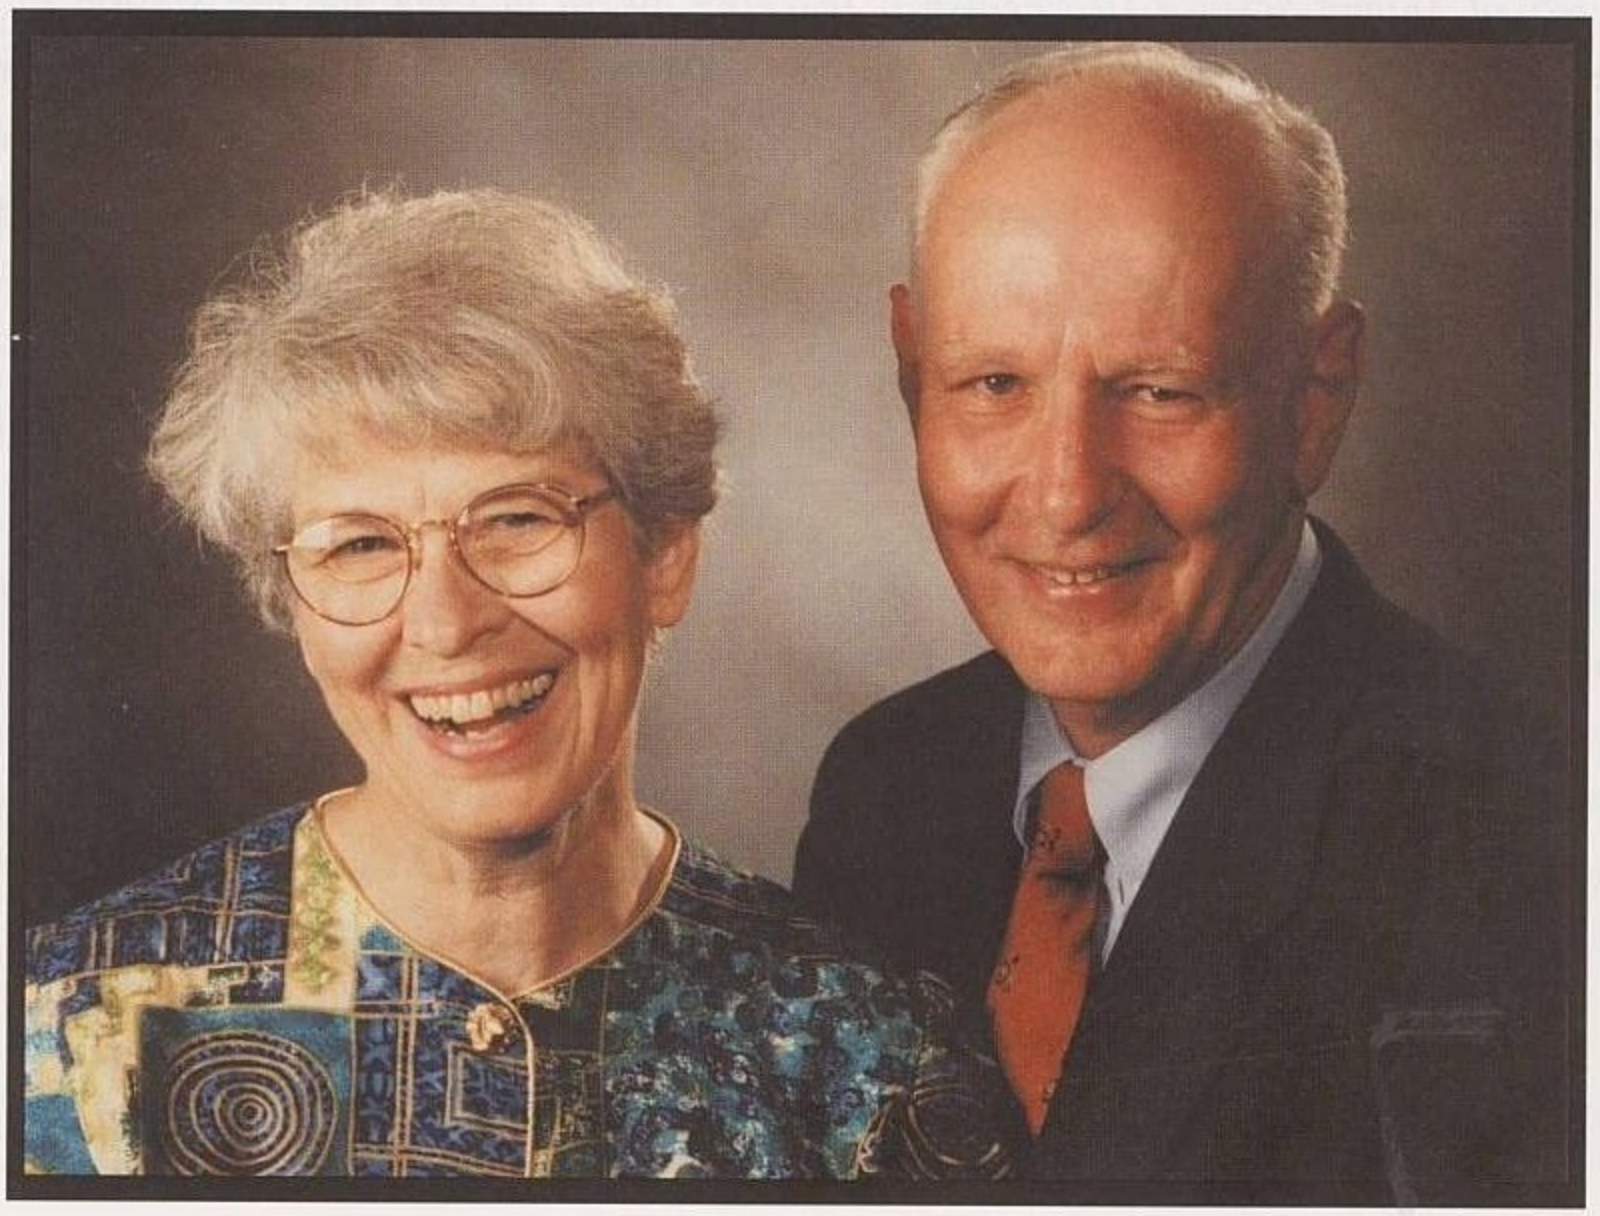
Dedication

To paraphrase Hodding Carter, there are two lasting benefits
we can give our students, children and other people we associate with.
"One is roots and the other is wings."

This book is dedicated to Dr. R.G. (Dick) Saacke and his wife, Ann, a couple who have been models for countless students, fellow educators/professionals, friends and their own children in emphasizing the importance of uncompromising commitment to high standards and values (**roots**). At the same time, they have always encouraged others to fly and to enjoy their journey (**wings**).



Ann Saacke and Dr. R.G. Saacke

The Author

P.L. (Phil) Senger grew up in Cary, North Carolina and received his B.S. in Zoology from North Carolina State University. He was awarded the M.S. and Ph.D. in reproductive physiology from the Department of Dairy Science at Virginia Polytechnic Institute and State University. He has been Professor of Animal Sciences at Washington State University where his primary teaching responsibilities include animal physiology and reproductive physiology. He has authored over 200 scientific, educational and popular press papers. Dr. Senger is currently President of Current Conceptions, Inc.

Dr. Senger has over 30 years of experience conducting research and teaching students, and clientele about reproductive physiology. He is the recipient of six teaching awards, including the *American Society of Animal Science Distinguished Teaching Award* in 1998 and the Marion E. Smith Faculty Achievement Award in 2005. He has received two national awards for research in reproductive physiology. Dr. Senger has been a frequent speaker, columnist and author about dairy reproduction to producers and veterinarians throughout the world. He is married and has three daughters. He enjoys racquetball, skiing, fishing, gardening and attempts golf.

Preface

The ultimate goal of **Pathways to Pregnancy and Parturition - 2nd Revised Edition** is to enable people to understand the principles of reproductive physiology. This discipline is a visual one and requires images of anatomical structures and physiologic processes. Good visual imaging makes learning easier, less time consuming and the knowledge is retained longer. Students, professors, industry professionals, veterinarians or those simply interested in the reproductive process are very busy. They do not have time to "deconfuse" themselves or others. In this context, we have tried hard to make this book a good investment in visual understanding.

There will always be room for considerable debate concerning what is "correct" and "incorrect" regarding many of the topics in this book. During my career as an educator and researcher I have come to realize that,

"It is not only about making sure the information is correct…
it is also about making sure people can understand it.
If they can't understand it, it really doesn't matter if it is correct."

Dr. R.C. Mittelhammer, one of my colleagues at Washington State University and a renowned educator in the field of econometrics once commented "**classes, textbooks and lectures should be much more than information dumps**." Many details and facts are presented in this book and we have purposely linked them to the principles and concepts. We have not "dumped" a plethora of facts on the reader. Instead, we have presented the concepts (and the facts that support them) in a logical sequence so that the reader can easily follow the progression of key events through the reproductive process.

Inspiration

I have received numerous suggestions, criticisms and praise regarding the 2nd Edition from university faculty, veterinarians, industry professionals and students from all over the world. Their reactions have always been directed toward increasing the power of this instrument to enlighten people about reproductive physiology. Such feedback has served as a huge source of inspiration to me and my associates during the preparation of the 2nd Revised Edition.

Blood, Sweat and Tears

Production of the 2nd Edition and the 2nd Revised Edition of **Pathways to Pregnancy and Parturition** has been more challenging than the 1st Edition. Remodeling requires that a mess be made before the final product can be visualized. Implementing the many changes, additions and modifications has at times been exhausting. People with boundless energy, patience and the relentless desire to produce quality have made huge contributions to this edition.

Those pictured above have become known as ***"The Gonadal Gossip Gang"***

Standing (left to right):

Sarah Bobbitt (not pictured) - Index and Glossary Revision

Knowledge and Know-How

The following scientists made valuable contributions to the scientific content of one or more chapters in this book.

R.P. Amann (Emeritus, Colorado State University)
L.F. Archbald (University of Florida)
C.E. Farin (North Carolina State University)
M.J. Fields (University of Florida)
D.L. Foster (University of Michigan)
H.A. Garverick (University of Missouri)
E.K. Inskeep (West Virginia University)
L. Johnson (Texas A&M University)
L.S. Katz (Rutgers University)
T.L. Ott (University of Idaho)
M.F. Smith (University of Missouri)
M. Tatum (Texas A&M University)
A. Tibary (Washington State University)

During the development of 2nd Edition, a number of Baccalaureate and Veterinary students contributed significantly. These individuals and their contributions are presented below.

Cerissa K. Blair - BS, Animal Sciences, Washington State University, 2002.
She assisted in the development of Figure 4-11 (inguinal hernia) in cooperation with the Washington State University Student Swine Cooperative.

Rebecca L. Cody - BS, Animal Sciences, Washington State University, 1998, DVM, Washington State University 2002.
Figures 3-9 and 3-10 were produced as part of a Washington State University Honors College Thesis entitled, "Intravascular Polymerization as a Method of Observing Countercurrent Exchange Systems in Bovine Reproductive Tracts," 1998. The project was sponsored by Current Conceptions, Inc., Pullman, WA.

Christina M. Davis - BS, Animal Sciences, Washington State University, 2002.
Figures 15-4 through 15-8 were produced as part of a Washington State University Honors College Thesis entitled, "A Full-Color Photographic Description of Postpartum Uterine Involution in the Dairy Cow," 2002. The project was sponsored by Current Conceptions, Inc., Pullman, WA.

Melinda Fernyhough - BS, Animal Sciences, Washington State University, 2000. Assisted with legend layout/design.

Brian R. Voortman - BS, Animal Sciences, Washington State University, 1998. DVM, Washington State University 2002. Assisted in the preparation of placental specimens and vascular casting.

The following individuals provided valuable technical assistance.

S.R. Fenimore - Radiology Technician, College of Veterinary Medicine, Washington State University
J.M. Hobbs - Clinical Lab Technician, Washington Animal Disease and Diagnostic Laboratory
P.L. Johnson - Instructional Lab Supervisor, College of Veterinary Medicine, Washington State University
F.M. Mellieon - Preliminary organization / layout
V.L. Mitzimberg - Technician Supervisor, College of Veterinary Medicine, Washington State University
T.R. Olson - Scientific Instructional Technician, College of Veterinary Medicine, Washington State University
L.M. Robinson - Scientific Instructional Technician, College of Veterinary Medicine, Washington State University
B.A. Toms - Project Manager, Cadmus Professional Communications

Table of Contents

CHAPTER 1

Introduction to REPRODUCTION

Take Home Message

Reproduction is a sequence of events beginning with development of the reproductive system in the embryo. After the animal is born, it must grow and achieve puberty by acquiring the ability to produce fertile gametes. This ability must be accompanied by reproductive behavior and copulation. After copulation, the sperm and egg meet, fertilization occurs and development of the preattachment embryo follows. The conceptus attaches to the uterus by a specialized organ called the placenta. It allows the conceptus to grow and develop to term. The fully developed fetus is born and the female giving birth to it must lactate to provide nourishment for the neonate. During or after lactation the dam must reestablish cyclicity before she can become pregnant again. Knowledge and understanding of the reproductive process will become increasingly important as the human population continues to grow and resources become increasingly scarce.

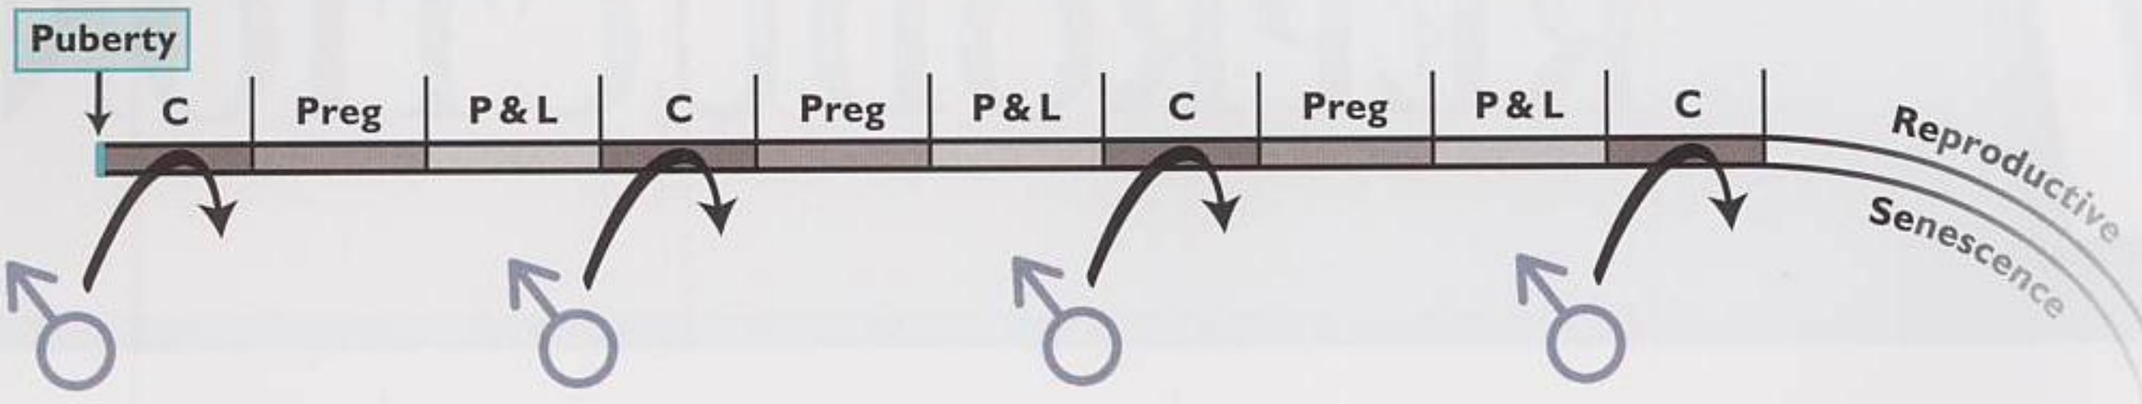
Welcome to the exciting and fascinating subject of reproductive physiology. Among the many scientific subjects in the natural sciences, knowledge about reproductive physiology commands interest even among those who have no scientific inclination at all. In its broadest sense, the subject of reproductive physiology carries with it interest, imagination, expectation, emotion and an intrinsic desire to know more. The average person on the street could care less about Boyle's Law, Beer's Law, the periodic table or the phylogenetic organization of plant and animal kingdoms. But, mention copulation, ejaculation, spermatozoa, pregnancy, the uterus, fertilization, embryo development or any of the myriad terms associated with reproduction and most people will be interested. Almost without exception, everyone wants to know more about the reproductive process, whether it relates to humans, food-producing animals, their pet or just for the sake of having more knowledge.

Reproductive Physiology Consists of Several Subspecialities

The field of reproductive physiology is a subspecialty of the physiology discipline. In its broadest context, reproductive physiology can be defined as the study of reproduction in animals regardless of species. In the field of Animal Sciences, reproductive physiology is a general term used to describe a field of study that deals primarily with reproduction in food-producing animals. The terms andrology, gynecology, theriogenology and obstetrics all imply a clinical application associated with reproductive function in humans and animals. **Andrology** is a branch of reproductive physiology that deals specifically with the study and treatment of male animals including humans. **Gynecology** is a branch of reproductive physiology and medicine that deals specifically with reproductive issues in women. **Theriogenology** is a branch of veterinary medicine that focuses on the reproductive system in animals. **Obstetrics** is a branch of reproductive physiology, veterinary medicine and/or human medicine that specializes in the female before, during and after parturition.

There is a wide breadth of opportunities in the field of reproductive physiology that range from animal production, clinical, educational and research applications. Also, pharmaceutical companies manufacture and market hundreds of hormones and drugs that manipulate reproductive functions in humans and animals. These corporations provide significant research, technology transfer and marketing opportunities for those with training in reproductive physiology.

Figure 1-1. Lifetime Sequence of Reproductive Events



After puberty, the female enters a period of cyclicity (C) in which repeated estrous or menstrual cycles occur. During the cycle, copulation between the male (♂) and female (♀) takes place. Copulation causes pregnancy (preg). At the end of gestation the female gives birth and enters the puerperium (P), a period of uterine and ovarian "recovery" and begins to lactate (L). These events are repeated throughout the female's lifetime until she enters reproductive senescence.

1

Successful reproduction is an orderly sequence of events. The major events of the reproductive process are **puberty**, **cyclicity**, **copulation**, **pregnancy** and **postpartum recovery/lactation**. Figure 1-1 illustrates the overall lifetime sequence of these reproductive events. As you can see from the figure, by far the majority of the "reproductive budget" is associated with the female.

Pathways to Pregnancy and Parturition is intended to help you develop a solid scientific understanding of the principles of reproduction in domestic animals. Further, it is intended to help you become fluent in the language of the subject matter. If you develop this fluency, you will enjoy a lifetime of understanding that will enable you to adapt successfully to new knowledge and technology that will affect reproduction in animals as well as humans.

As you use ***Pathways to Pregnancy and Parturition***, you will encounter a "**Sequence Map**" at the beginning of each chapter (See Figure 1-2). In the "sequence map," each major event is represented by a sphere positioned along the pathway. A sign, reading "**You Are Here**" lets you know exactly where the chapter you are about to read fits in the overall sequence of reproductive events. Each event in the "sequence map" has one or more chapters dedicated to it. These events are described briefly in the following pages.

As you read the chapters in this book you will encounter several features that are intended to make learning and understanding easy. The text of each chapter begins with a "**Take-Home Message**". This feature provides you with the main points of the chapter before you engage the details. The "Take-Home Message" should establish some questions in your mind that will then be answered later in the chapter. The "Take-Home Message" is also intended as a study guide, highlighting the main points of each chapter.

Fact Boxes are included throughout each chapter to give you a "quick read," to highlight important points, terms and/or sequences and to allow you to regroup your thoughts as you read the text.

Pathways to Pregnancy and Parturition includes the following aids to learning:

- ***sequence maps***
- ***take-home messages***
- ***fact boxes***
- ***bold type words***

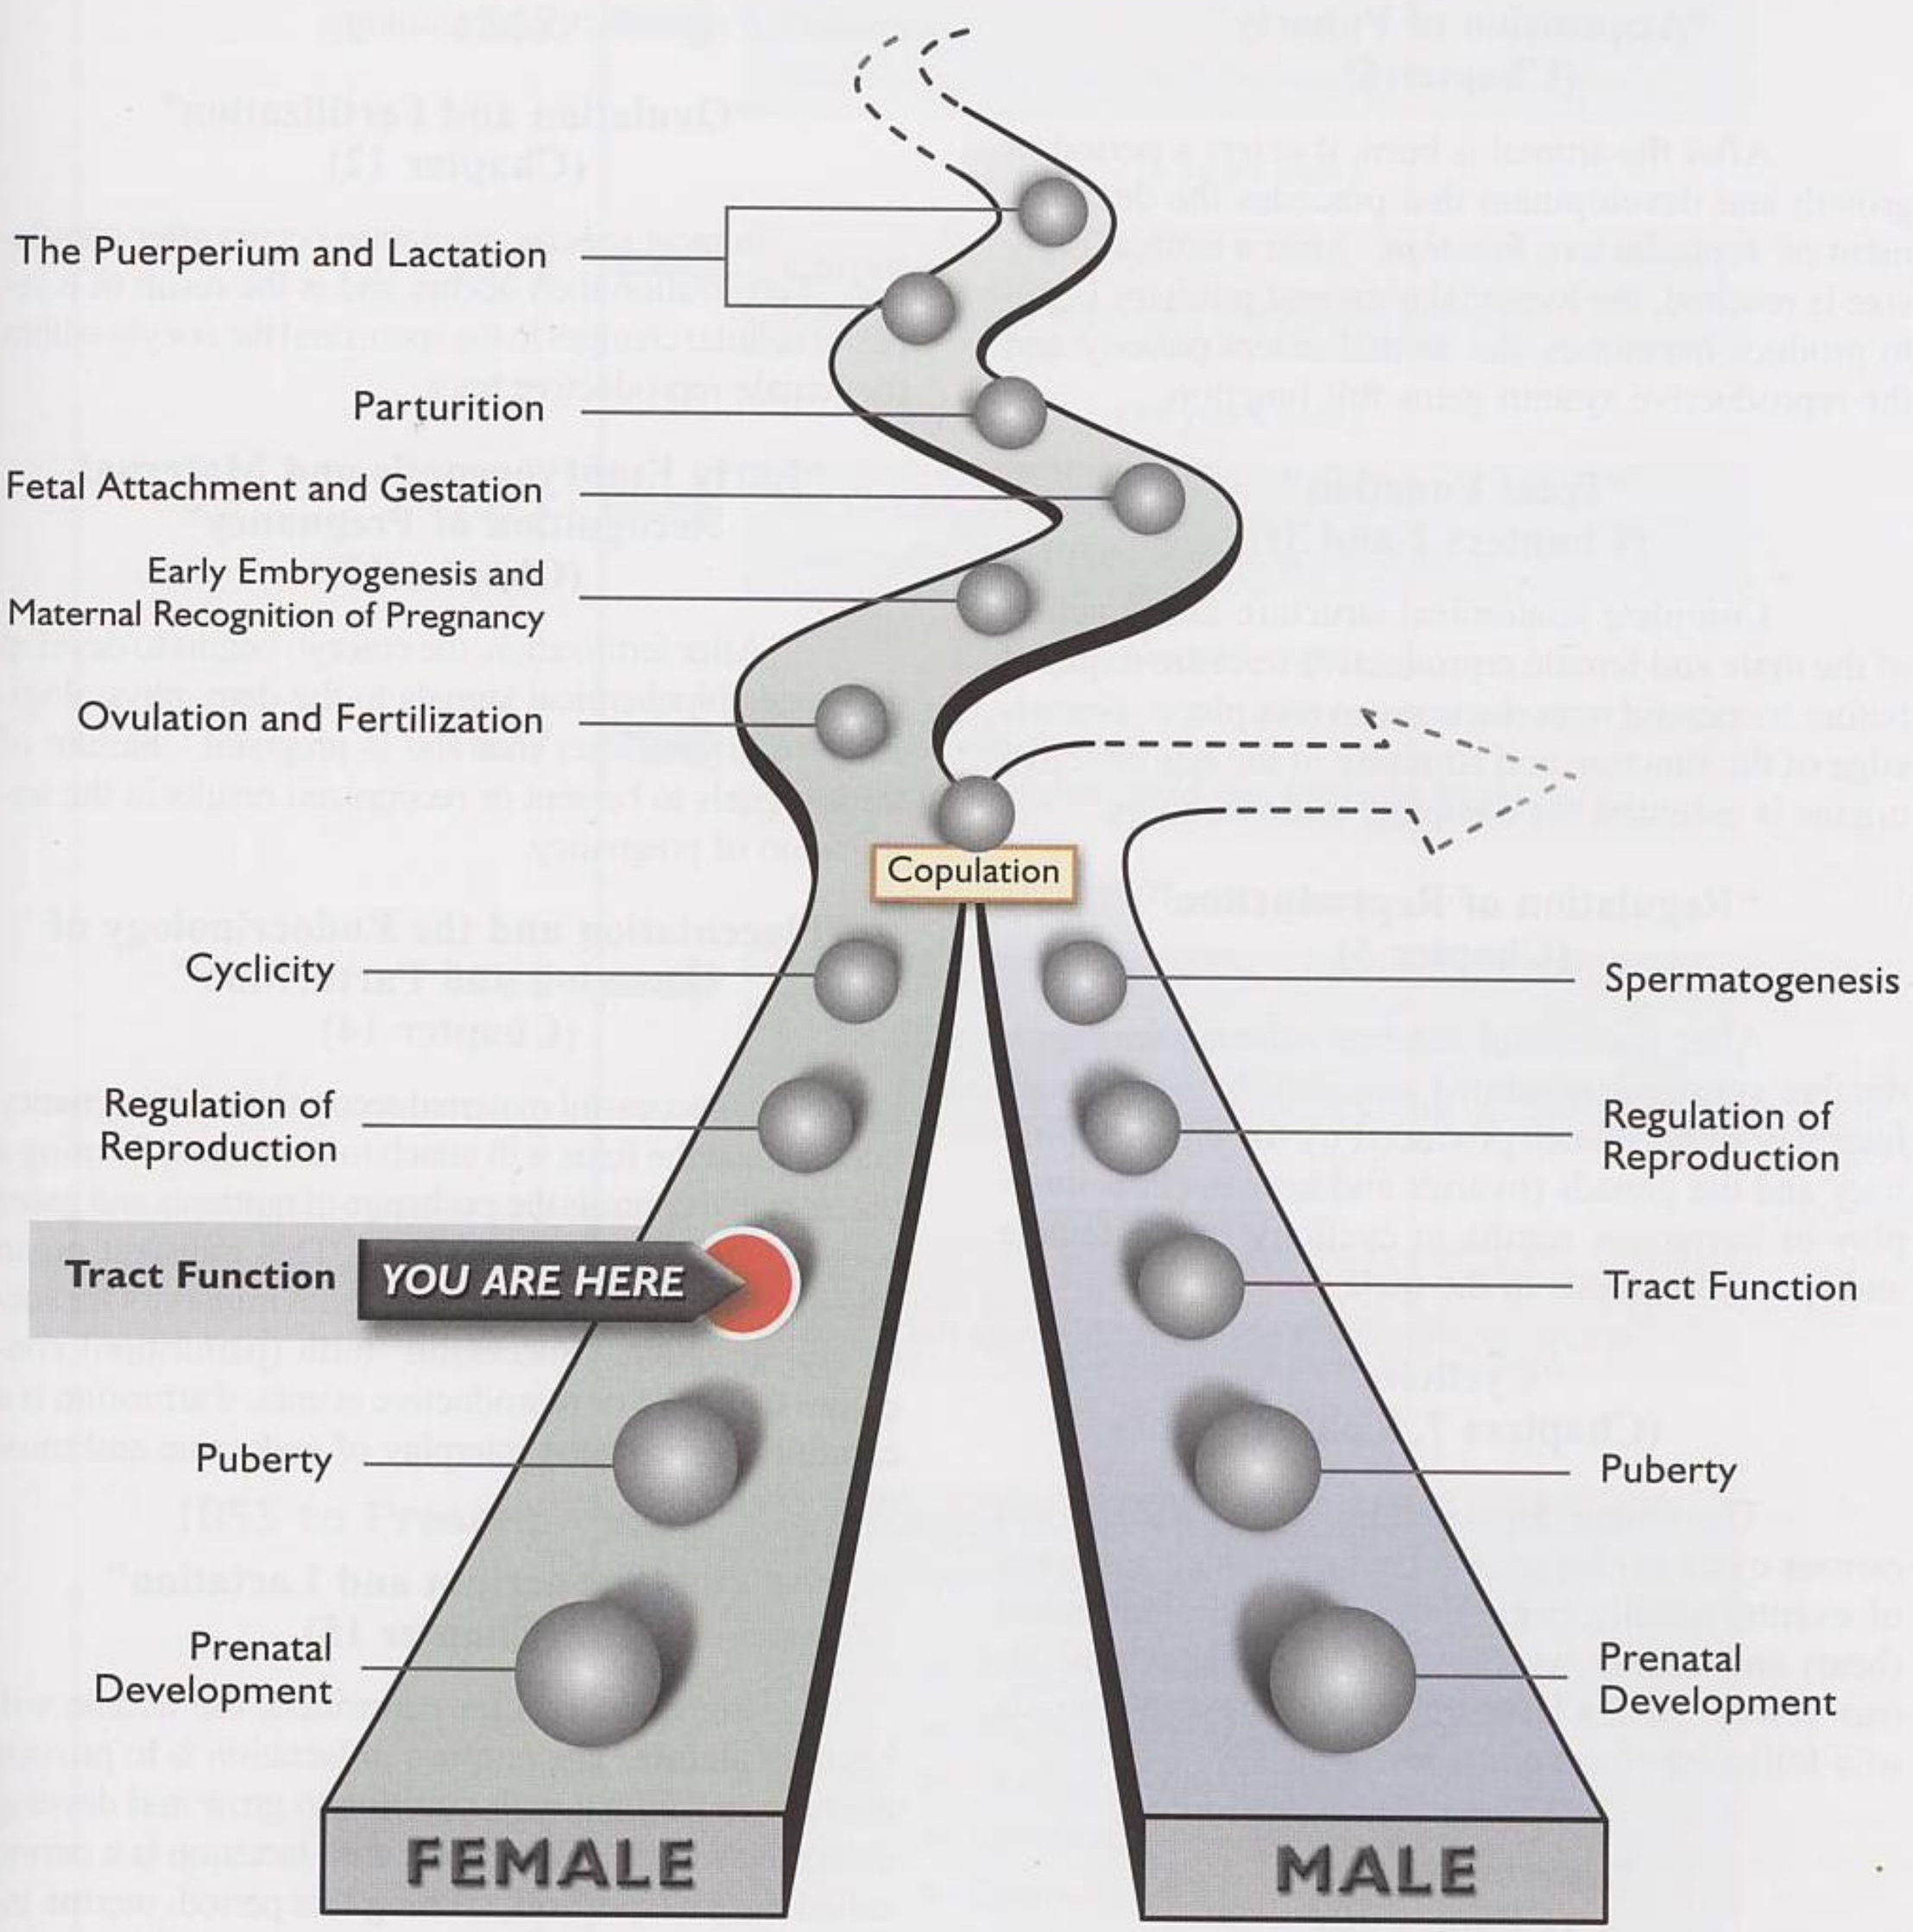
Many words and terms in this textbook are in **bold print**. They are important key words. You should understand them, know how to pronounce them, know how to spell them and be able to use them correctly in a discussion or in writing. In addition to the explanations appearing in the text, these terms are also defined in the glossary at the end of the book.

At the end of each chapter is a short section called "**Key References**". Important sources containing additional, in-depth information about the subject of the chapter are provided. In general, these are scientific review papers that will provide detail beyond what is presented in the chapter.

There are some remarkable reproductive phenomena throughout the animal kingdom. The section entitled "**Further Phenomena for Fertility**"(see **Key References**) is intended to present some of the interesting facts, observations and even myths relating to the topic of each chapter. This section will give species other than domestic animals a place to shine.

Figure 1-2. Sequence Map of Reproductive Events

The male and female have a common sequence of developmental events until after copulation. After copulation the female bears the responsibility for gestation, parturition, lactation and post-partum uterine repair. The arrow on the male pathway indicates his departure from the sequence after copulation. The sign "**You are here**" indicates where the chapter you are about to read fits in the sequence of reproductive events.



"Prenatal Development" (Chapter 4)

Sex of the embryo is determined at the time of fertilization. However, the development of a male or a female reproductive tract and the anterior and posterior pituitary occurs later, during development of the embryo.

1

"Acquisition of Puberty" (Chapter 6)

After the animal is born, it enters a period of growth and development that precedes the development of reproductive function. After a critical body size is reached, the hypothalamus and pituitary begin to produce hormones, the animal enters puberty and the reproductive system gains full function.

"Tract Function" (Chapters 2 and 3)

Complete anatomical structure and function of the male and female reproductive tract are required before successful reproduction can take place. Knowledge of the function and structure of the reproductive organs is essential for complete understanding.

"Regulation of Reproduction" (Chapter 5)

After the animal reaches puberty, the reproductive system is regulated precisely by an intricate interplay of hormones produced by the anterior pituitary and the gonads (ovaries and testes). This interplay of hormones results in cyclicity in the female and spermatogenesis in the male.

"Cyclicity" (Chapters 7, 8 and 9)

The female must exhibit estrous cycles. An estrous cycle is characterized as a repeated sequence of events, usually beginning with behavioral estrus (heat) and ending with a subsequent behavioral estrus several weeks later. The estrous cycle consists of a follicular phase and a luteal phase.

"Spermatogenesis" (Chapter 10)

After puberty, the male acquires the ability to produce large quantities of spermatozoa. These spermatozoa are produced on a continual basis in most males. Control of spermatogenesis is under the influence of pituitary hormones. Males are capable of producing between 1 and 25 billion spermatozoa per day.

"Reproductive Behavior and Copulation" (Chapter 11)

One of the characteristics associated with the acquisition of full reproductive potential is the display of reproductive behavior culminating in copulation and deposition of sperm into the female reproductive tract. The physiologic regulation of reproductive behavior is one of the most interesting, yet poorly understood components of reproductive physiology.

"Ovulation and Fertilization" (Chapter 12)

In most species, ovulation occurs after copulation. Fertilization then occurs and is the result of a series of cellular changes in the sperm and the oocyte within the female reproductive tract.

"Early Embryogenesis and Maternal Recognition of Pregnancy" (Chapter 13)

After fertilization, the embryo begins to develop and sends biochemical signals to the dam, physiologically "notifying" her that she is pregnant. Failure of these signals to be sent or recognized results in the termination of pregnancy.

"Placentation and the Endocrinology of Gestation and Parturition" (Chapter 14)

If successful maternal recognition of pregnancy occurs, then the fetus will attach to the uterus, forming a placenta that controls the exchange of nutrients and gases between the fetus and the dam. This transient organ (the placenta) also produces hormones important for successful gestation. Successful birth (parturition) concludes the series of reproductive events. Parturition is a carefully orchestrated interplay of endocrine and muscular events.

"The Puerperium and Lactation" (Chapter 15)

Immediately after parturition, the female will begin to **lactate**. The purpose of lactation is to provide the neonatal animal with nutrition to grow and develop until it is weaned. Coincident with lactation is a period called the **puerperium**. During this period, uterine involution occurs along with return to cyclicity. Involution of the uterus is a dramatic reduction in size of the uterus and repair of the endometrial epithelium. Generally, the postpartum female does not become pregnant a second time until uterine involution is complete. Factors that alter the rate of uterine involution impact reproductive performance.

Figure 1-3. The History of Reproductive Physiology

384 - 322 BC

Aristotle
Proposed that the fetus originates from menstrual blood

(1884 years later)

1562

Fallopius
Discovered and described the oviduct

(11 years later)

1573

Coiter
Discovered and described the corpus luteum

(99 years later)

1672

de Graaf
Discovered and described the antral follicle

(5 years later)

1677

van Leeuwenhoek
Discovered and described spermatozoa in semen

(103 years later)

1780

Spallanzani
Hypothesized that spermatozoa were the fertilizing agents and successfully artificially inseminated a dog

(45 years later)

1825

Dumas
Proved that spermatozoa were the fertilizing agents

(30 years later)

1855 to Present

Beginning of Modern Reproductive Physiology
(Below is in alphabetical order, not chronological order)

- *Artificial insemination*
- *Biochemical pregnancy detection*
- *Cloning*
- *Contraception*
- *Embryo culture/transfer*
- *Endocrinology*
- *Estrous synchronization*
- *Frozen semen*
- *In-vitro fertilization*
- *Sex selected semen and embryos*

The study of reproductive physiology started with Aristotle around 350 B.C. But, most of our knowledge has been generated during the past 100 years.

1

Now that you know the features of ***Pathways to Pregnancy and Parturition***, you should have some knowledge of the historical development of reproductive physiology and why reproduction is important. Aristotle provided the first recorded information on how he thought the reproductive system functioned in his book entitled ***Generation of Animals***. He believed that the fetus arose from menstrual blood. He had no way of observing spermatozoa in the ejaculate or the beginnings of embryo development. Therefore, he concluded, based on the observation that menstruation did not occur during pregnancy that the fetus was derived from menstrual blood. He also proposed that the conversion of menstrual blood to a fetus was initiated by seminal fluid deposited in the female during copulation. Aristotle also thought that semen was derived from all parts of the body and that the testes were simply pendular weights that kept the transport ducts (the ductus deferens) from becoming kinked or plugged with seminal fluid. Considering that Aristotle had no research tools whatsoever, his speculations were not totally unreasonable.

The next major observation in reproductive physiology, occurring almost 2,000 years later, was made by Fallopius, who described the oviducts. The name **Fallopian tube** reflects his discovery. A student of Fallopius, Coiter, discovered the **corpus luteum** in 1573. It wasn't until almost 100 years later that a scientist named Regnier de Graaf described the antral follicle that has been named the **Graafian follicle** in honor of his discovery. De Graaf killed female rabbits at half-hour intervals after they had copulated. He discovered that the number of "scar-like" wounds on the surface of the ovaries (we now know these to be ovulation sites) usually corresponded with the number of embryos in the uterus of the rabbit. However, de Graaf thought that the entire follicle was the egg.

A major technological breakthrough in the study of reproductive physiology was made by a Dutch scientist named van Leeuwenhoek, who developed a simple microscope. A medical student suggested to van Leeuwenhoek that semen might contain living cells. Using his microscope, van Leeuwenhoek observed semen and discovered that it contained small particles that moved about. He referred to these particles as "animalcules". While the first "animalcules" were observed in semen from a man afflicted with a venereal disease, van Leeuwenhoek found that similar "animalcules" were present in semen from males of many species and published a paper on his observations in 1677. The discovery that semen contained "animalcules" (spermatozoa) led to an outburst of speculation regarding their function. The most widely accepted speculation of the day was that the "animalcules" contained fully formed individuals within their cellular confines. In other words, the sperm head was thought to contain a microscopic, yet fully formed individual.

The father of modern artificial insemination was an Italian priest named Spallanzani. He showed that one drop of dog semen diluted with 25 pounds of fluid retained its ability to fertilize. Using the dog, he performed the first artificial insemination.

The fertilization process was not described until it was discovered that follicles contained ova and were precursors to the early embryo. A scientist named Dumas collected bodies about 1 mm in diameter from rabbit follicles. This discovery led Dumas to conclude that the "animalcules," now called spermatozoa, were responsible for uniting with the ovum and producing an embryo. Using rabbits, he demonstrated in 1825 that spermatozoa were the fertilizing agents. This early description of fertilization marked the beginning of modern reproductive physiology. Over 2,000 years elapsed from the original conjectures of Aristotle until it was understood that spermatozoa from the male were required to fertilize ova from the female. The major historical events leading to development of the modern discipline of reproductive physiology are presented in Figure 1-3.

The era of modern reproductive physiology that followed can be characterized as an "explosion of knowledge." While it is common knowledge today, recognition that the gonads produce steroid hormones that alter the function of the reproductive tissues and that the anterior pituitary controls the function of the gonads were major milestones of discovery. The understanding that females experience reproductive cyclicity and that they ovulate with predictable frequency continued the explosion of knowledge. Development of the radioimmunoassay for the measurement of hormones enabled the precise description of hormonal profiles in both the male and female. These discoveries opened the door for the development of methods for artificial manipulation of reproductive processes. In the 1940's and 1950's, understanding spermatozoal physiology and how these cells

function in test-tube environments led to successful artificial insemination in several species. It wasn't until the 1960's that it was understood that prostaglandin F_{2a} regulated the length of the estrous cycle in most mammalian females. The discovery that natural prostaglandin F_{2a} caused destruction of the corpus luteum made it possible to manipulate and alter estrous cycles and to control the time of ovulation. Such application is now commonplace in dairy and beef enterprises throughout the world.

Improvement in reproductive rate is a major goal in food animal production because a 3% increase would result in:

- ***1 million more beef calves/year***
- ***3.2 million more pigs/year***
- ***3.7 million more gallons of milk/year***

Once a certain fundamental level of understanding had been achieved, reproductive physiologists began to develop ways to perturb or to manipulate reproductive events within the animal. Such manipulations are a major goal in reproductive physiology research today. Techniques for enhancing reproduction are important when one considers that animal-derived food products are based on the ability of the species to reproduce. Small improvements in reproductive rate have profound positive effects on overall efficiency of production. For example, litter size in swine is an important characteristic that is a function of ovulation rate, fertilization rate and number of live pigs born. In dairy cows, failure to produce one calf every 13-14 months results in compromised milk production. Thus, the efficiency of milk production is reduced. In beef cattle, the reproducing cow is the fundamental production unit. Production of less than one calf per year reduces the efficiency of the beef herd. In sheep, the ability to give birth to twins and to nurse these individuals to weaning significantly improves production.

Any factor that improves reproductive performance even slightly has the potential of having a large impact on the efficiency of food animal production. For example, there are approximately 35 million beef cows in the American beef herd. If the overall reproductive rate could be improved by only 3%, an additional 1.05 million beef calves would be born in one year. In swine, a 3% increase in pigs weaned would translate into an increase of 3.2 million pigs per year in the national swine herd. In the American dairy herd, a 3% increase in pregnancy rate would translate into an additional 3.7 million gallons of milk per year. There will always be a need for managers of food animal enterprises, their veterinarians and related agribusiness service personnel to have a strong understanding of reproductive physiology, because proper application of new technology will require this knowledge.

The Global Population Crisis means that:

- ***in the time it takes you to read this sentence, 24 people will be added to the earth's population***
- ***within an hour, the number will reach 12,000***
- ***by day's end it will be 288,000***
- ***before you go to bed two nights from now, the net growth in the human population will be enough to fill a city the size of San Francisco***

There will be an increasing demand in the future for the development of new techniques to limit rather than enhance reproductive function. The human population must be controlled so that overpopulation does not erode worldwide resources and quality of life. Elimination of costly wastes associated with overpopulation of pets must be accomplished. In addition, methods to control the population growth of vermin and insects through reproductive manipulation will be needed as environmental concerns preclude the use of chemical control. The above needs will become more urgent with time. Therefore, there will be an increasing need for understanding the reproductive processes in more and more species.

The global challenge is to:

- ***decrease the rate of human population growth***
- ***increase reproduction efficiency in food-producing animals***
- ***educate the public about the importance of managing reproductive function in all species***

In addition to basic scientific understanding, better educational techniques must be developed to disseminate knowledge regarding reproductive processes so that individuals without specialized training can appreciate and apply techniques that will improve the quality of life in both humans and animals. Basic knowledge and understanding are the prerequisites for the solution to any problem. It is the intent of this book to provide this basic knowledge about reproductive physiology so that current and future problems in the field can be solved.

Key References

The "Further Phenomena For Fertility" section at the end of each chapter contains a variety of information from widely scattered sources. The references below were the source for some of the information. They also contain many additional interesting concepts about reproduction in humans and a variety of other species.

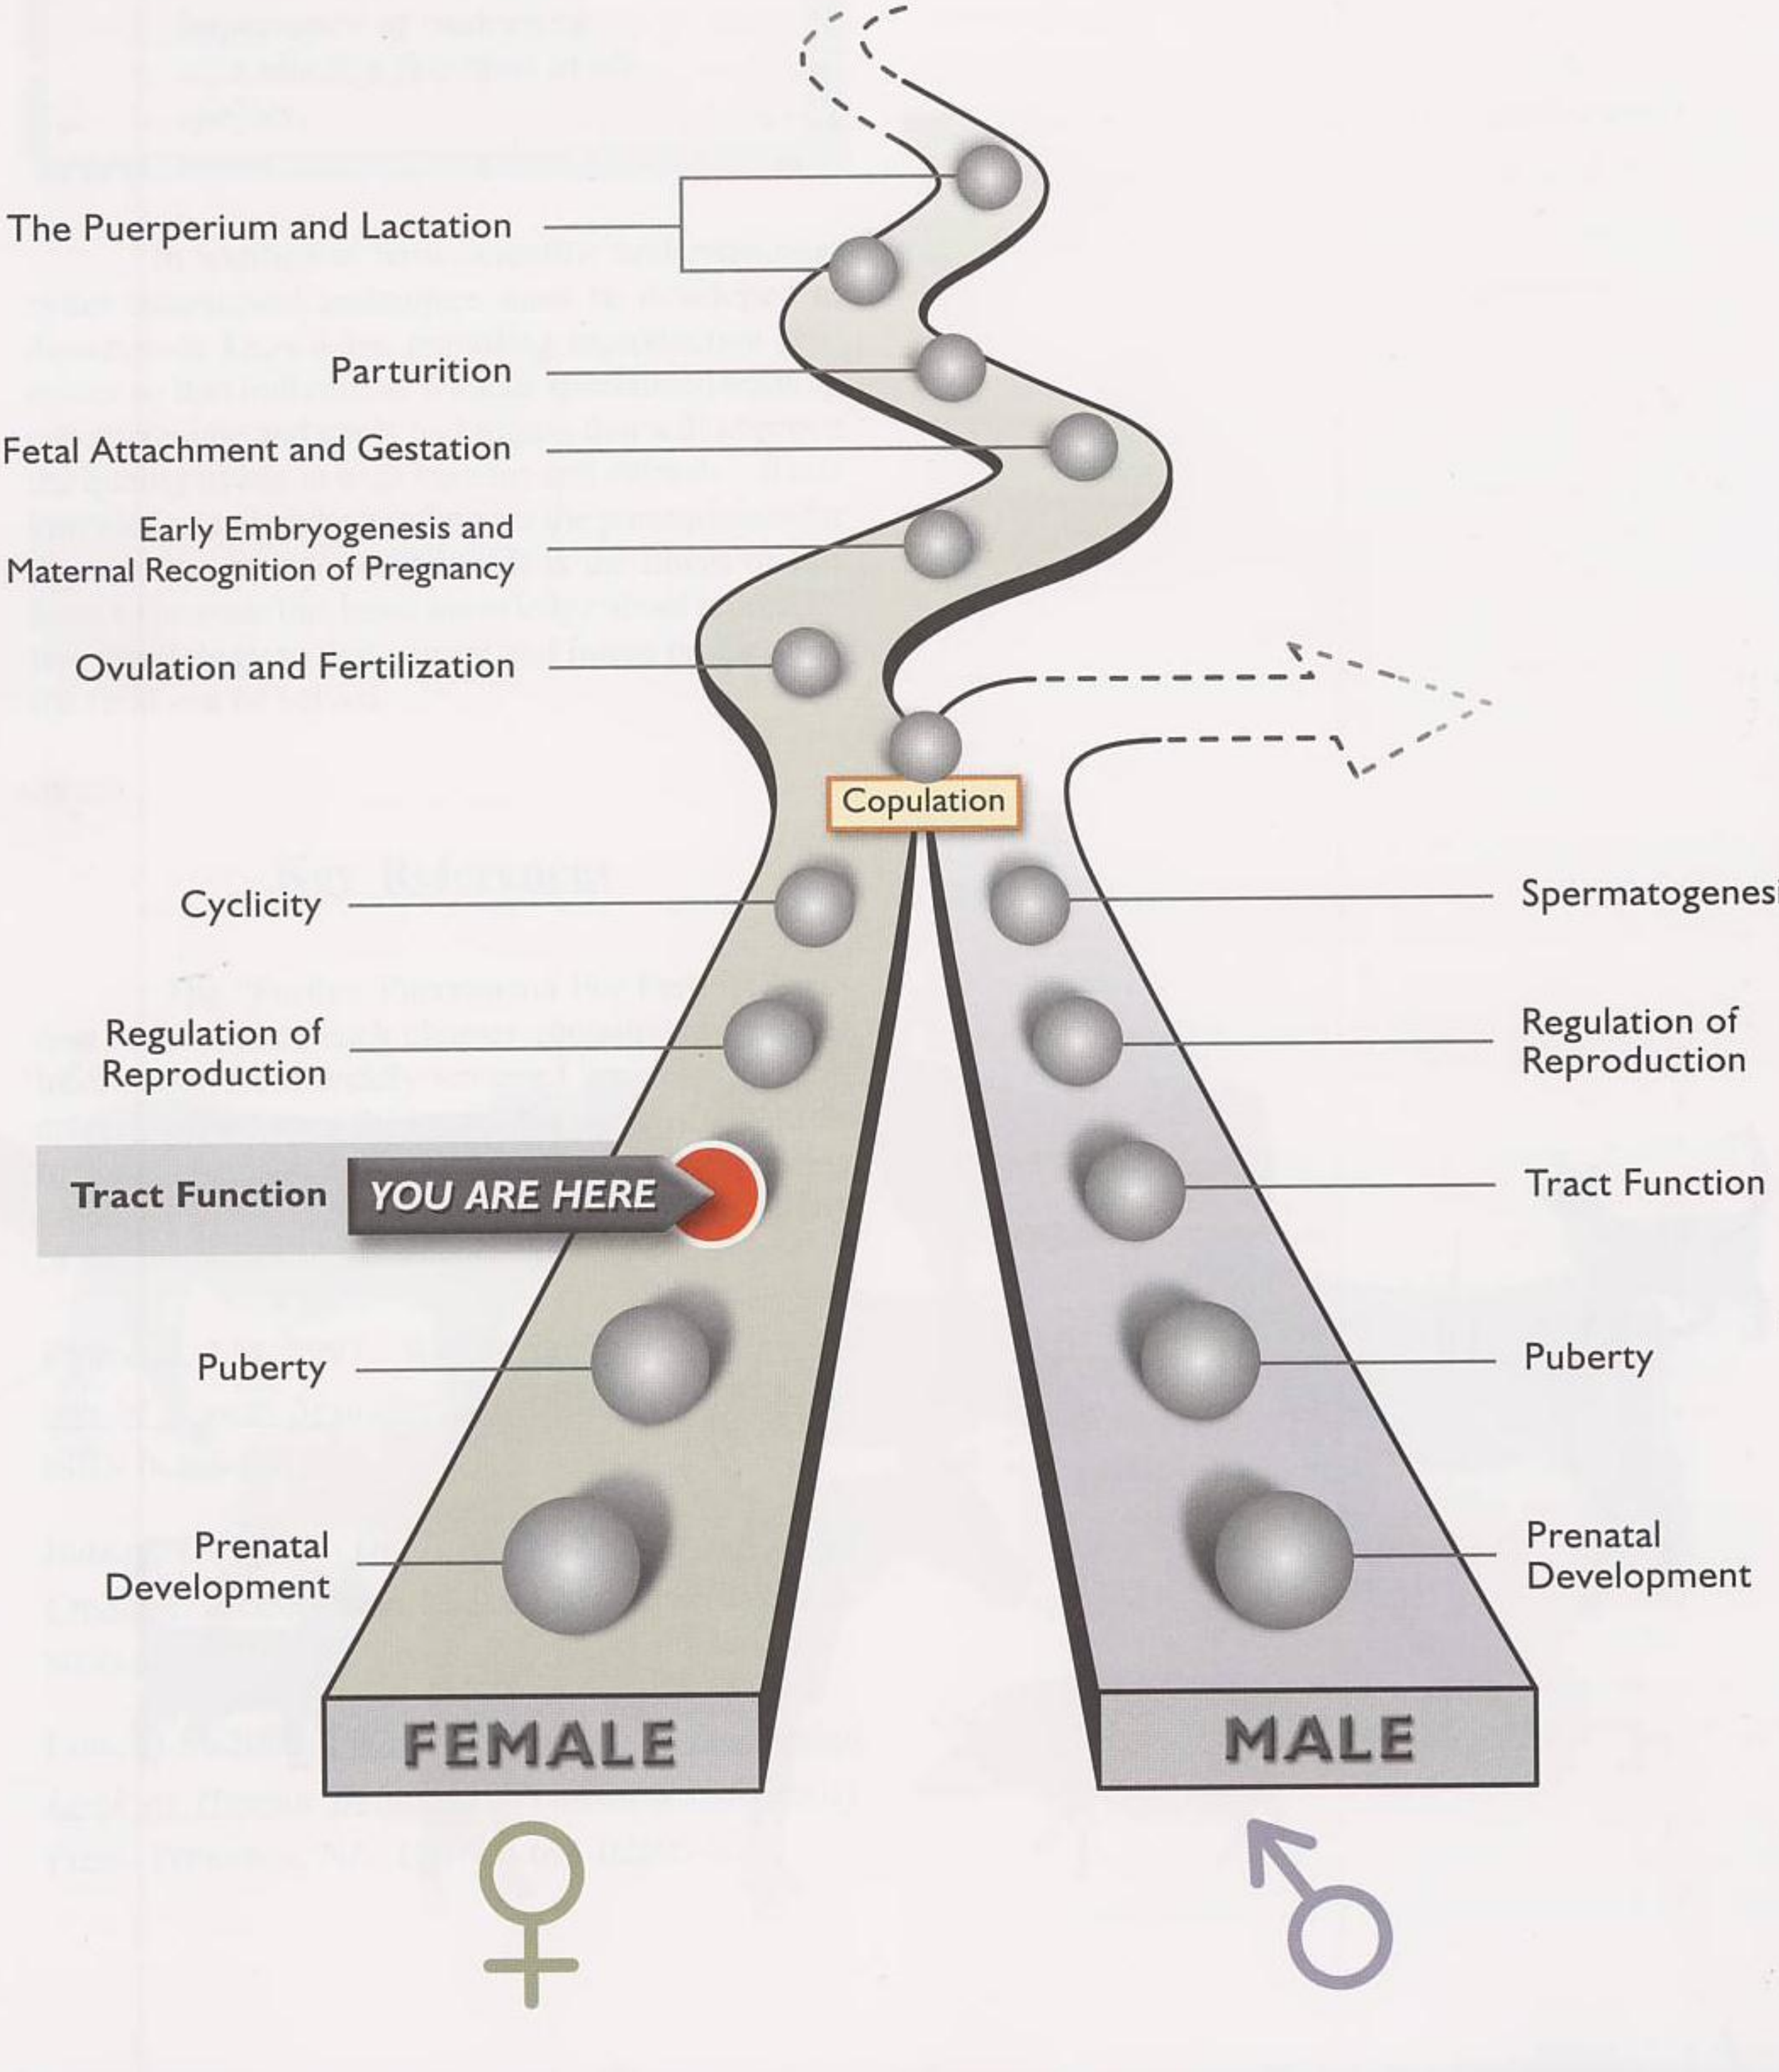
CHAPTER 2

The Organization and Function of the Female Reproductive Tract



Take Home Message

The female reproductive tract includes the ovaries, oviducts, uterus, cervix, vagina and the external genitalia. The ovaries produce gametes and a variety of hormones that act upon other parts of the reproductive tract. The oviducts provide the optimal environment for fertilization and preattachment development of the embryo. The uterus provides the environment for sperm transport, early embryogenesis and the site for attachment of the conceptus. The cervix is a barrier that secretes mucus during estrus and produces a cervical seal during pregnancy. The vagina is the copulatory organ and produces lubricating mucus during the time of estrus. Each tubular part of the tract has an outer serosal layer that is continuous with the peritoneum, a muscularis consisting of a longitudinal and circular layer of smooth muscle, a submucosal layer and a mucosal layer lining the lumen of each organ, that secretes substances vital to the function of each region.

The major structures of the female reproductive tract include the **ovaries** (the female gonads), **oviducts**, **uterus**, **cervix**, **vagina** and **external genitalia**. As you will see later in the chapter, each of these organs may be subdivided into components that represent specific anatomical regions. These components usually have specific names. In all domestic species, the reproductive tract lies directly beneath the rectum and is separated from it by the **rectogenital pouch** (See Figures 2-3, 2-4, 2-6 and 2-8). In the cow, mare, and camel this fortuitous anatomical relationship provides the opportunity for manual palpation (manipulation per rectum) and/or ultrasonic examination of the female reproductive tract to: 1) diagnose the ovarian status of the female; 2) diagnose pregnancy by determining the presence or absence of a fetus or of fetal membranes located within the uterus; 3) manipulate the tract for insertion of an artificial insemination syringe; 4) recover embryos using nonsurgical techniques and 5) identify reproductive tract abnormalities. The rectum of the ewe, bitch and queen is too small for the human arm/hand to be inserted and thus palpation per rectum cannot be performed in these females. In large gilts and sows, pregnancy can be ascertained by palpating the uterine artery after 40 or more days of gestation. Pregnant animals have a high degree of arterial tone and fremitus (vibration).

The female tract is a series of tubes. Each tube is organized in concentric layers called the:

- ***serosa (outer)***
- ***muscularis***
- ***submucosa***
- ***mucosa (inner)***

In its simplest form, the female reproductive tract can be considered as a series of interconnected tubes. Each of these tubes has distinct anatomical features. Thus, each tubular component can be identified easily. The tubular components of the female tract are the oviducts, uterus, cervix and vagina. Each component of the reproductive tract is characterized by having four distinct concentric layers. If you were to observe a cross-section of any one of the tubular components of the female reproductive tract you would see that the cross-section is composed of similar layers across all regions of the tract. These components are the **serosa**, **muscularis**, **submucosa** and **mucosa** (See Figure 2-1). The outer **serosal** coating is a single-cell layer of squamous (flattened) cells that simply cover the surface of the reproductive tract. The **muscularis** is usually a double layer of smooth muscle consisting of an outer longitudinal layer and an inner circular layer. The purpose of the muscularis is to provide the tubular components with the ability to contract. Such contractions are important for the transport of secretory products, gametes (spermatozoa and

ova) and early embryos to the appropriate location within the tract. The muscularis of the uterus is also important in expulsion of the fetus and fetal membranes during parturition.

Immediately beneath the muscularis is the **submucosa**. The submucosa is a layer of varying thickness (depending on the specific anatomical region of the tract). This region houses blood vessels, nerves and lymphatics. It also serves as a supporting tissue for the mucosal layer. The lumen in all the parts of the reproductive tract is lined with a secretory layer of epithelium known as the **mucosa**. Each part of the female reproductive tract is lined by a different type of mucosal epithelium. Each type of mucosal epithelium performs a different function depending on the region of the tract in which it is located. For example, the oviduct is lined with a mixture of ciliated and nonciliated simple columnar epithelium. The cells produce fluids and also move materials along the oviduct because of ciliary action (See Figure 2-12). The posterior vagina is lined with stratified squamous epithelium (See Figure 2-22) that provides the organ with protection during copulation.

The reproductive tract is surrounded by the peritoneum that is continuous with the broad ligament.

In the conceptus, the reproductive tract develops in a **retroperitoneal** position (behind the peritoneum). The peritoneum is the connective tissue lining of the abdominal cavity and completely surrounds or covers the reproductive tract. During embryonic development the tract grows and begins to push against the peritoneum. As the tract continues to grow it becomes completely surrounded by the peritoneum. A portion of the peritoneum eventually fuses to form a double layered connective tissue sheet that supports and suspends the ovaries, oviduct, uterus, cervix and the anterior vagina (See Figure 2-2 and 2-3) This suspensory tissue is called the **broad ligament** and can be seen *in situ* (in its normal place or its place of origin) in Figure 2-3. It consists of several anatomical components that support the various organs of the female tract. The broad ligament houses the vascular supply, the lymphatic drainage and nerves.

Components of the broad ligament are the:

- ***mesovarium***
- ***mesosalpinx***
- ***mesometrium***

The anterior (**cranial**) portion of the broad ligament attaches to and supports the ovary. This component is called the **mesovarium**. The mesovarium houses the blood and lymphatic vessels and nerves that supply the ovary and forms the **hilus** (See Figure 2-11) of the ovary. An additional supportive ligament for the ovary is also present in most species. This ligament is the **utero-ovarian ligament** (See Figure 2-13) and, as the name implies, it attaches the ovary to the uterus. The utero-ovarian ligament is sometimes called the **proper ligament of the ovary** and is not actually part of the broad ligament.

The **oviduct (salpinx)** is surrounded and supported by a thin, serous part of the broad ligament known as the **mesosalpinx**. A serous membrane is a smooth transparent surface that either covers, lines, or attaches to an organ. This delicate subdivision of the broad ligament not only supports the oviducts but serves as a **bursa**-like pouch that surrounds the ovary. The mesosalpinx helps to orient the infundibulum so that ova released at ovulation have a high probability of being directed into the oviduct. The nature and orientation of the mesosalpinx and the infundibulum in the cow, ewe, mare, sow, bitch and queen can be observed in Figures 2-13 and 2-14. In the bitch, the mesosalpinx completely encloses the ovary forming a nearly complete ovarian bursa that hides the ovary from direct view (See Figure 2-14)

The **mesometrium** is the largest and most conspicuous part of the broad ligament. It supports the **uterine horns (cornua)** and the body of the uterus. The dorsal portion of the mesometrium is continuous with the dorsal peritoneum and thus the uterus literally "hangs" from the dorsal body wall (See Figures 2-2 and 2-3).

Figure 2-1. Typical Tubular Structure of the Female Tract

The lumen is lined with epithelium called mucosa, that is supported by the submucosa. Typically, the muscularis is composed of an inner layer of circular smooth muscle and an outer longitudinal layer of smooth muscle. The serosa is the connective tissue covering the tract.

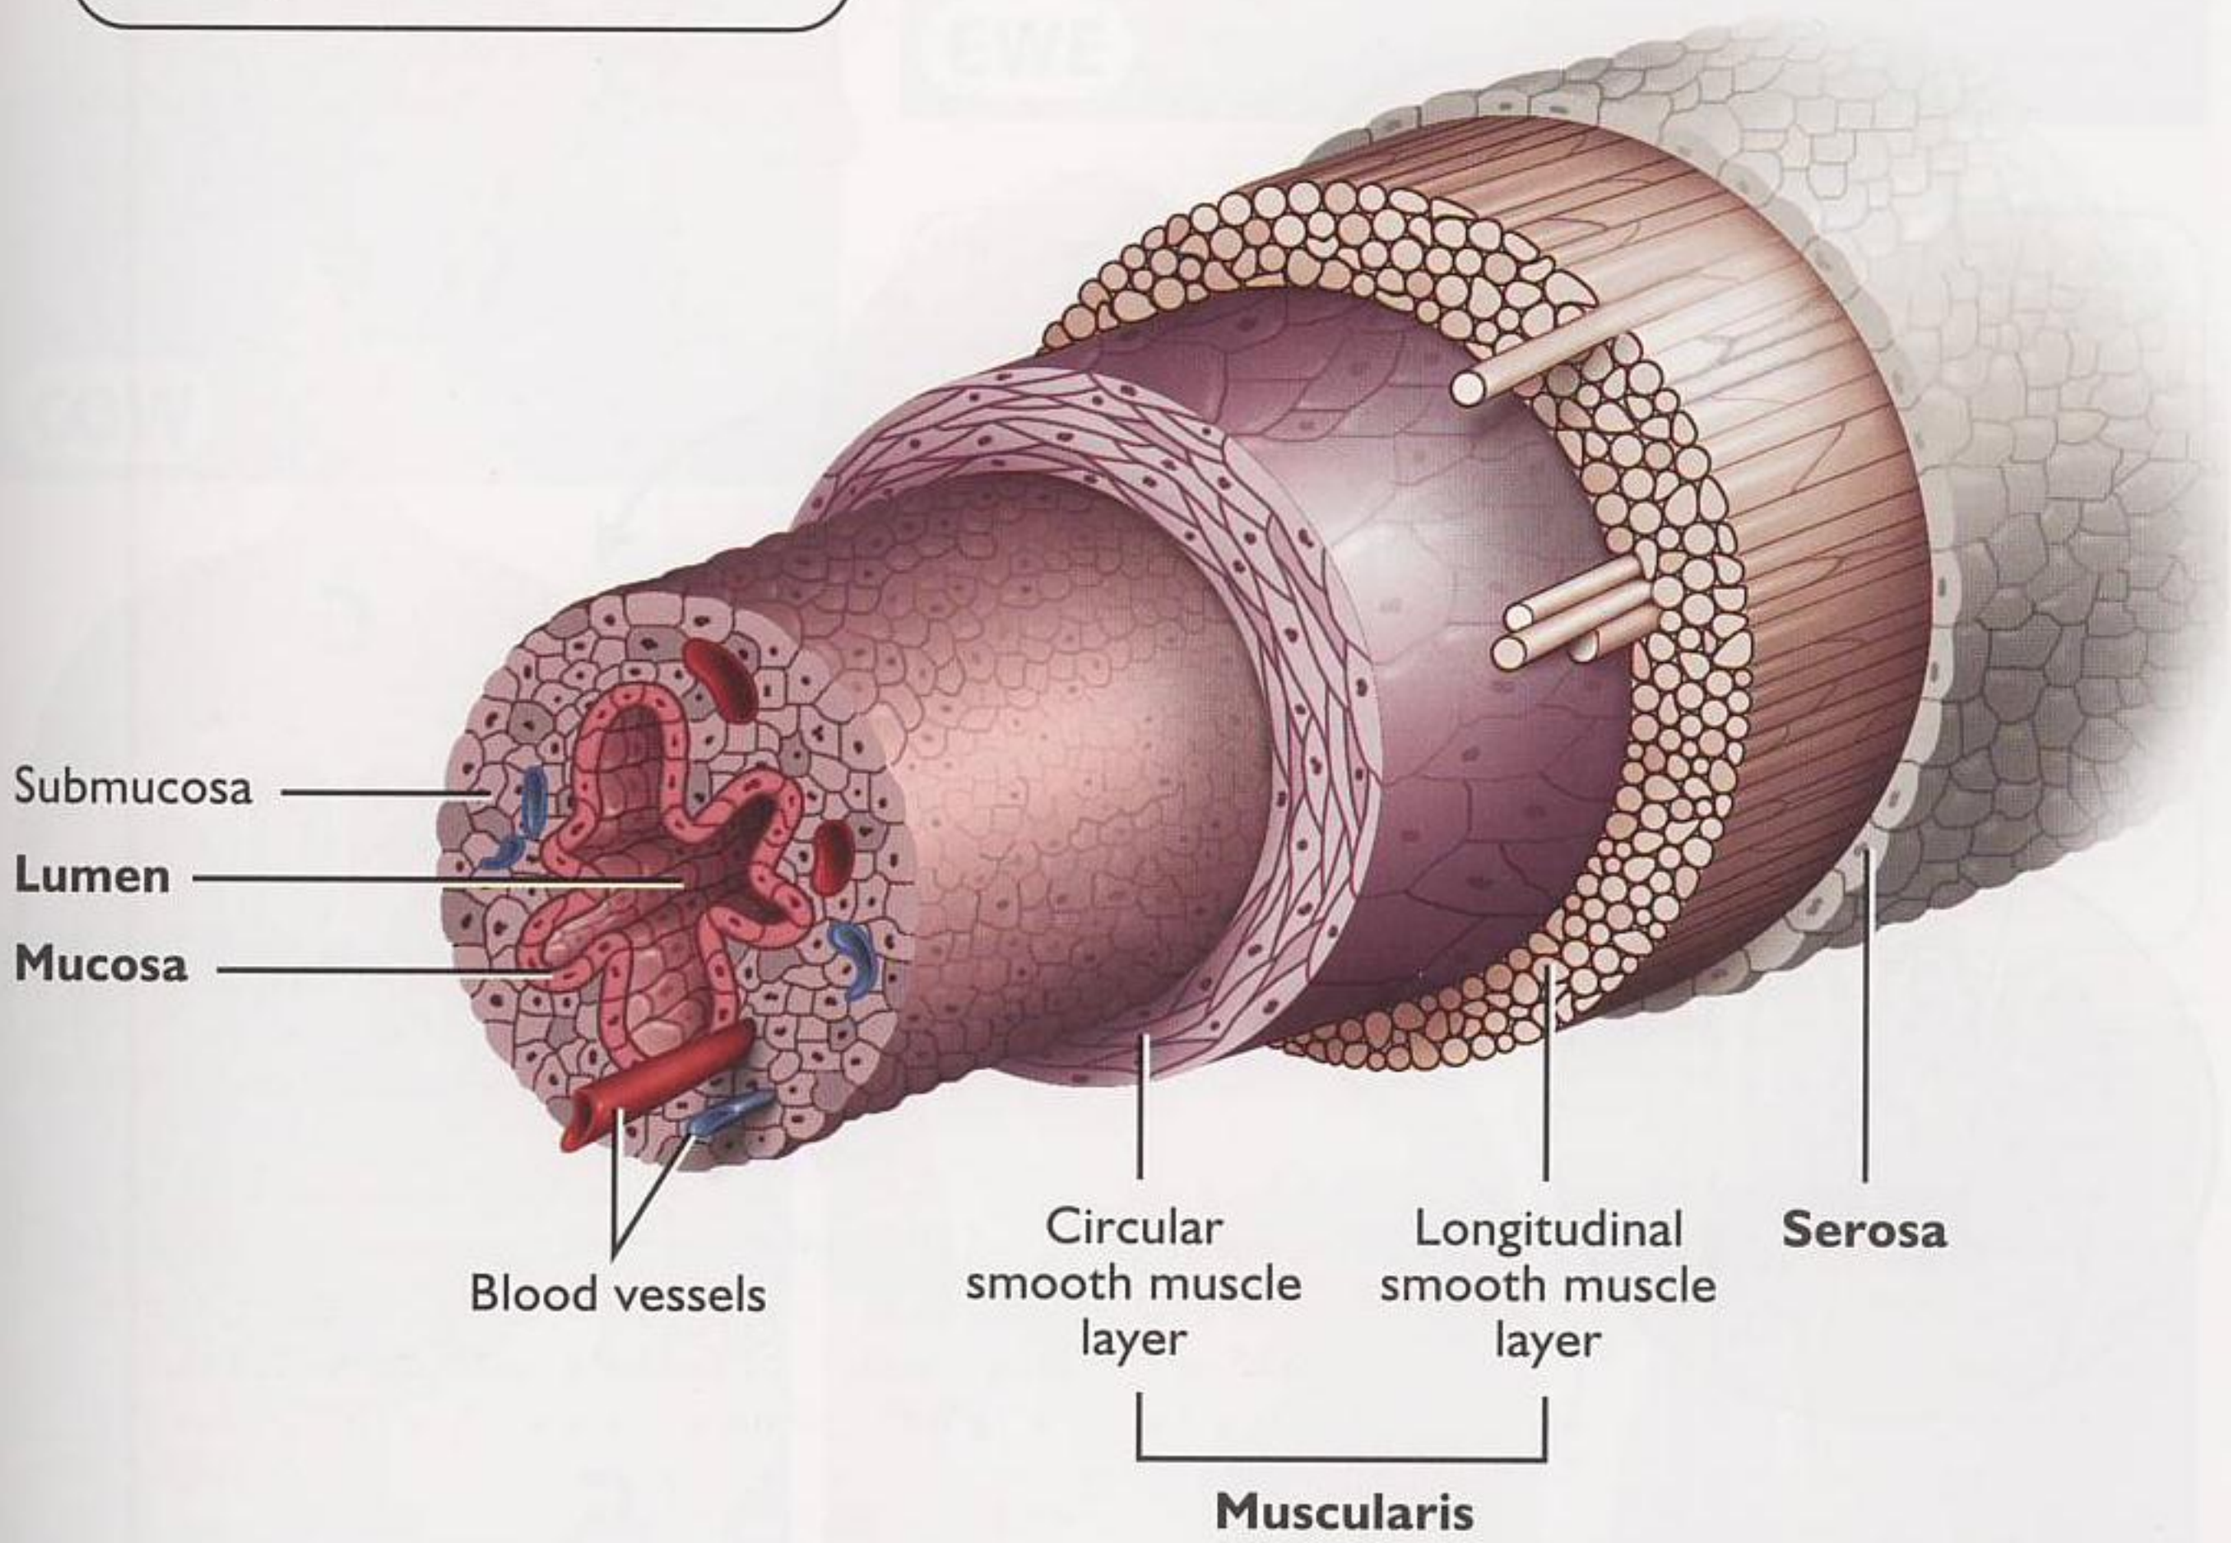


Figure 2-2. Embryonic Development of the Broad Ligament

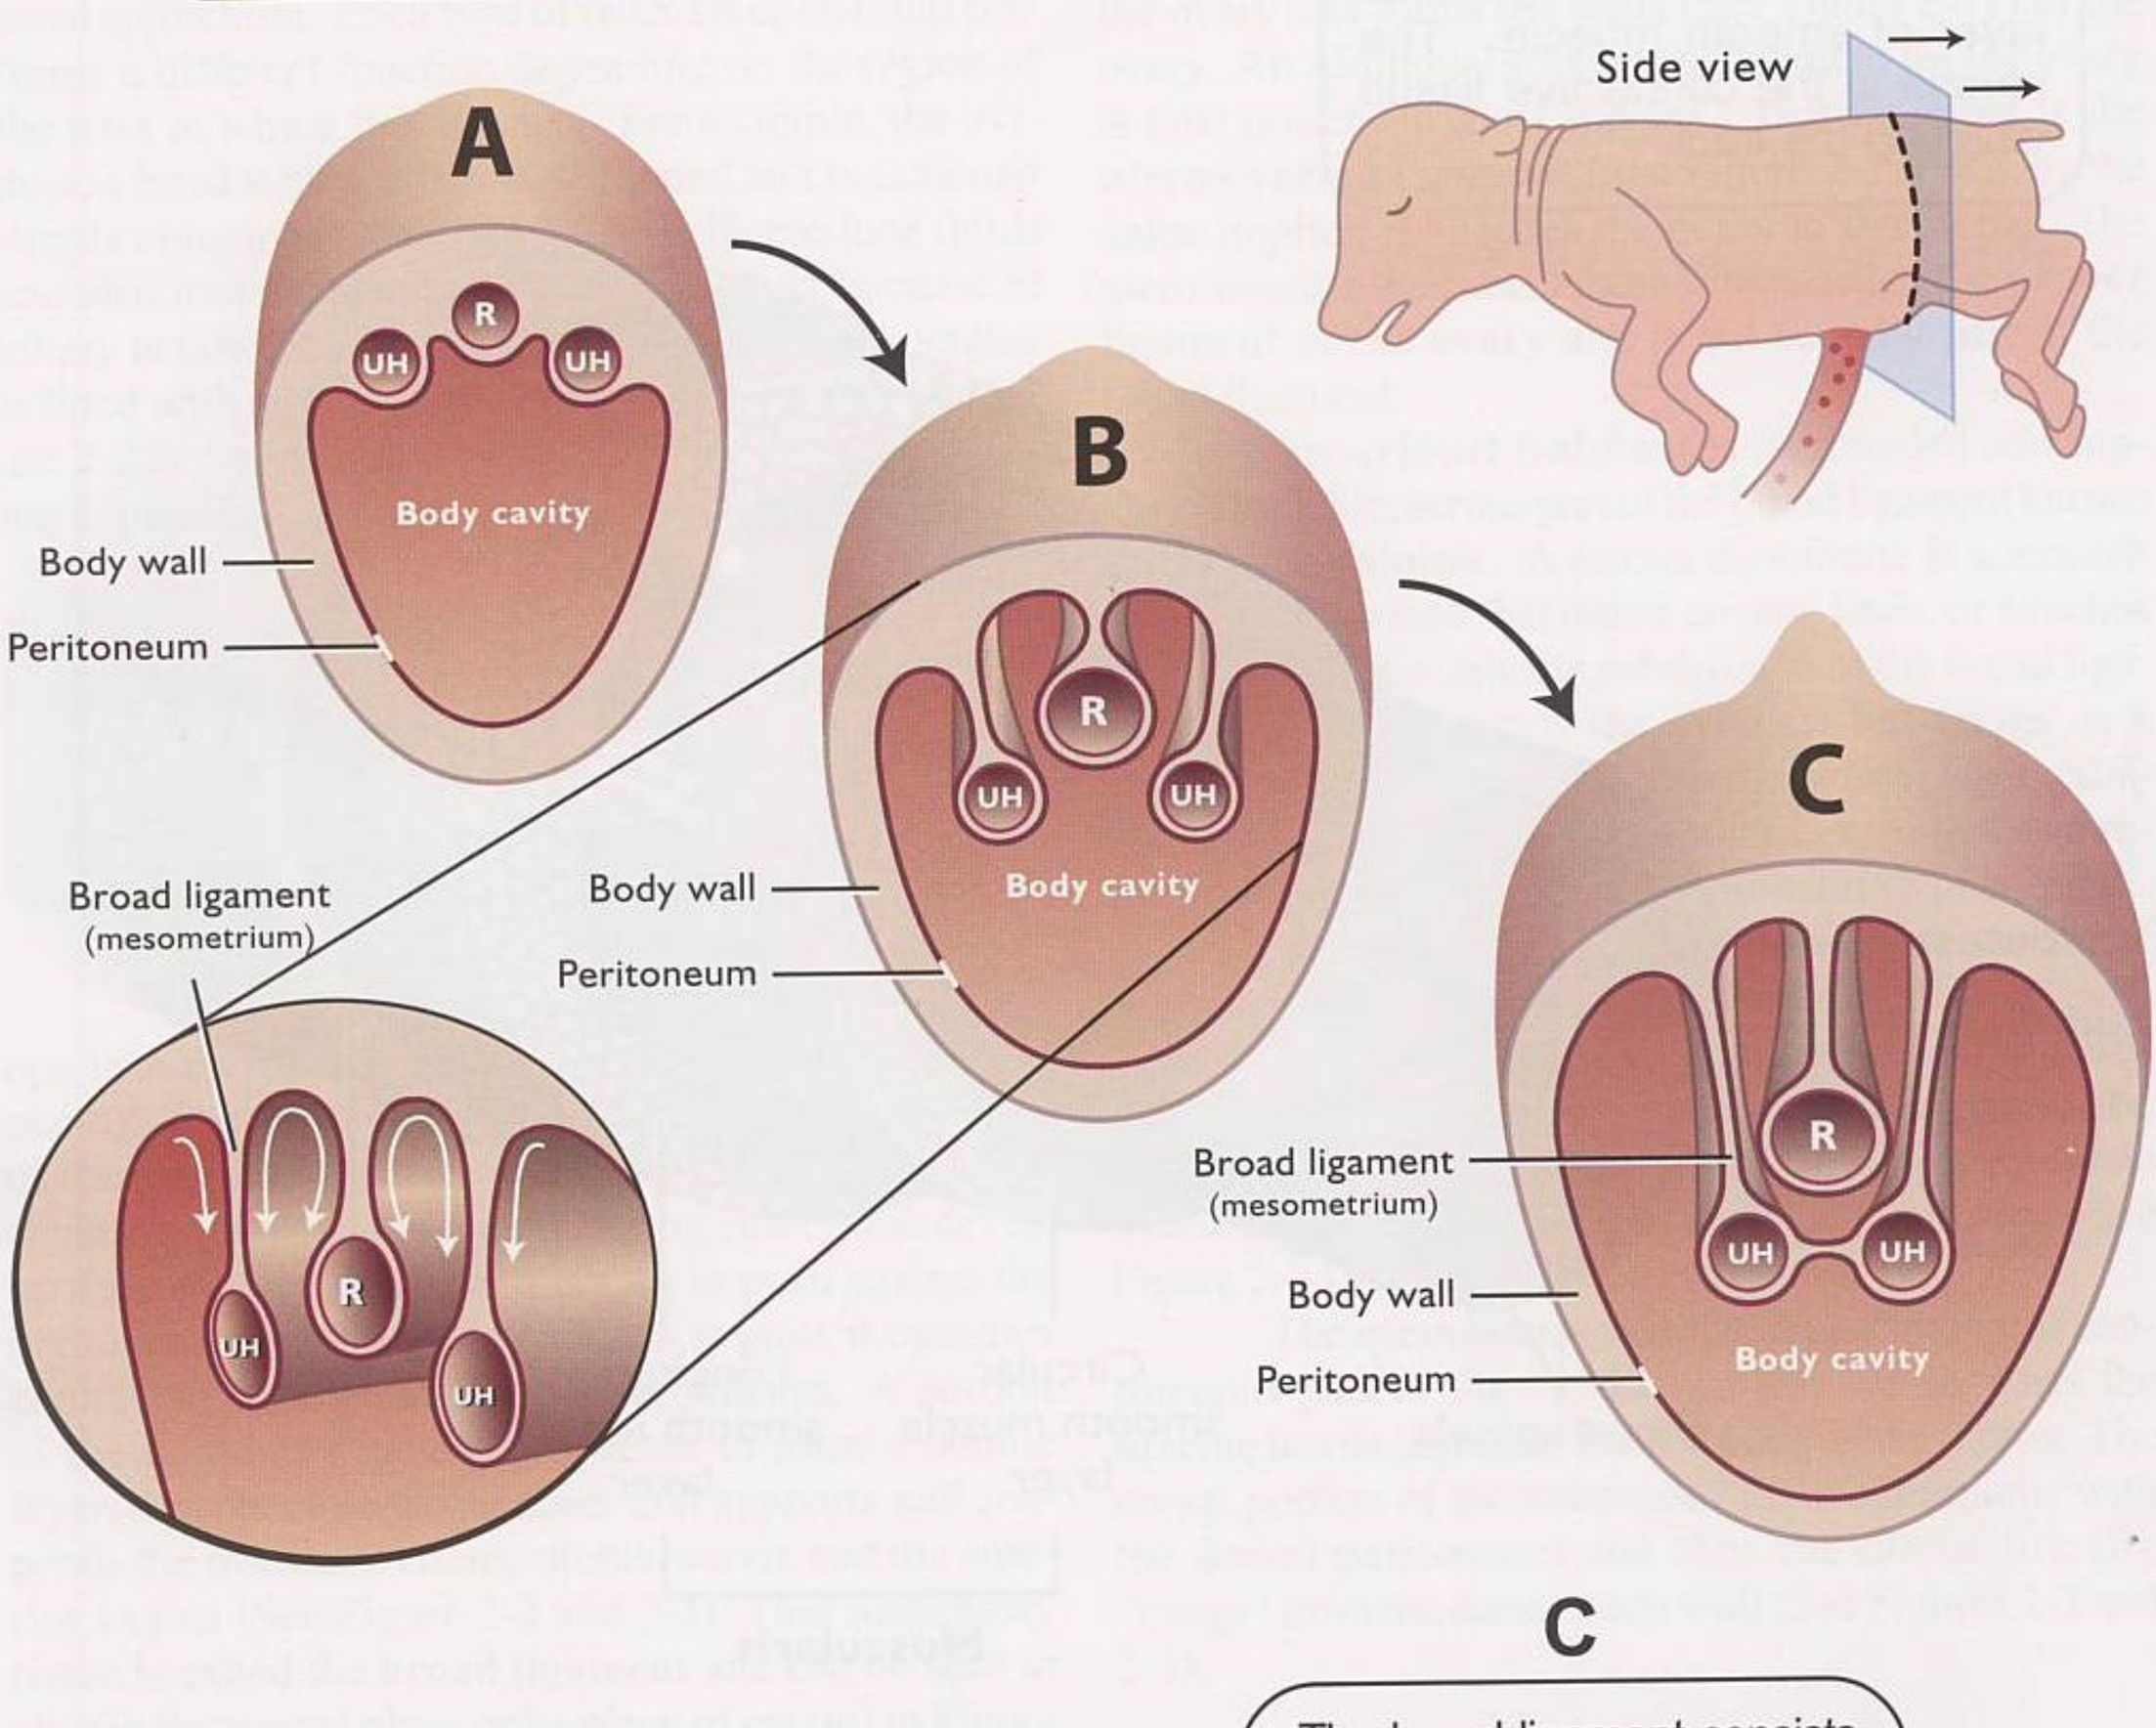
A

The uterine horns (UH) and the rectum (R) develop dorsal to the peritoneum. Development "behind" the peritoneum is called retroperitoneal.

B

As development advances, the uterine horn and rectum push into the body cavity (arrows in B) and eventually become completely surrounded by a layer of peritoneum (C).



C

The broad ligament consists of two layers of peritoneum that "sandwich" the tract between them. Each layer of peritoneum is continuous with the peritoneal lining of the body cavity.

Structures on the Ovary Undergo Constant Change

No other organ in the female body undergoes such a predictable and dramatic series of changes in such a short period of time as the ovary. For example, within a three to four week period ovulation occurs and antral **follicles** are transformed completely into a functional **corpus luteum** that produces progesterone. Later (2-3 weeks) the corpus luteum is destroyed, new follicles develop and produce large quantities of estrogen, ovulation occurs again and a complete ovarian cycle has occurred. This not only causes profound physiologic and behavioral changes in the female, but also causes profound morphologic changes in the ovary itself. These changes will be described in more detail in Chapters 7, 8, 9 and 11.

The **ovary** is an ovoid relatively dense structure, the primary functions of which are to produce female gametes (ova) and the hormones **estrogen** and **progesterone**. The corpus luteum also produces **oxytocin**, **relaxin**, **inhibin** and **activin**. Details about these hormones and their actions will be presented in subsequent chapters. In Figure 2-11, all of the ovarian structures of importance can be visualized. The ovary is composed of an outer connective tissue surface called the **tunica albuginea**. The tunica albuginea is covered by a single layer of cuboidal cells called the germinal epithelium. This layer has no function relating to production of the germinal cells and is thus erroneously named. Beneath the tunica albuginea is a zone referred to as the **ovarian cortex**. Generally (the mare is the exception), the ovarian cortex houses the population of oocytes. Cells surrounding oocytes will develop and produce follicles that will mature and eventually ovulate. The ovarian cortex also houses the functional **corpus luteum**, abbreviated **CL** (plural = **corpora lutea**), and the degenerating corpora lutea known as **corpora albicantia** (singular = corpus albicans). Corpora lutea ("yellow bodies") are relatively large, conspicuous structures that produce progesterone. Corpora albicantia can readily be observed on ovaries of most species. The word "albicans" is derived from the word "albino," that implies a white color. Corpora albicantia appear as white, scar-like structures and represent corpora lutea in various stages of degeneration from previous estrous cycles. Their white appearance is due to the increasing ratio of connective tissue (that appears white like a tendon) to secretory tissue. Thus, as the CL degenerates it undergoes a gradual color transition from an orange/yellow structure to a white scar-like structure. A good example of a corpus albicans can be seen in Figure 2-13 (sow).

The central part of the ovary is called the **ovarian medulla**. The medulla houses the vasculature, nerves and the lymphatics and is composed of relatively dense connective tissue.

Morphologically, the ovaries of the mare present several important exceptions to the information presented above. First, the ovarian medulla and cortex are reversed (cortex inside, medulla outside) when compared to other species. Second, ovulation occurs at only one location in the mare's ovary, while it occurs at random locations in the ovaries of the other mammals. Ovulation in the mare occurs in a specific anatomical location called the **ovulation fossa** (See Figure 2-13). Third, follicles can be palpated per rectum in the mare, but corpora lutea cannot. This is because corpora lutea do not protrude significantly from the ovarian surface but tend to penetrate into the ovarian tissue.

The ovaries of most females are relatively dense, turgid structures that can be distinguished tactilely from other tissues in the immediate anatomical vicinity in some species using palpation per rectum. By inserting the arm into the rectum (cow, mare, camel), the ovaries can be palpated by carefully manipulating the cranial portion of the tract. Determination of ovarian functional status can be made by identifying various structures (CL or follicles) on the ovaries. Utilization of an ultrasound probe inserted into the rectum allows detailed characteristics of ovarian structures in the cow and the mare to be observed. Recent use of this technology (See Chapter 8) has enabled a greater understanding of follicular growth patterns.

Within any region of the ovarian cortex, one can encounter several different types of **ovarian follicles** (See Figure 2-11). The various types of ovarian follicles represent different stages of follicular development and maturity. The process whereby immature follicles develop into more advanced follicles and become candidates for ovulation is referred to as **folliculogenesis** (See Chapter 8 for details).

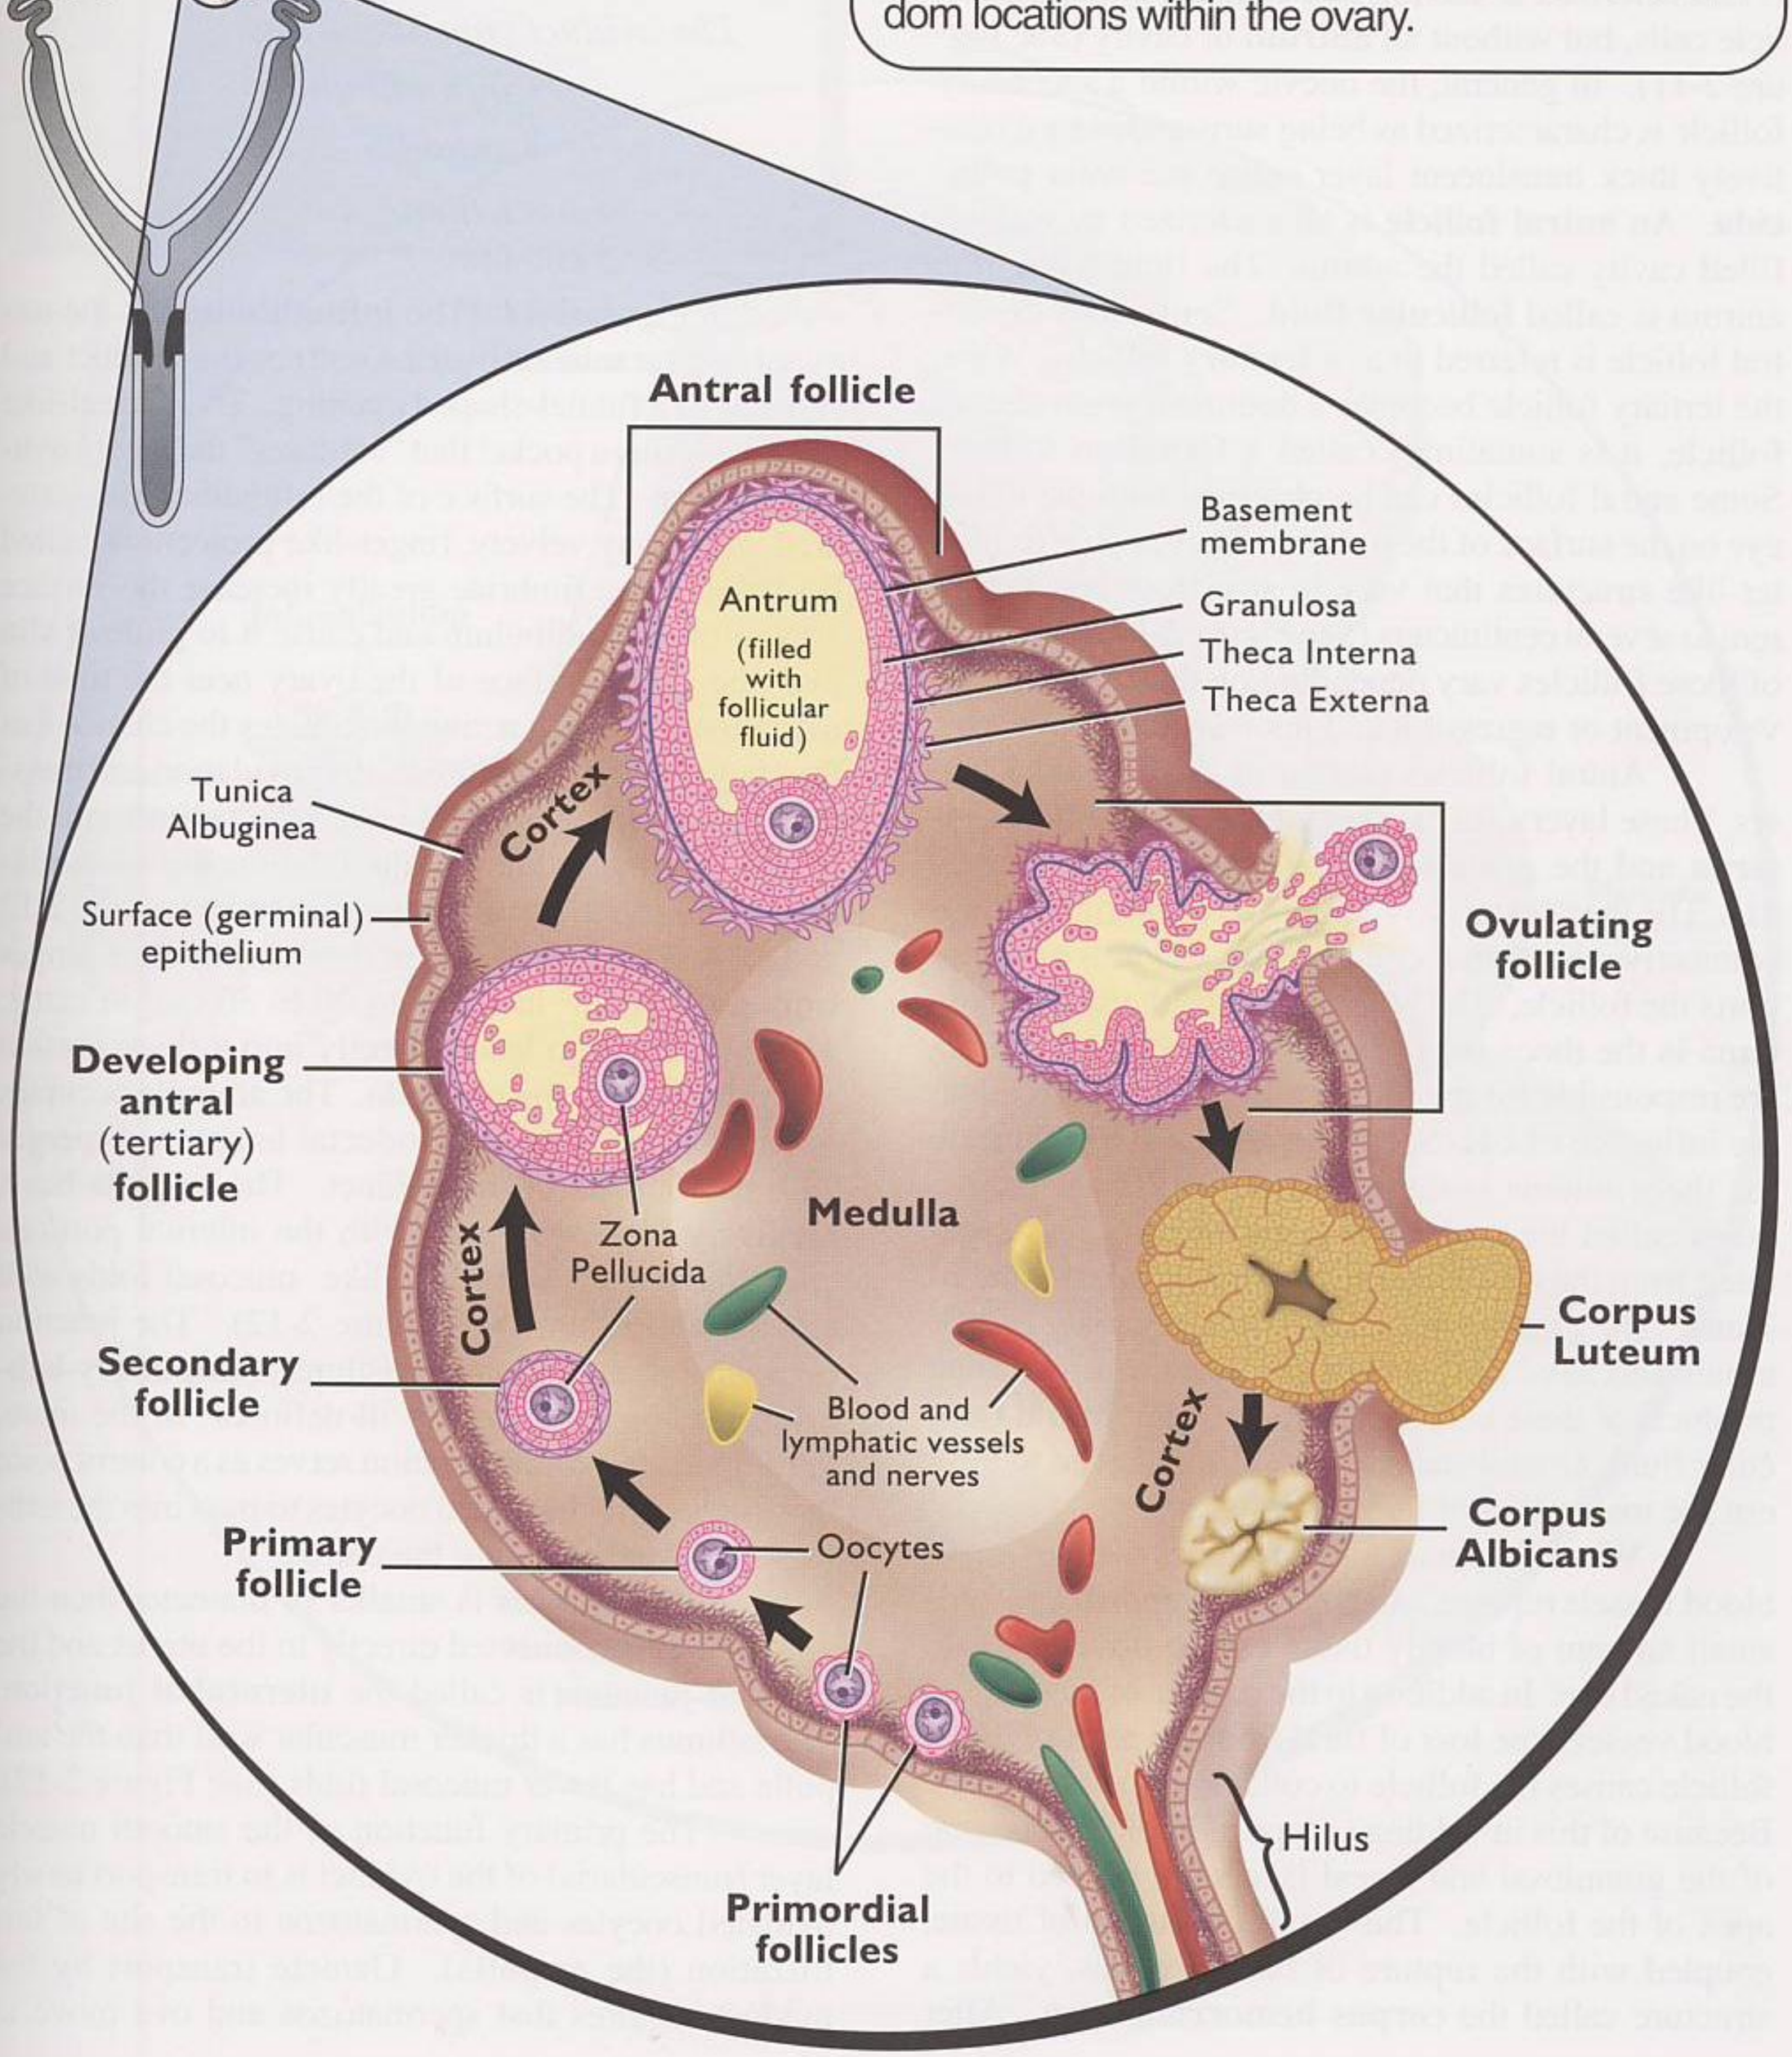
The primary ovarian structures are:

- *primary follicles*
- *secondary follicles*
- *antral follicles*
- *corpora lutea*
- *corpora albicantia*

There are four types of follicles present within the ovary. **Primordial follicles** that are microscopic, are the most immature and are the smallest encountered in the ovarian cortex. The oocyte (egg) within the primordial follicle is surrounded by a single layer of flattened (squamous) cells (See Figure 2-11). The

Figure 2-11. The Major Structures of the Ovary

In general, all types of follicles are present within the ovary at any point in time. However, developing and functional corpora lutea may or may not be present depending on the stage of the estrous cycle. With the exception of the mare, development (and regression) of all ovarian structures occurs at random locations within the ovary.



primordial follicle will develop into a slightly more advanced follicle called the **primary follicle**. The primary follicle is characterized by having an oocyte that is surrounded by a single layer of cuboidal (cube-like) epithelium or follicular cells (See Figure 2-11). Females are born with a lifetime's supply of primordial and primary follicles. Primary follicles do not divide into other primary follicles. Instead, they either develop into a more advanced secondary follicle or they degenerate. A **secondary follicle**, also microscopic, is characterized as having two or more layers of follicle cells, but without an **antrum** or cavity (See Figure 2-11). In general, the oocyte within a secondary follicle is characterized as being surrounded by a relatively thick translucent layer called the **zona pellucida**. An **antral follicle** is characterized by a fluid-filled cavity called the antrum. The fluid within the antrum is called **follicular fluid**. Sometimes the antral follicle is referred to as a **tertiary follicle**. When the tertiary follicle becomes a dominant preovulatory follicle, it is sometimes called a **Graafian follicle**. Some antral follicles can be observed with the naked eye on the surface of the ovaries. They appear as blister-like structures that vary in size from less than 1 mm to several centimeters (See Figure 2-13). The sizes of these follicles vary depending on their stage of development or regression and upon species.

Antral follicles consist of three distinct layers. These layers are the **theca externa,** the **theca interna** and the **granulosal cell layer** (See Figure 2-11). The theca externa is composed primarily of loose connective tissue that completely surrounds and supports the follicle. The layer just beneath the theca externa is the theca interna. Cells of the theca interna are responsible for the production of androgens under the influence of LH (See Chapters 5 and 8). Beneath the theca interna is the granulosal cell layer (sometimes called the **membrana granulosa**). It is separated from the theca interna by a thin basement membrane. The granulosal cells produce a variety of materials and have FSH receptors. The most important products of these cells are estrogen, inhibin and follicular fluid. Granulosal cells are also believed to govern the maturation of the oocyte.

When dominant antral follicles ovulate, small blood vessels rupture, causing local hemorrhage. This small amount of bloody tissue can be observed with the naked eye. In addition to the rupture of these small blood vessels, the loss of fluid from the antrum of the follicle causes the follicle to collapse into many folds. Because of this in-folding (a type of implosion), some of the granulosal and thecal layers are pushed to the apex of the follicle. This small protrusion of tissue, coupled with the rupture of blood vessels, yields a structure called the **corpus hemorrhagicum**. After the formation of the corpus hemorrhagicum ("bloody body"), the cells of the theca interna and the granulosal cells differentiate into luteal cells to form a corpus luteum. A detailed, full-color photographic presentation of corpora lutea formation as it relates to progesterone production during the estrous cycle is presented in Chapter 9. The corpus luteum produces progesterone and is essential for the maintenance of pregnancy.

A schematic illustration of the oviduct is presented in Figure 2-12. The **infundibulum** is the terminal end (cranial or ovarian end) of the oviduct and consists of a funnel-shaped opening. This funnel-like opening forms a pocket that "captures" the newly ovulated oocyte. The surface of the infundibulum is covered with many velvety, finger-like projections called **fimbriae**. The fimbriae greatly increase the surface area of the infundibulum and cause it to glide or slip over the entire surface of the ovary near the time of ovulation. Such an action maximizes the chance that the oocyte will be "captured" after ovulation and transported through an opening called the **ostium** into the ampulla of the oviduct. The relationship of the infundibulum to the ovary is presented in Figures 2-13 and 2-14. The surface area of the infundibulum ranges from 6 to 10 cm^2 in sheep to 20 to 30 cm^2 in cattle. The infundibulum leads directly into a thick portion of oviduct called the **ampulla**. The ampulla occupies one-half or more of the oviductal length and merges with the isthmus of the oviduct. The ampulla has a relatively large diameter, with the internal portions characterized by many fern-like mucosal folds with ciliated epithelium (See Figure 2-12). The junction between the ampulla and the isthmus (**ampullary-isthmic junction**) is generally ill-defined. In the mare, the ampullary-isthmic junction serves as a control point that allows only fertilized oocytes to pass into the isthmus and eventually into the uterus.

The oviduct consists of the:

- ***infundibulum***
- ***ampulla***
- ***isthmus***

The **isthmus** is smaller in diameter than the ampulla. It is connected directly to the uterus and the point of juncture is called the **uterotubal junction**. The isthmus has a thicker muscular wall than the ampulla and has fewer mucosal folds (See Figure 2-12).

The primary function of the smooth muscle layer (muscularis) of the oviduct is to transport newly ovulated oocytes and spermatozoa to the site of fertilization (the ampulla). Gamete transport by the oviduct requires that spermatozoa and ova move in

opposite directions so that they encounter each other in the ampulla. The mechanisms controlling gamete transport by the oviduct are not well understood.

The mucosa of the oviduct secretes substances that provide the optimum environment for the free-floating, unfertilized oocyte. It also sustains spermatozoal function until the oocyte arrives after ovulation. There is increasing evidence that the epithelium of the oviduct produces substances that facilitate the fertilizing capability of spermatozoa. After fertilization, the newly formed zygote must reside in the oviduct for a few days before it enters the uterus. Thus, the composition of the fluid secreted by the cells lining the oviduct is important for providing a suitable environment for the development of the early embryo.

In the cow, the **uterotubal junction** (often called the UTJ) is believed to regulate the movement of the embryo into the uterus. Under conditions of high estradiol, the uterotubal junction forms a "kink" (like a kink in a hose), thus blocking movement of embryos. As estradiol levels decrease, this kink straightens out; the lumen of the isthmus is no longer blocked by the kink and embryos can enter the uterine lumen with relative ease. In other species, the oviduct attaches to the uterus without an obvious kink-like anatomical constriction. In swine, constriction of the uterotubal junction serves as a major barrier to sperm transport and prevents excessive numbers of

spermatozoa from reaching the ampulla. Such blockage is believed to be important in the prevention of polyspermy in swine.

The Uterus is the Organ of Pregnancy

The uterus connects the oviducts to the cervix. In most mammals, the uterus consists of two **uterine horns** or **cornua**. The degree to which the uterine horns are developed constitutes the basis for classification of mammalian uteri.

Among mammals there are three distinct anatomical types of uteri (See Figure 2-15). The first of these is a **duplex uterus,** characterized as having two cervical canals that separate each uterine horn into distinct compartments. There are two types of duplex uteri. The first is characterized by having a single vaginal canal opening to the exterior. On the interior it bifurcates (splits) into two vaginas and two cervices. Marsupials have this type of uterus. In the opossum, this interesting female anatomical configuration is accommodated by the forked penis of the male. It is believed that after intromission, the male opossum deposits semen in each of the two sides of the reproductive tract simultaneously. The second, less complex type of duplex uterus is found in the rabbit. In this type of duplex uterus, there are two uterine horns and two distinct cervical canals connected to a single vaginal canal. Therefore, in species like the rabbit it is possible to artificially inseminate the female into one horn with sperm from one male and to artificially inseminate the contralateral (opposite) horn with semen from another male; the offspring will represent two genetic types. The rabbit is an excellent animal to use for the study of various experimental seminal or embryo treatments, because transuterine migration of the gametes or embryos is not likely to occur.

The **bicornuate uterus** is characterized by having two uterine horns and a small uterine body. The length of the uterine horns is dependent on the degree of fusion between the paramesonephric ducts in the developing female fetus (See Chapter 4 for details). In species where there is a high degree of fusion (mare) there are short uterine horns and a relatively large uterine body. When a moderate degree of fusion occurs, uterine horns of intermediate length result (cow, ewe and goat). And, when little fusion takes place between adjacent paramesonephric ducts, long uterine horns result (sow, bitch and queen). In all types of bicornuate uteri, the uterus opens into the vagina through a single cervical canal. An **internal** and **external uterine bifurcation** of the horns can be distinguished in the bicornuate uterus (See Figures 2-5, 2-7 and 2-9).

Figure 2-15. Types of Uteri Found in Mammals

(The solid brown area in each example represents the cervix)

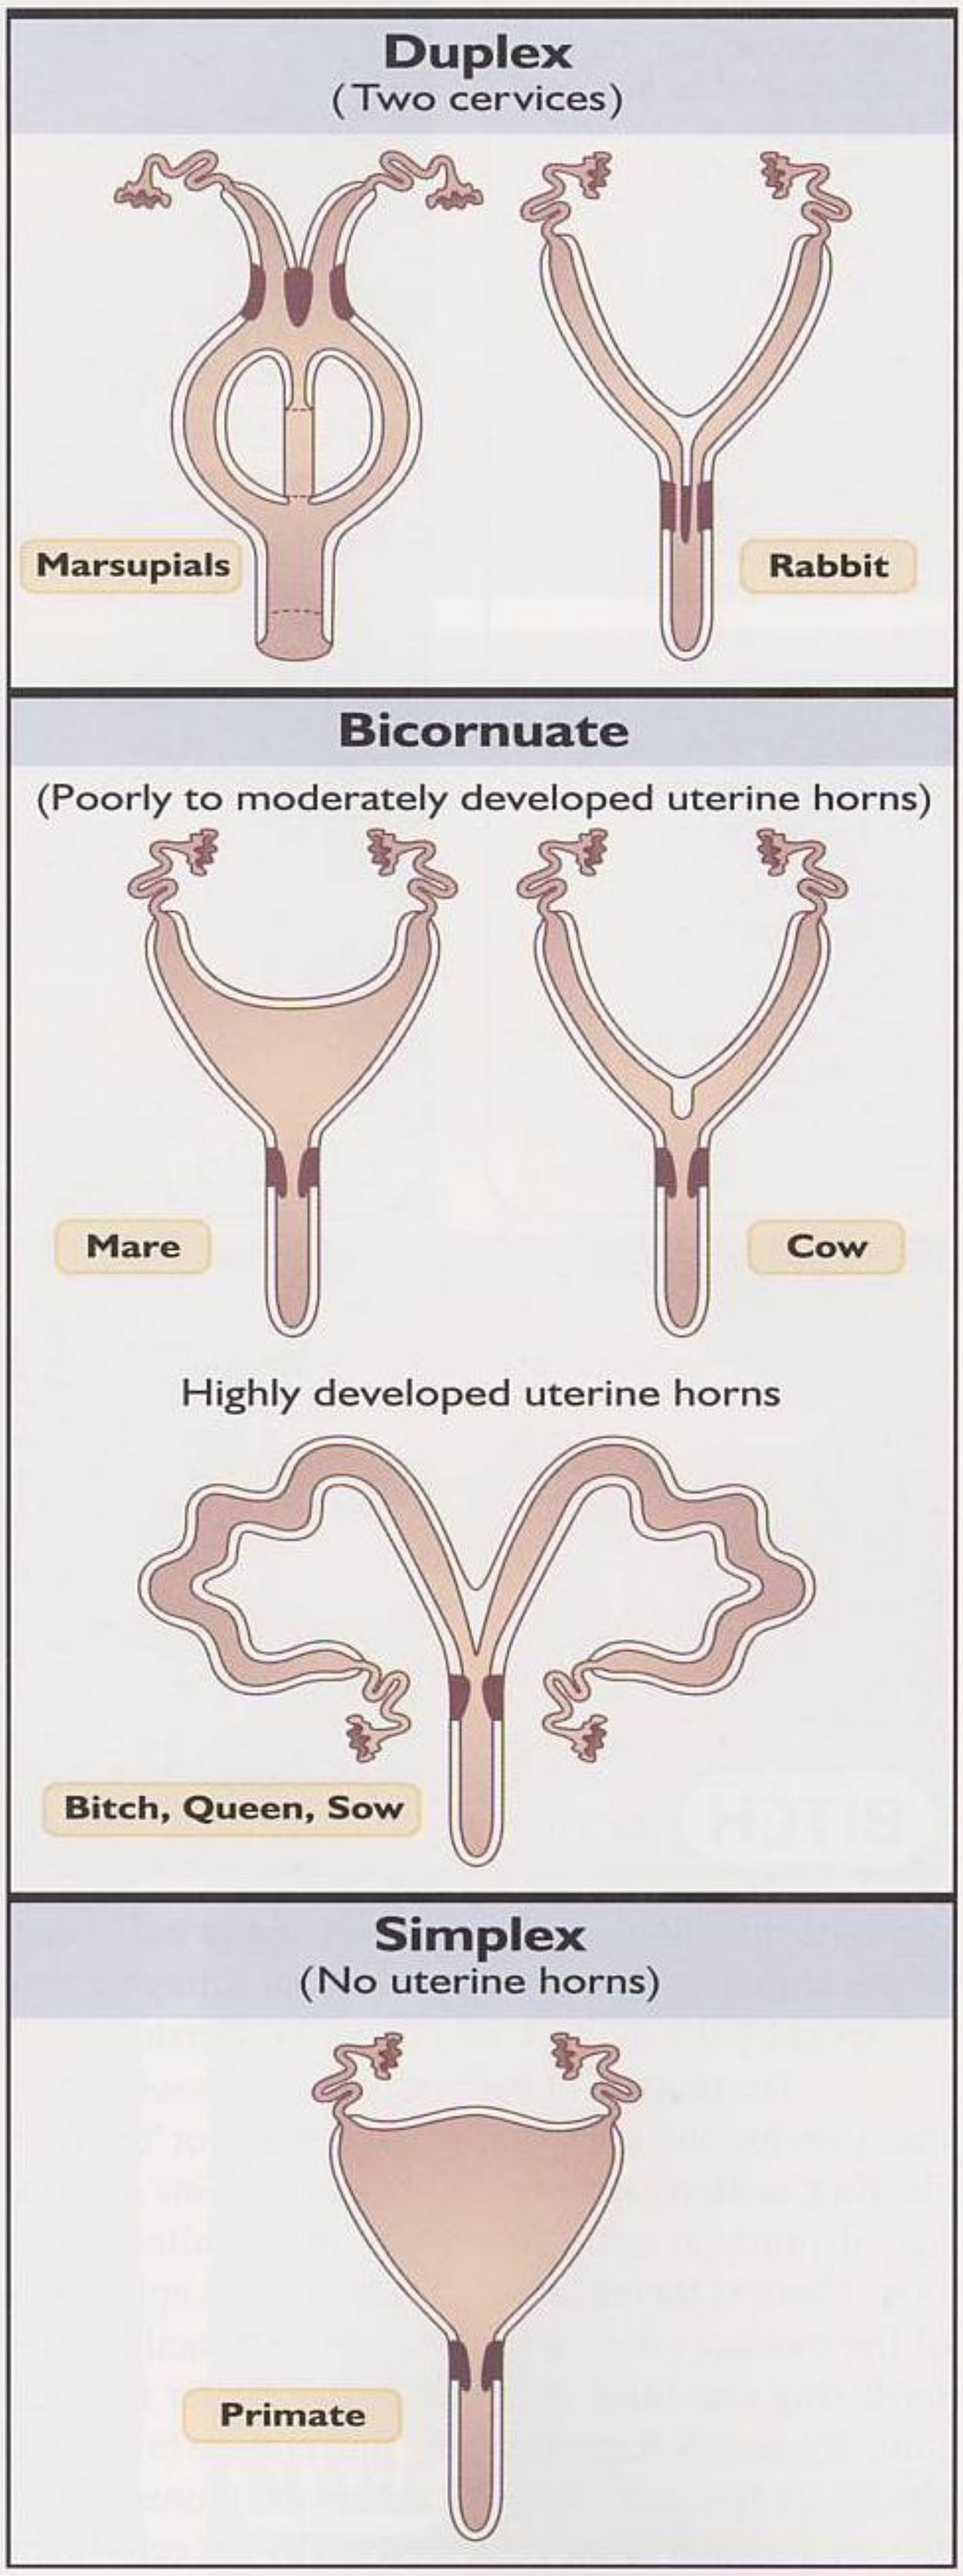

Figure 2-16. Schematic Illustration of Uterine Tissue

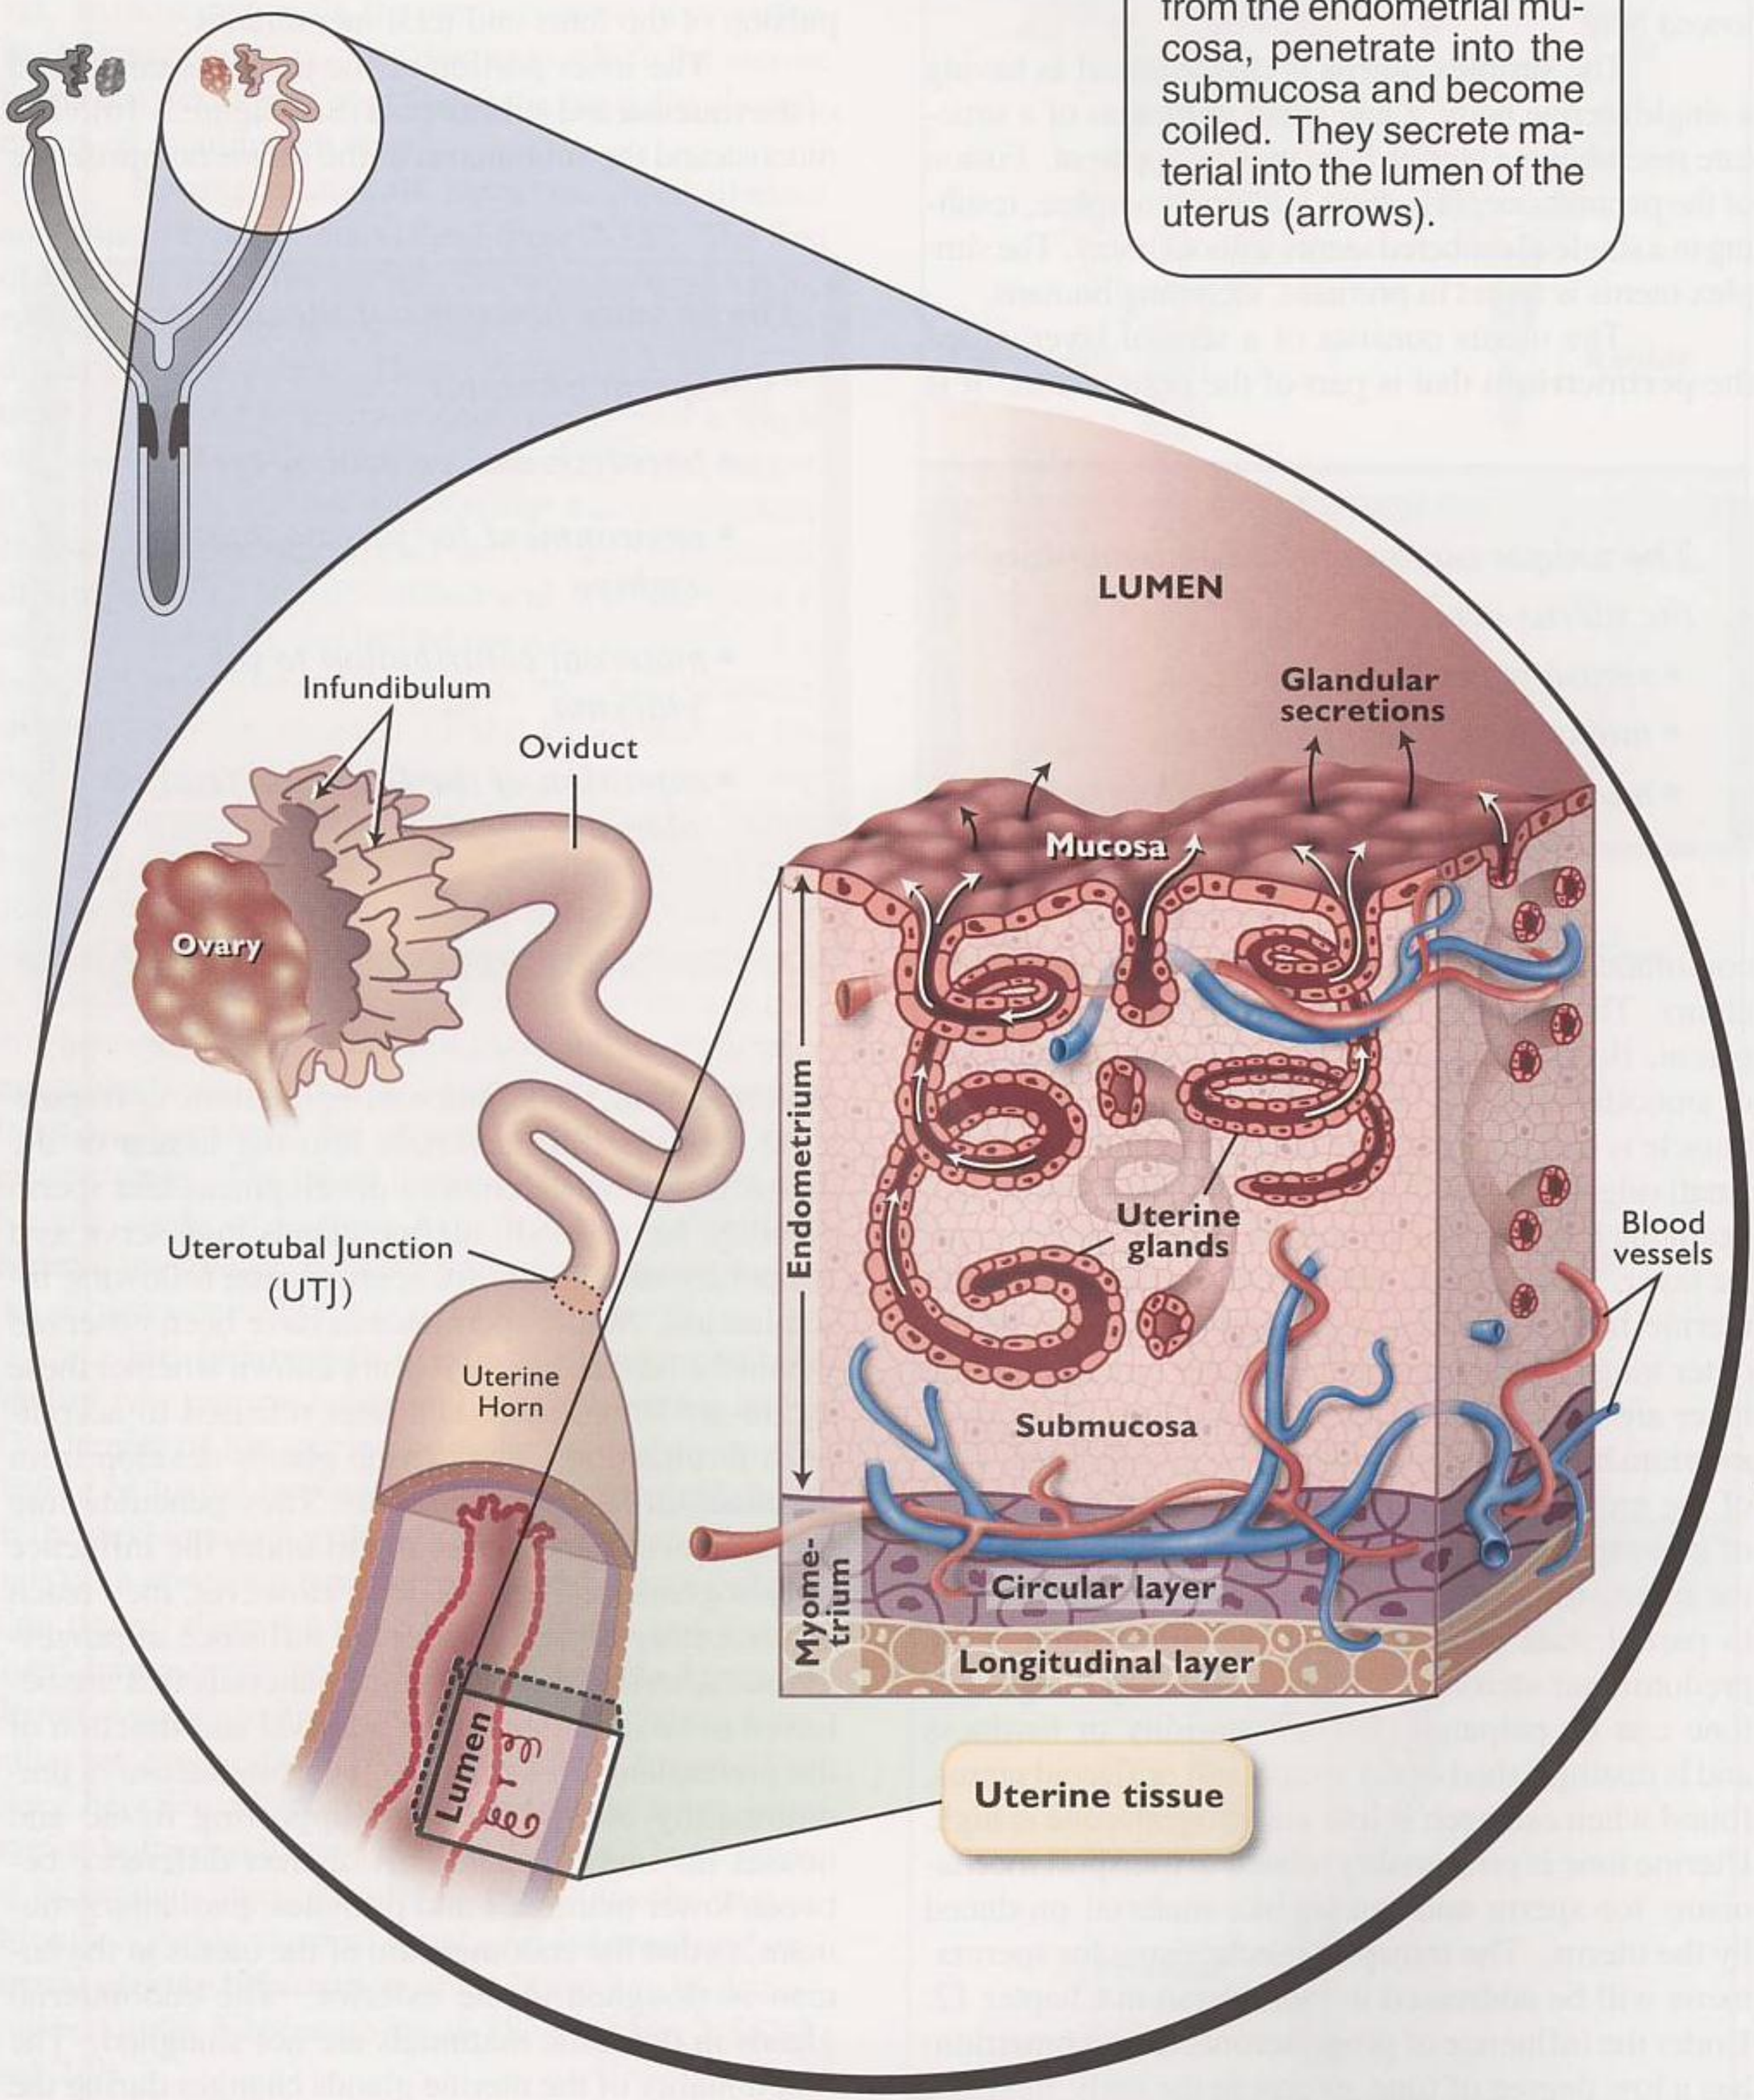

Figure 2-17. Excised Uterine Tissue

The uterus has been incised so that the endometrial surface can be visualized. In the cow and the ewe, caruncles (C) can be observed as protrusions from the endometrial surface. Blood vessels (V) are white, cord-like structures located beneath the surface of each caruncle. The endometrium of the sow and mare is characterized as having many endometrial folds (EF). Both the caruncles and the endometrial folds contribute to the maternal placenta if pregnancy occurs.

