## Foreword

Technetium-99m-labeled bone imaging agents were introduced to the nuclear medicine community almost 50 years ago, and the resultant literature has become a vast web of knowledge concerning the pathophysiology, diagnosis, and therapy of skeletal (and marrow) disorders. Many authors have attempted to organize and structure this information to produce an interactive heuristic approach to skeletal scintigraphy, pathologic soft tissue uptake, and the therapy of painful osteoblastic metastases. This writer is among those who have attempted to produce such a volume, and I know from this arduous experience how difficult is the task.

It is therefore an honor and a pleasure to write a foreword to the second edition of *Orthopedic Nuclear Medicine*, by Abdelhamid H. Elgazzar, MD, an internationally recognized nuclear medicine specialist, researcher, and highly productive author, whose analytic, incisive, and inquisitive mind gave early promise of an outstanding career.

Dr. Elgazzar has produced the finest monograph on skeletal imaging to date, an encyclopedic work, beautifully illustrated with planar and tomographic (SPECT and PET) scintigraphs and excellent correlative radiographs. Impressive histologic illustrations are an important part of the author's approach to explaining the basic science and pathophysiology behind scintigraphic findings. The book focuses on, and updates, its coverage of simultaneously imaging with SPECT or PET and computed tomography/magnetic resonance. Besides the technetium-99m bisphosphonates, there are thorough discussions of other important radiopharmaceuticals and their clinical applications, including fluorine-18-FDG of course, sodium fluoride-F-18, and gallium-68 (as the citrate and as a label for PMSA). The text is further complemented by a wise tabular approach to differential diagnosis, as well as by clear illustrative diagrams. The bibliography and index have been appropriately and extensively updated as well.

This second edition of *Orthopedic Nuclear Medicine* should receive the accolades of the international nuclear medicine/radiology community: practitioners, researchers, teachers, trainees, and students. Dr. Elgazzar has written a remarkable, updated, beautifully produced book.

## Preface to the Second Edition

Nuclear medicine and molecular imaging have continued to develop with impressive advances in recent years. With the introduction of newer radiotracers and the use of hybrid imaging, the role of nuclear medicine in orthopedics has further grown in diagnosis and treatment of various bone and joint diseases.

This new edition of the book has accordingly been significantly updated with newer applications of hybrid imaging and the use of positron emission tracers in bone diseases. This text with the update and addition of two new chapters provides students and medical professionals with a comprehensive and clearly presented update on nuclear medicine and molecular imaging applications in orthopedic medicine. Global vision was considered however, given the limited resources in some communities which necessitates keeping presentation of certain modalities and procedures with their updates. The book begins with a chapter presenting fundamental anatomic, physiologic, pathologic, and technical concepts relevant to understanding orthopedic functional imaging and its use in clinical practice. Subsequent chapters cover diagnosis of skeletal infections, trauma, vascular disorders, metabolic bone diseases, neoplastic bone diseases, soft tissue calcifications, and joint disorders. A chapter on bone marrow imaging and another on hybrid imaging in musculoskeletal disorders have been added in this edition. The final chapter is devoted to the use of radionuclides in the treatment of bone and joint diseases.

This text continues to be unique in its brief, yet comprehensive and in-depth, approach to clarity through the creative use of numerous illustrations and figures; many have been added and updated. Because an understanding of both normal pathophysiology and morbid pathophysiology is a prerequisite for the successful use of orthopedic nuclear medicine, necessary pathophysiological aspects are presented at the beginning of each chapter, followed by a description of the use of scintigraphy for the various disease processes as well as correlative imaging.

The book is intended for all those interested in orthopedics, including radiologists, orthopedic surgeons, internists, pediatricians, other clinicians, and nuclear medicine professionals at all levels. My aim is to advance knowledge in orthopedic nuclear medicine, clarify and increase awareness of its important impact on the management of benign and malignant conditions, and hence improve its use for patients with various bone and joint disorders.

Kuwait City, Kuwait

The bone develops by intramembranous and endochondral ossification. Intramembranous ossification occurs through the transformation of mesenchymal cells into osteoblasts, while in endochondral ossification, a pre-existing cartilage forms first and then undergoes ossification. Two types of bone tissues form the skeleton, compact or cortical bone and cancellous, trabecular, or spongy bone. The spongy bone has a turnover rate approximately eight times greater than that of cortical bones. The bone is formed of three types of cells: osteoblasts, which produce the organic bone matrix; osteocytes, which produce the inorganic matrix; and osteoclasts, which are responsible for bone resorption. The bone marrow converts into yellow, or inactive, marrow, gradually reaching an adult pattern by the age of 25 years. The yellow marrow may revert due to the stress associated with several pathological and physiological processes. Joints develop in the mesenchyme between the ends of bones and are classified into several types according to their functional features as well as the nature of the adjoining tissue. The principal response of the bone to injury, and disease, is reactive bone formation; this is the basis of increased uptake of bone-specific radiopharmaceuticals, namely, Tc-99m diphosphonates and F-18 sodium fluoride. Other specific bone and joint pathological changes define the patterns of uptake of other radiopharmaceuticals used for imaging such diseases [e.g., gallium-67, labeled leukocytes, thallium-201, Tc-99m methoxyisobutylisonitrile (MIBI), and F-18 fluorodeoxyglucose (FDG)]. The factors that ensure the best possible

quality and interpretation of radiopharmaceutical investigation include obtaining the relevant clinical information, proper preparation of the patients (including sedation of pediatric patients), meticulous positioning of patients, adequate image acquisition, familiarity of the normal appearance in different age groups (and normal variants), awareness of the technical pitfalls, and the strengths and limitations of each modality.

## 1.1 Introduction

Nuclear medicine plays a crucial role in the diagnosis and management of various skeletal diseases because of the ability of scintigraphy to reflect changes in bone physiology. This permits the early identification of diseases and injuries. The increasing use of this imaging modality for the investigation of benign bone disorders is noteworthy. Utilization and effective use of these modalities should be based on a basic understanding of bone anatomy and physiology, technical aspects of nuclear medicine techniques, and sources of errors in conducting and interpreting these modalities.

## 1.2 Anatomy and Physiology of Bone

### 1.2.1 Bone Development

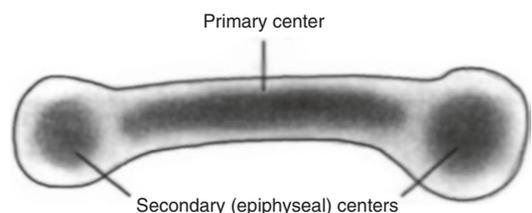

The bone develops by intramembranous and endochondral ossification. In some locations, such as the vault of the skull, intramembranous ossification alone occurs, while in other tissues, such as long bones, pelvis, and skull base, both intramembranous and endochondral ossifications occur. However, the process of bone formation is essentially the same and goes through the following steps [1]:

1. Osteoblasts differentiate from primitive mesenchymal cells.
2. Osteoblasts deposit a matrix that is subsequently mineralized.
3. Woven bone (primary spongiosa); this initial bone is characterized by an irregular network of collagen.

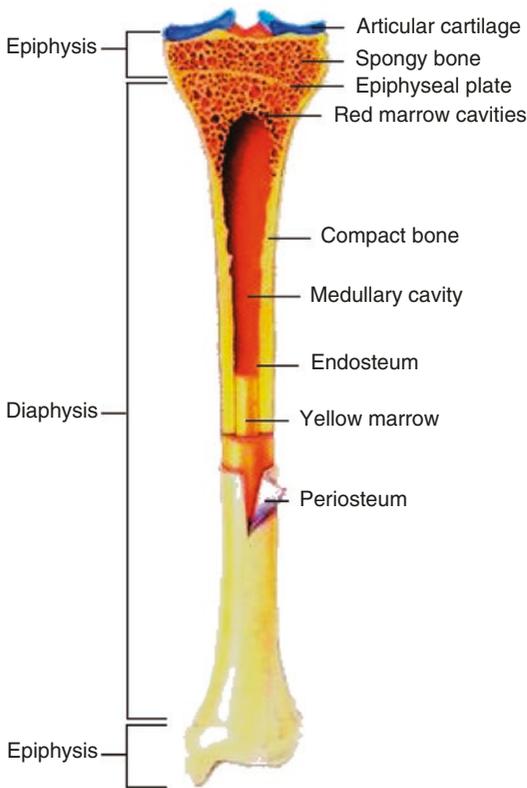

4. This temporary woven bone is replaced by the bone marrow in the marrow cavity or by the lamellar bone.

*Intramembranous ossification* occurs through the transformation of mesenchymal cells into osteoblasts. This is seen in the flat bones of the skull, parts of the mandible and clavicle from which these bones form [2, 3]. Thickening of the cortex of other bones is due to intramembranous ossification beneath the periosteum leading to an increase in the diameter of bones. In *endochondral ossification*, a pre-existing cartilage forms first and then undergoes ossification. Most of the skeleton forms by this type of ossification [2].

The initial sites of ossification are called the centers of ossification. These can be further classified into primary, such as those located in the central portions of long bones (i.e., the diaphysis which forms most of the shaft), and secondary, such as those located in the epiphyses and apophyses of long bones (Fig. 1.1). Virtually all primary centers are present at birth. Secondary ossification centers develop later at the end of the growing long bone. The epiphysis is separated from the shaft of the bone by the epiphyseal growth cartilage or physis. An apophysis is an accessory, secondary ossification center that develops later and forms a protrusion from the growing bone. This is where tendons and ligaments insert or originate. Examples of apophyses include the ischial tuberosity. The metaphysis is the part of the bone between the diaphysis and the physis. The diaphysis and metaphysis are covered by the periosteum, and the articular surface of the epiphysis is covered by articular cartilage (Fig. 1.2).

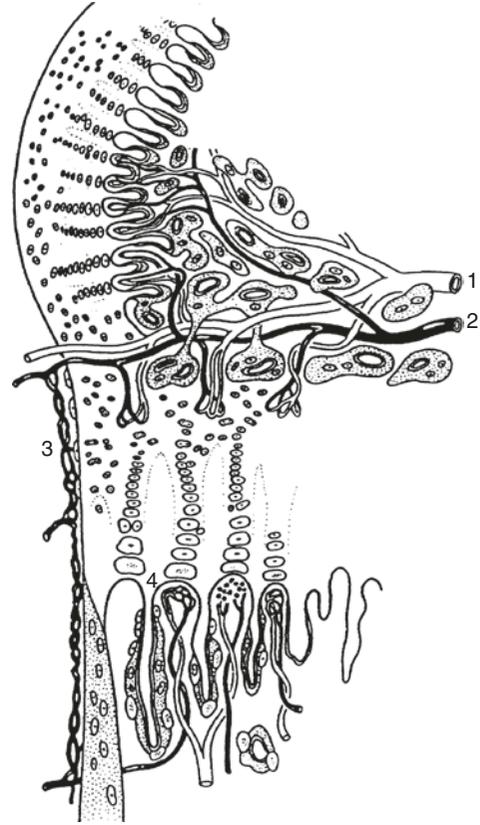

**Fig. 1.1** Primary and secondary ossification centers (from Shipman et al. [4], with permission)

**Fig. 1.2** The main elements of a long bone. The central region is the diaphysis which forms most of the shaft. The epiphysis is located at both ends of the bone separated from the shaft by the growth plate or physis. The part of the shaft between the diaphysis and physis is the metaphysis. The shaft (diaphysis and metaphysis) is covered by the periosteum. The articular surface of the epiphysis is covered by articular cartilage (from Thibodeau. Patton KI (1999): Anatomy and physiology Mosby p190 with permission)

**Growth Plate Development** Ossification progresses from the center toward the ends of the long bones where the frontier of intramembranous ossification advances and appears as an area of cellular activity that forms the growth plate (Fig. 1.3). This is the predominant site of longitudinal growth of the bone. Later, the ossification centers of the epiphysis and metaphysis fuse at the growth line. This halts growth and can only be recognized as a faint line. The long bone lengthens at the metaphysis while it thickens at the periosteum. In children knowledge of the location of the ossification centers is essential to correctly interpret the activity seen on scintigraphic studies.

**Fig. 1.3** The growth plate in a long bone. The diagram shows cartilage growth plate and adjacent metaphysis and epiphysis. Note the epiphyseal vein (1) and artery (2), the perichondrial vascular ring (3), the terminal loops of the nutrient artery (4) in the metaphysis and ongoing endochondral ossifications in the physis and epiphysis (from Gray's anatomy [5] with permission)

Apophyseal growth plates do not contribute to longitudinal growth of the bone and are present in the iliac crest, anterior superior and inferior iliac spines, ischium, and the lesser and greater trochanters (during the second decade). The apophyses fuse at variable ages (Table 1.1) and are particularly prone to avulsion [6].

## 1.2.2 Bone Anatomy

### 1.2.2.1 General Structural Features

Bone structure of normal adult bone can be summarized in four categories.

**Table 1.1** Sites and ages at fusion of the major apophyses

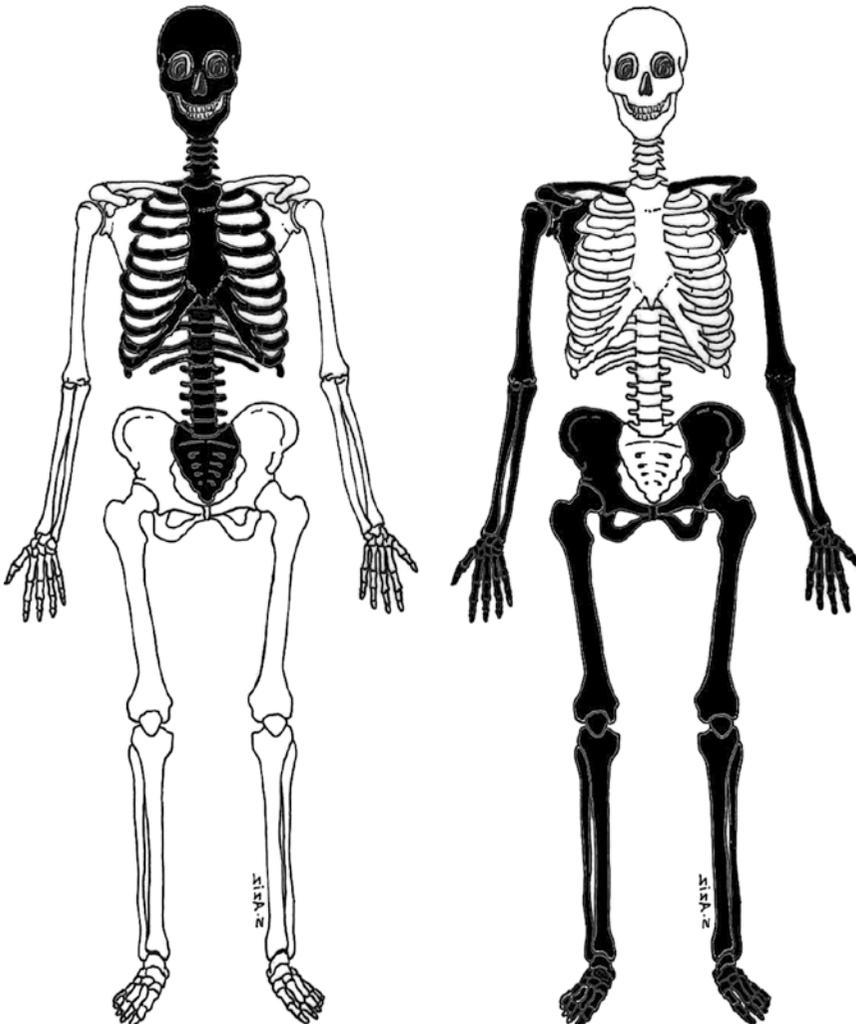

Site of apophysis	Age at fusion (years)	Attached muscle
Iliac crest	17–18	Abdominal wall muscles
Anterior superior iliac spine	16–20	Sartorius muscle
Anterior inferior iliac spine	25	Rectus femoris muscle
Symphysis pubis	20–25	Adductor group of muscles
Ischial tuberosity	20–25	Hamstring muscle
Lesser trochanter	18–19	Iliopsoas muscle
Greater trochanter	18–19	External rotators
Olecranon	18	Triceps
Distal radius	18	Brachioradialis

### Gross Level

The skeleton consists of two major parts, the axial skeleton and the appendicular skeleton (Fig. 1.4). The axial skeleton includes the skull, spine, and rib cage (ribs and sternum), while the appendicular skeleton includes the bones of the extremities, pelvic girdle, and pectoral girdle (clavicles and scapulae).

### Tissue Level

The bone is divided into two types of tissues forming the skeleton: compact or cortical bone and cancellous, trabecular, or spongy bone. The spongy bone has a turnover rate approximately eight times greater than the cortical bones and hosts hematopoietic cells and many blood cells.

**Fig. 1.4** Axial (*left*) and appendicular (*right*) skeletons

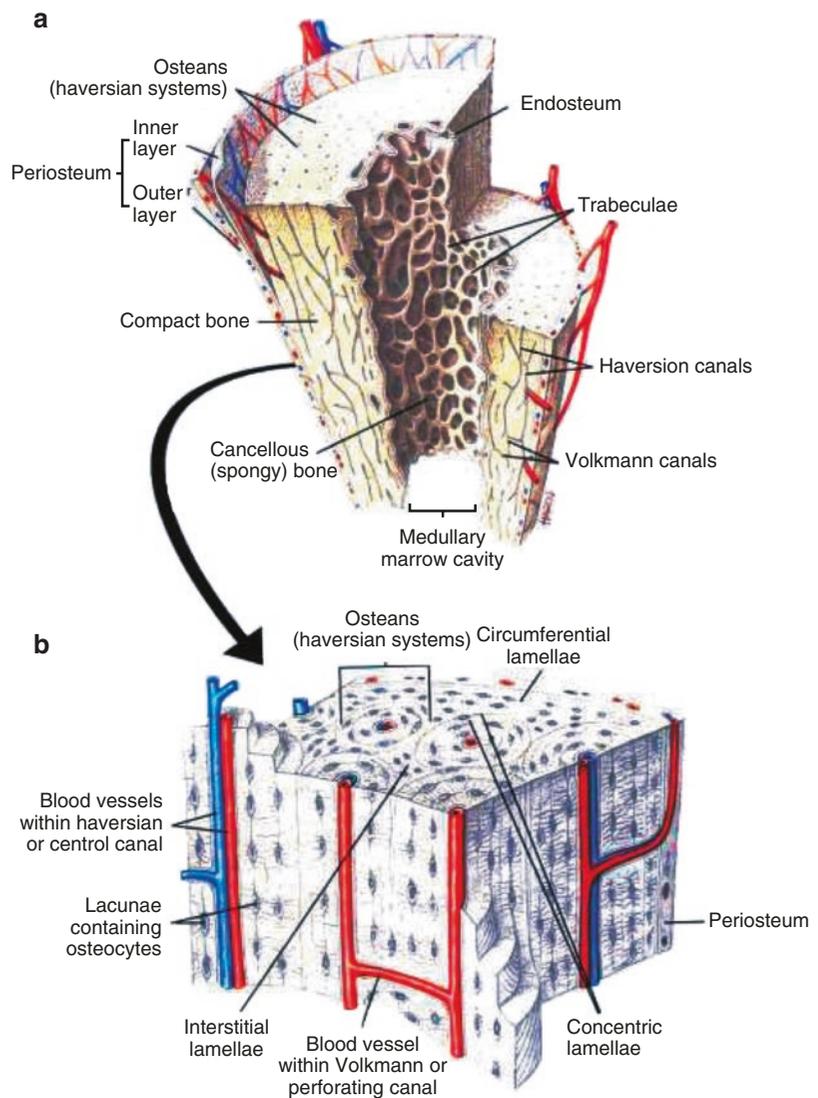

In mature bone, the compact bone forms an outer layer (cortex) which surrounds an inner one of loose trabecular, spongy bone in the medulla. The architecture is arranged in the haversian system (Fig. 1.5). The spongy portion contains hematopoietic cells, which produce blood cells, fat, and blood vessels. The compact bone constitutes 80% of the skeletal mass and contains 99% of the body's total calcium and 90% of its phosphorus.

The appendicular skeleton is composed predominantly of the cortical bone. The cortical bone is thicker in the diaphysis than in the metaphysis and epiphysis of long bones (Fig. 1.6). The blood supply to the metaphysis is rich and consists of

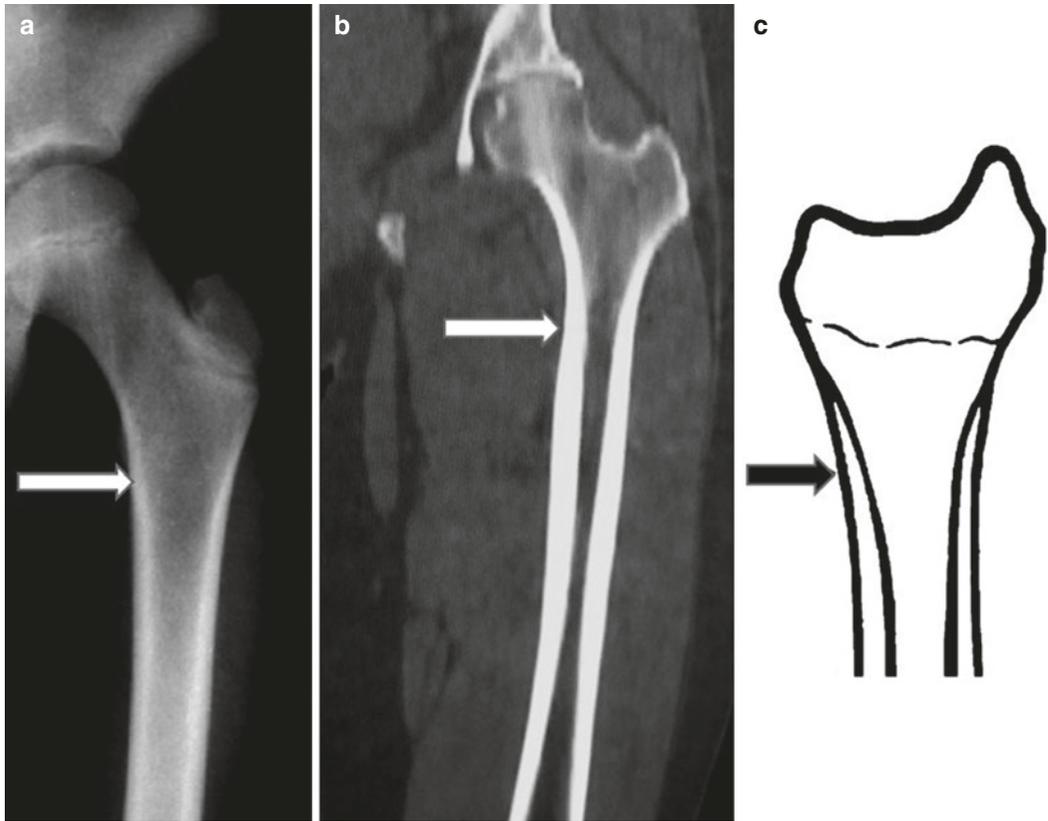

large sinusoids which slow the flow of blood. This is a feature that predisposes these sites to bacterial proliferation. The spine, on the other hand, is composed predominantly of cancellous bone in the body of the vertebra and compact bone in the end plates and posterior elements.

### Cellular Level

Three types of cells are seen in the bone: (1) osteoblasts, which produce the organic bone matrix; (2) osteocytes, which produce the inorganic matrix; and (3) osteoclasts, which are active in bone resorption [7]. Osteoclasts are derived from the hemopoietic system, in contrast

**Fig. 1.5** Structure of the compact and spongy bone (a). Longitudinal section of a long bone showing both compact and spongy or cancellous bone (b). Magnified view of compact bone (from McCarthy EF [2] with permission)

**Fig. 1.6** A radiograph (a) and CT (b) of the proximal parts of the femur illustrating the diaphyseal cortical bone that gradually thins in the regions of the metaphysis and epiphysis. (c) A schematic representation of this feature

to the mesenchymal origin of osteoblasts. Osteocytes are derived from osteoblasts that have secreted the bone around themselves [8].

### Molecular Level

At the molecular level, bone matrix is composed primarily of organic matrix (approximately 35%), including collagen and glycoproteins, and inorganic matrix (approximately 65%), which includes hydroxyapatite, cations (calcium, magnesium, sodium, potassium, and strontium), and anions (fluoride, phosphorus, and chloride) [9, 10]. Table 1.2 summarizes the major constituents of the bone and their function.

#### 1.2.2.2 Blood Supply of Bone

Skeletal blood supply varies according to age. In children epiphyseal, metaphyseal, and diaphyseal vessels are present. In adults all vessels intercommunicate. Nutrient and periosteal

arteries feed a rich network of vessels to supply the cortex and medulla (Fig. 1.7). This vasculature takes the form of interconnecting capillaries, sinusoids, and veins with hematopoietic spaces between sinusoids. It is estimated that blood flow to the spongy bone containing the marrow is 5–13 times higher than in the cortical bone [11].

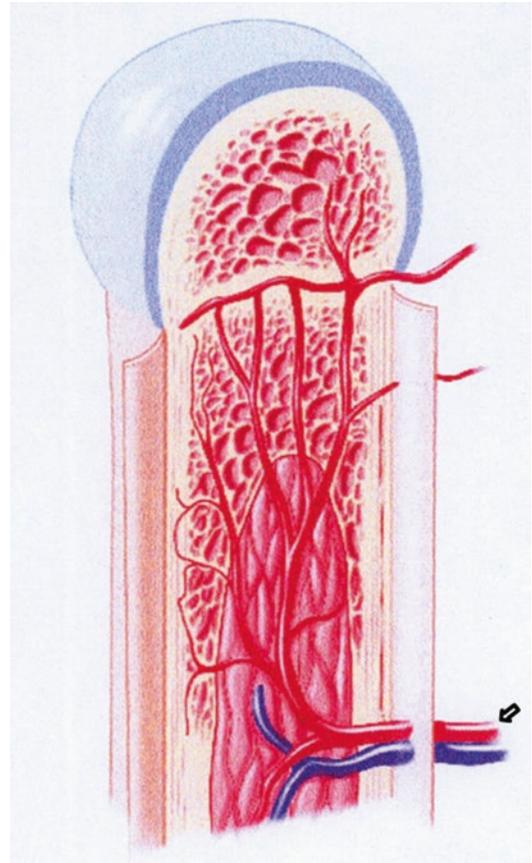

#### 1.2.2.3 Features of Individual Bones

Familiarity with the anatomical features of individual bones is a prerequisite for the proper interpretation of scintigraphic studies and the correlation with other imaging modalities. Bones can be generally grouped in four categories, long, short, flat, and irregular bones. Long bones include the femur, tibia, fibula, humerus, radius, and ulna. Short bones include the metatarsals, metacarpals, and phalanges. Flat bones include the ribs and sternum. Irregular bones include the vertebrae, pelvis, and skull. The long bones

**Table 1.2** Bone structures and their functions

Major structural elements	Function
<i>Bone cells</i>	
Osteoblast	Production of collagen and polysaccharide in the bone
Osteocytes	Produce bone inorganic matrix
Osteoclasts	Resorb bone, assist with mineral homeostasis
<i>Bone matrix</i>	
Organic matrix:	
Collagen fibers	Provide support and tensile strength
Proteoglycans	Control transport of ionized materials through matrix
Sialoprotein	Promotes calcification
Osteocalcin	Inhibits calcium/phosphate precipitation, promotes bone resorption
Laminin	Stabilizes basement membranes in the bone
Osteonectin	Binds calcium to bones
Albumin	Transports essential elements to matrix
Inorganic matrix:	
Calcium	Provides rigidity and compressive strength
Phosphate	Regulates vitamin D and hence promotes mineralization

consist of an epiphysis, metaphysis, and diaphysis. The periosteum is a fibrous and membranous layer that covers the bone shaft and is rich in osteoblasts. A similar layer separates the marrow cavity of the long bone from its cortical bone and is called the endosteum. Describing the detailed anatomical features of individual bone is beyond the scope of this text. However, a simple diagram illustrating the main features and parts of the major bones in addition to the bones of the hand and foot (Fig. 1.8) can serve as a quick reminder and reference for the interpretation and help with the swift identification of abnormalities. The availability of a skeletal model at the time of interpretation can also help localize the abnormalities shown by bone scintigraphy. Specific terms are used to describe locations of lesions on imaging modalities (including scintigraphy). Familiarity with these terms is important, and Fig. 1.9 summarizes the major descriptive terms used routinely.

**Fig. 1.7** Blood supply of a long bone. Nutrient vessels (*arrow*) penetrate the compact bone and form ascending and descending branches. Periosteal vessels also penetrate cortical osseous tissue. Both types eventually communicate with medullary sinusoids

## 1.2.3 Bone Physiology

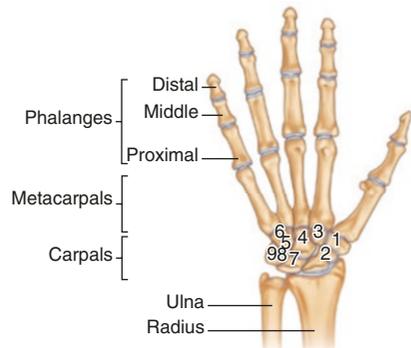

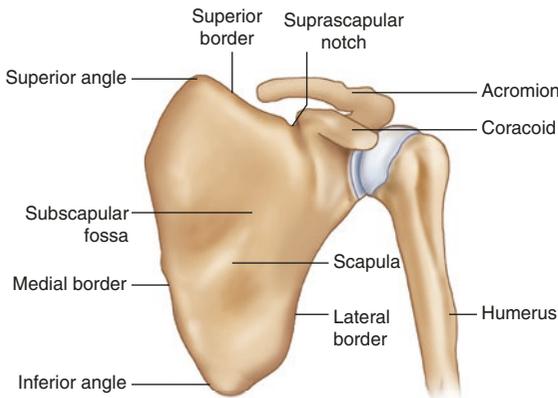

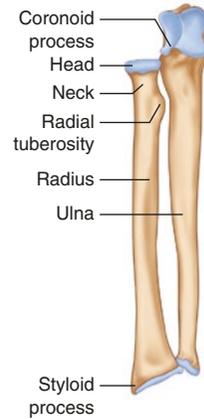

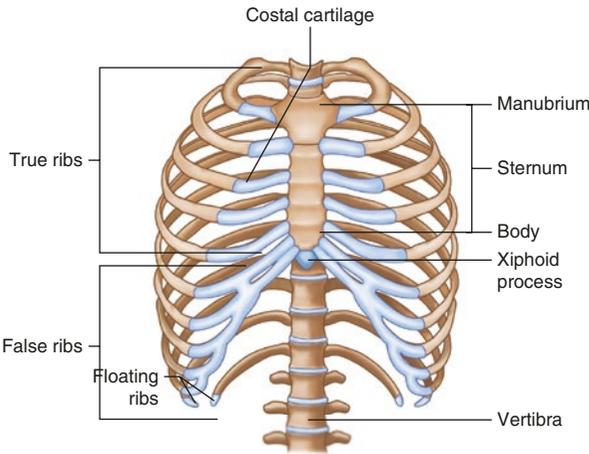

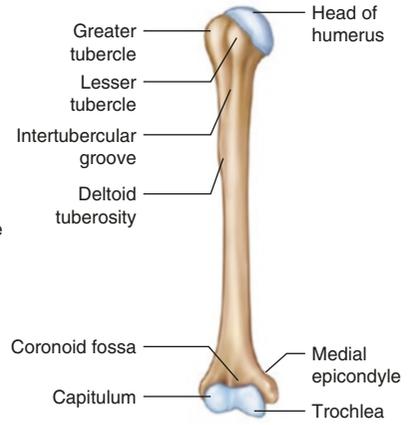

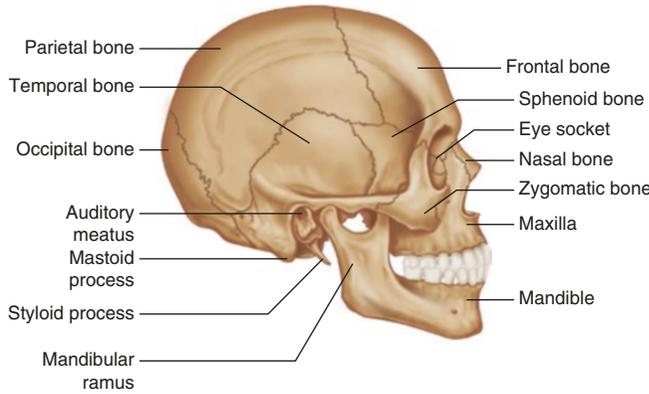

### 1.2.3.1 Bone Function

The bone is a rigid connective tissue, which provides support and protection for the vital organs and tissue of the body. Within certain bones such as the skull, vertebrae, and ribs, marrow cavities serve as sites of blood formation since these bones host the bone marrow. Bone has also an important function in mineral homeostasis.

### 1.2.3.2 Bone Metabolism

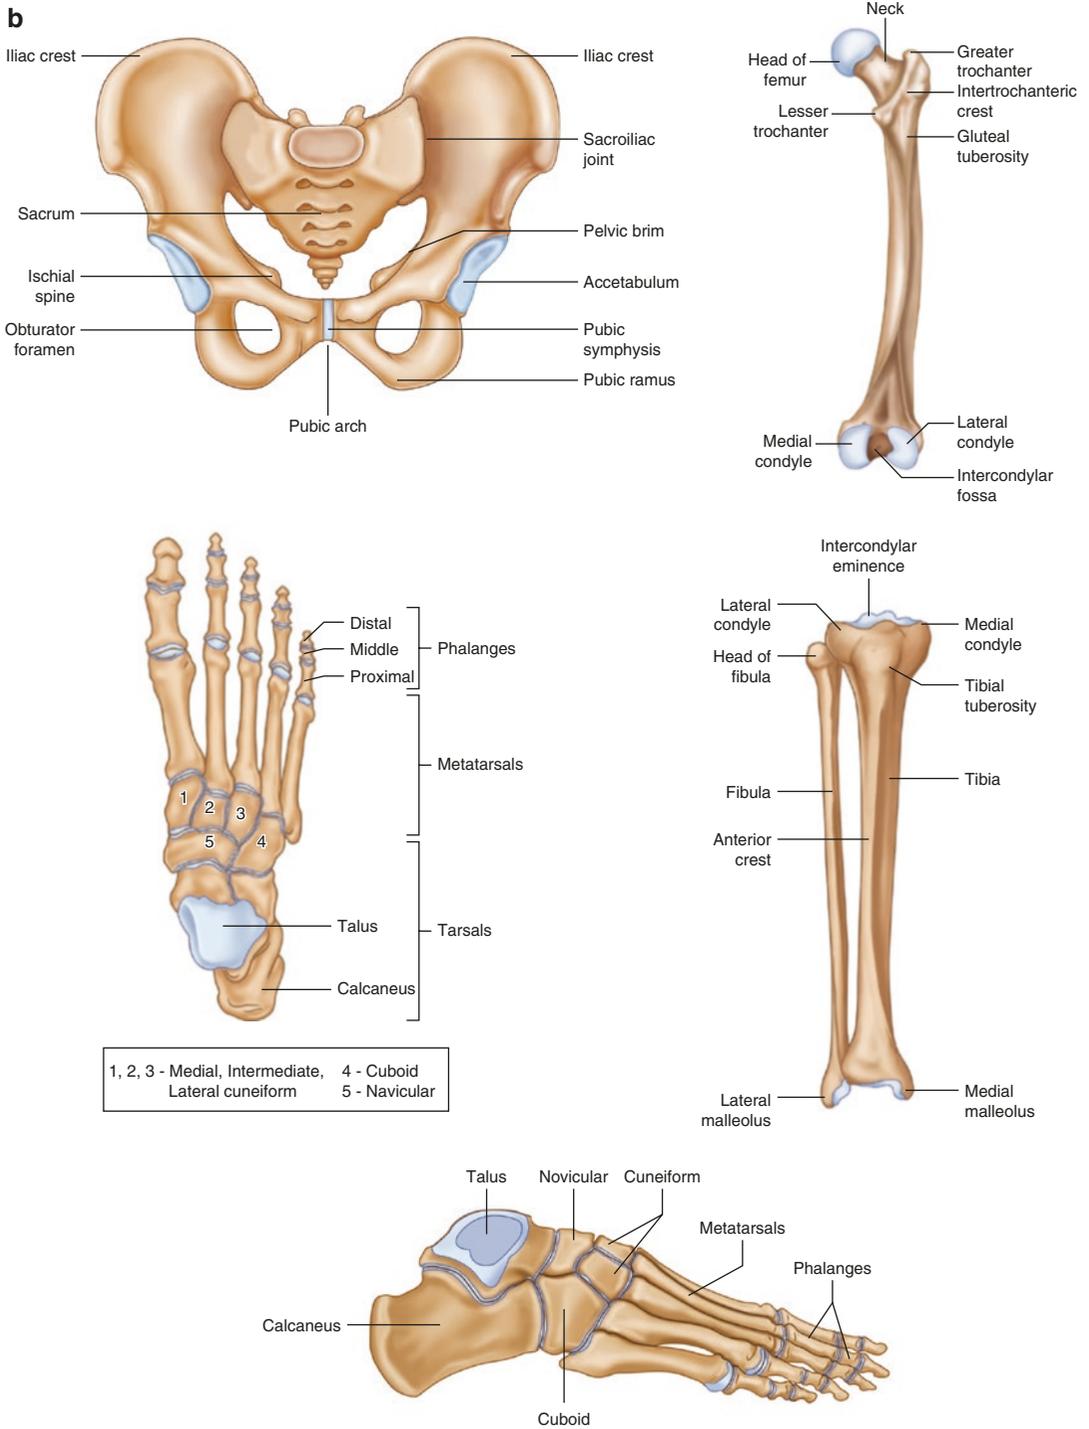

The bone was previously thought to be inactive at the cellular level, but it is in fact a dynamic tissue. Its cells are involved in complex intercellular interactions in the process of continuous

**Fig. 1.8** (a, b) Major bone of the human skeleton illustrating the main anatomic features necessary for planning the positions and the interpretation of the scintigraphic bone studies

**Fig. 1.8** (continued)

**Fig. 1.9** The major descriptive terms used to locate lesions within and around joint

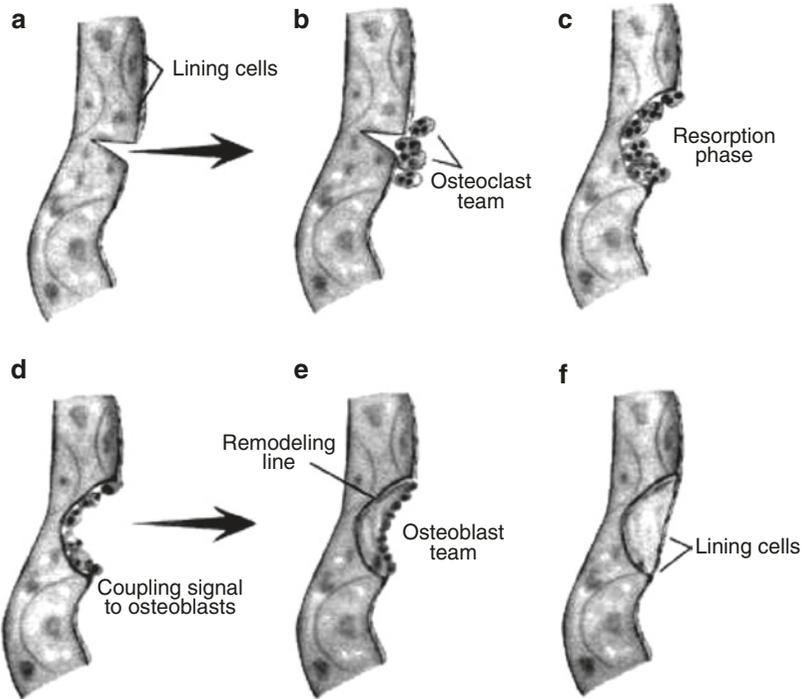

remodeling [12], whereby the bone is removed slowly and then replaced by the new bone.

Remodeling occurs throughout life with removal, and replacement, of the bone at different rates in different parts of the skeleton. It is estimated that 18% of the skeleton is replaced every year in adults, indicating that almost the entire skeleton is replaced every 5 years. The process is more active in the cancellous bone, with an approximate yearly replacement rate of 25% compared with 2% in the compact bone [7]. Bone remodeling functions by removing the injured bone (including the aging bone, which becomes weaker), reinforcing the bone in areas subject to abnormally increased stress, and, to a lesser extent, participating in calcium homeostasis by temporarily releasing calcium during the initial phase of remodeling [2]. Bone remodeling is carried out by teams of cells known as bone modeling units (BMU) in a four-stage cycle that begins with an activation stage. This could be due to the effect of the protein, osteocalcin, and results in recruiting osteoclasts. This stage is followed by stage of resorption during which groups of osteoclasts remove the bone, a stage that lasts for about 1 month. A reversal phase

then follows which attracts osteoblasts to the resorption site by a coupling signal. This is again not clearly understood but could be due to the effect of the growth factors IGF (insulin-like growth factor) and TGF- $\beta$  (transforming growth factor- $\beta$ ). This phase lasts for 1–2 weeks and is followed by the last phase of remodeling, the formation phase, which lasts for 5 months, during which time the osteoblasts line the resorption cavity and fill it with the new bone (Fig. 1.10).

The bone remodeling cycles are highly regulated (by parathormone, vitamin D, and numerous other factors such as growth hormone) [13], with the result that in normal healthy individuals, the amount of bone resorbed equals the amount of bone formed. The bone mass is thus unaltered. Under certain conditions, such as altered mechanical forces, metabolic bone disease, or metabolic and nutritional stress, this balance is disturbed [14]. Certain diseases are characterized by an increase in the rate of remodeling and are therefore known as high-turnover disorders; these may affect the entire skeleton or a single bone. Examples of such disorders include renal osteodystrophy and Paget's disease. In this group, both osteoblastic and osteoclastic activities

**Fig. 1.10** (a–f) Phases of remodeling cycle. (a) Microfracture in a trabecula signals for a team of osteoclasts. (b) An osteoclast team appears after the lining cells have retracted. (c) Osteoclasts begin the resorption phase and remove the portion of the bone containing the microfracture. (d) After the osteoclasts have done their work, a

coupling signal to the osteoblast is made. (e) Osteoblasts fill up the resorption cavity with the new bone. The interface of the resorption cavity and the new bone results in a cement line. (f) The osteoblasts have completed their work and the surface is again lined by lining cells (from McCarthy [2, p. 36], with permission)

are increased, but the amount of bone formed is usually less than the bone removed resulting in osteopenia. An exception is Paget's disease, in the latter stages of which the osteoblastic activity exceeds the osteoclastic activity [15].

The function of the bone marrow is to provide blood cells, based on the body's needs. For details please refer to Chap. 8.

### 1.3 Anatomy and Physiology of Bone Marrow

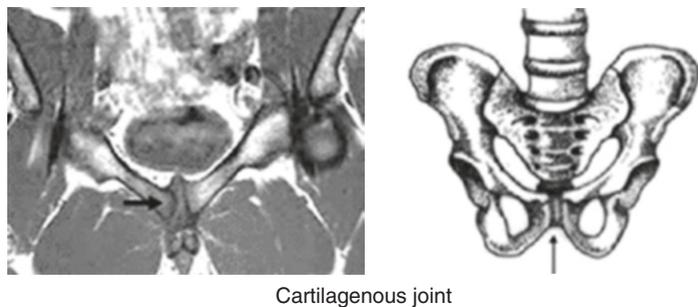

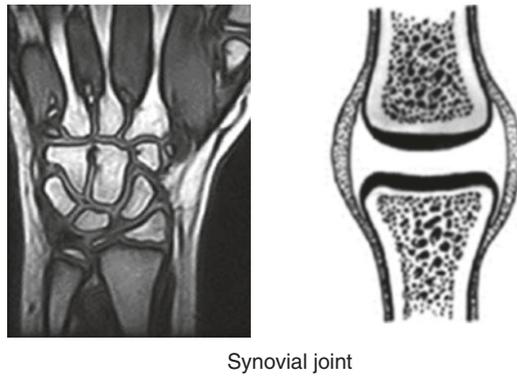

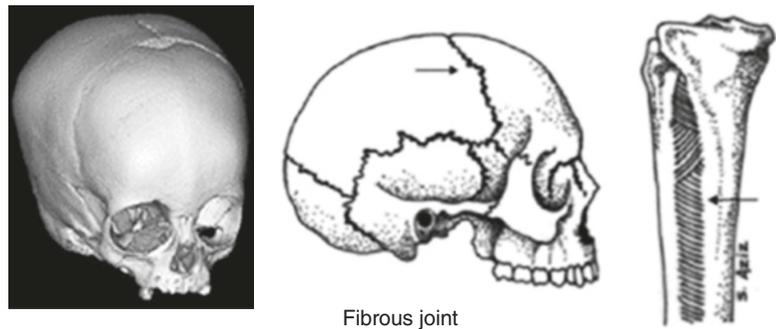

The bone marrow is the soft tissue that lies in the spaces between the trabeculae of bones. The bone marrow generally consists of several elements, including blood vessels, nerves, mononuclear phagocytes, stem cells, blood cells at different stages of maturation, and fat [7]. There are two types of marrow, red and yellow. The red marrow has active hematopoietic cells, while the yellow marrow consists mainly of fat and is not hematopoietically active.

### 1.4 Anatomy and Physiology of Joints

Joints develop in the mesenchyme that is present between the ends of bones. They are classified according to their functional features as well as the nature of the adjoining tissue into several types (Table 1.3). The mesenchyme develops into fibrous tissue in fibrous joints, hyaline cartilage in synchondrosis, fibrocartilaginous tissue in the symphysis, and into synovial membrane along with additional intra-articular structures in the synovial joints (Fig. 1.11). Familiarity with the major structural features of joints and their supporting structures

**Table 1.3** Classification of joints

Basis, major type	Types	Examples
<i>Nature of adjoining tissue</i>		
Fibrous	Suture	Skull sutures
	Syndesmosis	Radioulnar
	Gomphosis	Dental cement
Cartilaginous	Symphysis	Intervertebral disc, manubriosternal junction
	Synchondrosis	Growth plate
Synovial		Apophyseal joints, many extremity joints
<i>Extent of motion</i>		
Synarthroses (solid, nonsynovial), fixed or minimally movable	Fibrous and cartilaginous	Symphysis pubis
Diarthroses (cavitated), freely movable	Synovial	Knee, elbow

**Fig. 1.11** The main types of joints

(tendons, fasciae, and ligaments) is a prerequisite for the correct interpretation of nuclear medicine (and other types of) imaging. Synovial joints are considered to be specialized joints found mainly in the appendicular skeleton allowing free motion. The articulating surfaces of the opposing bones are separated by a cavity covered by a capsule with an articular cartilage covering the ends of both bones (Fig. 1.12). The inner surface of the joint capsule is formed by a synovial membrane which releases the synovial fluid (from a rich capillary network) into the articular cavity [16, 17]. The synovial fluid is a viscous fluid that serves to lubricate, nourish, and cushion the avascular joint cartilage. When the synovial space is infected, bacterial hyaluronidase decreases the viscosity of the syno-

vial fluid. Pain is then felt with stress on the joint capsule.

## 1.5 Spectrum of Bone and Joint Disease

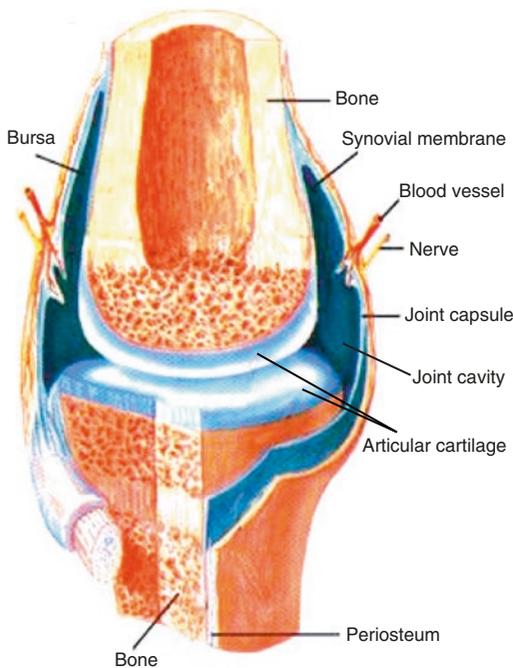

A variety of bone and joint diseases exist which may be primary or associated with other organ or systemic disease processes [2, 16, 17]. Consequently there are several ways to classify bone and joint diseases. Tables 1.4 and 1.5 show a simple classification for bone and joint diseases (with examples for further simplification).

**Table 1.4** Classification of bone diseases

Type	Example
<i>Nonneoplastic disorders</i>	
Congenital disorders	Osteopetrosis
Circulatory disorders	Osteonecrosis
Traumatic disorders	Stress fractures
Infectious disorders	Osteomyelitis
Metabolic disorders	Osteoporosis
Bone changes in systemic disease	Neuropathic joint disease of diabetics
<i>Neoplastic disorders</i>	
Primary tumors	Osteogenic sarcoma
Metastatic tumors	Metastases of breast cancer

**Table 1.5** Broad classification of joint disease

Type	Examples
<i>Inflammatory joint disease</i>	
1. Infectious	Infectious arthritis
2. Noninfectious	Rheumatoid arthritis, spondyloarthropathies
<i>Noninflammatory joint disease</i>	
1. Primary osteoarthritis	Age-related osteoarthritis
2. Secondary osteoarthrosis	Post-traumatic arthritis

**Fig. 1.12** Synovial joint structure (from Mourad [7], with permission)

## 1.6 Modalities for Imaging Bone and Joint Diseases

All the imaging modalities used for the diagnosis of bone and joint diseases fall into two complementary types, either morphological or functional modalities. Morphological modalities such as radiographs, ultrasonography, computed tomography (CT), and magnetic resonance imaging (MRI) depend mainly on structural changes, variations in density, and differences in proton

content in tissues. Functional modalities such as nuclear medicine techniques depend on the physiological changes. These modalities are numerous and no single modality is ideal in all situations. The choice of modality depends on the suspected condition, understanding of the strengths and limitations of each modality, and an understanding of the pathophysiology of the changes that occur in various pathological conditions and the associated comorbidities (Table 1.6).

**Table 1.6** Guideline to correlative imaging in bone disease

Disease condition	Standard radiograph	Scintigraphy	MRI	CT
Acute fractures	Modality of choice	Limited role used in battered child, small bones of hands and feet, and other locations where X-ray is not conclusive	Very useful in certain situations when other modalities are equivocal	
Stress fractures	Initial modality	Modality of choice	Sensitive, may prove more specific than scintigraphy	
Skeletal infections	Initial examination	Modalities of choice for multi focal infections	Suspected vertebral, children and diabetic foot infections	Detecting sequestra
Primary tumors	Initial examination	Limited role, determines multiplicity and metastases, specific diagnosis in some tumors (double density in osteoid osteoma, doughnut pattern in giant cell tumor and aneurysmal bone cyst)	Modality of choice Determines local extent	Osteoid osteoma, multiple myeloma
Metastases	Useful in multiple myeloma	Modality of choice	More sensitive than scintigraphy in purely lytic and vertebral lesions	
Assess tumor therapy	Limited role	Modalities of choice particularly PET, Tl-201 or Tc-99m MIBI if PET is unavailable		

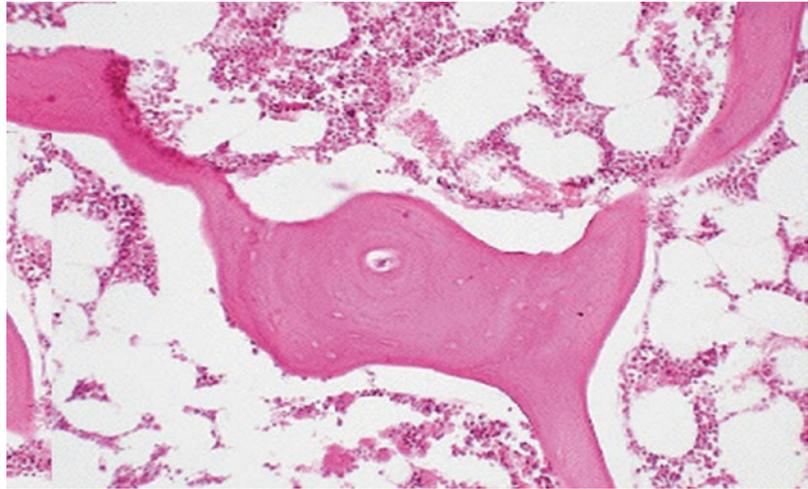

## 1.7 Diagnosis of Bone and Joint Diseases by Nuclear Medicine Techniques

The principle response of the bone to injury and disease is reactive bone formation. The bone formed in this way develops in stages. Initially, it is disorganized, active, and non-lamellar (woven), but later it may remodel to normal lamellar bone (Figs. 1.13 and 1.14). In comparison with normal

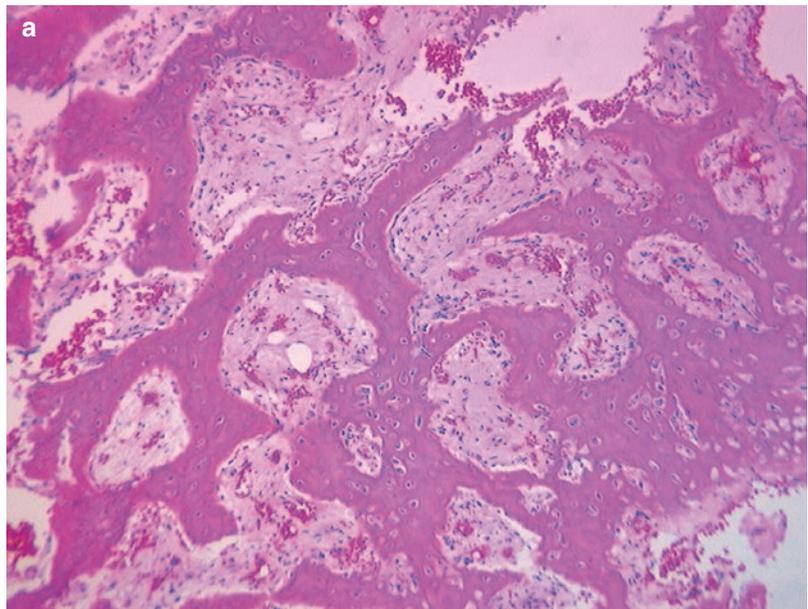

lamellar bone, the woven bone has a much larger surface area and is lined by metabolically active osteoblasts. Additionally, in the woven bone, the crystalline structures are smaller and have a larger surface area available for the absorption of bone radiopharmaceuticals [18, 19]. Accordingly, increased uptake of bone-specific radiopharmaceuticals is seen in such areas.

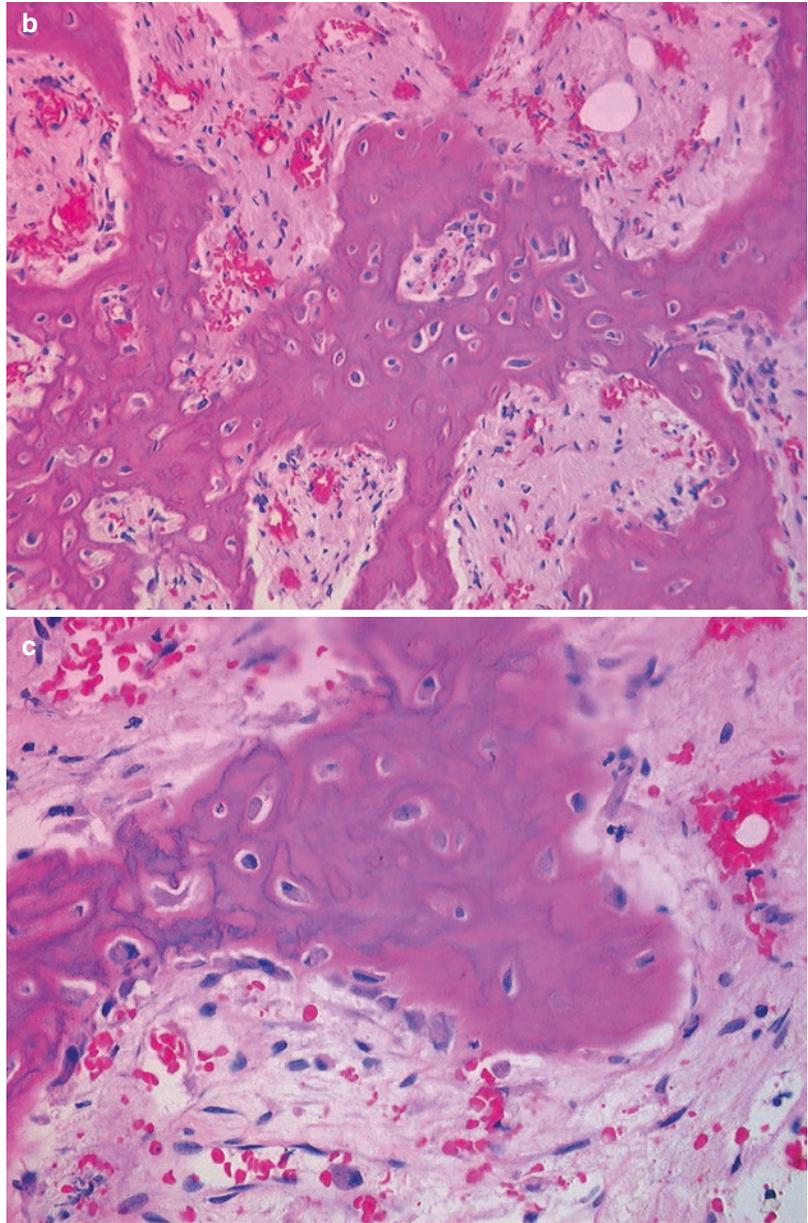

Imaging should be correlative and tailored according to the individual characteristics of each

**Fig. 1.13** Normal cancellous bone seen under polarized light which highlights the lamellar structure. The bony spicules are even, with occasional lacunae containing osteocytes. Cellular marrow is seen between the spicules of the bone

**Fig. 1.14** (a–c) The irregular and disorganized nature of the woven bone compared to the lamellar bone depicted in Fig. 1.13. This is emphasized at different microscopic magnification levels: (a)  $\times 10$  (b)  $\times 20$  (c)  $\times 40$

**Fig. 1.14** (continued)

case. Apart from bone scintigraphy using Tc-99m diphosphonates, nuclear medicine modalities include a range of techniques used to image bone diseases. These include gallium-67, labeled white blood cells using indium-111 oxine or Tc-99m HMPAO, Tl-201 imaging, Tc-99m MIBI imaging, bone marrow imaging using Tc-99m colloid, iodine-123 and I-131 MIBG, and PET imaging. Monoclonal and polyclonal antibody imaging is also used infrequently in bone disease, particularly in infections. The choice of a modality or combi-

nation of modalities is based on the individual case, the underlying disease, and the pathophysiology of the suspected condition(s), as well as the knowledge of radiation exposure (Tables 1.7, 1.8, 1.9, 1.10, 1.11, 1.12, 1.13, and 1.14). Knowledge of radiation exposure is particularly important in the pediatric age group and in pregnant women. The commonly used bone scintigraphy shows many patterns in a variety of benign and malignant bone diseases (some may be specific). Many of these patterns are better understood once the

underlying pathophysiological changes are appreciated (Table 1.15) and the clinical condition of the patient is known. Paying attention to the clinical and technical details can make the imaging results more specific than just localizing an abnormality.

## 1.8 Technical Considerations

### 1.8.1 Pre-imaging Considerations

#### 1.8.1.1 Bone Imaging Radiopharmaceuticals

Strontium-85, strontium-87m, and fluorine-18 were used as bone imaging radiopharmaceuticals before the introduction of technetium-99m to medicine in 1964. The first Tc-99m-labeled bone imaging agent to be described was stannous-

Large destructive lesion with rim of new bone formation	Doughnut pattern
Paget's disease, some primary or metastatic tumors	Bone expansion
Arthritis, CRPS-1	Periarticular increased uptake
Equilibrium of bone destruction and bone formation	Near-normal appearance

reduced Tc-99m triphosphosphate, followed by several other compounds with a higher bone uptake. The first was Tc-99m pyrophosphate, which was introduced before the diphosphonates that are still being used as the agents of choice for

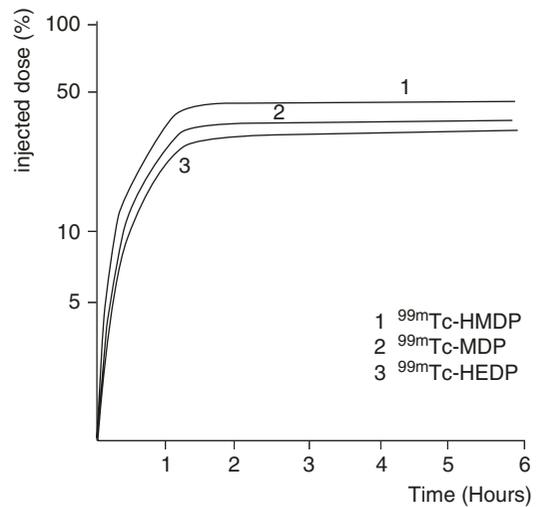

routine bone scintigraphy [23]. In addition, gallium-67 citrate, indium-111 oxine or Tc-99m HMPAO leukocytes, Tc-99m colloids, Tl-201 imaging, Tc-99m MIBI, F-18 PET, and Tc-99m- and In-111-labeled polyclonal and monoclonal antibodies are used. With the increasing availability of PET scanners, F-18 FDG and F-18 sodium fluoride are used particularly in searching for metastatic bone disease.

**Common Diphosphonate Radiopharmaceuticals**

Currently, Tc-99m diphosphonates are the radiopharmaceuticals most commonly used for skeletal scintigraphy (Table 1.16). These agents concentrate predominantly in the mineral phase of the bone (Table 1.17), which consists of crystalline hydroxyapatite and amorphous calcium phosphate. Using an in vitro assay, Francis et al. [24] showed that the competitive adsorption of Tc-99m diphosphonates in pure inorganic hydroxyapatite was 40 times that in pure organic bone matrix. These radiopharmaceuticals do not localize to a significant degree in osteoblasts or in the osteoid tissue. These various agents were found to have no significant difference in bone uptake (Fig. 1.15).

Several factors affect the uptake of diphosphonate in the skeleton, particularly the blood flow (an increased flow is matched by an increased uptake) and extraction efficiency. Pathological

foci containing woven bone show an increased uptake due to a higher extraction efficiency. Other factors (Table 1.18) such as the action of vitamin D also influence diphosphonate uptake. Accordingly, in children uptake of the radiopharmaceutical is particularly seen at the costochondral junctions, the metaphyseal ends of the normal long bones and in the facial bones. When the skeleton has matured, this uptake disappears. Overall the skeletal accumulation of diphosphonate decreases with age particularly in the extremities [25]. In a study of 49 females aged 14–79 years old and 47 males aged 6–89 years old with normal bone scans, the highest bone uptake in both sexes was obtained in individuals less than 20 years old with active epiphyseal

**Fig. 1.15** Bone uptake over time by three types of Tc-99m diphosphonates. Note that there is no significant uptake difference. Modified from [20], with permission

Sympathetic tone

growth plates. In men, bone uptake slowly decreased with age up to 60 years with a tendency toward increasing uptake values thereafter. In women, the mean uptake reached a minimum in the decade 20–29 years of age and then slowly increased with a positive linear correlation of uptake and age in those older than 55 years [26].

### Proper Utilization of Tc-99m Diphosphonates

The commonly used Tc-99m diphosphonate compounds should be used optimally within 2 h and no later than 6 h after preparation since they decompose with time due to the oxidation-reduction process. This process results in excess-free pertechnetate, which may lead to uptake in the thyroid gland, salivary gland, and gastric mucosa [23].

### Amount of Administered Activity

Table 1.19 summarizes the recommended dose and timing of imaging at different ages. The amount of activity to be used for an adequate bone scan is dependent on several factors, the most important of which is the age of the patient; the bone activity and the renal function are closely related to the patient's age. Patients under 30 can be injected with approximately 15 mCi (600 MBq), patients between the ages of 30 and 50 are injected with 20 mCi (750 MBq), while patients over the age of 50 years can be injected with 25 mCi (900 MBq). In children the activity administered is modified according to the weight of the patient. The younger the patient, the lower the activity and the shorter the time between

**Table 1.19** Administered activity of the current Tc-99m diphosphonates and timing of imaging according to the patient age

Age	Activity of Tc-99m diphosphonate	Time of imaging after injection
<i>Pediatric age</i>	According to weight	1.5–2 h
<i>Adults</i>		
Under 30 years	15 mCi	2 h*
30–50 years	20 mCi	3 h
Above 50 years	25 mCi	4 h

\*3 h, if extremities are the regions of interest

injection and acquisition of the images. In obese patients higher activity can be used [27].

### F-18 Sodium Fluoride

F-18 fluoride is a highly sensitive bone-seeking PET tracer. The mechanism of F-18 sodium fluoride resembles that of Tc-99m diphosphonates, with faster blood clearance and higher bone uptake than Tc-99m diphosphonates. The uptake of F-18 fluoride reflects blood flow and bone remodeling.

F-18 sodium fluoride PET/CT can be used to image the entire body from the top of the head to the toes or may be limited to a single anatomic region such as the head and neck, thorax, or abdomen and pelvis or the body between the skull base and middle of the thighs.

F-18 sodium fluoride PET bone scans are used mainly to detect bone metastases, including localization and determination of the extent of disease. F-18 sodium fluoride PET/CT improves the specificity of F-18 fluoride imaging as the CT component of the study allows morphologic characterization of the functional lesion and more accurate differentiation between benign lesions and metastases.

The administered activity is 5–10 mCi (185–370 MBq). A higher activity of 10 mCi (370 MBq) may be used in obese patients. Pediatric activity should be weight-based (0.06 mCi/kg [2.22 MBq/kg]), using a range of 0.5–5 mCi (18.5–185 MBq) [28].

#### 1.8.1.2 Patient Preparation

Patients must be properly prepared to achieve a diagnostically reliable study using Tc-99m diphosphonates. The referring physician and nursing team should also be familiar with such preparations. For a routine bone scan, the patient must be well hydrated depending on their clinical condition. The recommended ideal amount of fluid intake in adults between injection and imaging is 2000 ml, with a minimum of 500 ml [29]. The radiopharmaceutical activity and the time of imaging depend on the patient's age and underlying diseases. Using F-18 sodium, patients similarly should be well hydrated to promote rapid excretion of the radiopharmaceutical to decrease radiation dose and to improve image quality. Unless contraindicated, patients should drink 2 or

more 8 oz glasses of water within 1 h before the examination and another 2 or more glasses of water after administration of F-18 [28].

Patients should be prepared differently for studies using other radiopharmaceuticals, such as F-18 FDG, and there may no need for any specific preparation, such as with the use of labeled white blood cells and Tc-99m colloids. For the best results, however, the procedure, its duration, risks, and benefits of every study must be clearly explained to the patient.

Sedation for pediatric patients should be considered in order to obtain studies with good quality. This is particularly important in aiding interpretation in this age group. Sedation is frequently needed in patients below the age of 4 years and in older mentally retarded children. The most commonly used method is oral sedation using chloral hydrate, with a recommended dose of 75–100 mg/kg body weight to a maximum dose of 2.5 g. A lower dose of 50 mg/kg may not be sufficient in many cases, and adding a supplemental dose may not work in some patients, particularly if they have become agitated after the initial dose. Intravenous sedation using phenobarbital is another popular method. The recommended dose is 2.5–7.5 mg/kg body weight with a maximum of 200 mg. Other sedatives can also be used, as well as general anesthesia (in certain situations).

### 1.8.1.3 Patient History and Examination

Although a radiologist may read films with little history and no patient examination, bone scans cannot be adequately interpreted without detailed clinical information and a physical examination of the patient. A study illustrating this concept was conducted by Sundberg et al. [30], who found that the correct diagnosis of septic arthritis in children was achieved in 70% of cases when clinical information was included in the interpretation. This fell to only 13% when films were interpreted with no clinical information. Review of radiographs prior to the start of a study should be a routine practice, since it clarifies which special views might make the lesions more clearly visible. This also helps decide which areas may have a priority for

**Table 1.20** Essentially relevant information in patient's history for quality bone scan plan and interpretation

Information	Reasoning
Prior trauma (including accidents), surgery (including biopsy) of the bone and other tissues, presence of hardware with dates	Explain abnormal uptake and avoid confusion with current pathology
Whether the patient is left or right handed	Explain possible asymmetry of shoulder uptake as a normal variant and avoid false diagnosis
Occupation and physical activities	Explain certain findings such as joint uptake and help in the diagnosis of certain conditions such as fatigue, fractures in runners or ballet dancers
Therapy with steroids, etidronate or similar agents	Generalized decreased uptake
Tumors	Help in interpretation and explain certain findings such as dystrophic calcification
Patient body habitus fatty	Explain certain patterns as attenuation by tissue as in case of steatopygia
Chemotherapy with dates	Explain certain findings such as flare and expansion of the bone marrow
Radiation therapy with dates	Explain early flare and late cold lesions to avoid misinterpretation
Prior imaging studies	Comparison and correlation with bone images
Pregnancy and delivery	Decision-making regarding obtaining the study, explain certain postpartal findings in the pelvis such as diastasis

radionuclide angiography and blood pool imaging. Table 1.20 summarizes the important specific information which is needed before obtaining and interpreting bone scans.

### 1.8.1.4 Time of Imaging After Injection

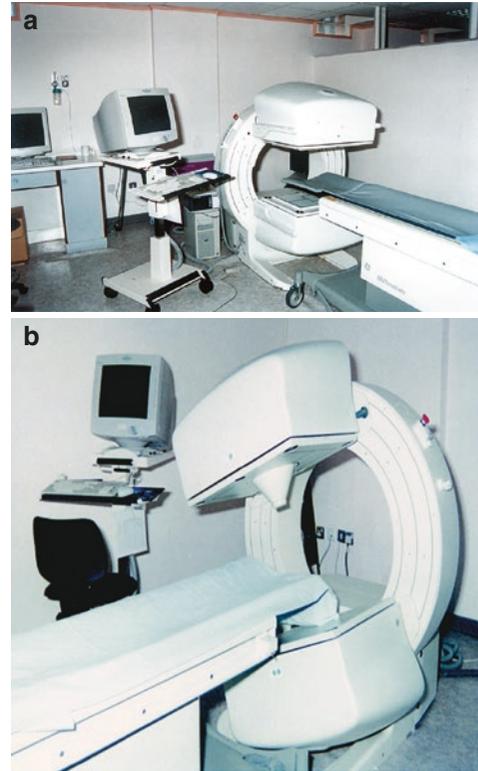

For patients under 30 years of age, the time of imaging generally is 2 h after injection. If the extremities are the areas of interest, this increases to 3 h. For patients aged 30–50 years, imaging should take place at 3 h (again, if the extremities are the area of interest the imaging should be delayed an hour). For

patients above 50 years of age, imaging is obtained at 4 h routinely. Further delay is needed if, in certain cases, there is delayed soft tissue clearance (e.g., kidney disease). Although adequate uptake by bone reaches adequate levels for imaging after 1 h, the additional delay is mainly related to the soft tissue clearance. This allows a better bone-to-background ratio for quality imaging. For F-18 sodium PET/CT study images are obtained normally 60 min postinjection.

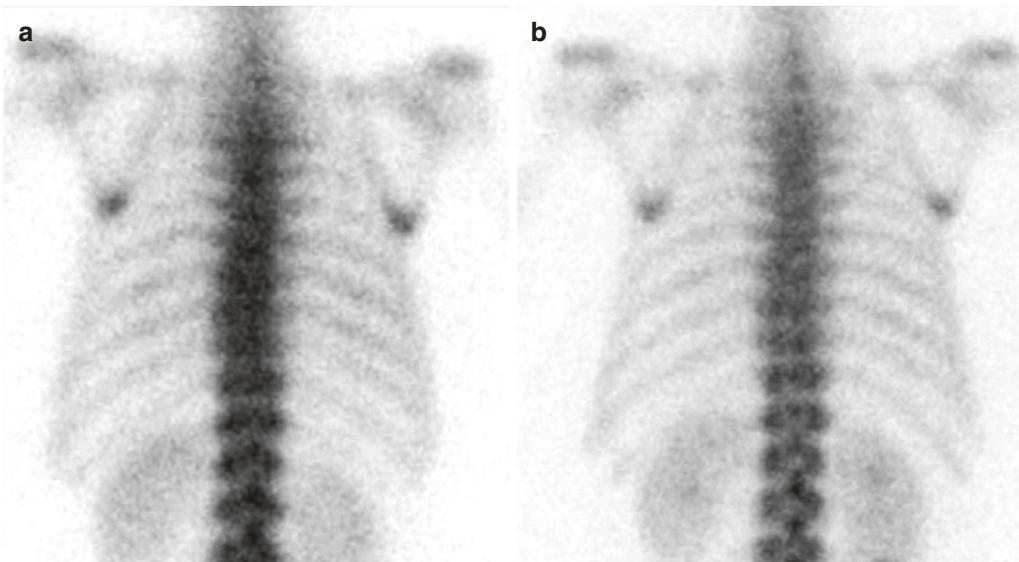

## 1.8.2 Imaging Considerations

### 1.8.2.1 Instrumentation

The clinical question being studied determines the use of single- or dual-head, wide field-of-view cameras which can be equipped with a variety of collimators. Dual-head cameras have the advantage of reducing the acquisition time and are particularly useful for routine whole-body scans. For the best results, the highest-resolution collimators should be used since resolution is important to recognize and localize abnormalities (Fig. 1.16). In addition to parallel-hole devices, pinhole (Figs. 1.17 and 1.18) and diverg-

**Fig. 1.17** (a, b) Dual-head gamma cameras equipped with pinhole collimator

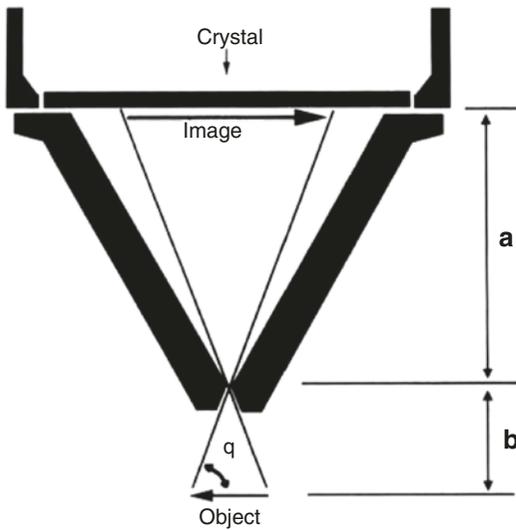

**Fig. 1.16** (a, b) Posterior Tc-99m MDP images acquired for the same count using (a) general-purpose and (b) high-resolution collimators for the same patient. Note the

difference in resolution with more details seen on high-resolution collimator images

ing collimators are used for the visualization of small skeletal structures or to image large patients, respectively. A pinhole collimator is particularly useful in pediatric patients and in imaging the small bones of the hands and feet and abnormalities of the knee and ankle in adults, since it provides adequate magnification as well

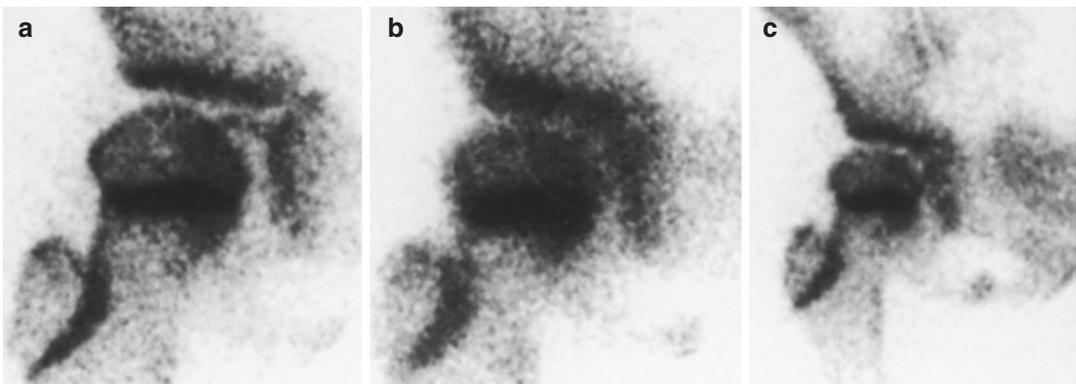

as resolution, which depends on the distance between the object and the collimator pinhole. This allows identification of details that may not be seen using a parallel-hole collimator or SPECT (Figs. 1.19 and 1.20). SPECT/CT and PET/CT are used again depending on the clinical question. Adding CT to functional instruments has added a great feature of identifying the anatomic details, better localization, and enhancing identification of pathological conditions.

**Fig. 1.18** The object magnification of a pinhole collimator. Crystal to pinhole distance ( $a$ ), pinhole to object distance ( $b$ ), angle at which photons pass through pinhole ( $\pi$ ), and pinhole diameter are all relevant parameters for determining magnification, sensitivity, and resolution (from Connolly et al. [31], with permission)

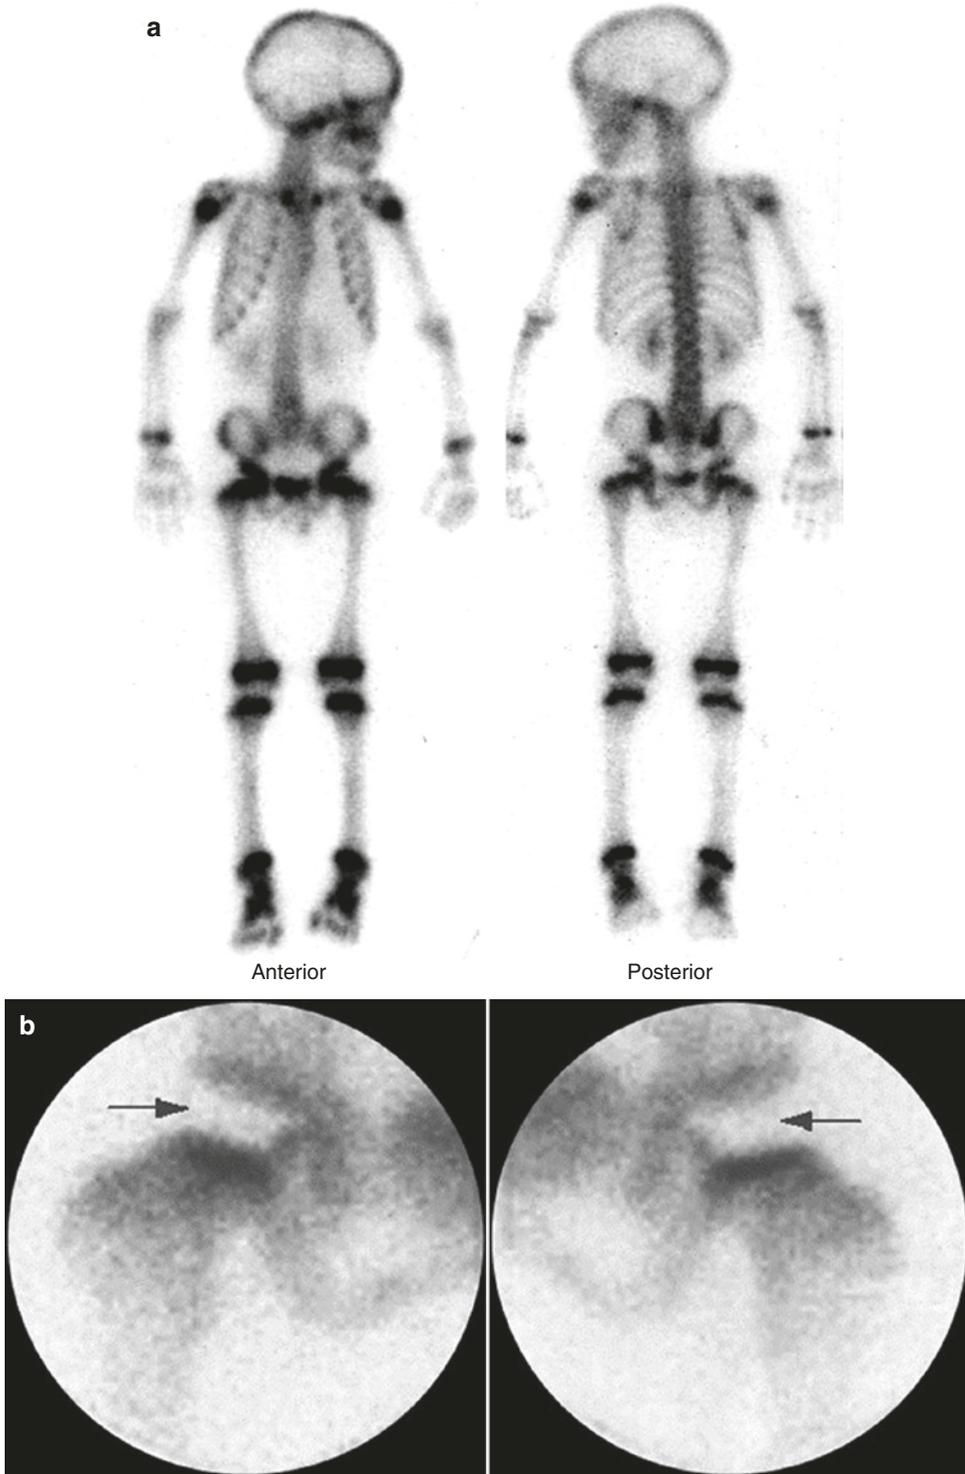

### 1.8.2.2 Positioning

Poor patient positioning can easily cause the appearance of false lesions (due to asymmetry) or artificially overlap bony structures which may obscure lesions. For whole body assure symmetrical position, hands beside body, and feet internally rotate using tape if necessary. Spot images are commonly needed whether routinely as additions to whole-body images or optionally based on findings on whole-body images. Accordingly physicians and technologists must be familiar with proper positions for different parts of the skeleton. The general rules for positioning patients for bone scanning are well known [29]. The choice of position is determined by clearly defining the clinical question that needs to be answered [32, 33]. Figure 1.21 shows the proper positioning for certain regions and the optional positions. Although whole-body imaging is

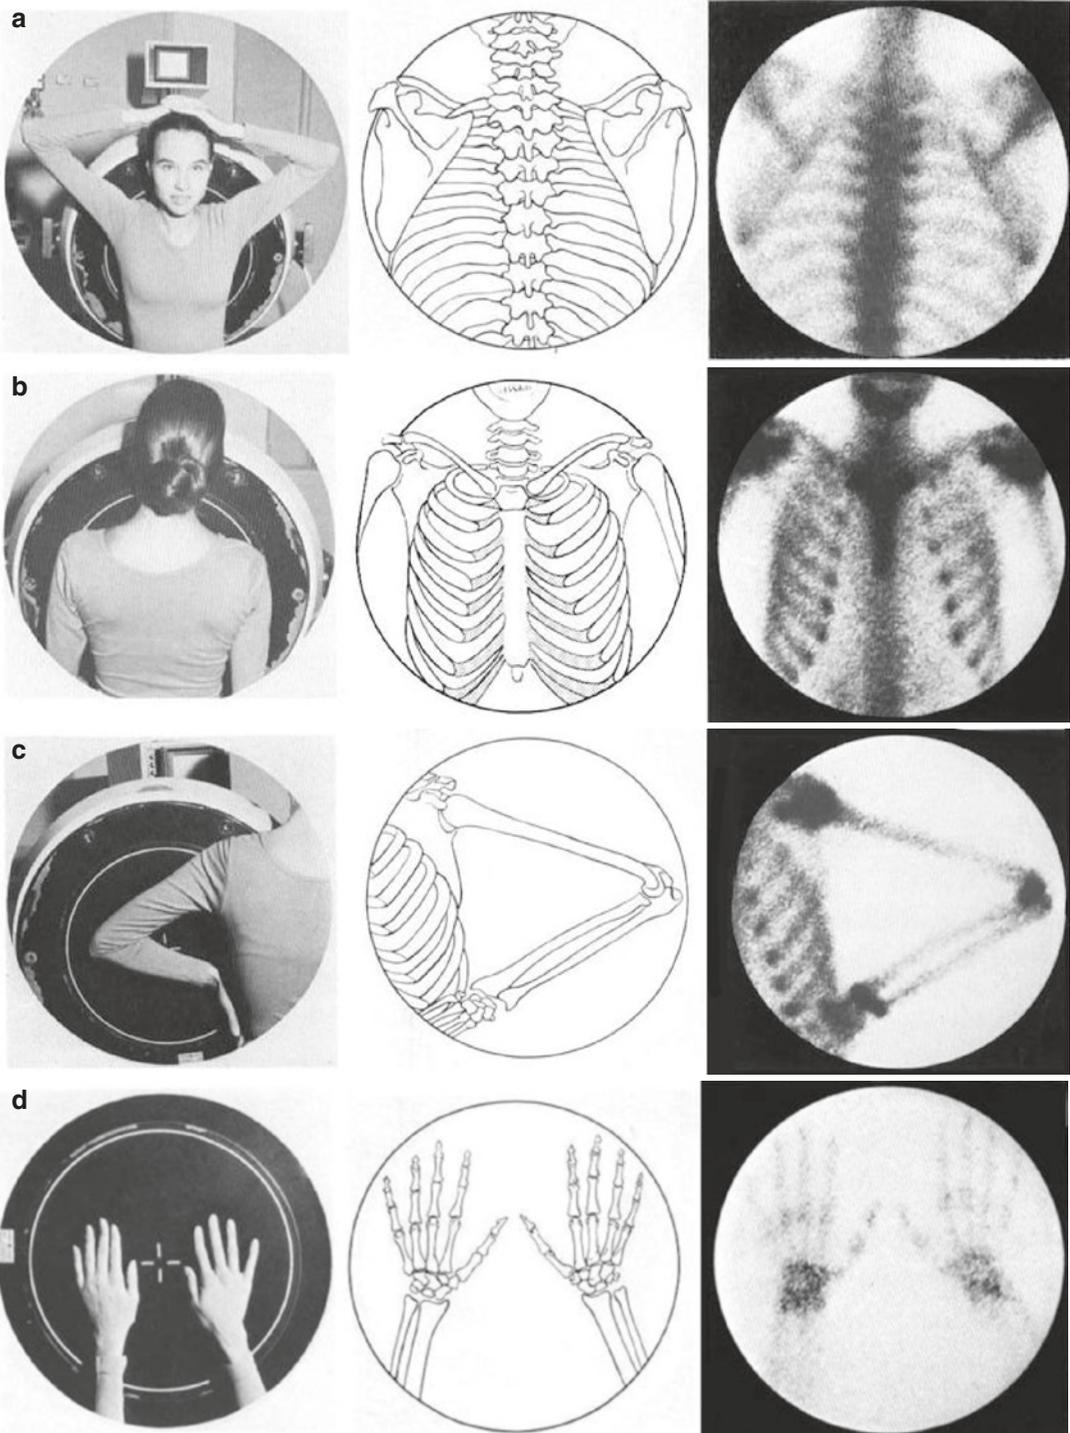

**Fig. 1.19** (a–c) Effects of pinhole diameter and pinhole-to-patient distance on resolution and magnification. (a) Image of right hip was obtained using 3 mm insert with collimator approximately 2.5 cm from skin surface. Resolution is superior to that provided using 4 mm insert

at the same distance from skin surface (b) and that provided using 3 mm insert approximately 10 cm from skin surface (c). Magnification is lower at greater distances. Count density is 150,000 for each image (from Connolly et al. [31], with permission)

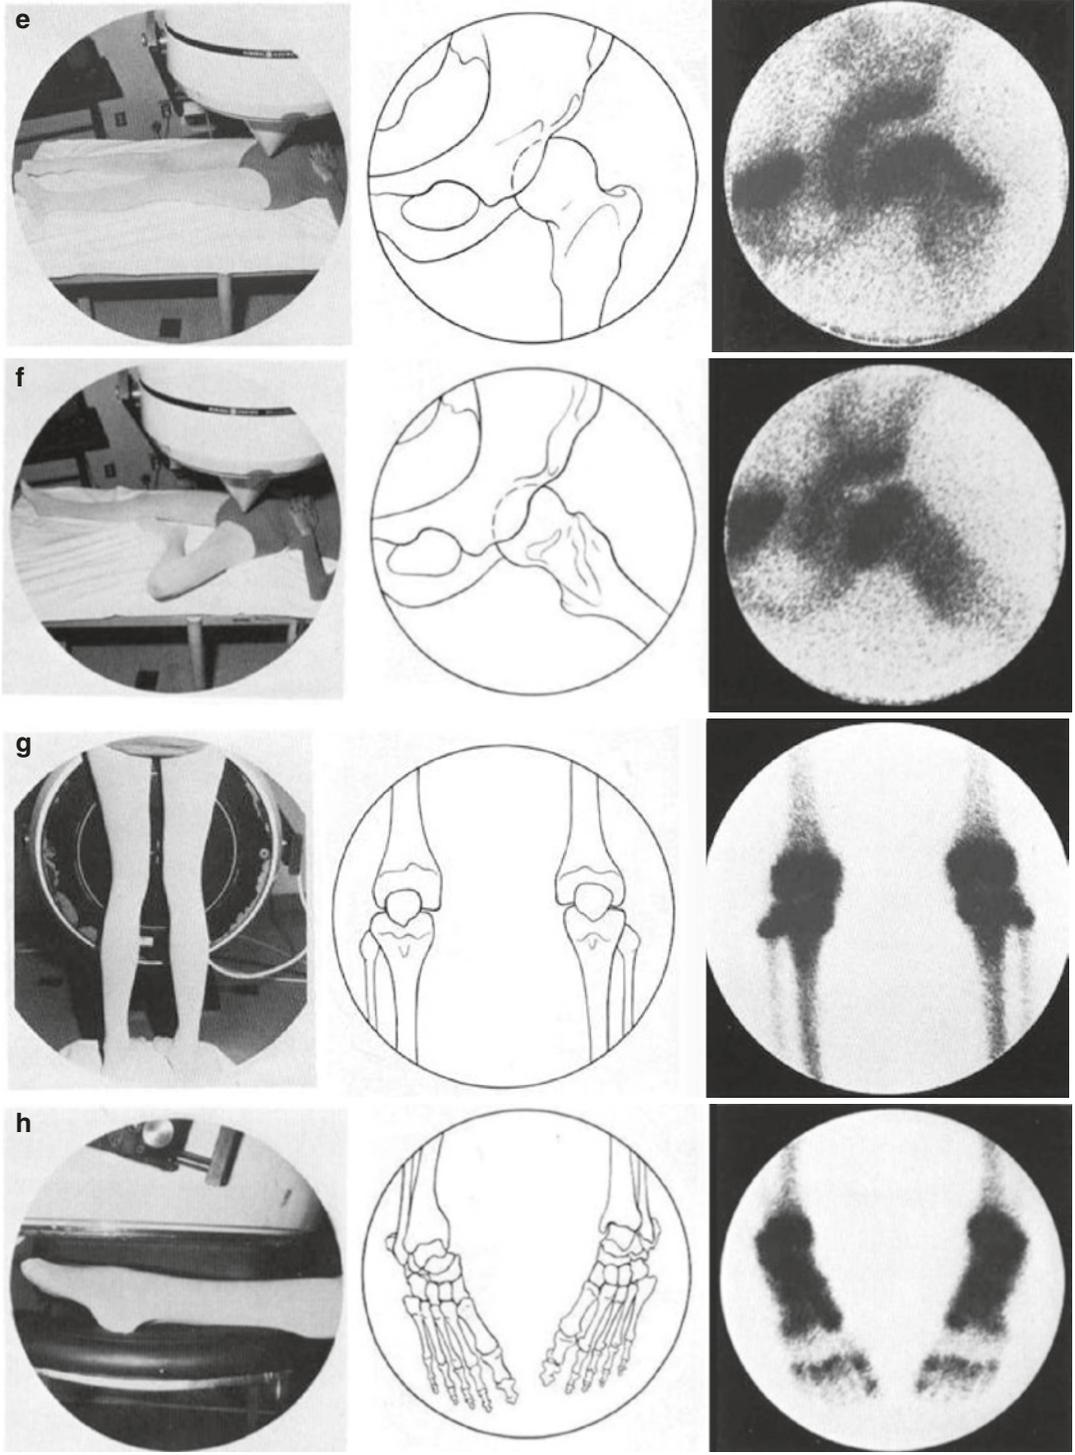

**Fig. 1.20** (a, b) Images of a hip using parallel-hole (a) and pinhole (b) collimators. Note the difference between the magnified pinhole view, showing clearly the photon-

deficient abnormality (*arrow*), and the parallel-hole image in this patient with bilateral osteonecrosis of the femoral heads

**Fig. 1.21** (a–h) Proper positioning of major parts of the skeleton for adequate imaging. Illustrated is the positioning of (a) posterior chest, (b) anterior chest, (c) arms, (d) hands, (e) anterior hip (pinhole), (f) anterior hip (pinhole) in a frog-leg position, (g) anterior knee and legs (note the

internal rotation separating tibiae from fibulae), (h) dorsal feet (note internal rotation allowing symmetry, visualization of bones, and minimizing overlap) (from Hughes; In Silberstein EB (ed): Bone scintigraphy [29], with permission)

**Fig. 1.21** (continued)

routinely utilized by the vast majority of practices, it is worth considering certain common optional positions since they can be valuable in resolving diagnostic dilemmas and help to alleviate confusion and uncertainty in interpretation. Such positions include the pelvic, oblique, and lateral views; the pelvic caudal view can be particularly useful in separating bladder and other

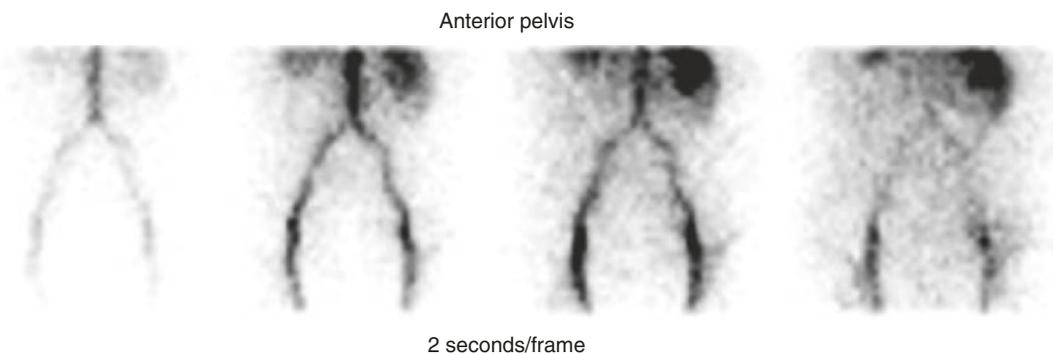

soft tissue activities from that of the bones (Fig. 1.22).

### 1.8.2.3 Acquisition

A dynamic flow study (radionuclide angiography) is acquired for 1-s frames for 60 s after the injection of the radiopharmaceutical. The region of interest should be within the camera's field of view (Fig. 1.23). This study should be done if there is a focal radiographic lesion, regional sign or symptom, or a site of prior surgery. Immediate static images (blood pool) follow for either 500–1000 kilocount (k) for spot images for the region(s) of interest or for 5 min for the whole-body image (Fig. 1.24). Flow studies show the vascular supply (vascularity), while blood pool images show the level of angiogenesis if present and the vascular status of the extravascular tissue. Delayed images (Figs. 1.25 and 1.26) are acquired for spot imaging (750 k over chest); all other images for the remainder of the skeleton are acquired for the same time. Whole-body imaging should be optimally performed at 2 million counts/whole-body view (20 min with a high-resolution collimator). The matrix size is usually  $256 \times 256$  for spot images, while it is  $1024 \times 256$  or  $2048 \times 512$  for whole-body images. To obtain the best resolution for a specific system and collimator, the matrix size should be chosen so that the pixel size is 1/3 to 1/2 of the system resolution determined by the full width at half maximum (FWHM). If the pixel size is too small, it

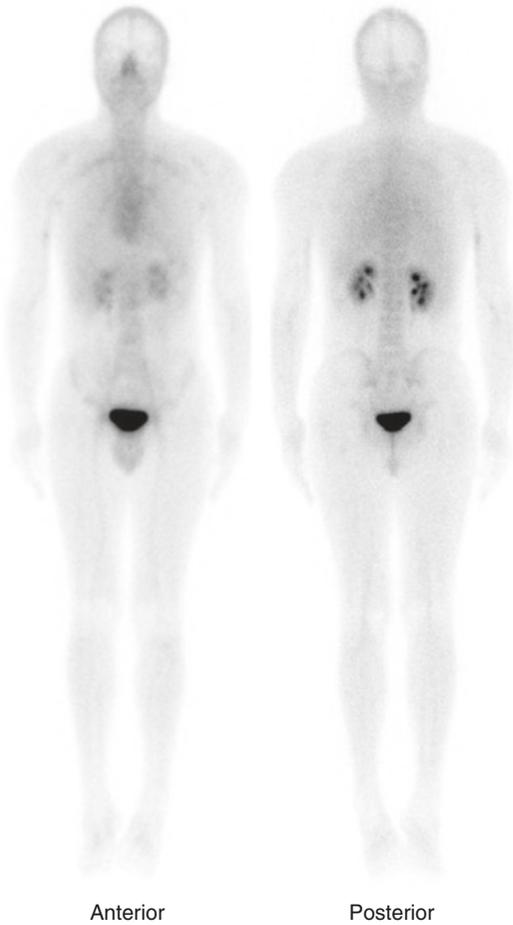

**Fig. 1.22** Caudal view of the pelvis showing clearly the pelvic bones with no possible overlap with the bladder or soft tissues

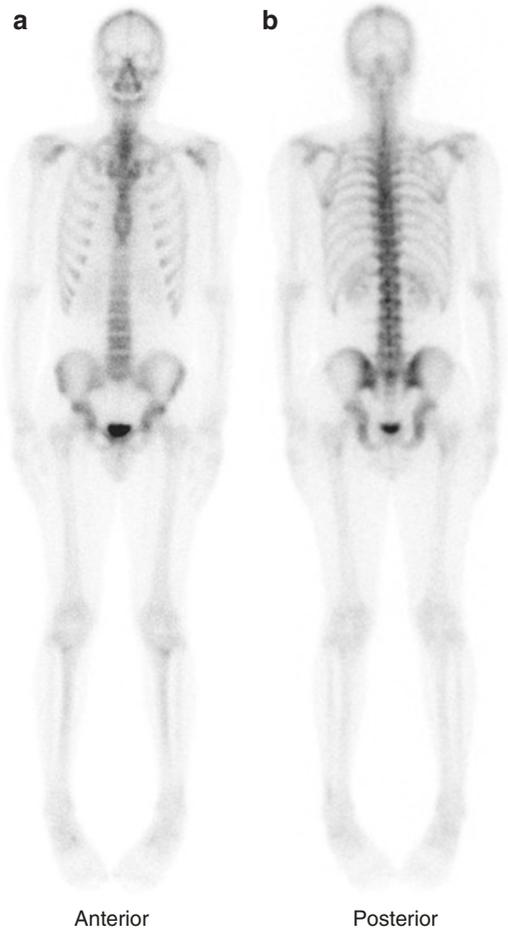

**Fig. 1.23** An illustrative example of a normal dynamic flow study (radionuclide angiography) of the pelvis and thighs of an adult. Note the symmetrical pattern. It is helpful for interpretation to remember that the level of the

bifurcation of the aorta corresponds roughly to the level of L4–5 and the bifurcation of common iliac artery to the level of the lesser trochanter

**Fig. 1.24** Normal early static (blood pool) image. Note the activity in the heart, kidneys, ureters, bladder, and narrow containing bones as pelvis and spine

**Fig. 1.25 (a, b)** Normal bone scan of the entire skeleton in an adult. Note higher uptake in certain areas such as the sacroiliac joints, iliac spine, vertebrae, sternum, and ends of long bones reflecting the metabolic activity, thickness, and the presence of bone marrow

causes noisy images, while if it is too large, it will cause a resolution worse than the system

resolution. The pixel size is calculated as follows:

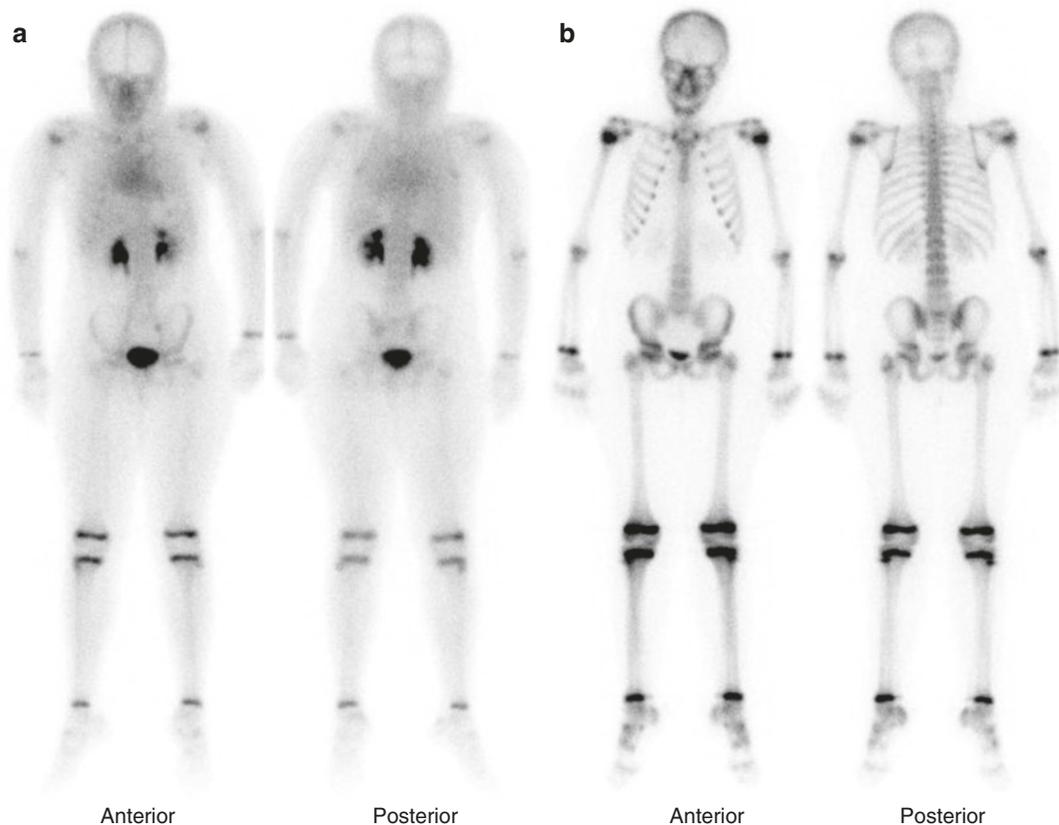

---

$$\text{Pixel size} = \frac{\text{Long axis of a rectangular detector or diameter of a circular detector}}{\text{Matrix size}}$$

---

Since the dimensions of the detector and system resolution are fixed, the matrix size is the parameter that can be changed to obtain an optimal pixel size and hence good image quality. With the use of the appropriate matrix, magnifying the images during acquisition, or processing, will have no effect on the resolution. A four-phase

bone scan is performed for the detection of certain disease processes with better specificity. The four-phase bone scan utilizes the fact that while radionuclide uptake ceases in the normal bone after approximately 4 h following injection, the accumulation continues in woven bone for several hours more [34]. In this way, in cases of

**Fig. 1.26** Normal bone scan in a 16-year-old child. Note the activity in the growth plates on blood pool (a) and delayed (b) images and the higher relative uptake in the

extremities compared to adults. This reflects the higher bone activity in the young

osteomyelitis and metastatic tumors [34, 35], a higher lesion-to-background ratio is obtained at 24 h than at 3–4 h. This technique can help improve specificity although it may cause some loss of sensitivity. Additional spot images are often required for a variety of reasons. One should remember to obtain orthogonal ( $90^\circ$ ) images, or oblique images, for the localization of abnormalities when these are noted in the initial images. Body contouring should be considered and the use of a camera that is equipped with automatic or semiautomatic body contouring is helpful; otherwise, additional spot images should be obtained (with the collimator close to the body part of interest, such as the extremities or skull).

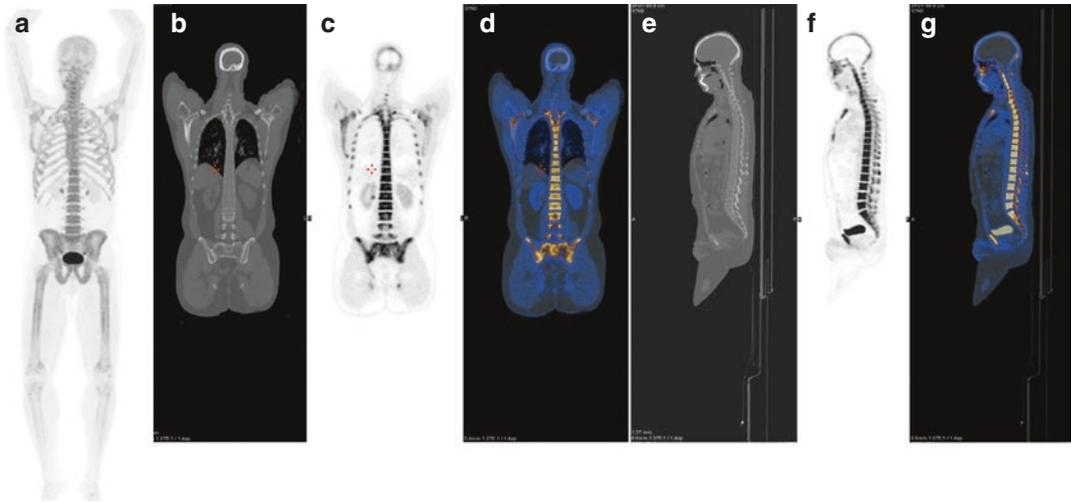

When a SPECT study is required, 25 to 30 s frames are acquired using a high-resolution collimator and a  $128 \times 128$  matrix. If a general-

purpose collimator is to be used, 20 s frames using a  $64 \times 64$  matrix are used. In either case, 64 frames are obtained through  $360^\circ$ .

With the increasing use of SPECT/CT and PET/CT, the positioning is overall similar to what is being followed for whole-body imaging using Tc-99m MDP (Fig. 1.27) and helps alleviate several pitfalls.

### 1.8.3 Post-Imaging Considerations

It is important to use a proper portrayal of the image on computer or proper film if applicable, as well as adequate image processing to insure accurate interpretation. The technologists as well as the interpreting physician should assess possible pitfalls and artifacts. If hard-copy films are used,

**Fig. 1.27** Whole-body coronal maximum intensity projection image (a) of a patient who received 4 mCi (148 MBq) of F-18 Sodium Fluoride. Selected cuts of CT,

F-18 NaF, and fused coronal (b, c, d) sagittal (e, f, g) torso images of the same patient show no abnormalities

the computer image should add useful information. Finally, knowledge of the detailed clinical history and review of other imaging modalities are mandatory at the time of reading, keeping in mind the possible causes of diagnostic errors.

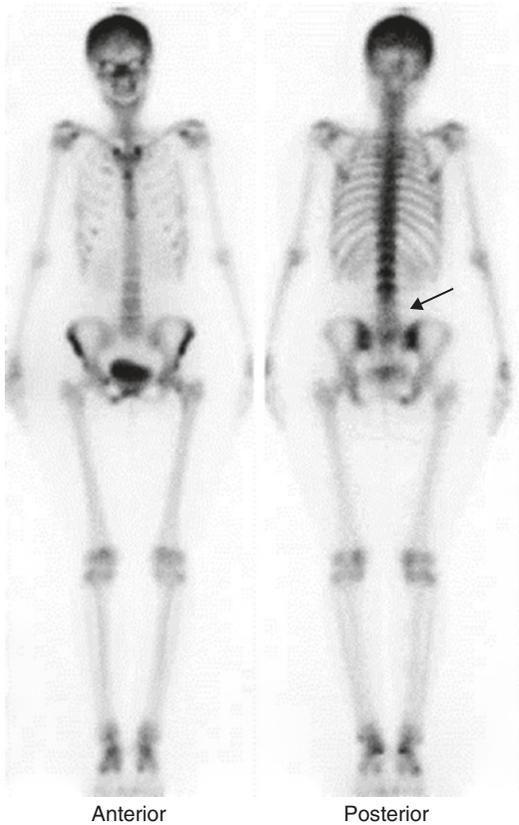

#### 1.8.4 Sources of Diagnostic Errors

**Factors Related to History and Physical Examination** Lack of adequate clinical assessment by physicians, including imaging specialists, leads to errors. It is crucial for adequate interpretation of bone scintigraphy to have a detailed patient history and to examine them. Many studies have shown the value of clinical information in improving the accuracy of the interpretation [34] as stated earlier. Prior pathology such as fractures or inflammation causes diagnostic errors if not known to the interpreting physician.

**Factors Related to the Patient** Errors can occur in imaging due to patient-related factors, including age, body habitus, underlying diseases, medications, hydration status, and lack of cooperation during the study (e.g., patient motion). Full knowledge of the patient's medical background and proper patient-physician communication are

needed with a clear explanation of the required preparation and procedure to ensure the patient's cooperation during the procedure. Imaging at the standard time for a patient with a debilitating disease will result in a scan with suboptimal quality; examination should be further delayed. Knowledge of the patient's condition can avoid subsequent errors and problems by planning a longer time to obtain the images. Another interesting issue is the steatopygia that can cause decreased uptake in the lower lumbar spine (Fig. 1.28) of patients with prominent fat in the buttock region [36]. This could also cause an appearance of abnormally increased uptake at the edge of a fat crease (Fig. 1.29) as well as errors in the interpretation of bone densitometry studies with an underestimation of the bone density value due to attenuation [27]. SPECT is useful to clarify the attenuation and edge effect seen on bone scans due to steatopygia.

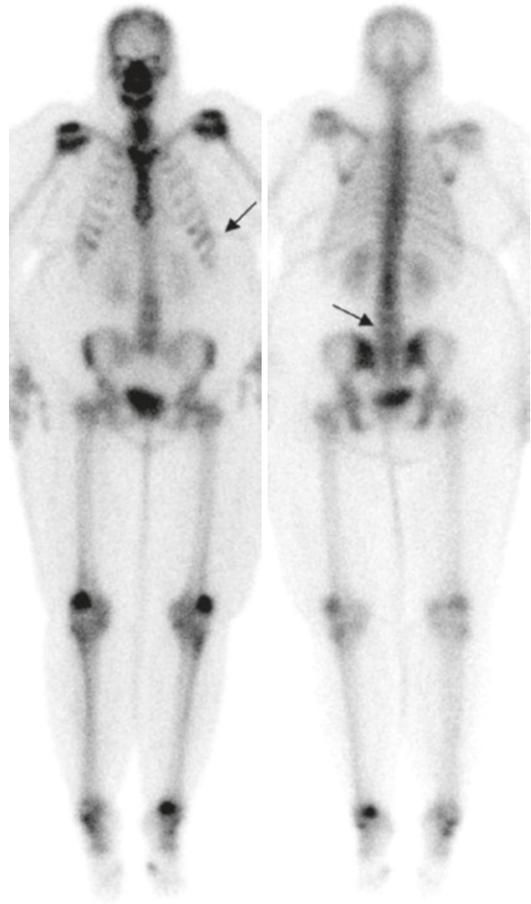

**Factors Related to Radiopharmaceuticals** The presence of aluminum in the generator eluate, injection of the tracer into an unintended compartment such as the arterial circulation or an interstitial space (Fig. 1.30), or introduction of air into the vial during preparation can significantly affect the quality of scan. Etidronate inhibits bone turnover and dramatically shows little

**Fig. 1.28** A whole-body scan of an obese patient showing the decreased uptake in the lower lumbar spine (*arrow*) due to the attenuation of fat in the buttocks (steatopygia)

uptake by bone coupled with a major distribution in the interstitial tissue [37–41]. Introduction of oxygen to the kit during preparation will cause oxidation and consequently increases the free technetium. The use of a solution several hours after preparation, particularly later than 6 h, will also cause the same problems, since the free technetium will be increased in the preparation. In both situations, uptake by the thyroid and gastric mucosa, and consequently bowel activity and other soft tissues (Fig. 1.30), will be seen and will make the scan quality inadequate, and free pertechnetate uptake will simulate or hide lesions. Table 1.21 lists causes of soft tissue uptake seen on bone scan secondary to technical and pathological technologies.

**Factors Related to Technique** Problems related to injection technique may cause variable hot

**Fig. 1.29** A whole-body bone scan in an obese patient illustrating the effect of body habitus on the images. Note the attenuation in the regions of the breast and buttocks (*arrow*). The activity used for such patients should be increased, and the duration between injection and imaging may be increased for better clearance of soft tissue activity and better target to nontarget ratios for better images

spots that can mimic, or mask, lesions. Inadequate count collection provides suboptimal images that leads to diagnostic errors such as missing abnormalities. Faulty positioning can lead to asymmetry, for example, with subsequent false diagnoses. A full bladder, as well as bladder diverticula, may again mask, or simulate, a lesion and negatively affect the quality of the study. This makes the visualization of the pelvic and hip regions difficult (Fig. 1.31a, b). This is a common source of diagnostic error and should always be dealt with through voiding, catheterization, delayed

**Fig. 1.30** A 3 h image of the hand of a patient who was injected intra-arterially illustrating retention of activity in the hand and forearm. Patient was difficult to inject in an attempt in the right arm before the activity was injected intra-arterially in the left arm

**Fig. 1.31** Colon activity of delayed Tc-99m MDP images due to bad tagging of the radiopharmaceutical

imaging, and special positioning such as caudal and oblique views of the pelvis. Problem in image fusion in SPECT/CT may lead to misinterpretation of positive findings.

**Factors Related to Interpretation** Non-familiarity with various normal and pathological findings can lead to misinterpretation due to lack of pattern recognition. In addition to pathological patterns of various diseases, recognition of normal patterns and those associated with normal variants is particularly important. Normal scans should generally show symmetry. In general, symmetry should be considered normal, and any asymmetry should be considered abnormal, until proven otherwise. Certain areas are normally known to show a relative increased uptake in both the pediatric and adult age groups due to higher bone turnover. These include:

1. Acromioclavicular joints
2. Sternoclavicular joints
3. Scapular tips
4. Costochondral junctions
5. Sacroiliac joints
6. Sternum

7. Frontal parasagittal areas
8. Lumbar and cervical spines anteriorly

Additionally, in the pediatric age group certain other areas of normally increased uptake are seen. These include:

1. Growth plates which should have clearly demarcated margins. Any irregularity or asymmetry should be viewed with suspicion. This is specially important since growth plate injuries, which are frequently overlooked, cause irregularities, and these areas have a predilection to osteomyelitis and neuroblastoma metastases.
2. Ischiopubic regions or the areas between distal ends of inferior pubic and ischial rami. The mass of cartilage in these areas ossifies between the ages of 4 and 12 years and may show uptake that can be confused with abnormal uptake.

In the normal whole-body scan, there will be some variation in the uptake due to normal variants. There may be a variety of reasons:

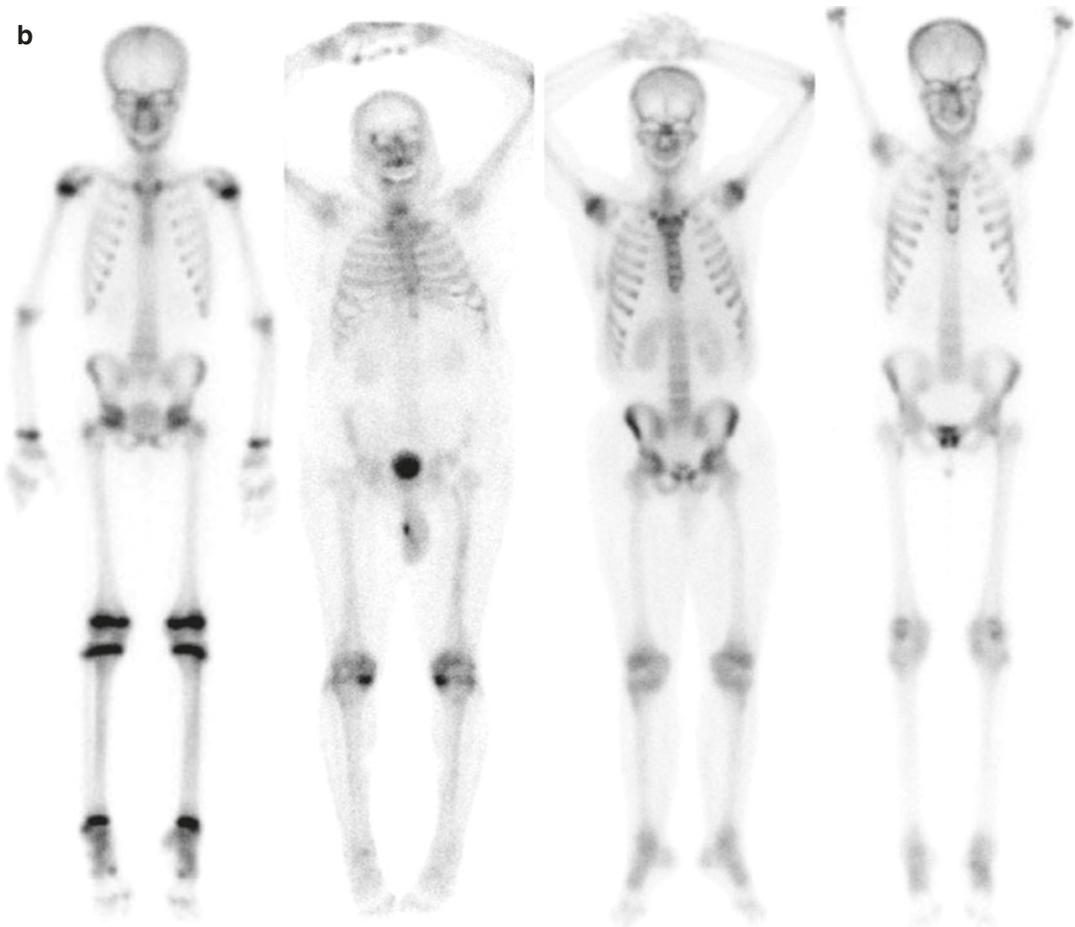

1. Effects of normal muscle stress:
  - The deltoid tuberosity (site of deltoid insertion) shows increased uptake in about 7% of patients and may be asymmetrical.
  - Insertions of the iliocostalis thoracis portion of the erector spinae muscles may cause linear uptake along posterior ribs vertically. This occurs in about 7% of individuals [41]. A similar pattern may be observed in the child because of “shine through” from the increased uptake in the costochondral junctions occurring normally at these growth sites.
2. The lower anterior part of the neck may show increased uptake which may be due to normal cervical lordosis and/or uptake in the thyroid cartilage.

3. An altered gait resulting from pain is frequently associated with diffuse increased accumulation in the asymptomatic lower extremity, particularly the foot.
4. The sternum shows many variations (Fig. 1.32), including transverse lines of increased uptake and prominent uptake at the junction of the xiphoid and the body of the sternum and at the junction of the manubrium and the body. Diffuse increased uptake may be seen as well as an oval-shaped cold area above the xiphoid process. This latter normal variant is most likely due to localized incomplete fusion and occurs in 2–31% of individuals [46].
5. Postpartal changes: Studies obtained following pregnancy may show alterations from the normal distribution resulting from the effects of pelvic diastasis, especially in the symphysis pubis, which may show increased uptake. Uni- or bilateral increased uptake in the sacroiliac joints is also seen.

a

For the early diagnosis of skeletal infections, the combined and coordinated efforts of the clinician and imaging specialist are crucial. Successful early diagnosis results in prompt treatment, which in turn may reduce morbidity. This chapter focuses on the complexities surrounding this clinical question. Knowledge of the pathophysiology of skeletal infection, as well as of the strengths and limitations of the multitude of imaging modalities available, aids clinicians in making a timely diagnosis. Information regarding the location of a suspected infection, the patient's age, and the history of other conditions such as diabetes, arthritis, trauma, and prior surgery needs to be available to nuclear medicine physicians and radiologists. These factors will affect the choice of optimal imaging modality. For any suspected skeletal infection, the initial modality is the standard radiograph. If this simple and inexpensive diagnostic test is not conclusive, other modalities should be considered particularly bone scan. Currently, magnetic resonance imaging (MRI) or a combination of bone and gallium scanning is the modality of choice for spondylodiscitis. Infection

of the diabetic foot is best imaged with combined (preferably simultaneous) bone- and white blood cell-labeled scintigraphy, best using SPECT/CT when available. MRI is comparable in accuracy, but more experience is needed in diagnosing such skeletal infections. Bone scans for suspected neonatal osteomyelitis have been found to be sensitive and specific for diagnosis. Advances in imaging technology, such as positron emission tomography (PET) and antibody labeling, provide other options, which improve the speed and accuracy with which osteomyelitis can be diagnosed. Utilizing the techniques widely used currently, an algorithm for the diagnosis of skeletal infection which incorporates the abovementioned variables and complicating conditions is presented.

---

## 2.1 Introduction

Despite the continuous advancement in prevention and treatment (particularly with antibiotics), infection remains a widespread problem. In fact, infection was first described in an Egyptian papyrus around 3000 BC [1]. Skeletal infection is a challenge to both clinicians and imaging specialists. Accurate and prompt diagnosis is very important to minimize complications such as sepsis, severe bone destruction, deformity, and growth arrest in children. Bone infections are complex processes that can manifest in various ways and mimic many other diseases. They are common in adults and children and occur both in immunologically competent and incompetent patients. The onset can be seen in individuals with no comorbidities, in those with a history of trauma and postoperative joint replacements, or among patients with diseases such as diabetes, hemoglobinopathies, and arthritis.

The dilemma that faces the medical community is reaching an early and accurate diagnosis of these infections. Although physical examination, laboratory tests such as white blood cell count and blood cultures, and standard radiographs are often positive in the later stages of osteomyelitis, these parameters are not adequate for diagnosis in the early stages. Modern imaging plays a crucial role in aiding clinicians in early diagnosis. For this reason,

physicians should be aware of the many imaging techniques suitable for skeletal infections. When this is combined with the patient's clinical background and an understanding of the pathophysiological basis behind skeletal infections, effective decision-making can be made to choose an optimal imaging examination.

## 2.2 Pathophysiology

### 2.2.1 Inflammation

#### 2.2.1.1 Definition

Inflammation is the complex non-specific tissue reaction to injury, which can be due to pathogenic agents such as bacteria and viruses (leading to infection), or agents such as chemical, physical, immunological, or radiation. Inflammation can be viewed as a protective reaction to the cause of cell injury as well as the consequences of such injury and can be lifesaving in certain situations. However, it may be potentially harmful and even life threatening [2].

#### 2.2.1.2 Classification

Inflammation is predominantly classified into acute and chronic. Acute inflammation is the immediate and early response to injury that has a relatively short duration lasting for minutes, hours, or a few days. Its main characteristics are exudation of fluid and proteins and immigration of leukocytes (predominantly neutrophils). On the other hand, chronic inflammation may last for weeks or years [3].

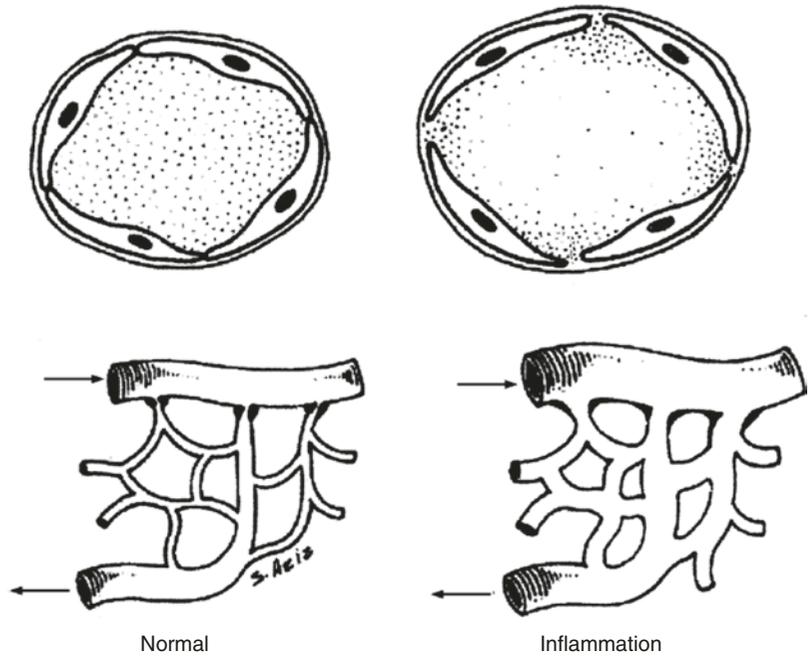

#### 2.2.1.3 General Pathophysiological Features

Acute inflammation has the following local pathophysiological features:

#### Vascular Changes

1. Vasodilation first involves the arterioles and then results in the local opening of new capillary beds and lasts for a variable period depending on the stimulus (Fig. 2.1).
2. Increased vascular permeability permits the escape of the protein-rich fluid and leukocytes (Fig. 2.1) into the extravascular space (exudate)

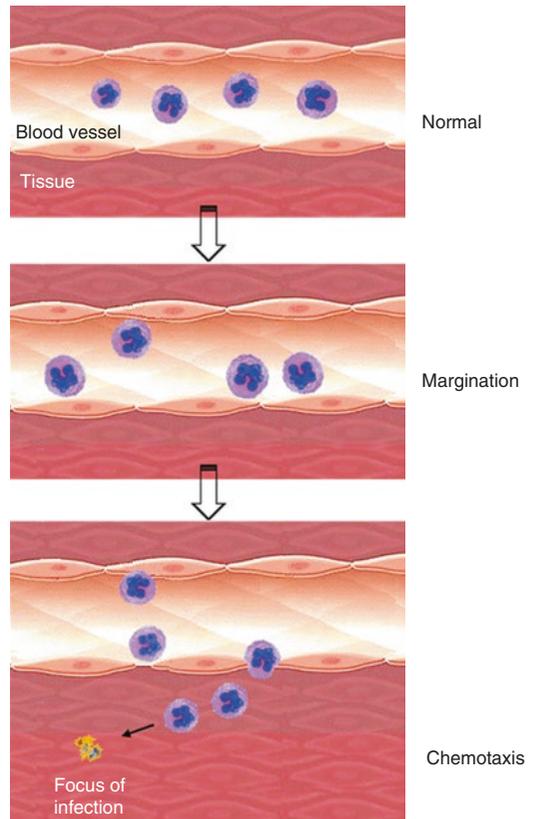

**Fig. 2.1** A dilated vessel showing the opening of the intercellular gaps that occur in inflammation compared to a normal vessel

[3]. This occurs due to the contraction of endothelial cells leading to a subsequent widening of the intercellular gaps, direct endothelial injury (resulting in endothelial cell necrosis and detachment), and leukocyte-mediated endothelial injury due to the release of toxic oxygen species and proteolytic enzymes by activated leukocytes. Endothelial cells may proliferate and form new blood vessels (angiogenesis), which remain leaky until they differentiate. Thus, angiogenesis also contributes to increased permeability.

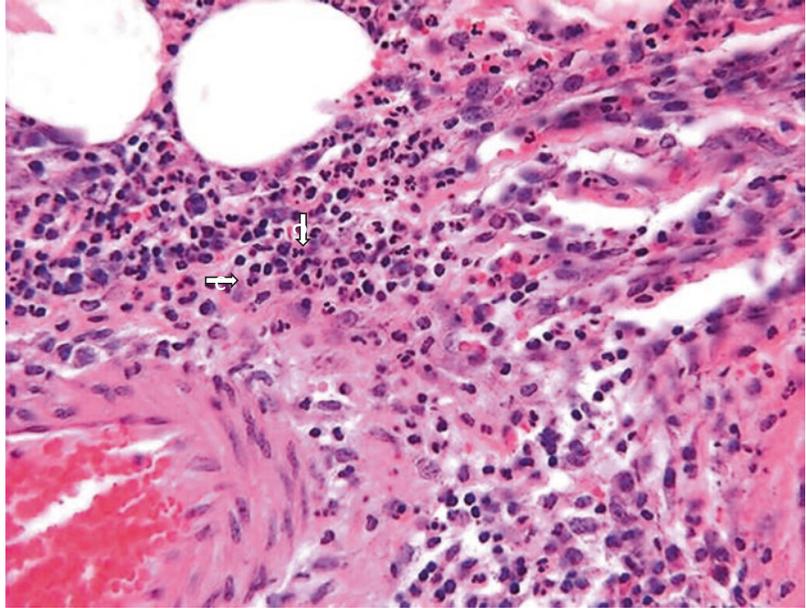

3. Slowing of circulation (stasis): Increased permeability and extravasation of fluid result in the concentration of red cells (which become packed in small vessels) and an increased viscosity of the blood. This leads to stasis.

**Cellular Changes** With stasis, leukocytes—predominantly neutrophils—are peripherally oriented along the vascular endothelium (leukocytic margination). Leukocytes then emigrate from the microcirculation across the endothelium and accumulate at the site of injury. Cells also migrate in the interstitial tissue toward a chemotactic stimulus, leading to aggregation at the site of inflammation (Figs. 2.2 and 2.3).

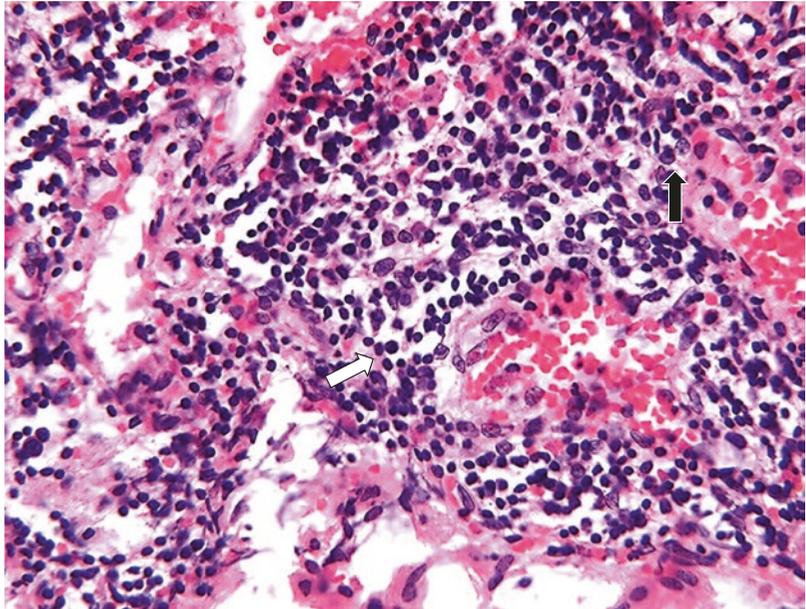

**Fig. 2.2** Cellular changes occurring during inflammation

**Fig. 2.3** Acute inflammation with polymorphonuclear leukocytes (*arrows*)

**Fig. 2.4** Chronic inflammation. Note the mononuclear cells (*arrow*) compared to polymorphonuclear cells in acute inflammation

Chronic inflammation, on the other hand, is characterized by a proliferative (fibroblastic) rather than an exudative response with predominantly mononuclear cell infiltration (macrophages, lymphocytes, and plasma cells) (Fig. 2.4). Vascular permeability is also abnormal.

#### 2.2.1.4 Healing

Healing of tissue in general is linked closely to inflammation since it starts with acute inflammation, which is considered the defensive phase of healing. The process consists of two overlapping phases, reconstruction and maturation, which include remodeling.

### 2.2.1.5 Inflammation in Cancer Patients

Patients with cancer can become immunocompromised due to the underlying malignancy, or as a result of cytotoxic chemotherapy, radiation, and other forms of therapeutic intervention. Some malignancies are associated with immune deficiency, which predisposes the patient to certain pathogens. For example, Hodgkin's and non-Hodgkin's lymphomas are associated with abnormalities of the cellular immune system that increase the risk to certain viral infections such as herpes simplex and varicella zoster and fungal infections such as *Cryptococcus*. On the other hand, patients with acute leukemia are highly susceptible to severe gram-negative bacterial infection due to quantitative, or functional, granulocytopenia. Patients with chronic lymphocytic leukemia and multiple myeloma are prone to infections with staphylococci and streptococci particularly pneumococcus. Therapeutic interventions including cytotoxic chemotherapy, corticosteroids, irradiation, and bone marrow transplantation produce deficiencies of the host's defense (e.g., neutropenia after cytotoxic chemotherapy, suppression of T cell defenses after bone marrow transplantation, disruption of natural skin and mucosal barriers). Furthermore, reduced food intake leads to poor nutrition and an increasing risk of infection, including skeletal infections [4].

### 2.2.2 Skeletal Infections

#### 2.2.2.1 Definitions

The term osteomyelitis is not synonymous with skeletal infection. "Osteomyelitis" should be used to describe an infection that includes bone marrow involvement. When infection starts in the periosteum, such as in cases of direct extension bone infection, it produces periostitis. At this stage, infection may not yet involve the cortex or marrow and is called infectious periostitis. When infection involves the cortex, the term infectious osteitis is used. When the marrow is involved as well, the term osteomyelitis is applicable (Fig. 2.5).

#### 2.2.2.2 Classification

Osteomyelitis may be classified into many types (Table 2.1) based on the route of infection, patient's age and physiology, etiology, date of onset, and other factors [5–9]. Osteomyelitis may be classified as acute or chronic according to the onset of symptoms and signs. It can also be classified as hematogenous or non-hematogenous according to the route of infection. In hematogenous osteomyelitis, the metaphyses of long bones are the most common site affected. Non-hematogenous osteomyelitis occurs as a result of the spread of a contiguous soft tissue infection, penetrating trauma, or inoculation (e.g., drug addicts). In these situations, infection may occur in any part of the bone. Osteomyelitis is also classified into infantile, juvenile, or adult types depending on the age of the

**Fig. 2.5** A diagram illustrating the extent of infection in osteomyelitis compared with the extent of infection in periostitis and osteitis

**Table 2.1** Various classifications of osteomyelitis

Basis of classification	Forms of osteomyelitis
Presentation	I. Acute
	II. Chronic
Route of infection	I. Hematogenous
	II. Direct extension (non-hematogenous)
Age	I. Infantile (including neonatal)
	II. Juvenile
	III. Adult
Causative organism	I. Pyogenic
	II. Nonpyogenic
Location of infection	I. Appendicular skeleton osteomyelitis:
	Metaphyseal
	Epiphyseal
	Diaphyseal
	II. Axial skeleton osteomyelitis (e.g., vertebral and bony pelvis osteomyelitis)
Prior pathology	I. Violated bone (complicated) osteomyelitis
	II. Non-violated bone osteomyelitis
Multifactorial (Waldvogel classification)	I. Hematogenous osteomyelitis
	II. Osteomyelitis secondary to contiguous infection
	III. Osteomyelitis associated with vascular insufficiency
Anatomy of disease and host physiology (Cierny-Mader classification of adult type)	Anatomic types:
	I. Medullary
	II. Superficial
	III. Localized
	IV. Diffuse
	Physiologic class:
	A. Normal host
	B. Compromised host:
	Systemic compromise
	Local compromise
Local and systemic compromise	
C. Prohibitive: Treatment worse than disease	

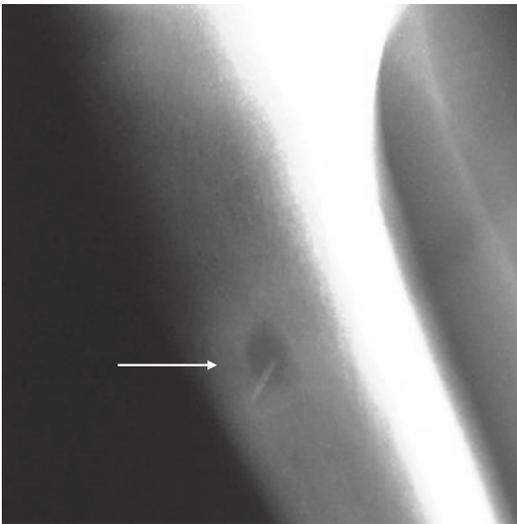

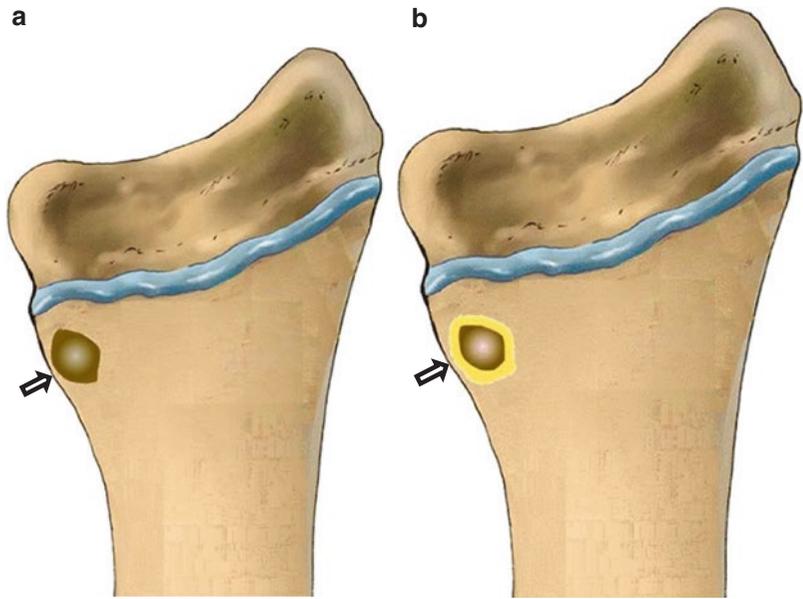

patient and into pyogenic and nonpyogenic depending on the etiology. Infantile osteomyelitis occurs in the first year of life, while the juvenile

type occurs between the age of 1 year and the age of closure of the physes; the adult type occurs after the closure of the physes. Cierny and Mader [7] introduced a clinical classification and staging based on the anatomy of the disease and the host physiology. Waldvogel also introduced another clinical classification based on the route of infection and whether vascular insufficiency is present [8]. Finally, it is important to consider the classification of osteomyelitis based on whether the affected bone has been violated by prior pathological conditions, since this is crucial for planning the imaging strategy [9].

### 2.2.2.3 General Pathophysiological Features

Acute hematogenous osteomyelitis occurs when organisms settling in the bone marrow initiate an acute inflammatory response by neutrophils. This is accompanied by local edema, vasospasm, ischemia, and thrombosis. These features are applicable to other types of acute skeletal infections. Thirty percent of such acute infections may progress to chronic osteomyelitis. Chronic osteomyelitis may follow a clinically obvious acute osteomyelitis, or be the initial presentation. The immune response includes chronic inflammatory cells (such as lymphocytes and plasma cells) and increased osteoclastic-osteoblastic reaction. If the normal blood supply to the bone is interrupted by the edema and thrombi produced by the inflammation, segmental bone necrosis or sequestrum will develop (Fig. 2.6a). The body's response can also stimulate the formation of a new layer of bone around the infection, creating an involucrum (Fig. 2.6b). This osteogenesis may occasionally continue long enough to give rise to a densely sclerotic pattern of osteomyelitis called a sclerosing osteomyelitis. If the periosteum becomes interrupted by the infectious process, a draining sinus will form [8]. A Brodie's abscess is an intraosseous abscess in the cortex that becomes walled off by reactive bone [10] (Fig. 2.7). It is an active infection that becomes isolated due to decreased organism virulence. Brodie's abscess, sequestrum, and involucrum can reactivate presenting as chronic active osteomyelitis.

**Fig. 2.6** Diagrammatic representation of the sequestrum (a) showing the necrotic segment of the bone (arrow) and involucrum (b) demonstrating the layer of new bone formation surrounding the focal infection (arrow)

**Fig. 2.7** Radiograph showing a Brodie's abscess

Osteomyelitis, and in particular the hematogenous form, is usually caused by gram-positive organisms, the most common being *Staphylococcus aureus* [8, 11, 12]. Group B streptococci are also common in infantile osteomyelitis. Gram-negative organisms such as *Pseudomonas aeruginosa* and *Klebsiella pneumonia* have also been encountered as the causative organisms in osteomyelitis, particularly in intravenous drug abusers, in vertebral

osteomyelitis, and in hospital-acquired infection. *Escherichia coli* may be the cause of vertebral osteomyelitis following urological surgery (Table 2.2).

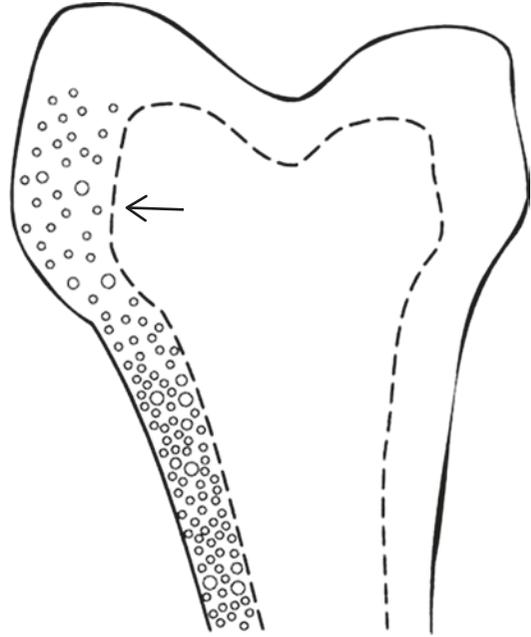

*Staphylococcus aureus* remains the most common causative organism for osteomyelitis and septic arthritis in children [13].

Acute hematogenous osteomyelitis is the most common type and occurs most frequently in children, affecting males approximately twice as often as females [14]. It has a predilection for the metaphyses of long bones, where the blood flow is rich and relatively sluggish since blood flows through the typically large intramedullary venous sinusoids in this region. This represents a good medium for bacterial lodgement and proliferation [6]. As mentioned earlier, the process starts by implantation of organisms in the bone marrow, and as the infection becomes established in the marrow, it provokes acute suppurative neutrophilic infiltrates and edema and is accompanied by vasospasm, thrombosis, and local ischemia. Subsequently infection may spread first to the subperiosteal space in the metaphyseal area. This is the path of least resistance, because the cortex of this area is porous (Fig. 2.8) and because the inflammatory response limits spread down to the medullary cavity. In children between 1 and approximately 16 years of age, the blood supply

**Table 2.2** Organisms associated with osteomyelitis in different clinical settings

Clinical situation	Most likely associated microorganisms
All types of osteomyelitis	<i>Staphylococcus aureus</i>
Infantile osteomyelitis	<i>S. aureus</i> and Group B streptococci
Diabetic foot osteomyelitis	<i>S. aureus</i> , <i>Enterococcus</i> , <i>Enterobacteriaceae</i>
Vertebral osteomyelitis	<i>S. aureus</i> , <i>Pseudomonas aeruginosa</i> , <i>Escherichia coli</i> , <i>Streptococcus</i>
Sickle cell disease	<i>Salmonella</i> , <i>S. aureus</i>
Intravenous drug abusers	<i>Pseudomonas aeruginosa</i> , <i>Klebsiella</i>
Immunosuppressed patients	<i>Salmonella</i> , <i>Aspergillus</i> , <i>Mycobacterium avium</i> complex, <i>Candida albicans</i>
Hospital-acquired infections	<i>Pseudomonas aeruginosa</i> , <i>Klebsiella</i>
Drinking raw milk in brucellosis-endemic areas	<i>Brucella</i>
Cat and human bites	<i>Pasteurella multocida</i> , <i>Eikenella corrodens</i>
Sharp object passing into the foot	<i>Pseudomonas aeruginosa</i>
Contamination of open wound by soil	<i>Clostridia</i> , <i>Nocardia</i>
Bone infections due to infected catheters	<i>Escherichia coli</i> , <i>Candida albicans</i>

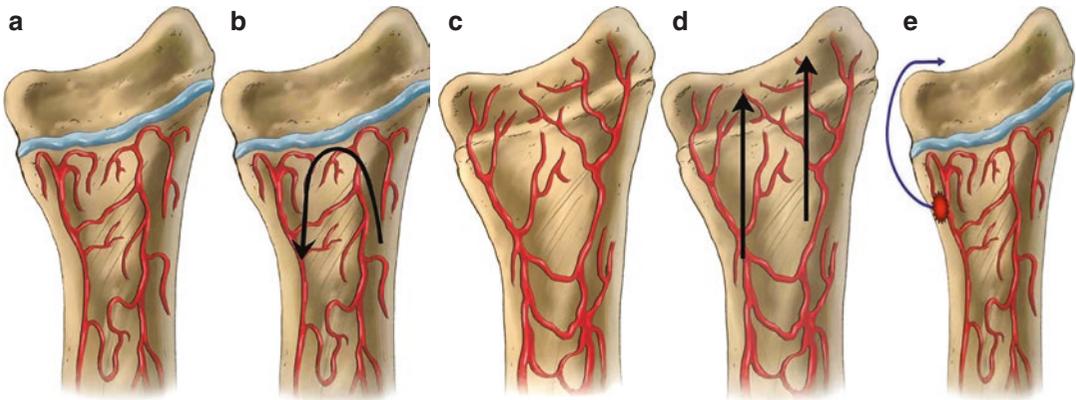

to the medullary space of the bone enters through the nutrient artery and then passes through the smaller vessels toward the growth plate. Once these vessels reach the metaphyseal side of the growth plate, they turn back upon themselves in loops (Fig. 2.9) to empty into large sinusoidal veins with a slower blood flow. The epiphyseal plate separating the epiphyseal and metaphyseal blood supplies acts as a barrier to the spread of infection (Fig. 2.9), making joint involvement less common in this age group [12] except when the infection is severe. In this situation, the infection may break through the bone and produce joint infection (Fig. 2.9). This occurs in the locations where the metaphysis is within the joint capsule [proximal femur in the hip joint, proximal humerus in the shoulder joint, distal tibia in the ankle joint, and proximal radius in the elbow joint (which is rarely involved)]. On the other

**Fig.2.8** A diagram illustrating the porous nature of metaphysis (arrow)

hand, in infants and adults, the terminal branches of the nutrient artery extend into the epiphysis as there is no growth plate barrier. This vascular communication between the epiphyses and metaphyses facilitates the spread of infection to adjacent joints (Fig. 2.9). In flat bones, acute hematogenous osteomyelitis is mainly found at locations with a vascular anatomy which is similar to that of the metaphyses such as the bony pelvis, vertebrae, and calcaneus [15].

#### 2.2.2.4 Features of Specific Forms

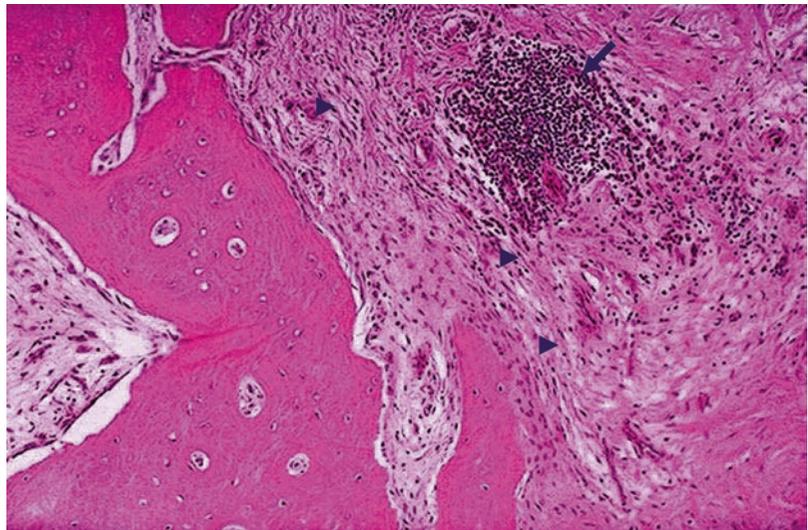

**Chronic Osteomyelitis** It is difficult to clearly differentiate between acute and chronic osteomyelitis. However, it should be noted that cases of obvious chronic osteomyelitis need special diagnostic handling and management. Chronic osteomyelitis has variously been defined as symptomatic osteomyelitis with a duration ranging from 5 days to 6 weeks [16]. Since the pathology of osteomyelitis varies with age, microorganisms, prior therapy, underlying diseases, and other factors, it is somewhat inappropriate to depend only on the duration of the disease to define chronicity. Chronic osteomyelitis has a less marked inflammatory cell

**Fig. 2.9** a–e Diagram illustrating the vascular communication between the metaphysis and epiphysis of long bones. When the growth plate is present (a), it acts as a barrier, and vessels turn on themselves forming loops. This acts as a barrier to prevent infection that is most commonly present in the metaphysis extending to epiphysis and adjacent joint

(b). On the other hand, in neonates after the closure of the growth plate (c), infection extends more easily to the joint (d) since there is free vascular communication between metaphysis and epiphysis. Figure (e) illustrates the path of severe infection which is able to involve the joint, when the growth plates is present, by breaking through the bone

**Fig. 2.10** A microscopic picture of the bone involved with chronic osteomyelitis. Note the focus of the mononuclear cell (arrow) accompanied with fibrosis (arrow heads) characteristic of chronic inflammation

reaction and may occur without preceding acute inflammation. Microscopically, chronic osteomyelitis predominantly shows lymphocytes and plasma cells (Fig. 2.10) rather than polymorphonuclear cells. There is a variable amount of necrotic tissue, and sequestra may form in some cases. The presence of necrotic tissue may also lead to draining sinuses or the organization in the medullary cavity forming Brodie's abscess. Because these abscesses and necrotic foci are avascular, levels of antibiotics sufficient to

eradicate the bacteria may not be achieved during treatment. Accordingly, bacteria may remain indolent for a long time (inactive disease). Reactivation of the disease may occur much later (even years) after the initial episode of active disease. It is important to evaluate patients for possible chronic disease and to either exclude or confirm the presence of chronic active infection since continuation of intravenous antibiotic therapy and/or surgical intervention to eradicate infection will depend on that determination [17].

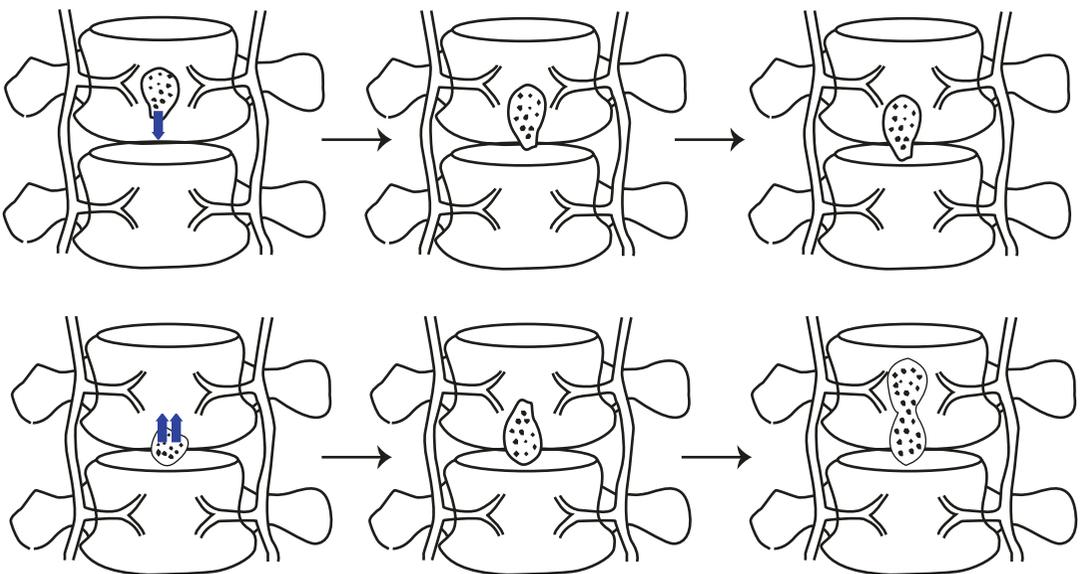

**Vertebral Osteomyelitis (Spondylodiscitis)** This is a specific form of osteomyelitis that has some unique features. The most commonly affected site is the lumbar region, followed by the thoracic and cervical spine. Several factors predispose an individual to vertebral osteomyelitis (Table 2.3). The disease occurs most frequently in adults with a mean age of 60–70 years, although it also occurs at all other ages including children. The pyogenic form is most often caused by *Staphylococcus aureus*, but streptococci and gram-negative bacteria are also involved [18–20]. Infection usually originates at a distant site with hematogenous extension to contiguous vertebral bodies (Fig. 2.11)

**Table 2.3** Predisposing factors for vertebral osteomyelitis (spondylodiscitis)

1. Old age
2. Diabetes mellitus
3. Drug addiction
4. Oral steroid therapy
5. Dialysis
6. Urinary tract infection
7. Genitourinary instrumentation
8. Prior back surgery
9. Bacteremia secondary to intravenous cannulation
10. Spinal trauma

and the intervening space via the ascending and descending branches of the posterior spinal artery. Extension to the posterior elements (pedicles, transverse processes, posterior spinous processes, and laminae) has been noted in 3–12% of cases. However, involvement of posterior elements only is exceedingly rare since only 15 cases have been reported to date. Other causes include extension of the infection from adjacent structures and complications following spinal surgery and trauma.

In adults, the causative organism generally settles in the richly vascularized subchondral vertebral end plates with an eventual progression of the infection into the adjacent intervertebral disc (which is relatively avascular), and the infection may progress to adjacent soft tissue structures. In childhood, the infection often starts at the discs, which are nourished by small perforating vessels. In either case, the local spread of infection eventually occurs and causes end plate destruction, disc space narrowing, and collapse. These changes may take weeks to be seen on radiographs [20, 21]. It typically affects older children with fever and back pain in the lumbar, thoracic, or cervical region [22, 23]. Since the disc is almost invariably involved in vertebral infections, the term spondylodiscitis is preferred [19,

**Fig. 2.11** The development and extension of infection in vertebral osteomyelitis

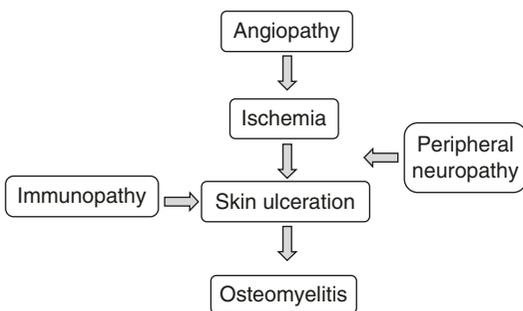

20, 22]. Discitis, however, often occurs separately without involving the bony structures of the vertebrae. In children under the age of 5 years, it almost exclusively affects the lumbar spine with no, or low-grade, fever. The child usually is unable to walk or has progressive limping [23].

**Diabetic Foot Osteomyelitis** Approximately 15% of diabetics develop foot osteomyelitis, which is most common in the metatarsal bones and proximal phalanges. The differentiation from neuropathic foot can be clinically and radiographically difficult. Diabetics are prone to infections which are secondary to the effects of their hyperglycemic state which leads to impaired leukocyte function. This immunopathy, along with diabetes-associated vascular disease (angiopathy) and peripheral nerve changes (neuropathy), may lead to skin ulceration and predispose the patient to pedal osteomyelitis (Fig. 2.12). Ulceration of the foot is 50 times more common in diabetics [24]. More than 90% of osteomyelitis of the foot of diabetic patients occurs as a result of the spread of infection from adjacent foot ulcers. If infection is present, prompt treatment is crucial to avoid amputation [25]. The incidence of amputation of the lower extremities is 25 times greater in diabetics than in the general population [24].

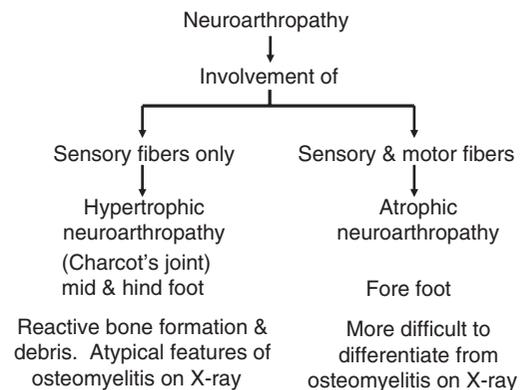

Neuroarthropathy is characterized by destructive joint changes. A combination of factors is involved. Loss of protective pain and proprioceptive sensation along with hyperemia (which is secondary to the loss of vasoconstrictive neural impulses) are thought to result in atrophic

neuropathy most frequently occurring in the fore-foot [26]. On the other hand, sensory fiber involvement only, without involvement of the sympathetic fibers, tends to result in hypertrophic neuroarthropathy, which occurs most frequently in the mid- and hindfoot (Fig. 2.13). Since the patient continues to walk and traumatize the foot, disuse osteoporosis is usually absent. Unnoticed trauma may also result in rapidly progressive destruction (Fig. 2.14), sometimes with disintegration of one or more tarsal bones within a period of only a few weeks. In this rapidly progressive form of neuroarthropathy, more inflammatory reaction is present [26–28].

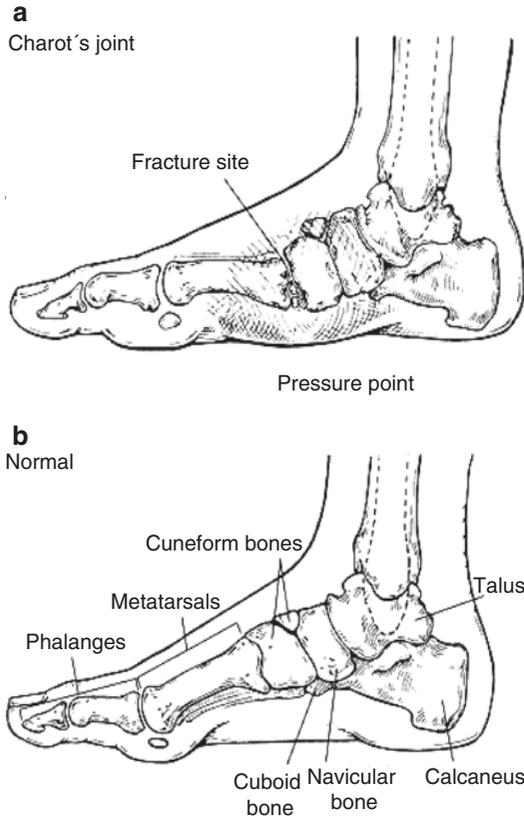

**Sickle Cell Disease Osteomyelitis** Since hemoglobin S is sensitive to hypoxemia, erythrocytes become viscous and abruptly sickle shaped when exposed to hypoxia. This may compromise the microvascular flow and may cause infarction, the most common skeletal complication of sickle cell disease. Although less common than infarctions, osteomyelitis is the second most common bacterial infection in children with sickle cell disease after pneumonia. For symptomatic sickle cell patients, distinguishing infarction from osteomyelitis is critical [16]. Osteomyelitis may occur as a primary event or may be superimposed on infarcts. This occurs because necrotic bone is a fertile site for such secondary infections. *Staphylococcus aureus* and *Salmonella* are the frequent causative organisms.

**Fig. 2.12** The changes associated with diabetes leading to osteomyelitis of the foot

**Fig. 2.13** Types of diabetic neuropathy and their characteristics (modified from Giurini et al. [29] with permission)

**Fig. 2.14** A diabetic foot showing the destructive changes of hypertrophic neuroarthropathy (**a**). A normal foot (**b**) is shown for comparison (from [29], with permission)

**Periprosthetic Infections** Hip and knee arthroplasties are two of the most common orthopedic procedures, exceeding 600,000 per year in the USA alone [30–32]. Between 10% and 25% of patients experience discomfort within 5 years after hip or knee replacement [33]. This can be due to loosening with or without infection.

Although the incidence of infection was reported previously to be as high as 4% after the primary surgery and 32% after revision of hip arthroplasty, the currently reported rate of infection after total hip or knee arthroplasties is only 0.5–2% and is less than 3% following revision surgery, with the infection occurring mostly within 4 months of operation [34, 35].

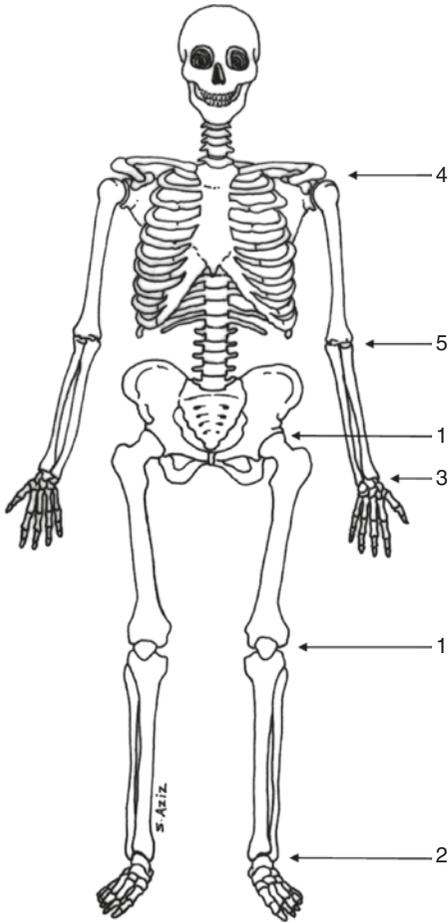

The cementless porous-coated prosthesis depends on bone ingrowth for fixation and induces more reactive bone formation than the

cemented prosthesis. Differences between cemented and porous-coated hip prostheses largely explain the scintigraphic patterns noted after hip arthroplasty. Depending on the location of the finding and type of prosthesis, “normal” activity may remain present for years. After knee replacements, on the other hand, the most common complications are fracture, dislocation, and avascular necrosis followed by loosening of the tibial component, with infection occurring less frequently than in the case of hip replacement [36].

**Infectious (Septic) Arthritis** The term refers to the invasion of the synovial space by microorganisms. The synovial space contains synovial fluid, which is produced by the rich capillary network of the synovial membrane. This fluid is viscous and serves to lubricate, nourish, and cushion the avascular joint cartilage. When the synovial space is infected, bacterial hyaluronidase causes a decrease of the viscosity of the synovial fluid, and pain is then felt with stress on the joint capsule.

Acute infectious arthritis is commonly caused by bacteria, while fungal and mycobacterial pathogens are seen more commonly in chronic arthritis. Acute septic arthritis is a medical emergency. Delay in diagnosis and treatment may result in the destruction of the articular cartilage and permanent disability. The lytic enzymes in the purulent articular fluid destroy the articular and epiphyseal cartilages. Additionally, pus in the joint space increases the intracapsular pressure, which may lead to epiphyseal ischemia. Other sequelae include dislocation, deformity, and destruction of femoral head and neck. Hence, drainage and antibiotic therapy must be considered without delay [16, 37].

Microorganisms reach the joint by a hematogenous route, contagiously from an adjacent osseous infection, or through traumatic/surgical inoculation. The joints most commonly involved in children are the hip (35%), knee (35%), and ankle (10%) (Fig. 2.15). When the synovium becomes hyperemic in septic arthritis, flow to adjacent extra-articular bone will also increase through the anastomoses from the synovial vascular network to juxta-epiphyseal and epiphyseal

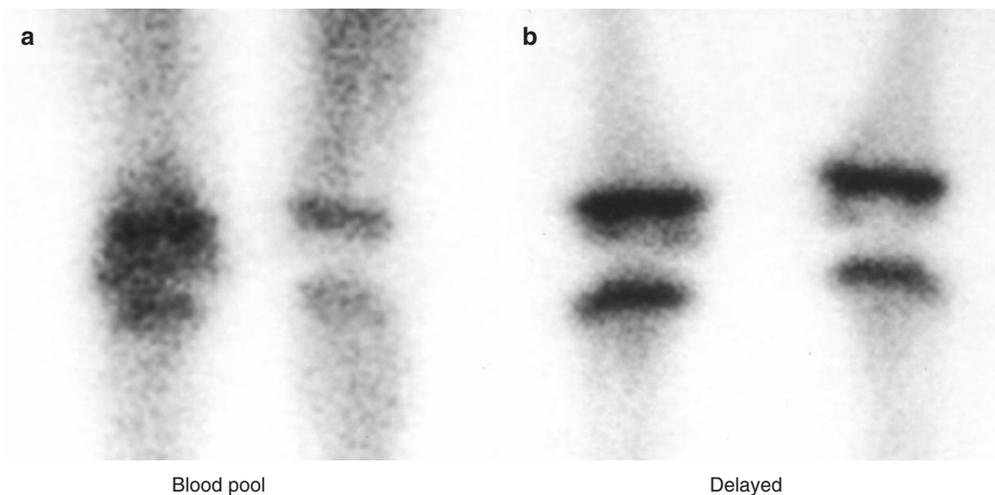

**Fig. 2.15** The joints commonly affected by infectious arthritis (*I* indicates highest incidence)

vessels supplying the epiphysis and metaphysis. Accordingly, increased uptake of bone-seeking radiopharmaceuticals on delayed images typically is seen around affected joints [37–39] (Fig. 2.16).

## 2.3 Imaging Skeletal Infections

### 2.3.1 The Need for Diagnostic Imaging

Clinical diagnosis in the late stages of infection is easily achieved in most instances. However, detecting early infection when complete resolution is still possible is a challenge to both physicians and radiologists. In early infection, the clinical picture may be confusing. Furthermore, laboratory findings, including elevated erythrocyte sedimentation rate and leukocytosis, are not specific for bone infection in the early stage. Serial blood cultures are positive in only 50–60% of cases [8, 40, 41]. Cultures of both blood and material obtained by needle aspiration of the involved bone yield a positive result in no more than 80% of cases. Delay in the treatment of osteomyelitis significantly diminishes the cure rate and increases the rate of complications and morbidity [42, 43]. Accordingly, imaging is needed in many cases to establish an early diagnosis.

