to compacted LV myocardium of ≥ 2.3 is considered diagnostic [62].

Arrhythmogenic RV cardiomyopathy

ARVC is characterized by global or regional dilatation of the RV (and in some cases the LV). Fatty and or fibrous replacement of the myocardium may be found on histology but this is not considered to be specific for the disease. As a result, the identification of myocardial fat on CMR is no longer considered a diagnostic criterion. Instead, RV dilatation with RV volumes indexed to body surface area with specific cut-offs for men and women and reduced RVEF as well as global and regional RV and LV myocardial dysfunction are the criteria released by the task force [63]. LGE of RV fibrosis has also been reported as a useful marker [64].

Hypertrophic cardiomyopathy

HCM is characterized by excessive myocardial hypertrophy, myocardial fibrosis, diastolic function abnormalities, and dynamic LV outflow tract obstruction. Cine images are useful for assessment of LV morphology, quantification of LV volumes and mass, and for visualization of the turbulent jet associated with systolic anterior motion of the mitral valve. Scattered areas of focal LGE are seen in the myocardium in areas of hypertrophy and are associated with decreased systolic thickening and perfusion deficits. In a recent study, LGE involving $\geq 15\%$ of LV mass was identified as a novel risk marker for sudden cardiac death (SCD) which can be used as an arbiter when conventional risk stratification is ambiguous [65]. CMR is very sensitive for detecting HCM in first-degree relatives of those with clinical HCM [66] and can identify the effects of alcohol septal ablation [67].

Sarcoidosis

Up to 50% of patients with pulmonary sarcoidosis have cardiac involvement which is the leading cause of death in these patients. Early contrast enhancement is useful for demonstrating areas of inflammation while LGE shows areas of irreversible injury [68]. Myocardial involvement could be subendocardial to transmural and does not follow a coronary distribution.

Amyloidosis

Myocardial amyloid accumulation is often a consequence of systemic amyloidosis with resultant increase in ventricular wall thickness. The amyloid protein has increased affinity for GBCAs resulting in a much faster clearance of the contrast from the blood than in other patients. The classic appearance is of a low signal “dark” blood pool and a very high SI myocardium that is difficult to “null” on LGE images. The T1 and T2 relaxation times of the

myocardium are shortened from the increased accumulation of GBCAs and this allows for detection with high accuracy [69].

Hemochromatosis

Cardiac iron overload in diseases such as thalassemia and hereditary hemochromatosis can lead to dilatation, hypertrophy, and dysfunction. The prognosis in this condition is based on the degree of cardiac involvement. Myocardial T2* quantification, which can be accurately determined, has been shown to be a more efficacious marker of cardiac iron involvement and guidance of chelation therapy than serial liver biopsies [35,70].

Pericardial disease

Pericardial disease represents a spectrum of diseases from congenital absence, pericardial effusion, and effusive constrictive pericarditis to constrictive pericarditis (CP) (Figure 10.2). CMR can provide information on the extent of pericardial disease (regardless of body habitus or prior surgical procedures), abnormalities in surrounding structures, and allows an accurate measurement of pericardial and related structures. It also provides superior tissue characterization including an estimate of inflammation [2,71]. Black blood T1-weighted SE CMR is used for morphologic assessment of the pericardium, intrathoracic and mediastinal structures. Black blood T2-weighted SE CMR highlights fluid-rich structures such as pericardial effusion or myocardial edema with concomitant myocarditis. SSFP cine allows visualization of effusion, the often tubular

configuration of the ventricles, and flattening/paradoxical motion of the interventricular septum in CP. It also allows for quantification of chamber size/function including RV/right atrial (RA) collapse. Ventricular interdependence, which is the sine qua non of diagnosis of CP differentiating it from restrictive cardiomyopathy, can be evaluated on real-time cine CMR. Other physiologic consequences of CP such as distension of the inferior vena cava/hepatic veins can be observed on various sequences. Tagged cine can be used to demonstrate tethering or adhesion of the pericardial layers which impairs the normal sliding motion of the pericardium across the myocardium. This is particularly helpful in the subset of patients with organized pericardial effusions or pericardial adhesions and normal pericardial thickness [2]. Perfusion CMR imaging is recommended to assess the blood supply of pericardial mass lesions and high SI on LGE suggests pericarditis.

Congenital heart disease

CMR may be used for assessing cardiac structure and function and blood flow through the heart, great vessels, cardiac shunts, and extracardiac conduits in individuals with simple and complex congenital heart disease (CHD) before and after surgical repair [72]. The ability of CMR to delineate complex anatomy and the lack of ionizing radiation is particularly attractive in the pediatric age group as serial follow-up studies are usually required [73]. CMR has high accuracy and reproducibility for assessment of ventricular cavity size and systolic function in CHD [74]. This is important as patients

Figure 10.2 Free breathing cine sequences on inspiration. (a) Four-chamber view showing flattening of the septum and tubular elongation of the ventricles with a small left pleural effusion. (b) Mid-short axis showing thick pericardium of ~ 8 mm (white arrow), septal flattening, and circumferential pericardial effusion. Myocardial tagging in diastole. (c, d) Four-chamber and mid-short axis showing adherent pericardium (arrowheads). LGE imaging. (e, f) Four-chamber and mid-short axis showing marked circumferential pericardial thickening and enhancement (white arrows) consistent with pericarditis. Patient was a 56-year-old man who developed cough and fever after a vacation. He presented 1 month after the onset of symptoms with shortness of breath and CMR was consistent with constrictive pericarditis.

with CHD tend to have unusual cardiac chamber shapes and sizes as a consequence of the baseline altered physiology or the numerous corrective procedures with concomitant exposure to cardiopulmonary bypass or deep hypothermic circulatory arrest.

CMR with PCVM for quantification of the pulmonary to systemic flow ratio (Q_p/Q_s) (shunt fraction) is useful in patients with simple CHD such as atrial and ventricular septal defects [75,76]. In tetralogy of Fallot (TOF), the regurgitant fraction of the often disrupted pulmonic valve can be quantified. The caval contributions of blood flow to each lung in patients with single ventricle physiology who have undergone Glenn and Fontan procedures can be determined [77]. CMR, often with CE-MRA, is also helpful for the assessment of abnormalities of the great vessels such as transposition and obstructive aortic anomalies such as aortic coarctation and interruption. CMR (SE, cine, dynamic PCVM) with CE-MRA is superior to other imaging modalities including echocardiography for combined anatomic (location and severity of narrowing) and physiologic (trans-coarctation pressures gradient and collateral flow assessment) of coarctation [2]. CMR and CE-MRA are useful for distinguishing true from pseudocoarctation and for assessing complications of repair such as restenosis or pseudoaneurysm formation [2]. Aortic arch anomalies and vascular rings (i.e., double aortic arch, right aortic arch with aberrant left subclavian artery, or mirror-image right aortic arch with left-sided ligamentum arteriosum) can cause varying degrees of compression of the trachea and/or esophagus, without or with symptoms stridor, dyspnea, cyanosis, or dysphagia. These anomalies and their potentially life-threatening complications can be imaged with CMR and/or CE-MRA [2].

Valvular heart disease

CMR may be used in the assessment of valvular stenosis, valvular and regurgitation, para- or perivalvular masses, perivalvular complications of infectious processes, or prosthetic valve disease. CMR is a particularly useful for identifying serial changes in LV volumes or mass that occurs with valvular dysfunction. Although cine SSFP is usually preferred for functional imaging, standard GRE sequences are preferred for jet visualization and qualitative assessment of valve disease because of their longer echo time [78]. Valve disease on GRE sequences is usually seen as a signal void or turbulent jet just above or below the valve. CMR planimetry of the aortic and mitral valves correlates with planimetry on echocardiography. CMR planimetry of the mitral valve often results in overestimation of the valve area relative pressure half-time secondary to translational motion of the heart [79,80]. Isolated mitral or tricuspid valve regurgitation can be estimated from the difference of the LV and RV stroke volumes. A more direct method for the outflow valves is to use PCVM to obtain the peak/mean velocities of the jet and the flow through a stenotic valve [81]. The pressure gradient is then calculated by plugging the velocities into the Bernoulli equation. Forward and reverse volume across a valve for the quantification of regurgitant fraction is also possible with PCVM. In-plane PCVM is helpful for assessing the direction of eccentric jets as is often the case with mitral or bicuspid aortic valve regurgitation.

Vascular disease

Aortic disease

CMR imaging techniques (e.g., spin echo, GRE, and cine PCVM; and 3D CE-MRA) permit the assessment of the anatomic abnormalities and the predisposing or resulting pathophysiologic changes

associated with diseases of the aorta [2]. These techniques are used in the following conditions:

- 1 Aneurysm: to elucidate etiology and identify associated aortic valve abnormalities for pre-surgical planning
- 2 Atherosclerosis and penetrating ulcer: to identify aortic pseudoaneurysms, non-communicating dissection
- 3 Traumatic injury: to identify aortic wall hemorrhage and differentiate between partial and circumferential tears
- 4 Dissection: to identify acute versus chronic states, delineate the extent and locate an entry and exit flaps, measure flow in the true and false lumen, differentiate from intramural hematoma and assess associated aortic valve involvement
- 5 Aortitis: detection of wall inflammation and measurement of wall thickness in response to treatment.

Post-surgical repair, CE-MRA can be used to assess disease progression or regression and postoperative complications [82,83].

Peripheral arterial disease

CMR is appropriate for patients with lower extremity claudication and for the evaluation of location and degree of stenosis for selection of patients for revascularization. 2D times of flight (TOF) techniques were used in the past but 3D CE-MRA has been shown to be more accurate for detecting and grading stenosis. For extended (up to 1 m) coverage, a multistation (“bolus chase”) CE-MRA with a single contrast injection is preferred. A hybrid technique with a supplemental dedicated CE-MRA of the lower extremities improves visualization of the infrapopliteal arteries especially in diabetic patients in whom arterial enhancement can be variable or fast. Prospective studies have shown CE-MRA to be more sensitive and specific for the detection of arterial stenosis of greater than 50% compared with duplex ultrasound [84]. In a randomized study of consecutive patients [85] randomized to either peripheral CE-MRA or 16-slice cardiac CT angiography (CTA), CTA was found to be less expensive with no statistically significant differences in patient outcomes (i.e., quality of life). Mean therapeutic confidence for CE-MRA and CTA were similar and comparable to that for digital subtraction angiography. CTA exposed participants to ionizing radiation and ionic contrast. Compared with CTA and ultrasound, CMR has the additional advantage of being able to characterize atherosclerotic plaque components.

Carotid disease

Carotid endarterectomy (CEA) or carotid artery stenting (CAS) is recommended in appropriate patients with severe symptomatic stenosis (70–99%). Various techniques including 2D and 3D TOF with or without CE-MRA have been utilized for the assessment of the carotid arteries. Availability of 3.0-T CMR units and recent developments in parallel imaging have greatly improved the performance of CE-MRA such that it rivals CTA and conventional angiography for the assessment of coronary stenosis and aneurysms [86–88]. PCVM has been found useful for the evaluation of peak velocity and flow of stenotic carotid segments and vertebral artery flow in subclavian steal syndrome.

Renal artery disease

CMR can be used to assess renal artery stenosis, dissection, aneurysmal dilatation, and quantify renal blood flow. Multiple renal arteries are common and CMR is useful for detecting the number

and location of the arteries as well as the configuration of renal blood supply in horseshoe kidneys. Renal and adrenal parenchymal mass lesions can also be detected on CMR. MRA for the assessment of renal artery stenosis including fibromuscular dysplasia has been well validated against digital subtraction angiography [16]. Some studies have estimated the sensitivity and specificity of 3.0-T MRA in the detection of intra-abdominal arterial stenosis as 100% and greater than 92%, respectively [89,90].

CMR for interventional cardiac procedures

Transcatheter aortic valve implantation

Transcatheter aortic valve implantation (TAVI) recently emerged as an alternative treatment option for patients considered high risk for surgical aortic valve replacement (SAVR). While CTA and echocardiography are more commonly applied in the evaluation of patients for TAVI, there are some specific situations in which CMR may be useful. Cine CMR can provide a detailed anatomic assessment of the AV that can be used to (i) identify the presence of congenital valvular abnormalities such as bicuspid aortic valve that may preclude TAVI, and (ii) obtain a directly planimetered aortic valve area [91] which is useful for assessing the severity of AS if there is a

discrepancy between clinical and echocardiographic findings. Direct comparison of CMR imaging and MDCT measurements of the aortic root and aortic annulus has shown close agreement [92,93]. In patients with renal insufficiency, gated non-enhanced MRA can be an alternative to CT for accurate measurements of the proximal aorta and evaluation of the aorto-iliofemoral system [94,95]. The major limitation of CMR for TAVI planning is inadequate visualization of calcified cardiac structures.

PCVM is useful for obtaining peak velocity of the aortic valve in patients with technically limited echocardiographic studies [96]. Significant mitral regurgitation is considered a relative contraindication to TAVI (primer) and concomitant aortic or mitral regurgitation can be quantified on PCVM. CMR is the ideal modality for assessing LV volumes, mass, and function to determine the optimal timing of intervention and identify patients in whom TAVI is contraindicated (i.e., LVEF <20%) [91]. LGE imaging can provide information about the extent of scarring related to CAD or help identify previously undiagnosed conditions such as cardiac amyloidosis which can alter prognosis [97].

CMR is beginning to show promise in the evaluation of post-TAVI complications (Figure 10.3). In general, GRE images with short echo times yield fewer artifacts from the implanted core valve than SSFP images [97]. The severity of perivalvular regurgitation

Figure 10.3 Post transcatheter aortic valve implantation (TAVI) complications: steady state free precession (SSFP) images showing a perivalvular aortic regurgitation 13 days post TAVI in a 90-year-old man. (a) Three-chamber view (white arrow). (b) Left ventricular outflow tract view showing the posterior jet (white arrow). (c) The jet (short white arrow) is located adjacent to the left atrium (LA) on the short-axis view. RA, right atrium. (d) SSFP images showing four-chamber view. (e) Two-chamber view of a pseudoaneurysm (white arrow) post-apical puncture for TAVI in an 86-year-old woman.

(PVR) was associated with increasing annulus diameter on both CMR imaging and MDCT [92]. The location and number of perivalvular regurgitation (PVR) jets can be determined and PCVM allows for quantification of aortic regurgitation which helps in the pre-procedural planning for closure devices when indicated. CMR is also useful for the assessment of PVR associated with longstanding surgically placed aortic and mitral valves.

Aortic coarctation

CMR has become the preferred non-invasive tool for selection for percutaneous intervention (PI) and surveillance after surgery or PI in patients with aortic coarctation. CMR is increasing being used due to its ability to generate both 3D anatomic and hemodynamic information without radiation exposure [98–101]. CE-MRA provides 3D visualization of arch geometry, aneurysmal formation, and collateral vessels. Aortic stents placed during intervention interfere with assessment of the coarctation post-intervention but collateral flow estimation is unaffected.

Right ventricular outflow tract dysfunction

Dysfunction of the right ventricular outflow tract (RVOT) post repair of TOF often leads to varying degrees of stenosis and regurgitation. CMR derived parameters of RV size and function are important for determining timing of intervention. CMR provides accurate information on anatomy, size, and geometry of the RVOT and pulmonary arteries. This is crucial in pre-procedural assessment for percutaneous pulmonary valve implantation, as certain anatomic criteria are to be met for the safe anchoring of the valve [98,102,103].

Emerging uses for CMR

Interventional CMR

Clinical cardiovascular interventional CMR (ICMR) has been demonstrated in specialized academic centers to be feasible and initial results are promising [104]. Using combined X-ray fluoroscopy (XRF) and MR (XMR), cardiac catheterizations have been performed in children for the last 10 years [105]. Invasive receiver coil imaging of peripheral arterial atheromata has been reported [106,107]. MRI datasets and real-time XRF have been combined for therapeutic procedures such as aortic stenting and high quality intra-arterial MRA with passive device placement in the iliofemoral arteries has also been reported [108–110].

Conclusions

CMR is a non-invasive radiation-free versatile imaging modality that allows high resolution visualization and functional assessment of cardiac structures; including wall motion analysis, quantification of cardiac function/blood flow, and myocardial tissue characterization. CMR also allows 3D anatomic depiction of cardiovascular structures but, unlike CT, does not require iodinated contrast. Although there are a few limitations of CMR, it has found wide application in the assessment of cardiovascular conditions and is also important in the multimodality planning of cardiac interventional procedures. Clinical ICMR is feasible and has the potential to revolutionize the field of interventional cardiology.

Case Study

A 59-year-old man with a history of hypertension, hyperlipidemia, and cocaine abuse was admitted to a local hospital with a 3-day history of substernal chest pain, dyspnea, and diaphoresis. His EKG was consistent with inferior ST elevation myocardial infarction. Coronary angiography showed right coronary artery thrombosis and PCI with thrombectomy and stenting to the right coronary artery was performed. He had an uneventful hospital course and was discharged home on guideline directed medical therapy (GDMT).

One month after discharge, he presented in congestive heart failure with shortness of breath, a new murmur, and an enlarged cardiac silhouette on chest X-ray. He was transferred to a tertiary care institution for further management. A transthoracic echocardiogram showed a small pericardial effusion, moderate to severe mitral regurgitation, and severe left ventricular dysfunction, LVEF 25%, with a basal inferolateral pseudoaneurysm and an inferoseptal ventricular septal defect with left to right flow. A CMR was performed for better assessment of the extent of pathology as well as calculation of the shunt fraction. The CMR confirmed the presence of

mitral regurgitation (Figure 10.4a), the extent of the large inferobasal pseudoaneurysm (Figure 10.4b, c), a true inferobasal aneurysm (Figure 10.4d), and communication between the left and right ventricles consistent with a rupture of the interventricular septum (Figure 10.4e). The calculated LVEF was 25%, RVEF 47% and the Qp/Qs was 1.9, consistent with a significant shunt.

He underwent surgical repair of the ventricular septal rupture and LV pseudoaneurysm/aneurysm. Six days post-surgery he had an episode of sustained monomorphic ventricular tachycardia. The electrophysiology team was consulted and an implantable cardiac defibrillator was placed. He was discharged home on the seventh postoperative day on GDMT. A pre-discharge echocardiogram showed slight improvement in LV systolic function, LVEF 30–35%, mild mitral regurgitation and a restrictive residual ventricular septal defect with a peak gradient of 102 mmHg.

This case illustrates the utility of CMR in the evaluation of complications post-MI/PCI in the stabilized patient. In this case, valuable information on the extent of ventricular damage was obtained for surgical planning.

Figure 10.4 SSFP images. (a) Three-chamber, (b, c) short-axis views showing a posteriorly directed mitral regurgitation jet (arrowhead) and the inferobasal pseudoaneurysm (white arrows). (d) Two-chamber view showing the true LV aneurysm (white arrows). (e) Four-chamber view showing the ventricular septal rupture in the inferobasal septum (small white arrow).

Stable Coronary Artery Disease

Abhiram Prasad¹ and Bernard J. Gersh²

The main objectives of treatment for stable angina are the relief of symptoms related to myocardial ischemia and improvement in prognosis. Significant progress has been made over the past three decades in drug therapy, percutaneous coronary intervention (PCI), and coronary artery bypasses grafting (CABG). While this chapter focuses on percutaneous revascularization, it is important to remember that medical therapy and secondary prevention have a central role in the management of coronary atherosclerosis. Secondary prevention via lifestyle modification, treatment of conventional risk factors (Table 11.1), and drug therapy (Figure 11.1) [1–3] reduces cardiovascular mortality, myocardial infarction, unstable angina, onset of heart failure, and the need for revascularization, likely by plaque stabilization and limiting the progression of atherosclerosis.

Guidelines on the management of stable angina

The most recent guidelines on the management of stable angina have been published by the European Society of Cardiology in 2013 [4] as well as by the American College of Cardiology (ACC) and the American Heart Association (AHA) in 2012 [5]. Additional relevant guidelines include the 2014 ESC/EACTS Guidelines on myocardial revascularization (Tables 11.2 and 11.3) [6], and the ACCF/AHA/SCAI 2011 Guideline for Percutaneous Coronary Intervention [7]. These guidelines are evidence based and should be the basis for clinical practice. However, there are several fundamental limitations of the trial data available on the management of stable angina. First, as with many clinical trials, the rigorous inclusion and exclusion criteria have resulted in a relatively small number of the screened patients being enrolled into the studies. This significantly limits the ability to generalize the findings to the larger population in daily practice. Moreover, clinical trials have generally excluded high risk patients with severe angina, severe atherosclerosis, severely reduced left ventricular (LV) systolic function, or multiple comorbid conditions. Second, the findings of clinical trials comparing treatment strategies often become outdated quickly because of the rapid evolution in clinical practice.

Indications for coronary angiography

The decision regarding whether to treat a patient with medical therapy or revascularization is based on the fundamental principal of risk stratification. The spectrum of risk for myocardial infarction and cardiovascular death is wide even in “stable” coronary artery disease (CAD). Initial risk stratification and thereby the decision to perform coronary angiography can be determined by a combination of clinical evaluation, and in most cases stress testing and an assessment of left LV function (Figure 11.2). Those with high risk features on clinical evaluation such as severe angina, unstable angina, and severe heart failure should proceed directly to coronary angiography without being subjected to a stress test. Coronary angiography is not indicated in low risk patients (Figure 11.3). The decision in intermediate risk patients should be based on severity of symptoms, response to initial medical therapy, functional status, lifestyle, and occupation. Moreover, a detailed discussion with the patient regarding the risks, benefits, alternatives, and goals of invasive assessment is required prior to proceeding with coronary angiography. Coronary angiography is indicated in patients with high risk features on non-invasive assessment irrespective of symptoms, severe angina (Class 3 of Canadian Cardiovascular Society Classification; CCS), diagnostic uncertainty after non-invasive evaluation, and patients with the possibility of restenosis following PCI in a coronary distribution supplying a moderate to large amount of myocardium.

Percutaneous coronary intervention for stable angina

Several randomized trials have compared the outcomes following PCI with medical management for stable angina [8–11]. These include the studies from the balloon angioplasty era such as the second Randomized Intervention Treatment of Angina (RITA-2) [9] and the Angioplasty Compared to Medicine (ACME) trials [10]. The studies and meta-analyses of the randomized trials [12,13] have consistently demonstrates that PCI does not reduce the likelihood of death or myocardial infarction, but is more effective in

Table 11.1 Optimal secondary prevention in stable coronary artery disease.

Risk factor	Goal/recommended intervention
Lipid management	LDL-C <1.8 mmol/L (<70 mg/dL) or >50% LDL-C reduction when target level cannot be reached Lifestyle modification including low fat-low cholesterol diet; and a moderate or high dose of a statin therapy should be prescribed, in the absence of contraindications or documented adverse effects Secondary goal is non-HDL cholesterol <130 mg/dL (<3.2 mmol/L) in pts with triglycerides >200 mg/dL (>2.2 mmol/L)
Blood pressure control	<140/90 mmHg (lowering to 130–139/80–85 mmHg may be better) Lifestyle modification and drug therapy (beta-blockers and ACE-inhibitors preferred)
Diabetes management	Hemoglobin A _{1c} <7.0% Lifestyle modification ± drug therapy
Smoking	Complete cessation. No environmental exposure
Weight management	Body mass index 18.5–24.9 kg/m ² , waist circumference: men <40 inches (<100 cm), and women <35 inches (88 cm) Regular physical exercise and restrict caloric intake
Physical activity	30–60 minutes of moderate-intensity aerobic activity, such as brisk walking, at least 5 days and preferably 7 days per week

relieving angina in patients with single and multivessel disease. Notably, there was an early hazard associated with PCI in the RITA-2 trial in which there was a greater likelihood of myocardial infarction related to the procedure, but the rates of death and myocardial infarction at 7 years was similar in both arms of the trial. In addition, studies conducted in the balloon angioplasty era had shown that there was an increased risk for emergency CABG in the

PCI treated group, but this was not reported in the recent Clinical Outcomes Utilizing Revascularization and Aggressive Drug Evaluation (COURAGE) trial, presumably because of the routine use of stent [14].

The COURAGE trial is the largest study to compare medical therapy with PCI and its findings are consistent with previous studies. The trial enrolled 2287 patients (approximately two-thirds with

two or three vessel disease) with stable CAD. The inclusion criteria were either a coronary stenosis ≥80% and classic angina without provocative stress testing, or a stenosis ≥70% in at least one proximal epicardial coronary artery and objective evidence of myocardial ischemia. A large number of patients were excluded from the trial because of high risk features such as a strongly positive stress test, persistent CCS class IV angina, an ejection fraction of <30%, refractory heart failure or cardiogenic shock, revascularization within the previous 6 months, and those with coronary anatomy unsuitable for PCI. The randomization was to either optimal medical therapy alone or PCI with optimal medical therapy. During a median follow-up duration of 4.6 years, there was no difference in the primary composite endpoint of death and nonfatal myocardial

infarction (19.0% vs. 18.5%; $p=0.62$). These findings must be interpreted in light of the facts that less than 10% of the patients screened met eligibility criteria for enrolment (as is the case in virtually all revascularization trials), 85% of patients were male, and that randomization was performed in the cardiac catheterization laboratory following angiography, which may have contributed to selection bias. The percentage of those requiring revascularization during follow-up were 21.1% of patients in the PCI arm, compared with 32.6% in the medical arm. The repeat revascularization rates in the PCI group would likely have been lower had drug-eluting stents (DES) been used. PCI was associated with a small reduction in the requirement for anti-anginal therapy and greater likelihood of freedom from angina; however, this benefit diminished over

time. Of note, approximately one-third of the patients in the medical arm had to cross over to PCI as a result of inadequate control of symptoms with optimal medical therapy. Finally, it is important to recognize that the findings of the COURAGE trial are also in keeping with earlier studies comparing CABG with medical therapy in which surgical revascularization did not improve survival or prevent myocardial infarction in patients with stable disease who had mild to moderate symptoms and good LV function.

Despite the overall conclusion of the COURAGE trial, the importance of risk stratification based on the magnitude of ischemic burden was highlighted by the results of the nuclear perfusion stress test substudy. The findings indicated that medical therapy alone was associated with a higher risk of mortality and infarction in patients who had a reversible perfusion defect involving more than 10% of the myocardium. These data suggest that a more sophisticated approach than subjective visual estimation of coronary stenoses and their ischemic potential is required in the management of stable CAD [15]. Measurement of fractional flow reserve (FFR) appears to be beneficial in the triage of patients with an intermediate stenosis who have not had a stress test prior to the angiogram. In the DEFER trial, patients with single vessel disease and an intermediate stenosis, an FFR ≥ 0.75 identified a low risk group of patients

who did not benefit from angioplasty at a follow-up of 5 years. In the more recent Fractional Flow Reserve versus Angiography for Multivessel Evaluation 2 (FAME 2) trial, the clinical utility of FFR measurement in patients with stable coronary artery disease being angiographically evaluated for PCI was assessed [16]. FFR was measured across all lesions with a $\geq 50\%$ diameter reduction in a major native epicardial coronary artery with a diameter of at least 2.5 mm and supplying viable myocardium. Patients with at least one stenosis with an FFR of ≤ 0.80 were randomized to FFR-guided PCI of all stenoses with FFR ≤ 0.80 with DES plus best medical therapy, or best medical therapy alone. The primary endpoint was a composite of death, myocardial infarction, or unplanned hospitalization leading to urgent revascularization at 24 months. The study was stopped prematurely by the data and safety monitoring board. After a mean duration of follow-up of 213 days, after randomization of 888 of the planned 1632 patients, the primary endpoint occurred in 4.3% who had PCI compared to 12.7% who were managed medically (hazard ratio [HR] 0.32, 95% CI 0.19–0.53). The difference persisted at 2-year follow-up. The reduction was driven by a lower rate of urgent revascularization in the PCI group. Though “urgent revascularization” is considered a “soft” endpoint, the definition used to define the events met criteria for an acute coronary syndrome

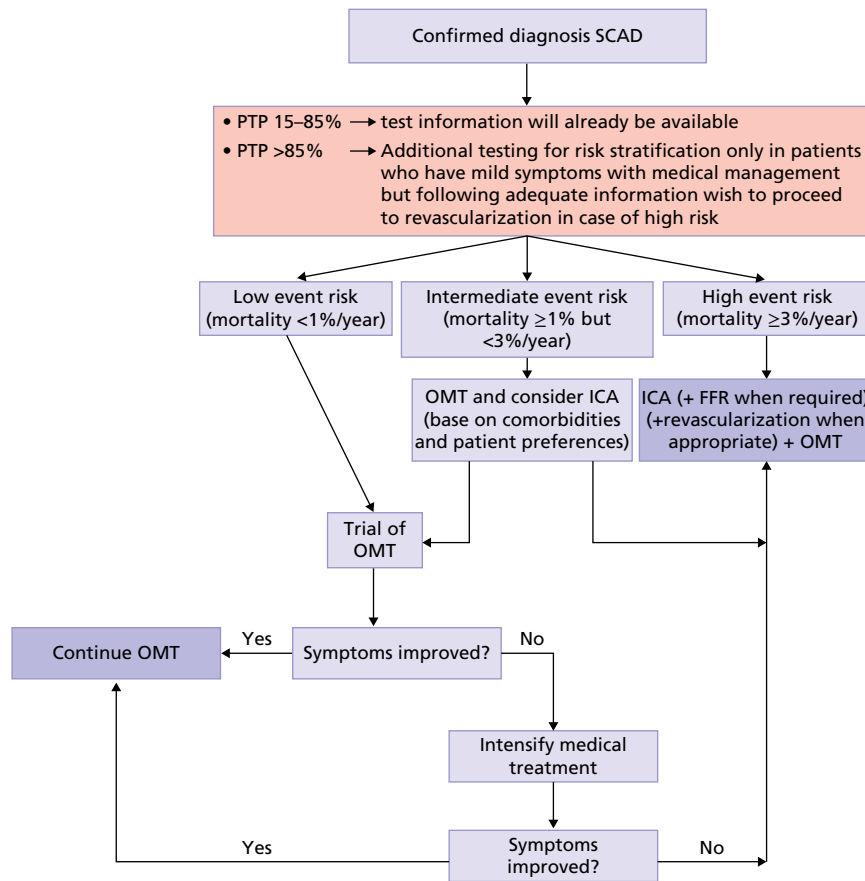

Figure 11.3 Management based on risk determination for prognosis in patients with chest pain and suspected stable coronary artery disease (SCAD) (ESC Guidelines). Reproduced by permission of Oxford University Press.

and 50% of the patients had objective evidence of ischemia. Limitations of FAME 2 include the premature termination of the trial, lack of non-invasive stress test documentation of ischemia prior to angiography, and the absence of double blinding of the assigned strategy such that the results of FFR measurement in the medical arm may have biased the patient's and/or physician's decision for preceding with crossover to PCI. Nevertheless, the findings of FAME 2 suggest that PCI is appropriate in patients with functionally significant stenosis involving a moderate or greater myocardial territory, and this is reflected in current guidelines (Table 11.2). Most interventionist use a FFR-guided strategy for intermediate (50–70% diameter stenosis) lesions in the absence of objective documentation of at least moderate ischemic burden in the coronary territory of interest or unclear results from stress testing.

The Medicine, Angioplasty, or Surgery Study (MASS) and MASS II trials have compared medical therapy with PCI and CABG in stable angina. The MASS trial enrolled patients with single vessel disease (>80% proximal left anterior descending artery stenosis) [17]. While balloon angioplasty and medical therapy were associated with greater need for revascularization, there was no difference in rate of death or myocardial infarction in the three groups during follow-up. The trial was conducted in the pre-stent era without modern medical therapy which limits the applicability of the findings to contemporary practice. The MASS II trial, however, was conducted in patients with multivessel disease, and had a similar design except that PCI was performed with bare metal stents in

most patients, and more contemporary medical therapy was implemented. At 5 years, the results were similar to the MASS trial in that there was no difference in death or myocardial infarction between the three treatment strategies, but the need for revascularization for refractory angina during follow-up was much higher with medical therapy and PCI [18].

A unique study in elderly patients with stable angina was the Trial of Invasive vs. Medical therapy in Elderly patients (TIME). At 1 year, the primary endpoint of quality of life was equally improved with both strategies. The invasive approach was associated with an early hazard, but there was no difference with regards to reduction in symptoms, death, or non-fatal infarction at 1 year. PCI did reduce the likelihood of subsequent hospitalization for uncontrolled symptoms [19].

A significant number of patients with CAD have asymptomatic or “silent” ischemia which is associated with an increased risk of cardiovascular events. The Asymptomatic Cardiac Ischemia Pilot (ACIP) study investigated the efficacy of three treatment strategies among patients with stable disease who had angina or silent ischemia from single or multivessel disease. Patients were randomized to angina-guided medical therapy, angina plus ischemia-guided medical therapy, or revascularization by either balloon angioplasty or CABG. At 2 years following randomization, revascularization was associated with a lower mortality and a reduction in the composite endpoint of death, myocardial infarction, and recurrent hospitalization [20]. An important study that evaluated treatment of silent ischemia is the Swiss Interventional Study on Silent Ischemia Type II (SWISSI II)

trial which compared medical therapy with balloon angioplasty among patients who had suffered a myocardial infarction, and had one or two vessel disease [21]. A surprising finding was that cardiac death and myocardial infarction were significantly lower in the group randomized to balloon angioplasty. While the findings of the ACIP and SWISSI II trials are significant, they need to be interpreted with the knowledge that both enrolled relatively small number of patients and that optimal medical therapy, as defined in the COURAGE trial, was not implemented.

The studies to date have had significant crossover to revascularization in those originally randomized to medical therapy and hence have been trials of “initial treatment strategies” rather than specific treatments. Thus, based on the evidence from the COURAGE trial and the preceding randomized clinical trials, it is reasonable to conclude that medical therapy is an appropriate *initial strategy* for a substantial proportion of patients with mild to moderately severe stable angina. PCI is suitable for those patients who are significantly symptomatic despite optimal medical therapy, or as *initial strategy* for those with a positive stress test at low workload, or have a moderate to large ischemic territory. Aggressive secondary prevention is essential regardless of the treatment strategy utilized. The findings of the Atorvastatin versus Revascularization Treatment (AVERT) trial showed that PCI in combination with inadequate lipid lowering therapy is associated with worse outcomes in patients with angina when compared with a strategy of optimal lipid management and medical therapy alone [11].

In BARI 2D, 2368 patients with type 2 diabetes mellitus and stable coronary artery disease (defined as either a $\geq 50\%$ stenosis of a major epicardial artery with a positive stress test or $\geq 70\%$ stenosis and classic angina) were randomized to either revascularization (CABG or PCI) within 4 weeks together with intensive medical therapy or to intensive medical therapy alone [22]. The decision regarding CABG versus PCI was based on clinical judgment, and made prior to randomization. At 5 years, there was no difference in the primary endpoints of the rates of survival (88.3% vs. 87.8%) or freedom from the composite of death, myocardial infarction, and stroke (77.2% vs. 77.7%). In the PCI stratum, there was no significant difference in primary endpoints between the revascularization group compared to the medical-therapy only group. However, in the CABG stratum, the rate of major cardiovascular events was significantly lower in the revascularization group. Patients selected for CABG had higher angiographic and clinical risk scores than those selected for PCI, and it was those with the highest clinical and angiographic risk profile who seemed to derive a benefit from CABG.

A recent meta-analysis from 12 randomized clinical trials with 37,548 patient-years of follow-up demonstrated that PCI compared with medical therapy alone was associated with a statistically significant 24% relative reduction in the risk of spontaneous non-procedural myocardial infarction (MI), at the cost of a 317% relative increase in the risk of procedural MI, with no overall difference in the risk of all MI. The point estimate for PCI versus medical therapy for the outcome of all-cause mortality and cardiovascular mortality paralleled that of spontaneous non-procedural MI (incident rate ratio = 0.70; 95% CI 0.44–1.09), but was not statistically significant [23]. In a network meta-analysis from 100 trials in 93,553 patients with 262,090 patient years of follow-up, new generation drug eluting stents (everolimus: rate ratio 0.75, 95% CI 0.59–0.96; zotarolimus (Resolute): 0.65, 95% CI 0.42–1.00) were associated with improved survival compared with medical treatment. However, balloon angioplasty (0.85, 95% CI 0.68–1.04), bare metal stents (0.92, 95% CI 0.79–1.05), or early generation drug eluting stents (paclitaxel: 0.92,

95% CI 0.75–1.12; sirolimus: 0.91, 95% CI 0.75–1.10; zotarolimus (Endeavor): 0.88, 95% CI 0.69–1.10) were not associated with improved survival compared with medical treatment. The findings suggest that there may be improved survival with new (second) generation DES but not with other PCI technology, compared with medical treatment. These reports are provocative and challenge the general dogma that PCI has no impact on mortality. The findings are especially notable because the randomized trials have generally limited the enrolment to patients with single vessel disease and have excluded high risk patients with left main disease or chronic total occlusion for whom revascularization can offer greater benefit. Thus, until further data are available and strategies for risk stratification are improved, therapeutic decisions ought to be based on guidelines, but tailored according to a combined assessment of the patient's clinical presentation, severity of ischemia, and coronary anatomy [24].

Comparison of percutaneous and surgical revascularization

The available evidence suggests that PCI and CABG are equivalent for the treatment of single vessel disease. This was specifically investigated in the MASS trial at a single center in which patients with significant ($>80\%$) proximal LAD stenosis were randomized to balloon angioplasty, CABG, or medical therapy. The data demonstrated that there was similar relief of symptoms with both forms of revascularization. However, revascularization resulted in a lower incidence of inducible ischemia compared to medical therapy alone, and all three strategies resulted in the effective treatment of limiting angina [17]. Similar findings have been reported from another small study of 134 patients with isolated proximal LAD stenosis in which angioplasty and CABG produced comparable results [25] also when the follow-up is prolonged to 10 years [26]. Importantly, the need for repeat revascularization during follow-up was greater with percutaneous revascularization using balloon angioplasty in both trials.

In the assessment of trials comparing surgery with PCI, an important premise is that none of these studies have specifically addressed the functional significance of the lesions treated. With respect to PCI in multivessel disease, the Fractional Flow Reserve vs. Angiography for Multivessel Evaluation (FAME) trial demonstrated that a targeted strategy guided by measurement of FFR provides superior outcomes at 1 year compared with treatment of all vessels with visually estimated significant stenoses [27]. Several randomized clinical trials [28–33] and meta-analyses of the data [34] have compared PCI directly with CABG for the treatment of single and multivessel disease. The studies, predominantly from the pre-stent era, were among relatively low risk patients with multivessel disease and preserved LV function. By design, the inclusion criteria for these trials had mandated that the coronary anatomy was suitable for both forms of revascularization, thereby excluding most patients with very complex coronary anatomy or chronic total occlusions. These older trials provided important lessons, but are not directly relevant to current practice because they predated stents and the widespread use of internal mammary artery graft in CABG.

The largest of these studies is the Bypass Angioplasty Revascularization Investigation (BARI) trial in which 1829 patients were enrolled. PCI was performed with balloon angioplasty which was associated with similar frequency of death, myocardial infarction, and recurrent angina when compared with CABG during 10 years of follow-up in the overall study population [35]. Not surprisingly, repeat revascularization was significantly less common in patients

randomized to surgery. One notable finding that has influenced current practice is that cardiac mortality was significantly lower (19.4% vs. 34.5%; $p=0.003$) amongst diabetics requiring glucose lowering therapy who were randomized to CABG and received at least one mammary graft. Potential explanations for this observation are that CABG offers complete revascularization and hence mitigates some of the adverse impact of the greater atherosclerotic burden and “future culprit” lesions, as well as the greater likelihood of restenosis and disease progression in diabetic patients. This finding has been confirmed in a more recent study [36] but the clinical relevance and applicability of the BARI study results have been questioned by the findings from the BARI registry, which highlighted the importance of clinical judgment. The patients in the registry had clinical characteristics that were similar to those in the randomized trial, but the survival among diabetic patients was similar regardless of whether angioplasty or CABG was performed. It has been speculated that the conflicting results between the registry and the trial may have been because the treatment assignment in the registry was at the discretion of the physicians who might have selected the most appropriate form of revascularization for each patient [37].

The Arterial Revascularization Therapy Study Part I (ARTS I) and the Stent or Surgery (SoS) trials have compared bare metal stent based PCI with CABG [38,39]. In the ARTS I trial, death and myocardial infarction were similar with both treatment strategies, but, as one might expect, complete revascularization was less often achieved and repeat revascularization was more frequent with percutaneous revascularization. The results of the SoS trial were similar but, for reasons that are unclear, there was an unexpected higher mortality associated with PCI (5% vs. 2%; $p=0.01$), likely unrelated to treatment selection as the difference was entirely a result of non-cardiac deaths. The long-term results (5–6 years) of the ARTS, ERACI II, and SoS trials, and a large (7812 patients) meta-analysis including 10 randomized trials of balloon angioplasty or stenting vs. surgery with a median follow-up of 5.9 years has been published [40–43]. In the meta-analysis, long-term mortality was similar after CABG and PCI in patients with multivessel CAD (hazard ratio 0.91, 95% CI 0.82–1.02; $p=0.12$). CABG was associated with a significantly lower mortality in patients with diabetes (HR 0.70, 0.56–0.87; $p=0.014$ for interaction) and patients aged 65 years or older (0.82, 95% CI 0.70–0.97; $p=0.002$ for interaction).

DES account for approximately 70–80% of stents used for contemporary PCI around the world but there are limited data comparing the outcomes between PCI using DES and CABG. There are three randomized clinical trials (SYNTAX, CARDia, and FREEDOM) to date [44–46]. Multicenter registry data from Arterial Revascularization Therapies Study II (ARTS II) has compared PCI using sirolimus DES with historical controls from the ARTS I trial [47]. The incidence of the composite primary endpoint of all-cause death, any cerebrovascular event, non-fatal myocardial infarction, or any repeat revascularization at 1 year in the DES group was similar to the CABG treatment arm of ARTS I. The rate of repeat revascularization was 8.5% in the DES group compared to 4.1% and 21.3% in CABG and PCI arms, respectively, of ARTS I. The 3-year results were consistent and confirmed, in patients with and without diabetes, the absence of significant differences in the combined endpoint when compared with the historical control of ARTS I surgical arm. While the data have inherent limitations of using historical controls, it had been suggested that PCI using DES might result in comparable outcomes to CABG, predominantly by decreasing repeat revascularization.

The Synergy Between PCI with TAXUS and Cardiac Surgery (SYNTAX) trial randomized 1800 patients with three vessel and/or left main disease to either CABG or PCI after a local interventional cardiologist and cardiac surgeon at each site prospectively evaluated eligible patients and determined that equivalent anatomic revascularization could be achieved with either strategy [44]. A score of anatomic complexity (SYNTAX score: www.syntaxscore.com) was prospectively calculated. Unlike most previous trials where a small minority of patients who were screened were ultimately enrolled, almost half of the 4337 screened were randomized, with the majority of those excluded were unsuitable for PCI. The rates of death and myocardial infarction at 12 months were similar in the two groups. Stroke was significantly more frequent in the CABG group (2.2% vs. 0.6%; $p=0.003$) while the incidence of stent thrombosis and symptomatic graft occlusion at 12 months were similar in the two groups (3.3 and 3.4%, respectively). An increased rate of repeat revascularization in the PCI group (13.5% vs. 5.9%; $p<0.001$) led to an excess of major cardiac and cardiovascular events in the PCI group, with the endpoint of the trial (non-inferiority of PCI using DES) not being met. Subgroup analysis based on the predetermined SYNTAX score showed that the negative outcome was confined to patients with high scores (>33 , 10.9% in the surgical arm vs. 23.4% in the PCI arm). The patients with left main disease had similar incidence of 12 month MACE in the surgical and PCI groups (13.7 vs. 15.8%; $p=0.44$). At 5-year follow-up, the composite primary endpoint (death from any cause, stroke, MI, or repeat revascularization) remained significantly higher (37.3% vs. 26.9%) in the PCI group due primarily to the higher rates of repeat revascularization and myocardial infarction. The rates of all-cause death and stroke were not different [48]. When analyzed by SYNTAX score, those with a score of <23 , inclusive of left main patients, there was no difference in the composite primary endpoint (32.1% vs. 28.6%; $p=0.43$). In those with a SYNTAX score of 23–32 with unprotected left main disease, the outcomes were similar (32.7% vs. 32.3%; $p=0.88$); but not in patients with three vessel disease in whom PCI had higher event rates for the primary composite endpoint (37.9% vs. 22.6%; $p=0.0008$). For patients with a SYNTAX score ≥ 33 , the rates were higher in patients with left main disease (46.5% vs. 29.7%; $p=0.003$) and those with three vessel disease without (41.9% vs. 24.1%; $p=0.0005$) unprotected left main disease. The results of the SYNTAX trial indicate that CABG remains the standard for patients with complex three vessel disease. However, in patients with less complex disease (i.e., left main coronary disease with low or intermediate SYNTAX scores, or three vessel disease with low SYNTAX scores), PCI is a reasonable alternative treatment to CABG. In patients with a high SYNTAX score, the potential advantages of surgery should be stressed, but PCI should not be denied to patients who have a strong preference or a very high surgical risk. However, these conclusions must be interpreted in the context of the trial's limitations, such as the use of a first generation (paclitaxel-eluting) stent, which has a higher rate of restenosis than current second generation drug-eluting stents. Also, the analyses of subgroups by SYNTAX score was not pre-specified or adequately powered, and therefore the findings should be considered hypothesis generating.

In the Coronary Artery Revascularization in Diabetes (CARDia) trial, 510 diabetic patients with multivessel or complex single vessel coronary disease were randomized to PCI using a stent (and routine abciximab) or CABG. The trial was underpowered for the primary endpoint (composite of all-cause mortality, myocardial infarction, and stroke), and at 1 year there was no difference between CABG

and the 69% of patients who received a DES (12.4% and 11.6%; $p=0.82$) [45]. In the Future Revascularization Evaluation in Patients with Diabetes Mellitus: Optimal Management of Multivessel Disease (FREEDOM) trial, 1900 patients with diabetes and multivessel (83% with three vessel) disease (median SYNTAX score of 26) were randomized to either PCI with a first generation (paclitaxel or sirolimus-eluting) stent or CABG. Both groups received optimal medical therapy [46]. At a median follow-up of 3.8 years, the primary composite endpoint death from any cause, non-fatal myocardial infarction, or non-fatal stroke was more frequent in the PCI group (26.6% vs. 18.7%; $p=0.005$). The benefit of CABG was predominantly because of lower rates of myocardial infarction and death from any cause while stroke was more frequent in the CABG group (2.4% vs. 5.2%; $p=0.03$ at 5 years). The findings of FREEDOM suggest that in patients with diabetes and advanced CAD, CABG is superior to PCI using first generation stents.

Comparison of coronary artery bypass surgery with medical therapy for stable angina

The European Coronary Surgery Study (ECSS), Coronary Artery Surgery Study (CASS), and Veterans Administration Cooperative Study (VA Study) are large randomized trials that have compared CABG with medical therapy among patients with mild to moderate angina [49–51]. The consistent finding from these studies was that surgical revascularization provides better symptomatic relief from angina but the benefit is lost over time, most likely because of vein graft failure and subsequent crossover to CABG in the medical treatment arm. The randomized trials and a meta-analysis [52] indicate that an initial strategy of surgical revascularization does not improve survival in the general population of CAD, but that there are specific subsets that either have a large amount of ischemic myocardium or significant LV dysfunction. Thus, patients with three vessel disease (especially in those with abnormal LV function), two or three vessels disease with >75% stenosis of the LAD or a markedly positive stress test derive prognostic benefit from CABG. In general, patients with severe symptoms have been excluded from the trials, but an analysis from registry data of the CASS study indicates that surgical revascularization probably improves prognosis in patients with severe angina who have multivessel disease, even in the absence of LV function or proximal LAD stenosis [53]. It is important to be aware that this evidence, which has been used to craft current guidelines, is limited by the fact that the randomized trials were all conducted in the early years of bypass surgery, and are not representative of the contemporary surgical techniques such as the routine use of internal mammary grafts or minimally invasive and off-pump surgery [54]. Conversely, the medical group did not benefit from the aggressive preventive measures which are now routine nor did they consistently receive beta-blockers or angiotensin-converting enzyme (ACE) inhibitors. Furthermore, the general applicability of these trials is limited by the fact that they did not enrol many women or patients over 65 years old.

Recommendations for revascularization in stable angina

Broadly speaking, revascularization is appropriate for patients with limiting symptoms despite optimal medical therapy, strongly positive stress tests, proximal multivessel disease, and those who prefer an interventional approach over medical therapy. The choice between PCI and CABG in any one patient is determined by the risks of the procedure, likelihood of success, and ability to achieve

complete revascularization with the two strategies as well as diabetic status and patient preference. While medical therapy is the cornerstone of treatment of stable angina, it is important to remember that there is no evidence that medical therapy alone improves prognosis in high risk patients, as defined in the clinical trials of medical treatment vs. CABG.

Patients with significant proximal LAD artery disease have a survival advantage with CABG over medical therapy, even in the absence of severe symptoms, LV dysfunction, or other lesions. PCI provides similar results among patients who have suitable anatomy for PCI of the proximal LAD and normal LV function (Tables 11.2 and 11.3).

CABG offers a survival advantage over medical therapy in patients with severe symptoms and three vessel disease, even in the absence of proximal LAD involvement or LV dysfunction. Patients with three vessel disease and LV dysfunction should have CABG. PCI is an alternative to CABG in those with angiographically suitable targets and normal LV function (e.g., SYNTAX score ≤ 22 ; Tables 11.2 and 11.3). Surgical revascularization is recommended for significant left main disease though PCI is an alternative in patients with SYNTAX score of ≤ 22 , and should be considered for those with a SYNTAX score of 23–32 (Tables 11.2 and 11.3).

In patients with diabetes mellitus, particularly in the setting of multivessel or diffuse disease, there is a survival advantage with CABG over PCI. PCI is reasonable for diabetics with discrete two vessel disease (e.g., SYNTAX score ≤ 22) and preserved LV function.

For the majority of patients with stable CAD who do not fall into the subgroups described, there is no documented survival advantage with revascularization. PCI and CABG should be offered for the treatment of symptoms refractory to medical therapy. The guidelines state that both forms of revascularization are suitable for two vessel disease, but in current practice the majority of these patients and those with single vessel disease are treated with PCI unless the lesions are angiographically unsuitable, or involve the proximal LAD [55].

Revascularization in asymptomatic patients should only be considered with the goal of improving prognosis. The guidelines for the treatment of asymptomatic patients are similar to those for symptomatic patients. However, the level of evidence for asymptomatic patients is weaker as the clinical trials have mainly included symptomatic patients. However, ischemia is an important therapeutic target in contemporary practice over and above the treatment of symptoms.

Conclusions

Unlike PCI for acute coronary syndromes, percutaneous revascularization does not prevent death or myocardial infarction in patients with stable angina. There remains the possibility that PCI can reduce hard endpoints in high risk patients, but clinical trials in these patient subsets have not been conducted. For patients in low risk subgroups, the main advantage of PCI is the ability to effectively and more rapidly relieve symptoms. In general, therefore, PCI is indicated for the treatment of symptomatic coronary atherosclerosis, particularly in patients who remain symptomatic limited despite optimal medical therapy. PCI is the preferred revascularization strategy for single vessel disease, younger patients (age <50 years), elderly patients with significant comorbid conditions, and those who are not surgical candidates. There is no clear indication for PCI in the treatment of asymptomatic disease.

CABG is also highly effective in relieving symptoms, but importantly it reduces mortality in high risk patients. This benefit is proportional to baseline risk profile of the patient. Complete revascularization is more likely to be achieved with CABG. Thus, CABG is preferred for high risk patients such as those with multivessel disease where complete revascularization is an important goal, particularly in three vessel disease, and in the presence of significant LV systolic dysfunction. Subgroups that should be considered for surgery include significant unprotected left main disease, three vessel disease, especially if there is impaired LV function, diffuse atherosclerosis, or one or more chronic total occlusion. Another important group of patients who may benefit with CABG are diabetics with three vessel disease. However, as with PCI, CABG does not reduce the incidence of non-fatal myocardial infarction. PCI for multivessel disease, even with the use of DES, is associated with higher rates of repeat revascularization than CABG.

Developments in medical therapy for secondary prevention, PCI and CABG result in limited data being available from clinical trials that reflect contemporary practice, especially in high risk patients. With regards to PCI, the initial optimism for the current generation of DES has been tempered by the concerns of late stent thrombosis and the potential need for long-term dual antiplatelet therapy.

PCI Strategies in Acute Coronary Syndromes without ST Segment Elevation (NSTEMACS)

Georgios E. Christakopoulos¹, Subhash Banerjee¹, and Emmanouil S. Brilakis^{1,2}

¹VA North Texas Health Care System and University of Texas Southwestern Medical Center, Dallas, TX, USA

²Minneapolis Heart Institute, Minneapolis, MN, USA

Coronary angiography and percutaneous coronary intervention (PCI) is key for the effective management of patients presenting with non-ST segment elevation acute coronary syndromes (NSTEMACS), as reflected in both the European Society of Cardiology (ESC) [1] and the American Heart Association/American College of Cardiology (AHA/ACC) guidelines [2]. This chapter reviews risk stratification, patient selection for cardiac catheterization, the role of PCI for revascularizing these patients, and the recommended adjunctive pharmacologic therapy.

Risk stratification

Risk stratification is critical for selecting treatment strategy (invasive vs. ischemia-driven) and timing (urgent, early, or delayed). High risk patients derive more benefit from more aggressive management strategies. Risk stratification is based on clinical, electrocardiographic, and laboratory findings (Box 12.1) and is often facilitated by use of risk scores that synthesize the impact of various parameters on patient outcomes (Table 12.1).

High risk manifests as myocardial injury and ischemia (e.g., ongoing chest pain, electrocardiographic changes, and cardiac biomarker increase), decrease in left ventricular function (cardiogenic shock and heart failure symptoms), and arrhythmias (such as ventricular tachycardia or fibrillation). Moreover, patients with prior coronary artery bypass graft surgery (CABG) are at increased risk for complications, as are patients with recent PCI, and those with comorbidities, such as chronic kidney disease and diabetes.

Two risk scores that are commonly used currently for risk stratification of NSTEMACS patients are the Global Registry of Acute Coronary Events (GRACE) score and the Thrombolysis in Myocardial Infarction (TIMI) score.

The GRACE risk score can be used in patients with both NSTEMACS and ST-segment elevation acute myocardial infarction. It is often considered more applicable to everyday clinical practice compared with other scores, as it was derived from a multinational registry of unselected patients from several hospitals around the world (Europe, Asia, North America, South America, Australia, and New Zealand). Eight parameters are used for calculating GRACE score:

- 1 Patient's age
- 2 Heart rate
- 3 Systolic blood pressure

- 4 Killip class [3]
- 5 Serum creatinine level
- 6 Cardiac arrest at hospital admission
- 7 ST-segment deviation in ECG
- 8 Elevated cardiac biomarkers.

The TIMI risk score for NSTEMACS is simpler than the GRACE score and is also widely used. It can be rapidly determined as the sum of seven variables (age ≥ 65 , at least 3 risk factors for coronary artery disease, prior coronary stenosis of 50% or more, ST-segment deviation on electrocardiogram at presentation, at least two anginal events in the past 24 hours, use of aspirin in the prior 7 days, and elevated serum cardiac markers) and can predict the composite of all-cause mortality, new or recurrent myocardial infarction and severe recurrent ischemia requiring urgent revascularization within 14 days from presentation, as follows:

- Score of 0–1 = 4.7%
- Score of 2 = 8.3%
- Score of 3 = 13.2%
- Score of 4 = 19.9%
- Score of 5 = 26.2%
- Score of 6–7 = at least 40.9%.

Invasive versus ischemia-guided approach

Patients presenting with NSTEMACS can be treated with a routine invasive strategy or with an initial ischemia-guided strategy. In general, the higher the baseline patient risk, the higher the likelihood of improving outcomes with aggressive treatment strategies, including cardiac catheterization and revascularization.

Patients with signs and symptoms of ongoing ischemia, such as refractory angina and hemodynamic or electrical instability, should undergo urgent/immediate angiography (within 2 hours).

Among stabilized NSTEMACS patients, a routine invasive management (Table 12.1) is recommended in patients who present with high risk features (such as dynamic electrocardiographic changes suggestive of ischemia, increased levels of cardiac biomarkers, or high risk scores) unless they have serious comorbidities or contraindications to coronary angiography and revascularization.

Patients treated with an ischemia-guided strategy are treated with medical therapy alone unless they develop refractory angina, have myocardial ischemia in non-invasive evaluation, or are

considered to have risk of adverse events (such as patients with high TIMI or GRACE risk score).

Several studies and meta-analyses have reported that a routine invasive approach is superior to a conservative approach in NSTEMACS [4,5]. A meta-analysis of eight trials including >10,000 patients revealed significant reduction in the risk of death, myocardial infarction, or rehospitalization with an acute coronary syndrome with an invasive strategy (odds ratio 0.78, 95% confidence interval 0.61–0.98) [5]. The benefit was observed in both men and high risk women, but not in low risk women, supporting a conservative approach for the latter group [5].

The optimal timing of coronary angiography for NSTEMACS patients undergoing invasive management remains controversial (Table 12.2); however, immediate coronary angiography (similar to primary PCI for ST-segment elevation acute myocardial infarction) is not warranted in NSTEMACS patients, except for those with hemodynamic or electrical instability or medically refractory angina [6]. Early angiography (within 24 hours from

presentation) provides rapid assessment of coronary anatomy and triage for revascularization, potentially preventing subsequent ischemic complications and expediting discharge from the hospital. Delayed angiography allows for stabilization of the patient and potential decrease of the intracoronary thrombus burden through antithrombotic therapy.

Some studies have suggested that delaying angiography for several days may be detrimental [7]. In the largest trial performed to date, the Timing of Intervention in Acute Coronary Syndromes (TIMACS) trial, routine early intervention (coronary angiography ≤ 24 hours after randomization) did not reduce the primary study endpoint (death, myocardial infarction, or stroke) compared with delayed intervention (coronary angiography ≥ 36 hours after randomization) in the overall study population [8]. However, early intervention was beneficial in the subgroup of patients with GRACE score >140 (13.9% vs. 21.0%; hazard ratio 0.65, 95% CI 0.48–0.89; $p=0.006$) [8].

A delayed (25–72 hours) invasive strategy may be acceptable for intermediate risk patients with a GRACE score <140 who have one or more of the following clinical features: history of diabetes mellitus, renal insufficiency (GFR <60 mL/min/1.73 m²), reduced systolic left ventricular function with an ejection fraction (EF) $<40\%$, history of recent PCI or prior CABG. In patients at low risk without recurrent symptoms or signs of ongoing ischemia, a non-invasive assessment of inducible ischemia should be performed before discharge, followed by angiography if the findings suggest high risk.

Coronary revascularization in NSTEMACS

In NSTEMACS patients with single-vessel coronary artery disease, ad hoc PCI is most frequently performed. In patients with multivessel disease (who represent more than 50% of NSTEMACS patients) the decision between culprit-lesion PCI, multivessel PCI, and CABG is more complex. In patients with hemodynamic instability, pulmonary edema, recurrent ventricular arrhythmias, or total occlusion of the culprit coronary artery, culprit lesion PCI is usually preferred. In contrast, CABG is preferred in stabilized patients with complex multivessel disease and a high SYNTAX score. In the Acute

Box 12.1 High-risk criteria for patients with non-ST segment elevation acute coronary syndromes (NSTEMACS)

Primary criteria

- Relevant rise or fall in troponin
- Dynamic ST- or T-wave changes (symptomatic or silent)
- GRACE score >140

Secondary criteria

- Diabetes mellitus
- Renal insufficiency (GFR <60 mL/min/1.73 m²)
- Reduced left ventricular function (ejection fraction $<40\%$)
- Early post-infarction angina
- Recent PCI
- Prior CABG
- Intermediate to high GRACE risk score

CABG, coronary artery bypass graft surgery; GFR, glomerular filtration rate; GRACE, Global Registry of Acute Coronary Events; PCI, percutaneous coronary intervention.

Table 12.1 Comparison of three risk scores used for risk stratification in patients with non-ST segment elevation acute coronary syndromes (NSTEMACS).

	PURSUIT	TIMI	GRACE
History	Age Gender Worst CCS class in last 6 weeks	Age ≥ 3 CAD risk factors Known CAD (stenosis $\geq 50\%$) Aspirin within 7 days Recent (<24 h) severe angina	Age Cardiac arrest during presentation
Examination	1. SBP 2. HR 3. Rales		1. SBP 2. HR 3. Killip class
ECG	ST-segment depression	ST-segment depression >0.5 mm	ST segment deviation
Laboratory tests		\uparrow Cardiac markers	\uparrow Cardiac markers Creatinine

CAD, coronary artery disease; CCS, Canadian Cardiovascular Society; GRACE, Global Registry of Acute Coronary Events; HR, heart rate; PURSUIT, Platelet glycoprotein IIb/IIIa in Unstable angina: Receptor Suppression Using Integrilin; SBP, systolic blood pressure; TIMI, Thrombolysis In Myocardial Infarction.

Table 12.2 Selection of an early invasive vs. ischemia-guided strategy in patients with non-ST segment elevation acute coronary syndromes (NSTEMACS).

	ACC/AHA guidelines	ESC guidelines
Immediate invasive (<2 h)	Refractory angina	Refractory angina with associated heart failure
	Signs or symptoms of new or worsening mitral regurgitation	
	Hemodynamic instability	Hemodynamic instability
	Sustained VT or VF	Life-threatening ventricular arrhythmias
	Recurrent angina or ischemia at rest or with low level activities despite intensive medical therapy	
Early invasive (within 24 h)	None of the above, but GRACE risk score >140	Grace score >140
	Temporal change in troponin	Relevant rise or fall in troponin
	New or presumably new ST depression	Dynamic ST- or T-wave changes (symptomatic or silent)
Delayed invasive (within 25–72 h)	None of the above but diabetes mellitus	Diabetes mellitus
	Renal insufficiency (GFR <60 mL/min/1.73 m ²)	Renal insufficiency (GFR <60 mL/min/1.73 m ²)
	Reduced LV systolic function (EF <0.40)	Reduced LV systolic function (EF <0.40)
	Early post-infarction angina	Early post-infarction angina
	PCI within 6 months	Recent PCI
	Prior CABG	Prior CABG
	GRACE risk score 109–140;TIMI score ≥2	Intermediate to high GRACE risk score (<140)

ACC, American College of Cardiology; AHA, American Heart Association; CABG, coronary artery bypass graft; ESC, European Society of Cardiology; EF, ejection fraction; GFR, glomerular filtration rate; GRACE, Global Registry of Acute Coronary Events; LV, left ventricular; PCI, percutaneous coronary intervention; VF, ventricular fibrillation; VT, ventricular tachycardia.

Catheterization and Urgent Intervention Triage Strategy (ACUTITY) trial compared with CABG, PCI for multivessel disease was associated with a lower risk of stroke, myocardial infarction, bleeding, and renal injury but significantly higher rates of subsequent revascularization at both 1 month and 1 year [9].

In a NSTEMACS patient with multivessel coronary artery disease undergoing PCI there is no consensus about whether the culprit lesion only or all obstructive lesions should be treated concurrently [10]; both approaches are acceptable and decisions should be made on a case-by-case basis taking into account the potential risks and benefits of the procedure [2,11,12]. In general, complete revascularization is associated with improved clinical outcomes [13,14], and should be pursued regardless of whether revascularization is with PCI or with CABG. Occasionally, identification of the culprit lesion can be challenging and could be facilitated by use of intravascular imaging with

optical coherence tomography, which can identify plaque rupture and thrombus formation [15]. In some cases no plaque rupture can be found, suggesting plaque erosion, which can often be successfully managed with medical therapy alone without stenting [16].

PCI: adjunctive pharmacologic treatment

Adjunctive pharmacologic therapy is critical for the success of PCI, but is also beneficial for patients treated with a conservative approach [17]. Table 12.3 summarizes the recommended antithrombotic therapy according to the ACC and ESC guidelines. Both guidelines recommend anticoagulation and dual antiplatelet therapy with aspirin (ASA) and a P2Y₁₂-receptor antagonist (prasugrel, clopidogrel, or ticagrelor) for NSTEMACS patients undergoing PCI.

Table 12.3 Summary of the guideline recommendations for antiplatelet and anticoagulant therapy among patients with non-ST segment elevation acute coronary syndromes (NSTEMACS).

ACC/AHA Guidelines	ESC Guidelines
<p>Antiplatelet therapy</p> <p>1. Aspirin is recommended for all patients at an initial dose of 81–325 mg (325 mg for all patients if not already on aspirin prior to PCI) Maintenance dose: 81–325 mg (indefinitely) (class I)</p> <p>2. A P2Y12 inhibitor is recommended in addition to ASA, and maintained over 12 months unless there are contraindications such as excessive risk of bleeding (class I). Options include:</p> <ul style="list-style-type: none"> • Prasugrel 60 mg loading dose, then 10 mg/day • Clopidogrel 600 mg loading dose, then 75 mg/day • Ticagrelor 180 mg loading dose, then 90 mg twice daily <p>Ticagrelor is preferred to clopidogrel in patients treated with an early invasive strategy and/or stenting (class IIA)</p> <p>Prasugrel is preferred over clopidogrel in patients not at high risk of bleeding (class IIA), and without a history of stroke or TIA (prasugrel is class III in such patients)</p> <p>DAPT beyond 12 months may be considered in patients undergoing stent implantation (class IIb)</p> <p>3. GP IIb/IIIa inhibitors</p> <p>GP IIb/IIIa inhibitor at the time of PCI is recommended in patients with NSTEMACS and high risk features (e.g., high troponin) not adequately pretreated with clopidogrel or ticagrelor (class I) or with high risk patients treated with UFH and adequately pretreated with clopidogrel (class IIa). Options include: abciximab, double-bolus eptifibatide or high dose tirofiban</p> <p>Anticoagulation therapy</p> <p>Performance of PCI with enoxaparin may be reasonable in patients treated with upstream subcutaneous enoxaparin for NSTEMACS (class IIb)</p> <p>Intravenous UFH is useful in patients with NSTEMACS undergoing PCI (class I)</p> <p>Bivalirudin is useful as an anticoagulant with or without prior treatment with UFH in patients with NSTEMACS undergoing PCI (class I)</p> <ul style="list-style-type: none"> • For patients who have received UFH, wait 30 min, then give 0.75 mg/kg IV loading dose, then 1.75 mg/kg/h IV infusion • For patients already receiving bivalirudin infusion, give additional loading dose 0.5 mg/kg and increase infusion to 1.75 mg/kg/h during PCI <p>In patients with NSTEMACS undergoing PCI who are at high risk of bleeding, bivalirudin monotherapy is preferred to the combination of UFH and a GP IIb/IIIa receptor antagonist (class IIa)</p> <p>Fondaparinux: If PCI is performed while the patient is on fondaparinux, an additional 85 IU/kg UFH should be given intravenously immediately before PCI because of the risk of catheter thrombosis (60 IU/kg IV if a GP IIb/IIIa inhibitor used with UFH dosing based on the target-activated clotting time) (class I)</p> <p>Fondaparinux should not be used as the sole anticoagulant to support PCI in patients with NSTEMACS due to an increased risk of catheter thrombosis (class III)</p> <p>Anticoagulation should be discontinued after invasive procedure unless otherwise indicated (class I)</p>	<p>1. Aspirin is recommended for all patients without contraindications at an initial oral loading dose of 150–300 mg (or 80–150 mg IV) Maintenance dose of 75–100 mg/day long term, regardless of treatment strategy (class I)</p> <p>2. A P2Y12 inhibitor is recommended in addition to ASA, and maintained over 12 months unless there are contraindications such as excessive risk of bleeds (class IA):</p> <ul style="list-style-type: none"> • Clopidogrel (300–600 mg loading dose, 75 mg/day dose), is recommended for patients who cannot receive ticagrelor or prasugrel or who require oral anticoagulation (class IB) • Ticagrelor (180 mg loading dose, 90 mg twice daily) is recommended, in the absence of contraindications, for all patients at moderate-to-high risk of ischemic events (e.g., elevated cardiac troponins), regardless of initial treatment strategy and including those pretreated with clopidogrel (which should be discontinued when ticagrelor is started) (class IB) • Prasugrel (60 mg loading dose, 10 mg daily dose) is recommended in patients who are proceeding to PCI if no contraindication (class IB) Pre-treatment with prasugrel in patients in whom coronary anatomy not known, is not recommended (class III) <p>3. GP IIb/IIIa antagonists should be considered for bail-out situations or thrombotic complications (class IIa)</p> <p>Pre-treatment with GP IIb/IIIa antagonists in patients in whom coronary artery anatomy is not known, is not recommended (class III)</p> <p>Fondaparinux (2.5 mg s.c. daily) is recommended as having the most favorable efficacy– safety profile regardless of the management strategy (class I)</p> <p>Bivalirudin (0.75 mg/kg bolus, followed by 1.75 mg/kg/h for up to 4 h after the procedure) is recommended as alternative to UFH plus GP IIb/IIIa receptor inhibitor during PCI (class I)</p> <p>UFH 70–100 IU/kg i.v. (50–70 IU/kg if concomitant with GPIIb/IIIa inhibitors) is recommended in patients undergoing PCI who did not receive any anticoagulant (class I)</p> <p>Enoxaparin (1 mg/kg s.c. twice daily) or UFH are recommended when fondaparinux is not available (class I)</p> <p>Enoxaparin should be considered as an anticoagulant for PCI in patients pretreated with s.c. enoxaparin (class IIa)</p> <p>Fondaparinux should not be used as the sole anticoagulant to support PCI in patients with NSTEMACS due to an increased risk of catheter thrombosis</p> <p>In patients on fondaparinux (2.5 mg/day s.c.), a single bolus UFH (85 IU/kg, or 60 IU/kg in the case of concomitant use of GP IIb/IIIa receptor inhibitors) is indicated during PCI (class I)</p> <p>Crossover of UFH and LMWH is not recommended (class III)</p> <p>Discontinuation of anticoagulation should be considered after PCI, unless otherwise indicated</p>

ASA, aspirin; DAPT, dual antiplatelet therapy; GP, glycoprotein; LMWH, low-molecular weight heparin; PCI, percutaneous coronary intervention; IV, intravenous; s.c., subcutaneous; UFH, unfractionated heparin.

Aspirin

Aspirin irreversibly inhibits the platelet cyclo-oxygenase-1 (COX-1). In view of its efficacy, low cost, and widespread availability, all NSTEMI patients should receive it, unless they have a contraindication [18]. According to the AHA/ACC guidelines patients that are on aspirin before PCI, should take 81–325 mg non-enteric coated aspirin before PCI, whereas patients not on aspirin should be given non-enteric coated aspirin (325 mg dose) as soon as possible before PCI. After PCI, aspirin should be continued at a dose of 81–325 mg/day indefinitely, unless contraindicated [2]. The ESC guidelines differ on dosing, recommending ASA for all patients without contraindications at an initial oral loading dose of 150–300 mg (or 80–150 mg intravenously); after PCI patients should be kept on aspirin at a maintenance dose of 75–100 mg/day, regardless of treatment strategy [1].

P2Y₁₂ receptor inhibitor

An oral P2Y₁₂ inhibitor should be administered in addition to aspirin to all NSTEMI patients undergoing PCI. Three oral P2Y₁₂ receptor inhibitors are currently used: clopidogrel, prasugrel, and ticagrelor (ticlopidine is seldom used currently because of potential for serious hematologic side effects).

In the Clopidogrel in Unstable Angina to Prevent Recurrent Events (CURE) trial, NSTEMI patients were randomized to clopidogrel or placebo. During a mean follow-up of 9 months, clopidogrel reduced the incidence of the cardiovascular death, MI, or stroke by 20% (9.3% vs. 11.4%; $p < 0.001$) [19]. In the Clopidogrel and Aspirin Optimal Dose Usage to Reduce Recurrent Events – Seventh Organization to Assess Strategies in Ischemic Syndromes (CURRENT-OASIS 7) trial, compared with standard dose clopidogrel (300-mg loading dose and 75 mg/day thereafter) double dose clopidogrel (600 mg loading dose on the first day, followed by 150 mg/day for 6 days and 75 mg/day thereafter) did not reduce the 30-day incidence of cardiovascular death, MI, or stroke (4.2% vs. 4.4%; $p = 0.30$), although it did reduce the risk of stent thrombosis among patients who underwent PCI [20].

Clopidogrel is a pro-drug that requires multistep activation and its efficacy is markedly affected by genetic factors, such as CYP 2C19 polymorphisms. In contrast, prasugrel and ticagrelor are more potent platelet inhibitors with consistent metabolism [21,22].

In the Trial to Assess Improvement in Therapeutic Outcomes by Optimizing Platelet Inhibition with Prasugrel–Thrombolysis in Myocardial Infarction 38 (TRITON-TIMI 38) 13,608 patients (74% of whom had NSTEMI) were randomized to prasugrel or clopidogrel (300 mg loading dose) [21]. Prasugrel was given after coronary angiography once the decision for PCI was made. During a median follow-up of 14.5 months, compared with clopidogrel prasugrel reduced the incidence of cardiovascular death, MI, or stroke (9.9% vs. 12.1%; $p < 0.001$), and the risk for stent thrombosis (of both bare metal and drug-eluting stents) [23], but also increased the risk for TIMI major and fatal bleeding [21]. Prasugrel was harmful in patients with prior transient ischemic attack or stroke and did not provide clinical benefit among patients ≥ 75 years old or with < 60 kg body weight [21]. In the Comparison of Prasugrel at the Time of Percutaneous Coronary Intervention (PCI) or as Pretreatment at the Time of Diagnosis in Patients with Non-ST Elevation Myocardial Infarction (ACCOAST) trial, pretreatment with prasugrel did not decrease ischemic complications when compared with administration at the time of PCI and was associated with higher risk for major bleeding [24]. In the Targeted Platelet

Inhibition to Clarify the Optimal Strategy to Medically Manage Acute Coronary Syndromes (TRILOGY ACS) study, prasugrel administration was not beneficial among NSTEMI patients treated with medical therapy without PCI [25].

The Study of Platelet Inhibition and Patient Outcomes (PLATO), randomized 18,624 patients (62% of whom had NSTEMI) to ticagrelor or clopidogrel [22,26]. Compared with clopidogrel, ticagrelor reduced the 12-month incidence of vascular death, MI, or stroke (9.8% vs. 11.7%; $p < 0.001$) and also reduced all-cause mortality (4.5% vs. 5.9%; $p < 0.001$). However, ticagrelor-treated patients had higher rate of non CABG-related major bleeding, dyspnea, and ventricular pauses lasting ≥ 3 s (but not requiring specific treatment). North American patients did not derive benefit from ticagrelor administration, likely because of co-administration of ≥ 100 mg/day aspirin [27].

Based on the benefits observed with prasugrel and ticagrelor in the above studies, the AHA/ACC guidelines favor them over clopidogrel (class IIa indication) [2]. The ESC guidelines go even further in recommending prasugrel and ticagrelor over clopidogrel, stating that clopidogrel should be used when prasugrel or ticagrelor are not available or are contraindicated in patients who cannot receive ticagrelor or prasugrel or who require oral anticoagulation (class I indication) [1].

The optimal duration of dual antiplatelet therapy after PCI for NSTEMI remains controversial. The currently guideline-recommended duration is 12 months unless there are contraindications or an excessive risk of bleeding [1,2]. Some studies have suggested that shorter duration of P2Y₁₂ inhibitor administration could be equivalent or superior to longer duration [28]. However, the largest study performed to date, the Dual Antiplatelet Therapy (DAPT) study, reported that compared with 12 months, 30 months of dual antiplatelet therapy were associated with lower risk of stent thrombosis (0.4% vs. 1.4%; hazard ratio 0.29, 95% confidence interval 0.17–0.48; $p < 0.001$), and myocardial infarction (2.1% vs. 4.1%; hazard ratio 0.47; $p < 0.001$), at the cost of increased risk for moderate to severe bleeding (2.5% vs. 1.6%, $p = 0.001$), and a nominal increase in all-cause mortality (2.0% vs. 1.5%; $p = 0.05$), although cardiac mortality was similar in both groups [29].

Glycoprotein IIb/IIIa inhibitors

Much of the evidence that supports use of glycoprotein (GP) IIb/IIIa inhibitors (abciximab, eptifibatide, or tirofiban) in NSTEMI patients was obtained in the era before the routine use of dual antiplatelet therapy. In a meta-analysis by Boersma *et al.* [30], GP IIa/IIIa inhibitors were only beneficial in patients with elevated troponin and in those who underwent revascularization within 30 days.

In the Early Glycoprotein IIb/IIIa Inhibition in Non-ST-Segment Elevation Acute Coronary Syndrome (EARLY-ACS) trial, routine upstream administration of eptifibatide did not benefit NSTEMI patients, except patients at the highest risk for ischemic complications (such as those with troponin elevation, ST deviation, diabetes, recurrent ischemia) and low risk for bleeding (age < 75 years) [31]. In patients pre-treated with P2Y₁₂ inhibitors, outcomes have been favorable with use of bivalirudin alone vs. UFH and GPI [9], leading to a significant reduction in GPI use in contemporary practice.

In summary, GP IIb/IIIa are infrequently used as pretreatment in NSTEMI patients who receive dual antiplatelet therapy and have intermediate/high risk features (class IIb indication in the AHA/ACC guidelines). They are indicated at the time of PCI in high-risk

patients undergoing PCI, whether they have been pretreated with a P2Y12 inhibitor (class IIa indication if unfractionated heparin is used as anticoagulant) or not (class I indication) [2].

Anticoagulation

Anticoagulation is recommended for all NSTEMACS patients undergoing PCI to reduce the risk of intracoronary and catheter thrombus formation. The type of anticoagulation is selected according to ischemic and bleeding risks as well as the efficacy–safety profile of the chosen agent for each patient individually. Parenteral anticoagulants used in patients with NSTEMACS undergoing PCI include unfractionated heparin (UFH), low molecular weight heparin (LMWH, usually enoxaparin), bivalirudin, and fondaparinux.

Unfractionated heparin has been used for many years for PCI. It has low cost; however, response to unfractionated heparin is variable, requiring measurement of its antithrombotic effect. In the largest study of enoxaparin in NSTEMACS, the Superior Yield of the New Strategy of Enoxaparin, Revascularization and Glycoprotein IIb/IIIa Inhibitors (SYNERGY) trial, 10,027 high-risk NSTEMACS patients treated with an early invasive strategy were randomized to enoxaparin or UFH [32]. Enoxaparin-treated patients had similar incidence of death or MI compared with those treated with UFH, but higher incidence of major bleeding [32]. As a result enoxaparin is infrequently used during PCI for NSTEMACS.

Bivalirudin is a direct thrombin inhibitor [9,33–35]. In the ACUITY trial, bivalirudin monotherapy was associated with a non-inferior rate of the composite ischemia endpoint (death, MI, or unplanned revascularization) (7.8% and 7.3%, respectively; $p=0.32$) and significantly reduced the rates of major bleeding (3.0% vs. 5.7%; $p<0.001$) as compared with bivalirudin + GP IIb/IIIa inhibitor and UFH + GP IIb/IIIa inhibitor [9,35]. However, among patients not pretreated with clopidogrel before PCI, the incidence of ischemic events was higher in the bivalirudin group (9.1% vs. 7.1%, RR 1.29; $p=0.054$ for interaction) [9].

Fondaparinux is a factor Xa inhibitor. In the Fifth Organization to Assess Strategies in Acute Ischemic Syndromes (OASIS 5) trial, patients receiving fondaparinux had lower 30-day mortality compared with those receiving enoxaparin (2.9% vs. 3.5%, HR 0.83, 95% CI 0.71–0.97; $p=0.02$), likely related to the lower risk for major bleeding (2.2% vs. 4.1% at 9 days; $p<0.001$) [36]. Patients undergoing PCI on fondaparinux had a threefold higher rate of guide catheter thrombus (0.9% vs. 0.3%), hence UFH (85 IU/kg without or 60 IU/kg with a GP IIb/IIIa inhibitor) should be administered to patients on fondaparinux who require PCI [37].

The European and American guideline recommendations for anticoagulation in NSTEMACS patients are summarized in Table 12.3 [1,2].

Conclusion

In summary, NSTEMACS are commonly encountered in daily clinical practice. Risk stratification is key for determining optimal treatment strategies, with higher risk patients deriving more benefit from more aggressive strategies. An early invasive approach is preferred for most high risk patients. Clinical outcomes can be improved by optimal selection of anticoagulation and antiplatelet treatments.

Interactive multiple choice questions are available for this chapter on www.wiley.com/go/dangas/cardiology.

Primary and Rescue PCI in Acute Myocardial Infarction and Elements of Myocardial Conditioning

Tayo Addo¹, Neil Swanson², and Anthony Gershlick²

¹University of Texas Southwestern Medical Center, Dallas, TX, USA

²University of Leicester, Leicester, UK

Acute myocardial infarction results when abrupt thrombotic occlusion of a major epicardial coronary occurs. Following extensive pathologic investigation, it is now quite clear that the underlying etiologic mechanism involves acute disruption of an atherosclerotic plaque generally previously moderate in severity. The resultant exposure of circulating blood to underlying plaque material results in platelet aggregation, thrombin generation, and thrombosis [1]. The severity of injury, often detected on the ECG as ST-segment elevation, indicates extensive and transmural myocardial ischemia owing to such abrupt termination of blood flow and lack of prior adaptation. A large region of myocardium undoubtedly suffers necrosis if not immediately addressed. Soon after the appreciation of thrombus and aggregated platelets at the occlusion site, substantial advances in care were made with the rapid administration of fibrinolytics, antiplatelets, and antithrombins aimed at re-establishing vessel patency. Collectively regarded as reperfusion therapy, these agents were studied extensively, in combination and with high efficiency, and resulted in improved survival [2–10]. Along with these reperfusion studies conducted in the late 1980s and throughout the 1990s, coronary angiography was employed to assess the efficacy of therapy and the following observations were made.

- 1 Reperfusion therapy, even with the most potent agents, did not always result in restoring optimal vessel patency.
- 2 Vessel patency and coronary myocardial blood flow were highly important determinants of survival.
- 3 Time to treatment was a powerful determinant of effectiveness.
- 4 The emerging technique of percutaneous transluminal coronary balloon angioplasty could be used effectively to establish blood flow either as the primary treatment or as salvage after unsuccessful medical reperfusion therapy [11].

Primary PCI

Initial experience and comparisons with thrombolytic therapy

The very early experience led by Hartzler and others indicated that percutaneous coronary intervention (PCI) was not only feasible in acute myocardial infarction, but the recanalization rate was very high, typically exceeding 90% [12]. However, others expressed

caution, reporting high complication rates including major bleeding and recurrent infarction, particularly when performed shortly after thrombolytic therapy [13]. Several trials were subsequently conducted comparing thrombolytic therapy with primary PCI spanning over 10 years and ultimately summarized in a meta-analysis by Keeley *et al.* [14]. Comprising 7739 patients, short-term mortality was reduced from 9% to 7%. Even when patients with cardiogenic shock were excluded, mortality was still reduced from 7% to 5%, with benefits sustained at longer term follow-up. Recurrent myocardial infarction was reduced from 6.8% to 2.5% and stroke reduced from 2% to 1% (Figure 13.1). In these initial trials primary PCI was delivered efficiently and at institutions with experience in the procedure, so there were concerns if this could be duplicated in real-world practice. Nonetheless, the results were widely embraced as angiography and intervention was safer and more predictable than fibrinolytic therapy. Efficacy was also confirmed in subsequent large non-randomized registries. In the Swedish Heart Intensive Care Admissions Registry [15], 16,034 patients receiving reperfusion with fibrinolytic therapy were compared with 7084 receiving primary PCI. Mortality at 1 year was reduced from 15.6% to 7.6% in favor of primary PCI. Given the limited number of hospitals capable of PCI and the resources required, it was initially unclear if this therapy could become the dominant strategy in reperfusion therapy. Over the past 15 years, however, access to primary PCI has risen substantially and it is now the treatment of choice in 80% of cases of acute myocardial infarction [16,17]. A number of small trials have compared thrombolytic therapy with primary PCI in patients presenting to non-PCI-capable hospitals where an efficient transfer could be accomplished. In a meta-analysis, these studies similarly confirmed the superiority of primary PCI in reducing ischemic outcomes [18]. The benefits of primary PCI have been noted despite a treatment-related delay of 60–120 minutes, and in subgroups such as the elderly, those with cardiogenic shock, and late presentation, where fibrinolytic therapy was much less effective.

Current delivery standards

The benefits of reperfusion therapy via primary angioplasty is similarly time dependent [19–21]. In the first few hours there is significant opportunity for myocardial salvage with demonstrable

Figure 13.1 Results of 23 randomized trials of percutaneous coronary intervention (PCI) versus lysis. CVA, cerebrovascular accident. Source: Adapted from Keeley *et al.* 2003 [14].

reductions in infarct size and the greatest reductions in mortality. These benefits decline with time although outcomes with reperfusion remain better for 24 hours as long as there is evidence of ongoing ischemia. When compared with fibrinolytic therapy, primary PCI is more efficacious in patients presenting later in the course of myocardial infarction. PCI establishes better vessel patency, coronary blood flow, and tissue reperfusion, all determinants of improved outcomes [22]. The infarct-related vessel is also revascularized by stent implantation nowadays, almost eliminating the risk of recurrent ischemia and infarction [23]. However, primary PCI is associated with an inherent delay because of the logistics of performing PCI versus the ease of administering thrombolytics. PCI must be accomplished expeditiously as delay in delivery of this therapy is associated with increased mortality. The best results are seen when a door-2-reperfusion time of <90 minutes is achieved. Figure 13.2 shows the current American College of Cardiology Foundation guidelines for effective delivery of primary PCI. When arriving at a primary PCI-capable facility, a door-2-reperfusion time of <90 minutes is the treatment goal. When arriving at a non-primary PCI facility, a rapid transfer program should be in place such that total initial contact to reperfusion time does not exceed 120 minutes. Otherwise thrombolytic therapy should be first offered, if appropriate, followed by transfer for possible salvage PCI. The maximum PCI-related delay has been deduced from large registries of acute myocardial infarction and it is generally accepted that a delay of >120 minutes abolishes the advantage of primary PCI [24]. Nonetheless, in subgroups where thrombolytics perform poorly such as delayed presentation, advanced age, and cardiogenic shock, primary PCI remains preferable [22]. Substantial gains have been made in recent years at reducing door-2-reperfusion time in primary PCI through education and hospital system-wide efforts [25,26]. Unfortunately, further reductions in overall mortality have not been realized despite reductions to well below 90 minutes in recent years. Changes in demographics and patient risk could account for some of this attrition [27,28].

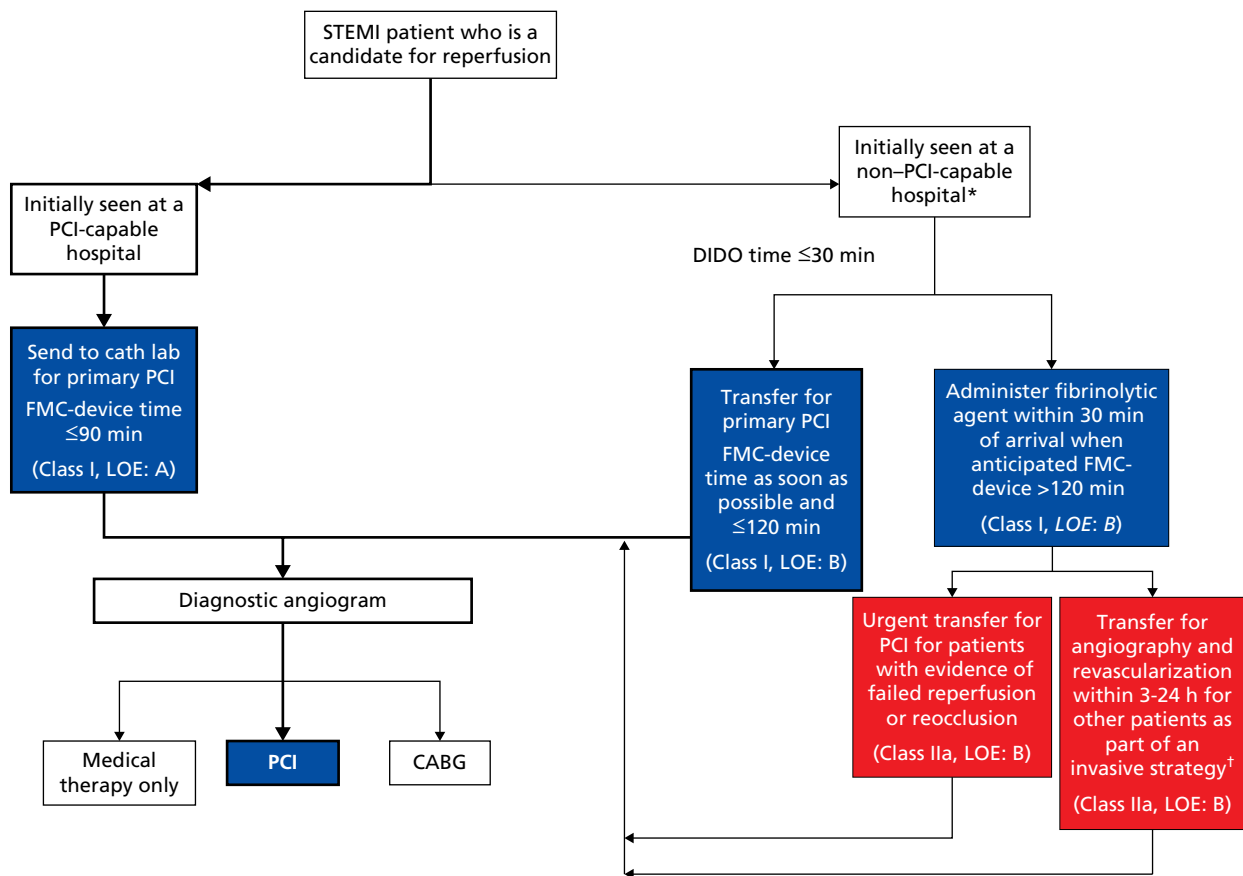

Technical approach and enhancements

The infarct-related vessel is occluded in most patients at the time of initial angiography. In others, a high grade stenosis is present with varying degrees of flow beyond the occlusion [22]. Thrombus

accounts for most of the obstruction present and it is often easily traversed with a standard guidewire, although figuring the course of the occluded vessel can be difficult without experience. The obstruction is also easily dilatable given the contents are thrombus and soft plaque. Once dilatation has been performed, normal flow (TIMI 3) is often restored. Repeated angioplasty or stent implantation can then be performed to achieve definitive revascularization. In a few patients, angioplasty and even stent implantation does not establish normal flow. This is typically because of severe myocardial damage, tissue edema, or embolization of thrombotic debris to the distal microvasculature. In the most severe cases, referred to as no-reflow, there is no flow from the vessel into the myocardial tissue. Reperfusion in such cases is unsuccessful and the prognosis is poorer [29]. Most of the challenge that occurs in primary PCI is related to clinical and hemodynamic stability. For example, ventricular fibrillation is an ongoing risk given active severe ischemia, and acute heart failure and pulmonary edema can develop suddenly. Profound left ventricular failure and bradyarrhythmias can also result in severe hypotension, shock, and cardiac arrest. The patient's clinical distress can also complicate the delicate measures required for vascular access and safe PCI, and the use of potent anti-coagulants increases acute bleeding risk. The procedure must therefore be accomplished expeditiously to terminate ongoing ischemia but attention to safety and rapid management of ischemic complications cannot be understated.

The technique has evolved in much the same way as PCI for coronary disease. Optimal balloon angioplasty was the initial method of revascularization and often carried the risks of abrupt vessel closure and restenosis. Stent implantation was introduced to overcome these limitations and proved successful. In the Controlled Abciximab and Device Investigation to Lower Late Angioplasty Complication (CADILLAC) trial, stent implantation was associated with reduced risk of abrupt vessel closure, and restenosis as well as repeat revascularization at longer term follow-up were significantly reduced [30].

Drug-eluting stents These were introduced to further reduce restenosis in PCI and although there were initial concerns about increased risk of stent thrombosis, several trials have shown efficacy and safety in primary PCI. The Harmonizing Outcomes with Revascularization and Stents in AMI (HORIZONS) trial randomly

*Patients with cardiogenic shock or severe heart failure initially seen at a non-PCI-capable hospital should be transferred for cardiac catheterization and revascularization as soon as possible, irrespective of time delay from MI onset (Class I, LOE: B). †Angiography and revascularization should not be performed within the first 2 to 3 hours after administration of fibrinolytic therapy.

Figure 13.2 Reperfusion therapy for patients with ST-elevated myocardial infarction (STEMI). CABG, coronary artery bypass graft; FMC, first medical contact. Source: O’Gara et al. 2013 [48].

assigned 3006 patients undergoing primary PCI to receive a paclitaxel-eluting stent or a bare metal stent in 3 : 1 ratio. Ischemia-driven target lesion revascularization was reduced from 7.5% to 4.5% with no increase in stent thrombosis [31]. In a meta-analysis comparing first generation drug-eluting stents with bare metal stents, target vessel revascularization was significantly reduced and there was no increase in stent thrombosis [32]. Newer generation drug-eluting stents have further improved outcomes [33,34]. In the Clinical Evaluation of the Xience-V Stent in Acute Myocardial Infarction (EXAMINATION) trial comparing current generation everolimus-eluting stents with bare metal stents, both restenosis and stent thrombosis were reduced. Current generation drug-eluting stents are now preferred in primary PCI for better short- and longer term outcomes provided that the recommendations of dual antiplatelet therapy are feasible.

Thrombectomy The infarct vessel in primary PCI by definition contains thrombus; occasionally thrombus is extensive and complicates revascularization by causing distal embolization and microvascular occlusions. This results in failure to establish normal coronary blood flow or tissue perfusion. Both of these events have been repeatedly shown to be associated with worse outcomes including higher mortality. Thrombus burden within the coronary artery can be reduced by aspiration thrombectomy, accomplished

either by manual aspiration through a catheter or aided by a mechanical device. The technique can be applied expeditiously during primary PCI and in most trials applying thrombectomy, coronary perfusion is improved as measured by either ST-segment resolution, thrombolysis in myocardial infarction 3 (TIMI 3) flow achieved or myocardial blush score. Early data were very persuasive and the technique was widely used [35]. In two recently completed definitive large trials, however, the efficacy and safety of aspiration thrombectomy has been seriously questioned [36,37]. In the Thrombus Aspiration during ST-segment Elevation myocardial infarction (TASTE) trial, 7244 patients were randomized to receive either manual aspiration along with primary PCI or to standard primary PCI. There was no difference in primary endpoint of mortality at 30 days, and no difference in mortality or other major adverse cardiac events at 1 year. In the TOTAL trial, 10,732 patients were similarly randomized to adjunct manual aspiration or routine primary PCI. The primary endpoint of cardiovascular death, recurrent myocardial infarction, cardiogenic shock, or severe heart failure at 6 months was no different in the two groups. Moreover, a pre-specified safety endpoint of stroke at 30 days was increased in the aspiration group. Routine aspiration thrombectomy in primary PCI therefore can no longer be recommended based on these trials, although in special instances for severe persistent angiographic thrombus, aspiration can help enhance vessel patency.

Radial access An advance in angiography and PCI came with the use of the radial artery rather than the femoral artery for vascular access. This technique—now embraced by a substantial number of operators—is associated with reductions in major bleeding and other vascular complications. On the hand, the procedure is technically more challenging and ultimately unsuccessful in 5–10% of cases. A number of trials have evaluated radial versus femoral artery access in managing patients with acute coronary syndromes including primary PCI for STEMI. In the Radial Vs Femoral Access for Coronary Intervention (RIVAL) trial, 7021 patients with acute coronary syndromes were randomized to undergo angiography and PCI via the radial versus the femoral artery. Ischemic outcomes were comparable between the two groups; however, vascular complications were reduced from 3.8% to 1.4% in the radial arm. In a pre-specified subgroup of 1958 with STEMI, ischemic outcomes, driven by mortality, were unexpectedly reduced from 5.2% to 3.1% [38]. In the RIFLE-STEACS, 1001 patients undergoing primary PCI were similarly randomized to radial or femoral access. Outcomes with radial access were significantly better, driven by reductions in major bleeding and cardiac mortality [39]. In these as well as other trials, reperfusion time was not compromised with the radial approach. In a meta-analysis involving more than 5000 patients, mortality was reduced from 4.7% to 2.7% and major bleeding from 2.9% to 1.4% [40].

In summary, radial access in primary PCI is an attractive technique when it can be performed without compromising reperfusion times. Major vascular complications and bleeding can be reduced and there are now strong suggestions of reduced mortality. However, confirmation in more definitive trials is needed.

Mechanical support Cardiogenic shock complicates 5–7% of acute myocardial infarction and is primarily the result of left ventricular failure caused by extensive infarction or multivessel coronary disease [41,42]. Prompt revascularization is considered the most effective intervention [43] and is highly recommended; however, in many patients shock persists and results in progressive circulatory failure and multi-organ failure with a high mortality rate. Rapid support using intra-aortic balloon pump (IABP) counter pulsation was long thought to be highly effective by augmenting coronary perfusion and reducing systemic afterload. The IABP Shock II trial was designed to study the effectiveness of this intervention [44]. Six hundred patients with myocardial infarction complicated by cardiogenic shock were randomized to receive IABP support after successful primary PCI or to receive routine post-intervention care. The primary outcome of 30-day all-cause mortality was no different in both groups and at 1 year follow-up, there remained no differences in mortality or other major adverse cardiac events. It remains unclear at this point if there is a benefit of mechanical support for shock in STEMI following successful primary PCI. It is possible that a greater level of support beyond what is capable with IABP is needed and investigation is currently underway to test whether more robust support as provided with the Impella® left ventricular assist will be effective [45].

Multivessel intervention: Multivessel coronary disease is frequently noted in primary PCI and associated with a worse prognosis [46]. To date, however, guidelines have advocated focus of the infarct (culprit) vessel with additional intervention reserved for a later date or driven by ischemia,[47,48]. Part of the rationale behind this is to avoid inducing ischemia or complication in other vessel territories at the time of acute myocardial infarction. Randomized

trials to address this issue had been lacking until recently. In the Preventive Angioplasty in Myocardial Infarction (PRAMI) trial, 465 patients with multivessel disease, having undergone successful primary PCI, were randomized to undergo additional revascularization of non-culprit severe stenoses or to undergo standard care with additional intervention driven by refractory angina. Patients assigned to additional revascularization experienced significantly lower major adverse events of cardiac death, recurrent myocardial infarction, or refractory ischemia [49]. In the Complete versus Lesion-only Primary PCI (CvLPRIT) trial, 296 patients were similarly randomized and patients undergoing complete revascularization demonstrated reductions in major adverse cardiac events including cardiac death, myocardial infarction, heart failure, and ischemia-driven revascularization at 12 months [50]. These data, though preliminary, suggest more complete revascularization appears safe and beneficial in patients undergoing primary PCI. Larger, more definitive, randomized trials are needed to confirm these findings.

Salvage and rescue PCI

Despite the remarkable availability of primary PCI in many communities, this therapy cannot be delivered to all in an efficient manner with target goals described. Many patients therefore continue to receive thrombolytic therapy as their primary reperfusion strategy and outcomes are generally very good. Several studies have evolved to define how patients should be managed after thrombolytic therapy, whether successful or not. When thrombolytic therapy is considered unsuccessful, as characterized by persistent or recurrent angina and/or ST elevation, it is generally agreed that rapid PCI is effective at providing successful reperfusion [51]. The Rapid Early Action for Coronary Treatment (REACT) study showed that compared with conservative care salvage primary PCI resulted in improved major cardiovascular events for 6 months [52]. Such salvage/rescue PCI can be expected in 15–25% of patient receiving thrombolytics and so a mechanism to transfer to a PCI center should be in place.

Beyond rescue PCI, there appear to be benefits of ultimately performing urgent PCI in most patients who have received successful reperfusion with thrombolytics. Thrombolytics simply restore coronary blood flow in the infarct vessel. A high grade stenosis remains with a disrupted plaque and is a source for recurrent thrombosis or persistent ischemia. Such recurrent ischemia can be seen in up to 25% of patients and is associated with increased mortality. Several trials tested the hypothesis that routine early angiography and intervention would be superior to strategy of invasive management guided by recurrent or inducible ischemia. In the largest trial, the Trial of Routine Angioplasty and Stenting after Fibrinolysis to Enhance Reperfusion in Acute Myocardial Infarction (TRANSFER-AMI) randomized 1059 patients and found that routine PCI performed a median of 4 hours after successful fibrinolysis was associated with reductions in major adverse cardiac events [53]. In a meta-analysis of similar trials with routine PCI performed within the first 24 hours, reductions in death and myocardial infarction were demonstrated at 1 year follow-up [54].

When primary PCI cannot be delivered rapidly as in a 90-minute reperfusion time, a strategy of thrombolytic therapy with subsequent transfer for routine PCI appears to be a reasonable alternative. This is especially relevant when a patient first arrives at a hospital not capable of performing primary PCI and rapid transfer would be difficult. Rapid transfer is logistically difficult for

many centers as delays eliminate the advantage of PCI over thrombolytics [55,56]. The Strategic Reperfusion Early after Myocardial Infarction (STREAM) trial randomized 1832 patients who could not receive primary PCI within expected guidelines to undergo pre-hospital fibrinolytics followed by salvage/routine PCI versus a strategy to proceed directly to primary PCI. Direct primary PCI was performed at a median of 178 minutes and >30% of the pre-hospital fibrinolytic therapy group required rescue PCI. Both arms ultimately had highly successful reperfusion and vessel patency. There was no difference in the primary endpoint of major adverse cardiac events; however, stroke was more common with the fibrinolytic arm [57].

Pharmacologic support before and during primary PCI

Pharmacologic therapy in primary PCI has evolved along with advances in supportive therapy for PCI in general, designed to enhance coronary patency, tissue level perfusion, and procedural safety. Numerous investigations of antiplatelets and antithrombins have been conducted since the initial procedural efficacy was shown utilizing standard intravenous heparin and oral aspirin.

Intra-procedural therapy investigations

To enhance thrombus management as was demonstrated with fibrinolytic therapy and in medical therapy for acute coronary syndromes, glycoprotein (GP) IIB/IIIa inhibitors were added to heparin in a series of primary PCI trials. The largest, the CADILLAC trial [58], randomized over 2000 patients to abciximab or placebo and found reductions in acute thrombotic complications including recurrent myocardial infarction. A meta-analysis of trials using abciximab showed clear reductions in recurrent myocardial infarction and trends toward lower mortality [59] but major bleeding was increased. Small molecule GP IIB/IIIa inhibitors, specifically high dose tirofiban and double bolus eptifibatid, were similarly investigated primarily in comparison with abciximab in multiple trials [60–62]. These generally showed comparable outcomes, particularly when viewed in aggregate, but no advantage in bleeding complications [63]. GP IIB/IIIa inhibitors are therefore a reasonable supportive therapy during primary PCI although they have been associated with an increase in major bleeding complications.