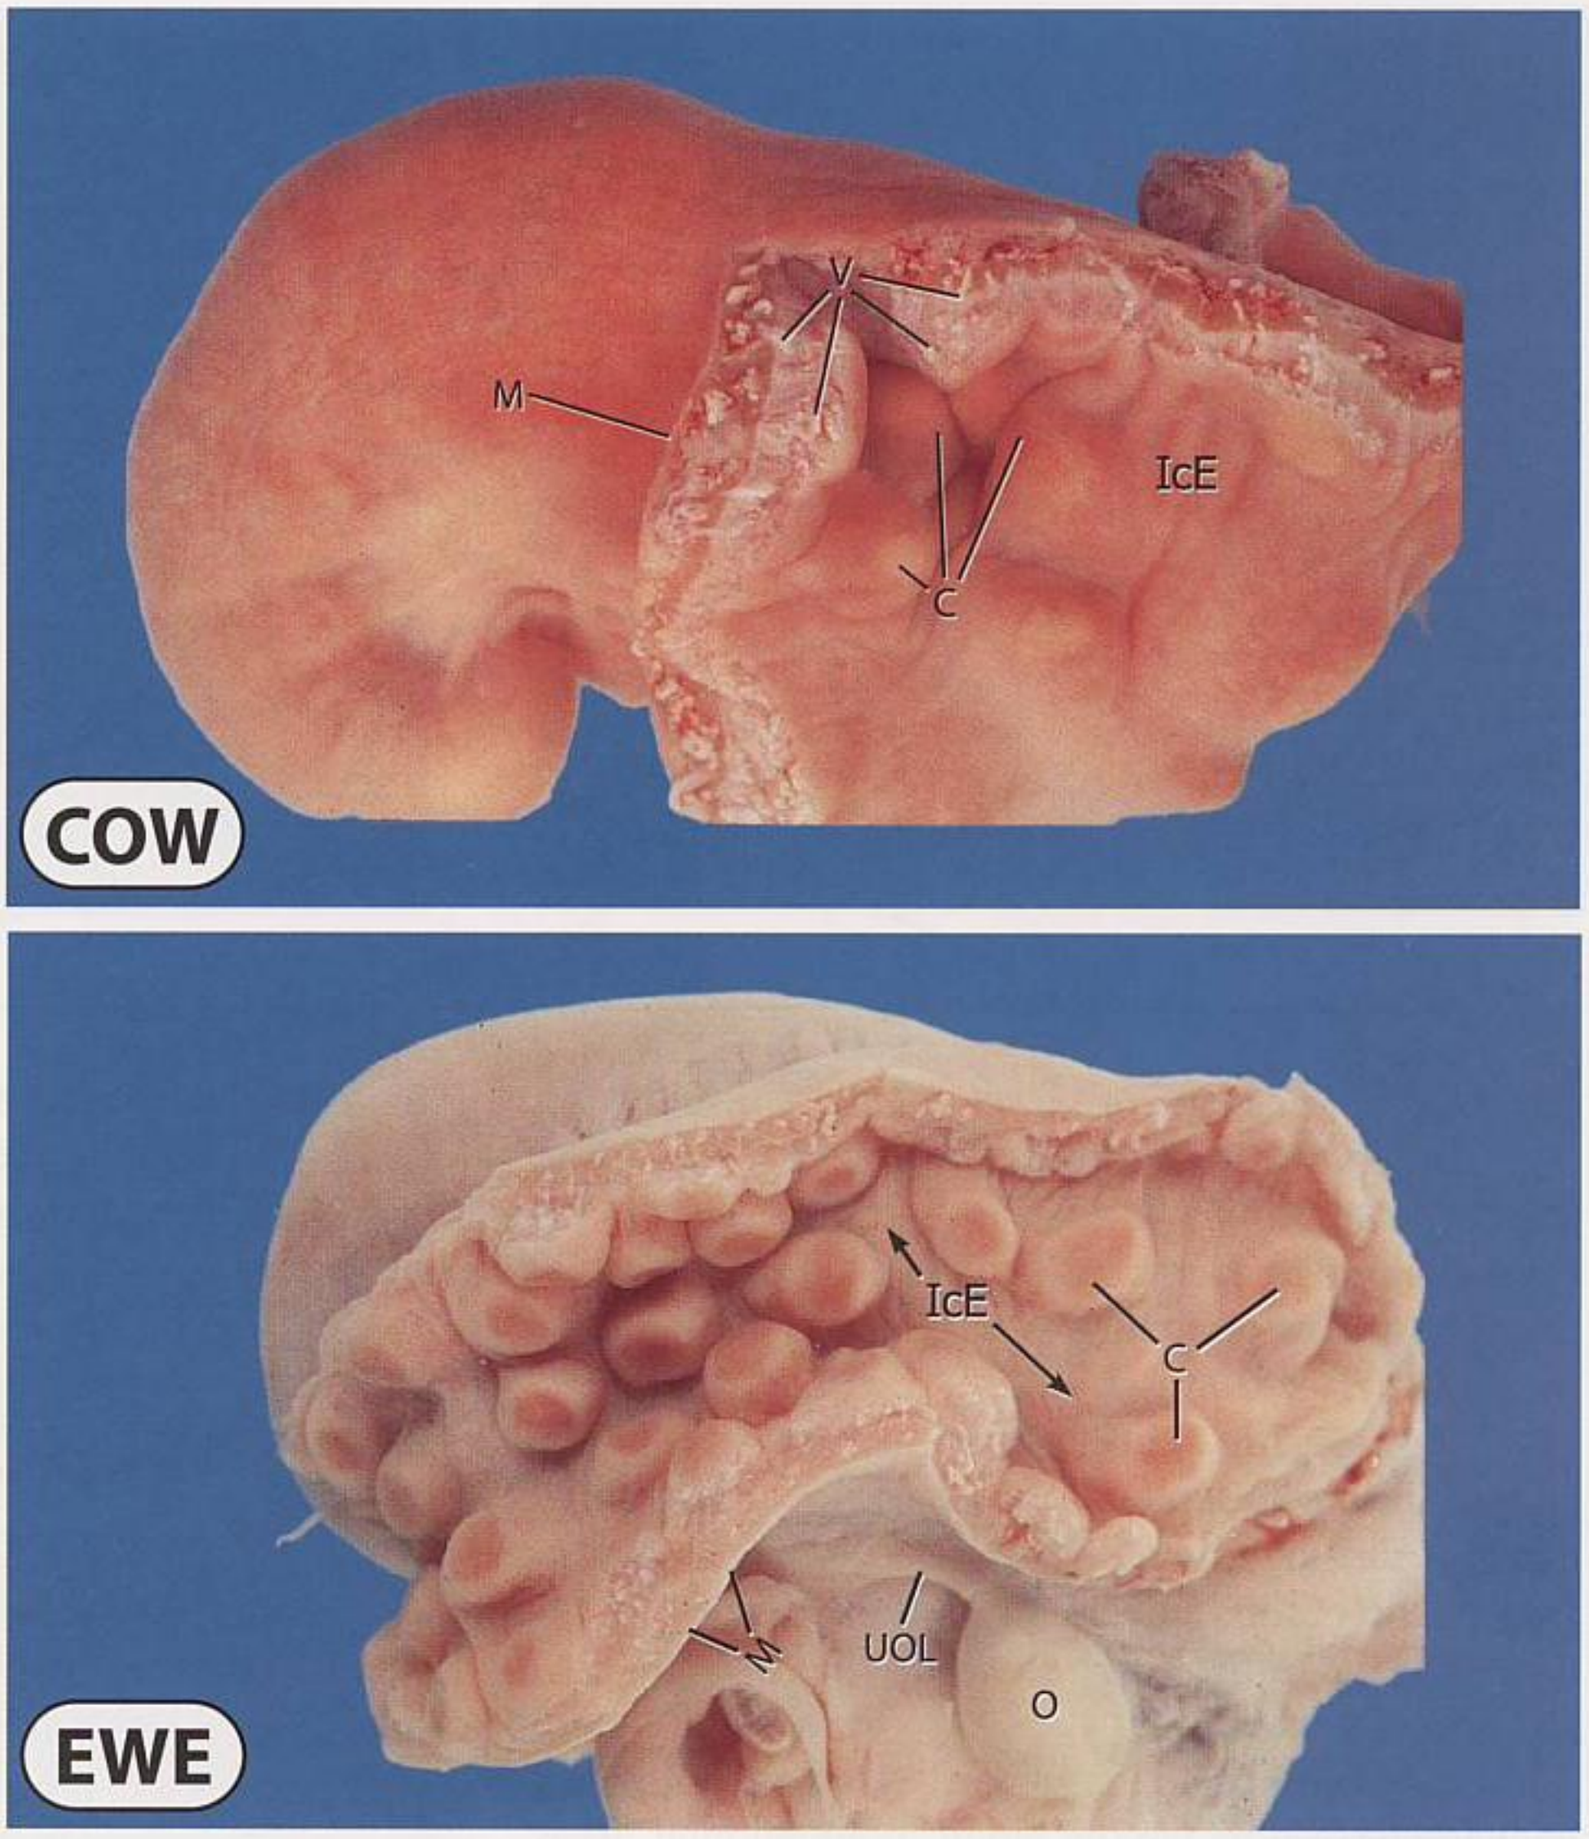

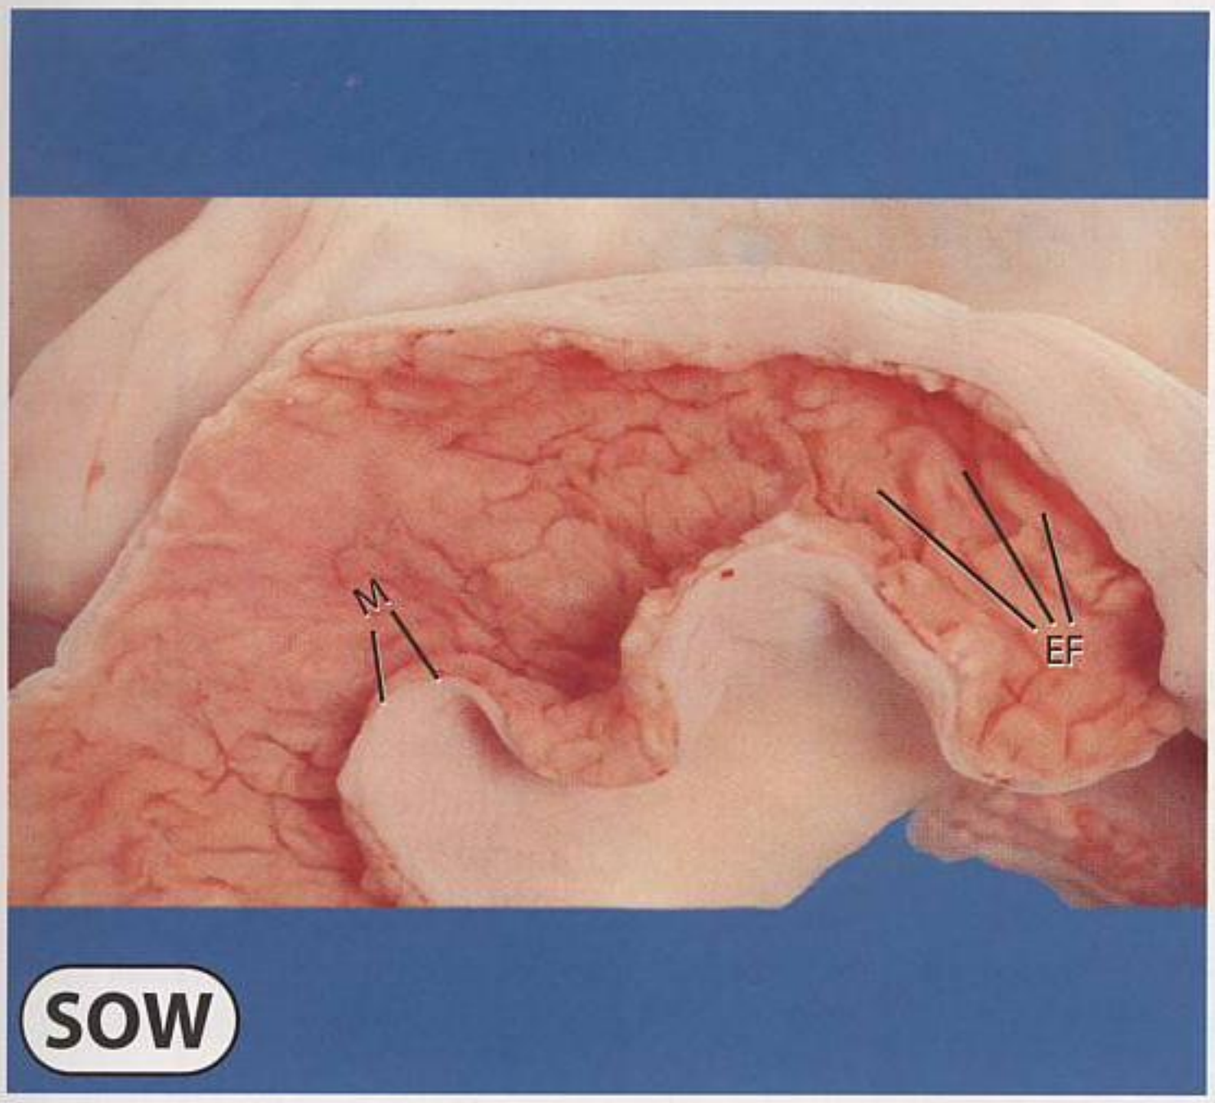

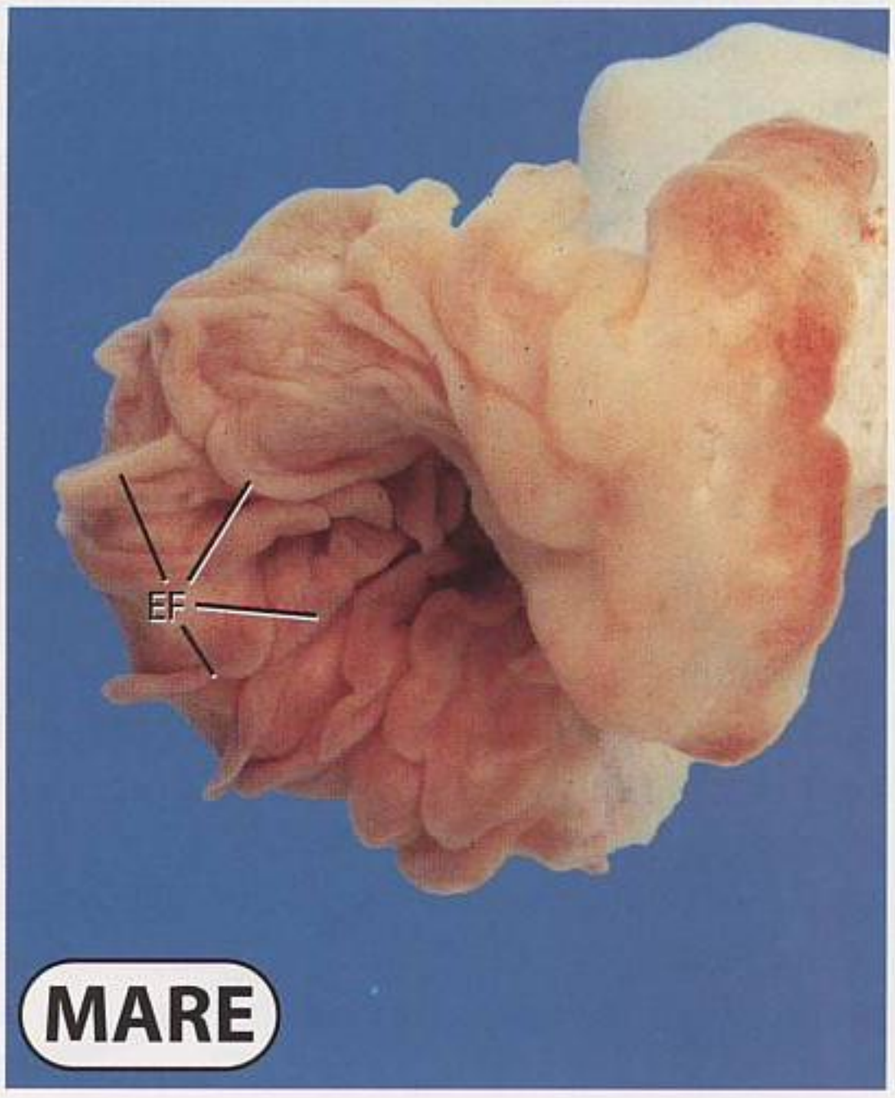

Figure 2-18. Excised Uterine Tissue

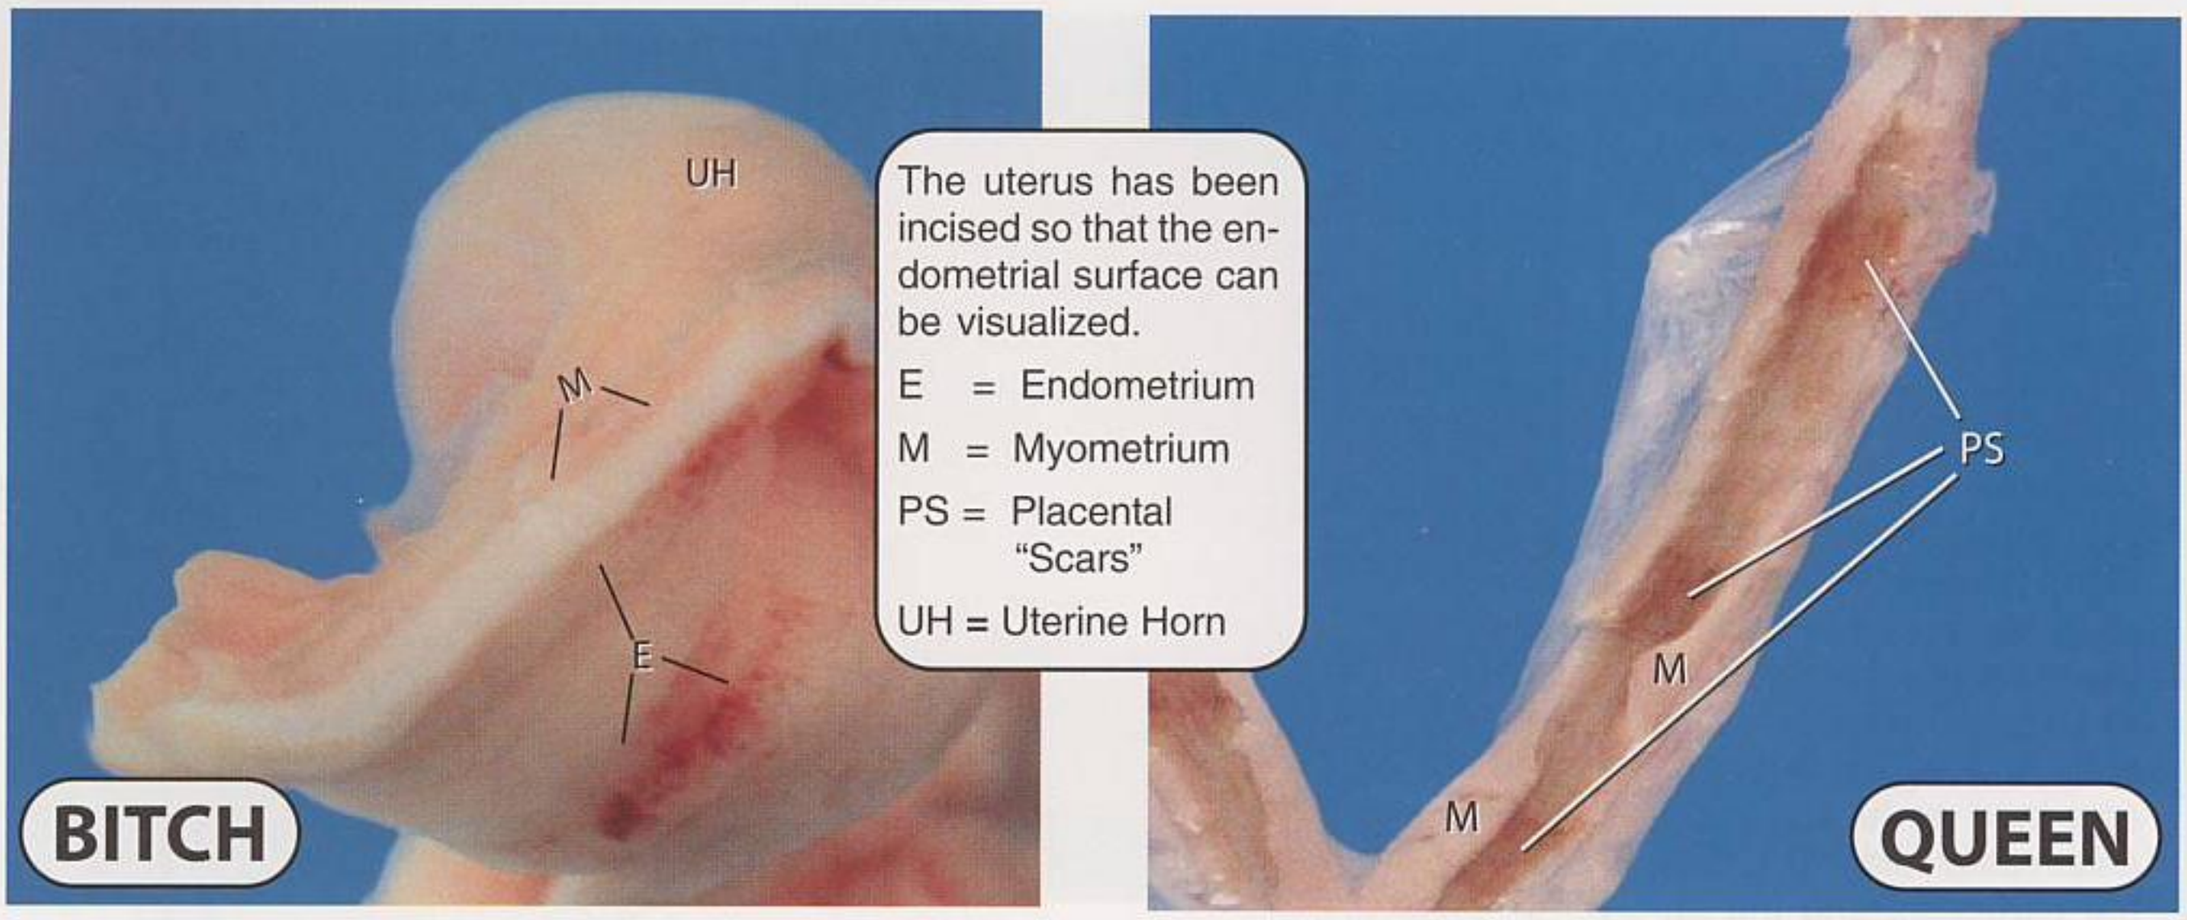

estrous cycle in a type of secretory "waxing and waning." In other words, secretory activity of the uterine glands changes as a function of the stage of the estrous cycle. The mechanisms whereby uterine glands may be lost (or replenished) in domestic animals remains undefined.

At a critical time during the estrous cycle the cells of the uterine endometrium produce **prostaglandin $F_{2\alpha}$**. Prostaglandin $F_{2\alpha}$ causes luteolysis or regression of the corpus luteum if the animal is not pregnant. Details of these important mechanisms are presented in Chapter 9.

In ruminants, the surface of the endometrium is characterized as having small, nonglandular areas that protrude from the surface of the endometrium. These small protuberances are referred to as **caruncles** and can be observed with a high degree of detail in Figure 2-17. These caruncular regions are highly vascularized and will give rise to the maternal portion of the placenta if attachment of the embryo occurs. In contrast to the cow and ewe, the endometrium of the sow and mare have no caruncles. Their endometrium is characterized by having many endometrial folds (See Figure 2-17). The folds will provide the uterine surface for the development of the placenta. Placental "scars" in the uterus of the queen (See Figure 2-18) are pigmented regions of the endometrium that represent sites of previous placental attachment. They appear as bands around the luminal surface of the uterus indicative of zonary placentation (See Chapter 14). These sites are not true scars that are permanent fibrous replacements of normal tissue. The sites are zones of uterine repair that will become less conspicuous several months postpartum. The presence of these discrete endometrial repair zones is useful to wildlife biologists who use them in postmortem evaluation of wild animals to approximate the number of young produced by a female within a certain period of time. Evaluation of these regions is most useful in monoestrus females (canids, felids and ursids) that have no immediate postpartum estrus. Exposure to estrogen during repeated estrous cycles hastens the uterine repair process and causes these repair zones to disappear at a faster rate.

The cervix is a relatively thick-walled, noncompliant organ that serves as a barrier to sperm transport in the ewe, cow, bitch and queen but not in the sow and mare. The cervix also isolates the uterus from the external environment during pregnancy by forming a barrier consisting of highly viscous mucus. Cervical anatomy differs significantly among species (See Figures 2-20 and 2-21). In general, however, it can be characterized as having a cervical canal (lumen) that is surrounded by single (bitch and queen) or multiple (cow, ewe, sow, mare) folds or rings protruding into the cervical canal (See Figures 2-19, 20, and 21). In the cow and the ewe, several of these rings form interlocking finger-like projections (See Figure 2-20). In the sow, the rings interdigitate in a very intimate fashion (See Figure 2-20). These inter-

The cervix provides lubrication, a flushing system and a barrier during pregnancy.

Figure 2-19. A Schematic of the Cervix

In the cow, ewe and sow the cervix has distinct rings that protrude into the lumen. The surface of the cervix has many crypts and folds that are covered with columnar epithelium. Some cells are ciliated. In the cow, a distinct fornix is present. To observe actual specimens see Figures 2-20 and 21.

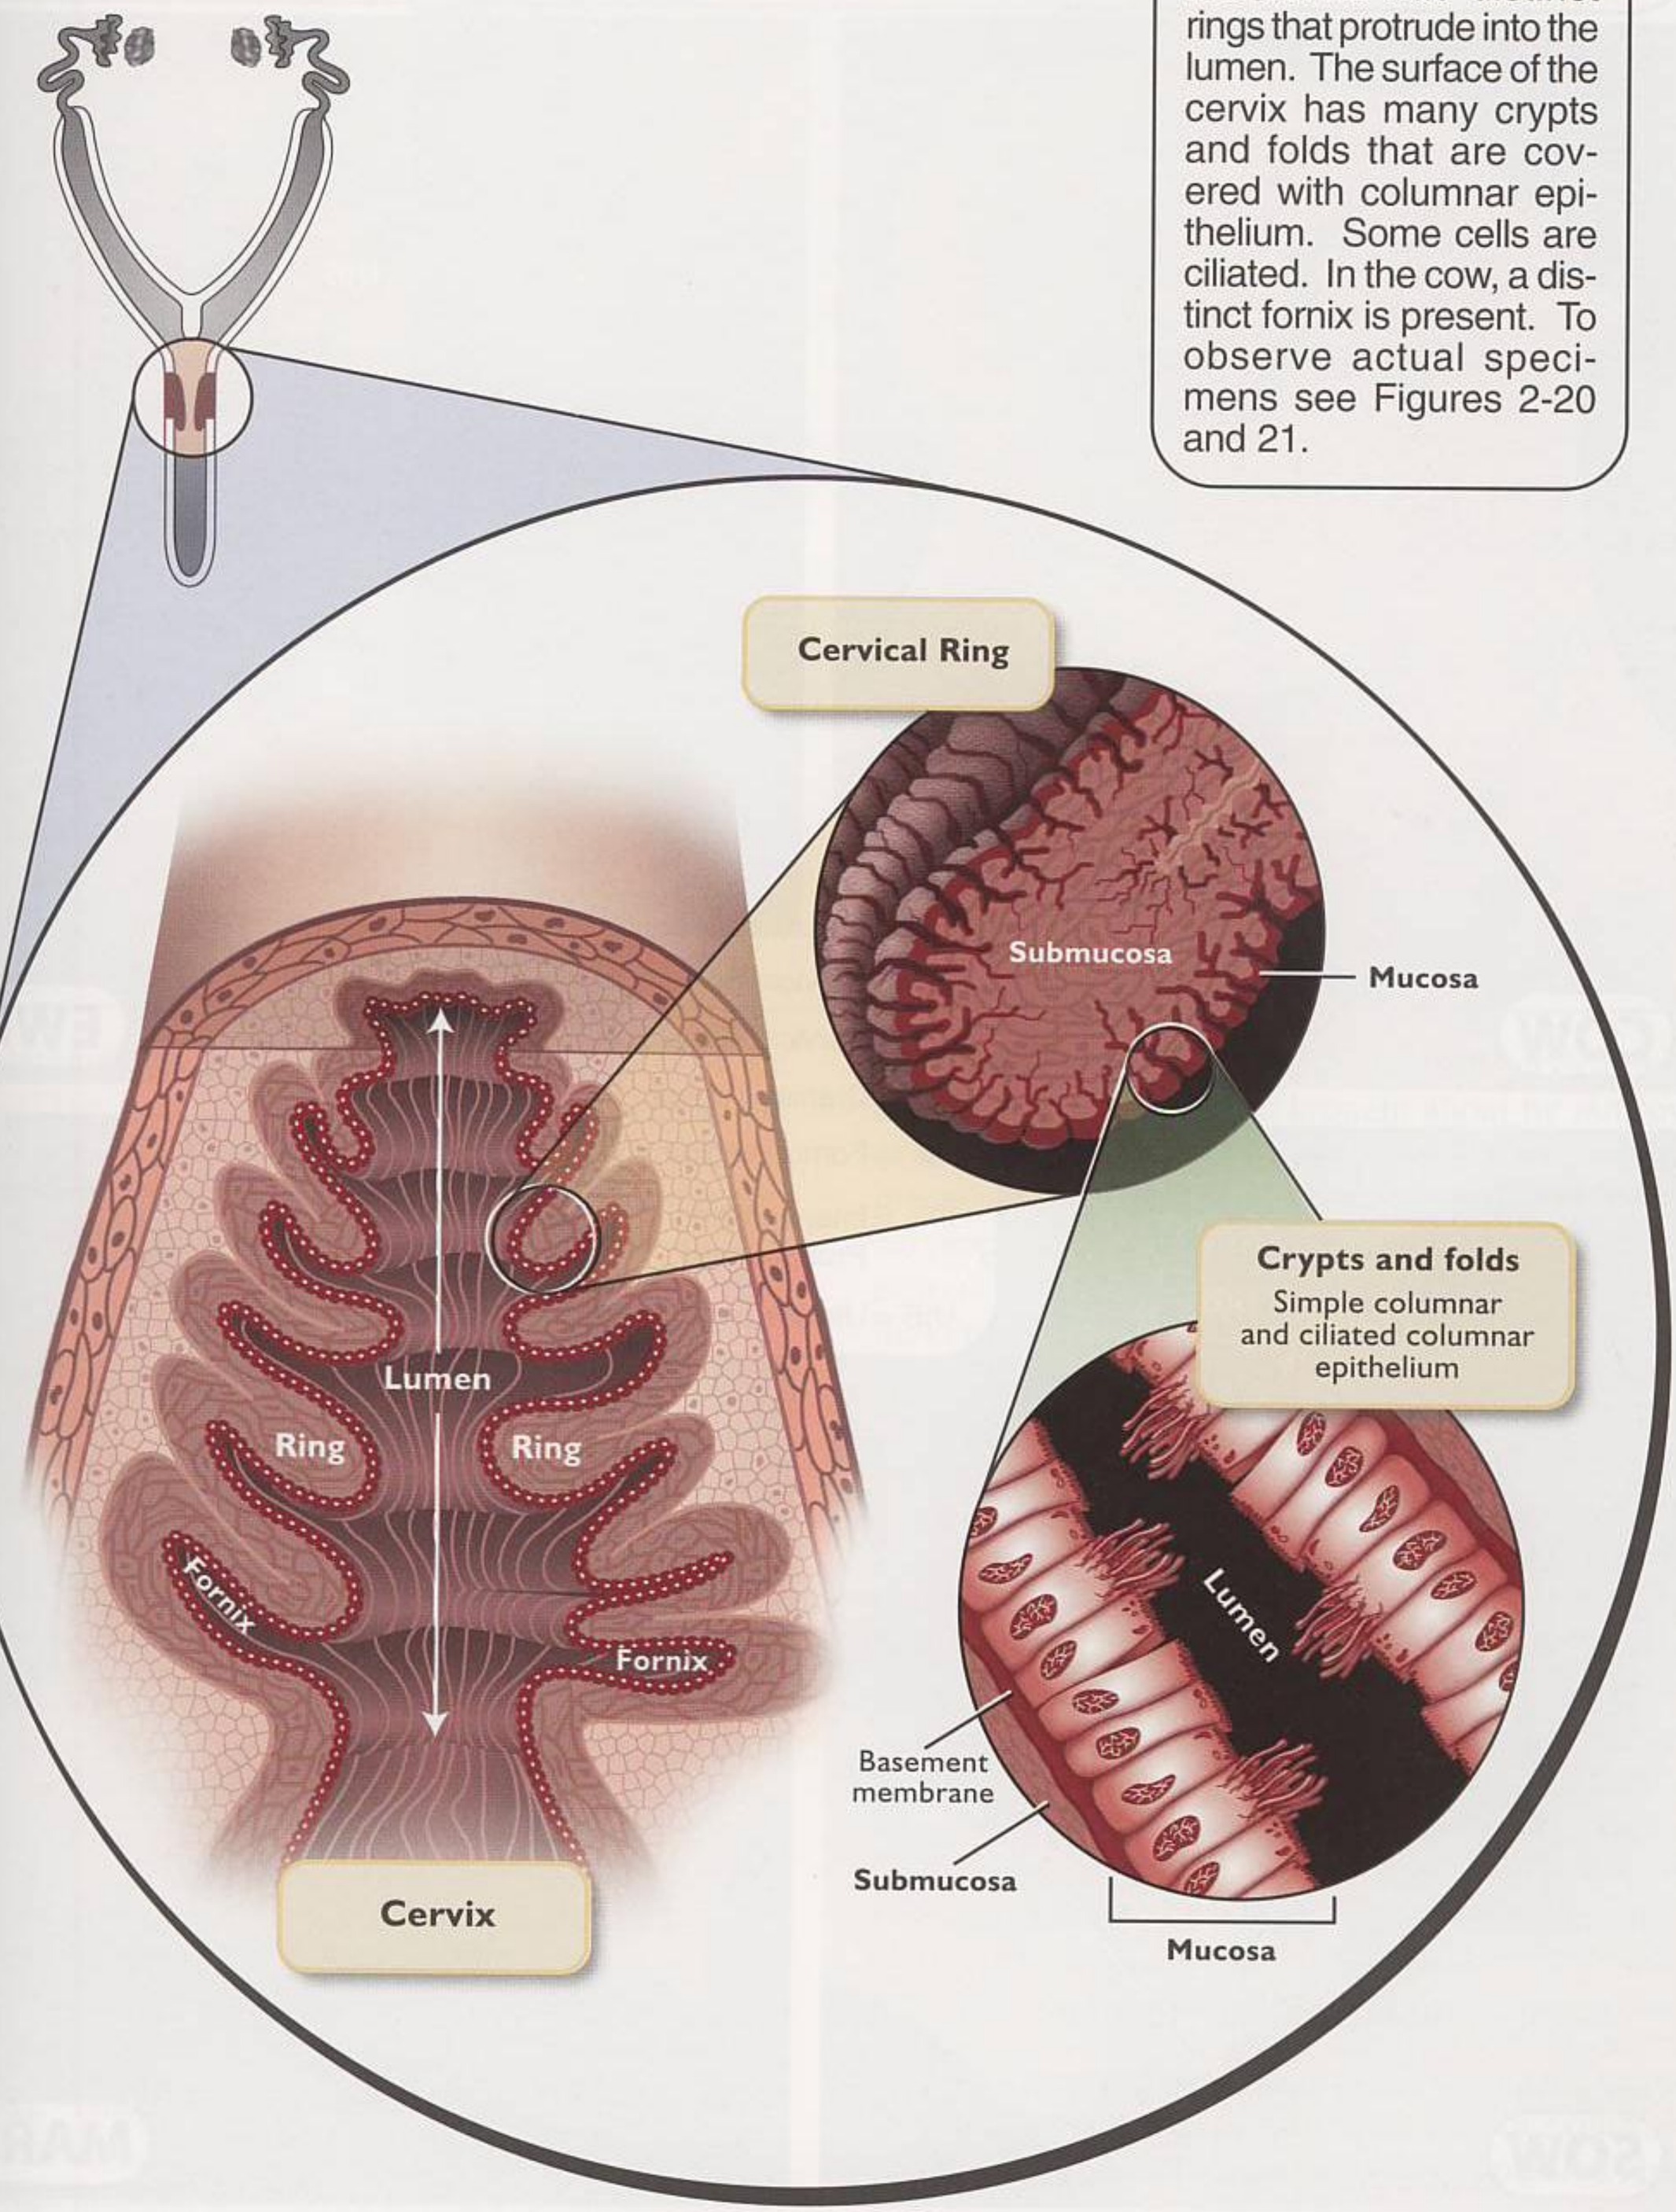

Figure 2-20. Excised Cervical Tissue

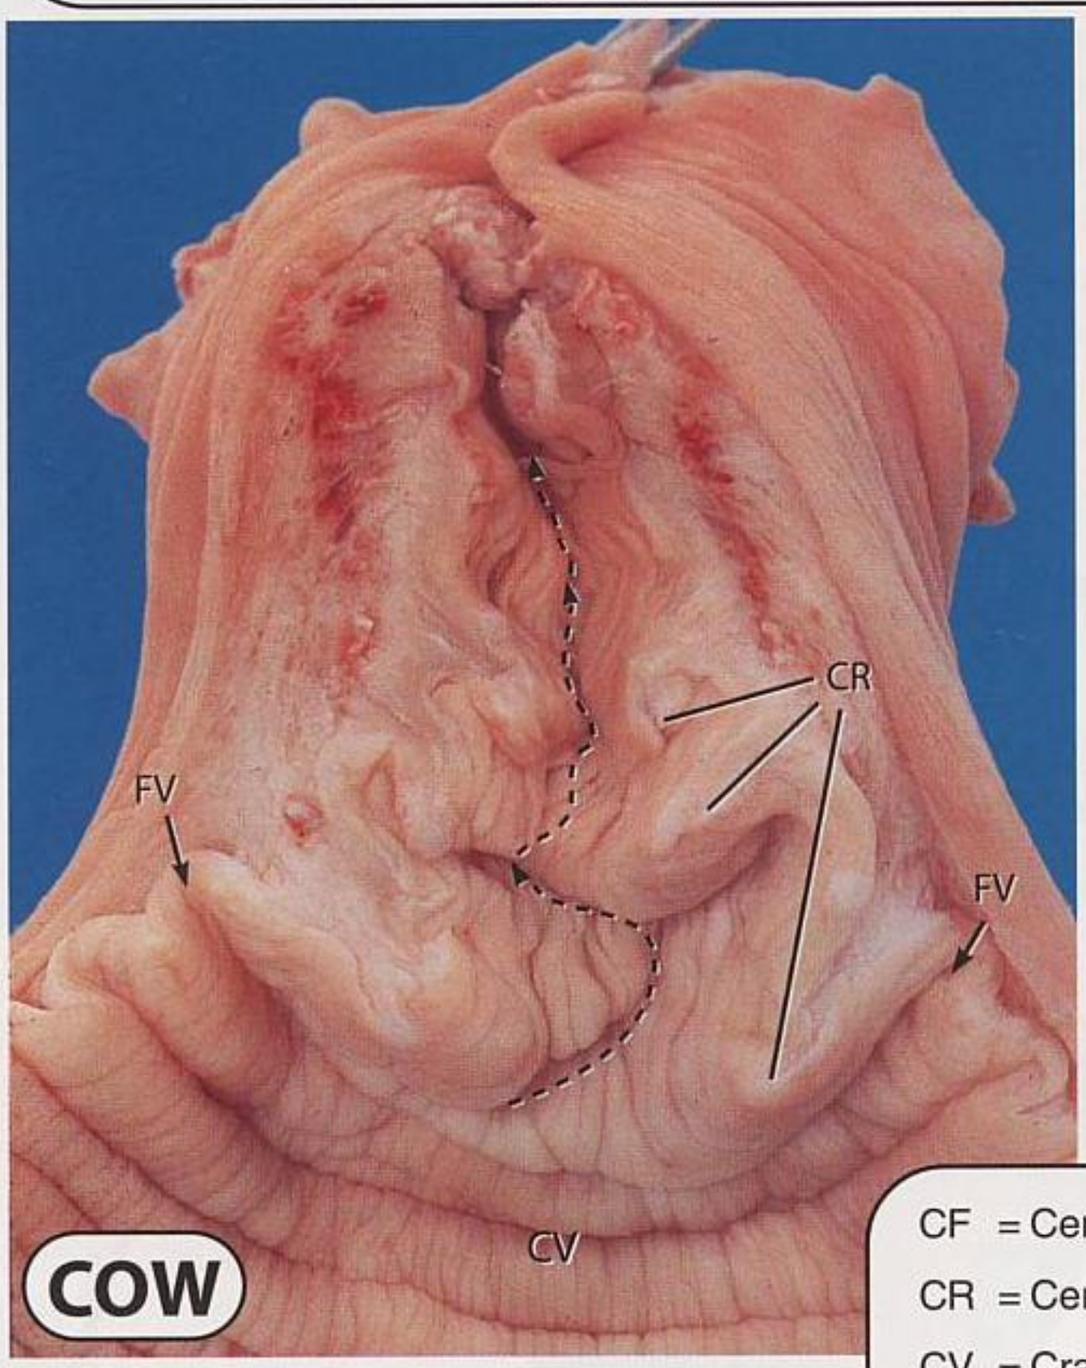
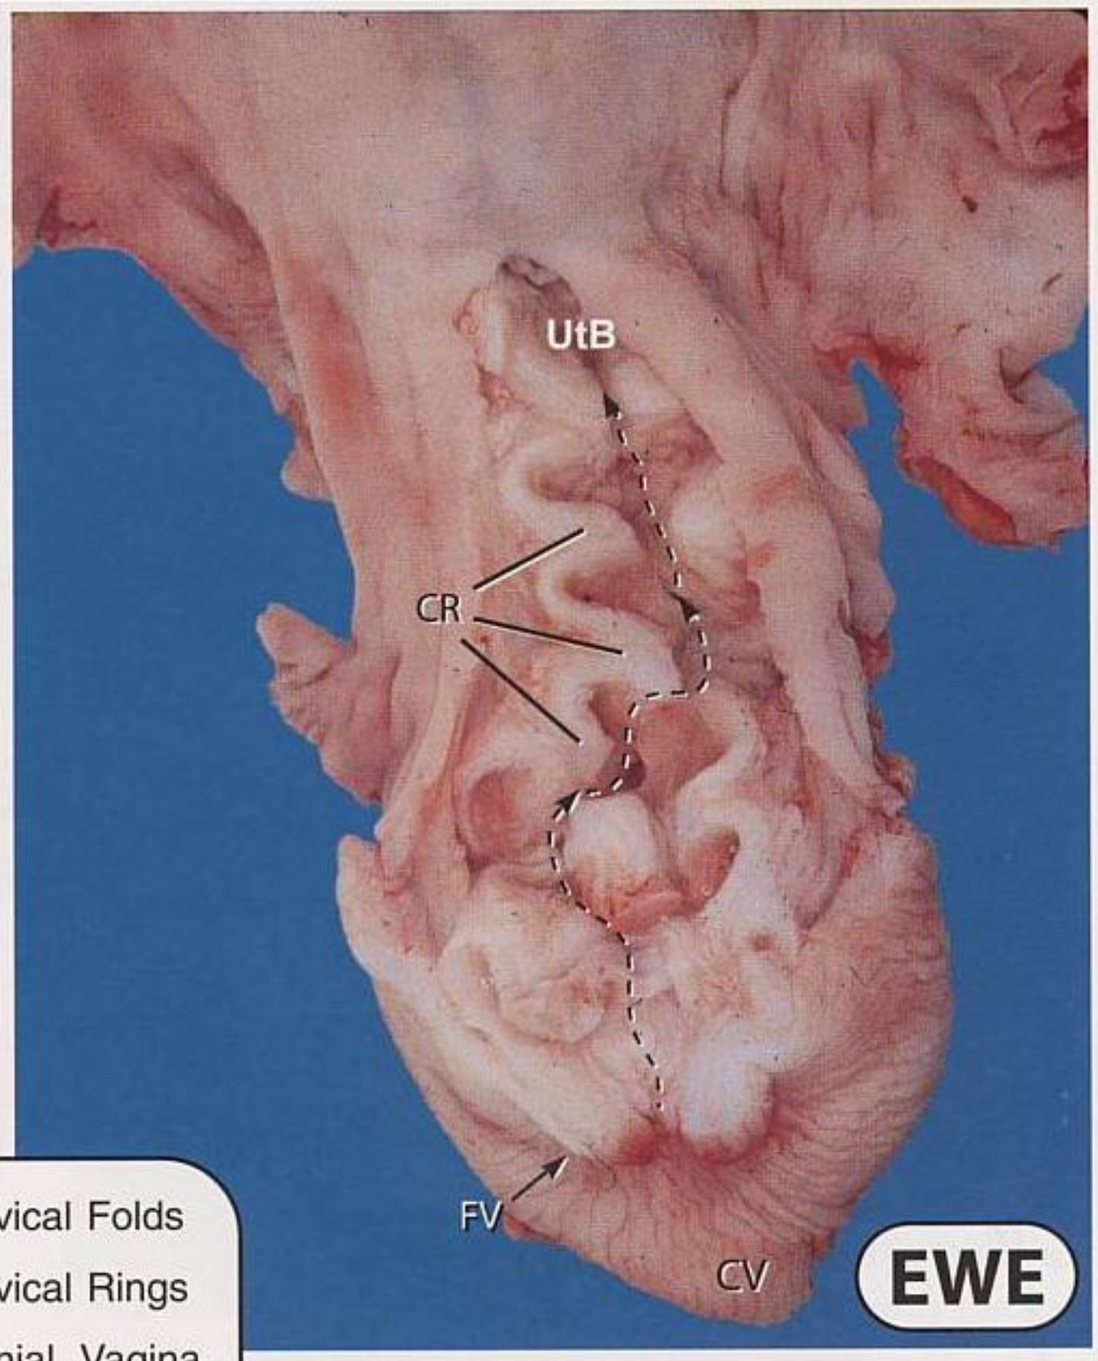
The cervix of the cow and ewe have distinct, well developed protrusions called cervical rings (CR). The sow has interdigitating prominences (IP). The mare has no cervical rings but has many longitudinal cervical folds (CF) that are continuous with the endometrial folds of the uterus. Arrows indicate the pathway of the cervical canal from the cranial vagina (CV) toward the uterus.





CF = Cervical Folds
CR = Cervical Rings
CV = Cranial Vagina

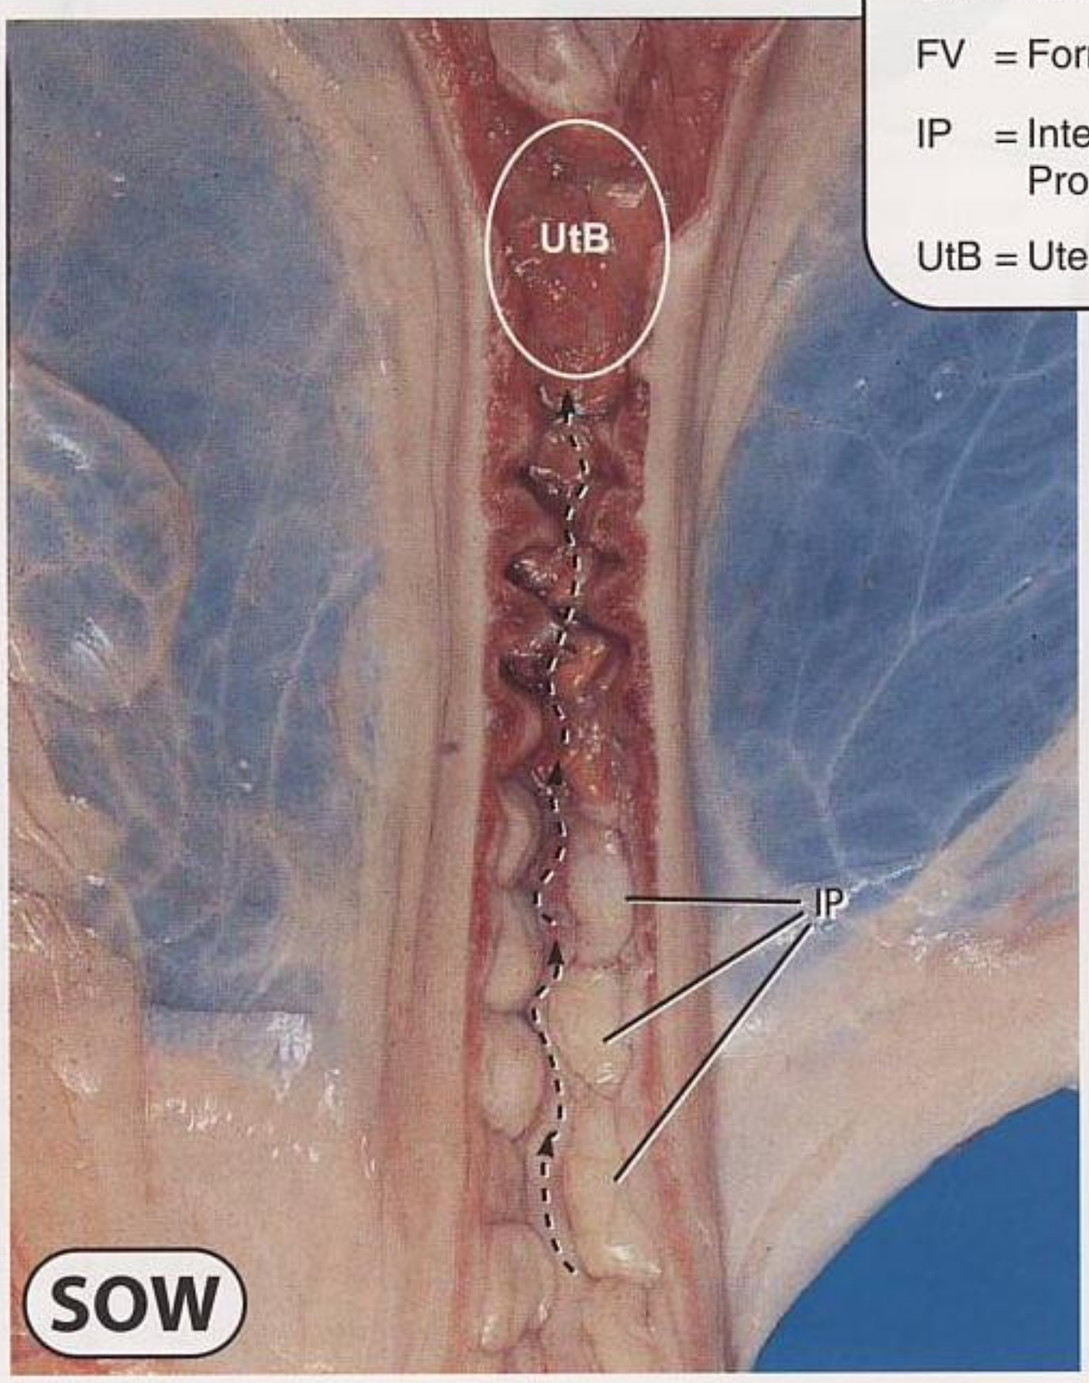
UtB = Uterine Body



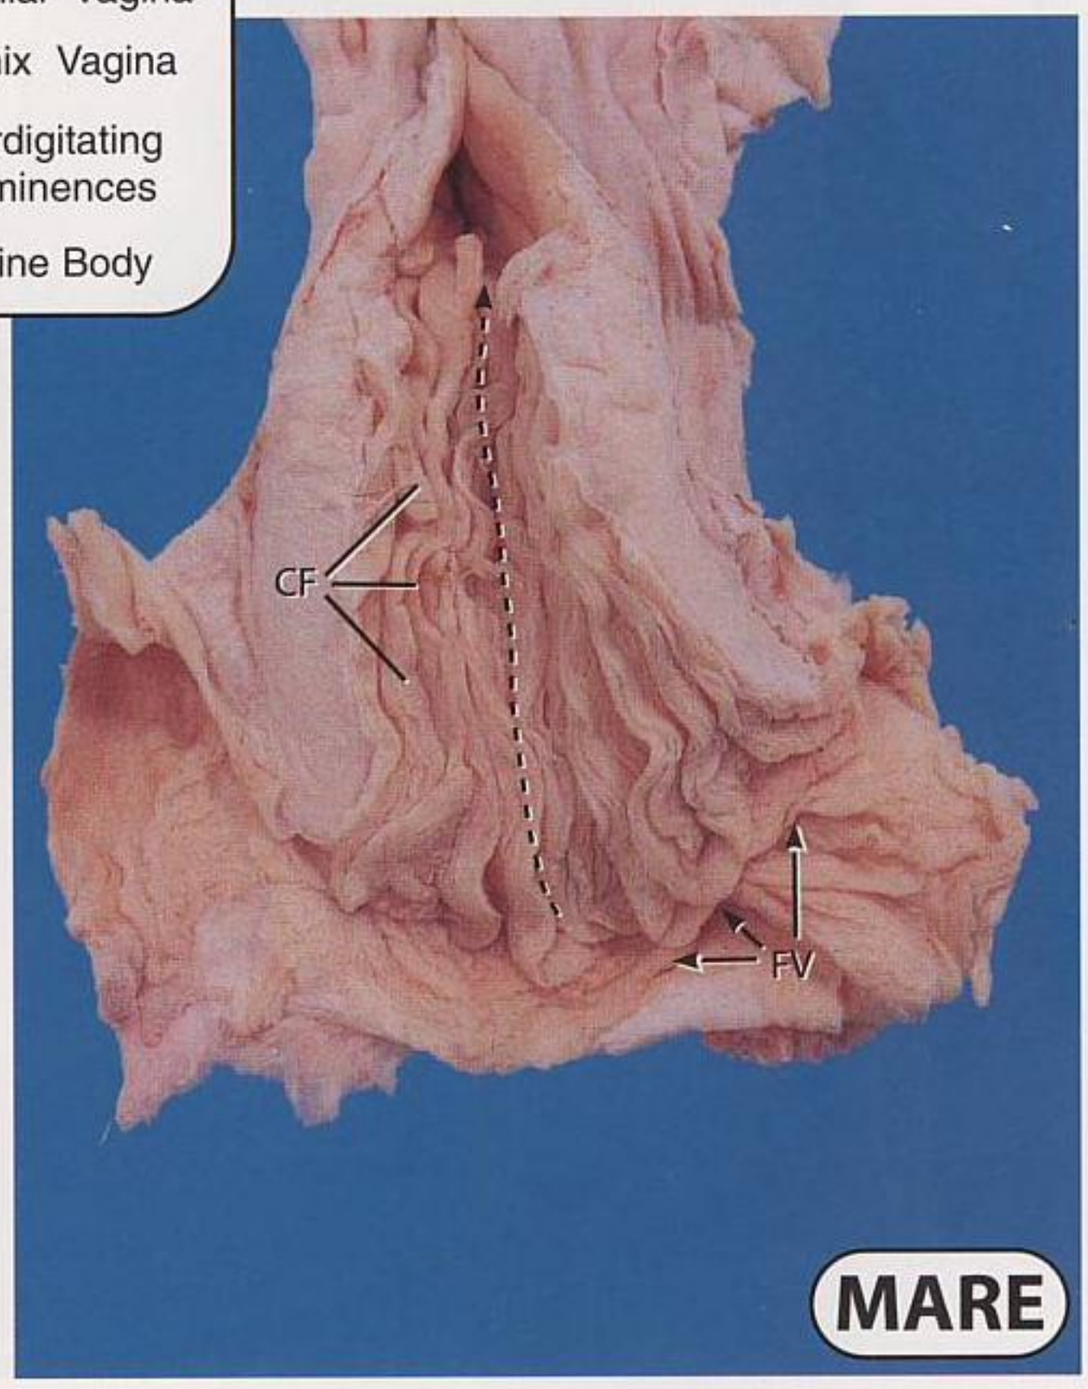


Figure 2-21. Excised Cervical Tissue

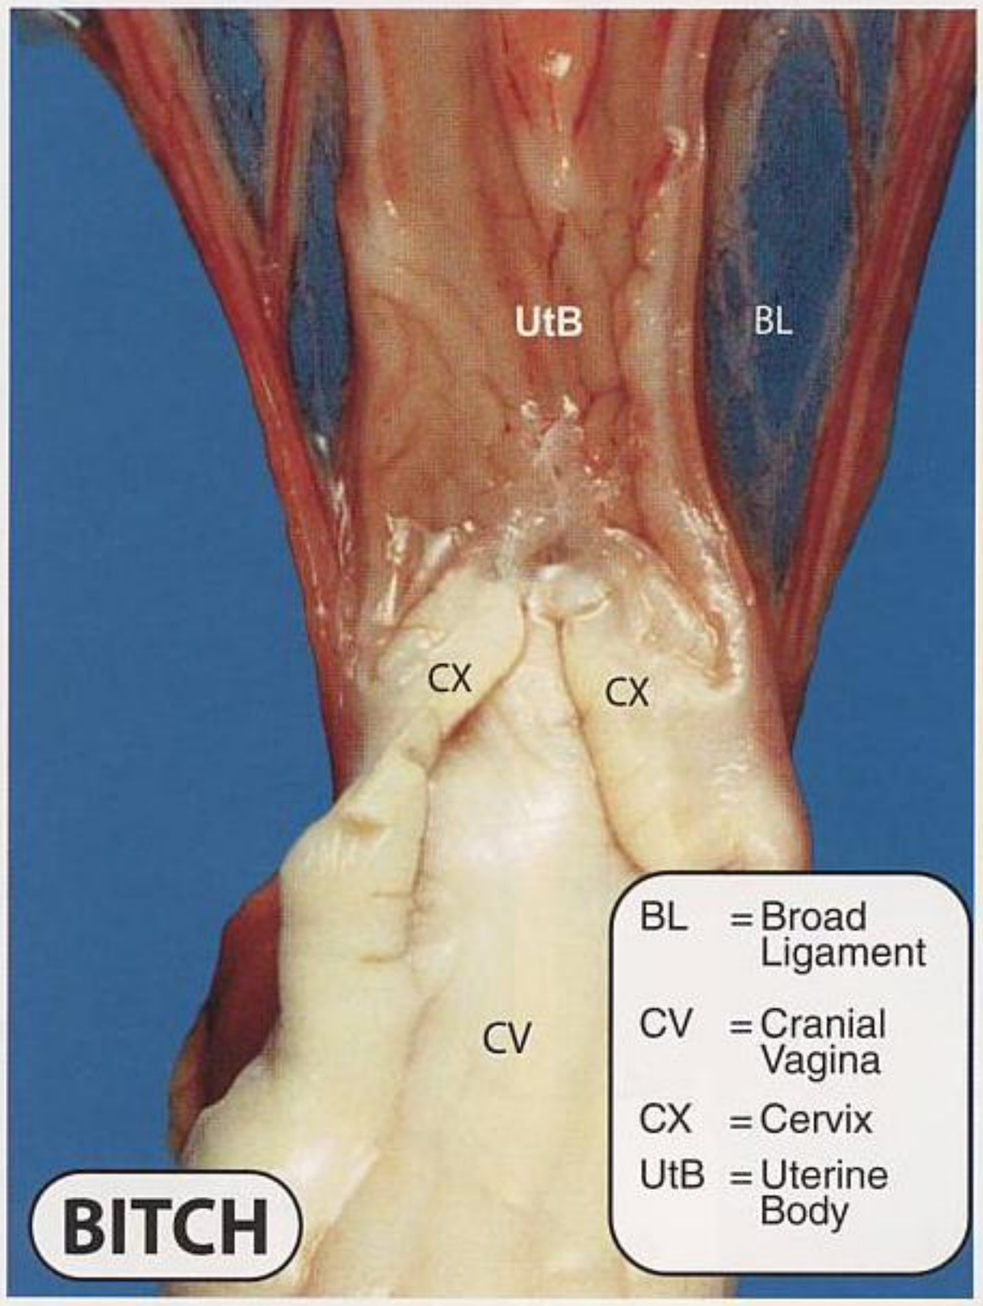

digitations require a special penile adaptation in the boar. The boar has a corkscrew or spiral twist in the glans penis so that during copulation the boar's penis becomes "locked" into the cervix. Thus, in the pig, initial deposition of the semen occurs in the cervix. Because of the large volume (200-500ml), most of the ejaculate quickly enters the uterus. The distinguishing feature of the mare's cervix is the presence of conspicuous, loose folds of mucosa that protrude into the vagina. The cervix of the mare is soft during estrus. During copulation the penis of the stallion presses against the soft cervix. Semen is ejaculated under high pressure and enters the uterus during ejaculation.

In the canine, a portion of the cervix protrudes caudally into the cranial vagina (See Figure 2-21). The cervix of the bitch does not contain elaborate rings or folds and is relatively smooth. In the queen, the cervix is quite small but thick walled when compared to the uterus or the vagina. Like in the bitch, the cervix is smooth and does not have elaborate surface folds.

A primary function of the cervix in the cow and ewe is to produce mucus during estrus. In the sow and mare, a much smaller quantity of mucus is produced. This mucus flows from the cervix toward the exterior and lubricates the vagina during copulation. Foreign material introduced during copulation (including sperm) is flushed out of the tract by cervical mucus. This flushing action brought about by outflow of mucus probably minimizes introduction of microorganisms into the uterus. The biochemical and physical properties of the mucus change as the stage of the estrous cycle changes. Details regarding the role of the cervix in the transport of spermatozoa will be presented in Chapter 12.

During pregnancy the cervix is responsible for isolation of the conceptus within the uterus from the external environment. Under the influence of progesterone, the mucus becomes quite viscous. In fact, the viscous mucus temporarily "glues" the folds of the cervix together so that foreign material cannot enter the uterus during gestation. This barrier is referred to as the **cervical seal of pregnancy**. Disruption of the cervical seal of pregnancy will generally cause abortion, because microorganisms can gain access to the interior of the uterus, causing infection and subsequent embryonic death.

The Vagina is the Copulatory Organ

The primary function of the vagina is to serve as a copulatory organ, as well as the site for expulsion of urine during micturition. It is also a passive birth

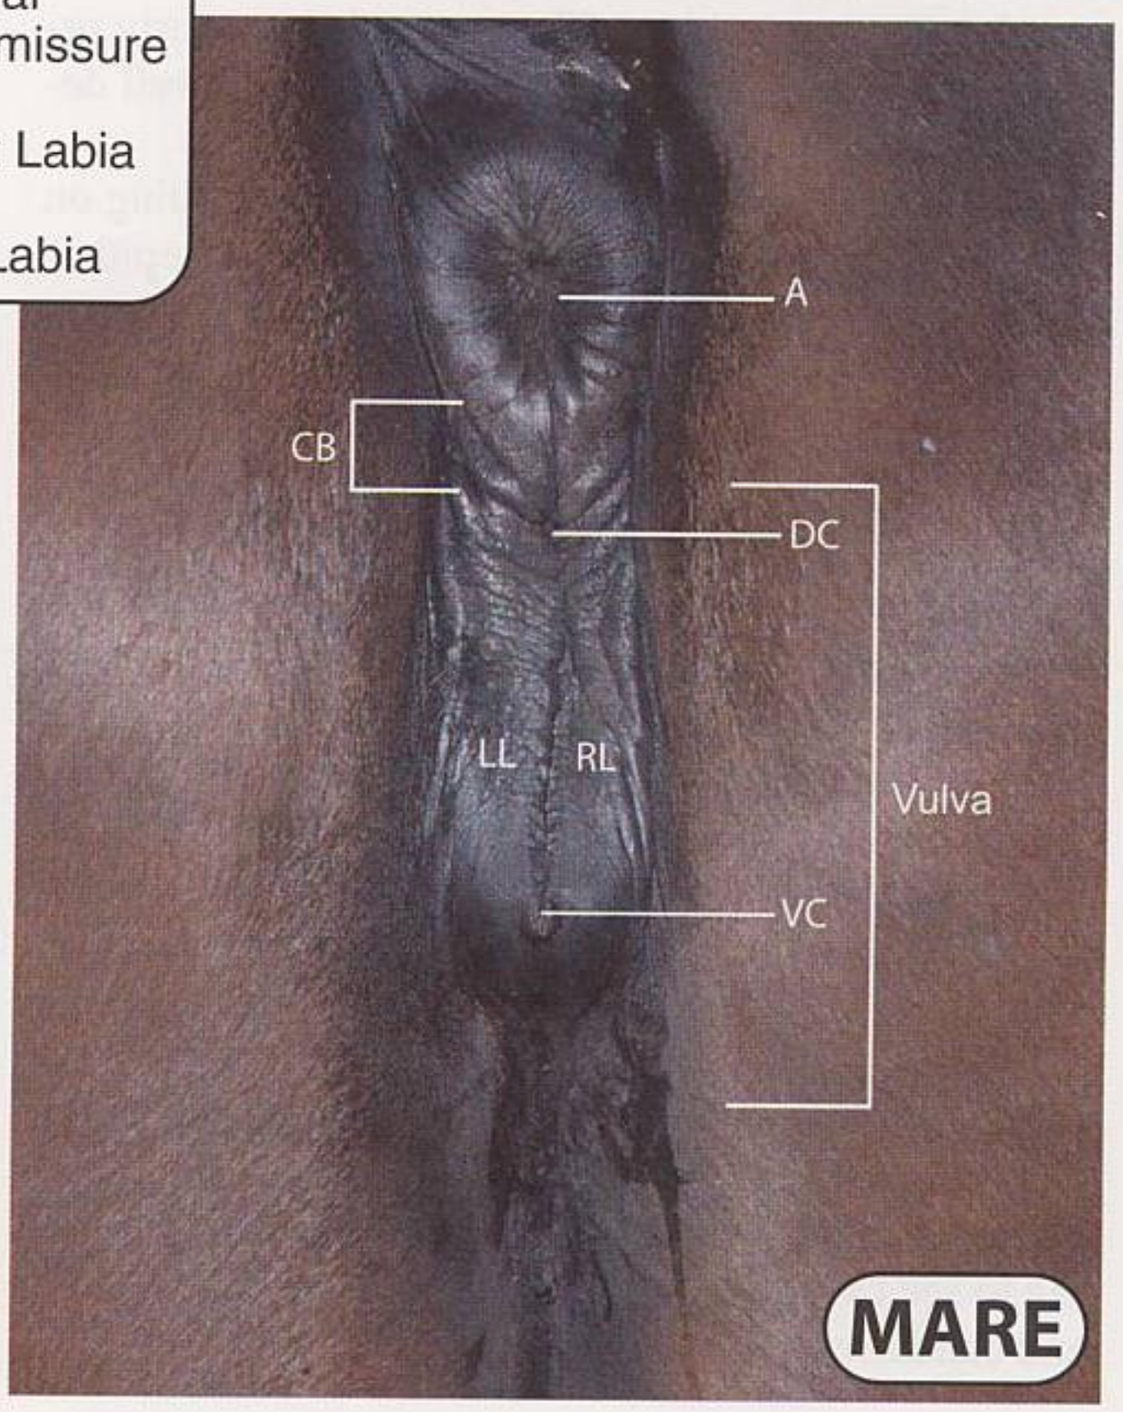

Figure 2-24. External Genitalia

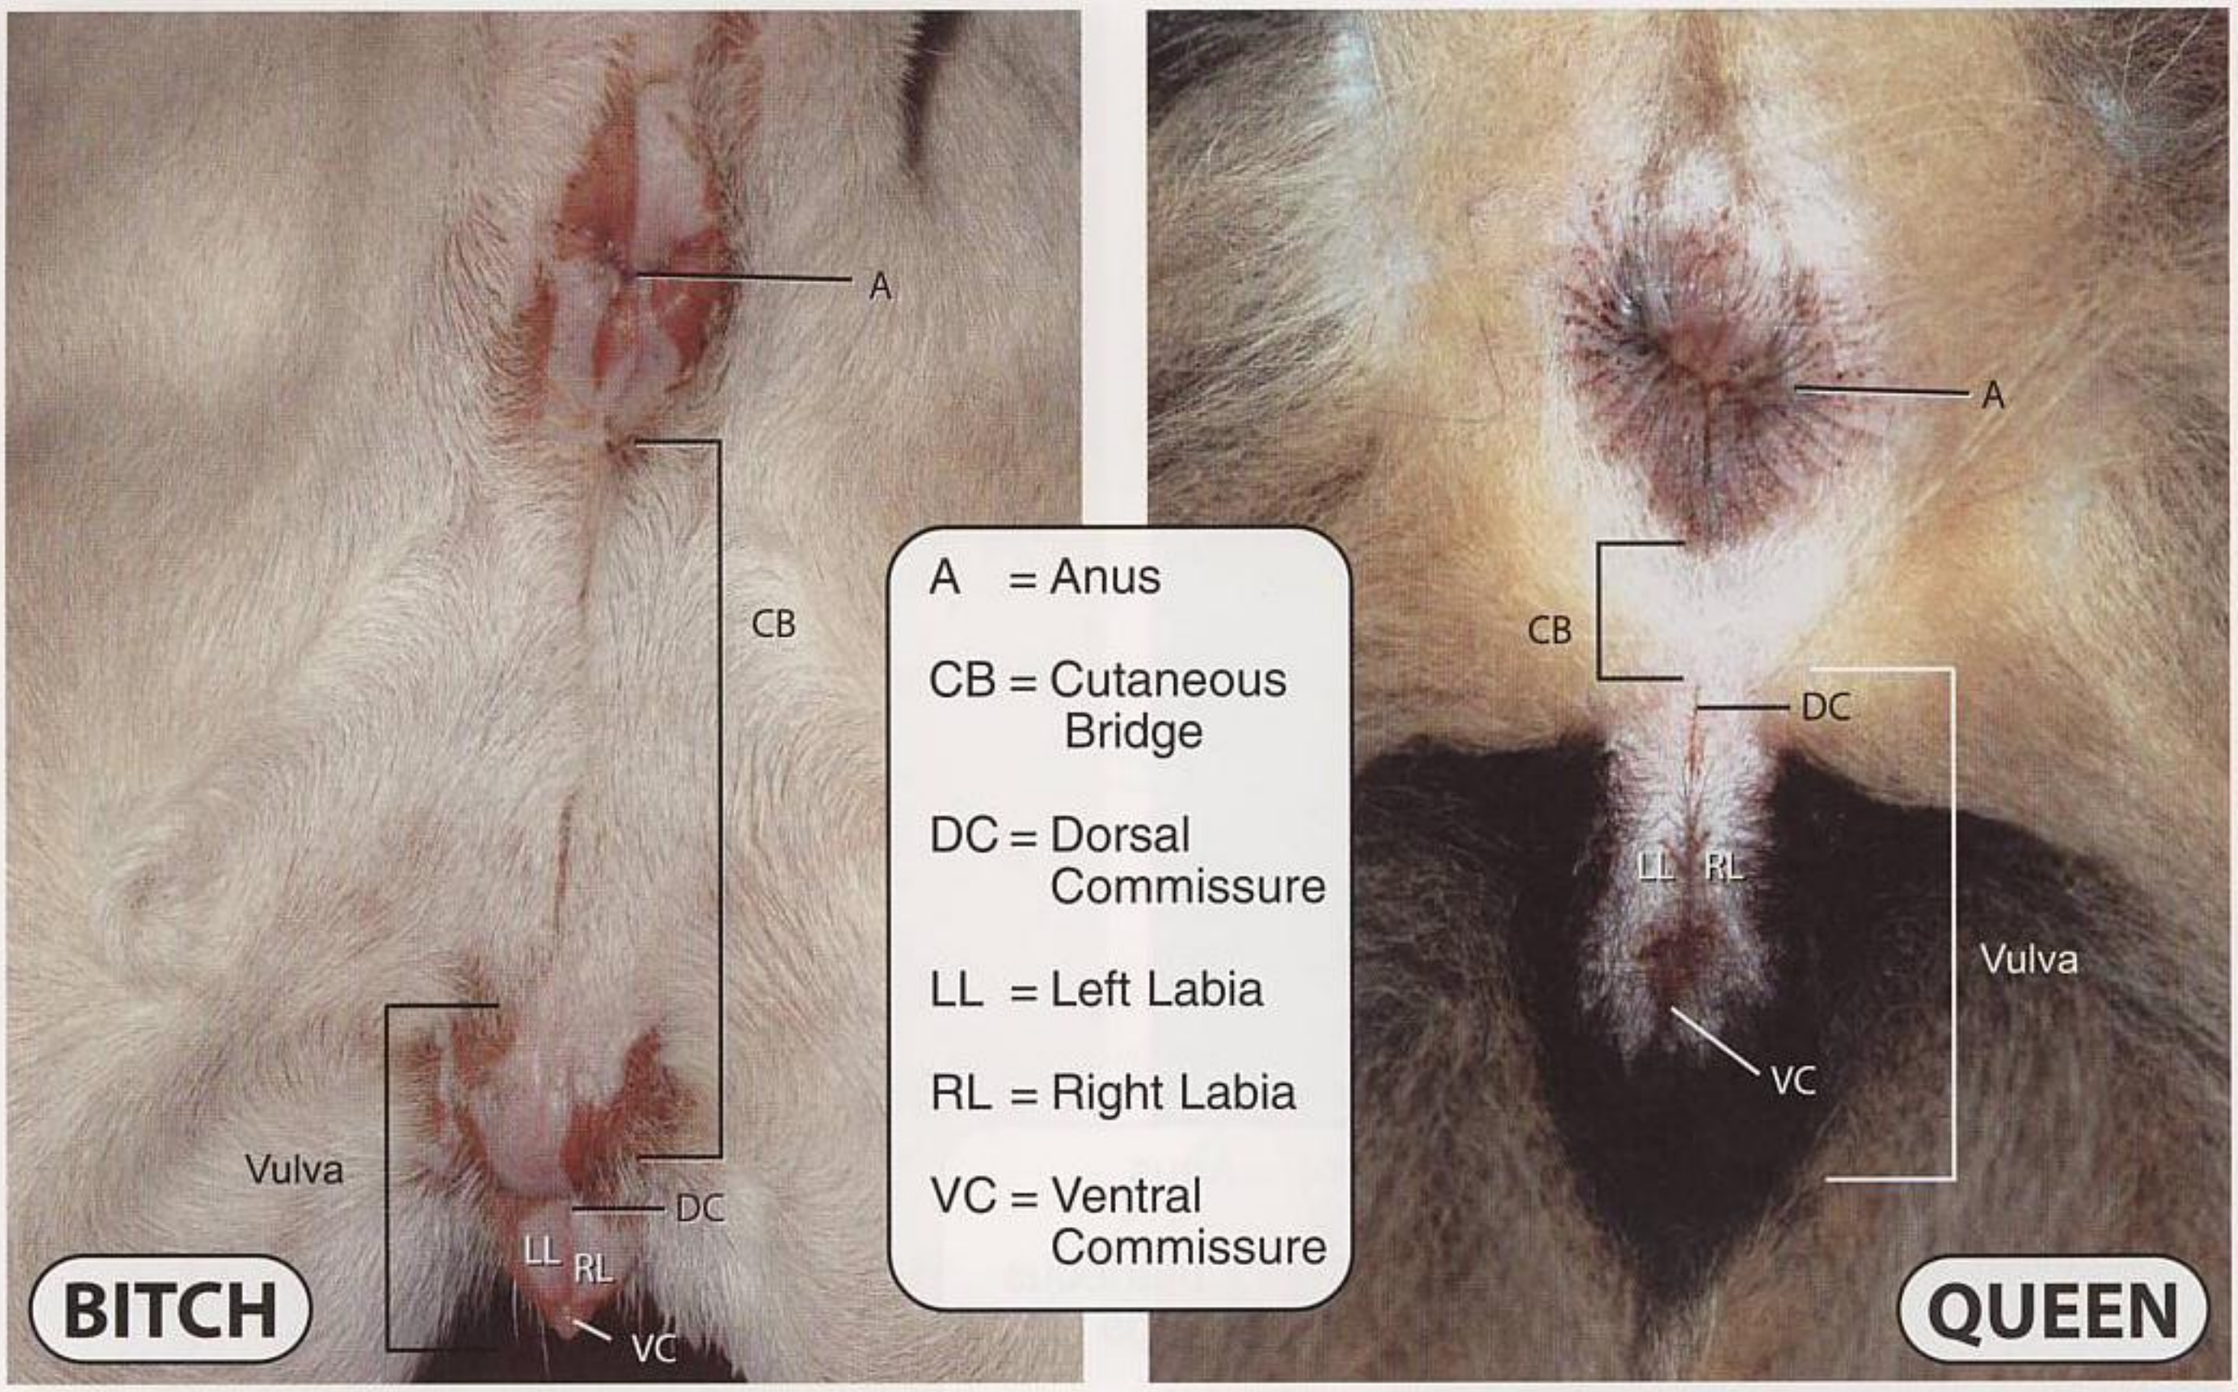

canal during parturition. The vagina has a poorly organized and ill-defined muscular layer and a well developed, highly adapted mucosal epithelium.

The mucosal epithelium varies depending on the specific region of the vagina. The luminal epithelium near the cervix (cranial vagina) is generally columnar and highly secretory in nature. In the cow, mare, and bitch the cervix protrudes into the anterior vagina, forming a crypt, or pocket. This crypt is referred to as the **fornix vagina** (See Figures 2-19 and 2-20). Spermatozoa are deposited in the fornix vagina by the bull during natural service. The fornix vagina is composed of columnar epithelial cells that, as in the cervix, secrete copious quantities of mucus during estrus. The sow does not have a fornix vagina.

Towards its caudal regions, the vagina begins to change its cellular composition. As you will see in Chapter 4, this organ is formed embryologically from two distinct anatomical regions. The cranial vagina originates from the paramesonephric ducts and fuses with the caudal vagina that originates from an invagination of the urogenital sinus. Thus, it is not surprising to see two distinct types of cells lining the cranial and caudal vagina. If you can inspect Figures 2-5, 2-7 and 2-9 you can readily observe the color difference between the vestibule and the vagina. This color difference is because of different epithelial types that make-up the two regions. The cranial vagina is characterized as having a high degree of secretory activity as evidenced by **columnar epithelium**, and some ciliated columnar epithelium. The caudal vagina is characterized as having **stratified squamous epithelium** (the same type of epithelium that comprises the skin) (See Figure 2-22). The degree of secretory activity and the thickness of the stratified squamous epithelium in the caudal vagina change with the endocrine status of the female. During the time of estrogen dominance (estrus), the stratified squamous epithelium thickens dramatically. Such thickening likely serves two protective functions. First, it mechanically protects the vagina during copulation. Secondly, the thickened mucosa prevents microorganisms from gaining entrance to the vasculature in the submucosa.

The vaginal epithelium responds to endocrine changes by changing its thickness. It is possible to exfoliate cells by lavage or swabbing the vagina in some species to determine the stage of the cycle by observing microscopically the type of cells present in

the fluid. For example, vaginal swabs from a bitch in estrus are characterized by containing sheets of squamous cells with distinct epithelial borders with or without nuclei. In the queen and rodents, squamous cells present in vaginal flushings indicate the influence of high estrogen upon the vaginal mucosa.

Since the caudal vagina, or the **vestibule,** develops from the ventral part of the cloaca, it belongs to both the urinary and the genital systems (See Chapter 4). The vestibule is the portion of the vagina that is common to the urinary system and the reproductive system (See Figure 2-22). It extends from the level of the external urethral orifice to the labia of the vulva. In most species, if the floor of the vestibule is carefully dissected, one can encounter **Gartner's ducts**. These often open directly into the vestibule and are blind sacs that represent the remnants of the **Wolffian duct**. These have no apparent function and simply represent an embryonic remnant of the male reproductive system of the embryo.

In the floor of the vestibule of the sow and the cow is a small, blind pouch that lies immediately ventral to the urethral opening. This blind pouch is referred to as the **suburethral diverticulum**. A **diverticulum** is a pouch or sac that diverts a main tube. The function of the suburethral diverticulum is unknown, but sometimes inexperienced inseminators can position the insemination rod or pipette into this blind pouch. Also, this blind pouch can be used as a landmark for the insertion of a urinary catheter to collect urine directly from a cow's bladder.

The vagina of the bitch contains a bulb-like structure that protrudes caudally into the vestibule. It lies directly above the urethral opening (See Figure 2-9). This structure is the **urethral tubercle** and it varies in size among bitches. The functional significance of the urethral tubercle is not known.

The **vulva** is the external part of the female reproductive tract. It consists of two **labia** (major and minor) that meet in the medial portion of the tract to form two **commissures** (sites of union). Under most conditions, the labia form a closure that minimizes the entrance of foreign material into the vagina.

The skin of the labia is part of the integument and has numerous sebaceous and sweat glands and hair follicles. The labia consist mainly of adipose tissue into which are imbedded small bundles of smooth muscle that are known as **constrictor vulvae** muscles. The purpose of these muscles is to insure that the labia stay in close apposition.

In the female, the region that surrounds the anus and the vulva and covers the pelvic outlet is referred to as the **perineum**. Between the dorsal commissure and the anus is a bridge of skin that is sometimes torn during parturition, generally resulting from an oversized or malpositioned fetus.

The ventral commissure of the vestibule houses the **clitoral fossa** (See Figure 2-9) that contains the **clitoris**, the female homologue of the penis. The clitoris is composed of erectile tissue and is covered with stratified squamous epithelium. It is well supplied with sensory nerve endings. The onset of estrus, accompanied by high estrogen levels, generally results in a continuous state of erection of the clitoris. The functional significance of this highly sensitized area has not been well established in domestic animals. However, clitoral stimulation at the time of insemination has been shown to increase conception rates in artificial insemination by up to 6% in beef cows, but not in heifers. The submucosa of the vestibule also houses the **vestibular glands** (also called Bartholin's glands). These glands are located in the caudal portion of the vestibule and actively secrete a mucous-like material during estrus.

Further PHENOMENA for Fertility

Early myths and folklore referred to "vagina dentata" that described a vagina with teeth. Vagina dentata is said to symbolize fear of castration, the dangers of sexual intercourse, of birth, etc.

The female bedbug has a vagina but it is apparently not the copulatory organ. When a male mounts the female bedbug, his penis cannot reach the vagina and therefore he thrusts it through her back and deposits sperm into her body cavity. The sperm lie dormant until the female bedbug sucks blood from her next human host. Once she has engorged her belly with blood the sperm are activated and swim to the ovaries. If a female mates multiple times she is likely to die from multiple stab wounds.

The Italian anatomist Gabriello Fallopius (1532-1562) is perhaps most widely recognized for his description of the oviducts that bear his name (Fallopian tubes). Fallopius, a recognized early authority on syphilis, has been credited with the invention of the condom. His Fallico Liber Absoltismus (published posthumously in 1564) contains a description of a "linen sheath" that is credited with decreasing the spread of syphilis that was very prevalent in Europe during his lifetime.

The word "hysterectomy" means surgical removal of the uterus. The word is derived from a notion espoused by Plato (347-266 BC). He thought that the uterus was a multichambered organ that could wander about the body causing hysteria in the host woman. He thought that if a woman went too long without becoming pregnant her uterus would become indignant and would wander around the body causing extreme anxiety, hysteria, respiratory insufficiency and all sorts of diseases. The cure was removal of the uterus that removed the possibility of hysteria and disease. In spite of its ancient and erroneous origin the term hysterectomy is still used today in the highest level of medical and scientific practice. A more descriptive term for removal of uterus would be "uterectomy". Author's Theory: This myth probably was originated by Greek males who recognized that pregnancy required copulation. The anxiety / disease causing fable "legitimized" their desire for frequent copulation.

Most birds have only a left ovary and oviduct that are functional. Some birds have two functional ovaries, but only the left oviduct is functional. Thus, when the right ovary ovulates there is nowhere for the oocyte to go except into the body cavity, where it is reabsorbed (the truest form of recycling). The oocyte cannot enter the left oviduct because a mesentery separates the right ovary from the left oviduct.

In the female hyena, the clitoris is very well developed. In fact, it is so well developed that it is almost impossible to distinguish the male hyena from the female hyena. The female also has a false scrotum. Of further note is the fact that the female is the dominant sex and produces as much or more testosterone than the typical male.

After mating, the female bumblebee eel worm undergoes a remarkable transformation. Her vagina actually inflates until it is almost 20,000 times larger than she is. At this point, the female's body is no longer needed, and it shrivels-up and disintegrates. However, as soon as the eggs within the vagina hatch and a new generation of worms emerge, the vagina also disintegrates.

In the small fish known as the Four-Eyed Anablep, the female's vagina is either on the left or the right. In the male, the penis is either on the right or the left. A male with a right penis must mate with a female with a right vagina and vice versa.

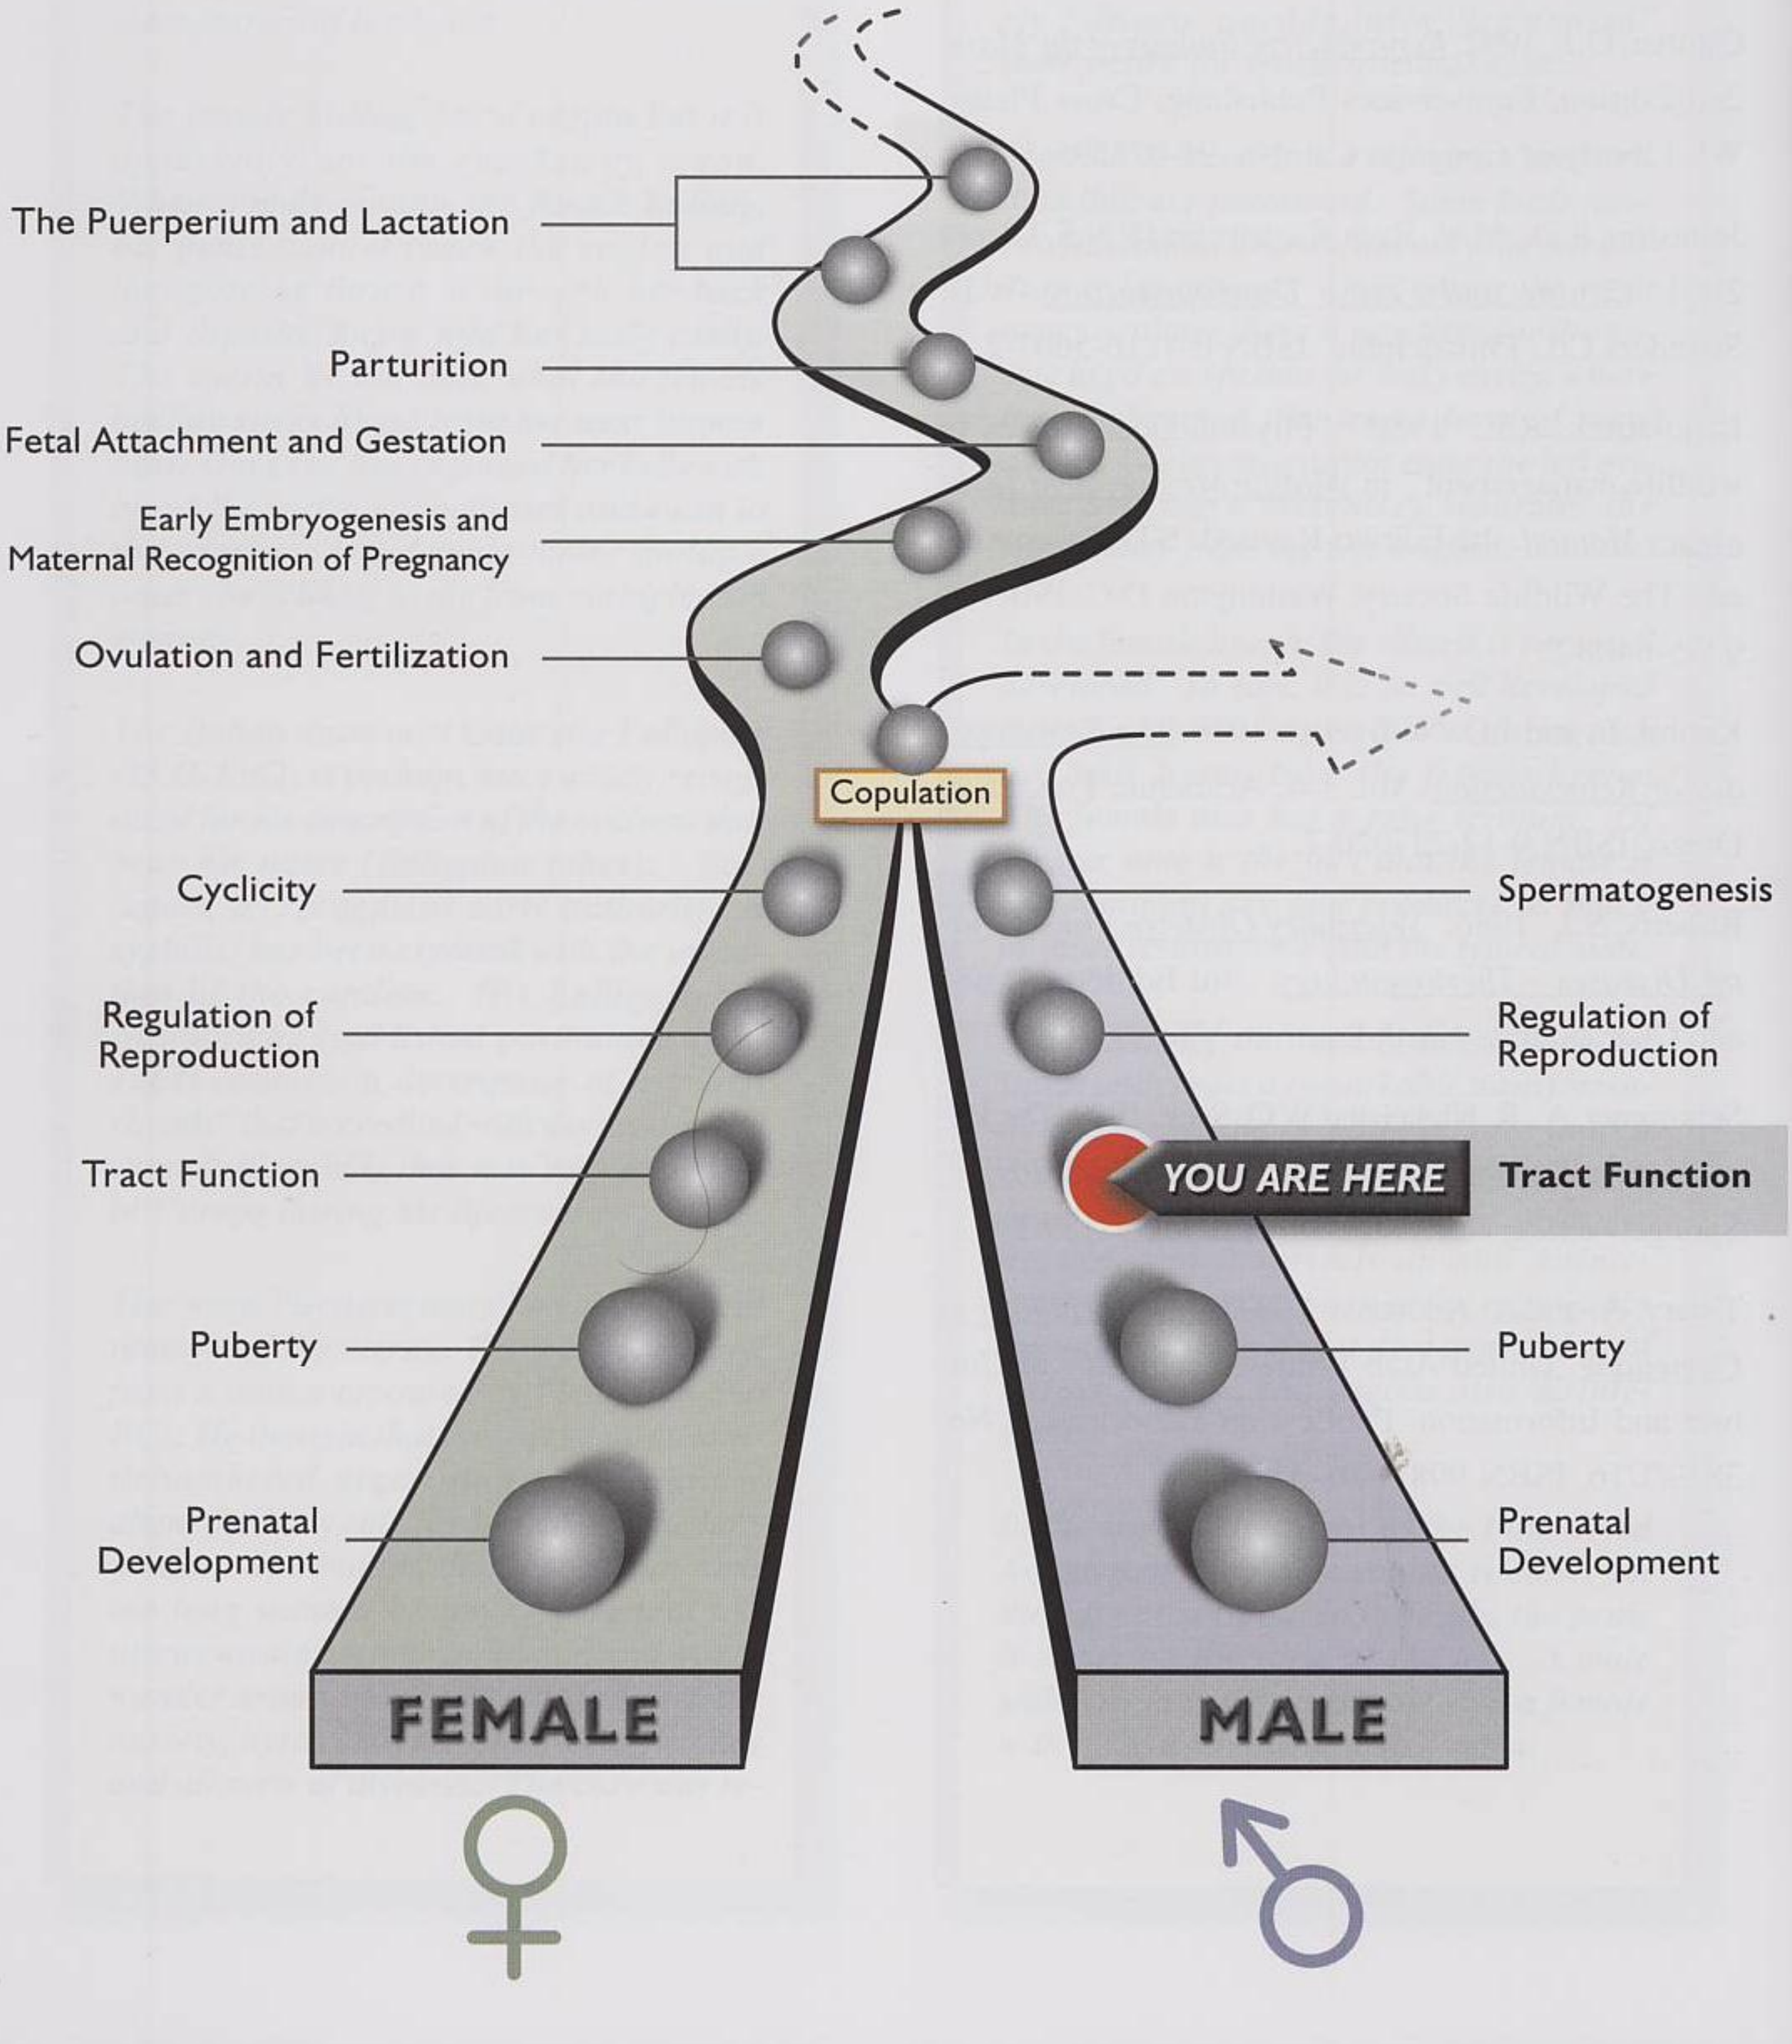
CHAPTER 3

The Organization and Function of the Male Reproductive System



Take Home Message

The male reproductive system consists of the spermatic cord, testis, epididymis, accessory sex glands and the penis. The testis produces spermatozoa and testosterone, as well as other substances such as inhibin, estrogen and a variety of proteins. The epididymis provides the environment for final maturation of spermatozoa and serves as a storage organ for these cells. The accessory sex glands produce seminal plasma and the penis is the copulatory organ.

The male reproductive system is analogous to a manufacturing complex (See Figure 3-1). The primary products of the "manufacturing" process are fertile spermatozoa. Hormones (such as testosterone) and other secretory products (epididymal fluid and seminal plasma) of the male system contribute to the efficiency of the overall manufacturing and delivery process.

The **testes** serve as the manufacturing and assembly plant for spermatozoa and have an immense potential output of spermatozoa. In fact, spermatozoal production in mammals ranges from < 1 to 25 billion spermatozoa per day for both testes in normal males. This computes to an amazing production rate of around 35,000 to 200,000 spermatozoa per second. In most mammals the testes descend outside of the body into the scrotum. A specialized cooling mechanism is required for successful **spermatogenesis** (production of sperm). Once produced, spermatozoa pass through the rete tubules and the efferent ducts, and enter the **head** (caput) and **body** (corpus) of the **epididymis** (the "finishing shops"). In the head and body of the epididymis, spermatozoa undergo changes that allow them to become fertile. After gradual transport through the body and head over several days, spermatozoa enter the **tail** (cauda) of the epididymis. The tail of the epididymis is equivalent to a warehouse and shipping center. Spermatozoa in the tail of the epididymis are capable of fertilization and are motile if diluted into an appropriate buffer solution. The tail of the epididymis serves as a storage organ for spermatozoa prior to ejaculation and, in the sexually inactive male, may contain 4 to 8 days production of sperm. In males who are ejaculating with regular frequency, fewer sperm may be found. Upon sexual excitation, the spermatozoa in the tail of the epididymis are "shipped" via contractions of the epididymal duct and the **ductus deferens** to a new location in the reproductive tract, the **pelvic urethra**. Final alterations and packaging take place during emission when spermatozoa are mixed with fluids produced by the **accessory sex glands**. Collectively this mixture of fluids (from the epididymal tail and the accessory sex glands) is known as **seminal plasma**. Mixing of seminal plasma with spermatozoa causes dilution and undoubtedly some biochemical and surface changes that facilitate spermatozoal function. Once sperm are mixed with seminal plasma, they are available for delivery by ejaculation. The delivery system is the **penis** and specific muscles are responsible for **erection**, **protrusion of the penis** and **ejaculation** of semen.

The remainder of the chapter will assist you in developing knowledge about the anatomy and function of the specific components of the male reproductive system.

The basic components of the male reproductive system are the:

- ***spermatic cord***
- ***scrotum***
- ***testis***
- ***excurrent duct system***
- ***accessory sex glands***
- ***penis and muscles for protrusion, erection and ejaculation***

The Spermatic Cord Connects the Testis to the Body

The **spermatic cord** extends from the inguinal ring (the passageway from the body cavity into the scrotum) to its attachment on the dorsal pole of the testis. It suspends the testis in the scrotum (See Figures 3-2 through 3-8). It is most highly developed in males like the ram and bull that have a pendulous scrotum. The spermatic cord provides the pathway to and from the body for the testicular vasculature, lymphatics and nerves. The spermatic cord also houses the ductus deferens, the **cremaster muscle** and a specialized vascular network called the **pampiniform plexus**.

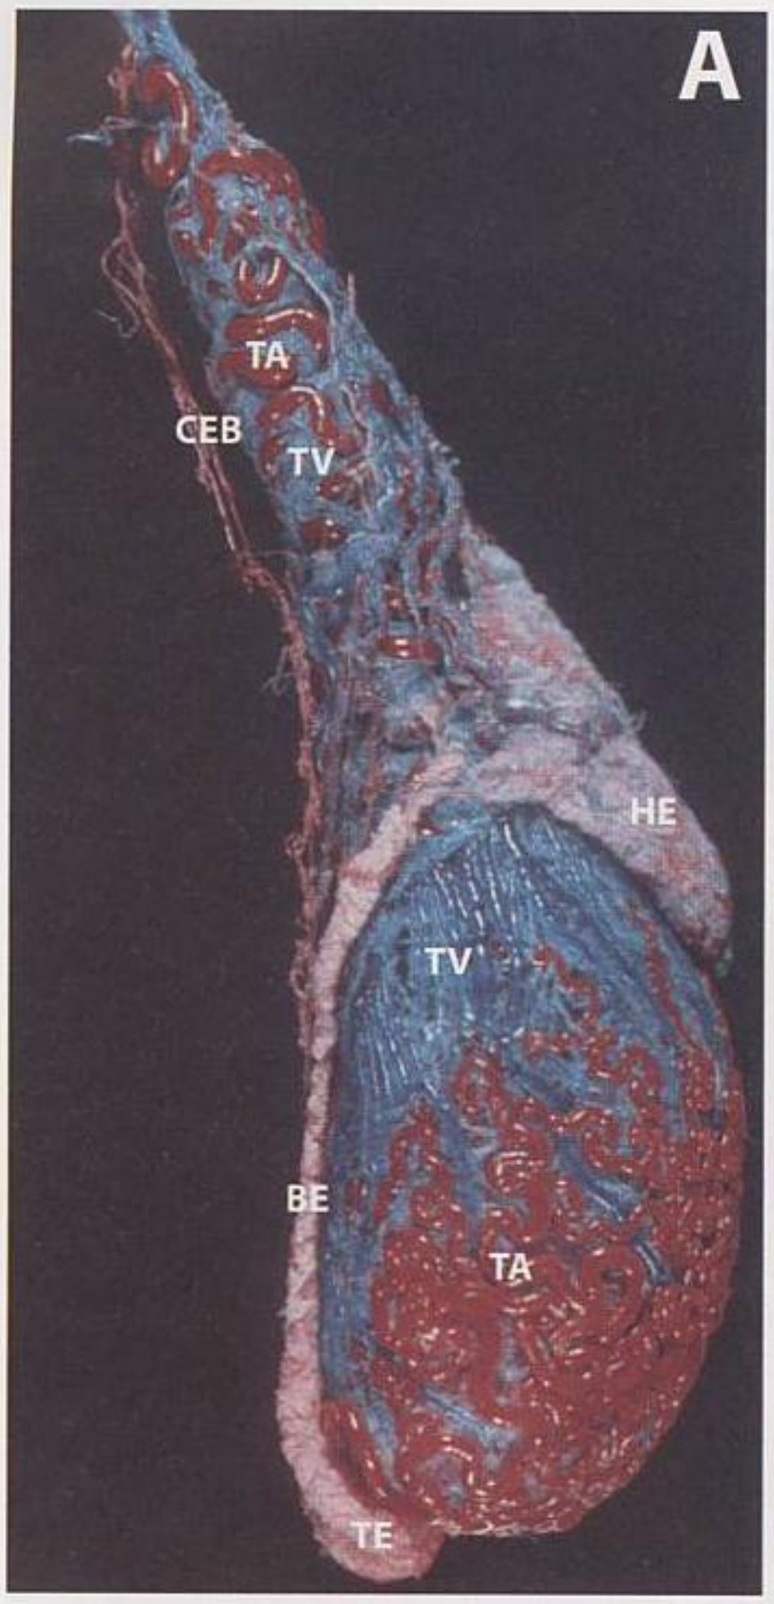
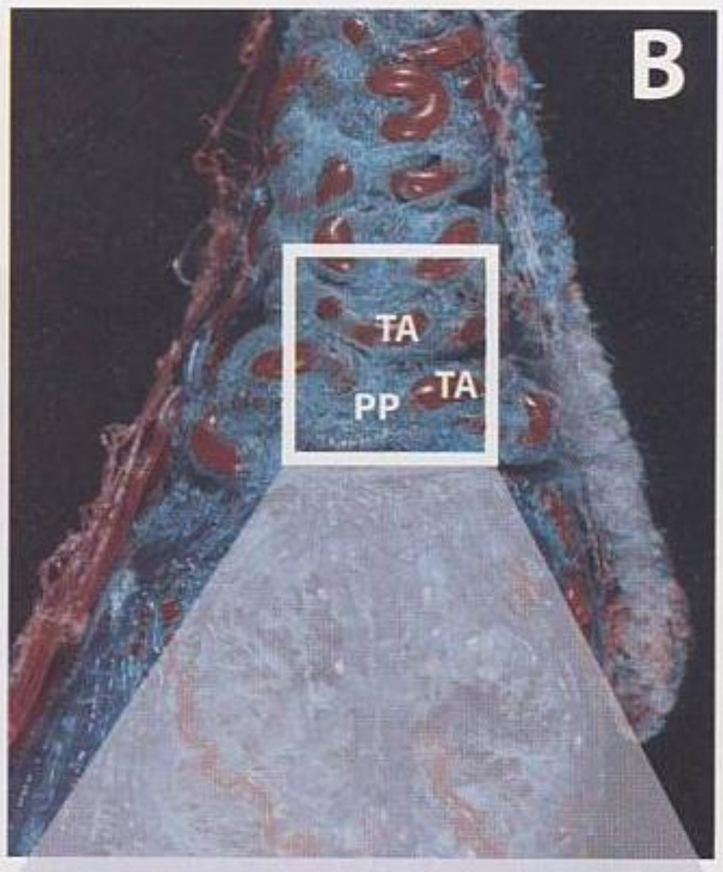
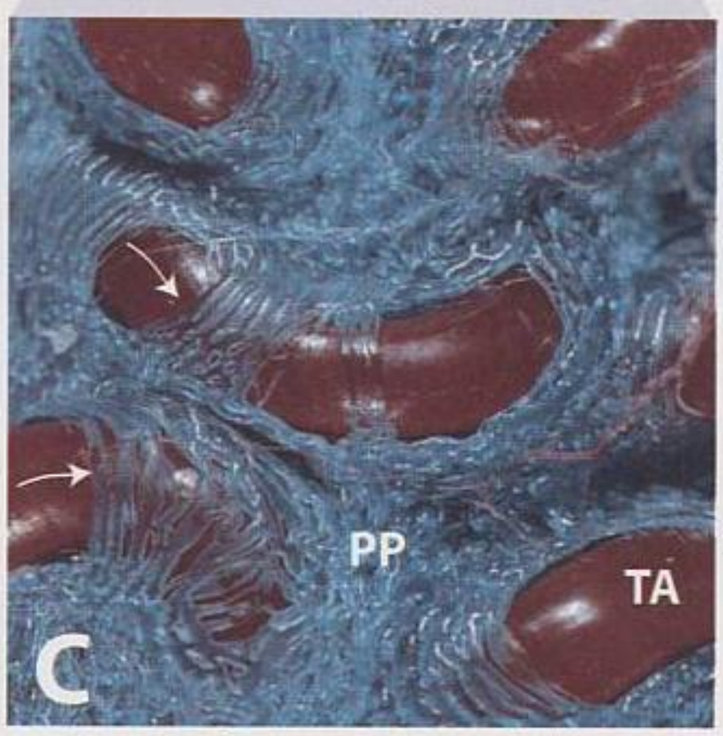
Figure 3-9. Vascular Heat Exchanger







(Photos from Cody, et al. 1999. *Biol. Repod.* 60(suppl.1):90)

A

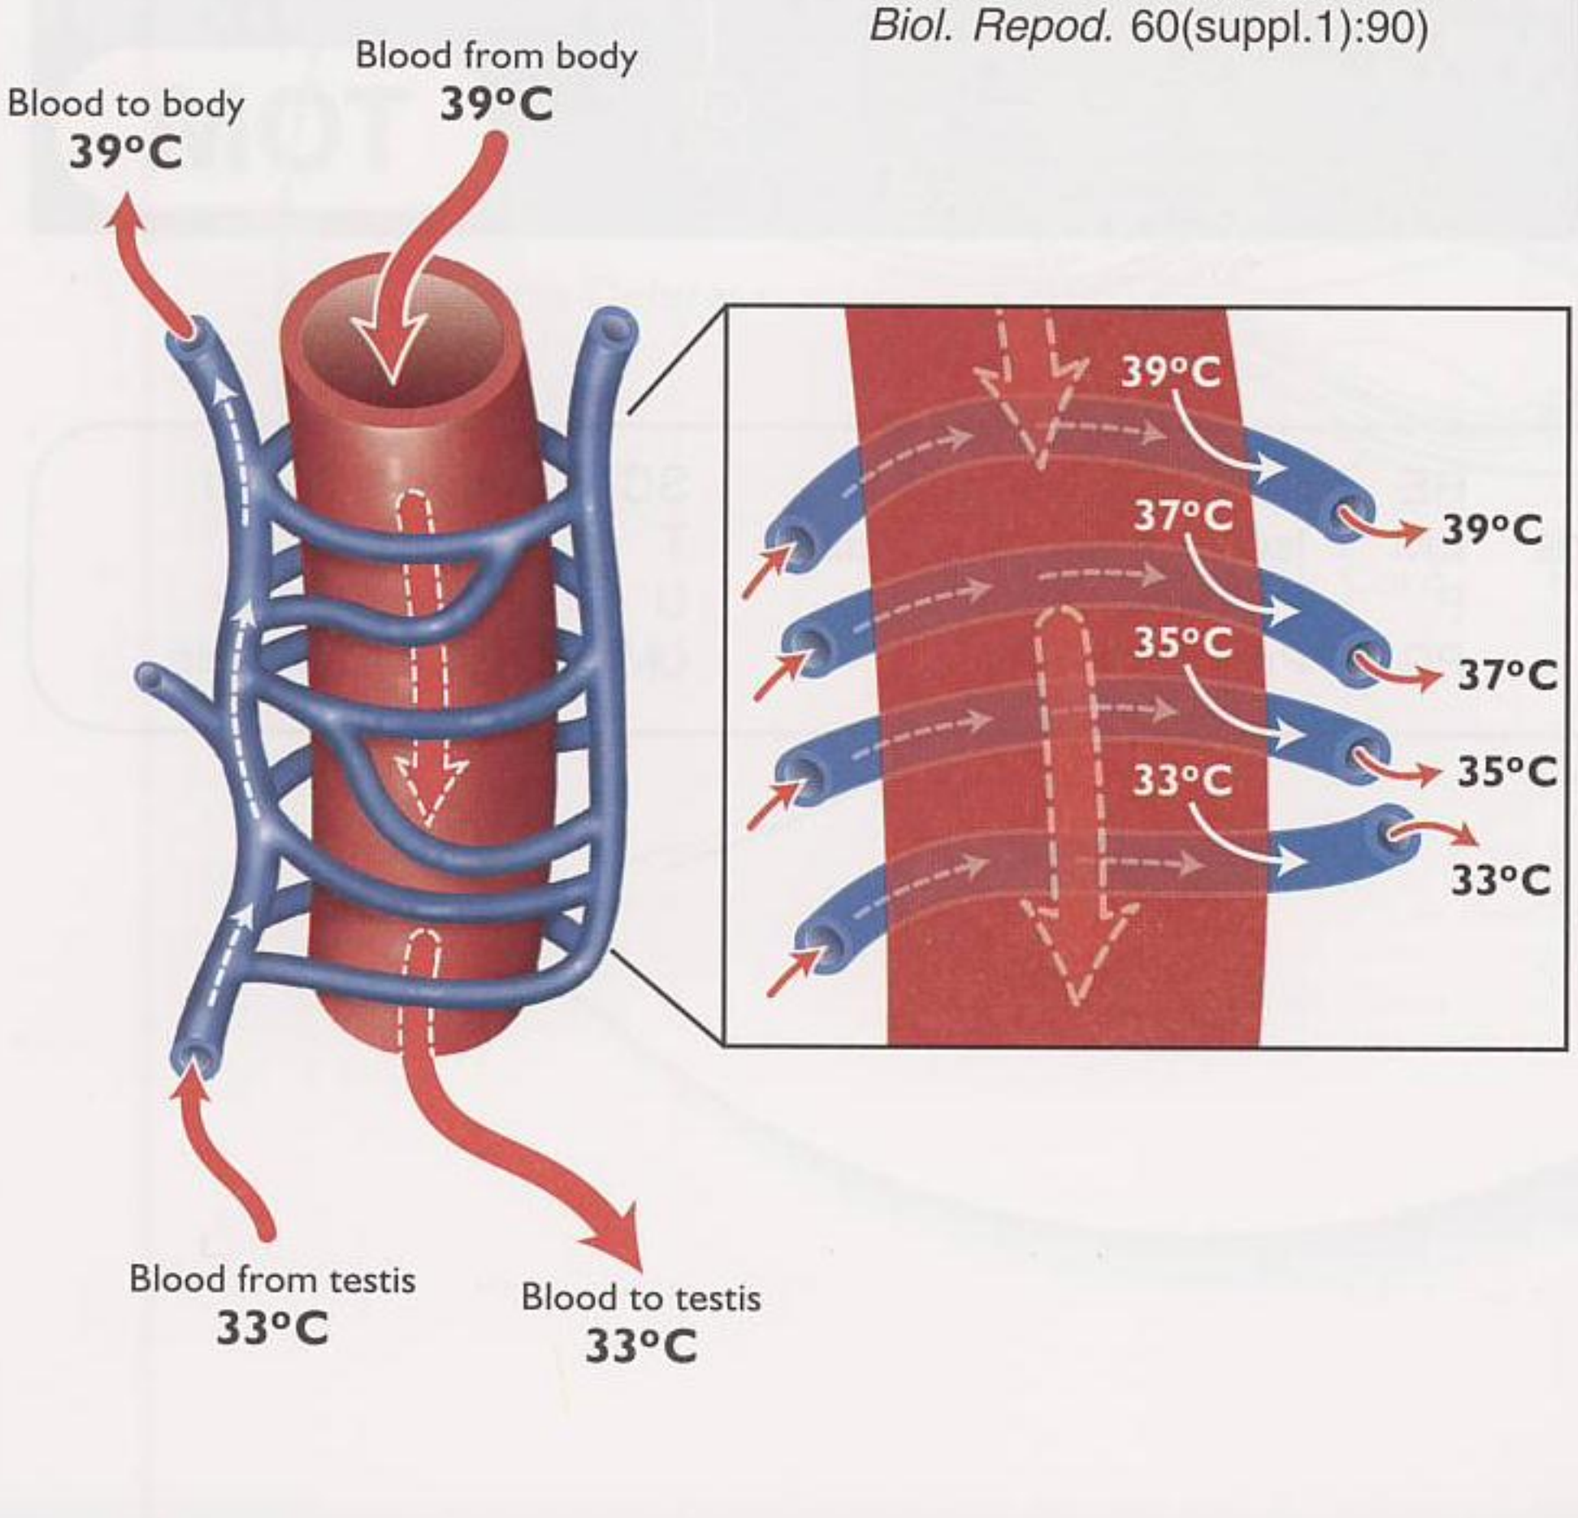
This photo enables visualization of the arterial and venous blood supply to the bull testis and epididymis. The testicular artery (TA) is highly convoluted and passes through the spermatic cord and surrounds the testis in the ventromedial area. In the spermatic cord, the testicular veins (TV) are in close proximity to the tortuous testicular artery. The testicular veins (TV) seen on the surface of the testicle return venous blood to the spermatic cord. A branch of the testicular artery, the caudal epididymal branch (CEB) can be observed. The head of the epididymis (HE), body of the epididymis (BE) and tail of the epididymis (TE) can be seen.

B

An enlarged view of a portion of the vascular cone. The highly convoluted testicular artery (TA) has an intimate relationship with the veins of the pampiniform plexus (PP).

C

A highly enlarged photograph showing the intimate relationship of the pampiniform plexus with the testicular artery (TA). Notice the finger-like "wrappings" (arrows) of the pampiniform plexus surrounding the testicular artery (TA). This intimate relationship provides the anatomical basis for the countercurrent heat exchanger.



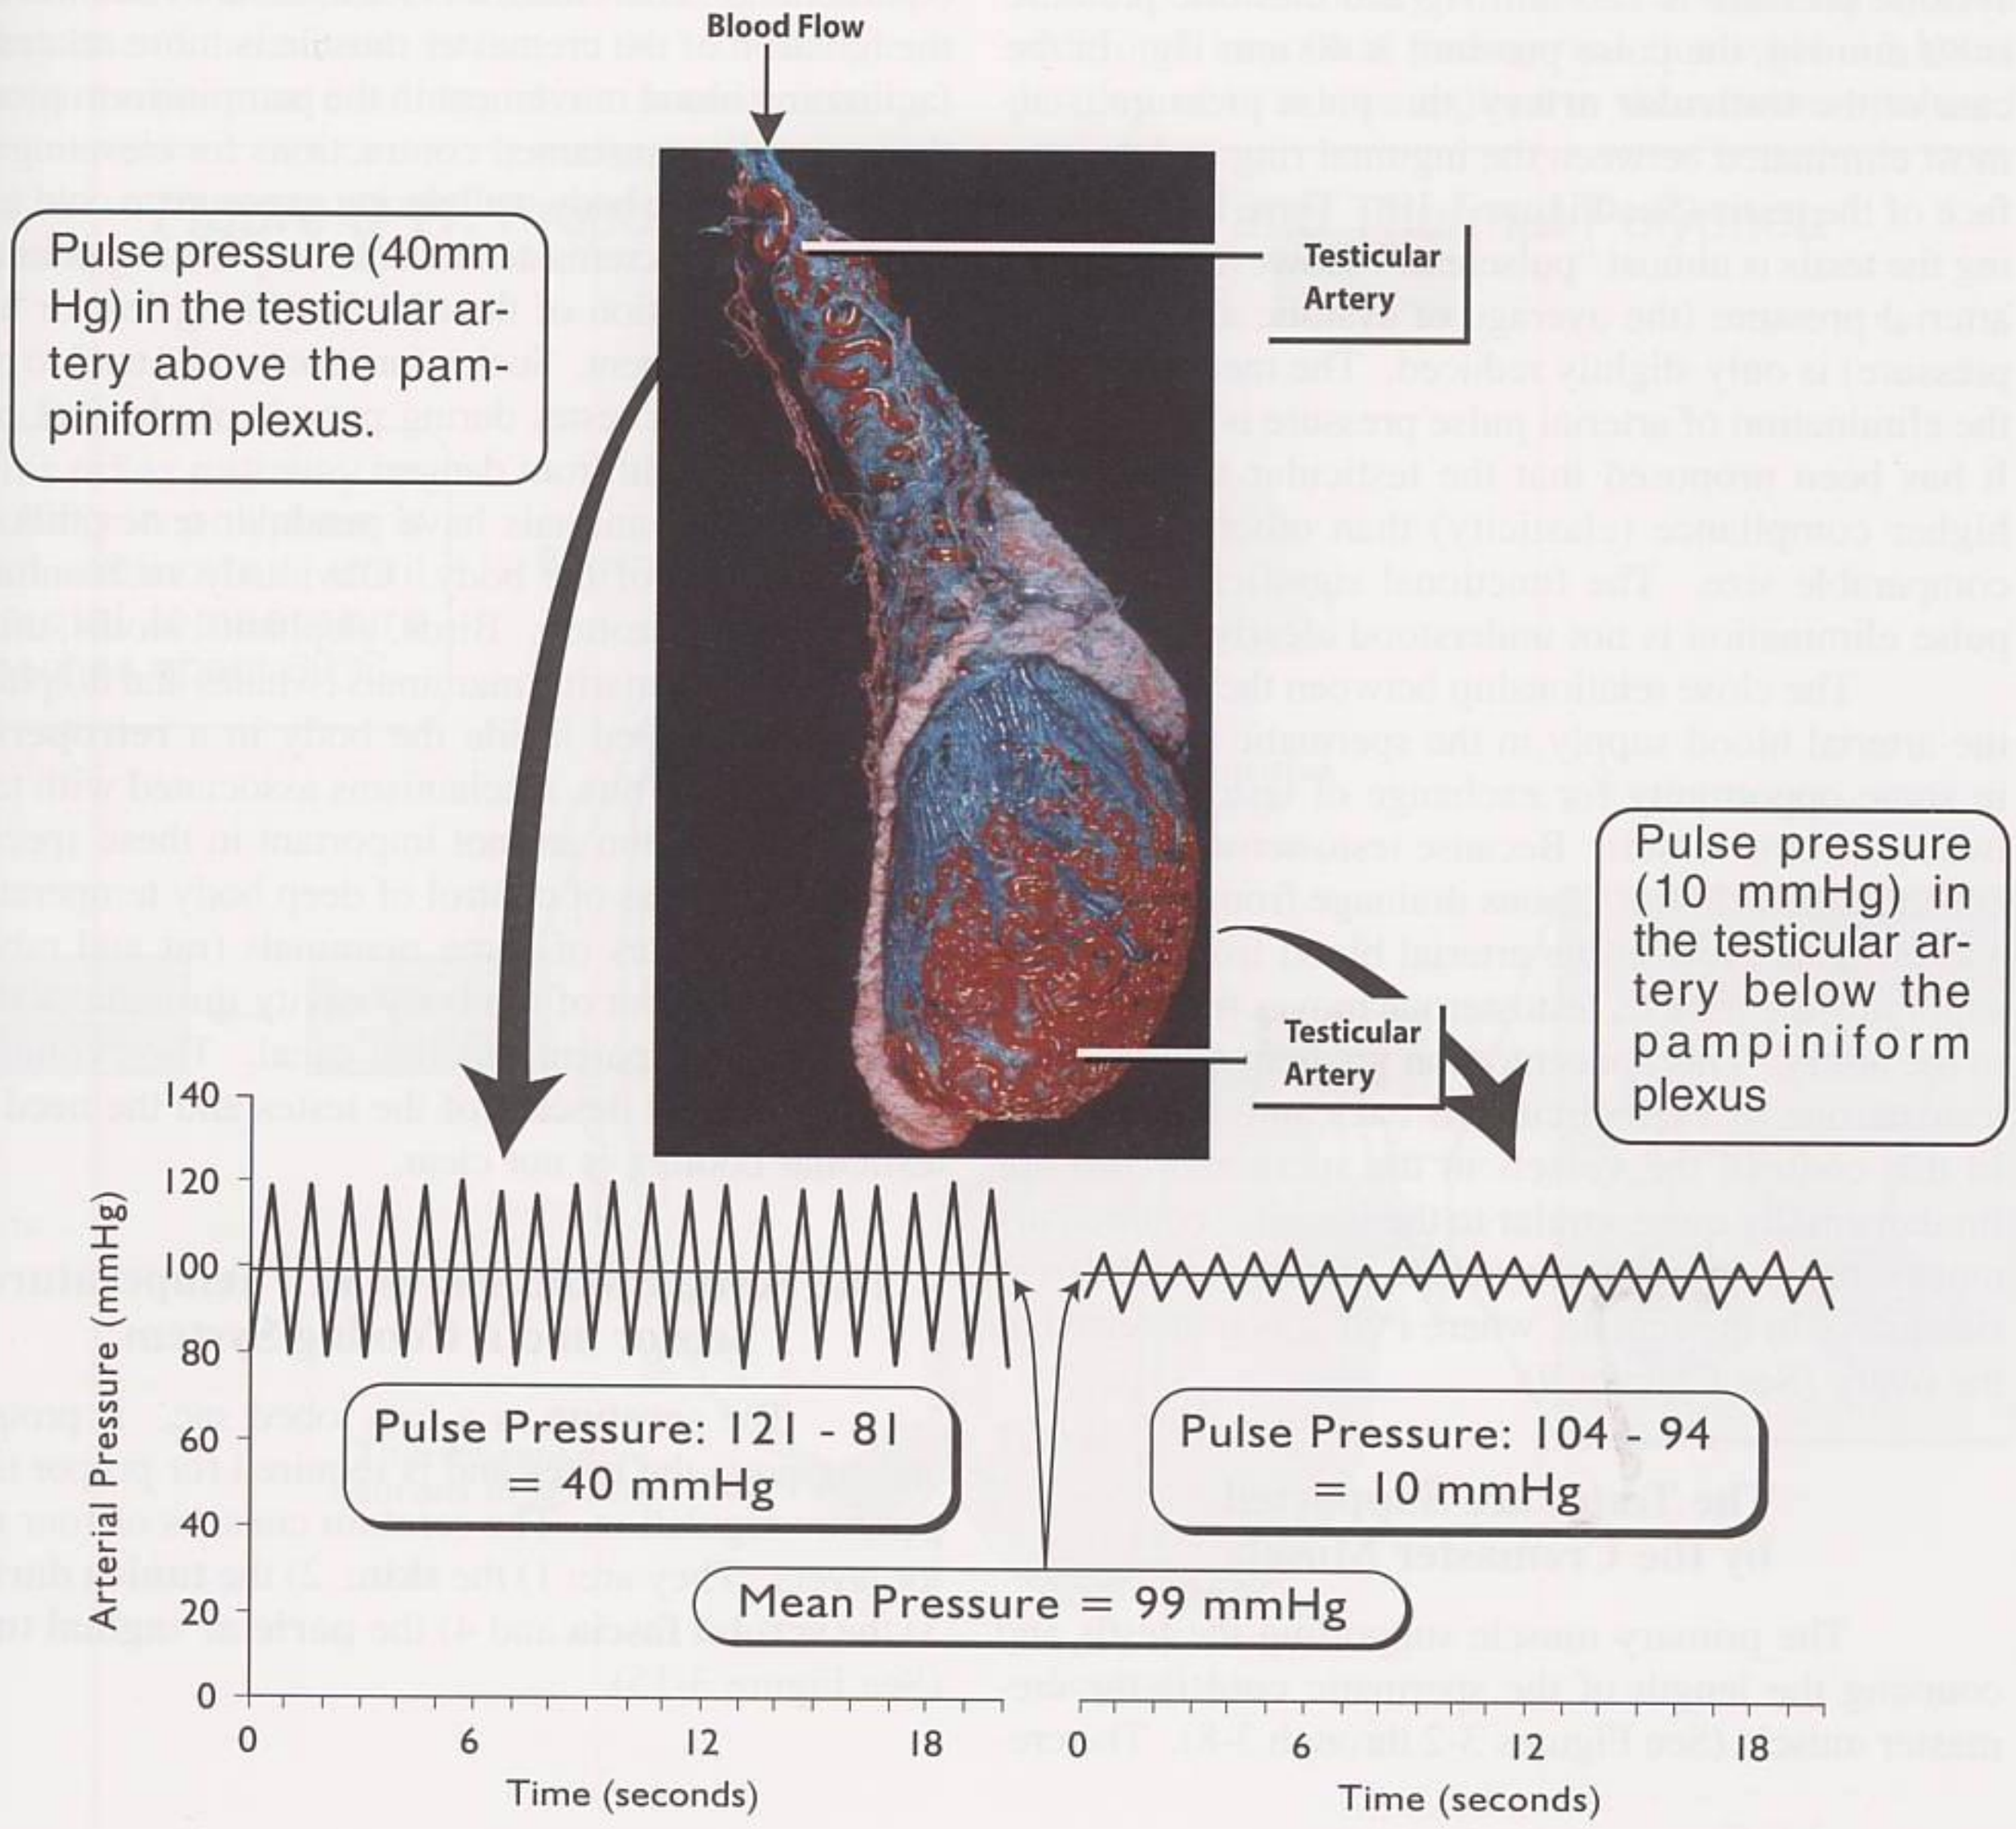
A large (6°C) temperature gradient exists between the body and the testes. Warm (39°C) arterial blood coming from the body is cooled on its way to the testis because the artery lies in close apposition to the veins that are returning cooler blood (33°C) from the testes.

The functions of the spermatic cords are to:

- *provide vascular, lymphatic and neural connection to the body*
- *provide a heat exchanger*
- *house the cremaster muscle*

The majority of the spermatic cord mass consists of the testicular artery and veins. The **testicular artery** branches from the abdominal aorta and is rather straight until it passes through the inguinal canal. Thereafter it becomes highly convoluted (See Figure 3-9). The testicular veins in the spermatic cord branch into an elaborate network that forms many intimate finger-like "wrappings" surrounding the highly convoluted testicular artery. This venous network is called the **pampiniform plexus**. The pampiniform plexus eventually forms a single vein that runs into the caudal vena cava. These relationships are illustrated in Figure 3-9. These highly specialized structures are important for proper temperature control of the testis. In most mammals, the testes must be 4 to 6°C cooler than the body

Figure 3-10. Pulse Pressure Elimination in the Spermatic Cord



in order for spermatogenesis to occur. The complex, intimate network of the spermatic artery and the spermatic veins forms a **countercurrent heat exchanger** (See Figure 3-9). Heat from the warm (39°C) arterial blood from the body is transferred to the cooler (33°C) venous blood leaving the surface of the testes (See Figure 3-9). This venous blood has been cooled by direct heat loss from the testicular veins through the skin of the scrotum. Maintenance of low testicular temperature is obligatory for spermatogenesis in domestic animals and man. Disruption or modification of this cooling mechanism will severely compromise, if not completely suppress, spermatogenesis.

The long convoluted testicular artery serves as a **pulse pressure eliminator**. Pulse pressure exists in all arteries throughout the body. Pulse pressure is what you feel when you palpate the radial artery in your wrist or the carotid artery in your neck. It is the difference between **systolic pressure** (heart contraction) and **diastolic pressure** (heart relaxation). For example, if systolic pressure is 120 mm Hg and diastolic pressure is 80 mm Hg, the pulse pressure is 40 mm Hg. In the case of the **testicular artery**, this pulse pressure is almost eliminated between the inguinal ring and the surface of the testis (See Figure 3-10). Thus, blood entering the testis is almost "pulseless." However, the mean arterial pressure (the average of systolic and diastolic pressure) is only slightly reduced. The mechanism for the elimination of arterial pulse pressure is not known. It has been proposed that the testicular artery has a higher compliance (elasticity) than other arteries of comparable size. The functional significance of this pulse elimination is not understood clearly.

The close relationship between the venous and the arterial blood supply in the spermatic cord results in some opportunity for exchange of testosterone between the two vessels. Because testosterone is at high concentrations in the venous drainage from the testicle and levels are low in the arterial blood from the body supplying the testicle, testosterone moves from the vein to the artery. This concentration gradient allows some testosterone to be recirculated back into the testicle. In this context, the vessels in the spermatic cord are fundamentally quite similar to the vascular countercurrent exchange system between the uterine vein and ovarian artery in the female, where $PGF_{2\alpha}$ is transferred to the ovary (See Chapter 9).

The Testes are Supported by the Cremaster Muscle

The primary muscle supporting the testis and coursing the length of the spermatic cord is the cremaster muscle (See Figures 3-2 through 3-8). The cremaster is a striated muscle that is continuous with the internal abdominal oblique muscle. It helps support the testis and aids in control of testicular temperature. Its temperature control function is probably related to the fact that when the cremaster muscle contracts and relaxes, it creates a "pumping action" on the pampiniform plexus, thus facilitating blood flow and enhancing cooling efficiency. Blood flow returning to the body from the testes is quite sluggish because the pressure is quite low in this high surface area plexus and there are no frequent muscle contractions to enhance venous return (like in the legs). Contractions of the cremaster muscle promote venous return of testicular blood and thus facilitates heat exchange. In some species (the ram and, to some degree, the bull) sexual excitation promotes a high degree of intermittent contractile activity of the cremaster muscle. During sexual excitation the testes move up and down in a rapid manner. Unlike the smooth muscle in the scrotum (**tunica dartos**), the cremaster muscle is not capable of sustained contractions. Therefore, it is reasonable to assume that the function of the cremaster muscle is more related to facilitating blood movement in the pampiniform plexus than providing sustained contractions for elevating the testes close to the body wall during exposure to cold temperatures. The cremaster muscle may be important in short-term elevation of the testicles during fear or high planes of excitement. Such a function would tend to protect the pendular testes during periods of physical confrontation or flight from danger.

Not all animals have pendular testes that are located outside of the body. Obviously such animals do not have a scrotum. Birds, elephants, sloths, armadillos and some marine mammals (whales and dolphins) have testes located inside the body in a **retroperitoneal** position. Thus, mechanisms associated with temperature regulation are not important in these species, except where loss of control of deep body temperature occurs. The testes of some mammals (rat and rabbit) move into and out of the body cavity throughout their lives through a patent inguinal canal. The evolutionary basis for the descent of the testes and the need for testicular cooling is not clear.

The Scrotal Skin Serves as a Temperature Sensor and a Cooling System

The **scrotum** is a two lobed sac. It protects and supports the testes and is required for proper temperature regulation. The scrotum consists of four major layers. They are: 1) the **skin**; 2) the **tunica dartos**; 3) the **scrotal fascia** and 4) the **parietal vaginal tunic** (See Figure 3-15).

The scrotum is a:

- ***thermosensor***
- ***swamp cooler***
- ***protective sac***

The scrotal skin is heavily populated with sweat glands. These sweat glands are required for maintenance of proper testicular temperature. The scrotal sweat glands are innervated by sympathetic nerves (See Figure 3-11). When the male experiences either elevated body temperature or elevated scrotal temperature, the hypothalamus detects this change and sends nerve impulses to the sweat glands. Sweating allows the scrotum (and thus the testes) to be cooled by evaporative heat transfer, like a swamp cooler.

The scrotal skin is endowed with large numbers of thermosensitive nerves. These sensory nerves govern both the degree of scrotal sweating and respiratory rate of the animal. In fact, in the ram changes in scrotal temperature can bring about dramatic changes in respiratory rate. For example, the rate of respiration of fully fleeced Merino rams begins to increase gradually when the skin temperature of the scrotum rises above 36°C. If the temperature of the scrotal skin continues to increase (40-42°C), the respiratory rate will increase suddenly and the ram will begin to pant (polypnea). Respiratory frequencies as high as 200 breaths per minute can occur under these conditions (See Figure 3-13). Warming an equivalent area of the flank or other parts of the body results in only small increases in respiratory rate. This response clearly shows that there is a highly developed neural pathway originating in the scrotum and terminating in the respiratory center of the brain (See Figure 3-11).

While cooling of the testes is obligatory for normal spermatogenesis, constant cooling does not appear to be necessary. For example, Australian researchers found that exposure of the scrotum to hot temperatures for periods of 16 hours per day did not influence sperm production rates. But after 8 hours or more of heat exposure motility was reduced significantly. An additional important finding was that when 16 hours per day of heat was applied to the scrotum, reduced

Figure 3-11. Proposed Scrotal Sweating and Thermal Polypnea Pathways in Rams

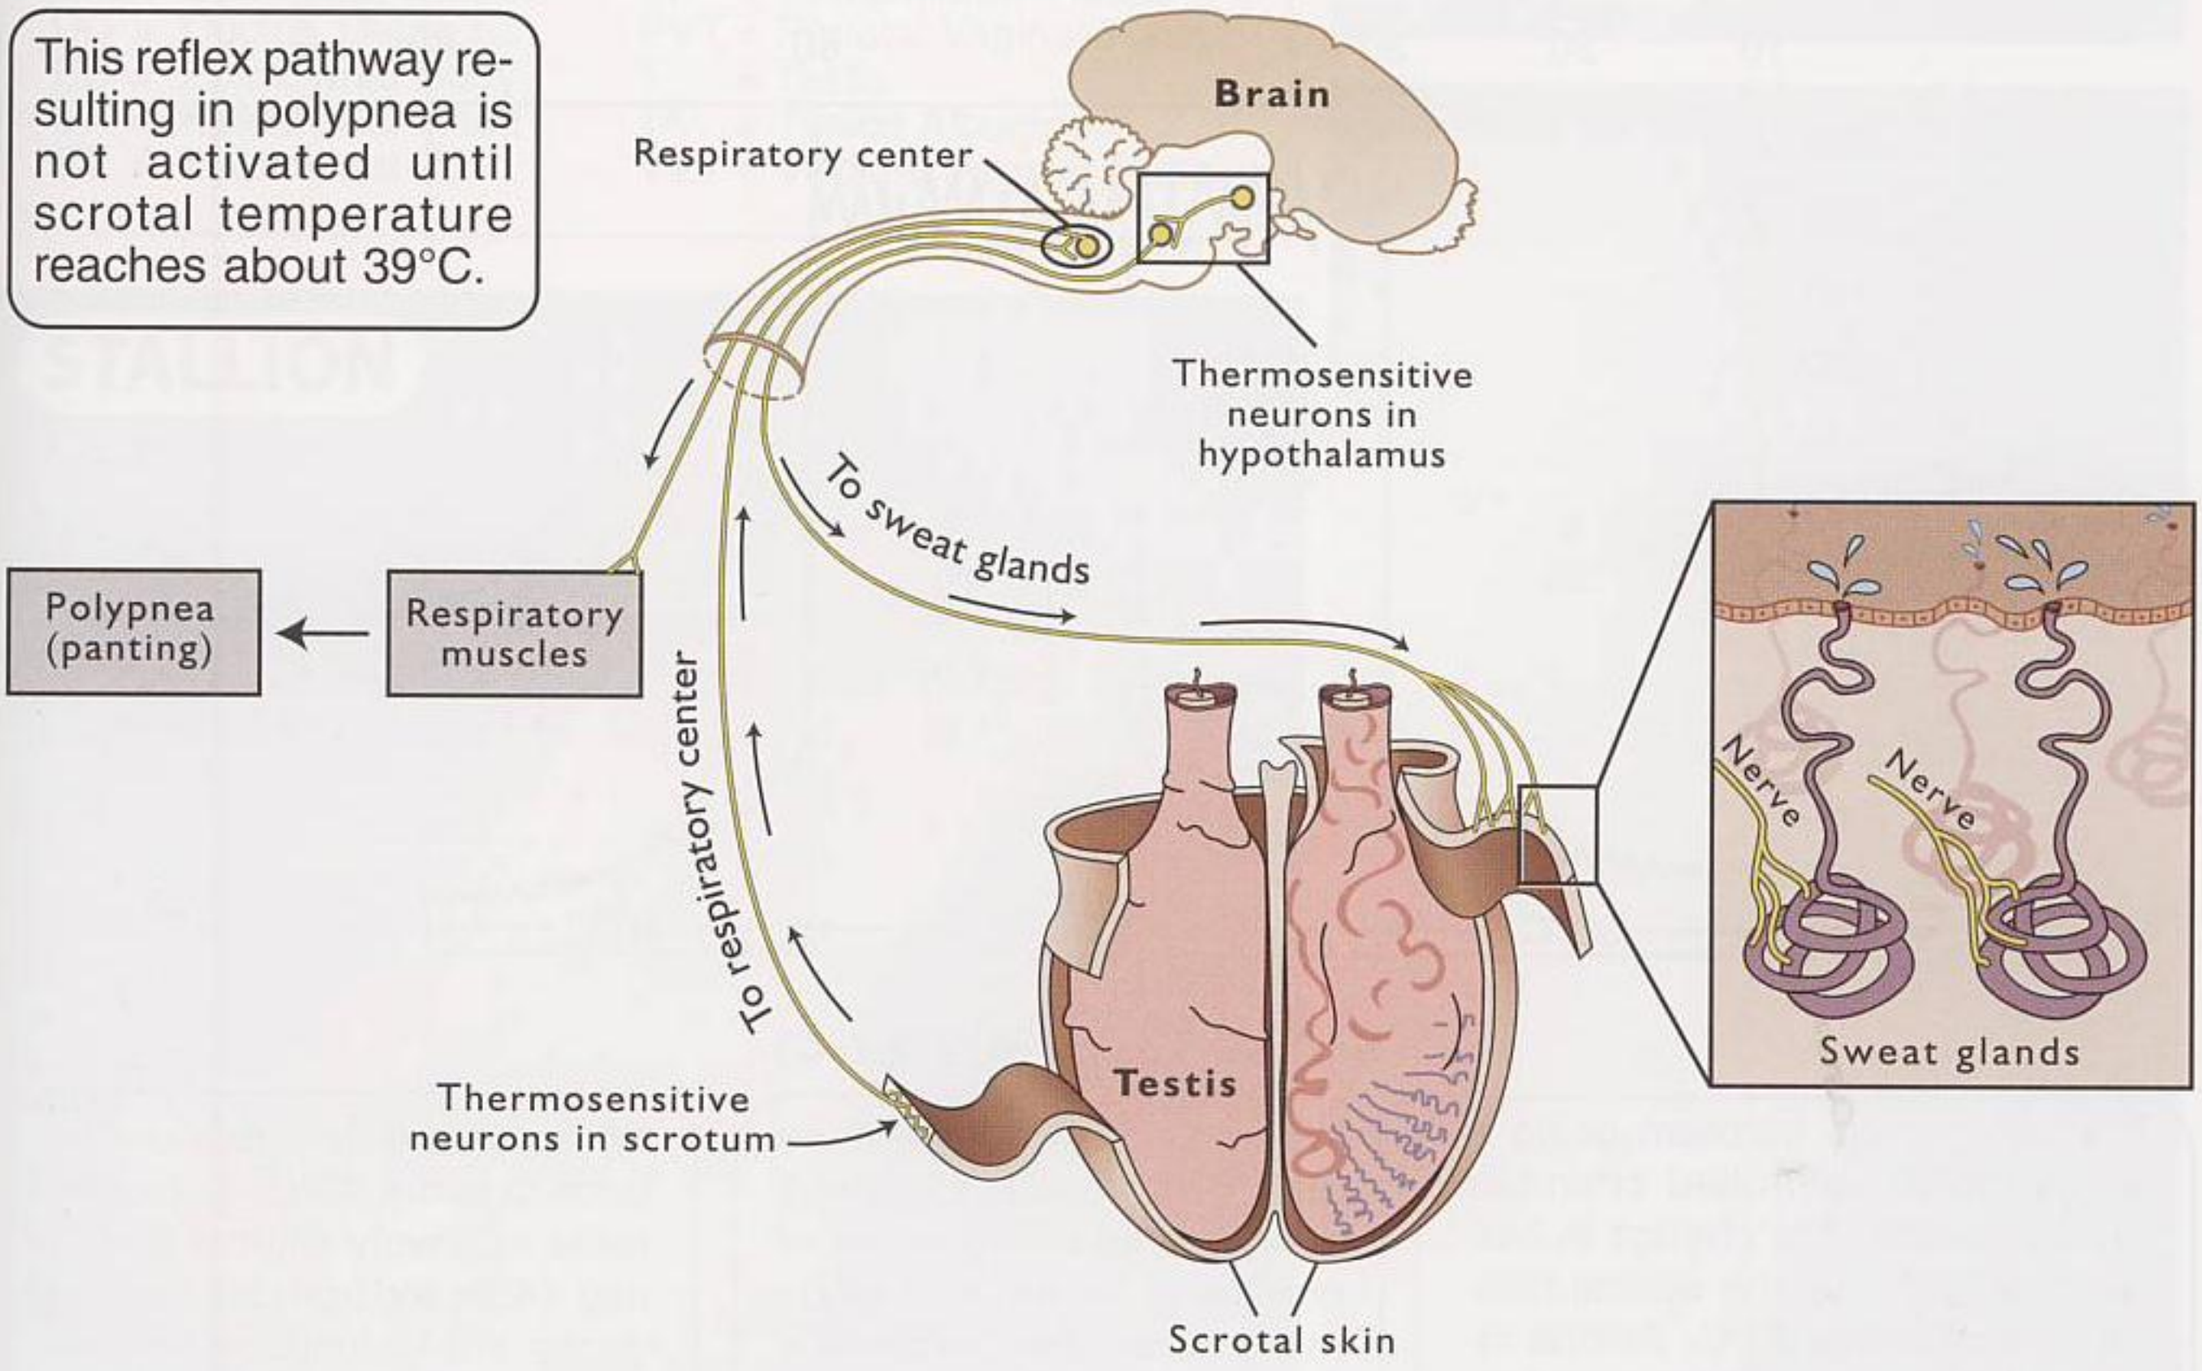


Figure 3-12. Infrared Thermogram of Bull Scrotum

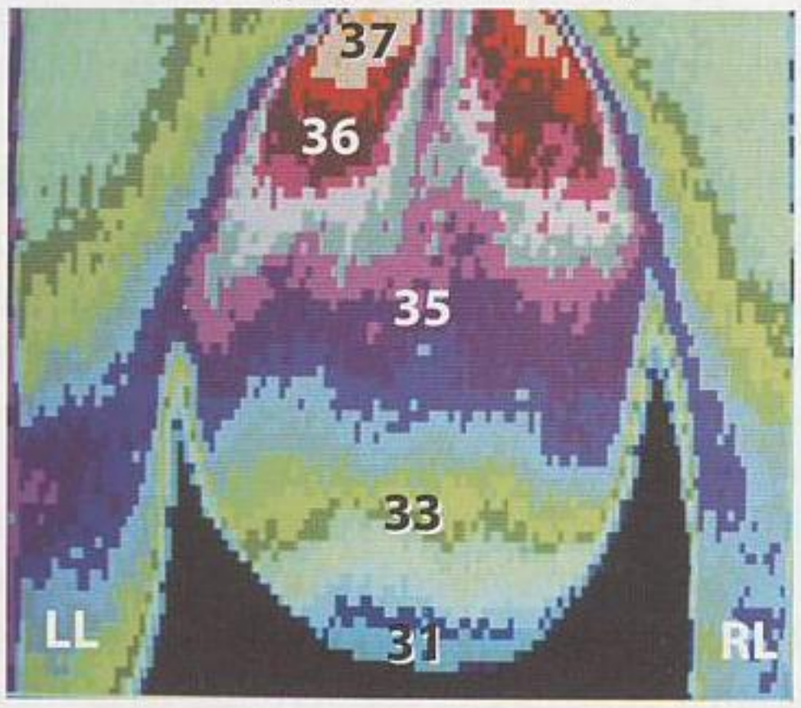
(Photo courtesy of G.H. Coulter, Agriculture and Agri-Food Canada, Lethbridge, Alberta *www.agr.gc.ca/science/*)

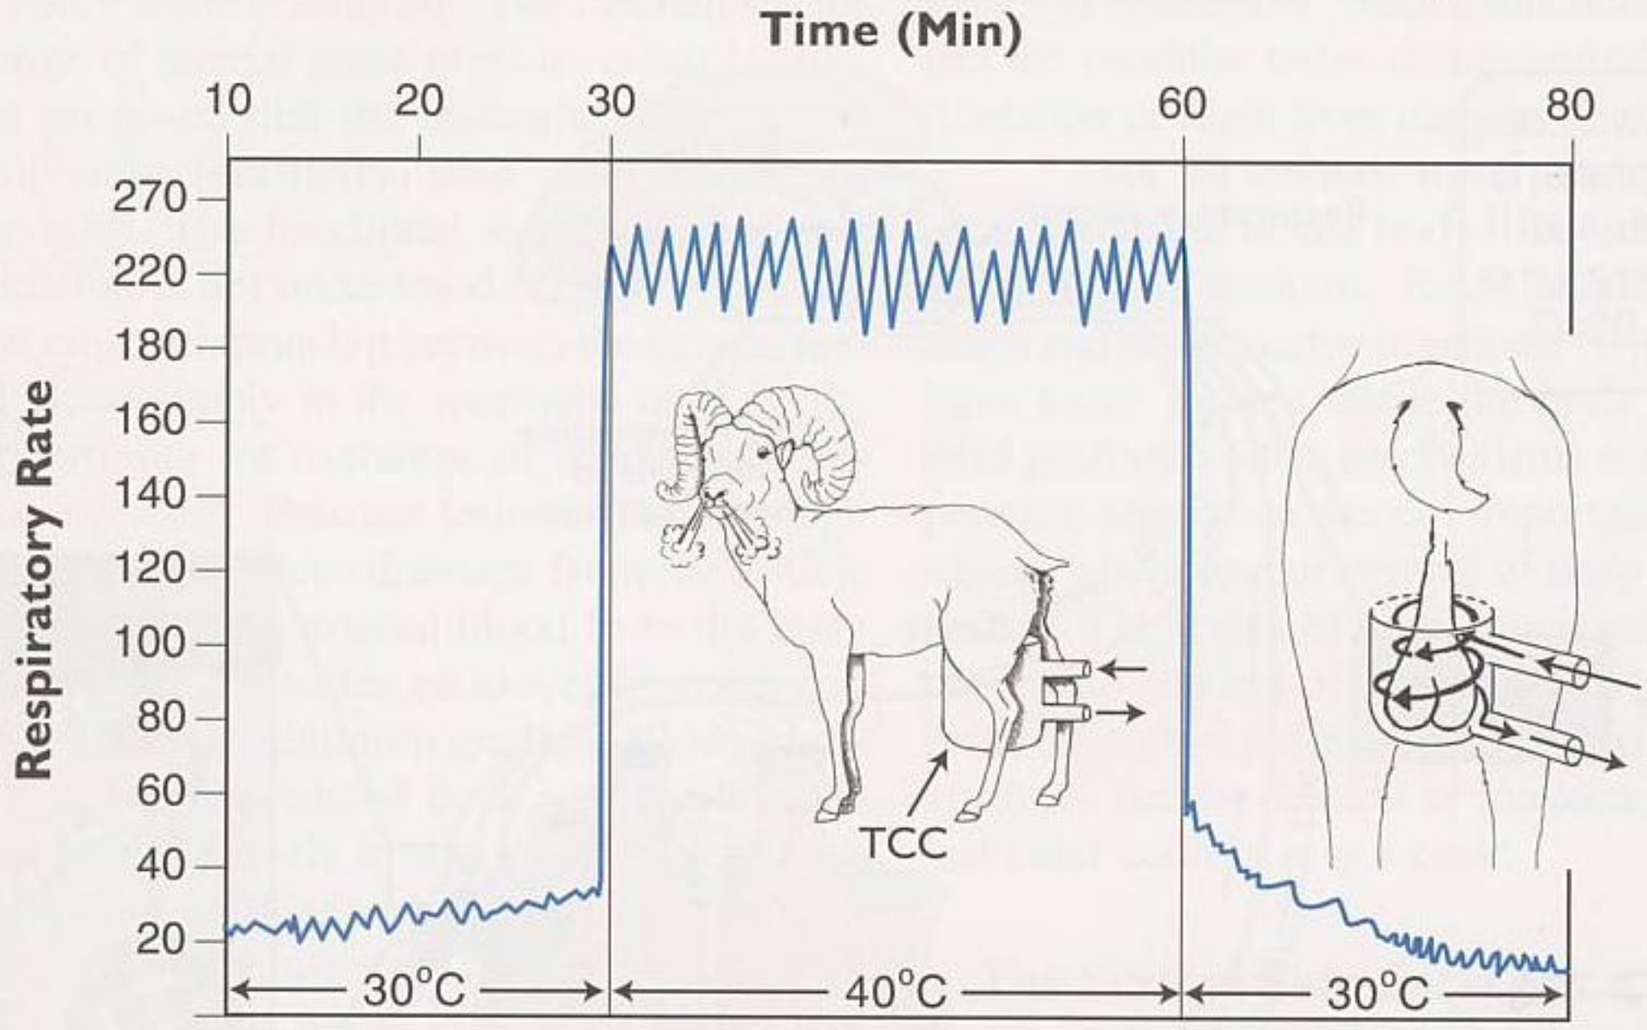


This is a caudal view of the scrotum of a mature bull. The symmetrical surface temperature pattern is typical of a bull with normal scrotal cooling. Each horizontal color band represents a different surface temperature. The warmest temperature (37°C) is in the region overlying the spermatic cords while the coolest region (31°C) is in the ventral scrotum. (LL = Left Leg, RL = Right Leg)

survival of embryos produced by normal females was observed even though sperm numbers were adequate. Such a finding implies that DNA in sperm is damaged by heat and that eggs fertilized by these sperm have a low probability of surviving. There appears to be significant variability with regard to the effect of scrotal heating upon spermatozoal production and viability. Further research is needed in this important area since the ambient temperature can often be managed/manipulated in the environment of the sexually active male, especially males used for artificial insemination.