**Fig. 2.16** **a, b** Bone scan of infectious arthritis showing the increased blood pool activity in the region of the knee joint (**a**). Delayed image (**b**) shows minimally increased uptake around the joint (hyperemic changes)

### 2.3.2 Imaging Modalities for Skeletal Infections

When confronted with the potential diagnosis of an early skeletal infection, both morphological and functional (scintigraphic) imaging modalities are frequently employed. Morphological modalities such as standard radiographs, ultrasonography, computed tomography (CT), and magnetic resonance imaging (MRI) depend mainly on structural changes, variations in the density, and differences in proton content in tissues. Functional modalities or nuclear medicine procedures, on the other hand, depend on physiological changes. No single modality is ideal in all situations and imaging should be tailored on an individual basis.

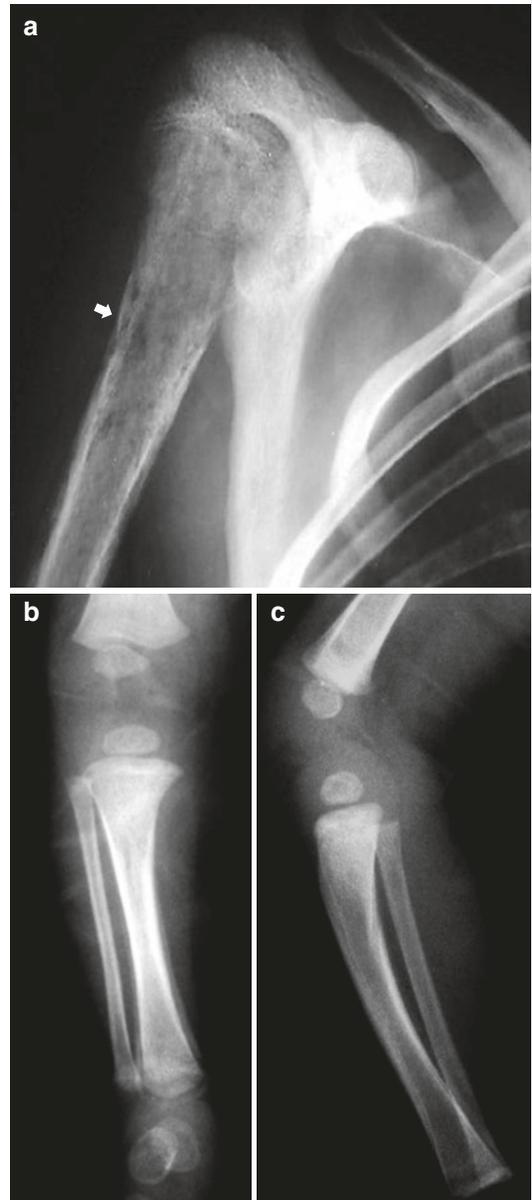

The choice of imaging modality often depends mainly on whether or not the bone has been violated (previously affected by other pathological conditions) and on the site of the suspected infection. Over the years, major changes and modifications have been introduced to improve the diagnostic accuracy of osteomyelitis imaging. Many of these changes were based on a better understanding of the pathophysiological basis of bone infection, which led to an increased recognition of the challenges and limitations which confront current imaging technology.

## 2.4 Diagnosis of Skeletal Infection by Imaging

### 2.4.1 Diagnosis Using Morphologic Imaging Modalities

#### 2.4.1.1 Standard Radiographs

Standard radiographs, although useful if they show the classic findings of bone destruction and periosteal reaction (Fig. 2.17), may not show abnormalities until 10–21 days after the onset of infection. A 30–50% loss of bone density must occur before radiographs show any abnormalities, and radiographs are therefore relatively insensitive to the presence of acute bone infections [8, 12]. Additionally, radiological findings are unreliable in establishing the diagnosis of osteomyelitis among patients with violated bone. In these situations, radiographic findings are non-specific, being diagnostic in as low as 3–5% of culture-

**Fig. 2.17** a–c (a) A radiograph of an adult patient with osteomyelitis showing the typical changes of bone demineralization, bone lysis, and cortical lucency (*arrow*). (b, c) Radiographs of a neonate with osteomyelitis demonstrating periosteal reaction

positive cases. Nevertheless, radiography should be the initial modality for the work-up of skeletal infection. Standard radiographs are relatively inexpensive, are easily obtained, may determine that another underlying pathological condition exists, and frequently aid physicians in deciding what sort of additional imaging studies are

required. From the cumulative data in the literature, the overall sensitivity for standard radiograph for skeletal infections is 28–94% and the specificity is 3–92% [44].

#### 2.4.1.2 Ultrasonography

Osteomyelitis in infants and children predominantly affects the growth-intensive end regions of the long bones. This is because the inflammatory process commonly affects the articular regions adjacent to the metaphyseal and epiphyseal sites. Ultrasound accordingly may be of benefit in this group of patients and can be helpful in planning the management [45–47]. In a study, ultrasonography was found to be a very useful tool both in detecting osteomyelitis in infants and children and in reducing the need for additional imaging modalities [43]. The common ultrasonography findings of osteomyelitis are intra-articular fluid collection and subperiosteal abscess formation. These findings were found to precede any radiological changes by several days. Ultrasonography is also helpful in guiding aspiration for immediate microscopic and later bacteriological examinations. The most helpful role of ultrasonography, however, is in the diagnosis and management of septic arthritis. In particular, ultrasonography is very sensitive in detecting joint effusions and may clearly define the extent of septic arthritis, differentiate septic arthritis from soft tissue abscesses or tenosynovitis, and help avoid unnecessary joint aspirations. This was illustrated by Jien et al. [48], who reported 31 patients with joint effusion detected by ultrasonography with 22 proven septic arthritis cases of the hip and knee joints; three patients with concurrent osteomyelitis were detected as well using ultrasonography, resulting in a sensitivity of 100% for septic arthritis. The nine patients without effusion had no proven septic arthritis, resulting in 100% specificity [48]. Although the number of patients in this study is small, it is in agreement with other reports indicating a generally high sensitivity and specificity of ultrasonography for detecting septic arthritis [49, 50].

#### 2.4.1.3 Computed Tomography

Following the highly successful introduction of MRI, CT has no major role in the diagnosis of

osteomyelitis. However, it is a complementary procedure that is useful in sensitively detecting sequestra and can be useful in chronic osteomyelitis, in particular when determining the presence, or absence, of the sequestra is important for decision-making (regarding possible surgical intervention) [51].

CT is superior to both MRI and plain film in depicting the bony margins and identifying a sequestrum or involucrum. The CT features are otherwise similar to plain films. The overall sensitivity and specificity of CT even in the setting of chronic osteomyelitis are low and according to one study were 67% and 50% [52].

CT scan however can be a useful method to detect early osseous erosion and to document the presence of sequestrum, foreign body, or gas formation and can show in some cases pathologic changes of infection in addition to proper localization of scintigraphic abnormalities when SPECT/CT is used, although generally is less sensitive than other modalities for the detection of bone infection.

#### 2.4.1.4 Magnetic Resonance Imaging

MRI offers excellent depiction of both bone and soft tissue infection. Accordingly, MRI is often used instead of CT for the diagnosis of osteomyelitis. MRI is also commonly useful in suspected unifocal hematogenous osteomyelitis. The advantages of MRI over CT include improved soft tissue contrast resolution, absence of beam-hardening artifacts from the bone, and multiplanar capabilities [53]. The sensitivity and specificity of MRI for osteomyelitis range from 60% to 100% and from 50% to 95%, respectively [53–57]. Although the average overall accuracy of MRI for the diagnosis of osteomyelitis is approximately similar to that of multiphase bone scans, it is not used routinely as it is more expensive and less available. It is used on an individual basis particularly when vertebral involvement is suspected, in complicated cases of chronic osteomyelitis when it is important to determine the extent of infection, in suspected diabetic foot osteomyelitis, and in situations when anatomical details are necessary for planning surgical intervention.

Magnetic resonance imaging is the most sensitive and most specific morphologic imaging modality for the detection of osteomyelitis and provides superb anatomic detail and more accurate information of the extent of the infectious process and soft tissues involved. It is currently preferred to use MRI as a primary imaging modality for diagnosis of osteomyelitis in non-violated bone. When contraindicated or multifocal disease is suspected, scintigraphic modalities including F-18 fluorodeoxyglucose (F-18 FDG) PET/CT are used [58–61].

MRI is particularly useful in the diagnosis of osteomyelitis in children given its accuracy that is similar to bone scan and FDG PET in this age group with presumably non-violated bones and lack of ionizing radiation. It requires however sedation or anesthesia in some patients and is generally less available than bone scan [62].

## 2.4.2 Diagnosis by Scintigraphic Methods

### 2.4.2.1 Radiopharmaceuticals for Infection Imaging

Many radioisotopes have been used to detect and localize infection (Table 2.4). Several mechanisms explain the accumulation of different radiotracers at the site of infection (Table 2.5). Since there are limitations of the available radiopharmaceuticals for infection, the search continues for better agents with ideal properties (Table 2.6) for infection imaging. Labeled white blood cells and gallium-67 are the most widely used agents. Sfakianekis et al. [63] found Indium-111 leukocyte imaging to be the most accurate for relatively acute infections (less than 2 weeks) with 27% false negatives among patients with prolonged infections. On the other hand, gallium-67 imaging had its highest sensitivity in long-standing infections with a false-negative rate of 19% in acute infections of less than 1 week's duration. Bitar et al. [64], in a comparative study using rabbits with experimental abscesses, found that indium-111 leukocytes were clearly superior to gallium for imaging early abscesses. Furthermore, the authors found that the accumulation of indium-111 leukocytes

**Table 2.4** Radiopharmaceuticals for infection [65–68]

1. Tc-99m diphosphonates
2. Gallium-67 citrate
3. Labeled white blood cells using In-111 oxime or Tc-99m HMPAO (Tc-99m hexamethylpropyleneamine oxime)
4. Labeled particles
1. Nanocolloid (almost abandoned)
2. Liposomes
5. Labeled large protein
1. Non-specific immunoglobulins
2. Specific immunoglobulins: polyclonal and monoclonal
(a) Antigranulocyte monoclonal antibodies
(b) Anti-E-selectin antibodies
6. Labeled receptor-specific small proteins and peptides
1. Chemotactic peptides
2. Interleukins
7. Labeled antibiotics: ciprofloxacin
8. Positron emission radiotracers
F-18 FDG
Ga-68 citrate
Ga-68-transferrin
F-18 sodium fluoride (NaF)
F-18 FDG-labeled leukocytes
Iodine-124 FIAU

I. Increased vascular permeability and capillary leakage
In-111 and Tc-99m human polyclonal IgG
In-111 monoclonal IgM antibody
In-111 and Tc-99m liposomes
In-111 biotin and streptavidin
Tc-99m nanocolloids
In-111 chloride
Gallium-67 citrate
II. Migration of white blood cells to the site of infection
In-111- and Tc-99m-labeled leukocytes
Tc-99m anti-white blood cell antibodies
III. Binding to protein receptors at site of infection
Ga-67 citrate (iron-containing proteins)
VI. Binding to white blood cells at the site of infection
Chemotactic peptides
Interleukins
V. Binding to bacteria
Tc-99m-labeled ciprofloxacin antibiotic
Ga-67 citrate
VI. Metabolic trapping
F-18 fluorodeoxyglucose
VII. Uptake by infection-induced osteogenesis
Tc-99m diphosphonates
F-18 sodium fluoride (NaF)

**Table 2.6** Ideal properties of radiotracers for infection localization

1. Easy to prepare
2. Low cost and wide availability
3. Rapid detection and localization of infections (< 3 h)
4. Low toxicity and no immune response
5. Rapid clearance from blood with no significant uptake in the liver spleen, GI tract, bone, kidneys, bone marrow, or muscle
6. Rapid clearance from the background
7. High sensitivity and specificity
8. Ability to differentiate infection from other inflammatory and neoplastic conditions
9. Ability to differentiate acute from chronic infection
10. Ability to monitor therapeutic response

in experimental subcutaneous abscesses was inversely proportional to the age of the abscess. In abscesses 1–2 h old, 6–8 h old, 24 h old, and 7 days old, 10.4%, 5.2%, 3%, and 0.73% of the injected dose, respectively, were accumulated in the abscesses. Gallium uptake, on the other hand, was not significantly affected by infection age (Table 2.7). In abscesses 7 days old, Ga-67 accumulated to a greater extent than indium-111-labeled leukocytes did. Thus, Bitar et al. and Sfakianakis et al. came to similar conclusions, namely, that labeled white blood cells are more suitable for infections of short duration. Figure 2.18 illustrates how chronic forms of skeletal infection, even when active, may show false-negative leukocyte studies due to the nature of the pathologic changes compared to acute infections.

Experimentally, McAfee et al. [69] showed that as many as 10% of circulating neutrophils accumulate daily at focal sites of inflammation. This high percentage of white blood cells migrating to the site of infection due mainly to chemotaxis -facilitates identification of the abscess on a scintigraphic image (Table 2.8). The authors also showed abscess/muscle uptake ratios of 3000:1 with In-111 white blood cells at 24 h compared to 72:1 with Ga-67. Accordingly a small dose of only 500  $\mu$ Ci of In-111 leukocytes is sufficient for positive identification and localization of abscesses on an image. In Ga-67 imaging, a higher dose of approximately 5 mCi is needed, which may be higher if SPECT is used. There is

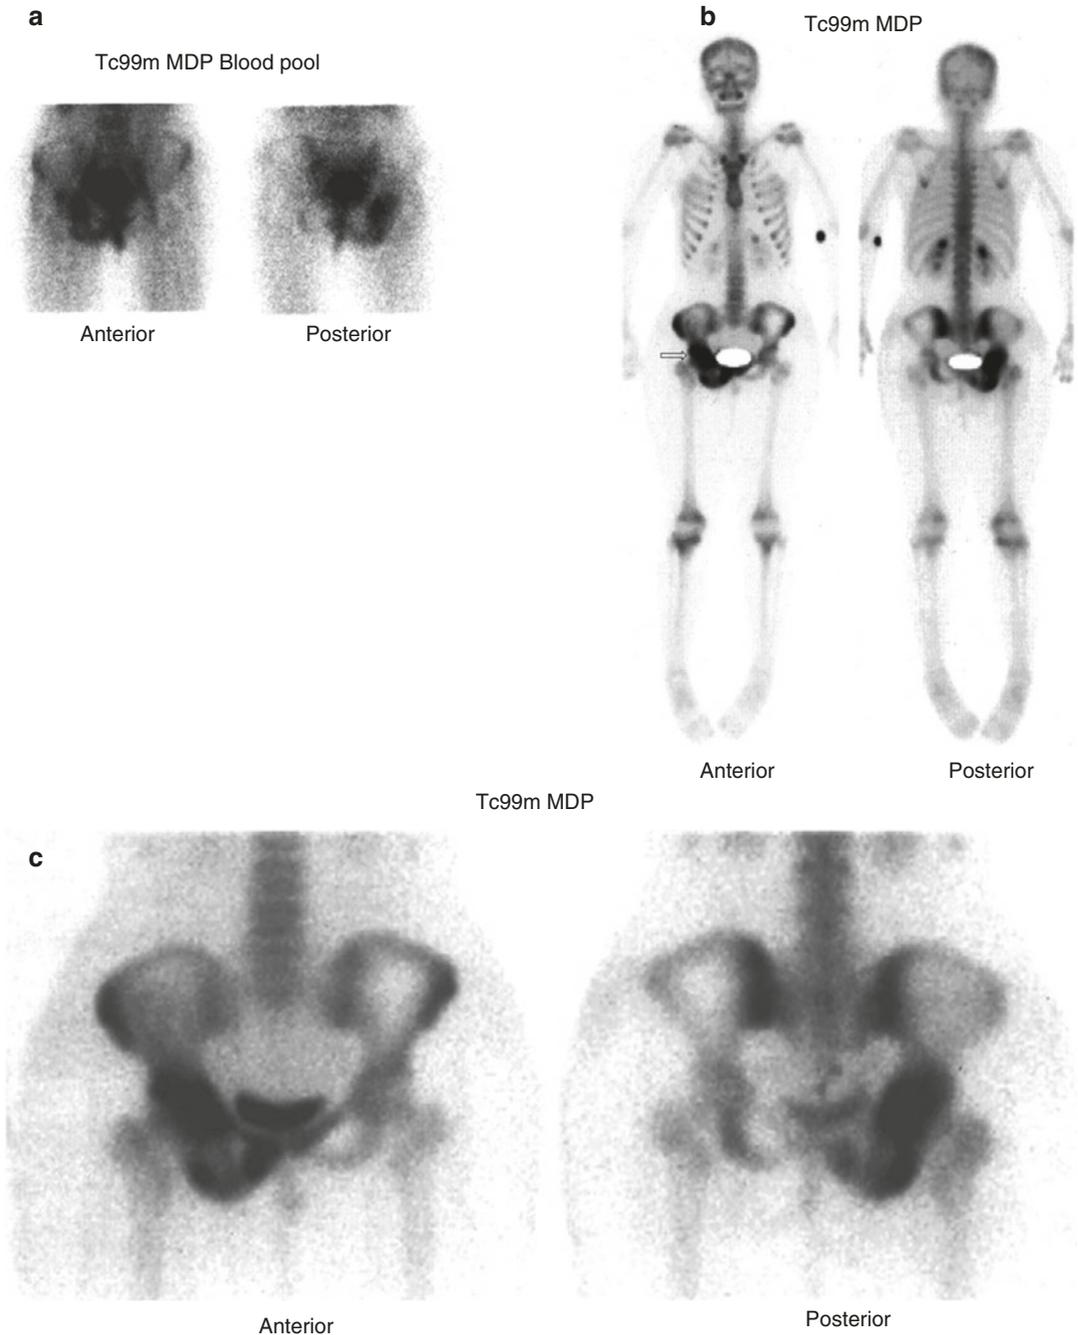

**Table 2.7** Relation of percent infection uptake of In-111 WBC and Ga-67 citrate and abscess age

Abscess age	Percent uptake	
	In-111 white blood cells (%)	Ga-67 citrate (%)
1–2 h	10.4	1.5
6–8 h	5.2	1.5
24 h	3	1.4
7 days	0.73	1.1

Data from Bitar et al. [64]

higher radiation dose to the spleen from 500  $\mu$ Ci of In-111-labeled white blood cells, but radiation doses to the gonads, marrow, and whole body are higher with 5 mCi of Ga-67 [69]. Overall, labeled leukocytes with In-111 or Tc-99m hexamethylpropyleneamine oxime (HMPAO) have a higher sensitivity and specificity than Ga-67 for acute infections [70, 71]. Several labeled antibodies have been used to diagnose bone and soft tissue infection. Tc-99m or I-123 monoclonal antigranulocyte antibodies and In-111 or Tc-99m-labeled human non-specific polyclonal immunoglobulin G (IgG) have been used in humans [65, 72–82]. Human non-specific polyclonal immunoglobulin (hIgG) is prepared commercially for intravenous therapeutic use and conjugated with diethylenetriaminepentaacetic acid (DTPA) carboxycarbonic anhydride [83]. In contrast to the labeled leukocyte technique, which is complicated and time consuming, IgG is readily available for convenient one-step labeling that is ready for injection within 30 min. Acquisition of gamma camera images at 6, 24, and 48 h postinjection is the standard method. The accumulation of IgG at injection sites has been shown to be due to non-specific accumulation of the protein secondary to increased vascular permeability [84]. In-111 and Tc-99m monoclonal antibody against granulocytes have also been used for detecting infections including those affecting the skeleton [83, 85, 86].

In-111- and Tc-99m-labeled chemotactic peptide analogues have been shown to be useful for detecting and localizing infections. These agents have a potentially important advantage over other radionuclide agents in that imaging can be performed less than 3 h postinjection, compared to the 18–24 h or more needed for most other agents [87–90]. Labeled liposomes have been used for

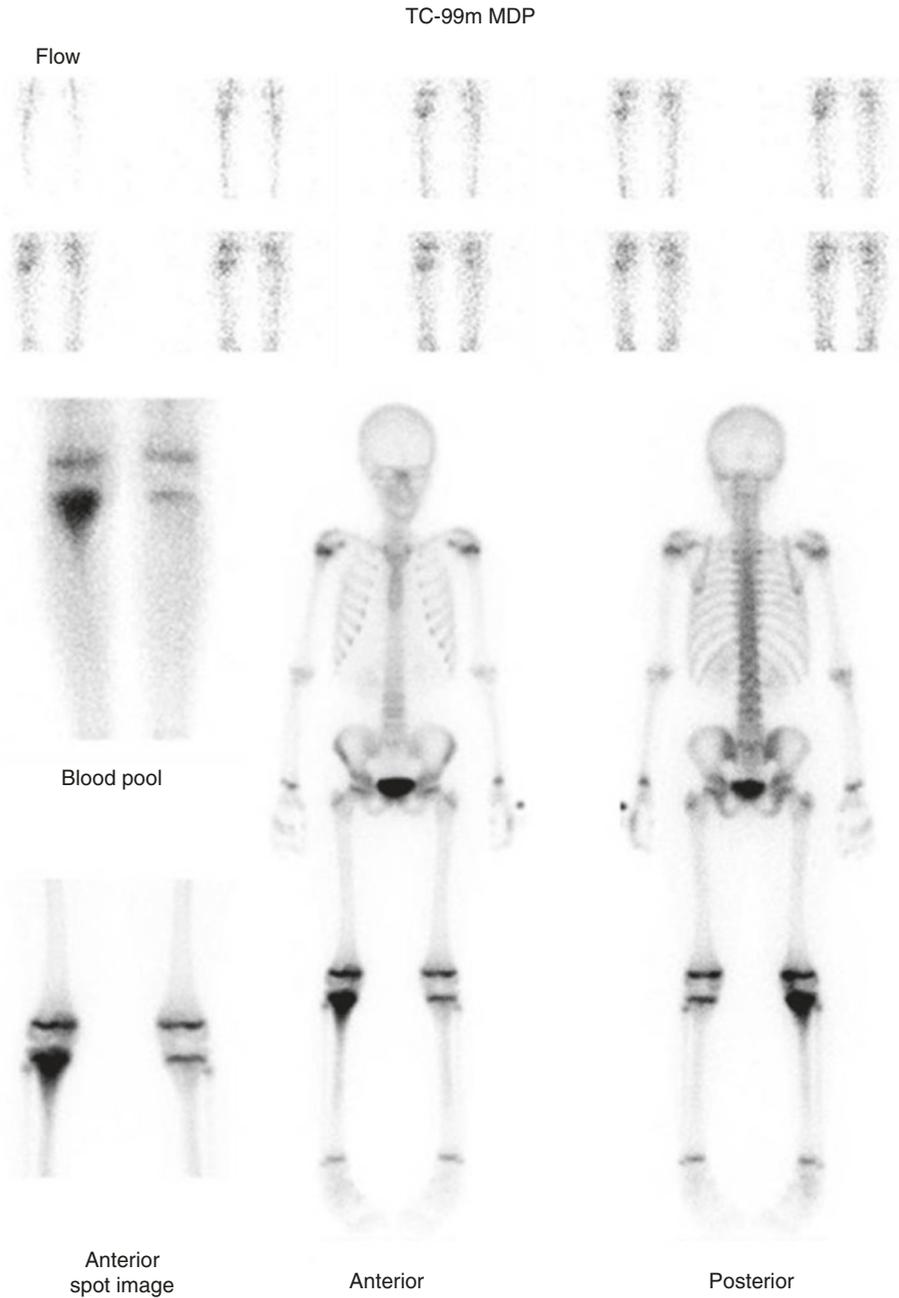

**Fig. 2.18** A three-phase bone scan and Tc-99m HMPAO-labeled leukocyte scans for an 81-year-old female patient with a long history of pain in the right groin region. Spot blood pool images of the pelvis (**a**) reveal increased activity in the right hip and groin regions. Delayed planar images (**b**, **c**) reveal focally increased uptake in the right acetabulum, ischium, and pubic bones. The subsequently obtained Tc-99m-labeled leukocyte scan (**d**) shows no significant accumulation of labeled leukocytes at the site

of the abovementioned abnormalities seen on bone scan. Only a focus of accumulation at a site of recent intramuscular injection is noted in the soft tissue of the left buttock region. Pathologically, tuberculous osteomyelitis was proven. This case illustrates how chronic forms of skeletal infection, even when active, may show false-negative leukocyte studies due to the nature of the pathologic changes compared to acute infections

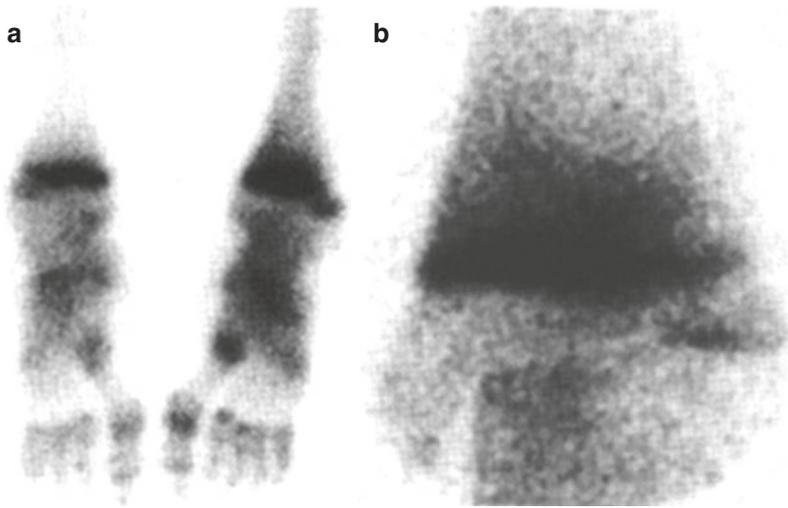

perfusion as seen in flow and blood pool images and a correspondingly increased uptake on delayed images (Fig. 2.19). Pinhole imaging can be of value in small children for better character-

ization of the delayed focal uptake (Fig. 2.20). This is different from cellulitis, which shows regionally, or diffusely, increased perfusion in the area involved with either no corresponding

**Fig. 2.19** A three-phase bone scan showing focally increased blood flow and blood activity in the region of the proximal right leg. Delayed image showing the corre-

sponding focus of increased uptake illustrating the classic scintigraphic pattern of acute osteomyelitis of the proximal right tibia on bone scan

**Fig. 2.20** Images from a case of acute hematogenous osteomyelitis illustrating the value of pinhole collimator. (a) High-resolution image shows the increased tracer uptake in the left distal metaphysis. (b) Pinhole magnifi-

cation image confirms increased uptake extending beyond physis into metaphysis (from Connolly et al. [100] with permission)

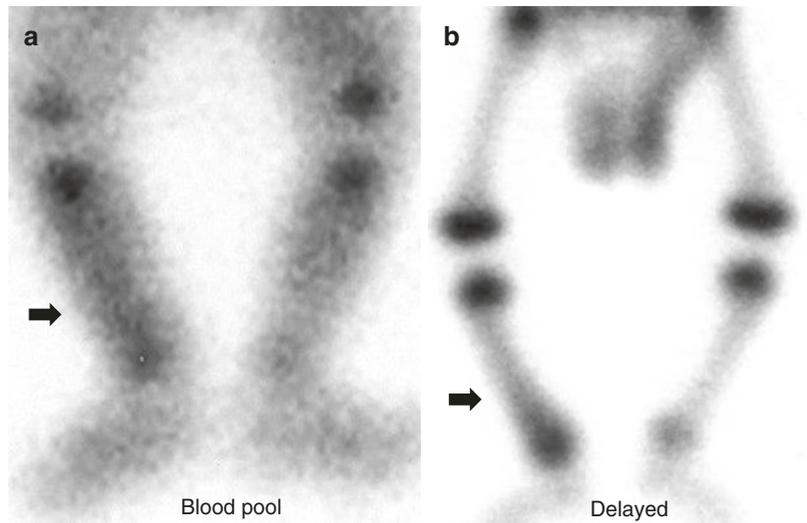

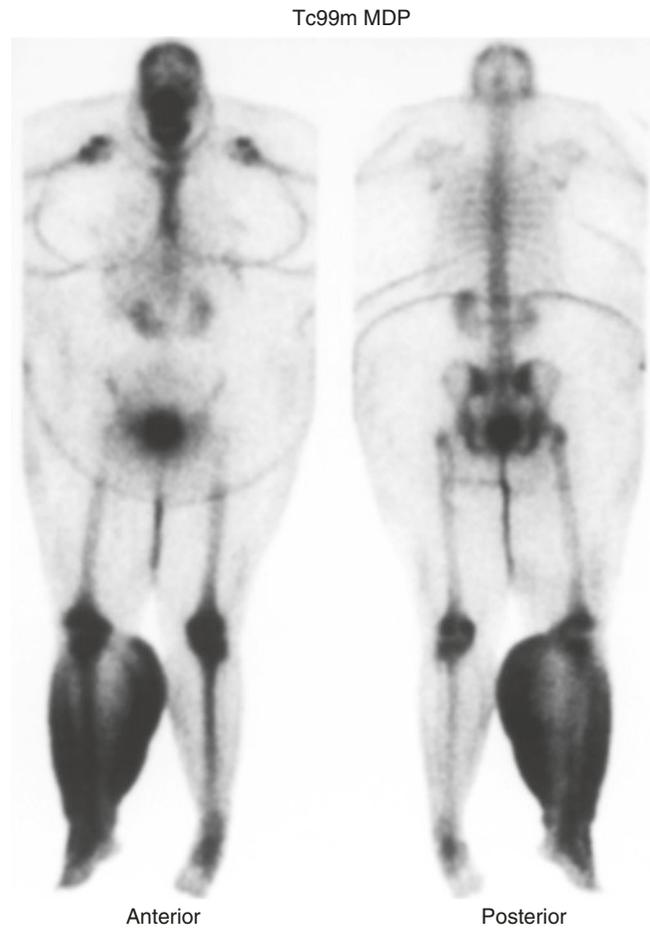

increase of uptake on delayed images or only mildly increased uptake secondary to the hyperemia of adjacent or surrounding soft tissue infection (Fig. 2.21).

It should be noted, however, that in some cases, osteomyelitis affects the entire bone or more than one bone, particularly in infants. The clearance of blood pool activity despite persistent bone uptake on delayed images may help differentiate such cases from cellulitis, which shows bone hyperemic changes on delayed images but with concomitant residual blood pool activity (Fig. 2.21). Four-phase bone scans can be of help in difficult cases to differentiate cellulitis from osteomyelitis.

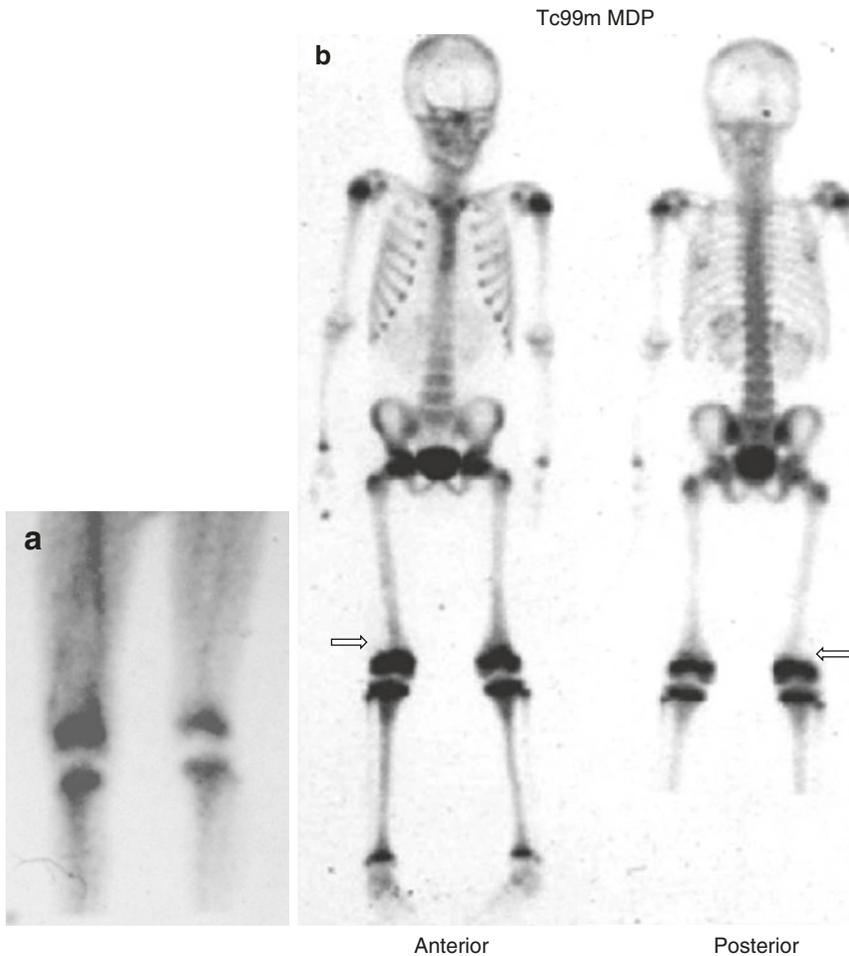

Bone scintigraphy is very sensitive in the early diagnosis of osteomyelitis [97, 101]. When the bone is not previously affected by other pathological conditions (non-violated), the bone scan has a high specificity as well [102–108] and is an efficient and cost-effective modality in the diagnosis of osteomyelitis. The overall sensitivity and specificity of bone scans for osteomyelitis in non-violated bone are 90–95%. However, there have been some reports of false-negative studies of cases with proven early acute osteomyelitis demonstrating either reduced, or normal,

accumulation of the radiopharmaceutical, particularly in neonates. However, these reports were based on the use of earlier gamma instrumentation. With the use of modern technology, more reports show high accuracy of bone scan in the diagnosis of neonatal osteomyelitis (Fig. 2.22) [109–111]. Tuson et al. [110] found that the positive predictive value of reduced uptake (a “cold” scan) in a selected group of patients was higher (100%) than that of a typical “hot” scan (82%), confirming an earlier report [112] that a “cold” scan (Fig. 2.23) indicates a more virulent disease. Cold lesions in this report [110] had an average shorter history (4 days) than hot scans (7 days) did. Cold foci on bone scan in cases of osteomyelitis are thought to be secondary to an increased intraosseous and subperiosteal pressure. Another report of seven cases with cold scan osteomyelitis also supported the earlier data [regarding the more aggressive nature of this infection that was also associated with elevated erythrocyte sedimentation rate (ESR), significantly elevated temperature and resting pulse, longer hospital stay, and higher rate of surgical interventions] [113]. When the bone scan is normal but the clinical picture strongly suggests osteomyelitis, a repeat bone scan within 24–48 h, Ga-67 citrate, or

**Fig. 2.21** Cellulitis with residual hyperemic changes in the right leg on delayed images

**Fig. 2.22** Neonatal osteomyelitis involving the right tibia. There is increased blood pool (**a**) and delayed (**b**) activity in the right tibia (arrows)

**Fig. 2.23** a, b A two-phase bone scan of a 7-year-old boy with fever, pain, and swelling in the region of the right knee. (a) There is increased vascular activity in the region.

(b) A photon-deficient area on delayed images in the lateral aspect of the right distal femoral metaphysis (arrows) illustrating an example of cold osteomyelitis

indium-111 leukocyte imaging may be helpful [54, 110, 114–118]. The normal appearance of bone scans at regions of osteomyelitis may be due to their being obtained during the transition from cold to hot phases [110].

When the bone is violated, the bone scan remains generally sensitive (90–95%) [119–134] but is non-specific (30%) [132]. Four-phase bone scans improve the specificity. This was demonstrated by Alazraki et al. [98], who reported that the specificity improved from 73% to 87% for three-phase bone scans in a selected group of patients, but the sensitivity dropped from 100% to 80%. Accordingly, when the bone has been violated, the bone scan alone may not establish the diagnosis,

requiring a complementary radionuclide modality, such as In-111 leukocyte or Ga-67; this improves the specificity. In this situation, the main benefit of the bone scan is to exclude the presence of osteomyelitis if it is unequivocally negative and to localize the abnormality better than other studies such as labeled leukocytes or gallium-67.

An attempt to improve the specificity of the three-phase bone scan was reported by Seldin et al. [135] among patients with diabetes. These authors classified hyperemia according to the time of its appearance compared to the surrounding soft tissue. Hyperemia that was apparent before, or at the same time as, the appearance of activity in the surrounding soft tissue was considered to be arterial,

and hyperemia which became evident only after the activity appeared in the tissue was considered venous. Bone scans accordingly were interpreted as showing acute osteomyelitis only when focal arterial hyperemia and increased activity on blood pool and delayed images were evident. Scans showing venous hyperemia were interpreted as soft tissue pathology or non-osteomyelitis conditions such as neuroarthropathy. Using these parameters, the authors reported a sensitivity of 94% and a specificity of 79%. This method, along with adding the fourth phase, may help decrease the number of additional diagnostic modalities needed, particularly when resources are limited.

Although the bone scan becomes positive very early in the course of the disease, it may not be useful in evaluating the response to treatment as it may remain positive for months after clinical resolution of the disease [136].

#### 2.4.2.3 Gallium-67 Citrate Imaging

The gallium-67 scan also becomes positive in osteomyelitis 24–48 h after the onset of symptoms [137]. Unlike a bone scan, Ga-67 activity generally returns to baseline approximately 6 weeks after successful treatment and can be used to monitor the clinical course of osteomyelitis [97, 136]. In the clinical setting of acute osteomyelitis, gallium-67 scans are 80–85% sensitive. On the other hand, positive gallium-67 scans are seen also with primary and metastatic neoplasms [98], chronic infections [138], and aseptic inflammatory and traumatic lesions [139]. Specificity accordingly is approximately 70% [17]. To improve specificity, Tumeh et al. [140] suggested that osteomyelitis is more likely to be present when Ga-67 uptake exceeds that of Tc-99m MDP or differs in distribution. If Ga-67 localization is less than Tc-99m MDP localization, infection is unlikely. If the two uptake patterns are equivalent, the findings may be indeterminate. These equivalent patterns can occur in up to 72% of patients with pre-existing focal abnormalities, and accordingly in complicated cases, such as diabetic or posttraumatic osteomyelitis, Ga-67 may not be able to differentiate osteomyelitis from neuroarthropathy or healing fractures [141]. Seabald et al. [142] studied 49 patients with

fracture non-unions 4–48 months after injury using Tc-99m MDP on day 1, combined Tc-99m MDP and indium-111-labeled leukocytes on day 2, and gallium-67 on day 3. Gallium-67 studies were interpreted as nondiagnostic if localization of the tracer at fracture sites was equal to that of Tc-99m MDP, positive if Ga-67 localization was greater than that of Tc-99m MDP, and negative if it was less than that of Tc-99m MDP. A total of 52% of culture-positive fracture sites showed a nondiagnostic pattern. Lewin et al. [124] using Tc-99m MDP and Ga-67 had a poor specificity for osteomyelitis in a highly selected group of patients, although combined Tc-99m MDP/Ga-67 yielded higher specificity than Tc-99m MDP alone in the group of patients with violated bone: The specificity for Tc-99m MDP bone scan was 25%, but when combined with Ga-67, it was 63%. Causes of Ga-67 false positives in this group included fractures and juvenile rheumatoid arthritis. Ga-67 combined with Tc-99m MDP, however, is particularly useful in the diagnosis of chronic active and vertebral osteomyelitis and has an accuracy similar to that of MRI [140, 143]. Love found, in a small number of patients, that SPECT gallium-67 and bone scans were more sensitive and specific than planar gallium-67 and bone scintigraphy (91% and 92% vs. 64% and 85%, respectively). The authors found that gallium SPECT alone has identical accuracy to combined Ga-67 and bone SPECT and suggested the use of Ga-67 SPECT alone in the diagnosis of vertebral osteomyelitis since it was also sensitive and slightly more specific than MRI in their series [144]. Currently, the role of Ga-67 imaging in musculoskeletal infection is limited almost exclusively to the spine and in some cases of chronic osteomyelitis for detecting active disease when FDG PET is not available (see later). Additionally it is used to follow up the response to therapy.

#### 2.4.2.4 Labeled Leukocyte Imaging

Indium-111 oxine and Tc-99m HMPAO leukocyte studies are widely used in the diagnosis of osteomyelitis as specific agents for infection. Overall, In-111 leukocyte studies are sensitive (88%) as well as specific (91%) for osteomyelitis [145] and are particularly useful in excluding

infection in a previously violated site of a bone such as posttraumatic, diabetic, and postsurgical conditions [146] and in some patients with pressure sores [147]. False-positive scans, however, have been reported with recent trauma and following arthroplasty, and, accordingly, in these situations, culture confirmation of positive scans, or the addition of a bone marrow scan, may be needed [148, 149]. Bone scintigraphy should be performed in conjunction with labeled leukocyte imaging for anatomical localization, although separating a bone from any adjacent soft tissue infection may still be difficult. Toward this end, the simultaneous acquisition of 24-h In-111 leukocyte and 3-h or 24-h Tc-99m MDP imaging has been employed. Schauwecker [150] studied 453 patients with bone and In-111 WBC scanning (173 sequentially and 280 simultaneously). It was possible by superimposing images to separate osteomyelitis from simple noninfectious bone turnover, or the adjacent soft tissue, particularly in the extremities. The overall sensitivity of this technique in locating infection in proven cases was 90% and the specificity was 91%. Determining that the infection was present in the bone rather than the adjacent soft tissue was more difficult, with a sensitivity of 84% and a specificity of 90% for proven osteomyelitis cases. Comparing sequential to simultaneous scanning shows that the simultaneous scans were able to separate the bone from soft tissue infection in 96% of the time, which is significantly higher than the 86% for sequential studies. Ezuddin et al. compared planar and SPECT simultaneous dual imaging of these agents and found that SPECT is superior in differentiating osteomyelitis from cellulitis. These authors reported 85% sensitivity and 100% specificity using SPECT and 85% sensitivity and 57% specificity with planar imaging in diagnosing osteomyelitis [151].

Tc-99m HMPAO-labeled leukocytes have been reported to yield an accuracy similar to that of In-111 leukocyte studies in the diagnosis of osteomyelitis but have the additional benefit of providing results on the same day [121, 152–154]. This technique may be particularly useful in children as the radiation dose is much lower than that of In-111 leukocyte technique. Its

disadvantage, however, is the inability to acquire dual Tc-99m MDP and labeled WBC simultaneously.

Indium-111-labeled leukocyte scans are not generally useful in the diagnosis of vertebral osteomyelitis as the images may show normal or decreased uptake and their accuracy is low [72, 73].

In addition to visual interpretation of labeled WBC studies, semiquantitative analysis could be used in doubtful cases with no cutoff for the percentage increase of uptake between 2–4 h images and 20–24 h images. Increasing uptake indicates infection [155].

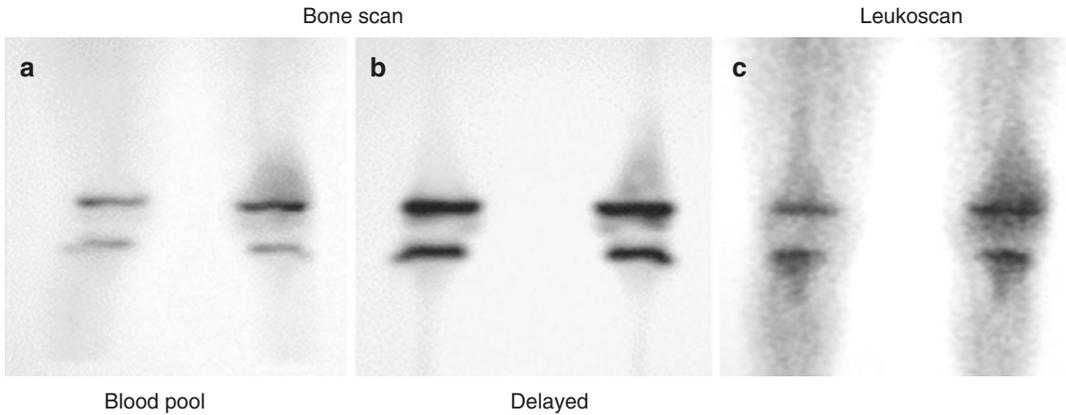

Semiquantitative analysis comparing ratio of early and delayed uptake to a reference area particularly mirrored contralateral region results in improving sensitivity, specificity, and accuracy [156].

#### 2.4.2.5 Immunoscintigraphy

Labeled antibodies have also been used for the diagnosis of osteomyelitis. In-111 or Tc-99m-labeled human non-specific polyclonal antibodies (IgG) and monoclonal antibodies such as labeled antigranulocyte antibodies. They are easier to prepare and use than labeled leukocytes. Leukoscan (anti-NCA-90) (Fig. 2.24) and fanole-somab (anti-NCA-95) were reported to have similar or better accuracy (90%) to WBC scan [157]. However, several studies showed variable results and suggest that these agents do not achieve the level of accuracy that was suggested earlier and are not accurate enough to replace WBC imaging for orthopedic infection [158–162].

This agent is not useful in the diagnosis of vertebral osteomyelitis and hip replacement [86, 163]. In a manner similar to the patterns of labeled white blood cells, this agent also showed cold lesions in vertebral osteomyelitis [163].

In-111 biotin is an alternative radionuclide agent that can be used for spinal infections. Biotin is a water-soluble B complex vitamin present in minute amounts in every living cell. Biotin is necessary for cell growth, fatty acid production, and metabolism of fats and amino acids. Since it is used as a growth factor by certain bacteria, In-111 biotin has been used to diagnose infection and is useful to diagnose spinal infections [164]. In-111 biotin does not accumulate in

**Fig. 2.24** 5y girl with fever and swelling over lower left femur. On Tc99m MDP bone scan there is increased blood pool in the metaphysis of the lower left femur (a) with corresponding increased uptake on delayed image (b). Tc99m leukoscan (c) was performed and shows

increased activity in the same region confirming osteomyelitis in the lower left femur. Note the mild degree of increased uptake on bone scan which should not be ignored in the pediatric age group

a normal bone or bone marrow, and there are few anatomic landmarks on the images [165] as it is reported that In-111 biotin, alone and in combination with streptavidin, accurately diagnoses spinal infections.

#### 2.4.2.6 Positron Emission Tomography Imaging

Positron emission tracers are known to concentrate in some inflammatory lesions including bone infections [166–168]. Positron emission tomography (PET) has been found to be useful in assessing the activity of chronic osteomyelitis and periprosthetic infections [169–173].

Fluorine-18 fluorodeoxyglucose (FDG) is transported into cells via glucose transporters. Activated inflammatory cells demonstrate increased expression of glucose transporters. It provides result within 30–60 min after tracer administration, imaging is not affected by metallic implant artifacts, and it has a much higher spatial resolution than other scintigraphic modalities [174].

It has been demonstrated that FDG PET has the highest diagnostic accuracy for confirming or excluding the diagnosis of chronic osteomyelitis in comparison with bone scintigraphy, MRI, or leukocyte scintigraphy [175]. Dual-time imaging with FDG PET helps differentiate malignant and

inflammatory processes in situations when distinction is essential since SUV remains stable or decreases inflammation while it increases over time in malignant lesions. MRI and F-18 FDG have comparable accuracy in diagnosing osteomyelitis [58].

Semiquantitative analysis adds to the advantages of FDG PET particularly high resolution. It facilitates differentiating infection from other conditions such as noninfectious inflammation and malignancy and in following up the response of therapy since FDG uptake normalizes quickly following trauma or surgery in approximately 3–4 months [176]. This modality is useful in acute osteomyelitis and is particularly helpful in diagnosis of chronic active osteomyelitis and spondylodiscitis [177].

Recent reports described Ga-68-citrate and Ga-68-transferrin as possible agents for PET imaging of infection. Ga-68 has half-life of 68 min compared to 78.3 h for Ga-67. Ga-68-citrate or Ga-68-transferrin was able to detect infected lesions in rats within 5–10 min postinjection, but a focal intense uptake at the lesion ( $SUV_{max}$ ) was visualized only at 30 min. In the patient studies, infection lesions were detected within 30 min postinjection. Blood pool and liver activities decreased during the period of study. There is no chemical difference between

Ga-67-citrate and Ga-68-Citrate, except for the radiolabel. In background uptake of Ga-68 and uptake by the liver, cardiac blood pool activity is much lower than Ga-67 at 60 min postinjection period. The short half-life of Ga-68 (68 min) may be advantageous from low dosimetry to the patients. The advantage of Ga-68 compared to FDG is that it is positive only in cases of infection. Preliminary reports suggest Ga-68-citrate PET/CT is useful in the diagnosis of suspected bone infections with reliable accuracy [178].

F-18 FDG was also used to label leukocytes for infection imaging. In a recent study, PET/CT imaging with F-18 FDG-labeled leukocytes was reported to have high specificity for the diagnosis of diabetic foot osteomyelitis in complicated diabetic foot. In the same study, F-18 sodium fluoride PET/CT bone imaging helped in the characterization of the extent of underlying Charcot's neuroarthropathy [179].

Previously Dumarey et al. found a high sensitivity and specificity of FDG-labeled leukocytes for the diagnosis of various infections including two patients with diabetic foot [180].

In a recent pilot study in patients with chronic osteomyelitis, early dynamic PET/CT with F-18 sodium fluoride offered additional information about early radiotracer distribution to standard NaF PET/CT, similar to a three-phase bone scan [181].

Iodine-124 fialuridine (FIAU) PET/CT is being investigated for use in infection imaging. Diaz et al. reported positive uptake in all eight patients with musculoskeletal infection and no accumulation in the single control subject [182].

In a recent study, juvenile pigs with pathological hematogenous *S. aureus* osteomyelitic lesions were dynamically PET scanned with O-15 water to quantify blood perfusion in osteomyelitis. Authors have found that perfusion is elevated compared to corresponding non-infected bone, but the elevation is significantly lower than in soft tissue lesions induced by the same *S. aureus* inoculation. They suggested that this seems to indicate less perfusion reserve in infected bones than in infected soft tissue, which could influence both successful therapy and healing [183].

### 2.4.3 Imaging Using Combined Modalities

Since no single morphological or scintigraphic modality is adequate in many cases with suspected skeletal infections when the bone is affected by a prior pathologic condition, different combinations of these modalities have been used to improve the diagnostic accuracy of imaging [184]. Combined modality approaches have particularly emerged to face the diagnostic challenges of complicated skeletal infections. Examples of these combinations are as follows:

- (a) Ga-67 and bone scans
- (b) Labeled white blood cell and bone scans
- (c) Labeled white blood cell, bone, and bone marrow scans
- (d) Labeled white blood cell and bone marrow scans
- (e) Bone and immunoscintigraphy scans
- (f) MRI, bone, and immunoscintigraphy studies
- (g) MRI, labeled white blood cell, and bone studies

This approach is commonly used in diabetic foot osteomyelitis, vertebral osteomyelitis, postarthroplasty infections, sickle cell disease infections, posttraumatic osteomyelitis, and chronic active osteomyelitis when a single modality cannot provide a diagnosis [16, 140, 185–191]. The use of these techniques and their accuracies is detailed throughout the chapter under the various, specific, forms of osteomyelitis. Table 2.9 shows the major morphological and scintigraphic modalities currently used for the diagnosis of skeletal infections.

---

## 2.5 Diagnosis of Specific Forms of Skeletal Infections

### 2.5.1 Diabetic Foot Osteomyelitis

As expected, bone scanning is very sensitive, but not specific, for the detection of infection in diabetes. This is because it is positive in cases of neuroarthropathy as well as infection, with a

specificity ranging from 0 to 70% (average of 27%) [17]. Accordingly, three-phase bone scanning cannot reliably separate infection from neuroarthropathy. The four-phase bone scan (using arterial hyperemia in flow studies for scan interpretation along with increased activity on blood pool and delayed images for diagnosing osteomyelitis) may improve the specificity. Ga-67

**Table 2.9** Summary of commonly used imaging modalities for skeletal infection

Modality	Advantages	Disadvantages	Typical findings and overall accuracy
Standard radiograph	Cost-effectiveness: No additional imaging needed if positive. Identify other causes of symptoms and signs (e.g., fracture). Assess comorbidities such as fractures and arthritis	Low sensitivity: Findings take up to 2–3 weeks to appear, delaying diagnosis Low specificity to identify infection in a violated bone	Cortical destruction (very sensitive finding) Soft tissue swelling with obliteration of fat planes Endosteal scalloping; cortical tunneling Ill-defined radiolucent lesions Sensitivity: 28–94% (average of 56%) Specificity: 3–92% (average 75%)
Computed tomography	Excellent visualization of the cortex Multiplanar and thin-slice reconstructions enhance ability to evaluate infection and identify sequestra	Less resolution than plain radiography Beam-hardening artifact	Increased attenuation of the bone marrow Periosteal reaction and new bone formation Sequestrum intraosseous and/or soft tissue gas
MRI	Excellent delineation of the soft tissue versus bone infections Evaluation of bone marrow edema Excellent for suspected vertebral osteomyelitis Very useful in neonatal pelvic osteomyelitis to identify associated soft tissue abscesses	Bone marrow edema is non-specific and can be seen in osteonecrosis, fractures, and metabolic bone disease Specificity is lower with small bones and in complicated cases of infection	Cortical destruction. Increased T2 signal (particularly on STIR) Decreased T1 signal and post-gadolinium enhancement Sensitivity: 60–100% (average, 90%) Specificity: 50–95% (average, 86%)
Multiphase bone scan	Earlier detection (24–48 h after infection) than radiographs Very high sensitivity for infections even in the presence of other comorbidities Whole-body imaging permits detection of infection at other unsuspected sites	Specificity decreases when other pathologies are present Scans will stay positive for a long time after infection heals, which therefore is not ideal for monitoring response to treatment	Focal increased activity on blood flow, blood pool, and delayed images Sensitivity: 90–95% Specificity: Non-violated bone 92% Violated bone 0–76% (average of 30%)
White blood cell scan alone or with bone scan	High specificity for infection. Improves bone scan specificity in the setting of violated bone Scans normalize as early as a few days and so may be used to monitor response to therapy	If used alone, difficult to differentiate bone versus soft tissue infections A tedious procedure Additional techniques such as bone marrow scan are needed when positive	Focal increased uptake average specificity: 84% Average sensitivity: 88% Dual imaging will show concordant uptake with bone scan in positive studies. Combined imaging increases sensitivity to 86–90% and specificity to 91–94% in violated bone cases

**Table 2.9** (continued)

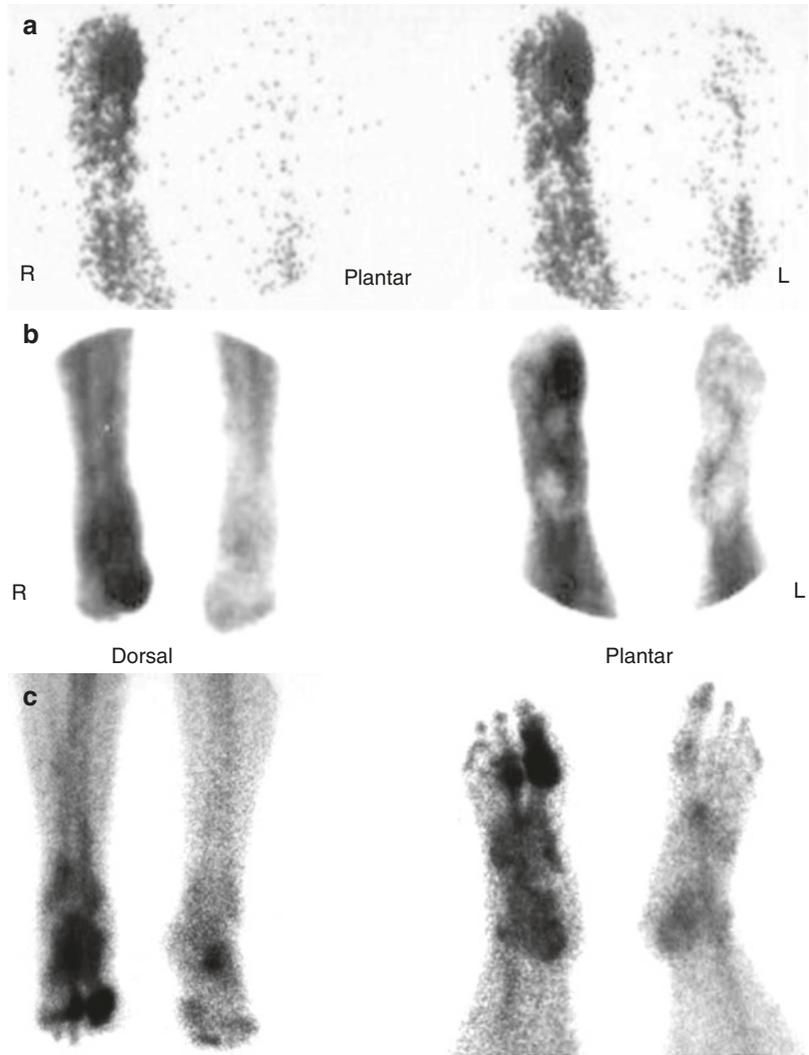

Modality	Advantages	Disadvantages	Typical findings and overall accuracy
Gallium-67 scintigraphy alone or with bone scan	Early detection of infection Scans return to normal in 6 weeks with successful therapy, allowing use for monitoring treatment Useful for chronic active and vertebral osteomyelitis	Positive findings can be non-specific and may be positive in other settings such as tumor and inflammation	Combined scanning is considered positive when they are spatially incongruent or spatially congruent with greater Ga-67 intensity than bone scan Average sensitivity: 89% Average specificity: 70%
Bone marrow scan as an addition to white blood cell scan only or along with bone scan	Improves specificity for infection in complicated cases, such as post-arthroplasty infections	Adds time and cost to the diagnostic imaging	Infection is confirmed when bone marrow activity is incongruent with the positive area on labeled white blood cell scan. If activity is congruent, it indicates physiologic bone marrow as a cause of WBC uptake
Ultrasound	Excellent for rapid and accurate detection of joint effusions in the setting of septic arthritis Identifies soft tissue and subperiosteal abscesses No radiation	Poor modality to visualize the bone Slightly less sensitive in effusion detection than MRI	Fluid collection adjacent to the cortex of infected bone with communication to the medullary cavity. Occasionally, superficial local defects and periosteal reactions in advanced cases Absence of joint effusion will rule out septic arthritis
FDG-PET	Useful in chronic active osteomyelitis, spondylodiscitis, and periprosthetic infections as a single modality. Also used in diabetic foot skeletal infections. Useful in early assessment of the response to therapy	Availability, expense	Focally increased uptake with moderate to high SUV Sensitivity: 95–100% (chronic osteomyelitis) 90% (periprosthetic infection) Specificity: 86–100% (chronic osteomyelitis), 89% (hip periprosthetic infection), 72% (knee periprosthetic infection)

is not able to discriminate between osteomyelitis in the diabetic foot and non-infected neuroarthropathy. Indium-111 leukocyte imaging is both sensitive and specific for diabetic foot infections. However, sensitivities range from 72% to 100% and specificities from 67% to 100% [192]. All ulcers which expose the bone were found to be associated with osteomyelitis (Fig. 2.25), and patients therefore may be treated without the need for imaging. However, patients with ulcers which did not expose bone are recommended to have indium-111 leukocyte studies in order to detect

the osteomyelitis [126]. False-positive results have been reported in several conditions, including rapidly progressive neuroarthropathy. The vast majority of neuroarthropathies are not rapidly progressive and show no abnormal accumulation of labeled leukocytes. Only in the minority of cases of the rapidly progressive variant does indium-111 white blood cell imaging show an increased uptake. Combined bone-labeled leukocyte imaging improves the accuracy of the diagnosis of foot osteomyelitis and its differentiation from soft tissue infection. Grerand [193] reported a

**Fig. 2.25 a-c**

Osteomyelitis in a case of diabetic foot in a 49-year-old woman with a 19-year history of diabetes mellitus and a recent history of an ulcer on the plantar surface of the right foot which exposed the bone. (a) Blood flow, (b) blood pool, and (c) delayed images show focally increased activity in the first metatarsal and proximal phalanx and second metatarsal bones. Since the overlaying pedal ulcer is exposing the bone, this positive bone scan suffices for diagnosis of osteomyelitis

sensitivity of 93% and a specificity of 83% for this dual-isotope technique and concluded that it can reliably determine the site and extent of osteomyelitis of diabetic foot. In a small number of patients, Vesco et al. reported a sensitivity of 85% and a specificity of 82% of the dual-isotope technique using Tc-99m HMPAO-labeled leukocytes [186]. False-positive results, however, can still occur in some cases of non-infected neuroarthropathy [187]. A decreasing lesion/background ratio of labeled white blood cells between 4 h and 24 h helps differentiate the condition from osteomyelitis, which does not show a decreasing ratio. Because of the poor spatial resolution of labeled

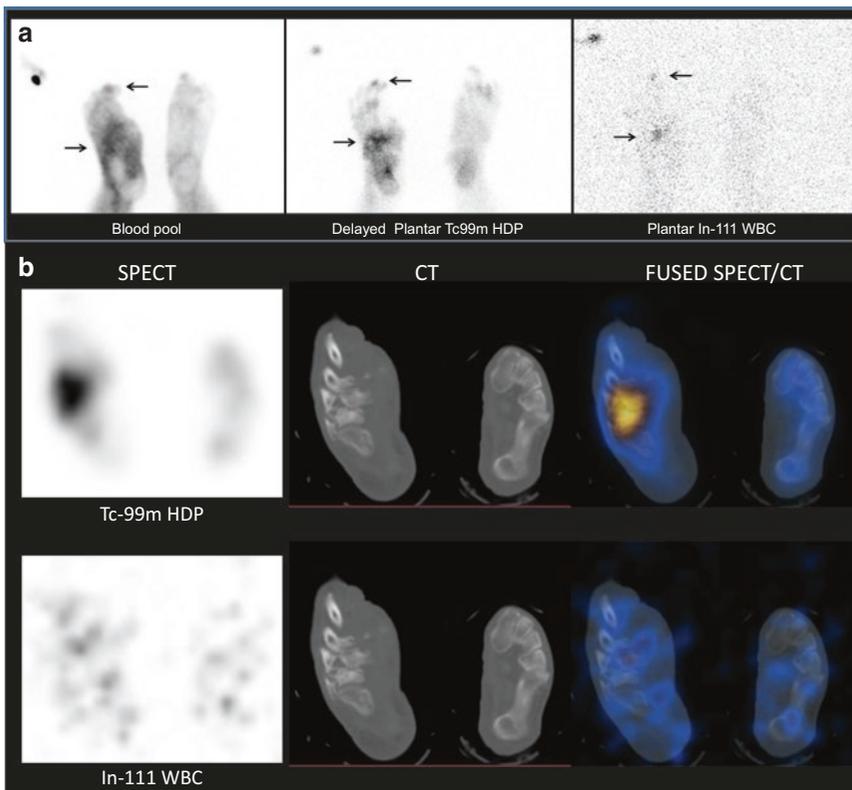

leukocyte studies, uptake in soft tissues could be incorrectly attributed to bone uptake and vice versa. Dual-isotope studies for diabetic foot permit better localization of white blood cell activity and consequently help increase the accuracy in differentiating osteomyelitis from cellulitis [185]. Collective studies have shown an average sensitivity of 83% for labeled leukocyte and combined bone-leukocyte scintigraphy. The average specificity, however, improved only from 64% for leukocyte scan alone to 80% when combined with bone scintigraphy [192].

Combined In-111-labeled leukocyte and Tc-99m sulfur colloid marrow scans further

improve the specificity since they differentiate marrow uptake of labeled leukocyte from uptake by actual bone infection.

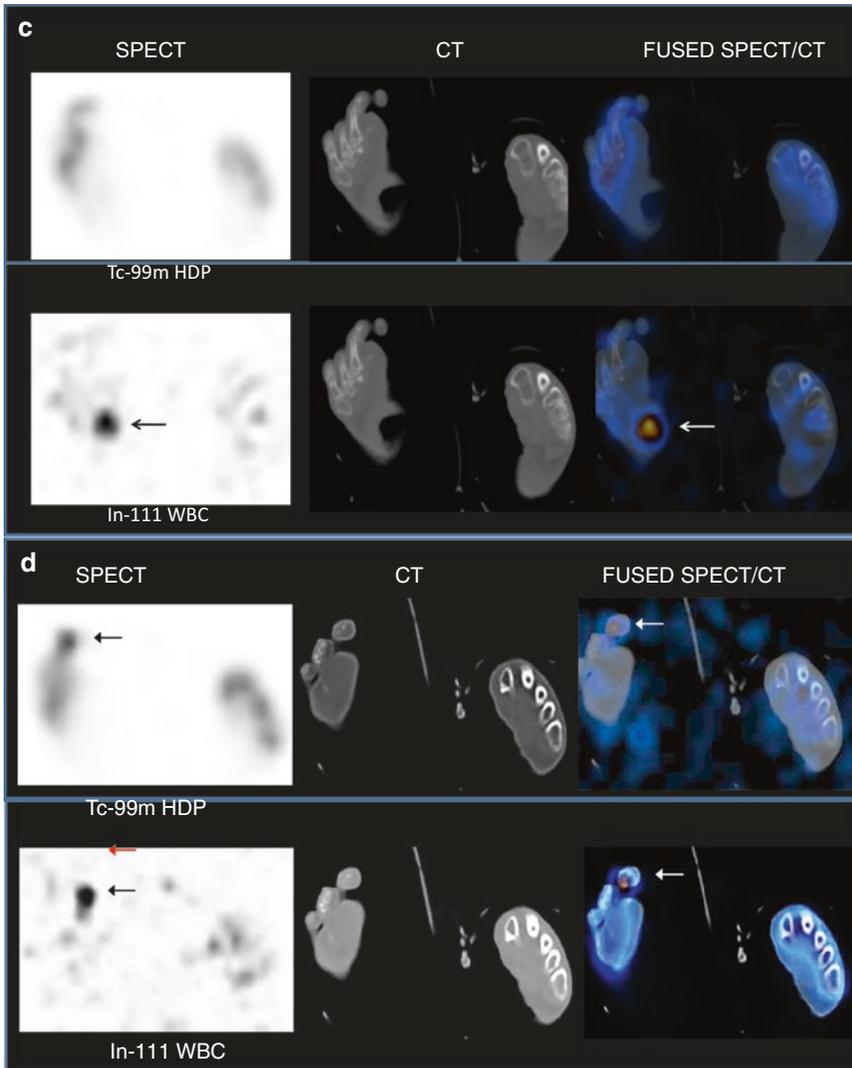

SPECT/CT imaging for diabetic foot osteomyelitis using Tc-99 MDP and In-111-labeled leukocytes (Fig. 2.26) is more accurate in diagnosing and localizing infection compared with conventional imaging. Additionally, it provided clear guidance and promoted many limb salvage procedures. Its use was associated also with

considerably reduced length of hospitalization compared with conventional imaging [194, 195]. A novel standardized hybrid image-based scoring system, Composite Severity Index (CSI), derived from Tc-99m-WBC SPECT/CT image was found to have prognostic value in diabetic foot infections. In a study of 77 patients, CSI of 0 had a 92% chance of favorable outcome, which fell progressively to 25% as indices rose to  $\geq 7$  [196].

**Fig. 2.26** Fifty-nine-year-old male diabetic patient S/P right great toe amputation presented with discharging ulcers on the right foot plantar surface, R/O osteomyelitis. (a) The blood pool image demonstrates foci of increased blood pool activity involving the probable distal third toe and mid-right foot. The delayed bone scan planar image demonstrates foci of increased radiotracer uptake in the same regions. On the In-111 WBC planar image, there are two foci of abnormal uptake also probably in the same areas (black arrows). (b) In the selected dual isotope SPECT/CT transaxial slices, there is increased Tc-99m HDP uptake in the right intermediate and lateral cuneiforms and intercuneiform joint without corresponding abnormality on the simultaneously obtained In-111 WBC images (arrows). These

findings are consistent with arthritic changes. (c) In the adjacent dual isotope SPECT/CT transaxial slices, there is increased In-111 WBC uptake (arrows) in a region of plantar ulcer without corresponding abnormal uptake on Tc-99m HDP bone scan consistent with soft tissue infection (blue arrows). (d) In another dual-isotope SPECT/CT transaxial slices, there is focal increased uptake in the right third distal phalanx on both bone scan and In-WBC scan images consistent with probable small focus of osteomyelitis (red arrows). Based on these images, the patient was effectively treated with soft tissue debridement of the large plantar ulcer and distal right third toe partial amputation as well as antibiotics and was saved from a major foot amputation (courtesy of Dr. S. Heiba with thanks)

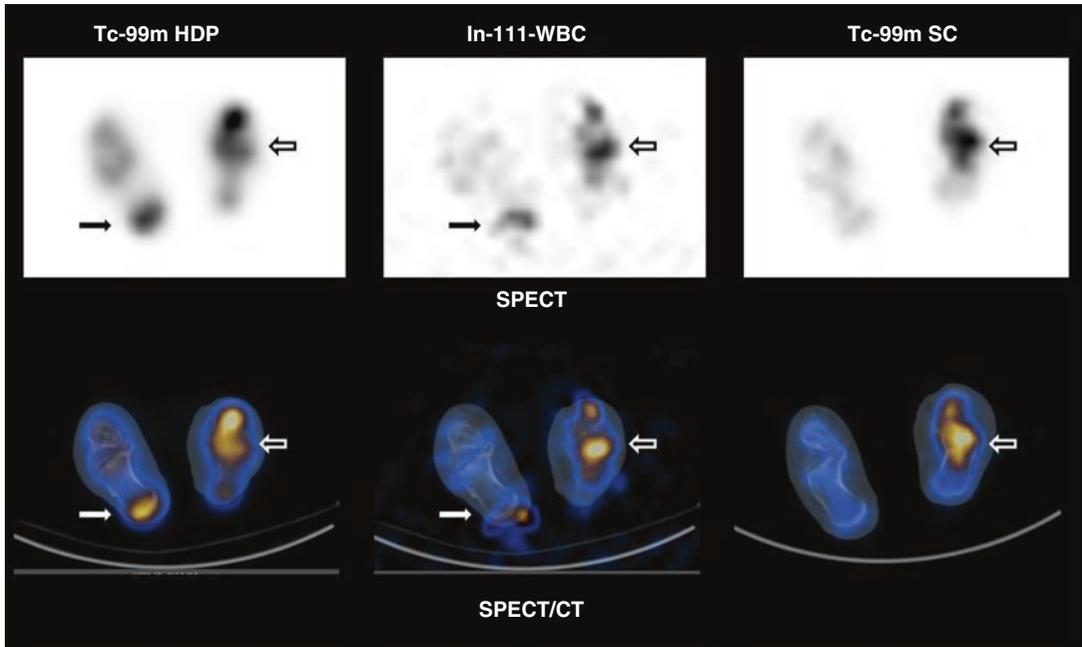

**Fig. 2.26** (continued)

Combined In-111-labeled-leukocyte and Tc-99m sulfur colloid marrow scans (Fig. 2.27) further improve the specificity, differentiating marrow uptake of labeled leukocytes from uptake by actual bone infection. Palestro et al. more recently found this approach superior to combined bone/leukocyte scintigraphy [197]. Simultaneous SPECT/CT of Tc-99m sulfur colloid (SC) and In-111 white blood cells (WBC) provides essentially perfect spatial registration of the tracers within anatomic sites of interest. Quantitation of this method for compensation for scatter and cross talk was reported recently to be

useful experimentally for improving quality, bias, and precision of Tc-99m activity estimates in simultaneous dual-radionuclide imaging of osteomyelitis [198]. SPECT/CT with In-111-labeled leukocyte combined with bone or bone marrow scan is currently the best imaging modality for diagnosing osteomyelitis [199].

MRI can differentiate between soft tissue and bone infections [54]. This is particularly important in diabetics and has been found useful in the diagnosis of diabetic foot osteomyelitis. Several investigators have found that MRI is clearly superior to standard radiographs and bone

**Fig. 2.27** White blood cell and bone marrow SPECT/CT studies in a patient with diabetes and suspected osteomyelitis. Focal uptake in right posterior calcaneal bone on In-WBC and Tc-99m HDP dual-isotope SPECT/CT (*solid arrows*) but no corresponding uptake on Tc-99m SC bone

marrow scan consistent with osteomyelitis with adjacent soft tissue infection on In-WBC images. Intense uptake in left anterior calcaneal and talus bones in on all images (*open arrows*) consistent with neuroarthropathy without evidence of infection

scintigraphy with a sensitivity and specificity approaching 100%. These studies, however, involved mostly severe infections with significant pathological changes. Newman et al. [200] reported a sensitivity of only 29% for relatively low-grade osteomyelitis compared to 100% for labeled leukocyte scanning of the same patients. The specificity was similar for both modalities. Cook et al. also reported a sensitivity of 91% and a specificity of only 69% for MRI [201]. Morrison et al. reported a lower accuracy of MRI for diabetic than for nondiabetic cases with a sensitivity and specificity of 82% and 80%, respectively, for diabetic osteomyelitis compared to 89% and 94% for nondiabetic bone infections [202]. MRI was compared to combined Tc-99m HDP bone scan and Tc-99m HMPAO-labeled scintigraphy in a small number of diabetic patients. MRI was 100% sensitive compared to 77% for the combined scintigraphic technique. The specificity was identical at 82% [186]. Beltran [53] reported the characteristic pattern of

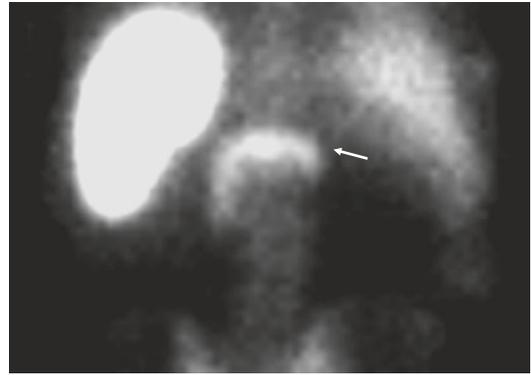

osteomyelitis as a high signal intensity from the marrow space on T2-weighted images. However, this finding itself is not specific for osteomyelitis and can be seen with other conditions including rapidly progressive neuroarthropathy, which may be indistinguishable from that of osteomyelitis. Finally, some authors suggested treating all patients with antibiotics when diabetic foot infection is suspected clinically as they are most cost-effective [203].

FDG PET/CT provides faster results (typically within 2 h). Although high sensitivity and specificity rates have been achieved for the differentiation of osteomyelitis from neuroarthropathy with a sensitivity of 80–95% and a specificity of 90–100 [204–207], the literature focusing on the use of F-18 FDG PET and PET/CT for diabetic foot osteomyelitis remains still limited [208, 209]. The role of FDG imaging in the evaluation of diabetic foot infection has yet to be clarified, with some investigators reporting high accuracy and others reporting just the opposite [176].

### 2.5.2 Vertebral Osteomyelitis (Spondylodiscitis)

Spinal osteomyelitis accounts for approximately 2–7% of all cases of osteomyelitis and occurs more often in the elderly [66]. Standard radiographs are neither sensitive nor specific for the diagnosis of the relatively common condition. Gadolinium-enhanced magnetic resonance imaging (MRI) is the imaging technique of choice for the evaluation of spinal infection [67]. It has an excellent sensitivity and specificity (96% and 94%, respectively) [143]. The characteristic changes for spondylodiscitis consist of a hypointense signal of the disc and vertebral body on T1-weighted images and a hyperintense signal of the same structures on T2-weighted images (due to edema) [66]. Although it is the imaging method of choice in the absence of metallic implants, it is not always possible to distinguish postoperative changes from infection [68].

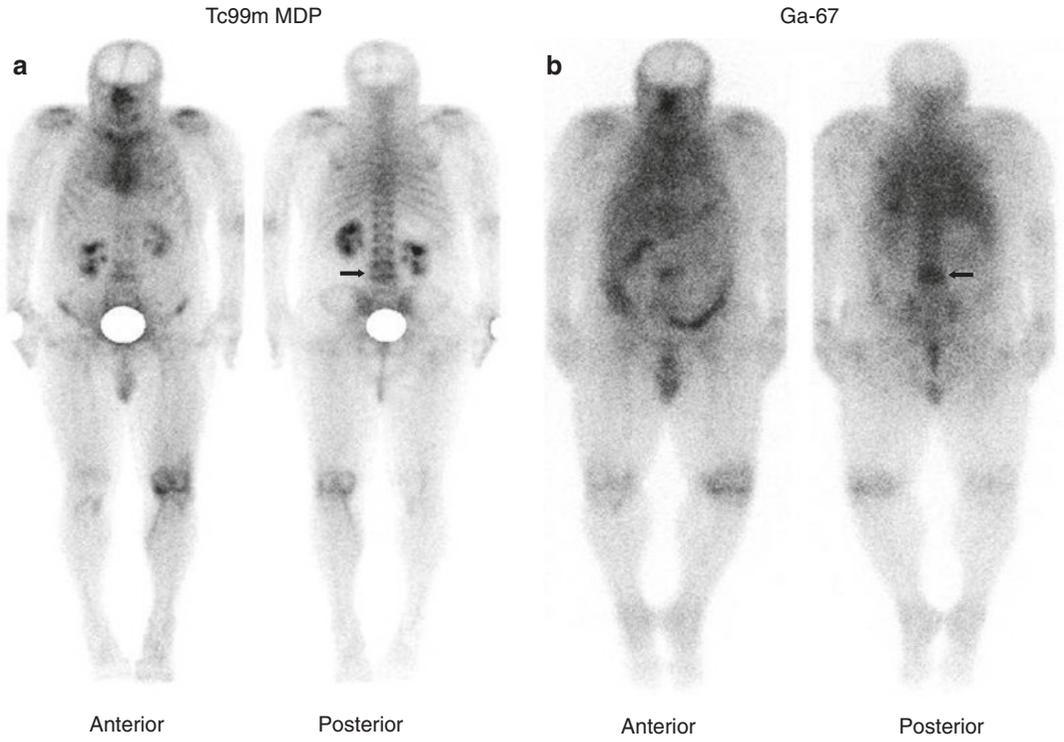

Nuclear medicine procedures are often performed as complementary techniques in the diagnosis of infection in the spine. Bone scanning is sensitive but is not specific and can be used as screening modalities although in elderly patients it may be false negative. Labeled leukocyte scanning using both indium-111 and Tc-99m HMPAO is also neither sensitive nor specific. This low sensitivity is due to the different patterns of uptake in cases of proven vertebral osteomyelitis including normal uptake, decreased uptake, or increased uptake [210, 211]. This was demonstrated by Palestro et al., who studied 71 patients with suspected vertebral osteomyelitis [211] and found that In-111 leukocyte scintigraphy showed increased, or decreased, uptake in 28 patients with proven osteomyelitis. Increased uptake (Fig. 2.28) was associated with a high specificity of 98%, but was only 39% sensitive for the condition. The photopenic pattern was neither sensitive (54%) nor specific (52%) for osteomyelitis. Whalen et al. [210], in a study of 91 patients with suspected vertebral osteomyelitis, also reported a sensitivity of 17%, a specificity of 100%, and an accuracy of 31% for indium-111 leukocyte imaging. The authors found photon-deficient areas at the sites of proven osteomyelitis in 50% of 18

**Fig. 2.28** In-111-labeled white blood cell studies for proven vertebral osteomyelitis showing a pattern of increased uptake

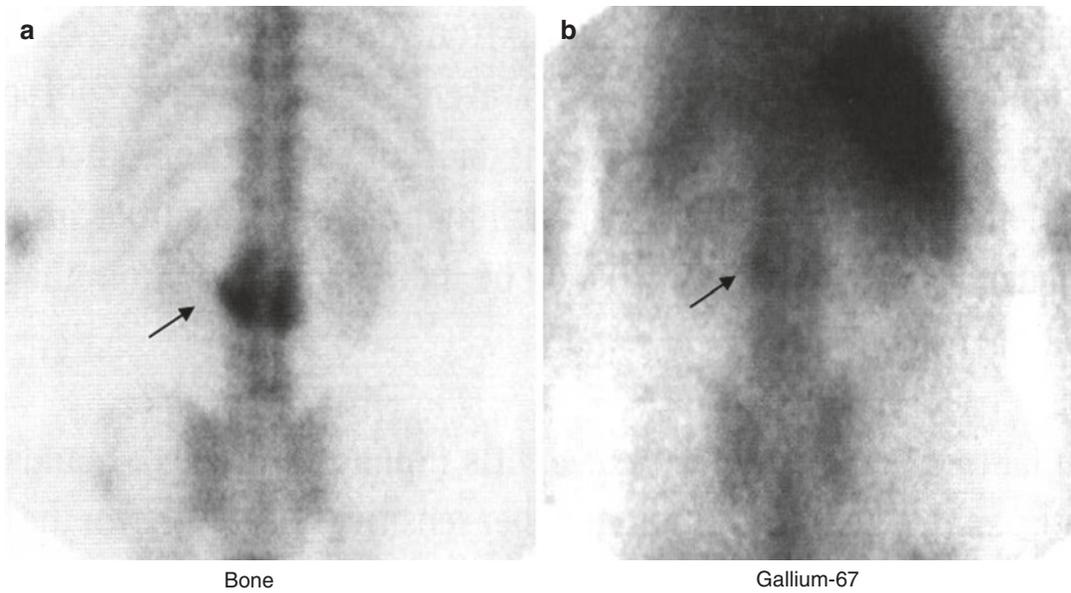

patients with proven osteomyelitis, and these were considered to be false-negative scans. Because the diagnosis of vertebral osteomyelitis is often delayed, most infections are chronic in nature, which can in part explain the low sensitivity of indium-111 leukocytes in their diagnosis. Photopenic areas on In-111 leukocyte imaging in proven vertebral osteomyelitis could be secondary to the secretion of anti-chemotactic factors by some causative organisms such as *Pseudomonas aeruginosa* and *Klebsiella pneumoniae*, which prevents enough accumulation of labeled cells at the site of infection [212]. Using Tc-99m HMPAO-labeled leukocytes, Ruther reported five cases of proven vertebral osteomyelitis that were all missed [130]. Hovi also reported three cases of proven infection detected by MRI but none by Tc-99m HMPAO-labeled leukocyte studies [213].

Gallium-67, on the other hand, has a sensitivity of 88% and a specificity of 100% when combined with Tc-99m MDP for the diagnosis of osteomyelitis [202], comparable to that of MRI, which is an excellent modality for the diagnosis of vertebral pathology including infection. For scan interpretation, the degree of bone uptake is compared to that of gallium-67; this allows the high specificity of this combined approach (Fig. 2.29, Fig. 2.30). Vertebral osteomyelitis and accompanying soft tissue infection have been reported to be diagnosed accurately with a single radionuclide procedure. Ga-67 SPECT was as accurate as bone and Ga-67 SPECT and as

**Fig. 2.29** Combined Ga-67 and bone scan in vertebral osteomyelitis showing an increased uptake on Ga-67 scan

which is more intense than that on bone scan, illustrating the pattern of osteomyelitis

**Fig. 2.30** Combined Ga-67 and bone scan in a case of suspected vertebral osteomyelitis showing less intense Ga-67 uptake than that of the bone scan (*arrows*) indicating no infection (courtesy of Dr. C. Palestro with thanks)

**Table 2.10** Accuracy of imaging modalities in the diagnosis of vertebral osteomyelitis (combined literature data)

Modality	Sensitivity (%)	Specificity (%)
Standard radiograph	50	57
CT	76	No information available
MRI	97	95
Bone scan	79	73
Ga-67 (planar)	85	77
Ga-67 SPECT	91	92
Combined bone/Ga-67 (planar)	92	94
In-111 WBC	30	98
Combined bone/Ga-67 SPECT	95	96
Ga-67 SPECT/CT	94	100
F-18 FDG PET/CT	97–100	90–100

sensitive as MRI (91%); the radionuclide study was slightly but not significantly more specific (92% vs. 77%) than MRI (Table 2.10). This procedure can be used as a reliable alternative when MRI cannot be performed and as an adjunct in patients in whom the diagnosis is uncertain [144]. Gratz et al. [214] used Ga-67 to identify vertebral osteomyelitis and determine the severity of infection and, potentially, the response to therapy. Although MRI was able to identify all the lesions, it failed to differentiate between mild infections and concurrent degenerative processes, and in these cases, Ga-67-SPECT was instrumental in reaching the correct diagnosis. In a study of vertebral osteomyelitis and discitis in children, Fernandez and associates found that the age of children with discitis alone is younger than those with vertebral osteomyelitis, and the duration of symptoms is shorter [23]. The authors also found that MRI detected 90% of discitis cases and 100% of osteomyelitis cases and concluded that MRI is the modality of choice for pediatric patients with suspected vertebral osteomyelitis [23].

Although MRI remains the modality of choice in diagnosing spondylodiscitis, bone and gallium SPECT/CT (Fig. 2.31) was found to be diagnostically equivalent and should be considered a viable supplementary or alternative imaging

modality particularly if there is contraindication or inaccessibility to MRI. The available data suggest that Ga-67 SPECT/CT (Fig. 2.32) has a sensitivity of 94% and a specificity of 100% [215]. Figure 2.32 depicts a bone SPECT/CT study with MRI of a case of vertebral osteomyelitis.

FDG PET/CT has been proven helpful in the diagnosis of spondylodiscitis (Fig. 2.33) and in detecting associated soft tissue involvement [216–218]. In a meta-analysis study involving 12 qualified studies on F-18 FDG and spondylodiscitis, the cumulative sensitivity and specificity were 97% and 88%, respectively [216].

F-18 FDG PET has been found more accurate than bone, Ga-67, and antigranulocyte antibody imaging and compares favorably with MRI for the diagnosis and follow-up of spondylodiscitis [217–223].

Gratz et al. [217] reported that they found F-18 FDG PET superior to MRI for low-grade spondylitis/discitis. Stumpe et al. [218] reported 100% sensitivity and specificity for F-18 FDG PET. MRI was 50% sensitive and 96% specific. In an investigation of patients with inconclusive conventional imaging results, the sensitivity and specificity of F-18 FDG PET/CT were 81.8% and 100%, respectively, versus 75% and 71.4%, respectively, for MRI [220]. Fuster et al. [221] compared F-18 FDG PET/CT and MRI. Sensitivity and specificity for F-18 FDG PET/CT were 83% and 88%, respectively, versus 94% and 38%, respectively, for MRI.

In patients with brucellar spondylodiscitis, F-18 FDG PET/CT identified all foci of infection seen on MRI and revealed additional spinal lesions in three patients, as well as new paravertebral soft tissue involvement and epidural masses. This additional information influenced patient management [222]. Nakahara et al. [224] reported that F-18 FDG PET/CT was superior to MRI for localizing sites of infection and guiding minimally invasive surgery.

F-18 FDG was found also to be useful for monitoring treatment response in spondylodiscitis. Riccio et al. [225] reported that patients with poor treatment response had persistent bone and soft tissue F-18 FDG uptake. F-18 FDG uptake confined to the margins of a destroyed disc after

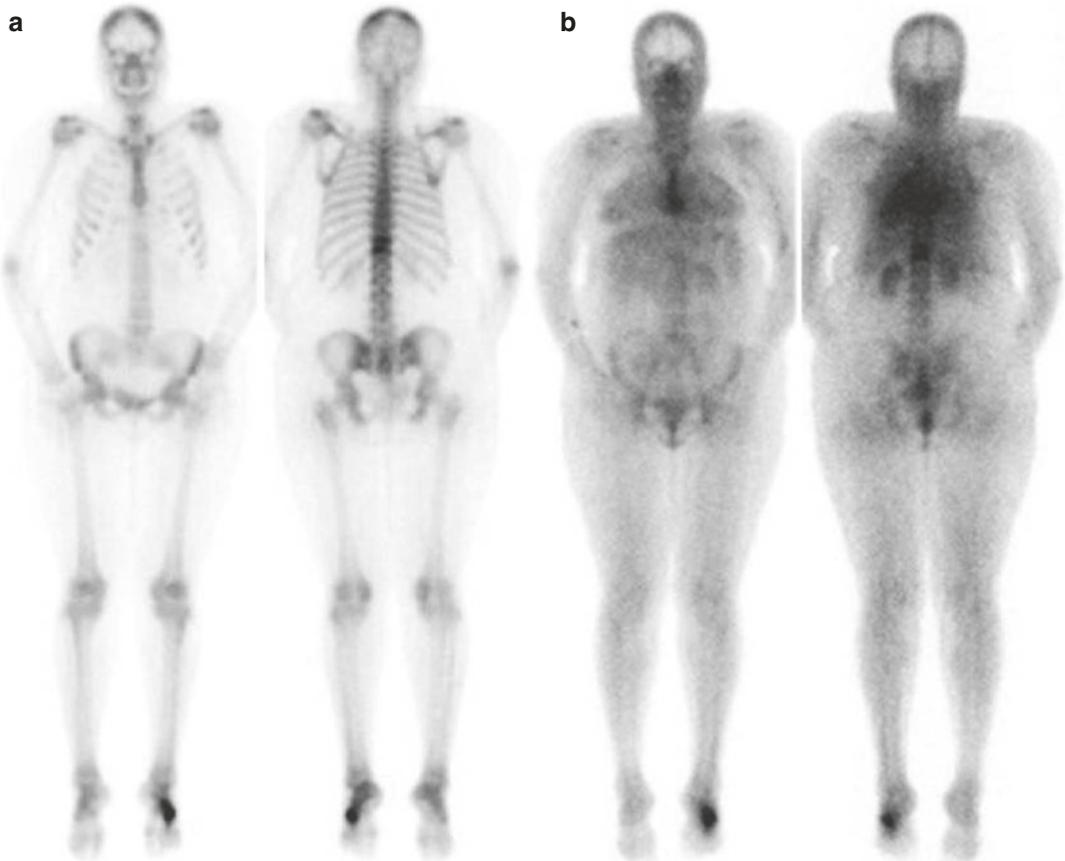

treatment did not indicate infection. Successful treatment of brucellar spondylodiscitis was associated with a significant decrease in F-18 FDG uptake [222]. Skanjeti et al. [223] reported that F-18 FDG PET/CT was more accurate than MRI (90% vs. 61.5%) for assessing treatment response. From the limited data available on the role of Ga-68 PET/CT imaging of spinal infection, an overall accuracy of 90% was found [226].

### 2.5.3 Chronic Active Osteomyelitis

Noninvasive diagnosis of chronic active skeletal infections remains a challenge. The radiological diagnosis of chronic active osteomyelitis is neither sensitive nor specific, while bone scintigraphy is

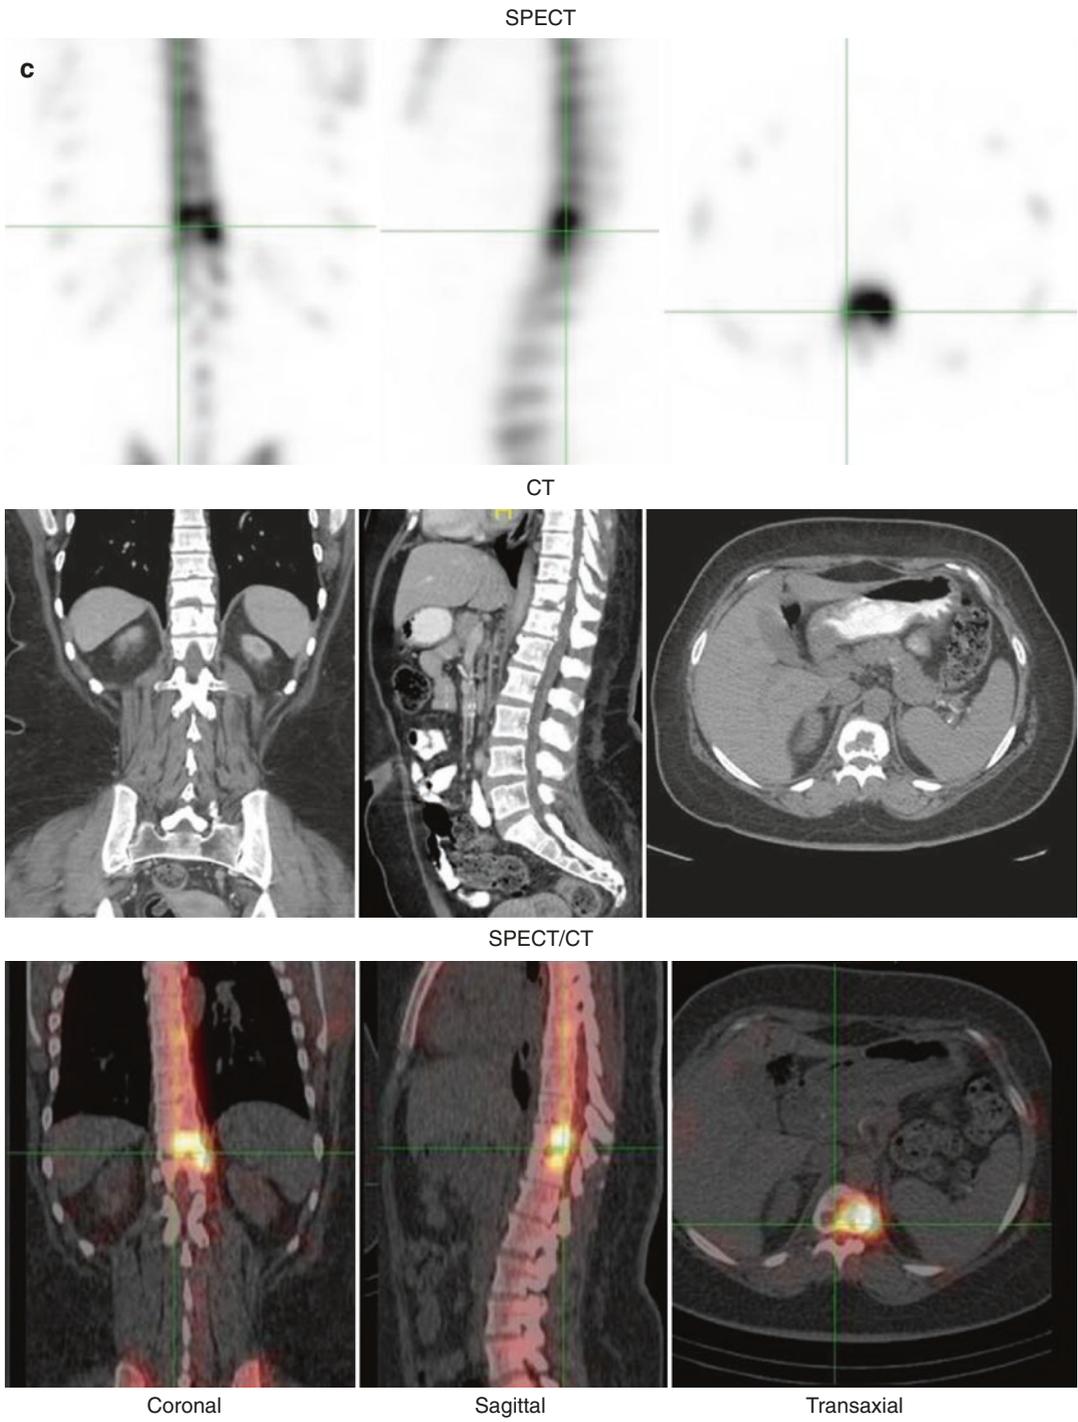

sensitive but not specific. This low specificity is due to the chronic bone repair that is associated with increased bone metabolism and increased uptake on bone scan in the absence of active infection. It is therefore difficult to differentiate bone turnover due to healing from chronic active disease, although increased activity in all phases of the bone scan is suggestive of chronic active disease. The bone scan accordingly cannot confirm the presence of active disease, but a negative scan accurately excludes it.

Gallium-67 citrate imaging is more specific than bone scanning for chronic osteomyelitis, although false positives commonly occur in conditions such as healing fractures, tumors, and non-infected prostheses. Combined Tc-99m MDP and gallium-67 scans can be helpful in making the

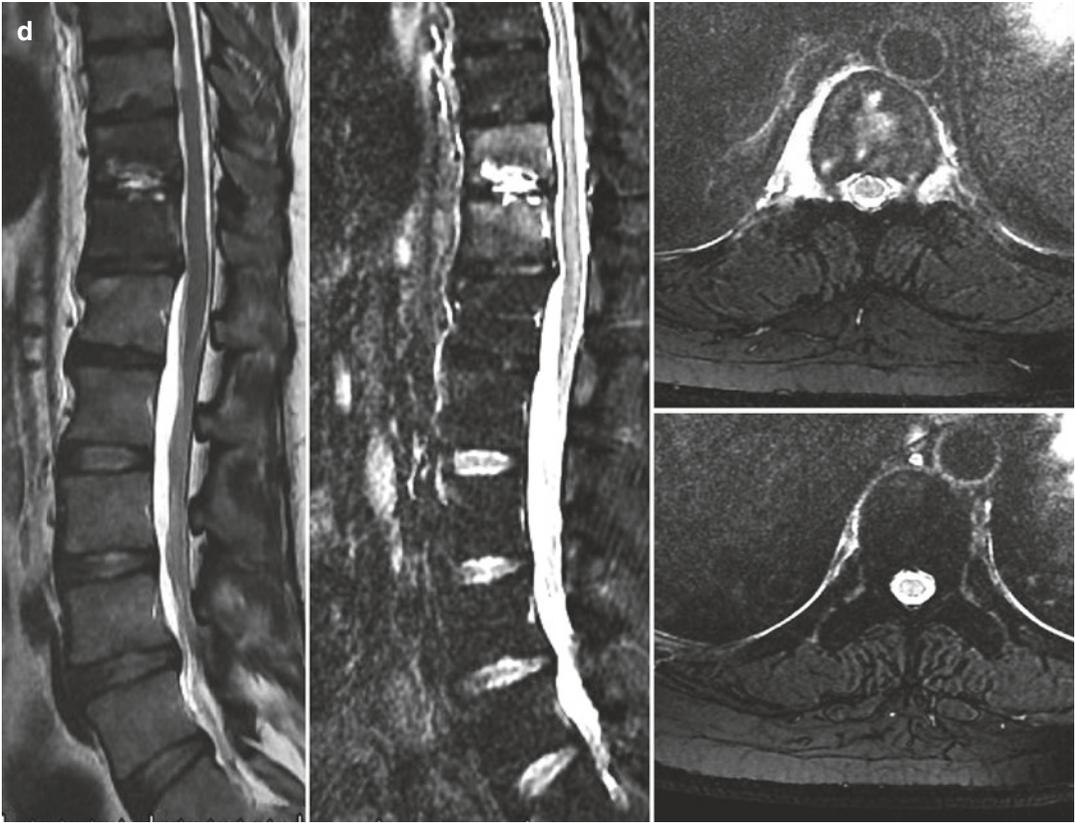

**Fig. 2.31** A combined bone and Ga-67 studies in a case of vertebral osteomyelitis. Bone scan (a) shows increased uptake in the 11th/12th dorsal vertebrae. Ga-67 study (b)

demonstrate corresponding increased uptake. Bone SPECT/CT study (c) demonstrates increased uptake involving the endplates correlating with MRI (d) study

**Fig. 2.31** (continued)

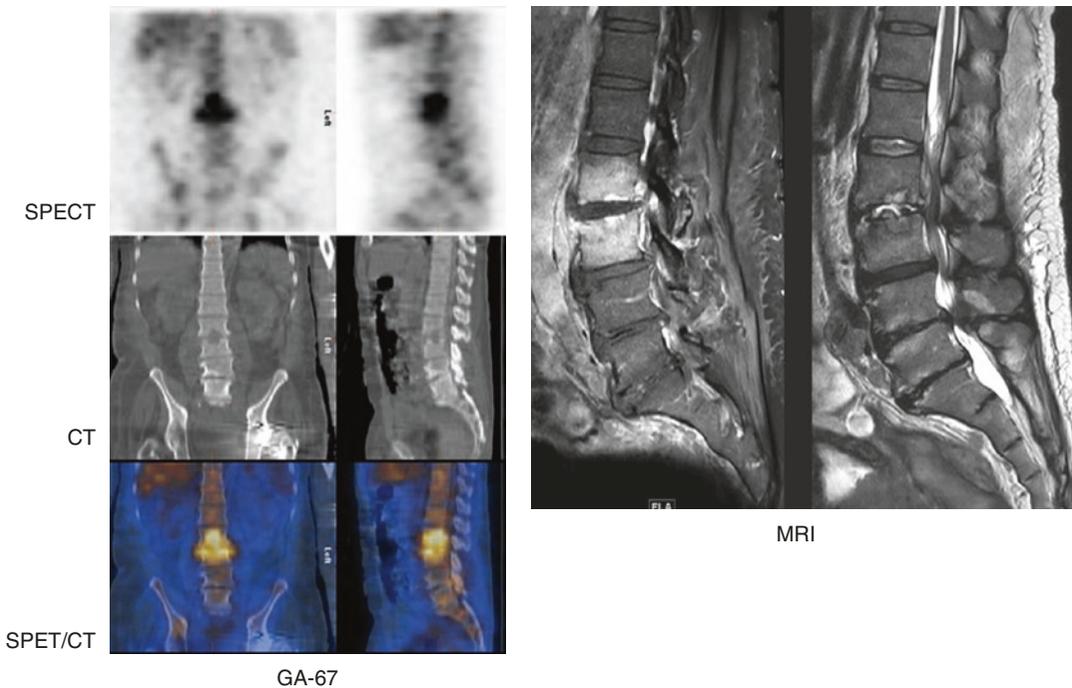

**Fig. 2.31** (continued)

diagnosis of active disease. As Tumeh et al. suggested, when gallium uptake exceeds Tc-99m MDP uptake in intensity or differs in spatial distribution, active osteomyelitis is present [140].

A controversy exists regarding the role of indium-111 leukocytes in the diagnosis of chronic osteomyelitis. Since the majority of labeled cells are polymorphonuclear cells, the test may be normal in true chronic active osteomyelitis (Fig. 2.34), and the results are variable and may be confusing. Tumeh and Tahmeh reported no advantage in using indium-111 leukocytes over Ga-67 as there was no significant difference between them in the sensitivity and specificity for chronic active osteomyelitis [227]. Determining the presence, or absence, of sequestra is important, as they need to be resected for the treatment of chronic active osteomyelitis to be useful [228]. CT is a sensitive modality for the detection of sequestra. MRI was found in limited numbers of

patients to be useful in detecting sequestra and was also useful in identifying the presence and sites of active chronic infection [229]. It was reported to be sensitive in detecting low-grade infections [188]. Sciuk et al. [65] used Tc-99m IgG and Tc-99m monoclonal antigranulocyte antibodies in 25 patients with suspected chronic osteomyelitis. Three-phase bone scanning was 71% sensitive and 50% specific. IgG was 71% sensitive and 100% specific, while monoclonal antibodies had 40% sensitivity and 100% specificity. Both agents were sensitive in peripheral lesions (5/6 for IgG and 6/6 for monoclonal antibodies), while in the central skeleton with active bone marrow, IgG was able to detect five of eight lesions while monoclonal antibodies detected none of the eight lesions. This study also confirmed the lack of specificity of multiphase bone scans for chronic osteomyelitis and suggested a possible role for labeled IgG as a more specific

**Fig. 2.32** Ga-67 SPECT/CT study of a patient with back pain demonstrating clearly intensely increased uptake in L-2/L-3 with clear benefit of

CT component in localizing the abnormal uptake. MRI (b) of the same patient showing the abnormality indication spondylodiscitis

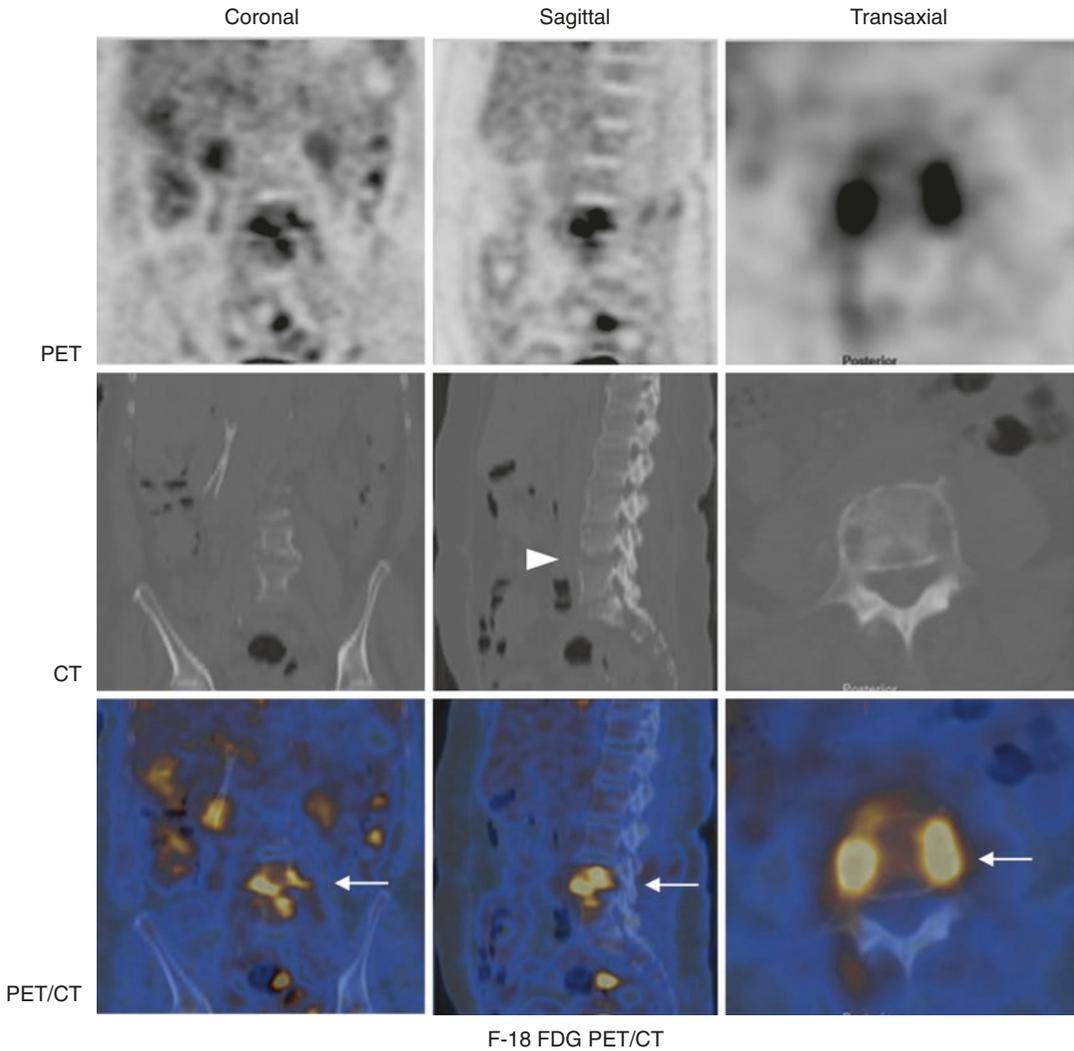

agent in both central and peripheral chronic bone infections. In this way, the combination of bone and Ga-67 scanning is highly recommended for detecting chronic active osteomyelitis (Fig. 2.34). MRI should be seen as a complementary procedure which is useful in equivocal bone and gallium scans. Combined MRI and bone/Tc-99m antigranulocyte antibody scintigraphy was found to be more sensitive and specific than MRI or bone/antigranulocyte antibody imaging. MRI was found to be 100% sensitive and 60% specific for chronic infection, while bone antigranulocyte antibody imaging was 77% sensitive and 50% specific, but 100% sensitive and 80% specific when combined with MRI [188].

PET has been found useful in assessing the activity of chronic osteomyelitis [169–173]. De Winter et al. reported 60 patients with suspected chronic musculoskeletal infection studied with F-18 FDG PET. Twenty-five patients had proven infection while 35 did not (based on histopathology, microbiologic culture, or clinical findings).

All 25 infections were correctly identified by two readers with a sensitivity of 100%. There were four false-positive cases, and the overall specificity was 88% (90% for central skeleton and 86% for peripheral skeleton). The authors concluded that this single technique is accurate, simple, and has a potential to become a standard technique for the diagnosis of chronic musculoskeletal infections [173]. Overall this technique has a sensitivity of 95–100% and a specificity of 86–100% [169–173].

The bone changes in chronic osteomyelitis can persist intermittently for years. Even with administration of contrast media, it is difficult to distinguish active infection from remodeling by both CT and MRI [230].

In a meta-analysis study, pooled sensitivity demonstrated that FDG PET was the most sensitive, with a sensitivity of 96% compared with 82% for bone scintigraphy, 61% for leukocyte scintigraphy, 78% for combined bone and leukocyte scintigraphy, and 84 for magnetic resonance imaging. Pooled specificity demonstrated

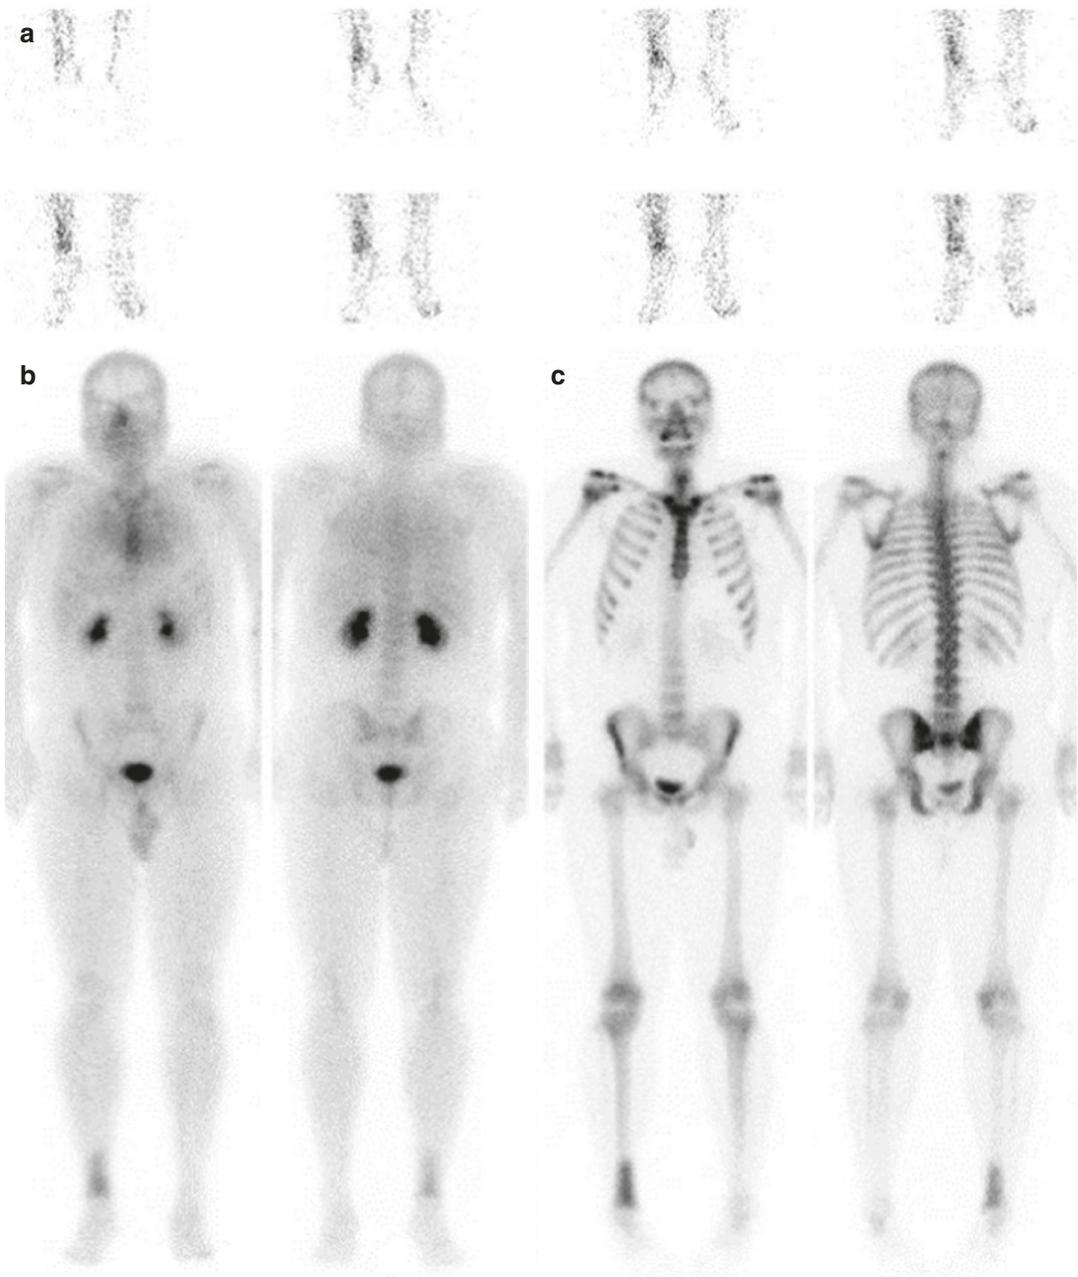

**Fig. 2.33** F-18 FDG PET/CT study in a patient with spondylodiscitis demonstrating increased uptake (arrows) in L-4/L-5. Localization is clear on CT component with destruction of endplates (arrow head)

that bone scintigraphy had the lowest specificity, with a specificity of 25% compared with 60% for magnetic resonance imaging, 77% for leukocyte scintigraphy, 84% for combined bone and leukocyte scintigraphy, and 91% for FDG PET (Fig. 2.35). The sensitivity of leukocyte scintigraphy in detecting chronic osteomyelitis in the peripheral skeleton was 84% compared with 21% for its detection of chronic osteomyelitis in the axial skeleton. The specificity of leukocyte scintigraphy in the axial skeleton was 60% compared with 80% for the peripheral skeleton [52].

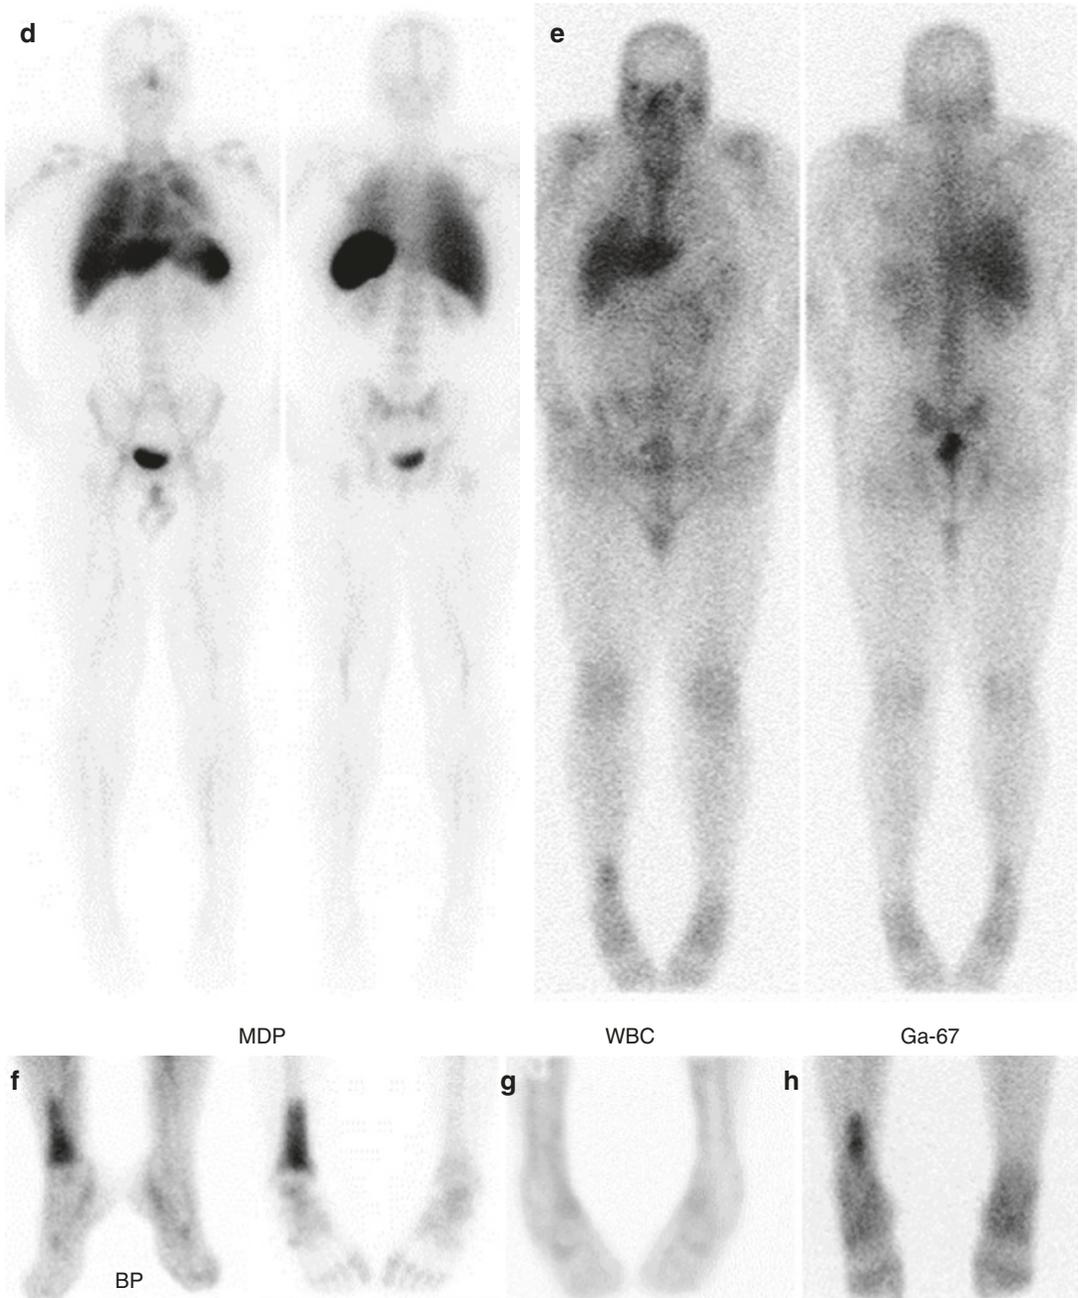

#### 2.5.4 Periprosthetic Infection

Making the distinction between a mechanical failure of a prosthesis and infection is not easy. Symptoms and signs of early infection are not specific and may be similar to those of the normal healing process. The erythrocyte sedimentation rate and leukocyte count are not sensitive, and the standard radiographic appearance of infection can mimic that of mechanical loosening. Standard radiographs demonstrate signs of loosening only in relatively advanced cases, and the technique is much less sensitive than bone scintigraphy, which

**Fig. 2.34** A 28 year-old male with swelling and pain of right distal leg for 3 months and a previous history of acute osteomyelitis of distal right tibia 7 years earlier. Tc99m MDP flow (**a**) and blood pool (**b**) images demonstrate hyperemia over the region of the distal right tibia corresponding to increased uptake on static image (**c**). Tc99m HMPAO labeled WBC study (**d**) shows no accumulation of labeled WBC in the area of abnormal pattern

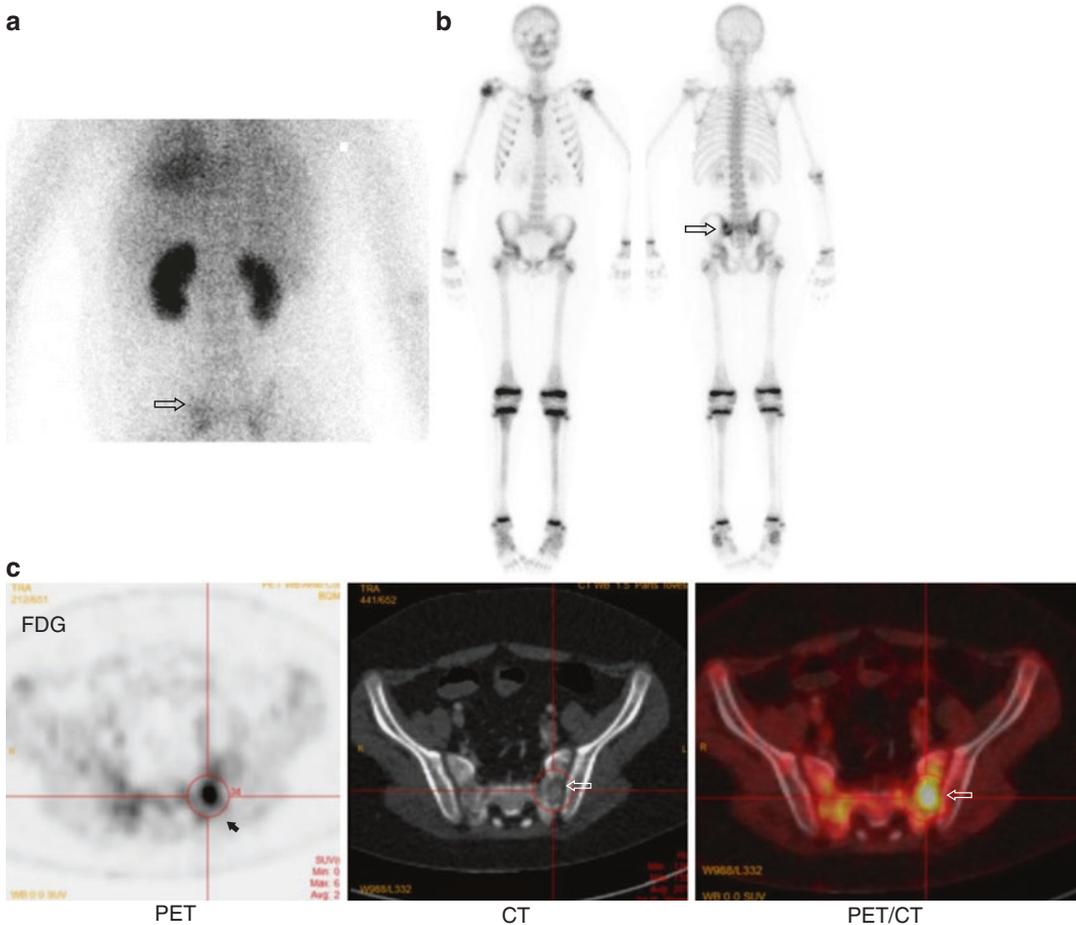

on MDP scan. Ga-67 whole body image obtained 48 hours post-injection (**e**) shows increased uptake in the right distal tibia which is incongruent with the pattern of uptake noted on bone scan as seen better on the spot images (**f**, **g**, **h**). This pattern indicates the presence of active chronic infection which can show negative WBC study given the nature of the chronic inflammatory process.

**Fig. 2.34** (continued)

detects signs of prosthetic loosening but is not very useful for differentiating loosening from infection [231]. Intense periprosthetic uptake suggests loosening and/or infection, and there is no scintigraphic pattern that is highly specific for the presence of infection. Furthermore, the pattern of normal postoperative increased uptake of

bone remodeling varies considerably depending on the type of prosthesis used. Aspiration arthrograms are more specific, but again the sensitivity as reported by Johnson [36] is only 67%. Joint aspiration and culture result in up to 15% false negatives [34, 35]. The late stages of infection can be detected easier on the basis of clinical

**Fig. 2.35** A patient with left sided back pain who had a bone scan showing mild asymmetry in blood pool activity (a) and delayed uptake (b) which are mildly increased in

the left side. F-18 FDG PET/CT (c) shows definitely increased activity on the left sacrum with features of Brodie's abscess on CT (arrows).

findings. It is crucial, however, to initiate treatment in the early stage as a progression to a serious infection may occur rapidly [85].

In the case of hip replacements, knowledge of the type of implant is important to plan a diagnostic strategy. In cemented total hip replacements, most asymptomatic individuals show no significant increase in bone remodeling adjacent to the stem after 6 months; however, mild to moderate uptake may be seen up to 12 months after the joint replacement. However, the distal tip, the greater trochanter, and the acetabular component show increased bone repair for at least a year or more after the procedure [231]. Bone scintigraphy of cemented hip replacement shows that focal uptake at the tip of the femoral component is more typical of loosening, while diffuse uptake around the

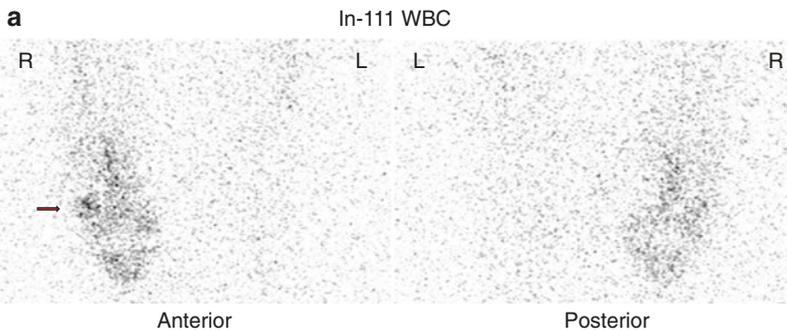

shaft is more typical of infection. These patterns, however, are not highly specific in discriminating loosening from infection [231]. In cementless porous-coated hip arthroplasty (which depends on bony ingrowth for fixation instead of cement), postoperative periprosthetic uptake on bone scintigraphy continues for 2 years or longer in asymptomatic patients and is more variable than the case with cemented prostheses [232, 233].

In knee replacement, postoperative increased uptake is also seen on bone scintigraphy in more than 60% of femoral components and 75–90% of tibial components for a long time of at least 1 year in asymptomatic patients [234]. Accordingly, for both cemented and porous-coated hip and knee replacements, bone scanning is more useful in excluding infections when it is clearly negative.

Combined bone and gallium-67 scans have better specificity than either scans alone. However, indium-111 leukocyte imaging has proved to be more accurate than a combined Ga-67 bone scan. Still, false-positive indium-111 leukocyte results occur as a result of physiological uptake by cellular bone marrow. Oswald et al. [233] found focal or diffuse accumulation of In-111 leukocytes around the prostheses for up to 2 years in 48% of uncomplicated cases. Combined bone-white blood cell scans are more accurate than white blood cell scanning alone and improve localization of abnormalities. Addition of Tc-99m sulfur colloid bone marrow to indium-111 leukocyte scanning helps further improve the specificity (Fig. 2.36). Palestro reported an improvement in specificity from 12% to 94% with the addition of sulfur colloid bone marrow scanning, while Seabald showed that specificity improved from 59% to 92% [43, 235]. A study is considered to be positive for infection when the indium-111 leukocyte uptake exceeds Tc-99m colloid activity on bone marrow scanning in extent and/or focal intensity (discordant pattern). If the relative intensity and distribution of indium-111-labeled leukocyte localization is equal to that of Tc-99m colloid (concordant pattern), the study should be considered negative for infection [43, 236]. Accordingly the procedure of choice for diagnosing the infection of joint replacements

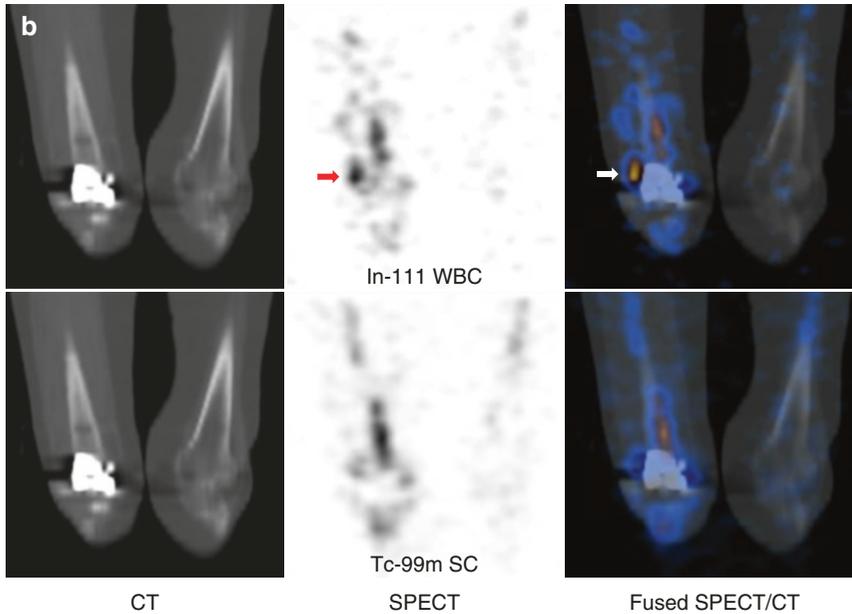

is combined labeled leukocyte-marrow scintigraphy, which has a diagnostic accuracy of more than 90% [43–45, 231, 234].

In some cases of early- or low-grade infection, there may not be sufficient alteration in the marrow to show a definite discordant or incongruent pattern on planar Tc-99m sulfur colloid scan compared to the indium-111 leukocyte finding. The use of combined In-111 white blood cell-bone and bone marrow SPECT imaging has further improved the diagnostic accuracy for detection of an infected hip prosthesis and is recommended by Seabald et al. [33, 237]. Logistically, bone marrow and bone SPECT images can be obtained first while the leukocytes are being labeled, and simultaneously combined In-111 WBC-bone SPECT images can be obtained the next day 16–24 h after injection of the labeled leukocytes [33, 237]. Furthermore, Magnuson et al. [125] suggested a grading system which compares the intensity of labeled leukocyte localization along the prosthesis to that of marrow uptake at the same location which can further improve the accuracy of this technique. It adds additional specificity in difficult cases, since the intensity and patterns of leukocyte and Tc-99m colloid marrow may vary with the type of prosthesis used (cemented vs. cementless), the time interval after surgery, and the number of revisions [33].

**Fig. 2.36** Seventy-seven-year-old female patient with a 2-year-old right knee arthroplasty presented with progressive knee pain and swelling. Planar views of indium-111 WBC scan (a) showed increased uptake in distal right femur and proximal right tibia (arrow). On a dual-isotope (indium-111 WBC/Tc-99m sulfur colloid) SPECT/CT scan (b), there was a congruent uptake in the distal femoral shaft and metaphysis on both scans consistent with

physiologic focal bone marrow activity. Additionally, there was a small focal collection of radiotracer on the lateral aspect of the right femur/prosthesis junction seen only on the indium-111 WBC window (arrows). Ultrasound showed a complex fluid collection within the subcutaneous tissues at the lateral aspect of the right knee. Subsequently, the patient underwent a CT-guided right lateral knee aspiration, which confirmed a *Staphylococcus aureus* abscess

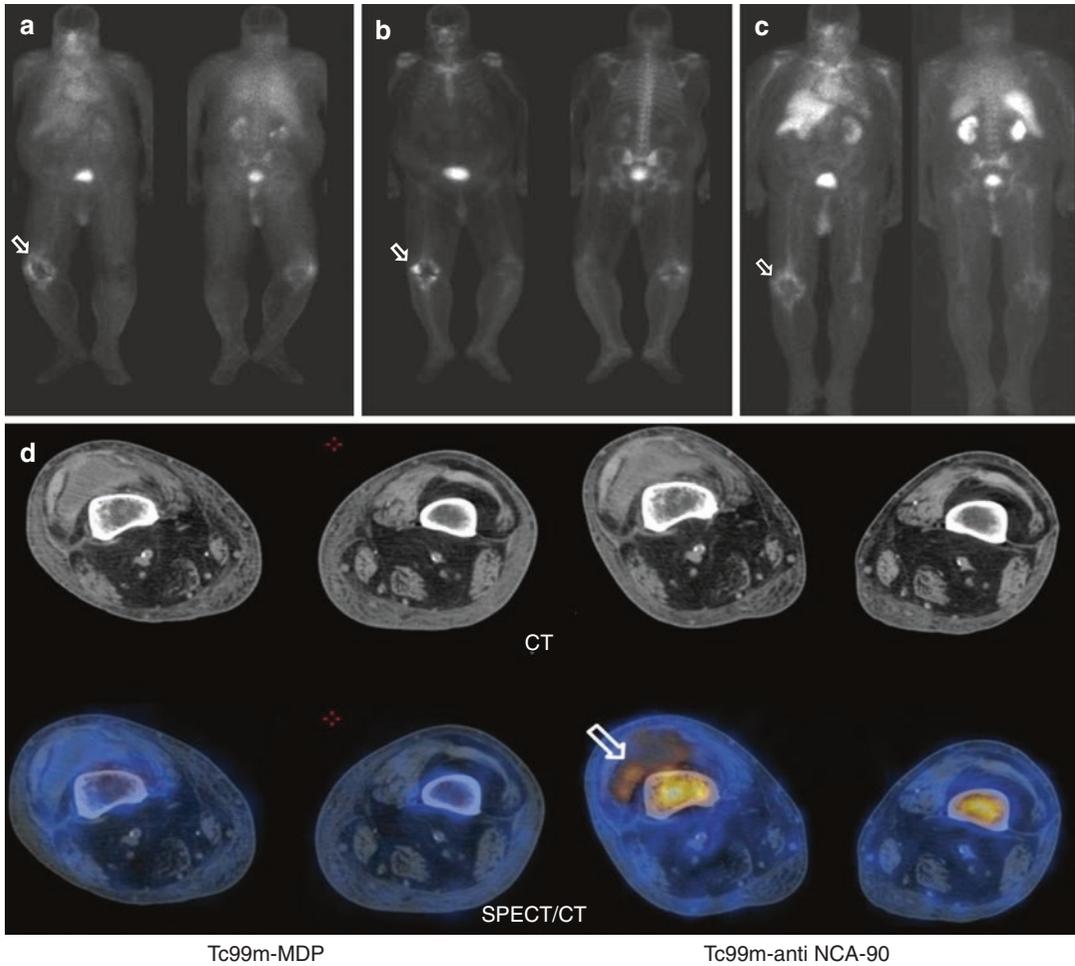

**Fig. 2.36** (continued)

Combined In-111 WBC and Tc-99m sulfur colloid SPECT/CT (Fig. 2.36) are adequate tools to diagnose (prosthetic) bone and joint infections. With a sensitivity of 100%, specificity of 91%, and accuracy of 95%, it seems to be significantly better than FDG PET. Tc-99m WBC is a very sensitive tool (95%) for imaging of infection in patients with metallic implants. Specificity is also high (93–100%) with SPECT/CT, but it seems dramatically lower (53%) in case of Tc-99m WBC SPECT alone. The improvement of specificity by addition of CT to SPECT is of substantial importance, as has been shown in multiple studies [199, 238].

Antibody imaging has also been used to diagnose infections in patients with hip and knee prostheses with a sensitivity of 70–100% and a specificity of 83–100% for Tc-99m antigranulocyte antibodies [65] (Fig. 2.37) and a sensitivity of 92% and a specificity of 88% for In-111-labeled IgG [83]. Annexin-V imaging shows greater uptake with infection than with aseptic loosening and has a high negative predictive value for prosthetic infection [239].

FDG PET has been shown to be useful in detecting infections and differentiating it from loosening in patients with hip and knee prostheses [240, 241]. Initial studies reported sensitivity and specificity for detecting infection of approx-

imately 90% and 89% for hip and 90% and 72% for knee periarthroplasty infections, respectively [240]. A more recent data reported an overall sensitivity of 91–100% [199]. Specificity, however, is strongly dependent on the used criteria to report infection based on both localization and intensity of FDG uptake, ranging from 9% to 97% [199]. Specificity is generally higher in hip prostheses, compared with knee prostheses [199]. Although the intensity of FDG uptake as determined by SUV values is important in making the diagnosis of malignancy, this is not the case with periprosthetic infections. Infected prostheses often show moderate increased uptake which is not higher than that noted with aseptic loosening [241]. However, the location of the increased uptake is more important in differentiating infection from loosening since infection is characterized by uptake along the interface between the bone and the prostheses, while in loosening it is around the neck and head [241]. Using this criterion, a sensitivity of 92% and a specificity of 97% have been reported [199]. This criterion however remains to be validated in a prospective study. A recent meta-analysis found that the sensitivity and specificity of FDG PET for diagnosing lower extremity prosthetic joint infection were 87% and 82%, respectively, lower than what has been reported for

**Fig. 2.37** Whole-body blood pool (a) and delayed (b) images of a 67-year-old male with history of bilateral knee prostheses 2 years earlier. Patient presented with right knee pain. The study shows increased blood pool and delayed uptake around the right knee prosthesis (arrows). Tc99m anti-NCA-90 (Leukoscan) was obtained and

shows increased uptake around the right knee prosthesis on whole-body images (c). Selected SPECT/CT images of both studies (d) clearly reveal increased antibody uptake localized accurately around the prosthesis (arrow) indicating periprosthetic infection

combined leukocyte-marrow imaging over the past 30 years [176].

### 2.5.5 Posttraumatic Osteomyelitis

The incidence of osteomyelitis secondary to open fracture is reported to be 2–16%, with a rate of 1–10% after open reduction with internal fixation of closed fractures [242]. Osteomyelitis is behind 5% and 10% of fracture non-unions, and almost all infected non-united fractures are associated with a previously open fracture, or open operative reduction, since fractures that are treated in a closed

manner rarely become infected [8, 33]. The three-phase bone scan can be used as a first screening method for diagnosing posttraumatic osteomyelitis. At this moment, the Tc-99m diphosphonate bone scan remains the gold standard when a bone scan is indicated; the F-18 NaF PET could be considered for the individual patient. The role of WBC scintigraphy in peripheral osteomyelitis is extensively studied. Prandini et al. described in a meta-analysis of published papers up to December 2005, in almost 3600 cases, a diagnostic accuracy of 89% [230]. The diagnostic accuracy of labeled leukocyte studies has been found to be very high: 97% and 100%, respectively [156, 243].

Simultaneous In-111-white blood cell-Tc-99m MDP bone imaging is more informative. Bone marrow scanning may further improve the specificity of white blood cell findings when physiological marrow uptake of labeled white blood cells is suspected as a cause of their accumulation.

A surgical site infection occurs in the early phase (first 2 weeks after surgery) and can usually be recognized by clinical examination, since mostly the well-known four signs of an infection (swelling, redness, pain, and heat) are present. In the later phases of posttraumatic osteomyelitis, these signs may not be present and diagnosis can be difficult.

Magnetic resonance imaging (MRI) is able to recognize infections; however, the metal implants can introduce artifacts, and its diagnostic accuracy decreases after recent surgery as differentiation between sterile inflammation and infected tissue is difficult [188, 244, 245].

### 2.5.6 Osteomyelitis in Patients with Sickle Cell Disease

Differentiating bone infarcts from osteomyelitis is clinically difficult. Initial radiographs are either normal or show non-specific changes. On bone scintigraphy, the findings vary. If bone scintigraphy is performed a week after the onset of symptoms, healing of the infarct may cause increased uptake rather than the typical pattern of a cold defect. To add more difficulty, osteomyelitis may also cause cold defects rather than increased uptake [19, 33, 189, 246]. Addition of Tc-99m sulfur colloid or gallium-67 imaging to bone scans enhances the specificity and can resolve the majority of diagnostic problems related to osteomyelitis in patients with sickle cell disease. If the bone scan shows areas of increased uptake, a bone marrow scan could be added. If the marrow scan of the area of interest is normal, it indicates osteomyelitis, while if radiocolloid photon deficiency is seen, it suggests a healing infarct. On the other hand, if the bone scan shows a photon-deficient area, Ga-67 may help differentiate osteomyelitis by showing incongruent pattern spatially or if gallium-67 uptake is more than that of bone scan. Infarcts will show a congruent pattern [189].

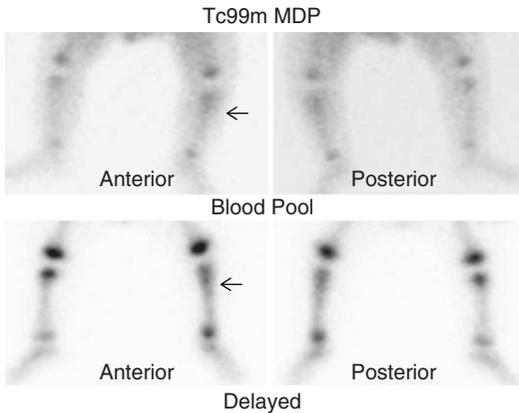

Labeled leukocytes have also been used, although we encountered technical difficulties in labeling cells of sickle cell patients with failed scans. MRI and contrast-enhanced CT scans have also been reported to be of help in patients with nondiagnostic radiographs and bone scan.

### 2.5.7 Neonatal Osteomyelitis

In neonates, the ability of infection to violate the growth plate predisposes them to an increased risk of joint involvement and extension into the adjacent bone. The periosteum is less approximated to the cortex in infants and children. The degree of periosteal reaction is increased, and subperiosteal abscesses are more likely to occur in neonatal and juvenile osteomyelitis. Scintigraphy has generally been thought to play a limited role in neonatal skeletal infections due to reported high false-negative rates. Connolly et al. [109] reported 99% sensitivity and specificity for neonatal osteomyelitis using bone scintigraphy utilizing today's modern gamma cameras. In their study, no single case was diagnosed only by MRI. However, the authors recommended MRI for pelvic osteomyelitis since it detects the drainable abscesses which commonly (20%) occur at this site [109]. Osteomyelitis following intraosseous infusion is a rare complication of such a procedure which is used as an alternative to central venous access in pediatric and also adults in emergency situations. It occurs more commonly in neonates particularly if the needle remains more than 24 h (Fig. 2.38).

### 2.5.8 Epiphyseal Osteomyelitis

In children osteomyelitis confined to the epiphysis is an entity seen particularly below the age of 4 years. The most frequently affected sites are the epiphyses of the distal femur and proximal tibia. The pinhole images are particularly valuable for correctly localizing the findings on bone scan, where isolated epiphyseal focally increased uptake is seen in delayed images corresponding to regional hyperemia seen on flow and blood pool images [247, 248].

**Fig. 2.38** Bone scan of a case of post-intraosseous infusion infection in a 9-month-old boy with congenital heart disease and history of recurrent pneumonia admitted with septic shock due to pneumonia. Intraosseous needle was inserted in the left tibia for urgent infusion and kept for 24 h, followed by swelling of the left lower leg. There was also mild leukocytosis. Blood culture showed Kleb pneumonia. X-ray was normal. Bone scan shows increased blood pool and uptake on delayed images in the left tibia (arrows) where the needle was inserted indicating skeletal infection

## 2.6 Follow-Up of Response to Therapy

Since many therapies for infection are relatively toxic, shortening the duration of therapy to the minimum required to control the infection is desirable. High success rates of antimicrobial therapy have not yet been achieved in bone and joint infections due to the physiological and anatomical characteristics of the bone [249]. Monitoring the response to infection therapy in cancer patients is complicated by the slow response in many patients.

Bone scanning is not a suitable modality for determining the response to therapy when treating skeletal infections because it may remain positive for years in the absence of active infection. Several nuclear medicine studies are generally useful to achieve the evaluation of the response to therapy, including Ga-67 [250], labeled white blood cells, FDG PET, and polyclonal and monoclonal radiolabeled antibodies.

Labeled white blood cell studies are particularly useful to follow-up the response to therapy [128, 251–253]. FDG PET is also a reliable

modality for follow-up of the response to therapy [59, 225, 254].

## 2.7 Differentiating Osteomyelitis from Infectious Arthritis

Although it is sometimes difficult scintigraphically to differentiate osteomyelitis from septic arthritis, it has been established that bone scans can identify joint involvement and distinguish bone from joint infection in up to 90% of cases [102, 110, 255]. Detailed clinical information is crucial in making the correct diagnosis. Sundberg et al. [255] studied 106 children suspected of having septic arthritis and showed that the bone scan interpretation was correct in 13% when read without clinical information, while the sensitivity improved to 70% when a clinical history was available. It is our experience that if we follow the criteria for the differentiation, it is possible in the vast majority of cases to make the distinction between infectious arthritis and osteomyelitis. In septic arthritis, there is periarticular distribution of the abnormal uptake, which is largely limited to the joint capsule and has a uniform pattern. On the other hand, osteomyelitis shows abnormal uptake beyond the confines of the joint capsule or shows uptake within the joint capsule that is non-uniform [102, 110]. Combined bone and gallium-67 or labeled leukocyte scintigraphy can provide more precise information in equivocal cases on bone scanning alone. SPECT/CT can be very helpful to make the distinction by accurate localization of the scintigraphic findings.

## 2.8 Differentiating Infection from Tumors

In certain situations, it is clinically difficult to differentiate between infection and tumors due to their similar manifestations. Labeled leukocyte scans can be useful in excluding infection if the study is negative. However, if the study is positive, it is more likely to be secondary to infection, although some false-positive studies resulting from tumor uptake have been reported [256].

MRI can also be useful, although differentiating tumors from infection in certain locations can be difficult [257, 258]. Thallium-201 imaging using latest modifications [259] can be useful in differentiating infection from the tumor. Early (20 min) and delayed (3 h) imaging, with or without SPECT, depending on the location, are useful in differentiating infection from a viable tumor. Absence of uptake will make a viable tumor unlikely. FDG uptake can be intense in cases with osteomyelitis simulating malignancy [254].

Decreasing the uptake ratio between early and delayed imaging is also suggestive of infection rather than a viable tumor, while a stable or rising ratio is more suggestive of a tumor [258] than infection. Matthies reported the use of early FDG PET (70 min postinjection) and delayed (2 h) imaging in differentiating tumor from benign conditions including inflammatory conditions [96].

It is clear that the imaging strategy for osteomyelitis is rather complicated given the many forms of the condition. The comorbidities complicate the issue, together with specific pathological aspects at different locations, as well as the strengths and limitations of the modalities. An algorithm is proposed in order to help choose the appropriate modality for the diagnosis in different clinical settings (Fig. 2.39).

## 2.9 Noninfectious Inflammatory Conditions

### 2.9.1 Chronic Nonbacterial Osteomyelitis

The term chronic nonbacterial osteomyelitis has emerged as a global term to describe a group of autoinflammatory bone diseases, including chronic recurrent multifocal osteomyelitis (CRMO); synovitis, acne, pustulosis, hyperostosis, osteitis (SAPHO) syndrome; and diffuse sclerosing osteitis (DSO). These disease entities are sterile bone lesions that may include associated systemic and dermatologic manifestations. Diagnosis is established on the basis of clinical and radiologic findings, coupled with a culture-negative biopsy but remains largely a diagnosis of exclusion with no universally agreed-upon diagnostic criteria [260].

The immunologic disturbances leading to these disease states are being studied; NSAIDs are first-line treatment [260–262].

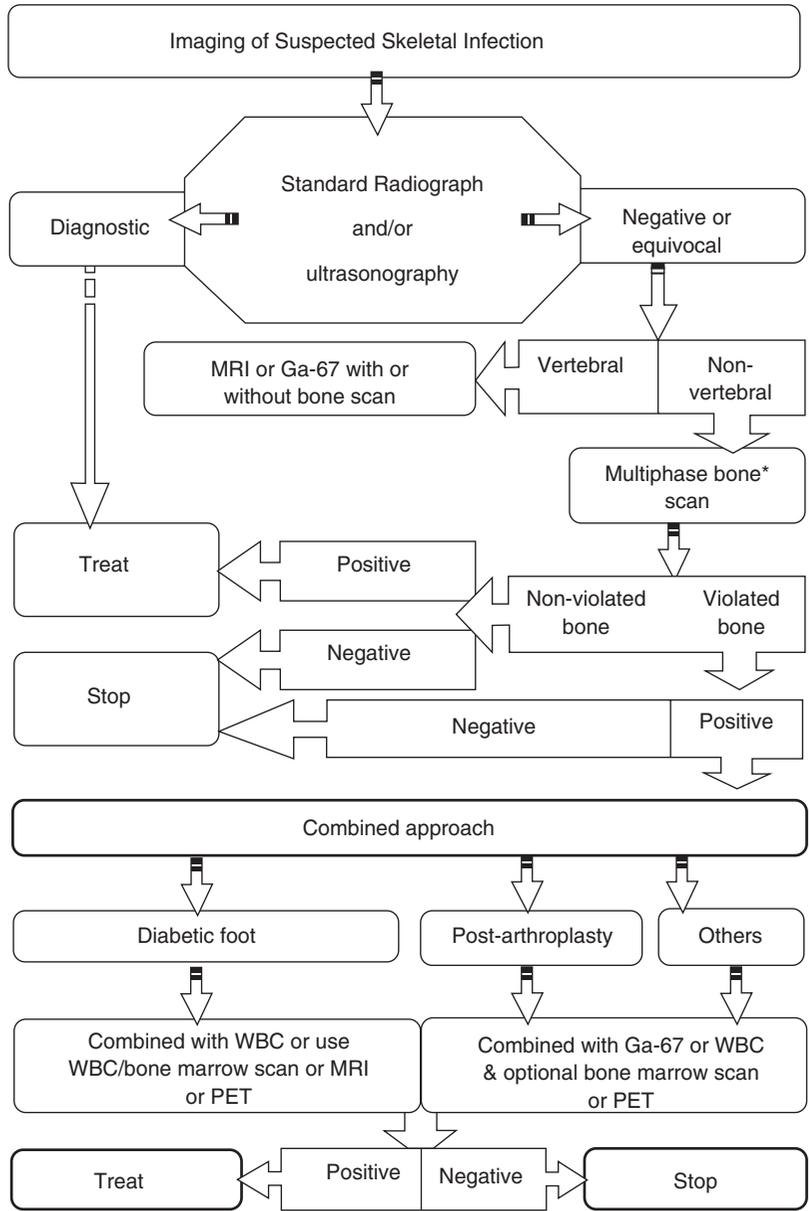

#### 2.9.1.1 Chronic Recurrent Multifocal Osteomyelitis

Chronic recurrent multifocal osteomyelitis, or Giedion's osteomyelitis, is a rare variant of osteomyelitis that primarily affects children and young adults and may be related to SAPHO syndrome (synovitis, acne, pustulosis, hyperostosis, osteitis). Recent study suggests that the condition may be more common than previously recognized [263]. Accordingly this condition represents a sterile osteomyelitis [264]. Clinically, it is characterized by an insidious, or acute, onset of pain, tenderness, and local swelling, mimicking acute osteomyelitis but usually without fever, leukocytosis, or elevated ESR [265]. Pain resolves spontaneously but may recur at the same site or at a different location. The disease mainly affects the metaphyses of the long tubular bones.

Sometimes, it has a symmetric distribution, that is, similar sites in both extremities are involved. The most commonly involved skeletal sites are the tibia, femur, clavicle, and fibula. Other bones involved are the pubic bones, calcaneus, and phalanges [195, 266]. On radiographs the lesion presents with lytic foci and associated sclerosis. Bone scan reveals multifocal areas of increased uptake that may be subtle in some cases.

The etiology of this disorder is unknown. Infectious and autoimmune causes have been suggested. Bone and blood cultures have always been reported to be negative. Early lesions contain polymorphonuclear (neutrophilic) leukocytic infiltrate in the marrow. Initial reports described isolation of organisms such as *Staphylococcus epidermidis* from biopsied lesions. However, these are now thought to represent contaminants rather than the causative bacteria. The more recent, larger cohorts have not identified evidence of a microbial etiology by culture or PCR amplification [267, 268]. In addition, antibiotic therapy does not alter disease course. Currently, CRMO is thought to be in the spectrum of autoimmune and autoinflammatory disorders. This is supported by the association of the condition with multiple autoimmune diseases, particularly

**Fig. 2.39** An algorithm for the diagnosis of osteomyelitis based on the pathophysiology of the disease and the profiles of the various imaging modalities available

\* MRI is a common alternative

palmoplantar pustulosis, psoriasis, and inflammatory bowel disease, in patients and family members, as well as by its response to corticosteroids [269, 270]. Long-standing lesions show fibrosis with predominantly lymphocytic infiltrates. Prominent formation of new reactive bone can be a dominant feature in later phases of the disease [271], and in the majority of those cases, the erythrocyte sedimentation rate is elevated. Some authors have

reported a high incidence of prior throat infections and elevation of the antistreptolysin O titers. The number of relapse episodes ranges from 1 to 6 [266]. In the differential diagnosis, it is helpful to consider the entire clinical picture and radiographic presentation of the lesion. Lymphoma of the bone almost never occurs in young patients whose disease presents with multifocal involvement of the metaphyseal regions.

### 2.9.1.2 Chronic Sclerosing Osteomyelitis

This disease is also known as Garre's osteomyelitis, Garre's sclerosing osteomyelitis, chronic osteomyelitis with proliferative periostitis, ossifying periostitis, nonsuppurative chronic sclerosing osteomyelitis, periostitis ossificans, nonsuppurative ossifying periostitis, or osteomyelitis sicca. It is a rare inflammatory disease of chronic nature, characterized by periosteal reactions, which induces new bone formation. It particularly affects children and adolescents [272]. It affects mainly the mandible [273, 274], but it can occur in any bone particularly metaphyseal regions of long bones [275]. It has been reported in association with several chronic autoimmune diseases, including inflammatory bowel disease, granulomatosis, psoriasis, and Takayasu's arteritis [275]. Clinically, it is characterized by insidious onset with pain in the affected bone in an episodic nature of variable durations. The function of the affected bone is generally preserved, and during the interval between crises, most patients appear healthy [273, 276].

### 2.9.2 Osteitis Condensans Ilii

Osteitis condensans ilii is a non-specific inflammatory condition of the iliac bone that is self-limiting. It predominantly affects women of child-bearing age, particularly the multiparous. Although the cause of the condition is not clear, the predominant theory suggests abnormal mechanical stress across the sacroiliac joints coupled with an increased vascularity during pregnancy and delivery [277, 278]. The condition is rare in men. Scintigraphically, an increased uptake is seen in the iliac bone at the region of sacroiliac joints that is usually bilateral and symmetric but can be asymmetrical and unilateral.

### 2.9.3 Osteitis Pubis

Osteitis pubis represents a non-specific inflammation of the pubic bones which follows delivery, pelvic operations and athletes. In men, it is particularly frequent after prostate or bladder surgery. Low-grade infection, trauma, and venous

congestion due to injury or inflammation are proposed etiologies [277]. Scintigraphically, there is intense uptake in the paraarticular regions of the pubic bones. MRI scans may show moderate to severe bone marrow edema at the pubic symphysis in patients with this condition [279].

### 2.9.4 Infantile Cortical Hyperostosis (Caffey-Silverman Disease)

See also [Chapter 3](#)

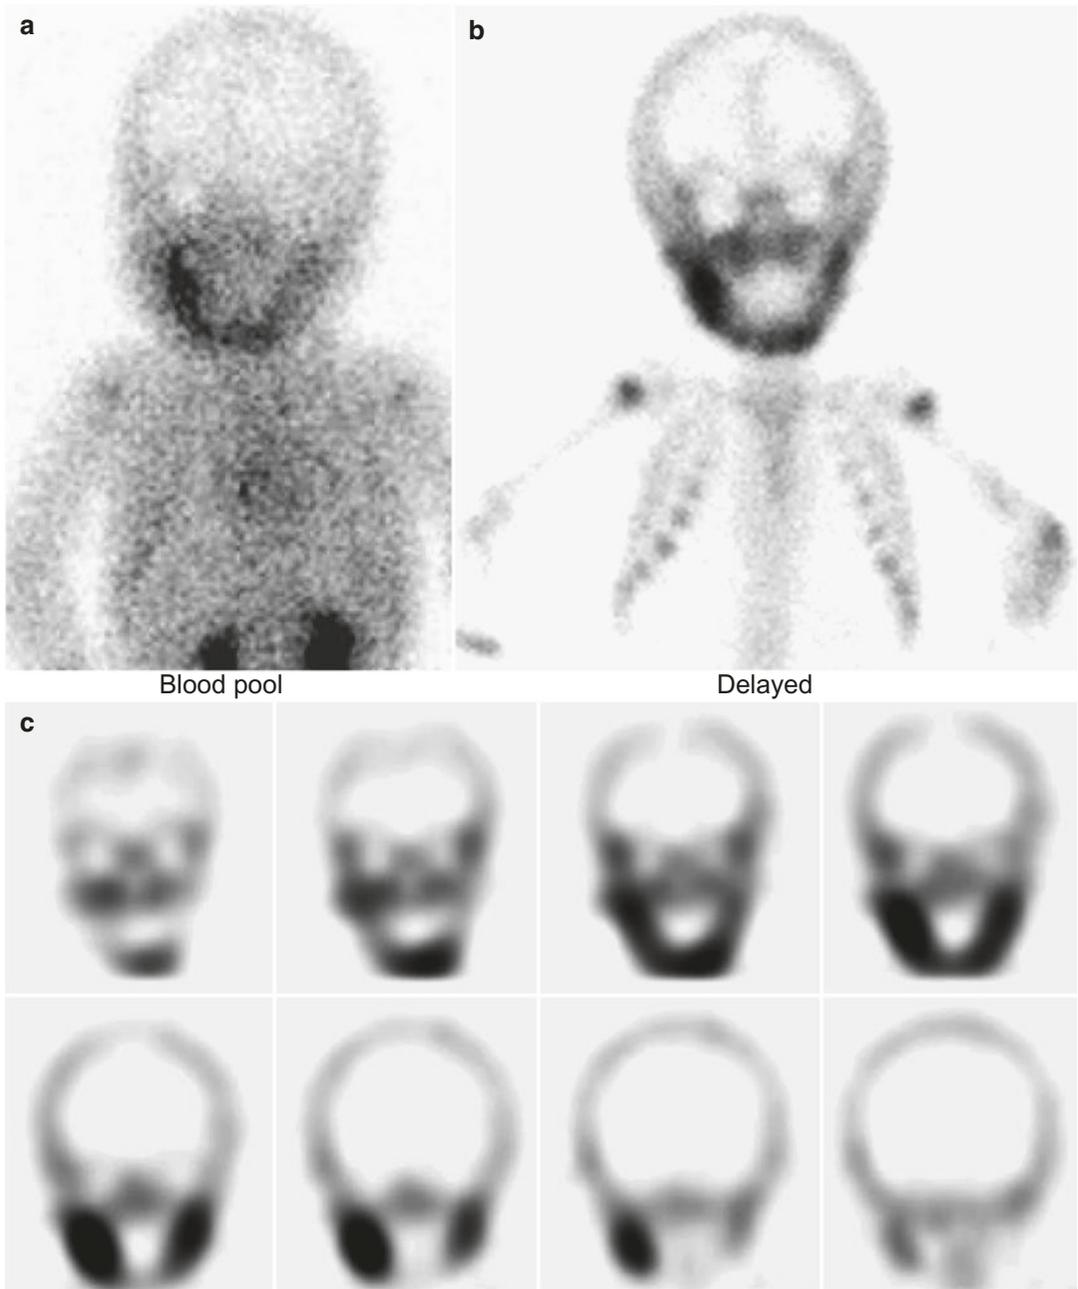

Infantile cortical hyperostosis is a rare inflammatory condition of early infancy described first by Caffey in 1946. The etiology is unknown with a tendency to be familial [280]. It is thought to be due to a genetic defect that is autosomally dominant. It presents during the first few weeks of life and usually before the age of 6 months. It most commonly affects the mandible (Fig. 2.40) followed by the clavicles, ribs, ulna, radius, tibia, and fibula and can affect any other bone but not usually the vertebrae, pelvis, and phalanges. There is extensive periosteal new bone formation which appears on bone scans as areas of irregularly increased uptake described by Bahk as "pumpy" [278]. The course is usually benign and the lesions resolve spontaneously in less than a year. Nonsteroidal anti-inflammatory drugs or steroids may be needed.

### 2.9.5 Sternoclavicular Hyperostosis

This chronic inflammatory process affecting predominantly adult men involves the sternum, clavicle and upper ribs, and adjacent soft tissue [281]. Increased uptake in the involved areas, which are usually bilateral and symmetrical, is the typical scintigraphic feature [282, 283].

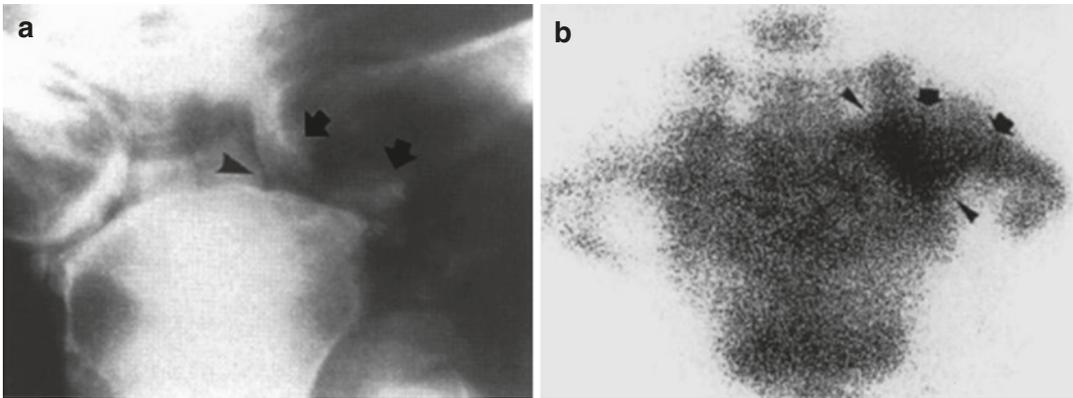

### 2.9.6 Osteitis Condensans of the Clavicle

This condition is also called condensing osteitis of the clavicle and occurs among women with an average age of 40 years with a history of stress to the sternoclavicular joint region [277]. It causes

**Fig. 2.40 a–c** Infantile cortical hyperostosis of the mandible in a 5-month-old boy with a history of fever, irritability, and swelling of the region of the right mandible. (a) Blood pool image shows the significantly increased level

of activity in the right-hand side of the mandible with a corresponding increased uptake on the delayed image (b). This is also seen clearly on the SPECT study (c)

**Fig. 2.41 a, b** Condensing osteitis of the clavicle. (a) Anterior conventional radiograph-tomogram of the sternoclavicular joints in a 48-year-old woman reveals irregular lysis and sclerosis in the medial end of the left clavicle (arrows) with narrowing of the adjacent sternoclavicular

joint (arrowhead). (b) Pinhole scan shows intense tracer uptake in the lower aspect of the medial clavicular end (arrows) with relatively more prominent uptake (specifically in the sternoclavicular joint) that is involved secondarily (arrow-heads) (from Bahk [278, p. 64], with permission)

pain that is commonly referred to the shoulder, and there is intense unilateral focal uptake in the medial end of the clavicle and the sternoclavicular joint which is clearly seen on pinhole imaging (Fig 2.41) [278].

## 2.10 Scintigraphic Patterns of Skeletal Manifestations of Poliomyelitis

Post-poliomyelitis syndrome causes variable musculoskeletal manifestations including pain, muscle weakness, and fatigue. These manifestations are commonly secondary to overuse and misuse of muscles and joints and could follow a fall. Musculoskeletal manifestations of polio include osteoporosis, soft tissue atrophy, growth disturbances, joint infections, arthritis, and synovitis. Muscle atrophy and growth disturbances are also felt to be the result of decreased activity. Premature closure of the growth plate is a well-known sequela of poliomyelitis [284]. This is felt to be the result of pelvic angular deformity with muscular and osseous weakening. Joint infections may occur because of immobilization with subsequent skin breakdown over pressure points. Osteoporosis is a profound effect of this

disease. Its etiology is thought to be similar to that which follows muscular inactivity with long-standing immobilization.

Bone scan can be useful in determining the underlying cause and follow-up [285, 286]. Marrafi et al. reported several scintigraphic patterns among poliomyelitis patients which include decreased blood pool activity in the affected lower limb of all patients, deformed ipsilateral hemipelvis with reduced uptake on the affected side in all patients with unilateral disease, stress changes with increased uptake in the bones of the contralateral lower extremity, and degenerative changes in multiple joints (shoulder, knee, hip, ankle, and spine). Significant scoliosis was only noted in the patient with bilateral disease [286].

Although metabolic bone diseases are common, they may be difficult to diagnose on the basis of clinical and radiological findings. Understanding their diverse manifestations using different imaging studies allows early and specific diagnosis. In the early stages of the disease, bone scintigraphy shows generalized increased uptake. As the disease progresses, bone scintigraphy has well-recognized features, such as focal and generalized increased uptake in the long bones, axial skeleton, and periarticular areas. Generalized uptake of the skull, mandible, and sternum is another pattern. Finally, focal uptake in the costochondral junctions, soft tissue calcification, and faint, or absent, kidney uptake are additional features. Knowledge of these different scintigraphic patterns helps obtain the highest diagnostic value. Important practical applications of bone scan in metabolic bone disease are the detection of focal conditions or focal complications of such generalized disease such as the detection of fractures in osteoporosis and pseudofractures in osteomalacia and the evaluation of Paget's disease, particularly disease activity.

## 3.1 Introduction

The osseous bone response to injury, regardless of the type, is characterized by increased remodeling and new bone formation in an attempt to repair the damage or to contain the noxious insult. This process is evidenced by focal increased

uptake of bone-seeking agents. In contrast, in metabolic bone disease, a general imbalance of the processes of bone formation and resorption is present. The net effect resulting from these two processes determines the scintigraphic patterns observed in metabolic bone disease.

Metabolic bone disease is usually linked to alterations of the calcium metabolism. Increased rates of bone turnover are present in most metabolic bone disorders often associated with decreasing calcium content of the affected bone. This explains why most metabolic disorders result in generalized increased radiopharmaceutical uptake on bone scans, reflecting this increased bone turnover. In some disorders, however, abnormal bone formation has a more localized character as is the case in hypertrophic osteoarthropathy, the pathogenesis of which is still poorly understood, although neurovascular abnormalities may be present.