Bivalirudin, a potent and specific thrombin inhibitor, was introduced as an alternative to intravenous heparin in PCI and subsequently compared with strategies involving intravenous heparin with routine and then selective use of GP IIB/IIIa inhibitors. The largest trial to date was the HORIZONS trial, which randomly assigned 3602 patients to receive bivalirudin or heparin with a GP IIB/IIIa inhibitor [64]. Overall, major adverse cardiac events were not different, but major bleeding complication was reduced leading to a superior net clinical outcome. The EUROMAX trial randomized 2218 patients scheduled for primary PCI to receive bivalirudin or heparin with optional GP IIB/IIIa inhibitor [65]. Outcomes were similarly improved with the primary benefit coming from reduced bleeding complications. In both trials, an increase in acute stent thrombosis was noted but this did not affect long-term outcomes. In HEAT PPCI, 1829 patients were randomized to bivalirudin versus heparin and GP IIB/IIIa inhibitors used selectively in each group [66]. In this trial, adverse cardiovascular events including stent thrombosis were higher with bivalirudin and there was no bleeding advantage. Finally, in the recently published BRIGHT trial involving 2194 patients, bivalirudin utilizing a longer infusion

strategy was compared with a heparin alone and heparin plus GP IIB/IIIa infusion regimen [67]. There were no differences in acute ischemic outcomes; however, bleeding was lowest with the bivalirudin alone therapy. In summary, bivalirudin can be used as alternative to heparin or heparin with a GP IIB/IIIa inhibitor in primary PCI. Lower bleeding complications can be expected but there is a small risk of acute thrombotic events which can be mitigated by longer anticoagulant therapy. In a recent trial, Stone *et al.* [67] demonstrated a reduction in infarct size with intracoronary delivery of abciximab on a background of bivalirudin therapy in patients with large anterior myocardial infarction. GP IIB/IIIa inhibitors should therefore remain a consideration in selected patients even when on a background of bivalirudin.

Pre-procedural therapy investigations

To enhance early vessel patency, several drugs have been proposed to improve primary PCI efficacy, a strategy referred to as facilitated primary PCI. Among these, fibrinolytics and antiplatelets have received the most rigorous study. Early evaluations of this strategy were fraught with adverse outcomes and in a meta-analysis of these early trials Keeley and Grimes [68] found significantly higher bleeding and ischemic complications with no ischemic advantage. These studies were conducted before significant improvements in PCI technique including the use of thienopyridine oral antiplatelets and coronary stents. More contemporary evaluations began with the Facilitated Intervention with Enhanced Reperfusion Speed to Stop Events (FINESSE) trial where 2452 patients were randomly assigned to facilitated PCI using either abciximab or combined abciximab and reteplase, initiated before primary PCI, or to standard primary PCI with abciximab initiated during the procedure [69]. Facilitated PCI was associated with higher early ST-segment elevation resolution and higher baseline TIMI 3 flow rate but PCI was ultimately equally successful in both groups. There was no difference in major cardiovascular endpoints that included death, late ventricular fibrillation, cardiogenic shock, or heart failure. Major bleeding was increased with facilitated PCI. Similarly, in the Ongoing Tirofiban in Myocardial Infarction Evaluation 2 (ON-TIME 2) trial, tirofiban was randomly administered pre-hospitalization in a facilitated fashion among 936 patients undergoing primary PCI [70]. ST-segment resolution was improved as well as early stent thrombosis but overall clinical outcomes were comparable. The oral antiplatelet ticagrelor was similarly investigated as a facilitating therapy in the Administration of Ticagrelor in the Ambulance or in the Catheterization laboratory (ATLANTIC) trial [71]. A total of 1862 patients were randomly assigned to receive ticagrelor initiated in the ambulance well before primary PCI or to standard primary PCI with ticagrelor initiated in the catheterization laboratory. In this study, unlike FINESSE and ON-TIME 2, there was no improvement in ST-segment elevation resolution. There was also no difference in major clinical outcomes, although acute stent thrombosis—which occurred rarely—was further reduced with early ticagrelor.

Post-procedural therapy investigations

Recurrent thrombotic event rates are higher in patients following STEMI and contribute to late mortality and recurrent myocardial infarction. These may be the result of recurrent thrombosis of the infarct-related vessel, including stent thrombosis, or new plaque disruption and acute coronary syndrome elsewhere. As platelets have an important role in atherothrombosis, long-term oral antiplatelets have been extensively investigated. The CLARITY TIMI-28

trial first suggested the effectiveness of oral P2Y₁₂ antagonists after myocardial infarction in patients who received thrombolytics along with aspirin [72]. In this trial, clopidogrel initiated soon after thrombolytics enhanced vessel patency at angiography days later and resulted in reduced risk for recurrent myocardial infarction at 30 days. In the Clopidogrel and Metoprolol in Myocardial Infarction Trial (COMMIT) trial, clopidogrel when added early to a large unselected population of patients with acute myocardial infarction resulted in reduced risk of overall death at as early as 4 weeks [73]. The CURRENT OASIS-7 trial investigated whether a short course of double dose clopidogrel soon after acute coronary syndrome would improve outcomes [74]. Among patients undergoing PCI, the higher dosing regimen resulted in reduced risk of recurrent myocardial infarction and stent thrombosis at 30 days. In this trial, over 6000 patients had STEMI and benefits were consistent in this group. The TRITON TIMI-38 trial tested the more potent oral thienopyridine prasugrel in patients with acute coronary syndrome including over 3500 patients with STEMI [75]. Prasugrel therapy was associated with significantly lower major adverse cardiac events, particularly recurrent myocardial infarction and stent thrombosis, over the 15-month period of study. The PLATO trial studied ticagrelor, a non-thienopyridine P2Y₁₂ inhibitor high risk patients with acute coronary syndromes. The rate of cardiovascular death and recurrent myocardial infarction was reduced, as was stent thrombosis. There were also over 7000 patients enrolled with STEMI and outcomes were comparable [76].

In summary, dual oral antiplatelet therapies improve outcomes in acute myocardial infarction managed with PCI. More potent agents appear to further reduce the risk of recurrent thrombotic events including recurrent myocardial infarction and stent thrombosis compared with standard dose clopidogrel. These agents should therefore be initiated as early as feasible and continued long term as suggested by guidelines.

Myocardial conditioning

The prospect of protecting the myocardium from irreversible damage during acute myocardial infarction has long been considered the holy grail in this line of therapy. To date only early reperfusion therapy has been proven to terminate and minimize extent of injury. Nonetheless, several investigations have explored pathways such as reducing cardiac mechanical work, enhancing ischemic adaptation, enhancing tissue level perfusion, delivering supplemental oxygen, manipulating metabolism, and reducing free radical damage. In the CRISP-AMI trial, the use of IABP counter-pulsation aimed at reducing cardiac work did not reduce infarct size among 337 patients with anterior myocardial infarction [77]. The IABP SHOCK II trial also found no benefit of this therapy in patients with cardiogenic shock following successful primary PCI. Remote ischemic preconditioning to enhance ischemic adaptation has been applied successfully in transplantation organ harvest and minimizes injury during cardiac surgery. Botker *et al.* [78] tested intermittent forearm ischemia using blood pressure inflation in 333 patients with acute ST-elevation myocardial infarction (STEMI). A reduction in infarct size was noted; however, given the limited study size, a larger clinical is needed. Vasodilatation of the microvasculature during acute ischemic injury was proposed to be protective and initially appeared promising with adenosine. However, the Acute Myocardial Infarction Study of Adenosine-II (AMISTAD-II) trial tested this hypothesis in 2118 patients and found no significant improvement in infarct size or clinical

outcomes [79]. In the AMIHOT trials, the effect of supersaturated oxygen therapy was tested in patients with acute myocardial infarction [80,81]. A reduction in infarct size was noted in patients with anterior myocardial infarction treated. However, given the small sample size, a larger trial powered for clinical endpoints is needed. To minimize energy consumption by switching from fatty acid metabolism to glucose metabolism, the CREATE-ECLA trial evaluated the effect of a glucose insulin potassium infusion in 20,201 patients with acute STEMI [82]. Despite prior positive preliminary data, there was no effect on mortality or other major adverse events including cardiogenic shock, cardiac arrest, or reinfarction. To combat inflammation and cell death via the complement pathway, the APEX-AMI investigators tested the monoclonal antibody pexelizumab in over 5700 patients with acute myocardial infarction undergoing primary PCI [83]. There was no effect on mortality or endpoints such as cardiogenic shock at 30 or 90 days.

In summary, the ability to limit myocardial damage from prolonged ischemia in acute myocardial infarction has remained unproven. While more investigation is needed, the most effective intervention to date remains early recognition of STEMI and rapid mechanical reperfusion via primary PCI.

The Management of Cardiogenic Shock and Hemodynamic Support Devices and Techniques

Bimmer E.P.M. Claessen, Dagmar Ouweneel, and José P.S. Henriques

Department of Cardiology, Academic Medical Center—University of Amsterdam, Amsterdam, The Netherlands

Even in the current era of primary percutaneous coronary intervention (PCI), cardiogenic shock remains a dramatic and lethal condition. The incidence of cardiogenic shock after myocardial infarction (MI) appears to be lowering from about 10% in the 1970s and 1980s to about 5–6% currently, potentially as a result of improvement in time-to-reperfusion and as a result of better techniques for reperfusion (primary PCI compared with thrombolysis) [1–5]. However, mortality after MI remains very high with recent studies reporting mortality rates of 40–65% [5,6]. This chapter reviews evidence on medical and mechanical management of cardiogenic shock.

Definition of shock

Shock is defined as a clinical condition where there is inadequate end-organ perfusion caused by failure of the heart to pump blood in adequate quantities. There is currently no uniform definition of cardiogenic shock in clinical practice or for research purposes. A couple of influential randomized clinical trials use definitions that are similar, but not identical.

In the SHOCK (should we emergently revascularize occluded coronaries for cardiogenic shock) trial, cardiogenic shock was defined by a combination of clinical and hemodynamic criteria [7,8]. Clinical criteria in SHOCK were hypotension (a systolic blood pressure of <90 mmHg for at least 30 minutes or the need for supportive measures to maintain a systolic blood pressure of ≥ 90 mmHg) and end-organ hypoperfusion (cool extremities or a urine output of <30 mL/hour, and a heart rate of ≥ 60 bpm). The hemodynamic criteria were a cardiac index of no more than 2.2 L/minute/m² of body-surface area and a pulmonary capillary wedge pressure of at least 15 mmHg [7,8].

In the IABP-SHOCK II (intra-aortic balloon pump in cardiogenic shock) trial, the following definition was used:

- 1 A systolic blood pressure of less than 90 mmHg for more than 30 minutes or needing infusion of catecholamines to maintain a systolic pressure above 90 mmHg;
- 2 Clinical signs of pulmonary congestion; and
- 3 Impaired end-organ perfusion.

The diagnosis of impaired end-organ perfusion required at least one of the following: altered mental status; cold, clammy skin and

extremities; oliguria with urine output of less than 30 mL/hour; or serum lactate level higher than 2.0 mmol/L [9].

Epidemiology

Cardiogenic shock after MI occurs in about 5–6% of cases in the current era of primary PCI, and occurred in about 10% of cases in the era before rapid mechanical reperfusion [1–5]. The incidence of cardiogenic shock may have declined, but mortality after cardiogenic shock remains very high, even in contemporary cohorts, with mortality rates of 40–60% [10,11].

An early study of 845 patients presenting with acute MI, not treated with thrombolysis or mechanical reperfusion, investigated risk factors for the occurrence of cardiogenic shock [1]. In this study, cardiogenic shock occurred in 60 patients (7.1%). Predictors of cardiogenic shock included age >65 years, left ventricular ejection fraction at hospital admission <35%, large infarct size (peak creatine kinase-MB isoenzyme >160 IU/L), diabetes mellitus, and previous MI. Risk factors in the GUSTO (Global Utilization of Streptokinase and Tissue-plasminogen activator for Occluded coronary arteries) trial, conducted in the era of thrombolysis, included: age, systolic blood pressure, heart rate, and Killip class upon presentation [12].

In the large (n=5745) APEX-AMI (assessment of pexelizumab in acute MI) trial, the incidence of shock was only 3.4% (n=196), most likely because this randomized controlled trial enrolled a relatively low-risk patient population [11]. In APEX-AMI the following risk factors for developing cardiogenic shock were identified: older age, female sex, hypertension, diabetes mellitus, and being a non-smoker.

Management of cardiogenic shock

Impact of coronary revascularization

Since the shock trial, early revascularization has been recognized as the primary treatment modality for cardiogenic shock. Current American College of Cardiology/American Heart Association (ACC/AHA) guidelines state a class I, level of evidence B indication for emergency revascularization with either PCI or coronary artery bypass graft (CABG) in suitable patients with cardiogenic shock from pump failure after ST-elevation myocardial infarction (STEMI) irrespective of the time delay from MI onset [13].

The landmark SHOCK trial randomized 302 patients with cardiogenic shock complicating MI in a 1 : 1 fashion to treatment with emergency revascularization (n=152) or initial medical stabilization (n=150). Revascularization incorporated emergency coronary angiography followed by either CABG or PCI. In the SHOCK trial, 30-day mortality rates were numerically lower in the early revascularization arm (46.7% vs. 56.0%; p=0.11). However, at 6 months mortality rates were significantly lower with early revascularization (50.3% vs. 63.1%; p=0.027) [7]. Furthermore, emergency revascularization was not only associated with improved survival, but also with improved quality of life, assessed by the multidimensional index of life quality and New York Heart Association (NYHA) heart failure class [14].

An important substudy investigated the clinical outcome in patients assigned to emergency revascularization in the SHOCK trial undergoing PCI compared with CABG [15]. Out of 128 patients undergoing emergency revascularization, 81 underwent PCI (63.3%) and 47 underwent CABG (36.7%). Patients undergoing CABG were at higher risk at baseline with a greater extent of coronary artery disease and a greater prevalence of diabetes mellitus. In the CABG group, 87.2% of patients were considered completely revascularized whereas only 23.1% of patients in the PCI group were considered completely revascularized. Despite the higher baseline risk profile of patients undergoing CABG, 1-year survival was similar in both treatment arms, suggesting a potential benefit of complete revascularization. Partly because of this substudy, current guidelines recommend complete revascularization during PCI for cardiogenic shock, as compared with culprit-vessel only PCI for MI without cardiogenic shock [13,16].

Left-ventricular assist devices and the intra-aortic balloon pump

Mechanical support devices aim to overcome the inability of the heart to pump adequate amounts of blood by supporting the circulation and increasing cardiac output. Moreover, support devices aim to unload the damaged left ventricle by afterload (pressure unloading) or pre-load reduction (volume unloading). Currently available devices include the intra-aortic balloon pump (IABP), the Impella axial flow pump, the TandemHeart device, and extracorporeal membrane oxygenation (ECMO) [17]. An overview of various characteristics of these devices is provided in Table 14.1.

IABP The IABP was introduced 1968. It is inserted percutaneously in the femoral artery and positioned in the descending thoracic aorta distal to the left subclavian artery and proximal to the renal artery branches. The IABP aims to augment coronary blood flow and systemic blood flow during diastole. The balloon is synchronized to the cardiac cycle and is rapidly inflated with helium gas during diastole and rapidly deflated immediately before systole. In a small study that randomized 40 patients in cardiogenic shock to optimal medical therapy alone or to optimal medical therapy and an IABP, no significant differences were observed in hemodynamic parameters such as cardiac output and systemic vascular resistance between the groups [18]. The IABP SHOCK II trial randomized 600 patients with cardiogenic shock complicating MI to treatment with an IABP or no IABP. Early revascularization and optimal medical therapy was provided in both study arms. The use of the IABP did not reduce 30-day or 1-year mortality [6,10]. Moreover, there were no differences in time to hemodynamic stabilization, the length of intensive care unit stay, serum lactate levels, dose and duration of catecholamine administration, or renal function [6].

Impella The Impella consists of a pigtail catheter at the tip functioning as the inlet for blood which is positioned in the left ventricle and uses a micro-axial rotary pump which is placed across the aortic valve to continuously expel blood into the aorta. There are three versions of the impella system: the Impella 2.5 which delivers up to 2.5L/min of flow; the Impella CP delivering up to 3.5–4.0L/min of flow which are both inserted percutaneously; and the Impella 5.0 which delivers up to 5.0L/min but requires a surgical cutdown for insertion [17]. Currently available evidence on the use of the Impella device in cardiogenic shock is limited to observational studies and a small randomized trial [19–21]. In the ISAR-SHOCK (efficacy study of LV assist device to treat patients with cardiogenic shock) trial, 26 patients with cardiogenic shock were randomized to IABP or Impella [19]. In this small study the cardiac index after 30 minutes of support was significantly higher in the Impella group compared with the IABP group (delta 0.49 ± 0.46 L/min/m² vs. 0.11 ± 0.31 L/min/m²; p=0.02). Overall 30-day mortality was similar in both groups.

TandemHeart The TandemHeart uses a continuous flow centrifugal pump which can deliver up to 4L/min of blood flow. It can be inserted using fluoroscopy guidance in the catheterization laboratory. The inflow cannula is inserted through the femoral vein and guided to the left atrium via an atrial septal puncture. The outflow cannula is inserted through the femoral artery and positioned at the level of the aortic bifurcation. In two small randomized clinical trials enrolling about 40 patients each, the TandemHeart was associated with significant improvements in hemodynamic parameters when compared with the IABP [22,23]. However, without direct left ventricular unloading the TandemHeart increases left ventricular afterload which partially offsets the potential cardiac workload benefits. Other concerns with the TandemHeart are the complications (bleeding and limb ischemia) and the complex insertion procedure.

ECMO Venoarterial ECMO consists of a centrifugal pump, a heat exchanger, and a membrane oxygenator. Venous blood is aspirated from the right atrium via the femoral vein, it is then guided to a pump which directs it to a membrane oxygenator, and is then guided via the outflow cannula into the descending aorta via the femoral artery. As this is quite a complex machine, it is associated with complications such as systemic inflammatory response, renal failure limb ischemia, and bleeding. Moreover, it increases both the afterload and the pre-load of the left ventricle resulting in increased oxygen demand which impedes myocardial protection [24].

Guideline recommendations for the IABP and left ventricular assist devices The 2014 European Society of Cardiology and the European Association for Cardio-Thoracic Surgery (ESC/EACTS) guidelines for myocardial revascularization no longer recommend the use of IABP in patients with cardiogenic shock (class III recommendation, level of evidence A) [16]. These guidelines state a class IIb, level of evidence C recommendation for the use of left ventricular assist devices “short-term mechanical circulatory support in ACS patients with cardiogenic shock may be considered.” The 2013 ACC/AHA guidelines state a class IIa level of evidence B recommendation for the use of the IABP. “The use of intra-aortic balloon pump (IABP) counterpulsation can be useful for patients with cardiogenic shock after STEMI who do not quickly stabilize with pharmacological therapy” [13]. The ACC/AHA recommendation for left ventricular assist devices is class IIb, level of evidence C “Alternative LV assist devices for circulatory support may be considered in patients with refractory cardiogenic shock.”

Table 14.1 Overview of mechanical support devices.

	IABP	ECMO	TandemHeart	Impella 2.5	Impella CP	Impella 5.0
Pump mechanism	Pneumatic	Centrifugal	Centrifugal	Axial flow	Axial flow	Axial flow
Cannula size	7–9 Fr	18–21 Fr inflow; 15–22 Fr outflow	21 Fr inflow; 15–17 Fr outflow	13 Fr	14 Fr	22 Fr; Surgical cut-down
Insertion technique	Descending aorta via the femoral artery	Inflow cannula into the right atrium via the femoral vein, outflow cannula into descending aorta via femoral artery	21 Fr inflow cannula into left atrium via femoral vein and trans-septal puncture and 15–17 Fr outflow cannula into femoral artery	12 Fr catheter placed retrograde across the aortic valve via the femoral artery	14 Fr catheter placed retrograde across the aortic valve via the femoral artery	21 Fr catheter placed retrograde across the aortic valve via a surgical cut-down of the femoral artery
Hemodynamic support (L/min)	0.5–1.0	>4.5	4	2.5	3.5–4.0	5.0
Implantation time	+	++	++++	++	++	++++
Risk of limb ischemia	+	+++	+++	++	++	++
Anticoagulation	+	+++	+++	+	+	+
Hemolysis	+	++	++	++	++	++
Requires stable heart rhythm	Yes	No	No	No	No	No

Vasopressors and inotropes

Rapid treatment of hypoperfusion and hypotension is essential when dealing with cardiogenic shock. Inotropes can be used to increase cardiac output and vasopressors to increase blood pressure. However, inotropes and vasopressors increase myocardial oxygen consumption and current guidelines suggest their use should be assessed on an individual patient basis [13]. Sympathomimetic agents are most commonly used in the setting of cardiogenic shock, but phosphodiesterase inhibitors and calcium sensitizers are also sometimes used.

Sympathomimetic agents Norepinephrine has a high affinity for the alpha-adrenergic receptor and has minor beta-agonistic effects. Therefore, norepinephrine is a potent vasopressor with limited inotropic effects. Dopamine has a variety of effects depending on the dosage. At low doses (1–2 µg/kg/min) it increases urine output by augmenting renal blood flow and natriuresis [25,26]. At intermediate doses (5–10 µg/kg/min) dopamine stimulates beta-1 adrenergic receptors, allowing for an increased stroke volume and an increased heart rate, increasing cardiac output. At high doses (>10 µg/kg/min) dopamine predominantly stimulates alpha-adrenergic receptors, causing vasoconstriction. A randomized study of 1679 patients with shock (septic, hypovolemic, and cardiogenic) assigned to dopamine or norepinephrine as the first line vasopressor showed more arrhythmic events in the dopamine group (24.1% vs. 12.4%; $p < 0.001$). A subgroup analysis of patients with cardiogenic shock showed that dopamine was associated with increased 28-day mortality compared with norepinephrine [27]. An alternative is dobutamine, which is a synthetic catecholamine with strong beta-1 and beta-2 receptor affinity. The beta-2 affinity of dobutamine may cause vasodilatation and can cause hypotension.

Phosphodiesterase inhibitors and calcium sensitizers Agents such as milrinone and enoximone increase the intracellular concentration of cyclic adenosine monophosphate (cAMP) by inhibiting the action of phosphodiesterase 3 [28]. Phosphodiesterase 3 is an enzyme found in the sarcoplasmic reticulum of cardiac myocytes and vascular smooth muscle cells that breaks down cAMP into AMP. The increased intracellular concentration of cAMP causes increased myocardial contractility, improved diastolic relaxation, and vasodilatation. Milrinone, the most widely used phosphodiesterase inhibitor, has a relatively long half-life of 2–4 hours. The calcium-sensitizer levosimendan sensitizes troponin C to calcium, thereby increasing the effects of calcium on cardiac myofilaments which increases cardiac contractility at low energy costs. Levosimendan also causes vasodilatation by opening ATP-dependent potassium channels [29,30]. Neither milrinone nor levosimendan have been tested in the setting of cardiogenic shock complicating MI and so experience with these agents in this setting is limited.

Conclusions

In conclusion, the incidence of cardiogenic shock is declining, but its clinical impact remains as significant as ever. Vasopressors and inotropes can be used to improve blood pressure and cardiac output, but they cause an increase in systemic vascular resistance and in pulmonary capillary wedge pressure and increase cardiac work and cardiac oxygen consumption. Therefore, the use of left ventricular assist devices is a promising treatment modality that is currently being investigated in larger randomized controlled trials.

Percutaneous Coronary Intervention in Unprotected Left Main

Gill Louise Buchanan¹, Alaide Chieffo², and Antonio Colombo²

¹Department of Cardiology, North Cumbria University NHS Trust, Carlisle, United Kingdom

²Interventional Cardiology Unit, San Raffaele Scientific Hospital, Milan, Italy

The presence of unprotected left main coronary artery (ULMCA) disease is a common finding in patients undergoing coronary angiography, typically observed in approximately 5–7% [1] and generally associated with concurrent triple vessel disease. Such patients receiving only medical therapy have increased mortality rates; indeed, data from the Coronary Artery Surgery Study (CASS) shows only 57% of those treated medically survive 5 years [2]. This is likely because the ULMCA subtends a large area [3] and significant disease can lead to left ventricular dysfunction and arrhythmias.

Until relatively recently the conventional form of treatment for the stenosed ULMCA has been coronary artery bypass grafting (CABG). The introduction of drug-eluting stents (DES) resulted in a significant reduction in restenosis and target lesion revascularization (TLR) following percutaneous coronary intervention (PCI) [4–18]. Due to such advances in coronary stent technology, in addition to antiplatelet pharmacology and adjunctive imaging techniques, the option of PCI has become more widely accepted. This has resulted in a change in the guidelines for myocardial revascularization, reducing the indication for CABG in this complex disease subset from Class I (level of evidence A) to Class II (level of evidence B) [19]. Indeed, the results of a number of clinical trials are awaited with anticipation, which may lead to further changes in the guidelines for ULMCA intervention in the future. This chapter discusses the available evidence for ULMCA PCI and practical issues that the operator encounters.

Current evidence for ULMCA revascularization

Numerous non-randomized, observational registries have demonstrated no significant differences between CABG and PCI in patients with ULMCA lesions with regards to major adverse cardiovascular and cerebrovascular events (MACCE), up to 5 years' follow-up (Table 15.1) [8,20–35].

Randomized trial data comparing PCI with CABG for the treatment of the ULMCA are shown in Table 15.2. The landmark Synergy between Percutaneous Coronary Intervention with TAXUS and Cardiac Surgery (SYNTAX) study was the first major randomized trial comparing CABG versus PCI with DES. The study

included a pre-specified subgroup of patients with ULMCA (PCI n=357; CABG n=348). At 12 months in this group, there was non-inferiority in MACCE (PCI 15.8% vs. CABG 13.7%; $p=0.44$), although there were higher rates of repeat revascularization amongst those undergoing PCI (PCI 11.8% vs. CABG 6.5%; $p=0.02$). Conversely, in the CABG group there were significantly higher rates of cerebrovascular events (PCI 0.3% vs. CABG 2.7%; $p=0.01$) [36].

The results of this study have now been published at 5 years' follow-up, confirming no differences in MACCE overall (PCI 36.9% vs. CABG 31.0%; $p=0.12$) [37]. However, although the results were similar between those patients with low (0–22; 30.4% vs. 31.5%; $p=0.74$) and intermediate (23–32; 32.7% vs. 32.3%; $p=0.88$) SYNTAX scores, in the high SYNTAX score group, CABG did appear to be a superior treatment option (≥ 33 ; 46.5% in PCI vs. 29.7% in CABG; $p=0.003$) [38]. It must be taken into account that these observations must be considered hypothesis-generating only, as non-inferiority was not achieved in the overall trial. Nonetheless, the results are encouraging for ULMCA PCI in those with low anatomic risk (<33 SYNTAX score). Of note, the SYNTAX study utilized first-generation DES which have consequently been shown to be inferior to the contemporary new generation DES in the incidence of repeat revascularization and, very importantly, stent thrombosis (ST).

There is growing evidence for the use of the new generation DES for ULMCA disease, with a number of registry studies reporting encouraging results. The Unprotected Left Main Stenting with a Second Generation Drug-Eluting Stent: One Year Outcomes of the LEft Main Xience V (LEMAX) Pilot Study was the first to publish the results assessing outcomes of 173 patients undergoing ULMCA PCI with the Xience V (Abbott Vascular, Santa Clara, CA, USA) everolimus-eluting stent (EES) [39]. Despite a relatively high risk group (mean SYNTAX score was 25.2 ± 9.5 and 81.0% of lesions affecting the distal bifurcation), the overall MACCE at 1 year was 15.1%, with all-cause mortality only being 2.9%. The occurrence of TLR and target vessel revascularization (TVR) were low overall (2.9% and 7.0%, respectively) and, moreover, the rate of probable or definite ST was low at only 0.6%. This study once more demonstrated higher MACCE in those with a high SYNTAX score (≥ 33) (25.0% vs. 12.0%, respectively; $p=0.05$).

Table 15.1 Observational registry studies comparing coronary artery bypass grafting versus percutaneous coronary intervention in the treatment of the unprotected left main coronary artery.

Study	Year	Patients (n)	Follow-up (months)	Cardiac death (%)	MACCE (%)

Le Mans, Study of Unprotected Left Main Stenting Versus Bypass Surgery; MACCE, major cardiovascular or cerebrovascular event; PRECOMBAT, Premier of Randomized Comparison of Bypass Surgery versus Angioplasty Using Sirolimus Eluting Stent in Patients with Left Main Coronary Artery Disease; SYNTAX, Synergy between Percutaneous Coronary Intervention with TAXUS and Cardiac Surgery.

There are a number of new generation DES, which have been demonstrated to have comparable outcomes in the treatment of the ULMCA. A total of 650 patients were randomized in the Drug Eluting Stent for Left Main Stem Disease (ISAR LEFT MAIN) 2 to EES versus zotarolimus-eluting stents (ZES), with a primary endpoint of death, myocardial infarction (MI), and TLR at 1 year. There were no differences between groups (ZES 17.5% vs. EES 14.3%; relative risk [RR] 1.26; 95% confidence interval [CI] 0.85–1.85; p=0.25) or in the risk of ST (0.9% vs. 0.6%; p>0.99) [40]. The currently available data are promising for the use of new generation DES for ULMCA PCI and the results of long-term follow-up are eagerly awaited.

There are a number of ongoing multicenter trials comparing new generation DES with CABG, such as the Premier of Randomized Comparison of Bypass Surgery versus Angioplasty Using Sirolimus-Eluting Stent in Patients with Left Main Coronary Artery Disease 2 (PRECOMBAT 2) which aims to evaluate the outcomes of 401 patients undergoing ULMCA PCI with EES with historical controls from the PRECOMBAT trial (randomized PCI with the first generation sirolimus-eluting stents [SES] versus CABG). The results of the landmark trial Evaluation of Xience Prime versus Coronary Artery Bypass Surgery for Effectiveness of Left Main Revascularization trial (EXCEL) are also expected. In this study, 2634 patients with ULMCA and a SYNTAX score ≤ 32 have been randomized to either CABG or EES (Xience Prime, Abbott Vascular,

Redwood City, CA, USA). The primary endpoint is the composite incidence of death, MI, or cerebrovascular events at a median follow-up duration of 3 years.

Current guidelines for ULMCA revascularization

As a result of the growing amount of positive data for the use of PCI in this high risk patient subset, current European practice guidelines have now accepted the role of ULMCA PCI [19]. Indeed, although CABG is a Class I indication (now level of evidence B), PCI in those patients with a SYNTAX score of ≤ 22 now has an equivalent Class I (level of evidence B) indication. Those patients with an intermediate SYNTAX score (22–32) have a Class IIa (level of evidence B) indication; however, CABG is still advocated in those with a SYNTAX score of ≥ 32 . With regards to the American Heart Association/American College of Cardiology/Society for Cardiovascular and Angiographic Interventions (AHA/ACC/SCAI) guidelines, PCI has a Class IIa (level of evidence B) in those with favorable anatomy for PCI (SYNTAX ≤ 22) and clinical conditions that present a greater risk of adverse events with CABG. In certain scenarios (e.g., in patients presenting with acute coronary syndromes and ST-elevation MI), ULMCA PCI is a Class IIa (level of evidence B) indication [41].

Multidisciplinary assessment and the use of risk scores

Each individual with ULMCA disease differs, both with regards to their clinical condition and comorbidities as well as their coronary anatomy. As such, it is advisable that every patient is discussed by the “heart team” to determine the most appropriate revascularization strategy to produce the best long-term outcomes for the patient. Indeed, assessment by the heart team in complex pathologies now has a Class I (level of evidence C) indication in recent guidelines [19].

A number of scoring systems have been devised to help with risk stratification prior to undergoing intervention. The traditional scores used by cardiothoracic surgeons are the Society of Thoracic Surgeons (STS) score and the Logistic European System for Cardiac Operative Risk Evaluation (EuroSCORE). Newer scores have been devised and validated by the interventional cardiologists and include the SYNTAX score, a prospective angiographic tool that grades the anatomic complexity of coronary artery disease (an online calculator can be found at www.syntaxscore.com). The use of the STS score and SYNTAX score are commented upon in both the European and in the AHA/ACC/SCAI guidelines as reasonable to calculate in patients with ULMCA disease [19,41].

More recently, other scoring systems have been developed which do not rely solely on anatomic factors, but also take into account other clinical issues relevant to the patient. Potentially, this leads to an improved means of risk stratification for the individual patient. The SYNTAX Score II considers coronary anatomy in addition to the factors assessed in the more traditional surgical scoring systems, which were associated with mortality at 4 years in the SYNTAX study (including age, creatinine clearance, left ventricular ejection fraction, peripheral vascular disease, female sex, and chronic obstructive pulmonary disease) [42]. A further risk model is the Global Risk Classification (GRC), which combines the SYNTAX score with the EuroSCORE [43] and has been demonstrated in patients undergoing ULMCA PCI to be a superior predictor of cardiac mortality. The New Risk Stratification Score (NERS) has been shown to more reliably predict major adverse cardiac events (MACE) than the SYNTAX score in high risk patients requiring ULMCA PCI [44]. Regardless, it is essential that each individual patient undergoes a thorough assessment of clinical and anatomic factors to enable effectual risk stratification and allow guidance in treatment strategy decision making.

Imaging and lesion assessment

The identification of the ULMCA generally arises following conventional diagnostic coronary angiography. This common tool allows basic assessment of the severity of disease, disease location (including involvement of the distal bifurcation), and lesion length. However, there is a large variability in intra- and inter-observer of the ULMCA [45,46] due to the short length of the vessel, with the absence of a normal segment for comparison. In addition, because of positive remodeling it can be difficult to form an accurate assessment and hence the use of adjunctive imaging modalities can have a crucial role prior to consideration of ULMCA revascularization.

Tools such as intravascular ultrasound (IVUS) and optical coherence tomography (OCT) allow more accurate assessment of the morphology of the disease and the significance in often complex coronary angiograms. The size of the vessel and the length of the lesion can be accurately determined by IVUS, to enable precise stent sizing in patients undergoing PCI. Furthermore, IVUS is vital

to guarantee adequate stent expansion and apposition following stent implantation, to potentially reduce the risk of events such as ST. The use of IVUS guidance over angiography guidance alone has been shown to reduce 3-year mortality in a subgroup analysis of patients treated with DES from the MAIN-COMPARE registry (IVUS 4.7% vs. no IVUS 16.0%; $p=0.049$) [47]. A more recent patient level pooled analysis of four registry studies demonstrated the use of IVUS to be associated with less cardiac death, MI, and TLR at 3 years (IVUS 11.3% vs. no IVUS 16.4%; $p=0.04$) and a lower incidence of definite and probable ST (0.6% vs. 2.2%; $p=0.04$) [48].

More recently, the use of OCT has come to the fore in the assessment and treatment of complex patient subsets undergoing PCI and due to the 10-fold higher axial resolution compared with IVUS, it has been demonstrated to be more sensitive in detecting malapposition and edge dissections in the assessment of the ULMCA [49]. This modality may gain an increasing role in the future in determining factors that may predispose an individual to ST (e.g., delayed or incomplete stent endothelialization or stent malapposition).

As an alternative to an anatomic assessment, it is possible to obtain an invasive functional assessment of the significance of an ULMCA “angiographically” intermediate lesion with the use of fractional flow reserve (FFR). A reading following achievement of maximal hyperemia of ≤ 0.75 is known to be an indicator of significant stenosis. Indeed, in patients with an equivocal ULMCA stenosis on coronary angiography, a strategy of revascularization based on the FFR measurement was associated with excellent survival and freedom from events at up to 3 years’ follow-up [50]. Another study of 213 patients with angiographically equivocal ULMCA lesions underwent FFR assessment and were referred for CABG if FFR < 0.80 (surgical group) or remained on medical management or underwent PCI to another target if FFR to ULMCA was ≥ 0.80 (non-surgical group). At 5 years, there was no difference in survival (surgical group 85.4% vs. non-surgical group 89.8%; $p=0.48$) [51]. These data support the notion that we should consider revascularization when ULMCA disease is functionally significant and not driven by the angiographic appearance alone.

Interventional approach

The ULMCA is as unique as each coronary artery and is made up of three diverse segments: the ostium, the main shaft, and the distal bifurcation. The bifurcation is more likely to form atherosclerotic plaque from shear stresses and subsequent flow disturbances, with the carina typically free of disease [52]. However, when the distal bifurcation is involved, this not only adds to the technical difficulties for the operator, but also leads to less favorable clinical outcomes and increased need for repeat revascularization than disease affecting only the ostium or the mid shaft [10,12]. Indeed, a large registry study comparing outcomes following ostial or shaft versus distal bifurcation disease in 1612 patients demonstrated the latter to have a higher MACE (propensity-score adjusted HR 1.48, 95% CI 1.16–1.89; $p=0.001$), at a median follow-up period of 1250 (interquartile range 987–1564) days. This again was largely because of the higher rate of TLR in this group [53]. Moreover, a recent study has shown that a true bifurcation lesion is a significant predictor of restenosis (23.0% vs 14.0%; $p=0.008$) [54].

Clinical outcomes when treating the ostium of the ULMCA alone are favorable with either revascularization strategy and a registry study has demonstrated comparable outcomes [55]. In this lesion subset, a number of studies have shown low event rates following PCI [5–7,55,56] and such a procedure is less technically

Figure 15.1 The treatment of an ostial left main stem lesion in an 84-year-old female patient with a SYNTAX score of 11. (a) shows the lesion at baseline; (b) demonstrates the implantation of a 3.5 × 8 mm drug-eluting stent; (c) the final angiographic end result.

challenging. Figure 15.1 illustrates a successful case of PCI to an ostial lesion.

Ideally, DES should be utilized in all ULMCA PCI, unless there are strong reasons not to use such a stent. A multicenter study of 147 patients undergoing PCI with DES ULMCA disease not involving the bifurcation, demonstrated a TLR rate of 0.7%, cardiac death rate of 2.7%, and MACE rate of 7.4% at long-term clinical follow-up (886 ± 308 days) [10]. The ULMCA ostium is typically large in diameter and, ideally, the stent should protrude back into the aorta by 1–2 mm and avoid the distal bifurcation. Several cine projections should be used to ensure accurate positioning of the stent, with the use of the left anterior oblique cranial view of particular value in clearly visualizing the ostium. In a similar fashion, ULMCA lesions involving the shaft alone should be treated, again avoiding the distal bifurcation if possible.

However, it is not surprising that the distal bifurcation is involved in 60–90% [57] and because of the marked variation in anatomy, no solo PCI strategy can be applied. Factors that need to be considered in determining the best form of intervention include the bifurcation angulation, distribution of the disease, the side branch size, and presence of disease. Conventionally, the main branch is the left anterior descending coronary artery, with the side branch the circumflex or intermediate artery. However, it must be remembered that the side branch can be just as important in terms of size and territory of distribution.

The important thing is to keep it simple if at all possible and if the disease affects the main branch alone (Medina classification 1,1,0 or 1,0,0), a provisional one-stent strategy with stent implantation from the ULMCA into the main branch would be the preferred option. Following optimization with post-dilatation and final kissing balloon inflation, a second stent should only be considered if dissection with reduced TIMI flow is apparent or if there is a significant residual stenosis (which could be assessed for functional significance with FFR). It is well known that a single stent approach for PCI of the ULMCA distal bifurcation has been demonstrated to have better outcomes [58,59] including a TLR rate almost equivalent to that for PCI of the ostium or body when DES are used [5,60].

In certain circumstances, two stents should be the strategy from the outset: if there is significant disease affecting both branches which are of favorable size with a large area of distribution and if the side branch disease is longer than 3–5 mm in length. Restenosis is typically confined to the side branch ostium [59,61]; however, TLR

rates can be up to 26%. A study has randomized 419 patients with distal bifurcation ULMCA disease to either the double kiss crush versus the culotte technique. The latter group sustained more MACE (16.3% vs. 6.2%; $p < 0.05$) largely because of higher TVR (11.0% vs. 4.3%; $p < 0.05$) [62]. Figure 15.2 illustrates the results following treatment of the distal bifurcation with the mini-crush technique. However, it must be emphasized that whichever technique is used, the operator should be confident and final kissing balloon inflation is essential to obtain the optimal result.

More recently, dedicated bifurcation stents have become a novel topic for consideration by interventional cardiologists. The Tryton® (Tryton Medical, Inc., Durham, NC, USA) can be used alongside a conventional DES in a “reverse culotte” technique, facilitating stenting and potentially improving angiographic results and clinical outcomes. The feasibility of this stent with EES was demonstrated in a prospective single arm study, including 52 patients with stable ULMCA disease. There was angiographic success in 100% and at 6 months’ follow-up TLR occurred in 12%, MI in 10%, and MACE in 22%, with importantly no ST [63]. In the future, with improvements in technology, there may be a greater usage of similar stents if procedural ease and outcomes become favorable.

Pharmacotherapy in ULMCA intervention

There are a number of different adjunctive pharmacologic agents available currently for use during PCI, including unfractionated heparin, bivalirudin, and the glycoprotein IIb/IIIa antagonists, the choice of which generally lies with the operator. However, a recent pooled dataset from three large randomized trials comparing bivalirudin with heparin has suggested that in the ULMCA group (177 patients) bivalirudin was associated with significantly less non-CABG-related bleeding (4.5% vs. 14.6%; RR 0.27; 95% CI 0.09–0.83; $p = 0.013$) despite a similar composite endpoint of death, MI, and TVR at 30 days (11.4% vs. 12.4%; $p = 0.513$) [64].

The stent type of choice is the DES and the typical accepted duration of treatment following elective DES implantation is at least 12 months of dual antiplatelet therapy (DAPT), with aspirin therapy continued indefinitely thereafter [41,65]. However, despite the fact that some current DES have CE mark for only 3 months DAPT, many interventionalists may actually recommend more prolonged DAPT because of the potentially catastrophic consequences should ST occur in the ULMCA. Indeed, the recent Dual Antiplatelet

Figure 15.2 The use of a two stent mini-crush strategy for the treatment of a 69-year-old male patient with a SYNTAX score of 24. (a) shows the disease affecting the distal bifurcation. (b) and (c) show positioning of the circumflex (3.0 × 18 mm) and left anterior descending coronary artery (3.5 × 23 mm) stents respectively. (d) demonstrates final kissing balloon inflation and (e) the final angiographic end result.

Therapy Study randomized 9961 patients to 12 months versus 30 months of DAPT. Prolonged treatment with DAPT reduced the rate of ST (0.4% vs. 1.4%; HR 0.29; 95% CI 0.17–0.48; $p < 0.001$) and MACCE (4.3% vs. 5.9%; HR 0.71; 95% CI 0.59–0.85; $p < 0.001$), with conversely more bleeding in the prolonged treatment group (2.5% vs. 1.6%; $p = 0.001$) [66]. Further studies are necessary to clarify the optimum regimen and duration of DAPT following the treatment of ULMCA with DES.

Hemodynamic support

Generally with good left ventricular function, patients can tolerate ULMCA PCI well with no requirement for hemodynamic support electively. Indeed, the risk of acute instability requiring intra-aortic balloon pump (IABP) support is only 8% [67]. However, if there is severe left ventricular dysfunction, systolic blood pressure < 90 mmHg, or acute coronary syndrome, a prophylactic IABP can be considered prior to the procedure. In addition, certain anatomic subsets, such as an occluded right coronary artery, dominant circumflex artery, or a heavy calcium burden that requires rotational atherectomy may undergo such support.

Currently the Impella 2.5 system (Abiomed Inc., Danvers, MA, USA), a minimally invasive left ventricular assist device, is available as an alternative means of hemodynamic support [68]. This device has been compared with the IABP in a randomized study of 452

patients requiring non-emergent PCI with complex triple vessel coronary artery disease or ULMCA with severely depressed left ventricular function. There was no difference in 30-day MACE between groups (IABP 40.1% vs. Impella 35.1%; $p = 0.227$); however, a trend for improved MACE at 90 days with the Impella 2.5 (IABP 49.3% vs. Impella 40.6%; $p = 0.066$) suggested there may be a benefit of this novel device in such situations if hemodynamic support is deemed necessary [69].

Conclusions

The treatment of the ULMCA remains a challenge for the interventional cardiologist, not only in procedural complexity but also the concurrent disease affecting many of the patients undergoing such a procedure. There has been increased enthusiasm in recent years because of a number of improvements within the field, including stent technology, adjunctive imaging, and pharmacotherapy which has resulted in the emergence of encouraging outcomes.

It must be remembered that each patient is an individual and should be risk stratified as such with the heart team involvement and careful consideration should be given to the strategy and pharmacotherapy regime. The results of randomized trials are eagerly awaited, which in time may lead to further changes in the guidelines for ULMCA PCI.

Bifurcation Lesion Stenting

Yves Louvard, Thierry Lefevre, Bernard Chevalier, and Philippe Garot

Institut Cardiovasculaire Paris Sud, Hôpital Privé Jacques Cartier, Massy and Hôpital Privé Claude Galien, Quincy, France

The history of coronary bifurcation treatment is superimposed with that of coronary angioplasty as illustrated in the early 1980s by the description of the kissing balloon technique [1]. Many technical strategies have been proposed under various names since the advent of stenting but they have not always been adequately assessed.

Results achieved in coronary bifurcations with bare metal stents were clearly not as good as those achieved in non-bifurcated lesions, especially with respect to restenosis and repeat interventions (TLR). These poor results fueled the development of dedicated stents while drug-eluting stents (DES) paved the way for enhanced techniques aiming at optimal angiographic results [2].

In order to compare the various techniques, a substantial number of randomized trials were carried out, the majority of which supported the provisional side branch (SB) stenting strategy (2013 ACC/AHA and 2014 ESC recommendations). The strategies recommended for the most complex lesions are still the subject of heated debate. Angioplasty of the distal left main is similar to bifurcation percutaneous coronary intervention (PCI) without any specific difficulties, but with a higher procedural risk. Indeed, as the angle between the two distal branches is wider and the vessel diameters are larger, many stents are unsuitable for treating such cases. Although provisional stenting is regarded as superior on the basis of findings from registries and sub-group analyses, no randomized trial has yet been performed.

Anatomy and function of a coronary bifurcation

As is the case for trees in nature or in other parts of the human body, coronary trees have a pseudo-fractal geometry consisting of self-similar repetition of the same modules which are asymmetrical and increasingly smaller coronary bifurcations (Figure 16.1). Each bifurcation is a single anatomic and functional entity with diameters defined by Murray's law as follows: $D^3_{\text{proximal}} = D^3_{\text{main distal}} + D^3_{\text{side branch}}$. For Huo and Kassab the exponent is 2.3. Finet's formula is simpler: $D_{\text{proximal}} = (D_{\text{main distal}} + D_{\text{side branch}})^{0.678}$ [3]. When two diameters of a bifurcation are known, the third can be calculated [4].

A coronary bifurcation is not only an anatomic entity, it is also a functional entity. There are, indeed, linear relationships between diameter, length, flow, and the myocardial mass supplied by a vessel [3]. The bifurcation carina or flow divider plays an important part in the distribution of flow required to supply the myocardium.

The anatomic configuration of coronary bifurcations has multiple implications for treatment strategies and also for quantitative angiography (QCA). From the origin of the vessel down to its distal extremity, the diameter decreases unevenly at each bifurcation and does not follow a linear pattern as in standard QCA software [5]. With this type of software in the main vessel segment proximal (PM) to the SB, the reference diameter is underestimated and the degree of stenosis is overestimated. In the segment distal to the SB (DM), the reference is overestimated as is the degree of stenosis compared to the actual dimensions of the vessel segments. By conventional QCA, the SB can be measured using two methods. Measurement from the ostium underestimates the degree of an ostial lesion as well as the reference diameter. The most commonly used method includes the proximal main branch in the analysis and overestimates the diameter, the degree of stenosis, and the frequency of ostial lesions. There is currently a variety of dedicated software products which have become indispensable for coronary bifurcation QCA [6].

Coronary bifurcation: a pro-atherogenic anatomy

In a linear coronary vessel, blood flow velocity is high during diastole (with a symmetric profile) generating high wall shear stress (WSS). In a vessel loop, the profile becomes asymmetric with high WSS on the outside and lower WSS on the inside of the loop.

In a bifurcation, the velocity is high at the level of the carina, generating high WSS on both sides of the carina, whereas flow is turbulent and even recirculating on the opposite walls resulting in low WSS [7]. High velocity persists in the coronary tree beyond the epicardial segments where the vascular area does not vary.

Low WSS is a documented pro-atherogenic factor whereas high WSS has a protective effect. In areas of high WSS, the endothelial

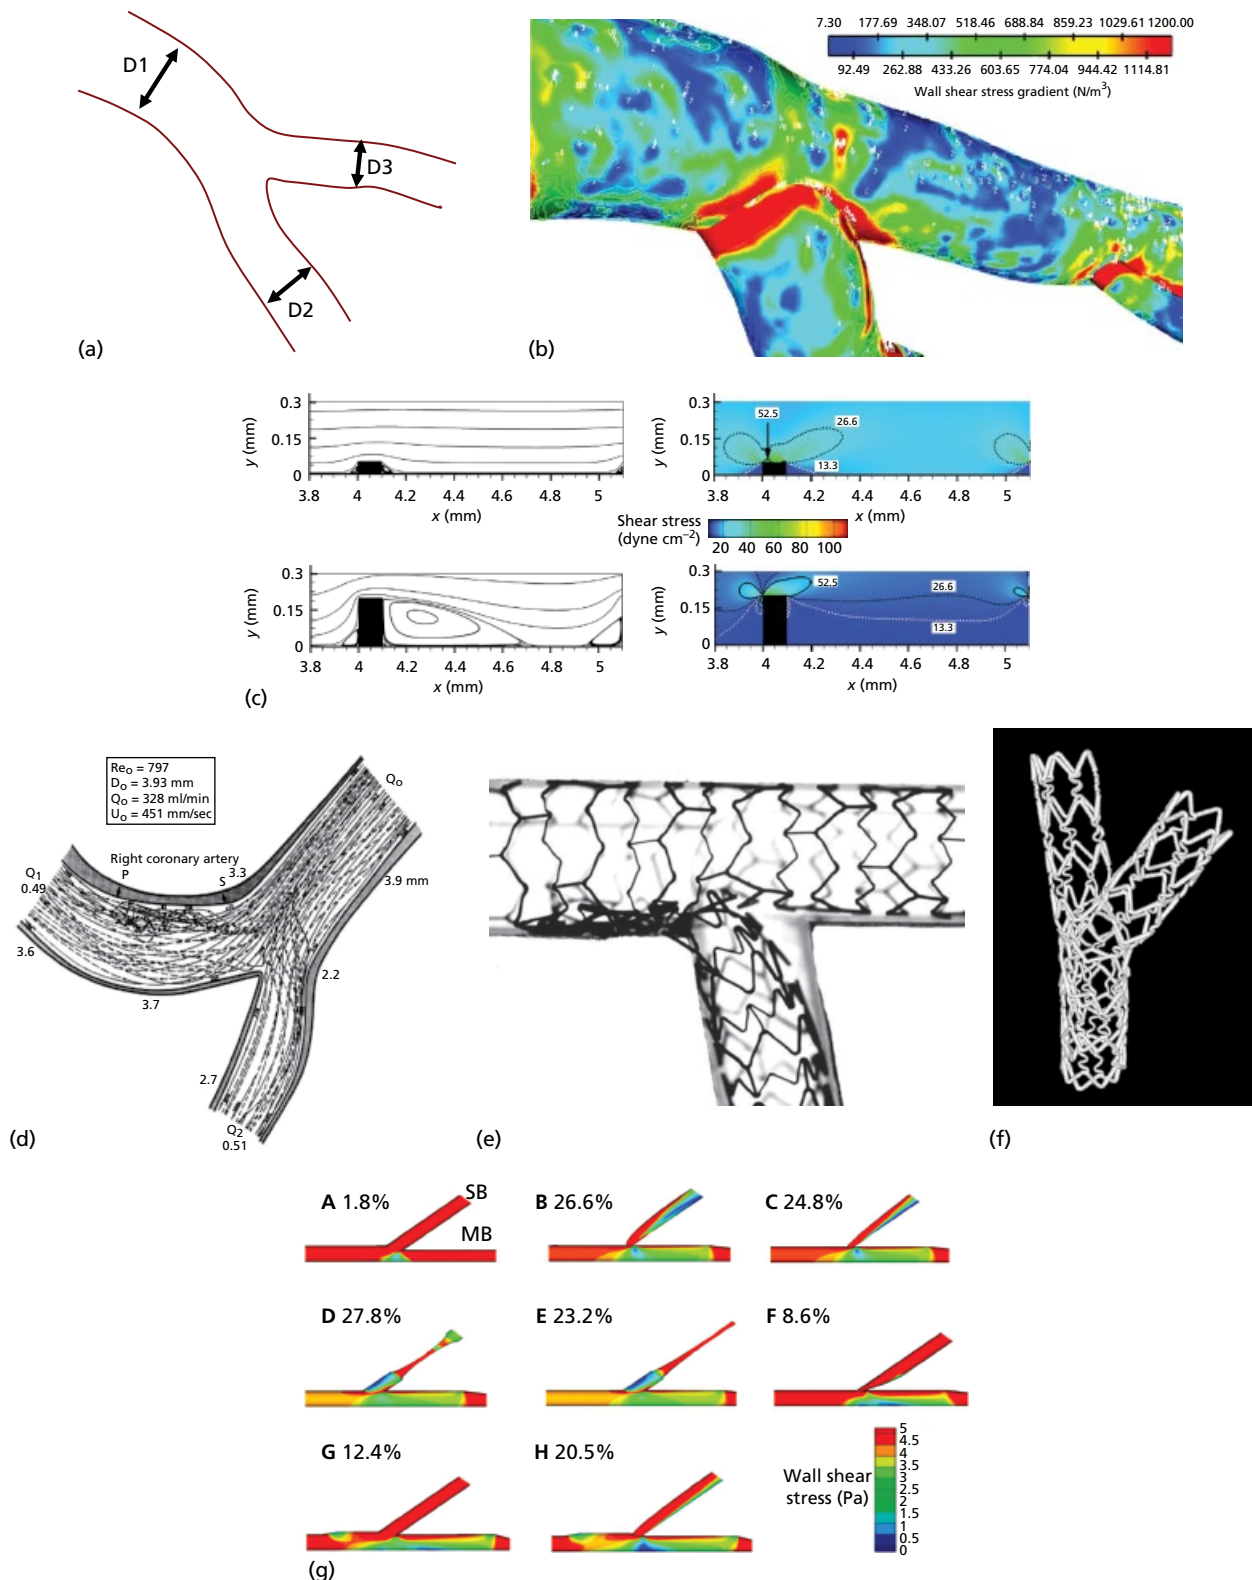

Figure 16.1 Coronary bifurcation fundamental aspects. (a): asymmetric branching, the modulus of the pseudo-fractal coronary tree. (b): Map of wall shear stress (WSS) derived from patient anatomy. Dark blue color corresponds to low WSS (Source: Soulis J, *et al. Hippokratia* 2014; **18**(1): 12–16). (c): Turbulences generated by stent struts, more important for thick stents, responsible for low WSS distal to a thick strut, as there is high WSS on the top of the strut (Source: Chestnutt and Han 2015 [18]). (d): flow in coronary bifurcation, linear with high velocity outside the curve and on both sides of the carina, turbulent (low WSS) opposite the carina (Source: reproduced from Asakura and Karino 1990 [7], Fig. 13, with permission of Wolters Kluwer). (e): Classic crush in an open angle bench bifurcation. The side branch (SB) stent is not apposed on the carina, there is an excess of metal in the proximal (PM) segment, if a kissing balloon (KB) is attempted there is a risk of crossing to the SB outside the stent (Source: Ormiston JA, *et al. Catheter Cardiovasc Interv* 2004; **63**(3): 332–336). (f): example of micro CT-scan of a bench stent deployment (Source: Ormiston JA, *et al. Catheter Cardiovasc Interv* 2004; **63**(3): 332–6). (g): WSS in various post-treatment scenarios in bifurcation models. In models with significant SB stenosis (B–E), low WSS areas were observed in the SB and lateral side of main branch (MB). Low WSS areas in the lateral side of MB were also more exaggerated in the post-kissing balloon angioplasty models (G and H) and carina shift model (F). Percentages of low WSS are indicated in each scenario. A is the original normal model and has the lowest surface of low WSS (Source: Na and Koo. *Korean Circ J* 2011; **41**: 91–96. Published under Creative Commons License 3.0).

cells are aligned along the flow with no intercellular space, whereas low WSS is associated with cellular disorientation, presence of intercellular space, and various other modifications [8].

Maps of WSS in a coronary vessel can be produced in models derived from real patients, confirming the relationship between low WSS and presence of atheroma. In a bifurcation, atheroma initially develops opposite the carina, as shown by anatomic-pathologic examination. Development of atheroma affects the pattern of intracoronary flow, which may in turn lead to circular progression of the plaque toward the carina [9].

Stent behavior in bifurcations

The deployment of stents in bench models reproducing more or less accurately “real” coronary bifurcations has considerably helped operators to identify difficulties and implement successful strategies. These models have been designed to match the technical conditions of “real” interventions as closely as possible.

The opening of a stent strut toward the SB in bifurcations with an acute angle results in the protrusion of struts in the SB ostium as well as stent distortion on the side opposite the SB. This double phenomenon is even more marked when opening a distal strut next to the carina and can be corrected by performing kissing balloon inflation. This is the basis of the provisional stenting strategy [10].

By systematically assessing techniques and dedicated stents in basic models of both bifurcations and non-bifurcations, Ormiston *et al.* [11] demonstrated the inadequacy of the Crush and Culotte technical strategies in bifurcations with an open B angle, which was further confirmed in clinical settings. Similarly, the Simultaneous Kissing Stent (SKS) technique is less attractive than initially thought, because it generates a neocarina, two semi-cylindrical channels wrapped up around each other, as well as malapposition areas.

Bench testing images using micro CT scan have become very useful investigation and teaching tools. The use of electron microscopes has made possible the analysis of polymer damage in certain settings. The most elaborate benches allow the analysis of bioresorbable stent deployment at 37° [12]. They are even sometimes derived from the anatomy of real patients with pulsatile perfusion or cyclic angle modification in order to test stent resistance to fracture. Modern DES are almost exclusively based on an open-cell design. Strut dimensions (thickness, but here more importantly width) and strut shape (rectangular, round, elliptical, and so on) influence the impact on SB origin and can affect re-crossing. The main differences between design are related to the number of connectors (two or three) and their types as they can connect to peak or to valleys in a straight or an oblique way; some designs include variations in strut connector width. The range of diameters are usually covered by two or three designs, with different cut-off according to the brand, which can impact the capability of overexpansion and maximal cell size opening as they have a different number of crowns [11]. A good knowledge of these data when selecting stents to treat bifurcation is the key to success. Bench tests have been carried out to evaluate the impact of different types of stent at the different steps of bifurcation stenting particularly in terms of residual ostial SB obstruction and malapposition [11]. However, differences are usually limited and the most important factor of variability is not the stent design but the relation of crowns and connectors with the SB ostium due to the absence of possible control at the time of implantation *in vivo*, when using non-dedicated stents. The result could be a V, W, T, or H shape of struts obstructing the SB, which explains the variability of final results in terms of strut apposition at the SB ostium after SB inflation and/or kissing balloon technique.

Digital simulation bench tests have recently been developed using more or less realistic bifurcation models and virtual stents with the same characteristics as commercially available stents. The most sophisticated models are derived from digital reconstruction based on angiographic, CT scan, or intraluminal (IVUS or OCT) patient data [13,14]. These simulation models have allowed the evaluation of technical strategies whose clinical outcome was uncertain: selection of the crossover stent diameter in provisional stenting and effect of proximal optimization technique (POT). Digital simulation provides data that cannot be obtained in real patients such as flow geometry before and after stenting, circumferential stress generated by stenting (overdilatation) with documented clinical impact [15], mapping and significance of low WSS areas in bifurcations with neointimal hyperplasia (NIH) opposite the carina [16].

Variations in flows can be analyzed according to strut thickness as there is recirculation behind the struts (known factor of restenosis) [17]. Analysis of flow behind the stent struts enables the identification of the triggering factors of thrombosis [18]. These data can be used to develop enhanced technical strategies as well as for teaching purposes or even for future pre-treatment

Coronary bifurcation stenosis

Definitions of coronary bifurcation lesions are generally based on the SB ostium diameter with relation to the potential myocardial complications associated with SB occlusion. This diameter is often similar to that of the smallest available stent (2.25 mm) which can be used to stent a 2-mm artery (1.1 : 1 ratio).

In order to include factors such as myocardial viability in the SB territory or its collateralizing role, the European Bifurcation Club (EBC), a coronary bifurcation treatment think tank founded in 2004, proposed the following definition: “a coronary artery narrowing occurring adjacent to, and/or involving the origin of a significant SB.” A significant SB is a branch that the operator does not want to lose [19].

Many classifications of bifurcation lesions based on angiography have been proposed, all of which are difficult to memorize. Some of these classifications are associated with arbitrary treatment strategies for each bifurcation type [20]. Medina’s is the simplest classification (Figure 16.2) [21] but does not provide complete lesion characterization and must be combined with dedicated QCA and other imaging methods which are now indexed as new Medina intravenous ultrasound (IVUS) or fractional flow reserve (FFR) classifications. The important characteristics to be taken into account before performing coronary angioplasty are the presence of calcifications, the length and degree of the SB ostium stenosis, the angle between the PM segment and the SB (A for access), or the angle between the two distal segments (B for between) [19]. Medina’s classification should be associated with precise delineation of the SB (before treatment for comparative studies) preferably based on the diameter and length of the distal artery. This description could follow Medina’s classification and be expressed as LAD1, LAD2, Dg2 [19].

Stenting techniques

Describing the techniques of coronary bifurcation stenting has become a difficult task owing to the creativity deployed by interventional cardiologists. Certain very similar technical strategies are known under different names, whereas very dissimilar techniques can be designated by the same name. Very few classifications of

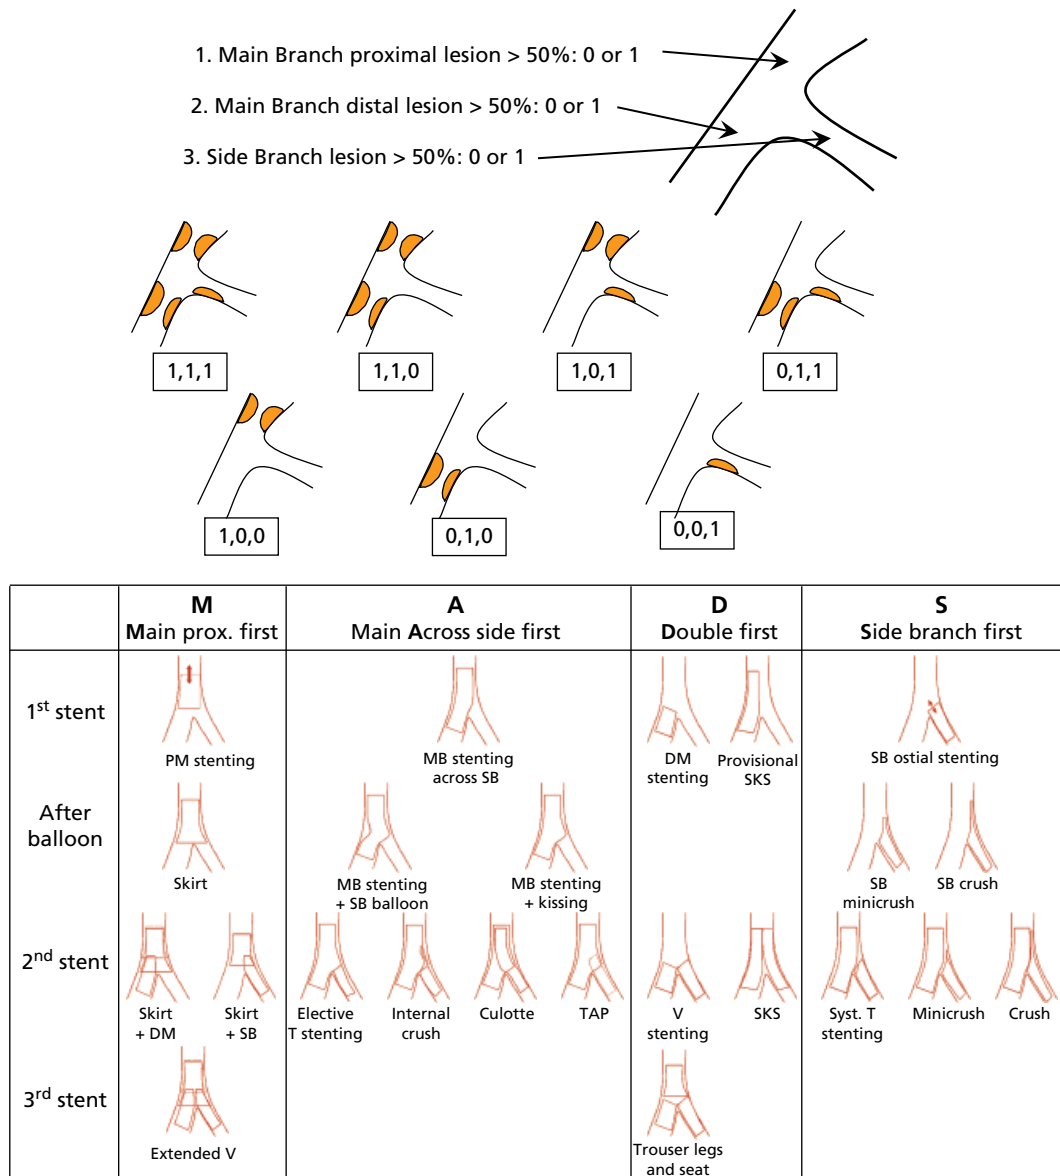

Figure 16.2 Top: the Medina classification: It consists in giving a binary value (1, 0) according to whether each of the segments (PM, DM, SB) previously defined is compromised or not (Source: Medina *et al.* 2006 [21]). Bottom: the MADS classification of bifurcation stenting techniques. Stenting strategies are indexed according to final stent placement. There are classified into strategies according to the position of the first implanted stent: M, proximal main; A, across; D, double; S, side branch.

stenting techniques have been published. The EBC has tried to find a method of classification that is both simple and open. The MADS classification is based exclusively on the final position of stents and on the order in which they are implanted (Figure 16.2) [19], thus allowing a simplified description according to the strategy implemented, namely, the position of the first stent. All strategies share common technical issues.

All the various strategies of stent placement in the MADS classification have been carried out in patients and have been published or reported. However, most of the recent techniques have not been specifically listed in the classification because their main variations from the standard techniques only involve balloon or wire maneuvers. Inverted strategies have been included in the classification to describe stent implantation techniques from the main artery to the smallest distal branch (i.e., “straight” Culotte described first

by Chevalier [22], A for “Across” strategy and the inverted Culotte stenting from PM to SB) all with their own technical problems.

The only way to perfectly describe and classify the various technical strategies implemented in patients would be an e-reporting system including all the preparation techniques, wire and balloon maneuvers.

Non-left main and left main stenosis clinical trials

One versus two stents?

Many trials, non-randomized in the era of bare metal stents (BMS), randomized or not in the era of DES, have compared the use of one vs. two stents in non-left main bifurcations.

In the era of BMS, the meta-analysis by Zamani and Kinlay [23] clearly underlined the benefit of single stent placement with respect to the occurrence of clinical events. Six randomized trials comparing single- versus double-stenting were carried out in Europe and were included in several meta-analyses which confirmed the absence of any differences in terms of mortality or repeat intervention [24–29]. The single-stent strategy was associated with a lower rate of myocardial infarction (MI) and a trend toward a reduced incidence of stent thrombosis. A meta-analysis of both randomized and non-randomized studies comparing QCA results showed a better acute gain in the SB ostium associated with the dual-stent technique, but also a higher late loss, which translated into an absence of mid-term differences in minimal luminal diameter (MLD) [30].

European studies comparing one- or two-stent strategies were discussed in reports of Asian trials in the DES era. The DK-Crush II trial [31], in particular, compared the provisional stenting strategy in patients with true bifurcation lesions (Medina 1,1,1 or 0,1,1) with the double kissing crush technique whereby two kissing balloon inflations are performed, the first inflation after placement of the first stent in the SB with minimal proximal crush using a balloon, and the second inflation at the end of the procedure. This randomized trial, which included 185 patients in each study group, observed no significant clinical differences at 6 months, but significant differences in the rates of death, MI, and TVR at 12 months after systematic follow-up angiography at 8 months. This study was included in a meta-analysis which highlighted a trend toward a potential benefit associated with a double stenting strategy in bifurcations with a large-diameter SB (sub-group analysis).

In the Korean randomized trial, PERFECT, no differences were observed between the Crush and the Provisional strategies in bifurcations with SB stenosis: MACE at 12 months: 17.8 vs. 18.5 for Crush and single stenting, respectively [32].

The patient-level meta-analysis of the Nordic I and BBC 1 trials generated particularly interesting findings [33]. Indeed, at 9 months a difference emerged with respect to the rates of death, MI, and TVR in favor of the single-stent strategy. This difference was consistent across all subgroups, especially in patients with a large SB and long lesions. Procedural time, X-ray exposure, and volume of contrast used were also lower in recipients of a single stent. The 5-year overall mortality rate was inferior in the single-stent strategy group (3.8% vs. 7.0%; $p=0.04$) [Behan, personal communication, EBC meeting 2014].

Final kissing balloon or not?

The potential benefits of final kissing balloon (FKB) are considered irrefutable when both branches of the bifurcation are stented [34]. The benefits of final kissing in provisional stenting procedures are still controversial. The Nordic III randomized study [35] did not show any clinical difference at 6 months, but demonstrated a difference in favor of kissing with respect to SB restenosis at 8 months. The COBIS I registry [36] pointed to a higher risk of TLR and MACE associated with FKB in contrast to COBIS II [37] which showed a reduction in target vessel revascularization in the main vessel or in both branches.

Two recent Korean randomized studies confirmed that systematic final kissing is not superior to the simple crossover strategy in bifurcations with a lesion-free SB. A higher restenosis rate was observed in the main vessel (3.8% vs. 7.0%; $p=0.018$) in the CROSS study [32]. In this study, systematic angiographic follow-up examination was performed at 8 months before clinical endpoint analysis (MACE: death, MI, TVR). The SMART-STRATEGY trial [38]

compared a conventional with an aggressive strategy after crossover stenting. In the “aggressive” strategy group the SB was treated in the presence of <TIMI 3 flow or >75% stenosis, in non-LM bifurcations, and with >50% SB stenosis in LM bifurcations. The conservative strategy was associated with a lower incidence of procedure-related myocardial necrosis (5.5% vs. 17.7%; $p=0.002$) and at 12 months the incidence of target vessel failure was similar in both groups (9.2–9.4%).

The efficiency of kissing and prevention of its potentially negative effects depend on the manner in which it is carried out [35]: use of non-compliant balloons at least in unstented SB in order to prevent the occurrence of dissection, short balloons to avoid oval distortion in the PM segment, stent diameters adapted to the distal diameters of the bifurcation, inflations in the SB in preparation for kissing, prolonged inflations, inflation in the SB first.

Which double stent technique?

Like the provisional stenting strategy, double stenting techniques have evolved. Crush has now become mini-crush whereby a stent strut is opened toward the SB following each stent implantation, with kissing inflation in most cases (Mini-DK-Crush) [39], which improves the success rate of final kissing. With respect to the Culotte technique, the proximal overlapping area has been reduced to a minimum (mini-Culotte) and POT is carried out at each stage of the procedure.

Two randomized trials compared two bifurcation stenting techniques: the NORDIC II trial found no significant differences between Crush and Culotte techniques at 6 months. However, there was a lower use of FKB in the Crush group (failure) as well as a trend toward more frequent biomarker elevation [40,41]. Opposite findings in the left main were reported in the DK-Crush III study [42].

The Simultaneous Kissing Stent (SKS) technique described by Sharma *et al.* [43] consists of the simultaneous deployment of two stents from the PM segment toward each of the two branches. This technique has not been compared with other strategies. It has inherent technical difficulties which are not easy to overcome. For instance, in cases of proximal dissection, a neocorena of variable length is generated, making any repeat intervention difficult. The advocates of this technique recommend the implementation of a life-long dual antiplatelet treatment.

Double stenting: a pro-thrombotic situation

The meta-analysis by Zimarino *et al.* [44] clearly demonstrated the excess rate of stent thrombosis in cases of double stenting (OR 2.31) associated with an increase in MI (OR 1.86). It also showed the relation between infarction and thrombosis. Peri-procedural biomarker elevation associated with double stenting techniques has no impact on patient outcome.

Are results applicable to distal left main stenting?

There are no randomized studies comparing the single and double stenting strategies in distal left main lesions. The findings of many registries suggest that the provisional SB stenting strategy should also be recommended in distal left main segments in the majority of cases.

Several important registries pointed to the superiority of the provisional strategy: improved TLR-free survival in a population of 773 patients with left main lesions undergoing single stent implantation, no differences between the double stenting, T, V, or Crush techniques in the Italian multicenter study by Palmerini *et al.* [45], lower

rate of cardiac death at 3 years in the study by Toyofuku *et al.* [46], a lower 1-year MACE rate in a sub-group of the Syntax trial.

Workhorse versus dedicated stents

Very few randomized studies comparing the provisional strategy with the use of a dedicated stent have been carried out. Recently, the Tryton dedicated stent was compared with the provisional strategy in bifurcations with a large SB. The TRYTON trial did not meet its non-inferiority primary endpoint as a result of an increased rate of peri-procedural MI [47]. However, bifurcations included in the study had an SB diameter often lower than specified in the inclusion criteria. A sub-group analysis of SBs with a diameter >2.25 mm demonstrated the non-inferiority of the TRYTON stent [48].

Bifurcation stenting general principles

Based on fundamental clinical data pertaining to non-left main and left main bifurcation stenting, three recommendations can be made:

1 The number of implanted stents should be limited, which may lead to implementation of the provisional SB stenting strategy. Alternatively, an SB stenting predictive score [49] or SB occlusion predictive score can be used in order to weigh up the advantages of stenting the SB first. A comparison between the two strategies in the same population would show that using the score used in the DEFINITION study, 30% of double stenting starting with the SB would be performed and 70% of provisional SB stenting strategies. If the provisional strategy were to be used,

the percentage of double stenting after final kissing balloon would be probably lower than 30% even in left main lesions.

- 2 Full deployment and apposition of a single stent layer is needed.
- 3 Compliance with the branching law of bifurcation should be respected.

Provisional side branch stenting strategy

Step-by-step provisional SB stenting is described in Figures 16.3 and 16.4. A jailed wire in the SB, hydrophilic or not, is a safe technique if the crossover stent is not deployed on the radiopaque segment of the wire.

Many predictors of SB occlusion have been described. They involve the presence of ostial lesions of the SB, lesion length, stenosis or homolateral plaque at the SB of the PM segment, calcified plaque opposite the SB, an acute coronary syndrome, lesions outside the left main. An acute B angle has been considered a predictive factor of occlusion resulting from carina shift when a stent larger than the diameter of the DM segment is implanted [50]. However, Zhang *et al.* [51] states that an open angle is a predictor of occlusion whereas Hahn *et al.* [52] concludes that the angle has no impact.

This recent study also questions the efficacy of a jailed wire in preserving SB patency. However, the jailed wire strategy can be considered as a predictor of patency restoration because of its use as a “landmark,” the change in the angle of SB access or in the setting of a salvage maneuver (reopening of the SB with a very small balloon inflated outside the stent). The size of the stent is selected on the basis of the DM segment diameter. The purpose of the POT is to give

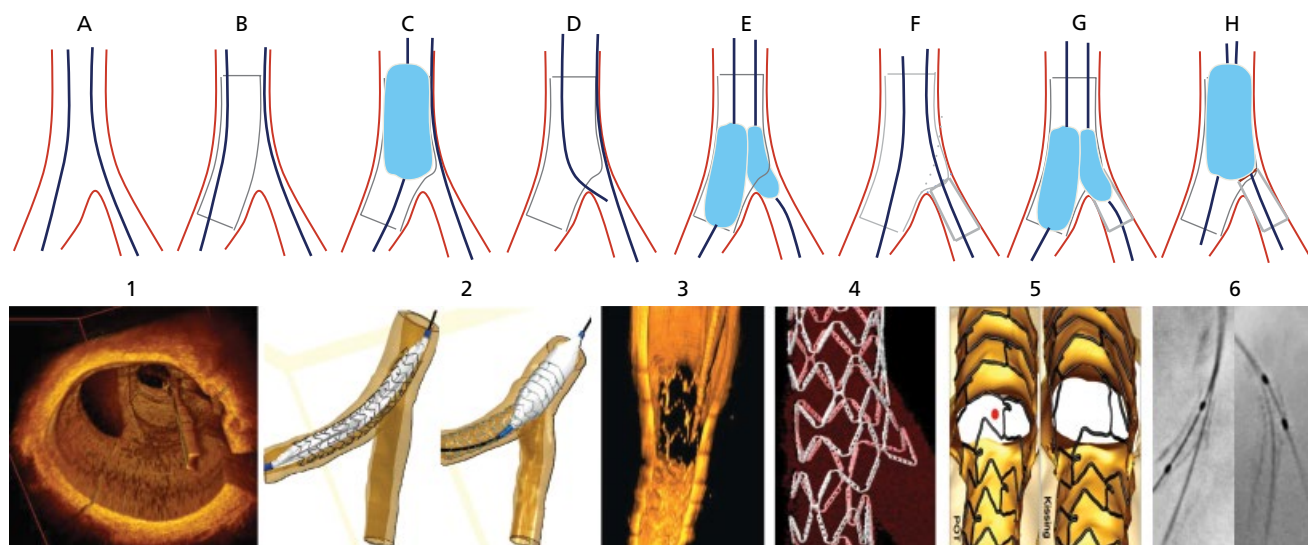

Figure 16.3 Provisional stenting strategy. A: 2 wires beginning with the most difficult branch. 1: Axial OCT view showing the position of the carina (flow divider). B: Stenting of the main branch across the SB protected by a jailed wire, diameter chosen from the DM segment. C: Proximal optimization technique (POT) proposed by Darremont, to give a second diameter, the one of the PM segment (matching that of the PM segment), to the stent. 2: Crossover stent deployment in a specific patient model, proximal malapposition. After POT the proximal segment of the stent is apposed, the cells are more opened in front of the SB if the big and short POT balloon is inflated with the distal marker in front of the carina. D: Main vessel wire, prepared with a long shape, is pulled slowly in front of the SB to enter the most distal cell facilitated by POT. 3: Online 3D OCT reconstruction showing the wire in the most distal cell. E: after de-jailed of the SB wire pushed in the distal main vessel, kissing balloon using short balloons, non-compliant for the SB, chosen from the two distal segments. Begin the inflation with the SB balloon. 4: When the most distal cell is entered toward the SB, there is metal projection in the ostium of the SB. 5: Ostium of the SB after POT only (left) and after kissing balloon (right). F: SB stenting when necessary performed as a T stenting or a TAP (T and Protrusion). 6: Stent enhancement showing on the left projection of metal in the SB ostium, ideal for T stenting, absence of projection after proximal cell crossing on the right leading to TAP stenting. G: Mandatory FKB after any double stenting implantation. H: Final POT to correct potential elliptical distortion created by kissing.

Figure 16.4 Inverted provisional stenting. 1–3: Bifurcation stenosis 1,0,1; LAD1,LAD1,Dg1. 4: After stenting from left anterior descending (LAD) to diagonal with a stent diameter adapted to diagonal, a POT is performed with a short balloon adapted to LAD diameter. 5: Result after POT. 6: Kissing balloon with short balloons adapted to the two distal diameters, non-compliant for LAD. 7: Second POT with the same balloon to correct the proximal oval distortion. 8–10: Result in three initial projections.

the crossover stent two distinct diameters corresponding to those of the two covered segments. This technique allows the reconstruction of the initial anatomy of the bifurcation and facilitates wire exchange when SB treatment is implemented by avoiding wire exchange outside the proximal part of the main branch (MB) [53].

The “crossover” stent should be implanted sufficiently proximal to the SB to accommodate a short, large-diameter balloon. Guidewire exchange is normally carried out by pulling back the main vessel wire (in the absence of any untreated dissection) in order to insert it in the SB through the most distal cell, thus allowing the projection of struts in the ostial segment of the SB opposite the carina. The jailed wire is subsequently removed from the SB and inserted into the DM segment. Though relatively safe, this maneuver can be associated with a risk of guiding-catheter penetration resulting in dissection or longitudinal stent distortion particularly in the setting of left main PCI.

Guide-wire exchange generally aims at treating the origin of the SB which is often stenosed as a consequence of the carina shift phenomenon. The resulting stenosis is non-significant in most instances as shown by FFR assessment of angiographically tight lesions [54]. This can be explained by the oval configuration of the SB ostium as visualized using the least optimal angiographic view, even though the actual reduction of the vascular area is minimal.

Kissing balloon inflation was the first specific technique applied to bifurcations and is still the subject of controversy. Alternatives to kissing balloon have been proposed on the basis of *in vitro* tests that need clinical validation. These include successive inflations in the side and main branches (Side, Main, Side: SMS) and above all POT-side-POT. It is sometimes recommended that a second stent should be implanted in the SB ostium in the presence of a dissection or residual stenosis, or even systematically in long lesions located in large vessels. In such cases, T or TAP (T and Protrusion) [55] placement can be performed depending on the coverage of the ostium by a crossover stent as visualized using

the stent enhancement technique (when the SB wire has been inserted in the most distal strut). Though a more complex technique, the straight Culotte stenting technique can also be used to treat the SB. In all cases, final kissing balloon with short non-compliant balloons after double stenting is indispensable and final POT useful to correct oval distortion.

The major advantage of provisional SB stenting lies in the fact that each step of the procedure can be adapted according to the results of the previous step. In small-diameter SBs, simple protection (use of a protection wire) during crossover stenting is sufficient. In large-diameter SBs, when flow in the SB is <TIMI 3, associated with chest pain and/or ST segment changes, reopening of the branch (SMS, POT-side-POT, or kissing balloon inflation) is necessary. If there is a significant difference between the PM and the DM diameters, POT should be performed and a cell should be opened toward the SB by means of kissing balloon or POT-side-POT, in order to ensure SB access in case further treatment should be required or to put the carina in its place.

Beginning with SB stenting

The initial stenting techniques starting with the SB were conventional T stenting with the frequent disadvantage of a gap at the SB ostium in Y-shaped bifurcations (Figure 16.5) [2]. This led to the modified T stenting whereby the SB stent protrudes into the MB in which a balloon has been inflated [2]. In the conventional Crush technique strategy, the SB stent is implanted far into the PM segment, then crushed with the crossover stent in the MB. Subsequently wiring the SB to perform the indispensable final kissing balloon inflation can prove difficult.

The most elaborate version of the Crush technique is currently the mini DK-Crush described by Chen *et al.* (Figure 16.3) [39]. This specific strategy does not use POT and, consequently, the size of the selected stent must match the PM diameter. Performing

Figure 16.5 Mini-DK-Crush technique. A: Two wires, implantation of a stent in the ostium of the SB with a small protrusion. B: Crush of the protrusion with balloon inflation in the main branch after SB wire removal. C: After recrossing toward the SB with a wire, first KB. D: Crossover stent implantation in the main vessel after SB wire removal. E: After rewiring the SB, second KB. F: final result. 1–7: Inverted Culotte. 1: Two wires, implantation of a stent chosen from SB diameter from PM to SB. 2: POT with a balloon adapted to PM diameter to avoid unintentional crush. 3: Use of the SB wire to re-enter the distal (DM) close to the carina. 4: After dejamming the main vessel wire, insertion in the SB and pre-dilatation toward the DM to prepare stenting. 5: Stent from PM (short protrusion) to DM, followed by POT after SB wire removal. 6: Wire recrossing th SB, close to the carina (distal cell). 7: Final KB.

kissing balloon inflation after Crush in the SB facilitates both the passage of the wire through the struts of the stent which is subsequently implanted in the MB and final kissing inflation.

There are two distinct Culotte techniques. The first was initially described as part of the provisional strategy. The second begins with stent implantation in the PM segment toward the SB, in order to avoid losing the SB. As the difference between the PM and SB diameters is sometimes significant, the second technique (Figure 16.3) requires POT in the PM on the SB wire immediately after implantation of the first stent in order to prevent the occurrence of wire exchange outside the stent toward the DM, which would result in unintended Crush.

Dedicated stent implantation

Bifurcation-dedicated stents represent the holy grail for the interventional cardiologist. Although many dedicated stents have been evaluated in the past 10 years, their superiority over the provisional strategy has not been demonstrated. There are currently four dedicated stents commercially available worldwide.

The BIOSS stent is the most recent dedicated device. Data pertaining to this stent have been collected in small registry studies. It is a balloon-expandable DES with large struts at the bifurcation level facilitating access to the SB. There is currently a sirolimus-eluting version of this stent.

The Stentys device was also evaluated in registry studies. It is a balloon-expandable stent, initially eluting TAXUS. The new generation is a sirolimus-eluting stent allowing accurate placement (inflation of the balloon results in the rupture of the sheath

covering the stent). The design of this stent enables easy access to the bifurcation branches with the possibility of “breaking” a strut during SB dilatation in order to achieve optimal SB coverage in cases of distal access.

The Axxess stent was broadly evaluated and compared with the provisional strategy in non-randomized studies. It is a balloon-expandable Biolimus A9-eluting stent. The stent design enables treatment of the MB segment proximal to the bifurcation with partial coverage of the SB ostium and distal MB segment. It is often necessary to implant one or even two additional stents for adequate coverage of the lesion. A version of this stent was specifically designed for left main lesions.

The Tryton stent is a balloon-expandable bare stent designed to facilitate bifurcation treatment using the Culotte technique. This stent is intended for “true” bifurcation lesions requiring a double stent technique. The stent design allows optimal coverage of the SB as well as loose coverage of the proximal MB facilitating access to the MB and placement of a DES in the MB. This is the only dedicated stent that has been assessed in comparison with the provisional strategy in a randomized trial in patients with “true” bifurcation lesions. The study failed to demonstrate the non-inferiority of the dedicated stent compared with the provisional strategy. However, the inclusion criteria, and especially the SB size >2.5 mm, were not adequately fulfilled in this study.

When taking into account patients meeting the inclusion criteria, the Tryton stent appears to be non-inferior to the provisional strategy. A study evaluating the Tryton stent specifically designed for left main lesions is currently underway. The new stent iteration will be a DES.

Bifurcation stenting with bioresorbable stents

The potential advantages of BRS in the treatment of bifurcations are the conformability of the scaffold, the absence of fracture at the level of the carina when two stents are implanted, and the possibility of restoring patency in the SB. However, given the long resorption time, especially with bioresorbable vascular scaffolds (BVS), the risk of thrombosis at 1–4 years cannot be eliminated.

Bench testing data pertaining to BVS [11] have evidenced some limitations for the treatment of bifurcations. Although BVS are compatible with a conventional provisional strategy with appropriate sizing, conventional kissing should not be performed as it can result in BVS fracture. According to the recommendations issued by the EBC, POT-side-POT should be performed if the SB needs attention or alternatively, “mini kissing” using short, non-compliant balloons which do not extend beyond the polygone of confluence, inflated at low pressures (≤ 5 atm).

Given the thickness of BVS (150 μm), dual-stent techniques may increase the risk of thrombosis. The only technique that we can currently recommend is T stenting with two BVS or one BVS in the MB and a DES in the SB. There are few data regarding the other BRS, but some seem to have a broader expansion potential, which could allow stenting with 2 BRS. The new BVS generation with 100- μm thickness provides interesting treatment possibilities.

Role of imaging in bifurcation stenting

The role of imaging (IVUS or OCT) in the treatment of bifurcations is still the subject of controversy. Although IVUS and OCT provide interesting information (apposition, stent positioning, access to the distal strut, technical mistakes) likely to improve the final result, only a few retrospective studies have shown potential benefits for left main stenting in particular.

In routine practice, we recommend that imaging techniques should be used when in doubt or during the learning phase, especially for left main treatment or when BRS are used.

Conclusions

The safe and efficient treatment of coronary bifurcation lesions requires appropriate knowledge of the anatomy and function of this specific entity. Remembering the lessons learned from bench testing during the procedure can help the operator overcome inherent difficulties. Simulation models are more associated with strategy and can be instrumental in achieving a reduction in the number of stents used, in avoiding stent overlap, and enabling appropriate stent apposition in order to restore an optimal anatomic configuration.

Several strategies have been accurately delineated. The Mini-DK-Crush and mini-Culotte techniques are recommended for complex lesions, whereas the provisional strategy can be implemented in practically all lesions.

One might have been justified in thinking that the advent of BRS would solve the issues related to bifurcation stenting. However, early experience has shown that these stents generate new technical and clinical problems such as thrombosis.

Risk Stratification Approach to Multivessel Coronary Artery Disease

Davide Capodanno and Corrado Tamburino

Ferrarotto Hospital, University of Catania, Catania, Italy

Myocardial revascularization in patients with multivessel coronary artery disease (MVD) can be accomplished by percutaneous coronary interventions (PCI) or coronary artery bypass grafting (CABG). Approximately two-thirds of patients who require revascularization have MVD and two-thirds of these have anatomy that is amenable to treatment by PCI or surgery. Today, more complex lesions and sicker patients are being taken for multivessel PCI than in the past. This has been brought about by increasing operator experience, technological advances such as the availability of drug-eluting stents (DES), and more potent antiplatelet therapy with glycoprotein IIb/IIIa receptor antagonists and clopidogrel. Other contemporary procedural improvements, such as the availability of newer generation DES and more potent antiplatelet drugs than clopidogrel for patients with acute coronary syndromes (ACS) (i.e., prasugrel or ticagrelor), are anticipated to improve further the outcomes of patients with MVD undergoing PCI. As a result, the frequency of multivessel PCI is expected to increase in the future.

Many factors must be considered when approaching a patient with MVD. First, these patients have a less favorable long-term outcome. They are more likely to have adverse clinical features including diabetes mellitus, prior myocardial infarction (MI), and reduced left ventricular function. Second, the functional significance and complexity of each lesion need to be assessed to determine the appropriate percutaneous strategy. Procedural complexity and the risk of multivessel intervention is increased when unfavorable anatomy such as chronic total occlusions (CTO), calcified bifurcation lesions, and diffusely diseased small vessels are present (Box 17.1). Third, the impact of restenosis needs to be considered. The decision to choose PCI as a revascularization strategy should be based not only on whether it can be done safely and successfully, but also on its short- and long-term benefits when compared with the alternative of medical or surgical treatment. A risk stratification approach in decision-making for revascularization of MVD is currently endorsed by clinical practice guidelines.

Revascularization strategy

The extent of planned revascularization, on all diseased lesions or directed to selectively targeted coronary segments, is a major determinant of treatment strategy.

Complete revascularization

The concept of complete revascularization was initiated from early studies on CABG which demonstrated that patients who were completely revascularized derived symptomatic and survival benefits over those who were incompletely revascularized. Patients with diabetes mellitus, extensive coronary artery disease, large ischemic burden, and left ventricular dysfunction required the most complete revascularization to achieve long-term event-free survival.

There is large variability in the definition of completeness of myocardial revascularization adopted by different studies. We propose a simple definition that takes into account the size of the vessel, the severity of the lesion, and the viability of the myocardial territory (Table 17.1). An anatomically complete revascularization is accomplished when all vessels with clinically significant stenosis ($\geq 50\%$ stenosis in vessel > 1.5 mm diameter) are treated irrespective of the underlying myocardial function. A functionally complete revascularization refers to cases in which only lesions supplying viable myocardium are treated. Therefore, revascularization may be anatomically incomplete but functionally adequate.

Although complete revascularization is the goal in most patients undergoing multivessel intervention, incomplete revascularization is common in clinical practice. The ability to achieve complete revascularization depends on the selection of patients. Reasons for not attempting to treat all diseased vessels include the presence of CTO, the presence of serious medical conditions such as severe left ventricular dysfunction, or the decision to treat only the “culprit lesion” that is thought to be responsible for the patient’s symptoms. Functionally adequate revascularization aims to treat all significant stenoses in vessels that supply viable myocardium. Lesions in small or diffusely diseased vessels and lesions serving infarcted territories can be safely left alone. Recently, some evidence has emerged that the prognosis of patients with MVD remains acceptable when the amount of incomplete revascularization does not exceed specific thresholds measured by adaptations of the anatomic SYNTAX score (i.e., residual SYNTAX score) [1].

Culprit lesion strategy

Culprit lesion refers to the lesion responsible for the acute coronary syndrome or the stenosis most likely responsible for the patient’s symptoms. The decision of whether to perform culprit vessel or

 Three vessel disease
 Diffuse disease

Table 17.1 Revascularization strategies in patients with multivessel coronary artery disease.

Complete numerical revascularization	The number of stenotic vessels must equal the number of distal anastomoses applied
Complete anatomic revascularization	Unconditional: all stenotic vessels are revascularized, irrespective of size and territory supplied Conditional: all stenotic vessels >1.5 mm in diameter and ≥50% diameter stenosis are revascularized
Complete functional revascularization	All ischemic myocardial territories are reperfused; areas of old infarction with no viable myocardium are not required to be reperfused
Complete revascularization by a predetermined scoring cut-off value	Scoring of stenoses in different vessels at different locations (weightings may be used). The overall extent of disease is a continuous variable, the treatment is another variable, and the post-treatment score determines completeness of revascularization Anatomic: irrespective of viable myocardium Functional: the post-revascularization score is calculated on the basis of the amount of remaining myocardium at risk (Jeopardy score)

complete revascularization needs to be individualized. In most cases of MVD, target or culprit lesion can be identified by a combination of historical data, electrocardiographic findings, angiography supplemented by radionuclide studies or intravascular imaging. Morphologic characteristics that are associated with an unstable or culprit lesion include scalloped edges, irregular borders, and the presence of thrombus. In patients in whom a culprit lesion or lesions can be determined, PCI can be directed to treat that lesion alone without exposing the patient to the risks of dilating other lesions not responsible for the patient's symptoms. If the patient continues to have angina or a subsequent stress test shows ischemia in that territory, a second procedure can be performed to revascularize the vessel that was previously not attempted.

Staged PCI

The decision to perform multivessel PCI in the same procedure or planned staged procedures include the desire to diminish procedural risk, avoid excessive contrast use, lessen patient discomfort,

and reduce physician fatigue. Whereas it is reasonable to attempt two simple lesions during the same procedure, the presence of complex lesion should deter the operator from attempting more than one lesion at a time. Staging potentially limits the amount of myocardium at risk in the event of acute closure. However, the incidence of acute closure is rare with the advent of stents and dual-antiplatelet therapy. In case of staging, the time interval for planning the second procedure varies from days to few months according to the operator's discretion. One approach is to stage at an interval of 4–8 weeks to allow the first lesion to stabilize.

On the other hand, multivessel PCI in a single procedure can be associated with several inherent advantages. It expedites patient care, avoids a second invasive procedure with its associated morbidity, and reduces total radiation exposure and potentially cost. However, multivessel intervention is associated with a higher procedural contrast use and should be avoided in situations where the risk of contrast-induced nephropathy is high.

Regardless of the strategy (staged or multivessel PCI), the order in which diseased vessels are treated needs to be planned. In ACS, the culprit lesion is treated first. In elective PCI for stable angina, the artery either supplying the largest amount of myocardium or involving the technically most difficult lesion is usually approached first. CTO are often the most technically demanding lesions to treat and are usually approached first in multivessel PCI. In the event of failed PCI to the CTO, the patient could be referred for CABG. Before attempting to open a CTO, it is important to determine the viability of the myocardium supplied by the occluded artery. The hypothesis that late mechanical reperfusion in patients with asymptomatic occluded infarct-related artery will improve long-term clinical outcomes remains to be proved.

Assessment of non-culprit or intermediate lesion

Assessment of a coronary lesion of intermediate severity continues to be a challenge. There can be significant observer variability in interpretation of the severity of an intermediate coronary lesion defined as luminal stenosis >40% but <70%. Intravascular imaging with intravascular ultrasound (IVUS) or optical coherence tomography (OCT) has become a more accurate standard for defining the severity of atherosclerosis and luminal dimensions compared to angiography. In the cardiac catheterization laboratory, coronary pressure wire-derived fractional flow reserve (FFR) can be used to determine the physiologic significance of a coronary stenosis that is distinct from the anatomic visualization provided by IVUS or OCT. This method relies on the decrease in intra-arterial pressure induced by a functionally significant stenosis to determine whether an intermediate lesion is producing ischemia.

High risk patients and risk stratification

The risk-benefit ratio must be assessed carefully for each patient with MVD. The risks of complications from PCI depend on several factors, including specific anatomic features of the artery and lesion, the overall cardiac and non-cardiac condition of the patient, and the clinical setting.

Risk models can be used to help predict the likelihood of procedural complication. For example, the Mayo Clinic risk score using seven variables (age, MI less than or equal to 24 hours, pre-procedural shock, serum creatinine level, left ventricular ejection

Table 17.2 SYNTAX score and SYNTAX-based model for risk stratification in MVD

Score	Components	Objective
SYNTAX score	Anatomic (angiographic)	Assessment of the location, extent, and complexity of coronary artery disease
Functional SYNTAX score	Anatomic + FFR	Similar to the SYNTAX score but calculated only on hemodynamically significant lesions
Residual SYNTAX score	SYNTAX score after PCI	A marker of completeness of revascularization by PCI
CABG SYNTAX score	Residual SYNTAX score after CABG	A marker of completeness of revascularization by CABG
SYNTAX Revascularization Index	$1 - [rSS/bSS] \times 100$	A marker of the proportion of CAD burden treated by PCI
Global Risk Score	SYNTAX score + EuroSCORE	Developed to improve the predictive power of the SYNTAX score by inclusion of clinical variables
Clinical SYNTAX score	SYNTAX score * ACEF score	Developed to improve the predictive power of the SYNTAX score by inclusion of clinical variables
Logistic Clinical SYNTAX score	SYNTAX score + ACEF Score	Developed to improve the predictive power of the SYNTAX score by inclusion of clinical variables
SYNTAX score II	SYNTAX score + clinical variables	Decision making for PCI vs. CABG

fraction, congestive heart failure, and peripheral artery disease) has been validated to predict MACE and procedural death with excellent discrimination [2]. The model was robust across many subgroups, including those undergoing elective PCI, those with diabetes mellitus, and in elderly patients.

Recently, novel scores have been developed to assess the long-term impact of PCI. Many of them originate from the pivotal SYNTAX score, an anatomic risk model created by merging of different existing angiographic classifications (Table 17.2). The SYNTAX score was originally conceived as an instrument to facilitate the discussion of interventional cardiologists and surgeons about revascularization options for a given left main or MVD patient during the so-called heart team meetings [3]. However, limitations of this score have been highlighted over time, which include the lack of clinical variables in the score algorithm [4]. The recently introduced SYNTAX score II tries to address this limitation (Table 17.2), but no validation of this score in patients with MVD is available so far.

Acute coronary syndrome

Patients with ACS frequently present with multiple complex coronary plaques. About 40–60% of patients who presented with acute MI have evidence of ulcerated plaques or thrombus in other than the infarct-related artery. Patients with intermediate to high risk non-ST elevation ACS, based on clinical, biomarker, and angiographic assessment, should undergo early revascularization. In this scenario, initial incomplete revascularization with PCI of the culprit lesion(s) is frequently preferred with subsequent staged PCI to non-culprit lesions if required. Whether the patient will ultimately need surgical bypass or staged PCI should be determined at time of initial angiography. If the patient is a surgical candidate, balloon

angioplasty alone or stents with a early coverage pattern (i.e., bare metal stents or certain second-generation DES) should be used to avoid delay to surgery caused by the need for prolonged dual-antiplatelet therapy.

In patients with MVD and ST-elevation MI (STEMI), the conventional strategy for primary PCI is recanalization of the infarct-related artery with decisions about PCI of non-culprit lesions at later follow-up guided by objective evidence of residual ischemia. The decision to defer non-culprit lesion PCI is supported by evidence of possible overestimation of non-culprit lesion severity in the setting of MI due to enhanced vascular tone often resistant to nitrate administration. However, with the improvement of PCI outcomes, recent studies have shown multivessel PCI during STEMI to be safe in selected patients compared with treating only the infarct-related artery [5]. Multivessel PCI during STEMI should be always considered when the patient remains hemodynamically unstable after PCI of the infarct-related artery. This can occur if there is more than one culprit vessel or critical stenoses in non-culprit vessels that supply a significant amount of myocardium not collateralized by the infarct-related artery. Potential advantages of multivessel PCI during STEMI include decrease in ischemic burden and improvement of left ventricular function.

Diabetes mellitus

Diabetic patients with MVD typically have smaller vessel size, longer lesion length, and greater plaque burden than non-diabetic patients. These adverse characteristics are associated with accelerated atherosclerosis, high restenosis rates, and less favorable long-term survival following PCI than non-diabetic patients. Most trials comparing CABG with PCI in diabetic patients have shown

increased long-term survival with CABG. Based on a recent large meta-analysis, CABG remains the preferred treatment for diabetic patients with MVD [6]. Whether the advent of second-generation DES can narrow the gap between PCI and CABG in MVD in terms of the need for repeat revascularization remains to be demonstrated.

The elderly

Elderly patients have a higher risk profile than younger patients and mandate thorough clinical evaluation before acceptance for PCI or CABG. The long-term benefit of PCI in the elderly remains controversial. Culprit lesion PCI for symptom relief may be adequate in most patients rather than aiming for complete revascularization despite more extensive coronary disease than younger patients.

Left ventricular dysfunction

Left ventricular dysfunction is a major determinant of peri-procedural risk. Complete revascularization of viable myocardium in patients with MVD and left ventricular dysfunction is associated with improved survival, although this relationship was not significant after adjustment for other baseline variables in the post-hoc analysis of a randomized trial [7]. Currently available non-invasive techniques to assess myocardial viability include thallium single photon emission computed tomography, dobutamine echocardiography, positron emission tomography with ¹⁸F-fluoro-deoxyglucose, and contrast-enhanced magnetic resonance imaging.

Renal dysfunction

Patients with renal dysfunction are at increased risk of developing contrast-induced nephropathy (CIN) and long-term mortality after PCI. The cornerstone of CIN prevention is adequate pre-hydration. In patient at increased risk for CIN, nephrotoxic medications should be withheld, renal protective strategies be considered for prophylaxis, and low or iso-osmolar contrast agents should be utilized. A strategy of staging the PCI initially targeting the culprit lesion is preferable to minimize contrast volume.

Three vessel disease

Triple vessel PCI is more likely to result in incomplete revascularization and less favorable outcomes than CABG. However, triple vessel disease can be highly heterogeneous. Patients with multifocal discrete stenoses are generally amendable to PCI whereas CABG is preferable for those with diffuse disease and multiple CTO. The SYNTAX score can help to identify those patients with three-vessel disease at lower risk of adverse long-term prognosis with PCI (i.e., those with SYNTAX score <22).

Revascularization in the era of drug-eluting stents

Three randomized trials (CARDIA, SYNTAX, and FREEDOM) have compared the outcomes of DES with CABG in patients with MVD. The Coronary Artery Revascularization in Diabetes (CARDIA) trial was designed to demonstrate non-inferiority of PCI to CABG in diabetic patients with MVD. The trial fell short of its planned recruitment, enrolling only 510 patients out of the intended 600, meaning that the non-inferiority parameters set for the trial were not reached because of insufficient power [8]. Twelve-month results showed no apparent difference between CABG and PCI in terms of the composite endpoints of death, non-fatal MI, and non-fatal stroke (10.5% vs. 13.0%; $p=0.39$). Comparing CABG

with a small subgroup of PCI patients who received DES rather than bare metal stents, the composite endpoint of death, non-fatal MI, and non-fatal stroke was 12.4% vs. 11.6% ($p=0.82$) again showing no difference in this composite endpoint.

The SYNERGY between percutaneous coronary intervention with TAXUS and cardiac surgery (SYNTAX) trial was the first randomized controlled trial to compare PCI using a first-generation DES with CABG in patients with left main disease and three-vessel disease. A total of 1800 patients were randomized in a 1 : 1 fashion to PCI or CABG. At 5 years, MACCE were 26.9% in the CABG group and 37.3% in the PCI group ($p<0.0001$), driven by significant increases in MI and repeat revascularization in the PCI group [9]. In the analysis of the cohort of patients with three-vessel disease, MACCE at 5 years were significantly higher with PCI than CABG (37.5% vs. 24.2%; $p<0.001$) [10]. PCI was also associated with higher rates of all-cause death, repeat revascularization, and the composite of death, stroke or MI, whereas the incidence of stroke was similar in the two groups. The risk of MACCE with PCI was significantly higher in patients with intermediate and high SYNTAX scores, but not in those with low SYNTAX score. The differences in MACCE between PCI and CABG were larger in diabetic patients. Overall, the SYNTAX trial suggests that CABG should remain the standard of care for patients with MVD when compared with first-generation DES, with the possible exception of those with less complex anatomy (i.e., low SYNTAX score), where PCI may be an acceptable revascularization strategy.