Measuring the cooling capacity of the testes is difficult. Historically, the cooling capacity and thermal regulatory function of the testes was measured by small temperature sensors that were implanted surgically in the vasculature and/or in the testicular tissue. A noninvasive technology called **infrared thermography** has been used by Canadian researchers to assess the cooling capacity of the testes. Infrared thermography measures the infrared emissions from a heat producing body. Thus, this technique quantitates the heat released from the surface of the scrotum. Males with faulty testicular cooling can be identified and eliminated as breeding males. While this technique

Figure 3-13. Scrotal Heating Induces Panting in Ram



Warming of the scrotum using a temperature controlled chamber (TCC) causes little change in respiratory rate until the scrotal temperature reaches 40°C. Arrows indicate the direction of the fluid flow in temperature warming device.

When a scrotal temperature of 40°C is reached, marked polypnea (panting or rapid breathing) occurs with respiratory rates often exceeding 200 cycles per minute.

When scrotal temperature returns to about 30°C, respiratory rates suddenly returns to normal. (Adapted from Waites, *The Testis* Vol I, Johnson, Gomes and Vandemark)

has not reached the stage where it can be applied to everyday livestock management activities, it has promise for evaluating testicular cooling capacity in bulls and other species. Testicular cooling is a function of both the vascular countercurrent heat exchanger (See Figure 3-9) and scrotal cooling (See Figure 3-11). Efficient testicular cooling requires that scrotal cooling occur so that the venous blood in the testicle can be cooled. Only after the venous blood has been cooled can the vascular countercurrent heat exchanger function properly.

In general, the scrotal skin (and spermatic cord) in mammals contains little fat. However, under certain management conditions, accumulation of scrotal fat may be a problem. For example, beef bulls being fed for maximum rate of gain in bull test stations are evaluated for their efficiency of growth. Under conditions of maximum nutrient intake, fat may accumulate in the scrotum as well as the spermatic cord. Such accumulation of fat would decrease the cooling effectiveness of the scrotum and pampiniform plexus and thus may reduce spermatogenic efficiency, spermatozoal viability and fertility.

The Tunica Dartos has the Ability to Elevate the Testes for a Sustained Period of Time

The **tunica dartos** (also called the **dartos muscle**) is a mesh-like smooth muscle layer that lies just beneath the scrotal skin (See Figure 3-15). The degree of contraction of this smooth muscle is constantly adjusted in response to changes in scrotal skin temperature. The sensory nerves initiating the changes in the tone (degree of contraction) of the tunica dartos are located in the scrotal skin. Unlike striated muscle (cremaster muscle), the smooth muscle of the tunica dartos can maintain sustained contractions. This characteristic allows the testes to be held close to the body for sustained periods during cold temperatures. On the contrary, during the hot summer months, the tunica dartos relaxes and thus the surface area of the scrotum increases substantially to facilitate cooling. This increase in surface area of the scrotum is closely linked to scrotal perspiration. As the scrotum perspires, the increased surface area allows for a greater rate of evaporative heat loss and more rapid and efficient cooling.

Development and maintenance of the contractile ability of the tunica dartos are under androgen control. For example, the ability of the tunica dartos to contract in response to cold temperatures is lost in castrated males because testosterone is absent.

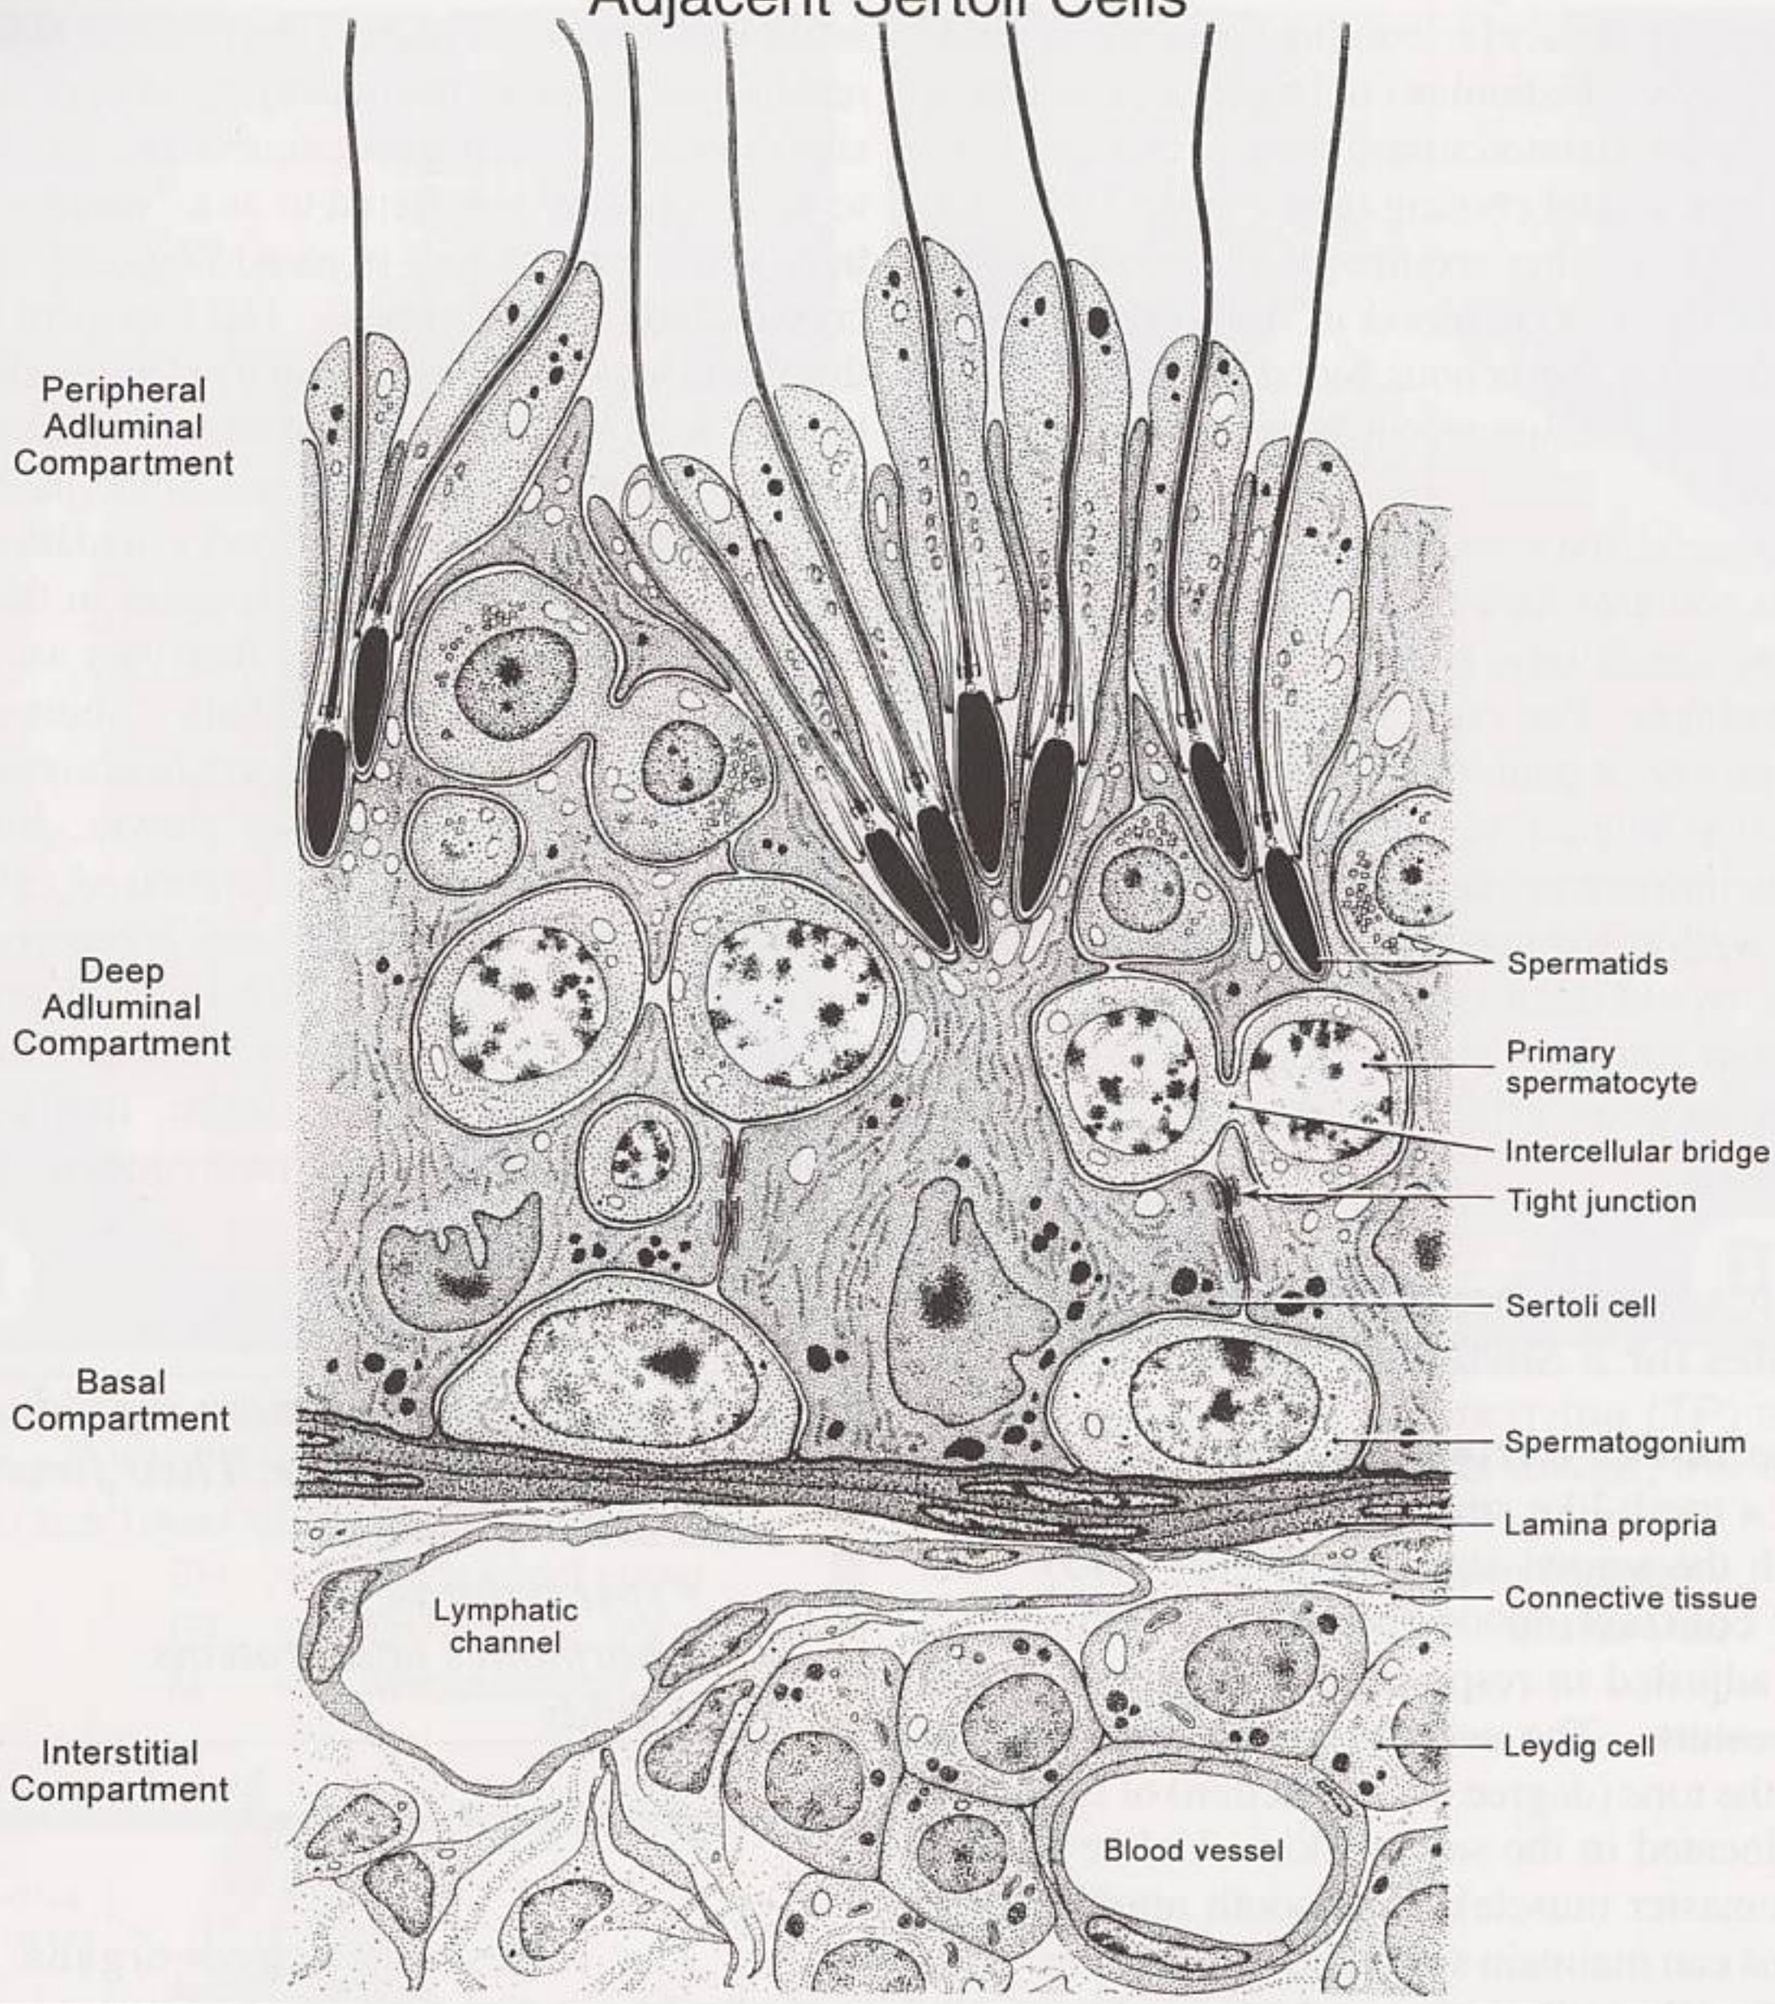
Artificial manipulation of the scrotum has been used to sterilize beef bulls. The scrotum may be artificially shortened to hold the testes next to the body, resulting in elevated testicular temperature and causing significantly reduced spermatogenesis. A bull subjected to this procedure is referred to as a "**short scrotumed**" bull. This type of bull is physiologically an artificial cryptorchid (See Chapter 4). The testes are forced into the dorsal region of the scrotum by placing a large rubber band around the lower portion of the scrotum. In 3 to 4 weeks the lower scrotum sloughs at the juncture of the rubber band because of restricted circulation. As you might expect, the weight of the testes in these bulls is less than in unaltered bulls. In fact, they are about one-half the weight of an unaltered bull. "Short scrotumed" males, while sterile, maintain normal testosterone levels, and thus maintain a high rate of growth. Research has shown that these bulls have increased efficiency of growth and have leaner carcasses compared to steers. Although this technique is not in widespread use, it illustrates the importance of an intact scrotum for testicular cooling. Furthermore, it illustrates the importance of androgens as promoters of growth and leanness.

The testes are the primary reproductive organs in the male. Their functions are to produce:

- ***spermatozoa***
- ***hormones and proteins***
- ***fluids***

The testes are paired organs that vary considerably in size and shape among species. They are considered the primary reproductive organs in the male because they produce both **spermatozoa** and the androgen **testosterone**. In addition, they produce inhibin, estrogens and a variety of proteins believed to be important to spermatozoal function. They also produce fluid that originates primarily from the seminiferous tubules. This fluid serves as a vehicle in which spermatozoa are suspended and facilitates their removal from the testes. The fluid produced by the testes (sometimes called rete fluid) also contains products synthesized by the Sertoli cells.

Figure 3-16. Relationship of the Germ Cells to the Adjacent Sertoli Cells



Peripheral Adluminal Compartment

During elongation of the spermatid nucleus, the spermatids are repositioned by the Sertoli cells to become imbedded within long pockets in the cytoplasm of an individual Sertoli cell. When released as a spermatozoon, a major portion of the cytoplasm of each spermatid remains as a residual body (cytoplasmic droplet) within a pocket of the Sertoli cell cytoplasm.

Deep Adluminal Compartment

The primary spermatocytes are moved from the basal compartment through the tight junctions between adjacent Sertoli cells into the adluminal compartment where they eventually divide to form secondary spermatocytes (not shown) and spherical spermatids. The spermatogonia, primary spermatocytes, secondary spermatocytes and spherical spermatids all develop in the space between two or more Sertoli cells and are in contact with them. Note the intracellular bridges between adjacent germ cells in the same cohort or generation.

Basal Compartment

Formation of spermatozoa in the seminiferous epithelium starts near the basement membrane. Here a spermatogonium divides to form other spermatogonia and, ultimately, primary spermatocytes. (From Amann, *J.Dairy Sci.* Vol. 66, No. 12, 1983)

The testis consists of the:
- *testicular capsule*
- *parenchyma*
- *mediastinum*
- *rete tubules*

The Testicular Capsule is a Dynamic "Suborgan" Covering the Testes

The covering of the testis, or **testicular capsule** is composed of two layers. They are the **visceral vaginal tunic** and the connective tissue capsule known as the **tunica albuginea**. The visceral vaginal tunic is closely associated with the tunica albuginea and these two layers can be separated using careful dissection (See Figure 3-14). The tunica albuginea sends many finger-like projections into the parenchyma of the testicle. These septal projections join with the **mediastinum** (See Figure 3-15). The interior surfaces of the tunica albuginea and the surfaces of the septal divisions forming the lobules are quite vascular. These surfaces are thus called the **tunica vasculosa** (See Figure 3-15).

The testicular capsule was once considered to be an inert covering whose sole function was to form the outer boundary of the testes. It is now apparent that the testicular capsule is a dynamic "suborgan" capable of undergoing changes in direct response to hormones and neurotransmitters. The tunica albuginea is not only composed of connective tissue, but contains smooth muscle fibers. Contractions of capsular smooth muscle can be induced by both acetylcholine and norepinephrine, two of the most widespread neurotransmitters in the body. These two important compounds cause contraction and relaxation of smooth muscle in the blood vessels and visceral organs throughout the body. Rhythmic cycles of contractions and relaxation of the testicular capsule serve to provide a pumping action thought to facilitate movement of spermatozoa into the rete tubules and efferent ducts.

The testicular parenchyma consists of:
- *seminiferous tubules*
- *interstitial cells of Leydig*
- *capillaries*
- *lymphatic vessels*
- *connective tissue*

The word **parenchyma** refers to the specific cellular mass of a gland or organ that is supported by a connective tissue network. The major cellular mass of the testis is therefore referred to as the parenchyma. It is a soft, tan (sometimes brown or gray) mass made up of seminiferous tubules and interstitial tissue (blood vessels, nerves, lymphatics, connective tissue and Leydig cells) (See Figure 3-15). The parenchyma can be divided into the **tubular compartment** and the **interstitial compartment** (See Figure 3-15). The tubular compartment consists of **seminiferous tubules** and all of the cells and material inside them. The interstitial compartment consists of all cells and materials outside the seminiferous tubules, such as blood vessels, connective tissue, lymphatics, nerves and the **interstitial cells of Leydig**, that produce testosterone.

The mediastinum is the central connective tissue core of the testis (See Figure 3-15) that houses ducts called rete tubules. The rete tubules (or rete testis) are tiny channels through which spermatozoa are transported out of the testis (See Figure 3-15). The dense connective tissue of the mediastinum helps prevent compression or collapse of the rete tubules so spermatozoa and fluid originating in the seminiferous tubules can move freely out of the testis.

The tubular compartment consists of:
- *seminiferous epithelium*
- *Sertoli cells*
- *developing germ cells*
- *peritubular cells*

The seminiferous tubules (comprising the tubular compartment of the parenchyma) are microscopic. They form highly convoluted loops (See Figure 3-15), the ends of which join with the **rete tubules**. Each loop of a seminiferous tubule is composed of a convoluted portion (**tubulus contortus**) and a straight portion (**rectus**) that join the rete tubule (See Figure 3-15). Spermatogenesis takes place predominantly in the tubulus contortus.

The seminiferous tubule is composed of a basement membrane and a layer of **seminiferous epithelium** (also called the **germinal epithelium**) (See Figure 3-16). The tubule is surrounded by contractile peritubular cells. Their contraction and the flow of fluid secreted by **Sertoli cells** allows newly formed spermatozoa to move into the rete tubules.

The seminiferous epithelium consists of two major regions known as the **basal compartment** and the **adluminal compartment**. Sertoli cells are anchored to the basement membrane and surround the developing population of germ cells. The relationship between the Sertoli cells and the germinal elements is shown in Figure 3-16.

Sertoli cells are the only somatic cells in the seminiferous epithelium. Once believed to be simply a supportive component for the germinal elements, they are now considered to be the cellular "governors" of spermatogenesis. Each Sertoli cell "hosts" a maximum number of developing germ cells, characteristic for a given species. Hence, testes with high numbers of Sertoli cells are capable of producing large numbers of spermatozoa. Conversely, testes with small numbers of Sertoli cells can only produce small numbers of spermatozoa. Sertoli cells are analogous to the granulosal cells of the ovarian follicle. However, unlike granulosal cells, the Sertoli cell contains receptors for both FSH and testosterone. Because Sertoli cells possess receptors to different hormones (protein and steroid), they have the capability of producing a variety of substances. A few examples are: 1) **androgen binding protein (ABP)**, a testosterone transport protein; 2) **sulfated glycoproteins (SGP) 1** and **2**, that are believed to be related to fertility acquisition (SGP-1) and providing a detergent effect that allows cells and fluids to move through the tubular network of the testis (SGP-2); 3) **transferrin**, an iron transport protein believed to be required for successful spermatogenesis and 4) **inhibin**, as in the female, a suppressor of FSH.

Adjacent Sertoli cells are tightly attached to each other on their lower lateral surfaces by a band of specialized junctions called **tight junctions**. The Sertoli cell junctional complexes separate the germinal epithelium into a basal compartment (See Figure 3-16) that houses spermatogonia and early primary spermatocytes and an adluminal compartment that houses all other germ cells. The name basal compartment reflects its position just above the basement membrane of the seminiferous tubule. The adluminal compartment implies a region adjacent to the lumen of the seminiferous tubule. The cell types found in the adluminal compartment are **primary** and **secondary spermatocytes** and **spermatids**. The junctional complexes between Sertoli cells form a specialized permeability barrier that prevents large molecular weight materials and immune cells from gaining access to the adluminal compartment.

The blood-testis barrier prevents immunologic destruction of developing germ cells.

The peritubular cells surrounding the seminiferous tubule and the Sertoli cell junctional complexes form the **blood-testis barrier**. The primary purpose of the blood-testis barrier is to prevent autoimmune reactions from destroying the developing germ cells. Materials in the interstitial compartment are first "screened" by the peritubular layer surrounding the seminiferous epithelium. The peritubular layer thus acts as the first barrier against large molecular weight materials (mainly immunoglobulins).

The junctional complexes (tight junctions) between Sertoli cells serve as the second barrier against immune cells and immunoglobulins. The most important feature of the blood-testis barrier is the exclusion of immune cells (macrophages and lymphocytes) and immunoglobulins (antibodies) from the adluminal compartment. This exclusion is important since these molecules would recognize the developing germinal elements as foreign because they are undergoing meiosis. Therefore, they are immunologically different from other cells within the body and thus generate an immune response. In addition to forming the blood-testis barrier, the Sertoli cell junctional complexes provide a type of control for materials entering and, at least in part, leaving the adluminal compartment.

The excurrent duct system consists of:
- ***efferent ducts***
- ***the epididymal duct***
- ***the ductus deferens***

Table 3-1. Time Required (Days) for Passage of Spermatozoa Through the Various Parts of the Epididymal Duct

Species	Head	Body	Tail	Total
Boar	3	2	4-9	9-14
Bull	2	2	10	14
Camel	0.2	0.3	1.5	4.2
Man	1-2	0.5	5	6.5-7.5
Ram	1	3	8	12
Stallion	1	2	6	9

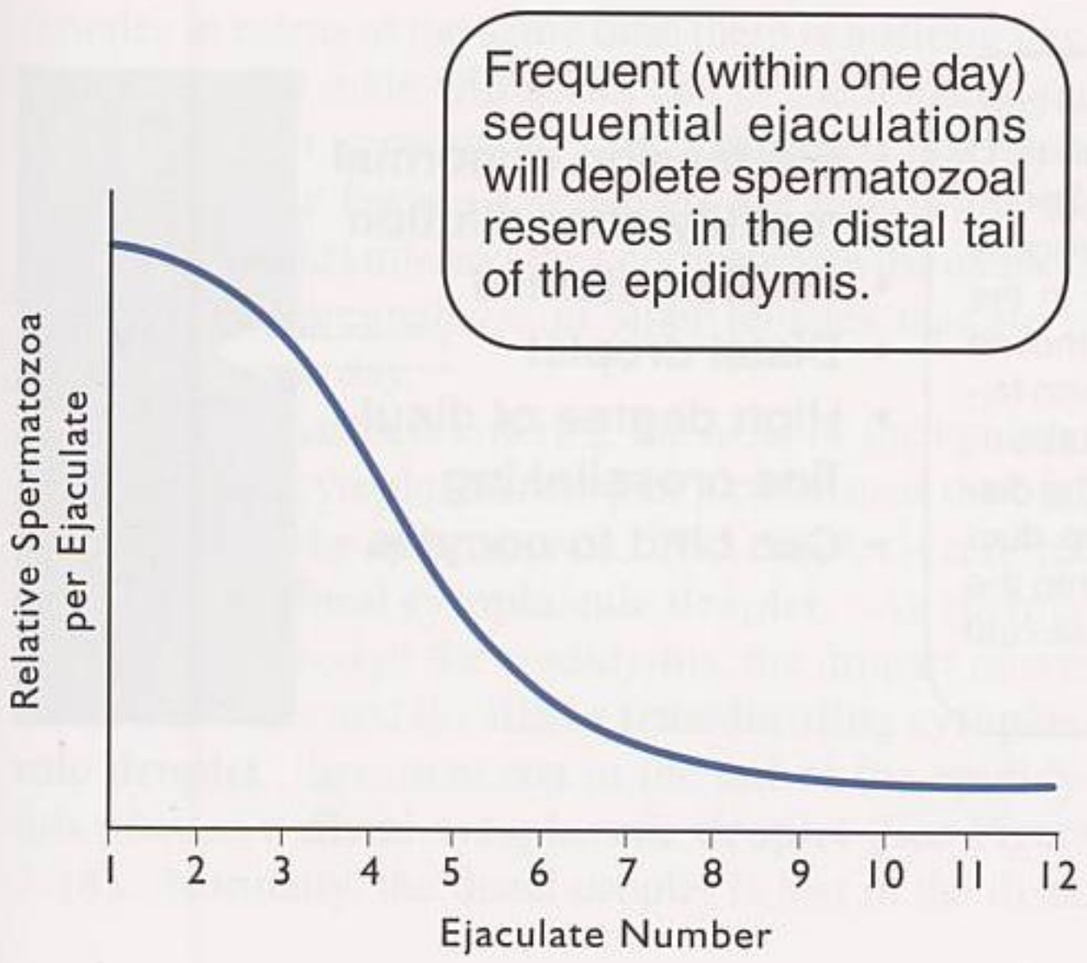
The Excurrent Duct System Allows for Final Maturation, Storage and Delivery of Spermatozoa to the Pelvic Urethra

The efferent ducts converge to a single duct, the **epididymal duct**. The function of the efferent ducts is to convey newly formed spermatozoa and tubular fluid (rete fluid) into the epididymal duct. The head of the epididymis contains the point of connection between the efferent ducts and the initial segment of the epididymal duct (See Chapter 4 for embryologic origin). The function of the epididymis is to provide the environment for final maturation of spermatozoa, resulting in acquisition of motility and potential fertility. The epididymis also serves as a storage reservoir for spermatozoa. Epididymal function is androgen dependent.

The epididymis is organized into three distinct regions known as the head (caput), the body (corpus) and the tail (cauda) (See Figures 3-2 through 3-7, 3-14, 3-15 and 3-18).

The epididymal duct is a single, highly convoluted duct ranging in length from 30 to 60 meters depending on species. It is surrounded by smooth muscle. This muscular layer is responsible for rhythmic contractions of the duct, forcing spermatozoa to travel along its course to the tail. The time required to transport spermatozoa from the proximal head of the epididymis to the distal tail is referred to as **epididymal transit time**.

Figure 3-17. Depletion of Spermatozoal Reserves in the Distal Tail of the Epididymis



Epididymal transit times through the head and body of the epididymis are remarkably constant within species (See Table 3-1). Smooth muscle in the tail of the epididymis is relatively quiescent except during periods of sexual excitation. When sexual stimulation occurs, the smooth muscle of the distal tail begins to contract vigorously, moving spermatozoa into the ductus deferens. Epididymal transit time through the head and body is not altered by sexual excitation. However, the number of sperm in the distal tail can be altered dramatically by the frequency of ejaculation. In sexually rested males, the sperm content of the tail is maximal, while males experiencing a high ejaculation frequency have 25% to 45% fewer sperm in the epididymal tail. Spermatozoa spending an unusually long time in the tail (such as after long periods of sexual rest) may be of poor quality when compared to sperm from animals ejaculated routinely (once or twice weekly). Some males tend to accumulate sperm in the epididymis rather than void them periodically, probably resulting in a loss of viability.

It is important to recognize that the epididymis is a dynamic organ that controls not only the maturation and fertility acquisition of spermatozoa but also their exit from the male reproductive system. With sperm production rates of several billion per day, it is easy to imagine that if the epididymis did not provide continual movement of sperm out of the male reproductive tract, there would be a buildup of immense pressure. Spermatozoal removal from the epididymis is caused by periodic contractions of the epididymis and ductus deferens, resulting in a gradual trickle of spermatozoa out of the tail, through the ductus deferens, into the pelvic urethra where they are flushed out of the tract during urination. This trickle allows removal of sperm from the epididymis on a continual basis. Sperm are not reabsorbed from the epididymal duct.

Factors that control epididymal transit are poorly understood but it is almost certain to be under the control of the nervous and the endocrine systems. Materials such as oxytocin, acetylcholine, prostaglandins and angiotensin II (a powerful vasoconstrictor produced by the kidney) have been shown to alter epididymal motility *in vitro*.

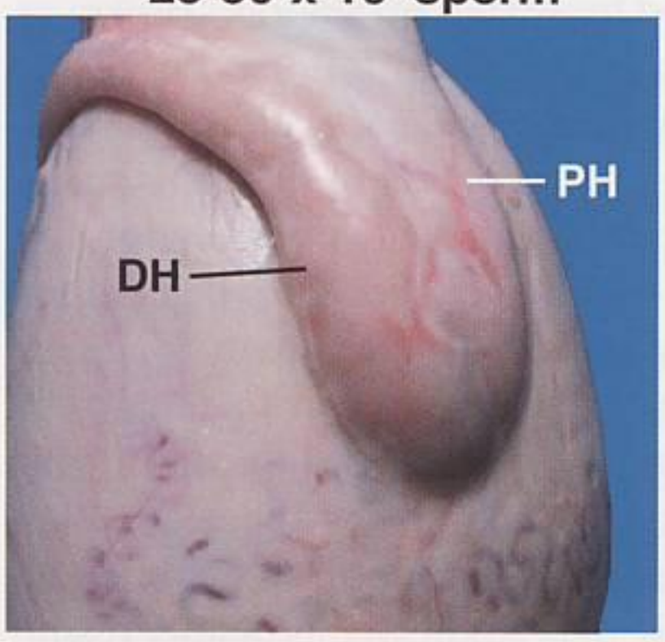
The changes in spermatozoal characteristics as they pass through the epididymis are summarized in Figure 3-18. As spermatozoa enter the efferent ducts and epididymal duct, their concentration is low because they are diluted in **rete fluid**. Most of this fluid is absorbed by the epithelium of the efferent ducts and the proximal head of the epididymis. Spermatozoa are concentrated immensely in the epididymis. For example, spermatozoal concentrations in the head of the epididymis may be 25 to 50 million, while in the tail concentration may exceed 2 billion. Changes in

Figure 3-18. Epididymis of a Typical Mammal

(The epididymis and sperm shown are from the bull. Micrographs of sperm are courtesy of Jere R. Mitchell, National Association of Animal Breeders, Columbia, MO, *www.naab-css.org*)

Head (Caput)

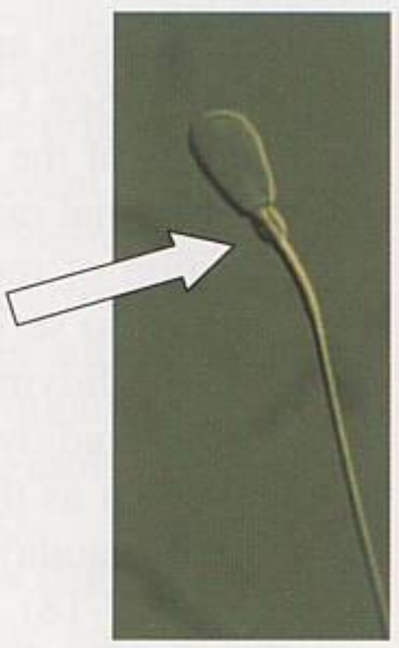
25-50 x 10^6 sperm



The head of the epididymis is subdivided into the proximal head (PH) and the distal head (DH). The proximal head reabsorbs a significant amount of rete fluid while the distal head secretes fluid into the lumen of the epididymal duct. Thus, concentration of sperm within the head of the epididymis increases and then decreases significantly.

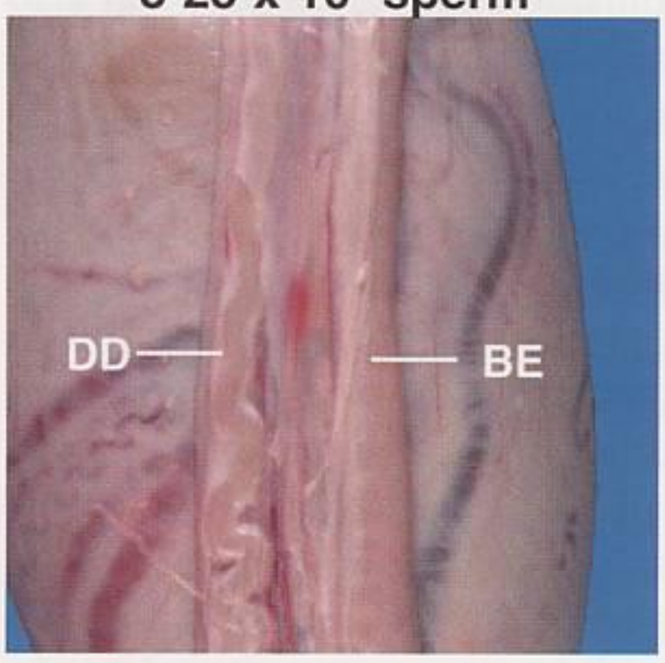
Spermatozoal Characteristic

- **Not motile**
- **Not fertile**
- **Proximal cytoplasmic droplet**
- **Low disulfide crosslinking**



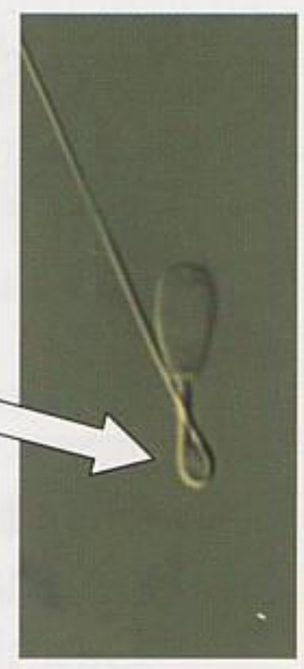
Body (Corpus)

8-25 x 10^9 sperm



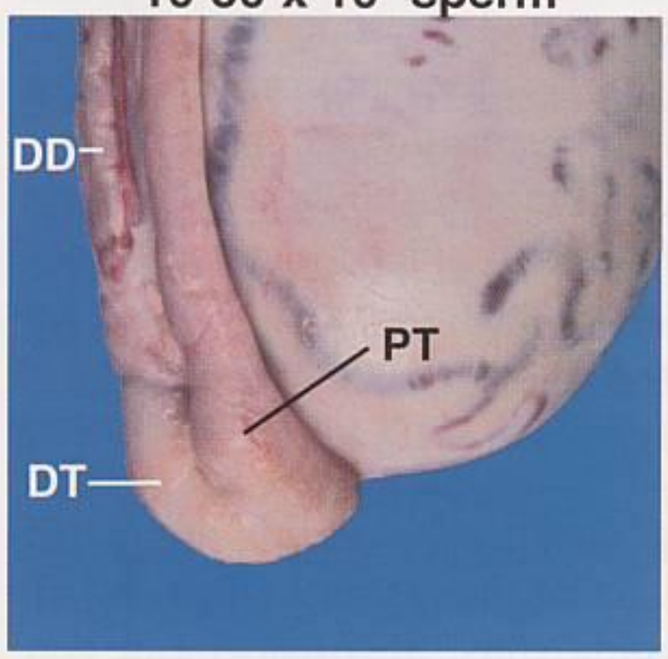
The body of the epididymis (BE) lies parallel to the ductus deferens (DD). Concentrations of sperm throughout the body of the epididymis remain relatively constant.

- **Some expression of motility after dilution**
- **Some expression of fertility**
- **Translocating cytoplasmic droplet**
- **Moderate to high degree of disulfide crosslinking**
- **Can bind to oocytes**



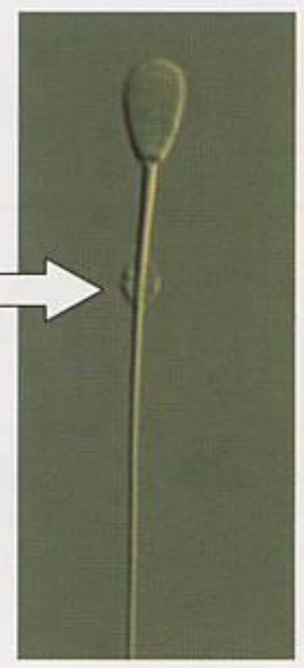
Tail (Cauda)

10-50 x 10^9 sperm



The tail of the epididymis consists of the proximal tail (PT) and the distal tail (DT). Sperm within the distal tail are eligible for ejaculation. Sperm in the proximal tail cannot be moved into an ejaculatory position following sexual stimulation. However, the sperm in the distal tail move through the ductus deferens (DD) and into the pelvic urethra during sexual stimulation.

- **Expression of normal motility after dilution**
- **Fertile potential**
- **Distal droplet**
- **High degree of disulfide crosslinking**
- **Can bind to oocytes**



spermatozoal concentration are the result of fluid reabsorption and secretion along the course of the epididymis. Not only is fluid absorbed, but the spectrum of proteins and other molecules in the fluid bathing the sperm is changed along the course of the epididymal duct.

The total spermatozoal content of the epididymal duct, the ductus deferens and the ampulla is referred to as the **extragonadal reserves** (**EGR**). Only the distal tail reserves are eligible for ejaculation. On a per ejaculate basis, the number of sperm removed from the tail reserves can be increased dramatically when the male is subjected to a series of sexual preparation maneuvers such as false mounting or restraint from mounting. Sexual preparation likely stimulates release of oxytocin from the posterior pituitary. This causes contractions of the smooth muscle surrounding the tail of the epididymis that move spermatozoa into the ductus deferens. Oxytocin also causes contractions of the smooth muscle in the ductus deferens that transports spermatozoa to the pelvic urethra where they are positioned for ejaculation. These mechanisms will be detailed in Chapter 11.

It is important to recognize that even though a male might have adequate spermatozoal production by the testes, depletion of the reserves in the tail of the epididymis can occur rapidly if repeated ejaculations take place (See Figure 3-17). For example, in mature bulls sperm in the ejaculate can be reduced to near zero after eight to ten successive ejaculations during a relatively short time period (several hours). Therefore, the number of fertile breedings a male can achieve will be limited by the size of his sperm reserves in the epididymal tail. From a practical viewpoint, the number of females a male can service in a 1-2 day period is dependent on his epididymal tail reserves, not the spermatozoal producing capability of the testes. It should be emphasized that when males are exposed to several females in estrus at the same time there is a strong likelihood that the male will select one of the females and inseminate her repeatedly. Such repeated insemination of a single female can deplete the reserves in the tail of the epididymis and thus compromise the chances of successful pregnancies in other females that are in estrus the same day.

Spermatozoa entering the head of the epididymis possess a cytoplasmic droplet located near the base of the head of the spermatozoa. This droplet is referred to as the **proximal cytoplasmic droplet**. As spermatozoa move through the epididymis, the droplet moves down their tails and is called a **translocating cytoplasmic droplet**. Spermatozoa in the tail of the epididymis possess a **distal cytoplasmic droplet** (See Figure 3-18). Normally, the distal droplet is lost in the distal tail or during ejaculation. A high proportion of ejaculated spermatozoa retaining a cytoplasmic droplet indicates faulty epididymal maturation.

Seminal Plasma is a Non-Cellular Fluid Vehicle for Spermatozoal Delivery to the Female

The epididymis and accessory sex glands are responsible for production of secretions that contribute to the liquid, noncellular portion of semen known as seminal plasma. **Seminal plasma** is not required for fertility, but is important in natural insemination where a fluid vehicle for delivery of the sperm is needed. Spermatozoa that are removed from the tail of the epididymis are equally as fertile as those that are ejaculated. In fact, when dairy bulls of genetic superiority die, spermatozoa can be flushed from the epididymal tail, processed and frozen. Artificial removal of these reserves can result in the generation of 600 to 1000 additional units of frozen semen.

In some species (the boar and stallion), the seminal plasma possesses special coagulation properties that plug the female reproductive tract and minimize loss of spermatozoa following copulation and ejaculation. The accessory sex glands secrete their products into the lumen of the pelvic urethra.

The **ampullae** are enlargements of the ductus deferens that open directly into the pelvic urethra. The enlargement is the result of a dramatic increase in the mucosa within the ampulla. The mucosa of the ampulla forms numerous pockets. The boar does not have conspicuous ampullae.

Seminal plasma is produced by the:

- ***epididymis***
- ***ampulla***
- ***vesicular glands (seminal vesicles)***
- ***prostate gland***
- ***bulbourethral glands (Cowper's glands)***

The **vesicular glands** are paired glands that are dorsocranial to the pelvic urethra. Vesicular gland secretions empty directly into the pelvic urethra. These glands were originally named the seminal vesicles. Early anatomists erroneously imagined that these glands were reservoirs for spermatozoa because there was a

visual similarity between the secretion of these glands and ejaculated semen. While the vesicular glands do serve as a reservoir for their own secretions, they do not serve as a reservoir for spermatozoa. The vesicular glands have openings within the pelvic urethra that are separate from those of the ampullae. In bulls and boars the vesicular gland contributes to a large proportion of the ejaculate volume. The gross anatomical configuration of the vesicular glands varies significantly among species. These are illustrated in Figures 3-19 and 3-20. In the bull and ram the vesicular glands are lobulated. In the boar they are well developed and contribute to a viscous, milky component of the seminal plasma. In the stallion the vesicular glands are elongated, hollow pouches.

The **prostate gland** lies in close proximity to the junction between the bladder and pelvic urethra. There is great species variation with regard to shape and location. The prostate may have two structural forms. The first is a **corpus prostate** in which the prostate is outside of the urethralis muscle and is visible as a heart-shaped (boar), or an H-shaped (stallion) structure. The second type is a **disseminate prostate** in which glandular tissue is distributed along the dorsal and lateral walls of the pelvic urethra. The disseminate prostate is sometimes referred to as the **urethral gland**. To observe the disseminate prostate one must make an incision in the pelvic urethra and expose the prostatic tissue. In the bull the prostate has two distinct forms and the corpus prostate is located near the neck of the bladder. In the boar the disseminate prostate is the major portion of the gland and the body of the prostate is often partially concealed by the vesicular glands. The ram does not have a prostatic body and its prostate is entirely disseminate. In contrast, the stallion has no disseminate prostate and the glands are characterized by two lateral lobes. The prostate is the only accessory sex gland in the dog and situated around the pelvic urethra at the neck of the bladder (See Figure 3-20). In the tom, the prostate consists of four lobes that are dorsal to the pelvic urethra (See Figure 3-20).

The **bulbourethral glands** are paired glands located on either side of the pelvic urethra near the ischial arch. These glands are usually small and ovoid and are characterized by being quite dense due to the high degree of fibrous connective tissue within them. In the ram, bull and stallion these glands are small and buried under the bulbospongiosus muscle. The boar is the notable exception with regard to the size of the bulbourethral glands. They are very large and dense and lie on the surface of the caudal two thirds of the pelvic urethra. These glands produce a viscous secretion that is important because it provides the gel fraction of the ejaculate and causes the seminal plasma to coagulate following ejaculation.

Secretions of the accessory sex glands contain an immense variety of components and ions, most of which have not been assigned a function. In general, most substances found in blood, including hormones and enzymes, can be found in seminal plasma. It is beyond the scope of this book to detail all of the secretory products of the accessory sex glands. However, among the most unique are fructose that serves as an energy source for spermatozoa.

The presence of these materials with regard to specific accessory sex glands varies among species. It should be emphasized that with the exception of fructose as an energy source, the precise role of the other materials is not known.

The accessory sex glands are dependent on testosterone for full development and maintenance of their structure and function. In fact, the weights of accessory sex glands can be used as a bioassay for androgens. In the absence of androgens, the weights of the accessory sex glands will be quite low. In contrast, when androgens are present the weights of the accessory sex glands are normal and their secretory activities are normal.

The Penis is the Copulatory Organ

The **penis** is composed of three parts. These are the **base** (root) **of the penis** where it is attached to the ischial arch, the **shaft** (the main portion of the penis) and the **glans penis** that is the specialized distal end.

The glans penis is heavily populated with sensory nerves and is the homologue of the female clitoris. Stimulation of the glans penis is the primary factor initiating the mechanisms of ejaculation. The morphology of the glans penis varies significantly among species. For example, the glans penis of the tom is covered with spines (See Figure 3-22). These penile spines are androgen dependent and disappear when orchidectomy (removal of the testicles) is performed. The purpose of the spines is not known but it has been proposed that these structures maximize vaginal stimulation during copulation and promote induction of ovulation. The glans penis of the alpaca contains a single stiff spiny appendage called the cartilaginous process. The function is not known but this modification can cause damage to the cervix and uterus if excessive copulation is allowed. The glans penis of the boar consists of a "corkscrew" configuration to enable penetration of the interdigitating prominences of the cervix.

The penis consists of:
- *a base*
- *a shaft*
- *the glans penis*

Bulls, boars and rams have a fibroelastic penis with limited erectile tissue encased in a non-expandable, dense connective tissue structure (tunica albuginea). In species with a fibroelastic penis, there is a **sigmoid flexure** (See Figures 3-2, 3-4 and 3-7). This is an S-shaped configuration along the shaft of the penis. The sigmoid flexure allows the penis to be retracted inside the body (within the sheath) until erection occurs. Erection is stiffening without a significant change in diameter. The sigmoid flexure is maintained by a pair of smooth muscles known as the **retractor penis muscles** (See Figures 3-2 through 3-7). These are attached dorsally to the coccygeal vertebrae and attached ventrally to the ventrolateral sides of the penis. When contracted, the retractor penis muscle holds the penis inside the sheath. When relaxed, the penis protrudes.

The shaft of the penis has an area of spongy, erectile tissue known as the **corpus cavernosum** that makes up the majority of the penile interior. In the ventral portion of the penis immediately surrounding the **penile urethra** is another area of spongy erectile tissue called the **corpus spongiosum**. Erection in the bull, boar, ram, stallion and camelids is brought about by a combination of relaxation of the retractor penis muscles and the rushing of blood into the corpus cavernosum and the corpus spongiosum (See Figures 3-21 and 3-22). The mechanism of erection and ejaculation will be presented in Chapter 11. The penile shaft of stallions, dogs and men have large corporal sinusoids that fill with blood following sexual stimulation (See Figures 3-21 and 3-22 and Chapter 11). The cavernous tissue in the dog consists of two morphologically distinct regions. These are the bulbus glandis and the pars longa glandis. The bulbus glandis forms a turgid bulb during erection that allows the "copulatory lock" during the final stages of copulation (See Chapter 11). The dog penis also has an os penis (baculum) that runs through the bulbus glandis and the pars longa glandis (See Figure 3-22). The penile urethra and corpus spongiosum are housed by a groove in the os penis (See Figure 3-22).

Erection, Protrusion of the Penis and Ejaculation are Under Muscular Control

The paired **ischiocavernosus muscles**, the muscles associated with the pelvic urethra and the penis, vary in size and form depending on the species. The ischiocavernosus muscles are relatively short paired muscles in the area of the root of the penis. These are strong muscles enclosing the crura that insert broadly on the lateral surface of the penis above the sigmoid flexure. They also connect the penis to the ischial arch.

Muscles associated with the pelvic urethra and the penis are:
- *urethralis*
- *bulbospongiosus*
- *ischiocavernosus*
- *retractor penis*

The **urethralis** is a striated muscle that surrounds the pelvic urethra in a circular manner. The urethralis muscle is a thick, powerful muscle responsible for movement of seminal plasma and spermatozoa into the penile urethra. The urethralis muscle is shown in Figure 3-19 and 3-20. The **bulbospongiosus muscle** overlaps the root of the penis and extends down the caudal and ventral surfaces. In the boar, ram and bull it extends only part way down the penis. This muscle also covers the bulbourethral glands. The function of the bulbospongiosus muscles is to empty the extrapelvic part of the urethra.

Further PHENOMENA for Fertility

In many mammalian species (bats, rodents, carnivores, shrews, moles and many primates--but not humans) there is a penile bone called the os penis or baculum. The baculum of the raccoon has a gentle sigmoid shape and makes an attractive, unique cocktail stirring device when cleaned, sterilized and polished.

The fully engorged penis of the bull elephant weighs over 25 kilograms (about 55 lbs).

The penis of lizards and snakes is paired and is called a hemipenis. It is an extension of the cloaca and is everted into the cloaca of the female during copulation. It contains spines and/or ridges that help sustain intromission.

In Brazil there is a species of monkey that has huge testicles relative to his body size. Unlike most mammals, this species of monkey has no competition amongst males for the right to breed the female. Instead, the female will copulate with many males in sequence. Therefore, the male with the largest testicles (that produce the most sperm) has the greatest probability of fathering the new baby monkey.

The word "testis" is derived from Latin and means "witness" or "spectator." The English words "testify" and "testament" were derived from testis. The reason for this derivation is not known. However, it has been proposed that the testes were witnesses to virility. Romans required that a witness be an adult intact male. Prepubertal boys, women or eunuchs could not serve as witnesses. Placing the hand on the testicles (or someone else's testicles) was a requirement while testifying in some cultures.

The prepuce of the male dromedary (one-humped camel) is pendulous and contains three groups of muscles that change the direction of the preputial orifice from caudal during urination to cranial during erection.

In parts of the world where the understanding of reproductive physiology is quite shallow, men wishing to father children try to improve their odds by eating sheep or bull testicles. Testicles are also believed to be an aphrodisiac (aphrodisiacs are named after the Greek goddess of love Aphrodite) and are believed to stimulate the reproductive appetite. Consumption of testicles is believed to increase the sex drive allowing the future father to copulate repeatedly. Little consideration was given to extragonadal reserves. One of the most potent forms of animal testes is believed to be the testicles of prisoners captured from neighboring tribes.

Every human male learns at a young age how painful it is to receive a blow to the testicles. The pain is excruciating and instantly radiates from the testis deep into the abdominal cavity. The testes are rich in nerve endings. The slightest blow to the testicle is painful. During embryogenesis, the testes are formed in the abdomen near the stomach and kidney. Nerves that originate in this region travel with the testes as they descends to hang freely in the scrotum. That is probably why the blow to the testicles feels like a punch in the stomach. Nerves in the scrotum are related to ones that are associated with the subcutaneous sensory nerves of the thigh and spinal cord. Thus, light stroking to the scrotum and the inner thigh is deemed pleasurable.

The armadillo has a penis that is about one-third its body length. A female armadillo gives birth to identical quadruplets. The four identical offspring are derived from a single fertilized egg that splits into four developing embryos (totipotency).

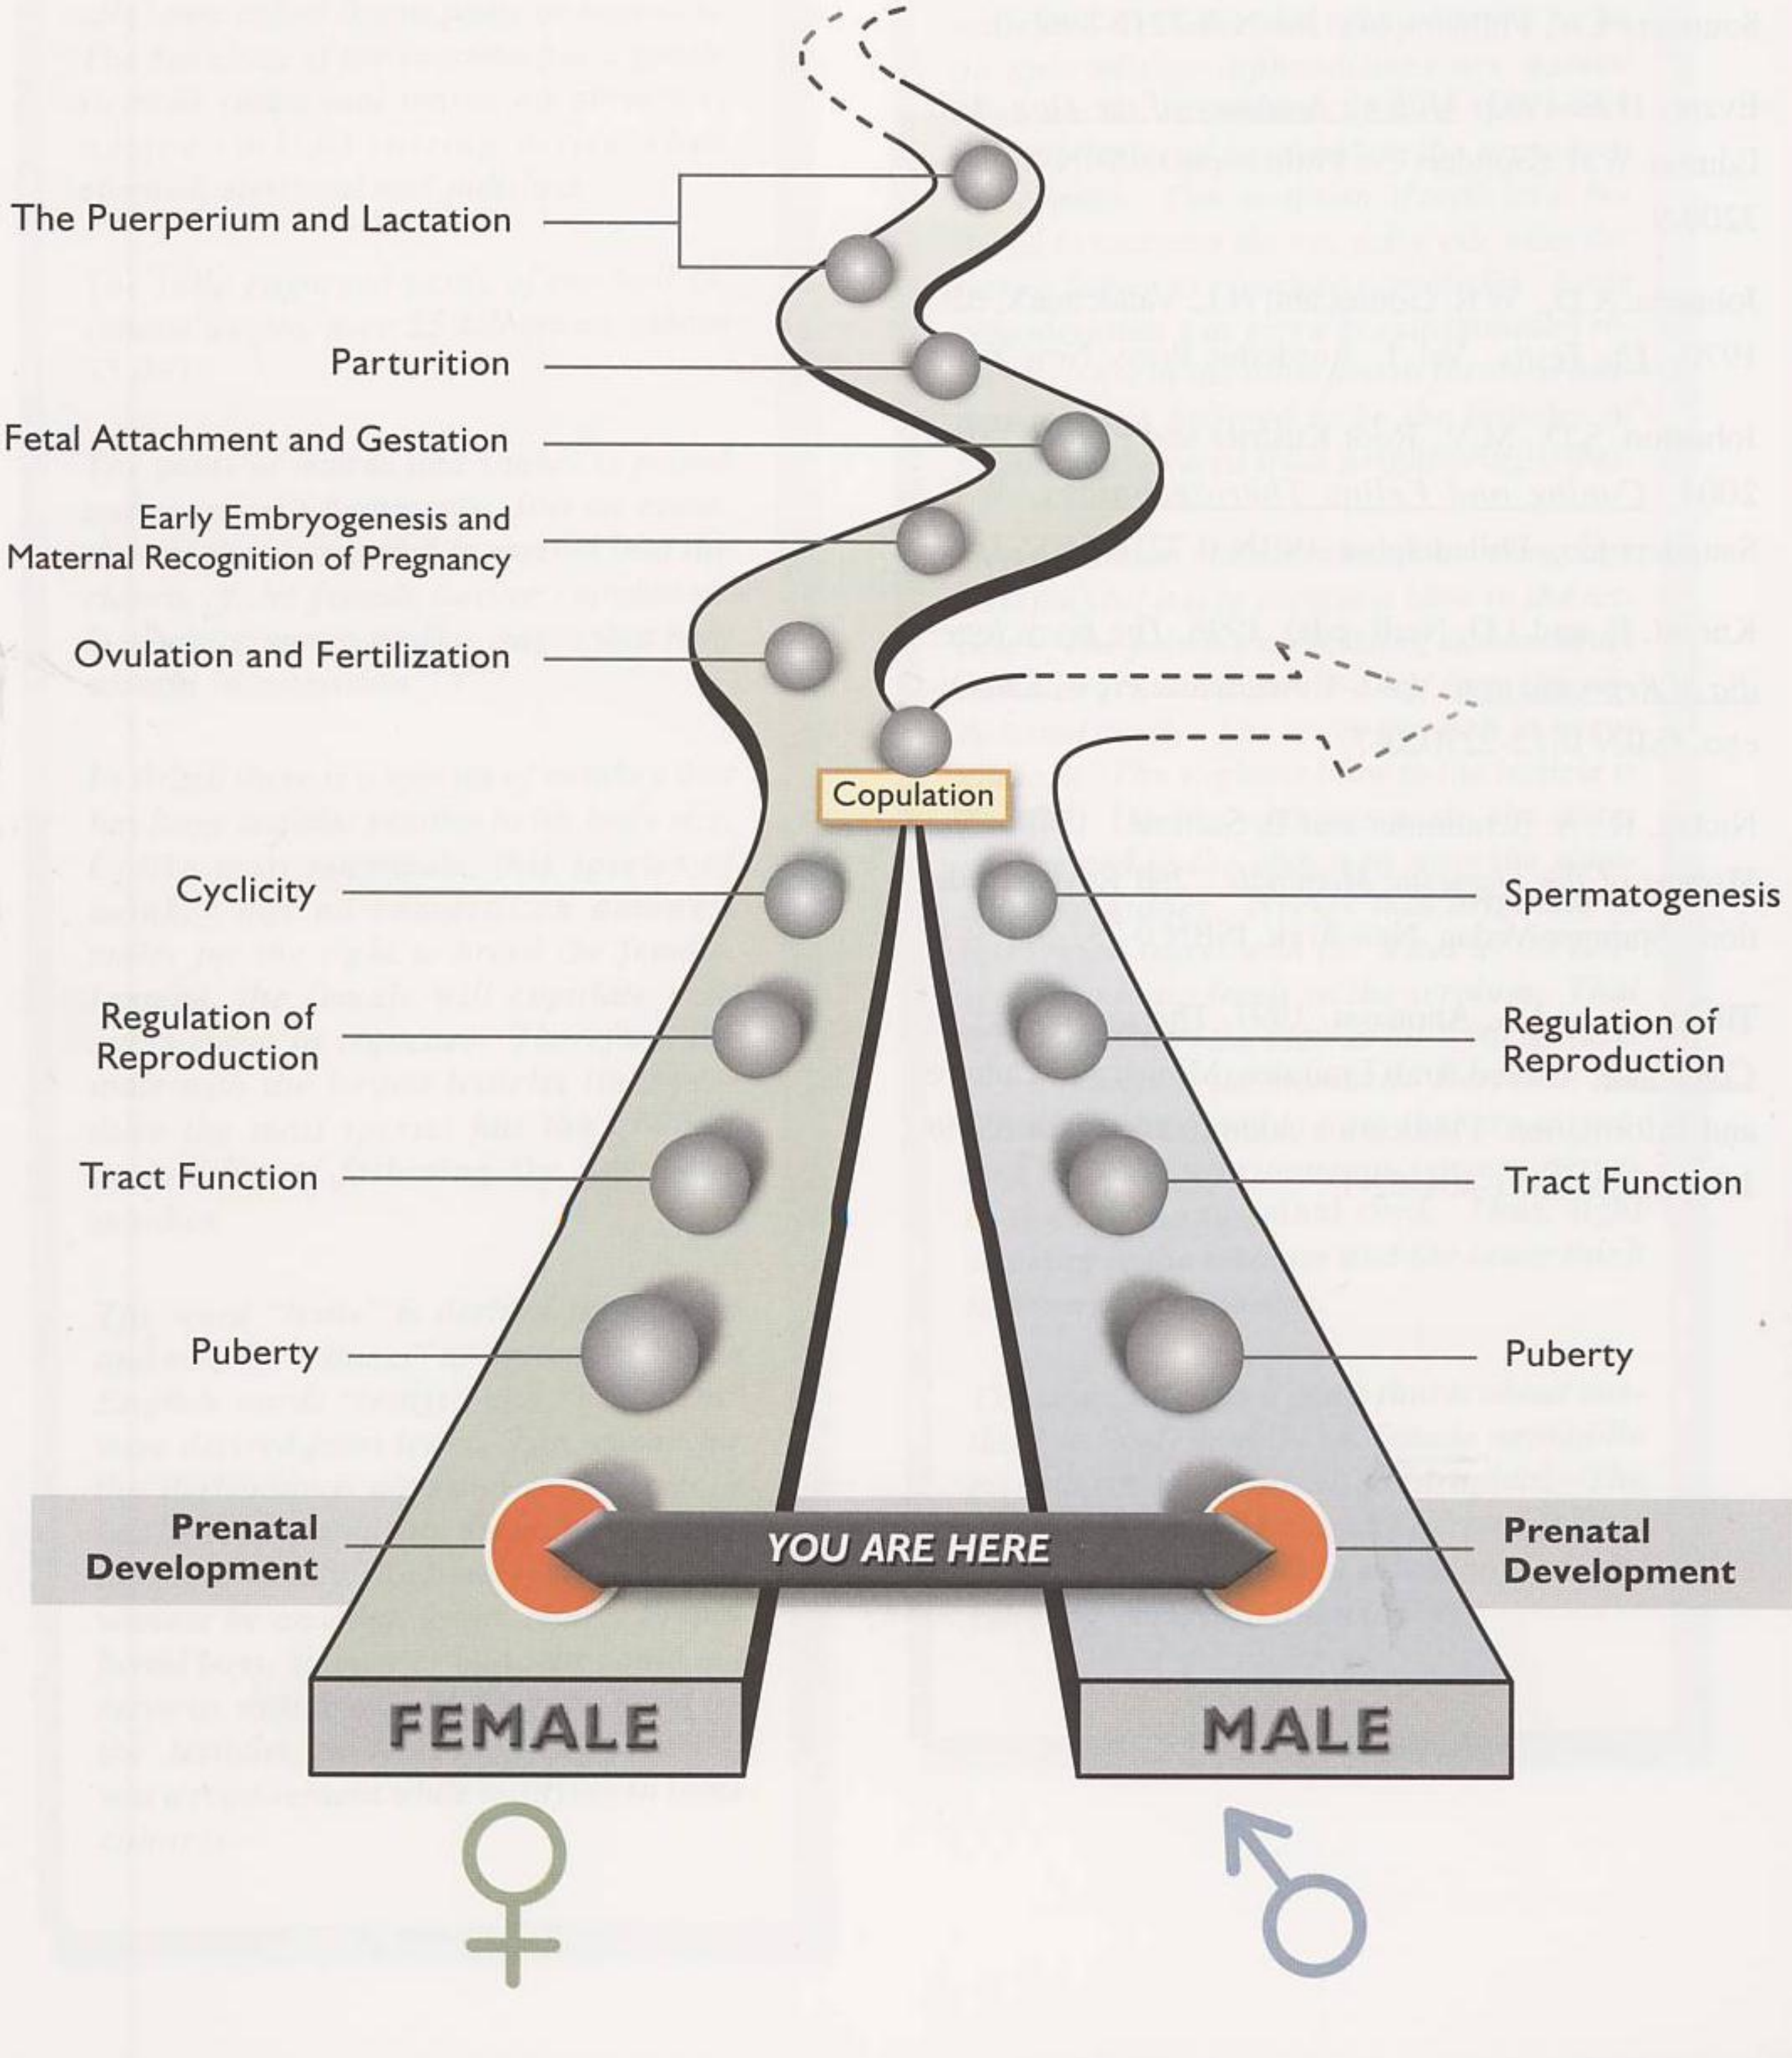
CHAPTER

4 Embryogenesis of the Pituitary Gland and the Male or Female Reproductive System



Take Home Message

The anterior and posterior lobes of the pituitary originate from two distinctly different tissues (neural and epithelial) and anatomical regions in the developing embryo. The anterior lobe originates from the roof of the mouth and the posterior lobe originates from the brain. The embryonic gonad develops into testes or ovaries, depending upon the chromosomal makeup of the cells of the genital ridge. The development of the male reproductive tract requires the presence of testicular determining factor (TDF) and the development of the female tract takes place in its absence. Both the male and the female reproductive tracts originate from a series of tubes. In the male, the mesonephric tubules and ducts are used to form the excurrent duct system. In the female, the paramesonephric ducts form the oviducts, uterus, the cervix and the cranial vagina.

The **embryogenesis** of the pituitary and the male and female reproductive tracts is a remarkably coordinated series of events involving the merging of several types of tissue that will ultimately form complete reproductive glands and organs. The normal development of the urogenital system in mammals is among the most complex of all organ systems and requires critical timing for successful development. Embryogenesis of the reproductive system must be understood from a practical viewpoint, because faulty development generates abnormalities that limit or prevent reproductive function in domestic animals and humans. For example, faulty embryogenesis often results in sterility of either the male or the female. The information presented in this chapter will not contain strict timelines because these vary significantly among species. However, the sequence of events presented is similar among most mammalian species.

During embryogenesis various cells form organs that **differentiate** from discrete **germ layers** that make up the embryo. **Differentiation** is the process whereby a group of unspecialized cells develops into

a functional, recognizable group of cells that have a common function. The germ layers that appear prior to embryo attachment to the uterus, are called the **endoderm**, **mesoderm** and **ectoderm**. The endoderm (**endo**=inside, **derm**=skin) is the innermost cellular layer of the embryo and will eventually give rise to the digestive tract, liver, pancreas, lungs and endocrine organs. The ectoderm (**ecto**=outer, **derm**=skin or layer) develops from the outer cells of the inner cell mass. As you will see in Chapter 13, the inner cell mass is a clump of cells that will become the embryo. The ectoderm will give rise to the central nervous system, sense organs, mammary glands, sweat glands, skin, hair, claws and hooves. The middle layer of the embryo is referred to as the mesoderm (**meso**=middle, **derm**=skin or layer). The mesoderm develops between the ectoderm and the endoderm. This germ layer gives rise to the circulatory, skeletal, muscular and urinary systems. Most of the reproductive system is derived from the mesoderm. A more complete listing of tissue derivations is presented in Table 4-1.

Figure 4-2. The Main Embryological Events in the Development of the Reproductive System

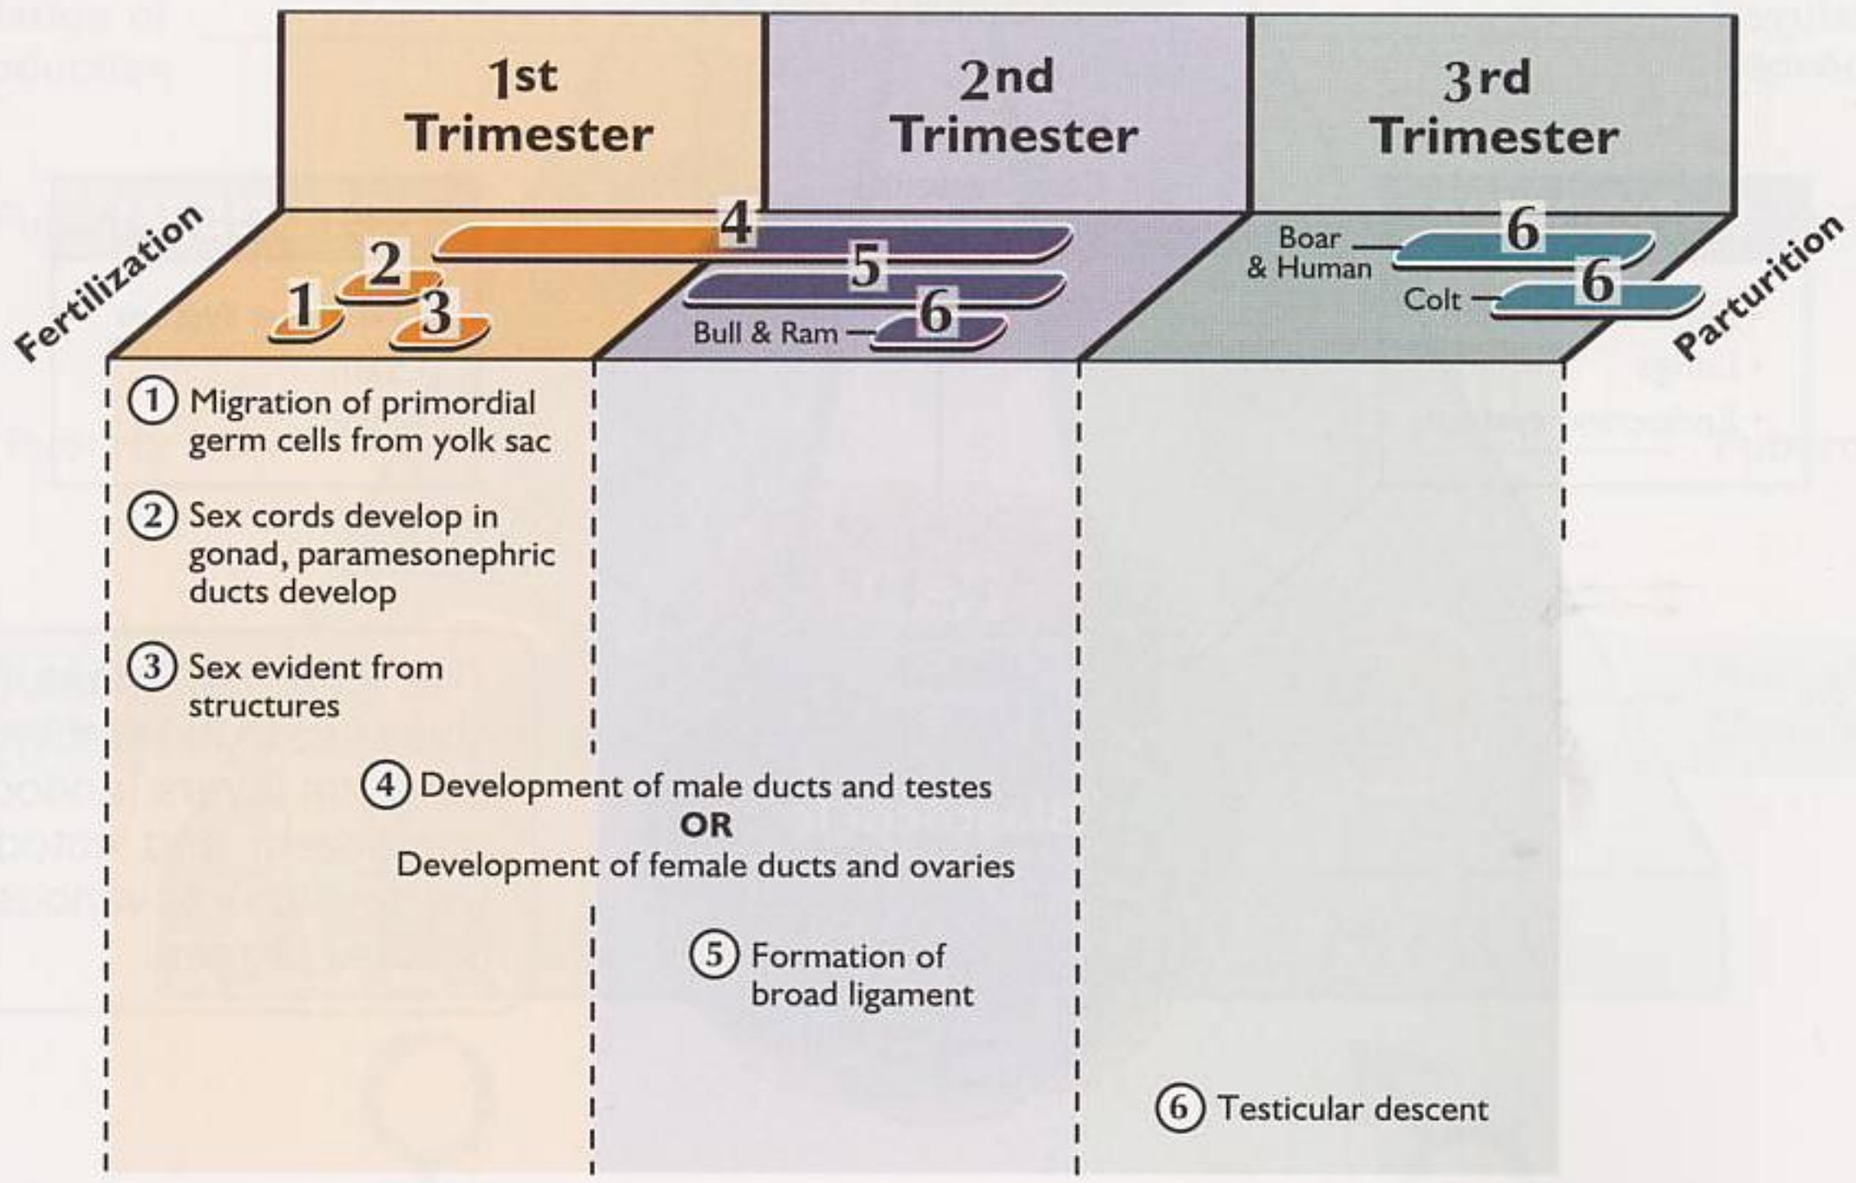

Figure 4-3. Embryonic Development of the Anterior and Posterior Lobes of the Pituitary

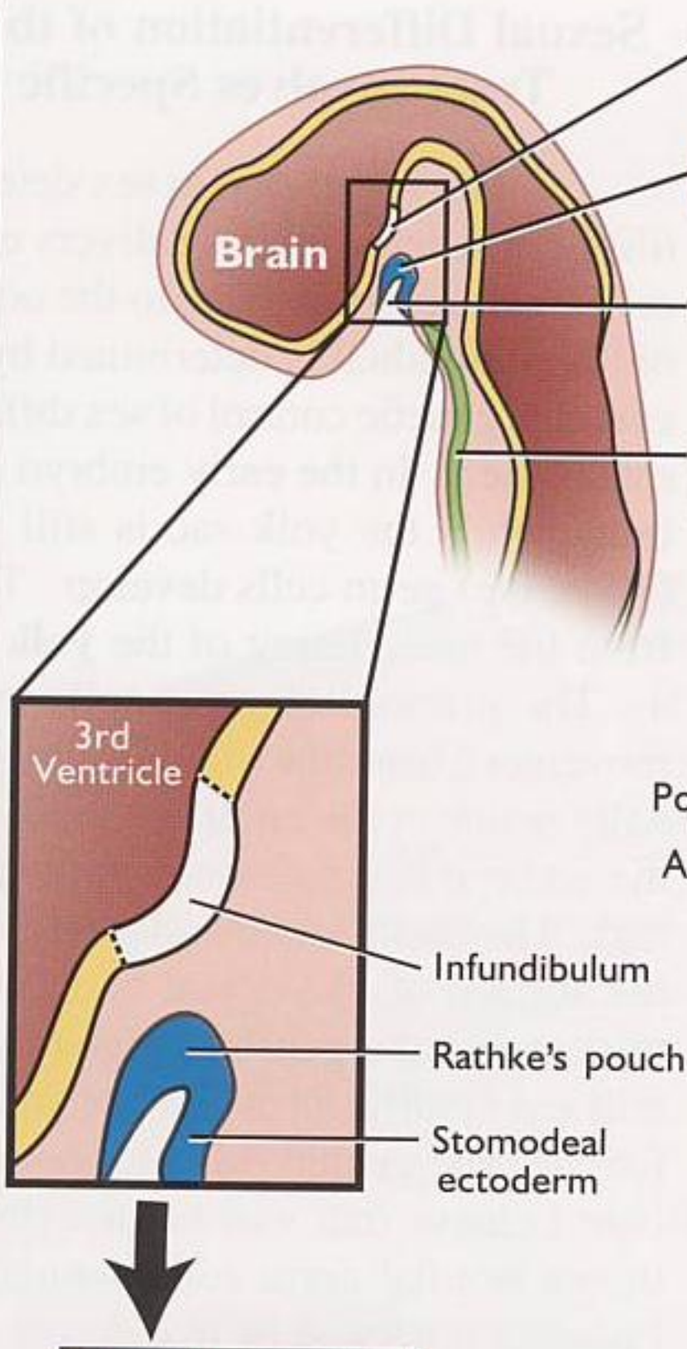
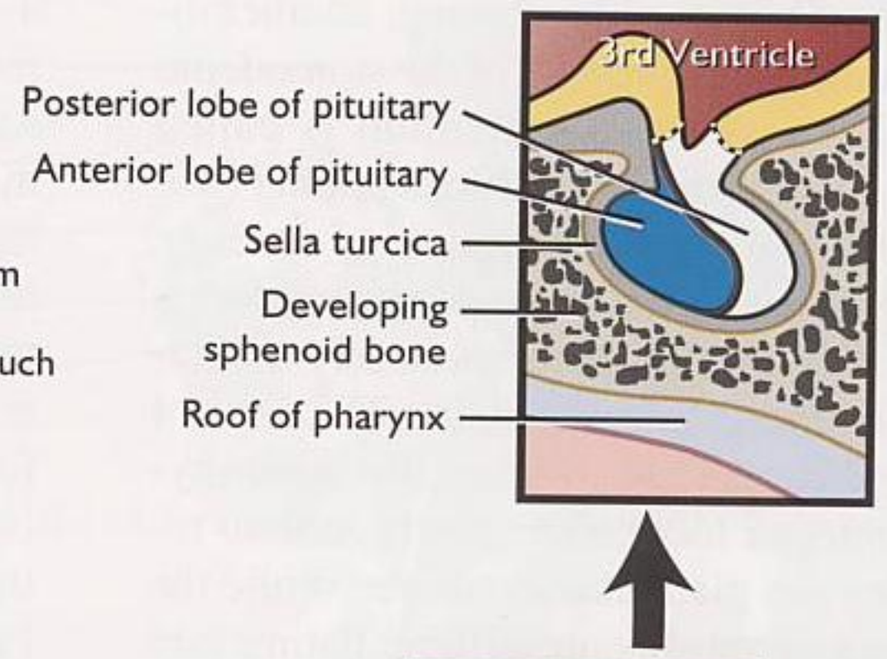
(Modified from Larsen, W.J., *Human Embryology*, with permission from Elsevier)

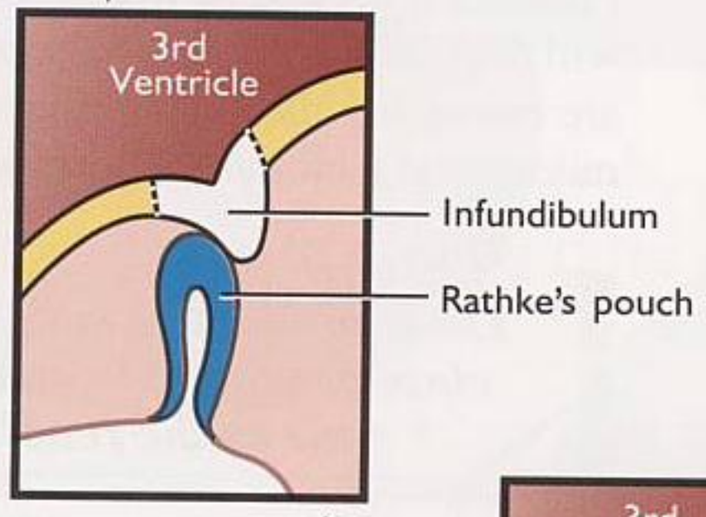
The posterior lobe of the pituitary is formed from a diverticulum (a sac diverting from the main cavity) from the floor of the brain. The third ventricle is a cavity within the brain that will be described more completely in Chapter 5. Once this outpocketing begins to form, it is referred to as the infundibulum.

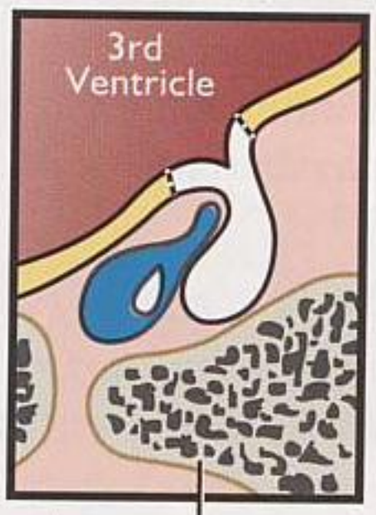


The anterior and posterior lobes become surrounded by a deep recess of the sphenoid bone known as the sella turcica (Turkish saddle).

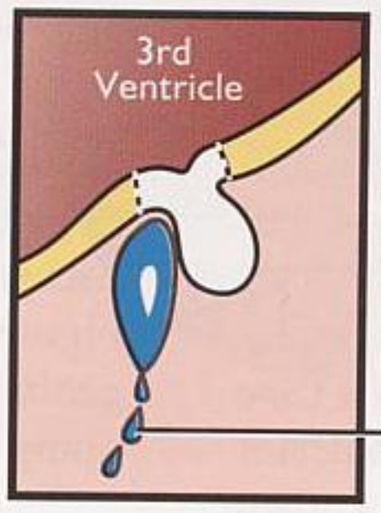


The anterior lobe of the pituitary forms as an evagination from the oral cavity, referred to as Rathke's pouch.





Rathke's pouch completely separates from the stomodeal ectoderm and becomes intimately associated with the new posterior lobe.



The stalk of Rathke's pouch begins to regress and eventually completely separates from the stomodeal ectoderm. At the same time, the infundibulum continues to evaginate to form the posterior lobe of the pituitary.

The Pituitary Gland Originates from the Brain and from Tissue in the Roof of the Mouth

The **posterior lobe** of the pituitary originates from neural tissue of the brain. The **anterior lobe** of the pituitary originates from a completely different type of tissue in the roof of the embryo's mouth. Tissue in the roof of the mouth, called **stomodeal ectoderm**, will give rise to the glandular tissue of the anterior lobe. Early in embryo development a **diverticulum** (a sac or pouch diverting from a main tube, channel or cavity) develops from the floor of the brain and grows ventrally toward the roof of the **stomodeum** (the embryonic mouth) (See Figure 4-3). This diverticulum is called the **infundibulum**. At the same time that the infundibulum is developing, another diverticulum originates from the roof of the stomodeum and grows dorsally. This diverticulum is called **Rathke's pouch,** or sometimes **Rathke's pocket** (See Figure 4-3). As Rathke's pouch continues to develop, it loses its continuity with the stomodeum and forms a discrete body of cells that become closely associated with the developing infundibulum. The cells of Rathke's pouch differentiate to form the **adenohypophysis** (the anterior lobe). The prefix **adeno** refers to tissues that are glandular in nature. While the cells of the adenohypophysis are differentiating into various specialized cells capable of producing a variety of hormones, the infundibulum differentiates to form the **neurohypophysis** (posterior lobe).

Hypophysis = pituitary
Adenohypophysis = anterior lobe
Neurohypophysis = posterior lobe

The posterior lobe contains the axons and nerve terminals (telodendria) of neurons whose cell bodies are located in the hypothalamus (See Chapter 5). As development of the pituitary nears its completion, a cranial bone known as the **sphenoid bone** (See Figure 4-3) begins to form around both the anterior and posterior lobes. This protective cavity is known as the **sella turcica**. This bony cavity is so named because it resembles the side view of the seat of a Turkish saddle.

It is important to understand that the dual embryonic origin allows the anterior and posterior lobe to perform entirely different functions. For example, the nerves of the posterior lobe cause a direct and rapid release of oxytocin that causes milk ejection by the mammary gland. In contrast, the adjacent anterior pituitary lobe consists of specialized glandular epithelial cells that produce glycoprotein hormones like follicle stimulating hormone and luteinizing hormone that are not produced by nerve cells.

Sexual Differentiation of the Reproductive Tract Involves Specific Substances

The initial step in sex determination is at fertilization when a sperm delivers either an X (female) or Y (male) chromosome to the oocyte. Thus, the sex of the individual is determined by the sperm and the eventual genetic control of sex differentiation has been established. In the early embryo (first 15% of gestation), when the yolk sac is still present, primordial (primitive) germ cells develop. These cells originate from the inner lining of the **yolk sac** (See Figure 4-4). The primordial germ cells migrate by ameboid movement from the yolk sac into the hindgut and finally reside in the undifferentiated gonad. The sex of the embryo is not obvious in the undifferentiated gonad. The undifferentiated gonad is located on the inner surface of the dorsal body wall and is known at this time as the **genital ridge** (or **gonadal ridge**). It will eventually form the gonads in the male or the female. The genital ridge forms medial to the embryonic kidneys that will be described below. Most of the primordial germ cells populate the genital ridge. Primordial germ cells that do not reside in this region will degenerate. During the time primordial germ cells are colonizing the genital ridges, they are undergoing mitosis and their numbers increase significantly.

The reproductive system develops in close proximity to and at the same time as the renal system.

When the primitive germ cells arrive in the genital ridge, they stimulate local connective tissue to proliferate. This results in the formation of compact strands of tissue called **primitive sex cords** (See Figure 4-4). These proliferating sex cords cause the genital ridges to enlarge and push toward the developing kidney (mesonephros).

During its development the embryo utilizes three morphologically distinct renal systems. The first, called the **pronephros (pronephric kidney)**, is a nonfunctional remnant of a primitive form of kidney found in lower animals. Early in embryogenesis, the pronephros regresses and is replaced by a functional, bilateral pair of intermediate kidneys known as the **mesonephros (mesonephric kidney)** (See Figure 4-5). The mesonephros produces urine that is drained by a bilateral pair of ducts called the **mesonephric ducts**.

Figure 4-4. Migration of Primordial Germ Cells from the Yolk Sac Into the Gonadal Ridge

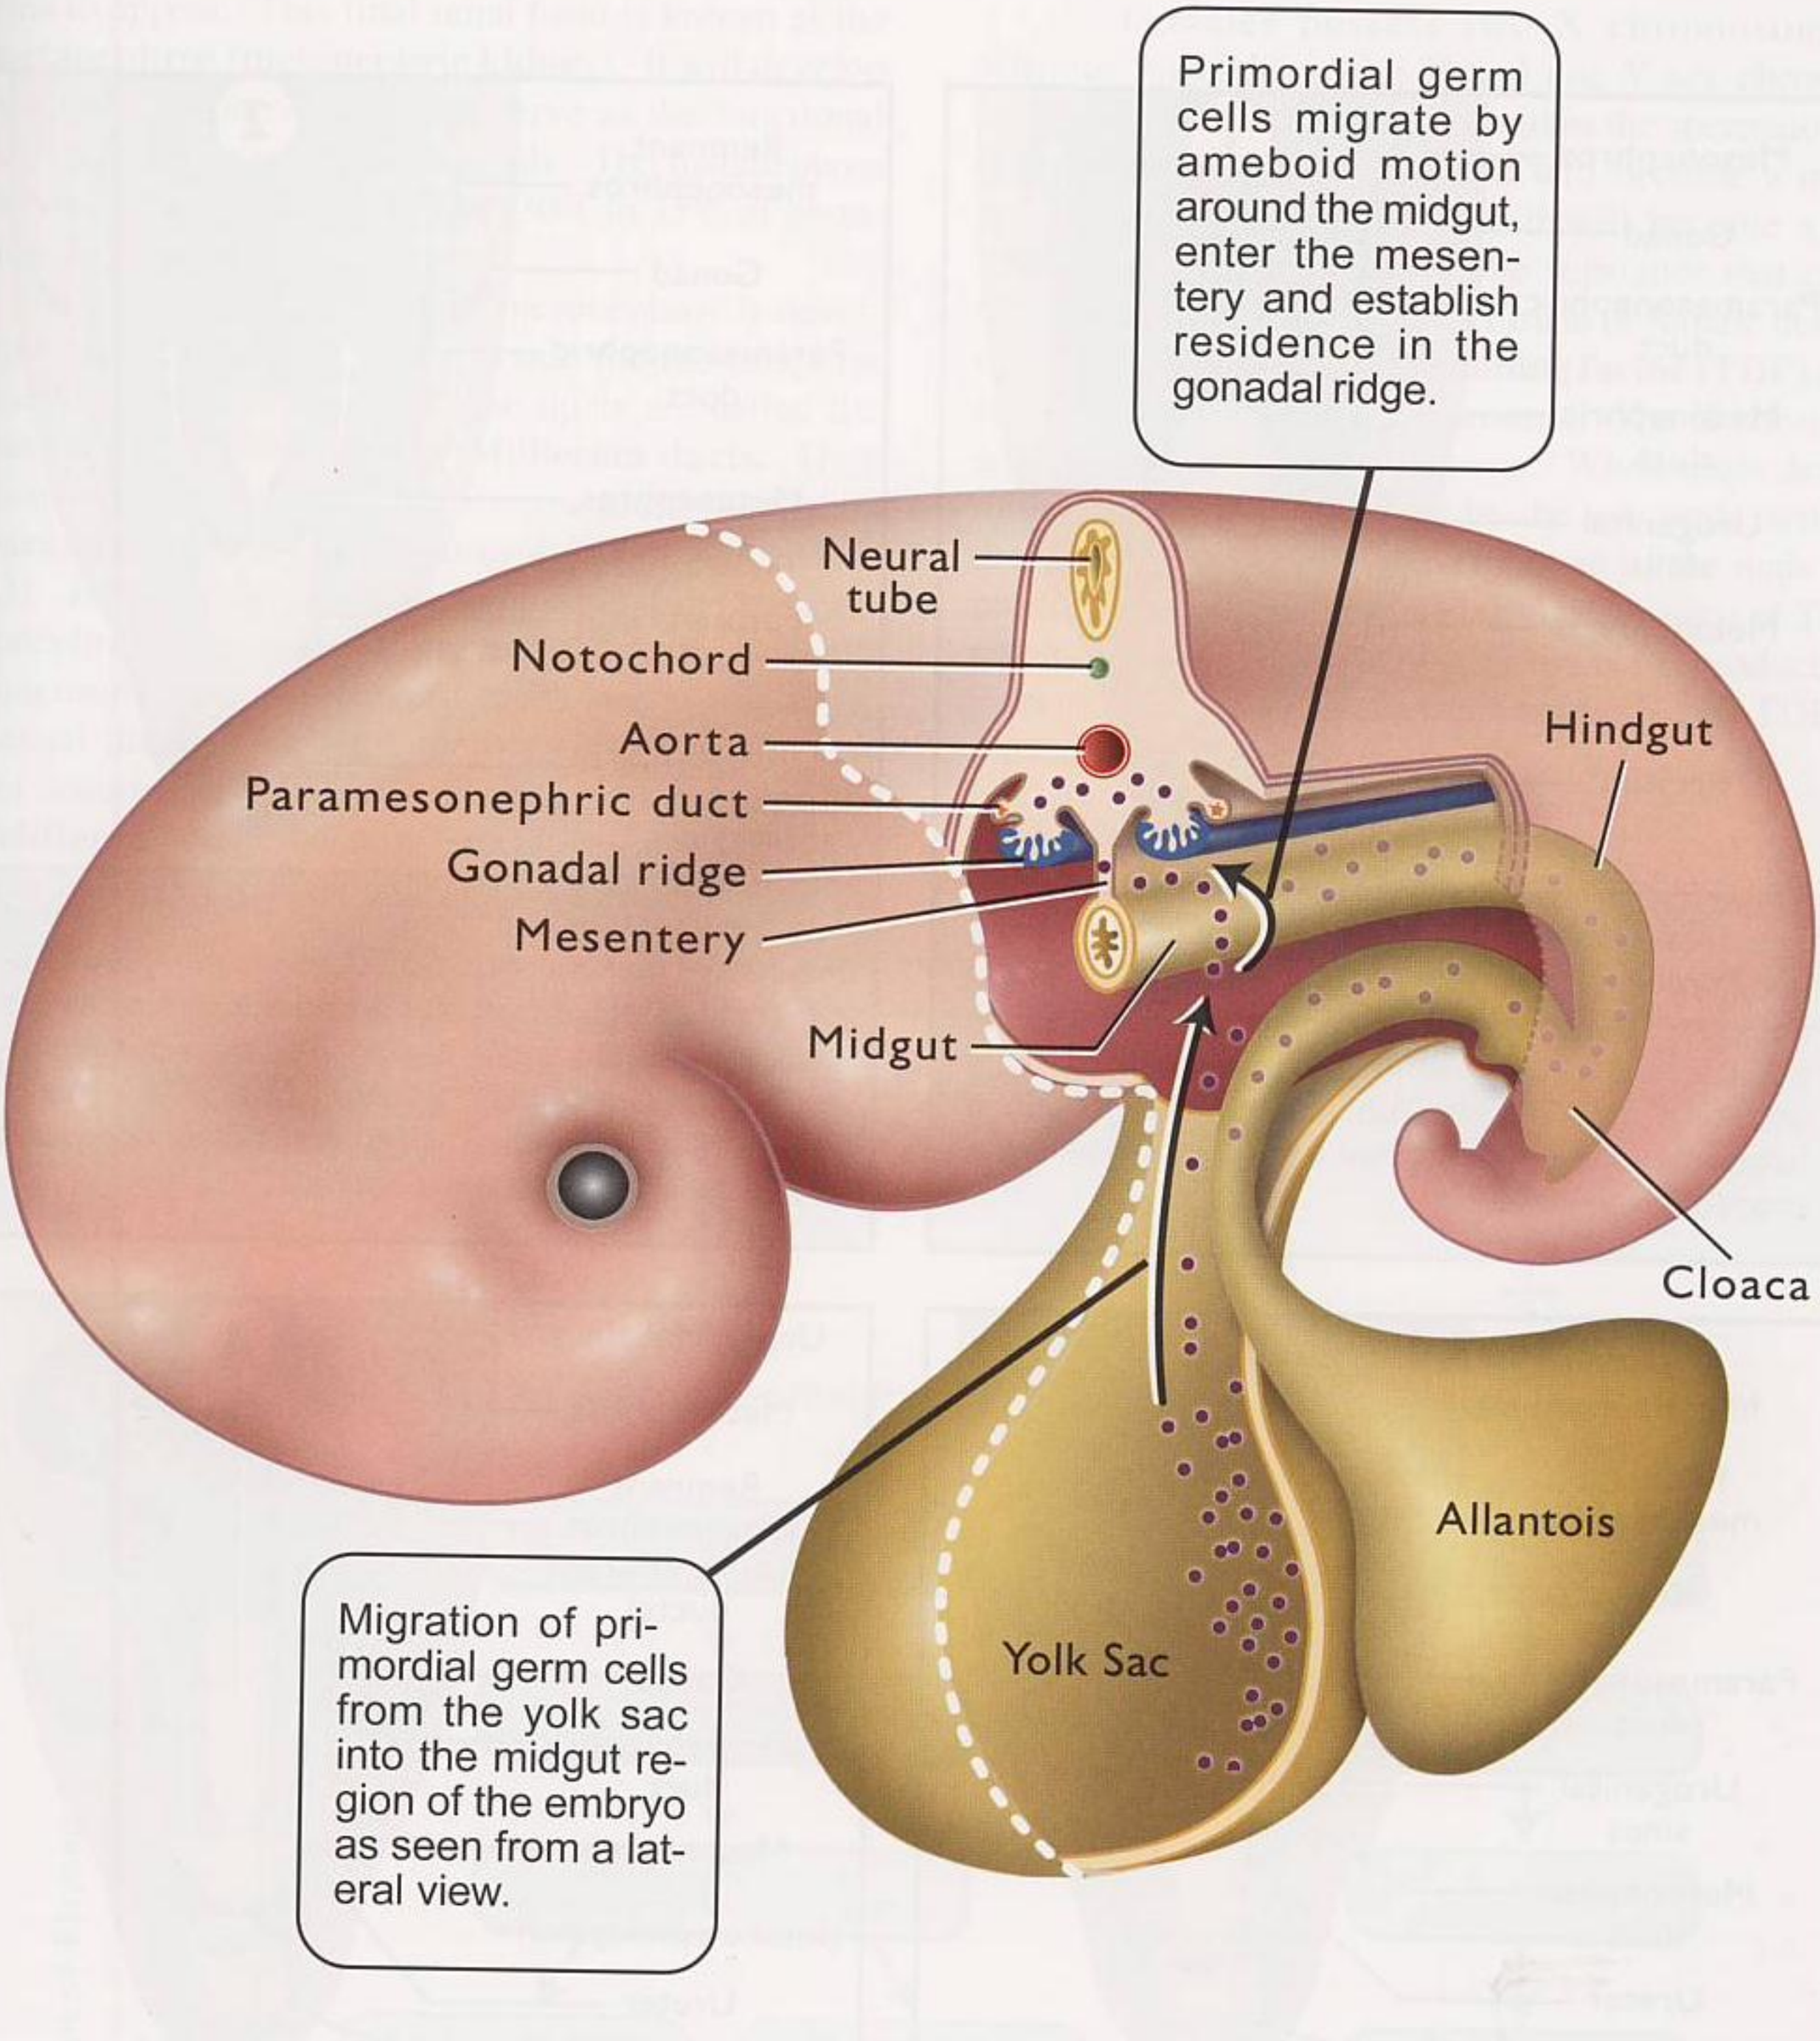


Figure 4-5. Development and Regression of the Mesonephros with Concurrent Development of the Gonad (Dorsal View)

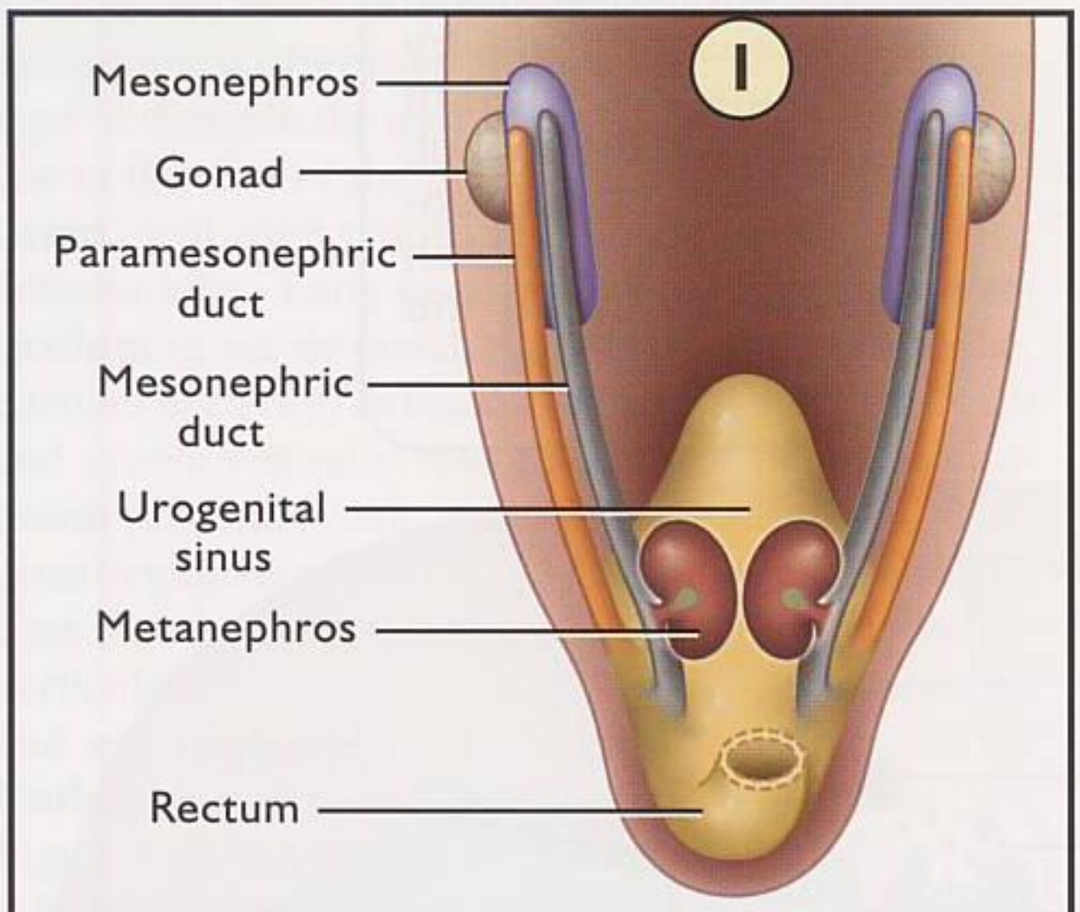
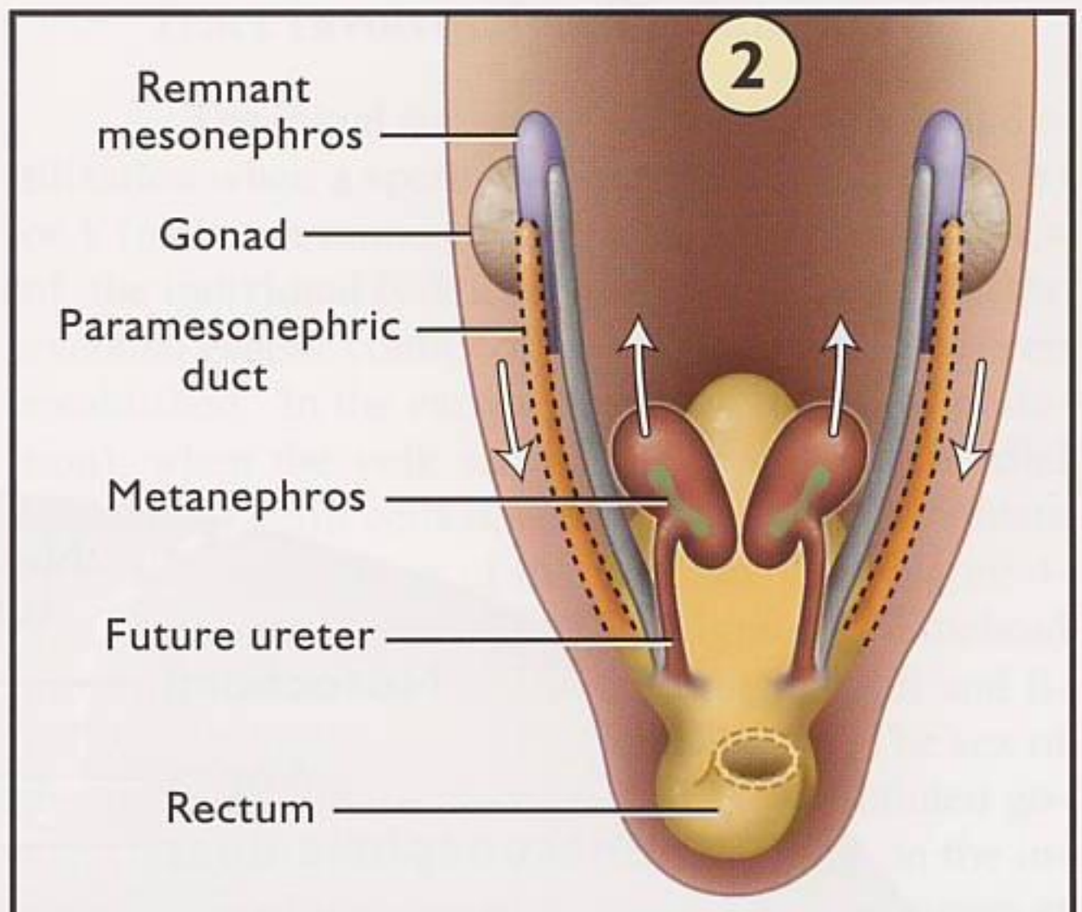
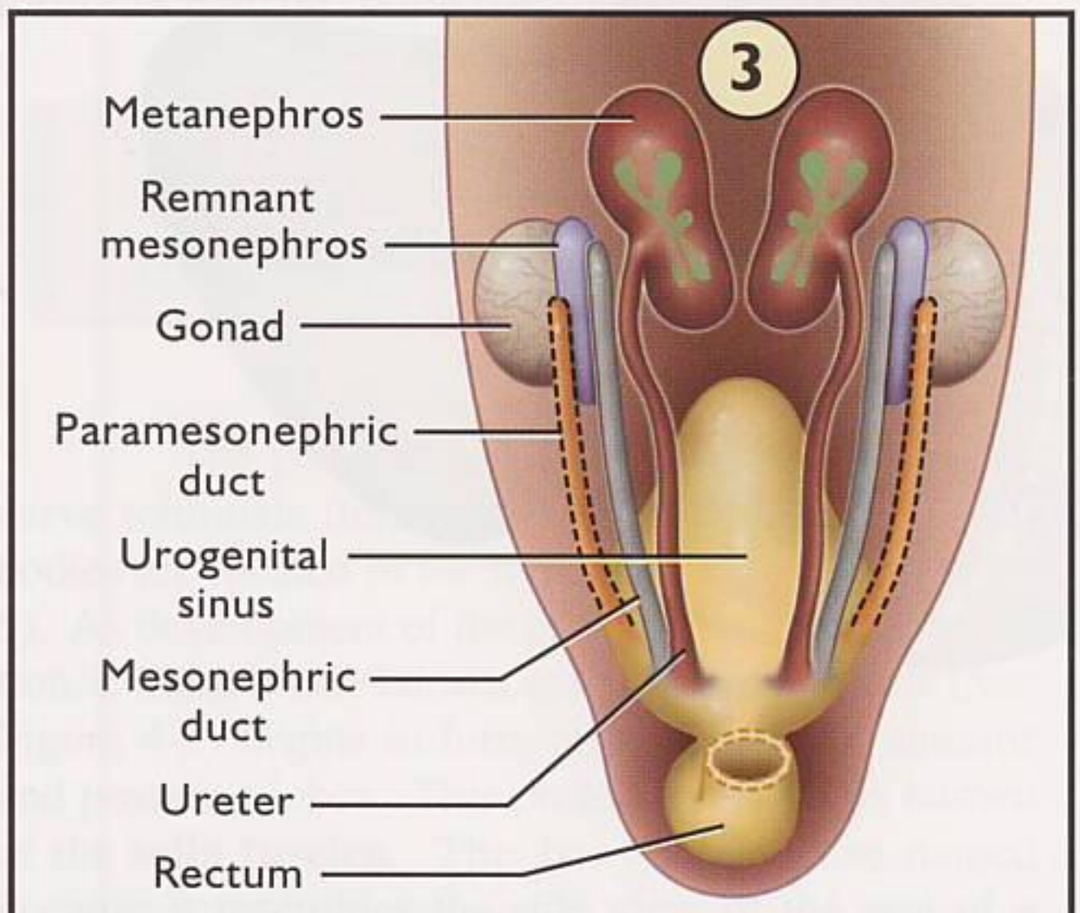


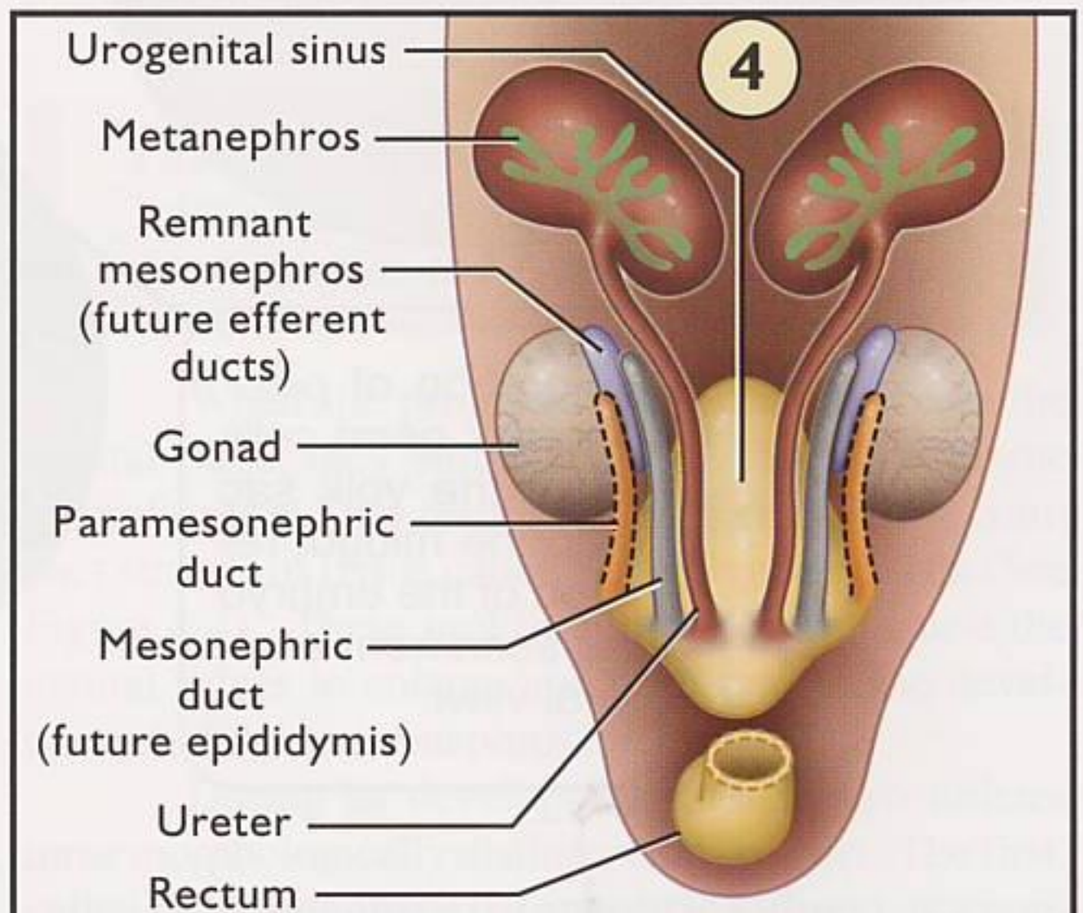
The mesonephros is closely associated with the undifferentiated gonad. At this stage, the mesonephros is functional and is a simple version of the adult kidney. The mesonephros is drained by a series of mesonephric tubules that merge into a larger mesonephric duct that transports urine to the urogenital sinus.



The metanephros initially forms as a small bud from the caudal mesonephric duct. The mesonephros begins to lose its function and decreases in size as the metanephros increases in size. The paramesonephric duct (dashed line) develops beside the mesonephric duct. Note that the gonad is also increasing in size relative to the mesonephros.



The gonad continues its enlargement as does the metanephros. The metanephric duct will become the ureter.



The metanephros becomes fully functional and the gonad becomes larger, while the mesonephros has almost completely regressed. In the male, some of the mesonephric tubules will form the efferent ducts and the mesonephric duct will form the epididymis and the ductus deferens. The paramesonephric ducts degenerate in the male.

These ducts were formerly called **Wolffian ducts**. The mesonephric ducts extend caudally and empty into the **urogenital sinus** (See Figure 4-5). By the first 10% to 15% of gestation the final form of kidney begins to appear. This final renal form is known as the **metanephros (metanephric kidney)**. It will develop functional nephrons and will serve as the functional form of kidney in adult mammals. The metanephros becomes functional by the first 30% to 35% of gestation.

At the same time the mesonephros is developing, a new pair of ducts beside the mesonephric ducts begin to develop. These ducts are called the **paramesonephric ducts** or **Müllerian ducts.** They form on either side of the mesonephric duct, thus **para**mesonephric (See Figures 4-4, 4-5, 4-7 and 4-13). Even though the mesonephric and the paramesonephric ducts are both present, the embryo is still "uncommitted" with regard to its sex at this time. Sexual differentiation of the organs *per se* still has not occurred. This stage is referred to as the **sexually indifferent stage** because morphologic discrimination between the male and female embryo cannot be made by simple observation.

Sexual Differentiation is Regulated by a Single Substance Directed by a Gene on the Y Chromosome

Females possess two X chromosomes, whereas males have one X and one Y sex chromosome. The sex chromosomes within the spermatozoa determine whether the embryo will become a male and develop testes or whether it will become a female and develop ovaries. The substance that controls the pathway toward either male or female development is called **testis determining factor (TDF)** and is controlled by the Y chromosome. The X chromosome does not have such a gene. When testis determining factor is synthesized by the sex cords within the primitive gonad, the development of the male reproductive system is stimulated. The absence of TDF results in the development of a female reproductive system. The pathway of events controlled by TDF is presented in Figure 4-6.

Figure 4-6. Pathway of Events Leading to Formation of the Male and Female Reproductive System

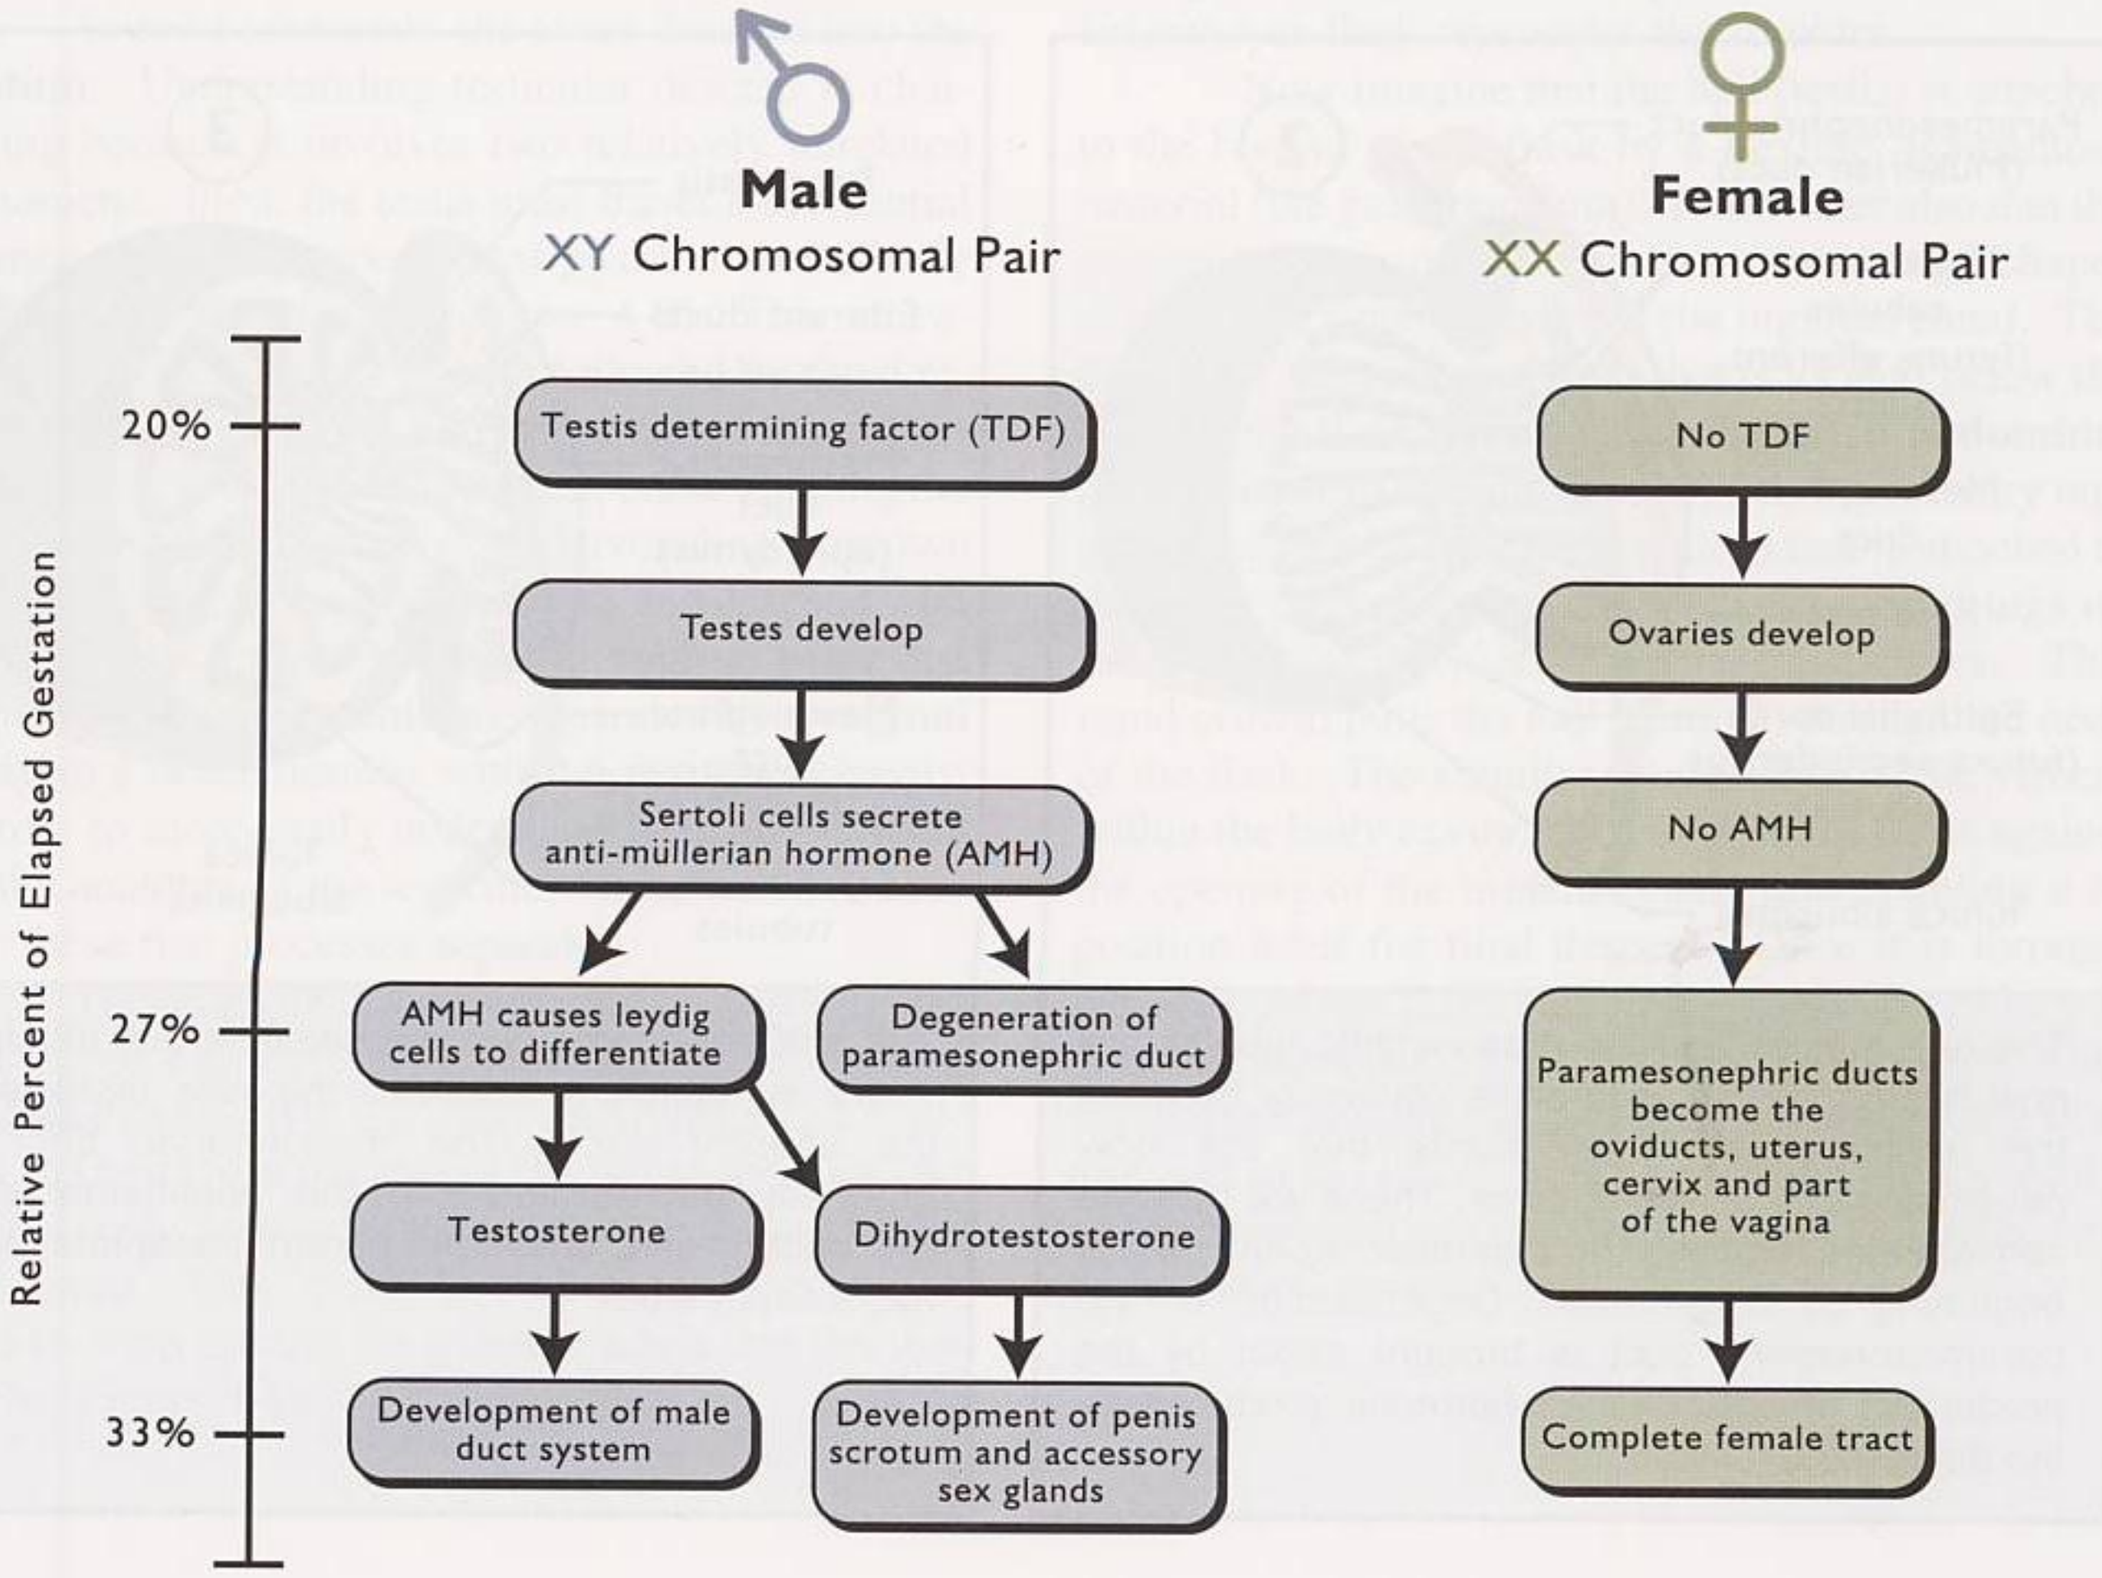


Figure 4-7. Developmental Sequence of the Testis

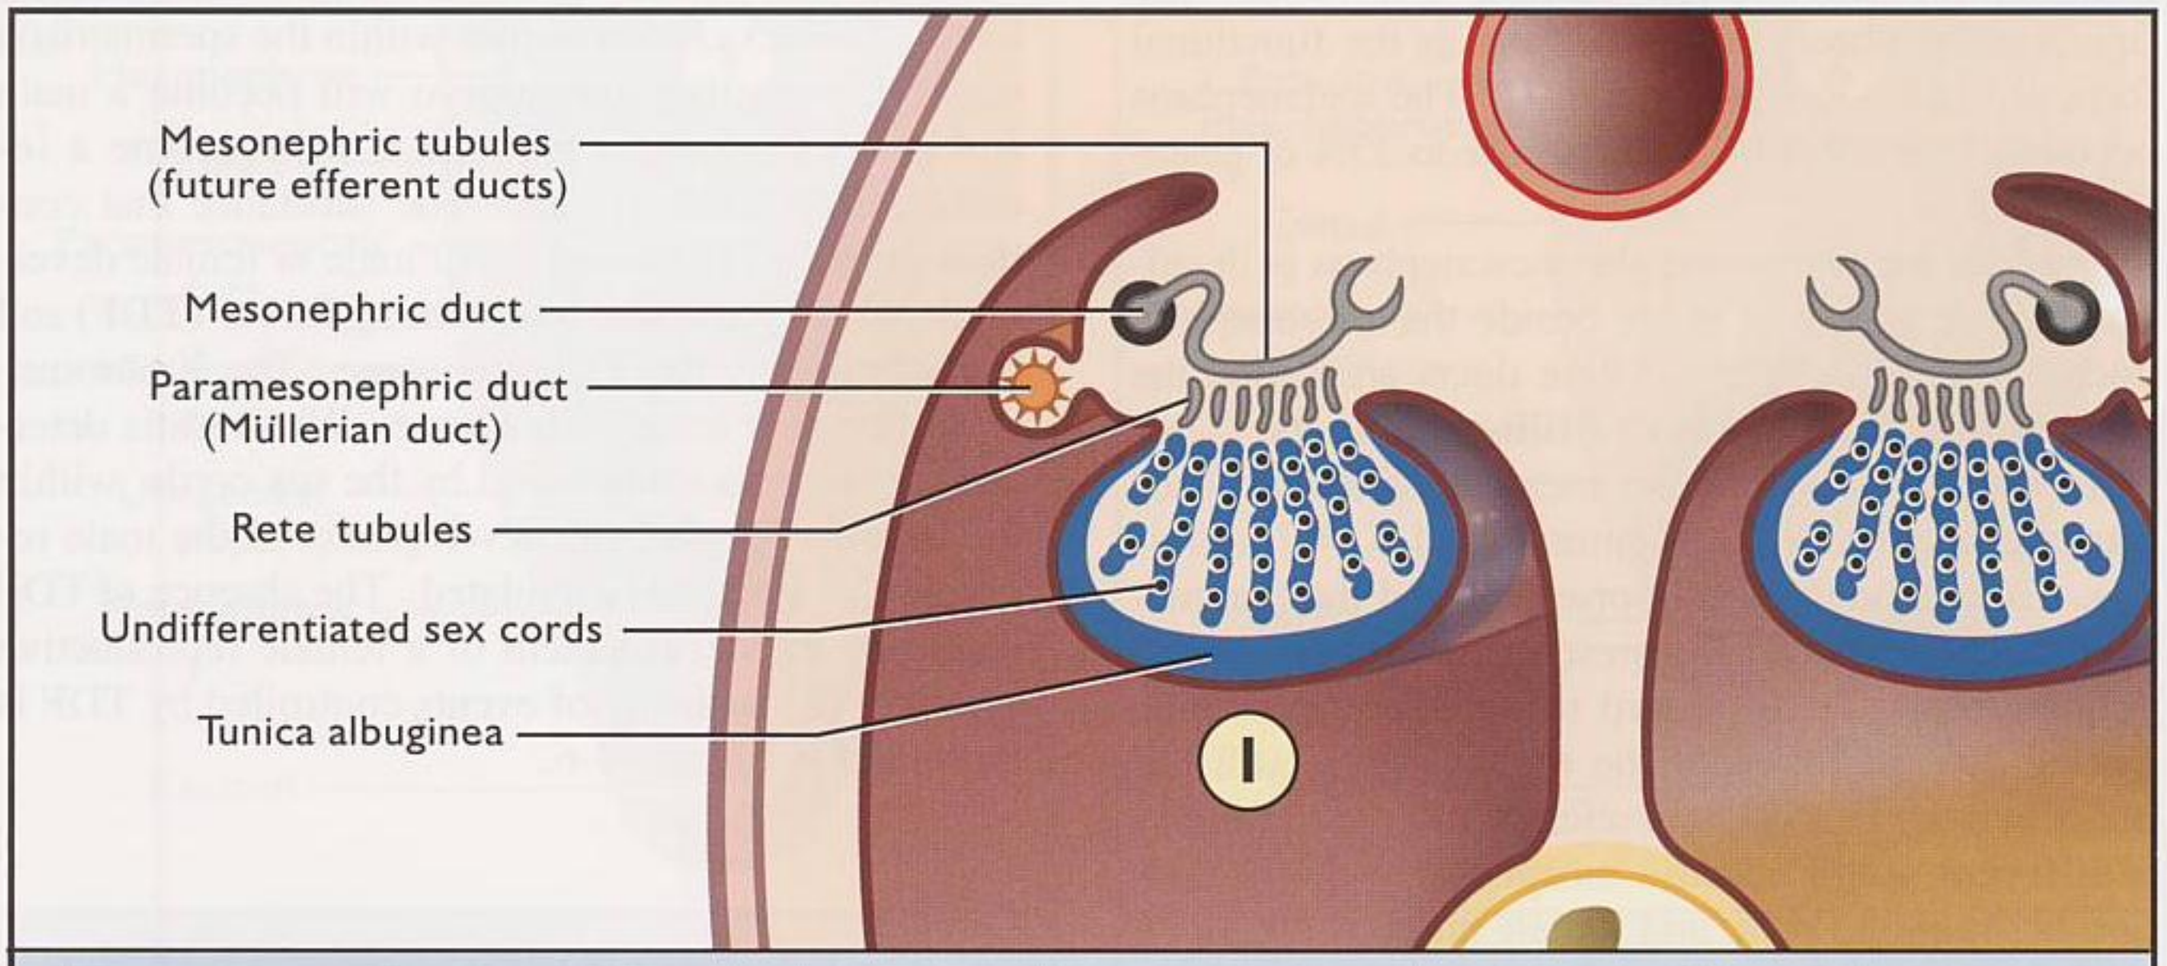
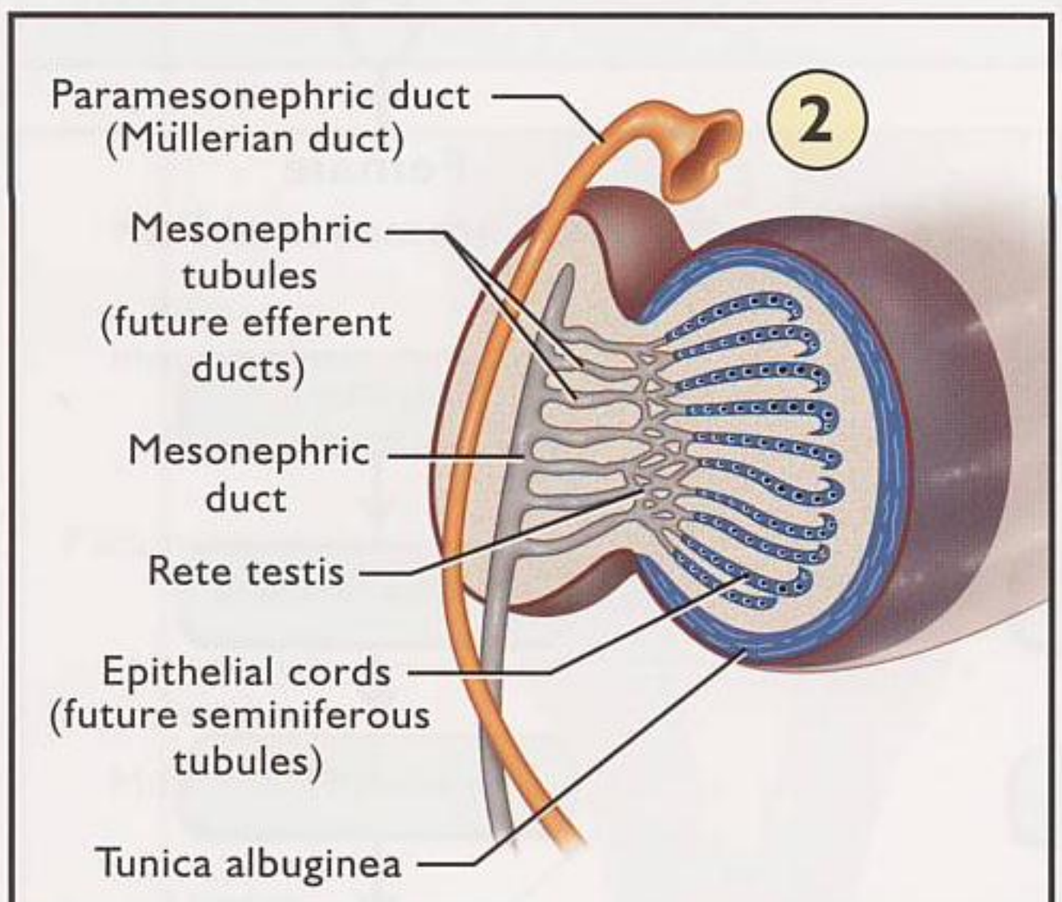
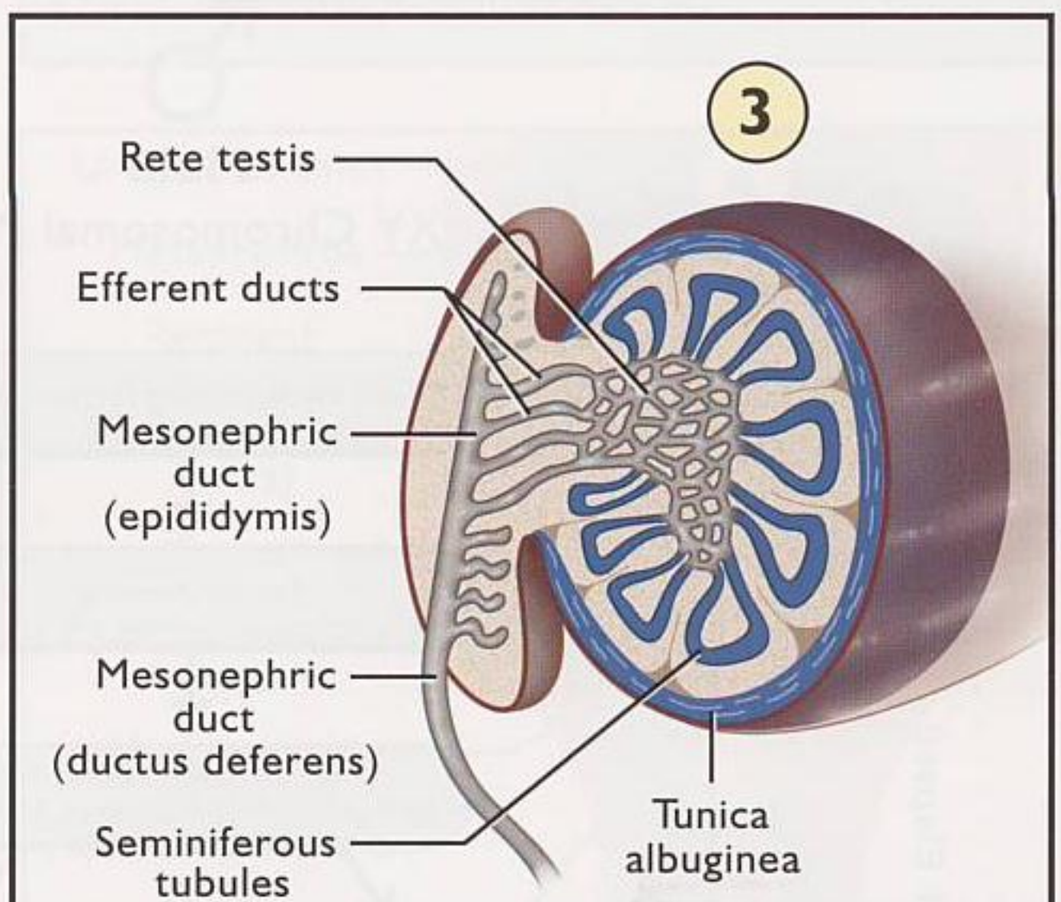


A transverse section through the developing gonadal region of the embryo. The undifferentiated sex cords begin to align themselves with the small rete tubules. The mesonephric tubules have not interconnected with the rete tubules. The surface of the undifferentiated gonad is covered with a layer of connective tissue called the tunic albuginea. The paramesonephric duct (Müllerian duct) is present, but serves no function.