The role of nuclear medicine in metabolic bone diseases is expanding. These conditions are not uncommon, and their diagnosis and therapeutic follow-up can be enhanced significantly by understanding and utilizing nuclear medicine. The most important advantages of bone scintigraphy in metabolic bone disease are its high sensitivity and its capacity to easily image the whole body. In the early stages of these diseases, bone scintigraphy may face difficulties in the detection of disease varieties because of the usual generalized increased uptake. When the disease progresses, bone scintigraphy has well-recognized patterns (and armed with knowledge of the pathophysiology and different abnormal appearances) and its highest diagnostic value is obtained. Certain congenital and developmental diseases such as osteopetrosis, medullary diaphyseal sclerosis, progressive diaphyseal dysplasia, infantile cortical hyperostosis, mandibular condylar hyperplasia and Gorlin's syndrome are highlighted below as they can be evaluated by scintigraphic methods.

---

### 3.2 Paget's Disease (Osteitis Deformans)

Paget's disease of bone is a chronic and focal metabolic bone disease first reported by Sir James Paget in 1877 when he described five cases of a

slowly progressive, deforming bone disorder he termed osteitis deformans [1, 2]. The name osteitis deformans suggests that he considered the disease to be a chronic inflammation of the bone. However, it is now known that the bone-resorbing osteoclast is primarily affected in Paget's disease, and whether an infectious agent is responsible for the disorder is still uncertain. The disease targets preferentially the axial skeleton affecting most commonly the pelvis in 70%, femur in 55%, lumbar spine in 53%, skull in 42%, and tibia in 2% of patients [3]. The disease is particularly important in the geriatric population, since it is the second most common metabolic bone disease after osteoporosis among this age group [4]. It is asymptomatic in 90% of affected individuals.

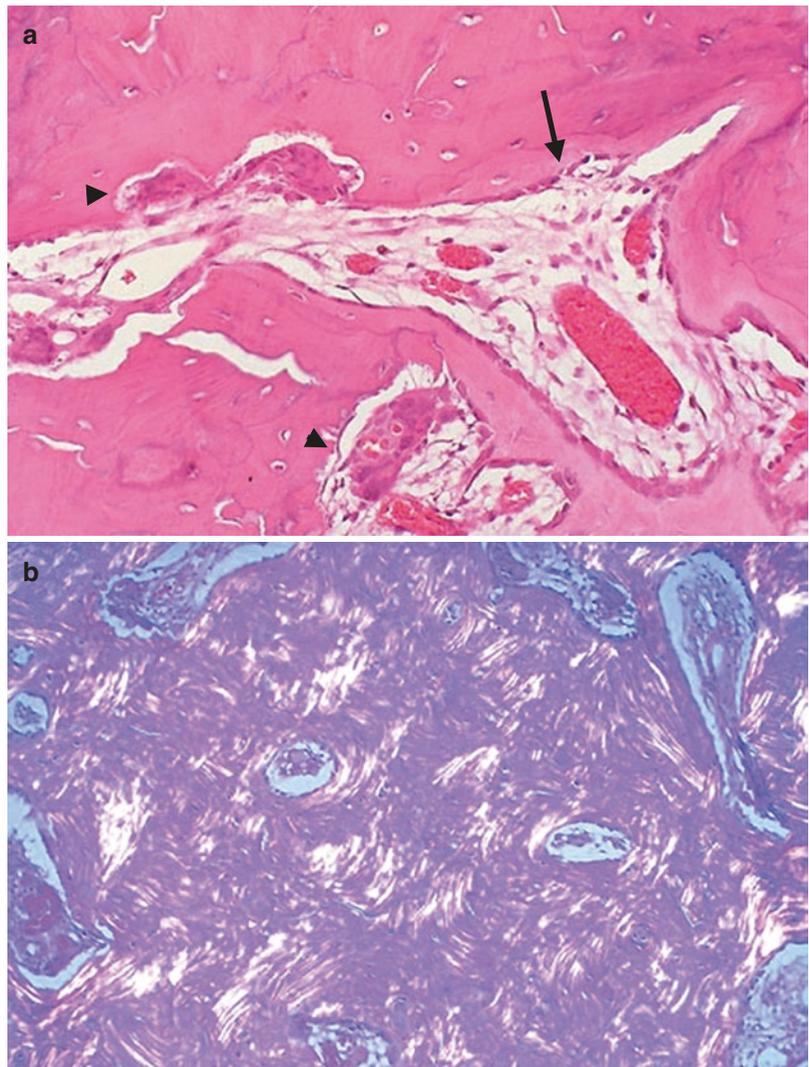

The incidence of the disease varies because of its distinctive geographic distribution throughout the world. The disease is generally common in temperate countries as North America, the UK, Australia, New Zealand, France, and Germany. The incidence is lower in Chile, Venezuela, Malta, and Switzerland, and the disease is rare in Africa, Asia, and the Middle East [5, 6] although it could be underestimated particularly in Asia [7]. In the USA, it has a near-equal sex distribution and the highest prevalence is in the northeastern states [8]. The disease is uncommon before the age of 55 years and increases in frequency with increasing age affecting approximately 4% of population above this age although in some countries the prevalence reaches 8–10% by the eighth decade of life [5, 9–13].

The etiology of Paget's disease is not known. More recent progress has focused on environmental as well as genetic etiologies for this disease [14]. Many studies have proposed that a slow virus is the causative agent, specifically paramyxoviruses [15] although direct observation of a virus has not been made [16–19]. It is postulated that the primary residence of the virus is the osteoblast, while the osteoclast represents a site of viral assembly. The infected osteoblasts produce excessive interleukin-6, which stimulates bone resorption and activates c-Fos proto-oncogenes, which interfere with normal bone development. The role of genetic factors in Paget's disease has been strengthened by the observation that as many as 15–30% of

patients may have a positive family history of the disease [20]. In fact rare inherited forms of Paget's disease are recognized. These are caused by mutations in genes that affect osteoclast differentiation and function. Among patients with family history of the classic disease, approximately 15% the disease is inherited as autosomal dominant with incomplete penetrance. Additionally 40–50% of patients with family history and 5–10% with sporadic disease carry SQSTM1 (sequestosome 1) which encodes p62, a protein that plays a key role in regulating osteoclast function. Other genes were also identified and all are involved in the

differentiation and function of osteoclasts [21–23].

Both bone resorption and formation occur at an increased rate in pagetic bone, but the pathology arises in osteoclasts. These primary bone-resorbing cells that are derived from the hemopoietic system, in contrast to the mesenchymal origin of osteoblasts, continuously migrate through and degrade the mineralized extracellular matrix of the bone. Reflecting their increased resorptive activity, osteoclasts in Paget's disease are markedly increased in number and size, have increased numbers of nuclei per cell (Fig. 3.1), and demonstrate an increased resorption capacity and increased

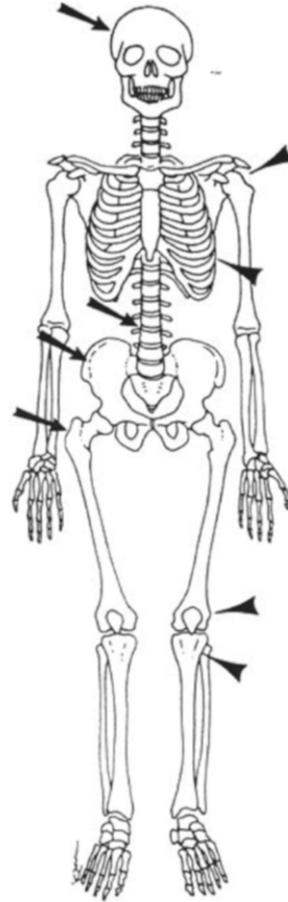

**Fig. 3.1** (a) Photomicrograph of a mixed osteoblastic-osteoclastic stage of Paget's disease. A line of osteoblasts is present forming new bone (*arrow*), and lacunae containing multinucleate osteoclasts are seen (*arrowheads*). The result is a patchwork mosaic of the bone without an even lamellar structure. (b) Under polarized light, the irregularities of the bony lamellae are apparent

sensitivity to 1,25-(OH)<sub>2</sub>D<sub>3</sub> (the active form of vitamin D). The responsible factor was shown to be the cytokine interleukin-6 (IL-6), a peptide produced by bone cells that increases the differentiation of monocyte-macrophage cells to osteoclasts. The excess IL-6 stimulates bone resorption and activates c-Fos proto-oncogenes, which interfere with normal bone development. Elevated levels of IL-6 have been demonstrated in bone marrow and peripheral blood in the majority of subjects with Paget's disease but not in controls. Other studies indicate a role of a more recently identified candidate gene on chromosome 18q [14].

Normal bone remodeling depends on a coupled metabolic response of bone-forming osteoblasts and bone-resorbing osteoclasts. Paget's disease is characterized by an initial phase of intense osteoclastic resorption followed by an increase in bone formation. Coupling remains intact in Paget's disease, resulting in a greatly excessive, but disordered, bone. This leads to the production of excessive, dense, but structurally deficient skeletal tissue (Fig. 3.1) with enlargement and softening of the bones affected. There is possible development of bony deformities and an increased risk of fracture. When the process affects bones near joints, it promotes the development of osteoarthritic changes in these joints. Hence for many patients, joint pain and limited mobility are major complaints. Although the reasons for the osteoarthritic changes are not clear, growth factors and cytokines produced by pagetic bone cells may promote the erosion of cartilage, leading to the development of osteoarthritis. In addition, sufferers from Paget's disease are also susceptible to the development of inflammatory arthritis: gouty arthritis, rheumatoid arthritis, psoriatic arthritis, and ankylosing spondylitis. However, it is osteoarthritis that is most often the source of chronic joint pain and limited mobility.

The disease is more commonly polyostotic. Approximately one third of Paget's disease patients have monostotic disease; 72% of such cases involve the pelvic bones [15]. The skeletal distribution of Paget's disease (Fig. 3.2) suggests that the disease predominates in bones containing red marrow and may be dependent on the blood supply. Normal hematopoietic bone marrow may

**Fig. 3.2** Skeletal distribution of monostotic Paget's disease. Very common (*arrows*) and common (*arrowheads*) sites are indicated. From Resnick D: Resnick bone and joint imaging. Elsevier, 1996 (with permission) [26]

be replaced by loose fibrous connective tissue. With time, the increased osteoblastic and osteoclastic activity ceases and the affected bones become sclerotic and marrow abnormalities return to normal [24]. Renier and Audran [25] have reported (in a large series of 200 patients with Paget's disease), 169 (85%) with polyostotic involvement, with data suggesting that the disease process spreads across a joint in some patients, even in the absence of degenerative joint disease. The authors reported several cases with extensive pagetic lesions seen on one side of a joint and a considerably smaller lesion on the other side. The study also found that Paget's disease may involve paired bones and involvement could be symmetrical [25].

Paget's disease begins with a phase of active and excessive bone resorption (lytic or resorption phase) which may progress rapidly and results in softening of bone. Pathological fractures, particularly of the femur and tibia, frequently occur. During this phase the bone trabeculae are slender and very vascular. Giant osteoclasts are present and have been shown to take up Ga-67 [27]. This is followed by a mixed phase characterized by the accelerated formation as well as resorption of the bone. If bone formation predominates in the mixed phase, this is sometimes called the osteoblastic phase, and the term "mixed" can be reserved for those with approximately equal resorption and formation. The final phase (the sclerotic or burned-out phase) is characterized by predominantly new bone formation, more disorganized structure, thick trabeculae, and less prominent vascular sinusoids [28]. In the active phases of the disease, the rate of bone remodeling may be up to ten times greater than normal, which is reflected by both elevated serum levels of alkaline phosphatase (a marker for increased bone formation) and by increased urinary excretion of collagen pyridinoline crosslinks (an index of increased bone resorption) [29].

In the lytic phase of Paget's disease, there are increased numbers of large multinucleate osteoclasts that may show bizarre shapes and contain as many as 100 nuclei, compared with 5–10 in normal osteoclasts. In the mixed phase, a profusion of osteoblasts and osteoclasts, evidence of high bone turnover, coexists in a matrix of highly vascularized fibrous tissue. This may facilitate the development of microfractures in long bones and basilar invagination when the base of the skull is diffusely involved. The late sclerotic phase is characterized by a disordered mosaic pattern of thickened lamellae.

Although asymptomatic in many patients, the disease causes symptoms particularly in older patients. Chronic pain is the most common complaint; it is present in two thirds of patients over 60 years old and is the presenting symptom in 5–30% of patients in general [20, 30, 31]. In contrast to the pain from degenerative joint disease, pagetic pain is typically increased at night (when the limbs are warm) and on weight bearing. Pain

in the extremities may be caused by the expansion of the bone with the involvement of the periosteum, whereas in the lumbar spine, pain may result from vertebral expansion, or collapse, as a result of microfractures [30, 31]. Localized disruption of bone architecture leads to an increased risk of pathological fractures in patients with Paget's disease, and it appears that there is also a significantly increased risk of vertebral fractures in uninvolved bones [32].

Calcification of the arterial walls frequently occurs in Paget's disease. Both coronary artery disease and peripheral vascular disease may occur at a relatively young age. Vascular calcification has been observed in as many as 50% of patients and is apparent on radiographs of the pelvis that show calcified femoral vessels [33]. Cardiac insufficiency occurs in Paget's disease due to lower peripheral vascular resistance and a higher stroke volume (compared with controls). This in turn may lead to progressively increased cardiac output [34]. Paget's disease of the bone is associated with an involvement of the central and peripheral nervous system. Neurological syndromes are uncommon but include headache, dementia, brain stem and cerebellar dysfunction, cranial neuropathies, myelopathy, cauda equina syndrome, and radiculopathies. Central neurological symptoms and signs in Paget's disease are caused by pagetic involvement of the skull with a subsequent reduction in the size of neural foramina. This leads to compression of the cranial nerves. Softening of the skull leads to basilar invagination with compression of the brain stem, cerebellum, and lower cranial nerves. The peripheral complications are due to compression by expanded bones [35, 36].

The most serious complication of Paget's disease is sarcomatous degeneration of pagetic bone. The incidence of sarcomatous degeneration varies from 0.1% in patients with limited Paget's disease to as high as 5–10% in those with extensive severe disease [37]. The occurrence of malignancy is more frequent in the presence of severe polyostotic disease [38] and increases with age; the mean age at discovery is 68 years. Multifocal sarcomatous degeneration, although uncommon, occurs mainly in polyostotic Paget's disease [39].

**Fig. 3.3** Radiograph showing typical osteolysis pattern of Paget's disease (*flame-shaped*)

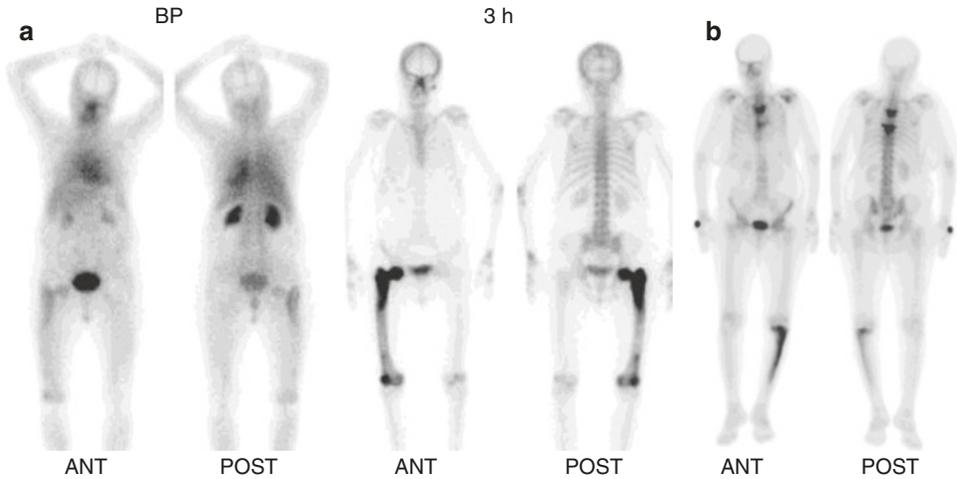

Although Paget's disease can be diagnosed economically with standard radiographs, other modalities are needed, particularly scintigraphy, given the limitations of standard radiography. The early radiological lesions of Paget's disease reflect severe localized osteolysis. These are typically "flame-shaped," or inverted "V," lesions that most commonly occur proximal to the distal epiphysis of a long bone and then gradually progress to the opposite end of the bone (Fig. 3.3). Osteoporosis circumscripta is the term applied to osteolytic lesions in the skull. In the vertebrae, osteolytic lesions may simulate malignancy. When the disease progresses, the ingrowth of fibrovascular tissue "mixed phase" and a high rate of bone remodeling may lead to

deformities of the skull, enlarged dense vertebral bodies, and slowly progressive deformities of weight-bearing bones. It should be noted that radiologically the pagetic process may be seen to involve subchondral bone but not to cross the joint space.

Magnetic resonance imaging (MRI) can add unique diagnostic information by demonstrating bone marrow changes when they are present and can contribute to a noninvasive diagnosis of Paget's disease in atypical presentations [40]. It can also demonstrate the presence, and extent, of several characteristic disease complications, including basilar impression, spinal stenosis, and secondary neoplasm [41].

Although bone densitometry studies have little to do with the diagnosis of Paget's disease, the bone density pattern should be known to avoid misinterpretation of density data. Although bone density may be increased in the bone that is affected by Paget's disease, density in noninvolved bones is unaffected. Osteoporotic vertebrae may be overlooked if the average value of bone mineral density is taken in the lumbar spine without reviewing each vertebra [42].

Using multiphase bone scanning, the dynamic flow and blood pool images show varying degrees of hyperemia at the sites of involvement, depending on the stage of the disease; the earlier the phase, the higher the degree of hyperemia. On delayed static images, the appearance of Paget's disease depends also on the phase of the disease. During the active lytic phase, involvement of Paget's disease is characteristically seen as intensely increased uptake which is uniformly distributed throughout the region affected (Figs. 3.4 and 3.5). An exception to this characteristic pattern of the early phase is the pagetic skull lesion, osteoporosis circumscripta, which shows an intense uptake at the periphery of the lesion, while the center is cold (Fig. 3.6) [43]. With time, the disease activity gradually decreases toward the sclerotic phase and uptake of the bone imaging agents decrease as well. The sclerotic phase may show practically no abnormal uptake of the radiopharmaceuticals, and hence the disease can be detected by radiographs and missed by bone scanning. In about 5% of cases, the radiograph may demonstrate

**Fig. 3.4** (a, b) Paget's disease. (a) Bone scan of a patient with monostotic disease affecting the entire right femur. There is increased blood pool activity of variable degrees

corresponding to the intensity of uptake on delayed images. (b) A patient with polyostotic disease involving two locations of the thoracic spine and left tibia

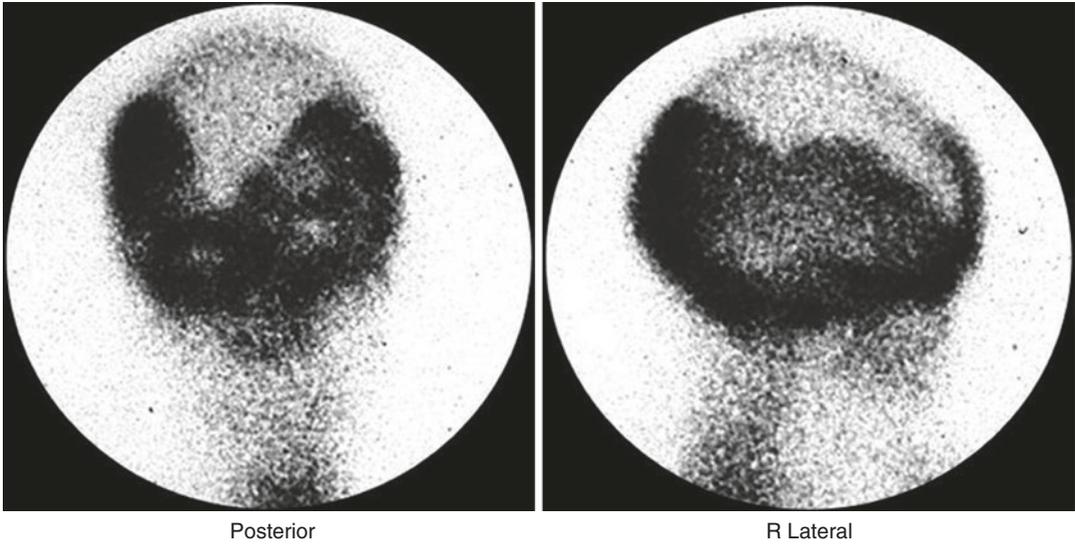

**Fig. 3.5** A case of monostotic Paget's disease in the lytic phase illustrating further the regionally diffuse intense uptake in the skull

diffuse pagetic involvement, for example, of the pelvis, whereas the bone scan reveals little uptake of the isotope in this stage. In this circumstance, the alkaline phosphatase level may be normal, or only slightly elevated, reflecting lesions that are sclerotic, relatively inactive, or burned out.

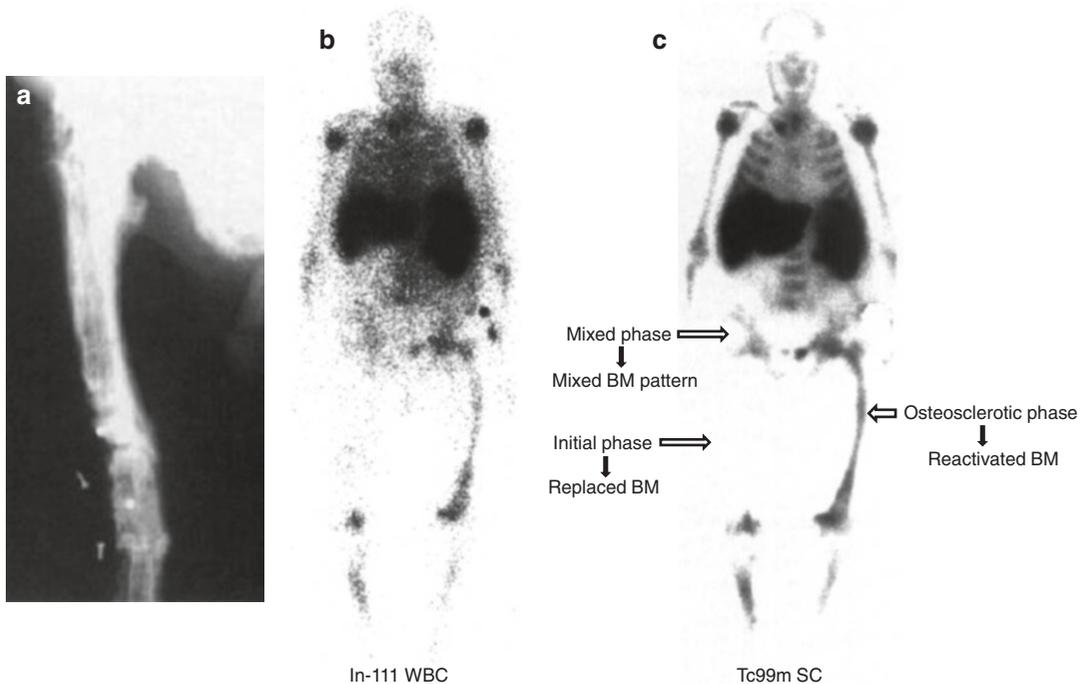

This is in contrast to the early lytic phase, when bone scanning is much more sensitive than radiographs and will identify 15–30% of lesions not visualized on radiographs [38, 43]. Bone scanning also detects abnormalities in bones that are difficult to explore by radiography, such as those in the sternum, ribs, and scapula [44].

Individual bones can simultaneously contain more than one stage of the disease process, reflecting variations of the duration of the disease at different sites. Paget's disease may show absent and expanded bone marrow uptake or a mixture of both. This can be explained by the presence of areas of advanced, sclerotic disease with active bone marrow and areas of earlier active disease with replaced bone marrow. Since In-111-labeled white blood cells are taken up by hematopoietic bone marrow, uptake is seen in areas of Paget's disease with active marrow (Fig. 3.7). This can mimic uptake of infection particularly when it is focal [45].

The therapeutic options for treating this disorder have advanced significantly during the past

**Fig. 3.6** Selected images of the bone scan of a patient with Paget's disease illustrating the cold scintigraphic pattern in the skull: "osteoporosis circumscripta"

**Fig. 3.7** (a–c) In-111 white blood cell images of pagetic bone mimicking infection in an 83-year-old man. This patient had Paget's disease at various phases who presented with a fracture of his right femur, as seen on the standard radiograph (a). The patient was later referred to rule out osteomyelitis at the fracture site. An In-111 white blood

cell scan (b) showed abnormal uptake at different sites including the right femur. A Tc-99m sulfur colloid bone marrow scan obtained later (c) showed a concordant pattern indicating physiological marrow uptake at the sites of the late-phase disease, while it is absent at those at earlier phases (from Elgazzar A et al. [45] with permission)

decade through the development of a nasal calcitonin preparation and the newer bisphosphonates [46]. The assessment of disease activity became a key element in caring for the patient with Paget's disease. Assessment of disease activity in Paget's disease can be generally achieved by imaging particularly bone scintigraphy [47], laboratory parameters reflecting biochemical alterations accompanying the disease, and bone biopsy. In one study a scintigraphic visual activity index, together with a quantitative activity index that reflects both the extent and activity of the disease, was obtained and added diagnostic value to the routinely used scintigraphy [48]. The quantitative activity index is calculated as a geometric mean for all the affected bones divided by a reference obtained in non-affected bones. Recently F-18 sodium fluoride PET is found to be useful in monitoring accurately the efficacy of treatment with bisphosphonates compared to Tc-99m bone scintigraphy [49–51].

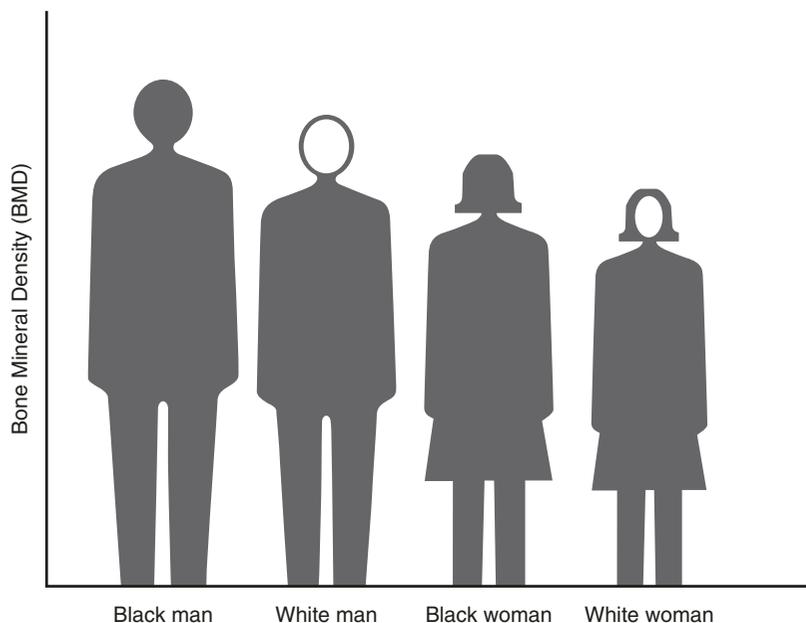

### 3.3 Osteoporosis

Osteoporosis is the most common metabolic disorder of the skeletal system. It has been estimated that it affects up to 20 million older

Americans, 90% of whom are postmenopausal [52]. Current estimates however suggest that 9.9 million Americans are affected by osteoporosis and 43 million with osteopenia [53].

Nearly one half of Caucasian women aged 50 years and older will experience an osteoporosis-related fracture in their lifetime [54]. In 2011, there were approximately 2 million osteoporotic fractures affecting US adults [55]. Osteoporosis is a condition in which bone tissue is reduced in amount increasing the likelihood of a fracture [56–58]. In other words the bone is quantitatively normal but qualitatively abnormal. Understanding the basic pathophysiology of bone density and remodeling is a prerequisite for understanding the disease and its evaluation.

Bone mass gradually increases during childhood and increases rapidly once the skeleton approaches maturity. The longitudinal skeletal growth slows [59] until it reaches the peak bone mass in the second decade although this is somewhat controversial [60]. At maturity, black men have a denser skeleton than white men and black women (Fig. 3.8), whereas white women have the least dense bones [61]. Generally men have an average 20% greater peak bone mass than women [62]. Peak bone mass appears to be a

**Fig. 3.8** Histogram illustrating peak bone mass density among men and women. Note that white women have the lowest value

major factor in determination of the risk of developing osteoporosis.

After reaching its peak, bone mass begins to decrease at a rate of 0.25–1% per year. Men demonstrate a gradual rate of bone loss that persists throughout the remainder of adult life. Women on the other hand undergo a rapid rate of bone loss in the perimenopausal and postmenopausal periods [62]. Loss of trabecular bone exceeds that of compact bone. Some investigators have determined that 50% of trabecular bone and 30% of compact bone will eventually be lost [63]. Generally lifetime bone losses for men are 20–30%, while some women may lose 50% or more [61]. In the postmenopausal period, women show a normal age-related annual bone loss of 1–2% in appendicular bone and about 4–8% in the spinal trabecular bone [62, 64, 65]. The factors related to bone loss in the perimenopausal and postmenopausal periods include age-related factors, estrogen deficiency, calcium deficiency, and other factors such as physical activity, smoking, alcohol consumption, and medications [56, 66].

Remodeling is crucial in maintaining the integrity of normal bone and altering the bone architecture in response to stress. Trabecular bone is remodeled more rapidly than cortical bone [61]. Trabecular bone has a turnover rate of up to eight times that of compact bone and is highly responsive to metabolic stimuli [67]. This high turnover rate makes it a primary site for detecting early bone loss and for monitoring the response to interventions [63, 68].

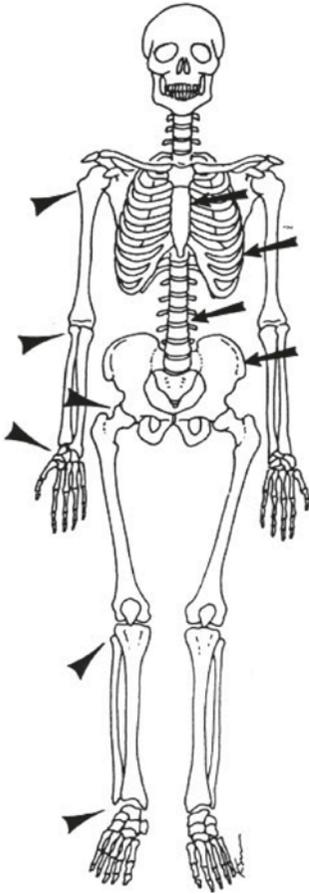

Osteoporosis is characterized by abnormal reduction in bone density and hence a decrease in the amount of calcified bone mass per unit volume of skeletal tissue. The basic mechanism behind this condition is decreased bone formation (osteoid formation) even though calcium deposition may be normal. The disease develops when the process of bone resorption and formation (remodeling cycle) is disrupted, leading to an imbalance. The complete remodeling cycle – activation of the basic multicellular units, bone resorption, and bone formation – normally takes about 4 months in adults. In patients with osteoporosis, this remodeling cycle may require up to 2 years. This can be attributed to the increase in

**Table 3.1** Etiology and classification of osteoporosis [78]

<i>Primary</i>
a. Involutional
Type I: Postmenopausal
Type II: Age related (Senile)
b. Idiopathic
Juvenile
Adult
<i>Secondary</i>
1. Prolonged immobilization
2. Steroid therapy
3. Diabetes mellitus
4. Prolonged heparin administration
5. Sickle cell disease
6. Cushing's syndrome
7. Rheumatoid arthritis
8. Scurvy
9. Multiple myeloma
10. Osteogenesis imperfecta (brittle bone disease)
11. Disuse or immobilization of a limb (regional osteoporosis)

the number of activated basic multicellular units, leading to resorption at more sites, an increased rate of resorption, an increased frequency of activation of basic multicellular units, and a delay in bone formation. Osteoporosis also occurs when the number of osteoblasts and osteoclasts in bone is inadequate.

There are numerous causes of osteoporosis [56]; many are metabolic in nature as advancing age and estrogen deficiency, while some are behavioral such as excess alcohol use and smoking (Table 3.1). Types of osteoporosis not considered metabolic in origin include juvenile osteoporosis, which affects younger individuals and is idiopathic rather than metabolic. The disease may be generalized, involving the major portions of the axial skeleton, or restricted to one region of the appendicular skeleton (Fig. 3.9). Senile osteoporosis, which is the most common type, often produces increased susceptibility to fractures in old age [69]. Since men have a greater peak bone mass than women, men are affected by senile osteoporosis later in life. Postmenopausal osteoporosis is also common, and a deficiency of estrogen leads to decreased

**Fig. 3.9** The distribution of abnormalities in generalized versus regional osteoporosis. In generalized osteoporosis (*arrows, on right-hand side*), the spine, the pelvis, the ribs, and the sternum are affected most commonly. In regional osteoporosis (*arrowheads, on left-hand side*), the appendicular skeleton is the predominant site affected, particularly in the periarticular regions. From Resnick D: Resnick bone and joint imaging. Elsevier, 1996 with permission [26]

bone formation. This is because estrogen is necessary to stimulate the production of new osteoblasts, which otherwise fail to lay down sufficient bone matrix. The prolonged use of steroids, or steroid overproduction (e.g., Cushing's syndrome), may cause osteoporosis since it increases the ability of the body to resorb bone (Table 3.2). Smoking lowers circulating estrogen levels in premenopausal women and accelerates the onset of menopause. Smoking is also an osteoporosis risk factor in men [70]. The disease has also been reported to be prevalent among patients with

liver cirrhosis [61, 71–76]. In one study, the prevalence of spinal osteoporosis was 20% in cirrhotic patients compared with 10% in controls [77]. Regional and transient osteoporosis occurs in portions of the appendicular skeleton when there is disuse, or immobilization, of a limb such as would happen with paralysis, or healing of a fracture in a cast. Osteoporosis usually appears after about 8 weeks of immobilization.

Since the condition results in brittle, or porous, bone, patients suffer more fractures. Compression fractures of the spine, distal radius, and femoral neck are more common in the presence of osteoporosis. Repeated and multiple vertebral fractures, often in the thoracic spine, may lead to kyphosis and other spinal deformities [79–81]. Fractures of the ribs, sternum, pelvis, and feet are also common in osteoporotic patients (Fig. 3.10).

Bone density evaluation can be performed by various densitometry methods which are used for three purposes: (1) assessment of individuals with a high risk for metabolic bone disease and estimation of the status of osteoporotic bone loss in perimenopausal women; (2) assessment of fracture risk for the spine, hip, and wrist; and (3) evaluation of the effectiveness of treatment, which aims

**Fig. 3.10** Tc99m MDP bone scan showing Multiple fragile (insufficiency) fractures in a patient with osteoporosis

to slow down the rate of calcium and bone loss and avoid complications such as fracture and deformities. These methods measure the radiation absorption by the skeleton to determine bone mass of the peripheral and total skeleton. Techniques include single- and dual-photon absorptiometry and dual-energy X-ray absorptiometry, quantitative computed tomography, and radiographic absorptiometry. Although osteoporosis can sometimes be obvious on standard radiographs, quantification of bone density from these radiographs is difficult and inaccurate. Dual-energy X-ray absorptiometry (DXA), however, is the most widely used technique and is considered currently the gold-standard method for the measurement of

bone mineral density. It provides stable calibration, good precision, and short scan times.

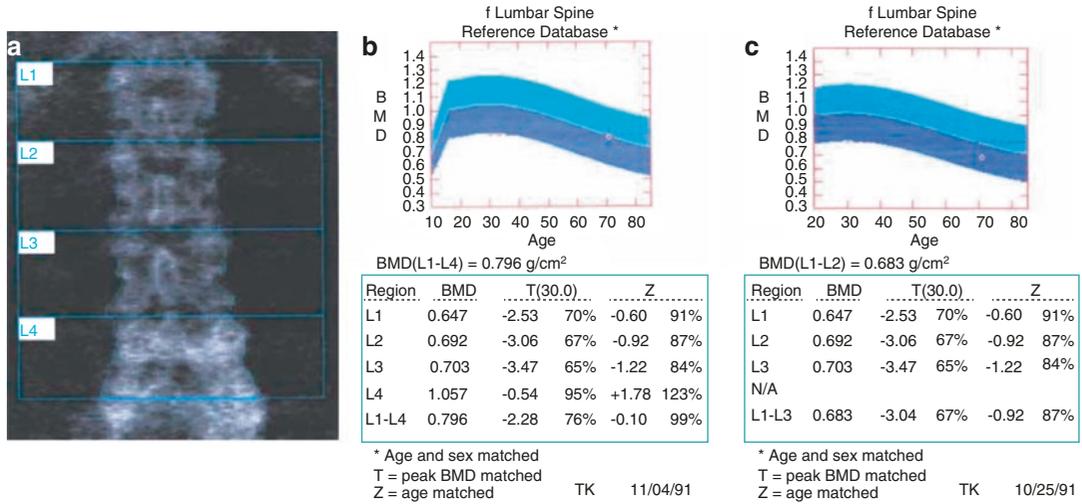

A measurement of hip bone mass density (BMD) has been shown to be most reliable in the assessment of the risk of hip fracture [82, 83]. The spine is considered the optimum site for monitoring the response to therapy [84] because the vertebrae are rich in the metabolically active trabecular bone. The radiation dose to the patient from a DXA scan is very low (1–10  $\mu\text{Sv}$ ) [85]. This is comparable to the average daily natural background radiation dose of 7  $\mu\text{Sv}$ . For the interpretation of DXA,  $T$ -, and to a lesser extent,  $Z$ -scores are used. The  $T$ -score relates the individual's density to that of young healthy adults and the  $Z$ -score relates the density to that of the same age group. The  $T$ -score is calculated by determining the difference between a patient's measured BMD and the mean BMD of healthy young adults, matched for gender and ethnic group, and expressing the difference relative to the young adult population:

$$T\text{-score} = \frac{\text{Measured BMD} - \text{Young adult mean BMD}}{\text{Young adult standard deviation}}$$

A  $T$ -score result therefore indicates the difference between the patient's BMD and the ideal peak bone mass of a young adult, and it may accordingly have a negative value if decreased.

Based on the  $T$ -score values, WHO has defined osteoporosis and osteopenia [86]. An individual with a  $T$ -score  $\leq -2.5$  at the spine, hip, or forearm is classified as having osteoporosis (Fig. 3.11), a  $T$ -score between  $-2.5$  and  $-1$  is classified as osteopenia (Fig. 3.12), while a  $T$ -score  $\geq -1$  is regarded as normal (Fig. 3.13). An additional fourth state of "established osteoporosis" has also been proposed, but in the presence of one or more documented low-trauma, or "fragility," fractures. According to the WHO definition of osteoporosis, the condition affects around 25–30% of all Caucasian postmenopausal women [87, 88]. This figure approximates to the lifetime risk of fracture for a 50-year-old woman.

Instead of comparing the patient's BMD with the young adult mean, the  $Z$ -score compares the bone density of the individual to the mean BMD

**Fig. 3.11** (a–c) A bone densitometry study of a patient with osteoporosis. Calculation (b) was repeated (c) after excluding L4 vertebra since it showed DJD on the scan (a). Final T-score is < -2.5 SD

expected for the patient’s peers (age-matched) as expressed in the following formula:

$$Z - \text{score} = \frac{\text{Measured BMD} - \text{Age matched mean BMD}}{\text{Age matched standard deviation}}$$

Although the Z-score is not as widely used as the T-score, it remains a useful concept since it expresses the patient’s risk of having an osteoporotic fracture relative to their peers. It is estimated that for every reduction of 1 SD in BMD, the likelihood of fracture increases by 1.5–2.5. Accordingly, patients with a Z-score ≤1 are at a substantially increased risk of fracture compared to their peers with a Z-score of 0. Presenting bone density results using T- and Z-scores is advantageous since it avoids the confusion present when using the actual BMD values that differ among between different pieces of equipment [89].

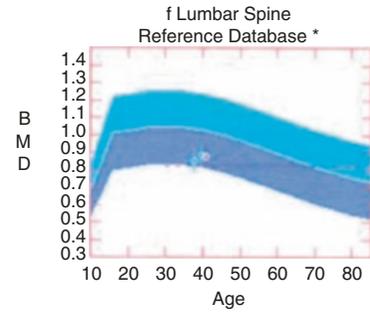

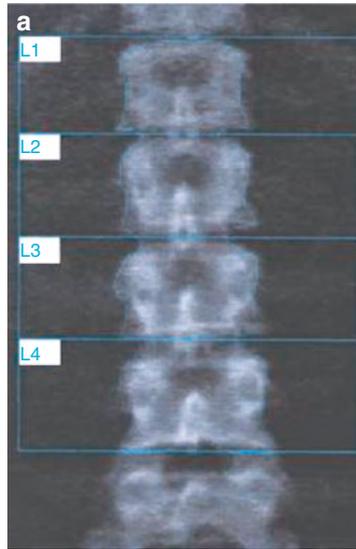

A careful visual examination of the scan image is important in the interpretation of DXA studies before reporting T- and Z-scores to ensure that values are not affected by artifacts. For spinal scans such artifacts include degenerative joint disease, vertebral fractures, and metal artifacts, as well as the effects of body habitus such as steatopygia and bands of fat (Fig. 3.14). The affected vertebra(e) should be excluded from analysis. For example, a patient was seen who had a low-normal

BMD and a bone mineral density of the L4 vertebra that was lower than the others; image analysis showed a defect in the right part of its body which was proven to be lung cancer metastasis. This again indicates that image analysis of bone densitometry should be evaluated carefully [90].

On the other hand, major sources of error in the case of the proximal femur are a short femoral neck, Paget’s disease of the femur or significant osteoarthritis, and incorrect rotation or abduction of the leg. The International Committee for Standards in Bone Measurement (ICSBM) has recommended the use of a total femur region of interest (ROI), instead of the widely used ROI on the femoral neck site, because of its larger area and therefore improved precision. The total femur ROI currently is being used increasingly for DXA scan reporting. In fact, using the total femur ROI and the hip BMD reference range of the third US National Health and Nutritional Examination Surveys reference range, significantly fewer patients will be diagnosed as having true osteoporosis than when using the femoral neck ROI and the manufacturer’s reference range. Consistency is, however, crucial in clinical practice, particularly when it comes to the follow-up of patients with osteoporosis [91–93].

Recently a new echographic diagnostic method was introduced using different ultrasound

methodology for the diagnosis of osteoporosis and fragility fractures [94].

### 3.4 Osteomalacia and Rickets

Osteomalacia arises from abnormal mineralization of the bone, predominantly as a result of vitamin D deficiency, with a decrease in bone density which is secondary to the lack of both calcium and phos-

phorus. It is worth noting that in osteomalacia, there is a normal amount of osteoid (bone formation), while it is decreased in osteoporosis. In other words, there is inadequate and delayed mineralization of osteoid in spongy and compact bone, which has a normal remodeling cycle as opposed to the delayed cycles in osteoporosis. Simply, in osteomalacia the osteoid tissue is normal in amount but soft since it lacks calcium, while in osteoporosis there is a lack of osteoid tissue as a whole. If osteo-

**Fig. 3.13** (a, b) A bone densitometry study with normal *T*-scores of > -1 SD

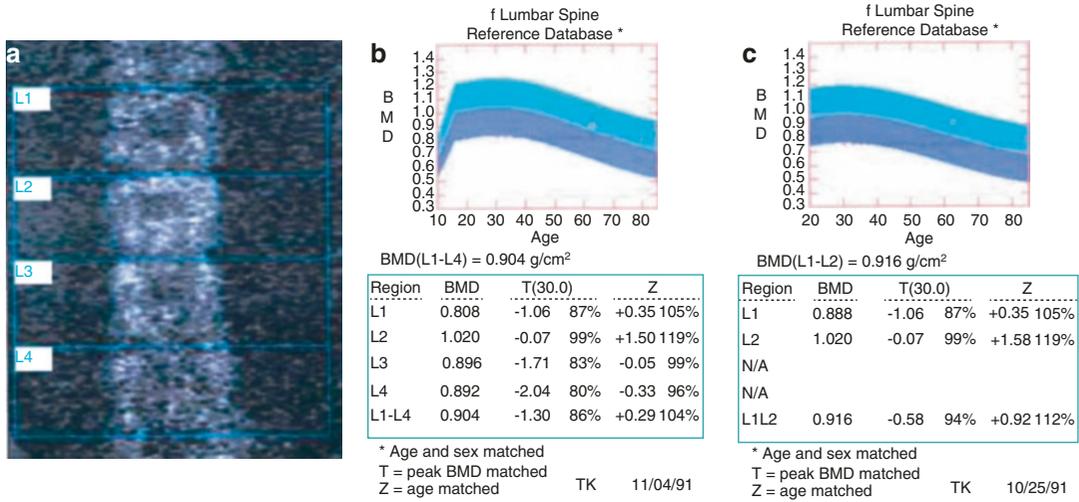

malacia occurs in growing bones before the closure of the growth plate, it is called infantile osteomalacia or rickets. Growing bones fail to mineralize and become soft with the resultant deformities. Growth plates and metaphysis are disorganized in patients with rickets with a decrease in the length and width of the growth plates.

Clinically, osteomalacia is manifested by progressive generalized bone pain, muscle weakness, hypocalcemia, pseudofractures, and, in the late stages, a waddling gait. Osteomalacia due to

vitamin D deficiency is often missed or is not diagnosed promptly in susceptible patients. This is probably because physicians are not sufficiently aware of this rare condition. In a study of 17 patients with osteomalacia due to vitamin D deficiency, only 4 were suspected by the referring physicians, although a gastrointestinal disorder that can lead to vitamin D deficiency was present in every patient [95].

Pseudofractures are common in patients with osteomalacia. Among 23 patients studied by

**Fig. 3.14** (a–c) Effect of steatopygia on bone mineral density. This study is of an obese patient with the buttocks causing attenuation artifact on lower lumbar region falsely

Reginato et al. [81], 7 showed characteristic pseudofractures, and 2 showed polyostotic areas of increased uptake on bone scans mimicking metastatic bone disease caused by pseudofractures [96]. Pseudofractures are most often seen in the ribs. It is uncommon to see pseudofractures in isolation at other sites such as the femoral neck or pelvis. The bone scan provides a sensitive means of identifying pseudofractures (Fig. 3.15), particularly in the ribs, where conventional radiology cannot detect the lesions [97]. However, lesions in the pelvis can on occasion be missed on the bone scan because of their symmetrical nature, or if they are obscured by bladder activity. In a comparative study with conventional radiography, all 15 patients presenting with osteomalacia were diagnosed by bone scan, whereas only 9 by radiography. Additionally, more pseudofractures were appreciated by the bone scan [38]. In another study, five patients suffering from osteomalacia had positive bone scans; follow-up studies showed a reverse of bone scan images after appropriate treatment with calcium and vitamin D [98]. Other studies have also confirmed the better sensitivity of bone scan over conventional radiography in the differential diagnosis between pseudofractures and metastatic disease when the lesions occur proximal to the knees and the elbows [99]. Pseudofracture detection is probably the most

decreasing the T-value. Exclusion of L3 and L4 resulted in normal overall T-score of the lumbar vertebra

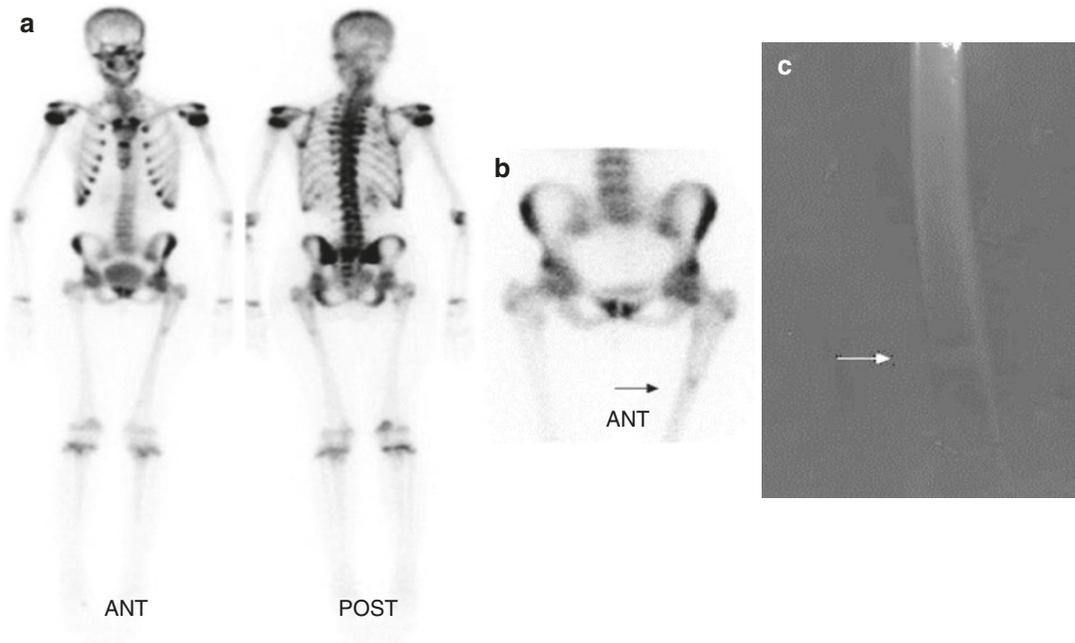

useful application of the bone scan in osteomalacia.

Tc-99m (V) DMSA was used in patients with osteomalacia [100]. Eight women aged 17–72 years (six with osteomalacia and two with primary hyperparathyroidism) were studied by bone scans and Tc-99m (V) DMSA scans, and many of the fracture and pseudofracture sites detected on bone scans were also visualized on Tc-99m (V) DMSA scanning, which was suggested by the authors as having potential as a screening method in patients with metabolic bone disease [100, 101].

### 3.5 Hyperparathyroidism

Overactivity of the parathyroid gland(s) results in excess secretion of parathyroid hormone (PTH). This promotes bone resorption and consequently leads to hypercalcemia and hypophosphatemia. Primary, secondary, and tertiary hyperparathyroidism all share elevated serum calcium and PTH.

Primary hyperparathyroidism is caused by a benign adenoma in approximately 80% of cases. Hyperplasia is essentially the cause in the remainder of cases, and carcinoma is a very rare cause. Secondary hyperparathyroidism results from compensatory hyperplasia in response to hypocalcemia. This may occur, for example, in

**Fig. 3.15** (a–c) Sixteen-year-old girl with a 4-year history of no dairy products in her diet. Referred for bone scan for diffuse bony pain and limping for 1 month. Laboratory results revealed hypocalcemia and very high ALP. Whole-body bone scan (a) shows the features of osteomalacia with increased uptake particularly in the

mandible, sternum, costochondral junctions, and spine. A small focus of uptake in the left femur is seen on whole-body images and spot image of the pelvis and femora (b) and represents a pseudofracture (*arrow*) also seen on standard radiograph (c)

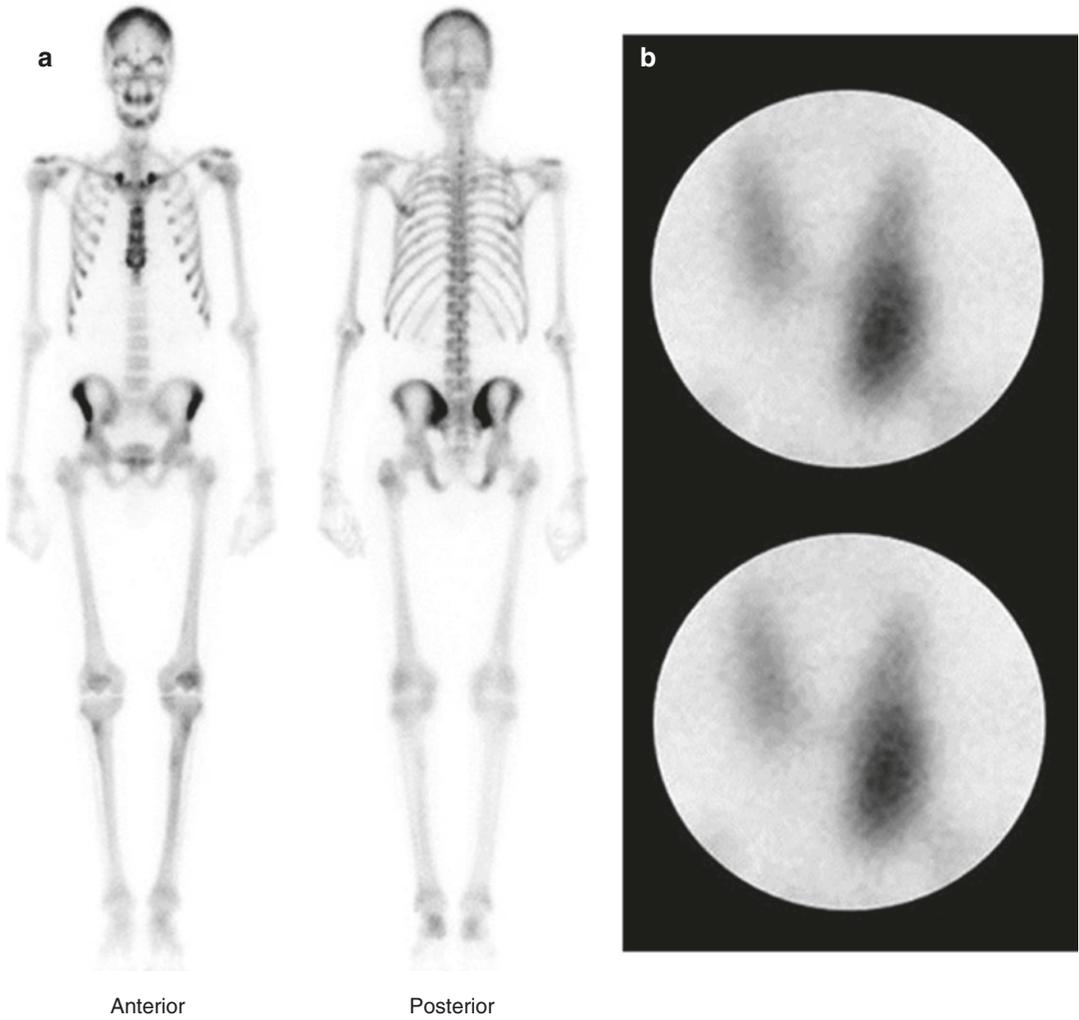

long-standing renal failure. Reduced renal production of 1,25-dihydroxyvitamin D<sub>3</sub> (active metabolite of vitamin D) leads to decreased intestinal absorption of calcium, resulting in hypocalcemia. Failure of the tubules to excrete phosphate results in hyperphosphatemia. The hypocalcemia is compensated by parathyroid hyperplasia and an excessive production of PTH [80, 81]. Tertiary hyperparathyroidism describes a condition of persistent PTH overproduction (even after a low calcium level has been corrected) as a result of autonomous hyperplastic parathyroid tissue.

In all forms of hyperparathyroidism, there is increased bone resorption and an associated increased osteoblastic activity leading to a generalized increased uptake of bone-seeking radiopharmaceuticals. This is less prominent in the primary form of the disease than in the other forms of hyperparathyroidism, which show other additional features of metabolic bone disease (Table 3.3).

**Table 3.3** Bone scan patterns in advanced metabolic bone disease [102, 103]

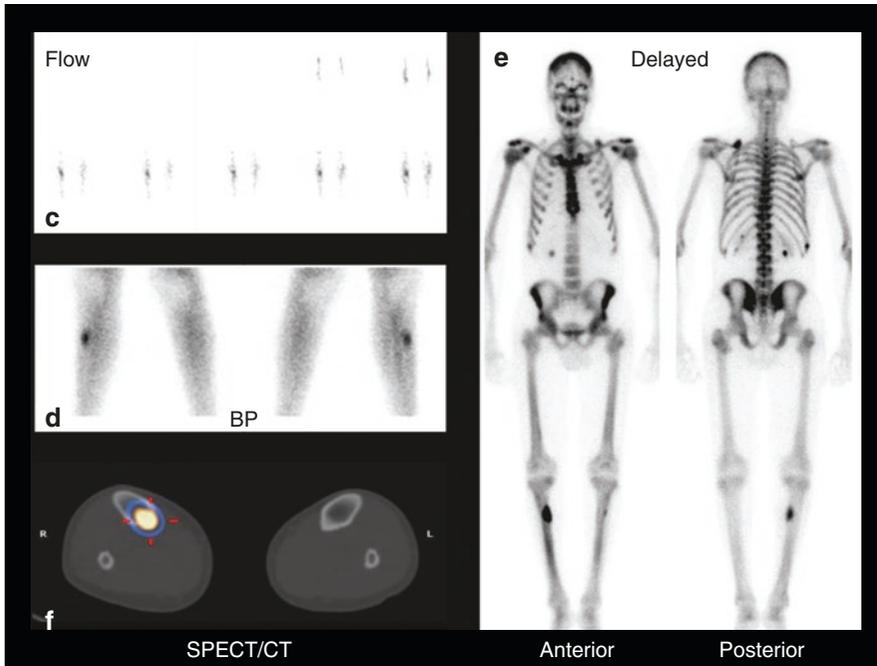

Generalized increased uptake with increased contrast between bone and soft tissue
Increased uptake in long bones
Increased uptake in axial skeleton
Increased uptake in periarticular areas
Increased uptake in calvaria
Increased uptake in mandible
Increased uptake in costochondral junctions (beads)
Increased uptake in sternum (“tie sternum”)
Foci of increased uptake due to fractures, pseudofractures, and brown tumor
Faint or absent kidney

After parathyroidectomy for primary or secondary hyperparathyroidism, hypocalcemia is generally transient, and normal parathyroid tissue recovers function quickly (usually within 1 week) even after long-term suppression. Severe and prolonged hypocalcemia may occur in some cases despite normal or even elevated levels of parathyroid hormone leading to hungry bone syndrome (Fig. 3.16) [104].

**Fig. 3.16** Fifty-year-old female with generalized bony pain. Bone scan (a) was obtained and shows diffuse increased uptake suggesting metabolic bone disease. Later the patient was diagnosed with hyperparathyroidism and a parathyroid localization study (b) showed an adenoma which was later surgically removed. Follow-up

bone scan (c, d, e) 4 weeks after surgery was obtained along with SPECT/CT (f) of the tibiae. The study shows continuing increased bone uptake with a focal uptake on the right tibia which was not clear on the initial scan representing brown tumor clearly visualized on SPECT/CT image

**Fig. 3.16** (continued)

### 3.6 Renal Osteodystrophy

Renal osteodystrophy is a metabolic bone condition associated with chronic renal failure. It is a frequent complication of renal insufficiency that has become more prevalent due to the improved survival of renal failure patients. This has led to increased number of patients with the condition, changed our understanding, and defined the forms of the disease [105, 106]. The pathogenesis of renal osteodystrophy is incompletely understood. However, two mechanisms predominate: secondary hyperparathyroidism and abnormal vitamin D metabolism following reduced renal function. Renal insufficiency results in the decreased excretion of phosphate, leading to hyperphosphatemia. This in turn causes a decrease of serum calcium

and a consequent secondary hyperparathyroidism. Also, since renal tissue is the site of activation of 25-hydroxy cholecalciferol into the 1,25-dihydroxy form of vitamin D which is the active form of the vitamin, chronic renal failure causes a decrease of the formation of the active form. This leads to reduced gastrointestinal absorption of calcium, producing hypocalcemia.

The major skeletal changes of the disease include osteitis fibrosa cystica, rickets, osteomalacia, osteosclerosis, and extra-osseous calcification, including tumoral calcinosis. Slipped capital femoral epiphysis, avascular necrosis including Legg-Perthes disease in children, and brown tumors are other associated pathological features [105–110]. Osteitis fibrosa is characterized by extensive medullary fibrosis and increased osteoclastic resorption

linked to PTH hypersecretion. Osteomalacia occurs mainly due to vitamin D insufficiency, aluminum intoxication, hypocalcemia, acidosis, and exceptionally due to hypophosphatemia. It should be mentioned that aluminum overload directly inhibits the osteoblast.

The clinical presentation of renal osteodystrophy is influenced by the patient's age at the onset of renal failure, the etiology of the renal disease, the geographical location, dietary intake (protein, phosphate, and calcium), and treatment modalities. The reported prevalence of each bone change mentioned varies and does not correlate well with the clinical findings and laboratory data. Currently the disease is believed to occur in three major types: high-turnover disease, low-turnover disease, and a mixed disease [80, 111–114]. An additional adynamic, or aplastic, bone disease has also emerged recently; the term has been used synonymously with low-turnover disease, but adynamic/aplastic disease should actually be considered as an extreme variant of the low-turnover type [115, 116]. The prevalence of different forms of the disease has changed significantly over the past decade.

The high-turnover form is the most common and presents typically with osteitis fibrosa and is linked to the development of secondary hyperparathyroidism; hence, it is sometimes described as “predominant hyperparathyroid bone disease.”

As mentioned above, high turnover can result in other disease processes locally or diffusely (Table 3.4).

**Table 3.4** High-turnover disorders

<i>Generalized disorders</i>
Primary hyperparathyroidism
Renal osteodystrophy (certain forms)
Type 1 (postmenopausal) osteoporosis
<i>Localized disorders</i>
Focal osteoporotic syndromes
Disuse atrophy
Complex regional pain syndrome type 1 (reflex sympathetic dystrophy)
Transient osteoporosis (oligodystrophy)
Paget's disease
Stress fractures
Fibrous dysplasia
Myeloproliferative disorders
Widespread metastases

Local processes include widespread metastases, fibrous dysplasia, Paget's disease, and myeloproliferative disorders. The latter include myelofibrosis, leukemia, lymphoma, Waldenström's macroglobulinemia, and aplastic anemia. High-turnover renal osteodystrophy is usually associated with tubular interstitial nephritis as an underlying disease of renal failure, since it is a slowly progressing form of renal pathology compared to glomerular disease, which has a rapidly progressive course with a lesser risk of developing high-turnover disease [112].

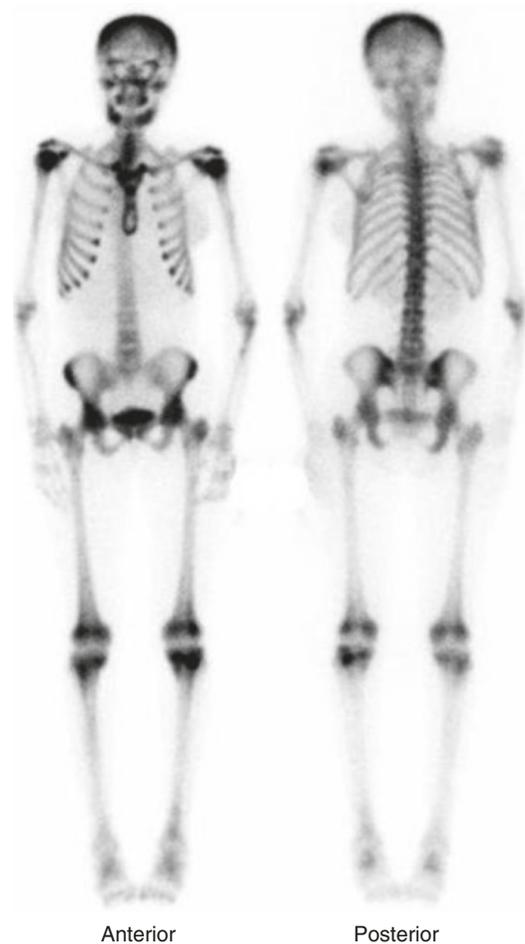

The low-turnover type may present with osteomalacia and osteoporosis, which can also occur in the high-turnover disease. The mixed form shows both osteomalacia and osteitis fibrosa. The use of high-dose pulsed intravenous, intraperitoneal, and oral calciferol (vitamin D) therapy resulted in significant decrease of serum PTH levels and inhibited the growth of osteitis fibrosa. These therapeutic protocols have led also to the increasing prevalence of low-turnover disease and to the development of adynamic disease variant particularly in the pediatric population [114].

Differentiation of the different forms is usually based on clinical data, laboratory findings, and standard radiographs, although it can be difficult.

Radiologically, skeletal deformities, thickening of the cortical bone, thickened irregular trabecular bone, osteonecrosis, extra-osseous calcification, and brown tumors can all be seen with variable frequency [117]. Brown tumors present as well-defined lytic lesions that may cause expansion seen on standard radiographs since they may involve the cortical bone.

Scintigraphically, diffusely increased uptake with increased skeletal to renal uptake ratio (Fig. 3.17) occurs in the high-turnover form. This uptake may be homogeneous or heterogeneous, with focal findings depending on the predominant pathophysiological process. One or more of the typical findings of metabolic bone disease on bone scan may be seen (Table 3.3). A mixture of these findings are seen in the mixed form, while in the low-turnover form, the decreased uptake can be seen if identified. It should be noted that there is no consistency in the patterns seen on standard radiographs and bone scans in patients

**Fig. 3.17** Diffuse increased uptake of metabolic bone disease

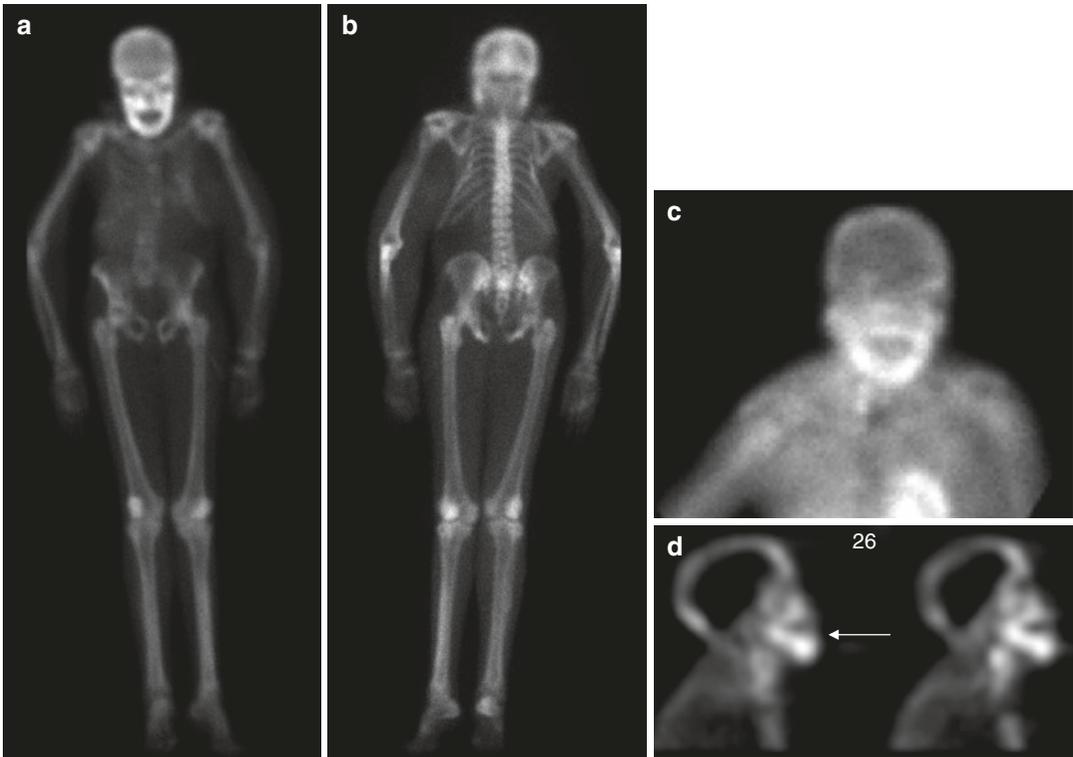

with renal osteodystrophy (Fig. 3.18). Bone scanning can be helpful in differentiating between cases of osteitis fibrosa and osteomalacia [117].

So et al. compared bone scan uptake in patients with renal osteodystrophy with and without diabetes. The authors found that the diabetes group showed significantly lower uptake than the nondiabetic group and indicated that diagnosing renal osteodystrophy in diabetic patients with renal failure by bone scan could be difficult [119].

Recently bone marrow scanning, using Tc-99m antigranulocyte antibody, has been suggested for the detection of bone marrow expansion. This

allows an evaluation of the extent of marrow fibrosis in patients with renal osteodystrophy [119]. Pentavalent Tc-99m dimercaptosuccinic acid (DMSA) was shown in one patient to be better than Tc-99m MDP in evaluating the response of osteodystrophy to therapy since it showed markedly decreased uptake with no significant difference before and after therapy [120]. We identified a case of renal osteodystrophy showing intense Tc-99m methoxyisobutylisonitrile (MIBI) uptake in the mandibular region of a scan that had been obtained to localize abnormal parathyroid glands [118]. This suggests that MIBI may be potentially useful for the evaluation of

**Fig. 3.18** (a–d) Renal osteodystrophy. Tc-99m MDP bone scan (a–b) of a patient with a long-standing renal insufficiency showing increased uptake in the mandible. Tc-99m MIBI planar (c) and SPECT (d) images obtained

as part of parathyroid localization study show corresponding increased radiotracer uptake (from Reczek J, Elgazzar A [118] with permission)

renal osteodystrophy if the imaging is extended to include the whole skeleton. MRI was also used in patients with renal osteodystrophy and was shown to provide detailed information about the bone marrow.

Bone metabolic activity in patients with renal osteodystrophy using F-18-NaF PET was evaluated. It was found that rate constant (K) PET studies of bone can differentiate low-turnover from high-turnover lesions of renal osteodystrophy and provide quantitative estimates of bone cell activity that correlate with histomorphometric data [121].

### 3.7 Complex Regional Pain Syndrome I (Reflex Sympathetic Dystrophy)

A new classification system, collectively called the complex regional pain syndromes (CRPS), has been devised in order to replace the nomenclature

of pain disorders previously termed reflex sympathetic dystrophy (RSD) and causalgia. CRPS replaced the name RSD since sympathetic changes and dystrophy may not be present through the disease course and no specific reflex arc is responsible for the condition. Pain in fact is secondary to multisynaptic pathologic changes involving the brain, spinal cord and peripheral nerves [122, 123].

A working group of the International Association for the Study of Pain (IASP) has further classified the new terminology into complex regional pain syndrome (CRPS) types I and II [124, 125]. CRPS I (previously reflex sympathetic dystrophy, RSD) is defined as a pain syndrome that usually develops after an initiating noxious event with no identifiable major nerve injury; it is not limited to the distribution of a single peripheral nerve, and the level of pain is out of proportion to the inciting event or expected healing response. It is associated during its course

with evidence of edema, changes in skin blood flow, abnormal sudomotor activity in the region of the pain or hyperalgesia. The site is usually the distal aspect of an affected extremity, is has or with a distal to proximal gradient. CRPS II, on the other hand, replaces the term causalgia and requires identifiable peripheral nerve injury [126, 127].

The Epidemiology of CRPS I has been reported in the literature with limited data from epidemiological studies before 2000. In 2003, Sandroni et al reported the incidence of CRPS type I to be 5.46 per 100,000 person-years and 0.82 per 100,000 person-years for CRPS type II [129], while de Mos et al. in 2007 estimated the combined incidence rate of CRPS to be approximately four times greater at 26.2 per 100,000 person-years [129]. Both studies were population based studies, and the differences were attributed to differences in ethnicity, application of criteria as well as socioeconomic background. Also, different incidences has been reported in the literature following orthopedic surgeries [130–133] or fracture [134, 135].

The pathophysiology of CRPS I (RSD) is not well understood. Investigations of this entity have resulted in confusing and conflicting theories about the etiology and pathophysiology [127]. It is believed that an imbalance between the sympathetic and neuroceptive sensory systems occurs after trauma. Normally, afferent C and A-delta fibers carry information from the skin neuroceptors to the neurons in the dorsal horns of the spinal cord. From this region, information is transferred to the higher central nervous system levels and also directed through sympathetic neurons and their efferent fibers. These sympathetic fibers control the tone of distal arterioles and capillaries. It is postulated that trauma, which could be trivial, minor, or nerve injury, causes an alteration or imbalance of these nociceptive-sympathetic contact sites, resulting in the vasomotor disturbances, pain, and dystrophic changes which form the features of this condition [136]. It also was suggested that the accompanying peripheral edema may be caused by an increased sympathetic stimulus to the lymphatic system [137]. Barad et al. Using MRI a recent study showed abnormal structural changes

in pain related regions of human brain in 15 patients with CRPS as compared to controls [138]. As mentioned in the literature the pathophysiology could be a combination of different factors including Inflammation [139, 140], Central and peripheral sensitization [141, 142], Altered sympathetic nervous system function [143], Circulating catecholamines [144, 145], Genetic factors [146–148], and Psychological factors [149].

Synovial histopathological changes have been found in patients with CRPS I. The most common findings are proliferation of synovial cells, subsynovial fibrosis, and vascular proliferation. As a result of vasomotor disturbances vasodilatation occurs as a prominent feature, leading to increased blood flow to the synovial and osseous tissues. Vascular changes can be demonstrated on Tc-99m diphosphonate blood pool images, which show increased peri-articular activity. The cell proliferation finding is a result of a synovium reaction which eventually leads to secondary fibrosis. Although inflammatory cellular infiltration is lacking, Leitha et al. a recent study has found that lateralization of regional hyperemia, increased micro-vascular permeability and bone metabolism in CRPS I parallel shifts in protein concentrations and blood cell counts. This suggests a sub-acute inflammatory process, even in patients with no overt signs of inflammation [150]. The adjacent bone undergoes increased turnover locally with some resorption. This explains the presence of radiographic and bone scintigraphic changes typical of RSD, as well as the changes at the level of the synovium.

The disorder has a wide spectrum of clinical presentations. The clinical course of the condition, which is probably under-recognized, consists of three stages: acute, dystrophic and atrophic [151–153]. The first stage is characterized by pain, stiffness, tenderness and swelling of the involved joint. In the second stage, there is still pain, tenderness and wasting of subcutaneous tissues and muscles. Thickened fascia and loss of color with cold skin are also seen. The third stage may last for months or become chronic. This stage is characterized by pronounced wasting of the muscles and subcutaneous tissue. Skin is atrophic and smooth-appearing

contractures are frequent. The joints of the upper extremity are most commonly involved; among them, the wrist is the most commonly affected followed by the hand, the shoulder and the elbow [152–154]. The onset of clinical manifestations may be hours or even months after the noxious event, characteristically includes a triad of autonomic, sensory and motor abnormalities. Sudomotor phenomena such as hypohidrosis or hyperhidrosis, trophic changes presenting as excessive hair growth, thin nails, and skin atrophy evidenced by the appearance of “glowing” skin, thinning of the epidermis and muscle atrophy, as well as contractures are also found. The most common symptom (90%) is pain, which is described as burning or stinging. Pain is often accompanied by hyperalgesia and allodynia. Other manifestations in this category are essential tremors in the affected limb, myoclonus and dystonia, which is most frequently observed in patients with type II CRPS [155].

There are no pathognomonic signs or symptoms and hence there is no definitive diagnostic test. Diagnosis is based on a complete medical history, symptoms and signs, severity of the injury and physical examination of the affected limb. In 1994, IASP published the first diagnostic criteria for CRPS which at first seemed to lack specificity. The IASP published a review of the clinical diagnostic criteria in 2007 called the “Budapest Criteria”, which has a sensitivity of 85% and a specificity of 69% [156, 157].

Although the diagnosis of CRPS I (RSD) depends on the clinical evaluation, multiphase bone scanning has an adjunct role in the diagnostic assessment of the disease, the disease staging, predicting the response to therapy, follow-up and in determining the prognosis of the disorder [1, 2, 4, 158–161]. MRI has also been reported to be a useful modality by showing bone and soft tissue edema when the disease is clinically active. MRI bone edema was found in some patients to move from one location to another during the follow-up [159].

The scintigraphic patterns and results depend on the duration of the disease, age of the patient population evaluated, the predisposing injury, location of the disease, and the varying scinti-

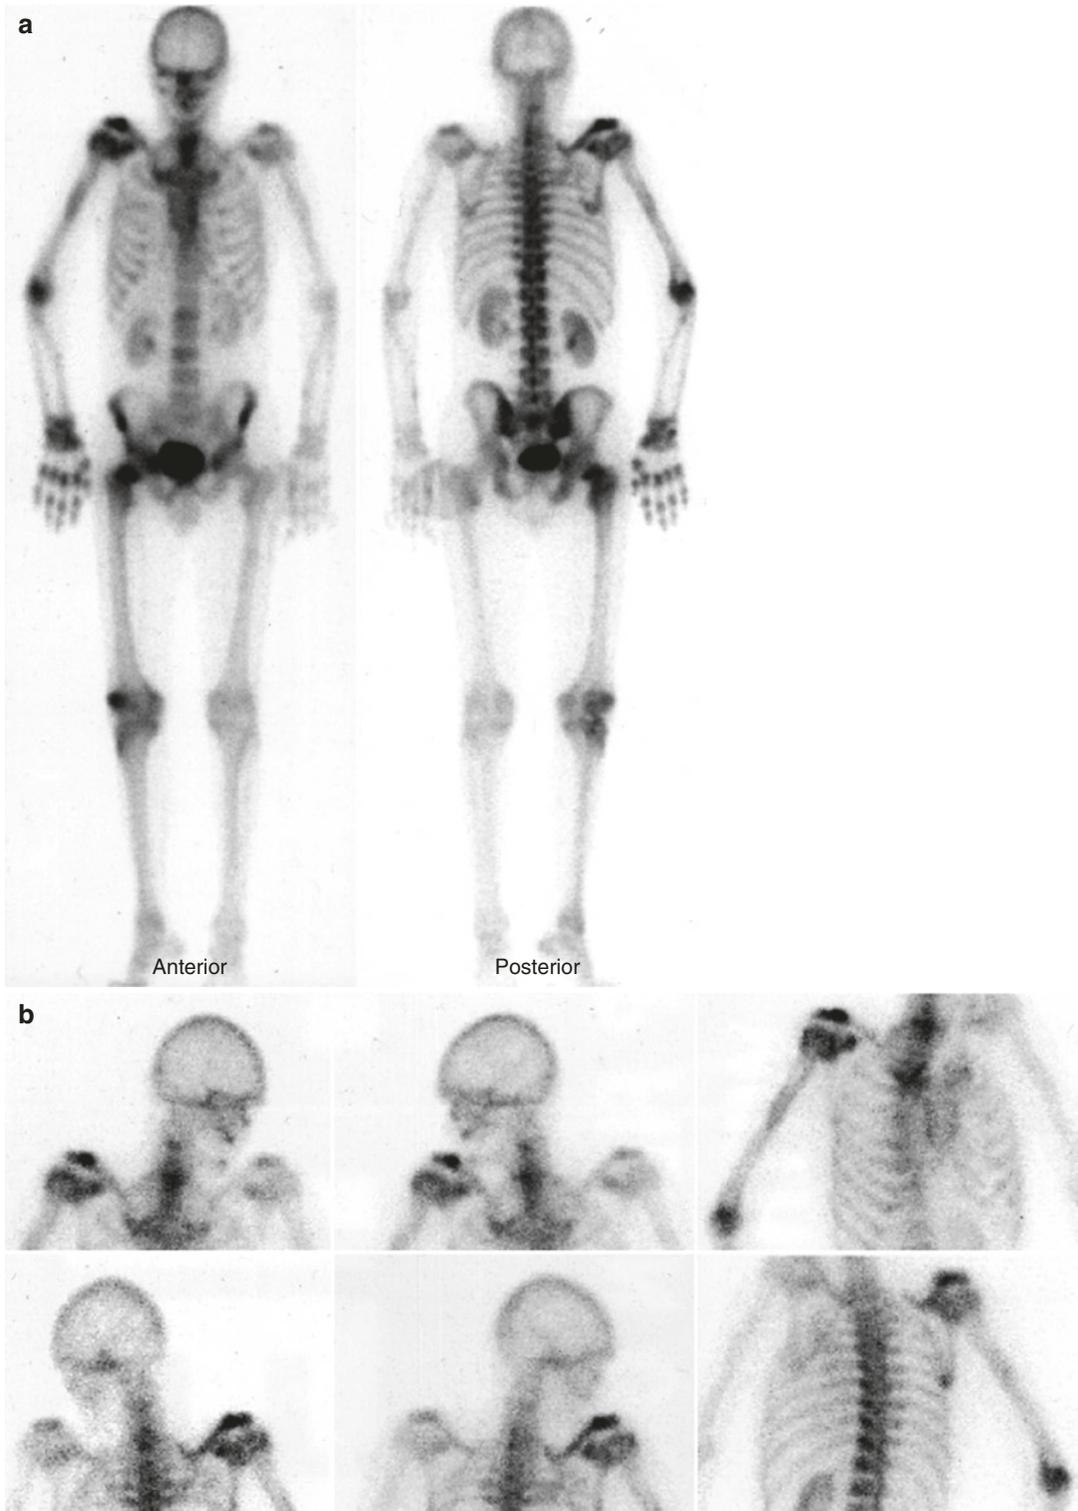

graphic scan interpretation criteria used [127, 159]. In the first, or acute stage (20 weeks), all three phases of the bone scan show increased activity. Typically, there is diffuse hyperemia of the affected hand, or foot, and peri-articular increased uptake of the affected region (or the whole extremity) (Figs. 3.19, 3.20, and 3.21). This pattern was found reliable for the diagnosis and in differentiating CRPS I from an inactivity atrophy [162]. After 20, and up to 60, weeks during the dystrophic phase, the first two phases normalize while the delayed phase images show increased peri-articular uptake. After 60 weeks (atrophic phase), the flow and blood pool images show a decreased perfusion with normal uptake on delayed images. In CRPS I in children, decreased perfusion and uptake are the most common manifestations (Table 3.5), a pattern that is rarely encountered in adults [163].

Multiphase bone scanning is very sensitive for detecting early CRPS I [164]. The sensitivity ranges between 73% and 96%, while the specificity is 86–100%. Since it is a sensitive modality for the disease, it is excellent in excluding CRPS I as it has high negative predictive value [160, 162, 165].

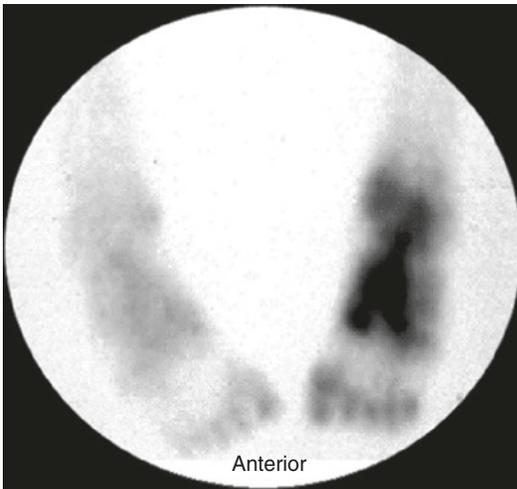

The bone scan assessment of the disease has been found to correspond closely to the clinical course of CRPS I and also in determining the stage of the disease. This is an important determination for therapeutic decisions. Bone scans have proved accurate, and useful, in staging the disease by evaluating the degree of vascular hyperemia on dynamic flow and early static images and the uptake on delayed static images [165]. Bone edema seen on MRI and scintigraphic radionuclide uptake remained positive for 6 months and were found to fade simultaneously thereafter [159].

The disease may progress and spread commonly to other sites [166–168]. Spread of pain can occur in 92% of patients [166, 169]. Maleki, et al reported independent spread in 70% of patients to another site [168]. Van Rijn found spread to contralateral limb in 53% and to ipsilateral limb in 30% of cases [167].

When bone scan was serially performed, it was found to be useful in predicting the response

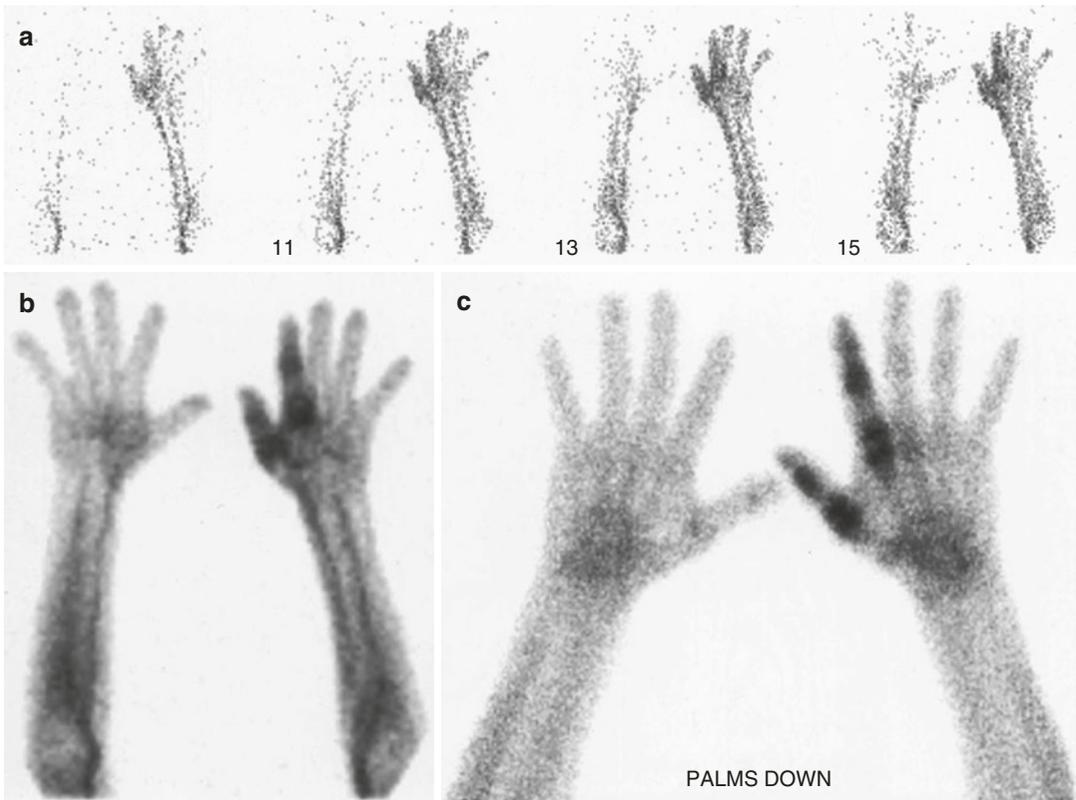

**Fig. 3.19** (a, b) Tc-99m MDP whole-body (a) and spot images (b) of a 40-year-old male patient with CRPS I (RSD) involving the right upper extremity with periarticular increased uptake in the shoulder, elbow, wrist, and hand joints regions. Increased periarticular uptake is also noted in the regions of the right hip and knee indicating possible involvement of the right lower limb as well

**Fig. 3.20** A spot image of Tc-99m MDP scan of a patient with CRPS I (RSD) involving left ankle and foot joints regions with increased periarticular uptake in these areas

to therapy. In patients with good and moderate response to treatment, the mean uptake ratios on bone images at initial scanning were significantly higher than in patients with poor outcomes. This indicates that multiphase bone scan has a prognostic value in CRPS I since marked uptake of the tracer indicates a better final outcome. At post-therapy final scans, the mean uptake ratios of patients with good, moderate and poor response to treatment did not differ significantly [142, 164].

Treatment may include non-pharmacologic therapy including Physical and occupational therapy [170], Psychological therapy [171], and/or Pharmacological medical treatment that may include corticosteroids, antioxidants, hyperbaric oxygen, botulinum toxin A, immunomodulation and surgery all has been reported in the literature with various effects [172–177].

**Fig. 3.21** (a–c) A three-phase bone scan of the hands of a 42-year-old male worker complaining of pain in his right hand. There is increased flow (a) and blood pool (b) activity in the radial aspect of the right hand with increased

periarticular delayed uptake around the joints of the thumb and index fingers (c) representing CRPS I (RSD) involving only part of the hand

**Table 3.5** Scintigraphic patterns of CRPS I (RSD)

Pattern on bone scans	Flow	Blood pool	Delayed images
<i>Typical pattern</i>	Increased	Increased	Increased
<i>Atypical patterns</i>			
RSD of children and adolescents	Decreased	Decreased	Increased
Paralysis, immobilization	Decreased	Decreased	Increased
Subacute	Normal	Normal	Increased
Late phase of RSD	Normal, decreased	Normal, decreased	Variable
Persistent use of painful limb	Decreased	Decreased	Decreased

Modified from [145]

### 3.8 Hypertrophic Osteoarthropathy

Hypertrophic osteoarthropathy is a rheumatic disorder characterized by bone pain, joint pain, and nearly always clubbing of fingers and/or toes. Two types of hypertrophic osteoarthropathy are recognized: primary and secondary. The primary type (also called pachydermoperiostosis) is less common and occurs in adolescence with spontaneous arrest of the process in young adulthood. A variant has been reported in a family [103]. The secondary form follows a variety of pathological conditions, predominantly intrathoracic. Lung cancer and other intrathoracic malignancies, benign lung pathologies, and cyanotic heart disease are common causes. Abdominal malignancies, hepatic and biliary cirrhosis, and inflammatory bowel disease are less common causes [178, 179, 180]. Nasopharyngeal carcinoma has also been reported as a cause [181].

The pathological condition is a form of periostitis and may be painful. Additionally clubbing of fingers and toes, sweating and thickening of skin may also be seen. Tubular bones may show periosteal new bone formation. This pathological feature explains the typical scintigraphic pattern of diffusely increased uptake along the cortical margins of long bones giving the appearance of “parallel tracks.”

The scintigraphic abnormalities are usually confined to the diaphyseal regions, although they may also occur in the epiphyseal bone (Fig. 3.22). The changes are usually bilateral but can be unilateral in approximately 15% of

**Fig. 3.22** Hypertrophic osteoarthropathy in a patient with lung cancer. Note the diffusely increased uptake in all bones of the lower extremities with a parallel track pattern in the femurs and tibiae

cases [180]. The tibia and fibula are affected most commonly, followed by the distal femur, radius, ulna, hand, foot, and distal humerus. The scapula, patella, maxilla, mandible, and clavicle are less commonly affected. The ribs and pelvis are rarely affected. The changes disappear after successful treatment of the lung cancer or other inciting pathology. The condition has no prognostic significance as there was no significant difference in survival between lung cancer patients with and others without hypertrophic osteoarthropathy [182]. The changes disappear following successful treatment of the inciting pathology, and scintigraphy is useful in evaluating the response to treatment of the condition [183].

### 3.9 Fibrous Dysplasia

Fibrous dysplasia is a developmental benign bone disorder that can affect any bone in the body. It is characterized by the presence of fibrous tissue containing trabeculae of non-lamellar bone (woven bone) which remains essentially unchanged and can be seen in lesions of long duration [184, 185]. The lesions cause thinning of the bone cortex and replacement of bone marrow. The condition may present as solitary lesion (monostotic) in 80–85% of cases, or with multiple foci (polyostotic). Although fibrous dysplasia is usually sporadic, in 3% of polyostotic fibrous dysplasia it is associated endocrinopathies with cafe-au-lait pigmentation and multiple endocrine hyperfunction, most commonly seen as gonadotropin-independent precocious puberty in girls, Cushing's syndrome, and is called the McCune-Albright syndrome [186]. Isolated endocrinopathy without the full McCune-Albright syndrome precocious puberty in girls may also occur including hyperthyroidism, hyperparathyroidism: renal stones, calcinosis, acromegaly, diabetes mellitus, Cushing's syndrome, and growth retardation.

The etiology of the condition is not entirely clear; however, there is growing evidence of a genetic mechanism. The syndrome is believed to be due to a constitutively activating mutation in

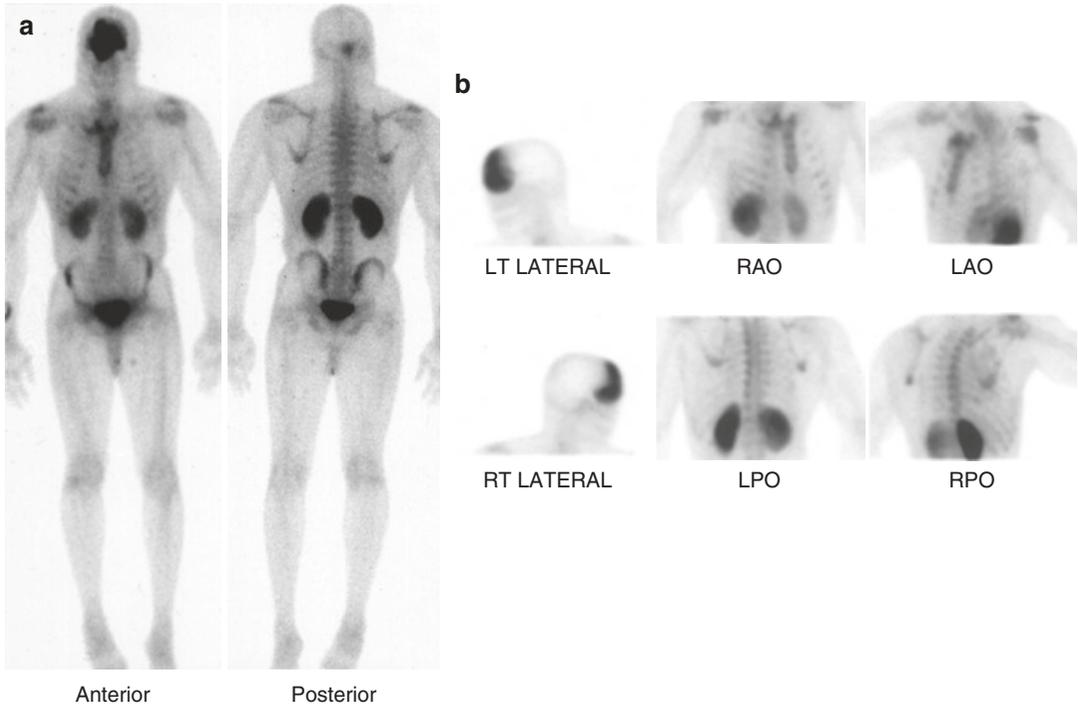

**Fig. 3.23** A standard radiograph of a patient with fibrous dysplasia of the proximal right femur. Note the bone expansion

the gene (*GNAS1*) encoding the subunit of the signal-transducing guanine nucleotide-binding protein (G protein).

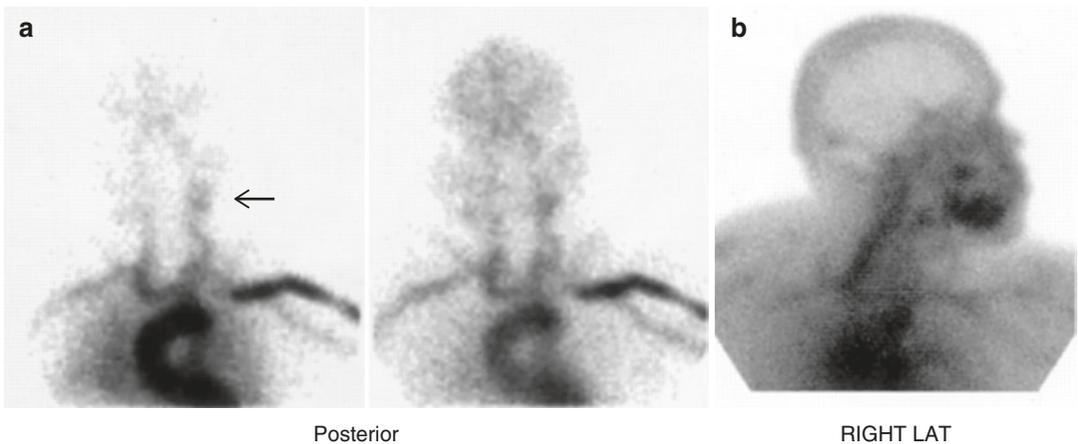

Standard radiographs show lucent areas with various amounts of ossification and cyst formation and may show expansion (Fig. 3.23). Fibrous dysplasia, in general, appears as an area of markedly increased uptake on bone scintigraphy (Fig. 3.24). Therefore, the possibility of fibrous dysplasia is likely to be excluded when the lesion shows no, or slightly increased, uptake [187]. The uptake of the radiotracer in the affected bones (commonly the craniofacial

bones, scapulae, ribs, pelvic bones, spine, and extremities) usually occurs in an asymmetric pattern and may be unilateral in the polyostotic variant. Bone scan is helpful in confirming the diagnosis and establishing the extent of bone

involvement (Figs. 3.25 and 3.26), which is usually greater than expected on the basis of symptoms and radiographic findings [188]. Single-photon emission computed tomography has been reported to provide additional

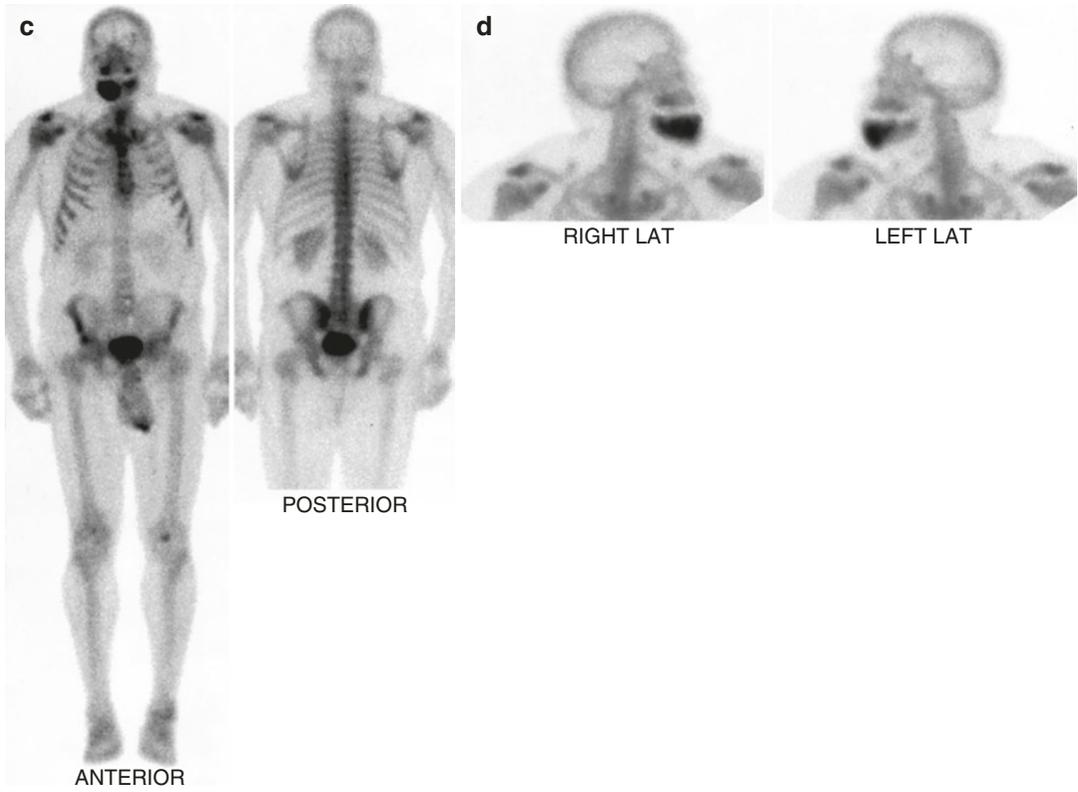

**Fig. 3.24** (a, b) Whole-body and spot bone scan images of a 38-year-old male show intensely increased uptake in the frontal bone of the skull involved with fibrous dysplasia

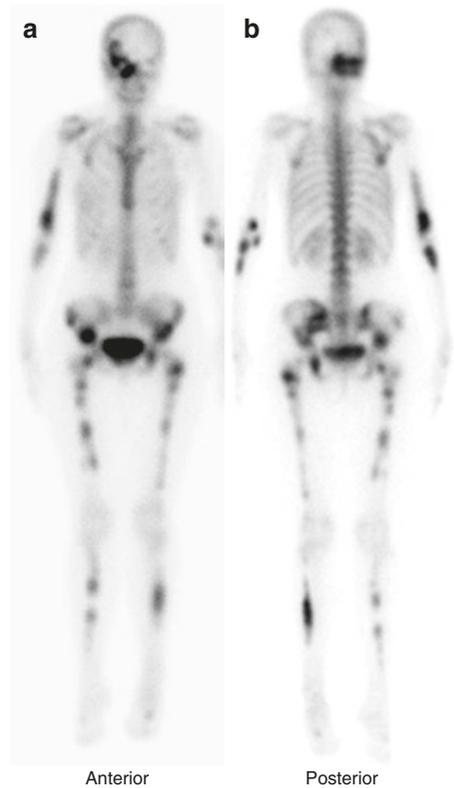

**Fig. 3.25** (a–d) Fibrous dysplasia. Three-phase bone scan of a 61-year-old man with history of pain in the right mandible for years. There is increased flow (arrow) to the region of the right mandible (a) and clearly increased

blood pool activity (b) to the same region. Whole-body delayed scan (c) and spot images of the skull (d) show intensely increased uptake in the right mandible. Biopsy showed fibrous dysplasia

**Fig. 3.25** (continued)

**Fig. 3.26** Tc-99m MDP whole-body scan of a 19-year-old girl demonstrating the scintigraphic pattern of polyostotic fibrous dysplasia

information particularly for lesions in cranial bones [189].

Images of fibrous dysplasia on computed tomography (CT), or MRI vary depending on the relative proportions of the fibrous and osseous components [190]. Helical CT is the optimal method for the evaluation of the skull lesions [191].

Using MRI, the condition shows a low signal intensity on T1-weighted images, while on T2-weighted images, it appears as either hyperintense or hypointense [192]. MRI could be particularly useful in the identification of a no-touch lesion, allowing avoidance of an unnecessary bone biopsy [193].

FDG PET studies are typically negative. Occasionally positive even intense uptake has been reported in case reports. It was proposed that the growth of fibrous dysplasia to be based on acceleration of bone mineral turnover without an increase in glucose metabolism.

Variability of FDG uptake may be due to differing numbers of actively proliferating fibroblasts [194].

A report of F-18 FDG-PET on fibrous dysplasia of the craniofacial bone showed signs of the acceleration of bone mineral turnover with an increased uptake on bone scintigraphy without elevated glucose utilization on fluorine-18-FDG PET. Accordingly it has been proposed that the growth of fibrous dysplasia appears to be based on the acceleration of bone mineral turnover without an increase in glucose metabolism [194].

---

## 3.10 Other Metabolic and Endocrine Conditions

### 3.10.1 Hypothyroidism

Hypothyroidism can be associated with certain skeletal manifestations, particularly in children. In adults they are usually mild. In hypothyroidism the rate of bone turnover is decreased and the calcium metabolism becomes abnormal, which may result in a slightly increased bone mass [195]. Ectopic calcifications in the soft tissue may also be seen.

### 3.10.2 Hyperthyroidism

Hyperthyroidism is associated with accelerated bone maturation in children and increased bone turnover and remodeling in adults. In adults over 50 years, a progressive osteoporosis that is more rapid than the postmenopausal type is seen among patients with hyperthyroidism. Treatment of hyperthyroidism leads to partial recovery of bone mineral content [195].

### 3.10.3 Fluoride Toxicity

Fluoride accumulates in the bone and, when present in abundant amounts, induces modifications of bone remodeling and causes osteoblastic stimulation and trabecular fragility [196, 197]. On scintigraphy this causes diffusely increased uptake of the radionuclide, stress fractures with focal uptake, or a pattern of osteomalacia which occurs when impaired renal function is present (even if mild) [198].

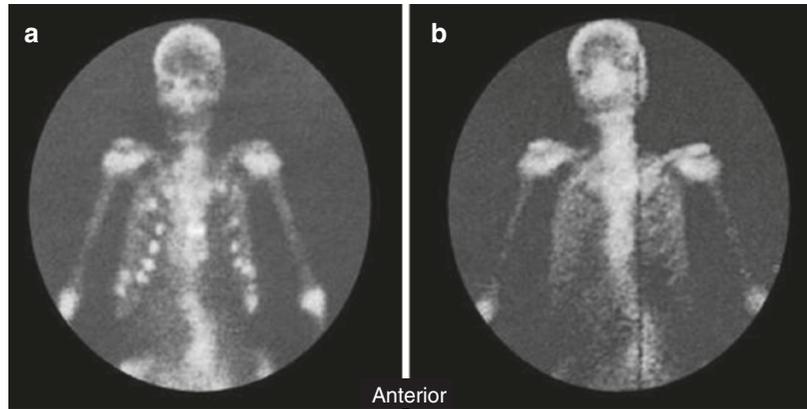

### 3.10.4 Aluminum Toxicity

Excess aluminum leads to blocking of mineralization by the aluminum deposits at the calcification sites. This can occur, for example, in association with renal dialysis using dialysis water containing a high aluminum content, or the use of aluminum-containing antacids, and can also lead to osteomalacia (Fig. 3.27) [199–200]. The scintigraphic pattern of this condition is distinctive, and bone scanning typically shows a lack of tracer uptake by bone and excessive uptake by soft tissue which reverts either to normal or to the pattern of hyperparathyroidism after treatment [201].

### 3.10.5 Hypervitaminosis A

Hypervitaminosis A is known to promote skeleton fragility by increasing osteoclast formation and decreasing cortical bone mass [202]. Hypervitaminosis A may cause hyperostosis of the diaphysis of long bones. It is seen scintigraphically as periosteal uptake in the femur, tibia, fibula, ulna, and/or sutures of the skull.

**Fig. 3.27 (a–b)**  
Tc-99m MDP bone scan of a patient with antacid-induced osteomalacia (a) before and (b) after 1 year of treatment with calcium phosphate, vitamin D, and sodium fluoride. Note the increased uptake in the costochondral junctions (from [200] with permission)

### 3.11 Osteopetrosis

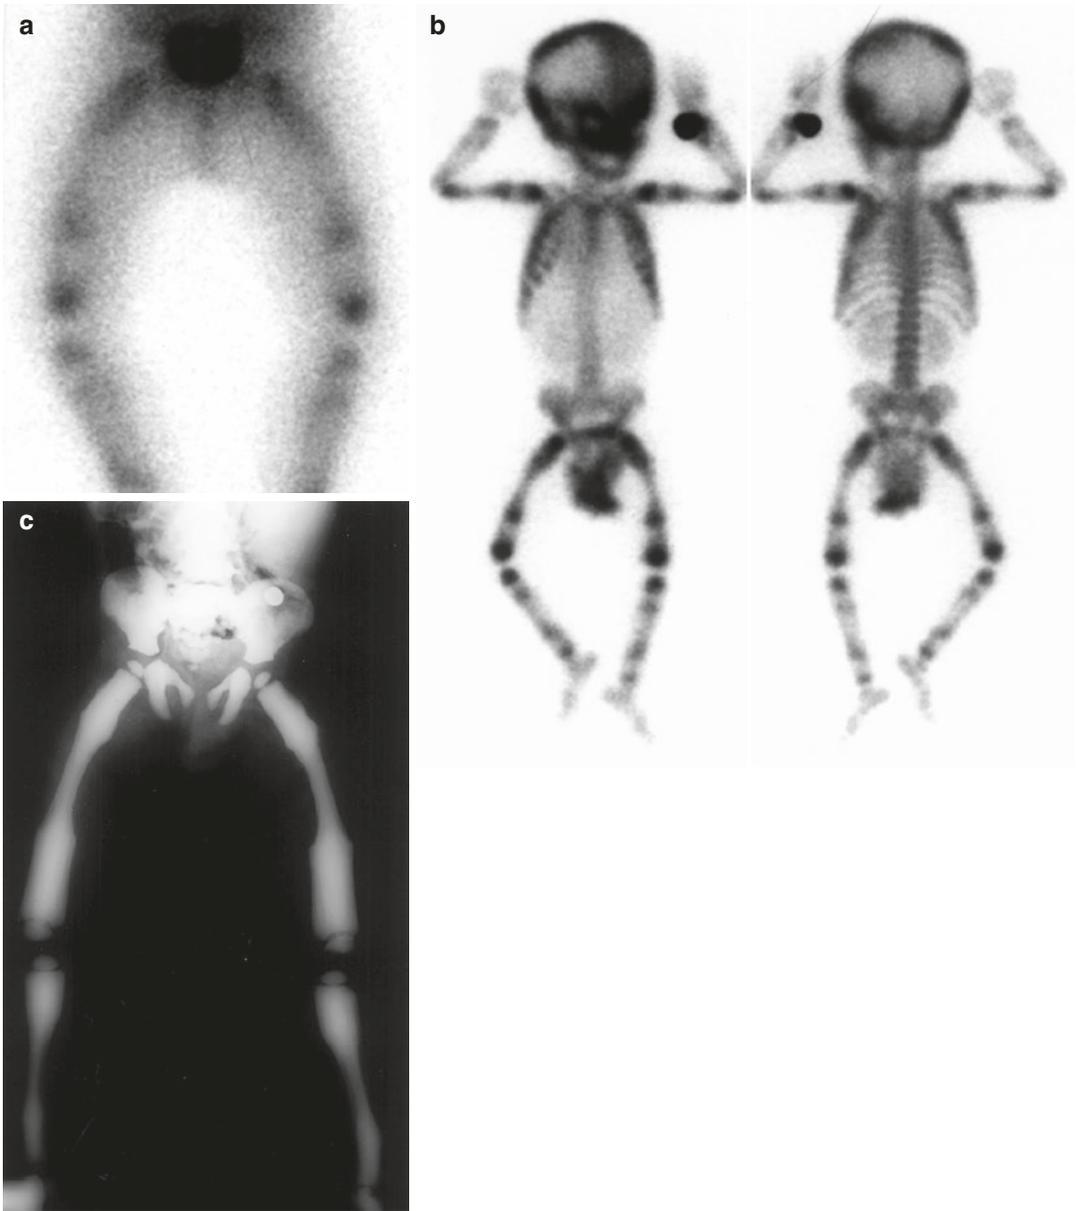

Osteopetrosis is a rare metabolic bone disease characterized by a generalized increase in skeletal mass. It is an inherited disorder characterized by a congenital defect in the development or function of the osteoclasts leading to defective bone resorption. The impaired bone resorption prevents formation of bone marrow cavities, causes delayed or absent tooth eruption and results often in abnormally shaped bones. The infantile malignant form is an autosomal recessive condition and usually results in death in the first years of life. The autosomal dominant type is seen in older children and adults. In recent years the genetic effects of some osteopetrotic mutations have been identified. Colony-stimulating factor 1 (CSF-1), the growth factor for cells of the mononuclear phagocytic system, which is also essential for the development of osteoclasts, was found to be deficient in osteopetrotic mice [203]. Standard radiographs show a characteristic pattern of generalized sclerosis of bones. On scintigraphy, there is a diffuse increased uptake that may also be a superscan [204] and can show nonuniform uptake with foci of hyperemia [205] (Fig. 3.28).

### 3.12 Medullary Diaphyseal Sclerosis (Medullary Diaphyseal Stenosis or Hardcastle Syndrome)

This is a hereditary condition believed to be transmitted within families by autosomal dominant inheritance [206]. The condition is characterized by multiple bone infarcts, cortical bone thickening, and medullary stenosis along the metaphyseal diaphyseal segments. It can be associated with malignant transformation with development of malignant fibrous histiocytoma [207, 208]. Bone scintigraphy has a pattern of increased uptake along the long bones with an irregular and nonuniform pattern and the malignant lesion can be identified using Tl-201 [209] (Fig. 3.29) or, potentially, FDG PET.

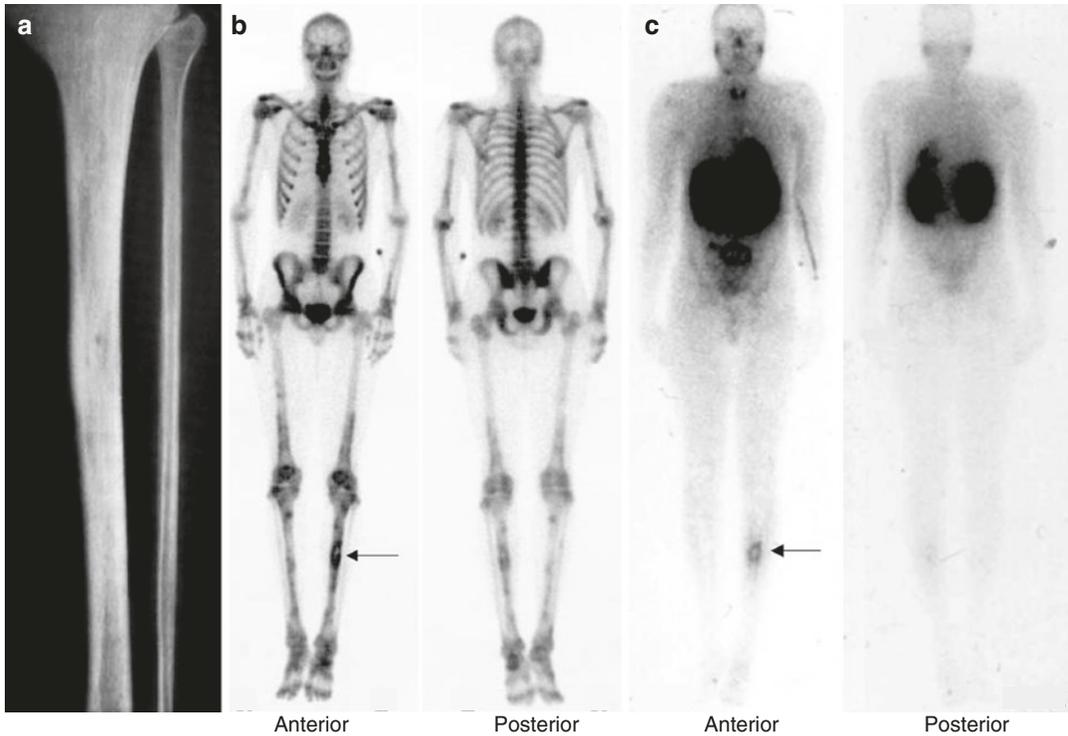

### 3.13 Gorlin's Syndrome

Gorlin's syndrome is an autosomal dominant condition with variable features involving many organs including the skin, teeth, eyes, central nervous system, endocrine system, and skeletal system [210, 211]. Nevoid basal cell carcinomas are the most important skin lesions. Mandibular and

**Fig. 3.28** (a, b) Osteopetrosis showing nonuniform blood pool activity in the lower extremities with foci of hyperemia (a). Delayed whole-body scan (b) shows diffusely increased uptake in the long bones of the lower

extremities and humeri. Standard radiograph (c) of the lower extremities show diffuse sclerosis in the femurs and tibiae (from [205] with permission)

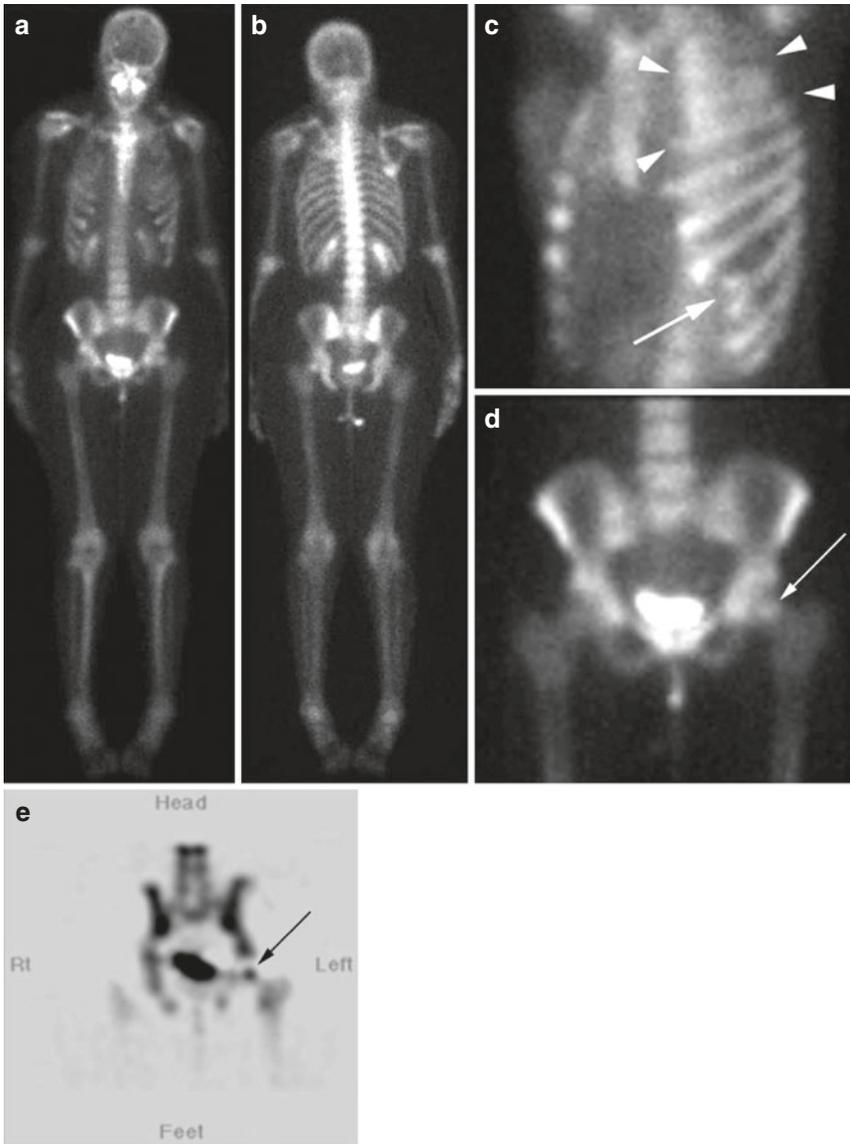

**Fig. 3.29** (a–c) Hardcastle syndrome. A standard radiograph of the left tibia and fibula of a 19-year-old male patient who complained of pain in his left mid tibia. There is marked sclerosis of the tibial shaft. Whole-body bone scan (b) shows nonuniform increased uptake in both

femurs and tibiae. TI-201 image (c) obtained for further evaluation of the mid-left tibial uptake shows focally increased uptake in the left tibia proven later to be malignant fibrous histiocytoma in this patient with Hardcastle syndrome (from [209] with permission)

maxillary keratocysts are the most important odontogenic feature and are of fundamental importance for the diagnosis. Calcification of the falx cerebri and tentorium cerebelli is the most typical CNS feature. Skeletal abnormalities include bifid, missing or fused ribs, frontoparietal bossing, dysplastic scapula leading to shoulder deformity (Sprengel's deformity), spina bifida, polydactyly of the hands and feet, and sclerotic bone lesions of the pelvis and lumbar vertebrae [211]. Awareness of the condition helps its identification on imaging; radiography and scintigraphy can show many of the typical features (Fig. 3.30).

### 3.14 Progressive Diaphyseal Dysplasia (Camurati-Engelmann Disease)

A rare hereditary disorder characterized by progressive bone formation along the periosteal and endosteal surfaces of long tubular bones with widening of their shafts. Other bones are also involved including the skull. The disease is an autosomal dominant and is usually manifested in childhood but can present later. The most frequent symptoms are pain and muscle weakness. Deafness can also occur due to otosclerosis. On bone scan there is diffusely increased uptake in

**Fig. 3.30** (a–e) Gorlin’s syndrome. Whole-body bone scan (a, b) of a 31-year-old female known to have Gorlin’s syndrome. Note the increased uptake in the maxillary deformed left scapula. Deformed left lower ribs are also seen which are clean on LAO (e) showing a bifid rib

(arrow) and short ribs (arrow heads). Increased uptake in the left hip focally is seen also in the whole body and is further clarified on spot planar image (d) and SPECT coronal section (e)

the skeleton with relative sparing of the spine, hands, and feet. The degree of uptake varies and widening of the long bones may be clearly apparent.

Radiologically there is sclerosis with focal lytic areas that correspond to foci of more intense uptake on bone scan [212, 213].

---

### 3.15 Infantile Cortical Hyperostosis (Caffey-Silverman Syndrome)

Infantile cortical hyperostosis (ICH) is a rare and mostly self-limiting condition affecting young infants. It is characterized by acute inflammation of the periosteum and the overlying soft tissue and is accompanied by systemic changes of irritability and fever [214]. Pain may be severe enough to result in pseudoparalysis.

Diagnosis may be delayed as this disorder mimics clinically osteomyelitis, hypervitaminosis A, rickets, scurvy, bone tumors, and child abuse. The etiology is unknown but could be familial and few familial cases with autosomal dominant and recessive patterns have been described [215]. Radiography is the most valuable diagnostic study in this condition. Cortical new bone formation (cortical hyperostosis) beneath the regions of soft tissue swelling is the characteristic feature. Although these findings in an infant can also be observed in rickets and scurvy, the absence of epiphyseal or metaphyseal alterations and the resolution of clinical and radiographic features over a period of time in patients with ICH allow its differentiation from these disorders. In cases of child abuse, in addition to calcifying subperiosteal hematomas, microfractures and metaphyseal

irregularities are seen. In hypervitaminosis A, there is a metaphyseal predilection, mandibular involvement is rare, and serum vitamin A levels are elevated [215]. The existence of two forms of Caffey disease has been suggested, a classical mild infantile form delineated by Caffey and Silverman and a severe form with prenatal onset [216, 217]. Caffey disease is mostly self-limiting and resolves within 6 months to 1 year and may not need any treatment [218].

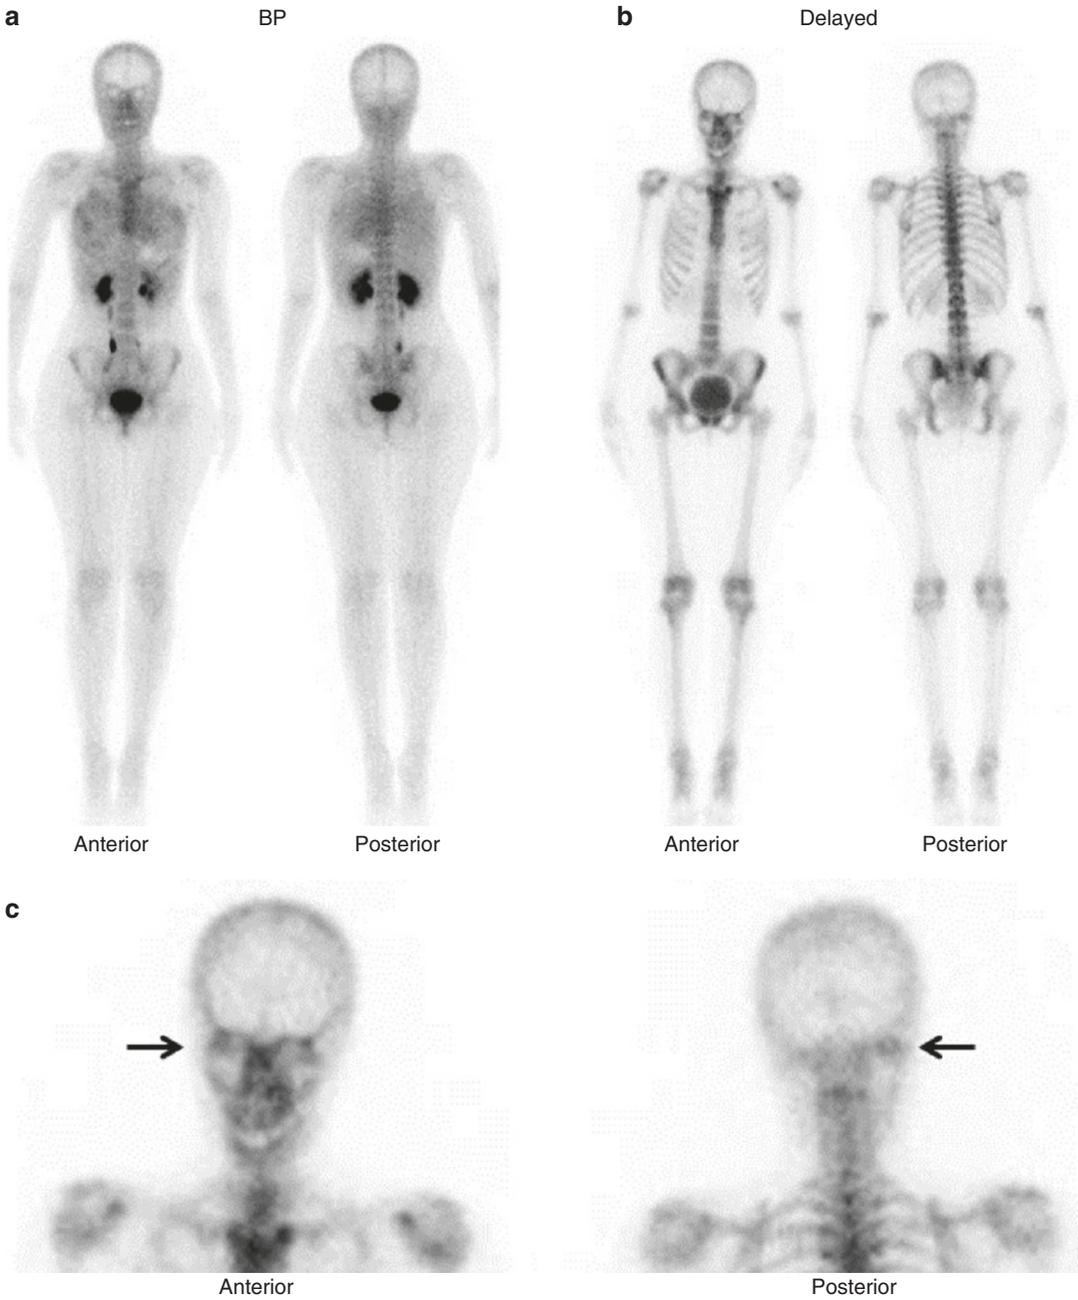

The condition can involve any bone except vertebrae and phalanges. Typically the subperiosteal new bone formation involves invariably the mandible (see Chap. 2, Fig. 2.38) followed by clavicle ribs and diaphysis of the long bones.

The classic extensive new bone formation which appears as irregular periosteal increased uptake on bone scan [219]. Agrawal reported patchy FDG uptake particularly in long bones in one patient with the disease [216]. The tibia is the predominant bone to be affected in the familial form, while the mandible is mostly affected in the sporadic form [220].

---

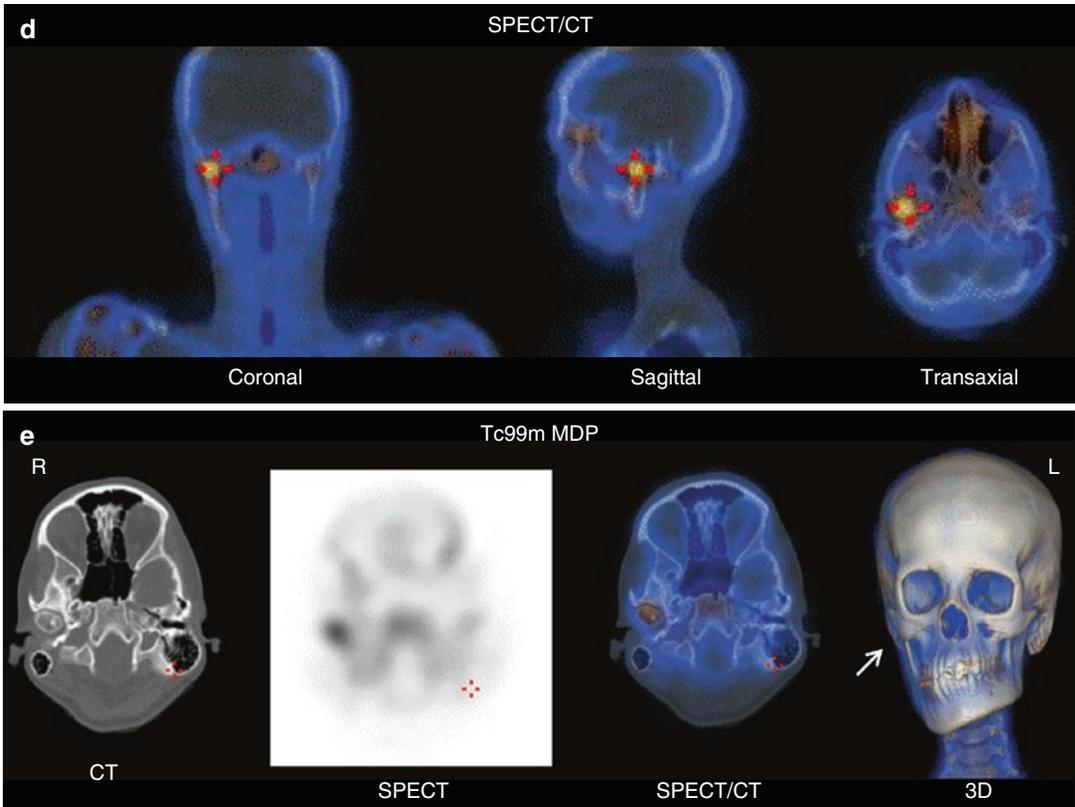

### 3.16 Mandibular Condylar Hyperplasia

Unilateral condylar hyperplasia is a developmental abnormality leading to asymmetry in condyles and may result in facial asymmetry. Increased uptake in one side on bone scan is seen and is better seen on SPECT or SPECT/CT (Fig. 3.31). F18 PET/CT is also found useful in diagnosis and evaluating activity of the condition. Quantitation of uptake has been suggested to be useful in confirming the diagnosis and guiding the treatment in non growing patients [221–225].

**Fig. 3.31** Tc99m MDP bone scan of a 21 year old female with enlargement of the right mandible. Whole body blood pool images (a) appear unremarkable. Delayed images (b) show mild asymmetry with more uptake in the right

mandibular condyle region seen better (arrows) on magnified images (c). SPECT/CT study (d, e) shows clearly the increased uptake in the right mandibular condyle and mandibular asymmetry noted on the 3 D image (arrow).

Nuclear medicine has a limited but important role in trauma and its complications. It is particularly useful and indicated in radiologically occult acute fractures including those in children who are the victims of physical abuse and in stress fractures. It is also used in the assessment of physeal closure and stimulation after trauma and to predict the outcome of leg length by semiquantitative analysis. Bone scintigraphy can also detect chronic ligament and acute and chronic meniscal lesions. Certain technical considerations, particularly related to meticulous positioning, the use of single-photon emission computed tomography (SPECT), and the use of magnification during acquisition, are important to maximize the diagnostic yield of scintigraphic modalities, particularly bone scan in traumatic disorders. SPECT/CT has become an important tool in the evaluation and management of a wider variety of orthopedic patients including many traumatic conditions.

## 4.1 Introduction

Despite advances in morphological modalities and nuclear medicine conventional, bone scintigraphy remains an important imaging technique in trauma since it is sensitive in detecting stress fractures and in assessing suspected injuries that are difficult to see on plain films. It is noninvasive and easily applied, and being very sensitive, a normal scintigram excludes pathophysiological

conditions or mechanical disorders of the bones and joints. Trauma to the musculoskeletal system may affect bone, cartilage, muscles, and joints. To each of these structures, trauma may cause immediate damage and late changes. Trauma is a common condition that affects all age groups. Additionally, sports injuries are becoming more frequent because of the increasing recruitment of individuals into fitness programs from the population that live a sedentary lifestyle. This is in addition to the elite athletes engaged in high-level fitness programs. Both groups are prone to injury for different reasons, the former from unaccustomed exercise and the latter from chronic overuse injuries. The childhood and adolescent athlete fall into a separate category due to the unique patterns of injury that affect the growing but immature skeleton. Although scintigraphy does not play a major role in the diagnosis and management of most fractures, it is valuable in certain situations such as occult fractures of the ribs and small bones of the hands and feet, fractures of physically abused children, and delayed union or non-union of fractures and in assessing the healing of fractures and bone grafts. Bone scintigraphy, however, is often used to detect stress fractures and can also play a role in the follow-up of these injuries.

## 4.2 Pathophysiology

### 4.2.1 Acute Fractures

Fracture is defined as a break in the continuity of a bone. Classification of fractures is not an easy issue since many of the classifications in current use mainly focused on particular anatomical locations, such as the acetabulum or the talar bone. Classifying fractures is an abbreviated way of describing the configuration of the fracture which can be used by clinical orthopedics to guide treatment and predict prognosis and possible complications [1]. For the purpose of simplification and for the purpose of this text, fractures generally can be classified according to several features (Table 4.1). Based on the extent of the break, fractures are classified as complete or incomplete. A complete fracture breaks the bone

**Table 4.1** Classifications of fractures

Based on extent of break:
Complete: bone is broken all the way through
Incomplete: bone is still one piece
Based on skin condition:
Open: broken skin
Closed: intact skin
Based on resulting number of bone fragments:
Comminuted: multiple bone fragment
Non-comminuted: only two fragments
Based on direction of fracture line:
Linear: line is parallel to the long axis of bone
Oblique: line is at oblique angle to the shaft of the bone
Spiral: line encircles the bone
Transverse: line is perpendicular to the long axis of bone
Based on cause of fracture:
Excessive force on normal non-violated bone: classic acute fracture
Pathological fracture: break at the site of pre-existing pathology
Stress fractures: localized or generalized
Fatigue fractures: abnormal stresses applied to normal bones
Insufficiency (fragile) fractures: usual stresses to abnormal bones

all the way through, while with incomplete fracture the bone is broken but stays as one piece. Fractures are also classified into open (previously called compound) if the skin is broken and closed (previously called simple) when the skin at the site of fracture is not broken [2]. The pattern of a fracture depends on the mechanism of injury. A compressive load produces compaction or oblique fracture. A bending load has a tendency to produce flat transverse fractures; however, a bending load on one side only is associated with compression on the other side, which may affect the pattern of the fracture. A torsional force tends to produce spiral fractures.

Other classifications are based on the number of bone pieces and the direction of the fracture line and other factors (Table 4.1). Pathological fractures occur at the sites of pre-existing abnormalities that weaken bone. A minimal force that usually would not cause a fracture of a normal bone may produce a pathological fracture. Transchondral fractures (osteochondritis dissecans) represent fragmentation and separation of portions of cartilage or cartilage

and bone. This type is most prevalent in adolescents and occurs typically in the head of the femur, ankle, kneecap, elbow, and wrist.

Bone contusion (bone bruise) is a term describing microfractures of the trabecular bone and edema or hemorrhage within the bone marrow. It normally resolves spontaneously within 8–12 weeks.

### 4.2.2 Stress Fractures

Stress fractures occur due to repeated stress; each episode is less forceful than that needed to cause acute fractures of the bony cortex. If this occurs in normal bones, the resulting fractures are called fatigue fractures, while if they occur in abnormal bones (e.g., osteoporosis), they are termed insufficiency fractures. These fractures commonly occur in the vertebrae, pelvis, and ribs due to trivial, commonly unnoticed trauma since the bones are fragile. Fatigue fractures are common in athletes, military recruits, and dancers with up to 95% affecting the lower extremities [3] (Table 4.2). Stress fractures are not, as previously thought, due to repeated traumatic microfractures; they are a focal area of increased bone turnover secondary to the repeated stress. The process starts with resorption cavities before being coupled by an osteoblastic response to replace the absorbed bone [4]. The process of rarefaction is faster than the osteoblastic process and will progress if the individual continues the stressful activity and trauma resulting in complete fracture through the zone of rarefaction. With repeated loading bone develops loss of its stiffness and strength. If scintigraphy is performed in the acute phase of less than 4 weeks, the flow and blood pool images show increased activity. Later, only delayed uptake will be seen while flow and blood pool activity gradually normalize.

Because bony remodeling continues for an extended time period, focal uptake on the delayed images resolves last. Uptake gradually diminishes in intensity over 3–6 months, but some increased uptake can last up to 1 year, even in uncomplicated stress fractures [5]. A grading system, based on the scintigraphic appearance, stress fractures are classified into

**Table 4.2** Location of stress fracture by activity

Location	Activity or event
Sesamoids of metatarsal bones	Prolonged standing
Metatarsal shaft	Marching; stamping on ground; prolonged standing; ballet; postoperative bunionectomy
Navicular	Stamping on ground; marching; long-distance running
Calcaneus	Jumping; parachuting; prolonged standing; recent immobilization
Tibia: mid- and distal shaft	Long-distance running
Proximal shaft (children)	Running
Fibula: distal shaft	Long-distance running
Fibula: proximal shaft	Jumping; parachuting
Patella	Hurdling
Femur: shaft	Ballet; long-distance running
Femur: neck	Ballet; marching; long-distance running; gymnastics
Pelvis: obturator ring	Stooping; bowling; gymnastics
Lumbar vertebra (pars interarticularis)	Ballet; lifting heavy objects; scrubbing floors
Lower cervical, upper thoracic spinous process	Clay labeling
Ribs	Carrying heavy pack; golf coughing
Clavicle	Postoperative radical neck
Coracoid of scapula	Trap shooting
Humerus: distal shaft	Throwing a ball
Ulna: coronoid	Pitching a ball
Ulna: shaft	Pitchfork work; propelling wheelchair
Hook of hamate	Holding golf club; tennis racquet; baseball bat

Data adapted from [3, 123, 148, 168]

milder or more severe. This grading system is shown on Table 4.3 [6]. The minimally symptomatic grade 1 or grade 2 stress fractures typically resolve more quickly and completely. This grading system can assist in prescribing the requisite rest and rehabilitation intervals [7]. The pattern of uptake of stress fractures is different from the pattern of a shin splint, which is another consequence of stress and occurs in the same patient population as fatigue fractures. Shin splints typically show normal flow and blood

pool images, with an elongated linear pattern of increased uptake on delayed images. They are most commonly found in the tibiae and may coexist with fatigue fractures in the same patient. The pattern seen with shin splints is due to subperiosteal bone formation [8].

Most stress fractures affect the lower extremity; however, injuries to the upper extremities account for more than 25% of all sports-related injuries but receive disproportionately less attention than lower extremity injuries [9].

### 4.2.3 Spondylolysis

Spondylolysis is a condition in which there is a loss of continuity of bone of the neural arch of the vertebra. The etiology of spondylolysis remains controversial. This is believed to be due to repetitive trauma or more probably stress related to flexion, extension, and rotation superimposed on congenital anatomic variation [10, 11]. The gap, or loss of continuity, most commonly occurs at the junction of the lamina when the vertebra is viewed from above, or between the superior and inferior articular processes (pars interarticularis or facetal joints) when viewed from the side (Fig. 4.1a). This condition affects mostly lumbar spine although rarely it affects other spine segments particularly cervical spine (cervical spondylosis) [12]. It most commonly affects the fourth and fifth lumbar vertebra, may or may not be symptomatic, and usually does not result in any neurological deficit but is a common cause of low back pain, particularly in children and young adults. The diagnosis is usually made using standard radiographs as the initial modality in patients with back pain. However, the condition is frequently not visible on radiographs [13]. Multidetector CT scan is more sensitive than radiographs in identifying the condition and in evaluating the size and extent of the fracture. Additionally it is the best modality for fracture healing follow-up [14]. The condition is missed even with CT in up to 15% of cases [13, 15, 16]. MRI using high-resolution multiplanar technique has been used to accurately identify pars interarticularis defects [14], and in a study by Campbell et al., MRI correlated with CT and SPECT imaging for the diag-

nosis of juvenile spondylolysis and they suggested that MRI can be used as an exclusive imaging modality [17]. However, the study did not compare MRI with SPECT/CT.

Scintigraphy is reserved for the detection of radiologically occult cases and for assessing the metabolic activity of the condition. Typically, focally increased uptake is seen in the region of pars interarticularis (Fig. 4.1b–e). SPECT is much more sensitive than planar imaging in detecting this abnormality. SPECT/CT is superior to SPECT and lesions are better visualized. In addition SPECT/CT provides information concerning metabolic activity which helps determine prognosis regarding healing process and helps in differentiating it from other conditions such as degenerative [16]. The treatment of this condition is usually conservative and the use of back support usually corrects the problem.

### 4.2.4 Spondylolisthesis

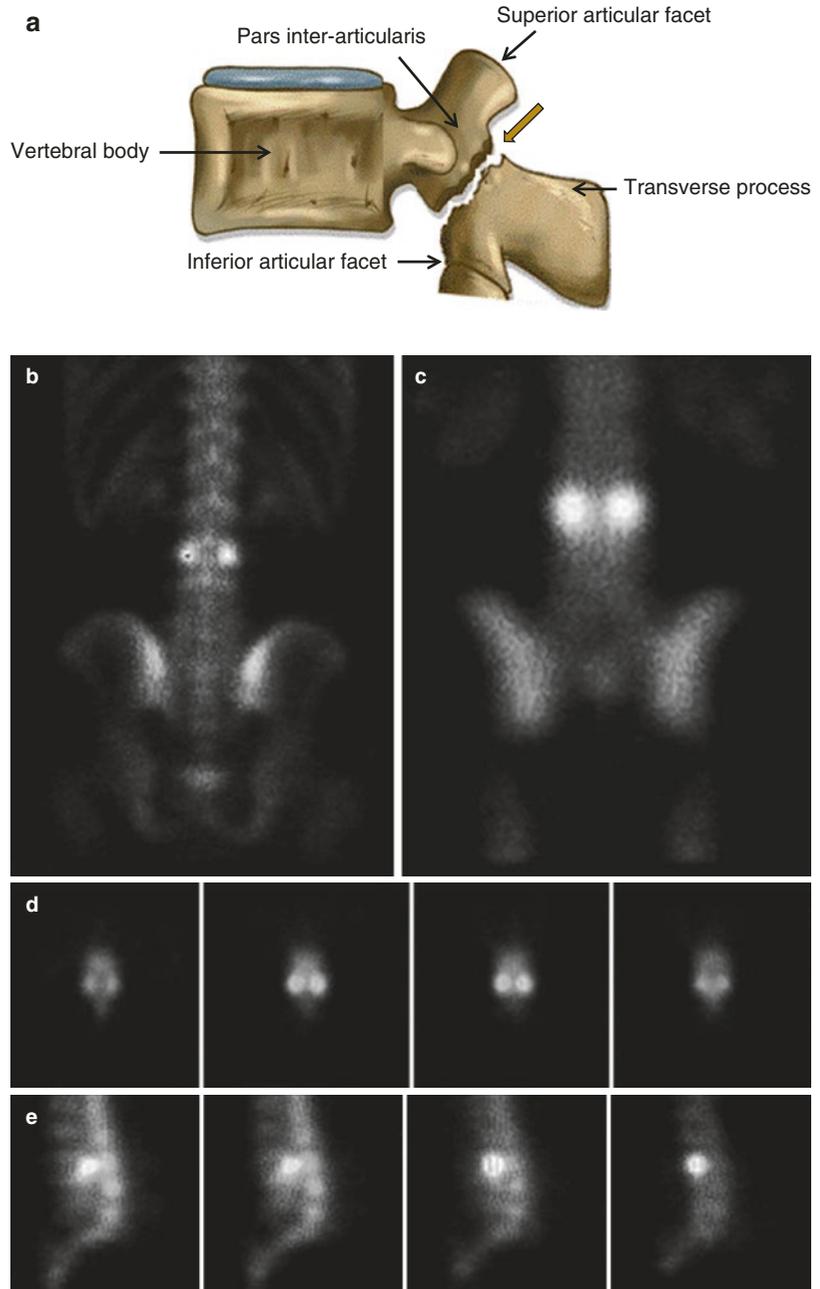

Spondylolisthesis is the forward or occasionally backward movement of one vertebra on another (Fig. 4.2), usually as a result of fracture of the neural arch. It is again most commonly seen in the fifth lumbar vertebra in which case there is a forward shift of L5 on the sacrum. It is less commonly seen at L4. In addition to the acquisition using parallel-hole high-resolution collimators, pinhole collimators and/or SPECT again are needed since they are more sensitive. SPECT/CT is now much better than planar and SPECT imaging since it provides more information. MRI is useful to evaluate the disk and nerve roots in patients with spondylolysis with or without spondylolisthesis [10].

### 4.2.5 Fracture Healing

Fracture union is defined as sufficient growth of the bone across the fracture line. The healing process of a fracture is outlined as follows:

1. There is formation of a hematoma following a fracture event: When a fracture disrupts the periosteum and blood vessels in the cortex, marrow, and the adjacent soft tissue, bleeding occurs and a hematoma forms between the

**Fig. 4.1** (a) A diagram illustrating the site of injury causing spondylolysis (*red arrow*) as seen from the lateral view of the vertebra. (b) A spot planar image of the pelvis and lumbar spine showing increased uptake in L3 vertebra affected by spondylolysis. Representative coronal section of SPECT study (c–e) shows the abnormalities

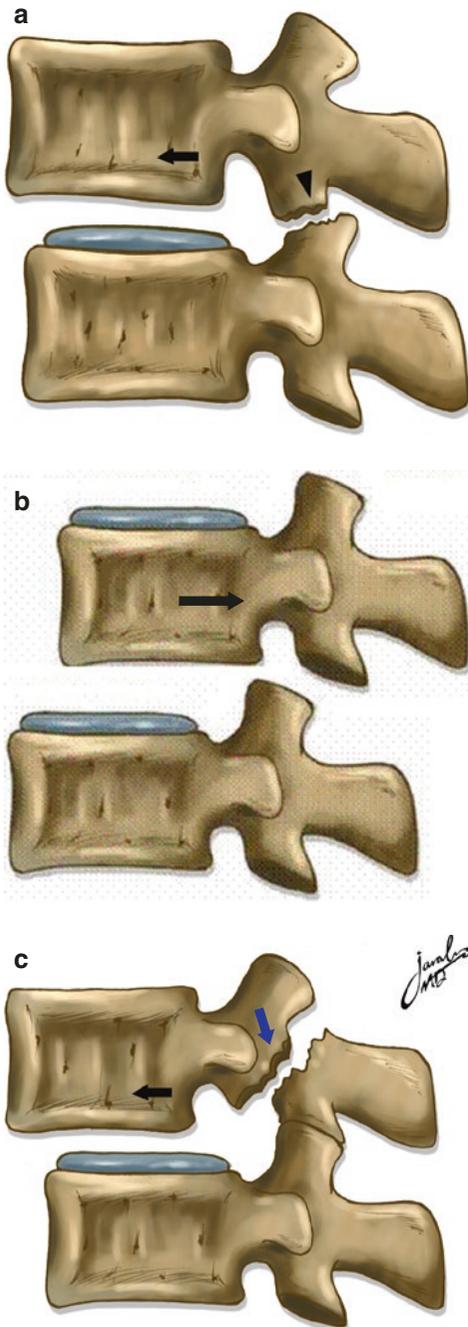

bony fracture ends, beneath the periosteum, and within the medullary cavity.

2. Invasion of granulation tissue occurs into the hematoma: Necrosis of the bone tissue adjacent to the fracture takes place immediately. This necrotic tissue, along with the effect of the traumatic injury, induces an inflammatory response with features of acute non-specific inflammation, including vasodilatation, extravasation of plasma and leukocytes, and infiltration with

leukocytes. Within 48 h, blood flow to the entire bone increases with organization of the hematoma around the broken ends of the bone into a fibrous network [18].

3. A procallus is formed along the outer surface of the shaft and over the broken ends of the bone by the bone-forming cells in the periosteum, endosteum, and marrow.
4. The callus starts to form with synthesis of collagen and matrix by osteoblasts (soft callus).

**Fig. 4.2** (a) Spondylolisthesis without spondylolysis (degenerative anterior spondylolisthesis). Apophyseal joint osteoarthritis (*arrowhead*) allows the inferior articular processes to move anteriorly, producing forward subluxation (*arrow*) of the superior vertebra onto the inferior vertebra. (b) Spondylolisthesis without spondylolysis but with backward subluxation (*arrow*) of the superior vertebra. (c) Spondylolisthesis with spondylolysis. Bilateral defects through the pars interarticularis (*blue arrow*) allow the usual anterior displacement (*black arrow*) of the vertebral body onto its neighbor. The alignment of the apophyseal joints is normal (adapted and modified from [5])

**Table 4.3** Factors affecting fracture healing

1. Patient age: non-union is rare in children unless there is another condition present as neurofibromatosis, infection, or extensive soft tissue damage
2. Weight bearing: stimulates healing of fractures
3. Fixation: stimulates union but does not accelerate repair itself
4. Nerve damage: is associated with rapid union with unknown mechanism
5. Damage of intramedullary canal and nailing: this may lead to delayed repair or to extensive reactive osteogenic activity
6. Blood supply: interrupted blood supply may cause delayed healing
7. Infection: may lead to delayed healing
8. Excessive use of steroids can cause delayed healing
9. Extent of fracture: severely displaced fractures, open fractures, loss of fragments, and extensive soft tissue damage cause delayed healing

Mineralization with calcium deposition (ossification) follows to complete the formation of calluses (woven bone).

5. Remodeling: Any unnecessary callus is resorbed as the process of healing continues, trabeculae are formed, and remodeling leads to alignment of the cortical bony margins and marrow cavity. The bone accordingly heals by forming new tissue rather than scar tissue.
6. Modeling: Reshaping of cortex.

Several factors affect this fracture healing process (Table 4.3), and if disturbances happen, delayed non- or malunion can result. *Delayed union* indicates that union does not occur at the expected time. This is difficult to determine objectively and varies with the site of fracture, although it is usually 3–4 months after the fracture. *Non-union* indicates the failure of the bone ends to grow together. Instead of new bone, dense fibrous tissue fills the gap between the broken ends and uncommonly it may be filled by fibrocartilaginous tissue. Necrotic tissue is not seen unless infection is present in the area of non-union. Delayed union and non-union are commonly seen in the tibia, fibula, and scaphoid bones. Less common sites are humerus, radius, ulna, and clavicle [19]. Occasionally, the gap between the bone ends contains a space filled with fluid. In this case, the term “false joint,” or *pseudarthrosis*, is applied, and persistent uptake of Tc-99m MDP continues to be

**Table 4.4** Features of the major types of fracture non-union

Feature	Hypertrophic non-union	Atrophic non-union
Blood supply to ends of fragments	Rich	Poor
Potential to heal under stable and correct environment	Yes	Unable to heal
Amount of new bone formation	Good amount	Small amount
Method of ossification of new bone formation	Endochondral and intramembranous	Endochondral
Apoptotic cell death	Increased <sup>a</sup>	Increased
Management	Typically no need for open debridement	Open decortication and cancellous bone graft

<sup>a</sup>Thought previously to be decreased

seen after the usual period of healing or postoperative changes. The fracture is considered non-united after 6 months, although certain fractures, such as a central fracture of the femoral neck, are considered non-united after only 3 months. Non-union is classified predominantly according to the radiological appearance into hypervascular (hypertrophic) and avascular (atrophic) and is based on the capability to produce a biological reaction. Standard radiographs show that hypertrophic non-union is rich in callus and has a rich blood supply in the ends of the fragments. These have the potential to heal under the correct stable environment [20]. Atrophic non-union, on the other hand, is considered to be relatively avascular at the ends of the fragments, acellular, and inert, and consequently it lacks the ability to heal under the correct stable environment [20]. This type is typically seen in tibial fractures treated by plate and screws. Both types contain fibrous tissue, hyaline cartilage, fibrocartilage, and areas of bone formation. However, the amount and type of bone formation may differ between the two types. As expected, the hypertrophic type contains more areas of new bone which ossifies by both endochondral and intramembranous ossification (Table 4.4). Atrophic non-union, on the other hand, has only few areas of bone formation which form predominantly by endochondral ossification [20]. Radiographs reflect most of these changes but do not show the biological changes which were studied by Reed and associates [20], who found that hypertrophic non-union shows increased apoptosis, or programmed cell death (PCD), in both types (Table 4.4). *Malunion* describes the healing of the bone in a non-anatomic orientation.

#### 4.2.6 Trauma to Bone-Adjacent Structures

**Skeletal muscle damage:** Muscle damage of variable degrees is commonly associated with fractures. The incidence of sepsis and other fracture-related complications, and, importantly, fracture healing, are significantly influenced by the severity of muscle and soft tissue damage. The classical criteria of skeletal muscle damage, such as color, consistency, bleeding, and contractility, are subjective. Research in animals and humans has shown the feasibility of more accurate objective ways to assess skeletal muscle damage using radionuclide imaging techniques [20]. Injury to skeletal muscle and soft tissue may result in the formation of regional ectopic calcification or heterotopic calcification in the soft tissue.

**Tendon and ligament injuries:** Tears to tendons are called *sprains*, while ligament tears are called *strains*. These injuries usually do not cause abnormal uptake on bone scintigraphy. On the other hand, complete separation of tendons or ligaments, with or without a portion of bone and/or cartilage, from their attachments is called *avulsions* and causes abnormal uptake on bone scans.

### 4.3 Scintigraphic Diagnosis of Acute Fractures

#### 4.3.1 Role of Scintigraphy in Acute Fracture

Although standard radiography is the modality of choice for the diagnosis of acute fractures, along with computed tomography (CT) and magnetic

resonance imaging (MRI) as complementary modalities in certain cases, bone scintigraphy still has a well-defined role in acute fracture diagnosis and follow-up. In certain locations of the skeleton, it is particularly valuable and can provide information that other modalities cannot supply, such as fractures of the ribs, sternum, pelvis, vertebrae, and the small bones of the hands and feet. Differentiation between an old and a recent vertebral fracture, hands/wrists, and feet/ankles is another important application. This was found to be also useful in detecting occult, or excluding active, bone damage after a traffic or industrial accident [21–24]. In many of these cases, initial radiographs are normal or nondiagnostic. In patients with osteopenia, this occurs mainly when radiographs are obtained before the appearance of a fracture line or new bone formation, since their detection is difficult, and when the fracture involves areas of the skeleton that are not easily seen with plain films, such as the pelvis and feet [25].

### 4.3.2 Scintigraphic Appearance of Acute Fractures

Most fractures are visualized scintigraphically within hours after the trauma event [26, 27]; the optimal timing of imaging a fracture is unclear, however, since in a small minority of older patients, the fractures may take several days to be visualized. It is, however, recommended that scintigraphy should be used at any time when there is uncertainty concerning the existence of a fracture [28]. Using this approach, Holder et al. [28] reported sensitivity of 95% and specificity of 97% for fractures if scintigraphy is performed within 48 h and 100% sensitivity if it is performed within 72 h or longer after injury. A few case reports have reported that scintigraphy may only show the fracture as late as 12 days after the injury [29, 30]. It has to be realized, however, that in addition to the patient's age, the bone metabolic activity and mineral content and the imaging technique are all factors that can significantly affect the timing of visualization of a fracture as well as the ability to detect it. Meticulous technique is crucial in achieving an accurate diagno-

**Table 4.5** Guide to technique and positioning for scintigraphic diagnosis of fracture and traumatic injuries

Location	Position
Wrist	Zoom or pinhole in ulnar deviation Zoom lateral view of wrist
Elbow	Zoom anterior, posterior, and skyline views
Shoulder	Zoom blood pools and delayed anterior and posterior views; pinhole anterior view; neutral versus abducted
Cervical spine	Zoom SPECT; pinhole, SPECT/CT
Thoracic spine	Zoom views in prone position with a pillow beneath, collimator against the skin; SPECT, SPECT/CT
Lumbar spine	Zoom planar in flexed position, collimator against skin, SPECT with oblique reconstruction, SPECT/CT
Pelvis	Subpubic and lateral views
Hips	Pinhole or zoom views in abduction/external rotation, SPECT, SPECT/CT
Knees	SPECT; pinhole, SPECT/CT
Ankle	Pinhole or zoom lateral and medial views; SPECT, SPECT/CT
Foot	Pinhole or zoom, SPECT/CT views in anterior oblique, lateral, medial, and plantar, SPECT/CT

Adopted and modified from [31]

sis, which can be achieved in the majority of cases by following certain technical principles [31]. The study of the patient should be tailored to the history and examination to maximize the scintigraphic diagnostic yield. Knowledge of the date and mechanism of injury, associated diseases, and interventions is crucial. Efforts should be made to position the region of suspected fracture with a minimum degree of overlap with other bony structures. Zoomed images in multiple projections with proper utilization of SPECT and SPECT/CT can increase the diagnostic yield of both bone and soft tissue pathology (Table 4.5). The value of the bone scan in the early diagnosis and management of fractures can be also increased by the accurate registration with radiographs, or at a minimum level careful correlation with the radiographs (Table 4.6) and a skeleton model (at the time of interpretation) [31–33].

The scintigraphic appearance of fractures depends on the time elapsed after injury (Table 4.7) [27, 34]. The scan can appear

**Table 4.6** Typical bone scan findings in different forms of trauma in correlation with standard radiographs

Pathology	Flow phase	Blood pool phase	Delayed phase	Radiograph
Contusion	Increased	Increased	Increased	Negative
Shin splints	Normal	Normal	Increased	Negative
Stress fracture	Increased	Increased	Increased	Negative for 2–4 weeks
Acute fracture	Increased	Increased	Increased	Usually abnormal
Old fracture	Normal	Normal	Increased	Usually abnormal
Avulsion fracture	Increased	Increased	Increased	Commonly equivocal
Transchondral fracture	Increased	Increased	Increased	Usually abnormal
Battered child	+/-	+/-	Increased	Commonly negative
Growth plate injury				
Early phase	Increased	Increased	Nonuniform uptake	Usually negative
Late phase	Decreased	Decreased	Nonuniform uptake	Difficult to detect
Lisfranc	Increased	Increased	Increased	Difficult to detect
Enthesopathies				
Active	Increased	Increased	Increased	Negative
Inactive	Normal	Normal	Fainter increased uptake	Negative

**Table 4.7** Scintigraphic appearance of acute fractures on multiphase bone scintigraphy

Phase of fracture	Duration	Scintigraphic appearance
First (acute) phase	3–4 weeks	Increased flow and blood pool activity at site of fracture; diffuse area of increased activity around fracture site on delayed images
Second (subacute) phase	8–12 weeks	Increased flow and blood pool activity at fracture site which may become more localized; well-defined intense uptake at fracture site on delayed images
Third (healing) phase	Variable	Gradual diminution of flow, blood pool activity, and delayed uptake intensity

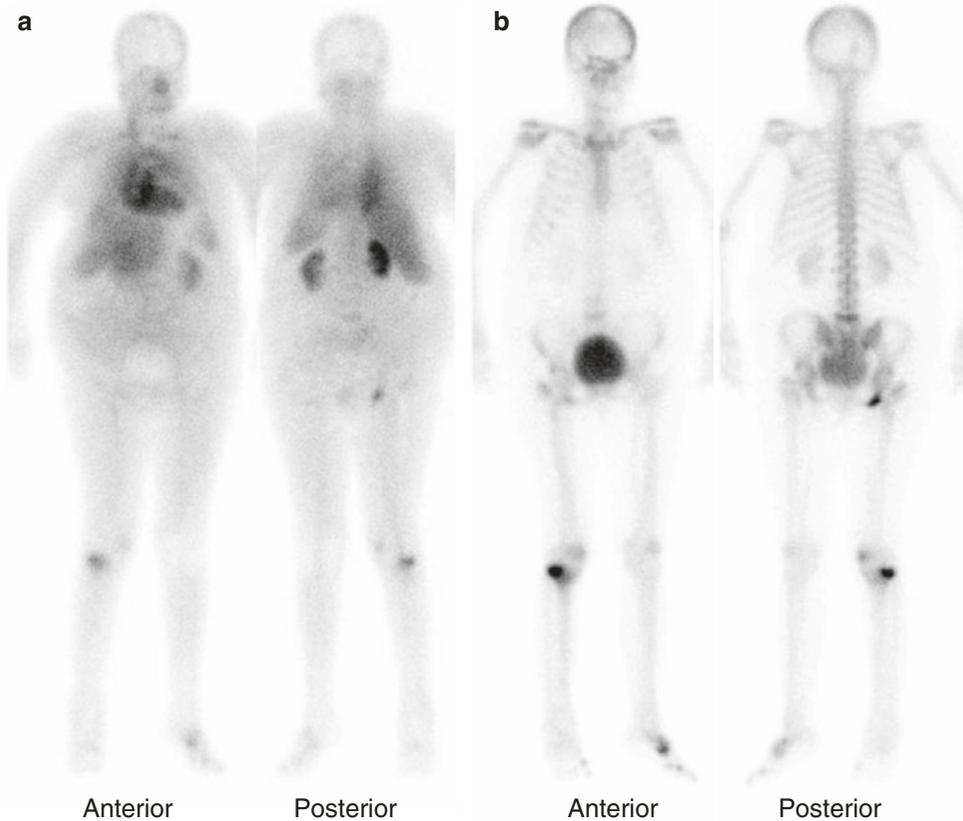

abnormal a few hours after the injury. Early on, fractures show focally increased flow and blood pool activity with a correspondingly increased activity on delayed images (Fig. 4.3). Later, flow and blood pool activity decreases progressively till they normalize. This may take up to 6 months (as determined experimentally and by following human fractures at

different times after the trauma) [27, 35], while delayed uptake remains positive for a longer time. This has been reported to be as long as 40 years, depending on the age and healing status of the patient [27].

### 4.3.3 Scintigraphic Imaging of Specific Fractures

#### 4.3.3.1 Rib and Sternal Fractures

Rib and sternal fractures can be difficult to detect using standard radiographs and scintigraphy can be of help in many cases. Erhan et al. [36] compared radiography to bone scintigraphy in the same patients and found that scintigraphy was more sensitive in both rib and sternal fractures during the early period of thoracic trauma. Standard radiography should, however, as in other bone diseases, be the initial imaging modality used, since it saves time and can show hemothorax, or pneumothorax, as well as the osseous abnormality being investigated [36]. Scintigraphically, rib fractures may be solitary and appear as a focus of increased uptake (Fig. 4.4), and in such cases it is difficult to differentiate the fracture by pattern alone from other conditions such as tumors. Fractures may also

**Fig. 4.3 a, b** Recent fractures in a 61-year-old woman (with a history of recent car accident). Tc-99m MDP bone scan obtained 10 days later shows abnormal uptake at the

sites of fractures in L5, right ischium, right proximal tibia, and left foot on both blood pool imaging (a) and delayed images (b)

present as multiple and are typically oriented vertically (Fig. 4.5), a pattern that is very suggestive of rib fractures. Occasionally, spiral rib fractures can appear as an elongated area of increased uptake, and in such situations it is again difficult to separate the entity from a malignancy scintigraphically. Sternal fractures are particularly difficult to be detected by radiographs, and bone scintigraphy has a crucial role in their diagnosis (Fig. 4.6).

#### 4.3.3.2 Scaphoid Bone Fractures

Occult fractures of the scaphoid bone occur frequently after carpal injuries and may lead to non-union. The diagnosis of scaphoid fracture is often difficult because of the low sensitivity of radiographs. Multiphase bone scintigraphy is considered to be the modality of choice for patients with nor-

mal radiographs. Pinhole imaging is particularly useful in showing the focal uptake and localizing it (Fig. 4.7). Bayer et al. [37] studied 40 patients, approximately 2 weeks after trauma, who had negative radiographs but clinically suspected scaphoid fracture, using a rapid version of bone scintigraphy (with images taken 15 min after radiotracer injection); 8 fractures of the scaphoid bone and 13 of other carpal bones were detected scintigraphically but not on radiographs [37]. In another prospective study of 50 patients with suspected scaphoid fractures, all the patients who had fractures demonstrated using standard radiography (either at the initial visit, or at 2 weeks) had positive bone scans (sensitivity 100%). Four of six patients who had a positive scan but negative first and second radiographs had persistent tenderness on clinical examination which required extended

**Fig. 4.4** Whole-body bone scan of a 39-year-old woman with a history of a fall showing a single focus of increased uptake in the left posterior third rib illustrating an example of a single rib fracture (*arrow*)

immobilization in a plaster cast. The overall positive predictive value of scintigraphy was 93%. All patients with a negative scan were clinically and radiologically negative at 2 weeks (negative predictive value 100%). Evidence of multifocal injury was present in 12 scans, but only in 1 radiograph [38]. SPECT/CT adds incremental value compared to other scintigraphic techniques. This hybrid modality can diagnose much more scaphoid lesions that cannot be seen on CT scan alone and is a sensitive follow-up examination for carpal fractures [39, 40].

Experience with MRI suggests that it can be a sensitive modality for the diagnosis of scaphoid

fractures and may prove more specific than scintigraphy. Additionally, significant ligamentous injury and carpal instability seen by MRI are not evident on scintigraphy [41, 42].