The Future Revascularization Evaluation in Patients with Diabetes Mellitus: Optimal Management of Multivessel Disease (FREEDOM) study compared PCI and CABG in 1900 diabetic patients with MVD. The primary outcome, a composite of death from any cause, non-fatal MI, or non-fatal stroke, occurred more frequently in the PCI group ($p=0.005$), with 5-year rates of 26.6% in the PCI group and 18.7% in the CABG group [11]. The benefit of CABG was driven by differences in rates of both MI and death from any cause, while stroke was more frequent with CABG.

Medical therapy

Patients with MVD have diffuse disease and progression of untreated plaques. Multiple stents only treat focal areas of most significant stenosis. Untreated vulnerable plaques could potentially develop into culprit lesions over time. Aggressive medical therapy with risk factor modification and lipid lowering is essential.

Conclusions

Patients with MVD comprise the majority of those undergoing PCI today and will likely remain so. With improved techniques, stents, and adjunctive drugs, short- and medium-term outcomes after PCI have improved significantly. However, based on the results of contemporary trials, CABG remains the standard of care for most of the patients with MVD and those with diabetes in particular.

If long-term outcomes after second-generation DES prove to be comparable with CABG, PCI may become the preferred revascularization strategy for many patients. The role of PCI in patients with multivessel disease will depend both on the patient's anatomy and the clinical setting in which the revascularization is planned. For each patient, the risk-benefit ratio should be examined, and risk scores can be helpful for decision-making. A PCI procedure should be performed only after considering all therapeutic options and their short- and long-term outcomes.

Chronic Total Coronary Occlusion

Gerald S. Werner¹ and Emmanouil S. Brilakis^{2,3}

Coronary chronic total occlusions (CTO) make up 18% of all significant coronary lesions observed during diagnostic angiography, as demonstrated recently in a cohort study of 14,400 angiographies from three Canadian centers [1]. The term “chronic coronary occlusion” had not been rigidly defined in recent years regarding the duration of the occlusion, and whether the inclusion was complete (TIMI 0 flow) or functional (TIMI I).

In order to find common ground for future development and discussion of technique and patient outcome, a consensus was reached by an European experts group which has now been accepted as the uniform definition of chronic total coronary occlusions as those with a documented duration of occlusion of at least 3 months, with absolutely no flow through the lesion itself (TIMI 0 flow) [2]. Occlusions within 1–3 months’ duration should be addressed as recent occlusions, and within a period of 4 weeks after an acute myocardial infarction, as subacute occlusions (e.g., lesions that were included in the Occluded Artery Trial [3].

Morphology of the occlusion

Another important characteristic of a CTO is the length of the actually occluded segment. This can only be assessed through simultaneous visualization of the proximal (ipsilateral) segment and the distal segment through collateral filling. As the majority of collaterals originate from the contralateral artery, this requires double injection with the contrast injection started first in the contralateral donor artery, then followed by the injection into the occluded artery.

For the interventional strategy of entering, passing, and leaving the occluded segment, the basic pathoanatomic features of a CTO have to be kept in mind (Figure 18.1). We discriminate a proximal cap of the occlusion, which is often fibrotic or calcified and can provide considerable resistance to the wire advancement. Then along the occlusion length follows a segment of loose fibrous tissue or organized thrombus. Especially in long-standing occlusions, it may include islets of calcifications, which provide an obstacle to the advancement of the wire through this part of the occlusion until the distal cap is encountered. The resistance of the distal cap is usually lower than the proximal cap, presumably because of the lower pressure of about 30–40 mmHg existing in this collateralized segment of the occluded

artery [4]. The segment distal to the occlusion is often tapered and constricted and provides a small target for the distal wire entry.

A few pathologic studies carried out more than 15 years ago in small number of patients, often with functional occlusions, reported a considerable number of residual channels and also so called microchannels (diameter <200 μm) within the occlusion [5,6]. However, a recent pathohistologic study in a larger number of patients provided evidence that microchannels are not a typical feature of CTOs; instead negative remodeling is frequently observed [7].

Indications for treatment

The CTO is a unique set of lesions with regard to the complexity of the required interventional technique, but also with regard to the discordant view on the indication to treat these lesions. The latter is reflected by the low representation of CTOs among lesions treated by percutaneous coronary intervention (PCI) [1], while on the other hand, the presence of a CTO appears to bear a specific additional prognostic risk if left untreated [8–10]. Patients with a CTO sometimes present with stable angina pectoris, but especially exercise limitation and dyspnea are more prevalent than in non-occlusive lesions [11].

Sometimes, CTOs are detected when other coronary lesions progress and lead to unstable angina. Patients with acute coronary syndrome and ST-elevation infarct are at particularly high risk if the collateral supplying artery is involved in an acute myocardial infarction as the territory at risk is larger than with a single acute occlusion [12].

A limitation to accept CTOs as a unanimous target for PCI is the lack of a randomized study to answer this issue. However, the wealth of data from prospective registries and meta-analyses already provide considerable evidence to treat CTOs [13,14]. The indication is based on three basic goals:

- 1 To relieve exercise limiting symptoms of angina or dyspnea, especially in patients with preserved left ventricular (LV) function, or to resolve ischemia caused by the CTO, similar to the indication in stable angina caused by non-occlusive lesions;
- 2 To improve regional LV dysfunction in the territory of the occluded artery, provided there is residual viability; the latter can nowadays be readily assessed by magnetic resonance imaging with late contrast enhancement [15,16];

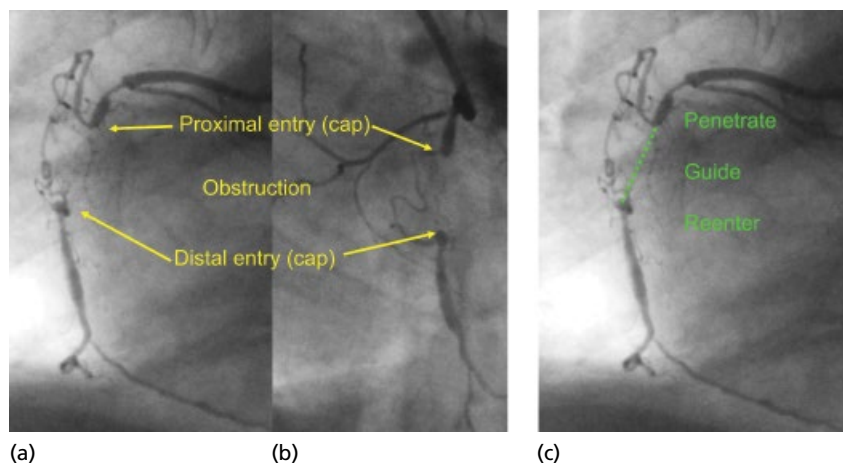

Figure 18.1 The basic features of a chronic total coronary occlusion (a and b) and the technical steps of recanalization (c).

3 To achieve complete revascularization in patients with multivessel coronary artery disease, as leaving a CTO untreated affects the outcome in these patients, as demonstrated by the post hoc analysis of the SYNTAX trial and other subanalysis [10].

An indispensable prerequisite to opening a CTO is the presence of collaterals to supply the distal occluded segment. In the absence of collaterals, no viable myocardium would have survived. On the other hand, physiologic assessment of collateral function demonstrated that even angiographically well-developed collaterals are not sufficient to prevent ischemia and cannot be an excuse for not revascularizing a CTO [17,18]. The fractional flow reserve measured distal to an occlusion before actually opening it is about 0.4, which is well below the level of 0.8 uniformly accepted as threshold for interventional treatment in non-occlusive lesions (see Chapter 6).

Patients with a concomitant CTO and an acute coronary syndrome caused by a non-occlusive lesion should be treated for this culprit lesion first, before considering the recanalization of a CTO. In stable patients, however, complete revascularization should be the ultimate goal. Therefore, a staged PCI approach should start with the CTO first, especially as lesions in the collateral supplying artery would be treated at increased risk if the CTO were not treated [19]. If the CTO procedure fails, the patient can still be referred for coronary artery bypass graft (CABG) surgery for complete revascularization [10].

Basic rules of engagement

To cross a CTO we need to visualize the distal segment in order to direct our guidewire progress, and we often need to resort to more rigid wires than in non-occlusive lesions. The latter go along with a potential damage of the arterial wall, deviation into the subintimal vascular space, or even perforation toward the pericardium, which requires special emphasis on control of the wire position during each and every step of wire advancement (Figure 18.2).

The absolute prerequisite for a CTO procedure is to reduce risk and avoid complications. The indication is a mere symptomatic one, as prognostic considerations are not backed by randomized trials. Therefore the CTO procedure should not harm the patient in any way, and the first rule of engagement is to always be absolutely sure where the tip of the wire is positioned. A second sheath for injection of contrast to visualize the collateral filling from the

contralateral artery is therefore always mandatory except in those cases where a coronary occlusion is approached, and there is collateral filling from ipsilateral branches. However, the most frequent occlusion, the right coronary and the left anterior descending (LAD) artery, usually require such a double injection. For a regular antegrade recanalization approach it is often sufficient to use a small diagnostic sheath (4 or 5 Fr) for the contralateral visualization to save on contrast volume, but if visualization is poor, larger catheter sizes should be chosen.

The second rule of engagement is to provide optimum backup for the procedure. Even if a wire can be passed rather effortlessly, the passage of balloons and stents can fail because of lack of backup. Especially for the right coronary artery, the regular JR guide may not provide adequate support, and an AL1 is generally preferred. However, there is a balance to be made between catheter size and shape, and this requires careful planning right at the start of the procedure. A large diameter such as 8 Fr (preferred by Japanese operators) will provide enforced support even with less aggressive shapes, and it provides ample working space for complex techniques using double wires with microcatheters, double balloons, and so on. The large diameter is also recommended when a subintimal re-entry approach might be necessary using special devices (Stingray re-entry balloon and wire). A large diameter with less aggressive shape is especially important for proximal or ostial occlusions, where deep guide engagement is not possible or counterproductive. In non-ostial lesions, a smaller guide size of 6 Fr will require deeper engagement for adequate support. The predominantly used catheter size in Europe is 7 Fr, which provides proper support and working lumen. It is important to always use catheters with side holes, especially for the right coronary artery, to avoid local dissections during contrast injection into the occluded proximal artery, and to avoid hypoperfusion of proximal side branches.

For the left coronary artery (LCA), the guide catheter has to be selected according to the length of the left main artery, and the angle of take off of the occluded artery. For LAD occlusions an extra backup shape provides the ideal support, while occasionally the classic AL2 or 3 may be ideal for proximal circumflex occlusions.

The third rule of engagement is to advance guidewires with the support of a microcatheter, to start with soft wires in order not to damage the proximal arterial segments with aggressive rigid wires. For example, a sharp-angled take off from the LCA may require

Figure 18.2 Bilateral contrast injection is essential for control of the wire position and advancement and direction. Proximal right coronary artery (RCA) occlusion (a) with recanalization wire in a posterolateral side branch (b, arrows). Proximal RCA occlusion (c) with recanalization wire outside of the distal vessel lumen (d, arrow).

soft hydrophilic wires to negotiate it, whereas the required angle and the wire stiffness will be inadequate for the actual occlusion. The advancement of a microcatheter through the difficult proximal angulation will be almost always possible, and once positioned at the proximal end of the CTO, the soft wire can be exchanged for a dedicated recanalization wire (Figure 18.3).

Guidewire selection and handling

Guidewire selection incorporates a great deal of personal preference and operator experience [20,21]. In general, however, one can discriminate and advise on the use of the two basic guidewire features—hydrophilic PTFE wires and metal wires—which have hydrophilic coating to various extents.

There is not a single wire that serves all lesions and all circumstances, and a familiarity with several wires from each family is mandatory. For CTO procedures, two features of a guidewire are of utmost importance: tip stiffness and torque control. Wires can be used in incremental fashion with increasing tip stiffness when the previous wire encounters resistance. Torque control is a major feature of dedicated CTO wires in order to facilitate maneuvering of the wire in long resistive lesions.

While wire development was a gradual and slow process for many years, now an ever-wider and improved variety of guidewires have become available which have led to changes in wire selection and preference over the past 5 years. Wire selection depends on the planned approach to the occlusion, which is determined by the angiographic features of the lesion. Basically, three technical approaches

Figure 18.3 Proximal left anterior descending (LAD) occlusion with tapered entry (a). The tip shape for entering the LAD is different from what is required for navigation within the occlusion. After advancing a soft wire into the LAD, a microcatheter (b, arrow tip) is advanced, and the wire exchanged with a different tip shape. Further advancement is controlled by bilateral contrast injection in two planes (c and d).

are discriminated; drilling, penetrating, and sliding techniques. Some wires suit one of these categories best, but basically, each wire can be manipulated to work in one of these basic modes. A wire can be selected to “test” the proximal cap, but often needs to be changed during the procedure. Flexibility in wire selection is required throughout the whole procedure.

The tip shape is the first and basic step of wire manipulation, and often requires modification during the progress of the procedure. In non-occlusive lesions a basic rule of thumb is to adapt the radius of the tip angle to the size of the artery in which the wire is to be advanced. A major difference with tip shapes in CTOs is that the vessel diameter at the lesion site is practically zero, because it is occluded. Therefore the length of the proximal tip angle should be as short as possible with a moderate 30–45° angle. Within the occlusion, no secondary angle is added. Most recent wires are even shipped with preformed tiny preshaped tips of less than 1 mm length.

A detailed description of how to select wires would go beyond the scope of this chapter, and, most importantly, would be outdated before its publication given the current speed of wire development, but the following remarks give a brief idea of the criteria and sequence of wire selection.

Occlusions with a distinct entry point

Depending on the resistance of the proximal cap, which may be deduced from information on the duration of the occlusion or visible calcification, the wire can be selected accordingly (Figure 18.3). For presumably soft plaques (CTO <1 year) a Fielder XT could be selected, or a Gaia 1. For more resistant occlusions, a Gaia 2 might work as primary wire, or an Ultimate 3. The Fielder XT (more recently XT-A) is a tapered low tip force wire, the tapered Gaia

wires have higher tip force with high torque control, and the Ultimate has a tip diameter like normal workhorse wires of 0.014 inch. Wire manipulation is improved by advancing the microcatheter about 1 cm close to the wire tip. The wire is carefully rotated and advanced mainly by observing the fluoroscopic image, less so according to tactile feedback.

Occlusions without any discernible entry point

These occur typically at the site of side branches (Figure 18.4). Penetration requires tapered tip wires such as the Confianza Pro 9 and 12 g wire with 0.009 inch tip diameter, or the Progress 140 T or 200 T. The recently available Gaia 2 and 3 are also ideal wires for penetrating the proximal cap; however, with calcified caps the Confianza wires are preferable. Penetration into the subintimal vessel space can occur and therefore requires careful monitoring and control of the wire approach.

Occlusions with suspected residual lumen

The sliding technique rests on the low friction advancement of PTFE wires and is ideal for occlusions with suspected residual lumen (Figure 18.5). These wires are widely (over)used, as they promise a fast approach because of the low friction, but they are poorly steerable and will easily leave the vessel lumen. Typical wires of this type are the Pilot family wires. Recently, low tip force wires became available like the Fielder XTR, which is ideal for atraumatic probing of residual channels. The Pilot wire, if used gently and carefully, will also be successful in crossing even difficult-looking occlusions (Figure 18.6). High tip force Pilot wires can also be used in in-stent CTOs.

No single technique serves all lesions, and all approaches should be utilized and combined as required.

Figure 18.4 Proximal RCA occlusion with two side branches (a). Perforation of the proximal cap is required with a Confianza wire (b arrow).

Figure 18.5 (a) Proximal RCA occlusion with a long intracoronary channel (spontaneous secondary recanalization). A Whisper LS wire is gently advanced and successfully reaches the distal vessel lumen (b and c), and the procedure is concluded successfully (d).

Figure 18.6 A proximal RCA occlusion with sidebranch and no visible entry (a). Still, a Pilot 50 wire can be successfully advanced gently (b) and reaches the distal vessel (c and d) as confirmed by contrast staining around the wire.

Advanced antegrade recanalization techniques

The basic approach is to advance a single wire gently with just enough force for slow advancement. The tip of the wire gives tactile feedback to the experienced operator about the intravascular position; however, this is not always reliable. Wire advancement requires fluoroscopic checking by monitoring in at least two orthogonal projections and occasional contralateral contrast injections. Not infrequently, the first wire enters the subintimal space, which is recognized by missing the distal entry of the occlusion outside of the contrast-filled lumen. A decision then needs to be made either to proceed with wire manipulation or switch to a subintimal re-entry approach. This decision is based on familiarity with the technique, and anatomic features of the distal cap.

If a wire-based approach is used, then the first wire can be used as a helpful guide to the general direction of the vessel course and can enable the manipulation of a second parallel wire slightly deviating from the initial course to successfully enter the distal lumen. This is the parallel wire technique (Figure 18.7). Often, the first wire is a moderately stiff wire and the second wire is of increased stiffness, but a tapered wire (e.g., Gaia 2 or Confianza Pro). This technique can be accommodated by modern 6 Fr guide catheters. However, if both wires are supported by a microcatheter or over-the-wire balloon (the see-saw technique), a larger diameter of 7 or 8 Fr is required [22]. If necessary a third wire can even be introduced.

The main issue with the multiple wire approach is not to advance the primary wire within the false lumen far beyond the distal entry point in order to avoid a subintimal hematoma that might obstruct the distal entry and make the manipulation of a second wire difficult or even impossible because of loss of contrast filling of the compressed distal lumen.

The deviation of the primary wire from the true vessel lumen can occur at any point during advancement, but it often happens at the

entry into the proximal cap. A refined technique to control this and modify the entry point is by use of intravascular ultrasound (IVUS). An IVUS probe is advanced, after purposeful dilatation of the wrong channel, into this false lumen, and under IVUS imaging and orientation of the relative wire positions and the IVUS catheter on fluoroscopy, a wire can be redirected into the true lumen [23].

Sometimes, when an occlusion includes several side branches, the wire can be directed only in one of the secondary branches. If this cannot be controlled after some effort, it may be prudent to dilate the occlusion toward this side branch with a small-sized balloon. Not infrequently, this maneuver then provides easy access to the other occluded branches: termed the sesame open approach. In these situations, where the operator wants to access another branch at often acute angles, the use of a dual-lumen microcatheter (TwinPass, Crusade) is helpful, with an over-the-wire lumen ending at a distal side port [24].

In situations where the direction of the guidewire advancement is defined, but the wire will simply not penetrate the intended segment, the support of the wire needs enhancement. This can be achieved by inflating an over-the-wire balloon proximal to the occlusion, or by using other enhancements of guide support such as the anchoring balloon technique or the Guideliner or Guidezilla guide extension catheters.

Antegrade dissection and re-entry

A frequent situation during the course of antegrade wire manipulation is the subintimal wire position. Antegrade dissection and re-entry techniques aim to cross the occluded vessel segment through the more compliant subintimal space, followed by re-entry into the distal true lumen. Antegrade dissection can be achieved using a “knuckled” guidewire (usually a polymer-jacketed guidewire) (STAR [25], mini-STAR [26]), but the reliability of the wire re-entry

Figure 18.7 Typical example of the advantage of parallel wiring: the first wire Gaia 2 misses the distal target to the right (a, arrow), and a second Gaia 2 in parallel misses the target initially to the left (b, arrow tip); finally the first wire is redirected to enter the distal lumen (c, arrow), which was confirmed in a second plane.

Figure 18.8 Long occlusion of the left circumflex artery (a; between arrows) with collateral supply from the contralateral right artery, and also from epicardial diagonal branches. Initial attempt with parallel wire technique, both wires below or above the distal target (arrow head) in LAO projection (b). The StingRay catheter with two radiopaque dot markers (arrow heads) is advanced into the subintimal space below the distal collateral-filled target (c; arrow). The StingRay balloon is inflated and appears as parallel lines in the RAO projection (c1) and single line in LAO projection (c2). The single line indicates, that we look from the side on the catheter, with one side port exiting on top, one below. The StingRay wire is then directed toward the side port, that points toward the target (d; arrow), and exits in this example at the proximal side port before the two markers (arrow). The catheter is then exchanged for a microcatheter, then advanced into the true distal lumen, and a soft wire exchanged for the StingRay wire. The final result after stenting of this limited subintimal re-entry (e).

is not controllable. With the advent of the dedicated BridgePoint re-entry device (Boston Scientific; Natick, MA, USA), a more reliable re-entry can be achieved. It consists of the CrossBoss catheter, a metal catheter with a 1-mm distal atraumatic tip that is advanced with a rapid-spin technique to provide either a passage through the occlusion or a passage into the subintimal space. In the latter case, re-entry can then be achieved with the Stingray system. The Stingray balloon has a flat shape with two side exit ports, and self-orient so that one exit port faces the true lumen and the other faces the adventitia upon low-pressure inflation (2–4 atm) [27]. The Stingray guidewire is a stiff (12 g) guidewire with a 0.009 inch tapered tip which is advanced through the side port of the Stingray balloon facing the distal true lumen under fluoroscopic guidance

until it re-enters the true lumen (Figure 18.8) [28,29]. The length of the dissection should be minimized [30], as extensive dissection–re-entry techniques have been associated with high restenosis and re-occlusion rates [31,32].

Retrograde approach

The success rate of conventional and advanced wire techniques has been increased by wires with improved torque control. However, there remain limitations in long and calcified occlusions, and in those with inadequate guide catheter support. Often it is difficult to determine the entry into the occlusion, and therefore alternative approaches are desirable. The retrograde approach provides such

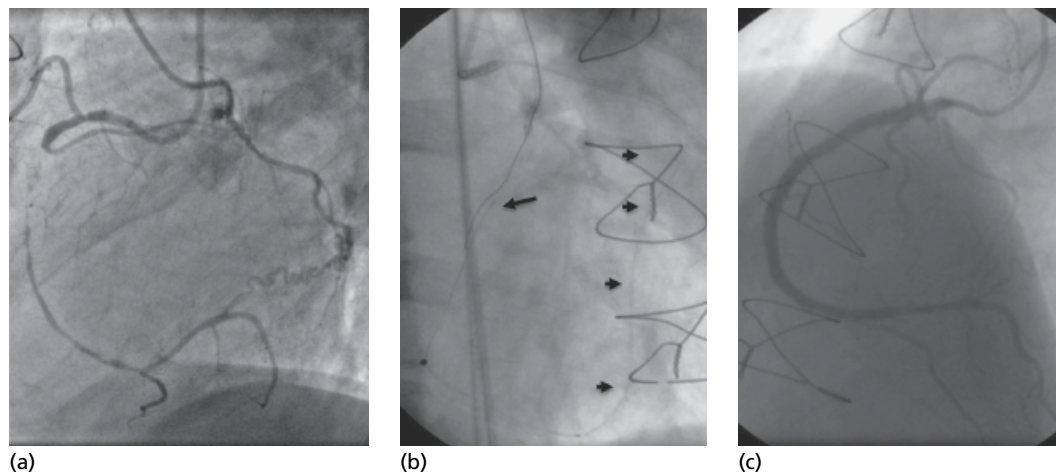

Figure 18.9 A proximal RCA occlusion in a post coronary artery bypass graft (CABG) patient, which was tried twice before antegradely (a), but could not be crossed with successful distal re-entry. A retrograde approach is chosen (b) and a wire passed through a septal perforator into the posterior descending artery (b; arrow heads) and then advanced toward the distal cap of the occlusion. The recanalization was completed with the reverse CART technique at the point where the wire overlap (b; arrow), and then followed by stent placement (c).

an enhancement of technical means by taking the reverse route of occlusion passage from the distal to the proximal cap. As the distal cap is often softer than the proximal cap, the advancement of the wire may be easier than from the antegrade approach. This can be achieved via a patent bypass graft, but as this is a rare coincidence, the retrograde approach via collateral connections is the most frequent means of access as developed by Dr. Osamu Katoh [33–35]. In principle, several pathways can be used, but the septal connections are those best approached causing the least danger to the patient in case of collateral damage. Ideally, small trans-septal thread-like collateral connections (CC1 collateral connections [36]) should be used for the approach to either the occluded right coronary artery or LAD. This approach should be used only after extensive experience with the antegrade approach and so is only briefly mentioned and described here (Figure 18.9).

The rapid development of wires to cross the collaterals and devices to support this approach (microcatheters) have made it more easily applicable than 5 years ago. In principle, either the retrograde wire is used as a marker for the antegrade approach, or the retrograde wire is advanced through the occlusion into the proximal artery and into the antegrade guiding catheter. The first approach is still valid, especially to save contrast medium, but the latter retrograde passage is the most frequently applied technique. Depending on whether the wire passes through the lumen (true lumen crossing) or deviates into the plaque wall, passage needs to be facilitated by inflating a balloon over an antegrade wire (reverse CART technique) [37].

The retrograde approach proceeds by means of very structured steps, but it requires in all cases, except for an ostial occlusion, the positioning of an antegrade wire into the body of the occlusion. This can be done as a first step, or needs to be done after collateral passage. The steps are as follows:

- 1 Selection and passage of the collateral, now achieved in the majority of cases with a soft and atraumatic Sion wire; even epicardial collateral connections can now be successfully passed. The main obstacle remains the tortuosity of the collateral path.
- 2 After reaching the vessel distal to the occlusion a microcatheter is advanced through the collateral (Corsair) which dilates the

collaterals and serves as an extension of the guide catheter. In epicardial tortuous connections, a Finecross or similar microcatheter is preferred.

- 3 Exchange the microcatheter for a wire to pass the occlusion. Here often softer wires than for the antegrade approach can be used, but basically wires are used as required. The goal is to achieve either a passage through the occlusion or at least a long zone of overlap with the antegrade wire. If no passage is possible, then the CART maneuver is applied with antegrade balloon inflations to open the space for passing the retrograde wire into the proximal true lumen.
- 4 The wire then is advanced into the guiding catheter or an extension of the guiding catheter (GuideLiner, Guidezilla [38]), followed by the microcatheter. The retrograde wire is then exchanged for a >300 cm wire to enable externalization of this wire from the antegrade Y-connector.

Thus, a wire is provided that extends via the collateral through the occlusion and provides ideal support to perform the final steps of dilatation and stent placement. The collaterals need to remain protected from this wire by the microcatheter, which is retracted into the artery distal to the occlusion. Before finally removing the collateral “gear,” a contrast injection ensures the integrity of the passed collateral.

Hybrid approach for intervention of chronic total occlusions

In the USA, the “hybrid” approach had been promoted as a means to structure the approach to CTOs as an algorithm based on four CTO angiographic features obtained using dual injection: (i) proximal cap ambiguity; (ii) lesion length; (iii) quality of the distal vessel; and (iv) presence of collateral vessels that are appropriate for the retrograde approach [39]. When the proximal cap is ambiguous or the distal target vessel is diffusely diseased, a primary retrograde approach is favored. Otherwise, an antegrade approach is initially pursued using guidewire escalation for short (<20 mm in length) lesions, and a primary antegrade dissection strategy for longer (≥20 mm) lesions. Early change in crossing strategy is recommended if the initially selected approach fails to achieve progress.

Balloon dilatation

After the guidewire is successfully advanced across the occlusion, and most importantly, its correct intravascular position checked in at least two orthogonal views with a contralateral injection, a balloon needs to be advanced. This is facilitated by modern low-profile balloons with diameters down to 1–1.25 mm to be followed by an adequately sized balloon [21].

There are several techniques available to increase support if even a small balloon cannot be advanced [40,41]. They are intended to improve and stabilize the guide catheter position in the ostium. In some instances with heavily calcified lesions a rotablator is required; however, it can be extremely difficult to exchange the recanalization wire for the delicate 0.010 inch rotablator guidewire. This can be achieved with the aid of a support catheter, which is advanced as far as possible into the occlusion. If this can be achieved, a small rotablator burr is used. Another device useful in this situation is a laser catheter, but because of high hardware costs and limited applications these devices are rarely found in catheterization laboratories [42]. A device that can help in achieving the initial headway through the occlusion is the Tornus support catheter (ASAHI Intec Inc.) which can be screwed across the occlusion once a guidewire is in position [43].

Deciding the appropriate balloon size for the subsequent full lesion dilatation can be difficult. Therefore, nitroglycerine is frequently given intracoronary to increase the distal vessel size which is always constricted after the recanalization [44,45].

Stent placement

The advent of the drug-eluting stent reduced the target vessel failure rate considerably into ranges that are comparable with non-occlusive lesions [46,47]. The need for long and multiple stents no longer appears to have a considerable impact on vessel patency, although the issue of long-term freedom from very late stent thrombosis is not yet established in this specific lesion subset. When comparing previous and present results of stents in CTOs it needs to be kept in mind that parallel to the introduction of DES the complexity of CTOs successfully recanalized tended to increase in dedicated centers with improved techniques.

When planning stent coverage after balloon dilatation of a CTO, liberal coverage and maximizing stent expansion is advantageous to avoid focal restenosis at the edges of the stent when they are implanted within severely atherosclerotic segments, and to reduce flow turbulence to avoid stent thrombosis. However, extensive stenting can lead to stent fractures, which was observed in first generation DES, but is still a problem in more recent DES [48]. All available data show that the frequently diffuse and often occlusive restenosis in bare metal stents changed with DES to predominantly focal restenosis at the edge or within the stent, which can be treated by focal stenting.

The future perhaps lies with bioabsorbable scaffolds, and initial experience appears promising, but it remains to be established whether a full-metal jacket can and should be replaced with a full-plastic jacket after complex recanalization procedures especially of the right coronary artery.

Intravascular ultrasound in CTOs

IVUS can be of use during several steps of the interventional process. As an advanced adjunctive technique requiring considerable expertise and experience, it can be used to locate the entry into an occlusion if a side branch takes off right at the proximal cap and

the IVUS can be positioned at the take off of this side branch. If the guidewire is advanced into the subintimal space, an IVUS catheter advanced into this false space can help with re-entering the true lumen [20].

With increasing use of the retrograde approach, IVUS is used to identify the wire position of the antegrade and retrograde wire with respect to lumen and subintimal space, and to assist in decision making as to the most appropriate technique [20,49]. Where IVUS is of general advantage, even with less experience in the abovementioned fields, is the assessment of stent placement and optimal stent expansion [50,51]. Diffuse atherosclerosis makes it difficult to place the proximal and distal stent borders within a less diseased segment to avoid edge stenosis, and to expand the stent fully because of underestimation of the actual media to media vessel diameter. Full lesion coverage and expansion are key factors to obtain long-term success in these lesions.

When to stop a procedure

The important question arises, if a procedure appears not to be achieving success, as to when to stop, either to opt for a subsequent second attempt, which is sometimes a feasible choice, or to opt for alternative methods like surgical revascularization. There may be technical reasons to stop the procedure, and also safety aspects. From the outset it must be clear that a recanalization requires considerable laboratory time, typically 90–120 minutes, but can extend well beyond these limits. Therefore, a sufficient time slot must be reserved to avoid the abortion of a potentially successful procedure because of logistic reasons.

There are three main reasons to stop the procedure.

- 1 To avoid radiation damage [52,53]. Fluoroscopy time will run typically into 40–60 minutes, sometimes even longer. To avoid radiation damage to the patient's skin low radiation dose protocols should be applied, the fluoro pulse rate reduced, and fluoro image storage preferred to filming whenever possible. From the start of the procedure, radiation should be at a minimum. Angulation must be changed and adjusted frequently to avoid a single spot high radiation load [54].
- 2 To avoid contrast-induced nephropathy [55,56]. The maximum amount of contrast for each individual patient should be set before the start of the procedure with reference to the patient's age and kidney function. Contrast use can be reduced by using the retrograde marker wire technique to avoid repetitive contrast injections during wire manipulation, and by using IVUS to assess the vessel instead of contrast agent. Additional technical devices are also available and can be used in critical patients (see Chapter 27).
- 3 The procedure should be stopped if complications occur that cannot be easily managed, or the strategy fails, with no alternative plan. In general, a second attempt after 4–6 weeks can be attempted if there are viable alternative options for a successful conclusion [21].

Complications

The published data show no difference in complication rates between occlusive and non-occlusive lesions, but these comparisons were not made with advanced techniques and new dedicated guidewires [57,58]. A recent meta-analysis gives an estimate of typical CTO complications such as perforation and tamponade, but other complications seem to be underestimated, as radiation damage and contrast-induced nephropathy especially were not regularly reported in

previous studies [59]. More recent data show that the retrograde approach seems to be safe with only moderately higher risk regarding perforations [60,61]. In view of the often disputed indication for CTO PCI, and the viable option of surgical revascularization, the interventional procedure must be undertaken safely.

To avoid the complication of vessel perforation every care has to be taken to recognize and correct false wire positions, and never following these wires with balloons without absolute certainty of the correct intraluminal wire position. Dissections and perforations can lead to contrast staining of the myocardium, which is not necessarily a reason to stop the procedure so long as it does not compromise the collateral vessel supply.

The wire can also leave the lumen once it has passed the occlusion and is positioned distally. The stiff wires can easily damage the distal vessel lumen when they are left in place during the balloon and stent procedure. Therefore, the distal wire tip should be always kept in view, and very stiff wires should be exchanged for regular guidewires with soft tips as soon as possible, for example after the first balloon dilatation.

However, as vessel damage and pericardial effusion is an intrinsic risk, a basic rule is to avoid any other anticoagulant than heparin during the procedure, which can be readily reversed by protamine sulfate. There are also no data to support the use of glycoprotein IIb/IIIa antagonists in CTOs.

The operator needs to be experienced in placing a pericardial drain if needed, but often this can be avoided by rapidly obstructing the leakage with a balloon inflated for several (more than 10) minutes to seal the damage. If this does not work, negative pressure suction on a microcatheter advanced far into the distal vessel helps, or thrombus injection through this microcatheter. The problem will be difficult to control if the leakage is fed not only by the antegrade course, but also via collaterals. If the sources of the leakage cannot be sealed, for example by the use of coils, removal of the coronary gear and then reversal of heparin anticoagulation with protamine sulfate and a pericardial drainage for some time is the only option, and in case of continuing effusion a surgical repair.

Other complications observed are inflicted on neighboring vessels during the approach toward the occlusion. Here particular care is required as damage with partial vessel occlusion can put the patient at severe risk as one artery is already chronically occluded. Stiff wires should not be advanced through the left main artery across angles to avoid such damage, and should rather be advanced through over-the-wire catheters, which are put into position with the help of regular floppy guidewires.

New types of complications occur through the application of the retrograde wire technique. Particular care and foresight is required not to use the singular principal supplying collateral as any damage would immediately lead to severe ischemia. Furthermore, epicardial and specifically apical collateral connections are prone to damage and may even be ruptured, leading to a life-threatening acute tamponade. On the other hand, damage inflicted within the transseptal pathway is rarely severe and resolves without sequelae. These advanced techniques should only be carried out by the most experienced operators after extensive experience in safe application of conventional and advanced antegrade wire techniques.

Percutaneous Coronary Intervention of Arterial and Vein Grafts

Bimmer E.P.M. Claessen¹, José P.S. Henriques¹, and George D. Dangas²

¹Department of Cardiology, Academic Medical Center—University of Amsterdam, Amsterdam, The Netherlands

²Department of Cardiology, Mount Sinai Medical Center, New York, NY, USA

Coronary artery bypass graft (CABG) surgery was introduced in the 1960s and is an effective technique to treat coronary artery disease [1]. In CABG, coronary stenoses or occlusions are bypassed using arterial (most commonly the left internal mammary artery; LIMA) or venous conduits (most commonly the greater saphenous vein). In recent years, the number of CABG surgeries has been in decline as a result of technical advances in percutaneous coronary intervention (PCI) which is now the most commonly used coronary revascularization technique [2]. However, even in the era of PCI with drug-eluting stents (DES) and dual antiplatelet therapy (DAPT), CABG surgery is associated with improved 5-year clinical outcomes, with the most outspoken benefit in patients with diabetes mellitus and complex coronary artery disease [3–5]. Nonetheless, long-term results of CABG surgery are limited by gradual progression of coronary artery disease in the native vessels but also by gradual failure of bypass conduits [6]. Therefore, patients who underwent CABG surgery may require secondary revascularization. This chapter provides an overview of the challenges of PCI in patients with failing arterial or venous bypass grafts.

Scope of the problem

Secondary revascularization after previous bypass surgery is not uncommon. For example, in the contemporary Synergy Between Percutaneous Coronary Intervention with Taxus and Cardiac Surgery (SYNTAX) trial, repeat revascularization had occurred in 13.7% of patients undergoing CABG surgery after 5 years' follow-up [5]. In the SYNTAX trial, 1800 patients with multivessel coronary artery disease were randomized to treatment with CABG surgery using state-of-the-art techniques using arterial grafts where possible, or PCI with TAXUS paclitaxel-eluting stents (Boston Scientific, Natick, MA, USA) [7]. An analysis from the US National Cardiovascular Data Registry (NCDR) reported that between 2004 and 2009 17.5% of all PCI procedures (300,902 of 1,721,046) were performed with patients who had previously undergone CABG surgery [8].

The etiology of graft failure after CABG surgery is different depending on its timing. Graft occlusion of venous conduits within the first year after CABG surgery occurs in approximately 3–10% of

patients in contemporary trials and registries and aspirin has been useful in diminishing this problem [7,9,10]. This is mostly caused by surgical problems such as kinking due to excessive graft length, pre-existing pathology in the vein graft, poor flow distal to the anastomosis resulting in acute postoperative failure, or as a response to vascular injury analogous to vascular injury after PCI. Late failure of bypass graft conduits results from attrition of saphenous vein grafts (SVGs) and/or progression of atherosclerotic disease in the native coronary arteries.

Arterial conduits are superior to venous conduits in terms of long-term graft patency. A study in 1254 patients who underwent CABG surgery reported 10-year patency rates of 61% for SVGs and 85% for internal mammary artery (IMA) grafts. Recent evidence from a meta-analysis comparing bilateral IMA and single IMA grafting showed a survival benefit with bilateral IMA grafting after a mean follow-up period of 9 years [11]. A secondary analysis in a cohort of 1419 patients undergoing CABG with an arterial graft to the left anterior descending artery (LAD) from the SYNTAX trial and registry showed that 5-year clinical outcomes in the CABG cohort were comparable in patients who received venous conduits or arterial conduits as a second graft [12]. Therefore, the follow-up duration in the SYNTAX subanalysis may be too short to detect an advantage with arterial conduits which is likely to arise between 5 and 20 years of follow-up.

Secondary revascularization after CABG surgery: PCI or repeat surgery?

As of 2015, only one randomized trial has compared PCI with CABG in post-CABG patients. The Angina with Extremely Serious Operative Mortality Evaluation (AWESOME) trial included 142 patients in a randomized trial comparing CABG with PCI in post-CABG patients [13]. Additionally, 719 patients were enrolled in a physician-directed registry. In this small randomized trial, there were no differences in terms of survival between the CABG and PCI arms at 3-year follow-up (73% vs. 76%, respectively).

Current US and European guidelines recommend a heart team approach in order to decide on the optimal revascularization technique in patients undergoing secondary revascularization

after previous CABG surgery for ischemia refractory to medical therapy [14,15]. The 2011 American College of Cardiology/American Heart Association (ACC/AHA) guideline on coronary artery bypass surgery states that a number of factors favoring repeat CABG include “vessels unsuitable for PCI, the number of diseased bypass grafts, availability of the LIMA for grafting, chronically occluded arteries and good distal targets for bypass graft placement. Factors favoring PCI over CABG include limited areas of ischemia causing symptoms, suitable PCI targets, a patent graft to the LAD artery, poor CABG targets, and comorbid conditions” [16].

PCI for acute postoperative graft failure

Occlusion of SVGs has been reported to occur in approximately 10% of grafts within 30 days of CABG surgery [10]. Acute graft failure after CABG surgery can be suspected by changes in the electrocardiogram (ECG) such as ST segment elevation or the development of new Q waves, by elevated biomarkers, by new wall motion abnormalities on echocardiography, hemodynamic instability, or a combination of these findings. Emergency angiography followed by PCI is the preferred strategy to manage acute postoperative graft failure [17]. However, redo CABG surgery is performed if multiple grafts are occluded or if the anatomy is not suited for PCI. Even with rapid emergency angiography and PCI, acute graft failure is associated with high in-hospital mortality, analogous to mortality after acute stent thrombosis after PCI [18]. For example, a recently published observational study of 54 patients undergoing emergency coronary angiography within 30 days after CABG surgery between 2004 and 2008 reported a 30-day mortality rate of 26% [17]. In the context of PCI within hours to days after CABG surgery there is an increased risk of perforation at the site of the freshly made anastomosis [17]. Current guidelines recommend that the target for PCI should be the body of the native vessel or the IMA graft, while the acutely occluded SVG should be avoided because of the risk of embolization and/or perforation [15].

PCI in degenerated saphenous vein grafts

The majority of PCIs after CABG surgery are performed in the native coronary system as reported by an analysis in 300,902 procedures from the NCDR comprising patients with previous CABG [8]; 62.5% of patients in this study underwent PCI in native vessels only and 37.5% underwent PCI in at least one bypass graft with the vast majority of these grafts being SVGs (SVG 34.9%, arterial graft 2.5%, both arterial and SVGs 0.2%).

Treatment of SVGs with PCI is associated with high rates of major adverse cardiac events (MACE). A patient-pooled meta-analysis of 3958 patients included in five randomized controlled trials and one registry investigating embolic protection devices in SVGs reported a 30-day MACE (defined as death, myocardial infarction, or target vessel revascularization) rate of 13.8% in patients treated with conventional guidewires and 9.6% in patients with embolic protection devices [19]. The strongest predictors of 30-day MACE were a larger estimated plaque volume and a high degree of SVG degeneration. Analyses from a registry of approximately 1000 patients undergoing PCI with bare metal stents (BMS) in SVGs have shown that female gender and diabetes mellitus are both associated with an increased risk of adverse events after SVG PCI [20,21].

Another prognostically unfavorable characteristic of patients undergoing SVG or arterial graft PCI, particularly in the presence

of extensive occlusions in the native coronary circulation, is that they typically have a low left ventricular ejection fraction. In these patients, the use of a hemodynamic support device can be indicated to optimize the extent of complete revascularization and minimize peri-procedural complications [22,23].

Guiding catheter selection

Guiding catheter selection depends on the insertion site of aorto-coronary bypass grafts in the aorta. Usually, grafts to the distal right coronary artery (RCA) or distal left circumflex coronary artery (CX) are located cranially above the ostium of the RCA; these grafts can be engaged by a Multipurpose, Judkins Right, or Amplatz Right or Left guiding catheter [24]. Grafts to the left coronary artery (LCA) are usually inserted in the aorta cranially to the ostium of the LCA; these grafts can be engaged by a Judkin Right, Hockey Stick, Left Coronary Bypass, or Amplatz Left guiding catheter.

Bare metal or drug-eluting stents in SVG interventions

In *de novo* coronary artery lesions the use of current-generation DES is associated with improved outcomes in terms of safety (death, myocardial infarction, stent thrombosis) and efficacy (target lesion and target vessel revascularization) compared with first-generation DES and BMS [25,26]. A large number of studies have also shown that DES implantation reduces the risk of repeat revascularization compared with BMS in SVG PCI [27]. Moreover, an analysis from 3063 patients undergoing SVG PCI in the Swedish Coronary Angiography and Angioplasty Registry (SCAAR) reported lower mortality rates in patients who received DES compared with BMS [28]. Current guidelines support the use of DES in SVGs (Class I, level of evidence A) [15]. A significant vessel mismatch occurs (particularly in SVG to diagonal or distal marginal branches) at the distal anastomosis level, which occasionally precludes the use of any stent at these locations. A particularly challenging situation is SVG disease in association with significant stenosis in the native coronary artery distal to the SVG anastomosis: typically, those distal vessels are of small caliber and present with diffuse disease and calcification. It is not unusual that no revascularization option is possible and cell or gene therapy protocols have been employed in such cases. Interestingly, this type of unfavorable anatomy is not necessarily related to low global regional systolic function.

Embolic protection devices in SVG interventions

Because of the high atheromatous load of degenerated vein grafts, PCI of SVGs is associated with an increased risk for distal embolization resulting in peri-procedural myocardial infarction [19]. A number of individual clinical trials and meta-analyses of clinical trials support the use of embolic protection devices in SVG intervention to reduce the occurrence of distal embolization [19,29–31].

Three distinct types of embolic protection devices have been developed. Distal occlusion aspiration devices comprise the first class; these devices contain an inflatable occlusion balloon which is passed distal to the lesion and inflated to prevent antegrade blood flow. The balloon is mounted on a hypotube which is used as the guidewire for stenting or balloon angioplasty. The PCI is performed while the blood in the SVG is stagnant, and any debris is subsequently removed by an aspiration catheter. Examples of this type of embolic protection device include the PercuSurge GuardWire (Medtronic, Minneapolis, MN, USA) and the TriActiv System (Kensey Nash Corp, Exton, PA, USA).

Distal embolic filters are the second class of embolic protection devices and the most commonly used type. These devices have a

shrunk filter mounted on the distal part of a guidewire. The filter with a pore size of 100–110 μm is positioned distal to the lesion and subsequently deployed. Distal embolic filters allow for antegrade blood flow while capturing debris of similar size to the aforementioned distal occlusion system [32]. After stenting or balloon angioplasty, accumulated plaque debris is retrieved using a retrieval catheter. Examples of this type of embolic protection device include the Spider (Abbott Vascular, Abbott Park, IL), the FilterWire (Boston Scientific, Natick, MA, USA), and the Interceptor Plus (Medtronic Vascular, Santa Rosa, CA, USA).

Finally, a proximal occlusion aspiration device (Proxis, St. Jude Medical, Minneapolis, MN, USA) was found to be effective in SVG PCI, but its manufacture was discontinued and it is no longer commercially available [33].

Currently, the use of embolic protection devices is listed as a Class I, level of evidence B recommendation by both the ESC and ACC/AHA guidelines [15,34].

Use of glycoprotein IIb/IIIa inhibitors in vein graft PCI

Because of the high thrombotic burden of degenerated vein grafts, the glycoprotein IIb/IIIa inhibitors (GPIs) which inhibit platelet aggregation have been investigated in SVG PCI. However, use of GPIs in SVG PCI was not found to result in a reduction of adverse ischemic events. A pooled analysis of individual patient data ($n = 627$) from five randomized controlled trials investigating GPIs in SVG PCI reported a numerically higher rate of adverse events (death, myocardial infarction, or revascularization) at 6-month follow-up in SVG PCI when GPIs were used compared with placebo (39.4% vs. 32.7%; $p = 0.07$) [35].

Radial approach in vein graft PCI

A recent randomized controlled trial investigated 128 consecutive patients who had previously undergone CABG surgery and who were referred for cardiac catheterization to radial or femoral vascular access [36]. In this small study, radial access was associated with longer procedural time (34.2 ± 14.7 vs. 21.9 ± 6.8 minutes; $p < 0.01$), longer fluoroscopy time (12.7 ± 6.6 vs. 8.5 ± 4.7 minutes; $p < 0.01$), and increased contrast use (171 ± 72 mL vs. 142 ± 39 mL; $p < 0.01$). Moreover, access site crossover occurred in 17.2% of patients in the radial group. However, outcomes were similar in patients who underwent PCI. This study suggests that the radial approach in vein graft PCI should preferably be used by operators who have extensive experience with radial PCI and angiography. In our opinion, the exact location of the graft and the distance of its proximal anastomosis from the innominate artery, and its relation to the great vessel and arch tortuosity are very important factors in determining the feasibility of a radial approach and the access site laterality (left versus right radial).

PCI in arterial conduits

If arterial grafts require intervention, this need most commonly arises during the first year after CABG surgery as the most common mechanism of arterial graft narrowing is a response to injury (analogous to the mechanism of restenosis after PCI) [8]. Arterial grafts using the radial artery are known to have a tendency to develop coronary spasm, which complicates PCI of these types of grafts [37]. Calcium channel blockers have been used empirically by many surgeons after arterial graft conduit implantation (particularly radial grafts). Arterial grafts are notably resistant to atherosclerotic deterioration particularly within

their shafts; therefore anastomotic lesions are the most common. There is limited clinical evidence on the subject of PCI of arterial grafts. A different behavior of anastomotic and shaft lesions has been suggested with use of BMS and balloons, respectively, as first line of treatment; DES implantation has changed this practice. A small retrospective study suggests that DES implantation in arterial grafts results in a reduction in target lesion revascularization compared with BMS [38].

Guiding catheter selection for LIMA and RIMA grafts

A LIMA graft can be engaged via the left radial artery or via the femoral route. The most commonly used catheter shapes or the Judkins Right 4 or the IMA. For successful wiring of a tortuous LIMA a soft hydrophilic wire, perhaps supported by a 1.5 mm balloon may be required. In patients where the LIMA takes off from the proximal ascending part of the left subclavian artery, the use of a guiding catheter with a 0.035 inch guidewire inside can allow non-selective injection and advancement of a 0.014 inch wire into the IMA, then the guidewire can be retracted and the catheter directed toward the IMA with help from the 0.014 inch wire.

The right IMA (RIMA) can be engaged by IMA or Judkins Right 4 shaped catheters using the right radial artery or the femoral approach. When using the femoral approach, engaging the RIMA may prove challenging, and an approach using a guidewire as described above can be helpful.

Conclusions

PCI in patients who have undergone CABG surgery is a frequently encountered clinical problem. These are typically patients with high rates of risk factors for coronary sclerosis in addition to numerous extracardiac comorbidities. In patients with medically refractory anginal complaints after previous CABG surgery, a tailored approach to secondary revascularization should be devised by the heart team. If PCI is deemed the most appropriate revascularization technique, guidelines recommend treatment of the native coronary artery system. If this is contraindicated and PCI of degenerated vein grafts is performed, the use of embolic protection devices and placement of DES rather than BMS is recommended. We have to also keep in mind that the achievement of the most optimal final luminal diameter in graft lesions has been associated with a greater post-procedure myocardial injury and operators should take account of this trade-off [39].

Interventional Approach in Small Vessel, Diffuse, and Tortuous Coronary Artery Disease

Robert Pyo

Montefiore Medical Center, Albert Einstein College of Medicine, New York, NY, USA

Unfavorable factors for percutaneous coronary intervention (PCI) include small caliber of coronary vessels, diffuse lesion length, and significant coronary artery tortuosity. Small caliber of coronary arteries is associated with increased restenosis. Diffuse or long lesions are associated with decreased procedural success and are associated with higher rates of restenosis. PCI of tortuous lesions are also associated with decreased procedural success rates which stem chiefly from difficulty in delivering devices. Difficulty in device delivery not only makes intervention challenging, but also makes anatomic and physiologic assessment of lesions difficult. However, with thoughtful application of technique and use of supportive equipment, PCI of these difficult lesion subsets can be accomplished with a high degree of success and safety.

Small vessel disease

Definition and prevalence

A small coronary artery is defined as a vessel with a reference vessel diameter of less than 2.5–2.75 mm [1,2]. Usually, the caliber of the vessel is determined by angiographic evaluation. However, if there is diffuse coronary artery disease, the reference vessel diameter may not be easily discernable and the true vessel diameter can easily be underestimated by using angiography-based estimates. In these cases, imaging with intravascular ultrasound (IVUS) or optical coherence tomography (OCT) is sometimes needed to confirm true vessel size.

Percutaneous interventions of small vessels are relatively common and compromise approximately 25–30% of coronary procedures [3,4]. Patients with small diameter coronary arteries tend to be older and are more likely to be female. They also tend to have higher frequencies of concomitant disease such as heart failure and diabetes [5].

Anatomic and physiologic assessment

Physiologic assessment of small vessel coronary artery disease is important. Because of the relatively poorer outcomes after PCI, intervention should be entertained only for clinically significant lesions. Lesions with angiographic diameter stenosis of greater than 70% when compared to reference vessel diameter are generally

considered physiologically important and are thought to potentially cause ischemia [6,7]. However, visual estimation of stenosis severity by angiography alone can be difficult if the reference vessel diameter is small. IVUS, OCT, and fractional flow reserve (FFR) can be employed to aid in the evaluation of the clinical significance of small vessel disease.

Intravascular ultrasound

Evaluation of small vessel coronary arteries with IVUS can be performed effectively. Availability of smaller 5 Fr IVUS catheters makes delivery easier. Images are assessed in a similar fashion to larger arteries and the principal analysis is assessment of minimal lumen cross-sectional area (CSA). For larger vessels with reference diameters of greater than 3.0 mm, a CSA of less than 4.0 mm² is generally correlated with ischemia which is proven by nuclear imaging [8]. For smaller vessels, the cut-off CSA below which ischemia is thought to occur is smaller. In the Fractional Flow Reserve and Intravascular Ultrasound Relationship Study (FIRST), coronary artery lesions in vessels with varying reference vessel diameters were evaluated with FFR. The best cut-off CSA for lesions in vessels with reference vessel diameters less than 3.0 mm was 2.4 mm². Lesions with CSA below this cut-off were likely to have an “ischemic” FFR value of less than 0.8 [9].

Fractional flow reserve

Measurement of FFR can be useful in assessing the physiologic significance of lesions in small coronary arteries. FFR has been validated as an important tool for identifying lesions that when treated with PCI lead to improved clinical outcome. Although most of the data supporting the use of FFR have been derived from studies that evaluated larger coronary arteries, evidence supports the use of this modality in smaller coronary arteries as well [10]. In the FAME study, 20–30% of the coronary arteries that were studied were less than 3.0 mm in diameter and the average reference vessel diameter was 2.5 mm [11]. In the Phantom study, evaluation of patients with FFR could identify those patients with small coronary artery disease in whom PCI could be safely be deferred [12]. The FFR cut-off for physiologic significance in small coronary arteries appears to be in the range 0.75–0.80, and values less than this cut-off range correlate with ischemia.

Optical coherence tomography

OCT is a relatively new imaging modality compared to IVUS. Rather than using ultrasound, it uses infrared light to obtain cross-sectional images of coronary arteries. Compared with IVUS, it has the distinct advantage of having superior resolution. In order to image optimally, the blood in the coronary artery must be washed out with dye. In smaller vessels, this washout may not be optimal because of the distal location of the vessels. The correlation between ischemia and OCT-derived CSA has not been rigorously validated.

Technical aspects

PCI of small vessel disease can be challenging. Delivery of devices is often difficult because of the distal location of the small vessels. Small vessels can also be at bifurcations and all the challenges of bifurcation PCI are compounded by the small size of the vessel. Stent sizing can be difficult because of tapering of a small vessel to even smaller dimensions. However, the application of a well-executed plan can make intervention easier.

Device delivery

Delivery of devices to the distal portion of the coronary bed is difficult but can be accomplished safely with application of the correct technique and equipment. A “buddy wire” is often used [13,14]. In this technique, two wires are delivered into the target vessel. One of the wires is a stiff support wire that enhances delivery. Commonly used wires in this category are the Mailman™ (Boston Scientific, Marlborough, MA, USA) and the Grand Slam (Abbott, Abbott Park, IL, USA). These wires enhance delivery by “straightening” bends proximal to the lesion and provide a “rail” over which device delivery is facilitated. Furthermore, in cases where guide support is suboptimal, the use of a stiff support wire will help to support the guide in a coaxial position for optimal device delivery. The second wire is the delivery wire or the wire over which the balloon or stent will be delivered. This wire is a softer wire which allows passage of devices, even through tortuous vessel segments, without significant biasing effect (for more on wire bias see the section on diffuse vessel disease).

In cases where equipment delivery is particularly difficult even with the use of the buddy wire technique, mother-and-child guide extenders facilitate delivery. Two commonly used varieties are the Guideliner (Vascular Solutions, Minneapolis, MN, USA) and Guidezilla (Boston Scientific, Marlborough, MA, USA). These devices provide additional support for device passage by allowing deep intubation of coronary arteries. Additionally, in cases of unusual take off angle of the coronary ostium or anomalous coronary ostium take off, these devices can provide coaxial support. In particularly challenging cases, these devices can be advanced over the shaft of an inflated balloon to “super” deep seat the device into the coronary vasculature (for details of this technique see the section on tortuous vessel disease). The balloon can then be deflated, withdrawn, and the stent can be delivered through the deep-seated guide extender. Care must be taken when using these devices for deep intubation because coronary dissections can occur as these devices are advanced into the coronary vasculature.

Bifurcation lesions

Treatment of bifurcation lesions in small vessels should employ a one-stent strategy. The stent should be placed into the larger branch after ballooning the smaller branch pre-emptively to prevent abrupt closure. Re-crossing into the jailed side branch routinely to treat an angiographically “pinched” side branch with balloon dilatation should not be performed because of the possibility of causing stent

deformation [15]. If ischemic symptoms develop or angiographically suboptimal flow is observed in the unstented side branch, the stent strut should be re-crossed into the smaller unstented side branch with a guidewire and the jailing stent strut opened with a small non-compliant balloon inflated to high pressure. The segment of the vessel before the bifurcation is small and therefore may not allow simultaneous kissing balloon inflation. A final high pressure inflation of a non-compliant balloon in the stented main branch will in most cases be sufficient to re-align the stent struts without re-closure of the unstented side branch. Use of sequential balloon inflation rather than simultaneous kissing balloon inflation does not appear to make a difference in clinical outcome [16]. In fact, sequential balloon dilatation rather than simultaneous kissing balloon dilatation was associated with a more favorable anatomic outcome in the main branch [17]. The small caliber of the parent portion of the vessel can preclude any meaningful two-stent strategy and even if such a strategy is employed the in-stent restenosis rate is high. In general, a one-stent strategy should be used to treat bifurcation lesions in small coronary arteries.

Device size

The availability of smaller balloons and stents has made PCI of small vessel disease easier and safer. Balloons as small as 1.2 mm allow crossing and dilatation of distal lesions in small vessels feasible [18]. Some of these smaller balloons are mounted on relatively stiff shafts that promote efficient delivery of forward force. Plain old balloon angioplasty (POBA) has produced acceptable results [3]. However, if vessel size allows, treatment with drug-eluting stents (DES) is preferred to balloon angioplasty alone. DES are now available in diameters as small as 2.25 mm.

Clinical outcomes

Clinical outcomes of percutaneous intervention of small vessel disease are poor compared to similar procedures of larger caliber vessels [19]. Poor outcomes are primarily brought about by the increased rates of in-stent restenosis (ISR) and target vessel revascularization (TVR). POBA was often used as a treatment for small vessels and, at least when compared to bare metal stents (BMS), appeared to yield equal results. The TVR rate at 6 months was approximately 20% at 6 months’ follow-up [3]. This rate is much higher than the 6 month TVR rate of approximately 10% following placement of BMS in large vessels [20]. The advent of DES substantially improved ISR and TVR rates after stenting in small coronary arteries. The rate of revascularization was 4% at 9 months’ follow-up [21,22]. With the advent of second generation DES, patency rates after stenting small coronary arteries have improved even more [23].

Key points and summary

- Intervention of small vessel coronary arteries is relatively common and comprises 20–30% of all percutaneous interventions in some series.
- Angiography is the most commonly employed method of assessing small vessel disease severity. However, other modalities including IVUS and FFR have been validated in studies and are reasonable adjunctive modalities to assess physiologic importance of small vessel coronary artery disease.
- PCI of small vessel disease can be challenging. Factors that contribute to difficulty include potential distal location of small vessels, proximal tortuosity, and location at bifurcation points. However, with use of proper equipment and technique, percutaneous intervention can be performed safely.

- A small diameter makes matching vessel to equipment size potentially challenging. However, recent introduction of smaller balloons and DES have made PCI more effective. Second generation DES as small as 2.25 mm in diameter are available and the use of these stents is associated with good clinical outcomes which are superior to simple balloon angioplasty and use of BMS.

Diffuse vessel disease

Definition and prevalence

Diffuse coronary artery disease is characterized by atherosclerotic plaques greater than 20 mm in length [24]. Certain subsets of patients are more likely to have diffuse coronary artery disease. Diabetic patients tend to have diffuse, multivessel coronary artery disease and are more likely to undergo surgical revascularization. South Asian patients as a whole tend to have severe diffuse coronary artery disease that may not be amenable to either surgical or percutaneous revascularization [25]. Patients who have undergone cardiac transplantation sometimes present with diffuse occlusive coronary artery disease. In this group of patients, the disease is often caused by transplant vasculopathy which is a result of a diffuse proliferation of smooth muscle cells [26]. Less commonly, atherosclerotic lesions can occur in coronary arteries of transplanted hearts, but these lesions tend to occur in a more focal pattern [27]. Uncommonly, diffuse coronary artery disease develops in response to a general inflammatory process in patients with vasculopathies [28].

Anatomic and physiologic assessment

Coronary angiography is most often used to identify diffuse coronary artery disease. However, because of diffuse involvement of the coronary artery, it is often difficult to determine the disease-free reference diameter of the vessel and thus makes estimation of percent stenosis problematic. Indeed, in some cases an estimation of the reference vessel size is impossible and the vessel as a whole is described as “moderately diffusely” or “severely diffusely” diseased. Therefore, modalities other than angiography are needed in some cases to quantify the extent of diffuse coronary artery disease.

Intravascular ultrasound and optical coherence tomography

IVUS is useful in characterizing diffuse coronary artery disease. In cases where assessment of percent stenosis is difficult because of lack of a clear reference vessel diameter, measurement with IVUS is an alternate method to assess severity of disease and implications for physiologic importance. A plaque with a CSA of less than 4.0 mm² measured by IVUS in a vessel with a reference vessel diameter of at least 3.0 mm is generally thought to cause ischemia [8]. Lower CSA thresholds for ischemia have been identified in vessels with reference diameters of less than 3.0 mm [9]. In addition, imaging with IVUS identifies more severe segments of diffuse disease which can be selectively stented. IVUS-guided spot stenting of the most severely diseased areas spares the need for implantation of long stents and can be associated with better outcomes [29].

OCT yields similar information to IVUS. Additionally, it has the advantage of superior resolution and can yield important qualitative data about the lesion such as degree of calcification [30]. Furthermore, its superior resolution facilitates identification of stent malapposition which occurs relatively more frequently when diffuse lesions are stented. OCT can then be used to guide corrective measures with high pressure balloon dilatation.

Fractional flow reserve

Because it is often difficult to ascertain an accurate percent stenosis of a diffuse lesion, FFR is a valuable tool to gauge its physiologic importance. Particularly in cases where there are severe lesions in tandem that are separated by less severely diseased segments, pull-back of the FFR wire can isolate lesions that are hemodynamically significant. In this technique, the FFR wire is placed across a diffuse lesion and under maximal hyperemia a hemodynamic assessment of the entire lesion is made. If the FFR value is significant (≤ 0.8) under maximal hyperemia, the wire is pulled back proximally from the most distal portion of a diffuse lesion. If there is a significant pressure drop across a lesion (approximately 10 mmHg), that lesion is treated with PCI. It is important to perform a FFR measurement of the entire diffuse lesion again after stenting, because the physiologic interaction between serial lesions is accounted for by more than a hemodynamic drop which is simply the additive effect of the serial lesions [31]. For example, an initially hemodynamically insignificant proximal lesion can become significant by FFR after the more distal lesion is treated with a stent. This more proximal lesion should be treated in order to render the entire diffuse lesion hemodynamically insignificant. This concept is illustrated in Figure 20.1. In cases where there is no significant drop across a particular area of a diffuse lesion, either the entire lesion has to be stented to obtain hemodynamic benefit or the patient is not a good candidate for PCI and should be considered for surgical revascularization.

Figure 20.1 (a) A fractional flow reserve (FFR) wire advanced beyond two sequential lesions (1 and 2) registers a clinically significant value. (b) During pullback, a 10 mmHg drop is registered across the distal lesion (2) but a significant pressure drop is not registered across the proximal lesion (1). (c) Once the distal lesion is treated with a stent (2) the FFR wire is placed distal to the stent and pulled back again. No pressure drop is registered across the stented segment (2), but a significant pressure drop is recorded across the proximal lesion (1) – the proximal lesion should be stented.

Technical aspects

Percutaneous intervention of diffuse coronary artery disease is challenging. Deciding how much of the vessel to stent may not be straightforward and therefore adjunctive diagnostic modalities to coronary angiography, such as IVUS or FFR, may have to be employed to determine the extent of stenting. Even after deciding which segment to treat, delivery of devices across areas of diffuse disease can be difficult. In particular, lesions that are calcified and/or occupy bends in the vessel can be particularly challenging.

Device delivery

Stent delivery into diffuse coronary artery lesions can be difficult because of increased mechanical resistance, location of disease around vessel bends, and in certain subsets of patients such as those with chronic kidney disease associated with calcification. Therefore it is important to pre-treat these lesions adequately prior to making an attempt to deliver a stent. There should be a low threshold for preparing a lesion with rotational atherectomy in diffusely calcified lesions (see Chapter 22 for details of this technique). Use of rotational atherectomy will significantly increase the likelihood that all portions of the diffuse lesion will be uniformly and adequately dilatable with a balloon. After rotational atherectomy, a high pressure balloon sized 0.5 mm smaller than the reference vessel diameter should be inflated to high pressures at the areas to be stented. The use of a balloon sized slightly smaller than the vessel, inflated to high pressures ensures adequate expansion of the lesion without undue barotrauma.

Even after adequate balloon dilatation and expansion, delivery of a stent can be difficult. The same techniques to enhance stent delivery in small vessels can be used. The use of a stiff support wire enhances delivery by providing a more stable platform to advance devices such as a balloon or stent. If a “buddy wire” system is used and the lesion occurs at a bend in the vessel, it is helpful to advance the stent over the softer non-support wire, because there will be less biasing against the vessel wall. This concept is illustrated in Figure 20.2. In straight lesions, delivery of the stent can be tried over the support wire if it fails to deliver on the softer wire. Guide extenders provide further support. Care should be used when “deep seating” these devices into coronary arteries with diffuse disease, because the risk of dissection is higher than when it is advanced into relatively disease-free segments of coronary arteries. In general, these devices should not be advanced into a segment of the artery that for whatever reason cannot be stented.

Plain old balloon angioplasty

In some cases diffuse coronary artery disease is not amenable for therapy with stents: the stents is undeliverable or the vessel size too small. If surgical revascularization is not feasible, stand-alone balloon angioplasty may be the only treatment option. When treating a lesion with only angioplasty or POBA, a long non-compliant balloon sized 1 : 1 to the vessel should be inflated to nominal pressure. Contemporary non-compliant balloons come in lengths of up to 30 mm. After the lesion is sufficiently dilated, the balloon should be kept inflated for about 1 minute at 50% of nominal pressure. This prolonged ballooning at less than nominal pressure will “tack up” potential dissection flaps without causing excessive barotrauma to the vessel. It is important to utilize a non-compliant balloon. Inflation of a long compliant balloon in a diffuse lesion at the high pressures that are required to adequately dilate a lesion can result in severe local barotrauma and flow-limiting dissection as a result of uneven inflation. The results from balloon-only treatment

Figure 20.2 (a) 90° angulation in the vessel has set up a condition for wire bias. (b) The stiff support wire has “straightened” the vessel at the expense of causing wire bias against the vessel. Delivery of a device over this wire may be problematic because it may be “biased” against the vessel wall. Delivery over the device over the less stiff delivery wire is associated with less bias.

of diffuse coronary artery disease when compared to stenting are poor. Restenosis rates and target lesion revascularization rates can be as high as 42% and 21%, respectively [32]. Furthermore, balloon angioplasty of diffuse lesions can result in flow-limiting dissections demanding bailout stenting, which is associated with a high rate of peri-procedure myocardial infarction [32,33]. POBA should be used as a last option for treatment of diffuse coronary artery disease.

Stent

The use of BMS in the treatment of diffuse coronary artery disease improved procedural success when compared to balloon angioplasty only, but TVR rates remained high [32,33]. The use of DES significantly improved patency rates over the use of BMS and decreased revascularization rates to single digits [21,22]. Long second generation DES are available: both everolimus- and zotarolimus-eluting stents are available in 38 mm lengths. Revascularization rates after 9–12 months’ follow-up after treatment of lesions longer than 30 mm with these stents are under 10% [34–36]. For lesions longer than 38 mm, placement of sequential stents with overlap is required. First generation DES overlap has been associated with increased in-stent restenosis rates [37]. Second generation

DES have been associated with better outcomes when placed in an overlapping configuration [38,39]. When more than two stents are used, overlap length should be minimized. The newer generation stents have thin strut architecture and therefore can be hard to visualize with fluoroscopy. Use of enhanced stent visualization imaging techniques (“stent boost”) can improve visualization to minimize overlap length [40].

Clinical outcomes

Percutaneous treatment of diffuse coronary artery disease is associated with less favorable outcome than treatment of more focal disease. Stand-alone balloon angioplasty is associated with poor outcome and should be avoided. Stenting diffuse coronary artery disease has been associated with poorer outcome than stenting focal disease. In fact, stent length has been identified as an independent predictor of in-stent restenosis [41]. Diffuse disease is prevalent in diabetics and presents a therapeutic dilemma. These patients are often not ideal candidates for surgical bypass because of poor targets for distal anastomosis [25]. Use of second generation DES have produced acceptable outcome in patients with diffuse coronary artery disease and should be used when possible.

Key points and summary

- The prevalence of diffuse coronary artery disease is high in patient subsets such as diabetics. The diffuse nature of disease can make them poor targets for bypass surgery and clinically significant disease must be treated percutaneously in selected cases.
- Angiography is the most common way to assess the severity of diffuse coronary artery disease. However, in some cases identifying a non-diseased part of the vessel to measure a reference vessel diameter can be challenging, and imaging modalities such as IVUS or OCT have to be employed. Additionally, the use of FFR is especially useful in evaluating severe sequential lesions in diffuse coronary artery disease.
- Delivery of equipment can be difficult in diffuse coronary artery disease, especially if the lesion is calcified or occupies a bend. Adequate vessel preparation prior to stent delivery is essential. Treatment with rotational atherectomy, followed by high-pressure balloon angioplasty, is essential prior to stent delivery if calcification is present. Use of buddy wire technique and guide extenders can help overcome resistance caused by biasing effects and long lesion length.

Tortuous vessel disease

Definition and prevalence

Coronary artery tortuosity is simply the presence of significant bends in the coronary vasculature. In the setting of PCI, vessel tortuosity is assessed in the portion of the vessel prior to the lesion. Various schemes have been proposed for quantifying the severity of coronary tortuosity [24,42]. Excessive tortuosity is defined by at least one bend $>90^\circ$ or >2 bends $>60^\circ$. Therefore, in general, the more acute the angle and the more bends prior to the lesion characterize increasingly tortuous coronary arteries. Excessive tortuosity is associated with decreased chance of PCI success and is associated with a greater likelihood of adverse outcome.

Coronary tortuosity is not infrequent. In some series, the prevalence of this anatomic finding is as high as 39% [43]. Although coronary tortuosity can occur in any vessel, the prevalence is higher in the left circumflex artery simply because the first bend of this artery as it comes off the left main artery can occur at a steep angle.

Additionally, the obtuse marginal branches of the left circumflex coronary artery often arise at close to 90° angles and contribute to general vessel tortuosity. The left anterior descending coronary artery has the second highest incidence of coronary tortuosity followed by the right coronary artery [43]. Fortunately, there is an inverse relationship of coronary tortuosity and presence of atherosclerotic coronary artery disease. However, in some cases, tortuosity itself can lead to ischemia because of changes in blood flow through the tortuous segments [42,44].

Anatomic and physiologic assessment

Coronary angiography is the mainstay of assessing lesions in tortuous coronary arteries and analysis of multiple views is required to assess lesions. If significant tortuosity is present in more than one coronary artery, overlap of the vessels results in an illusion of stenosis because of the Mach effect [45]. Every effort should be made to “open up” bifurcation points where this effect can be especially misleading. Lesion assessment should be undertaken before wiring tortuous coronary arteries because pseudo-lesions can appear [46]. Other modalities can be used to supplement data obtained from the coronary angiogram, but vessel tortuosity makes any method prone to producing artifactual data.

Intravascular ultrasound

Use of IVUS can be challenging in imaging tortuous vessels because it can be difficult to deliver in tortuous coronary arteries. The use of smaller 5 Fr imaging systems can make delivery easier. In particularly challenging cases, the IVUS catheter can be delivered using the buddy wire technique. Even after successful delivery of an IVUS catheter, care must be used in interpreting the data. Images obtained from tortuous segments of a coronary artery are difficult to analyze because wire bias can make acquisition of coaxial images difficult. Sudden decrease in CSA without corresponding increase in plaque burden, abrupt change in vessel geometry from a circular shape to an oval shape, or inexplicable changes in the relative areas of the vessel structures are clues that point to potential introduction of artifacts by vessel tortuosity.

Fractional flow reserve

FFR data can be difficult to obtain because of the challenges of negotiating vessel tortuosity with the wire. FFR wires can be difficult to maneuver. One way to overcome this is to use a more maneuverable wire to “straighten” the coronary artery prior to advancing the FFR wire. When using this technique, it is important to remove the non-FFR wire prior to obtaining hemodynamic data. Failure to do so can introduce artifact. Alternatively, the Acist Rxi™ (Eden Prairie, MN, USA) system allows delivery of the FFR device over any wire the interventional cardiologist chooses. Once an FFR device is delivered, care must be taken in analyzing the data as the accordion effect of the FFR device in a tortuous vessel can yield false positive results [47].

Technical aspects

Device delivery

Device delivery can be difficult in tortuous coronary artery disease. Use of the buddy wire system is a commonly used technique to overcome vessel tortuosity. Often, a stiff “support wire” is paired with a softer wire. Examples of support wires include the Mailman™ (Boston Scientific, Marlborough, MA, USA) and the Grand Slam (Abbott, Abbott Park, IL, USA). It is easier to wire with the non-support wire first and then wire with the less maneuverable support

Figure 20.3 (a) A severely tortuous right coronary artery with severe lesions in the proximal and distal portions (red arrows). (b) A 2.5 mm non-compliant balloon inflated in the distal right coronary artery to serve as anchor (red arrow). A Guideliner™ (Vascular Solutions, Minneapolis, MN, USA) is introduced into the proximal right coronary artery over the shaft of the inflated balloon (open arrow). (c) A Guideliner™ is advanced over the inflated balloon anchor to the distal right coronary artery (red arrow). (d) A stent was delivered through the Guideliner™ and successfully deployed in the distal lesion (red arrow). A similar approach was used to successfully treat the proximal right coronary artery lesion (open arrow).

wire. Initially, devices should be advanced on the softer non-support wire. Often, the support wire will be so biased against the tortuosity that device delivery over this wire is difficult (Figure 20.2). If delivery over the softer wire is unsuccessful, an attempt to deliver the device over the support wire is sometimes successful.

Use of guide extenders can be crucial in successful completion of a tortuous coronary artery percutaneous intervention. These devices provide added support and allow a coaxial configuration of the guide–guidewire system to enhance delivery. The guide extenders can be “delivered” or deep-seated into the coronary artery over a wire. Deep seating is enhanced by advancing the guide extenders over two wires or over a support wire. In particularly tough cases, a balloon can be advanced into the distal portion of the target coronary artery and the guide liner can be advanced over the uninflated balloon. If the guide extender cannot be advanced over the uninflated balloon, further support can be obtained by inflating the balloon to serve as an anchor. The guide extender can then be advanced over the shaft of the inflated balloon. The anchoring

balloon should be sized 0.5 mm smaller than the reference vessel diameter so that barotrauma to the vessel is minimized. This concept is illustrated in Figure 20.3. In some cases the guide extender can be advanced over the inflated balloon shaft past the coronary artery lesion. If this is accomplished, the stent can then be advanced within the guide extender to the desired location and then unsheathed. Using this technique long stents can be delivered in extremely tortuous vessels.

When using deep seating techniques with the guide extenders, one should be aware of pitfalls. Significant decrease in coronary perfusion can occur due to the physical presence of the guide extender and straightening of the vessel. As a result the arterial pressure from the guide system may be damped and frequent non-invasive blood pressure monitoring has to be performed to assess for true systemic pressure. Frequent and repeated checks for ischemia should be performed and if detected the guide extender should be withdrawn immediately. Contrast dye injection through a deep-seated guide extender should be avoided as much as possible. When

it is absolutely necessary, cautious injections of small volumes of dye should be utilized. Large volume dye injection through a damped guide system can result in ventricular fibrillation. Additionally, hydrostatic trauma from an aggressive dye injection causes dissection. Significant dissection can also occur when advancing the guide extenders. This complication can be mitigated by advancing the guide extender over the shaft of the balloon.

Rotational atherectomy

Percutaneous intervention of tortuous coronary arteries with concomitant calcification can be particularly challenging. The key challenge is to deliver stents past a calcified tortuous bend. The use of rotational atherectomy can make delivery of devices much easier, but care must be taken because the risks of causing serious flow-limiting dissection and life-threatening coronary perforation are much higher when used in this subset of coronary artery disease. Often, the floppy RotaWire™ (Boston Scientific, Marlborough, MA, USA) is used, because this causes less bias than the extra support variety. In particularly challenging vessels, a transit catheter such as the Finecross™ (Terumo Cardiovascular Systems, Ann Arbor, MI, USA) is used to facilitate wiring of the lesion with a guidewire. Wires without a spring coil configuration at the tip such as the Fielder™ (Abott Laboratories, Abbott Park, IL, USA) or the Kinetix™ (Boston Scientific, Natick, MA, USA) can negotiate a tortuous coronary artery effectively and efficiently. Once the lesion is wired, the transit catheter is advanced past the lesion, the initial guidewire withdrawn, and the RotaWire™ advanced past the lesion through the transit catheter. The transit catheter is then withdrawn over the RotaWire™. A 1.25 mm burr is recommended to treat tortuous vessels, particularly if the lesion encompasses a bend. As a result of the bias caused by the wire, the 1.25 mm burr will make contact with the vessel wall and adequate vessel modification can be accomplished. Use of a larger burr greatly increases the probability of complications.

In tortuous vessels, the treatment of complications can be challenging. For example, it can be impossible to deliver a covered stent in cases of perforation. In cases of flow-limiting dissections, an unplanned quick delivery of a stent into a suboptimally prepared lesion is challenging. If the dissection is in the proximal portion of a major vessel, prolonged slow flow or no flow can result in catastrophic hemodynamic or arrhythmogenic consequences. Therefore, deliberate, carefully conducted, rotational atherectomy with a small burr is essential. In this very challenging subset of vessels, “less” may truly be “more.”

Clinical outcomes

Percutaneous coronary intervention of tortuous coronary artery disease can be difficult and fraught with potential complications. Significantly tortuous coronary arteries, designated AHA vessel classification types B and C, are associated with low success rates for successful intervention. Tortuous coronary arteries that are calcified are particularly difficult to address with percutaneous intervention. Potentially life-threatening complications can occur and prove difficult to treat.

Key points and summary

- Coronary tortuosity is not an infrequent finding. Tortuous coronary arteries with associated calcification represent one of the most challenging subset of vessels to perform percutaneous interventions.
- Assessment of coronary artery disease is performed primarily with angiography. Use of adjunctive imaging modalities such as

IVUS can be problematic because vessel tortuosity may not yield coaxial views. FFR should be used with caution because significant accordion effects yield false positive results.

- Adequately preparing the vessel prior to attempting stent delivery is crucial. Rotational atherectomy is very useful to prepare calcified vessels, but should be used cautiously because significant complications can occur and often these complications cannot be addressed quickly because of the difficulty in delivering corrective devices. Use of small burr size (1.25 mm) is mandatory and atherectomy runs should be deliberately slow and cautious.
- Device delivery can be enhanced by using buddy wire techniques and by using guide extenders. Guide extenders can be associated with significant complications such as vessel dissection. Guide extenders should never be traversed over a vessel segment that for whatever reason cannot or should not be stented.

In-Stent Restenosis in New Generation DES Era

Marco G. Mennuni and Patrizia Presbitero

Department of Cardiology, Humanitas Research Hospital, Rozzano, Milan, Italy

In-stent restenosis (ISR) represents the key limitation of bare metal stent (BMS) implantation as a result of excessive neointimal hyperplasia within the implanted stent. Drug-eluting stents (DES) were developed to address this limitation [1]. At the beginning of the DES era, the rate of restenosis reported was around zero [2]. Since then, interventionists have progressively employed DES in the treatment of patients with increasingly complex disease. As a consequence, DES restenosis rates have risen [3]. During the last decade, early generation DES were replaced by new generation devices releasing limus analogues, through more biocompatible polymer coatings, applied on thinner stent platforms. The favorable biocompatibility of new generation DES translated into an improved safety and efficacy profile, rendering these devices the standard of care for percutaneous coronary intervention (PCI) in current clinical practice. Nevertheless, ISR with the subsequent need for repeat revascularization is still observed in up to 10% of patients treated with new generation DES during long-term follow-up [4].

Definition

Angiographic restenosis, or “binary restenosis” after PCI, is defined as $\geq 50\%$ luminal narrowing at follow-up angiography. The most widely accepted definition of clinical restenosis, assessed as a requirement for ischemia-driven repeat revascularization, was proposed by the Academic Research Consortium, and it requires both an assessment of luminal narrowing and the patient’s clinical context [5].

Incidence

ISR was observed in around 20–30% of patients treated in BMS pivotal trials. The antiproliferative effectiveness of early generation DES reduced this incidence by approximately 70% [3]. A further significant improvement was obtained with new generation DES. It is noteworthy that antiproliferative effectiveness of DES was shown to be consistent across a wide spectrum of patient populations, including those traditionally considered at higher risk of ISR such as patients with acute myocardial infarction and with diabetes mellitus (Table 21.1). Clinical registries, which include patients

with more complex coronary lesions, are probably more accurate in revealing the true incidence of ISR in the real world, but could underestimate the restenosis rate because of underreporting of clinical events and low rates of angiographic follow-up. Restenosis rates from registries are 30%, 15%, and 12% at 6–8 months with BMS, first generation, and new generation DES, respectively [4].

The last technical evolution of DES is the bioresorbable vascular scaffold (BVS) system. This platform has a bioabsorbable polylactic acid scaffold with a bioabsorbable polylactic acid coating that elutes everolimus. At the beginning of BVS use, they had similar problems to BMS, which were mainly a result of the inadequacy of preimplant lesion preparation and stent deployment issues, such as lack of good expansion, geographic missing, and overlapping of thick struts, leading to a high incidence of restenosis. Nowadays, following the improvement in BVS technology and deployment technique, the rate of restenosis is around 3–5%; however, data are limited [6].

Clinical presentation

Although some cases of ISR are silent, the majority lead to ischemic symptoms. Reports on the presentation of both BMS and DES restenosis have shown that unstable angina is a frequent manifestation (20–60%). Moreover, depending on the definitions applied, both BMS and DES restenosis presented as myocardial infarction in 1–20% of patients [3]. During the last decade, among patients treated with DES, clinical presentation seems to be similar irrespective of DES generation [7].

Pathophysiologic mechanisms

Possible mechanisms of ISR after DES implantation have been thoroughly studied in the last decade. According to the available evidence, specific mechanisms have a different role according to timing of ISR presentation. The majority of data is derived from studies on ISR occurring within the first 12 months after DES implantation (early ISR) when excessive neointimal formation appears to be the dominant mechanism [8,9]. Conversely, late ISR—occurring beyond the first 12 months after DES implantation—appears to be triggered by different biologic mechanisms.

Table 21.1 Incidence of restenosis after first and new generation DES implantation in the randomized trial, grouped by selected population, all-comers, diabetic, and acute myocardial infarction patients.

Early restenosis

Biologic factors

Drug resistance Excessive neointimal hyperplasia is characterized by proliferation and migration of vascular smooth muscle cells and extracellular matrix formation as a response to local injury after stent deployment. Antiproliferative agents released by DES aim to suppress this process by inhibiting the cell cycle. Two classes of agents have been applied to DES for this purpose: paclitaxel and rapamycin analogues (i.e., “limus”).

Paclitaxel binds to the β -tubulin subunit of microtubules and interferes with microtubule dynamics during mitosis [10]. Resistance to paclitaxel has been described and appears to be associated with increased expression of the *mdr-1* gene and its product P-glycoprotein, β -tubulin mutation, changes in apoptotic regulatory and mitosis checkpoint proteins, and potentially the overexpression of interleukin-6 [11,12]. Currently, the relevance of paclitaxel resistance in the context of ISR remains unknown.

Limus agents inhibit the function of the mammalian target of rapamycin (mTOR), blocking protein synthesis, cell cycle progression, and cell migration [13]. Genetic mutations and defects of mTOR or mTOR-related proteins (FKB12P, p27-Kip1, etc.) can influence the sensitivity to limus agents, and confer drug resistance [14]. Moreover, it has been suggested that the presence of diabetes with hyperinsulinemia can determine mTOR-inhibition resistance of vascular smooth muscle cells proliferation [15–17]. This evidence could explain the strong association between insulin resistance and ISR [18,19]. Nevertheless, this hypothesis has not been confirmed by prospective clinical investigations.

Hypersensitivity In the BMS era, allergic reactions to nickel and molybdenum released from stainless steel stents were potential triggering mechanisms for ISR. The platform material used in many novel DES are alloys (e.g., cobalt chromium), which have a lower nickel content than stainless steel, and do not appear to trigger the adverse proliferative response and hypersensitivity [3].

Mechanical factors

The efficacy of DES is based on delivering therapeutic concentrations of drug to the underlying tissue. Hemodynamic environments surrounding the stent modulate the drug distribution pattern to the arterial wall. *In vitro* and *in vivo* studies have shown that drug release appears to be sensitive to flow alteration secondary to wall displacement and stent malapposition [20,21]. Therefore, a number of mechanical factors could determine the occurrence of ISR.

Incomplete stent apposition Incomplete stent apposition, defined as the lack of contact between at least one stent strut and the underlying intimal surface of the vessel, increases the risk of ISR. Typical causes of incomplete stent apposition:

- 1 Inadequate stent implantation because of stent–vessel size mismatch; stent under-expansion despite adequate stent–vessel ratio because of low implantation pressure or complex plaque;
- 2 Acute or chronic stent recoil;
- 3 Resolution over time of thrombus located between the stent struts and the vessel wall; and
- 4 Positive vessel remodeling.

A further classification has been created according to the timing of incomplete stent apposition diagnosis: acute (i.e., diagnosed

post-stent deployment) or acquired (i.e., not present post-procedure, but identified at follow-up assessment). Early detection of incomplete stent apposition remains crucial, because acute incomplete stent apposition affects the overall vascular response, leading to delayed stent strut coverage [22].

Stent fractures Stent fractures have been associated with ISR, because of its potential decrease in local drug delivery at the fracture point and/or mechanical injury. Stent fracture after both first generation DES have been reported, with an incidence rate of 2–3% [23,24], with a restenosis rate ranging from 15% to 65% [25–28]. Predictors of stent fracture:

- 1 Use of long stent
- 2 Use of large high-pressure balloon post-dilatation
- 3 Use of sirolimus-eluting stent (SES)
- 4 Stenting on a bend $>75^\circ$, and
- 5 Stenting in a right coronary artery or in a saphenous vein graft [29–32].

The observed rate of stent fracture and the association with major adverse pathologic events were comparable across first and new generation devices, indicating that careful long-term follow-up remains important even after everolimus-eluting stent (EES) implantation [33].

Technical factors

Stent gap and incomplete plaque coverage represents a theoretical mechanism of stent restenosis. Stent gap has been demonstrated to be associated with ISR [34]. Theoretically, the amount of local drug deposition to the vessel wall decreases at the gap site. Considering that the safety and efficacy of overlapping DES have been reported, stent gaps should be avoided [35]. When treating ostial, bifurcation, and/or long lesions, it is sometimes difficult to avoid incomplete lesion coverage [36]. The presence of geographic miss during the procedure (injured or diseased segment not covered by stent or balloon-artery size ratio <0.9 or >1.3) is associated with increased risk of total vascular reocclusion (TVR) and myocardial infarction at 1 year [37]. Today, the availability of new generation DES with better mechanical performance characteristics and greater stent length allow them to cover very long lesions, avoiding multiple stents [38]. The recommended technique includes predilatation with shorter balloons, using a longer single stent to cover the entire area of balloon injury, and post-dilatation within the stented regions using short high-pressure balloons. Following these recommendations, the proximal margin restenosis rates have decreased [39,40]. However, recent data studying angiographic patterns of restenosis demonstrate the persistence of a high rate of edge restenosis among those with a focal presentation [7].

Late restenosis

In addition to early restenosis factors, a late restenosis might be secondary to hypersensitivity reactions or new atherosclerotic processes. Early generation DES are associated with delayed arterial healing and hypersensitivity reactions resulting in chronic inflammation. A hypersensitivity reaction to polymer, drug, or scaffold leads to restenosis [41]. Second-generation DES have been developed to overcome these issues. In a pathologic study, use of new generation cobalt chromium EES (CoCr-EES) resulted in greater strut coverage with less inflammation than SES or

paclitaxel-eluting stent (PES) [33]. Nevertheless, a hypersensitivity reaction has been reported in second generation DES in both CoCr-EES stent and zotarolimus-eluting stent (ZES) [42].

The presence of chronic hypersensitivity phenomena can also trigger a neoatherosclerotic process. Late and impaired healing of the endothelium, after DES, facilitates lipid deposition within neointima [43]. In this setting, neointima is more prone to develop neoatherosclerosis and unstable plaque either behind the stent or within the intraluminal neointima [44–46]. In light of the fact that late DES failure is more likely to progress to acute myocardial infarction, and worse outcomes [47], early detection of subcritical in-stent neoatherosclerotic plaques can be used as a marker of high risk lesions and patients.

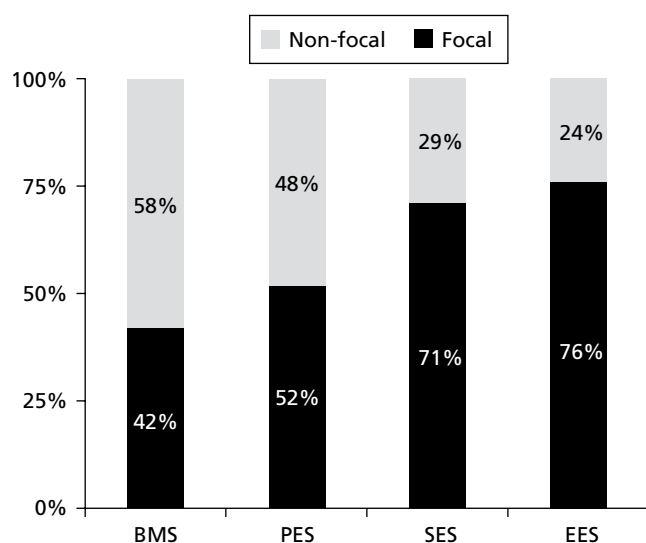

Figure 21.1 Morphologic pattern of restenosis across different stent generation. BMS, bare metal stent; EES, everolimus-eluting stent; PES, paclitaxel-eluting stent; SES, sirolimus-eluting stent. Source: Adapted from Mehran *et al.* [48], Cosgrave *et al.* [57], and Lee *et al.* [8].

Morphologic pattern of DES restenosis

The classification of angiographic patterns of ISR has been shown to be of crucial prognostic significance [48–50]. The incidence and pattern of restenosis were different between BMS and DES, and among different type of DES. In particular, BMS resulted in a diffuse pattern in 60% of restenosis cases. The rate of diffuse restenosis decreased to 40–50% with use of first generation PES [51], and further lowered with SES (about 20%) in both randomized trial and registry (Figure 21.1) [52,53]. A comparison study between PES and SES confirmed higher incidence of diffuse and occlusive restenosis with PES when compared with SES use [54]. Restenosis presenting as total occlusion is rare, but remains associated with worse outcome at follow-up [55]. Recently, a retrospective study on new generation DES (everolimus and zotarolimus) reported diffuse restenosis rate similar to SES, around 15–20% of ISR cases [56].

Prognostic implications for morphologic patterns of ISR

Mehran *et al.* [48] reported that target lesion revascularization (TLR) at 1 year after repeat intervention for ISR increased progressively with ISR classification (focal 19%, intra-stent 35%, proliferative 50%, total occlusion 83%; $p < 0.001$). Similar to BMS, first generation DES ISR studies demonstrated that diffuse patterns were associated with worse clinical outcomes [3,49,57]. The diffuse pattern even in new generation DES is theoretically associated with adverse events, but no evidence has yet been reported.

Predictors of DES restenosis

Unfavorable demographic, clinical, and angiographic characteristics confer an increased risk for ISR after DES implantation. These data are mainly based on first generation DES experience and are summarized in Table 21.2. The predictive factors for first generation DES restenosis identified from real-world data seem to be similar to those for BMS, such as small vessels, longer stents, and stent underexpansion [58–61]. Currently, with use of newer generation DES, lesion length might not be associated with higher risk of restenosis, because of better healing properties, thinner profile, and availability of longer sizes that lead to a theoretical reduction of stent overlapping. On the other hand, thinner struts might result in a higher rate of stent fractures, which is strongly

Table 21.2 Predictors of restenosis.

Demographics characteristics	Clinical characteristics	Lesion characteristics	Procedural characteristics
Age	Diabetes mellitus	Multivessel coronary disease	Multiple lesion treatment
Female gender	Multivessel CAD	ISR	Type of DES
		Bypass graft	Final MLD
		LAD	
		Ostial lesion	
		Chronic total occlusion	
		Small vessel	
		Length	
		Severe calcification	

CAD, coronary artery disease; DES, drug-eluting stent; ISR, in-stent restenosis; LAD, left anterior descending; MLD, minimum lumen diameter.

associated with restenosis [61]. Recent studies confirmed older age, multivessel treatment, small vessel size, increased stented length, complex lesion morphology, diabetes mellitus, and prior bypass surgery as predictors of restenosis after new generation DES implantation [4,62,63]. Considering that post-minimal lumen diameter is a major factor in restenosis, optimal acute angiographic result remains crucial even after new generation DES implantation.

Role of intravascular imaging

Intravascular ultrasound (IVUS) and optical coherence tomography (OCT) permit detailed cross-sectional imaging of the deployed stents. Factors associated with DES restenosis can be detected through IVUS and or OCT information. IVUS and OCT complement each other for the study and diagnosis of incomplete stent apposition. IVUS has higher tissue penetration power (4–8 mm) compared with OCT (1–3 mm), but it has lower axial resolution (150 vs. 15 μ m). With these characteristics IVUS enables the visualization of the external elastic membrane, to quantify the vessel size and to assess positive vascular remodeling [64], while OCT allows a sharper picture of the stent–lumen interface [65]. IVUS is important in evaluation of the mechanical factors that contribute to stent restenosis:

- 1 Stent underexpansion
- 2 Edge problems and stent gaps in multiple stenting
- 3 Stent fracture
- 4 New atherosclerosis vs. neointimal hyperplasia.

Furthermore, intravascular imaging is very important in the optimization of restenosis to guide the choice between new balloon and stent size.

Approach to DES restenosis

Despite the many studies analyzing the best treatments for stent restenosis that have been published, the optimal strategy for DES restenosis remains poorly defined. Evidence from meta-analyses seems to suggest a similar efficacy of drug-eluting balloons (DEB) and DES [66].

Drug-eluting balloon

The local application of antiproliferative drugs with a balloon for treatment of ISR emerged from the limitations of current techniques: the high occurrence of restenosis with conventional balloon angioplasty or with the debulking technique, and the shortfalls of implanting an additional metal layer, particularly in small vessels and in bifurcations. The available DEB deliver paclitaxel, eluted at 3 μ g/mm². DEB are coated with a matrix composed of paclitaxel and a hydrophilic spacer (matrix carrier). This coating method allows the best solubility of paclitaxel and its transfer to the vessel wall [67]. The hydrophilic character of the matrix carrier and the lipophilic properties of paclitaxel support the release of the drug from the balloon to the vascular wall, and the drug elution lasts 1 week. However, matrix represents a key limitation of this technology; it makes DEBs rigid and thick compared to the conventional balloon, so it is more difficult to navigate them through tortuous and narrow vessels. Nevertheless, DEB has some theoretical advantages over DES:

- 1 Avoiding stent-polymer inflammation trigger
- 2 Delivery of antiproliferative drug exactly where the barotrauma has been induced by balloon, and
- 3 Avoiding multiple layers of stents.

Several studies on DEB either vs. conventional balloon angioplasty (BA), DES, or both showed a better performance of DEB compared with BA, and an equivalent or only mildly worse performance in comparison with PES in term of clinical and angiographic outcomes [68–75]. As a matter of fact, although binary restenosis and late lumen loss were similar between DEB and PES, target lesion revascularization was only mildly higher in DEB than PES. These findings suggest that in big vessels, use of new DES for treatment of restenosis might offer better results in term of further revascularization [72]. Theoretically, the extent of restenosis burden, such as in case of diffuse ISR or total occlusion, may be responsible for a suboptimal performance of DEB. The persistence of large amount of intimal hyperplasia or neoatherosclerotic plaque not properly squeezed after preliminary ballooning is well detectable by angiography; it is important to carefully evaluate the angiographic result after a balloon pre-dilatation, before deciding to proceed with DEB or to shift to DES implantation.

Drug-eluting stent

As the clinical and angiographic results of DES use for BMS restenosis were superior to those with conventional therapy in several randomized trials, DES are also used as a re-treatment modality for DES restenosis. Almost all the studies comparing clinical and angiographic effects of re-DES treatment with conventional therapy for DES restenosis showed a superiority of DES. As a result, guidelines recommend DES to treat patients with ISR irrespective of the type of the initial stent (BMS or DES) [76]. The longer follow-up at 4 years after treatment of BMS restenosis with SES reported an incidence of further restenosis of 25% [77]. The incidence of new restenosis after DES re-treatment varies greatly between 4% and 20% in the various series within 1 year; for these reasons the long-term efficacy of further DES deployment remains uncertain. As drug resistance may be the mechanism of DES restenosis, it was conceived that the placement of a different DES could be more effective in treating DES restenosis compared with the same DES. However, (i) almost all the studies available compared SES vs. PES and few data are available with different “limus” stent, and (ii) the studies showed contradictory results [78]. More recently, use of new generation DES for treatment of BMS restenosis was tested in the RIBS-V trial [74]. This study showed that both EES and PEB provided very low clinical and angiographic recurrence of restenosis, but with EES showing superior angiographic results. Likewise, the RIBS-IV trial analyzed the treatment of DES restenosis and it resulted in similar findings to RIBS-V [79]. From these data it seems that the new generation DESs represent a good approach even in patients with focal pattern to treat DES ISR.

As far as BVS is concerned in treatment of ISR, anecdotal reports show that its use is feasible and theoretically attractive because it avoids multiple metal layers deployed on the vessel wall. However, many concerns regard strut thickness, lack of flexibility, radial strength, and recoil, to contraindicate BVS use for restenosis treatment.

Proposed treatment strategies of DES restenosis

As the etiologies of DES restenosis are diverse, it is recommended to use IVUS or OCT in order to understand the mechanism of restenosis, and to drive therapeutic strategy. Figure 21.2 proposes an algorithm for the current approach to new generation DES restenosis. If restenosis is focal within the stent body or secondary to stent underexpansion, DEB use is recommended; while if the focal edge is involved, which probably means uncovered atherosclerotic plaque or plaque shift, a new generation DES is recommended, and

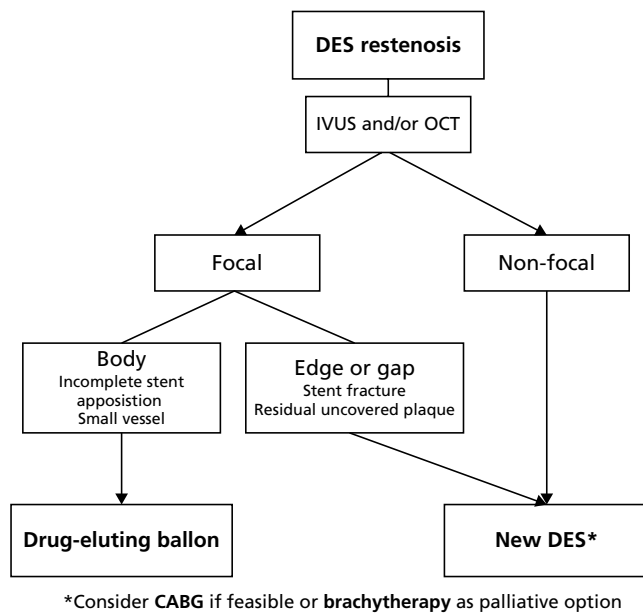

Figure 21.2 Algorithm for the treatment of drug-eluting stent (DES) restenosis. CABG, coronary artery bypass graft; IVUS, intravenous ultrasound; OCT, optical coherence tomography.

different drug elution use might be considered. In small vessels (diameter less than 2.5 mm) use of DEB is preferable in order to avoid a further metallic layer. In diffuse disease, which is currently rare, DEB could be a good choice, because of lack of long-term follow-up after second generation DES used in this setting. However, in case of suboptimal angiographic results, after high-pressure balloon angioplasty resulting in persistence of a high amount of material unable to be squeezed by the balloon, DES in DES is the best option.

Despite advances in percutaneous coronary intervention (PCI) technology, difficulty in crossing or dilating calcified coronary lesions remains one of the greatest challenges in contemporary practice. Given that the aging population, increased rates of renal failure, and diabetes mellitus all contribute to the burden of coronary calcification, it is likely that this will be a growing problem. Compared with non-calcified lesions, increased intracoronary calcium deposition leads to a higher incidence of major adverse cardiovascular events, particularly myocardial infarction [1]. They are also associated with a higher frequency of restenosis, target lesion revascularization (TLR), vessel dissection during PCI, failure to deliver a stent, balloon ruptures, and undilatable lesions [2–7]. Furthermore, up to 50% of stents deployed in calcified lesions have been shown to have asymmetric expansion, potentially increasing the likelihood of restenosis and stent thrombosis [8,9].

Many of these challenges can be overcome by adequate lesion preparation. This chapter summarizes three atherectomy techniques (AT) that are employed as treatment strategies for calcific coronary lesions:

- 1 Rotational atherectomy (RA) – the oldest and perhaps most widely used
- 2 Orbital atherectomy (OA) – a relatively newly developed modality, and
- 3 Excimer laser coronary atherectomy (ELCA).

Background

Rotational atherectomy

Arterial dissection, early vessel elastic recoil, and later restenosis because of cell proliferation lead to a failure to maintain vessel patency after plain old balloon angioplasty (POBA). Long and calcified lesions are particularly non-compliant and high balloon inflation pressures may be needed. Shearing forces, persistence of the shifted atheromatous mass (containing cells capable of proliferation), and a stimulus to proliferation resulting from balloon injury are important features in determining POBA failures. An ablative technique that can restore vessel patency by selectively removing atheromatous bulk without injuring more normal vessel components has the potential to overcome some of the shortcomings of POBA. In this context, RA was developed in the late 1980s as an alternative

percutaneous method for lumen enlargement [10,11]. Randomized trials demonstrated some advantages of RA over POBA in procedural success but not in reducing rates of restenosis [12,13]. Additionally, the subsequent development of routine stenting very effectively solved the POBA problems of vessel dissection and elastic recoil thereby discouraging more widespread adoption of RA.

However, problems with cell proliferation and in-stent restenosis (ISR) remained major determinants of TLR, affecting as many as one-third of stented lesions. Balloon treatment of ISR was frequently complicated by recurrent restenosis, particularly when restenosis was diffuse along the length of the stent. The persistence and elastic recoil of the proliferating cell mass were thought to be responsible for balloon failure and recurrent restenosis. Therefore a benefit for lesion ablation with RA was postulated. However, the success of RA in this situation remained equivocal after the publication of two randomized trials with contrary findings [12,14,15]. Stent development, with the introduction of drug-eluting stents (DES), has significantly reduced rates of ISR as a reason for TLR. However, a major challenge to contemporary PCI is the accessibility of some lesions, particularly calcified lesions, to balloon or stent placement, or to balloon dilatation. In complex lesions, even high inflation pressures may not achieve satisfactory stent expansion in as many as half of the cases. Restenosis and acute stent thrombosis occur more frequently following such procedures.