The rete tubules and the mesonephric tubules are now interconnected to provide continuity between the undifferentiated sex cords that are now developing into epithelial cords. These will become seminiferous tubules. The paramesonephric duct is beginning to degenerate. Degeneration of the paramesonephric duct is brought about by the production of antimüllerian hormone produced by the developing testis.



The epithelial cords become seminiferous tubules. There is continuity between the rete testis and the efferent ducts. The mesonephric duct is gradually transformed into the epididymis and the ductus deferens. The paramesonephric duct has disappeared.

Part of the male tract is derived from the mesonephros
- *mesonephric tubules →efferent ducts*
- *mesonephric ducts →epididymis and ductus deferens*

In the male embryo, portions of the mesonephric kidney are appropriated for use in the reproductive tract at about the same time that the paramesonephric ducts begin to degenerate. Between 5 and 15 **mesonephric tubules** penetrate into the primitive gonad and make connections with the primitive sex cords via the **rete testis**. The rete testis is a network of tiny ducts that connect the seminiferous tubules to the **efferent ducts**. The efferent ducts are derived from the mesonephric tubules (See Figure 4-7). The mesonephric duct will give rise to the epididymis and ductus deferens. Together, the **efferent ducts**, the **epididymis** and the **ductus deferens** are appropriated to become the **excurrent extragonadal duct system** of the male reproductive tract.

The Testes are Formed at the Level of the Ribs. They Descend into the Scrotum Late in Gestation

In most mammals, the testes descend into the **scrotum**. Understanding testicular descent is challenging because it involves two relatively unrelated phenomena. First, the testis must travel a substantial distance from a retroperitoneal position in the body cavity to the scrotum (See Figure 4-8). This movement involves the rapid growth followed by rapid regression of a ligamentous structure called the **gubernaculum**. The second challenge in understanding the process of descent involves understanding how two layers of peritoneum cover the testis and descend with it. These two layers, the **visceral vaginal tunic** and the **parietal vaginal tunic** are separated by a **vaginal cavity** that is continuous with the peritoneal cavity. In order to more easily understand testicular descent and the anatomy of the testicular tunics we shall consider these two processes separately.

The testes lie in a retroperitoneal position and are attached caudally to the ligamentous gubernaculum (See Figure 4-8). The gubernaculum extends caudally and resides in the area of the future scrotum. As the fetal body grows the testes are pushed against the peritoneum. This "pushing-out" causes the peritoneum to wrap around the gubernaculum and the testes (See Figure 4-8).

The descent of testicles has three phases. They are:
- *growth and elongation of the fetal body away from the testes*
- *rapid growth of the extra abdominal gubernaculum*
- *shrinkage of the gubernaculum within the scrotum*

The first phase involves growth and elongation of the body away from the stationary testis. The second phase involves the rapid growth of the distal gubernaculum. The distal portion of the gubernaculum is that portion that has passed through the inguinal ring (See Figure 4-8) and forms an outgrowth into the future scrotum.

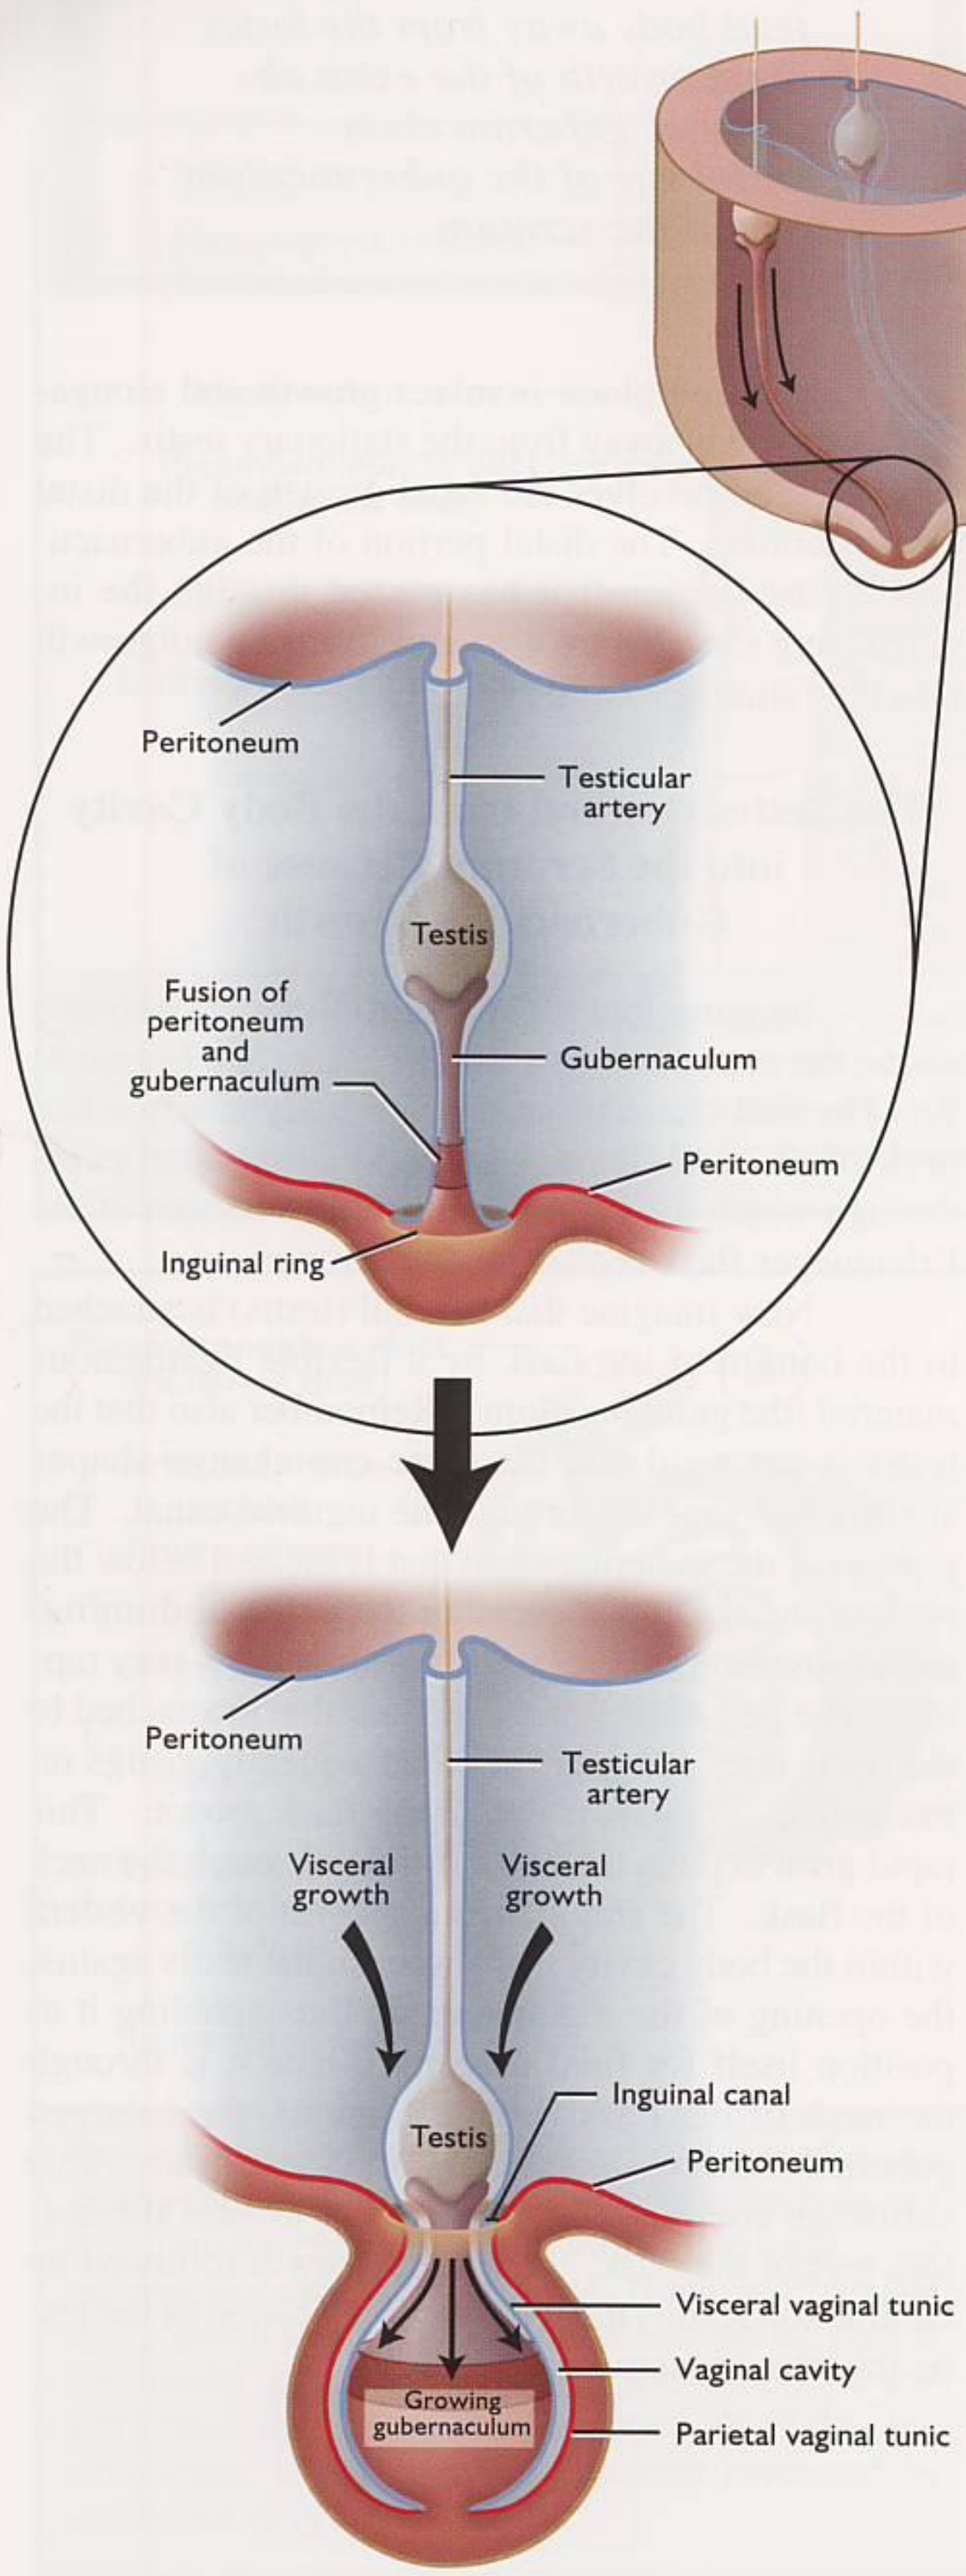
The Testes Descend from the Body Cavity into the Scrotum Because of Gubernacular Growth

Imagine that a flexible ball was positioned above the neck of an Erlenmeyer flask (See Figure 4-9). The ball (testis) is inside the body cavity. The neck of the flask is analogous to the inguinal canal through which the ball must pass. The bottom of the Erlenmeyer flask represents the scrotum.

Now imagine that the ball (testis) is attached to the bottom of the flask by a flexible ligamentous material (the gubernaculum). Remember also that the testis is not rigid and therefore can change shapes slightly and squeeze through the inguinal canal. The portion of the gubernaculum that is located below the neck of the flask (representing the **extra-abdominal gubernaculum**) begins to enlarge and grow very rapidly. The part of the gubernaculum that is attached to the testis does not grow and consequently it tugs on the testicle, as the part within the flask grows. This rapid growth pulls the ball (testicle) through the neck of the flask. The simultaneous growth of the viscera within the body cavity tends to push the testis against the opening of the inguinal canal thus enabling it to position itself for final descent. Once it is through the neck of the flask (inguinal canal), the enlarged gubernaculum begins to shrink or regress in size. This shrinkage continues to pull the ball toward the bottom part of the flask. This rapid growth followed by contraction results in physical translocation of the testis into the scrotum.

Figure 4-8. Major Steps in the Descent of the Testes

(Growth and subsequent retraction of the gubernaculum causes the testes to descend from the level of the tenth thoracic vertebra into the scrotum)

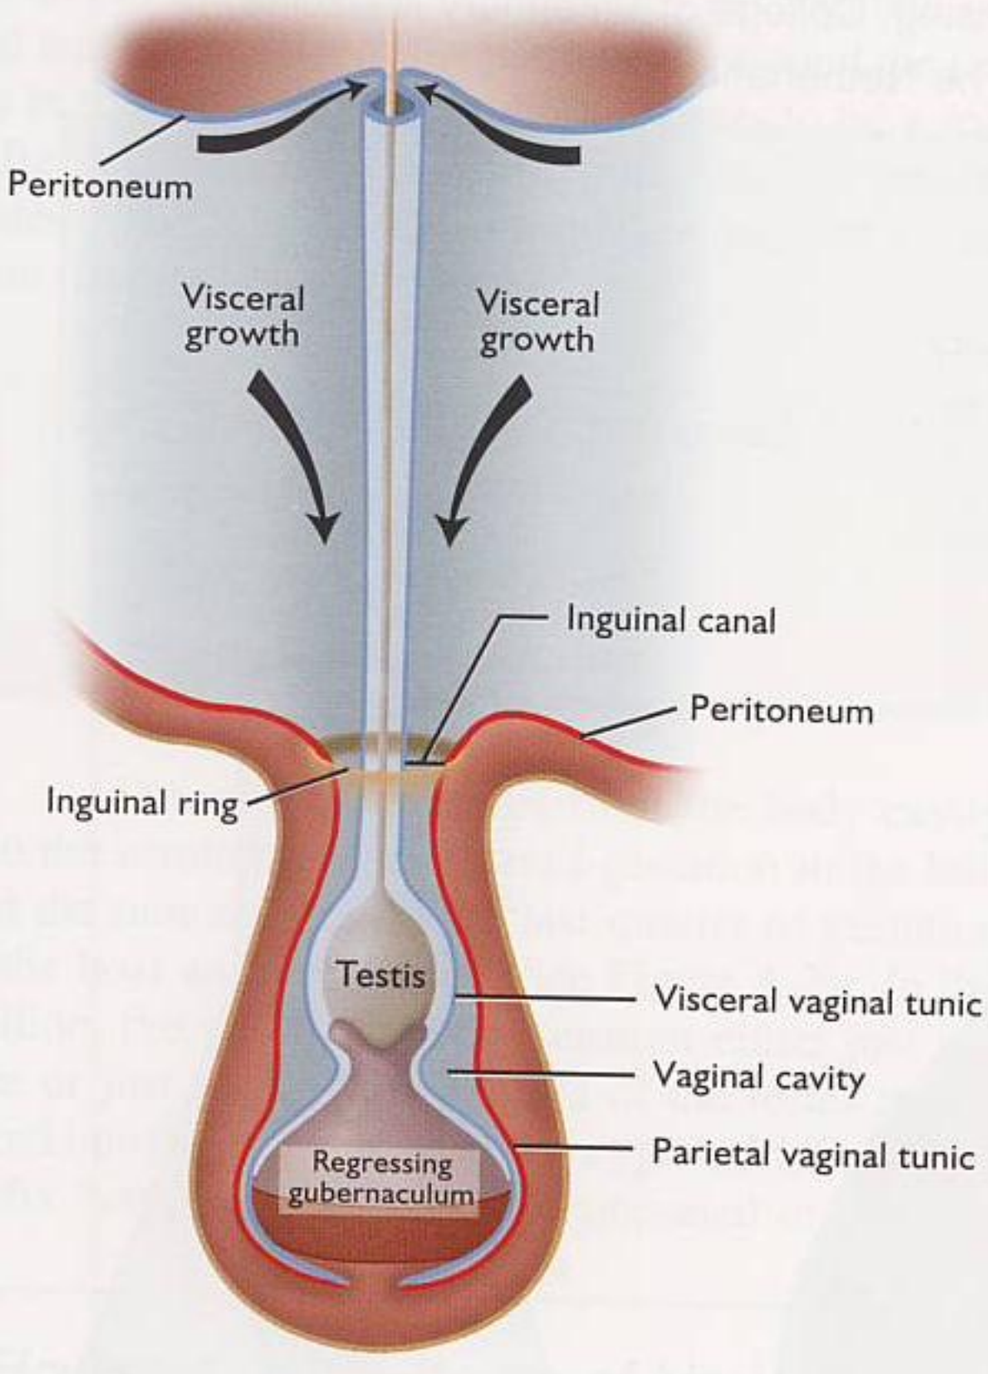


Step 1

Before descent occurs, the testes lie in a retroperitoneal position and are attached caudally to the ligamentous gubernaculum. Cells of the peritoneum infiltrate the gubernaculum in the inguinal region and form a junction with it. This fusion is important because it binds the peritoneum to the gubernaculum and will allow the vaginal process to form as the distal gubernaculum grows toward and into the scrotal region.

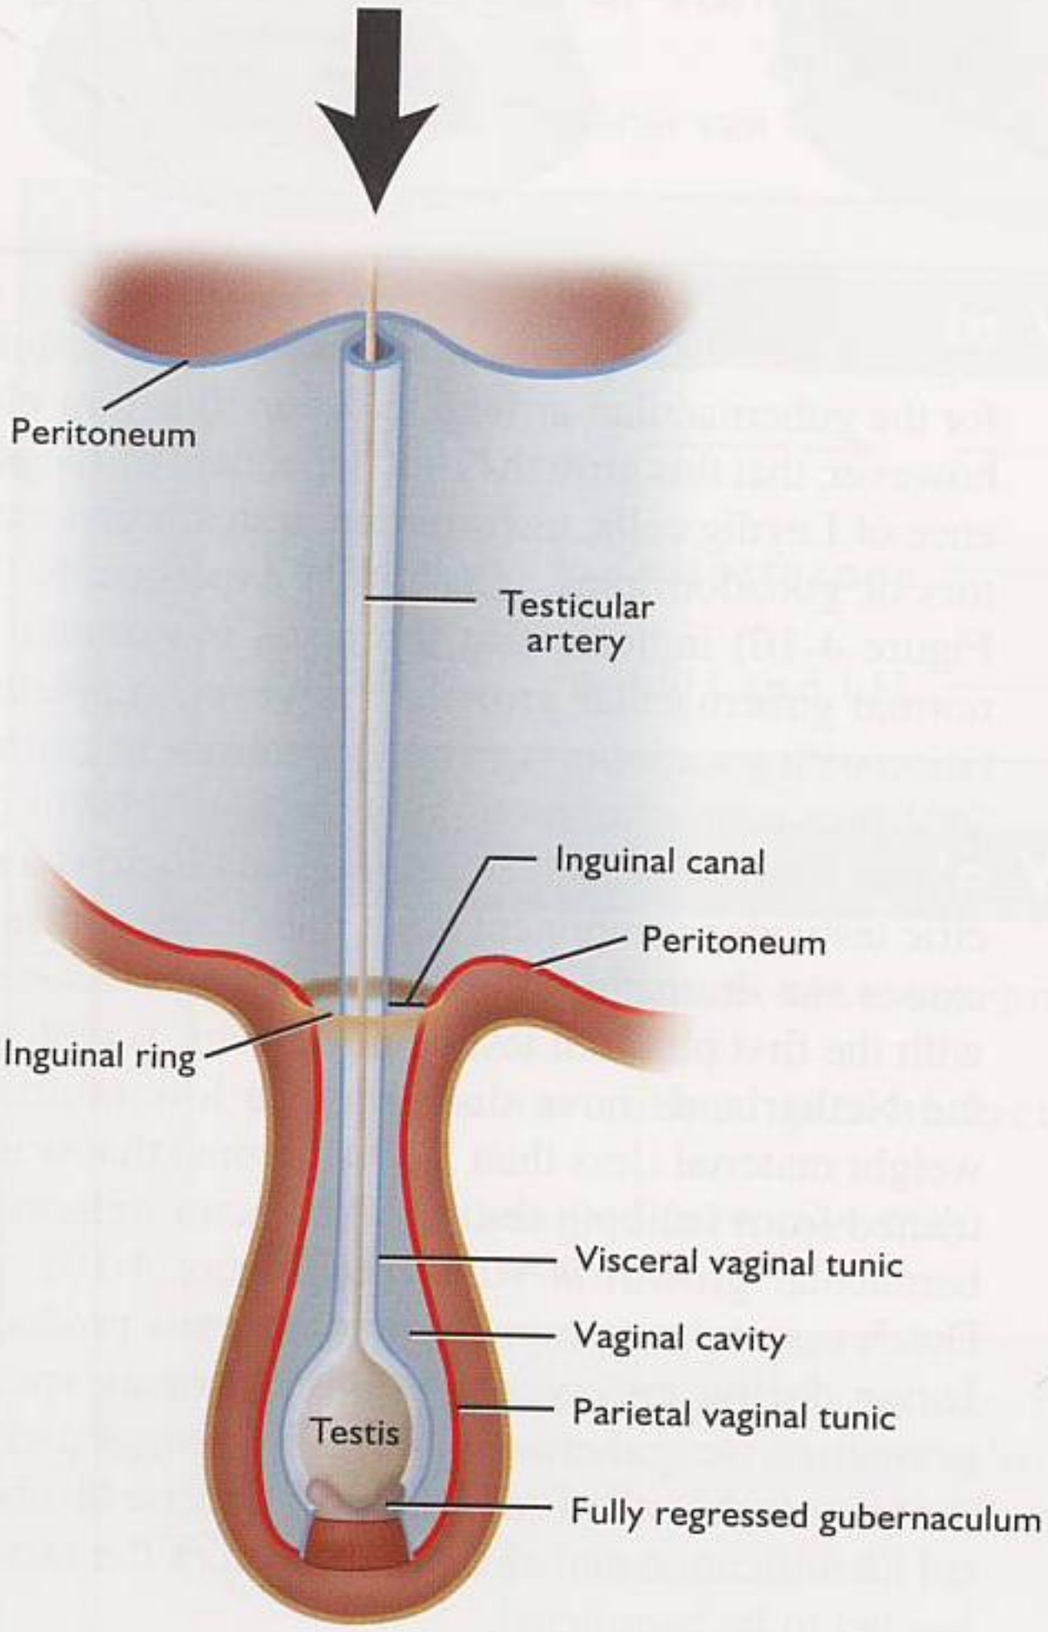
Step 2

After the gubernaculum penetrates the inguinal ring, there is rapid growth of the distal gubernaculum. This rapid growth of the gubernaculum in the scrotal region is the "force" responsible for mechanically moving the testes into the inguinal canal.



Step 3

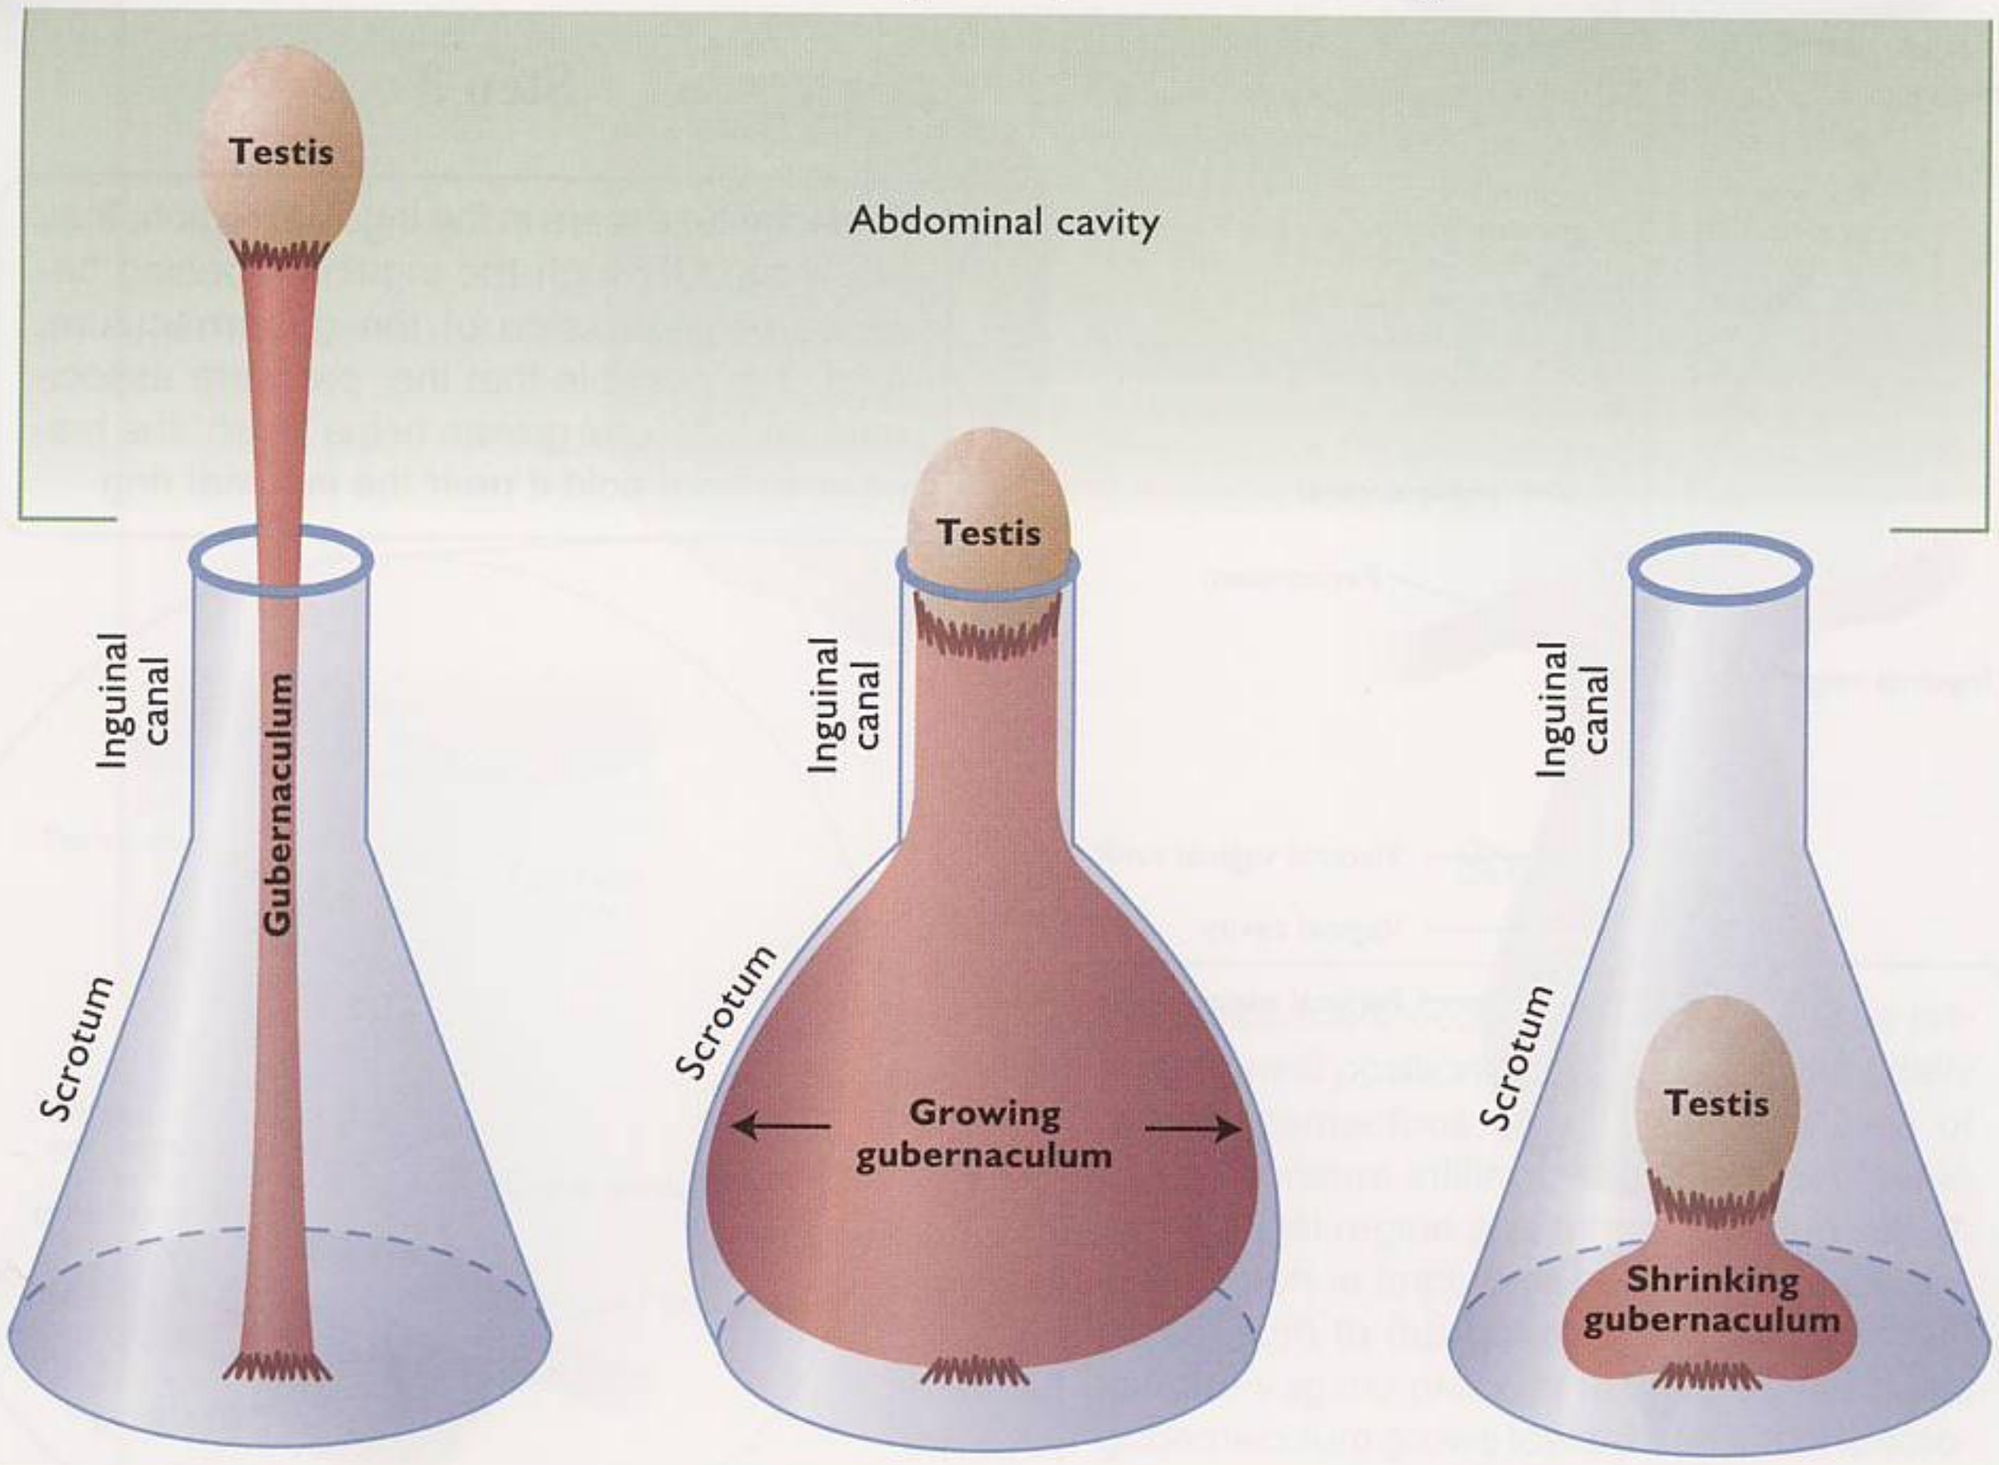
Once the testes are in the inguinal region, they are moved through the inguinal opening because of regression of the gubernaculum. Also, it is possible that the pressure associated with visceral growth helps "push" the testis or at least hold it near the inguinal ring.



Step 4

The gubernaculum continues to regress. As this regression occurs, it continues to move the testes deeper into the scrotum and cause a complete encapsulation of each testis by the inner layer of the peritoneum known as the visceral vaginal tunic. The outer layer of the peritoneum is the parietal layer of the vaginal tunic. When the testis has fully descended, the gubernaculum has regressed to a small knot that attaches the testis to the bottom of the scrotum. The vaginal process contributes to the two tunicae of the testis. The inner (visceral) layer covers the testis, epididymis and spermatic cord and the outer (parietal) layer forms a continuous fold that lies directly adjacent to (but is not attached to) the visceral vaginal tunic. Together these two layers form the vaginal cavity (vaginal process).

Figure 4-9. Example of Testicular Descent Using a Ball and Flask Model
(Derived from discussions wiht Dr. C.J.G. Wensing, College of Veterinary Medicine, State Univerisity Utrect, The Netherlands.)



Two Layers of Peritoneum Surround the Descended Testicle

After complete descent of the testes, you can see that the **vaginal process** is continuous with the peritoneal cavity and the testis is surrounded by a double layer of peritoneum (See Figure 4-8). The layer of peritoneum immediately adjacent to the testis is the **visceral vaginal tunic** and the layer away from the testis is referred to as the **parietal vaginal tunic** (See Chapter 3 for actual example). The space between the tunics is the vaginal cavity. The space between the visceral and parietal vaginal tunic is continuous with the body cavity that houses the viscera. These tunicae are slippery and allow the testis to move freely within the scrotum during physical activity and during contraction of the external cremaster and the tunica dartos muscles.

Now that you are able to visualize the mechanics of testicular descent, it is important to understand the factors that control this event. The most important component of testicular descent is the growth and regression of the gubernaculum. An important question is, "What controls this growth and regression?" The presence of the testes is required for the gubernacular growth to occur. It is now clear, however, that this growth is not dependent on the presence of Leydig cells, testosterone, testosterone receptors or gonadotropins. Castration experiments (See Figure 4-10) indicate that the testis is essential for normal gubernacular growth. However, supplementation with gonadotropins and testosterone in castrated fetal pigs cannot promote gubernacular growth (See Figure 4-10). Therefore, it appears that there is a specific testicular component other than testosterone that causes the dramatic gubernacular growth associated with the first phase of testicular descent. Scientists in the Netherlands have discovered a low molecular weight material (less than 3,500 daltons) that was extracted from fetal pig testes. This factor induced gubernacular growth *in vitro* (See Figure 4-10). The Dutch researchers proposed that the testis produces a factor during embryogenesis that causes specific growth of the gubernaculum. They suggested that the factor(s) be called "**descendin**." Precise biochemical identification and characterization of the factor(s) has yet to be completed.

Regression (shrinkage) of the gubernaculum results in the final passage through the inguinal canal and orientation of the peritoneum around the testis in the scrotum. While there appears to be a specific substance that governs gubernacular growth ("descendin"), factors that cause gubernacular regression have not been identified.

Two common testicular descent abnormalities are:

- ***cryptorchidism***
- ***inguinal herniation***

Descent of the testes from the body cavity into the scrotum occurs by mid-gestation in the bull and the ram and during the last quarter of gestation in the boar and the human (See Figure 4-2). In the stallion, the testes enter the scrotum either just before or just after birth. Failure of the testes to descend into the scrotum is called **cryptorchidism**. The prefix "crypt" means hidden, concealed or not visible to the naked eye. "Orchid" is a Latinized-Greek word referring to the testis. Thus, the word cryptorchid literally means "a testis that is hidden from view." Bilateral cryptorchidism results in sterility. However, cryptorchid testes are capable of producing testosterone. Thus, the cryptorchid male possesses secondary sex characteristics that are normal and has normal reproductive behavior.

Because of the anatomical continuity between the vaginal process and the body cavity (See Figure 4-8), it is possible for portions of intestine to pass into the vaginal cavity and enter the scrotum. When a portion of the intestine passes through the inguinal canal into the vaginal cavity, **inguinal herniation** has occurred. In humans, diagnosis of the presence of an inguinal hernia can easily be made by applying pressure to the lateral inguinal regions and asking the patient to cough. Such a maneuver allows the physician to feel the intestine rebound (or bounce) during the cough, inside the vaginal tunics.

Figure 4-10. Effects of Various *In Vivo* and *In Vitro* Treatments Upon Growth of the Gubernaculum

(From Fentener van Vlissingen et al. 1998. *Endocrinology*. 123:2868)

In Vivo

Fetal ♂	→	limited gubernacular growth
Fetal ♂	+ Testosterone →	limited gubernacular growth
Fetal ♂	+ FSH and LH →	limited gubernacular growth

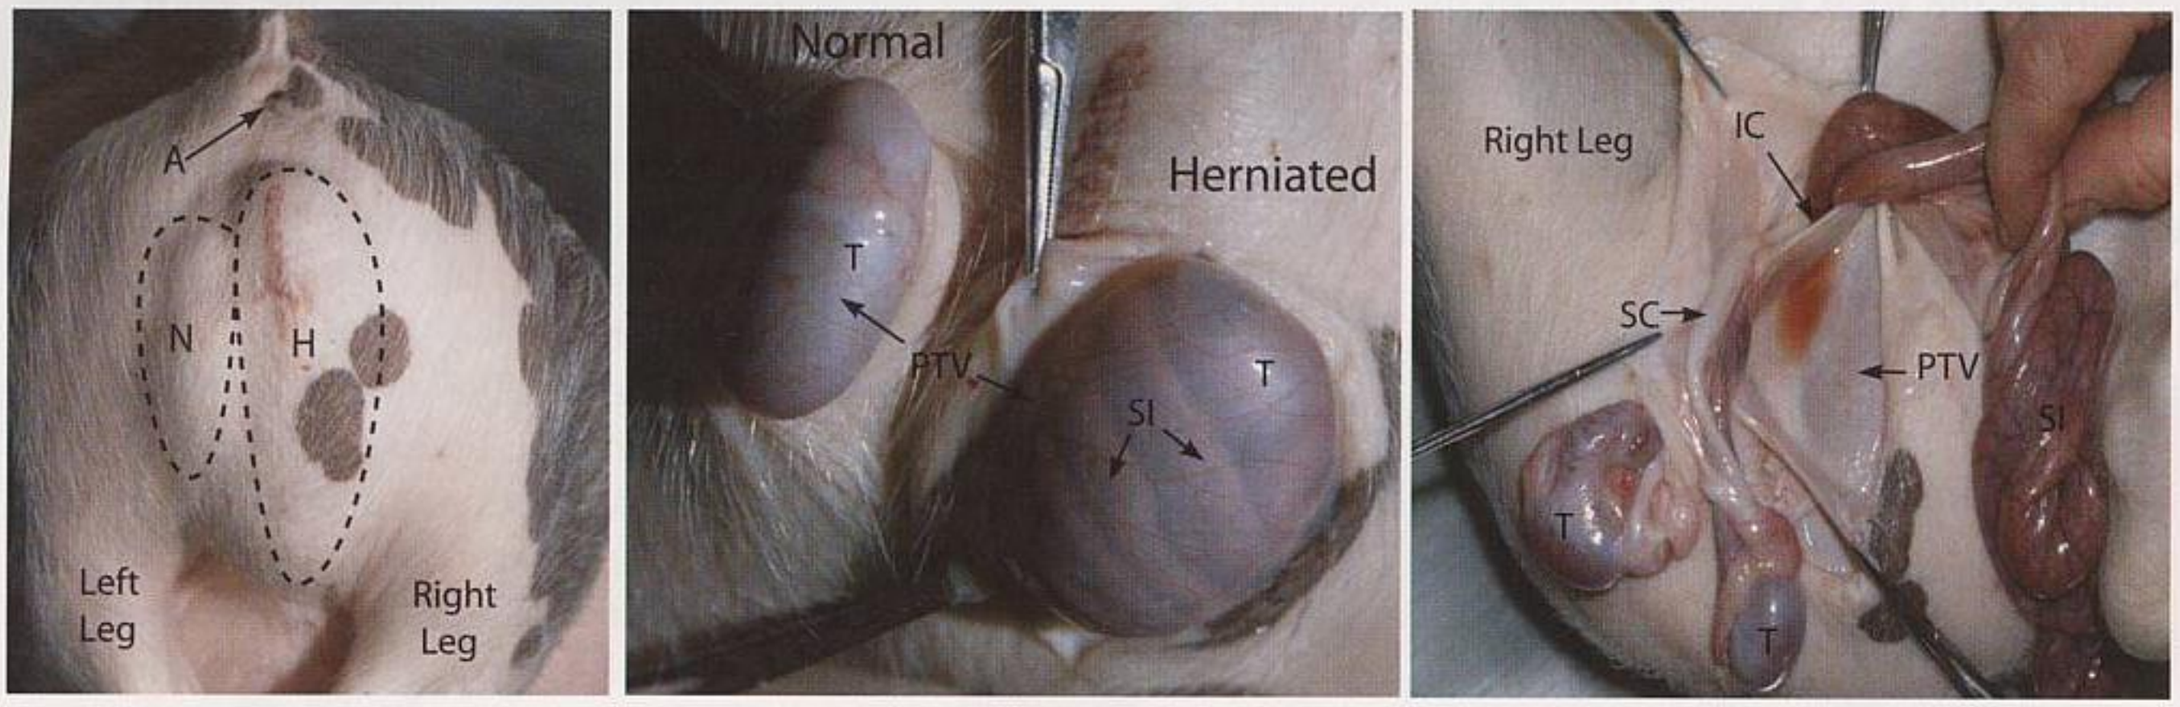
In Vitro

Gubernacular cells + testosterone	→	no growth
Gubernacular cells + growth factors *	→	no growth
Gubernacular cells + low MW testicular extract	→	signficant growth

* Epidermal growth factor, insulin, fibroblast growth factor, platelet derived growth factor and transforming growth factor

⚲ = Castrated male

Figure 4-11. Caudal View of a Young Boar with an Inguinal Hernia



Caudal view of the scrotum showing the anus (A), the normal (N) and the herniated (H) side. Notice that the herniated side is significantly larger than the normal side.

Incised scrotum showing the normal and the herniated side containing the small intestine (SI) and testicle (T). The arrows indicate the parietal vaginal tunic (PVT), covering all of the structures inside the vaginal cavity.

Posterio-ventral view showing completely exteriorized testicles (T), spermatic cord (SC) and small intestines (SI). The SI shown was previously within the confines of the vaginal cavity. The parietal vaginal tunic (PVT) has been incised thus allowing structures to be viewed. The point of entrance for the small intestine and spermatic cord into the inguinal canal (IC) can be observed.

Inguinal herniation is not uncommon in swine and occurs in about 1 in 200 males. Figure 4-11 illustrates this condition in a young boar. Figure 4-12 schematically illustrates the position of the intestine in the vaginal cavity (between the visceral and parietal tunics). You can clearly see the presence of the intestine within the vaginal process in the young boar (middle photograph). In most cases, the herniation can be repaired quite easily during castration. By twisting the testicle (within the parietal vaginal tunic), the intestines are pushed back through the vaginal cavity (within the inguinal canal) into the body cavity. Since the inguinal canal in the boar is located more dorsally than in other species (See Chapter 3) the intestines tend to remain in the body cavity because it is difficult for them to reenter the vaginal cavity. Nevertheless, ligation of the parietal and visceral vaginal tunics is usually performed to prevent further herniation. Typically, this procedure is performed by members of the management team within the swine production unit.

Development of the Female Reproductive Tract Requires the Absence of Testis Determining Factor

In the absence of testis determining factor (TDF), certain cells of the sex cords differentiate into primitive follicular cells and the bulk of the genital ridge becomes the ovary (See Figure 4-13).

Females contain the X chromosome. It lacks the gene that governs the production of TDF (See Figure 4-6). As a result, cells in the primitive gonad of the female do not differentiate into Sertoli cells. Since there are no Sertoli cells, anti-müllerian hormone cannot be produced. Therefore, the Leydig cells cannot produce testosterone and the male reproductive tract cannot develop. In other words, the development of the female reproductive tract takes place because of the absence of TDF.

In the absence of TDF, the epithelial cords, (sex cords), fragment into cellular clusters, each enclosing a primitive germ cell. These clusters of germ cells penetrate less deeply into the interior of the future ovary than in the male. Thus, primordial follicles are formed along the outer surface of the ovary and will eventually become the cortex of the ovary. Rete tubule formation in the ovary is not pronounced (See Figure 4-13) and a direct connection between

Figure 4-12. The Position of the Intestine with Inguinal Herniation

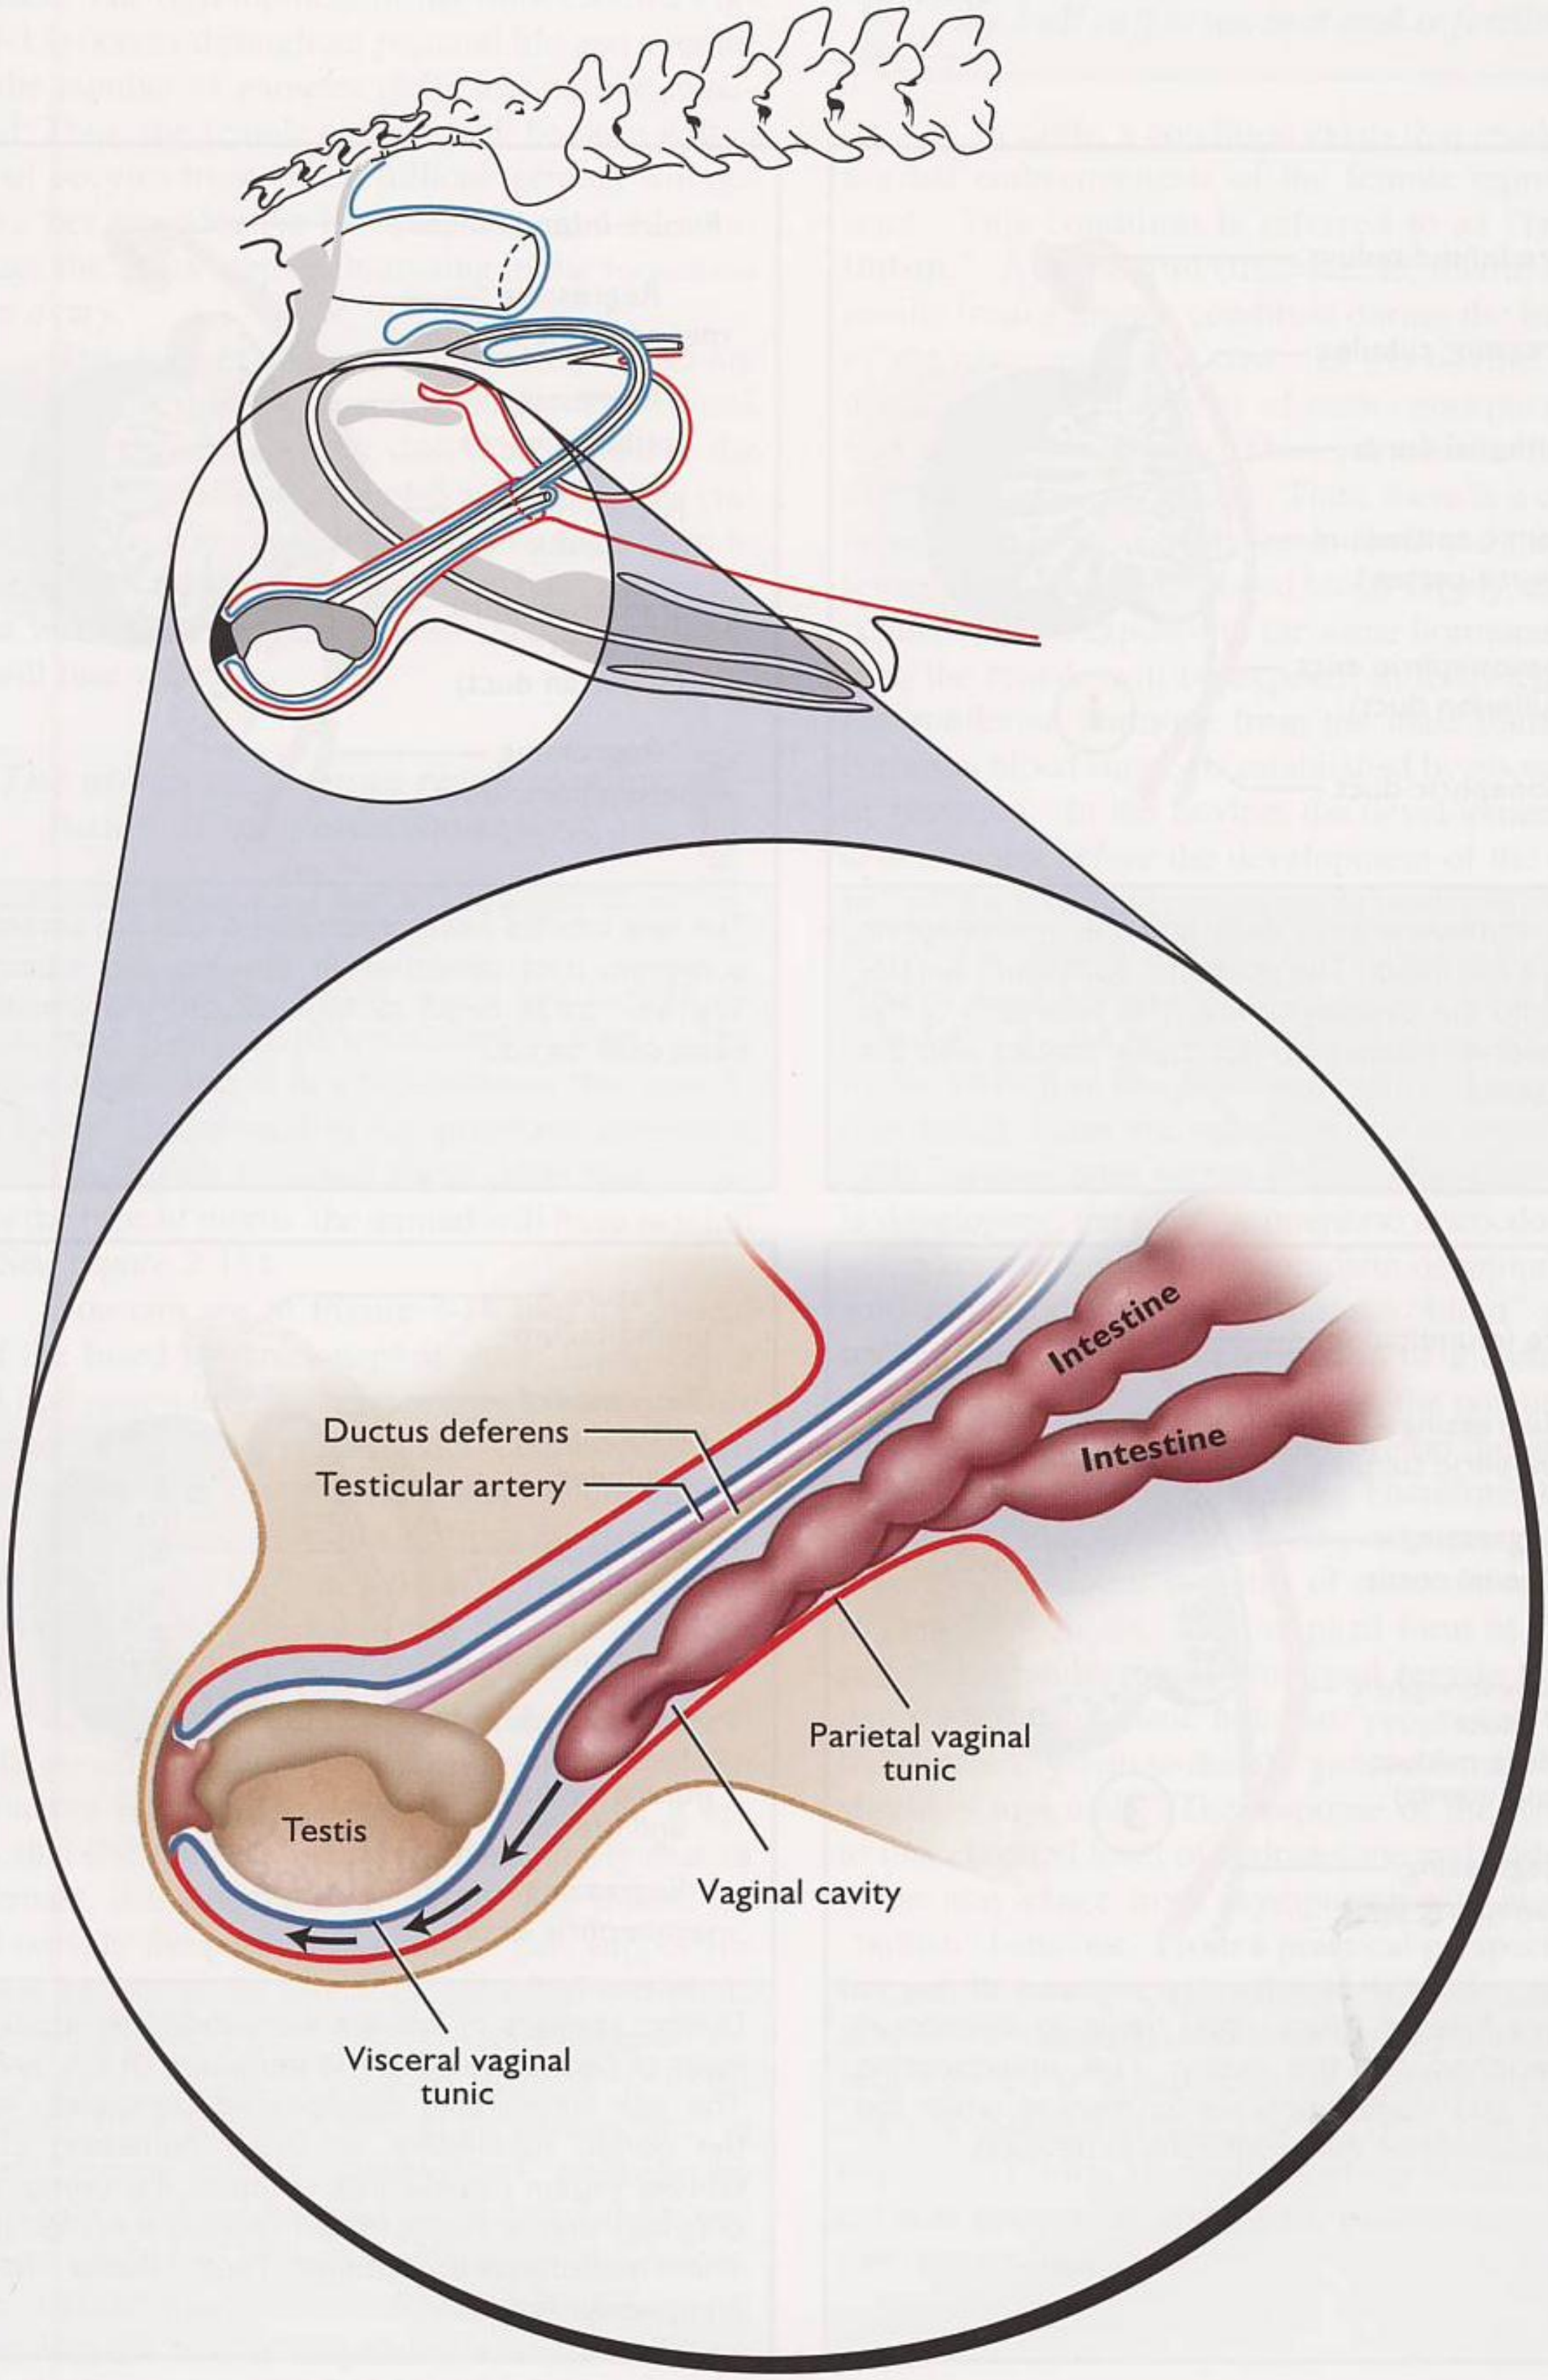


Figure 4-13. Development of the Ovary, the Paramesonephric Ducts and Regression of the Mesonephros

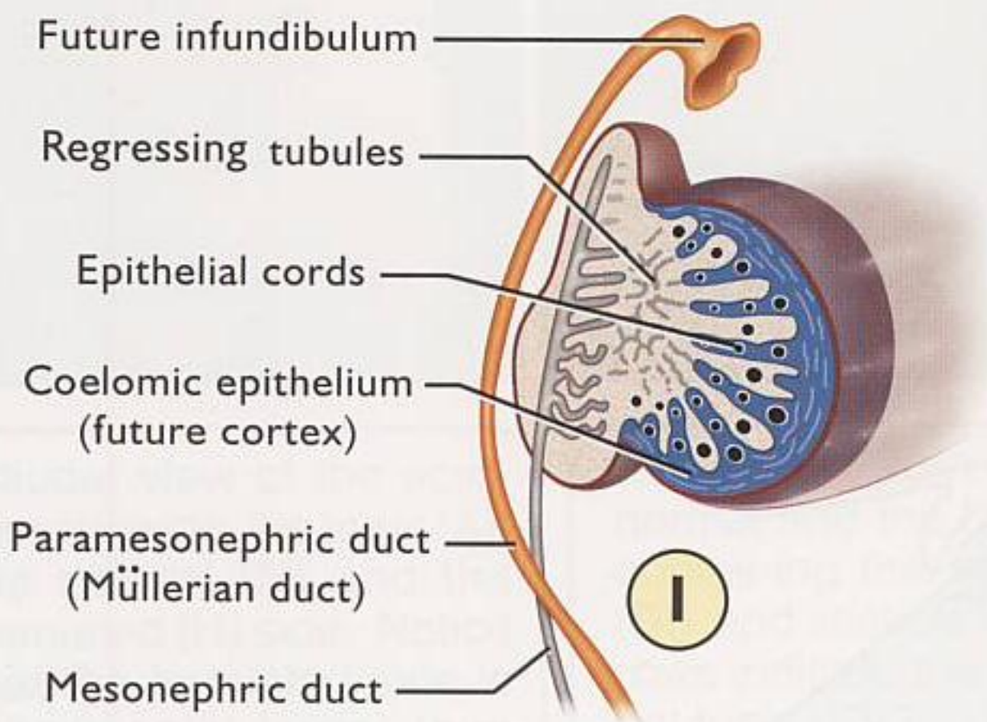
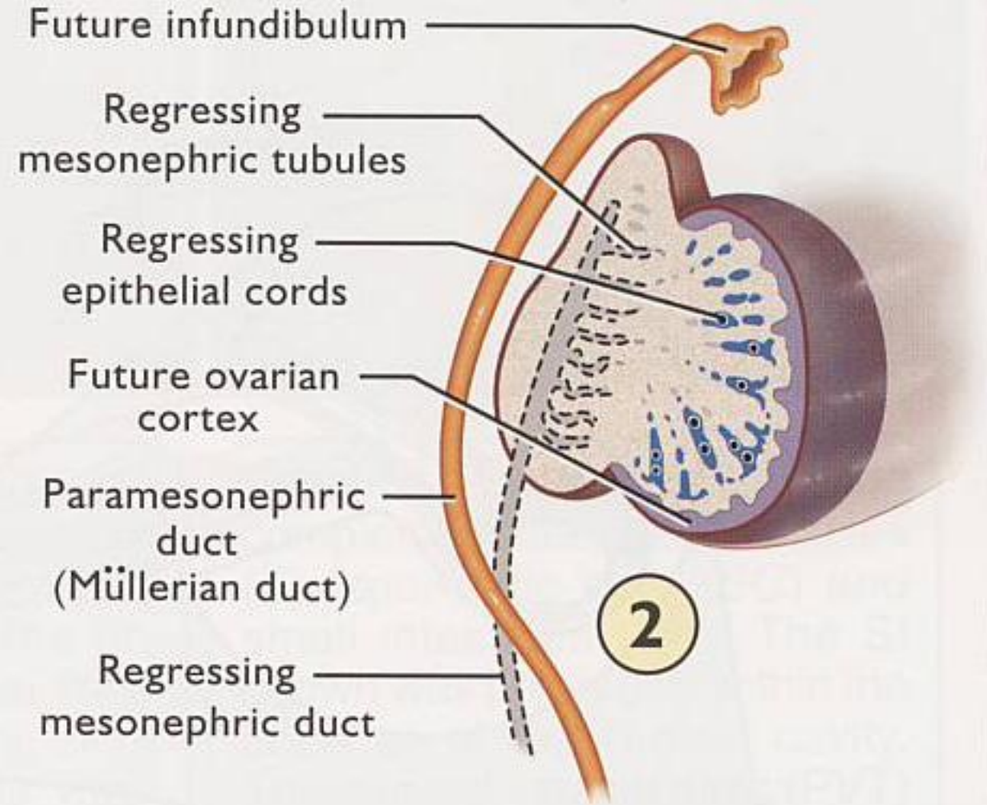
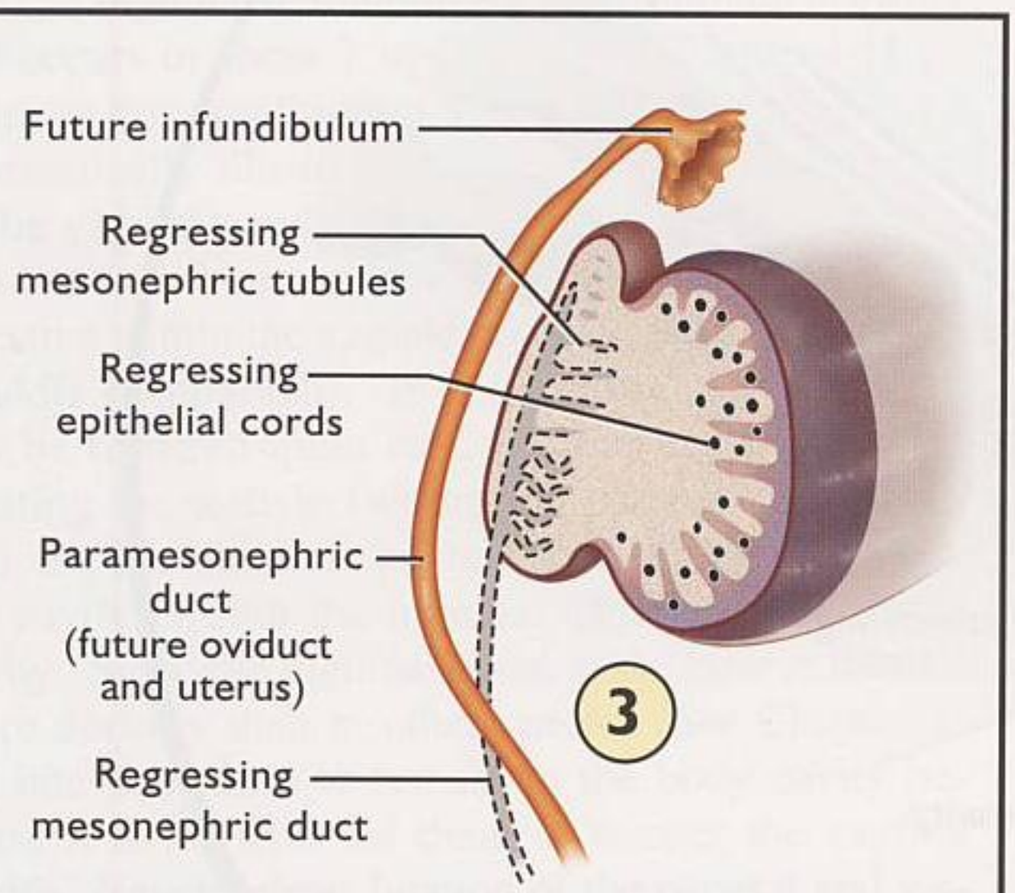


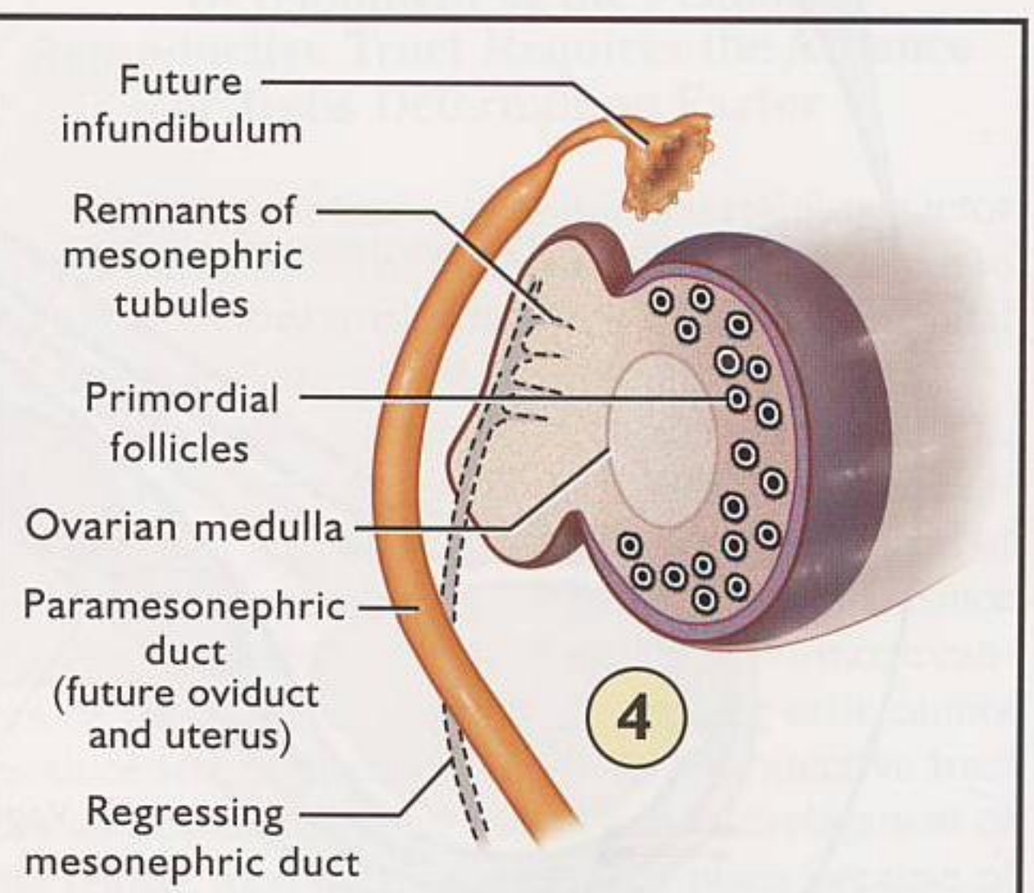
The paramesonephric duct and the mesonephric duct are still intact. The coelomic epithelium will develop into the ovarian cortex. The remnants of the mesonephric tubules do not make contact with the rete tubules.



The rete tubules have disappeared and the paramesonephric duct continues to develop and enlarge. The sex cords begin to regress, but the primitive germ cells do not.



Primitive follicles (black dots) begin to develop at the periphery of the ovary. The mesonephric tubules and ducts continue to regress while the paramesonephric duct continues to develop.



Distinct clusters of follicles surrounded by a single layer of cells develop at the periphery of the ovary. The sex cords have disappeared completely and the gonad resembles an ovary consising of a cortical region (region that contains the primordial oocytes) and a nongerminal region, the medulla. The mesonephric tubules and ducts have completely regressed.

the rete tubules and the mesonephric tubules does not occur. Therefore, there is no tubular outlet for the gametes. The development of the follicles (See Figure 4-13) occurs throughout prenatal life and eventually the number of gametes (follicles) will be maximized. Thus, the female embryo will be born with a pool of oocytes from which folliculogenesis will occur for her reproductive lifetime. Figure 4-13 summarizes the major steps culminating in the formation of the ovary.

The ducts of the female reproductive tract are provided by the paramesonephric ducts. The cranial part of each paramesonephric duct runs parallel to the mesonephric duct (See Figures 4-5 and 4-13). The cranial part of the paramesonephric duct remains open to the peritoneal cavity, but the caudal end butts against the dorsal wall of the urogenital sinus (See Figure 4-14) and will fuse with it.

The uterus and vagina result from a fusion of the paramesonephric ducts.

The oviducts, uterus, cervix and cranial vagina develop from the paramesonephric ducts. The paramesonephric ducts fuse together near their attachment to the caudal wall of the primitive urogenital sinus. The degree to which these ducts fuse determines the type of uterus the animal will have in adult life (See Figure 2-15).

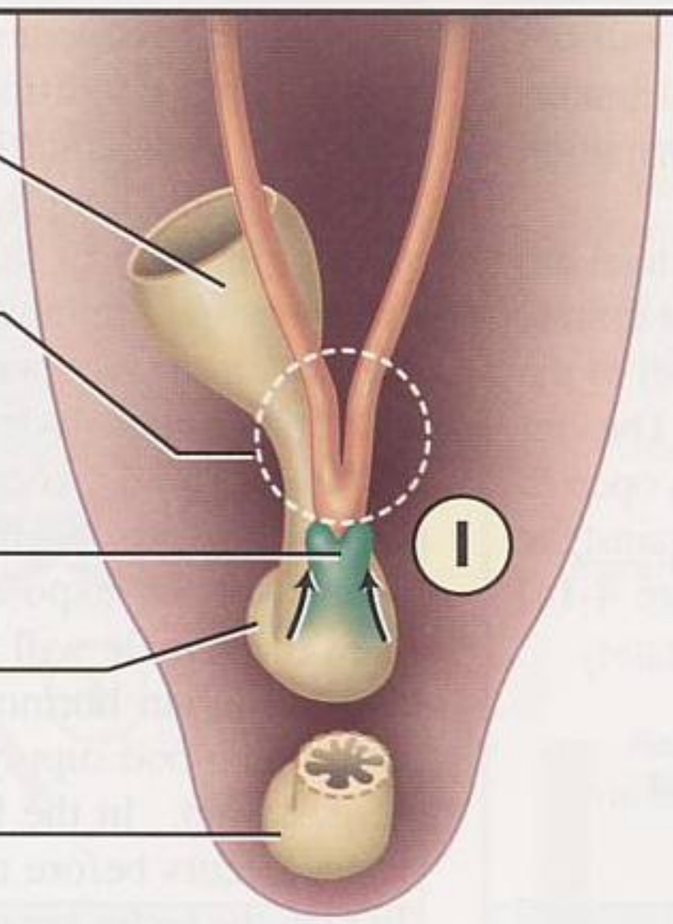
You can see in Figure 4-14 that the caudal tip of the fused paramesonephric ducts fuses with a small bud protruding from the urogenital sinus. This fusion results in a duct system that is continuous from the exterior to the interior. Note that the cranial vagina, cervix and uterus originate from the paramesonephric ducts (and thus mesoderm). The caudal vagina and vestibule originate from the ectoderm that is a portion of the urogenital sinus.

It is important to note that both the male and female gonad and duct system originate behind the peritoneum (**retroperitoneal**). Even though it appears that the reproductive tract, particularly that of the female, is inside the body cavity, it is indeed located outside the peritoneal cavity. This supportive tissue is known as the broad ligament and surrounds the uterus, supporting it from a dorsal and lateral aspect. Figure 4-15 and 2-2 shows that the entire reproductive tract originates behind the peritoneum. In fact, the female tract is "sandwiched" between the genital fold. The genital fold will become the broad ligament consisting of the mesometrium, the mesosalpinx and the mesovarium. Recall from Chapter 2 that the female tract is suspended by the broad ligament that is continuous with the dorsal peritoneum.

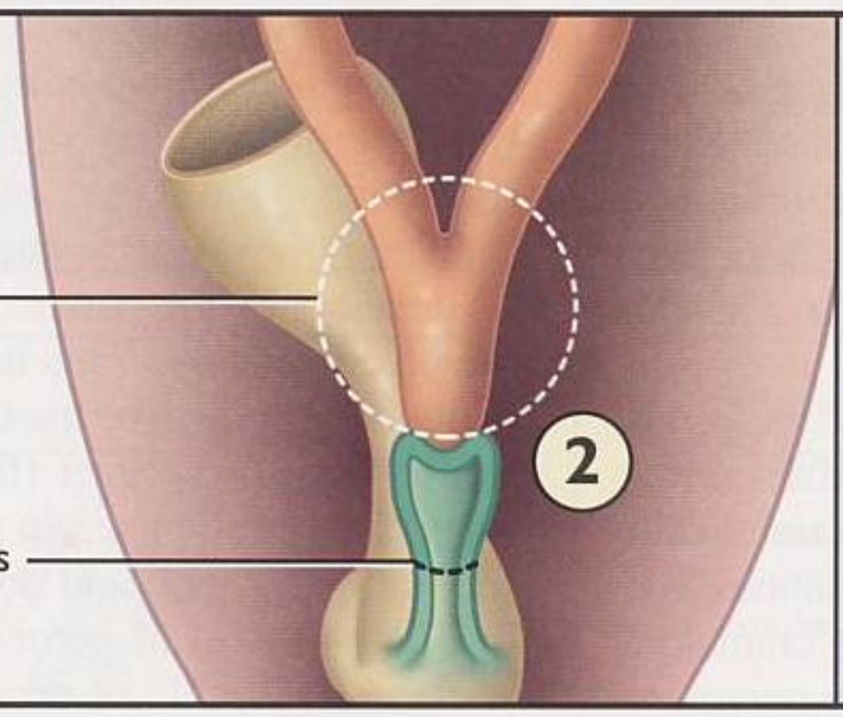
A freemartin is a heifer born twin to a bull. The heifer calf is sterile, but the bull calf is normal and is fertile.

In cattle, a condition exists that results in abnormal embryogenesis of the female reproductive tract. This condition is referred to as "**freemartinism**." A freemartin (free=sterile, martin=bovine) results from a unique condition during the formation of the placenta in the cow. In the bovine, the extraembryonic membranes of each conceptus fuse to form a common chorion. These membranes (chorion) share the same cotyledons. Thus, there is a common blood supply between the male fetus and the female fetus. Because of this shared blood supply, each conceptus will be exposed to the same hormonal milieu (i.e., the female will be exposed to testosterone and anti-müllerian hormone from the male fetus). This common blood supply is established by about day 39 of gestation. In the bovine, the development of the testes occurs before the development of the ovaries. In fact, the testes are recognizable by day 40, whereas the ovaries require several weeks longer to develop. As you now know, the testes produce a substance called anti-müllerian hormone. This hormone inhibits the growth of the paramesonephric ducts (Müllerian ducts). Since the female twin is exposed to anti-müllerian hormone as the female reproductive tract is developing, the paramesonephric ducts do not develop completely. This incomplete development results in reproductive tracts that are "blind" and **canalization** of the tract (formation of a canal or lumen) is not complete. In addition, the potential ovaries cease to grow and do not develop the appropriate complement of germ cells. Therefore, the ovaries are incapable of producing estrogen and often produce substantial amounts of testosterone as well as androstenedione. This atypical form of steroidogenesis not only causes abnormal female reproductive tract development, but also "programs" the central nervous system so that the genetic female behaves similarly to a male. The response of the freemartin to this elevated level of testosterone and androstenedione may range from asymptomatic to significant "bullish" behavior. From a practical perspective, the freemartin can be used effectively to detect estrus. Since these animals' central nervous system has been programmed to be male-like, they are generally more aggressive than the typical female in seeking out other females in estrus. By supplementing freemartin heifers with exogenous androgens, maleness can be further accentuated.

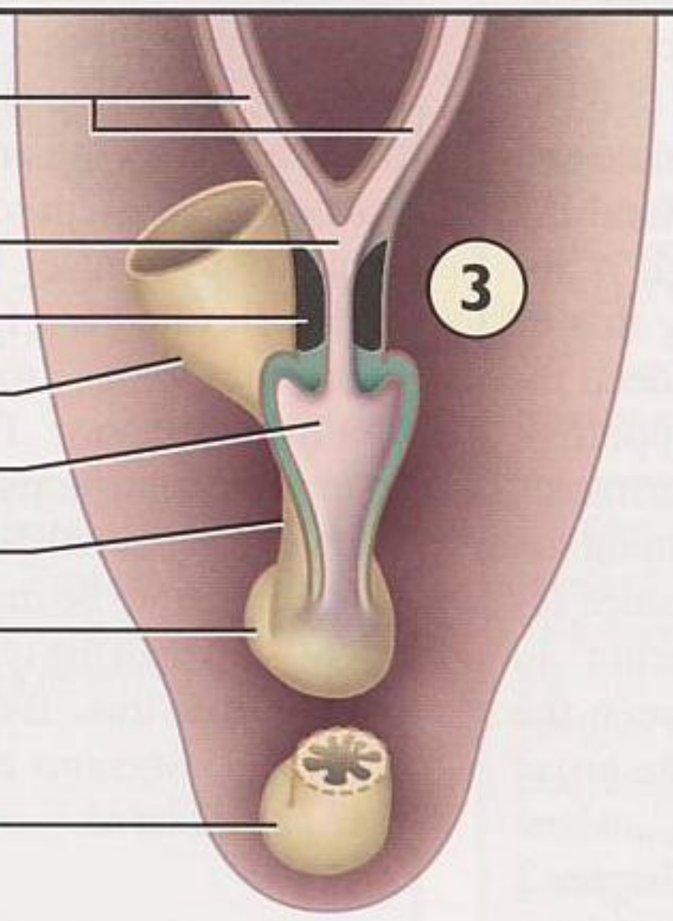
Figure 4-14. Fusion of Paramesonephric Ducts with the Urogenital Sinus to Form the Vagina (Dorsal View)



The paramesonephric ducts are beginning to fuse (circled area) and will form the cervix and uterine body. A small bud evaginates from the caudal urogenital sinus and attaches to the fused paramesonephric ducts.

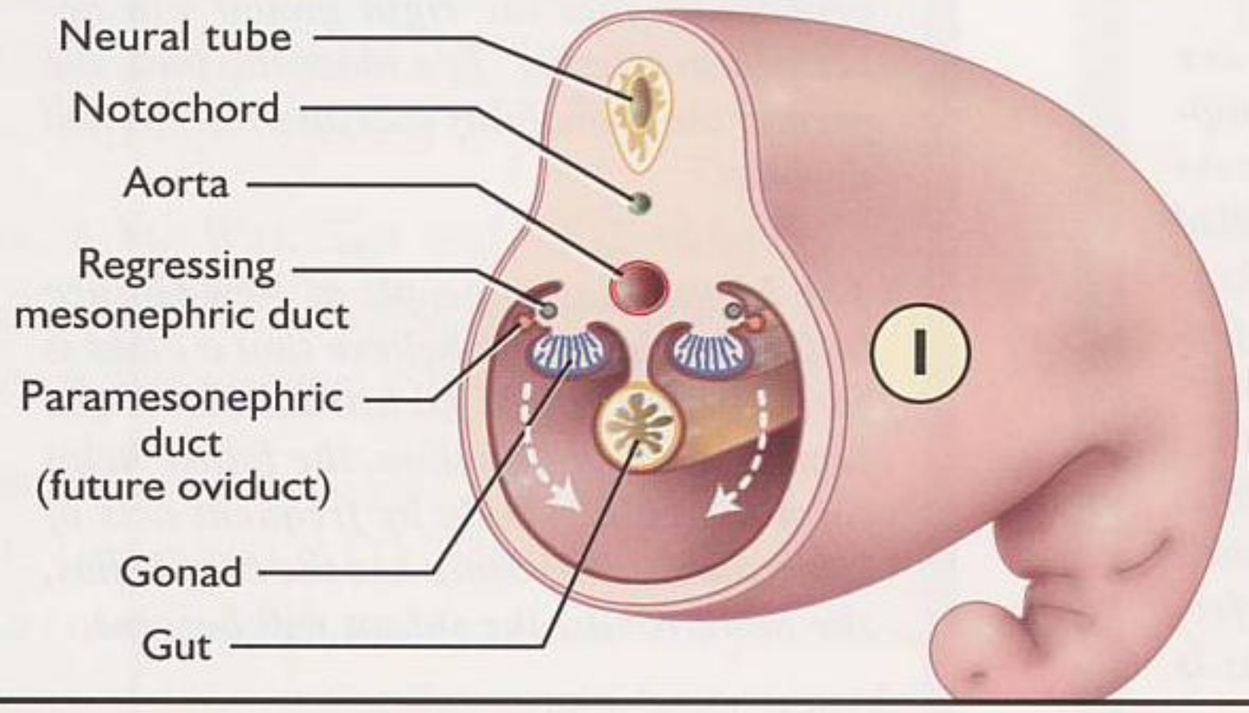


The paramesonephric ducts continue to fuse, forming a more defined cervix and a more developed vagina. The bud of the urogenital sinus elongates.



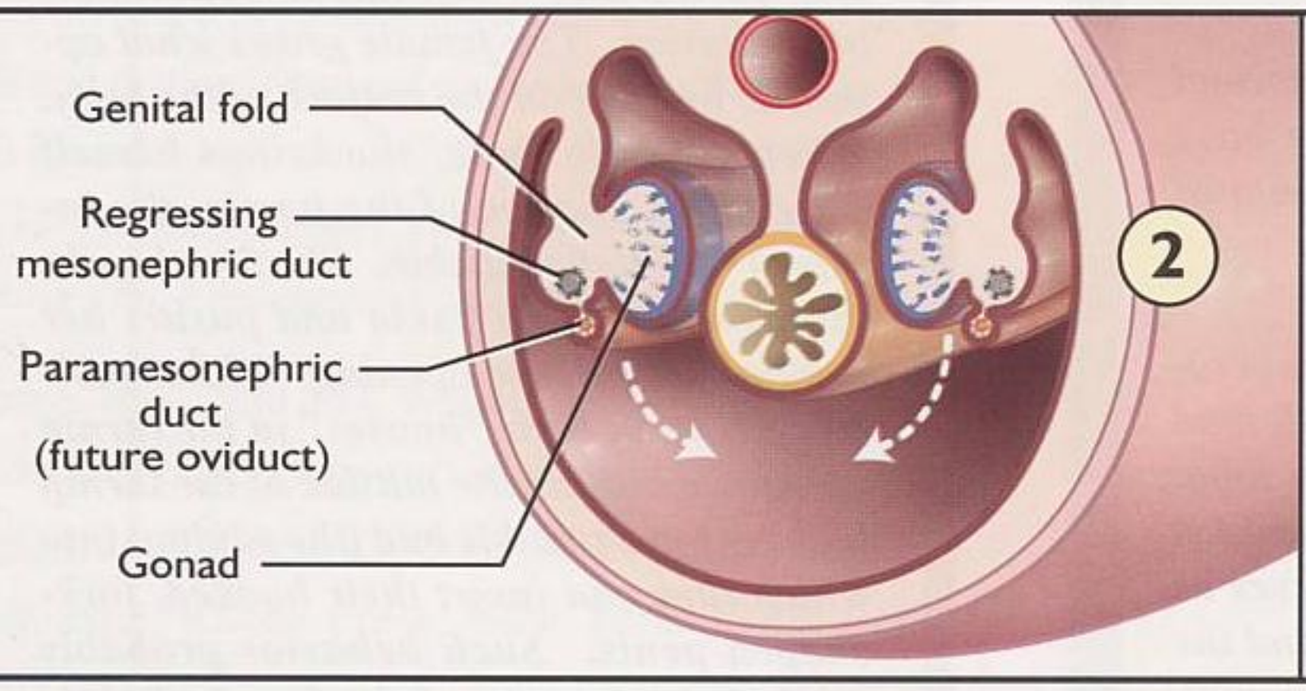
Points of fusion have now formed a definitive cervix and the cranial and caudal vagina. The vestibule has stratified squamous epithelium because it originates from the urogenital sinus that invaginates from the exterior skin.

Figure 4-15. Formation of the Supportive Structures of the Female Tract

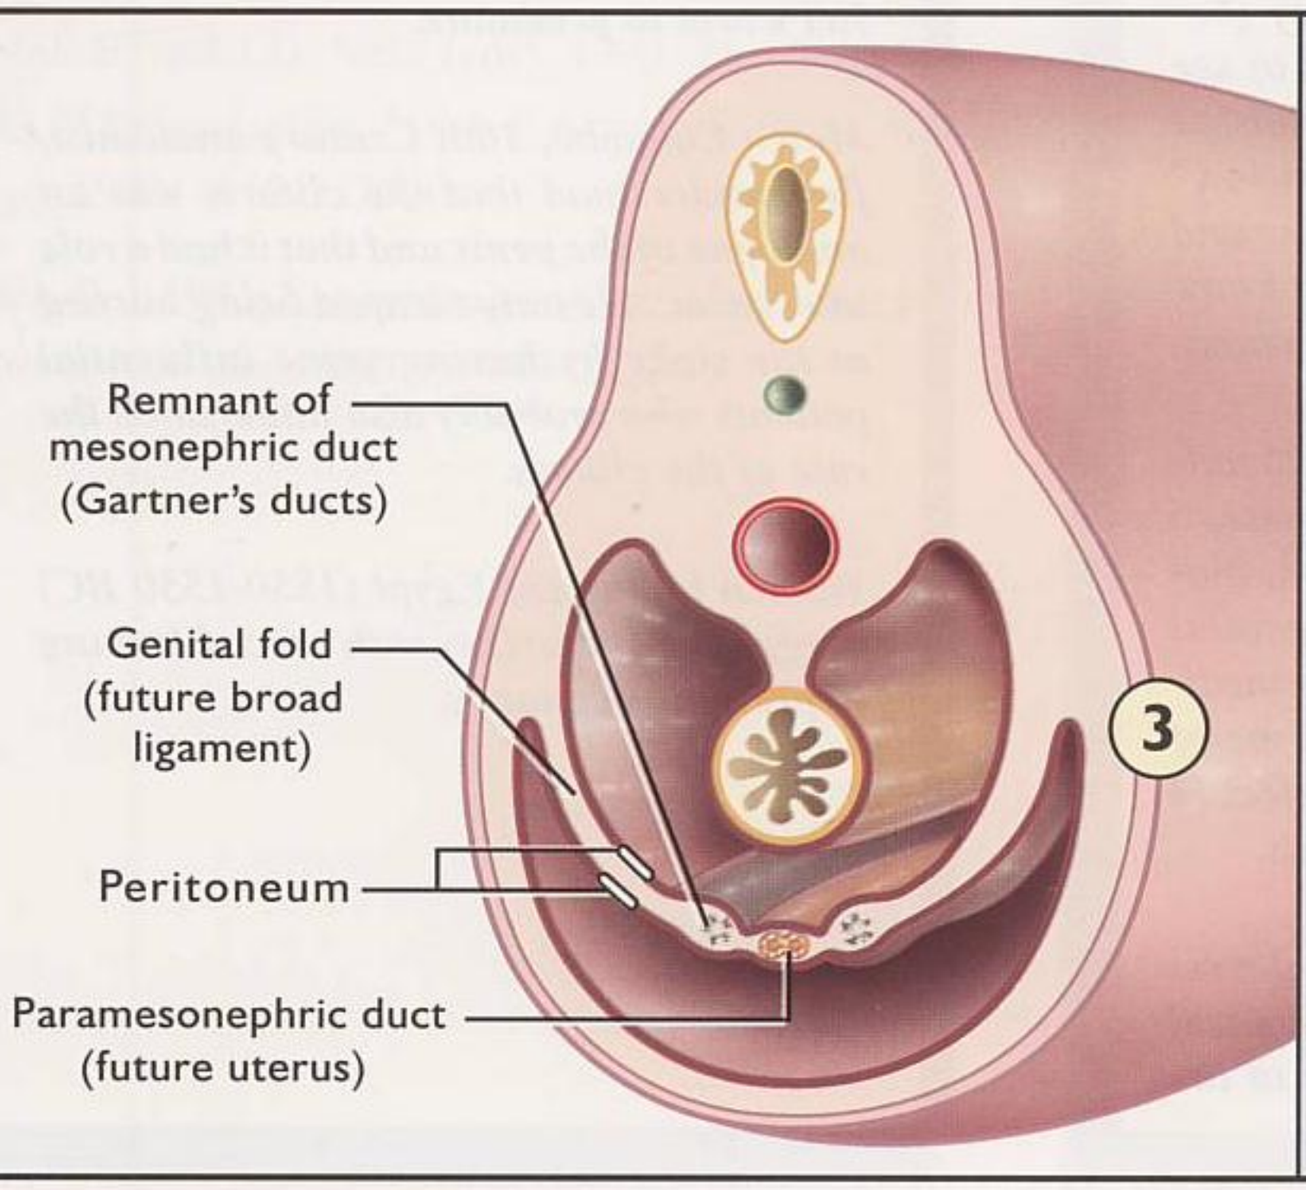


Cranial

In the more cranial region of the embryo the gonad and paramesonephric duct are quite separated. They may move ventrally (arrows) but never entirely fuse. Thus, the ovaries and the more cranial portions of the future uterus and oviducts (paramesonephric ducts) never fuse in most species.



As the section becomes more caudal, the gonadal ridges as well as the paramesonephric ducts become more closely associated during their ventral movement. However, they still do not completely fuse.



Caudal

In the more caudal regions, the paramesonephric ducts have comepletely fused, thus creating either the body of the uterus, the cervix or the cranial vagina. The remnants of the mesonephric ducts sometimes embed themselves in the wall of the vagina; these remnants can be seen in the adult animal and are called Gartner's ducts. It should be noted that the reproductive tract is sandwiched between two layers of peritoneum referred to as the genital fold. This connective tissue layer from the peritoneum forms the broad ligament that supports the femal reproductive tract in the abdominal cavity.

Further PHENOMENA for Fertility

All species do not develop a distinct sex (separate testes and ovaries) like this chapter explains. Some individuals possess both an ovary and a testis and are called hermaphrodites. Sea basses are synchronous hermaphrodites, meaning that fertile spermatozoa and oocytes in an ovotestes are present at the same time within a single fish. Self-fertilization is possible, but these fish have group-spawning events to insure genetic heterogeneity. Self-fertilization is advantageous if a sea bass is not present at the spawning event.

Testicles sometimes stray from the normal path of descent. In humans, they have been found under the skin of the root of the penis and in front of the anus.

In some species the guardian of embryogenesis is the male. The female bell toad lays her eggs in strings 3 to 4 feet long. The male wraps the egg string around his body. For about one month he serves as the "uterus," making sure that he and the eggs are exposed to the appropriate environment. He hides during the day (because he doesn't want his buddies to see him) and seeks water at night to moisten the eggs. Apparently, at "parturition" (hatching), the male sits in the water and the tadpoles swim away. We do not know the endocrine basis for this phenomenon.

In 1975, there were approximately 125 million babies born in the world. Of these, 6 million had chromosomal disorders, biochemical disorders or major congenital birth defects that required extensive medical resources. The most frequent type of disorder was a major congenital defect (4 million) due to faulty embryogenesis.

In chickens (and some ducks and doves) "sex" can be reversed after birth. Removal of the functional left ovary results in the development of the nonfunctional right gonad into a testis or ovotestis (a gonad containing follicles of ovulatory size and tubules with spermatozoa). The younger the bird at ovariectomy, the greater the probability that the right gonad will develop into a testis. The older the bird, the greater the probability that an ovotestis will develop.

The Mount Hagen people of New Guinea in the South Pacific believe that a child is formed from stored menstrual blood and semen. During gestation, the father helps form the child's body by frequent acts of intercourse. The more sex the couple has, the more robust the infant will become.

The Turnip Eel worm has unusual mating behavior. The female grows what appear to be buds on the surface of the body. When ready to mate, she brings herself close to the surface of the turnip, the inside of which she inhabits. She then breaks through the turnip's skin and pushes her vagina through the opening. Males periodically leave their "houses" in the turnip and move around the outside of the turnip looking for a suitable bud (the vagina) into which they can insert their hooked, fork-shaped penis. Such behavior probably minimizes exposure of the female Turnip Eel worm to predators.

Mateo Colombo, 16th Century anatomist, first understood that the clitoris was an analogue of the penis and that it had a role in orgasm. He only escaped being burned at the stake by having some influential patients who probably also understood the role of the clitoris.

Women in ancient Egypt (1850-1550 BC) plugged their cervixes with crocodile dung to prevent pregnancy.

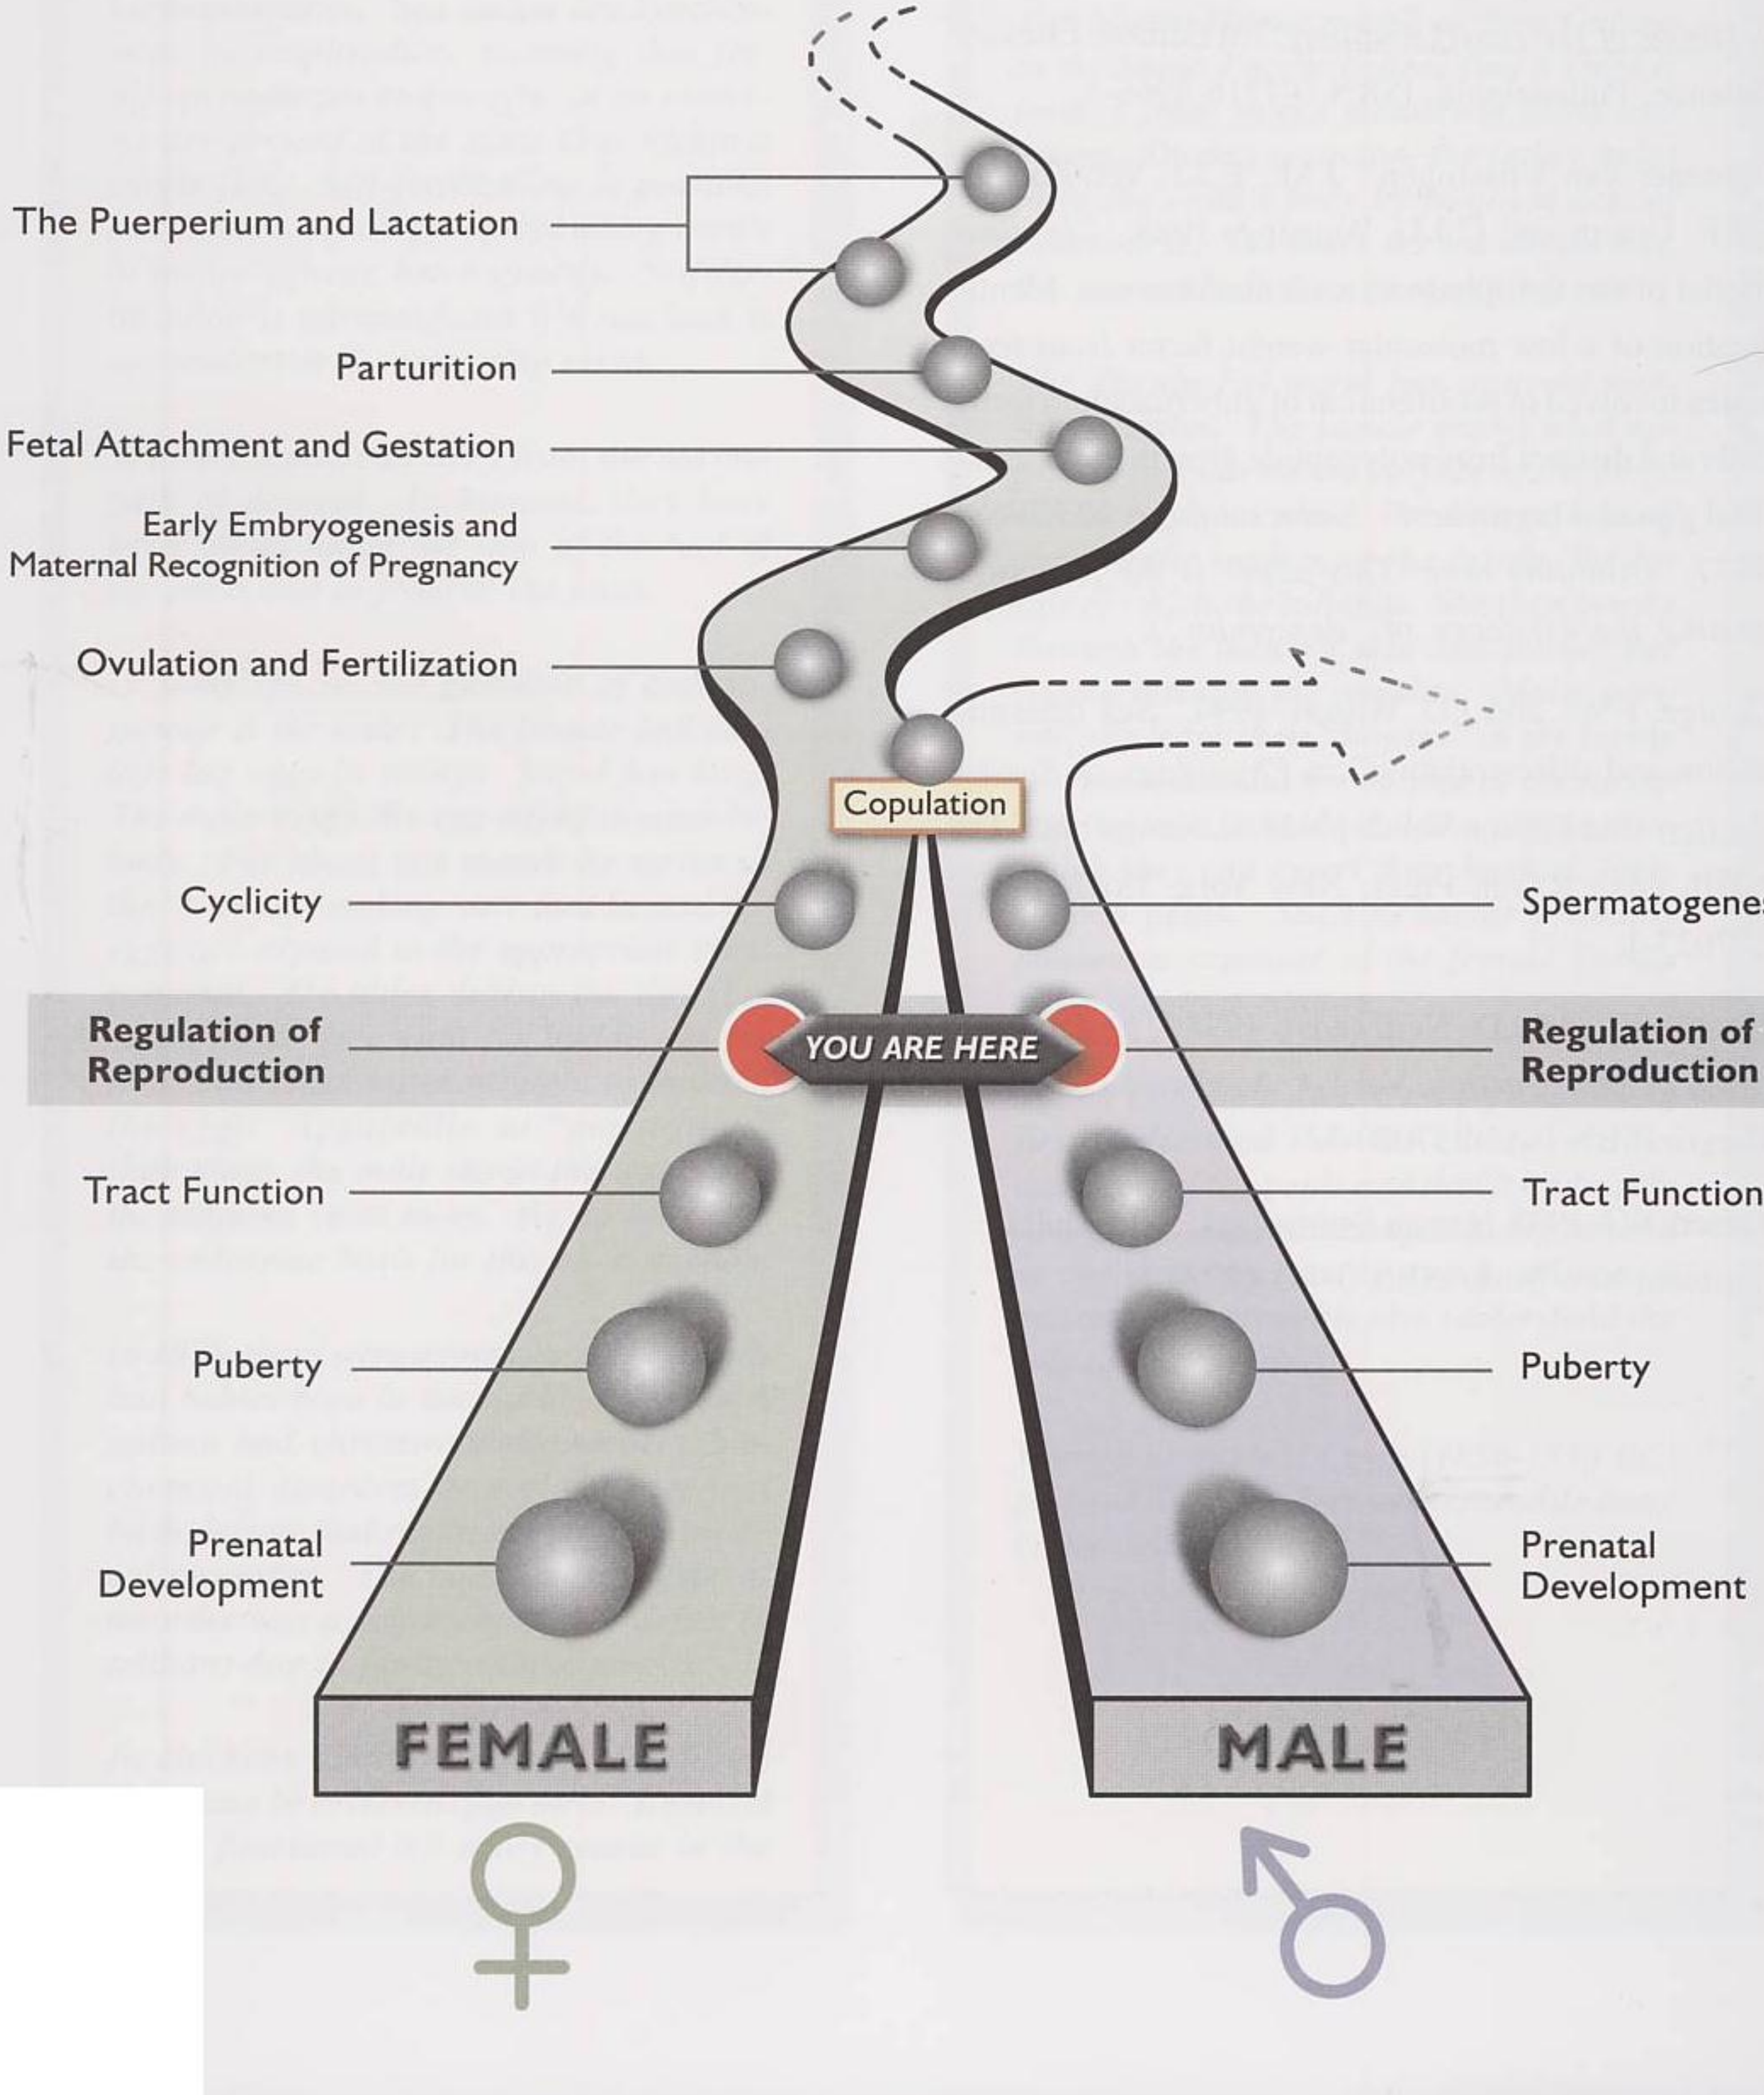
CHAPTER 5

Regulation of REPRODUCTION

Nerves, Hormones and Target Tissues



Take Home Message

Hormones originate from endocrine glands or nerves. They enter the blood and cause cells in target tissues containing specific receptors to produce new products or new hormones. The original hormones and the products of their action are necessary for successful reproduction. Protein hormones act via plasma membrane receptors and exert effects in the cytoplasm of the cell. Steroid hormones act through nuclear receptors and cause transcription and translation that results in the production of new proteins. Both types of hormones cause changes in the function of the target cells.

Reproduction is regulated by a remarkable interplay between the **nervous system** and the **endocrine system**. These two systems interact in a consistent display of teamwork to initiate, coordinate and regulate all reproductive functions. In order to understand and appreciate the role of these two systems, you must first focus on the control that each system exerts independently.

Neural control is exerted by:
- ***simple neural reflexes***
- ***neuroendocrine reflexes***

The fundamental responsibility of the nervous system is to translate or **transduce** external stimuli into neural signals that bring about a change in the reproductive organs and tissues. The fundamental pathways of nervous involvement are a **simple neural reflex** and a **neuroendocrine reflex.** The functional components of these two pathways are sensory neurons (afferent neurons taking neural signals toward the spinal cord), the spinal cord, efferent neurons (nerves leaving the spinal cord and traveling to the target tissue) and **target tissues** (See Figure 5-1). Target tissues are those organs that respond to a specific set of stimuli.

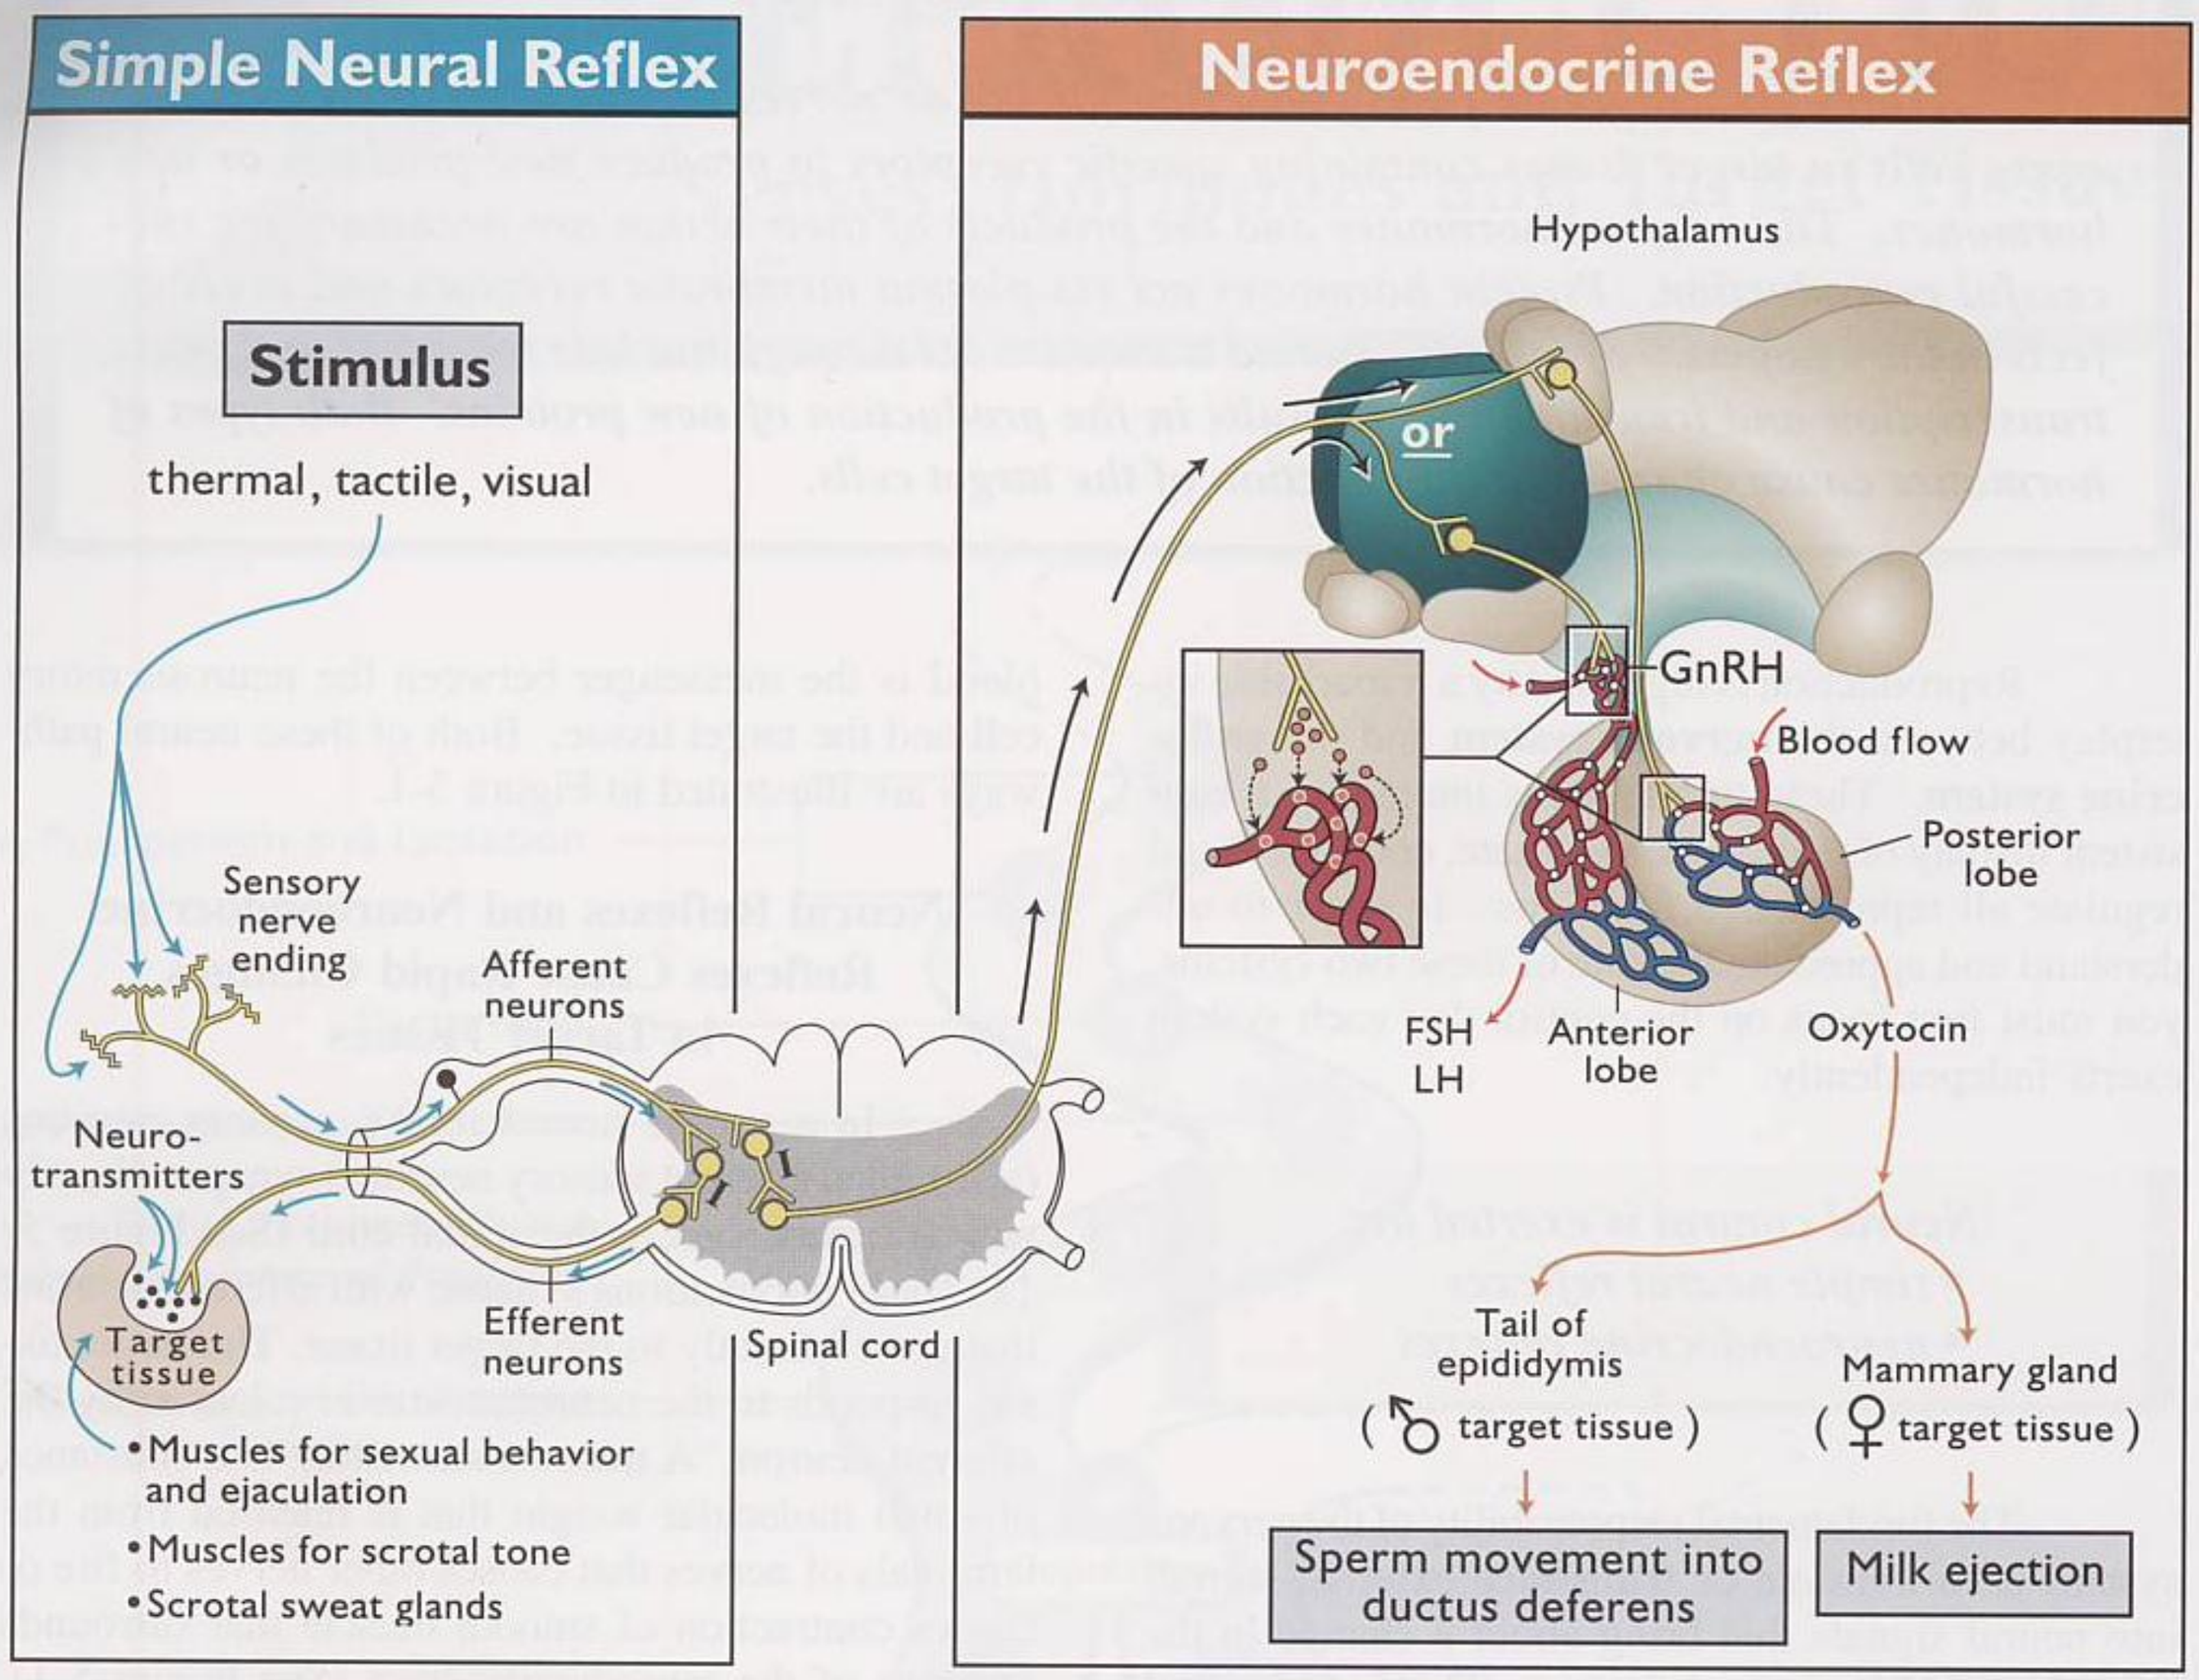
The basic difference between the simple neural reflex and the neuroendocrine reflex is the type of delivery system each uses. For example, a simple neural reflex employs nerves that release their neurotransmitters (messengers) directly onto the target tissue. In other words, the target tissue is directly innervated by a neuron. In contrast, a neuroendocrine reflex requires that a **neurohormone** (a substance released by a neuron) enter the blood and act on a remote target tissue. Neurons releasing neurotransmitters may also be referred to as **neurosecretory cells**. Direct innervation of the target tissue does not exist in the neuroendocrine reflex. Instead, the neurohormone in the blood is the messenger between the neurosecretory cell and the target tissue. Both of these neural pathways are illustrated in Figure 5-1.

Neural Reflexes and Neuroendocrine Reflexes Cause Rapid Changes in Target Tissues

In a simple neural reflex, sensory neurons (also called afferent sensory neurons) synapse directly with **interneurons** in the spinal cord (See Figure 5-1). These interneurons synapse with efferent neurons that travel directly to the target tissue. The target tissue responds to the neurotransmitter released by the efferent neuron. A **neurotransmitter** is a substance of small molecular weight that is released from the terminals of nerves that causes other nerves to fire or causes contraction of smooth muscle that surrounds portions of the reproductive tract (See Figure 5-1). An example of a simple neural reflex in reproduction is ejaculation. A stimulus originating in the glans penis is recognized by sensory neurons. Signals are then transmitted to the spinal cord where they synapse with efferent neurons that cause a series of highly coordinated muscular contractions resulting in expulsion of semen. A detailed pathway of this neural event will be presented in Chapter 11. Another example of a simple neural reflex that impacts the reproductive system involves temperature sensitive neurons located in the scrotum (described in Chapter 3). When scrotal temperature decreases, sensory neurons in the scrotum recognize this decrease and send sensory signals to the spinal cord. Efferent nerves travel to the tunica dartos in the scrotum and release neurotransmitters that initiate contraction that elevates the testicles to bring them closer to the body, thus warming them.

The **neuroendocrine reflex** (See Figure 5-1) is quite similar to a simple neural reflex. This type of reflex also starts with sensory neurons. They synapse with interneurons in the spinal cord. Efferent neurons traveling from the spinal cord **synapse** with

Figure 5-1. Neural and Neuroendocrine Reflexes



other neurons in the hypothalamus. The hypothalamic neurons release small molecular weight materials from their terminals. These materials are referred to as **neurohormones** because they are released into the blood rather than directly onto the target tissue. Neurohormones released into capillaries travel to a target tissue elsewhere in the body. The classic example of a neuroendocrine reflex is the suckling reflex. When suckling occurs, sensory nerves in the teat of the lactating female detect the tactile stimulus. These sensory signals travel to the spinal cord and then to the hypothalamus where they synapse with other nerves. The hypothalamic neurons then depolarize ("fire"), causing release of **oxytocin** directly from nerve terminals located in the posterior lobe of the pituitary. Oxytocin is stored as a neurosecretory material in the nerve terminals of the posterior lobe of the pituitary. When these neurosecretory cells "fire," oxytocin is released, enters the blood, travels to the target tissue (in this case, myoepithelial cells of the mammary gland) (See Chapter 15) and causes these cells to contract, resulting in milk let-down (milk ejection from the mammary alveoli). In addition, other forms of stimuli, such as visual or auditory, can cause milk let-down if the animal is preconditioned to respond to these stimuli. For example, the sight or sound of the newborn may elicit a similar response without direct mammary stimulation. Also, many dairy cows

entering the milking parlor receive visual or auditory stimuli prior to actual mammary stimulation by either the sight or sounds of the equipment and begin to experience milk let-down prior to entering the parlor.

Inhibitory neurons block or stop the action of other excitatory neurons.

The neural pathways illustrated in Figures 5-1 and 5-2 deal exclusively with excitatory neurons (neurons that cause other neurons or tissues to be excited or activated). However, another type of neuron is widespread throughout the central nervous system. This type of neuron is known as an **inhibitory neuron** and rather than excite, it inhibits other neurons. In order to understand fully the possible action of inhibitory neurons, you must first understand the functional difference between inhibitory and excitatory neurons. The distinguishing feature between the inhibitory and excitatory neurons is the type of neurotransmitter that is released from each. An **excitatory neurotransmitter** will increase the probability of a postsynaptic action potential (firing of the nerve). An **inhibitory neurotransmitter** will decrease the chance of a postsynaptic action potential. Thus, the probability that the postsynaptic neuron will fire is controlled by the ratio of presynaptic excitation and presynaptic inhibition.