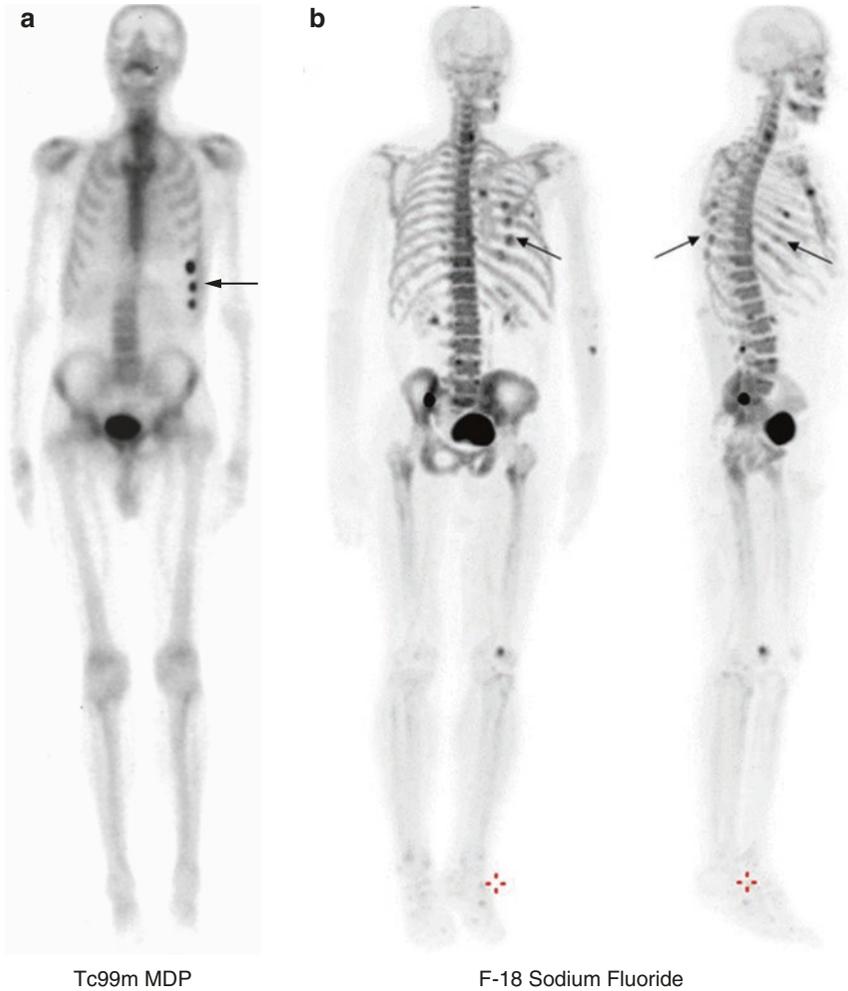

#### 4.3.3.3 Lisfranc Fracture and Other Feet Fractures

The tarsometatarsal joint complex is known as Lisfranc after Jacques Lisfranc de Saint Martin, a French surgeon in Napoleon army. Lisfranc injury includes fracture and fracture dislocation of the tarsometatarsal (Lisfranc) joints that is difficult to diagnose since it is not easy to visualize on radiographs [43]. Studies showed at least 30% cases are overlooked or misdiagnosed on radiographs [43–46]. In our experience radiographs missed 10 out of 11 cases with Lisfranc fracture [47]. CT particularly 3D and MRI are useful when radiographs are negative [46]. Bone scintigraphy is more sensitive than radiographs and is particularly useful when other modalities are not diagnostic. Bone scintigraphy shows increased flow, blood pool, and delayed activity focally or in a transverse fashion (Fig. 4.8). Small focal abnormalities in the feet and ankles can be localized well enough by SPECT/CT to make specific orthopedic diagnoses on the basis of their location and CT information (Figs. 4.9 and 4.10).

#### 4.3.3.4 Pediatric Fractures and Traumatic Injuries

##### Growth Plate Injuries

Injury to the physis, or growth plate, in children may lead to the arrest of growth and/or angular deformities of the limbs. On scintigraphy, normal growth plates appear as thin, well-demarcated lines. The physis is recognized as the site of endochondral ossification and is responsible for a bone's growth in length. Although the band of increased uptake seen on scintigraphic bone images is referred to as the growth plate, it actually does not correspond to the lucent band present on a bone radiograph that is also referred to as the growth plate. The radionuclide growth plate corresponds to the dense band of the bone in the metaphysis adjacent to the radiographic growth

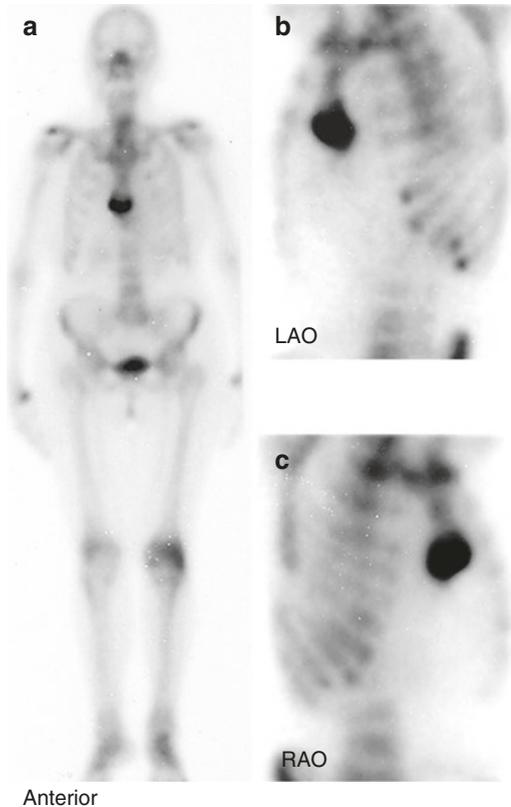

**Fig. 4.5** Tc99m MDP anterior whole body image (a) and Representative images of F-18 sodium fluoride study (b) showing typical pattern of vertically oriented multiple rib

fractures (*arrows*), which should not be confused with the typical pattern of metastases

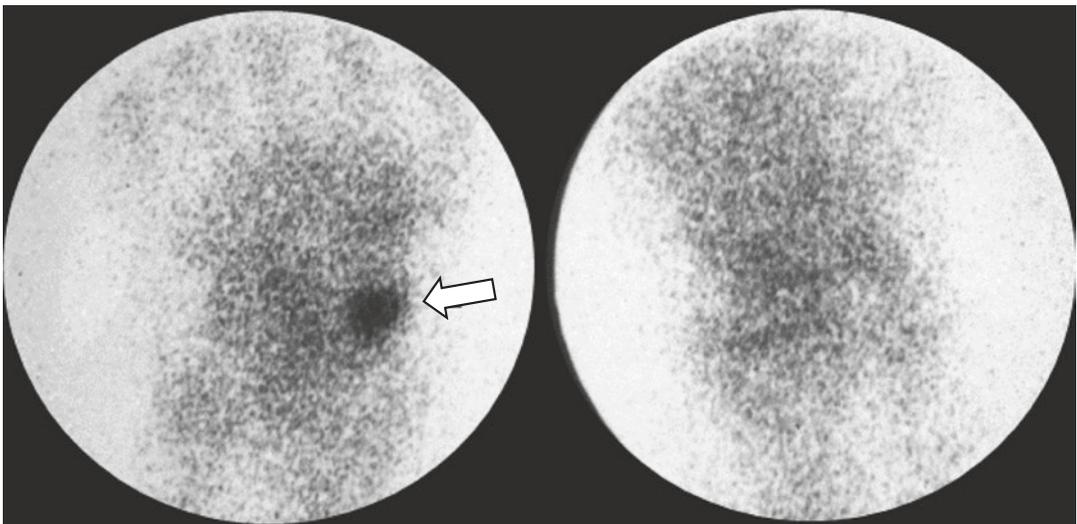

plate and is described in radiographic anatomy as the zone of provisional calcification. The normal scintigraphic appearance of the growth plate varies with age. In infants and young children, the physis has a thick and oval-shaped appearance. With maturation it becomes linear, and in adolescence it shows progressively decreasing activity. Growth plates in different regions of the skeleton close at different times. Skeletal maturation occurs earlier in females than in males [48]. Using quantitative data from normal children, greater activity is present in the medial half of the distal femoral growth plate than the lateral half,

while in the proximal tibial growth plate (Fig. 4.11), the lateral half shows more activity than the medial [48]. Stress factors and mechanical loading influence the scintigraphic uptake at the growth plate. For example, when an extremity is placed at rest, as with prolonged immobilization, activity in the growth plate decreases in comparison with the contralateral weight-bearing extremity. This can occur also in ambulatory patients with a gait disturbance which results in differential weight bearing. On the other hand, increased growth plate uptake can occur on generalized or regional basis. Systemic and meta-

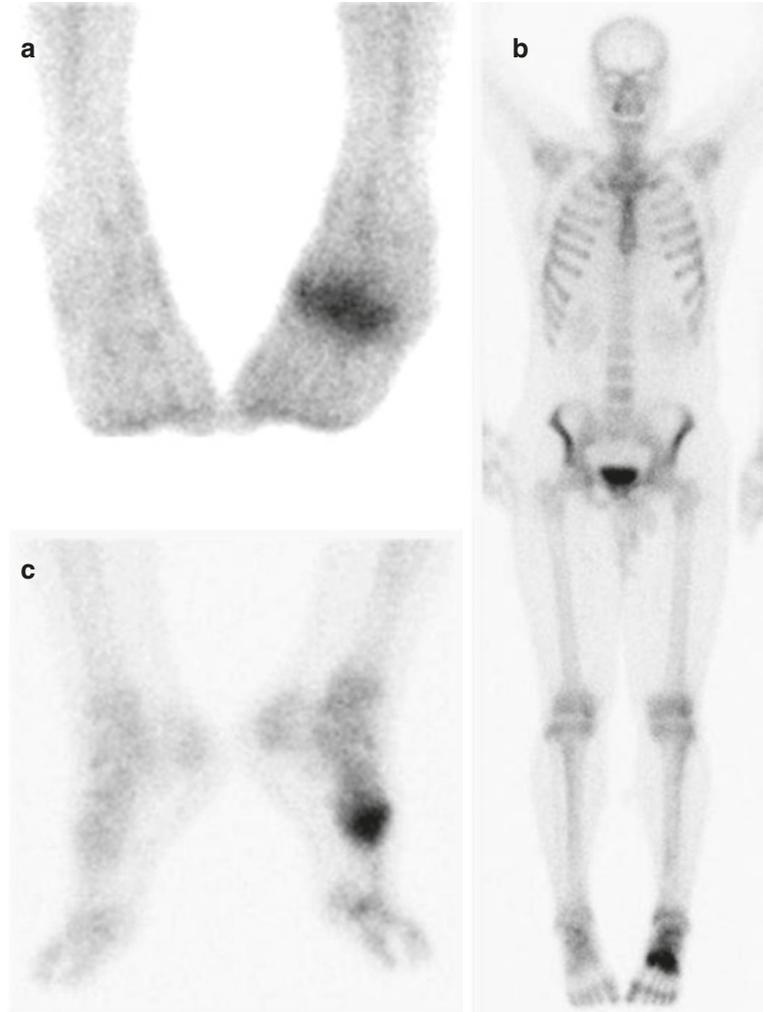

**Fig. 4.6** a–c Fracture of the sternum seen on whole-body Tc-99m MDP bone scan (a) and anterior oblique chest views (b, c)

bolic diseases may result in a generalized increase in growth plate uptake throughout the skeleton. Trauma, infection, and other conditions that relate to increased metabolic bone activity may result in uniform increased activity in the plate or segmental abnormal uptake. Fractures and slipped capital femoral epiphysis result in uniformly increased plate activity at the involved location. Segmental increase, and decrease, in a growth plate is of particular importance, since it is associated with the development of angular deformities. When an incident such as trauma and infection directly involves the growth plate, or occurs near the growth plate, segmental abnormal uptake will be seen and deformity may follow. Also a fracture in the metaphysis of a long bone can provoke angular deformity by stimulating an adjacent growth plate. Harcke [48] described the increased growth plate activity with metabolic bone disease and documented a return to normal after successful treatment. Such injuries, particularly fractures, may cause permanent closure of segments of growth plates [49]. Partial arrest of the growth plate occurs when an osseous or cartilaginous bridge forms across the plate. If this occurs laterally, the relatively accelerated activity of the medial growth plate will

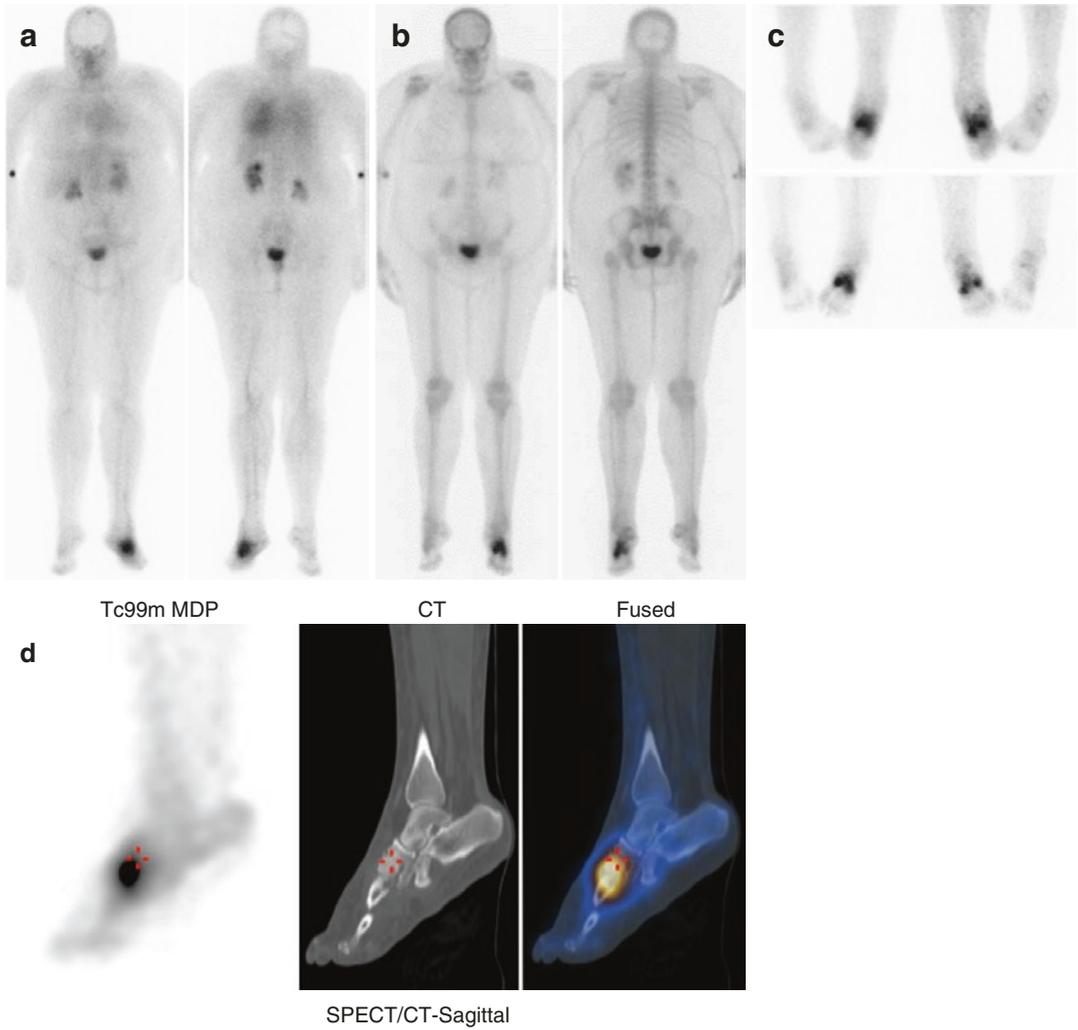

**Fig. 4.7** Fracture of the left scaphoid (carpal navicular) bone (arrow) as seen on pinhole imaging, which has the additional advantage of magnification and better localization of abnormalities

**Fig. 4.8** a–c Lisfranc fracture pattern on bone scan showing increased blood pool (a) and uptake on whole body (b) and spot (c) images at the site of left tarsometatarsal joints

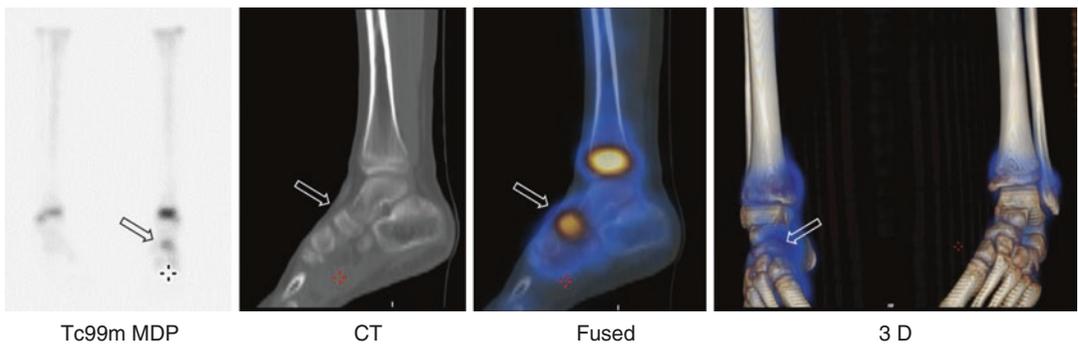

result in a valgus deformity, while if the barrier is located on the medial side and normal physis continues to grow laterally, it will cause a varus deformity [50]. These angular deformities can also occur secondary to contiguous chronic hyperemia of a metaphysis, or epiphysis, (such as after a fracture to these locations which stimulates the activity of the adjacent part of the physis) resulting in unequal growth with a subsequent deformity [51]. CT and MRI are accurate in identifying segmental closure [52]. MR imaging, with its ability to depict the cartilaginous structures of developing bones, has become the modality of choice for evaluating children with growth disorders and directing surgical manage-

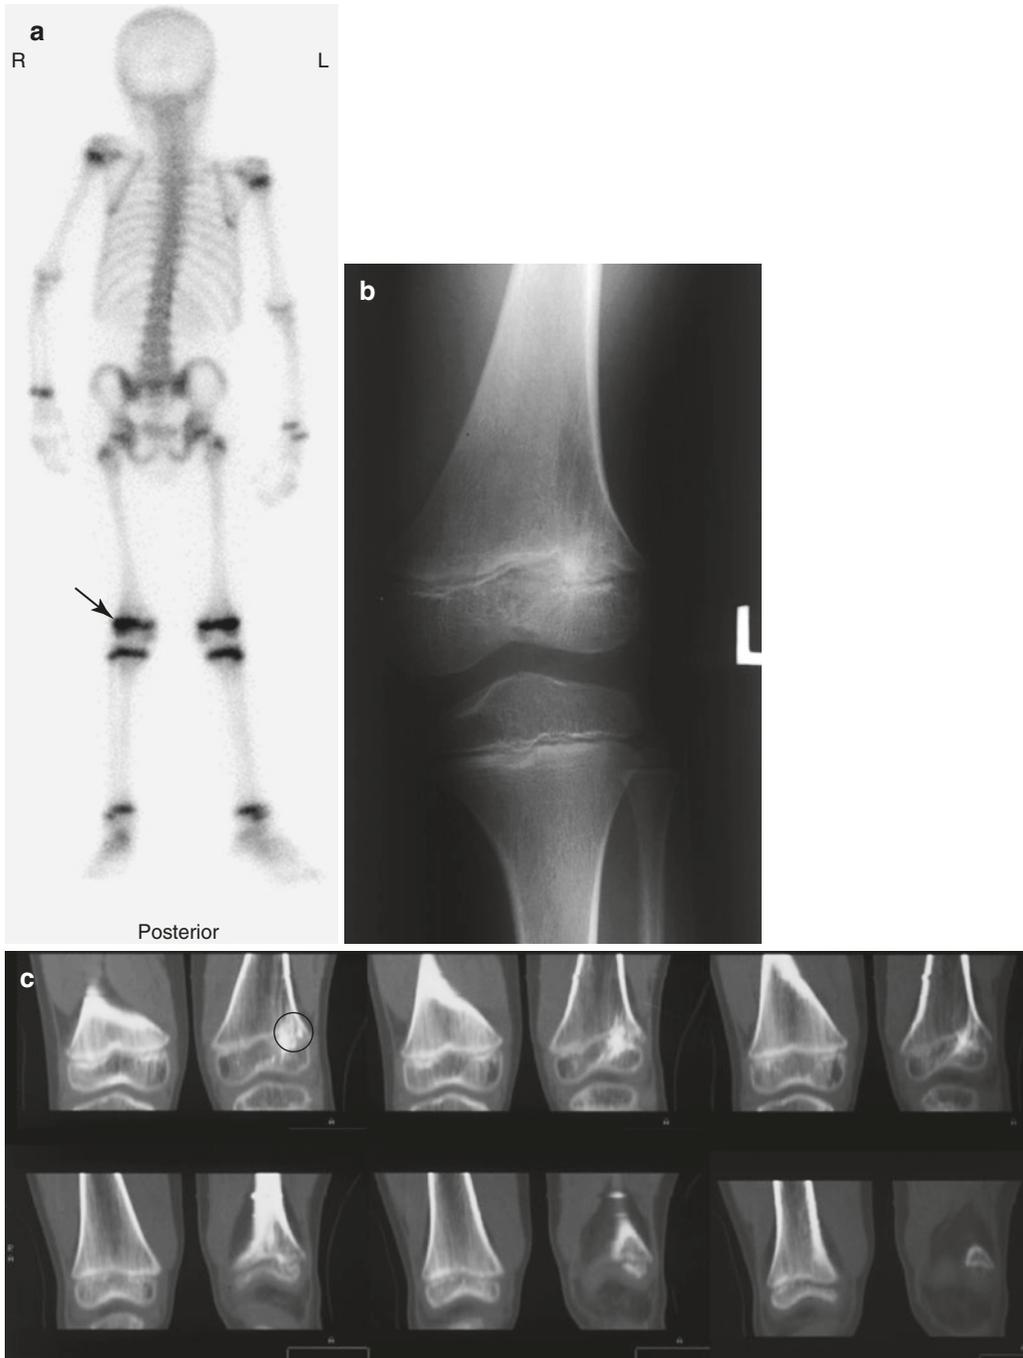

ment [53]. The physiological status of the growth plate is difficult to evaluate using morphological imaging. Scintigraphic imaging complements anatomical studies by reflecting the physiological status of the growth plate and has the advantage of being quantitative. It can also detect the abnormalities earlier than morphological modalities and can help particularly in detecting segmental growth plate arrests that are difficult to determine using these modalities [54–57]. A key to the comparison of growth plate uptake is having both plates symmetrically positioned on the same large view. On scintigraphy, differences in activity and configuration of the growth plates can be identified particularly on early blood pool images

**Fig. 4.9** A case of Lisfranc fracture of the left foot of a 59-year-old female showing focally increased blood pool activity and delayed uptake on whole-body blood pool (a), delayed whole body (b), and spot (c) images. Selected SPECT/CT sagittal images (d) clarified the nature and localization of the abnormality

**Fig. 4.10** Selected SPECT/CT images of a 9-year-old boy presented with pain after a twist of his right ankle. X-ray and CT did not show any abnormality. Bone scan and SPECT/CT show increased uptake in the right navicular bone localized well by the CT component including 3D image indicating fracture

**Fig. 4.11** a–c Growth plate injury. Whole-body anterior (a) and posterior bone scan of a 4-year-old boy with pain in his left knee. (b) The scan shows increased uptake in

the lateral aspect of the left distal femoral growth plate (arrow). Standard radiograph (c) and MRI images of the same patient illustrating the same injury (circle)

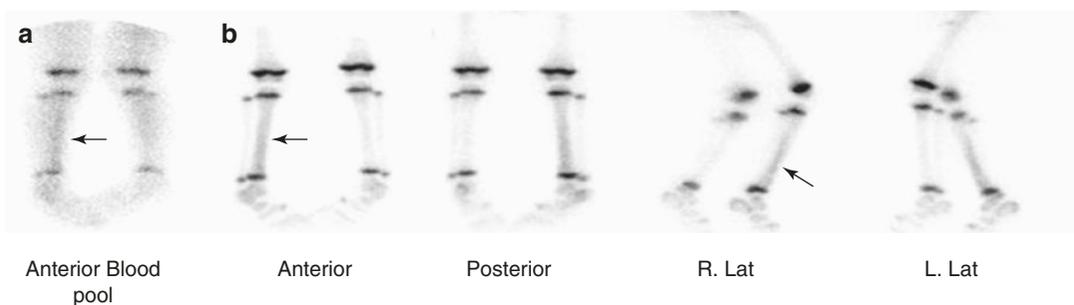

which show the differences better than delayed images [58]. Both sides must be symmetrically positioned within the field of view. Segmental closure can be better identified using a pinhole view [48, 58]. In addition to asymmetric and segmental differences in uptake, a blurred growth plate appearance can also be seen with adjacent epiphyseal and/or metaphyseal injuries [58]. These findings are not permanent, as shown by Etchebehere et al. [59], who studied 18 children with uncomplicated femoral fractures using multiphase bone scintigraphy at 3 different times (2–5 months, 6–12 months, and 18–24 months). Visual analysis of the blood flow, equilibrium, and delayed images showed increased activity in the distal femoral growth plates during the first and second time intervals, but not during the third [59]. Scintigraphy is considered to be the only imaging modality capable of assessing the magnitude of physeal stimulus caused by femoral fractures and predicting a favorable, or unfavorable, outcome of leg length by semiquantitative analysis. SPECT imaging can detect, and locate, the decreased metabolism associated with post-traumatic closure of the physeal plate which predicts growth arrest and deformities [25, 48, 54].

Surgical closure of a growth plate (epiphysiodesis) is performed in children who develop progressive leg length deformity. Scintigraphy can be used to determine the success of the procedure. At 4 months the blood pool and delayed images should demonstrate a decreased uptake in the surgically treated physis. An

unsuccessful procedure shows persistent uptake at an above-normal level. Assessment earlier than 4 months may show normal or increased uptake that is due to the healing process. By 4 months a growth plate that is closing can be identified. Complete closure after epiphysiodesis appears to take approximately 8 months [48].

### Toddler's Fracture

Fractures in children differ from those of adults. Since children's bones are more plastic and absorb more energy before breaking, the fractures often do not involve complete separation of the bone into two fragments. Although the term toddler's fracture has been considered typically a non-displaced spiral fracture of the mid-tibia in young preschool children (Fig. 4.12) who are beginning to ambulate (typically 9 months to 3 years), the term is also applied to fractures of other bones in this age group, including the fibula, calcaneus, talus, metatarsals, and cuboid. Scintigraphy has a great value in identifying these fractures, which are commonly occult radiographically [60–63]. The toddler's fracture of the cuboid bone is relatively common and may be due to forced plantar hyperflexion of the foot and shows a radiological abnormality close to the articular surface of the cuboid with the calcaneus [64]. A focus of increased uptake is seen at the site of the fracture which can be seen and localized better by pinhole imaging. Although toddler's fracture of the tibia is one of the most common in young children, child

**Fig 4.12** 18-month-old girl who stopped walking 1 week earlier. Study shows increased blood pool activity (a) in the right tibia (arrow). On spot-delayed images (b) there is

increased uptake involving approximately the lower three quarters of the shaft of the right tibia (arrows). The pattern illustrates the scintigraphic feature of toddler's fracture

abuse must be considered particularly in children under 2 years [65].

Toddler's fractures usually heal without treatment; hence, identification of these fractures is crucial for alleviating parental anxiety and avoiding unnecessary diagnostic tests to identify other potential causes of the patient's symptoms than it is for planning therapy.

### Tarsal Coalition

This condition is due to fusion of the talus and calcaneus or the navicular and calcaneus bones. It occurs due to failure of normal segmentation of the ossification centers during embryogenesis but does not become symptomatic before the second decade of life. Radiographic modalities are the primary diagnostic tools (Fig. 4.13); however, when they are equivocal, bone scintigraphy with pinhole imaging can be of significant value by showing focal uptake in the subtalar region indicating coalition. This activity is due to the abnormal motion of the fused bones inducing a stress reaction at the adjacent bone because of the abnormal motion created by the fused bones [58, 66, 67].

Increased radionuclide accumulation in a hypertrophic spur, the talar beak, is a frequent finding in patients with symptomatic subtalar coalition. It results from the abnormal joint mechanics which produce repetitive trauma on

the talar periosteum. Bone scintigraphy therefore is useful in identifying talocalcaneal coalition as the cause of foot pain. SPECT/CT is useful in identifying increased activity associated with congenital anomalies, such as tarsal coalition and Bertolotti's syndrome, which helps confirm them as the cause of the patient's symptoms and provides information that is useful in determining appropriate clinical management [68].

### Battered Child Syndrome

Aside from cutaneous findings, such as bruising and contusions, fractures are the next most common findings in abused children [69]. Therefore, when abuse is suspected in an infant, a complete skeletal survey should be obtained for the entire skeleton. Radiographs of the chest should include oblique views to improve visualization of rib fractures. Fractures having the highest association with child abuse are rib fractures, classic metaphyseal lesions (CMLs), scapular fractures, sternal fractures, and spinous process fractures [70].

Bone scintigraphy is useful in identifying abused children. It is more sensitive than radiographs, with up to 50% additional sensitivity by showing foci of increased uptake at different sites, particularly those known to be common for radiographically occult fractures, such as the ribs and pelvis [71, 72].

Bone scintigraphy may be added to the investigation for bony injuries. Scintigraphy may be used in complicated cases that cannot otherwise be determined by radiographs and is particularly useful for identification of rib fractures [69].

Rib fractures in infants younger than 1 year are highly specific for abuse. The fractures typically occur in the posterior and lateral aspects of the ribs and less commonly anteriorly. CMLs in infants are also highly specific findings of abuse [73]. These fractures are most commonly seen at the knee, followed by the ankle and shoulder (proximal humerus). The proposed mechanism is shearing with torsion and torque of the extremities that lead to metaphyseal fractures. The fracture line is nearly parallel to the physis. Fractures are commonly identified in association with findings of abusive head trauma. Since find-

**Fig. 4.13** Tarsal coalition (*arrow*) as seen in an illustrative cut of CT scan of the feet. Compare to the normal contralateral side

ings of abusive head trauma are frequently non-specific, detection of fractures in these patients has important implications in identifying abusive injuries [74].

It was found that some lesions are seen by skeletal survey alone and others seen only by scintigraphy. Accordingly it was suggested that both modalities should be used in cases with suspected child abuse [75–77]. The American College of Radiology (ACR) appropriateness criteria state that bone scintigraphy is “indicated when clinical suspicion of abuse remains high and documentation is still necessary” [78].

Fluorine-18 NaF PET has potential advantage over Tc-99m-labeled methylene diphosphonate (MDP) based upon superior image contrast and spatial resolution. F-18 NaF PET has been reported superior to conventional scintigraphy for the evaluation of child abuse. In one case it detected all sites of trauma shown by initial and follow-up skeletal surveys, including bilateral metaphyseal fractures of the proximal humeri [79].

### Scheuermann’s Disease

Although this condition is not clearly due to trauma and the etiology has not been defined, it is included here since it occurs in the active age of 13–17 years and trauma is a suspected underlying cause. It is a destructive form of osteochondrosis featuring erosions of the endplates of two adjacent vertebrae with a decrease in the height of the intervertebral space (Fig. 4.14) and anterior wedging of thoracic vertebrae by 5° or more, as seen on lateral standard radiographs, and may lead to kyphosis. Scheuermann’s disease also occurs less commonly in the lumbar spine. On scintigraphy, there is no, or only mild, increase of uptake by the vertebrae, a feature that may help separate this condition from others such as tumors and infections which show a significant degree of abnormal uptake [80, 81].

### Osteochondritis Dissecans (Transchondral Fractures)

Osteochondritis dissecans affects young adults and children, with males affected three times more frequently than females. The condition is

**Fig. 4.14** A diagram illustrating the erosions of the end plates and narrowing of the intervertebral space associated with Scheuermann’s disease (*upper diagram*). A normal intervertebral space and adjacent end plates (*lower diagram*) is shown for comparison

classified into juvenile and adult forms according to whether it occurs in patients with an open or closed growth plates, respectively [82]. The proposed causes include trauma, ischemia, and a genetic predisposition. The theory of ischemia is not widely accepted since the most common site of the condition, namely, the lower end of the femur, is rich in vascular supply. Although the exact cause remains unsettled, the trauma theory is more widely accepted as prior trauma has been reported in up to 60% of patients [25, 83–86]. The condition may result from separation of a segment of cartilage and the subchondral

bone from the articular surface whether completely or partially. It most commonly affects the medial femoral condyle, followed by the lateral femoral condyle, the lateral tibial condyle, and the patellofemoral compartment [87]. Osteochondritis dissecans also occurs in the bones around the elbow, commonly among baseball players, as reported by Takahara et al. and others [85, 88]. The condition is also common among individuals who have played baseball actively since childhood [85, 88], and repetitive throwing is considered to be one of the main etiological factors of this disease [88–90]. During the acceleration phase of throwing, the elbow joint may be stressed into a valgus position [91] and the capitellum may be subjected to compression and shear forces [92–94].

Minzuta et al. [95] described the clinical presentation of six athletically active children, aged 6–12 years, with symptomatic osteochondritis dissecans of the lateral femoral condyle developed after total resection of the discoid lateral meniscus. The condition presented as a recurrent pain in the treated knee which started 36–65 months after surgery. All patients had been continuously engaged in sports activity after surgery before the recurrence of pain. On arthroscopy, softening was found in two knees, a separated fragment in two knees, and a completely loose fragment in two further knees. The authors suggested that repeated impaction in sports activities on the immature osteochondral structures under altered mechanical force transmission after total resection of the discoid meniscus might be a predisposing factor in the development of osteochondritis dissecans of the lateral femoral condyle [95]. Standard radiographs and MRI are usually adequate to make the diagnosis. MRI is the most important examination as it enables analysis of bone quality and edema and good assessment of subchondral separation and cartilage condition [96, 97]. Multiphase bone scanning is used when other modalities are equivocal and there is a need to determine the stability of the joint and prognosis scintigraphically. The pattern of abnormalities on scintigraphy depends on the time elapsed and the severity of injury. Accordingly, a scintigraphic classification (Table 4.8) has been proposed which can be of value in determining the prognosis and

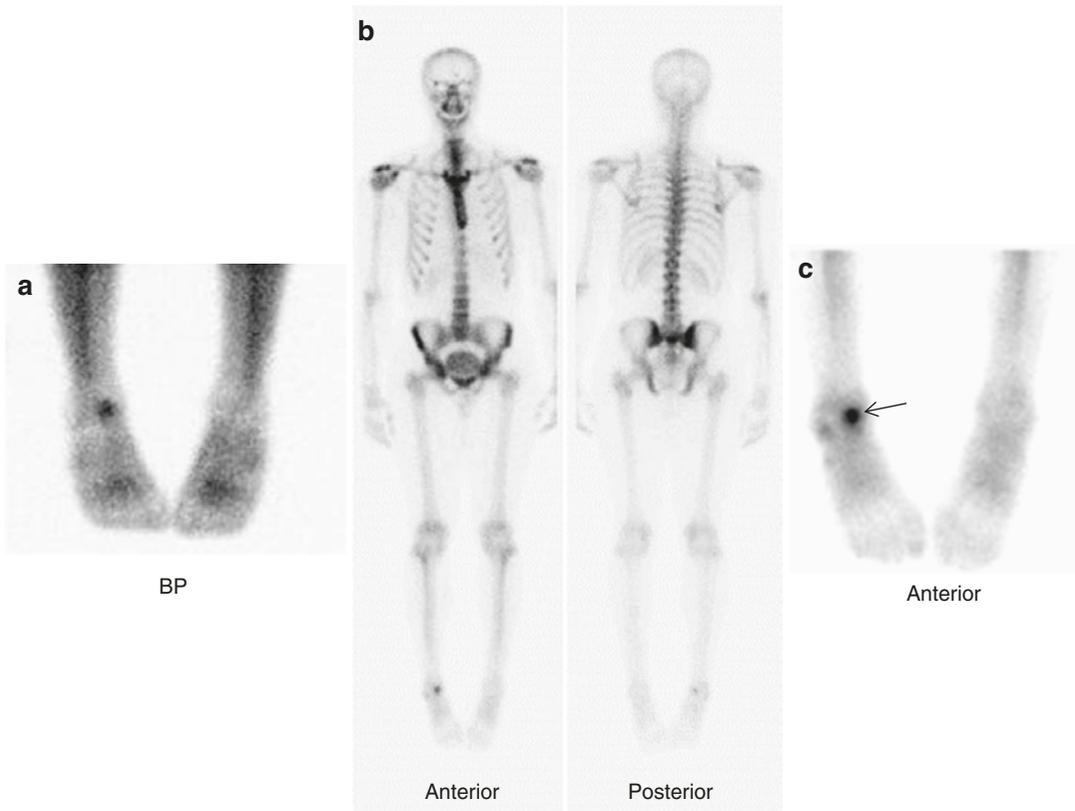

**Table 4.8** Scintigraphic classification of osteochondritis dissecans of the femoral condyle

Stage	Scintigraphic pattern	Clinical significance
0	Normal multiphase scan	
I	Normal multiphase scan with abnormal radiographs	Stable lesion, asymptomatic
II	Focally increased activity on delayed images	Stable lesion, pain starts
	Focally increased blood pool and delayed uptake at site of lesion	Unstable lesion
III	Focally increased activity on all phases in and around lesion	Unstable lesion
IV	Same as in stage III with increased uptake in juxta-articular tibial Plateau	Unstable lesion

management [98, 99]. Figure 4.15 illustrates scintigraphic appearance of osteochondritis dissecans stage II. Paletta et al. [100] found a very high prognostic value for scintigraphy among patients with open physes. The authors reviewed the records of 12 patients, aged 9–16 years, with osteochondritis dissecans of the knee, including bone scan results, clinical course, healing time, and final outcome, to determine the prognostic value of scintigraphy. Patients were divided into those with open physes (distal femoral and proximal tibial) and those with closed physes. Four of the six patients with open physes had increased activity on the bone scan and all achieved healing with nonsurgical treatment. The remaining two patients had decreased activity on bone scan and nonsurgical treatment failed, necessitating surgery. On the other hand, all the six patients with closed physes had increased activity on the bone scan, but only two had healing of the osteochondral lesions without surgery. Accordingly, the authors found that quantitative bone scanning had a 100% predictive value for the prognosis in this group of osteochondritis dissecans patients with open physes, but for those with closed physes, the predictive value was lower [100].

### Slipped Capital Femoral Epiphysis

This term describes displacement of the femoral head from the femoral neck at the site of the

**Fig. 4.15** A multiphase bone scan of a 19-year-old male complaining of pain in the right ankle region of sudden onset. Blood pool spot image (a) shows increased blood pool activity corresponding to focally increased uptake on

whole-body (b) and spot (c) delayed images in the distal end of the right tibia. The case illustrates the findings of osteochondritis dissecans which were confirmed by MRI in this patient

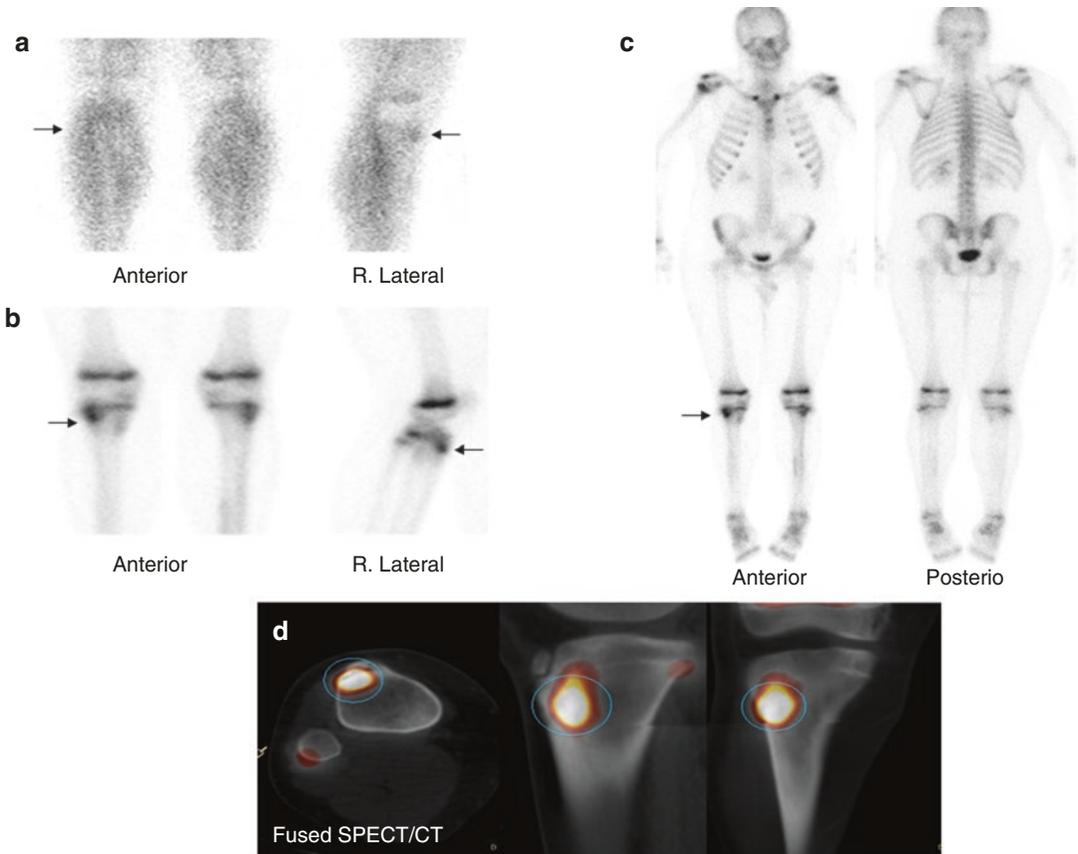

growth plate during growth. The etiology and biomechanical, biochemical, and hereditary factors are still under investigation [101]. The condition affects adolescent boys more often than girls and is more frequent among patients of African descent. The condition can be unilateral or bilateral and is usually diagnosed with standard radiographs. Scintigraphy is used when it is difficult to make a diagnosis using radiography, such as in cases of bilateral displacement or when the clinical situation is complicated by osteonecrosis, which occurs in approximately 15% of cases [58].

On bone images, there is increased uptake at the site of the growth plate and the adjacent femoral metaphysis, a finding that probably reflects the increased metabolic activity at the site of the plate disruption [58]. Additionally, significant displacement is due to the abnormal posteromedial relationship of the femoral head to the femoral neck.

When osteonecrosis is present, other scintigraphic findings include increased periarticular uptake, illustrating an associated reactive synovitis, and photon deficiency of the femoral head. Scintigraphy can also be useful in assessing whether the treatment is adequate. This is determined by demonstrating fusion of the growth plate.

#### **Osgood-Schlatter Disease (Tibial Tuberosity Avulsion Injury)** (See also Chap. 5)

This condition is a common self-limited cause of knee pain in preadolescent and adolescent children although it can occur in adults. It occurs particularly in active children and is simply an avulsion injury from contractions of the quadriceps muscles at their insertion into proximal tibial tuberosity. It can also be viewed as inflammation of the patellar tendon insertion on the tibial tuberosity due to overuse with or without

**Fig. 4.16** Osgood-Schlatter disease in a 14 year old boy with recurrent pain anterior to his right knee worsening with activity. Tc99m MDP planar and SPECT/CT was obtained. The blood pool images (a) show slightly

increased activity over the right tibial tuberosity corresponding to the increased activity on delayed whole body (b) and spot (c) images (arrows). SPECT/CT images (d) clearly demonstrated the localised uptake (circles).

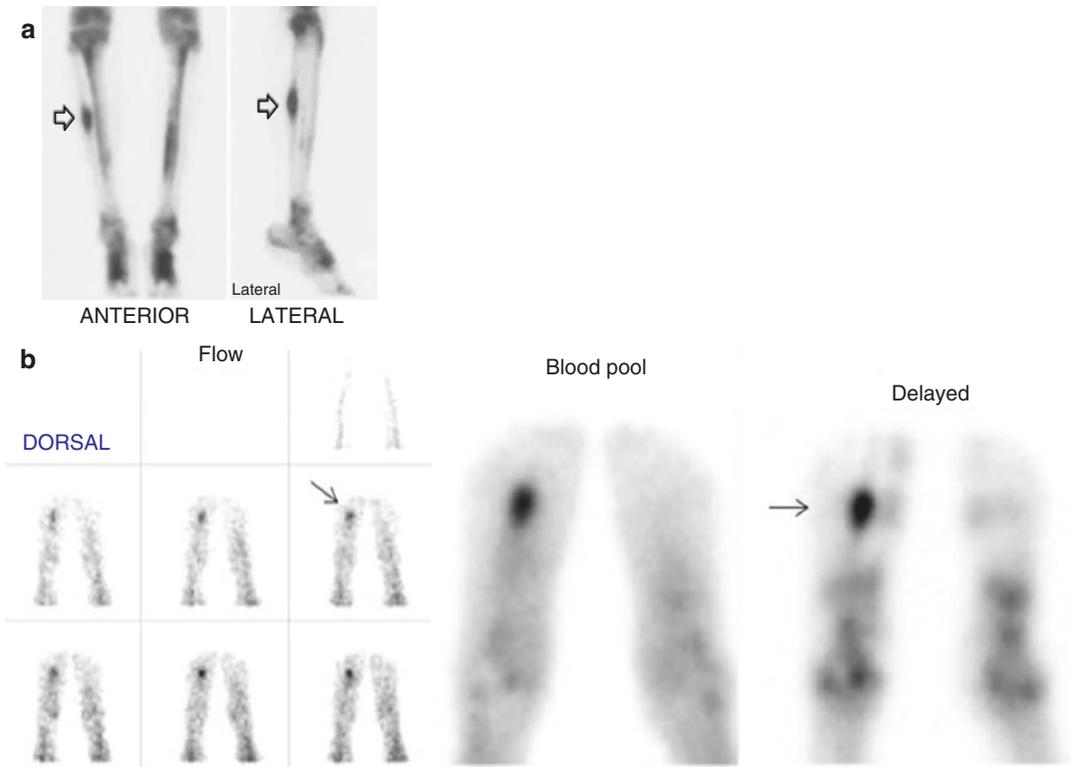

fragmentation of the apophysis of the tibial tuberosity [102]. It is included among the group of osteochondroses. The condition can be bilateral. Although the condition is diagnosed by ultrasonography and MRI, familiarity with the condition helps detect the disease on scintigraphic studies (Fig. 4.16).

#### 4.4 Scintigraphic Diagnosis of Stress Fractures

##### 4.4.1 Role of Scintigraphy in Stress Fractures

Contrary to the case of acute fracture diagnosis, scintigraphy has a major role in the diagnosis of stress fractures, whether due to fatigue or insuffi-

ciency, since standard radiographs take additional time to show the fractures. It was determined that bone scan was abnormal as early as 6 weeks prior to the appearance of conventional roentgenographic changes [103]. Additionally scintigraphy can differentiate more reliably between recent and old fractures [104]. Holder et al. [105] studied 16 patients with stress-related bone injuries and normal standard radiographs with MRI and two-phase bone scanning. The average sensitivity, specificity, and positive and negative predictive values for the presence of stress-related injuries of MRI were 66%, 90%, 96%, and 45%, respectively, while for scintigraphy, all abnormal and normal findings were correctly identified. Those authors recommend bone scintigraphy as the initial imaging modality of choice for patients with clinically suspected stress-related injuries and a low probability

**Fig. 4.17** (a) Representative images of a Tc99m MDP bone scan for a 23 years old man with an 8 week history of right shin pain. There is fusiform focus of prominent increased uptake in the shaft of the right fibula illustrating

the pattern of fatigue fracture. (b) another example of stress fracture in the foot with focally increased flow, blood pool with corresponding focus of increased uptake on delayed images

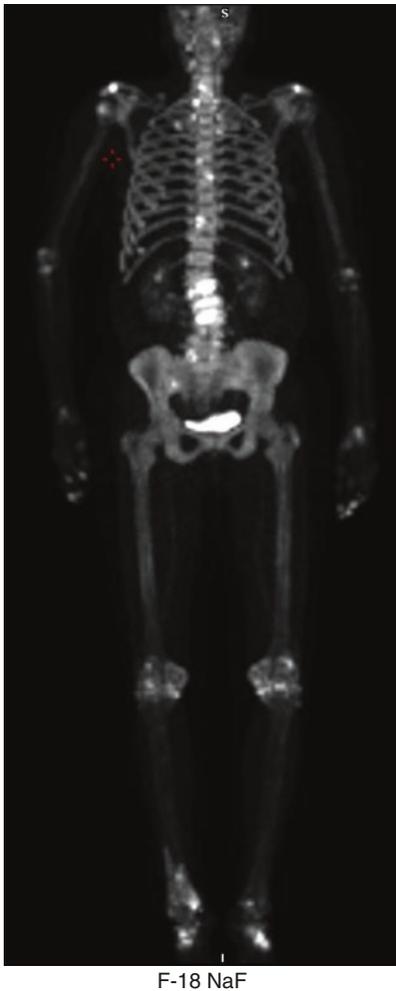

of other active bone diseases such as infection or neoplasm [105]. Recently CT, MRI, and SPECT/CT are more utilized depending on the location and availability. SPECT/CT is particularly useful in the suspected fractures of the ankle, feet, and spine [106].

#### 4.4.2 Scintigraphic Appearance of Stress Fractures

If scintigraphy is performed in the acute phase within 4 weeks, the flow and blood pool images show increased activity (Fig. 4.16). The delayed uptake typically involves less than one fifth of the bone in this phase. Later, only a delayed uptake will be seen. In general, three patterns of uptake on delayed images can be recognized in fractures: a focal band of uptake, diffuse uptake, or peripheral linear uptake parallel to the periosteum [6]. Complete, or partial, scintigraphic resolution

occurs within 4–6 months in the presence of normal healing [6]. Fractures may be single, or multiple (Fig. 4.17, 4.18), particularly in athletes and patients with osteoporosis. Multiple fractures, particularly in osteoporotic patients, may simulate metastatic disease (Fig. 4.18) [107]. Scintigraphically, stress fractures can be staged into five stages as proposed by Zwas [6] based on the amount of bone involvement (Fig. 4.19): stage I involves less than 20%, as mentioned earlier; stage II involves 20–40%; stage III involves 40–60%; stage IV involves 60–80%; and in stage V 80–100% of the bone is involved (complete fractures). Another and simpler grading scintigraphic system was proposed (Table 4.9). The minimally symptomatic grade 1 or grade 2 stress fractures typically resolve more quickly and completely. This grading system can assist in prescribing the needed rest and rehabilitation intervals [7].

However, many different stress fracture classification systems are in the literature. A study

F-18 NaF

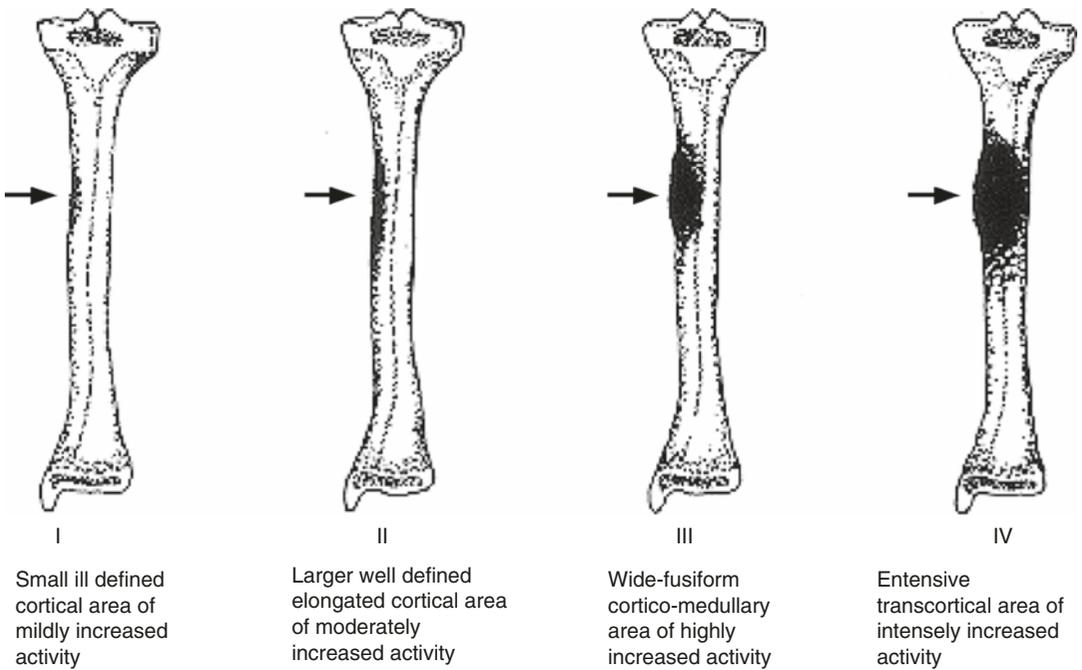

**Fig. 4.18** Multiple insufficiency fractures in the spine, pelvis, ribs, and extremities on F-18 sodium fluoride study of a 79-year-old woman. The pattern may be confused for bony metastases

reviewing the classification systems published in 43 articles concluded that the gold standard classification system for describing stress fractures has yet to be determined. The review found some classification systems being referenced. Some classification systems were based on radiographs alone, while others used a variety of radiographic modalities, including radiographs, bone scans, computed tomography, ultrasound, and magnetic resonance imaging. These systems depend on the imaging modalities, but few include clinical parameters. Many are site specific [108]. Of those that are widely applicable, no general classification

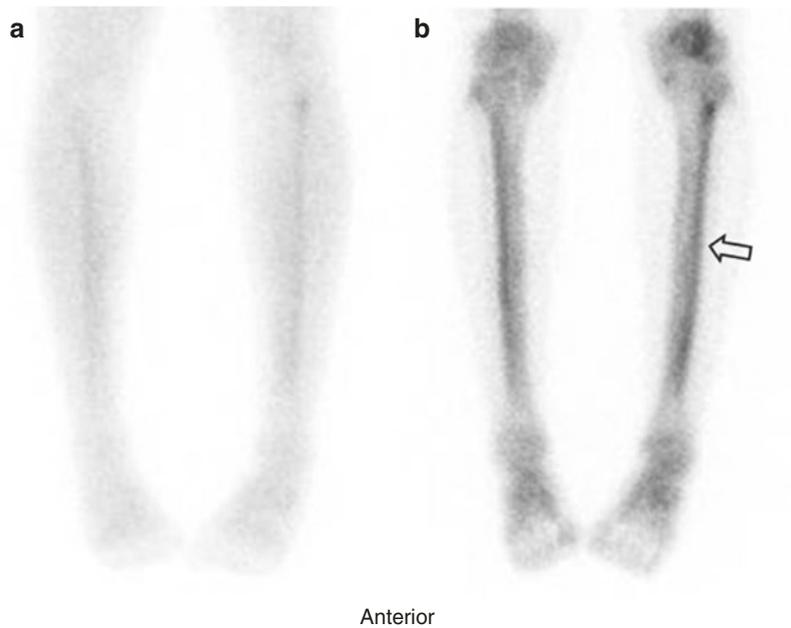

system has been shown to be reproducible, easily accessible, safe, inexpensive, and clinically relevant [109].

Localization of stress fractures is important and should be included in the report since the prognosis can be different. The less frequently encountered anterior tibial stress fractures are more prone to complications such as non-union and avascular necrosis. It is important to note that sometimes anterior fractures show decreased rather than the typical increased uptake focally. Fractures of the femoral neck have the potential for avascular necrosis and displacement. These fractures may show focal uptake along the medial femoral neck but less commonly show a transverse band of increased uptake extending across the femoral neck.

Shin splint results from extreme tension on the muscles, or muscle groups, inserting onto the tibia and to a lesser extent the femur or other bones. This leads to periosteal elevation with reactive bone formation. It is most commonly found in the tibia also known as tibial stress syndrome and may coexist with fatigue fractures. It is characterized by exercise-induced pain and tenderness typically along the posterior medial and anterior lateral aspects of the tibia and anterior medial aspect of the femur. Differentiating shin splints from stress fractures is crucial since the management is different. Radiographs are normal. Scintigraphically, the flow and blood pool are typically normal, although slightly increased activity may occasionally be seen. Using delayed images, there is longitudinal increased uptake along the diaphysis which can be faint and most commonly involve the posteromedial and anterolateral aspects of the tibial cortex (affecting usually one third of the bone length) and the anteromedial border of the femur, affecting usually the upper or midportions of the bone (Fig. 4.20). Both posterior and anterior tibial changes may present in the same individual. The locations of abnormalities suggest that the entity is related to the soleus muscle in the case of tibial splints and the adductor muscle group in the case of the femoral splints [8, 110, 111]. Shin splints also occur in the upper extremity bones.

**Fig. 4.19** A diagram illustrating four stages of stress fracture. Stage V represents complete fracture (diagram from Zwas [6] with permission)

**Fig 4.20** A linear pattern of increased uptake seen at the tibiae illustrating bone scintigraphic pattern of shin splint. Although typically blood pool activity is normal in some cases such as this case, blood pool (a) may show a linear mild hyperemia corresponding to the uptake pattern on delayed image (b)

**Table 4.9** Scintigraphic grading for stress fractures

Grade	Pattern
1	Small, ill-defined cortical area of mildly increased activity
2	Better-defined small cortical area of moderately increased activity
3	Wide to fusiform, cortical-medullary area of highly increased activity
4	Transcortical large area of intensely increased activity

### 4.4.3 Scintigraphic Diagnosis of Specific Stress Fractures

#### 4.4.3.1 Stress Fractures of the Feet

Stress fractures of the feet and ankle, fatigue or insufficiency, are frequently radiographically occult in their acute and subacute phases. The sensitivity of radiography is low and was 18% in one series [6].

Common sites of these fractures in this region include the distal fibula, metatarsals, calcaneus, talus, sesamoid, and navicular bones [112]. Fractures of the feet and ankle are classified into high risk and low risk. High-risk fractures involve navicular bone, talus, fifth metatarsal, sesamoid, and medial malleolus [113]. MRI is sensitive in detecting these fractures in patients with negative radiographs [114]. Scintigraphy is useful in detecting such fractures [115]. Small focal abnormalities in the feet and ankles can be localized well enough by SPECT/CT to make specific orthopedic diagnoses on the basis of their location. Accordingly SPECT/CT should be used to diagnose and localize fractures of the feet because of its added value in accurate localization and in differentiating fractures from other conditions such as joint disease [68].

#### 4.4.3.2 Stress Fractures of the Ribs

Stress fractures of the ribs are common and may be due to repetitive mechanical movement of the upper extremities as seen in golf and rowing sports or in older patients after coughing, hard straining, or other trivial traumas.

In a collaborative review study at 3 institutions, Lord et al. [116] documented 19 cases of stress fractures of the ribs in golfers (the fourth to sixth ribs were the most commonly injured). All fractures occurred along the posterolateral aspect of the ribs, and nine patients had fractures in

more than one rib. Plain radiographs were helpful diagnostically. However, bone scintigraphy was necessary to reach a diagnosis in three cases. Stress fractures of the ribs in golfers may be more common than previously realized, and it is believed that fatigue of the serratus anterior is the mechanism of injury [117].

A case of multiple cough-induced stress fractures and arthropathy has been documented using Tc-99 bone scanning in a high-altitude climber. It has been proposed to add the term “high-altitude cough syndrome” to the medical terminology to identify this discrete medical problem of exposure to very high altitude [118].

Single or multiple foci of increased uptake are seen on bone scan with corresponding blood pool activity in recent fractures.

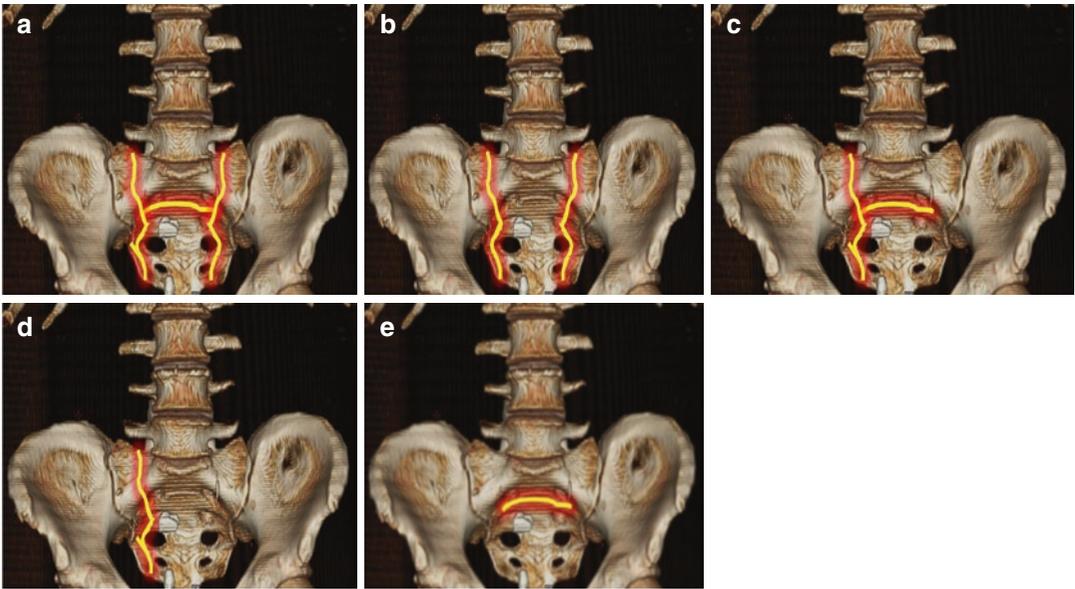

#### 4.4.3.3 Stress Fractures of the Tibia

Tibia is the most common location of stress fractures [119]. These fractures cause severe pain focally and if neglected may cause complete fracture which commonly is complicated by non-union. They occur most frequently in the anterior proximal third in children and at the junction of the middle and distal thirds in adults.

Fifty-two patients with a history and physical examination suggestive of tibial stress fracture underwent a tuning fork test (TFT) followed by a bone scan in order to compare the performance of the TFT with nuclear scintigraphy for the identification of tibial stress fractures. The TFT was performed by applying a 128-Hz tuning fork to the anterior surface of the bared tibia. If the patient reported a marked exacerbation, or reproduction, of the shin pain in a localized area of the tibia, the TFT was considered positive. The sensitivity and specificity of the tuning fork test were 75 and 67%, respectively. The TFT is not sensitive enough to rule out a stress fracture on the basis of a negative test [120] and cannot replace bone scan.

#### 4.4.3.4 Stress Fractures of the Femur

Stress fractures of the femur may involve the femoral neck, intertrochanteric region, and/or the shaft of the bone. The three femoral sites mostly prone to stress fracture are neck, medial proximal shaft, and distal shaft [121]. The fractures may be

**Fig. 4.21** (a–e) A diagram illustrating patterns of sacral fractures as seen on scintigraphy

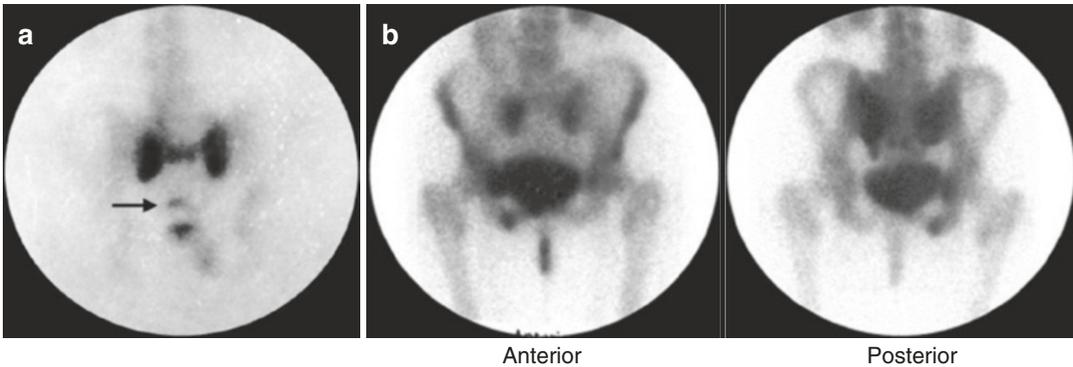

fatigue fractures, which mainly occur in athletes, or insufficiency fractures occurring particularly in older individuals. In either situation, these fractures may lead to significant morbidity, particularly if not treated promptly. Fatigue fractures of the femoral neck may be compressive, typically at the inferior border due to a compressive effect created when the supero-inferior and infero-superior forces meet, or tensile at the superior margin due to injury in adduction [28, 122]. On multiphase bone scanning, which is indicated when radiographs are normal, the fractures present with increased flow, blood pool activity, and varying degrees of increased delayed uptake [28, 122, 123]. Fernandez et al. [123] indicated that the fractures of the neck may show only subtle degree of uptake and may be missed unless the images are analyzed carefully along with careful looking at the pelvis and other bones for associated abnormalities. In our experience, SPECT is important in detecting abnormalities of the femoral neck and can provide important information.

#### 4.4.3.5 Pelvic Fractures

Sacral stress fractures may be an underdiagnosed cause of low back and buttock pain. They occur as fatigue fractures in young active per-

sons and as insufficiency fractures among elderly osteoporotic individuals particularly women [124]. Sacral stress fractures should be included in the differential diagnosis of athletes with low back pain, particularly runners and volleyball players [125].

Pelvic insufficiency fractures may be due to postmenopausal status as a complication of osteoporosis, high-dose corticosteroids, rheumatoid arthritis, or local irradiation. The fractures usually occur in the sacroiliac joint and in the pubis and can mimic bone metastases on bone scans. Knowledge of the nature of the trauma and osteoporosis is essential in order to rule out metastatic disease and thus avoid inappropriate treatment. Although radionuclide bone scanning is useful in the early detection of pelvic insufficiency fractures, CT can provide a definitive diagnosis in many patients [126]. Insufficiency fracture of the sacrum as a cause of lower back pain is not uncommon, especially in postmenopausal women with risk factors. Insufficiency fracture of the sacrum is often radiographically occult. Sacral fractures can present in several patterns (Fig. 4.21). Bone scintigraphy is the method of choice for the diagnosis. The typical scintigraphic pattern is H-shaped uptake (Fig. 4.22a), which presents in

**Fig. 4.22** (a) An example of sacral fractures showing the H pattern with two vertical fractures and connecting horizontal fracture. Smaller horizontal sacral fracture is also

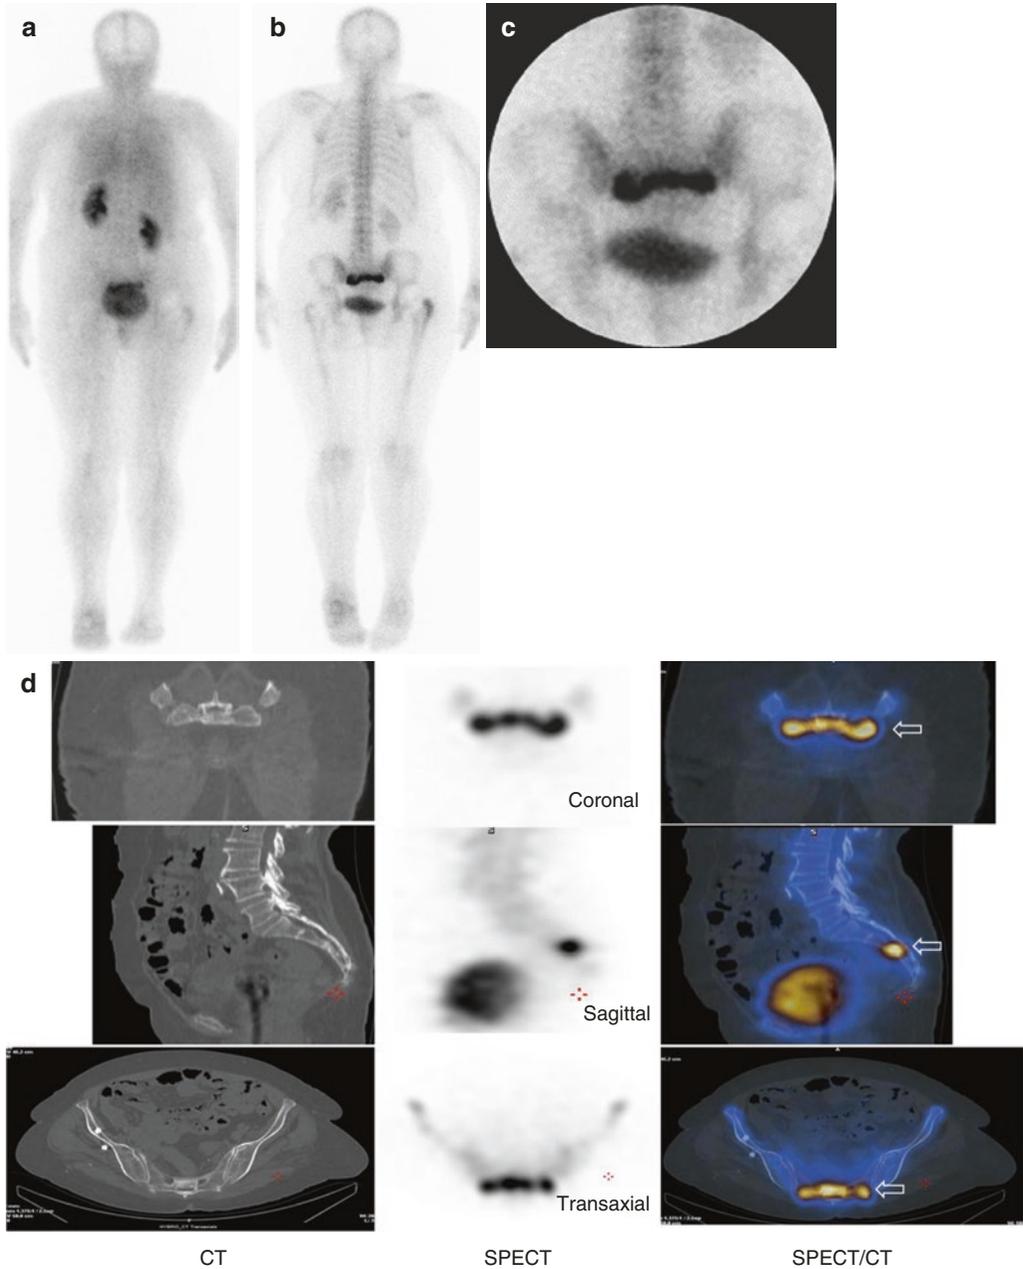

noted (*arrow*). (b) A case showing another pattern of sacral fractures; bilateral vertical fractures

approximately 20% of cases. This sign occurs when the radiotracer activity appears as the letter H, with the vertical components along the sacral ala and the horizontal component crossing the sacral body. The most common pattern, however, is unilateral vertical uptake, which is present in approximately 32% of cases, followed by horizontal uptake in 27% (Fig. 4.23), half H-shaped uptake in 14% (Fig. 4.24), and bilateral vertical uptake in the sacral wings (Fig. 4.22b) in 7% [127, 128]. When the Honda sign and its variants (missing portions of the H) were identified, the sensitivity and positive predictive value were found to be 96% and 92%, respectively [129]. Bone scintigraphy is not only an adequate procedure for the detection of often radiographically occult sacral fractures but also for revealing the often concomitant fractures, since further fractures are identified in 85% of cases, with the main locations in the pubic bone, spine, and ribs [127]. Bilateral fracture of the sacrum has also been associated with pregnancy, and it is not clear whether it represents an insufficiency fracture due to transient osteoporosis of the sacrum associated with pregnancy or a fatigue fracture due to unaccustomed stress related to rapid and excessive weight gain in the last trimester of pregnancy (Fig. 4.22b) [130]. The radiotracer activity of these fractures can be variable at follow-up and may be present 8–10 months after the initial presentation.

#### 4.4.3.6 Vertebral Fractures

Although vertebral fractures can be traumatic and pathological, they are mostly due to insufficiency. Vertebral insufficiency fractures are known to show a marked female predominance and a concave deformity of the affected vertebra. Vertebral fractures are the earliest and most common osteoporotic fractures. The prevalence of vertebral fractures increases steadily with age, ranging between 20% for 50-year-old postmenopausal women and 65% for older women. The majority of vertebral fractures are not connected with severe trauma [131]. They show a wide range of fracture distribution and the vertebral height and low consistency between the vertebral deformity seen on the lateral radiograph and positive abnormality on bone scanning. These findings emphasize the difficulty of radiographic diagnosis of vertebral fractures [132]. Scintigraphy is a sensitive modality for the diagnosis of vertebral fractures (Fig. 4.25) and is useful in determining the age of fractures [133].

Fatigue fractures of the vertebrae mainly occur in active young adults and children. Thirty-three athletes complaining of back pain of more than 1 month's duration and with normal radiography of the lower spine were all studied using scintigraphy. From this group 24 were studied with SPECT, which detected 28% more lesions than planar imaging [134]. SPECT has an additional value in localizing the abnormalities of vertebra; this can also aid in the etiologic

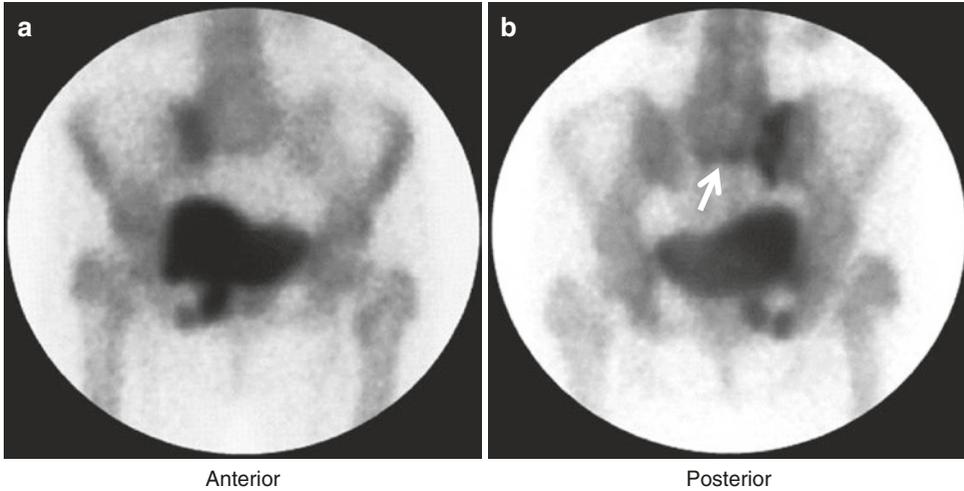

**Fig. 4.23** Example of a horizontal sacral fracture. Whole-body blood pool image (a) shows increased blood pool activity horizontally across the sacral region. Whole-body delayed (b) and spot (c) images show corresponding

linear increased uptake across the sacrum which is also clearly seen (arrows) in representative coronal, sagittal, and transaxial SPECT/CT study (d)

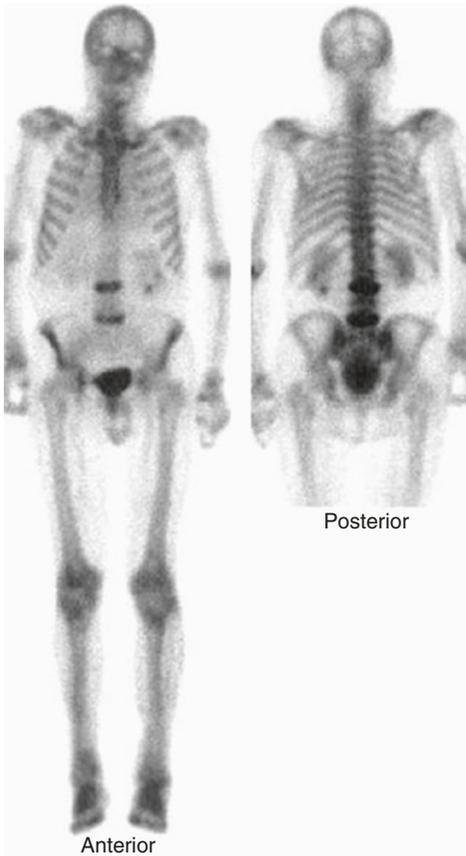

classification of the abnormality based on the location (Fig. 4.26).

SPECT/CT scanning has allowed detection of subtle, non-specific abnormalities on bone scans and interpreting them as specific focal areas of

pathology (Fig. 4.27). Abnormalities in the spine can be separated into those caused by pars fractures, facet joint arthritis, or osteophyte formation on vertebral bodies. Compression fractures can be distinguished from severe degenerative

**Fig. 4.24** (a, b) Unilateral vertical uptake with a connected fainter horizontal uptake (*arrow*) representing another pattern of sacral fractures

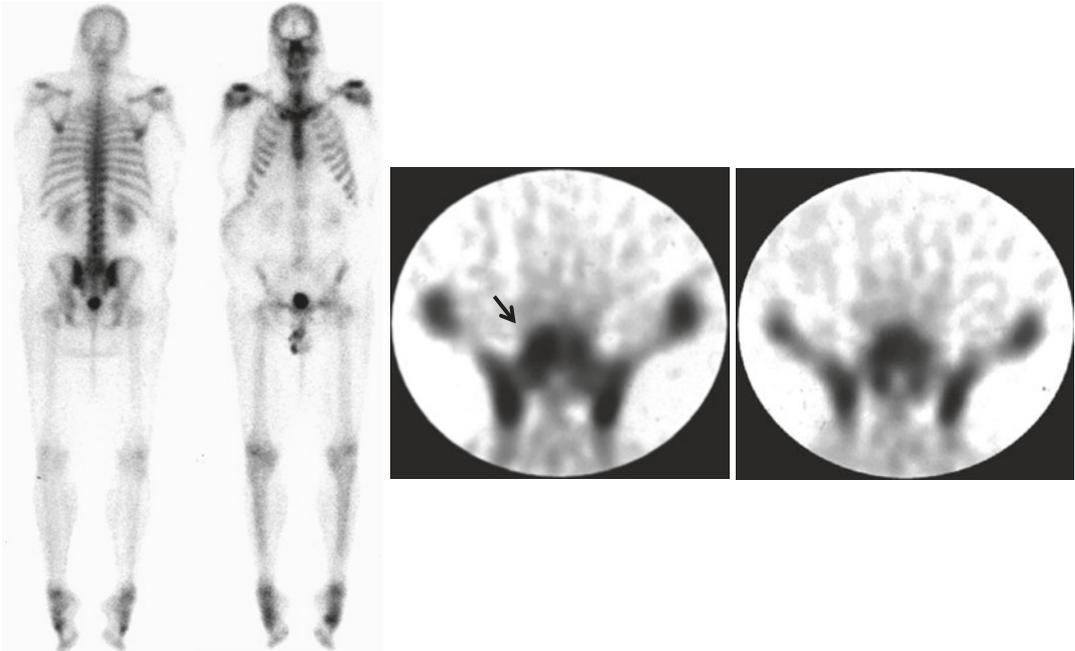

**Fig. 4.25** Compression fractures at the lumbar spine showing typical scintigraphic pattern

disease, both of which appear as increased uptake across the spine on either planar or SPECT imaging. Localizing activity in patients who have had spinal fusion can provide tremendous insight into the causes of therapeutic failures. Moreover, when radiographic imaging provides equivocal or inadequate information, SPECT/CT can provide a road map for further diagnostic studies and has been invaluable in planning surgery. Additionally it enables to localize activity within a bone or at an articular surface which allows distinguishing between fractures and joint disease (see Chap. 10, Fig. 10.5) [68].

#### 4.4.3.7 Schmorl's Node

Unlike the known horizontal disk herniations into the spinal canal or neural foramina, Schmorl's nodes are herniation of nucleus pulposus upward or downward through the cartilaginous and bony end plate into the body of an adjacent vertebra. Usually, they are involving the inferior end plate of lower thoracic and lumbar vertebral bodies. However, the involvement of both the inferior and the superior end plates is not uncommon. They affect mostly the thoracolumbar [135]. They are usually asymptomatic. However, they can become a source of chronic lower back pain. Quiescent Schmorl's nodes are common found in around 75% of autopsies, at all ages, more frequently in males [136].

**Fig 4.26** (a) A whole-body bone scan of a patient complaining of low back pain. The scan shows no definite abnormalities. (b) Representative transaxial cuts of the

SPECT study show focally increased uptake in the right side of L5 vertebra, illustrating the value of SPECT to identify and localize spine abnormalities

A number of theories have been proposed in an attempt to explain the pathogenesis of Schmorl's nodes; however, no consensus currently exists. It is believed that Schmorl's nodes develop following back trauma in the majority of cases. Axial load may produce forces capable of inducing sufficient pressure within the nucleus pulposus that can act on the cartilaginous end plate, causing deformity and herniation [137, 138].

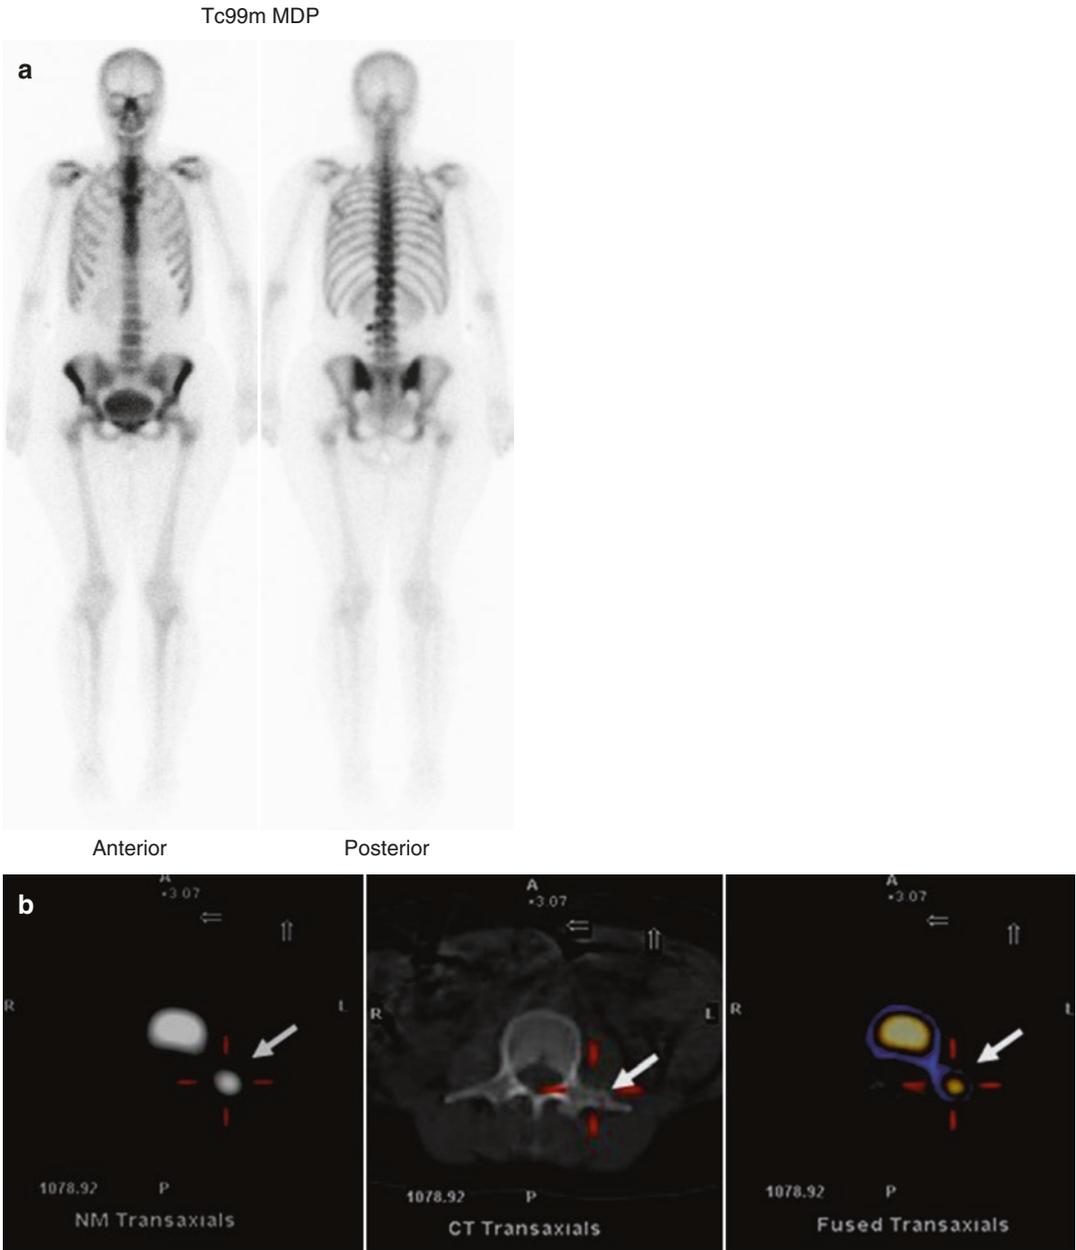

On plain radiographs they appear as small lucent lesions typically involving the inferior end plate of lower thoracic and lumbar vertebral bodies. Involvement of both the inferior and the superior end plates is not uncommon [139]. A sclerotic margin may be present. The lesions are better identified on CT images, showing the same pattern as radiographs. MRI is the procedure of choice for the diagnosis, and lesions are best seen on the sagittal sequences and usually exhibit the same signal characteristics as the adjacent disk, with a thin rim of sclerosis at the margins [138]. Acute herniation can appear more aggressive with surrounding bone marrow edema and peripheral enhancement. These acute features evolve

gradually over months. Acute Schmorl's nodes have been reported to be FDG-PET avid [136].

Lesions can show increased TC-99m methylene diphosphonate uptake on bone scintigraphy mimicking metastasis. SPECT/CT can help in making this differentiation (Fig. 4.28). Differentiation of SN from metastasis is essential [140].

#### 4.4.3.8 Patellofemoral stress syndrome

This condition also known as patellofemoral pain syndrome is one of the most common musculoskeletal disorders and is reported to occur in 15%–33% of the active adults and 21%–45% of adolescents. Among adolescents it is reported to be more common among girls [141]. The patient may present with either pain is either sharp and acute or diffuse and chronic pain. It is believed to be due to abnormal motion or pressure between the patella and femur. Chondromalacia and malalignment were believed to be behind the condition but recently overuse surfaced as a more important factor. Although the exact etiology is not clear, several factors are known to predispose

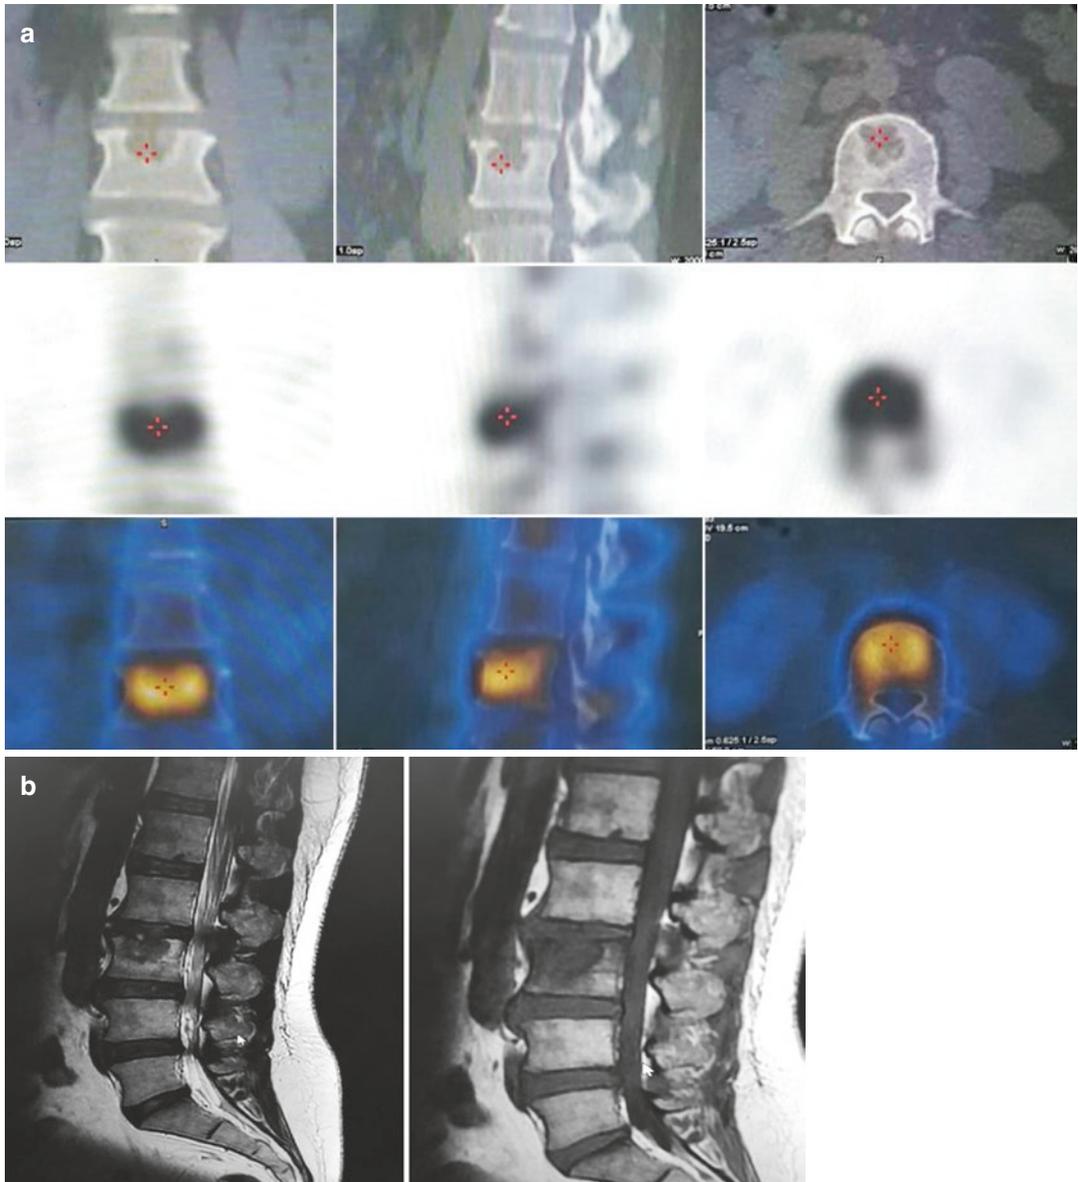

**Fig 4.27** Whole-body Tc-99m MDP scan of a patient with back pain. The study shows a small focus of increased uptake in the left side of L3 (*arrow*) which is not specific

for a certain diagnosis. SPECT/CT study shows a fracture (*arrow*) clarifying the cause of the uptake

to the condition. These include acute trauma, overuse, surgery, excessive weight, prolonged synovitis, immobilization and congenital anomalies of the patella.

In many patients with the condition it is difficult to precisely locate the origin of the pain even with detailed history and proper clinical examination. Scitigraphically, the condition can show diffuse

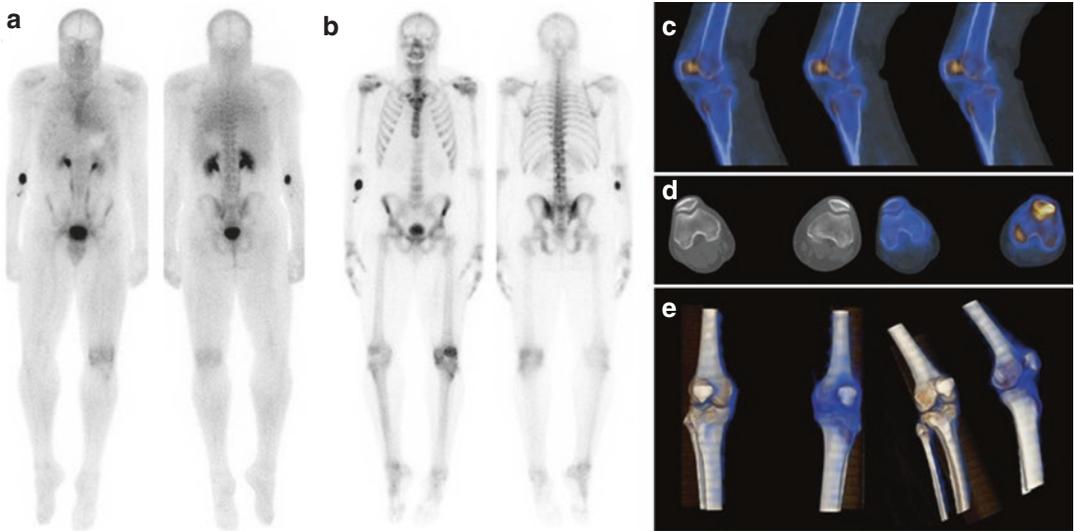

**Fig 4.28** Representative sections of Tc-99m MDP SPECT/CT study (a) of a patient with back pain. The study shows increased uptake in L3 vertebra with a destruction

of the upper end plate. On MRI images (b) abnormality of the vertebrae extending to the intervertebral disk is noted confirming the diagnosis of Schmorl's node

uptake in patella and also in the other two of the three compartments of the knee (proximal tibia and distal femur). SPECT/CT is a valuable tool to diagnose the condition [142–144] as it can clearly identify the condition. Uptake in the patellofemoral

compartment is a confirming pattern which can be seen clearly on SPECT/CT (Fig 4.29). PET/CT using F-18 fluoride has also been reported to be useful in the diagnosis of the condition and provides additional information compared to MRI [145].

**Fig. 4.29** Twenty one year old male with history of trauma and surgery for left cruciate legament 2 months earlier. He presented with left knee pain. Whole body bone blood pool images (a) show mild hyperemia over the left knee joint. Whole body static images (b) show increased uptake in the left patella with milder increased uptake diffusely periarthric-

ularly and in the left tibial tuberosity. Representative sagittal (c), transaxial (d) SPECT/CT study shows clearly the increased uptake in the left patello-femoral compartment and the diffuse milder uptake illustrated further on 3D images (e). These findings represent the scintigraphic patterns of patello-femoral pain syndrome

## 4.5 Scintigraphic Evaluation of Fracture and Bone Graft Healing

### 4.5.1 Evaluation of Fracture Healing

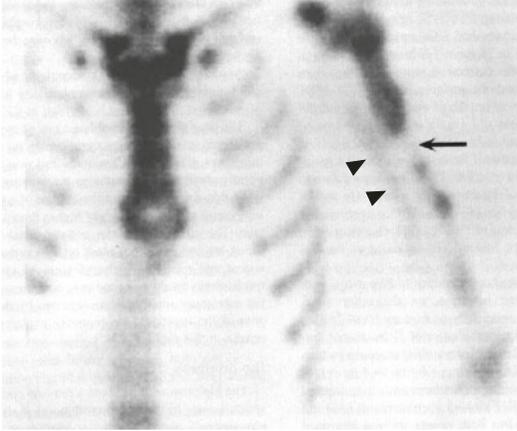

Approximately 60% of fractures heal scintigraphically within 1 year and 90% by 2 years [146]. However, healing also depends on the location of the fracture. Vertebral fractures, for example, take longer to normalize, with only 59% returning to normal by 1 year after the fracture compared to 79% for rib fractures [27].

A scintigraphic study of the healing process of closed tibial shaft fractures was carried out in 40 patients treated nonoperatively, comprising 32 men and 8 women; the average age was 30.6 years. Scintigraphic scans were obtained at 6, 12, and 24 weeks after the fracture, and an activity index was calculated taking the mean of three consecutive uptake counts for both the fractured leg and the normal opposite leg, used for comparison. The results showed that the activity index in general decreased progressively from the first to the third evaluation during healing [147].

Multiphase bone imaging is essential for differentiating hypervascular from avascular (atrophic) non-unions (Fig. 4.28) and for monitoring delayed union [25]. As the name implies, in hypervascular non-union, there is increased flow and blood pool activity along with varying degrees of delayed uptake. On the other hand, in avascular non-unions which require surgical intervention (since nothing will be added by waiting), there is no increased flow, or blood pool activity, and the activity at the site of fracture is decreased on delayed images.

### 4.5.2 Evaluation of Bone Graft Viability

Multiphase bone scanning is an excellent modality for monitoring graft viability noninvasively and offers a simple method for the assessment of the graft's physiological status (Fig. 4.30). Autologous graft revascularization shows an increased uptake on all phases of the scan and eventually becomes uniform to adjacent bone as it is incorporated. Allografting initially shows a photon deficient

**Fig. 4.30** Atrophic non-union. A comminuted fracture of the right humerus due to a gunshot is bridged by a long fibular strut graft placed medially 8 months prior to the bone scan. There is absence of uptake (*arrow*) corresponding to the non-union fracture site. Linear uptake in the medial aspect (*arrow heads*) is at the viable fibular graft (from [148] with permission)

area and gradually shows filling by uptake on serial scans. As initially shown in experimental studies by Stevenson et al. [149], the revascularization of a conventional graft commences at the host-graft junctions with subsequent extension from these sites throughout the graft until finally there is complete integration. Velasco et al. [150], for example, utilizing split rib grafts in ten patients, observed this pattern in nine patients in whom there was consolidation of the graft but observed no uptake in the remaining graft, which failed. With micro-vascularized bone grafts, three-phase scintigraphy is particularly useful because it permits assessment of both the integrity of the blood supply to the bone graft and the viability of the bone demonstrated by functioning osteocytes. Breggren et al. [151] emphasized the importance of the timing of such studies. If they are performed more than 1 week postoperatively, there may be a false-positive bone image due to the onset of creeping substitution whereby new bone is formed on the surface of the graft. However, Itoh et al. [152] favored serial three-phase imaging, since it not only permitted assessment of the vascular potency at an early stage but also allowed continuing observation of any complications. They also drew attention to a patient with an iliac bone graft in whom, following the demonstration of negative

findings in all phases of scintigraphy, hyperbaric therapy was undertaken with subsequent serial bone images showing an improvement in the vascularity and in the bone uptake in the grafted bone.

The utility of planar bone scintigraphy was evaluated for discerning bony union after spinal fusion surgery, especially in cases of clinically and radiologically suggested pseudarthrosis. Between 1991 and 1996, Bohnsack et al. [153] performed bone scintigraphy on 42 patients (21 women, 21 men; mean age: 42 years) after spinal fusion surgery and just before their admission to the hospital for material removal. The fusions comprised 29 lumbosacral, 6 thoracolumbar, 3 lumbar, 2 thoracolumbosacral, 1 thoracic, and 1 cervical. The mean fusion spanned four segments, and the mean time between spinal fusion and material removal was 27 months. Based on scintigraphy, pseudarthrosis was suspected in five patients, and the condition was confirmed in four patients during operation, two diagnosed and two undiagnosed. The accuracy of the method was 88%; sensitivity, 50%; specificity, 93%; positive predictive value, 40%; and negative predictive value, 95%. The authors concluded that the sensitivity and positive predictive value of bone scintigraphy are low for possible instability after spinal fusion and that the method is not sufficient to reliably diagnose pseudarthrosis after spondylodesis [153].

### 4.5.3 Evaluation of Metallic Implants for Removal

The decision to remove metallic implants from patients with fractures with bridging plates, or interlocking nails, is based on subjective criteria. Multiphase bone scanning was found to be a useful guide in timing the removal of the implants. Mild uptake indicates consolidation and implants can be removed, while intense uptake indicates an unconsolidated fracture and implants should not yet be removed [154]. Recently SPECT/CT has been found useful to detect a lack of fixation of the metallic implants and hence instability of the spondylodesis by evaluating the focal bone mineralization activity in relation to the pedicle screws [155]. MRI has much lower diagnostic value in the

presence of metallic implants. SPECT/CT has better sensitivity and specificity than CT [156, 157].

## 4.6 Scintigraphic Diagnosis of Injuries to Bone-Adjacent Structures

### 4.6.1 Avulsion Injury

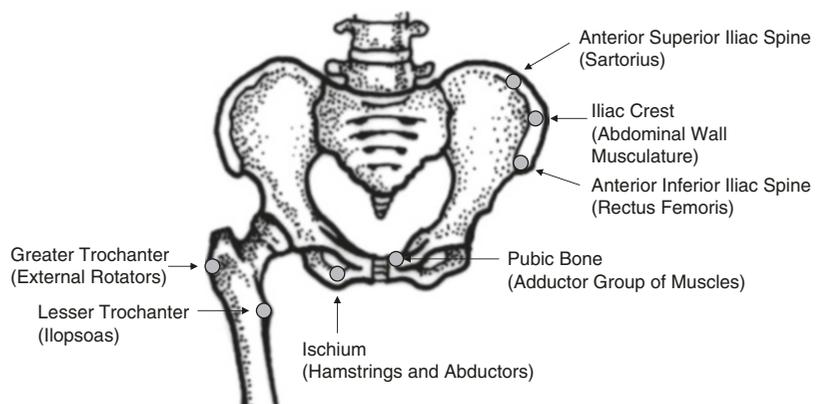

Apophyseal growth cartilage is the weakest point in the musculotendinous unit until they become ossified and is hence particularly prone to being avulsed due to the sudden forceful or repetitive muscular traction.

Figure 4.31 illustrates the major apophyses sites focusing on the pelvic and proximal femoral apophyses and the muscles that attach to them. Common locations of such injuries, at the site of insertion of certain muscles (e.g., the powerful hamstring muscles attaching to the ischium and the brachioradialis muscle to the distal radius), are the ischium, greater and lesser trochanters, anterior superior and anterior inferior iliac spine, iliac crest, and distal radius [157–159]. Avulsion injuries present with acute pain and are common in adolescents. Early diagnosis is important in order to reduce the continuing displacement of the fragment which occurs particularly in avulsions of the ischium, a common injury caused by the power of the hamstring muscles (Fig. 4.32). The condition needs at least 6 weeks of reduced activity for healing. Some avulsions can be readily identified by

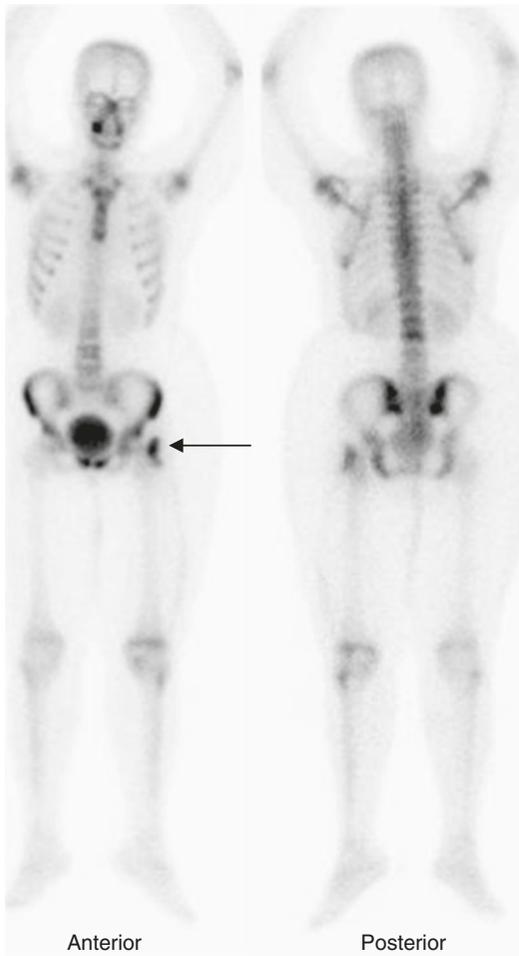

standard radiography, where displacement of the apophysis from its normal position is seen. CT and/or MRI are able to define the separation better; however, in other cases, particularly locations such as iliac crest and anterior inferior iliac spine, the displacement may be difficult to detect radiographically. In such cases scintigraphy is helpful and may be the first investigative technique to point to the diagnosis [157]. The scintigraphic findings depend on the displacement and the time of the study since the injury. The fragment may be clearly seen in its displaced site, but as healing proceeds, a localized increase in uptake, often intense, may be seen along with focally increased uptake on blood pool images (Fig. 4.32) and may also be possibly shown on flow study analysis [9, 123, 158]. Bone scintigraphy has the capability of detecting early avulsion before the onset of edema or changes in the bone marrow that are detected by MRI. If this capability is combined with precise anatomical localization of lesions, it enriches the diagnostic value of this modality in sports medicine [31].

### 4.6.2 Skeletal Muscle Injury

Since muscle injury causes release of muscle protein myosin from the injured cells, In-111-labeled antimyosin antibodies can be used to detect and assess the extent of skeletal muscle damage [6, 160] which is an important parameter affecting fracture healing.

**Fig. 4.31** Sites of pelvic and proximal femoral apophyses and their muscle attachments (in parentheses)

**Fig. 4.32** Avulsion injury in the region of the left greater trochanter in a patient with history of recent trauma

#### 4.6.3 Post-Traumatic Soft Tissue Calcification

Heterotopic bone formation may be associated with trauma (but not exclusively). Bone scanning has a valuable role in its diagnosis, and more importantly follow-up, in order to determine the maturity and appropriate time for surgical intervention [161]. Early in the immature phase, there is increased flow, blood pool activity, and delayed uptake. The flow and blood pool activity decrease gradually until they stabilize, indicating normalization (see Chap. 8 for more details).

#### 4.6.4 Meniscal and Ligament Tears

MRI is known to be the modality of choice for the diagnosis of these tears. However, it may not be possible to perform MRI due to a contraindication or lack of availability. In addition, it is associated with a false-negative rate of approximately 20%. Planar imaging has limited value, and SPECT and/or pinhole imaging help in the diagnosis. For acute tears it has a sensitivity of 88%, negative predictive value of 91%, and positive predictive value of 83% [25]. Pinhole imaging can significantly facilitate the localization of the abnormal uptake.

#### 4.6.5 Enthesopathies (See also Chap. 7)

The sites of insertion of tendons, ligaments, and articular capsule to bone are called entheses. These sites are metabolically active and can act in manner similar to the periosteum at their sites. Trauma, degeneration, and/or inflammation of these sites can result in regional periosteal reaction with osteoblastic bone activity. Plantar fasciitis and Achilles tendinitis, which typically show increased flow and blood pool activity with varying degrees of focally increased activity on delayed images on scintigraphy, are major examples. Enthesopathies are commonly seen as sporting injuries and are associated with conditions as spondyloarthropathies [162].

#### 4.6.6 Impingement Syndromes

This is a group of painful conditions caused by friction of joint tissue. They are classified into bone impingement, soft tissue impingement, and entrapment neuropathy. Although occurring less frequently than meniscal and ligament injuries, impingement syndromes must be taken into consideration when looking for skeletal disorders. Diagnostic imaging, particularly MRI, is very useful as it allows a proper and correct diagnosis procedure for any single condition. Scintigraphy

is a complementary modality; however, physicians interpreting bone scans should be aware of the entity and its findings for proper diagnosis of skeletal conditions. The disorders can be seen in the joint regions of the upper and lower extremities, including the shoulders, elbows, hips, knees, ankles, hands, and feet [163–165].

Rotator cuff impingement syndrome is an example of an upper extremity disorder. Carpal tunnel syndrome is the most common peripheral entrapment neuropathy of the upper limb; it is caused by compression of the median nerve at the wrist. Tarsal tunnel syndrome is the most important ankle entrapment neuropathy causing burning pain and paresthesias in the toes and sole of the foot [166]. The ankle impingement syndrome is a frequent condition in both athletes and the normal population. Examples of this syndrome include anterior tibiotalar impingement, found frequently in dancers following repeated extension of the ankle joint (dorsiflexion). Posterior impingement syndrome of the ankle results from repeated plantar flexion, often among ballet dancers and gymnasts. Consequently, the os trigonum, an accessory ossicle that occasionally forms a synostosis with the posterior aspect of the talus, can become compressed between the calcaneus and the posterior lip of the tibia, eventually creating a fracture [167].

Knee impingement syndromes are very frequently reported in both professional and amateur sportsmen. The sites of symptom onset are divided into the medial, lateral, anterior, and posterior portions. Patellofemoral disorders are the most frequent anterior knee syndromes and are associated with incorrect torsional movements of the lower limbs or local dysplasia. Among posterior impingement syndromes, the most frequent abnormalities involve the insertional tract of the mid-calf muscle, associated with a bursa reaction and insertional popliteus hypertrophy. The most frequent abnormality in medial syndromes involves the parapatellar synovial fold whose symptoms can be often mistaken for a meniscal injury. In lateral syndromes, involvement of the distal insertional tract of the broad fascia tensor tendon with bursa reaction is the most frequent [168]. Scintigraphically, focal area of increased

uptake at the site of injury is characteristic, and pinhole views can again help significantly in localization of the abnormality. Femoroacetabular impingement, also known as hip impingement, is a painful syndrome with limited motion resulting from subtle developmental abnormalities of the proximal femur and acetabulum. It was recently suggested to contribute premature degeneration of the hip leading to secondary osteoarthritis in cases otherwise were thought to have idiopathic or primary osteoarthritis. [169–170]. It was also found to be associated with femoral neck stress fractures and stress reactions [171]. The scintigraphic bone scan changes can be identified best by SPECT/CT [172].

Osteonecrosis is a common condition that is believed to develop after an ischemic event in the bone and bone marrow and is likely due to intravascular coagulopathy. It may be secondary to many other known causes, such as trauma, sickle cell disease, and steroid intake. It may also be primary, or idiopathic, with no apparent cause such as Legg-Calvé-Perthes disease in the pediatric age group and spontaneous osteonecrosis of the femoral head and knee in adults. Bone scintigraphy is more sensitive than standard radiographs. MRI is an excellent complementary modality. Generally, early on, bone scanning shows decreased activity with a subsequent progressive increase in uptake, which starts at the periphery. SPECT is more sensitive than planar imaging, and pinhole imaging is particularly useful in children and small bones. Osteonecrosis may affect one bone or can be multifocal. The osteochondroses are a group of conditions mostly affecting children and adolescents that are characterized by the alteration of endochondral ossification; some forms feature osteonecrosis, such as Freiberg's disease (affecting the second metatarsal head), Kohler's disease (affecting the navicular bone and occasionally the patella), and Osgood-Schlatter disease (affecting the tibial tuberosity).

## 5.1 Introduction

Bone infarction or osteonecrosis most typically occurs in the metaphyseal region of the long bones, often around the knee. The terms aseptic

and avascular necrosis (AVN) are generally applied to areas of epiphyseal or subarticular involvement, as is commonly seen in the femoral head. The terms bone infarct or osteonecrosis are used for the metaphyseal and diaphyseal regions. Since there is a synonymous use of these terms, they are used interchangeably. A variety of conditions predispose to bone infarction, including exposure to compressed air, such as in caisson workers and divers; Gaucher's disease; chronic pancreatitis; gout; pregnancy; exposure to radiation; and collagen or vascular disorders. Osteonecrosis also occurs with no recognizable cause [1].

The classification of vascular bone disorders is difficult to unify, as is the case with other categories of bone diseases. When osteonecrosis occurs in the growing skeleton, it is included in the group of disorders collectively called osteochondroses. These involve the epiphyses or apophyses of the growing bones. The process is due to osteonecrosis in some cases and to trauma or stress in others. In addition to avascular necrosis, the osteochondroses often demonstrate similar pathological features, such as transchondral fractures, reactive synovitis, degeneration, and cyst formation. This group is discussed elsewhere in the book, and only the diseases that feature necrosis are discussed here.

## 5.2 Pathophysiology

Osteonecrosis is thought to develop after an ischemic event in the bone and bone marrow [2]. Although the cause of ischemia remains unknown, Jones claimed that intravascular coagulopathy is an intermediary event initiated by several seemingly unrelated risk factors, including alcoholism, hypercortisolism, hyperlipidemia, and allograft organ rejection (hypersensitivity reactions) [3]. Intravascular coagulopathy occurs in the capillary-sinusoidal beds, arteries, or veins. The resulting vascular compromise leads to imbalances between the demand and supply of oxygen to osseous tissues and consequently avascular necrosis of the bone or osteonecrosis. There are many causes for osteonecrosis (Table 5.1). In some cases the underlying cause cannot be determined, and in this situation the condition is called

primary, idiopathic, or spontaneous osteonecrosis. This commonly affects the femoral head, distal femur, tibial plateau, carpal bones, and humeral heads. Following the interruption of blood supply, blood-forming and mesenchymal cells of the marrow as well as primitive osteoblasts are involved first and die 6–12 h after the cessation of blood flow. Bone cells including osteocytes and mature osteoblasts die 12–48 h later, followed by the fat cells, which are most resistant to ischemia, later (Table 5.2 and Fig. 5.1). This sequence of events may explain why bone marrow scintigraphic changes, with decreased uptake, appear earlier than bone scan abnormalities [4, 5]. Ischemia does not directly affect the cartilage. The articular cartilage receives most of its nutrition by direct absorption from the synovial fluid. Cartilage, however, cannot resist persistent elevation of

**Table 5.1** Causes of osteonecrosis

1.	Trauma (fracture or dislocation)
2.	Hematologic diseases (sickle cell anemia, thalassemia, polycythemia, hemophilia, myeloproliferative disorders)
3.	Exogenous or endogenous hypercortisolism (corticosteroid medication, Cushing's syndrome)
4.	Renal transplantation
5.	Alcoholism
6.	Pancreatitis
7.	Dysbaric (Caisson disease)
8.	Small vessel disease (collagen vascular disorders)
9.	Gaucher's disease
10.	Hyperuricemia
11.	Irradiation
12.	Synovitis with elevation of intra-articular pressure (infection, hemophilia)
13.	Idiopathic (spontaneous osteonecrosis)

**Table 5.2** Time sequence of cell death after ischemia

Cell	Time of death after interruption of blood supply
Blood-forming cells	6–12 h
Mesenchymal cells	6–12 h
Primitive osteoblasts	6–12 h
Bone cells including osteocytes and mature osteoblasts	12–48 h
Fat cells	2–5 days

intracapsular pressure for more than 5 days, after which time degeneration begins.

When the reparative process is initiated, it is carried out by neovascularization through the collateral circulation advancing from the periphery of the area of necrosis or by recanalization of the occluded vessels. This newly formed granulation tissue provides all the elements necessary for the formation of bone matrix and new bone deposition by young osteoblasts. This repair process may, however, be altered. Bone collapse may occur, resulting from structural weakening and external stress. Bone collapse and cartilage damage can result in significant deformity [5, 6].

### 5.3 General Scintigraphic Features and Staging

Bone scans and magnetic resonance imaging (MRI) are the most valuable imaging modalities in the diagnosis, and follow-up, of avascular necrosis. The different scintigraphic patterns of femoral head avascular necrosis correlate with the sequence of pathological events. During the first 48 h, the morphology of the bone is preserved, and the radiographs are normal. Osteoblastic uptake on bone scanning varies from absent to almost normal which reflects the greater relative resistance of mature osteoblast to ischemia. Subsequently a cold area of necrosis develops. This avascular pattern will be seen

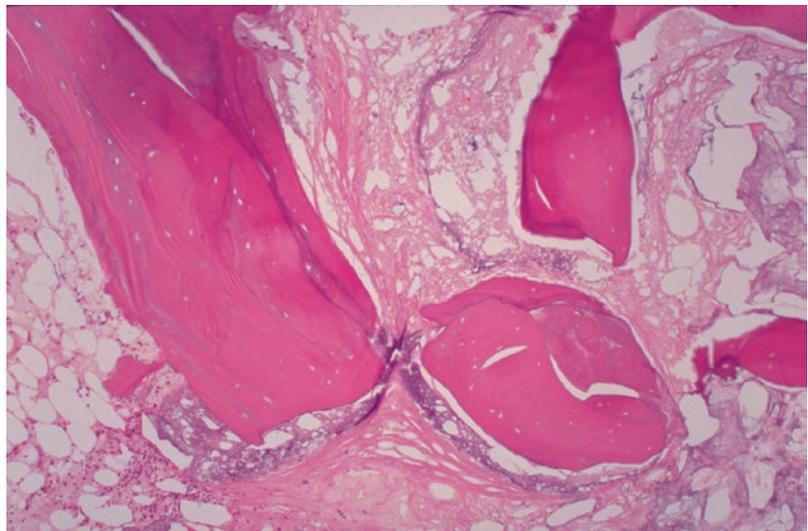

immediately if interruption of the blood supply is abrupt and severe.

The next stage begins with the reparative process. In this stage, hyperemia is frequent, and there is diffuse demineralization of the area surrounding the necrotic tissue. This stage is characterized scintigraphically by progressively increased technetium diphosphonate uptake starting at the boundaries between the site of necrosis and the normal tissue and beginning after 1–3 weeks. This increased uptake will eventually advance around a central photopenic area and lasts for a few months.

As the reparative process is completed, uptake returns to normal. However, in cases with bone collapse increased uptake may persist indefinitely. Is characterized by collapse of the articular cartilage with degenerative changes on both sides of the joint with a resultant increased periarticular uptake.

Single-photon emission computed tomography (SPECT) is useful in the diagnosis of femoral head avascular necrosis, particularly when the reparative process is thought to have started. SPECT can detect a center of decreased uptake, a finding that increases the accuracy of bone scanning for the diagnosis of the condition.

It should be noted that no uniform method for staging osteonecrosis is yet available, and depending on the site of the disease, three to seven stages may be used by different investigators [7–20]. These classification and staging systems depend predominantly on imaging particularly MRI and

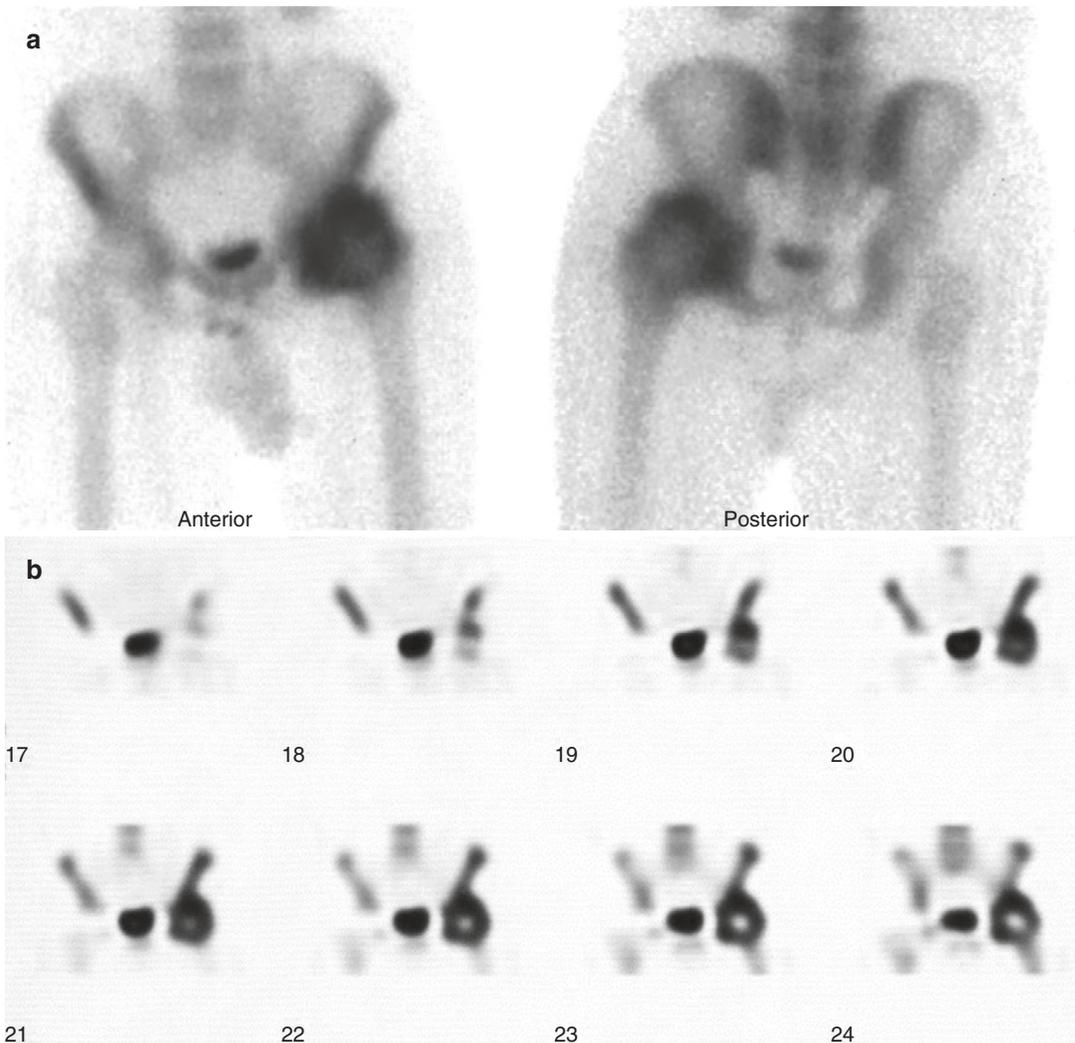

**Fig. 5.1** A photomicrograph of a necrotic bone. Note the paucity of cells in marrow spaces

no ideal system is agreed on to date and it is difficult to create [21].

The patterns of abnormalities seen on bone scintigraphy vary according to the site of osteonecrosis. Specifically, the pattern in the knee region is different from the pattern in the femoral head. Since the knee is richly supplied by blood, we see hot, or increased, uptake as the usual pattern. In the femoral head, on the other hand, one sees a decreased uptake and later a “cold in hot” pattern or only a hot pattern. The “cold in hot pattern” is very specific since most patients will not show the classic cold pattern by the time they have the scintigraphy. SPECT is useful in resolving the

cold center in an apparently hot lesion on planar images (Fig. 5.2). In patients with osteonecrosis of the femoral head, the blood supply is absent from the avascular segment and the area appears cold, whereas the reparative area with new vascular formation around the necrotic lesion appears hot on bone scanning. On the other hand, in the distal femur and the proximal tibia (knee region), the anteroposterior bone volume is larger, and the blood supply from vascular anastomosis is richer than in the femoral head. Thus, bone uptake on the anteroposterior or posteroanterior plane tends to increase. Therefore, all lesions are thought to demonstrate focally increased bone uptake. The

**Fig. 5.2** a, b Planar (a) and SPECT (b) imaging of osteonecrosis of the left femoral head illustrating the additional diagnostic value of the technique in resolving the specific scintigraphic pattern of the condition

patterns of increased bone uptake look partially similar to the patterns in osteoarthritis of the knee [22, 23]. SPECT/CT is more accurate than SPECT and has also an advantage in assessing the reparative process at different stages of osteonecrosis compared to MRI [24]. It should be noted that F-18-FDG may accumulate in areas of osteonecrosis and may mimic malignancy due to the presence of inflammatory cells [25–31].

## 5.4 Distinctive Forms of Osteonecrosis

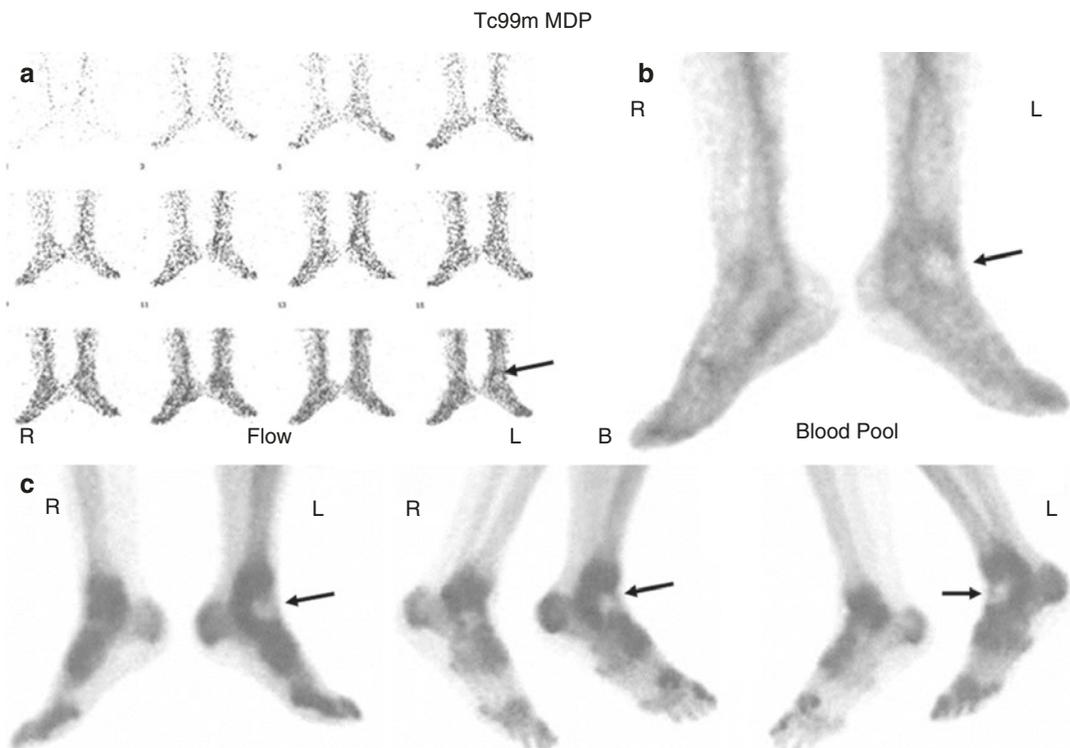

### 5.4.1 Post-traumatic Osteonecrosis

Following a fracture, bone death of variable extent on either side of a fracture line is relatively common. Necrosis of a relatively large segment of the bone following fracture or dislocation is, however, generally restricted to sites that possess a vulnerable

blood supply with few arterial anastomoses. The femoral head, the body of the talus (Fig. 5.3), the scaphoid bone, and the humeral head are such sites [6]. Other locations include the carpal hamate and lunate and the tarsal navicular bone. These bones are characterized by an intra-articular location and limited attachment of soft tissue in addition to the peculiarities of their blood supply [5].

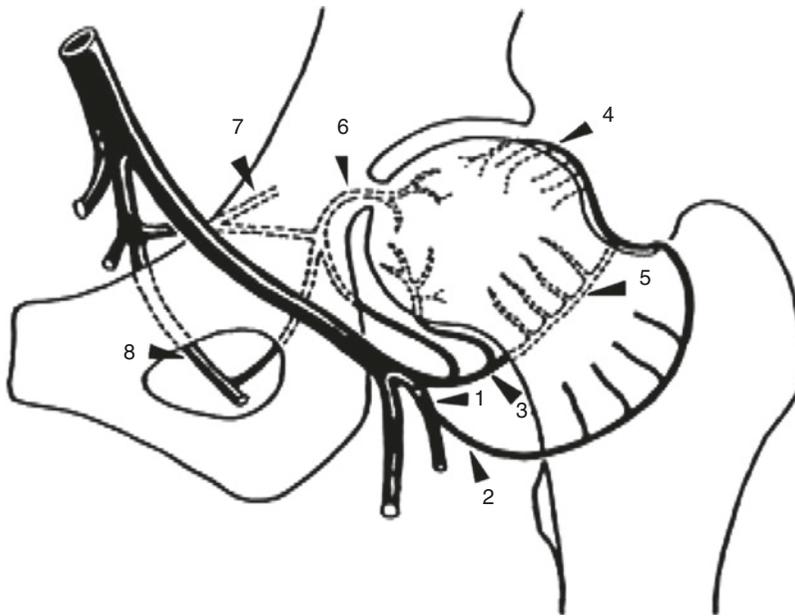

### 5.4.2 Osteonecrosis of the Femoral Head in Children (Legg-Calvé-Perthes Disease)

Legg-Calvé-Perthes disease is an idiopathic hip disorder that produces ischemic necrosis of the growing femoral head and may lead to permanent femoral head deformity as the most significant sequel [32]. This condition predominates in boys aged 4–7 years old. The blood supply to the adult femoral heads is via the circumflex femoral

**Fig. 5.3** a–c Post-traumatic osteonecrosis. Osteonecrosis of the talus bone in a 34-year-old male with history of foot trauma 2 months earlier. Flow images (a) show an ill-defined area of decreased flow in the region of the left talus,

better seen on blood pool images (b), which also show a rim of increased blood pool activity. On delayed images (c) there is a photon-deficient area in the left talus surrounded by a rim of increased activity, indicating healing

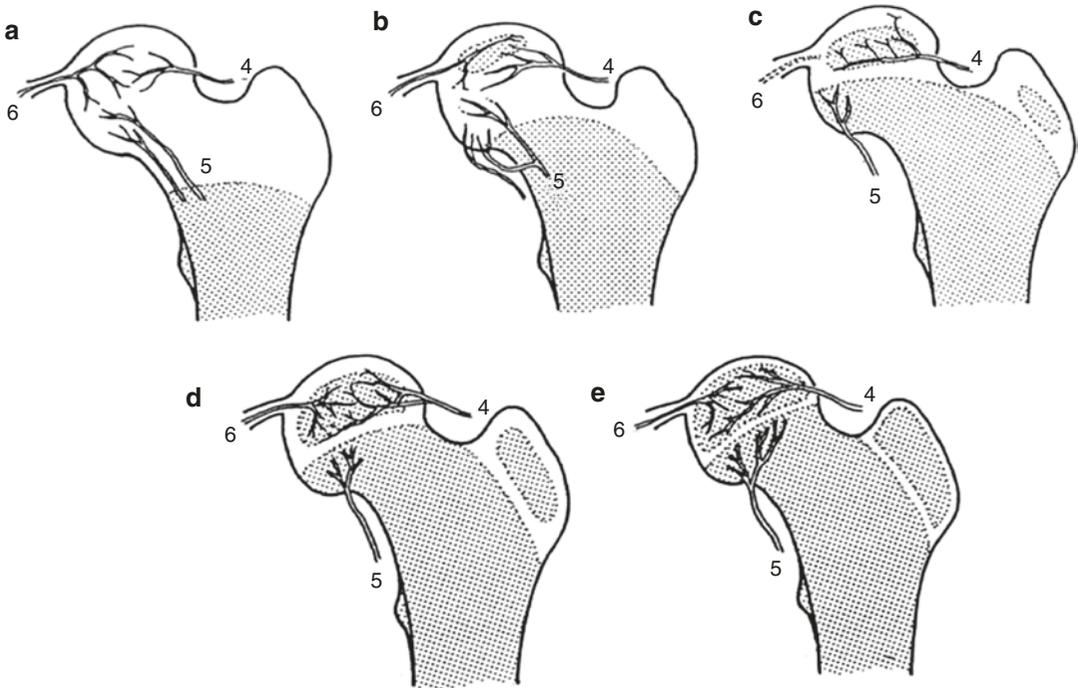

**Fig. 5.4** Femoral head vasculature in adults. The major blood supply is derived from the profunda femoris artery (1) from which arise the lateral (2) and the medial (3) circumflex arteries (the medial and lateral circumflex arteries may arise from the femoral artery rather than the profunda femoris artery in some individuals). As these latter vessels pass anterior and posterior to the femur to anastomose at the level of the trochanters, they send off small branches beneath the capsule of the hip joint. These branches,

including the superior retinacular (lateral epiphyseal) arteries (4) and the inferior retinacular (inferior metaphyseal) arteries (5), raise the synovial membrane into folds or retinacula. A second supply of blood is derived from the vessels of the ligamentum teres. Here, the foveal (medial epiphyseal) arteries (6) can be noted. Additional regional vessels are the inferior gluteal artery (7) and the obturator artery (8) (From Resnick and Niwayama [84], with permission)

branches of the profunda femoris artery (Fig. 5.4). This adult pattern of femoral head vasculature usually becomes established with closure of the growth plate at approximately 18 years of age. Before this, in infancy and childhood, variable vascular patterns are noted (Fig. 5.5). The changing pattern of femoral head vascular supply with age may explain the prevalence of Legg-Calvé-Perthes disease in individuals between the age of 4 and 7 years and the high frequency of necrosis following femoral neck injury in children. Fractures of the femoral neck (occurring more often as intracapsular than extracapsular fractures) are the most common cause. Other causes include dislocation of the hip and slipped capital femoral epiphysis. Although MRI is currently used commonly for the diagnosis [33], bone scintigraphy is an integral part of the work-up of patients suspected of having the condition. In our own experience, pinhole imaging (Fig. 5.6) has

proved to be a valuable tool in the evaluation of this condition and is preferred to SPECT in this age group. Pinhole imaging must be used routinely in these age group patients with suspected Legg-Perthes disease rather than parallel hole. Additionally since the anterolateral aspect of the femoral head (the principal weight-bearing region) is typically involved, but no region of the head is necessarily spared and involvement is not uniform, pinhole imaging using frog leg and straight anterior positions is recommended for better resolving the abnormalities of this condition. The sensitivity and predictive values of early postoperative bone scanning for the detection of early avascular necrosis of the femoral head after surgical treatment of slipped capital femoral epiphysis were evaluated by Fragniere et al. The authors reviewed records of 49 patients (64 hips) operated with a mean follow-up of 3 years. Sixty-one out of 64 hips had an early

**Fig. 5.5** Femoral head vascularity in infancy and childhood. Blood supply to neonates (a), infant and child between 4 months and 4 years of age (b), child between 4 and 7 years of age (c), preadolescent between 7 and 12 years of age (d), and adolescent between 12 and the

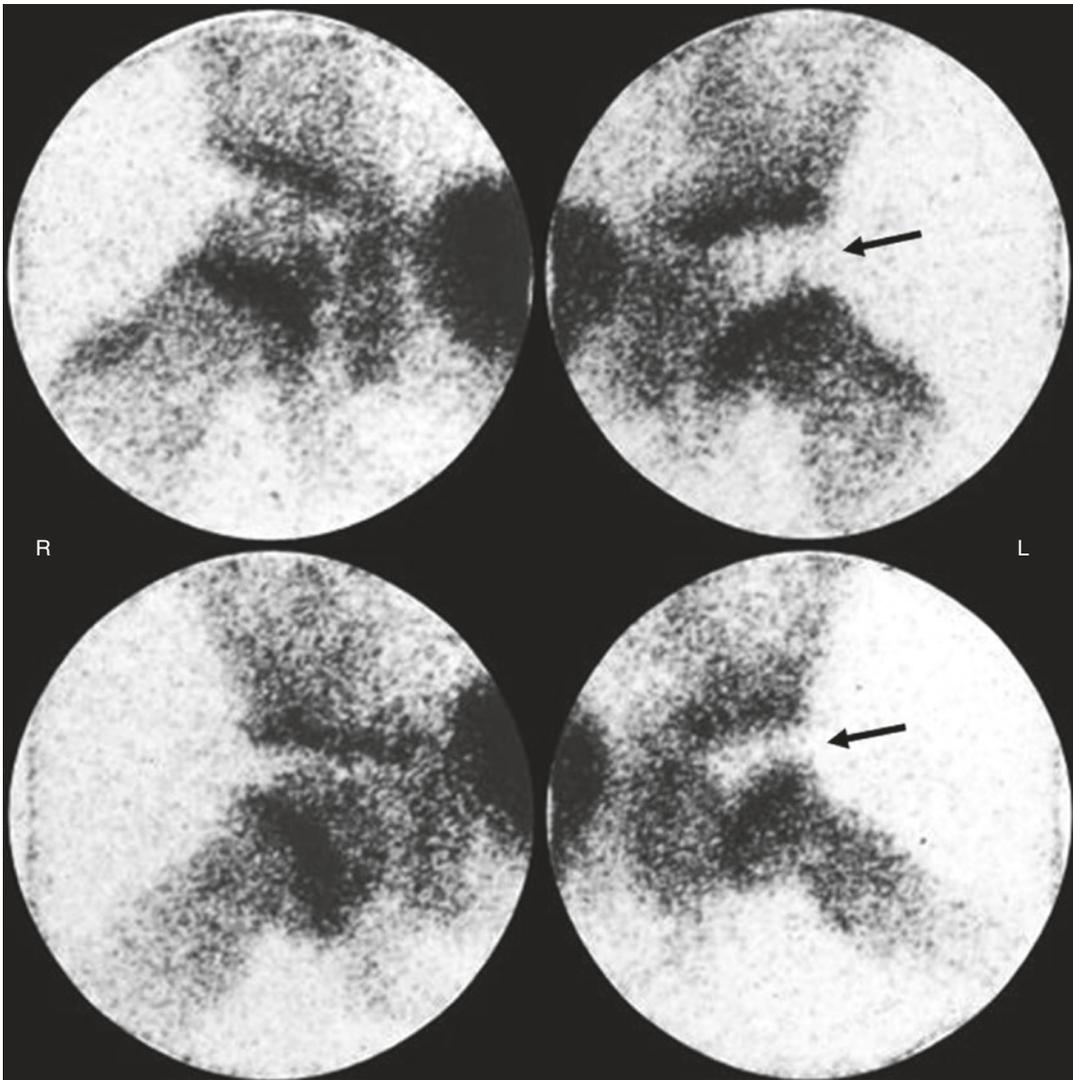

time of closure of the growth plate (e). Illustrated are the superior retinacular (4), inferior retinacular (5), and foveal (6) arteries (From Resnick and Niwayama [84], with permission)

postoperative bone scan. The three hips that developed AVN showed a significant decrease in radionuclide uptake. There were neither false-positive nor false-negative cases in this series [34]. The authors concluded that bone scintigraphy has excellent sensitivity and predictive value for detection of AVN after surgical treatment of slipped capital femoral epiphysis.

Bone scintigraphy has proven also to have prognostic value. Conway introduced a prognostic classification [35] of two pathways; pathway A is defined by the early appearance of a lateral column formation (before any radiologic sign) in the capital femora; epiphysis indicating early and rapid revascularization. This pathway is associated with good outcome. The pathway B is defined by centrally extended scintigraphic activity from the base of the capital femoral epiphysis or by the absence of the activity in the epiphysis (lateral column formation) after 5 months. The

prognostic value of this classification was reconfirmed by Comte et al. [36] who showed that the presence of lateral column formation (pathway A) has a positive predictive value of 85% for good outcome. On the other hand, the pathway B with the absence of lateral column formation has a 97% positive predictive value for poor final outcome. Comte found that the appearance of hyperactivity of the metaphyseal growth plates is additional prognostic information since it indicated poor outcome. Value of bone scintigraphy in determining prognosis is also in terms of the short time in which the prognostic information can be obtained since it may be seen as early as the time of presentation but generally during 5 months duration after the insult.

The value of scintigraphy in predicting the course of the disease was illustrated by Tsao [37], who studied 44 consecutive patients treated for Legg-Calvé-Perthes disease. The patients

Pinhole Hips

**Fig. 5.6** Bone scan pinhole image showing the pattern of Legg-Calvé-Perthes disease of the right hip. Typically a cold area is noted involving the femoral head (*arrows*)

underwent serial technetium-99m diphosphonate bone scintigraphy and were followed up for an average period of 4.4 years. The bone scintigraphy classification characterizes cases into the two Conway pathways. Pathway A had 20 hips. The average age at presentation was 6.1 years. At last follow-up, this group had an average Mose classification of 1.2 and Catterall score of 2.4, without any patient having head-at-risk signs or requiring operative treatment. Pathway B had 20 hips. The average age at presentation was 5.8 years. At last

follow-up, this group had an average Mose classification of 5.2 and a Catterall score of 3.5, and 18 patients had head-at-risk signs, with 11 requiring operative treatment. Bone scintigraphy classification preceded the radiographic head-at-risk signs by an average of 3 months, allowing earlier treatment and correlated with subsequent femoral head involvement [37].

MRI is also very useful in predicting the course of the disease particularly later in the course of the disease during the fragmentation

stage [38]. In patients with Legg-Calvé-Perthes disease, progressive degenerative changes may develop in subsequent years.

### 5.4.3 Osteonecrosis of the Femoral Head in Adults

Femoral head is a common site of osteonecrosis in adults as is the case in pediatric population. It is a common disease entity with approximately 20,000 new cases reported each year in the USA [39, 40]. The condition commonly occurs secondary to trauma, long-term corticosteroid use, alcohol abuse, chronic pancreatitis, renal transplantation, systemic lupus erythematosus, and others. Generally the condition affects young men in their late thirties and early forties and is initially unilateral, but with progression it becomes bilateral in up to 72% of cases [41]. As many as 30% of individuals with conditions such as systemic lupus erythematosus or sickle cell anemia will develop osteonecrosis of the femoral head. Additionally, osteonecrosis is the underlying diagnosis in as many as 12% of more than 500,000 total hip arthroplasties performed in the USA [21]. When the cause or an underlying condition cannot be identified, the condition is classified as spontaneous or primary osteonecrosis of the femoral head; this is usually seen in older patients. Although MRI is currently considered the imaging modality of choice [42], scintigraphy is still used and valuable in the early diagnosis, follow-up, and in determining the prognosis in both primary and secondary forms [43, 44]. Several studies have shown that MRI is more accurate than scintigraphy, while others showed the opposite [45–47]. Later with the use of SPECT, other studies showed better accuracy than MRI [48]. SPECT was found more sensitive than MRI for the detection of femoral head osteonecrosis in renal transplant recipients. The diagnostic sensitivity of the two modalities was compared in the early detection of femoral head osteonecrosis in 24 patients after renal transplantation, with 32 femoral heads confirmed as having secondary osteonecrosis. The patients underwent both bone SPECT and MRI within

1 month of each other because of hip pain but had normal findings on plain radiography. SPECT was considered positive for osteonecrosis when a cold defect was detected in the femoral head, and the defect was further classified according to the presence of an adjacent increased uptake: type 1 = a cold defect with no adjacent increased uptake; type 2 = a cold defect with adjacent increased uptake. MRI was considered positive for osteonecrosis when a focal region with low signal intensity on T1-weighted images was seen in the femoral head. SPECT detected osteonecrosis in all 32 femoral heads, resulting in a sensitivity of 100%, whereas MRI detected osteonecrosis in 21 femoral heads, with a sensitivity of 66%. SPECT showed the type 1 pattern in 13 and type 2 in 19 cases. Ten of the 13 femoral heads with the type 1 pattern were false negative on MRI, whereas only 1 of 19 with the type 2 pattern was normal on MRI. There were six femoral heads with normal MRI findings and abnormal SPECT findings (type 1 pattern) in three patients, for whom hip pain decreased and radiographic findings were normal during follow-up. Follow-up bone SPECT showed a decreasing area of cold defect in four femoral heads [48].

Blood pool imaging, or the early static phase of the multiphase bone scan, was also found to be useful in establishing early the hemodynamic changes in patients with osteonecrosis of the femoral head and in estimating early the hemodynamic changes. Three-phase bone scintigraphy was performed on 19 renal allograft recipients between 3 and 9 weeks after they underwent renal transplantation by Kubota et al. [49]. Regions of interest were assigned bilaterally in the femoral heads, diaphyses, and soft tissue. The head-to-diaphysis ratio in each phase was then calculated. Osteonecrosis occurred in eight femoral heads of four patients; three had no abnormal MRI findings at the time of bone scintigraphy. On blood pool imaging and delayed bone scan phases, the head-to-diaphysis ratio was significantly lower than that in the non-osteonecrosis patients [49].

Recently SPECT/CT has been found to be more accurate than planar and SPECT techniques and adds incremental value compared with

SPECT [50, 51]. Agrawal et al. reported an accuracy of 96% for SPECT/CT compared to 67% and 78% for planar and SPECT, respectively, for femoral head osteonecrosis [51]. SPECT/CT is also useful in the assessment of the reparative process [20]. In most current reports, MRI is considered the procedure of choice as it is generally the most sensitive and other modalities are reserved for specific situations. CT is needed to exclude subchondral fractures and scintigraphy when physiologic information is needed and when MRI cannot be obtained [52]. Recently F-18 fluoride PET has been also found to be the most accurate for the diagnosis of the condition as it was reported to be 100% sensitive and specific compared to 96.5% sensitivity and 100% specificity for MRI [53]. However, the cost and radiation exposure would limit the use of F-18 PET/CT to specific cases as in postoperative patients with hardware and in patients complaining of pain at multiple bone and joint regions as well as when quantitation is needed.

Using pinhole scintigraphy, higher tracer uptake at the reactive interface in early phases of femoral head osteonecrosis has been found to indicate a bad prognostic sign for femoral head collapse even in the same stage of the disease [43, 54].

#### **5.4.3.1 Spontaneous Osteonecrosis of the Femoral Head in Adults**

Although no specific cause is recognized for this condition, abnormality of the fat metabolism, leading to fatty marrow infiltration or vascular embolization, is the most popular hypothesis [55]. Spontaneous (primary) osteonecrosis of the femoral head affects men more frequently than women and is usually seen between the fourth and the seventh decade of life. Unilateral and bilateral involvement may be seen. The reported incidence of bilateral disease has varied from 35% to 70%, influenced mainly by the method of examination and the duration of follow-up. Despite the high frequency of bilateral involvement, the condition is usually first manifested as unilateral. The pathological findings are virtually identical to those in other varieties of osteonecrosis. SPECT is more sensitive (85%) than planar

imaging (55%) in demonstrating photopenia in the femoral heads [56].

The sensitivity for the diagnosis of osteonecrosis of the femoral head for bone scintigraphy equipped with a pinhole collimator and with a high-resolution parallel collimator was compared by Maillefert et al. in 16 patients. A total of seven patients were found with bilateral osteonecrosis, while nine had unilateral osteonecrosis of the femoral head. Pinhole scintigraphy documented a photopenic defect in 78% of the necrotic hips, while imaging with a high-resolution parallel collimator documented a defect in 48%. There was no false-positive diagnosis of osteonecrosis of the femoral head using either technique [57]. However SPECT is preferred for diagnosis of femoral head osteonecrosis in adult patients.

Staudenherz documented the value of bone scintigraphy in differentiating osteonecrosis and the bone marrow edema syndrome [58]. Forty-eight symptomatic adult patients (with a final diagnosis of osteonecrosis, bone marrow edema syndrome, other hip pathologies, and one normal hip) were examined with dynamic bone scintigraphy visually and qualitatively. A cold spot in the femoral head in both the blood pool and the delayed bone phases was seen only in 24% of osteonecrotic hips. Only 36% of patients with bone marrow edema syndrome of the hips showed diffuse tracer accumulation in the femoral head, neck, and the intertrochanteric region in the blood pool phases. The presence of this uptake increased the accuracy of differentiating osteonecrosis and bone marrow edema syndrome. The authors found that osteonecrosis could be differentiated from bone marrow edema syndrome with an accuracy of 86% if the signs of the femoral head and intertrochanteric uptake were taken into consideration.

Scintigraphy also has a prognostic implication. Large cold areas are associated with a higher rate of collapse. Hasegawa reported that all four patients with large cold areas on scintigraphy had bone collapse within 1 year after osteotomy surgery for osteonecrosis despite good recovery of the weight-bearing surfaces immediately after operation on standard radiographs [59] Another

study found similar results in pediatric patients who had surgery for slipped capital femoral epiphysis [34]. SPECT/CT is currently preferred over SPECT for the diagnosis of all types of osteonecrosis of the femoral head since it adds the benefit of CT in accurate localization and identifying possible other causes for the abnormal uptake seen on SPECT images [50, 51].

#### 5.4.4 Spontaneous Osteonecrosis of the Knee

Although osteonecrosis around the knee is observed in association with steroid therapy, sickle cell anemia, other hemoglobinopathies, and renal transplantation, it may also occur as a spontaneous or idiopathic pathology. The first description of idiopathic osteonecrosis of the medial femoral condyle as a pathologic entity was by Ahlback and colleagues in 1968 [60]. The blood supply in the knee joint is derived from a rich anastomosis of the five major constant arteries, namely, the superior medial and lateral, the middle, and the inferior medial and lateral genicular arteries [61]. Spontaneous osteonecrosis can affect any part of the knee [62–67]. It occurs most characteristically in the medial femoral condyle but can also affect the medial portion of the tibial plateau, the lateral femoral condyle or lateral portion of the tibial plateau, the distal femoral metaphysis, and the proximal tibial metaphysis. It rarely affects the patella alone or in combination with the medial femoral condyle [62].

The condition affects predominantly women above 60 years and is characterized by the abrupt onset of knee pain, localized tenderness, stiffness, effusion, and restricted motion. Unilateral involvement is more common than bilateral. The pathogenesis of this condition is not clear. Vascular insufficiency associated with age is a proposed etiology. The finding of microfractures in the subchondral bone with secondary disruption of the local blood supply has also been emphasized. A predominant role of meniscus injury in the pathogenesis of spontaneous osteonecrosis has also been proposed. This condition may not even be a true osteonecrosis and is pro-

posed to be due to subchondral insufficiency fractures in osteopenic bone, with no evidence of necrosis. These insufficiency fractures may lead to fluid accumulation in the bone marrow, which results in subsequent edema with focal ischemia, and eventually necrosis [63]. Radiographs are usually normal at the time of presentation, and weeks or months may pass before changes are seen. Scintigraphy is a more sensitive modality and is helpful in early detection. Scintigraphy may reflect the likely pathogenesis of microfractures and vascular disruption. In up to 6 months after the onset, there is increased blood flow, blood pool activity, and uptake on delayed images. From 6 months to approximately 2 years, the blood flow and blood pool activity decrease, while delayed uptake may persist. The bone scan tends to return to normal after 2 years, except in patients who develop joint collapse and secondary osteoarthritis [56]. Osteochondritis dissecans, which affects young patients and does not classically involve the weight-bearing surface of the femoral condyle, should not be confused with spontaneous osteonecrosis (see Chap. 4). Osteoarthritis, which commonly affects the knee, can also be confused with the condition but is usually limited to the joint subchondral bone, whereas osteonecrosis tends also to involve the adjacent shaft [64].

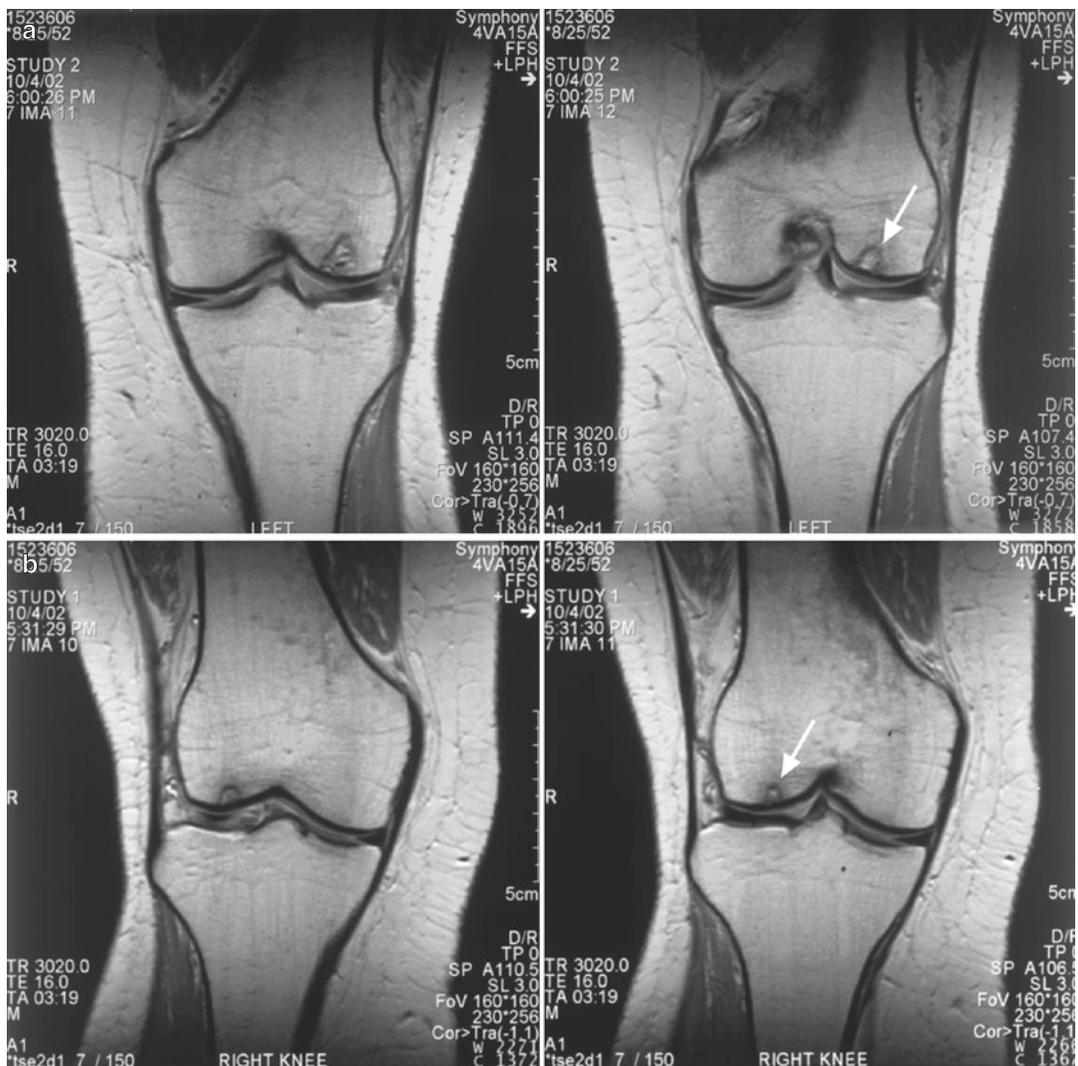

The disease follows a four-stage course according to Koshino classification [67], which consists of a progression from no radiographic findings (stage I); to a slight flattening of the medial femoral condyle (stage II); followed by the appearance of a radiolucent lesion (stage III); and finally, articular cartilage collapse (stage IV). Although stages I and II are potentially reversible, stages III and IV are associated with irreversible destruction of the subchondral bone and articular cartilage. Overall, all four stages have somewhat similar signs and symptoms (pain, tenderness, effusion, and synovitis). However, radiographic findings and radionuclide bone scans, computed tomography (CT), and MRI findings vary considerably according to the clinical stage of the disease. In general, stages I and II are considered early stages in the natural history and potentially are reversible or show no progression.

### 5.4.4.1 Stage I

Stage I is the earliest stage and also is referred to as the incipient stage. Often the patient has intense symptoms that last for a relatively short period (6–8 weeks), after which they may subside. These patients then may become asymptomatic. Standard radiographs are typically normal. Although MRI has not been accepted widely as a reliable diagnostic method for detecting stage I osteonecrosis, it has been shown that patients with normal T2-weighted images tend to show no progression and even may present with

spontaneous resolution of the disease. In contrast, abnormalities in T2-weighted images have been related to further progression of the disease (Fig. 5.7) [68, 69].

Bone scanning, however, is a reliable tool for the diagnosis of stage I idiopathic osteonecrosis of the knee. Bone scans are always positive in these cases and show an increased uptake of the radionuclide at the site of the lesion. This is indicative of subchondral bone necrosis. Even though bone scan is not a specific imaging modality for the diagnosis of idiopathic osteonecrosis

**Fig. 5.7** MR images of bilateral osteonecrosis of the femoral condyles. Small low signal intensity lesion is seen in the subarticular end of the femur bilaterally surrounded by a rim of hypointense signal (arrows)

of the knee, when considered in association with the clinical signs and symptoms of the patient, it clearly can help the clinician to establish a diagnosis.

Patients with stage I osteonecrosis of the knee usually do not require surgery and can be treated conservatively. In the minority patients with stage I osteonecrosis of the knee who have only limited destruction of the subchondral bone, the knee may remain stable or even show spontaneous resolution. However, the majority of these patients progress to stage II.

#### 5.4.4.2 Stage II

Two to 4 months after the onset of the disease, a characteristic slight flattening of the medial femoral condyle can be observed. This can be detected mainly in anteroposterior or tangential radiographs of the knee. Flattening of the medial femoral condyle is indicative of stage II. The radiographic findings in this stage may still be somewhat obscure, but abnormal MRI findings are commonly suggestive of osteonecrosis. In addition, radionuclide scintigraphy can be of major assistance in establishing the diagnosis, because radionuclide uptake is as much as 5–15 times greater in the affected knee. CT scanning, even though it is not diagnostic, can provide more details regarding the appearance of the osteonecrotic lesion, because it permits good resolution and makes it possible to measure the size of the lesion.

#### 5.4.4.3 Stage III

Three to 6 months after the onset of the disease, a radiolucent lesion can be observed in plain radiographs. This is the so-called crescent or rim sign and is indicative of segmental necrosis of the subchondral bone with articular cartilage destruction. Bone scans, CT, and MRI are not essential to make the diagnosis, because plain radiographs usually provide a clear and characteristic picture when positive.

#### 5.4.4.4 Stage IV

Nine months to 1 year after the disease onset, and sometimes even earlier, typical radiographic findings of this stage are usually present. These

include additional subchondral bone and articular cartilage destruction that may extend over the entire transverse diameter of the medial femoral condyle, leading to complete articular collapse.

Bone scintigraphy has an important diagnostic role especially in stages I and II, where radiographic changes are often obscure (Fig. 5.7), while in stage III and IV, radiographs usually suffice.

Stages I and II idiopathic osteonecrosis of the knee are treated conservatively with aspirin, anti-inflammatory drugs, and partial weight bearing, and in most cases show spontaneous recovery, while patients with stage III or IV usually need surgery. Overall, the prognosis of the disease is severe because approximately 80% of the patients deteriorate to the extent that they need surgical reconstruction, whereas less than 20% have either spontaneous resolution or no additional deterioration of the lesion.

There are significant differences between idiopathic and secondary osteonecrosis (Table 5.3), especially regarding the clinical presentation and the location, extent, and MRI appearance of the lesions. These differences are probably due to a difference in the pathogenic mechanism. Secondary osteonecrosis generally occurs in younger patients (Fig. 5.8) and typically has an insidious onset with mild or vague pain, the lateral compartment of the knee are often involved, and the lesions seen are usually larger than spontaneous; in the great majority of cases, they involve the femoral condyles and/or tibial plateaus. Bilateral distribution and multifocal involvement are often seen in this form. Additionally, MRI is able to demonstrate different patterns of abnormalities between the idio-

**Table 5.3** Comparison of forms of osteonecrosis of the knee

Characteristic	Primary	Secondary
Patient's age	Typically elderly	Young
Onset	Sudden	Insidious
Pain	Severe	Mild
Size of lesions	Small	Large
Distribution of lesions	Unilateral	Commonly bilateral

**Fig. 5.8** Bilateral osteonecrosis of the knee illustrating the typical pattern on bone scintigraphy. Note the focal increased flow and blood pool (a) with corresponding focally increased uptake on delayed image (b)

pathic and secondary types [70]. A retrospective review of 37 consecutive patients with osteonecrosis of the knee confirmed by bone scintigraphy and/or MRI was reported by Narvaez et al. [70] and focused on the comparison of idiopathic and secondary types of osteonecrosis. Idiopathic osteonecrosis of the knee was typically a disease of the elderly, characterized by severe knee pain of sudden onset, unilateral involvement, and restriction of the lesions generally to one femoral condyle or tibial plateau, with predilection for the medial compartment of the joint [70].

#### 5.4.5 Multifocal Osteonecrosis

Nontraumatic osteonecrosis of the femoral head is often accompanied by other sites of osteonecrosis. Multifocal osteonecrosis [71, 72] or multiple osteonecrosis is defined as a disease affecting two or more separate anatomical sites. LaPorte et al. reported that when multifocal osteonecrosis was defined as a disease affecting three or more separate anatomical sites, it could be found in 32/1056 (3%) patients with osteonecrosis [71]. All 32 of those patients had osteonecrosis of the femoral head and knee. The authors also reported that osteonecrosis was seen in the shoulder (28 patients) and ankle (8 patients) [71]. In a multicenter study, using the same definition of multifocal osteonecrosis [72], 101 patients with femoral head disease additionally had osteonecrosis of the knee (96%), shoulder (80%), and/or ankle (44%). On the other hand, Shimizu et al. reported that multiple osteonecrosis which affected two or more separate anatomical sites was observed by MRI screening in 167 of 250 patients (67%) with steroid-related osteonecrosis of the femoral head and that the most common site beside the femoral head was the lateral femoral condyle (49%), followed by the distal femoral metaphysis (37%), the medial femoral condyle (32%), and the humeral head (24%) [73]. Accordingly, among patients with multifocal osteonecrosis, the knee is a major affected site, second only to the femoral head. A total of 214 knee joints in 107 patients with osteonecrosis of the femoral head were studied

by Sakai et al. [67] using bone scintigraphy compared with MRI. Associated osteonecrosis of the knee was classified into five sites: The femoral condyles, distal femoral metaphysis, tibial plateau, proximal tibial metaphysis, and patella. Based on the diagnosis by MRI, osteonecrosis of the femoral condyles was the most common (40%), followed by osteonecrosis of the distal femoral metaphysis (15%), proximal tibial metaphysis (10%), patella (3%), and tibial plateau (0.9%). The sensitivity and specificity of bone scintigraphy for femoral condyle lesions were 63% and 71% respectively, and sensitivity was 89% for the large- or medium-sized lesions (as judged by MRI). The sensitivity for other locations mentioned was poor, but these lesions have a low likelihood of collapse. Accordingly, the authors concluded that bone scintigraphy is useful for screening since it is highly sensitive for disease of the femoral condyles which bears a high risk of collapse of the knee [74]. The limitation of this study is the use of MRI as a gold standard.

Overall, technetium bone scintigraphy is valuable for screening for multifocal osteonecrosis in patients with osteonecrosis of the femoral head [75, 76]. Bone scintigraphy has several advantages which make it suitable for this task: Many joints can be visualized at one time on total body images to determine whether multiple osteonecrosis exists, and it can be used for patients with cardiac pacemakers, intracranial clips, and claustrophobia, who cannot undergo MRI.

#### 5.4.6 Sickle Cell Disease Osteonecrosis

Sickle cell disease is a relatively common hereditary hematologic disorder. The disease is caused by the replacement of glutamic acid of  $\beta$ -chains with valine. The disease has numerous consequences; one of the most common is injury to bone [77]. Osteonecrosis and osteomyelitis are the most common complications [78]. The bone manifestations occur similarly in other hemoglobinopathies and most commonly affect the femora, tibiae, and humeri [79, 80]. Since sickle cell

osteonecrosis most commonly involves the femoral and humeral heads, although it can affect any bone of the skeleton, it is possible that the increased length of the nutrient arteries supplying the marrow in the long bones makes them more susceptible to occlusion. Necrosis of the femoral head is one of the significant skeletal disorders in sickle cell disease patients. Neonates who have sickle cell disease do not often develop osteonecrosis because of the high fetal hemoglobin level. Although the pathogenesis of the vascular occlusion leading to an infarct is not entirely clear, vaso-occlusion of the marrow is considered to be one of the main culprits in sickle cell crises. Since hemoglobin S is sensitive to hypoxemia, erythrocytes become viscous and sickle abruptly when exposed to hypoxia. This may compromise the microvascular flow and cause necrosis, the most common skeletal complication of sickle cell disease [81]. The signs of acute infarction can include warmth, tenderness, erythema, and swelling over the site of vaso-occlusion [80]. However, these clinical signs are non-specific and may also be seen in acute osteomyelitis, which may occur as a primary event or may be superimposed on infarcts; necrotic bone is a fertile site for such secondary infections [79, 80]. Thus, recognition of bone marrow infarction often relies on the use of imaging modalities. MRI has not been found to have the specificity or sensitivity of radionuclide studies [82].

The scintigraphic diagnosis may be straightforward using Tc-99m MDP scan (Fig. 5.9), which shows photon-deficient areas early on. SPECT and pinhole images are very valuable, particularly in resolving a photon-deficient area in the middle of the increased uptake at the reparative process. During this phase it can be difficult to differentiate osteonecrosis from osteomyelitis, and adding gallium-67 or bone marrow scanning may be essential (see Chap. 2). Acute chest syndrome in sickle cell patients is characterized by chest pain that can mimic several pulmonary disorders, including pulmonary embolism and pneumonia [83]. This condition is believed to be a sequela of osteonecrosis of the ribs (Fig. 5.10) and is usually associated with pulmonary infiltrates on chest radiography.

**Fig. 5.9** Sickle cell disease infarcts: whole-body scan shows multiple foci of increased uptake in the humeri, femora, and ribs representing healing infarcts. An area of decreased uptake is noted in the medial aspect of the left distal femur representing a more acute infarct (*arrow*)

Whole-body imaging cannot be overemphasized and should include the ribs in addition to the area of interest if different.

#### 5.4.7 Dysbaric Osteonecrosis

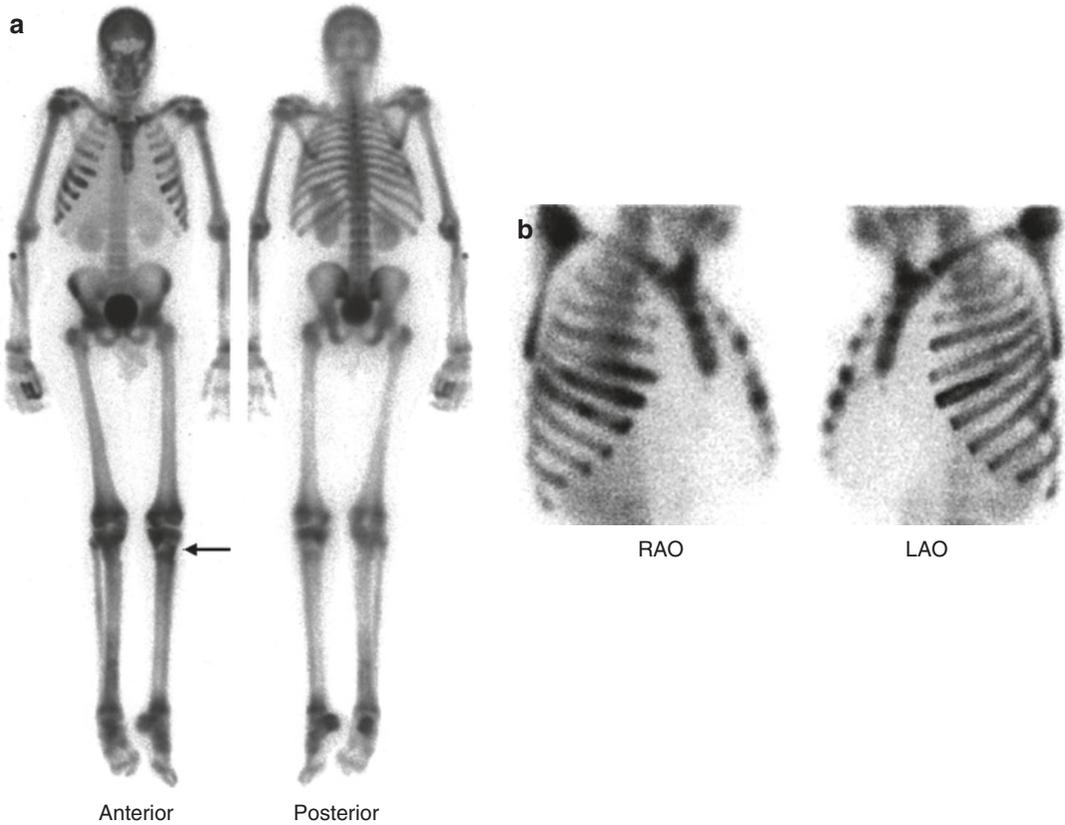

This type of osteonecrosis occurs in patients subjected to a high-pressure environment such as deep-sea divers. The exact cause of ischemia is debated. Immobilization of gas bubbles blocking

the vascular channels is considered to be the major factor by many investigators. This occurs due to the liberation of gas bubbles (mainly nitrogen) into the blood and tissue of an individual who was exposed to a hyperbaric environment and has then undergone decompression too rapidly [84]. The shoulders, hips, knees, and ankles are commonly involved in this type of osteonecrosis.