RA alters the physical characteristics of the obstructing lesion, reducing its physical bulk and rigidity, and increasing the accessibility of the debulked coronary segment to balloon and stent devices. As such, RA improves lesion access and can optimize minimum lumen diameter (MLD) gains as an adjunctive technique to enable and/or optimize stenting. RA offers more predictable lesion preparation and consequently avoids the risk of vessel perforation from very high balloon dilatation inflation pressures.

Excimer coronary laser atherectomy

Excimer lasers are pulsed gas lasers that use a mixture of a rare gas and halogen as an active medium to generate pulses of short wavelength, high-energy ultraviolet light. After application of an electrical discharge, energy absorbed by the individual atoms results in their being in a higher energy state. Electronic excitation of one of the atoms (halogen) initiates bonding with the other atomic species

(argon, krypton, or xenon), resulting in the formation of an electronically “excited dimer” molecule or “excimer.” As the molecule returns toward the ground state, short wavelength (and corresponding high photon energy) ultraviolet radiation is emitted. Work in the 1980s demonstrated that the ultraviolet radiation emitted by an excimer laser could be used to inscribe exceptionally clean and precise etching cuts in cardiovascular tissue including atherosclerotic coronary artery segments [16], and subsequently in vein grafts [17] and native coronary artery disease [18–20]. Early clinical results in the era of POBA were mixed [21,22]. Randomized studies comparing ELCA, RA, and POBA showed that procedural success was better with RA than ELCA and POBA but high rates of TLR were seen with all three modalities at 6 months’ follow-up [23].

The development of coronary stents, with adjunctive RA, resulted in reduced use of ELCA as a routine technique. However, it still has a key role as an adjunct in specific clinical situations: the treatment of non-crossable or non-expandable coronary lesions; under-expanded stents [24,25]; and in aortocoronary saphenous vein grafts where there is a preponderance of fibro-calcific as well as thrombotic material [26–28]. It has also shown utility in the setting of acute myocardial infarction and large thrombus burden [29,30].

Orbital atherectomy

The Orbital Atherectomy System (Diamondback 360° OAS, Cardiovascular Systems, CSI, St. Paul, MN, USA) is a technique that has recently become available as an adjunctive tool for coronary lesion preparation. This has become an established technique in the treatment of calcific peripheral vascular disease and has recently shown utility in the coronary arena. Although relatively new, with the first study showing safety and efficacy only being published in 2014 [31], it will add to the catheter laboratory armamentarium in the treatment of severe coronary calcification.

Rotational atherectomy

Technical considerations

The business end of rotational atherectomy (Rotablator, Boston Scientific, MA, USA) is a nickel-plated brass elliptical burr coated with diamond microchips on the front or crossing surface of the burr, with the rear half of the burr having no diamond chips and therefore no ablating surface (Figure 22.1). Rotational speeds up to 190,000 rpm are transmitted via a flexible drive shaft enclosed within a Teflon sheath (4.3 Fr) connected to a gas-driven turbine. Burr sizes

Figure 22.1 Rotablator system with burrs, console, Rotalink system. (a) A single advancer can be used for multiple burr exchanges. (b) The diamond-coated burr is advanced on the guidewire and torque transmitted via the Teflon-coated 4.3 Fr sheath. (c) Control console and foot pedal. Images courtesy of Boston Scientific.

of 1.25, 1.5, and 1.75 mm can be accommodated by most 6 Fr guiding catheters. Notably, the use of a 1.75 mm burr with the 6 Fr guide will cause pressure dampening. The minimum guide size for a 2.0 mm burr is 7 Fr. Burr sizes of 2.15 and 2.25 mm can be accommodated by most 8 and 9 Fr guiding catheters. Burr sizes of 2.38 and 2.50 mm require alternative guides with 9 and 10 Fr lumen diameters, respectively. Following passage of a proprietary spring-tipped steel guidewire (Boston Scientific, RotaWire, 0.009 inches) into the distal vessel beyond the target lesion, the shaft-mounted burr is advanced into position proximal to the lesion over the RotaWire.

In some of the early RA studies, inability to pass the RotaWire into the distal vessel accounted for most procedural failures. A variety of RotaWires with different characteristics is now available. Many operators believe that these wires are less torque responsive than other coronary guidewires, and therefore it can be difficult to wire a complex lesion primarily with a RotaWire. In this instance, a regular .014 inch guidewire can be used to cross the lesion and an over-the-wire balloon or microcatheter tracked through the lesion after which the crossing wire is exchanged for a RotaWire. This technique can be used to traverse particularly challenging lesions such as chronic total occlusions (CTO).

A saline-based infusion cocktail delivered through the Teflon-coated sheath provides lubrication for the drive shaft. Heparin anticoagulation (typically 70 IU/kg 5000 IU in 500 mL normal saline) and vasodilators (verapamil 5 mg and isosorbide dinitrate 5 mg) are frequently added to the cocktail and are delivered directly into the coronary artery. Systemic anticoagulation aims for an activated clotting time of about 300 seconds. Historically, a temporary transvenous pacemaker was often positioned when rotabating right coronary artery disease or dominant left circumflex lesions to manage the transient atrioventricular block that often occurred. However, with contemporary practice using smaller burrs, shorter runs, and atropine pre-treatment, bradyarrhythmic complications are rare and pacing is unnecessary.

Once an appropriately sized burr is in position proximal to the lesion and it is confirmed that cocktail is reliably being delivered, the drive is switched on and engaged. Rotational speeds are typically between 130,000 and 150,000 rpm [7,13]. More rapid rotational speeds generate excessive heat and also result in greater platelet activation [32]. Lower speeds can result in ablative behavior less selective for atheroma, but in general is associated with fewer complications. The burr is advanced slowly into and beyond the target lesion and with care taken to maintain rotational speed as the burr encounters friction; if rotational speed drops, retreat from the target lesion may be necessary. Significant decrements in rotational speed (>5000 rpm) must be avoided as these are associated with excessive heat production through friction and are associated with poorer immediate and long-term outcomes [33,34]. Sudden drop in burr speed is also associated with burr trapping in the lesion, hence the cautious advancement and attention to burr speed.

Burr advancement is best accomplished in a piecemeal “pecking” fashion rather than through steady constant movement. The recommended movement comprises short (about 10–20 second) runs of slow, smooth advances of the burr into the lesion followed by retreat. The burr should not be forced through the lesion. Because the rear of the burr does not have an abrading surface, the device can become trapped beyond the lesion and it can be difficult to pull back. The operator should retreat from the lesion between “pecks” in order to maintain rotational speed and enable coronary blood flow to flush ablative debris beyond the lesion.

After the lesion is crossed, the spinning burr is passed back and forth across the lesion until the operator feels no further significant

resistance to the burr. Larger burrs can then be selected and the procedure repeated, typically until a maximum burr size of 60–80% of the reference vessel diameter has successfully crossed the lesion. More modest degrees of ablation can be associated with fewer short and long-term complications [34,35], and in any case may be considered satisfactory if the principal indication for RA has been to debulk rather than abolish the lesion (as an adjunct to stenting) or to facilitate tracking of balloons or stents across the target lesion. A strategy using a single 1.5 or 1.75 mm burr is satisfactory for the majority of cases.

The rotating burr abrades atherosclerotic material, selectively removing non-compliant tissue to improve vessel patency. Intravascular ultrasound (IVUS) examination following RA typically demonstrates a circular lumen with a smooth distinct luminal–vessel wall interface distinct from that seen following balloon barotrauma [36]. The diameter of the newly created lumen usually tends to exceed that of the largest burr used, perhaps because of non-axial movement of the burr about its long axis, or as a consequence of vessel spasm during ablation [11,36].

In vitro studies suggest that normal (compliant, soft) vascular tissue is relatively unharmed and therefore not easily abraded, but that more rigid, calcified structures are more amenable to abrasion [11,36]. Burr abrasion generates minute particles (5–10 µm) which are propagated distally into and through the coronary microcirculation. Consequences of distal microembolization of these atheromatous particles and of platelet activation by the rotating burr are believed to contribute to vessel spasm and no-reflow complications observed during RA. *In vitro*, glycoprotein (GP) IIb/IIIa inhibitors attenuate platelet activation resulting from RA, and are associated with fewer ischemic complications although in practice with good technique and appropriate burr sizing, no-reflow is a rare complication. A small randomized study showed that use of GP IIb/IIIa inhibitors results in lower increases in serum cardiac enzyme concentrations during RA [37], although larger studies are required to support routine use.

Indications for RA

Calcific lesions

The principal indication for RA is in the treatment of calcific lesions, which in the absence of lesion preparation or modification confer an increased likelihood of procedural failure, stent underdeployment, restenosis, and major complications [38]. In such lesions, RA both enables and optimizes stenting, facilitating procedural success in complex lesions, chronic total occlusions, ostial lesions, and bifurcation lesions associated with bulky plaque and vessel geometry unfavorable for stent deployment [8,23,39–44].

In-stent restenosis

Although it had previously been established as a promising treatment option for ISR with favorable outcomes, in the DES era RA has largely been superseded in this situation by balloon angioplasty, drug-eluting balloons, cutting or scoring balloons, DES, or coronary artery bypass grafting (CABG) [45]. The two randomized studies that have addressed this issue have reported apparently discrepant results. The single-center US Rotational Atherectomy versus Balloon Angioplasty for Diffuse In-Stent Restenosis (ROSTER) study [15] reports that RA was associated with a much lower rate of repeat stenting than POBA (10% vs. 31%; $p < 0.001$) and a lower TLR incidence (32% vs. 45%; $p = 0.042$). Importantly, one-third of patients evaluated for inclusion in ROSTER were excluded from the study if prior IVUS demonstrated evidence of inadequate stent expansion.

The multicenter European Angioplasty versus Rotational Atherectomy for Treatment of Diffuse In-Stent Resenosis Trial (ARTIST) [14] did not evaluate adequacy of stent expansion with IVUS prior to randomization. Balloon treatment was associated with better outcome; 6-month event-free survival was significantly better after POBA than with RA (91% vs. 80%; $p < 0.01$). IVUS results at follow-up are consistent with the interpretation that a factor favoring POBA was the resulting stent overexpansion. As registry data suggest that as many as 50% of stents are incompletely deployed [8], and ROSTER detected this in one-third of their ISR patients, ARTIST results may be heavily biased by results of balloon treatment of inadequate stent expansion. ARTIST should therefore not be considered to have evaluated the efficacy of RA for treating ISR occurring in optimally deployed bare metal stents (BMS). It is intuitive that RA is most beneficial for removal of intimal hyperplasia but less effective for radial expansion of an underexpanded stent. If RA is contemplated for use in DES ISR, pre-treatment imaging with IVUS or optical coherence tomography (OCT) may be warranted to first elucidate the mechanism of restenosis.

Contraindications to RA

Contraindications to RA include saphenous vein graft lesions, thrombus, dissection, and occlusions through which a guidewire will not pass, although there are reports in the literature of successful use of RA despite contraindications.

Avoiding complications

The complications of RA are similar to those of PCI, and include vascular access complications, stroke, myocardial infarction, urgent CABG, death, dissection, perforation, acute vessel closure, side branch loss, and slow-flow and/or no-reflow. Additional complications of RA includes burr entrapment, estimated at 0.5–1%. Smaller burr sizes (burr–artery ratio < 0.7) reduces angiographic complications and peri-procedural enzyme release with similar procedural success [34,35]. Smaller burrs permit use of smaller guide catheters and therefore sheaths, permitting safe and effective transradial RA in the majority of cases, and resulting in fewer vascular complications. Smaller guide catheter use also limits RA-associated stroke [46].

Slow-flow and no-reflow during RA are likely related to microvascular embolization of atherosclerotic debris and thrombus. Strategies to prevent this include antiplatelet therapy, vasodilators, and meticulous technique. Vasodilators used for the purpose of reducing slow-flow and no-reflow include adenosine, calcium antagonists, nitroglycerine, and nicorandil.

Techniques to avoid burr entrapment have been described earlier. If this does occur, timely action is required to remove the entrapped burr. The most common solution in the literature is surgical removal with CABG; however, interventional approaches can be divided into two techniques: dilation of the lesion with balloon angioplasty, and burr removal facilitated by deep catheter intubation. These are described in detail elsewhere [47].

Excimer laser coronary atherectomy

Technical considerations

Background technical considerations to ELCA have already been described. The CVX-300 cardiovascular laser excimer system (Spectranetics, Colorado Springs, CO, USA) uses xenon chloride (XeCl) as the active medium. Consequently, the light emitted is pulsed and lies in the ultraviolet B (UVB) region of the spectrum

with a wavelength of 308 nm and a tissue penetration depth of 30–50 μm . This shallow absorption depth limits medial and adventitial tissue damage in standard PCI. Significant thermal ablation is avoided because of the pulsed delivery of high-energy pulses that last only a fraction of a second. The number of pulses emitted during a 1 second period is known as the pulse repetition rate. The duration of each pulse is termed a pulse width, which can be modified according to the nature of the treated lesion.

Tissue breakdown via photo-ablation occurs in three steps. First, rapid UV light absorption occurs resulting in severing of carbon–carbon bonds, with subsequent dissipation of energy. This energy dissipation leads to evaporation of intracellular water to produce a steam bubble that advances ahead of the laser catheter. Tissue breakdown occurs as a result of rapid expansion and contraction of these steam bubbles. The threshold energy required for the penetration of UV light into the surrounding tissue and the subsequent creation of a steam bubble is called fluence (range: 30–80 mJ/mm^2). High pulse energy delivery is more efficacious in managing calcified lesions. The resultant debris particles are $< 10 \mu\text{m}$ in diameter with minimal risk of distal embolization [48].

ELCA catheters are compatible with a standard 0.014 inch guidewire and are available in four diameters for use in the coronary artery (0.9, 1.4, 1.7, and 2.0 mm). The catheters most commonly used have a concentric array at the tip, but eccentric laser catheters are also available which are potentially better for debulking in ISR (Figure 22.2a). The larger diameter devices (1.7 and 2.0 mm catheters) are primarily used in straight sections of large diameter vessels, for example saphenous vein grafts. They require 7 and 8 Fr guide catheters, respectively. Both the 0.9 and 1.4 mm are 6 Fr compatible catheters but only the 0.9 mm X-80 ELCA catheter is routinely used in balloon failure and CTO cases because of its excellent deliverability, high power, and repetition rate settings. The 0.9 mm catheter contains 65 fibers of 50 μm diameter each and the radiopaque marker on this catheter is set back from the tip, making the device extremely deliverable.

In cases where the balloon has failed to cross a lesion, this rapid-exchange ELCA catheter is advanced to the lesion and, during continuous saline flush, lasing commences with gentle slow forward traction of the catheter. As the pulsed UV light emitted has a shallow penetration depth there is a low risk of dissection and vessel perforation. However, it is imperative to advance the catheter slowly and cautiously when dealing with very resistant lesions. In these cases there is often a tendency for even a supportive guide catheter to “back out” of the coronary artery, which would prevent saline from reaching the point of laser–plaque interaction, and increase the risk of complications.

Saline infusion technique

It is critically important to note that both blood and iodinated contrast media, in comparison to water or saline, almost completely absorb the excimer laser energy. This results in the formation of cavity microbubbles at the site of energy delivery (Figure 22.2c, d) which subsequently potentiates the effects of pressure waves increasing the likelihood of vessel wall dissection [49]. Therefore the removal of contrast media and blood at the laser tip or energy delivery site has become mandatory; this is achieved with saline flushing [50]. This results in direct delivery of the energy to the atherosclerotic material and leads to lower dissection rates [51].

This is achieved in practical terms by attaching a 1 L bag of 0.9% saline to the manifold via a three-way tap allowing saline to be injected with a 20 mL Leur-lock syringe when required. It is

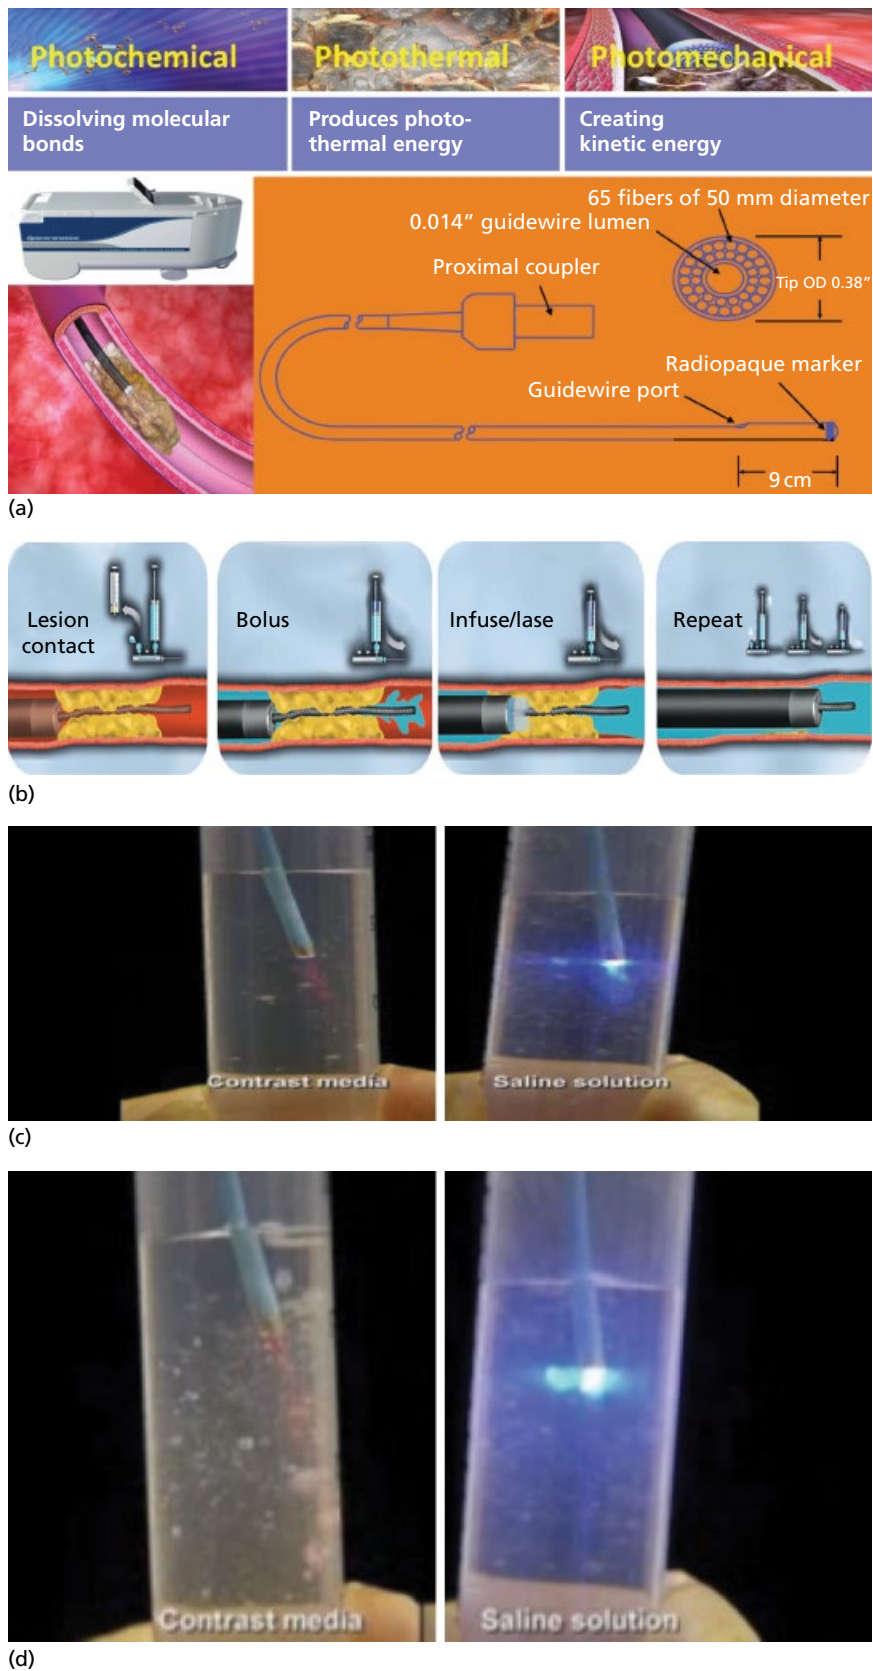

Figure 22.2 Excimer coronary laser atherectomy (ECLA). (a) Mechanism of action of ECLA. (b) Process of performing a saline bolus and infusion in the ECLA process. (c, d) Demonstration of the importance of saline infusion to prevent the formation of microbubbles that are evident when the laser is activated in contrast medium. Images courtesy of Cardiovascular Systems, Inc.

important to visualize directly under fluoroscopy that all contrast is flushed from the guide catheter in the selected starting position for lasing, and that the saline does not get mixed with contrast. Some 5 mL of saline should be infused prior to laser activation followed by a slow injection continued at a rate of 2–3 mL/s throughout the lasing process (usually 5–10 seconds; Figure 22.2b). It is important to ensure that the guide catheter is well intubated into the coronary artery to ensure saline delivery to the laser catheter tip.

When dealing with CTO lesions, it is advisable not to use the saline technique. When crossing the CTO with a guidewire, a section of the guidewire passage can be outside the true lumen of the vessel. Any antegrade injection can result in propagation of a dissection plane and ultimately result in a longer length of stenting if not immediate no-reflow phenomena. Furthermore, the saline infusion is unlikely to reach the intended target given the lack of runoff from the lesion and will therefore be ineffective. It is also likely that using ELCA without saline in this setting will permit greater energy at the proximal or distal cap of the occlusion, ultimately facilitating the ELCA effect.

It should be noted that ELCA is not recommended when the operator is aware that there is a long length of subintimal guidewire positioning as can occur during typical antegrade dissection re-entry. ELCA catheters are relatively indiscriminate in performing tissue ablation and will essentially “modify” any tissue in their field of delivery. Within the subintimal space the catheter would lie in closer proximity to the media and adventitia of the vessel and could cause perforation. For non-crossable and non-dilatable lesions, whether or not in the context of CTO, the highly deliverable 0.9 mm X-80 catheter is favored with a maximum fluence (energy) of 80 mJ/mm² and a repetition rate of 80 Hz. Activation for 10 seconds is followed by a mandatory rest of 5 seconds between each lasing period, which is continued until either the catheter has traversed the lesion or sufficient lesion modification has occurred to permit balloon crossing or expansion.

The major advantage of ELCA is that the catheter is utilized on the standard 0.014 inch guidewire and so, unlike RA, it can be used more easily without the need to exchange wires. This is of particular importance during CTO because it prevents any loss of distal wire position once the lesion has been crossed. Once ELCA has successfully traversed the lesion the procedure can be completed with balloon angioplasty and stenting.

We have previously reported the combined use of ELCA and RA as the “RASER” technique and have utilized this in many procedures [52]. Lesions that cannot be treated with RA initially, because of inability to advance a RotaWire, can first be treated with ELCA with the understanding that the device will not fully debulk the lesion to permit stenting. However, the “pilot hole” created by ELCA can then be used to pass a RotaWire, either independently or via a microcatheter exchange technique, to permit subsequent RA and achieve procedural success.

Indications for ELCA

Chronic total occlusions

ELCA has additional beneficial properties other than simply being able to cross or adequately debulk the resistant lesion. The ablative effect is transmitted across the atherosclerotic plaque, any organized thrombus, fibrosis, and calcification, which comprise the main architecture of a CTO. During recanalization attempts, the friable thrombus can induce platelet aggregation and promote the release of vasoconstrictor agents. This leads to a pro-thrombotic milieu that presents an additional challenge to an already technically demanding procedure. ELCA has a suppressive effect on platelet

aggregation and can sever links within the fibrin mesh leading to clot dissolution [52,53]. ELCA is unlikely to have any significant effect on the calcification within a lesion but the ablation of material supporting the calcified plaque weakens the overall lesion to permit successful balloon traversing and expansion.

Non-dilatable lesions

ELCA was first approved for use in cases of balloon failure during PCI in the USA in 1992 by the US Food and Drug Administration. However, there are few data on its use, particularly in contemporary practice. There are several reports of its use for balloon failure in the balloon angioplasty era [54–56]. The technology available at that time was limited to 1.4, 1.7, and 2.0 mm laser catheters and the laser energy delivered was much lower than in current practice with a maximum of 60 fluence and 25 Hz. It was also prior to the practice of continuous saline flushing during lasing, which has been shown to decrease complications [51]. Complication rates in these patients were high (8% significant dissection, 3% perforation, 3% acute stent thrombosis, and 3% emergency bypass surgery) and laser success rates were only 37%, although clinical success was obtained in 89%. Advances in PCI (with improved wire and balloon technology, the near universal use of coronary stents and the introduction of various drug-eluting stents) have increased the range of indications for PCI and improved outcomes since the 1990s.

Underexpanded stents

The ablative capabilities of ELCA are based on absorption of its energy in the atheroma, leading to photomechanical and photothermal processes. Using high power energy, the 0.9 X-80 catheter has been shown to cross even heavily calcified lesions. Even if the target lesions are not directly in the focus of laser beam, the specific interaction of ELCA energy in blood vessels induces acoustic shock waves propagating on to the surrounding structures. This effect becomes even more desirable when treating underexpanded coronary stents. Underexpanded coronary stents pose a significant risk for stent thrombosis and subsequent adverse clinical outcomes. There are very few reports on the use of ELCA to treat under expanded stents [57,58]. In our experience, this is a very good indication, in the presence of calcific coronary stenosis, for the use of ELCA. The laser catheter ablates tissue on the abluminal surface of the stent allowing lesion modification and subsequent expansion of an originally underexpanded stent.

Avoiding complications

ELCA complications are on the whole similar to those encountered during routine PCI as described earlier with RA. Specific issues arise from interruption of the continuous saline flush or contamination with contrast which can generate excessive heat and bubbles. Dissection re-entry techniques for CTO also require specific attention if the catheter is subintimal. Scrupulous technique and a procedure volume to maintain operator skills are essential to utilizing this technology safely.

Orbital atherectomy

Despite the mature nature of RA, which has been in clinical use since the 1980s, the persistence of angiographic and clinical complications highlights the potential for further progress in technology and technique. OA is a technique that has recently become available for coronary intervention (Diamondback 360° OAS, Cardiovascular Systems, CSI, St. Paul, MN, USA). Distinct from

Figure 22.3 Diamondback 360° Orbital Atherectomy System (OAS): (a) The OAS consists of the hand-held Diamondback 360 Coronary Orbital Atherectomy Device, the Saline Infusion Pump (OAS pump), ViperWire® Coronary Guide Wire, and the ViperSlide® Lubricant. (b) The diamond-coated crown. Images courtesy of Boston Scientific.

RA, OA works on the principle of elliptical burr movement, with variations in effective ablation diameter based on varying rotational speed rather than just on varying burr size. The OAS is a percutaneous endovascular system that incorporates the use of centrifugal force and differential sanding to modify calcified lesions. The OAS uses an eccentrically mounted, diamond-coated 1.25 mm crown (Figure 22.3) which orbits over an atherectomy guide wire at high speeds [59]. The position of the crown within the vessel is controlled using a handle. As atherectomy proceeds, a thin layer of plaque is removed with each pass of the crown. This process allows the crown to modify and remove portions of the calcified lesion while the more elastic tissue flexes away from the crown to create a channel 1.25–1.75 times greater than the crown size depending on the rotational speed chosen (two options are available by pressing a button on the device). The crown sizes available are 1.25, 1.5, 1.75, and 2.0 mm in diameter for endovascular interventions. The 1.25 and 1.5 mm crowns can be delivered using a 6 Fr guide catheter. Notably, only the 1.25 mm crown is indicated for use in the coronary artery (this crown can operate in two speed settings as controlled by a button on the device). Larger crowns are used for peripheral vascular interventions. A dedicated guidewire (ViperWire®, Cardiovascular Systems) and flush/lubricating system are required (ViperSlide®, Cardiovascular Systems).

There are important mechanical and technical differences between RA and OA that translate to significant differences in technical and clinical application of these two devices. First, there is directionality to ablation with RA. Because only the front portion of the RA burr is diamond-coated, ablation can only occur during forward movement. In contrast, ablation occurs during both forward and backward movement when OA is used. Therefore, instead of the “pecking” motion that is used with RA, a slow back and forth movement is used with OA. Second, because the leading edge of a RA burr has an ablative surface, RA can be used in very restrictive plaques such as CTO. In contrast, the OA crown is displaced 6.5 mm proximal to the leading edge which has no ablative surface. Therefore, there must be enough room to advance the device at least 6.5 mm before any ablation can occur. Lastly, the rotation of

OA is orbital while rotation of RA is more concentric. This difference has important implications for lesion selection. In general, OA should not be used in cases where there is a large transition from a large lumen to a smaller lumen. A prototypical example is an aorto-ostial lesion. RA is used in modification of these lesions and OA is contraindicated for use in this lesion subtype. The large unrestricting “lumen” of the aorta allows the maximal orbit possible for a given rotational speed. As the device is introduced into the ostial lesion, the orbit diameter is suddenly restricted and becomes smaller. This abrupt change can result in vessel dissection.

OA has several potential advantages over RA. During ablation, the elliptical orbit allows blood to flow past the crown, thus continually dispersing debris, cooling the crown, and reducing risk of thermal injury. RA uses a concentric burr that does not allow blood to flow past. The particles created by OA are also smaller, in the order of 2 μm compared to 5–10 μm created by RA [60,61], which theoretically should be easier to clear from the microcirculation. Additionally, as the crown ablating area can be regulated via rotational speed, it reduces the need to exchange to an alternative size crown during the procedure.

Two studies have been published to evaluate the safety and efficacy of OA. In ORBIT I [59], 50 patients with calcific coronary artery disease underwent OA with good procedural success and freedom from major adverse cardiac events (MACE) at 30 days. ORBIT II [31] was a non-randomized study which enrolled 443 patients with severely calcific coronary lesions in 49 sites in the USA, showing an 89.6% freedom from MACE at 30 days and 88.9% procedural success. Interestingly, the rate of slow-flow or no-reflow was very low, occurring in <1% of patients, rates of post-device coronary dissection were around 5.9%, and acute vessel closure of 0.9%, which compare favourably to RA series. In-hospital TLR and death rates appear lower than in published RA series (with all the caveats of historical control comparisons). A randomized study of OA compared with RA would need to be performed to assess the performance of OA in the treatment of severe calcific coronary disease, but early results are encouraging. This technology adds to the catheter laboratory armamentarium in the treatment of severe coronary calcification.

Conclusions

A rapidly aging population, a greater incidence of diabetes and kidney disease, together with improved long-term results with contemporary drug-eluting stent technology has increased the complexity of coronary disease that is now treated by PCI. This includes severely calcific disease, vein graft disease, ISR, complex bifurcation disease, and CTO. RA, ELCA, and OA provide tools to treat these complex lesions, which is essential for the adequate stent tracking, expansion, and apposition that are the cornerstones of procedural success.

Thrombus-Containing Lesions

Giovanni Luigi De Maria and Adrian P. Banning

Oxford Heart Centre, Oxford University Hospitals, John Radcliffe Hospital, Oxford, UK

Atherosclerotic plaque disruption is a key event in the pathophysiology of acute coronary syndromes (ACS). Plaque erosion and rupture are identified as potential mechanisms associated with atherosclerotic plaque instability [1] and result in the exposure to the bloodstream of plaque components and procoagulant molecules. Subsequent intraluminal activation of the coagulative cascade results in platelet activation and formation of blood clot and thrombus [2].

Intraluminal thrombus is probably a universal feature of ACS as it is predominantly responsible for the accelerated process of vessel occlusion or subocclusion that characterizes the spectrum of ACS, from ST elevation ACS to non-ST-elevation ACS. However, the prevalence of thrombus-containing lesions identifiable on angiography varies across the spectrum of coronary syndromes from 5–17% in patients with stable angina [3–5], to 75–90% [3–5] in patients with unstable angina or non-ST-elevation ACS [5,6], and almost 100% patients with ST-elevation myocardial infarction (STEMI).

Understanding the potential hazards that can be encountered when treating thrombotic lesions is crucial and being familiar with the strategies to deal with thrombus-containing lesion is mandatory for an interventional cardiologist.

Initial management requires:

- 1 Recognition of the presence of thrombus and its quantification.
- 2 Understanding that a thrombus-containing lesion is unpredictable and prone to sudden evolution; during the course of the procedure an apparent type A lesion with TIMI flow 3 can rapidly evolve into a blocked vessel with TIMI flow 0 and consequent hemodynamic deterioration.
- 3 Understanding that thrombus and debris deriving from the disrupted unstable plaque can embolize distally downstream of the coronary microcirculation, blunting the benefit of revascularization.
- 4 Being aware that thrombotic lesions are usually associated with high vascular tone and this, together with the presence of thrombotic debris, presents challenges to optimal stent sizing, with consequent increased risks of stent underexpansion and/or malapposition.

Consequently, the approach to achieving a successful interventional outcome for a patient with thrombus-containing lesion requires “recognition and a cautious respect to minimize distal embolization and optimize flow.” This chapter describes an interventional approach

to managing thrombus-containing coronary lesions. Advice on the adjunctive pharmacologic management of thrombotic lesions is detailed in Chapters 41–42.

How to deal with thrombus-containing lesions

Access site

When dealing with thrombus-containing lesions, selection of vascular access site is critical, especially in the setting of STEMI. There is no doubt that the radial approach is the preferred strategy for any interventional procedure and this has been confirmed recently by demonstration of a mortality benefit associated with a lower risk of bleeding with a radial than a femoral approach [7–9]. This benefit is especially evident in the acute setting with the potential requirement for potent antiplatelet agents (e.g., GP IIb/IIIa inhibitors).

When faced with the potential restrictions of the radial route, especially in smaller female patients, patients with arterial spasm, or complex tortuous anatomies with radial loops or remnants [10], options include sheathless guiding catheters [11], or balloon-assisted tracking to deal with radial artery spasm. This allows access to the aortic root with a 6 Fr guiding catheter without needing to downsize to 5 Fr [12]. Starting the procedure with a 5 Fr guiding catheter precludes the possibility of performing thrombus aspiration in most left coronary cases (occasionally a 5 Fr guide can be used in the right coronary as a thrombus aspiration device). Switching to a femoral approach should be undertaken when the balance of risk favors this approach.

Identification of thrombus

Identification and quantification of thrombus are extremely important as they tailor the appropriate management in terms of adjunctive pharmacotherapy and adjunctive mechanical devices to minimize the occurrence of distal embolization. Recognizing that we are dealing with a thrombus-containing lesion is usually straightforward based on the clinical presentation and angiography. Sometimes, however, distinguishing thrombus and calcium on angiography alone can be challenging. Troponin elevation prior to arrival in the catheter laboratory, suggesting ongoing myocardial damage, can be considered to be a marker of possible thrombotic burden but there are situations in which troponin negative patients

Figure 23.1 Two examples of stent thrombosis. Panels a1, b1 show the variable appearance of thrombus at coronary angiogram. In panel a1 the vessel is completely occluded at the site of the old stent (edges highlighted by yellow arrowheads) with TIMI 0 flow. In panel b1 blood flow is maintained but there is a clear area of haziness at the site of the stent (yellow arrowheads). Panels a2, a3 provide the OCT appearance of the thrombotic lesion with clear and well detailed identification of the thrombotic material protruding toward the lumen (white arrows). The lack of shadowing confirms the possible “young” age of the thrombus, which looks like a white thrombus. Panels b2, b3 provide the intravenous ultrasound (IVUS) appearance of the thrombotic lesion. The lower spatial resolution of IVUS accounts for a less detailed definition of the thrombotic material, appearing as a low echogenic (black) area (pale yellow arrows). Compared with optical coherence tomography (OCT), the highest penetration of the ultrasound accounts for the better visualization of the whole vessel wall behind the thrombotic material.

can have considerable thrombus demonstrable by angiography, as for example in patients with degenerate vein grafts.

Thrombus identification on angiography is considered routine but operators should remember that angiography has only 26% sensitivity in predicting the presence of thrombus [5,13]. Thrombotic lesions are usually identified on angiography as an area of vessel filling defect or vessel haziness during contrast injection. Thrombus can cause different degrees of vessel stenosis and blood flow impairment, and it is possible to find vessel occlusion with TIMI flow 0 or alternatively a normal flow in a non-diseased vessel and an imposed area of haziness corresponding to adherent thrombotic material. When this type of angiographic appearance occurs in the absence of atherosclerosis a potential embolic pathogenesis associated with atrial fibrillation or paradoxical embolism should be considered.

A useful method to quantify coronary thrombus on angiography is represented by the Thrombus Score, proposed by Sianos *et al.* [14]. Five classes are described with progressively increasing gravity: grade 0 corresponds to no angiographic evidence of thrombotic material; grade 1 is possible thrombus, appearing as a convex hazy lesion with irregular contours; grade 2 is definite thrombus $\leq 1/2$ the vessel diameter; grade 3 is definite thrombus $>1/2$ but <2 vessel diameters; grade 4 is definite thrombus ≥ 2 vessel diameters; grade 5

is inability of thrombus burden assessment, also after guidewire passage, for persistence of TIMI flow 0.

Intracoronary intravascular ultrasound (IVUS) and optical coherence tomography (OCT) have higher sensitivity and specificity than angiography and allow better thrombus definition, quantification, and characterization. Historically, care was needed when using intracoronary imaging for thrombotic lesions but this is now usually safe. However, in cases of massive thrombus, high quality interpretable images are not possible unless antegrade coronary flow is established.

The high spatial resolution of OCT (Figure 23.1) allows the most detailed definition of thrombus, appearing as a mass attached to luminal surface or floating within the lumen, and even makes possible the discrimination between red and white thrombus [15]. Red thrombus has high backscatter and high attenuation while white (platelet-rich) thrombus has less backscatter, is homogeneous, and has low attenuation. Besides qualitative assessment, OCT offers the possibility for an accurate quantitative assessment of thrombotic burden; a number of classification criteria have been proposed [16–19]. Additionally, OCT can detect mechanical issues associated with stent thrombosis [20]. Both case series and studies have showed the high sensitivity and specificity of OCT in detecting

stent malapposition, stent underexpansion, incomplete strut coverage, and new atherosclerosis, thus providing information about the pathophysiology of early and late stent thrombosis. This is especially useful when excluding pharmacologic issues, such as non-response or early interruption of antiplatelet drugs [21,22]. Consequently, OCT should currently be considered the imaging modality of choice when investigating the mechanisms of stent thrombosis.

Although OCT has the best spatial resolution, IVUS has the advantage of providing detail about the vessel wall behind the thrombus. However, identifying fresh thrombus on IVUS can be challenging especially when flow is slow and thus careful examination of images is recommended. Compared to infrared light, ultrasound can penetrate thrombus, which appears as a non-homogenous hypoechogenic (dark) intraluminal area, overlying the vessel wall inner surface which can be completely assessed [23]. It must be noted that organized thrombus usually appears more echogenic (gray-white) and can be difficult to differentiate from intimal hyperplasia or fibrous plaque. According to its collagen content it can produce an acoustic shadow making the thrombus hard to distinguish from fibrous plaque.

Routine intravascular imaging techniques are not recommended when dealing with thrombotic lesions but can be useful in the following situations:

- 1 Mismatch between clinical presentation and the angiographic appearance. Is this thrombus or calcium?
- 2 Uncertain non-obstructive or partially obstructive angiographic plaque appearance.
- 3 Exact thrombotic burden quantification for research purposes.
- 4 Optimizing difficult stent sizing.

Wiring

Conventional workhorse guidewires are usually considered as first choice for wiring the vast majority of thrombus-containing lesions, especially in situations in which coronary anatomy downstream to the culprit lesion is unknown because of vessel occlusion.

A first attempt to pass a wire is useful to “feel” the lesion typology, facilitating the initial discrimination of fresh thrombus from old thrombus and/or a thrombus-containing lesion from a chronic total occlusion. Particular care must be taken when approaching the thrombotic lesions with the guidewire. The wire might (i) be occlusive to flow; (ii) disrupt the unstable plaque with possible dissection; or (iii) dislodge the overlying thrombus downstream with possible vessel occlusion from distal embolization. The general rule “never let the guidewire come back from a safe position distally to the target lesion” is especially valid when dealing with thrombotic lesions.

When a first attempt at wiring using a workhorse guidewire has failed it is usual to step up to a hydrophilic guidewire. The hydrophilic coating reduces friction significantly increasing the trackability, making such guidewires helpful tools in localizing channels through the thrombus or to negotiate the true lumen in cases of dissection. Recommendations in handling this type of guidewire are no different from those applied in the context of non-thrombotic lesions. The low tactile sense associated with this typology of guidewires favours subintimal passage, coronary dissection, or perforation. For these reasons, (i) these wires should be handled by experienced operators; (ii) tip wire position should always be tested with contrast injection before moving to the next step of the procedure, and (iii) ideally, whenever it is possible and safe, these guidewires should be exchanged with a workhorse guidewire before moving to the next stage of the procedure.

To confirm wire position when TIMI flow is still 0 or becomes 0 after guidewire passage, an easy approach is to gently advance a low profile deflated balloon and to reassess. Subsequently, if there is persistent uncertainty, a second approach with a microcatheter (FinecrossMG, Terumo, Japan; or Corasir, Asahi Intecc Co., Japan) can be used to visualize the distal portion of the coronary tree, thus confirming the position of the guidewire which can then be replaced with a workhorse wire.

Lesion preparation

The most serious complication during treatment of thrombus-containing lesions is the occurrence of distal embolization of atherothrombotic material with consequent microvascular obstruction and no-reflow phenomenon. Consequently, despite evolution in practice, thrombus-containing lesions continue to be associated with poor procedural results and higher rates of death, myocardial infarction, arrhythmic complications, and the need for urgent revascularization [24].

It has been demonstrated that thrombus manipulation during balloon angioplasty and stenting is associated with the “cheese grater” effect, leading to thrombus detachment and downstream washout of athero-thrombotic debris [25].

Thrombus debulking can be achieved by two approaches: pharmacologic and mechanic. These strategies are not mutually exclusive, but can have an additive effect, especially in the setting of large myocardial infarction [26,27]. The first approach relies mainly on GP IIb/IIIa inhibitors and is dealt in detail in Chapter 42. The second strategy consists of mechanical prevention of distal embolization by either: (i) balloon and/or filter protection devices aiming to trap debris liberated during predilation/stenting; or (ii) thrombectomy, aiming to directly remove the thrombotic material from the lesion site.

Proximal and distal protection devices

There are currently three main types of balloon and filter protection devices [28]:

- 1 Distal occlusion devices (Percusurge, Medtronic, Santa Rosa, CA, USA; TriActiv system, Kensey Nash, Exton, PA, USA).
- 2 Distal filters (FilterWire EX, Boston Scientific, Natick, MA, USA; SpiderRX and SpiderFX, ev3 Inc., Plymouth, MN, USA).
- 3 Proximal occlusion devices (Proxis (St. Jude Medical, St. Paul, MN, USA).

Distal occlusion devices mainly consist of a balloon inflated distally to the thrombotic lesion soon after the passage of the guidewire. In this way debris dislodged during predilation and stenting phases will be prevented from reaching the coronary microcirculation by the inflated balloon. The debris is then aspirated before the distal balloon is deflated. The main advantages of these devices are their relatively smaller profile (usually 0.026–0.033 inch) and their theoretical ability to trap most debris including small particles and even soluble matter. Conversely, the main drawbacks are (i) the prolonged ischemia associated to distal occlusion during their application; (ii) the risk of proximal side branch embolization; (iii) inability to visualize the target vessel distally to the occlusive device; and (iv) potential inability to aspirate debris located at the fornices of the inflated balloon [28].

Distal filters consist of baskets placed distally to the lesion with the intention to trap debris liberated during predilation and stenting. At the end of the procedure, the filter packed with atherothrombotic debris is retrieved by means of a “filter retriever.” The main advantages offered by filter devices are their ease of use, the

possibility of preserving distal perfusion during the adoption, and the possibility of keeping visualization of the target vessel distally to the filter device during the procedure. The main limitations of filter devices consist in the larger profile of the sheath (0.040–0.050 inch) needed to keep the filter folded during the crossing of the target lesion with consequent risk of dislodgement of athero-thrombotic debris. The larger profile may eventually require a gentle predilation before the deployment of the device with increased risk of distal embolization. Compared with distal occlusive devices, filter devices are prone to the passage of distal emboli (especially if small in size, e.g., <100 μm) through filter pores or between the filter and the vessel wall if the filter is not completely apposed to the vessel wall [28].

Finally, proximal occlusion devices consist of a balloon inflated proximally to the lesion, thus blocking blood flow and thus the driving force washing athero-thrombotic debris toward the coronary microvasculature. Proximal protection offers theoretical advantages over distal protection including the ability to protect the distal vascular bed without first crossing the lesion with a bulky device, which may itself cause distal embolization. Additionally, some vessels are not suitable for distal protection systems because of the lack of an appropriate “landing zone” for the device, because of tortuosity, plaque disease, or both.

Of all these protection devices, only distal filters are regularly used in clinical practice. Their adoption has been established in percutaneous coronary intervention (PCI) on saphenous vein grafts [29,30], because randomized trials failed to show a clinical benefit in PCI on native vessels [31,32]. Embolization during device deployment, a delay to PCI due to device deployment, and “filter no-reflow” occurrence have been claimed as possible mechanisms explaining the failure of filters in PCI on native vessels [28,33].

Thrombectomy

Theoretically, reduction of thrombus burden by thrombectomy should (i) prevent the risk of distal embolization; (ii) improve a better visualization of the atherosclerotic lesion; (iii) improve the evaluation of vessel size; (iv) favor direct stenting; (v) prevent stent malapposition, after disappearance of the thrombus initially located between the stent struts and the vessel wall [34].

Two main kinds of thrombectomy devices are available: manual (or aspiration) and mechanical. In manual thrombectomy devices, thrombus aspiration is obtained by application of a suction force exerted by the operator. In mechanical devices, aspirating force is produced by specific device-related mechanisms.

Manual thrombectomy

Manual thrombus aspiration devices consist of 6 Fr compatible dual lumen catheters. The smaller lumen is used to deliver the device over a conventional 0.014 inch guidewire over a short monorail rapid exchange system. The larger lumen presents one or more distal apertures and is connected to a Luer lock syringe. By creating a vacuum in the Luer lock syringe a negative pressure is produced leading to aspiration of thrombotic material while crossing the lesion site. Figure 23.2 summarizes the main steps for the preparation of the thrombus aspiration catheter.

A successful manual thrombectomy is performed by: (i) aspirating while crossing the thrombus; (ii) performing multiple passes across the target thrombus; and (iii) aspirating while withdrawing the aspiration catheter back into the guiding catheter. Aspirating while crossing the thrombus reduces the risk of distal embolization, conversely aspirating during withdrawal prevents the risk that the

aspirated thrombus is lost downstream in the coronary artery or, even worse, in the aorta (Figure 23.3). For this reason a deep intubation of the guiding catheter during thrombus aspiration catheter withdrawal, and complete clearance of the guiding catheter (by blood aspiration and/or by blood back-spilling through the open valve of the Y connector) before proceeding to contrast injection are recommended. The optimal number of aspiration passes is debated but theoretically at least three passes are recommended. It is possible that the amount of residual thrombus detected by intravascular imaging could be a guide in the decision to make additional catheter passes [35].

Two parameters determine the efficacy of a manual thrombectomy: deliverability and aspiration rate. The main technical characteristics of manual thrombus aspiration catheters available on the market are summarized in Figure 23.4. The catheter deliverability depends on catheter pushability and trackability and on coronary anatomy (tortuosity, calcifications, and vessel size). Hydrophilic coating, metallic braided shaft, or metallic stylet have been applied to the most recent generation of thrombectomy catheters to improve their trackability and pushability.

Aspiration rate is expressed by the formula: $\Delta P\pi r^4/8\mu L$ [36,37]. The aspiration rate is thus affected positively by the depression created by the Luer lock syringe (ΔP) and by the minimum radius of the aspiration catheter (r). Conversely, high thrombus viscosity (μ) and aspiration catheter length (L) negatively affect the aspiration rate. It is thus clear that larger lumen aspiration catheters are more effective at the expense of difficult application in thrombotic lesions located in small vessels. Similarly, thrombus aspiration performance can be hampered in very old, organized, and high viscous thrombi. It is possible to hypothesize that modification of thrombus viscosity might improve the efficacy of thrombus aspiration, for example by local injection of GP IIb/IIIa inhibitors through dedicated a delivery device (Clearway RX, Atrium Medical, Hudson, NH, USA; Amicath, IHT, Spain) or through the thrombectomy catheter itself [17].

A drawback of aspiration catheters is the ability to extract thrombotic material from the region of the vessel closer to the tip of the device. It is logical to think that the aspiration performance is affected by the distance of the thrombotic material from the tip of the device itself. The position of the catheter within the lumen is definitely affected by the position of the guidewire and thus the “bias wire” strategy can help to improve aspiration efficacy. This technique consists of changing the position of the guidewire toward a side branch [38], thus changing the position of the thrombus aspiration catheter itself, eventually facilitating closer position of its tip toward the thrombotic lesion. Intravascular imaging helps to guide this maneuver by showing very high residual thrombotic burden after the first thrombus aspiration pass and thus favoring a further thrombectomy pass after the guidewire position has been changed.

Although they are user-friendly devices, manual thrombus aspiration catheters are associated with several complications: (i) coronary spasm; (ii) distal embolization during crossing; (iii) dissection; (iv) perforation; and (v) proximal displacement of thrombus with potential embolization down to previously unaffected arteries [39].

After the first studies ascertaining the benefit of manual thrombectomy in terms of myocardial reperfusion (assessed by ST resolution, myocardial blush grade (MBG) [40–45], contrast echocardiography [46,47], and cardiac magnetic resonance [48]), it was the TAPAS trial that suggested a potential benefit in terms

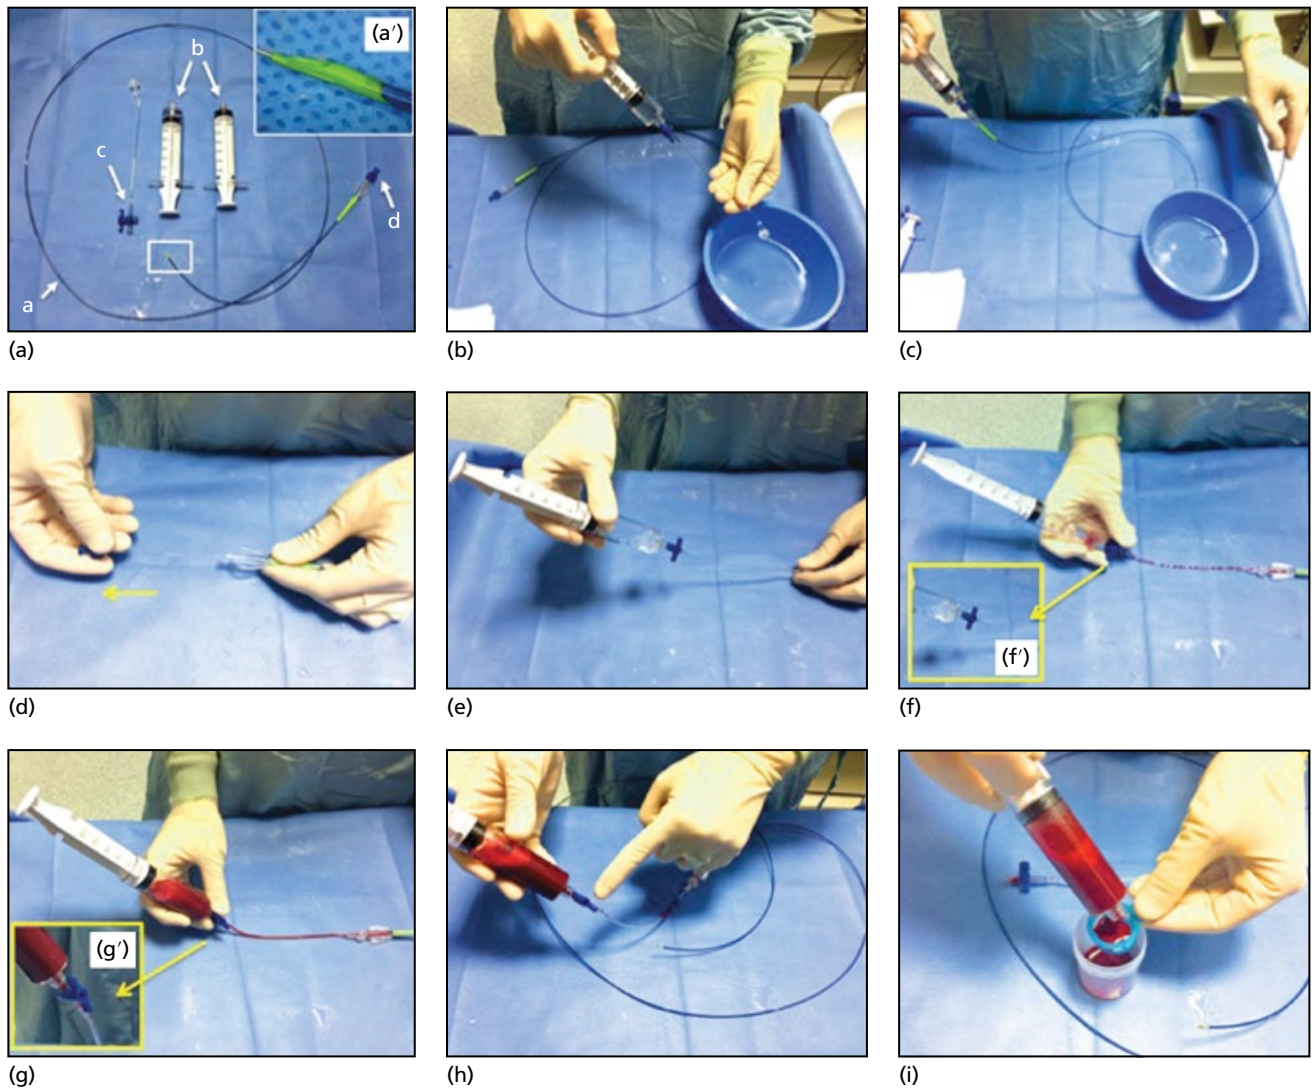

Figure 23.2 The preparation of a thrombus aspiration catheter (Export Advance, Medtronic in the example). (a'). Detail of thrombus aspiration catheter tip. (b, c) Flushing tube extension and aspiration catheter. (d) Once the aspiration catheter is placed at the site of the target lesion the stylet is removed (this step is to be considered only for aspiration catheter with stylet). (e, f) Luer lock syringe is connected and vacuum is made. (f'): Detail of the one-way-tap orientation in this stage. (g) By opening the one-way tap aspiration is started. (g'): Detail of the one-way-tap orientation during aspiration. (h) At the end of the aspiration the catheter is retrieved keeping the one-way tap open in order to maintain aspiration during the withdrawal. (i) The syringe is emptied into the filter and debris collection can be assessed.

of long-term mortality leading to a change in the guidelines. More recently, the TASTE trial failed to show a clear benefit from routine manual thrombectomy in a larger population of 7244 patients with STEMI [49]. Notably, 40% of potential patients were excluded and up to two-thirds of patients presented with a low thrombotic burden and all-cause mortality was the primary endpoint. The recently published results of the larger TOTAL study conducted on 10,063 patients confirmed a lack of benefit from routine manual thrombus aspiration [50]. In line with the previous smaller trial, the TOTAL trial detected a benefit of thrombectomy in terms of soft endpoints like ST resolution and occurrence of distal embolization; however, the trial showed no difference in major adverse cardiac event (MACE) rate at 180 days in patients

treated with thrombectomy compared with those receiving PCI alone [50]. Even if a longer follow-up is needed before drawing definite conclusions, it is evident that both the TASTE and TOTAL studies highlight the need for a more accurate use of thrombectomy. Accordingly, the recent European guidelines recommend manual thrombectomy only in selected patients: those with clear evidence of high thrombotic burden and feasible coronary anatomy [51].

Mechanical thrombectomy

With mechanical thrombectomy devices the thrombus is first lysed before extraction. Thrombus lysis is achieved through different mechanisms according to the device adopted.

(a)

(b)

(c)

Figure 23.3 Keeping aspiration maintaining a negative pressure in the Luer lock syringe is essential during withdrawal of the aspiration catheter. In this case, manual thrombus aspiration was performed in a very highly thrombotic lesion of the right coronary artery (a). During the first pass with the thrombus aspiration catheter, blood back-spilling in the syringe stopped relatively soon. The thrombus aspiration catheter was then withdrawn and a large amount of thrombotic debris attached to the tip of the aspiration catheter was observed (b). Withdrawing the aspiration catheter maintaining aspiration was crucial in this case, preventing the embolization of thrombotic debris. For safety reasons the guiding catheter was replaced with a new one and further passes with a new thrombus aspiration catheter were performed retrieving a very large amount of thrombotic material (c).

The X-Sizer (ev3 Inc., Plymouth, MN, USA) is an over-the-wire dual-channeled catheter with a spinning helical tip in the first channel, which fragments the thrombus. At the same time, a miniature vacuum system in the second channel removes the debris created.

The AngioJet rheolytic thrombectomy System (Possis Medical, Inc. Minneapolis, MN, USA) makes use of the Venturi effect to remove thrombus. Saline is injected at high pressure through small steel tubing by an external pump, creating an area of low pressure around the jet, which pulls surrounding blood, including thrombus, into the catheter.

The ThromCat XT (Kensey Nash, Exton, PA, USA) combines flushing via three ports at the distal tip, with powerful suction from five ports, with a helix spinning at 95,000 rpm macerating the thrombus retrieved.

The Rinspiration System (Kerberos Proximal Solutions Inc., Sunnyvale, CA, USA) employs simultaneous irrigation and aspiration of the vessel to remove thrombus by three lumens: a 25 cm monorail wire lumen allows passage over a standard 0.014 inch coronary guidewire, a second lumen for aspiration, and a third lumen for injection of saline through perforations located proximal to the aspiration lumen.

Mechanical thrombectomy devices have a theoretical advantage of better thrombus extraction and greater profiles, but lower flexibility and steeper learning curve are their main weak points. Furthermore, the high risk of device stent-entrapment observed for the X-Sizer has led to the withdraw of this device from the market. Randomized trials directly comparing manual with mechanical aspiration have reported no differences between the two approaches in terms of MACE, but highlighting a higher

Figure 23.4 Summary of the main technical characteristics of the manual thrombus aspiration catheters available on the market. The technical characteristics are grouped according their influence on aspiration rate and trackability/pushability, which are the two main parameters determining the performance of a manual thrombus aspiration device.

rate of successful deployment with the manual thrombectomy devices [52,53].

Consequently, mechanical thrombus aspiration has a niche role in very thrombotic lesions; for example, in patients with large thrombus burden located at the site of very ectatic segments where, for obvious “geographic” reasons, the performance of conventional manual aspiration catheters is expected to be limited (Figure 23.5).

Excimer laser

Excimer laser coronary angioplasty (ELCA) is used to reduce thrombotic burden. The system consists of an excimer laser generator (CVX-300, Spectranetics, CO, USA) and a pulsed xenon-chlorine laser catheter (available diameters 0.9, 1.4, 1.7, and 2.0 mm). The laser catheter delivers excimer energy (wavelength 308 nm, pulse length 185 ns) with a fluence (energy per surface unit) ranging from 30 to 80 mJ/mm² and a pulse repetition rate ranging 25–80 Hz. Fluence and pulse repetition rate are parameters that the operator can modify to improve the performance according to the characteristics of the target lesion.

A safe and effective laser photo-ablation strategy requires attention to the three “S’s”: size, slow, and saline. In other words, (i) it is crucial to choose a laser catheter correctly sized to the target vessel diameter; (ii) the catheter must be advanced slowly; and (iii) constant saline flushing at the tip of the catheter during its advancement is required. Saline infusion guarantees that blood and contrast dye are cleared from the tip of the catheter. Blood and contrast dye can absorb the energy delivered by the catheter and favor the development of microbubbles with increased risk of vessel dissection.

The excimer laser produces vaporization of the thrombus through three mechanisms: photochemical, photothermal, and photomechanical [54]. The photochemical action is the result of UV light hitting the tissue at a rate of up to 125 billions per second, with a 50 μm penetration, and leading to billions of molecular bonds fractured per second. The photothermal effect derives from absorption of energy by the thrombus, with consequent molecular vibration and heating and vaporization of intracellular water, ultimately ending in cellular rupture and thrombus disruption by vapor bubbles. Finally, the photomechanical effect derives from

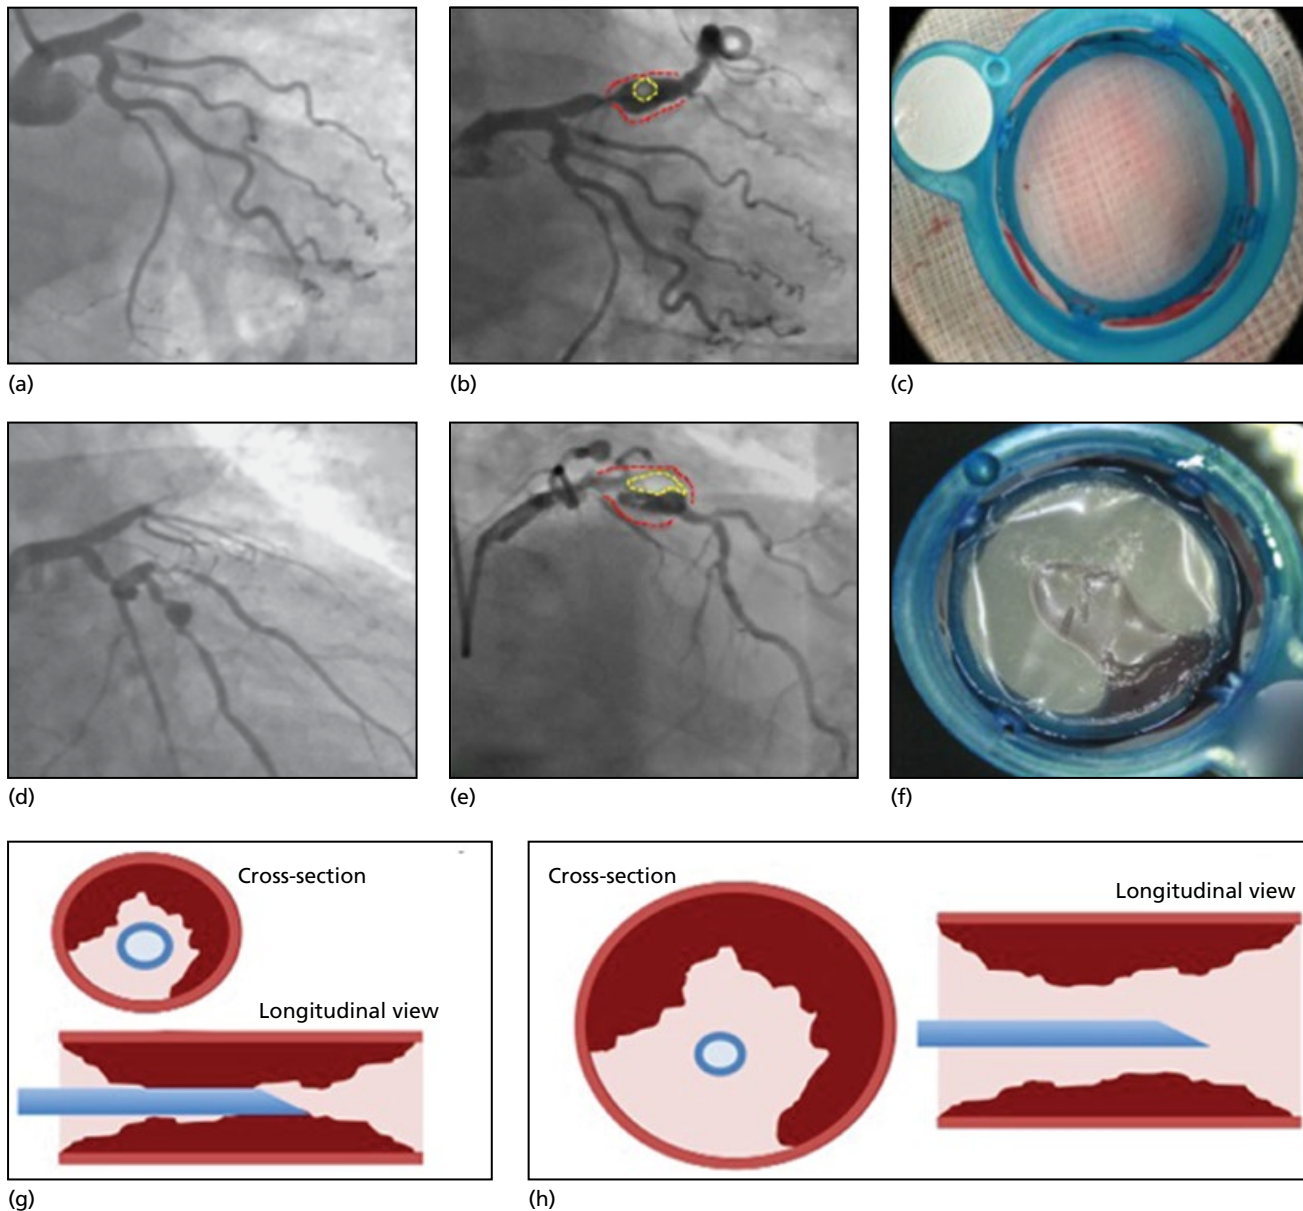

Figure 23.5 Ectatic and aneurismatic coronary segments represent an anatomic scenario in which performance of manual thrombus aspiration can be suboptimal for evident “geographic” reason. (a, b) and (d, e) show two examples of patients with anterior ST-elevation myocardial infarction (STEMI), with culprit lesion located at the site of a large aneurismatic segment containing a large amount of thrombus. The dotted red lines detect the contours of the aneurism, while the dotted yellow lines detect the contours of the thrombotic material. Manual thrombus aspiration was performed in both cases with retrieve of no thrombus in the filter (c, f). In normal vessels (g) the manual aspiration catheter is able to get in touch with the thrombus, with higher probability of removing both thrombus hanging in the lumen as “parietal” thrombus adherent to vessel wall. In large ectatic/aneurismatic segments a geographic miss because of the large dimension of the vessel accounts for the lower ability of the manual aspiration catheter to reach thrombotic debris, especially when adherent to the vessel wall (h). For this reason thrombus-containing lesions at the site of ectatic/aneurismatic segments could be a scenario for a possible application of mechanical thrombus aspiration devices, known to have a theoretically higher thrombus aspiration capacity.

the vibration and collapse of vapor bubbles mechanically breaking down the target tissue. Excimer laser adopts light in the UV range and spectroscopy analysis on thrombus reveals how excimer wavelength is ideally suited for absorption by the fresh thrombus [55], to the point that a “platelet stunning” action has been described,

resulting in a local, direct, and inhibitory effect on platelet aggregation kinetics [56].

In the CARMEL study, the excimer laser has been tested in a population of 151 patients with myocardial infarction resulting in an improvement of both residual stenosis and flow rate. Interestingly,

the greater benefit from laser application was observed in patients with larger thrombotic burden [57]. Encouraging results have also been described in terms of improved reperfusion assessed by TIMI flow and MBG in patients with myocardial infarction treated with excimer laser [58].

Stenting

Stenting, with or without post-dilatation, is usually the final step of the revascularization procedure. It has a recommendation IA according to the current guidelines for the treatment of patients with both non-ST-segment elevation ACS and STEMI and thus also with thrombotic lesions [51].

Considerations during stent deployment include: (i) stent sizing, as undersizing with consequent malapposition is possible in the acute vasospastic environment; and (ii) the process of stent expansion is associated with increased risk of distal embolization. In order to minimize the risk of distal embolization associated with stenting, two modifications are currently under consideration. The first is deferring stenting in the acute phase, especially in the setting of STEMI and the second is the use of dedicated mesh stents.

Some studies have reported the feasibility and safety of a deferring stent strategy with restoration of TIMI flow by balloon dilatation or thrombectomy alone [59], which demonstrated a lower final infarct size in some patients with STEMI [60]. This approach needs to be tested in larger randomized clinical trials, but should be considered when thrombosis is evident on chronic

or severe calcific lesions. In these cases, deferring stenting for a staged rotablation-assisted PCI or excimer laser should be considered.

Beside the deferring stent approach, evidence is also growing in favour of stents designed to reduce the occurrence of distal embolization. The MGuard (InspireMD, Tel Aviv, Israel) is a newly developed metal stent designed to trap the athero-thrombotic debris behind a polyethylene-terephthalate mesh anchored to the external surface of the struts. So far the stent has shown positive results for soft endpoints such as final TIMI flow and MBG, while no differences have been observed in terms of mortality or MACE rate compared to conventional bare metal stents [61].

Conclusions

In the treatment of thrombus-containing lesions, each step of the procedure, from access selection to stenting, is of crucial importance and requires clear planning and understanding of the underlying coronary anatomy and lesion characteristics. A large armamentarium of drugs and devices is available for the interventional cardiologist; however, as the TASTE trial demonstrates, indiscriminate adoption of every technique in every patient is not to be recommended. Consequently, identification of the subset of patients at higher risk of suboptimal final result that might benefit from additional or alternative strategies is desirable and this represents the new challenge in the treatment of thrombus-containing lesions.

Case study

A 50-year-old man with no previous past cardiologic history presented with anterior STEMI. Coronary angiogram confirmed acute occlusion of large left anterior descending (LAD) (Figure 23.6a). After wiring, thrombus aspiration was performed and TIMI 3 flow was restored (b). Predilatation was then performed with 2.0 × 15 mm (c), 2.5 × 15 mm (d) semi-compliant balloons and even 3.0 × 15 (e) and 3.5 × 15 mm non-compliant balloons inflated at high pressure (up to 20 atmospheres). In all cases, however, a complete inflation of the balloon (highlighted by yellow arrows in c, d, and e) was impossible to achieve because of possible high calcific burden. After a failed attempt to cross the lesion with a cutting balloon, the patient's clinical condition was reviewed (patient was symptom-free and TIMI 3 flow) and the procedure was stopped. The patient was transferred to the coronary care unit to complete the bivalarudin infusion and continue double antiplatelet therapy with 75 mg aspirin and 90 mg ticagrelor twice daily. A rotablation-assisted PCI to LAD was scheduled within 48 hours from the index procedure.

After 48 hours the patient had a second angiogram as scheduled (f). Before proceeding to rotablation an intravascular imaging with optical coherence tomography (OCT) was

performed. OCT was useful because it excluded the presence of high residual thrombotic burden and confirmed the presence of a high calcific burden (g, white arrowheads). Rotablation with a 1.75 mm burr was then performed. Balloon expansion was still limited so rotablation with a 2.00 mm burr was performed allowing a successful predilatation with a full expansion of a 3.0 × 15 mm non-compliant balloon (h). The procedure was then completed with stenting with a 3.5 × 38 mm drug-eluting stent post-dilated with a 4.0 × 15 mm non-compliant balloon, achieving a good final angiographic result (i).

The case shows how deferring stenting in the setting of a thrombus-containing lesion is safe and should be considered when even an aggressive predilatation resulted in a suboptimal outcome. In such a scenario, deferring a hemodynamically stable patient with good TIMI flow to a rotablation-assisted PCI after 24–48 hours is a reasonable option. In this case, intravascular imaging not only confirmed the large calcific component of the plaque, but it was also useful in excluding large residual thrombus, thus allowing rotablation to be performed with fewer concerns about the risk of distal embolization.

Specialized Balloons in Percutaneous Coronary Intervention: Cutting, Scoring, Gliding, and Drug-Eluting Balloons

Bimmer E.P.M. Claessen¹, José P.S. Henriques¹, and George D. Dangas²

¹Department of Cardiology, Academic Medical Center—University of Amsterdam, Amsterdam, The Netherlands

²Department of Cardiology, Mount Sinai Medical Center, New York, NY, USA

Balloon angioplasty was the only available treatment in the early days of percutaneous coronary intervention (PCI). Major drawbacks of balloon angioplasty alone were elastic recoil, acute vessel closure, and restenosis [1]. The development of coronary artery stents subsequently revolutionized the field of interventional cardiology, virtually eliminating elastic recoil and acute vessel closure [1,2], but they also introduced the new problem of stent thrombosis and were still limited by relatively high rates of in-stent restenosis [3,4]. Bare metal stents (BMS) were succeeded by drug-eluting stents (DES) which currently are the standard of care for treating most coronary artery lesions [5]. Nonetheless, balloon angioplasty is still an integral part of interventional cardiology in the current era. Lesion preparation by predilation is vital for allowing stent delivery to severely narrowed and calcified lesions. This is particularly important in the current era of bioresorbable vascular scaffolds (BVS) which require meticulous lesion preparation before implantation [6]. A number of specialized balloons such as cutting balloons and scoring balloons have been developed to facilitate lesion preparation. Moreover, several specialized balloons have been developed specifically for a dedicated purpose, for example a short gliding balloon which can be employed for side branch ostial dilatation in bifurcation lesions, or the clearway catheter which is designed for intracoronary delivery of pharmaceutical agents [7–11]. Finally, a new class of drug-coated balloons have been developed which show great potential in treating in-stent restenosis lesions and *de novo* lesions [12]. This chapter provides an overview of specialty balloons currently used in the field of interventional cardiology.

Cutting and scoring balloons

Cutting balloons were introduced in the early 1990s in an attempt to limit vascular injury and elastic recoil [13]. On a cutting balloon a number of cutting edges of small metal blades are mounted on the surface of the balloon along the longitudinal axis. As compared with regular angioplasty balloons, cutting balloons were hypothesized to have an advantage by cutting into the media with a sharp incision, inducing less medial smooth muscle cell stretch leading to fewer

stimuli for intimal proliferation. Although the initial clinical experience with the cutting balloon was favorable [14], the introduction of coronary artery stents proved more effective at reducing restenosis and reducing acute vessel closure [1,2], thus reducing the indications for using a cutting balloon. Current European Society of Cardiology (ESC) guidelines mention that preparation and debulking with a cutting balloon may be useful in highly calcified, rigid, ostial lesions [15]. The American College of Cardiology/American Heart Association (ACC/AHA) guidelines include a class III recommendation (level of evidence A) stating that cutting balloon angioplasty should not be performed routinely during PCI [16]. There is also a class IIb recommendation (level of evidence C) stating that cutting balloon angioplasty might be considered to avoid slippage-induced coronary artery trauma during PCI for in-stent restenosis or ostial lesions in side branches.

Scoring balloons are composed of a minimally compliant balloon encircled by a scoring element (typically a wire) which creates focal concentrations of dilating force, minimizing balloon slippage and assisting in the expansion of stenotic coronary arteries. Essentially this recreates the local environment of a regular balloon inflation alongside a “buddy wire” which is embedded into the lesion and also acts as an anti-slippage element. Starting with the FX-minirail (Abbott Vascular, no longer manufactured), several different types of scoring balloons are currently commercially available, the most common being the AngioSculpt Scoring Balloon Catheter (AngioScore, Fremont, CA, USA), which is a conventional nylon-blend balloon encircled with spiral nitinol scoring wires, and the Scoreflex scoring catheter (OrbusNeich, Hong Kong, China), which has only one protruding element on the surface of the balloon; it has an extremely short tip which wraps the guidewire used to deliver the device longitudinally along the balloon as a second scoring element. Their use has evolved in similar indications as the cutting balloon. The AngioScore balloon has been tested in a small cohort (n=93) of patients undergoing PCI of bifurcation lesions with a provisional side branch stenting approach and DES in the main branch [17]. At 9-month follow-up this simple provisional strategy for complex true bifurcation PCI resulted in low rates of target lesion revascularization (3.3%).

The Glider balloon in coronary bifurcation lesions

The Glider balloon (TriReme Medical, Pleasanton, CA, USA) is a short balloon (4 mm) that is specifically designed for use in bifurcation lesions. In the most commonly used technique for bifurcation lesion PCI, provisional side branch stenting, final kissing balloons to correct carina shift after deployment of the main vessel stent is frequently performed. However, final kissing balloons can be technically challenging because of challenges in crossing the main vessel stent struts with a balloon. The Glider balloon is designed with an oblique cut at the distal tip to facilitate crossing into the side branch: once the shorter aspect of the oblique tip has stopped at the difficult to cross side branch ostium, the balloon is rotated and the longer aspect of the balloon is then expected to emerge beyond the ostium allowing opening of the strut with inflation. In theory, because of its short length (4 mm) it also minimizes the risk of side branch dissection [18].

An observational study in 236 consecutive bifurcation lesions where final kissing balloon dilatation was attempted reported successful kissing balloons with conventional angioplasty balloons in 221 lesions (93.5%) [11]. In the 15 lesions where conventional balloons did not pass, the Glider balloon crossed in 12 patients (80%). Similar results were reported in another registry study comprising 125 patients with 131 bifurcation lesions [19]. These data suggest that the Glider balloon is a useful bail-out device for recrossing stent struts in bifurcation stenting if conventional angioplasty balloons fails.

Clearway catheter for intracoronary drug delivery

The Clearway catheter (Atrium Medical, Hudson, NH, USA) is a microporous PTFE balloon mounted on a 2.7 Fr rapid exchange catheter which has been investigated in patients undergoing primary PCI for ST-segment elevation myocardial infarction (STEMI). This balloon occludes coronary blood flow, contains the thrombus, and allows for local infusion of a pharmaceutical agent [20]. It was investigated in the INFUSE-AMI trial (intracoronary abciximab infusion and aspiration thrombectomy in patients undergoing percutaneous coronary intervention for anterior ST-segment elevation myocardial infarction) which randomized 452 patients with an anterior STEMI and an occluded proximal or mid left anterior descending coronary artery (LAD) [10]. All patients underwent primary PCI using bivalirudin and were randomized in a 2 × 2 factorial design to one of four arms:

- 1 Local infusion of the glycoprotein IIb/IIIa platelet inhibitor abciximab using the Clearway catheter and thrombus aspiration using a manual thrombus aspiration device
- 2 Local infusion of abciximab but no thrombus aspiration
- 3 Thrombus aspiration but no abciximab infusion, or
- 4 No abciximab infusion and no thrombus aspiration.

In this relatively small study, infarct size at 30-day follow-up was significantly smaller in patients treated with local infusion of abciximab, but not in patients undergoing manual thrombus aspiration.

Flash Ostial dual balloon angioplasty catheter

This specialized balloon catheter (Cardinal Health, CA, USA) is designed to address the protrusion of stent struts to the aorta when a stent is placed in an aorto-ostial lesion. It is designed to use as the

final step of angioplasty/stent implantation. It consists of a balloon-in-balloon technology and is delivered as a monorail over a 0.014 inch wire. The inner balloon is inflated first (nominal diameter to the stent implanted) and anchors at the ostium; then the outer (soft) balloon is inflated which dilates up to 20 mm within the aorta, thereby pushing the protruding struts toward the aortic wall. Ideally, this facilitates strut apposition and allows easier re-engagement of catheters at future procedures. The current sizes allow its use in left and right coronary as well as renal and subclavian procedures.

Drug-eluting balloons

Drug-eluting balloons, also often referred to as drug-coated balloons, were designed to facilitate local delivery of anti-restenotic drugs. By using highly lipophilic drugs, short contact times of a few minutes are sufficient for adequate drug delivery. The majority of drug-eluting balloons currently used in clinical practice elute the cytotoxic drug paclitaxel, which is also sometimes used on drug-eluting stents (DES). However, most current DES types elute an analogue of the anti-inflammatory and cytostatic drug sirolimus. Paclitaxel is excellently suited for use on drug-eluting balloons because of its rapid uptake and prolonged retention into the coronary vessel wall [21]. Given the paclitaxel-eluting DES have not fared as well as the DES eluting limus-type drugs, reservations remain on whether the paclitaxel-eluting balloons indeed represent the maximum capacity this technology offers. Recent developments in drug delivery have led to sirolimus (analogue) -eluting balloons using nanomicrospheres. By using lipophilic nanospheres to encapsulate the drug, the uptake of the drug can be enhanced by the increased lipophilicity and the duration of drug elution can be lengthened by regulating drug release from the nanosphere–drug complexes. Studies using these novel nanotechnology-based sirolimus (analogue)-eluting balloons are currently being performed and are anticipated over the next years. In the following section, the drug-eluting balloons discussed are all paclitaxel-eluting balloons.

DEB in in-stent restenosis lesions

The widespread use of second-generation DES has drastically reduced the incidence of in-stent restenosis (ISR), a common problem with BMS [22]. Nonetheless, ISR still occurs in 2–10% of lesions treated with DES, depending on stent type and lesion characteristics, and is notoriously hard to treat [4]. DES ISR can be treated by repeat placement of a DES, but concern exists about negative consequences of having multiple layers of stent [23]. Therefore, a drug-eluting balloon may be well suited for treatment of ISR lesions, allowing for acute lumen gain and local delivery of antiproliferative pharmaceutical agents.

The safety and efficacy of the drug-eluting balloon for treatment of BMS ISR was established in the small PEPCAD II (paclitaxel-eluting PTCA-balloon catheter in coronary artery disease) randomized trial which enrolled 131 patients with BMS ISR who were randomly allocated to treatment with a TAXUS paclitaxel-eluting stent or a drug-eluting balloon [24]. At 6 month-angiographic follow-up, in-segment lumen loss was significantly lower in the drug-eluting balloon group (0.17 ± 0.42 vs. 0.38 ± 0.61 mm; $p = 0.03$), with binary restenosis rates (defined as >50% stenosis) of 20% in the TAXUS group and 9% in the drug-eluting balloon group ($p = 0.08$). At 3-year clinical follow-up, rates of target lesion revascularization (TLR) were 9.1% in the drug-eluting balloon group and 18.5% in the TAXUS group ($p = 0.14$) [25].

The performance of drug-eluting balloons in the treatment of DES ISR was evaluated in the ISAR-DESIRE 3 (intracoronary stenting and angiographic results: drug-eluting stent in-stent restenosis: 3 treatment approached), PEPCAD China ISR, and RIBS IV (restenosis intra-stent of drug-eluting stents: drug-eluting balloon versus everolimus-eluting stent) randomized controlled trials [26–28]. These studies showed that using a paclitaxel-eluting balloon results in comparable or superior outcomes compared with using paclitaxel-eluting DES in ISR lesions. However, the RIBS IV trial, which compared the paclitaxel-eluting balloon with the second generation everolimus-eluting stent, reported superior outcomes in terms of angiographic (late loss) and clinical (TLR) endpoints with the everolimus-eluting stent [27]. Another recent observational study raised concerns about the durability of the efficacy of the drug-eluting balloon in 468 patients with 550 ISR lesions (of which 436 lesions were DES ISR; 79.3%) [29]. Patients underwent quantitative coronary angiography analysis at 6 and 18 months after the index procedure. At 18 months, late lumen loss was significantly greater in patients with DES ISR compared with BMS ISR. Moreover, in the DES ISR group, approximately 25% of patients underwent TLR after 18 months. These results underscore the complexity of the problem of DES ISR and suggest that DES ISR treatment with drug-eluting balloons could benefit from more aggressive lesion preparation, for example with scoring or cutting balloons before deployment of the drug-eluting balloon.

DEB in de novo lesions

Drug-eluting balloons have also been used for treatment of de novo coronary artery lesions, either by themselves, or combined with BMS implantation. A small study randomized 30 patients with a single de novo coronary artery lesion to treatment with BMS alone, predilatation with a drug-eluting balloon followed by BMS implantation, or BMS implantation followed by postdilatation with a drug-eluting balloon. In this small study, angiographic outcomes were better when drug-eluting balloons were used, with no difference between use before or after BMS implantation [30].

This potential clinical application of drug-eluting balloons was coined as a potentially safe alternative to first-generation drug-eluting stents, which were hampered by high rates of very late stent thrombosis [31]. However, the introduction of second-generation DES with biocompatible or bioresorbable polymers eluting sirolimus or its analogues has since been proven to be a safer and more effective alternative to first generation DES with better angiographic results compared with drug-eluting balloons for de novo coronary artery lesions [5,32].

Nonetheless, drug-eluting balloons could be an attractive treatment option for small coronary vessels which was first studied in the small (n = 182) randomized BELLO (balloon elution and late loss optimization) trial [33]. Patients undergoing PCI of a lesion with a reference vessel diameter <2.8mm by visual estimation were randomized to treatment with a drug-eluting balloon and provisional BMS (which was used in 20% of patients) or a TAXUS paclitaxel-eluting stent. At 2-year clinical follow-up, TLR rates were numerically lower in the drug-eluting balloon group (6.8% vs. 12.1%; p = 0.25). A major shortcoming of this study is the fact that paclitaxel-eluting DES were used, whereas next generation everolimus-eluting DES have been shown to yield superior outcomes in terms of repeat revascularization and death/myocardial infarction compared with paclitaxel-eluting DES [34].

The drug-eluting balloon has also been investigated in bifurcation lesions, where they may form an attractive option to minimize side branch restenosis. The BABILON trial (paclitaxel-coated balloon

catheter in bifurcated coronary lesions) enrolled 108 patients with de novo bifurcation lesions which were randomized to treatment with provisional T-stenting with BMS or everolimus-eluting DES. In this study, all patients underwent sequential main branch and side branch dilatation with a drug-eluting balloon [35]. At 2-year clinical follow-up, angiographic outcomes were similar for the side branches. However, in the main branches, everolimus-eluting DES implantation led to reduced TLR rates compared with BMS implantation (3.6% vs. 15.4%; p = 0.045). Therefore, the role for drug-eluting balloons in de novo coronary artery lesions seems limited to treatment of side branches in bifurcation lesions or vessels with small reference diameters that do not allow for stent implantation.

DEB in acute myocardial infarction

The use of drug-eluting balloons in acute myocardial infarction has been investigated because it theoretically eliminates the risk of stent thrombosis after primary PCI. To date, a total of two non-randomized observational studies have reported on the use of drug-eluting balloons in the setting of acute myocardial infarction. A 100-patient registry from a large tertiary referral center in the Netherlands showed that a drug-eluting balloon-only strategy was feasible in 41 patients, while 59 patients required additional stenting [36]. At 1-year clinical follow-up, two patients had died, while three patients had undergone TLR. Another non-randomized study of 40 patients with STEMI undergoing primary PCI with drug-eluting balloons showed less favorable results with the drug-eluting balloon [37]. At 6-month clinical follow-up, seven major adverse cardiovascular events occurred (17.5%); one non-cardiac death, five TLRs, and one target vessel revascularization. Given the conflicting results of these two studies, the role of the drug-eluting balloon in primary PCI is currently not clear, and more research is needed to provide additional data on safety and efficacy of this treatment strategy.

Conclusions

Specialized balloons of several types have been developed, each with their own clinical applications. In most day-to-day PCI cases, “standard” compliant and non-compliant balloons are sufficient. Nonetheless, specialized balloons are of particular value in select situations, and can be used to optimize lesion preparation (cutting balloon, scoring balloon), to treat ISR (cutting balloon, scoring balloon, and drug-eluting balloon), intracoronary drug delivery (clearway catheter), or treatment of side branches in bifurcation lesions (Glider balloon, drug-eluting balloon). Further research is needed to establish the applicability of novel sirolimus (analogue) -eluting balloons, and the use of drug-eluting balloons in de novo coronary artery disease and acute myocardial infarction.

Coronary dissection, perforation, and the no-reflow phenomenon are some of the most dreaded complications occurring in the catheterization laboratory and have been associated with a high rate of major adverse outcomes [1–14]. Although operator experience, equipment, drugs, and device technology continually improve, major dissection, abrupt closure, arterial perforation, and no-reflow remain the primary reasons for failure of percutaneous coronary intervention (PCI). While some instances of these complications are subtle, others are dramatic and can result in abrupt vessel closure, myocardial infarction, need for urgent coronary artery bypass surgery, pericardial tamponade, heart failure, cardiogenic shock, and even death. As a result, interventional cardiologists need to be vigilant for these complications and initiate therapy without delay. Improvements in PCI technique and equipment, primarily with the widespread use of coronary stents, has significantly decreased the incidence of acute closure and the need for emergency revascularization. Furthermore, innovative percutaneous approaches to the management of coronary perforation have included the use of covered stents and microcoil vessel occlusion. This chapter discusses the risk factors, recognition, and contemporary approach to managing peri-procedural complications related to PCI.

Coronary artery dissection Dissection following PCI

By definition, separation of the media by hemorrhage with or without an associated intimal tear is termed coronary artery dissection. PCI depends upon mechanical dilatation of the artery or ablation of atherosclerotic plaque and is therefore essentially associated with plaque fracture, intimal splitting, and localized medial dissection; these tears can extend into the media for varying distances and degrees, and even extend through the adventitia resulting in frank perforation. Historically, acute vessel closure is the most feared complication of coronary artery dissection, and in the pre-stent era occurred in 2–14% of patients [15–19]. Subsequently, because of improvements in PCI technique and equipment, primarily the widespread use of coronary stents—compared to balloon angioplasty—acute closure and the need for emergency coronary artery bypass surgery (CABG) have decreased significantly, despite the increasing complexity of cases. In contemporary interventional

practice, including the use of stents in patients with moderate to high risk acute coronary syndromes, the incidence of abrupt vessel closure is less than 1% [20], and most laboratories report emergency CABG rates below 0.5% [21].

Dissections have been classified by the National Heart, Lung, and Blood Institute (NHLBI) according to their angiographic appearance [22,23]. The modified NHLBI criteria defined dissection as angiographically detectable intimal or medial damage manifesting as a radiolucent area within the vessel or as an extravasation of contrast medium after an interventional procedure. These criteria were refined into a more detailed classification system and are graded based upon their angiographic appearances as types A–F (Table 25.1). Type A dissections represent minor radiolucent areas within the coronary lumen during contrast injection, with little or no persistence of contrast after the dye has cleared. Type B dissections are parallel tracts or a double lumen separated by a radiolucent area during contrast injection, with minimal or no persistence after dye clearance (Figure 25.1). Type C dissections appear as contrast outside the coronary lumen (“extraluminal cap”), with persistence of contrast after dye has cleared from the lumen (Figure 25.2). Type D dissections represent spiral (“barber shop pole”) luminal filling defects, frequently with excessive contrast staining of the dissected false lumen (Figure 25.3). Type E dissections appear as new, persistent filling defects within the coronary lumen (Figure 25.4). Type F dissections represent those that lead to total occlusion of the coronary lumen without distal antegrade flow (Figure 25.5) [24].

During the balloon angioplasty era, some studies have attempted to distinguish minor dissections from detrimental major ones. In general, type A and B dissections are clinically benign and do not adversely affect procedural outcome. Conversely, types C–F are considered major dissections and carry a significant increase in morbidity and mortality. Major dissections are characterized by numerous morphologic features: (i) a linear intraluminal filling defect or luminal staining evident in two projections; (ii) a linear filling defect extending greater than 20 mm; and (iii) dissection types C–F according to NHLBI criteria [25]. Major dissections also create intraluminal filling defects of sufficient size to produce a reduction in luminal diameter of at least 50% and/or a reduction in distal coronary flow. Huber *et al.* [25] demonstrated that abrupt closure, myocardial infarction, and bypass grafting occurred in fewer

than 3% of patients with NHLBI type B dissections. Conversely, dissection types C–F were associated with complication rates of 12–37%. Persistent extraluminal contrast, new persistent filling defects, and spiral dissections portend adverse clinical outcomes.

Previous studies in the pre-stent era identified risk factors for the development of coronary artery dissection. Angiographic predictors include calcified lesions, eccentric lesions, long lesions, complex

lesion morphology (ACC/AHA type B or C), and vessel tortuosity. A balloon to artery ratio >1.2 also predisposes to dissection [26,27].

The dissection can occur after overly vigorous attempts at guide-wire passage, following balloon predilatation before the planned stent implantation, or even after stenting.

Stent edge dissections are common as the junction between stent metal—and more recently between bioresorbable vascular scaffold (BVS) strut—and reference segment tissue is a site of compliance mismatch (Figure 25.6). Intracoronary ultrasound (IVUS) or optical coherence tomography (OCT) does not seem to predict coronary dissection on preintervention analysis of lesion morphology or plaque composition [28]. A recent study evaluated the frequency, predictors, and detailed assessment of OCT detected stent edge dissections in 230 patients. The overall incidence of OCT-detected edge

Table 25.1 National Heart, Lung and Blood Institute (NHLBI) classification system for coronary artery dissection types. Types A and B are generally clinically benign, whereas types C–F portend significant morbidity and mortality.

Type A	Coronary dissection with only minor radiolucent areas within the coronary lumen without a reduction in coronary flow
Type B	Minimal or no dye persistence in the presence of parallel track or a double lumen separated by a radiolucent area during contrast injection
Type C	Dissection with persistent extraluminal dye after contrast injection
Type D	Spiral dissection
Type E	Dissection with new and filling defects
Type F	This dissection does not fit any of the above types A–E and is associated with impaired flow or total occlusion of the vessel

Figure 25.2 Type C dissection at diagonal branch after balloon dilatation. The arrow shows a focal and persistent extraluminal dye contrast.

Figure 25.1 Type B dissection after balloon dilatation at right coronary artery (a). Notice the radiolucent parallel track at proximal and mid segments of the vessel (arrows) (b).

dissection was 37.8%, and most (84%) of them were not apparent on angiography. Additional stenting was performed in one-fourth of all dissections, which were longer, had bigger dimensions, and promoted deeper vascular injury. Of note, non-flow-limiting, small, and superficial dissections left untreated proved benign over time [29].

Ischemic complications in the current era usually occur as manifestations of edge dissections after metallic stent or BVS implantation, which can predispose to device thrombosis. The treatment of coronary edge dissection with stent implantation depends on the combination of angiographic assessment, flow assessment, and signs or symptoms of ischemia. Minor dissections should not be treated unless they result in lumen compromise; the vast majority have sealed when imaged at follow-up. In contrast, larger dissections are

associated with an increased risk of progression to total occlusion (abrupt closure) of the treated arterial segment [16,25]. The potential strategies of treatment include: (i) stent implantation; (ii) bypass surgery; or (iii) medical treatment alone. The choice of stenting vs. conservative management or surgery is therefore made on a case-by-case basis. In general, in the vast majority of dissections necessitating treatment, stent implantation is the first choice [29].

Intramural hematoma is a variant of dissection. By IVUS or OCT, intramural hematomas are typically crescent-shaped, with straightening of the internal elastic membrane (Figure 25.7). In general, unless focal, superficial, and small, an intramural hematoma should be treated because of the propensity for propagation and lumen compromise.

Figure 25.3 Type D dissection at right coronary artery after balloon dilatation for planned stent implantation. Despite the spiral dissection, there is no flow impairment.

Figure 25.4 Type E dissection. A spiral dissection at the right coronary artery after balloon angioplasty dilatation for stenting. Notice the extensive filling defects (arrows) with lumen narrowing at the mid portion of the artery.

Figure 25.5 Mild disease at circumflex artery by angiogram. Diagnostic IVUS was performed to interrogate the plaque stenosis. During the procedure a type F dissection has been observed; notice the spiral dissection (arrows) associated with total occlusion of the vessel.

Figure 25.6 Distal edge dissection by angiography and optical coherence tomography (OCT). Left anterior descending artery in the anterior–posterior cranial view after two Absorb bioresorbable vascular scaffold (BRS) implantations. Note a subtle distal edge dissection by angiography (arrows). OCT shows that the BRS struts are well apposed and expanded (a, arrows); note a deep edge dissection just beyond the BRS struts involving the intima and media with a flap (b, arrows). (c) is a magnified image.

Figure 25.7 Edge coronary hematoma with true (a) and false (b) lumen by Optical coherence tomography (OCT). Right coronary artery in LAO view pre (left) and post (middle) after Absorb bioresorbable vascular scaffold (BRS) implantation. There is no sign of distal edge dissection by angiography. OCT (right) shows that BRS struts are well apposed and expanded (a, arrows); there is also a small hematoma/dissection behind the struts (a in panel a); note an edge hematoma from 11 to 5 o'clock (a in panel b) with crescent shape, but with no lumen compromise b.

Guide catheter-induced dissection

The incidence of iatrogenic coronary artery dissection at the time of cardiac catheterization or PCI is not known. Catheter-induced dissection with retrograde extension to the aortic root is rare and has been estimated to occur in approximately 0.008–0.02% of diagnostic catheterizations and 0.06–0.07% of PCIs (Figure 25.8) [30,31]. The natural history of catheter-induced coronary artery dissections is varied. In some cases, dissections lead to acute closure of the vessel with myocardial infarction [32]. In other circumstances, retrograde extension of the dissection back to involve the aorta can occur [33,34], and in other cases, dissections of the coronary artery have been associated with persistently normal (TIMI-3) flow without ischemia, and have healed without any intervention [35]. Several factors are associated with increased risk for catheter-induced artery dissection:

- 1 Left main disease
- 2 Use of Amplatz-shaped catheters
- 3 Catheterization for acute myocardial infarction
- 4 Catheter manipulations
- 5 Vigorous contrast media injection
- 6 Deep intubations of the catheter within the coronary artery
- 7 Variant anatomy of the coronary ostia, and
- 8 Vigorous, deep inspiration [36], and the recanalization of chronic total occlusion (CTO) [37].

The management of catheter-induced coronary dissection depends on the patency of the distal vessel and the extent of propagation of the dissection. In general, in the presence of myocardial ischemia or acute closure, PCI or CABG is mandated to prevent acute myocardial infarction or even death. There have been reports of successful outcomes with coronary artery stenting [38] and CABG [32,39]. Nevertheless, in the absence of ischemia the therapeutic options are less clear. Conservative management of guide catheter-induced coronary artery dissection has met with successful outcomes in selected patients [32,35]. The choice of stenting vs. conservative management is therefore made on a case-by-case basis.

Figure 25.8 Catheter-induced dissection with retrograde extension of the dissection back to involve the aorta root (black arrows). Notice the spiral dissection with narrowing at the right coronary artery (white arrows).

Coronary artery perforation

Incidence

Coronary artery perforation represents a disruption of the vessel wall through the intima, media, and adventitia. Coronary perforation can engender localized pseudoaneurysm, perivascular hematoma, arterioventricular fistula, or hemopericardium. Angiographically, a perforation is defined as evidence of extravasation of contrast medium or blood from the coronary artery, during or following PCI. Few data are available on the true incidence of coronary perforation with balloon angioplasty alone. Various case series, many of which include the use of atherectomy devices, report an incidence ranging from 0.1% to 0.9% [2,25,40–43]. Some studies have described the incidence of coronary perforation to be 2–10 times higher in all published series using atheroablative techniques (directional atherectomy, excimer laser, rotablator, and transluminal extraction catheter) than with balloon angioplasty with or without stenting [44,45]. Ellis *et al.* [1] have reported the first large-scale series reflecting practice in 1990 and 1991. Of 12,900 procedures, 0.5% were complicated by coronary perforation. The incidence of perforations with balloon angioplasty alone was 0.1%, while that associated with rotablation was 1.3% and with excimer laser was 1.9%. The excimer laser probably carries the highest risk of coronary perforation (up to 3%) [1,46]. However, the device-related learning curve can also explain the higher rates of complications. For example, in a series, coronary perforation in conjunction with excimer laser use occurred in 1.2% of 3000 consecutive patients, but decreased to 0.3% in the last 1000 patients [46]. Other important information emerged from the Ellis *et al.* report. First, over-sizing of the angioplasty balloon was one of the key causes of perforation. Second, and most importantly, the development of cardiac tamponade was associated with high mortality (20%).

The actual incidence of guidewire-related coronary perforation is most likely higher than reported because it remains unrecognized and self-limited in several cases. The incidence of coronary perforation by the guidewire was 0.21% in the series by Dippel *et al.* [41] and 0.36% in the series by Fukutomi *et al.* [42]. In the later series, perforation occurred at the treatment site in 12 cases, in a distal vessel in 10 cases, and could not be localized in 5 cases [42]. In the series by Witzke *et al.* [47], coronary perforation by guidewire use was observed in 20 of 39 cases (51%). Of these cases, perforations occurred while trying to cross the lesion with a guidewire in 11 patients (55%). Based on these data, the authors emphasized that the distal migration of the guidewire is an important factor contributing to coronary perforation, and that meticulous care of the guidewire should be taken, especially in patients treated with glycoprotein platelet (GP) IIb/IIIa receptor inhibitors. The use of hydrophilic-coated guidewires, especially in complex cases, can be associated with higher rates of distal perforation than non-hydrophilic wires because of wire migration.

In the largest experience thus far assessing the incidence and outcomes of coronary perforation, our group analyzed of 12,921 patients treated with PCI in three randomized trials: REPLACE-2, ACUTY, and HORIZONS-AMI [48]. We found that coronary perforation occurred in 0.27% of cases. Noteworthy, at 30 days, patients with versus those without coronary perforation had significantly (all *p* values <0.001) higher rates of 30-day mortality (11.4% vs. 1.0%), myocardial infarction (MI) (Q-wave, 22.9% vs. 5.7%; non-Q wave, 17.1% vs. 4.9%), target vessel revascularization (TVR) (20.1% vs. 1.8%), and composite endpoint of death/MI/TVR (31.4% vs. 7.8%). The proportion of perforation that progress on to tamponade ranges between 10% and 50%. In Fejka *et al.*'s series [44], almost 50% of

those developing tamponade died. Of note, of 31 cases of tamponade, 14 presented more than 4 h after the procedure. The mortality of these later presenters was lower than those who had a more precipitous course within the catheterization laboratory (21% vs. 59%), but it was still considerable. In addition, according to the authors it was not possible to identify by angiography the bleeding point leading to tamponade in 10 of the 14 late presenters, suggesting that the most likely mechanism was guidewire distal branch perforation. In our study [48], mortality of the patients who developed hemopericardium and tamponade following perforation was 80%.

In cases involving CTOs, perforations from the use of stiff guidewires are the most commonly observed type, mainly divided into: (i) perforation of the false lumen while advancing a stiff wire into the false lumen; and (ii) distal small branch perforation after crossing a CTO lesion. The most important recommendation during CTO angioplasty is to not advance any device over the guidewire unless the operator is sure of where the distal end of the guidewire lies. In general, special treatment is not required for false lumen perforation because it usually disappears after dilatation of another false lumen. However, if a device is advanced over the guidewire through the perforation, this usual self-limited complication can become a life-threatening situation. In distal small branch perforations, the most important consideration is performing careful observation via angiography. These perforations can cause late tamponade because the operator is often not able to detect them. At the end of the procedure, even in successful cases, a final angiography should be carefully performed.

Classification

A classification system for coronary perforations related to the angiographic appearance of blood extravasation (Table 25.2) was created based on the analysis of prospectively recorded data from a total of 12,900 PCI procedures from 11 US sites during a 2-year period [1]. Coronary perforation occurred in 62 patients (0.5%). Type II perforation was the most frequent perforation type in this series (50%), followed by type III (25.8%), and type I (21%); the minority of cases were characterized by cavity spilling (3.2%) [1]. Of note, the NHLBI classification system for coronary dissections overlaps with the Ellis classification model, with NHLBI type C coronary dissections corresponding angiographically with Ellis type I perforations (Figures 25.9, 25.10, and 25.11) [25].

In addition, other studies have evaluated the proposed classification system as a tool to predict outcome and to serve as the basis of management [1,49–51]. Analysis showed that:

- Type I perforations rarely result in tamponade or in myocardial ischemia.
- Type II perforations have high treatment success rates when managed with prolonged balloon inflation, and commonly have

low occurrence of persistent contrast extravasation, consequently resulting in a low incidence of adverse sequelae [49].

- Type III perforations are associated with the rapid development of hemodynamic compromise and life-threatening complications, including abrupt tamponade, need for emergent bypass surgery, and very high mortality. Notably, type III perforations with contrast spilling into either the left or right coronary ventricle or coronary sinus do not have catastrophic consequences and are commonly benign [50,51].