Figure 5-2. The Major Pathways and Steps of a Simple Neural Reflex and a Neuroendocrine Reflex

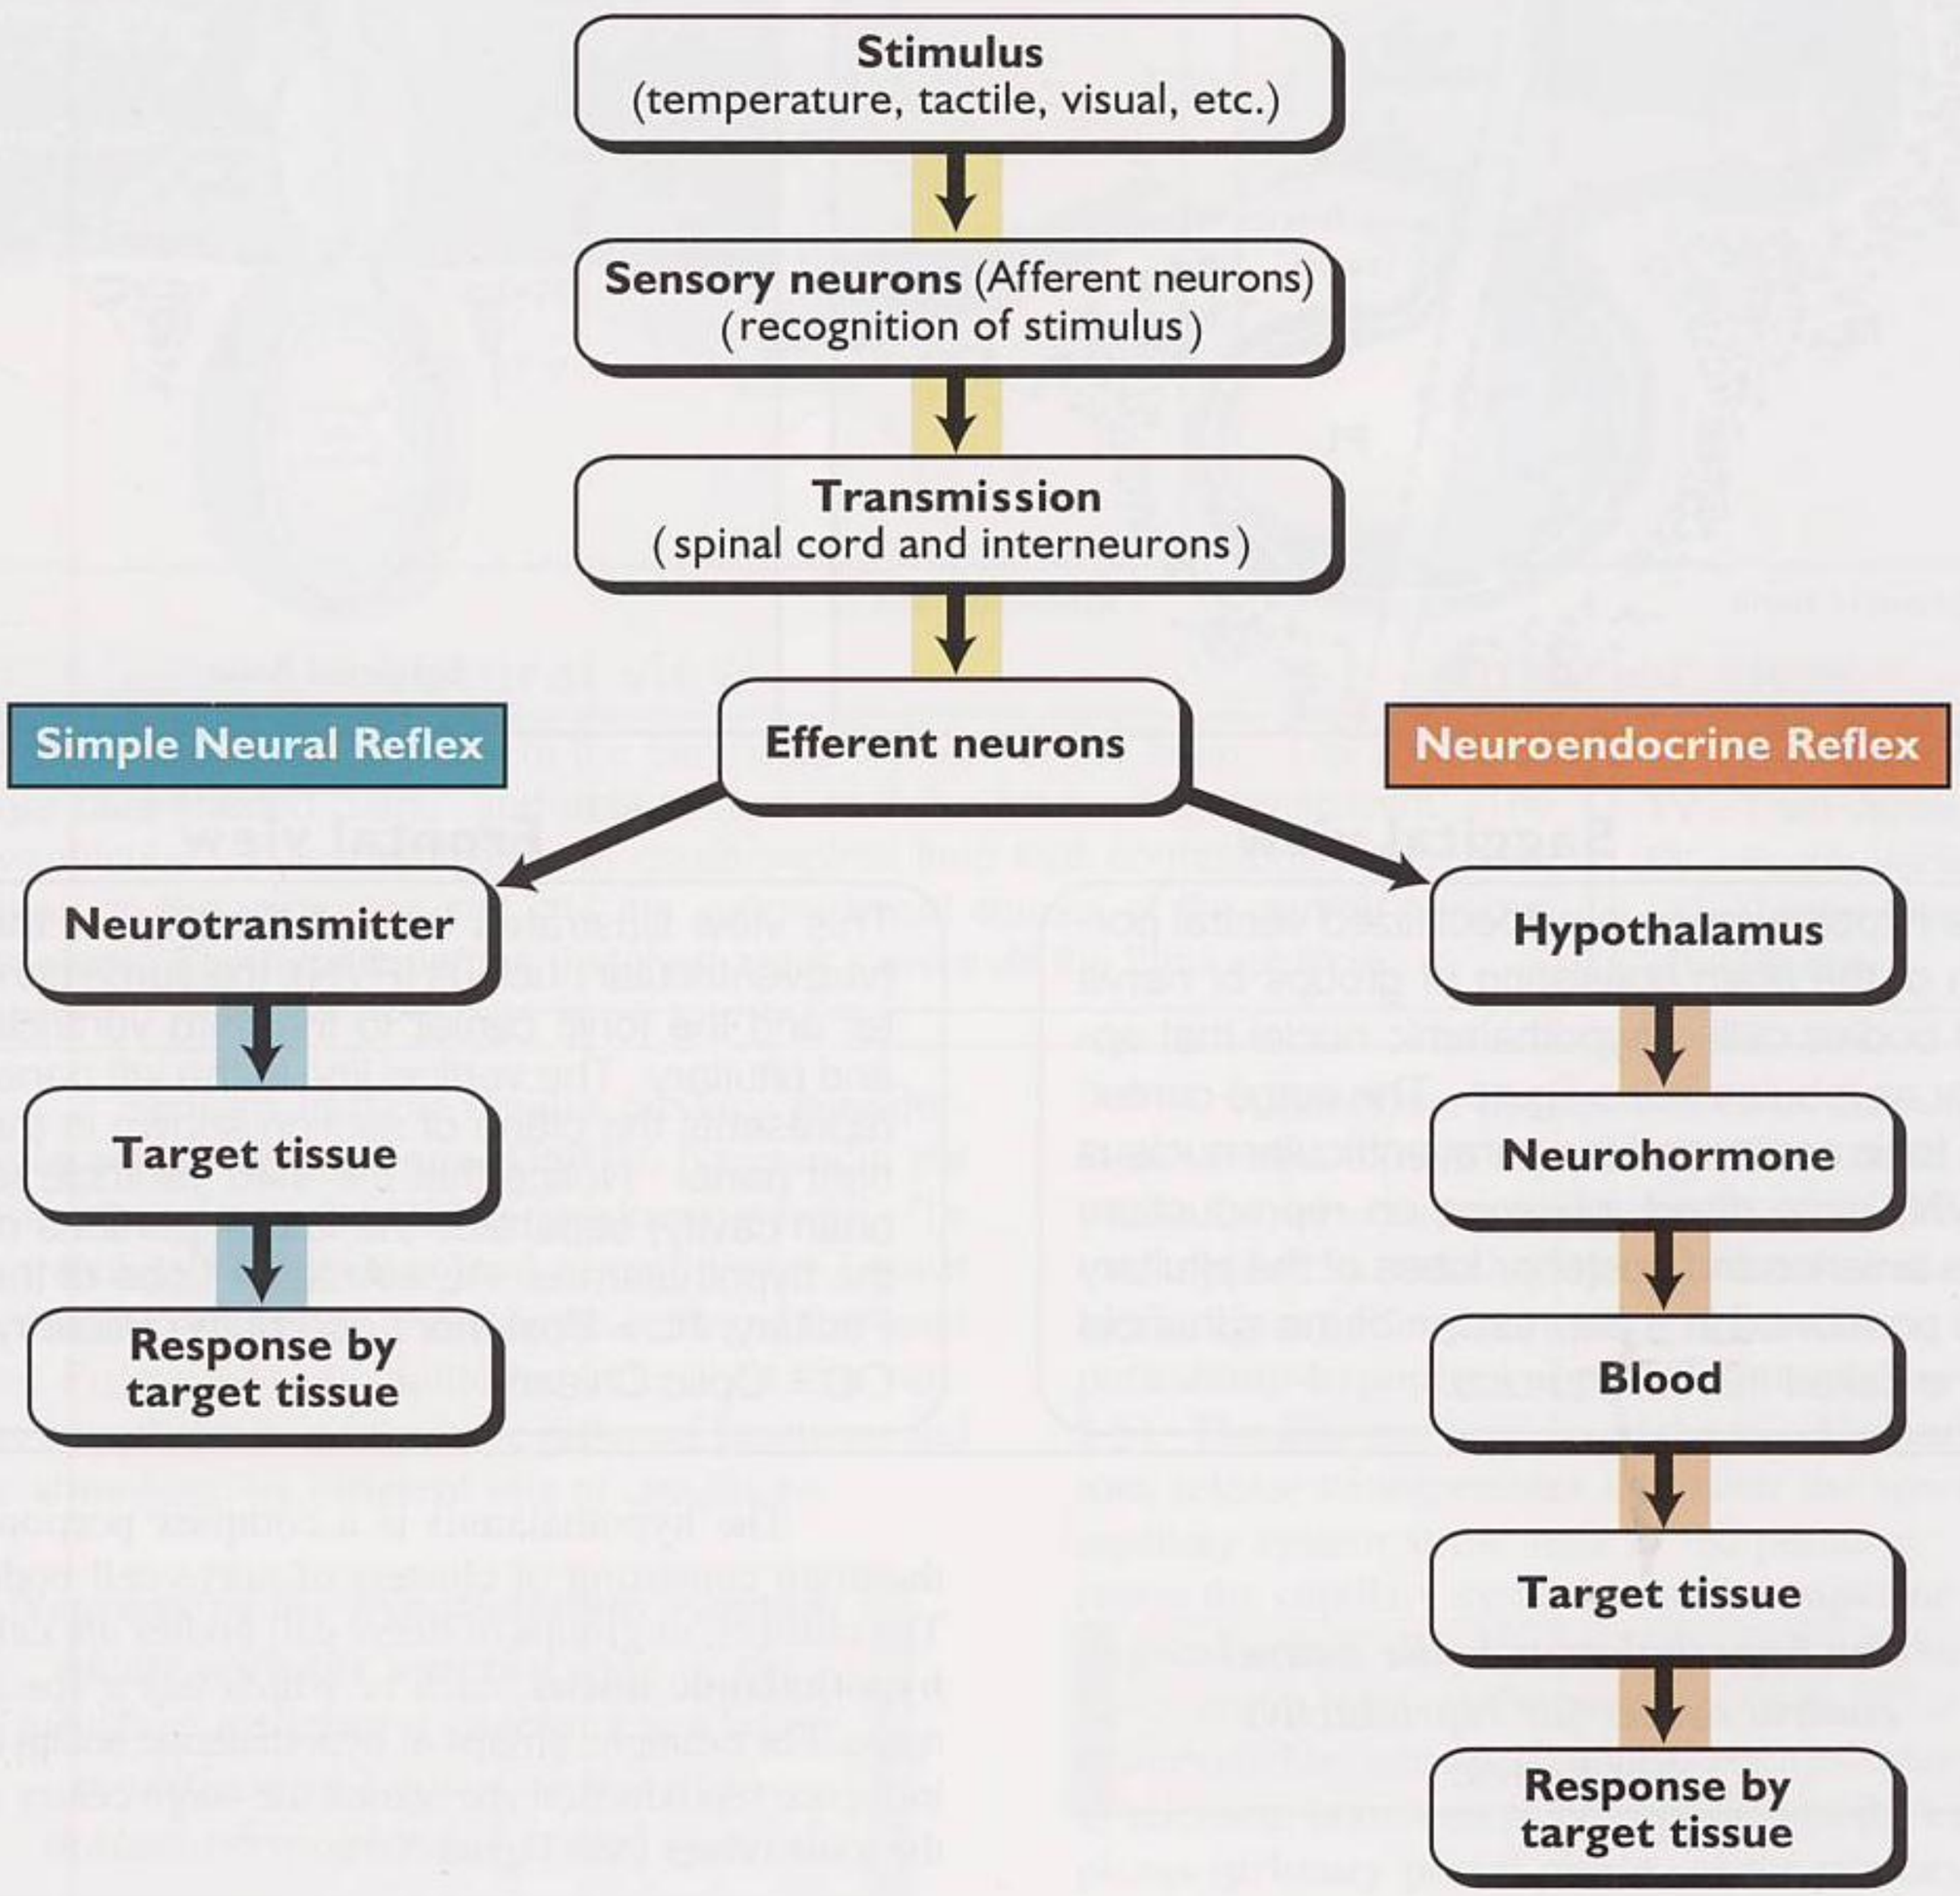


Figure 5-3. Anatomy of the Typical Mammalian Hypothalamus and Pituitary

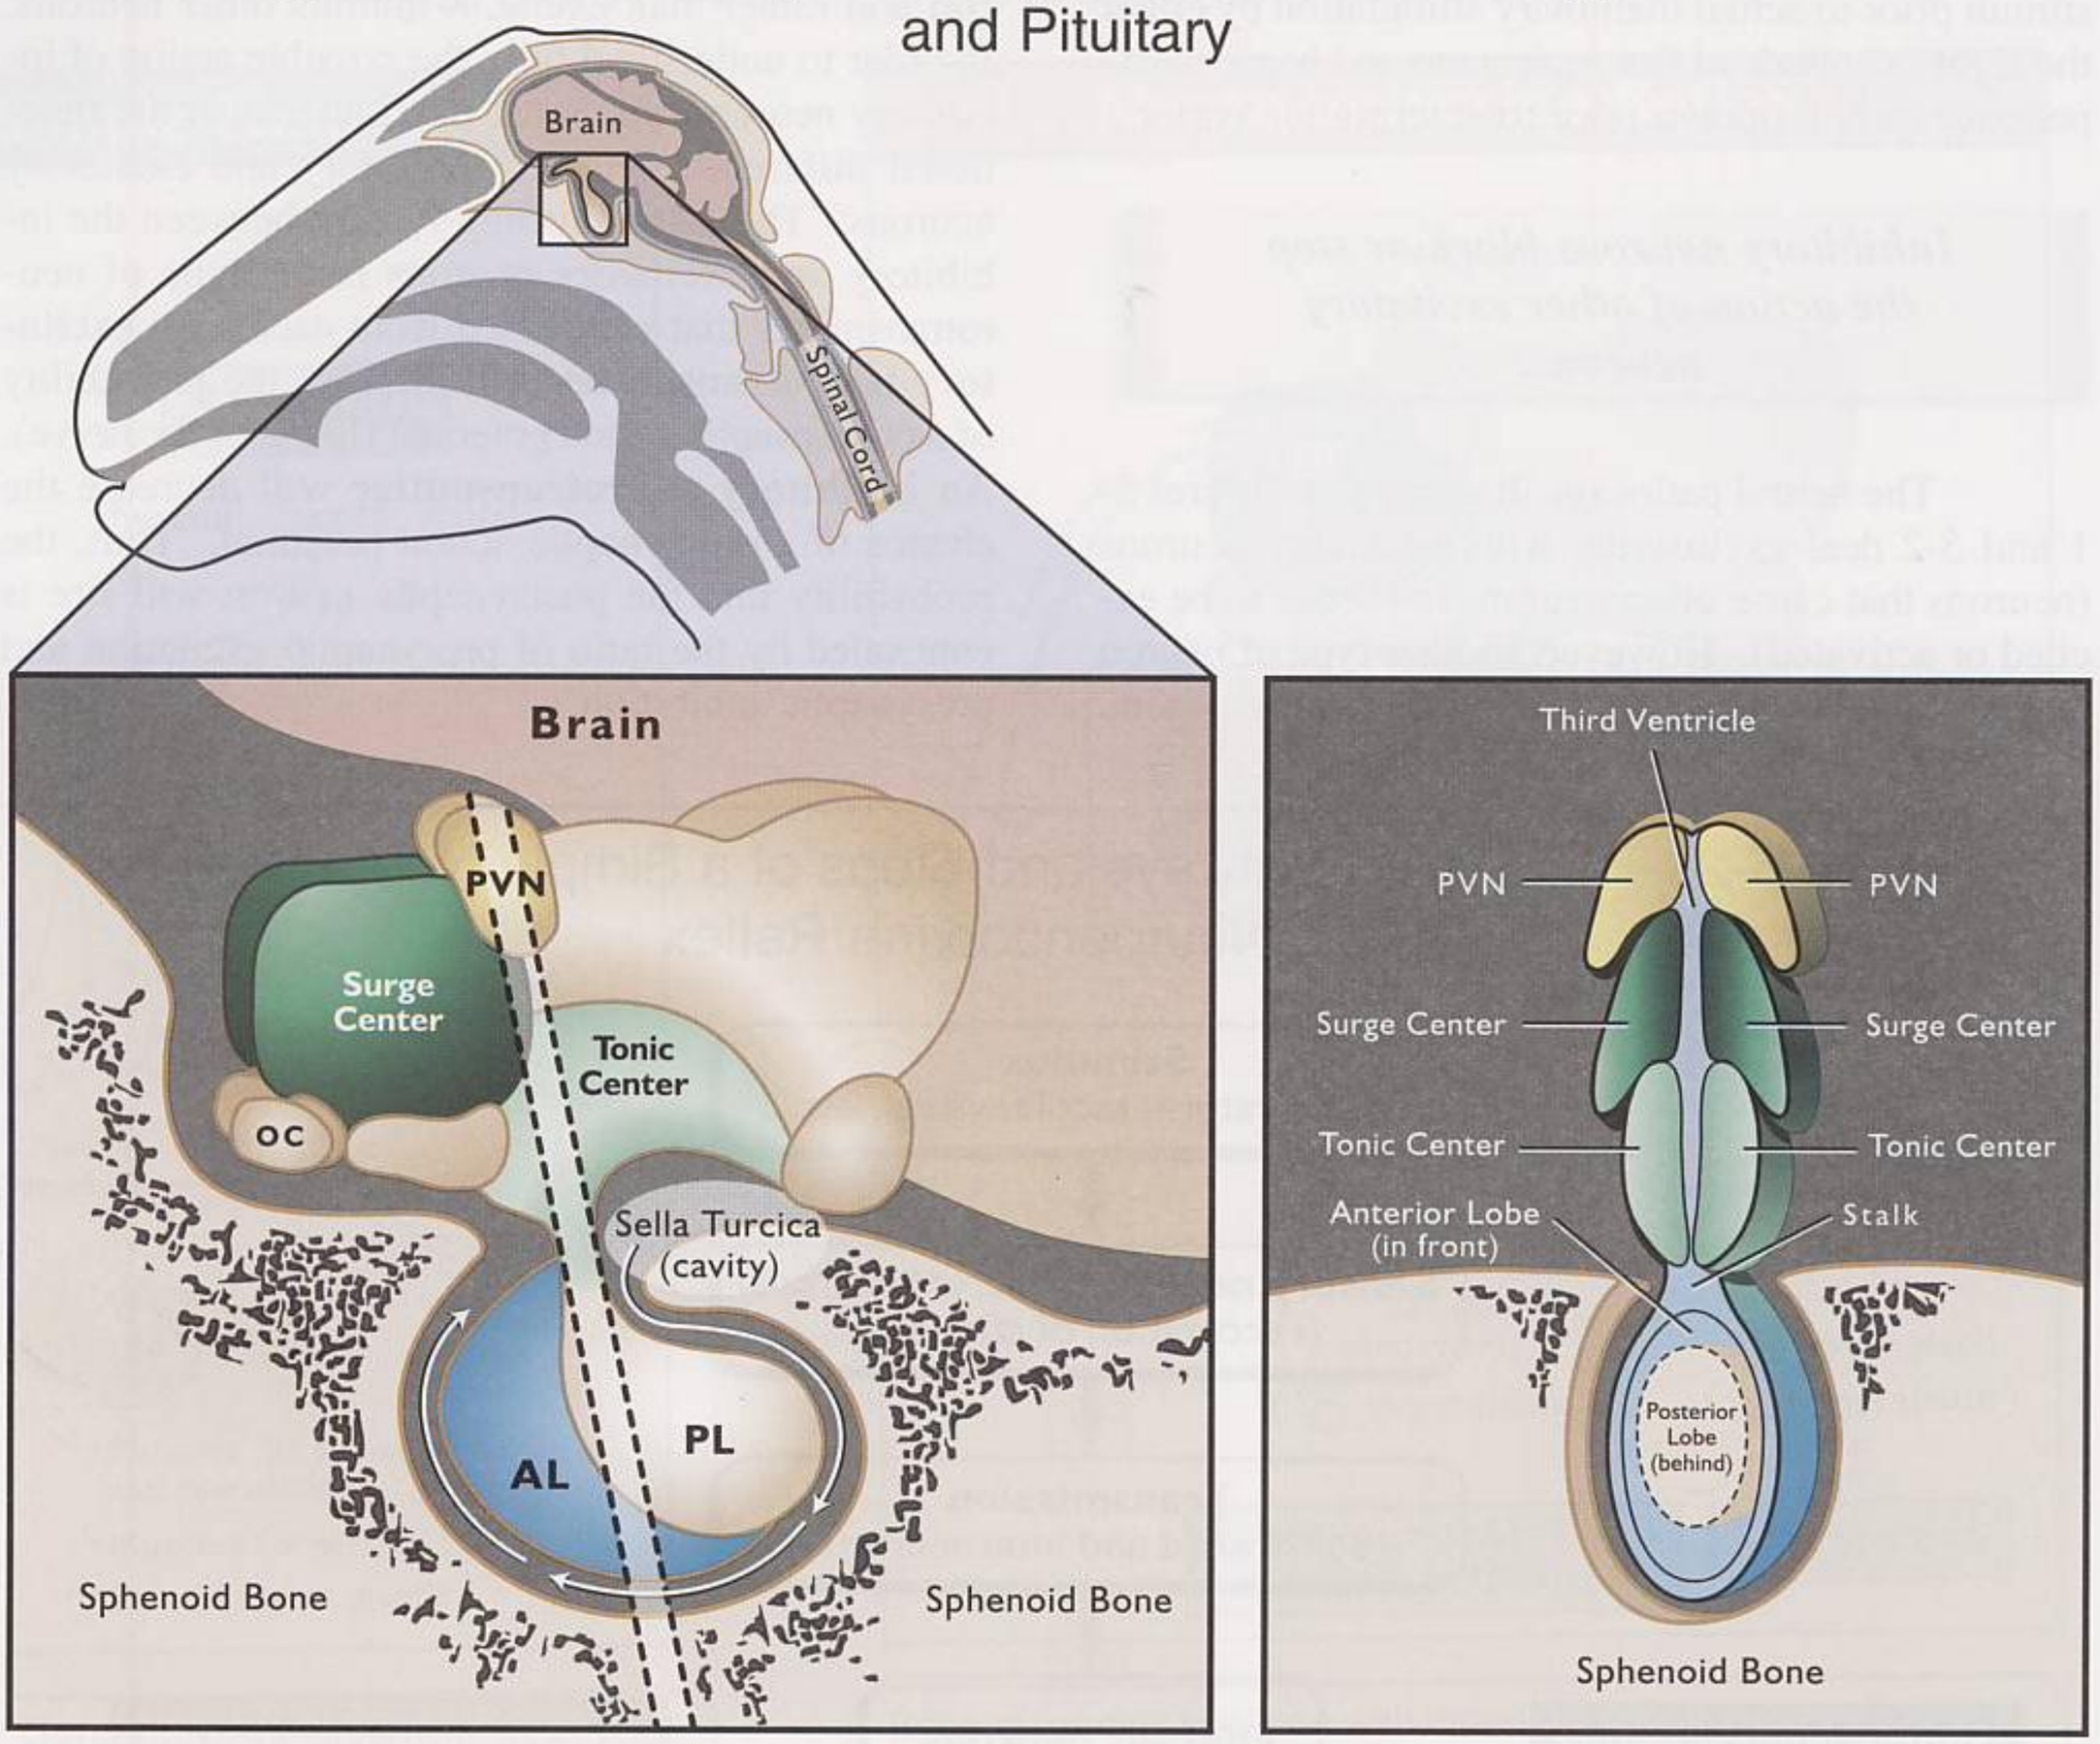


Saggital view

The hypothalamus is a specialized ventral portion of the brain consisting of groups of nerve cell bodies called hypothalamic nuclei that appear as lobules in the figure. The surge center, the tonic center and the paraventricular nucleus (PVN) have direct influence on reproduction. The anterior and posterior lobes of the pituitary are positioned in a depression of the sphenoid bone called the sella turcica.

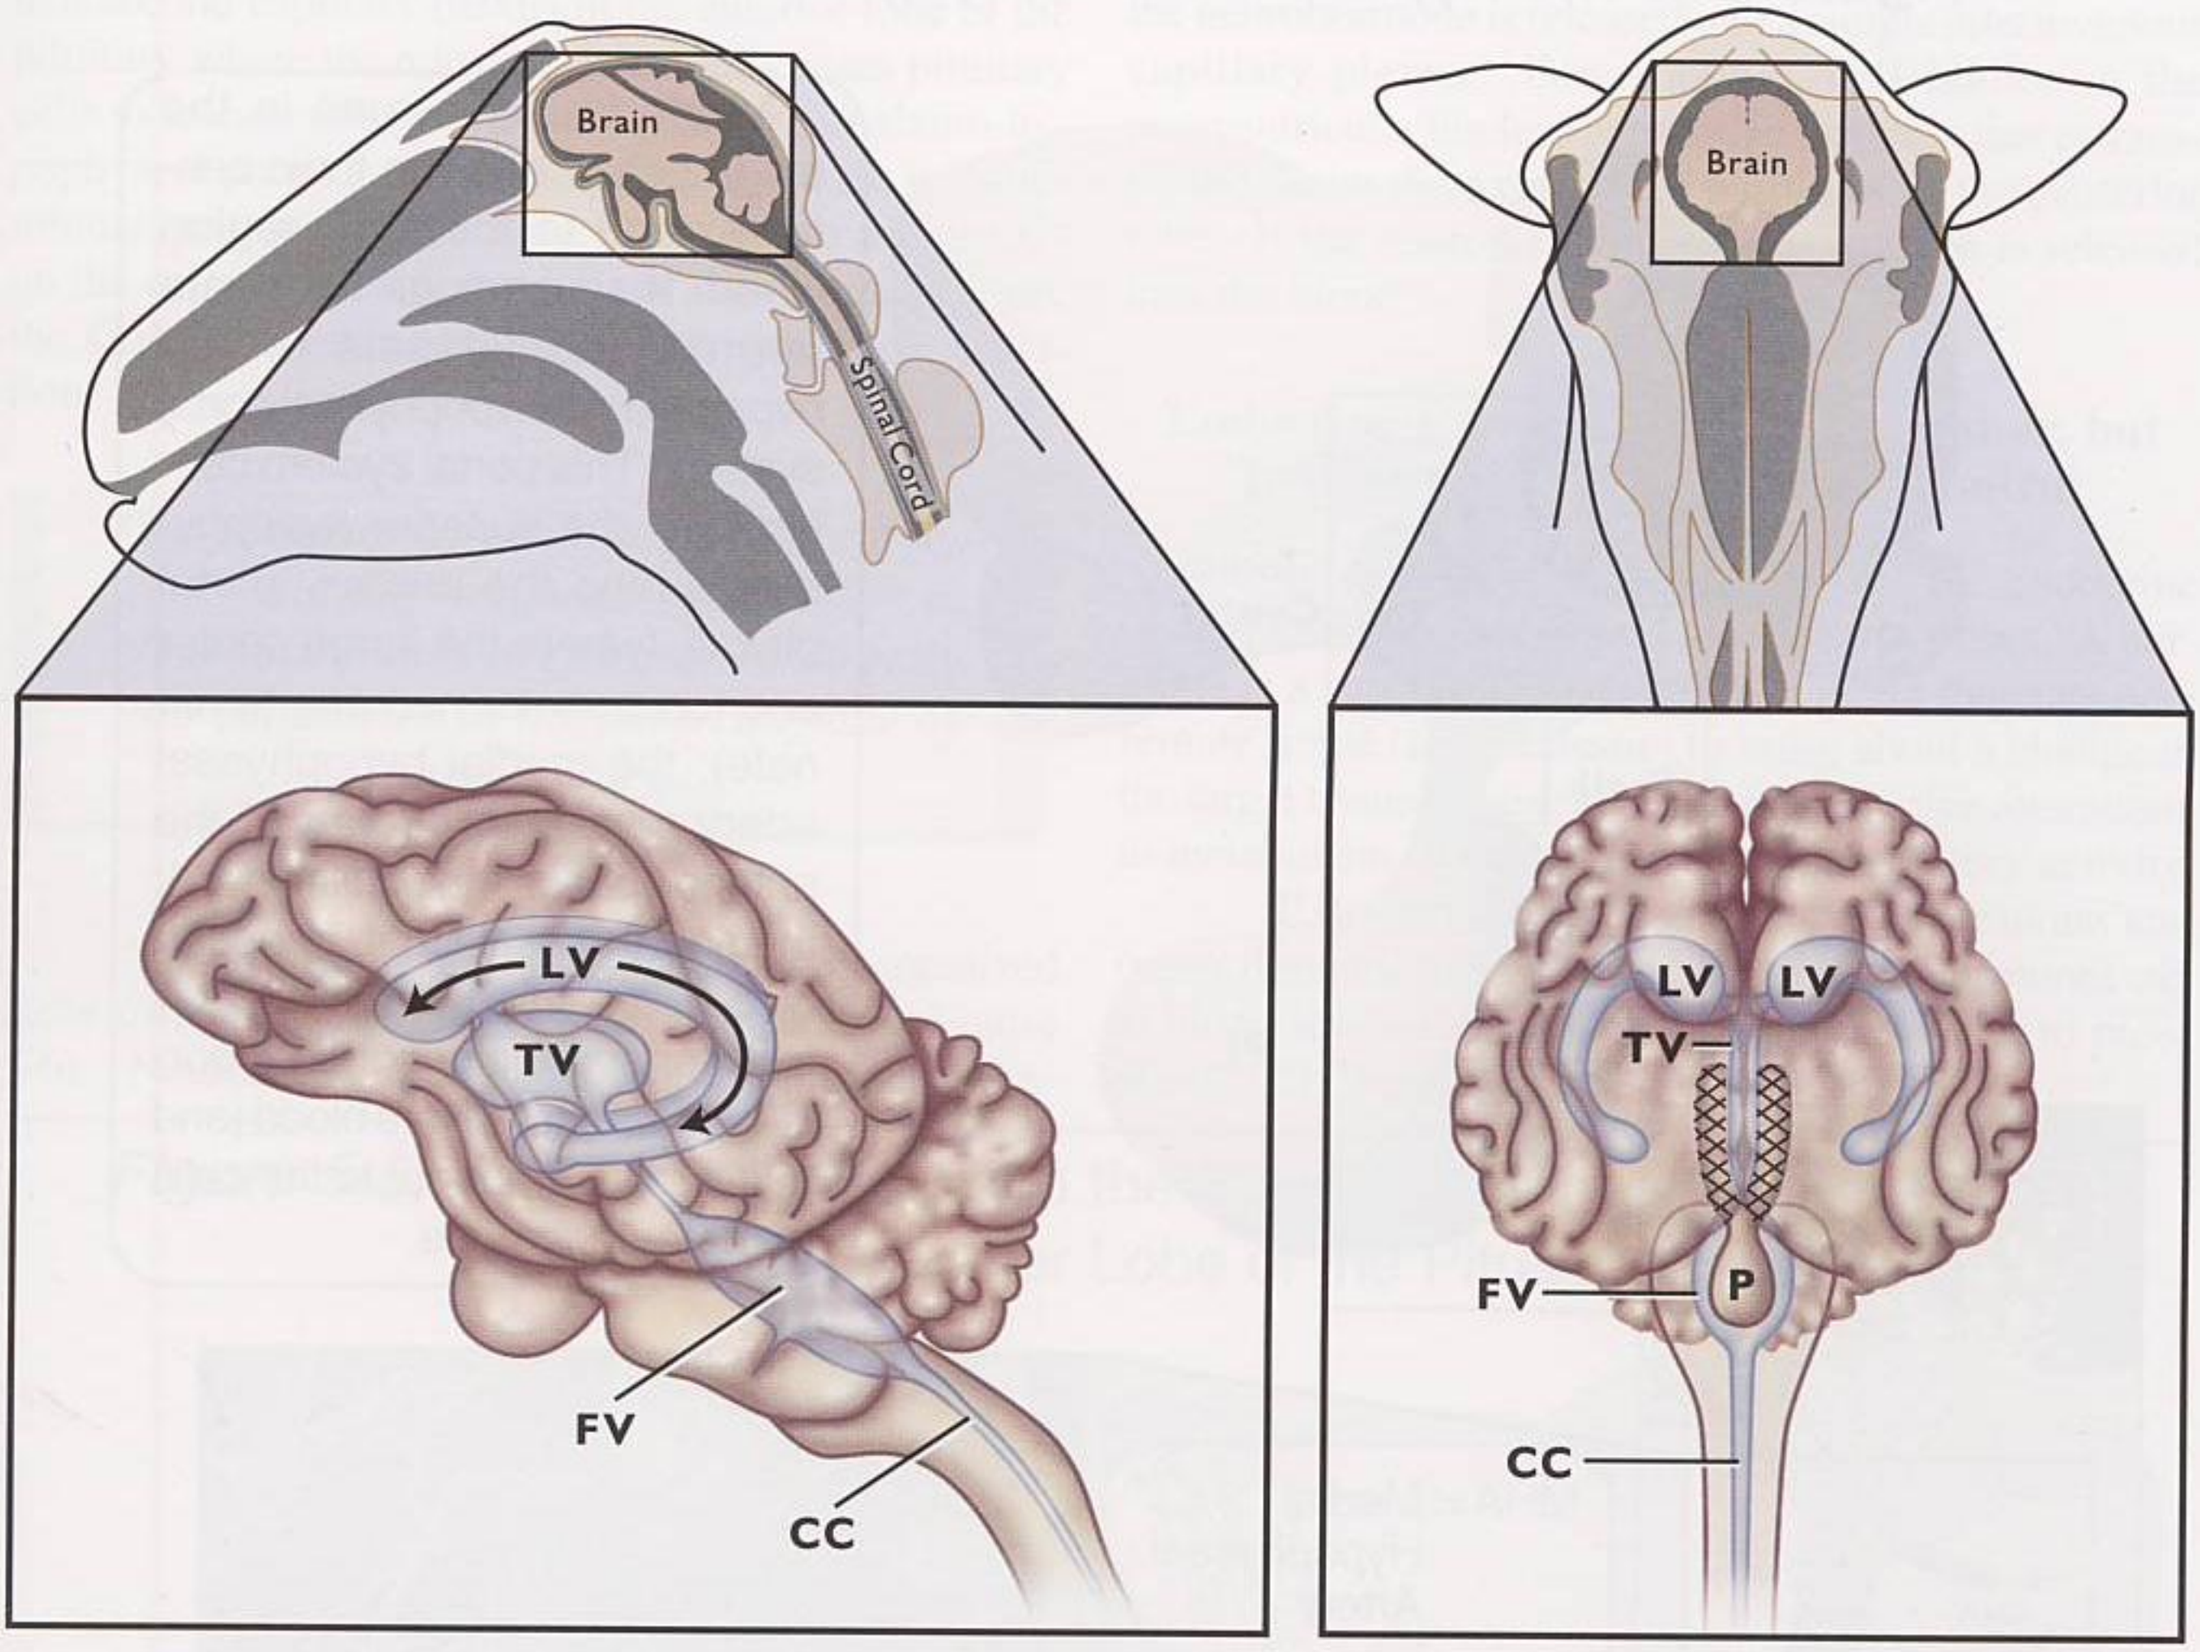
Frontal view

This view illustrates the relationship of the paraventricular nucleus (PVN), the surge center and the tonic center to the third ventricle and pituitary. The vertical line in the left panel represents the plane of section shown in the right panel. Notice that the third ventricle (a brain cavity) separates the lateral portions of the hypothalamus. AL = Anterior Lobe of the Pituitary, PL = Posterior Lobe of the Pituitary, OC = Optic Chiasm.

The hypothalamus is the neural control center for reproductive hormones.

The hypothalamus is a complex portion of the brain consisting of clusters of nerve cell bodies. The clusters, or groups of nerve cell bodies are called **hypothalamic nuclei**, each of which has a specific name. For example, groups of hypothalamic nuclei that influence reproduction are named the surge center and the tonic center (See Figure 5-3).

Figure 5-4. Ventricular System of the Brain



Lateral view **Anterior view**

Lateral and anterior views of the ventricular system of the brain. The ventricles are blue-shaded "bags" and appear here as if the brain were transparent. The ventricular system is filled with cerebrospinal fluid that continuously circulates through the ventricles and into the subarachnoid spaces of the central nervous system. The hypothalamus (hatched area) surrounds the third ventricle.

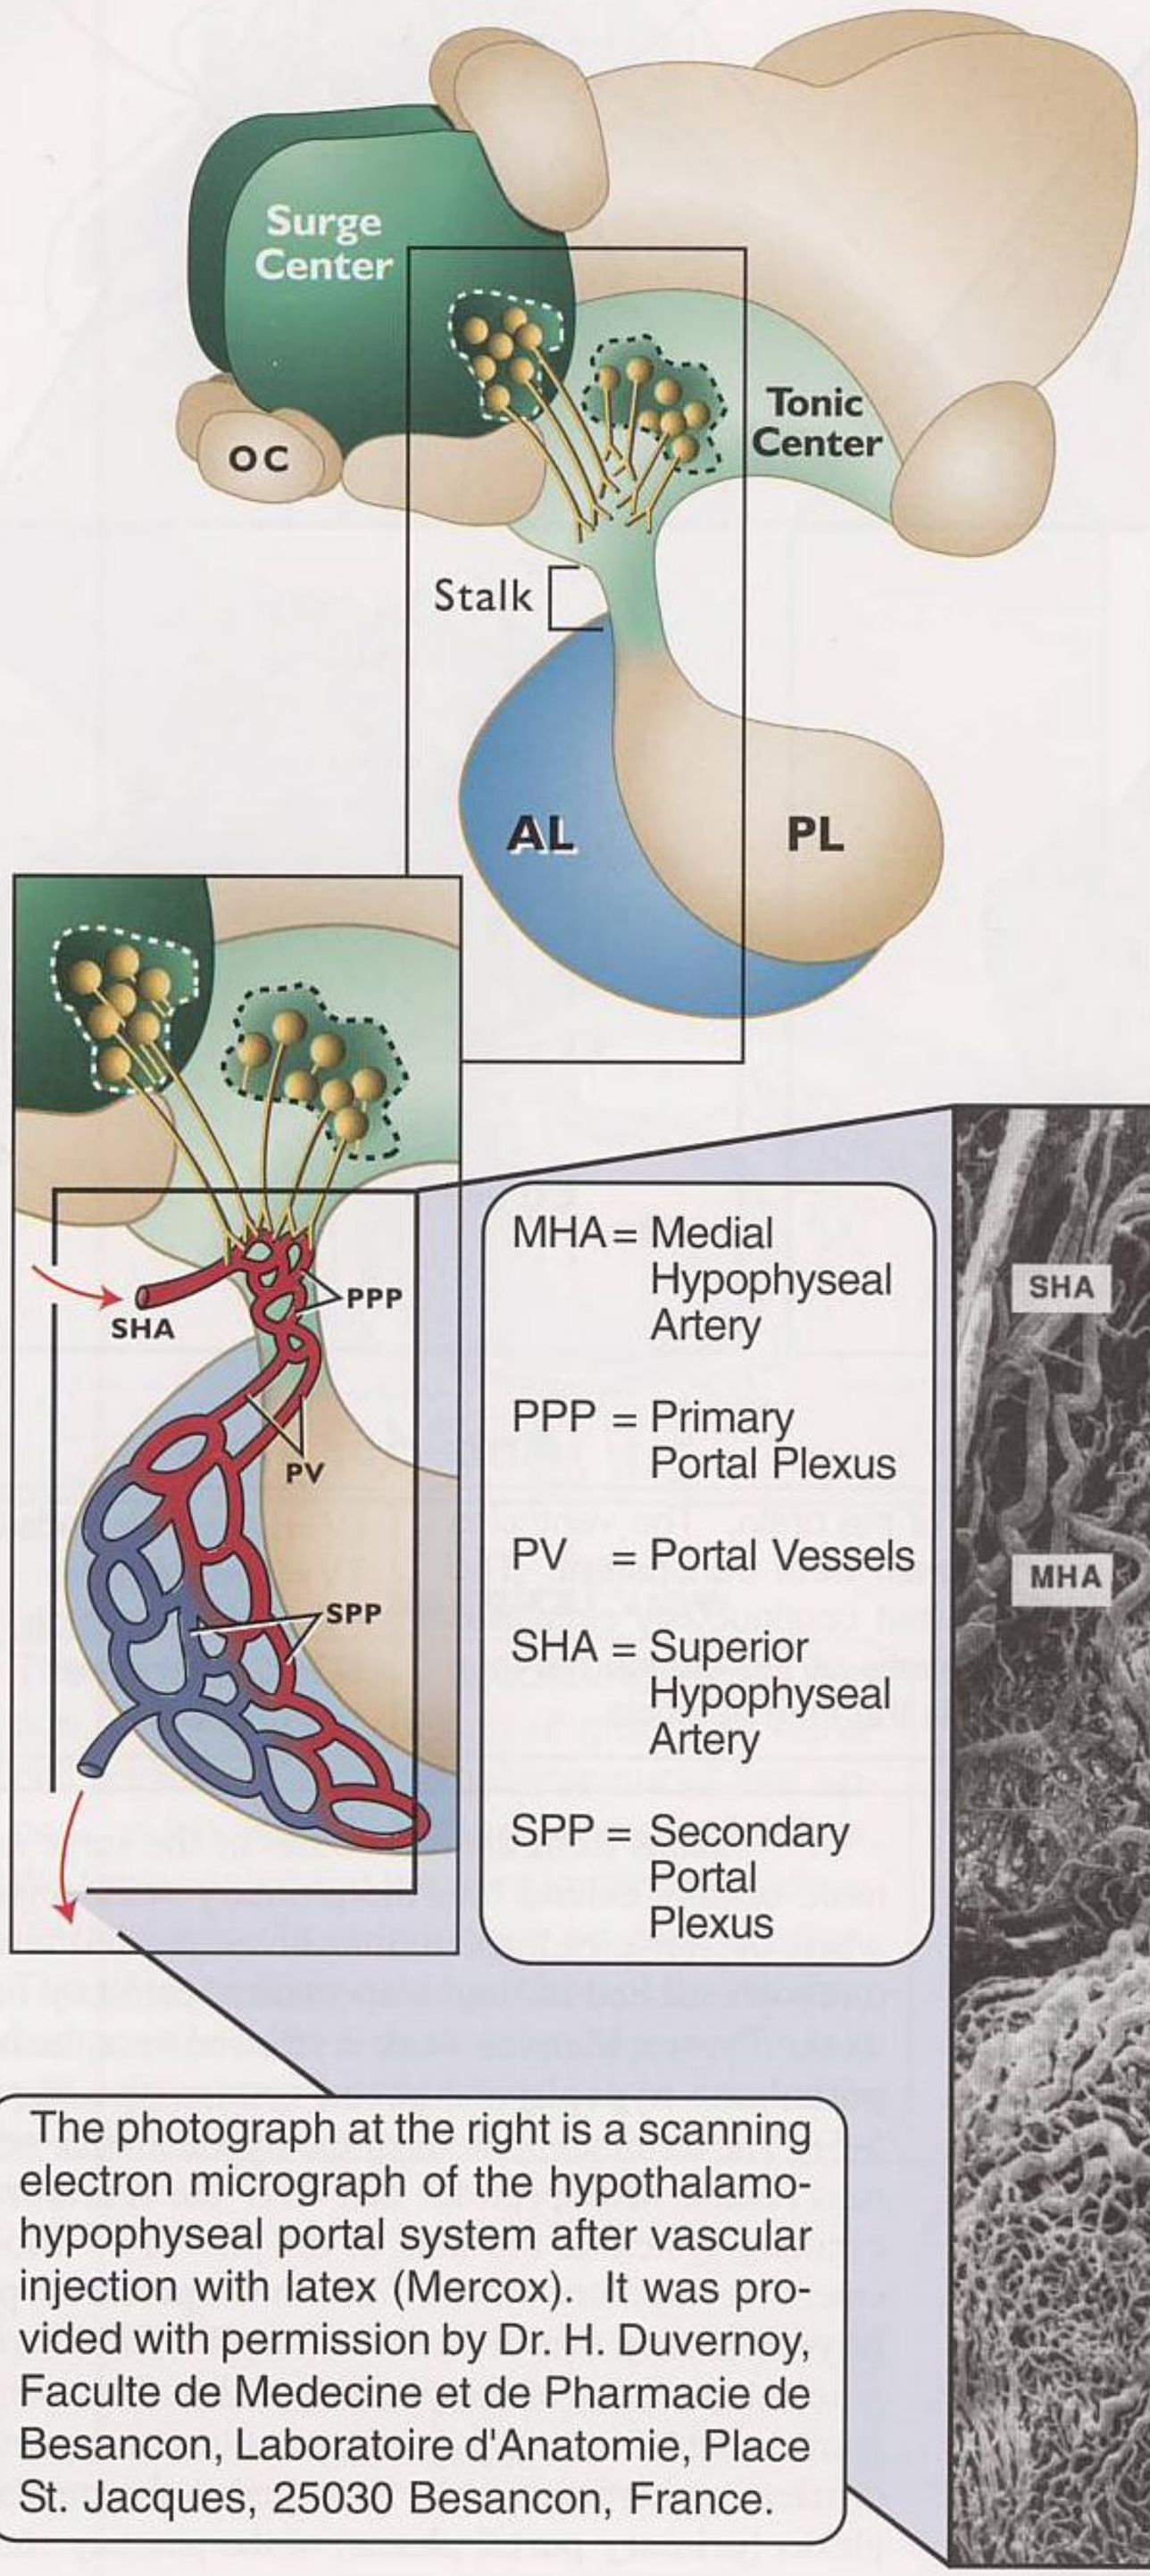
LV = Lateral Ventricles
TV = Third Ventricle
FV = Fourth Ventricle
CC = Central Canal
P = Pituitary

Neurons in these regions produce **gonadotropin releasing hormone** (GnRH). Neurons in the paraventricular nucleus (PVN) produce oxytocin. The hypothalamic nuclei surround a small cavity known as the third ventricle, found in the center of the brain (See Figure 5-4). It should be understood that various hypothalamic nuclei have different functions and are stimulated by different sets of conditions.

Neurons in the hypothalamus communicate with the anterior lobe of the pituitary utilizing a special circulatory modification known as the hypothalamo-hypophyseal portal system.

Axons from the cell bodies of the surge and tonic centers extend into the pituitary stalk region where the nerve endings (terminal boutons) terminate on a sophisticated and highly specialized capillary network. This capillary network is referred to as the **hypothalamo-hypophyseal portal system** (See Figure 5-5). The terminal boutons of the hypothalamic neurons release neuropeptides that enter the specialized capillary system at the stalk of the pituitary. Blood enters the capillary system from the **superior hypophyseal artery** that divides into small arterial capillaries at the level of the pituitary stalk. This portal system enables extremely small quantities (picograms) of releasing hormones to be deposited in the capillary plexus (**primary portal plexus**) of the pituitary stalk.

Figure 5-5. The Hypothalamo-Hypophyseal Portal System



Axons from neurons in the surge center and the tonic center extend to the stalk region where their endings terminate upon blood vessels of the hypothalamo-hypophyseal portal system. This portal system consists of: the superior hypophyseal artery; the primary portal plexus, (where the surge center and tonic center neurons terminate); the medial hypophyseal artery that supplies part of the anterior lobe of the pituitary (AL); the portal vessels that transport blood containing releasing hormones; and the secondary portal plexus that delivers blood (and releasing hormones) to the cells of the anterior lobe.

The photograph at the right is a scanning electron micrograph of the hypothalamo-hypophyseal portal system after vascular injection with latex (Mercox). It was provided with permission by Dr. H. Duvernoy, Faculte de Medecine et de Pharmacie de Besancon, Laboratoire d'Anatomie, Place St. Jacques, 25030 Besancon, France.

Releasing hormones are then transferred immediately to a second capillary plexus in the anterior lobe of the pituitary where the releasing hormone causes pituitary cells to release other hormones. The hypothalamo-hypophyseal portal system is important because it allows minute quantities of releasing hormones to act directly on the cells of the anterior lobe of the pituitary before the GnRH becomes diluted by the systemic circulation.

The posterior lobe of the pituitary does not have a portal system. Neurohormones are deposited directly into capillaries in the posterior lobe of the pituitary.

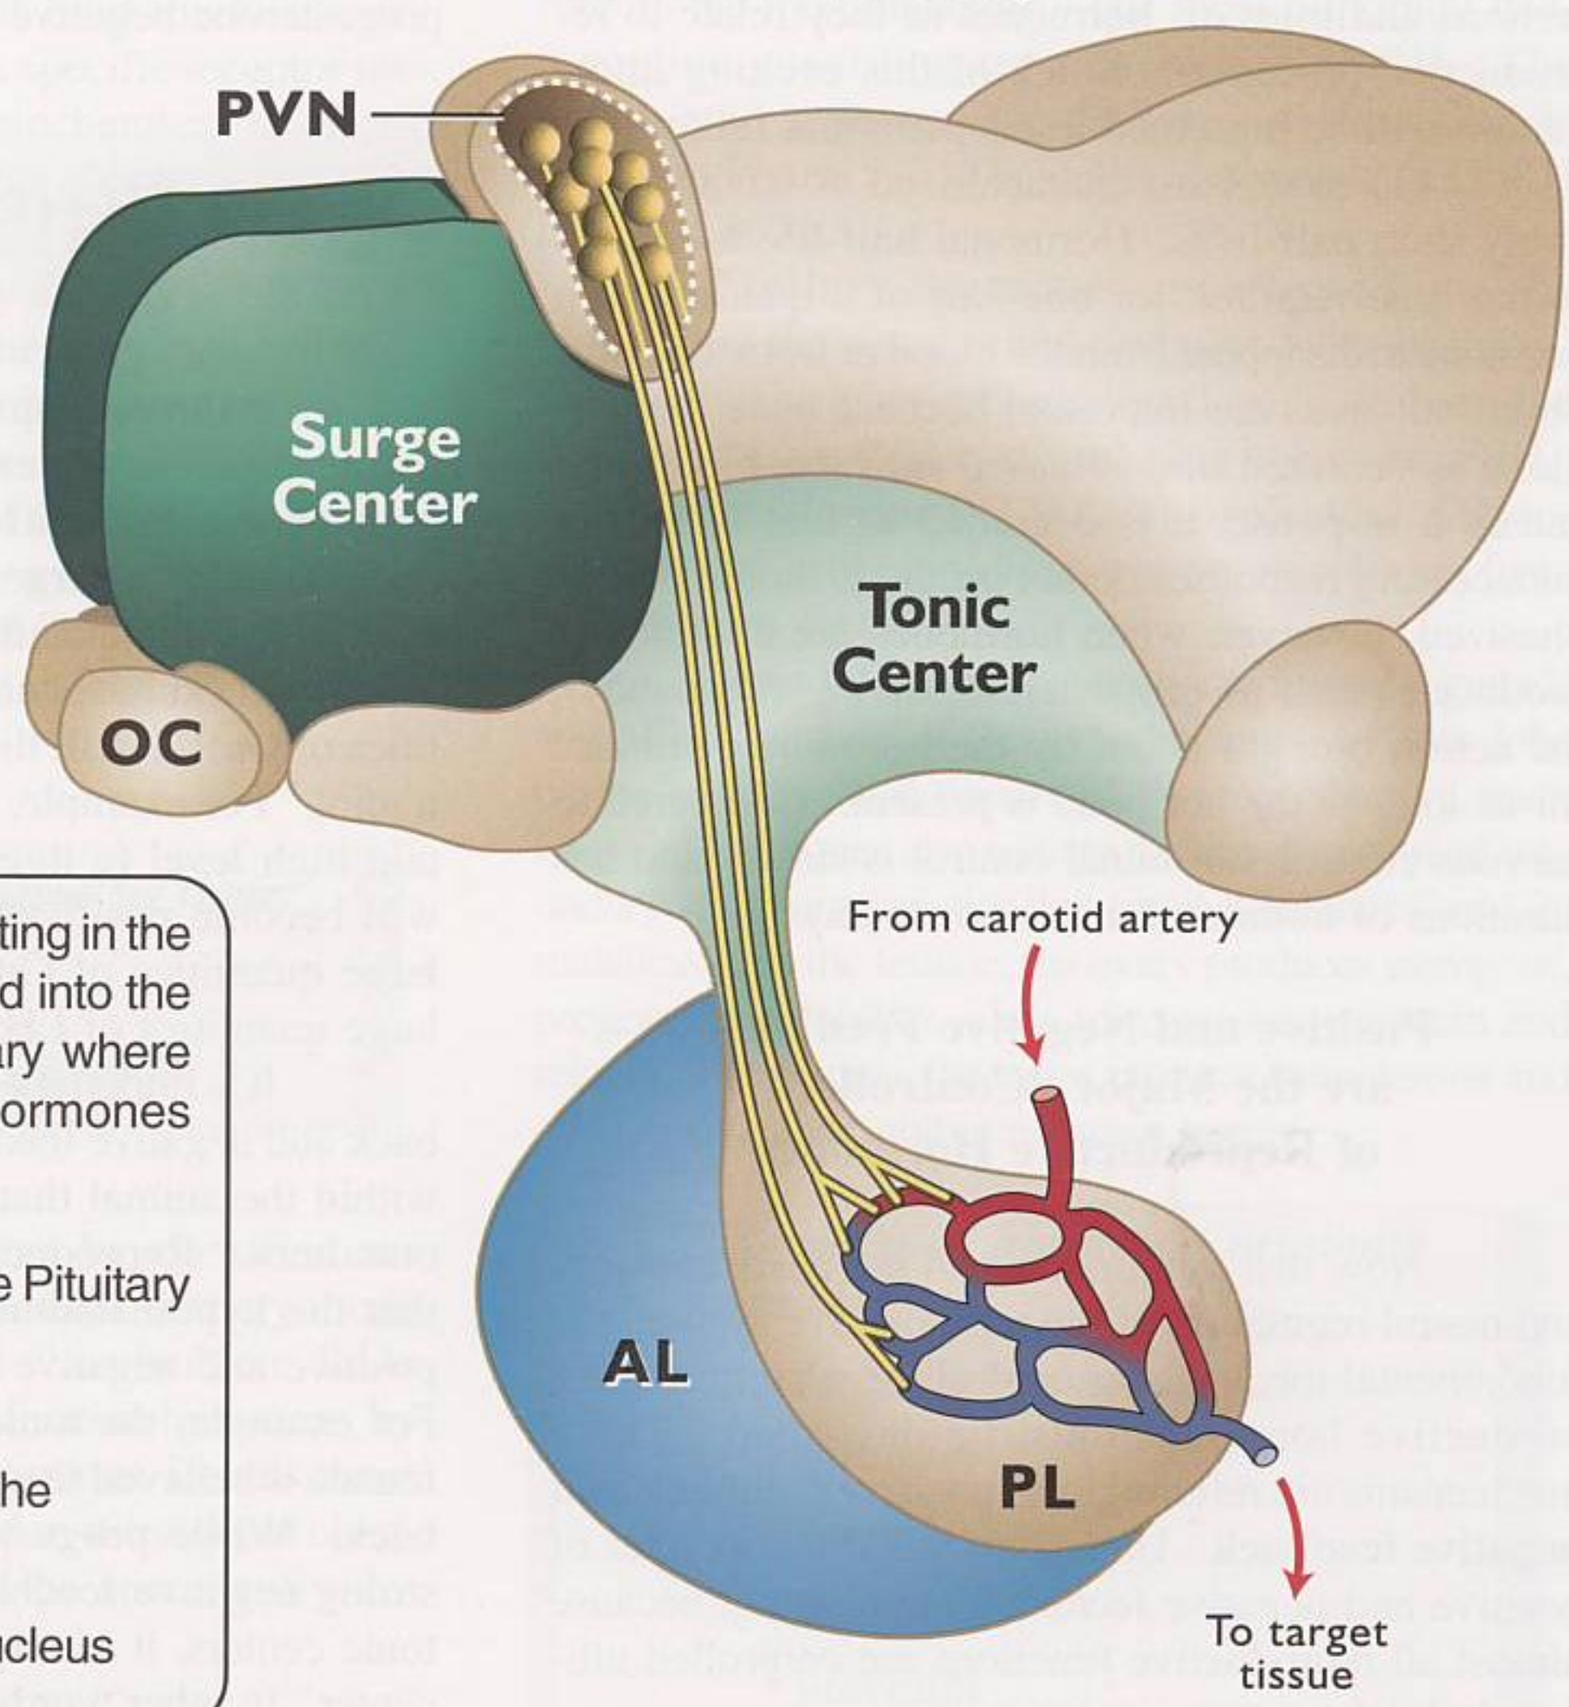
The posterior lobe of the pituitary is organized quite differently from the anterior lobe (See Figure 5-6). Neurons from certain hypothalamic nuclei extend directly into the posterior lobe of the pituitary where the neurohormone is released into a simple arteriovenous capillary plexus. For example, cell bodies in the paraventricular nucleus synthesize oxytocin that is transported down the axon to the terminals in the posterior lobe. If the neuron is stimulated, oxytocin is released into the blood.

Endocrine Control is Generally Slower, but Longer Lasting than Neural Control

In contrast to neural regulation, the endocrine system relies on **hormones** to cause responses. A hormone is a substance produced by a gland that acts on a remote tissue (**target tissue**) to bring about a change in the target tissue. These changes may involve alterations in metabolism, synthetic activity and secretory activity.

Extremely small quantities of a hormone can cause dramatic physiologic responses. Hormones act at blood levels ranging from nanograms (10^{-9}) to picograms (10^{-12}) per ml of blood (See Table 5-1).

Figure 5-6. Relationship Between the Paraventricular Nucleus and the Posterior Lobe of the Pituitary



Axons from neurons originating in the hypothalamus (PVN) extend into the posterior lobe of the pituitary where they release their neurohormones into a capillary plexus.

AL = Anterior Lobe of the Pituitary

OC = Optic Chiasm

PL = Posterior Lobe of the Pituitary

PVN = Paraventricular Nucleus

Table 5-1. Illustration of exponents, decimal places and common weight designations used in describing quantities of substances. The shaded area indicates the range of hormone weights per milliliter of blood that cause physiologic responses

Exponent	Name
1.0_{-1}	**gram**

5

The ability to measure extremely small quantities of hormones has brought about an explosion of knowledge regarding the quantities, patterns of secretions and roles of hormones as they relate to reproductive processes. Much of this exciting information will be presented in chapters that follow.

Hormones are characterized as having relatively short half-lives. Hormonal **half-life** is defined as the time required for one-half of a quantity of a hormone to disappear from the blood or from the body. Short half-lives are important because once the hormone is secreted and released into the blood and causes a response, it is degraded so that further or unnecessary responses do not occur. It should be emphasized, however, when hormones are continually produced (such as progesterone during pregnancy), the action brought about by the hormone continues for as long as the hormone is present. Compared to nervous control, hormonal control is slower and has durations of minutes, hours or even days.

Positive and Negative Feedback are the Major "Controllers" of Reproductive Hormones

Now that you understand the basic anatomy and neural regulation of the reproductive system, the fundamental mechanisms controlling secretion of reproductive hormones must be described. These mechanisms are referred to as **positive feedback and negative feedback**. Understanding the principles of positive and negative feedback is important because almost all reproductive functions are controlled ultimately by these two mechanisms.

Negative feedback= suppression of GnRH neurons
Positive feedback= stimulation of GnRH neurons

Positive and negative feedback control the secretion of GnRH that in-turn controls the secretion of the gonadotropins FSH and LH. For the purpose of the discussion here, we will use progesterone that causes strong negative feedback at the hypothalamic level. Progesterone strongly inhibits GnRH neurons and therefore when progesterone is high, GnRH neurons secrete only basal levels of GnRH. Such basal secretion while allowing for some follicular development will not allow sufficient follicular development for the production of high levels of estradiol. Therefore, females under the influence of progesterone (midcycle or pregnant) do not cycle for the period of time that progesterone is high. The equation below describes the fundamentals of progesterone-induced negative feedback. By consulting Chapter 9 more details about the fundamental concepts of progesterone negative feedback can be appreciated.

$\uparrow P_4 \rightarrow \downarrow GnRH \rightarrow \downarrow FSH\&LH \rightarrow$ Little follicular development

In direct contrast to negative feedback, positive feedback activates the GnRH neurons in the hypothalamus. You will learn in Chapter 8 that the female contains a surge center that is responsible for producing large quantities of GnRH that induce ovulation. The surge center will not release large quantities of GnRH until there is positive feedback by estradiol. For example, when estradiol reaches a certain high level (a threshold level), the surge center will become positively stimulated and will release large quantities of GnRH that cause the release of large quantities of LH that stimulate ovulation.

It is important to recognize that positive feedback and negative feedback are independent controls within the animal that exert two distinctly different outcomes. Reproductive endocrinologists believe that the hypothalamus has different sensitivities to positive and negative feedback of gonadal steroids. For example, the tonic center in both the male and female is believed to respond mostly to negative feedback. While progesterone in the female exerts a strong negative feedback on both the surge and the tonic centers, it mostly exerts its effect on the tonic center. In other words, the tonic center is quite sen-

sitive to negative feedback. In contrast, the surge center responds mostly to positive feedback of estradiol. Therefore, it can be said that the surge center is very sensitive to positive feedback. The reasons that these two components of the hypothalamus differ with regard to their sensitivities to positive and negative feedback is the subject of current research. Researchers are attempting to define how these different subsets of neurons are regulated by two different controls.

Reproductive hormones:
- ***act in minute quantities***
- ***have short half-lives***
- ***bind to specific receptors***
- ***regulate intracellular biochemical reactions***

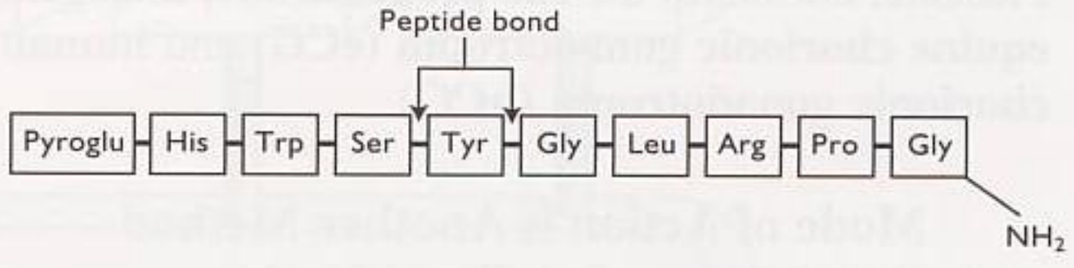
In order for a hormone to cause a response, it must first interact specifically with the target tissue. For this interaction to occur, the cells of the target tissue must have receptors that bind the hormone. Binding of the hormone with its specific receptor initiates a series of intracellular biochemical reactions that will be discussed later in this chapter.

Hormonal regulation of a biochemical reaction is generally tied to secretory activity of the target cell. When exposed to a hormone, the target cell synthesizes substances that are not produced unless the hormone is present. For example, estradiol (produced by the ovary), causes the cells of the cervix to secrete mucus. This change is caused by a series of biochemical or synthetic pathways within the cells of the cervix. The steps in these processes will be detailed later in this chapter.

Hormones can be classified by their:
- ***source***
- ***mode of action***
- ***biochemical classification***

Reproductive hormones can be classified according to their source of origin, their primary mode of action and their biochemical classification. Table 5-2 summarizes hormonal classification by source, by target tissue and by their primary actions. Details about these hormones will be presented in subsequent chapters where their functions will be specifically described in the female and in the male.

Figure 5-7. Amino Acid Sequence of GnRH



Glandular Origin Constitutes One Method of Hormonal Classification

Hypothalamic hormones are produced by neurons in the hypothalamus. Their role is to cause the release of other hormones from the anterior lobe of the pituitary. The primary releasing hormone of reproduction is **gonadotropin releasing hormone (GnRH)** (See Figure 5-7). **Neuropeptides** of hypothalamic origin are very small molecules generally consisting of less than twenty amino acids. These small peptides are synthesized and released from neurons in the hypothalamus. The most important neuropeptide governing reproduction is GnRH. The amino acid sequence for GnRH, a decapeptide, is shown in Figure 5-7. The molecular weight of GnRH is only 1,183.

Pituitary hormones are released into the blood from the anterior and posterior lobes of the pituitary. The primary reproductive hormones from the anterior lobe are **follicle stimulating hormone (FSH), luteinizing hormone (LH)** and **prolactin. Oxytocin** is the primary reproductive hormone released from the posterior lobe.

Gonadal hormones originate from the gonads and affect function of the hypothalamus, anterior lobe of the pituitary and tissues of the reproductive tract. Gonadal hormones also initiate the development of secondary sex characteristics that cause "maleness" or "femaleness." In the female, the ovary produces estrogens, progesterone, inhibin, some testosterone, oxytocin and relaxin. In the male, the testes produce testosterone and other androgens, inhibin and estrogen.

Reproductive hormones originate from the:
- ***hypothalamus***
- ***pituitary***
- ***gonads***
- ***uterus***
- ***placenta***

Hormones are also produced by the uterus and the placenta. These are responsible for governing cyclicity and maintenance of pregnancy. An example of a uterine hormone is **prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$)**. Placental hormones include **progesterone**, **estrogen**, **equine chorionic gonadotropin (eCG)** and **human chorionic gonadotropin (hCG)**.

Mode of Action is Another Method of Hormonal Classification

Neurohormones are synthesized by neurons and are released directly into the blood so that they can cause a response in target tissues elsewhere in the body. A neurohormone can act on any number of tissues provided that the tissue has cellular receptors for the neurohormone. An example is oxytocin of posterior lobe of the pituitary origin.

Releasing hormones are also synthesized by neurons in the hypothalamus and cause release of other hormones from the anterior lobe of the pituitary. They can also be classified as neurohormones because they are synthesized and released by neurons. An example is gonadotropin releasing hormone (GnRH) that controls the release of FSH and LH from the anterior lobe of the pituitary.

Gonadotropins are hormones released by the **gonadotroph cells** of the anterior lobe of the pituitary and they stimulate the gonads. The suffix "**tropin**" means having an affinity for or to nourish. Thus, these hormones have a stimulatory influence on the gonads (the ovary and the testis). Gonadotropins are **follicle stimulating hormone (FSH)** and **luteinizing hormone (LH).** Luteinizing hormone is responsible for causing ovulation and stimulating the corpus luteum (CL) to produce progesterone. Luteinizing hormone causes testosterone production in the male. Follicle stimulating hormone causes follicular growth in the ovary of the female. It stimulates Sertoli cells in the male and is probably a "key player" in governing spermatogenesis.

Reproductive hormones can cause:

- *release of other hormones (releasing hormones)*
- *stimulation of the gonads (gonadotropins)*
- *sexual promotion (steroids)*
- *pregnancy maintenance*
- *luteolysis (destruction of the CL)*

Sexual promoters (estrogen, progesterone, testosterone) are produced by the gonads of both the male and the female to stimulate the reproductive tract, to regulate the function of the hypothalamus and the anterior lobe of the pituitary and to regulate reproductive behavior. These hormones also cause the development of secondary sex characteristics. The sexual promoters are the driving force for all reproductive function.

Human chorionic gonadotropin (hCG) and **equine chorionic gonadotropin** (eCG) are produced by the early embryo (conceptus). These placental hormones cause stimulation of the maternal ovary.

Pregnancy maintenance hormones are in high concentrations during times of pregnancy. They are responsible for maintenance of pregnancy (e.g., progesterone) and, in some cases, assisting the female in her lactation ability. **Placental lactogen** promotes development of the mammary gland of the dam and is therefore **lactogenic**.

General metabolic hormones promote metabolic well-being. Such hormones are **thyroxin** from the thyroid gland, the **adrenal corticoids** from the adrenal cortex and **growth hormone (somatotropin)** from the anterior lobe of the pituitary. Thyroxin regulates metabolic rate of the animal. The adrenal corticoids perform a host of functions ranging from mineral metabolism to regulation of inflammatory responses. Growth hormone helps regulate growth, lactation and protein metabolism. These general metabolic hormones are all necessary for optimum reproduction. However, they are considered to exert an indirect rather than a direct effect on reproductive function.

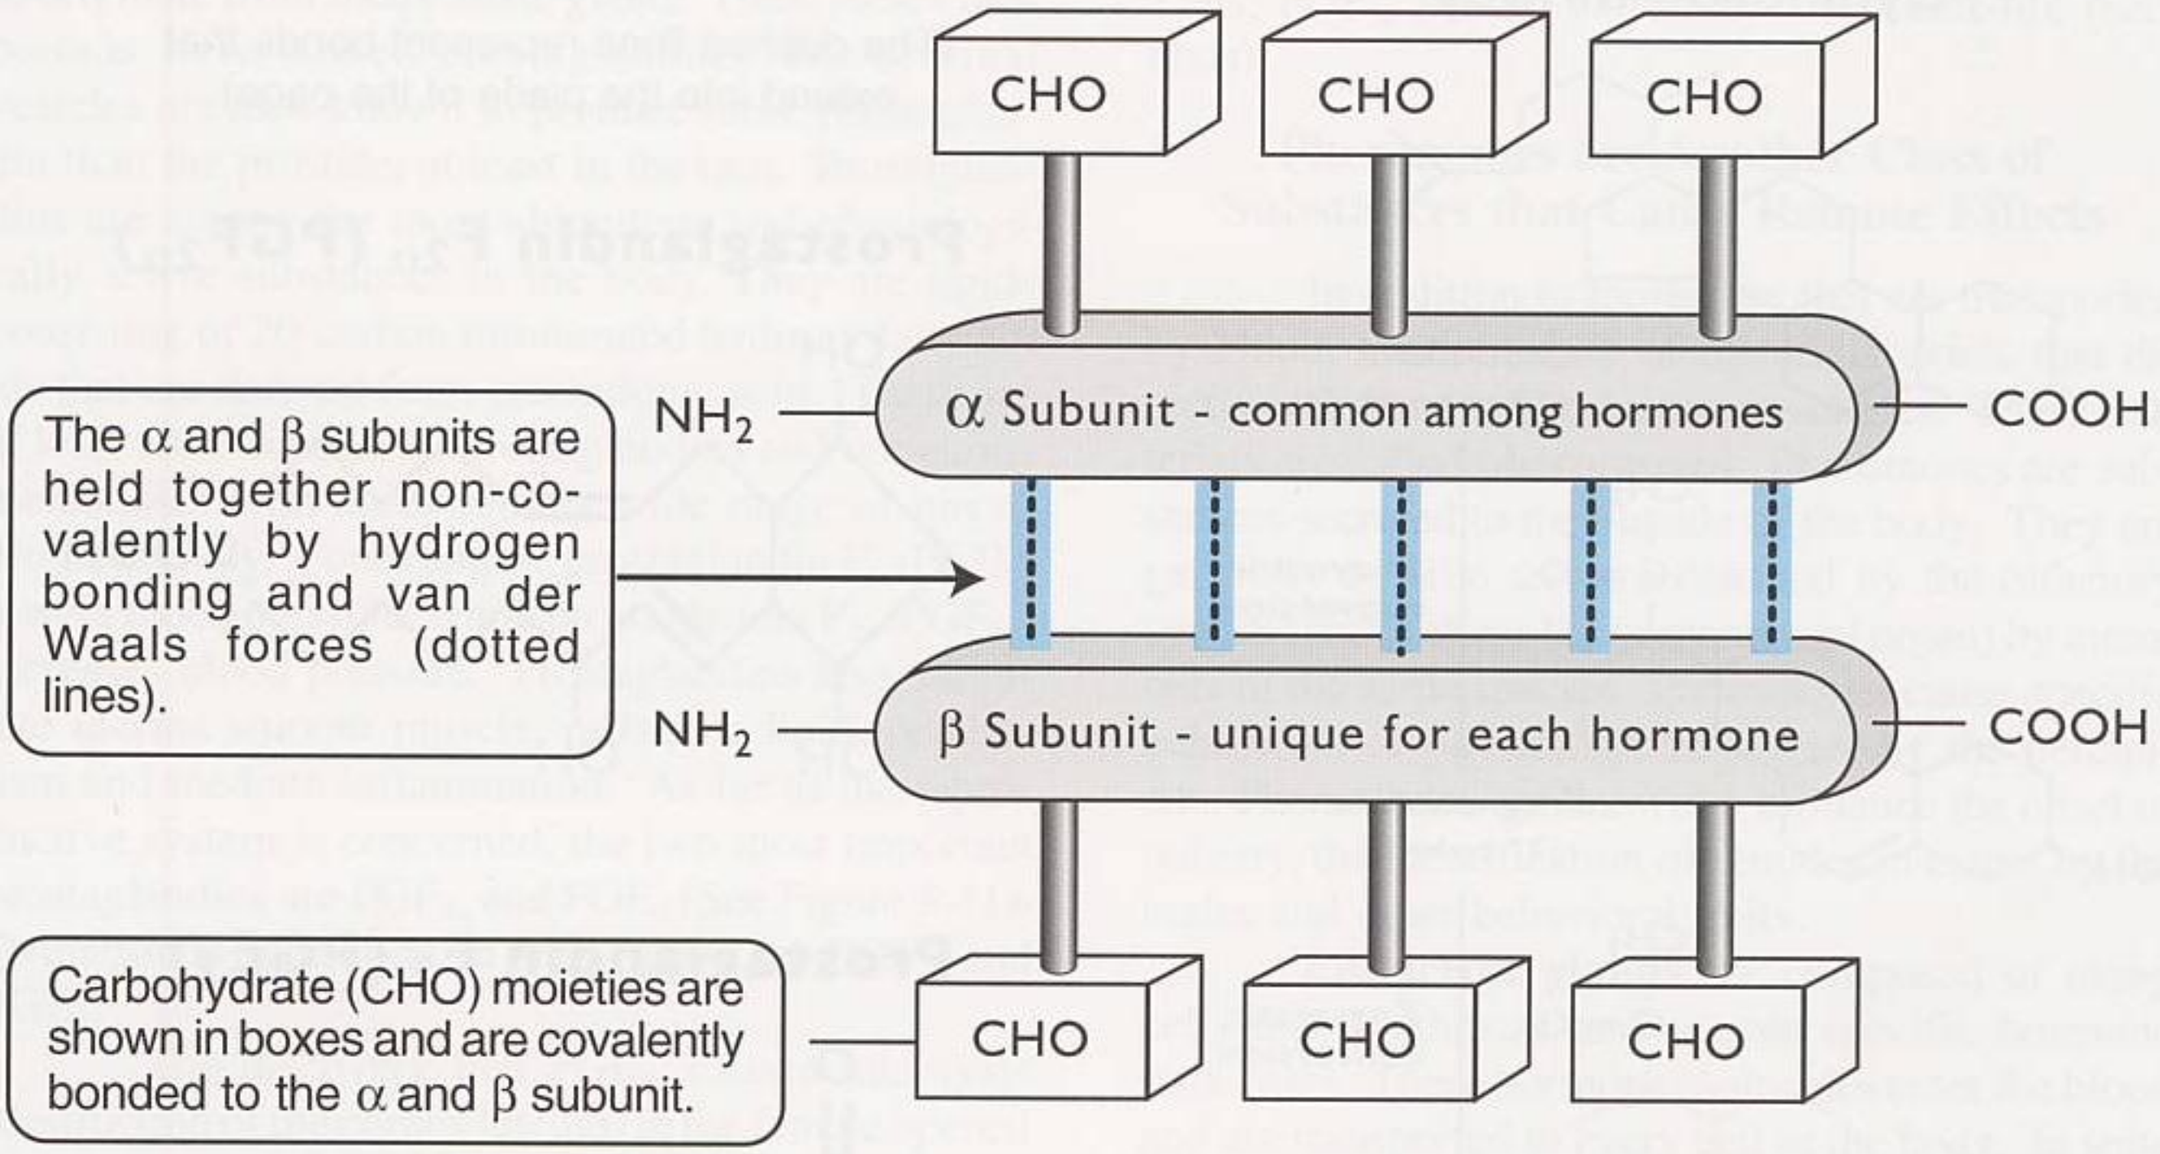
Luteolytic hormones cause destruction of the corpus luteum. The suffix "**lytic**" is a derivative of the word lysis. Lysis means decomposition, disintegration or dissolution. Luteolytic hormones, therefore, cause the corpus luteum to stop functioning. The major luteolytic hormone is **prostaglandin $F_{2\alpha}$** ($PGF_{2\alpha}$). As you shall see in Chapter 9, $PGF_{2\alpha}$ causes a decrease in secretion of progesterone by the corpus luteum.

Hormonal Biochemical Structure Constitutes Another Classification Method

Peptides are relatively small molecules with only a few amino acids joined by peptide bonds. The most important reproductive peptide is GnRH shown in Figure 5-7.

Glycoproteins are polypeptide hormones that contain carbohydrate moieties and range in molecular weight from several hundred to 70,000. Some glycoprotein hormones are composed of two side-by-side polypeptide chains that have carbohydrates at-

Figure 5-8. Diagram of an Anterior Lobe Glycoprotein Hormone



tached to each chain. These polypeptide chains have been designated by biochemists as the **alpha (α)** and **beta (β) subunits** (See Figure 5-8). The anterior lobe of the pituitary produces glycoprotein hormones that all have the same α subunit but different β subunits. The α subunit for FSH, LH and thyroid stimulating hormone (TSH) are identical within species. However, the β subunit is unique to each individual hormone and gives each of these glycoprotein hormones a high degree of specificity and function. Individual α and β subunits of these molecules have no biological activity. If an α subunit of one hormone is combined with the β subunit of another hormone, the activity will be determined by the hormone that contributed the β subunit. The α and β subunits are held together with hydrogen bonds and van der Waals forces and thus are not covalently attached (See Figure 5-8).

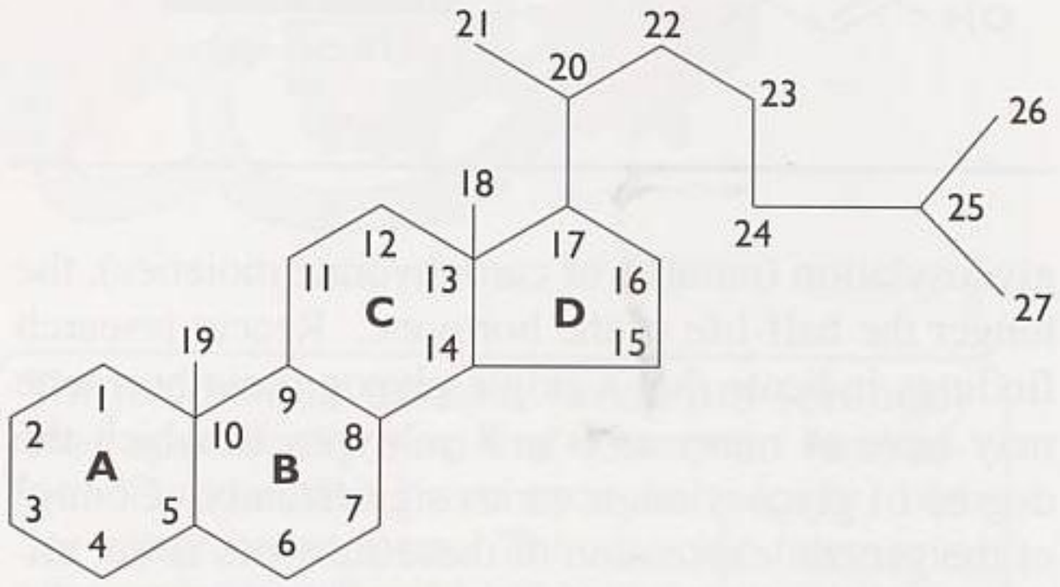
Inhibin is another glycoprotein hormone that contains an α and one of two possible β subunits (designated β_A or β_B). This hormone appears to have the same physiologic activity regardless of which β subunit is present. Inhibin suppresses FSH secretion from the anterior lobe of the pituitary.

Researchers have identified a protein from follicular fluid that consists of two β subunits. They have termed this material "**activin**." "Activin" has been shown to cause release of FSH in pituitary cells in culture. It therefore causes the opposite of inhibin in-vitro. This function has not been demonstrated in the intact animal and thus, it is not as yet considered a hormone.

Prolactin is an example of a protein that consists of a single polypeptide chain rather than containing an α and β subunit.

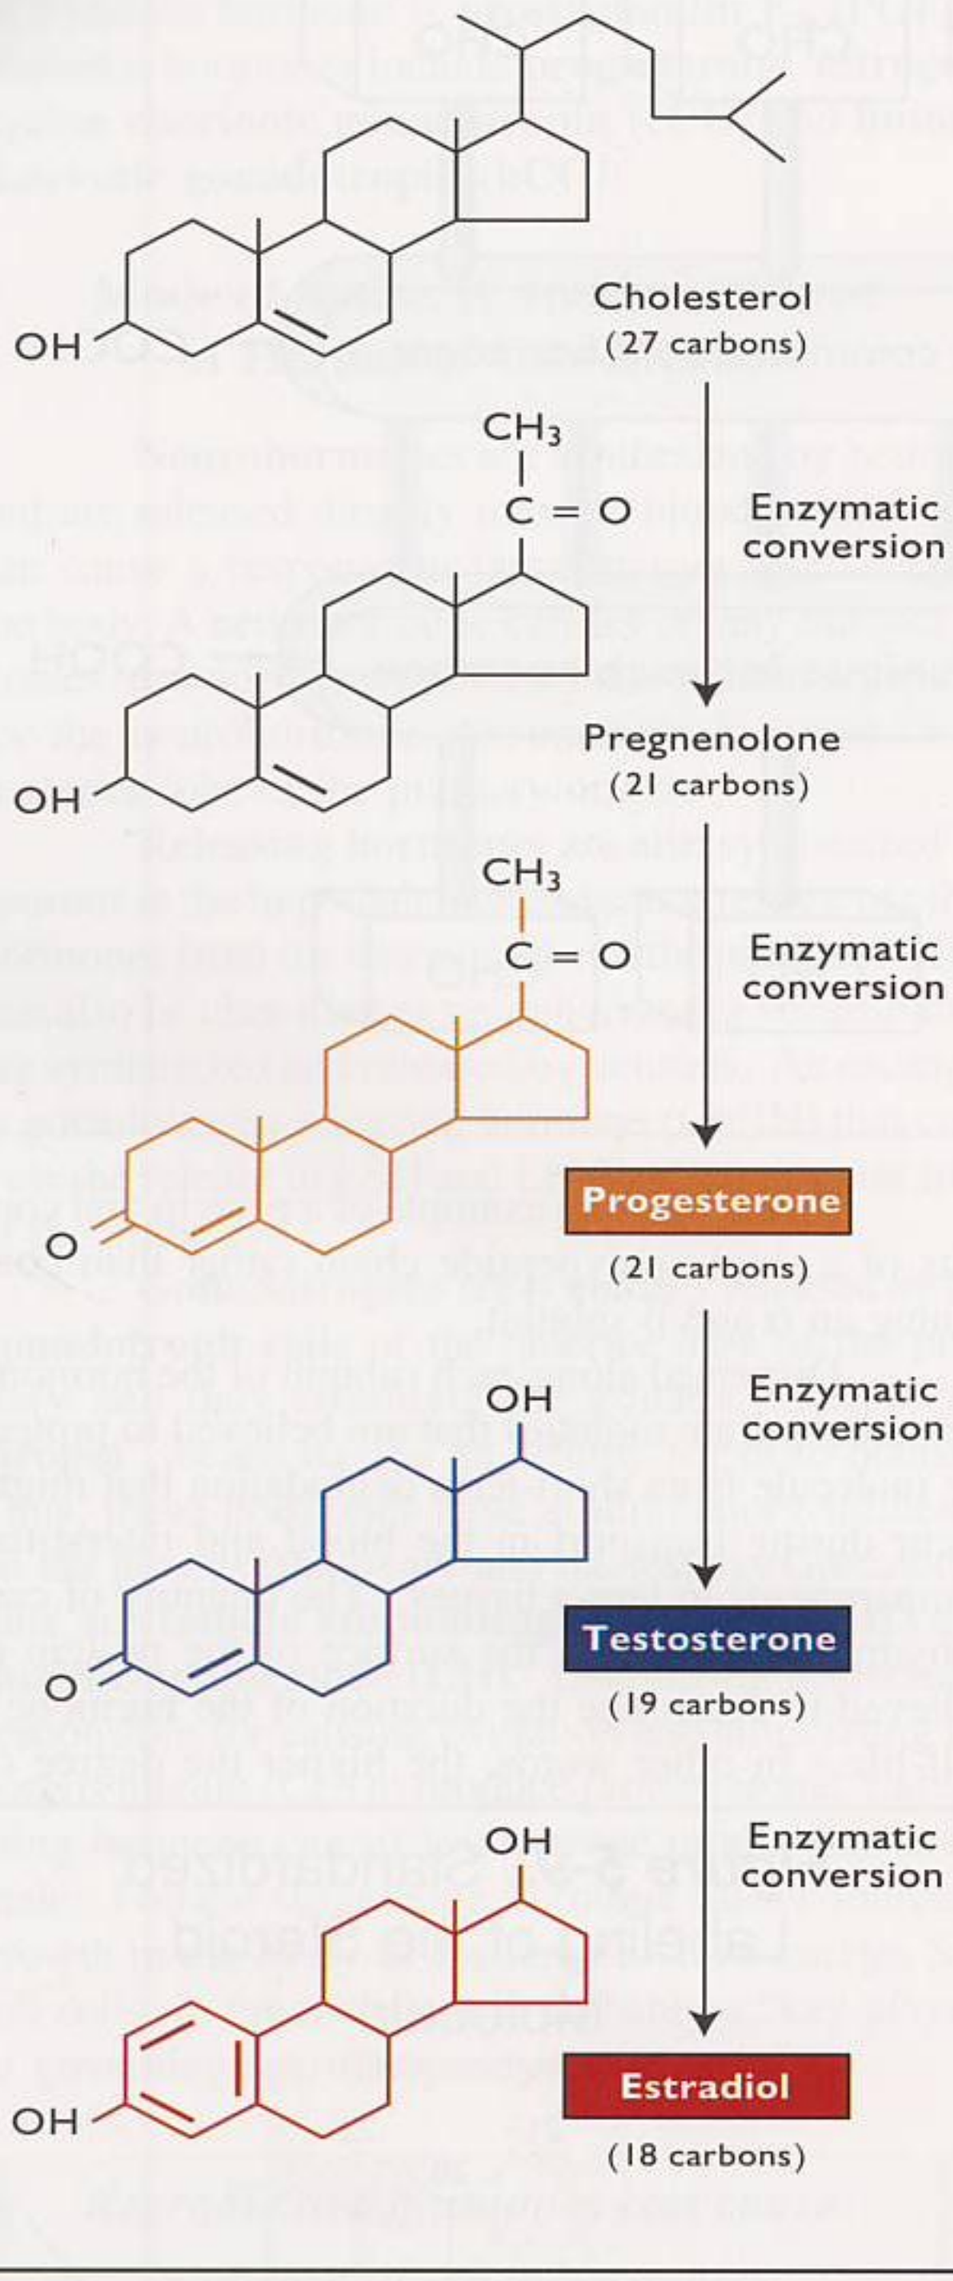
Dispersed along each subunit of the hormone are carbohydrate moieties that are believed to protect the molecule from short-term degradation that might occur during transport in the blood and interstitial compartments to target tissues. The quantity of carbohydrate moieties on the surface of the protein is believed to determine the duration of the hormone's half-life. In other words, the higher the degree of

Figure 5-9. Standardized Labeling of the Steroid Molecule



A, B, C and D designate specific rings.
Numbers designate specific carbons.

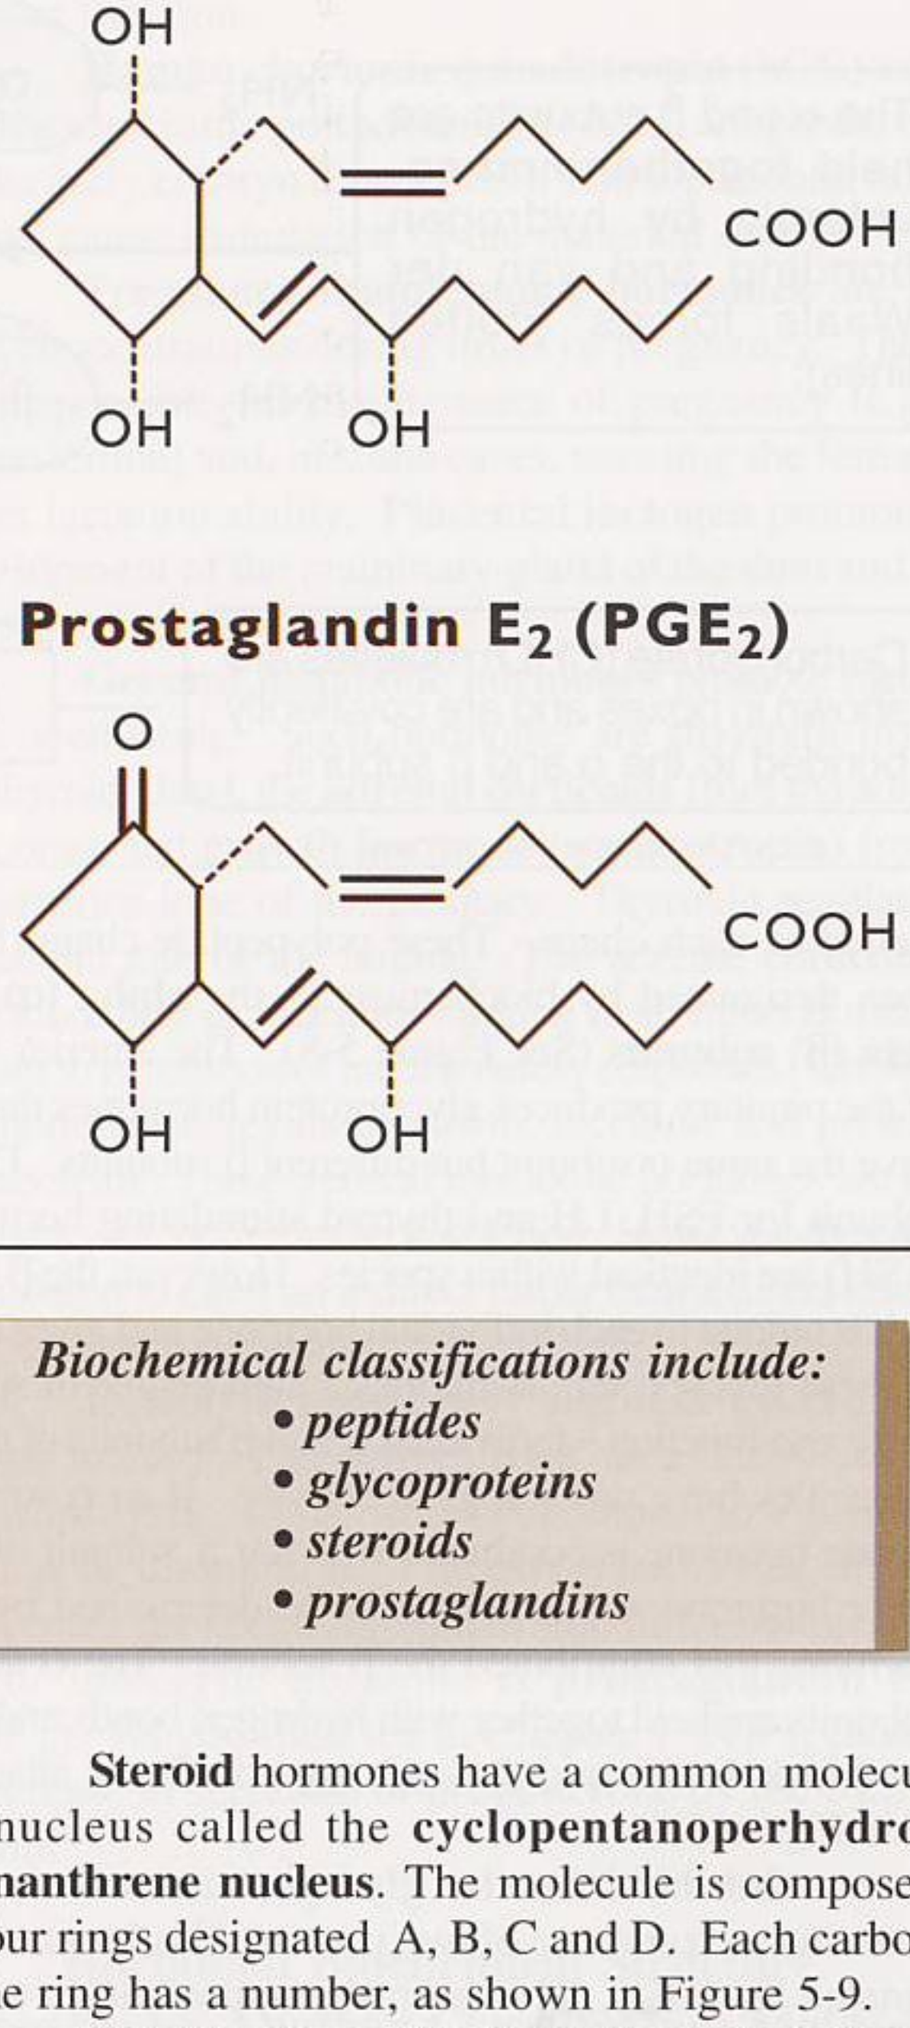
Figure 5-10. Gonadal Steroid Synthetic Pathway



glycosylation (number of carbohydrate moieties), the longer the half-life of the hormone. Recent research findings indicate that a single glycoprotein hormone may have as many as 6 to 8 subtypes in which the degree of glycosylation varies significantly. Control of the genetic expression of these subtypes is not understood. Glycoprotein hormones can be degraded easily by proteolytic enzymes in the digestive tract. Therefore, they are not effective when given orally.

Figure 5-11. Structure of $PGF_{2\alpha}$ and PGE_2

(The dashed lines represent bonds that extend into the plane of the page)



Biochemical classifications include:
- ***peptides***
- ***glycoproteins***
- ***steroids***
- ***prostaglandins***

Steroid hormones have a common molecular nucleus called the **cyclopentanoperhydrophenanthrene nucleus**. The molecule is composed of four rings designated A, B, C and D. Each carbon in the ring has a number, as shown in Figure 5-9.

Steroids are synthesized from cholesterol through a series of complex pathways involving many enzymatic conversions. Figure 5-10 illustrates the major biochemical transformations that occur in the gonadal steroid synthetic pathway. Notice the high degree of structural similarity between estradiol and testosterone. Steroid molecules are sexual promoters and cause profound changes in both the male and female reproductive tract and these will be discussed in later chapters.

Prostaglandins were first discovered in seminal plasma of mammalian semen and were believed to originate from the prostate gland. Thus, these compounds were named prostaglandins. The seminal vesicles are now known to produce more prostaglandin than the prostate, at least in the ram. Prostaglandins are among the most ubiquitous and physiologically active substances in the body. They are lipids consisting of 20-carbon unsaturated hydroxy fatty acids that are derived from arachidonic acid. There are at least six biochemical prostaglandins and numerous metabolites with an extremely wide range of physiologic activity. For example, prostaglandin E_2 (PGE_2) lowers blood pressure, while prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) increases blood pressure. Prostaglandins also stimulate uterine smooth muscle, influence lipid metabolism and mediate inflammation. As far as the reproductive system is concerned, the two most important prostaglandins are $PGF_{2\alpha}$ and PGE_2 (See Figure 5-11). Ovulation is controlled, at least in part, by $PGF_{2\alpha}$ and PGE_2.

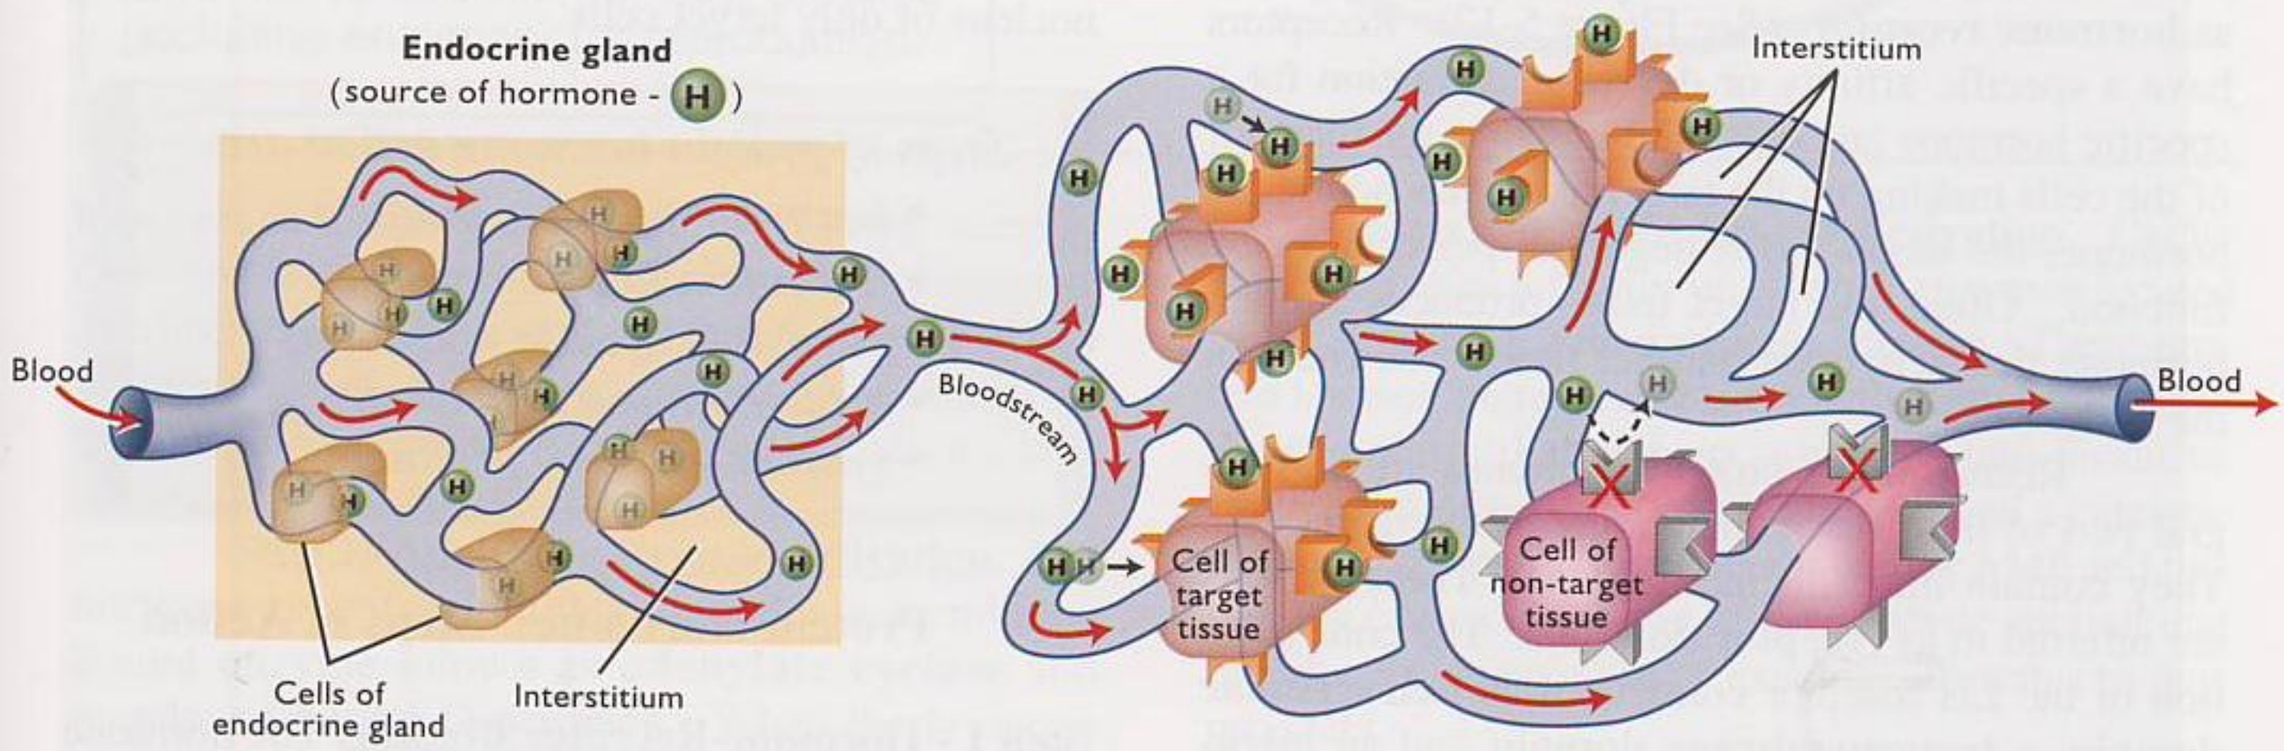
The discovery that $PGF_{2\alpha}$ caused luteolysis (destruction of the corpus luteum) in the female opened a new world of application for the control of the estrous cycle. Use of prostaglandins as a tool for reproductive management is now routine and some of these strategies will be discussed in Chapter 9. Prostaglandins are rapidly degraded in the blood. In fact, almost all of $PGF_{2\alpha}$ is removed from blood during one pass through the pulmonary circulation (30 seconds). Thus, $PGF_{2\alpha}$ has an extremely short half-life (seconds).

Pheromones are Another Class of Substances that Cause Remote Effects

In addition to molecules that are transported by blood, another class of materials exists that directly influences reproductive processes. These materials are called **pheromones**. Pheromones are substances secreted to the outside of the body. They are generally volatile and are detected by the olfactory system (and perhaps the vomeronasal organ) by members of the same species. Pheromones cause specific behavioral or physiologic responses by the percipient. Pheromones are known to influence the onset of puberty, the identification of females in estrus by the males and other behavioral traits.

Endocrine glands are composed of many cells that synthesize and secrete specific hormone molecules. These hormone molecules enter the blood and are transported to every cell in the body. In spite of the fact that every cell in the body is exposed to the hormone, only certain cells are capable of responding to the hormone. Tissues containing these cells are called **target tissues**. For example, if a hormone's responsibility is to cause the cervix to synthesize

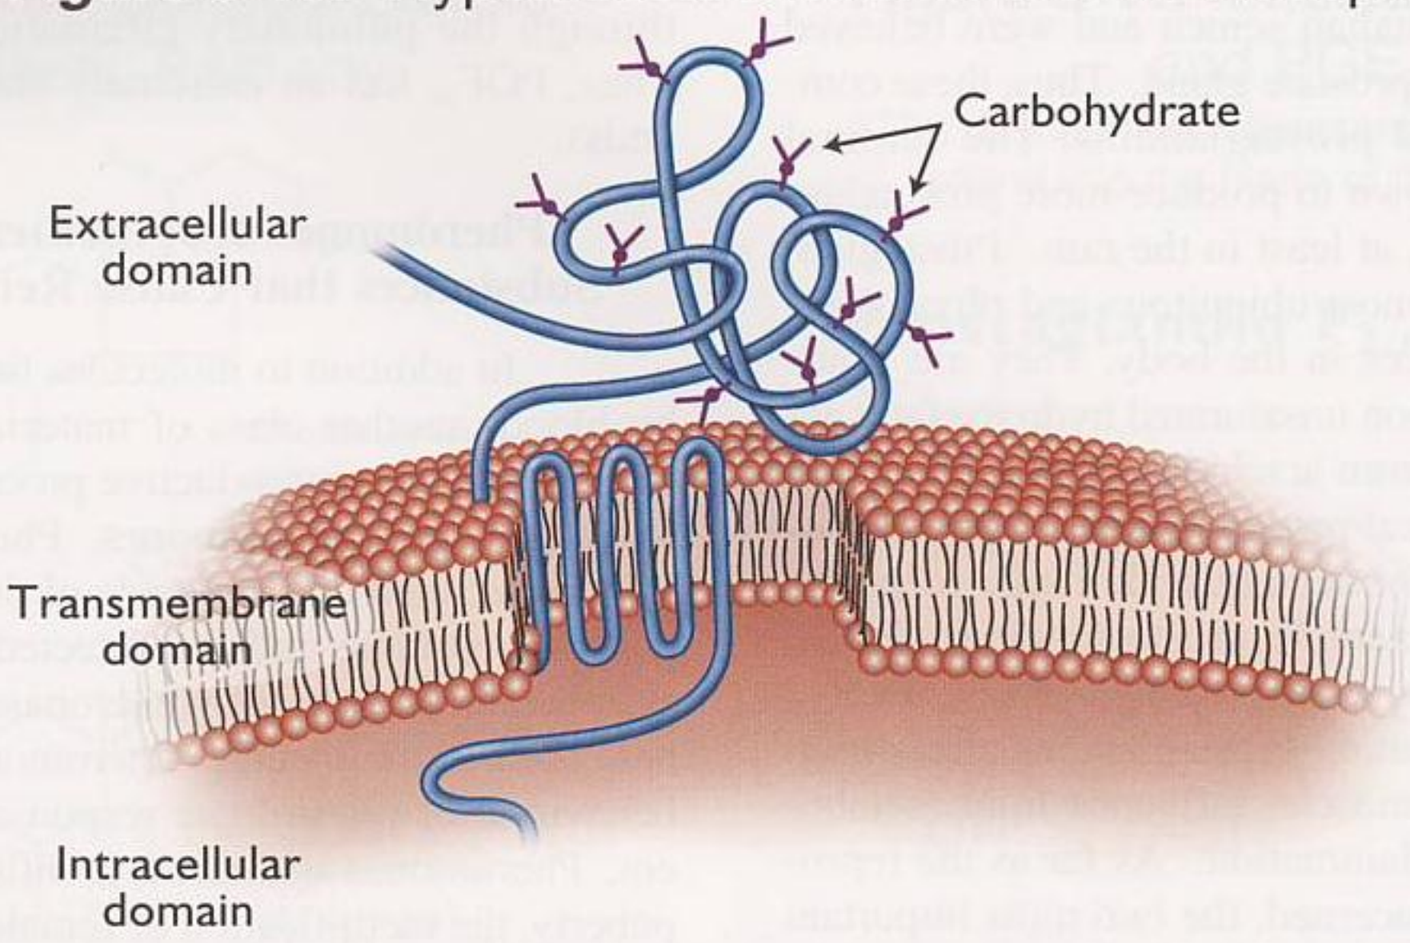
Figure 5-12. Target Tissues Bind Hormone, Other Tissues Do Not



Hormones (green spheres) are produced by cells of the endocrine gland and are released into the blood. The blood delivers the hormone to the target tissues.

Target tissues contain receptors (orange) that specifically bind the hormone. Nontarget tissues also have receptors (gray) but for other hormones. The specific hormone shown here will not bind to these receptors. Therefore, the non-target tissue will not respond.

Figure 5-13. Hypothetical Model of the LH Receptor



mucus, other organs such as the liver, the kidney or the pancreas will not produce mucus in response to the hormone.

Hormone action requires the presence of specific receptors on target cells.

Target tissues are distinguished from other tissues because their cells contain specific molecules that bind a specific hormone. These specific molecules located in the cells of target tissues are known as **hormone receptors** (See Figure 5-12). Receptors have a specific affinity or degree of attraction for a specific hormone and thus bind it. Once the receptor of the cells making up the target tissue has bound the hormone, the target tissue begins to perform a new function. Often, the target tissue produces another hormone that acts upon another tissue elsewhere in the body.

Receptors for protein hormones are an integral part of the plasma membrane of the target cell. They contain three distinct regions. These regions are referred to as **receptor domains**. The configuration of the LH receptor consists of an **extracellular domain**, a **transmembrane domain** and an **intracellular domain** (See Figure 5-13).

Protein hormones utilize plasma membrane bound receptors. Steroid hormones diffuse into the cell and attach to specific nuclear receptors.

The extracellular domain has a specific site that binds the specific hormone. When this site is occupied, the transmembrane domain changes its configuration and activates other membrane proteins known as G-proteins. The number of transmembrane "loops" may vary as a function of receptor type. The function of the intracellular domain of the receptor is not clear.

In contrast to the action of protein hormones, steroid action requires nuclear receptors. Steroid hormones are passively transported through the cell membrane of all target cells because of their lipid solubility, but they bind to specific receptors within the nucleus of only target cells.

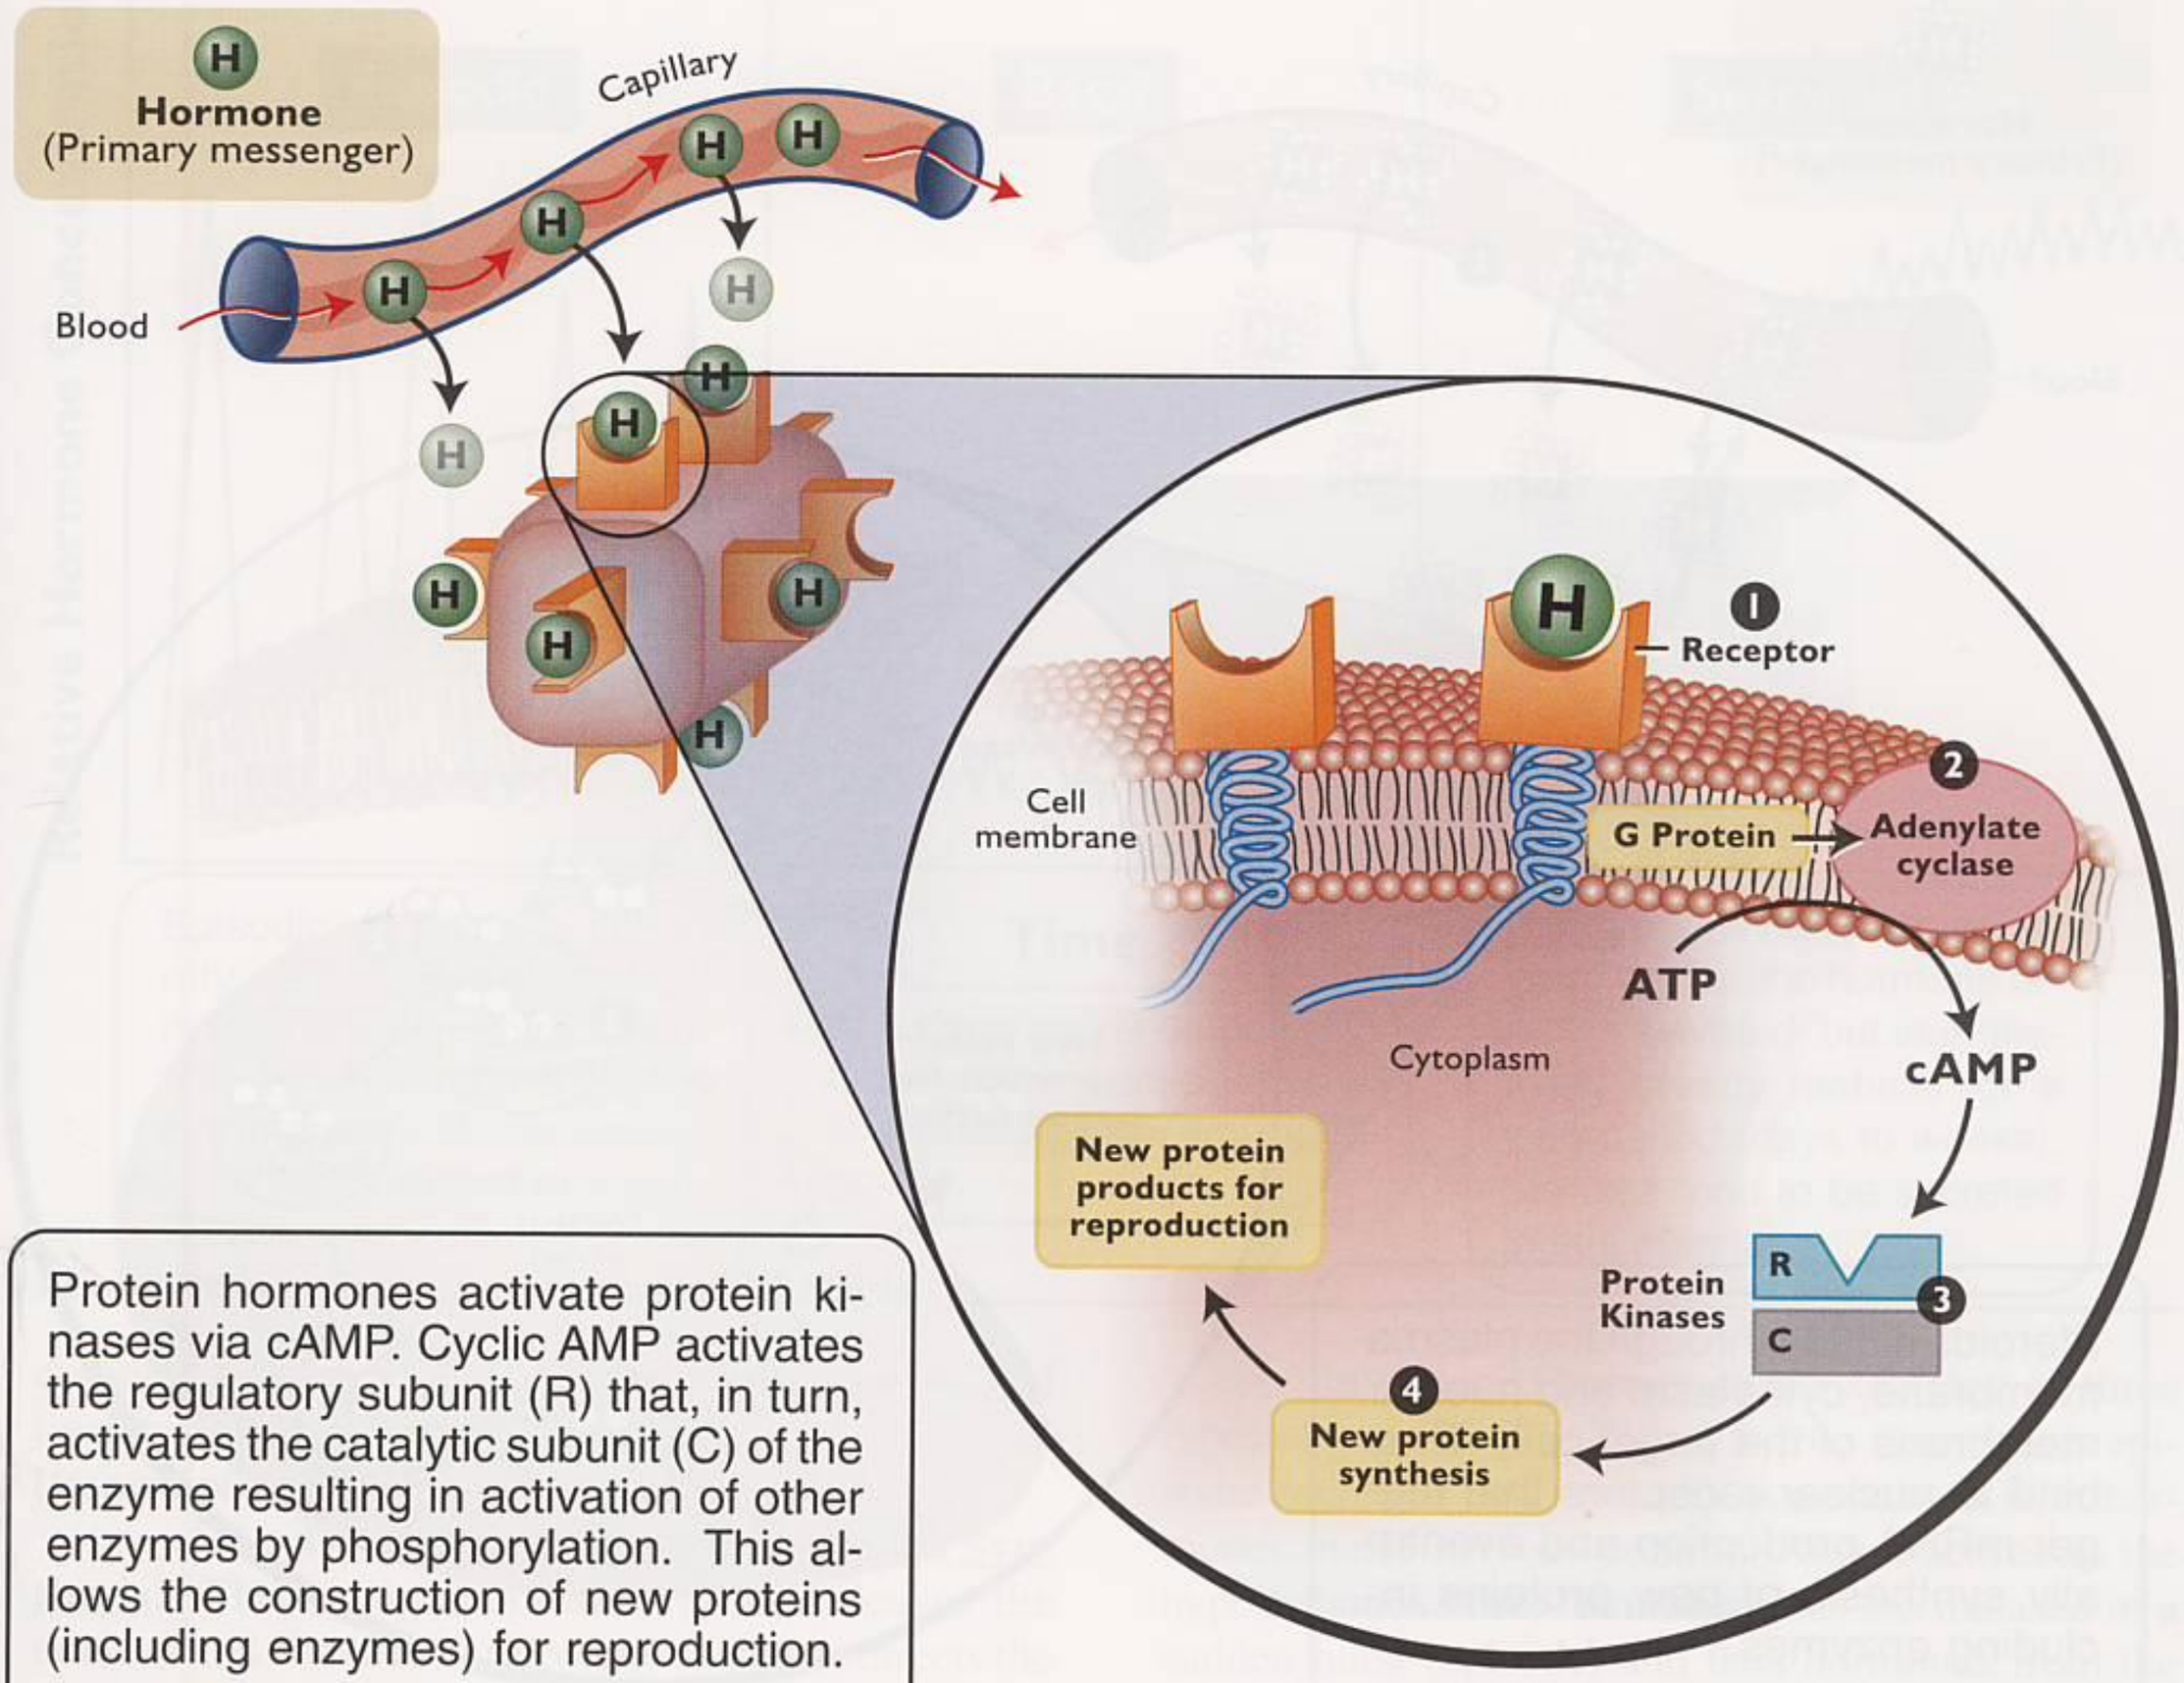
Steps of protein hormone action are:
- ***hormone-receptor binding***
- ***G-Protein activation***
- ***adenylate cyclase activation***
- ***protein kinase activation***
- ***synthesis of new products***

Protein Hormones: Steps of Action

Step 1 - <u>Hormone-Receptor Binding.</u> The hormone diffuses from the blood into the interstitial compartment and binds to a membrane receptor that is specific for the hormone. The binding occurs on the surface of the membrane of the target tissue cells (See Figures 5-12 and 5-13). In general, receptors to the gonadotropins are sparsely distributed on the surface of the target cells. In fact, only 2,000 to 20,000 LH or FSH receptors are present per follicle cell. Hormone-receptor binding is believed to be brought about

Figure 5-14. Protein Hormone Mechanisms of Action

(Circled numbers in the figure are steps of action described in the text)



Protein hormones activate protein kinases via cAMP. Cyclic AMP activates the regulatory subunit (R) that, in turn, activates the catalytic subunit (C) of the enzyme resulting in activation of other enzymes by phosphorylation. This allows the construction of new proteins (including enzymes) for reproduction.

by a specific geometric configuration of the receptor that "fits" the geometric configuration of the hormone. The hormone receptor binding is much like fitting two adjacent pieces of a puzzle together. The affinity of the hormone-receptor binding varies among hormones.

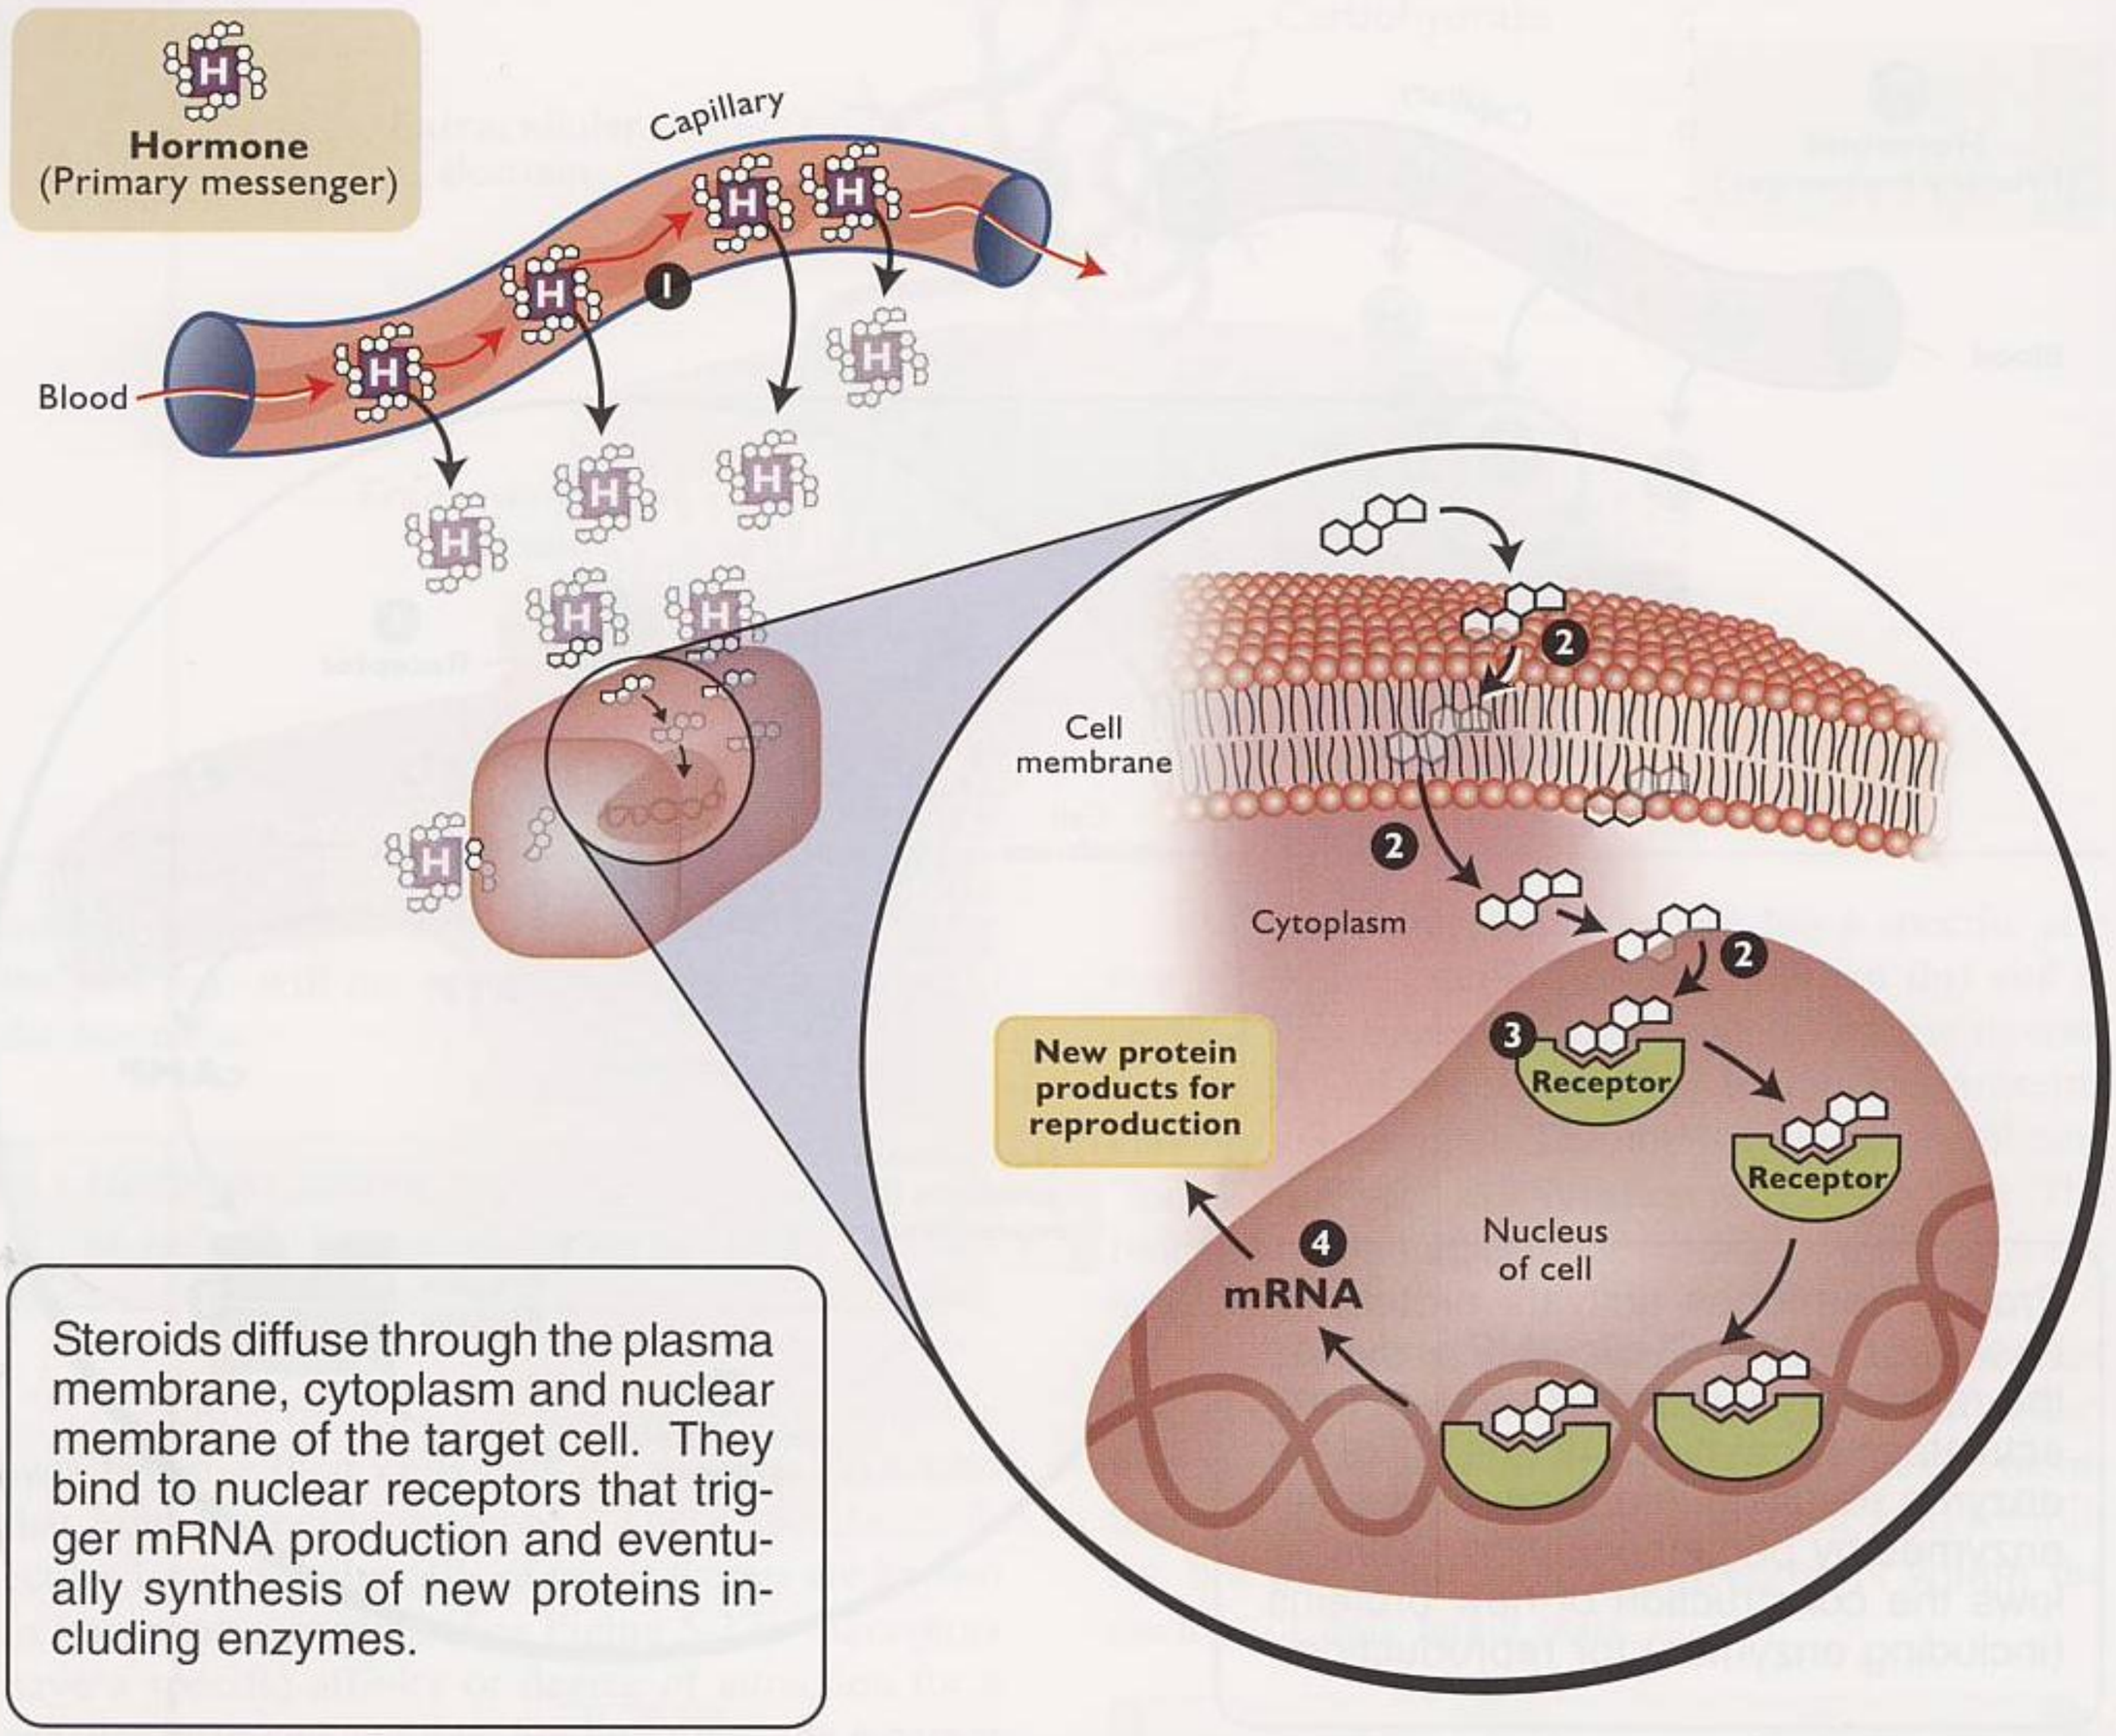
Step 2 - <u>Adenylate Cyclase Activation</u>. The hormone-receptor complex activates a membrane bound enzyme known as **adenylate cyclase** and membrane bound **G-proteins.** When the hormone receptor complex is formed, the G-protein is transformed in a way that activates adenylate cyclase (See Figure 5-14). The active form of this enzyme converts **ATP** to **cyclic AMP** (cAMP) within the cytoplasm of the cell. Cyclic AMP has been termed the "**second messenger**" in the pathway because cAMP must be present before further "downstream" events can occur. The primary messenger is the hormone itself.

Step 3- <u>Protein Kinase Activation</u>. Cyclic AMP activates a family of control enzymes located in the cytoplasm called **protein kinases**. These protein kinases are responsible for activating enzymes in the cytoplasm that convert substrates into products. Protein kinases consist of a regulatory and a catalytic subunit. The regulatory subunit binds cAMP and this binding causes activation of the catalytic subunit that initiates the conversion of existing substrates to new products.

Step 4 - <u>Synthesis of New Products</u>. The products made by the cell are generally secreted and these secretory products have specific functions that enhance reproductive processes. For example, the gonadotropins (FSH and LH) bind to follicle cells in the ovary that results in the synthesis of a new product, estradiol. When steroids are synthesized, they are not actively secreted, but simply diffuse through the plasma membrane into the interstitial spaces and into the blood.

Figure 5-15. Steroid Hormone Mechanisms of Action

(Circled numbers in the figure are steps of action described in the text)



Steroids diffuse through the plasma membrane, cytoplasm and nuclear membrane of the target cell. They bind to nuclear receptors that trigger mRNA production and eventually synthesis of new proteins including enzymes.

Steps of steroid hormone action are:

- *steroid transport*
- *movement through the cell membrane and cytoplasm*
- *binding of steroid to nuclear receptor*
- *mRNA synthesis and protein synthesis*

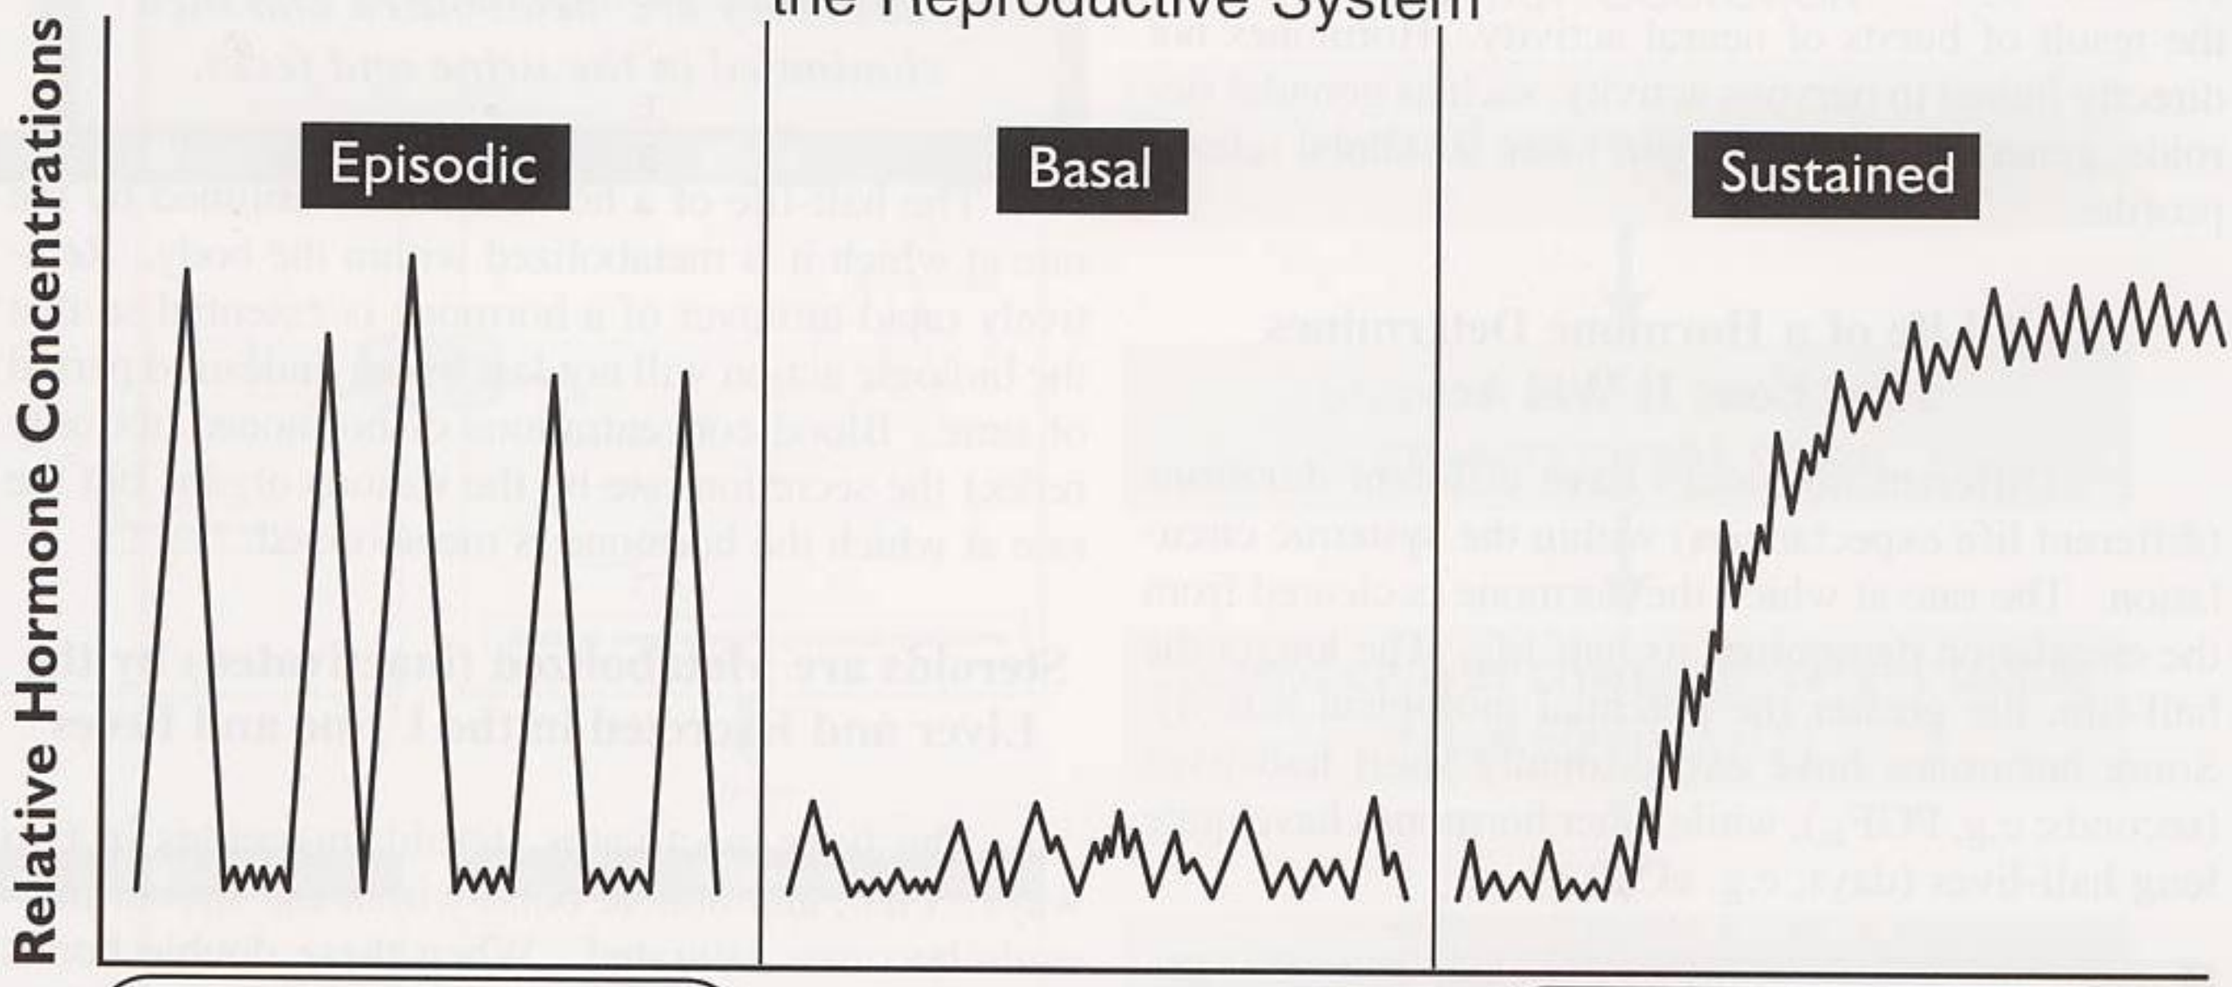
Steroid Hormones: Steps of Action

Step 1 - <u>Steroid Transport</u>. Steroid hormones are transported in the blood by a complex system. Steroids are not water soluble and therefore cannot be transported as free molecules. Therefore, they must attach to molecules that are water soluble. Steroids bind to a variety of plasma proteins in a nonspecific manner. Some steroids have specific carrier proteins. These transport proteins carry steroids in the blood and interstitial fluid to the cell membranes of all cells. The binding of steroids to plasma proteins tends to extend the half-life of these hormones.

Step 2 - <u>Movement through the Cell Membrane and Cytoplasm</u>. When the steroid-carrier protein complex travels into the interstitial compartment and comes in contact with target cells, the steroids disassociate from the carrier protein and diffuse through the plasma membrane because of their lipid solubility (See Figure 5-15). After the steroid molecule enters the cell, it diffuses through the cytoplasm and into the nucleus.

Step 3 - <u>Binding of Steroid to Nuclear Receptor</u>. If the cell is a target cell, the steroid binds to a specific nuclear receptor. The steroid-receptor binding is similar to protein-receptor binding in that the steroid must "fit" the receptor. The steroid-receptor

Figure 5-16. Typical Patterns of Hormonal Secretion by the Reproductive System



complex is referred to as a **transcription factor** and initiates DNA-directed messenger RNA synthesis (transcription).

Step 4 - <u>mRNA Synthesis and Protein Synthesis</u>. The newly synthesized mRNA leaves the nucleus and attaches to ribosomes where it directs the synthesis of specific proteins that will enhance the reproductive process. A few examples of steroid-directed synthesis are: 1) mucus from the cervix during estrus; 2) "uterine milk" from the uterine glands; and 3) seminal plasma components from the accessory sex glands in the male.

"Strength" of hormone action depends on:
- ***pattern and duration of secretion***
- ***half-life***
- ***receptor density***
- ***receptor-hormone affinity***

The physiologic activity of a hormone depends on several factors including pattern and duration of hormone secretion, half-life of the hormone, receptor density and receptor-hormone affinity. These factors determine the magnitude and duration of action of hormones.

In general, hormones are secreted in three types of patterns (See Figure 5-16). One type is episodic secretion that generally is associated with hormones under nervous control. When nerves in the hypothalamus "fire," neuropeptides are released in a sudden burst (episode) and thus hormones from the anterior lobe of the pituitary tend to be released in an episodic manner as well. A typical pattern of episodic release is shown in Figure 5-16. Organization of episodes into a predictable pattern is referred to as **pulsatile secretion**. Pulsatile secretion is required for an animal to have a normal estrous cycle. Prepubertal and noncyclic lactating animals are characterized by episodic secretion (unpredictable pattern) of hormones. A second type of secretion is a basal (tonic) pattern. Here, the hormone stays low, but fluctuates with low amplitude pulses. Sustained hormone release is a third type of hormonal pattern or profile. In this type, the hormone remains elevated, but in a relatively steady, stable fashion for a long period of time (days to weeks). Steroids tend to be secreted in a more stable fashion because the glands producing the steroids are generally producing them continuously rather than as a function of neural activity (that causes a pulsatile release). High progesterone during diestrus or pregnancy is an example of a sustained pattern of hormone secretion.