#### 5.4.8 Osteochondroses Featuring Osteonecrosis

The osteochondroses are a group of conditions affecting children and adolescents that are characterized by disturbance of endochondral ossification in which both chondrogenesis and osteogenesis are deranged after a previously normal growth process. The condition can occur in any bone that grows by endochondral ossification, and the exact cause is in general undefined; many theories have been proposed, but none has proven satisfactory. Since certain conditions show osteonecrosis, the conditions have been placed among vascular disorders of the bone. Other investigators include the group among overuse injury syndromes since many are common among athletes [85]. Still others classify the group with degenerative diseases since degeneration occurs in these conditions followed by ossification in one or more of the ossification centers [86]. Accordingly, the osteochondroses are viewed as conditions with variable features including but not limited to osteonecrosis, traumatic changes, and degenerative changes. The actual expression will depend on the specific form of the disease (Table 5.4). Legg-Calvé-Perthes disease and osteochondritis dissecans have been included in this group by some investigators. Legg-Calvé-Perthes disease is discussed above, and osteochondritis dissecans is presented in Chap. 4.

The group may be categorized into (1) intra-articular conditions such as Kohler's disease, Freiberg's disease, and Panter's disease; (2) physal conditions such as Scheuermann's disease; and (3) nonarticular conditions affecting any

**Fig. 5.10** a, b Sickle cell disease infarcts with recent pain in the left knee corresponding to a relatively acute infarct of the proximal left tibia (*arrow*). Other infarcts are healing, including those in the long bones of the upper and lower extremities, skull and ribs, as seen on the whole-

body bone scan (a). There is a history of chest pain representing acute chest syndrome associated with the multiple rib infarcts, as clearly demonstrated by anterior oblique views (b) (From Sisayan R, Elgazzar A [83] with permission)

other skeletal site, such as Osgood-Schlatter disease, which affects the tibial tuberosity. In general osteochondroses resolve spontaneously and are self-limited [87].

Currently osteochondroses can be categorized into two subgroups. The first group of osteochondroses is basically characterized by ischemic osteonecrosis caused by trauma or physical injury, and the second group is primarily associated with fracture of a developing apophysis or secondary ossification center in infancy and adolescence. The diseases of the first group include Legg-Calvé-Perthes disease, Friedrich's disease, Freiberg's disease, Kienböck's disease, and osteochondrosis of the first metatarsal sesamoid, while those of the sec-

ond group consist of Osgood-Schlatter disease, Scheuermann's disease, Sever's disease, slipped capital femoral epiphysis, and osteochondritis dissecans [88–90].

Abnormally increased uptake on a bone scan in a classic area of involvement for each condition should raise the possibility of a specific condition. Without knowledge of the specifics of each of these conditions, the uptake will be interpreted as non-specific and the condition may pass undiagnosed.

#### 5.4.8.1 Freiberg's Disease

This condition was originally described as osteonecrosis of the second metatarsal head, but it is now known also to affect the first and third (and

**Table 5.4** Osteochondroses

Involved bone	Disease	Probable nature of condition
Capital femoral epiphysis	Legg-Calvé-Perthes disease	Osteonecrosis
Metatarsal head(s)	Freiberg's disease	Osteonecrosis or stress fracture
Carpal lunate	Kienböck's disease	Osteonecrosis
Tarsal navicular	Kohler's disease	Developmental/osteonecrosis
Capitellum of humerus	Panner's disease	Traumatic
Phalanges of hand	Thiemann's disease	Familial or traumatic
Tibial tuberosity	Osgood-Schlatter disease	Avulsion injury
Proximal tibial epiphysis	Blount's disease	Disturbance of growth/trauma
Vertebra	Scheuermann's disease	Degenerative
Patella	Sinding-Larsen-Johansson disease	Trauma or stress
Calcaneus (apophysis of os calcis)	Sever's disease	Variation in ossification
Ischiopubic synchondrosis	Van Neck's disease	Variation in ossification
Fifth metatarsal base	Iselin's disease	Variation in ossification
Iliac crest apophysis	Buchman's disease	Variation in ossification
Symphysis pubis	Pierson's disease	Unclear
Head of humerus	Hass disease	Osteonecrosis
Heads of metacarpals	Mauclaire disease	Unclear
Lower ulna	Burns' disease	Unclear

possibly other) metatarsal heads. The condition presents usually in late adolescence and may lead to degenerative joint disease as a late complication, in a manner similar to several other osteochondroses.

#### 5.4.8.2 Kohler's Disease

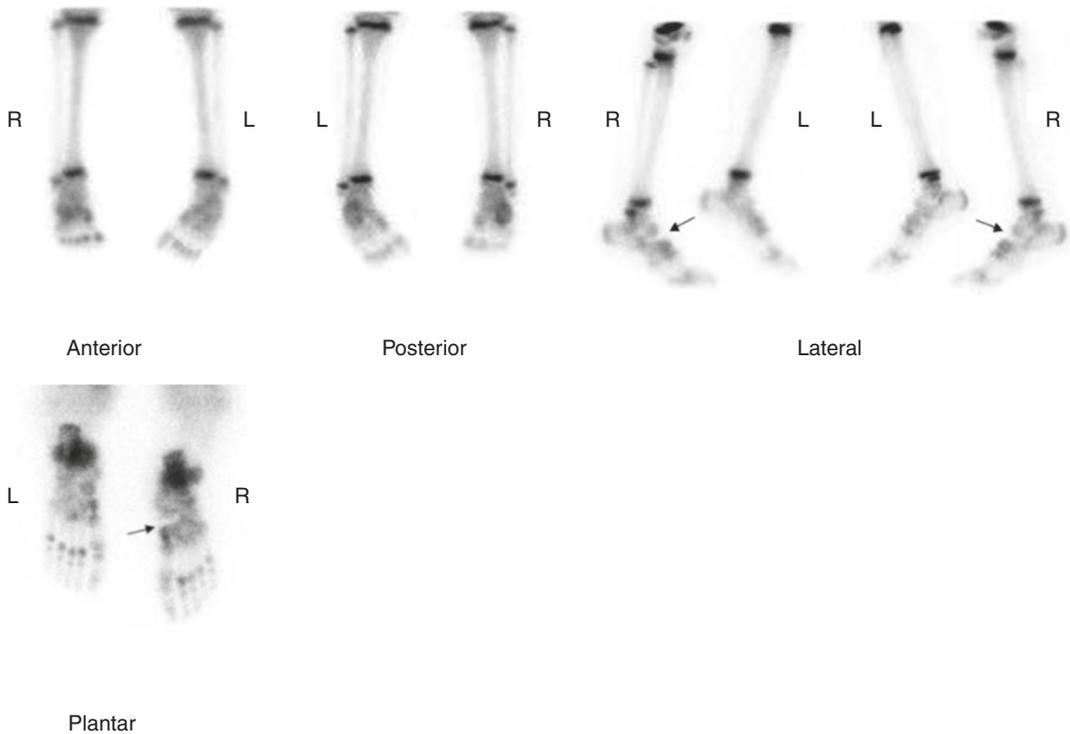

Osteonecrosis of the tarsal navicular leads to specific changes on radiographs, namely, flattening, sclerosis, and irregular rarefaction, the features of this condition which was originally described by Kohler in 1908. The condition has an excellent outcome and rarely affects children [91]. Recently, cases of the disease have been described in the patella [92]. In the early phase of disease, bone scans may demonstrate decreased tracer uptake (cold area) if bone scan is performed early (Fig. 5.11). Subsequently a focus of increased

uptake is seen at the site of the tarsal navicular bone in the reparative phase [93].

#### 5.4.8.3 Osgood-Schlatter Disease

(See also Chap. 4)

This condition affects the tibial tuberosity at the site of insertion of the patellar tendon. It affects boys more often than girls and is bilateral in approximately 25% of cases. The disease was believed to be due to repetitive overuse stress leading to ischemic necrosis; however, more recently it has been proved to be due to avulsion of the secondary ossification center due to repetitive tensile extension forces from the quadriceps applied to the apophyseal cartilage of the tibial tuberosity. This will lead to avulsion of segments of the anterior cartilage and/or anterior bone of the tuberosity [94].

**Fig. 5.11** Bone scan of a 6 year old boy with right foot edema and pain for 2 months. There was no history of trauma. No fever. Planar images were obtained for the entire skeleton. Anterior (a) and posterior (b) of the feet and

legs did not show any definite abnormalities. Lateral images (c, d) and plantar view (e) show a photon deficient area at the site of tarsal navicular bone of the right foot (arrows) representing the pattern of early phase of Kohler's disease

Benign and malignant primary bone tumors are rare, while metastatic disease is a common occurrence. The efficacy of the several currently available imaging modalities in the detection, staging, and follow-up of patients with skeletal neoplasia varies. Evaluation of bone tumors involves a multimodality approach. Standard radiographs play an important role in the diagnosis of both primary and metastatic tumors. Computed tomography (CT) scan and magnetic resonance imaging (MRI) are often complementary and are particularly useful in primary bone tumors. CT scan is especially useful in evaluating the cortex. MRI is superior in evaluating the extent of several primary tumors and detecting bone marrow lesions. The role of bone scintigraphy in preoperative evaluation of primary tumors is limited. Bone scintigraphy, on the other hand, is an excellent cost-effective screening modality in detecting metastatic disease in patients with skeletal and extraskelatal malignancies. In breast, lung, and head and neck tumors, bone scan is rarely positive for metastasis in patients with low stage disease. PET using F-18 sodium fluoride and FDG or combined is more sensitive in detecting metastases. Metaiodobenzylguanidine (MIBG) scintigraphy is valuable in children with neuroblastoma. Conventional bone scan and other radionuclide modalities are valuable in the long-term follow-up of several cancers and in estimating the prognosis. The therapeutic response of malignant bone disease can particularly be assessed using PET and alternatively Tl-201 and Tc-99m methoxyisobutylisonitrile (MIBI).

## 6.1 Introduction

Primary bone tumors are rare while metastatic bone tumors are common and have a significant impact on decision-making regarding choice of therapy and its modification. The evaluation of bone tumors, whether they are primary or metastatic, involves several imaging modalities. Standard radiographs, computed tomography (CT) scanning, magnetic resonance imaging (MRI), and several functional modalities can all be used in a complementary way depending on

the strengths and limitations of each of those modalities. Functional nuclear medicine modalities generally have a limited role, in the imaging of primary bone tumors, but are very useful in the initial detection of metastatic disease, the follow-up of the response to therapy, and in estimating the prognosis. Various radiopharmaceuticals such as Tc-99m diphosphonates, I-123 or I-131 MIBG, thallium-201, Tc-99m MIBI, and positron emission tomography (PET) scanning are all used for bone tumor imaging (Table 6.1). With the advances in MRI and PET imaging and their

**Table 6.1** Main radiopharmaceuticals for tumor imaging

Radiotracer	Characteristics	Uptake mechanism at tumor area
Tc-99m MDP, Tc-99m HDP	Diphosphonate	Adsorption to hydroxyapatite crystals by reactive bone formation
F-18 sodium fluoride	Sodium fluoride	Incorporates into hydroxyapatite crystals forming fluorapatite
Tc-99m MIBI	Lipophilic agent	Accumulates preferentially within living malignant cells due to the higher transmembrane electrical potential as a consequence of the higher metabolic rate than in the surrounding normal cells
Thallium-201	Potassium analogue	Adenosine triphosphatase pump
Gallium-67	Ferric ion analogue	Simple diffusion of unbound tracer facilitated by the increased permeability of tumor cells compared to normal cells. Binding of iron binding globulins which are present in higher concentration within interstitial fluid of the tumor
F-18 FDG	Glucose analogue	Facilitated diffusion of FDG which is similar to glucose will be overutilized by these cells compared to normal tissue. This is caused by preferential anaerobic metabolism, an increase in number of glucose transporter molecules, increased activity of hexokinase isoenzymes, and decreased activity of the glucose-6-phosphatase enzyme resulting in the metabolic trapping of FDG in malignant cells and increased uptake
C-11 methionine	Amino acid analogue	Increased amino acid metabolism by tumor cells. Used to evaluate amino acid uptake and protein synthesis, providing an indicator of tumor viability
I-131 MIBG, I-123 MIBG	Noradrenaline analogue	Enters neuroendocrine cells by an active uptake mechanism via the epinephrine transporter and is stored in the neurosecretory granules

applications, the role of each of the morphological and functional imaging modalities is constantly changing along with recommendations of when to use each. The use of nuclear medicine modalities in a correlative imaging approach in primary and metastatic bone tumors and the current recommendations for effective utilization of imaging in bone tumor diagnosis and management will be discussed below.

## 6.2 Pathophysiology

### 6.2.1 Primary Bone Tumors

The various primary bone tumors are generally classified, based on their cell of origin, into osteogenic, chondrogenic, collagenic, and myelogenic tumors (Fig. 6.1).

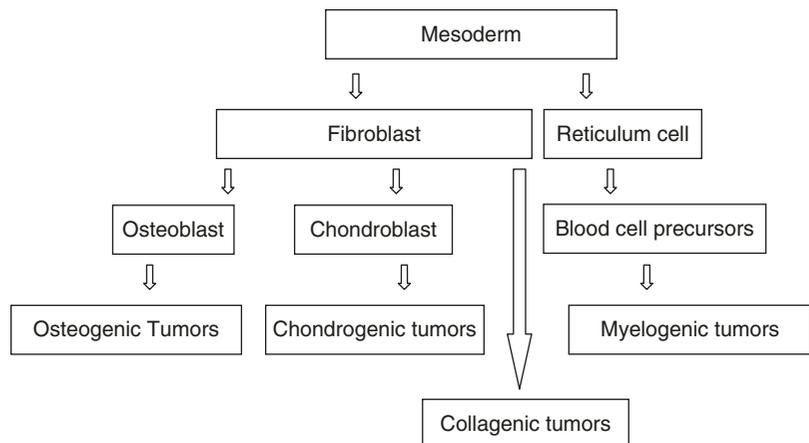

#### 6.2.1.1 Osteogenic Tumors

Osteogenic tumors originate from a bone cell precursor, the osteoblast, and are characterized by the formation of bone or osteoid tissue. These tumors include osteoid osteoma, osteosarcoma, and osteoblastoma.

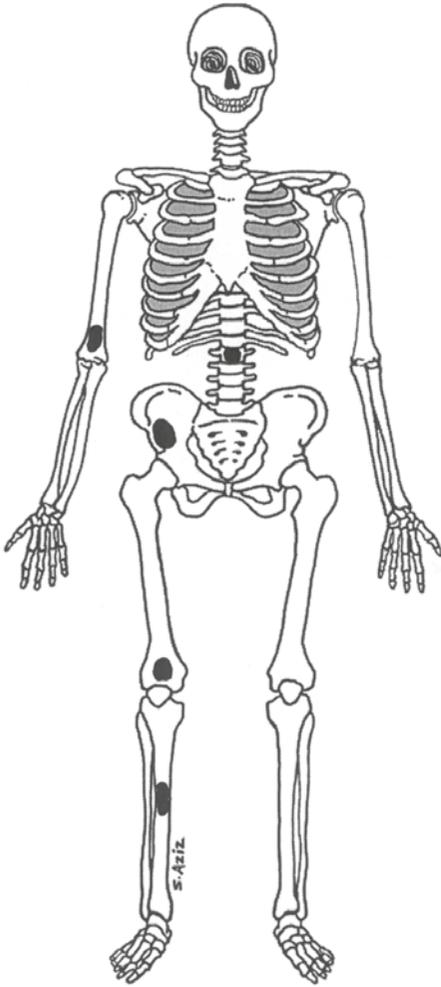

*Osteoid osteoma* is a solitary, benign lesion of bone thought to be a benign osteogenic tumor typically occurring in late childhood, adolescence, and young adulthood although the precise nature remains still controversial since some suggest it is inflammatory or an unusual process of healing and repair [1]. The lesion is characterized by its

small size (less than 2 cm), self-limited growth, and the tendency to cause extensive reactive changes in the surrounding bone tissue.

The lesion classically presents with severe pain at night that is dramatically relieved by nonsteroidal anti-inflammatory drugs (NSAIDs). The tumor has been shown to express very high levels of prostaglandins, particularly PGE2 and PGI2. The high local levels of these prostaglandins are presumed to be the cause of the intense pain seen in patients with this lesion. Studies have shown strong immunoreactivity to cyclooxygenase-2 (COX-2) in the nidus of the tumor but not in the surrounding reactive bone. COX-2 is one of the mediators of the increased production of prostaglandins by osteoid osteomas and may be the cause of the secondary changes shown by MRI [2, 3]. The usual sites of involvement (Fig. 6.2) include the bones of the lower extremities, pelvis, and spine. More than half of the lesions occur in lower extremity long bones, with the proximal femur being the most common site. In the spine, the lesions almost exclusively occur in the posterior vertebral elements. In addition, they may occur in a juxta-articular bone within a synovial cavity where they are termed intra-articular osteoid osteomas. Intra-articular osteoid osteoma accounts for approximately 13% of all osteoid osteomas and presents as a monoarthropathy [4]. Osteoid osteomas are most commonly located in diaphyseal or metaphyseal cortices but may occasionally be located in the medullary cavity or

**Fig. 6.1** Origin and classification of primary bone tumors

**Fig. 6.2** Usual sites of involvement of osteoid osteoma

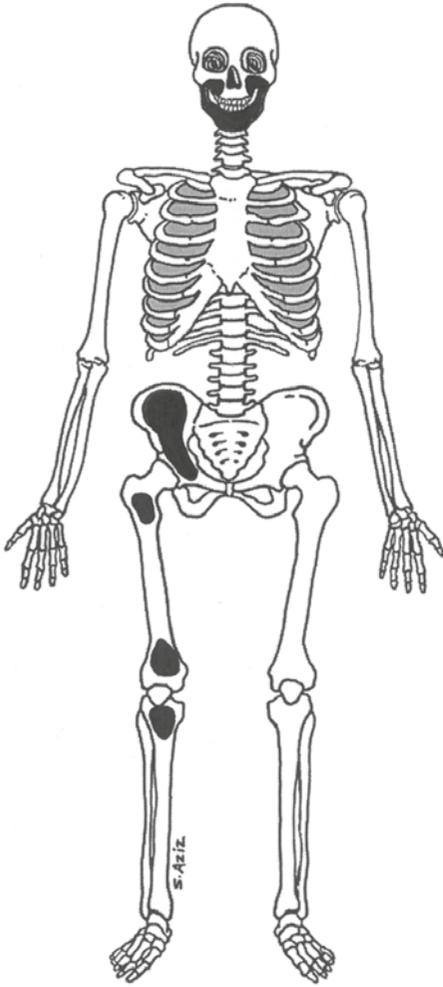

periosteum. Osteoid osteomas are rarely found in the epiphysis [1].

*Osteoblastoma* is a tumor related to osteoid osteoma and has an almost identical histological appearance, but the nidus is larger in size. It is commonly seen in the spine and can occur in any other location. Compared to osteoid osteoma, benign (conventional) osteoblastomas have a higher growth potential, exceeding 2 cm in diameter. Peripheral reactive bone sclerosis may be minimal or absent. Although it has a similar age and gender distribution as that of osteoid osteoma, osteoblastoma has a unique predilection for the axial skeleton, with more than 40% involving

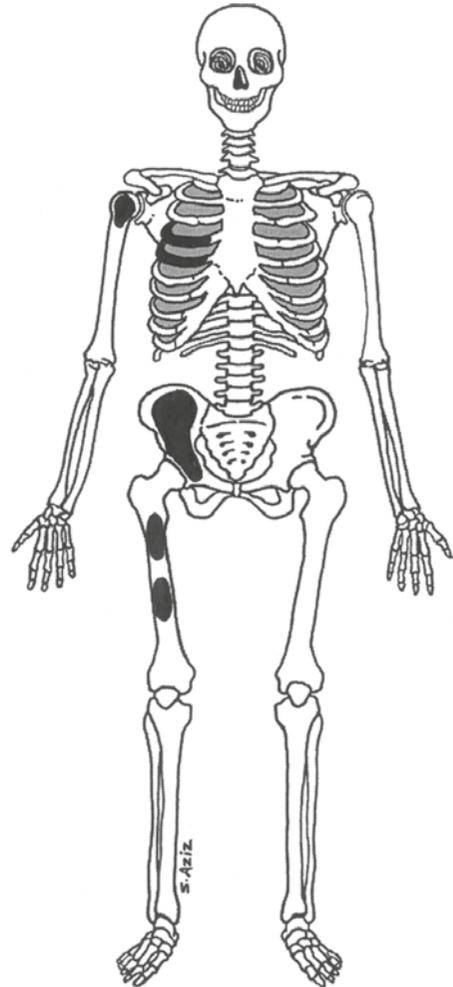

the vertebral column, sacrum, and pelvis [5]. Jaw is the second most frequent site followed by other craniofacial bones. As in the case of osteoid osteoma, osteoblastomas also frequently arise in extremity long bones, especially in the proximal femur and humerus, but less frequent than osteoid osteoma. However looking at the appendicular skeleton, the lower extremity is the most common location for osteoblastoma where 35% of the lesions occur.

Aggressive osteoblastoma is a very rare variant that represents a borderline lesion between osteoblastoma and osteosarcoma. These tumors are likely to recur, do not metastasize, and are characterized microscopically by the presence of epithelioid osteoblasts [5].

*Osteogenic sarcoma* is an osteogenic tumor with sarcomatous tissue. It is the most common malignant bone-forming tumor. It is more common in males than females (ratio of 3:2) due to their longer periods of skeletal growth. Sixty percent of cases occur before the age of 20 years, corresponding to the peak period of skeletal growth. A secondary peak incidence is found between 50 and 60 years of age, mainly in patients with a history of prior radiation therapy years earlier [6]. The bones with the highest growth rate are most frequently affected, characteristically the long tubular bones, especially in the metaphyseal region (Fig. 6.3). Additionally, within a specific bone, the frequency of tumor occurrence corresponds to the sites of greatest growth rate. Therefore, the distal femur and proximal tibia are the most frequently involved sites where 50% of the tumors occur. Approximately 15–20% of patients with osteosarcoma present with visible macrometastatic disease. Most metastatic lesions are found in the lung and other sites are the bones, pleura, pericardium, kidney, adrenal gland, and the brain [7, 8]. Approximately 1–3% of patients with osteosarcoma have tumors in the multiple bony sites at the time of diagnosis. Whether these tumors arise synchronously or are metastatic lesions from a primary tumor site is not clear [9]. Bone marrow involvement in osteosarcoma, however, is rare [10, 11].

**Fig. 6.3** Usual sites of involvement of osteogenic sarcoma

**Fig. 6.4** Usual sites of involvement of chondrosarcoma

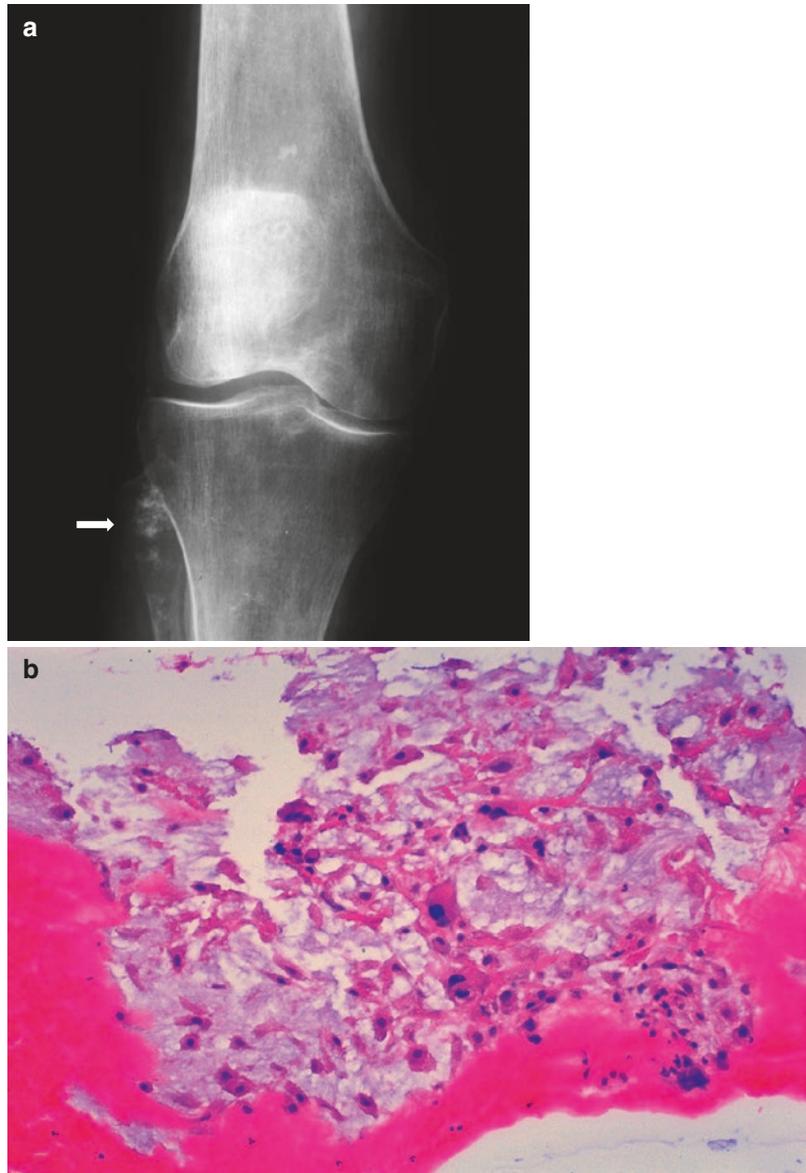

### 6.2.1.2 Chondrogenic Tumors

All tumors that produce cartilage, primitive cartilage, or cartilage-like substance are called chondrogenic. The most common malignant chondrogenic tumor is chondrosarcoma. Two types of this malignant tumor are recognized: (a) primary chondrosarcoma, occurring mainly in patients aged 50–70 years, and (b) secondary chondrosarcoma, which is derived from the benign chondrogenic tumor enchondroma and occurs more frequently in patients aged 20–30 years. Chondrosarcoma is more common in men than in women, often arising in the metaphysis or diaphysis of long bones (Figs. 6.4

and 6.5a), particularly the femur and in the pelvis. It is extremely rare in the spine, craniofacial bones, and small bones of the hands and feet. The neoplasm consists of hyaline cartilage with bands of anaplastic cells and fibrous tissue (Fig. 6.5b). The tumor may infiltrate the joint spaces located near the end of the long bone.

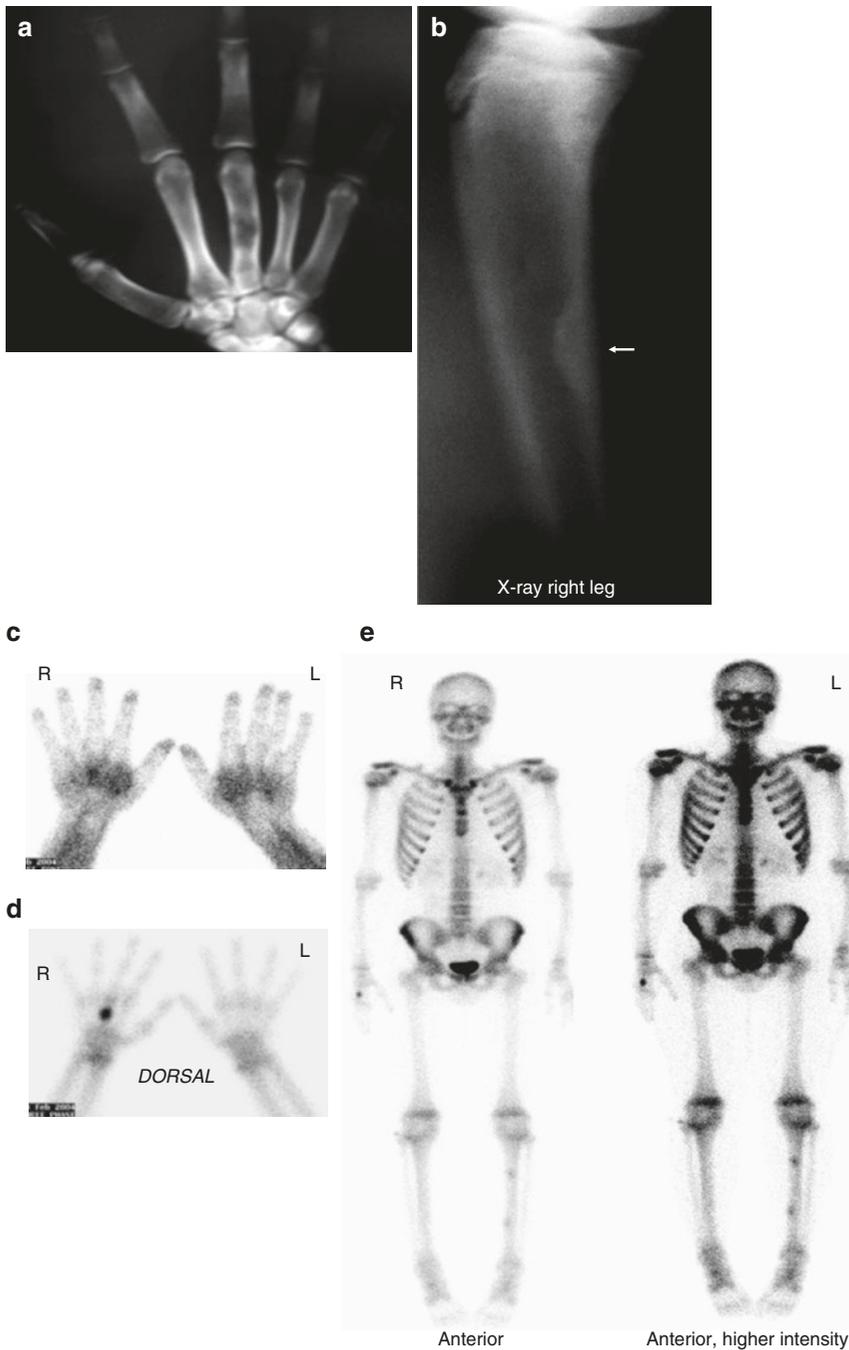

Chondroma is the benign chondrogenic tumor which is an uncommon benign tumor that characteristically forms mature cartilage. The tumor is encapsulated with a lobular growing pattern. It is formed of chondrocytes (cartilaginous cells) that resemble normal cells and produce cartilaginous matrix. It is found mostly in the small bones of the hand and/or feet, although it can also occur in long,

**Fig. 6.5 a, b** Standard radiograph (a) of chondrosarcoma of the right fibula of a 39-year-old man. There is irregular calcification at the site of the tumor in the upper end of the fibula (*arrow*). (b) A photomicrograph of chondrosarcoma illustrating numerous bizarre tumor cells with large nuclei but cells retain some recognizable cartilaginous appearance

tubular bones, primarily the humerus, femur, and ribs. Occasionally, focal areas of myxoid degeneration may result in a mistaken diagnosis of chondrosarcoma. Chondromas are classified according to their location into enchondroma within the medullary cavity of bone, periosteal chondroma found on the surface of the bone, and soft tissue chondroma found in the soft tissue. The primary significance of enchondroma is related to its complications, most notably pathological fracture and a small incidence of malignant transformation. Enchondromas are

usually solitary but may be multiple (Fig. 6.6). Multiple enchondromas occur in three distinct disorders: Ollier disease which is a nonhereditary disorder characterized by multiple enchondromas with a predilection for unilateral distribution (Fig. 6.6) and Maffucci syndrome which is another nonhereditary disorder less common than Ollier disease. This syndrome features multiple hemangiomas in addition to enchondromas. The third form is metachondromatosis which consists of multiple enchondromas and osteochondromas, and

**Fig. 6.6 a–e** A 17-year-old boy presenting at the age of 12 years with swollen and painful right hand after playing boxing. He was diagnosed with a benign enchondroma of the third right metacarpal bone. At the age of 14 years, he had a recurrent pain of the upper third of the right leg and was also diagnosed with a benign enchondroma. Follow-up radiography of the right hand (a) revealed no changes in the size or characters of the previously diagnosed enchondroma of the middle metacarpal bone (arrow). Left leg (b) demonstrated a mixed density scalloped eccentric lesion (arrow) in the upper half of left

tibia believed to be mostly benign. The patient was referred to the Nuclear Medicine Department for an annual follow-up. A three-phase bone scan was obtained 3 h after IV injection of 25.3 mCi of Tc-99m MDP. The blood pool images (c) of both hands show moderate focal increase uptake in the mid-right hand. The delayed images of the hands (d) show intense focal uptake in the third right metacarpal bone. The whole-body images (e) show two foci of increased uptake in the left tibia, one in the upper third and one in the lower third representing multiple enchondromas

**Table 6.2** Malignant bone tumors and patient age

Age	Tumor
1–30	Ewing's sarcoma
	Osteosarcoma
30–40	Fibrosarcoma and malignant fibrous histiocytoma
	Malignant giant cell tumor
	Reticulum cell sarcoma
	Parosteal sarcoma
	Metastases
40+	Myeloma
	Chondrosarcoma

Adapted from [12]

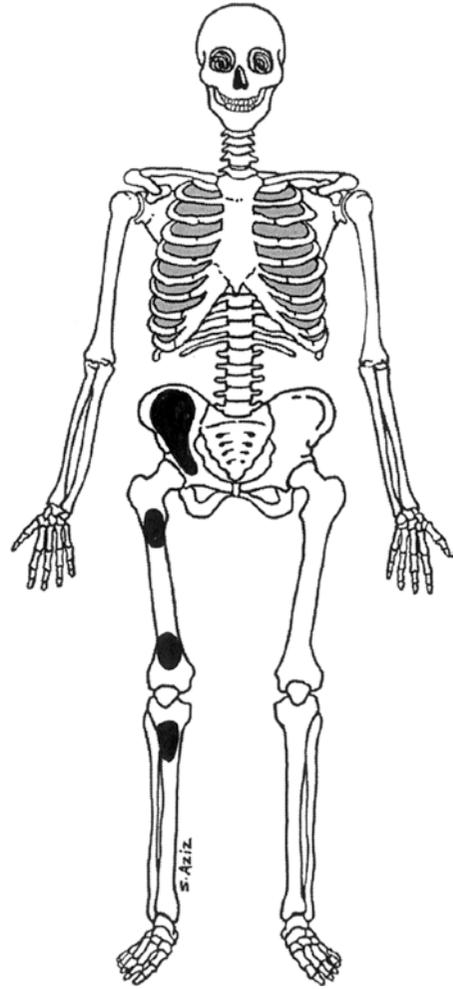

it is the only one of the three disorders that is hereditary as autosomal dominant.

### 6.2.1.3 Collagenic Tumors

Collagenic tumors are the primary bone tumors that produce fibrous connective tissue. *Fibrosarcoma* is a malignant collagen-forming spindle cell tumor that occurs in a wide range of ages, but it occurs most frequently in patients between 30 and 40 years (Table 6.2). It occurs slightly more commonly among females. A secondary form may occur following Paget's disease, radiation therapy, and long-standing osteomyelitis. The tumor is located most frequently in the metaphysis of the femur or tibia (Fig. 6.7), although every bone of the skeleton can be involved. It begins in the marrow cavity and infiltrates the trabeculae. Histological examination typically reveals collagen, malignant fibroblasts, and occasionally giant cells.

### 6.2.1.4 Myelogenic Tumors

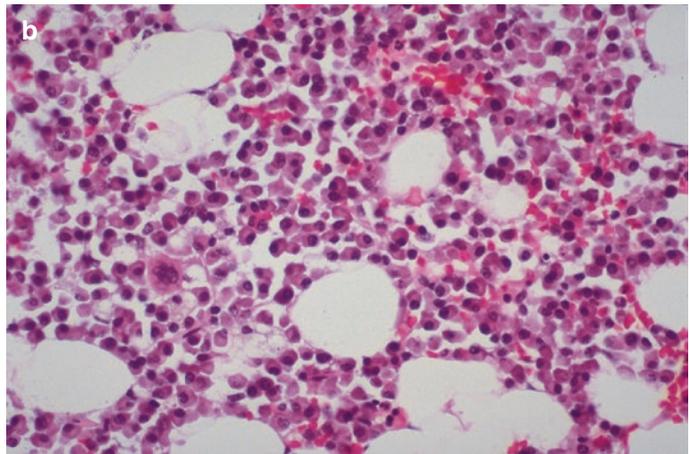

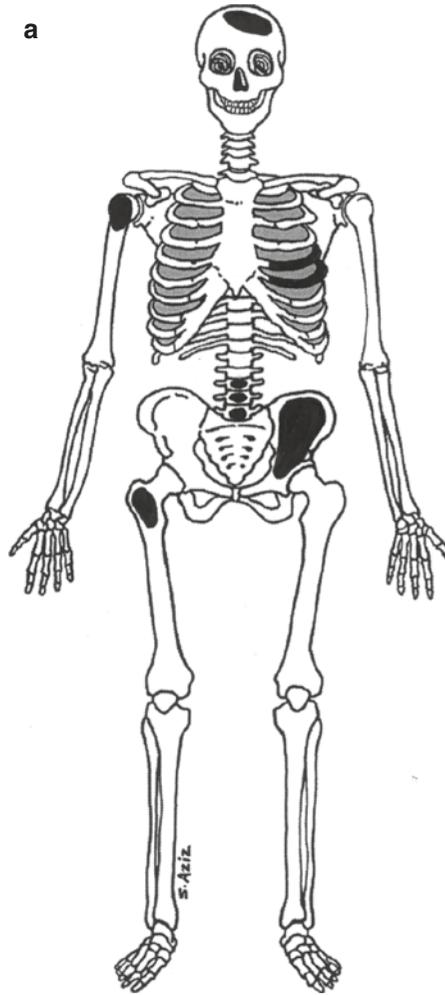

Myelogenic tumors are the group of bone tumors that originate from various bone marrow cells. *Myeloma* originates from the plasma cells of the reticuloendothelial element of the bone marrow and may be solitary or multifocal. It is a highly malignant tumor that occurs more commonly in patients above 40 years of age with a peak in the eighth decade of life. It occurs more frequently in males and blacks. The tumor has a poor prognosis and radiation and chemotherapy have limited success. It mainly affects the spine, pelvis, ribs, skull, and proximal bones of the extremities (Fig. 6.8). Patients are known to develop renal failure, ane-

**Fig. 6.7** Fibrosarcoma, usual sites of involvement

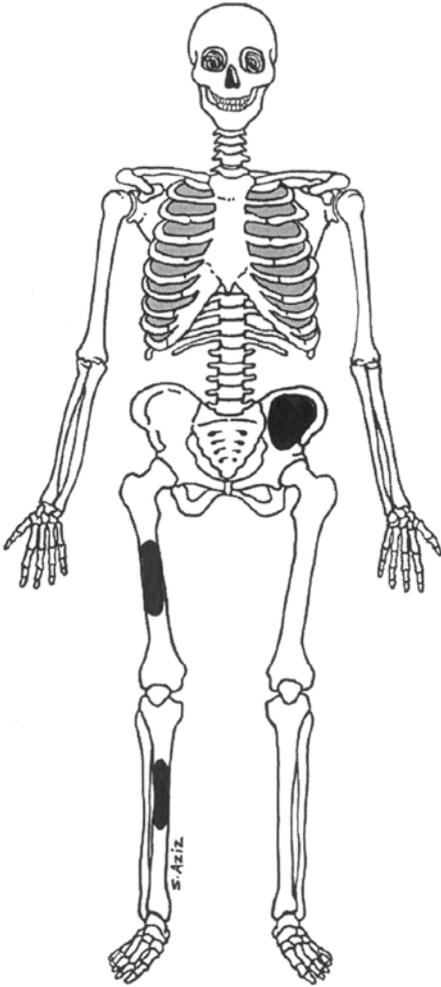

mia, thrombocytopenia, and urine that contains Bence Jones protein. Bone pain is common and may progress over time during the course of the disease, and pathological fractures may also take place. *Ewing's sarcoma* is another malignant tumor originating from the bone marrow and is most frequently encountered between the ages of 5 and 15 years and is rare after the age of 30 (Table 6.2). It is more common in males and in whites. It is characterized by a chromosomal translocation between chromosomes 11 and 22. Typically it occurs in the diaphysis of the long bones such as the femur and tibia and in flat bones such as the pelvis (Fig. 6.9); however, any bone may be affected. After originating from marrow, *Ewing's sarcoma* spreads through the bone cortex

**Fig. 6.8 a, b** Myeloma. (a) Usual sites of involvement. (b) A photomicrograph of a histologic section of myeloma showing well-differentiated myeloma cells that are easily recognizable as plasma cells but with more prominent nuclei

to form a tissue mass which does not contain osteoid. The tumor metastasizes early into the lung, other bones, bone marrow, lymph nodes, liver,

spleen, and the central nervous system. The prognosis is often poor, particularly if the tumor involves the pelvic rather than the long bones.

**Fig. 6.9** Ewing's sarcoma, usual sites of involvement

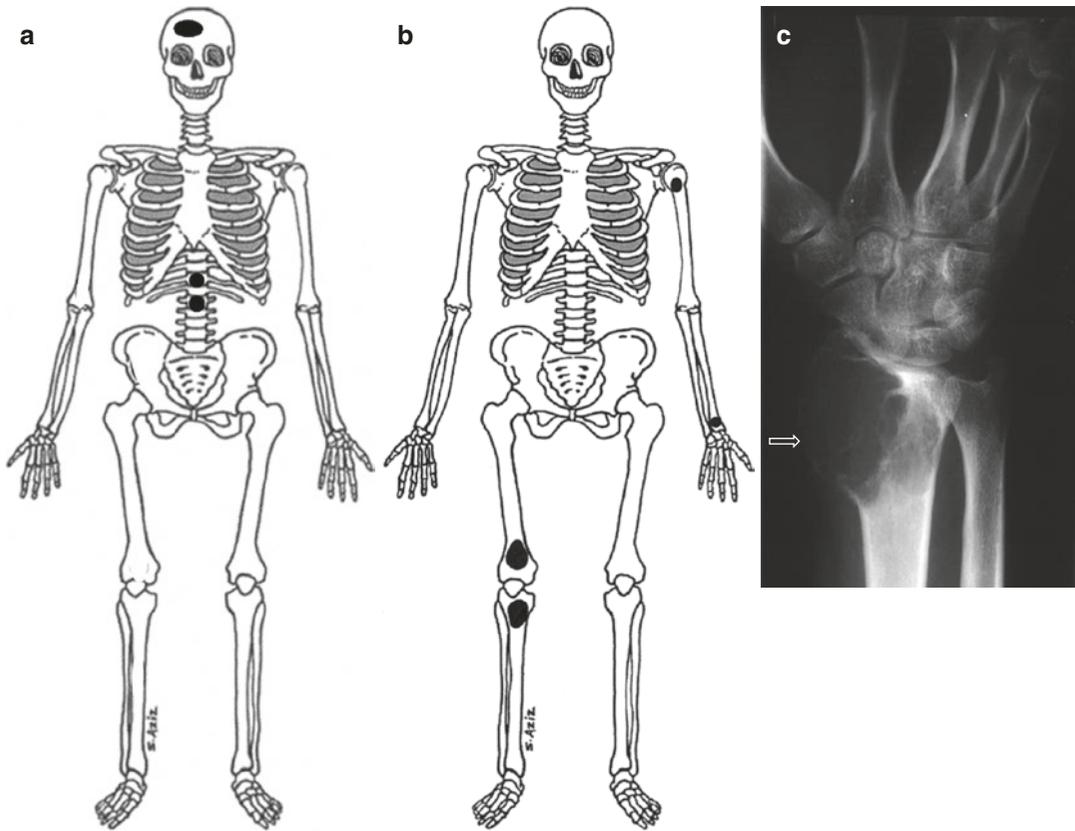

#### 6.2.1.5 Other Tumors and Tumorlike Lesions

**Bone hemangiomas** are rare benign, malformed vascular lesions, overall constituting less than 1% of all primary bone neoplasms. They occur most frequently in the vertebral column (30–50%) and skull (20%) (Fig. 6.10a) but can occur anywhere in the body, and thus any bone can be affected including the long bones, short tubular bones, and ribs. It is multiple in approximately one third of cases particularly within the vertebral column. Osseous hemangioma generally occurs more commonly in females than males, with a ratio of 3:2. The peak incidence is in the fifth decade, although

osseous hemangiomas can be encountered at any age. Bone hemangiomas usually occur in the medullary cavity, but uncommonly, surface-based hemangiomas are encountered in the cortex, periosteum, and subperiosteal regions. The rare periosteal and other surface-based hemangiomas tend to occur in younger patients. Bone hemangiomas are usually asymptomatic lesions discovered incidentally on imaging or postmortem examination but occasionally may cause pain and compression of neural elements [13]. Vertebral hemangiomas are the most common benign tumor of the spinal column, and they occur most frequently in the lower thoracic and upper lumbar spine. They are usually localized to the vertebral body, less frequently extending into or exclusively affecting the posterior arch. Long-bone hemangiomas are uncommon and are found mainly in the tibia, femur, or humerus. They have a predilection for the metaphyseal or diaphyseal regions but can involve the epiphyses and even extend across the joint space. Skull hemangiomas affect most commonly the frontal bone. Gross pathology usually reveals well-demarcated, unencapsulated lesions with cystic red cavities. Microscopic examination shows hamartomatous proliferations of vascular tissue within endothelial-lined spaces.

There are four histologic variants of hemangioma, classified according to the predominant type of vascular channel: cavernous, capillary, arteriovenous, and venous. These types can coexist. Bone hemangiomas are predominantly of the cavernous and capillary varieties. Cavernous hemangiomas most frequently occur in the skull, whereas capillary hemangiomas predominate in the vertebral column; overall, the former type is most common in bone [14, 15].

**Giant cell tumors** are difficult to classify although many practitioners include them with the myelogenic tumors since they are believed to originate from the fibrous tissue of the bone marrow. The tumor occurs in patients between 10 and 70 years of age, although it is more commonly seen in patients between 20 and 40 years old. Females are affected more often than males. The tumor occurs mainly around the knee, in the

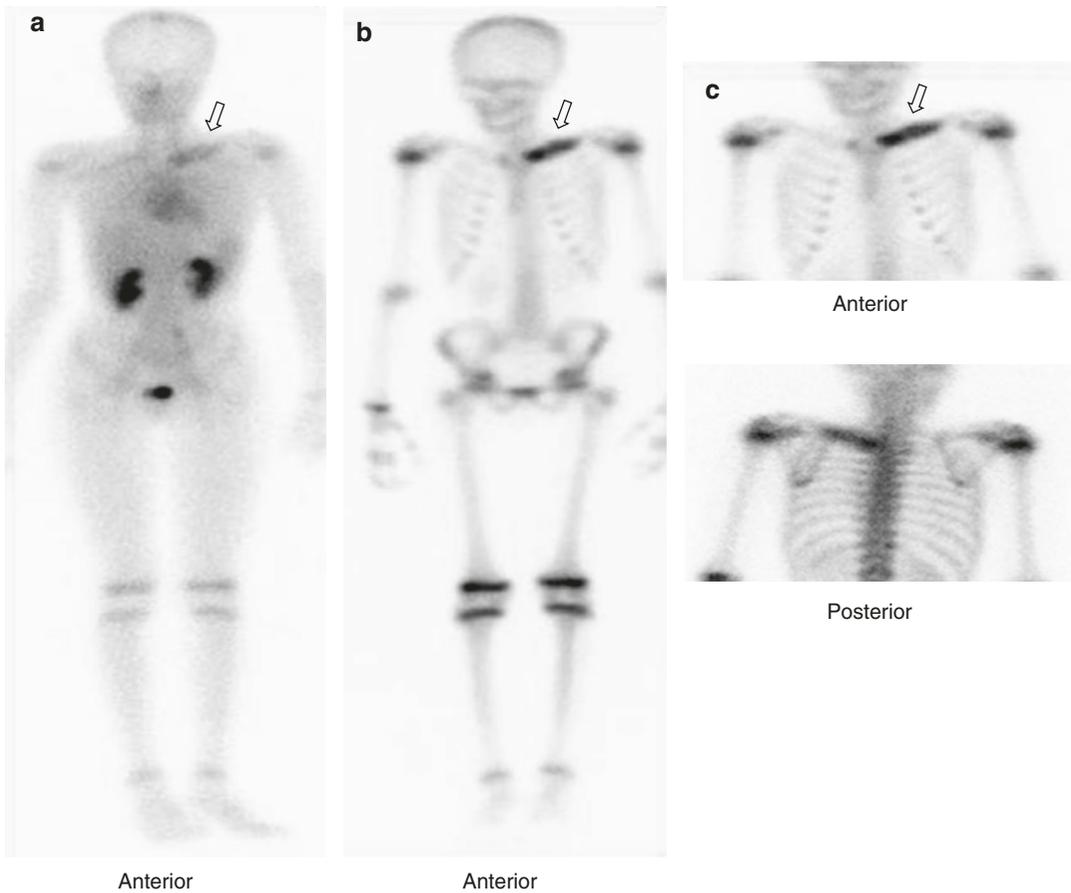

**Fig. 6.10** a–c Bone hemangioma, common sites of involvement (a) Giant cell tumor. Sites of involvement (b). A standard radiograph (c) of a giant cell tumor of the distal radius with significant osteolysis

radius, and in the humerus (Fig. 6.10). Seven percent of giant cell tumors occur in the spine. The sacrum is affected in 90% of such cases. The tumor is usually located in the upper sacrum and frequently lateralized in a sacral wing. It has a high regional recurrence rate often extending locally into adjacent soft tissues, but distant metastases occur more rarely. It consists particularly of osteoclast-like giant cells and anaplastic stromal cells with a minor component of osteoid and collagen [16].

Radiography typically shows a lytic lesion with cortical expansion. CT demonstrates absence of mineralization and the lack of a sclerotic rim at the margins of the tumor. Bone scintigraphy shows increased radiotracer uptake in all phases (Fig. 6.11). The tumor usually has low to

intermediate signal intensity on T1-weighted MR images. Areas of high signal intensity can suggest relatively recent hemorrhage. More specifically, most giant cell tumors of the spine have low to intermediate signal intensity on T2-weighted images. This appearance seems to be caused by hemosiderin deposition and high collagen content. Enhancement of the lesion reflects its vascular supply. Cystic areas, foci of hemorrhage, fluid-fluid levels, and a peripheral low-signal-intensity pseudocapsule may also be seen.

**Chordoma** is a rare, slowly growing, primary malignant bone neoplasm arising from notochordal remnants in the midline of the neural axis and involves the adjacent bone. It occurs in adults usually in the sixth and seventh decades of life.

**Fig. 6.11** Giant cell tumor of the left clavicle seen on Tc-99m MDP bone scan as increased blood pool activity (a) and increased uptake on whole body (b) and spot (c) delayed images (arrows)

The main malignant potential of chordomas rests on their critical locations adjacent to important structures, their locally aggressive nature, and their extremely high rate of recurrence. Along with lymphoproliferative tumors, chordomas are the most common primary malignant neoplasm of the spine in adults. The tumor rarely metastasizes. CT and MRI are essential for an accurate evaluation. Myelography is used to determine intraspinal extension. Although chordoma is a low-grade and slow-growing tumor, it has generally a poor long-term prognosis despite its low tendency to metastasize. Death is often related to local recurrence. Prognosis depends on the possibility of margin-free en bloc resection [17]. Since the tumor may cause significant bone destruction when aggressive, it can be seen as a cold lesion on bone scan although more commonly it causes increased or normal uptake.

### Aneurysmal Bone Cyst

Aneurysmal bone cyst (ABC) is a benign bone lesion of unknown origin although it is thought to be due to a reactive process secondary to trauma, increased venous pressure, or hemorrhage into a pre-existing lesion most commonly a giant cell tumor. It usually occurs between the ages of 5 and 20 years but can be at any age. It is a relatively rare lesion that represents 1.4–2.3% of primary bone tumors. Lesions are usually well defined and mostly solitary. It can be found in any bone. The spine is involved in 3–20% of cases [17]. Histologically, ABC consists of blood-filled cystic spaces separated by a spindle cell stroma with osteoclast-like giant cells and osteoid or bone production [18]. Mineralized chondroid-like material is present histologically in about one third of cases. Spindle cell proliferation is the predominant histologic component of the rare solid variant [18].

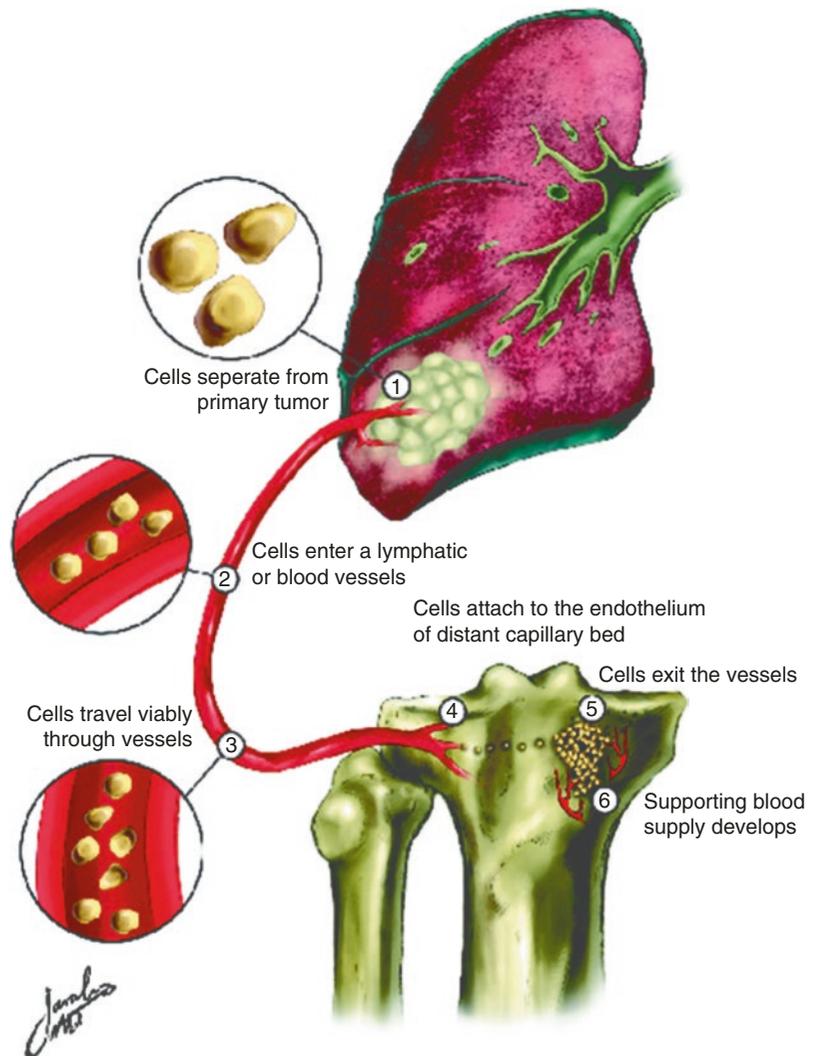

The natural history of aneurysmal bone cysts evolves through four radiologic stages: initial, active, stabilization, and healing [19]. In the initial phase, the lesion is characterized by a well-defined area of osteolysis. This is followed by a growth phase, in which the lesion has a purely lytic pattern and sometimes ill-defined margins. Later, during the stabilization phase, the characteristic soap bubble appearance develops as a result of maturation of the bony shell. CT and MR imaging typically show a well-defined lesion with internal septation [19]. Fluid-fluid levels at CT are commonly seen and are indicative of hemorrhage with sedimentation and are also seen on MRI and better demonstrated in this modality [20]. The predominant bone scintigraphic finding

is moderate to intense uptake at the periphery of the lesion with little activity at its center (“doughnut sign”), a finding that is found in about 64% of cases. However, this pattern is not specific, since it is also found in giant cell tumor, chondrosarcoma, and telangiectatic osteosarcoma [21].

## 6.2.2 Metastatic Bone Disease

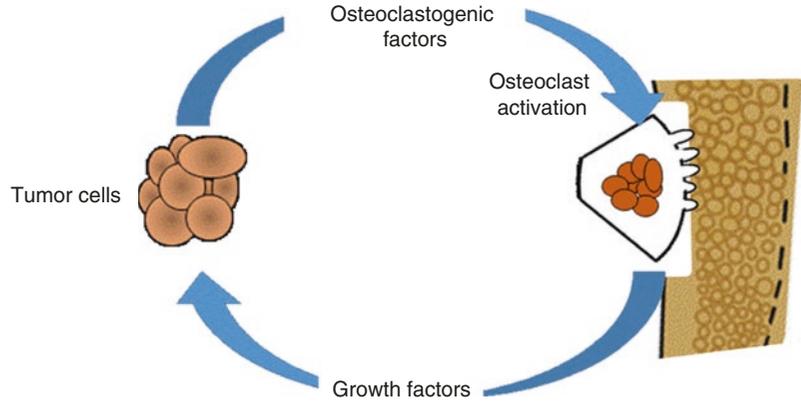

### 6.2.2.1 Definition

Metastasis is defined as the transfer of disease from one organ, or part, to another not directly connected with it [22]. The following sequential events are generally required for metastatic spread of tumors (Fig. 6.12).

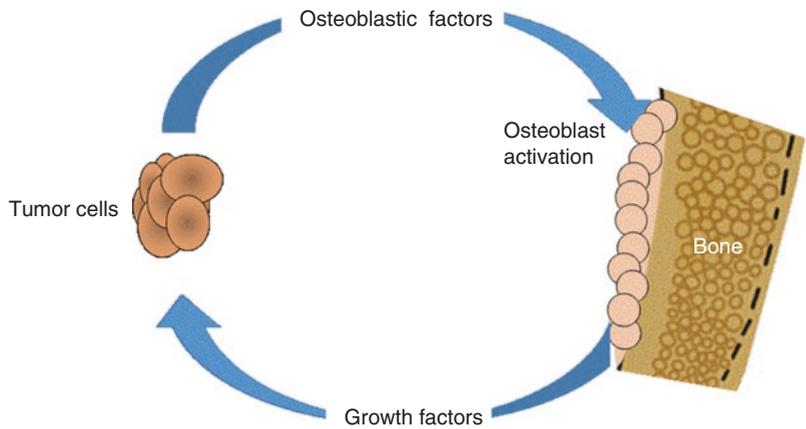

**Fig. 6.12** Sequential events generally required for metastatic spread of tumors

**Fig. 6.13** Vicious cycle in osteolytic metastases

**Fig. 6.14** Vicious cycle in osteoblastic metastases

1. Separation of neoplastic cells from primary tumors
2. Access of separated cells to an efficient lymphatic channel or blood capillary
3. Survival of cells during the transport
4. Successful attachment of cells to the endothelium of a distant capillary bed
5. Exit of cells from the vessel at the new site
6. Successful development of a supporting blood supply for the cells at the site

Once tumor cells invade bone matrix they produce growth factors that can stimulate osteoclasts and/or osteoblasts. Tumor cells produce factors which vary based on tumor type that directly or indirectly induce formation of osteoclasts and also stimulate them. Osteolytic metastases are destroying bone by activated osteoclasts rather than by tumor cells [23]. Tumor cells then release a variety

of growth factors that promote bone resorption [24]. On the other hand, the bone mineral matrix contains many growth factors that are released during bone remodeling, providing a fertile microenvironment for tumor cell colonization and proliferation. Bone resorption by osteoclasts releases growth factors from the bone matrix that stimulate tumor growth and further bone destruction in a vicious cycle (Fig. 6.13) [24]. In the case with osteoblastic metastases, tumor cells secrete osteoblastic factors that stimulate the release of bone growth factors from the bone microenvironment to further enhance survival and proliferation of tumor metastasis (Fig. 6.14).

#### 6.2.2.2 Methods of Tumor Cell Transport

The pathophysiology of skeletal metastases includes two major events, transport of viable

tumor cells to bone and interaction of these cells with osseous tissue. Other than **direct extension**, tumor cells are transported to produce metastases by:

### Lymphatic Spread

This method of spread is relatively unimportant to the transport of tumor cells to the skeleton. Metastases in regional draining lymph nodes may, however, secondarily involve the adjacent bones.

### Hematogenous Spread

This is a major route for the dissemination of malignant cells to distant bones, which occurs via the arterial or venous systems, particularly the vertebral plexus of veins of Batson. The relative roles of the arterial and venous systems in the spread of the tumor to the bone are difficult to define. Metastases occur predominantly in the axial skeleton (specially the spine) and may be present in the absence of pulmonary, and other organ, involvement. This is a combination of findings which supports the significance of Batson's vertebral plexus in tumor spread. This vertebral plexus of veins consists of an intercommunicating system of thin-walled veins with low intraluminal pressure. These veins frequently do not have valves and communicate extensively with veins in the spinal canal and with the caval, portal, intercostal, pulmonary, and renal venous systems. Hematogenous bone metastasis in humans generally begins in the medullary cavity and then involves the cortex.

### Intraspinal Spread

This route for transporting malignant cells allows the secondary deposits in the spinal canal to develop in patients with intracranial tumors. This occurs by subarachnoid spread occurring secondary to fragmentation of a tumor bathed with cerebrospinal fluid, shedding of portions of the tumor at the time of the surgery, ependymal breaching by the primary intracranial tumor, or fissuring occurring secondary to hydrocephalus [25].

### 6.2.2.3 Bone Response to Metastases

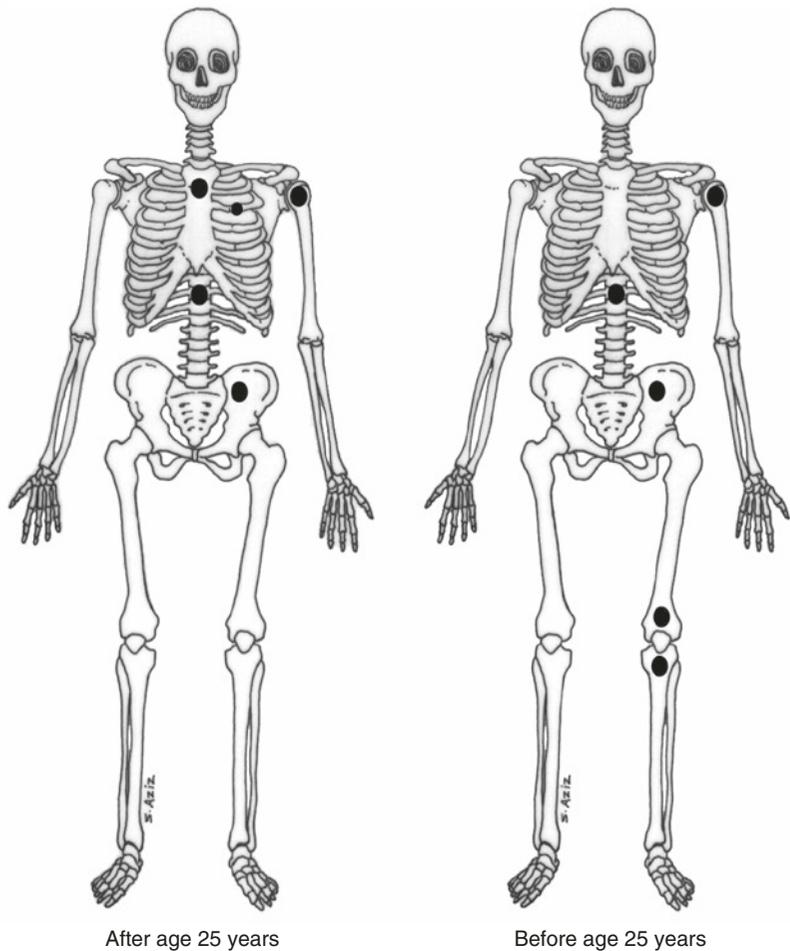

The osseous response to metastatic lesions includes:

1. Bone resorption where there is increased bone resorption secondary to malignant disease. Osteoclast, tumor cells, tumor cell extract, monocytes, and macrophages may all be involved in the process [25, 26].
2. Bone formation which occurs in two types:
  - (a) Stromal bone formation, which occurs earlier, is quantitatively a less important mechanism of bone formation associated with metastasis. In this type of bone formation, ossification occurs in areas of fibrous stroma within the tumor. This occurs only in those skeletal metastases, which are associated with the development of fibrous stroma such as those of carcinoma of the prostate. Highly cellular tumors have little, or no, stroma and are not associated with this type of bone formation.
  - (b) Reactive bone formation which occurs in response to bone destruction. Immature woven bone is deposited and is subsequently converted to lamellar bone. In highly anaplastic, rapidly growing tumors, lymphomas, myeloma, or leukemias, reactive bone formation may be only minor or insignificant [27].

### 6.2.2.4 Distribution of Bone Metastasis

The distribution of skeletal metastases varies with the type of primary malignant tumor. However, metastases typically involve the axial skeleton (80%), which is a region rich in red bone marrow (Fig. 6.15). Factors favoring the predominant involvement of the red marrow include a large capillary network, a sluggish blood flow, and the suitability of this tissue for the growth of tumor emboli. It is estimated that the blood flow to cancellous bone containing marrow is 5–13 times higher than that of cortical bone [28]. In the appendicular skeleton, the pelvic bones are the most commonly involved. In decreasing order of occurrence, the usual locations of bone metastases

**Fig. 6.15** Distribution of metastases according to age

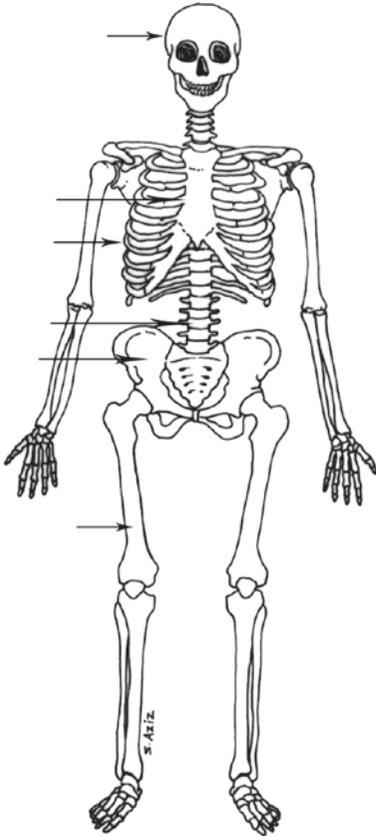

are the vertebral column, pelvic bones, ribs, sternum, femoral and humeral shaft, and the skull (Fig. 6.16). Less common sites of skeletal metastases (Fig. 6.17) include the scapula, mandible, patella, and the bones of the extremity distal to the elbow and knees [29]. Within the spine, metastases involve the lumbar region most commonly followed by the thoracic and cervical areas. Within the vertebra, metastases are more common in the vertebral body (Fig. 6.18) followed by the posterior elements [30]. The explanation for the involvement of the spine as the most common site for the occurrence of metastases includes the Batson's venous plexus [31] which provides direct communication between the spine and numerous other locations in the body (Fig. 6.19) and the large amount of bone mass and bone marrow. A possible

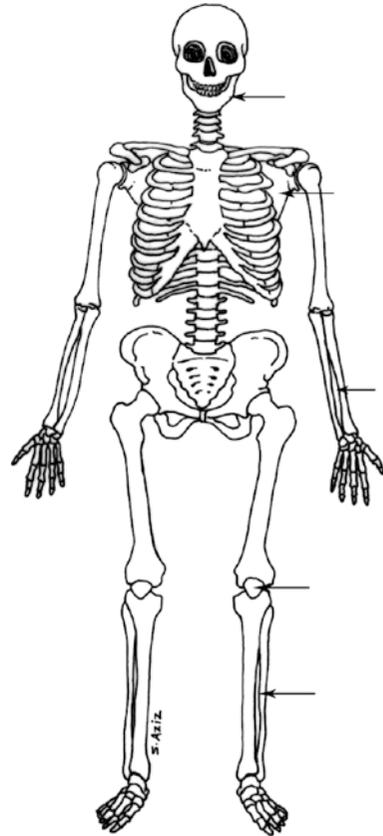

explanation for the low frequency of metastases in the distal portion of the extremities is the blood supply, which is largely limited to the arterial provision and the relative absence of red bone marrow (this is a suitable medium for the growth of metastatic tumor cells).

#### 6.2.2.5 Classification of Bone Metastases

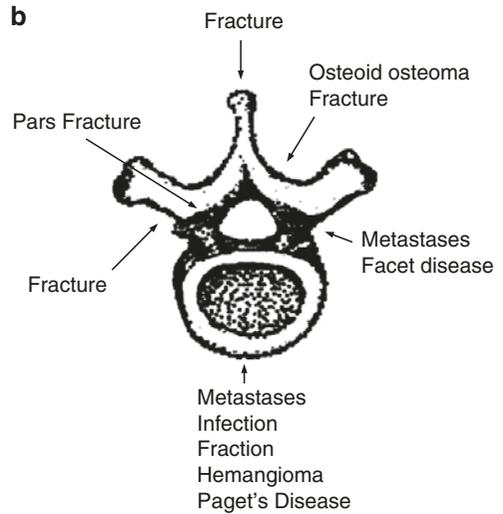

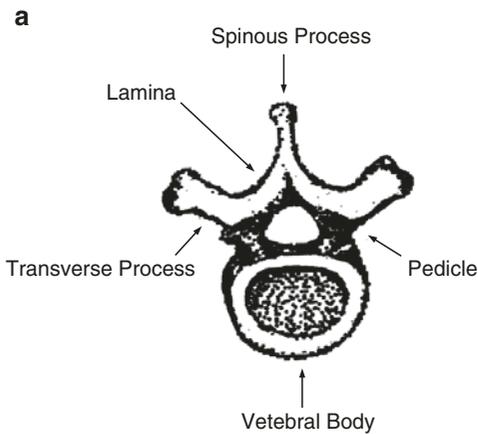

Bone metastases can be classified according to several factors including the number of lesions, location, calcium contents, and patterns of bone response. The skeleton may at times respond to the various metastatic tumor foci in a predictable manner; however, this is not always the case, and sometimes bone metastases show, for example, either purely osteoblastic lesions or mixed osteoblastic/osteolytic lesions in some sites and purely

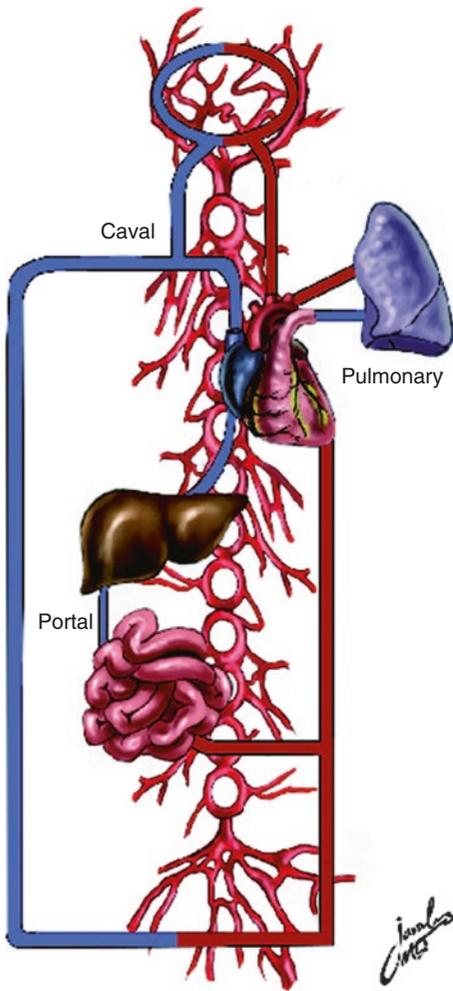

**Fig. 6.16** Usual locations of bone metastases (*arrows*)

**Fig. 6.17** Uncommon locations of bone metastases (*arrows*)

**Fig. 6.19** Batson's plexus

osteolytic lesions in other sites. Based on the pattern of bone response, metastases can be classified from the radiographs into purely osteolytic (Table 6.3), purely osteoblastic (Table 6.4), or mixed osteolytic osteoblastic (Table 6.5).

#### 6.2.2.6 Sources of Bone Metastases

Certain tumors are known to be common sources of bone metastases. The following primary tumors are the most common to metastasize in the bone: prostate, breast, lung, thyroid, and kidney. Bladder and uterine carcinomas are less common sources. In children, skeletal metastases originate mostly from neuroblastoma, Ewing's sarcoma, and osteosarcoma. In adult males, car-

cinoma of the prostate accounts for 60% of bone metastases while in females, breast cancer accounts for 70% of such metastases [32].

#### 6.2.2.7 Sequelae of Skeletal Metastases

Skeletal metastases may lead to some local and generalized consequences (Table 6.6).

##### Local Consequences

###### Bone Destruction

Both direct and indirect mechanisms of bone destruction are involved in the bone loss associated with tumor invasion of bone [33].

Direct stimulation of bone loss: Tumors cause increased osteoclastic activity and consequently bone destruction through secretion of tumor-derived substances that directly stimulate osteoclasts. These substances include parathyroid hormone-related protein, transforming growth factor alpha, transforming growth factor beta, and prostaglandins.

Indirect stimulation of bone loss by tumors occurs, on the other hand, by substances secreted by the tumor that stimulate first the immune cells (Tcells) or activated bone cells which in turn release osteoclast-stimulating cytokines such as tumor necrosis factor (TNF) and interleukin-1 (IL-1) which increase the osteoclastic activity and cause bone destruction (Fig. 6.20).

**Table 6.6** Consequences of skeletal metastases

Local
Bone destruction
Pathological fractures
Periosteal new bone formation
Soft tissue extension
Bone expansion
Generalized or metabolic
Malignant hypercalcemia
Hypocalcemia
Oncogenic osteomalacia

### Pathological Fractures

Metastases cause weakening of the involved bones and may lead to fractures in the vertebrae (compression fractures) or long bones, most commonly affecting the proximal portion of the femur [24].

### Periosteal New Bone Formation

In general, a periosteal reaction due to metastases is minimal (if present) compared to significant new bone formation in association with primary bone tumors.

### Soft Tissue Extension

Soft tissue masses may infrequently present regionally in association with metastases.

This occurs particularly with rib lesions in association with myeloma and in the pelvis in association with colon cancer.

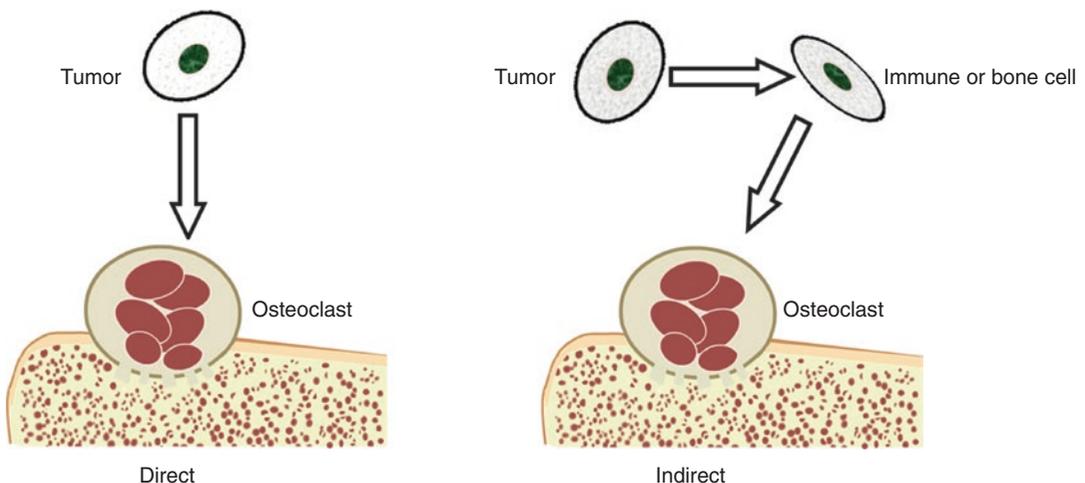

### Bone Expansion

Bone expansion may occur with both osteolytic and osteoblastic lesions. Carcinomas of the prostate, kidney, and thyroid and hepatocellular carcinoma are particularly known to cause expansile metastatic lesions (Fig. 6.21).

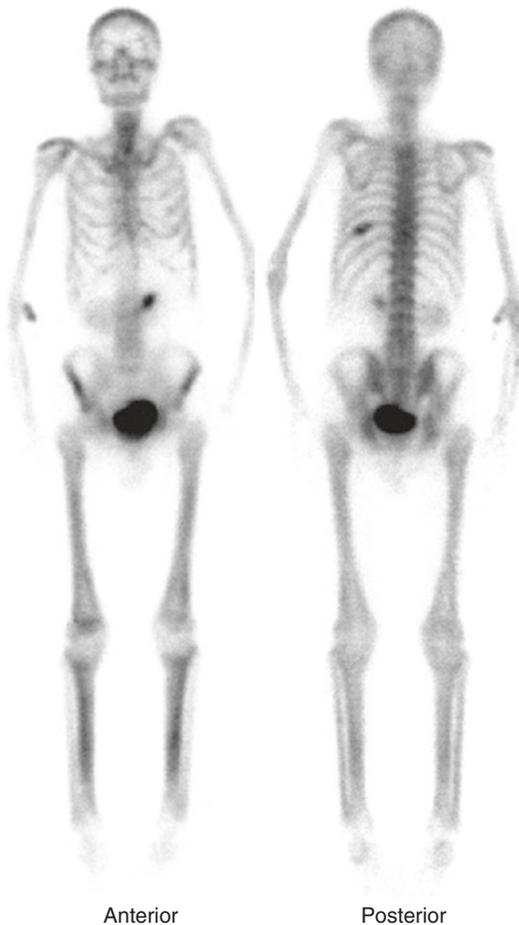

## Generalized or Metabolic Consequences

### Malignant Hypercalcemia

Malignant hypercalcemia occurs in up to 20% of cancer patients and can be associated with

**Fig. 6.20** Direct and indirect destruction of bone by metastases

**Fig. 6.21** Whole-body scan of a 60-year-old man with lung cancer. Expanded metastatic lesion of the left ninth rib posteriorly is seen. The scan shows also hypertrophic osteoarthropathy with diffusely increased uptake in the bones of the extremities

metastases due to destruction of the bone but also with primary tumors in the absence of skeletal metastases.

Lung cancer is the most frequent tumor to cause hypercalcemia comprising 36% of malignancies causing hypercalcemia followed by breast cancer (25%) and hematological malignancies as myeloma and lymphoma (14%) [33]. Deposition of calcium in various soft tissues also occurs in cancer patients. This metastatic calcification was first described by Virchow in 1855 and is associated with metastatic neoplasms but is not limited to cancer as it can also occur in chronic renal disease, hemodialysis, parathyroid tumors, hyperparathyroidism, and others.

The calcific process principally affects the blood vessels, periarticular soft tissue, lungs, stomach, kidneys, and myocardium.

#### Hypocalcemia

An unidentified humoral substance capable of stimulating osteoclasts in some cancer patients with skeletal metastases is proposed to be the underlying mechanism behind the presence of hypocalcemia in up to 16% of cancer patients. It also occurs as one of the metabolic manifestations of tumor lysis syndrome [34].

#### Oncogenic Osteomalacia

In some patients with skeletal metastases, depressed levels of 1,25-dihydroxy vitamin D<sub>3</sub>, hypocalcemia, and hypophosphatemia are recognized and can be associated with a generalized weakness and pain of bones and muscles (oncogenic osteomalacia). Oncogenic osteomalacia is characterized by hypophosphatemia (which occurs secondary to inappropriate phosphaturia), reduced concentrations of serum calcitriol, and defective bone mineralization. Removal of tumors results in complete reversal of these biochemical defects [35].

## 6.3 Imaging of Primary Bone Tumors

### 6.3.1 Overall Role of Imaging

Morphological imaging modalities play a major role in evaluating the local extent of the primary tumors of bone. MRI has become the examination of choice for local staging (Fig. 6.22; Table 6.7) while standard radiographs are the initial and most specific technique for the diagnosis of such tumors. Using several radiotracers including Tc-99m MDP, thallium-201 (Fig. 6.23), Tc-99m MIBI (Fig. 6.24), gallium-67, F-18 sodium fluoride, F-18 fluorodeoxyglucose (FDG) (Fig. 6.25), and others, scintigraphy helps in the diagnosis, grading, and the evaluation of the response to chemotherapy of the primary bone tumors. Bone scintigraphy has a limited role in local staging but is still the modality of choice in detecting distant metastases.

**Fig. 6.22** a, b MRI images of a patient with osteogenic sarcoma of the distal left femur with clear delineation of its extent. MRI is the current modality of choice for local staging of such primary tumor

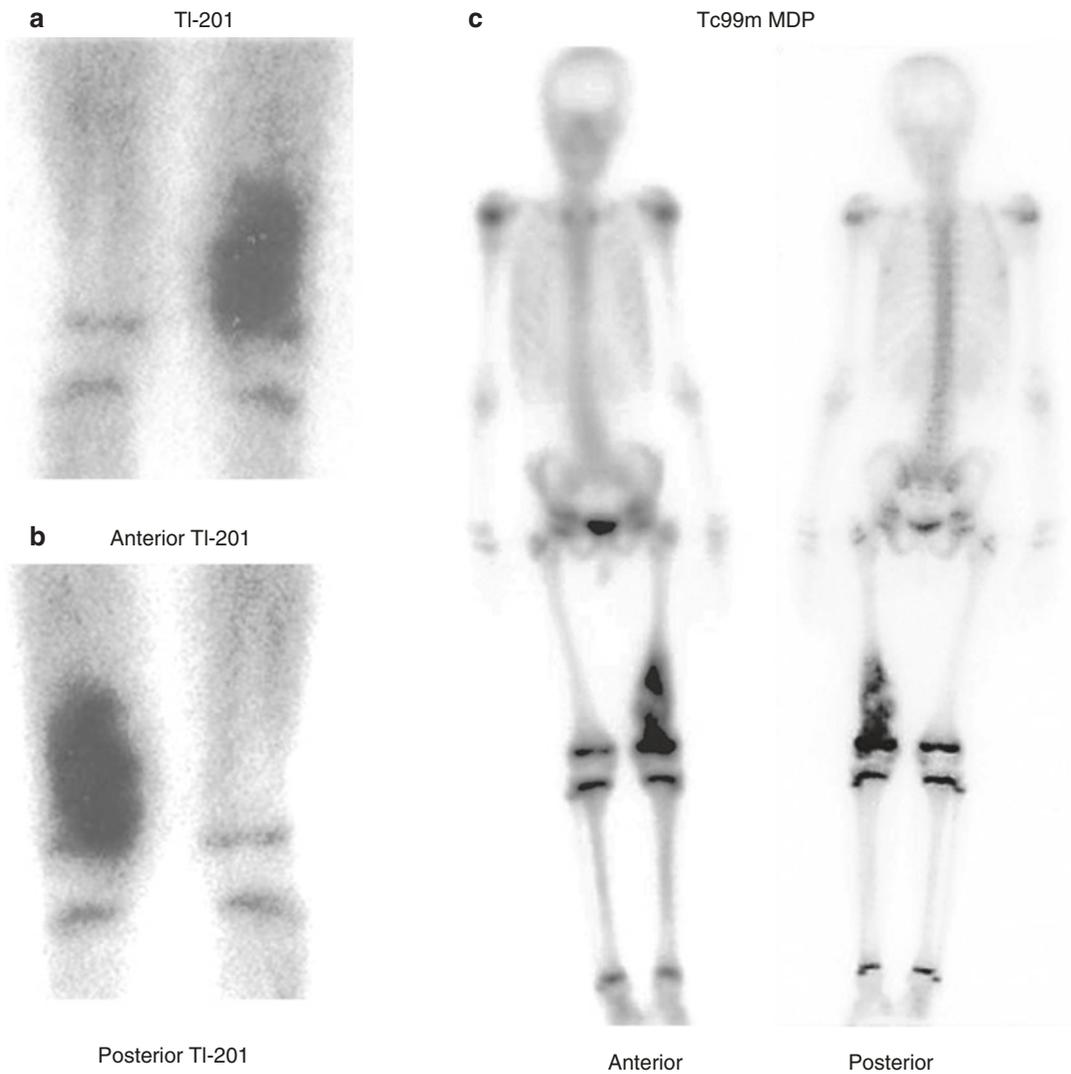

**Table 6.7** Uses of MRI in malignant bone disease

1. Local staging of primary bone tumors
2. Suspected vertebral metastases or equivocal vertebral lesions on bone scan
3. Patients with neurologic symptoms suggesting vertebral involvement or when spinal cord compression is suspected
4. Solitary bone lesions

Bone scintigraphy may detect metastatic and other lesions as small as 2 mm [37]; however, the sensitivity depends on the nature of the lesion as well as its location. The specificity, however, for malignancies including metastases is low. F-18 FDG and, when not available, thallium-201 and Tc-99m MIBI can help in differentiating malignant from benign bone lesions [36, 38–41]. Thallium-201 and F-18 FDG imaging showed a positive correlation between the grade of the tumor and the retention of thallium-201 and the degree of FDG uptake by a single tumor type [41]. Sequential Tl-201 scintigraphy before, and after treatment, is useful in assessing the degree of response of the tumor to chemotherapy. The early prediction of the chemotherapeutic effect by Tl-201 scintigraphy during treatment will affect the management of patients who do not respond to therapy. Thallium-201 is also used for the

detection of the early recurrence of tumors [42]. PET is increasingly used to evaluate the response to therapy [43] (Table 6.8) and is considered to be the modality of choice for this purpose (when available). In a recent study [44] 17 patients with primary bone tumors (11 osteosarcomas, 6 Ewing's sarcomas) treated with chemotherapy before surgery were studied using FDG PET studies. PET showed a decrease of more than 30% in tumor to non-tumor ratios (T/NT) in all patients who had good responses as subsequently determined histologically. Patients with poor responses had increasing or unchanged T/NT ratios or decreasing ratios of less than 30% [44].

PET also has a role in detecting the distant metastases of primary bone tumors. However, the accuracy may be dependent on tumor type and location. In a study looking at the detection of osseous metastases in 70 patients with histologically proved malignant primary bone tumors (32 osteosarcomas, 38 Ewing's sarcomas), FDG PET was compared to Tc-99m MDP bone scintigraphy. Among 54 proven osseous metastases (49 from Ewing's sarcomas, 5 from osteosarcomas), FDG PET had a sensitivity of 90%, a specificity of 96%, and an accuracy of 95% compared to 71%, 92%, and 88% for bone scintigraphy. For Ewing's sarcoma patients, the sensitivity, speci-

**Fig. 6.23** a–c Tl-201 in a bone tumor (a 13-year-old boy with a mass in his left thigh). Note the intense Tl-201 uptake (a–b) bone which corresponds to the tumor as seen on Tc-99m MDP bone scan (c)

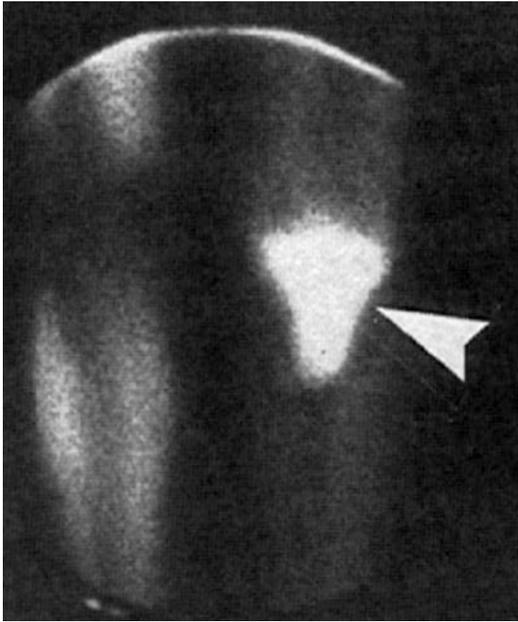

ficity, and accuracy of FDG PET and bone scan were 100%, 96%, and 97% and 68%, 87%, and 82%, respectively. None of the five osseous metastases from osteosarcoma were detected using FDG PET, but all were detected using bone scintigraphy. The study suggests that the sensitivity, specificity, and accuracy of FDG PET in the detection of osseous metastases from Ewing's sarcomas are superior to those of bone scintigraphy, while FDG PET seems to be less sensitive than bone scintigraphy in the detection of osseous metastases from osteosarcoma [45, 46]. The standardized uptake value (SUV) of F-18 FDG

PET was determined by Aoki et al. [47] in 52 primary bone lesions, 19 malignant and 33 benign prior to tissue diagnosis. Overall, there was a statistically significant difference in SUV between benign (2.18) and malignant (4.34) lesions in general. However, there was no statistically significant difference in SUV between certain benign lesions including fibrous dysplasias, chondroblastomas, sarcoidosis, and Langerhans cell histiocytosis and those of chondrosarcoma and osteosarcoma [47]. Another study of 40 patients with primary bone lesions showed a considerable overlap of SUV values between benign

and malignant lesions, although the values in malignant lesions were in general significantly higher than those in benign lesions [48].

On FDG PET/CT, variable degrees of uptake are reported [49]. Generally malignant tumors show

more avidity than benign tumors, and more aggressive tumors show also more avidity within the same type of tumor [50]. It should be noted that F-18 FDG uptake is seen in several primary benign tumor and tumorlike conditions [50–53] (Table 6.9).

### 6.3.2 Imaging of Major Specific Primary Tumors

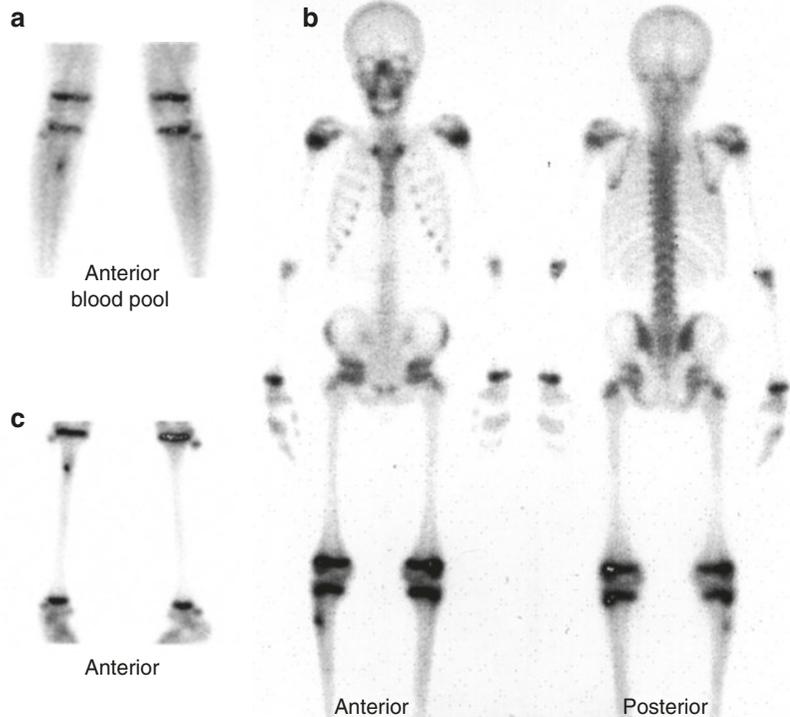

#### 6.3.2.1 Osteoid Osteoma

This benign tumor is most common in children, particularly boys. Typically it presents in the lower extremities, pelvis, or less commonly in the spine. Characteristically these lesions are intracortical and diaphyseal in location, although

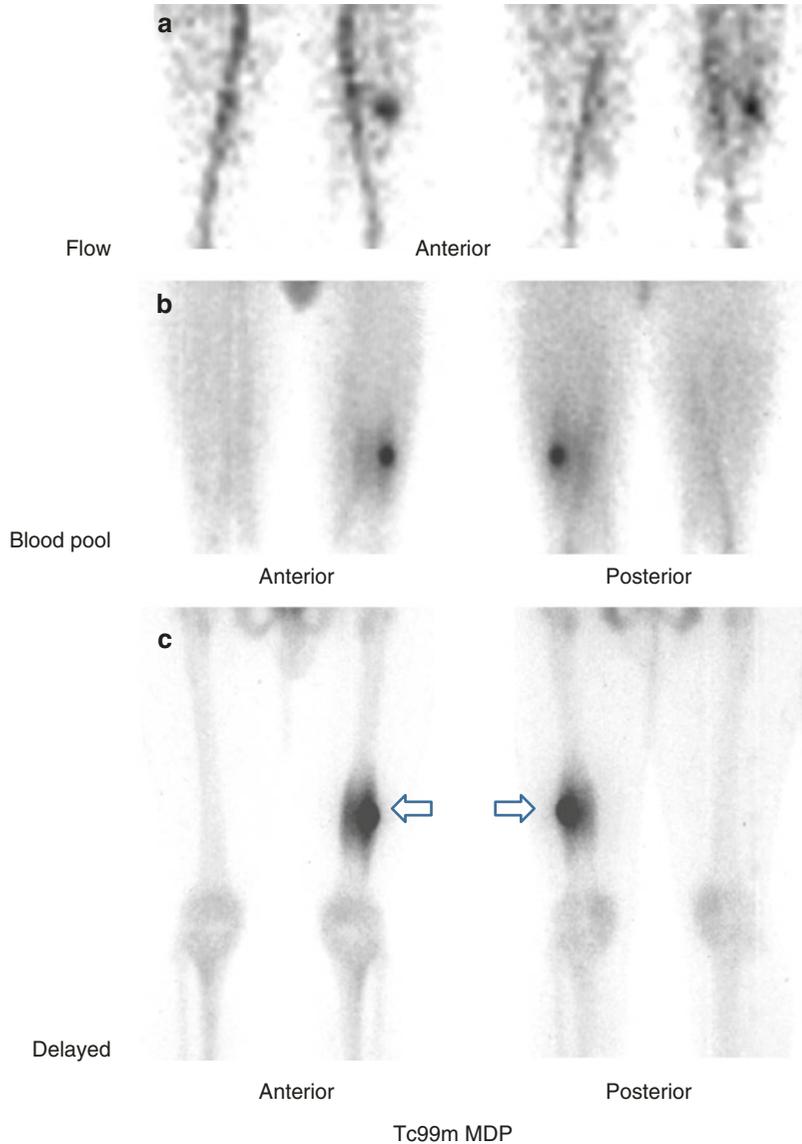

**Fig. 6.26** A representative cut of a CT scan of osteoid osteoma of the left tibia of an 18-year-old patient. Note the values of CT in demonstrating the nidus (*arrow*)

they occasionally involve the metaphysis. On standard radiographs, the characteristic appearance is a small (less than 1.5–2 cm), cortically based radiolucency (nidus) surrounded by marked sclerosis and cortical thickening, combined with the classic clinical history of pain, worse at night, that is relieved by aspirin. Using CT, an area of increased bone density surrounding a lucent nidus is typical of this tumor (Fig. 6.26). In intra-articular osteomas, CT is less accurate. In one study CT scans were accurate in two thirds of the intra-articular and in 90% of extra-articular cases [54]. Scintigraphically there is a focal area of increased flow, increased blood pool activity, and increased delayed uptake (Fig. 6.27) [55]. A specific scintigraphic pattern of a double intensity may be seen as a more intense uptake corresponding to the nidus and a peripheral area of less intense activity (Fig. 6.28). The nidus of the tumor must be removed during surgery to avoid regrowth. Single-photon emission computed tomography (SPECT) may help to localize an osteoid osteoma before surgery, and a gamma probe is a useful operating room tool for localizing this tumor. The symptoms of

**Fig. 6.27** Bone scan of osteoid osteoma. There is slightly increased blood pool activity (a) and an intensely increased uptake on the whole body (b) and spot image (c) in the area of the tumor located in the right tibia

**Fig. 6.28** a–c Flow (a), blood pool (b), and delayed (c) images of a patient with osteoid osteoma of the left femur showing intense flow and blood pool activity and on delayed images the specific pattern of double intensity (arrow)

osteoid osteoma are cured by removing the nidus. “En bloc” resection is often not successful because the nidus is hard to find and remove totally. Since the nidus is best localized with CT [56], surgery under CT control using standard equipment usually available in the operating room has been recently used successfully for CT-guided removal of the nidus [57]. MRI also shows intramedullary high intensity areas in the nidus on T2-weighted images, and this was suggested to be due to high level of COX-2 expression in neoplastic osteoblasts in the nidus [3].

Intra-articular osteoid osteomas present special problems. Joint effusion and lymphoproliferative synovitis, similar to that seen in rheumatoid arthritis, are often seen with these lesions and may suggest an arthritic condition. Recent advances in the use of thermocoagulation of the nidus have led to a radical change in the management. Reported success rates for treatment by the use of percutaneous radiofrequency electrodes have ranged from 80% to 90%, with no need for additional procedures or medications for at least 2 years [5].

### 6.3.2.2 Osteoblastoma

As stated earlier this tumor is related to osteoid osteoma and most commonly affects spine and lower extremities. Scintigraphically, osteoblastoma shows an intense uptake similar to osteoid osteoma. Radiographically, a pattern of lysis with, or without, a rim of surrounding sclerosis is characteristic (Fig. 6.29). Extensive surrounding sclerosis is usually absent; however, the surrounding inflammatory changes are often identified using MRI.

### 6.3.2.3 Osteochondroma

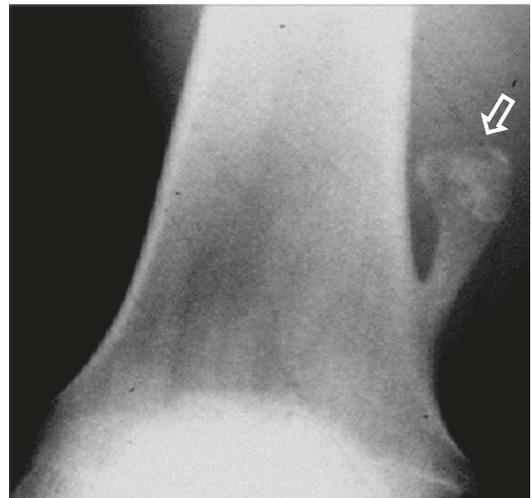

This tumor can appear as sessile/pedunculated (exostosis) or as sessile. The lesions, particularly the pedunculated (Fig. 6.30 and 6.31), have a central core of cancellous bone surrounded by a shell of cortical bone and covered by a cap of hyaline cartilage. It can be familial, and multiple, forming the entity of hereditary multiple exostoses that is discovered in childhood. We have encountered a case of this condition where the patient had more than 300 lesions, which show variable degree of uptake on bone scintigraphy (Fig. 6.32). Standard radiographs and CT scanning usually are enough to detect the lesions; however, bone scanning is particularly useful in detecting multiple lesions and also following up patients who have hereditary disease since there is a risk of malignant transformation in up to 30% of cases [58]. MRI delineates and assesses the thickness of cartilage cap and is useful in planning tissue biopsy of the lesions. A cartilage cap 1.5–2 cm thick in a skeletally mature person is highly suggestive of malignant transformation. Scintigraphically a variable degree of uptake is seen which may reflect the lesion's activity; however, active peripheral lesions, particularly if small, may not show enough uptake to be detected on bone scans [59–61].

### 6.3.2.4 Osteogenic Sarcoma

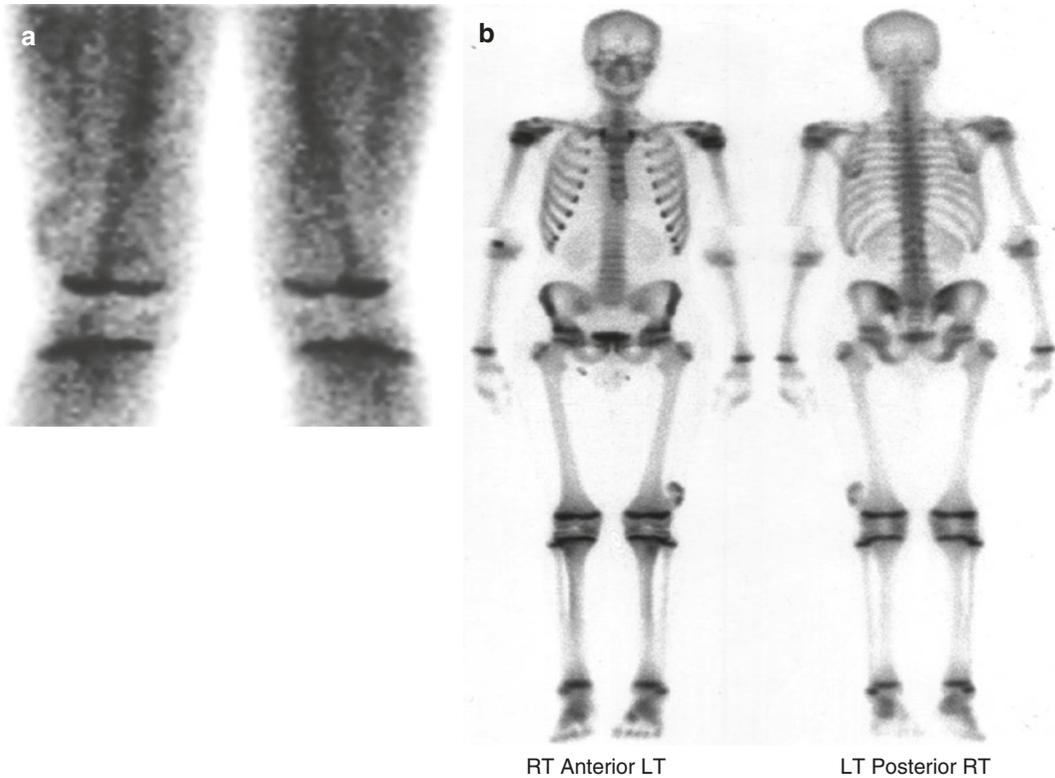

Scintigraphically, osteogenic sarcoma presents as an area of intense uptake. Rarely, the tumor may present as a cold lesion [62, 63]. CT and, particularly, MRI are superior to bone scanning in evaluating the extent of the tumor. SPECT/CT is useful in localizing the scintigraphic uptake and extent

**Fig. 6.29** X-ray illustrating the typical pattern of osteoblastoma. Osteoid osteoma has similar appearance but is smaller in size

**Fig. 6.30** Radiographic appearance of a pedunculated osteochondroma originating from the distal end of the femur

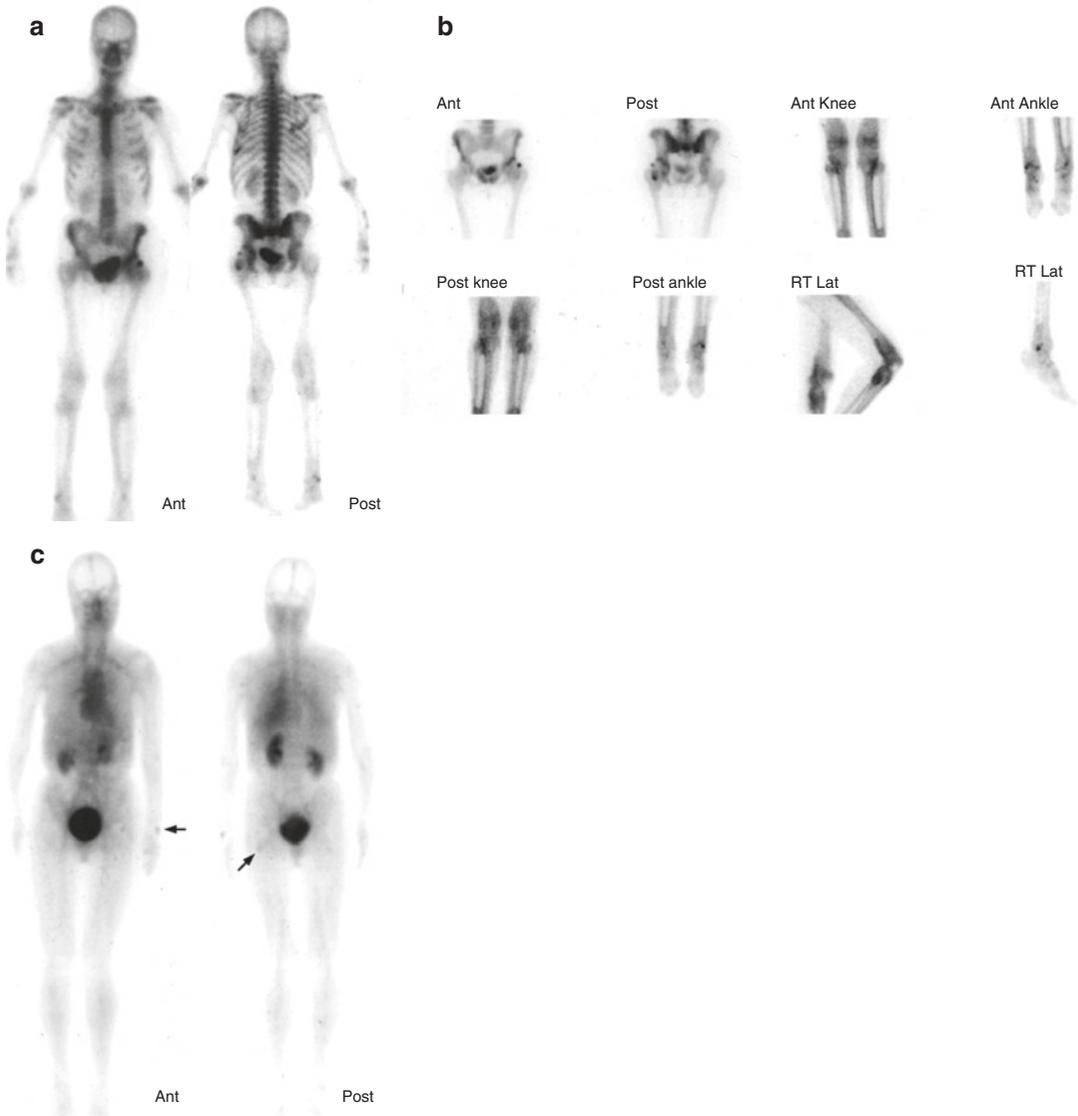

**Fig. 6.31** Solitary osteochondroma in the left distal femur in a 14-year-old athletic boy who complained of pain and swelling in the left distal thigh for 1 week before he was referred for a bone scan. There is increased blood

pool activity (a) and delayed uptake (b) in the pedunculated lesion that was proved to be osteochondroma after surgery

of the tumor (Fig. 6.33). Bloem [64] evaluated the relative value of MRI, CT, Tc-99m bone scintigraphy, and angiography prospectively in the local tumor staging of 56 patients with a primary bone sarcoma. MRI was significantly superior to CT and scintigraphy in defining intraosseous tumor lengths and as accurate as CT in demonstrating the cortical bone and joint involvement (Fig. 6.34). Additionally MRI was superior to CT in demonstrating involvement of skeletal muscle. Bone metastases are extremely rare at the time of presentation. McKillop et al. [65] have investigated the value of bone scanning at the time of presentation and during follow-up. The authors found only 1 patient out of 55, with bone metastases. On the other hand, during follow-up bone metastases developed in a further 20 patients who also developed abnormal bone scans, with approximately half of them asymptomatic. The

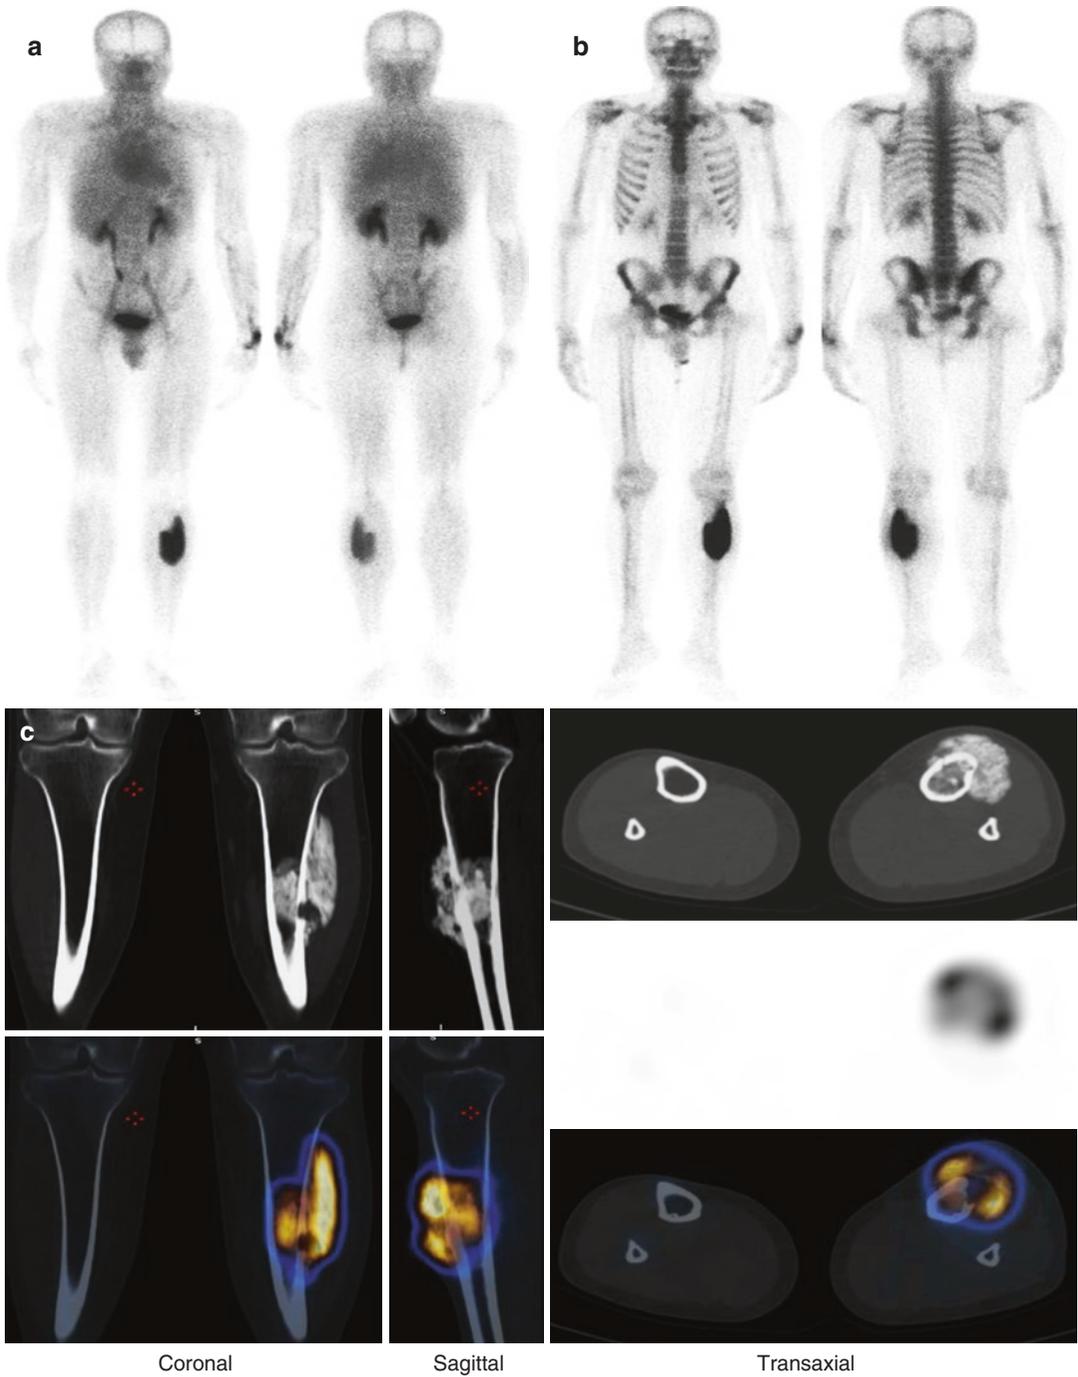

authors concluded that the initial bone scan yield although small is justified at the time of presentation because the results may profoundly alter the treatment of the patient and is indicated for all patients (routinely) during follow-up even if they are asymptomatic.

Bone scintigraphy is useful in detecting tumor recurrence. In a study of 27 patients (6 osteosarcomas, 21 Ewing's sarcomas) [60], FDG PET examination was performed for the diagnosis, or exclusion, of recurrent disease. Conventional imaging techniques consisted of MRI of the primary tumor site, thoracic CT, and Tc-99m MDP bone scintigraphy. The reference methods were the histopathological analysis and/or the clinical and imaging follow-up. In 25 examinations, reference methods revealed 52 sites of recurrent disease. The sensitivity, specificity, and accuracy of FDG PET in the detection of recurrences from

**Fig. 6.32** a–c Bone scan of a patient with multiple osteochondromas. Note the numerous small foci of increased uptake in the cervical spine, ribs, pelvis, bones of the lower extremity, and right forearm seen on whole body (a)

and spot images (b). On whole-body blood pool images (c), some lesions show increased blood pool activity (arrows)

**Fig. 6.33** Twenty-four-year-old patient with osteogenic sarcoma. Tc-99m MDP bone scan planar images show intense blood pool (a) and delayed uptake (b) at the site of

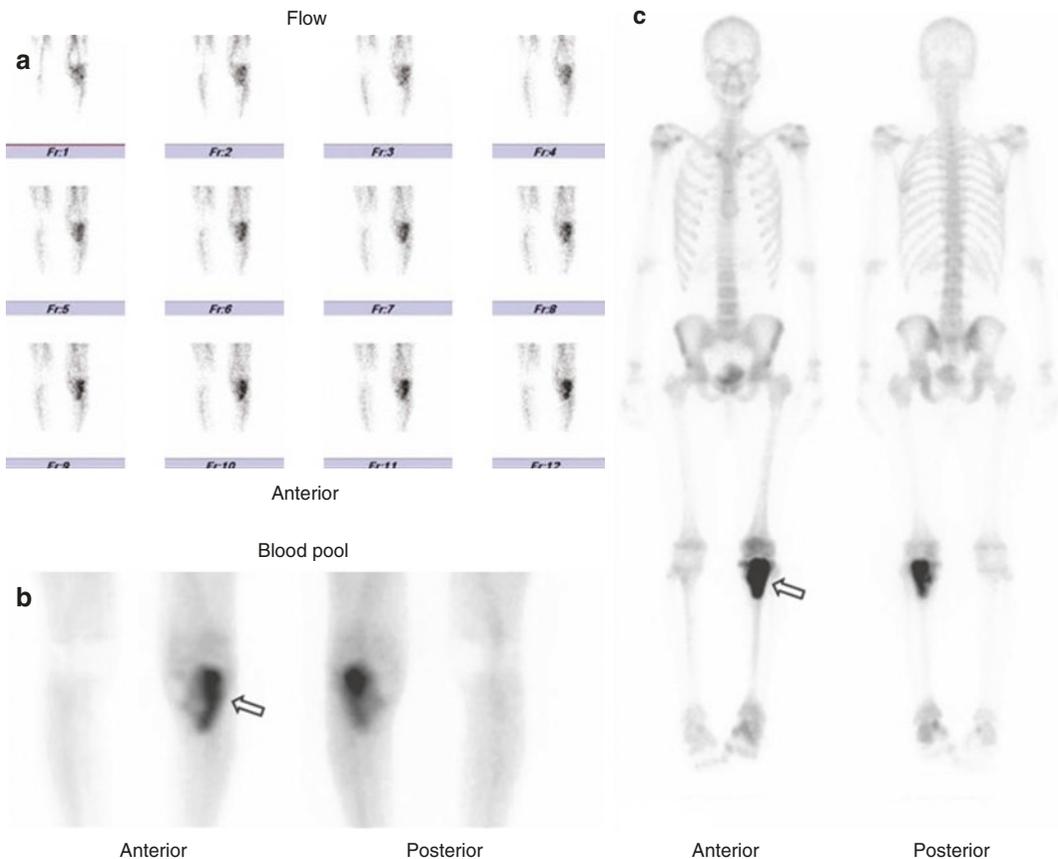

the tumor in the left proximal tibia. SPECT/CT images (c) show accurate delineation of the tumor extent and localization of the radiotracer uptake

osseous sarcomas were high (96%, 81%, and 82%, respectively) but showed only a small advantage in the detection of osseous and soft tissue recurrences compared with conventional imaging [66].

To follow up the response of the tumor to therapy, PET has proved useful [43, 44, 67]. Tc-99m MIBI and thallium-201 are also useful for this purpose and predict the prognosis. Studies have suggested that P-glycoprotein (Pgp) expression is a prognostic factor for patients with osteosarcoma. Some investigators have found a relationship between the washout rate of Tc-99m MIBI and the Pgp score, with a significant difference in washout rate being observed between patients with high and patients with low Pgp expression [68]. Others have found that Tc-99m

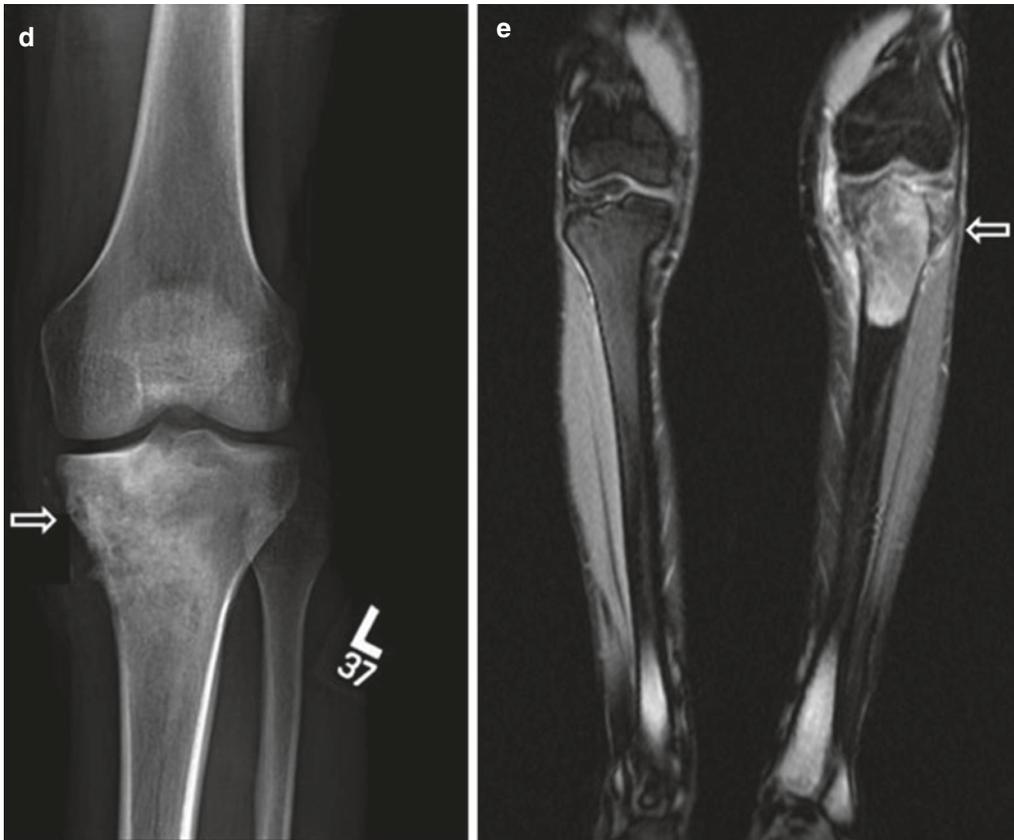

MIBI imaging is not an effective predictor of prognosis since the Tc-99m MIBI half-life and uptake ratio showed no correlation with histological necrosis following induction chemotherapy and did not correlate with P-glycoprotein expression [69]. Using thallium-201, the pattern of doughnut uptake was found to be a predictor of lower event-free survival in patients with extremity osteogenic sarcoma but does not correlate with the histological response to therapy [70].

The initial glucose metabolism of primary osteosarcoma, as assessed by F-18 FDG PET using tumor to non-tumor ratios, provides prognostic information related to the grading and biological aggressiveness. High F-18 FDG uptake correlates with poor outcome and F-18

**Fig. 6.34** Fourteen-year-old male with pain and swelling of the left upper leg proven later to be osteogenic sarcoma. Bone scan showing hypervascularity (a) and intense delayed uptake (b, c) corresponding to the X-ray (d) and MRI (e) findings.

Note the mildly diffuse increased uptake in the bones of the left lower extremity due to disuse. No distant metastases. Note the outlines of the tumor on MRI images which is superior to bone scan in regional staging of the tumor

**Fig. 6.34** (continued)

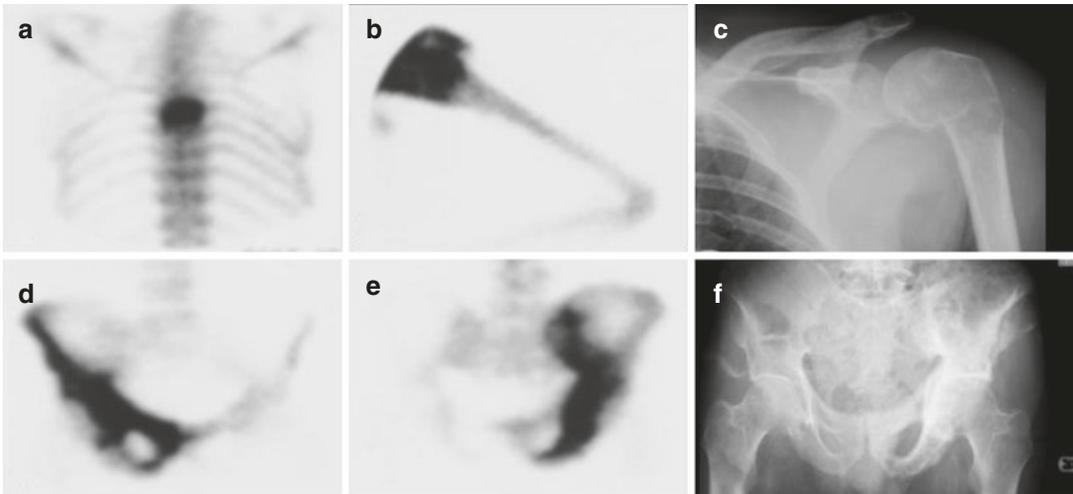

FDG uptake may be complementary to other well-known factors in judging the prognosis in osteosarcoma [50, 71, 72].

### 6.3.2.5 Myeloma

Traditional staging of myeloma depends partially on the extent of the disease evaluated by full skeletal survey. The tumor presents on radiographs as osteolytic areas due to demineralization of bone by the tumor (Fig. 6.35). Tc-99m MDP, Tc-99m MIBI, and thallium-201 have all been used to image multiple myeloma, and the bone mineral density can be measured using dual energy X-ray absorptiometry [73, 74]. Bone scanning is generally viewed to be unreliable for staging, although in a recent study reviewing the literature (comparing the usefulness of conventional skeletal

**Fig. 6.35** The typical osteolytic myeloma lesions on a standard radiograph

**Fig. 6.36** Fifty-seven-year-old male patient with back pain and general weakness was found to have multiple myeloma. Tc-99m MDP spot images (a–d) show foci of increased uptake in the right proximal humerus, fifth tho-

racic vertebra, and right hemipelvis. X-rays of the right humerus (e) and pelvis (f) show abnormalities with lytic lesions corresponding to the findings of bone scan in the right humerus and right hemipelvis

radiography and bone scans in diagnosing the osteolytic lesions of myeloma), it has been shown that bone scintigraphy (considered by many to have no role in the detection of osteolytic lesions of myeloma) is in fact more sensitive than radiography in the detection of lesions in the ribs, scapula, and spine [75]. Radiographs, however, are also known to underestimate the extent of bone and bone marrow involvement [76]. Although cold areas are commonly seen on bone scans, increased uptake is the most common scintigraphic pattern (Fig. 6.36) [77, 78]. This should not contradict the fact that myeloma is the most common tumor to cause cold lesions on bone scanning (Table 6.10). Regarding the use of Tl-201, Watanabe et al. studied 19 patients with multiple myeloma with both Tl-201 and bone scintigraphy. The authors found that the combination of Tl-201 and bone scintigraphy was more accurate than bone scintigraphy alone in detecting lesions of multiple myeloma [78].

Alexandrakis studied 28 patients with multiple myeloma using Tc-99m MIBI in compari-

son with Tc-99m MDP, standard radiographs, CT scan, and MRI. Tc-99m MIBI scintigraphy was found to detect bone marrow lesions in myeloma patients that could not be detected using other imaging methods, and it was able to provide prognostic information related to the disease activity and multidrug resistance. This

was because the intensity of Tc-99m MIBI uptake correlated well with disease activity as determined by lactate dehydrogenase (LDH), C-reactive protein (CRP),  $\beta$ 2-microglobulin, and serum ferritin [79]. MRI has been found to be more accurate than other modalities in assessing the tumor sites [80, 81], and CT scanning has an established role in the evaluation of regional disease [82]. A common limitation of both MRI and CT, however, is the frequent inability to differentiate the active disease from necrosis, bone fracture, and other benign disease. Durie et al. [83] used whole-body FDG PET in 66 patients with multiple myeloma and found it very useful in identifying active disease, patients with remission, and those with relapse. The authors found it is particularly useful in evaluating nonsecretory myeloma and found that detected residual, or recurrent, disease after therapy especially extramedullary is a poor prognostic factor. Finally, the staging, follow-up, and determination of the prognosis of patients with myeloma depend on the use of multiple modalities that are complementary. Bone scintigraphy is not highly accurate in detecting myeloma sites, although it can be useful in certain locations. Standard radiography is known to underestimate the extent of the disease. Tl-201 and Tc-99m MIBI have no clear role in this tumor. CT scan and MRI are the most useful but cannot determine the activity of the disease, and PET/CT (Fig. 6.25) has proven to be a reliable predictor of prognosis in patients with multiple myeloma [84].

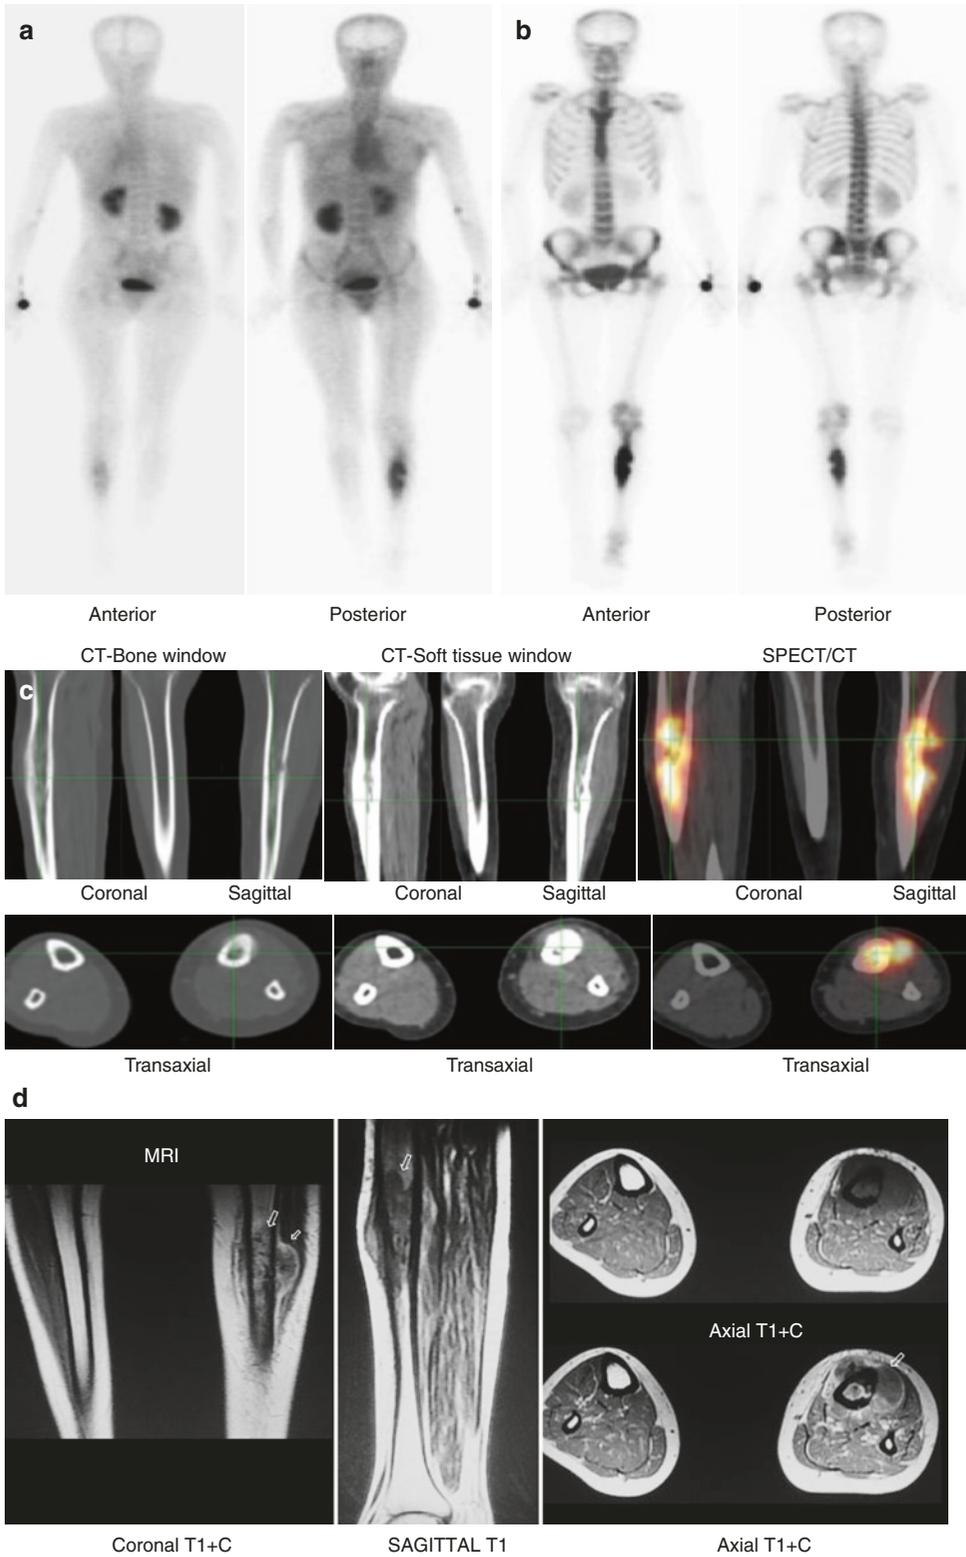

### 6.3.2.6 Ewing's Sarcoma

As with other primary bone tumors, morphological imaging modalities, including CT and MRI, are the principal imaging modalities for assessing the local extent of this tumor. Bone scanning is, however, indicated when metastases need to be excluded particularly if SPECT/CT is used (Fig. 6.37). The detection of the osseous metastases of Ewing's sarcoma, therapy monitoring,

and the diagnosis of recurrences are useful clinical indications for FDG PET [85]. FDG PET has been reported to detect more lesions of metastatic Ewing's sarcoma than bone and gallium scans, especially for those with bone marrow involvement [86, 87]. Tc-99m MIBI has also been used in this tumor to provide an imaging assessment of multiple drug resistance. The presence, or absence, of Tc-99m MIBI uptake at diagnosis, or after therapy, has been found to have no prognostic significance. Tc-99m MIBI was present in the two tumors that were P-glycoprotein positive and in only one of four tumors that were P-glycoprotein negative. Tc-99m MIBI imaging does not appear to be useful in Ewing's sarcoma [88].

### 6.3.2.7 Bone Hemangiomas

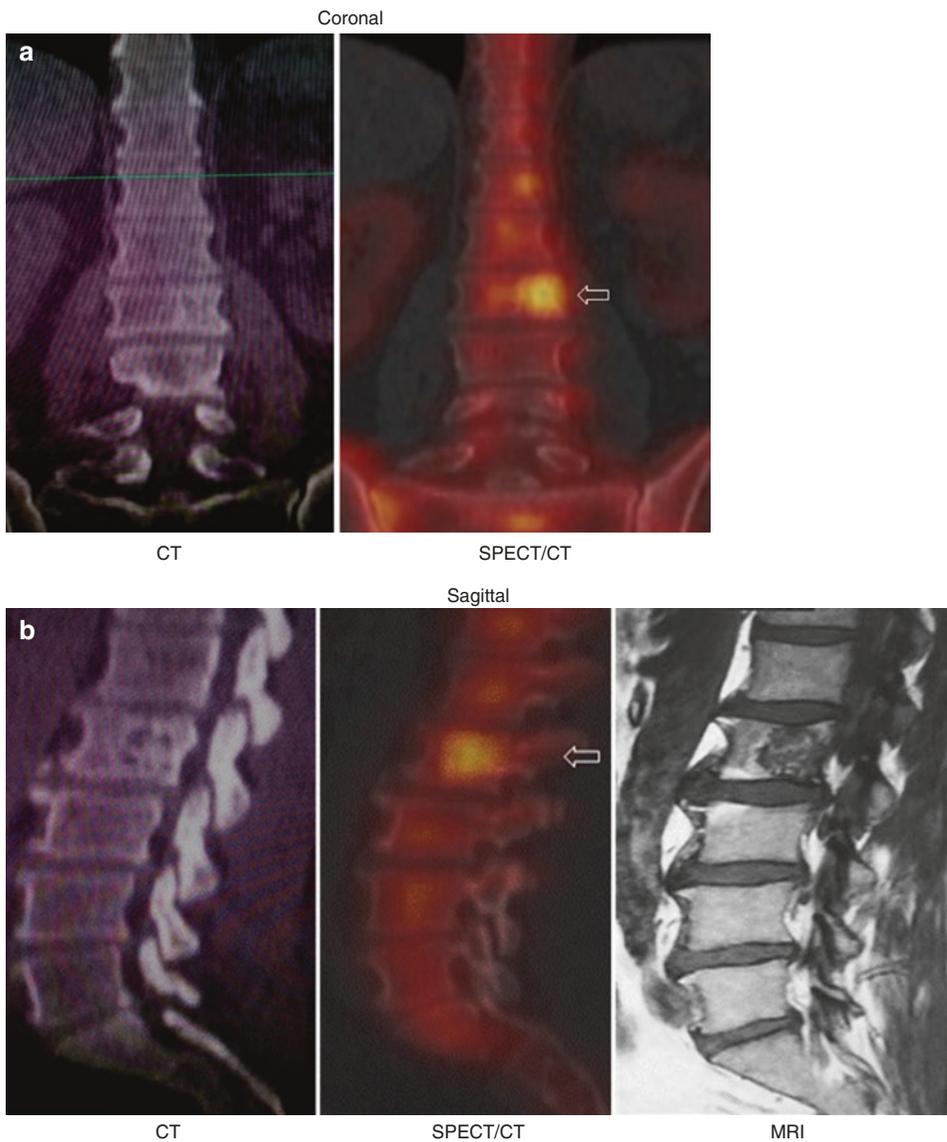

On Tc-99m MDP bone scintigraphy, hemangiomas show variable degrees of uptake. Typically, multiphase bone may reveal increased tracer uptake in all phases (perfusion, blood pool, and delayed), with a progressive increase in uptake, most marked in the delayed static images. Single-phase bone scintigraphy, though, has a far lower specificity since hemangiomas vary in their aggressiveness and hence in the degree of bone turnover, with variable degrees of radiotracer uptake (Table 6.11). Accordingly on bone scan, it may demonstrate either increased (Fig. 6.38) or decreased to absent uptake (Fig. 6.39) or even normal uptake and therefore generally adds minimal information. SPECT may be helpful in vertebral hemangiomas [89], and Tc-99m-labeled red cells will show accumulation by the tumor as the case with hemangiomas at other sites. When cold lesions are seen, metastatic bone disease must be ruled out because it is the most frequent cause of photon-deficient lesions on bone scintigraphy (Fig. 6.39). On F-18 FDG PET/CT, hemangioma is one of the causes of "cold" vertebrae. CT and MRI images can demonstrate typical signs of hemangioma which support diagnosis [90–93].

**Fig. 6.37** Twenty-five-year-old female with biopsy-proven Ewing's sarcoma in the left tibia. On Tc-99m MDP study, the tumor shows increased blood pool activity (a) and intensely increased uptake on delayed images (b). No other lesions are seen to suggest distant metastases. SPECT/CT study (c) and MRI (d) delineates accurately the extent of the tumor

**Table 6.11** Scintigraphic patterns of primary benign bone tumors and tumorlike lesions

Tumor	Typical Pattern on MDP/NaF
Osteoid osteoma	A focal area of increased activity in all three phases and double intensity sign
Osteoblastoma	Increased uptake in all three phases
Osteochondroma	Variable degree of uptake
Giant cell tumor	Increased uptake in all three phases
Chordoma	Increased or normal uptake
Aneurysmal bone cyst	Moderate to intense uptake at the periphery of the lesion with little activity at its center (“doughnut sign”)
Bone hemangioma	Variable (Increased, decreased or normal uptake)

**Fig. 6.38** A case of vertebral hemangioma on Tc-99m bone SPECT/CT study coronal (a), sagittal (b) and transaxial (c) illustrating the typical scintigraphic pattern of increased uptake (arrow). SPECT/CT images demonstrate increased activity in the left half of the L2 vertebral body. Low-dose CT images show “polka-dotted”

appearance due to the thickened vertebral trabeculae. Representative cuts of sagittal and transaxial MRI also show the characteristic pattern. Previously taken diagnostic CT image of this patient was consistent with hemangioma in L2 vertebra (not shown here)

## 6.4 Scintigraphy and Correlative Imaging of Metastatic Bone Disease

Bone is the third most common site of metastatic disease. Skeletal metastases are clinically significant because of the associated symptoms, complications such as the pathological fracture, and their significant impact on staging, treatment, quality of life, and prognosis. Therefore, detection of bone metastases is an important part of treatment planning. The frequency with which metastases are detected varies considerably with the type of primary tumor and with the methodology used for detection. In general, four main modalities are routinely utilized clinically: standard radiography, CT scanning, scintigraphy, and MRI (Table 6.12) [94].

PET is increasingly used particularly for the detection of bone metastases and added diagnostic value. Bone scanning, however, is still the most widely used and the most practical and cost-effective screening technique for assessing the entire skeleton for bone metastases. However, a variable false-negative rate occurs particularly in certain locations such as the spine and in lesions confined to bone marrow [95]. In a study of 18 patients with known malignant tumors and suspected bone metastases, whole-body bone marrow MRI detected 91% of the confirmed malignant lesions, whereas bone scintigraphy detected 85% [96]. Detection of vertebral metastases was shown to depend on the size of the lesion and their location. Lesions less than 2 cm in diameter and intramedullary lesions are not

likely to be detected compared to subcortical and transcortical lesions since cortical involvement is likely to be the cause of positive findings on bone scanning of vertebral metastases [97].

Other studies confirmed the value of MRI in detecting bone metastases and the superior sensitivity compared to planar bone scintigraphy and even F-18 FDG PET/CT [98, 99]. In a recent study, FDG PET/MRI was 100% sensitive compared to 94% for FDG PET/CT; however, FDG PET/CT was found to be better than MRI in benign lesions [99]. SPECT/CT significantly improves the specificity of bone scintigraphy for metastases. In a study on 308 patients with breast cancer (211) and prostate cancer (97), SPECT/CT was 97% sensitive and 94% specific for detecting skeletal metastases compared to 93% and 78% for planar bone scan and 94% and 71% for bone SPECT [100]. The results illustrate the impact of adding CT scan to scintigraphy in improving the accuracy. Thirty-seven patients with 42 focal lesions of the axial skeleton were studied prospectively with planar and SPECT scintigraphy as well as with SPECT/CT [101]. Histologic, MRI, and clinical follow-up findings were used as the reference standard. A specific diagnosis was made with planar scintigraphy in 64% of cases, with SPECT in 86%, and with SPECT fused with CT in all cases. This study further illustrates the added value of CT in increasing the specificity in diagnosing bone lesions by scintigraphy. In a study of 26 children and adolescents with histopathologically proven small-cell neoplasms, whole-body MRI and F-18 FDG PET/CT were found to have comparable accuracy in the diagnosis of bone metastases and far more accurate than bone scintigraphy [102].

A study showed that FDG PET has a better specificity but a lower sensitivity for detecting malignant bone metastases when compared with bone scanning. Twenty-four patients, with biopsy-proven malignancies and suspected bone metastases, had whole-body FDG PET and bone scan. In 39 bone lesions with discordant findings between FDG PET and bone scanning, the final diagnosis revealed eight metastases with positive FDG PET findings. They were not detected on bone scanning indicating that no false-positive findings occurred using PET. On the other hand, 11 metastatic and

Ultrasonography

20 benign bone lesions (with positive bone scan findings) were not detected using FDG PET [103]. In another study of 56 patients with malignant lymphoma, whole-body FDG PET was shown to have a high positive predictive value and was more sensitive and specific than bone scintigraphy in 12 patients with bone metastases [104].

A prospective study of 44 patients with prostate, lung, or thyroid carcinomas showed a sensitivity of 83% for bone scanning in detecting malignant and benign osseous lesions in the skull, thorax, and extremities and a sensitivity of 40% in the spine and pelvis [105]. F-18-FDG PET was more sensitive in detecting osseous lesions and detected all the lesions that were detected by bone scanning. With bone scans, the sensitivity in detecting osseous metastases appears highly dependent on the anatomical localization of these lesions, whereas the detection rates of osteoblastic and osteolytic metastases were similar. Higher detection rates and more accurate differentiation between the benign and malignant lesions with F-18-FDG PET suggest that F-18-FDG PET should be used when possible [105]. Accordingly, PET has proven to be useful especially in tumors known to produce atypical patterns of metastases especially osteolytic. The higher spatial resolution of PET compared to gamma cameras and the routinely included tomography are characteristics that increase the sensitivity of this modality in detecting metastases. F-18 sodium fluoride (NaF) PET/CT is currently used more in bone diseases. Many studies found that F-18 NaF PET/CT is most accu-

rate in detecting metastatic bone disease and is more accurate than planar bone scan (Fig. 6.40) and also FDG PET/CT [106–119]. In a direct comparison of F-18 NaF, F-18 FDG and MDP bone scintigraphy, some patients showed skeletal metastases seen on F-18 NaF and not seen on either of the other two scans [108]. A meta-analysis study comparing F-18 NaF to MDP planar and SPECT studies showed F-18 sodium fluoride PET or PET/CT has excellent diagnostic performance for the detection of skeletal metastases, but the estimated effective dose and average cost-effective ratio are at a disadvantage compared with bone scintigraphy planar or bone scintigraphy planar and SPECT [120, 121]. More cost-effectiveness studies are needed to evaluate improved treatment planning and decreased incidence of noncurative surgical intervention that may be obtained from increased diagnostic sensitivity of F-18 NaF PET [122]. Although F-18 FDG has advantages over F-18 NaF particularly detecting soft tissue as well as bone pathology, F-18 NaF is probably preferred for detecting metastases in some tumor known to show low avidity for FDG such as thyroid and renal cell carcinomas [123].

Combined F-18 sodium fluoride and F-18 FDG has recently been found to be useful in better detection of bone metastases, and this combined technique needs refinement including ratio of radiotracers administered [124]. This single session-combined technique can be utilized in staging of soft tissue and bone disease and covers both osteoblastic and osteolytic metastatic lesions [124].

**Fig. 6.40** Images of Tc-99m MDP (a) and F-18 sodium fluoride (b) illustrating the superiority of F-18 PET in detecting metastases and the superior resolution compared to MDP scan

## 6.4.1 Scintigraphic Patterns of Bone Metastases on Bone Scans

### 6.4.1.1 Typical Pattern

The most common and typical pattern (Table 6.13) of bone metastases is that of multiple randomly

**Table 6.13** Patterns of bone metastases on bone scan

Symmetric

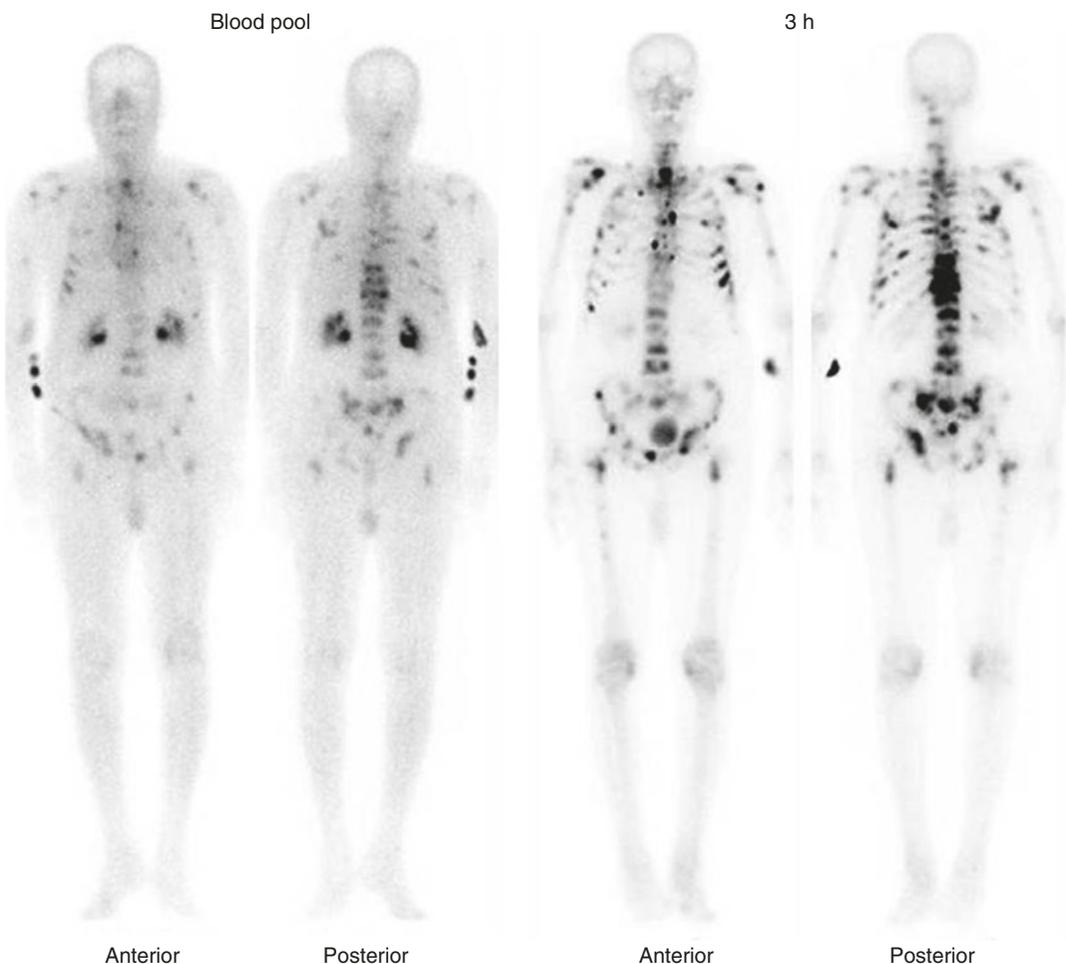

distributed foci of increased uptake (Fig. 6.41); these are usually found in the axial skeleton and follow the distribution of the bone marrow including the shoulder girdle.

There is relatively less extensive involvement of the ribs. Metastases present in the peripheral bones of the extremities are rare [125]. Certain pathologies other than metastases, particularly hematogenously disseminated infections of bone [126–130], can cause a pattern that may mimic metastases (Fig. 6.42; Table 6.14).

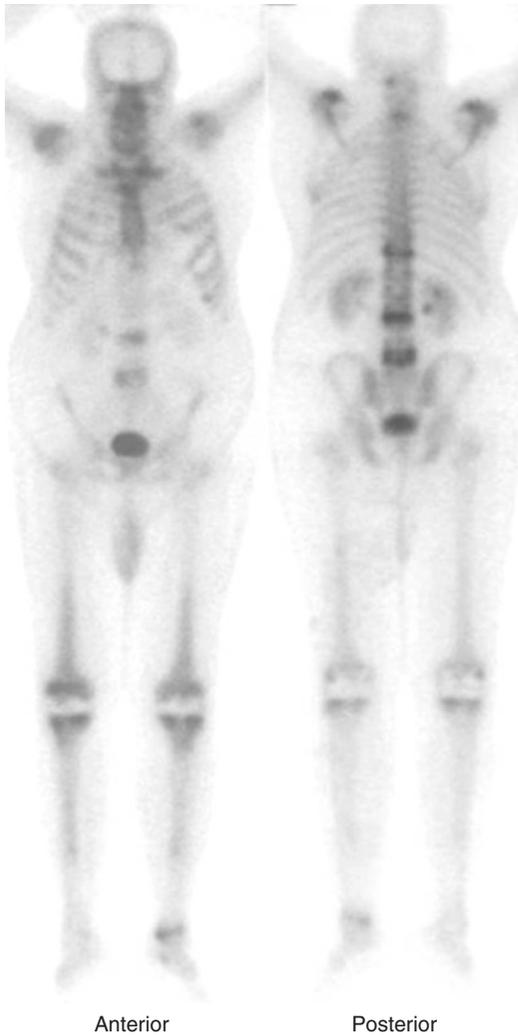

### 6.4.1.2 Atypical Patterns

#### Solitary Lesion

In cancer patients solitary metastasis on bone scan (Fig. 6.43) occurs in the axial and appendicular

**Fig. 6.41** The most common and typical pattern of bone metastases is that of multiple randomly distributed foci with increased uptake

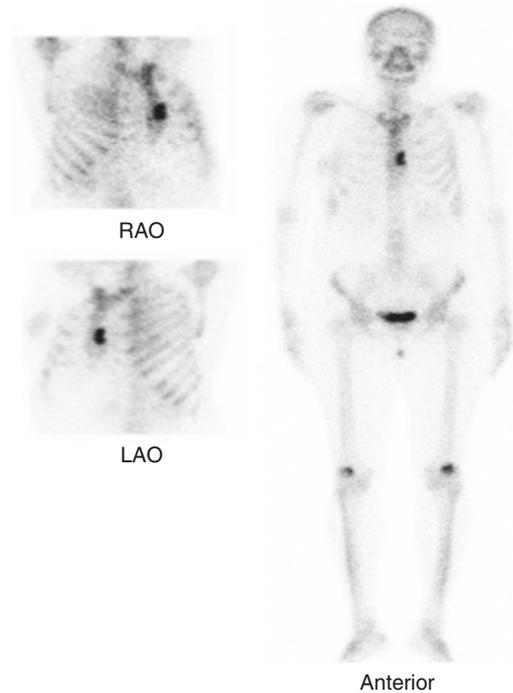

**Fig. 6.42** A whole-body bone scan of a patient with brucellosis with scintigraphic abnormalities of multiple foci of increased uptake. The foci in the spine and ribs in this case can be confused for bone metastases (from [131] with permission)

skeleton to varying degrees. These lesions are commonly asymptomatic and are not suspected clinically. Less than half of these lesions are present on radiographs. These facts further emphasize the importance of obtaining a scan of the entire skeleton in cancer patients. The incidence of malignancy (Table 6.15) in solitary lesions varies with the location and may also be linked to the type of the primary tumor [38, 105, 132–146]. The incidence is highest in the vertebrae and low

in the skull and extremities. Within the vertebral column, the location is also linked to the probability of malignancy. A study using bone scintigraphy in 109 patients yielded the following probability intervals for the intraosseous

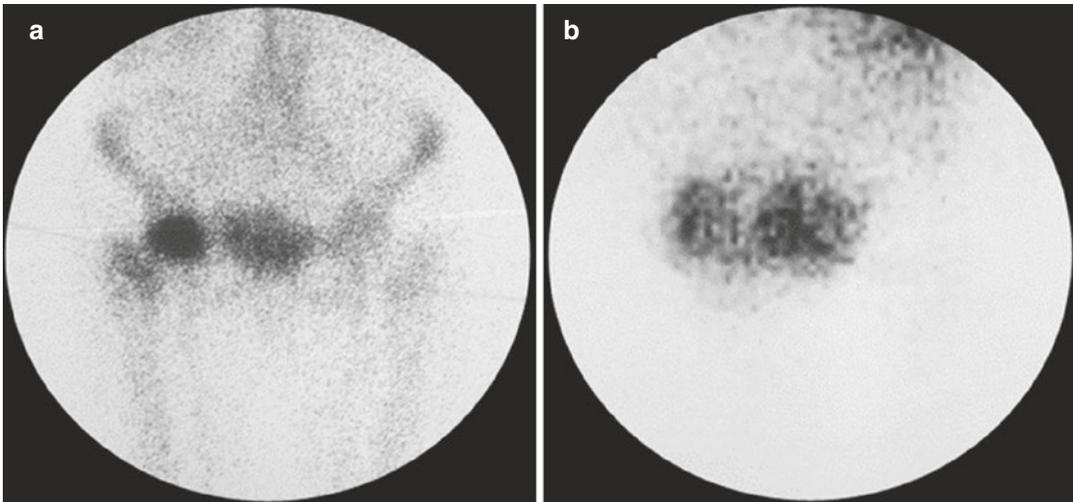

**Table 6.15** Incidence of malignancy in solitary bone lesions in cancer patients [38, 132–144]

Tomada [144]	2001	23

malignant lesions distributed in the lumbar spine: pedicle 88–100%, vertebral body 36–57%, spinous process 19–81%, and facet joints 0.8–21% [146]. The authors concluded that lesions affecting the pedicle are a strong indicator for malignancy, whereas involvement of the facet joints is usually related to benign disease. Lesions affecting the vertebral body, or the spinous process, do not show a clear tendency toward being either malignant or benign. However, in this study in contrast to other studies, a significant probability of malignancy (>36%) was observed in lesions exclusively affecting the vertebral body. When the solitary rib lesion is elongated it carries a higher incidence of malignancy. A solitary hot spot in the skull is rare and is predominantly benign in nature. Retrospective evaluation of bone scans over 10 years was performed to determine the incidence of a solitary hot spot in the skull. A review of the reports of bone scans in 9968 patients yielded 37 (0.37%) patients with a solitary hot spot in the skull [143]. In the group of 27 patients with extraskeletal malignancy, the hot spot was secondary to metastasis in 4 patients and of a nonmetastatic origin in 15. In the remaining eight patients, the cause was indeterminate. Two of the four metastatic foci were located along the suture lines. The authors indicated that the location of a hot spot along the suture lines may not

always be a normal variation and can represent a solitary bone metastasis. Regarding the primary tumor type, although the incidence of malignancy in solitary bone lesion in patients with lung cancer presence was reported to be higher, others found no significant difference [143, 147]. Tomoda reviewed 1167 consecutive bone scans of patients with a history of lung, breast, or prostatic cancer [144]. There were 185 bone scans (lung 121, breast 36, prostate 28) showing solitary hot spot. Of the solitary hot spots, 42 lesions (23%) were malignant: 30 (25%) lung cancer cases, 8 (22%) breast cancer cases, and 4 (14%) prostatic cancer cases. The difference in the frequency of bone metastasis according to the site of primary tumor was not significant.

A wide array of imaging modalities is available for etiologic classification of solitary lesions of bone. The standard radiograph remains the initial imaging modality of choice and is an influential factor in determining whether further imaging is required. Although uptake on bone scanning is non-specific, certain patterns are known to occur in certain lesions and have a higher specific diagnostic value. Osteoid osteoma may show a specific pattern of double intensity, bone islands should show no significant uptake, and giant cell tumors may show a characteristic pattern of the “doughnut sign” [148]. Bone scanning is useful in distinguishing bone islands from other sclerotic lesions, particularly malignancies, since any significant uptake should raise the suspicion of malignancy or other aggressive lesions other than bone islands [149]. SPECT/CT helps in resolving the dilemma in many cases by identifying the features of certain condition and their accurate location and making the diagnosis. MRI is the examination of choice for staging solitary tumors of bone [150]. However, differentiation between benign and malignant etiologies remains largely unanswered by these modalities. FDG PET provides a more accurate differentiation between such lesions [105]. A study using FDG PET examined 83 patients with 37 histologically proven malignancies and 46 benign lesions [53]. The study looked at the standardized uptake value (SUV), global influx (Ki), computation of the transport constants K1–K4 with consideration of

**Fig. 6.44** (a, b) Solitary bone lesion in the right femoral head (arrows) in a patient with non-Hodgkin's lymphoma as seen on the Tc-99m MDP static bone scan spot view of

the pelvis (a). Increased Tl-201 uptake is seen in the same lesion (b)

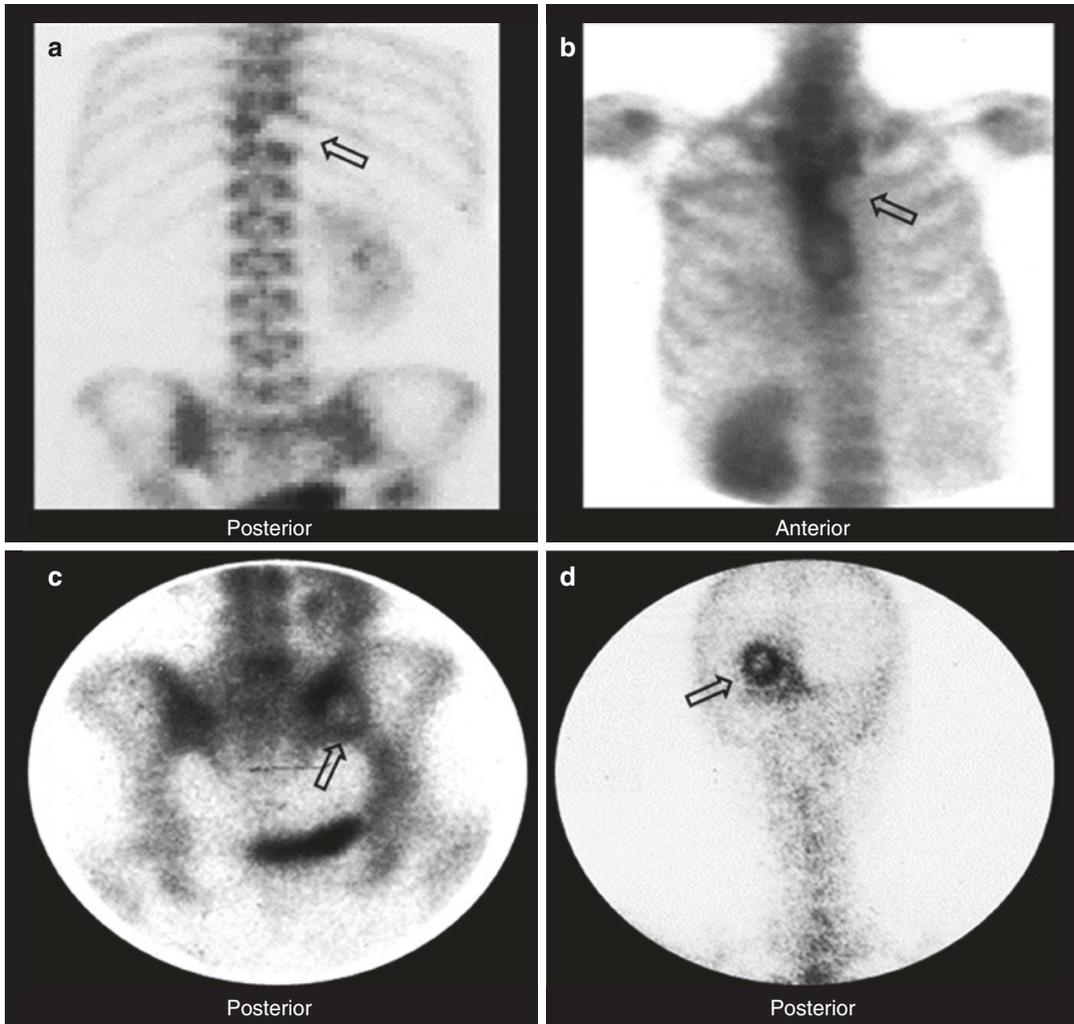

the distribution volume (VB) according to a 2-tissue-compartment model, and the fractal dimension based on the box-counting procedure (parameter for the inhomogeneity of the tumors) were all determined. The mean SUV, the vascular fraction VB, K1–K4, and Ki were significantly higher in the malignant compared with benign lesions. Using the SUV alone, there was some overlap, which limited the diagnostic accuracy. The SUV alone showed a sensitivity of only 54%, a specificity of 91%, and a diagnostic accuracy of 74%. The fractal dimension was superior and showed a sensitivity of 71%, a specificity of 82%, and an accuracy of 77%. The combination of the SUV, fractal dimension, VB, K1–K4, and Ki revealed the best results with a sensitivity of 76%, a specificity of 97%, and an accuracy of 88%. The authors recommended the use of the full F-18 FDG kinetics to classify a bone lesion as malignant or benign [53].

Elgazzar et al. [38] evaluated 28 patients with solitary bone lesions found on Tc-99m MDP scans. Using 2 mCi of thallium-201 chloride, visual assessment, and lesion-to-background ratio determination, they found a significant uptake with a mean lesion-to-background ratio of 4.2 in malignant lesions and a mean lesion-to-background ratio of 1.37 in benign lesions

(Fig. 6.44). Using early and delayed imaging and determination of retention of Tl-201 by the lesion is more accurate than using early imaging only for the etiologic classification of lesions since it decreases the overlap between malignant and certain benign conditions such as tuberculosis [42]. Despite these limitations when PET is not available, Tl-201 can be considered the “PET of the poor.” Tc-99m MIBI may also be used similarly to help differentiate benign from malignant lesions when PET is not an option.

### Cold Lesions

Aggressive tumors may cause cold lesions on bone scan (Fig. 6.43). This is seen commonly in multiple myeloma and renal cell carcinoma [151]. Other tumors include primary tumors as osteolytic osteogenic sarcoma, fibrosarcoma and chordoma, and metastatic lesions of breast and lung cancers, lymphoma, neuroblastoma, and osteogenic sarcoma. A high number of counts, higher intensity images, and review of the images on computer screens are essential for the better detection of cold lesions on bone scanning. A cold lesion in the sternum constitutes a special problem since a highly variable normal appearance of the sternal area makes interpretation of the possible cold lesion difficult using planar

**Fig. 6.45** a–d Cold metastatic lesions at different locations. (a) Cold lesion in a vertebral body in a patient with renal cell carcinoma. (b) Cold lesions of the sternum in a patient with renal cell carcinoma. Note the location and asymmetry of the lesions which are features to differenti-

ate such metastatic lesion from normal variants. (c) and (d) show two cold lesions in the iliac bone and skull, respectively. Some cold lesions may have a surrounding rim of increased activity as in these two lesions while others will not show this pattern

bone imaging. A normal variant of a photopenic area in the lower sternum is not uncommon and is reported in 2–31% of patients [152]. These normal variants occur especially in the area above the xiphoid process of the sternum in which an oval photopenic area on anterior planar images may be seen. This finding is most likely caused by localized incomplete fusion. The variant is seen more clearly on SPECT images. Differentiation from malignancy appears to be related to lesion symmetry, location, midline, and evenly distributed

radioactivity surrounding the edge of the photopenic area [152]. Malignant lesions typically occur at the sternal lateral edges and may be surrounded by nonuniform activity (Fig. 6.45). SPECT/CT and F-18 sodium fluoride have proven useful in detecting solitary lesions particularly in the spine [17, 101, 153]. Additionally F-18 sodium fluoride and F-18 FDG help in differentiating benign from malignant lesions. F-18 sodium fluoride with dual time point acquisition was found to be more helpful in this regard [51, 154].

Hot lesions may show a relatively normal appearance with time (reflecting a point of equilibrium between osteoblastic activity and the bone destruction by the tumor). It appears that skeletal lesions may evolve through phases involving increased uptake, an equilibrium, and then a decreased uptake. The second phase can result in minimal abnormalities of focal, nonuniform, minimally increased uptake or even near normal patterns that can be missed on scans. This phenomenon has been particularly observed and studied in rib lesions [155].

### Flare Pattern

Successful treatment of metastatic disease may be accompanied by an initial apparent deterioration of some lesions on the bone scan, followed by improvement. New sites of activity can be seen along with the more typical change of increasing intensity of pre-existing lesions following chemotherapy. These apparently new lesions probably represent very small lesions, small cold lesions, or lesions in the equilibrium phase that existed but could not be seen on earlier studies. The healing process that occurs as a response to chemotherapy, or hormonal therapy, in the areas of metastases is behind the increasing activity on the follow-up scan of pre-visualized lesions as well as the visualization of presumably pre-existing, previously undetected very small lesions [156]. This phenomenon occurs in the metastatic disease of many tumors, particularly breast, lung, and prostate metastases. It can be seen for up to 8 months, or even longer, after chemotherapy, but usually by 3 months the distinction between progression and this pseudo-progression can be made on the follow-up bone scan in most cases [157, 158].