Risk factors for coronary perforation

Risk factors for coronary perforation during standard PCI can be classified as: (i) patient-related; (ii) procedure-related; or (iii) device-related risk factors (Table 25.3).

Patient-related factors

Patient characteristics that have been associated with a risk of perforation include age, female gender, renal insufficiency, and history of prior CABG [1,40,48,52,53]. In a multicenter study by Ellis *et al.* [1], patients who developed perforation were almost 10 years older than those who had no perforation. In addition, women represented 46% of patients with perforation but only 16% of patients without this complication. Calcification presents a technical challenge for the interventionist. It often requires very high-pressure balloon inflation—either for predilatation or for post-dilatation—in order to achieve success [40]. The study found that 93% were complex, ACC/AHA class B2 or C, and 58% exhibited heavy calcification. Recently, Généaux *et al.* [54] evaluated data from 6855 patients presenting with acute coronary syndromes in whom PCI was performed from two large-scale randomized controlled trials: ACUITY and HORIZONS-AMI. By multivariable analysis, the presence of moderate or severe target lesion calcification was an independent predictor of 1-year definite stent thrombosis and ischemic target lesion revascularization (TLR).

Procedure-related factors

The use of oversized compliant balloons coupled with relatively high deployment or post-dilatation inflation pressures to achieve full stent expansion and minimize residual stenosis after stent implantation can cause vessel wall perforation [1,40,55]. Several mechanisms are involved, including overstretching of the most compliant coronary artery segment, a high-pressure jet caused by balloon rupture, and outward pushing of a stent strut through the vessel wall. Procedural success and complication rates as a function of balloon-to-vessel ratio and high inflation pressure have been reported in numerous studies. In a study by Colombo *et al.* [55], the use of a high balloon-to-vessel ratio (1.2 : 1) with a mean pressure of 12 atm for the treatment of coronary stenosis in 60 patients was associated with a mean final percent stenosis of –8% with one case of a coronary rupture. Conversely, usage of a similar balloon-to-vessel ratio with a higher inflation pressure (mean of 15 atm), applied in the next 300 patients yielded a slight improvement in the final percent stenosis (mean –10%), but at the expense of an increase in the incidence of vessel rupture and major dissection (3.4%). Finally, in a different subgroup, usage of a smaller balloon-to-vessel ratio of only 1.0 but with a higher mean pressure (16 atm), applied in 162 patients, yielded a percent residual stenosis of 1% with a rate of coronary rupture reduced to 0.7%. Similarly, in a series by Ellis *et al.* [1] the mean balloon-to-artery ratio in patients treated with plain balloon angioplasty was significantly higher in those who developed coronary perforation compared with those

Table 25.2 Classification of coronary perforations.

Type I	Extraluminal crater without extravasation
Type II	Pericardial or myocardial blush without contrast jet extravasation
Type III	Extravasation through frank (≥ 1 mm) perforation
Cavity spilling	Perforation into anatomic cavity chamber, coronary sinus, etc.

Figure 25.10 Type III perforation. This patient underwent a previous stent implantation in the mid right coronary artery. Follow-up catheterization showed restenosis with chronic total occlusion (a). (b) shows that the guidewire has been crossed and the balloon has been inflated at the origin of the acute marginal branch **a**; the distal portion of the stent is shown in (b), arrow **b**. Notice the perforation with contrast extravasation in (c).

who did not (1.19 ± 0.17 vs. 0.92 ± 0.16 ; $p = 0.03$). The same findings were reported by Stankovic *et al.* [56], where a high balloon-to-artery ratio was associated with a 7.6-fold increase in the odds of coronary perforation.

Vessel determinants associated with coronary rupture include lesion severity with American College of Cardiology/American Heart Association (ACC/AHA) type B or C lesions, and the presence of a more highly calcified lesion has also been associated with coronary rupture [52,57,58]. Of note, PCI for CTO is also associated with an increased risk [40].

Device-related factors

Coronary perforation can be caused by the guiding catheter, balloon rupture, guidewire, IVUS/OCT catheter, embolic protection device, and atheroablative and CTO devices [56,59,60]. Dippel *et al.* [41] reported that, of more than 6000 interventions, ablative procedures were accorded a 6.8-fold risk of perforation. In addition, the perforations with these technologies were often Ellis type III. Recently, stiffer wires for CTO procedures have been developed to dramatically enhance the ability to cross the lesions. Vessel perforation has become particularly important with the introduction of stiff wires

Figure 25.11 Chronic total occlusion at mid right coronary artery (a). Failed attempts leads to vessel dissection and perforation type III with pericardial effusion (b).

Table 25.3 Risk factors for coronary perforation.

Patient-related	Procedure-related	Device-related
Female gender	High balloon/stent-to-artery ratio	Stiff wire
Older age	High inflation or post-dilatation pressure	Hydrophilic-coated wire
Renal insufficiency	Extremely distal location of the guidewires	Cutting balloon
	Treatment of chronic total occlusion	Atheroablative devices
		IVUS/OCT in the false lumen

IVUS, intravenous ultrasound; OCT, optical coherence tomography.

for penetrating the proximal and distal caps of CTO. However, dilating a subintimal channel can not only result in vessel occlusion or perforation, but also prohibit future surgical grafting of the coronary artery. Special attention must also be taken when hydrophilic wires are used because of their propensity for subintimal passage and perforation of end capillaries. These wires easily enter thin-walled vasa vasorum, which are prone to perforation either directly from the wire or from the subsequent dilatations. Recently, Stathopoulos *et al.* [61] analyzed 23,399 PCI and identified 73 patients complicated by coronary perforation, of which 31 were guidewire induced. In-hospital mortality was similar for patients with guidewire-induced and non-guidewire-induced perforations. Tamponade conferred a threefold increase in the long-term probability of death and guidewire-induced coronary perforation during elective PCI had the best survival.

Cardiac tamponade as well as requirement for emergency surgery are important risk factors for overall mortality with coronary perforation [1,57].

Management and treatment of perforation

Coronary perforation carries a significant mortality risk. Therefore, management and treatment are important and should be initiated very rapidly. The strategy for treating coronary perforation is best

determined by specific angiographic type and clinical circumstances. Based on angiographic classification, a treatment algorithm for coronary perforations was proposed by Dippel *et al.* [41]. In general, type I perforations usually respond to conservative measurements. Stenting over the blemish often successfully deals with the problem site. In many of these conditions, prolonged proximal balloon inflation helps solve the problem. When limited pericardial effusion occurs, as in type I or II perforations, serial echocardiography can suggest clues to ongoing leakage, as evidenced by changes in the effusion size. Early diastolic right ventricular collapse and late diastolic right atrial collapse are early signs of cardiac tamponade and precede the onset of hypotension.

In limited perforations (types I and II) not caused by guidewire use, maintaining guidewire position across the perforation site is crucial, and careful balloon compression of the perforation site is usually recommended to limit further extravasation. In patients receiving heparin, reversal of the anticoagulant effects should be considered. In an analysis of the Mayo Clinic PCI database, administration of protamine sulfate and prolonged balloon inflation were the most common treatments performed after identification of a coronary perforation [52]. In those patients receiving unfractionated heparin (UFH), IV protamine sulfate should be given, with subsequent dose titration guided by anticoagulation status, to rapidly and

easily reverse the anticoagulation effects [42,62]. Reversal of heparin anticoagulation should target an activated clotting time (ACT) of 150 seconds. Protamine partially neutralizes the anti-IIa activity, but not the anti-Xa activity of low-molecular-weight heparin [63,64]. Importantly, protamine has been safely administered to facilitate hemostasis following coronary stent deployment without adverse ischemic sequelae [65]. However, this safety has not been well demonstrated following drug-eluting stent (DES) implantation [66]. GP IIb/IIIa inhibitor infusion should be stopped whenever perforation occurs, regardless of the severity. The effects of abciximab can be reversed by platelet transfusion; eptifibatid and tirofiban have no antidote but have a relatively short half-life lasting several hours. Direct antithrombin agents (e.g., bivalirudin) are more problematic, as there is no antidote for this class of agents. However, we have shown treatment of patients experiencing coronary perforation with adjunctive antithrombotic therapy of bivalirudin monotherapy was not associated with worse outcomes compared than treatment with UFH plus GP IIb/IIIa inhibitors [48].

Pericardiocentesis should be performed only in the presence of cardiac tamponade with hemodynamic or echocardiographic cardiac compromise [41].

In type I perforation, management is commonly limited to careful observation for 15–30 minutes with repeated injections of contrast media, associated with the measures described above. In type II perforation, the first step in management is placement of a standard balloon catheter (2–3 atm pressure) to seal the perforation [41,67]. Then, heparin reversal and GP IIb/IIIa inhibitor discontinuation should be promptly instituted. Echocardiographic assessment should be performed without delay. Emergent cardiac surgery is reserved for those patients who do not achieve hemostasis with these conservative measures. In type III perforation, an immediate aggressive treatment strategy is required, including adequate volume resuscitation, administration of catecholamines, and, frequently, urgent pericardiocentesis. Immediate reversal of anticoagulation with IV protamine sulfate and platelet transfusion in abciximab-treated patients is critical. According to the algorithm proposed by Dippel *et al.* [41], treatment of type III perforation should start with standard balloon catheter inflation at the site of perforation for at least 5–10 minutes to provide time to perform pericardiocentesis. Subsequent prolonged balloon inflation can successfully seal a type III perforation or provide time to place an additional device to assist the treatment. The site of coronary perforation must be completely sealed and confirmed by an angiogram performed at least 10 minutes following treatment. Intermittent or continuous pericardial catheter aspiration should be employed overnight. Furthermore, the authors recommend in-hospital observation for an additional 24 hours with repeat echocardiography prior to discharge or on the day following pericardial catheter removal [41].

Devices and materials for coronary perforation

Several devices and materials have been used for sealing the perforation site, such as plugs, coils, glues, beads, and covered-stents. Plugs, coils, glues, and beads are usually used for small (types I or II) or distal perforations caused by the guidewire. These perforations cannot be sealed with covered stents, which are more useful for pinhole perforations. Coil embolization of coronary perforations, especially of the distal vessel, has also been used as a percutaneous bailout treatment [68,69]. In general, most studies report microcoil embolization with platinum or stainless steel coils ranging from 0.014 to 0.025 inches in diameter [70,71]. These are delivered through dedicated microcatheters and are ideal suited to this purpose (Figure 25.12). However, larger coils have been used in coronary

artery ruptures or in large segment perforations [72,73]. Other, rather innovative methods of sealing distal vessel perforation have been reported: injection of thrombin [70,74]; autologous clotted blood [75]; tris-acrylgelatin microspheres [76]; fibrin glue [77]; subcutaneous adipose tissue [78]; polyvinyl alcohol foam [79]; and ethylene-vinyl-alcohol-copolymer (Onix) [80]. Any material that includes clotting and plugging the small perforation will suffice. Autologous vein-covered stents have also been described as an effective treatment option for successful percutaneous sealing of perforations [81,82]. However, isolating the graft (typically a cephalic vein) by cutdown and mounting and suturing it onto a metallic stent is time-consuming and an improbable emergency treatment for free-flowing perforation and pericardial tamponade [83].

If cardiac tamponade develops and low blood pressure ensues, pericardiocentesis and drainage with a pigtail catheter are required. An important point to consider is the need to use two guiding catheters in order to be able to control the perforation with the inflated balloon while being ready to advance a covered stent if needed. When extravascular flow is observed on angiography despite prolonged balloon inflation, a covered stent should be used to stop the leakage. If a life-threatening perforation occurs while working with a smaller guide requiring the covered stent for sealing, a balloon angioplasty catheter (or stent delivery balloon) should immediately be inflated across the tear in the coronary vessel to provide temporary hemostasis. Another guide catheter should then be introduced via contralateral femoral artery access and used to cannulate the coronary ostium after gently disengaging the other guide. The covered stent should be introduced into the new guide over a second guidewire and passed just proximal to the occluding balloon, which is then deflated and retracted, allowing passage of the new guidewire and the covered stent for definite closure of the perforation [84].

A bare metal stent covered by an ultrathin polymer (polyethylene terephthalate) mesh sleeve on its external surface, the MGuard[®] stent (InspireMD, Tel Aviv, Israel), has been described as an option for sealing coronary perforations (Figure 25.13) [85,86]. The protective net is composed of micron-level fibers with pore size of $\leq 200\ \mu\text{m}$. It was developed to block the plaque and thrombus detachment from the arterial wall during and after the intervention to reduce embolization. The MGuard[®] stent is a combination of a bare metal stent and an embolic protection device, intended to represent a feasible and safe treatment option in patients with STEMI and saphenous vein graft (SVG) intervention.

Covered stent device description

The most widely used device is the polytetrafluoroethylene (PTFE) covered stent which can reduce the mortality related to coronary perforation to 10% [56]. The currently available coronary stent graft is a balloon expandable, slotted-tube stent. The Jostent/Graftmaster RX[®] coronary stent graft device (AbbottVascular Devices, Abbott Park, IL, USA) consists of an ultrathin (75 μm), biocompatible, and expandable PTFE layer sandwiched in between two coaxial 316L stainless steel, slotted-tube, balloon-expandable stents. Available lengths of the stent are 16, 19, and 26 mm, with diameters of 2.8–4.8 mm. The main limitations of the stent are an enhanced propensity for stent thrombosis, which can be diminished by high-pressure prolonged balloon inflation (for optimal expansion, the recommended inflation pressure is 15–16 atm for at least 30 seconds to allow for complete stent expansion), IVUS/OCT evaluation for proper implantation, and prolonged antiplatelet therapy that includes aspirin and thienopyridines. Several reports have described the use of the PTFE-covered stent in treating coronary perforations, with favorable results [1,81,84,87–89].

Figure 25.12 Right coronary artery in the RAO cranial view pre PCI in a patient with non-ST elevation myocardial infarction. The target vessel was the posterior descending artery, which is occluded. (a) After vessel recanalization using Whisper hydrophilic coated wire (Abbott Vascular, USA), the tip of the wire went inadvertently through in the very distal part of the vessel (b) causing perforation with contrast jet extravasation to the left ventricle (c). The perforation was successfully sealed using Azur platinum coil with expandable hydrogel polymer (d) (Terumo, Japan).

Figure 25.13 Left anterior descending artery in the RAO cranial view after multiple DES implantation (left). After post-dilatation with non-compliant balloon a type I perforation with extraluminal crater without extravasation is noted (arrows). Protamine was administered for heparin reversal following Mguard stent implantation. The site of the perforation is completely sealed after stenting (right).

In a multicenter, retrospective, international registry, Lansky *et al.* [84] reported the use of Jostent® coronary stent grafts in 41 cases of coronary perforations. Perforations were relatively severe: 16.7% Ellis type I, 54.2% type II, and 29.1% type III. Of the 41 patients, >1/3 (n = 14) experienced life-threatening complications before stent graft implantation, including pericardial tamponade (12.2%), cardiogenic shock (9.8%), and cardiac arrest (2.4%). A total of 52 coronary stent grafts were used to treat the 41 perforations (mean 1.3 per lesion). All coronary stent grafts were placed successfully, with 92.9% of the perforations sealed completely and 7.1% partially. One patient developed abrupt vessel closure after coronary stent graft deployment, resulting in an overall procedure success rate of 96.4%.

Based on a comparison of outcomes of coronary perforations in two Milan centers before and after 1998, Stankovic *et al.* [56] showed that the use of the covered stent was associated with a significant reduction of in-hospital major adverse cardiac events (MACE) (death, any MI, and TVR) in type III perforations (91–33%), but had no impact on the clinical course of type II perforations. A two-center study in Europe reported 49 cases of coronary perforation complicating a total of 10,945 PCI procedures (0.45%) [87]. Adequate sealing of the perforation was not achieved by conventional methods (perfusion balloon, reversal of anticoagulation, platelet transfusion with/without pericardiocentesis) in 29 of 49 patients (59%). The first 17 of 29 patients in this series were treated with Palmaz-Schatz™ stents (attempted in five but successful in only two patients) and/or with emergent cardiac surgery (15 patients). In the subsequent 12 of 29 patients, perforations were treated with PTFE-covered stents. In this series, PTFE-covered stents successfully sealed 91% of coronary perforations after other conservative approaches failed. In the same series, pericardial effusion without hemodynamic impairment was identified less frequently in patients receiving another stent and/or undergoing urgent cardiac surgery. Although PTFE-covered stents are considered to be the device of choice in the treatment of coronary perforations, in some situations the use of this stent is technically difficult or even impossible because of its limitations, including limited flexibility and tractability, especially in diffusely diseased vessels. Furthermore, the use of covered stents in native coronary arteries must be undertaken with caution, given the potential for side branch coverage with subsequent myonecrosis. Another recently available covered stent outside the USA is the Direct-Stent® Stent-Graft (InSitu Technologies InC. MN, USA), which consists of a single layer of ePTFE polymer with proprietary micro-porous technology. Available lengths of the stent are 10 and 38 mm, with diameters of 2.25–60 mm.

Early and late clinical outcome

For the patient with major perforation in hospital, careful observation with frequent hemodynamic monitoring is required after the procedure, and follow-up angiographic examination should be performed the next day. After making sure there are no adverse findings, the patient can be discharged.

Sequelae of coronary perforations range in severity from none to devastating, and are fraught with early (often instant) and/or late complications. Based on the series by Ellis *et al.* [1], a clear correlation exists between the angiographic type of coronary perforation and early complications. In this series, mortality and Q-wave MI were entirely limited to type III perforations. The majority of cases of emergent CABG and tamponade were also associated with type III perforations (63% for both complications), while emergent CABG and tamponade were remarkably lower in type I and II

coronary perforations. Interestingly, a recent study showed that despite treatment of more complex disease, the incidence of coronary perforation has not increased, which has been confirmed by a meta-analysis performed by Shimony *et al.* [90,91].

In the series described by Dippel *et al.* [41], clinical outcomes were quite favorable in patients with type II perforations: there were no cases of death or emergency CABG, with only one patient (5.3%) requiring pericardiocentesis. Importantly, these outcomes were achieved despite fairly infrequent reversals of procedural anticoagulation (21.1%), platelet transfusion (15.8%), or the use of prolonged perfusion balloon catheter inflation (26.3%), although the majority of patients (73.7%) received abciximab during PCI. In contrast, patients with type III perforations had a higher rate of mortality (21.4%), pericardial tamponade (42.9%), and emergent CABG (50.0%), despite more aggressive therapies including the use of protamine (64.3%), platelet transfusions (50.0%), and prolonged perfusion balloon catheter inflations (87.7%). Similarly, in a series by Stankovic *et al.* [56], all cases of in-hospital death and/or emergency CABG were associated exclusively with type III coronary perforations. Al-Lamee *et al.* [92] confirmed those findings, showing a high acute mortality (during the procedure and in-hospital mortality of 3.6% and 14.8%, respectively) and high long-term mortality and MACE rates (15.2% and 41.3%, respectively) after grade III coronary perforation.

A number of reports have emphasized that pericardial tamponade can develop several hours after coronary perforation. In a series by Ellis *et al.* [1], there was a 5–10% incidence of delayed (24 hours or more post-PCI) tamponade, arguing for careful patient monitoring, especially during that time period. Delayed pericardial tamponade typically results from a guidewire-related perforation and occurs not infrequently in patients undergoing recanalization of a CTO. Fukutomi *et al.* [42] reported five cardiac tamponades occurring in a total of 25 patients; in 12 patients, signs of tamponade emerged immediately after coronary perforation, while a delayed presentation (after a mean time of 4.9 ± 3.4 hours) occurred in 13 patients who were all treated for CTO lesions. In the same series, a guidewire caused coronary perforations in 8 of 13 patients (61.5%), with a delayed development of pericardial tamponade. Finally, in a series by Fejka *et al.* [44] analyzing 31 cases of cardiac tamponade occurring in a total of 25,697 procedures (0.12%) during a 7-year period, tamponade was diagnosed during the procedure in 17 patients (55%) at a mean time of 18 minutes from the start of PCI; in 14 patients (45%), tamponade presented later (mean time 4.4 hours post-PCI, range 2–15 hours). The same study clearly demonstrated that cardiac tamponade related to coronary perforation was associated with high rates of mortality; 13 of 31 patients (42%) in this series died. Mortality was especially high for those patients who developed cardiac tamponade during PCI compared with those who developed delayed tamponade (59% vs. 21% of patients).

The no-reflow phenomenon

No-reflow (or slow-flow or slow-reflow) phenomenon during PCI refers to a condition of decreased or absent antegrade coronary blood flow without angiographic evidence of a persistent mechanical obstruction [93,94]. By definition, no-reflow can be diagnosed only after excluding other causes of reduced antegrade flow such as dissection, spasm, thrombus, or a residual high-grade stenosis. It occurs rarely in elective PCI, but far more frequently in patients who present with acute MI. Persistent no-reflow has important prognostic implications and has been associated with unfavorable

clinical outcomes [8–10,95]. Patients who develop no-reflow during PCI have a significantly higher incidence of in-hospital and long-term complications such as MI, stent thrombosis, heart failure, negative ventricular remodeling, ventricular tachycardia, and death [8–14,96].

Incidence

The overall incidence of angiographic no-reflow phenomenon during PCI ranges from 0.2% to 2%. Higher rates have been reported for primary PCI (5–23%), SVG (9%), and rotational atherectomy (12%) [8,13,96–98]. It has been observed more commonly in diabetics, in lesions with a large thrombotic burden, and in patients without pre-infarction angina, suggesting a protective effect from ischemic preconditioning [6,7,12,14,93]. Also, it is more pronounced with longer periods of coronary occlusions [94]. Of note, except for thrombus-containing long lesions and degenerative SVGs, it can be difficult to predict the risk of no-reflow based on the angiographic appearance of a lesion. Furthermore, other causes of impaired coronary flow can simulate no-reflow including dissection, intracoronary thrombus formation, intracoronary bubble injection, epicardial coronary spasm, or remaining high-grade stenosis.

Pathophysiology

The pathophysiology of no-reflow is complex and not entirely understood, but appears to be multifactorial. Potential mechanisms differ depending on the clinical setting and lesion type undergoing PCI. In humans, it appears to be a combination of distal embolization, inflammation, and microvascular spasm [12,14,93,99–101]. Substantial capillary damage can also be seen with intraluminal obstruction resulting from endothelial swelling, capillary plugging, and microthrombi. An observed relationship between plaque volume, necrotic core, and distal coronary perfusion after PCI suggests that the release of material from the plaque is related to, if not causal, in distal microvascular obstruction. In fact, aspiration of coronary arteries in patients with thrombotic lesions and no-reflow has shown embolic debris (containing both thrombi and atheromatous gruel) in the majority of cases [100]. Vasospasm appears to have a central role in the pathogenesis of no-reflow irrespective of the clinical scenario in which it occurs. Experimental data suggest that microvascular vasospasm is caused by the release of serotonin, angiotensin II, thromboxane, and α -adrenergic agonists [8,102–104]. The local release of these vasoconstrictor substances impairs capillary autoregulation and increases reflex sympathetic activity.

Other mechanisms that have been implicated include oxygen free radical-mediated injury, reperfusion injury with loss of microvascular integrity [100,101], endothelial dysfunction, neutrophil infiltration, platelet aggregation, plasminogen activator inhibitor-1, tissue factor, and inflammatory factors (sCD40L, soluble E-selectin) [93,100,101,105]. The triggers of no-reflow during PCI appear to be distal embolization of plaque and/or thrombus with subsequent microcirculatory spasm. Thus, no-reflow is a major problem in the treatment of acute MI, thrombus-containing lesions, large plaque burden, rotational atherectomy, and SVG (Figure 25.14) [106].

Prevention

Possible approaches to prevent the no-reflow phenomenon include the use of mechanical aspiration, distal embolic protection, direct stenting, systemic infusion of GP IIb/IIIa inhibitors, and intracoronary infusion of vasodilating or antithrombotic/thrombolytic

agents. Apart from antiplatelet agent, all pharmacological drugs should be injected superselectively into the target vessel in order to reach effectively areas of myocardium.

Thrombectomy and aspiration

Occlusive thrombosis from an unstable atherosclerotic plaque is the substrate of most acute MIs. Therefore, macro- and micro-embolization during PCI in acute MI results in obstruction of the microvascular network and subsequently in reduced efficacy of reperfusion and myocardial salvage [107]. Use of adjunctive thrombectomy during primary PCI has been associated with significant improvement in coronary flow before stent implantation as well as post-procedural epicardial and myocardial perfusion with less distal embolization. However, its benefit for long-term survival is controversial [108–110]. For instance, in the INFUSE-AMI trial [109], patients randomized to aspiration thrombectomy vs. no aspiration had no significant difference in infarct size at 30 days, absolute infarct mass, or abnormal wall motion score. The multicenter, prospective, randomized TASTE trial [110], enrolled 7244 patients from the national comprehensive Swedish Coronary Angiography and Angioplasty Registry (SCAAR). Patients with STEMI undergoing PCI were randomly assigned to manual thrombus aspiration followed by PCI or to PCI only. Disappointingly, routine thrombus aspiration before PCI compared with PCI alone did not reduce 30-day mortality among patients with STEMI (2.8% vs. 3.0%). Finally, with regard to mechanical thrombectomy, the results of randomized trials do not show benefit [111,112].

Distal protection devices

The use of distal protection devices during SVG PCI has decreased the incidence of no-reflow during PCI in several studies, and confirmed the role of distal embolization in the development of this complication. As a result of their proven effectiveness in preventing distal embolization, no-reflow and MACE, the AHA/ACC/SCAI recommend the use of distal embolic protection devices when technically feasible in patients undergoing PCI to SVGs [113,114]. The SAFER trial established that the routine use of a distal protection device is associated with a reduced incidence of no-reflow in the treatment of degenerated SVGs [115].

The efficacy of a distal embolic protective device in acute STEMI was addressed in the multicenter EMERALD trial. Despite the removal of debris, there was no difference between the two groups in terms of ST segment resolution at 30 minutes (63% vs. 62%) and left ventricular infarct size (12.0% vs. 9.5%). In addition, MACE at 6 months were similar in the two groups (10% vs. 11%). The lack of benefit persisted when only patients undergoing primary PCI were evaluated [116]. Other subgroup analysis did not identify any subset of patients in whom an advantage of distal protection occurred [116,117].

Several explanations can be proposed regarding these negative findings. First of all, we should consider that in the setting of acute MI distal embolization can induce an additional, although limited, myocardial necrosis. This increase plays a minor part against the large background of necrosis resulting from ischemia and/or reperfusion. This condition differs from embolization that may occur in SVGs, in which the myocardial area distal to the graft is viable. Also, the type of device used and its crossing profile, operator experience, and technique of usage may have a relevant role. Whatever part embolic protection devices might play, they cannot be employed in all patients, but only in a minority of them with particular clinical or anatomic features and the problem is how to select patients who

Figure 25.14 Scanning electron microscopy (SEM) of the aspirated material from saphenous vein graft in an 80-year-old patient with a history of prior coronary artery bypass graft surgery. Coronary angiography showed a severe lesion in the saphenous vein graft to obtuse marginal (a). Slow-phenomenon was observed even after thrombus aspiration (b) and distal protection distal. SEM showing fibrin network, entrapped erythrocytes, activated platelets, and cholesterol crystals (*) (c, d).

may benefit from dedicated devices. The indiscriminate utilization of this resource to all patients not only represents an unjustified adjunctive cost, but is also associated with increased procedural time and reperfusion delay.

Direct stenting

In patients with an acute STEMI undergoing primary PCI, direct stenting can reduce embolization of plaque constituents, lowering the incidence of the no-reflow phenomenon, thereby increasing myocardial perfusion and salvage. Direct stenting can also

improve myocardial perfusion and the incidence of death, MI, or heart failure compared with conventional stenting in patients who undergo PCI after fibrinolysis [118–121].

Systemic glycoprotein IIb/IIIa inhibitors

It is unclear whether GP IIb/IIIa inhibitors when infused peripherally reduce the incidence of no-reflow, because data addressing this issue are limited and inconsistent.

The effect of GP IIb/IIIa receptor inhibitors in preventing no-reflow during SVG intervention has been disappointing [122].

Roffi *et al.* [123] performed a pooled analysis of five randomized intravenous GP IIb/IIIa inhibitor trials (EPIC, EPILOG, EPISTENT, IMPACT II, and PURSUIT) showing that prophylactic administration of these agents does not improve outcomes during PCI of SVG.

Intracoronary infusions

An intracoronary infusion of adenosine, verapamil, streptokinase, or abciximab has been evaluated in studies for its ability to improve myocardial reperfusion, prevent reperfusion injury, and salvage ischemic myocardium at the time of primary PCI. In the INFUSE-AMI trial [109], patients with large anterior STEMI presenting early after symptom onset and undergoing primary PCI with bivalirudin anticoagulation, infarct size at 30 days was significantly reduced by bolus intracoronary abciximab (6.8% vs. 17.9%) delivered to the infarct lesion site but not by manual aspiration thrombectomy. Patients randomized to intracoronary abciximab also had a significant reduction in absolute infarct mass (18.7 vs. 24.0 g). The routine use of abciximab during primary PCI has yet to be adopted after the results of larger clinical trials.

Verapamil pre-treatment has been shown to be effective in reducing no-reflow during SVG intervention in a small (n=32) randomized trial [124]. However, the intragraft verapamil failed to reduce the mortality or MI in patients with no-reflow and has not been incorporated into clinical practice.

Chronic statin therapy

It has been suggested that statin therapy reduces myocardial injury after PCI. Plaque stabilization and other pleiotropic effects of statin therapy could lower rate of no-reflow, improve wall motion, and left ventricular ejection fraction [125].

Treatment

Once no-reflow occurs, every attempt must be made to reverse it in order to reduce the risk of adverse outcome [126]. During PCI procedures, no-reflow can manifest as acute ischemia and be associated with chest pain, ECG changes, bradycardia, conduction disturbances, and hypotension leading to marked hemodynamic instability and cardiogenic shock. However, there are also rare cases of no-reflow that occur without any clinical sequelae. The initial evaluation and treatment of no-reflow consists of maintaining hemodynamic and electrophysiological stability. Box 25.1 provides a guide to the evaluation and management of no-reflow.

As the predominant abnormality during no-reflow appears to be microvascular constriction, different vasoactive drugs have been employed for the treatment of this phenomenon and their efficacy depends on coronary artery vasodilatation and hyperemia induction especially at the microvascular level [7,93,99,122].

Nitroglycerin

In fact, nitroglycerin (NTG) is not effective in reversing no-reflow and is given at the onset of no-reflow in order to exclude epicardial coronary spasm. It has been shown that NTG administration results in an increase in minimum lumen diameter that is not further increased by nitroprusside [127]. NTG also did not change any of the examined angiographic parameters (TIMI grade, corrected TIMI frame count, and TIMI myocardial blush) compared with baseline values (after stent deployment). This lack of effect on no-reflow has been confirmed in a number of studies [8,11].

Box 25.1 Strategy for evaluating and management of no-reflow

- 1 Exclude dissection, epicardial spasm, thrombus at lesion site, distal macro-embolism or air embolism
- 2 Check ACT levels (250–300 s)
- 3 Ensure oxygenation, hemodynamic stability, and maintain adequate coronary perfusion pressures
- 4 Intracoronary nitrates to exclude epicardial coronary artery spasm
- 5 Administer pharmacologic agents super-selectively into distal arterial bed by infusion catheter/microcatheter or over-the-wire balloon
 - a. Nitroprusside 80–200 µg bolus (up to 1000 µg total dose). Consider alternating with boluses of epinephrine 50–200 µg
 - b. Adenosine 10–20 µg high velocity boluses repeated as needed (10–30 doses)
 - c. Verapamil 50–200 µg bolus (up to 1000 µg total dose with temporary pacemaker standby)
 - d. Second-line agents for which evidence is less strong: epinephrine 50–200 µg, nicorandil 2 µg, papaverine 10–20 µg, nicardipine 200 µg, diltiazem 0.5–2.5 mg over 1 min up to 5 mg
- 6 Consider administering a glycoprotein IIb/IIIa receptor inhibitor intracoronary/intragraft or intravenous

Nitroprusside

NTG and nitroprusside (NTP) are both donors of nitric oxide, an endothelium-derived compound that has multiple vascular functions, including vasodilatation, inhibition of platelet adhesion, and anti-inflammatory activity [128]. Nitric oxide is a potent vasodilator in the resistance arteriolar circulation [129] and plays a significant part in the control of coronary blood flow through the microcirculation [130]. However, there is an important distinction between NTG and NTP. Resistance vessels, which primarily determine coronary blood flow, have a decreased capacity for enzymatic conversion of NTG into nitric oxide. Unlike NTG, NTP is a direct donor of nitric oxide and is reported to require no intracellular metabolism to derive nitric oxide; thus making nitric oxide available to the microcirculation and effectively dilating these distal vessels.

NTP has gained favor with many operators for its rapid and marked vasodilating effect with limited systemic hypotension. However, its dosage and efficacy in different clinical settings are not yet clearly established, because available information is derived from retrospective analysis of angiographic findings in different clinical conditions with different doses, routes of administration, and efficacy assessments [99,127,128]. A standardized NTP protocol has been suggested [127]:

- 1 Insert a multifunction catheter or over-the-wire balloon into the culprit vessel
- 2 Initial 80-µg bolus of NTP is selectively administered distal to the site of stent implantation or balloon dilatation via the multifunction catheter.
- 3 If no response, boluses of NTP with an increment of 40 µg each time is repeated every 2 minutes.
- 4 NTP boluses are continued until TIMI 3 flow is achieved or systolic blood pressure decreases to <80 mm Hg.

It was observed that the initial 80-µg bolus restored normal TIMI flow normal in 58% of patients (7 of 12) with acute MI and in 44% of patients (4 of 9) with SVG stenosis. The maximal dose (120–160 µg) restored normal TIMI flow in all remaining patients with acute MI but in only one additional patient with SVG stenosis. This standardized protocol for intracoronary NTP administration

succeeded in normalizing coronary flow in all patients with acute MI but in only 55% of patients with slow flow in SVG.

Two important factors why NTP has not been shown to be effective in some of the previous studies:

- 1 **Local drug delivery:** we believe that selectively delivering the drug distal in the coronary bed via a microcatheter is essential and superior to injection via guiding catheter or systemically. This exploits its maximal effect at the target site and allowing, when necessary, the use of higher doses of NTP without detrimental systemic effects on blood pressure. Agents administered via the guiding catheter will preferentially distribute to areas with normal flow.
- 2 **Incremental doses:** in a large proportion of patients only large doses of NTP were effective. Because of its relatively short half-life (50–70 s), a greater effect of NTP cannot be obtained by repeated cumulative small boluses but only by single large boluses.

Verapamil

Intracoronary calcium-channel blockers such as verapamil have been administered for no-reflow during PCI for acute MI and have been shown to improve microvascular perfusion and myocardial salvage [104]. Although microvascular and macrovascular spasm may be calcium mediated [131], their mechanism of action may go beyond the fact that they act directly on the vascular smooth muscle rather than nitric oxide. In the setting of acute ischemia invoked by balloon inflations during PTCA, verapamil has been shown to increase the ischemic tolerance significantly. Its cardioprotective effects are ascribed to the reduction of calcium influx into the ischemic myocardial cell, restitution of the calcium homeostasis, and improved myocardial blood flow by relief of microvascular spasm [132,133]. Verapamil can also affect platelet aggregation in the setting of acute MI by reducing the effects of catecholamines [132–134].

Verapamil is the most studied drug for the treatment of no-reflow. It has been shown that verapamil only improves TIMI flow grade in 67–89% and up to 88% when administered with NTG [6,8,11,104,135].

A major limitation of verapamil and the main reason why many interventionalists are reluctant to use it are because of its adverse effects such as hypotension, prolonged heart block, and a negative inotropic effect. In a patient who is already hypotensive or having conduction disturbances from no-reflow, we would strongly advise not using verapamil. Similarly, in patients with severe left ventricular dysfunction, this negative inotropic agent should not be used.

Adenosine

Adenosine has a very short half-life (usually a few seconds) and is well tolerated without significant side effects. It is capable of dilating the coronary resistance vessels and appears to be more potent than verapamil for relieving microvascular spasm. The vasodilator effect of this drug is mediated by specific adenosine A_{2A} and A_{2B} receptors and related to the opening of ATP-sensitive K⁺ channels. Furthermore, adenosine has been suggested to have a role in the preservation of endothelium integrity [136–138]. In experimental studies, adenosine has also been shown to inhibit neutrophil accumulation, superoxide generation, and adherence of coronary endothelium as well as cardiac release of endothelin [136]. Although the preventive effect of adenosine against no-reflow may be due to both the vasodilator and anti-

inflammatory actions of the drug, the beneficial effect observed after no-reflow is more likely a result of its vasodilator action. Unlike verapamil, adenosine has little potential to cause prolonged detrimental effects upon atrioventricular conduction or myocardial contractility.

Prior studies [138,139] have shown that adenosine has a beneficial effect in treating no-reflow during SVG intervention. One of the novel aspects of the study by Fischell *et al.* [139] was the use of repetitive forceful injections of adenosine and saline flushes using a small-volume (3 mL) syringe. In an *ex vivo* model intended to simulate the conditions of no-reflow, the authors demonstrated the potentially beneficial effects of this approach in generating greater velocity and pressure during saline administration. It is likely that the mechanical advantage afforded by a small syringe allows more effective delivery of the active vasodilator to the target vascular bed, without the need for a drug infusion catheter. It is also possible that these forceful injections help to mechanically drive debris and/or aggregating platelets through the microvascular bed and into the coronary and then systemic venous circulation. Two studies have compared the combination of adenosine and NTP, at doses of 50–200 µg, with adenosine alone. Both agents mediate vasodilation in the coronary microcirculation in different but potentially additive mechanisms and the combination has been shown to be superior to adenosine alone [136,140].

Other agents

Several other approaches to the treatment of no-reflow have been published such as intracoronary or intragraft injections of abciximab, nicorandil, epinephrine, nicardipine, diltiazem, urokinase, abciximab, intra-aortic balloon pumps, and papaverine [6,141–144].

Intravenous platelet GP IIb/IIIa receptor inhibitors are usually administered in cases of no-reflow when distal embolization is considered to be the predominant underlying cause. They resolve any platelet-rich thrombi that has occurred and prevent platelet plugs from developing. However, only a single case report suggests utility in this setting [142]. There are also anecdotal reports regarding the use of antiplatelet agents (abciximab) to treat no-reflow after failed treatment with intracoronary verapamil in native coronary arteries. In addition, a report by Heitzer *et al.* [145] has found that the GP IIb/IIIa inhibitors (tirofiban and eptifibatid) improve the bioavailability of vascular nitric oxide in patients with coronary artery disease, by blocking platelet–endothelial interactions, which potentially adds vasodilator properties to these agents.

Nicorandil is a direct ATP K⁺ channel opener and as the vasodilatory action of adenosine is mediated by these channels, nicorandil has been attempted in treating no-reflow, either alone or in combination with adenosine. However, data are still limited [146]. Finally, intracoronary epinephrine has been shown to improve flow in 69% of PCI patients with refractory no-reflow [147]. However, data on all the above agents are still limited to small case series or anecdotal reports and thus these agents have not been incorporated into daily practice.

Prognosis of no-reflow

No-reflow has been associated with an increase in MI of up to 32% and a 5–15% higher incidence of death [6–8]. The reversibility of no-flow is an important prognostic factor in that it has been associated with a lower 30-day mortality rate [126]. Although restoration of epicardial flow does not always imply complete reperfusion at the myocardial level, achievement of TIMI 3 flow is extremely important

for improvement of myocardial function and outcome [6,9]. No-reflow has also been associated with long-term detrimental effects, including an increased risk for cardiac death, congestive heart failure, malignant arrhythmias, and a decrease in ejection fraction. The predictors of death with no-reflow include cardiogenic shock, large amount of jeopardized myocardium, history of congestive heart failure or left ventricular ejection fraction < 30%, age \geq 65–70 years, multivessel disease (especially with collaterals from the index vessel to another location), female gender, and prolonged time needed to restore flow [6–8]. We have recently shown in a large-scale HORIZONS-AMI trial that failure to restore normal TIMI flow after PCI in STEMI occurred in 12.9% of patients, and was associated with a twofold higher mortality at 3-year follow-up [96].

Conclusions

Coronary dissection with vessel occlusion, coronary perforation following coronary angiography or PCI, and the no-reflow phenomenon are dreaded complications occurring in the catheterization laboratory. These complications can result in acute MI, need for urgent coronary artery bypass surgery, pericardial tamponade, heart failure, and death.

The management of coronary dissection depends on the patency of the distal vessel and the extent of propagation of the dissection. In general, in the presence of MI or acute closure, coronary stenting is mandated.

For coronary perforation, the treatment strategy depends on the type of vessel and the location of the injury. Principles include prompt recognition of perforation, immediate balloon tamponade of the injured vessel, rapid reversal of anticoagulation or antiplatelet therapy, addressing hemodynamic instability, involvement of surgeons if appropriate, and specific treatment of the vessel perforation or rupture with a bailout device such as embolization coils or covered stents.

The no-reflow phenomenon is a diagnosis of exclusion and needs to be treated promptly with superselective distal intracoronary injection of nitroprusside (associated or not to adenosine) using an over-the-wire angioplasty balloon or intracoronary infusion microcatheter. During SVG intervention, an embolic protection device should always be used if technically feasible to prevent no-reflow.

³ University of Miami Miller School of Medicine, Miami, FL, USA

Technologic advances in the design of catheters and devices have allowed a more aggressive approach to percutaneous coronary intervention (PCI), which has resulted in an increase in the volume and complexity of procedures. As a result, the frequency of non-cardiac complications has also risen. The most common complications following percutaneous interventions are related to vascular access and are linked to the complexity of the coronary intervention. Muller *et al.* [1] reported a 2.6% incidence of vascular access complications following routine PCI, which increased to 6% ($p < 0.0001$) after complex interventions. The purpose of this chapter is to describe the incidence, predisposing factors, and treatment options for some of the most common non-cardiac complications following PCI.

Femoral vascular access complications

Bleeding

Access site bleeding is the most frequent complication following femoral arterial access. Transfusion of red blood cells after PCI has been reported in 1.8–6.5% of cases [2–4]. Risk factors associated with bleeding complications are shown in Box 26.1.

Fewer femoral complications have been noted in patients undergoing elective PCI using 6 Fr compared to 7 or 8 Fr guiding catheters (13.8% vs. 23.5%; $p < 0.01$) [5,6]. However, other studies have not shown sheath size to be an important risk factor [7,8]. Bleeding complications are reduced when heparin is discontinued after the procedure without any adverse impact on cardiac outcomes [9,10]. Likewise, sheath removal as early as possible after the procedure can also decrease bleeding [7,11,12]. Bleeding complications associated with glycoprotein IIb/IIIa platelet receptor inhibitor use have been reduced by reducing the heparin dosage (70 IU/kg) [4,12].

A mass or fullness at the access site suggests the presence of a hematoma. However, this finding can be difficult to appreciate in obese patients in whom significant blood loss can occur without obvious physical signs. The management of access site bleeding depends on the severity and hemodynamic consequences of bleeding.

In general, access site bleeding is controlled by manual or mechanical compression and reversal of anticoagulation. If bleeding continues despite these steps, more aggressive therapies including percutaneous intervention or surgical therapy are considered.

If patients with bleeding complications have received abciximab (Reopro, Eli Lilly, Indianapolis, IN, USA), normally functioning

platelets can be transfused without interference from the tightly bound drug. The same does not apply to the small molecule platelet glycoprotein IIb/IIIa inhibitors, eptifibatid (Integrilin, Cor Therapeutics, South San Francisco, CA, USA) and tirofiban (Aggrastat, Merck, West Point, PA, USA). These small molecules are competitive inhibitors, not tightly bound to the receptor, leaving excess-free drug available to inhibit the transfused platelets. However, their shorter half-life allows the antiplatelet effects to wear off after several hours.

Retroperitoneal bleeding

The incidence of retroperitoneal hematoma formation has been reported in 0.12–0.44% of patients after an interventional procedure [13–15]. The risk of bleeding into the retroperitoneal space is increased with a high femoral puncture (above the inguinal ligament) and with a back wall puncture of the vessel [15]. Knowledge of the femoral vascular and inguinal anatomy is helpful in minimizing this risk. The goal is to access the common femoral artery corresponding to the vascular segment overlying the medial third of the femoral head.

The signs and symptoms of retroperitoneal bleeding include hypotension, abdominal distension or fullness, and pain [15,16]. The diagnosis of retroperitoneal bleeding are confirmed by computed tomography (CT) or abdominal/pelvic ultrasound [17,18]. If retroperitoneal bleeding is suspected, anticoagulation should be reversed and discontinued. Volume resuscitation with crystalloid solutions and/or blood products should be administered if volume depletion is clinically evident. Alternatively, if bleeding causes hemodynamic embarrassment, emergency angiography from the contralateral femoral access site can be considered to localize the bleeding site. Once the bleeding site has been identified, tamponade of the bleeding with an angioplasty balloon will stabilize the patient. If prolonged balloon inflation is not effective in stopping the blood loss, consideration is given to placing a covered stent (Wallgraft, BSC, Watertown, MA, USA) to seal the leak. Open surgical repair may also be considered [19].

Pseudoaneurysm

A pseudoaneurysm occurs when a hematoma continues to communicate with the arterial lumen. Following PCI, routine ultrasound screening will reveal pseudoaneurysms in up to 6% of

Box 26.1 Risk factors for femoral access bleeding [2–4]

Female gender
Elevated blood pressure
Prolonged in-dwelling sheath time
Larger diameter sheath
Older age
Low body weight
Obesity
Larger heparin dose
Thrombolytic agents

patients compared to a 3% incidence if symptoms initiate the ultrasound investigation [20]. Low arterial access (superficial femoral artery or profunda femoris artery entry) has been associated with pseudoaneurysm formation [21]. Other risk factors include female sex, age greater than 70 years, diabetes mellitus, and obesity [8].

Patients with pseudoaneurysms often present with pain at the access site several days following the intervention. On physical examination, a pulsatile hematoma can be present with a systolic bruit. Management of a femoral pseudoaneurysm is dependent on its size, severity of symptoms, and need for continued anticoagulation. A small pseudoaneurysm (≤ 2 cm) will often resolve spontaneously. Larger pseudoaneurysms should be treated with ultrasound-guided compression, percutaneous thrombin/collagen injection, endovascular coil insertion, or by placement of covered stents. Surgical repair of pseudoaneurysms is usually reserved for the failure of less invasive approaches.

Ultrasound-guided compression

In 1991, Fellmeth *et al.* [22] described ultrasound-guided compression repair (UGCR) of femoral artery pseudoaneurysms. This method causes thrombosis of the pseudoaneurysm by compressing the neck of the pseudoaneurysm with the ultrasound probe and causing stasis. Variable success rates, ranging from 55% to 90%, have been reported [22–26].

Although many pseudoaneurysms can be successfully treated by this technique, UGCR does have limitations. It is time-consuming and labor-intensive. Compression times vary from 10 minutes to as long as 300 minutes, with 30 minutes being the average [27]. Intravenous sedation and analgesia are often required because this procedure can be uncomfortable for the patient. If the patient must continue anticoagulation after successful compression, close follow-up is necessary as the risk of recurrence or rupture of the pseudoaneurysm is increased [25]. Predictors of failure of UGCR to treat pseudoaneurysms include obesity, large pseudoaneurysm size, concomitant anticoagulation therapy, and groin discomfort [25–27]. Ultrasound-guided compression is unattractive or contraindicated in the presence of infection, a tense hematoma, or limb-threatening ischemia.

Ultrasound-guided thrombin injection

Percutaneous thrombin injection into the pseudoaneurysm with ultrasound guidance is another technique to treat pseudoaneurysms [28–34]. Despite its introduction in 1986, this technique has only recently gained wide acceptance. Multiple series have reported success rates of 86–97% for treatment of femoral artery

pseudoaneurysms using bovine thrombin (500–10,000 IU) with sonographic guidance [29,30,32,34].

A risk associated with thrombin injection is that the injected thrombin can exit the pseudoaneurysm, enter the native circulation, and cause distal extremity thrombosis. Pezzullo *et al.* [34] described distal thrombin embolization in 1 of 23 patients, and Cope and Zeit [35] reported distal thrombin embolization in 2 of 4 (50%) patients. The risk of distal embolization can be minimized by directing the needle away from the neck of the pseudoaneurysm, thereby minimizing the risk of injecting thrombin into the native circulation.

Another technique to prevent distal thrombin embolization is the use of angioplasty balloon occlusion of the femoral artery at the site of the pseudoaneurysm neck during thrombin injection to prevent embolization. We have reported the successful closure of four femoral pseudoaneurysms using percutaneous thrombin injection with balloon occlusion (Figure 26.1) [36]. Briefly, the technique requires contralateral femoral artery access and inflation of a peripheral angioplasty balloon, sized 1 : 1 to the diameter of the reference vessel, across the origin of the pseudoaneurysm. This occludes flow in the common femoral artery and completely obstructs any flow into or out of the pseudoaneurysm. Thrombin is then percutaneously injected into the pseudoaneurysm sac without risk of distal embolization. The stasis induced by balloon occlusion facilitates thrombosis of the pseudoaneurysm with very small amounts of thrombin.

Patients who have had previous exposure to thrombin or bovine proteins are at risk of immunologic cross-reactivity. Reported side effects include the development of hypotension, bradycardia, and the formation of inhibitors of coagulation factors, all presumed secondary to the immunologic cross-reactivity of bovine thrombin [37–39]. One report described an anaphylactic reaction after thrombin injection of a femoral pseudoaneurysm in a patient who had had repeated exposures to bovine thrombin [33]. Patients who have had prior exposure to bovine thrombin should undergo skin testing to detect possible allergy.

Biodegradable collagen injection

Percutaneous closure of femoral pseudoaneurysm by biodegradable collagen injection is an innovative approach. Hamraoui *et al.* [40] described this technique by injecting bovine collagen guided by angiography from the contralateral site. The overall success rate for this procedure was 108/110 (98%).

The advantages of this treatment include reduction in the risk of migration of the collagen plug through the neck of the pseudoaneurysm, and no reported cross-reaction to human factor V [40]. However, its disadvantages include the need for contralateral femoral arterial access, and utilization of a large introducer sheath [41].

Covered stents

Covered stents have been used successfully to exclude femoral artery pseudoaneurysms [41,42]. Waigand *et al.* [41] described the successful treatment of 32 pseudoaneurysms with a covered stent. Thalhammer *et al.* [42] reported the successful treatment of 16 pseudoaneurysms with covered stents. The use of covered stents is not ideal if the pseudoaneurysm involves the bifurcation of the common femoral artery into the superficial femoral artery and the profunda femoris artery, as it will cause occlusion of the branch vessels. Placement of a self-expanding covered stent into the common femoral artery may preclude future vascular access at this site. Covered stents can also be associated with an increased risk of

Figure 26.1 (a) Arrowhead points to the pseudoaneurysm in the common femoral artery. (b) Isolation of the pseudoaneurysm with an inflated peripheral balloon catheter; pseudoaneurysm is filled by direct contrast injection. (c) Arrowhead points to the site of the resolved pseudoaneurysm after thrombin injection into aneurysm sac.

subacute stent thrombosis and late stent occlusion, especially when deployed in a common femoral artery with poor run-off [41,42].

Coil embolization

Successful closure of pseudoaneurysms has been reported with coil embolization [41,43]. Waigand *et al.* [41] reported closure of the channel between the artery and the pseudoaneurysm by placing coils in 12 patients. In smaller channels, 0.014 inch coils (3 × 40 mm) were delivered through a 3 Fr Tracker (Target Therapeutics) catheter, while larger coils (0.35 inch, 6 × 30 mm) were delivered in larger channels through a 5 Fr angiographic catheter.

Coil embolization of femoral pseudoaneurysms appears to be effective, but can be time-consuming [41]. Other disadvantages include the potential for persistent flow between loosely packed coils. If the coils are placed superficially, local discomfort and pressure necrosis of the overlying skin can occur [43].

Surgical repair

Surgical repair, the conventional treatment of femoral artery pseudoaneurysms, has largely been replaced with non-surgical techniques. While surgery is effective, it is associated with significant morbidity, including postoperative discomfort, wound infection, increased costs, and prolonged hospital stay. The current strategy in most centers is to reserve surgical repair of a femoral pseudoaneurysm for those instances in which percutaneous therapies fail.

Arteriovenous fistulae

Arteriovenous fistulae (AVF) occur during vascular access when the percutaneous needle punctures the femoral artery and the overlying vein, creating a fistulous communication when the sheath is removed. The incidence of post-catheterization AVF is approximately 0.4% [14]. The risk of creating an AVF is increased by either a high or low femoral puncture, multiple puncture attempts, and prolonged clotting times [8]. Fistulae may not be clinically evident for several days following the procedure. Clinically, AVF is

characterized by a continuous to-and-fro murmur over the access site. In some cases, there may be a swollen and tender extremity as a result of venous dilatation, and in severe circumstances arterial insufficiency (steal syndrome) occurs [41]. The diagnosis of a suspected AVF can be confirmed by color flow Doppler ultrasound.

Most AVF following PCI are small, not hemodynamically significant, and close spontaneously [42]. Symptomatic AVF require closure to prevent increased shunting and distal swelling and tenderness. Ultrasound-guided compression and the use of covered stents on the arterial side of the fistula have been successful in small numbers of patients [44]. In 1994, Uhlich *et al.* [44] successfully closed a large AVF with a covered stent. Waigand *et al.* [42] reported successfully closing 21 AVF using covered stents. Thalhammer *et al.* [42] reported the use of covered stents in nine AVF. A significant disadvantage related to the use of covered stents for closure of an AVF is the increased incidence (12–17%) of stent thrombosis [44].

Percutaneous coil embolization has also been described in a small number of patients for the treatment of AVF. However, experience with this technique remains limited [45]. Surgical repair, the traditional therapy for closure of catheterization-related AVF, when necessary, has been displaced by percutaneous methods. Once again, surgical correction is reserved for those patients who fail a less invasive approach.

Lower extremity ischemia

Local thrombosis of the femoral artery or lower extremity vessel related to the access site is unusual, reported to occur in less than 1% [46,47]. Risk factors include larger catheters or sheaths in relatively small arteries (catheter–artery mismatch), the presence of peripheral vascular disease, advanced age, cardiomyopathy, and the presence of hypercoagulable states (e.g., protein C or protein S deficiency, the lupus anticoagulant). In the absence of predisposing factors, vessel dissection or spasm can contribute to arterial thrombosis.

Signs and symptoms are those typically found with acute extremity ischemia (the five Ps): pain, pallor, paresthesia, pulseless, and polar (cold). The diagnosis of ischemia is suggested by physical examination and can be confirmed by duplex ultrasound. Patients with symptomatic, acute limb ischemia following vascular access should undergo angiography to characterize the anatomic basis for the ischemia. Treatment options include balloon angioplasty to restore flow with or without a selective infusion of thrombolytic therapy, stents, or catheter thrombectomy. If percutaneous methods fail, surgical thrombectomy and repair are required [47].

Dissection

Iatrogenic dissection of the femoral or iliac artery from PCI ranges from 0.01% to 0.4% [48,49]. Vascular access dissection contributes to the development of distal extremity ischemia, pseudoaneurysm, or thrombus formation. The recognition of a vascular dissection should be followed by angiography to characterize the extent of the dissection. Treatment includes balloon angioplasty, endovascular stent placement, or surgical repair to stabilize a flow-limiting dissection.

Infection

Local infection at the site of arterial access occurs in less than 1% of patients following coronary interventional procedures [50]. The most common organisms isolated are *Staphylococcus aureus* and *S. epidermidis* [33]. Pyrogenic reactions following cardiac catheterization generally occur within 1 hour of the procedure and manifest as fever, chills, and lethargy.

Upper extremity vascular access complications

Radial artery access

Transradial access for interventional coronary catheterization is being performed with increasing frequency because hemostasis can be obtained easily by local compression of the superficial course of the radial artery. Patients ambulate immediately after the procedure. A normal Allen's test prior to the radial artery access ensures that radial arterial occlusion does not endanger the viability of the hand.

Kiemeneij *et al.* [51] reported successful coronary cannulation in 93%, 95.7%, and 99.7% of patients randomized to undergo percutaneous transluminal coronary angioplasty (PTCA) by the radial, brachial, and femoral approaches, respectively. A randomized comparative study of PTCA using the radial, brachial, and femoral approaches reported that major access site complications were similar for brachial (2.3%) and femoral artery access (2.0%) but that no major complications occurred with radial artery access [51,52]. In a series of 563 patients who underwent transradial angioplasty with 6 Fr guiding catheters, asymptomatic radial artery occlusion was found in only 2.8% of patients.

Although the radial artery is small in size, the availability of low profile catheters and devices makes it possible to perform PCI using 6 or 7 Fr sheaths via the radial artery. In a study comparing PTCA with abciximab using either transradial or transfemoral approaches, no major access site bleeding complications occurred in the radial artery group, compared to 7.4% in the femoral artery group ($p=0.04$) [53]. The transradial approach allows immediate post-procedural ambulation resulting in increased patient comfort. The disadvantages of the transradial approach include more frequent access failure than for the femoral approach, and the inability to perform procedures requiring larger sized sheaths.

Brachial artery access

Percutaneous brachial access has largely replaced the surgical cut-down (Sones technique) method for obtaining brachial artery access. The Society for Cardiac Angiography and Intervention registry data suggested that the risk of access site-related thrombosis increases fourfold with the brachial approach (0.96% vs. 0.22%; $p<0.001$) compared with the femoral approach [47]. The most common complications associated with brachial artery access are bleeding, thrombosis, pseudoaneurysm formation, and brachial nerve compression. Thrombotic complications are more common than bleeding complications for brachial access compared to the femoral approach [54]. If a pulse deficit or other ischemic symptom suggests thrombosis after cannulation of the brachial artery, local thrombolysis or catheter thrombectomy are performed. If the problem is an intimal flap or dissection, angioplasty or stent placement can be required to restore antegrade flow. If these less invasive measures are not successful, surgical repair is required.

Complications related to vascular closure devices

Vascular access closure devices are designed to facilitate hemostasis after percutaneous interventions and have been used to reduce the time to ambulation and to decrease hospital length of stay. In these regards, all currently available devices in the USA have shown favorable results [55–60]. However, these devices are prone to specific complications and have not been demonstrated to reduce access site complications.

A retrospective single-center experience of 425 patients treated with a collagen plug closure device (Angioseal, Daig, St. Paul, MN, USA) reported device failure (8%), bleeding (0.2%), pseudoaneurysm formation (0.5%), femoral artery stenosis (1.4%) as shown in Figure 26.2, infection (0.2%), and the need for surgical repair in 1.6% [56].

In another trial of 1001 patients, two collagen plug devices, Vasoseal (Datascope, Montvale, NJ, USA) and Angioseal, and a suture-mediated device (Techstar, Perclose, Redwood City, CA, USA) were compared to manual compression for hemostasis. Both collagen plug devices were found to have higher complication rates (1.5%; $p=0.02$, and 2.6%; $p=0.0002$, respectively) than manual compression (0.5%). The complications associated with the suture-mediated device, Techstar, were not different from those of manual compression [56]. In a series including 1200 consecutive suture closure (Techstar) patients, complications included the development of a hematoma (2.1%), the need for vascular surgery (0.6%), retroperitoneal hemorrhage (0.3%), blood transfusion (0.7%), local infection (0.5%), and pseudoaneurysm formation (0.1%) [57].

In the initial US Feasibility Trial using the Duett vascular closure device (Vascular Solutions, Minneapolis, MN, USA), a vascular sealing device comprised of a balloon delivery catheter and a flowable procoagulant consisting of thrombin and collagen, Mooney *et al.* [58] reported 4.7% of patients developed hematomas larger than 6 cm in diameter, and 2.3% of patients developed pseudoaneurysms.

A few centers around the country have developed endovascular rescue procedures for acute vessel closure related to abrupt femoral access closure devices, particularly for Angioseal (Daig, St. Paul, MN, USA) (Figure 26.2) and Perclose (Redwood City, CA, USA) (Figure 26.3), with anecdotal encouraging results. This involves obtaining contralateral femoral access, crossing over to the affected

Figure 26.2 Angioseal common femoral artery injury. (a) demonstrates Angioseal closure injury of the common femoral artery with thrombus. (b) shows the lesion crossed with a 0.14 inch wire, distal embolic protection, and a balloon in place for dilatation. (c) shows the lesion after balloon dilatation and embolic debris in the filter. (d) shows the final result with wire and embolic protection removed.

Table 26.1 Comparison of femoral artery hemostasis techniques.

	Pneumatic (%)	Manual (%)	C-clamp (%)	p
Prolonged time	35	13	20	<0.0001
Bleeding	16	3	4	<0.0001
Crossover	27	1	1	<0.001
Discomfort	3.1	2.2	1.9	<0.001

Prolonged time=greater than 13 min. Bleeding=in-laboratory bleeding. Crossover occurred when an alternative method was required to achieve hemostasis. Discomfort was measured on a 1 (min) to 10 (max) point scale. Source: Lehmann KG, *et al.* 1999 [59].

limb, advancing a 0.035 inch hydrophilic wire, traversing the closure device lesion, and exchanging the wire with a 0.035 inch exchange catheter. A 0.014 inch filter is then advanced into the superficial femoral artery and a 0.014–0.035 inch balloon is advanced into the lesion and inflated; progressively larger balloons are used until the lesion is expanded and closure device is released. The filter is then retrieved with the remnants of the closure device and antegrade flow is usually re-established. Directional atherectomy can be used in cases of endovascular deployment of plug-based devices (e.g., Angioseal collagen plug) after wire crossing and distal filter deployment. A stent is rarely advisable in the common femoral artery location. Referral for surgical repair of the femoral arterial access should also be considered because the exposure is rather superficial, often under local anesthesia and sedation.

Complications related to compression devices

Manual femoral artery compression has been compared with device compression with either a C-clamp or a pneumatic compression device (Femostop, RADI Medical Systems, Uppsala, Sweden) in 400 patients [59]. The pneumatic compression device required longer compression time, and patients experienced an increased frequency of bleeding, more frequent crossover to an alternate technique, and an increase in patient discomfort (Table 26.1) [59]. In another study of 185 PCI patients in whom abciximab was given, Chamberlain *et al.* [60] compared three different methods of femoral artery closure: Vasoseal (collagen plug), Perclose (suture closure), and Femostop (pneumatic compression). Vasoseal and Perclose had significantly lower rates of successful hemostasis than Femostop (78.8%, 85.7%, 100%, respectively; $p < 0.001$). Vasoseal was the only device with infection reported as a complication (1.9%; $p = \text{NS}$) [60].

Renal Insufficiency and the Impact of Contrast Agents

Michael Donahue and Carlo Briguori

Laboratory of Interventional Cardiology and Department of Cardiology, Clinica Mediterranea, Naples, Italy

Chronic kidney disease (CKD) is recognized as a major global public health problem affecting 8–16% of the adult population worldwide [1]. The Kidney Disease: Improving Global Outcomes (KDIGO) study defines CKD as abnormalities of kidney structure or function, present for 3 months or longer, with implications for health. Glomerular filtration rate (GFR) is generally accepted as the best overall index of kidney function while albuminuria is the best marker of kidney damage. The preferred equation to calculate estimated glomerular filtration rate is that of the Chronic Kidney Disease Epidemiology Collaboration (commonly known as the CKD-EPI) [2]. CKD is classified into six stages of estimated GFR (1, 2, 3A, 3B, 4, and 5) and three albuminuria stages (1, 2, and 3), with stage 1 representing normal values and the higher stages reflecting more severe disease [3]. A GFR <60 mL/min/1.73 m² is referred as decreased GFR and a GFR <15 mL/min/1.73 m² as kidney failure [3].

The prevalence of coronary artery disease (CAD) in patients with CKD is high and is a major cause of morbidity and mortality [4]. A meta-analysis by the CKD Prognosis Consortium demonstrated associations of GFR <60 mL/min/1.73 m² with subsequent risk of all-cause and cardiovascular mortality, kidney failure, acute kidney injury (AKI), and CKD progression in the general population and in populations with increased risk for cardiovascular disease [4,5].

Myocardial revascularization in patients with CKD by either percutaneous or surgical approaches is aggravated by a higher rate of complications than in patients without CKD [6–12]. Contrast-induced acute kidney injury (CIAKI) represents one of the most common complications in this subset of patients.

Contrast-induced acute kidney injury

CIAKI is defined as the acute kidney damage occurring following iodinated contrast media (CM) exposure in the absence of other causes.

CIAKI is the third most common cause of hospital-acquired AKI after impaired renal perfusion and use of nephrotoxic medications, and accounts for 10% of all causes of hospital-acquired renal failure [13–15]. CIAKI is also associated with increased health resource utilization, prolongation of hospital stay, increased long-term mortality, and accelerated progression of CKD and represents a powerful predictor of poor early and late outcome [16].

Risk factors and scores

Various cut-off criteria have been proposed to identify a clinically relevant renal function deterioration following contrast agent exposure. Currently, an increase in serum creatinine (sCr) $\geq 25\%$ and/or ≥ 0.5 mg/dL (44 mmol/L) from baseline assessed within 48 hours after CM exposure is generally accepted as the recommended threshold [17,18].

Several risk scores have been proposed to assess the individual risk of developing CIAKI. They represent an effective tool to identify patients at high risk for CIAKI who would benefit from prophylactic therapy. Risk factors for CIAKI are: age ≥ 75 years, pre-existing CKD, diabetes mellitus, high volume of CM, multiple myeloma, heart failure, hemodynamic instability, or other cause of reduced renal perfusion. CKD (defined as a eGFR < 60 mL/min/1.73 m²) represents the most important predictor, therefore it is recommended to estimate in each patient exposed to CM the baseline renal function by estimating the glomerular filtration rate (eGFR) using the CKD-EPI or the Modification of Diet on Renal Disease (MDRD) equations to estimate GFR (eGFR), instead of focusing solely on sCr. The risk score proposed by Mehran *et al.* [19] is simple to calculate and very useful for individual patient risk assessment. An increased score is strongly associated with CIAKI, from 7.5% (low risk score) to 57.3% (high risk score). A new score has been recently elaborated by Gurm *et al.* [20] which requires a computer for calculation and, unlike the previous score, has the benefit of being composed solely of preprocedural variables. The prediction model stratifies patients into low risk ($<1\%$), intermediate risk (1–7%), and high-risk ($>7\%$) categories based on the risk of CIAKI and has a higher discrimination than previously reported models. These scores are very useful in clinical practice for two reasons: (i) because they allow better definition of the risk in individual patients before contrast exposure, and (ii) consequently, help clinicians to target the most appropriate prophylactic strategy in each patient.

Pathophysiology

The mechanisms by which CIAKI occurs are complex and not well understood. However, it is widely held that a combination of mechanisms (hemodynamic, toxic, and osmotic) need to act in concert to cause CIAKI (Figure 27.1) [21].

Figure 27.1 Pathogenesis of contrast-induced acute kidney injury (CIAKI): the combination of mechanisms that acting in concert lead to CIAKI.

Medullary hypoxia

The deeper portion of the outer medulla, which is particularly exposed to hypoxic damage, is the kidney region where contrast nephrotoxicity take place. Hypoxia derives mainly from decrease in renal medullary perfusion. CM augments fluid viscosity and the resistance to flow in renal tubules; the increase of renal interstitial pressure reduces both renal medullary flow and glomerular filtration rate and can lead to diminished renal perfusion (tubuloglomerular feedback). Contrast osmolarity seems to have a role, but only if it is high (>1000 mOsm/kg of H₂O).

Renal tubular damage

CM promote reactive oxygen species (ROS) generation. Oxygen radicals are highly reactive and can directly damage renal endothelial-epithelial cells or induce renal microvessel constriction (e.g., via endothelin-A receptor activation). In addition to the ischemic changes to the renal tubules, CM has a cytotoxic effect on the tubular epithelial cells by activating apoptosis via three mechanisms: (i) ROS, (ii) JNK and p38 kinases, and (iii) the intrinsic (or mitochondrial) pathway of apoptosis [22,23]. This effect seems to be time- and dosage-dependent.

Diagnosis and novel biomarkers

The classifications of CIAKI proposed are based on the variation of two parameters: sCr or GFR, and urinary flow. The diagnostic criteria for kidney damage are summarized in Table 27.1 [24,25]. Levels of sCr usually begin to rise within 24–48 hours of CM exposure, peaking at 2–3 days and returning to baseline values within 2 weeks. This is mainly caused by two significant limitations of

dosing sCr. First, creatinine excreted in the urine is not solely a result of glomerular filtration, but also of renal tubular secretion. This means that changes in sCr will underestimate the true fall in GFR. Second, following an acute fall in GFR, less creatinine is excreted. The retained creatinine is distributed in total body water and, although the injury induced by CM impairs GFR almost immediately, it requires 24–48 h for the fall in GFR to be reflected in an elevated level of sCr. This implies an intrinsic delay of treatment of patients who will develop CIAKI and, on the contrary, a prolonged hospital stay in patients who will not develop CIAKI. Serum creatinine levels are still considered the major marker of CIAKI, but for these limitations other biomarkers that allow an earlier diagnosis of AKI have been proposed [26].

The cystatin C (CyC) is produced at a relatively constant rate by nucleated cells and is not affected by renal tubular secretion or pharmacologic treatments [27]. In a study on 410 patients with CKD undergoing percutaneous procedures, an increase in serum CyC $\geq 10\%$ in 24 hours after the procedure showed a sensitivity of 100% and a specificity of 86% in predicting CIAKI [28]. In addition, the CyC demonstrated to be an independent predictor of adverse events at follow-up [28,29].

The neutrophil gelatinase associated lipocalin (NGAL) is a protein whose production is induced by an acute injury to the renal tubular epithelium. The NGAL has been shown to be one of the most promising biomarkers of AKI, an increase both in the serum and urinary NGAL within 2–4 hours after administration of CM is a strong predictor of CIAKI [30–32]. A recent meta-analysis found that NGAL levels between 100 and 270 ng/mL have a high sensitivity and specificity for AKI [33].

Table 27.1 RIFLE and AKIN criteria [24,25].

RIFLE criteria (7 days)		
Class	Criteria: GFR	Criteria: urine output
R–Risk	Increase sCr \times 1.5 or GFR decrease $>$ 25%	$<$ 0.5 mL/kg/hr for 6 hr
I–Injury	Increase sCr \times 2 or GFR decrease $>$ 25%	$<$ 0.5 mL/kg/hr for 12 hr
F–Failure	Increase sCr \times 3 or GFR decrease $>$ 75% or SCr \geq 4 mg/dL	$<$ 0.3 mL/kg/hr for 24 hr or anuria for 12 hr
L–Loss	Persistent kidney failure $>$ 4 weeks	
E–ESKD	Terminal kidney injury $>$ 3 months	
AKIN criteria (48 hour)		
Stage	Criteria: serum creatinine	Criteria: urine output
1	Increase of sCr \times 1.5 or $>$ 0.3 mg/dL	$<$ 0.5 mL/kg/hr for 6 hr
2	Increase of sCr \times 2	$<$ 0.5 mL/kg/hr for 6 hr
3	Increase of sCr \times 3 or $>$ 4 mg/dL	$<$ 0.3 mL/kg/hr for $>$ 24 hr or anuria for 12 hr

eGFR, estimated glomerular filtration rate; sCr, serum creatinine.

The kidney injury molecule-1 (KIM-1) is a transmembrane adhesion protein of type 1, the expression of which increases in the proximal tubule cells in response to ischemic injury. A soluble form can be detected in the urine of animal models and in patients with acute renal failure due to CIAKI [34].

Prevention of CIAKI

The optimal strategy to prevent CIAKI remains uncertain. At present, the best approach to prevent CIAKI is to identify patients at risk using risk scores, to minimize the amount of administered CM (low or iso-osmolality contrast) and provide adequate periprocedural hydration [35]. The use of antioxidant compounds like *N*-acetylcysteine (NAC) or statins, although not part of the official recommendations, also seems to have a role in preventing CIAKI [36–39], while the use of nephrotoxic drugs should be suspended for at least 2 days prior to CM exposure. The role of prophylactic renal replacement therapies (RRT), such as hemofiltration, is still debated and limited to patients at very high risk.

Volume supplementation

Hydration is considered one of the major beneficial measures for prevention of CIAKI [35]. Volume supplementation prevents CIAKI mostly via two mechanisms:

1 The inhibition of arginine-vasopressin (via vagal inputs from the mechanoreceptors located at the atrial–venous junctions and by a direct effect of osmolality on the supra-aortic nuclei), and

2 The increase in medullary perfusion and regional pO_2 by inducing an increase of urine flow rates, that reduces the concentration of CM in the tubule and expedites CM excretion [21,40].

This implies a reduction of the exposure time of tubular cells to the toxic effects of CM. Hydration with isotonic saline (0.9% NaCl) should be started intravenously 12 hours prior to the procedure at a rate of 1 mL/kg/h and should be continued for 12 hours following the procedure. In patients with unstable hemodynamic conditions, where there is a particular concern regarding volume overload, at least 0.5 mL/kg/h intravenous saline infusion should be received before contrast exposure. The post-procedure hydration target can be adjusted according to urine output which should remain above 150 mL/h. The optimal hydration regimen should be defined according to a pre-defined clinical marker. Two markers have been identified: (i) urine flow rate [41], and (ii) left ventricular end-diastolic pressure (LVEDP) [42].

Urine flow rate High urine flow rate reduces the incidence of CIAKI via several effects. Data from the PRINCE study indicated that the increase in urine flow rate (\geq 150 mL/h) reduces the toxic effect of CM [43]. The RenalGuard system (PLC Medical System, Inc. Franklin, MA, USA) has been developed to facilitate optimal hydration therapy [44]. This device allows high urine output to be achieved while simultaneously balancing urine output and venous fluid infusion to prevent hypovolemia. Randomized trials [45,46] have demonstrated the effectiveness of this system in significantly reducing the incidence of CIAKI compared with standard hydration in patients at high risk.

Left ventricular end diastolic pressure The POSEIDON trial [42] sought to determine the efficacy of a novel fluid protocol based upon the LVEDP. This single center study included 396 patients undergoing cardiac catheterization with an estimated GFR \leq 60 mL/min/1.73 m² and one or more of diabetes mellitus, history of congestive heart failure, hypertension, or age $>$ 75 years and who were randomly allocated to LVEDP guided volume expansion or standard hydration (control group). Both groups received intravenous 0.9% sodium chloride at 3 mL/kg for 1 hour prior to cardiac catheterization. In the LVEDP group, the fluid rate was adjusted according to the LVEDP as follows: 5 mL/kg/hr for LVEDP $<$ 13 mmHg; 3 mL/kg/hr for 13–18 mmHg, and 1.5 mL/kg/hr for $>$ 18 mmHg. The control group hydration rate was 1.5 mL/kg/hr. For both groups, the fluid rate was set at the start of the procedure, continued during the procedure, and for 4 hours post-procedure. CIAKI occurred less frequently among patients randomized to the LVEDP-guided group than the control group (6.7% vs. 16.3%; $p=0.005$).

It is still controversial whether some solutions are superior to others. Evidence suggests that hydration with sodium bicarbonate, compared with isotonic saline, represents an effective strategy to prevent CIAKI [47–51]. However, the recent randomized trial for the prevention of contrast induced nephropathy in patients with chronic kidney disease, the Bicarbonate or Saline Study (BOSS) trial, enrolling 376 patients who underwent either coronary or peripheral angiogram, failed to demonstrate a superiority of sodium bicarbonate over sodium chloride solution in preventing CIAKI, although a reduction in the the death rate was seen [52]. The use of sodium bicarbonate infusion allows volume supplementation for shorter periods and can also further reduce the generation of injurious oxygen-free radicals. The higher amount of bicarbonate in the proximal convoluted tubule can buffer the higher amount of

H⁺ due to cellular hypoxia and facilitate Na⁺ reabsorption through the electrogenic co-transporter [53]. Free-radical formation is promoted by an acidic environment typical of tubular urine but is inhibited by the higher pH of normal extracellular fluid [54]. It has been hypothesized that alkalinizing renal tubular fluid with bicarbonate reduces injury [47]. Patients undergoing volume supplementation with the abovementioned protocol should receive 154 mEq/L NaHCO₃ as a bolus of 3 mL/kg/hour for 1 hour prior to CM administration, followed by an infusion of 1 mL/kg/hour for 6 hours after the procedure.

Contrast media

Type of contrast agents

Osmolality has an important role in the pathophysiology of CIAKI [21]. It has been reported that low osmolality (LOCM) and iso-osmolality contrast agent (IOCM) are less nephrotoxic than high osmolar contrast agents (HOCM) [55]. HOCM is highly charged and highly osmolar (≈ 1500 mOsm/kg H₂O). It is still controversial whether IOCM (≈ 290 mOsm/kg H₂O) is less nephrotoxic than LOCM (≈ 700 – 800 mOsm/kg H₂O). While early studies suggested a role for osmolality in the pathogenesis of CIAKI at high osmolalities (>1000 mOsm/kg H₂O), for CM with an osmolality in the range of 290 to approximately 800 mOsm/kg H₂O, other physicochemical characteristics, such as viscosity, perhaps have a greater role in the development of CIAKI blocking the protective benefit of lower osmolality [56]. To date, no consensus has been reached on the relative importance of osmolality and viscosity and the current guidelines recommend the use of either IOCM or LOCM (other than iohexol and ioxaglate) in patients with CKD undergoing angiography [57].

In the NEPHRIC trial [58], enrolling 126 patients with diabetes mellitus and CKD, CIAKI occurred in 3% of patients in the IOCM group and 25% in the LOCM group ($p=0.003$). However, this result has not been confirmed in other observational [59] and randomized trials [60]. In the CARE trial [60], 414 patients with an eGFR of 20–59 mL/min scheduled for a percutaneous coronary procedure were randomized to LOCM iopamidol (796 mOsm/kg of H₂O) or IOCM iodixanol (290 mOsm/kg H₂O). No significant differences overall and in the subgroup of diabetic patients existed in the primary CIAKI endpoint (a post-procedural sCr increase of ≥ 0.5 mg/dL) or in the secondary CIAKI endpoints (a post-procedural sCr increase of $\geq 25\%$ over baseline, a post-dose eGFR decrease of $\geq 25\%$ and the mean peak change in serum creatinine of >0.50 mg/dL). Finally, in a meta-analysis comparing the iso-osmolar iodixanol with LOCM, the pooled relative rate (RR) was 0.68 (95% CI 0.46–1.01; $p=0.06$), while in the studies that included only patients with decreased kidney function after CM administration the RR was 0.59 (95% CI 0.33–1.07; $p=0.08$). However, when iohexol was the LOCM used, the risk of CIAKI was significantly lower than with iodixanol (RR 0.38; 95% CI 0.21–0.68; $p<0.01$) [61].

Volume of contrast agents

The use of a small volume of contrast dye and the avoidance of closely spaced repetitive studies represents one of the most important recommendations to prevent CIAKI [18]. Low volume has been variably defined as a total absolute volume <100 mL, <125 mL, <140 mL, or a volume adjusted for body weight of <5 mL/kg (to a maximum of 300 mL) divided by the plasma creatinine concentration [62]. It has been suggested that use of the iodine dose:glomerular filtration rate (I/GFR) ratio may be a more expedient way of

improving risk assessment of CIAKI than the most common practice of estimating CM dose from body weight alone [63]. Chapters 4, 7, and 18 illustrate some of the principles used to minimize contrast use. General recommendations include limitations in the diagnostic angiogram pre-PCI to few essential views especially for urgent unstable patients for whom treatment should be limited to the culprit artery, injections limited to the minimum required to assess proper positioning of devices and final result, filming the balloon during expansion or using fluoroscopic optimization of the stent visualization (stent “boost” modality), or using automated contrast injectors and catheters without side holes.

Pharmacologic therapy

The generation of ROS subsequent to CM exposure of vasa recta and tubule cells and the consequent apoptosis activation have been considered an important pathophysiologic cause of CIAKI [21]. In recent years many clinical studies have been conducted to test the use of antioxidant compounds in an attempt to prevent CIAKI. The most investigated drugs are NAC, ascorbic acid, and statins.

N-acetylcysteine

NAC is a thiol compound classically known as a mucolytic agent, which is used to thin mucus especially in patients with respiratory disease. NAC is a potent antioxidant that scavenges a wide variety of oxygen-derived free-radicals. It may be capable of preventing CIAKI by stopping direct oxidative tissue damage and also by improving renal hemodynamics [64–66]. The antioxidant effect of NAC seems to be dose-dependent [67,68]. The molecular mechanisms of NAC on CIAKI prevention have been clearly elucidated in *in vitro* experiments. Recent studies demonstrate that NAC exerts its antioxidant properties preventing kidney cell death by inhibiting oxygen-free radical production and thus stress kinases and apoptosis activation upon CM exposure [69,70]. However, the results on the use of NAC are conflicting. While initial studies by Tepel *et al.* [64] showed that NAC (600 mg orally twice daily) plus hydration was more effective than hydration alone in preventing CIAKI in patients with CKD undergoing computed tomography, a recent large randomized trial [71] failed to demonstrate the superiority of NAC versus placebo in reducing the incidence of CIAKI in patients undergoing coronary angiography. Although a recent meta-analysis of 30 trials showed a renoprotective benefit with NAC [72], the most recent guidelines do not recommend NAC for CIAKI prevention [35].

Ascorbic acid

Additional evidence of the effectiveness of an antioxidant strategy comes from the observation by Spargias *et al.* [73], who investigated the impact of ascorbic acid in preventing CIAKI. *In vitro* and *in vivo* studies have also demonstrated a role for ascorbic acid in the prevention of CIAKI [74,75]. A combination of different antioxidant compounds was tested by Briguori *et al.* [76]. Consecutive patients with CKD were randomly assigned to prophylactic administration of 0.9% saline infusion plus NAC, sodium bicarbonate infusion plus NAC, or 0.9% saline plus ascorbic acid plus NAC. The combined prophylactic strategy of sodium bicarbonate plus NAC was superior in preventing CIAKI in patients at medium-to-high risk undergoing contrast exposure. The lack of favorable protective effect of the combination of ascorbic acid plus NAC compared to NAC alone suggests additional and/or alternative mechanism(s) (other than antioxidant effect) which require further investigation. We

hypothesize that NAC and ascorbic acid work through similar pathways while the protective action of bicarbonate may be different in comparison to NAC and therefore additive.

Statins

Besides the common use of the 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors to decrease cholesterol levels, they have several “pleiotropic” effects through their non-lipid-related mechanisms acting on inflammation responses, endothelial function, plaque stability, thrombus formation, and apoptotic pathway [77]. *In vitro* models indicate that pre-treatment with atorvastatin prevents CM-induced renal cell apoptosis by reducing stress kinase activation and restored the survival signals mediated by Akt and Erks signal transduction pathways [78]. Many studies have investigated the effectiveness of statins pre-treatment in reducing the incidence of CIAKI [78–83] and demonstrated that preprocedural high dose statin treatment reduces the risk of CIAKI and the need for RRT in patients undergoing coronary angiography and/or percutaneous interventions. Moreover, most recent investigations confirmed that rosuvastatin in statin-naïve patients with both stable and acute coronary syndrome scheduled for early invasive procedure could prevent CIAKI [82,83]. The most recent guidelines recommend high doses of statin for CIAKI prevention [35].

Other medications

Because of the potential role of focal renal vasoconstriction induced by contrast agents, numerous vasodilator drugs have been tested for prevention of CIAKI. Theophylline [84], nifedipine [85], adenosine [86], endothelin receptor antagonists [87], atrial natriuretic peptide [88], dopamine, and fenoldopam [89–91] do not seem to be effective. A randomized double-blind placebo-controlled trial showed that prophylactic administration of iloprost in patients with CKD, undergoing coronary angiography and/or intervention, may protect against CIAKI [92].

Compelling data support that neither mannitol nor furosemide offer additional protection against radiocontrast-induced nephrotoxicity as compared with saline hydration alone in either diabetic or non-diabetic patients [93,94].

Ischemic remote preconditioning

In addition to the effects of local ischemia, remote ischemia can protect distant organs or tissue during subsequent ischemia [95]. This has been termed remote ischemic preconditioning (RIPC) [96]. RIPC is a method by which the deliberate induction of transient non-lethal ischemia of an organ protects against subsequent ischemic injury of another organ. The potential use of RIPC has been mostly evaluated in the setting of myocardial protection. There are also preliminary data suggesting that RIPC prior to both cardiac surgery and CM administration protects against AKI [97]. In a randomized double-blind trial, 100 patients with CKD were subjected to RIPC or to a sham procedure prior to elective coronary angiography [98]. RIPC was induced by intermittent arm ischemia generated by four cycles of 5-minute inflation of a blood pressure (BP) cuff to 50 mmHg above individual systolic pressure within 45 minutes before angiography. The sham procedure consisted of inflation of a BP cuff to individual diastolic pressure, followed by deflation to 10 mmHg. All patients received also acetylcysteine and a continuous saline infusion. The incidence of CIAKI was 6% in the RIPC group versus 20% in the sham group (OR 0.21, 95% CI 0.07–0.57). In a second trial, 225 patients with a

non-ST-segment elevation myocardial infarction were randomly assigned to receive RIPC or a sham procedure prior to the coronary intervention [99]. RIPC consisted of four cycles of 30 second inflation, followed by 30 seconds deflation of the stent balloon during the PCI procedure; the sham procedure consisted of four cycles of 30-second inflation to only 3 atm pressure, followed by deflation. Even in this study, CIAKI occurred less frequently in the RIPC group than in the sham group (12.4% vs. 29.5%, respectively, OR 0.34, 95% CI 0.16–0.71). These results, although compelling (particularly because RIPC is conferred using different modalities and at different time points prior to contrast exposure), require confirmation in larger randomized trials to determine the underlying mechanism of protection and before RIPC can be recommended as a preventive measure for CIAKI [100]. In addition, the safety of repetitive balloon inflations in a coronary artery post-stenting remains unclear.

Renal replacement therapy

Hemofiltration is expensive, time consuming, logistically cumbersome, and associated with significant risks. Its effectiveness compared with other less expensive strategies is not well established so this treatment modality should be reserved for patients who already have fairly advanced renal insufficiency [101]. Marenzi *et al.* [102] found that, compared with intravenous saline, hemofiltration administered as prophylactic therapy in high-risk patients was associated with: (i) a lesser likelihood of the serum creatinine rising >25% (5% vs. 50%); (ii) a lesser likelihood of requiring dialysis (3% vs. 25%), and (iii) a lower in-house (2% vs. 14%) and 1-year mortality (10% vs. 30%). However, it has been pointed out that creatinine removal by the hemofiltration procedure can be sufficient to explain the decreased frequency of elevation in the serum creatinine. Moreover, the control group had an unusually high incidence of acute renal failure, attributable to the excessive volume of contrast media used and, possibly, to the absence of optimal pharmacologic prophylaxis. Patients in the hemofiltration group were cared for in an intensive care unit; their greater intensity of care relative to the control group may explain why hemofiltration was associated with improved short- and long-term survival. In contrast, the same authors found that hemofiltration performed only post-contrast exposure is not effective [103]. Recently, data from Spini *et al.* [104] confirmed that continuous renal replacement therapy (CRRT) performed before and after PCI is more effective for CIAKI prevention in patients with severe CKD in comparison to CRRT performed only after, is capable of significantly reducing sCr levels and increasing eGFR values, and is associated with a lower mortality rate during follow-up. Given the aforementioned limitations, the applicability of these findings to current clinical practice remains unclear. Table 27.2 depicts the approach proposed to prevent CIAKI based on current evidence.

Conclusions

The optimal strategy to prevent CIAKI remains uncertain. The most recent guidelines [35,105] recommend: (i) a peri-procedural intravenous volume expansion with isotonic sodium chloride, (ii) the use of a low or iso-osmolality contrast agents, and (iii) to limit the volume of the administered contrast agent. Adequate hydration should be guided according to LVEDP and/or urine flow rate. The RenalGuard system seems to be helpful in preventing CIAKI by allowing a high urine flow rate and optimal fluid balance. Statins can be effective in reducing oxidative stress and therefore preventing

Table 27.2 Checklist for estimating the risk of CIAKI and prevention strategies in patients undergoing percutaneous procedures.

Risk assessment		
1 eGFR calculation		
2 Risk score assessment (Mehran, Gurm)		
3 Nephrologic consultation (eGFR <15 mL/min/1.73 m ²). Indication for elective RRT		
Prophylaxis		
1 Intravenous hydration	Normal saline	0.5–1 mL/kg/hr 12 hr before and 12 hr after
2 Drugs		Maintain urine flow rate >150 mL/hr or LVEDP-guided:
		<13 mmHg = 5 mL/kg/hr
		13–18 mmHg = 3 mL/kg/hr
		>18 mmHg = 1.5 mL/kg/hr
	Sodium bicarbonate	154 mEq/L 3 mL/kg/hr ≥1 hr before and 1 mL/kg/hr for 6 hr after
	Renalguard system (eGFR <30 mL/min/1.73 m ² and/or Mehran risk score >11)	Maintain urine flow rate ≥300 mL/hr
	Statins	Atorvastatin 80 mg Rosuvastatin 40 mg
	N-acetylcysteine	1200 mg b.i.d. before and after
Iodinated contrast media	Iso- and low osmolar (beside ioxalate and ioexol) Limited volume (mL)	<ul style="list-style-type: none"> • Prolong the time-interval between CM-enhanced studies • Staged procedures for complex multivessel disease • Alternative CM (CO₂ for peripheral procedures) • Automated contrast injectors
Serial control of serum creatinine	At 48–72 hr: additional controls if clinically indicated

Radiation Management in Interventional Cardiology

Stephen Balter¹ and Charles E. Chambers²

¹Columbia University Medical Center, New York, NY, USA

²Penn State Hershey Medical Center, Hershey, PA, USA

Optimal clinical outcomes, the minimum of clinical complications, and the avoidance of harm to staff are among the pillars supporting any successful interventional cardiac laboratory. Achieving such results requires continuing diligence and commitment from the host institution, all physician operators, and laboratory staff. Space constraints limit this chapter to selected topics but additional reviews are available in the literature [1–4].

Fluoroscopically guided interventions (FGI) can be unnecessarily radiologically hazardous to the patient [5] unless a knowledgeable operator [3] takes appropriate precautions. High level factors that should be considered include the following:

- The total “dose” delivered to the patient is influenced by equipment configuration, individual patient factors, and the operator’s skill. Caution: dose in a radiologic sense has several different connotations beyond, the usual meaning found in pharmacology; this difference is discussed later. Operators are expected to be mindful of radiation use during each procedure and continuously justify continuing with the procedure based on the current risk–benefit balance.
- Technology can only serve to define dose rates. The total dose delivered by a FGI procedure is dependent upon both dose rates and the time that the beam is on.
- Fluoroscopes are general purpose instruments. Appropriate configuration to accommodate the current clinical task is an essential part of continuous optimization of the procedure. Unacceptable patient irradiation and/or image quality will occur if the equipment is not appropriately configured.

Measurements of radiation

X-rays are classified as a form of ionizing radiation because each X-ray photon contains enough energy to ionize atoms and disrupt molecular bonds. The biologic effects of ionizing radiation are different from the essentially thermal effects of non-ionizing radiation (e.g., microwaves) on tissue. The detection and management of X-ray injury is substantially different from conventional burn management.

The common pharmacologic usage of *dose* is the entire aspirin tablet administered to a patient. The concentration of aspirin in the patient’s blood (e.g., ng/100 mL) can be measured when necessary. Radiologic *dose* is the local concentration of energy extracted from

a radiation field when it interacts with matter. Because the radiation field in a patient is never uniform, different regions of the patient receive different *doses* from a fluoroscopic procedure. Figure 28.1 schematically illustrates these concepts.

No single number can describe either the total physical distribution of radiologic dose in a patient from a FGI or the overall biologic risk of that irradiation. Nevertheless, multiple “dose” indicators have been developed and are used for patient radiation management and risk evaluation.

The five fluoroscopic “dose” indicators commonly used in interventional cardiology are shown in Table 28.1. Peak skin dose (PSD) and reference point air kerma ($K_{a,r}$) provide indices of tissue reaction risk in individual patients. Kerma area product (KAP) relates to the total amount of radiation experienced by patients and staff. Effective dose (E) is used to estimate cancer risk (for populations, not for individuals). Although commonly reported, fluoroscopic time is of little value for estimating patient risk.

Interventional fluoroscopes are flexible instruments that are configurable on a case-by-case basis to meet the requirements of that procedure. Figure 28.2 is a block diagram of the key components of an interventional fluoroscope. System operation is determined by the combination of operator selectable parameters and feedback elements designed to stabilize system performance and imaging. The operator is a crucial element in many of these control loops.

Radiobiology

Although radiation exposure associated with isolated episodes of care is typically limited, all radiation exposure confers risk, and these risks are well established. Deterministic effects are dose dependent direct health effects of radiation, for which a threshold is believed to exist. Deterministic effects of fluoroscopy typically present within weeks of exposure as skin injury. For the operator and staff, eye injury in the form of a specific fluoroscopic related cataract, posterior subcapsular, is seen in individuals with high dose exposure over time [6–8].

Patient-related factors associated with skin injury include smoking, poor nutrition, compromised skin integrity, obesity, overlapping skin folds, and skin location [9]. Ethnic differences are seen, with those individuals with light-colored hair or skin being more susceptible. An autosomal recessive ATM gene present

in 1% of the population predisposes an individual to increased radio sensitivity. Certain disease states, hyperthyroidism, diabetes, and autoimmune and connective tissue disorders, as well as chemotherapeutic agents, place an individual at increased risk for

Figure 28.1 Radiologic dose is the concentration of energy received by a small mass of matter (1 Gy = 1 joule/kg) at a specific point. None of the (red) points in this figure received the same dose from the irradiation. Factors include distance from the source, tissue attenuation, and scatter.

tissue injury. Individuals who have had recent radiation exposure or any previous high dose radiation tissue injury are more susceptible to subsequent tissue injury.

Stochastic effects are biologic effects of radiation that occur by chance in a population of exposed persons, for which no clear threshold exists; whereas probability is proportional to radiation dose, severity is dose-independent. A stochastic injury occurs when there is injury to the DNA backbone that does not properly heal itself. The result is not cell death but a mutation leading to either a cancer or a genetic abnormality. A single X-ray photon can cause this change; it is not directly dose related, even though the risk of acquiring such injury increases with dose. Because of the time required for one transformed cell to multiply into an observable tumor, the latent period for cancer induction is years to decades after the irradiation.

Patient radiation management

Managing patient radiation is generally divided into actions that are required before, during, and after a procedure [4,10,11]. Additional considerations are needed for pregnant and pediatric patients. Box 28.1 is a sample check-list covering key points. A few of these points are also essential for staff safety. Each facility should develop its own check-list.

Table 28.1 Radiologic dose indicators.

Indicator	Unit	Definition	Comments
Peak skin dose (PSD)	gray	Maximum dose delivered to any portion of the patient's skin during a procedure (includes backscatter from the patient's tissues)	Severity of injury is related to the PSD Real-time PSD displays on interventional fluoroscopes are available on some newer fluoroscopes PSD can be evaluated after the procedure if direct measurement film is used during the case or by calculations in newer systems
Reference point air kerma ($K_{a,r}$)	gray	Total air kerma delivered to a defined point relative to the X-ray gantry from a procedure (excludes scatter)	Usable to estimate the risk of a skin reaction $K_{a,r}$ displays are currently available on essentially all interventional fluoroscopes The relationship between PSD and $K_{a,r}$ is highly dependent on beam motion and geometry
Kerma area product (KAP)	Gycm ²	Total amount of radiation emitted from an X-ray tube during a procedure (excludes scatter)	Used to estimate staff irradiation and patient effective dose, KAP displays are currently available on essentially all interventional fluoroscopes KAP can be calculated by multiplying $K_{a,r}$ by the field size at the reference point
Effective dose (E)	mSv	Calculated value representing a risk weighted whole-body irradiation	Used to estimate the cancer risk to a hypothetical person, E can be estimated from KAP and other factors E cannot be measured; it is always a calculated quantity
Fluoroscopic time (FT) <i>Should NOT be used as the only radiation metric for interventional procedures</i>	min	Time that the X-ray beam is on in a fluoroscopic mode. <i>(Obsolete as a quantity for estimating radiation risk)</i>	FT does not account for variations in X-ray output with changes in patient size and ignores the much higher dose rate contribution from cine

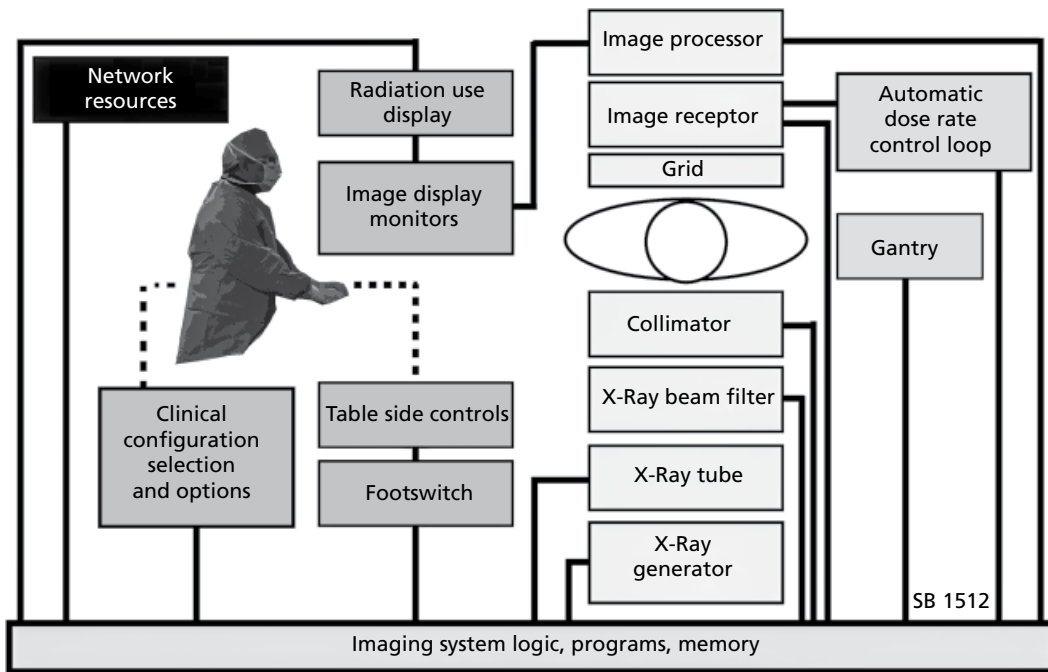

Figure 28.2 Block diagram of an interventional fluoroscope showing key components and control loops. Note that the operator functions as an important control element by selecting technique factors, FOV, geometry, etc.

Box 28.1 Example of a radiologic check-list

Pre-procedure:

- Obtain patient's radiation history; check patient's skin if positive for prior recent exposure
- Extend radiation aspects of informed consent when appropriate for high risk cases
- Plan alternative beam orientations for forthcoming case when necessary

Time out:

- Verify that fluoroscopic system settings are correct for the planned procedure
- All staff should be wearing their personal radiation monitors (staff safety item)
- All staff wearing their radiation and non-radiation personal protective equipment (staff safety item)
- Ancillary radiation shielding devices present in laboratory (staff safety item)

During procedure (reminders to be reviewed during time out):

- Use lowest dose rate settings consistent with immediate clinical goal
- Operator (and staff) aware of radiation use during procedure
- Operator aware of beam angles used during procedure
- Operator assess risk–benefit at each dose notification

Post-procedure:

- Complete patient dosimetry recorded in medical record and case report
- Substantial dose of radiation justified in medical record when appropriate
- Patient notified if substantial dose of radiation was used; and given their initial follow-up processes
- Patients receiving substantial doses are followed as appropriate

Pre-procedure aspect of radiation dose management

Assess the risk–benefit ratio of performing the procedure. Radiation should be one element of this assessment particularly in heavy patients, patients who have undergone multiple procedures, and in

patients who have had a major interventional procedure within a few months prior to the planned procedure.

Informed consent should appropriately include radiation issues. In most cases, the focus should be on potential skin reactions. This is especially important for complex procedures and for patients who are at increased risk because of their body size or radiation history. Fetal risk and its management must be discussed with pregnant patients. A discussion of cancer risks should be included for patients below the age of 60 and might be offered to all patients.

Time out

The physician should personally verify that the patient identification has been entered into the fluoroscope and that it is properly configured for the planned procedure. One of the standard protocols installed on the machine may be appropriate; however, adjusted protocols can be used to meet specific clinical requirements. The time-out process should also include verification that all staff are wearing appropriate radioprotective equipment and radiation monitors. Available radioprotective shielding (table, face, and mobile) should be properly deployed.

Procedural aspects of radiation management

The physician must continuously manage radiation from the onset to the completion of the procedure. Conceptually, radiation management is similar to contrast agent or other drug management during the procedure. The dose needed from moment to moment, and for the entire procedure, is titrated in the patient's best interest.

Table 28.2 summarizes physician radiation management during a procedure. Some items are focused on minimizing staff irradiation. Most serve to avoid unnecessary patient irradiation. Steps taken to

Table 28.2 Procedural physician radiation management items.

	Management	Effect
General		
A	The system should be configured to the lowest dose-rate modes consistent with immediate clinical activities. Reconfiguration is needed either when images are clinically inadequate or when a lower dose rate mode will comfortably suffice for present activities. (Check during time out)	Incorrect technique selection might increase patient dose by a factor of 10 without contributing to the needs of the procedure
B	Never produce radiation unless the operator's eyes are on the primary image monitor	This might save 10% or more of the entire radiation dose
C	The use of retrospectively stored fluoroscopy instead of cine documentation will always save radiation and also can save contrast media	Saves several 10s of % when stored fluoro replaces cine for documenting inflations, etc.
Specific		
1	The low dose rate mode (for both fluoro and cine) should be initially tried in every case. Escalate the dose rate only when images are inadequate for procedural requirements. The goal is sufficient image quality to perform the procedure without spending radiation and other resources on unnecessarily high quality image	Typically each higher step doubles the dose rate for that mode
2	Fluoroscopic and cine frame rates should be set to the minimum required for adequate temporal resolution and image noise	Dose rate decreases with decreasing frame rate. % change differs between manufacturers
3	The primary operator should control beam on time. The beam should only be on when needed by this person to observe motion	Irradiating the patient without observing the monitor is a total waste of radiation
4	Where possible, change the imaging beam angle during long procedures. This will help minimize peak skin dose	Dose is always local. Sufficient beam motion irradiates different tissue and minimizes reactions
5	Minimize beam orientations that place a great thickness of tissue between the patient and image receptor	Every 4–5 cm additional tissue in the beam doubles the skin dose rate
6	The X-ray tube should be as far from the patient as possible. Spacing reduces skin dose by increasing the Source to Image receptor distance	Increasing the spacing from 38 cm (minimum defined by spacer) to 45 cm decreases skin dose rate by approximately a factor of 2 (All else constant)
7	Examination table height should to facilitate the primary operator's comfort. This often contributes to quicker device manipulation and therefore less beam on time	Total dose = dose-rate × time. Reduced time may be a greater benefit than maximizing spacing
8	The image receptor should always be as close to the patient as practicable. This minimizes input dose rates	Reducing spacing as much as possible can save 25% of dose-rate in thick patients
9	Cine should only be used only when necessary. Most interventional fluoroscopes have the capability of retrospectively storing the most recent 10–30 seconds of fluoroscopy. The judicious use of this mode avoids the higher dose rates required for cine and can reduce the total contrast volume	Typical cine dose rates are 10 times as high as fluoro dose rates for the same view
10	Higher magnification factors usually require higher levels of patient irradiation. They should be avoided where possible	Dose rates for image intensifiers usually increase by a factor of 4 when the magnification is doubled. For flat-panel detectors the increase is usually a factor of 2

Table 28.3 Notification and substantial radiation dose level (SRDL) levels [4].