In general, hormones that are controlled by nervous activity have a short duration of secretion that is the result of bursts of neural activity. Hormones not directly linked to nervous activity, such as gonadal steroids, generally have a longer, more sustained release profile.

Half-Life of a Hormone Determines How Long It Will Act

Different hormones have different durations (different life expectancies) within the systemic circulation. The rate at which the hormone is cleared from the circulation determines its half-life. The longer the half-life, the greater the potential biological activity. Some hormones have exceptionally short half-lives (seconds; e.g. $PGF_{2\alpha}$), while other hormones have quite long half-lives (days; e.g. eCG).

Hormonal potency is influenced by:
- ***receptor density***
- ***hormone receptor affinity***

The density of target tissue receptors varies as a function of the cell type as well as the degree to which hormones promote (**up-regulate**), or inhibit (**down-regulate**) synthesis of hormone receptors. Factors such as animal condition and nutrition may play a role in influencing receptor numbers. As you will see later on, different hormones promote synthesis of receptors to either themselves or other hormones. For example, FSH promotes the synthesis of LH receptors by the follicular cells. The higher the degree to which a cell is populated with receptors, the higher the degree of potential response by the target cell.

Receptors vary with regard to their affinity for various hormones. In general, the greater the affinity of the hormone for the receptor, the greater the biologic response.

Hormone **agonists** are **analogs** (having a similar molecular structure) that bind to the specific receptor and initially cause the same biologic effect as the native hormone. Some agonists promote greater physiological activity because they have greater affinity for the hormone receptor. Other analogs, called **antagonists**, have greater affinity for the hormone receptor, but promote weaker biologic activity than the native hormone. Antagonists decrease the response of target cells by having a weaker biological activity than the native hormone or by occupying hormone receptors and thus preventing the native hormone from binding. In either case, the antagonist interferes with native hormone action.

Hormones disappear from the body because they are metabolized and then eliminated in the urine and feces.

The half-life of a hormone is determined by the rate at which it is metabolized within the body. Relatively rapid turnover of a hormone is essential so that the biologic action will not last for an undesired period of time. Blood concentrations of hormones not only reflect the secretion rate by the various organs but the rate at which the hormone is metabolized.

Steroids are Metabolized (inactivated) by the Liver and Excreted in the Urine and Feces

The liver inactivates steroid molecules in two ways. First, any double bond within the steroid molecule becomes saturated. When these double bonds are reduced, the molecule is rendered inactive. The second change to the steroid molecule is that a sulfate or **glucuronide** residue is attached (See Figure 5-17). The glucuronide form of the steroid molecule is water-soluble and thus it can be excreted into the urine. This is important because there are no specific binding proteins to carry steroids into the bladder. The fact that steroid metabolites appear in the urine is the basis for testing athletes for "illegal" performance enhancing steroids. The equation in Figure 5-17 illustrates the transformation that occurs in the progesterone molecule in the liver and its excretion metabolites. Notice that all three unsaturation sites (double bonds) in progesterone have been reduced. Each steroid is metabolized in slightly different ways and produces different metabolites. For example, testosterone forms both a glucuronide (like progesterone) and a **sulfate salt** that is excreted in the urine (See Figure 5-17).

Steroids are also eliminated in the feces. It is assumed that they enter the gut through the bile duct in a conjugated form (glucuronide or sulfate). They are not digested per se in the gut. But, bacterial action undoubtedly modifies the form of the steroid prior to defecation. The amount of time that steroids (or their conjugates) remain intact (stable) in feces has yet to be completely defined. It is known that fecal concentrations change after defecation as a function of bacterial metabolism, and exposure to ultraviolet radiation. The specific type of steroid molecule also impacts its longevity in the gut and the feces. Endocrinologists recommend that fecal samples be collected and analyzed within one day after defecation. The general pathway of excretion/elimination of steroids from the body after they are metabolized is presented in Figure 5-18.

Figure 5-17. Metabolism of Progesterone and Testosterone

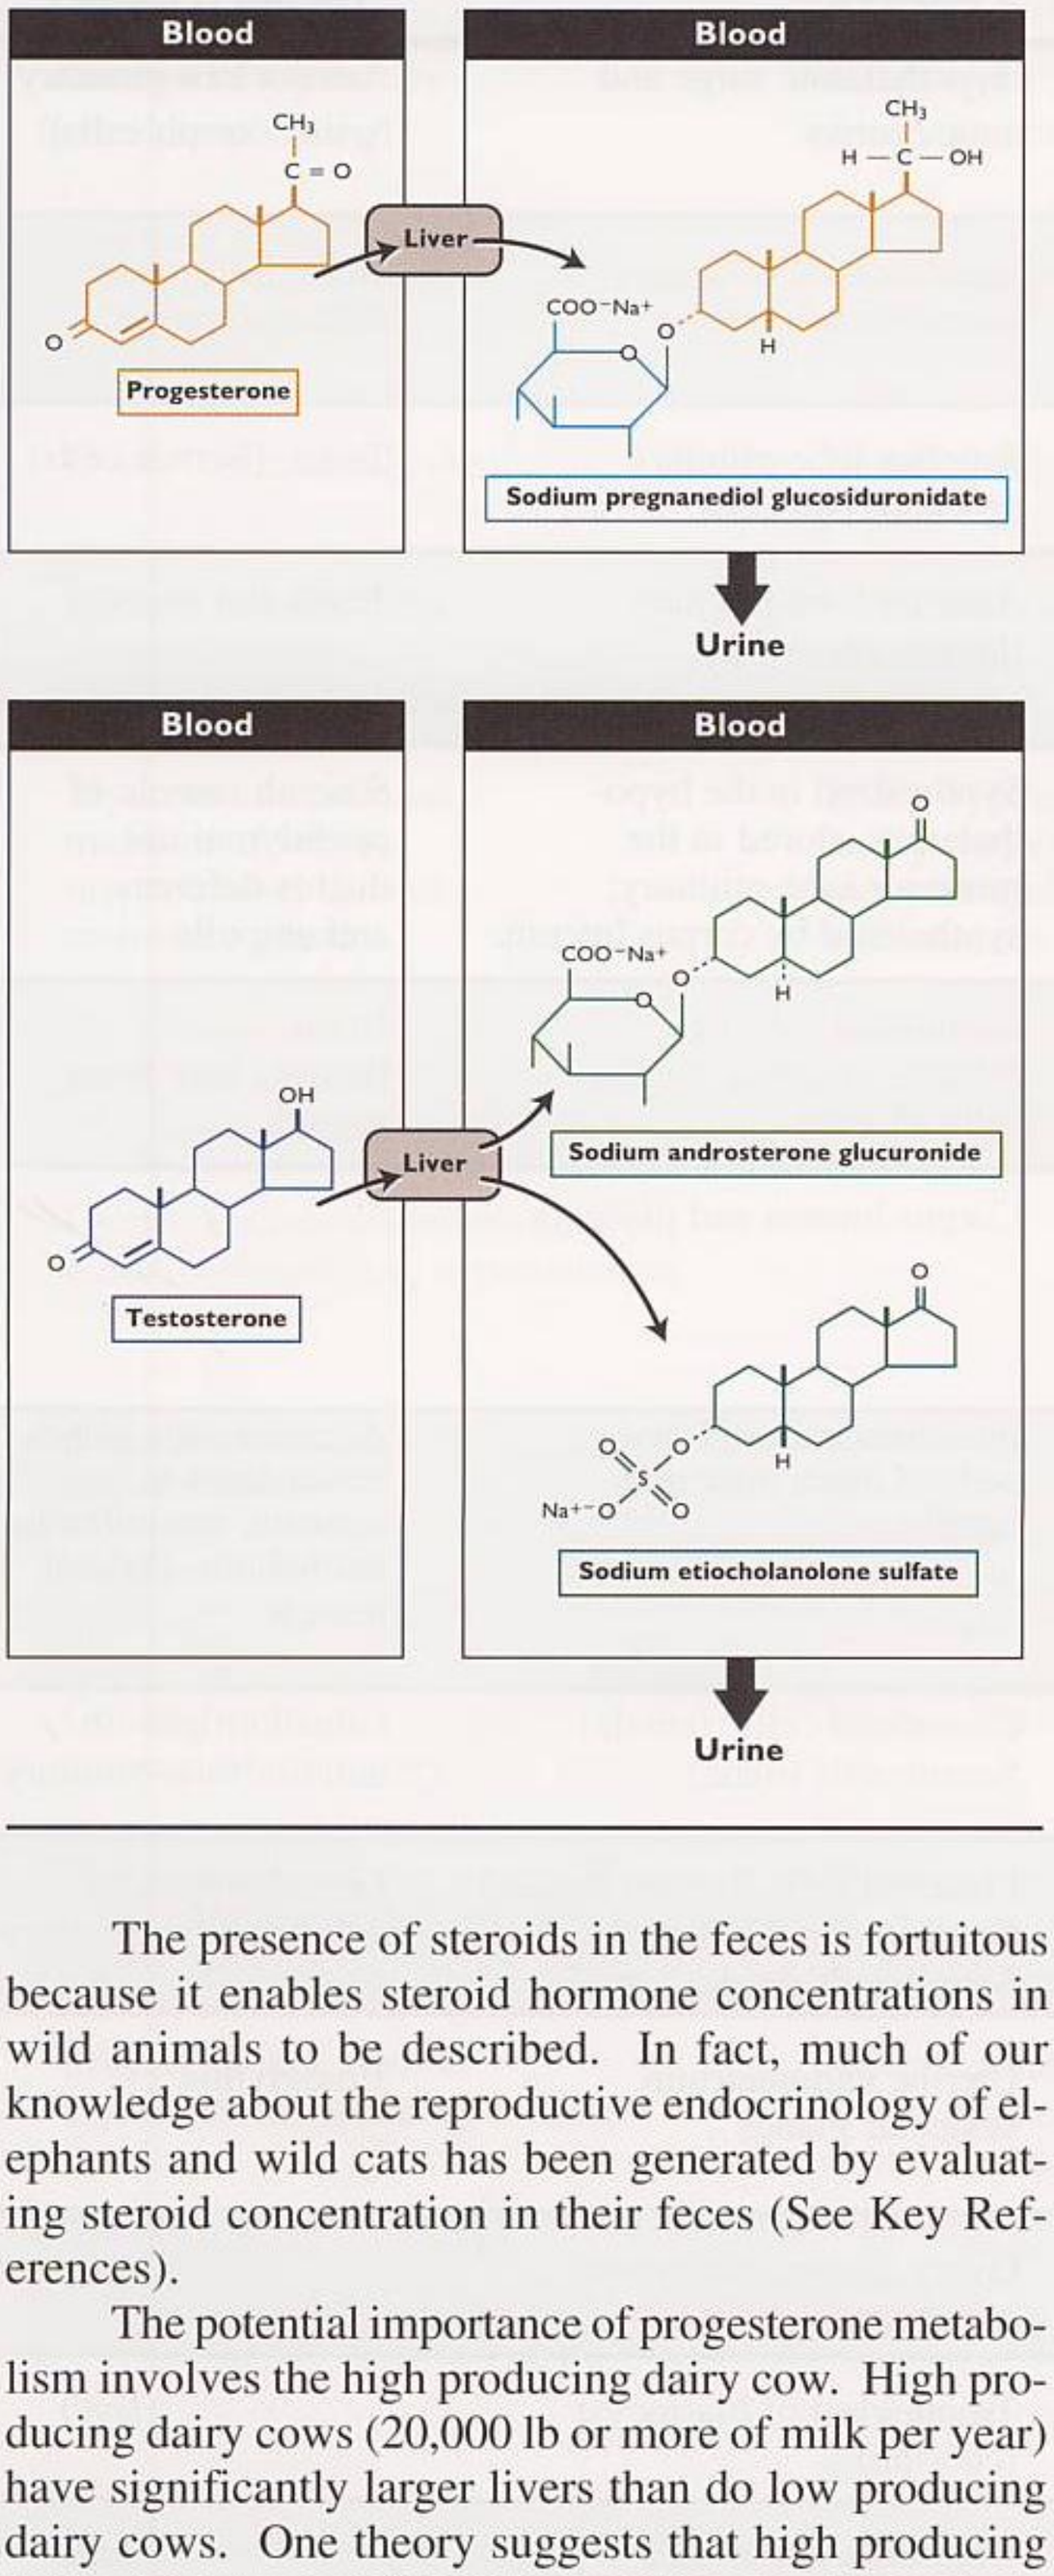


Figure 5-18. Fate of Steroids After Secretion

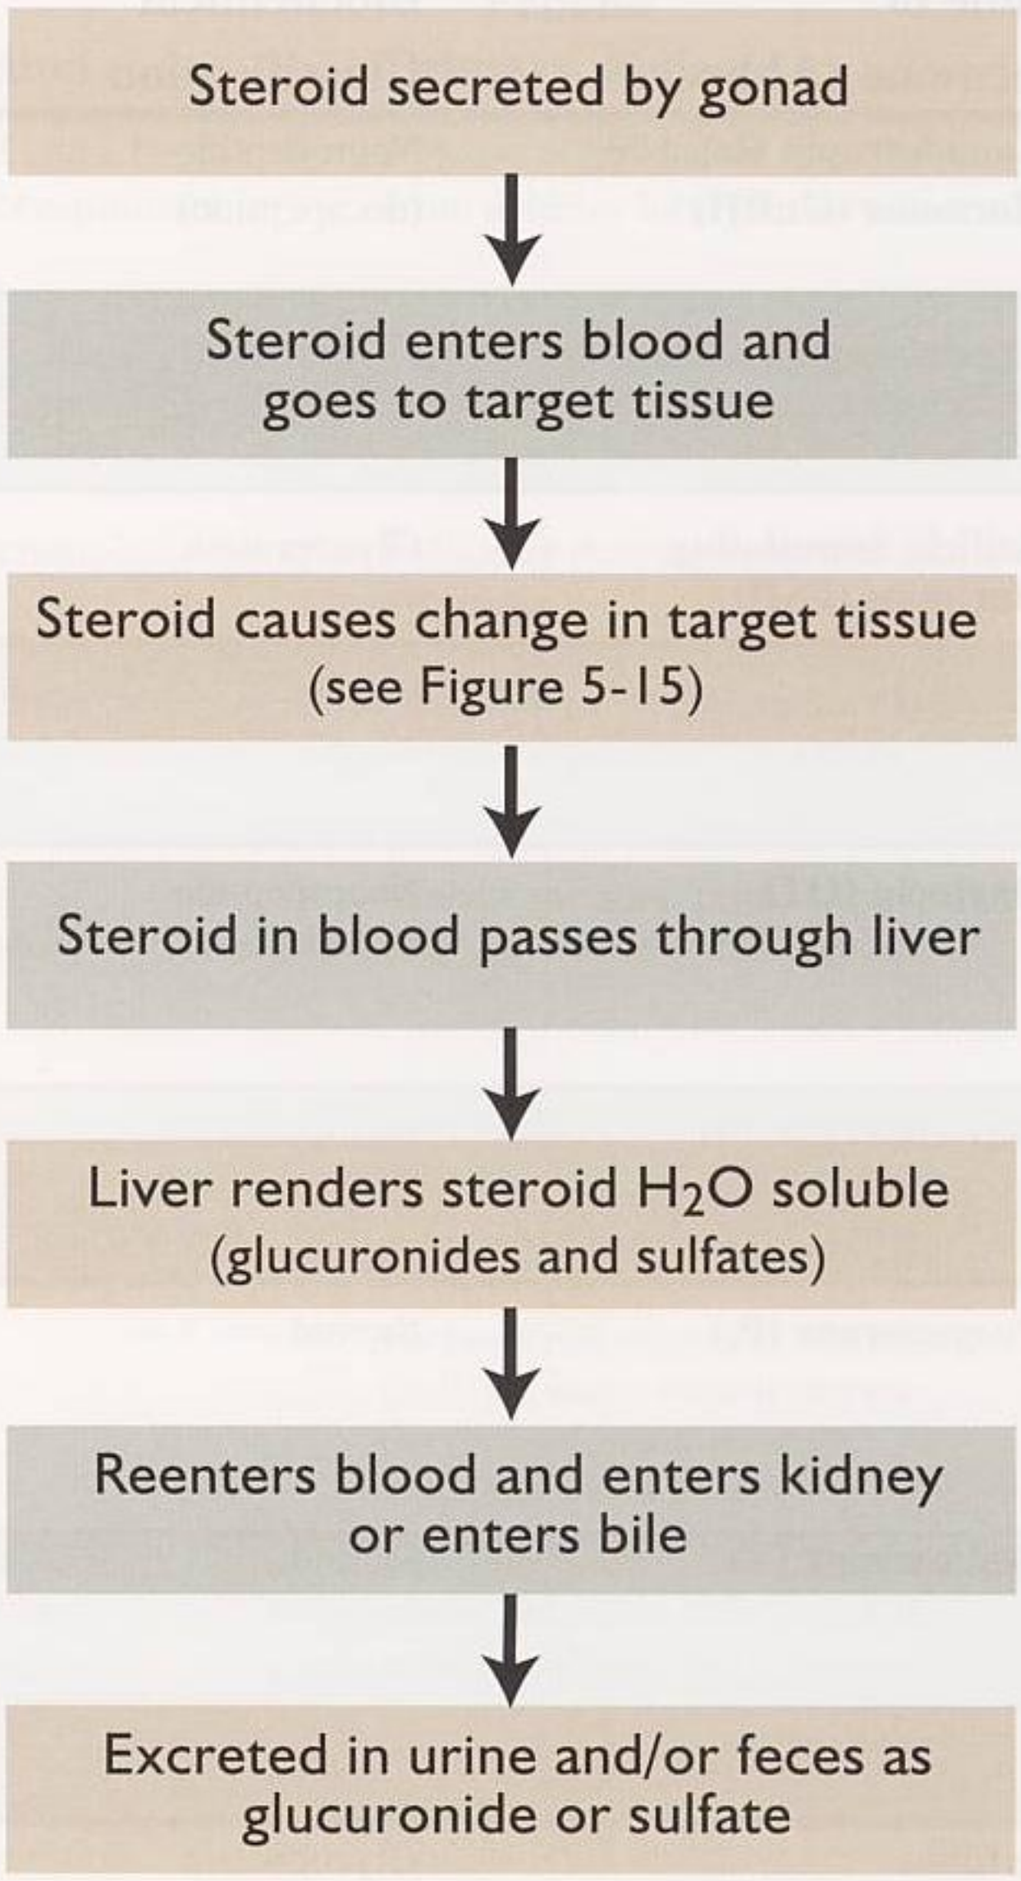


The presence of steroids in the feces is fortuitous because it enables steroid hormone concentrations in wild animals to be described. In fact, much of our knowledge about the reproductive endocrinology of elephants and wild cats has been generated by evaluating steroid concentration in their feces (See Key References).

The potential importance of progesterone metabolism involves the high producing dairy cow. High producing dairy cows (20,000 lb or more of milk per year) have significantly larger livers than do low producing dairy cows. One theory suggests that high producing dairy cows may metabolize progesterone and even estrogen at a faster rate than their lower producing contemporaries. Such rapid metabolism may cause temporary sub-fertility because the uterus, during early pregnancy, may not be capable of providing an optimum environment for embryo survival (because progesterone is low). Further research is needed to validate this theory. Nevertheless, the rate of hormone metabolism may be an important ingredient that governs fertility of the female in many species.

Protein Hormones are Degraded in the Liver and Kidneys

The half-life of pituitary gonadotropins is very short and is between 20 and 120 minutes depending on the hormone and species. **Chorionic gonadotropins** (human chorionic gonadotropin-hCG and equine

Table 5-2. Summary of Reproductive Hormones
(Colors shown below are used in graphics throughout the book)

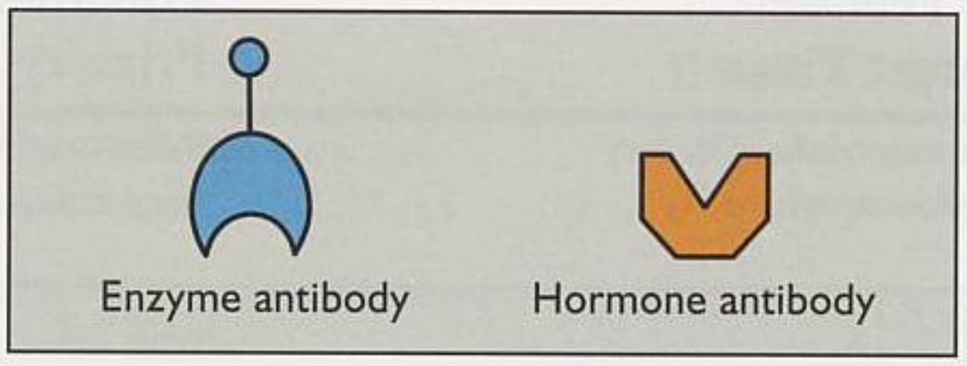
Name of Hormone (Abbrev.)	Biochemical Classification	Source	Male Target Tissue
Gonadotropin Releasing Hormone (GnRH)	Neuropeptide (decapeptide)	Hypothalamic surge and tonic centers	Anterior lobe-pituitary (gonadotroph cells)
Luteinizing Hormone (LH)	Glycoprotein	Anterior lobe (pituitary) (gonadotroph cells)	Testis (interstitial cells of Leydig)
Follicle Stimulating Hormone (FSH)	Glycoprotein	Anterior lobe-pituitary (gonadotroph cells)	Testis (Sertoli cells)
Prolactin	Protein	Anterior lobe-pituitary (lactotroph cells)	Testis and brain
Oxytocin (OT)	Neuropeptide (octapeptide)	Synthesized in the hypothalamus, stored in the posterior lobe-pituitary; synthesized by corpus luteum.	Smooth muscle of epididymal tail, ductus deferens and ampulla
Estradiol (E_2)	Steroid	Granulosal cells of follicle, placenta, Sertoli cells of testis	Brain Inhibits long bone growth
Progesterone (P_4)	Steroid	Corpus luteum and placenta	
Testosterone (T)	Steroid	Interstitial cells of Leydig, cells of theca interna in female	Accessory sex glands tunica dartos of scrotum, seminiferous epithelium, skeletal muscle
Inhibin	Glycoprotein	Granulosal cells (female) Sertoli cells (male)	Gonadotrophs of anterior lobe-pituitary
Activin	Glycoprotein	Placental cells (human female) Granulosal cells (female) Sertoli cells (male)	Gonadotrophs of anterior lobe-pituitary
Prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$)	Prostaglandin (C-20 fatty acid)	Uterine endometrium, vesicular glands	Epididymis
Prostaglandin E_2 (PGE_2)	Prostaglandin (C-20 fatty acid)	Ovary, uterus, embryonic membranes	
Human chorionic gonadotropin (hCG)	Glycoprotein	Trophoblast of blastocyst (chorion)	
Equine chorionic gonadotropin (eCG)	Glycoprotein	Chorionic girdle cells	
Placental lactogen	Protein	Placenta	

Table 5-2. Summary of Reproductive Hormones

Female Target Tissue	Male Primary Action	Female Primary Action
Anterior lobe-pituitary (gonadotroph cells)	Release of FSH and LH from anterior lobe-pituitary	Release of FSH and LH from anterior lobe-pituitary
Ovary (cells of theca interna and luteal cells)	Stimulates testosterone production	Stimulates ovulation, formation of corpora lutea and progesterone secretion
Ovary (granulosal cells)	Sertoli cell function	Follicular development and estradiol synthesis
Mammary cells, corpus luteum in some species (rat and mouse)	Can induce maternal behavior in females and males	Lactation, maternal behavior and corpora lutea function (some species)
Myometrium and endometrium of uterus, myoepithelial cells of mammary gland	$PGF_{2\alpha}$ synthesis and pre-ejaculatory movement of spermatozoa	Uterine motility, promotes uterine $PGF_{2\alpha}$ synthesis, milk ejection
Hypothalamus, entire reproductive tract and mammary gland	Sexual behavior	Sexual behavior, GnRH, elevated secretory activity of the entire tract, enhanced uterine motility
Uterine endometrium, mammary gland, myometrium, hypothalamus		Endometrial secretion, inhibits GnRH release, inhibits reproductive behavior, promotes maintenance of pregnancy
Brain, skeletal muscle, granulosal cells	Anabolic growth, promotes spermatogenesis, promotes secretion of accessory sex glands	Substrate for E_2 synthesis, abnormal masculinization (hair patterns, voice, behavior, etc.)
Gonadotrophs of anterior lobe-pituitary	Inhibits FSH secretion	Inhibits FSH secretion
Gonadotrophs of anterior lobe-pituitary	Stimulates FSH secretion	Stimulates FSH secretion
Corpus luteum, uterine myometrium, ovulatory follicles	Affects metabolic activity of spermatozoa, causes epididymal contractions	Luteolysis, promotes uterine tone and contraction, ovulation
Corpus luteum, oviduct		Ovulation, stimulates corpus luteum secretion of progesterone
Ovary	Increase growth of fetal testis	Facilitate production of progesterone by ovary
Ovary		Causes formation of accessory corpora lutea
Mammary gland of dam		Mammary stimulation of dam

Figure 5-19. Use of the ELISA as a Method to Measure Hormones

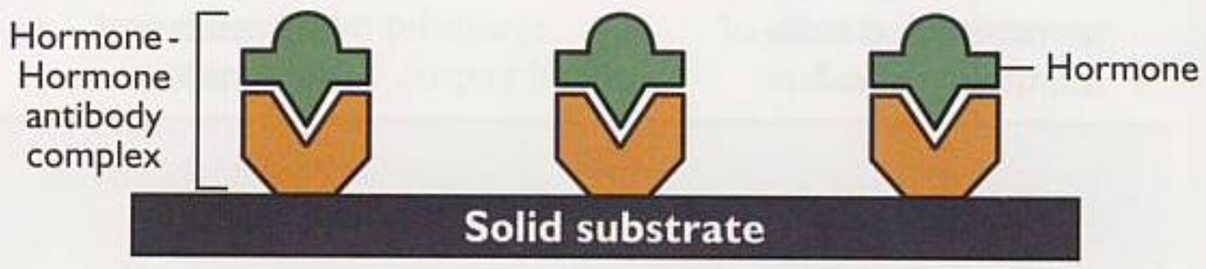
Step 1: Two types of antibodies are required. One antibody reacts specifically with a hormone ("hormone antibody"). A second antibody reacts with the hormone-antibody complex and this antibody has an enzyme attached to it ("enzyme antibody").



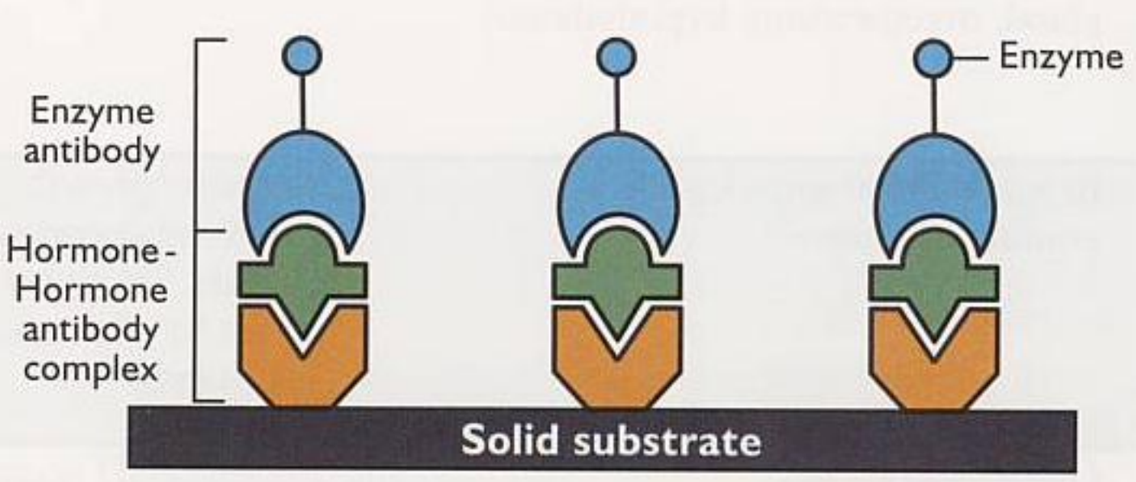
Step 2: The "hormone antibody" (a protein) is tightly attached to a solid support surface.

5

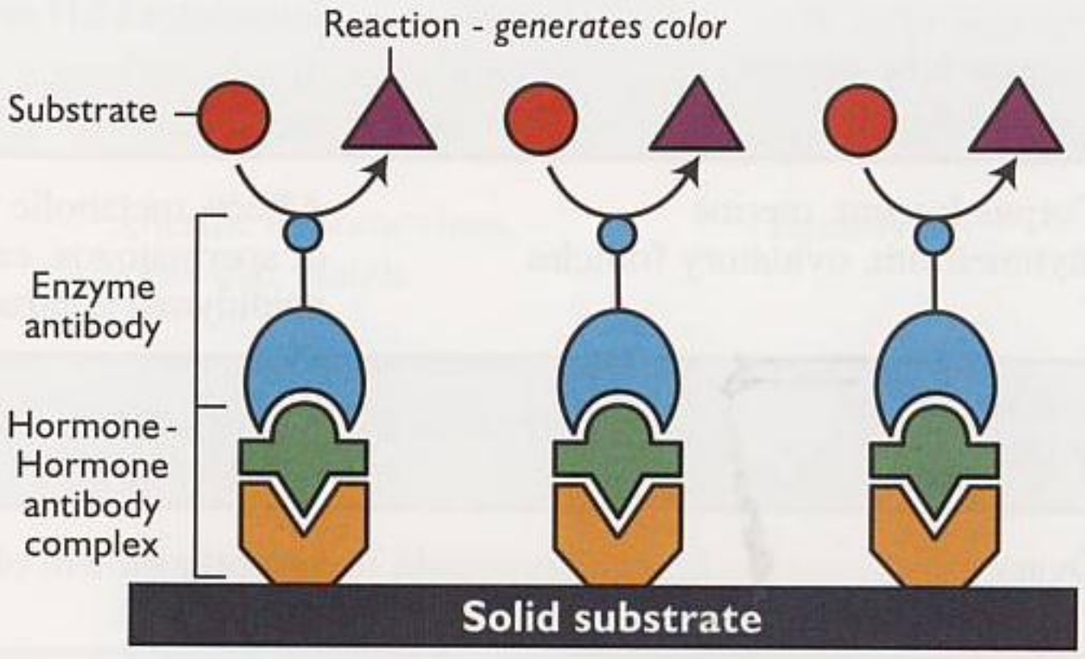
Step 3: When the specific hormone (usually a protein) is present in a solution, it binds ("immunosorbent") to the "hormone antibody" and forms a hormone-antibody complex.



Step 4: The "enzyme antibody" then reacts against the hormone-antibody complex, generating a larger antibody complex with the enzyme component exposed to the solution.



Step 5: After the "enzyme antibody" binds to the original complex, a substrate is added to the solution and the enzyme attached to the "enzyme antibody" causes a color to be generated. Generation of a color is the basis for the ELISA system.



chorionic gonadotropin-eCG) have longer half-lives (hours to days). This longer half-life has practical application because hCG and eCG have been used as superovulation drugs in domestic animals because their physiologic activity generally lasts a longer period of time in-vivo than GnRH. Removal of polysaccharide side chains (**glycosylation sites**) from gonadotropins significantly reduces their half-life. Gonadotropin molecules that have lost their glycosylation, bind to liver cells, are internalized and degraded within the cytoplasm of the liver cell. In addition to denaturation in the liver, the kidneys likely play an important role in elimination of glycoprotein hormones. For example, glycoprotein hormones are significantly smaller than typical serum glycoproteins. The glomerular filtration limit for molecules within the kidney is around 55,000 Daltons. Any glycoprotein hormone that has a molecular weight of less than 55,000 potentially can be eliminated in the urine. Such is the case for human chorionic gonadotropin. Human chorionic gonadotropin at least in part is filtered through the kidney and eliminated in the urine thus providing an avenue for a rapid patient-side pregnancy test in women. It should be emphasized that oral administration of protein hormones is not effective because these proteins are denatured in the gastrointestinal tract and lose their biologic potency because here they are broken-down into amino acid fragments.

Hormones can be detected in physiologic fluids (blood, saliva, urine, lymph, tears, feces) using radioimmunoassay (RIA) and enzyme-linked immunosorbent assay (ELISA) technology.

The **radioimmunoassay (RIA)** has revolutionized our understanding of endocrine physiology in almost all species of animals during the past 40 years. The radioimmunoassay requires the use of radioactive hormones. In the test tube, radioactive hormone competes with the same hormone from an animal's blood that is not radioactively labeled. The amount of radioactive hormone that binds is inversely proportional to the concentration of unlabeled hormone in the animal's blood. A detailed description of the RIA is beyond the scope of this text. However, consultation of the reference by Nett and Malvey in Key References section at the end of this chapter will provide you with more details. Radioimmunoassay technology requires specialized radioisotope-approved laboratories, expensive isotope detection equipment and the need for expensive disposal methods. The RIA is being replaced gradually by a more user-friendly assay called the **enzyme-linked immunosorbent assay (ELISA)**. The **ELISA** has provided many convenient ways to detect and measure hormones. It's applications continue to expand.

The principle of the ELISA involves a series of well-controlled steps that are designed to determine the presence or absence of specific hormones under a variety of conditions. The ELISA can also determine the quantity of the hormone present in a sample under more sophisticated laboratory conditions. The major steps of the ELISA are described in Figure 5-19.

The advantage of the ELISA over the RIA is that no radioisotopes are required, the test can be conducted on-site with minimal training, it has no health/safety hazard issues and it is relatively inexpensive. One of the most successful and popular applications of the ELISA is a one-step, over-the-counter pregnancy test for women. ELISA tests are also being used for pregnancy detection in cows and bison. A more complete description of the hormones of pregnancy will be presented in Chapter 14. In addition to pregnancy detection, ELISA has very widespread on-site use, ranging from detection of pathologic microorganisms to environmental contaminants. It should be emphasized that there are many variations and biochemical strategies used to produce ELISA systems. However, the basic principle involved in all applications is the use of a color-generating enzyme linked to a specific antibody (See Figure 5-19).

Further PHENOMENA for Fertility

In the 19th century, French doctors reported that the eating of frog legs by French soldiers in North Africa caused two outbreaks of priapism (painful and prolonged penile erection). The attending physicians noted that the symptoms amongst the soldiers resembled those seen in men who had overindulged in a drug called cantharidin (popularly known as "Spanish Fly"). This material is extracted from a beetle for its purported value as an aphrodisiac. One of the attending French physicians dissected a local frog and discovered that its gut was full of beetles that produced cantharidin. Recently, researchers have shown that frogs eating this beetle have levels of cantharidin in their thigh muscles that are high enough to cause human priapism.

The word pituitary is derived from the Latin word "pituita" that means mucus. The existence of the pituitary gland was recognized as early as 200 AD. It was thought to be a mucus-secreting organ for lubrication of the throat. Mucus from the pituitary was thought to be transported into the nose and then into the nasopharynx where it could lubricate the throat.

The dramatic effects of male castration have been recognized for over 2,000 years. The testis was known to control virility and sterility. Castration was always (and still is) regarded as a catastrophic event. However, it was deemed useful under certain sets of conditions such as generating guardians for harems and male singers with high pitched voices.

The scientific discipline of endocrinology originated from a belief in "organ magic." Consumption of human or animal organs was thought to increase powers or cure ailments. For example, warriors thought that eating the hearts of their enemy increased their courage. Eating the thyroids of sheep was thought to improve the intelligence of the mentally retarded; liver from wolves cured liver ailments; brain from rabbits cured nervousness and fox lungs cured respiratory disorders. Throughout recorded history sex gland consumption was believed to increase sexual prowess. As early as 1400 BC, Hindus prescribed testicular tissue for male impotence. The "birthday" of modern endocrinology was stimulated by the famous report of Brown-Séquard who injected himself with testicular extracts. The aging Brown-Séquard reported in 1889 that these extracts reversed the effects of age, made him feel significantly more vigorous and corrected his failing memory. His report, even though erroneous, prompted a rush of "gland treatments" by the medical profession of the day. Brown-Séquard's error stimulated careful scrutiny by scientists and physicians. This scientific scrutiny led to the development of modern endocrinology.

The leading cause of death in the early 1900's in young women was childbirth...they bled to death. The discovery that an extract from the brain caused uterine contractions and reduced uterine blood flow was a major breakthrough. It was soon discovered that the brain extract was oxytocin. It was and still is administered to women to prevent bleeding during childbirth as well as to enhance uterine contractions for expulsion of the fetus.

The first interest in reproductive physiology was strongly linked to human sex. The first account of "reproductive physiology" was recorded in about 3200 B.C. in Mesopotamia. People of that age had no idea how the reproductive system functioned or even what its parts were (except for the external genitalia). However, they were apparently quite anxious to apply "technology" to evaluate reproduction. For example, women in Mesopotamia devised "home pregnancy tests" that involved urinating on different materials such as grain and sprouts. Whether or not the sprouts germinated determined the pregnancy status of the female. Also, women wishing to know their pregnancy status would insert an onion into the vagina. If the onion smell was detected on her breath she was deemed pregnant.

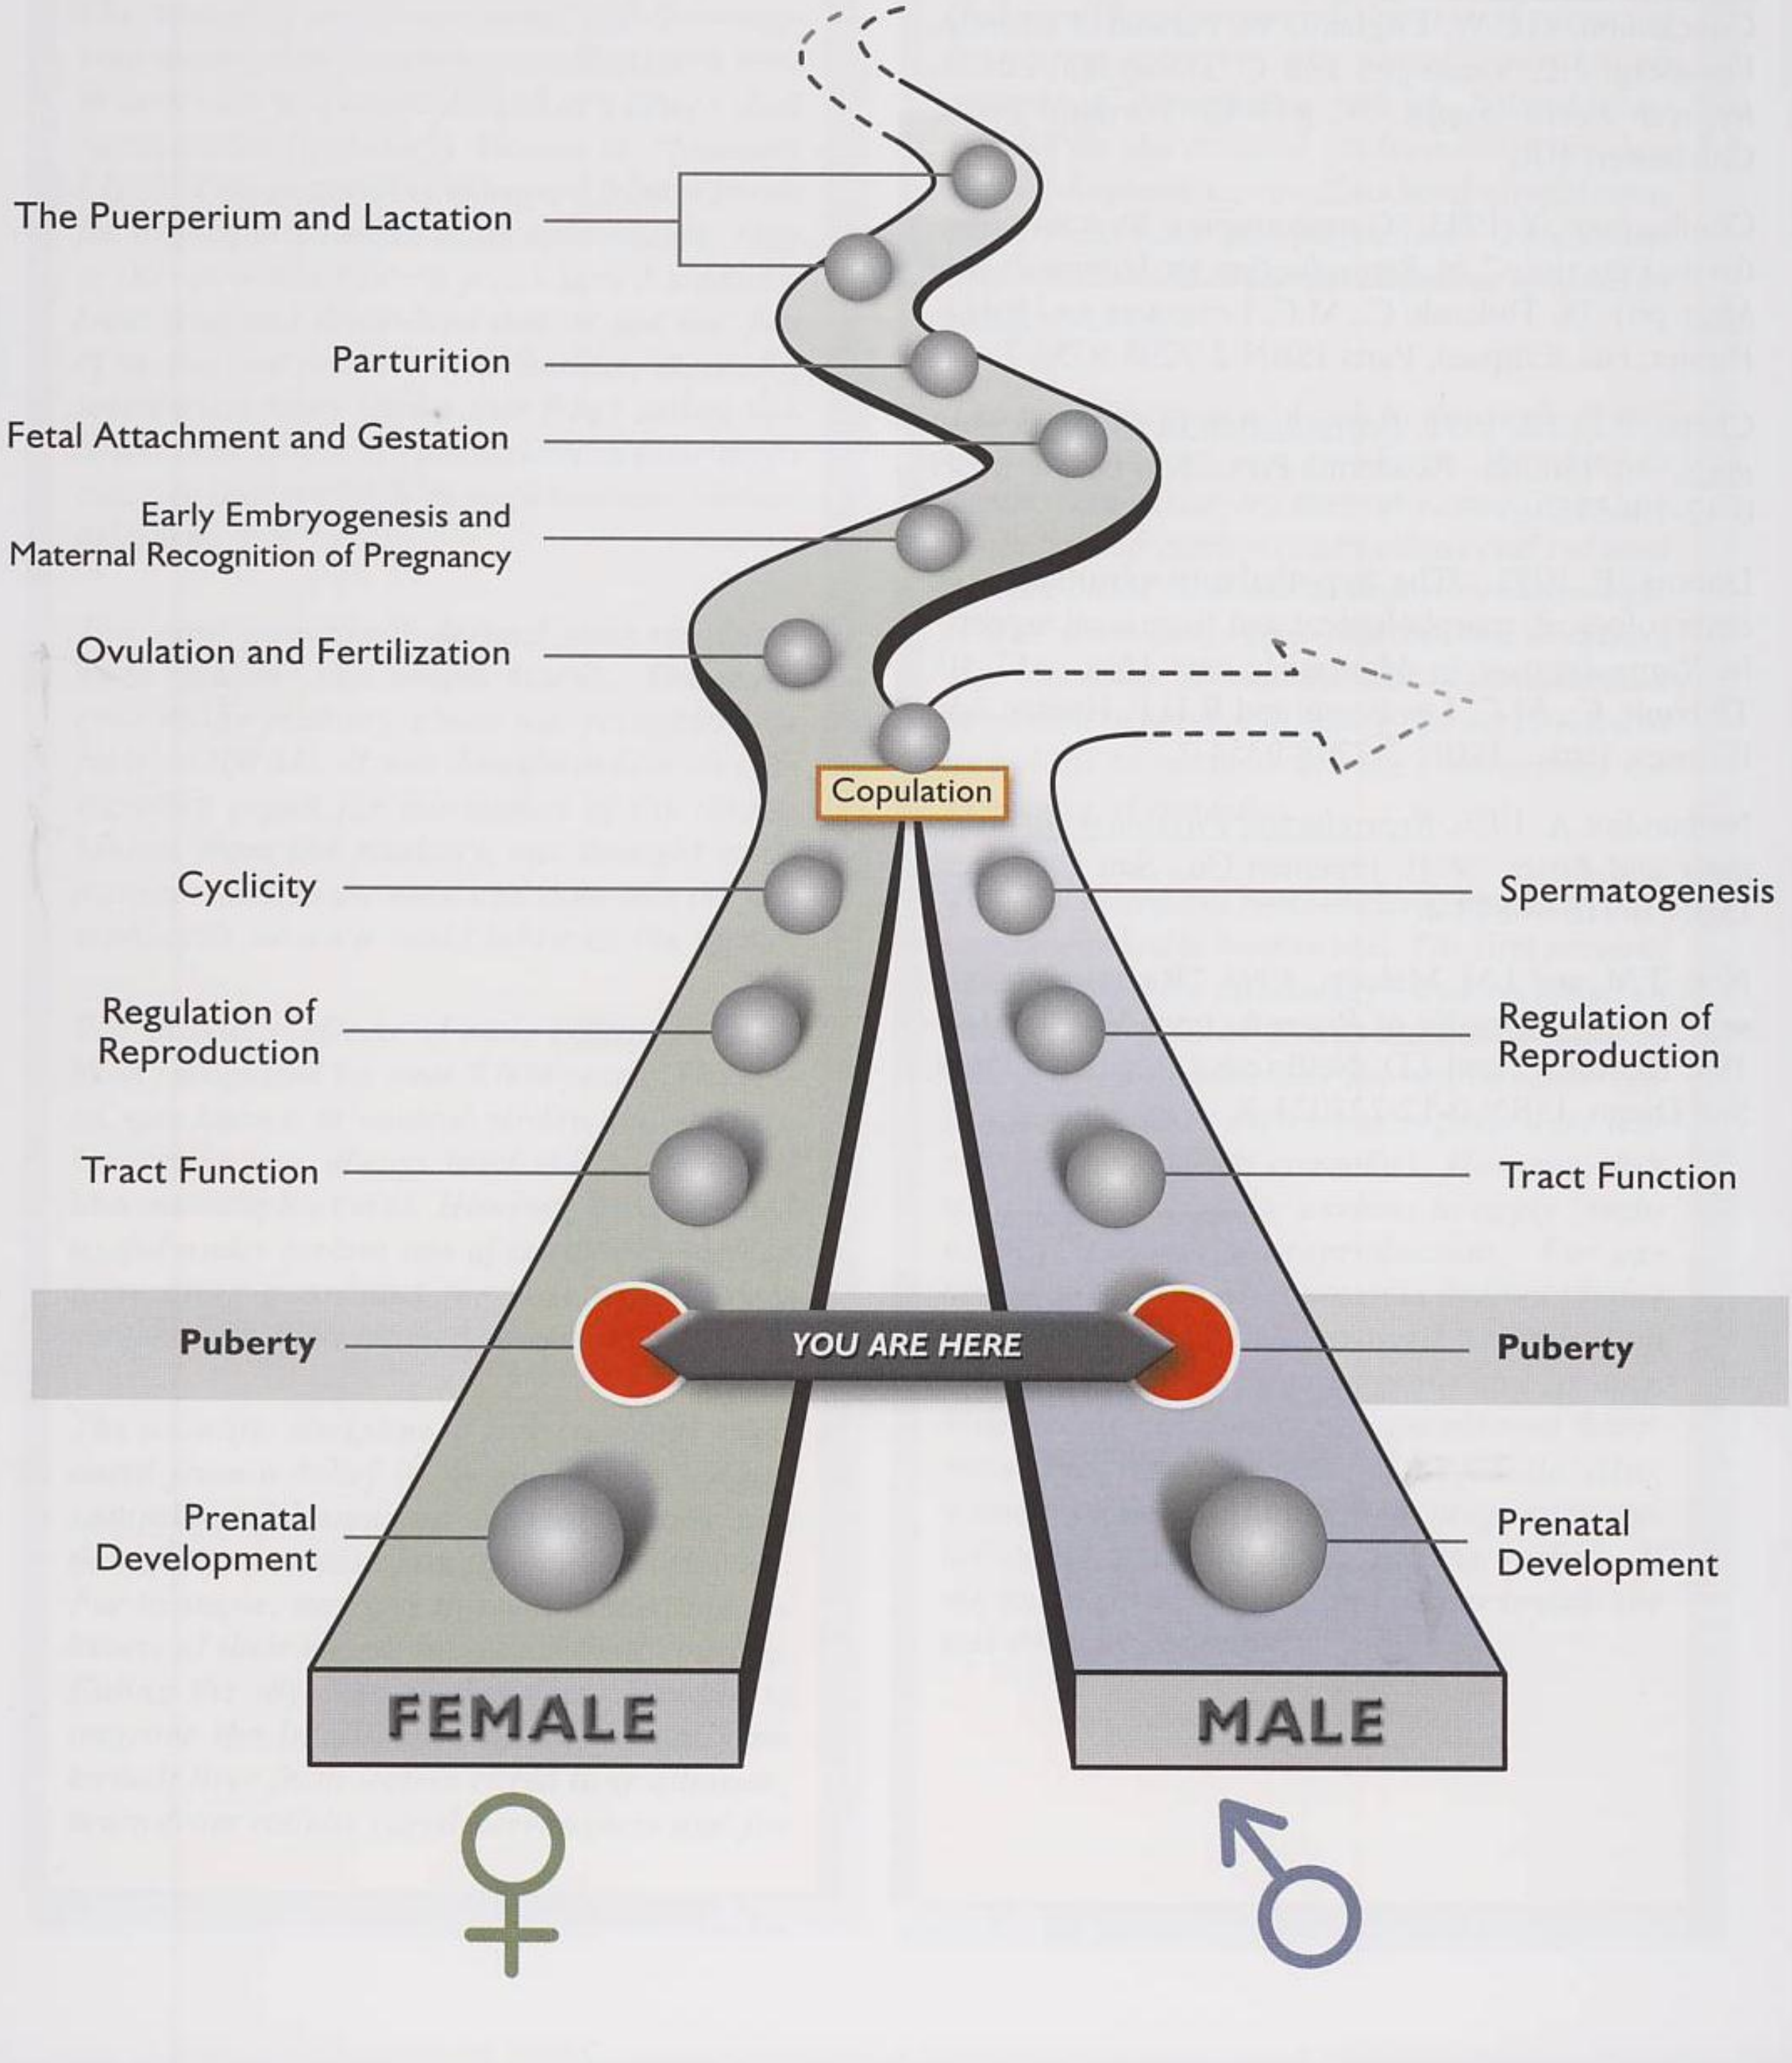
CHAPTER 6

Puberty



Take Home Message

Puberty is the process of acquiring reproductive competence. The onset of puberty depends upon the ability of specific hypothalamic neurons to produce GnRH in sufficient quantities to promote and support gametogenesis. In the female, hypothalamic GnRH neurons must develop the ability to respond to estradiol positive feedback before they can produce sufficient quantities of GnRH to cause ovulation. Development of hypothalamic GnRH neurons is influenced by: 1) development of threshold body size, 2) exposure to a variety of environmental and social cues, and 3) the genetics of the animal.

Before engaging the subject of puberty it is necessary for you to understand that there are fundamental differences in the hypothalamus of the male and female. These differences are established prenatally and remain throughout the reproductive life of both sexes.

The hypothalamus is inherently female. Testosterone defeminizes the hypothalamus during embryogenesis and "eliminates" the GnRH surge center in the male.

During prenatal development in the male, testosterone from the fetal testis "defeminizes" the brain. In contrast, the female fetus has no testis to produce testosterone and she therefore develops a GnRH surge center in the hypothalamus. In order for testosterone to "defeminize" the hypothalamus, it must first be converted to estradiol. Since the fetal ovaries produce estradiol, a logical question is, "Why doesn't the female hypothalamus become defeminized?" The answer to this question lies in the inability of fetal estradiol in the female to cross the blood-brain barrier and gain access to the hypothalamus. A protein called **alpha-fetoprotein** binds estradiol and prevents it from crossing the blood-brain barrier (See Figure 6-1). Therefore, estradiol cannot affect the hypothalamus. Alpha-fetoprotein is a glycoprotein synthesized by the embryonic yolk sac and later the fetal liver. It serves as a fetal blood osmotic regulator and a carrier of fatty acids. In the male, testosterone crosses the blood-brain barrier, is converted to estradiol in the brain and the estradiol "defeminizes" the hypothalamus, thus minimizing surge center function. There is good evidence that complete "defeminization" of the male hypothalamus requires postnatal exposure to androgens. For example, if bulls are castrated at or near birth, they have some ability to produce a GnRH surge. Continued exposure to androgens is apparently required to render the surge center inoperative.

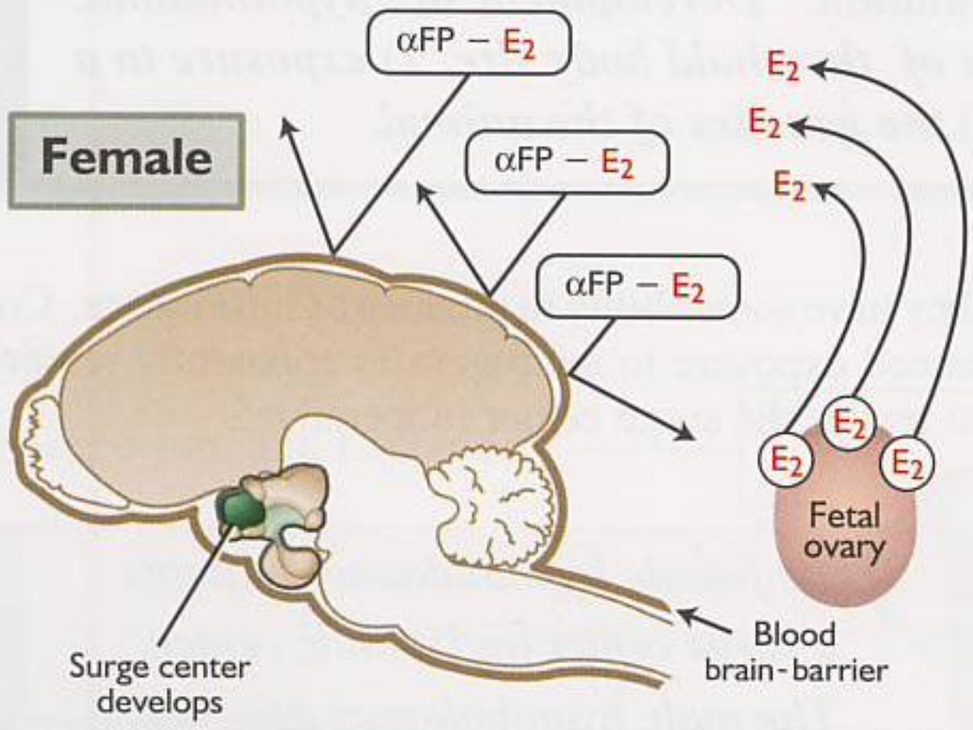
The female hypothalamus contains a surge center and a tonic center. The male hypothalamus does not appear to have a surge center.

The fundamental difference in the endocrine profiles of the postpubertal male and female is that LH does not surge in the male, but maintains a relatively consistent day-in and day-out episodic pattern of secretion. The episodes occur every 2 to 6 hours in the postpubertal male. This steady GnRH pulsatile rhythm also results in steady pulses of LH and, in turn, a steady pulsatile release of testosterone. In contrast, you can readily see in Figure 6-2 that LH and estradiol surge about every 20 days in the female. The frequency of these surges will vary among species depending on the length of their estrous cycles. During the time between the surges, low amplitude repeated LH pulses are present.

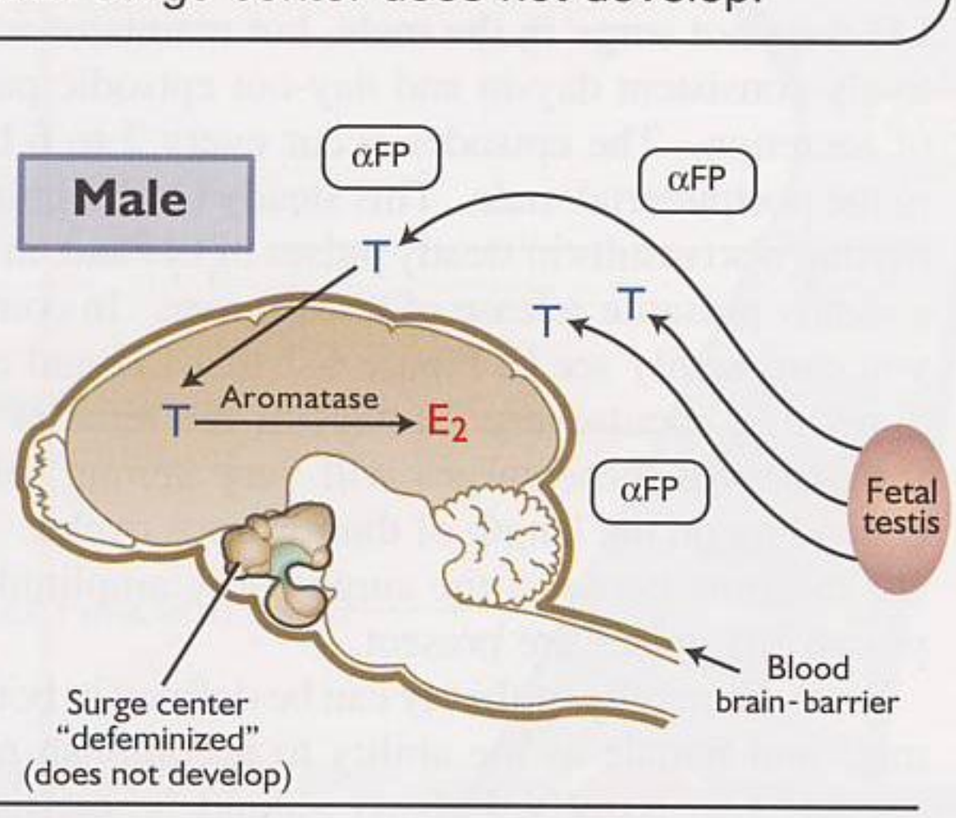
Generally, **puberty** can be defined in both the male and female as the ability to accomplish reproduction successfully. Puberty should be considered as a process not a single event. The word puberty originated from the Latin word *pubscere* that means "to be covered with hair". This definition applies to the development of hair in the pubic area, armpits and legs in women and men. Also, the development of the beard in men is an indicator of pubescence. The original definition of the word puberty related to the presence of hair in certain anatomical regions. This obviously does not apply to other animals. The fundamental requirement for pubertal onset is the secretion of GnRH at the appropriate frequency and quantities to stimulate gonadotropin release by the

Figure 6-1. Alpha Fetoprotein (α-FP) and the Blood Brain Barrier

In the female, α-FP prevents E_2 from entering the brain. The hypothalamus is thus "feminized" and the surge center develops.



In the male, Testosterone freely enters the brain because α-FP does not bind it. Testosterone is aromatized into estradiol and the male brain is "defeminized". Therefore, a GnRH surge center does not develop.



anterior pituitary lobe. Gonadotropins will promote gametogenesis, steroidogenesis and the development of reproductive tissues. The number of neurons that secrete GnRH, their morphology and their distribution within the hypothalamus are established well before pubertal onset. However, their degree of function increases as puberty begins. Neuroendocrinologists believe that the most important "drivers" of pubertal onset are the ability of presynaptic neurons to provide information to the GnRH neurons. In other words, the limiting factor for pubertal onset appears to be the ability of presynaptic neurons to transmit information to GnRH neurons so that GnRH secretion will increase. Function of these neurons may be influenced by: 1) plane of nutrition, 2) exposure to certain environmental or social cues and 3) the genetics of the individual.

The Onset of Puberty has Many Definitions in Females

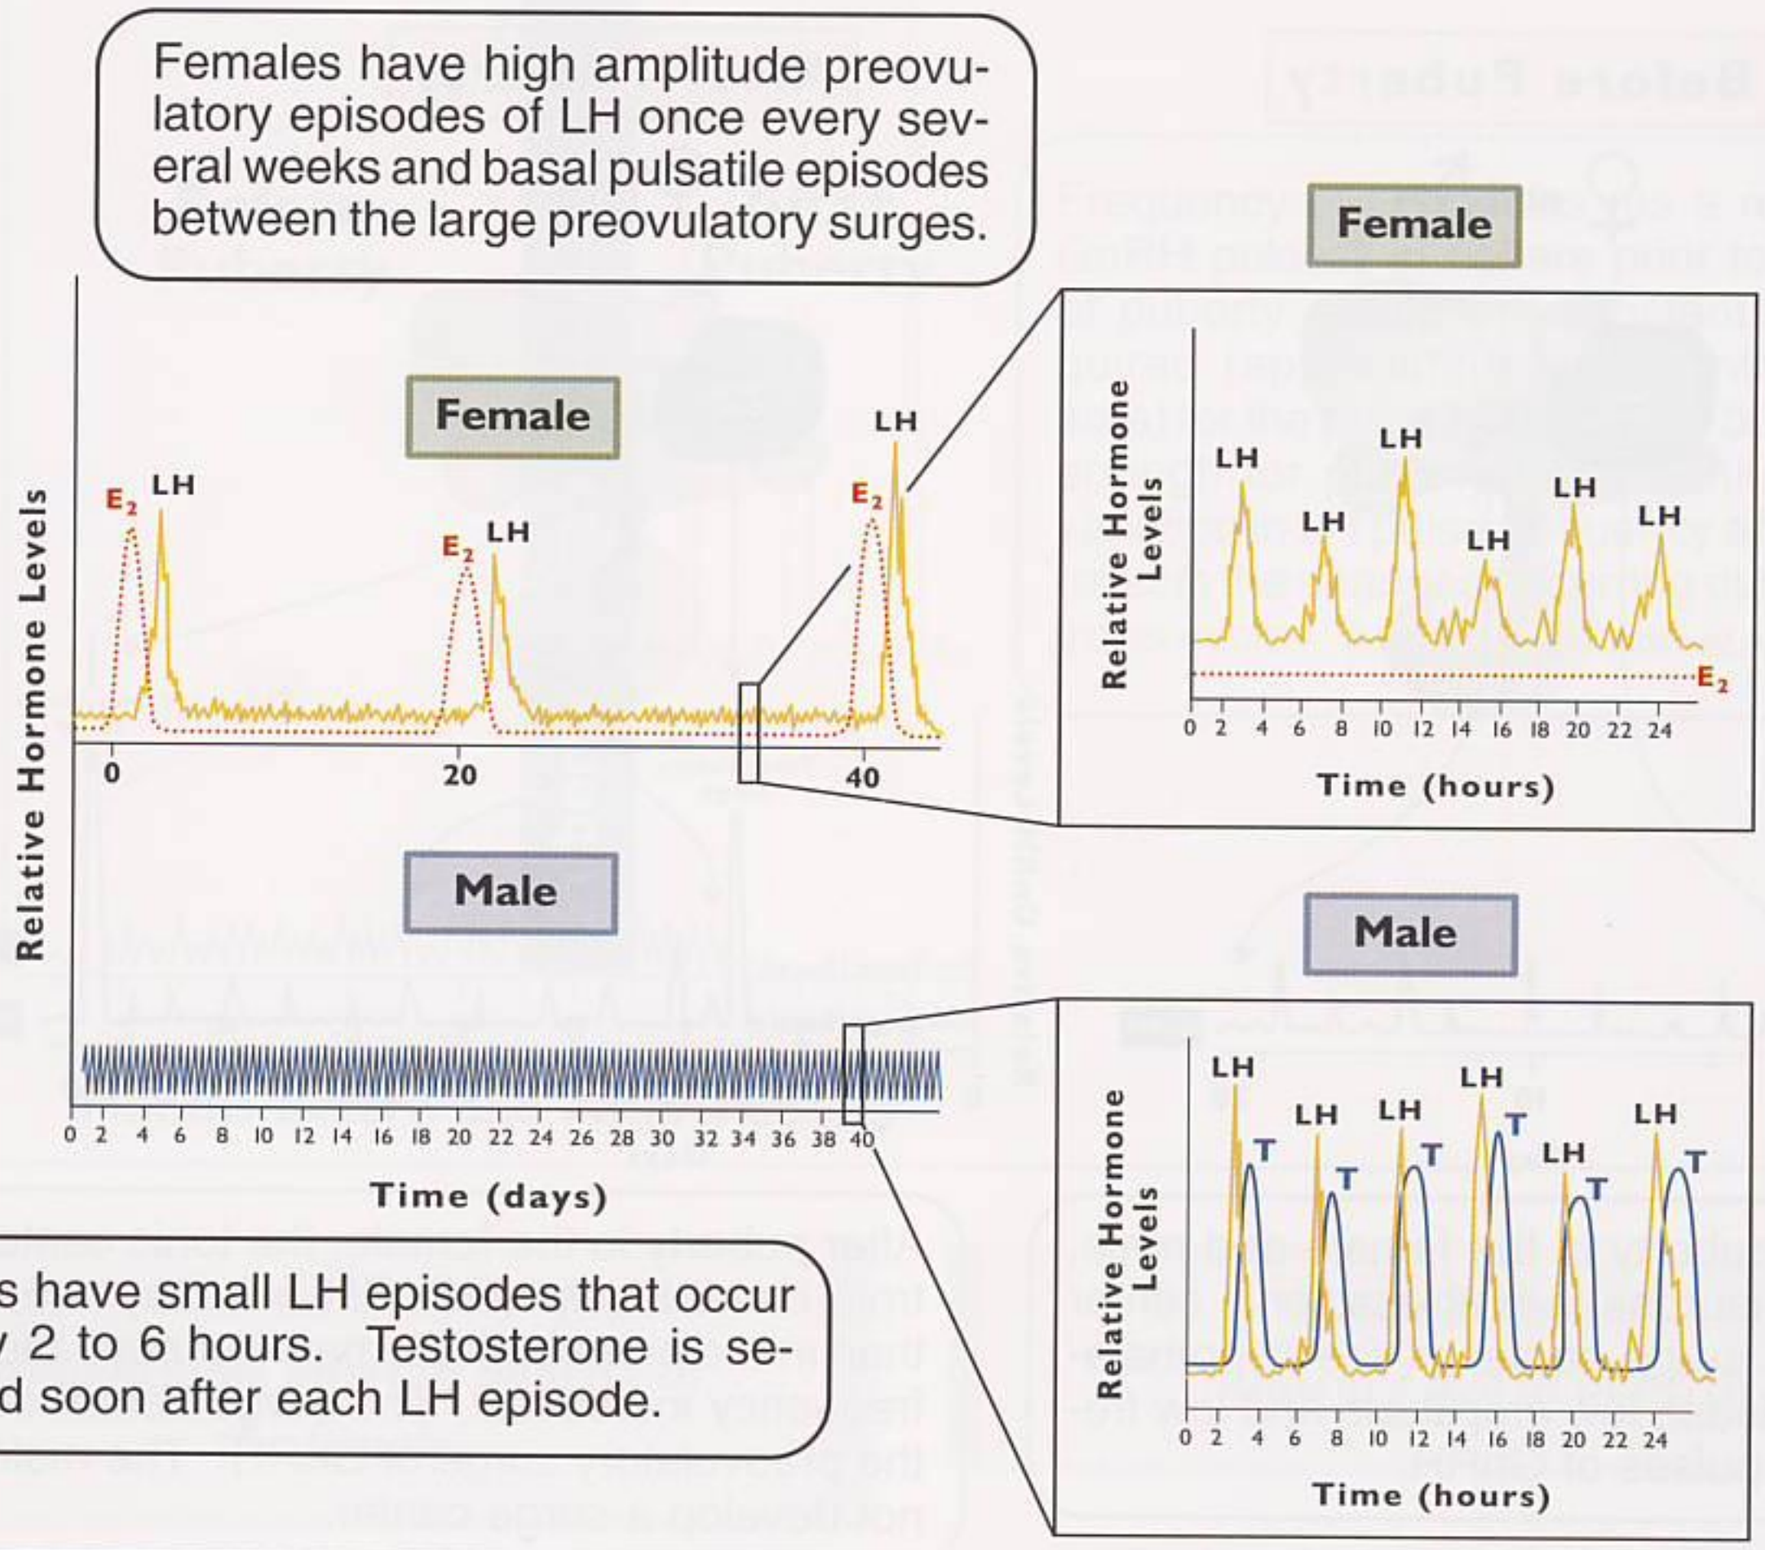
Several criteria can be used to define puberty in the female. Some examples are presented below.

Age at first estrus (heat). This is the age that the female becomes sexually receptive and displays her first estrus. The age at first estrus is relatively easy to determine because females show outward behavioral signs of sexual receptivity, especially in the presence of the male. The first ovulation generally is not accompanied by behavioral estrus in heifers and ewes. This has been termed "silent ovulation." Thus, the age at first estrus may not reflect true acquisition of puberty.

Age at first ovulation. This is the age when the first ovulation occurs. To determine this critically, manual or visual validation is required. This can be accomplished using palpation of the ovary per rectum in animals that are large enough to permit insertion of the hand and arm into the rectum (cow and camelids). Ultrasonographic imaging can be used to greatest advantage in the mare to determine ovarian status. When ovulation has occurred, a soft depression on the surface of the ovary can be palpated. In smaller animals (sow, ewe, dog and cat) surgical procedures allowing the ovary to be visualized directly enable determination of ovulation. In addition, laparoscopic observation can be used to determine when ovulation occurs. All of the above techniques require frequent observations of the ovary to determine precisely when ovulation occurred. Thus, although age at ovulation is a good criterion for puberty, it is difficult to determine.

Age at which a female can support pregnancy without deleterious effects. This definition is most applicable from a practical standpoint in all domestic animals and humans. The goal for food producing species is to generate the highest possible number of offspring in the shortest time interval without compromising the well-being of the dam or the neonate. Acquisition of a threshold body size is important in controlling the onset of puberty. The energy requirements for follicular development, ovulation and ova/embryo transport are quite small. However, the metabolic costs of pregnancy and lactation are high. Thus, it makes biologic sense that the female cross a "metabolic threshold" before puberty occurs.

Figure 6-2. Females and Males are Quite Different in Their LH Secretory Pattern



The Onset of Puberty has Many Definitions in Males

As in the female, the onset of puberty in the male can be defined in several ways.

Age when behavioral traits are expressed. Generally, males of most species acquire reproductive behavioral traits (mounting and erection) well before they acquire the ability to ejaculate and produce spermatozoa. These behavioral traits are relatively easy to determine since mounting behavior and erection of the penis can be observed readily.

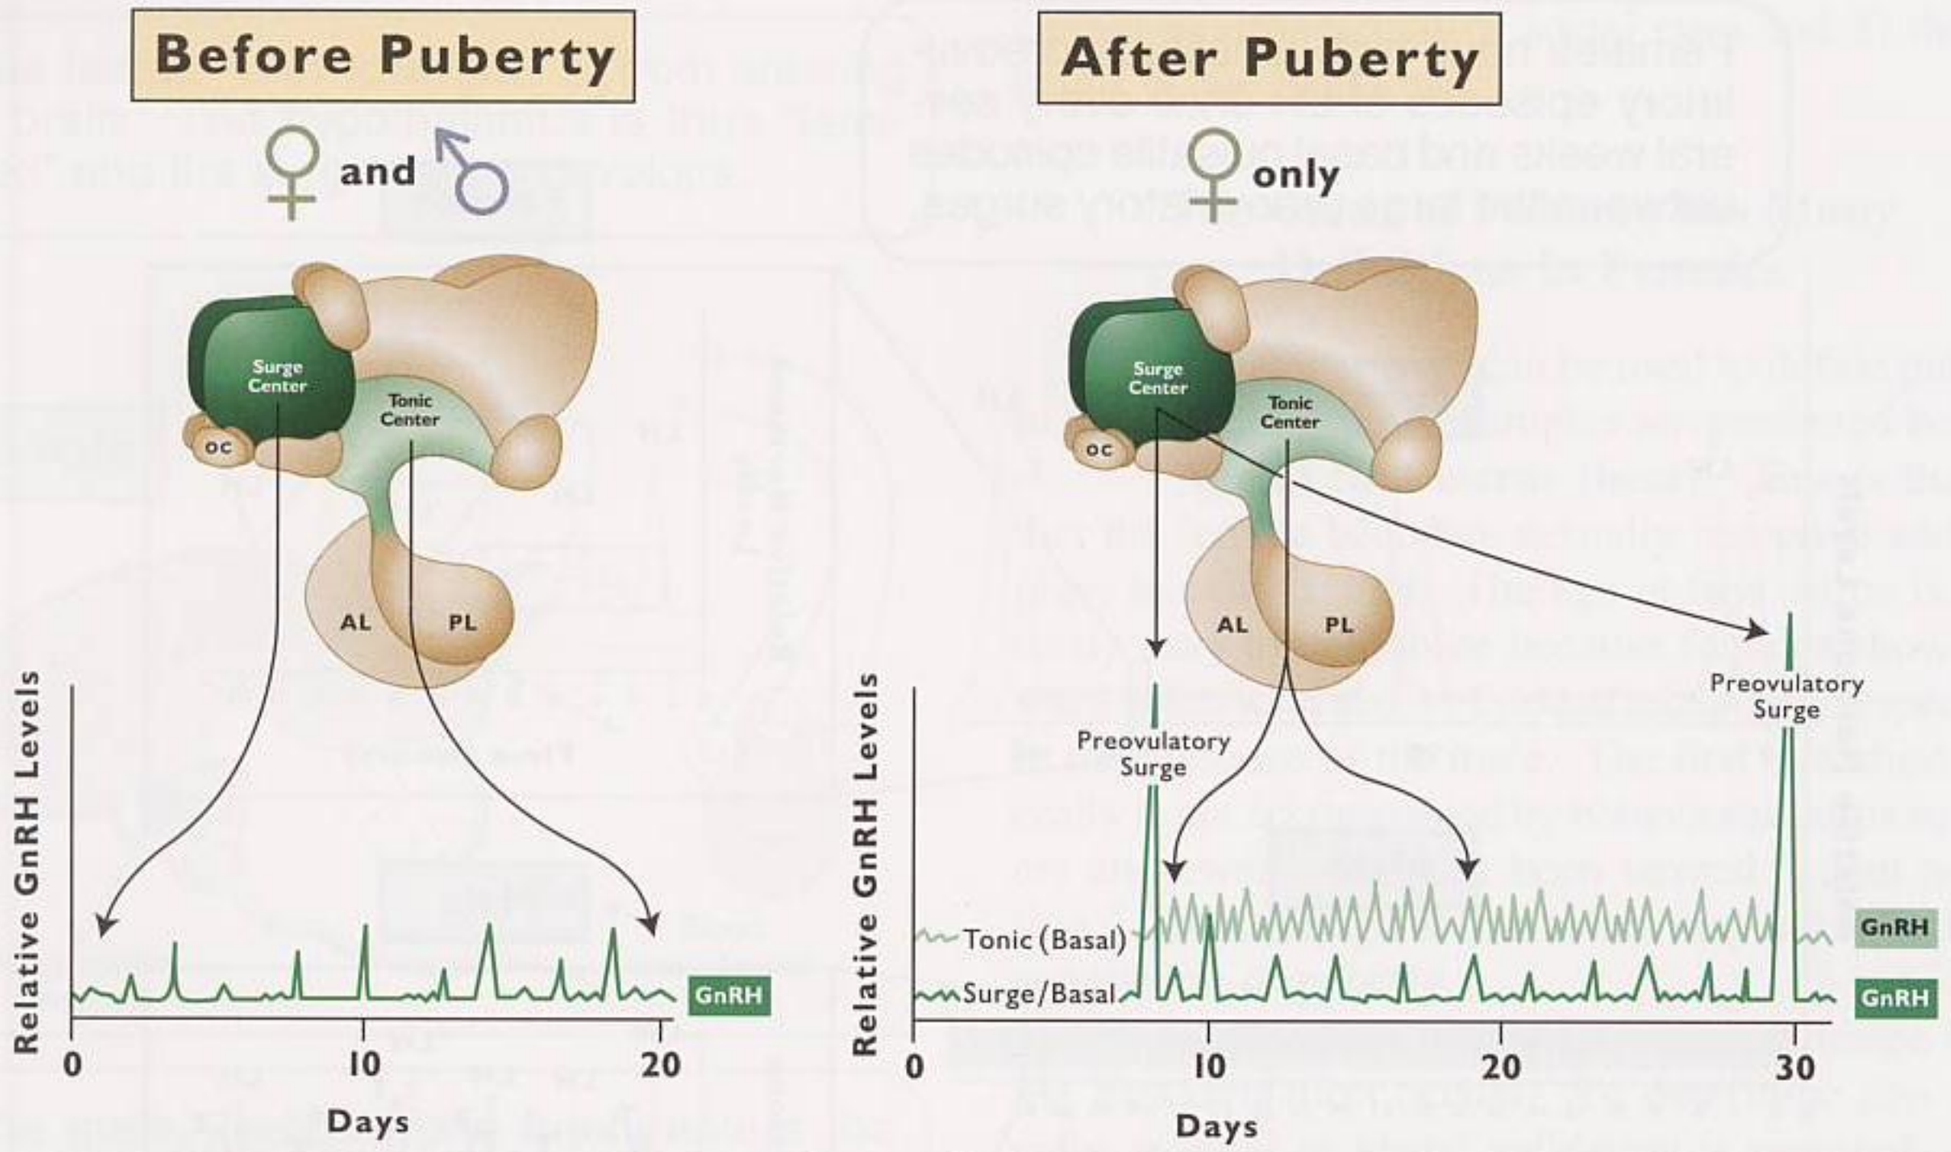
Age at first ejaculation. The process of ejaculation is quite complex and requires closely coordinated development of nerves, specific muscles and secretion of seminal fluids from the accessory sex glands. When development of all these components occurs, ejaculation can take place. Generally, the ability to ejaculate substantially precedes the ability to produce sufficient spermatozoa to achieve fertilization.

Age when spermatozoa first appear in the ejaculate. The male acquires the ability to produce seminal fluid and to ejaculate before spermatozoa are available to be ejaculated. To determine precisely when the first spermatozoa are available, one must collect ejaculates at least once per week. This is relatively easy to do, since ejaculates can be collected by an artificial vagina from the boar, bull, dog, ram or stallion. After behavioral characteristics have developed and the male is willing to mount a receptive female (or surrogate female), frequent seminal collections can be made. This enables determination of the age at which spermatozoa appear in the ejaculate.

Age when spermatozoa first appear in the urine. As you have read in Chapter 3, most of the spermatozoa produced by the testes are lost in the urine during periods of sexual rest (sexual abstinence). The presence of spermatozoa in the urine clearly indicates that spermatogenesis is occurring. Frequent collection of urine is difficult in large domestic animals and requires special equipment. Therefore, this method for assessing pubertal onset has limitations.

Age when the ejaculate contains a threshold number of spermatozoa. Even though an ejaculate may contain spermatozoa, there may be insufficient numbers to accomplish optimum fertilization. Therefore, the presence of a threshold (minimum

Figure 6-3. Changes in Hypothalamic Secretion of GnRH Before and After Puberty



Before puberty in the female and male, GnRH neurons in both the tonic center and the surge center of the hypothalamus release low amplitude and low frequency pulses of GnRH.

After puberty in the female, the tonic center controls basal levels of GnRH but they are higher than in the prepubertal female because the pulse frequency increases. The surge center controls the preovulatory surge of GnRH. The male does not develop a surge center.

number) of spermatozoa is required. These thresholds vary among species. In general, they reflect minimum seminal characteristics required to achieve pregnancy following copulation. From a practical viewpoint, this is the most valid criterion for puberty in the male since it defines the ability of the male to provide enough spermatozoa for successful fertilization.

The female must reach a threshold body size before puberty can be achieved.

The age at which puberty is acquired varies among and within species. This variation is summarized in Tables 6-1 and 6-2. The factors contributing to the variation in pubertal onset constitute the discussion in the remainder of this chapter.

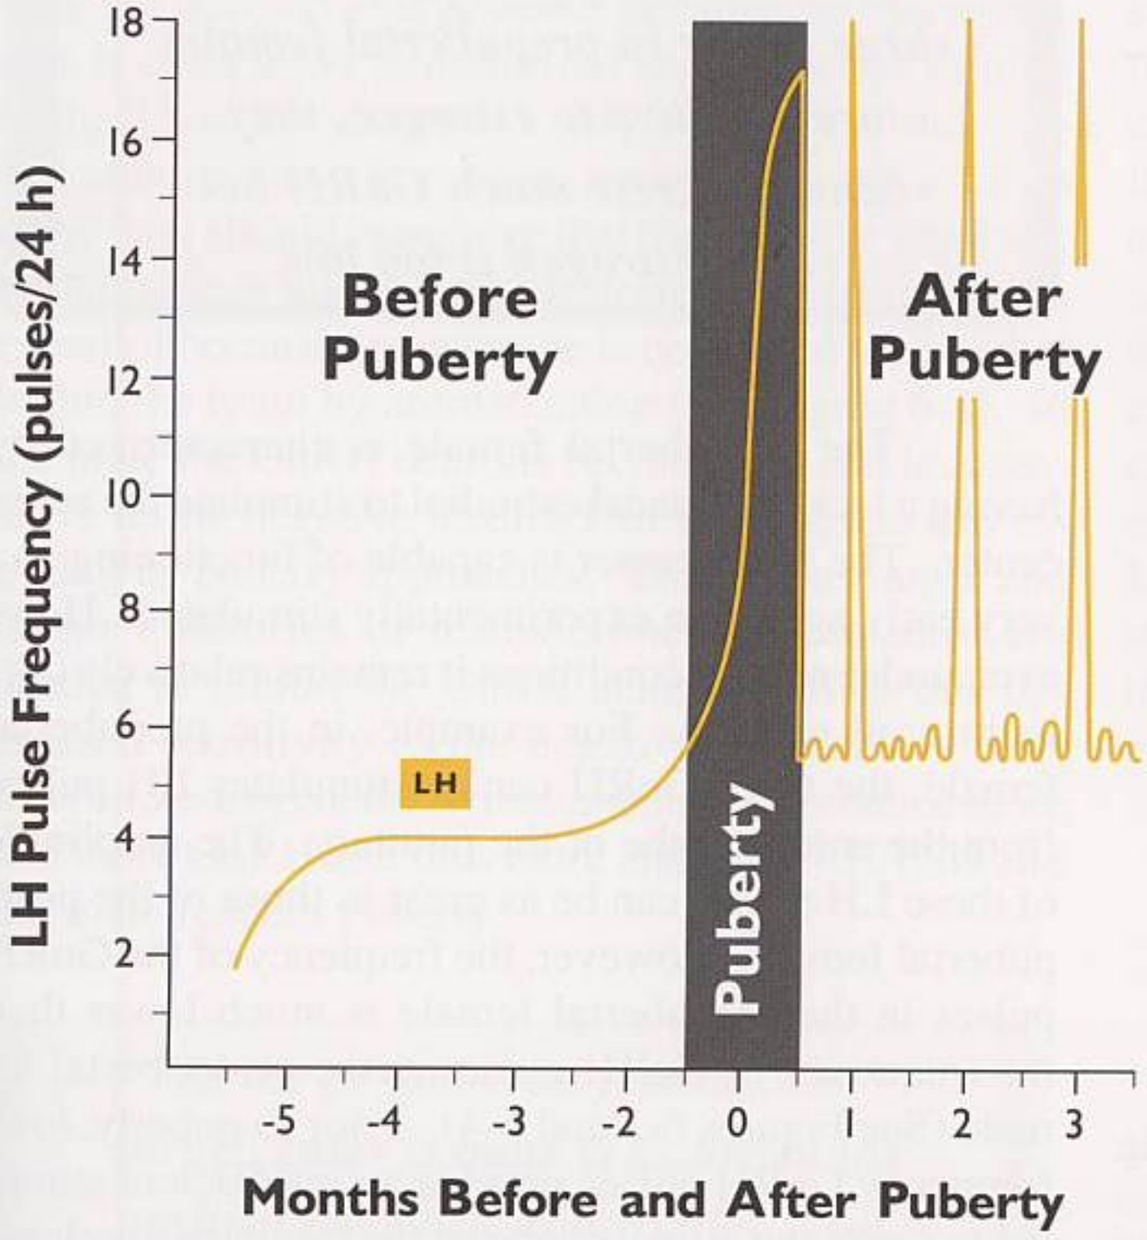
At least two general factors impact the development of the hypothalamic GnRH neurons in the female. They are: 1) development of a threshold body size and/or composition and 2) exposure to certain environmental or social cues.

Table 6-1. Average Ages (Range) of Puberty in the Male and Female of Various Species

Species	Male	Female
Alpaca[2]	2-3 yrs	1 yr
Bovine	11 mo (7-18)	11 mo (9-24)
Camel[2]	3-5 yrs	3 yrs
Canine[1]	9 mo (5-12)	12 mo (6-24)
Equine	14 mo (10-24)	18 mo (12-19)
Feline	9 mo (8-10)	8 mo (4-12)
Llama[2]	2-3 yrs	6-12 mo
Ovine	7 mo (6-9)	7 mo (4-14)
Porcine	7 mo (5-8)	6 mo (5-7)

[1] Very breed dependent - See Johnston *et al*. in **Key References**.
[2] See Tibary and Anouassi in **Key References**.

Figure 6-4. LH Frequency Before and After Puberty



Frequency of LH pulses (as a reflection of GnRH pulses) in heifers prior to the onset of puberty. Note the substantial time required (approximately 2 months-shaded area) for the pulse frequency to become high enough for puberty to be achieved. The variation in LH pulse frequency after puberty reflects the changes occurring during the estrous cycle. (Modified from Kinder *et al*. 1994)

Certain external or social factors influence the onset of puberty in the female.

Genetics (breed) influence age at puberty.

As far as we know, all female mammals must acquire a certain body size before the onset of puberty can be initiated. A current hypothesis contends that the female must develop a certain degree of "fatness" before reproductive cycles can be initiated. The relationship between metabolic status and function of GnRH neurons has not been completely described, but there is good evidence that metabolic signals effect the production of GnRH.

Several external factors modulate the timing of puberty and these vary significantly among species. These factors include: 1) season during which the animal is born (sheep); 2) the photoperiod that the animal is experiencing during the onset of puberty (sheep); 3) the presence or absence of the opposite sex during the peripubertal period (swine and cattle) and 4) the density of the groups (within the same sex) in which the animals are housed (swine). Almost certainly similar external factors impact puberty in humans but these have not been studied intensively. Whatever the species-specific factor(s) may be, they affect the secretion of GnRH.

The breed of the animal has an important influence on the age at which puberty is attained in both the male and the female. For example, dairy heifers reach puberty at around 7 to 9 months of age while British beef breeds reach puberty between 12 and 13 months. *Bos indicus* breeds may not reach puberty until 24 months of age. Table 6-2 summarizes the influence of breed upon age of puberty in cattle, swine, sheep and dogs.

How Do the Hypothalamic GnRH Neurons Acquire the Ability to Release GnRH in High Frequency Pulses?

It has been well established that the onset of puberty is not limited by the potential performance of the gonads or the anterior lobe of the pituitary. For example, the anterior lobe of the pituitary of the prepubertal animal will produce FSH and LH if stimulated by exogenous GnRH. Also, the ovaries of prepubertal females will respond by producing follicles and estradiol when stimulated with FSH and LH. Therefore, the onset of puberty is not limited by the gonadotropin

Table 6-2. Influence of Breed on Age at Puberty in Domestic Animals

Species	Average Age at Puberty (Months)	
	Female	Male

producing ability of the anterior lobe of the pituitary or the ability of the ovary to respond to gonadotropins. The failure of the hypothalamus to produce sufficient quantities of GnRH to cause gonadotropin release is known to be the major factor limiting pubertal onset.

The developing hypothalamus can be compared to a rheostatically controlled switch for a lighting system. As the rheostatically controlled switch is gradually turned up, the lights in the room gradually become brighter and brighter until they reach full intensity. Likewise, the development of the hypothalamus occurs in a gradual fashion during growth of the animal, rather than suddenly, like an on-off switch. The factors that cause the rheostatically controlled switch (hypothalamus) to turn on completely will be described in subsequent sections of this chapter.

As you have read previously (See Chapter 5), the hypothalamus contains a **tonic GnRH center** and a **preovulatory GnRH center** (**surge center**). Before ovulation can occur, full neural activity of the surge center must be achieved (See Figure 6-3). Such an activity results in sudden bursts of GnRH known as the **preovulatory GnRH surge**. In other words, the GnRH neurons must fire frequently and release large quantities of GnRH in order to cause the preovulatory LH surge (See Figure 6-3). As you will soon discover in Chapter 8 the preovulatory GnRH surge is a series of rapid, high amplitude pulses. Inability of the surge center to function results in ovulation failure. In addition to the need to have a functional surge center in the female, the tonic center must also reach a certain functional state. The tonic GnRH center regulates the tonic frequency of GnRH pulses.

Even though the neurons in the surge center in prepubertal females are sensitive to estrogen, they cannot secrete much GnRH because estrogen is too low.

The prepubertal female is characterized by having a lack of gonadal estradiol to stimulate the surge center. The surge center is capable of functioning at a very early age when experimentally stimulated. However, under normal conditions it remains relatively dormant until puberty. For example, in the prepubertal female, the tonic GnRH center stimulates LH pulses from the anterior lobe of the pituitary. The amplitude of these LH pulses can be as great as those of the postpubertal female. However, the frequency of the GnRH pulses in the prepubertal female is much lower than the frequency of GnRH pulses in the postpubertal female (See Figures 6-3 and 6-4). Prior to puberty, low-frequency GnRH pulses provide an insufficient stimulus to cause the anterior lobe of the pituitary to release FSH and LH at high levels. Therefore, follicular development (even though it does occur before puberty), cannot result in high circulating estradiol concentrations. Estradiol therefore remains below the minimum threshold that is necessary to trigger firing of GnRH neurons in the surge center.

In the male, the onset of puberty is brought about because of decreased hypothalamic sensitivity to negative feedback by testosterone/estrogen.

As you recall from Chapter 5, the secretion of GnRH from neurons in the surge center and the tonic center is controlled by positive and negative feedback. Puberty will be initiated when GnRH neurons can respond completely to positive and negative feedback. Understanding the acquisition of this ability is the key to understanding how the onset of puberty is accomplished. We know that GnRH neurons are similar in number, function and distribution within the hypothalamus in both the male and the female. We also know that the male and female are quite different with regard to their endocrine profiles after puberty is reached (See Figure 6-2).

As described earlier in this chapter, the male does not develop a surge center because the hypothalamus is completely defeminized shortly before or after birth. Thus, the male has a very simple feedback system after puberty. It involves a negative feedback loop only. You should recognize that the negative feedback in the male is due to some testosterone and mostly to estradiol because testosterone is converted to estradiol within the brain by aromatization (See Figure 6-1). In the male the GnRH neurons become less and less sensitive to the negative feedback of testosterone and estradiol as puberty approaches. This means larger and larger quantities of testosterone and estradiol are needed to inhibit the GnRH neurons. With this decreased sensitivity to the negative feedback of testosterone/estrogen, the hypothalamus can produce more and more GnRH and thus more and more LH/FSH and the male reaches puberty.

In the prepubertal female, the surge center is quite sensitive to the positive feedback of estradiol. But, the surge center cannot release "ovulatory quantities" of GnRH because the ovary cannot produce high levels of estradiol.

In the female, the surge system is present by "default" and is separated anatomically from the tonic center (See Figure 6-3). From a functional prospective, the surge center responds primarily to a positive feedback stimulus. For example, the prepubertal female does not ovulate although the sensitivity of the surge center to positive feedback by estrogen is quite high. Failure to ovulate occurs because the ovaries do not produce enough estrogen to activate the highly sensitive surge center. In a sense, the surge center lies dormant in the prepubertal female even though it is capable of responding to estradiol. The reason that it lies dormant is that the prepubertal ovary does not produce sufficient quantities of estradiol to stimulate the surge center to secrete high amplitude pulses of GnRH. At low levels of estrogen, the tonic center has a high sensitivity to negative feedback and therefore does not produce high levels of GnRH and gonadotropins remain low. During the pubertal transition, however, the negative feedback sensitivity by the tonic center to estradiol decreases and consequently higher and higher amounts of GnRH are produced that stimulate the ovary to produce more and more estrogen. When estrogen levels reach a certain threshold, it now causes a massive discharge of GnRH from the surge center (positive feedback). Ovulation can take place and puberty ensues. It should be emphasized that the sensitivity of the surge center to positive feedback never changes and always remains high even before birth. It is the sensitivity to negative feedback that is decreased and triggers the onset of puberty in the female. The decreased sensitivity to negative feedback by the tonic center means that smaller and smaller quantities of estradiol can stimulate the release of GnRH and thus LH and FSH are secreted. These gonadotropins then stimulate more follicles and more and more estradiol is produced until finally the surge center releases the preovulatory surge of GnRH.

A Certain Degree of "Fatness" is Required for the Onset of Puberty in the Female

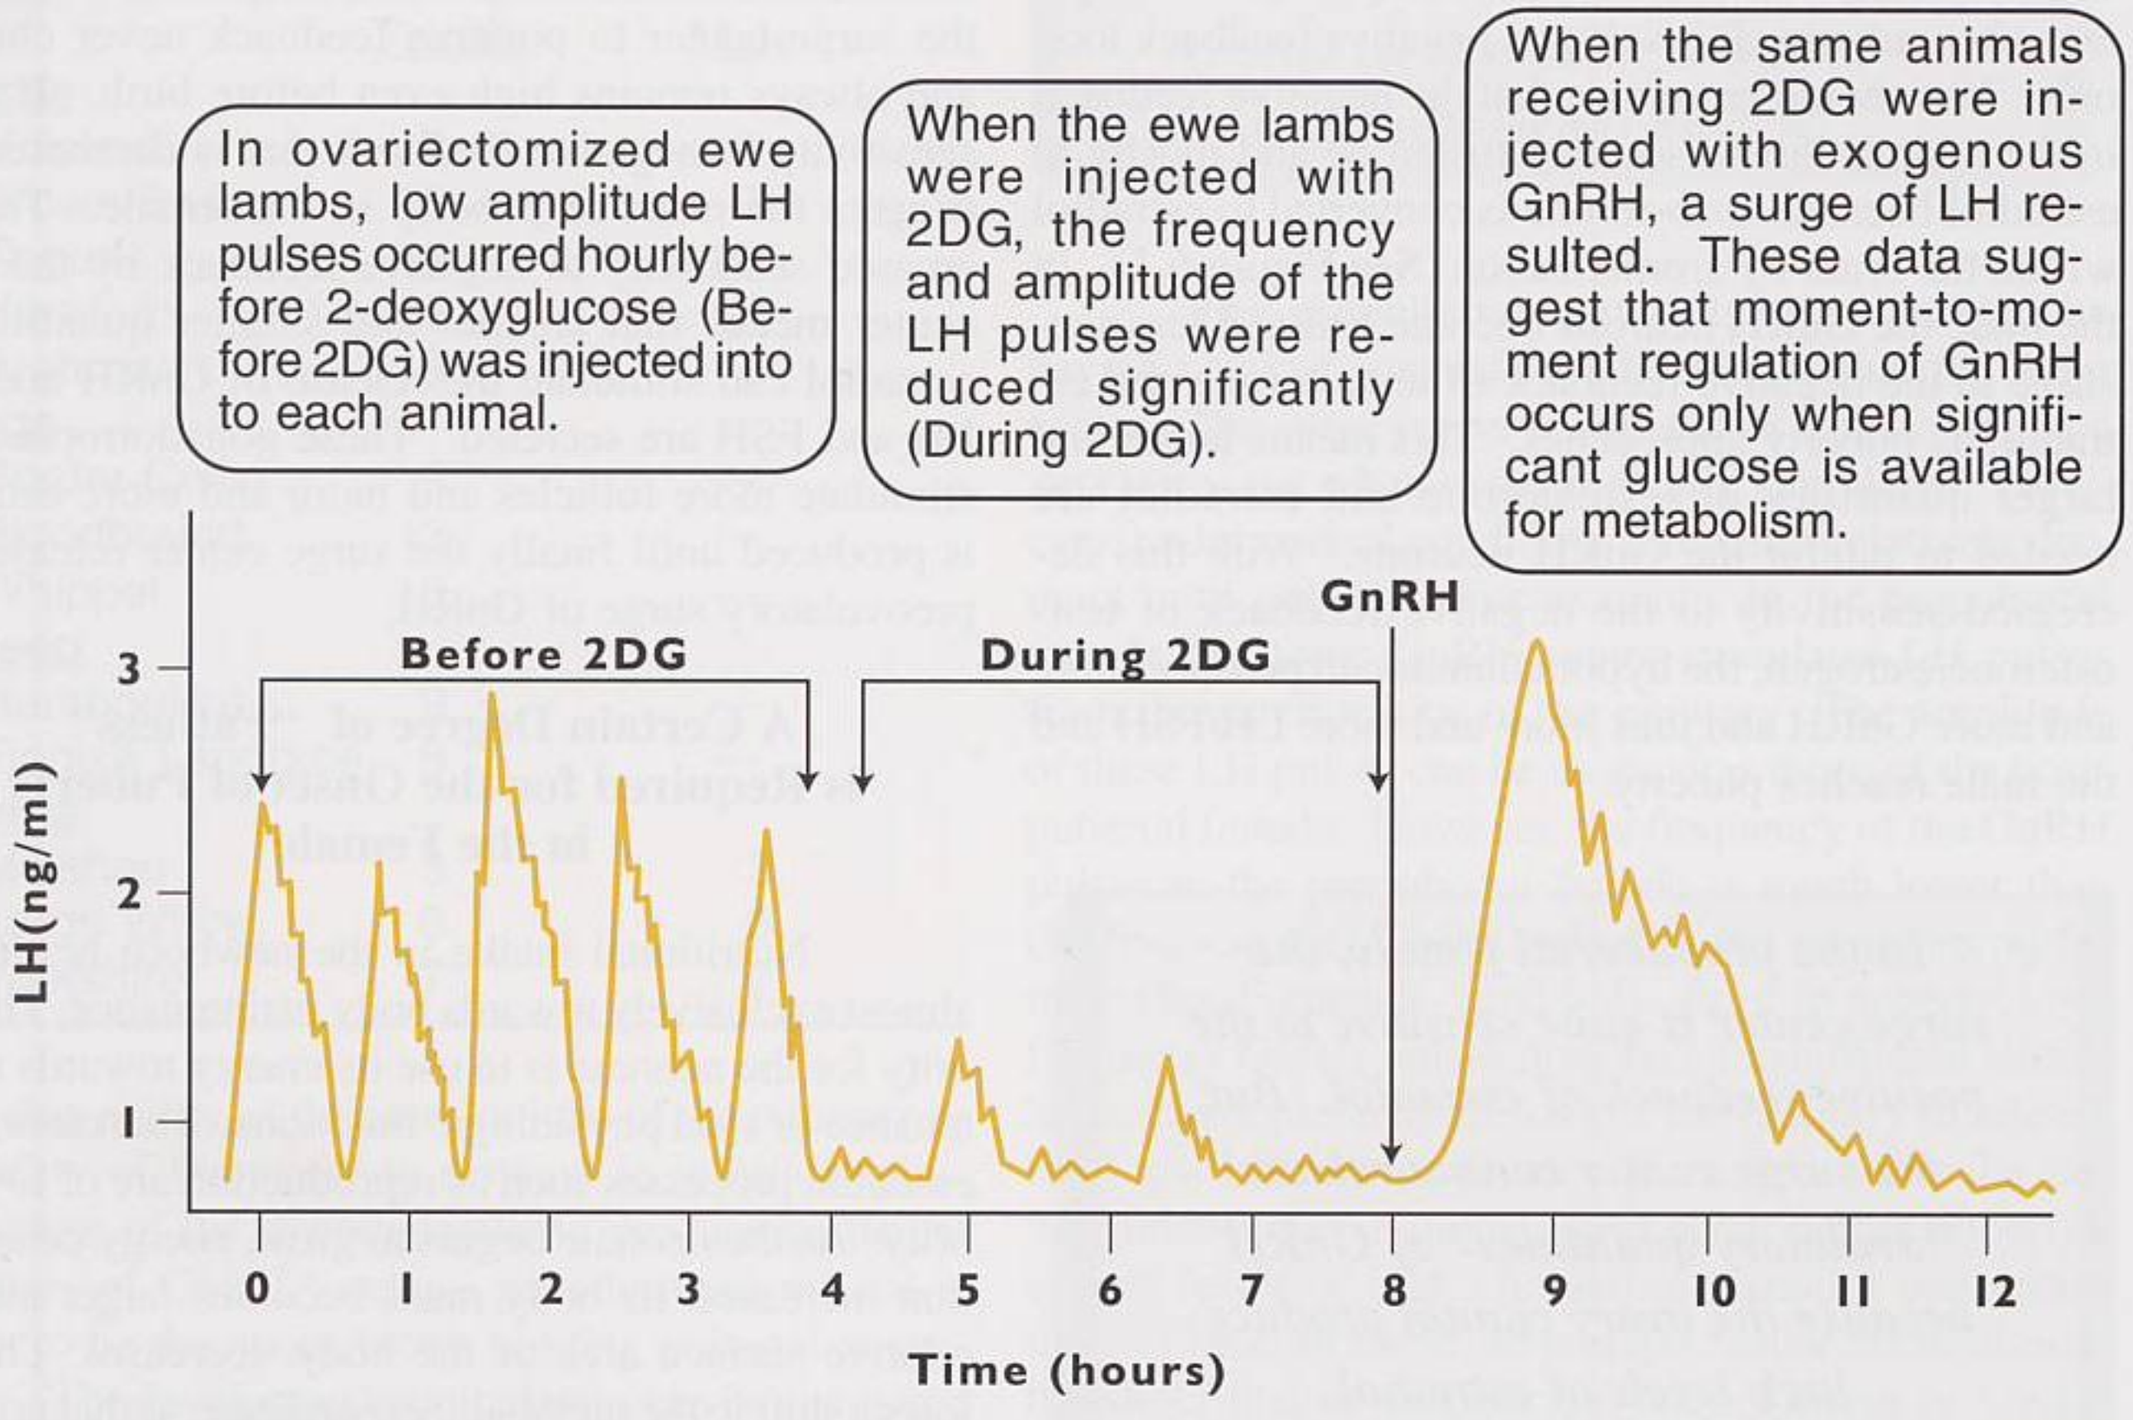
Nutritional intake in the newborn is directed almost exclusively towards body maintenance. The priority for the neonate is to use its energy towards maintenance of vital physiologic functions. Therefore, nonessential processes such as reproduction are of low priority. As the neonate begins to grow, energy consumption increases, its body mass becomes larger and the relative surface area of the body decreases. This allows a shift in the metabolic expenditure so that nonvital physiological functions begin to develop. As this shift occurs, the overall metabolic rate decreases and more internal energy becomes available for nonvital functions. This excess internal energy can be converted into fat stores and the young animal begins to place priority on reproduction and the onset of puberty begins. The threshold level of fat accumulation required for the onset of puberty has not been determined.

It should be emphasized that "fatness" alone does not promote the onset of puberty. Females can be extremely fat at a very young age and not be pubertal. Both body maturation and amount of body fat are important in regulating the age of pubertal onset.

GnRH neurons detect "moment-to-moment" changes in blood glucose and fatty acids.

The central question regarding how metabolic status triggers puberty is, "What metabolic factors affect GnRH neurons and how are these factors recognized?" There is evidence to indicate that initiation of high frequency GnRH pulses is under the influence of

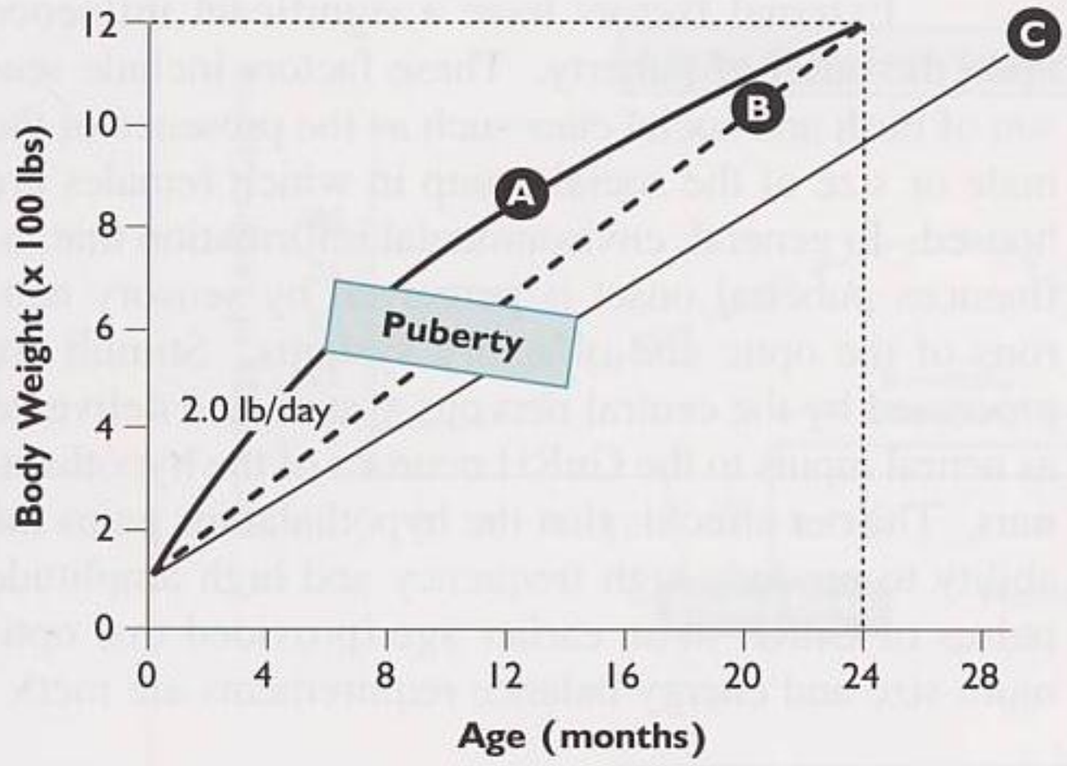
Figure 6-5. Glucose Can Affect Hypothalamic Control of GnRH Secretion
(Modified from Foster, 1994)



glucose and free fatty acid levels in the blood. For example, when female hamsters were treated concurrently with inhibitors of fatty acid (methylpalmoxorate) and glucose oxidation (2-deoxyglucose, 2DG) their estrous cycles were disrupted. The rationale for using inhibitors of glucose and fatty acid oxidation was that these inhibitors reduce available internal energy. Thus, effects on reproduction could be studied while normal energy balance was maintained versus when it was disrupted. When these metabolic inhibitors were injected into ovariectomized prepubertal ewes, pulsatile LH secretion was suppressed almost immediately (See Figure 6-5). The rationale for using ovariectomized ewe lambs was to remove all possible effects of ovarian steroids on the hypothalamus. Thus, the researchers were able to interpret the results based solely on the action of the metabolic inhibitors without confounding effects associated with ovarian steroids. In addition to reduced frequency, the amplitude of the LH pulses also decreased in some sheep. These data strongly suggest that the hypothalamic GnRH neurons (or presynaptic neurons) are sensitive to concentrations of glucose in the circulating blood.

A practical illustration of the impact of nutrition on the age of pubertal onset in dairy heifers is shown in Figure 6-6. A major goal in the management of the dairy heifer is to achieve a successful, uncomplicated birth by 24 months of age. In order for this to occur, appropriate nutrition and adequate body size must be achieved. Figure 6-6 describes the relationship between age and weight of heifers as it relates to the onset of puberty and nutritional level. Curve A illustrates the growth rate and age at onset of puberty (first estrus) when heifers were fed to gain 2.0 pounds per day for the first 12 months. Heifers fed this diet reached puberty between 6 and 8 months. If continued into the second year, this feeding regimen can result in over-conditioned heifers. The second nutritional level (curve B) allows the heifer to reach the same target weight (1200 pounds at 24 months), but heifers grow at a uniform weight of 1.5 pounds per day for the entire 24 month period. All heifers in this group will be in estrus for the first time between 9 and 11 months of age. Growth illustrated in curve C is slower (1.2 pounds per day), resulting from restricted feeding or lower quality feeds. Most of these heifers will reach puberty by 12 months, but they will be too small for successful pregnancy and parturition even though they are capable of becoming pregnant.

Figure 6-6. The Relationship Between Plane of Nutrition, Growth and Average Daily Gains with Onset of Puberty in Dairy Heifers



A = High plane of nutrition (2.0 lb/day average daily gain)
B = Moderate plane of nutrition (1.5lb/day average daily gain)
C = Low plane of nutrition (1.2 lb/day average daily gain)

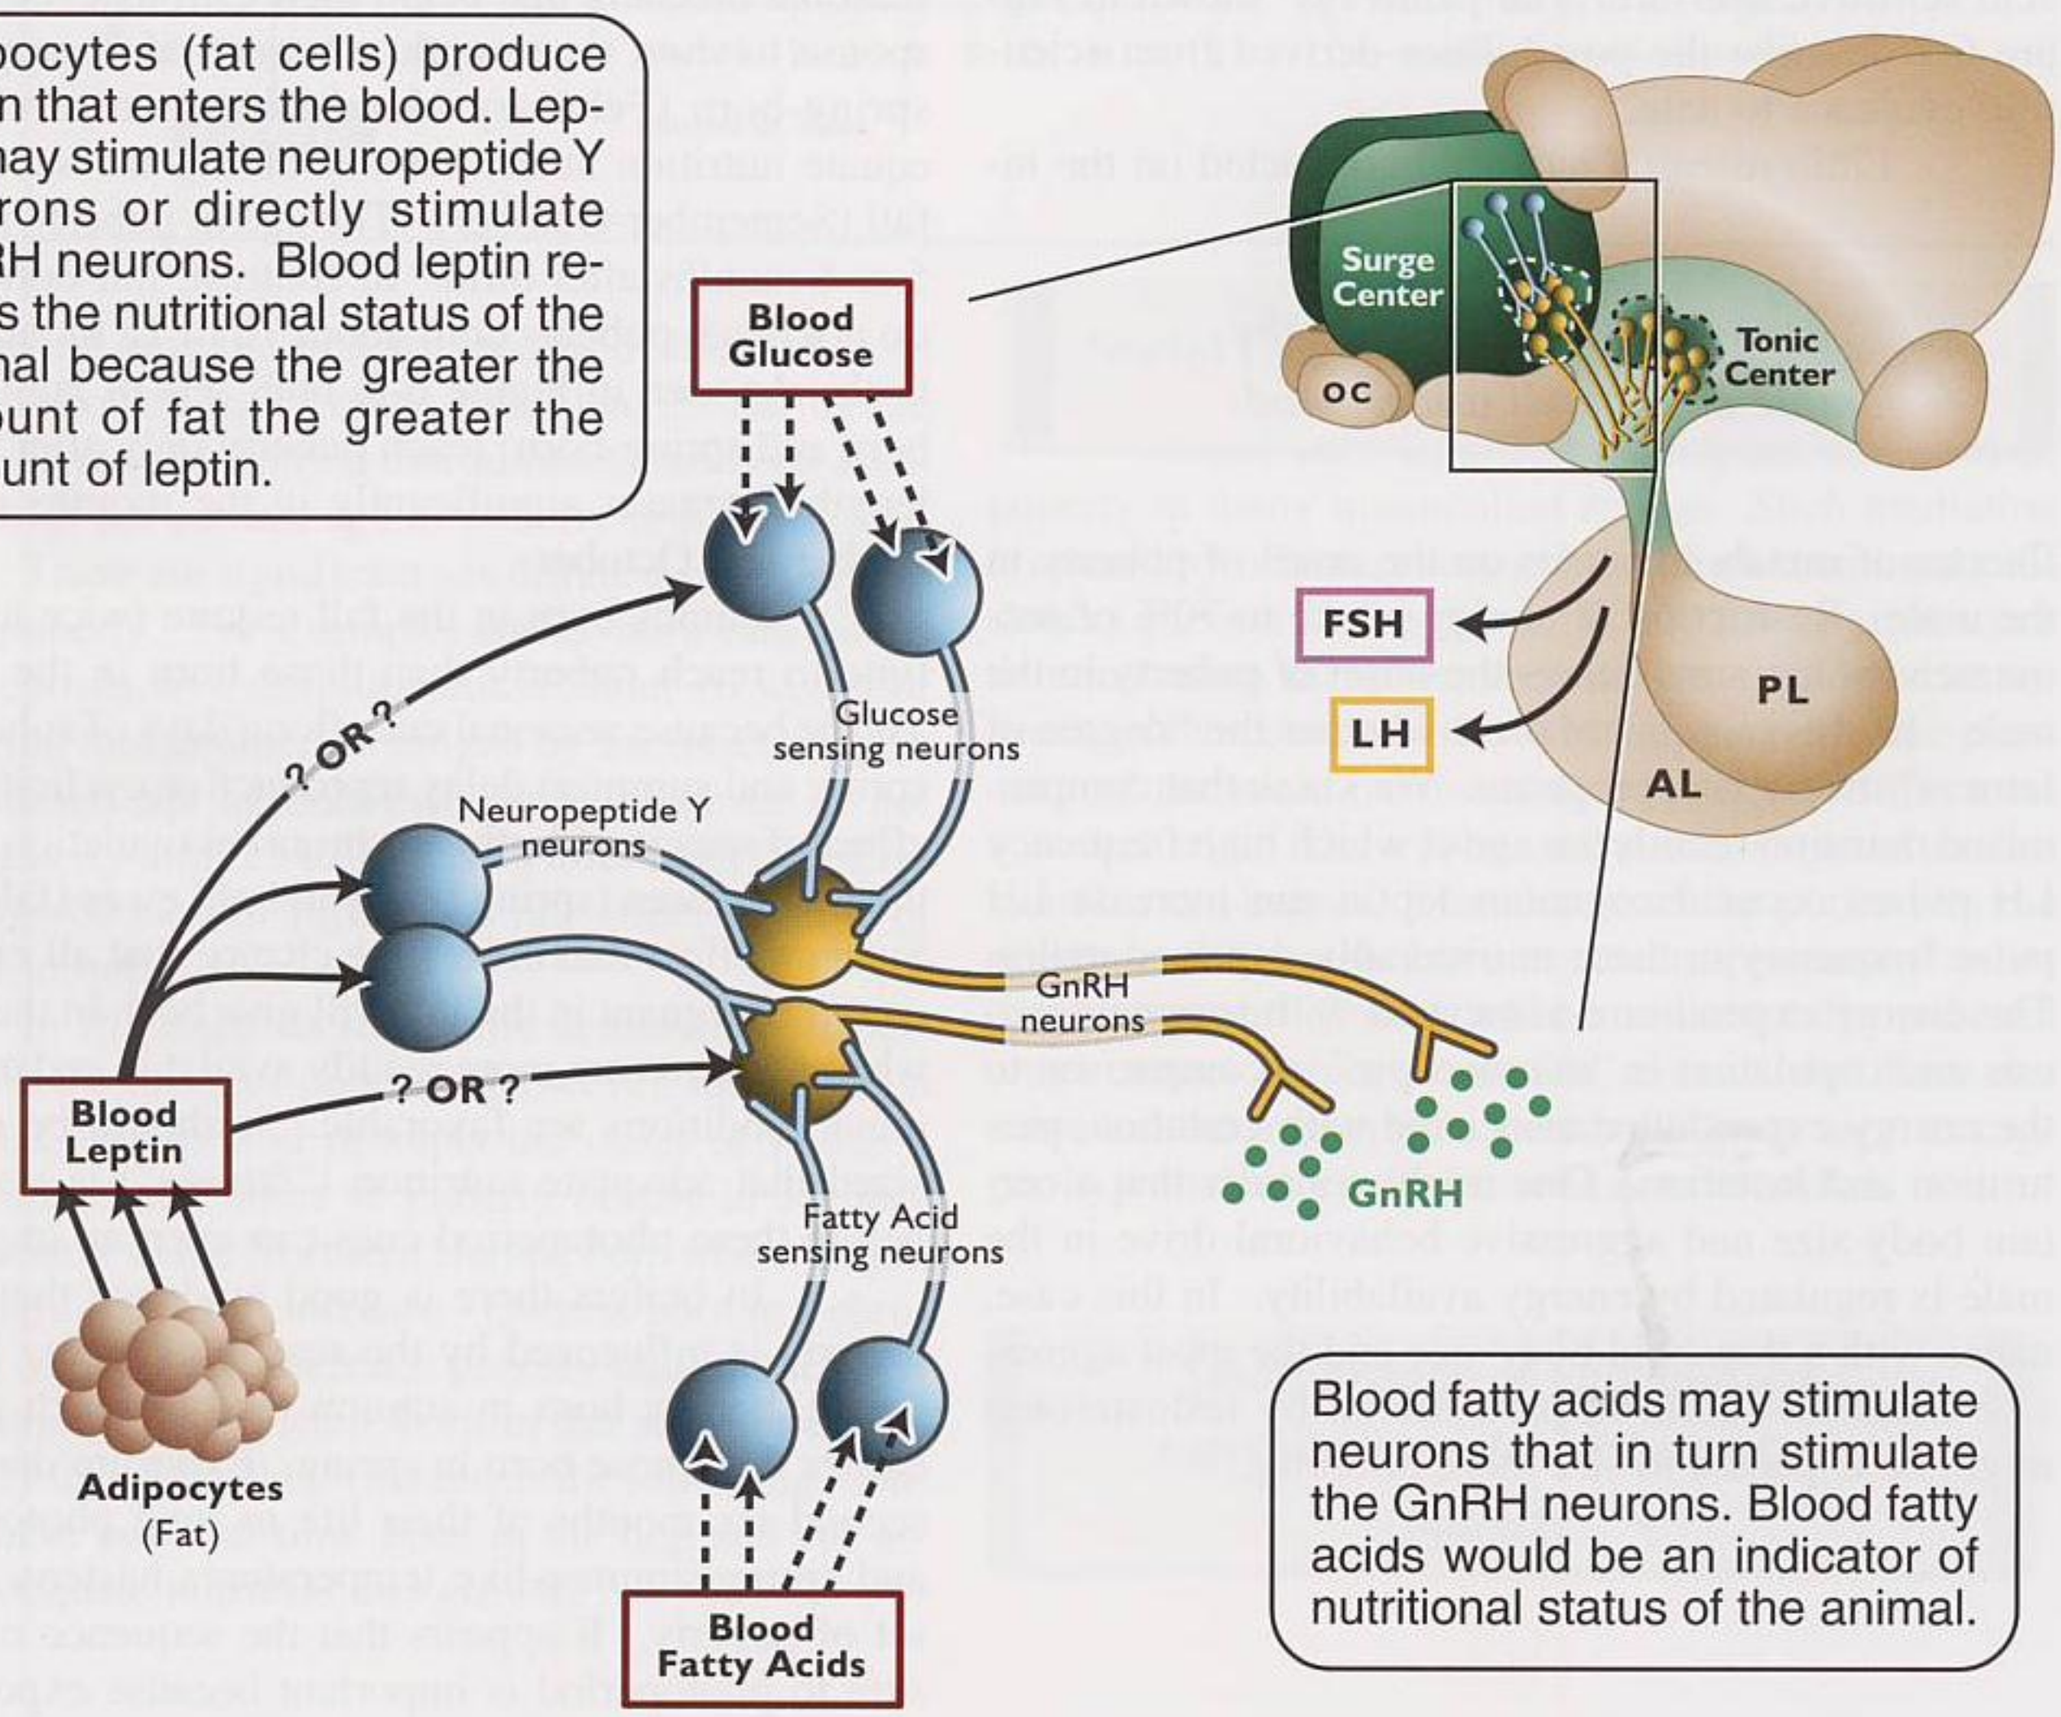
Age at first parturition should be 24 months and the primiparous heifer should weigh 1,200 lb.

(Modified from Head in *Large Herd Dairy Management*, Van Horn and Wilcox, eds. American Dairy Science Association. 1992)

Figure 6-7. Possible Influence of Metabolic Signals Upon GnRH Neurons

Blood glucose levels, another indicator of metabolic status, might stimulate glucose sensing neurons that in turn stimulate GnRH neurons.

Adipocytes (fat cells) produce leptin that enters the blood. Leptin may stimulate neuropeptide Y neurons or directly stimulate GnRH neurons. Blood leptin reflects the nutritional status of the animal because the greater the amount of fat the greater the amount of leptin.



Blood fatty acids may stimulate neurons that in turn stimulate the GnRH neurons. Blood fatty acids would be an indicator of nutritional status of the animal.

Any discussion of the metabolic signals that may influence the onset of puberty would not be complete without mentioning **leptin**. Leptin is a hormonal peptide, discovered in 1994, that is produced by **adipocytes** (fat cells). The amount of leptin in the blood is directly related to the amount of fat in the body. Receptors to leptin are found in the liver, kidney, heart, skeletal muscles and pancreas. The discovery that leptin receptors are also present in the anterior lobe of the pituitary and hypothalamus has sparked significant interest in the possibility that leptin might play an important role in mediating the onset of puberty in mammals. Leptin may be an important signal that "notifies" GnRH neurons that nutritional status is adequate because a threshold degree of "fatness" has been achieved (See Figure 6-7). A recent experimental observation that supports this possibility is that leptin injections increase LH pulse frequency in the prepubertal ram.

The exact mechanisms whereby metabolic signals are detected and converted to hypothalamic neural activity have not been described. It appears that there are three types of presynaptic neurons that can stimulate GnRH neurons. These are: 1) leptin sensitive neurons; 2) glucose sensitive neurons and 3) fatty acid sensitive neurons. The pathways shown in Figure 6-7 describe the possibilities derived from scientific evidence to date.

Little research has been conducted on the influence of metabolic status on the onset of puberty in the male. Restriction of energy intake to 70% of recommended amounts delays the onset of puberty in the male. However, it is not clear whether the "degree of fatness" theory is appropriate. We know that compromised nutrition retards the age at which high frequency LH pulses occur. Exogenous leptin can increase LH pulse frequency in these nutritionally deprived males. The energy expenditure associated with spermatogenesis and copulation is "microscopic" in comparison to the energy expenditure associated with gestation, parturition and lactation. One might consider that a certain body size and aggressive behavioral drive in the male is regulated by energy availability. In this case, males with a threshold body size and the most aggressive behavior (both, in-part, driven by testosterone) might be expected to sire more offspring.

"Fatness" for puberty in the male is not well understood.

Environmental and Social Conditions Impact the Onset of Puberty in the Female

External factors have a significant influence upon the onset of puberty. These factors include season of birth and social cues such as the presence of the male or size of the social group in which females are housed. In general, environmental information that influences pubertal onset is perceived by sensory neurons of the optic and olfactory systems. Stimuli are processed by the central nervous system and delivered as neural inputs to the GnRH neurons of the hypothalamus. The net effect is that the hypothalamus gains the ability to produce high frequency and high amplitude pulses of GnRH at an earlier age (provided that optimum size and energy balance requirements are met).

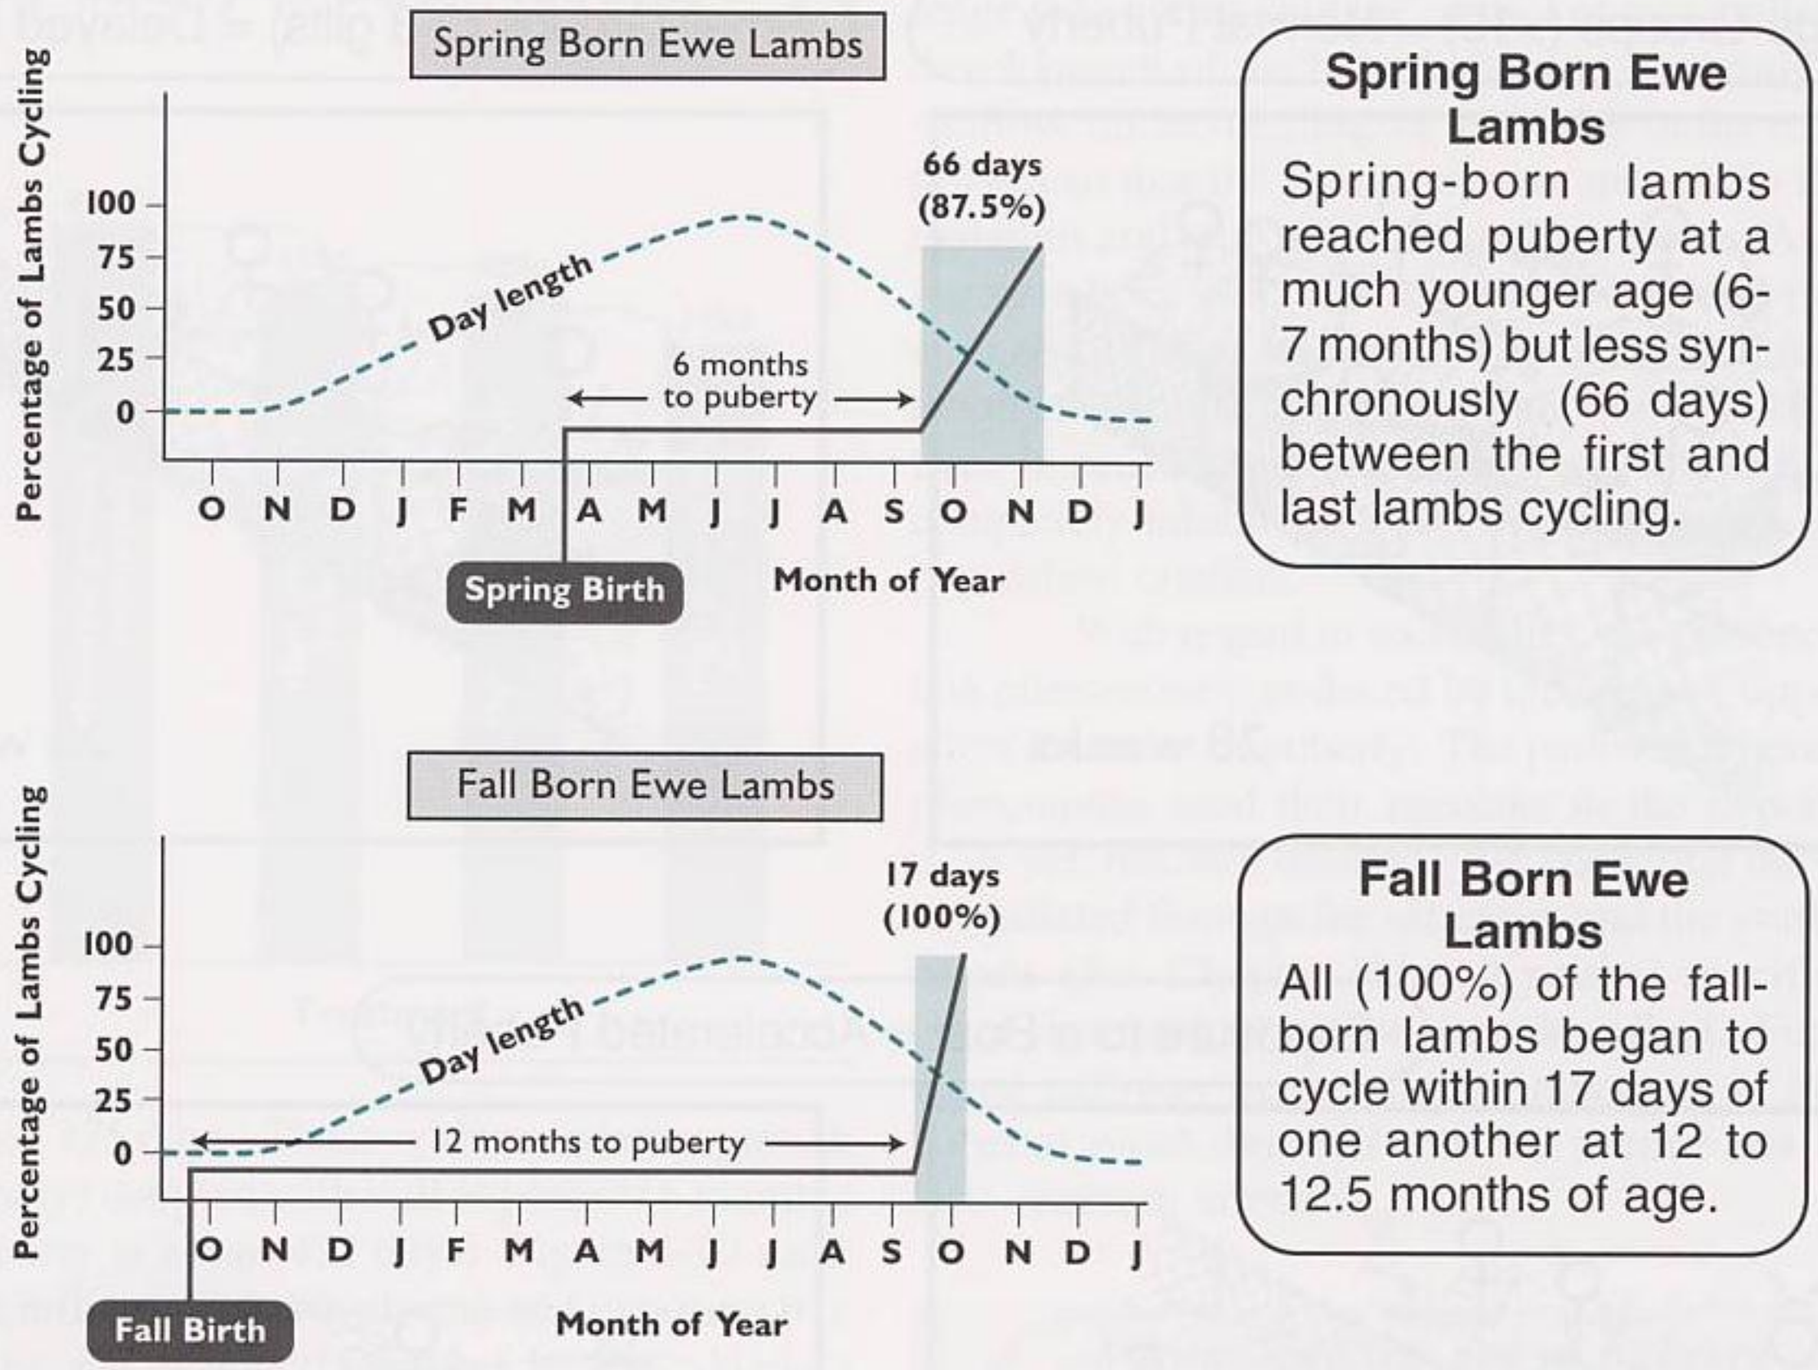
Season of Birth and Photoperiod are Important Modulators of Pubertal Onset

The month of birth will influence the age of puberty, particularly in seasonal breeders, provided no artificial illumination alters natural photoperiod cues. Sheep are a good example of these because they are seasonal breeders that begin their estrous cycles in response to short day lengths. In natural photoperiods, spring-born (February-March) lambs receiving adequate nutrition attain puberty during the subsequent fall (September-October). The age at puberty is about 5 to 6 months after birth. In contrast, fall-born lambs do not reach puberty until about 10 to 12 months after birth. As seen in Figure 6-8, both sets of lambs (fall-born and spring-born) reach puberty only after the day length decreases significantly in the months of September and October.

Lambs born in the fall require twice as much time to reach puberty than those born in the spring. This is because seasonal cues (long days of subsequent spring and summer) delay reproductive cyclicity. This effect of season of birth synchronizes ovulation in both the young ewes (spring born) and old ewes (fall born). Such an effect maximizes the chance that all ewes becoming pregnant in the fall will give birth in the spring when nutrients are more readily available and environment conditions are favorable. It should be emphasized that adequate nutrition ("fatness") is necessary before these photoperiod cues can exert an impact.

In heifers there is good evidence that age at puberty is influenced by the season of birth. For example, heifers born in autumn tend to reach puberty earlier than those born in spring. Exposure during the second six months of their life to long photoperiods and spring/summer-like temperatures hastens the onset of puberty. It appears that the sequence of exposure to photoperiod is important because exposure to

Figure 6-8. The Month of Birth Influences Age of Puberty
(Modified from Foster, 1994)



short days during the first six months of life (fall-born calves) followed by increasing day lengths during the second six months (spring and summer) has been associated with the earliest age of puberty in heifers.

There are significant sex differences in the timing of puberty. For example, spring-born ram lambs begin reproductive development at about 10 weeks of age during midsummer, as judged by the onset of spermatogenesis. Spring-born ewe lambs, however, do not reach puberty until 25 to 35 weeks after birth (See Figure 6-8). Season of birth does not affect the age of puberty in bull calves.