Practically it may be difficult to wait for 3 months to evaluate the efficacy of therapy using bone scans after the start of chemotherapy or endocrine therapy. Measuring type 1 carboxy-terminal telopeptide (ICTP), a bone resorption marker, has been suggested to help monitor the patients' responses to combination chemotherapy and may prevent the prolonged ineffective therapy or unnecessary changes in therapy as a result of the flare phenomenon [159]. F-18 FDG was used to evaluate the bone metastases before,

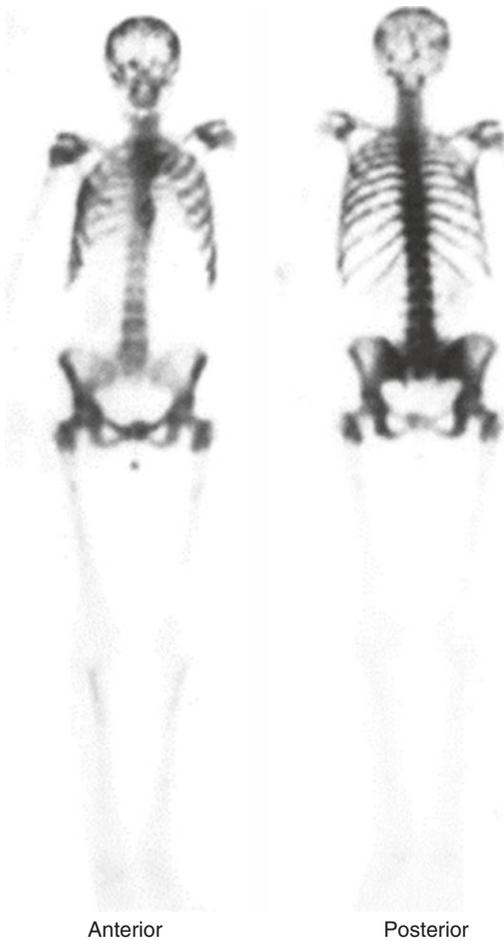

and after, endocrine therapy in a patient with metastatic bone disease of the prostatic carcinoma as seen on bone scans. PET demonstrated heterogeneous FDG uptake in the bones with regions of metastases and up to a 4.79-fold increase of SUV. Bone pain improved 2 weeks after receiving 500 mg diethylstilbestrol diphosphate daily as well as luteinizing hormone-releasing hormone analogue. Serum prostate specific antigen (PSA) decreased after 2 months. Bone scanning after treatment showed little, or no, change compared to that before treatment (with more uptake at lumbar vertebral lesions). Repeat PET showed decreases in fluorodeoxyglucose uptake compared with the pretreatment scan indicating a favorable response to treatment [160]. The information on the response to chemotherapy or hormonal therapy is provided more rapidly and accurately by PET than bone scanning; providing the opportunity exists early to select a more effective therapy in cases of unfavorable response.

### Diffuse Pattern

With advanced metastatic disease, the entire axial skeleton may be involved by a large number of tumor cells causing increased extraction of radiopharmaceutical. This pattern may be interpreted as normal depending on the display intensity and should also be differentiated from other causes of diffusely increased uptake in the skeleton (superscan) such as hyperparathyroidism, other metabolic bone diseases, and Paget's disease (Table 6.16).

**Table 6.16** Causes of diffuse increase of skeletal uptake on bone scan

Advanced metastatic bone disease
Primary and secondary hyperparathyroidism
Hypertrophic osteoarthropathy
Renal osteodystrophy
Acromegaly
Aplastic anemia
Hyperthyroidism
Leukemia
Waldenström's macroglobulinemia
Myelofibrosis
Hypervitaminosis D
Paget's disease

**Fig. 6.46** Tc-99m MDP bone scan illustrating the pattern of diffuse metastases (superscan). Note that the appendicular skeleton is essentially spared compared with the pattern of superscan secondary to metabolic bone disease

A superscan secondary to metastases shows increased uptake that is usually confined to the axial skeleton (Fig. 6.46) while in case of metabolic disorders it also involves the skull, mandible, and a variable length of the long bones. A preferential increase of uptake at the costochondral junctions and sternum is additional features of metabolic disease superscan [161].

### Symmetrical Pattern

Metastases may unusually present as symmetrical lesions. Certain tumors are known to produce this pattern (Table 6.17), particularly in pediatric neuroblastoma. The pattern has also been

**Table 6.17** Tumors known to produce symmetrical bone metastases

Neuroblastoma
Retinoblastoma
Embryonal rhabdomyosarcoma
Breast carcinoma
Lung carcinoma (rare)

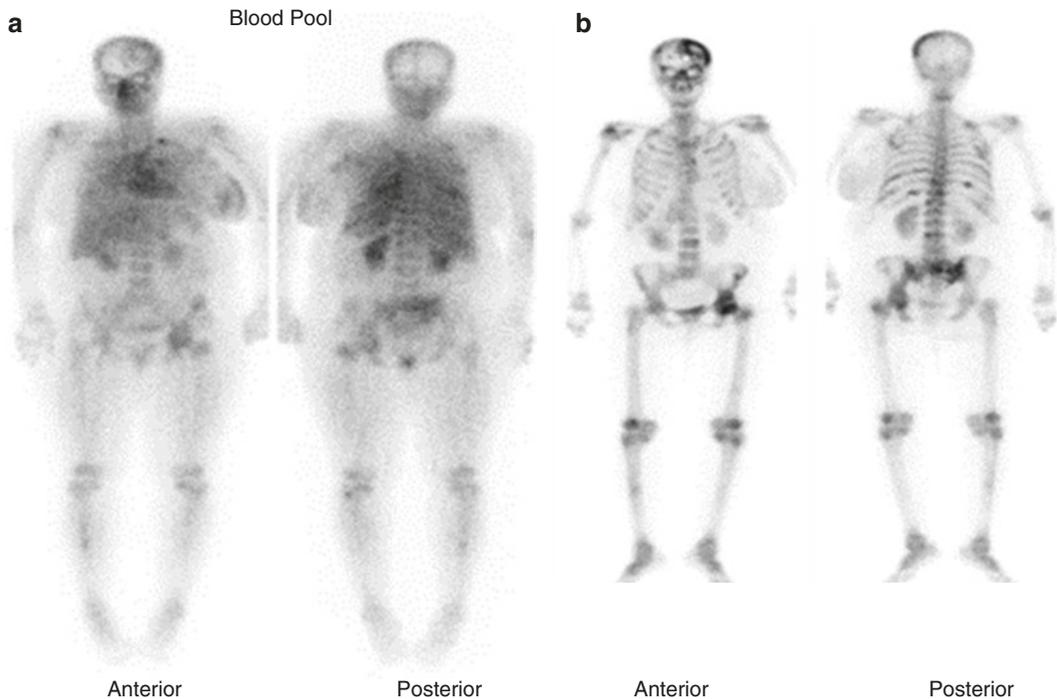

reported in other tumors such as lung cancer [162, 163].

## 6.4.2 Scintigraphic Evaluation of Metastases of Certain Tumors

### 6.4.2.1 Metastases of Breast Cancer

Breast cancer is a common source of skeletal metastases. Patients with advanced breast cancer frequently have bone metastases [164–166]. The average incidence of metastases is, however, low, with incidences of less than 5% in stages 1 and 2 disease (the range varies from 0% to 40%). In clinical stage 3, the incidence of bone metastases is 20–45%. Thus, routine scanning during this stage is necessary, which may not be the case during the early clinical stages [167–169]. This was confirmed in a study of 250 patients with breast cancer, which showed metastases in 3% of patients with pathological T1–2, N0–1 disease, compared to 30% of patients with pathological stage T3–4 or N2 disease [170]. Bone pain is an appropriate indication for scanning, either at diagnosis or follow-up, because the documentation of metastases allows instituting the appropriate definitive therapy or palliation. However, pain has not been found to be an extremely accurate marker for metastatic disease [171, 172]. Shutte found evidence of metastases in only 60% of patients with persistent bone pain [172].

Radiologically, the tumor usually produces purely osteolytic or mixed osteolytic/osteoblastic lesions (Table 6.5). Rarely, breast cancer gives rise to purely osteoblastic lesions. Standard radiographs are less sensitive and impracticable to screen for metastases compared to bone scintigraphy. This has been reconfirmed in a recent study of 100 patients presenting with metastatic breast

**Fig. 6.47** A Tc-99m MDP whole body static bone scan of a 51-year-old female with left breast cancer illustrating mixed osteoblastic and osteolytic metastases

cancer, 67 of whom had skeletal metastases [173]. Sixteen (24%) of these 67 patients had radiographically occult metastases. Using bone scintigraphy metastases are almost always hot in appearance although cold lesions may be seen (Fig. 6.47). The bone metastases develop most rapidly during the first 2 years, and it is appropriate to obtain frequent follow-up scans, perhaps every 6 months during this period [166, 168, 174]. However, in its published guidelines about breast cancer surveillance, the American Society of Clinical Oncology (ASCO) indicated that data are insufficient to recommend routine bone scans, chest radiographs, blood counts, tumor markers, liver ultrasonograms, or CT scans in early clinical stages of the disease [175]. Initial, and follow-up, bone scans provide prognostic information by showing the extent of metastatic disease and evaluating the effectiveness of hormonal and other standard breast cancer therapies [176].

Among patients with breast cancer who have metastatic bone disease, the response to therapy and ultimate prognosis are often closely linked. Metastatic breast cancer with the disease limited

to the bone has a better prognosis than when other distant sites are involved. This appears to be the case both in terms of the initial metastatic involvement and later disease recurrence [177–179]. Coleman et al. [180] recently reviewed the follow-up results for 367 patients with breast cancer who had a first occurrence of metastatic disease solely in the skeleton. The authors found that the 139 patients in whom the disease remained confined to the skeleton had a median survival 6 months longer than the patients who later developed metastases in other visceral locations. The extent of bone metastases at the initial relapse also appears to be of prognostic importance. This is because the subset of patients with breast cancer, with initial bone involvement at only one or two sites, has a survival advantage over patients with more extensive metastases at the time of initial positive scintigraphic findings [176].

In a report of 101 patients with bone metastases, who were studied with serial bone scans and radiography during treatment, patients whose scans showed disease regression had the longest

survival, followed by those with a stable scintigraphic and radiographic pattern; the shortest survival was for those with disease progression [181]. The importance of adequate follow-up and appreciation of scintigraphic flare was stressed by Vogel et al. [182] in reviewing data from a Scandinavian hormonal therapy trial, in which 29% of patients had evidence of flare on the scans performed 8 or 16 weeks after initiation of treatment. As the increased bone uptake seen in the flare phenomenon is usually associated with a response to therapy and healing, it is obviously important that the relevance of the finding be appreciated to avoid an effective therapy being discontinued.

Bone scintigraphy has been reported to be false negative for vertebral metastases among patients with estrogen-receptor negative or highly proliferative tumors. In these patients, MRI has proven more useful and is therefore recommended as the optimal radiological modality for postoperative follow-up [183].

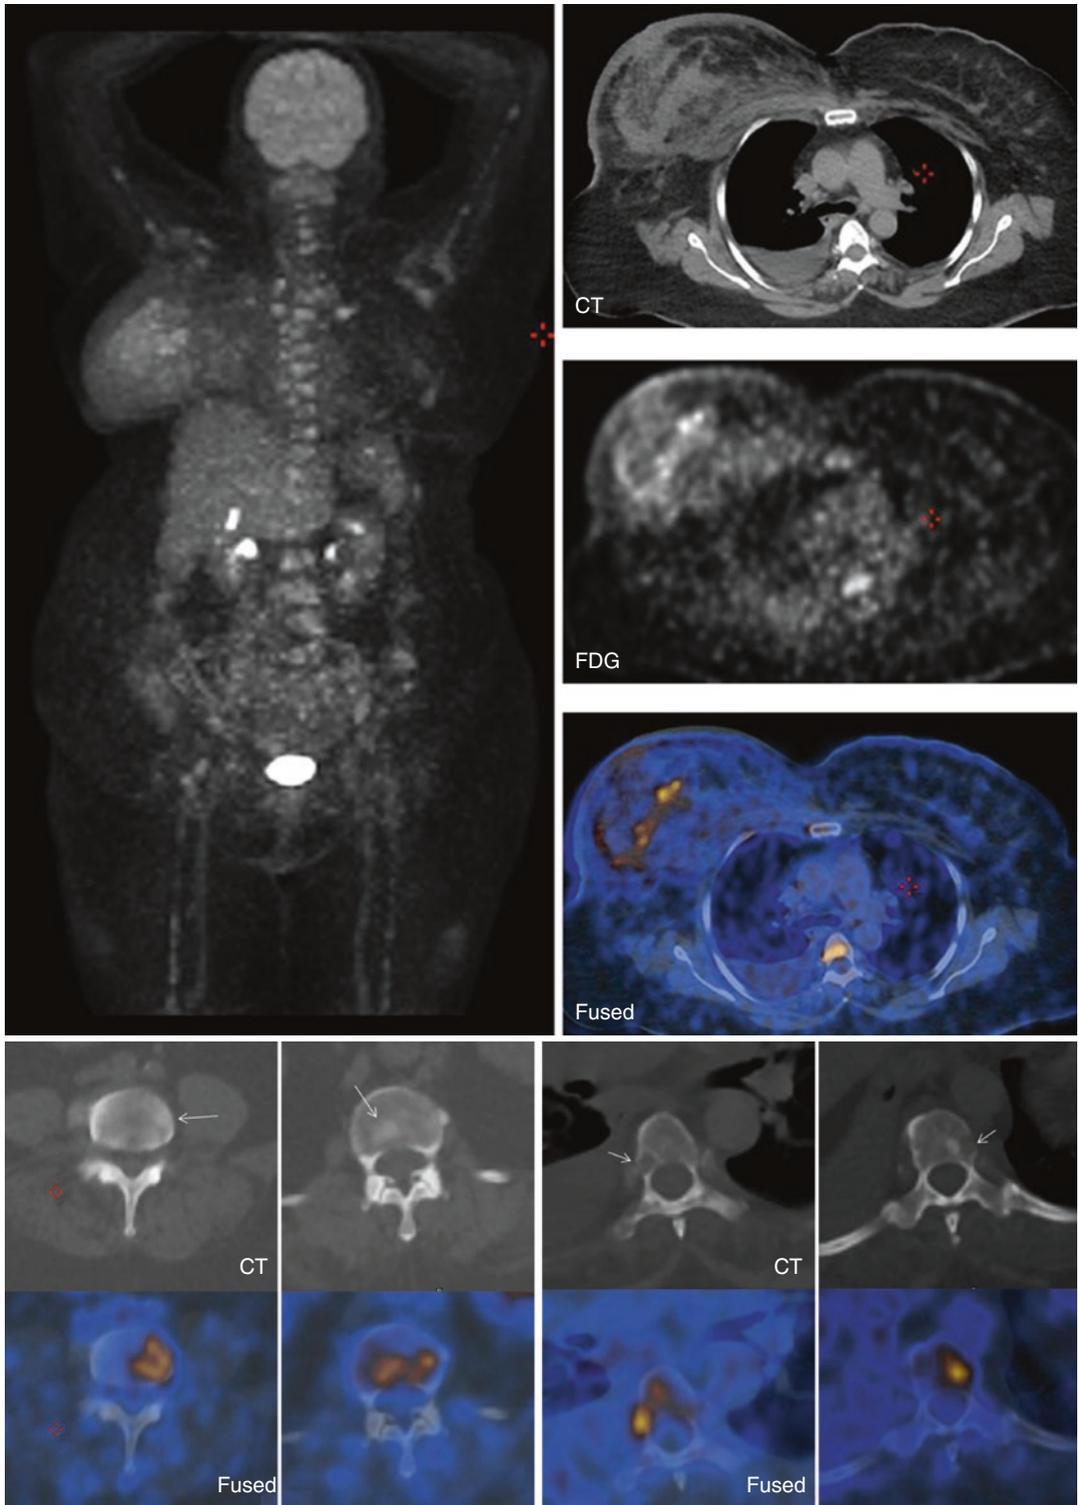

F-18 FDG PET is used to detect breast cancer metastases. It appears to be a powerful tool that has potential in detecting bony metastases with a high sensitivity and specificity study. Data indicate that it may have the ability to demonstrate the very early bone reactions when small bone marrow metastases are present. The ability to perform the early detection of bone metastases would have a significant effect on clinical management [184, 185]. Schirrmeyer studied 17 patients with 64 bone metastases detected on FDG PET [186]. Only 29 metastases were detected in 11 patients with bone scanning. In a study of 51 female patients with breast cancer who had PET together with a bone scan within one month, the sensitivity, specificity, and accuracy of the bone scan for the detection of bone metastases were 78%, 81%, and 80%, respectively. PET had a sensitivity, specificity, and accuracy of 78%, 98%, and 94%, respectively [185].

Another study of 34 patients with carcinoma of the breast compared PET to bone scanning. The area under the receiver-operating characteristic curve was 1.00 for PET and 0.82 for bone scanning ( $p < 0.05$ ). The PET scan changed the treatment recommendation for four of the patients, compared to what would have been recommended if only information from the bone

scanning was available [117]. A study comparing FDG PET to bone scan in 23 patients with breast cancer demonstrates the superiority of FDG to bone scan in detecting purely osteolytic metastases which are associated with poorer prognosis. FDG PET showed however fewer osteoblastic metastases than bone scan [186]. The use of bone scans and F-18 FDG PET however is not being recommended for routine breast cancer follow-up in an otherwise asymptomatic patient with no specific findings on clinical examination [187]. Figure 6.48 illustrates a case with inflammatory breast cancer with lytic and osteoblastic metastases on F-18 FDG PET/CT study.

#### 6.4.2.2 Metastases of Prostate Cancer

Metastatic bone disease is found to exist in 8–35% of patients with prostatic carcinoma at the time of diagnosis [158, 188]. Bone pain has low predictive value in detecting metastatic disease [189]. Bone scans have been shown to be vastly superior to radiographs, and more accurate than acid phosphatase determinations, in the detection of bony metastasis [188, 190]. Jacobson reviewed the bone scan patterns of benign and malignant uptake in 432 patients with newly diagnosed prostate carcinoma in relation to prostate-specific antigen (PSA) levels determined within 4 months of scintigraphy [191]. The metastatic disease prevalence increased from 1% for PSA levels of  $<20$  ng/ml to 58% for PSA levels of  $<100$  ng/ml. The majority (69%) of the patients with limited skeletal metastases had PSA levels of  $<100$  ng/ml, while almost all patients (89%) with extensive skeletal involvement had PSA levels of  $<100$  ng/ml. Among those with limited metastatic disease, most (13/16; 81%) had at least one lesion in the pelvis or sacrum; the next most common sites were in the thoracic and lumbar spine (38%). A case of extensive bone metastases and normal PSA level has also been reported recently [192]. Other studies have shown different results. In the series of Wymenga et al. [193], the results of bone scans were related retrospectively to levels of serum PSA and alkaline phosphatase (ALP) in 363 patients with newly diagnosed prostate cancer. One hundred eleven patients had a positive bone scan. Bone scan was positive in 19 of 144 (13%) patients with a PSA level of  $<20$  ng/ml. On

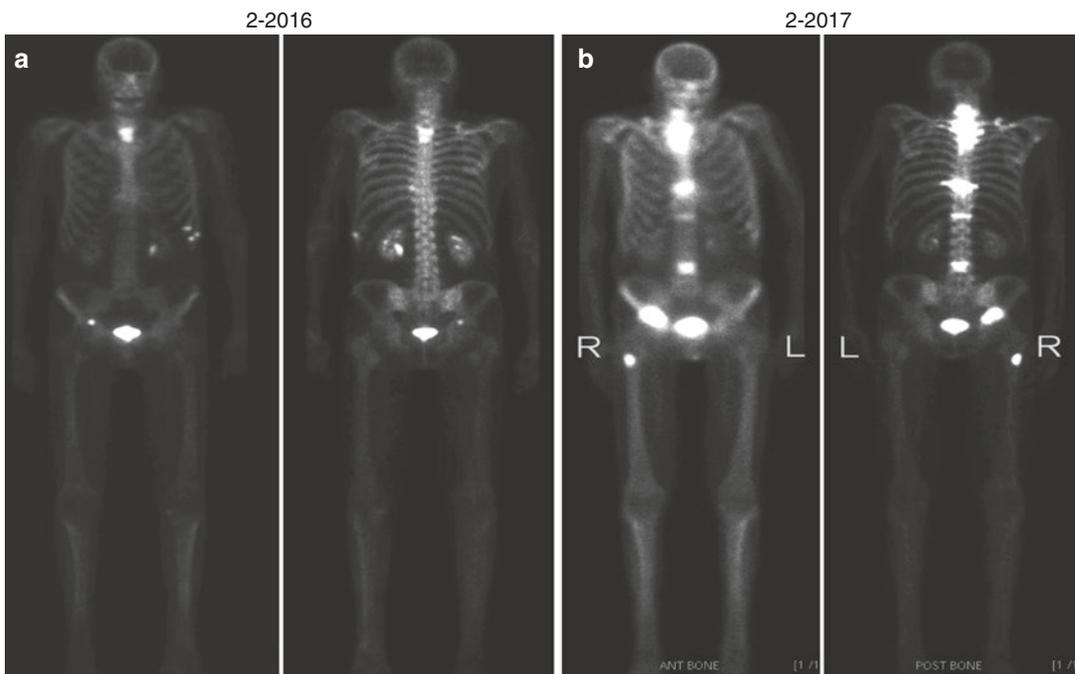

**Fig. 6.48** Representative images of F-18 FDG PET/CT study of a patient with inflammatory carcinoma of the right breast with multiple metastases. The CT component

helped clarify the nature of the lesions (*arrows*) since some are osteoblastic while others are osteolytic

the other hand, the bone scan was positive in 51% of patients with a PSA level of <20 ng/ml. A threshold level of 100 U/l for ALP gave a better accuracy. Therefore, elevated ALP values correlated better with an abnormal bone scan than did PSA levels; ALP levels of <90 U/l indicated a 60% chance for the presence of bone metastases. The authors recommended newly diagnosed and untreated prostate cancer patients to undergo bone scintigraphy if there is bone pain or if the ALP levels are <90 U/l. Contrary to other recent reports that discourage the routine use of a bone scan when the serum PSA level is <20 ng/ml, this study indicated a greater chance of a positive bone scan in patients with low PSA levels [193]. A total of 446 patients with newly diagnosed prostate cancer were also reviewed by Rydh et al. [194]. Among 214 patients with PSA levels <20 ng/ml, 9 showed positive bone scans. The

incidence of bone metastases was particularly low among patients with PSA levels <20 ng/ml who have small and well-differentiated tumors [194].

With the modern PSA-based diagnostic strategies, many patients were diagnosed with while asymptomatic and metastases were found in only 10% of patients which indicates that there is no need for every newly diagnosed patients to have bone scan performed. PSA level, Gleason's score, and PSA doubling time (PSADT) determine the need for bone scan and/or follow-up scan [188]. High PSA, high Gleason's score, and a short PSADT are important to decide which patient needs bone investigations including bone scan (Fig. 6.49) to search for bone metastases. Staging baseline bone scans in PCa patients might be considered only for patients with a biopsy Gleason score >7 or with a PSA >10 ng/ml and palpable disease (cT2/T3) prior to treatment [195].

**Fig. 6.49 a–b** Initial whole-body bone scan (a) of a 71-year-old male with prostate cancer. PSA was 107.4 ng/ml at that time. The study shows foci of increased uptake in the upper thoracic spine, left ninth costovertebral junction, and right iliac bone likely due to metastases. Additionally foci of increased uptake in the left lower ribs are noted likely traumatic in nature. On follow-up the PSA level rose to 555 ng/ml. Follow-up bone scan (b) was

obtained and showed progression of the skeletal metastases with appearance of new lesions in the lower cervical spine, T-12, L-4, and proximal right femur and overall worsening of the pre-existing lesions in the spine and right iliac bone with increased size and radiotracer uptake. Near normalization of the left lower ribs is noted probably indicating healed fractures

Follow-up bone scintigraphy has been shown to be quite valuable in assessing the response to therapy. Fitzpatrick reported that the bone scan demonstrates changes in response to therapy before either acid or alkaline phosphatase, prostate size, or symptomatology demonstrated alterations [196].

Prognostic information can be obtained from the bone scan since patients with a positive scan at the time of diagnosis generally do not survive as long as those with negative scans [131].

PET has been investigated in the detection of prostatic cancer bone metastases. F-18 sodium fluoride has several advantages over conventional bone scan and is more sensitive in detecting bone metastases [197]. Jadvar et al. studied 37 patients with biochemical (PSA) relapse of prostate cancer after definitive therapy for localized prostate tumor (26 radical prostatectomy, 11 external beam radiation therapy), and negative conventional imaging were studied by F-18 FDG and F-18 NaF PET/CT on 2 separate days within the same week [198]. F-18 NaF PET/CT was useful in detecting occult osseous metastases, whereas the yield of F-18 FDG PET/CT was relatively limited. Accordingly, F-18 NaF PET/CT positivity tends to associate with increasing PSA level in prostatectomized men. C-11-acetate, a newer tracer for the detection of prostate cancer with PET, was evaluated in 22 patients with prostate cancer who underwent PET imaging after intravenous administration of 20 mCi (740 MBq) of C-11 acetate [199]. Eighteen of the 22 patients were also studied with F-18 FDG PET. Standardized uptake values for each tumor were investigated for tracer activity 10–20 min after C-11-acetate administration and 40–60 min after F-18 FDG administration. Adenocarcinoma of the prostate showed a variable uptake of C-11 acetate with SUVs ranging from 3.27 to 9.87. In contrast, SUVs for F-18 FDG ranged from 1.97 to 6.34. Visually, C-11-acetate accumulation in the primary prostate tumors was positive in all patients, whereas F-18 FDG accumulation was positive in only 15 of 18 patients. Bone metastases in two patients were C-11-acetate avid [199]. In another study, F-18 FDG and L-methyl-C-11-methionine (C-11 methionine) PET were compared in patients with metastatic prostate cancer [200]. The C-11 methi-

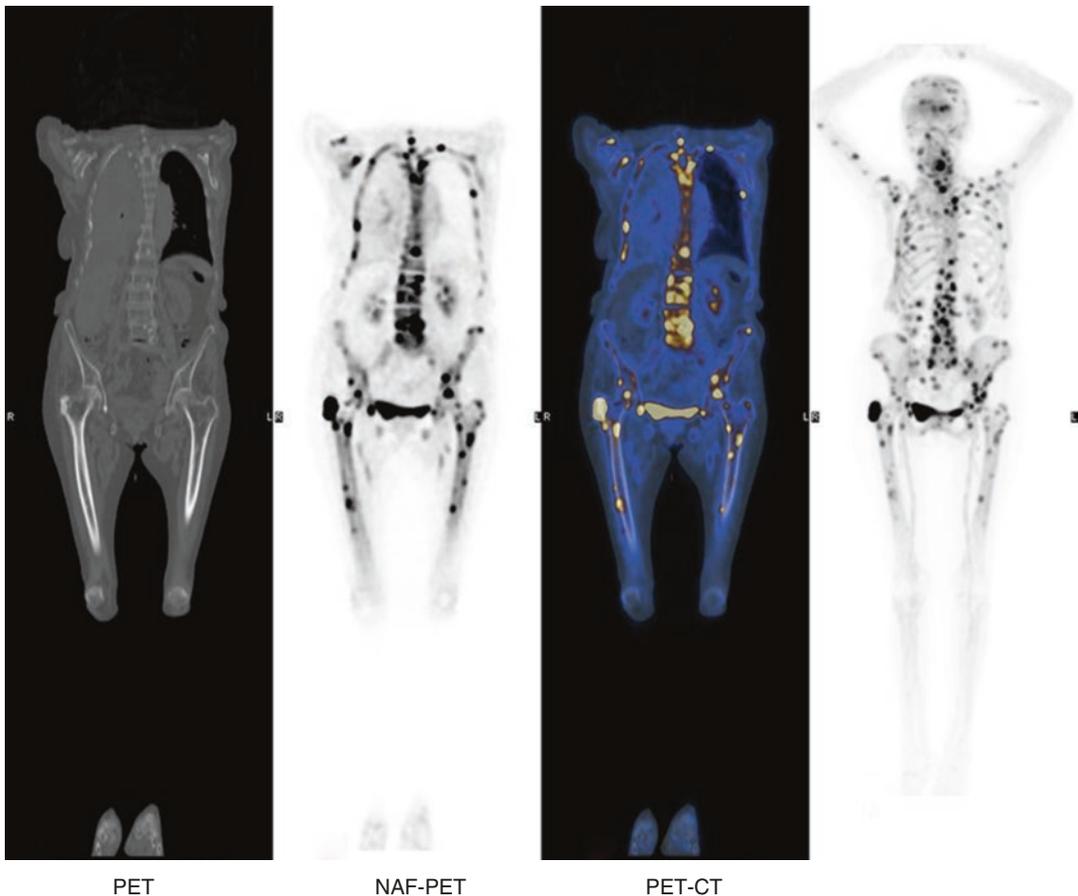

onine PET identified significantly more lesions than F-18 FDG. The sensitivities of F-18 FDG PET and C-11 methionine PET were 48% and 72%, respectively. A more recent study provided additional evidence for superior detection of bone metastases by both F-18 sodium fluoride PET and F-18 choline or C-11 choline PET with or without CT compared with conventional bone scintigraphy [197]. It was proposed that F-18 sodium fluoride PET/CT and C-11 choline or F-18 choline PET/CT be alternatives for conventional bone scintigraphy for the detection of bone metastases in patients with prostate cancer. MRI in a meta-analysis study was found however to be more sensitive than choline PET/CT in detecting metastases from prostate cancer. However, choline PET/CT showed the highest specificity compared to MRI as well as bone scan [201]. Prostate-specific membrane antigen (PSMA) is a transmembrane protein that has considerable overexpression on most prostatic cancer cells. Recently, Ga-68 PSMA PET/CT has gained high attention for accurate staging of primary prostate cancer and restaging after biochemical recurrence. Recent studies showed promising results with Ga-68 PSMA ligand in detecting metastatic disease in both soft tissues and bone. Some authors suggested that Ga-68 PSMA PET may be superior to F-18 NaF PET for the evaluation of therapy response to Ra-223 therapy in bone metastases. In a recent study, Ga-68 PSMA-PET/CT resulted in a major change in management in 53% of patients with biochemical recurrence [202].

#### 6.4.2.3 Metastases of Lung Cancer

Lung cancer metastasizes to the bone via three possible routes: lymphatic spread to the mediastinal nodes with direct extension to the bone, lymphatic spread to para-aortic nodes with subsequent direct extension to bone and invasion of pulmonary veins, and then by transport of tumor through the arterial circulation to any part of the skeleton including bones of appendicular skeleton. The lesions are predominantly osteolytic, or mixed, although osteoblastic lesions can occur in the minority of cases, particularly with small cell and adenocarcinoma [24]. The detection of bone metastases is important in the management

of patients with lung cancer because bone metastasis has a major impact on the choice of treatment modality and the prognosis [25]. There are controversies regarding the use of routine preoperative bone scanning in patients with lung cancer although knowledge of the metastases could save the patient from a major surgery and significant cost. Bone scanning is generally sensitive in detecting metastases of lung cancer although it has been shown to be false negative, not infrequently in metastases of the spine. A study of 110 patients with lung cancer compared bone scanning to PET for the detection of bone metastases [203]. Using clinical and radiological correlation, or clinical evolution as the gold standard, the comparison of PET to bone scan demonstrated the following: a sensitivity 90%

for each, a specificity 98% vs. 61%, positive predictive value 90% vs. 35%, and negative predictive value 98% vs. 96% [203]. In one study, 54 patients with small-cell lung cancer, or locally advanced non-small-cell lung cancer, were prospectively examined with planar bone scan, SPECT of the vertebral column, and F-18 FDG PET [113]. Among 12 patients with vertebral metastases, planar bone scintigraphy was abnormal in six, while SPECT detected metastases in 11 and F-18 FDG PET detected all. Accordingly, FGD-PET was the most accurate for screening for bone metastases (Fig. 6.50), and SPECT imaging improves the accuracy of vertebral metastases [113]. Park et al. studied the effects of abnormal bone scan findings on the prognosis of patients with lung cancer [204].

**Fig. 6.50** F-18 sodium fluoride PET/CT study of a 58-year-old male patient with lung cancer. The study shows multiple bony metastases clearly seen in the spine,

sacrum, sternum, left femoral neck, and acetabulum. Note the excellent resolution of the technique

**Fig. 6.51** Renal cell carcinoma metastasis. There is foci-decreased uptake (*arrows*) commonly seen with this neoplasm

The overall survival of patients with abnormal bone uptake was not significantly different from those without abnormal uptake. However, the patients with more than two abnormal bone uptakes had a significantly shorter survival than those with no abnormal uptake [204]. A more recent study using meta-analysis of the literature between 1995 and 2010 found the pooled patient-based sensitivity for metastases of F-18 FDG or PET/CT is 93% and specificity is 95% compared to 87% and 82%, respectively, for bone scan [205]. The pooled lesion-based sensitivity and specificity were 93% and 91% for FDG and 92% and 57% for bone scan. This study again illustrates the superior specificity for FDG PET/CT to bone scan [205]. Another study showed F-18 FDG PET/CT superior to bone scan in the detection of osteolytic metastases in NSCLC [116]. FDG PET/CT detected

more metastatic lesions than F-18 NaF PET in the staging of NSCLC [116].

#### 6.4.2.4 Metastases of Renal Cell Carcinoma

Renal cell carcinoma often presents with distant metastases with the most common sites being the lung, liver, and bone [206]. Radiologically, the metastatic lesions are predominantly osteolytic and in some cases expansile. They are produced through (1) lymphatic channels to para-aortic, hilar, paratracheal, and/or mediastinal nodes with subsequent invasion of bone and (2) invasion of renal veins transporting tumor cells to the inferior vena cava, right atrium, and then pulmonary vessels to be disseminated to bones [167, 201, 207].

As with many other tumors, bone scanning is currently considered a sensitive tool for detecting the bone metastases of primary renal cell carci-

noma. Scintigraphically, the metastases are seen predominantly as foci of increased uptake, although cold lesions are common (Fig. 6.51) and found in approximately 8% of metastatic lesions of this tumor. The utility of performing whole-body bone scintigraphy as part of a routine staging workup for patients with renal cell carcinoma is currently being debated. In patients with renal cell carcinoma, several groups have proposed that bone scanning should be limited to those with bone pain or elevated ALP levels. However, the proportion of patients with the various disease stages in whom the diagnosis may be missed based on such indications is not currently clear. In addition, ALP as an indicator for the use of bone scanning is controversial, and the profile of renal cell carcinoma has changed in recent years because of early detection. The incidence of stage T1a disease with the tumor measuring 4 cm or less in diameter is increasing due to earlier diagnosis. Accordingly, the incidence of bone metastases is also increasingly seen [208–210] with longer follow-up periods. In general, the incidence of bone metastases in the early stages of the tumor is low, and bone scan was even suggested to be omitted from markup of patients with this tumor [209]. A number of groups have recommended preoperative bone scanning in renal cell carcinoma cases only when bone pain is present [211–213]; however, pain is not a reliable predictor of bone metastases. Others have reported that ALP is a better predictor of outcome than bone scans for renal cell carcinoma [213, 214]. In a study by Koga et al. [215], bone metastases were detected in 34 out of 205 patients (17%) at the time of diagnosis. Bone scans had 94% sensitivity and 86% specificity. Of the 124 patients with clinically localized, stages T1–2 N0 M0 disease, bone metastases were found in six patients (5%), whereas 28 of 81 (35%) with locally advanced or metastatic disease had bone metastasis, including 12 (35%) who complained of bone pain. Accordingly, if a bone scan is omitted in patients who are free of bone pain, more than a half of those with bone metastasis could be missed [215].

Since the early detection of bone metastasis using bone scanning and surgical resection may

improve survival, and also since bone scanning is helpful for localizing the site of biopsy, or surgical removal in such cases, it is recommended that a preoperative bone scan is obtained. However, there is still no consensus on this issue, and a more recent recommendation limits the use of bone scintigraphy to cases with elevated bone markers or those with bone pain and same criteria for follow-up bone scans [216]. FDG PET appears to have a potential role in accurately detecting the renal cell carcinoma metastases. In a recent study, Tc-99m MDP bone and FDG PET were compared in 18 patients with renal cell carcinoma [217]. Among 52 lesions, 40 were proven to be metastases and 12 were proven to be benign. FDG PET accurately diagnosed the 40 malignant lesions, while bone scanning accurately diagnosed only 31 of metastatic lesions.

#### 6.4.2.5 Metastases of Thyroid Cancer

Bone scintigraphy is considered to lack sensitivity in detecting bone metastases from thyroid cancer due to the nature of such metastases as having no, or only a slight, osteosclerotic bone reaction. The anatomical distribution of bone metastases was reported by Schirmer [218] as follows: spine, 42%; skull, 2%; thorax, 16%; femur, 9%; pelvis, 26%; and humerus and clavicle, 5%. The sensitivity of bone scanning was 64–85% and the specificity was 95–81%. The combination of bone scintigraphy and whole-body iodine 131 scan was 100% sensitive in detecting metastatic bone disease [218]. In addition to I-131 and bone scintigraphy, Tl-201, Tc-99m MIBI, and FDG PET have a complementary role in identifying bone metastases of this tumor, particularly in those patients with negative bone and I-131 scans and elevated thyroglobulin levels since they can detect lesions not otherwise detected by a single modality [39, 219]. FDG PET and thallium-201 were compared in a study of 32 patients with well-differentiated thyroid cancer in combination with I-131 with results in detecting metastases that are 94% concordant. Thus, a combination of I-131 and FDG PET or Tl-201 was recommended as the method of choice for detecting metastatic lesions after total thyroidectomy [220]. F-18 sodium fluoride was compared to planar and SPECT bone scans and F-18 FDG in 11

patients and showed significantly higher sensitivity and accuracy for F-18 sodium fluoride compared to planar bone scan and FDG PET/CT [221]. However, when SPECT was added, sensitivity and accuracy of bone scan were improved to match to those of F-18 sodium fluoride PET/CT of 100% for patients and near those of F-18 sodium fluoride based on metastatic lesions. However, the number of cases was rather small [221].

#### 6.4.2.6 Metastases of Other Tumors

##### Gynecological Tumors

Bone metastasis in cervical cancer is generally rare except in patients with a clinical suspicion of the metastatic disease. In a study of 38 patients with cervical cancer and suspicion of metastasis, 12 were confirmed as having metastasis, and all were also detected by bone scanning (100% sensitivity) [222]. Currently, bone scanning is not routinely used preoperatively, but it is the investigation of choice for screening patients with symptoms suggestive of metastasis in all stage of the disease. Bone scanning also offers an addi-

tional advantage of reviewing the kidney size to look for ureteric involvement and subsequent hydronephrosis.

##### Lymphomas

The bone is affected in up to 20% of patients with Hodgkin's lymphoma and in up to 25% in those with non-Hodgkin's lymphoma. Furthermore, 3–5% of non-Hodgkin's lymphomas are primary tumors of bone (Fig. 6.52) [223–232]. Routine bone scintigraphy, however, is of limited value in the clinical assessment of untreated patients with Hodgkin's disease [227]. On the other hand, scintigraphy has an important role in following up bone lymphomas and predicting the outcome after therapy. A study reconfirmed the value of Ga-67 in evaluating the response to therapy in 44 patients with lymphoma and bone involvement and found it superior to CT, since 61% of successfully treated patients showed negative Ga-67 scans compared to 21% for negative CT findings [233].

Bone marrow involvement in non-Hodgkin's lymphoma, and in Hodgkin's disease, is of great therapeutic and prognostic significance. FDG PET scanning is valuable in this regard (Fig. 6.53). In a series of 50 patients, FDG PET was compared to bone marrow biopsy [234]. The latter is the gold standard for bone marrow involvement. The results for PET were sensitivity of 81%, specificity of 76%, positive predictive value of 62%, and negative predictive value of 90% [234].

##### Gastrointestinal Tumors

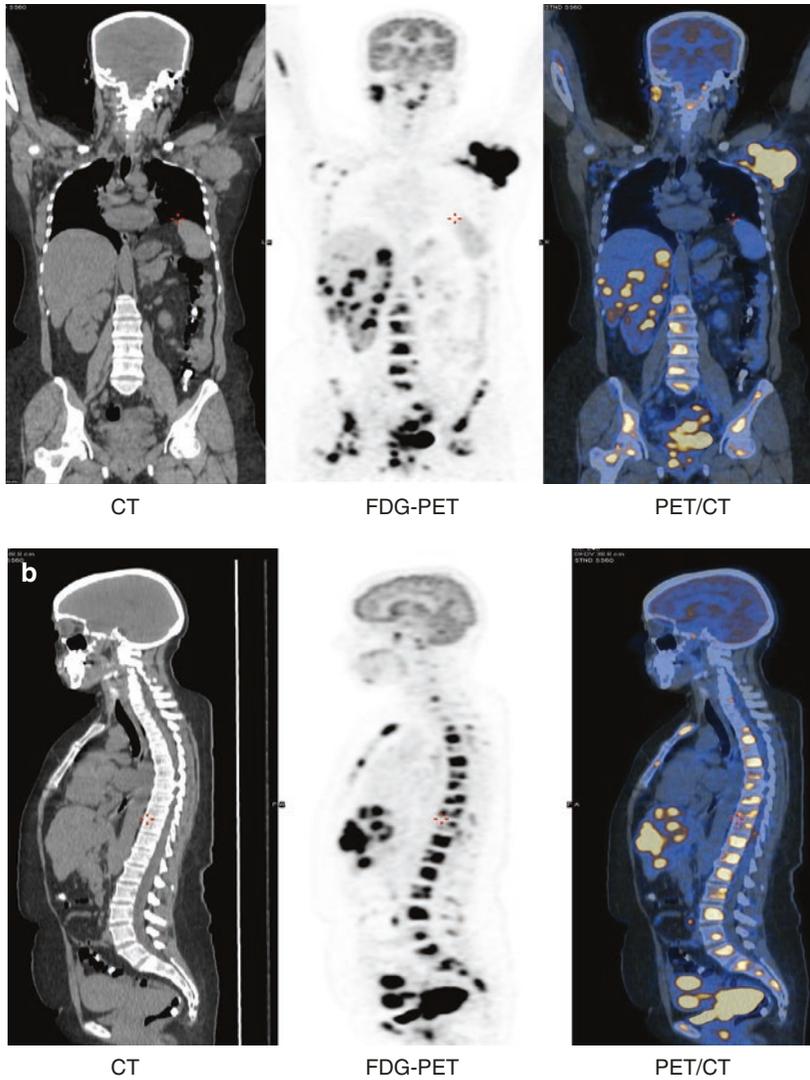

Gastrointestinal malignancies do not commonly metastasize to the bone although the frequency has increased in recent years due to the longer survival of patients. Gastric carcinoma is relatively common in the Asian population, and the incidence of bone metastases could be as high as 45% among patients with stage III disease [235] (Fig. 6.54). In such a group of patients with high pretest probability of metastases, bone scanning may be considered routinely preoperatively.

##### Nasopharyngeal Carcinoma

The routine use of bone scanning in detecting metastases is controversial although as many

**Fig. 6.52** Standard radiograph illustrating a primary bone lymphoma which appears as a destructive lesion in the neck of the left humerus

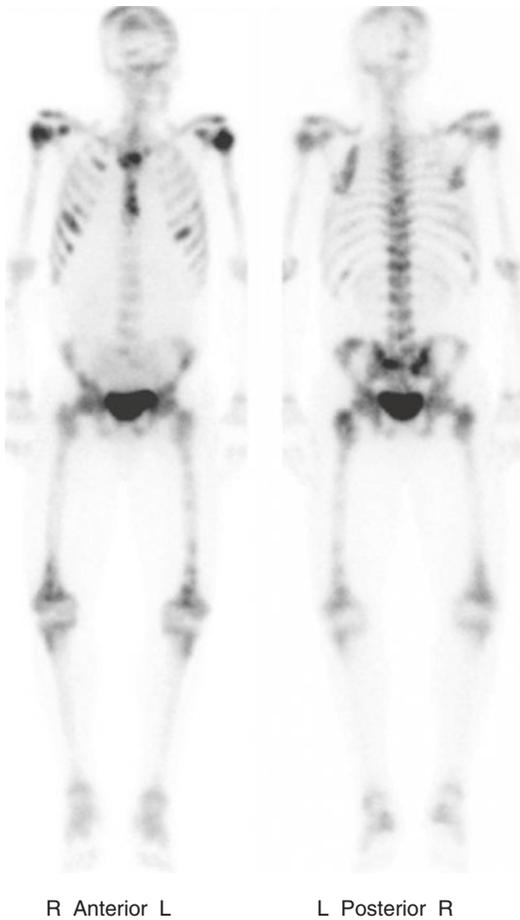

**Fig. 6.53** FDG PET/CT study of a 60-year-old male patient with non-Hodgkin's lymphoma with involvement of his bony skeleton with clearly seen metastases of the spine and pelvis as seen on coronal (a) and sagittal (b) representative cuts

as 23% of newly diagnosed cases showed bone metastases [236]. SPECT bone scanning was found in a small series of patients to be more sensitive than CT scanning in assessing the skull base involvement by nasopharyngeal carcinoma [228].

### Neuroblastoma

Howman-Giles found 29 out of 63 patients (46%) with neuroblastoma with bone metastases [162] including nine symmetrical metastases. Bone scanning has been used to assess the metastatic

disease of bone. I-123 MIBG has the advantage of showing both skeletal and extraskelatal tumor sites and has been suggested to replace bone scanning in detecting bony involvement by the tumor [229]. MIBG was found overall to be less sensitive than bone scanning in detecting bone metastases by some investigators [230]; however, in most investigators' experience, the extent of metastatic bone and bone marrow lesions is defined most accurately by MIBG [231, 232, 237]. Hadj-Djiiiani et al. reported 30 sites of metastases in eight patients with neuroblastoma

**Fig. 6.54** A whole-body bone scan of a 20-year-old male with gastric carcinoma metastasizing to bone

imaged by both I-123 MIBG and bone scans; 12 were detected only by MIBG, while 7 were only seen by bone scan [238]. Overall, however, MIBG identified more lesions than bone scanning. Interestingly the highest incidence of false negatives on both modalities was histologically proven ganglioneuroblastoma [238]. Currently both modalities are commonly used routinely as they provide combined complementary information. Bone scanning provides relatively better resolution and accordingly better localization of the lesions, while MIBG may detect different lesions in bones as well as extra-osseous lesions.

### Kaposi's Sarcoma

Four forms of Kaposi's sarcoma are known. The chronic, or classic, form primarily affects men older than 50 years and is associated with a second malignancy, usually of the lymphoreticular or hematopoietic system. The second form, the lymphadenopathic form, predominantly affects young African children. The third form is the transplantation associated. This affects less than 0.5% of patients who receive renal transplants, but has also been reported after other organ transplants and in association with immunosuppressive therapy. The fourth form of Kaposi's sarcoma is the HIV-related form, which affects young patients and may manifest clinically in any location.

Bone involvement has been reported in all four forms and develops during the more advanced stages of the disease. A patient who presents initially with Kaposi's sarcoma of the bone invariably has extraskelatal tumors as well. Bone scanning, Tl-201, and Ga-67 are all used for the diagnosis, and combined Ga-67 and Tl-201 can differentiate the tumor from others. The most common scintigraphic pattern is thallium-positive and gallium-negative images; however, this is not consistent, particularly in the presence of a concomitant infection [239–241].

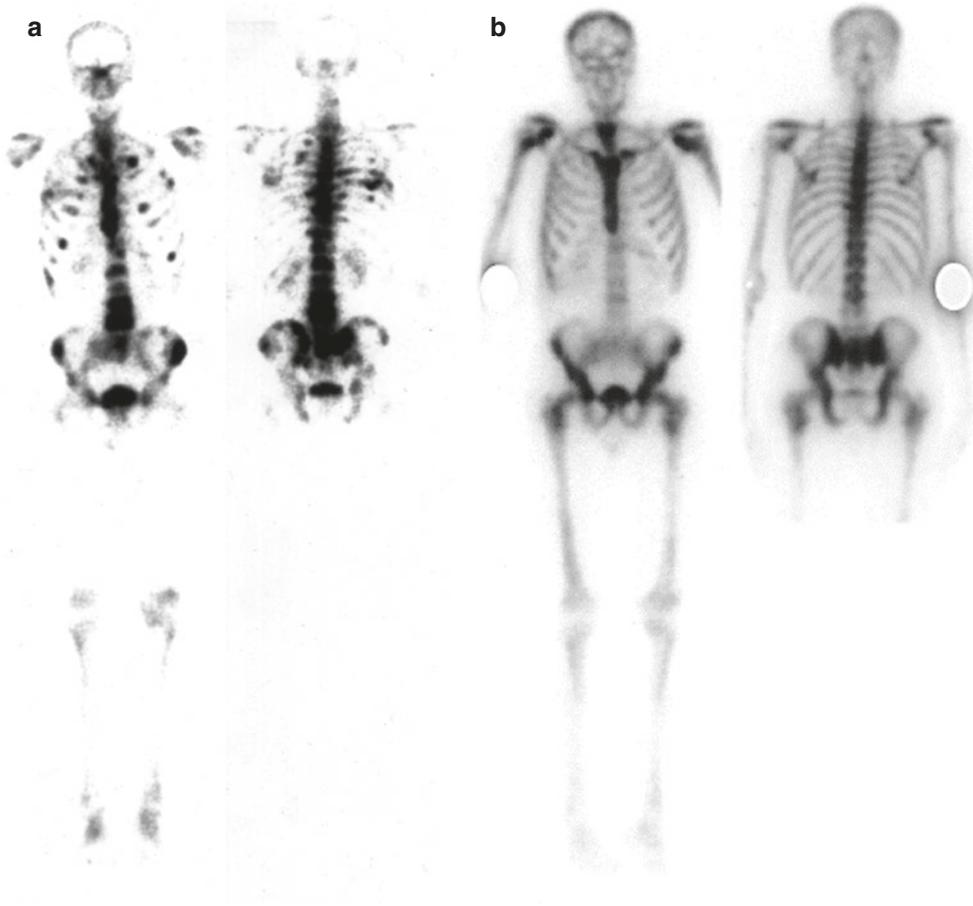

### Carcinoid Tumor

A recent retrospective study evaluated a group of patients with carcinoid tumors and bone metastases [242]. All bone metastases occurred in 55 patients with midgut carcinoids. Plain radiography did not contribute to the diagnosis of bone metastases since it showed a sensitivity of 44%, while MRI was the most sensitive (100%). Bone scintigraphy showed a sensitivity of 90% and octreotide scintigraphy 60%. In nine patients, both octreotide and bone scintigraphy were performed and of 45 bone lesions, 22 (49%) were visualized by both modalities, 13 (29%) were visualized with octreotide scintigraphy but not with bone scintigraphy, and 10 (22%) were visualized with bone scintigraphy but not with octreotide scintigraphy [242].

## 6.5 Follow-Up of Malignant Bone Disease

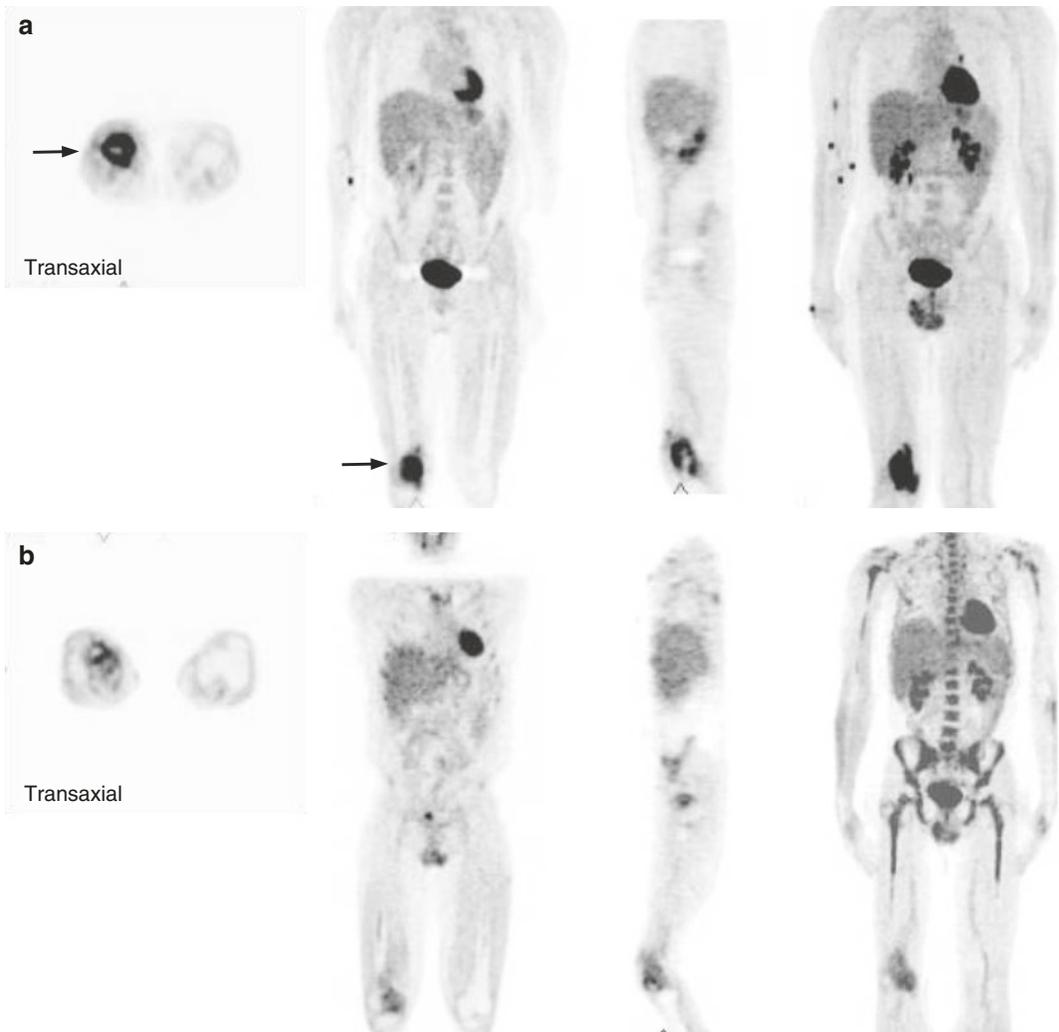

Scintigraphy has a great value in assessing the response of metastatic bone disease to therapy [243]. Several radiotracers including F-18 FDG are used for this purpose; bone scintigraphy is still a good modality for the follow-up of metastatic bone disease of many tumors, and depending on the tumor, available resources, and cost, PET/CT using F-18 FDG, F-18 NaF, F-18 choline, C-11 choline, and others can provide better

assessment. A favorable response is indicated when a decreasing number of scintigraphically observed lesions or decreasing activity is seen (Fig. 6.55, Fig. 6.56) [244]. It may also show a decreasing activity in the primary extra-osseous tumor if it shows tracer uptake initially such as neuroblastoma. Patients with stable scans have survived up to twice as long as those with scintigraphic evidence of progressive bone disease [119]. Citrin et al. [194] found that 7 months were required for a bone scan to show a favorable response but only 4 months to show a progres-

**Fig. 6.55** (a) Tc-99m MDP bone scan of a patient with prostatic carcinoma illustrating widespread bone metastases. (b) Follow-up scan illustrating improvement with

decreasing activity and lesions in response to hormonal therapy for 1 year

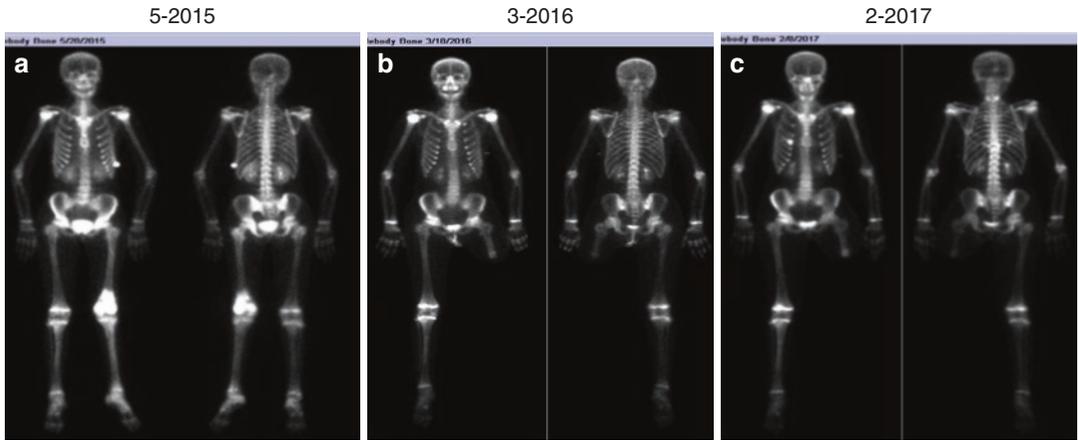

**Fig. 6.56** a, b F-18 FDG PET study of a patient with osteogenic sarcoma of the distal right femur showing intense increased uptake in initial study (a) (arrow)

which on follow up study (b) after chemotherapy before surgery shows decreasing uptake illustrating good response

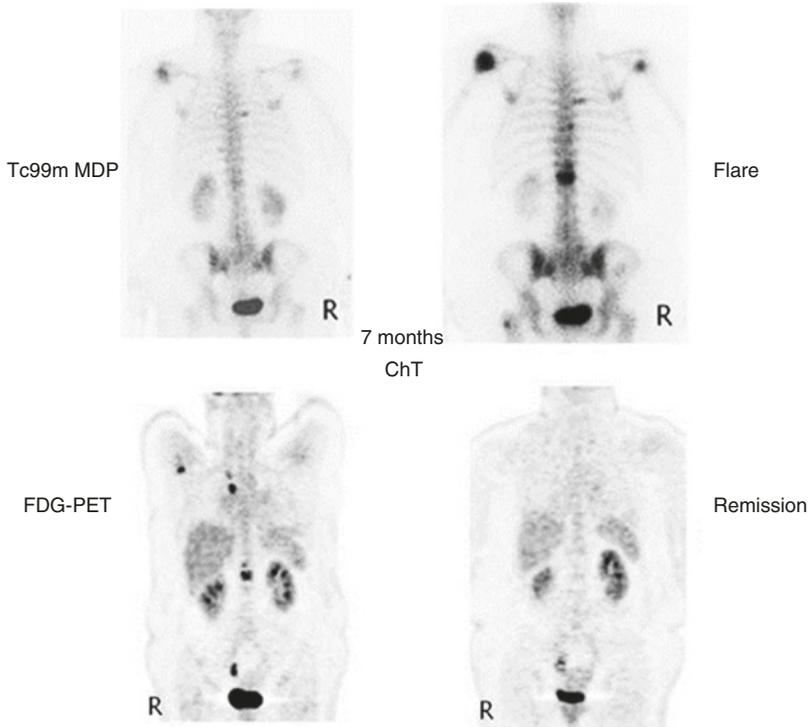

sion of disease [244]. He therefore advocates a follow-up scan 3–6 months after instituting therapy. Progression is confirmed if the number of lesions increases or the activity of the known lesions dramatically increases (Fig. 6.57). Increasing activity, however, must be applied with great caution because of the potential pitfall of the flare effect, which causes transient increases of activity of the pre-existing lesions, following the institution of effective therapy. This is presumably due to reactive bone forma-

tion due to the healing accompanying the therapy [245]. PET can readily solve the problem of flare, when available, by showing a decreasing activity in the post-therapy scan without waiting 3 months, or sometimes longer, to obtain the same result from bone scintigraphy delaying possible change in treatment strategies (Figs. 6.58 and 6.59). Tl-201, Tc-99m MIBI, and particularly PET imaging are also useful in assessing the response to therapy by primary bone tumors (Fig. 6.57).

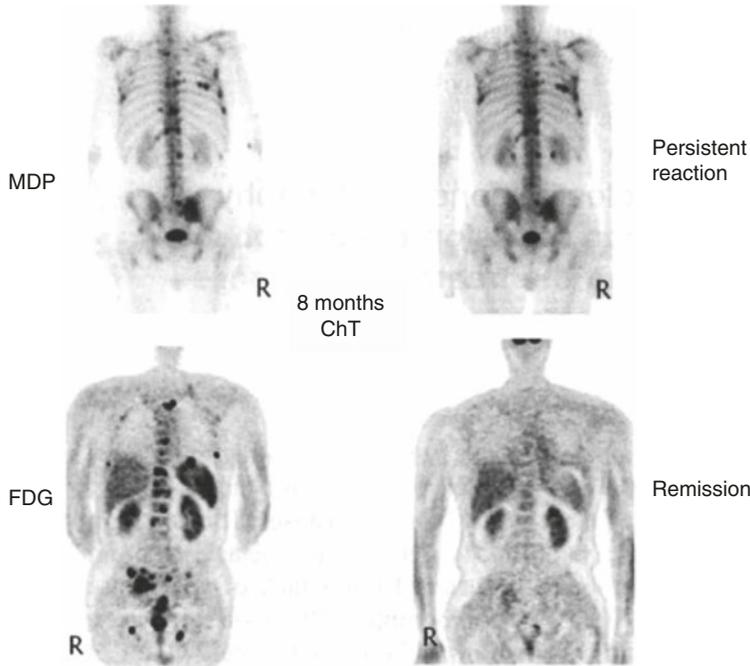

**Fig. 6.57** a–c Initial whole-body bone scan (a) of a 14-year-old female with osteosarcoma of the distal left femur. Typical pattern of intense uptake is noted in the primary tumor (arrow) and in a lesion in the left tenth rib (arrow head). Patient was treated with chemotherapy fol-

lowed by above-knee amputation. Follow-up bone scan (b) showed no abnormalities. The left tenth rib lesion showed resolution. Another follow-up scan (c) showed new lesions in the right fifth rib anteriorly and in the mid-to lower thoracic spine indicating progression

**Fig. 6.58** A 49-year-old woman with breast cancer (N1M0) who had undergone mastectomy and axillary lymph node dissection on the right side. The patient had no evidence of disease for 3 years. She presented with a CA 15.3 tumor marker. BS showed uptake in the left humeral head suspicious of necrosis on the basis of long-term corticotherapy and nonspecific uptake in the spine (top left). PET showed intense FDG uptake in both the humeral head and the seventh right costovertebral junc-

tion and first lumbar vertebra (bottom left). The patient was treated with chemotherapy. Seven months after treatment, BS showed persistent uptake in the left humeral head with increased activity in the right humeral head, seventh right costovertebral junction, and first lumbar vertebra (top right). PET scan showed resolution of the previous lesions (bottom right). On the basis of the PET findings, the results on BS should be interpreted as representing a flare phenomenon (from [246] with permission)

**Fig. 6.59** A 55-year-old man recently diagnosed with non-small right lung cell cancer. BS (*top left*) and PET (*bottom left*) in the staging showed multiple bone metastases, with a different distribution, probably due to the lytic/blastic behavior. The patient was treated with chemotherapy. Eight months after treatment, BS remained similar

(*top right*). PET scan showed resolution of previous lesions (*bottom right*). On the basis of the PET findings, BS results should be interpreted as representing a persistent bone reaction, not active metastatic disease (figure printed with permission from [246])

Although scintigraphy has a limited role in the diagnosis of rheumatic diseases, it can provide important complementary information, and familiarity with the scintigraphic patterns of different disease conditions of the joints and periarticular structures is important. Scintigraphy, however, could be more useful in evaluating the activity of the disease processes. The scintigraphic pattern of different arthropathies varies depending on the type and phase of the condition. Some conditions affect mainly small or large joints, while others affect both in either symmetrical or asymmetrical fashion. Primary osteoarthritis and rheumatoid arthritis show a classically symmetrical uptake. When large joints as the shoulders, hips, or knees are only involved, it indicates certain conditions such as osteoarthritis, ankylosing spondylitis, calcium pyrophosphate dihydrate (CPPD) crystal deposition disease, or joint infection. In addition to Tc-99m diphosphonates, other radionuclides are used in the diagnosis and follow-up of these conditions. These include  $^{111}\text{In}$ - and  $^{99\text{m}}\text{Tc}$ -labeled poly- and monoclonal antibodies such as Tc-99m-labeled human polyclonal immunoglobulin G, Tc-99m-anti-E-selectin-Fab, respectively, Tc-99m hexamethylpropylene amine oxime (Tc-99m HMPAO), Tc-99m SC, Tc-99m nanocolloid, F-18 sodium fluoride, and F-18 fluoro-2-deoxy-D-glucose (FDG). The use of SPECT, SPECT/CT and pin-hole techniques should be remembered since they add diagnostic value to the scintigraphic methods. F-18 FDG PET/CT has the ability to quantitatively assess the degree of arthritis activity.

## 7.1 Introduction

Studying arthritis can be difficult because of the wide variety of disease patterns, the significant overlap of the various types, and the lack of a clear and unified classification of this group of disorders. This chapter provides an overview of the evaluation of the arthropathies and related joint disorders in a simplified version that is in no way complete but will help the reader in identifying the major scintigraphic and correlative imaging patterns along with the necessary pathophysiological features of the relevant joint disorders. The reader may refer to Chap. 1 for the basic anatomical and physiological basis of joint diseases.

Generally, several modalities are used to diagnose and follow up joint diseases. Standard radiographs remain the initial modality of choice among the morphological modalities. Scintigraphy is needed in certain situations to help in the differential diagnosis and to evaluate the activity of the diseases. Among the scintigraphic methods, bone scanning was the most helpful and cost-effective technique. The value of bone scanning was illustrated by Duncan [1], who studied 136 bone scans. This is the most common diagnostic imaging service requested by Australian rheumatologists. The primary indications for scanning were to confirm a clinical diagnosis (38%), to exclude a diagnosis (34%), and to accurately localize the site of pain (17%). The common diseases that rheumatologists were attempting to confirm, or exclude, with bone scanning were inflammatory arthritis such as rheumatoid arthritis and the possibility of differentiating it from malignancy and fracture. Bone scans were successful in excluding a diagnosis in 87% and confirming a diagnosis in 80% of cases. In 32% bone scans altered the clinical diagnosis, and in 43% they changed the course of disease management. Bone scan results prevented further investigations in 60% [1]. Single-head and dual-head pinhole images were reported to further enhance the role of bone scintigraphy in joint diseases [2]. The added value of dual-head pinhole bone scintigraphy using two opposing pinhole-collimated detectors is to obtain a pair of magnified images

of the bone and joint at the same time thereby reducing the scan time [3].

## 7.2 Classification

No unified classification for the many types of joint diseases is available.

Arthropathies, however, can be grouped into two main categories: inflammatory and noninflammatory [4] (Table 7.1). The inflammatory joint disease group is further classified into infectious and noninfectious. The infectious type is caused by bacteria, mycoplasmas, fungi, viruses, or protozoa, while the noninfectious subgroup is caused by immune reactions such as rheumatoid arthritis and spondyloarthropathies; the deposition of crystals in, and around, the joint (e.g., gout which is caused by deposition of monosodium urate crystals); or vasculitis such as Behçet's disease. Alternatively, the inflammatory joint disease group can also be subclassified into an immuno-inflammatory subgroup including rheumatoid arthritis, infectious or crystal deposition arthritis associated with a connective tissue disease (e.g., systemic lupus erythematosus), and those associated with vasculitis such as Behçet's disease. The noninflammatory joint disease is

**Table 7.1** Main types of joint disease with major examples

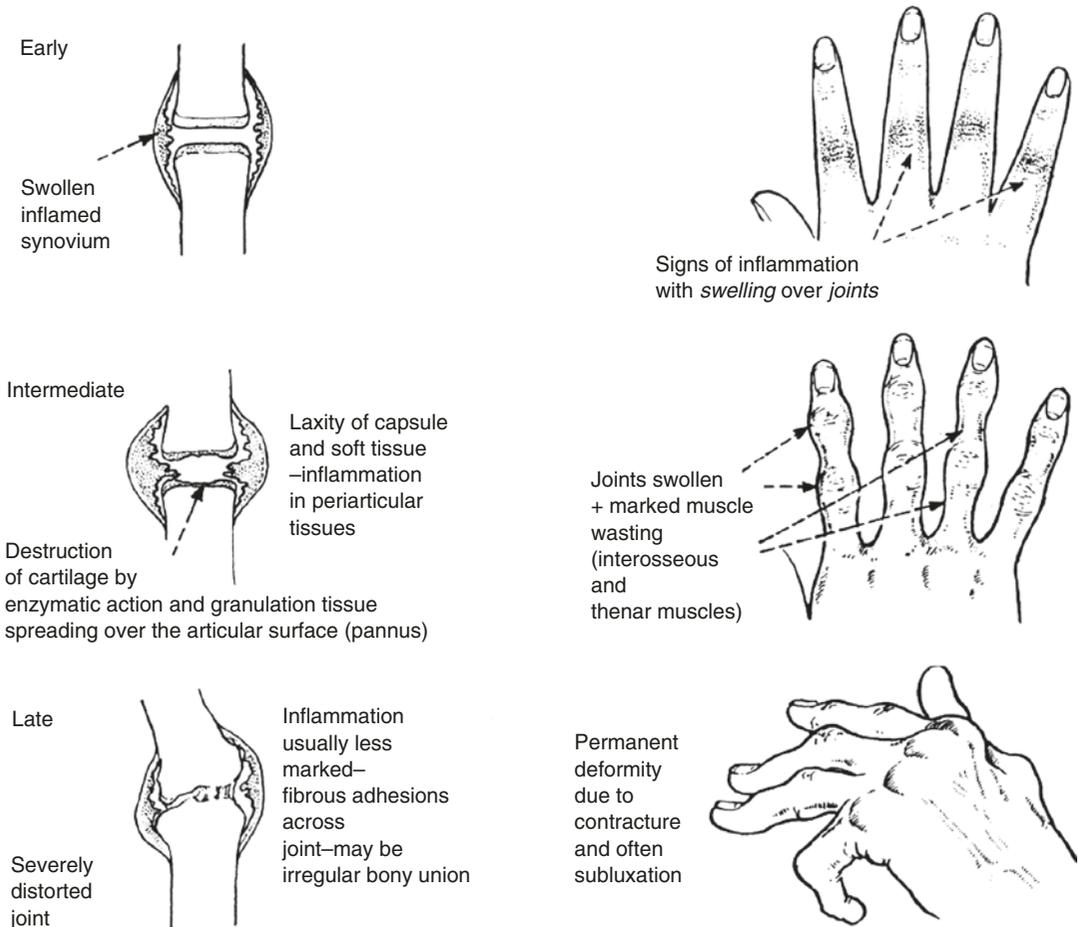

A. Inflammatory joint disease
1. Infectious
Infectious arthritis
2. Noninfectious
Rheumatoid arthritis
Crystal deposition arthropathies (gouty arthritis, CPPD)
Sacroiliitis
Neuropathic joint disease
Spondyloarthropathies
Ankylosing spondylitis
Psoriatic arthritis
Reactive arthritis (formerly Reiter's disease)
Inflammatory bowel disease-associated arthritis
B. Noninflammatory joint disease
1. Primary osteoarthritis
2. Secondary osteoarthritis

exemplified by the common osteoarthritis, or degenerative joint disease, which can be idiopathic (primary) or secondary. It should be noted that certain conditions such as neuroarthropathy and sacroiliitis have multiple overlapping pathogenic features which may be immunological, vascular, and degenerative.

### 7.3 Rheumatoid Arthritis

This autoimmune disease causes inflammation of the connective tissue mainly in the joints. It is thought that microvascular injury and mild synovial cell proliferation initially occur along with obliteration of the small blood vessels. The syno-

vial inflammatory response is triggered by immune complexes in the blood and synovial tissue through activation of plasma protein complement. This complement activation stimulates release of kinin and prostaglandins which cause the increase in vascular permeability in the synovial membranes and attracts leukocytes from the circulation to the synovial membrane. Inflammation eventually spreads from the synovial membrane to the articular cartilage, joint capsule, and surrounding tendons and ligaments with resultant pain, loss of function, and joint deformity (Figs. 7.1 and 7.2). The small joints of the hands, joints in the feet, and the wrists, elbows, ankles, and knees are the most commonly affected. Synovitis activity is the domi-

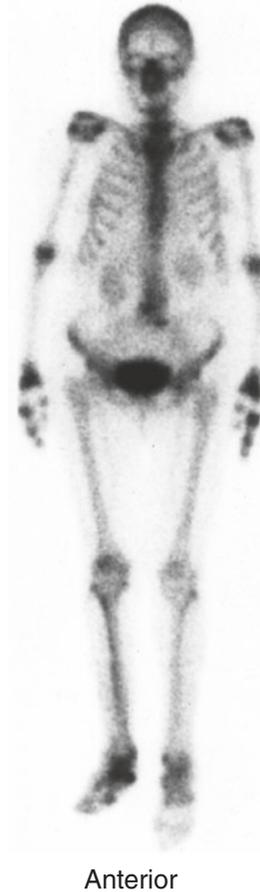

**Fig. 7.1** The major pathological changes of rheumatoid arthritic joints (from “Illustrated Pathology” [78] with permission)

**Fig. 7.2** Radiograph of a hand showing deformities associated with rheumatoid arthritis

nant clinical variable that determines the therapeutic approach in patients with rheumatoid arthritis. At present, the amount of painful and swollen joints assessed by physical examination is generally used to measure the degree of synovitis activity. A gold standard for the assessment of synovitis activity is not available [5].

Using bone scintigraphy, the disease presents symmetrically with increased perfusion and delayed uptake periarticularly in the areas of the joints affected. These are commonly the small joints of the hands, joints in the feet, and the wrists, elbows, ankles, and knees (Figs. 7.3 and 7.4). In-111- and Tc-99m-labeled poly- and monoclonal antibodies are also used to image rheumatoid arthritis. Tc-99m polyclonal human immunoglobulin-G (HIG) has been shown to be a successful agent in the depiction of active inflammation in rheumatoid arthritis [7]. Sahin compared the uptake behaviors of Tc-99m HIG and Tc-99m MDP in rheumatoid arthritis. A total of 25 patients with rheumatoid arthritis and its variants presenting with active inflammation were included in this study. Target-to-background (T/B) ratios were obtained exclusively over the joint regions. Tc-99m HIG T/B ratios of the active joints in rheumatoid arthritis were significantly higher than those of the non-active joints and the

**Fig. 7.3** Bone scan of a patient with rheumatoid arthritis. Note the symmetrical pattern of increased uptake in multiple joints of the extremities

control group of patients with well-diagnosed osteoarthritis. Tc-99m HIG T/B ratios in active joints showed a progressive increase between 2 and 24 h images. The T/B ratios in Tc-99m MDP bone scans were higher in all the active joints than in joints of non-active rheumatoid arthritis and those of controls, but significant differences were only detected in wrist and elbow joints, and the detection rate of active joint inflammation with Tc-99m HIG was higher than with Tc-99m MDP [8]. Monoclonal antibody which reacts with porcine E-selectin was evaluated to image rheumatoid arthritis. Tc-99m-labeled Fab fragment of 1.2B6 and Tc-99m HDP were used by Jamar et al. [9] in ten patients. Images were obtained 4 h and 20–24 h after injection. Two normal volunteers were also imaged. The diagnostic accuracy, using

**Fig. 7.4** Bone scan of a 34-year-old male known to have active rheumatoid arthritis. Note the symmetrical involvement of the particularly affected elbow joints

joint tenderness or swelling as the clinical standard, was 88%, higher than that of Tc-99m HDP (57%) as a result of the low specificity of the latter in rheumatoid arthritis. No uptake of Tc-99m-Fab was observed in the inactive or normal joints, whereas Tc-99m HDP was taken up by all joints to a varying degree, making the decision as to whether a particular joint is actively involved or chronically damaged very difficult. The authors concluded that Tc-99m-anti-E-selectin-Fab scintigraphy can be used successfully to image synovitis with better specificity than Tc-99m HDP bone scanning [9].

Labeled leukocytes have been used to evaluate the activity of the disease. In a study by Gaal

and associates [10], the applicability of Tc-99m hexamethylpropylene amine oxime (Tc-99m HMPAO)-labeled leukocyte joint scintigraphy in the assessment of disease activity was tested in 21 patients with rheumatoid arthritis. The degree of accumulation of Tc-99m HMPAO leukocytes showed no correlation with a patient's age and gender, duration of disease, use of disease modifying antirheumatic drugs, or any laboratory parameters. However, a significant correlation was found between the global regional accumulation of the labeled leukocytes of the hands and feet and the clinical assessment of joint activity [10].

In a study of 41 patients with arthritis which remained unclassified despite conventional clinical, biochemical, and radiographic (hands and feet) examinations, bone scan along with MRI was helpful in classifying patients as having rheumatoid or nonrheumatoid arthritis in 39 out of 41 patients. The presence of MRI synovitis, MRI erosion, and bone scintigraphic pattern compatible with rheumatoid arthritis showed that 100% specificity for the diagnosis based on fulfillment of ACR criteria 2 years later was considered the standard reference [11].

Clear visualization of inflamed joints in patients with active rheumatoid arthritis using Tc99m-labeled anti-TNF mAb with a high specificity has been reported. Joint accumulation of this agent is partly due to specific TNF targeting and is highly predictive for active inflammation [12]. In a small study of seven patients with active rheumatoid arthritis, visual assessment of FDG uptake showed a significant correlation with clinical evaluation of disease activity in patients with RA undergoing anti-inflammatory treatment [13]. For studying rheumatoid arthritis patients, several monoclonal antibodies and their fragments, including anti-TNF- $\alpha$ , anti-CD20, anti-CD3, anti-CD4, and anti-E-selectin antibody, have been radiolabeled mainly with  $^{99m}\text{Tc}$  or  $^{111}\text{In}$ . Scintigraphy with these radiolabeled antibodies can offer possibility for the study of rheumatoid arthritis patients and allows better staging of the disease and diagnosis of the state of activity by early detection of inflamed joints that might be difficult to assess and might provide a possibility to perform "evidence-based

biological therapy” of arthritis with a view to assessing whether an antibody will localize in an inflamed joint before using the same unlabeled antibody therapeutically. This might prove particularly important for the selection of patients to be treated with biological therapies as these can be associated with severe side effects and are expensive [14].

Radiolabeled leukocyte scintigraphy was suggested to be useful in assessing disease activity in patients with rheumatoid arthritis and assessing the effect of therapy [10, 15].

---

## 7.4 Crystal Deposition Arthropathies

Apart from gout, there are several other types of calcium deposition that can lead to arthritis [16]. These include CPPD (pseudogout), calcium hydroxyapatite crystals, and calcium oxalate crystals (oxalosis).

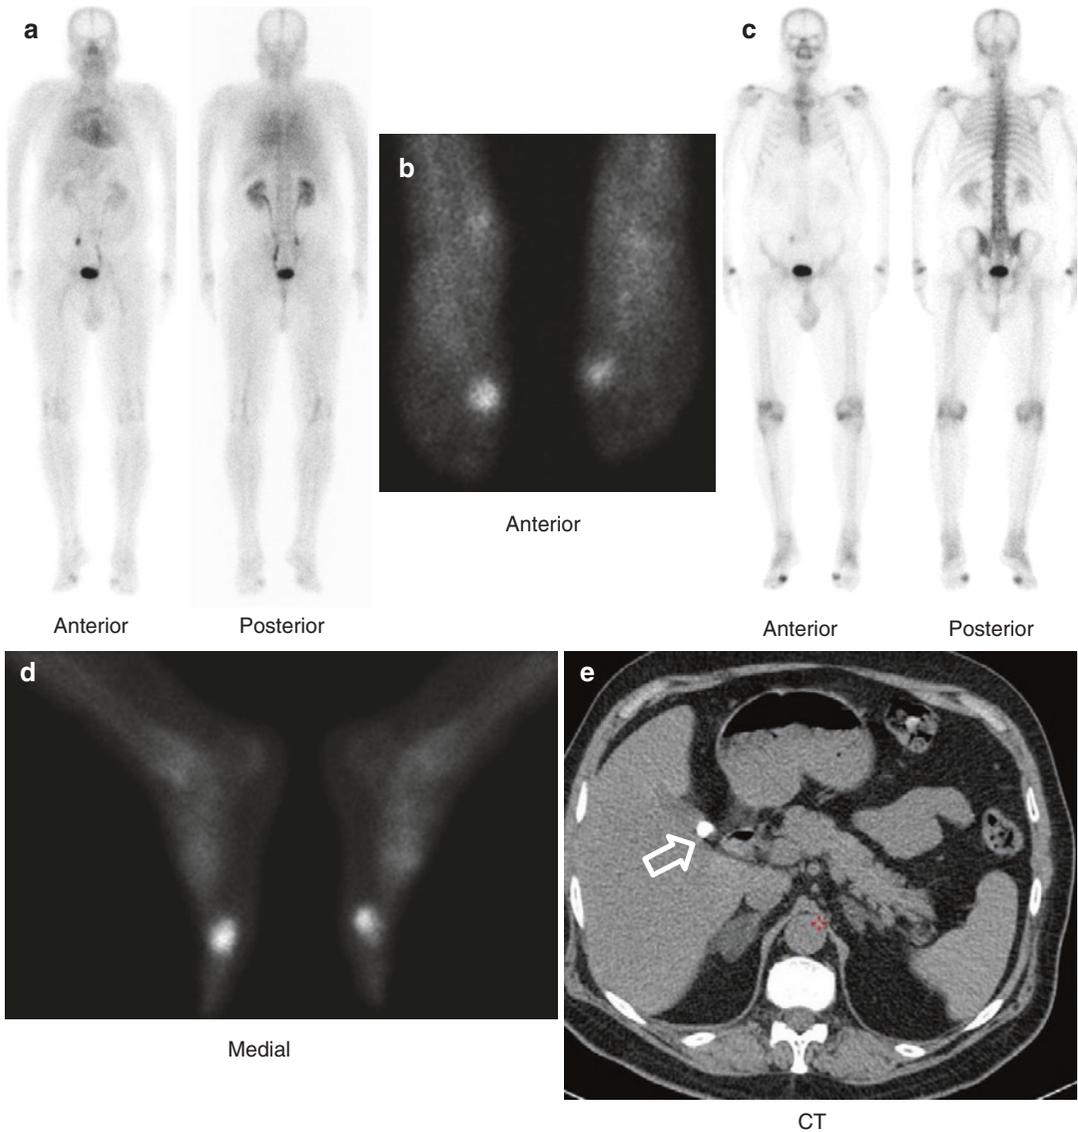

### 7.4.1 Gouty Arthritis

Gout is a metabolic disorder that results in hyperuricemia and leads to the deposition of monosodium urate monohydrate crystals at various sites in the body, especially joint cartilage. It continues to be a health problem worldwide despite the availability of effective therapies. The disease is rare in children and premenopausal females and uncommon in males under 30 years of age. The prevalence is influenced by genetic factors, alcohol consumption, obesity, and hypertension. There is an association between hyperuricemia and cardiovascular disease which seems to be linked to insulin resistance [17]. It is closely linked to purine metabolism and kidney function. An accelerated rate of purine synthesis may occur in some individuals with overproduction of uric acid since the latter is a breakdown product of purine nucleotides [18]. In other individuals, the rate of breakdown, rather than synthesis, of purine nucleotides is accelerated, also resulting in high levels of uric acid. Uric acid is predominantly

eliminated via the kidney. Urate excretion by the kidney may be sluggish due to a decrease in the glomerular filtration of urate or an acceleration of urate reabsorption. Urate crystals are deposited in the renal interstitium, causing impaired renal flow, and may also precipitate, resulting in renal stones. Uric acid crystallizes when it reaches certain concentrations in fluids, forming insoluble crystals that can precipitate in the connective tissue of different parts of the body. When this process involves the synovial fluid, it causes acute inflammation of the joint. Although the effect is the same, classic gouty arthritis is caused by deposition of monosodium urate crystals, while deposition of calcium pyrophosphate dihydrate crystal causes pseudogout [19].

Monosodium urate crystal deposition triggers an acute inflammatory response in the synovial membrane and other tissues of the joints. Leukocytes, particularly neutrophils, are attracted out of the circulation to phagocytize the crystals. Trauma is the most common aggravating factor. Therefore, the great toe is a common presenting site (50% of initial attacks); this is due to the chronic strain during walking.

The available data regarding scintigraphy in gout are generally limited [20]. When seen on bone scan, there is increased flow, blood pool activity, and delayed uptake in the areas of the joint involved. The ankle, knee, and the first metatarsophalangeal joint (Fig. 7.5) are the joints most often affected [21, 22]. The most typical is, however, that of the metatarsophalangeal joint of the great toe, called podagra. The current scientific literature has not shown white cell imaging to be useful in differentiating between infection and the acute inflammatory phase of gout [23, 24]. Case reports of FDG PET/CT in gout showed articular and periarticular FDG uptake [25, 26]. Soft tissue FDG uptake corresponding to tophi has also been reported [27]. These findings are not specific for gout. Case of gouty tophus of the patella was evaluated by positron emission tomography (PET) using a combination of an amino acid analog emitter, L-[3-F-18]-alpha-methyl tyrosine (FMT), which does not accumulate in malignancies and showed increased levels of

**Fig. 7.5** (a–e) Bone scan of a patient with gouty arthritis. Blood pool whole-body (a) images and spot image of the feet (b) show increased activity of the first metatarsophalangeal joint region bilaterally. Whole-body delayed images (c) show increased uptake in the tarsometatarsal

joints bilaterally seen clearly on spot image (d) in addition to increased uptake in the hands and knees. Representative section of CT of the abdomen (e) of the same patient shows a calculus of the gall bladder likely urate

metabolic activity, and the glucose analog emitter, F-18 FDG, which essentially accumulates in malignancies did not show appreciable activity. This case report suggests that PET may be useful for the preoperative evaluation of gouty tophus, including detection and differentiation from malignant tumors [28].

#### 7.4.2 Calcium Pyrophosphate Dihydrate Deposition Disease

Calcium pyrophosphate dihydrate (CPPD) deposition disease was described approximately 50 years ago when calcium pyrophosphate dihydrate crystals were identified in the synovial fluid of patients who had gout-like symptoms with no

urate crystals identified. The term chondrocalcinosis and pyrophosphate arthropathy were also applied to the same disease. It generally occurs in elderly individuals and is said to affect 20–30% of people older than 65 years and 30–60% of those older than 85 years. In most cases it is relatively asymptomatic, but it can occasionally cause severe disabling arthritis [16]. It may occasionally form tumorlike masses, and in this case the term tophaceous pseudogout is applied. Patients with gout have an increased chance of having CPPD as well. Up to 40% of the patients with gout concomitantly have CPPD.

---

## 7.5 Infectious Arthritis (See also Chap. 2)

In children, infectious (septic) arthritis usually occurs secondary to hematogenous seeding, but it can also be produced by direct extension of osteomyelitis. More than half of the patients are younger than 2 years old. A recent history of trauma is found in one third of patients, and nearly 50% have recent otitis media or an upper respiratory tract infection. Infectious arthritis secondary to adjacent osteomyelitis can occur in joints where the metaphysis is within the capsule (hip or shoulder). It can be found in infants, because of the epiphyseal location of osteomyelitis. *Staphylococcus aureus* is the major causative agent followed by the *Streptococcus* species. In children less than 2 years old, *Haemophilus influenzae* is the main causative agent, although its incidence has decreased following the introduction of vaccination [29]. Patients present with fever, pain, limitation of movement, and limp, and infants may demonstrate joint dislocation. The hip and knee are the most commonly affected joints in children, while the shoulder is more often affected in neonates. Rapid cartilage destruction and bone ischemia caused by increased intracapsular pressure lead to sequelae such as growth discrepancies, limitation of movement, and dislocation. Accordingly, the condition is an orthopedic emergency, and any delay in diagnosis often leads to catastrophic sequelae. Permanent loss of joint function occurs in up to 25–50% of patients [30–

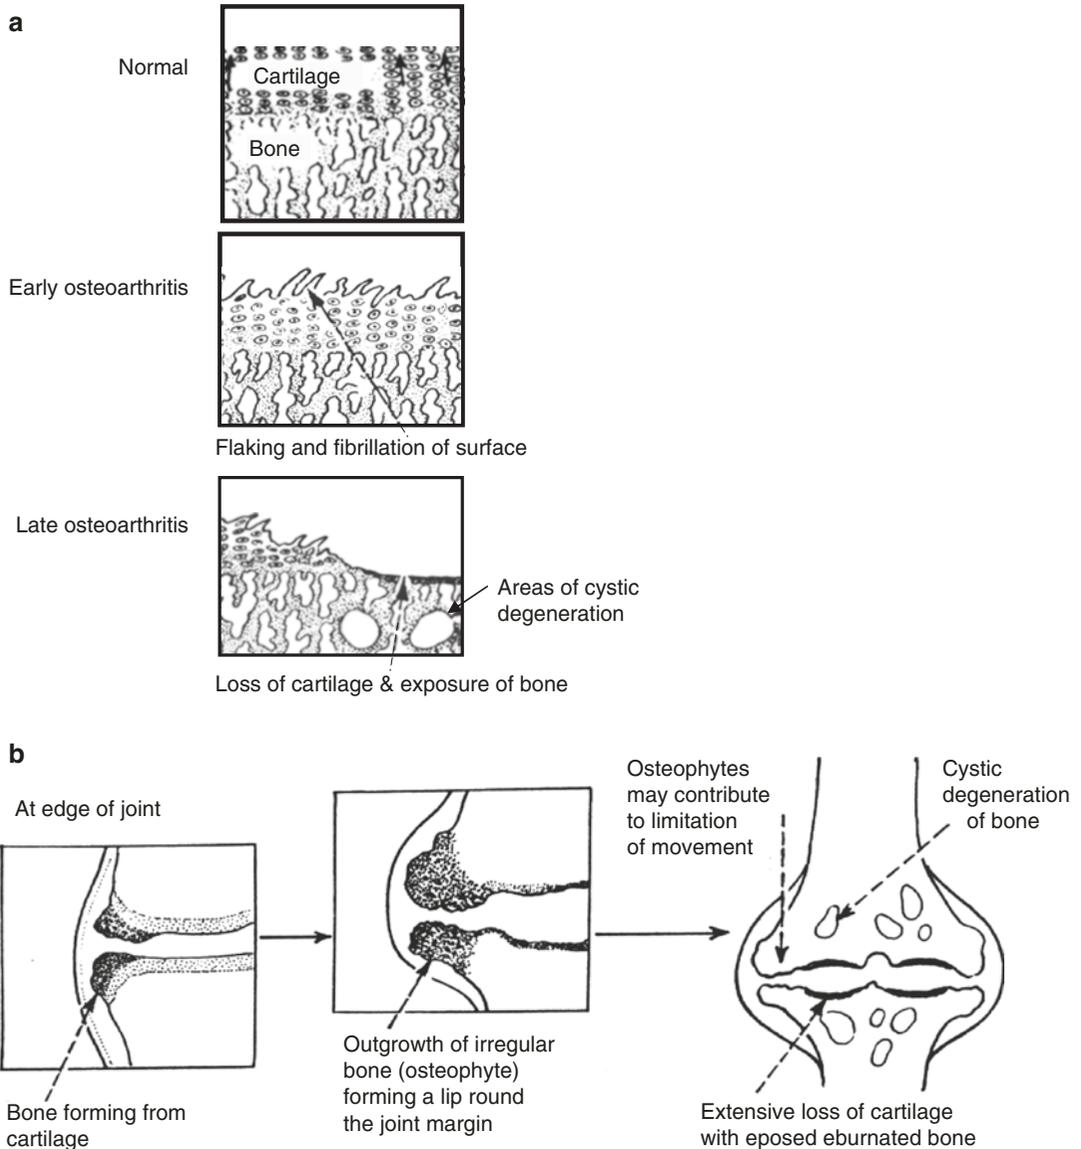

32]. The diagnosis can be made from clinical observation and joint aspiration. Combination of joint and blood cultures allows identification of the pathogen in two thirds of cases [29, 32]. Ultrasound allows the rapid identification of joint effusion and can act as a guide during aspiration. It should be noted that ultrasound cannot differentiate whether the joint effusion is the result of infection, or just inflammation, since the severity of effusion of the septic hip group may not be greater than the non-infectious synovitis [33]. Sonography can also be used to detect the extent of the infection, since it may reveal the periosteal elevation, subperiosteal abscess, and cortical erosion much earlier than radiographs if metaphyseal osteomyelitis has occurred [34]. In cases of equivocal ultrasonography and if the presence of osteomyelitis is to be evaluated, bone scanning is the modality of choice (see Chap. 2). SPECT/CT can improve the diagnostic ability and certainty.

---

## 7.6 Osteoarthritis

Osteoarthritis can be primary with no known predisposing factors (idiopathic), or it can be secondary due to several etiologies. Both primary and secondary forms of osteoarthritis have the same pathological characteristics (Fig. 7.6). Primary, or idiopathic, osteoarthritis is the most common type of noninflammatory joint disease. Although it can affect any joint, the joints most commonly involved are the hand joints, wrists, lower cervical spine, lumbar spine, sacroiliac joints, hips, knees, ankles, and foot joints (Fig. 7.7). Aging is an important risk factor although the cause of osteoarthritis is unknown. Premature cartilage degeneration due to an inherited genetic defect encoding for the structural components of the articular cartilage has been suggested as the etiology for this condition.

Primary osteoarthritis progresses with age. Diffuse idiopathic skeletal hyperostosis (DISH), common in elderly, can be considered among the noninflammatory joint diseases included in the primary osteoarthritis although it is a characteristic entity since the predominant feature is

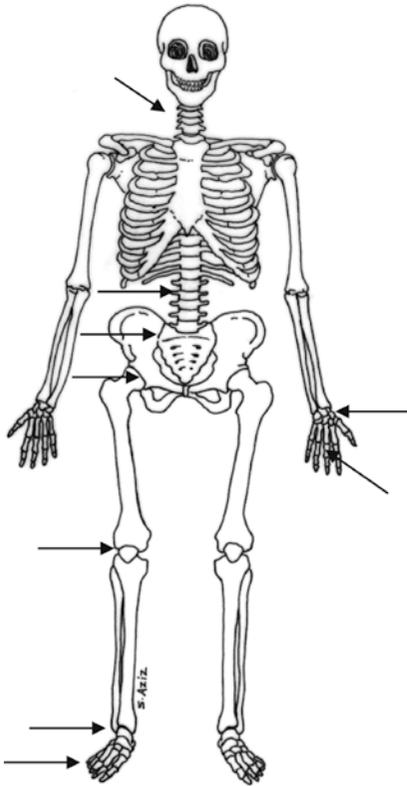

**Fig. 7.6** (a, b) The major pathologic changes of osteoarthritis (from [78] with permission)

ossification of related soft tissue (see later). Secondary osteoarthritis occurs when the predisposing cause is known, e.g., following intra-articular fracture or other trauma (post-traumatic osteoarthritis), rheumatoid diseases, neurogenic and metabolic disorders, xenobiotic agents, and recurrent hemarthrosis (as may occur among hemophiliac patients and following certain forms of osteochondrosis and osteonecrosis). The pain of osteoarthritis is caused by intracapsular tension, muscle spasm, abnormal stress on

the bone, and increased intraosseous venous pressure.

The ability of the articular cartilage to repair is very limited. Intrinsic repair occurs in infants, as the chondrocytes are still able to proliferate. Extrinsic repair occurs by granulation tissue growing from the adjacent bone. The granulation tissue changes to fibrocartilage, which is inferior to normal cartilage in its mechanical properties.

The changes that occur to the articular cartilage in osteoarthritis involve a progression

**Fig. 7.7** Joints commonly involved with osteoarthritis

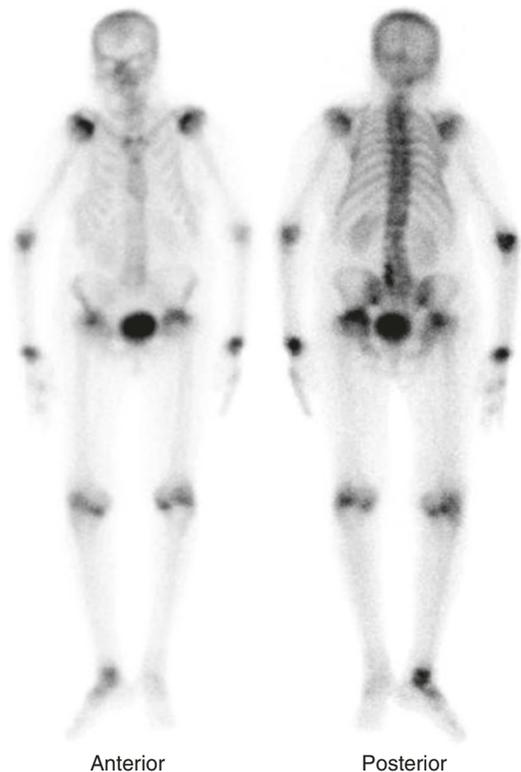

from fibrillation to erosion, and then in the advanced stages, it leads to the complete loss of cartilage. At this point the exposed bone is exposed to increased stress, becomes more compressed, and shows subarticular sclerosis [35].

Thus, the pathological features of osteoarthritis include gradual loss of the articular cartilage, thickening and hardening (sclerosis) of the bone underneath the cartilage (subchondral sclerosis), and formation of osteophytes (spurs). As the articular cartilage erodes, the cartilage-coated osteophytes often grow into the joint. Small pieces of osteophyte may break off and become liberated within the synovial cavity. These pieces, called joint mice, irritate the synovial membrane resulting in synovitis and joint effusion. In addition, the joint capsule may thicken and in some

cases adhere to the underlying bone, causing limitation of movement.

Accordingly osteoarthritis involves all of the tissues of the synovial joint including loss of cartilage. Some investigators suggest that osteoarthritis is best defined as failed repair of damage that has been caused by excessive mechanical stress on joint tissues [36].

Osteoarthritis is often generalized, affecting multiple joint sites simultaneously. One survey found that as much as 26% of osteoarthritis (based on a pool of 809 patients with knee or hip replacements because of osteoarthritis) presents as a generalized joint disease [37]. The generalized osteoarthritis may be associated with enthesopathies. The osteoarthritic changes can

**Fig. 7.8** Bone scan of a 65-year-old female with severe osteoarthritis complaining of generalized joint pains. Scan shows intensely increased uptake in multiple joints of the upper and lower extremities

**Fig. 7.9** Bone scan in a patient with osteoarthritis. Moderately increased uptake is noted in the knees, elbows, wrists, and spine. A focus of increased uptake in L1 is extending to the left beyond the boundaries of the vertebra and is corresponding to an osteophyte seen radiographically

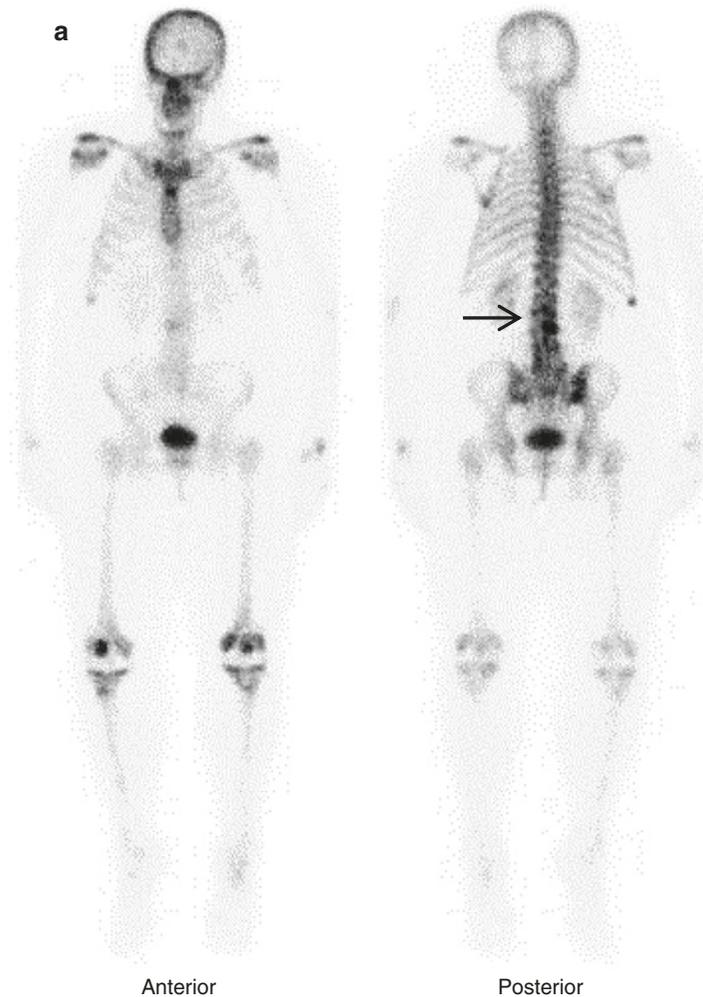

usually be seen on standard radiographs as well as other morphological modalities. Using bone scintigraphy, increased periarticular uptake is commonly seen as an incidental finding in the commonly involved joints. The degree of uptake is proportional to the severity of the disease (Figs. 7.8 and 7.9) [38]. Bone scan is useful to detect generalized osteoarthritis [39], and SPECT/CT and F-18 NaF PET/CT are very useful since CT shows osteophytes clearly as

well as enthesopathies that can be associated with generalized osteoarthritis and provides exact localization helping in specific diagnosis (Figs. 7.10 and 7.11).

Osteoarthritis can be associated with popliteal cysts. This originally called Baker's cyst is a synovial fluid-filled mass located in the popliteal fossa. Most commonly popliteal cyst is considered to be a distension of the bursa located beneath the medial head of the gastrocnemius muscle.

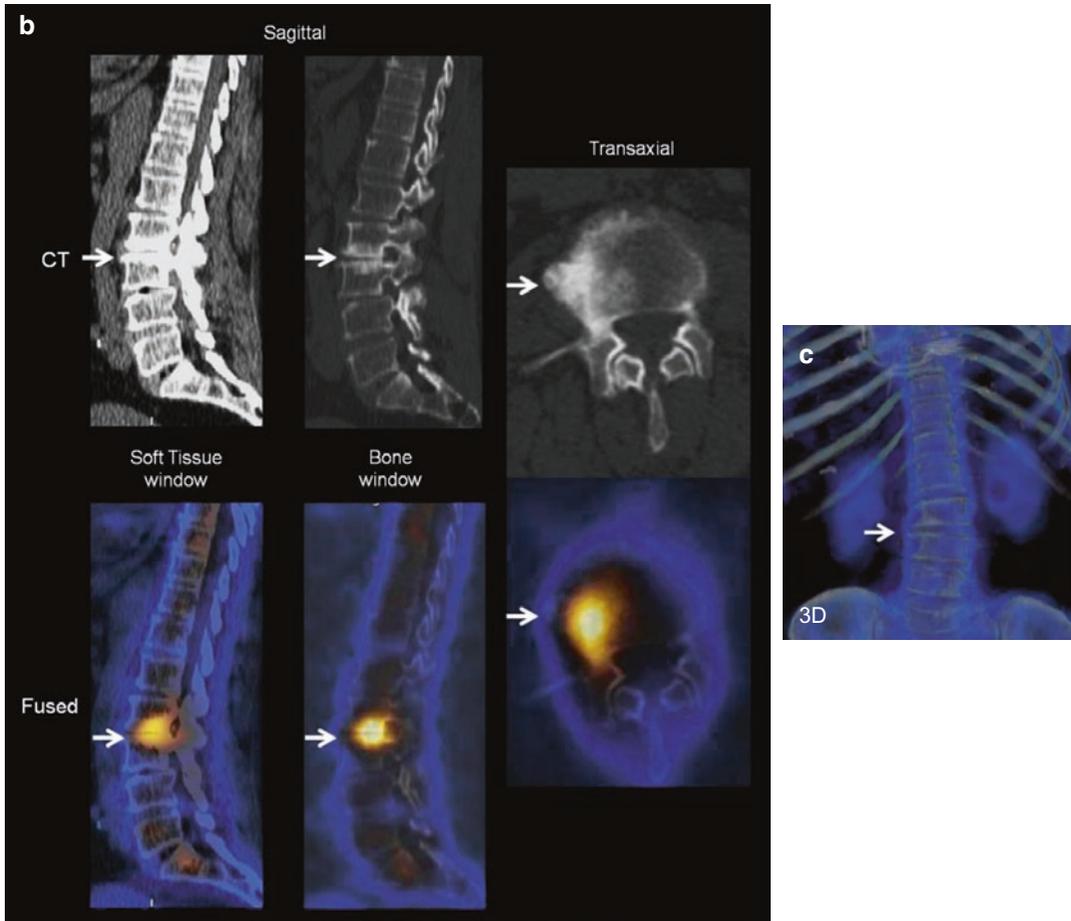

Usually, in an adult patient, an underlying intra-articular disorder is present. In children, the cyst can be seen with a normal knee joint [40]. In one study Baker's cysts were detected in 72/195 (37%) patients with knee osteoarthritis (Fig. 7.12). Abnormal and intense tracer accumu-

lation in early-phase bone scintigraphy was significantly more frequent in osteoarthritic knees with Baker's cysts (97 and 56%, respectively), than in those without (89 and 40%, respectively). In this study clinical and radiographic variables could not predict the presence of those cysts [41].

**Fig. 7.10** Whole-body Tc99m MDP bone scan (a) and representative images of SPECT/CT study (b) showing L-2/L3 arthritis with clear localization of uptake and

visualization of osteophytes on the CT component and 3D fused image (c)

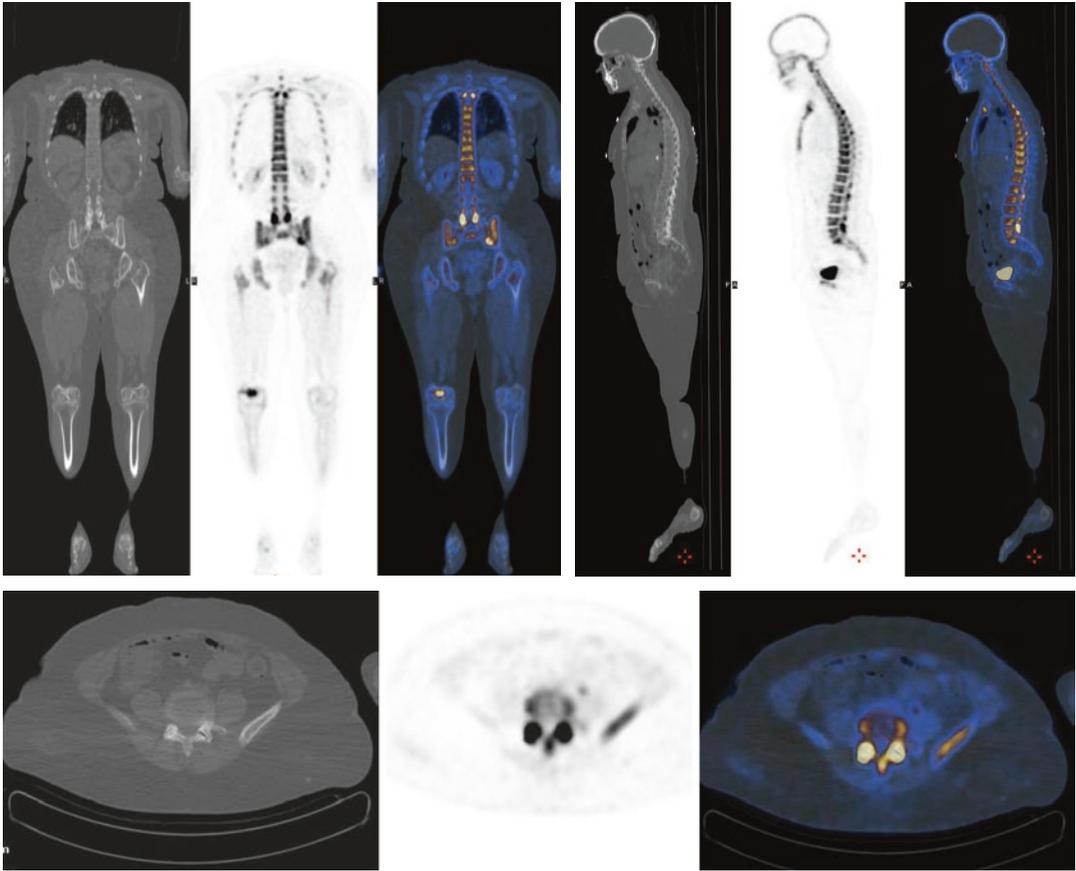

**Fig. 7.10** (continued)

## 7.7 Sacroiliitis

The sacroiliac joints may be involved in degenerative diseases, or septic processes, as well as in the different arthropathies. Infection involving the sacroiliac joint is an uncommon condition in which non-specific clinical features and delayed radiographic features may lead to incorrect diagnoses and delayed, or inappropriate, treatment. Sacroiliac infections occur due to the hematogenous spread of organisms, and a history of pre-existing infection is often present, particularly a cutaneous, pharyngeal, postpartum, urinary tract infection, or osteomyelitis elsewhere [42]. The most frequently isolated organisms include staphylococci [43, 44]. Whether the infection begins in the joint, or within the adjacent bone, is

controversial. Nixon emphasizes that it is far more likely that infection begins in the bone (ilium), where, similar to the metaphyses elsewhere, the vascular anatomy predisposes this site to blood-borne infection [44]. The role of scintigraphic imaging studies in the evaluation of patients with sacroiliitis is controversial and is generally of limited value [45]. Planar and SPECT bone scintigraphy, Tc-99m SC, and Tc-99m nanocolloid along with quantitative methods have all been used for the diagnosis. Diagnosis of sacroiliitis with bone scintigraphy may be difficult even with a quantitative approach. However, in a recent study, the clinical importance of bone scan quantitative indices in the diagnosis of sacroiliitis were reevaluated in 45 patients with suspected sacroiliitis and 46

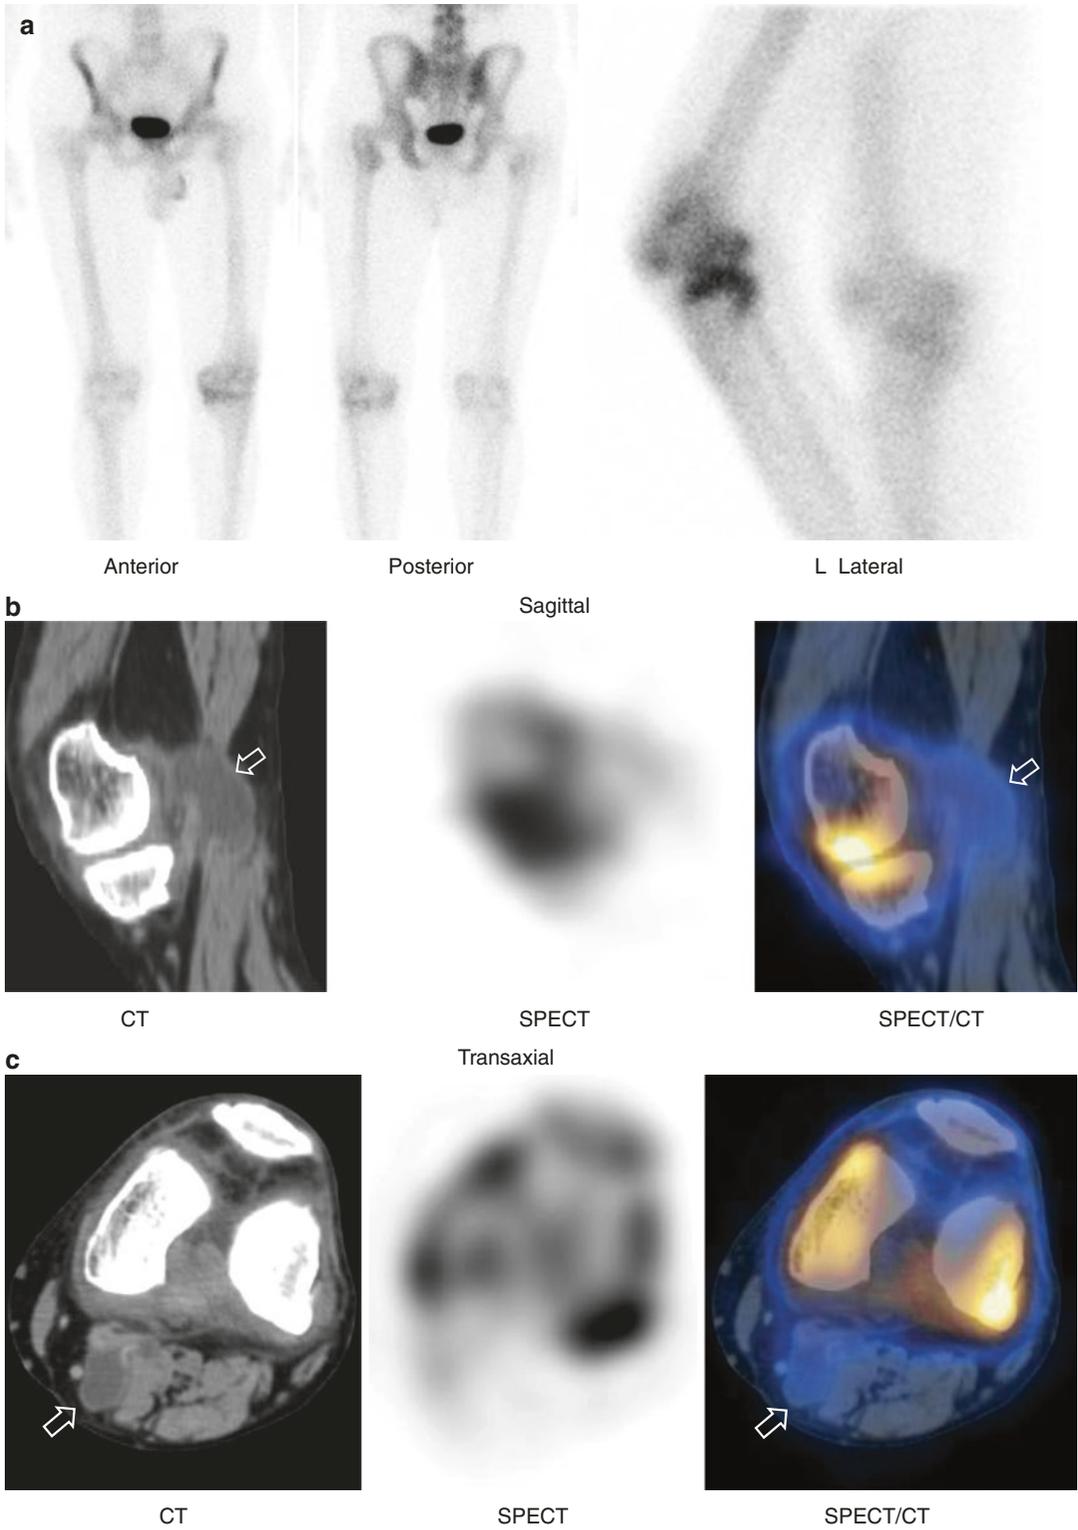

**Fig. 7.11** F-18 sodium fluoride PET/CT study of a patient with low back pain. The study shows increased uptake in L-5 bilaterally which is localized clearly in the facet joints indicating facet joint arthropathy

patients without sacroiliitis. Among 45 patients with suspicion of sacroiliitis, 15 had final diagnosis of sacroiliitis, and all of the Tc-99m methylene diphosphonate planar and SPECT bone scintigraphy results of these patients were concordant with sacroiliitis. There were eight false-positive results in other 30 patients. Seven of these eight patients had normal index values. If the scintigraphy would be evaluated in conjunction with indices, the specificity would increase from 73% to 97%, but sensitivity decreases from 100% to 80%. Accordingly use of sacroiliac index values to confirm positive results can increase the specificity of bone scintigraphy [46].

A combination of bone and bone marrow scintigraphy has been proposed as an alternative method that may have a role in characterizing patients with active sacroiliitis that has been

found typically to show a decreased bone marrow uptake [47, 48]. A total of 31 patients who were clinically suspected to have sacroiliitis were studied using bone and bone marrow scans by Bozkurt et al. [47]. Both visual and quantitative assessment of MDP uptake and a visual assessment of the sulfur colloid uptake in the sacroiliac joints were performed. Increased Tc-99m MDP uptake with decreased/normal sulfur colloid uptake was the most common scintigraphic pattern seen in the acute phase of sacroiliitis cases in which radiographic findings were normal or slightly changed. In at least eight patients, bone marrow uptake of sulfur colloid was clearly decreased, supporting the diagnosis [47]. SPECT bone scan was found to have the excellent accuracy (97% sensitivity and 90% specificity) [49]. SPECT/CT as well as F-18 sodium fluoride PET/CT can be

**Fig. 7.12** Selected images of Tc99m MDP bone scan (a) of a 34-year-old male with pain in the left knee region. Images reveal increased uptake in the left knee joint region periarticularly. Sagittal (b) and transaxial (c) images of SPECT/CT study show increased uptake clearly

at periarticular locations of the left knee joint. Additionally there is a popliteal cyst (arrows) seen on CT images with no corresponding radiotracer uptake. The case illustrates osteoarthritis with popliteal (Baker's) cyst

even more helpful in illustrating the exact location of uptake, its distribution pattern, and anatomic details (see Chap. 10, Fig. 10.8).

---

## 7.8 Neuroarthropathy (See also Chap. 2)

Neuroarthropathy is characterized by destructive joint changes. Loss of protective pain and proprioceptive sensation along with hyperemia secondary to loss of vasoconstrictive neural impulses is thought to result in atrophic neuropathy, most frequently occurring in the forefoot [50]. On the other hand, absence of sympathetic fibers in the presence of sensory fiber involvement tends to result in hypertrophic neuroarthropathy, which occurs most frequently in the mid- and hindfoot. Since the patient continues to walk and traumatize the foot, disuse osteoporosis is usually absent. Unrelenting trauma may also result in rapidly progressive destruction, sometimes with disintegration of one or more tarsal bones within a period of only a few weeks. In this rapidly progressive form of neuroarthropathy, there is a greater degree of inflammatory reaction than in other types. A long history of diabetes mellitus with a combination of angiopathy, neuropathy, and immunopathy predisposes the patient to pedal osteomyelitis, which may be difficult to differentiate from neuroarthropathy (particularly the rapidly progressive form). Metatarsal bones and the proximal phalanges are the most commonly involved sites [50, 51].

The condition is characterized by cartilage destruction, bony collapse, synovial and capsular hypertrophy, and disorganization of the joints involved. Radiography shows diffuse soft tissue swelling, joint space narrowing, subluxation, slanting joint deformity, and irregular destruction and exophytic derangement of the bone. Scintigraphically, neuroarthropathy presents with an increased uptake to variable degrees on bone scan and gallium-67 scans which cannot differentiate the condition from osteomyelitis. Furthermore, the condition may cause false-positive results of labeled leukocyte scans, since the rapidly progres-

sive neuroarthropathy may cause abnormal accumulation of labeled leukocytes simulating osteomyelitis. Simultaneous In-111 leukocyte and Tc-99m bone scanning is the most accurate technique for differentiating both conditions. Bone scanning using a pinhole collimator shows bizarre tracer uptake in and around the diseased joint, possibly showing fragmentation.

---

## 7.9 Spondyloarthropathies

This group of disorders was formerly called rheumatoid variants and shares common clinical and radiographic features, with characteristic involvement of the sacroiliac joints and spine, and to various degrees, the peripheral joints are linked to HLA-B27 histocompatibility antigen. The group includes ankylosing spondylitis, psoriatic arthritis, reactive arthritis (Reiter's disease), enteropathic spondylitis (ulcerative colitis, Crohn's disease, and Whipple's disease), and an entity known as undifferentiated spondyloarthropathy. Many of these conditions are seronegative and HLA-B27 positive; hence they are also called seronegative spondyloarthropathies. Additionally, these disorders are also characterized by (1) absence of rheumatoid factors in the blood, (2) absence of subcutaneous nodules, (3) and familial aggregation.

Although plain radiographs are the first line of imaging investigation, they are often unable to demonstrate the early changes of sacroiliitis which are needed in order to establish the early diagnosis of seronegative spondyloarthropathy. The radiographic appearances of each of the inflammatory diseases involving the sacroiliac joints are similar. Differences in symmetry and severity may, however, suggest the correct diagnosis (Table 7.2).

Other imaging modalities, including conventional tomography, bone scintigraphy, computed tomography, and MRI, have improved the visualization of inflammatory changes in the sacroiliac joints [53]. MRI is considered the most sensitive modality although it is not diagnostic in some conditions [54]. SPECT/CT is an important modality currently to diagnose these conditions.

### 7.9.1 Ankylosing Spondylitis

Stiffening and fusion (ankylosis) of the spine and sacroiliac joints causing, most frequently, low back pain and stiffness characterize this chronic inflammatory joint disease which is the most common type of the seronegative spondyloarthropathies. It predominantly affects the axial joints, particularly the sacroiliac joints, with a strong genetic predisposition associated with HLA-B27. Other joints such as the hips, knees, and shoulders are involved in approximately 30% of patients. The condition usually affects males and begins in adolescence with inflammation of the fibrocartilage in cartilaginous joints (primarily in the vertebrae) along with infiltration of inflammatory cells (mainly macrophages and lymphocytes) into the fibrous tissue of the joint capsule, cartilage, and periosteum. This process is followed by repair of cartilaginous structures by the proliferation of fibroblasts that secrete collagen, which later becomes organized into fibrous scar. This scar eventually undergoes calcification and ossification leading to a loss of flexibility and fusion of joints [55].

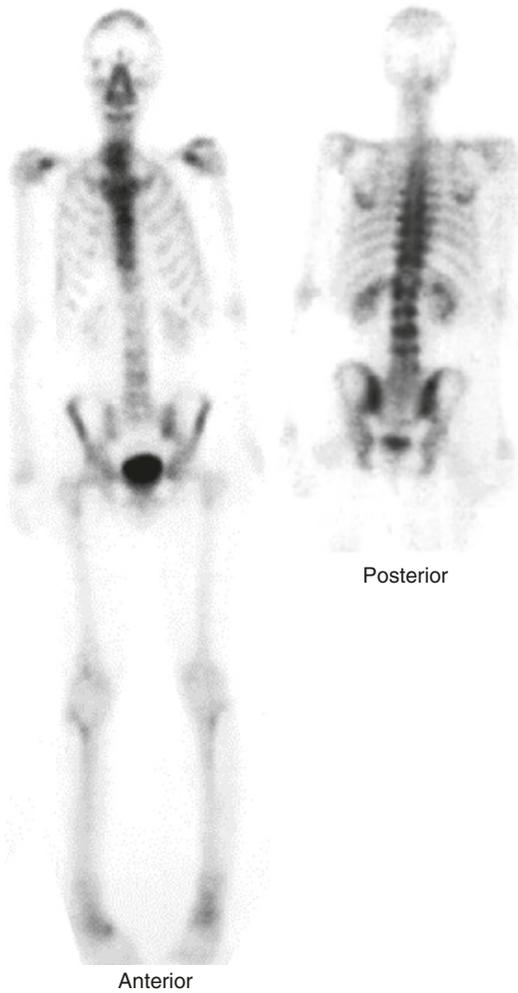

Scintigraphically, the patterns vary according to the disease stage. In the early stages, scintigraphy reveals typical, but not always symmetrical, intense tracer uptake in both sacroiliac joints. Associated spinal lesions may, or may not, be present at this stage. Later, as the spine

becomes involved (Fig. 7.13), pinhole scintigraphy reveals patchy uptake in the apophyseal joints, horizontal band-like uptake in the disco-vertebral junctions, and midline segmental uptake in the spinous processes and the interspinous ligaments [2]. Bone scan is of limited accuracy in detection of sacroiliitis in cases with established ankylosing spondylitis [45] unless combined with CT.

### 7.9.2 Psoriatic Arthritis

The association of psoriasis with a specific type of arthritis is now well established and can be differentiated on the basis of spotty involvement, negative rheumatoid factor, the radiographic and scintigraphic findings, and sometimes a positive HLA-B27 antigen test. Distribution is asymmetrical, spotty, or sometimes unilateral, more regularly affecting the upper extremity joints, including fingers, typically with inflammatory involvement of the distal interphalangeal joints.

Yun et al. [56] described a patient with psoriatic arthritis in whom an increased level of F-18 FDG uptake was seen in the joints of the hands. The areas of increased activity correlated well with the regions of symptoms reported by the patient. This finding illustrates the potential use of F-18 FDG PET to quantitatively assess the degree of arthritis activity [56].

**Fig. 7.13** Ankylosing spondylitis in a 32-year-old male with known ankylosing spondylitis and low back pain. There is increased uptake in sacroiliac joints and multiple vertebrae

### 7.9.3 Reactive Arthritis (Reiter’s Disease)

The syndrome as described originally by Hans Reiter in 1916 comprises a triad: non-gonococcal urethritis, arthritis, and conjunctivitis. Willkens et al. [57] defined the condition as an episode of arthritis lasting longer than 1 month in association with urethritis or cervicitis. The associated synovitis develops after a primary infection distant from the joint, mainly localized in the genitourinary (uroarthritis) or the

**Table 7.3** Classic scintigraphic findings of major joint diseases

Disease	Scintigraphic findings
Rheumatoid arthritis	Symmetrical uptake involving small and large joints
Gouty arthritis	Uptake of metatarsophalangeal joint of the great toe and large joints, commonly symmetrical
Ankylosing spondylitis	Symmetrical intense tracer uptake in both sacroiliac joints and spine
Osteoarthritis	Uptake of large joints, symmetrical in primary type
Reactive arthritis	Asymmetrical uptake of large and small joints and spine
Psoriatic arthritis	Asymmetrical uptake of large and small joints typically of upper extremity, including fingers, and spine
Infectious arthritis	Uptake involving a large joint
Enteropathic arthritis	Uptake of large joints (asymmetrical), sacroiliac joints (symmetrical), and spine

gastrointestinal (enteroarthritis) tract [58]. The disease can also follow salmonellosis, shigellosis, and yersiniosis, in which case it can be described as post-enteric reactive arthritis. Because of the possible involvement of the spine and entheses, and the HLA-B27 association, reactive arthritis is considered to be one of the spondyloarthropathies. Recently, bacterial components, or viable bacteria, were found in the involved joints. Radiologically, the first signs to be observed in joints include periarticular soft tissue swelling, joint space narrowing, and osseous erosions in the absence of significant osteoporosis. Periosteal thickening may be noted in the pelvis, trochanters, and heel. The spurs in the plantar and posterior aspects of the calcaneus and the “sausage digit” deformity in the toes are other important signs. Asymmetrical, or even symmetrical, sacroiliitis may be seen.

Bone scintigraphy appears to be the method of choice for the panoramic mapping of the characteristic spotty, asymmetrical foci of the polyarthritis and spondylopathy (Table 7.3). In general, the grade of tracer uptake in a lesion appears roughly to parallel the activity of the inflammatory process. Particularly when augmented with the pinhole imaging, bone scintigraphy has

proven to be more sensitive, and often more specific, than radiography in revealing the associated early enthesopathies, especially in the heel and knee [59].

### 7.9.4 Enteropathic Spondylitis

Enteropathic arthropathies are induced by, or associated with, inflammatory bowel diseases, including ulcerative colitis, Crohn's disease, Whipple's disease, intestinal bypass surgery, and celiac disease. The exact cause-and-effect relationship between arthritis and the inflammatory bowel diseases has not been fully clarified, although both an immune mechanism and articular infection (either primary or secondary to intestinal infection) have been implicated. In recent years the importance of a genetic role in the evolution of enteropathic arthropathies has been discussed. Approximately 90% of patients with ulcerative colitis and Crohn's disease who develop spondylitis or sacroiliitis demonstrate HLA-B27 antigen [60]. The most common radiographic changes are periarticular soft tissue swelling and osteoporosis.

Whole-body bone scintigraphy is useful for the demonstration of the asymmetrical pattern of peripheral joint involvement and the occurrence of sacroiliitis and spondylitis (Table 7.3).

Pinhole scintigraphy can again show clearly the irregular spotty, or patchy, uptake in the periarticular bones and joint space narrowing.

## 7.10 Other Arthropathies and Related Conditions

### 7.10.1 Behçet's Syndrome

This is an uncommon disorder characterized by the presence of recurrent oral and genital ulceration and relapsing iritis. It is named after Halushî Behçet, a Turkish dermatologist who described it in 1937. The disease is more common in Mediterranean countries and Japan. Diagnosis is made by the presence of recurrent aphthous oral ulcers along with two of the following: (1) recur-

rent genital ulcers, (2) uveitis or retinal vasculitis, and (3) cutaneous pustules or erythema nodosum or cutaneous pathergy and synovitis. Patients with a European heritage (e.g., North America) seldom have a cutaneous pathergy; instead, an association with the following may be added: large vessel vasculitis, meningoenophalitis, or cerebral vasculitis [61]. Arthritis occurs in nearly one half to three quarters of cases and is usually polyarticular. Sacroiliitis and spondylitis have rarely been noted and permanent changes are uncommon.

### 7.10.2 Costochondritis (Tietze's Syndrome)

This is a painful condition that is self-limited and short-lived. It was first described by Tietze in 1921 [62] and is also termed costosternal syndrome. The condition is common and affects the costochondral junction, usually in young individuals. Although trauma and infection have been proposed, the etiology remains unknown. Although any rib can be affected, the first and second ribs are most commonly involved [63].

The radiographic study is unremarkable in most of the cases. Bone scintigraphy simply reveals increased tracer uptake without specific features [64], but pinhole scintigraphy can demonstrate characteristic alterations [65]. During the active phase, intense tracer uptake may appear in the whole costal cartilage, which is enlarged, producing a "drumstick" appearance. Later, in the chronic phase, the abnormal uptake becomes reduced in size and localized in the costochondral junction. The latter is now shrunken owing to the resolution of the inflammation and shows a "comma-like" appearance.

### 7.10.3 SAPHO Syndrome

SAPHO syndrome is characterized by synovitis, acne, palmoplantar pustulosis, hyperostosis, and osteitis. There is tenderness and swelling of the small and large joints of the feet, ankles, knees, hips, sacroiliac joints, and shoulders. Bone

scanning may be helpful in diagnosing arthritis associated with the SAPHO syndrome. Tc-99m MDP scanning can detect signs of arthritis not seen with other imaging methods. This is because the arthritis is inflammatory in nature and does not always cause the bone erosion that is able to be detected by morphological imaging. Such findings on bone scanning, along with presence of hidradenitis, can also lead to the correct diagnosis of SAPHO syndrome [66].

## 7.10.4 Synovitis

### 7.10.4.1 Transient Synovitis (See also Chap. 4)

Transient synovitis is a self-limited, non-specific, inflammatory joint disease of transient nature among children. Other terms for the condition of the hip are irritable hip syndrome, observation hip, transitory arthritis, transitory coxitis, and simple serous coxitis. Boys are affected much more often than girls since it is found most frequently in boys between 5 and 10 years of age. It preferentially affects the hip, or knee, and subsides without antibiotics. The etiology has not been firmly established, but the most likely mechanisms include viral infection and a hypersensitivity reaction to infection occurring elsewhere in the body.

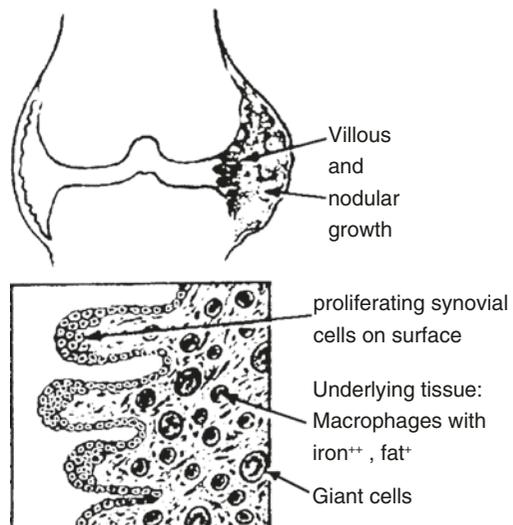

The basic radiographic abnormality is capsular distension, and in the majority of patients, no abnormalities are detected. Using three-phase bone scanning, transient synovitis demonstrates diffusely increased joint activity on the blood flow and blood pool images. On the delayed images, there is diffusely increased tracer uptake in the subchondral layers of periarticular bones covered with the synovium. The increased tracer uptake in the subchondral bone in synovitis has been accounted for by the increased blood flow through the anastomotic vascular channels induced by hyperemia in the inflamed synovium [67]. The degree of uptake is minimal, barely delineating the femoral head and acetabular fossa. This may be so subtle so that it can hardly be recognized on planar images. Pinhole imaging, however, can identify subtle changes [68]. Other patterns include normal or decreased uptake [69, 70].

### 7.10.4.2 Synovitis in Renal Transplantation

Following a renal transplant, or during long repeated hemodialysis, acute or chronic synovitis may supervene [71]. Generally the articular inflammation is simple, but occasionally infection has been reported [72]. Radiographically, the inflamed joint capsule is distended, and the periarticular soft tissues are swollen when the process becomes chronic. The joint space is narrowed, and the periarticular bones are diffusely osteoporotic (usually mild to moderate). Pinhole scintigraphic changes are much more similar to those noted in other types of synovitis, although they are usually mild unless complicated with an infection.

### 7.10.4.3 Pigmented Villonodular Synovitis

Pigmented villonodular synovitis (PVNS) is a chronic, inflammatory process of the synovium that causes synovial proliferation. A swollen joint with lobular masses of synovium occurs (Fig. 7.14), which causes pain and joint destruction. The condition affects individuals in their third to fourth decade of life and in most cases is monoarticular, predominantly affecting the knee

**Fig. 7.14** Pathological changes of pigmented villonodular synovitis (from [78] with permission)

(80%), followed by the hip and ankle. It is rarely polyarticular [73]. Scintigraphically, non-specific activity is seen periarticularly [74–76]. Tl-201 has also been reported to accumulate in this condition [77].

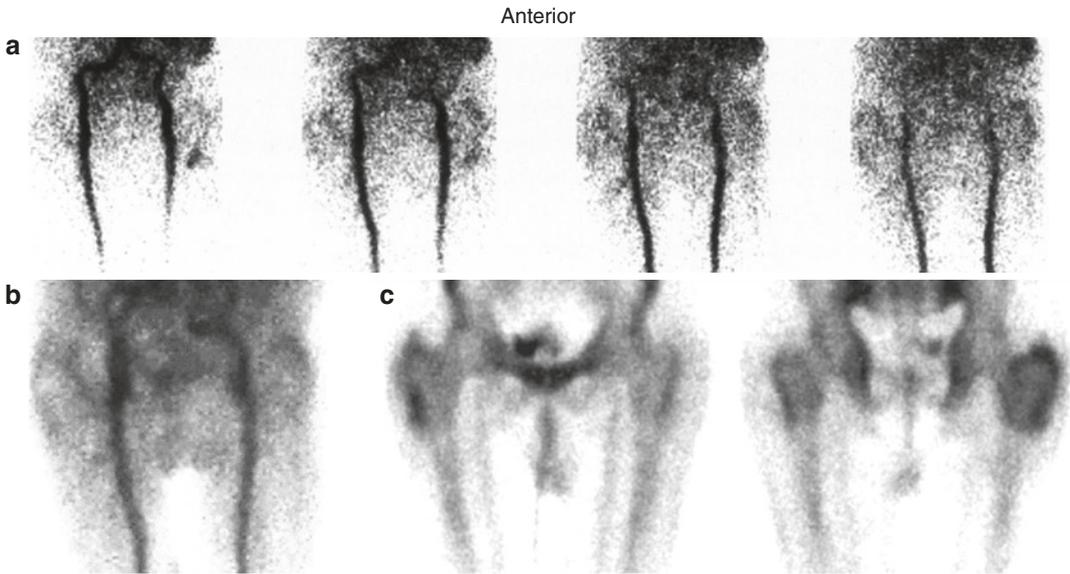

---

## 7.11 Periarticular Soft Tissue Syndromes

Periarticular soft tissue syndromes such as tenosynovitis, bursitis, and plantar fasciitis are characterized by local pain, tenderness, and swelling in the bursa, tendon sheath, or enthesis (the insertion of tendon, ligament, or capsule into the periarticular bones). Individual lesions may present as bursitis, tenosynovitis, capsulitis, fibrosis, or calcification. Trauma and repeated physical irritation are the common causes of this painful inflammation in the periarticular soft tissue structures. Idiopathic lesions are not rare. Standard radiography often plays a decisive role in the diagnosis of bursitis, tenosynovitis, and plantar fasciitis. Ultrasonography can play a crucial role in confirming the diagnosis of bursitis and in guiding needle aspiration. Bursitis shows abnormal amounts of fluid in the bursae and the associated synovial hypertrophy on ultrasound [79, 80]. In these conditions planar bone scanning may reveal increased tracer uptake in the regions of the involved bursa, tendon, or enthesis. However, the anatomical site of a lesion is extremely difficult to assess by planar imaging. In contrast, pinhole scintigraphy can reveal the anatomy of a lesion so that it points to the diagnosis of bursitis or tenosynovitis. SPECT/CT has revolutionized the role of nuclear medicine to diagnose these conditions and is the preferred scintigraphic modality. It should be noted that, in bursitis and tenosynovitis, bone scintigraphy may reveal intense tracer uptake when secondary erosion, reactive osteitis, and sclerosis in the neighboring bone are present. These secondary bone alterations are seen in association with trochanteric bursitis, subdeltoid bursitis, supra-acromial bursitis, sub-acromial bursitis, sub-Achilles tenosynovitis, and plantar fasciitis [81].

### 7.11.1 Diffuse Idiopathic Skeletal Hyperostosis (DISH)

Diffuse idiopathic skeletal hyperostosis (DISH), also known as Forestier's disease or senile ankylosing hyperostosis, is a common progressive noninflammatory bone and entheses disorder of unknown etiology affecting in the elderly population as it is estimated to occur in up to 30% of men older than the age of 50 years. It is characterized by calcification and ossification of the spinal and various extraspinal soft tissues, mainly entheses, ligaments, and joint capsules. These ossifications create intervertebral bridges [82–84]. It is thought to be most probably related to abnormal bone cell growth/activity reflecting the influence of metabolic factors that lead to new bone formation. Recent studies confirm that patients with DISH have a greater body mass index and higher serum uric acid levels and are more likely to have diabetes mellitus [85]. The classical site of involvement is the vertebral column with right anterolateral soft tissue ossification being the most characteristic feature. In the thoracic spine, the right side is preferentially involved. Although patients may be asymptomatic, back pain and spinal stiffness may develop. However, the disease is not limited to the spine and may affect multiple peripheral sites independently. Extraspinal manifestations may also be present and include neurologic symptoms and increased risk of heterotopic ossification after total hip arthroplasty. Prophylaxis to prevent heterotopic ossification may even be indicated for these patients [6]. Despite the significant prevalence, awareness of the disease is still low and often leads to misdiagnosis. Therapeutic approach is different in diseases with similar symptomatology, so it is important to raise awareness of this condition [86]. The diagnosis is made radiographically by the presence of osteophytes on the anterolateral margin of at least four (more recently three) consecutive vertebral bodies, the preservation of disc height, and the lack of changes associated with spondyloarthropathy or degenerative arthritis [82, 87]. The condition produces characteristic alterations in both spinal and extraspinal structures and is

**Fig. 7.15** (a–c) Trochanteric bursitis of the hips with increased flow, blood pool, and delayed activity in the right and to a lesser extent the left side

distinct from other spinal disorders including spondylosis deformans, intervertebral osteochondrosis, and ankylosing spondylitis. SPECT/CT is an important modality in identifying the condition and differentiating it from other causes of increased uptake on bone scan (see Chap. 10, Fig. 10.7).

### 7.11.2 Septic Bursitis

This condition may result from penetrating trauma, extension from a nearby septic arthritis or bacteremia. The superficially located bursae (e.g., the bursae of the olecranon and patella) are more commonly involved than the deep bursae (e.g., the trochanteric bursae). This condition may be confused with septic arthritis [88]. Trochanteric bursitis most frequently occurs in elderly and obese patients, and its presentation may require a bone scan to exclude a traumatic cause for the pain. A history of frank trauma can usually only be elicited in about 25% of patients, although Allwright et al. [89] suggested that it might be caused by inflammation or related to gluteal tendon insertion strain and associated periosteal reaction. In addition to the general fea-

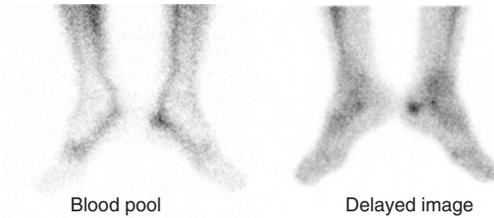

tures presented above, the authors described the characteristic scintigraphic findings of this condition on delayed images: a short linear band of moderate uptake confined to the superior and lateral aspects of the greater trochanter (Fig. 7.15).

### 7.11.3 Septic Tenosynovitis

This condition also results from penetrating injuries, or the spread of infection from a contiguous injury, and generally involves the flexor tendons of the hands and feet of diabetic patients. Early diagnosis is important to avoid complications particularly tendon necrosis and extension of infection to the adjacent joints [88].

### 7.11.4 Plantar Fasciitis

This condition, also known as calcaneal periosteitis, can occur as an isolated entity such as occupational injury and degenerative changes, or it may accompany spondyloarthropathies. It causes heel pain and can be easily diagnosed by planar or pinhole multiphase bone scan by identifying focal usually subtle increases blood pool

**Fig. 7.16** Plantar fasciitis on bone scan. There is linear increased blood pool activity along the plantar aspect of the feet. On delayed images there is a focus of increased uptake in the calcaneus in the left foot but no abnormal uptake in the right foot. This illustrates the two classic scintigraphic patterns of plantar fasciitis

and delayed uptake at the site of insertion of the long plantar tendon into the calcaneal base (Fig. 7.16).

## 8.1 Introduction

Bone marrow imaging has an important role in evaluating specific aspects of bone marrow anatomy, physiology, and pathology. This chapter provides a brief review of bone marrow structure and function essential to the understanding of basic principles of bone marrow radionuclide imaging and its clinical uses. Imaging bone marrow using indium-111 chloride, technetium-99m (Tc-99m)-labeled microcolloids, or Tc-99m-labeled monoclonal antigranulocytic and antimyelocytic antibodies is presented. Results of studies evaluating bone marrow scanning in several disease processes are summarized. Special attention is paid to the importance of bone marrow scintigraphy in inflammatory bone disease.

## 8.2 Development and Structure of Bone Marrow

The bone marrow is the principal hematopoietic tissue in the adult human being and contains the great majority of the hematopoietic stem cells and the hematopoietic inductive microenvironment that triggers differentiation of the stem cells into each blood cell type, characteristic of the diverse cell lineages such as myeloid (granulocytic, monocytic, and erythroid cell) and lymphocytic series of cells. Bone marrow is the soft tissue that lies in the spaces between the trabeculae of bones (Fig. 8.1). Bone marrow

**Fig. 8.1** Histologic section from a biopsy of an adult illustrating active hematopoietic tissue (*arrows*) with hematopoietic cells

**Table 8.1** Bone marrow composition

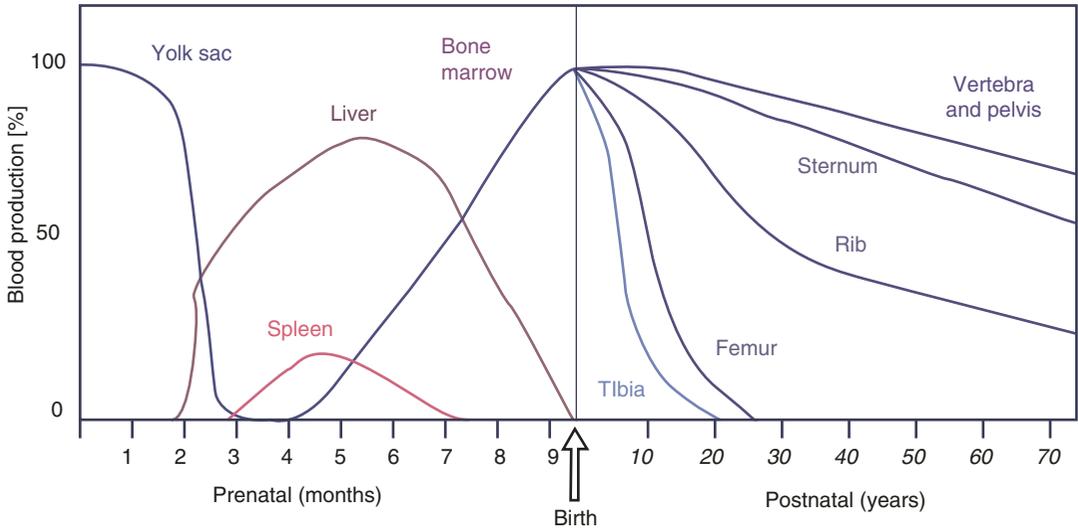

Component	Red marrow (%)	Yellow marrow (%)
Water	40	15
Protein	20	5
Fat	40	80

weighs approximately 3000 g in normal adult men and 2600 g in women. There is a dual blood supply to the bone marrow consisting of a periosteal capillary network and a nutrient artery that penetrates the bony shaft and divides into multiple branches in the marrow tissue. The blood flow through the bone marrow has been estimated to be about 10 ml/min/100 cm<sup>2</sup> in normal volunteers, as assessed with positron emission tomography using a <sup>15</sup>O-labeled CO<sub>2</sub> steady-state technique [1].

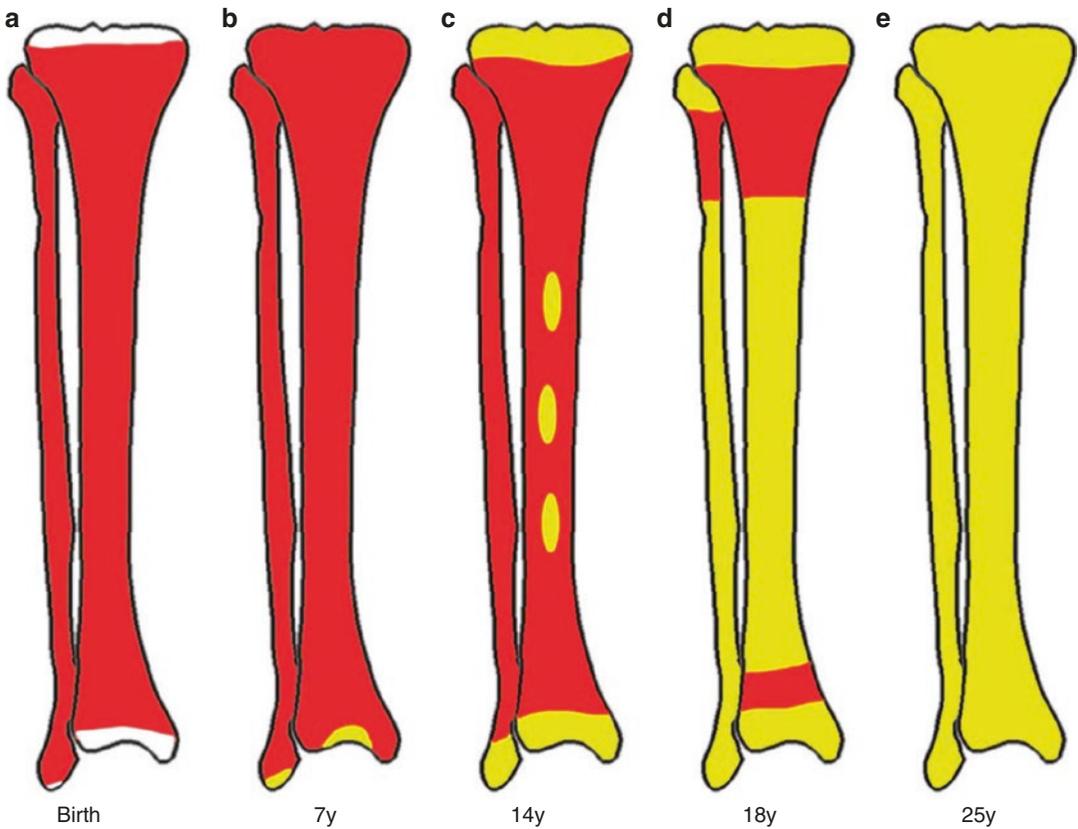

Bone marrow generally consists of several elements, including blood vessels, nerves, mononuclear phagocytes, stem cells, blood cells at different stages of maturation, and fat [2]. There are two types of marrow, red and yellow. The red marrow has active hematopoietic cells, while the yellow marrow consists mainly of fat and is not hematopoietically active (Table 8.1).

The function of bone marrow is to provide blood cells, based on the body's needs. Active bone marrow is present in adults in the pelvic bones (34%), vertebrae (28%), cranium and mandible (13%), sternum and ribs (10%), and proximal ends of humerus and femur (4–8%) [3]. Considerable changes are known to occur in the site and nature of hematopoiesis at different stages of development from embryo to adult. Figure 8.2 illustrates the sites of pre- and postnatal hematopoiesis.

The various blood cells develop from stem cells by multiplication, differentiation, orderly maturation, and release of mature cells from the bone marrow to the peripheral circulation. From 20 weeks of fetal life, the bone marrow becomes increasingly active in blood cell formation, and it constitutes the main hematopoietic organ at birth. During the first 2–3 postnatal years, the bone marrow shows very active hematopoiesis in all bones in the body. During childhood there is a gradual replacement of active, hematopoietic (red) marrow by relatively inactive, fatty (yellow) marrow. This change starts in the diaphyses of long bones and extends toward the epiphyses (Fig. 8.3). In early adulthood, active

**Fig. 8.2** Relationship between hematopoiesis of the liver and bone marrow before birth

**Fig. 8.3** Bone marrow distribution in a long bone illustrating changes during development over the years till the adult pattern is reached by about 25 years of age: (a) birth, (b) 7 years, (c) 14 years, (d) 18 years, (e) 25 years

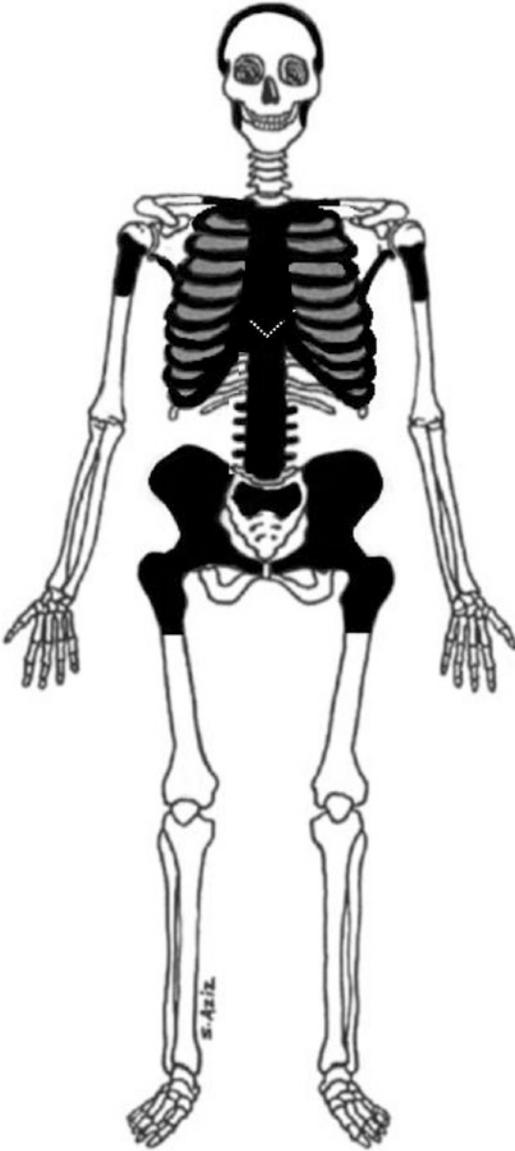

hematopoietic marrow is confined to the epiphyses of the long bones and all areas of the flat bones (axial skeleton) such as the sternum, ribs, cranium, vertebrae, and pelvis. Even in these “active” hematopoietic tissues, fat cells constitute approximately half of the total marrow tissues. The red and yellow marrow each constitutes half of the bone marrow weight. Since half of the red marrow is fatty, 75–80% of the total bone marrow in the adult human is virtually adipose tissue [1]. The hematopoietic cells in the red marrow gradually recede with advancing age from about 60% in the first decade to about 30% in the eighth decade of life [2]. When there is an increased need for blood cell formation in response to a hematological stress (e.g., hemolytic anemias), there is an expansion of active hematopoietic tissues to the areas containing predominantly fatty, yellow marrow and sometimes to the liver and the spleen causing “extramedullary hematopoiesis.” The hematopoietic cells in the extramedullary hematopoietic foci develop from the stem cells which migrate to those sites from the bone marrow via the circulating blood [4].

---

### 8.3 Conversion and Reconversion

Bone marrow starts hematopoiesis in the fourth intrauterine month. It overrides the liver in this function by the sixth month and becomes fully responsible for hematopoiesis by birth [5]. Normally at birth almost the entire fetal marrow space is occupied by red (hematopoietic) marrow except the cartilaginous epiphyses (Fig. 8.2) which later contain red marrow (on ossification) during the first few months of life. The conversion from active red to yellow, non-hematopoietically active marrow starts in

the immediate postnatal period, although it may begin just before birth in the terminal phalanges of the feet and hands. The conversion is a steady and progressive process that occurs at different rates in different bones as well as within an individual bone. The rate of conversion is fastest in the femora, followed by the ribs, sternum, and vertebrae. Within the long bones, it is fastest in the midshaft. This process begins in the extremities and progresses, in general, from peripheral to central skeleton and from diaphyseal to metaphyseal regions in individual long bones. One year after birth, the conversion is complete in the phalanges of the feet and hands. By the age of 7 years, conversion is significant in the distal epiphyses of long bones, and by age 12–14 years, conversion is clear in the midshaft of long bones with steady progress subsequently until the age of 25 (Fig. 8.4), by which point the conversion is complete in all bones, leaving red marrow in the vertebrae, sternum, ribs, pelvis, skull, and the proximal portions of femora and humeri. A small amount may be detected in the calcaneus. This normal adult pattern of hematopoietic bone marrow is not consistent, and variations are frequently encountered. Some adults, for example, show red marrow in the distal third of the femora and humeri or even sometimes in the entire shafts. Small islands of red marrow may also persist within the fatty marrow and are probably the basis of reconversion. Furthermore, with increasing demand for red cells, and due to certain pathological conditions (Table 8.2), reconversion of yellow to red marrow may take place. This process follows the reverse order of the initial red to yellow marrow conversion. It starts in the axial skeleton, followed by the extremities in a proximal to distal manner [5–7]. This process of reconversion is important since it also contributes to the variable distribution of bone marrow.

**Fig. 8.4** Adult bone marrow distribution. This pattern is not consistent, and there is natural variation which may be altered by many pathological conditions

## 8.4 Alterations to Bone Marrow

Normal variations of the distribution of active bone marrow have been established. A more recent study of 16 normal subjects (aged between 8 and 57 years) using 3.0 Tesla MRI confirmed significant normal

**Table 8.2** Causes of reconversion of yellow to red marrow leading to alterations of marrow distribution

1. Chronic anemia, particularly hemolytic

8. Leukemia
9. Orthopedic surgery
10. Fractures
11. Infections
12. Possibly elevation of surrounding temperature

variations of marrow composition [8]. In addition to the variability of marrow distribution at different ages and among adults, acquired alterations in the distribution of hematopoietic bone marrow may occur due to surgery, trauma, infection, and other destructive processes (Table 8.2). This is particularly important since it can explain the different findings from several nuclear medicine studies that might otherwise be thought to be abnormal (due to infection or replacement of bone marrow by an infiltrative processes) [5–7, 9, 10].

## 8.5 Imaging of Bone Marrow

Many imaging techniques are being increasingly employed and explored in order to determine the anatomical distribution of hematopoietic tissues in the bone marrow and other organs and to evaluate their significance in the diagnosis and management of various hematological and bone disorder (Table 8.3). MRI and several scintigraphic modalities are commonly used to image bone marrow for evaluation of its status, diagnose diseases affecting bone and bone marrow, as well as to differentiate certain conditions such as infection from infarct. Depending on the clinical problem, the appropriate modality is selected. MRI has become the preferred modality in many clinical

**Table 8.3** Clinical uses of bone marrow imaging

Identifying marrow replacement by primary or secondary tumors
Determination of amount of active marrow after radiation and chemotherapy when further therapy is being considered

Assess expansion of functional bone marrow
Detection of extramedullary hematopoiesis
Evaluation of bone marrow transplantation

situations in adults and pediatric populations. MRI is a highly sensitive technique for imaging normal and abnormal bone marrow and can detect differences between normal bone marrow and fatty, fibrotic, hypercellular, and hemosiderotic bone marrow [11]. SRIR sequence provides higher tissue contrast and is particularly useful in evaluating bone marrow. Dual-energy CT virtual noncalcium technique has also been proposed in bone marrow imaging since it can subtract calcium from cancellous bone, allowing bone marrow assessment and potentially making post-traumatic bone bruises of the knee detectable with CT [12]. Scintigraphic imaging however provides a whole-body picture of the functioning hematopoietic tissue and is used in other situations and in conjunction with other scintigraphic procedures for accurate diagnosis of certain conditions such as complicated skeletal infections (Table 8.4).

## 8.6 Bone Marrow Scintigraphy

Bone marrow scintigraphy is sensitive and can depict a functional image of the bone marrow using radiopharmaceutical agents that localize in the bone marrow such as Tc-99m-labeled sulfur colloid, Tc-99m nanocolloid, and monoclonal antibody (Tc-99m MAb). Considering the functional aspects of bone marrow, scintigraphy should be ideally capable of imaging the patho-

physiological changes relating to the different functional cell lineages [13–17] such as erythropoietic imaging, reticuloendothelial imaging (RE cell imaging), and granulopoietic imaging (Table 8.5).

A commonly used radiotracer used in bone marrow imaging is technetium-99m (Tc-99m)-labeled colloids which, when injected into the blood, are rapidly cleared by the phagocytic cells

in the blood, bone marrow, and liver (Kupffer cells) and by the RE cells in the spleen. In most nuclear medicine laboratories, Tc-99m sulfur colloid (particle sizes ranging from 100 to 1000 nm) is used. It has been found that in normal adults, about 5% of the injected radioactivity is distributed in the RE cells of the bone marrow, 80–85% in the liver, and 10% in the spleen [13, 14]. As a result, bone marrow in the lower thoracic and upper lumbar spine cannot be properly visualized by Tc-99m colloid imaging due to overlapping radioactivity over the liver and the spleen (Fig. 8.5). Tc-99m sulfur colloid that is improperly prepared or is more than approximately 2 h old degrades image quality, potentially causing erroneous conclusions.

In Tc-99m-labeled monoclonal antibodies (Tc-99m MAb) directed against non-specific iron-reacting antigen 95 (NCA-95), a differentiation antigen of granulopoiesis has been obtained [13, 18–20] and clinically applied for the imaging of granulopoietic marrow [21–23]. Using this complex (Tc-99m Ab), bone marrow scans of much-improved quality have been obtained without significant superimposition of the liver and spleen, and the radioactivity over the bone marrow was found to be 2–4 times that with Tc-99m colloid [22, 23]. High-quality images with homogeneous distribution of Tc-99m Ab in hematopoietic bone marrow have been obtained [13, 24].

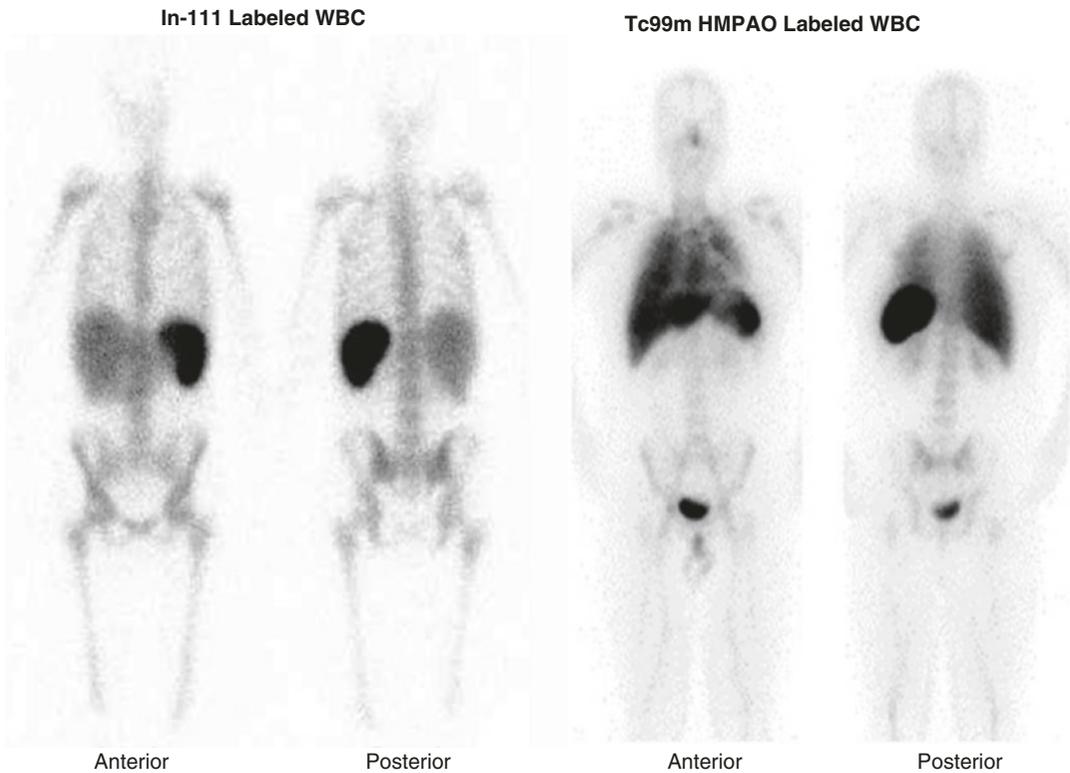

Indium-111 chloride has been used as a marrow imaging agent but with indifferent results, and the exact target of In-111 has not been properly identified. This radiotracer is produced in a cyclotron, has a half-life of 2.8 days, and emits photons with energies of 173 and 247 KeV. Approximately 1–5 mCi (37–185 MBq) of In-111 chloride is injected intravenously, and images are obtained 24–48 h later. Following intravenous injection, In-111 is rapidly complexed with serum transferrin and eliminated from the plasma with a half-life of 5 h [12–14]. About 30% of the In-111 is distributed to the bone marrow, 20% to the liver, 7% to the kidneys, 1% to the spleen, and the remaining all over the body without any specific tissue accumulation. A scintigraphic scan with In-111 shows a distribu-

**Fig. 8.5** Normal Tc-99m sulfur colloid whole-body scan. Note that bone marrow in the lower thoracic and upper lumbar spine cannot be properly visualized due to overlapping radioactivity over the liver and the spleen

tion of activity similar to that of Tc-99m-labeled colloids in patients with normal bone marrow [13, 15, 16].

Leukocytes labeled with either In-111 or Tc-99m are used for bone marrow imaging and are generally used for the localization of infections or abscesses [13, 25–27]. A study claimed that Tc-99m-WBC activity correlated better with hematopoietic cellularity than In-111 chloride activity [15, 26, 28]. However, tomographic techniques used with In-111-labeled granulocytes showed that the bone marrow to liver

**Fig. 8.6** Normal In-111-labeled WBC (a) and normal Tc-99m-WBC (b) whole-body scans

activity ratio was higher than that for Tc-99M-WBC indicating that with In-111-labeled leukocytes, the activity over the liver is significantly less than that of colloidal agents [13, 27–29] (Fig. 8.6).

$^{18}\text{F}$ -FLT fluorothymidine has also been used successfully to determine the degree of bone marrow cellularity and the numbers of cycling cells in patients with bone marrow disorders. This radiotracer may be helpful to distinguish separate hematological disorders.  $^{18}\text{F}$ -FLT uptake is related to the rate of DNA synthesis and increases with higher proliferation rates of cells in many types of cancer. Uptake of  $^{18}\text{F}$ -FLT in bone marrow is common, and visualization and quantification of the activity of the bone marrow compartment helped distinguish different hematological disorders such as myelodysplasia, chronic myeloproliferative disorders, myelofibrosis, aplastic anemia, or multiple myeloma. In a study on patients with several hematological disorders, a significant increase in  $^{18}\text{F}$ -FLT uptake was observed in all of the studied patients with

myelodysplasia and myeloproliferative disorders. In contrast, patients with myelofibrosis and aplastic anemia demonstrated a decline in bone marrow  $^{18}\text{F}$ -FLT uptake compared with healthy control subjects. Comparable results were observed in osteolytic lesions of patients with multiple myeloma [30].

F-18 FDG has been used to assess the aging effect on bone marrow metabolism. Furthermore it has been investigated along with MRI quantitatively for accurate calculation of metabolic activity of bone marrow [31].