Dose metric	First notification	Subsequent notifications (increments)	SRDL
$D_{\text{skin,max}}^a$	2 Gy	0.5 Gy	3 Gy
$K_{a,r}^b$	3 Gy	1 Gy	5 Gy ^b
KAP (P_{KA}^c)	300 Gy cm^2 ^d	100 Gy cm^2 ^d	500 Gy cm^2 ^d
Fluoroscopy time	30 min	15 min	60 min

^a $D_{\text{skin,max}}$ is peak skin dose, requiring calculations by physicist.

^b $K_{a,r}$ is total air kerma at the reference point.

^c P_{KA} is air kerma-area product. Caution: different fluoroscopes use different display units.

^dAssuming a 100 cm^2 field at the patient's skin. For other field sizes, the P_{KA} values should be adjusted proportionally to the actual procedural field size (e.g., for a field size of 50 cm^2 , the SRDL value for P_{KA} would be 250 Gy cm^2). Source: NCRP 2010 [4], Fig. 4.7. Reprinted with permission of the National Council on Radiation Protection and Measurements, <http://NCRPpublications.org>.

avoid wasting patient irradiation will often simultaneously reduce irradiation to staff.

Integrating other imaging modalities during catheterization (trans-esophageal and intracardiac echocardiography) reduces radiation exposure. CT three-dimensional reconstruction can be used for intra-procedural real-time overlays during complex transcatheter interventions, such as closure of para-valvular leaks. Rotational angiography might be used as well [12]. The information obtained through 3D reconstructions eliminates the need for several biplane cine acquisitions and is particularly useful in patients requiring complex pulmonary artery rehabilitation, where it allows the operator to exactly determine the best angles that profile individual lesions requiring transcatheter interventions.

Staff should periodically remind operators of radiation use [4]. Table 28.3 summarizes dose metrics that are available on a specific fluoroscope and can be used for this purpose.

Post-procedural aspects of radiation management

Actual radiation use for every procedure should be documented in the patient's medical record and procedure report [13]. Fluoroscopic time is a totally inadequate measure of either potential skin injury or of cancer risk. Data must include all of the available dose metrics shown in Table 28.3 which are reported by the interventional fluoroscope.

Exceeding the predefined substantial radiation dose level (SRDL) triggers additional clinical documentation and patient communication. Procedures performed below this the SRDL are unlikely to result in clinically important tissue reactions. Injuries are rare below twice the SRDL but become more frequent at higher doses (Figure 28.3). The default SRDL for interventional cardiology is a $K_{a,r}$ of 5 Gy at the reference point.

The operator should explicitly report the medical necessity for the documented radiation level in the procedure report using enough detail to be understandable for case review purposes. These events, as with all essential aspects of laboratory radiation safety,

Figure 28.3 Dry desquamation (poikiloderma) at 1 month in a patient receiving approximately 11 Gy calculated peak skin dose. Source: Chambers CE, *et al.* 2011 [1].

should be a regular component of the catheterization laboratory quality improvement program.

The patient (and family) should receive pre-discharge radiation instructions when an SRDL is exceeded. (Fluoroscopic time should only be used as the trigger if none of the other metrics in Table 28.3 are available for a specific procedure.) The key points relevant to this process are shown in Table 28.4.

Staff radiation safety

“X-rays” are essential for both diagnosis and therapy. Though the benefits are quantifiable with decreased morbidity and mortality, the risks of radiation are less clear. In interventional cardiology, the importance of a radiation-conscious environment is stressed where protection for the patient protects the staff and vice versa. Methods for measuring patient dose, monitoring staff dose, implementing appropriate training, and managing radiation dose from the outset of the procedure are important components of a catheterization laboratory radiation safety program.

Personal dose monitoring

Staff radiation levels are known [4,14] and generally well below regulatory dose limits provided that best practices are followed. However, there is no way to detect radiologic safety failures unless all individuals in the laboratory always wear and return their radiation monitors as specified by the institution's radiation safety officer (RSO) (different institutions use different protocols). The RSO will contact individuals when radiation levels are of concern (generally between 10% and 30% of the regulatory limits). Nevertheless, all users should periodically review their records with the RSO.

Shielding

Protective garments must be worn by all persons who are in the procedure room when the X-ray beam is on. These garments are designed to protect the gonads and 80% of the active bone marrow. The standard is a 0.25–0.5 mm lead apron, which stops approximately 90% of the scattered radiation [15]. Separate thyroid shielding (also approximately 90% reduction) is recommended for younger workers as well as all individuals whose externally worn dosimeter at collar level exceeds 4 mSv in a month [16]. Long-term deleterious

Table 28.4 Post-procedure patient notification and follow-up.

Patient-centric: pre-discharge	
This should always be done as a personal communication. It should be supplemented by a written reminder	
1	Your procedure required a substantial amount of radiation for its completion
1a	(Less than twice a SRDL): Because of this, it is possible that you might have some skin reddening from this. In many cases, it will fade in time and not reoccur. In some cases you will have some cosmetic skin discoloration
1b	(More than twice a SRDL): You are at increased risk for a clinically significant skin reaction from the procedure. (Escalate the warning for higher values)
2	Avoid damaging your skin. Do not scratch or scrub the area where we worked
3	For the next year, please tell all of your healthcare providers that you had a procedure that used radiation and may have caused a skin reaction
4	In a month, have a family member examine your back for a red area about the size of a hand. If anything is seen please contact the catheterization laboratory for further instructions. (Figure 28.3 illustrates a fluoroscopic radiation injury)
Physicians and laboratory staff	
A	Patient should be called proactively at 1.5 × SRDL If the patient cannot be directly contacted, consider informing the referring physician
B	The laboratory must be prepared to handle such calls. The discussion should be with a physician or radiation trained mid-level provider
C	If the individual taking the call cannot absolutely rule out a radiation etiology, the patient should be scheduled for an examination by the physician performing the procedure. If a physician visit is needed, the patient should be reminded to avoid further skin injury
D	Based on the physician's examination of the patient's skin, appropriate follow-up visits, referrals, or treatments should be recommended

SRDL, substantial radiation dose level.

effects from protective garments are well documented with methods for potential improvement currently being addressed by the multispecialty occupational health group in the interventional laboratory [17]. Proper protective garment care, including hanging aprons on designated racks with adequate hangers and periodic inspection for damage, is an essential part of radiation safety.

Recent epidemiologic studies give reason for concern regarding potential eye injury, presenting as posterior subcapsular cataract formation [6,7,18–20]. Radiation-specific eye protection works if properly selected and used [21,22]. The glasses must fit properly for both protection and comfort, provide 0.25 mm lead equivalent protection, and have additional side shielding. Well-designed eye shielding reduces dose to the lens of the eye by approximately two-thirds.

Radiation shielding of the operator's hands is generally counterproductive when the hands are in the useful beam because the shielding drives the system to greater output, increasing patient and often staff dose. Protective hand equipment is often labeled with warnings against placing the hands in or near the beam. The best rule is to avoid seeing your hands on the monitor. Labeling on "protective" gloves often warns users not to put their hands in the beam while wearing the gloves (Figure 28.4).

Current shielding provides substantial reduction in operator dose and should be used routinely [23–25]. Transparent ceiling-mounted shielding with a patient contour cutout protects the operator's upper body. When positioning this shield, the origin of scatter X-rays is from the patient, to block this scatter directed toward the operator's

head and arms. The operator should only see the area being imaged by looking through the shield. In-laboratory moveable barriers provide protection for staff required to be in the procedure room, while individuals not required in the fluoroscopic suite should remain in the control room. Disposable radiation-absorbing non-lead patient sterile drapes also help to reduce staff dose but do not always provide a substantial benefit [26].

Specific radiation safety considerations

Women and fluoroscopic guided procedures

The fetus of a pregnant patient can be at risk for potential stochastic injury and, at high (fetal) dose, the induction of a deterministic effect [27,28]. Deterministic effects in the embryo-fetus for absorbed doses below 50 mGy are seldom detectable, while doses in excess of 100 mGy can cause gestation time and dose-dependent developmental effects. The safest policy is to avoid elective procedures during pregnancy. The benefits and risks to both mother and fetus of performing a planned procedure need to be carefully considered with informed consent essential. Even in the absence of known risk factors, approximately 5% of live births possess some form of congenital malformation. With proper procedure planning to exclude abdomen or pelvis exposure (consider radial access) and, if available, consultation with a qualified medical physicist, embryo-fetus exposure can be limited to scatter radiation with very low and usually acceptable risk.

Figure 28.4 Worst practice: an example of unnecessary irradiation of an operator's hands during the insertion of a transradial device. A radiation shield is seen on the left and the patient's arm on the right. The majority of the operator's hands are irradiated by the unattenuated beam passing between the shield and patient. Safety rule: operators should not see their hands on the monitor.

Whether it is staff or physician, the pregnant worker is best protected in a laboratory that utilizes best practices for radiation safety. Each hospital should have a radiation safety policy for pregnant workers that addresses occupational exposure, dosimeter use and readings, duties including call, and risk–benefit of additional shielding. It is unlawful to prevent pregnant employees from working in occupations that may expose them to radiation. All pregnant workers should have a specific dosimeter, to be worn at the waist under the protective garment, issued and read monthly. The work-related restriction limit for the embryo-fetus radiation exposure equivalent dose is 0.5 mSv/month. Once a pregnancy is identified, the expectant mother should not receive more than 1 mSv according to the International Commission on Radiation Protection (ICRP) and 5 mSv according to the National Commission on Radiation Protection (INCRP) for the remainder of the pregnancy [28,29]. It should be noted that reference values of 1 mSv are seldom recorded *for an entire year* in this location [30].

Pediatric patients

Equipment routinely used for pediatric procedures of any kind should be appropriately designed, equipped, and configured for this purpose. Appropriate modifications should be made to accommodate the variable procedural requirements as well as the wide age and weight range of these patients [31,32]. The use of unmodified adult settings for small patients (<40 kg) can result in both unnecessary patient irradiation and substandard image quality.

Children born with congenital heart disease frequently undergo numerous diagnostic and therapeutic catheterizations, with potential harmful cumulative long-term effects of radiation exposure [33,34]. This raises significant concern when children survive to potentially manifest these late effects of radiation exposure. The importance of radiation dose reduction in the pediatric patient has been emphasized through the Image Gently and Step Lightly campaigns [31,32].

Training and education

The potential benefits for all operators, no matter what skill level (achieved or perceived), to be thoroughly trained in radiation safety with regularly updates should not be understated. Fetterly and colleagues at the Mayo Clinic succeeded in a 40% radiation dose reduction (CAK) over a 3-year period by implementing a culture and philosophy of radiation safety in the catheterization laboratory [1,35,36]. The interventional cardiologists' goal is to do the best for their patients, and in so doing, protect the staff and themselves. In the multi-task environment of the cardiac catheterization laboratory, mandatory radiation safety training, with annual updates, will allow all operators, new and experienced, to achieve this goal throughout their career.

Radiation quality processes

The American College of Cardiology Foundation/American Heart Association/Society for Cardiovascular Angiography and Interventions (ACC/AHA/SCAI) 2011 PCI Guidelines [37] reconfirmed the requirements for all cardiac catheterization laboratories with interventional programs have a quality improvement program specific for the laboratory. This requires more than just outcomes review; it necessitates appropriate processes for best patient care be implemented. Radiation safety, including patient radiation dose review [38], must be among these processes. Compliance with local regulatory requirements only assures a basic level of safety anywhere in an institution. The catheterization laboratory is a much more demanding environment [35,39,40] and should accept the financial and administrative responsibilities of maintaining greater safety margins for both patients and staff [41].

Key topics include the following: design of the laboratory and adjacent spaces; equipment selection, configuration, quality control, and service; staff radiation protection; and patient radiation management. Degrees of assistance with these topics can be provided by experts, such as medical and health physicists. The laboratory medical director should accept the responsibility of keeping these experts engaged in laboratory operations on a routine basis instead of relying on "strangers" when an emergency occurs.

Both the physician and support staffs need enough usable current knowledge to recognize problems and ask for help when necessary. Ultimately, operator training and experience are essential to maintaining radiation safety on a case-by-case basis.

Conclusions

Radiation safety is one of several priorities that must be attended to in the cardiac catheterization laboratory. The interventional cardiologist is required to take the leadership role. Establish a radiation safety program for the laboratory, incorporating the physicist for radiation training, equipment purchase, and safe maintenance. Require and document the appropriate radiation safety training both upon employment and with annual updates. Purchase and properly operate imaging equipment with dose limiting capabilities and appropriate dose notification. Utilize all available above and

below table shielding as well as personal protective garments and glasses. Mandate the wearing of the dosimetry badge(s) by incorporating badge use as a component of the pre-procedure “time out.” Manage radiation dose throughout the case, not just upon high dose notification. Establish follow-up parameters with policies for those patients receiving high radiation doses. When a radiation conscious environment has been established in the cardiac catheterization laboratory, the patients, staff, and physicians will all benefit.

Concepts of Cell Therapy and Myocardial Regeneration

Kevin O’Gallagher¹, Zoë Astroulakis², Alex Sirker³, and Jonathan M. Hill¹

³Department of Cardiology, UCLH and St Bartholomew’s Hospital, London, UK

Over the past 15 years, stem cell therapy has emerged as a potential therapeutic intervention in ischemic heart disease, engaging the interests of basic scientists and cardiologists alike. Despite recent advances in pharmacologic and catheter-based interventions for coronary heart disease, myocardial salvage is often incomplete resulting in a process of adverse left ventricular (LV) remodeling leading to symptomatic heart failure. This chapter discusses the relevance of cell therapy to interventional cardiology, outlining the progress of over a decade of clinical trials, and looks to future directions for clinical research.

Origin of concept

The concept of the adult stem cell was born over 30 years ago, following the identification of a bone marrow cell capable of reconstituting hematopoiesis in irradiated mice [1]. However, it is only in the last 15 years that the relevance of this work to cardiology was realized with the description, from the late Jeffrey Isner’s laboratory, of bone marrow derived stem/progenitor cells that could regenerate cells constituting the cardiovascular system [2]. This challenged the previously held belief that the vascularization of adult ischemic tissue was restricted to the proliferation and migration of mature endothelial cells. Indeed, Isner’s group went on to provide evidence that these cells could home to sites of ischemia and participate in new blood vessel formation, a process previously thought to be restricted to embryonic development. Furthermore, work involving animal models of ischemia demonstrated that bone marrow mononuclear cells (BMNCs) and endothelial progenitor cells (EPC) could participate in myocardial neovascularization with evidence of functional improvement [3–7].

The next key development, and now widely recognized as the landmark paper within the field of cardiovascular cell therapy, was the description by Orlic *et al.* [8] working in Piero Anversa’s group, that a bone marrow derived population of cells from one mouse could be transplanted into recipient mice with myocardial infarction and become incorporated into the area of myocardial injury, exhibiting immunohistochemical evidence of transdifferentiation as well as leading to demonstrable changes in LV function. Further work has shown that stem cells are able to transdifferentiate into

multiple different cardiovascular cell types including endothelial cells, vascular smooth muscle cells, and cardiac myocytes [9–12].

Subsequent controversies notwithstanding, the papers from the Isner and Anversa groups heralded the beginning of intense activity in cardiovascular therapy which continues to this day. However, many key questions remain regarding the putative mechanisms of action.

Myocardial regeneration

Within cardiology, stem cell therapy has generated huge interest by challenging the long-held paradigm of developmental biology that the heart is a terminally differentiated organ, and as such cannot be repaired. Previously, the extent of myocardial necrosis had been shown to be intimately linked to the duration of coronary artery occlusion [13,14]. Such studies were critical in creating the drive forward in reperfusion therapy, but also led clinicians and scientists alike to think of myocardial injury as an irreversible event. Indeed, any improvement in LV function post-myocardial infarction (MI) was thought to result from a combination of hypertrophy and fibrosis. Such ideas were called into question with the observation that adult hearts contained large numbers of mitotic figures [15–17]. However, the proportion of mitotic cardiomyocytes was extremely small, suggesting they could not function alone as an effective repair system. The possibility that these dividing cells might have arisen from an extra-cardiac source, such as the bone marrow, was postulated by studies performed in sex-mismatched cardiac transplant patients. In males receiving female hearts, cardiac biopsies revealed Y-chromosome-carrying cardiomyocytes [17–19], intimating that cells from an extra-cardiac source could potentially engraft and differentiate into cardiac tissue. This marked the first recognition that the heart could receive cells from an extra-cardiac source. To explain this phenomenon, it was suggested that these cells might have arisen from the bone marrow, being released and engrafting either as a low-level process of continual renewal or in direct response to injury [8,11]. Alternative suggestions included the possibility of a locally resident population of cardiac stem cells, with self-renewing, multipotent, and clonogenic potential [20].

Mobilization of stem/progenitor cells

Studies in humans have confirmed that BMNCs and EPCs are indeed mobilized from the bone marrow to sites of ischemia at the time of myocardial infarction [21]. This occurs in response to the release of cytokines leading to the chemotactic migration of stem and progenitor cells to the area of injury. Such cytokines include vascular endothelial growth factor (VEGF) and stromal derived factor-1 (SDF-1) [22]. Reduced oxygen tension in ischemic tissue leads to an increase in SDF-1 levels in response to the upregulation of hypoxia-inducible factor-1 (HIF-1) in endothelial cells [23,24]. This hypoxic gradient directs the migration and homing, and increases the adhesion of, CXCR4-expressing progenitor cells to ischemic tissue [25]. It has been shown that impaired CXCR4-mediated cell signaling contributes to the reduced neovascularization capacity seen in patients with coronary artery disease [26], and modifications of this pathway appear to offer promise for the enhancement of cell homing and retention. In addition, the capture of cells at the site of ischemia has been shown to be aided by the upregulation of integrins and intercellular adhesion molecules [27–30], and by the mediation of platelets [31].

Mechanism of action

However, it is still unclear as to the exact mechanism by which transplanted cells exert their beneficial effects on cardiac function. Proposed mechanisms include endothelial differentiation (thereby aiding vascular regeneration and improving blood supply to the infarct border zone and so improving regional/global systolic LV function), cellular fusion, transdifferentiation to cardiomyocytes and/or via paracrine effects on the local cellular milieu, and the issue remains controversial.

Several studies have suggested that BMNCs co-localize with non-myocardial cells such as fibroblasts [32]. However, these observations are so far anecdotal and could be explained by methodologic issues such as the release of dye from apoptotic cells in the area of fibrosis or by the use of unfractionated bone marrow, which includes other cell precursor populations. Nonetheless, they are consistent with the basic postulate that stem cells differentiate along milieu-dependent pathways. Damaged adult myocardium is devoid of key embryonic growth factors, meaning an inability to recreate the necessary environment to stimulate myocyte growth or regeneration. This presents a challenge, and accordingly stimulates the search for novel strategies to encourage transplanted cells down the cardiac differentiation pathway prior to transplantation, if not *in situ*.

Choice of cell type for cardiac cell therapy

Although the majority of work has been performed using BMNCs (either selected or unselected), other cell types can be used, including mesenchymal stem cells, skeletal muscle myoblasts, and cardiac stem cells. Mesenchymal stem cells (MSC) are stromal cells, found both in the bone marrow and adipose tissue. The “immune-privileged” status [33] of MSC allows both autologous and allogenic use: this, combined with the ability to deliver the treatment intravenously, represents an attractive “off-the-shelf” aspect to this therapy. Skeletal myoblasts (SMs) can be easily and conveniently harvested via muscle biopsy. However, there is debate surrounding the safety of this technique, particularly on the issue of their potential for arrhythmogenesis [34–36]. Cardiac stem cells (CSC), either as ckit⁺ cells or cardiosphere-derived cells, are resident undifferentiated cells with the ability to differentiate into beating myocytes.

Cell therapy following acute myocardial infarction

The first wave of trials examining bone marrow (BM) cell therapy in the setting of acute MI indicated that autologous unselected BM cell therapy was indeed both safe and feasible, and the noted improvements in LV function paved the way for larger scale randomized clinical trials which unfortunately sometimes generated conflicting and controversial results. This has largely arisen as a result of key differences in the cell population used, the time and mode of delivery, and the different methodologies used to assess changes in LV function. For many clinicians, the demonstration of safety alone is insufficient grounds on which to proceed to larger clinical studies. Indeed, many cite that the statistically significant changes in LV function are clinically insignificant, and further studies are not currently justified.

Cell type

The transfer of autologous BMNCs is attractive as a form of cell therapy because of the relative ease by which it can be obtained, the lack of requirement for *ex vivo* expansion, and of course the lack of risk of rejection by the recipient. It also supports the idea that no particular cell type should be omitted, and that functional recovery is dependent upon a balance between the various sub-populations present in the mononuclear fraction. As such, the majority of clinical trials so far have used unfractionated BMNCs [37–40].

The problem with using unfractionated BMNCs, however, is that any functionally superior subgroup of cells would have to compete for engraftment along with all the other “non-stem” cells. CD34⁺ cells have been shown to mediate cardiac repair by inducing angiogenesis, inhibiting apoptosis and by promoting myocyte recovery in experimental models of myocardial infarction [41]. Indeed, it has been shown that CD34⁺ enriched BM cells are up to seven times more efficient at engrafting in ischemic myocardium [42]. In addition to the CD34⁺ marker expressed by stem/progenitor cells, CD133 (a prominin 5 transmembrane glycoprotein 1 marker) is co-expressed in a substantial number of hematopoietic cells with potent angiogenic capacity [43–45]. The intracoronary injection of CD133⁺ enriched BM cells has been shown to be feasible, and to be associated with the promotion of cardiac recovery in a small study, albeit with a slightly increased incidence of in-stent restenosis and re-occlusion [46]. CD133⁺ cells have been shown to enhance functional response in patients following an acute MI [47].

Timing of cell delivery

The timing of cell delivery is an obvious design difference between trials. The course of the normal healing processes at the time of MI seems to coincide with the expression of putative homing signals favoring cell engraftment via transendothelial passage during the early days post-reperfusion. However, when cells were transplanted within 24 hours of optimal reperfusion therapy no benefit was seen in global left ventricular ejection fraction (LVEF) [39]. This has led to the suggestion that the early pro-inflammatory environment required for healing in MI is toxic to stem/progenitor cells either in terms of survival or function or both, given that initial ischemia and reperfusion injury are characterized by the rapid rise of reactive oxygen radicals and inflammatory cytokines, and that this explains the lack of benefit seen when therapy is delivered within the first 24 hours. Consistent with this theory are the findings of the sub-analysis of the REPAIR-AMI trial [40] indicating that the greatest benefit is seen when delivery occurs more than 4 days

post-reperfusion. However, this suggestion was not borne out in the Timing in Myocardial infarction Evaluation (TIME) trial, which found that, following acute MI, timing of cell therapy (3 vs. 7 days) had no significant effect on either global or regional parameters of LV function [48]. Similar, negative results were also reported from the SWISS-AMI (no significant difference in early (5–7 days) or late (3–4 weeks) administration of BMNC versus control) [49] and LateTIME (BMNC 2–3 weeks post acute MI) [50] trials. Furthermore, collaborative meta-analysis suggests that timing of cell therapy has no significant effect on markers of LV remodeling [51].

Homing and engraftment

Even the positive reports from randomized clinical trials using autologous BMNC transplantation have shown at best a 6–9% increase in measures of LV function, and it is difficult to understand how such a small increase in global LVEF could be translated into significant clinical improvement. Countering the idea that stem cells transdifferentiate into functioning cardiomyocytes, Hofmann *et al.* [42] used 2-[¹⁸F]-fluoro-2-deoxy-D-glucose (18F-FDG) labeling to follow the fate of intracoronary delivered unselected and CD34⁺ enriched autologous BMNCs in patients following acute MI. They noted that only 1.3–2.6% of unselected BMNCs could be detected in the myocardium following intracoronary delivery, with the majority of detected activity in the liver and spleen. However, when they delivered CD34⁺ enriched BMNCs they found increased engraftment in the infarct border zone to 14–39% of the total detectable activity. Furthermore, a study examining the 1 day kinetics of transplanted cells indicated that engraftment is a temporary phenomenon, with myocardial activity dropping off between 2 and 20 hours post-intracoronary delivery from ~5% to ~1% [52–54]. Additionally, in patients with a history of MI more than 6 months prior, myocardial activity disappeared altogether. This would suggest any positive effects are likely to occur by means other than by direct tissue incorporation. Factors accounting for the transiency of cell retention could be related to a reduced adhesive status of the myocardial microcirculation, and/or the functional performance of delivered cells. Studies are required to investigate this further, and to examine whether pharmacologic manipulation of the microcirculation either at the time of, or prior to, cell delivery makes any difference. Further important differences between trials include whether they were randomized/blinded and/or placebo-controlled, the methods used in assessing LV function and duration of follow-up.

Non-BMNC cell therapy

Although the majority of trials have been performed using BMNC, other sources have been used. The CARDIOSphere-Derived autologous stem Cells to reverse ventricular dysfunction (CADUCEUS) prospective, randomized, controlled study studied the effect of intracoronary administration of cardiosphere-derived stem cells (CDC) post-MI. Both 6-month and 1-year follow-up suggest significant improvement in scar size, mass, and viable mass, but no improvement in LVEF compared with controls [55,56].

Trials and meta-analyses

The majority of trials utilizing cell therapy in the context of acute MI have utilized BMNC as the therapy of choice. REPAIR-AMI, REGENT, and SWISS-AMI are the largest studies to date. REPAIR-AMI was a multicenter double-blinded randomized placebo-controlled trial of patients with ST-elevation MI (STEMI) and

impaired LV function, with the treatment arm receiving unfractionated BMNC. In the treatment arm there was a significant improvement in LV function (as measured by quantitative LV angiography) compared with placebo [40]. One-year follow-up for a combined endpoint of death, recurrence of MI, or revascularization was significantly reduced in the treatment arm [57]. The REGENT randomized placebo-controlled trial compared the use of selected (CD34⁺, CXCR4⁺) with unfractionated BMNC in patients with revascularized acute MI and reduced LVEF [58]. No significant difference in Δ LVEF, quantified by MRI, was seen between treatment groups and control; however, there was a trend for benefit in those with lower baseline LVEF.

Several meta-analyses, utilizing data from published studies, have been produced in recent years. Unfortunately, the results of these are in many ways as disparate as the results of individual studies themselves.

Delewi *et al.* [51] report in a collaborative meta-analysis of clinical trials that intracoronary injection of BMNC in patients with acute MI is associated with a significant improvement in LVEF (2.55%, with a reduction in left ventricular end-systolic volume index (LVESI) and end-diastolic volume index (LVEDI)) compared with placebo. Subgroup analysis suggested that the largest benefit is seen in those <55 years old and those with baseline LVEF <40%. However, de Jong *et al.* [59] found that the significant improvement in LVEF seen in cell therapy is abolished when only MRI-derived (rather than other modalities) data is used. The Francis group have raised concerns regarding discrepancies in reporting of cell therapy trials [60]. A meta-analysis from the same group found that in the minority of studies where no discrepancies could be identified, the mean change in LVEF from cell therapy was –0.4% [61]. Most recently in the ACCRUE study, Gyöngyösi *et al.* [62] reported the results of a prospective Individual Patient Data meta-analysis of 1252 patients from 12 trials utilizing intracoronary cell therapy in patients with recent MI. No clinical benefit, either from avoidance of major adverse cerebrovascular and cardiac events (MACCE) or improvement in LV function, was identified.

Current trials

The Effect of Intracoronary Reinfusion of Bone-Marrow-derived Mononuclear Cells on All Cause Mortality in Acute Myocardial Infarction (BAMI) study, currently recruiting, promises to be the largest randomized controlled trial investigating cell therapy following acute MI (n = 3000) [63]. Given the large number of intended participants compared to previously published studies (both trials and meta-analyses) and the use of mortality as primary endpoint, its results are eagerly awaited.

Cell therapy in chronic ischemic heart disease

While the majority of trials have examined the effects of cell therapy in acute MI, only a limited number of trials have focused their attention on its use in chronic ischemic heart disease. One of the first studies looked at a small group of patients undergoing elective coronary artery bypass graft surgery (CABG), in whom they found improved myocardial perfusion and metabolism after enriched CD133⁺ cells were injected into the infarct border zone [64]. Similar observations were noted in an open-label randomized study where patients with LV dysfunction undergoing CABG surgery together with direct intramyocardial injection of BMNCs showed better functional improvement than with CABG alone [65].

Perin *et al.* [66] went on to study the electromechanically mapped guidance of transendomyocardially injected BMNCs in patients with refractory angina and myocardial ischemia. They demonstrated not only that it was procedurally safe, but that it was associated with clinical improvement detectable at 3 months and maintained to 12 months. However, when the Perin group carried out the FOCUS-CCTRN study, a phase 2 randomized double-blind, placebo-controlled trial utilizing endomyocardial injection of BMNC in symptomatic patients with ischemic cardiomyopathy (BMNC arm $n = 61$, control $n = 31$), no significant improvement in left ventricular end-systolic volume (LVESV), maximal oxygen consumption, or reversibility (assessed by SPECT) was demonstrated [67].

A randomized, blinded placebo-controlled trial of 26 patients with chronic total arterial occlusions was conducted, where autologous granulocyte colony-stimulating factor (G-CSF) mobilized circulating progenitor cells were injected down percutaneously revascularized coronary arteries. Assessment of LV function by magnetic resonance imaging showed that LVEF in treated patients had increased by 14% while infarct size had been reduced by 16%. Notably, there was a demonstrable improvement in regional wall motion at the target site [68].

The controlled crossover Transplantation of Progenitor Cells and Regeneration Enhancement–Chronic Heart Disease (TOPCARE-CHD) trial enrolled 75 patients with stable chronic ischemic heart disease who had previously sustained an MI [69]. Here, patients were randomly assigned to receive BMNCs, circulating progenitor cells, or no cells into the (patent) coronary artery supplying the most dyskinetic LV region. The increase in mean LVEF seen in the BMNC group was modest (2.9%), but significantly greater than in the circulating progenitor and control groups. The crossover phase of the study indicated that BMNC therapy was indeed associated with a greater increase in both global and regional LV function.

Pogljajen *et al.* [70] published the results of a prospective crossover trial ($n = 33$) in which the effect of endomyocardial implantation of selected CD34⁺ cells in patients with ischemic cardiomyopathy. The 6-month treatment phase was associated with significant improvements in LVEF, NT-proBNP, and 6 minute walk test.

The CAuSMIC Study, a phase I randomized, open-label, controlled trial studying endomyocardial implantation of skeletal myoblasts in patients with ischemic cardiomyopathy, with improved New York Heart Association (NYHA) functional status and a trend toward reduction in LV dimensions [71].

The Scipio trial, a randomized phase I trial assessing cardiac stem cells (SCS) in patients with chronic ischemic cardiomyopathy undergoing CABG, produced early reports indicating feasibility and safety in addition to significant improvement in LVEF and reduction in infarct size [72]. It should be noted, however, that “concerns about the integrity of certain data” in the published study have been raised and are being investigated at the time of writing [73].

The POSEIDON trial (a comparison of allogenic vs. autologous MSC in chronic ischemic cardiomyopathy), while lacking a control group, met its primary endpoint in demonstrating the safety of allogenic MSC [74].

National and international task forces

The European Society of Cardiology has established a task force for the future of stem cell therapy in cardiology [75]. A similar task force has been established by the National Heart, Lung and Blood

Institute, which has provided a framework to coordinate the resources and funding of cardiovascular cell-based therapy in the USA [76]. Both of these groups offer clear advice, and warn against research proceeding without international consensus, aiming to avoid further small, underpowered studies.

Conclusions

Despite recent technological and pharmacologic advances made within the field of interventional cardiology reducing mortality from coronary artery disease, it continues to cause significant morbidity and efforts have been directed to developing ways of improving endothelial and myocardial function in patients in order to prevent future coronary events. The last two decades have seen an explosion of interest in the use of autologous stem cell therapy to improve the outcome for patients living with coronary heart disease. Unfortunately, the results of published randomized controlled trials and indeed meta-analyses have been conflicting, particularly in the post-acute MI population. Although the delivery of autologous stem cells to the heart appears to be safe, many unanswered questions remain regarding their mechanism of action, the optimum cell type, method, and timing of delivery. It is anticipated that future larger scale randomized controlled trials, particularly the BAMI trial, will provide us with the answers to some of these in due course.

CHAPTER 30

Statistical Essentials in the Design and Analysis of Clinical Trials

Usman Baber¹ and Stuart J. Pocock²

¹ Icahn School of Medicine at Mount Sinai, New, NY, USA

² London School of Hygiene and Tropical Medicine, University of London, London, UK

The rapidly changing landscape of cardiology has been driven by an increasing wealth of clinical data within the scientific literature. Clinical decisions are therefore strongly influenced by the appropriate implementation of evidence-based medicine, requiring the clinician to have an understanding of clinical trial design, and commonly utilized biostatistical analyses. The chapter begins with succinct descriptions of fundamental statistical principles. Significance testing, the estimation of the magnitude of effect, and the interpretation of p-values are discussed, before the discussion of advanced techniques, such as the analysis of time to event data. This is followed by brief explanations of the basic principles of clinical trial design and planning, addressing issues of bias, sample size and power, and commonly used trial designs. Each topic is coupled with examples from published clinical trials.

The fundamentals Significance tests and p-values

In a well-conducted clinical trial, particularly with double-blind randomized trials, the possibility of bias is minimal and therefore the observed outcome difference between treatment groups is either a genuine effect or due to chance variation. Significance tests enable one to assess the strength of evidence that a real effect is present rather than a chance finding. There are three main types of outcome data analyzed in contemporary studies with different measures and tests of association as shown in Table 30.1.

While the calculations differ, the underlying principle is the same for all significance tests. For example, in the Strategies for Multivessel Revascularization in Patients with Diabetes (FREEDOM) trial, 1900 patients with diabetes mellitus (DM) were randomly allocated to either percutaneous coronary intervention (PCI) (n = 953) or coronary artery bypass graft (CABG) (n = 947) and followed for at least 2 years with a primary composite outcome of death, non-fatal myocardial infarction, or non-fatal stroke. At 5 years, the number (%) of patients with a primary outcome event in the PCI and CABG groups was 205 (26.6%) and 147 (18.7%), respectively, with a log-rank p-value of 0.005.

The interpretation of the p-value is predicated on the formulation of the null hypothesis, which in the case of the FREEDOM trial assumed that both PCI and CABG were equally effective revascularization approaches in patients with DM and multivessel coronary artery disease (CAD). Then the p-value is defined as the probability p of detecting a difference of 26.6% vs. 18.7% or larger under the assumption that no true difference exists (i.e., the null hypothesis is true).

The answer from the log-rank test is $p = 0.005$.

The smaller the probability p, the more convincing the evidence to contradict the null hypothesis. In the case of the FREEDOM trial, we have strong evidence that CABG reduces the risk of the primary endpoint compared to PCI.

Estimating the magnitude of effect

Conventional metrics to quantify the magnitude of a treatment effect (i.e., measure of association) include the risk ratio or relative risk; relative risk reduction, odds ratio, and number needed to treat. Examples of calculating each are provided in Table 30.2 with corresponding examples from the FREEDOM trial.

There is no “correct” singular metric to quantify a treatment effect. Often, it is recommended to incorporate several of these to appreciate both relative and absolute effects.

Ninety-five percent confidence interval to express uncertainty

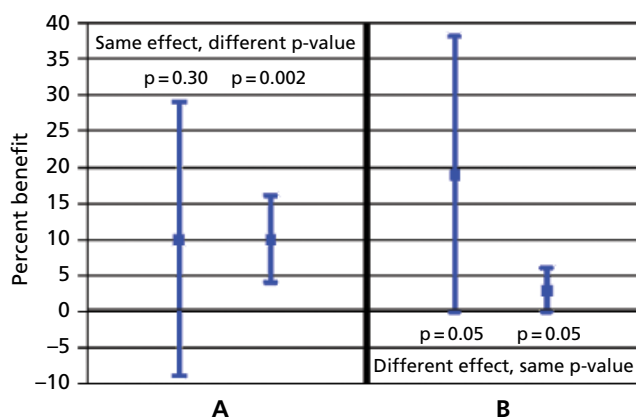

Any estimate of treatment effect in a clinical trial contains some random error, and calculating a confidence interval (CI) enables one to see within what range it is plausible that the true effect lies. For instance, the observed relative risk in the TYPHOON trial is 0.51 while the 95% CI is 0.33–0.80. This means that one is 95% sure that the true relative risk is in this interval. To be precise, there is a 2.5% chance that the true RR lies below 0.33 and 2.5% that the true RR is greater than 0.80. The larger the trial, the tighter the CI becomes. Specifically, to halve the CI width one needs a trial four times the size.

Table 30.1 Three main types of outcome data are analyzed in contemporary studies with different measures and tests of association.

Type of data	Example	Measure of association	Test of association
Binary	In-stent restenosis	Odds ratio	Chi-square test
Time to event	Time to death	Hazard ratio	Log-rank test
Quantitative	Late loss (mm)	Mean	t-test

Table 30.2 Common measures of association and calculations.

Measure of association	Calculation	FREEDOM example
Relative risk (RR)	Event rate in group 1 Event rate in group 2	0.187/0.266 = 0.70
Relative risk reduction (RRR)	1-RR	1-0.70 = 0.3
Odds ratio (OR)	(Prob of event in group 1/Probability of no event in group 1) / (Prob of event in group 2/Probability of no event in group 2)	(0.187/0.813) / (0.266/0.734) = 0.63
Number needed to treat (NNT)	1/Absolute risk reduction	1/(0.266-0.187) ~ 13

**Figure 30.1** Interpreting p-values.

Interpreting p-values

Use of significance tests is often misleadingly oversimplified by putting too much emphasis on whether p is above or below 0.05. A $p < 0.05$ means the result is statistically significant at the 5% level, but is an arbitrary guideline. It does not mean one has firm proof of an effect. By definition, even if two treatments are truly identical there is a 1 in 20 chance of reaching $p < 0.05$. Also, $p > 0.05$, not statistically significant (or n.s.), does not necessarily mean no true difference exists.

This concept is illustrated graphically in Figure 30.1. In the left-hand panel of this figure, similar treatment effects are obtained from two different studies, one of which is significant and one is not. The lack of significance alone should not be the sole metric on which to interpret the findings, particularly as the effect size appears to be large, albeit imprecise. In contrast, in the right-hand panel, a p -value of 0.05 is obtained with two very different effect sizes, one which is large and another that is much smaller. Again, focusing on the p -value alone as the sole discriminator of importance in treatment effect would ignore the very large and perhaps clinically relevant gradient of effect between the treatments.

Link between p-values and confidence intervals

If we have $p < 0.05$ then the 95% CI for the risk ratio (or odds ratio) will exclude 1, while if $p > 0.05$ is observed then the 95% CI will include 1. Thus, by looking at the CI alone one can infer whether the treatment difference is significant at the 5% level.

Time to event data

Many major trials study time to a primary event outcome. For instance, the ACUTY trial studied composite ischemia: death, myocardial infarction, or unplanned revascularization over 1 year follow-up.

A Kaplan–Meier life-table plot is the main method of displaying such data by treatment group (Figure 30.2). It displays the cumulative percentage of patients experiencing the event over time for each group. This method takes account of patients having different lengths of follow-up (e.g., any lost to follow-up before the intended 1 year).

Such a plot is a useful descriptive tool, but one needs to use a log-rank test to see if there is evidence of a treatment difference in the incidence of events. For instance, the heparin + IIb/IIIa ($n = 4603$) and bivalirudin alone ($n = 4612$) groups had composite ischemia in 15.4% and 16.0% of patients, respectively. The log-rank test uses the total data by group displayed to obtain $p = 0.29$ (i.e., the data are consistent with the null hypothesis of no treatment difference). The log-rank test can be thought of as an extension, indeed improvement, to the simpler chi-squared test comparing two percentages because it takes into account the fact that patients have been followed for, and deaths occur at, differing times from randomization.

With time to event data, the *hazard ratio* is used to estimate any relative treatment differences in risk. It is similar to, but more complicated to calculate, than the simple relative risk already mentioned. It effectively averages the instantaneous relative risk occurring at different follow-up times, using what is commonly called a Cox proportional hazards model. In this case the hazard ratio comparing bivalirudin with heparin + IIa/IIIa is 1.06 with 95% CI 0.95–1.17. Thus, there is an observed 6% increase in hazard but the 95% CI includes 1 reflecting the lack of statistical significance.

Figure 30.2 Kaplan–Meier life-table plot showing pattern of treatment difference over time (e.g., ACUITY 1-year follow-up).

Quantitative data

For a quantitative measure of patient outcome it is common to compare the mean outcomes in each treatment group. For example, in the SYMPPLICITY HTN-3 study, 535 patients with resistant hypertension were randomized in a blinded fashion to either renal denervation or sham control with a primary efficacy endpoint of change in office systolic blood pressure (SBP) at 6 months. The mean change from baseline in the renal denervation and sham groups was -14.1 ± 23.9 mmHg and -11.7 ± 25.9 mmHg, respectively. The mean change between groups was -2.39 mmHg (95% CI -6.89 to 2.12 ; $p = 0.26$).

The standard deviation (SD) summarizes the extent of individual patient variation around each mean. If the data are normally distributed then appropriately 95% of individuals will have a value within two standard deviations either side of the mean. This is sometimes called the *reference range*. However, for a clinical trial outcome measure it is more useful to calculate the *standard error of the mean* (SEM) which is SD/\sqrt{N} . That is, precision in the estimated mean increases proportionately with the square root of the number of patients. The 95% confidence for the mean is $\pm 1.96 \times SEM$.

Trial design: the fundamentals

When planning a clinical trial much energy is devoted to defining exactly what is the *new treatment*, who are the eligible *patients*, and what are the primary and secondary *outcomes*. Then the following statistical design issues need to be considered.

Control group

One essential is that the trial is *comparative* (i.e., one needs a *control group* of patients receiving a standard treatment who will be compared with patients receiving the new treatment). Such standard treatment can either be an established active treatment or no treatment (possibly a placebo). Of course, all patients in both groups have good medical care in all other respects.

Randomization

One needs a fair (unbiased) comparison between new treatment and control, and *randomization* is the key requirement in this regard. That is, each patient has an equal chance of being randomly

assigned to new or standard treatment. Furthermore, the method of handling random assignments is such that no one can predict in advance what each next patient will be assigned to. Thus, randomization ensures there is no selection bias in deciding which patients get new or standard treatment. Such selection bias is a serious problem in any observational (non-randomized) studies comparing treatments, making them notoriously unreliable in their conclusions.

As a consequence, randomization minimizes the possibility that treatment groups will significantly differ in baseline characteristics. The possibility for chance variation can never be completely eliminated, however, even in a randomized study design. To further guarantee that key baseline features will not influence the treatment effect, randomization can also be stratified, a common approach in multicenter studies.

In addition, randomization helps to ensure that all other aspects of patient care, and also the evaluation of patient outcome, is identical in both treatment groups. In this respect it is often important to make the trial *double blind* whereby neither patients nor those treating them and evaluating their response know which treatment each individual patient is receiving.

If a trial cannot be made double blind one can nevertheless require *blinded evaluation* of outcome by people not aware of which treatment each patient is on.

Trial size and power calculations

For a trial to provide a reliably precise answer as to the relative merits of the randomized treatments one needs a sufficiently large number of patients. *Power calculations* are the most commonly used statistical method for determining the required trial size.

Each power calculation entails the following five steps, itemized in Table 30.3:

- 1 Choose a *primary outcome* for the trial.
- 2 Decide on a *level of statistical significance* required for declaring a “positive” trial. Five percent significance is usually chosen.
- 3 Declare what you expect the *control groups results* to be.
- 4 Declare the *smallest true treatment difference* that is important to detect. Large treatment effects, if present, can be detected in relatively small trials so it is relevant to focus on what reasonably modest effect one would not wish to miss.

Table 30.3 Key components of sample size/power calculations.

Component	Comments
Outcome type	Proportion; time to event; mean
Type I error (alpha)	Level of significance to declare a "significant" result. Typically 0.05
Control group rate	Risk for events in non-experimental arm
Meaningful difference	Smallest true difference with clinical impact
Type II error (beta)	Probability of declaring no difference when in fact one exists. Typically 0.1 or 0.2. Power = 1 – Beta

Table 30.4 Impact of incorrect sample size assumptions on study power.

Component of power calculation	Assumption compared to actual	Effect on power	Example
Sample size	Lower than expected	Reduced	VA CARDS
Detectable difference	Higher than expected	Increased	FAME 2
Event rate	Lower than expected	Reduced	GRAVITAS

5 Declare with what *degree of certainty* (statistical power) one wishes to detect such a difference as statistically significant. From such information there are statistical formulae that provide the required number of patients.

It is important to note that sample size is estimated in the design phase of a study using a priori assumptions that may or may not end up being correct. The implications of incorrect assumptions are not trivial. Poor design can result in an underpowered study that is unable to demonstrate reductions with a treatment effect that is in fact beneficial, thereby depriving patients of a therapeutic option. Alternatively, poor enrolment or event rate assumptions that are not realistic can result in significant expenditure of both human and financial resources in the execution of a study that is ultimately futile. Appreciating the nuances of sample size calculations is critical to the interpretation of clinical trial results, both positive and negative. Table 30.4 provides several examples of trials that were either under- or overpowered based on initial assumptions.

In the VA CARDS trial, investigators designed a multicenter randomized trial comparing CABG with PCI in patients with DM and CAD. The trial required 790 patients to yield 90% power to detect a 40% reduction in the primary endpoint. However, the trial was stopped early because of slow enrolment, after enrolling only 198 patients. The CI for the treatment effect was very wide, 0.47–1.71, and although this included the detectable difference for which the study was powered (RR 0.6), the small sample size rendered the results imprecise and non-significant. In contrast, in FAME 2, De Bruyne *et al.* compared revascularization versus medical therapy in patients with stable CAD and fractional flow reserve (FFR) values

≤0.8. The study assumed an event rate of 18.0% in the control arm, relative risk reduction of 30%, and 816 patients per group to provide 84% power. Although the event rate assumption in the control arm was close to actual (19.5%), the study was halted after only 54% of projected enrolment because of a much larger than expected relative risk reduction of 61%. Finally, Price *et al.* designed the GRAVITAS trial to examine the impact of standard vs. high-dose clopidogrel on reducing 6-month outcomes in patients with high on-treatment platelet reactivity. The investigators assumed a 6-month event rate of 5.0%, risk reduction of 50%, and a sample size of 2200 to provide 80% power. Although the trial enrolled the required sample size, event rates were only 2.3% in each group, yielding a non-significant and imprecise treatment effect of 1.01 (0.58–1.76).

Often, a single clinical trial is neither large nor representative enough to evaluate a particular therapeutic issue. Then, *meta-analyses* can be of value in combining evidence from several related trial to reach an overall conclusion.

Additional topics in clinical design and analysis

Superiority and non-inferiority designs

This chapter so far has discussed the fundamentals of trial design and statistical analysis. Clearly there are many other important issues that need to be tackled in the design, conduct, analysis, and interpretation of clinical trials. All we can do here is briefly alert the reader to these topics and encourage them to pursue further from other courses, textbooks, publications, and so on.

In *trial design* we have concentrated on parallel group trial with just two treatments. In this context the most common trial types include superiority and non-inferiority designs. The key difference between these trial types relates to the expression of the null and alternative hypotheses for each respective design. In a classic superiority trial the null hypothesis states that there are no differences between the experimental and control treatments whereas in a non-inferiority trial the null hypothesis is formulated as the experimental treatment is worse than control by a pre-specified margin. Similarly, the alternative hypothesis for a superiority trial assumes that the experimental and control treatments are different (i.e., experimental is "superior") while in a non-inferiority framework the alternative hypothesis states that the experimental arm is no worse than the control by a pre-specified margin. The possible interpretation of trial results is predicated on the study design, as shown in Figure 30.3. The choice of superiority as compared to a non-inferiority design is influenced by a number of factors including cost, existing therapies, and side effect profiles of different treatments. Novel oral anticoagulants (NOACs), for example, require less monitoring than conventional anticoagulation with oral vitamin K antagonists. Demonstration of non-inferiority, therefore, may be sufficient evidence to choose a NOAC as was shown in the large randomized ROCKET-AF trial comparing rivoraxaban to warfarin. In addition, the great efficacy of certain treatments can require prohibitively large and expensive trials designed to show superiority.

Intention to treat and per-protocol analyses

Most major trials use *analysis by intention to treat* whereby all patients are included in their randomized groups even though they did not all fully comply with the intended treatments. Such an analysis gives an unbiased comparison of the treatment policies as they were delivered in practice, a so-called *pragmatic trial*. *Per protocol analyses*, which exclude any patient follow-up when not on

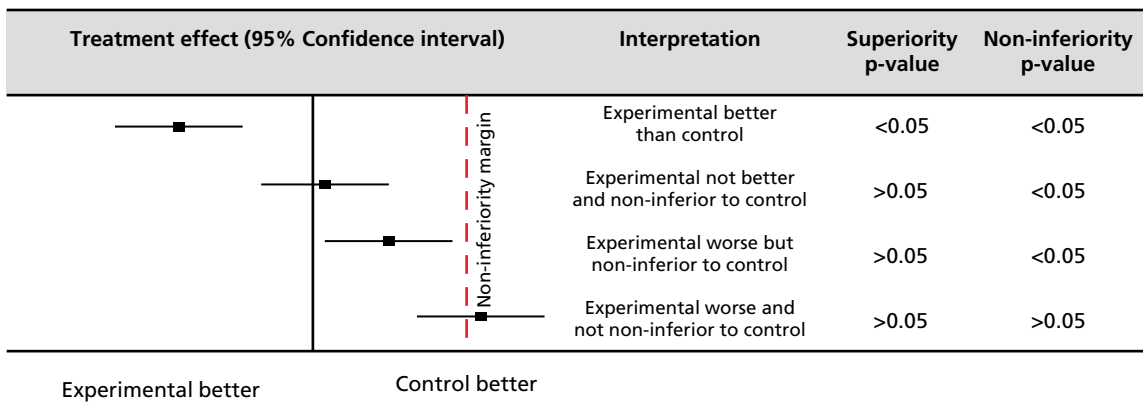

Figure 30.3 Example of the most common trial type, including superiority and non-inferiority designs. The possible interpretation of trial results is predicated on the study design.

randomized treatment, are potentially biased as it could be the sicker patients who opt out.

Reporting of trial findings in medical journals, at conference presentations, and to regulatory authorities need to be of the highest standards whereby an unbiased and detailed report of all relevant findings is presented.

The objectives, methods, discussion, and conclusions need to be clearly presented in a balanced report. In particular, results and interpretations should include any safety issues (adverse

events) as well as efficacy findings. For publications in medical journals, the CONSORT guidelines are helpful to authors, editors, referees, and readers in enhancing the quality assessment of any trial report.

Historical Perspective of Sirolimus and Paclitaxel-Eluting Stent Clinical Studies

Adriano Caixeta¹, Leonardo Guimarães¹, Philippe Généreux², and George D. Dangas³

¹Hospital Israelita Albert Einstein; Universidade Federal de São Paulo, São Paulo, Brazil

²Columbia University Medical Center, New York, NY, USA

³Department of Cardiology, Mount Sinai Medical Center, New York, NY, USA

Over the past decades, the field of percutaneous coronary intervention (PCI) has been rapidly evolving since the first balloon angioplasty in 1977. Bare metal stents (BMS) were developed and significantly improved the acute success and reproducibility of PCI results compared to balloon angioplasty [1,2]. However, stent-mediated arterial injury elicited neointimal hyperplasia, leading to restenosis and the need for repeat revascularization in about one-third of patients [3–6]. Drug-eluting stents (DES) with antiproliferative drugs attached via polymer on the stent surface were developed as a logical next step in the evolution of PCI. These devices were designed to maintain the mechanical advantages of BMS over stand-alone balloon angioplasty, while releasing antiproliferative agents directly to the arterial wall to combat the neointimal hyperplasia occurring after conventional BMS placement. First-generation DES including sirolimus and paclitaxel have shown clear evidence of clinical success with the application of the right dose and release kinetics. This chapter discusses the clinical data on sirolimus and paclitaxel-eluting stents from pivotal trial to multivessel disease treatment, focusing on their historical contribution to interventional cardiology.

Initial studies of first-generation DES

In 2003, the Food and Drug Administration (FDA) approved the use of the two first-generation DES: the CYPHER sirolimus-eluting stent (SES; Cordis Corporation, Johnson & Johnson, Miami Lakes, FL), and the TAXUS paclitaxel-eluting stent (PES; Boston Scientific Corporation, Maple Grove, MN). The FDA decision was based on the results of pivotal randomized clinical trials comparing a given DES with a comparator BMS in relatively non-complex lesions that constitute the “on-label” indications for DES use. In these early trials, the use of DES was demonstrated to reduce restenosis and repeat revascularization rates by 50–90% compared to BMS across all lesion and patients subsets [7].

In addition, DES has shown benefits with respect to reduced repeat revascularization and other restenosis-related endpoints in more complex lesions, including acute myocardial infarction (MI), chronic total occlusions, in-stent restenosis, diffuse disease, saphenous vein grafts, and bifurcation lesions [8–13]. In fact, given the observed relative reductions in restenosis-related endpoints with

DES, it follows that as the overall (absolute) risk of restenosis rises—as is observed with more complex lesion subsets—the absolute benefit of DES over BMS should increase. Thus, confidence in DES subsequently swelled, and as positive results from subsequent trials for a variety of expanded indications surfaced, physicians rapidly expanded the patient populations treated with DES to include other “off-label” indications. In the years immediately after DES approval, “off-label” use of these devices was estimated to occur in up to 65% of cases [14,15].

Paclitaxel-eluting stent

Paclitaxel was approved by the FDA in 1992 as an antineoplastic agent to treat metastatic ovarian malignancies. Paclitaxel is a natural diterpenoid extracted from the bark, roots, and leaves of several *Taxus* species, including *Taxus brevifolia* and *Taxus media*. Its effect has been mainly explained by its ability to stabilize microtubules and thereby inhibit cell division in the G0/G1 and G2/M phases [16]. Several studies have shown that paclitaxel inhibits the development of neointimal hyperplasia in different *in vitro* and in animal models of restenosis [17–20].

Overview of the TAXUS clinical trials

The safety and efficacy of the polymer-based paclitaxel-eluting TAXUS stent system have been investigated in six studies: TAXUS I [21], TAXUS II [22], TAXUS III [23], TAXUS IV [24,25], TAXUS V *de novo* [8], and TAXUS VI [26]. All studies, with the exception of TAXUS III, were randomized, double-blind, multicenter investigations that compared the paclitaxel-eluting Taxus™ stent with BMS. TAXUS III was an open-label investigation. Primary endpoints varied by study and included one or more of the following: 30-day major adverse cardiac events (MACE) (TAXUS I and TAXUS III), 6-month in-stent volume obstruction caused by neointimal proliferation (TAXUS II), and 9-month ischemia driven target vessel revascularization (TVR) (TAXUS IV, TAXUS V *de novo*, and TAXUS VI).

TAXUS I enrolled 61 patients and was a feasibility study designed to assess the safety of Taxus™ slow-release vs. BMS. At 12 months, the MACE rates were 10% and 3% in the control and Taxus™ groups, respectively, demonstrating excellent long-term safety. These results

were maintained through the 4-year follow-up with no new MACE in any TAXUS patient between 1 and 4 years.

TAXUS II studied 536 patients in 38 sites in a randomized, double-blind, controlled study of the safety and efficacy of the Taxus stent system on the NIRx stent platform. In this study, two sequential cohorts (testing slow and moderate-release TAXUS formulations) enrolled patients with standard risk de novo coronary artery lesions. The 6-month results showed strong clinical performance as demonstrated by lower MACE and target lesion revascularization (TLR) rates in TAXUS patients compared with patients who received a BMS. The 6-month MACE rates were reduced from 19.8% in the control group to 8.5% for the slow-release formulation cohort ($p=0.0035$) and 7.8% for the moderate-release formulation cohort ($p=0.0019$). At 12 months, the MACE rate in the slow-release cohort remained low at 10.9% compared with the control rate of 21.7% ($p=0.0082$) and the TLR rate was 4.7% compared with 14.4% for the control group ($p=0.0035$). At 12 months, the moderate-release formulation cohort reported a 9.9% MACE rate ($p=0.0048$ vs. control) with a 3.8% TLR rate ($p=0.0010$ vs. control). The 3-year follow-up for TAXUS II results were maintained with no new TLR or stent thrombosis occurring in the TAXUS groups.

TAXUS III was a single-arm registry examining the feasibility of implanting Taxus stent for the treatment of in-stent restenosis. The trial enrolled 29 patients, of whom 28 were treated with the Taxus NIRx stent platform. The trial confirmed safety and reported no stent thrombosis, no deaths, and a binary restenosis rate of 16% at 6 months. From 6 months to 3 years, there was only one cardiac death and no stent thrombosis.

Similarly, in the large randomized TAXUS IV trial, randomizing 1314 patients with single de novo non-complex coronary lesions, the 9-month rate of ischemia-driven TVR was 4.7% with PES vs. 12.0% with BMS, again a highly significant difference with similar relative effects observed across all subgroups [25].

TAXUS V was a randomized, double-blind trial studying 1156 patients at 66 sites in the USA using the slow-release formulation (Express² stent platform). TAXUS V expanded on the TAXUS IV pivotal trial by studying a higher risk patient population, including patients with small vessels, and long lesions requiring multiple overlapping stents—the most challenging lesions and highest risk patients ever studied in a randomized controlled DES trial in the USA. The primary endpoint of the trial was 9-month TVR, which was significantly lower in the TAXUS group (12.1%) than in the control group (17.3%; $p=0.0184$). At 9 months, the overall MACE rate in the TAXUS group was 15.0%, compared with 21.2% in the control group ($p=0.0084$). The study also reported a TLR rate of 8.6% in the TaxusTM cohort compared with 15.7% in the control group ($p=0.0003$). In addition, stent thrombosis rates were identical between TaxusTM and control group stents (0.7% each). These clinical benefits were maintained at 1 year with an overall MACE rate of 18.9% in the TAXUS group compared to 25.9% in the control group ($p=0.0052$) and a TLR rate of 11.2% in the TAXUS group vs. 19.0% in the control group ($p=0.0003$).

TAXUS VI, an international trial studying 446 patients with complex coronary artery disease at 44 sites, was designed to establish the safety and efficacy of the moderate-release formulation (on the Express² stent platform) in the treatment of longer lesions. The trial had a primary endpoint of 9-month TVR. The study's TVR rate was 9.1% in the TAXUS group vs. the control group rate of 19.4% at 9 months ($p=0.0027$). Additionally, the TaxusTM group had a TLR rate of 6.8% (compared with 18.9% in the control group; $p=0.0001$) and an in-segment binary restenosis rate of 12.4% (compared with 35.7% in the control group; $p<0.0001$). The results sup-

ported safety as demonstrated by low MACE rates (16.4% MACE rate at 9 months in the TAXUS group compared with 22.5% in the control group; $p=0.1208$). The 2-year follow-up data for TAXUS VI demonstrated that the safety and efficacy benefits associated with a moderate-release formulation of the TaxusTM were maintained at 2 years; a continued significant reduction in TLR rate (9.7% for the TAXUS group, as compared with 21.0% for the control group; $p=0.0013$). Stent thromboses remained low and comparable to control rates (0.9% for both the TaxusTM group and the control group). The 2-year results for TAXUS VI support long-term safety with increased local exposure of the vessel to paclitaxel released from the moderate-release formulation compared to the levels released from the slow-release formulation. Even with an *in vitro* dosing rate 8–10 times greater than the commercialized slow-release formulation, no compromise in safety was observed.

Longer-term data from the five pivotal PES trials, including 3513 patients, has been reported; these data demonstrate durable reductions in clinical restenosis endpoints with similar overall safety for TaxusTM vs. BMS (Figure 31.1) [24]. The cumulative incidence of stent thrombosis was similar between TaxusTM and BMS (2.1% vs. 1.7%; $p=0.46$). Subgroup analyses also demonstrated a similar relative benefit of TaxusTM vs. BMS for diabetics, and all vessel sizes (Figure 31.2). In brief, this patient-level meta-analysis

Figure 31.1 Pooled analysis from five TAXUS randomized clinical trials. Kaplan-Meier curves of cumulative rates of target vessel revascularization comparing TaxusTM stent with bare metal stent (BMS).

Figure 31.2 Target lesion revascularization up to 5-year follow-up. Subgroup analysis summary from 5 TAXUS pivotal randomized clinical trial. Subgroup analysis shows relative benefit of TaxusTM vs. BMS for diabetics, all vessel sizes and all lesion length.

from the five principal TAXUS trials concluded that at 3–5 year follow-up, polymer-based PES compared to BMS stents result in:

- 1 No significant differences in death or MI;
- 2 No significant increase in stent thrombosis;
- 3 No significant increase in late stent thrombosis by Academic Research Consortium (ARC) definitions; and
- 4 Sustained reduction in target lesion and TVR.

Sirolimus-eluting stent

First FDA approved in 1999 as prophylaxis for kidney transplant rejection, sirolimus is a macrolytic lactone produced by *Streptomyces hygroscopicus*. The primary mechanism of action of sirolimus's inhibition of neointimal hyperplasia is probably related to its ability to bind to FK binding protein-12 (FKBP-12) in cells; this complex binds to and inhibits activation of the mammalian target of rapamycin (mTOR), preventing progression in the cell cycle from the G1 phase to the S phase [27]. Its anti-inflammatory and antiproliferative properties reduce smooth muscle cell proliferation in the arterial wall following stent-induced injury [28,29]. With the low-release formulation of the Cypher™, 50% of the drug is released in the first 2 weeks and most of the sirolimus is released within 4 weeks after stent implantation.

Overview of the Cypher® clinical trials

Following the success of the first pilot study of the SES in 45 patients for suppressing intimal hyperplasia [30,31], the safety and efficacy of the polymer-based sirolimus-eluting Cypher® stent system have been investigated in four major studies: RAVEL [32], SIRIUS [33], E-SIRIUS [34], and C-SIRIUS [35].

The RAVEL trial, a randomized trial of 238 patients, compared SES with a standard BMS in patients with angina pectoris. At 6-month angiographic follow-up, the in-stent late luminal loss was significantly lower in the SES group (-0.01 ± 0.33 mm) than in the standard stent group (0.80 ± 0.53 mm; $p < 0.001$), with a remarkable reduction in the rate of restenosis (0% vs. 26.6%; $p < 0.001$). The rate of MACE, a composite of death, MI, coronary artery bypass grafting (CABG), or TVR at 1 year was 5.8% for SES-treated patients vs. 28.8% for BMS-treated patients ($p < 0.001$), mostly driven by a higher rate of revascularization of the target vessel in the standard stent group. At 3-year follow-up, these results were maintained, demonstrating a persistent reduction in MACE with SES compared to BMS (15.5% vs. 33.1%; $p = 0.002$) [36].

The SIRIUS trial, a 1058-patient randomized trial comparing the Cypher® DES to its uncoated BMS, has led to FDA approval of SES in 2003. More complex than in the RAVEL trial, lesion length was 15–30 mm with vessel diameters of 2.5–3.5 mm. Both the primary endpoint, the rate of target vessel failure (a composite of cardiac death, MI, or revascularization of the target vessel) and the rate of MACE at 9 months was markedly lower among SES-treated patients (8.6% vs. 21.0%; $p < 0.001$ and 7.1% vs. 18.9%; $p < 0.001$, respectively). The benefit of SES was observed in all tested subgroups in the trial, including diabetic patients, and irrespective of vessel size. Additionally, longer term follow-up from SIRIUS has also demonstrated a persistently maintained benefit of SES over BMS, with 5-year rates of target vessel failure of 22.5% vs. 34.7% ($p < 0.0001$) and MACE of 20.3% vs. 33.5% ($p < 0.0001$), respectively [37].

Performed in Canada and Europe, C-SIRIUS and E-SIRIUS have shown similar results to the SIRIUS study. In these trials, the overall rate of angiographic restenosis was markedly lower with SES than BMS (in-stent: 3.1% vs. 42.7%; $p < 0.001$; in-segment: 5.1% vs. 44.2%;

Figure 31.3 Pooled analysis from four Cypher® randomized clinical trials. Kaplan–Meier curves of cumulative rates of target vessel revascularization comparing Cypher® stent with BMS.

Figure 31.4 Target lesion revascularization up to 5-year follow-up. Subgroup analysis from four Cypher® randomized clinical trials. Subgroup analysis shows relative benefit of Cypher® vs. BMS for diabetics and vessel sizes, and all lesion length.

$p < 0.001$). Reductions in MACE with the use of SES compared to BMS were also observed. A pooled analysis at 2-year follow-up of the three SIRIUS studies has shown significant reductions in MACE (10.6% vs. 26.3%; $p < 0.001$) with SES compared to BMS [38].

Longer term data from the four pivotal SES trials, including 1748 patients, has been reported; these data demonstrate durable reductions in clinical restenosis endpoints with similar overall safety for Cypher® vs. BMS (Figure 31.3) [39]. The cumulative incidence of stent thrombosis was similar with Cypher® and BMS (2.1% vs. 2.0%; $p = 0.99$). Subgroup analyses from the 5-year follow-up of the SIRIUS study also demonstrated a similar relative benefit of Cypher® vs. BMS for diabetics and all vessel sizes (Figure 31.4). From this independent, patient-level meta-analysis from the four principal Cypher® trials it may be concluded that at 5-year follow-up of patients with single de novo native coronary lesions 2.5–3.5 mm in diameter and ≤ 30 mm in length, polymer-based SES compared to otherwise equivalent BMS result in:

- 1 No significant differences in death or MI;
- 2 No significant increase in stent thrombosis;
- 3 No significant increase in late stent thrombosis by ARC definitions; and
- 4 Sustained reduction in target lesion and TVR.

Acute myocardial infarction

The use of DES in acute MI has been studied in both observational registries as well as in randomized clinical trials. In a recent meta-analysis of eight randomized trials in 2786 patients with a follow-up of up to 24 months, the use of first-generation DES compared to BMS was associated with a significantly reduced risk of reintervention, without any difference in the rate of death, recurrent MI, and stent thrombosis [40]. First-generation DES have shown to decrease significantly the TLR and repeat revascularization at 2 years with a significant decrease of the 2-year risk-adjusted mortality rate [41]. These data are quite reassuring regarding the safety of use of DES in acute coronary syndrome.

The TYPHOON trial, a randomized trial of in 712 patients, compared SES with BMS in patients undergoing primary PCI. This study has shown a significant reduction in MACE in favor of the SES treatment (5.6% vs. 13.4% with BMS; $p < 0.001$), largely driven by a lower rate of TVR [10]. At 8 months, angiographic follow-up demonstrated reductions in late loss and restenosis among patients treated with SES. No differences between the two groups were seen in term of rates of death, recurrent MI, and stent thrombosis.

In the SESAMI trial of 320 patients, treatment with SES was associated with a lower rate of restenosis (9.3% vs. 21.3%; $p = 0.032$) and with a reduction in TLV and MACE [42]. In the MISSION! trial, a randomized trial of SES vs. BMS in 310 patients undergoing primary PCI, treatment with SES was associated with a lower in-segment late luminal loss at 9 months (0.68 ± 0.57 mm vs. 0.12 ± 0.43 mm) and a lower TLV rate (3.2% vs. 11.3%; $p = 0.006$) [43]. Rates of death, MI, and stent thrombosis were not different. However, IVUS study shows that late stent malapposition at 9 months was present in 12.5% of BMS patients and in 37.5% of SES patients ($p < 0.001$), raising concern about the long-term safety of SES in patients with ST-elevation MI (STEMI). However, the PASSION trial, a randomized trial of PES vs. BMS in 619 patients undergoing primary PCI, treatment with PES was associated with a non-significant trend in the rate of death from cardiac causes or recurrent MI (5.5% vs. 7.2%; $p = 0.40$) and in the rate of TLV (5.3% vs. 7.8%; $p = 0.23$) [9]. There was a trend toward a lower rate of serious adverse events in the PES group than in the uncoated-stent group (8.8% vs. 12.8%; $p = 0.09$).

The Harmonizing Outcomes with Revascularization and Stents in Acute Myocardial Infarction (HORIZONS AMI) trial [44] randomized 3602 patients from 123 centers in 11 countries. All patients had STEMI with a symptom onset of less than 12 hours. Patients were first randomized in a 1 : 1 fashion to unfractionated heparin plus a glycoprotein (GP) IIb/IIIa inhibitor (abciximab or eptifibatid) or to bivalirudin monotherapy plus provisional GP IIb/IIIa inhibitors. The implantation of the paclitaxel-eluting Taxus™ stent compared with the BMS Express™ stent resulted in a significant 41% reduction at 1 year in the primary efficacy endpoint of ischemia-driven TLR (4.5% vs. 7.5%, HR 0.59, 95% CI 0.43–0.83) and a significant 56% (10.0% vs. 22.9%, HR 0.44, 95% CI 0.33–0.57) reduction in the major secondary efficacy endpoint of binary restenosis. MACE, a composite of all-cause mortality, reinfarction, stroke, and stent thrombosis, were equivalent with the two stents (8.1% vs. 8.0%, HR 1.02, 95% CI 0.76–1.36). At 3 years, compared with 1802 patients allocated to receive heparin plus a GP inhibitor, 1800 patients allocated to bivalirudin monotherapy had lower rates of all-cause mortality (5.9% vs. 7.7%; $p = 0.03$), cardiac mortality (2.9% vs. 5.1%; $p = 0.001$), reinfarction (6.2% vs. 8.2%; $p = 0.04$), and major bleeding not related to bypass graft surgery (6.9% vs. 10.5%, $p = 0.0001$), with no significant differences in ischemia-driven TVR, stent thrombosis, or composite adverse events. Compared

with 749 patients who received BMS, 2257 patients who received a PES had lower rates of ischemia-driven TLR (9.4% vs. 15.1%; $p < 0.0001$) after 3 years, with no significant differences in the rates of death, reinfarction, stroke, or stent thrombosis. Stent thrombosis was high ($\geq 4.5\%$) in both groups [45,46]. Combining the HORIZONS study with other registries and randomized trials increases the number of patients with MI treated with DES and provides reassurances about efficacy and safety of DES in this clinical setting [47]. Currently, novel generation of DES implantation is the default therapy for patients with STEMI [48].

Multivessel disease

Patients with complex multivessel coronary disease represent a high risk subgroup of patients for PCI. Three randomized trials have compared first-generation DES with CABG, which comprises the main data in recent guidelines on myocardial revascularization [49,50].

The Coronary Artery Revascularization in Diabetes (CARDia) study [51] enrolled 510 patients in a randomized trial from 24 centers in the UK and Ireland, to compare the safety and efficacy of PCI with stenting against CABG in patients with diabetes and symptomatic multivessel coronary artery disease. This trial initially began using BMS, but when DES became available patients received Cypher™ stents. Cypher™ stents were used in 69% of patients and BMS in 31% patients undergoing PCI. A total of 254 patients were randomized for CABG and 256 for PCI, and at 1 year follow-up the composite rate of death, MI, and stroke was 10.5% in the CABG group and 13% in the PCI group (HR 1.25, 95% CI 0.752–0.9), and repeat revascularization rates of 2.0% and 11.8%, respectively. There was no difference in all-cause mortality rates. The CARDia study was the first trial of coronary revascularization in diabetic patients but did not show that PCI was non-inferior to CABG for a period of up to 5 years.

The Future Revascularization Evaluation in Patients with Diabetes Mellitus: Optimal Management of Multivessel Disease (FREEDOM) trial [52] enrolled 1900 patients with multivessel coronary artery disease (mean SYNTAX score: 26.2 ± 8.6) and diabetes; these patients were randomized 1 : 1 to CABG or PCI and followed for a minimum of 2 years. In the PCI group, Cypher and Taxus stents were used in 51% and 43% of patients, respectively. At 30 days, the primary outcome (composite of death from any cause, non-fatal MI, or non-fatal stroke) occurred in fewer patients in the PCI group than in the CABG group. However, 5-year events rate were 26.6% in the PCI group and 18.7% in CABG group (95% CI 3.3–12.5). Five year rates of all-cause mortality were 16.3% in the PCI group versus 10.9% in the CABG group ($p = 0.049$), MI also statistically differed favoring CABG group with 13.9% in PCI group and 6.0% in the CABG group. There were fewer strokes in the PCI group (2.4% vs. 5.2%; $p = 0.03$). In summary, the FREEDOM trial found that CABG was superior to PCI in patients with diabetes and advanced coronary artery disease. CABG was associated with significantly reduced risks of death and MI but a higher risk of stroke during the 5-year study (Figure 31.5). The results in favor of CABG were consistent across all the prespecified subgroups, including severity of disease as assessed by the SYNTAX score (Figure 31.6).

Synergy between PCI with Taxus and Cardiac Surgery (SYNTAX) trial was a prospective multicenter study, which randomized 1800 patients with three-vessel or left main coronary artery disease to undergo CABG (897 patients) or PCI with Taxus stent (903 patients). At 1 year, the rate of primary endpoint was higher in the PCI group than the CABG group (17.8% vs. 12.4%; $p = 0.002$), mainly because of higher rates of repeat revascularization in the

Figure 31.5 FREEDOM study. Kaplan–Meier estimates of the composite primary outcome of death, myocardial infarction (MI), or stroke truncated at 5 years after randomization.

Figure 31.6 FREEDOM study. Primary composite outcome according to subgroup. Five-year composite event rates for death, myocardial infarction, or stroke are shown. LAD, left anterior descending artery; LVEF, left ventricular ejection fraction.

stent group (13.5% vs. 5.9%). Patients were stratified into three groups: low SYNTAX scores (0–22), intermediate scores (23–32), and high scores (≥32). The rate of primary endpoint in the stent group was similar to that in surgery group in patients with low complexity of disease (SYNTAX score ≤22; 32.1% vs. 28.6%, respectively; p=0.43). The benefit of CABG emerged among patients with intermediate (SYNTAX score 23–32; 36% vs. 25.8%; p=0.008) or high disease complexity (SYNTAX ≥33; 44% vs. 26.8%; p=0.001) [53]. Based on these findings, CABG remains the standard treatment for patients with multivessel artery disease [54]. After 5 years’ follow-up, Kaplan–Meier estimates of major adverse cardiac or cerebrovascular events (MACCE) were 26.9% in the CABG group and 37.3% in the PCI group (p <0.0001). Estimates of MI (3.8% in the CABG group vs. 9.7% in the PCI group; p <0.0001) and repeat revasculari-

zation (13.7% vs. 25.9%; p <0.0001) were significantly increased with PCI versus CABG. All-cause death (11.4% in the CABG group vs. 13.9% in the PCI group; p=0.10) and stroke (3.7% vs. 2.4%; p=0.09) were not significantly different between groups. In the CABG group, 28.6% of patients with low SYNTAX scores had MACCE versus 32.1% of patients in the PCI group (p=0.43); however, in patients with intermediate or high SYNTAX scores MACCE was significantly increased with PCI (intermediate score, 25.8% of the CABG group vs. 36.0% of the PCI group; p=0.008; high score, 26.8% vs. 44.0%; p <0.0001) (Figures 31.7, 31.8, 31.9 and 31.10).

From this independent large-scale trial it can be concluded that at 5-year follow-up of patients with multivessel disease that CABG should remain the standard of care for patients with complex lesions (high or intermediate SYNTAX scores). For patients with less complex disease

Figure 31.7 SYNTAX trial. Kaplan–Meier estimates of major adverse cardiac or cerebrovascular events (MACCE) at 5-year follow-up in the overall population.

Figure 31.9 SYNTAX trial. Kaplan–Meier estimates of MACCE at 5-year follow-up in patients with intermediate SYNTAX score.

Figure 31.10 SYNTAX trial. Kaplan–Meier estimates of MACCE at 5-year follow-up in patients with higher SYNTAX score.

(low SYNTAX scores) or left main coronary disease (low or intermediate SYNTAX scores), PCI is an acceptable alternative. Notwithstanding, all patients with complex multivessel coronary artery disease should be reviewed by both a cardiac surgeon and an interventional cardiologist to reach consensus on optimum treatment [55].

Left main coronary artery disease

CABG is considered as the treatment of choice for unprotected left main coronary artery stenosis, although PCI can be an acceptable alternative in some patients with left main stenosis.

The Premier of Randomized Comparison of Bypass Surgery versus Angioplasty Using Sirolimus-Eluting Stent in Patients with Left Main Coronary Artery Disease (PRECOMBAT), a prospective, open-label trial, randomized 600 patients to PCI with SES (300 patients) or to CABG (300 patients). The primary endpoint of MACCE after 1 year occurred in 26 patients in the PCI group and 20 patients in the CABG group. In the PRECOMBAT trial, PCI with Cypher stents were shown to be non-inferior to CABG in patients with left main coronary artery disease with respect to the composite endpoint of death, MI, stroke or TVR at 1 year [56]. At 5 years, MACCE occurred in 52 patients in the PCI group and 42 patients in the CABG group (cumulative event rates of 17.5% and 14.3%; $p=0.26$). The two groups did not differ significantly in terms of death from any cause, MI, or stroke as well as their composite (8.4% and 9.6%; $p=0.66$). Ischemia-driven TVR occurred more frequently in the PCI group than in the CABG group (11.4% and 5.5%; $p=0.012$).

In the SYNTAX trial, unprotected left main cohort ($n=705$) was predefined and powered. The MACCE rate at 5 years was 36.9% in PCI patients and 31.0% in CABG patients ($p=0.12$). The mortality rate was 12.8% and 14.6% in PCI and CABG patients, respectively ($p=0.53$). Stroke was significantly increased in the CABG group (PCI 1.5% vs. CABG 4.3%; $p=0.03$) and repeat revascularization in the PCI arm (26.7% vs. 15.5%; $p<0.01$). MACCE events were similar between arms in patients with low–intermediate SYNTAX scores but significantly increased in PCI patients with high scores (≥ 33) [57].

Randomized trials, meta-analyses, and registries

Five-year follow-up data from the pivotal randomized trials has demonstrated durable and sustained reductions in TLR and TVR with both first-generation DES compared with BMS, with no significant differences in endpoints such as death, MI, or stent thrombosis [39]. These findings have been paralleled in meta-analyses of randomized trials comparing DES with BMS including not only the pivotal trials, but also trials for a variety of other indications, including acute MI [40,58].

One of the most extensive meta-analyses to date comparing BMS with DES included 38 trials, a total of 18,023 patients, at a follow-up of up to 4 years [59]. There was no significant difference in overall or cardiac mortality in this analysis between BMS, SES, or PES. Moreover, both SES and PES had significantly lower rates of repeat TLR than BMS. While SES was associated with lower rates of MI when compared with both BMS and PES, the number of patients needed to treat to prevent one MI event was about 100, which did not impact overall or cardiac mortality. With regard to stent thrombosis, there were no differences between BMS, SES, or PES with respect to overall stent thrombosis. Interestingly, there was trend of late temporal separation, suggesting that BMS had a lower incidence of definite stent thrombosis at 4 years. While the reported rate of late stent thrombosis was higher with PES than BMS and SES, wide confidence intervals preclude any definitive conclusions in this regard

(Figure 31.11). Although this large collaborative meta-analysis has clearly demonstrated no worse safety of both first-generation DES (SES and PES) compared to BMS with reductions in revascularization endpoints, head-to-head comparative data of SES with PES

Figure 31.11 Network meta-analyses comparing BMS and drug-eluting stents (DES) included 38 trials, a total of 18,023 patients, at a follow-up of up to 4 years. Kaplan-Meier curve for death (a); myocardial infarction (b); target lesion revascularization (c); and ARC definite stent thrombosis (d).

have been mixed. In a meta-analysis of 16 randomized trials comparing SES with PES including 8695 patients, SES reduced the risk of target lesion and stent thrombosis compared to PES, without significant differences in risk of death or MI [60]. However, in the latest randomized trial comparing SES with PES in 2098 patients, there were no differences between SES and PES in the rate of MACE, defined as cardiac death, MI, TLR, or TVR.

In addition to data from randomized trials and meta-analyses of these trials, there has been a great deal of data presented and published recently from “real-world” registries of first-generation DES use. While a detailed summary of these data is beyond the scope of this review, a brief overview of the types of registry data currently available is instructive, and illustrates both the strengths and weaknesses of these types of analyses.

Most of these observational, non-randomized comparisons of BMS and first-generation DES fall into two types. The first type consists of a comparison between BMS and DES use occurring during two distinct time periods, a period with predominant use of BMS use (before or in the early stages of DES adoption) and a period with predominant DES use. The second type of analysis consists of a comparison between BMS and DES from a single period of concurrent BMS and DES use. Unlike randomized trials, these types of analyses evaluate both BMS and DES use in “real-world” patients, without restrictions of relatively strict patient and lesion inclusion and exclusion criteria. However, both types of analysis are of course observational, and are limited by differences between patients treated with BMS or DES. While the sequential type of comparison attempts to limit selection bias (or decision making swaying the choice of one type of stent over the other), this analysis is subject to bias relating to differences in case selection, adjunctive pharmacology, and procedural factors between two different time periods. Similarly, while the concurrent type of registry may be less subject to these latter biases, selection bias can have a major role in explaining differences between treatment groups. As a result, observational, non-randomized comparisons between treatment groups are extremely valuable, but must be interpreted with caution despite efforts to statistically adjust for baseline differences between comparator groups.

Historically, the majority of registry data comparing first-generation DES with BMS included follow-up of up to 4 years. Consistent with randomized trial data, these registries demonstrate significant reductions in TLV and other clinical endpoints related to restenosis. In addition, with the exception of the original presentation of the Swedish SCAAR registry that demonstrated increased mortality among DES-treated patients, no other registry (including the re-analysis of SCAAR) has demonstrated a statistically detectable increase in mortality or MI with DES compared to BMS [13,61–65]. In fact, the greater part of these registries have demonstrated up to 20% reductions in all-cause mortality with DES compared to BMS even in adjusted analyses.

Additionally, several registries have assessed the risks and benefits of first-generation DES use specifically in “off-label” patients, or patients who would have been excluded from the pivotal DES vs. BMS trials. In a single center registry of 1164 consecutive patients receiving BMS and 1285 consecutive patients receiving DES, the use of DES was associated with lower all-cause mortality (HR 0.72, 95% CI 0.54–0.94), and non-fatal MI or death (HR 0.78, 95% CI 0.62–0.98) compared to BMS in cases of “off-label” stenting. This study demonstrated an elevated risk associated with “off-label” use independent of stent type, but simultaneously demonstrated a greater relative benefit to DES vs. BMS when “off-label” stenting occurs [13]. Although late stent thrombosis occurred with first-generation DES in “off-label” settings, and did not happen with BMS, the relative

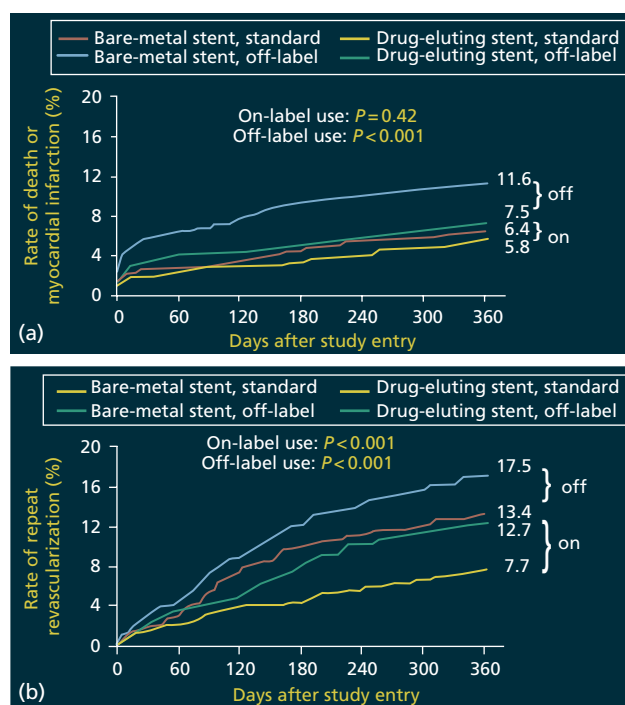

Figure 31.12 NHLBI Registry. Kaplan–Meier curves of death or myocardial infarction (a) and for target vessel revascularization (b) between “on-label” vs. “off-label” use.

benefit of reduced TLV, non-fatal MI, or death, and all-cause mortality would appear to outweigh this risk in “off-label” settings. Similarly, in the NHLBI Dynamic registry, there was no difference in the adjusted risk of death or MI at 1 year associated with “off-label” first-generation DES use compared to BMS use despite a greater prevalence of comorbid conditions among DES-treated patients. Consistent with other randomized trial and registry data, the risk of repeat revascularization was significantly lower with first-generation DES, regardless of the setting (Figure 31.12) [63].

In summary, the preponderance of both randomized and registry data including thousands of patients with follow-up in some cases of up to 5 years, supported the use of first-generation DES in reducing restenosis-related events with no untoward effects related to death or MI, and in fact a possible reduction in mortality observed in registry series.

Finally, in a recent head-to-head comparison of Cypher vs. Taxus, Zhang *et al.* [66] evaluated 76 studies including more than 15,000 patients in randomized controlled trials and over 70,000 patients in adjusted observational studies. At overall-term follow-up, SES significantly reduced TLR (RR 0.61, 95% CI 0.49–0.76), TVR (RR 0.67, 95% CI 0.54–0.83), MACE (RR 0.79, 95% CI 0.72–0.87), MI (RR 0.85, 95% CI 0.73–0.99), in-segment restenosis (RR 0.50, 95% CI 0.38–0.65) in randomized controlled trials compared with PES. In addition, lower rates of death (RR 0.91, 95% CI 0.83–1.00), any stent thrombosis (RR 0.62, 95% CI 0.45–0.86), definite stent thrombosis (RR 0.59; 95% CI 0.45–0.77) were found in patients receiving SES in adjusted observational studies (Figures 31.13 and 31.14). Largely similar results were found at short and long-term follow-up, and in patients with diabetes, acute MI, or long lesions. From this independent meta-analysis the authors concluded that SES significantly reduced the short, long, and overall-term risk of TLR/TVR, MACE, and restenosis, and overall-term risk of MI in randomized controlled trials, compared

Figure 31.13 Relative risks and 95% confidence intervals of other clinical endpoints associated with SES versus PES. MACE (a), MI (b), all-cause death (c), cardiac death (d), death/MI (e) were evaluated in short-term (≤ 1 year), long-term (>1 year), and overall-term follow-up. Adj-OS, adjusted observational study; CD, cardiac death; CI, confidence interval; Death + MI, the composite of death and myocardial infarction; MACE, major adverse cardiac event; MI, myocardial infarction; No., number of the studies; Non-adj OS, non-adjusted observational study; PES, paclitaxel-eluting stents; RCT, randomized controlled trial; RR, relative risk; SES, sirolimus-eluting stent. with PES. Lower rates of death and stent thrombosis were also observed in observational studies in SES-treated patients.

Nevertheless, issues such as incomplete delayed re-endothelialization and neointimal growth, enhanced platelet aggregation and inflammation, late-acquired incomplete stent apposition, and localized hypersensitivity reaction have been observed to occur with both first-generation DES. Novel DES systems have been introduced with the aim to improve outcomes while diminishing adverse events.

Safety concerns with DES and the introduction of novel generation DES

In late 2006, safety concerns were raised about these first-generation DES. Two meta-analyses and a large observational registry study individually suggested increases in adverse clinical endpoints with

DES largely emerging following the first year of stent implantation [67–69]. These initial data, combined with additional data demonstrating that first-generation DES are associated with a small but measurable risk of late stent thrombosis (stent thrombosis occurring beyond 30 days) [70,71], were widely reported in the media and lay press, and generated considerable controversy and concern for patients, physicians, device companies, and regulatory bodies alike.

Data from numerous trials and registries have shown that the overall rate of acute and subacute stent thrombosis appears to be no different for DES or BMS [25,33]. However, in analyses incorporating long-term follow-up, there is a small but finite risk of late stent thrombosis associated with DES use [70,72]. In theory, this occurrence of late stent thrombosis would be expected to increase mortality and non-fatal MI rates for DES-treated patients, but most

studies, including meta-analyses inclusive of the early cautionary data, found no differences in death and MI at extended follow-up [58,72]. Moreover, subsequent re-analysis of the large Swedish registry study that initially raised concerns over DES safety with additional follow-up to 4 years and the addition of more patients has demonstrated no differences in hard clinical endpoints between DES and BMS.

As part of interventional cardiology history, there appears to be some consensus that while first-generation DES was likely associated with a slightly increased rate of late stent thrombosis compared to BMS, at least with “on-label” DES use, these risks appeared to be offset by reductions in restenosis-related outcomes, and thus there was no observed increases in hard safety endpoints such as death or MI with the use of first-generation DES compared to BMS. Finally, new generation DES and bioresorbable vascular scaffolds have been introduced in the armamentum of interventional cardiology in recent years; novel generation DES (including everolimus, zotarolimus, and biolimus-eluting stents) have been demonstrated to be safer and more efficacious than first-generation DES and are discussed in other chapters.

Conclusions

Historical approaches to SES and PES development and clinical data are reviewed in this chapter. The first-generation DES has overcome the obstacle of restenosis and consequent need for repeat revascularization over BMS. However, long-term safety issues have arisen. While there was a likely greater risk of late stent thrombosis with first-generation DES, the preponderance of data suggested that they were not associated with increases in death, MI, or other “hard clinical endpoints” compared to BMS, and were durably associated with reductions in restenosis-related endpoints, with potentially even greater absolute benefits (and risks) in “off-label” utilization.

As PCI continues to adapt and evolve, new developments in DES technology are currently in use. Aside from novel-generation stents, a whole host of new DES technologies are currently under active investigation. Bifurcation DES systems, DES with bioresorbable polymers, non-polymer DES approaches with surface modification to obviate the use of a polymer, and even wholly bioresorbable vascular scaffolds are all currently in use in clinical practice or are being tested in clinical trials.

Compared to their bare metal predecessors, drug-eluting stents (DES) have undisputed efficacy in preventing in-stent restenosis. First-generation DES pushed the boundaries of percutaneous coronary intervention, permitting the application of minimally invasive techniques to clinical scenarios that once fell strictly in the surgical domain. Despite their efficacy and resulting enthusiastic use, however, concerns rapidly surfaced over their long-term safety. Evidence suggesting an increased risk of late stent thrombosis and restenosis resulted in a comprehensive reconsideration of the first-generation DES.

The countless studies that emerged from this reassessment provided new insights into the complex relationship between stent and vessel wall, and a renewed focus on the stent platform, polymer, and drug. Factors such as strut thickness, polymer biocompatibility, and drug release kinetics are now known to influence vascular endothelial healing, a major factor in long-term stent outcomes. Such insights have subsequently informed the design of the second-generation DES, resulting in the use of more biocompatible drug-eluting polymers, more effective drug formulations, and more resilient platform materials.

Cobalt-chromium (CoCr) stents were largely born out of the need for a new generation of coronary stents preserving or improving the safety, efficacy, and deliverability of earlier iterations. The superior biomechanics and biocompatibility of these alloys serve as the platform for increasingly varied and innovative approaches to stent design. Overall, it appears that the second-generation DES retain the anti-restenotic efficacy of first-generation DES while maintaining protection against late stent thrombosis [1–4]. While several second-generation DES are now in clinical use, this chapter focuses on the market-leading CoCr everolimus-eluting stents (EES), which have become the standard against which new stents and scaffolds are compared.

This chapter begins with a brief discussion of several material and chemical properties of CoCr alloys that contribute to these stents' superior biomechanics and biocompatibility. This discussion provides context for the subsequent technical description of the CoCr-EES and the clinical trials evaluating their safety and efficacy. Finally, it should be understood that the chemical and material properties discussed are not meant to be exhaustive nor meant to suggest that CoCr alloys are the single best material for coronary stents; other excellent materials exist and more are in development.

Rather, the goal is to illustrate that while CoCr alloys do have their limitations, they achieve a better balance than materials such as stainless steel. These concepts not only help explain the clinical success of CoCr-DES, but may also serve as a framework to better understand the performance of other important and commonly used stent materials such as the titanium and platinum alloys.

Material and chemical properties of cobalt-chromium alloys

The three overarching elements in the design of traditional DES are platform, polymer, and drug. Alteration in these features accounts for much of the variety seen in currently available stents (Figure 32.1). Although each element is critical, the platform's biomechanics and biocompatibility have key roles in a stent's overall performance. The CoCr alloys possess key material and chemical properties that improve their performance compared to stainless steel and many other materials used in coronary stents.

Platform biomechanics

Role of strut thickness

For more than a decade, stent design has prioritized thinner struts as a result of numerous studies demonstrating significantly improved outcomes compared to stents with thick struts [5,6]. While thick struts provide radial and longitudinal strength, they characteristically lack the flexibility and conformability critical in maintaining stent apposition without inducing vessel deformity and injury. Thinner struts demonstrate better apposition to the vessel wall and cause less disruption of local hemodynamics [7–11]. Stents with thinner struts also show less vascular inflammation [12,13] and thrombosis [7]. These findings may partially explain rapid and more complete endothelial healing seen with thin struts [14].

Strut thickness also impacts stent deliverability, the qualitative ease with which a stent is visualized, tracked to the target, and adequately deployed. Thinner struts increase flexibility to better negotiate complex vascular anatomy, reduce crossing profiles to navigate across lesions, and present less obstruction of side branch access. Thin struts, however, are less radio-opaque and thus decrease the operator's ability to visualize the stent under fluoroscopy to ensure safe and effective deployment.

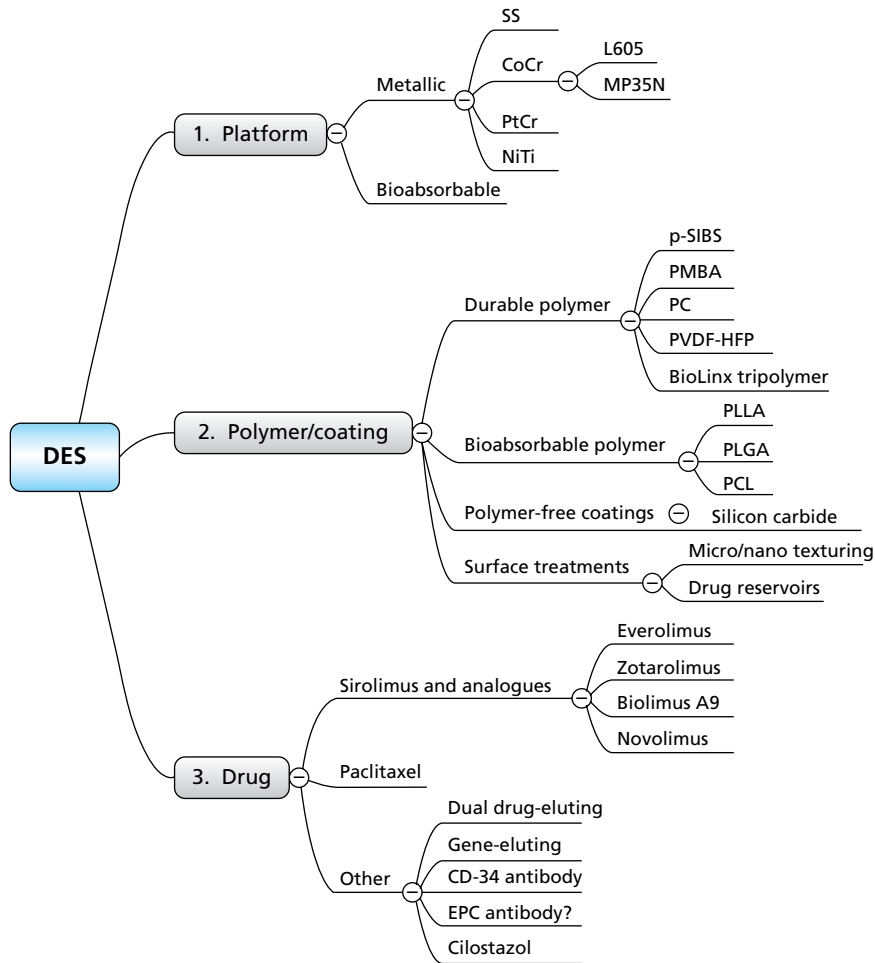

Figure 32.1 Components of drug-eluting stents (DES).

While these observations formed a strong driving force toward thinner struts, stainless steel was not strong or dense enough to fabricate thin struts while maintaining characteristics essential to coronary stents. In fact, the push toward thinner and thinner struts has led to concerns about recoil, longitudinal stent deformation, and stent fracture with newer stent platforms [15,16]. While these mechanical complications remain rare events overall, they have been associated with restenosis and thrombosis [17]. Some reports suggest, for instance, that longitudinal deformation occurs more frequently with platinum-chromium based stents [18] whereas others have found no correlation [19]. Ongoing studies suggest that in addition to certain clinical factors such as stent length and vessel diameter, the number and arrangement of longitudinal connectors between hoops are more significant determinants than strut thickness or material [15,16,20–22].

Ultimately, the material properties of the platform outline the fundamental limits of its design and deliverability. The tensile strength, yield strength, elasticity, and density of the platform material define the thinnest struts possible while maintaining strength, flexibility, and radio-opacity. While stainless steel has long been used in medical devices, it has several limitations in the context of coronary stents and the particular need for thinner stent struts. Relative to stainless steel, the CoCr alloys have struck a better balance. The most commonly used CoCr alloys, L605 and MP35N, vary in composition, but their biomechanical properties are similar

Table 32.1 Composition of stainless steel and cobalt-chromium alloys.

Alloy	Element composition (%)							
	C	Fe	Co	Cr	Ni	W	Mo	Mn
316L	0.03	64	—	18	14	—	2.6	2.0
MP35N	0.025	1.0	35	20	35	—	10	0.15
L605	0.1	3.0	52	20	10	15	—	1.5

(Table 32.1) [23]. Both L605 and MP35N have higher tensile strength, yield strength, elastic modulus, and density than 316L stainless steel because of key differences in chemical composition.

Crystal structure of metals

The mechanical properties of alloys depend on their chemical composition and crystal structure of the metal (Table 32.2). Most metals have a crystalline structure in which atoms form repeating unit cells that can take various arrangements such as face-centered cubic, body-centered cubic, and hexagonal closely packed. Simplistically speaking, these arrangements determine how closely atoms are packed together, thereby determining properties such as strength, density, and magnetism. Further, unit cell arrangements can

transform from one to another depending on factors such as temperature and the presence of impurities.

Many pure metals contain defects in the regular crystalline arrangement because of atoms missing from their expected position, interjection of atoms where they are not expected, or slight

Table 32.2 Mechanical properties of stainless steel and cobalt-chromium alloys.

Material	Density (g/cm ³)	UTS (MPa)	Yield strength (MPa)	Elastic modulus (GPa)
316L	7.9	670	340	193
MP35N	8.4	930	414	233
L605	9.1	1000	500	243

UTS, ultimate tensile strength.

misalignment of bonds. Ultimately, these defects result in a polycrystalline material with countless crystal grains and planar facets (Figure 32.2a–c). Crystal defects partially account for the brittleness of pure metals and the deformability of metals in general, but defects can be removed or mitigated by various metallurgical techniques, thereby altering mechanical properties of the metal.

Alloying, or solid-solution strengthening, is one technique to stabilize crystal defects and strengthen pure metals. The addition of other elements effectively hinders deformation around defects due to differences in intermetallic bond strength and atom size (Figure 32.2d). Another technique is grain-boundary strengthening, which involves applying a force (such as with a hammer) to the metal or alloy to decrease grain size and reposition the defects to coalesce with the newly formed grain boundaries*. This is relevant because certain alloyed elements can also affect grain size; elements that reduce grain size can effectively increase the overall alloy strength. Finally, the temperature at which alloys are worked can induce transformations in the unit cell arrangement (such as

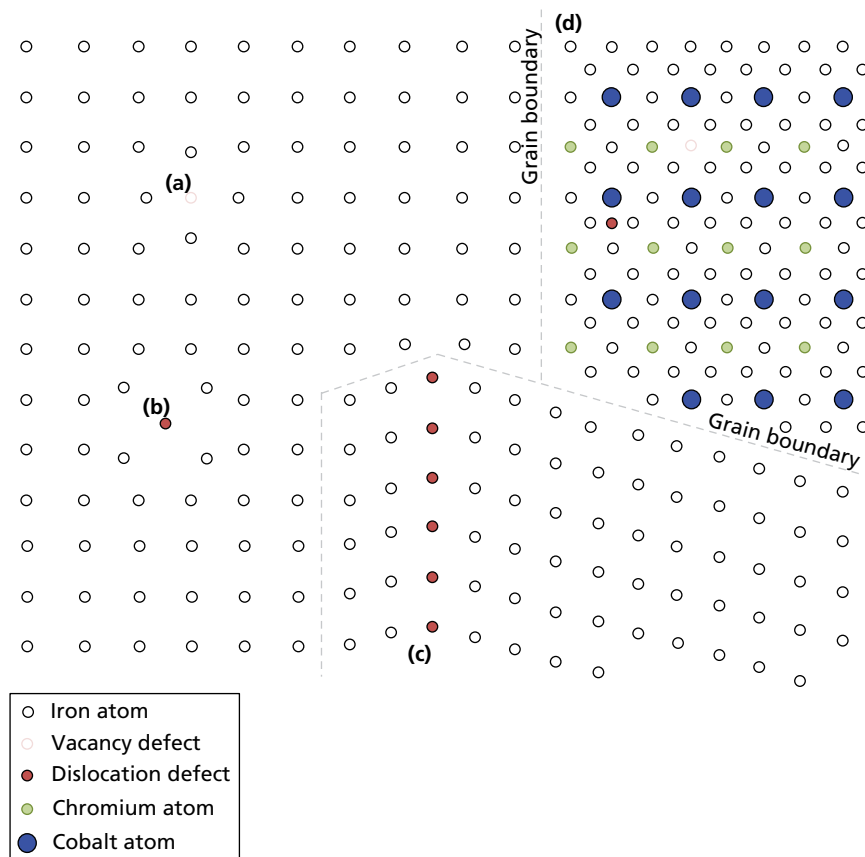

Figure 32.2 Schematic representation of metallic crystal structure, defects, and strengthening. (a) Vacancy defects in the crystal cause misalignment of bonds and a point susceptible to deformation. (b) Dislocation defects result in misalignment of bonds and susceptibility to deformation. (c) Linear or planar dislocation defects result in the formation of a new crystal grain and boundary. (d) Cobalt and chromium atoms stabilize defects and allow closer packing of atoms to strengthen alloys and increase wear resistance.

*As the surface of a crystal grain is generally formed by planes, planar boundaries define the interface where two crystal grains meet. Given a constant volume of polycrystalline metal, decreasing crystal grain size increases the number of grains and planar boundaries, akin to increasing surface area. Grain-boundary strengthening effectively ushers atomic crystal defects into planar boundaries, an inherently less unstable arrangement than randomly dispersed defects. In short, point and line defects are less stable than plane defects, although this mechanism breaks down with extreme reductions in grain size.

body-centered to face-centered cubic transformation), which again affects electromagnetic and mechanical behavior.

These concepts are introduced in order to demonstrate that the increased strength, elasticity, and density of CoCr alloys can be tied to the specific effects of cobalt, chromium, tungsten, and molybdenum on the crystal structure of the alloy. During CoCr alloy fabrication, the atomic structure of cobalt (more specifically, the number and arrangement of its electrons) facilitates a partial transformation of the unit cell arrangement from face-centered cubic to hexagonal closely packed structure. The resulting combination of closely packed but distinct unit cell configurations significantly increases the alloy's strength and wear resistance [24]. This type of unit cell rearrangement and strengthening does not occur in stainless steel.

In many alloys, chromium binds with carbon to form extremely strong chromium-carbides, which stabilize defects and grain boundaries. While carbides in CoCr alloys are generally chromium-based, cobalt, tungsten, and molybdenum can substitute for chromium and exert their own strengthening effects. Furthermore, tungsten promotes even distribution of carbides through the alloy; molybdenum decreases crystal grain size, reducing the destabilizing effect of crystal defects [24,25].