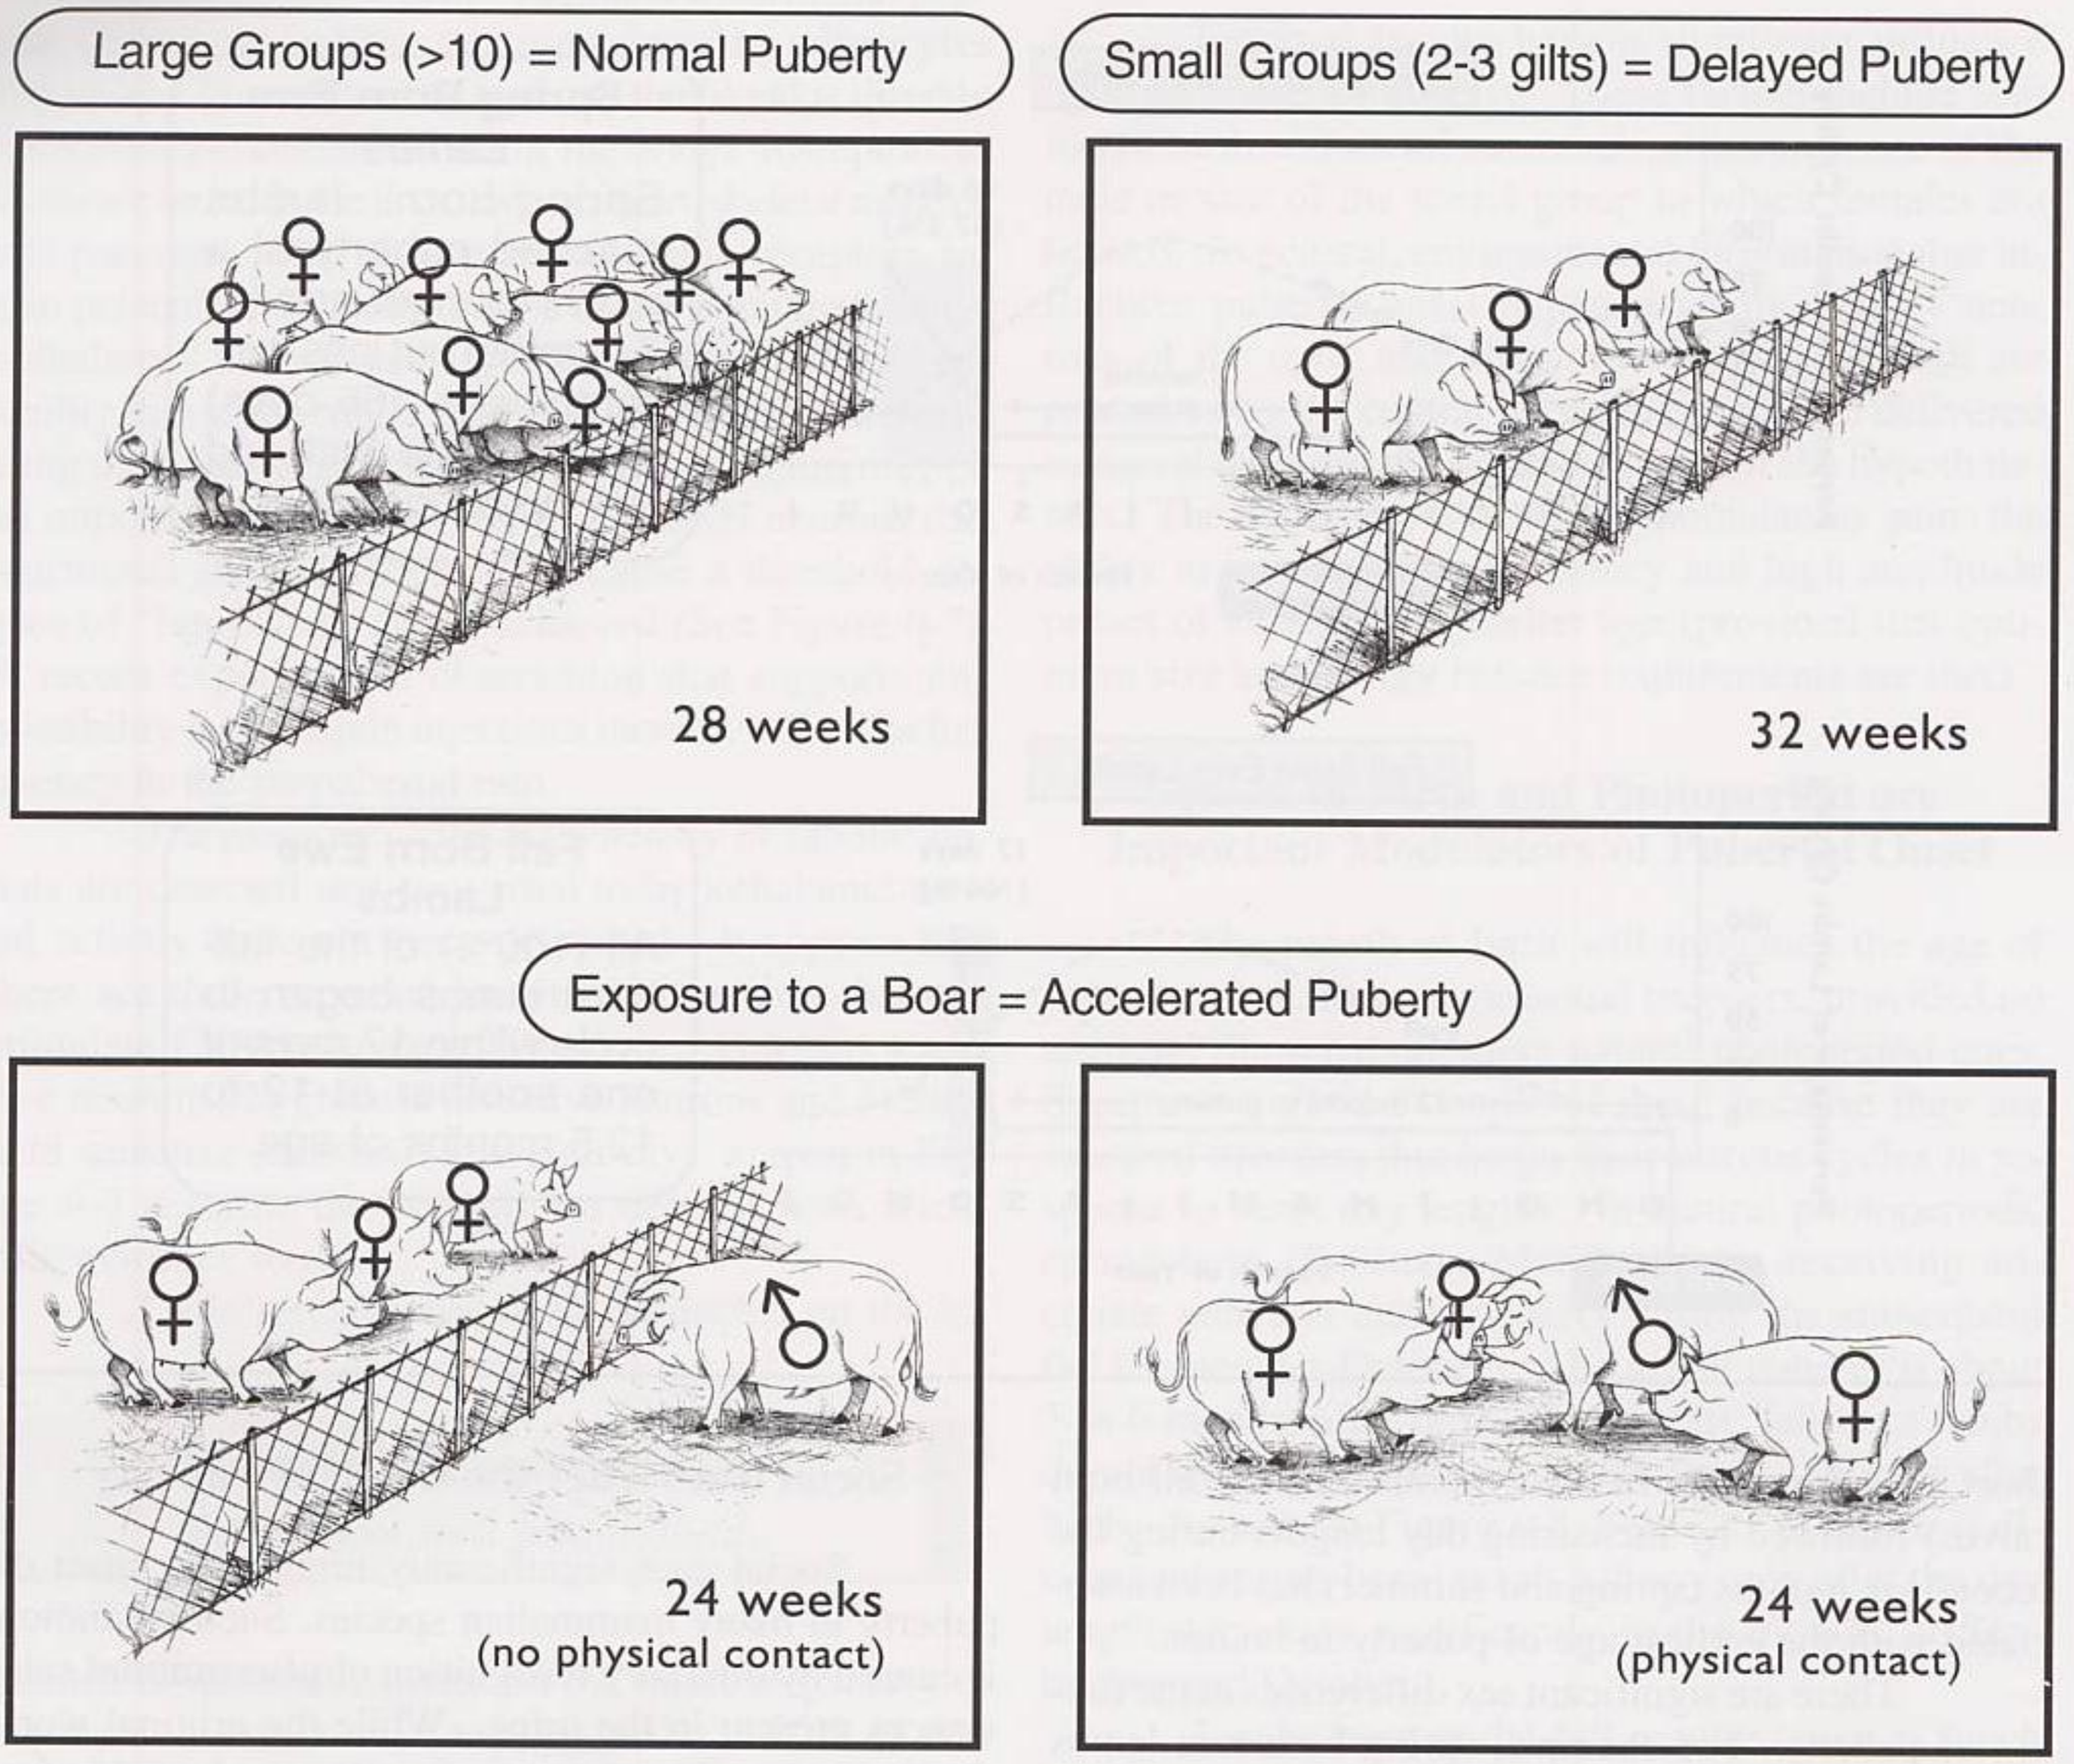
In the bitch there is little seasonality associated with the onset of puberty. However, in the queen increased photoperiod prompts the onset of puberty. For example, the onset of puberty occurs in January and February in the Northern Hemisphere where length of daylight begins to increase. Queens born in February and March may not reach puberty until the following spring. Those queens born in the summer or fall are likely to display their first estrus the following January. These pubertal time lines in the dog and cat assume adequate nutrition and growth.

Social Cues Alter the Onset of Puberty

Social cues significantly impact the onset of puberty in many mammalian species. Such mediation is caused by olfactory recognition of **pheromonal** substances present in the urine. While the original work demonstrating this phenomenon was conducted in rodents, enhancement of the onset of puberty by the presence of the male has been demonstrated in the ewe, sow and cow. The evolutionary advantage of such a stimulus is obvious. Females reaching puberty in the presence of the male have a greater opportunity to become pregnant. One should be reminded that pubertal onset cannot be accelerated in animals that have not achieved the appropriate metabolic body size to trigger hypothalamic responsiveness to estradiol.

Small groups of gilts housed together have delayed onset of puberty.

Figure 6-9. The Effects of Small Groups vs. Male Exposure on the Onset of Puberty



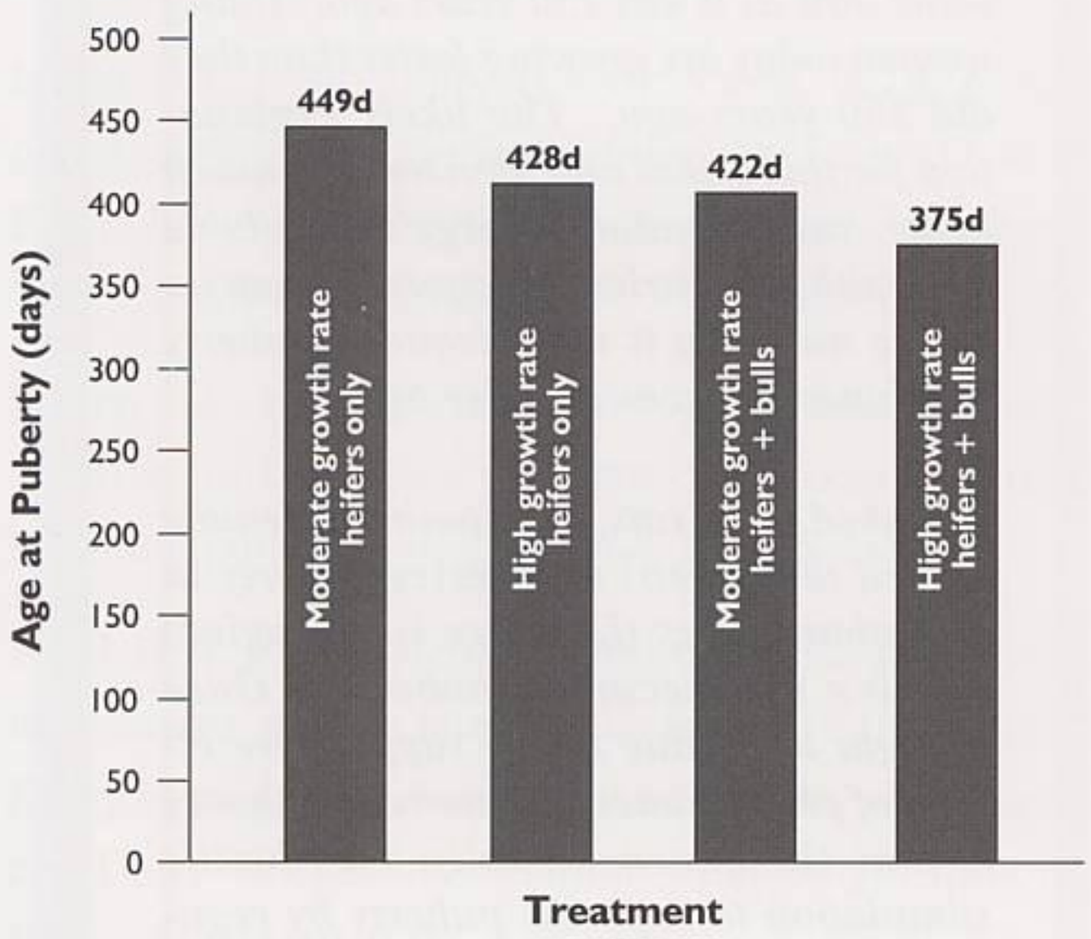
Certain social cues inhibit the onset of puberty. Gilts housed in small groups have delayed puberty when compared to gilts housed in larger groups. If prepubertal gilts are housed in groups of 10 or more, these females will enter puberty at the expected time (28 weeks). However, if the group size is decreased to only two or three gilts, they will enter puberty at a later time than their counterparts housed in larger groups (See Figure 6-9).

Presence of the male hastens the onset of puberty.

Gilts that are housed in small groups and exposed to a boar will enter puberty at an earlier age than either of their large or small grouped counterparts that are not exposed to a boar. An important point to recognize is that the presence of the male, either in visual contact with the females or in direct physical contact with them, will hasten the onset of puberty in gilts (See Figure 6-9). Such observations are valuable for swine management because the age of puberty can be reduced by properly managing the social environment.

Nebraska researchers have shown conclusively that bulls accelerate the onset of puberty in beef heifers. However, there was an interaction between growth rate and exposure to the bull (See Figure 6-10). For example, heifers with a high growth rate (1.75 lb/day) and exposure to a bull for about 6 months reached pu-

Figure 6-10. Influence of Growth Rate and Bull Exposure Upon the Age of Puberty in Beef Heifers



berty at about 375 days. Those with a moderate growth rate (1.4 lb/day) coupled with bull exposure (6 months) reached puberty at about 422 days. Figure 6-10 summarizes the influence of growth rate and exposure to a bull upon the age at puberty in beef heifers. Heifers with a high growth rate that were exposed to the bull attained puberty 74 days earlier than heifers with a moderate growth rate and no exposure to a bull. Heifers with moderate growth rate and exposure to bulls reached puberty 53 days earlier than moderately growing heifers without bulls. Clearly, presence of the bull hastens the onset of puberty in the beef heifer.

Unfortunately, little research has been conducted describing the effect of female-on-male or male-on-male social influences and their impact on the onset of puberty. Virtually all of the research has been conducted describing the influence of the male on the onset of puberty in the female rather than the opposite.

The Story on the Onset of Puberty is Not Complete

As you now know, the onset of puberty involves the capability of the hypothalamic neurons to produce high frequency and high amplitude GnRH pulses. This capability is influenced by achieving the appropriate energy metabolism/body size and appropriate exposure to external modulators such as photoperiod, size of social groups and the presence of the male. Genetics of the animal likely plays a role in how these cues are generated within the animal (metabolic signals) and/or perceived (external cues, metabolic signals).

The exact mechanisms that enable estradiol to control GnRH secretion by the hypothalamus during the peripubertal period are unknown. A major challenge is to understand the impact of metabolism on the development of the hypothalamus. Currently, there is shallow understanding of how the brain recognizes growth so that the proper signals are sent to the hypothalamus and reproduction can commence. As increasing metabolic demands are placed on food producing animals, a better understanding of the impact of metabolism upon hypothalamic function will be imperative. In pets and vermin it may be desirable to delay or completely inhibit the onset of puberty as a means of population control.

With regard to social cues, the presence of certain pheromones produced by the same or opposite sex alters the onset of puberty. The pathway whereby these pheromones send their message to the hypothalamus is, as yet, not well defined. We know that the pathway is mediated through the olfactory and the vomeronasal organs (See Chapter 11), but neither specific agents nor a clear pathway have been described. Further, the visual pathway may be quite important in mediating pubertal onset, but this sensory avenue has received little research attention.

Minimizing the age at puberty in the male is more advantageous than in the female.

From a genetic improvement/reproductive management standpoint, it would be beneficial if the onset of puberty could be shortened, particularly in the male. If one could develop techniques to perturb the system in the male so that spermatogenesis occurs 4 to 6 months earlier (particularly in animals where artificial insemination is practiced), the generation interval could be reduced and genetic improvement could be accelerated. For example, spermatogenesis is initiated in Holstein bulls at between 9 and 11 months. If puberty could be initiated several months earlier, this would mean that semen from genetically superior bulls could be used earlier in the male's life and thus expensive bull maintenance and wasteful accumulation of excessive males could be reduced. This same principle could hold true in swine and poultry where considerable reproductive "down-time" is spent waiting for the onset of puberty in the male. Since the female must maintain a successful pregnancy and deliver live offspring, there is clearly a physiologic limit to hastened pubertal onset in females. Such a limit is not imposed on the male since artificial insemination requires spermatozoa only and does not require that the male reach a threshold body size to support pregnancy and lactation.

Further PHENOMENA for Fertility

An anomaly of the captive environment for the endangered clouded leopard is that males and females must be paired before they reach puberty. If they are housed together after puberty the male becomes very aggressive and frequently injures or even kills the female. This happens even after long introduction efforts with animals kept in adjacent pens and making sure that animals are placed together only when the female is in estrus. This behavior does not happen in the wild.

It is said that puberty begins during the night in children. Concentrations of gonadotropins are low during the day and night in prepubertal children but as the transition into adulthood occurs, the nighttime concentrations also increase as puberty progresses. The notion that night is a special time for maturation is really not true because when the sleep cycle is reversed, the pubertal rises in gonadotropin secretion are also reversed. It seems as if these increases in GnRH secretion are associated with REM (rapid eye movement) stages of sleep, although the physiological and adaptive reasons for this phenomenon are not known.

The famous boys' choirs in Europe consisted entirely of prepubertal boys. It was recognized that their high pitched clear voices were "ruined" during and after puberty. Many of these boys were orchidectomized so that their boyhood voices could be retained. Castrato choirs were composed of adult male singers castrated in boyhood so as to retain soprano or alto voices.

The age of puberty in girls is decreasing. From records kept (in Norway) about the time of menarche (first menses) we know that puberty occurred at about 17 years of age in the mid-1800s. Today, this same reproductive endpoint occurs at 12 years of age in Europe and the US. Interestingly, the body weight at menarche is the same now as it was 150 years ago. Young women today are growing faster than they did 150 years ago. The likely explanation for this is that nutrition today is much better and that more energy is available in wealthy countries. In poorer countries where nutrition is not adequate, puberty continues to occur at older ages.

In naked mole rats, the dominant female (called the queen) suppresses puberty in the subordinates (i.e. there is no vaginal opening that occurs at puberty). Once thought to be due to the suppressive effects of pheromones, a more recent theory is that the queen actually uses tactile stimulation to suppress puberty by regularly having physical contact with each female.

Some young women do not find out until puberty that they are genetically males but their sex cannot be reassigned. The condition is most commonly diagnosed when girls are brought to the clinic because of delayed pubertal progression (no breast development, no menarche). Upon genetic evaluation, such rare individuals are diagnosed as males having a deficiency in receptors for androgens. Clearly, they will never be able to bear children, but they also cannot be treated to become normal males physiologically as exogenous testosterone will have no effect because of the receptor deficiency. The only course of action is to administer estrogens and to produce the secondary sex characteristics typical of a woman. The testes should be removed surgically to prevent the development of carcinomas that are often associated with intra-abdominal testicular tissue.

Victorian women (1837-1901 AD) inserted wooden blocks inside their vaginas to obstruct the passage of sperm.

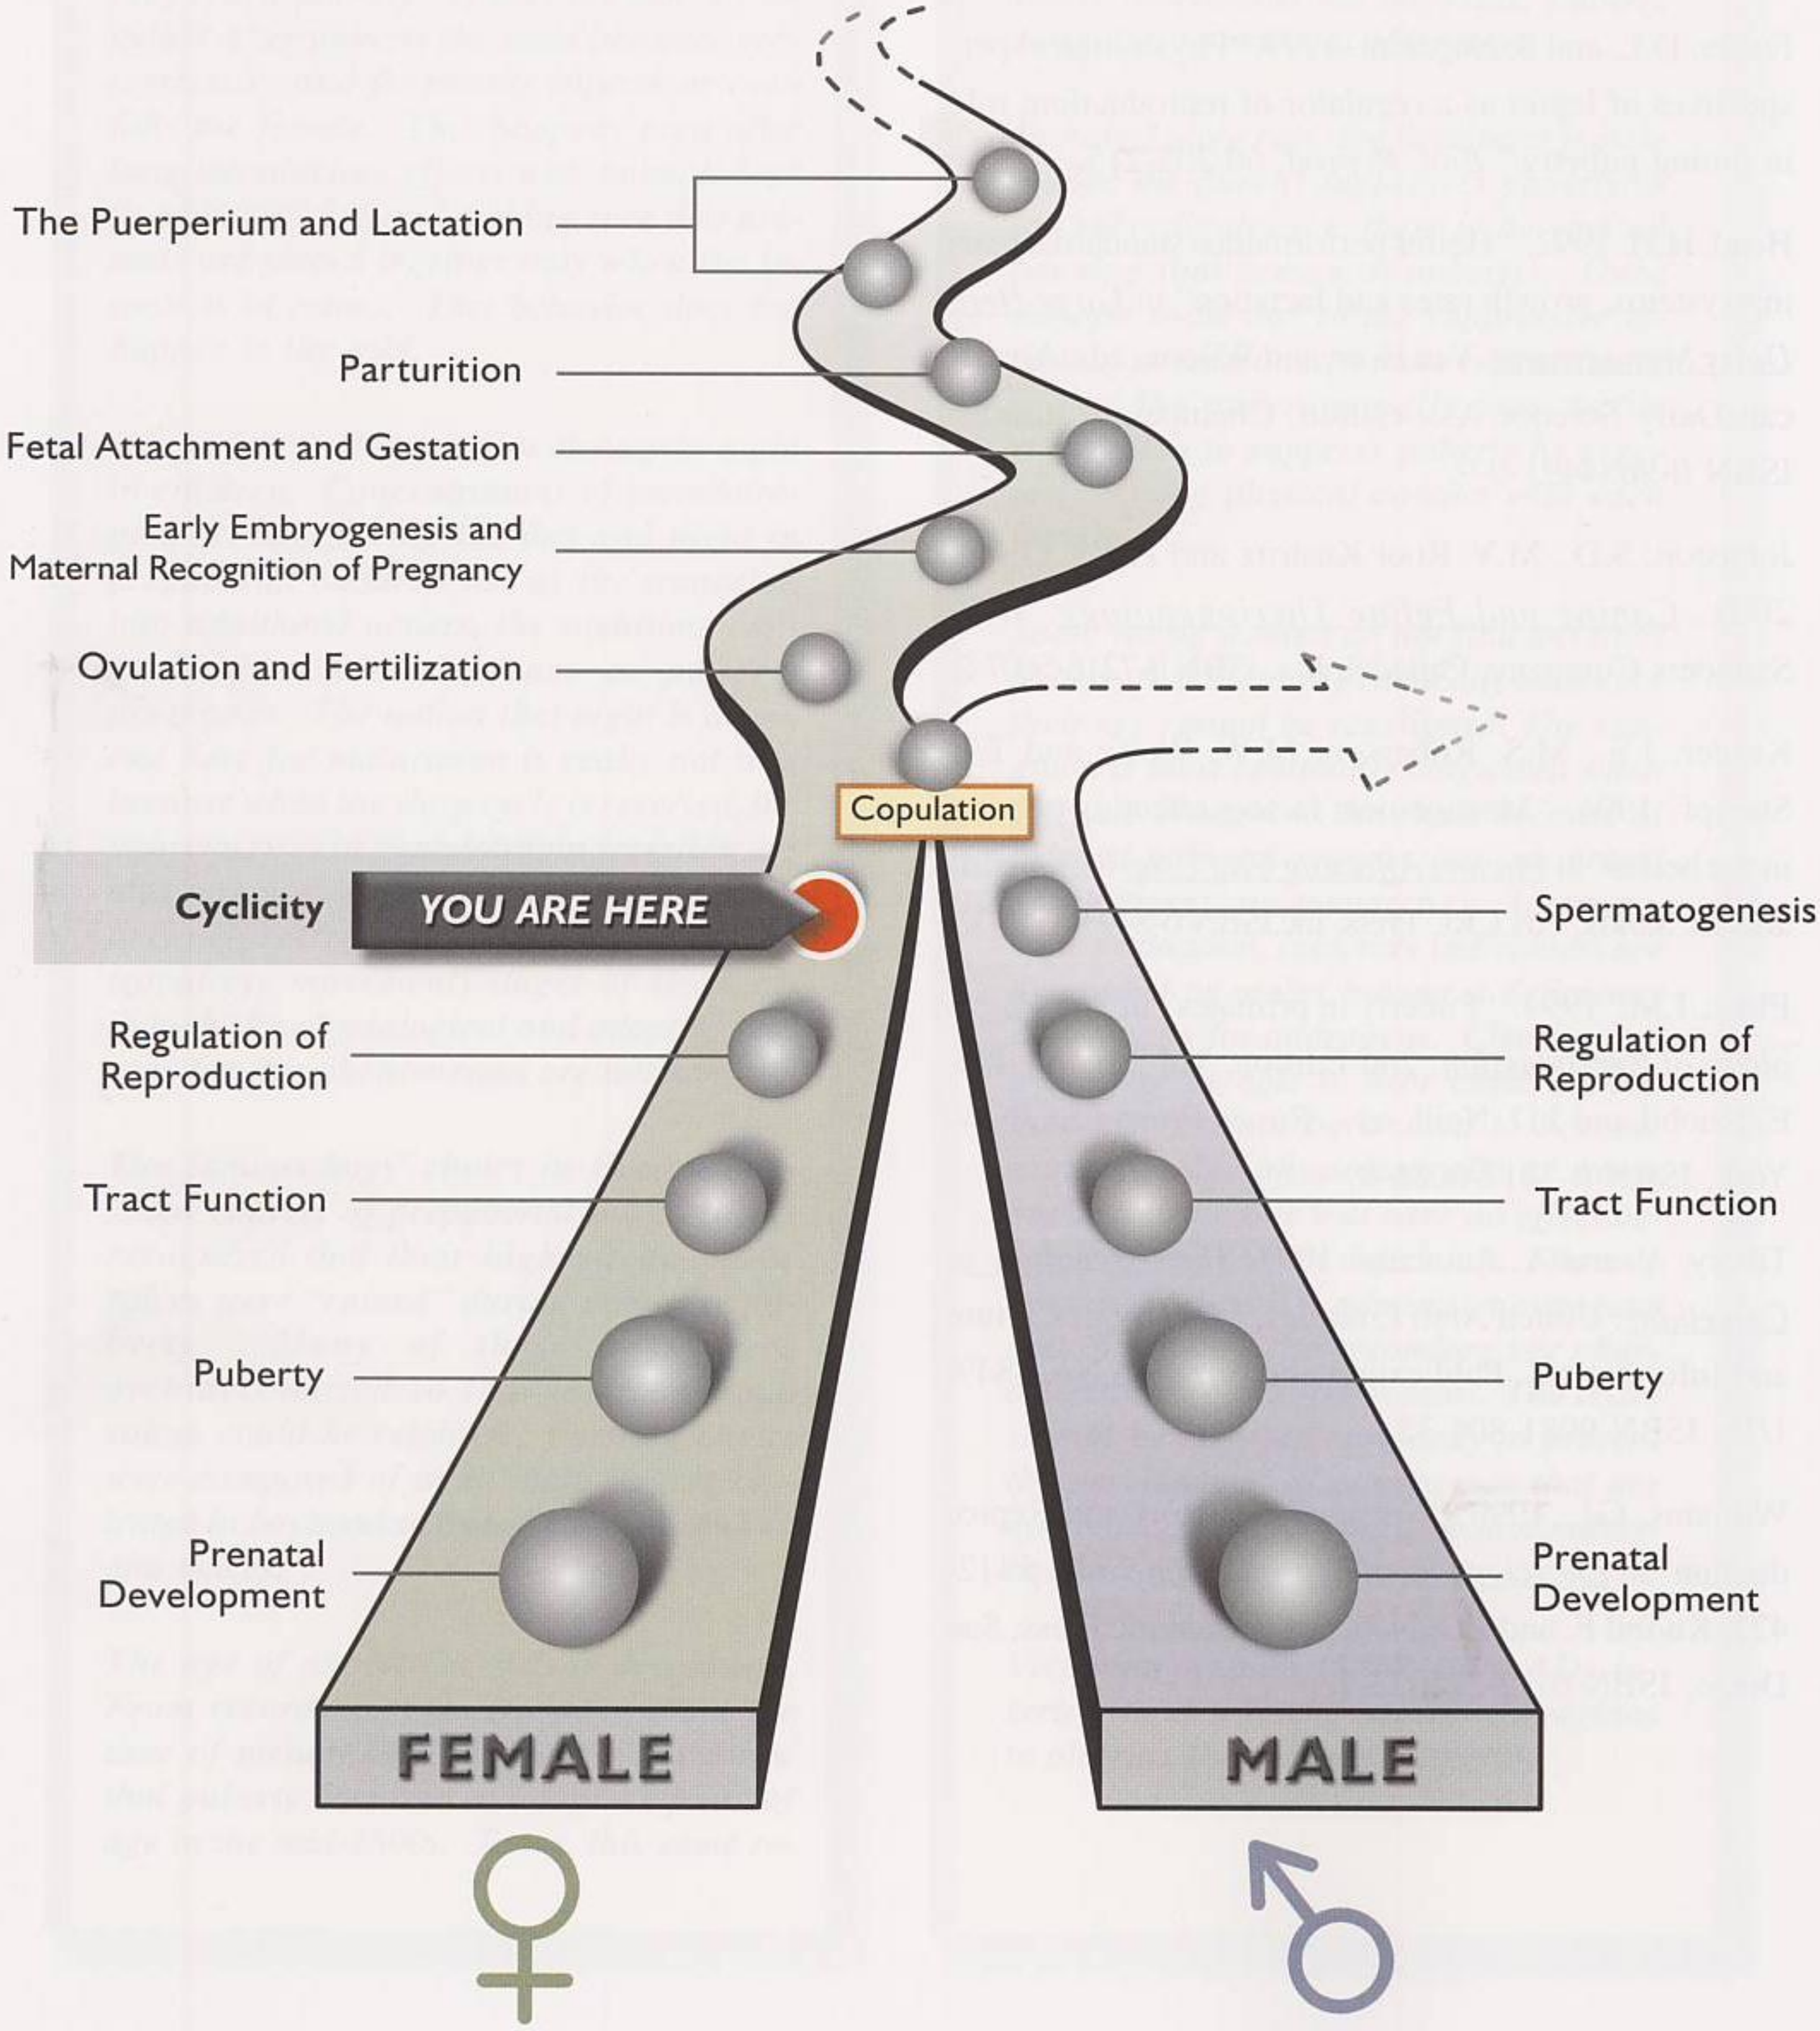
CHAPTER 7

Reproductive Cyclicity - Terminology and Basic Concepts



Take Home Message

Reproductive cyclicity (estrous and menstrual cycles) provides females with repeated opportunities to become pregnant. The two types of reproductive cycles are the estrous cycle and the menstrual cycle.

An estrous cycle consists of the physiologic events that occur between successive periods of sexual receptivity (estrus or heat) and/or ovulations. Each cycle consists of a follicular phase and a luteal phase. The follicular phase is dominated by the hormone estradiol from ovarian follicles. Estradiol causes marked changes in the female tract and initiates sexual receptivity in females with estrous cycles. The luteal phase is dominated by the hormone progesterone from the corpus luteum that prepares the reproductive tract for pregnancy. Periods of time when estrous cycles cease are called anestrus. Anestrus is caused by pregnancy, season of the year, lactation, certain forms of stress and pathology. Amenorrhea refers to the lack of menstrual periods and is caused by many of the same factors that cause anestrus.

A menstrual cycle consists of the physiological events that occur between successive menstrual periods (about 28 days). At the conclusion of the luteal phase in the menstrual cycle, the endometrium is sloughed to the exterior (menstruation). No endometrial sloughing occurs in animals with estrous cycles. Each menstrual cycle consists of 3 distinct phases that reflect the condition of the uterine endometrium. The cycle starts with menses (about a 4-6 day period) where the endometrium is sloughed to the exterior. The second phase (about 9 days) is the proliferative phase in which follicles develop and produce estradiol. The endometrium begins to grow and increase in thickness. The final phase, the secretory phase (14 days), is dominated by the corpus luteum that produces progesterone and estradiol. The endometrium grows and continues to increase in thickness as a function of progesterone. At the end of this 28 day period the endometrium begins to slough again if the female is not pregnant.

This chapter will provide you with fundamental knowledge about reproductive cyclicity. Among mammals, reproductive cyclicity consists of the estrous cycle and the menstrual cycle. Both types of cycles provide the female with repeated opportunities to become pregnant. The fundamental differences between these types of reproductive cycles will be presented in the two sections that follow entitled, **Estrous Cycles** and the **Menstrual Cycle**. There are species exceptions to some of the principles described. Most of these exceptions will be described in later chapters especially Chapters 8 and 9 that deal specifically with the follicular and luteal phases.

ESTROUS CYCLES

After puberty, the female enters a period of reproductive **cyclicity** that continues throughout most of her life.

Estrous cycles consist of a series of predictable reproductive events beginning at **estrus** (heat) and ending at the subsequent estrus. They continue throughout the adult female's life and are interrupted by pregnancy, nursing and by season of the year in some species. Cyclicity may also cease if nutrition is inadequate or environmental conditions are unusually stressful. Pathologic conditions of the reproductive tract, such as uterine infection, persistent corpora lutea or a mummified fetus may also cause **anestrus** (a period when cyclicity stops). **Estrous cycles** provide females with repeated opportunities to copulate and become pregnant. Sexual receptivity and copulation are the primary behavioral events that occur during estrus. Copulation generally occurs early in the estrous cycle and takes place prior to ovulation. If conception (pregnancy) does not occur, another estrous cycle begins, providing the female with another opportunity to mate and conceive. When conception does occur, the female enters a period of **anestrus** that ends after **parturition** (giving birth), **uterine involution** (acquisition of normal uterine size and function) and **lactation**.

<u>Author's Note:</u> *After years of teaching about reproductive cyclicity and listening to repeated student feedback, I have concluded that developing a thorough understanding of the estrous cycle in animals makes understanding the menstrual cycle very easy. The reverse is not necessarily true.*

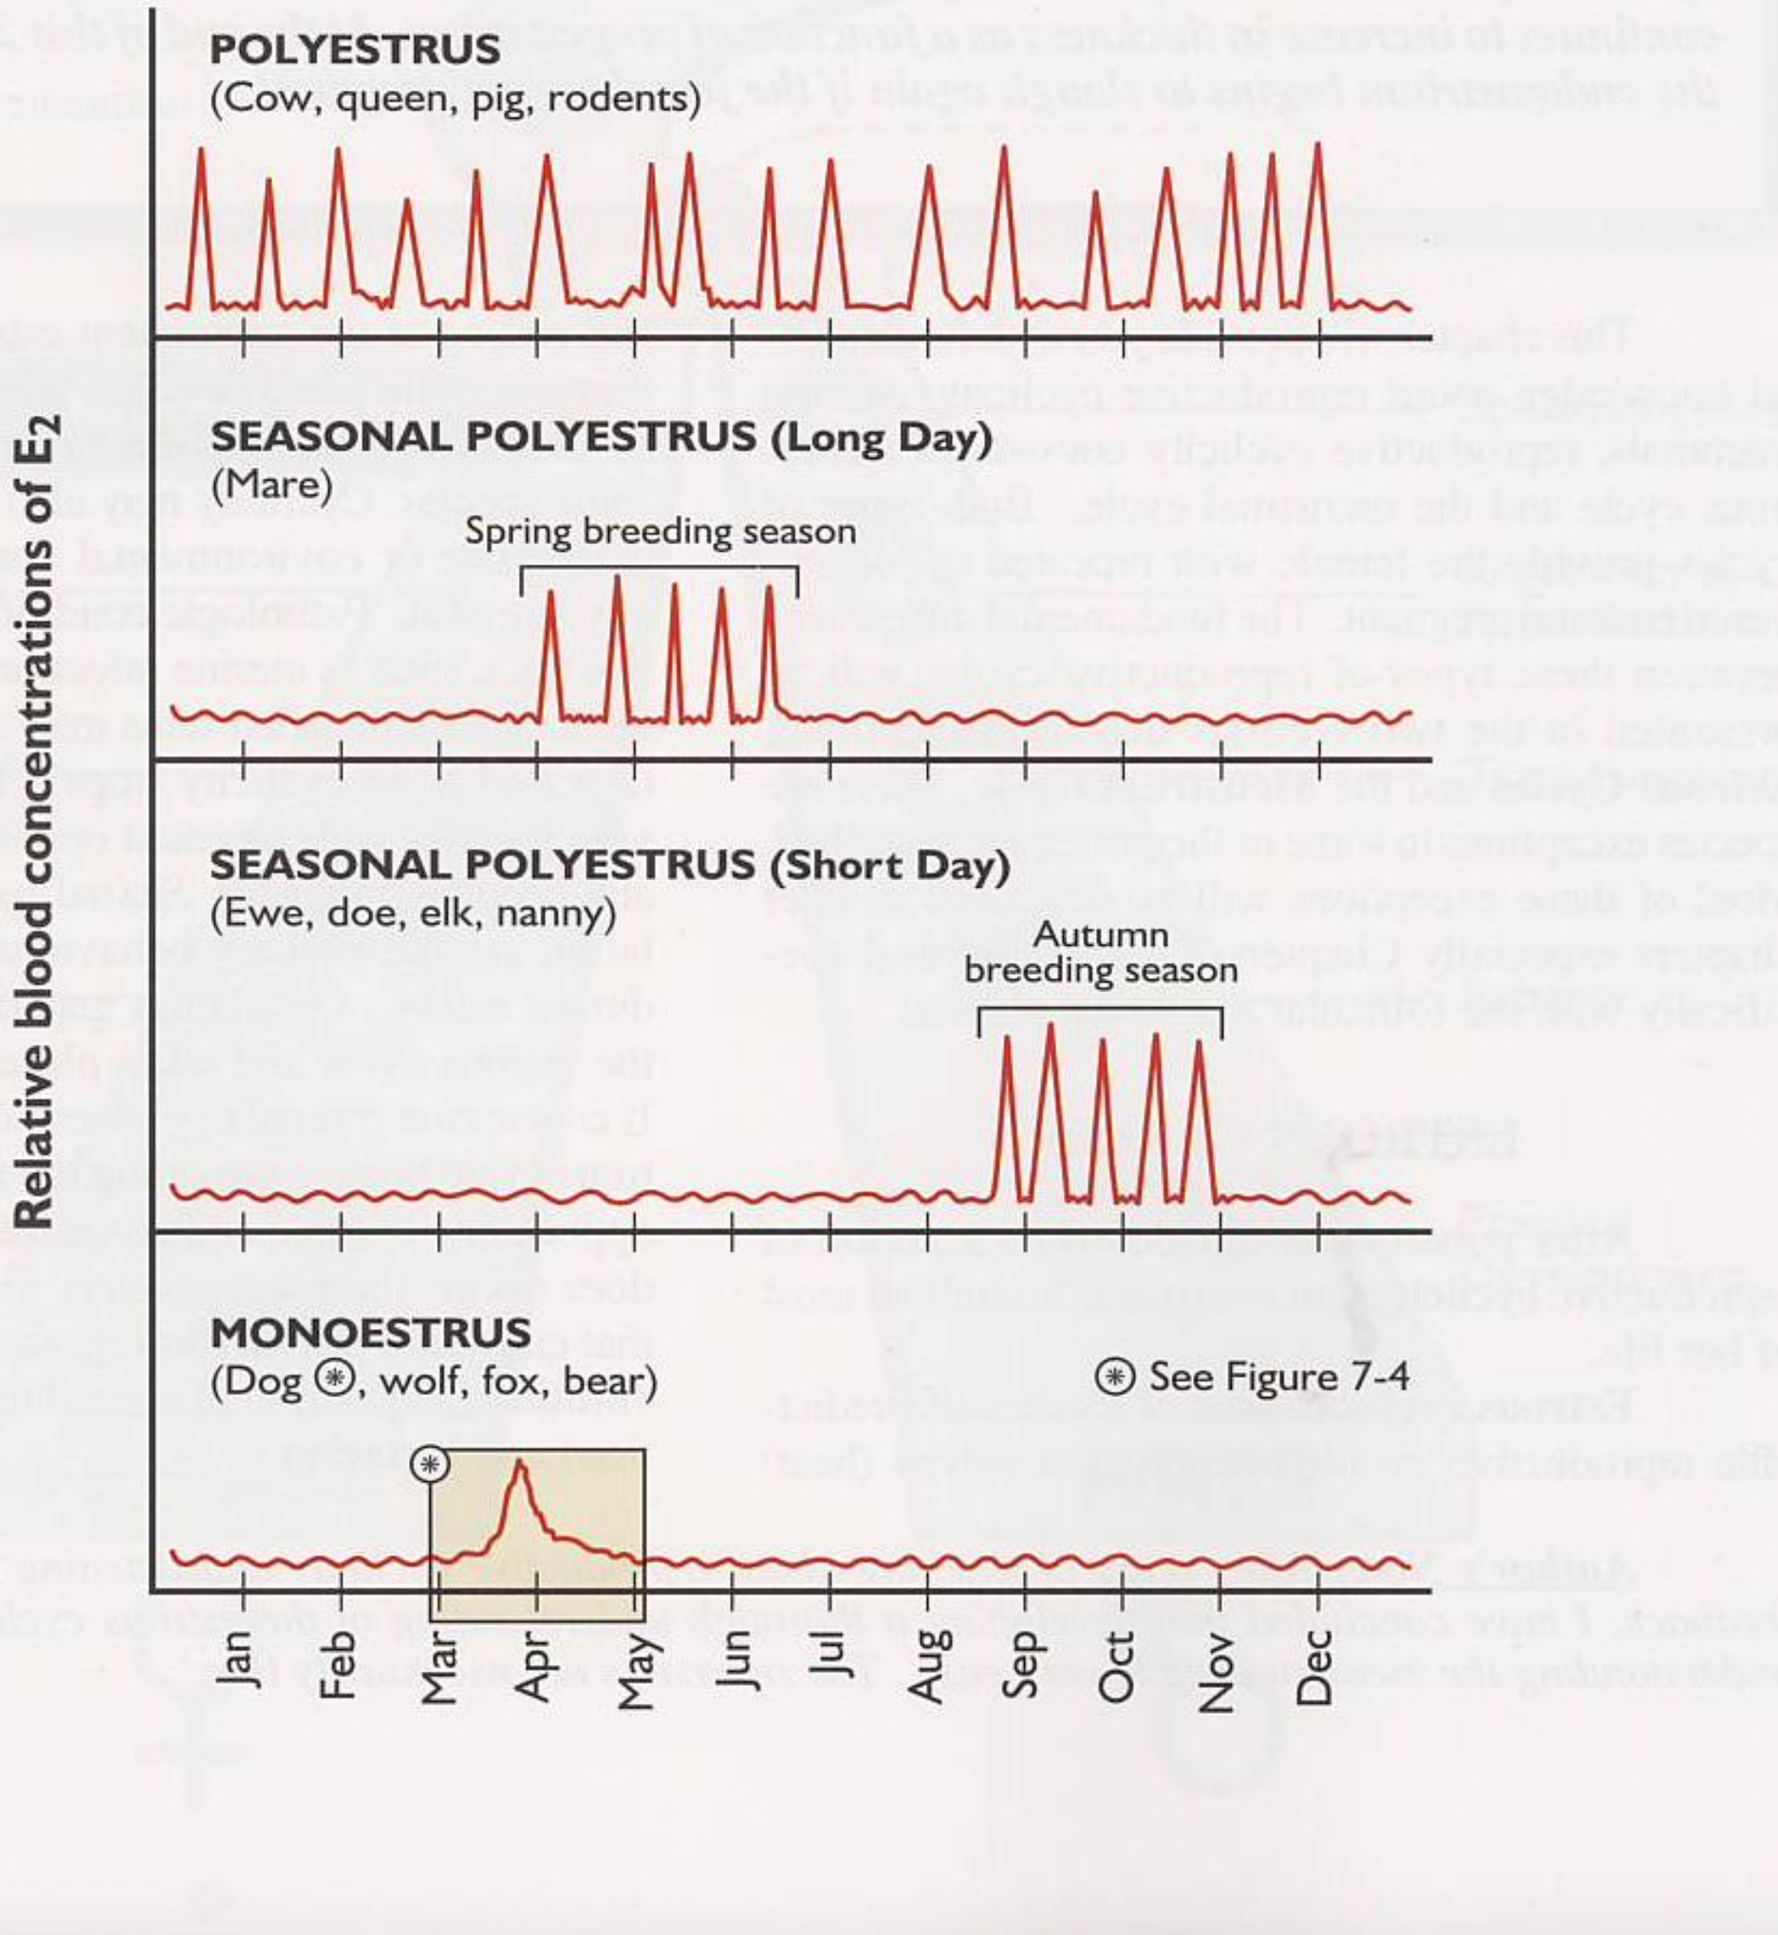
Terminology Describing Reproductive Cyclicity can be Confusing

The words used to describe the estrous cycle are spelled similarly, but have subtly different meanings. The proper use of the words **estrus** and **estrous** must be understood to prevent confusion. The word estrus is a noun, while estrous is an adjective. **Oestrus** and **oestrous** are the preferred spellings in British and European literature. **Estrual** is also an adjective and is used to identify a condition related to estrus. For example, an estrual female is a female in estrus. An estrous cycle is the period between one estrus and the next. Estrus is the period of sexual receptivity. Estrus is commonly referred to as **heat**. The term estrus (oestrus) originated from a Greek word meaning "gadfly, sting or frenzy". This word (oestrus) was used to describe a family of parasitic biting insects (*Oestridae*). These insects caused cattle to stampede with their tails flailing in the air as the insect buzzed around them. The behavior occurring in females in estrus was deemed similar to that observed during these insect attacks. Thus, the term oestrus or estrus was applied to the period of sexual receptivity in mammalian females. Another common term used to describe reproductive pattern is **season**. This refers to several estrous cycles that may occur during a certain season of the year. For example, a mare "coming into season" begins to show cyclicity and visible signs of estrus. She will cycle several times during her "season" (See Figure 7-1).

ESTRUS is a noun.
"The cow is displaying estrus."

ESTROUS is an adjective.
"The length of the estrous cycle in the pig is 21 days."

Figure 7-1. Types of Estrous Cycles as Reflected by Annual Estradiol (E_2) Profiles



Examples of other words that can lead to confusion in spelling and usage are: **anestrous** vs. **anestrus** and **polyestrous** vs. **polyestrus**. If the word is used as an adjective, it is spelled **-ous**. For example, "polyestrous females have repeated estrous cycles." If the word is used as a noun, it is spelled **-us**. For example, "the female is experiencing anestrus."

The three types of cyclicity are:

- ***polyestrus***
- ***seasonally polyestrus***
- ***monoestrus***

Estrous cycles are categorized according to the frequency of occurrence throughout the year. These classifications are **polyestrus, seasonally polyestrus** and **monoestrus** (See Figure 7-1). Polyestrous females, such as cattle, swine and rodents, are characterized as having a uniform distribution of estrous cycles that occur regularly throughout the entire year. Polyestrous females can become pregnant throughout the year without regard to season. Seasonally polyestrous females (sheep, goats, mares, deer and elk) display "clusters" of estrous cycles that occur only during a certain season of the year. For example, sheep and goats are **short-day breeders** because they begin to cycle as day length decreases (autumn). In contrast, the mare is a **long-day breeder** because she initiates cyclicity as day length increases in the spring.

Monoestrous females are defined as having only one cycle per year. Dogs, wolves, foxes and bears are animals that are characterized as having a single estrous cycle per year. Domestic canids typically have three estrous cycles every two years but they are generally classified as monoestrus. In general, monoestrous females have periods of estrus that last for several days. Such a prolonged period of estrus increases the probability that mating and pregnancy can occur. Each type of cycle pattern is represented in Figure 7-1.

The Estrous Cycle Consists of Two Major Phases

The estrous cycle can be divided into two distinct phases that are named after the dominant structure present on the ovary during each phase of the cycle. These divisions of the estrous cycle are the **follicular phase** and the **luteal phase**. The follicular phase is the period from the regression of corpora lutea to ovulation. In general, the follicular phase is relatively short, encompassing about 20% of the estrous cycle (See Figure 7-2). During the follicular phase, the primary ovarian structures are growing dominant follicles that produce the primary reproductive hormone, **estradiol**.

During the follicular phase:

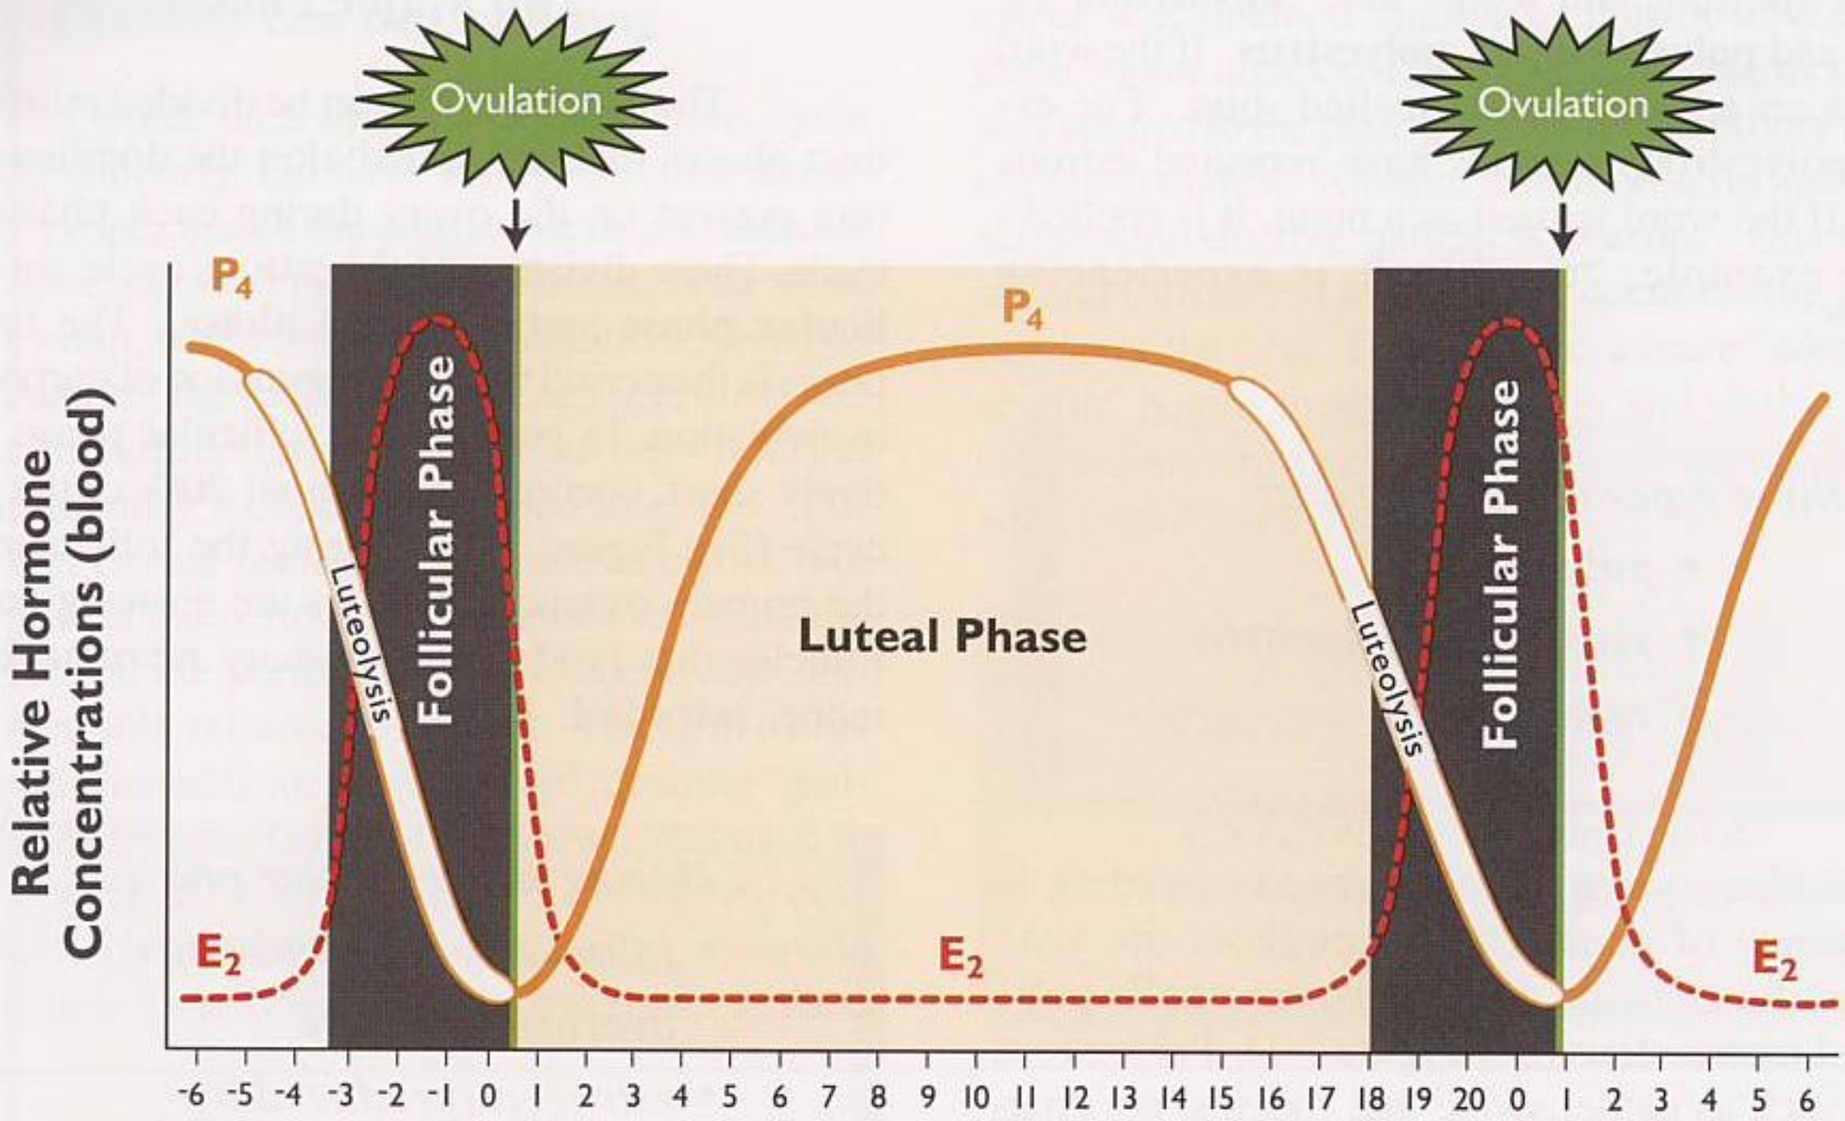
- ***follicles = the dominant ovarian structure***
- ***estrogen (produced by follicles) = the dominant hormone***

The **luteal phase** is the period from ovulation until corpora lutea regression. The luteal phase is much longer than the follicular phase and, in most mammals, occupies about 80% of the estrous cycle (See Figure 7-2). During this phase, the dominant ovarian structures are the corpora lutea (CL) and the primary reproductive hormone is **progesterone**. Even though the luteal phase is dominated by progesterone from the CL, follicles continue to grow and regress during this phase but they do not produce high concentrations of E_2. Details of follicular growth are presented in Chapter 8.

During the luteal phase:

- ***corpora lutea = the dominant ovarian structures***
- ***progesterone (produced by corpora lutea) = the dominant hormone***

Figure 7-2. Phases of the Estrous Cycle



The follicular phase begins after luteolysis that causes the decline in progesterone. Gonadotropins (FSH and LH) are therefore produced that causes follicles to produce estrogen (E_2). The follicular phase is dominated by E_2 produced by ovarian follicles. The follicular phase ends at ovulation. Estrus is designated as day 0.

The luteal phase begins after ovulation and includes the development of corpora lutea that produce progesterone (P_4). The luteal phase also includes luteolysis that is brought about by prostaglandin $F_{2\alpha}$.

7

Follicular phase = Proestrus + Estrus
Luteal phase = Metestrus + Diestrus

The Estrous Cycle can be Divided into Four Stages

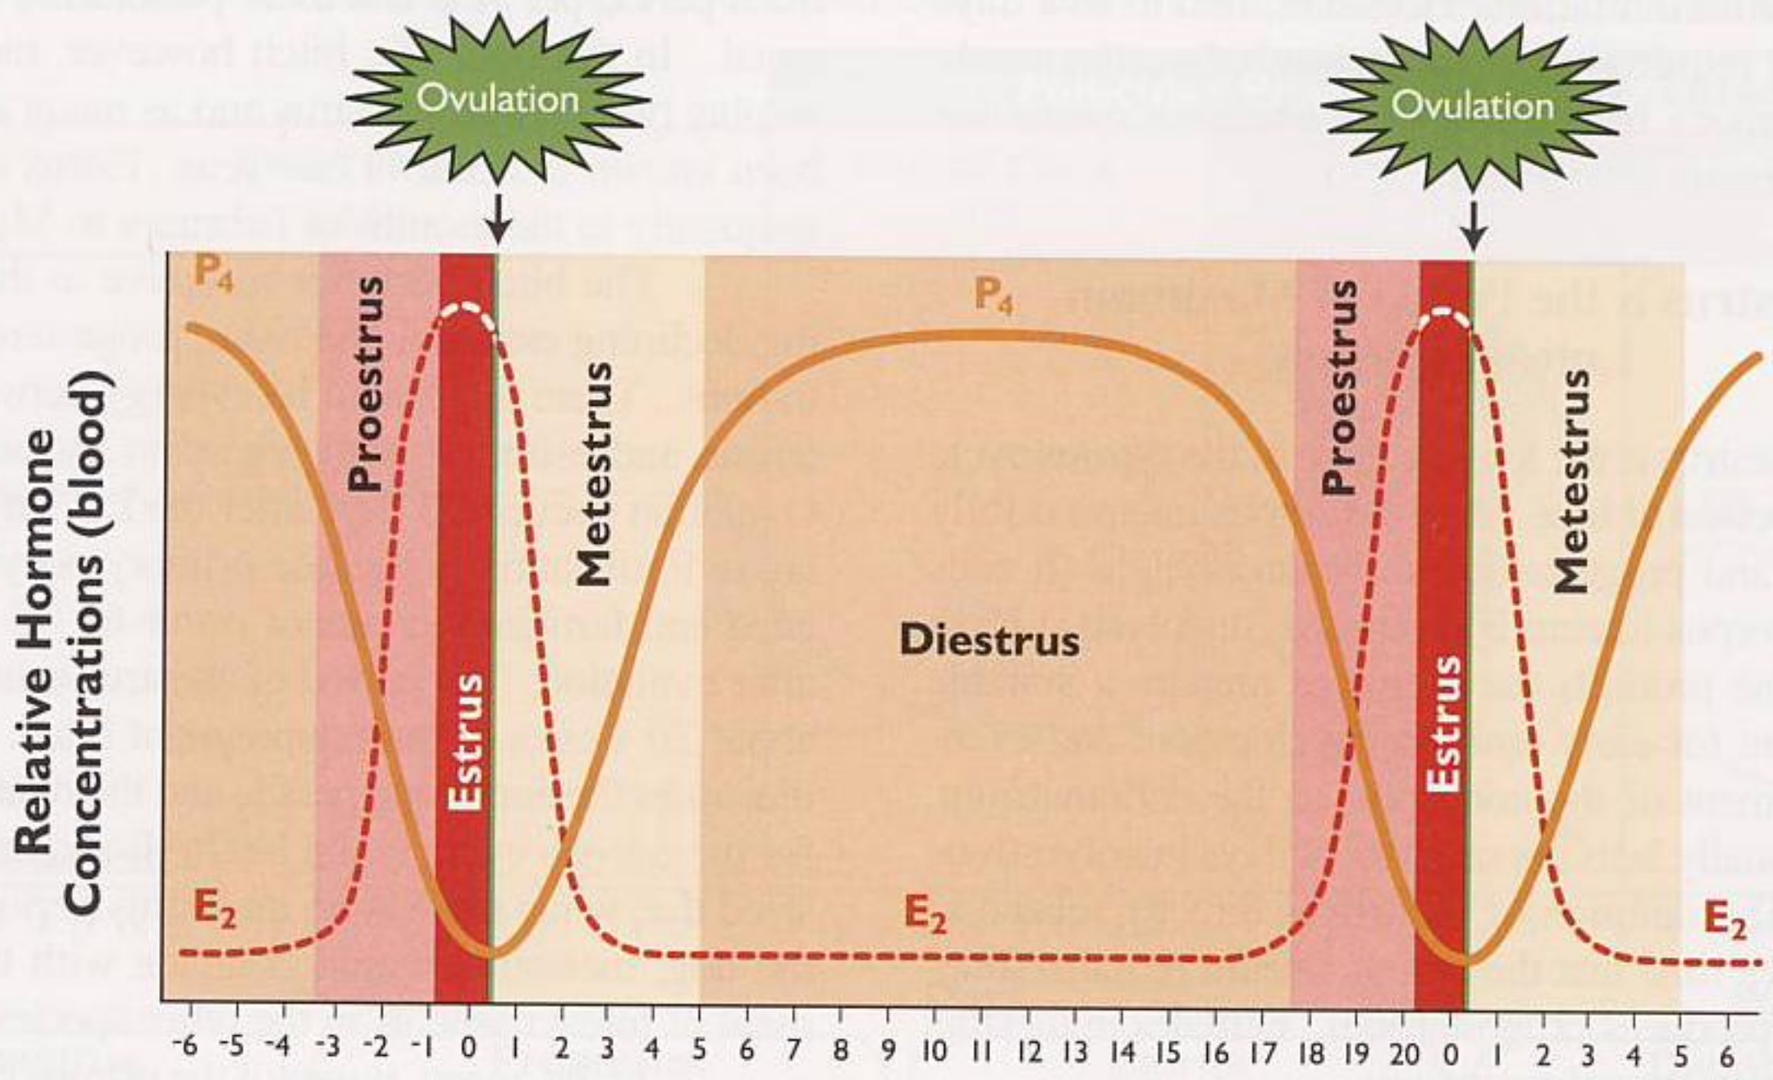
The four stages of an estrous cycle are **proestrus, estrus, metestrus** and **diestrus**. Each of these stages is a subdivision of the follicular and luteal phases of the cycle. For example, the follicular phase includes proestrus and estrus. The luteal phase includes metestrus and diestrus.

Proestrus is the Period Immediately Preceding Estrus

Proestrus begins when progesterone declines as a result of luteolysis (destruction of the corpus luteum) and terminates at the onset of estrus. Proestrus lasts from 2 to 5 days depending on species and is characterized by a major endocrine transition, from a period of progesterone dominance to a period of estrogen dominance (See Figure 7-3). The gonadotropins FSH and LH are the primary hormones responsible for this transition. It is during proestrus that follicles are recruited for ovulation and the female reproductive system prepares for the onset of estrus and mating.

<u>Proestrus</u> = Formation of ovulatory follicles + E_2 secretion
<u>Estrus</u> = Sexual receptivity + peak E_2 secretion
<u>Metestrus</u> = CL formation + beginning of P_4 secretion
<u>Diestrus</u> = Sustained luteal secretion of P_4

Figure 7-3. Stages of the Estrous Cycle



Proestrus is characterized by a significant rise in estradiol (E_2) produced by developing follicles.

When estradiol reaches a certain level, the female enters behavioral estrus and then ovulates.

Following ovulation, cells of the follicle are transformed into luteal cells that form the corpus luteum (CL) during metestrus.

Diestrus is characterized by a fully functional CL and high progesterone (P_4).

7

Estrus is the Period During Which the Female Allows Copulation

Estrus is the most recognizable stage of the estrous cycle because it is characterized by visible behavioral symptoms such as sexual receptivity and mating. Estradiol is the dominant hormone during this stage of the estrous cycle. It not only induces profound behavioral alterations, but causes major physiologic changes in the reproductive tract.

When a female enters estrus, she does so gradually and is not sexually receptive at first. She may display behavioral characteristics that are indicative of her approaching sexual receptivity. These include increased locomotion, phonation (vocal expression), nervousness and attempts to mount other animals. However, during this early period she will not accept the male for mating. As the period of estrus progresses, so does the female's willingness to accept the male for mating. This willingness is referred to as **standing estrus**. It is during the time of estrus that the female displays a characteristic mating posture known as **lordosis**, so named because of a characteristic arching of the back in preparation for mating. Standing behavior (lordosis) can be observed by humans and used as a diagnostic tool to identify the appropriate time to inseminate the female artificially or to expose her to the breeding male. The average duration of estrus is characteristic for each species. However, the range in the duration of estrus can be quite large even within species (See Table 7-1). Understanding and appreciating the magnitude of these ranges is important because it allows one to predict cyclic events with a degree of accuracy.

Metestrus is the Transition from Estrogen Dominance to Progesterone Dominance

Metestrus is the period between ovulation and the formation of functional corpora lutea. During early metestrus both estrogen and progesterone are relatively low (See Figure 7-3). The newly ovulated follicle undergoes cellular and structural remodeling resulting in the formation of an intraovarian endocrine gland called the corpus luteum. This cellular transformation is called **luteinization** (See Chapter 9).

During metestrus, progesterone secretion is detectable soon after ovulation. However, two to five days are usually required after ovulation before the newly formed corpora lutea produce significant quantities of progesterone (See Figure 7-3).

Diestrus is the Period of Maximum Luteal Function

Diestrus is the longest stage of the estrous cycle and is the period of time when the corpus luteum is fully functional and progesterone secretion is high. It ends when the corpus luteum is destroyed (luteolysis). High progesterone prompts the uterus to prepare a suitable environment for early embryo development and eventual attachment of the conceptus to the endometrium. Diestrus usually lasts about 10 to 14 days in polyestrous females. The duration of diestrus is directly related to the length of time that the corpus luteum remains functional (i.e. produces progesterone). Females in diestrus do not display sexual receptivity.

The Estrous Cycle of the Bitch Varies from Patterns Previously Described

The estrous cycle of the domestic bitch has a different timing of the cycle stages. The estrous cycle of the bitch consists of proestrus, estrus, diestrus and anestrus. The onset of proestrus is usually considered to be the beginning of the estrous cycle. Wild canids (wolf, coyote, Australian dingo) display only one estrous period per year and these periods are usually seasonal. In the domestic bitch however, most females display two periods of estrus and as many as four have been known to occur in one year. Estrus occurs most frequently in the months of February to May.

The bitch becomes receptive to the male during declining estradiol and rising progesterone concentrations. There appears to be synergy between progesterone and estradiol with regard to estrous behavior. Ovulation occurs 2-3 days after the LH surge. The delay in fertilization is because primary oocytes are ovulated and fertilization cannot occur for 48 to 72 hours after ovulation. The period of anestrus usually lasts for about 20 weeks in the nonpregnant bitch. Figure 7-4 illustrates the endocrine profile and the relative timeline for the estrous cycle in the bitch. It should be emphasized that while there is no metestrus period defined in the dog, metestrus would coincide with the development of luteal tissue as in the other species.

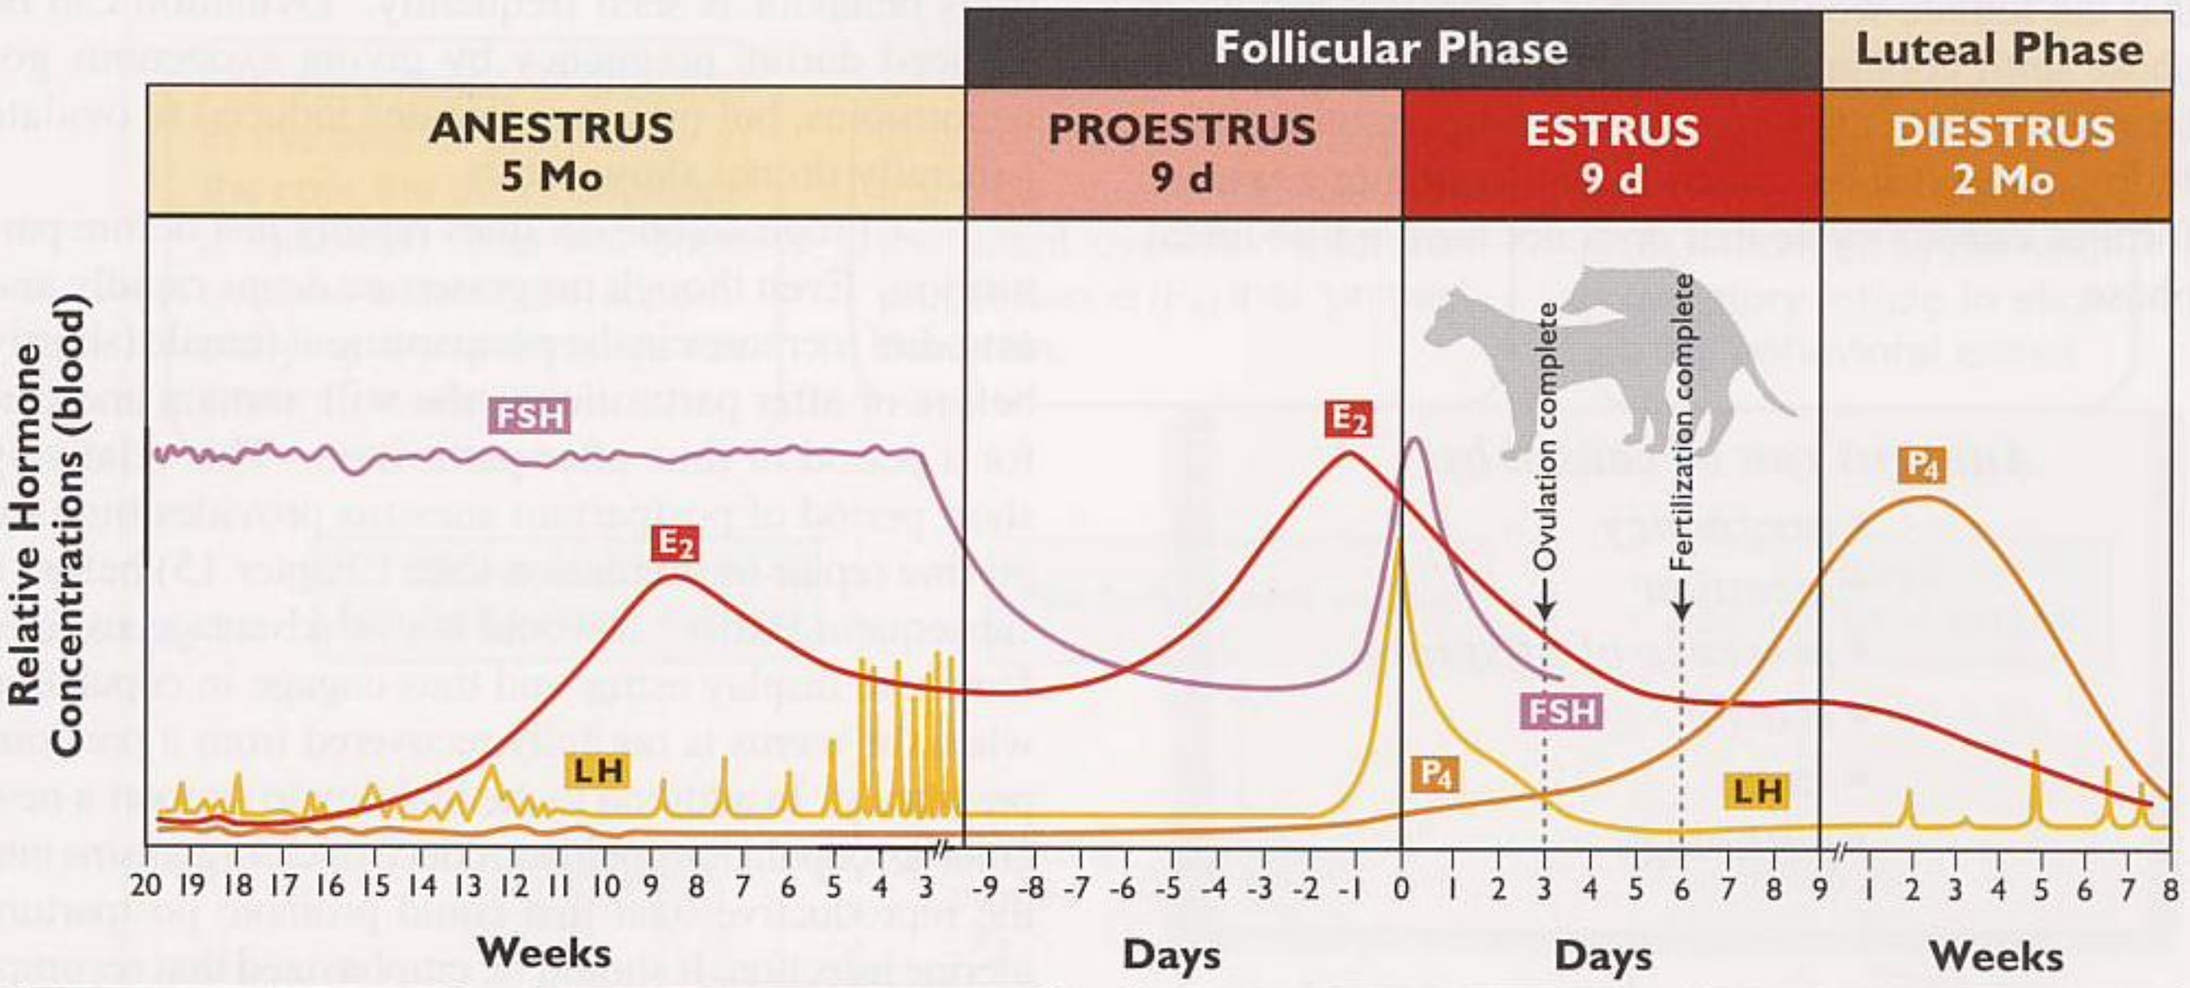
In the queen, stages of the estrous cycle include proestrus, estrus, **postestrus**, diestrus and anestrus. There is little evidence for seasonality in queens and they tend to be polyestrus animals. Felids are induced ovulators and copulation is required for induction of the LH surge. Postestrus is a term used to describe an interestrus period that follows estrus in a queen that has not been induced to ovulate by copulation (See Figure 7-5). In queens that have not copulated, no ovulation occurs and no corpora lutea form. Therefore, neither

Table 7-1. Characteristics of Estrous Cycles in Domestic Animals

		Length of Estrous Cycle		Duration of Estrus		Time From Onset of Estrus to Ovulation	Time From LH Surge to Ovulation
Species	**Classification**	**Mean**	**Range**	**Mean**	**Range**		
Alpaca	Polyestrus	15d	(11-18d)	5d	(4-5d)	Induced Ovulator	26-36h
Bitch	Monoestrus	6 mo	(3-9 mo)	9d	(4-21d)	4-24d	2-3d
Cow	Polyestrus	21d	(17 - 24d)	15h	(6 - 24h)	24 - 32h	28h
Ewe	Seasonally polyestrus (Short Day)	17d	(13 - 19d)	30h	(18 - 48h)	24 - 30h	26h
Llama	Polyestrus	10d	(8-12d)	5d	(4-5d)	Induced Ovulator	24-36h
Mare	Seasonally polyestrus (Long Day)	21d	(15 - 26d)	7d	(2 - 12d)	5d	2d
Queen	Polyestrus	17d	(4-30d)	9d	(2-19d)	Induced Ovulator	30-40h
Sow	Polyestrus	21d	(17 - 25d)	50h	(12 - 96h)	36 - 44h	40h

Figure 7-4. The Annual Reproductive Cycle of the Bitch

(Modified from Johnston, Root Kustritz and Olson. 2001. *Canine and Feline Theriogenology)*



Anestrus

A period of reproductive quiescence. This long anestrus period is responsible for a cyclic profile of three cycles in two years.

Proestrus

Proestrus begins with the appearance of a blood-tinged vaginal discharge and by vaginal swelling. It ends when the bitch accepts the male for mating. The ovaries contain large follicles at the onset of proestrus. Estradiol gradually increases and peaks slightly before the onset of estrus.

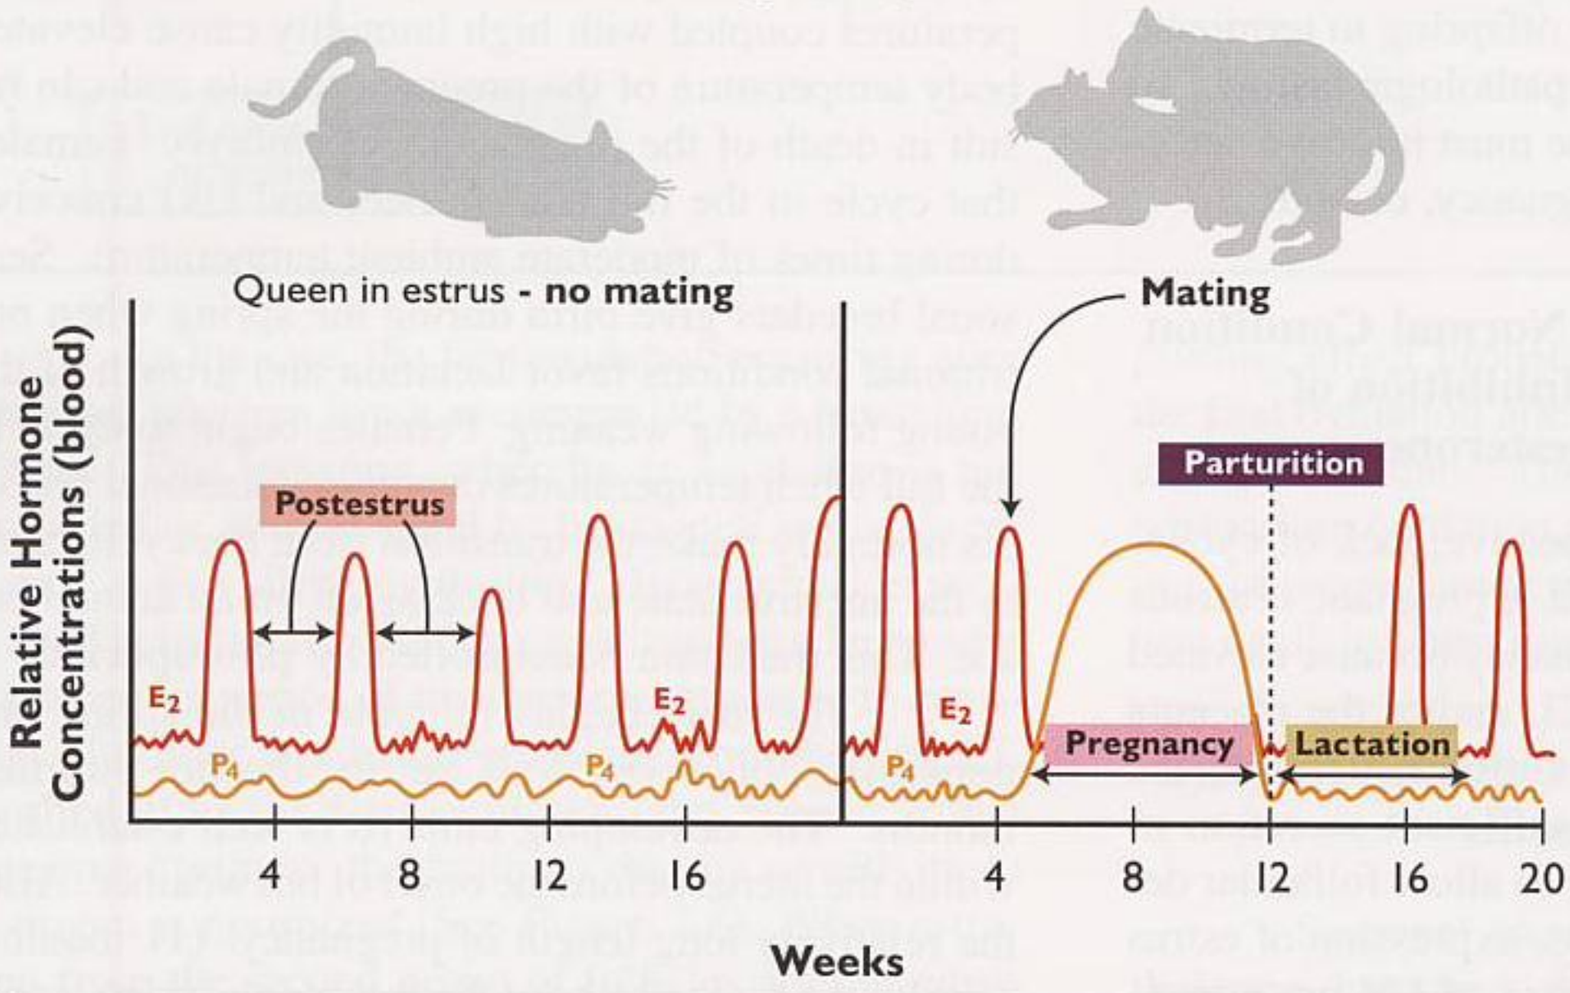
Estrus

Shortly after peak estradiol, behavioral estrus begins. Both LH and FSH peak in early estrus. Ovulation is completed at about the third day of estrus and fertilization is completed at about the sixth day. Progesterone increases during the latter part of estrus signifying luteinization.

Diestrus

Both pregnant and open bitches are considered to be in diestrus. Pregnancy status does not alter the length of diestrus. Progesterone peaks at about 15 days then decreases gradually. Bitches that do not become pregnant are often considered to be pseudopregnant.

Figure 7-5. Reproductive Cyclicity Profile of Queens With and Without Copulation



When mating occurs during estrus, ovulation is induced, fertilization occurs and pregnancy takes place. After ovulation corpora lutea are formed causing a marked elevation in progesterone. After a 60 day gestation period, parturition occurs and lactation ensues. Lactational anestrus does not occur in the cat because she will come into estrus while she is lactating.

A queen enters estrus (about 9 days) every 17 days. If copulation does not occur, the queen enters a postestrus phase and comes into estrus a few days later. Since the queen is an induced ovulator, when mating does not occur, ovulation does not occur and a CL is not formed.

metestrus (CL formation) nor diestrus occurs. As in most induced ovulators, it would be appropriate to consider that the female would remain in a constant follicular phase until copulation occurs. After copulation the female ovulates and only then do corpora lutea form. In this context induced ovulators constitute a special form of estrous cycle that does not have a true luteal phase.

Anestrus can be caused by:

- ***pregnancy***
- ***lactation***
- ***presence of offspring***
- ***season***
- ***stress***
- ***pathology***

Anestrus Means "Without Cyclicity"

Anestrus is a condition when the female does not exhibit regular estrous cycles. During anestrus the ovaries are relatively inactive and neither ovulatory follicles nor functional corpora lutea are present. Anestrus is the result of insufficient GnRH release from the hypothalamus to stimulate and maintain gonadotropin secretion.

It is important to distinguish between **true anestrus** caused by insufficient hormonal stimuli and **apparent anestrus** caused by failure to detect estrus or failure to recognize that a female is pregnant. To eliminate true anestrus, one must normally improve the female's nutrition, remove offspring to terminate lactation, or eliminate stress or pathologic factors. To eliminate apparent anestrus, one must improve detection of estrus, detection of pregnancy, or both.

Gestational Anestrus is a Normal Condition Brought About by Inhibition of GnRH by Progesterone

From a practical perspective, lack of cyclicity is a major clue that a female is pregnant. Estrous cycles do not occur during pregnancy because elevated progesterone from either the CL and/or the placenta exert a negative feedback on GnRH neurons in the hypothalamus. This prevents sufficient secretion of FSH and LH from the pituitary to allow follicular development and ovulation. Thus, expression of estrus and potential preovulatory surges of LH are nonexistent. Occasionally however, cows and ewes will display behavioral estrus during pregnancy, but the incidence is low (3% to 5%). The reason for display of estrus in pregnant cows and ewes is not understood. In certain breeds of pregnant sheep (Rambouillet) estrous behavior is seen frequently. Ovulation can be induced during pregnancy by giving exogenous gonadotropins, but pregnant females induced to ovulate generally do not show estrus.

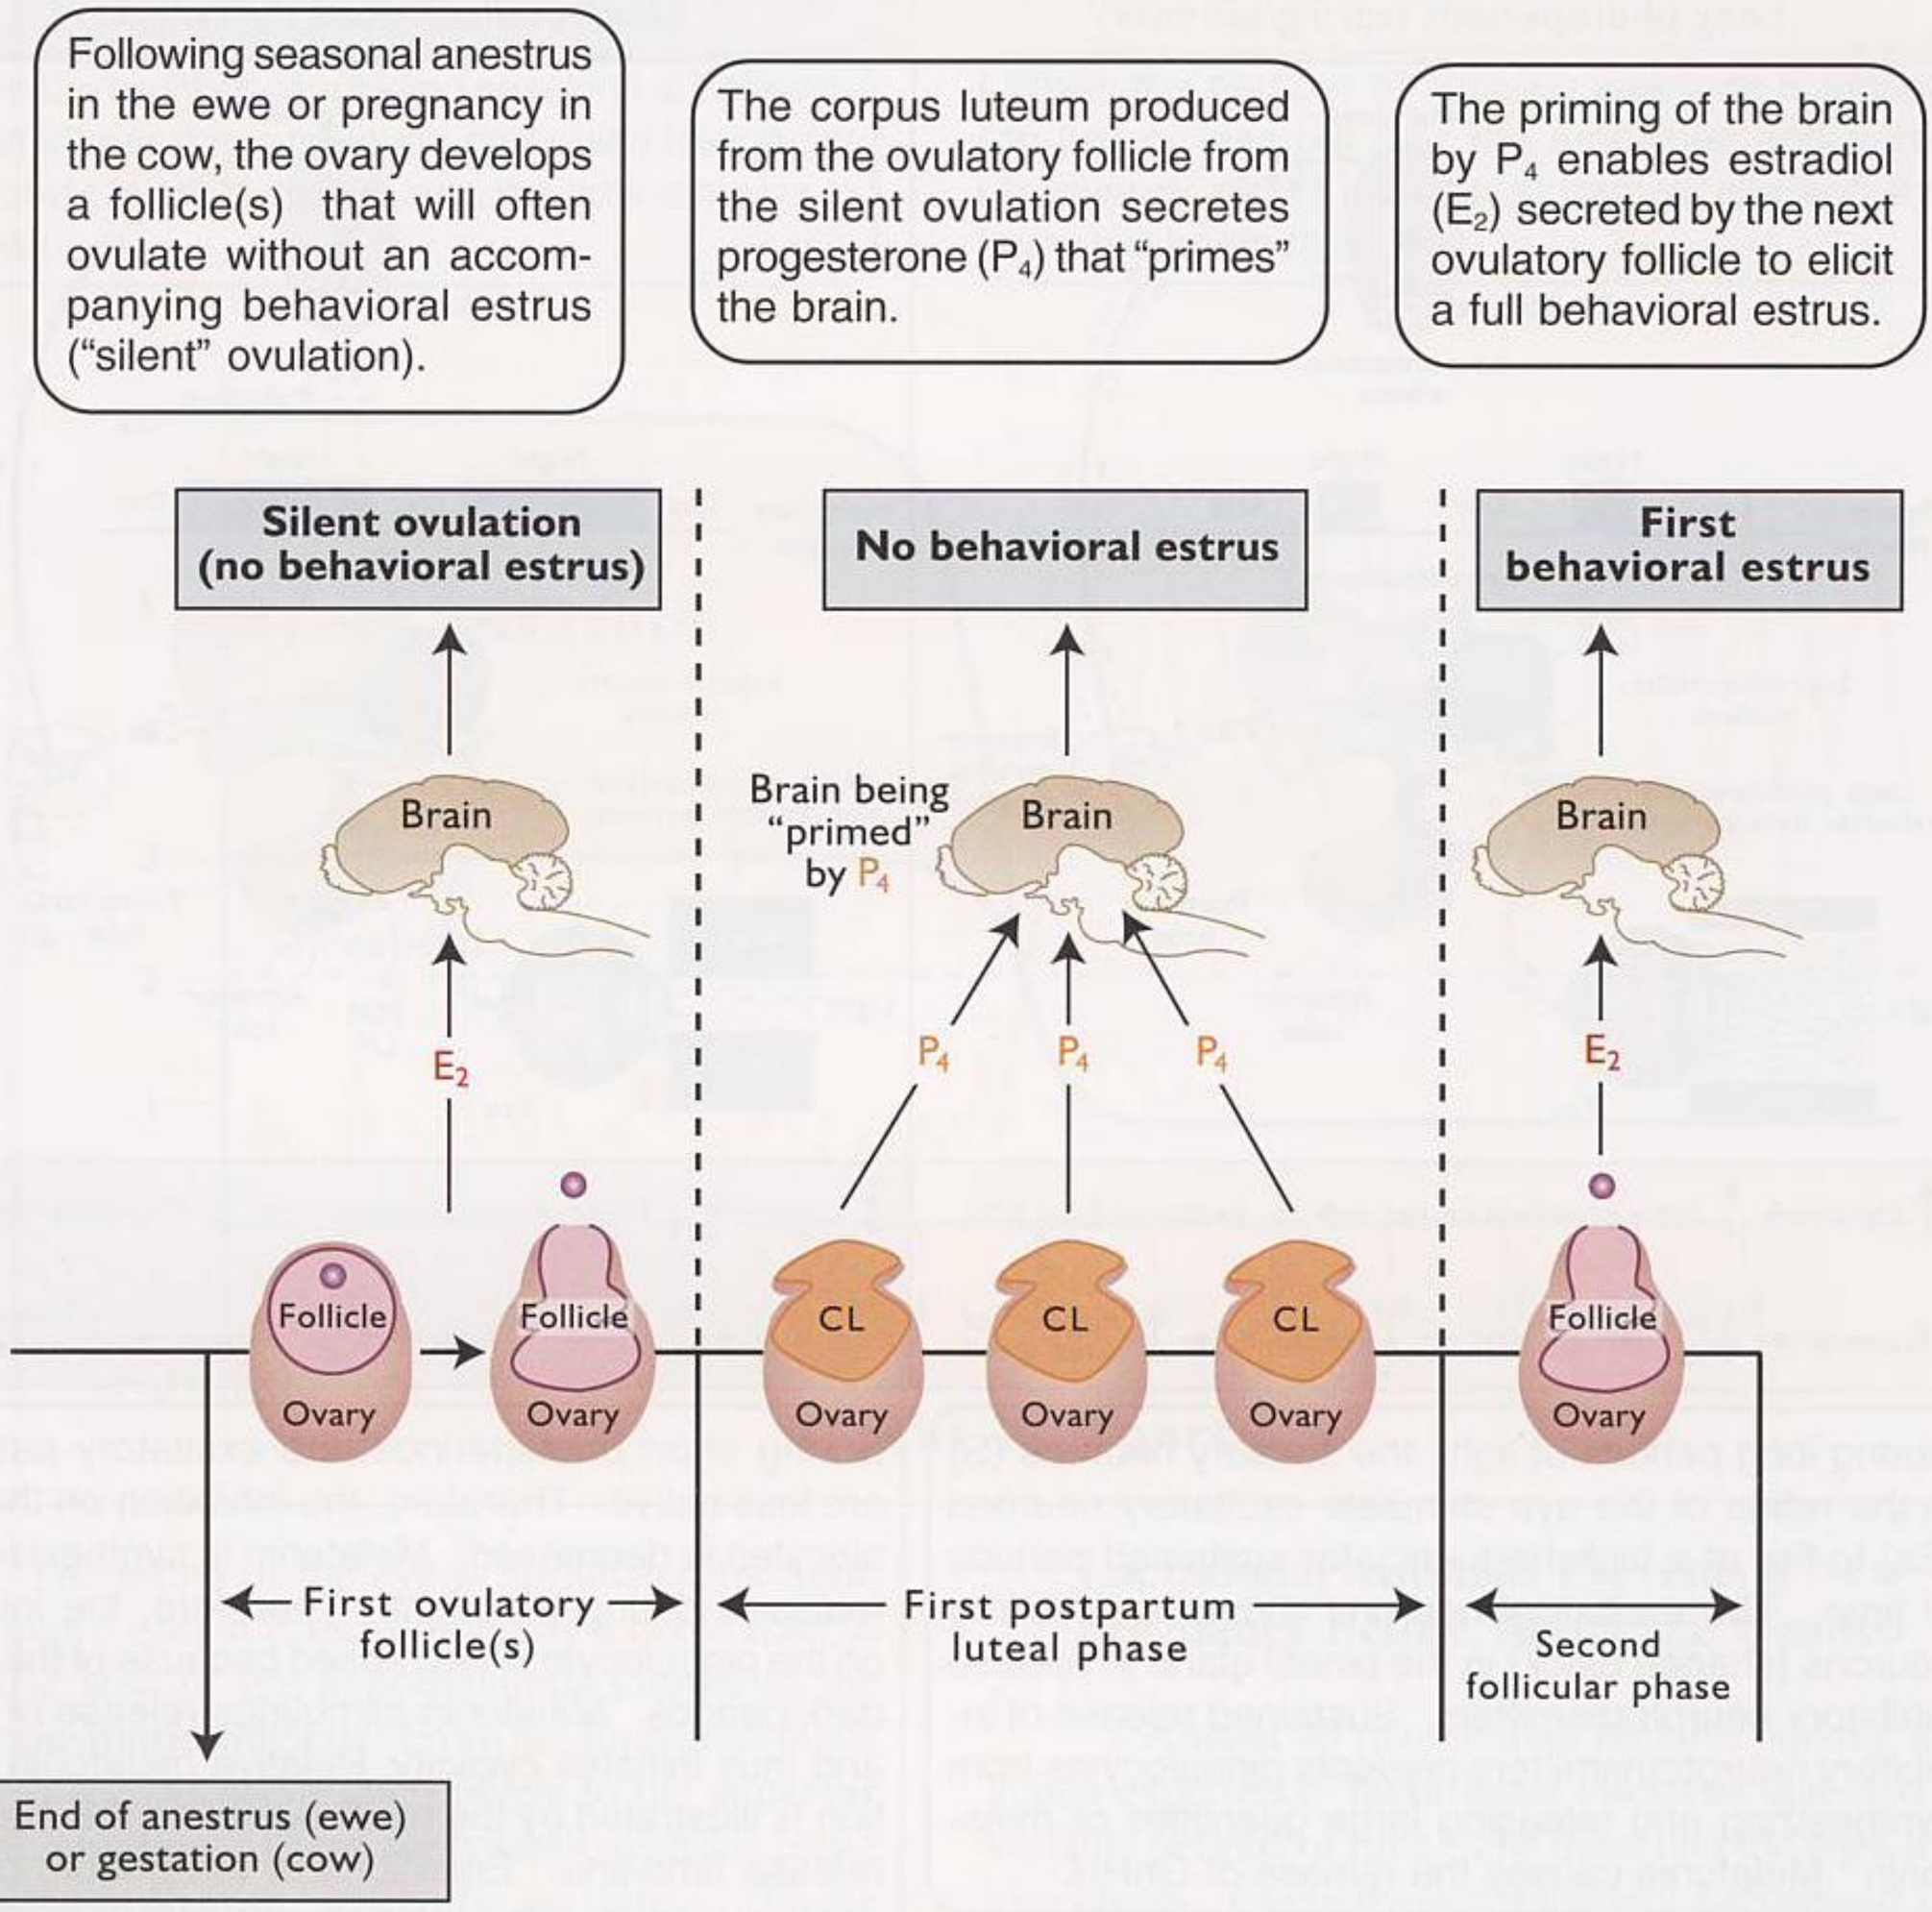
Progesterone declines rapidly just before parturition. Even though progesterone drops rapidly and estradiol increases in the periparturient female (shortly before or after parturition), she will remain anestrus for a period of time after parturition. This relatively short period of postpartum anestrus provides time for uterine repair or involution (See Chapter 15) before a subsequent estrus. It would not be advantageous for a female to display estrus and thus engage in copulation when the uterus is not fully recovered from a previous pregnancy. In addition to the inability to support a new embryo, copulation could introduce microorganisms into the reproductive tract that could promote postpartum uterine infection. It should be emphasized that resumption of postpartum ovarian activity depends on species. For example, mares, alpacas and llamas resume cyclicity within a week after parturition and acquire normal fertility within 2 to 3 weeks after parturition.

Seasonal Anestrus is a Normal Condition

Seasonal anestrus probably evolved as a way of preventing females from conceiving during periods of the year when survival of the developing embryo and the neonate would be low. For example, preattachment embryo survival is known to be reduced significantly when ambient temperatures and humidity are high during the summer months. High temperatures coupled with high humidity cause elevated body temperature of the pregnant female and can result in death of the preattachment embryo. Females that cycle in the fall (sheep, deer and elk) conceive during times of moderate ambient temperature. Seasonal breeders give birth during the spring when nutritional conditions favor lactation and growth of the young following weaning. Females begin to cycle in the fall when temperatures decrease. Seasonal breeders normally make the transition from the cyclic state to the anestrus state and back again on an annual basis. This transition is controlled by **photoperiod**.

The mare begins to cycle in the spring and generally conceives well before the hot summer months. The developing embryo is well established within the uterus before the onset of hot weather. Also, the relatively long length of pregnancy (11 months) enables the foal to be born the following spring, again providing optimum timing for conception and birth as it relates to environmental/nutritional conditions.

Figure 7-6. Influence of Estradiol (E_2) and Progesterone (P_4) Upon the Brain and Subsequent Behavioral Estrus in the Cow and Ewe

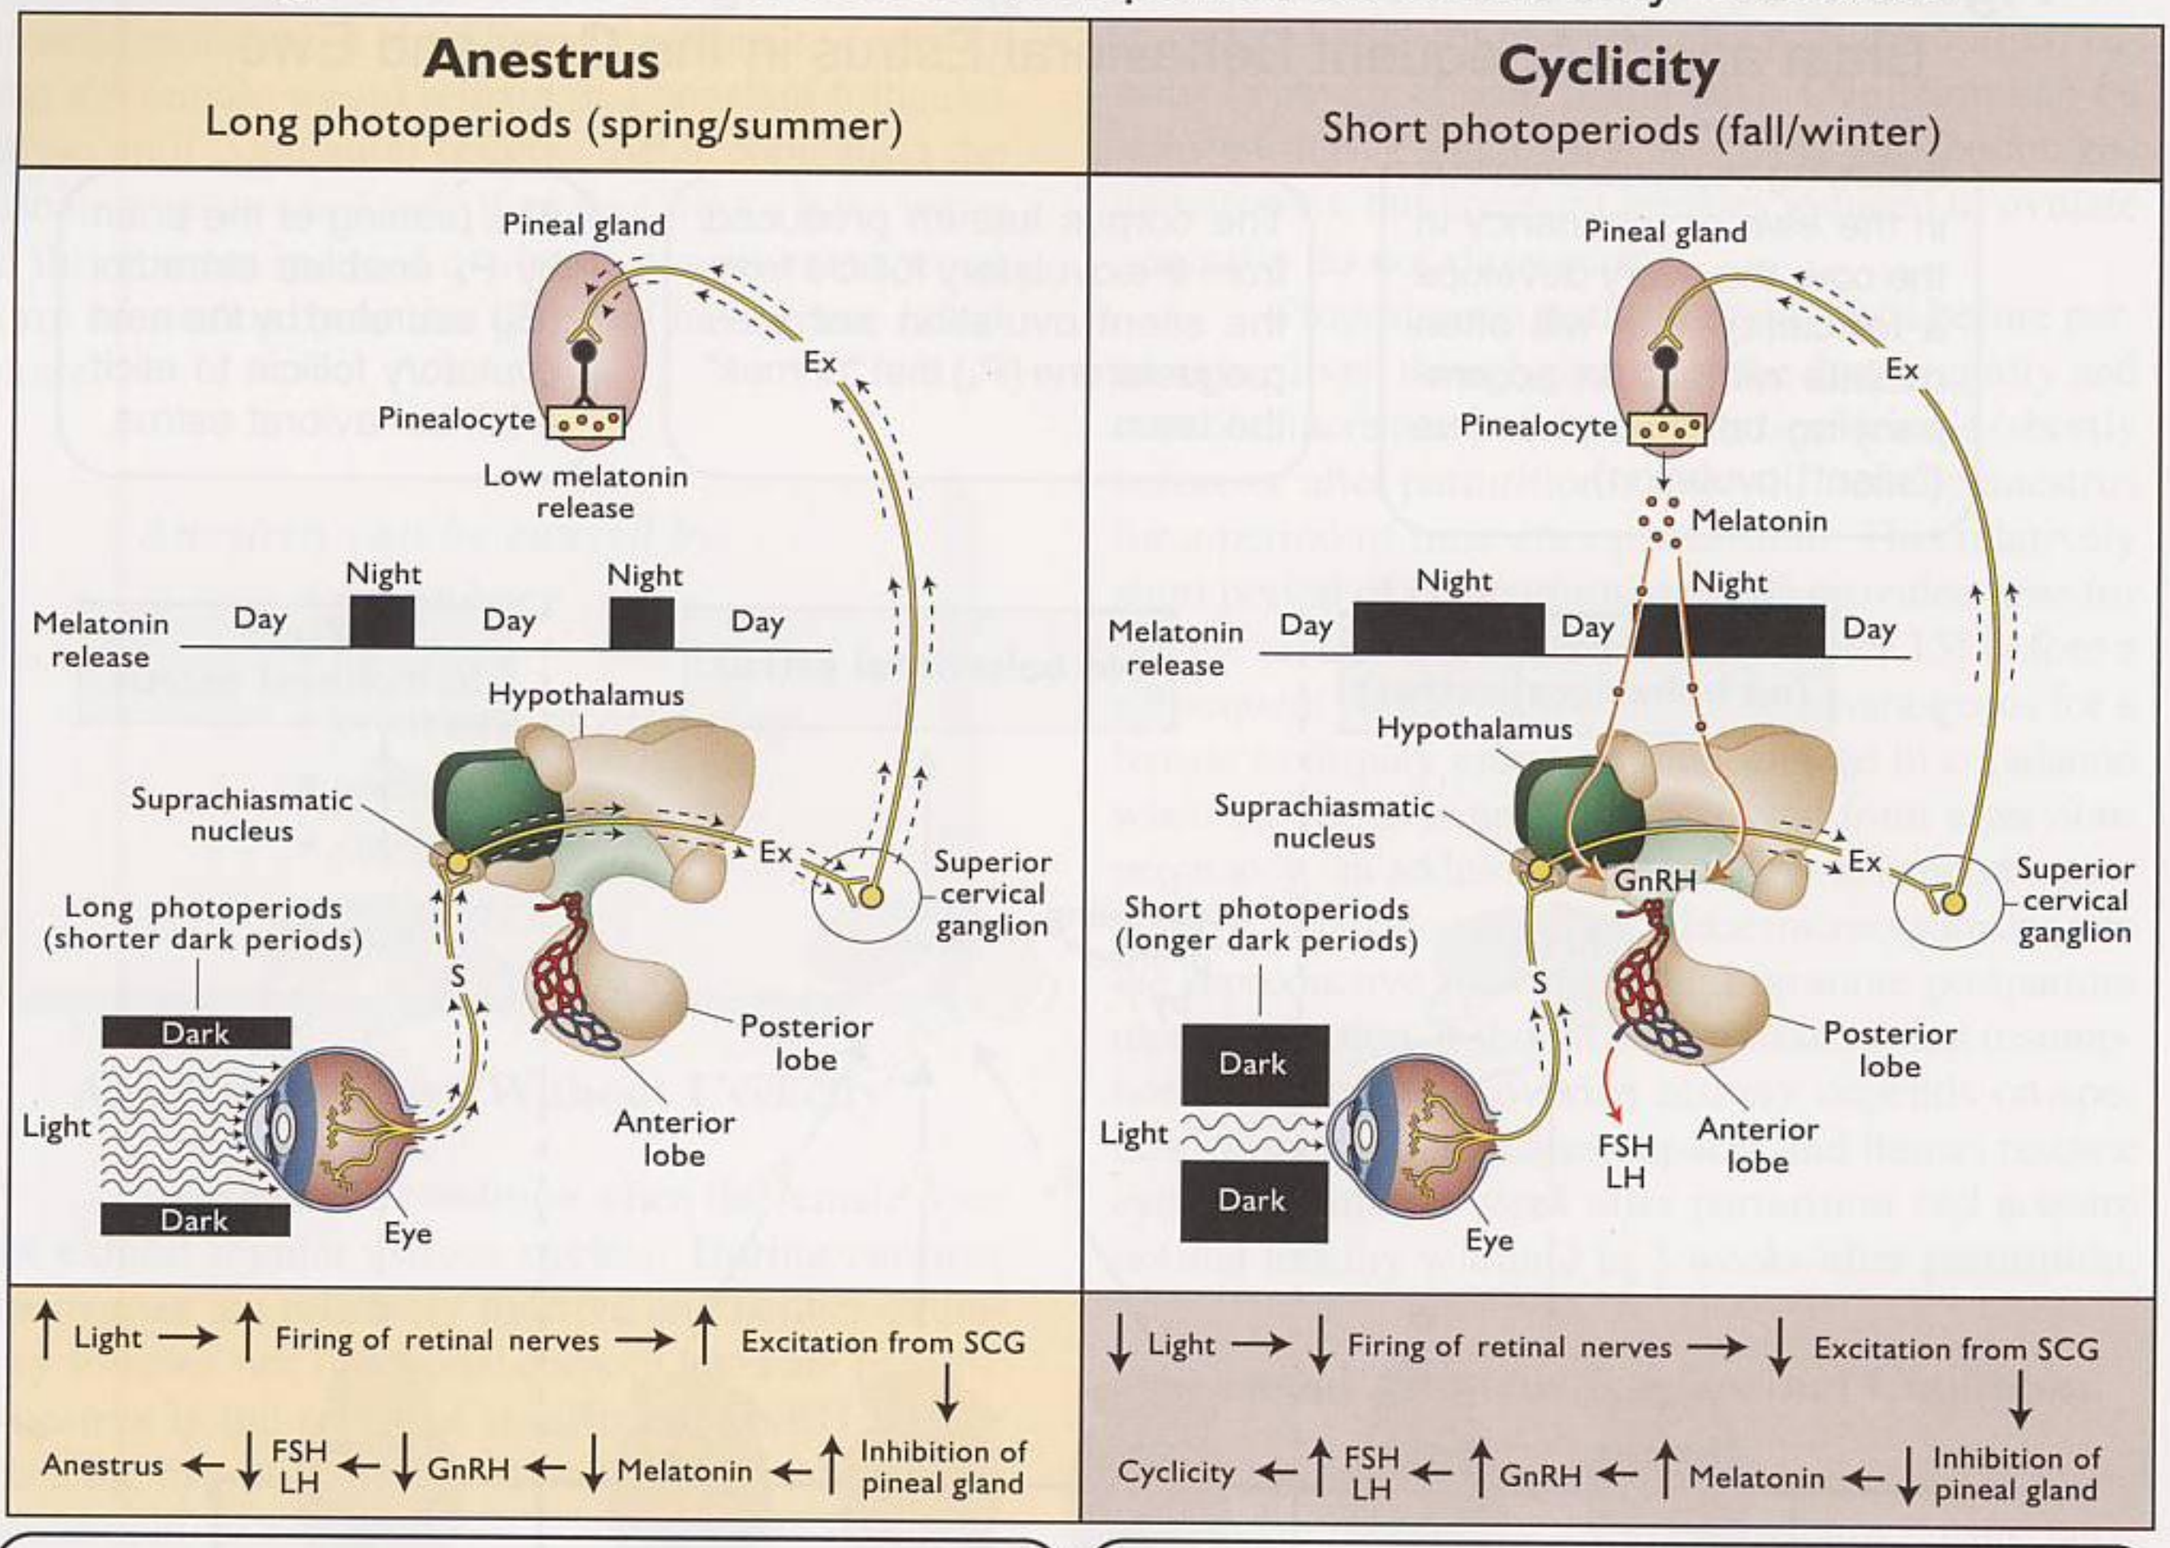


In the ewe, the first ovulation occurring after seasonal anestrus is not accompanied by a behavioral estrus. This situation, whereby an ovulation is not preceded or accompanied by behavioral estrus, is referred to as a **silent ovulation**. For maximal expression of behavioral estrus, progesterone must be present for a certain period of time prior to exposure to estrogen. In other words, progesterone from the first CL formed after the first ovulation and after seasonal anestrus "primes" the brain so that its sensitivity to estrogen is optimized (See Figure 7-6). When estrogen from the second group of follicles after anestrus appears, the female displays behavioral estrus because her brain has been primed by progesterone thus allowing it to be "turned on" by estrogen. A similar priming effect probably is necessary in cattle, since the first ovulation after parturition (calving) is generally a silent one. The corpus luteum from the first postpartum ovulation provides the cow with a "priming" of progesterone prior to the initiation of postpartum cyclicity (See Figure 7-6).

Onset of Seasonal Cyclicity is Similar to the Onset of Puberty

Seasonal anestrus is characterized by hypothalamic dormancy with regard to GnRH secretion (as in the prepubertal female). Before the breeding season commences, the hypothalamus must be able to release GnRH in sufficient quantities to elicit a

Figure 7-7. The Effect of Photoperiod on Short-Day Breeders



During long periods of light, the sensory neurons (S) in the retina of the eye stimulate excitatory neurons (Ex) to fire at a high frequency for sustained periods of time. The excitatory neurons stimulate inhibitory neurons (shaded black) in the pineal gland to release inhibitory neurotransmitters. Sustained release of inhibitory neurotransmitters prevents pinealocytes from synthesizing and releasing large quantities of melatonin. Melatonin causes the release of GnRH.

During short photoperiods, the excitatory pathways are less active. Therefore, the inhibition on the pinealocytes is decreased. Melatonin is synthesized and released during the night. Therefore, the inhibition on the pinealocyte is decreased because of the longer dark periods. Melatonin stimulates release of GnRH and thus initiates cyclicity. Relative melatonin secretion is illustrated by the black boxes on the melatonin release time-line. Equations at the bottom of each panel summarize the main events of this model.

response by the anterior lobe of the pituitary. The release of FSH and LH at levels capable of maintaining follicular development and causing ovulation is required.

Seasonal breeders can be categorized as either **long-day breeders** or **short-day breeders** (See Figure 7-1). The mare is characterized as a long-day breeder because as the day length increases in the spring the mare begins to cycle. During the short days of the winter months, the mare is in anestrus. Short-day breeders are animals that begin to cycle during the short days of the fall. Animals such as sheep, deer, elk and goats are categorized as short-day breeders. The duration of the breeding season varies among and within species. For example, in sheep, the Merino breed has a period of cyclicity that ranges from 200 to 260 days, while blackface breeds have shorter periods of cyclicity ranging from 100 to 140 days.

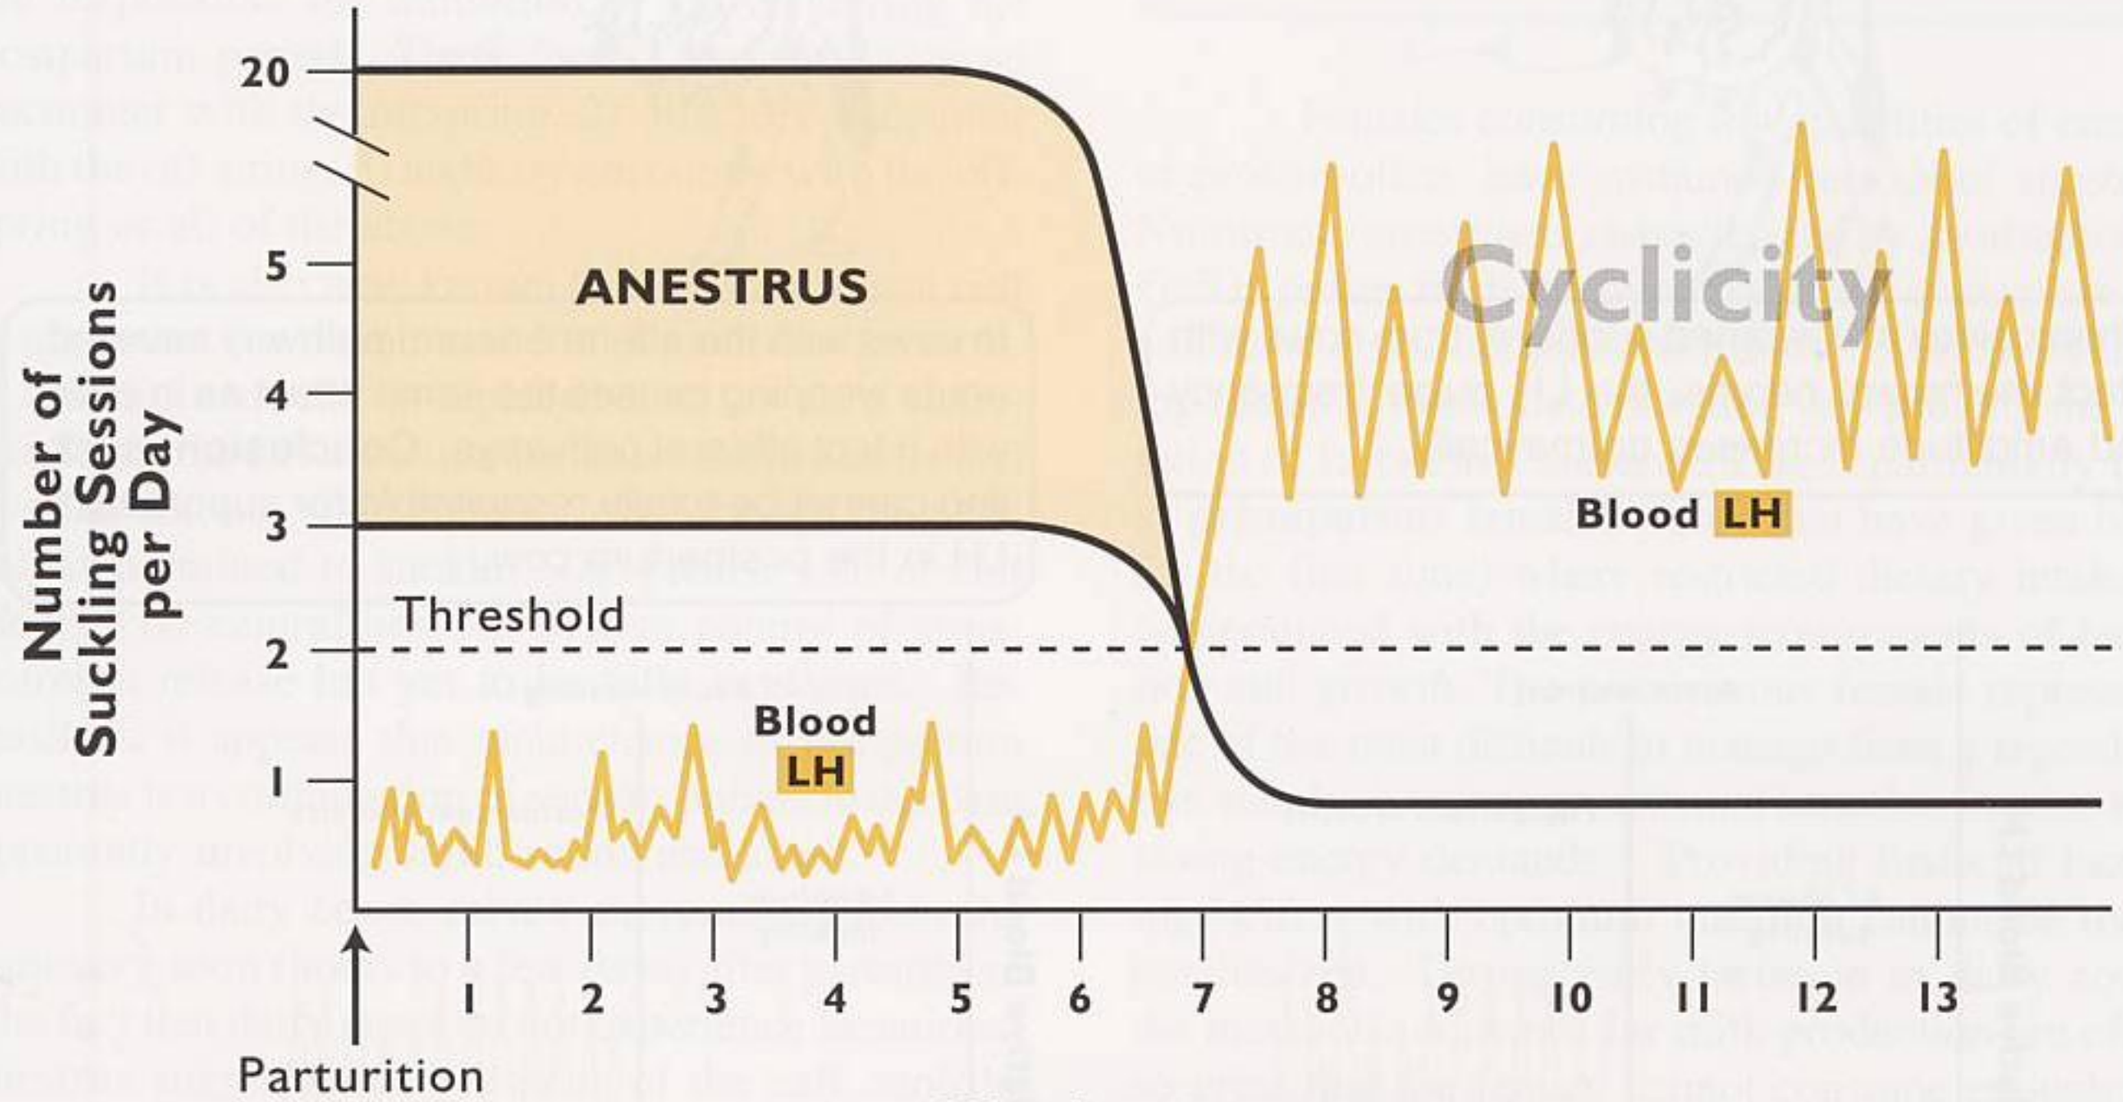
The two primary factors that influence the onset of the breeding season are photoperiod and temperature. Photoperiod is by far the most important. It is well known that artificial manipulation of the photoperiod can alter the cyclicity of the seasonal breeder.

A major question that must be answered in order to understand the influence of day length on the onset of reproductive activity is, "How is photoperiod translated into a physiologic signal?" The basic pathway for induction of cyclicity by short day-length is presented in Figure 7-7.

Figure 7-8. Influence of Suckling Frequency Upon Blood LH (a Direct Indication of GnRH Release) in Postpartum Beef Cows
(Derived from the data of Dr. G.L. Williams, Texas A&M University, Beeville)

When the number of suckling sessions is between 3 and 20 per day, amplitude and pulse frequency of blood LH are quite low and the cow remains in anestrus.

When the number of suckling sessions is limited to two or less per day, the amplitude and pulse frequency of LH increases dramatically and the cow will begin to cycle.

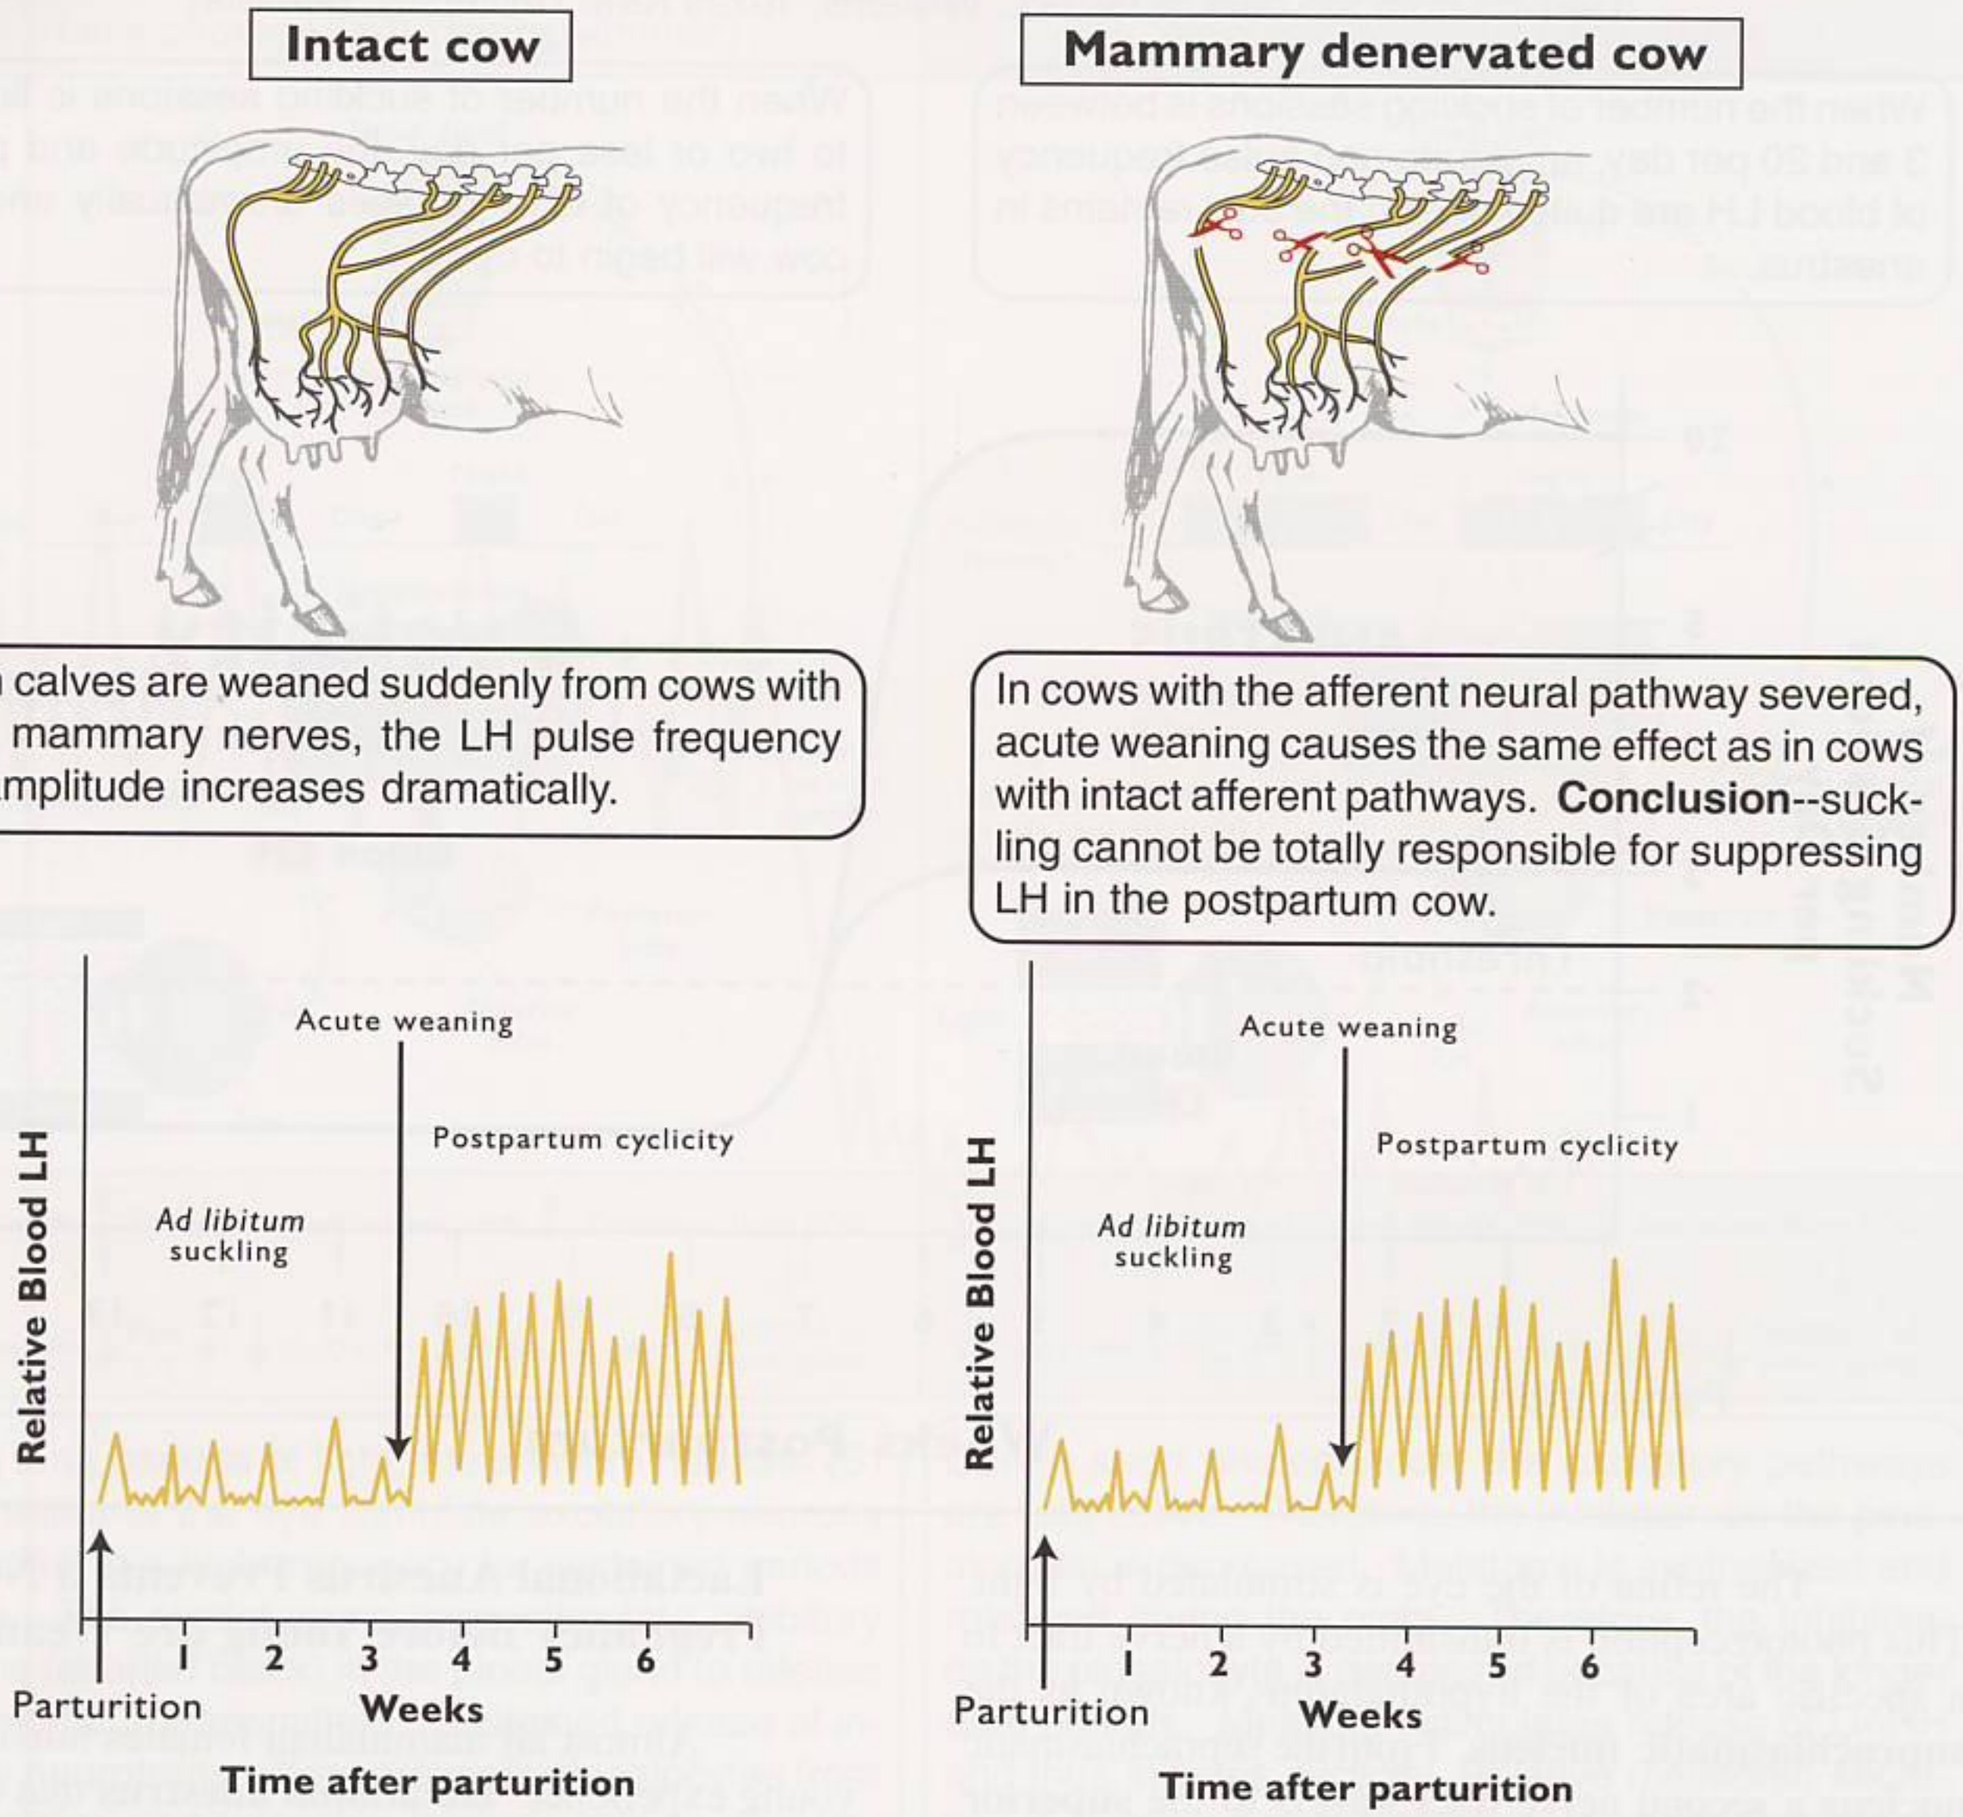


The retina of the eye is stimulated by light. This photoreception is transmitted by a nerve tract to a specific area of the hypothalamus known as the **suprachiasmatic nucleus**. From the suprachiasmatic nucleus a second nerve tract travels to the **superior cervical ganglion**. These presynaptic neurons cause the postganglionic neurons to fire. These postganglionic neurons synapse with inhibitory neurons that make contact with cells in the **pineal gland** (**pinealocytes**). Pinealocytes secrete a hormone called **melatonin**. Melatonin is synthesized and released only during the night hours. Melatonin stimulates GnRH secretion and thus promotes cyclicity. During the daylight hours, the light sensed by the retinal cells of the eye activates an excitatory neural pathway at the level of the pineal gland where inhibitory neurons continue to fire, thus inhibiting the release of melatonin from the pinealocytes. In contrast, during the dark hours this inhibitory pathway is "shut-down" because the firing of nerves in the light-sensitive areas in the retina is diminished. Thus, the inhibition of the pinealocytes has been significantly reduced and melatonin can be released from these cells.

Lactational Anestrus Prevents a New Pregnancy Before Young are Weaned

Almost all mammalian females nursing their young experience **lactational anestrus** that lasts for variable periods of time. The mare and the alpaca are exceptions. Cyclicity is completely suppressed during lactation in the sow. When weaning takes place, the sow will display estrus and ovulate within 4 to 8 days. In the suckled cow, cyclicity is delayed by as much as 60 days after parturition. The duration of lactational anestrus is influenced by the degree of suckling in the cow. However, suckling by itself does not appear to be important when the frequency is greater than two suckling sessions per day. Suckling sessions of two or less per day promote return to cyclicity, while greater than two sessions per day tend to cause postpartum anestrus (See Figure 7-8). There is a threshold of about two sessions per day above that anestrus will be maintained and below that the cow will return to cyclicity. It does not seem to matter whether there are 3 or 20 suckling sessions per day. In other words, the effect of suckling does not operate in a continuum but rather in a threshold manner.

Figure 7-9. *Ad Libitum* Suckling Results in Suppression of LH Amplitude and Pulse Frequency



Mammary stimulation is not totally responsible for lactational anestrus.

It has been almost universally accepted that repeated sensory stimulation of the teat during suckling causes inhibition of gonadotropin release from the anterior lobe of the pituitary in the postpartum female. However, recent research findings from Texas A&M University Research Center in Beeville, Texas indicate that this long-standing concept is probably incorrect. In fact, data now show that direct neural stimulation of the mammary gland does not inhibit gonadotropin release in the cow. Figure 7-9 illustrates the typical pattern of LH release during *ad libitum* suckling in the beef cow. During the time of intense suckling, LH in the blood is quite low. When the suckling is suddenly terminated (acute weaning), increased episodes of LH occur within 2 to 3 days after the calves are removed and the postpartum female resumes cyclicity. The response for the intact cow shown in Figure 7-9 implies that mammary stimulation is the cause of inhibition of GnRH, resulting in basal LH levels during the suckling period. However, when cows were subjected to complete mammary denervation (transection of the nerve tracts supplying the mammary gland), the response in blood LH was identical to that of the intact cow. Transection of all of the nerves to the mammary gland would be expected to remove immediately any inhibition on the hypothalamus brought about by mammary stimulation. However, as you can see by comparing the right and left panels of Figure 7-9, there was no dif-

ference between suckled females with intact neural pathways to the mammary gland when compared to suckled females with transected mammary neural pathways. Clearly, if suckling alone prevented the hypothalamus from producing GnRH, then females in which nerves supplying the mammary gland were transected would have hastened elevations of LH following parturition. Since this did not occur, the interpretation is that factors other than teat stimulation are responsible for inhibition of GnRH during the postpartum period. These factors may be 1) visual encounter with the offspring, 2) olfactory encounter with the offspring, 3) auditory encounter with the offspring or all of the above.

It is also now known that the cow's own calf is important for maintenance of postpartum anestrus. If a cow's own calf is replaced with an alien (unrelated calf) the LH secretion increases dramatically and ovarian activity soon follows, even though the alien calf is permitted to suckle. The precise role of calf identity on central nervous system control of gonadotropin release has yet to be fully explained. Regardless, it appears that maintenance of postpartum anestrus is a combination of sensory inputs to the dam apparently involving sight, sound and smell.

In dairy cows, calves are removed from the dam very soon (hours to a few days) after parturition. The fact that dairy cows do not experience lactational anestrus suggests that presence of the calf contributes to this suppression of reproduction in beef cows.

The bitch does not have lactational anestrus because the anestrus that occurs normally during the cycle lasts about 4-5 months in the presence **or** absence of lactation. You will recall from Figure 7-4 that the bitch has significantly elevated progesterone following estrus. This elevated progesterone is sufficiently long to support and maintain pregnancy. Following parturition and during lactation, the bitch enters a period of anestrus that is independent of lactation. In this context, lactational anestrus does not exist in the bitch.

Many queens display estrus and ovulate seven to ten days after parturition (See Figure 7-5). Some of these queens will be bred and conceive during the time that they are lactating. Other queens will not conceive at this first postpartum estrus. Most reproductive physiologists agree that the queen may have some lactational anestrus, but it is not uniform. In some queens, lactational anestrus appears to exist until about two to three weeks after weaning. Critical experiments describing the impact of lactation, suckling, and presence of the neonate have not been conducted in the bitch or the queen. Understanding the mechanisms of lactational anestrus may enable the development of techniques that suppress reproduction in these species. Such suppression is important since many pregnancies in these species of pets are not desired by pet owners.

Anestrus can result from negative energy balance.

Females consuming low quantities of energy or protein often have sustained periods of anestrus. Nutritional anestrus is characterized by an absence of GnRH pulses from the hypothalamus, inadequate secretion of gonadotropins and inactive ovaries. In nursing females, inadequate nutrition will prolong the duration of lactational anestrus. This is particularly true in **primiparous** females (those that have given birth for the first time) where restricted dietary intake is compounded with the energy requirements of lactation and growth. The primiparous female represents one of the most difficult to manage from a reproductive standpoint since growth and lactation impose two strong energy demands. Providing first-calf lactating heifers with optimum nutrition cannot be overemphasized. During early lactation in dairy cows, the metabolic demands for milk production are often so great that the female cannot consume enough dietary energy to meet her metabolic needs. This negative energy balance is often related to delayed postpartum cyclicity (nutritional anestrus). In non-lactating cycling females, prolonged periods of inadequate nutrition will also cause anestrus. However, undernutrition must be severe and must occur for a prolonged period for cyclicity to cease entirely. Nutritionally anestrous females respond to adequate nutrition by resuming their estrous cycles.

THE MENSTRUAL CYCLE

The menstrual cycle is defined as the events that occur between the onset of two successive menstrual periods. The duration of the menstrual cycle in women averages 28 days with a range to 24-35 days. **Menses** (**menstruation**) is defined as the sloughing of the endometrium to the exterior. Menses is commonly referred to as the **menstrual period** (or period). The fundamentals of the menstrual cycle are quite similar to the estrous cycle.

The menstrual cycle differs from the estrous cycle in the following ways:

- ***there is no defined period of sexual receptivity***
- ***there is a period of endometrial sloughing called menses (menstruation)***
- ***the timeline for description of the cycle begins and ends with menses, not ovulation or estrus***

In the menstrual cycle, the follicular phase occupies one half of the cycle while in species with an estrous cycle it only occupies 20% or less of the cycle. During the follicular phase, follicles grow and develop producing high levels of estradiol causing an LH surge that causes a spontaneous ovulation in women. A major difference in the description of the menstrual cycle compared to the estrous cycle is that ovulation occurs at day 14 rather than at the beginning and end of the cycle. The beginning of the cycle is defined as the onset of menses. This came about because it was an observable component of the menstrual cycle as is behavioral estrus in the estrous cycle. Menses lasts between 2 and 5 days. Following sloughing of the endometrium there is a gradual increase in GnRH that triggers the release of FSH and LH. As you can see from Figure 7-10, estrogen increases with advancing follicular development during the follicular phase and progesterone is low as in other mammals.