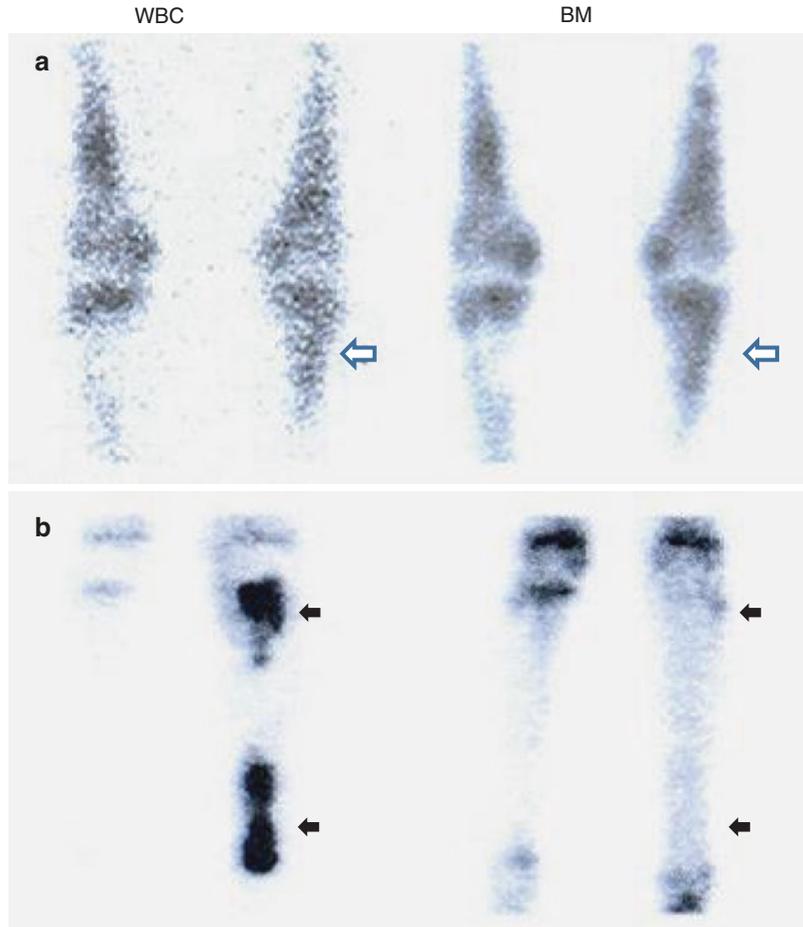

---

## 8.7 Clinical Uses of Bone Marrow Scintigraphy

### 8.7.1 Diagnosis of Skeletal Infections

Autologous-labeled leukocytes combined with sulfur colloid bone marrow scan are the current nuclear medicine gold standard for the diagnosis

**Fig. 8.7 (a–b)**  
 Representative images of dual WBC and BM studies (a) show matching uptake (arrows) negating the presence of skeletal infection while (b) demonstrating incongruent pattern of infection (arrows)

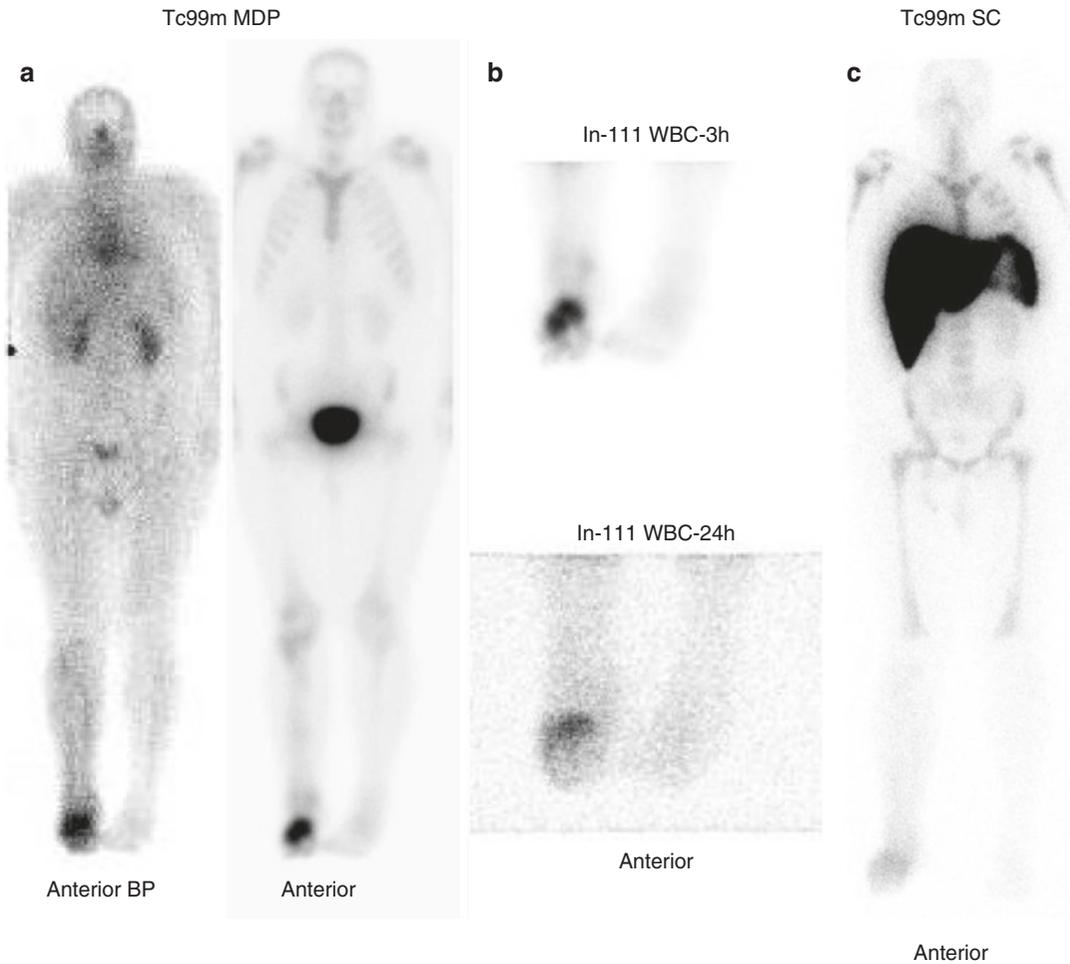

of most skeletal infections. However, its use can be problematic in relation to specificity since it is accumulating in normal active bone marrow. Overall, combining WBC imaging and technetium-99m (Tc-99M) sulfur colloid imaging provides an accuracy of approximately 90%. This combined approach is particularly useful for diagnosing osteomyelitis in violated bone suspected infection where altered marrow distribution may be present. If there is no labeled WBC activity in the region of interest, marrow imaging is not useful. The sulfur colloid image becomes photopenic within about 1 week after the onset of infection, so that the study should be interpreted cautiously in the acute setting. Labeled WBC accumulation in lymph nodes may cause false-positive interpretation, although nodal activity can usually be recognized because it is typically round, discrete, multifocal, linear in distribution, and often bilateral [32]. The bone marrow scan is

particularly helpful in diagnosis of infection following trauma including surgery, diabetic foot osteomyelitis, and in sickle cell disease patients. Congruent WBC and marrow finding excludes osteomyelitis, while incongruent pattern indicates osteomyelitis (Fig. 8.7).

### 8.7.1.1 Diagnosis of Diabetic Foot Osteomyelitis

Osteomyelitis and neuro-osteoarthropathy are limb-threatening complications of diabetic neuropathy with very different therapies. Distinguishing between them may be difficult, but it is important [33]. Labeled leukocyte imaging is the radionuclide procedure of choice for evaluating diabetic pedal osteomyelitis. FDG PET has shown accuracy in diagnosing diabetic foot osteomyelitis but has not replaced the labeled leukocyte technique. Labeled leukocytes accumulate in uninfected neuropathic joints, and

**Fig. 8.8** Tc-99m MDP bone scan (a), In-111-labeled white blood cell study (b), and Tc-99m SC bone marrow scan (c) for a patient suspected of having diabetic foot osteomyelitis. The studies show increased uptake in right midfoot on bone scan. On labeled WBC study, there is a

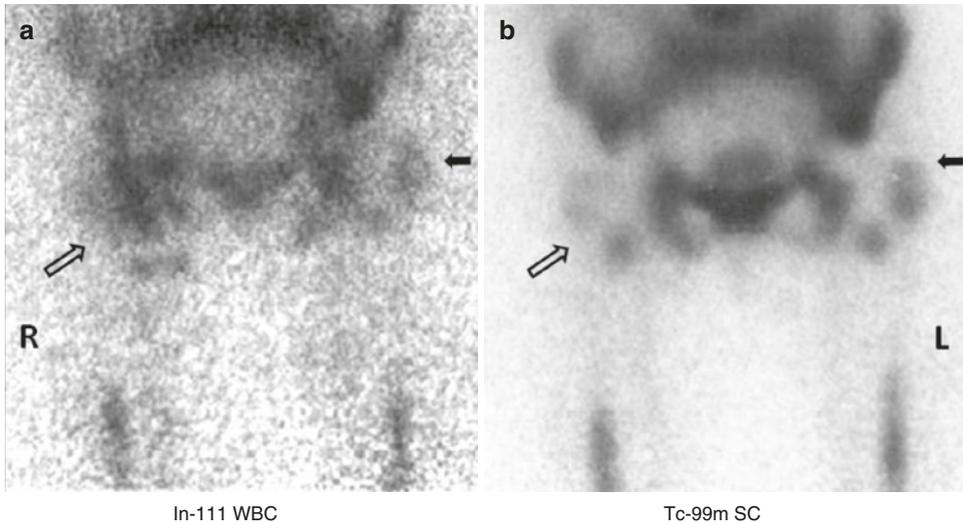

matching area of increased accumulation which decreased in intensity on 24 h image compared with 3 h image. SC study shows matching uptake indicating that the finding is not indicating osteomyelitis but rather due to neuro-osteoarthropathy

marrow scintigraphy may be needed to determine whether infection is present. Adding bone marrow scan when labeled WBC is positive is essential to verify the presence of osteomyelitis (Figs. 8.8 and 2.28 in Chap. 2). Currently dual WBC and colloid bone marrow SPECT/CT is the modality of choice as it is highly accurate, considerably improves detection, and helps in discriminating neuro-osteoarthropathy from osteomyelitis. Additionally adding CT provides

precise anatomical localization in the diabetic foot [34]. Alternatives to labeled leukocyte imaging include radiolabeled antibodies and radiolabeled antibiotics although their reported accuracies are variable (see also Chap. 2).

### 8.7.1.2 Diagnosis of Prosthetic Joint Infection

Leukocyte imaging (either with In-111 or Tc-99m) combined with bone marrow scan has

**Fig. 8.9** Labeled WBC and bone marrow studies of a patient with bilateral hip replacement. Labeled WBC image (a) shows accumulation in the right hip region and to a lesser extent in the left. Tc-99m SC bone marrow image (b) shows tracer uptake in the right hip region

incongruent with the abnormal uptake in WBC image (*open arrows*) representing the pattern of infection. On the left side, the colloid uptake is matching the WBC accumulation around the prosthesis (*solid arrows*) indicating no infection

high sensitivity and specificity for diagnosing prosthetic joint infection (Fig. 8.9) and currently is the procedure of choice for the evaluation of infected prosthetic joints [35, 36]. Bone marrow scan has also been used in conjunction with using Tc-99m sulesomab for patients with suspicious hip and knee arthroplasties. Adding Tc-99m nanocolloid bone marrow scan increased the specificity of Tc-99m sulesomab from 20 to 100% in a study of 27 patients [37].

### 8.7.1.3 Differentiation Between Bone Infarction and Acute Osteomyelitis in Children with Sickle Cell Disease

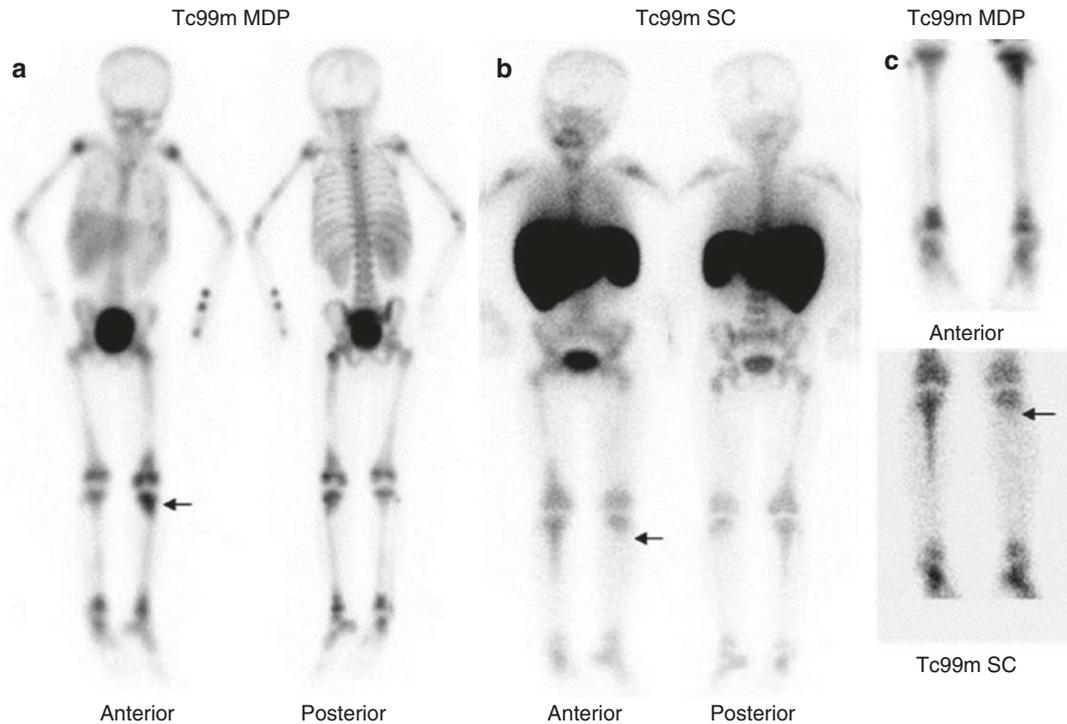

The differentiation of bone infarction from acute osteomyelitis in patients with sickle cell disease is challenging since the clinical presentations of the two conditions are similar, and imaging and

laboratory studies are of limited value. Adding bone marrow scan to bone scan resolves most of the dilemma faced in many cases to differentiate osteomyelitis from the more common bone necrosis [38]. Figure 8.10 illustrates osteonecrosis in a patient with sickle cell anemia.

### 8.7.2 Assessment and Follow-Up of Gaucher's Disease

Gaucher's disease is a lipid storage disease secondary to deficiency of a lysosomal hydrolase, glucocerebrosidase. This leads to deposition of glucocerebroside particularly in white blood cells and involves the spleen, liver, bone marrow, kidneys, lungs, and brain.

CT, bone scan, and bone marrow scans are all used to evaluate the extent and severity of the disease as well as in the follow-up. The Tc-99m SC

**Fig. 8.10** Bone scan and bone marrow scan for a 12-year-old patient with sickle cell disease and pain in the left knee region for 4 weeks. Bone scan (**a**) shows increased uptake in the proximal left tibia (*arrow*). Tc-99m sulfur bone marrow scan (**b**) shows uptake in the proximal end of the

left tibia only partly matching the abnormal uptake of bone scan with the lower part of the bone abnormality having no matching uptake on bone marrow images (*arrow*) particularly clear on spot images (**c**) confirming healing phase of avascular necrosis rather than infection

scan was found to be more effective than CT and MDP bone scans in overall assessment of the severity of bone marrow involvement. The disease causes infiltration of bone marrow and reticuloendothelial organs such as the liver and spleen. The effect of replacing variable areas of bone marrow leads to bone marrow expansion and may lead to bone infarcts. Accordingly, Tc-99m sulfur bone marrow may demonstrate three distinct patterns of uptake: peripheral expansion of normal marrow (Fig. 8.11), greater marrow expansion with patchy areas lacking uptake (Fig. 8.12), and greater loss of uptake with retention of the nuclide in other reticuloendothelial organs and circulation [39].

### 8.7.3 Treatment Planning in Cancer Patients

Bone marrow scan has proven useful in radiation therapy treatment planning of some tumors. CT scan is used for planning in patients receiving intensity-modulated whole-pelvic radiation therapy (IM-WPRT). Tc-99m SC bone marrow SPECT was found useful if added to CT in treatment planning process to reduce the volume of marrow irradiated and reducing the dose to the areas of high active bone marrow identified by the SPECT component. Tc-99m SC SPECT is a useful adjunct to CT in planning for IM-WPRT [40].

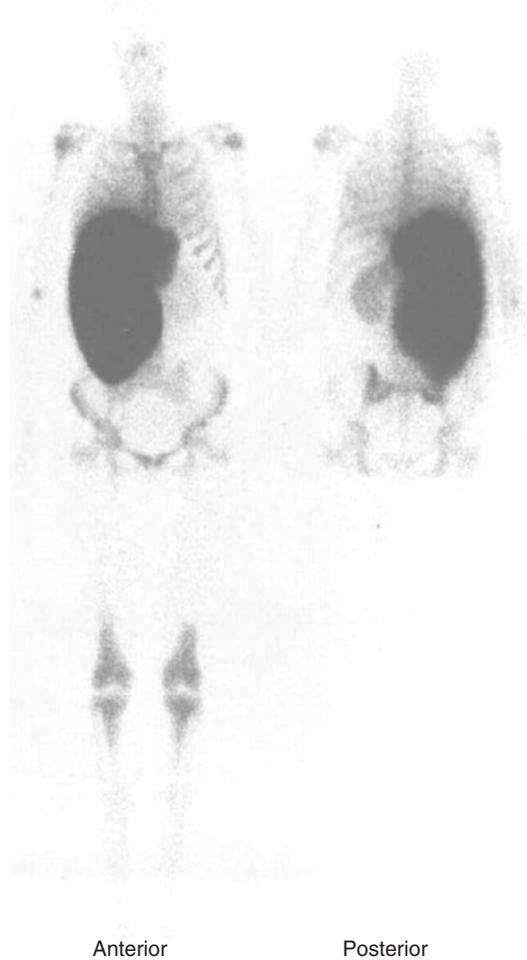

**Fig. 8.11** Tc-99m sulfur colloid study of a patient with Gaucher's disease showing patterns of peripheral expansion of normal marrow

It has also been suggested that bone marrow scan can be useful in patients with advanced metastatic disease of prostate cancer, especially those who are anemic, by identifying those patients at risk from myelosuppressive therapy [41].

#### 8.7.4 Paget's Disease

Normal hematopoietic bone marrow may be replaced by loose fibrous connective tissue,

**Fig. 8.12** Tc-99m sulfur colloid study of a 34-year-old male with known Gaucher's disease. Images demonstrate marrow expansion with patchy cold areas

and at late stages, it will be restored. Accordingly on radionuclide bone marrow scan, the appearance of bone marrow varies depending on stage of the disease. In active lytic phase, bone marrow is not visualized in the bone involved since it is replaced. In mixed phase, it will appear as nonuniform uptake. The sclerotic burned-out phase with new mature bone formation marrow will be again seen in the affected bone. Understanding these changes and patterns on bone marrow scans is crucial for proper interpretation of labeled WBC studies (see Chap. 3, Fig. 3.7).

### 8.7.5 Bone Marrow Tumors and Bone Marrow Extension

Bone marrow scintigraphy has little value in the detection of skeletal metastases since it is restricted to those areas of the skeleton containing active marrow [42, 43]. However, in 25 of 30 patients with bone metastases from prostatic carcinoma, red bone marrow extension was observed by bone marrow scintigraphy [44]. Bone marrow extension was also seen in five of eight patients with prostatic carcinoma without bone metastases in the same study. Regeneration and extension of marrow after ablative doses of radiotherapy can be assessed with bone marrow scan [45]. Similarly, abnormal bone marrow extension was observed in 61% of the patients with breast cancer. This finding seems to represent a reaction of the reticuloendothelial system to the disease dissemination—even microscopic—and, as such, to have prognostic value [46]. Bone marrow scintigraphy using anti-granulocyte antibodies is highly sensitive in detecting Hodgkin's lymphoma and high-grade NHL [47]. Bone marrow scanning, using Tc-99m antigranulocyte antibody, has also been suggested for evaluation of the extent of marrow fibrosis in patients with renal osteodystrophy by evaluation of bone marrow expansion [48].

### 8.7.6 Other Uses

Bone marrow scintigraphy combined with bone scan has been proposed in the diagnosis of active sacroiliitis. Bozkurt et al. studied 31 patients who were clinically suspected to have sacroiliitis using bone and bone marrow scans. Both visual and quantitative assessments of MDP uptake and a visual assessment of the sulfur colloid uptake in the sacroiliac joints were performed. Increased Tc-99m MDP uptake with normal/decreased sulfur colloid uptake was the most common scintigraphic pattern seen in the acute phase of sacroiliitis cases in which radiographic findings were normal or slightly changed. In at least eight patients, bone marrow uptake of sulfur colloid was clearly decreased which further supports the diagnosis [49].

There are three major types of extrasosseous calcification: dystrophic, metastatic, and heterotopic. Dystrophic calcification involves the deposition of calcium in damaged tissue and is not usually associated with hypercalcemia. In metastatic calcification, calcium deposition occurs in normal tissue due to hypercalcemia and/or hyperphosphatemia due to a variety of disease conditions, particularly metabolic disorders following renal failure. Heterotopic ossification describes a unique condition that may, or may not, follow trauma and is due to a complex pathogenetic mechanism believed to be due to transformation of certain primitive cells of mesenchymal origin in the connective tissue septa within muscles into bone-forming cells. Bone scanning can detect all types of soft tissue calcification, usually serendipitously, in cases of dystrophic and metastatic calcification. In the case of heterotopic ossification, bone scanning has a more defined role in early diagnosis of the condition, in follow-up, and in determining the proper timing of surgical intervention. Cardiac calcinosis, which is one of the rare findings of metastatic calcification, can be fatal, and bone scanning can be a sensitive noninvasive method for its detection; this is in addition to the occasional discovery as an incidental finding on a bone scan performed for other reasons. Calcification of the skin, or calcinosis cutis, can occasionally be seen on bone scans, and familiarity with the findings and the patterns of other types of calcification help enrich the

diagnostic value of the bone scintigraphy. Scintigraphy is useful in evaluating the degree of muscle necrosis of rhabdomyolysis.

## 9.1 Introduction

Scintigraphy is able to detect certain soft tissue pathologies. Soft tissue calcification is an important example of a condition that can be suspected during diagnosis, or it can be found serendipitously when scintigraphy is performed during the investigation for another suspected pathology. Calcification of soft tissue can be seen using several scintigraphic studies; however, bone scan is the main scintigraphic modality that is able to visualize the condition. Pathological calcification can be classified into three major types: dystrophic calcification, metastatic calcification, and heterotopic bone formation. Certain forms, however, can be difficult to classify into these categories since they may involve more than one variety. One example is calcinosis cutis, which will be considered separately. Familiarity with the appearance of extraskelatal soft tissue calcification is important since it can help identify certain disease processes and aid in the differential diagnosis of a skeletal abnormality.

## 9.2 Dystrophic Calcification

This type of calcification occurs in the setting of normal serum calcium and phosphate levels. The primary abnormality is damaged, inflamed, neoplastic, or necrotic tissue. Tissue damage may be from mechanical, chemical, infectious, or other factors. Calcification usually is localized to a specific area of tissue which is injured, although it may be generalized in some disorders (Table 9.1). The mechanism appears to be loss of intracellular calcium in the injured cells with an

Rothmund-Thomson syndrome <sup>b</sup>

<sup>a</sup>A rare autosomal recessive disease, characterized by premature aging of connective tissues caused by a mutation in the gene RecQ helicase which is involved in DNA replication and cell reproduction

<sup>b</sup>A hereditary and familial disease characterized by short stature, cataracts, pigmentation of the skin, baldness, and abnormalities of the bones, nails, and teeth caused by a mutation in the gene RecQ helicase

increased calcium-binding capacity. Examples include calcification in infarcted myocardial muscle, atheromas, amyloid tissue, and fibrocystic disease of the breast and in the centers of tumors such as lymphomas, breast tumors, ovarian fibroma, hepatoblastoma, and other primary and metastatic tumors (Figs. 9.1 and 9.2). In lymphomas it is reported to occur after therapy, and only rarely before therapy, and it is more commonly seen in non-Hodgkin's lymphomas [1–6]. Benign and malignant breast disease, in

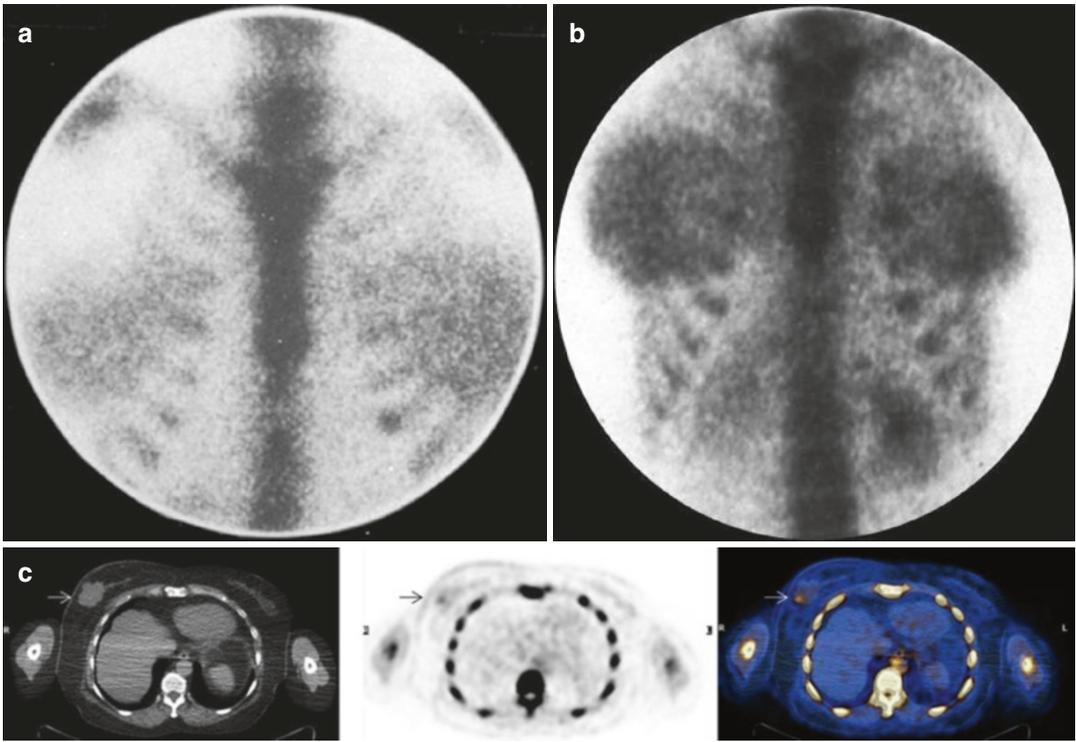

**a****b**

**Fig. 9.1** (a, b) Bone scan (a) showing calcification in a liver metastases in a patient with breast cancer. CT scan (b) illustrates the hepatic metastases

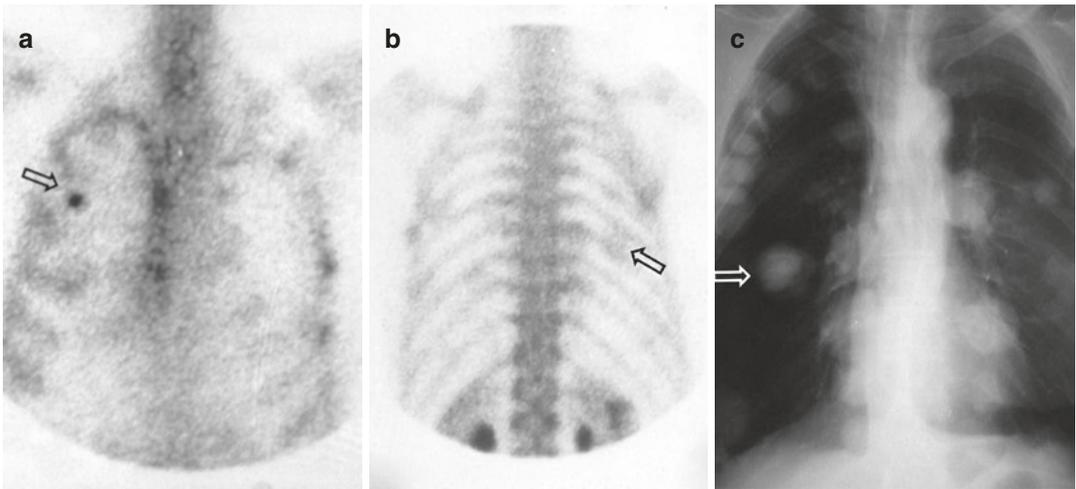

particular fibrocystic disease, commonly shows dystrophic calcification, which can be seen in many patients on mammography as patterns of microcalcification that can differentiate benign from malignant tumors [7]; it can also be seen incidentally on bone scans (Figs. 9.3 and 9.4). Certain skin tumors, such as pilomatrixoma (or calcifying epithelioma of Malherbe), have a particular tendency to calcify, the syringomas and basal cell carcinomas less frequently calcify. Arterial calcium deposits detected usually by radiography and sometimes noted on bone scans (Fig. 9.5) are considered to be a marker of sub-clinical atherosclerotic disease and an independent predictor of subsequent vascular morbidity and mortality [8].

### 9.3 Metastatic Calcification

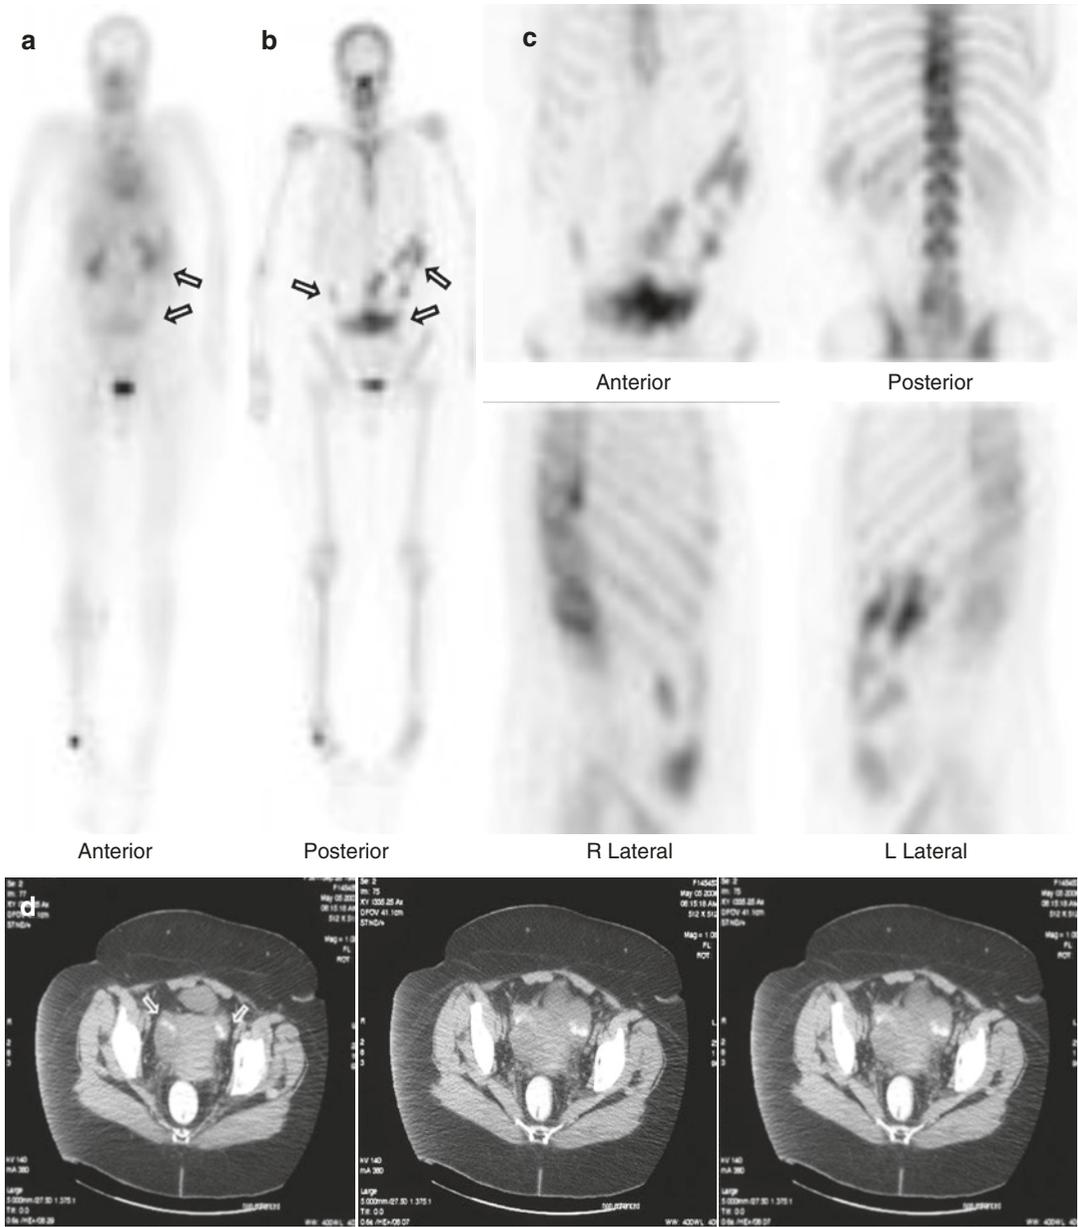

Metastatic calcification, first described by Virchow in 1855, describes the calcification of viable undamaged normal tissue as a result of hypercalcemia and/or hyperphosphatemia. This may be associated with an increased calcium phosphate product locally or systemically. This can be due to metabolic alterations such as with renal failure, hemodialysis, hypervitaminosis D, and hyperparathyroidism, or it may be due to increased bone demineralization resulting from bone tumors or disseminated metastases (Table 9.2). Therapy with phosphate, steroids, and calcium infusion has also resulted in metastatic calcification. Calcium deposition is frequently widespread. The calcifying process affects principally the blood vessels, peri-articular soft tissue, lungs, stomach, kidneys (Fig. 9.6), and myocardium and to a lesser extent the skin and skeletal muscles of the extremities. There are diffuse and nodular forms, with the diffuse form being more common [9–11]. Metastatic calcification, affecting the myocardium and lungs, is a frequent and potential lethal complication of

**Fig. 9.2** (a–c) Two examples of breast calcification due to fibrocystic disease seen incidentally on bone scans (a, b) and on F-18 NaF study (c) of a patient with right breast cancer showing tumor uptake (arrows)

**Fig. 9.3** (a–c) Anterior and posterior chest images of a bone scan (a–b) show dystrophic calcification (arrow) in lung cancer. Chest X-ray (c) shows the tumor (arrow)

**Fig. 9.4** Tc-99m MDP whole-body blood pool image (a) showing irregular areas of increased blood pool activity in the mid lower abdomen extending to the left side superolaterally (arrows). Whole-body delayed (b) and spot (c) images show intensely increased soft tissue uptake in the lower mid abdomen in a mass-like pattern and linear uptake in the left abdomen corresponding to blood pool finding (arrows). Additionally, there is a focus of soft tis-

sue uptake in the right abdomen (arrow). Spot images (c) of the abdomen showing clearly the soft tissue uptake. Representative sections of CT scan (d) show tumor masses containing calcification (arrows) foci. Tumor masses were found at sites corresponding to the location of soft tissue calcification noted on bone scan. This was later proven after surgery to be a mucinous cystadenocarcinoma of the uterus

Milk-alkali syndrome
Sarcoidosis
Calciophylaxis

chronic renal failure (Figs. 9.7 and 9.8), which is rarely detected before death because of the absence of specific radiographic abnormalities [11]. When metastatic calcification is periarticular, large deposits are frequently found around the large joints, such as the knees, elbows, and shoulders, with a symmetrical distribution. A specific form of metastatic calcification that currently has no definite treatment is calciophylaxis. This condition has a high morbidity and mortality rate, is often found

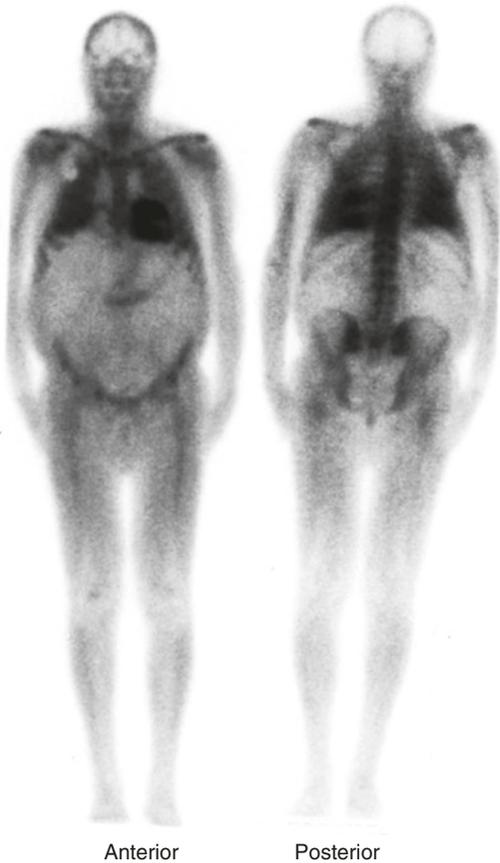

**Fig. 9.6** Metastatic calcification affecting kidneys of a patient with hypercalcemia

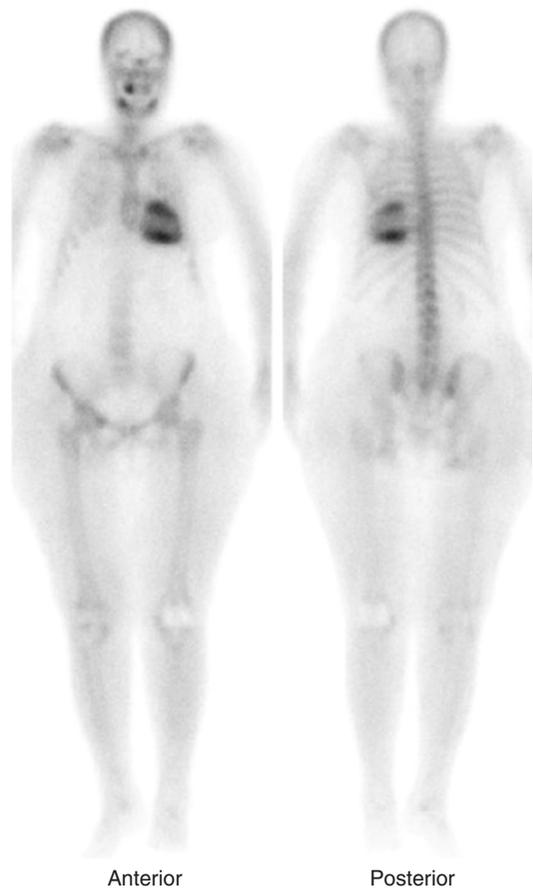

in patients with renal failure and is characterized by soft tissue calcification and painful skin ulceration. A serum calcium-phosphorus product of more than 60 mg/dl indicates a high risk for calciophylaxis. The diagnosis is made by an incisional biopsy showing calcification of the small, subcutaneous arteries [12]. The condition occurs in up to 4 % of patients with end-stage renal disease on hemodialysis or who have recently received renal transplant. However, it does not exclusively occur in ESRD and similar extraskeletal calcification can be seen in other conditions that result in hypercalcemic state including hypervitaminosis D, primary hyperparathyroidism, sarcoidosis and milk alkali syndrome.

Histologically it is characterized by medial arterial calcification. It also involves subintimal fibrosis and arterial occlusion in the absence of vasculitic changes. Subcutaneous or dermal vascular thrombosis may also be present leading to skin necrosis and ulceration which may lead to sepsis.

Many clinical factors and conditions have been associated with calciophylaxis. These include female gender, obesity (BMI >30) and high phosphorus level. Different medications are associated

**Fig. 9.7** Metastatic calcification in a patient with renal failure of long duration with diffuse Tc-99m MDP uptake in the lungs and myocardium and stomach uptake in the lungs, myocardium, and stomach on whole-body bone scan

**Fig. 9.8** Cardiocalcinosis of a 65-year-old woman with a history of long-standing chronic renal failure and hyperparathyroidism. Note the intense uptake in the heart noted on whole-body Tc-99m MDP bone scans

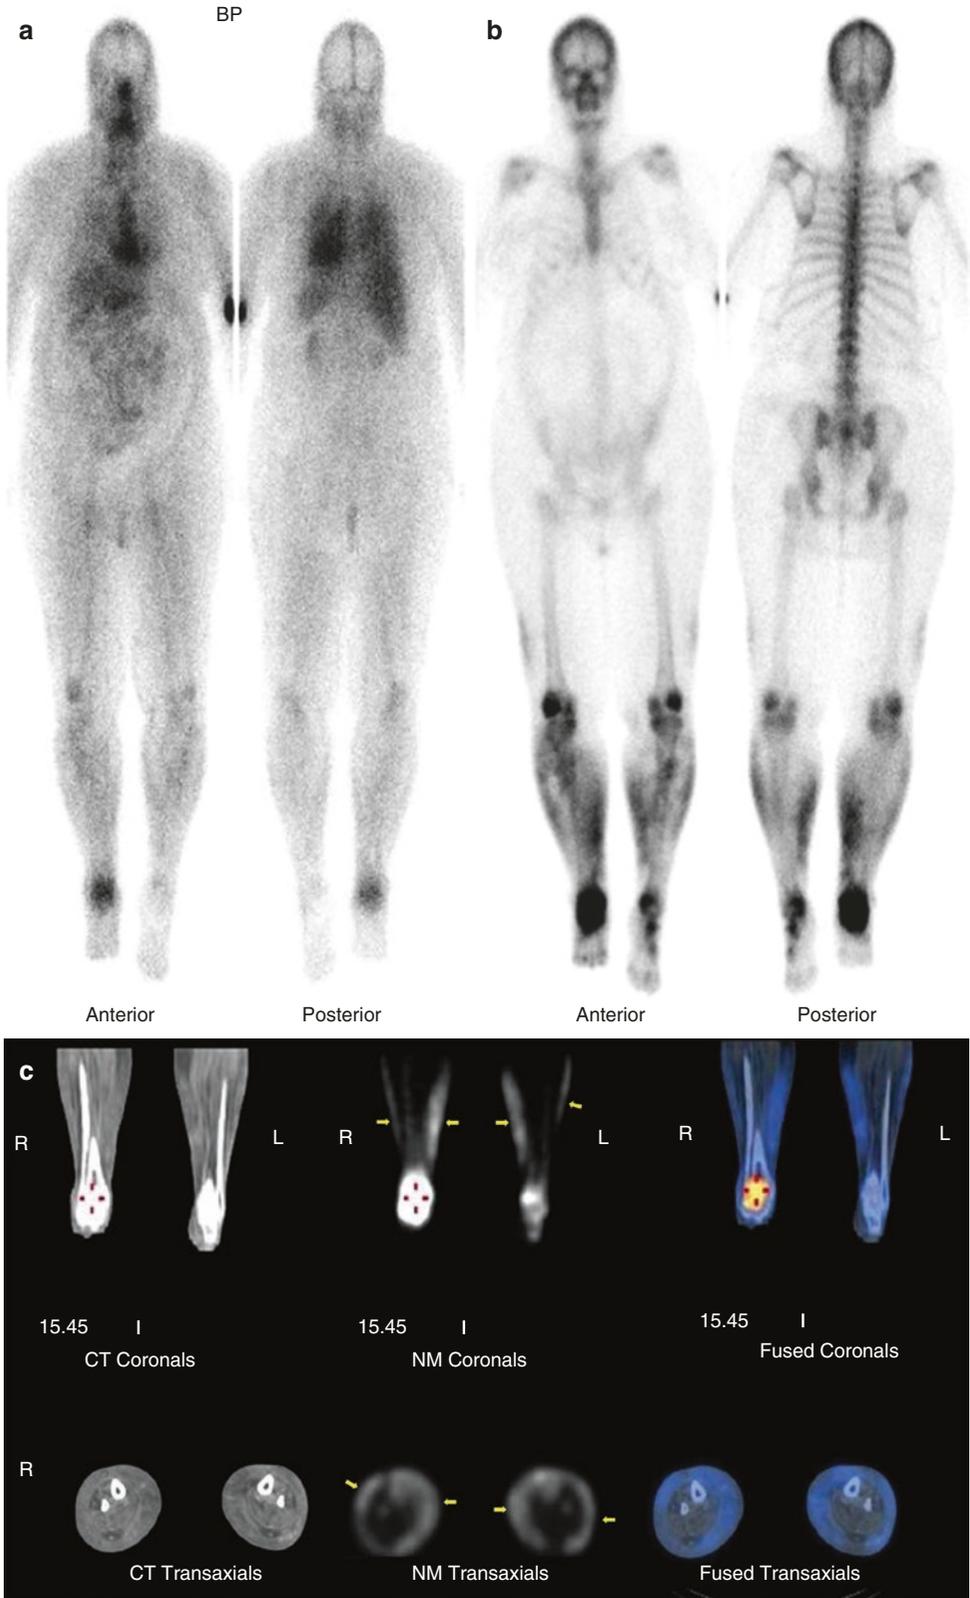

with increased risk of developing calciphylaxis like warfarin, calcium based binders and vitamin D analogues, and systemic steroids. Primary hyperparathyroidism and autoimmune conditions like rheumatoid arthritis, SLE, Sjogren's syndrome and Crohn disease have been reported in patients with calciphylaxis.

There is no specific diagnostic test of calciphylaxis and the diagnosis is clinical. Elevated serum calcium, phosphorus, PTH and the calcium-phosphorus product are observed in some patients, however, these abnormalities are not always present. The diagnosis is usually suggested by the characteristic necrotic skin lesions which typically appear as violaceous and/or black lesions. Skin biopsy is can be done for con-

firmation; however, there is a concern of poor healing of the biopsy site.

Many treatment strategies can be used depending on the severity of the disease. These include local wound care, control of calcium and phosphorus level, parathyroidectomy, and IV sodium thiosulfate. However, the response to these therapeutic modalities is poor and optimal treatment is prevention of this condition.

A three phase bone scintigraphy with technetium 99m methylene diphosphonate may have a role in the diagnosis of calciphylaxis (Fig. 9.9). However, the exact sensitivity and specificity of this technique is unclear. Bone scan can show the extent of vascular calcification and can be used to monitor the response to therapy.

## 9.4 Heterotopic Bone Formation

Increased ectopic osteoblastic activity, or heterotopic bone formation (HBF), is defined as the presence of bone in soft tissue where it does not normally exist. HBF was first described in 1883 by Reidel, and in 1918 Dejerne and Ceillier reported that HBF frequently occurred among soldiers who had experienced spinal cord trauma as combatants in World War I [13]. The bone tissue that forms during heterotopic ossification is qualitatively normal.

### 9.4.1 Pathophysiology

There are two major forms of HBF: acquired and hereditary. By far the more common is the acquired form, in which HBF is usually either precipitated by trauma (such as fracture, total hip arthroplasty, or direct muscular trauma) or has a neurogenic cause (such as spinal cord injury or central nervous system injury). The rare hereditary form can be of two types: fibrodysplasia ossificans progressiva or myositis ossificans progressiva and progressive osseous heteroplasia. The acquired form of HBF may occur after virtually any type of musculoskeletal trauma. Other conditions associated with HBF include burns, sickle cell disease, hemophilia, tetanus, poliomyelitis, multiple sclerosis, toxic epidermal necrolysis, and cancer. HBF occurs infrequently in the absence of a precipitating event or condition. HBF includes specific entities such as myositis ossificans and neurogenic heterotopic ossification. Myositis ossificans describes a post-

traumatic soft tissue ossification that occurs next to long bones. In many clinical practices, myositis ossificans is usually seen among patients who have sustained trauma such as operative procedures, e.g., total hip arthroplasty (THA), fractures, dislocations, and direct trauma to muscle groups (mainly the quadriceps femoris and brachialis muscles). Other reported sites include abdominal incisions, wounds, and sites in the gastrointestinal tract [14]. The neurogenic form follows trauma to the “nervous system” and is most commonly seen after spinal cord injury. Patients are typically adolescents, or adults, with 75% of patients below 30 years of age with no sex predominance. This subtype often occurs after closed head injuries, strokes, central nervous system infarctions, and tumors [15, 16]. Tumoral calcinosis, another specific form of HBF, features large amounts of bone formation resembling tumor masses. Heterotopic bone formation has been identified as a relatively common and unexpected finding in end-stage valvular heart disease. Bone morphogenetic proteins 2 and 4 (BMP 2/4), potent osteogenic morphogens, were expressed by myofibroblasts and preosteoblasts in areas adjacent to B- and T-lymphocyte infiltration in valves where ossification was identified [17].

The incidence of acquired HBF varies greatly among patient populations. Among patients with spinal cord injury, the incidence ranges from 20 to 30%, and once HBF develops, there is up to a 35% chance that the patient will eventually have significantly limited joint motion [18]. Among patients with closed head injury, HBF develops in 10–20%, and in 10% of these patients with HBF, limitations in joint motion will develop [15].

**Fig. 9.9** The whole body blood pool images (a) show low grade increased blood pool in the calf area bilaterally and intense increased blood pool activity in the right ankle region. Delayed images (b) show diffuse uptake involving the skull and the sternum with non-visualization of the kidneys and urinary bladder secondary to renal failure. There is intense uptake in the right ankle joint and diffuse soft tissue uptake is noted in the calve areas bilaterally more prominent at the medial aspects and to a lesser extent in the thighs. SPECT/CT (c) images performed

over the legs and feet demonstrated increased radiotracer (*arrows*) uptake at the subcutaneous tissue (*arrows*) with sparing the muscular compartment of the calves. These areas of increased radiotracer uptake correspond to areas of calcification in the CT images indicating calciphylaxis. The intense uptake at the right distal tibia and calcaneus bone corresponds to cortical destruction and sclerosis as well as calcification in subcutaneous tissue on CT images which correspond to diffuse uptake on MDP images representing also soft tissue calcification

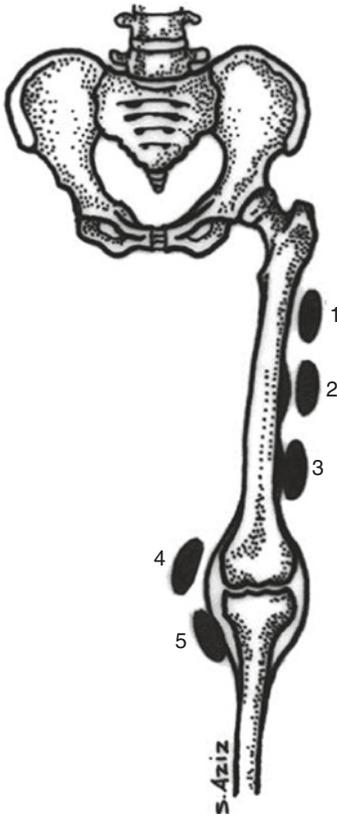

A more recent study again found the prevalence of HBF is higher among patients with traumatic spinal cord injury (11%) than among those with traumatic brain injury (4%) in their patient group [19]. A case of heterotopic ossification was reported in bilateral hip joints and bilateral knee joints associated with encephalitis [20]. The condition was also reported after the use of bone morphogenetic protein 2 (BMP 2) for posterolateral lumbar fusion [21, 22]. The incidence of HBF after total hip arthroplasty has been reported to range from 0.6 to 90%, although most studies agree that the incidence of HBF is approximately 50–55% [18, 23, 24]. The HBF that forms after THA is commonly minor and not clinically significant.

The onset of HBF usually occurs 3–12 weeks after injury, most commonly at 2 months post-injury, although it can occur as late as 1 year, or even later. The most commonly involved areas, in decreasing order of frequency, are the hip, knee, shoulder, and elbow. Only rarely is the foot involved [25, 26]. In spinal cord injury, HBF always occurs below the level of injury. At the knee, the medial aspect is most commonly affected. In patients with head injury or stroke, HBF almost always occurs on the affected side.

The pathogenesis of HBF is distinct from metastatic and dystrophic soft tissue calcification and is still debated. However, it is believed to be secondary to transformation of pluripotent mesenchymal cells present in the connective tissue septa within the muscle into osteogenic cell line [27]. Chalmers et al. [28] proposed three conditions needed for heterotopic ossification (HO): osteogenic precursor cells, induction agents, and a permissive environment. Urist et al. [27] postulated a small ( $<0.025 \mu\text{m}$ ), hydrophobic bone morphogenetic protein, which would be capable of changing the development of mesenchymal cells in the muscle from fibrous tissue into the bone (when respiratory and nutritional requirements are also present) [27]. It has been postulated that the bone morphogenetic protein is liberated from the normal bone in response to venous stasis, inflammation, or diseases of the connective tissue attachments to the bone, conditions that often accompany immobilization or trauma [27]. Some investigators proposed the presence of a centrally

mediated factor [29, 30], and prostaglandin  $E_2$  ( $\text{PGE}_2$ ) has also been suggested as a mediator in the differentiation of the primitive mesenchymal cells [31]. The heterotopic bone may begin some distance from the normal bone, moving toward it later [27]. Interestingly, experiments have also shown that muscle injury alone will not cause the ectopic ossification, concomitant bone damage also being required [27]. Kurer et al. [32] took sera from four paraplegic patients with HBF and four paraplegic patients without HBF; the sera were incubated with human osteoblasts in tissue culture, and their metabolic activity was measured quantitatively. These investigators found that the sera of the patients with HBF had significantly greater levels of osteoblast-stimulating factors, which may contribute to the pathogenesis of HBF. Other contributing factors include hypercalcemia, tissue hypoxia, changes in sympathetic nerve activity, prolonged immobilization, remobilization, and disequilibrium of parathyroid hormone and calcitonin [33, 34].

Early in the course of HBF, edema with exudative cellular infiltrate is present, followed by fibroblastic proliferation and osteoid formation [35]. The distinctive morphological features of myositis ossificans, which are illustrative of HBF as a whole, help the pathologist distinguish myositis ossificans from malignant neoplasms such as parosteal osteosarcoma or osteochondroma. Bone formation occurs in the connective tissue between the muscle planes and not within the muscle itself [35]. Myositis ossificans shows ossification principally in the periphery, so that an ossified and radiopaque peripheral rim surrounds a nonossified and radiolucent center; the opposite is true of osteosarcoma, a malignant tumor that often features dense central ossification [5, 36]. On histological examination, myositis ossificans shows cellular fibrous proliferation, osteoid, and primitive bone, which, if biopsied too early, may be mistaken for that of osteosarcoma [5]. Rossier noted that, after approximately 30 months, the pattern in HBF approached that of the normal young adult bone [37]. Anatomically, paraarticular HBF is always extra-articular [32, 35, 37], but it may be attached to the joint capsule without disrupting it. Occasionally, HBF may be

**Fig. 9.10** Relation of heterotopic bone formation to the joints and bone cortex. HBF is always extra-articular, but it may be attached to the joint capsule without disrupting it. Occasionally, HBF may be attached to the cortex of adjacent bone with, or without, cortical disruption, 1, 2 and 3 illustrate parosteal while 4 and 5 represent para-articular heterotopic bone formation

attached to the cortex of the adjacent bone with, or without, cortical disruption (Fig. 9.10).

The course of acquired heterotopic bone formation is relatively benign in 80% or more of cases. In the remaining cases, patients often develop significant loss of motion, and ankylosis occurs in up to 10%. Loss of joint mobility and the resulting loss of function are the principal complications of HBF [25, 38, 39]. Other complications include peripheral nerve entrapment and pressure ulcers [40, 41]. HBF following spinal cord injury can lead to various complications, including venous thrombosis, autonomic dysreflexia, and pressure ulcers, and can be refractory to oral indomethacin and local irradiation [42]. Mesan and Bassano reported an acute fracture occurring through pre-

existing, quiescent, post-traumatic HBF of the gastrocnemius muscle as a rare sequela of HBF [43]. Clinical, laboratory, radiographic, and scintigraphic criteria have been used to follow the course of HBF and to assist in its treatment.

During formation of HBF, initially immature connective tissue, fibroblasts, ground substance, and collagen fibers are seen. Eventually, usually within 7–14 days, osteoblasts are noted, located irregularly in osteoid. New bone formation may start with multiple foci within the mass of immature connective tissue. Hypervascularity is noted where these centers of ossification appear. As mineralization progresses, amorphous calcium phosphate gradually is replaced by enlarging hydroxyapatite crystals. These multiple foci of osteogenesis may be of simultaneous onset within the lesion, but do not necessarily evolve at identical rates.

Commonly, after approximately 6 months, the appearance of true bone is noted, with cancellous bone, mature lamellar bone, and bone marrow which contains predominantly adipose tissue and only a minor amount of hematopoiesis (if any). The mature bone appears intermixed with the immature bone until full maturation into lamellar corticospongiosal bone occurs.

Serial serum alkaline phosphatase estimations can be useful. Elevation suggests bone growth, but the amount of increase is not proportional to the extent of HBF. The alkaline phosphatase level also may return to normal before maturity, or it may remain elevated for a prolonged period.

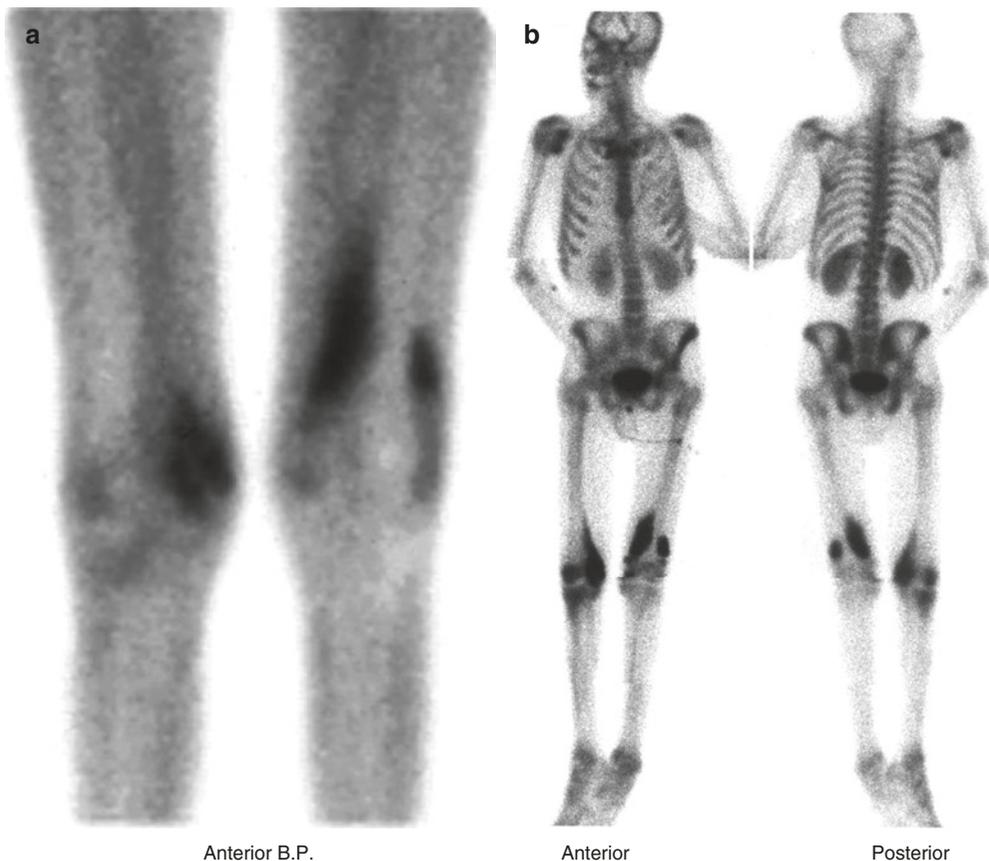

The two rare inherited forms of heterotopic ossification, fibrodysplasia ossificans progressiva and progressive osseous heteroplasia, are due to gene mutations, are characterized by progressive bone formation, and are the most severe forms of heterotopic bone formation. In fibrodysplasia ossificans progressiva, activating mutations in activin receptor type-1, a bone morphogenetic protein type I receptor, along with underexpression of multiple antagonists of this protein induce heterotopic endochondral ossification. In progressive osseous heteroplasia, the heterotopic ossification is secondary to formation of mainly intramembranous bone tissue in response to inactivating mutations in the GNAS gene [44, 45].

### 9.4.2 Scintigraphic Evaluation

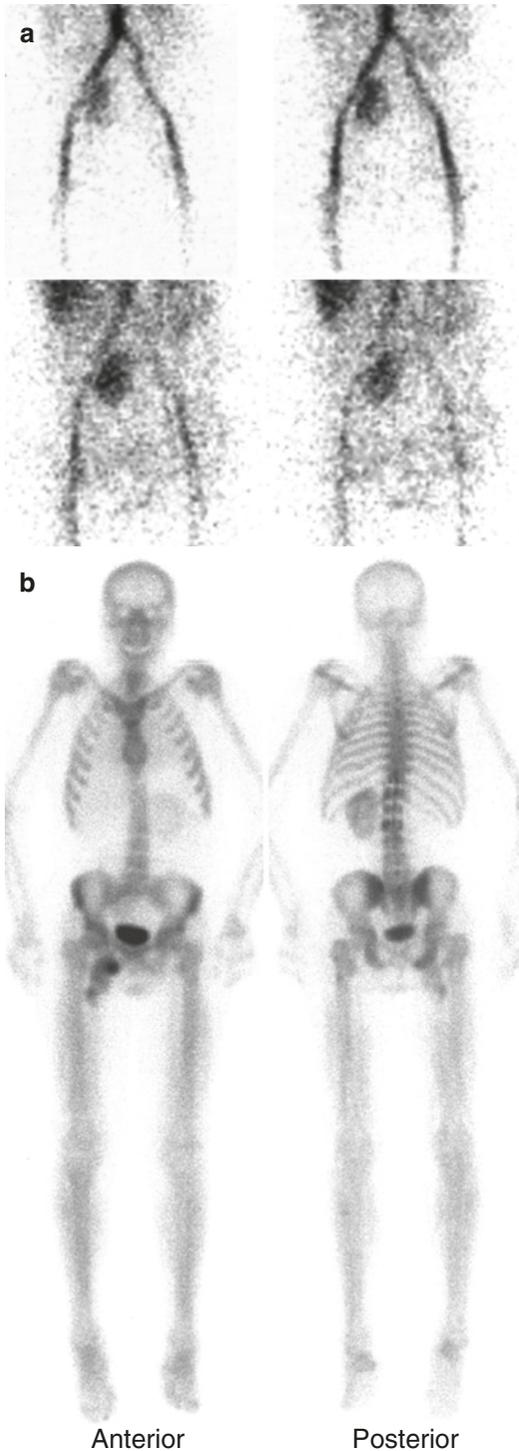

Multiphase bone scanning is the most useful investigation, as it can detect HBF at the onset of clinical symptoms. These early phases are the most important for early diagnosis and monitoring of the ossification process. Freed [46] evaluated the three-phase bone scan in the detection of HBF and found that a marked vascular blush and increased blood pool about the hips preceded the development of clinical HBF by 2–4 weeks. Assessment of the maturity of the HBF is important because of the fact that resection prior to maturity almost always leads to a recurrence of HBF although some investigators prefer resection before maturation as it was claimed that recurrence is not associated with early surgery before 6 months [19]. Recurrence may be seen on X-ray or other imaging modalities or may be a clinical

finding as swelling without any impact on patient function, or it may cause pain and/or loss of function [47, 48]. Bone scintigraphy is considered the most reliable means of determining the maturity of HO. Serial bone scans, performed weekly for 4–6 weeks, with decreasing uptake over time suggest maturation, although uptake can vary with serial examinations that make assessment of maturation less than 100% accurate.

Blood flow and pool images have detected incipient heterotopic bone formation 2 1/2 weeks after injury, with delayed scintigraphs becoming positive about 1 week later. These scintigraphic findings precede positive radiographs by 1–4 weeks [49]. Scintigraphically, the condition is classified as immature when the blood flow and blood pool activity are increased (Figs. 9.11, 9.12, and 9.13). When the blood flow and blood pool patterns normalize, or stabilize, after showing

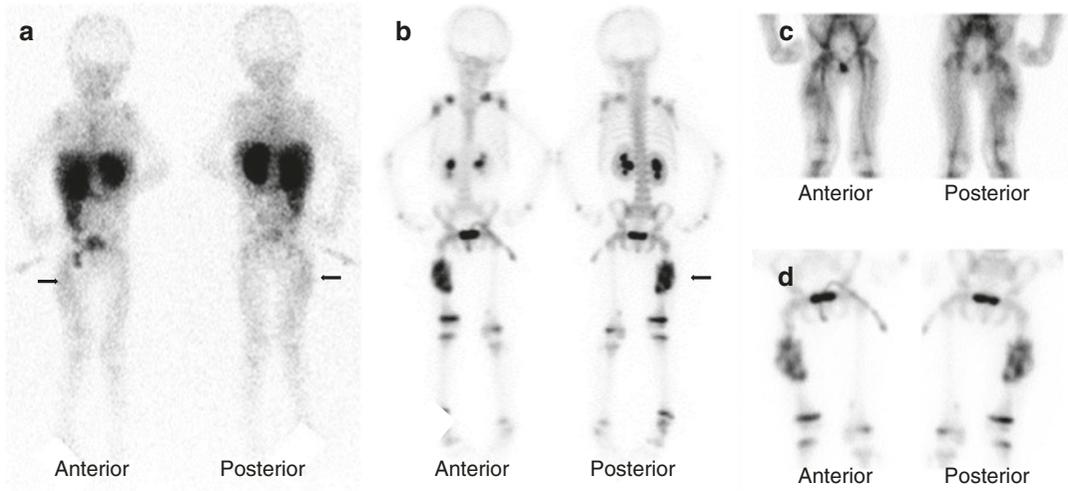

**Fig. 9.11** (a, b) Multiphase bone scans of immature heterotopic bone formation. Increased blood pool activity (a) is seen in the distal thighs. Delayed images show intense parosteal and paraarticular uptake (b)

**Fig. 9.12** (a, b) A case of immature heterotopic bone formation of the right groin seen on a flow (a) and delayed (b) images

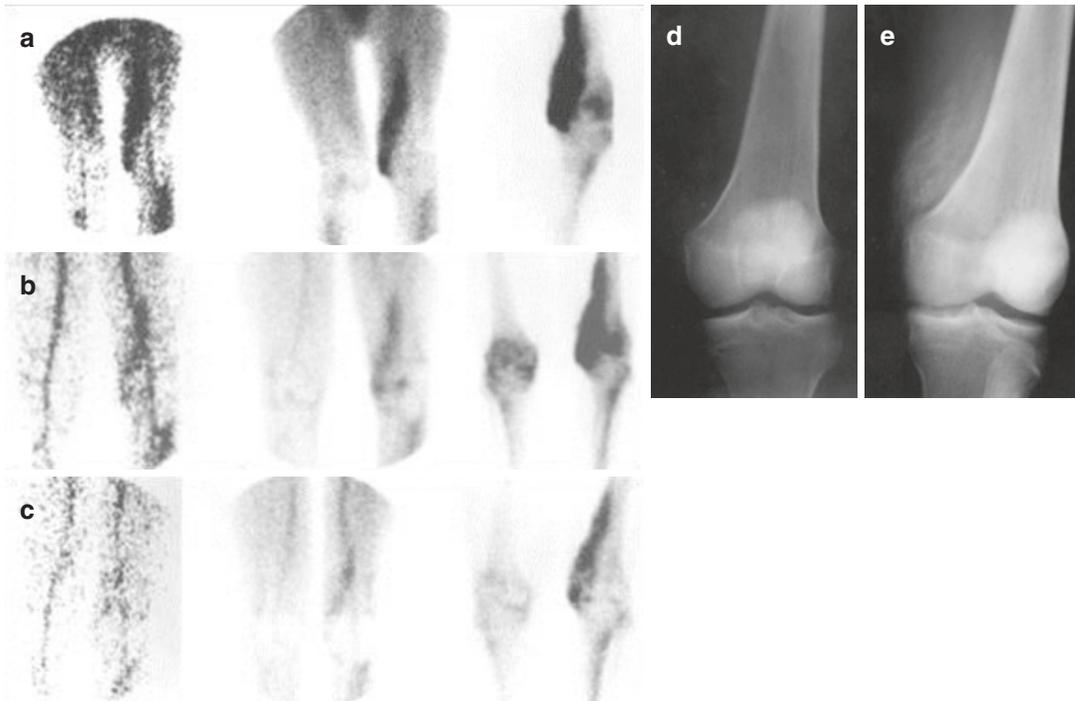

decreasing activity, the condition is considered to be mature. As heterotopic bone progresses from immature to mature, the three-phase bone scan typically shows progressive reduction in the activity of all three phases (Fig. 9.14). The majority of bone scans return to baseline within 12 months, although some patients reach the mature phase much earlier, or later. Since surgical intervention during the immature phase often leads to recurrence, serial bone scans are useful in monitoring the activity of the disease in order to determine the appropriate time for the surgical removal of heterotopic bone with minimal risk of recurrence. In several reported series, preoperative serial bone scans, with quantitation of the uptake ratios between heterotopic and normal bone, have successfully identified those patients who remained free of heterotopic ossification following surgery (i.e., those patients with decreasing, or stable, scintigraphic activity as measured by this quantitative technique). Serial bone scans have been used successfully to monitor the metabolic activity of HBF and determine the appropriate time for surgical resection, if needed, and to predict postoperative recurrence [37, 46, 50, 51]. A technique can be used for the serial quantitative bone scanning to assess the maturity of heterotopic ossification—based on the original 1977 report of Tanaka et al. [51]. The quantitation method of serial bone scans can also be a useful objective means to stage the maturity and can be obtained by simply using serial determinations of abnormal uptake relative to a normal skeletal structure. Serial quantitative bone scans that show a sharply decreasing trend followed by a steady state over a 2- to 3-month period are the most reliable scintigraphic parameter for determining whether HBF has reached maturity [52]. It should be noted that heterotopic ossification can be reversible and may be absorbed and disappear on imaging if small.

Since it is difficult to correctly localize sites of uptake on planar and even in SPECT (Fig. 9.15) images, the SPECT/CT (Fig. 9.16) should be very useful in such situations and allows better detection of extraskelatal soft tissue abnormalities and in differentiating them from other causes of

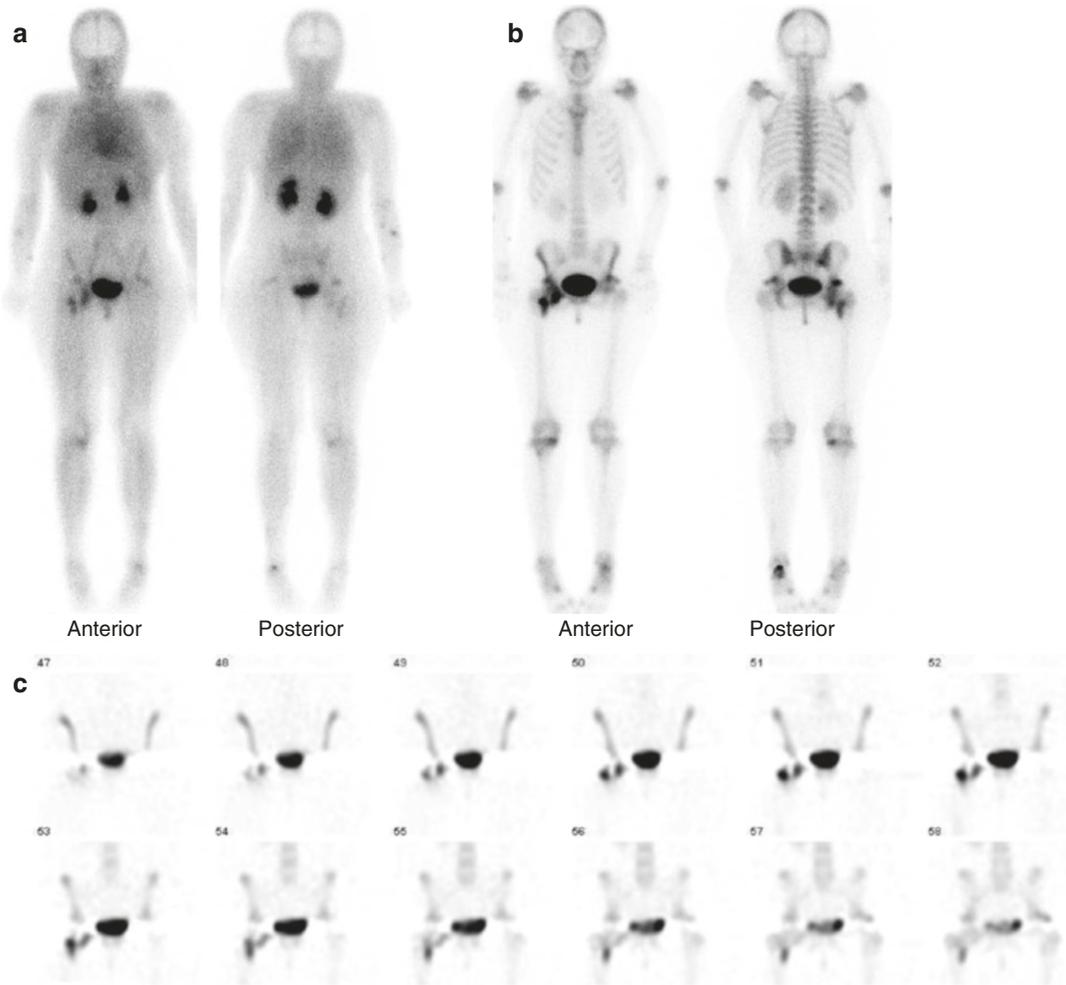

**Fig. 9.13** Five-year-old boy with history of motor vehicle accident and fractures of clavicles and right femur 2 months earlier. Now with fever and swelling in the right thigh suspected to be infection. No response to antibiotics for a week. Tc-99m MDP scan shows increased blood

pool activity in the mid-right thigh (a) corresponding to increased uptake on delayed images (b) which appear to surround the bone. Spot blood pool (c) and delayed (d) images of the thighs show the same findings of immature heterotopic ossification in this child

**Fig. 9.14** As the heterotopic bone develops from immature to mature, the three-phase bone scans typically show a progressive reduction in the activity of all three phases from initial study (a) to 12-month (b) and 18-month (c) follow-up studies at the site of HBF in the medial aspect

of the distal left thigh. Note that plain radiograph was negative at the time of presentation (d) which became positive with calcification at the time of the follow-up bone scan at 12 months (e) (from [16] with permission)

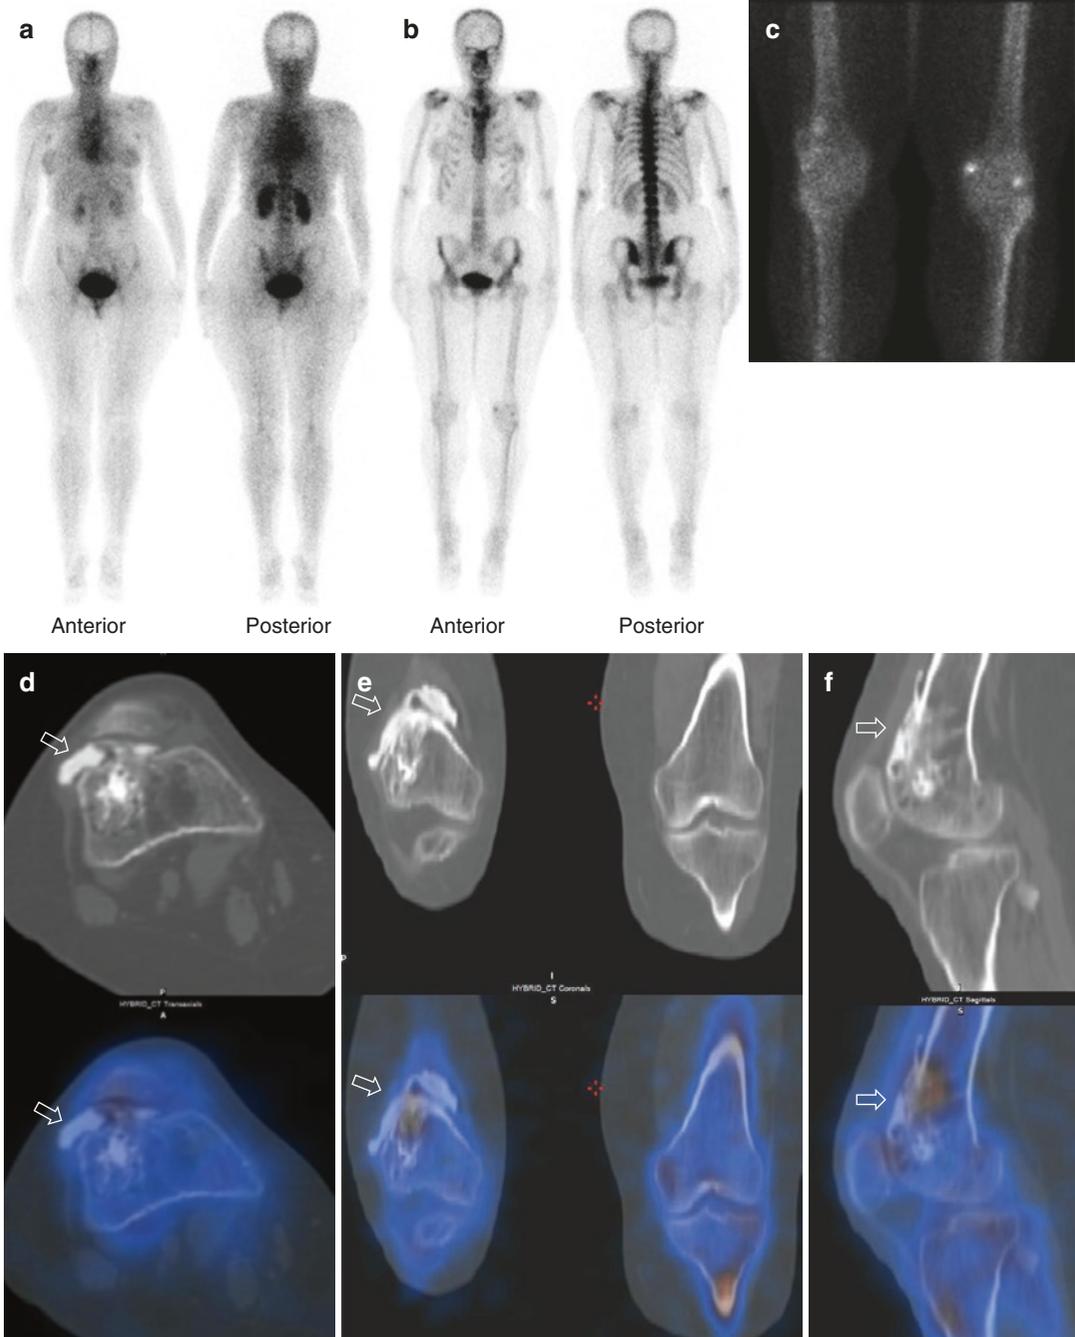

**Fig. 9.15** Tc-99m MDP bone scan for a 27-year-old female with history of asthma developed ARDS and was in ICU for 6 weeks. Patient developed pain in right hip region which on bone scan showed increased blood pool

activity (a) and corresponding uptake on delayed images (b). SPECT study (c) reveals more clearly the location of the areas of abnormalities around the bone

abnormal uptake although it has not been verified yet. A study of 12 patients with spinal cord injuries with heterotopic ossification in 16 hips were studied by SPECT/CT [53]. Two patients showed marked osteoblastic activity, five had moderate activity, five has mild activity, and the remaining six hips showed no activity on SPECT/CT. The authors claimed that the higher the osteoblastic activity, the less the maturity and the higher the risk of recurrence after surgery although none of the patients studied had resection of the lesions since all patients had functional range of motion. This study did not use flow or blood pool to deter-

mine maturity and also no evidence of recurrence. Two reviews on SPECT/CT in extraosseous uptake of Tc-99m MDP and in total hip arthroplasty also mentioned heterotopic ossification as one of the conditions SPECT/CT would be helpful in without presenting any data publications [54, 55]. A study on its role in assessment of a painful hip after total hip arthroplasty found SPECT/CT helpful in three cases of heterotopic ossification as a reason for pain [56].

Several pathological conditions can clinically mimic the scintigraphic appearance of early HBF (Table 9.3). Clinically patients may

**Fig. 9.16** Blood pool (a) and static whole-body (b) images of a 63-year-old female with history of pain in her left knee and a history of left knee surgery. The study shows mildly increased focal uptake in the left knee region seen better on spot image (c). Representative section of transaxial (d), coronal (e), and sagittal (f) SPECT/

CT study of a case of post-traumatic heterotopic bone formation in the left knee region illustrating the value of SPECT/CT in localizing the distribution of the extraskel-etal ossification (arrow) and helps in the diagnosis. Three-dimensional (g) image from the study further clarified the nature of the abnormality

**Fig. 9.16** (continued)

Cellulitis
Thrombophlebitis
Deep vein thrombosis
Neoplasms including recurrent tumors
Osteosarcoma
Osteochondroma

present also with a picture of acute inflammation including fever that was also reported to be prolonged [57].

Osteomyelitis may represent a difficult diagnostic challenge on scintigraphy, particularly since gallium-67- and, rarely, indium-111-labeled white blood cells accumulate in areas of immature heterotopic bone formation (Figs. 9.17 and 9.18). The uptake of gallium-67 by foci of heterotopic bone formation undergoing osteogenesis, with considerable osteoblastic activity, may be explained by the fact that this radionuclide shares some of the properties of bone-imaging agents. Fortunately,

gallium-67 uptake in HBF has been found to be proportional to the uptake of Tc-diphosphonates, in contrast to its relatively greater uptake in sites of osteomyelitis. Since gallium-67 uptake otherwise might be mistaken for infection or a tumor, this proportionality can help differentiate HBF from osteomyelitis. Therefore, in the appropriate clinical setting, HBF is a diagnostic consideration for patients with a positive gallium-67 scan [16]. F-18 FDG uptake was reported among pitfalls in a rim of myositis ossificans [58].

### 9.4.3 Correlative Imaging

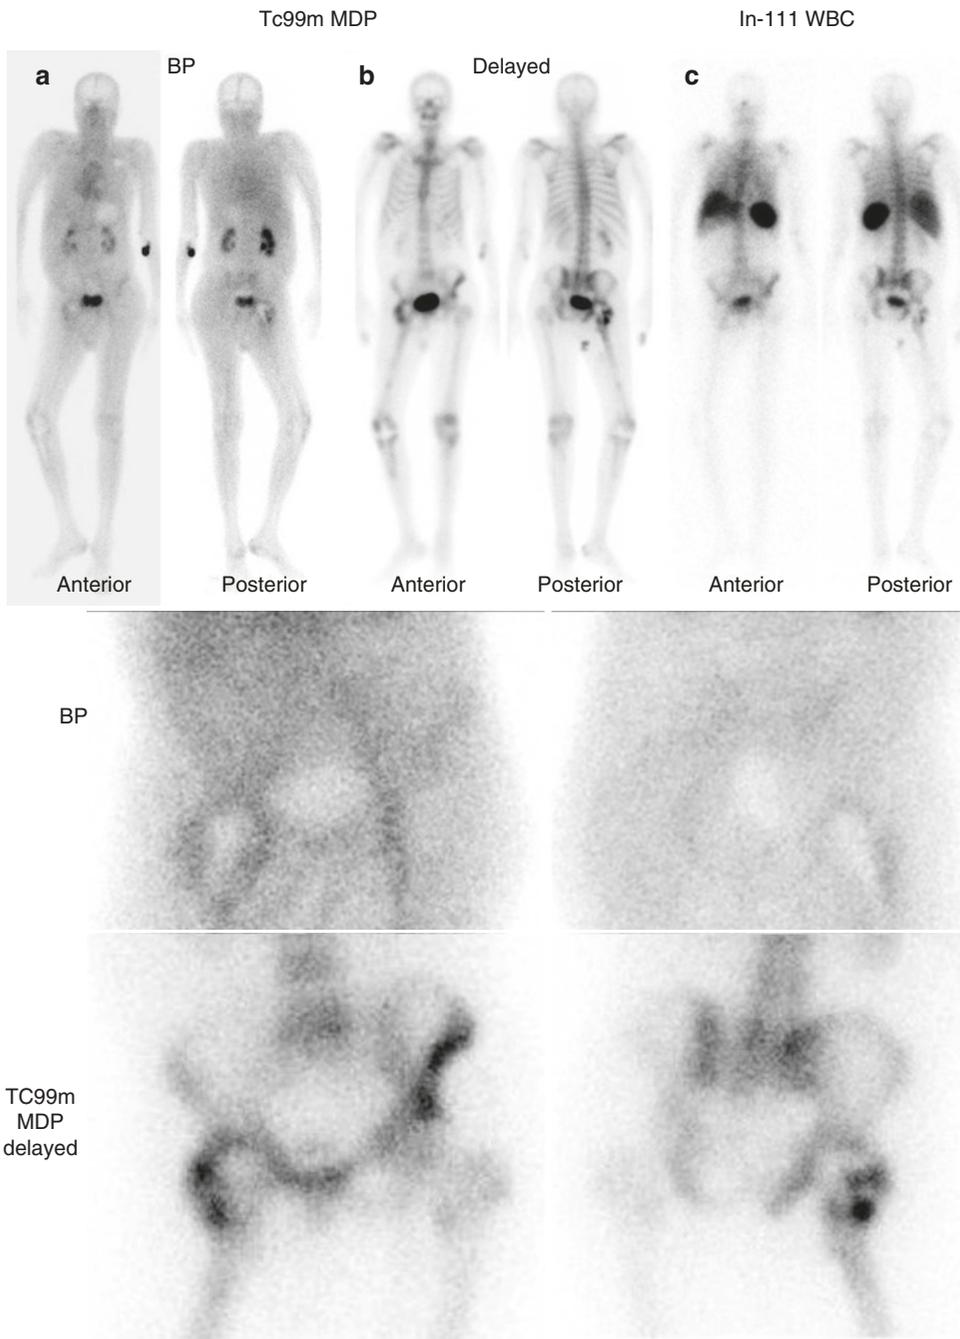

On standard radiographs, soft tissue calcification must occur for radiographic evidence of HBF to be present; radiographs are not helpful in the early stages.

Radiological examinations do not show evidence of HBF until a flocculent patchy appearance develops, as calcium is deposited about 7–10 days after the onset of clinical symptoms. This patchy appearance coalesces and enlarges on subsequent examinations, and, by 2–3 months, the boundaries of the HBF demarcate with the appearance of mature bone. Radiographs, however, are not reliable at assessing maturity of HBF as the more mature areas may hide immature areas. Computed tomography (CT) and magnetic resonance imaging (MRI) are useful in delineating the local anatomy prior to resection. However, the role of CT and MRI in the evaluation of other aspects of HBF, such as maturity, has not been well established.

### 9.4.4 Special Forms of Heterotopic Bone Formation

#### 9.4.4.1 Myositis Ossificans Progressiva

One congenital and rare form of HBF is called myositis ossificans progressiva or fibrodysplasia ossificans progressiva [59]. This autosomal dominant congenital disease is often associated with other skeletal abnormalities, including malformation of the great toes and shortening of digits, as well as other clinical features such as deafness

**Fig. 9.17** Bone scan and indium-labeled WBC studies of a 60-year-old female with history of pain in the right hip after being bedridden since she has right hip replacement 9 months earlier. The patient has also a history of right knee replacement earlier. Blood pool images (a) show hyperemia around the right hip. Whole-body delayed images (b) demonstrate increased uptake in the lateral aspect of the right hip prosthesis extending beyond the bone boundaries. There is also mildly increased uptake

around the right knee prosthesis. Labeled WBC study (c) shows mild accumulation at the site of the right hip prosthesis at the site of extra-osseous abnormality on bone scan images. Spot images of blood pool, static MDP, and labeled WBC clarified further the abnormalities. This case illustrates the WBC accumulation in immature (inflammatory) phase of heterotopic bone formation which should not be confused with skeletal infection

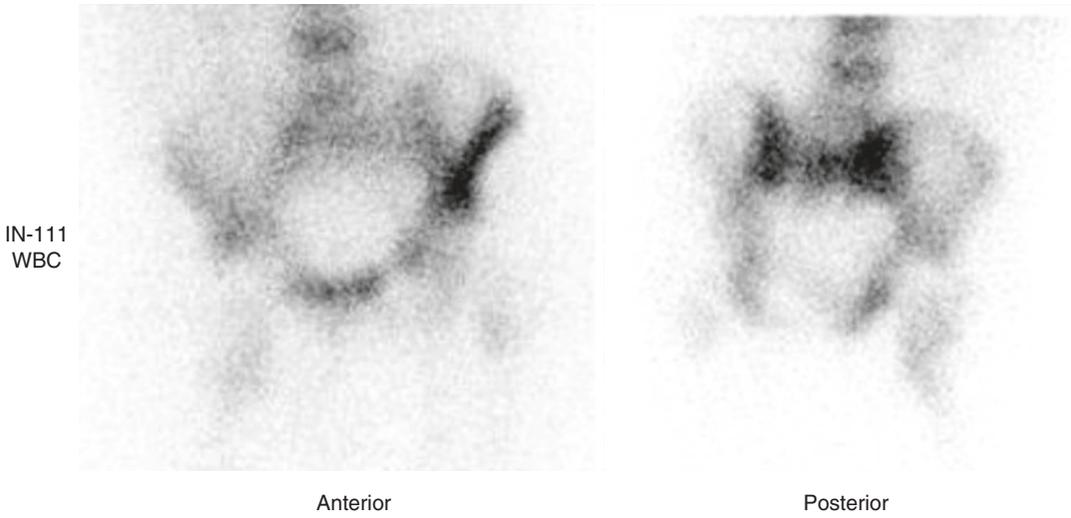

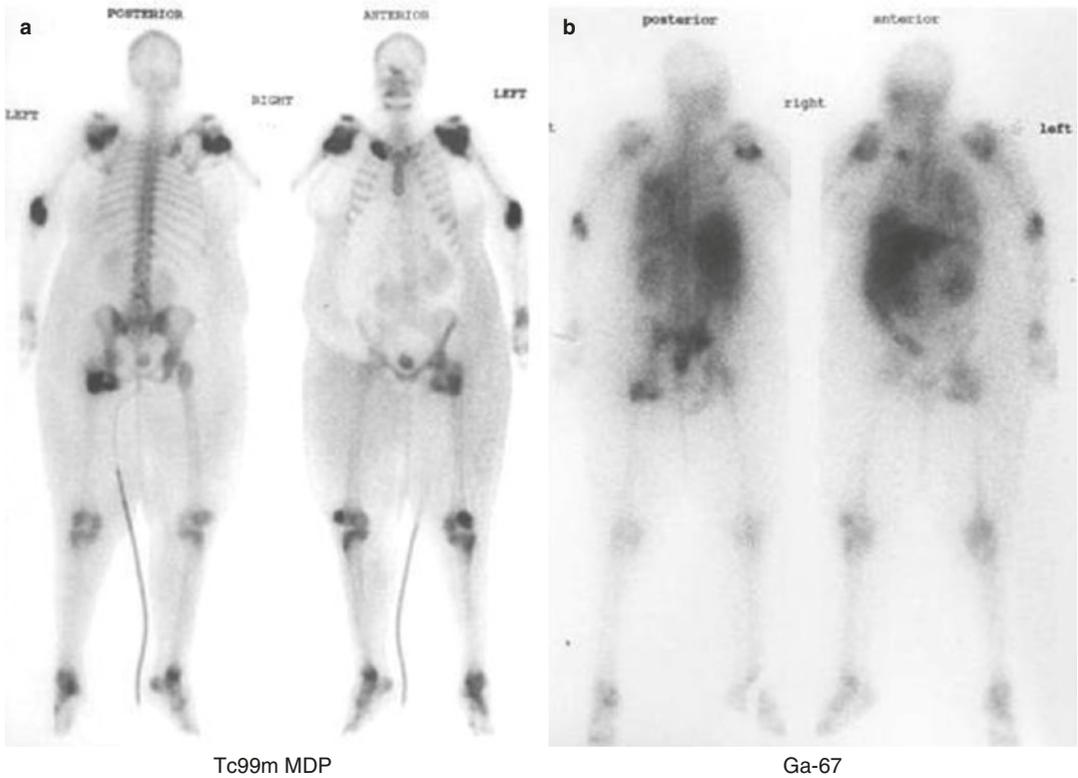

Fig. 9.17 (continued)

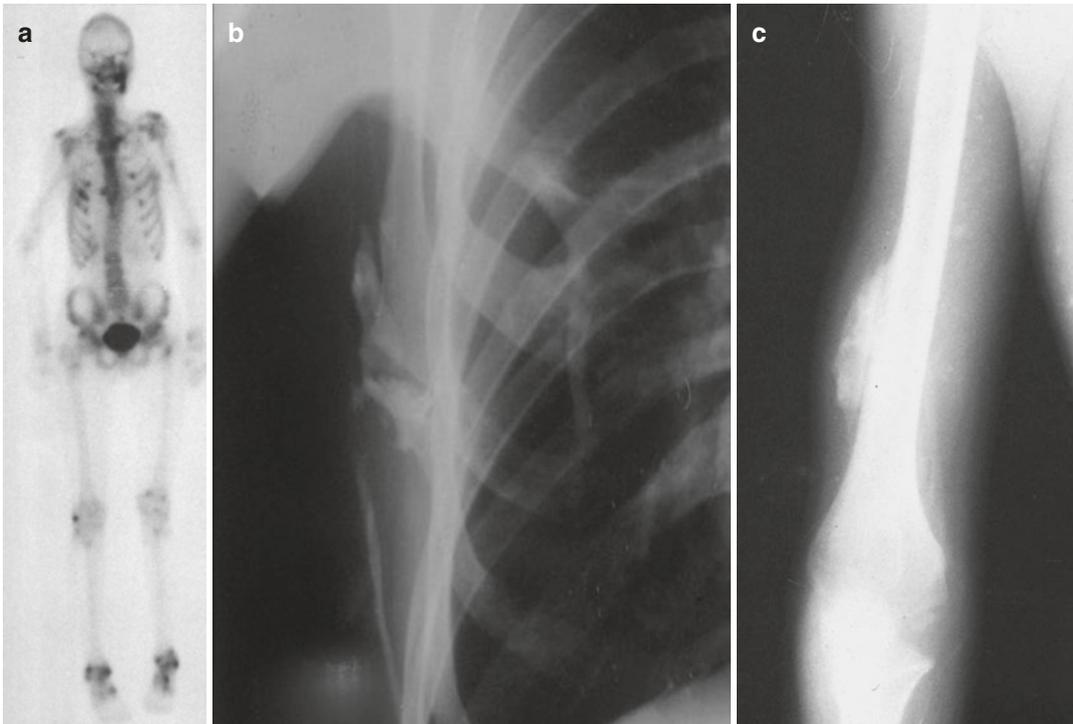

**Fig. 9.18** A case of 49-year-old quadriplegic woman with fever and left hip pain for 4 weeks. Tc-99m MDP bone images (a) reveal foci of increased uptake in the shoulders, elbows, and left hip regions which appear to extend beyond bone boundaries. Arthrotic changes in other joints are also noted. Ga-67 study (b) shows

increased uptake at the abovementioned foci of increased bone uptake. This case illustrates the gallium uptake in immature heterotopic bone formation which should not be mistaken with skeletal infections (from [52] with permission)

and baldness. Although the symptoms have been reported to develop in patients with this disease prior to 4 years of age, the diagnosis is frequently missed [60]. The soft tissue ossification present may be mistakenly attributed to bruising or even a sarcoma. Initial failure to appreciate the significance of the toe and other digit malformations is also common. Progression to a severely impaired joint mobility with ankylosis by early adulthood is the hallmark of this disease. Radiologically, there are several features including soft tissue calcification of the subcutaneous and fascial connective tissue, tendons, ligaments, and skeletal muscles; exostoses; joint malformations; abnormal vertebral bodies; and changes to the hands and feet. Scintigraphically, some features could be identified (Fig. 9.19), particularly the soft tissue calcification around the joints, mandible, maxilla, shoulders, ribs, and parasternal and paraspinal regions, which are seen as areas of increased uptake [59].

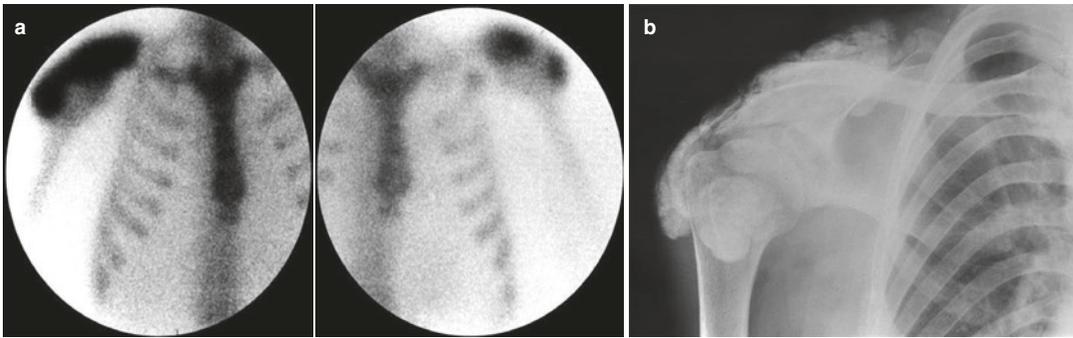

#### 9.4.4.2 Tumoral Calcinosis

Tumoral calcinosis is an unusual and benign condition characterized by large, calcified, periarticular soft tissue masses of calcium phosphate near the large joints such as the hip, the shoulder, and the elbow, in addition to the wrist, feet, and hands. The condition is uncommon in the spine and rarely reported around the temporomandibular joint [62]. This periarticular calcium deposition can be observed in the absence of vascular, or visceral, calcification and is associated with normocalcemia and normal kidney function which can be subclassified as a primary form (idiopathic or hereditary). However, the condition may also be found in a wide variety of conditions, such as primary or secondary hyperparathyroidism, scleroderma, renal osteodystrophy associated with chronic renal disease, hypervitaminosis D, milk-alkali syndrome, trauma, and sarcoidosis [61, 63–66]. The condition is observed with increasing frequency in

**Fig. 9.19** (a–c) A case of myositis ossificans progressiva with a whole-body scan (a) showing multiple foci of increased uptake in the regions of the mandible bilaterally, chest, mid left arm, left trochanter area, right knee, and

feet. Radiographs of the chest (b) and left arm (c) illustrating the soft tissue calcification (arrows) corresponding to the findings of bone scan at these areas (from [59] with permission)

**Fig. 9.20** (a, b) Tumoral calcinosis: Selective spot views of Tc-99m MDP bone scan of the chest (a) showing increase uptake in the right shoulder and to a lesser extent

the left shoulder region. Corresponding calcified masses around the right shoulder seen on radiograph (b)

patients with chronic renal failure on dialysis. Although tumoral calcinosis has been reported in patients ranging from age 5 months to 83 years, it usually becomes manifest in the second decade of life. Men and nonwhites are affected more commonly than women and Caucasians. A family history is apparent in 30–40% of cases, and an autosomal recessive pattern of inheritance has been suggested [67–69]. Familial cerebral and peripheral vascular aneurysms have also been reported in association with tumoral calcinosis. Patients may be admitted to surgical clinics because of tumorlike painless swellings, which may be solitary or multiple. They may interfere with joint motion, although calcification does not involve the joints and the bones, and before they are diagnosed sufficiently, the patients experience repeated surgical excisions associated with loss of function [64]. In a literature review of 121 cases of tumoral calcinosis, Smack et al. proposed three pathogenetically distinct subtypes of tumoral calcinosis: (1) primary normophosphatemic tumoral calcinosis, in which patients have normal serum phosphate, normal serum calcium, and no evidence of disorders previously associated with soft tissue calcification; (2) primary hyperphosphatemic tumoral calcinosis, in which patients have elevated serum phosphate but have normal serum calcium and no evidence of disorders previously associated with soft tissue calcification; and (3) secondary tumoral calcinosis, in which patients have a concurrent disease capable of causing soft tissue calcification [70].

Radionuclide imaging is the most reliable and simplest method of detecting and quantifying the lesions. The calcified masses show increased uptake of Tc-99m diphosphonates (Fig. 9.20). Characteristically, the calcified masses in the appendicular skeleton are visible on plain radiographs. The radiographs usually reveal lobulated, homogeneous, densely calcified periarticular masses, usually around the large joints, with normal joint spaces. Sometimes the condition may not be apparent on standard radiographs and may not be diagnosed as tumoral calcinosis before surgery. CT can disclose the presence of fluid-calcium levels (sedimentation sign), and MRI displays a low signal density on T1- and T2-weighted images [71, 72].

These radiological characteristics allow tumoral calcinosis to be distinguished in many cases from other diseases which produce soft tissue calcification, although a biopsy may be needed to exclude musculoskeletal tumor [61, 63].

#### 9.4.4.3 Progressive Osseous Heteroplasia

Progressive osseous heteroplasia is a recently identified disorder characterized by HBF with the development of highly structured, mineralized tissue histologically identifiable as true bone. It is uncommon and can cause a variety of clinical features such as short metacarpals and metatarsals. The condition appears to affect females more than males and is sporadic, although familial associations and atypical phenotypes have been reported [73].

Unlike the orderly deep heterotopic ossification in patients with fibrodysplasia ossificans progressiva, progressive osseous heteroplasia patients are primarily affected by ossification of the skin and subcutaneous tissue [74].

#### 9.4.4.4 Tumoral Calcium Pyrophosphate Dihydrate Crystal Deposition Disease

This rare condition is another variant of HBF that can also produce large masses of calcium deposits simulating tumoral calcinosis. It is seen in adults and is more common in males. Histologically, there is calcification with crystal deposits and chondroid metaplasia. The majority of crystals are rhomboid in shape (characteristic of calcium pyrophosphate dihydrate crystal deposition disease [CPPD]), but some needle-shaped crystals may also be identified, which resembled urate crystals. Yamakawa [75] reviewed 54 reported cases of tumoral CPPD and proposed two categories based on the anatomic location: the central (head and neck) type (33 patients) and the distal (extremity) type (21 patients). The patients in these two groups were not different with respect to age and gender, but those with the central type often presented with a painful mass (15 patients, 46%) or neurological disturbances (11 patients, 33%). Patients with the distal type presented with a painless mass or swelling (12 patients, 57%), but none had neurological signs, although 8 (38.1%) presented with an acute attack similar to tophaceous gout. Tumoral CPPD should be differentiated from tophaceous gout, tumoral calcinosis, and malignant or benign tumors [75].

---

## 9.5 Calcinosis Cutis

Calcinosis cutis is a term used to describe a group of disorders in which calcium deposits form in the skin and subcutaneous tissue and connective tissue sheaths around the muscles. Virchow initially described calcinosis cutis in 1855. Calcinosis cutis is presented here separately since it is difficult to categorize with the dystrophic, metastatic, or heterotopic types of calcification. Etiologically, dystrophic, metastatic, iatrogenic, and idiopathic

varieties may be identified. Some rare types may even be variably classified as dystrophic or idiopathic. These include calcinosis cutis circumscripta and calcinosis cutis universalis. Most lesions of calcinosis cutis develop gradually and are asymptomatic. However, the history and evolution of the lesions depend on the etiology of the calcification. Patients with dystrophic calcification may provide a history of an underlying disease, a pre-existing dermal nodule (which represents a tumor), or an inciting traumatic event. Patients with metastatic calcification most frequently have a history of chronic renal failure. Cases of idiopathic calcinosis cutis usually are not associated with prior trauma or disease. Those who develop iatrogenic calcinosis cutis generally have a history of recent hospitalization.

When the calcium deposits are localized to a small area, it is called calcinosis cutis circumscripta, and if it is diffuse, it is called calcinosis cutis universalis. In all cases of calcinosis cutis, insoluble compounds of calcium primarily of hydroxyapatite crystals, or amorphous calcium phosphate, are deposited due to local and/or systemic factors. The pathogenesis of calcinosis cutis is not completely understood, and a variety of factors can be recognized. Metabolic and physical factors are most important. Ectopic calcification can occur in the setting of hypercalcemia and/or hyperphosphatemia when the calcium-phosphate product exceeds 70 mg/dl, without preceding tissue damage. These elevated extracellular levels may result in increased intracellular levels, calcium-phosphate nucleation, and crystalline precipitation. Alternatively, damaged tissue may allow an influx of calcium ions, leading to an elevated intracellular calcium level and subsequent crystalline precipitation. Tissue damage also may result in denatured proteins that preferentially bind phosphate. Calcium then reacts with bound phosphate ions, leading to the precipitation of calcium phosphate [70, 76–82].

### 9.5.1 Calcinosis Cutis Universalis

This entity describes diffuse calcium deposits in the skin, subcutaneous tissue, and connective tis-

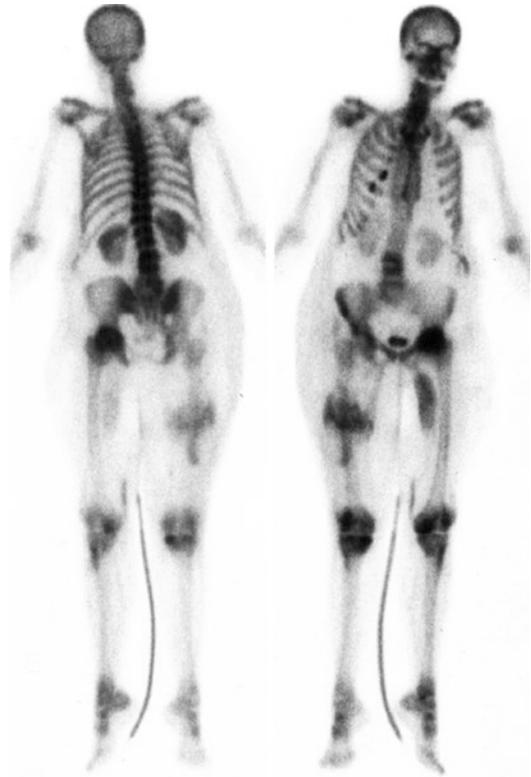

sue sheaths around the muscles but not within the muscles as is the case with myositis ossificans. It is seen mostly in association with scleroderma and polymyositis [83–86]. On bone scintigraphy, it shows uptake of variable degrees in a diffuse fashion in large areas of the skin and subcutaneous regions.

### 9.5.2 Calcinosis Cutis Circumscripta

This condition is a form of localized calcium deposition in the skin. If dystrophic, it is secondary to localized causes of dystrophic calcification such as trauma, insect bites, acne, and certain skin tumors. If it is metastatic, or associated with systemic causes of dystrophic calcifications, it generally occurs earlier and tends to involve the extremities, whereas calcinosis universalis occurs later and usually is more widespread [87].

## 9.6 Rhabdomyolysis

Rhabdomyolysis, also called myoglobinuria, is a condition that follows muscle damage secondary to infectious and noninfectious injuries including viral infections, electrical injury, certain drugs, trauma, and excessive physical activity, as in runners and military recruits. The condition can be severe and life threatening. The most severe form is sometimes called crush syndrome. Milder forms are included in compartment syndromes. The condition is characterized by excess myoglobin in the urine since intracellular muscle protein is released with muscle damage and appears in urine. Certain injuries will cause variable degrees of muscle death. The dead muscle will have an increased calcium content and is sensitively identified using Tc-99m MDP bone scanning which can be used to evaluate the degree of muscle necrosis. The influx of calcium ions into muscle cells occurs secondary to damaged cell membrane integrity which also allows bone-seeking radiotracers to form stable complexes inside muscle cells [14]. A variable degree of abnormally increased uptake (Fig. 9.21) is seen in the affected muscle(s) [88–90].

**Fig. 9.21** Rhabdomyolysis of both thighs in a patient with a recent history of motor vehicle accident

## 10.1 Introduction

Although the use of SPECT/CT, PET/CT, and PET/MR in different bone diseases was discussed in several chapters of this book, a separate chapter putting together the clinical uses and impacts of such important modalities in the diagnosis and follow-up of bone diseases is thought to be warranted given the importance of such modern imaging modalities.

The clinical utility and effectiveness of bone scan, planar scan, and SPECT have been proven without CT. In most patients, bone scan without CT provides sufficient information for the diagnosis. Accordingly adding CT should only be in select situations when bone scans show lesions of indeterminate nature and/or location. In such situations, CT is added for a limited region of interest to improve the specificity of bone scintigraphy. PET/CT and PET/MR have revolutionized the impact of nuclear medicine in the diagnosis and follow up of diseases including bone pathologies particularly in neoplastic disease.

---

## 10.2 SPECT/CT

Combining the latest SPECT imaging technology with multislice CT allows detection of subtle, non-specific abnormalities on bone scans and interprets them as specific focal areas of pathology. Compression fractures can be distinguished from severe degenerative disease, both of which can

**Table 10.1** Clinical uses of SPECT/CT in bone diseases

cause intense activity across the spine on either planar or SPECT imaging. Localizing activity in patients who have had spinal fusion can provide information on the causes of therapeutic failures. Infections of the spine now can be diagnosed with gallium SPECT/CT. Small focal abnormalities in the feet and ankles can be localized well enough to make specific orthopedic diagnoses based on their location. Additionally when radiographic imaging provides equivocal or inadequate information, SPECT/CT can provide a road map for further diagnostic studies and has been invaluable in planning surgery and biopsies. The ability to localize activity within a bone or at an articular surface has allowed us to distinguish between fractures and joint disease. Table 10.1 summarizes the main uses of SPECT/CT in bone diseases.

## 10.2.1 Uses of SPECT/CT in Neoplastic Diseases

### 10.2.1.1 Skeletal Metastases

Malignant lesions may be difficult to differentiate from nonmalignant conditions by bone scan, particularly when there is a single hot spot or a small number of lesions. SPECT/CT significantly improves the specificity of bone scintigraphy for metastases. In a study on 308 patients with breast cancer (211 patients) and prostate cancer (97 patients), SPECT/CT was 97% sensitive and

94% specific for detecting skeletal metastases compared to 93% and 78% for planar bone scan and 94% and 71% for bone SPECT [1]. The results illustrate the impact of adding CT scan to scintigraphy in improving the accuracy. Among oncology patients, SPECT/CT is used to further evaluate a doubtful hot spot on the whole-body scan, spot images, and SPECT since it improves the specificity of planar imaging and SPECT alone. In such situations, the hybrid imaging would detect nonmalignant abnormality and obtain additional evidence supporting a metastasis in addition to accurately determine the location of the abnormality (Figs. 10.1, 10.2, and 10.3). SPECT/CT has been proven useful for interpreting radionuclide bone scan results in patients with bone malignancies, showing far better specificity than planar imaging or SPECT alone, most notably in the evaluation of spinal abnormalities. SPECT/CT provides an accurate evaluation of the site of the lesions and also supplies other information that can be useful in non-malignant conditions such as trauma, infections, and joint disease [2].

In a study of 40 patients with carcinoma of the prostate, 50 lesions were seen on planar bone scintigraphy. On planar and SPECT scans, reviewers rated 61% of lesions as equivocal. On reporting the SPECT/CT scans, only 8% of lesions were equivocal, 24% were reported as malignant, and 68% were reported as benign [3].

Among 102 patients with breast cancer, 52 indeterminate lesions on planar scintigraphy were analyzed in correlation with SPECT and SPECT/CT. On SPECT there were 15 indeterminate lesions while only 3 on SPET/CT. The improvement was mostly for lytic lesions. In patients with solitary bone lesions, management was decided based on the classification by SPECT/CT [4].

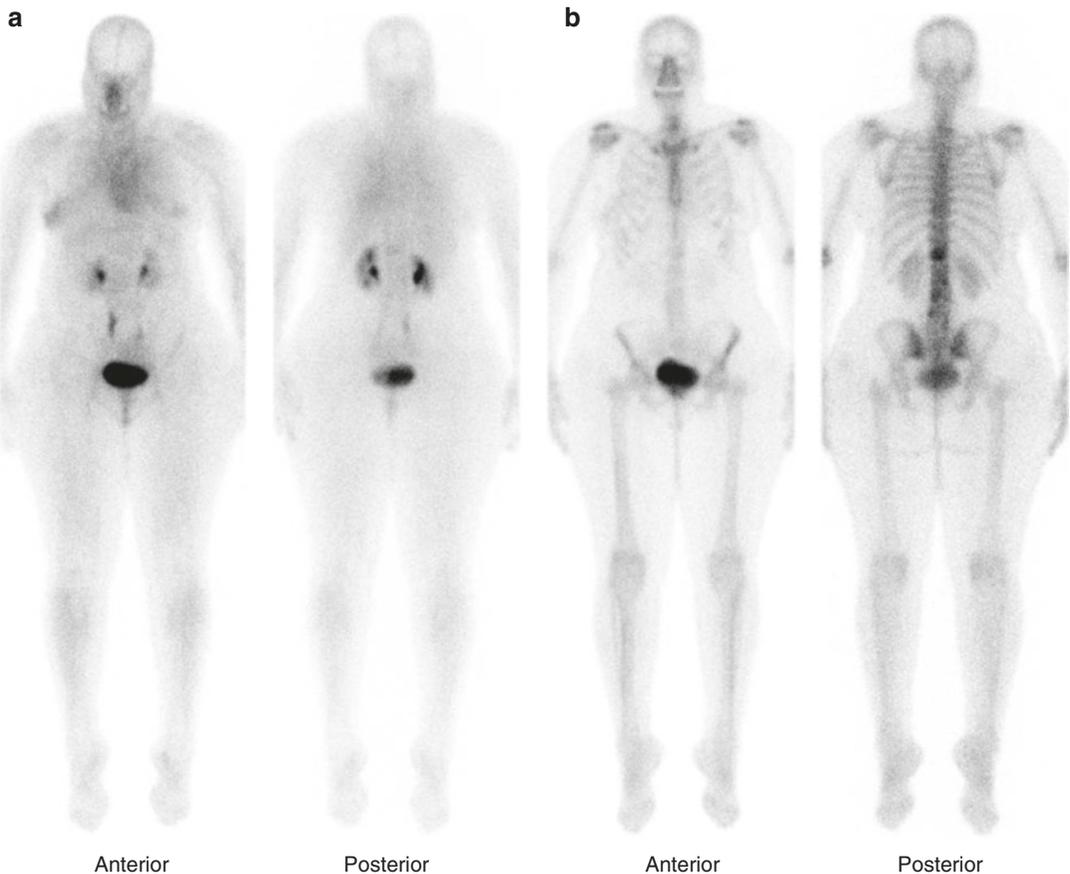

In a study of 52 lesions classified as indeterminate by SPECT, 48 (92%) were correctly classified as nonmalignant or malignant by SPECT/CT [5]. Another study of 37 patients with 42 spinal focal lesions, all lesions doubtful by SPECT alone were classified by SPECT/CT, which leads to correct diagnosis in 100% of cases, compared to 64% with whole-body radionuclide scanning and 86%

with SPECT alone [6]. Additionally in patients with tumors, SPECT/CT improved the confidence in interpretation of bone scans by physicians, by improving lesion localization, confirming the diagnosis suggested by the planar images, or supplying or correcting the diagnosis [7, 8].

Forty-two patients with 189 skeletal lesions were studied. The primary tumors were mainly breast (22 patients) and prostate cancer (8 patients). The overall accuracy of SPECT/CT was significantly higher than SPECT (79% vs. 52% for patients and 92% vs. 67% for lesions). Authors recommended SPECT/CT when avail-

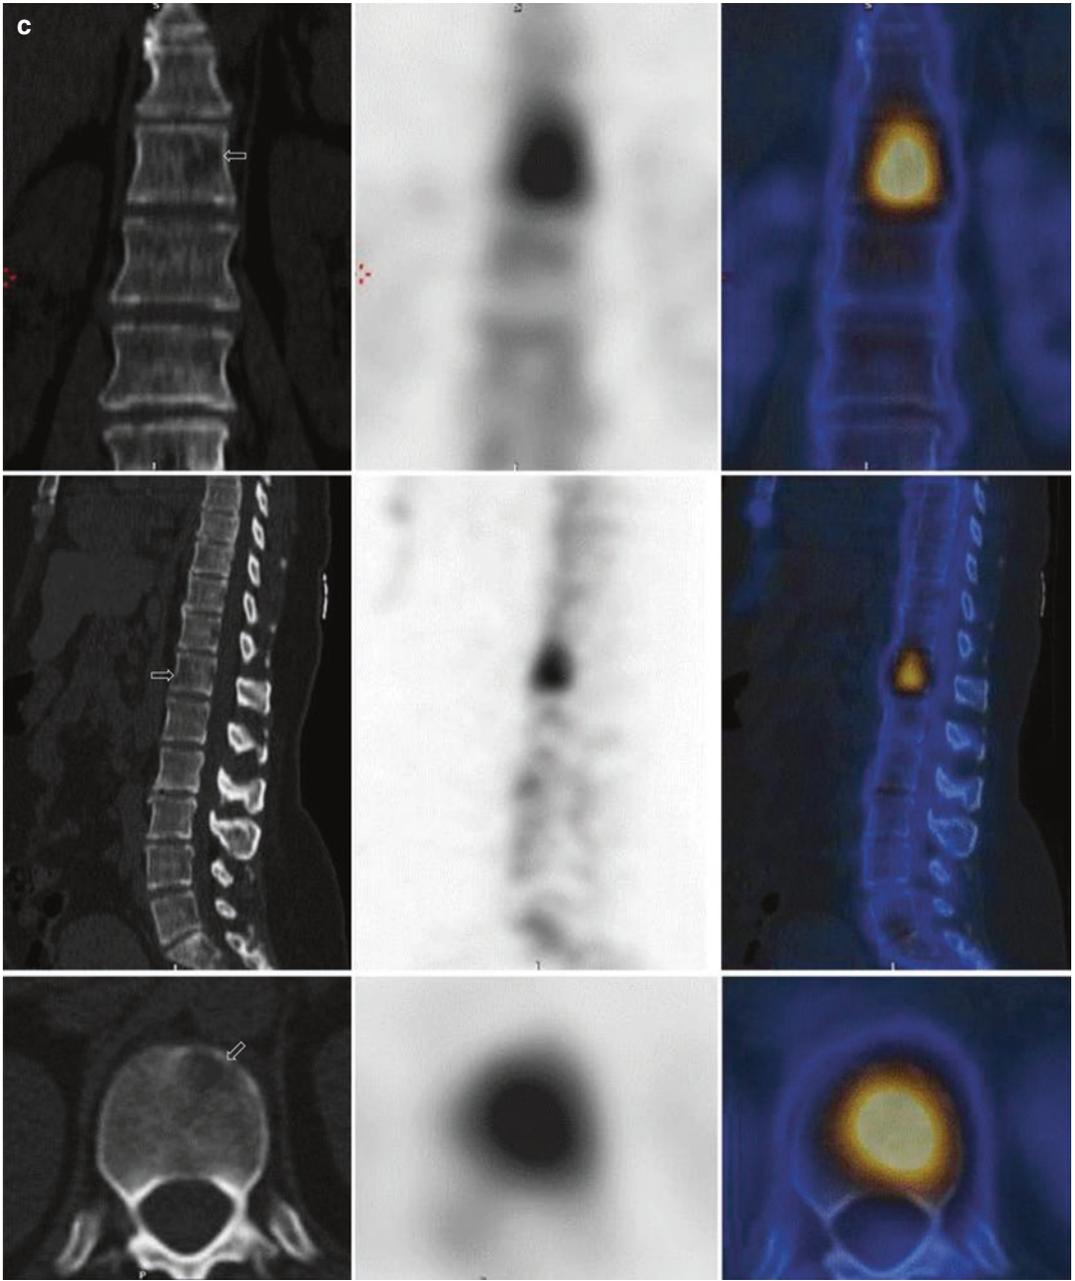

able in patients in whom correct classification of equivocal lesions is expected to alter the patient's management [9].

In a recent study, the results of bone scintigraphy (both planar and SPECT), SPECT and CT or radiography, and SPECT/CT were compared with respect to their precise location and nature (benign or malignant) of each lesion. SPECT/CT allowed correct classification of 85% of lesions compared to 36% for SPECT [11]. The higher accuracy of SPECT/CT is mainly due to the correct identification of benign bone abnormalities in equivocal findings [10–12].

**Fig. 10.1** A 52-year-old female with pathologically proven breast cancer referred for bone scan to rule out metastases. Blood pool images are unremarkable (a). Delayed whole-body images (b) show an intense focus of increased uptake in D12 vertebra and smaller foci of

mildly increased uptake in the L2 to L4 vertebrae. SPECT/CT study (c) shows clearly the D12 lesion is corresponding to a lytic metastatic lesion in the vertebral body (arrow) and degenerative changes in the lumbar spine

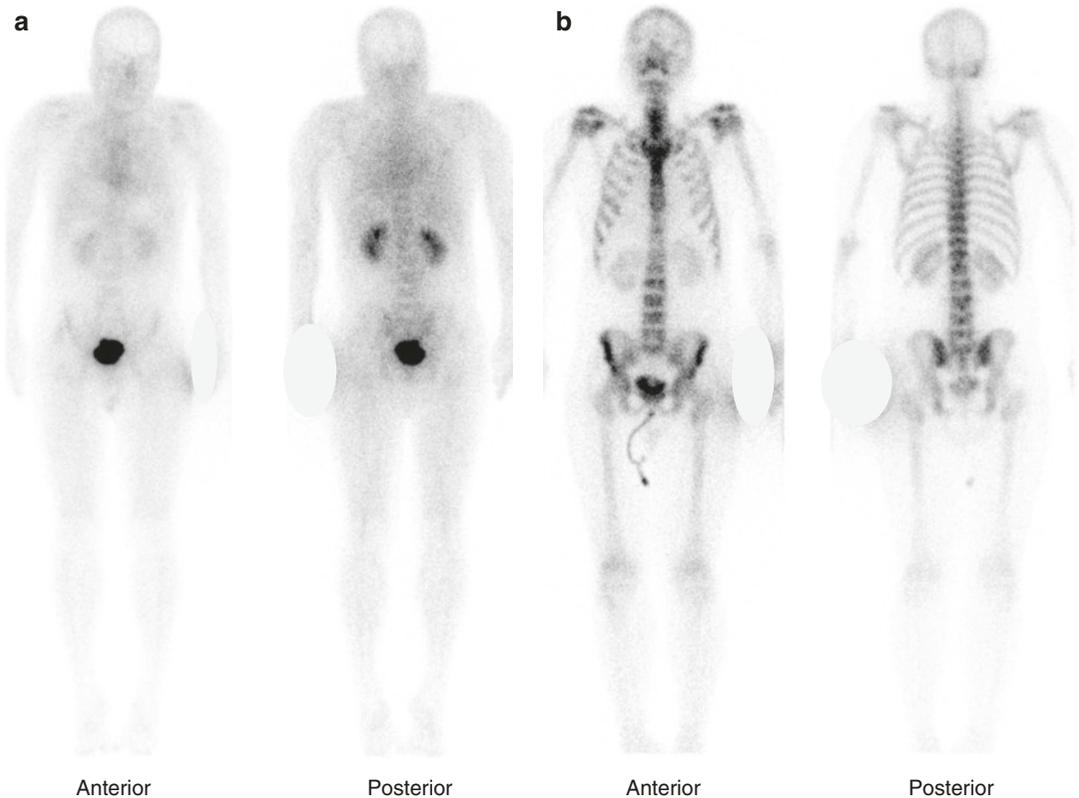

**Fig. 10.1** (continued)

### 10.2.1.2 Benign bone Tumors

Osteoid osteomas show foci of intense activity on bone scan, and a lucent nidus can usually be identified on CT, but the findings can be difficult to interpret when they occur in the small bones such as those of the midfoot as well as in hip region. SPECT/CT can be helpful to confidently diagnose the condition by correlating the scintigraphic findings with CT images [13]. SPECT/CT can also be of help in a specific diagnosis of vertebral hemangioma given the non-specificity of the scintigraphic pattern seen on bone scan (see Chap. 6).

### 10.2.2 Uses of SPECT/CT in Nonneoplastic Diseases

In one study analyzing the clinical benefit of SPECT/CT in 89 non-oncologic patients with inconclusive bone scans, 59% of patients' CT component was critical in diagnosing the lesions as fractures, osteochondral lesions, non-ossifying fibroma, enchondroma, fibrous dysplasia, spurs, osteoid osteoma, bursitis, spondylolysis, or osteoarthritis [14]. Another study of 71 patients without cancer who had pain in the extremities found the use of SPECT/CT increases diagnostic accuracy in the evaluation

**Fig. 10.2** Tc-99m MDP SPECT/CT study of a 50-year-old female with breast cancer. Whole-body blood pool images (a) show no abnormalities. Whole-body delayed images (b) show nonuniform uptake in the lumbar spine. Sagittal (c) and transaxial (d) representative sections of

SPECT/CT study show clearly the cold lesions in the posterior part of the L2 vertebral body and anterior part of the L5 vertebral body on CT scan which are not appreciated on planar images

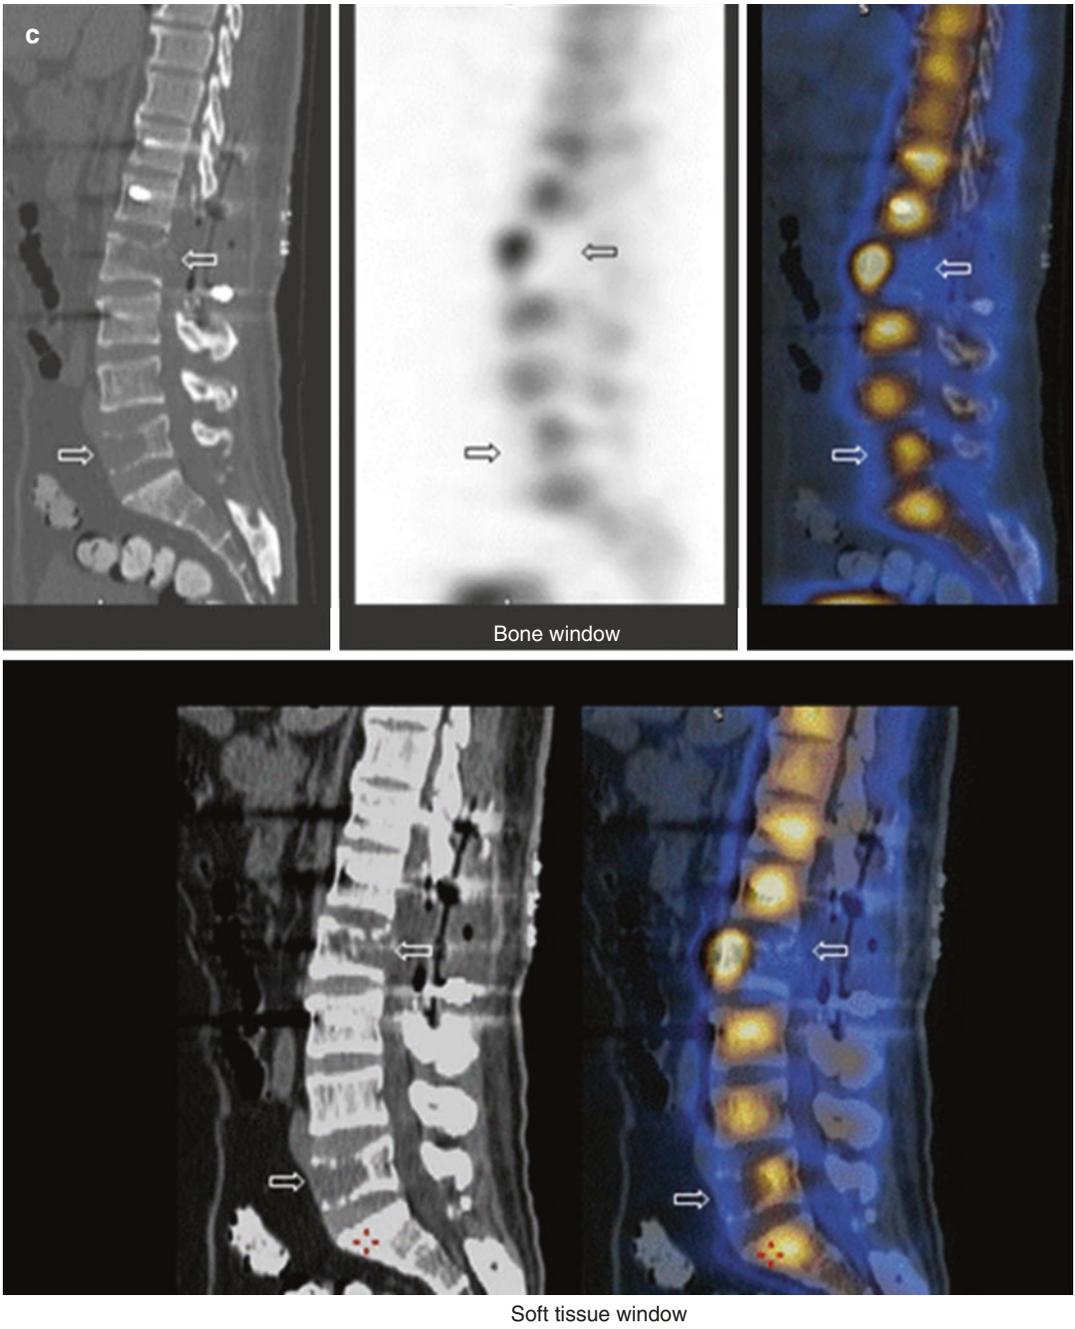

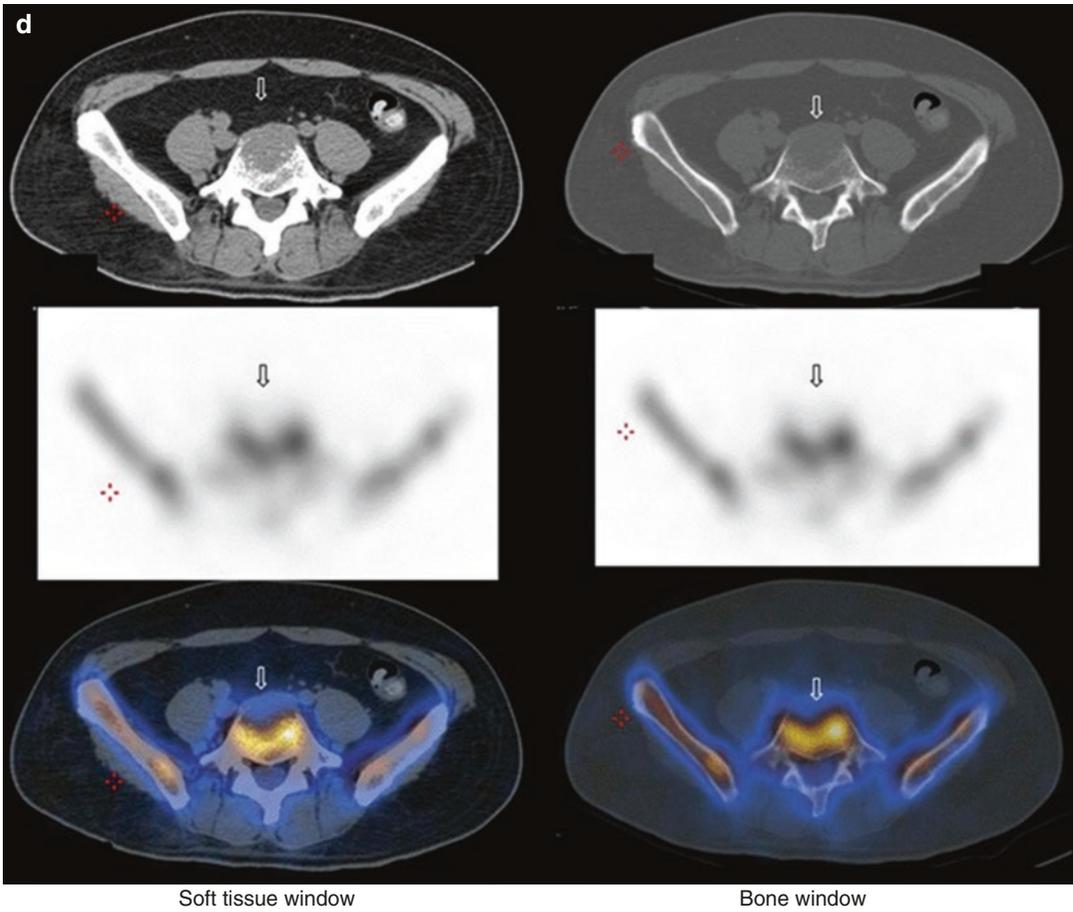

Fig. 10.2 (continued)

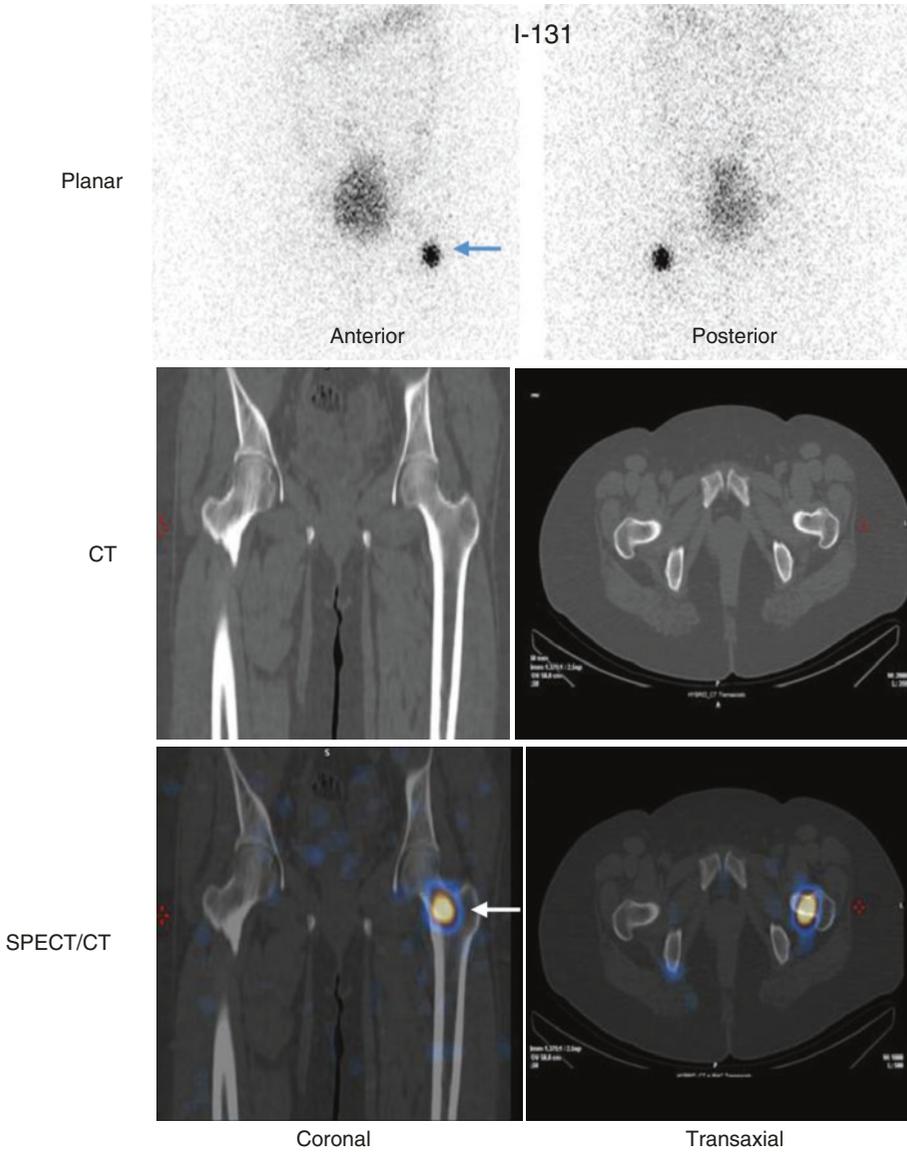

**Fig. 10.2** (continued)

of orthopedic disorders affecting the extremities compared to bone scan alone and SPECT. SPECT/CT findings led to revision of the diagnostic category in the cases of 23 of 71 patients [15].

### 10.2.2.1 Trauma Fractures

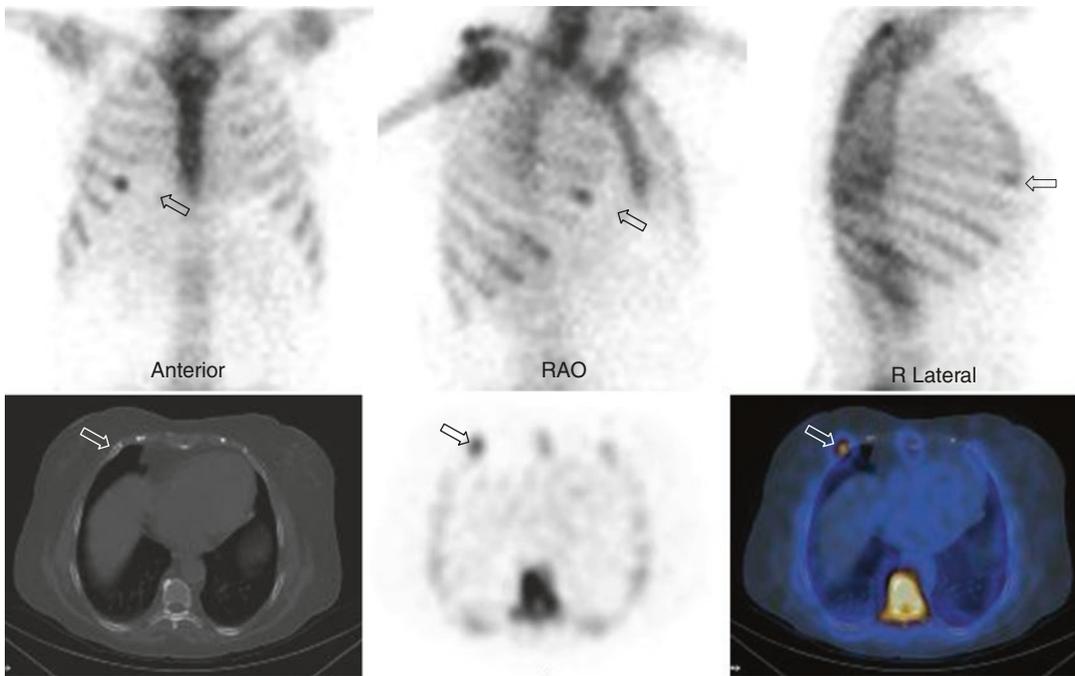

Most traumatic bone lesions are diagnosed by conventional plain radiography or CT. In patients whose radiographs are inconclusive, bone scan helps in identifying fractures (Fig. 10.4) and is able to reveal additional missed fractures in more than half of patients with polytrauma [16]. Accurate information on

the location of the abnormalities can also contribute to the diagnosis. SPECT/CT is particularly helpful in patients with postoperative or post-traumatic changes, when precise localization of a focus of residual hyperactivity may provide important clues. In a case series study of 80 trauma patients, SPECT/CT was significantly better than planar bone scan in detecting and localizing lesions and decreased the proportion of indeterminate diagnoses from 61% to 7%. It assisted in the identification of ligament or tendon avulsions, osteochondral lesions, post-traumatic osteoarthritis, fissures, fatigue fractures, and other fractures [2].

**Fig. 10.3** Selected images of I-131 study of a 31-year-old female with papillary thyroid carcinoma. Planar images of the pelvis (a) show a focus of intense uptake in the left upper thigh (arrow). Selected images of the

SPECT/CT study (b) localized accurately the uptake focus in the left intertrochanteric area of the left femur (arrows)

**Fig. 10.4** Multiple planar and selected transaxial SPECT/CT images of the chest demonstrate focally increased activity at right sixth costochondral junction, consistent with rib fracture

### Spine Conditions

#### Compression Fractures

Multiphase bone scan has long been used to detect and help establish the age of compression fractures. However, accurate localization of the fractures is now critical for managing patients because of the advent of vertebroplasty and kyphoplasty. Since injecting cement into the vertebral body is used to stabilize the vertebrae, it is more important than ever to be certain that we identify the acute fracture. MRI is often used, but cannot be performed in some patients and is non-specific in others. SPECT/CT is helpful in patients with an acute back pain and a history of compression fractures (Fig. 10.5). CT scan may show varying degrees of compression in more than one vertebra, but uptake on the fused bone scan images will identify the site to be injected with cement, and patient's pain can be resolved within a short time even within 24 h [17].

#### Spondylolysis

Many teenagers with back pain are evaluated with MRI when plain X-rays are normal. Although bone scan is highly sensitive to the presence of fractures of the pars interarticularis, it may fail to demonstrate a large number of these lesions, and therefore, SPECT imaging is required. However, SPECT/CT is able to distinguish between fractures of the pars and other abnormalities that cause focal areas of increased activity such as facet joint arthritis [18].

#### Spinal Fusion

Patients with intractable low back pain or those with significant neurologic symptoms may undergo spinal fusion to stabilize the spine, restricting motion to prevent symptoms such as in cases with disk herniation. A significant number of patients will have either residual or recurrent pain, and further treatment depends

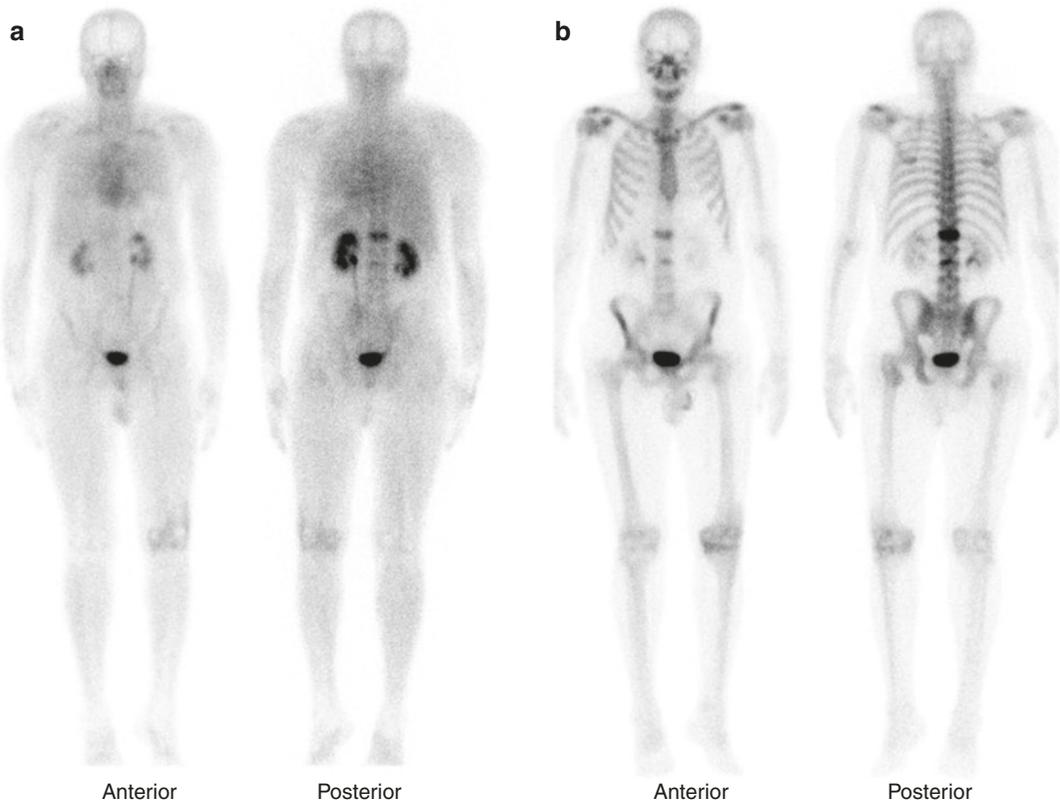

on distinguishing several possible causes. There may be failure of the surgical hardware, which usually is associated with fracture of the bone graft and formation of a pseudarthrosis. In such situation, CT often shows a lucent area surrounding the pedicle screws, and the bone scan shows increased uptake in a pattern seen in other forms of hardware loosening. There may also be facet joint arthritis or disk space degenerative disease at adjacent levels due to the transmission of forces, either above or below the area of rigidity created by the surgery.

SPECT/CT makes it possible to find the cause of residual or recurrent symptoms and helps surgeons limit surgery for fusion to the involved joints [19].

#### Ankle and Foot Trauma

Disorders of the ankle and foot are common and represent a significant clinical challenge. Ankle and foot pain may be due to a variety of conditions including fractures, osteoarthritis, tarsal coalition, osteochondritis dissecans, inflammation, and soft tissue pathology. SPECT/CT is an excellent technique for the evaluation of such complex pathology since CT images provide details of the bone anatomy while the bone scan provides the functional information.

**Differentiation of soft tissue and skeletal pathology:** MRI is routinely used in the evaluation of soft tissue pathology of the feet, including tendinosis, bursitis, and fasciitis, and for the diabetic foot. It has been successfully used in the management of diabetes-related osteomyelitis. Optimal evaluation

**Fig. 10.5** Whole-body blood pool (a) and delayed (b) images demonstrate diffusely increased vascularity/hyperemia and osteoblastic activity in the L1 vertebra. There is also slightly increased focal osteoblastic activity in the upper end of L3 vertebra on the right and degenera-

tive/post-traumatic changes in the left knee. Sagittal, coronal, and transaxial SPECT/CT and MIP images clearly demonstrate the compression fracture in the body of L1 vertebra. Mild focal uptake in the upper end of L3 vertebra is likely due to degenerative changes

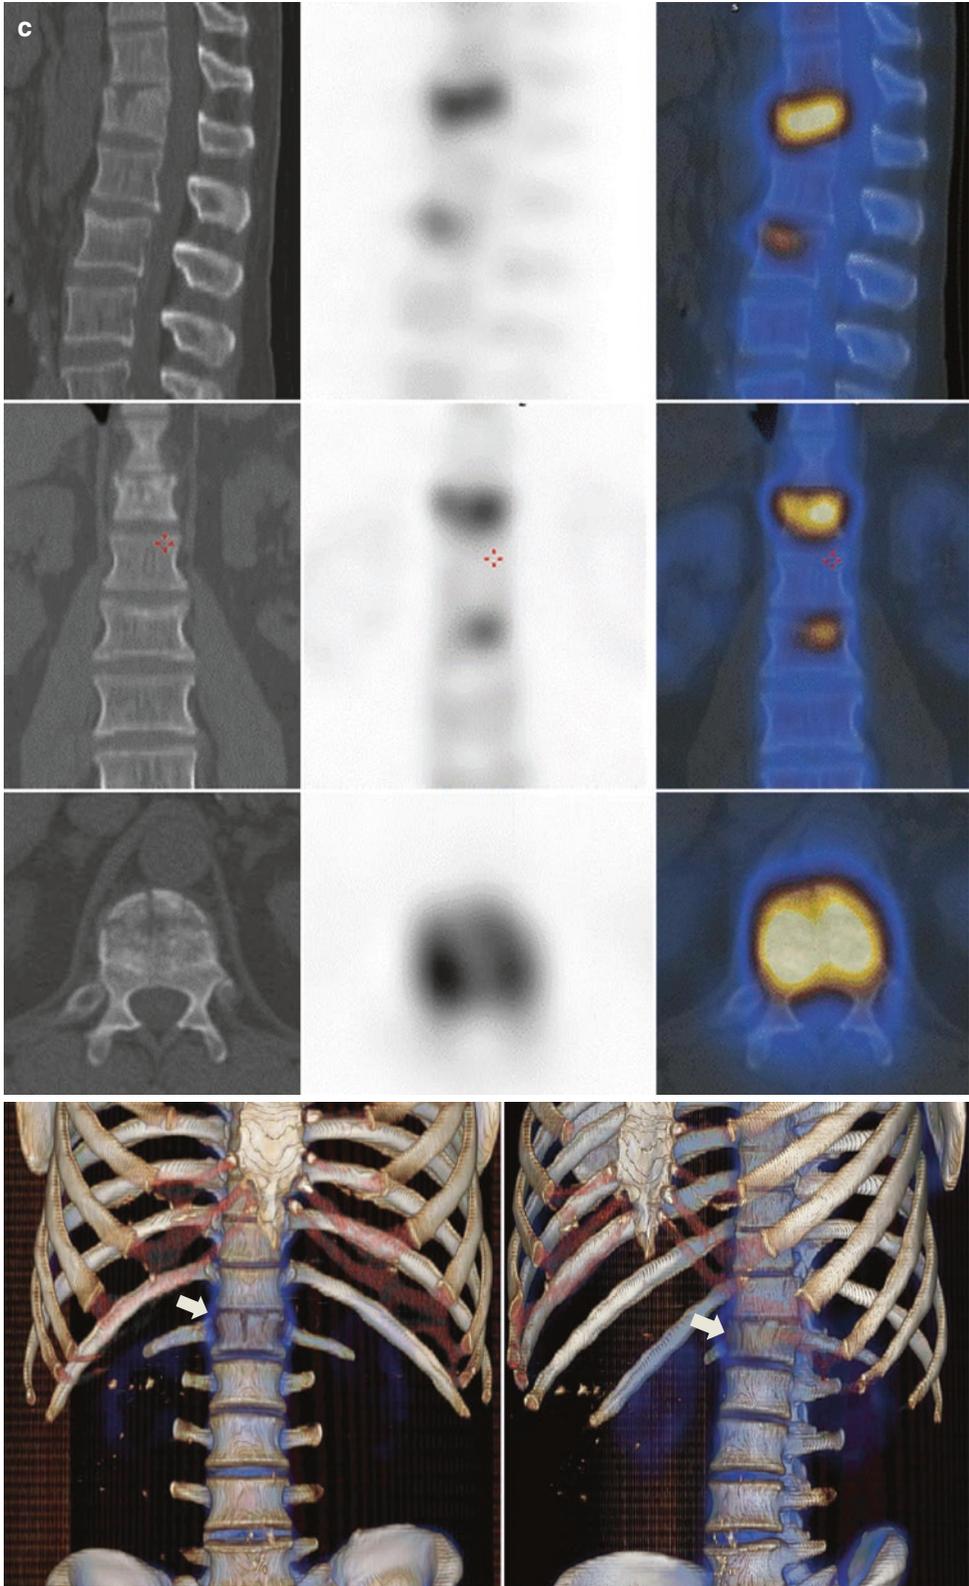

Fig. 10.5 (continued)

of tendinous pathology, however, remains elusive, and in a recent study, maximum of 27% of patients who presented with clinical evidence of posterior tibial tendon disease had a normal MR examination result [20]. Some of the potential disadvantages that one must be aware of with MRI are metallic artifacts associated with hardware or micrometallic material in an operative bed, which are more pronounced in high-field systems and worse with increasing field strength. Postoperative follow-up imaging in the presence of micrometallic artifacts may not be carried out using a high-field system. Also, due to claustrophobia, the use of general anesthesia has been seen in a maximum of 10% of patients imaged in a closed high-field MR system, and obese patients frequently cannot be imaged in the constrained geometry of closed systems.

SPECT studies performed in patients with equivocal findings noted on planar bone scans have demonstrated improved sensitivity and specificity, although it has shown only limited benefit in the evaluation of foot pathology.

#### **Postoperative evaluation of joint fusion:**

Joint arthrodesis has long been used for the treatment of painful malalignment or arthritis of the hindfoot. Successful osseous union after joint arthrodesis is usually expected to occur within 6 months of the procedure and is confirmed if no joint motion is detected on clinical examination. There is evidence of trabeculation across the arthrodesis site as observed on plain film radiographs. Delayed union is defined as a successful fusion 6–9 months after surgery.

In patients who continue to suffer from pain after arthrodesis, nonunion is suspected. Other complications that result in persistent pain after arthrodesis include overload of the adjacent joints, with development of arthritis in about 30% in the medium term [21]. This postoperative assessment of the success of fusion has been routinely evaluated using X-ray and CT techniques. MRI would be unsuitable in this situation because of in situ metal hardware or the presence of micrometallic artifacts. Computed tomography scanning is useful in identifying nonunion sites associated with pain, but may provide limited information if metal implants are retained because of scatter effects. SPECT/CT may provide a valuable technique for the evaluation of continuing pain in the context of arthrodesis with in situ hardware as sites of altered

metabolic activity on the bone scan would allow a more focused examination of the area on the CT study. This may improve the accuracy of identifying nonunion, malunion, or subjacent arthritis as the cause for continuing pain [22].

#### **Osteochondritis Dissecans**

Osteochondritis dissecans is a repetitive stress injury seen particularly in young athletes. Overuse of a joint leads to disruption in the blood supply to the adjacent bone. Bone and cartilage fragments often separate because of devitalization of the sub-articular region, and these fragments may cause severe pain in the joint. Although the condition has been described in the knee, hip, and elbow, it is usually seen in the ankle. The patients present with vague ankle pain and most often have no recollection of a single injury. The cystic degeneration that occurs in these patients is confined to the talar dome. In patients in whom pain persists after rest and physical therapy, surgery is often recommended to smooth the articular surface and remove fragments of bone and cartilage that may be interfering with motion. By excavating the lesion, a new bone is allowed to regrow. SPECT/CT has been used to confirm that the lesion is likely to be the cause of the patient's pain and to aid in surgical planning [22].

#### **Tarsal Coalition**

Tarsal coalition is a condition in which there is congenital fusion of two of the tarsal bones with either a bony or fibrous bridge (see Chap. 3). These abnormal connections cause abnormal stress on the hindfoot, with pain usually beginning in the early teenage years. Surgery is required to separate the bones in those patients who do not respond to conservative treatment.

Bone SPECT/CT gives additional useful information in tarsal coalition [23]. The significance of the SPECT/CT is its ability to confirm that the radiographic abnormality is accounted for patient's pain [24] by proper localization of radionuclide activity.

#### **Wrist and Hand Trauma**

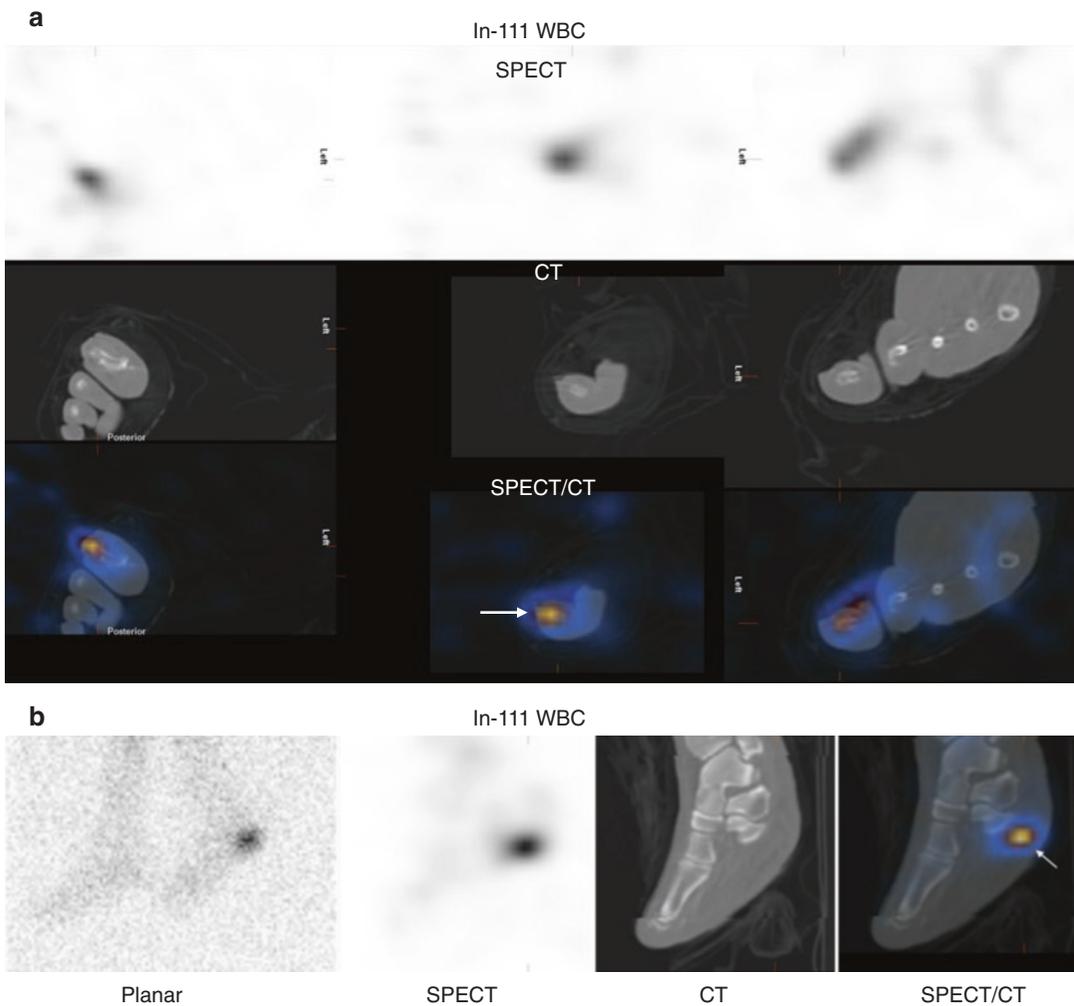

SPECT/CT is valuable in accurate diagnosis and localization of occult fractures of the wrist and small bones of the hand and in differentiating fractures from osteoarthritis lesions and osteonecrosis [25–27].

**10.2.2.2 Infections**

Labeled white blood cell imaging has proven highly sensitive and specific in the diagnosis and follow-up of patients with suspected osteomyelitis. SPECT/CT improves further the accuracy of labeled leukocyte imaging in patients with suspected osteomyelitis by providing accurate anatomic localization (Fig. 10.6) and precise definition of the extent of infection [2, 28]. SPECT/CT differentiated soft tissue from bone involvement both in patients with osteomyelitis and in patients with orthopedic implants. It allows correct diagnosis of osteomyelitis in patients with violated bone

after trauma and identifies synovial infection without prosthesis involvement in patients with a knee implant [29]. SPECT/CT improves the diagnostic performance of three-phase bone scan for osteomyelitis by avoiding false-positive or equivocal results by increasing the specificity from 50% to 86% in a study of 31 patients suspected of bone infection and have abnormal findings on multiphase bone scintigraphy who underwent additional SPECT/CT [30].

SPECT/CT was found useful for the evaluation of painful knee prosthesis in 85.5% of cases and helped in confirming mechanical loosening and in excluding other causes such as infection

**Fig. 10.6** (a) In-111 labeled leukocyte SPECT/CT selected images for a diabetic patient with suspected osteomyelitis of the right foot. Focal activity is seen at the distal phalanx of the right great toe (arrow) associated with cortical thinning on low dose CT consistent with osteomyelitis. Note the value of CT component in localization of abnormality and

increasing the certainty of the diagnosis (b) Diabetic male patient with draining wound in the left hindfoot. In-111 WBC study shows focal accumulation on planar image (arrow) which is difficult to evaluate if there is calcaneal bone involvement. SPECT/CT localizes the focal activity as being in the soft tissue (arrow). No bony involvement

and patellofemoral osteoarthritis [3]. SPECT/CT is also helpful in distinguishing vertebral from paravertebral soft tissue infection [12].

The role of SPECT/CT for the diagnosis of diabetic foot infection has been established by labeled leukocytes. Leukocyte scanning was positive in 16 of 19 lesions. SPECT/CT changed the interpretation of the planar and SPECT images for 10 of 19 suspected sites (52.6%): It excluded osteomyelitis in six cases, revealed bone infection in one case, and revealed both bone and soft tissue infection in three cases. SPECT/CT can be useful for a more accurate diagnosis of diabetic foot infection by labeled leukocyte imaging [31].

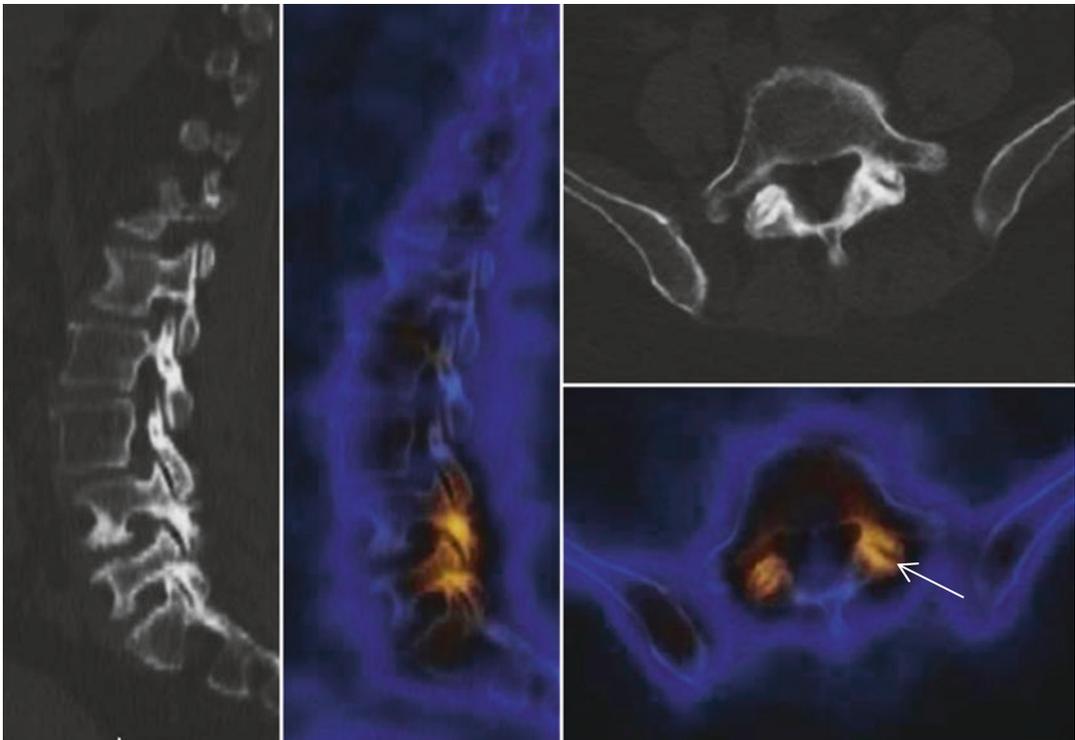

Combined bone scintigraphy and WBC scan and, when needed, WBC scan and bone marrow scanning using SPECT/CT were used in 213 patients with suspected diabetic foot osteomyelitis. SPECT/CT was found highly accurate modality that considerably improves detection and discrimination of soft tissue infection and osteomyelitis while providing precise anatomic local-

ization in the diabetic foot [32]. SPECT/CT can also be useful in chronic osteomyelitis since it detects sequestra [33].

### 10.2.2.3 Other Nonneoplastic Diseases

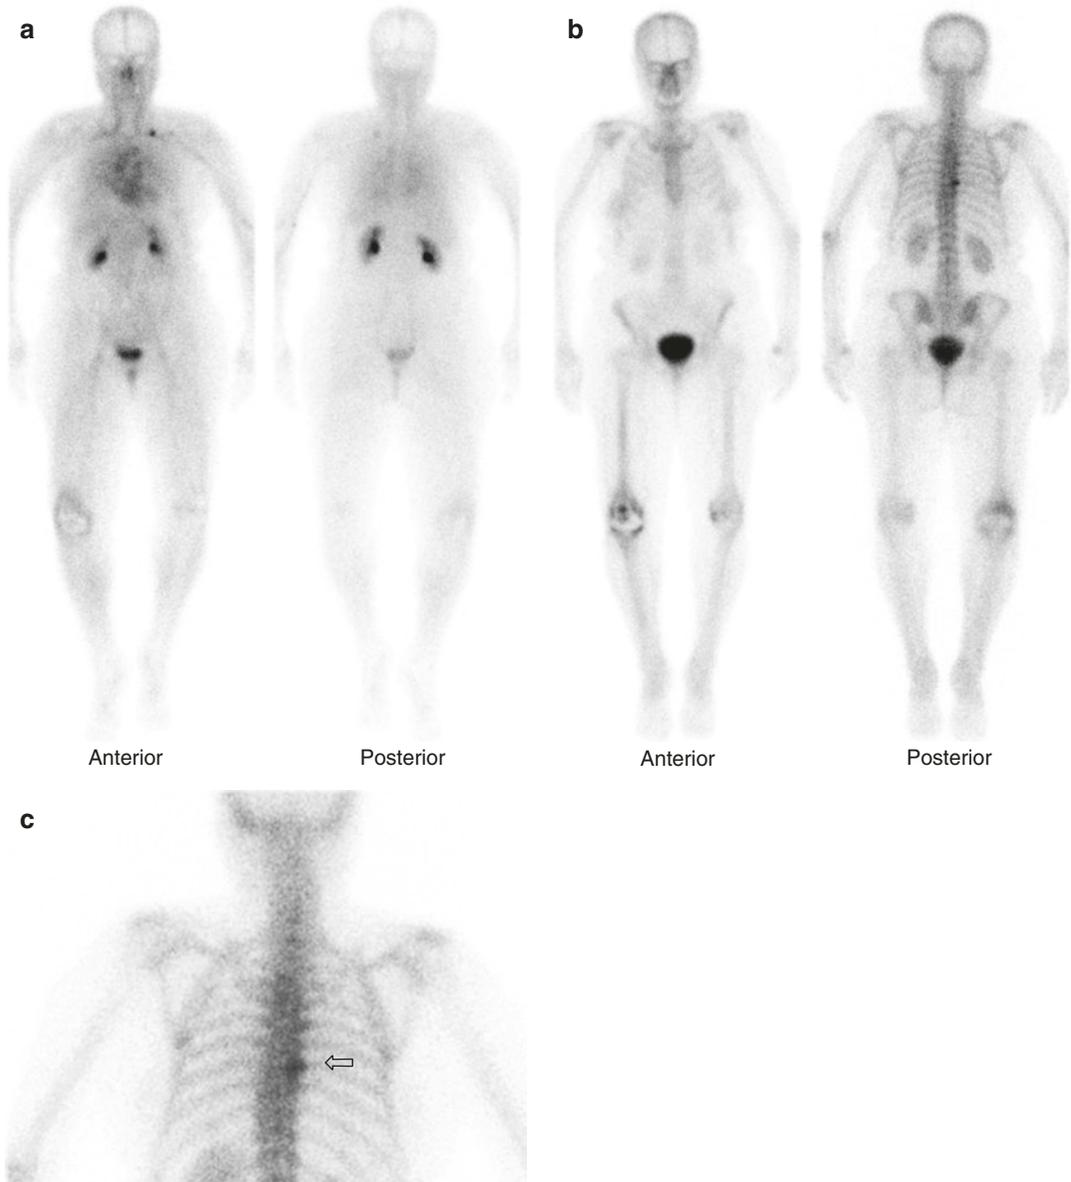

#### Osteoarthritis

In patients with osteoarthritis, the many changes visible by radiography and CT can be correlated with the radionuclide bone scanning data to confirm that any hot spots are due to the degenerative disease. Osteoarthritis is not an indication for diagnostic scintigraphy. SPECT/CT may be useful to confirm that a focal bone reaction is related to degenerative changes [34]. However, the main indication of SPECT/CT is differentiating osteoarthritis from other causes of increased uptake, most notably bone metastases. Osteoarthrosis of the spine includes intervertebral osteochondrosis, spondylosis deformans, apophyseal joint osteoarthritis (Fig. 10.7), costovertebral osteoarthritis, diffuse idiopathic skeletal hyperostosis (Fig. 10.8),

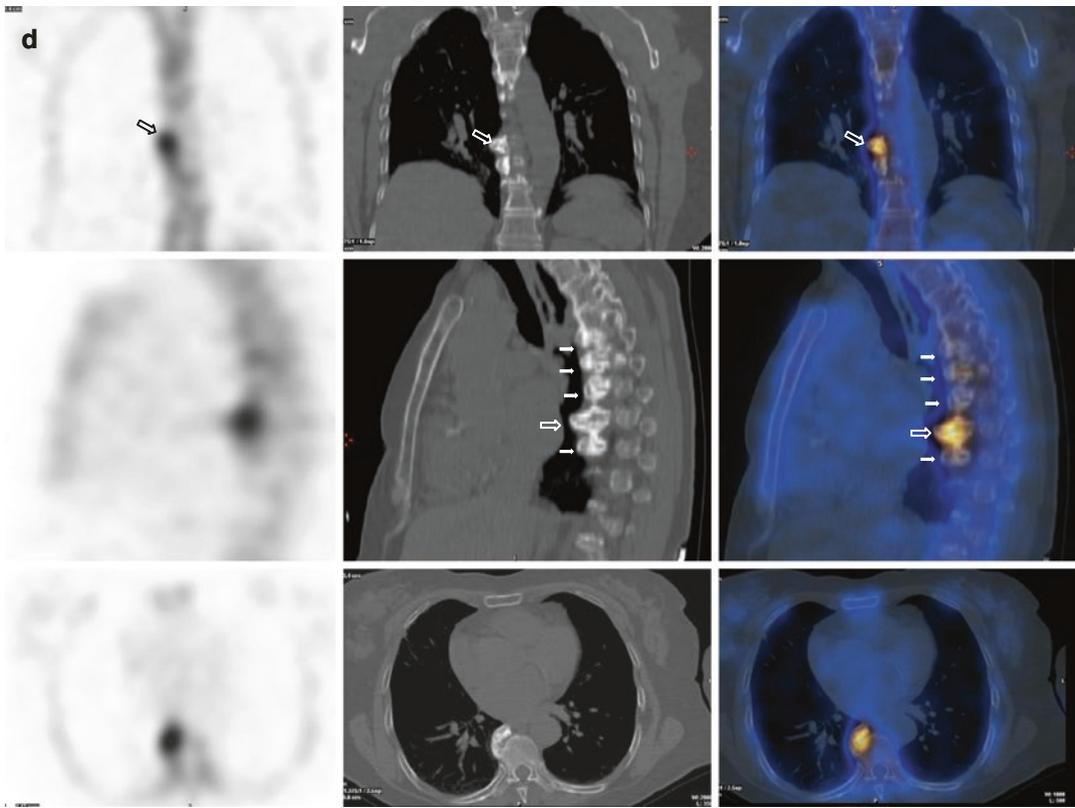

**Fig. 10.7** Representative sagittal slices of SPECT/CT study for a 69-year-old patient complaining of back pain. Images reveal increased uptake in the opposing end plates of L2/L3 (*arrows*) with narrowing of the disk space.