Thus, the specific chemical composition of CoCr alloys imbues the material with properties that allow the fabrication of thin-strut (<100 μm) stents while maintaining strength, flexibility, and radiopacity in addition to long-term resistance to wear, fatigue, and corrosion [25–28]. From a clinical standpoint, these biomechanical characteristics have contributed to reduced endothelial injury, thrombosis, and restenosis compared to stents with thicker struts [29,30]. These concepts help explain some of the limitations of stainless steel and some of the reasons cobalt, platinum, and titanium alloys perform so well in coronary stents.

Platform biocompatibility

Biocompatibility is an obvious requirement for any implanted device, but its definition has evolved over time and fluctuates considerably in accordance with the setting and desired outcomes [31]. For metallic coronary stents, biocompatibility requires resistance to thrombosis and low inflammatory potential. These characteristics are not inherent even to gold and turbostratic carbon, materials successfully used in other blood-contacting devices, but which have not worked well in coronary stents [32–35]. The CoCr alloys, however, continue to show their biocompatibility through low rates of restenosis and thrombosis [29,30] in addition to reduced need for revascularization historically compared to stainless steel BMS [36]. While likely related to thinner struts and improved biomechanics, several material and chemical properties of CoCr also contribute to improved resistance to thrombosis and inflammation.

Surface characteristics and resistance to thrombosis

Resistance to thrombosis is a vital characteristic of any coronary stent as metal is a potent trigger of fibrin deposition and platelet adhesion. While the detailed thermodynamic and electrochemical mechanisms of stent thrombosis are beyond the scope of this discussion, this process is again influenced by stent material properties and surface characteristics [12,37,38].

In brief, the energy differential between blood and metallic stent surface contributes not only to protein deposition on the stent, but also influences which proteins are deposited (fibrin, fibronectin, albumin, etc.) and the extent to which these proteins are denatured by contact with the metallic surface [38]. In fact, varying

conformations of adherent fibronectin have been shown to have differential affinity for platelet, monocyte, and endothelial cell adhesion depending on which intermolecular binding domains are exposed upon adhering to metal [39]. This can influence propensity for thrombosis, restenosis, and endothelial coverage.

The energy differential between the stent surface and blood depends upon the material surface energy, a measure of the stability of molecular bonds at the surface relative to that of internal molecules; surface potential, a measure of electrical conductivity; and surface texture [38,40]. The empirical characterization of surfaces is extremely complex, and a clearly defined relationship between surface characteristics and thrombosis has remained elusive [41,42]. Simplistically speaking, however, CoCr alloys have low surface energy, low surface potential, and a surface readily electro-polished relative to other materials used in stents, all of which contribute to reduced thrombogenicity [37,43].

These observations are supported by the empirical measurement of fibrin and platelet adhesion *in vitro*, which can reasonably approximate the thrombo-resistance and inflammatory nature of various materials. For example, materials such as gold, manganese, and turbostratic carbon have high rates of *in vitro* fibrin, platelet, and monocyte adhesion [44], corresponding to high rates of restenosis seen with stents containing these materials [33,34]. In contrast, L605 CoCr shows a low rate of fibrin deposition, minimal monocyte adhesion, and good endothelial cell migration characteristics [44], again supported by clinical results demonstrating low thrombogenicity and restenosis [29,30].

Corrosion resistance and reduced inflammation

In addition to thick stent struts and early durable polymers, metal release from corroding stent platforms has been suggested as another source of vascular toxicity and chronic inflammation [45]. Corrosion has been postulated to explain the singular failure of gold-coated stents: surface irregularities imparted by the galvanization-coating technique may have caused cracks in the gold layer resulting in corrosion and leaching of toxic and inflammatory metal ions into surrounding tissues [33,42,46]. Refinement of the gold coating technique resulted in better surface texture and integrity, and eliminated excessive restenosis altogether [46].

Clearly, corrosion resistance depends on mechanical integrity of the platform. As seen with the gold-coated stents, cracks and fissures may have acted as a nidus for propagating corrosion (Figure 32.3). The high elasticity, wear, and fatigue resistance of the CoCr alloys reduce their propensity to fracture, and thus partially explain their superior corrosion resistance. However, compared with stainless steel and other commonly used device materials, CoCr alloys demonstrate superior corrosion resistance mainly because of *in vivo* oxidation of the metallic stent surface [25,47]. Surface oxidation creates a passive film that acts somewhat like a natural sealant and reduces metal release into surrounding tissues [48]. The importance of surface oxide formation cannot be overstated when considering that, as lone elements, cobalt, chromium, and nickel are highly toxic, yet once alloyed and oxidized they form a highly biocompatible, non-toxic material.

Interestingly, the stability of the formed oxide is more important in preventing metal release than quantitative metal content itself. Although both L605 and MP35N CoCr alloys contain a relatively high percentage by weight of nickel (10% and 35%, respectively), their superior oxide stability prevents nickel release seen in slightly more corrosion-prone alloys such as stainless steel. This superior

Figure 32.3 Stent corrosion. Scanning electron micrograph of the surface of a nickel-titanium stent with cracks (a, b, d) and corrosion pits upon closer examination (c, e). Source: Halwani DO, *et al. J Biomed Mater Res B* 2010; 95B: 225–238. Reproduced with permission. Copyright © 2010 Wiley Periodicals, Inc.

oxide stability is mainly because of high chromium content of CoCr alloys, although nickel and molybdenum also contribute. In a cobalt matrix, high chromium content in particular induces spontaneous surface oxidation to form a highly stable Cr_2O_3 oxide [24]. As a result, CoCr alloys have significantly greater corrosion resistance than stainless steel [47].

Lastly, it should be noted that the same element can have opposing effects on mechanical strength and corrosion resistance, hence the difficulty and importance of achieving balanced performance. Tungsten, for instance, improves strength and wear resistance of L605, but may also contribute to its slightly lower corrosion resistance than MP35N. On the other hand, MP35N lacks tungsten and can therefore be slightly more corrosion resistant at the expense of some mechanical strength. These are, of course, simplified explanations of highly complex phenomena, but still serve to illustrate how chemical and material properties relate to real-world clinical performance.

Cobalt-chromium everolimus-eluting stents: technical overview

Platform

The CoCr-EES are conscribed by the Xience V, Prime, Xpedition, and Alpine (Abbott Vascular, Santa Clara, CA, USA). Since the initial introduction of the Xience V in 2006, these stents have undergone only incremental changes marked by minor alterations in the platform design and delivery system.

The Xience V was based on the L605-CoCr Multi-Link Vision (Abbott Vascular) platform, which features $81\mu\text{m}$ struts and an open-cell design characterized by in-phase sinusoidal hoops linked by three longitudinal connectors per hoop. Each longitudinal

connector has a small C-shaped loop to enhance flexibility (Figure 32.4). The Xience V was subsequently replaced by the Xience Prime, and more recently by the Xpedition and Alpine.

The Xience Prime, Xpedition, and Alpine EES are based on the L605-CoCr Multi-Link 8 (Abbott Vascular), which features slightly longer cells and minor modifications to the proximal hoop, but is otherwise nearly identical to the Multi-Link Vision. Both of these platforms provide thin struts while maintaining excellent radial strength, longitudinal strength, flexibility, and radio-opacity [15,20,26].

Polymer

All of the Xience stents employ a biocompatible durable polymer coating consisting of a primer layer and a polymer-drug layer with a total thickness of $7.8\mu\text{m}$. The primer, poly n-butyl methacrylate (PMBA), is synthesized from methacrylate monomers and serves to adhere the drug-eluting polymer to the platform. The drug-eluting layer is a combination of polyvinylidene fluoride-hexafluoropropylene (PVDF-HFP) and everolimus mixed in a ratio of 83 : 17%, which is then applied to the entire PMBA-primed stent surface.

As the durable drug-eluting polymers are permanent, rapid endothelial healing and long-term resistance to thrombosis and chronic inflammation are essential to long-term safety. As with the CoCr alloys, the PVDF-HFP polymer possesses chemical and material properties that significantly enhance its clinical performance.

Polymer chemical structure

PVDF-HFP is a semi-crystalline polymer with an entirely saturated carbon-carbon backbone, which increases resistance to hydrolysis, oxidation, and enzymatic cleavage. This oxidative stability may

Figure 32.4 Xience stent. The Xience V/Multi-Link Vision has an open-cell, in-phase sinusoidal pattern with three longitudinal connectors between adjacent hoops. The longitudinal connectors feature a C-shaped loop (asterisk) to increase flexibility. The Xience Prime, Xpedition, and Alpine are based on the Multi-Link 8 platform, which features slightly longer connectors resulting in longer cells, but is otherwise identical to the Multi-Link 8.

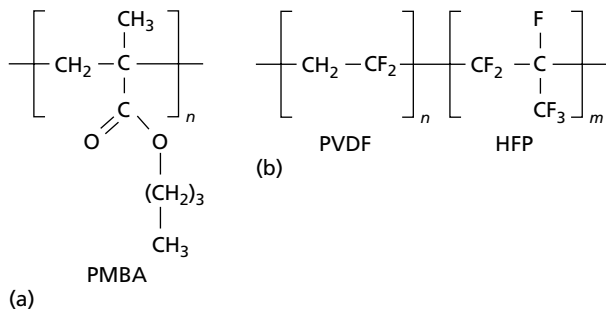

Figure 32.5 Chemical structure of poly n-butyl methacrylate (PMBA) and polyvinylidene fluoride-hexafluoropropylene (PVDF-HFP). (a) Chemical structure of PMBA. (b) The completely saturated, partially fluorinated carbon-carbon backbone of PVDF-HFP increases its oxidative stability and resistance to thrombosis.

reduce the formation of inflammatory degradation products. Additionally, approximately 50% of the carbon backbone is saturated with fluorine to form a highly inert, hydrophobic stent surface resistant to thrombosis (Figure 32.5) [39]. Although hydrophobic surfaces are theoretically more prone to thrombosis, this has not been borne out by experiments comparing hydrophilic polymers to hydrophobic fluorinated polymers [49]. Instead, the high energy C-F bond's thermodynamic stability and relative non-polarity lower the surface energy and potential, respectively, of the CoCr platform [50]. These characteristics explain fluoropassivation, an empirically observed improvement in endothelial healing, resistance to thrombosis, and reduced inflammatory potential of fluorinated polymers [3,39,49–52].

Glass transition temperature for polymers

A brief word about glass transition temperature for polymers, T_g , the temperature below which polymers are brittle and prone to cracking, and above which they are pliable and elastic; it is the energy required to overcome intermolecular forces resisting fluid

motion of polymer chains. PVDF-HFP has a very low T_g of -29°C , resulting in inherently high elasticity and fatigue resistance at body temperature. This is particularly important in both the short and long term, as more brittle polymers can crack during balloon expansion or with constant cardiac motion and arterial pulsatility.

In summary, the semi-crystalline fluorinated structure and low T_g of PVDF-HFP contribute to high oxidative stability, resistance to fatigue and cracking, low thrombogenicity, and favorable drug release kinetics.

Drug

Everolimus is a partially synthetic analogue of sirolimus (rapamycin), a naturally occurring compound formed by *Streptomyces hygroscopicus*. Sirolimus and its analogues bind cytosolic FK-506 Binding Protein-12 (FKBP12) to form a complex inhibiting the mammalian target of rapamycin (mTOR), resulting in cytostatic G1-phase cell cycle arrest. Everolimus may also selectively clear macrophages from atheromas, theoretically stabilizing vulnerable plaques, but the clinical significance remains to be elucidated [53].

Sirolimus analogues are synthesized by manipulating various carbon side-chain atoms. The sirolimus derivatives have similar *in vivo* potency and efficacy in their formulations for coronary DES but have highly varied lipophilicity. Everolimus is more lipophilic than sirolimus, resulting in increased local vascular uptake, particularly into lipid-rich atheroma, and lower systemic distribution. This has allowed the EES to contain a lower concentration of drug ($100\ \mu\text{g}/\text{cm}^2$).

The CoCr-EES has demonstrated excellent short- and long-term endothelial healing similar to bare metal stents and superior to the first-generation DES (Figure 32.6) [54]. This is partially caused by the kinetics of drug release, an important contributor to endothelial healing and clinical outcomes. The polymer-drug formulation of the CoCr-EES results in approximately 30% drug release within the first 24 hours after implantation, leading to 80% release by 30 days and complete elution by 120 days. The mechanisms of polymeric drug-elution are complex, but suffice it to say that the low T_g of

Figure 32.6 Cobalt-chromium everolimus-eluting stents (CoCr-EES) apposition and tissue coverage by optical coherence tomography (OCT). Intracoronary OCT provides high-resolution *in vivo* imaging of the coronary lumen, intimal-medial vessel structure, and stent struts. PVDF-HFP and the miscibility of polymer and drug (as both are hydrophobic) factor into controlled drug release.

Xience stents: clinical trials

A multitude of trials have proven the short- and long-term safety and efficacy of the CoCr-EES compared to first generation DES, and now these stents are considered the standard comparator for newer devices and scaffolds. As such, several landmark studies investigating the Xience EES are presented (Table 32.3).

SPIRIT I-IV

SPIRIT FIRST was a prospective trial randomizing 56 patients to the Xience V-EES or the Multi-Link Vision (Guidant/Abbott Vascular, Santa Clara, CA, USA) L605 CoCr BMS [55]. Early angiographic results from SPIRIT FIRST showed excellent performance of the Xience V-EES compared to the Multi-Link Vision CoCr BMS (6-month in-stent late lumen loss of 0.1 vs. 0.87 mm; $p < 0.001$), along with a non-significantly lower rate of clinical events (7.7% vs. 21.4%; $p = \text{NS}$), as a result of low sample size resulting in lack of power to assess clinical outcomes. Long-term data confirmed that the early findings of superior safety and efficacy of the Xience V-EES over the Multi-Link Vision were consistently maintained over 5 years [56].

The SPIRIT II-IV trials compared the Xience V-EES with the Taxus paclitaxel-eluting stent (PES) (Boston Scientific, Natick, MA, USA). Early angiographic results from SPIRIT II demonstrated superior performance of the XV-EES compared to the Taxus PES, with a 6-month in-stent late lumen loss of 0.11 vs. 0.36 mm ($p < 0.0001$) [57]. Although 2-year angiographic and intravascular ultrasound (IVUS) outcomes suggested a “late catch up” phenomenon with the XV-EES, there was no concomitant increase in adverse clinical events [58]. After 5 years, the XV-EES remained superior to the Taxus PES as evidenced by lower cardiac mortality, clinically driven TLR, and ischemia-driven MACE [59]. Interestingly, there was a lower incidence of definite or probable stent thrombosis in the EES group despite significantly lower dual antiplatelet therapy (DAPT) adherence at 5 years.

SPIRIT III showed a similar pattern of early angiographic superiority of the Xience V-EES over the Taxus PES in terms of 8-month

in-stent late lumen loss (0.16 vs. 0.30 mm; $p = 0.002$), along with significantly lower 1-year major adverse cardiac events (MACE) (6.0% vs. 10.3%; $p = 0.02$) [60]. Superiority of the Xience V-EES was maintained at 5 years, with significantly lower rates of target vessel failure (TVF), target lesion failure (TLF), MACE, and all-cause death than the Taxus PES [2].

SPIRIT IV randomized 3690 patients with broad inclusion criteria to the Xience V-EES or the Taxus Express 2 PES (Boston Scientific). At 1 year, the EES showed significant reduction in ischemia-driven target lesion revascularization (TLR), TLF, target vessel revascularization (TVR), TVF, MACE, definite stent thrombosis, and any MI compared to the PES [61]. At 3 years, the Xience V-EES remained superior in terms of rates of death, target-vessel MI, TLF, and definite or probable stent thrombosis. Only ischemia-driven TLR became non-significant, though trended lower, for the EES. These results suggest that the main advantage of the Xience V-EES is its persistent and superior safety rather than efficacy over the Taxus PES [1].

A patient-pooled meta-analysis of 4989 patients (EES $n = 3350$; PES $n = 1639$) in the SPIRIT II, III, and IV randomized trials reaffirmed superior outcome with the EES compared with the TAXUS PES up to 3-years follow-up (as the final follow-up data for SPIRIT IV were collected at 3 years) [1]. This meta-analysis showed a reduction in all-cause mortality (3.2% vs. 5.1%; $p = 0.003$) with the EES compared with the TAXUS PES. It has been hypothesized that reduced rates of repeat revascularization, myocardial infarction, and stent thrombosis with the EES have subsequently led to a significant reduction in this hard endpoint.

COMPARE I

The COMPARE I trial examined clinical outcomes in 1800 patients undergoing elective or emergent PCI randomized to the Xience V-EES or the TaxusLiberte PES (Boston Scientific). Of note, 74% of lesions were complex (Type B2/C) and the study population had a high acuity, with 27% of all participants presenting with ST-elevation myocardial infarction (STEMI). At 1 year, the Xience V-EES showed significantly lower clinical event rates [62]. After 2 years, the continued superiority of the Xience V-EES was driven mainly by decreased TVR, MI, and definite or probable stent thrombosis, as the difference between stents widened further for these measures [63].

Table 32.3 Selected trials

Trial	XV-EES versus:	Trial design	Selected inclusion/exclusion criteria	n	1° endpoint	Outcomes*	Conclusions
SPRIT FIRST	MLV-BMS	Prospective, randomized, single-blind	I: One de novo lesion treatable with single 3.0 x 18mm stent; silent, stable or unstable ischemia E: AMI; unprotected LM lesions, CTO, bifurcation lesions, heavy calcification, ISR; thrombus, LVEF <30%	60	In-stent LLL at 6 months	1°: 0.10 vs. 0.87 mm, p <0.001	XV-EES significantly reduced restenosis versus BMS; non-significantly lower rate of clinical events with EES
SPRIT II	Taxus PES	Prospective, randomized, single-blind	I: up to 2 de novo lesions in different arteries; RVD 2.5–4.25 mm, length ≤28 mm E: AMI within 3 days; LVEF <30%; ostial, LM, bifurcation lesions; heavy calcification, thrombus	300	In-stent LLL at 6 months	1°: 0.11 vs. 0.36 mm, p <0.0001 for superiority	XV-EES superior to PES in reducing in-stent LLL; low rates of clinical events in both groups
SPRIT III	Taxus PES	Prospective, randomized, single-blind	I: up to 2 de novo lesions in different coronary arteries; RVD 2.5–3.75 mm, length ≤28 mm; stable or unstable angina, or inducible ischemia E: Acute or recent MI, prior PCI in target vessel or planned within 9 months, non-target vessel intervention within 90 days prior or 9 months after	1002	In-segment LLL at 8 months	1°: 0.14 vs. 0.26 mm, p=0.003	XV-EES significantly reduced in-segment LLL compared to PES; lower rates of 12-month TVF and MACE
SPRIT IV	Taxus Express 2 PES	Prospective, randomized, single-blind	I: Up to 3 de novo lesions in 1–2 epicardial arteries; RVD 2.5–3.75 mm, length ≤28 mm E: Left main trunk disease; recent MI, CTO, thrombus, or complex bifurcation	3687	Ischemia-driven TLF (CD, TV-MI, ID-TLR)	1°: 4.2% vs. 6.8%, p=0.001	XV-EES superior to PES for TLF; significantly lower rates of ID-TLR MI, and ST
XIENCE V USA	none	Prospective, observational, single-arm	I: treatment with only EES E: Limited exclusion criteria	5054	Definite and probable ST; Composite CD and MI at 12 months	1°: ST - 0.84% CD/MI - 6.5%	XV-EES shows excellent safety and efficacy in an unselected population
COMPARE I	TaxusLiberte PES	Prospective, randomized, single-blind	I: Elective or emergent PCI; complex lesions (type B2/C) E: limited exclusion criteria; non-compliance or contraindication to 12 months DAPT; planned major surgery within 30 days	1800	Composite of all death, non-fatal MI, TVR at 12 months	1°: 6.2% vs. 9.2%, p=0.02	XV-EES safe and effective in an all-comer population

EXAMINATION	MLV-BMS	Prospective, randomized	I: STEMI within 48 hours E: limited exclusion criteria; STEMI due to stent thrombosis	1498	Composite all death, any recurrent MI, any revascularization	1°: 11.9% vs. 14.2%, p=0.19	XV-EES did not lower primary composite endpoint, but reduced TLR and ST
EXCELLENT	Cypher SES	Prospective, randomized, open-label	I: Any number and location of lesions; silent ischemia, stable and unstable angina; RVD 2.25–4.25mm E: STEMI within 72 hours, LVEF <25%, >50% stenosis of LM; CTO, in-stent restenosis, bifurcations requiring 2 stents	1443	In-segment LLL at 9 months	1°: 0.11 vs. 0.06mm, p=0.09 (p _{non-inferiority} =0.0382)	XV-EES non-inferior to SES for inhibition of LLL; similarly low rates of clinical events in both groups
EXECUTIVE: Prospective arm	Taxus PES	Prospective, randomized	I: Multivessel disease; RVD 2.5–4.0mm; length <28mm; acceptable candidate for CABG E: AMI within 72 hours; LM, arterial or venous graft lesion; heavy calcification	200	In-stent LLL at 9 months	1°: -0.03 vs. 0.23 mm, p=0.001	XV-EES significantly lowers LLL versus PES in patients with multivessel disease and low-to-intermediate SYNTAX score
EXECUTIVE: Retrospective arm	none	Single-arm	I: Multivessel disease; RVD 2.5–4.0mm; length <28mm; acceptable candidate for CABG E: AMI within 72 hours; LM, arterial or venous graft lesion; heavy calcification	400	Composite of all-cause death, MI, or ischemia-driven TVR at 12 months	1°: 9.2%	XV-EES shows low MACE rate in patients with multivessel disease
TWENTE	Resolute ZES	Prospective, randomized, single-blind	I: Stable or unstable ischemia; no limits on lesion length or RVD E: STEMI; limited exclusion criteria	1391	Composite of CD, MI, clinically-driven TVR at 12 months	1°: 8.1% vs. 8.2%, p=0.94	XV-EES and R-ZES have similarly low clinical event rates in an unselected, complex population

AMI, acute myocardial infarction; CABG, coronary artery bypass graft; CD, cardiac death; C-SES, Cypher sirolimus-eluting stent; CTO, chronic total occlusion; DAPT, dual antiplatelet therapy; ISR, in-stent restenosis; LLL, late lumen loss; LM, left main; MLV-BMS, Multi-Link Vision bare metal stent; RVD, reference vessel diameter; R-ZES, Resolute zotarolimus-eluting stent; ST, stent thrombosis; STEMI, ST-elevation myocardial infarction; TLF, target lesion failure; T-PES, Taxus paclitaxel-eluting stent; TVR, target vessel revascularization; XV-EES, Xience V everolimus-eluting stent.

* All values are presented as XV-EES versus comparator stent.

EXAMINATION

The EXAMINATION trial studied 1498 patients presenting with STEMI, randomized to the Xience V-EES or the Multi-Link Vision (Abbott Vascular) CoCr BMS [64]. The primary endpoint was the composite of all-cause death, any MI, any revascularization at 1 year, and was specifically chosen to encompass the wide range of variables that may account for post-STEMI outcomes.

Ultimately, while the composite primary endpoint results did not show a significant difference between groups, the Xience V-EES significantly reduced TLR, TVR, and definite early stent thrombosis at 1 year [64]. These differences were maintained at 2 years: the Xience V-EES significantly reduced any repeat revascularization (TLR 2.9% vs. 5.6%; $p=0.009$; TVR 4.8% vs. 7.9%; $p=0.014$) and definite or probable stent thrombosis compared to BMS (1.3% vs. 2.8%; $p=0.04$). However, overall rates of all cause death, cardiac death, and MI remained similar [65].

It is interesting to note that the Xience V's reduction in definite or probable stent thrombosis was driven mainly by lower early ST despite nearly 100% DAPT compliance in both groups. It remains unclear if this can be attributed to a polymer-mediated protective effect against thrombosis, but may be of particular significance in patients presenting with STEMI, where thrombus dissolution can lead to late acquired incomplete stent apposition (ISA), uncovered struts, and stent thrombosis.

EXCELLENT

The EXCELLENT trial compared clinical and angiographic outcomes of 1443 patients randomized to the Xience V/Promus EES or the Cypher sirolimus-eluting stent (SES) (Cordis, Miami, Florida) over 5 years. The primary endpoint, in-segment late lumen loss at 9 months, was similar for both stents (EES 0.11 vs. 0.06 mm, $p=0.09$), as were all other angiographic and clinical outcome measures [66]. Long-term data will be critical in demonstrating any differences in the incidence of very late stent thrombosis and other measures of clinical safety and efficacy of the Xience V against the standard bearer Cypher SES.

EXECUTIVE

While the landmark SYNTAX study demonstrated the role of angiographically determined disease complexity in delineating surgical versus percutaneous management of patients with multivessel disease [67], these studies were based largely on first-generation DES data.

The EXECUTIVE trial prospectively and retrospectively evaluated outcomes in patients with multivessel disease and low-to-intermediate SYNTAX scores [68]. The prospective arm examined 200 patients randomly receiving either EES or PES, with a primary endpoint of 9-month in-stent late lumen loss and secondary endpoint of 12-month composite all-cause death, MI, or ischemia-driven TVR. The retrospective arm evaluated outcomes from a registry of 400 patients who received EES, with a primary endpoint of composite all-cause death, MI, or clinically driven TLR.

For the prospective arm, 9-month in-stent late lumen loss results showed superiority of the EES over PES (-0.03 vs. 0.23 mm; $p=0.001$). Comparison of 12-month clinical outcomes for the prospective and retrospective arms showed that the composite endpoint was reached in 9.2% of the registry patients, 11.1% of EES, and 16.5% of PES ($p=0.30$). The EXECUTIVE study showed that in patients with multivessel disease and low-to-intermediate SYNTAX scores treated with PCI, EES provides significantly better 9-month angiographic outcomes over PES, but clinical outcomes at 1 year are similar.

TWENTE

The TWENTE trial randomized 1391 patients to the Xience V-EES or the Resolute-ZES (Medtronic, Santa Rosa, CA, USA). Of note, the study protocol had limited exclusion criteria, mandated strict discontinuation of DAPT at 12 months, and encouraged stent post-dilatation. The primary endpoint of TVF at 1 year was similar between stents (ZES 8.2% vs. 8.1%; $p=0.94$) [69].

At 2 years, the TWENTE trial showed overall similar clinical results between stents in patients with complex lesions and off-label indications [70]. Despite lower clinically driven TLR with the Xience V-EES, this did not translate to higher rates of TLF or cardiac death in the Resolute-ZES group (TLF: ZES 10.8% vs. 11.6%; $p=0.65$; cardiac death: ZES 1.6% vs. 2.7%; $p=0.14$). Similarly, the incidence of late stent thrombosis was similar (ZES 1.2% vs. 1.4%; $p=0.65$), as was the rate of very late stent thrombosis (VLST; ZES 0.3% vs. 0.3%; $p=1.00$) after discontinuation of thienopyridine. Of the four patients with VLST, there was no clear temporal association between discontinuation of DAPT and thrombosis.

Most interesting is that while DAPT adherence at 2 years was extremely low as a result of protocol mandate (much lower than other comparable trials, such as Leaders, Resolute AC, Compare, Spirit IV), the rate of very late stent thrombosis was similar to these studies. These observations have raised significant questions regarding the optimal duration of DAPT.

Second-generation DES and dual-antiplatelet therapy

The excellent overall hemocompatibility of the CoCr stents has led to preliminary observations that early discontinuation of standard 12-month duration of DAPT may not increase the rate of late stent thrombosis in low-risk patients [71–74]. Several meta-analyses further suggest that longer durations of DAPT do not reduce adverse cardiovascular event rates but significantly increase the risk of bleeding [75,76].

A substudy of the EXCELLENT trial, which evaluated 1443 patients with EES or SES, further randomized these patients to 6 or 12 months of DAPT [71]. At 12 months, the primary endpoint of TVF was 4.8% for 6-month DAPT versus 4.3% for 12-month DAPT ($p=0.001$ for non-inferiority). The risk of TVF was non-significantly higher in patients with SES in the 6-month group compared to 12 months, but there was no difference in the EES groups. Additionally, while there was a non-significantly increased rate of stent thrombosis in the 6-month group, five out of six events occurred while still on DAPT. Interestingly, subgroup analysis showed that diabetic patients in the 6-month group had higher TVF than the 12-month group, suggesting that a longer duration of DAPT could be beneficial in diabetic and other high-risk patients.

One-year results from the Xience V USA Registry of over 8000 real-world patients suggest that whereas DAPT discontinuation prior to 30 days post-PCI is a strong, independent predictor of stent thrombosis (HR 8.63; $p=0.008$), discontinuation after 30 days is not a risk factor for late stent thrombosis at 1 year [77]. Pooled analysis of the RESOLUTE trials reported similar findings with the Resolute ZES, showing that the 1-year stent thrombosis rate in patients who interrupted DAPT prior to 30 days was 3.61%, compared to 0.11% in patients who interrupted DAPT after 30 days [78]. Both of these studies show that regardless of DAPT status, most stent thrombosis occurred within 30 days, suggesting that other factors likely contribute to early stent thrombosis.

While these results are not definitive and no conclusive recommendations have been made pending ongoing studies, they highlight the clinical relevance of hemocompatibility of all stent components.

CoCr-EES in specific lesion subsets

Bifurcation lesions

PCI of true bifurcation lesions is regarded as technically challenging and many studies have compared an initial one-stent or a dedicated two-stent strategy in this lesion subset. A single-center observational study of 319 patients undergoing true bifurcation PCI with CoCr-EES reported superior angiographic outcomes and comparable clinical outcomes with a two-stent strategy compared with a one-stent strategy [79]. Acute gain was improved with a two-stent strategy (0.65 ± 0.41 vs. 1.11 ± 0.47 mm; $p > 0.0001$) and at 1-year clinical follow-up rates of target vessel revascularization (two-stent 5.8% vs. one-stent 7.4%; $p = 0.31$), myocardial infarction (two-stent 7.8% vs. one-stent 12.2%; $p = 0.31$), and major adverse cardiovascular events (two-stent 16.6% vs. one-stent 21.8%; $p = 0.21$) were non-significantly lower with a two-stent strategy. A similar study by the same investigators including only diabetic patients showed qualitatively similar results [80]. These studies suggest that the CoCr-EES may be well-suited for a dedicated two-stent approach in true bifurcation lesions.

In-stent restenosis

The performance of the CoCr-EES in in-stent restenosis lesions (ISR) was evaluated in the XIENCE V USA prospective multicenter registry [81]. A total of 383 out of 5215 patients underwent PCI of ISR lesions (7.4%). At 1 year, target lesion failure occurred in 10.9% of patients, MI in 2.2%, TLR in 10.3%, and cardiac death in 1.4% of patients. This study showed that the treatment of ISR with CoCr-EES is safe and efficacious at 1 year follow-up. However, rates of adverse events were significantly higher than patients who underwent PCI of non-ISR lesions. The use of CoCr-EES for ISR lesions was compared with paclitaxel-eluting balloons, balloon angioplasty, PES, and SES in a network meta-analysis of seven randomized trials [82]. This Bayesian meta-analysis showed that paclitaxel-eluting balloons and Co-Cr EES had the highest probabilities for being the best treatment option.

Small vessels and long lesions

A patient-pooled meta-analysis using data from 6283 patients included in the SPIRIT II, III, IV, and COMPARE randomized controlled trials (EES $n = 3944$; PES $n = 2239$) showed that patients with long lesions (>13.4 mm) in small vessels (<2.65 mm) have the lowest rates of adverse events [83]. This study showed that the CoCr-EES as compared with the PES resulted in significantly improved outcomes in patients with long lesions and/or small vessels, and non-significantly improved outcomes in patients with short lesions in large vessels.

Multivessel disease

The recently published Randomized Comparison of Coronary Artery Bypass Surgery and Everolimus-Eluting Stent Implantation in the Treatment of Patients with Multivessel Coronary Artery Disease (BEST) trial included a total of 880 patients with multivessel coronary artery disease who were randomly assigned to PCI with EES or CABG [84]. Patients with left main coronary artery disease were excluded. At a median follow-up of 4.6 years, there were no significant differences in terms of death or myocardial infarction between both groups. There was, however, an increased rate of repeat revascularization, because of a significantly higher rate of non-target lesion revascularization in the PCI group. This study suggests that PCI with CoCr EES may be an alternative to CABG surgery in anatomically complex multivessel disease.

Conclusions

The CoCr-EES have repeatedly and consistently demonstrated safety, efficacy, and deliverability compared to earlier stainless steel bare metal and first-generation DES. Their clinical success can be attributed to improvements in each of the three design elements of DES: the platform, polymer, and drug. The detailed mechanistic exploration of these improvements lends insight into factors that will continue to be important in stent design and optimizing clinical outcomes. In particular, what has emerged is the absolute importance of vascular endothelial integrity and function.

The CoCr-EES are now the standard comparator for new stents and scaffolds, but regardless of their excellent safety and efficacy, the permanent nature of these devices remains their lasting pitfall as persistent sources of endothelial injury. It is expected that ongoing advances in stent design will continue to shift the paradigm toward bioabsorbable materials that better maintain endothelial integrity and natural vasomotor function over time.

The critical role of intravascular injury in thrombosis has been well understood for over a century [1]. The advent of coronary intervention further underscored the potentially catastrophic consequences of vessel injury, namely stent thrombosis and restenosis. Interventional practice has evolved in the face of these clinical pressures and as a result, stent thrombosis and restenosis have become increasingly rare. Along with dual antiplatelet therapy and refined stent deployment technique, advances in stent design have revolutionized the treatment of ischemic heart disease.

With the goal of reducing vessel injury, the conventional approach to stent design has prioritized flexibility and conformability to the vessel wall. This strategy has contributed to several immensely successful devices, among them the platinum-chromium everolimus-eluting stents. From alloy composition to polymer and drug biocompatibility, the platinum-chromium stents have benefited from deeply considered design. These stents have capitalized upon the strengths of the platinum-chromium alloy along with the demonstrated safety and efficacy of the everolimus-fluorinated polymer combination. A more recent variant utilizing a fully biodegradable drug-eluting polymer has also shown promising results [2].

The second-generation drug-eluting stents have undoubtedly reduced vessel injury and resulted in excellent clinical outcomes [3,4]. There are concerns, however, that the design elements contributing to high flexibility have also increased risk for mechanical compromise [5,6]. While the clinical significance remains inconclusive, the observations of longitudinal stent deformation with newer platforms have renewed the understanding that stent design and performance are, in essence, a study of compromise and balance.

This chapter begins with a brief discussion of the platinum-chromium alloy and then examines the role of stent architecture in the risk for longitudinal deformation. We present technical aspects of the platinum-chromium everolimus-eluting stents and several landmark trials evaluating their clinical performance.

Material properties and biomechanics of the platinum-chromium alloy

As with cobalt-chromium (CoCr) alloys, development of the platinum-chromium (PtCr) alloy was driven by the clinical need for stronger and denser materials than stainless steel. These materials

allow fabrication of thinner stent struts, which have repeatedly been shown to improve clinical restenosis outcomes [7].

In searching for new stent alloys, extensive analysis identified platinum as an ideal material partly because it is very soluble in stainless steel in the austenitic phase. That is, unlike many other materials, platinum stabilizes the iron-chromium matrix in a way that allows the further addition of platinum without development of brittle or magnetic phases [8]. Further testing of the PtCr alloy showed that 33% platinum content provided optimum characteristics for both ease of fabrication and stent biomechanics [9,10].

The success of the PtCr alloy derives, in part, from the fact that platinum largely replaces iron and nickel while maintaining adequate levels of chromium and molybdenum (Table 33.1). Certain elements such as chromium and molybdenum stabilize natural defects in the alloy's crystal structure through mechanisms such as solid-solution strengthening, grain refinement, and development of extremely strong metal carbides. Upon detailed analysis, PtCr alloy demonstrates a face centered cubic arrangement of atoms, fine grain crystals, and chromium carbides [8,10]. These characteristics contribute to high mechanical strength and fatigue resistance.

PtCr is significantly denser than stainless steel and the CoCr alloys, but its elastic modulus and tensile strength lie between the two. These properties have translated to the ability to fabricate thin struts (<100 μm) while maintaining necessary strength and radio-opacity. Additionally, compared with CoCr alloys, lower elastic modulus has contributed to less stent recoil [11,12]. In essence, materials with a high elastic modulus require a higher degree of deforming force to overcome the elastic limit in order to induce permanent deformation. Because CoCr alloys have a high elastic modulus, CoCr stents are theoretically at higher risk of recoil than PtCr and stainless steel stents given the same expanding force (Table 33.2). While this has been supported experimentally, however, the clinical relevance of this difference is unclear [12].

Biocompatibility: surface characteristics and resistance to corrosion

Stent corrosion and metal ion release into vascular tissues are increasingly viewed as contributors to vascular inflammation and perhaps even thrombosis [1,13,14]. In addition to mechanical

Table 33.1 Composition of platinum-chromium (PtCr) compared with stainless steel and cobalt-chromium (CoCr) alloys.

Alloy	Element composition (%)							
	Pt	Fe	Co	Cr	Ni	W	Mo	Mn
PtCr	33	37	–	18	9	–	2.6	0.05
SS (316L)	–	64	–	18	14	–	2.6	2
CoCr (MP35N)	–	1	35	20	35	–	10	0.15
CoCr (L605)	–	3	52	20	10	15	–	1.5

Table 33.2 Mechanical properties of PtCr compared with stainless steel and CoCr alloys.

Material	Density (g/cm ³)	UTS (MPa)	Yield strength (MPa)	Elastic modulus (GPa)
PtCr	9.9	834	480	203
316L	7.9	670	340	193
MP35N	8.4	930	414	233
L605	9.1	1000	500	243

UTS, ultimate tensile strength.

integrity of the stent platform, resistance to corrosion is primarily due to the formation of metal oxides at the stent surface. Certain surface oxides can act as a passive film reducing corrosion and metal ion release; chromium oxide is particularly resistant to corrosion [15]. Experimental data show that PtCr alloy preferentially forms chromium oxide over less effective iron and nickel oxides, likely because platinum has replaced these elements in the alloy [10,15].

In addition to corrosion resistance, biomaterial characteristics such as surface energy, potential, and texture are postulated to have a role in the propensity to induce thrombosis and inflammation. The precise molecular mechanisms of thrombosis and inflammation are outside the scope of the current discussion, but the process can be roughly conceptualized as a balance between thermodynamic, kinetic, and electrochemical factors that favor protein and cell deposition ultimately leading to coagulation and inflammation [16–26]. This balance is affected by the total energy of the system conscribed by the stent, vessel, and blood components [18,19].

Briefly, almost immediately upon device exposure to blood, a thin layer of protein and water are adsorbed onto the device surface. The deposited proteins undergo varying degrees of conformational change and denaturation depending on the surface characteristics of the device. The induced protein conformational changes expose different molecular binding domains that have varying affinity for other blood proteins. Protein adsorption and conformational changes that result in endothelial cell adhesion can protect against thrombosis and improve vascular healing. In contrast, protein adsorption and conformational changes that lead to

platelet activation and leukocyte adhesion ultimately predispose to thrombosis and inflammation [27].

Generally, blood-contacting materials with more stable surfaces tend to be less thrombogenic and inflammatory [24,28]. As a noble metal, the inert nature of platinum is also thought to contribute to the surface stability and biocompatibility of the PtCr stents [8,10]. Experimental observations show that platinum is present in relatively high quantities at the surface of PtCr stents [8,10]. Further biocompatibility studies demonstrate high rates of endothelial cell coverage and low rates of fibrin and platelet adhesion to PtCr stents [10,28–30]. Most recently, the OMEGA trial of the PtCr bare metal stent showed low rates of clinical restenosis and stent thrombosis (target lesion failure in 11.5% at 9 months, stent thrombosis in 0.6% at 12 months) [31], demonstrating *in vivo* biocompatibility comparable to or better than previous stainless steel and CoCr bare metal stents [32,33].

Longitudinal stent deformation and the role of stent architecture

Longitudinal stent deformation (LSD) refers to the elongation or shortening of a stent after deployment. Several mechanisms of LSD have been proposed, and most cases result from impingement of guidewires and secondary devices, or traction by deflated balloons caught on stent struts [34,35]. In other words, LSD is typically caused by the application of an external force resulting in mechanical distortion rather than spontaneous stent deformation. The majority occurs in the proximal region of stents [34]. Other risk factors associated with LSD include calcified and tortuous arteries, left main stenting, bifurcation stenting, small vessel diameter, longer lesions, and more stents, as these factors presumably increase the chance of guidewire impingement or balloon traction [36,37].

LSD appears to be extremely rare, having been discovered in less than 1% of deployed stents [35,37–41]. Given the rarity of LSD, the true incidence and clinical significance remain unclear. Whereas some studies have associated LSD with a higher risk of adverse events such as in-stent restenosis and stent thrombosis [34,42], other studies have found no correlation [35,40]. Similarly, some studies suggest that the PtCr stents are most commonly affected [35,38,40,41], but others show no particular susceptibility [39,43,44]. Several significant confounding biases have been proposed, most notably observer bias due to operators' heightened sensitivity to this complication, and detection bias due to the increased radio-opacity of platinum resulting in increased detection rates with these stents [34,38]. Nevertheless, a number of bench studies conducted thus far have elucidated factors in stent design that predispose the PtCr stents to longitudinal compromise [5,6,38,45].

In examining design factors contributing to LSD, it is worth considering the Promus Element (Boston Scientific, Natick, MA, USA), an early PtCr stent featuring 81 μ m struts and an offset peak-to-valley serpentine ring design. Widened peaks were designed to redistribute intra-stent forces to improve radial strength and longitudinal flexibility [11]. Adjacent rings were joined by two short longitudinal connectors angled at approximately $\sim 45^\circ$ from the longitudinal axis. These connectors together formed a secondary double helix structure along the length of the stent, purported to add another element of longitudinal flexibility (Figure 33.1).

Susceptibility to LSD is primarily because of the number of connectors between rings and the arrangement of rings. Bench tests suggest that stents with three or more longitudinal connectors per

Figure 33.1 Promus Element stent. Image provided courtesy of Boston Scientific. © 2016 Boston Scientific Corporation or its affiliates. All rights reserved.

ring are less susceptible to deformation than those with two connectors [5,6,45]. This makes sense as the connectors help maintain a constant distance between adjacent rings. Additionally, the alignment of the Element's connectors have made these stents particularly susceptible to torque exerted by guidewire impingement. Because the connectors were angled at $\sim 45^\circ$ from the longitudinal axis, applied force is redirected to the joint between the connector and ring thereby increasing susceptibility to compression [5,37].

The arrangement of rings also contributes to longitudinal integrity. In-phase or offset ring patterns easily nest together upon bending or compression, clearly increasing flexibility but also the risk of deformation [45]. In stents with an out-of-phase ring pattern, the peak-to-peak arrangement of struts acts like surrogate longitudinal connectors or welded points; that is, with a longitudinal compressive force the rings do not nest together and instead, the peaks abut against each another, reducing susceptibility to both diffuse and point compression.

While bench testing has elucidated important stent design factors and potential mechanisms of LSD, the clinical applicability of these results is still debatable. Furthermore, it still remains unclear whether the early PtCr stent platforms were definitively prone to longitudinal deformation. Regardless, documented observations of mechanical compromise have underscored the role of stent architecture in biomechanical performance. Minor design changes to the Promus Element that followed seem to have improved the longitudinal integrity of the PtCr stents [5], and large-scale trials suggest that these stents are, at the very least, non-inferior to the cobalt-chromium based stents [3,4,35,40].

Promus Element and Premier EES Platform

As previously described, the Promus Element (Boston Scientific, Natick, MA, USA) is based on the Omega bare metal PtCr platform, which features 81–86 μm struts (81 μm for 2.25–3.5 mm diameter and 86 μm for 4.0 mm diameter) and serpentine rings with two short longitudinal connectors per ring. These connectors are angled at approximately 45° relative to the longitudinal axis of the stent. The Element Plus is identical except for an updated balloon catheter delivery system.

Figure 33.2 Promus Premier stent. Image provided courtesy of Boston Scientific. © 2016 Boston Scientific Corporation or its affiliates. All rights reserved.

In response to concerns about longitudinal stent deformation, the Omega platform was modified and renamed the Rebel. This updated platform now has four connectors between the first and last two rings (Figure 33.2) and serves as the basis for the Promus Premier (Boston Scientific).

Polymer

The Promus Element and Premier stents have a biocompatible, durable polymer consisting of a poly n-butyl methacrylate (PMBA) primer and polyvinylidene fluoride-hexafluoropropylene (PVDF-HFP)-everolimus drug-eluting layer identical to the Xience V CoCr-EES (Abbott Vascular, Santa Clara, CA, USA). The total thickness of the polymer layer is approximately 7 μm . The biocompatibility and clinical performance of this drug-polymer combination has been demonstrated by numerous studies [46–50].

In brief, the excellent performance of this durable polymer lies in its completely saturated, partially fluorinated carbon-carbon backbone structure which results in a highly stable drug-eluting polymer resistant to oxidative breakdown and inflammatory response. The PVDF-HFP chemical structure also confers a high degree of surface stability, which may contribute to thromboresistance [24,51–53]. Lastly, the high flexibility of PVDF-HFP at body temperature (glass transition temperature for polymers) improves its resistance to peeling and cracking over the long term, further enhancing its durability and biocompatibility.

Drug

Everolimus is a partially synthetic analogue of sirolimus (rapamycin), a naturally occurring compound. These drugs function by binding FK-506 binding protein-12 (FKBP12) and inhibiting the mammalian target of rapamycin (mTOR), causing cytostatic G1-phase cell cycle

arrest. Some evidence suggests that everolimus can also selectively clear macrophages from atheromas, theoretically stabilizing vulnerable plaques [54].

Everolimus is more lipophilic than sirolimus, which increases local vascular uptake particularly into lipid-rich atheroma, and lowers systemic distribution. This has allowed the EES to contain a lower concentration of drug ($100\ \mu\text{g}/\text{cm}^2$). The polymer-drug formulation of the PtCr-EES results in approximately 30% drug release within the first 24 hours after implantation, leading to 80% release by 30 days and complete elution by 120 days.

Clinical trials

PLATINUM QCA

In PLATINUM QCA, 100 patients with a single de novo lesion treated with a single PtCr-EES stent had 30-day follow-up for clinical events, and later underwent repeat angiography and intravascular ultrasound (IVUS) at 9 months to evaluate in-stent late lumen loss (Table 33.3) [55]. The primary endpoint, 30-day composite of cardiac death, myocardial infarction (MI), target lesion revascularization (TLR), or ARC-defined definite or probable stent thrombosis, was 1.0% due to a single case of peri-procedural stent thrombosis. Coronary angiography at 9 months demonstrated an overall in-stent late lumen loss of 0.20 ± 0.28 mm, comparable to historical data for the CoCr-EES from SPIRIT I, II, and III [50,56,57]. Post-procedure IVUS imaging further demonstrated a low rate of acute incomplete stent apposition (ISA; 5.7% for PtCr-EES vs. 34.4% for CoCr-EES in SPIRIT III) and no persistent or late acquired ISA at 9 months (vs. 25.6% for CoCr-EES in SPIRIT III at 8 months) [55,57].

PLATINUM

The PLATINUM trial randomized 1530 patients to either the PtCr-EES or CoCr-EES [58]. The primary endpoint, target lesion failure (TLF) at 12 months, demonstrated no significant difference between the stents (PtCr-EES 3.4% vs. CoCr-EES 2.9%; $p_{\text{non-inferiority}} = 0.001$, $p_{\text{superiority}} = 0.60$). Intention-to-treat analysis further demonstrated no significant differences in 12-month rates of TLF (3.5% vs. 3.2%; $p = 0.72$), cardiac death or MI (2.0% vs. 2.5%; $p = 0.56$), TLR (1.9% vs. 1.9%; $p = 0.96$), or ARC-defined definite or probable stent thrombosis (0.4% vs. 0.4%; $p = 1.00$) [58].

Three-year results of the PLATINUM study demonstrated comparable clinical outcomes between the PtCr-EES and CoCr-EES, with similar rates of all-cause death (PtCr-EES 3.7% vs. CoCr-EES 4.3%; $p = 0.62$), cardiac death (1.2% vs. 1.9%; $p = 0.27$), MI (2.3% vs. 2.5%; $p = 0.81$), ischemia-driven TLR (3.5% vs. 4.9%; $p = 0.21$), and ARC-defined definite or probable ST (0.7% vs. 0.5%; $p = 0.76$) [59].

As an early pivotal trial, the PLATINUM study necessarily excluded complex patients, which may explain the low overall rates of clinical events compared with earlier studies of the CoCr-EES [60–62]. Nonetheless, this trial has demonstrated the clinical safety and efficacy of the PtCr-EES through at least 3 years.

PLATINUM Small Vessel and Long Lesions

More complex lesions were evaluated in the PLATINUM Small Vessel and Long Lesion trial [63]. The small vessel arm included 94 patients receiving a single 2.25 mm-diameter Promus Element stent for lesions in vessels with a reference diameter of 2.25–2.5 mm. At 1 year, the rate of TLR was 2.4%, considerably lower than historical data for small caliber Taxus Element (7.3%), BioMatrix Flex (9.6%),

and Xience V (5.1%) stents [64–66]. The rate of TLR continues to remain low through at least 2 years (2.5%), and preliminary 4-year data show a TLR of 3.6% [63,67].

Similarly, the PLATINUM long lesion arm evaluated 102 patients receiving a 38 mm stent for lesions 24–34 mm in length [63]. In this group the 1-year rate of TLR was 3.1%, similar to historical data for the Cypher (Cordis/Johnson & Johnson, Warren, NJ, USA) sirolimus-eluting stent (2.4%) and lower than for the Taxus Express (7.2%) and BioMatrix Flex (12.4%) [68,69]. At 2 years, TLR is 5.2% and preliminary 3-year results show a TLR rate of 6.2% [63,67]. Collectively, these findings demonstrate the long-term clinical safety and efficacy of the PtCr-EES in patients with long lesions and small vessel disease.

DUTCH PEERS

The DUTCH PEERS trial evaluated 1811 patients randomized 1 : 1 to the Resolute Integrity (Medtronic) CoCr zotarolimus-eluting stent or the Promus Element [40]. This study was particularly noteworthy for its minimal exclusion criteria and complex patient population: 20% of subjects presented with ST-elevation MI, 25% presented with non-ST-elevation MI, and 66% of lesions were complex (type B2/C). The primary endpoint of target-vessel failure at 1 year demonstrated no significant difference between stents (ZES 6% vs. EES 5%; $p_{\text{non-inferiority}} = 0.006$). Similarly, there was no significant difference in the rate of definite ST (ZES 0.3% vs. EES 0.7%; $p = 0.34$), and no ST occurred beyond 3 months [40].

In DUTCH PEERS, operators reported suspicion for longitudinal deformation based on visualization during angiography. Further evaluation of these selected cases showed that while LSD occurred in none of the Resolute Integrity stents and in 0.6% (9/1591) of Promus Element stents ($p = 0.002$), none of these cases of LSD were associated with adverse clinical events [40]. A systematic analysis of LSD was not undertaken in DUTCH PEERS, and several biases such as the higher radio-opacity of platinum stents preclude any conclusions about the risk of LSD with the Promus Element in this study.

HOST-ASSURE

The HOST-ASSURE trial randomized 3755 South Korean patients 2 : 1 to the Promus Element PtCr-EES or the Resolute (Medtronic) CoCr-ZES, respectively, with minimal exclusion criteria [35]. The primary endpoint, TLF at 1 year, was reached in 2.9% of PtCr-EES and 2.9% of CoCr-ZES patients ($p_{\text{non-inferiority}} = 0.0247$). The rate of definite or probable stent thrombosis at 1 year was low and showed no significant difference between stents (PtCr-EES 0.36% vs. CoCr-ZES 0.67%; $p = 0.229$). A systematic study of angiograms demonstrated a 0.21% incidence of LSD with PtCr-EES (7/2491 studies) whereas no LSD was observed with CoCr-ZES. Similar to other studies, however, these cases of LSD were not associated with adverse events at 1 year [35].

SCAAR

Analysis of clinical outcomes from the Swedish Coronary Angiography and Angioplasty Registry (SCAAR) has demonstrated the clinical safety and efficacy of the Promus Element stent in a large and unselected population [70]. This study compared the rates of restenosis and definite stent thrombosis among 13,577 first and second-generation DES implanted in 8375 procedures. At 1 year, the rates of restenosis and definite stent thrombosis were not

Table 33.3 Summary of clinical trials of Promus Element.

Trial	PtCr-EES versus:	Trial design	Selected inclusion/exclusion criteria	n	1° endpoint	Outcomes*	Conclusions
PLATINUM QCA	none	Prospective, single-arm	I: Single de novo lesion; silent, stable or unstable ischemia; RVD 2.25–4.0mm E: MI within 72 hours; elevated cardiac enzymes at PCI; unprotected LM lesions, CTO, bifurcation lesions, heavy calcification, ISR; thrombus, LVEF <30%	100	Composite of cardiac death, MI, TLR, definite or probable ST at 30 days	1°: 1.0% 2°: In-stent LLL at 9 months; 0.17 ± 0.25mm	The PtCr-EES demonstrates acceptable safety and efficacy through 12 months
PLATINUM	CoCr-EES (XV)	Prospective, randomized, single-blind	I: Up to two de novo lesions; RVD 2.5–4.25 mm, length ≤24mm E: AMI within 72 hours; LVEF <30%; ostial, LM, true bifurcation lesions; heavy calcification, thrombus, angulation, tortuosity	1530	TLF at 12 months	1°: 3.4% vs. 2.9%, P ^{superiority} = 0.60, P ^{non-inferiority} = 0.001	PtCr-EES non-inferior to CoCr-EES for TLF at 12 months; acceptable safety and efficacy with both stents
PLATINUM SV	none	Prospective, single-arm	I: Single de novo lesion; RVD 2.25–2.5 mm, length ≤28mm E: Acute or recent MI, LVEF <30%, CTO, LM lesions, bifurcation lesions, thrombus	94	TLF at 12 months	1°: 2.4% 2°: TLF at 2 years 4.7%	PtCr-EES shows low rate of TLF in small vessels; acceptable safety and efficacy in small vessels
PLATINUM LL	none	Prospective, single-arm	I: Single de novo lesion; RVD 2.5–4.25 mm, length 24–34mm E: Acute or recent MI, LVEF <30%, CTO, LM lesions, bifurcation lesions, thrombus	102	TLF at 12 months	1°: 3.2% 2°: TLF at 2 years 8.8%	PtCr-EES shows low rate of TLF in long lesions; acceptable safety and efficacy in long lesions
DUTCH PEERS	CoCr-ZES (R)	Prospective, randomized, single-blind	I: Treatment with only EES E: Limited exclusion criteria	1811	TVF at 12 months	1°: 5% vs. 6%; p = 0.42	Both stents are safe and effective in an all-comer population
HOST-ASSURE	CoCr-ZES (R)	Prospective, randomized, single-blind	I: Broad E: LVEF <25%	3755	TLF at 12 months	1°: 2.9% vs. 2.9%, P ^{superiority} = 0.98; P ^{noninferiority} = 0.0247	PtCr-EES non-inferior to CoCr-ZES for TLF at 1 year; LSD seen only in PtCr-EES but not associated with adverse clinical events
SCAAR	CoCr-EES (XP, XV), CoCr-ZES (E, R), SS-SES (C), SS-PES (TE, TL)	Observational	I: Treatment with DES E: None	13577 stents	Clinical restenosis and stent thrombosis at 12 months	Restenosis: 2.8% vs. 2.7% (all other DES) Stent thrombosis: 0.2% vs. 0.5% (all other DES)	PtCr-EES demonstrates similar rates of restenosis and stent thrombosis to all other DES combined

AMI, acute myocardial infarction; BMS, bare metal stent; C, Cypher; CD, cardiac death; CoCr, cobalt-chromium; CTO, chronic total occlusion; DAPT, dual antiplatelet therapy; E, Endeavor; EES, everolimus-eluting stent; ISR, in-stent restenosis; LLL, late lumen loss; MLV, Multi-Link Vision; PE, Promus Element/Premier; PES, pacitaxel-eluting stent; PtCr, platinum-chromium; R, Resolute; RI, Resolute Integrity; S, Synergy; SES, sirolimus-eluting stent; SS, stainless steel; ST, stent thrombosis; TE, Taxus Express; TL, Taxus Liberté; TLF, target lesion failure; TLR, target lesion revascularization; XP, Xience Prime; XV, Xience V; ZES, zotarolimus-eluting stent.

significantly different between the Promus Element and all other DES (restenosis, PtCr-EES 2.8% vs. 2.7%; stent thrombosis, PtCr-EES 0.2% vs. 0.5%). When compared with individual stents, however, the Promus Element showed significantly lower rates of restenosis and stent thrombosis than the Endeavor (Medtronic) ZES. Although LSD was not evaluated in this study, if it did occur with the Promus Element, it did not appear to significantly influence clinical events at 1 year [70].

Synergy EES

Platform

The platform of the Synergy (Boston Scientific) PtCr-EES has 74–81 μm struts (74 μm for 2.25–3.5 mm and 81 μm for 4.0 mm). The overall architecture of this stent is similar to the Rebel BMS, namely featuring an offset peak-to-valley ring arrangement, two short, angled longitudinal connectors in the body of the stent, and four connectors at the proximal and distal ends. Aside from thinner struts, the main alterations include reduced peak radius and less angled connectors, which collectively improve longitudinal strength.

Polymer

The Synergy employs a fully biodegradable poly-DL-lactide-coglycolide (PLGA) polymer applied to the abluminal surface of the stent with a maximum thickness of 4 μm . Compared with the Element and Premier stents, this formulation results in a greater than 50% reduction in the total weight of polymer used [11]. Spontaneous hydrolysis of the ester bonds of PLGA results in complete degradation to CO_2 and water by 4 months after implantation, leaving a bare metal stent in place.

Drug

Everolimus has demonstrated excellent safety and efficacy in its formulation for coronary stents. Combination with the PLGA polymer, however, results in a slightly different drug release profile than previous EES. The co-formulation of PLGA-everolimus used in the Synergy stent results in a burst of drug release in the first 7 days, leading to approximately 50% release in 30 days, 80% by 60 days, and nearly complete release by 90 days. Because of its lipophilic properties, everolimus is preferentially taken up by local vascular tissues and continues to be released from this tissue reservoir through 120 days post-implantation. *In vivo* porcine studies demonstrate that the Synergy-EES elicits vascular tissue responses similar to the Xience V and Promus Element, and is completely endothelialized by 30 days [30,71].

Clinical trials

EVOLVE I

The EVOLVE I first-in-human trial examined the early safety and efficacy of full-dose and half-dose Synergy EES compared to the benchmark durable polymer Promus Element (Table 33.4). In this trial 291 patients were randomised 1 : 1 : 1 to the Promus Element, Synergy, or Synergy reduced-dose stents and were subsequently followed for 30-day clinical events and 6-month angiographic measures [2]. The primary clinical endpoint was 30-day TLF, which occurred in 0, 1.1%, and 3.1% of patients in the Promus Element, Synergy, and Synergy half-dose, respectively; the rate of

TLF at 6 months was 3.1%, 2.2%, and 4.1%, respectively. The primary angiographic endpoint of 6-month in-stent late lumen loss demonstrated non-inferiority of both Synergy stents compared to the Promus Element (Promus Element: 0.15 ± 0.34 mm; Synergy: 0.10 ± 0.25 mm ($p_{\text{noninferiority}} < 0.001$), Synergy half-dose: 0.13 ± 0.26 mm ($p_{\text{noninferiority}} < 0.001$). These findings remained consistent even after adjustment for small but statistically significant differences in baseline reference vessel diameter. While the study was underpowered to detect significant differences in clinical outcomes, the overall the rate of clinical events remained low and similar between all three stents, with no cases of stent thrombosis over 6 months [2].

EVOLVE II

EVOLVE II randomized 1684 patients 1 : 1 to the Synergy or Promus Element Plus stents for treatment of stable CAD or NSTEMI [72]. Other inclusion criteria included ≤ 3 lesions in ≤ 2 vessels, lesions ≤ 34 mm in length and RVD 2.25–4 mm. Major exclusion criteria included STEMI, left main disease, chronic total occlusion, graft occlusion, and in-stent restenosis. The primary endpoint, 12-month TLF, was reached in 6.7% of Synergy patients versus 6.5% of the Promus Element Plus patients ($p = 0.83$, $p_{\text{noninferiority}} = 0.0005$). Similarly, no significant differences were observed for clinically indicated TLR (2.6% vs. 1.7%; $p = 0.21$) or definite or probable stent thrombosis (0.4% vs. 0.6%; $p = 0.50$) [72]. Overall, this study demonstrated that the Synergy stent is non-inferior to the Promus Element Plus for TLF at 1 year; other clinical measures show similar safety and efficacy between the stents in relatively uncomplicated disease. The EVOLVE II pharmacokinetic and diabetes substudies are ongoing.

BIO-RESORT TWENTE

BIORESORT TWENTE is an ongoing trial evaluating 3540 patients with minimal exclusion criteria. Patients are randomized 1 : 1 : 1 to the Synergy, Orsiro (Biotronik) thin-strut CoCr platform with degradable sirolimus-eluting PLLA polymer, and Resolute Integrity (Medtronic) CoCr platform with durable zotarolimus-eluting polymer [73].

Conclusions

Because of their deeply considered design, the platinum-chromium EES have demonstrated excellent overall safety and efficacy since their introduction. While the early Promus Element was hampered by concern over longitudinal deformation, larger studies suggest that this complication remains extremely rare and does not appear to be systematically associated with significant adverse clinical events. The subsequently redesigned Promus Premier has largely mitigated the risk for longitudinal compromise, and long-term clinical outcomes demonstrate continued safety and efficacy of these stents. Along with the CoCr-EES, these stents have taken their place as standard comparators against which new stents must be proven. Finally, the recent biodegradable polymer Synergy-EES has shown clinical outcomes comparable to the benchmark DES in early pivotal studies. Larger, longer-term studies in more complex patients are ongoing. Given the novelty and promise of fully biodegradable drug-eluting polymers, these results are awaited with anticipation.

Table 33.4 Summary of clinical trials of Synergy stent.

Trial	Synergyversus:	Trial design	Selected inclusion/exclusion criteria	n	1° endpoint	Outcomes*	Conclusions
EVOLVE I	Promus Element, Synergy 1/2-dose	Prospective, randomized, single-blind	I: Single de novo lesion; RVD 2.25–3.5 mm; length <28 mm E: Acute or recent MI; LM or bifurcation lesions; thrombus	291	Clinical: 30day TLF Angiographic: 6 month in-stent LLL	30 day TLF: PE 0% vs. Sy 1.1% vs. Sy½ 3.1% 6-mo LLL: PE: 0.15±0.34 mm Sy: 0.10±0.25 mm, P _{noninf} < 0.001 Sy½: 0.13±0.26 mm, P _{noninf} < 0.001	Synergy demonstrates noninferior angiographic efficacy to the Promus Element at 6 months; the rate of adverse clinical events was low
EVOLVE II	Promus Element Plus	Prospective, randomized, single-blind	I: ≤3 lesions in ≤2 vessels; RVD 2.5–4.0 mm; length <34 mm E: STEMI; LM or graft lesions; CTO; in-stent restenosis	1684	TLF at 12 months	6.7% v 6.5%; p = 0.83, P _{noninf} = 0.0005	Synergy noninferior to Promus Element Plus for TLF at 1 year; both stents demonstrate low rates of adverse clinical events at 1 year
BIO-RESORT TWENTE	Orsiro, Resolute Integrity	Prospective, randomized, single-blind	I: Broad E: Limited exclusion criteria	3540	TVF at 12 months	(Study ongoing)	(Study ongoing)

LLL, late lumen loss; PE, Promus Element stent; RVD, reference vessel diameter; STEMI, ST-elevation myocardial infarction; Sy, Synergy stent; Sy½, Synergy half-dose stent; TLF, target lesion failure; TVF, target vessel failure.
* All outcome data presented as Synergy stent versus comparator unless otherwise noted.

Metallic stents represent one of the most important steps for the treatment of coronary artery disease (CAD) and the second revolution in interventional cardiology after the introduction of plain old balloon angioplasty (POBA) by Gruntzig [1–3]. The long search for the ideal stent made some improvements along the way, sometimes by taking two steps forward and one step back, but today the question whether the ideal stent exists is still open.

The biodegradable vascular scaffold (BVS) technology represents one of the most interesting developments in the field of interventional cardiology in recent years, because in theory BVS yield the same results as metal stents but, by being completely resorbable in time, also carrying the exciting possibility of complete anatomic and functional “vascular restoration.” This phenomenon is a continuous process with three main phases: revascularization, reabsorption of the device, and restoration of vessel integrity and function [4]. Key steps in the biodegradable stent revolution, including the first-in-man results of magnesium [5,6] and poly-L-lactide (PLLA) stents [7,8], have been reported and future clinical trials will test whether “vascular restoration therapy” could provide greater durability of results following percutaneous coronary intervention (PCI). A growing number of studies is being published on this topic, and a large number of devices are being tested on humans.

The ABSORB BVS (Abbott Vascular, Santa Clara, CA, USA) is the most used biodegradable stent on the market, with more than 100,000 devices implanted in patients all over the world. However, only one randomized trial is available, the ABSORB II randomized controlled trial, which compared the ABSORB BVS with the Xience drug-eluting stent (DES) at 1 year [9].

ABSORB bioresorbable vascular scaffold

The device

The ABSORB BVS is constituted by a PLLA backbone covered by a 1:1 mixture of an amorphous matrix of poly-D, L-lactide (PDLLA) and the antiproliferative drug everolimus (100 $\mu\text{L}/\text{cm}^2$). PLLA is a semi-crystalline polymer consisting of crystal lamella (regions with high concentrations of polymer with crystalline structure) interconnected with random polymer chains forming an amorphous segment [10]. The first version of this scaffold (1.0), used in the ABSORB Cohort A study, had a crossing profile of 1.4 mm, strut thickness of 150 μm , and consisted of out-of-phase zigzag hoops

linked together by thin and straight bridges. This device had to be kept refrigerated at -20°C to ensure device integrity. The second generation (1.1), tested in Cohort B, can be stored at room temperature, has the same strut thickness but in-phase zigzag hoops linked by bridges (Figure 34.1) [11]. Also, the polymer has a lower hydrolysis (*in vivo* degradation) rate in order to improve the radial force of the device.

Several studies have reported similar performances with the Absorb 1.1 and the everolimus-eluting metallic stent in terms of acute gain and late lumen loss (LLL) [12]. Also, non-significant differences were recently found for acute absolute recoil when comparing Absorb BVS with Xience (0.20 ± 0.21 and 0.13 ± 0.21 mm, respectively; $p=0.32$), implying that both devices have similar radial strength [13]. Importantly, the higher conformability and flexibility shown by Absorb BVS contribute to less change in vessel geometry and curvature; these properties could finally restore a healthy balance between the shear stress and cyclic strain interplay, possibly resulting in restoration of vasomotor tone, late luminal enlargement with late expansive remodeling, and vessel compliance restoration [14–16].

The reabsorption process

The main chemical process responsible for *in vivo* molecular weight degradation of BVS is hydrolysis. The amorphous regions binding the crystallites are less packed and therefore water can penetrate more easily and start the process. The whole process of hydrolysis has five stages: hydration, depolymerization by hydrolysis (reduction of molecular weight), loss of mass (with scission of amorphous tie chains and subsequent loss of radial strength), dissolution of the monomer, and formation of carbon dioxide and water into the Krebs cycle, excreted through the kidneys or lungs [17]. The timing of the whole process is of paramount importance for its performance. The mechanical integrity and the absence of recoil should continue over a period of 6 months, during which time the biologic process of restenosis decreases (according to this, a permanent device would be possibly unnecessary beyond this time) [18]. Over time, the polymer is replaced by a provisional matrix made of proteoglycan and then by *de novo* connective tissue (Figure 34.2) [19].

The whole reabsorption process has also been demonstrated with the use of optical coherence tomography (OCT) and

qualitative assessment of BVS struts over time has been proposed as follows: preserved box, open box, dissolved bright box, and dissolved black box, in order of decreasing reflectivity (Figure 34.3) [20]. The OCT analysis performed within the ABSORB Cohort A study has shown that the complete absorption of the scaffold takes place up to 3 years from implantation [8]. After the reabsorption process, tissue adaptation seems to cause a cellular reorganization, which positively impacts on the key step of “vascular restoration” [20].

BVS implantation technique

The mechanical properties of the BVS substantially differ from metal stents and consequently the implantation technique differs slightly from the standard for metal stents. The Abbott Vascular elaborated a list of manufacturer’s advice according to which some steps are of paramount importance in order to achieve a safe and effective scaffold deployment: pre-dilatation of the lesion in all cases; slow scaffold expansion (increasing of 2 atmospheres every 5 seconds); treatment of bifurcation lesions is discouraged as well as post-dilatation, which is suggested only in case of unsatisfactory angiographic results. If post-dilatation has to be performed, balloons should be ≤ 0.25 mm larger than the nominal diameter of the Absorb scaffold; inflation pressure should remain in accordance with the characteristic of the balloon expandability to avoid unacceptable dilatation of the scaffold, which is 0.5 mm over the nominal value. Atherectomy, cutting balloon, or brachytherapy are also discouraged. Given these recommendations, BVS deployment still represents a delicate procedure where each step, such as

Figure 34.1 Absorb biodegradable vascular scaffold (BVS) structure and design (high-resolution microscope image).

accurate scaffold sizing, pre-dilatation, and post-deployment optimization, is extremely important.

The ABSORB program

The Absorb BVS has been supported by a robust, well-structured, international, investigator-sponsored (ABBOTT Vascular) program, designed to promote the clinical use of the Absorb BVS for the treatment of atherosclerotic vascular lesions (Table 34.1). The first-in-man study using BVS was the Absorb Cohort A study which enrolled 30 patients undergoing first generation (Absorb BVS 1.0) scaffold implantation for the treatment of single, not complex, lesions [9]. The 5-year clinical outcomes have been excellent, with 3.4% of major adverse cardiovascular events (MACE) mainly being myocardial infarction (MI) occurrence [21]. Subsequently, to enhance the mechanical strength of the struts and to reduce immediate and late recoil, the revised version BVS 1.1 was introduced and tested in the ABSORB Cohort B study [11]. It reported good clinical and imaging outcomes at 6 months on a larger population of patients ($n = 101$) for up to 3 years, with a MACE rate of 10.1% [22]. In order to build a body of evidence to support a broader utilization of the Absorb BVS, a prospective, single-arm, open-label clinical study (the ABSORB EXTEND) was designed [23]. The 1-year results were reassuring, with rates of 4.3% MACE, 2.9% MI, and 0.8% scaffold thrombosis (ST). To date, the 3-year follow-up data of 250 patients implanted with BVS in the ABSORB EXTEND study showed 9.3% cumulative MACE, with 6.0% TLR and 1.2% definite/probable ST rate [24]. Importantly, in the ABSORB EXTEND, as per study protocol (same for Cohorts A and B), left main and arterial or saphenous vein graft (SVG) lesions were excluded, as well as in-stent restenosis, totally occluded vessels, lesions treated with brachytherapy or Rotablator, lesions involving a bifurcation or ostial lesions. Also, lesions with excessive tortuosity, heavy calcification, or visible thrombus were not treated with the Absorb BVS. The same types of lesion have been treated in the first randomized study comparing metallic with fully biodegradable stents eluting the same drug (everolimus) [9]. The ABSORB II randomized controlled trial had a 2:1 single-blinded design with a sample population of 501 patients and a sophisticated quantitative computerized angiography (QCA) primary endpoint of nitrate-induced vasomotion and in-stent late loss at 3 years [9]. The 1-year clinical follow-up

Study	Study design	Stage	n ^a	Follow-up
ABSORB cohort A	Observational, prospective	Completed	30	5 years
ABSORB cohort B	Non randomized, open label	Completed	101	5 years
ABSORB EXTEND	Observational, prospective	Active, not recruiting	=1000	3 years
ABSORB II	Randomized, single blind	Active, not recruiting	330	3 years
ABSORB PHYSIOLOGY*	Randomized, single blind	Terminated	35	2 years
ABSORB FIRST	Observational, perspective	Recruiting	1800	2 years
ABSORB III	Randomized, single blind	Recruiting	1502	3 years
ABSORB IV	Randomized, single blind	Recruiting	3000	3 years
ABSORB Japan	Randomized, single blind	Active, not recruiting	265	3 years
ABSORB China	Randomized, open label	Active, not recruiting	200	2 years
ABSORB UK	Observational, prospective registry	Recruiting	100	3 years

* 1 patient recruited

^an=number of patients.

included an elaborated analysis of immediate results including QCA and IVUS data. In this trial, the Absorb scaffold did not show any significant difference on the primary endpoint compared with the Xience at 1 year; a lower cumulative rate of recurrent or worsening angina reported through adverse event forms was reported in the Absorb arm when compared with the Xience arm. However, final in-stent minimum lumen diameter and IVUS minimum lumen cross-sectional area were significantly smaller in the Absorb group than in the Xience group. Also of interest, there was a trend toward higher MI and ST in the Absorb arm (4.5% vs. 1.2%; $p=0.06$ for MI and 0.9% vs. 0.0%; $p=0.55$ for ST) [9, 25]. The B-SEARCH Registry by Simsek *et al.* [26] has to be mentioned here because it enrolled patients ($n=88$) from ABSORB Cohort A, Cohort B, and ABSORB EXTEND studies (thus, with same characteristics of lesion complexity); only one adverse event was recorded (non-target vessel revascularization) at 1-month follow-up. Of note, in order to test the performances of the Absorb BVS in more complex settings, some sub-studies involving ABSORB EXTEND population of patients were conducted, with interesting results [27–29]. Muramatsu *et al.* [27] analyzed 1209 side branches from 436 patients treated with BVS and found that scaffold implantation was associated with a higher incidence of post-procedural side branch occlusion compared with EES. Another study from Muramatsu *et al.* [28] evaluated the device-oriented composite endpoint (DoCE) at 1-year follow-up including cardiac death, target vessel MI, and target lesion revascularization, in a population of diabetic patients treated with BVS. They compared diabetic patients from ABSORB Cohort B and ABSORB EXTEND studies to diabetic patients treated with everolimus-eluting metal stents (EES) in pooled data from the SPIRIT trials, by applying propensity score matching. Diabetic patients treated with the BVS had a similar incidence of the DoCE compared with diabetic patients treated with EES in the matched study group (3.9% for the BVS vs. 6.4% for EES; $p=0.38$), with no differences in the incidence of definite or probable ST (0.7% for both diabetic and non-diabetic patients with the BVS; 1.0% for diabetic patients with the BVS vs. 1.7% for diabetic patients with EES in the matched study group).

Also interesting results come from a recent study by Diletti *et al.* [29], aiming to assess the impact of vessel size on long-term outcomes after Absorb BVS implantation in the Cohort B population of patients. At 2 years' follow-up, similar clinical and angiographic outcomes were reported in small and large vessel groups. Notably, a significant late lumen enlargement and positive vessel remodeling were observed in small vessels.

In summary, in the ABSORB program, Absorb BVS has shown very good safety and efficacy results in not complex lesions, even when compared with its metallic counterpart, Xience. Several studies are ongoing within the same program and will further evaluate this device in different populations of patients with different endpoints.

Registries

To date, taking into account published and ongoing studies, there are almost 30 “real-world” studies or registries using the Absorb BVS worldwide. For this reason, a huge and still accumulating number of data are being reported, justifying the interest of the interventional cardiology community. The GHOST-EU Registry has recently been published and is the first large multicenter international registry assessing the early and mid-term clinical outcomes of PCI with everolimus-eluting Absorb BVS [30]. The study involved 10 European centers, enrolling 1189 patients with 1731 Absorb BVS implanted. The percentage of type B2 or C treated

lesions (51%, according to the ACC/AHA classification) roughly represents a “real-world” scenario. The primary outcome, target lesion failure (TLF), defined as the combination of cardiac death, target vessel MI, or clinically driven target lesion revascularization (TLR), showed a cumulative incidence of 2.2% at 30 days and 4.4% at 6 months. Interestingly, the GHOST-EU Registry recorded a high 6-month ST of 1.5% and an annual ST of 2.1% (Table 34.1). Even higher ST rates were found in the “real-world” AMC Registry where 135 patients were included [31]. In this study, Kraak *et al.* [31] treated a real-world population of patients (62% of type B2 or C lesions) with both Absorb BVS and Xience DES, and reported a MI rate of 3.0% vs. 3.0%, respectively, while worse outcomes were observed for cardiac death (0.8% vs. 0%), TLR (6.3% vs. 3%), and ST (3.3% vs. 0%), the latter representing the higher 6-month rate of ST to date (3%). Interesting data come from two single-center studies evaluating the BVS performance in the highest setting of lesion complexity (both enrolling >80% type B2 + C lesions, according to the ACC/AHA classification) [32, 33]. The first study, by Costopoulos *et al.* [32], yielded 92 patient pairs (92 patients with 137 lesions treated with BVS and 92 patients with 124 lesions treated with EES), by propensity score matching. Clinical outcomes at 6 months were similar between the two groups with respect to TLR (3.3% vs. 5.4%; $p=0.41$) and MACE (3.3% vs. 7.6%; $p=0.19$). Importantly, the ST rate was 0% in both groups. Similarly, Mattesini *et al.* [33] performed the same comparison in 100 patients (50 treated with BVS and 50 with second-generation DES) presenting only with complex lesions (B2 or C in 100% of cases); they reported a low percentage of malapposed struts in both groups (BVS 2.1% vs. DES 2.4%), with 4% MACE and no ST.

A small number of “real-world” studies enrolling only patients with acute coronary syndrome (ACS) have been published to date, with interesting data from small populations of patients. The Prague 19 study by Kočka *et al.* [34], enrolling consecutive patients with ST-elevation MI (STEMI), compared 41 patients implanted with Absorb BVS with 57 patients who received a metal stent. Interestingly, in the BVS group, the study reported a lower percentage of diabetic patients (2.5% vs. 24.1%; $p=0.003$) but a higher percentage of manual aspiration thrombectomy (37.5% vs. 12.3%; $p=0.011$). The latter finding is of interest because the higher strut thickness of BVS should allow better entrapment of thrombotic material between the stent and the vessel, the “snow racket concept,” which is the main feature of this novel device [35, 36]. The Prague 19 study reported only two adverse events in the BVS arm, with only one ST (subacute) also documented at OCT (which was available for 21 patients). Diletti *et al.* [35] recently published the results of the BVS STEMI study, a prospective single-arm study enrolling patients with STEMI ($n=49$) undergoing BVS implantation. OCT imaging was also performed in 31 patients, revealing a low malapposition rate (seven scaffolds with >5% malapposed struts). The clinical outcomes at 1 month follow-up were excellent with only 2.6% MACE (one non-Q wave MI) and no ST. The largest study to date involving ACS patients by Gori *et al.* [37] reported results from 150 consecutive patients after BVS implantation, compared with 103 patients implanted with EES in the same time period. The 6-month MACE rate was similar between both groups (all $p>0.5$), but a high definite/probable ST rate was reported (2.7%), mostly acute and subacute. In two out of the three ST cases, authors found an incomplete expansion of the BVS at OCT as a possible explanation.

Recently, the EVERBIO II study design has been published [38]. This is a single-center, randomized study comparing three typologies of drug-eluting stents (the Absorb™, the Promus Element™, and

the Biomatrix Flex™) in a broader setting of lesions. The primary endpoint is in-stent LLL at 9 months as assessed by QCA; the secondary endpoints are divided into angiographic and clinical findings at up to 5 years' follow-up. A standard implantation technique was used for all devices and post-dilatation was performed in 36% of cases in the Absorb group. The 9-month results did not find any significant difference in LLL among devices, but in-segment LLL was significantly higher in the Absorb BVS than the EES/BES group (NCT01711931). The constrictive effect found by Gogas *et al.* [39] and the neointimal hyperproliferation at the scaffold proximal edge have been claimed as possible explanations [40]. The most recent published study enrolling patients with ACS, the RAI Registry, reported the 6-month outcomes from a population of 74 patients with STEMI, showing very high procedural success rate (97.3%) as well as low TLR and ST rates (4.1% and 1.3%, respectively). Of note, multiple overlapping BVS during primary PCI did not show any significant difference in clinical outcome when compared with single BVS implantation [41].

Intracoronary imaging guidance

IVUS

Several large studies have been published indicating that IVUS can be important for optimal DES stent expansion and lower malapposition rates in complex PCIs (multivessel disease and/or left main coronary artery stenting) [42], and its value has also been recognized in improving clinical outcomes after PCI [43–47]. A recent meta-analysis of more than 24,000 patients comparing IVUS with angiography-guided PCI outcomes showed lower rates of all-cause mortality, MI, target vessel revascularization, and ST in the IVUS-guided group [48]. Interestingly, OCT has been extensively used throughout most of the ABSORB program studies; however, given the wide availability of IVUS-guided PCI clinical data and the presence of standardized criteria for optimizing stent implantation, IVUS still represents a widely used tool for intracoronary imaging trials [49].

Optical coherence tomography

OCT is an established tool for the diagnosis and treatment of coronary lesions; its utility in improving clinical outcomes of patients undergoing PCI has been demonstrated [50]. This technology allows better visualization of both struts and the vessel wall, with an axial resolution 10-fold higher (14 μm) than IVUS, thus allowing better identification of stent failure (e.g., stent malapposition, dissection, tissue protrusion, and thrombus). However, OCT is not able to measure plaque burden because of its shallow penetration depth (1–2 mm) [51].

A recent study by Allahwalla *et al.* [52] reported that despite achieving angiographic success in all BVS implantations, further optimization was required in over one-quarter of patients on the basis of OCT findings. Although a comprehensive consensus document has been developed for acquisition, measurement, and reporting of intravascular optical coherence [53], whether IVUS criteria for optimal stent placement can be translated to OCT-guided stent implantation is still unknown. Notwithstanding these limitations, OCT is currently considered the “gold standard” imaging technique for the evaluation of biodegradable scaffolds; in fact, the BVS allows the assessment of the vessel wall behind the struts without the usual shadowing of metallic struts as seen in OCT analysis [54]. As a result, the use of OCT for BVS deployment has been widely accepted, and has contributed significantly to the

knowledge of the Absorb BVS characteristics and its interplay with the coronary wall [8,54]. OCT is especially recognized as an essential tool for the optimization of BVS in complex lesions such as bifurcations [55,56]. Looking at the most recent data, possible explanations of results from BVS “real-world” studies could also be reached for the use of intracoronary imaging guidance.

In conclusion, intracoronary imaging with IVUS and OCT is a useful tool in guiding BVS implantation, and the two modalities seem to be complementary. While IVUS could be more helpful for the evaluation of the plaque morphology and in the preparation phase, OCT allows better qualitative scaffold analysis and follow-up evaluation. Overall, both technologies ensure reliable lumen and scaffold measurements.

Clinically tested bioresorbable vascular scaffolds

During the long hunt for the ideal bioresorbable stent several attempts have been made. However, only a few of the proposed devices have been clinically tested on humans and an even smaller number have been clinically safe and effective enough to be commercialized. In this section we provide an overview of those BVS clinically tested in humans (Figure 34.4).

Igaki-Tamai Stent

The Igaki-Tamai PLLA coronary stent was the first fully bioresorbable stent to be implanted in humans, with complete degradation taking 18–24 months. The stent has a helical zigzag design, which differs from previous knitted formats. This results in less vessel wall injury during implantation and therefore less initial thrombus formation and reduced intimal hyperplasia [57]. The stent is mounted on a standard angioplasty balloon and is both self-expanding thermally and by balloon. Self-expansion occurs in response to heating the PLLA, which is achieved by the use of heated contrast (up to 70°C) to inflate the delivery balloon. Stent expansion is further optimized by inflating the delivery balloon to 6–14 atm for 30 seconds, and the nominal size of the stent is achieved by continued self-expansion at 37°C in the 20–30 minutes after stent deployment. The stent has a standard length of 12 mm and is available in diameters of 3, 3.5, and 4 mm; the stent strut thickness is 0.17 mm. An 8-Fr guiding catheter is required because the stent is initially constrained by a sheath that is removed once it crosses the lesion. At either end of the stent, to aid visualization, are two radiopaque cylindrical gold markers.

The first-in-humans study of the Igaki-Tamai stent (15 patients, 19 lesions, 25 stents) demonstrated no MACEs or ST within 30 days and 1 repeat PCI at the 6-month follow-up. Encouragingly, the loss index (late loss/acute gain) was 0.48 mm, which was comparable to BMS, and demonstrated for the first time that BRS did not induce an excess of intimal hyperplasia. Furthermore, IVUS imaging demonstrated no significant stent recoil at day 1, and continued stent expansion was observed in the first 3 months of follow-up [58].

A second, larger study of 50 elective patients (63 lesions, 84 stents) also showed promising results. IVUS performed at the 3-year follow-up demonstrated the complete absence of stent struts, and angiographic analysis demonstrated a mean diameter stenosis of 25% compared with 38%, 29%, and 26% at 6, 12, and 24 months, respectively. Clinical outcomes at 4-year follow-up showed rates of overall and MACE-free survival of 97.7% and 82.0%, respectively [59].

Figure 34.4 Structures and designs of clinically tested BVS: (a) DESolve, (b) Igaki Tamay, (c) AMS, (d) Rezolve.

Despite these impressive results, the failure of the stent to progress was related primarily to the use of heat to induce self-expansion. There were concerns that this could cause necrosis of the arterial wall, leading to excessive intimal hyperplasia or increased platelet adhesion, leading to ST [60]. None of these concerns were substantiated in the initial studies; however, only low-risk patients were enrolled. After completion of the Biodegradable peripheral Igaki-Tamai stents PERSEUS study [61], the stent became available in Europe for peripheral use, but so far it is not available for coronary use.

Tyrosine polycarbonate: REVA stent

The REVA stent (Boston Scientific, Natick, MA, USA) is a tyrosine poly (desaminotyrosyltyrosine ethyl ester) carbonate stent that is both resorbable and radio-opaque after the chemical modification of tyrosine to incorporate iodine molecules. The polymer degrades into water, carbon dioxide, and ethanol; in addition, tyrosine is metabolized by the Krebs cycle. The resorption time of the stent is dependent on the mass of the polymer, with reported times of 18 or 12 months for the high- and low-molecular weight polymers, respectively. In addition to its radio-opacity, the REVA stent also has a distinctive slide-and-lock design that provides both flexibility and strength. During the deployment of a standard deformable stent, significant strain is concentrated at hinge points; the consequence of straining a polymer beyond its yield point is a significant loss of mechanical strength. The slide-and-lock design eliminates hinge points and therefore minimizes polymer strain by 75% over a wide range of deployment diameters, thereby preventing deformation and weakening of the polymer during stent deployment. The locking mechanism maintains the acute lumen gain after stent deployment and provides additional support to the stent during

vessel remodeling. Company data report negligible recoil and a radial force that is superior to the Multi-Link Vision BMS (Abbott Vascular, Santa Clara, CA, USA) [62].

The multicenter first-in-human clinical study of the REVA stent, the REVA Endovascular Study of a Bioresorbable Coronary Stent (RESORB) study, enrolled 30 patients from June 2007. The study was designed to evaluate the safety of the stent in de novo lesions 12 mm in length and 3.0–3.5 mm in diameter. The primary endpoint was MACE at 30 days; the secondary endpoint was IVUS and QCA-derived parameters at the 6-month follow-up. Follow-up at 6 months showed the absence of any significant vessel recoil as indicated by the external elastic lamina, which went from 15.5 ± 4.0 to 15.3 ± 3.1 mm². Unfortunately, focal mechanical failures driven by polymer embrittlement led to a higher-than-anticipated rate of TLR (66.7%) at 4–6 months' follow-up [63].

Redesign of the stent has ensued, resulting in the second-generation ReZolve (Rezolve2) stent. This stent has a more robust polymer, a spiral slide-and-lock mechanism to improve clinical performance, and a coating of sirolimus. ReZolve2 is a lower profile and sheath-less version of the first-generation ReZolve scaffold and offers significantly improved deliverability and an approximate 30% increase in scaffold strength to provide increased support to significant coronary artery lesions before being resorbed by the body. REVA began implanting ReZolve2 in patients in March 2013. So far no results are available in literature.

Poly (anhydride ester) salicylic acid: IDEAL stent

The IDEAL biodegradable stent (Bioabsorbable Therapeutics Inc, Menlo Park, CA, USA) consists of a backbone of polyanhydride ester based on salicylic acid and adipic acid anhydride and an 8.3- μ g/mm coating of sirolimus, potentially giving the stent both

anti-inflammatory and antiproliferative properties. The vascular compatibility and efficacy of this biodegradable salicylate-based polymer have previously been demonstrated in the porcine model. Most notably, the polymer was associated with reduced inflammation compared with a standard BMS and Cypher stent [64]. This was very likely because of the anti-inflammatory properties of salicylic acid following absorption by the vessel wall after its release. Drug elution was found to be complete after 30 days, and complete stent degradation occurred over a 9- to 12-month period. The 8-Fr compatible, balloon-expandable stent is radio-opaque and does not require any special storage.

In July 2009, the 11 patients enrolled in the multicenter first-in-humans Whisper trial completed their 12-month follow-up. Primary results have shown stent safety and confirmed structural integrity of the stent with no evidence of acute or chronic recoil. Unfortunately, insufficient neointimal suppression has been demonstrated [65]. This is likely to be the consequence of inadequate drug dosing, particularly considering that the surface area dose of sirolimus is only one-quarter of that found on the Cypher stent. The rapid elution of sirolimus may also be a contributing factor.

A second-generation stent has been developed with a higher dose of sirolimus and a slower drug release pattern. Furthermore, the stent design has been optimized, which has resulted in a reduced crossing profile (6-Fr compatible) and thinner struts (175 μm). Although the program was on hold in early 2009, there are no results available in literature yet.

The DESolve scaffold

The DESolve Myolimus-Eluting Bioresorbable Coronary Scaffold System (Elixir Medical Corporation, Sunnyvale, CA, USA) is a PLLA-based polymer scaffold coated with the antiproliferative drug myolimus mounted on a rapid exchange balloon catheter delivery system. The DESolve scaffold is formed using proprietary techniques from a bioresorbable polylactide-based polymer with strut thickness of 150 μm and incorporates two platinum-based radio-opaque markers at either end to aid in placement. The scaffold is coated with a matrix of polylactide-based polymer and myolimus at a 3 mg/mm dose; more than 85% of the drug is released over 4 weeks. The system has a crossing profile of 1.47 mm and is 6-Fr catheter compatible. The scaffold is designed to resorb in about 1 year. The degradation process of PLLA-based polymers occurs primarily by hydrolysis and is metabolized *in vivo* via the Krebs cycle into carbon dioxide and water [66]. Important differentiating features of the DESolve scaffold include:

- 1 Its ability to self-correct to the vessel wall in cases of minor malapposition when expanded to the nominal diameter, which is accomplished using a proprietary processing technique;
- 2 The ability of the scaffold to maintain radial strength and vessel support for the critical 3- to 4-month period of vessel healing [67] while subsequently resorbing in about 1 year;
- 3 A wide safety margin for expansion where a 3.0-mm scaffold can be expanded to 4.5 mm in diameter without strut fracture.

Pre-clinical *in vivo* test results assessing the bioresorption profile of the DESolve scaffold using molecular weight measurements by gel permeation chromatography have demonstrated bioresorption of the DESolve scaffold with molecular weight reduction of >95% takes about 1 year.

The first-in-man trial assessing the safety of the DESolve scaffold has been recently published [68,69]. The study enrolled 16 patients with simple lesions (<12 mm). Acute procedural success was

achieved in 15 of 15 patients receiving a study scaffold. At 12 months, there was no scaffold thrombosis and no MACE directly attributable to the scaffold. At 6 months, in-scaffold LLL (by QCA) was 0.19 ± 0.19 mm; neointimal volume (by IVUS) was $7.19 \pm 3.56\%$, with no evidence of scaffold recoil or late malapposition. Findings were confirmed with OCT and showed uniform, thin neointimal coverage (0.12 ± 0.04 mm). At 12 months, multislice computed tomography demonstrated excellent vessel patency.

The DESolve scaffold has been available in Europe since the beginning of 2014. To the best of our knowledge so far there are no data available from the aforementioned first-in-man trial.

Interactive multiple choice questions are available for this chapter on www.wiley.com/go/dangas/cardiology

The Biolimus Stent Family

Anna Franzone, Raffaele Piccolo, and Stephan Windecker

Department of Cardiology, Bern University Hospital, Bern, Switzerland

Biolimus

Chemical features and properties

The Biolimus peculiar chemical structure ($C_{55}H_{87}NO_{14}$, molecular weight 986.29 Da) consists of a 31-membered triene macrolide lactone that preserves the core sirolimus ring structure with a 2-ethoxyethyl group addition to the hydroxy group at position C(40) of the sirolimus molecule. The modification at position 40 of the rapamycin ring confers higher lipophilicity (approximately more than 10-fold) than sirolimus (Figure 35.1). As a consequence, it attaches more rapidly and enters the smooth muscle cell (SMCs) membranes in the coronary vessel wall and inhibits their proliferation. In the STent Eluting A9 BioLimus Trial in Humans (STEALTH PK) study, blood levels of Biolimus were measured through a liquid chromatography–tandem mass spectrometry assay in 27 moderate to high risk patients, 28 days and 6 months after receiving the BioMatrix stent. The highest measured blood concentration at any time point was 394 pg/mL. At 28 days following stent placement, 51.8% of patients had Biolimus concentrations less than the lower limit of quantitation (LLOQ; 10 pg/mL). Drug concentrations in the blood samples collected after 3 and 6 months were not detectable. At 9-month follow-up, no adverse events possibly, probably, or definitely related to Biolimus were reported [1].

The drug acts through the binding to an intracellular immunophilin, the FK506-binding protein 12 (FKBP12), which is upregulated in human neointimal SMCs [2]. The FKBP12–rapamycin complex, in turn, binds to a specific cell cycle-regulatory protein, the phosphoinositide 3-kinase mammalian target of rapamycin (mTOR), and inhibits its activation. mTOR is involved in crucial steps of cell proliferation, because it regulated the transition from the G_1 to S phase of the cell cycle [2]. It acts by phosphorylating a number of key proteins including those associated with protein synthesis (p70s6kinase) and initiation of translation (phas-1). The inhibition of mTOR is ultimately associated with a cytostatic effect with the arrest of the cell cycle in the late G_1 phase (Figure 35.2).

The Biosensor stent family

Biosensor International has pioneered the use of the Biolimus within a biodegradable-polymer coated device, the BioMatrix stent. Changes of the metal platform and/or the delivery system compared

with the first BioMatrix stent generated three new devices: BioMatrix Flex, BioMatrix NeoFlex, and Axxess (a bifurcation-dedicated stent). Moreover, a polymer-free Biolimus-eluting stent (BES; the BioFreedom) has also been launched (Figure 35.3).

In the BioMatrix, BioMatrix Flex, and BioMatrix NeoFlex, Biolimus is immersed at a dose of 15.6 $\mu\text{g}/\text{mm}$ into the biodegradable L-poly-lactic acid (PLA) polymer. This is a synthetic polymer (aliphatic polyester) obtained from processing and polymerization of lactic acid monomers. Its degradation occurs within 6–9 months, primarily by hydrolysis and through two stages: (i) a non-enzymatic chain scission of the ester groups leads to a reduction in molecular weight; and (ii) the low molecular weight oligomers are metabolized by microorganisms in carbon dioxide and water through interaction with the Krebs cycle [3]. PLA acts by protecting the drug from contacts with body substances that could modify its chemistry before reaching the targeted area and by controlling the concentration of active ingredient release. The high drug-carrying capacity of PLA results in a significant reduction of the amount of carrier polymer used as compared with durable coatings of the first generation drug-eluting stent (DES; 225 vs. 1227 μg for the paclitaxel-eluting (PES) Taxus stent and 301 for the sirolimus-eluting (SES) Cypher stent).

PLA and Biolimus are mixed in a 1 : 1 ratio to create a 10- μm thick matrix that covers solely the abluminal surface of the stents. This asymmetrical coating allows a targeted drug release that attains directly in the surrounding coronary wall with limited systemic exposure. These stents differ in the specific metal platform and the delivery catheter.

The BioMatrix stent consists of the S-Stent™ Platform that is made of a 316 low carbon vacuum melt (LVM) stainless steel, laser-cut, tubular stent with 16.3–18.4% metal surface area, a strut thickness of 112 μm , and coated with a layer of parylene C that serves as primer for the adhesion of the matrix to the stent surface. The coating formulation is applied to the stent via an automatic micropipette coating process. The stent is pre-mounted on to a high pressure, semi-compliant rapid exchange balloon delivery system available in six and nine cell models. The delivery catheter has two radio-opaque markers, which fluoroscopically mark the ends of the stent to facilitate its proper placement. The typical platform with corrugated ring and Quadrature Link™ design combines high flexibility and deliverability with adequate support and scaffolding.

Figure 35.1 Chemical structure of Biolimus. The replacement of hydrogen by alkoxy-alkyl group at C(40) position of the sirolimus structure provides higher lipophilicity and peculiar pharmacokinetic properties.

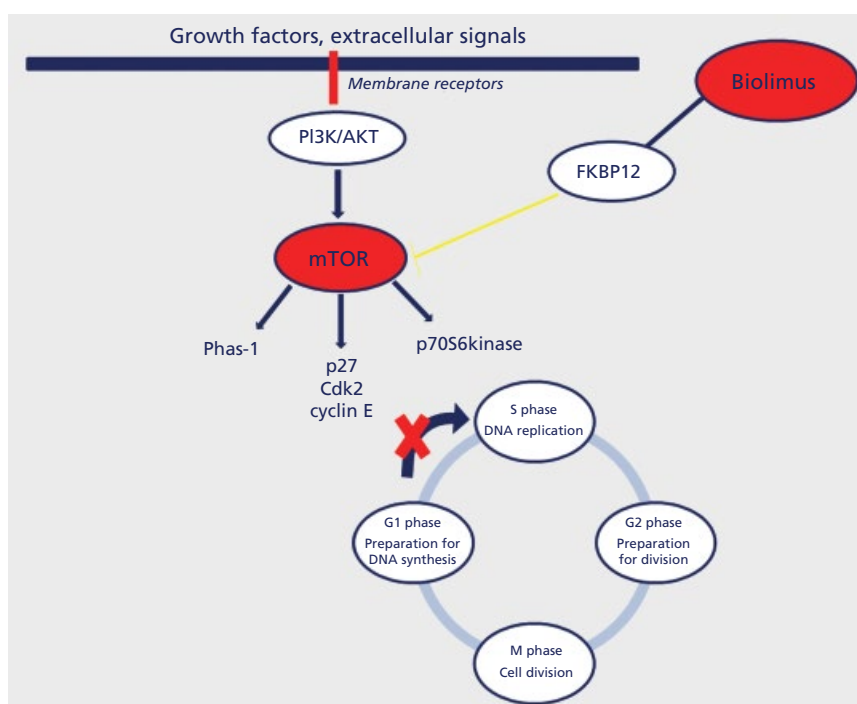

Figure 35.2 Mechanism of action of Biolimus. The cytostatic effect (arrest of the cell cycle in the transition from phase G1 to phase S) is achieved through the FKBP12-mediated inhibition of mammalian target of rapamycin (mTOR).

The BioMatrix Flex (Conformité Européenne (CE) marked in 2010) has a modified platform design, the Juno™ Stent Platform, in which a curved strut connector (radius-shaped) substitutes the straight connector of the existing platform. Moreover, its additional features include a larger initial cell opening than the original (improving side branch accessibility), an increased between struts difference (1.47–1.56 mm), and the absence of a primer coating (parylene C) to adhere the polymer and drug to the stent.

The BioMatrix NeoFlex was launched in 2013 and presents superior trackability, crossability, and pushability as consequence of an additional improvement of the delivery system (lower lesion entry profile). It also features a further improvement of the Quadrature link design of the platform with a novel “S-shaped” connector link.

The AXXESS stent is a self-expanding, bifurcation dedicated device, CE marked in July 2010. It has a nitinol (nickel-titanium alloy) platform with a conical shape (flared distal diameter) and a

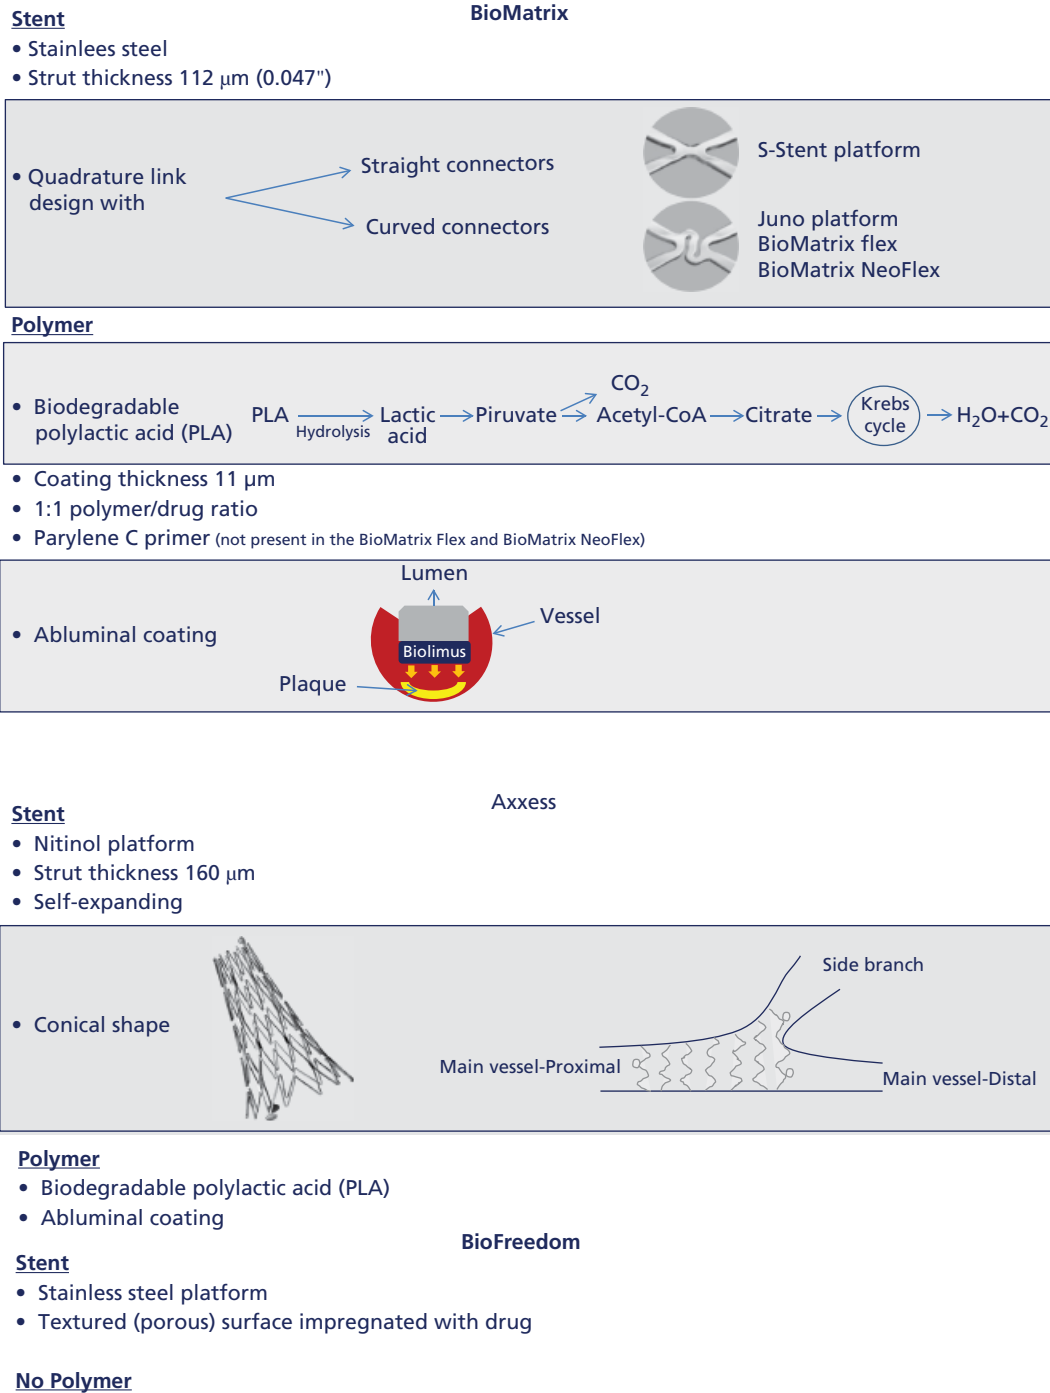

Figure 35.3 The main components of the Biosensor International Biolimus-eluting stents.

strut thickness of 0.16 mm and is specifically designed to conform to anatomy at the level of the bifurcation carina (up to an angle of 70°). Hereto, the device can accommodate vessels of 3.0–4.25 mm diameter, and is available in three different lengths (9, 11, and 14 mm). The stent elutes Biolimus at a concentration of 22 μg/mm of stent length.