Additionally in the L4/L5, there is facet osteoarthritic changes (*arrows*). This illustrates how SPECT/CT facilitates recognition of osteoarthritis

**Fig. 10.8** Whole-body blood pool (a) and delayed images (b) of a 68-year-old female with upper back pain. The patient has a history of right knee replacement. The blood pool images reveal mild hyperemia around the right knee prosthesis with matching uptake on delayed images. There is a focus of increased uptake in the right eighth costovertebral junction (arrow), seen also on spot image (c). SPECT/CT (d) of the thoracic spine region shows clearly

a big osteophyte corresponding to the focal uptake on planar images (open arrow). Additionally there are osteophytes in the three vertebrae above and one vertebra below; this is the most prominent abnormality with mild activity (solid arrows). The SPECT/CT clarified the nature of the abnormalities in five adjacent vertebrae indicating the pattern of diffuse idiopathic skeletal hyperostosis

**Fig. 10.8** (continued)

ossification of the posterior longitudinal ligament, and degenerative changes of the supraspinous and interspinous ligaments. Each of these is characterized by morphological abnormalities that allow for their differentiation from other pathologies such as tumor and inflammation [35]. Additionally the precise localization of the disease is crucial for selective surgical treatment.

### Sacroiliitis

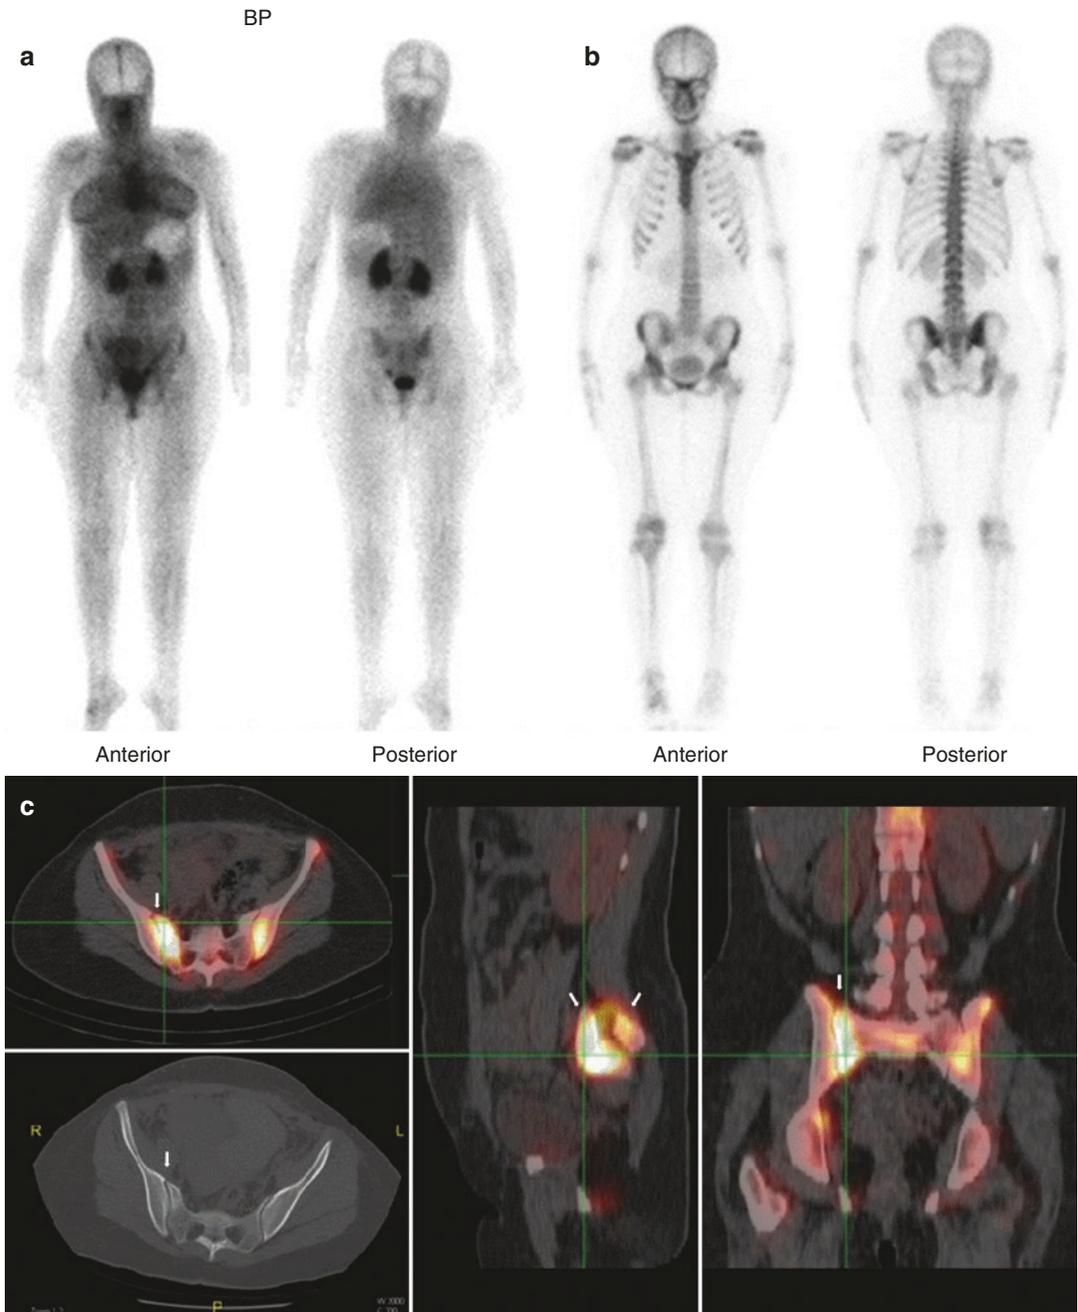

The role of scintigraphic imaging studies in the evaluation of patients with sacroiliitis is controversial [36]. Diagnosis of sacroiliitis with bone scintigraphy may be difficult even with a quantitative approach. Planar and SPECT bone scintigraphy, Tc-99m SC, and Tc-99m nanocolloid along with quantitative methods have all been used for the diagnosis [37–40]. The use of sacroiliac index values to confirm positive results can increase the specificity of bone scintigraphy [37]. SPECT bone scan was found to have the best accuracy

among scintigraphic studies [40]. SPECT/CT can be even more helpful in illustrating the exact location of uptake, its distribution pattern, and anatomic details (Fig. 10.9).

In a recent study, bone SPECT/CT was found to be more useful than conventional bone scintigraphy in identifying sacroiliitis in early axial spondyloarthritis patients, even with mild sacroiliac joint changes in plain radiography [41]. Since it can cause focal uptake overlying sacroiliac joint, lumbosacral transitional vertebra (Bertolotti syndrome) should be thought of during interpretation, and SPECT/CT has also been reported to identify the condition [42, 43].

### Heterotopic Bone Formation

Several pathologic conditions can clinically mimic the heterotopic bone formation in addition to its scintigraphic appearance in its early phase. It is difficult to correctly localize sites of uptake on planar and even on SPECT images. Although

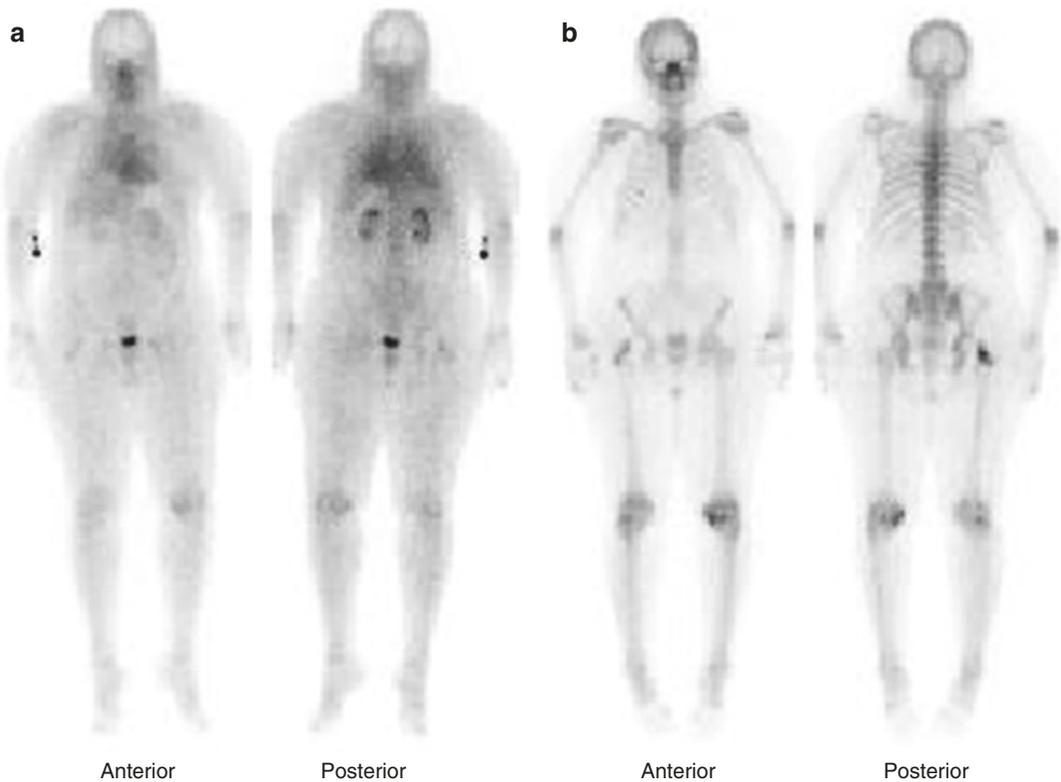

**Fig. 10.9** A Tc-99m MDP bone scan of a 60-year-old female complaining of right-sided low back pain. Blood pool images (a) show mildly increased uptake on the right sacroiliac joint corresponding to similar pattern on delayed images (b). Representative sections of SPECT/

CT study (c) show periarticular uptake in the right sacroiliac joint (arrows) which confirms the diagnosis of sacroiliitis and illustrates the added value of combining CT to bone scan

enough data are not available yet regarding the use of SPECT/CT in the evaluation of heterotopic bone formation, it should be logic that accurate localization of abnormalities is useful to establish the extraosseous nature of the formed bone (Fig. 10.10) to reach the diagnosis and to differentiate it from other causes of abnormal uptake. Only few reports indicated heterotopic ossification on SPECT/CT studies with one study on its role in assessment of a painful hip after total hip arthroplasty and found SPECT/CT helpful in three cases of heterotopic ossification as a reason for pain, and another study found it useful to determine maturity of the condition [44–47].

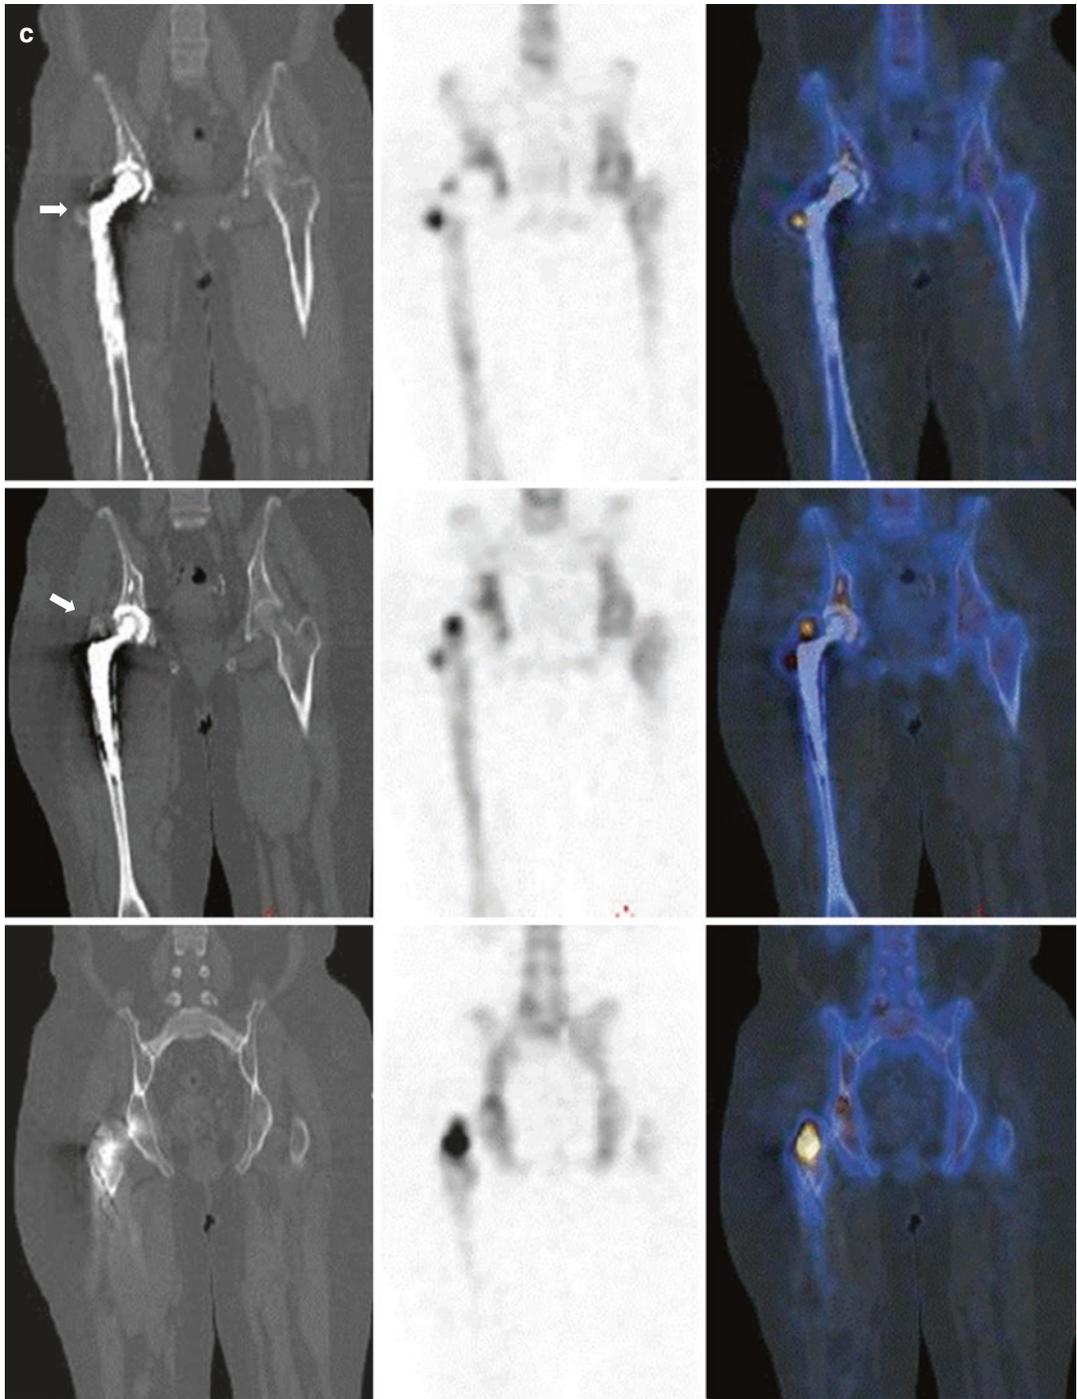

### Osteonecrosis

Although enough data is not available regarding SPECT/CT in evaluating osteonecrosis, our experience and available data suggest its role in improving the diagnosis by accurate localization of the scintigraphic abnormality (Figs. 10.11 and 10.12) and finding other pathologies explaining the abnormalities. Its value was particularly reported in evaluation of osteonecrosis of the jaw where SPECT/CT allowed the delineation of the necrotic core even though MRI was unable to visualize it. In oncology patients treated with bisphosphonates therapy which seems associated with osteonecrosis of the jaw, an increased uptake

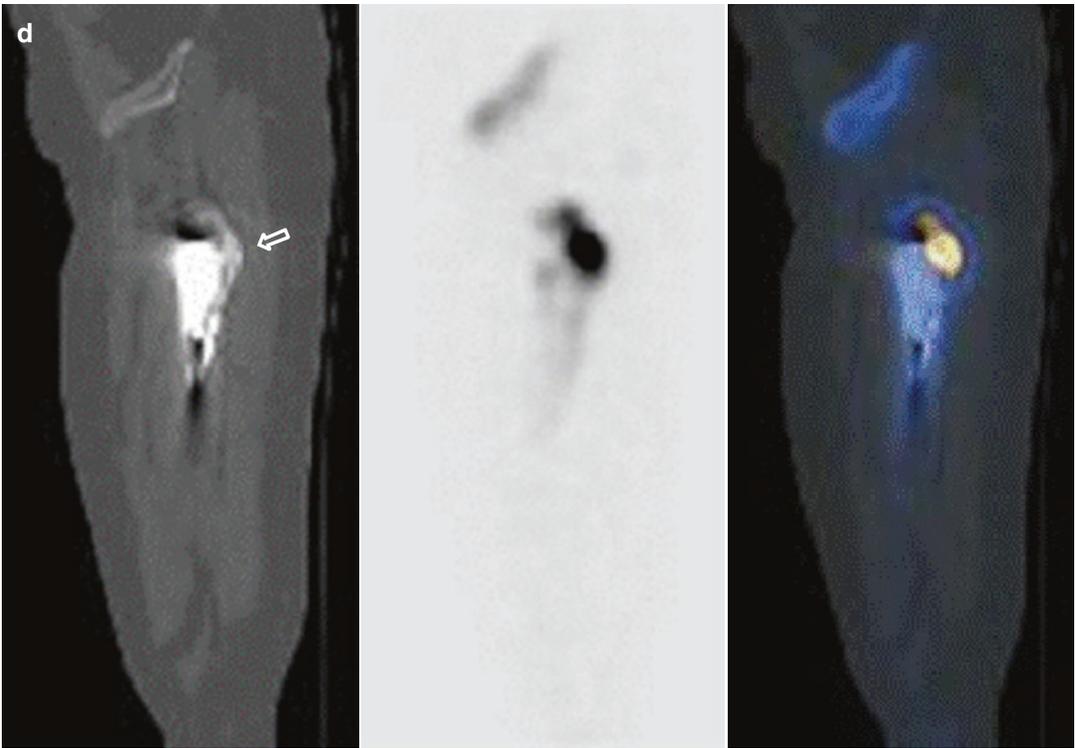

**Fig. 10.10** In this 63 year old female patient with history of right total hip replacement, whole-body blood pool (a) and delayed images (b) demonstrate hyperemia and increased osteoblastic activity posterolateral to the right trochanteric region. Selected coronal and sagittal SPECT/

CT images (c) localized the soft tissue calcifications posterolateral to the right trochanteric region and clearly extending beyond the bone boundaries on CT/SPECT images indicating heterotopic ossification

**Fig. 10.10** (continued)

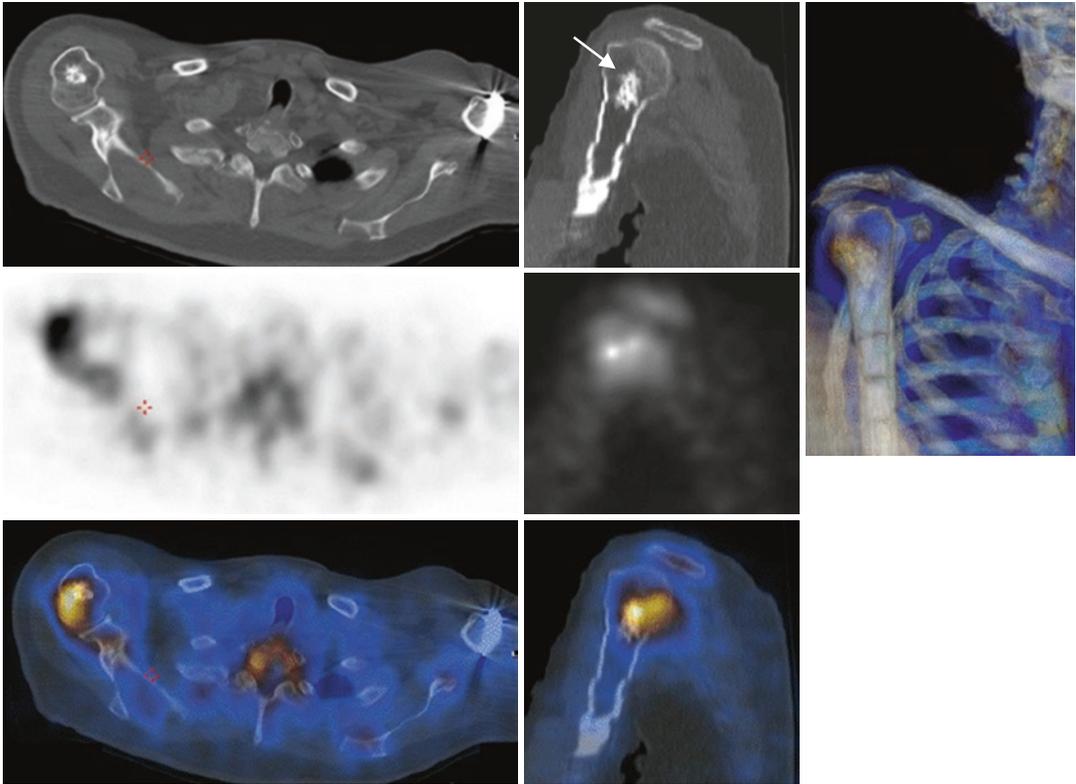

**Fig. 10.10** (continued)

of Tc-99m MDP in maxillary bones may suggest probable osteonecrosis. In such cases, SPECT/CT may be of value in increasing the diagnostic accuracy of bone scanning. In a study, it was of particular value in 8 of 15 patients, allowing discrimination of the osteonecrotic core from nearby hyperactivity due to a viable bone [48]. SPECT/CT is also valuable in osteonecrosis of the femoral head [49]. In 44 patients with 64 affected femoral heads, the diagnostic accuracy of planar

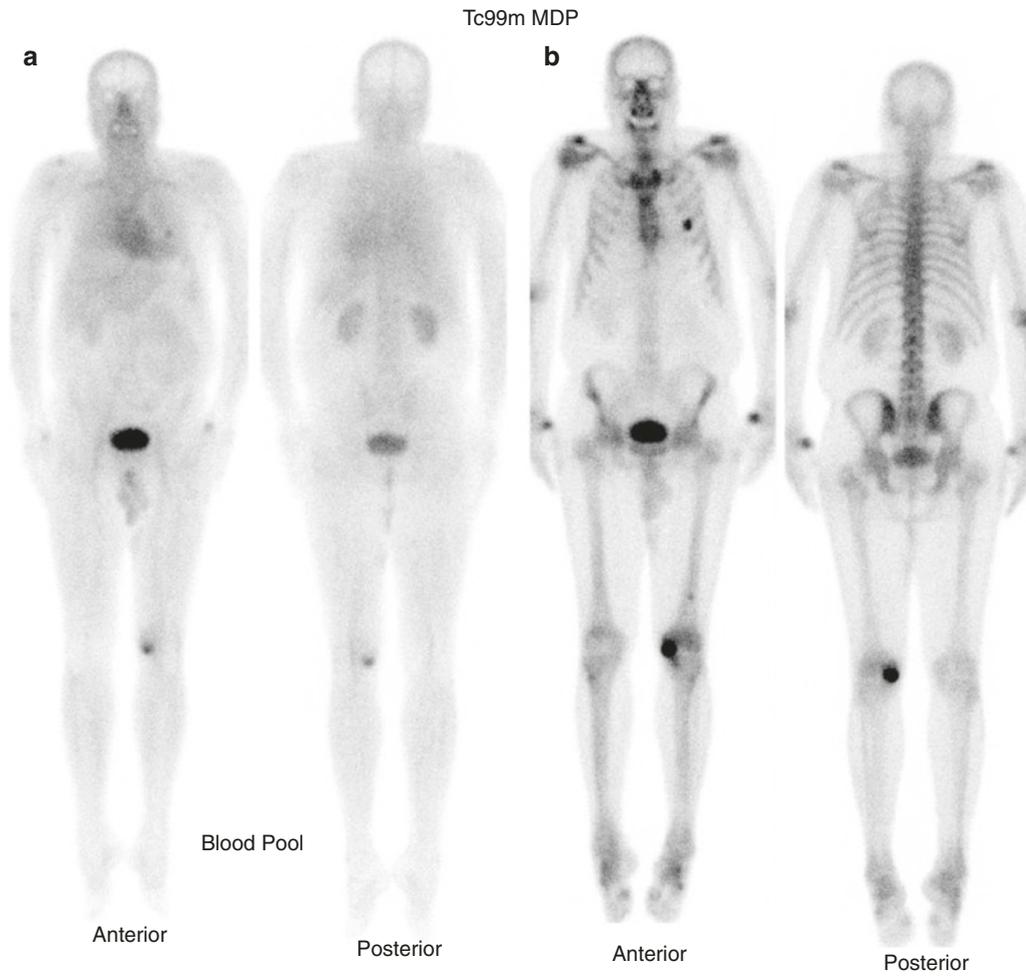

bone scintigraphy, SPECT, and SPECT/CT was 67, 78, and 95%, respectively, for the diagnosis of AVN of the femoral head [50].

In nine patients with osteonecrosis of the femoral head who underwent free vascularized fibular grafting, SPECT/CT was obtained 2 weeks and 6 months following surgery. Findings revealed a progressive increase of femoral head uptake in all cases, suggesting subchondral graft bone viability [51].

**Fig. 10.11** In this patient with subcapital bone infarct, selected SPECT/CT slices and MIP images of the shoulders demonstrate sclerotic areas in the site of infarcted

area on CT (*arrow*) and increased osteoblastic activity around the location of the infarct particularly laterally in the humeral head on SPECT

**Fig. 10.12** Tc-99m MDP and labeled WBC SPECT/CT of a 62-year-old male who presented with left knee pain for 2 weeks. On Tc-99m MDP planar images, there is increased blood pool activity (**a**) and delayed uptake (**b**) in the medial side of the left knee. SPECT/CT study helped localizing the uptake in the left medial femoral condyle

(**c**). In-111 WBC was also obtained and shows no corresponding uptake (**d**). The case represents spontaneous osteonecrosis of the femoral condyle. SPECT/CT helped accurate localization and consequently facilitated the diagnosis

Tc99m MDP

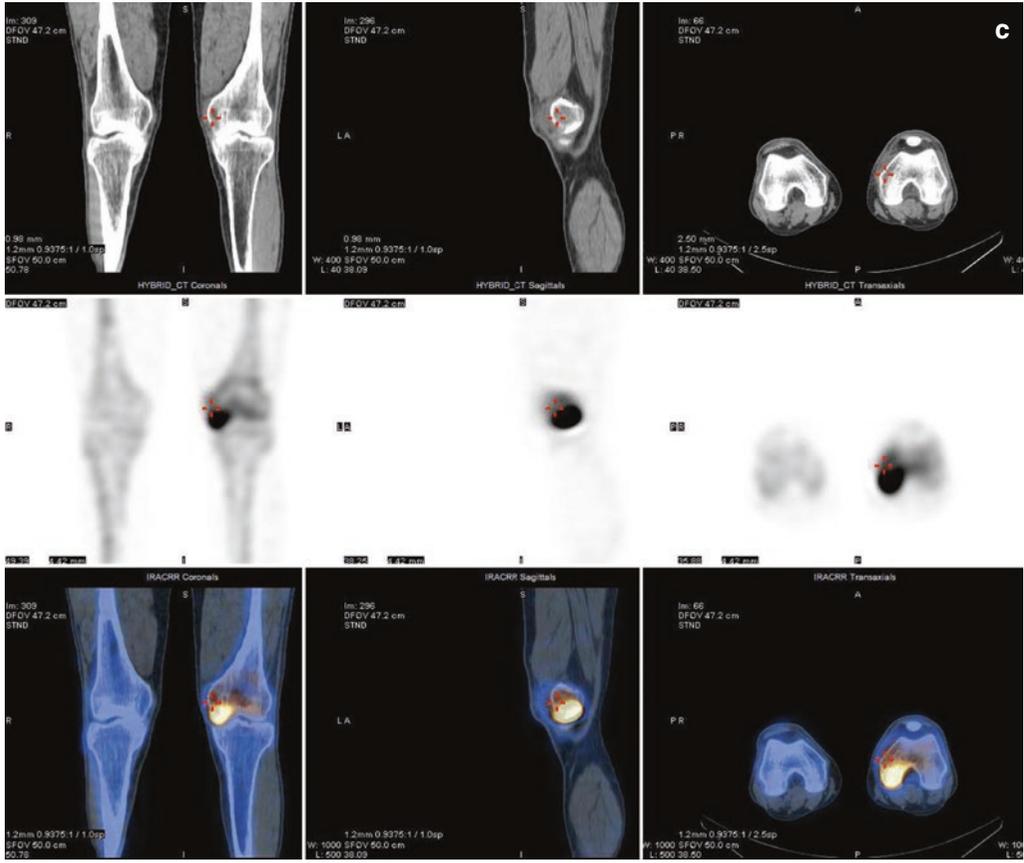

Fig. 10.12 (continued)

**Fig. 10.12** (continued)

## 10.3 PET/CT

PET/CT utilizing several radiotracers is being used for malignant and benign bone diseases. These include F-18 FDG, F-18 NaF, F-18 choline, C-11 choline, GA-68 PSMA, GA-68 citrate, and others. The most popularly used modalities for bone disease are F-18 FDG and F-18 NaF and more recently their combined use.

### 10.3.1 F-18 FDG PET/CT

PET/CT using F-18 FDG has several useful applications in the diagnosis and follow-up of bone diseases (Table 10.2).

**Table 10.2** Clinical uses of FDG PET/CT in bone disease

1. Evaluate response to therapy of primary or metastatic bone disease
2. Detection of recurrence of primary bone malignancies
3. Early differentiation of progression and flare of metastatic disease seen on bone scan
4. Solitary bone lesion on bone scan
5. Detection of metastatic bone disease
6. Diagnosis and follow-up of certain infections (chronic active osteomyelitis, vertebral osteomyelitis, diabetic foot osteomyelitis)

#### 10.3.1.1 Detection of Metastatic Bone Disease

(See also Chap. 6)

Although data comparing sensitivities of Tc-99m diphosphonate bone scan to F-18 FDG PET/CT are not consistent [52–56], FDG PET has proven to have better specificity and is valuable in detecting purely osteolytic lesions and is more accurate differentiation between the benign and malignant lesions [54, 57, 58].

#### 10.3.1.2 Follow-Up of Primary and Metastatic Tumors

Although bone scan is still a good modality for the follow-up of metastatic bone disease of many tumors, PET/CT can provide better assessment depending on the tumor, available resources, and cost. PET/CT using F-18 FDG, F-18 NaF, F-18 choline, C-11 choline, and others is used for follow-up of primary and metastatic bone disease. FDG PET/CT can also be of value when post-therapy flare effects of metastatic disease need to be differentiated from progression without delay [59].

#### 10.3.1.3 Skeletal Infections (See also Chap. 2)

F-18 FDG is useful in osteomyelitis and is particularly helpful in diagnosis of chronic active osteomyelitis and spondylodiscitis [60].

#### Chronic Active Osteomyelitis

It has been demonstrated that FDG PET has the highest diagnostic accuracy for confirming or excluding the diagnosis of chronic active osteomyelitis in comparison with bone scintigraphy,

MRI, or leukocyte scintigraphy [61]. FDG PET has been found useful to assess the activity of chronic osteomyelitis [62–67]. De Winter et al. reported on 60 patients with suspected chronic musculoskeletal infection studied with F-18 FDG PET. Twenty-five patients had proven to have infection, and all were correctly identified by two readers with a sensitivity of 100%. There were four false-positive cases, and overall specificity was 88% (90% for central skeleton and 86% for peripheral skeleton). The authors concluded that this single technique is accurate and simple and has a potential to become a standard technique for the diagnosis of chronic musculoskeletal infections [64]. From the studies reported, the overall technique has a sensitivity of 95–100% and a specificity of 86–100% [62–65].

Dual-time imaging with FDG PET helps to differentiate malignant and inflammatory processes in situations when distinction is essential since SUV remains stable or decreases in inflammation, while it increases over time in malignant lesions. MRI and F-18 FDG have comparable accuracy in diagnosing osteomyelitis [68].

F-18 FDG with semiquantitative analysis facilitates differentiating infection from other conditions such as noninfectious inflammation and malignancy and in following up the response of therapy since FDG uptake normalizes quickly following trauma or surgery in approximately 3–4 months [60, 69].

### **Spondylodiscitis (Vertebral Osteomyelitis)**

Although MRI is the imaging method of choice for diagnosis of vertebral osteomyelitis in the absence of metallic implants, nuclear medicine procedures are often used. The use of SPECT/CT has been discussed above. In a study performed on 30 consecutive patients, all five cases with proven disk space infection showed positive PET studies. Because none of the patients with degenerated disk space demonstrated FDG uptake, even in the presence of substantial end plate abnormalities, the authors suggested that FDG PET may be useful for excluding disk space infection in equivocal MR findings [70]. FDG PET is sensitive, has superior image quality, and is completed in a single session. The specificity of FDG PET may also be superior to that of con-

ventional tracers because degenerative bone disease and fractures usually do not produce intense FDG uptake [71].

### **Diabetic Foot Osteomyelitis**

F-18 FDG PET/CT has also been used for the diagnosis of diabetic foot osteomyelitis. It provides faster results (typically within 2 h). Although high sensitivity and specificity rates have been achieved using PET/CT for the differentiation of osteomyelitis from neuroarthropathy with a sensitivity of 80–95% and a specificity of 90–100% [72–75], the literature focusing on the use of F-18 FDG PET and PET/CT for diabetic foot osteomyelitis remains still limited [76, 77]. The role of FDG imaging in the evaluation of diabetic foot infection has yet to be clarified, with some investigators reporting high accuracy and others reporting just the opposite [78].

### **Post-arthroplastic Infections**

FDG PET has been shown to be useful in detecting infections and differentiating it from loosening in patients with hip and knee prostheses [79, 80]. Initial studies reported sensitivity and specificity for detecting infection of approximately 90% and 89% for hip and 90% and 72% for knee periarthroplasty infections, respectively [80]. A more recent data reported an overall sensitivity of 91–100% [81]. Specificity, however, is strongly dependent on the used criteria to report infection based on both localization and intensity of FDG uptake, ranging from 9% to 97% [81]. Specificity is generally higher in hip prostheses, compared with knee prostheses [81]. Although the intensity of FDG uptake as determined by SUV values is important in making the diagnosis of malignancy, this is not the case with periprosthetic infections. Infected prostheses often show moderate increased uptake which is not higher than that noted with aseptic loosening [79]. However, the location of the increased uptake is more important in differentiating infection from loosening since infection is characterized by uptake along the interface between bone and the prostheses, while in loosening it is around the neck and head [79]. Using this criterion, a sensitivity of 92% and a specificity of 97% have been reported [81]. This criterion however remains to be validated in a prospective study.

A recent meta-analysis found that the sensitivity and specificity of FDG PET for diagnosing lower extremity prosthetic joint infection were 87% and 82%, respectively, lower than what has been reported for combined leukocyte-marrow imaging over the past 30 years [78].

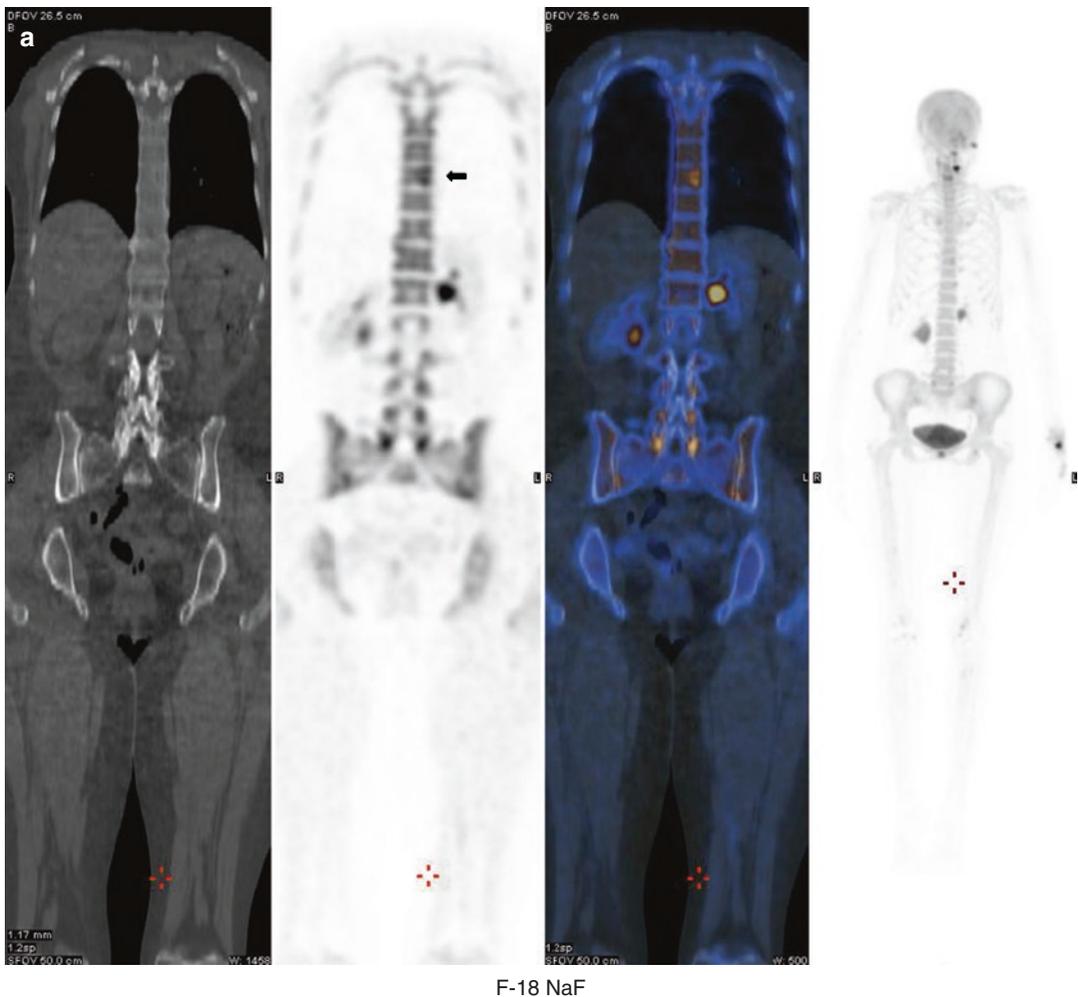

### 10.3.2 F-18 Sodium Fluoride PET/CT

F-18 sodium fluoride (NaF) PET/CT is currently used more in bone diseases (Table 10.3). Many studies found that F-18 NaF PET/CT is most accu-

rate in detecting metastatic bone disease (Fig. 10.13) and is more accurate than planar bone scan as well as FDG PET/CT [57, 82–96]. Although F-18 FDG has advantages over F-18 NaF particularly in detect-

**Table 10.3** Clinical uses of F-18 NaF PET/CT

Detection of bone metastases
Detection of occult fractures in adults and pediatrics (including child abuse and stress fractures)
Evaluation of bone viability after trauma (e.g., fracture healing) and surgery (e.g., graft viability)
Osteonecrosis (femoral head and mandible)
Assessment of metabolic bone disease activity

**Fig. 10.13** Representative images of F-18 NaF for a patient with histologically proven breast cancer referred to rule out metastases. Coronal (a), sagittal (b), and transaxial (c) selected images show an increased uptake focally

in T-9. CT scan helped in classifying the lesion as hemangioma rather than metastases. Note that FDG (d, e) showed no uptake at the site of the lesion

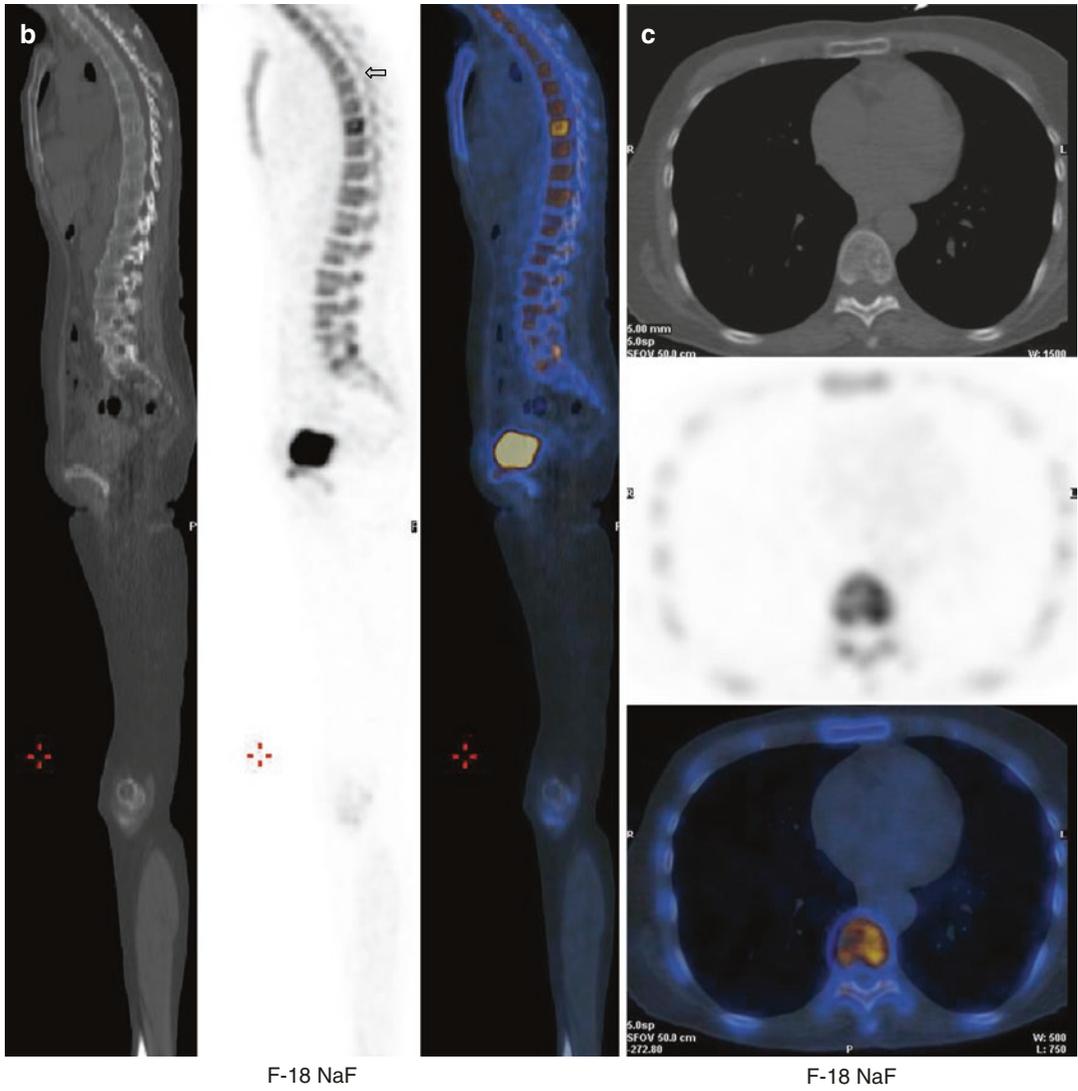

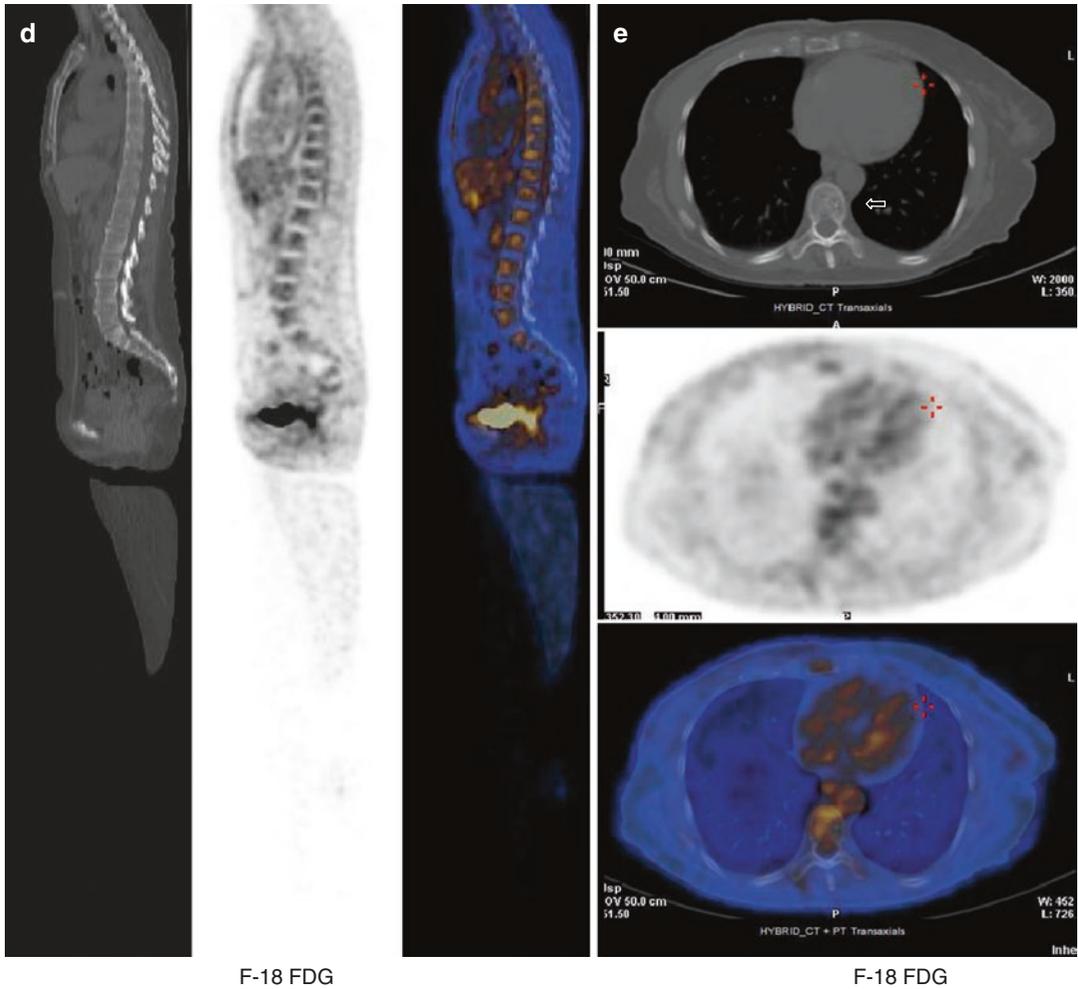

Fig. 10.13 (continued)

**Fig. 10.13** (continued)

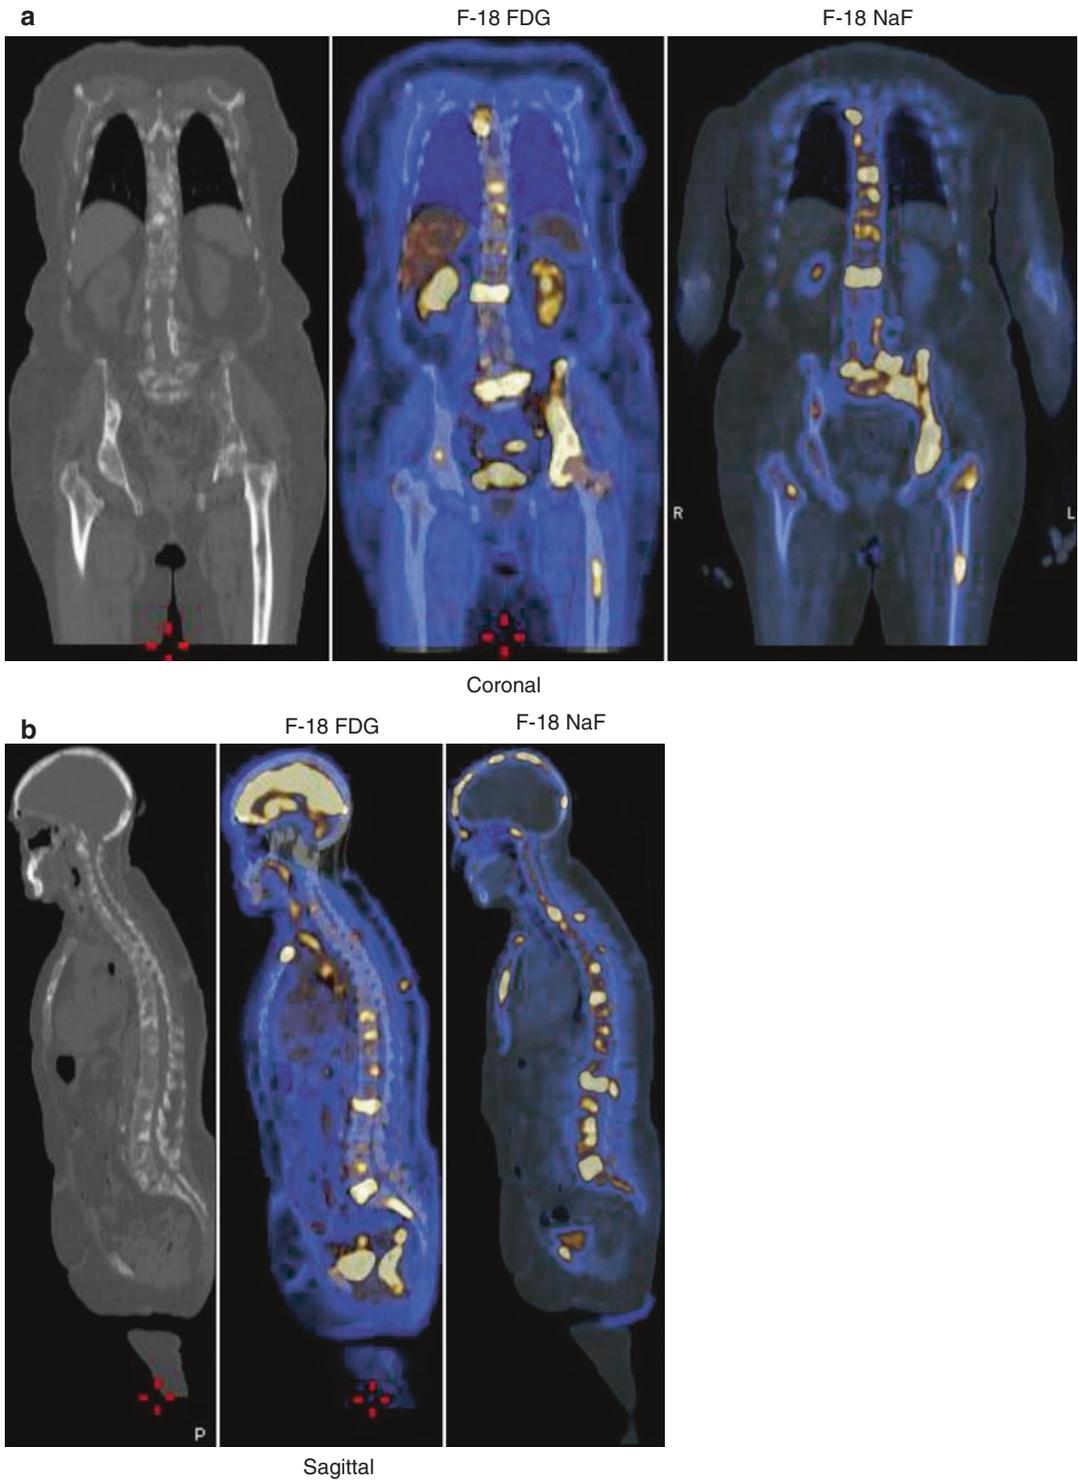

ing soft tissue and bone pathology, F-18 NaF is probably preferred for detecting metastases in some tumors that are known to show low avidity for FDG such as thyroid carcinoma [97].

### 10.3.3 Combined F-18 NaF and F-18 FDG PET/CT

In a direct comparison of F-18 NaF, F-18 FDG, and MDP bone scintigraphy, some patients showed skeletal metastases seen on F-18 NaF and not seen on either of the other two scans [84].

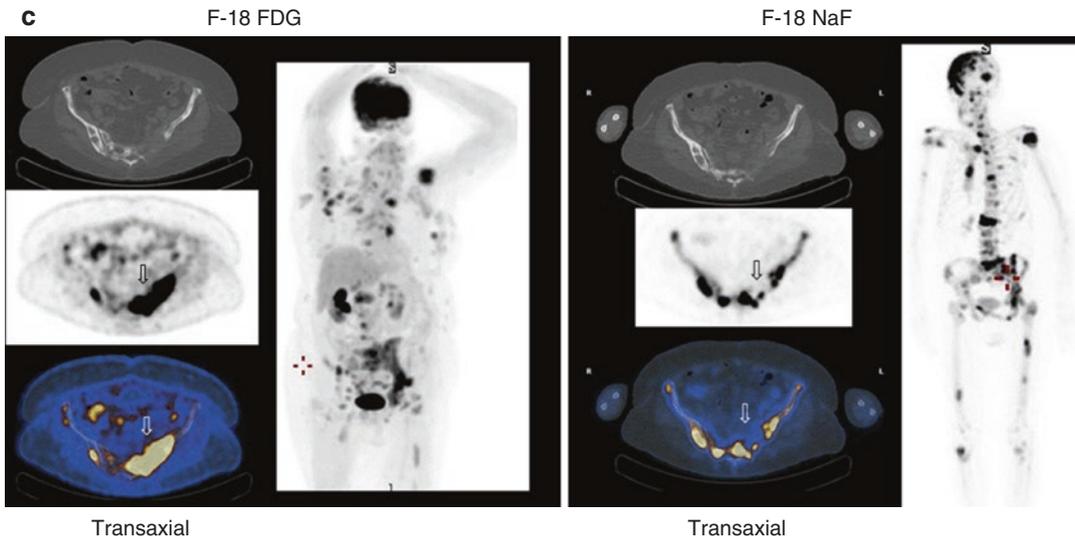

However, F-18 FDG has advantages over F-18 NaF particularly in detecting soft tissue and bone pathology especially in tumors known to produce atypical patterns of metastases especially osteolytic (Figs. 10.14 and 10.15).

Combined F-18 NaF and F-18 FDG has recently been found to be useful in better detection of bone metastases. This combined technique however needs refinement including ratio of radiotracers administered. This single-session combined technique can be utilized in staging of soft tissue and bone disease and covers both osteoblastic and osteolytic metastatic lesions [98].

**Fig. 10.14** F-18 sodium fluoride (a, b, c) and F-18 FDG representative images of a patient with breast cancer. The studies show extensive bone metastases seem better on NaF study. Note that an osteolytic lesion (*arrows*) showed

no NaF uptake, although there is uptake at its borders, but showed intense uptake in the lesion on FDG (*arrows*). Also note the detection of soft tissue metastases such as in the left axilla on FDG images

**Fig. 10.14** (continued)

### 10.3.4 Ga-68-Citrate PET/CT

Recent reports described Ga-68-citrate and Ga-68-transferrin as possible agents for PET imaging of infection. Ga-68 has a half-life of 68 min compared to 78.3 h for Ga-67. Ga-68-citrate or Ga-68-transferrin was able to detect infected lesions in rats as focal intense uptake at the lesion within 30 min. In patient studies, infection lesions were detected within 30 min postinjection. The short half-life of Ga-68 (68 min) may be advantageous from low dosimetry to the patients. The advantage of Ga-68 compared to FDG is that it is positive only in cases of infection. Preliminary reports suggest Ga-68-citrate PET/CT is useful in the diagnosis of suspected bone infections with reliable accuracy [99].

### 10.3.5 Ga-68 PSMA PET/CT

Ga-68 PSMA (Prostate-specific membrane antigen) PET/CT has been proven useful in diagnosis

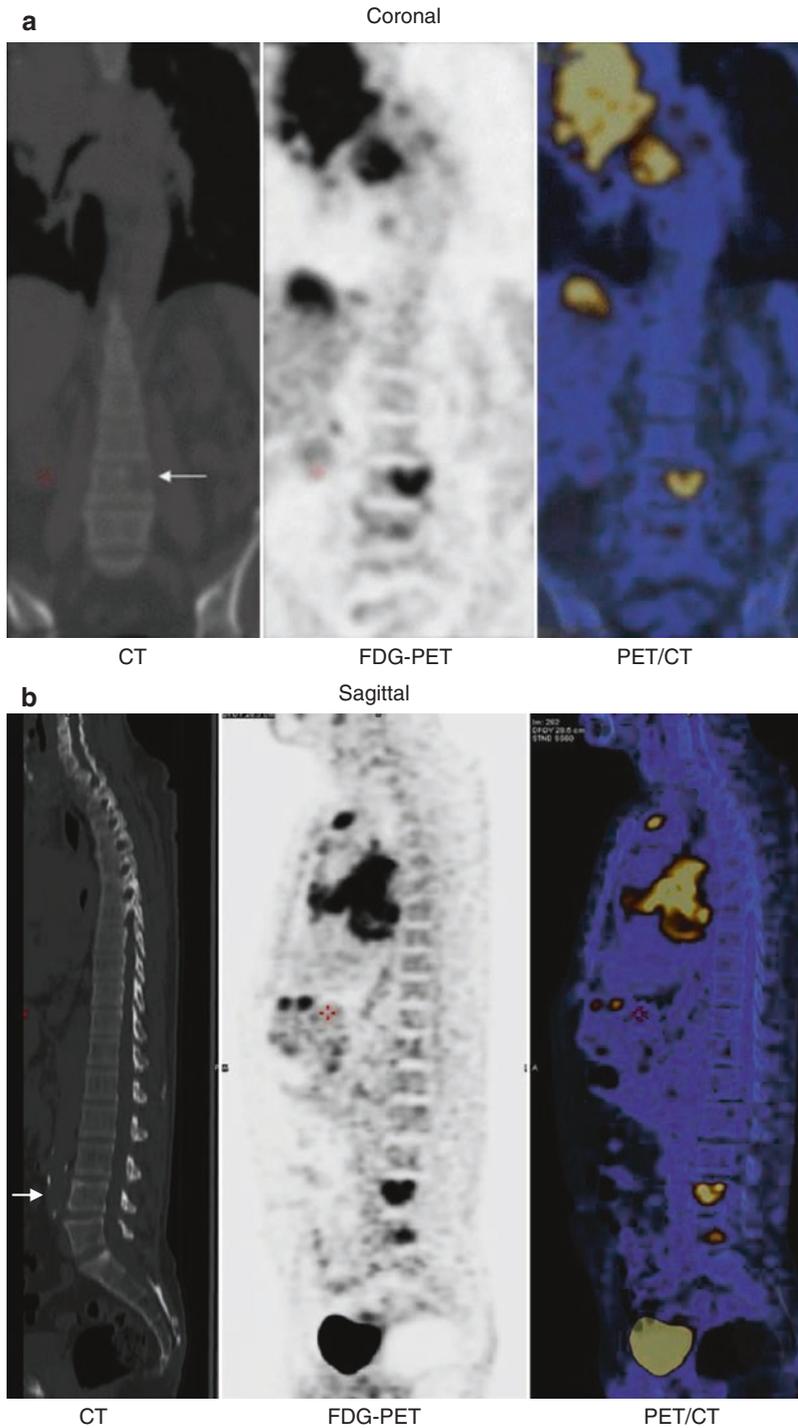

and follow-up of bone metastases in patients with prostatic carcinoma (Fig. 10.16) since it is very highly specific with very high agreement with PET/MRI studies using the same radiotracer [100, 101].

## 10.4 PET/MR

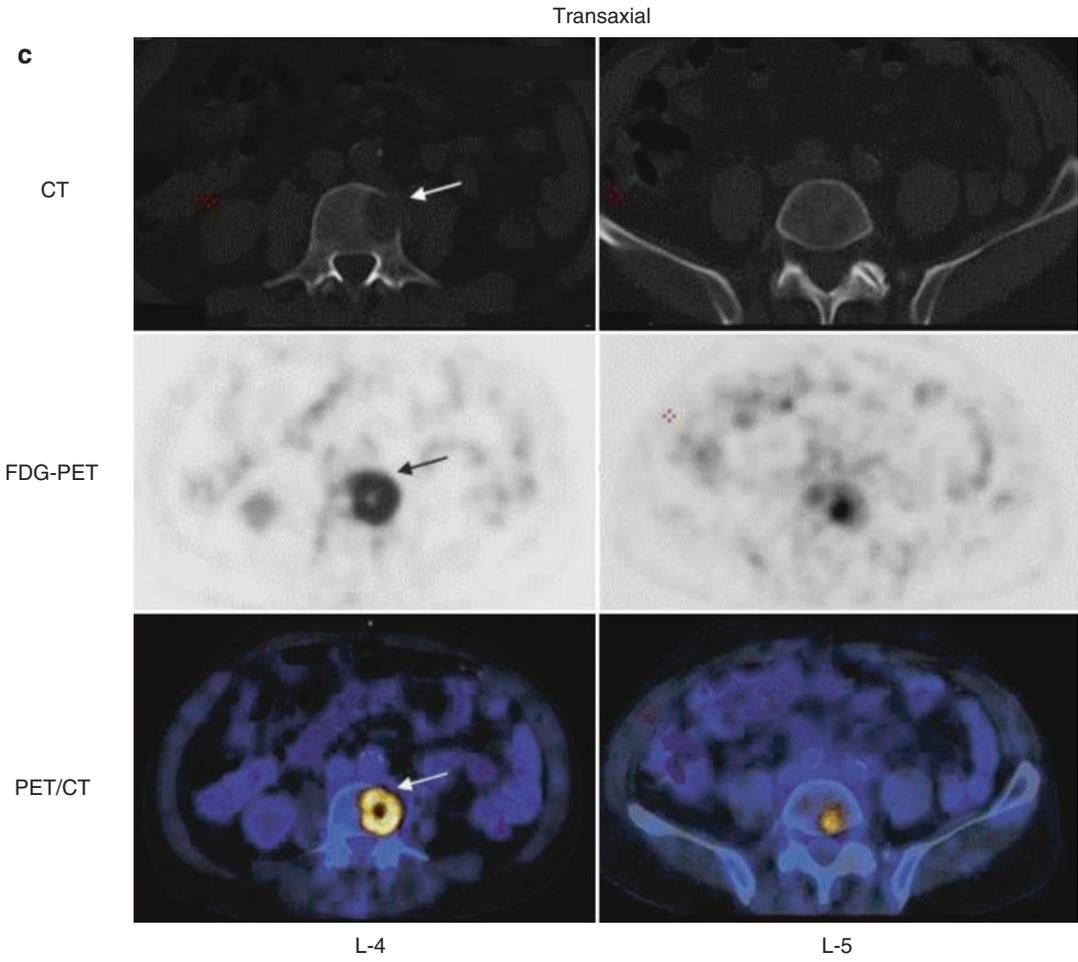

Studies confirmed the value of MRI in detecting bone metastases and the superior sensitivity compared to planar bone scintigraphy and even F-18 FDG PET/CT [102, 103]. In a recent study, FDG PET/MRI was 100% sensitive compared to 94% for FDG PET/CT, although FDG PET/CT was found to be better than MRI in benign lesions [103].

The use of 18 F-NaF PET/MRI in the diagnosis of bone metastases from prostate cancer was reported to be promising [104].

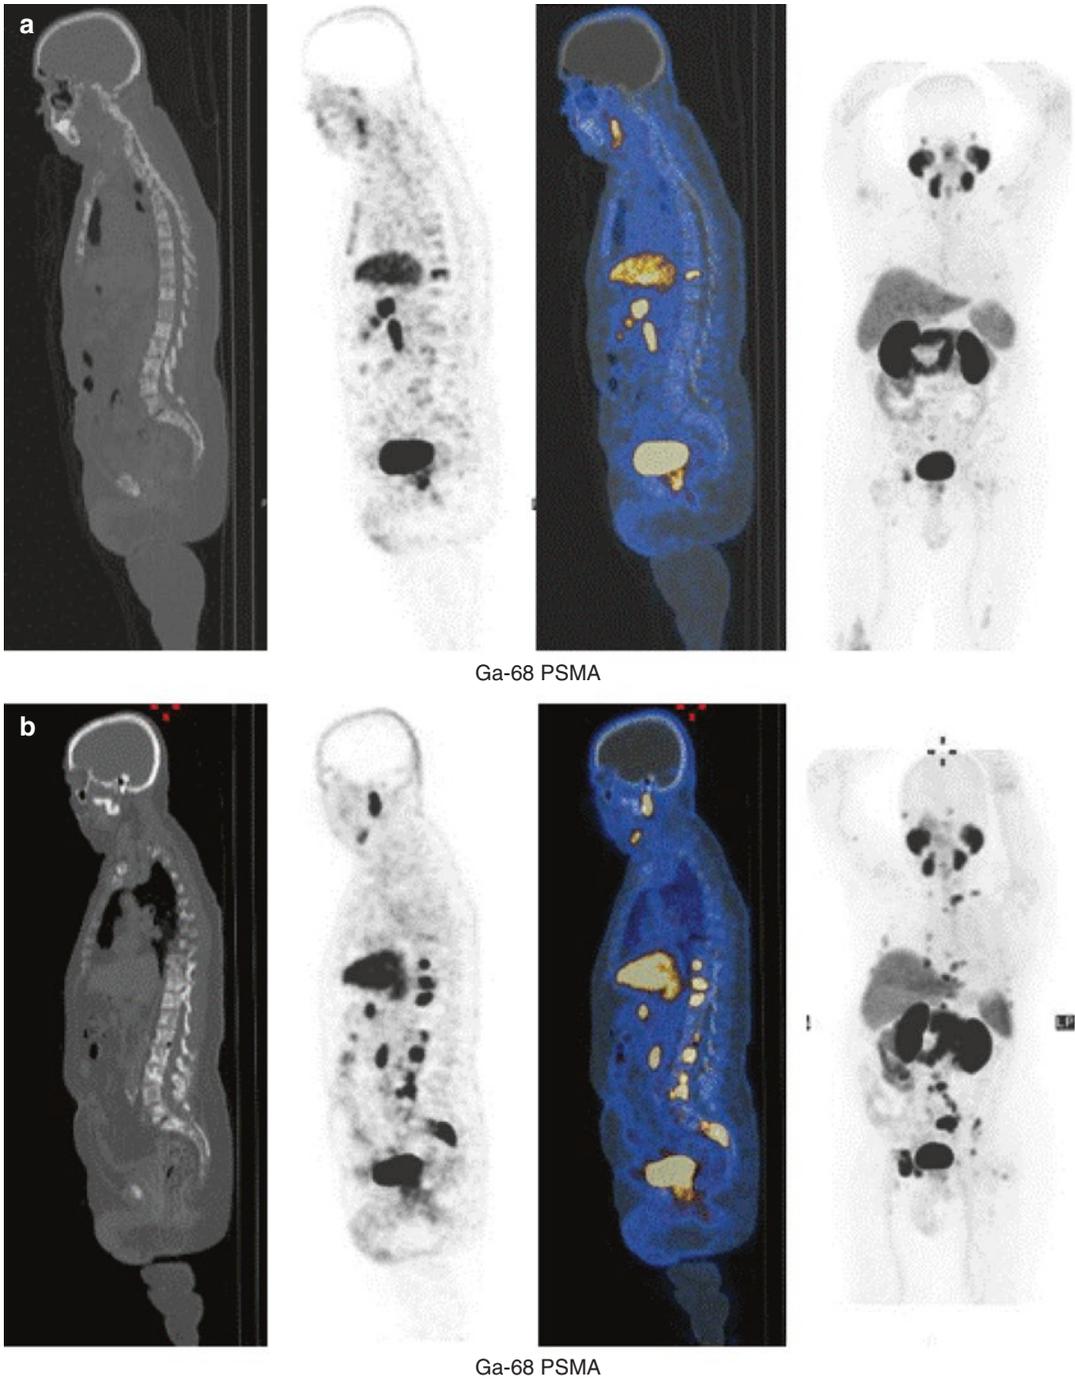

NaF PET/MR was reported to be useful in differentiating metastatic lesions from benign lesions and for cases in which bone scintigraphy and PET/CT are inconclusive [105].

**Fig. 10.15** FDG PET/CT study of a 62-year-old male with huge right lung cancer. The patient has metastases in the brain, liver, and pleura beside the bulky mediastinal lymphadenopathy. There is also L4 lytic lesion (*arrow*) destroying left-sided cortex with soft tissue extension to the paraspinal space. L5 small metastasis is also seen (*arrow head*)

**Fig. 10.15** (continued)

**Fig. 10.16** Selected images of Ga-68 PSMA initial (a) and follow-up (b) studies for a patient with carcinoma of the prostate. The follow-up study, performed 4 months after the initial study, showed progression of the bone metastases

Clinically, bone metastases are manifested by pain and the loss of mechanical stability. Standard treatment options for bone metastases include external beam radiotherapy and analgesics. The use of radionuclides provides an alternative modality for controlling pain. The currently routinely employed agents such as Sr-89, Sm-153, and Re-186 have only mild side effects, and response rates of 70–89% can be achieved. The novel radionuclides, such as Lu-177 and Ra-223, have also been reported to have good response rates and low side effects. It was reported that treatment with alpha-emitter Ra-223 also improves survival. Radionuclide therapy provides an attractive alternative to surgical synovectomy in the management of patients suffering from chronic inflammatory joint disease. It is noninvasive and easily accepted by the patient, and the side effects are related to the leakage of radioactivity from the joint requiring special care and follow-up. Other applications of radionuclide therapy for bone tumors such as osteogenic sarcoma and multiple myeloma are still being investigated. Combination of I-131 MIBG with other modalities improves the therapeutic response in patients with refractory or relapsed neuroblastoma. Novel Lu-177 somatostatin analogues appear to be promising in the treatment of relapsed or primary refractory high-risk neuroblastoma.

## 11.1 Introduction

Nuclear medicine therapy uses open radioactive sources for the selective delivery of radiation to tumors or target organs. The basis for successful radionuclide therapy is that sufficient uptake and prolonged retention of the radiopharmaceutical occur in the target tissues. In the treatment of bone pain secondary to metastases, the use of strontium-89 (Sr-89), rhenium-186 (Re-186), and samarium-153 (Sm-153) has been routinely used. Additionally, I-131 MIBG and indium-111 (In-111) pentreotide have been used in the treatment of some neuroendocrine tumors, the use of radio-labeled monoclonal antibodies intrating lymphomas, and radionuclide synovectomy is available for certain arthritides (Table 11.1).

Radionuclide therapy for cancer is viewed as combining the advantage of target selectivity (seen also with techniques such as brachytherapy or external beam radiotherapy) with that of systemic therapy (as with chemotherapy). Short-term side effects are few and are limited to the myelosuppression. When a complete cure is feasible, the long-term consequences of radionuclide therapy, such as fertility disorders and leukemia, or other secondary cancers, compare favorably with the risks accepted for chemotherapy and radiotherapy. For benign disorders such as thyrotoxicosis and arthritis, radionuclide therapy provides an excellent alternative to surgery or medical treatment.

**Table 11.1** Therapeutic applications of nuclear medicine

<i>Oncological</i>
1. Lymphomas and leukemias
2. Polycythemia rubra vera
3. Solid tumors (thyroid carcinoma, neuroblastoma, metastatic neuroendocrine tumors, primary osteogenic sarcoma, liver cancer, and liver-dominant metastatic disease)
4. Treatment of metastasis-induced bone pain
5. Multiple myeloma
<i>Non-oncological</i>
1. Benign thyroid disease particularly hyperthyroidism
2. Radionuclide synovectomy
3. Bone marrow ablation
4. Intravascular radionuclide therapy for prevention of restenosis

## 11.2 Treatment of Cancer-Related Bone Pain

### 11.2.1 Rationale

Approximately 75% of patients with advanced cancer have pain due to skeletal metastases [1]. The pain may be intractable and affect the quality of life of the patients especially if it is associated with immobility, anorexia, and anxiety. Cancer-induced bone pain is a complex syndrome which involves inflammatory and neuropathic mechanisms (Table 11.2) [2, 3]. In healthy bone, RANK-ligand (receptor activator of nuclear factor  $\kappa$ ) regulates osteoclasts and osteoblasts to maintain balanced resorption and formation of bone, respectively [2, 3]. In the presence of a bone metastasis, increased expression of RANK-ligand leads to increased osteoclast activity and bone destruction [1, 2]. Direct tissue damage caused by tumor growth causes inflammatory infiltration which initiates a release of various growth factors, cytokines, interleukins, chemokines, prostanoids, endothelins, and other mediators which are believed to contribute to the development and/or maintenance of pain [2, 4–10]. The neuropathic component of the pain can result from various mechanisms which involves cancer-induced damage to the sensory nerves caused by infiltration and/or compression by the tumor cells, tumor-induced hyperinnervation, and stretching or denervation as the bone expands and degrades [2, 11]. Local inflammatory mediators sensitize peripheral nerve endings within the bone marrow and bone matrix [3]. Destruction of nerve endings by cancer invasion leads to a hyperexcitability state within the spinal cord [2, 3].

**Table 11.2** Possible mechanisms of metastases-induced bone pain

1. Stretching periosteum as the bone expands
2. Increased expression of RANK-ligand causing increased osteoclast activity and bone destruction
3. Direct bone invasion and local destruction. Cancer-induced damage to the sensory nerves and hyperexcitability state within the spinal cord
4. Cell-secreted pain modulators such as cytokines, interleukins, chemokines, prostanoids, endothelins
5. Inflammatory mediators sensitizing peripheral nerve endings

Cancer-related bone pain can be controlled by medical treatment, usually narcotics, external beam radiation therapy, or radionuclide therapy. Pain relief can be induced in 60–90% of cases by external radiotherapy delivering 2000–3000 rads [12, 13]. Controlling the pain from multiple metastases using external beam radiotherapy is, however, difficult. Hemibody irradiation using 800 rads to the lower half of the body and 600 rads to the upper half has resulted in complete response in 30%, partial response in 50%, and no response in 20% of patients. Significant side effects such as nausea, vomiting, diarrhea, as well as bone marrow toxicity are observed in one third of patients. In 9% of cases, the side effects can be life-threatening [14].

Radionuclide palliative therapy has the advantages of targeting all the involved sites but limiting the dose to normal tissue [15]. The palliative option using radionuclide methods appears underutilized in clinical practice. In a study [16], oncologists perceived the systemic radionuclide therapy as being less appropriate for palliation of metastatic bony pain than opioid analgesics. Radionuclide therapy was used in patients with widespread metastatic disease, who would not benefit much from such therapy. On the other hand, oncologists rated the appropriateness of the radionuclide therapy as low in the patient with limited early disease, in whom the greatest benefit would in fact be derived from such intervention [16].

### 11.2.2 Radiopharmaceuticals

The most frequently used agents for bone palliation today are strontium-89 (St-89) chloride, rhenium-186 (Re-186) ethylene hydroxy diphosphonate [17], and samarium-153 (Sm-153) ethylenediaminetetramethylene phosphonate [18]. The list of radiopharmaceuticals for bone palliation also includes rhenium-188 (Re-188), phosphorus-32 (P-32), tin-117m (Sn-117m), and new tracers lutetium-177 (Lu-111) and radium-223 (Ra-223). Ra-223 dichloride has recently been licensed in the USA and Europe for the treatment of men with castration-resistant prostate cancer and symptomatic bone metastases [19]. A recent

preliminary biodistribution study of calcium-45 (Ca-45) Cl<sub>2</sub> was carried out in normal Wistar rats over a period of 2 weeks that indicated selective skeletal uptake with insignificant retention in any of the vital organ/tissue [20]. The biodistribution pattern of Ca-45 Cl<sub>2</sub> was found to be comparable to its well-established and clinically approved counterpart, Sr-89 Cl<sub>2</sub> [20].

The uptake of these bone-seeking radiopharmaceuticals by metastases is many (up to 20) times higher than that of normal bone [21]. These agents (Table 11.3) are absorbed into hydroxyapatite crystal at the site of reactive bone formation in a manner similar to Tc-99m diphosphonates. The radiopharmaceuticals, which are currently used for bone pain control, cause only mild transient bone marrow suppression.

#### 11.2.2.1 Strontium-89 Chloride

Systemic radionuclide therapy using Sr-89 chloride was first used to relieve pain from bony metastases in 1937 and regained popularity in the 1980s. It is a pure  $\beta$ -emitter with a relatively long half-life of 50.5 days. It is a chemical analogue of calcium, and accordingly it concentrates avidly in areas of high osteoblastic activity. After intravenous injection, strontium quickly accumulates in the mineral bone matrix where active bone formation takes place. Therefore, there is preferential uptake in and around metastatic tumor deposits. This has been confirmed by external measurements using the gamma-emitting radionuclide Sr-85 (with autoradiography) and Sr-89, whose concentration is 2–20 times greater in bone metastases than normal bone [21]. The biological half-life of Sr-89 in bone lesions is about 90 days compared to about 2 weeks in normal bone, which can be explained by the immature nature of reactive bone compared to normal lamellar bone. This selective uptake and prolonged retention at sites of increased bone mineral turnover provide precise targeting of bone lesions. The radionuclide is typically administered as a single 150 MBq (4 mCi) intravenous dose. Overall, pain relief occurs in up to 80% of patients, of whom 10–40% became effectively pain-free. The mean duration of palliation is 3–4 months [23, 24]. In addition, Sr-89 chloride may cause slowing of the metastatic progression due to inhibition of

**Table 11.3** Radiopharmaceuticals for bone pain palliation

Radiopharmaceuticals	Physical half-life	Maximum energy of beta-emission (MeV)	Average beta energy	Maximum range in tissue (mm)	Usual dose and route of administration	Approximate efficacy (%)	Toxicity	Duration of effect
Phosphorus-32 orthophosphate	10.3 days	1.71	0.695 MeV	8.0	370–777 MBq (10–21 mCi), IV in divided doses	80	Significant marrow suppression in one third of patients (occasionally up to 36 months)	1.5–11 months
Strontium-89 chloride	50.5 days	1.46	0.583 MeV	6.8	1.5 MBq/kg (0.04 mCi/kg) or 150 MBq (4 mCi)/patient, IV	79	Mild transient marrow suppression, longer than that with Re-186 or Sm-153 and less than with P-32	4–15 months
Rhenium-186-HEDP	3.7 days	1.08	0.346 MeV	4.7	1295 MBq (35 mCi), IV	80	Mild transient marrow suppression	5 weeks–12 months
Samarium-153-EDTMP	46.3 hours	0.81	0.234 MeV	3.4	37 MBq/kg (1 mCi) i.v.	69	Mild transient marrow suppression	1–11 months
Tin-117m DTPA	13.6 days	0.13–0.15	Conversion electrons	0.3	5.29–10.58 MBq/kg (0.143–0.286 mCi/kg) i.v.	70	Mild transient marrow suppression	Not well defined
Re-188	16.9 hours		2.1 MeV	< 10 mm	1158 MBq (31 mCi)	80	No severe side effects or hematopoietic toxicity	1–3 mo
Lu-1776	73 days	0.497 MeV	0.133 MeV	2–4 mm	29.6–37 MBq/kg	80	No significant toxicity	3–15 mo

Modified from Elgazzar and Maxon [22]

expression of the cell adhesion molecules (E-selectins) that participate in the metastatic process. A significant transient decrease in serum E-selectin concentration was observed after systemic radionuclide therapy in a study on 25 men with metastatic prostate carcinoma [25] and may open a window for clinical trials.

#### 11.2.2.2 Phosphorus-32 Orthophosphate

This radionuclide is rarely used for the treatment of bone metastases. Dosimetric studies have demonstrated a relatively high dose to the bone marrow from the highly energetic  $\beta$ -particles of this radionuclide causing myelosuppression with pancytopenia (Table 11.3). An increased incidence of acute leukemia has been reported, although this was following P-32 therapy in patients with polycythemia vera.

#### 11.2.2.3 Samarium-153 Ethylenediaminetetramethylene Phosphonate

Sm-153 is produced in the nuclear reactor by neutron activation of both natural Sm-203 and 98% enriched Sm-152 targets. It has a relatively short half-life of about 48 h. Coupling of the radionuclide to ethylene diamine tetramethylene phosphonate (EDTMP) leads to the high uptake of the radionuclide by bone. Gamma camera imaging is possible due to the 103 keV gamma ray emitted during decay of Sm-153. The resulting images are similar to those obtained with Tc-99m-MDP, or other diphosphonates, showing increased uptake at the site of metastases. The calculated lesion-to-normal-bone ratio was reported to be 4.0 and the lesion-to-soft-tissue ratio, 6.0 [26].

Administration of Sm-153-EDTMP according to the supplier's recommendations at 37 MBq (1 mCi)/kg would deliver a bone marrow dose of 3.27–5.90 Gy, which would induce myelotoxicity as a side effect. Dosimetric calculation by urine collection and whole-body scintigraphy has been used to limit the bone marrow dose to 2 Gy by Cameron and associates [15]. This was achieved by anterior and posterior whole-body images obtained 10 min and 5 h after the intravenous injection of 740 MBq (20 mCi) of Sm-153-EDTMP with determination of the bone activity by imaging and

by counting the activity in urine collected for 5 h. The total administered activity of Sm-153-EDTMP predicted on a 2 Gy bone marrow dose was found to be 35–63% of the standard recommended dose of 37 MBq/kg (1 mCi/kg). The authors reported pain relief in eight of the ten patients treated using this dosimetric method [27].

#### 11.2.2.4 Rhenium-186 Ethylene Hydroxy Diphosphonate

In a manner similar to Sm-153, Re-186 has been coupled to a bone-seeking phosphonate, ethylene hydroxy diphosphonate (EHDP). This radionuclide emits  $\beta$ -particles with a maximum energy of 1.07 MeV and gamma photons with an energy of 137 keV which allows bone scanning. Re-186-EHDP undergoes renal excretion within 6 h after intravenous injection, as is the case with the common bone scanning agents. At 4 days, 14% of the radioactivity remains in the bone [28].

Several studies have shown encouraging clinical results of palliative therapy using Re-186-HEDP with an overall response rate of 70% for painful osseous metastases from prostate and breast cancer. Myelosuppression has been limited and reversible, which makes repetitive treatment safe [29]. In a study by Kucuk et al. [30], 31 patients with various cancers (ten prostate, ten breast, four rectum, five lung, two nasopharynx) and bone metastases were studied. Therapy was delivered using a fixed dose of 1295 MBq (35 mCi) of Re-186-HEDP. When necessary, the same dose was repeated two to three times after an interval of 10–12 weeks. The mean response rate was 87.5% in patients with breast and prostate cancer, 75% in patients with rectal cancer, and 20% in patients with lung cancer. The overall response rate was 67.5%, and the palliation period varied between 6 and 10 weeks. The maximal palliation effect was observed between the third and seventh weeks [30].

#### 11.2.2.5 Tin-117m Diethylenetriamine-pentaacetic Acid

Tin-117m (Sn-117m) is a reactor-produced radionuclide, with a half-life of 13.6 days. Contrary to the other radionuclides mentioned above, this radionuclide emits internal conversion electrons. Sn-117m is linked to diethylenetriaminepentaacetic

acid (DTPA). More than 50% of the administered activity is absorbed by the bone in patients with metastatic carcinoma, with a bone-to-red-marrow ratio of up to 9:1. Its 159 keV photon energy allows correlative imaging with a similar uptake pattern as Tc-99m-MDP [31].

In a preliminary study in ten patients by Atkins et al. [32], none of the patients who received Sn-117m-DTPA for palliation developed marrow toxicity. Another study on 47 patients treated with Sn-117m-DTPA, the experimental mean absorbed dose to the femoral marrow was 0.043 cGy/KBq. Compared to P-32 orthophosphate, Sn-117m-DTPA yielded an up to eightfold therapeutic advantage over the energetic  $\beta$ -emitter P-32. Accordingly, the authors suggested that an internal conversion electron emitter such as Sn-117m offers a large dosimetric advantage over the energetic  $\beta$ -particle emitters permitting higher administered activity for alleviating bone pain, while minimizing marrow toxicity [33].

#### 11.2.2.6 Rhenium-188-Labeled Dimercaptosuccinic Acid Complex (DMSA) and Hydroxyethylidine Diphosphonate (HEDP)

Re-188 has a physical half-life of 16.9 h, which is shorter than that of Sm-153 and Re-186. It has maximum beta energy of 2.1 MeV, with an average penetration in soft tissue of 3 mm. Re-188 can be eluted from commercially available tungsten-188/Re-188 generators that can be used up to 6 months.

Re-188-(V)DMSA, a potential therapeutic analogue of the tumor imaging agent Tc-99m-(V)DMSA, is selectively taken up in bone metastases. In a study by Blower et al. [34] of ten patients with prostate carcinoma and bone metastases studied by Tc-99m-(V)DMSA and Re-188-(V)DMSA to compare their biodistribution, the authors found only minor differences between both radiopharmaceuticals. Accordingly Tc-99m-(V)DMSA scans are predictive of Re-188-(V)DMSA biodistribution and can be used to estimate tumor and renal dosimetry and assess suitability of patients for Re-188-(V)DMSA treatment

[34]. This advantage makes this tracer a candidate for more trials as a potentially successful agent for bone metastases palliation.

Biodistribution study in mice showed that Re-188-HEDP had a high bone affinity with a mean uptake ratio of 12.3 [35]. The post-therapy Re-188-HEDP scintigraphy showed no uptake in other organs than the skeleton and kidneys in a patient with prostate cancer metastatic to bone [35]. The Re-188-HEDP images were identical to the Tc-99m-HDP scintigraphy, showing the same number and localization of metastases [35].

#### 11.2.2.7 Lutetium-177 Ethylenediaminetetramethylene Phosphonic Acid (EDTMP)

Lu-177 has favorable decay characteristics for therapeutic use. It has a half-life of 6.73 days and emits  $\beta$ -particles with maximum energies of 497 keV (78.6%), 384 keV (9.1%), and 176 keV (12.2%) to stable Hf-177. It has also  $\gamma$ -emission which allows scintigraphic evaluation of biodistribution and dosimetry. Because it has low energy and low tissue penetration range, it causes less bone marrow suppression which is a major advantage.

#### 11.2.2.8 Radium-223 Dichloride

Ra-223 is an alpha-emitter. It concentrates in the bone surface with inclusion in the bone calcium hydroxyapatite as a substitute of calcium during mineral formation [36]. It has a half-life of 11.4 days and a mean path length of less than 0.1 mm in soft tissue. Ra-223 decays by producing four  $\alpha$ -particles with a total energy deposition of 28.2 MeV [36]. Ra-223 is rapidly cleared from the blood. Approximately 80% of the radioactivity is out of the vascular bed within 15 min of injection, and only 4% of the injected activity is still in the blood at 4 h and less than 1% at 24 h [36].

### 11.2.3 Mechanism of Action

Metastatic bone pain is believed to be due to both mechanical factors (local bony destruction) and humoral factors (secretion of certain mediators by tumor and peritumoral cells). Although the mechanism of action is not completely known,

radionuclide therapy is thought to deliver sufficient energy from the sites of reactive bone directly to the malignant cells and/or to peritumoral cytokine-secreting cells that may be responsible for the patient's pain.

Pain relief by radiation was found to be independent of the radiosensitivity of the tumor, and therefore the mechanism of action does not involve actual killing of the tumor cell. It is more likely that radiation interrupts processes that are maintained by humoral pain mediators in the microenvironment of the tumor [37]. This view is also supported by an absence of a dose-response relationship [38].

### 11.2.4 Choice of Radiopharmaceutical

It has been demonstrated that myelosuppression is less severe using radionuclides with relatively shorter half-lives (Table 11.4). Other physical properties including radiolabeled conjugate biological uptake and clearance, product-specific activity, range and type of emissions, and resultant effects on tumor and normal tissue cellular survival should be all considered along with the clinical outcome to choose a radiopharmaceutical. The response rate of different radiopharmaceuticals currently in use appears not to differ signifi-

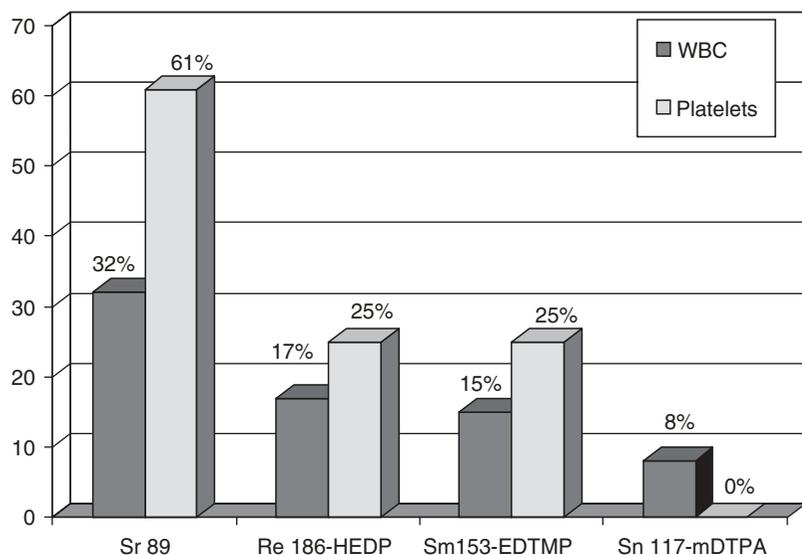

cantly [39]. The side effects, which are mainly hematological, vary among the agents used (Fig. 11.1), being more pronounced with P-32 than with the other agents. Sn-117m DTPA differs from the other radiopharmaceuticals in that it emits internal conversion electrons rather than  $\beta$ -particles. Since internal conversion electrons have a low energy and shorter path in tissue, they seem to result in less marrow toxicity.

A multi-center observational study including 29 nuclear medicine departments was conducted by the Italian Association of Nuclear Medicine between 1996 and 1998 to evaluate the efficacy and toxicity of radionuclide therapy of painful bone metastases in a large number of patients. Out of 818 treatments performed using single i.v. doses of 4 mCi (148 MBq) of Sr-89 chloride or 35 mCi (1295 MBq) of Re-186-HEDP, 610 were

**Table 11.4** Dosimetric features of bone pain radiopharmaceuticals

Radiopharmaceutical	Radiation dose (rad/mCi)		
	Bone	Red marrow	Bone/red marrow ratio
Strontium-89	63	40.7	1.6
Rhenium-186	7.0	3.0	2.3
Samarium-153	15.4	2.8	5.5
Sn-117m	65.1	9.8	6.6

Adapted from [40], with permission

**Fig. 11.1** Histogram showing the hematological effects of common radionuclides used for treating painful metastases

suitable for evaluation (527 with Sr-89 and 83 with Re-186-HEDP). Eighty-one patients received up to five treatments with a total number of 100 re-treatments. Patients were followed up for a period of 3–24 months. The results of the clinical outcome were no response in 19%, mild response in 21.3%, good response in 33.3%, and excellent response in 26.4% of cases. Re-treatments showed significantly worse responses (48% with good or excellent response), in comparison to first treatment. The duration of palliation was 5.0+/-3.5 months and was longer in the cases of patients who had excellent response in the first treatment; in patients with limited metastases; in patients with a good clinical condition, when life expectancy exceeded 3 months; in radiologically osteoblastic or mixed bone lesions; and when Sr-89 was used. Overall, mild-to-moderate myelosuppression was observed in 25.5% of cases of first treatment and in 38.9% of re-treatments. Therapy did not seem to prolong life, although scintigraphic regression of bone metastases was observed in some cases. There was no statistically significant difference in the palliative efficacy and toxicity between the two radiopharmaceuticals either in first treatment or in re-treatments [41].

Recently, computational models were used to estimate the percentage of deoxyribonucleic acid (DNA) damage, the probability of correct DNA repair, and the radiation-induced cellular effects post-irradiation with selected particles emitted by P-32, Sr-89, Y-90, Sn-117m, Sm-153, Ho-166, thulium-170 (Tm-170), Lu-177, Re-186, Re-188, and Ra-223. Ra-223 alpha particles, Lu-177 beta minus particles, and Tm-170 beta minus particles induced the highest cell death of all investigated particles and radioisotopes [42].

The same authors also performed a comparative analysis of the measured therapeutic response of different radiopharmaceuticals. Based on previously published data, there was a lack of substantial differences in palliative efficacy among radiopharmaceuticals. However, when the comparative analysis added factors such as patient's life expectancy, radionuclides' physical characteristics such as tissue penetration range and half-life, and health economics to guide the rational selection of a radiopharmaceutical for palliative treatment of bone metastases, Lu-177- and Re-188-labeled radiophar-

maceuticals appeared to be the most suitable radiopharmaceuticals for treatment of small-, medium-, or large-sized bone lesions, respectively [43].

## 11.2.5 Clinical Use

### 11.2.5.1 Current Indications

Radiopharmaceutical therapy is indicated for the treatment of patients with painful, multifocal, bone metastases. However, patients with pain that is secondary to either the spinal cord or peripheral nerve invasion by adjacent metastases will not benefit from such treatment.

### 11.2.5.2 Contraindications

Absolute contraindications are pregnancy and continuing breastfeeding. Relative contraindications include preexisting severe myelosuppression, urinary incontinence, insufficiency, or pathological fractures and spinal cord compression. A very short life expectancy is a relative contraindication since it takes 1–3 weeks for the pain to be relieved by this type of therapy.

### 11.2.5.3 Clinical Response

The response to these radiopharmaceuticals is more, or less, similar with an average success rate of 69–80% [22, 28, 44–46]. A prospective study of 75 patients with prostatic carcinoma and bone metastases, who were treated with Sr-89 over a 10-year period, was conducted by Windsor [47]. The therapy was successful in 42 (56.0%) patients, unsuccessful in 13 (17.3%), and unchanged in 20 (26.7%). More patients with scintigraphic super scans had an unsuccessful outcome, while the majority of those with fewer metastatic sites had successful outcomes. Patients with a successful outcome had a significantly better survival rate after Sr-89 injection. The study indicated that early treatment with Sr-89 in patients with fewer bone metastases is more likely to be successful, with a longer time before further therapy is required [47]. A retrospective study of 57 patients who received Sr-89 (38 patients), or Sm-153 (19 patients), for prostate cancer with bone metastases was reported by Dickie in 1999 [48]. A total of 40 patients had radionuclide therapy alone, and 28/40 (70%)

responded with a beneficial effect on pain. There was no difference in the response rates between the Sm-153 and Sr-89 patients regarding the effect on pain or the time to progression (median of 2–3 months for all patients) [48].

Another study conducted by Sciuto et al. [49] evaluated the therapeutic efficacy of Sr-89 and Re-186 in the palliation of painful bone metastases from breast cancer. A total of 50 patients with painful multifocal bone metastases from breast cancer were randomized into two groups of 25 patients each according to the radiopharmaceutical used. The overall response rate was 84% (21/25) for Sr-89 and 92% (23/25) for Re-186, respectively. The onset of pain palliation appeared significantly earlier in the group treated with Re-186 ( $p < 0.0001$ ). The duration of pain relief ranged from 2 to 14 months in the group treated with Sr-89 and from 1 to 12 months in the group treated with Re-186 ( $p = 0.39$ ). A moderate hematological toxicity was apparent in both groups. Platelet and white blood cell counts returned to baseline levels within 12 weeks after Sr-89 administration and 6 weeks after Re-186 administration ( $p < 0.01$ ). The authors concluded that Re-186 has a significantly faster onset of pain relief [49]. In a study, Ashayeri et al. reported their experience with the use of Sr-89 in 41 patients with multiple osseous metastases of breast and prostate carcinomas. More than two thirds of patients responded favorably and opioid doses were lowered [50]. Experimentally, the effect of Sr-89, Re-186, Sn-117m, or Sm-153 on hematopoietic stem cell survival was found to be mild and comparable [51].

In 277 patients with intense sustained pain caused by bone metastases from various cancers, bone pain diminished 54% after 3 weeks postinjection of Sm-153-EDTMP and up to 74% after 12 weeks, according to a visual analogue scale [52]. In an earlier study, 61 patients with painful bone metastases from various cancers were treated with Re-188 HEDP. There was prompt and significant relief of bone pain in 80% of patients overall. There were no severe side effects or hematopoietic toxicity [53]. In a recent study, Re-188-HEDP treatment of painful bone metastases in prostate and breast cancer patients provided overall pain response rate of 69% in 45

patients and overall quality of life response rate of 68% in 47 patients. Repeated treatment resulted in similar pain response. Hematological side effects were mild and transient [46].

A recent systematic review evaluated the efficacy of different bone-seeking radiopharmaceuticals for palliation of malignant bone pain from prostate cancer. Ten studies used Sr-89, 7 Sm-153, 12 Re-186, 2 Re-188, 2 Ra-223, and 3 reported on a combination of different radionuclides [54]. Overall, pain response percentages greater than 50–60% were seen with each radionuclide. Hematological toxicity was reported in 26 of the 36 studies and more than half of these trials stated no grade 3/4 leukopenia or thrombocytopenia occurred.

In a recent phase-2 clinical study, Lu-177 EDTMP was found to be a safe and effective radiopharmaceutical for bone pain palliation in patients with metastatic prostate and breast carcinoma [55]. The overall response rate in all 44 patients was 86% in this study. It was recently reported that Lu-177 EDTMP has pain response efficacy similar to that of Sm-153 EDTMP [56]. Pain relief with Lu-177 EDTMP was 80%: 50% complete 41.67% partial and 8.33% minimal. Alavi et al. used Lu-177 EDTMP in 30 patients [57]. Total response to treatment was achieved in 25 patients (83%), and there was no bone marrow suppression or hematological toxicity at the end of the evaluation. Phase II randomized, placebo-controlled study was conducted to evaluate efficacy and safety of radium-223 in patients with castration-resistant prostate cancer and painful bone metastases [58]. Radium-223 showed highly favorable safety profile, with no evidence of second malignancies at 24-month follow-up [58]. Potential role of Ra-223 in breast cancer is being evaluated with international trials [59]. There are currently many ongoing phase 2 and 3 clinical trials of Ra-223 use in metastatic prostate cancer [59, 60].

Radionuclides such as Sr-89, Sm-153, and Re-186 are routinely used for pain palliation, but there is no evidence that they prolong survival when used as single agents [61]. Repeated bone-targeted treatment with Re-188 HEDP improved posttreatment overall survival from 4.50 to 15.66 mo in patients with progressive hormone-

refractory prostate cancer [62]. A phase 2 study showed significant improvement in overall survival in patients receiving alpha-emitter Ra-223 vs. placebo [58]. In a phase 3 study (ALSYMPCA trial) in 921 patients with castration-resistant prostate cancer and bone metastases, Ra-223 improved overall survival. Ra-223 was also associated with low myelosuppression rates and fewer adverse events [63].

It is clear that the difference in half-life and the extent of bone metastases has an effect both on the onset and the duration of pain relief. Relief rates using the newer agents are not significantly different and are comparable with those of external beam radiotherapy but side effects are minimal and compare favorably with those of a previously used agent (P-32).

The use of a radionuclide along with chemotherapy for palliation is being investigated and may prove useful. Palmedo et al. reported a case of a patient with disseminated bone metastases due to breast cancer and multifocal pain [64]. Because of persisting pain after a first cycle of chemotherapy, 1295 MBq (35 mCi) of Re-186 HEDP was administered, and excellent pain relief was observed. Subsequently, the patient received combined chemotherapy and Re-186 HEDP therapy and remained pain free. A follow-up Tc-99m MDP bone scan showed significant regression of osseous metastases. The authors speculated that the combination of Re-186 HEDP and chemotherapy resulted in significantly increased palliation of the metastatic bone disease [64].

Patients with progressive metastatic castration-resistant prostate cancer and  $\geq 3$  bone lesions received Sm-153-EDTMP every 9 weeks and docetaxel every 3 weeks [65]. Authors in this study indicated that Sm-153-EDTMP can be safely combined with docetaxel at full doses on an ongoing basis in patients with metastatic castration-resistant prostate cancer. Twelve patients with multiple bone metastases from hormone-refractory prostate cancer were treated with a single application of Sm-153 lexidronam and 6-weekly infusions of docetaxel. Overall 1-year survival was 48.6%. The average pain score was reduced from 5.1 to 1.4 with decrease of  $\geq 2$  in 58.3% of patients [66]. Ra-223 is approved for use in both pre-

docetaxel and post-docetaxel clinical settings, with a recommended treatment regimen of six cycles [67, 68]. Retreatments with Re-186 HEDP under zoledronic acid (a bisphosphonate) provide continuing effectiveness in metastatic bone pain and are safe enough, if an acceptable baseline hematological status exists [69]. The association between Ra-223 and osteoclast-targeted agents (bisphosphonates) was also investigated [63]. Statistically significant delay in symptomatic skeletal-related events was seen only in patients receiving bisphosphonates, suggesting a likely positive interaction between Ra-223 and osteoclast-targeted agents. Recently, Sideras et al. reported that consecutive administration of two different radionuclides such as Re-186 HEDP and Sr-89 Cl was much more effective and safe than Sr-89 Cl with chemotherapy and Re-186 HEDP with bisphosphonates [70].

#### 11.2.5.4 Precautions and Radiation Safety

All patients must have a bone scan within 8 weeks of the treatment. A complete blood count (CBC) should be obtained before ordering the radiopharmaceutical to ensure suitability of the patient for treatment. An intravenous line should be established, and an injection should be given over no less than 1 min. Patients with renal failure may need reduction of the administered dose since the radiopharmaceuticals are eliminated by urine. If the patient is on hemodialysis, she/he could receive the therapy, but the radiation safety officer should be notified to oversee the process. If the patient is incontinent, special home instructions should be provided regarding use of a condom catheter or an indwelling bladder catheter.

In most countries, radionuclide treatment for bone pain palliation can be given on an outpatient basis. Moro et al. [71] conducted a series of measurements of the superficial contamination inside the confinement room and also the dose to those individuals close to patients who underwent palliative radionuclide therapy for bone metastases (with Sm-153-EDTMP using radioactivities less than 3 GBq). The results showed that the contamination of the location and objects close to the treated patients was low. Measurements of the external

radiation showed that in the proximity of the confinement room, the permitted dose to members of the public was not exceeded. The dose to those who took care of the patients including family members was less than 20  $\mu$ Sv. The study confirmed a very low exposure to nearby public, nursing staff, and family members taking care of the patient [71].

The United States Nuclear Regulatory Commission has amended its regulations concerning patients who receive therapeutic doses of radioactivity allowing patient release based on a total effective dose equivalent (TEDE) limit of 5 mSv (500 mrem) instead of the activity administered or retained [1110 MBq (30 mCi)] or the dose rate [0.05 mSv/h (5 mrem/h) at 1 m]. The current TEDE-based release criteria are less restrictive than the previous activity-based or dose rate-based release criteria [72] and allows outpatient treatment using high activity, such as 150 mCi of I-131.

### 11.3 Radionuclide Synovectomy

There is currently a need for a definitive treatment for joint pain associated with many arthropathies especially rheumatoid arthritis after failure of conventional medications. Therapeutic nuclear medicine offers an alternative to surgical synovectomy. Several radiopharmaceuticals (Table 11.5) can destroy the synovial membrane when injected intra-articularly (radionuclide synovectomy or radiosynoviorthesis), and the patients become pain free.

#### 11.3.1 Rationale

The intra-articular administration of radiopharmaceuticals in a colloid form is effective in more than 60% of patients with rheumatoid arthritis and other arthritic diseases. The choice of radionuclide, dose, and injected volume is determined by the size of the joint and the range of the  $\beta$ -particle spectrum suitable for the thickness of the synovium. Table 11.6 summarizes the major benefits of this technique.

#### 11.3.2 Radiopharmaceuticals

Several radiopharmaceuticals have been used since radiosynovectomy was first introduced in 1952 by Fellingner and Schmid as a therapy for synovitis. Yttrium-90 colloid, erbium-169 citrate colloid, rhenium-186 colloid, and others are used to treat

**Table 11.6** Major benefits of radiosynovectomy

1. Effective	Excellent to good results in approximately 60–75% of treated patients
2. Cost-effective	An alternative to surgical synovectomy with significant savings
3. Quality of life	Improvement in approximately 75% of patients with ability to perform new tasks associated with job, school, or recreation
4. Additional advantages	No postoperative physical therapy needed to prevent/relieve joint stiffness associated with surgical synovectomy

Adapted from [73], with permission

**Table 11.5** Radiopharmaceuticals used for intra-articular therapy

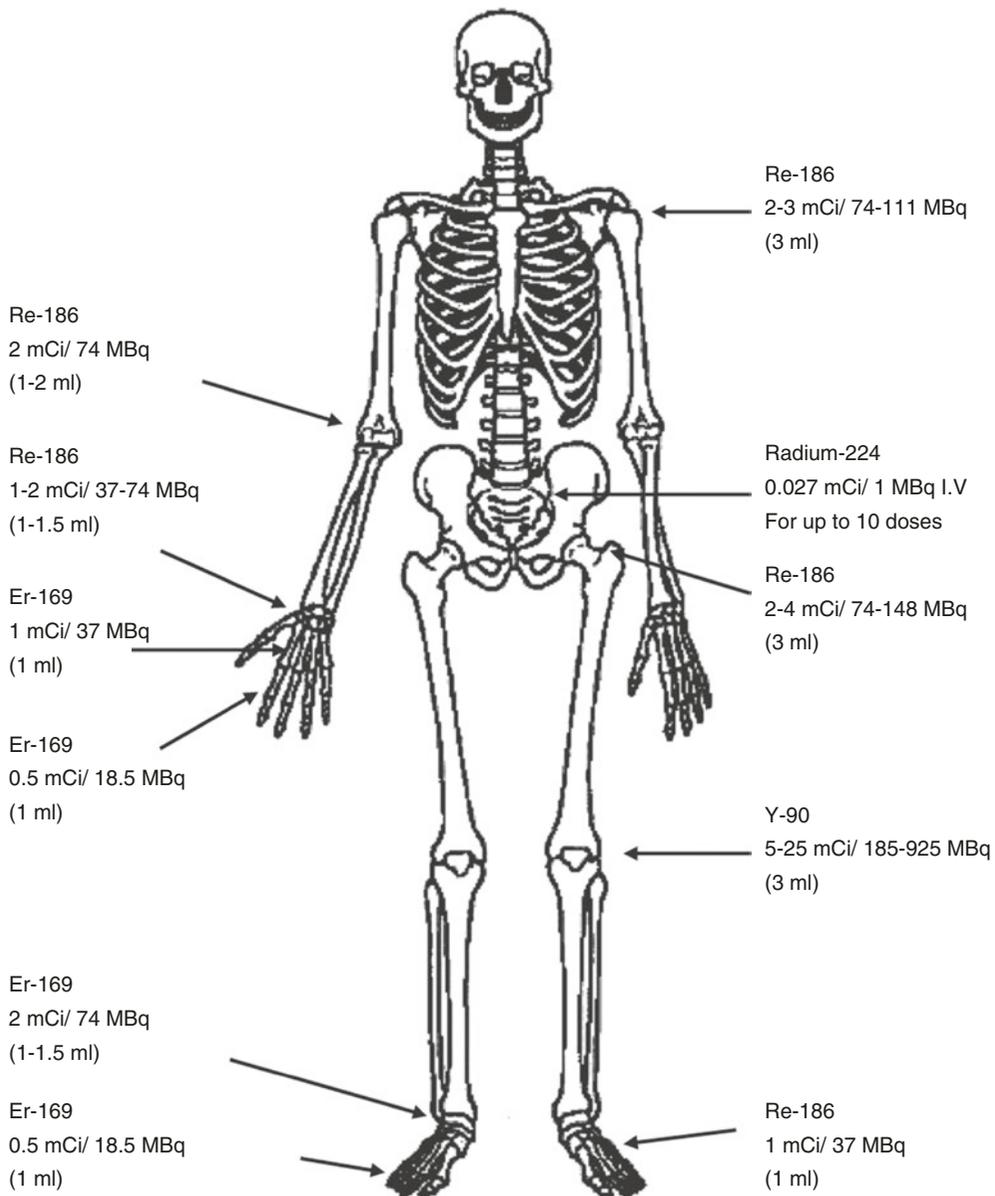

Colloidal radiopharmaceutical	Physical half-life in days	Maximum energy		Range in soft tissue (mm)		Particle size ( $\mu$ m)
		Type	$\beta$ (MeV)	Max.	Mean	
Au-198	197	$\beta, \gamma$	0.96	3.6	1.2	20–70
P-32	14.0	$\beta$	1.7	7.9	2.6	500–2000
Re-186 sulfide	3.7	$\beta, \gamma$	0.98	3.6	1.2	5–10
Y-90 citrate	2.7	$\beta$	2.2	11.0	3.6	100
Dy-165 FHMA	0.1	$\beta, \gamma$	1.29	5.7	1.8	3000–8000
Er-169	9.4	$\beta, \gamma$	1.0	1.0	0.3	10

<sup>a</sup>2.2 mm in inflamed synovial tissue (Modified from [73], with permission)

chronic synovial disease [50, 51]. Since these colloid preparations vary in their physical characteristics and accordingly the range of penetration, they are used differently to achieve the therapeutic effects and avoiding injuring the surrounding tissue. Yttrium-90 citrate, or silicate, is generally used for large joints such as the knee; rhenium-186 colloid is used for the shoulder, elbow, hip, and ankle; and erbium-169 citrate is used for the small joints in the hands and feet (Fig. 11.2).

### 11.3.2.1 Yttrium-90 Colloid

This radionuclide is used predominantly for radionuclide synovectomy of the knee joint, although it is also used for malignant pleural and peritoneal effusions. The pharmacological characteristics of the silicate and citrate forms are the same. The average range in tissue is 3.6 mm and the maximum is 11 mm. After direct intra-articular administration, the colloid penetrates into the superficial cells of the synovia. Small

**Fig. 11.2** The choice of radiopharmaceutical for different joints

numbers of particles may be transported through the lymphatic system, mainly after active or passive movement of the joint, from the knee to the regional lymph nodes. The safety of this modality of management has been reported, and hence the patient's age should not be regarded as a limiting factor [74]. It is recommended that Y-90 radiosynovectomy can be performed in young patients because the amount of synovium is still moderate. This is because once the degree of synovitis has become severe, the expected results of radioactive synoviorthesis are worse [75].

In a study, radioactive Y-90 was injected into 163 joints. Of these patients 115 were hemophiliacs suffering from recurrent hemarthroses. The median age at the time of the initial administration of Y-90 was between 11 and 15 years and the median follow-up period was 11 years. Over 80% of the patients with hemophilia reported a decrease in the number of hemarthroses, and 15% stopped bleeding altogether in the treated joint [74]. Rodriguez [75] reported the results of 66 Y-90 synoviortheses on 44 persons with hemophilia (45 knees, 12 elbows, 9 ankles). The average age was 21.1 years (range 9–39 years). A quantity of 5 mCi (185 MBq) of Y-90 was injected into the knee and 3 mCi (111 MBq) into the elbow and ankle. The average follow-up was 3.5 years (range 1–6 years). Of the 45 knees, there were 8 excellent, 10 good, 15 fair, and 12 poor results. Of the 12 elbows there were three excellent results, five good, three fair, and two poor. Of the nine ankles there were no excellent results, four good, three fair, and two poor. The elbows had better results than the knees and ankles. The best results were obtained in the youngest patients and in those with a moderate degree of synovitis [75].

A study of the efficacy of Y-90 silicate therapy in rheumatoid knee synovitis was reported by Gencoglu using Tc-99m human polyclonal immunoglobulin G (HIG) scintigraphy for evaluating 15 patients (13 women, 2 men; mean age, 53.5+/-8.4 years) with rheumatoid arthritis who had radionuclide synovectomy using 185 MBq (5 mCi) Y-90 silicate in 24 knee joints with chronic persistent synovitis. Radiological and clinical evaluations and Tc-99m HIG scans were

performed in each patient before radionuclide synovectomy. Each patient was reassessed 3, 6, 9, and 12 months after therapy using clinical examination and Tc-99m HIG scintigraphy. In 14 of the 24 knee joints that had an excellent, or good, clinical response to Y-90 silicate therapy, the Tc-99m HIG index values at 3 months after treatment were significantly lower than the pretreatment index values. In 13 of these 14 joints, these low index values and clinical results remained constant throughout 1 year of follow-up. The remaining patient experienced severe pain and swelling as a result of recurrent arthritis at 9 months, and the Tc-99m HIG index value increased at 9 months after therapy. In 10 of 24 knee joints that had a fair or poor clinical response, Tc-99m HIG index values were statistically similar before and after radionuclide therapy [76].

#### **11.3.2.2 Rhenium-186 Sulfide (Re-186 Colloid)**

This radiopharmaceutical is particularly used for radionuclide synoviorthesis of the hip, shoulder, elbow, wrist, or ankle joint. After intra-articular injection, the radiopharmaceutical is absorbed by the superficial cells of the synovia. Beta-radiation leads to coagulation necrosis and sloughing of these cells similar to other radionuclides used for synoviorthesis.

#### **11.3.2.3 Erbium-169 Citrate (Er-169 Colloid)**

Because of its shorter penetration range in soft tissue, this is more suitable for radionuclide synoviorthesis of the metacarpophalangeal, metatarsophalangeal, and proximal interphalangeal joints.  $\beta$ -Radiation of the absorbed radiopharmaceutical in the synovia causes coagulation necrosis and sloughing of cells as with other colloid used for other joints. Er-169 colloid has an affinity to chelate; therefore the simultaneous administration of iodine contrast media containing EDTA should be avoided.

#### **11.3.2.4 Phosphorus-32 Chromic Sulfate**

P-32 chromic phosphate has a 14-day half-life; has several times larger particles than Y-90

silicate, Re-186, Er-169, or Au-198 colloids; and emits only  $\beta$ -radiation. The  $\beta$ -radiation from P-32 chromic phosphate has a soft tissue penetration midway between them, at 2–3 mm. It has been used by some investigators to treat patients with rheumatoid arthritis and hemophilic arthritis because of these physical advantages [77, 78].

### 11.3.2.5 Radioactive Gold

Radioactive gold (Au-198), with a mean soft tissue penetration of only 1–2 mm, has been used also for radiosynovectomy. It has a physical half-life of 197 days and a colloid particle size ranging from 20 to 70  $\mu\text{m}$ .

### 11.3.2.6 Rhenium-188 Colloid

Since it is a generator-produced  $\beta$ -emitting radionuclide, the importance of Re-188 for radionuclide therapy is increasing rapidly. Jeong [79] prepared Re-188-tin colloid and compared its properties with Re-188-sulfur colloid. The authors found that Re-188 tin colloid was advantageous over Re-188-sulfur colloid since it showed higher labeling efficiency, better control of the particle size, and lower residual activity in the injection syringes [79].

### 11.3.2.7 Dysprosium-165

This radionuclide has a short half-life of 2.3 h, energetic  $\beta$ -emission with a tissue penetration of 5.7 mm, and very large particle size of 3–8 nm. This radionuclide has a 3.6 abundance of  $\gamma$ -emission that can be used by the  $\gamma$ -camera to detect a possible leak. It has been showed to have a response rate of 65–70% with the best results being obtained in patients in early-stage joint disease [73].

### 11.3.2.8 Holmium-166 Ferric Hydroxide

The first experience with Ho-166 was reported by Ofluoglu and colleagues [80]. The knee joints of 22 patients were treated with a mean activity of 1.11 GBq (30 mCi). Ho-166 has a maximum  $\beta$ -energy of 1.85 MeV with a mean penetration in inflamed synovial layer of 2.2 mm and a maximum of 8.7 mm. Its particle size is 1.2–12 nm.

### 11.3.2.9 Samarium-153 Hydroxyapatite

Biodistribution study with Sm-153 hydroxyapatite demonstrated good distribution in the joint with low extra-articular activity accumulation [81].

### 11.3.2.10 Mechanism of Action

Although the mechanism of action cannot be totally explained, the current belief is that after intra-articular administration of the radioactive particles, they are absorbed by the superficial cells of the synovium.  $\beta$ -radiation leads to coagulation necrosis and sloughing of these cells.

## 11.3.3 Choice of Radiopharmaceutical

The choice of radiopharmaceutical depends on the physical characteristics and the size of the joint to be treated and the disease status. The therapeutic agents are particulate in nature and labeled with  $\beta$ -emitting radionuclides. The tissue penetration of the radiation is proportional to the energy of the  $\beta$ -particles. For example, Y-90, with its highly energetic  $\beta$ -emission, has a mean soft tissue penetration of 3–4 mm, while rhenium-186 has a mean penetration of 1–2 mm, the  $\beta$ -emission of phosphorus-32 has a soft tissue penetration midway between them at 2–3 mm, and both radioactive gold and Re-186 have a mean soft tissue penetration of only 1–2 mm. Such radiopharmaceuticals with a shallow depth of penetration are not optimal for large joints such as the knee or for patients with an extensively thickened synovium such as the case with rheumatoid arthritis and pigmented villonodular synovitis. Because radiation exposure rate is proportional to the severity of the post-therapy inflammatory reaction, a radionuclide with a moderately long half-life of days may be preferred to that with a half-life of a few hours. Also, it appears that there is an inverse relationship between the size of radioactive particle used and the tendency for the radiocolloid to leak from the joint space, which in general makes the choice of a relatively large radiocolloid more appropriate. A radionuclide that emits only  $\beta$ -radiation would

have more advantages than one that emits both  $\beta$ - and  $\gamma$ -radiation to minimize whole-body radiation.

The size of the joint and thickness of the synovium as well as proximity of the nontarget organs of the joint are important in the selection of the radionuclide for the treatment. Beta-emitters have different penetrability in the tissues. Torres et al. reported the absorbed dose profiles for P-32, Y-90, Re-188, Lu-177, Cr-51, Sm-153, and Er-169 for radiosynoviortheses treatment [82]. The therapeutic range of each radionuclide in the synovial tissue was also calculated. Therapeutic ranges (mm) for Y-90, P-32, Re-188, Lu-177, Sm-153, and Cr-51 and Er-169 were 2.22, 2.1, 2.1, 1.3, 1.6, 0.0012, and 0.18 mm, respectively. The values they reported can be a useful tool to prescribe adequate quantities of radionuclides for radionuclide synovectomy and provide information about the degree of radiation damage to articular cartilage.

Practically, Y-90 is usually recommended for large joints (knee joint), Re-186 for the treatment of medium joints (such as elbow, shoulder, and hip), and Er-169 citrate for the small joints (such as fingers, toes, and metatarsophalangeal joints) (Fig. 11.2). Er-169 is only available in Europe.

## 11.3.4 Clinical Uses

### 11.3.4.1 Indications

Radionuclide synovectomy is mainly indicated in treating diseased joints in hemophiliac patients and patients with von Willebrand's disease with chronic synovitis and hemarthropathy, rheumatoid arthritis, pigmented villonodular synovitis, psoriatic arthritis, ankylosing spondylitis, and collagenosis.

Relative indications include persistent effusion after joint prosthesis [83].

### 11.3.4.2 Contraindications

The absolute contraindications for the use of the therapeutic radiopharmaceutical colloids for synovectomy are pregnancy and continued breastfeeding. Other contraindications include fresh fracture, serious liver disease, myelosuppression, and acute infections. The therapy is not contrain-

dicated in children or young adults, but therapy should only be administered if the estimated benefit outweighs the potential risks [83]. The presence of a Baker cyst in the knee joint is considered, by some, as a contraindication. Ultrasonography is particularly important for the knee joint to exclude the presence of a Baker cyst, which is an evagination of the medial dorsal part of the joint capsule in communication with the main joint. If there is inflammation in the knee joint, the effusion can be pumped into the Baker cyst by the enhanced motion. If a valve mechanism exists in the connection duct, this could have a deleterious effect after radiosynovectomy. The increased pressure in the cyst might lead to its rupture and the radioactive fluid getting into the surrounding tissue of the joint. The consequence could be possible necrosis of the muscles, nerves, and blood vessels. Accordingly some authors consider Baker cyst, which is not an uncommon occurrence, a contraindication for a radiosynovectomy of the knee joint. Recent arthroscopy is also a contraindication, and radiosynovectomy should be delayed for 4–6 weeks after arthroscopy [83].

### 11.3.4.3 Patient Preparation

Two- or three-phase bone scan should be obtained before planning therapy in order to assess the degree of inflammation of the joint and soft tissue. It should also be obtained in order to be able to decide if radiosynovectomy is possible and if the patient really could benefit from this kind of therapy. Scintigraphy is particularly important in order to evaluate the extent of abnormalities in the joint to be treated. Quantitation methods could be used before and after therapy. A history of arthroscopy must be checked. Ultrasound or MRI is also helpful to assess the amount of effusion, joint space, and the status of the synovium. This ensures the homogeneous distribution of the radiopharmaceutical. A complete blood cell count should be obtained before therapy, and a pregnancy test must be obtained for women of childbearing age. Injections should be performed using aseptic technique. Radiosynovectomy can generally be repeated in 6 months.

#### 11.3.4.4 Treatment Protocol and Clinical Outcome

The protocol of radiosynovectomy varies with the size of the joint treated. Generally radiosynovectomy of the knees, elbows, ankles, and joints of the hands and feet is performed on an outpatient basis under local anesthesia. Sedation, or general anesthesia, is used for children. Shoulder and hip treatment can also be performed as an outpatient but is recommended to be performed under radiographic guidance [75]. The injection technique also depends on the joint (Figs. 11.3, 11.4, 11.5, 11.6, and 11.7).

Depending on the radiopharmaceutical used, the distribution of injected radiotracer can be imaged. Bremsstrahlung imaging following intra-articular injection of Y-90 can be obtained using planar, SPECT, or PET/CT imaging techniques [85]. Intra-articular distribution of Re-186 and Sm-153 distribution can be imaged by planar or SPECT imaging [81].

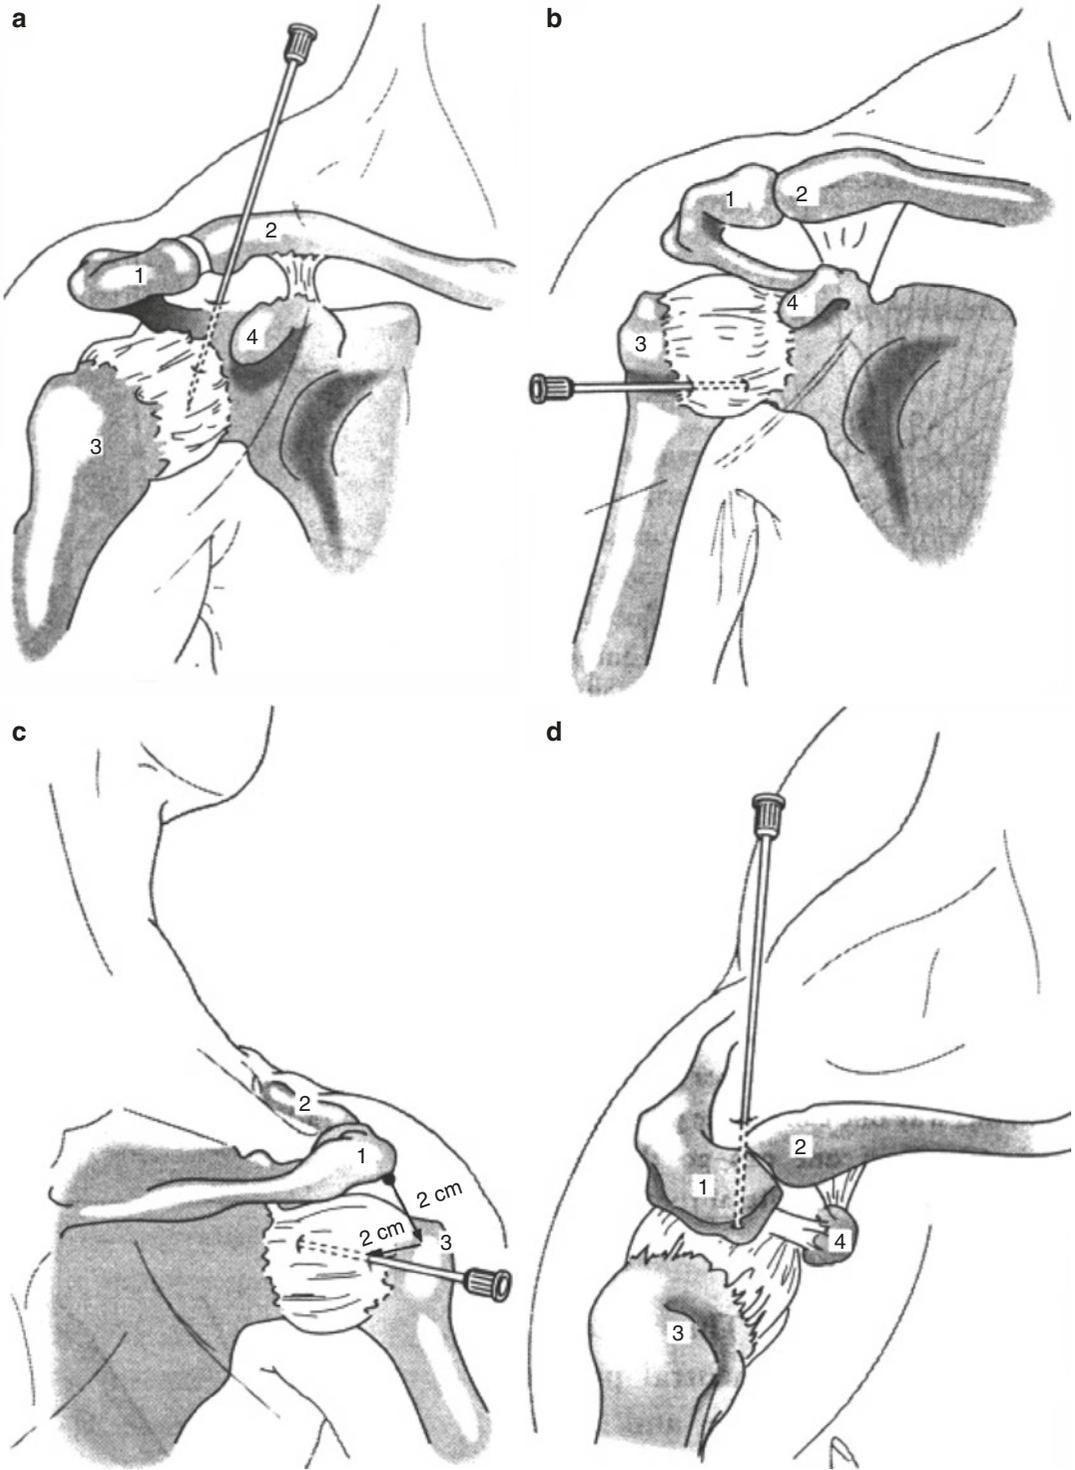

The largest number of treated patients is those with rheumatoid arthritis and hemophilia. Generally good results are obtained among these patients as well as those with psoriatic arthropathy. On the other hand, in osteoarthritis with recurrent joint effusion, radiosynovectomy has not been as successful in relieving the symptoms, and a good response is reported in 40–70% of patients [86]. In patients with advanced cartilage destruction or bone-on-bone interaction, the synovial membrane is likely to be practically nonexistent. Accordingly, patients with less radiological damage generally show better results than those with more severe damage. If there is initially a poor response or a relapse, more than half the patients may benefit from a reinjection [87, 88]. In a review of literature [89] of 2190 joints treated with radiosynovectomy, with a minimum of 1 year follow-up but without specifying the radiopharmaceutical used, the overall success rate was 73%. For rheumatoid arthritis it was 67%, whereas it was 56% for osteoarthritis, 91% for hemophilia and von Willebrand's disease, and 77% for pigmented villonodular synovitis [89].

#### Hemophilia

Good results in patients with hemophilia who suffered from recurrent hemarthroses have been previously reported using Y-90 [73]. Heim et al. [74] used Y-90 in the knees of 58 patients with hemophilia, and a favorable response was noted in 84% of patients after 34 months of follow-up. In 1996 a small study consisting of ten joints in ten patients with hemophilia was performed by Fernandez-Palazzi et al. with Re-186 [84]. Excellent results were reported in 9/10 patients (90%) following treatment. The authors chose to use Re-186 because its physical properties are similar to those of Au-198, but without the  $\gamma$ -radiation, thereby minimizing whole-body radiation.

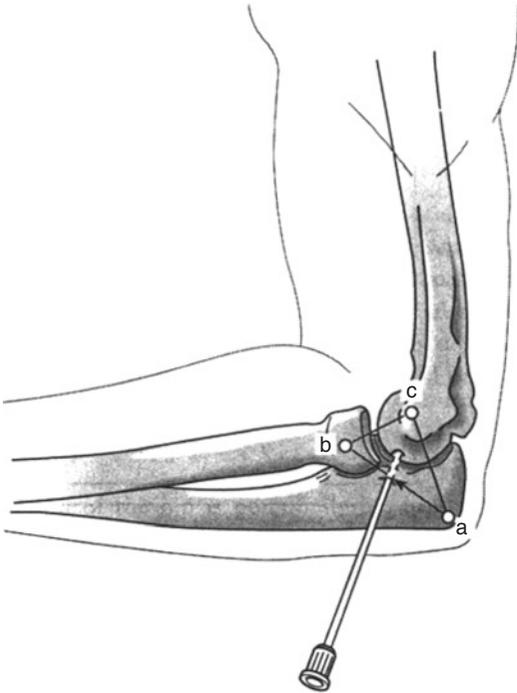

Some authors prefer P-32 for hemophilia because of its physical characteristics (the half-life of 14 days) which provide a theoretical advantage of a more gradual deposition of energy and a minimization of the severity of potentially acute inflammatory reactions. Additionally, the relatively large size of the P-32 colloid minimizes the potential for joint leakage. Furthermore P-32 is a pure  $\beta$ -emitter with only 2.6 mm of radiation penetration in soft tissue, which minimizes radiation dose.

In a recent report of 38-year period, 500 radiosynovectomies were performed in 443 joints of 345 patients with hemophilia diagnosed with chronic synovitis [90]. The radiosynovectomy was carried out with either Y-90 or Re-186. On average, the number of hemarthroses decreased by 64.1% and articular pain decreased by 69.4%. The degree of synovitis showed a reduction of 31.3%. No cancer was observed in this group of patients during the 38-year period. Effectiveness of 185 MBq (5 mCi) versus 740 MBq (20 mCi) of Sm-153 hydroxyapatite (HA) in knees of hemophilic patients was assessed recently [91]. Authors observed significant improvement in the synovectomy of hemophilic knees treated with 740 MBq (20 mCi) of Sm-153 HA. They concluded that the less penetration of Sm-153's beta-radiation was compensated by the increased biological effect with the higher used activity.

Table 11.7 summarizes the efficiency of radio-synovectomy in treating hemophilic joints

## Arthritis

### Rheumatoid Arthritis

Rheumatoid arthritis affects 1–2% of the population worldwide. The inflammatory process of the arthritic joint is characterized by cellular proliferation with the synovial lining becoming hyperplastic and may thicken to 10–12 cells in thickness with a large increase in the percentage of macrophage-like cells associated with an increased secretion of synovial fluid and secretion of cytokines and enzymes that are capable of degrading cartilage matrix and bone, leading to joint destruction. There is also formation of synovial granulation tissue (pannus) (see Fig. 7.1, Chap. 7) [95, 96].

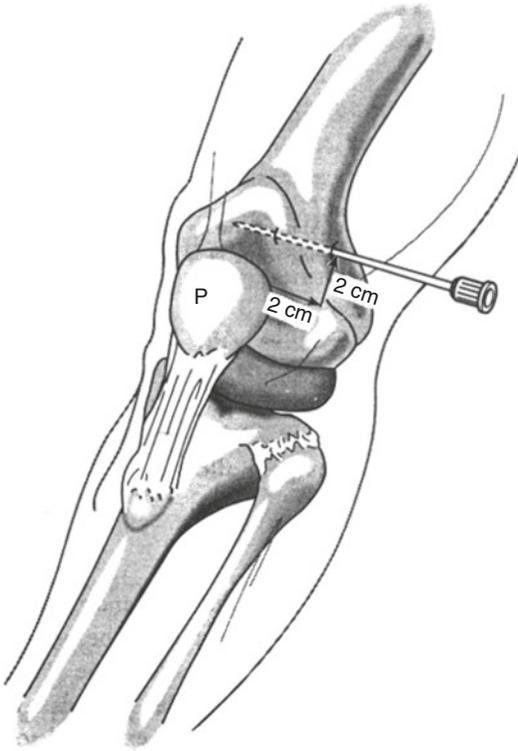

Surgical synovectomy for treating intractable rheumatoid joint disease has the disadvantages of the risks of complications from anesthesia, the need for an approximately 2-week postoperative

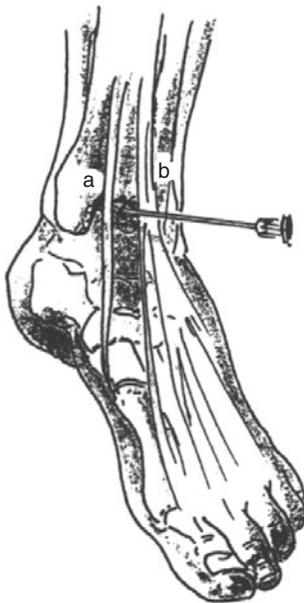

**Fig. 11.5** (a–c) Hip synoviorthesis should be carried out with the help of two important cutaneous landmarks: the anterosuperior iliac spine (a) and the pubic tubercle (b). In this way, one can get the position of the center of the femoral neck (c). Then one can proceed via the inferomedial route (1) or through the superolateral route (2). From [84], with permission

hospitalization, the need for rehabilitation that may take as long as 6 months, and frequent loss of motion as the final result.

The success rate for therapy of rheumatoid arthritis using Re-186 is 86% and using Er-169 is 82% [97, 98]. Using Au-198, approximately 70% of rheumatoid patients benefited, with the most benefit from the procedure being obtained in the early stages of the disease [99–101]. However, the  $\gamma$ -radiation and leakage of the small Au-198 colloid from the joint lead to some concerns regarding whole-body radiation. Moreover, the maximum tissue range is 4 mm, and the average tissue penetration depth is approximately 1 mm; this may be inadequate to treat an extremely inflamed synovial lining, which may be greater than 5 mm in thickness. Y-90 may be preferred for these reasons [99–104]. Y-90 has the advantage of being a pure  $\beta$ -emitter, with a higher

**Fig. 11.6** Knee synoviorthesis (right knee) through the suprapatellar-lateral route. The injection is made above the lateral corner of the patella (*P*) and directly into the suprapatellar pouch. From [84], with permission

**Table 11.7** Results of radiosynovectomy in hemophilic patients

Author	Year	Radionuclide	Favorable response (%)
Erkon [92]	1991	Y-90	81
Fernandez-Palazzi [84]	1996	Re-186	90
Siegel [93]	1994	P-32	80
Rivard [78]	1994	P-32	78
Heim [74]	2001	Y-90	80
Siegel [73]	1997	P-32	75
Chew [94]	2004	P-32/Re-186	80
Rodriguez-Merchan [90]	2014	Y-90/Re-186	69.4

energy and a greater maximum tissue penetration than Au-198 (11 mm vs. 4 mm), making it an attractive agent for radiosynovectomy. Using Y-90 for the knee joint, decrease in pain, joint effusion, and motility are reported in 60% of patients 6 months after radiosynovectomy.

The results of the treatment of approximately 1500 rheumatoid joints by Grove, using Y-90, were good in approximately 67% of joints, and no side effects were noted over a follow-up of several years [105].

Seventy-six middle-sized joints were treated each with Re-186 sulfate and other 80 small joints with Er-169 citrate [106]. The effect of treatment was evaluated at 6 and 12 months following the treatment. Radionuclide treatment decreased pain of the affected joints; however the influence upon joint motion was minimal. The best treatment results were observed in shoulders and elbows, while the ankles were the worst to respond to the treatment. However the beneficial effect on pain and swelling reduction was only transient and declined over 12 months [106].

In 18 patients with persistent rheumatoid knee synovitis treated with intra-articular Sm-153 particulate hydroxyapatite combined with triamcinolone hexacetonide, symptom relief was maintained in 56% patients at 6 months and in 44% of patients at 12 months following treatment [107].

Lu-177 hydroxyapatite (HA) particles showed promising results in preclinical studies in Wistar rats bearing arthritis in knee joints [108]. In preliminary clinical investigation, there was significant

improvement in the disease conditions in ten patients with rheumatoid arthritis of knee joints treated with Lu-177 HA [109]. Dos-Santos et al. compared Y-90 plus triamcinolone hexacetonide (Y/TH) to Sm-153 plus TH (Sm/TH) in 84 patients (90 knees) with chronic knee synovitis and rheumatoid arthritis. Regarding the pain, there was a significantly better response in the Y/TH group versus the Sm/TH group and versus TH alone at 48 weeks [110].

#### Other Arthropathies

Arthropathies in which radiosynovectomy may prove to be successful include pigmented villonodular synovitis, psoriatic arthritis, ankylosing spondylitis, osteoarthritis, and collagenosis. Franssen et al. [111], using Y-90 in the treatment of pigmented villonodular synovitis of the knee, showed improvement in 50% of patients with a 32-month follow-up. Additionally, Alexieva and Kunnev [112] showed favorable results in 80% of patients treated with Y-90 for ankylosing spondylitis, psoriatic arthritis, and collagenosis involving the knee joint. Radium-224 has also been used successfully to treat ankylosing spondylitis. It is a decay product of thorium-232 and emits both  $\alpha$ - and  $\beta$ -particles with a mean range in soft tissue of 50 mm and 8 mm, respectively. It has a physical half-life of 3.64 days and is administered as ten intravenous injections at intervals of 1 week. The cumulative total activity administered should not exceed 10 MBq (0.27 mCi). Approximately 90% of treated patients become pain-free for many years [113]. Patients with psoriatic arthropathies also show satisfying and encouraging results [114] after radiosynovectomy.

#### 11.3.4.5 Side Effects of Radiosynovectomy

The side effects of radiosynovectomy depend on the radiopharmaceutical used, the activity administered, and more importantly the technique of administering the dose. The side effects include necrosis of the extra-articular soft tissue, febrile reaction, local pain, and leakage of radiopharmaceutical from the joint via lymph nodes.

The most important side effect is the leakage of the radioactivity from the joint since it has the

potential of causing infertility [115], although there is no evidence of patients treated for arthritis [116].

#### Radiopharmaceutical Leakage

Leakage of the radionuclide from the treated joint has limited the use of radiation synovectomy as an alternative to surgical treatment. Unconjugated radionuclides will diffuse through the joint, and they must therefore be conjugated with a nondiffusible particle to prevent leaking. Accordingly, the currently used therapeutic radionuclides are in colloidal form, where the particles are small enough to be phagocytized by the synovial tissue, but not small enough to escape from the joint before being phagocytized. Thus, the particle size is critical in limiting the leakage from a synovial joint. Immobilization of the treated joint for 48–72 h is necessary to minimize the leakage by means of blood and lymphatic transport [117]. To avoid radionecrosis, needle placement is confirmed by fluoroscopy and flushing the needle with saline prior to removal to avoid needle tract necrosis. Rivard reported leakage in only 3 of 71 radiosynovectomies using P-32 colloid with a mean percentage leakage of 0.6% (range 0.1–2%) [78]. In a review of 100 radiosynovectomies [118], the maximum leakage was 2.5% of the target dose, and it occurred in one patient. Winston et al. [119], using P-32 in rheumatoids, reported a maximum leakage of 3.2% in only one patient.

#### Post-therapeutic Regional Inflammatory Reaction

Further side effects can be painful reactions in the treated joint (treated with a cold pad and analgesia), edema of the forearm after treatment of the wrist joint, and exceptional joint infection.

#### Somatic and Genetic Effects

Available data point to a negligible somatic and genetic risk [120]. Therefore younger patients may be treated with radiosynovectomy if the benefit outweighs the risk. Because the whole-body dose from the  $\beta$ -emitting radionuclides used for radiation synovectomy is low, the effects, if any, on chromosomes are considered to be a result of

the leakage to the inguinal lymph nodes. The hypothetical disadvantage of radiosynovectomy is that the radioactivity may theoretically diffuse from the joint and adversely affect chromosomal material or induce late radiation-induced neoplasms. Rivard et al. [78] reported that perhaps the strongest argument for the safety of intra-articular radiocolloids is the long-term follow-up of the more than 5000 radiosynovectomies performed since 1971, mainly in patients with rheumatoid arthritis, none of whom have been reported to have developed radiation-induced malignancies. Early studies with Au-198 reported that greater than 10% and as much as 60% of the activity was found in the draining lymph nodes, and yet there have been no reports linking the use of this agent to hematogenous malignancies or sarcomas. De la Chapelle et al. also noted no correlation between any detectable lymph node activity and the detection of chromosomal aberrations [115]. Rivard et al. [78] found no chromosomal aberrations at 1 week or at 6 months after P-32 chromic phosphate injection in the knees of seven hemophilic patients [78].

### **Radiation Sickness**

This is a rare side effect seen in about 3% of patients after radiosynovectomy. Patients transiently have a slightly increased temperature and feel sick, but no special therapy is necessary.

---

## **11.4 Other Radionuclide Therapies**

Certain promising radionuclide therapies are being tried both on animals and humans. These are focused on treating certain primary and metastatic malignancies such as neuroblastoma, multiple myeloma, osteosarcoma, and metastatic prostatic cancer.

### **11.4.1 Treatment of Primary Osteogenic Sarcoma**

Targeted radionuclide therapy using Sm-153-EDTMP was reported to provide a substantial

palliative effect in a case of primary osteogenic sarcoma in the first lumbar vertebra which had relapsed with progressive back pain after conventional treatment modalities had failed. The patient was bedridden and developed paraparesis and impaired bladder function. On a diagnostic bone scan, intense radioactivity was localized in the tumor. The patient was twice treated with Sm-153-EDTMP, 8 weeks apart using 35 and 32 MBq/kg (0.86 and 0.94 mCi/kg) body weight, respectively. After a few days, the pain was significantly relieved and by the second radionuclide treatment, the paresis subsided. For 6 months he was “up and about” without any neurological signs or detectable metastases. Eventually, however, the patient redeveloped local pain and paraparesis, was reoperated, and died 4 months later. The authors concluded that this dramatic transient improvement observed in this case warrants further exploration using Sm-153-EDTMP as a boost technique, supplementary to conventional external radiotherapy [121].

Another case was also reported which illustrated high-activity Sm-153-EDTMP therapy within a multimodal therapy concept to improve local control of an unresectable osteogenic sarcoma with poor response to initial polychemotherapy. A 21-year-old woman with an extended, unresectable pelvic osteogenic sarcoma and multiple pulmonary metastases was treated with high activity of Sm-153-EDTMP. Afterwards, external radiotherapy of the primary tumor site was performed and polychemotherapy continued, followed by autologous peripheral blood stem cell reinfusion. Within 48 h after Sm-153-EDTMP treatment, the patient had complete pain relief. After 3 weeks, the response was documented by three-phase Tc-99m MDP bone scintigraphy with a decrease in the tracer uptake in the primary tumor and metastases and whole-body F-18 FDG PET with an interval decrease of uptake. Accordingly, further evaluation of the feasibility and efficacy of this multimodal therapy combination of high-activity Sm-153-EDTMP therapy, external radiation, polychemotherapy, and stem cell support for unresectable osteogenic sarcoma is warranted [122].

An animal study was conducted on 15 dogs with spontaneous osteogenic sarcoma and local pain, which were treated with Sm-153-EDTMP. The tumors were located in the extremities, scapula, maxilla, and the frontal bone. The dogs were injected intravenously one to four times with Sm-153-EDTMP, 36–57 MBq/kg (0.97–1.54 mCi) body weight. Three dogs had surgery in addition to the radionuclide treatment. Platelet and white blood cell counts showed a moderate and transient decrease with no other toxicity observed. The average tumor dose after a single injection was approximately 20 Gy. Seven dogs had metastases on autopsies. Although none of the dogs was cured, nine dogs had obvious pain relief, and five of them seemed pain-free: one for 20 months and one for 48 months. The authors suggested that high tumor radiation doses may be deposited in dog osteosarcomas by Sm-153-EDTMP, and the ratio between the tumor dose and the dose to surrounding tissues is favorable. The treatment gives pain relief and may cause tumor growth delay, and the combination of surgery and Sm-153-EDTMP may prolong life significantly and possibly cure the disease, because the development of metastases appears to be postponed [123].

Recently it was suggested that Ra-223 may have greater potential to become widely used against osteosarcoma as a targeted therapy and has more potential to be used with chemotherapy against osteosarcoma and bone metastases [124].

### 11.4.2 Metastatic Prostate Carcinoma

A study was conducted to explore the effects of Re-186-HEDP treatment on the progression of lumbar-skeletal metastasis in an animal model (Copenhagen rat) and to correlate the eventual treatment efficacy with the radionuclide tissue distribution. The Re-186-HEDP administration, given either 1 day or 8 days after surgical induction of lumbar metastasis, was found to significantly increase the symptom-free survival of the animals. These results were confirmed by a significant decrease in the presence of histologically

detectable tumor tissue. Biodistribution studies demonstrated the uptake of the major part of the radionuclide within bone tissue, concentrated in areas of bone formation and turnover. These results show that radionuclide treatment with Re-186-HEDP is a potentially efficacious treatment option in prostate cancer disseminated to the skeleton [125].

Lu-177 PSMA-617 radioligand is a promising new therapeutic agent for the treatment of the patients with metastatic castration-resistant prostate cancer. Studies have demonstrated that Lu-177 PSMA-617 radioligand treatment is safe and effective and also increases overall survival [126–128]. In Rahbar et al.'s study, any PSA decline occurred in 59% and 75% of patients after one and two therapies with Lu-117 PSMA-617 radioligand. Moreover, a PSA decline of 50% or greater occurred in 32% and 50% [128]. Lu-PSMA-617-targeted radionuclide therapy was administered to patients with metastasized castration-resistant prostate cancer and resistant to other treatments. Twenty-one of 30 patients had a PSA response [129].

Ra-223 dichloride is another promising agent in the treatment of bone metastases in patients with castration-resistant prostate cancer. Phase 2 and phase 3 studies demonstrated that Ra-223 treatment increases survival and time to first skeletal-related events in patients with castration-resistant prostate cancer and bone metastases. [58, 63].

### 11.4.3 Multiple Myeloma

High-dose Ho-166-DOTMP (Ho-166-1, 4, 7, 10-tetraazocyclododecane-1,4,7,10-tetramethylene-phosphonic acid) in treating patients with multiple myeloma has been reported [130]. Thirty-two patients were treated with 581–3987 mCi with an average of 2007 mCi (74.3 GBq). Ho-166 has a half-life of 26.8 h and a  $\beta$ -emission of 1.85 MeV (51%) and 177 MeV (48%) as well as a 80.6 keV (6.6%)  $\gamma$ -emission suitable for a  $\gamma$ -camera imaging. The  $\beta$ -particles have a mean range of 4 mm in soft tissue and can deliver high levels of radiation to the marrow and trabecular bone [130].

The radiopharmaceutical has selective bone uptake and rapid urinary excretion of the remaining activity. However, due to the high doses used, catheterization and continuous irrigation of the urinary bladder after therapy has to be used to reduce radiation dose to the bladder mucosa. This agent has a potential to treat patients with resistant multiple myeloma. However, clinical studies with an emphasis on the outcome in comparison with the currently used high dose of chemoradiotherapy with or without stem cell rescue are warranted to evaluate the impact on the poor survival of patients affected by the tumor. Also more studies are needed to compare the adverse effects of this agent to the incidence of systemic toxicities of the currently available radiopharmaceuticals [131, 132].

Alpha-radioimmunotherapy (RIT) with bismuth-213 (Bi-213) was reported to be good alternative to melphalan in mice grafted with multiple myeloma cells. No animal was cured after melphalan treatment, whereas 60% of the mice survived with RIT alone at day 22 after tumor engraftment with only slight and reversible hematological radiotoxicity [133]. In a murine model of multiple myeloma, promising therapeutic efficacy of Bi-213-labeled anti-mCD138 for the treatment of residual disease in the case of multiple myeloma was reported with only moderate and transient toxicity [134].

Chemokine receptor-4 is often expressed with high density by myeloma cells. Chemokine receptor targeted radiotherapy with novel radio-labeled (Lu-177 or Y-90) peptides appears to be promising [135].

#### 11.4.4 Treatment of Neuroblastoma

Bone and bone marrow are the two most common sites of metastases in patients with neuroblastoma. Iodine-131-MIBG has been used to treat patients with stage 4 neuroblastoma including those with bone metastases after failure of all other modalities of therapy. The response rate was approximately 35% [136]. In a large phase 2 trial, I-131 MIBG was administered as monotherapy in patients with progressive, refractory, or

relapsed high-risk MIBG-avid neuroblastoma. One hundred forty-eight patients with cryopreserved stem cells available received 18 mCi/kg (666 MBq/kg) of I-131 MIBG, and 16 patients without available cryopreserved stem cells received 12 mCi/kg (444 MBq/kg) of I-131 MIBG. The overall complete plus partial response rate was 36%. There was also age-related response to I-131 MIBG therapy. Patients aged 12 years or older had 55% response rate compared to 40% response in patients aged less than 12 years. The response rate was significantly higher for patients with disease limited either to the bone and bone marrow or to the soft tissue compared with patients with both [137].

To maximize the therapeutic effect of I-131 MIBG, treatment was also combined with high-dose chemotherapy followed by autologous stem cell transplant [138–141]. Activity and toxicity of I-131 MIBG when combined with carboplatin, etoposide, and melphalan (CEM) and autologous stem cell transplantation have been investigated in a phase 2 study [141]. Combination of I-131 MIBG and myeloablative doses of CEM chemotherapy was associated with promising event-free survival and overall survival, though low overall response rates were seen in patients with relapsed or primary refractory disease. The addition of I-131 MIBG to the transplantation preparative regimen did not result in increased hematological or non-hematological organ toxicity [141].

I-125-MIBG has also been used for bone marrow infiltrates. It was recently suggested that I-125-MIBG is dosimetrically superior to I-131 MIBG therapy for small bone marrow metastases from neuroblastoma. Authors recommended considering adding I-125 MIBG to I-131 MIBG in multimodality therapy as these two isotopes could be complementary in terms of their cumulative dosimetry [142].

Neuroblastoma may express somatostatin receptors. Six children who had abnormally high uptake on the Ga-68 DOTATATE PET/CT scan were proceeded to treatment with Lu-177 DOTATATE [143]. Authors in this study suggested that Lu-177 DOTATATE is safe and feasible in children with relapsed or primary refractory high-risk neuroblastoma. In a recent study, four

pediatric patients with refractory neuroblastoma received 17 cycles of palliative peptide receptor radionuclide therapy (10 In-111DOTATATE; 5 Lu-177DOTATATE; 1 combined In-111 and Lu-177DOTATATE; 1 combined Lu-177 and Y-90DOTATATE). There was no significant toxicity attributed to peptide receptor radionuclide therapy. All had objective responses. Two survivors were 40 and 56 months from peptide receptor radionuclide therapy commencement [144].

### 11.4.5 Bone Marrow Ablation

The bone marrow can be ablated by radionuclide therapy for patients requiring bone marrow transplantation. In seven splenectomized young adult beagle dogs, Parks et al. reported that Ho-166 treatment results in complete ablation of hematopoietic marrow cell populations within 7 days [145]. Fe-52 was used to ablate marrow-based diseases before marrow transplantation in 14 patients. No untoward effects were noted after Fe-52 injections. The patients recovered hematopoiesis without toxicity in excess of that expected with conventional conditioning alone. The median follow-up was 8 months and three patients have relapsed [146].

## Glossary

- Ankylosing spondylitis** The most common type of spondyloarthropathies with chronic inflammatory changes leading to stiffening and fusion (ankylosis) of the spine and sacroiliac with a strong genetic predisposition associated with HLA B27. Other joints, such as hips, knees, and shoulders, are involved in approximately 30% of patients.
- Apophysis** An accessory secondary ossification center that develops late and forms a protrusion from the growing bone where tendons and ligaments insert or originate.
- Avulsion** Complete separation of tendons or ligaments, with or without a portion of bone and/or cartilage.
- Behçet's syndrome** An uncommon disorder characterized by recurrent oral and genital ulceration, uveitis, or retinal vasculitis, cutaneous pustules, or erythema nodosum and synovitis. The disease is more common in Mediterranean countries and Japan than in the United States.
- Bone contusion (bone bruise)** A term describing microfractures of trabecular bone together with edema or hemorrhage within the marrow.
- Brodie's abscess** An intraosseous abscess in the cortex that becomes walled off by reactive bone.
- Calciphylaxis** Soft tissue calcification in response to administration of an agent after induction of a hypersensitive state.
- Calcinosis cutis** A term used to describe a group of disorders in which calcium deposits form in the skin, subcutaneous tissue, and connective tissue sheaths around the muscles but not within the muscles.
- Chronic nonbacterial osteomyelitis** This term has emerged as a global term to describe a group of autoinflammatory bone diseases, including chronic recurrent multifocal osteomyelitis (CRMO), synovitis, acne, pustulosis, hyperostosis, osteitis (SAPHO) syndrome, and diffuse sclerosing osteitis (DSO). These disease entities are sterile bone lesions that may include associated systemic and dermatologic manifestations.
- Costochondritis (Tietze's syndrome)** A common painful condition that affects the costochondral junction, usually in young patients, and is self-limiting. The etiology remains unknown, although trauma and infection have been proposed. It can affect any rib, but the first and second ribs are most commonly involved.
- Complex regional pain syndrome type I (reflex sympathetic dystrophy)** A pain syndrome that usually develops after an initiating noxious event with no identifiable major nerve injury, is not limited to the distribution of a single peripheral nerve, and is disproportional to the inciting event or expected healing response.
- CPPD** Calcium pyrophosphate dihydrate deposition disease, also called pseudogout and chondrocalcinosis: a type of crystal deposition arthropathy with such crystals deposited in cartilage, synovium, tendons, and ligaments.
- Diffuse idiopathic skeletal hyperostosis (DISH)** Also known as Forestier's disease or senile ankylosing hyperostosis; *is a common progressive noninflammatory bone and enthesial disorder of unknown etiology* affecting the

elderly population (up to 30% of men older than the age of 50 years). It is characterized by calcification and ossification of the spinal and various extraspinal soft tissues, mainly entheses, ligaments, and joint capsules.

**Dystrophic calcification** A type of soft tissue calcification that occurs in the setting of normal serum calcium and phosphate levels and occurs in damaged, inflamed, neoplastic, or necrotic tissue.

**Endochondral ossification** Most of the skeleton forms by this type of ossification, where a preexisting cartilage forms first and then undergoes ossification.

**Enteropathic arthropathies** Arthropathies associated with inflammatory bowel diseases, including ulcerative colitis, Crohn's disease, Whipple's disease, intestinal bypass surgery, and celiac disease.

**Entheses** The sites of insertion of tendons, ligaments, and articular capsule to bone.

**Enthesopathy** A pathologic process affecting entheses particularly trauma and/or inflammation resulting in regional periosteal reaction with osteoblastic bone activity.

**Fibrous dysplasia** A benign bone disorder characterized by the presence in the fibrous tissue in lesions of trabeculae of non-lamellar bone (woven bone) which remains essentially unchanged.

**Flare pattern on bone scan** An initial apparent deterioration of primary or some or all metastatic lesions on the bone scan, followed by improvement usually accompanying successful treatment.

**Fracture delayed union** Delay of fracture union beyond the expected time (usually 9 months).

**Fracture nonunion** Complete cessation of repair process of a fracture.

**Fracture** A break in the continuity of a bone.

**Gout** A metabolic disorder that results in hyperuricemia and leads to deposition of monosodium urate monohydrate crystals in various sites in the body, especially joint cartilage.

**Heterotopic ossification** A specific type of soft tissue calcification that may or may not follow trauma and is due to a complex pathogenetic mechanism believed to be due to transforma-

tion of certain primitive cells of mesenchymal origin in the connective tissue septa within muscles into bone-forming cells.

**Hypertrophic osteoarthropathy** A form of periostitis that may be painful and may be associated with clubbing of fingers and toes, sweating, and thickening of skin. It may be primary or may follow a variety of pathologic conditions, predominantly intrathoracic, and is characterized by periosteal new bone formation.

**Impingement syndromes** A group of painful conditions caused by friction of joint tissue, which include bone impingement, soft tissue impingement, and entrapment neuropathy, depending on the type of tissue involved.

**Inflammation** A complex nonspecific tissue reaction to injury caused by many agents such as living agents such as bacteria and viruses, leading to infection, or nonliving agents, including chemical, physical, and immunologic factors or radiation.

**Intramembranous ossification** Occurs through the transformation of mesenchymal cells into osteoblasts, seen in flat bones of the skull, part of the mandible, and part of the clavicle.

**Involucrum** A layer of new bone formation around the site of skeletal infection formed secondary to the body's response to that infection.

**Lisfranc injury** Fracture or fracture-dislocation of tarsometatarsal joints.

**Malunion** Healing of a bone in a nonanatomic orientation.

**Mandibular condylar hyperplasia** A unilateral developmental abnormality of the mandible leading to asymmetry in condyles that may result in facial asymmetry.

**Metastatic calcification** The type of soft tissue calcification that involves viable undamaged normal tissue as a result of hypercalcemia and/or hyperphosphatemia associated with increased calcium phosphate product locally or systematically.

**Myositis ossificans progressiva** The congenital and rare form of heterotopic ossification.

**Osteochondritis dissecans** Transchondral fracture with fragmentation and separation of portions of cartilage or cartilage and bone; most prevalent in adolescents.

- Osteomalacia** Abnormal mineralization of bone with a decrease in bone density secondary to lack of both calcium and phosphorus with no decrease in the amount of osteoid (bone formation).
- Osteomyelitis** A term applied to skeletal infection when it involves the bone marrow.
- Osteopetrosis** A rare inherited metabolic bone disease characterized by a generalized increase in skeletal mass due to a congenital defect in the development or function of the osteoclasts, leading to defective bone resorption.
- Osteoporosis** Reduction of bone tissue amount increasing the likelihood of fractures.
- Oxalosis** Deposition of calcium oxalate crystals that leads to arthropathy.
- Pathologic fracture** A fracture at a site of pre-existing abnormalities that weaken bone.
- Patellofemoral stress syndrome (patellofemoral pain syndrome)** A common musculoskeletal disorder believed to be due to abnormal motion or pressure between the patella and femur secondary to chondromalacia and malalignment, but overuse is currently believed to be the most important etiology. It causes pain, sometimes sharp and acute.
- Plantar fasciitis (calcaneal periosteitis)** An inflammatory condition that can occur as an isolated entity, e.g., secondary to occupation or degenerative, or may accompany spondyloarthropathies.
- Podagra** A term describing affection of the metatarsophalangeal joint of the great toe in gout, the most typical finding of gouty arthritis.
- Progressive diaphyseal dysplasia (Camurati-Engelmann disease)** Rare autosomal dominant hereditary disorder characterized by progressive bone formation along the periosteal and endosteal surfaces of long bones and sometimes the skull with widening of bones. It is usually manifested in childhood but can present later. It may cause pain, muscle weakness, and occasionally deafness.
- Pseudarthrosis** A gap between the fracture bone ends containing a space filled with fluid. Also termed "false joint."
- Reactive arthritis (Reiter's disease)** A syndrome characterized by a combination of nongonococcal urethritis, arthritis, and conjunctivitis.
- Renal osteodystrophy** A metabolic condition of the bone associated with chronic renal failure.
- Rheumatoid arthritis** An autoimmune disease causing inflammation of connective tissue, mainly in the joints, with synovial inflammatory response triggered by immune complexes in the blood and synovial tissue through activation of plasma protein complement. This inflammation spreads from the synovial membrane to the articular cartilage, the joint capsule, and the surrounding tendons and ligaments, leading to pain, loss of function, and joint deformity.
- SAPHO syndrome** A syndrome characterized by synovitis, acne, palmoplantar pustulosis, hyperostosis, and osteitis. The small and large joints of the feet, ankles, knees, hips, right sacroiliac joints, and shoulders are affected by the synovitis.
- Scheuermann disease** A destructive form of osteochondrosis with erosions of the end plates of two adjacent vertebrae and anterior wedging of thoracic vertebrae.
- Schmorl's node** Herniation of nucleus pulposus upward or downward through the cartilaginous and bony end plate into the body of an adjacent vertebra. Usually involves the inferior end plate of the lower thoracic and lumbar vertebral bodies. Involvement of both the inferior and the superior end plates is not uncommon.
- Septic tenosynovitis** An inflammatory condition affecting generally the flexor tendons of the hands and feet of diabetic patients and resulting from penetrating injuries or spread of infection from a contiguous focus of infection.
- Sequestrum** Segmental bone necrosis that develops when normal blood supply to the bone is interrupted by the edema and ischemia produced by the inflammation.
- Shin splints** Periosteal elevation with reactive bone formation secondary to extreme tension on muscles or muscle groups inserting on bones.
- Slipped capital femoral epiphysis** Displacement of the femoral head from the femoral neck at the site of the growth plate during growth.
- Spondyloarthropathies** A group of seronegative arthropathies formerly called rheumatoid

variants that share common clinical and radiographic features with characteristic involvement of the sacroiliac joints, the spine, and, to various degrees, the peripheral joints, are linked to HLA B27 histocompatibility antigen, and include ankylosing spondylitis, psoriatic arthritis, reactive arthritis (Reiter's disease), and enteropathic spondylitis.

**Spondylolysis** A loss of continuity of bone of the neuroarch of the vertebra due to stress or trauma.

**Spondylolisthesis** Forward movement of one vertebra on another, usually as a result of fracture of the neuroarch.

**Sprains** Tears of ligaments.

**Strains** Tears of tendons.

**Stress fracture** A pathologic condition of bone due to repeated episodes of stress, each less forceful than that needed to cause acute fracture of the bony cortex.

**Synovial joints** Specialized joints that are found mainly in the appendicular skeleton and allow free motion.

**Tarsal coalition** Fusion of the talus and calcaneus or of the navicular and calcaneus due to failure of normal segmentation of their ossification centers during embryogenesis.

**Toddler's fracture** Fracture in preschool children which is typically a non-displaced spiral fracture of the mid-tibia but also includes fractures of other bones, such as the fibula, calcaneus, talus, metatarsal, and cuboid bones.

**Transient synovitis** A joint inflammation of unknown origin and self-limiting course affecting most frequently boys between 5 and 10 years of age. It was previously known as toxic synovitis and affects preferentially the hip or knee and subsides without antibiotics.

**T-score** A parameter used to express bone mineral density by relating an individual's bone density to the mean BMD of healthy young adults, matched for gender and ethnic group.

**Tumoral calcinosis** A type of soft tissue calcification characterized by large, calcified, periarticular soft tissue masses of calcium phosphate near the large joints such as the hip, the shoulder, and the elbow, in addition to the wrist, hands, and feet.

**Woven bone** Immature non-lamellar bone that is later normally converted to lamellar bone.

**Z-score** A parameter used to express bone mineral density by comparing the bone density value of an individual to the mean value expected for his/her age group.