The deployment requires a 7-Fr approach and is made easier through four highly visible radio-opaque markers, three located at the tip of the stent and the fourth pointing the proximal edge of the

stent. The crimped stent is contained in a cover sheath. Before definite deployment, stent position can be further adjusted as long as the cover sheath contains more than half of the stent length and the radio-opaque markers can be used to control the retrieval of the stent by the sheath. Pre-dilatation of main vessel and side branch (using one of the standard bifurcation techniques) is highly recommended for tight lesions and calcified vessel segments as it can facilitate lesion crossing and optimal distal flaring at the carina site. After the AXXESS stent is implanted, additional stents can be

placed through it in the distal main branch and/or distal side branch to achieve an acceptable angiographic result. Final high pressure and kissing balloon inflations are recommended in this overlap region, while avoiding vessel damage outside the stent edges.

A specific version of the AXCESS System has been designed for left main coronary artery (LMCA) bifurcation lesions, allowing for larger diameters (up to 4.75 mm) and distinct bifurcation angles (flare-end diameters of 8, 10, and 12 mm).

The BioFreedom drug-coated stent (DCS; CE approved in 2013) consists of a stainless platform with a micro-structured abluminal (outer) surface which allows the controlled release of Biolimus without the use of a polymer. The drug is harbored in crevices on the abluminal surface and almost completely (98%) transferred to the vessel wall within 28 days.

Clinical evidence

Table 35.1 provides an overview of the studies investigating the performance of the Biosensor International BES.

BioMatrix

Registries and non-randomized studies The STEALTH PK study was designed to specifically assess the pharmacokinetics of Biolimus after elution from the BioMatrix stent.

The Biolimus Eluting A-9 Coronary Stent Obviating Luminal Narrowing I (BEACON I) was a prospective registry compiled in multiple centers in Asia. It included 443 patients (602 lesions) with de novo or restenotic native coronary artery lesions treated with the BioMatrix stent. The primary endpoint was target vessel revascularization (TVR) at 6 months, and secondary endpoints included major adverse cardiac events (MACE; defined as composite of death, coronary artery bypass graft (CABG), Q-wave and non-Q-wave myocardial infarction (MI), and TVR) at 30 days, 6 months, and 12 months. The 30-day MACE was 3.5% with no events of new revascularization. At a median follow-up of 7.2 months, the MACE rate was 5.2% including 0.9% TVR and 0.2% target lesion revascularization (TLR) [4].

The BEACON II was a prospective, observational registry assessing clinical outcomes in real world, all-comers patients (n=497) receiving the BioMatrix stent at the site of native coronary artery or saphenous vein graft (SVG) lesions (with the exception of protected or unprotected left main) in Asia-Pacific countries. The primary endpoint was the 12-month rate of MACE, defined as a composite of cardiac death, MI, and ischemia driven-TLR. Key secondary endpoints included ischemia-driven target lesion failure (TLF) and TLR at 12 months; rates of MACE and definite stent thrombosis (ST) up to 5 years. In a total number of 742 target lesions (mean target lesions per patient 1.49 ± 0.74), 31% were longer than 20 mm, 24% showed moderate-severe calcification, and 14% were bifurcation lesions (side branch >2 mm). Device success (defined as achievement of a final residual in-stent diameter stenosis of $<30\%$) was 98.5%; lesion success (defined as attainment of $<30\%$ in-stent residual stenosis of the target lesion using any percutaneous method) was 98.7% and procedural success (defined as achievement of device success without the occurrence of in-hospital MACE) was 97.8%. MACE rate at 4-year follow-up was 9.4%. Definite very late stent thrombosis (VLST) events were rare (0.4%) and specifically none of these events occurred in patients receiving the BioMatrix stent in native coronary arteries [5,6].

The e-BioMatrix Registry was a prospective, multicenter, observational registry designed to assess outcomes in 5472 all-comers patients treated with either the BioMatrix or the BioMatrix Flex

stent across 57 European sites between April 2008 and August 2011. Criteria for inclusion were age >18 years and implantation of one of the BioMatrix family DES (any size, any vessel) without limitations of the number of treated lesions, vessels, or lesion length. Approximately 50% of patients presented with acute coronary syndrome (ACS). Patients were excluded if additional stents (different from the study stent) were used or if any lesions were treated with other techniques (e.g., stand-alone balloon angioplasty, atherectomy). The primary endpoint was the incidence of MACE at 12 months, defined as a composite of cardiac death, any MI, and clinically indicated TVR. Pre-defined secondary endpoints included the individual components of the primary endpoint, ST, major bleeding, and MACE at 24 months. The registry had two components: the e-BioMatrix PMS (Post-Marketing Surveillance) and the e-BioMatrix PMR (Post-Marketing Registry), which differ only with regard to the level of source data verification. The PMS registry collected all baseline data, all MACE, ST, and bleeding events through a monitoring system; the PMR registry monitors only cardiac-related events. The overall incidence of MACE was 4.5% (cardiac death 0.9%, MI 1.7%, clinically indicated TVR 2.8%) at 12 months and 6.8% at 24 months (cardiac death 1.5%, MI 2.4%, clinically indicated TVR 4.3%). Rate of definite or probable ST was 0.6% at 12 months and 0.2% between 12 and 24 months; the majority of such events occurred within the first 30 days (58.5%) and in patients still on dual antiplatelet therapy (DAPT). Despite its low incidence, ST was associated with high 24-month mortality (27.5%). Major bleeding occurred in 1.7% of patients at 12 months and 0.4% at 12–24 months with a mortality rate of 9.1%. Contrary to 12-month observations, comorbidities (as expressed by the Charlson index) were found independent predictors of MACE at 21 months by multivariate analysis [7,8].

The e-BioMatrix registry family also include arms enrolling patients treated with the BioMatrix in non-European countries. The e-BioMatrix India aims to evaluate the 2-year clinical safety and efficacy outcomes in 1189 patients (1418 lesions) prospectively enrolled between December 2008 and February 2012. An interim analysis involving 987 patients showed a 12-month incidence of MACE and ST of 0.45 and 0.2 per 100 person-years, respectively. No case of ST was reported among the 37% of patients who completed the 2-year follow-up [9]. A subgroup analysis showed comparable clinical outcomes among patients with diabetes mellitus (n=485) with a MACE rate of 0.62% and a single case of probable ST reported [10].

Asia-Pacific registries also include single-center experiences from Thailand and Indonesia confirming satisfactory early angiographic performance of the BioMatrix stent and mid-term clinical outcomes in more than 400 patients [5].

Randomized studies (Figure 35.4)

BioMatrix vs. bare metal stent The STEALTH I trial was a first-in-man, multicenter, prospective study assessing the safety and efficacy of the BioMatrix stent. It randomly assigned, in a 2 : 1 ratio, 120 patients with single de novo lesions, undergoing percutaneous coronary intervention (PCI), to receive the BioMatrix Stent (n=80, 82 lesions) or the control Gazelle S-Stent (n=40, 40 lesions), a bare metal stent (BMS) with identical design. The angiographic primary endpoint, in-lesion late lumen loss (LLL) at 6-month follow-up, was significantly reduced in the BioMatrix group (0.14 ± 0.45 mm) compared to the control group (0.40 ± 0.41 mm; $p=0.004$). A significant reduction of the in-stent LLL was also reported (0.26 ± 0.43 vs. 0.74 ± 0.45 mm; $p < 0.001$). Binary restenosis rates were low in both

Table 35.1 Overview of clinical studies with the Biosensor International Biolimus-eluting stents.

Study name [ref], year (results available)	Design	Country	Patients	Setting	Planned follow-up	Primary endpoint	Status
BioMatrix							
STEALTH PK [1], 2011	Single Arm Registry	Europe	27	Stable CAD	1 year	Systemic concentrations of Biolimus at 28 days and 6-months	Completed
BEACON I [4], 2006	Single Arm Multicenter Registry	Asia	292	Stable CAD and UA	1 year	TVR at 6 months	Completed
BEACON II [5,6], 2012	Single Arm Multicenter Registry	Asia-Pacific	497	Stable CAD and UA	5 years	MACE* at 12 months	4-year FU completed
e-BioMatrix [7,8], 2015	Single Arm Multicenter Registry	Europe	5000	Stable CAD and ACS	5 years	MACE† at 12 months	2-year FU completed
STEALTH I [12,13], 2005	Randomized Multicenter BioMatrix vs. Gazelle BMS	Europe South America	120	Stable CAD	5 years	In-lesion LLL at 6 months	Completed
LEADERS [16,17], 2008	Randomized Multicenter BioMatrix vs. Cypher Select SES	Europe	1707	Stable CAD and ACS	5 years	CV death, MI, clinically indicated TVR at 9 months	Completed
COMFORTABLE AMI [14,15], 2012	Randomized Multicenter BioMatrix vs. Gazelle BMS	Europe Asia	1161	STEMI	2 years	Cardiac death, target vessel-related reinfarction, and ischemia-driven TLR at 1 year	Completed
EVERBIO II [23], 2015	Randomized Single Center BioMatrix vs. Promus Element EES and vs. Absorb BVS	Europe	240	Stable CAD	5 years	Angiographic LLL at 9 months	9-month FU completed
SORT OUT VI [21], 2015	Randomized Multicenter BioMatrix vs. Resolute Integrity ZES	Europe	1502	Stable CAD and ACS	5 years	Composite of safety (cardiac death and MI) and efficacy (TLR) at 12 months	1-year FU completed
Separham <i>et al.</i> [22], 2011	Randomized Single Center BioMatrix vs. Xience EES	Asia	200	Stable CAD and ACS	1 year	Composite of cardiac death, MI, and clinically driven TVR at 1 year	Completed
STACCATO [24], 2014	Randomized Single Center BioMatrix vs. Xience EES	Europe	64	Stable CAD and ACS	9 months	Percentage of uncovered struts assessed with OCT, at 9 months	Completed

AXXESS AXXESS Plus [25], 2007	Single Arm Multicenter Registry	Europe South America Oceania	139	Stable CAD and UA	5 years	In-stent LLL in parent vessel and side branch at 6 months	Completed
DIVERGE [26,27], 2009	Single Arm Multicenter Registry	Europe Australia Oceania	302	Stable CAD and UA	5 years	MACE rate at 9 months*	Completed
AXXENT [28], 2009	Single Arm Multicenter Registry	Europe	33	Stable CAD	6 months	Percent neointimal volume obstruction (IVUS) at 6 months	Completed
COBRA [29], 2015	Randomized Multicenter Xience vs. AXXESS	Europe	40	Stable CAD and UA	9 months	Stent strut coverage as assessed with OCT at 9 months	Ongoing (preliminary results for 20 patients)
BioFreedom BioFreedom FIM [31,32], 2008	Randomized Single Center BioFreedom vs. Taxus Liberté	Europe	180	Stable CAD and UA	5 years	In-stent LLL at 12 months	4-year FU Completed
EGO-BIOFREEDOM [33], 2015	Single Arm Prospective Study	Europe	100	Stable CAD and UA	2 years	Strut coverage assessed with OCT at 9 months	Completed

ACS, acute coronary syndrome; BMS, bare metal stent; BVS, bioresorbable vascular scaffold; CAD, coronary artery disease; CV, cardiovascular; EES, everolimus-eluting stent; FU, follow-up; IVUS, intravascular ultrasound; LLL, late lumen loss; MACE, major adverse cardiac events; MI, myocardial infarction; OCT, optical coherence tomography; SES, sirolimus-eluting stent; TLR, target lesion revascularization; TVR, target vessel revascularization; UA, unstable angina; ZES, zotarolimus-eluting stent.

* Cardiac death, clinically indicated MI (Q-wave and non-Q-wave) and clinically indicated TLR.

† Cardiac death, MI (Q-wave and non-Q-wave), or clinically indicated TVR.

‡ All-cause death, MI, and ischemia-driven TLR.

Figure 35.4 Rates of major adverse cardiac events (MACE) (a) and stent thrombosis (ST) (b) and key angiographic findings (c) across the main randomized trials evaluating the performance of the BioMatrix stent.

groups (3.9% vs. 7.7%; $p = \text{NS}$) and lower than expected particularly in the control group [11]. Intravascular ultrasound (IVUS) analysis performed at the time of the angiographic follow-up revealed a comparable incidence of late incomplete apposition (3%) for both groups and a significantly lower percentage of neointimal volume (ratio between neointimal volume and stent volume) in patients receiving the BioMatrix stent (2.6% vs. 23.5%; $p < 0.001$). Comparable clinical safety emerged with similar 6-month event-free survival (96.3% vs. 97.5%; $p = 0.72$) without significant difference in TLR rates [12]. The preserved safety profile persisted until 5-year follow-up with a MACE (death, MI, or TLR) rate of 18.1% in the BioMatrix group and 10.5% in the control group [13].

The Comparison of Biolimus Eluted From an Erodible Stent Coating With Bare Metal Stents in Acute ST-Elevation Myocardial Infarction (COMFORTABLE AMI) was a randomized, superiority trial comparing the efficacy and safety of the BioMatrix stent with the Gazelle BMS in 1161 patients presenting with STEMI undergoing primary PCI, at 11 sites in Europe and Israel, between September 2009 and January 2011. Patients were excluded in presence of

mechanical complications of acute MI, known allergy to any study medication, use of vitamin K antagonists, planned surgery unless DAPT could be maintained throughout the peri-surgical period, history of bleeding diathesis or known coagulopathy, pregnancy, participation in another trial, inability to provide informed consent, and life expectancy of less than 1 year. The pre-specified primary study endpoint was the device-oriented composite of cardiac death, target vessel-related reinfarction, and ischemia-driven TLR. Secondary endpoints included the patient-oriented composite of death, any reinfarction, and any revascularization, as well as target vessel-related reinfarction, and any revascularization (percutaneous and surgical procedures), cardiac death, all-cause mortality, Q-wave and non-Q-wave reinfarction, stroke, and ST. At 1 year, the primary endpoint occurred in 4.3% of patients receiving the BES and in 8.7% of patients receiving the BMS (HR 0.49, 95% CI 0.30–0.80; $p = 0.004$). The difference was driven by a lower risk of target vessel-related reinfarction (0.5% vs. 2.7%, HR 0.20, 95% CI 0.06–0.69; $p = 0.01$) and ischemia-driven TLR (1.6% vs. 5.7%, HR 0.28, 95% CI 0.13–0.59; $p < 0.001$). Cardiac death was not significantly

different (2.9% vs. 20.3.5%; $p=0.53$). The rate of definite ST was 0.9% in patients treated with BES and 2.1% in patients treated with BMS (HR 0.42, 95% CI 0.15–1.19; $p=0.10$) [14]. These differences were maintained at 2-year follow-up. The rate of the primary endpoint was 5.8% in patients assigned to receive the BioMatrix stent and 11.9% in control group (HR 0.48, 95% CI 0.31–0.72; $p<0.001$). The angiographic control performed in 103 patients at 13 months showed a significant lower in-stent percent diameter stenosis in BES patients compared with patients treated with BMS (12.0 ± 7.2 vs. 39.6 ± 25 ; $p<0.001$). No differences in DAPT compliance were observed between the study groups at any time point and approximately 18% of all patients continued thienopyridines throughout 2 years [15].

BioMatrix vs. first generation DES The Limus Eluted From A Durable Versus ERodable Stent Coating (LEADERS) was a prospective, multicenter, non-inferiority trial including 1707 patients, randomized, after coronary angiography, to receive the BioMatrix Flex or the durable polymer SES Cypher SELECT stent (Cordis, Miami Lakes, FL, USA). Patients with stable coronary artery disease (CAD) or ACS at presentation could be enrolled; other inclusion criteria were the presence of one or more, significant (>50%), coronary artery stenosis in a native vessel or SVG. Exclusion criteria included pregnancy; known intolerance to aspirin, clopidogrel, heparin, stainless steel, sirolimus, biolimus, or contrast material; inability to provide informed consent; participation in another trial; or planned surgery within 6 months of PCI unless DAPT was maintained throughout the peri-operative period. The primary endpoint of the trial was the rate of MACE, defined as the composite of cardiac death, MI, or clinically indicated TVR within 9 months. Secondary endpoints included MACE and its individual components, angiographic and clinical ST at 30 days, 6 months, 9 months and 1–5 years. BES proved to be non-inferior to SES for the primary endpoint at 9 months (9% vs. 11%, RR 0.88, 95% CI 0.64–1.19; p for non-inferiority = 0.003, p for superiority = 0.39) [16]. Optical coherence tomography (OCT) performed during angiographic follow-up at 9 months showed a more complete strut coverage in 20 patients treated with the BioMatrix stent (29 lesions with 4592 struts) compared with patients receiving SES (26 patients, 35 lesions with 6476 struts). Three lesions in the former group and 15 lesions in the latter had $\geq 5\%$ of all struts uncovered (difference 233.1%, 95% CI 261.7–210.3; $p<0.01$) [17].

Early findings were confirmed up to 5-year follow-up: MACE rate 22.3% vs. 26.1%, RR 0.83 (95% CI 0.68–1.02; p for non-inferiority <0.0001 , p for superiority = 0.069). Moreover, at this time point, the more comprehensive patient-oriented composite endpoint (including all-cause death, any MI, and all-cause revascularization) was significantly reduced with the BioMatrix stent (35.1% vs. 40.4%, RR 0.84, 95% CI 0.71–0.98; p for superiority = 0.023). Definite VLST from 1 to 5 years was also significantly reduced with the BioMatrix stent (0.7% vs. 2.5%, RR 0.26, 95% CI 0.10–0.68; $p=0.003$) [18]. Several post hoc analyses explored the performance of the novel device in specific clinical and/or angiographic settings. The non-inferiority of the BioMatrix was confirmed in 429 patients with small vessel disease (defined as reference diameter <2.75 mm) as equivalent LLL (0.17 ± 0.47 vs. 0.22 ± 0.51 mm; $p=NS$), percent diameter stenosis ($24.9\pm 20.7\%$ vs. $23.8\pm 21.3\%$), and binary restenosis rates (12.8% vs. 9.7%) were reported, compared with 434 patients in the durable polymer SES arm. Moreover, rates of MACE and TLR at 1 year were similar (12.1% vs. 11.8%; $p=0.89$ and 9.6% vs. 7.4%; $p=0.26$, respectively) [19]. Patients with acute MI (ST-segment elevation MI (STEMI) and non-ST-segment elevation MI

(NSTEMI)) treated with the BioMatrix stent ($n=280$) experienced lower rate of the patient-oriented composite endpoint compared with the SES at 5-year follow-up (28.9% vs. 42.3%, RR 0.61, 95% CI 0.47–0.82; $p=0.001$). In patients with STEMI, specifically, the BioMatrix stent implantation significantly reduced the rate of the primary endpoint (24.4% vs. 39.3%, RR 0.55, 95% CI 0.36–0.85; $p=0.006$), MACE (12.6% vs. 25.0%, RR 0.47, 95% CI 0.26–0.83; $p=0.008$), and cardiac death (3.0% vs. 11.4%, RR 0.25, 95% CI 0.08–0.75; $p=0.007$). Moreover, a trend toward reduction in definite ST was observed (3.7% vs. 8.6%, RR 0.41, 95% CI 0.15–1.18; $p=0.088$) [20].

BioMatrix vs. second generation DES The Scandinavian Organization for Randomized Trials with Clinical Outcome VI (SORT OUT VI) was an open-label, randomized, multicenter, non-inferiority trial performed at three sites across Denmark including 1502 patients (1883 lesions) assigned to receive the durable-polymer zotarolimus-eluting stent (ZES) (Resolute Integrity, Medtronic CardioVascular, Santa Rosa, CA, USA) and 1497 patients (1791 lesions) to receive the BioMatrix Flex stent. Patients with stable CAD or ACS and at least one coronary lesion with more than 50% stenosis in a vessel with a diameter of 2.25–4.00 mm were included. The primary endpoint was a combination of safety (cardiac death or MI not clearly attributable to a non-target lesion) and efficacy (clinically indicated TLR) at 1 year. It occurred in 79 (5.3%) and 75 (5.0%) patients, respectively, proving the non-inferiority of the ZES compared with the BES (absolute risk difference 0.0025, upper limit of one-sided 95% CI 0.016%; $p=0.004$) [21].

Separham *et al.* [22] randomly assigned 200 patients undergoing PCI of de novo coronary lesions to receive the BioMatrix or the Xience everolimus-eluting stent (EES; Abbott Vascular). At 1 year, the rates of cardiac death (0% in both groups), MI (2% vs. 0%; $p=0.49$), and clinically driven TVR (0% in both groups) were similar for the study groups. No ST was reported in either group.

The performance of the BioMatrix Flex stent was tested in comparison with that of a durable polymer EES (Promus Element, Boston Scientific) and with the everolimus-eluting bioresorbable scaffold (Absorb BVS, Abbott Vascular) in the Comparison of Everolimus- and Biolimus-Eluting Stents With Everolimus-Eluting Bioresorbable Vascular Scaffold Stents II (EVERBIO II) trial. This was a single-center trial including 240 all-comers patients randomly assigned to receive one of the abovementioned devices in a 1 : 1 : 1 ratio. The only study exclusion criteria was a reference vessel diameter >4.0 mm which does not allow the Absorb implantation. The angiographic follow-up showed similar LLL among groups, at 9 months (primary endpoint). Clinical outcomes were also comparable: the rates of patient-oriented MACE (death, MI, and any revascularization) were 27% in patients treated with bioresorbable vascular scaffolds (BVS) and 26% in the EES/BES group ($p=0.83$) and the device-oriented MACE (cardiac death, MI, and TLR) rates were 12% in BVS and 9% in the EES/BES group ($p=0.6$) [23].

The Assessment of Stent sTrut Apposition and Coverage in Coronary ArTeriEs with Optical coherence tomography in patients with STEMI, NSTEMI and stable/unstable angina undergoing everolimus vs. biolimus A9-eluting stent implantation (STACCATO) study was a single-center, prospective, randomized trial comparing tissue coverage in coronary lesions stented with durable fluoropolymer-coated EES (Xience V/Xience PRIME) or with the BioMatrix stent. It included 64 patients (64 lesions) with stable CAD or ACS at presentation and de novo coronary lesions. The primary endpoint, percentage of uncovered struts as assessed with OCT 9 months after

PCI, was significantly lower with the use of the EES ($4.3 \pm 4.8\%$ vs. $8.7 \pm 7.8\%$; $p=0.019$). No difference in the average percentage of malapposed struts at baseline ($6.8 \pm 6.9\%$ vs. $6.9 \pm 7.0\%$, respectively; $p=0.974$) and at follow-up ($0.1 \pm 0.3\%$ vs. $0.6 \pm 1.3\%$; $p=0.143$) was reported. Neointimal thickness at 9 months was $109 \pm 43 \mu\text{m}$ in EES vs. $64 \pm 18 \mu\text{m}$ in BES ($p<0.001$), and angiographic LLL was 0.15 mm in EES vs. 0.10 mm in BES ($p=0.581$). Comparable rates of MACE and ST were reported [24].

Ongoing studies Table 35.2 lists the ongoing studies evaluating the performance of the BioMatrix stent. Among these, the Comparative Effectiveness of 1 Month of Ticagrelor Plus Aspirin Followed by Ticagrelor Monotherapy Versus a Current-day Intensive Dual Antiplatelet Therapy in All-comers Patients Undergoing Percutaneous Coronary Intervention With Bivalirudin and BioMatrix Family Drug-eluting Stent Use (GLOBAL LEADERS, NCT01813435) is an investigator-sponsored trial aiming to enroll around 16,000 all-comer patients in approximately 132 centers (in Europe, North America, South America, and Asia-Pacific) to assess the potential benefits of new antiplatelet regimens. The randomization will occur at the time of the index procedure prior to PCI. Subjects will be stratified according to center and according to the clinical presentation (stable CAD or ACS). All the randomized patients will be treated with the BioMatrix Flex stent or the

BioMatrix NeoFlex stent and will receive peri-procedural bivalirudin. After PCI, they will receive (1 : 1) either ticagrelor plus aspirin for 1 month followed by 23 months of ticagrelor monotherapy or standard DAPT for 12 months followed by aspirin monotherapy for 12–24 months. The primary study outcome will be the composite of all-cause mortality or non-fatal new Q-wave MI at 2 years.

AXXESS

The AXXESS Plus was a prospective, single-arm, multicenter, and non-randomized study evaluating the safety and efficacy of the AXXESS BES for the treatment of patients with de novo bifurcation lesions. A total of 139 patients from Europe, Brazil, and New Zealand, with history of stable or unstable angina, met the following inclusion criteria and were entered in the study: target lesion located within 5 mm of a bifurcation; main branch reference vessel diameter between 2.5–4.0 mm; side branch diameter >2.25 mm and lesion length <15 mm; total length of the lesion in the main branch <34 mm. The primary endpoint was in-stent LLL in parent vessel and side branch at 6-month follow-up, as measured by quantitative computerized angiographic analysis (QCA). The safety endpoint was a composite of MACE at 6 months after the procedure, defined as any death, Q-wave or non-Q-wave MI, or ischemia-driven TLR. Satisfactory levels of procedural and angiographic success were reported (94.9% and 100%, respectively). All patients were stented

Table 35.2 Ongoing BioMatrix stent studies.

Study name and/or identifier number	Sites	Design	Setting	Endpoints
NCT01947439	Asia	Randomized BES vs. ZES	Multivessel PCI	All-cause death, non-fatal MI, any revascularization at 2 years
SORT-OUT VIII NCT02093845	Europe	Randomized BES vs. EES (Synergy stent)	Non-selected patients with ischemic heart disease	Device-related TLF at 1 year
OCT SORT-OUT VIII NCT02253108	Europe	Randomized BES vs. EES (Synergy stent)	Non-selected patients with ischemic heart disease	Combined endpoint of vessel wall healing parameters assessed by OCT at 3 months
PONTINA NCT01060306	Europe	Observational BES vs. BMS	Patients with stable CAD or ACS undergoing LM PCI	Assessment of neointimal coverage by OCT at 6 months
CHOICE NCT01397175	Asia	Randomized BES vs. EES vs. ZES	All-comers patients	Device-oriented composite at 2 years
DETECT-OCT NCT01752894	Asia	Randomized BES vs. EES (angio- vs. OCT-guided PCI)	Stable CAD or unstable angina	Percentage of neointimal coverage by OCT at 3 months
DESTINY TRIAL NCT01856088	South America	Randomized BES vs. SES (Inspiron Stent)	Stable or unstable angina	LLL at 9 months
ROBUST NCT00888758	Europe	Randomized BES vs. EES	STEMI	MACE at 9 months

ACS, acute coronary syndrome; BES, Biolimus-eluting stent; CAD, coronary artery disease; EES, everolimus-eluting stent; LLL, late lumen loss; LM, left main; MACE, major adverse cardiac events; MI, myocardial infarction; OCT, optical coherence tomography; PCI, percutaneous coronary intervention; SES, sirolimus-eluting stent; TLF, target lesion failure; ZES, zotarolimus-eluting stent.

with the Axxess-Plus stent, with 80.9% having additional stents placed distally (42% having stents in both the distal main vessel and side branch, 29.4% having stents into the distal main vessel only, and 9.6% with a stent into only the side branch). In-stent late loss in the AXXESS group was 0.09 ± 0.56 mm. Late ST was observed in three cases, two of which were associated with confirmed premature DAPT discontinuation. In-stent restenosis in the main vessel was 7.1% and in the side branch was 13.7% (7.9% when a DES was implanted). The TLR rate at 6 months was 7.5%. Six-month IVUS analysis was performed in 49 cases (35.2%) and showed effective lesion coverage along with significant neointimal suppression: the neointimal volume obstruction percentage was $2.28 \pm 2.17\%$, with a minimum lumen area of 7.86 ± 2.63 mm² [25].

The Drug-Eluting Stent Intervention for Treating Side Branches Effectively (DIVERGE) study was a prospective, multicenter registry with the aim of expanding the results of the AXXESS Plus study to a broader population while keeping strict protocol indications such as the obligatory use of SES as additional stents for the parent vessel and the side branch if the residual diameter stenosis exceeded 30%. Lesion criteria for inclusion were any bifurcation with significant side branch (≥ 2.25 mm) and parental vessel-side branch angulation $< 70^\circ$. The primary endpoint was the rate of MACE, a composite of death, MI, and TLR at 9 months. Secondary endpoints included in-segment restenosis, late loss, and percent neointimal volume obstruction. Overall, 302 patients were included across 14 sites in Europe, Australia, and New Zealand. Of procedures, 12.3% involved AXXESS only; additional stenting of side branch involved 21.7% patients (17.7% in the distal parent vessel and 4.0% in the side branch vessel); 64.7% received stents in both vessels. The 9-month MACE rate was 7.7% (0.7% death, 3.3% non-Q-wave MI, 1.0% Q-wave MI, 4.3% TLR) and 21.3% at 5 years (6.5% death, 8.6% MI, 12.4% TLR). Of patients originally enrolled in the study, 96.3% (291) were available for this long-term follow-up. Only five cases (1.7%) of definite VLST were reported, none of them resulting in death [26,27].

The AXXESS Stent in Left Main Coronary Artery Bifurcation Lesions (AXXENT) trial was a prospective, single-arm, multicenter study designed to evaluate the safety and efficacy of the AXXESS BES for the treatment of LMCA bifurcation lesions in 33 patients. Six-month IVUS analysis (performed in 26 subjects) showed 12.4% increase in volume and significant neointimal suppression (percent neointimal volume obstruction was $3.0\% \pm 4.1\%$ with a minimal lumen area of 10.3 ± 2.6 mm). Interestingly, lumen area was significantly smaller in the left circumflex coronary ostium compared with the left anterior descending ostium at follow-up, probably because of greater neointimal formation and inadequate stent expansion [28].

The multicenter Complex Coronary Bifurcation Lesions: Randomized Comparison Of a Strategy using a Dedicated Self-Expanding Biolimus A9-eluting Stent vs Culotte Strategy using Everolimus-eluting Stents (COBRA) trial aims to compare the dedicated AXXESS stent with a conventional Culotte strategy assessing vessel healing (through OCT and QCA at 9 months) and clinical outcomes. Patients with true bifurcation lesions will be randomized to receive the AXXESS stent plus two BioMatrix or two Xience EES implanted with the Culotte technique (encompassing minimized overlap and final kissing balloon). The primary endpoint is strut coverage at 9-month follow-up. Secondary endpoints will include OCT and QCA parameter at 9 months and clinical outcomes up to 5 years. Preliminary analysis performed on the first 40 patients enrolled (20 for each arm) showed no significant difference in the percentage of uncovered struts at 9 months. Furthermore, a delayed neointimal coverage was observed in the proximal main vessel

compared with more distal segments in patients receiving the Culotte technique whereas a trend toward a higher percentage of uncovered struts in all bifurcation segments was reported for subjects in the AXXESS arm. These findings have been related to differences in strut thickness, polymer, and antiproliferative drug between the study devices [29].

BioFreedom

Pre-clinical studies proved the long-term efficacy of the BioFreedom stent compared with SES in terms of late restenosis (reduced neointimal proliferation) and persistent inflammation (decreased fibrin, granuloma, and giant cells) [30].

The BioFreedom FIM included a total of 182 patients diagnosed with symptomatic ischemic heart disease and coronary lesions amenable to percutaneous treatment with DES. Inclusion criteria also were native vessels diameter ≥ 2.25 and ≤ 3 and lesion length ≤ 14 mm. Patients were divided in two cohorts on the basis of different time-point for angiographic and IVUS follow-up (after 4 or 9 months for cohort 1 and 2, respectively) and randomized to receive either the BioFreedom standard dose ($15.6 \mu\text{g}/\text{mm}$) or the BioFreedom low dose ($7.8 \mu\text{g}/\text{mm}$) or the PES Taxus Liberté (Boston Scientific). DAPT was recommended for at least 6 months after stent implantation. The primary endpoint was in-stent LLL at 12 months (cohort 2). Secondary endpoints included in-stent LLL at 4 months (cohort 1), MACE (composite of all death, MI, emergent CABG and TLR) and ST rate at 30 days, 4, 12 months and up to 5 years; clinically driven TLR, TVR, and TVF at 4, 12 months, and up to 5 years; in-stent/in-segment binary restenosis at 4 months; in-stent/in-segment Minimum Lumen Diameter (MLD) at 4 months; neointimal hyperplasia volume at 4 and 12 months measured by IVUS; biolimus concentrations pre/post procedure at discharge and 30 days. Both BioFreedom SD (0.08 mm) and LD (0.12 mm) groups demonstrated a significant reduction in late loss at 4 months compared to Taxus (0.37 mm) ($p < 0.0001$ and 0.002, respectively). The percentage of neointimal volume obstruction was significantly reduced in the BioFreedom Standard Dose arm, compared to both BioFreedom Low Dose and Taxus Liberté. In the second study cohort (including 107 patients), in-stent LLL in patients receiving BioFreedom SD was 0.17 mm, compared with an in-stent LLL of 0.35 mm in the Taxus Liberté group. When combining the cohorts, BioFreedom SD demonstrated sustained safety up to 12 months, including absence of ST [31]. After 4 years, similar rates of MACE in the BioFreedom SD and Taxus Liberté groups were reported (13.6% vs. 13.3%) with no evidence of ST [32].

The EGO-BIOFREEDOM trial was designed to assess the time frame, degree of endothelialization, and the subsequent neointimal proliferation through OCT evaluation in patients treated with the BioFreedom stent. This single center study included 100 “real-world” patients (with the exclusion of those with STEMI at presentation) who received baseline and 9-month OCT and were randomized to six groups according to timing of the blinded OCT follow-up. The primary outcome included OCT findings on coverage (degree of endothelialization/coverage) from 1 to 9 months. Secondary outcomes were OCT endpoints (neointimal area and neointimal thickness), QCA endpoints (LLL at 9 months), and clinical endpoints (MACE and ST at 9 and 12 months). Early strut coverage was classified into six categories (A, B, C: uncovered struts; D, E, F: covered struts); early coverage increased progressively from a minimum of 48.16% at 1 month to 97.14% (median) at 5 months. In each group of 20 patients, the range variations of percentage of coverage were much wider in the earlier (1–2 months) groups whereas nearly

complete coverage was observed in the later months with more mature neointimal tissue (brighter intensity and more homogenous in appearance). Median strut coverage at 9 months reaches 99.55% (IQR 98.17–99.93%; min 85.41%, max 100%). Nine-month neointimal thickness remained very low at 0.10 mm (0.05–0.16 mm) in 55 patients. In-stent neointimal volume percentage increased from 4.3% (IQR 2.1–7.5%) in the first 5 months to 13% (9.4–15.9%) at 9 months. Four patients had in-stent restenosis requiring treatment (TLR rate 4%); no other target vessel-related infarct or cardiac death or definite or probable late ST were recorded [33].

The Leaders Free trial (NCT01623180) is an ongoing multicenter, randomized, double-blind trial comparing the BioFreedom stent with the Gazelle stent in approximately 2500 patients at high bleeding risk using a short (1 month) course of DAPT testing the non-inferiority for the primary safety endpoint (a composite of cardiac death, MI, and ST) and the superiority for the primary efficacy endpoint (clinically driven TLR) at 1 year.

The BioFreedom US IDE Feasibility Trial (NCT02131142) is a multicenter, prospective study started in August 2014, with the aim to collect additional safety (MACE, defined as the composite of cardiac death, MI, TLR, and definite ST) and effectiveness (LLL at 9 months) data for the use of the BioFreedom stent in patients with de novo, native coronary lesions.

The Nobori stent

The Nobori stent (Terumo, Tokyo, Japan) resembles the two main components of the BioMatrix stent: (i) the bare metal (stainless steel) platform with open cell, quadrature link design and strut thickness of 120 µm; (ii) the abluminal coating (toward vessel) with the biodegradable PLA as drug carrier, parylene C as primer coating and Biolimus at dose of 15.6 µg/mm stent length. The main difference is related to a different coating process: chemical vapor deposition is used for the Nobori whereas automated autopipette are used for the BioMatrix stent.

Preclinical and pharmacokinetic studies

Endothelial coverage proved to be complete 14 days after the implantation of the Nobori stent in porcine coronary arteries evaluated with the scanning electronic microscope without a significant vessel reaction up to 15 months compared with vessels treated with BMS [34]. Other reports showed a lower inflammatory profile compared with vessels implanted with the first generation SES or with the durable-polymer EES [35].

The NOBORI PK study evaluated the pharmacokinetics of Biolimus eluted from Nobori stent as well its tolerability and safety profile in 20 patients with de novo coronary lesions: the highest Biolimus blood concentration measured in blood samples obtained at different time points (before the procedure and 48 h, 7 and 28 days, 3, 6, and 9 months after stent implantation) was 32.2 pg/mL and was not associated with the occurrence of adverse events. The median time for the maximum concentration was 2 hours (0.05 hours to 3 months). After 6 months, only one patient had detectable Biolimus systemic levels whereas no measurable concentrations were found at 9 months [36].

Clinical evidence (Table 35.3)

Registries

The NOBORI CORE study compared the Nobori stent with first-generation Cypher SES in 107 patients with de novo coronary lesions (142, diameter 2.5–3.5 mm). Angiographic 9-month follow-

up revealed a similar in-stent LLL (0.10 ± 0.26 vs. 0.12 ± 0.43 ; $p=0.66$) and binary restenosis (1.7 vs. 6.3%; $p=0.32$) whereas in-stent diameter stenosis was significantly lower in the Nobori group ($13 \pm 10\%$ vs. $20 \pm 12\%$; $p=0.002$) [37]. In a subgroup of patients ($n=43$), rapid atrial pacing was used to evaluate the endothelial function through the assessment of vasomotion: the use of the Nobori was associated with a preserved endothelial function and vasomotion [38]. Several factors contribute to this effect (polymer, asymmetric coating, drug); however, the clinical relevance of this effect needs further investigation.

The NOBORI 2 was a prospective, multicenter, single-arm registry evaluating the performance of the Nobori stent in a broad range of clinical settings. Indeed, it included 3067 patients across Europe and Asia between April 2008 and March 2009; approximately 73% of them had an off-label indication for the use of the Nobori stent. At 1 year, the overall rate of the device oriented endpoint or TLF (composite of cardiac death, MI, and TLR) was 3.9% (5.1% after 2 years). Patients in off-label group experienced significantly higher rates of the primary endpoint both after 1 and 2 years (TLF: 4.5% vs. 2.2% at 1 year and 5.9% vs. 2.8% at 2 years). The rates of ST were 0.68% and 0.80%, at 1 and 2 years, respectively [39].

The Italian Nobori Stent Prospective Registry (INSPIRE 1) included 1066 all-comers patients (1589 lesions) treated with the Nobori stent at seven Italian sites between February 2008 and July 2012. At 1 year, the primary endpoint (composite of cardiac death, MI, and clinically driven TVR) occurred in 4.0% of patients. TLF (secondary endpoint) occurred in 4.6% of patients. The rates of both primary and secondary endpoints were higher in patients with complex lesions. Definite and probable ST rate was 0.6% and was not significantly higher in the complex lesions group (0.9%) [40].

Randomized studies (Figure 35.5)

Nobori vs. first generation DES The NOBORI I trial compared the Nobori stent with the Taxus stent. The study was a randomized (2 : 1), prospective, controlled, non-inferiority trial with two arms: in the NOBORI I Phase I trial patients in the comparator group received the Taxus Express PES (Boston Scientific, Natick, MA, USA) whereas in the NOBORI I Phase II trial the Taxus Liberté PES was used. Overall, 362 patients with up to two de novo lesions in two epicardial vessels were included. The primary endpoint was angiographic in-stent LLL at 9 months, while secondary endpoints were MACE at 30 days, 4, 9, and 12 months, and yearly up to 5 years. In the NOBORI I Phase I, LLL was significantly lower in the Nobori group (0.15 ± 0.27 vs. 0.32 ± 0.33 mm; $p=0.006$). The NOBORI I Phase II proved both the non-inferiority and the superiority of the Nobori stent over the Taxus in terms of LLL (0.11 ± 0.30 vs. 0.32 ± 0.50 mm; $p<0.001$). Binary restenosis and neointimal volume obstruction were also significantly lower in the Nobori group. Regarding overall clinical outcomes after 5 years, no differences were reported in the composite of death and MI (10.9% vs. 11.2%) and the number of TLR was lower in patients treated with the Nobori stent (6.3% vs. 16%). The rates of ST were 0.0% and 3.2% in the Nobori and Taxus groups, respectively ($p=0.014$) [41].

In the SORT-OUT V trial 2468 patients were randomized (1 : 1) to the Nobori or the Cypher stent at three Danish sites. It was a non-inferiority trial and the primary endpoint was a composite of cardiac death, MI, definite ST, and TVR at 9 months. Clinical baseline features identified a moderate risk population with a considerable number of patients in both groups with diabetes, history of PCI and ACS at presentation. The primary endpoint occurred in 4.1% of

Table 35.3 Overview of clinical studies with the Nobori Biolimus-eluting stent.

Study name [ref], year (results available)	Design	Country	Patients	Setting	Planned follow-up	Primary endpoint	Status

Figure 35.5 Rates of MACE (a) and ST (b) and key angiographic findings (c) across the main randomized trials evaluating the performance of the Nobori stent.

patients in the Nobori group and 3.1% of patient in the SES group (p for non-inferiority=0.06, and p for superiority=0.22). However, a significantly larger proportion of patients in the Nobori stent group had definite ST at 12 months than did those in the SES group (0.7% vs. 0.2%, risk difference 0.6%, 95% CI 0.0–1.1; p=0.034) questioning the non-inferiority of the novel device [42].

Nobori vs. second generation DES The COMPARE II was an open-label, prospective, randomized (2 : 1), controlled, non-inferiority trial enrolling 2707 patients (4025 lesions) across 12 European sites between January 2009 and February 2011. Patients were randomized to receive the Nobori stent (n=1795) or the thin strut Xience stent (n=912). High-risk patients were largely represented in the study population: 58% presented with an ACS, 22% had diabetes, and 63.5% of lesions were classified as B2/C type according to

AHA/ACC classification. At 12 months, the primary endpoint, a composite of safety (cardiac death and non-fatal MI) and efficacy (clinically indicated TVR) occurred in 5.2% and 4.8% of patients treated with Nobori and Xience, respectively, proving the non-inferiority of the Nobori stent. Definite ST was 0.7% in the Nobori and 0.4% in Xience group [43].

The NOBORI Biolimus-Eluting Versus XIENCE/PROMUS Everolimus-Eluting Stent Trial (NEXT) was a prospective, multi-center, randomized, open-label trial evaluating the non-inferiority of the Nobori stent compared with a durable polymer EES (Xience or PROMUS) in terms of TLR at 1 year in 3235 patients mainly suffering from stable CAD (83% of patients). The study proved the non-inferiority of the Nobori stent with a TLR rate of 4.2% in both study arms (p for non-inferiority <0.0001, and p for superiority=0.93). The cumulative rate of definite ST was also similar

Table 35.4 Ongoing Nobori stent studies.

Study name and/or identifier number	Sites	Design	Setting	Endpoints
e-NOBORI Registry NCT01261273	Europe Asia, Central and South America	Observational	All-comers	Freedom from TLF (cardiac death, target vessel MI and TLR) at 1 year
IRIS NOBORI NCT01348360	Asia	Observational Comparative (vs. first-generation DES)	Non-selected patients with ischemic heart disease	Composite of cardiac death, MI, and TVR at 1 year
NAUSICA NCT01401036	Asia	Randomized Nobori vs. uncoated stent	Acute MI	MACE at 1 year
BEGIN NCT01574586	Asia	Randomized Nobori vs. Xience	Patients with stable CAD undergoing bifurcation lesions PCI	Minimum lumen diameter of the side branch ostium in bifurcation at 8 months
ISAR-TEST 6 NCT01068106	Europe	Randomized Nobori vs. Xience	All-comers	Composite of cardiac death, MI, and TVR at 1 year

ACS, acute coronary syndrome; CAD, coronary artery disease; DES, drug-eluting stents; LLL, late lumen loss; MACE, major adverse cardiac events; MI, myocardial infarction; PCI, percutaneous coronary intervention; TLF, target lesion failure; TLR, target-lesion revascularization; TVR, target-vessel revascularization.

between the two study groups (0.25 vs. 0.06%; $p=0.18$). The angiographic sub-study, including 528 patients, confirmed the non-inferiority by showing an in-segment LLL of 0.03 ± 0.39 vs. 0.06 ± 0.45 mm (p for non-inferiority <0.0001 ; p for superiority = 0.52) [44]. The safety and efficacy outcomes remained comparable through 3 year and beyond 1 year after stent implantation: TLR rates were 7.4% and 7.1%, $p=0.8$; cardiac death 2.7% vs. 2.4%, $p=0.57$; MI 4.0% vs. 3.7%, $p=0.72$; TVR 11.3% vs. 9.9%, $p=0.21$; ST 0.31% vs. 0.26%, $p=0.74$ in the Nobori and in the EES groups, respectively [45].

The SORT OUT VII trial compared the efficacy and safety of the thin strut, cobalt-chromium biodegradable polymer sirolimus-eluting Orsiro stent (Biotronik, Switzerland) and the Nobori stent in 2525 all-comers patients. At 1 year, the primary endpoint (target lesion failure defined as a composite of cardiac death, MI not related to other than index lesion, and TLR) occurred in 3.8% of patients receiving the Orsiro stent and in 4.6% of patients receiving the Nobori stent (p for non-inferiority <0.0001). Moreover, patients treated with the Orsiro stent experienced a significantly lower rate of definite ST (0.4% vs. 1.2%, RR 0.33, 95% CI 0.12–0.92; $p=0.03$) [46].

The randomized, multicenter, prospective LONG-DES V trial compared the Nobori stent with the Promus Element EES (Boston Scientific, USA) in 500 patients with long (≥ 25 mm) coronary lesions. In-segment LLL (primary endpoint) was comparable between the two groups at 9 months (0.14 ± 0.38 vs. 0.11 ± 0.37 mm; 95% CI -0.053 to 0.091 ; p for non-inferiority = 0.03, p for superiority = 0.45), as well as in-stent LLL (0.20 ± 0.41 vs. 0.24 ± 0.38 mm; $p=0.29$). No significant differences in the rate of composite outcome of death, MI, and TVR were reported (41, 16.7% in Nobori arm vs. 42, 16.5% in Promus arm; $p=0.94$) [47].

However, the performance of the Nobori stent in large vessels (≥ 3.0 mm in diameter) was evaluated in the BAsel Stent Kosten-Effektivitäts Trial–PROspective Validation Examination II (BASKET-PROVE II) study, a randomized, multicenter European

trial assigning, in a 1 : 1 : 1 ratio, 2291 patients to either the Nobori or the Xience or to the thin-strut silicon-carbide-coated BMS, PRO-Kinetic (Biotronik). The cumulative incidence of the primary endpoint (combined cardiac death, MI, and TVR) was 7.6% with the Nobori, 6.8% with Xience, and 12.7% with PRO-Kinetic. The Nobori stent proved non-inferiority to the Xience (absolute risk difference 0.78%; p for non-inferiority = 0.042) and superior to BMS (absolute risk difference, -5.16 ; -8.32 to -2.01 ; $p=0.0011$). However, the use of the Nobori stent was not associated with an improved safety profile because no decrease in the occurrence of very late ST was reported [48].

Ongoing studies assessing the performance of the Nobori stents are reported in Table 35.4.

The Xtent

The XTENT Custom NX stent (Xtent, Menlo Park, CA, USA) was a customizable BES with a modular design made of multiple interdigitated 6-mm segments whose length could be customized according to the lesion length at the treatment site. This peculiar feature had the potential advantage to avoid overlapping stents when treating long lesions. Three studies proved the safety and effectiveness of this device (CUSTOM I, II, III) in 220 patients. However, because of industrial financial difficulties it has not been available since August 2009.

Evidence from pooled data

The considerable number of studies comparing biodegradable polymer BES with durable-polymer DES prompt the pooling of the available data in several meta-analyses. Biodegradable polymer BES did not significantly reduce the risk of MACE but demonstrated a significantly lower risk of very late ST when compared with durable polymer DES in a meta-analysis including eight randomized trials [49]. In a large-scale network meta-analysis, biodegradable

polymer BES were associated with superior clinical outcomes compared with BMS and first-generation DES, similar rates of cardiac death, MI, and TVR when compared with second-generation durable-polymer DES, and higher rate of definite ST compared with cobalt-chromium EES [50].

Safety concerns were also issued by two other network meta-analyses assessing the safety and efficacy of durable polymer DES and biodegradable polymer BES: at 1 year, higher rates of ST and MI were reported for patients treated with BES compared with patients receiving new-generation, cobalt chromium EES [51,52].

The Biotronik Stent Family

Anna Franzone, Raffaele Piccolo, and Stephan Windecker

Department of Cardiology, Bern University Hospital, Bern, Switzerland

The Pro-Kinetic Energy and the Orsiro stent share two main components: the cobalt chromium platform and the unique passive coating (PROBIO).

Cobalt chromium platform

The introduction of cobalt chromium (CoCr) alloys in place of stainless steel as metallic platforms when manufacturing coronary stents aimed to improve the devices' properties and their final performance. Specifically, the CoCr alloy L605 is comprised of cobalt (52%), chromium (20%), nickel (10%), tungsten (15%), manganese (1.5%), and iron (3%). Its higher density than stainless steel (9.1 vs. 8 g/cm³) ensures higher radio-opacity. Moreover, this platform features excellent radial strength as a consequence of higher tensile strength (1000 vs. 595 MPa) and elastic modulus (243 vs. 193 GPa); thinner struts (in the region of 80–90 μm compared to strut thicknesses of 130–140 μm for earlier 316L devices); high toughness, corrosion resistance, and wear resistance [1,2].

Passive coating

PROBIO is a highly biocompatible, thin-layer (80 nm), amorphous silicon carbide (hydrogen-rich, phosphorous-doped modification a-SiC:H coating with two main functions: (i) to reduce the thrombogenic properties of metal stents and (ii) to promote regenerative endothelial coverage. It is deposited onto the surface of the stent through a plasma-enhanced chemical vapor deposition technique.

The coating acts mainly by inhibiting unwanted interactions between stent and surrounding tissue which promote platelet aggregation, leukocyte and complement activation, smooth muscle cell proliferation, and other reactions favoring thrombus formation and neointimal hyperplasia.

PROBIO is a “non-activating passive” biomaterial that blocks the electron transfer processes on the stent surface. The latter phenomenon results from the contact between the metal platform and blood cells and is ultimately responsible for the transformation of fibrinogen to fibrin. The unique PROBIO electronic structure inhibits the deposition and activation of cells and proteins on the stent surface. Moreover, this coating reduces metal ion (cobalt, tungsten, nickel, and chromium) diffusion from the stent platform by creating a diffusion barrier that seals the bare

metal surface and prevents corrosion and the associated immune vessel reaction [3].

PROBIO has also been proved to facilitate endothelial coverage: endothelial cells (the best interface between blood and vessel) have shown a superior ability to form a continuous layer on the PROBIO-coated stent surface than on the 316L stent surface [4].

Carrie *et al.* [5] evaluated the performance of the a-SiC:H coated stainless steel Tenax stent in 241 moderate-risk patients: successful deployment without procedural or clinical events were recorded in 95.4% of patients, with a 7.1% 1-year target lesion revascularization (TLR) rate and 15.8% 1-year incidence of major adverse cardiac events (MACE). The Tenax for the Prevention of Restenosis and Acute Thrombotic Complications, a Useful Stent Trial in Patients with ACS (TRUST) study randomly assigned 485 patients with unstable angina to percutaneous coronary intervention (PCI) with a Tenax stent or non-coated stent. In the subgroup of patients with Braunwald IIIB symptoms, those receiving a Tenax stent, compared to those receiving a non-coated stent, had a lower incidence of death, myocardial infarction (MI), or ischemia-driven target vessel revascularization (TVR) at 6 months (4.7% vs. 15.3%; $p=0.02$) with a trend to reduced events at 9- and 18-month follow-up [6].

PRO-Kinetic Energy

The PRO-Kinetic coronary stent system is a cobalt chromium alloy tubular stent sculpted by laser from a single tube of L-605 CoCr alloy, pre-mounted on a semi-compliant, low profile balloon. The stent consists of circular segments at each end followed by a transition zone and helically arranged struts in the middle. Each loop of the helix is connected to the next loop by three longitudinal struts. The three main stent components have a specific role: (i) helical meanders give flexibility to the stent and allow a smooth crimped profile; (ii) wedge-shaped transitions at the stent ends allow consistent scaffolding throughout the entire length of the stent; (iii) longitudinal connectors provide stability and support. The strut thickness is 60 μm/0.0024 inch per 2.0–3.0 mm stent, 80 μm/0.0031 inch per 3.5–4.0 mm stent, and 120 μm/0.0047 inch per 4.5–5.0 mm stent. The delivery system consists of a rapid exchange catheter (5 Fr compatible) with the PANTERA balloon (made of semi-crystalline co-polymer material); the enhanced force transmission (EFT) shaft improves kink resistance and pushability

because of the gradual transition from the proximal to the distal part of the shaft. Device crimping is achieved through an advanced thermal technique ensuring secure stent retention forces as well as a smooth, low crossing profile (0.95 mm/0.037 inch).

Clinical evidence

The PRO-Heal registry included 145 patients with symptomatic coronary artery disease (CAD) treated with the PRO-Kinetic stent (161 lesions, 59% B2 and C lesions according to AHA/ACC classification) at a single German center, between February 2006 and June 2007. Procedural success was achieved for almost all patients (141/145, 97.2%). After 6 months, late lumen loss (LLL) was 0.75 ± 0.71 mm (in-stent) and 0.79 ± 0.72 mm (in-segment); TLR occurred in 4.9% of patients and the MACE rate was 5.6%. These results were considered encouraging and achieved through the beneficial effect of the passive coating on endothelial coverage [7].

Kornowski *et al.* [4] conducted a single-center, non-randomized, consecutive registry to evaluate the short and intermediate-term clinical performance of the PRO-Kinetic coronary stent in 515 all-comers patients (540 lesions) with moderate-high clinical and angiographic profile risk. At 6 months they reported a MACE rate of 8.7% (3.5% mortality, 1.9% cardiac mortality, 1.4% of any MI, TVR 6.4%).

The larger MULTIBENE study was a prospective, non-randomized study including 202 patients with single de novo lesions treated with the PRO-Kinetic stent at 10 European sites. At 6 months, the primary endpoint, target vessel failure (TVF), defined as a composite of cardiac death, MI, and TVR, occurred in 10.9% of patients while the rate of MACE (a composite of cardiac death, MI, TLR, and coronary artery bypass graft, CABG) was 11.4%. No cardiac death or stent thrombosis (ST) occurred. In-segment LLL was 0.66 ± 0.61 mm and binary restenosis was 20.8%, as determined in the angiographic subgroup including 72 subjects [8].

The ENERGY registry was a prospective, non-randomized, multicenter, observational registry evaluating the safety and effectiveness of the PRO-Kinetic stent in 1016 all-comers patients (1074 lesions, 61% A/B1). MACE (composite of cardiac death, MI, and clinically driven TLR) rates at 6, 12, and 24 months were 4.9%, 8.1%, and 9.4%; TLR rates were 2.8%, 4.9%, and 5.4%, and definite ST rates were 0.5%, 0.6%, and 0.6%, respectively [9].

The Efficacy and Safety of PRO-Kinetic Metal Alloy Stent in Hospitalized Patients with Acute ST-Elevation Myocardial Infarction (PROMETHEUS) was a prospective, open-label, single-arm cohort design involving multiple Korean sites. A total of 64 patients undergoing primary PCI were enrolled. Procedural success was achieved in 100% of the lesions. There was one case of in-hospital death resulting from cardiac tamponade. At 6 months' clinical follow-up, the rate of MACE (defined as all-cause death, new MI, and TLR) was 7.8% with TLR occurring in four patients (6.3%). Angiographic follow-up data were available for 42 patients (65.6%) and showed an in-stent LLL of 1.02 ± 0.62 mm and in-segment LLL of 0.99 ± 0.64 mm. Binary restenosis occurred in 53% of lesions with reference vessel diameters (RVDs) ≤ 3.0 mm, 25% of lesions with RVDs between 3.0 and 3.5 mm, and 0% of lesions with RVDs > 3.5 mm ($p = 0.006$), suggesting a better performance of the stent in large vessels [10].

Similar results were reported for a retrospective study on a cohort of 117 patients presenting with acute coronary syndrome (32% unstable angina, 36% non-ST-segment elevation myocardial infarction (NSTEMI), 33% ST-segment elevation myocardial infarction (STEMI)). MACE rates were 8.5% and 11.1% at 6 and 12 months' follow-up, respectively. The incidence of cardiac death, MI, and

TLR was 2.6%, 3.4%, and 2.6%, respectively, at 6 months, and 4.3%, 4.3%, 2.6%, respectively, at 12 months [11].

In the PRO-Vision Study, the PRO-Kinetic stent was compared with an uncoated stent with the same alloy (MULTI-LINK VISION; Abbott Vascular, Santa Clara, CA, USA) in terms of 1-year rate of TLR (defined as either reintervention in the stent, including 5-mm proximal and distal margins, or CABG because of restenosis). In the PRO-Kinetic group ($n = 1353$) TLR was significantly higher (9.0% vs. 5.6%; unadjusted OR 1.61, 95% CI 1.24–2.08; $p < 0.001$) than the Vision group ($n = 1378$). Even after adjustment for multiple factors (post-intervention minimal luminal diameter, total implanted stent length, NSTEMI or unstable angina at presentation, triple vessel stenting), the use of PRO-Kinetic stents remained an independent predictor for revascularization (adjusted OR 1.57, 95% CI 1.18–2.10; $p = 0.002$) [12].

The BIOHELIX-I (NCT01612767) is a prospective, non-randomized, multicenter study to support the US Food and Drug Administration approval of the PRO-Kinetic stent. It has recently completed the enrolment of 329 patients in the USA, Europe, and South America. The primary endpoint for the study is the rate of TVF, encompassing cardiac death, MI, and ischemia-driven TVR, 9 months after stent implantation.

Orsiro

The Orsiro stent consists of an ultrathin (60 μm) CoCr alloy platform with a hybrid combination of passive and active coatings: the PROBIO (silicon carbide) and the high molecular poly-L lactic acid (PLLA) polymer. This polymer compound is used as a carrier for the supply and release of sirolimus and completely degrades during a period of 12–24 months (Figure 36.1). PLLA and the drug are mixed in a matrix (BIOLute) that completely coats the stent body surface; it has an asymmetric thickness (7.5 μm abluminal and

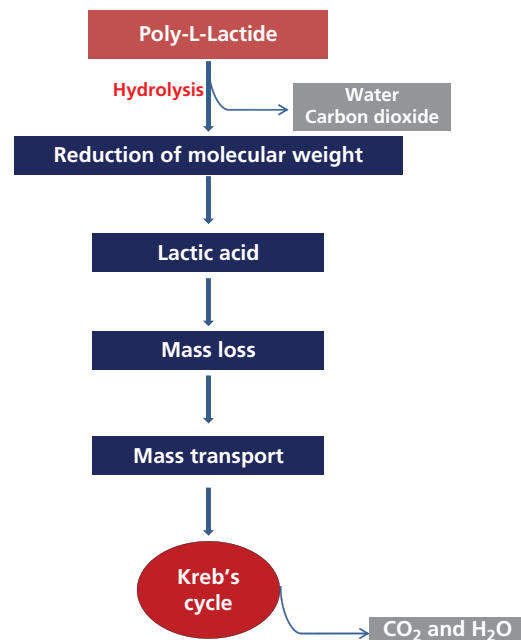

Figure 36.1 Metabolism of poly-L-lactide (PLLA). Hydrolysis of PLLA results in the loss of molecular weight, and reduction in strength and mass; ultimately the PLLA is metabolized into lactic acid, carbon dioxide (CO_2), and water (H_2O).

3.5 μm luminal) enabling a greater drug dose on the abluminal side. The drug load is 1.4 $\mu\text{g}/\text{mm}^2$ stent surface. The thickness of the coated stent struts is 60 μm for stents with a nominal diameter of 2.25–3.0 mm and 80 μm for the two larger sizes (3.50–4.00 mm).

Clinical evidence

Table 36.1 provides an overview of completed and ongoing studies evaluating the performance of the Orsiro stent.

The BIOFLOW-I was a prospective first-in-man trial including 30 patients with significant (diameter stenosis 50–90%) single de novo lesion in one coronary artery (with a reference vessel diameter between 2.5 and 3.5 mm and lesion length ≤ 22 mm) treated with the Orsiro stent at two sites in Romania. Patients were all followed up with angiography at 4 and 9 months and a small subgroup (15 patients) also had a concomitant intravascular ultrasound (IVUS) evaluation. Angiographic LLL was 0.12 ± 0.19 mm and 0.05 ± 0.22 mm at 4 and 9 months, respectively. At 1 year, the composite MACE (cardiac death, ischemia-driven TLR, and target vessel MI) was 10%. There was no report of ST. The IVUS analysis showed that the majority of patients did not develop any neointimal hyperplasia with a volume obstruction not measurable (0%) and extremely small (0.07%) at 4 and 9-month follow-up, respectively [13].

The multicenter, randomized BIOFLOW-II trial established the non-inferiority of the Orsiro stent compared to the durable polymer everolimus-eluting Xience stent (X-EES) in a total of 452 patients with stable or unstable CAD. The primary endpoint, LLL at 9 months, was 0.10 ± 0.32 mm in the Orsiro group vs. 0.11 ± 0.29 mm in the X-EES group (95% CI 0.06–0.07; p for non-inferiority < 0.0001). At 1 year, similar rates of target lesion failure (TLF) were reported (6.5% vs. 8.0%, HR 0.82, 95% CI 0.40–1.68, log rank test; $p = 0.58$) without cases of ST. This trend was confirmed at 2 years in the overall population (10.0% vs. 8.4%; $p = 0.5648$) as well as in the diabetic subgroup ($n = 128$, 9.7% vs. 9.1%; $p = 0.8975$) and in patients with small vessels disease ($n = 259$, 9.4% vs. 13.3%; $p = 0.3153$).

At 9 months, two subgroups of patients were followed up with serial optical coherence tomography (OCT) and IVUS ($n = 55$ and 56, respectively). OCT showed similar neointimal thickness among lesions allocated to Orsiro and X-EES (0.10 ± 0.04 mm² vs. 0.11 ± 0.04 mm²; $p = 0.37$) whereas a potential difference in neointimal area at follow-up was argued by IVUS (Orsiro: 0.16 ± 0.33 mm² vs. X-EES: 0.43 ± 0.56 mm²; $p = 0.04$) [14,15].

The multicenter randomized BIOSCIENCE trial proved the non-inferiority of the Orsiro stent to the X-EES in a broad population including 2119 patients with stable CAD or acute coronary syndromes (ACS). There was no significant difference in the rate of the primary endpoint, TLF (composite of cardiac death, target vessel MI, and clinically indicated TLR) at 12 months: 6.5% in patients assigned to the Orsiro group ($n = 1063$) and 6.6% in patients assigned to the X-EES group ($n = 1056$) (p for non-inferiority < 0.0004). Similarly, no significant differences were reported for definite ST (0.9% vs. 0.4%; $p = 0.16$) (Figure 36.2). This trend was preserved up to 2-year follow-up (TLF 10.5% vs. 10.4%, RR 1.00, 95% CI 0.77–1.31; $p = 0.979$). Two pre-specified subgroup analyses were performed to assess the outcomes in patients with STEMI at presentation ($n = 407$) and in patients with diabetes mellitus ($n = 486$). Improved clinical outcomes were reported for STEMI patients treated with the Orsiro as compared with the X-EES (TLF 3.3% vs. 8.7%, RR 0.38, 95% CI 0.16–0.91; $p = 0.014$) whereas the non-inferiority to the X-EES was confirmed among the high-risk diabetic patients (TLF 10.9% vs. 9.3%, RR 1.19, 95% CI 0.67–2.10; $p = 0.56$) [16,17].

In order to monitor the performance of the Orsiro in the real-world practice, the BIOFLOW-III was initiated as an international, prospective, multicenter, open-label study. It included 1356 all-comers patients between August 2011 and March 2012. At 1 year, the primary endpoint (TLF defined as composite of cardiac death, target vessel Q-wave or non-Q wave MI, emergent CABG, clinically driven TLR) occurred in 5.1% of patients. A comparable performance was reported in subgroups of patients with multivessel disease and acute MI [18].

In the prospective multicenter HATTRICK-OCT study, 44 patients presenting with ACS were randomly assigned (1 : 1) to be implanted with the Orsiro stent or with the Resolute zotarolimus-eluting stent (R-ZES) with the aim of comparing tissue coverage and apposition by OCT after 3 months. The percentages of uncovered and malapposed struts were significantly lower in patients treated with the Orsiro (3.9% and 2.6% vs. 8.9% and 5.3%, respectively). To test the effect of stent composition on coronary vasodilator function, coronary flow reserve (CFR) was also measured at the procedure. However, no significant differences were found [19].

The SORT OUT VII compared the efficacy and safety of the Orsiro stent and the Nobori stent in 2525 all-comers patients. At 1 year, the primary endpoint (TLF defined as a composite of cardiac death, MI not related to other than index lesion, and TLR) occurred in 3.8% of patients receiving the Orsiro stent and in 4.6% of patients receiving the Nobori stent (p for non-inferiority < 0.0001). Moreover, patients treated with the Orsiro experienced a significantly lower rate of definite ST (0.4% vs. 1.2%, RR 0.33, 95% CI 0.12–0.92; $p = 0.03$) [20].

Absorbable metal scaffolds

The evolution of the Biotronik Absorbable Magnesium Scaffolds is depicted in Table 36.2.

Magnesium in bioresorbable devices

Magnesium is a mineral with an essential role for human physiology: it is responsible for bone metabolism, supports the immune functions, helps to maintain normal muscle and nerve function, and has a role in maintaining a normal heart rhythm. It is also a biocompatible metal whose two major limitations are low corrosion resistance and insufficient mechanical strength. As consequence, alloys with other metals such as calcium, zinc, manganese, and other rare earth elements have been developed for specific use into bioresorbable and biocompatible implant materials. These alloys have a strength-to-weight ratio comparable with that of strong aluminum alloys and alloy steels [21]. Because of its unique electrochemical properties, magnesium is more electronegative than other metals used for implants and has shown antithrombotic properties *in vivo* [22,23]. Heublein *et al.* [24] were the first to investigate magnesium alloys for cardiovascular stents. They implanted an AE21 alloy stent in the coronary artery of experimental animals and observed a negligible inflammatory response up to 56 days. The Lekton Magic coronary stent (made of the WE43 magnesium alloy) was then produced by Biotronik and tested in porcine coronary arteries. Despite not being associated with larger lumen, at 28 days and 3 months neointimal area was significantly lower in magnesium alloy stent vessel segments than stainless steel vessel segments [25].

The first successful implantation of a biodegradable metal stent in human was performed by Zartner *et al.* [26] in the left pulmonary artery of a preterm baby with a congenital heart disease.

* Cardiac death, clinically indicated MI (Q-wave and NQ-wave), emergent CABG, and clinically indicated TLR.

[†] Cardiac death, MI (Q-wave and NQ-wave), or clinically indicated TLR.

[‡] Cardiac death, MI (Q-wave and NQ-wave), or clinically indicated TVR.

[§] Cardiac death, MI (Q-wave and NQ-wave), or clinically indicated TLR.

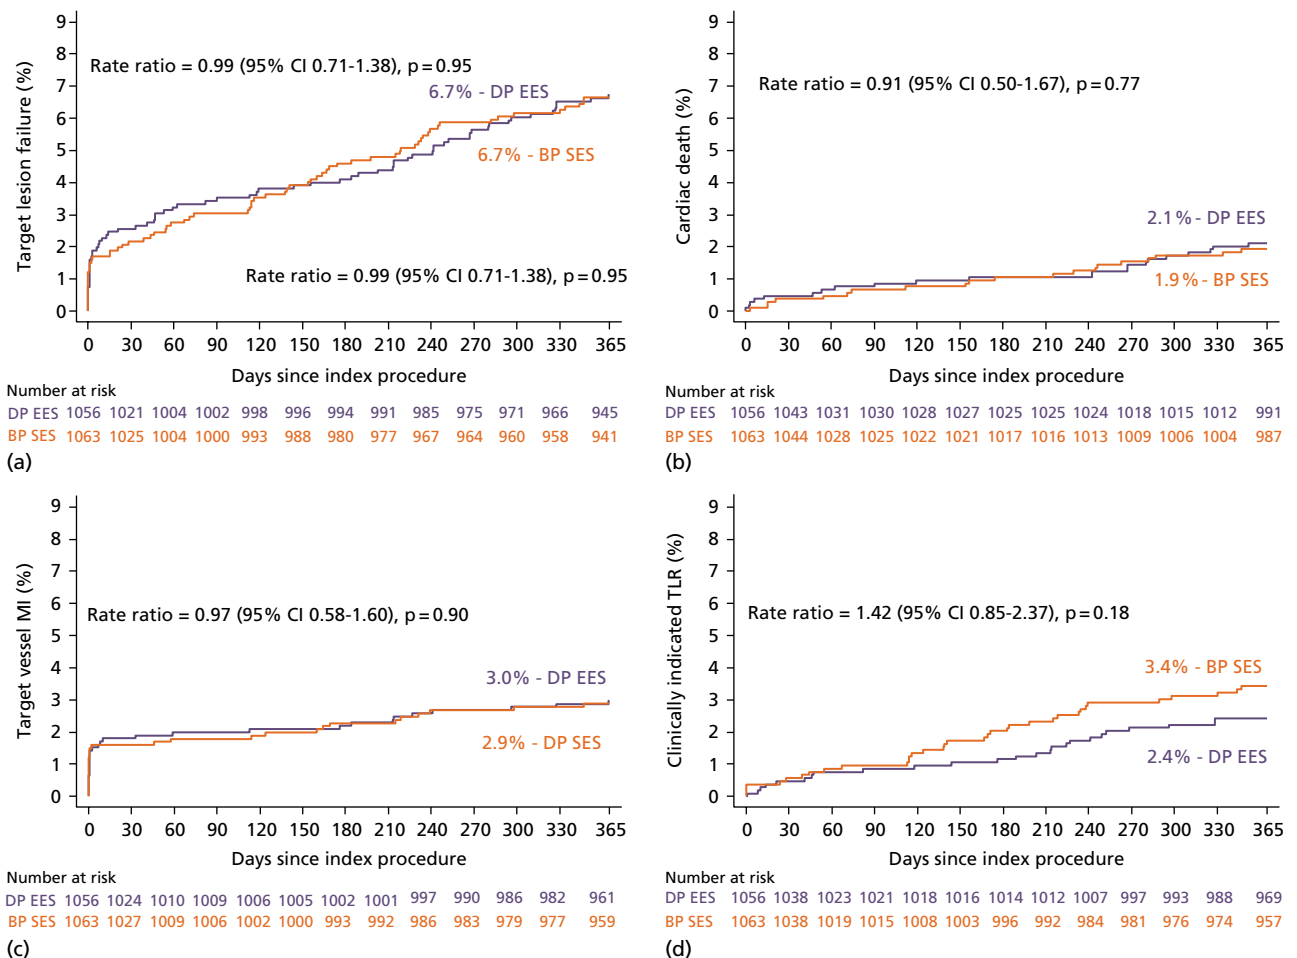

Figure 36.2 Results of the BIOSCIENCE trial. Time-to-event curves for the primary endpoint (target lesion failure) and the individual components of the primary endpoint up to 12 months follow-up. Target lesion failure (a), cardiac death (b), target vessel myocardial infarction (c), clinically indicated target lesion revascularization (d).

First-generation magnesium absorbable vascular scaffold

The balloon-expandable AMS-1 is composed of 93% magnesium and 7% rare earth metal. It is laser cut from a WE-43 magnesium alloy tube into sinusoidal in-phase hoops linked by straight bridges. Strut thickness is 165 μm ; its crossing profile is 1.2 mm. It is radio-lucent and does not contain radio-opaque markers. The device has a low elastic recoil (less than 5%) and a good initial radial strength with high collapse pressure (0.8 bar), similar to traditional stainless steel stents; however, it only provides radial support for 1–2 weeks. It is rapidly endothelialized and mostly degraded into inorganic ions within 60 days. However, this process does not induce a sustained inflammatory vessel reaction [25].

The PROGRESS AMS was a first-in-man, single arm study assessing the feasibility and the safety of the AMS-1 in 63 patients with single de novo coronary lesions. Although no event of death, MI, or ST was reported up to 1 year, the long-term patency was disappointing with a TLR rate of 23.8% at 4 months and 45% at 12 months. The LLL was 1.08 ± 0.49 mm and resulted from a faster than expected scaffold degradation resulting in an insufficient radial strength and vessel recoil. Intravascular imaging showed complete scaffold resorption at 4 months and the significant reduction of luminal dimensions were attributed for 45% to neointima

formation, 42% to negative remodeling, and 13% to an increase in the plaque area outside the stent [27,28].

New magnesium absorbable vascular scaffolds

The findings of the PROGRESS AMS study prompted the development of ameliorated scaffolds to address the exaggerate vessel recoil by increasing the degradation time. The 6-Fr compatible, pre-mounted AMS-2 featured a different alloy (with >90% magnesium, zirconium, yttrium, and rare earth metals) and a new design with a square cross-sectional shape of the strut (no more rectangular) and a reduced strut thickness (120 μm). The new alloy was slower resorbable and with a higher collapse pressure than AMS-1 (1.5 vs. 0.8 bar). The device showed prolonged mechanical integrity, improved radial strength and reduced neointimal proliferation in animal studies but was not tested in humans [29].

The AMS-3 (drug-eluting AMS, DREAMS) was coated with the poly(lactide-co-glycolide) (PLGA), a bioresorbable matrix (1 μm) for the controlled release of paclitaxel (0.07 $\mu\text{g}/\text{mm}^2$). The best lactide to glycolide ratio for the PLGA polymer formulation, ensuring the optimal resorption time and drug elution, was established by experimental studies: 73 magnesium scaffolds with different combinations of lactide to glycolide and 36 control stents (18 TAXUS Liberté, 18 eucaTAX) were implanted in porcine coronary arteries.

Table 36.2 Absorbable magnesium scaffolds.

	AMS 1	AMS 2	AMS 3 (DREAMS 1G)	DREAMS 2G
Alloy	WE43	Refined WE43*	Refined WE43*	Refined WE43*
Drug (dose)	No	No	Paclitaxel (0.07 µg/mm ²)	Sirolimus (1.4 µg/mm ²)
Polymer	No	No	PLGA	PLLA
Scaffold design	4 crown/4 link	4 crown/4 link	6 crown/3 link	6 crown/2 link Two markers
Strut thickness (µm)	165	120	120	150
Magnesium absorption time (months)	1	2	3	12
Trials	PROGRESS AMS	No	BIOSOLVE-I	BIOSOLVE II (ongoing)
Late lumen loss (mm)	0.83 ± 0.51 (at 4 months)	–	0.64 ± 0.50 (at 6 months) 0.52 ± 0.39 (at 12 months)	–

PLGA, Poly(lactide-co-glycolide); PLLA, Poly(L-lactic acid).

* >90% Magnesium, zirconium, yttrium, and rare earth metals.

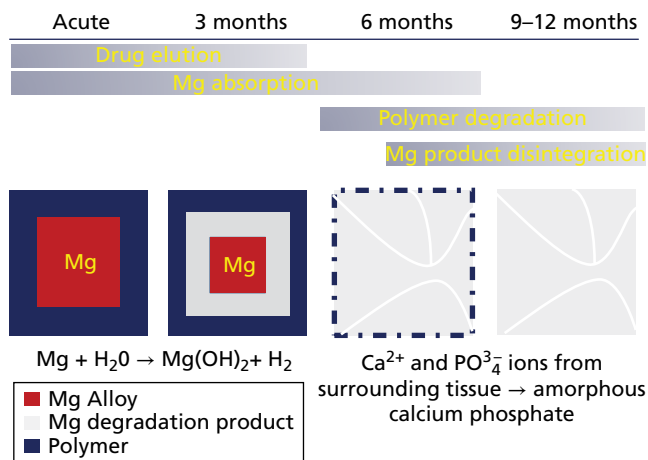

Figure 36.3 Resorption rates of metal scaffolds. Drug release occurs within the first 3 months after device implantation. Magnesium (Mg) resorption starts early through hydrolysis whereas polymer biodegradation occurs at 6–12 months after implantation.

The formulation with 85 : 15 high-molecular-weight ratio was equivalent to TAXUS Liberté and superior to eucATAX regarding LLL, intimal area, fibrin score, and endothelialization. The study allowed the identification of two phases in the resorption process of magnesium: (i) in the acute phase, the presence of water caused the formation of a mixture of magnesium hydroxide, oxygen, and magnesium carbonate; (ii) later, ions from surrounding tissue form a compound of amorphous calcium phosphate that fills the voids previously occupied by the dissolved struts (Figure 36.3).

The scaffold is balloon-expandable (semi-compliant) and is centered between two radio-opaque markers guiding proper positioning under fluoroscopy. It is available in the following dimensions: 3.25 or 3.5 mm in diameter and 16 mm in length.

The first-in-man BIOSOLVE-I trial assessed the safety and the performance of this device in 46 patients (47 lesions) enrolled at five European centers. Device and procedural success was 100%. The primary endpoint, target lesion failure (defined as a composite of cardiac death, target vessel MI, and clinically driven TLR) occurred in two patients (4%) at 6 months and three (7%) at 12 months (two clinically driven TLRs and one peri-procedural MI). No events of cardiac death or scaffold thrombosis were reported.

The in-scaffold LLL was 0.65 ± 0.5 mm at 6 months and 0.52 ± 0.39 mm at 12 months. Serial OCT performed in seven patients (5791 struts) showed 92.7% of apposed struts at 6 months and 99.8% at 12 months with only 0.1% persistent incomplete strut apposition and 0.1 late acquired incomplete strut apposition. A restoration of vessel geometry was also noted at 6 months, with the angulation of the treated segments reported to increase from 14.9 ± 12.0 immediately post-procedure to 26.1 ± 15.9 at late follow-up [30].

The second-generation DREAMS, DREAMS 2G, has a modified platform (WE43 alloy with 6-crown 2-link design and a strut thickness of 150 µm) with radio-opaque markers (tantalum) at both ends. The scaffold is coated with a bioresorbable polylactic acid polymer (7 µm) and elutes sirolimus at a dose of 1.4 µg/mm². It is currently being evaluated in the BIOSOLVE-II (NCT01960504), a prospective, multicenter trial aiming at the enrollment of 121 patients with de novo lesions in up to two coronary arteries. The primary endpoint is in-segment LLL at 6 months. Clinical outcomes will be assessed up to 3-year follow-up.

PK Papyrus stent

The PK Papyrus (Conformité Européenne (CE) marked in 2013) is a covered coronary stent system indicated for acute coronary artery perforations. It shares with the PRO-Kinetic and the Orsiro stent the common CoCr L-605 platform with the amorphous silicon carbide coating. Moreover, it has a unique single-layer coating made of 90 µm polyurethane membrane through an electrospinning process. The thin coating enables a 24% lower crossing profile in comparison with other covered devices. It is 5 Fr compatible and is available in a wide range of size (2.5–5.0 mm in diameter and 15–26 mm in length).

Drug-eluting stents (DES) were primarily conceived to reduce in-stent neointimal formation and therefore minimize the occurrence of restenosis, the major drawback of percutaneous coronary interventions (PCI) with plain old balloon angioplasty (POBA) and bare-metal stents (BMS) [1–4]. The development of DES has been pioneered through a combination of increased understanding of the biology of restenosis, the selection of drugs that target one or more pathways in the restenotic process, controlled-release drug delivery strategies, and the use of the stent as a delivery platform. Therefore, the clinical effects of DES are highly dependent on each of the components of the complex platform–drug–polymer, as well as the interactions among these elements.

Although first-generation DES Cypher (sirolimus-eluting stent; Cordis, Johnson & Johnson, Warren, NJ, USA) and Taxus (paclitaxel-eluting stent; Boston Scientific, Natick, MA, USA) have effectively achieved their main goal, reducing restenosis across virtually all lesions and patients subsets [5–11], their safety has been limited by suboptimal polymer biocompatibility, delayed stent endothelialization leading to late and very late thrombosis, and local drug toxicity [12–17], which ultimately prompted the development of biodegradable and polymer-free DES systems.

Additional improvements include the development of more modern platforms (e.g., better deliverability, radiopacity, flexibility, and radial strength) as well as the use of novel antiproliferative agents or reduced doses of current approved antiproliferative drugs.

It is important to highlight that the level of efficacy and long-term safety achieved with the current generation of durable and biodegradable polymer DES systems is very high and difficult to surpass. The current focus of metallic DES research is on the development of technologies to promote faster vessel healing allowing the shortening of dual antiplatelet therapy (DAPT) and therefore minimizing the bleeding risks associated with these medications [18,19].

This chapter briefly describes the main recent modifications in DES systems with emphasis on changes in metallic platforms, development of novel antiproliferative agents, and the ways to carry and control their distribution in the coronary artery, highlighting novel durable and biodegradable polymer coatings as well as non-polymeric DES systems.

Metallic platforms

Metallic alloys

Available DES platforms vary in metallic composition, strut design, and thickness. All these parameters have an important role. The main metallic alloys available for the stent platform include 316L stainless steel, cobalt chromium (CoCr), platinum chromium (PtCr), nitinol, and tantalum.

For the first-generation of DES struts, including Cypher® and Taxus®, the predominant material used was 316L stainless steel. This alloy has low elastic recoil (<5%), good radial strength, and excellent processing properties. Conversely, among its limitations, relatively low radio-opacity and flexibility as well as higher nickel content, which might trigger local inflammatory responses and restenosis, represent the major drawbacks of this alloy [20].

Most currently available DES systems use CoCr alloys (L605) in their platforms, which can provide superior radial force and better radio-opacity, with significantly thinner struts. CoCr appears to minimize the adverse proliferative response that accompanies the incorporation of other alloys (e.g., gold, nickel, molybdenum, and chromium), while enhancing visibility and flexibility. Although there is some evidence that the strut thickness of BMS can influence rates of restenosis and target lesion revascularization (TLR) [21–23], it is still unclear whether this association applies in a similar manner to DES. Recent experimental data suggested that strut thickness is positively correlated with less thrombus formation on the surface of the stent [24].

More recently, platinum alloys have been incorporated into clinical practice. As potential advantages, this metal is twice as dense as iron and cobalt, more malleable, corrosion and fracture-resistant, which allows the achievement of even thinner struts with equal or better radio-opacity. Also, the amount of nickel in platinum alloys is reduced, minimizing the potential disadvantages associated with this metal.

For novel self-expandable stents (e.g., Cardiomin™, Axxess™, STENTYS™), nitinol, an alloy of nickel and titanium, has been used as the predominant material because of its unique shape memory, biocompatibility, fatigue resistance, and superelastic properties.

Stent and strut design

Basically, there are two stent designs: coil and slotted tube. However, platforms can also vary according to the percentage of metal coverage, number of struts, and strut thickness and morphology. Most of the currently used DES have a slotted tube and open cell design. While open cell stents tend to be easier to navigate in challenging coronary anatomies and also provide easier access to side branches, they also have less radial strength and less coverage of the lumen, which can impact drug distribution in tortuous anatomies. Additionally, to minimize edge barotrauma preventing dissections, current stents have round struts.

Medtronic has recently developed a novel non-slotted tube design consisting of a single, continuous strand of wire formed into sinusoid. The stent is then wrapped in a helical pattern to ensure maximum flexibility and conformability. This concept will be tested in their all-new polymer free drug-filled stent (DFS).

Delivery systems

Although the first metallic stent used in humans for PCI was a self-expanding Wallstent [25], the vast majority of current DES use balloon-expandable delivery technology.

None of the self-expanding stents has found broad application in the clinical scenario, mainly because of the drawbacks associated with this technology, such as the need to precisely match stent size to vessel size; different and sometimes technically challenging release mechanisms; and stent foreshortening during deployment. However, at present, a few dedicated self-expanding devices are being used in niche situations such as bifurcations (Axxess™, Stentys™, Capella™) [26–28], STEMI (Stentys™) [29], and small vessels (Cardiomind™) [30].

Antiproliferative agents

The ideal antiproliferative agent would be able to suppress excessive neointimal growth, with selectivity for suppression of smooth cell proliferation while maintaining endothelial cell proliferation and function. Additionally, it would have a wide therapeutic window and low inflammatory potential.

The antiproliferative efficacy of a drug is linked to its local pharmacokinetics and physicochemical properties (e.g., more lipophilic agents are non-soluble in water and tend to stay longer in the local tissue with better and more homogeneous distribution into the arterial wall) and to the stent strut configuration (e.g., open vs. closed-cell design, stent–artery coverage).

Most of the currently available DES use limus-related drugs, such as sirolimus, everolimus, Biolimus A9, zotarolimus, and novolimus. These agents bind to intracellular receptor FKBP-12 and inhibit the mammalian target of rapamycin (mTOR), blocking the cell cycle of the smooth muscle cell (SMC) from the G1 to S phase [31,32].

Sirolimus was the first member of the limus family to be successfully used to prevent restenosis after PCI. The other currently used limus agents are usually synthetic or semi-synthetic analogs of sirolimus with modification in the hydroxyl group at position C40 (everolimus and zotarolimus) or position 42-O (Biolimus A9), or by the removal of a methyl-group from carbon C16 (novolimus). Although these modifications impact their pharmacokinetics, these limus agents have been proven to be very effective antiproliferative agents in the clinical scenario.

An alternative to the limus agents is paclitaxel, which stabilizes the microtubules, thereby inhibiting cell division in the G0/G1 and G2/M phases. This agent has many favorable characteristics for

local drug delivery, such as high degree of lipophilicity and long-lasting antiproliferative effects at relatively low concentrations. However, its beneficial anti-restenotic effects have been associated with local cytotoxicity and cell necrosis [33,34]. For this reason, limus family antiproliferative agents have been preferred.

Polymer coatings and alternative drug release technologies

Polymers serve as the interface between the stent and vascular tissue and function as the antiproliferative drug carrier, also controlling its release. Additional coating layers are found in many DES, and consist of either a top coating, to delay the drug release, or a base coating, to increase polymer adherence to the stent struts.

Both first-generation DES (Cypher and Taxus) used durable thick polymers to carry and control the release of their antiproliferative agents. The permanent presence of these polymers has been correlated to inflammatory responses and local toxicity in preclinical analysis [35–38]. Furthermore, durable polymers used in first-generation DES have been associated with mechanical complications (e.g., polymer delamination and “webbed” polymer surface leading to stent expansion issues) and non-uniform coating resulting in erratic drug distribution.

As a consequence, in recent years, the focus of clinical research has been on the development of novel drug carrier systems including more biocompatible durable polymers, biodegradable polymers, and non-polymeric stent surfaces.

Biodegradable polymers allow drug elution by drug diffusion or matrix degradation while durable polymers use particle dissolution. Conversely, non-polymeric DES systems incorporate alternative technologies such as reservoirs, surface modifications, and nanoparticles to carry and control the release of antiproliferative agents.

Current durable polymer DES

Although the current trend in DES development has moved toward biodegradable and polymer-free systems, three of the most used DES worldwide, Xience/Promus everolimus-eluting stent and Resolute zotarolimus-eluting stent, still follow the durable polymer concept. Both devices have built a strong body of scientific evidence, both in terms of efficacy and safety, and therefore have become the “gold standard” for novel technologies to be compared to.

Compared with the first generation of DES with durable polymers, these new devices not only incorporate more biocompatible materials such as acrylic and fluoro polymers but also change the metallic alloy on their platforms (from stainless steel to CoCr or PtCr) achieving thinner struts and lower crossing profiles to tackle more cumbersome anatomies. Their efficacy and safety has been tested in controlled trials in the most varied and complex patient profiles and coronary anatomies, with outstanding results. To summarize their clinical evidence, two recent meta-analyses showed their superiority over other clinically available devices.

Bangalore *et al.* [39], analyzing the outcomes of 258,544 patient-years of follow-up enrolled in 126 randomized trials showed that among all stent types, the newer generation durable polymer DES (zotarolimus-eluting stent Resolute, CoCr everolimus-eluting stents, and PtCr everolimus-eluting stents) were the most efficacious stents (lowest target vessel revascularization rates), and CoCr everolimus-eluting stents were the safest with significant reductions in definite stent thrombosis (rate ratio 0.35, 0.21–0.53), myocardial infarction (MI) (0.65, 0.55–0.75), and death (0.72, 0.58–0.90) compared with BMS [39].

Windecker *et al.* [40] investigated whether revascularization improves prognosis compared with medical treatment among patients with stable coronary artery disease. In order to achieve this, the authors built a Bayesian network meta-analysis to combine direct within-trial comparisons between treatments with indirect evidence from other trials while maintaining randomization. A total of 93,553 patients with 262,090 patient-years of follow-up were included from 100 randomized clinical trials. All PCI strategies, including POBA, BMS, and durable DES (first and newer generations) were included and compared with coronary artery bypass grafting (CABG) and medical treatment. They concluded that among patients with stable coronary artery disease, CABG reduces the risk of death, MI, and subsequent revascularization compared with medical treatment. All stent-based coronary revascularization technologies reduce the need for revascularization to a variable degree. However, only newer generation everolimus and zotarolimus-eluting stents improved survival compared with medical treatment [40].

Table 37.1 contains a brief description and angiographic performance of most currently used DES with durable polymers [41–45].

Biodegradable polymers DES

Since durable, thick polymers of first-generation DES seem to have a central role in perpetuating local vascular inflammatory reactions and potentially inducing the occurrence of late and very late stent thrombosis, the concept of a polymer that carries and controls the drug release during an proper period of time and then erodes and vanishes from the vascular surface seems to be very attractive.

Most of the systems presented in this section utilize poly-L-lactic acid (PLLA) and poly-D,L-lactide (PDLLA), which are progressively eroded by shortened ester bonds and ultimately degrade into lactic acid. Table 37.2 contains a brief description of the main components of the DES systems reviewed in this section [46–57]. It is beyond the scope of this chapter to detail all clinical trials with these devices; therefore, we focus mainly on the largest clinical studies with long-term clinical data available.

In the LEADERS trial, the BioMatrix™ stent was shown to be non-inferior to the first-generation durable polymer Cypher sirolimus-eluting stent, with respect to a composite endpoint of cardiac death, MI, and ischemia-driven target vessel revascularization at 12-month follow-up (BioMatrix 10.6% vs. Cypher 12.0%, $p=0.37$) [46,58]. This non-inferiority has recently been confirmed at 5-year follow-up. Importantly, the BioMatrix stent showed a significantly lower incidence of definite very late stent thrombosis at 5-year follow-up (hazard ratio 0.26, 95% CI 0.10–0.68). The LEADERS trial not only provided the first evidence of improved clinical outcomes compared to first-generation DES, but is also the proof of concept in terms of biodegradable polymer DES.

A pooled data analysis of the randomized ISAR-TEST 3, ISAR-TEST 4, and LEADERS trials also showed that the DES with biodegradable polymers were associated with a lower risk of very late stent thrombosis as well as MI compared to the Cypher SES [59].

Based on the safety findings related to these devices, the Global LEADERS trial is currently recruiting patients to compare treatment with BioMatrix followed by the use of DAPT (aspirin + ticagrelor) for 1 month and then ticagrelor alone for additional 23 months with placebo. This study aimed to include 16,000 all-comer patients and was powered to compare the composite of all-cause mortality or non-fatal new Q-wave MI up to 2 years post-randomization.

However, the utility of biodegradable polymer stents in the context of excellent clinical outcomes with newer generation durable

polymer stents still needs to be proven. A recent meta-analysis including 126 randomized trials and 258,544 patients treated with BMS, first- and second-generation durable polymer DES and biodegradable polymer DES failed to show the superiority of the biodegradable DES over new generation durable polymer DES. Indeed, newer generation durable polymer stents, and especially CoCr everolimus-eluting stents, presented the best combination of efficacy and safety in this meta-analysis [39].

It is important to highlight that not all biodegradable polymer DES are the same. While BioMatrix/Nobori are the most extensively evaluated devices in this category, they are still mounted on a thick (>120 μm) stainless steel platforms and their polymer erodes over 6–9 months, which is a long period of time compared to most recently developed biodegradable polymer systems such as Synergy or Orsiro.

Nevertheless, in the coming years we can expect much data on these devices because the majority of new DES programs are based on biodegradable polymer technology.

Non-polymeric DES

Non-polymeric DES have the potential to offer improved vascular healing avoiding the long-term negative effects of polymers. However, polymers in DES systems are intended not only to carry antiproliferative drugs, but also to control their release.

Most of the time, modifications in the surface of the platform are necessary to carry the antiproliferative agent (Figures 37.1 and 37.2). Alternatively, the drug can be directly attached to the stent surface by covalent bonds or crystallization/chemical precipitation or dissolved in a non-polymeric biodegradable carrier (e.g., nano particles) [60].

We will not go into detail on all clinical programs with these devices. Table 37.3 contains a brief description of the main components of the currently available (clinically or under investigation) polymer-free DES systems as well as the angiographic findings (late loss) in their first-in-man trials [61–63].

It is important to note that this is still a relatively new field in interventional cardiology and long-term data as well as larger controlled trials should be expected soon. Among the various promising polymer-free technologies, the BioFreedom™ stent deserves specific mention. Preclinical studies have reported lower injury scores; lower numbers of struts with fibrin, granulomas, and giant cells; significantly lower percentage of diameter stenosis; and greater endothelialization with the BioFreedom stent at 180-day follow-up compared to the Cypher SES. The first-in-man trial enrolled 182 patients who were randomized to receive either BioFreedom with standard dose (SD) Biolimus A9 (15.6 mg/mm), BioFreedom with low dose Biolimus A9 (7.8 mg/mm), or TAXUS Liberté PES. At 12 months, the in-stent LLL was 0.17 mm in the BioFreedom SD, which became the commercially available version.

Based on the enthusiastic initial findings, Biosensors initiated an audacious clinical trial, the LEADERS FREE, which had two primary objectives assessed by two separate primary endpoints: (i) to demonstrate in PCI candidates who are at high risk for bleeding and treated for 1 month with DAPT only, that the BioFreedom is non-inferior to the bare-metal comparator as measured by the a safety composite primary endpoint of cardiac death, MI, or stent thrombosis at 1 year; and (ii) to demonstrate superior efficacy of the BioFreedom by the incidence of clinically driven TLR at 1 year [64]. This trial recently completed enrollment and the primary endpoints will be presented soon.

Table 37.1 Main current durable polymer drug-eluting coronary stent systems.

Stent	Manufacturer	Anti-proliferative drug, dose and time of release	Platform alloy and thickness	Polymer type, thickness, location	Late-loss	Clinical trial
Endeavor™	Medtronic	Zotarolimus (10 µg/mm), 100% released in 2 weeks	CoCr, 91 µm	Phosphorilcoline (PC), 3 µm, abluminal	0.61 mm (12 months)	ENDEAVOR II ⁴¹
DESyne™	Elixir Medical	Novolimus (5 µg/mm), 80% released in 3 months and 100% up to 6 months	CoCr, 80 µm	Poly n-butyl methacrylate (PBMA), < 3 µm, abluminal	0.11 mm (9 months)	Excella II ⁴²
Promus Element™	Boston Scientific	Everolimus (1 µg/mm ²), 87% released in 3 months	PtCr, 81 µm	Copolymer of polyvinylidene fluoride co-hexafluoropropylene and Poly n-butyl methacrylate (PBMA), 6 µm, circumferential	0.17 mm (9 months)	PLATINIUM QCA ⁴³
Resolute Integrity™	Medtronic	Zotarolimus (10 µg/mm), 85% released in 2 months	CoCr, 91 µm	BioLinx (C19 hydrophilic polymer/polyvinyl pyrrolidinone/C10 hydrophobic polymer), 4.1 µm, abluminal	0.22 mm (9 months)	RESOLUTE FIM ⁴⁴
Xience V/Prime/Expedition	Abbott Vascular	Everolimus (1 µg/mm ²), 80% released in 1 month and 100% up to 3 months	CoCr, 81 µm	Copolymer of polyvinylidene fluoride co-hexafluoropropylene and Poly n-butyl methacrylate (PBMA), 7.6 µm, circumferential	0.10 mm	SPIRIT II ⁴⁵

CoCr, cobalt-chromium; PtCr, platinum-chromium

Table 37.2 Main current biodegradable polymer drug-eluting coronary stent systems.

Stent	Manufacturer	Anti-proliferative drug, dose and time of release	Platform alloy and thickness	Polymer type, thickness, location and duration of bioabsorption	Late-loss	Clinical trial
BioMatrix / NOBORI™	Biosensors / Terumo	Biolimus A9 (15.6 µg/mm) / 45% released in 1 month and 100% up to 3 months	SS, 112 µm	PLA, 10 µm, abluminal, absorption in 9 months	0.11 – 0.13 mm (9 months)	LEADERS ⁴⁶ / NOBORI ⁴⁷
Biomime™	Meril Life Science	Sirolimus (1.25 µg/mm ²), 100% released in 1 month	CoCr, 65 µm	PLL/PLGA, 2 µm, abluminal, absorption N/A	0.15 mm (8 months)	MERIT ⁴⁸
Combo™	OrbusNeich	EPC + Sirolimus (5 µg/mm) / 95% released in 3 months	SS, 100 µm	PLA/PLGA/CAP 3-5 µm, abluminal, absorption in <3 months	0.39 mm (9 months)	REMEDEE ⁴⁹
DESyne BD™	Elixir Medical	Novolimus (5 µg/mm), 90% released in 3 months	CoCr, 81 µm	PLA, <3 µm, absorption in 6-9 months	0.16 mm (6 months)	EXCELLA BD* ⁵⁰
Excel™	Biosensors	Sirolimus (195-376 µg) / release profile not informed	SS, 119 µm	PLA, 10-15 µm, absorption in 6-9 months	0.21 mm (6-12 months)	CREATE ⁵⁰
FIREHAWK™	MicroPort	Sirolimus (3.0 µm/mm), 75% released in 1 month and 90% up to 3 months	CoCr, 86 µm	PDLLA, abluminal (groove-filled), absorption in 9 months	0.13 mm (9 months)	TARGET I ⁵¹
INSPIRON™	SCITECH	Sirolimus (1.4 µg/mm ²), 80% released in 1 month	CoCr, 75 µm	PLA, PLGA, 5 µm, abluminal, absorption in 6-9 months	0.19 mm (6 months)	INSPIRON ⁵²
MiStent™	Micell	Sirolimus (9 to 11 µg/mm), 100% released in 2 months	CoCr, 64 µm	PLGA, abluminal, thickness N/A, absorption in 3 months	0.08 mm (8 months)	DESSOLVE ⁵³
ORSIRO™	Biotronik	Sirolimus (1.4 µg/mm ²), 50% released in 1 month	CoCr, 60 µm	PLLA with silicon carbide layer, 7 µm, circumferential, absorption between 12 and 24 months	0.10 mm (9 months)	BIOFLOW II ⁵⁴
SYNERGY™	Boston Scientific	Everolimus (5.6 µg/mm), 50% released in 2 months	PtCr, 71 µm	PLGA, 4 µm, abluminal, absorption in 4 months	0.10 mm (6 months)	EVOLVE ⁵⁵
Supralimus™	Sahajanand Medical	Sirolimus (6.6 µg/mm),	SS, 80 µm	Blend (PLLA-PLGA - PCL-PVP), 4-5 µm, abluminal, absorption in 7 months	0.09 mm (6 months)	SERIES ⁵⁶
Ultimaster™	Terumo	Sirolimus (3.9 µm/mm), 100% in 3-4 months	CoCr, 80 µm	PDLLA/PCL, abluminal, absorption in 3-4 months. Polymer thickness not informed	0.04 mm (6 months)	CENTURY ⁵⁷

CoCr, cobalt-chromium; N/A, not available; PCL, poly-L-lactide-co-ε-caprolactone; PDLLA, poly-D, L-lactic acid; PLA, polylactide; PLGA, poly-lactide-co-glycolide; PLLA, poly-L-lactic acid; PtCr, platinum-chromium; PVP, poly-vinyl-pyrrolidone; SS, stainless steel.

Future perspectives

PCI with bioabsorbable vascular scaffolds (BVS) has created interest because the need for mechanical support for the healing artery is temporary, and beyond the first few months there are potential disadvantages of a permanent metallic prosthesis. There are several potential advantages of this novel technology:

- 1 Reduction in the occurrence of special late and very late stent thrombosis. Once the antiproliferative drug and the temporary scaffold disappear, the possibility of thrombotic events in the site of PCI is considerably reduced.
- 2 Restoration of endothelial function. Once the “rigid” scaffold structure is removed, the shear stress is restored, favoring also late luminal increasing. Furthermore, the full patency of “jailed” side branches might be recovered.
- 3 Potential pediatric role because they allow vessel growth and do not need eventual surgical removal.
- 4 Possibility of vessel assessment with non-invasive imaging modalities such as coronary CT or MRI. The current technology of metallic stents results in excessive artifacts on angio CT, which precludes a definite non-invasive assessment of the stented segment. The absorbable scaffolds allow a clear visualization of the entire coronary tree from day one.
- 5 Possibility of further revascularization therapies in the treated segments. A current complaint is that the use of a “full metal jacket” to treat diffuse coronary disease might preclude CABG (or even repeat PCI) in case of future failure of PCI. As the BVS will be absorbed, in case of disease progression the surgeon would still have coronary segments to perform graft anastomosis.

Figure 37.2 Drug-filled stent (DFS). Based on the continuous sinusoidal technology, this stent features a novel tri-layer wire design, with an outer cobalt chromium layer for strength, a middle tantalum layer for enhancing radiopacity, and an innermost core layer which is removed, creating a continuous strut lumen that is coated with drug. Sirolimus is eluted from the core upon implantation through holes on the abluminal surface of the stent, which allows for controlled and sustained polymer-free drug elution. Source: © Medtronic 2016. Conclusions

Current approaches to the development of DES are reviewed in this chapter. Although first-generation DES placed great emphasis on efficacy, long-term safety issues have arisen resulting in their replacement in clinical practice.

Newer metallic DES with durable and/or degradable polymer has been shown to decrease the risk of revascularization and ST events. However, the optimal stent design, the ideal polymers, antiproliferative drugs, and their degradation and release kinetics are still under investigation. Nevertheless, there is no doubt that DES will continue to play a pivotal part in the treatment of coronary artery disease, but future designs need to incorporate features that reduce thrombosis and promote endothelialization. Through the integration of mechanical, pharmacologic, and manufacturing endeavors, the development of an ideal DES is within reach.

Interactive multiple choice questions are available for this chapter on www.wiley.com/go/dangas/cardiology