In the menstrual cycle:

The follicular phase = menses (5 days) + proliferative phase (9 days)

The luteal phase = secretory phase (14 days)

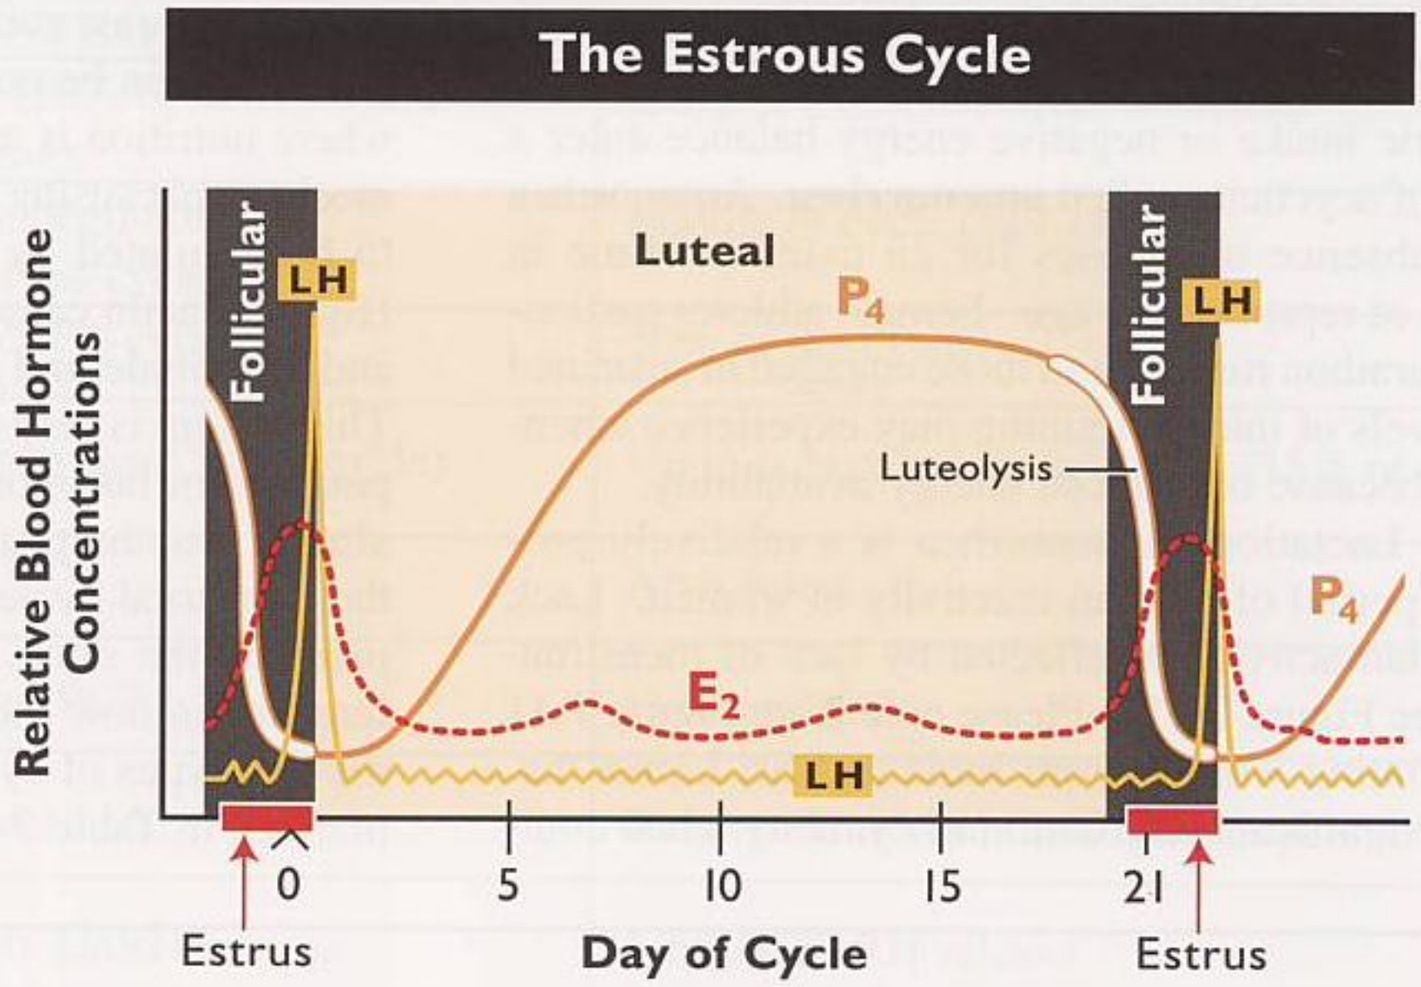
The **proliferative** and **secretory** phases of the cycle refer to the changes in endometrial thickness. At the beginning of the proliferative phase, the endometrium sloughs (menses) and then it begins to increase in thickness in response to estradiol (See Figure 7-10). During the secretory phase, progesterone increases dramatically (as does estrogen). Both are produced by the corpus luteum. Under the influence of progesterone and estrogen the endometrium begins to proliferate and increase to its maximum thickness. This proliferation prepares the endometrium for secretory activity that provides an optimum environment for the embryo if conception occurs following ovulation. Figure 7-10 illustrates the endocrine profile during the menstrual cycle and relates this to the proliferative and secretory phase of the cycle. For comparison, the top panel of Figure 7-10 illustrates the typical hormone profiles of the estrous cycle.

A question that is invariably asked is "Why have most species evolved with definitive periods of sexual receptivity and the human female has not?" While experiments to discover the reasons for this discrepancy have never been conducted, a prominent theory explaining this lack of defined periods of sexual receptivity is presented below. It is believed that at one time during the evolution of primates there was a significant amount of competition for the right to breed the female. It is believed during this evolutionary period there were periods of sexual receptivity amongst primates. But, because males spent undue time competing for the opportunity to copulate with sexually receptive females the role of the male and female in food gathering was compromised. Fighting for the right to copulate was a huge distraction. Groups of females who displayed more widespread sexual receptivity created a situation in which males did not spend as much time competing for the opportunity to copulate because copulation could occur over a wider time-frame, thus allowing more opportunities to seek food and shelter. This proved beneficial and gradually continuous sexual receptivity evolved.

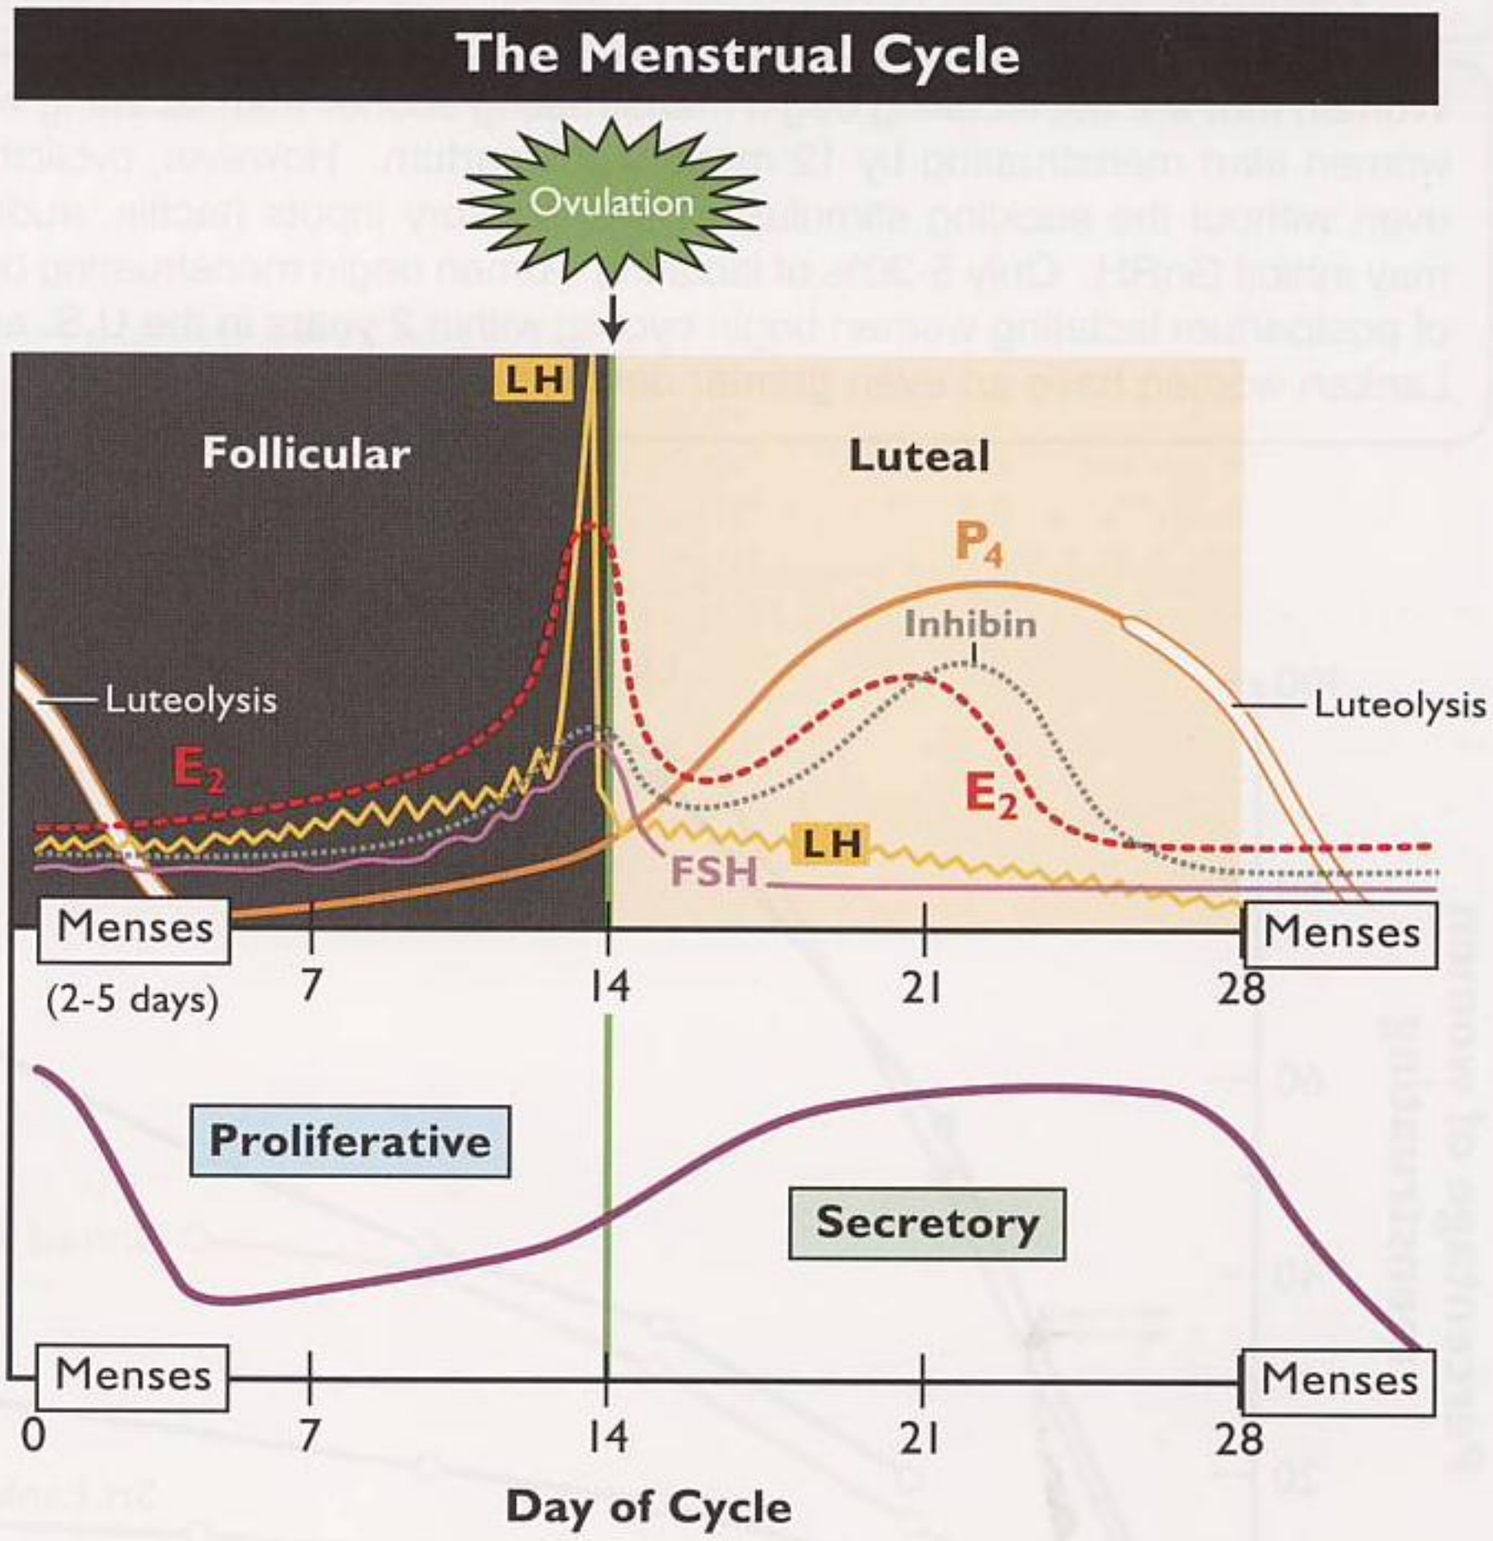
Menopause in the human female is analogous to anestrus. Anestrus is defined as a period without defined estrous cycles and likewise menopause is a period without cyclicity. However, the causes of anestrus relate to lactation, nutrition and season while the cause of menopause is due to the depletion of follicles within the ovary that produce estrogen and progesterone after ovulation. As you now should know, cyclicity is "driven" by ovarian steroids. Thus, menopause occurs in women when their ovarian supply of follicles is depleted. A more detailed discussion of menopause will be presented in Chapter 8.

Figure 7-10. Comparison Between the Estrous Cycle and Menstrual Cycle

The estrous cycle begins, and ends, with estrus and/or ovulation. The follicular phase is short and the luteal phase long.



The menstrual cycle begins (day 0) and ends with the start of menses (day 28). Ovulation occurs in the middle of the cycle. The follicular and the luteal phase are the same length (about 14 days each).



During the initial 3-5 days of the proliferative phase the endometrium decreases rapidly in thickness because it is sloughed to the exterior during menses. With rising E_2, the endometrium begins to proliferate and increase in thickness. After ovulation, the CL produces P_4 that causes further proliferation and initiates secretory activity of the endometrium. Luteolysis initiates another menstrual period.

Lack of Cyclicity is Called Amenorrhea in Women

It is well known that human females that have isocaloric intake or negative energy balance enter a period of acyclicity called **amenorrhea**. Amenorrhea is the absence of menses for an extended time in women of reproductive age. Female athletes particularly marathon runners and those engaged in sustained high levels of intense training may experience amenorrhea because of reduced energy availability.

Lactational amenorrhea is a relatively prolonged period of ovarian inactivity in women. Lack of ovarian activity is reflected by lack of menstruation (See Figure 7-11). Please note from Figure 7-11 that lactating women from India and Sri Lanka displayed significant retardation of cyclicity when compared to women from the USA and the United Kingdom. While cultural differences exist between these subpopulations, nutritional aspects may be important. Lactation can be considered a form of contraception where nutrition is a limiting factor. The physiologic mechanism causing lactational amenorrhea is believed to be regulated by high prolactin during lactation. High prolactin causes a decrease in GnRH frequency and amplitude and thus a decrease in LH and FSH. This system is very effective during the first 6 months postpartum but more and more women start cycling after 6 months postpartum. The primary events of the menstrual cycle and the estrous cycle are fundamentally the same. However, there are marked differences in how these events are expressed between the two types of cycles. These differences are summarized in Table 7-2.

Figure 7-11. Influence of Lactation Upon Return to Cyclicity in Women

(Modified from Mepham. 1987. *Physiology of Lactation*)

Women that are not lactating begin menstruating sooner than lactating women. About 90% of non-lactating women start menstruating by 12 months postpartum. However, cyclicity is delayed in postpartum women even without the suckling stimulus. Other sensory inputs (tactile, auditory, visual and perhaps olfactory) may inhibit GnRH. Only 5-30% of lactating women begin menstruating by 12 months. Also, only about 70% of postpartum lactating women begin cycling within 2 years in the U.S. and United Kingdom. Indian and Sri Lankan women have an even greater delay in their return to cyclicity.

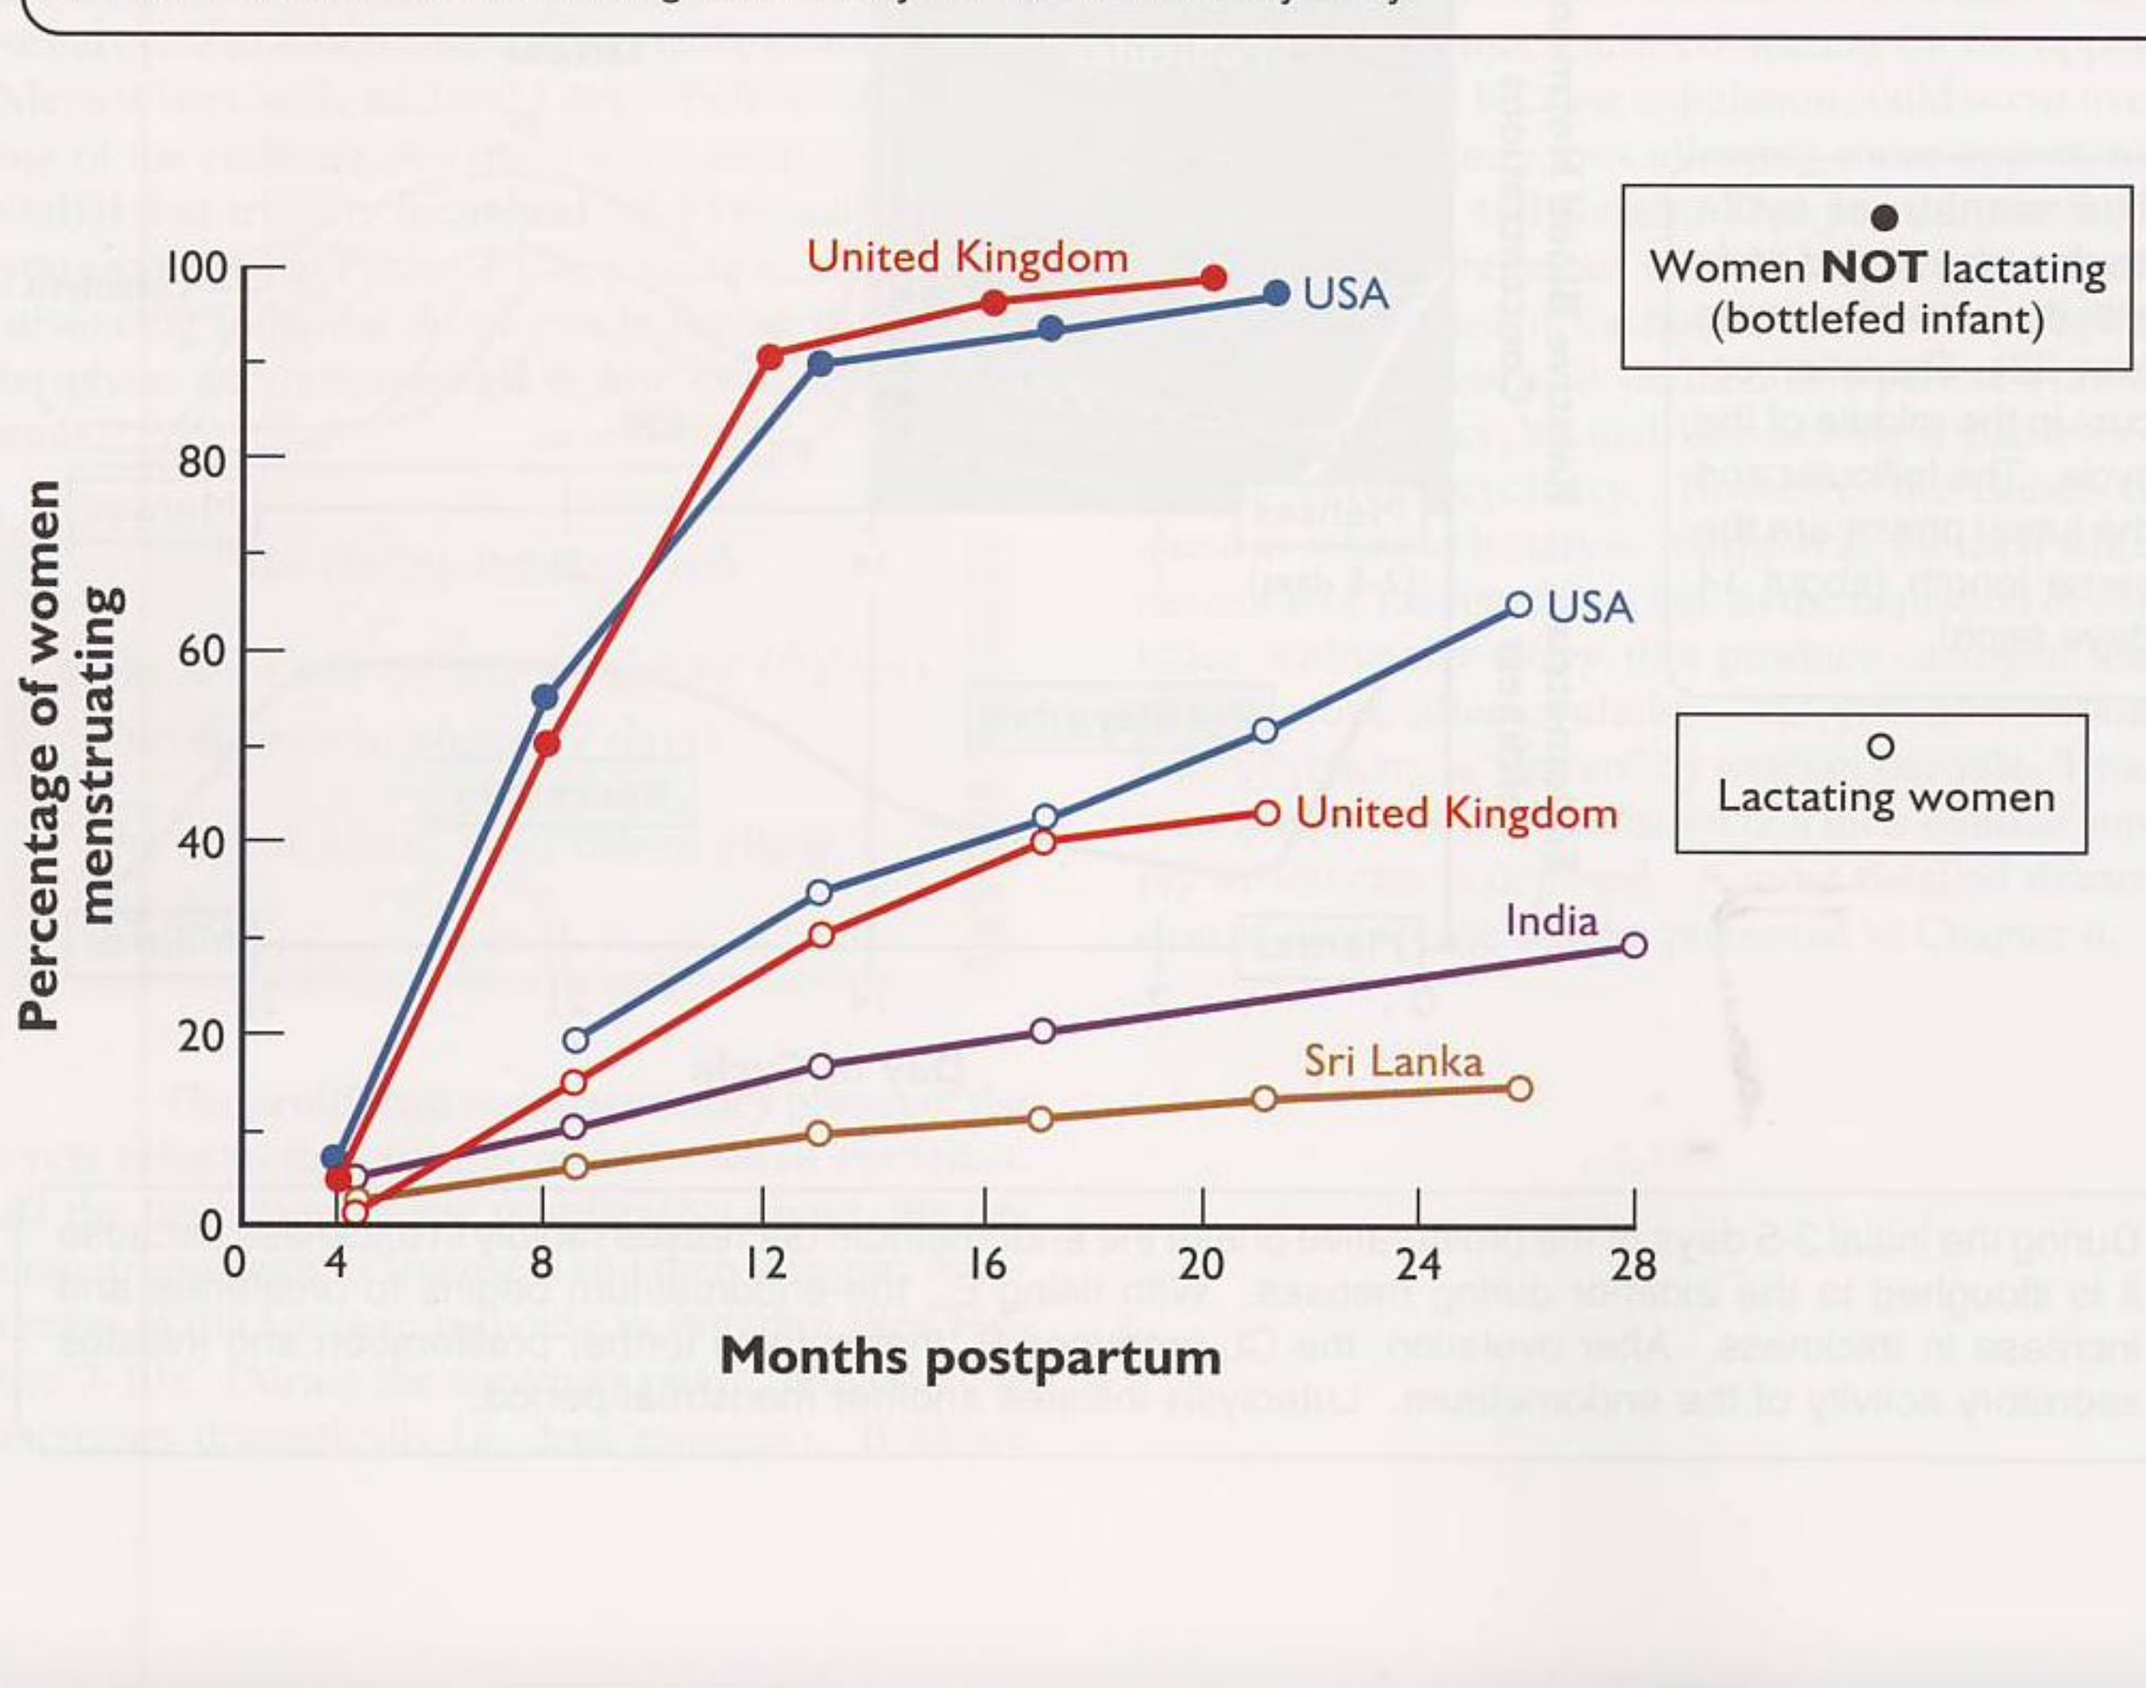


Table 7-2. Cycle Event Comparison Between the Estrous Cycle and Menstrual Cycle

EVENT	ESTROUS CYCLE	MENSTRUAL CYCLE
Follicular Phase	Short (20% or less of cycle duration)	Long (50% of the cycle duration)
Ovulation	At the beginning and end of the cycle	Middle of cycle (day 14)
Luteal Phase	80% of the cycle	50% of the cycle
Fertile Period	24 hrs or less (5% of cycle)	Up to 6 days before ovulation (18% of cycle)
Endometrial Sloughing	None	After luteolysis
Luteolysis	Uterine $PGF_{2\alpha}$	Ovarian $PGF_{2\alpha}$
Sexual Receptivity	Well defined	Relatively uniform throughout cycle
Progesterone function and sexual receptivity	Inhibits GnRH release Inhibits sexual receptivity	Inhibits GnRH release Does not influence sexual receptivity
Menopause	None described	Well characterized (follicular depletion)

Further PHENOMENA for Fertility

The word "menstrual" (as in menstrual cycle) is derived from the Latin word meaning month. In historical Latin folklore the moon was believed to regulate not only the tides of the sea, but also the monthly "emotional tides" of women.

Some female bats are very aggressive and prey on the males of their species, thus minimizing the opportunity for successful copulation and pregnancy. To offset this problem, males hibernate after the females. Thus, males can then safely breed the "sleeping" females. This is not a "silent estrus"!!! Ovulation does not occur until after hibernation. The sperm are stored in the female tract until ovulation when they fertilize the oocytes.

In primitive societies, menstruating women were isolated from the tribe and forced to occupy a small "menstrual hut" located away from the village. Menstruation was believed to be responsible for assorted ills such as crop failures, bad luck in hunting and fishing, death of livestock, failure of food to be preserved and failure of beer to ferment. Reproductive processes were blamed because of ignorance about them.

Dairy cows are afflicted by a condition called cystic ovarian disease, often called "cystic ovaries". One type of cystic ovarian disease results in nymphomania (excessive or uncontrollable sexual desire). Follicles fail to ovulate and continue to produce estradiol that causes the cow to be in constant estrus.

Women were not employed in the opium industry during the 19th century because it was believed that menstruating women would make the opium bitter.

Prostitutes encounter spermatozoa on a frequent basis. It is known that prostitutes have blood titers of antisperm antibodies. Some prostitutes even have severe allergic reactions.

The mouthbrooder fish is so called because fertilization actually takes place in the female's mouth. First, she releases her ova into the water, then she turns around and swallows them. When the male swims by she mistakes the distinctive spots on his anal fin for more of her eggs. She opens her mouth to swallow them and catches his sperm instead. It is not known whether fertilization rates are higher in these species where it occurs in a confined space to other species of fish where milt is deposited over the eggs in moving water.

Unlike humans, other animals apparently do not have menopause. For example, chimpanzees live to be forty years old but show no signs of menopause. The female African elephant remains reproductively competent until she is in her nineties.

Lactational amenorrhea can be considered as a form of contraception. !Kung hunter gatherers live in the Kalahari Desert in southern Africa. In the absence of any form of artificial birth control, the mean birth interval is 4.1 years and the mean completed family size 4.7 children. Nutritional status may be a contributory factor. However, !Kung neonates practice a very high suckling frequency. The mother always carries her infant in a sling so that it is able to suckle ad libitum. Suckling occurs about four times an hour, for periods of 1-2 minutes; frequent suckling also occurs at night. It is not known if there is a threshold number of suckling sessions required to inhibit GnRH in women (like in cows).

During the Middle Ages (500-1500 AD) women throughout Europe hollowed out lemon halves and used them to cover the cervix in the same way women use the diaphragm today.

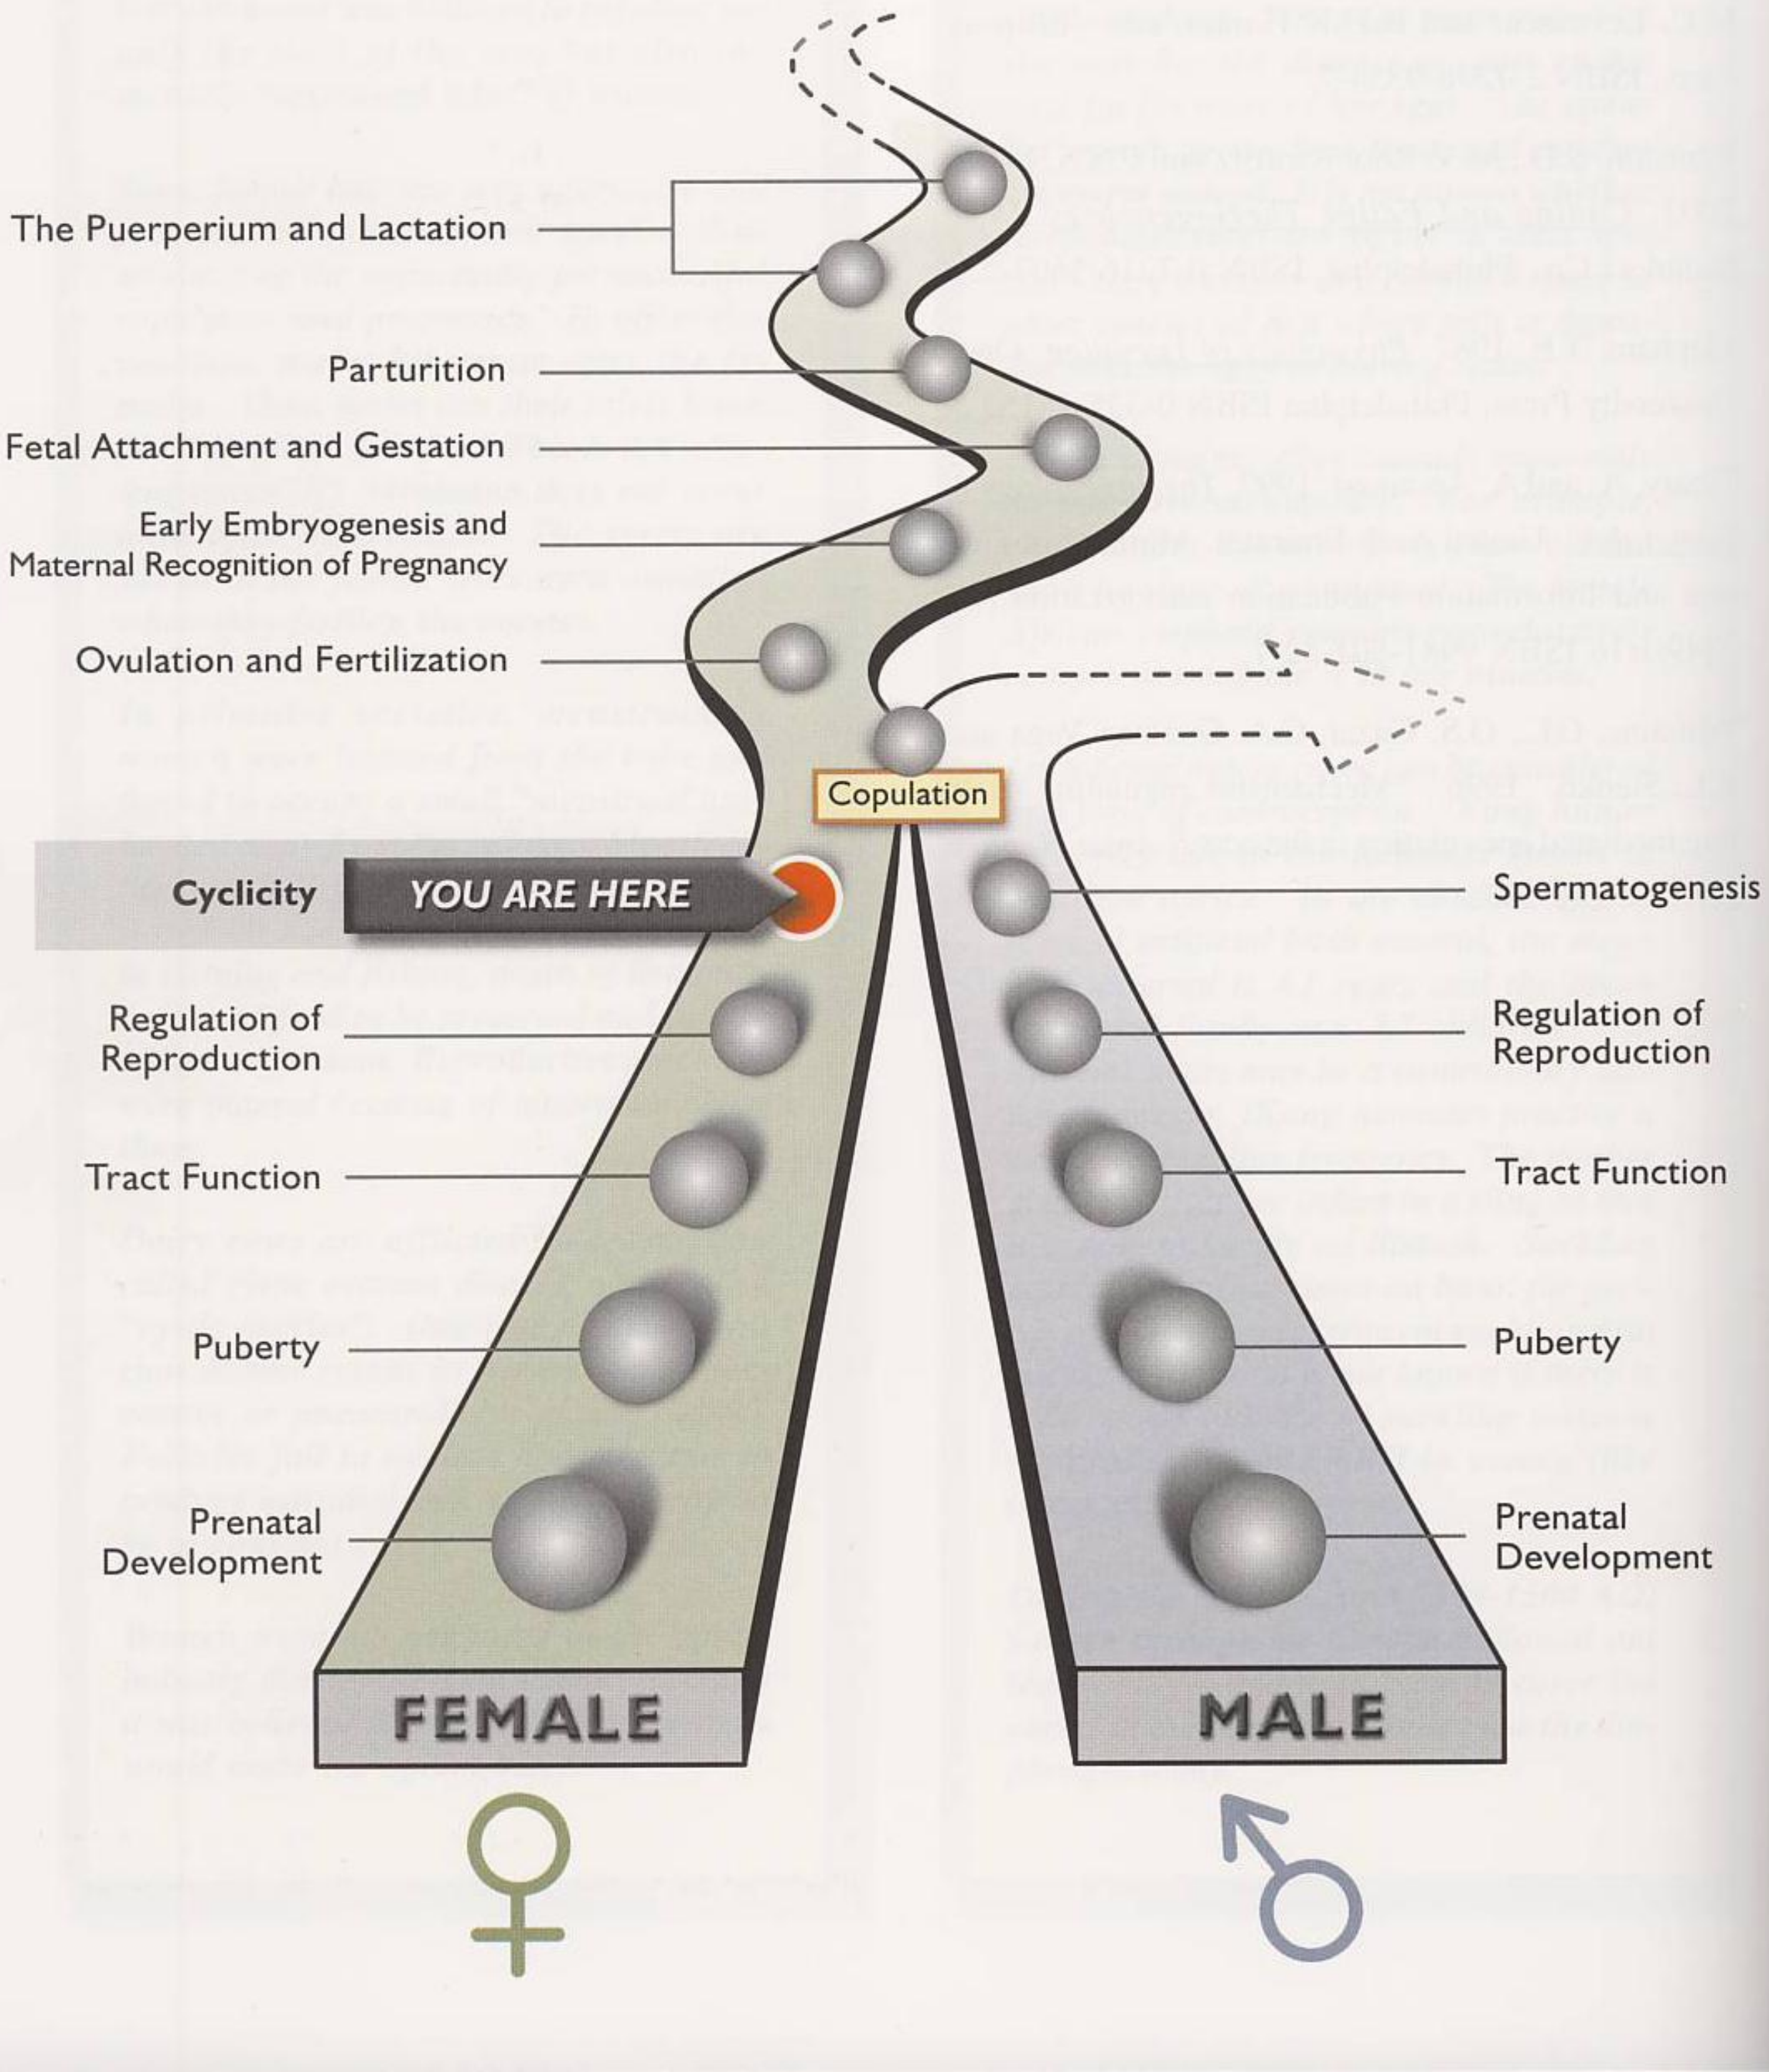
CHAPTER 8

Reproductive Cyclicity - The Follicular Phase



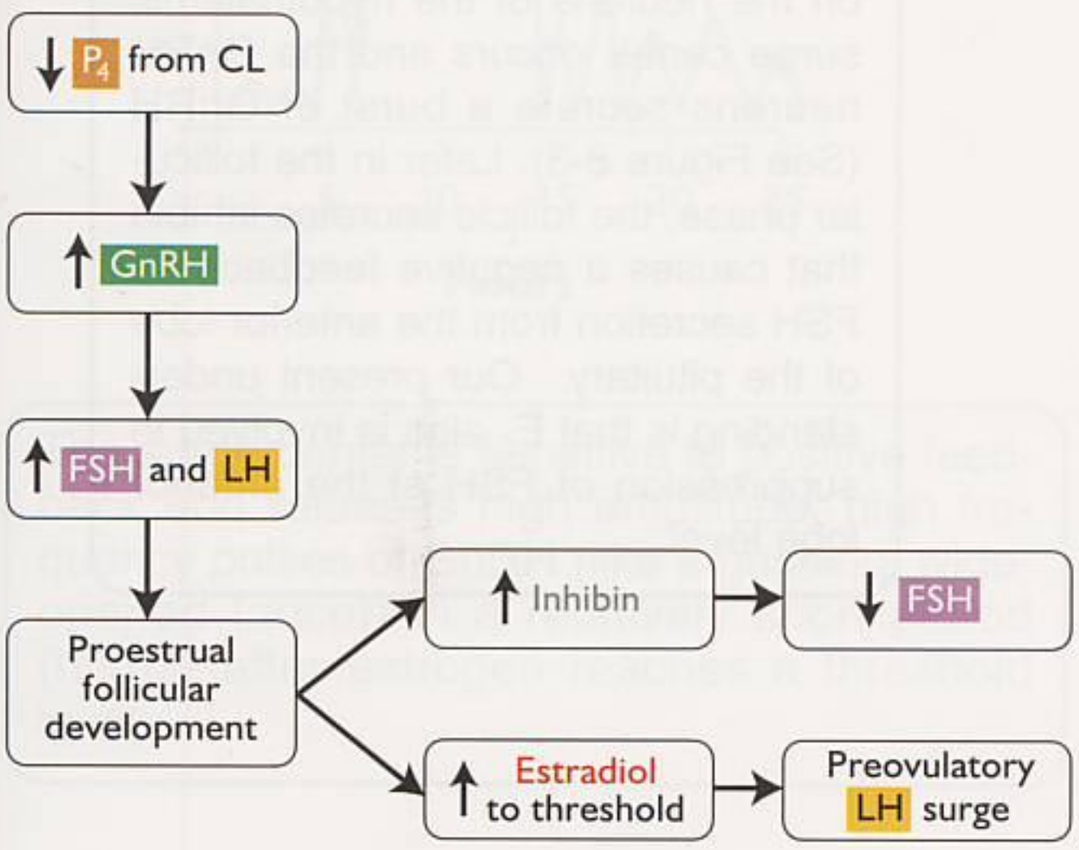
Take Home Message

The follicular phase consists of four major events. They are: 1) elevated gonadotropin release from the anterior lobe of the pituitary; 2) follicular growth and preparation for ovulation; 3) sexual receptivity and 4) ovulation. Estrogen is the dominant hormone that is produced by developing follicles and causes profound changes in the reproductive tract preparing it for copulation. Reproductive behavior is induced by estrogen in non-primate mammals. Estrogen also controls the onset of the preovulatory LH surge that causes ovulation. Ovulation is a cascade of physiological and biochemical changes that culminate in rupture of dominant follicles and release of the oocyte from the ovary.

It is important to recognize that the follicular phase is initiated after luteolysis that results in a marked reduction in progesterone. Therefore, the negative feedback by progesterone on the hypothalamus is removed and GnRH is released at higher amplitudes and frequencies than during the preceding luteal phase. At first, this causes FSH and LH to be released at higher concentrations, thus promoting follicular development and the production of estrogen. Later in the follicular phase, FSH secretion declines (See Figure 8-4). The main steps in this process are presented in Figure 8-1.

Recall from Chapter 7 that the follicular phase of the estrous cycle consists of **proestrus** and **estrus**. During the follicular phase four significant events take place. They are: 1) gonadotropin release from the anterior lobe of the pituitary; 2) follicular preparation for ovulation; 3) sexual receptivity and 4) ovulation. These components will be described in the remainder of this chapter and in Chapter 11 (Reproductive Behavior).

Figure 8-1. Primary Steps Leading to the Preovulatory LH Surge



Gonadotropin Release is Controlled by Ovarian Estrogen and Hypothalamic GnRH

The follicular phase is governed by the hypothalamus, the anterior lobe of the pituitary and the ovary through the production of estradiol in the absence of progesterone. The relationship between these components is illustrated in Figure 8-2.

The hypothalamus plays an obligatory role in regulating estrous cycles because it produces **gonadotropin releasing hormone** (**GnRH**) that is responsible for stimulating the release of the gonadotropins FSH and LH.

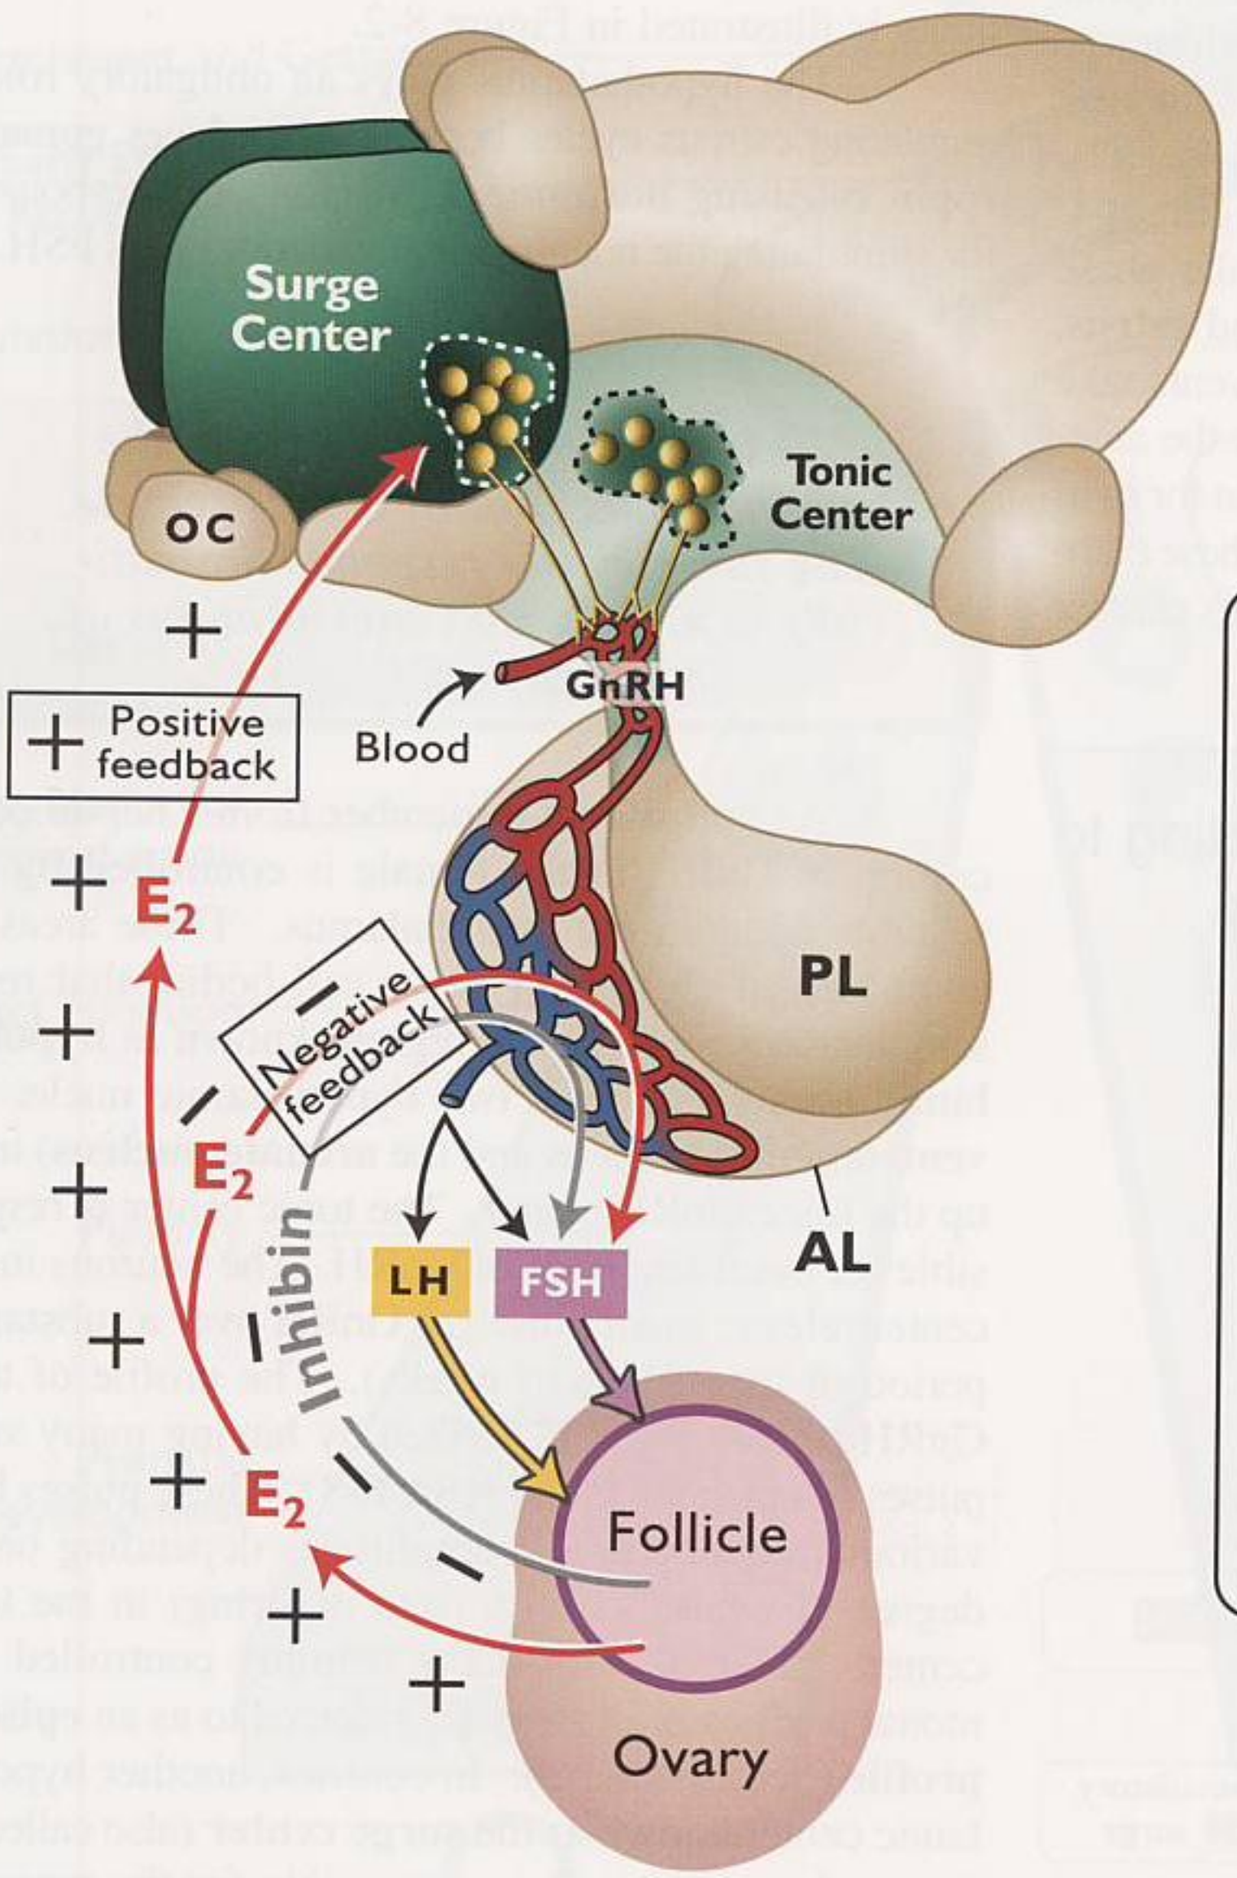
The tonic and surge centers in the hypothalamus control GnRH release. The surge center responds dramatically to high blood concentrations of estradiol.

As you should remember from Chapter 5, secretion of GnRH in the female is controlled by two separate areas in the hypothalamus. These areas are composed of clusters of nerve cell bodies that represent anatomically discrete regions known as **hypothalamic nuclei**. At least two hypothalamic nuclei (the **ventromedial nucleus** and the **arcuate nucleus**) make up the tonic GnRH center. The tonic center is responsible for basal secretion of GnRH. The neurons in this center release small pulses of GnRH over a substantial period of time (days to weeks). The profile of tonic GnRH release is characterized by having many small pulses or episodes (See Figure 8-3). These pulses have various frequencies and amplitudes depending on the degree of neural activity (rate of firing) in the tonic center. Thus, as with many neurally controlled hormonal profiles, this pattern is referred to as an **episodic profile** (See Chapter 5). In contrast, another hypothalamic center known as the **surge center** (also called the "preovulatory center") is responsible for the preovula-

tory release of GnRH that stimulates a surge of LH, causing ovulation. Anatomically, the surge center consists of three nuclei called the **preoptic nucleus**, the **anterior hypothalamic area** and the **suprachiasmatic nucleus**. This center releases basal levels of GnRH until it receives the appropriate positive stimulus. This stimulus is known to be a threshold level of estrogen in the absence of progesterone. When the estrogen concentration in the blood reaches a certain level, a large quantity of GnRH is released from the terminals of neurons, the cell bodies of which are located in the surge center. Release of GnRH is caused by depolarization (action potentials) originating in the cell bodies of neurosecretory cells. In natural conditions, the preovulatory surge of GnRH occurs only once during the estrous or menstrual cycle. However, tonic release of GnRH occurs from these neurons during the entire estrous cycle.

The release of GnRH by the tonic and preovulatory centers in the hypothalamus may be compared to water faucets. Tonic (basal) release is analogous to a leaky faucet (See Figure 8-3) from which small quantities of water drip from the faucet over a relatively long period of time. In contrast, release of GnRH from the preovulatory center is analogous to opening a faucet fully for a short period of time and then suddenly turning it off. Water gushes forth and then stops. A threshold level of estrogen (without progesterone) is necessary to open the faucet fully.

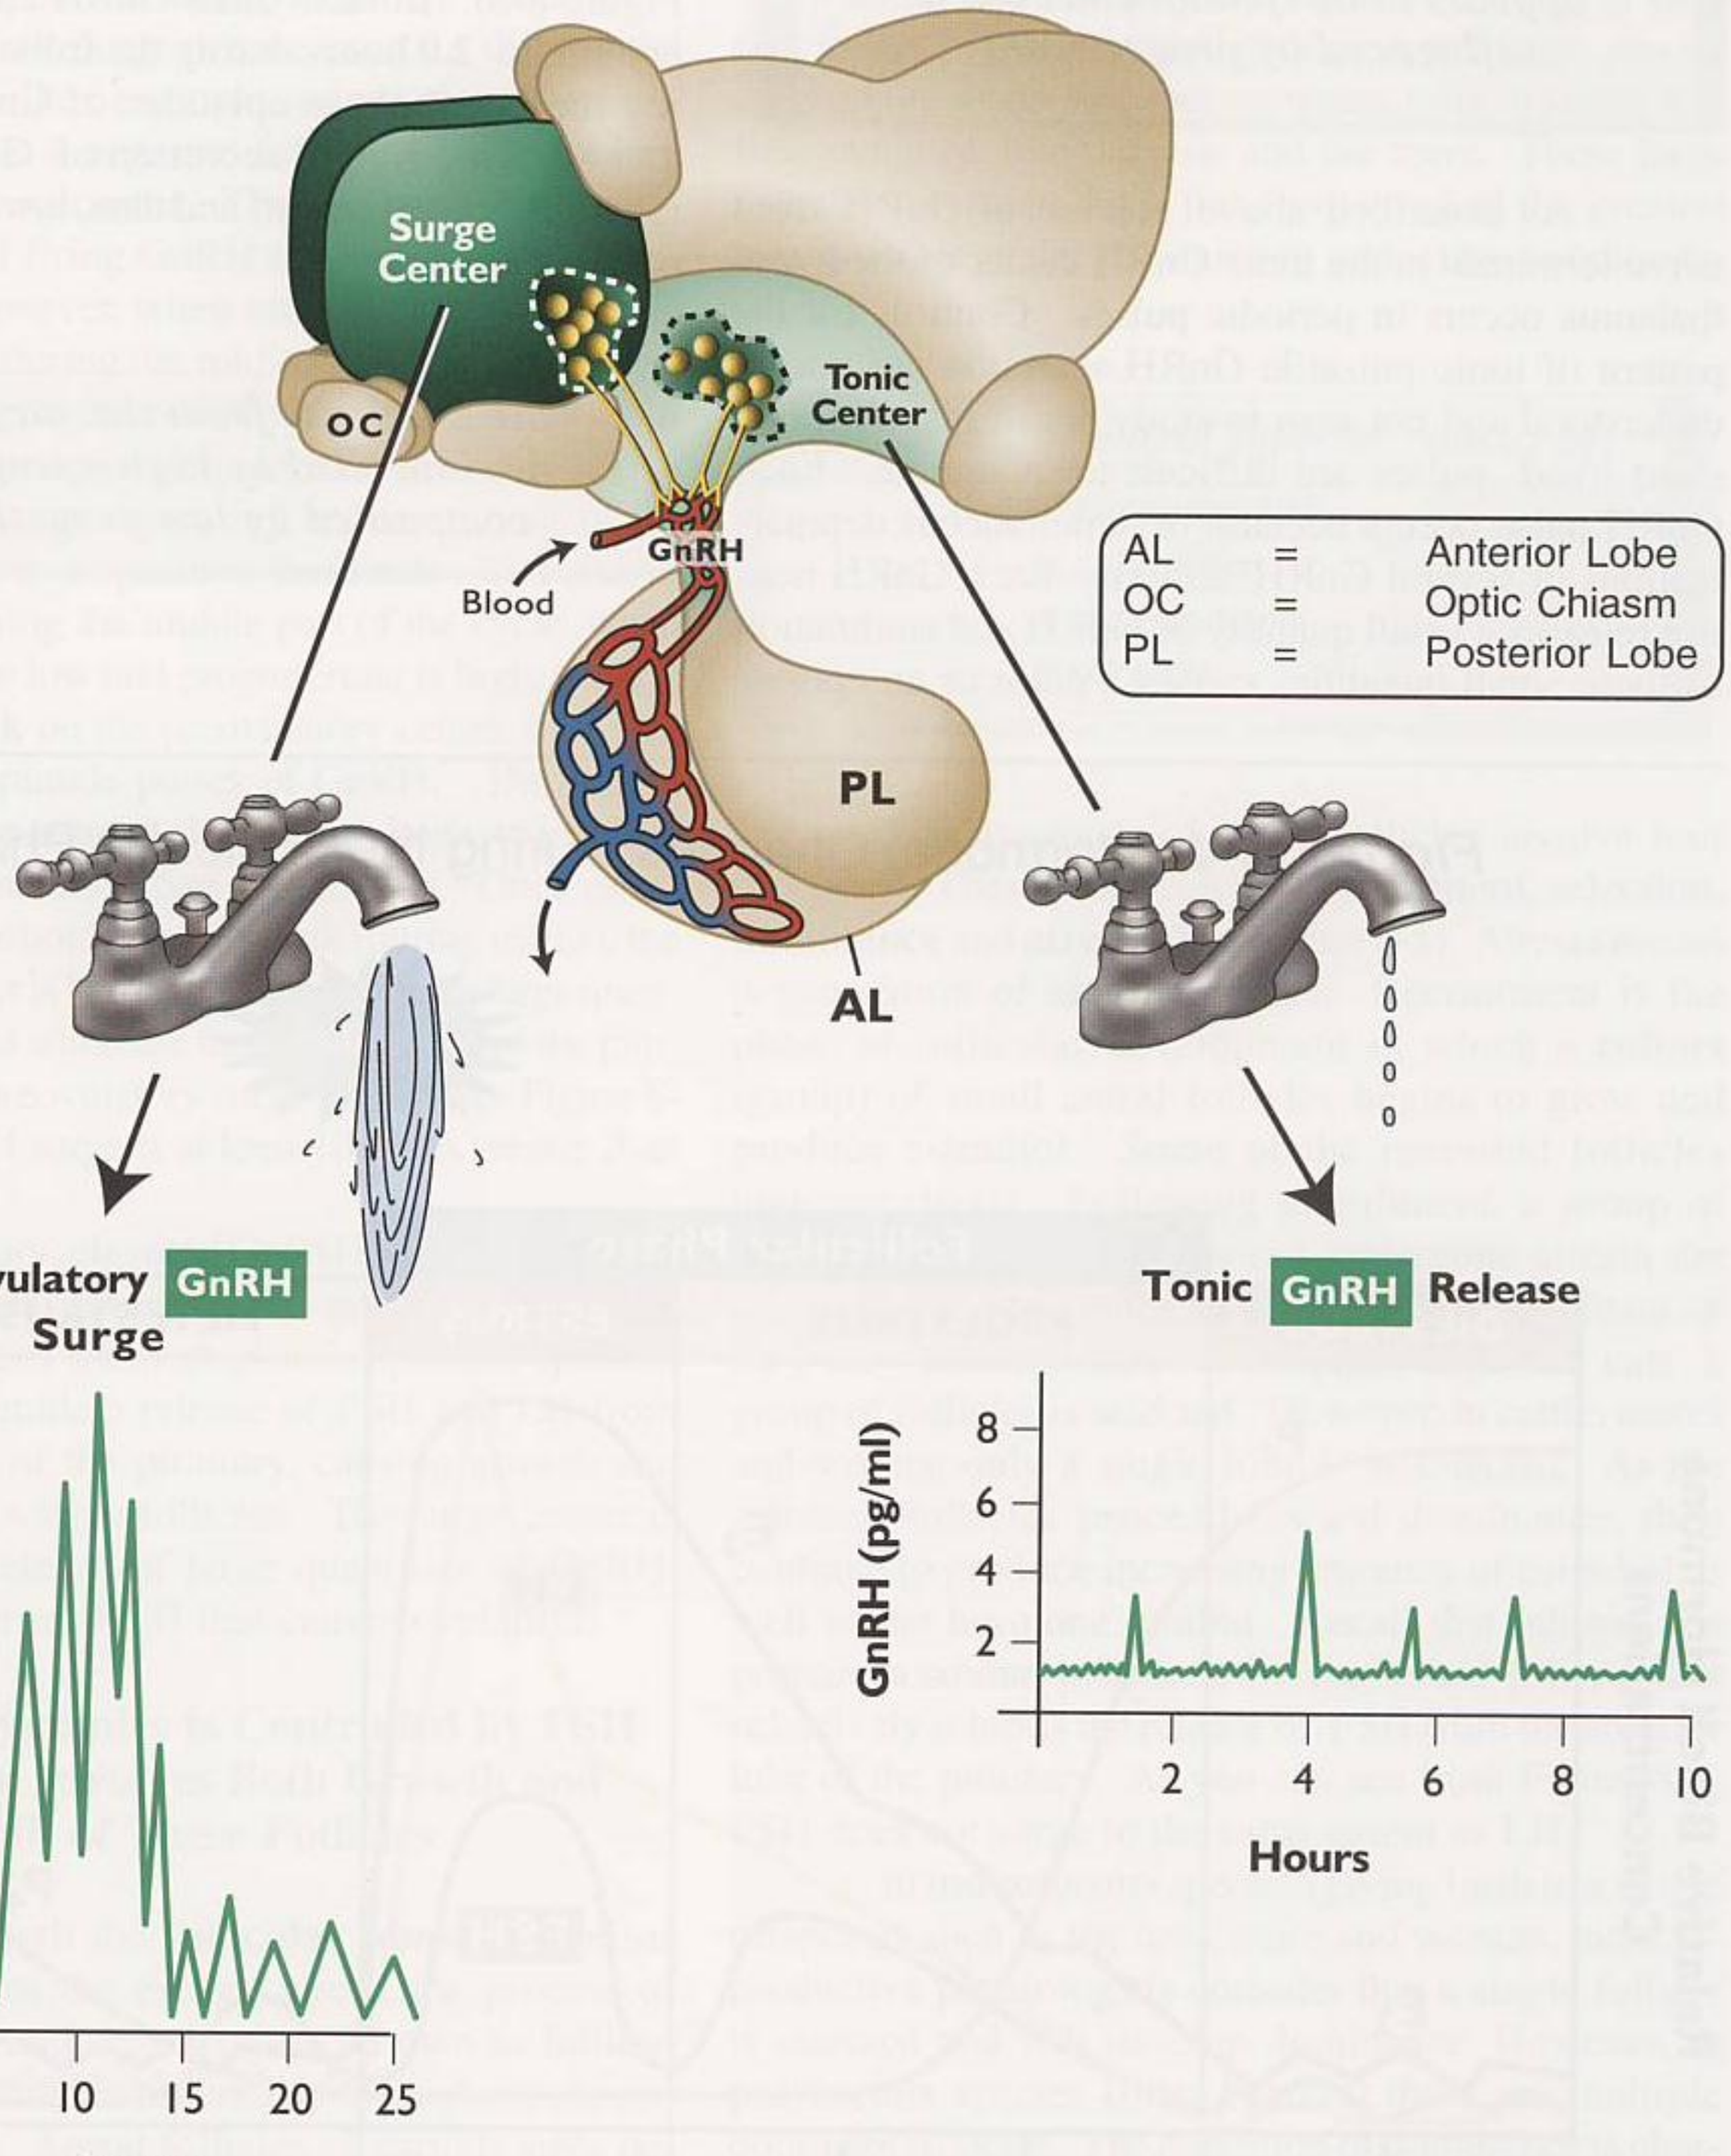
Figure 8-2. The Relationship Between the Hypothalamus, the Pituitary and the Ovary During the Follicular Phase



AL	=	Anterior Lobe
E_2	=	Estradiol
OC	=	Optic Chiasm
PL	=	Posterior Lobe

Early in the follicular phase, GnRH pulse frequency begins to increase (because of low P_4), thus causing FSH and LH to be secreted from the anterior lobe of the pituitary. These gonadotropins stimulate ovarian follicles to secrete estradiol, a positive feedback on the neurons of the hypothalamic surge center occurs and the GnRH neurons secrete a burst of GnRH (See Figure 8-3). Later in the follicular phase, the follicle secretes inhibin that causes a negative feedback on FSH secretion from the anterior lobe of the pituitary. Our present understanding is that E_2 also is involved in suppression of FSH at the anterior lobe level.

Figure 8-3. GnRH Release From the Hypothalamic Tonic and Surge Centers



The surge center is sensitive to positive feedback and releases high amplitude, high frequency pulses of GnRH (like a gushing, wide-opened faucet) in a relatively short period (hours) after estrogen reaches a threshold level.

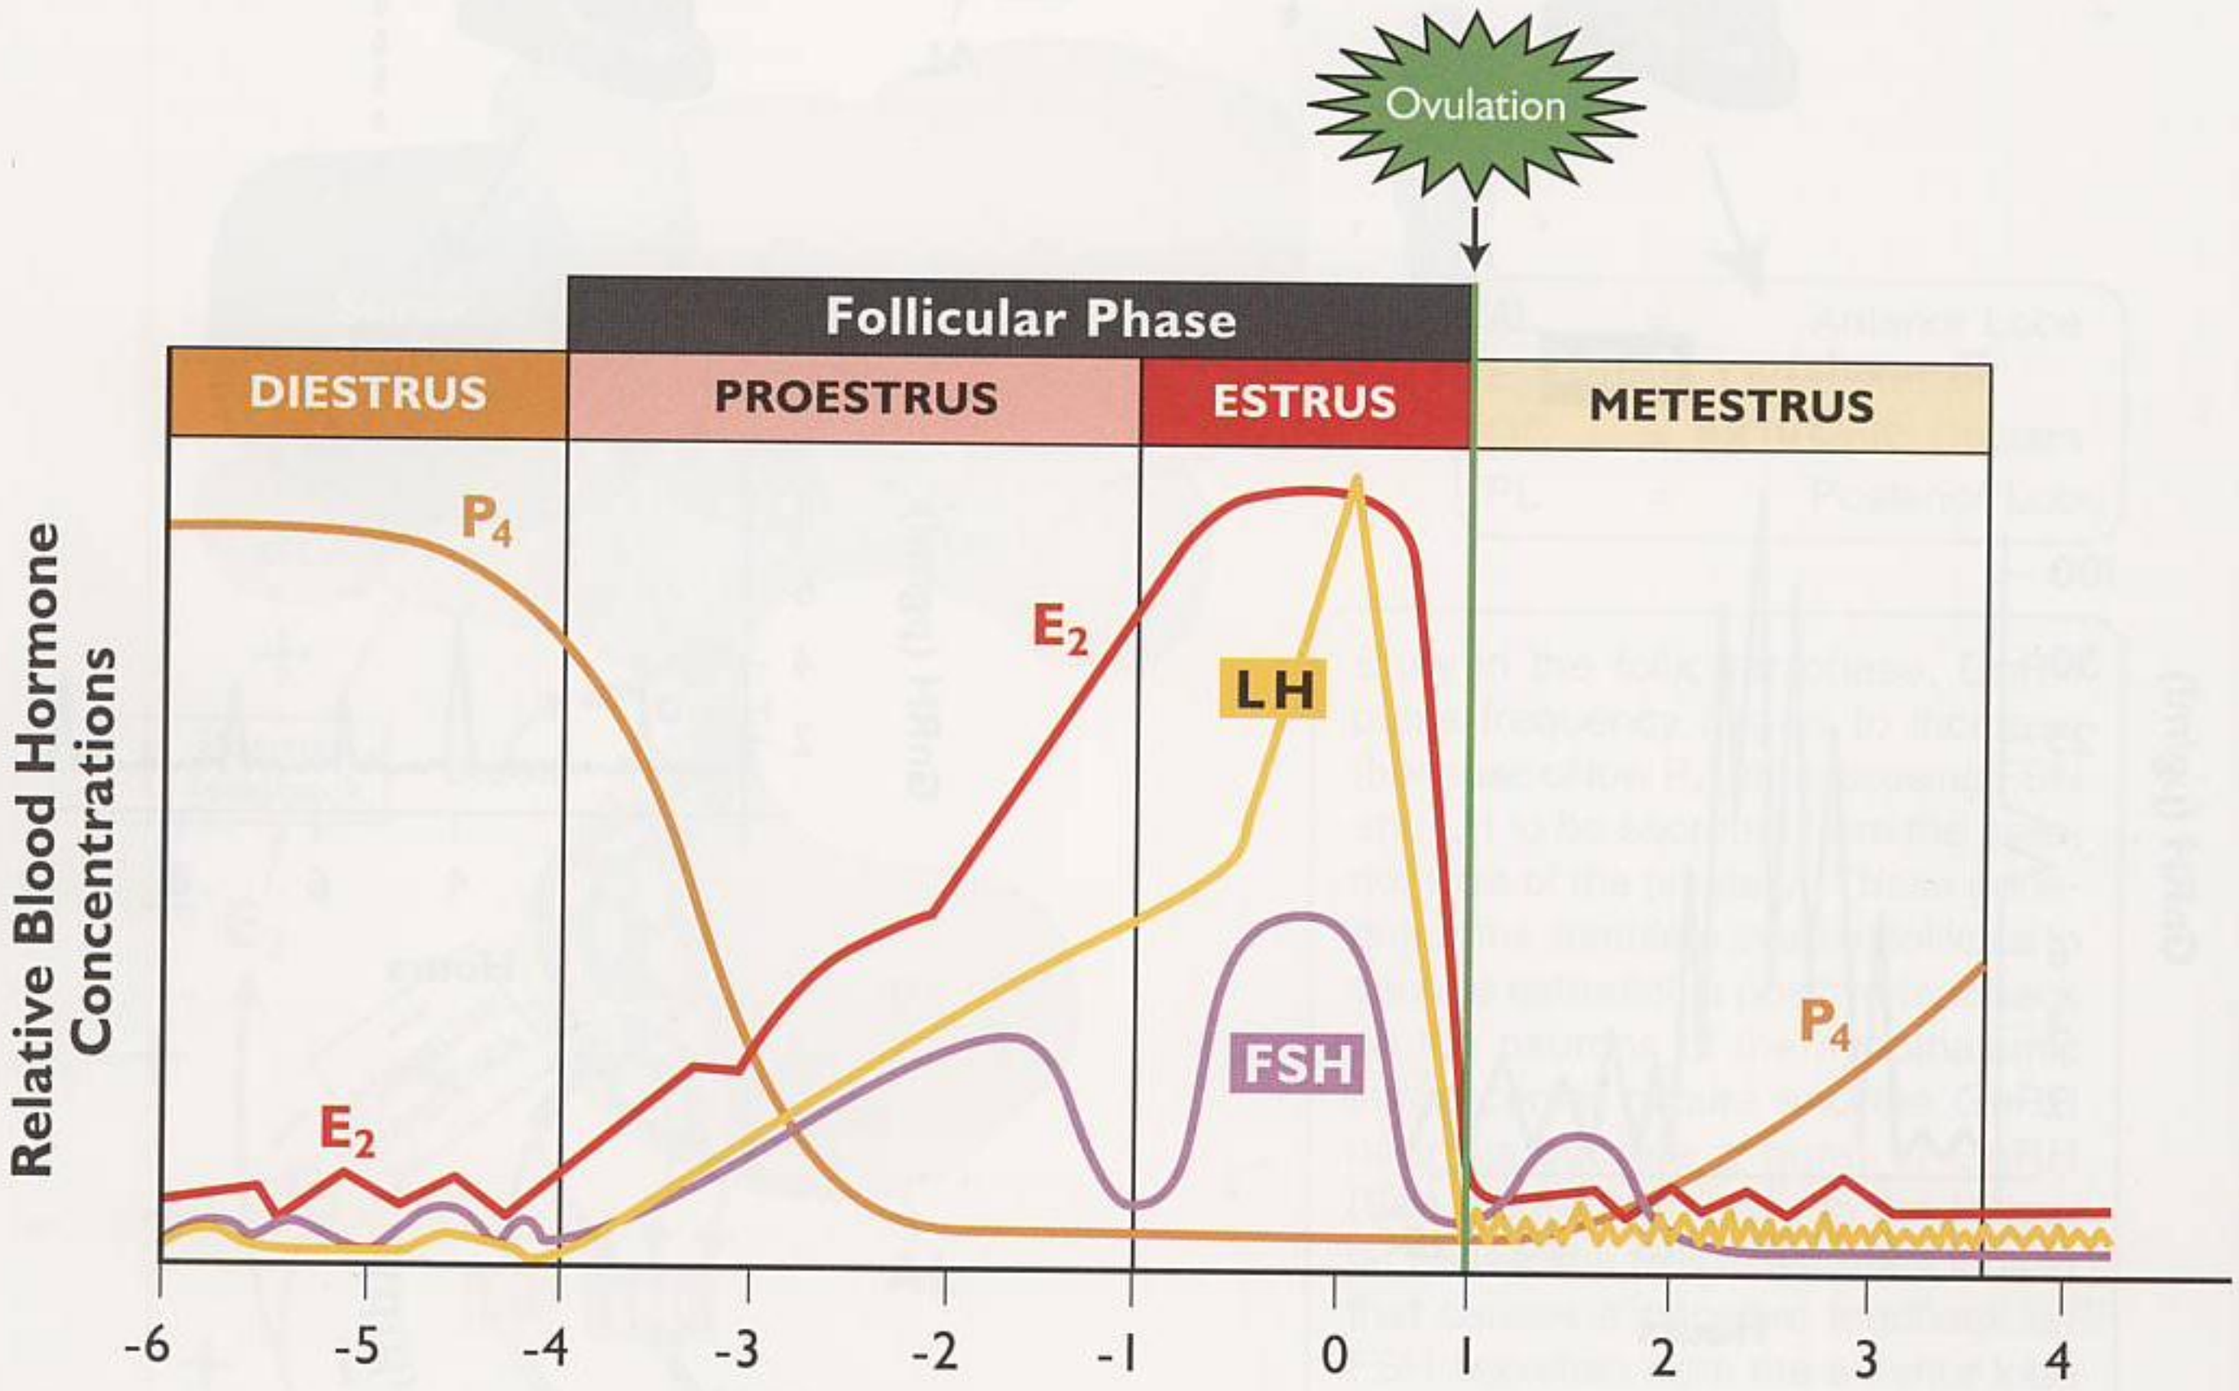
The tonic center releases small episodes of GnRH in a pulsatile fashion similar to a dripping faucet. This episodic release is continuous throughout reproductive life.

GnRH release from the tonic center appears to be spontaneous but is influenced by progesterone.

As described above, release of GnRH from nerve terminals in the tonic GnRH center of the hypothalamus occurs in periodic pulses. Controls for the pattern of tonic pulsatile GnRH secretion are poorly understood and not easy to study because such small, short-lived pulses are difficult to quantitate. Each GnRH pulse occurs because of simultaneous depolarizations of several GnRH neurons. Each GnRH neuron releases a small quantity of GnRH and summation of these small quantities causes a pulse or an episode to occur. The release of GnRH from tonic center neurons occurs spontaneously in a rhythmic fashion (See Figure 8-3). In fact, small GnRH episodes occur every 1.5 to 2.0 hours during the follicular phase. During the luteal phase episodes of GnRH occur every 4 to 8 hours. Neural secretion of GnRH is very low (5pg/ml of blood serum) and thus, low amplitude pulses of LH are released.

GnRH release from the surge center is controlled by high estrogen accompanied by low progesterone.

Figure 8-4. Hormonal Changes During the Follicular Phase



Proestrus

As progesterone (P_4) drops, FSH and LH increase together in response to GnRH. FSH and LH cause the production of estradiol (E_2) by ovarian follicles (See Figure 8-2).

Estrus

When recruited follicles develop dominance, they produce estradiol and inhibin that suppresses FSH secretion from the anterior lobe of the pituitary. Thus, FSH does not surge with the same magnitude as LH. When estrogen reaches a threshold level (peak), the preovulatory surge of LH occurs, inducing ovulation.

The preovulatory surge of GnRH is controlled by the combination of high estradiol and low progesterone. In mammals (including humans), estradiol in the presence of low progesterone exerts a differential effect on GnRH. For example, estradiol in low concentrations causes a negative feedback (suppression) on the preovulatory center. That is, low estrogen reduces the level of firing GnRH neurons in the preovulatory center. However, when estradiol levels are high, as they would be during the mid-to late follicular phase (See Figure 8-4), the preovulatory center responds dramatically by releasing large quantities of GnRH. This stimulation in response to rising concentrations of estradiol is referred to as **positive feedback**. You should recognize that during the middle part of the cycle, when estradiol levels are low and progesterone is high, there is **negative feedback** on the preovulatory center, thus preventing high amplitude pulses of GnRH. During the follicular phase (proestrus), the follicles begin to produce more and more estradiol (See Figure 8-4). Once estradiol reaches a threshold level, or peak (during estrus), the preovulatory center is "turned on" and releases large quantities of GnRH that stimulate the anterior lobe of the pituitary to secrete a preovulatory surge of LH (See Figure 8-3). In fact, the LH surge is at least 10 times greater than a tonic LH pulse.

In summary, elevated GnRH is essential for initiating the follicular phase of the estrous cycle. The tonic center releases small amplitude episodes (pulses) of GnRH that stimulate release of FSH and LH from the anterior lobe of the pituitary, causing growth and development of ovarian follicles. The surge center is responsible for release of large quantities of GnRH, thus causing a surge of LH that causes ovulation.

Follicular Dynamics is Controlled by FSH and LH and Involves Both Growth and Death of These Follicles

Even though the **follicular phase** comprises only about 20% of the estrous cycle, the process of follicular growth and degeneration (known as **follicular dynamics**) occurs continuously throughout the entire estrous cycle. Antral follicles of various sizes develop in response to tonic levels of FSH and LH and these antral follicles are always present. If you were to examine the ovaries at any point during the estrous cycle, you would see a significant number of antral follicles of various sizes. These antral follicles have been classified by scientists studying follicular dynamics as small, medium or large depending on their diameter. For example, in the pig the small, medium and large classifications consist of follicles measuring less than 3mm, 4 to 6mm and greater than 6mm in diameter, respectively. However, in the mare, the sizes of these same classifications are: less than 10mm, 10 to 20mm and greater than 20 mm respectively. The number of small antral follicles may exceed 100 for a pair of ovaries in the pig. Large follicles almost always can be seen on the ovaries in species where only a single follicle ovulates, like the cow and the mare. These large follicles represent those that have reached the greatest size possible under the existing endocrine conditions.

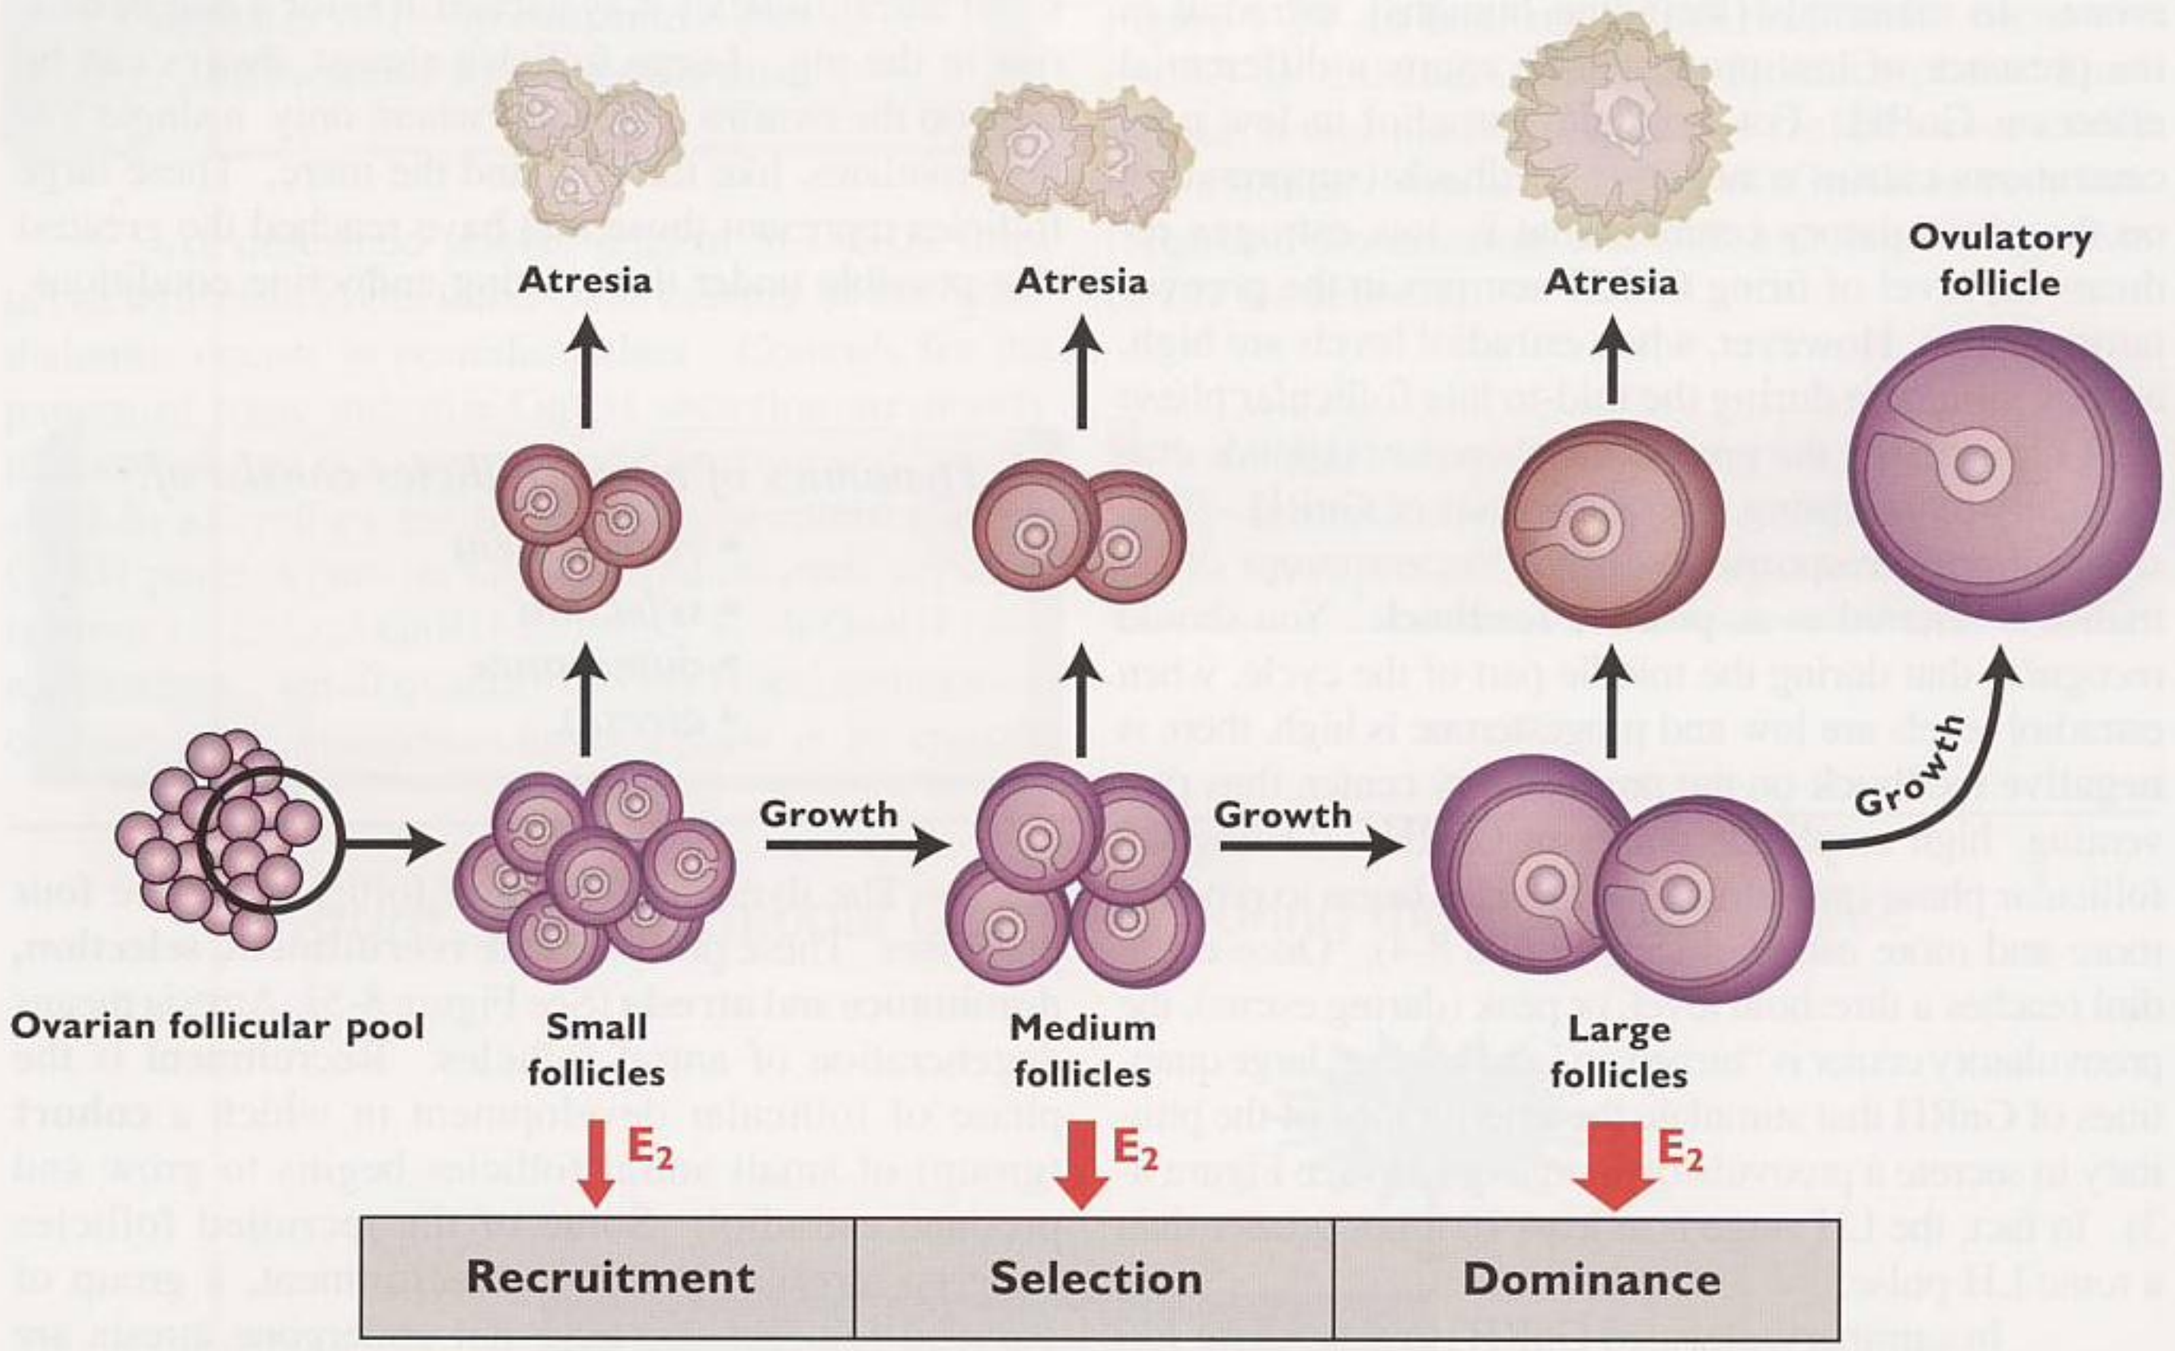
Dynamics of antral follicles consist of:

- ***recruitment***
- ***selection***
- ***dominance***
- ***atresia***

The dynamics of antral follicles involve four processes. These processes are **recruitment**, **selection, dominance** and **atresia** (See Figure 8-5). Atresia means degeneration of antral follicles. Recruitment is the phase of follicular development in which a **cohort** (group) of small antral follicles begins to grow and produce estradiol. Some of the recruited follicles undergo atresia. Following recruitment, a group of growing follicles that have not undergone atresia are selected. Selected follicles may become dominant or they may undergo atresia. In pigs, dogs and cats, a group of follicles is selected. However, in cattle, mares and women only a single follicle is selected. As the selected follicles proceed toward dominance, they continue to produce increasing amounts of estradiol as well as the hormone inhibin. Recall that inhibin is a protein hormone produced by the antral follicle that selectively inhibits the release of FSH from the anterior lobe of the pituitary. As you can see from Figure 8-4, FSH does not surge to the same extent as LH.

In **monotocous** species (giving birth to a single offspring) such as the cow, mare and woman, most reproductive physiologists consider that a single follicle is selected and will develop dominance. However, in **polytocous** species (litter bearers) there are multiple dominant follicles. The condition of dominance is characterized by one or more large preovulatory follicles exerting a major inhibitory effect on other antral follicles from the recruited and selected cohort. This inhibitory influence is thought to be caused by a combination of the production of inhibin and estradiol by the dominant follicle and reduced blood supply to some follicles. Suppressed FSH concentrations in the blood, coupled with reduced blood supply to some follicles results in atresia. Only those follicles receiving a large blood supply (and thus higher levels of gonadotropin) continue to grow and ovulate.

Figure 8-5. Follicular Recruitment, Selection and Dominance



Recruitment
Small antral follicles are recruited from the ovarian pool and produce small amounts of E_2.

Selection
Follicles are selected from previously recruited small follicles and either become atretic or develop further. Selected follicles produce moderate amounts of E_2.

Dominance
Selected follicles that do not become atretic become dominant follicles that produce large quantities of E_2. Dominant follicles will ovulate. In polytocous species, more than one follicle is selected. However, in monotocous species only a single follicle is selected.

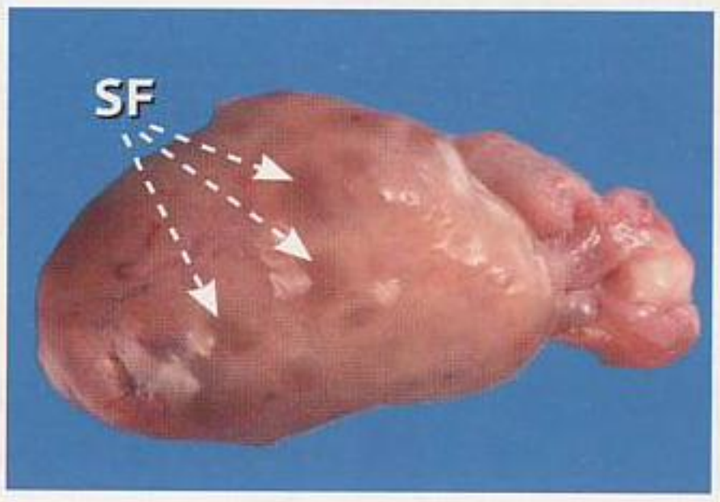
Atresia occurs continuously throughout folliculogenesis.

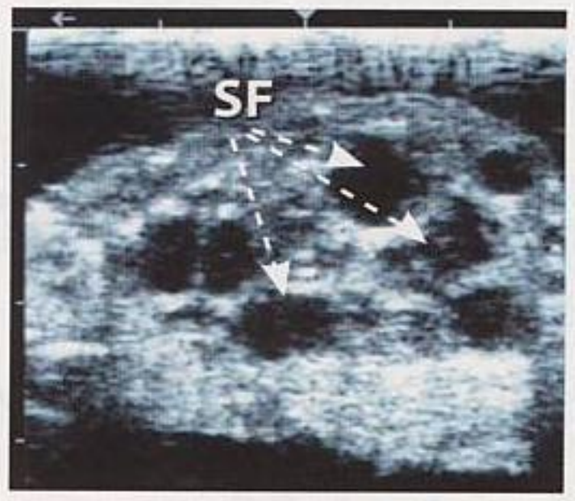
The process of **atresia** involves far more follicles than does the process of dominance. In fact, over 90% of ovarian follicles undergo an irreversible degenerative process called atresia. The word atresia in the follicular context refers to the closure or disappearance of the antrum that accompanies the degenerative changes of an antral follicle. At any one point in time during the postpubertal reproductive period, the proportion of atretic antral follicles is quite high. For example, if you were to examine the ovaries of a rat, about 70% of antral follicles would be in some stage of atresia. In the mouse 50% are atretic, in the rabbit 60% and in the human 50 to 75%.

As you can see in Figure 8-7, during metestrus (days 3 to 5 in cattle), a group of follicles is recruited. However, these follicles are not exposed to the appropriate endocrine conditions for continued development and undergo atresia within the ovary. During diestrus, a second follicular wave occurs, but these follicles also undergo atresia. Note that the first two follicular waves begin and terminate during times in the cycle when progesterone is increasing or is at its highest level (See Figure 8-7). Neither complete follicular development nor ovulation can occur under progesterone dominance. However, the dominant follicle of each wave will ovulate if luteolysis occurs. During progesterone dominance, GnRH is released in low quantities only and thus FSH and LH are low. It should be emphasized that even though follicles in the first two follicular waves become atretic they still produce some estradiol.

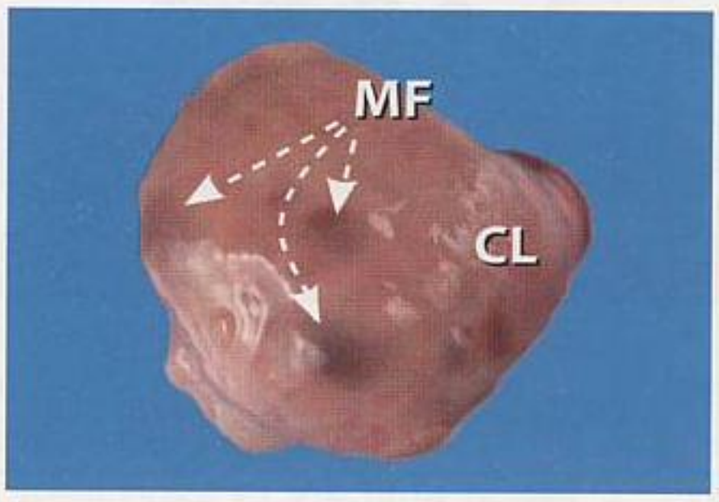
Figure 8-6. Bovine Ovarian Follicles and Their Respective Ultrasonographic Images

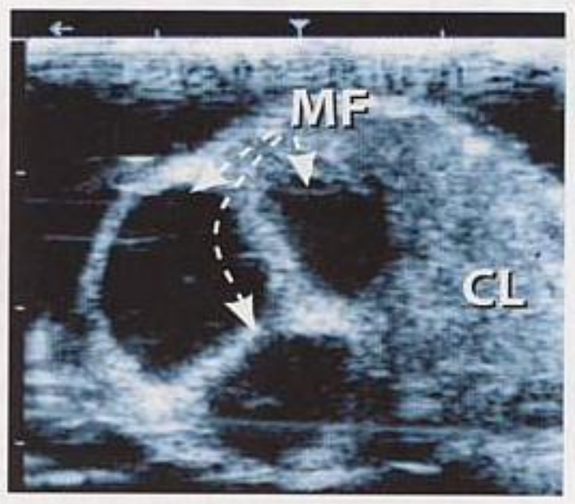
This ovary contains many small antral follicles (SF). There are no large structures on this ovary indicating that this ovary is not participating in the current cycle. More follicles appear in the ultrasonographic image than appear in the photograph because ultrasound imaging allows observation of follicles beneath the surface of the ovary.



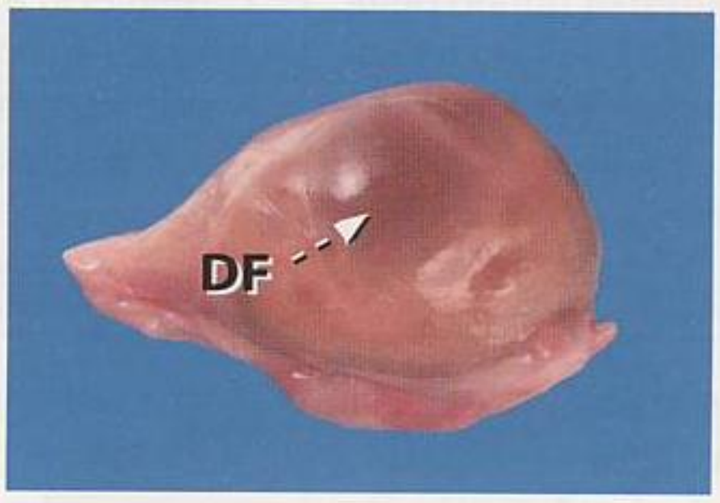


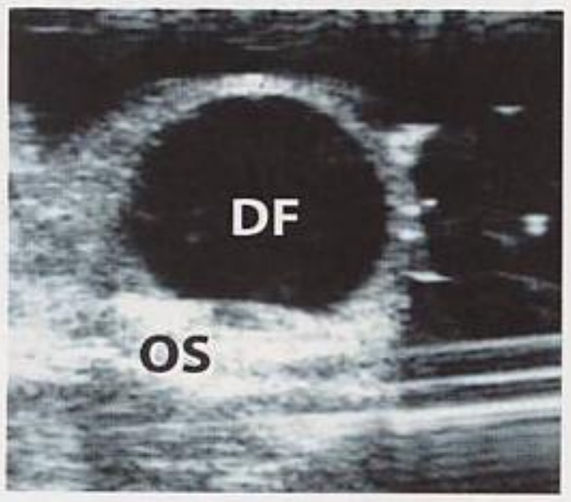
This ovary contains three medium antral follicles (MF) and a corpus luteum (CL) that appear in both images.





This ovary contains a dominant follicle (DF). The ultrasonogram shows that the follicle penetrates deep into the center of the ovary. Fluid-filled cavities generate a black image while dense tissue like the ovarian stroma (OS) generates a gray to white image. This follicle could easily be palpated per rectum. However, the exact size of the follicle would be difficult to ascertain. Ultrasound technology allows changes in diameter to be measured precisely.





In fact, midcycle estradiol increases and declines with each follicular wave but blood concentrations are low. After luteolysis (corpus luteum regression), a third wave of follicles develops. One or more of these follicles will develop into the dominant and the preovulatory follicle. It must be emphasized that the endocrine condition for final follicular development will exist only after luteolysis and subsequent decline in progesterone that removes the negative feedback on the hypothalamus. Also it is important to recognize that the number of follicular waves within a given cycle varies among and within species.

The phenomenon of follicular dynamics was discovered and described in the cow using ultrasonography. Ultrasonography is among the most important imaging techniques used in reproductive research and diagnostics. It can be used in pregnancy diagnosis, fetal aging and growth, description of change in ovarian structures, detection of fetal abnormalities and

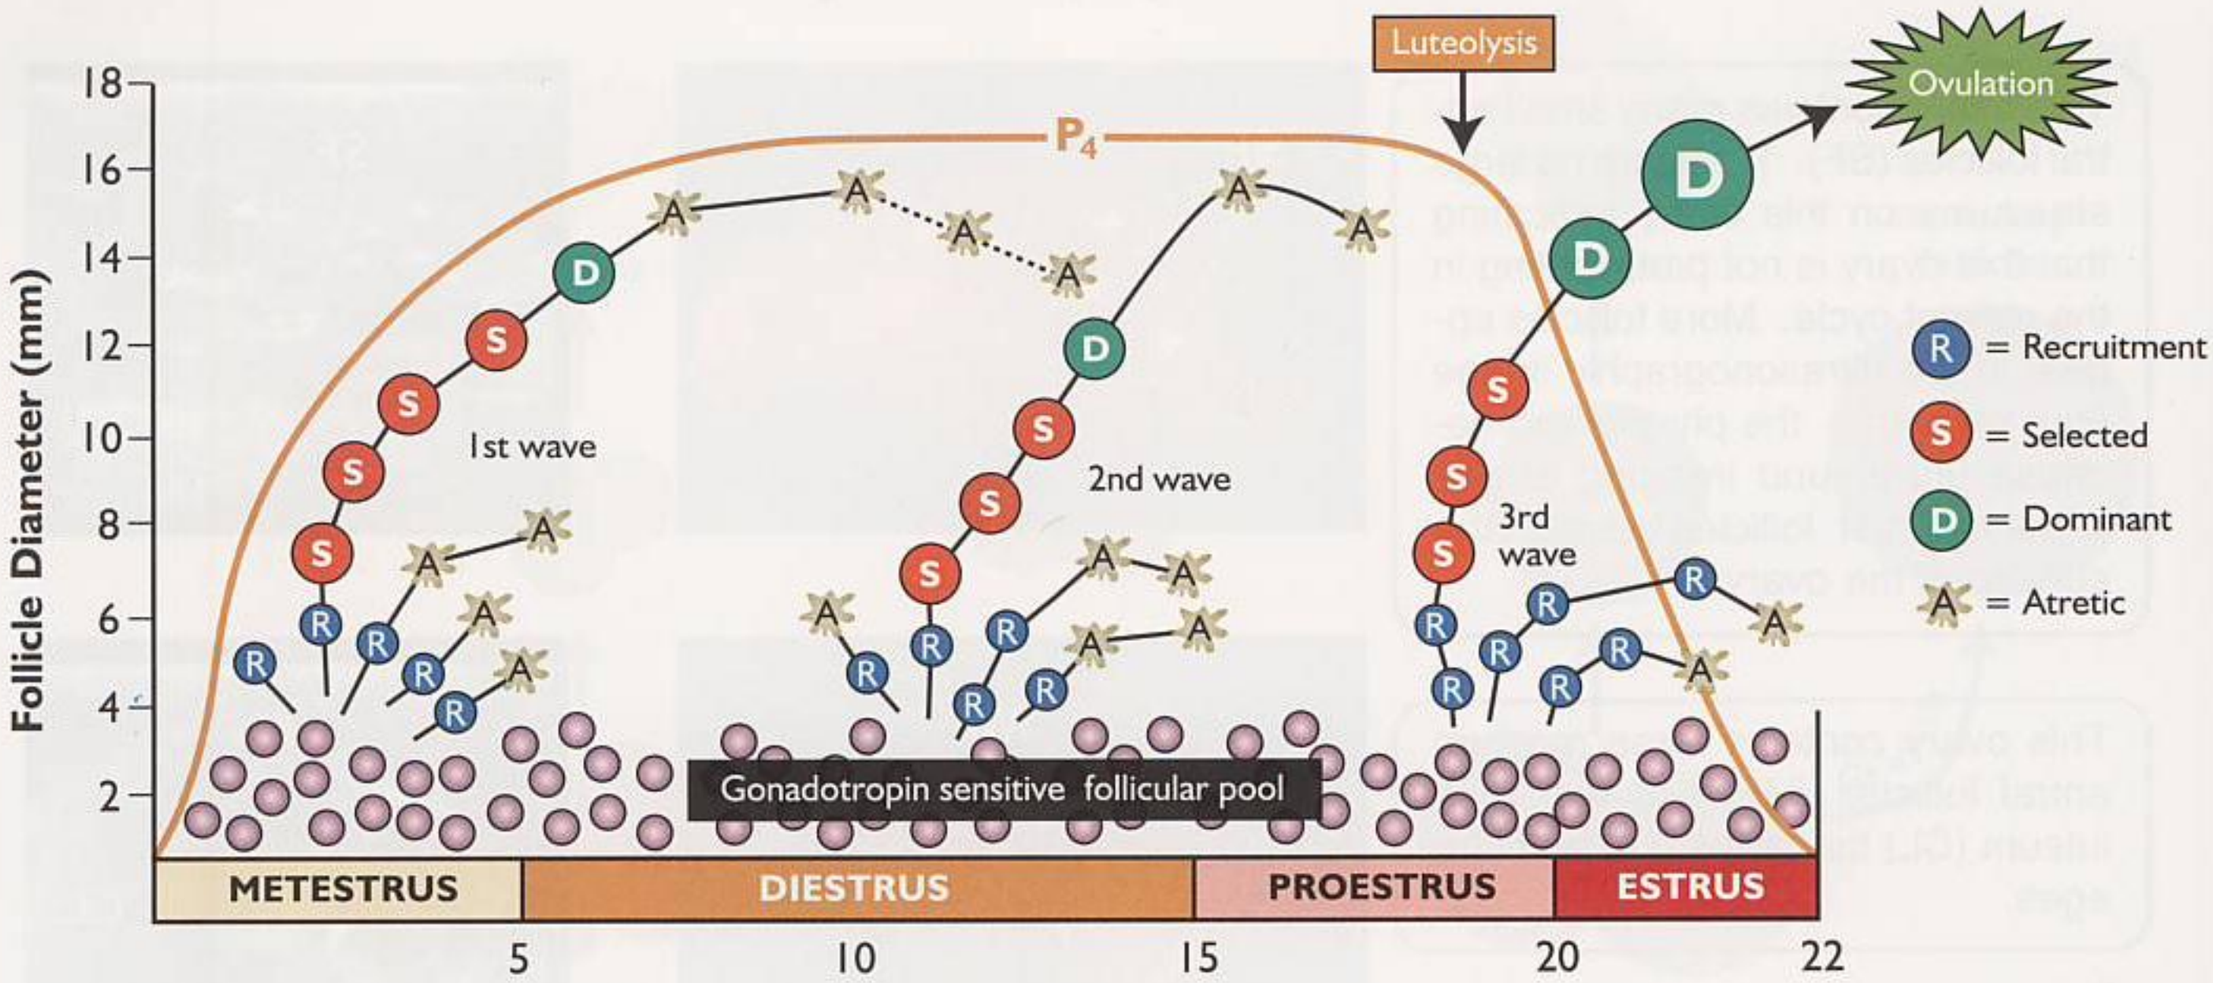
<u>Recruitment</u> = high FSH + low LH + no inhibin + no estradiol

<u>Selection</u> = low FSH + moderate LH + low inhibin

<u>Dominance</u> = low FSH + high LH + high inhibin

<u>Atresia</u> = degeneration of follicles

Figure 8-7. Several Follicular Waves Occur During One Cycle
(Modified from Lucy et al. 1992)



The first two follicular waves occur either during progesterone elevation (metestrus) or during peak progesterone production (diestrus). Follicles recruited and selected during these phases of the cycle will become atretic.

The last follicular wave (occurring after luteolysis) results in a dominant follicle that will ovulate. Only those follicles recruited during or after luteolysis will become eligible for ovulation. Follicles from any wave that are in the growth phase when luteolysis occurs are capable of ovulation.

diagnosis of the presence of twins in mares, cows and women. One of the primary advantages of ultrasonography is that it is minimally invasive and can be used without surgery. By examining the ovaries with ultrasonography in large animals on a daily basis, one can determine how populations of antral follicles change in size and numbers over time. In addition, follicular dynamics can be studied intensely in food producing animals because ovaries can be obtained postmortem and large numbers of females are slaughtered annually. This provides an opportunity to directly relate the actual ovarian structures to their ultrasonographic images. Figure 8-6 is a series of ovaries showing dominant, small and intermediate sized follicles on the surface of ovaries and their respective ultrasonographic images.

Follicular waves of antral follicles are not unique to the estrous or menstrual cycle. They occur before puberty, during pregnancy, during anestrus (or amenorrhea) and during the puerperium. However, follicular waves occurring during these times do not yield dominant follicles that produce threshold levels of estradiol. Further, they significantly reduce the number of follicles available for future ovulation. It is important to recognize that if the CL, during the luteal phase is precociously regressed with $PGF_{2\alpha}$, the first or second wave dominant follicle(s) can mature and become the preovulatory follicles. This follicular response is the basis for synchronized estrus and ovulation programs in cattle and will be described in detail in Chapter 9.

The above discussion has focused almost entirely on growth and atresia of antral follicles. You should recognize that the majority of a follicle's lifetime is spent in preantral stages. Recruitment, selection and dominance are relatively short-term processes when compared to the preantral stages. Recent scientific literature proposes that follicular dynamics be subdivided into two components. The first has been designated as the **initial recruitment phase** involving a continuous recruitment of dominant primordial follicles into a growing follicle pool that terminates with atresia. The second has been termed **cyclic recruitment**. Cyclic recruitment starts after puberty and is the result of elevated FSH levels that occur during each cycle.

More Frequent LH Pulses Occur in the Preovulatory Follicular Wave than the Previous Waves

Preparation of the follicle for ovulation occurs under a set of endocrine conditions that is different from the first waves. The fundamental difference is that FSH and LH are at higher concentrations than during the time of previous waves because the inhibition of GnRH by progesterone has been removed. Figure 8-8 illustrates the relative roles of FSH and LH during the preovulatory wave of follicle development. Preovulatory follicles are recruited and selected during proestrus and eventually dominate during estrus. Elevated levels of FSH induce recruitment of follicles from the gonadotropin sensitive pool within the ovary. Once the follicles

Figure 8-8. Relative Gonadrotropin, Inhibin and Estradiol Secretion During Proestrus by Recruited, Selected and Dominant Follicles

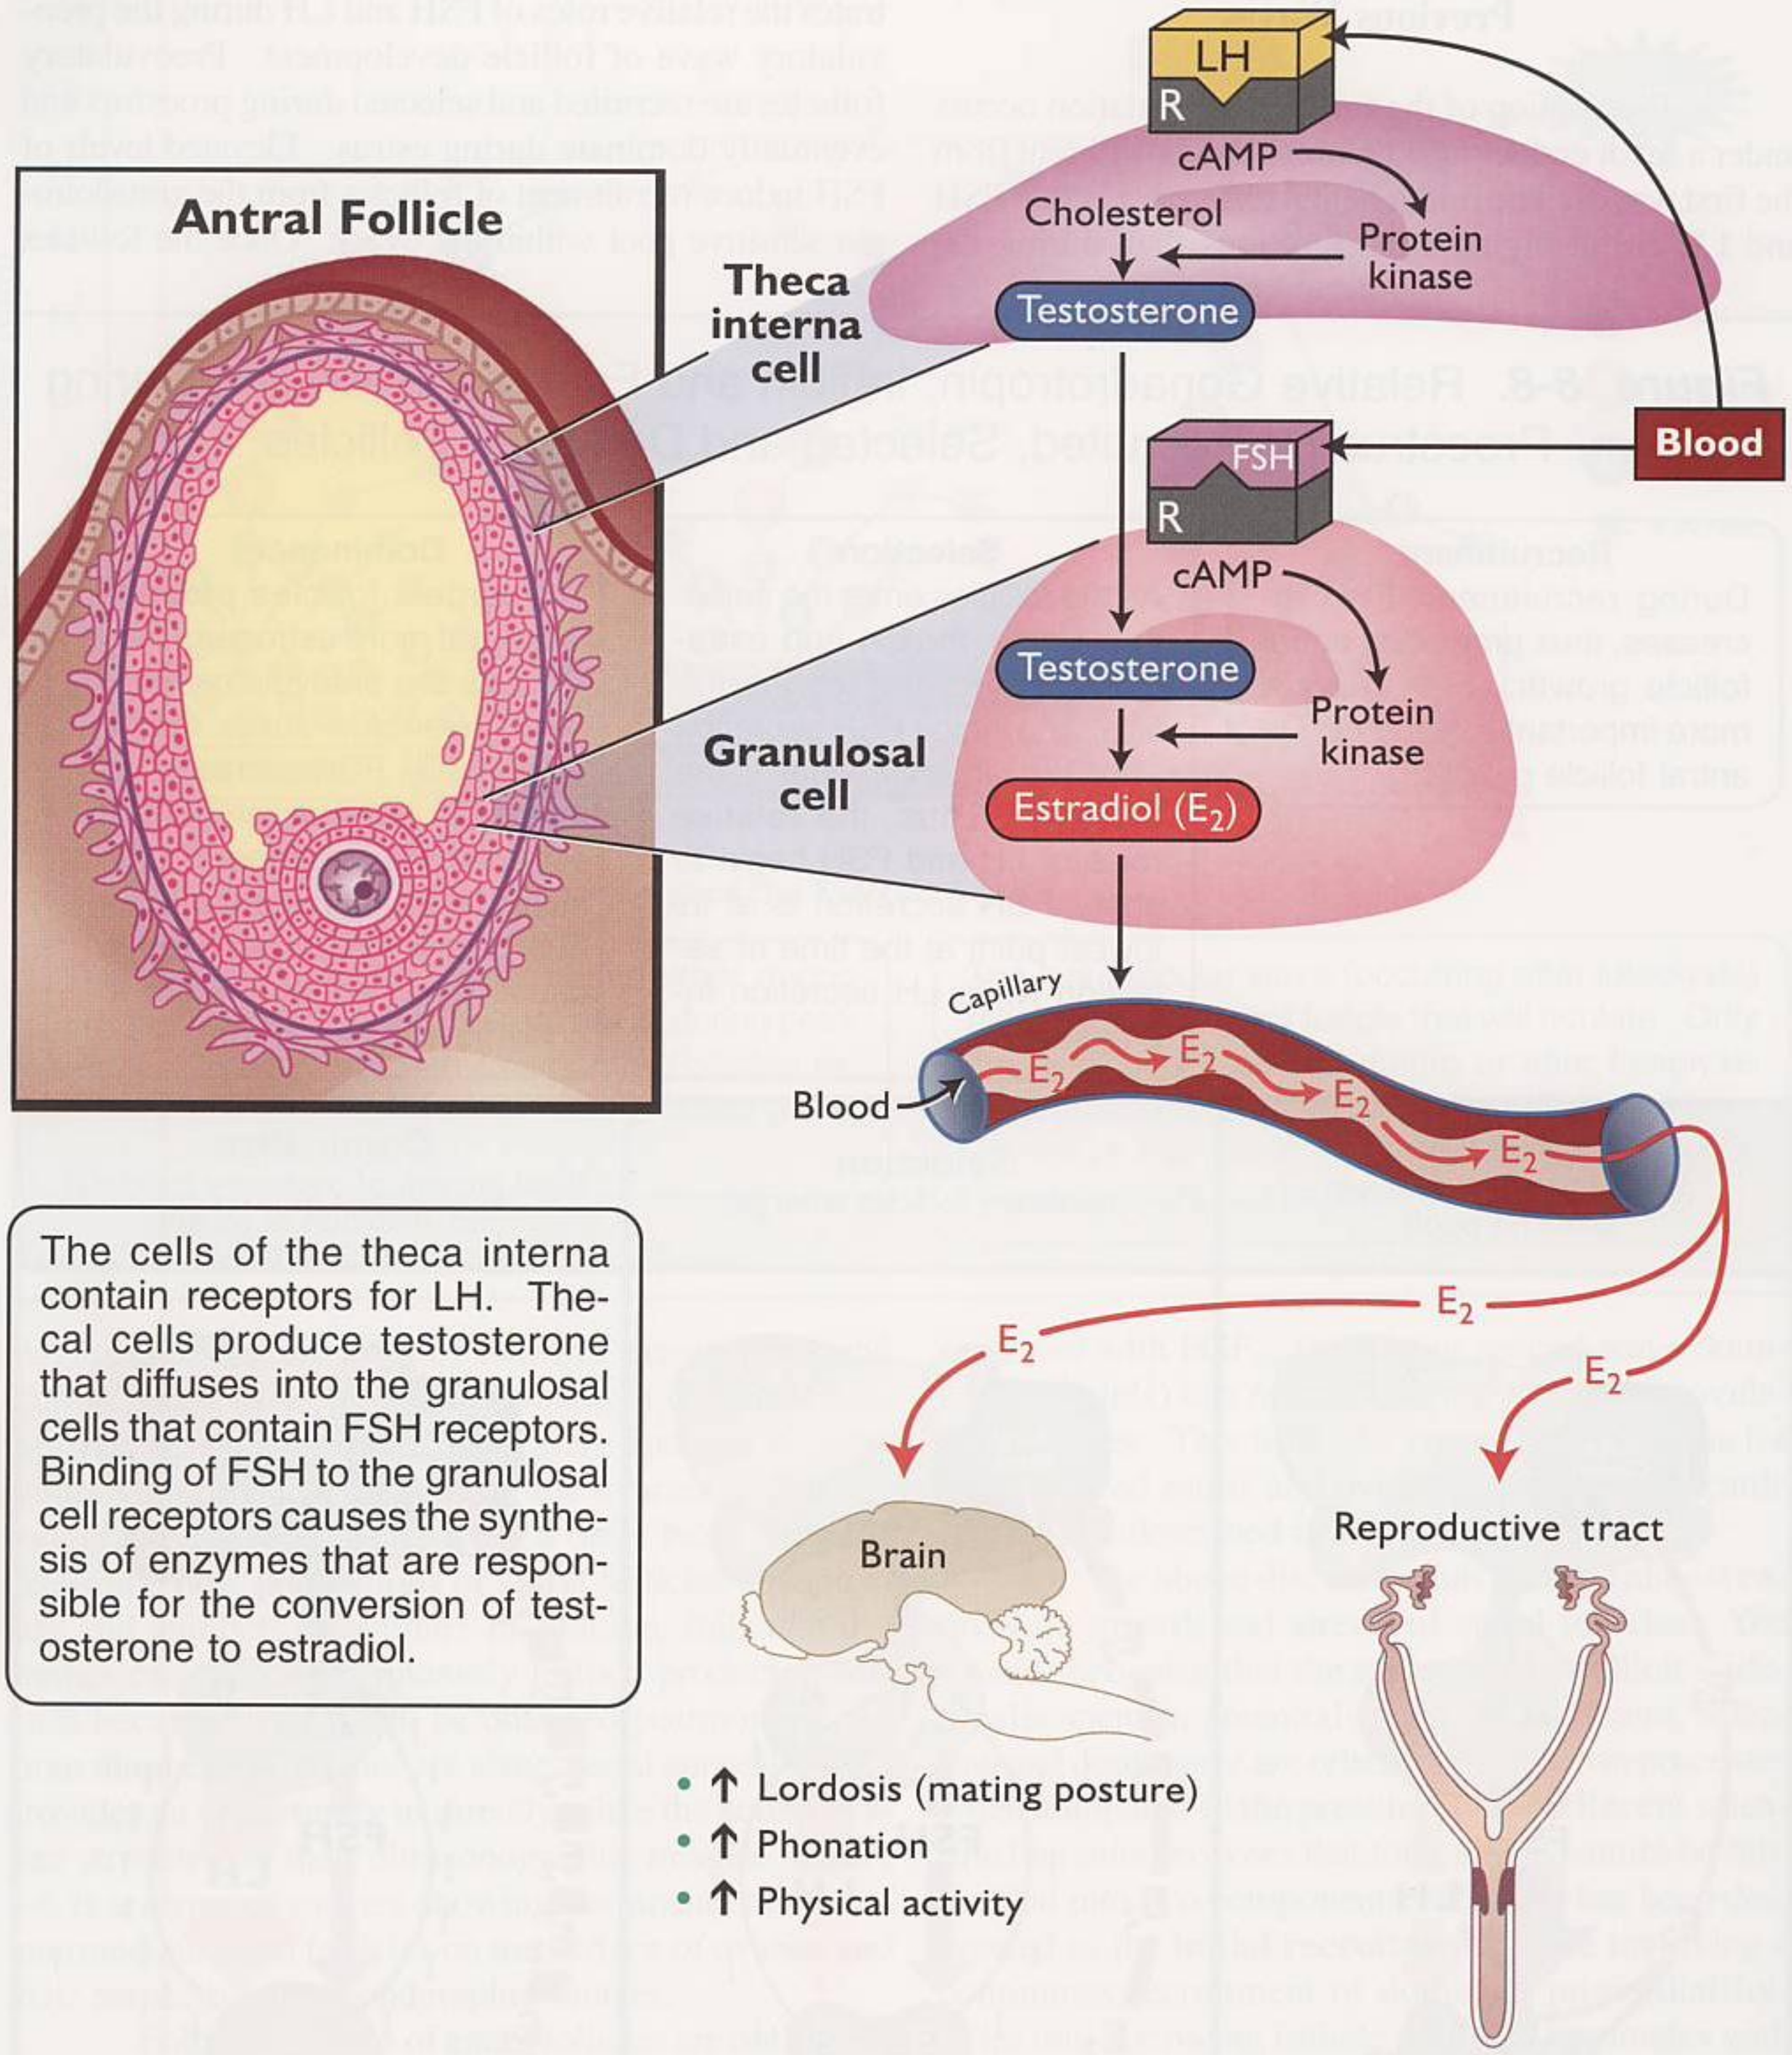
Recruitment
During recruitment, FSH increases, thus prompting antral follicle growth. FSH plays a more important role than LH in antral follicle growth.

Selection
As the follicles enter the selection phase, inhibin and estradiol are produced (by the follicle) and inhibit FSH secretion from the anterior lobe of the pituitary. Thus, the relative roles of LH and FSH begin to shift. FSH secretion is at its lowest point at the time of selection while LH secretion increases.

Dominance
The largest follicles produce more and more estrogen. This prompts the preovulatory center to release a surge of LH. Additionally, FSH secretion remains low because inhibin and estradiol are secreted in high levels by the dominant follicle. This drop in FSH is believed to cause other antral follicles to undergo atresia.

Recruitment (entry into gonadotropin sensitive pool)	**Selection** (ovulatory follicles emerge)	**Dominance** (final growth of ovulatory follicle(s) and inhibition of others)
		Small follicles	Medium follicles	Large follicles

Figure 8-9. The "2-Cell, 2-Gonadotropin Model" For Estrogen Synthesis



The cells of the theca interna contain receptors for LH. Thecal cells produce testosterone that diffuses into the granulosal cells that contain FSH receptors. Binding of FSH to the granulosal cell receptors causes the synthesis of enzymes that are responsible for the conversion of testosterone to estradiol.

are recruited, they begin to produce estradiol and small quantities of inhibin. As the inhibin levels increase (during selection), the degree of negative feedback on the anterior lobe of the pituitary increases. Thus, FSH begins to decline and LH begins to become more important than FSH in follicular development. As soon as FSH concentrations decline to a certain point, recruitment of other follicles stops. In addition, excess follicles in the cohort (those originally recruited) become atretic. The stage of dominance during proestrus leading to ovulation is characterized by continued decreasing FSH levels and increasing LH levels. The dominant follicle continues to grow, even though FSH levels are reduced, because apparently the dominant follicle's requirement for FSH is reduced. Estradiol levels from the dominant follicle are now approaching threshold and the dominant follicle is now reaching its maximum size. When estradiol levels reach threshold, the preovulatory LH surge occurs that dramatically alters the function of the follicle. Estrogen secretion by the dominant follicle declines abruptly once the preovulatory surge of LH occurs (See Figure 8-4).

"The 2-Cell, 2-Gonadotropin Model" Describes Estrogen Synthesis

During follicular development, LH binds to LH-specific membrane receptors located on the cells of the theca interna of the developing follicle (See Figure 8-9). The binding of LH to its receptors activates a cascade of intracellular events, described in Chapter 5. The net effect is conversion of cholesterol to testosterone. Testosterone then diffuses out of the cells of the theca interna and enters the granulosal cells. The granulosal cells contain receptors for FSH. When FSH binds to its receptor, it causes the conversion of testosterone to estradiol. This 2-cell, 2-gonadotropin pathway continues to function until levels of estrogen increase to a threshold that induces the preovulatory LH surge. An important step in the preparation of the follicle for ovulation is the synthesis of LH receptors by granulosal cells. When the LH receptors are present, the preovulatory LH surge can exert its full effect on the follicle to cause ovulation.

The primary target for estrogen is the reproductive tract tissue. The mucosal epithelium of the female tract responds dramatically to estrogens depending on the specific organ within the tract. In the vagina (particularly the caudal vagina) the mucosa increases in thickness in response to estradiol. Stage of the estrous cycle in some species (dog, cat, rodents) can be diagnosed by performing vaginal lavage by flushing fluid back-and-forth within the vagina and then removing a portion of the fluid. If an isotonic buffered solution is used to lavage the vagina, squamous cells will exfoliate into the solution without significant damage. They can then be stained and observed with a microscope. Cells from rodents in estrus are cornified like that of skin. Cornified cells are irregular in shape and appear "crusty" using the microscope. The presence of these cornified cells reflects the growth of the vaginal mucosa during estrus under the influence of estradiol. In other species like the dog and cat sheets of squamous cells indicate estrus. Changes in vaginal cytology are species unique and their appearance has various clinical interpretations (See **Key References**).

The major effects of estrogen on the reproductive tract are:

- ***increased blood flow***
- ***genital swelling***
- ***change in tissue electrical conductivity***
- ***leukocytosis***
- ***increased mucosal secretion***
- ***initiation of uterine gland growth***
- ***elevated myometrial tone***

The cervix and cranial vagina respond to estradiol by producing mucus. This mucus serves to: 1) lubricate the vagina and cervix in preparation for copulation; 2) flush foreign material such as bacteria out of the tract following copulation and 3) in the cow, low viscosity mucus provides "privileged pathways" for spermatozoa to traverse the cervix and to enter the uterus.

The uterus responds to estradiol by proestrual development of the uterine glands. As you learned in Chapter 2, uterine glands originate from the luminal epithelium and penetrate into the submucosa of the endometrium. The secretion of estradiol by the dominant follicles brings about this initiation of glandular growth.

As pointed out in Chapter 2, the oviductal mucosa consists of simple columnar and ciliated columnar epithelium. Like the rest of the reproductive tract, the epithelium of the oviduct increases its secretory rate under the influence of estrogen. In addition, the cilia within the oviduct increase their beat frequency to allow for gamete and fluid transport.

One of the major effects of estrogen on the female reproductive tract is increased blood flow (**hyperemia**) to all of the organs. This increased blood flow facilitates secretion throughout the entire reproductive

Figure 8-10. Relationship Between Estradiol and Vulvar Resistance (Impedance) in the Cow

(From Lehrer et al. 1991)

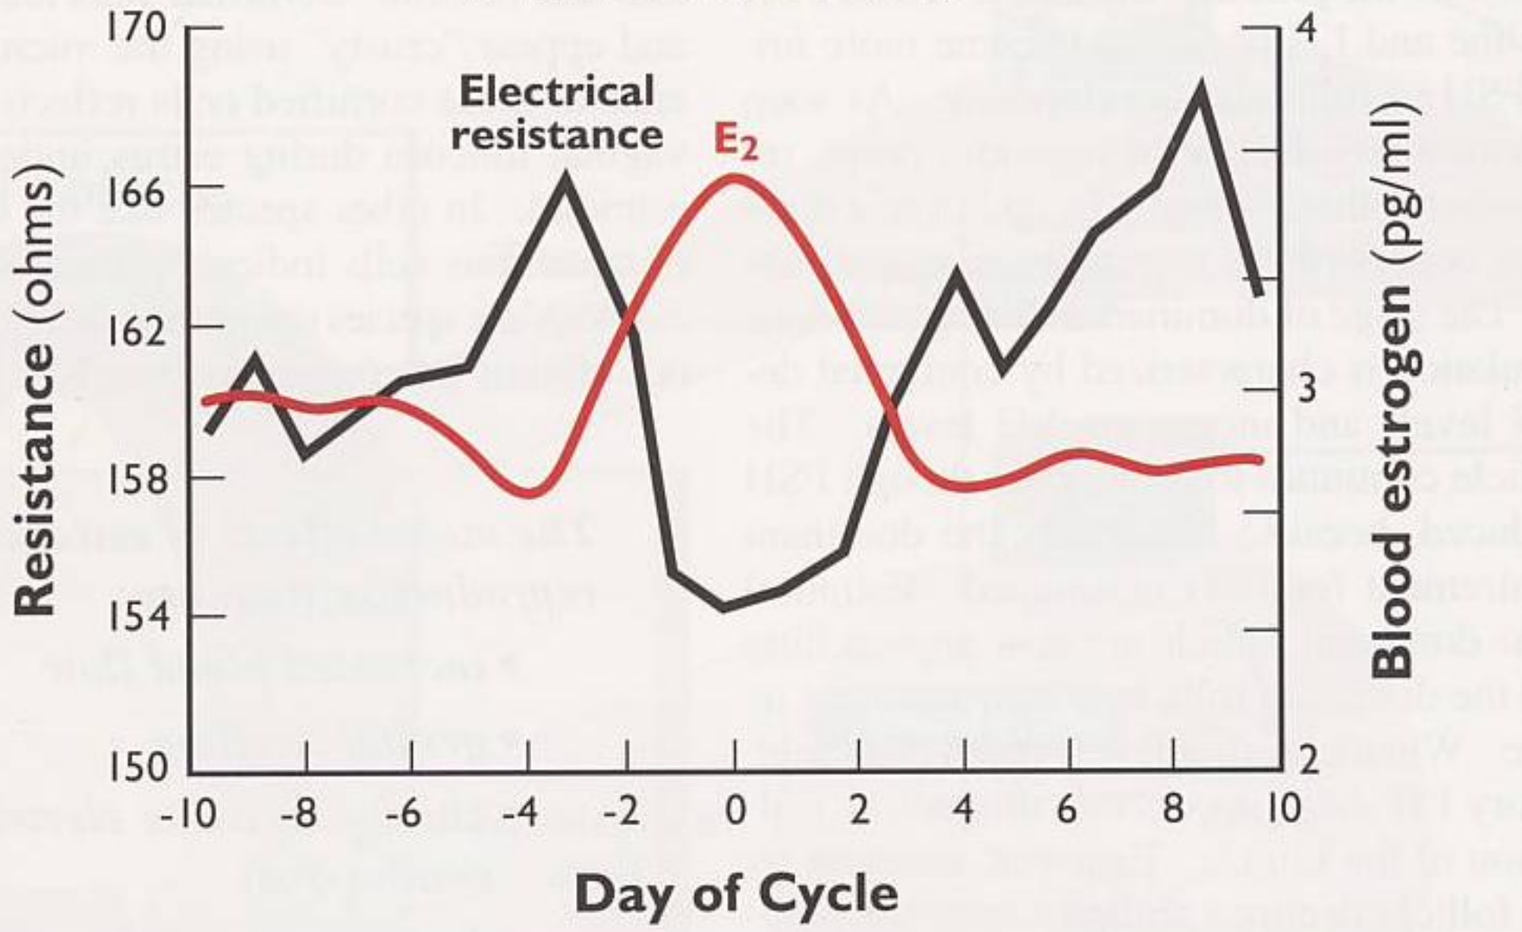


Figure 8-11. Relationship Between Vulvar Impedance and Reproductive Events in the Cow

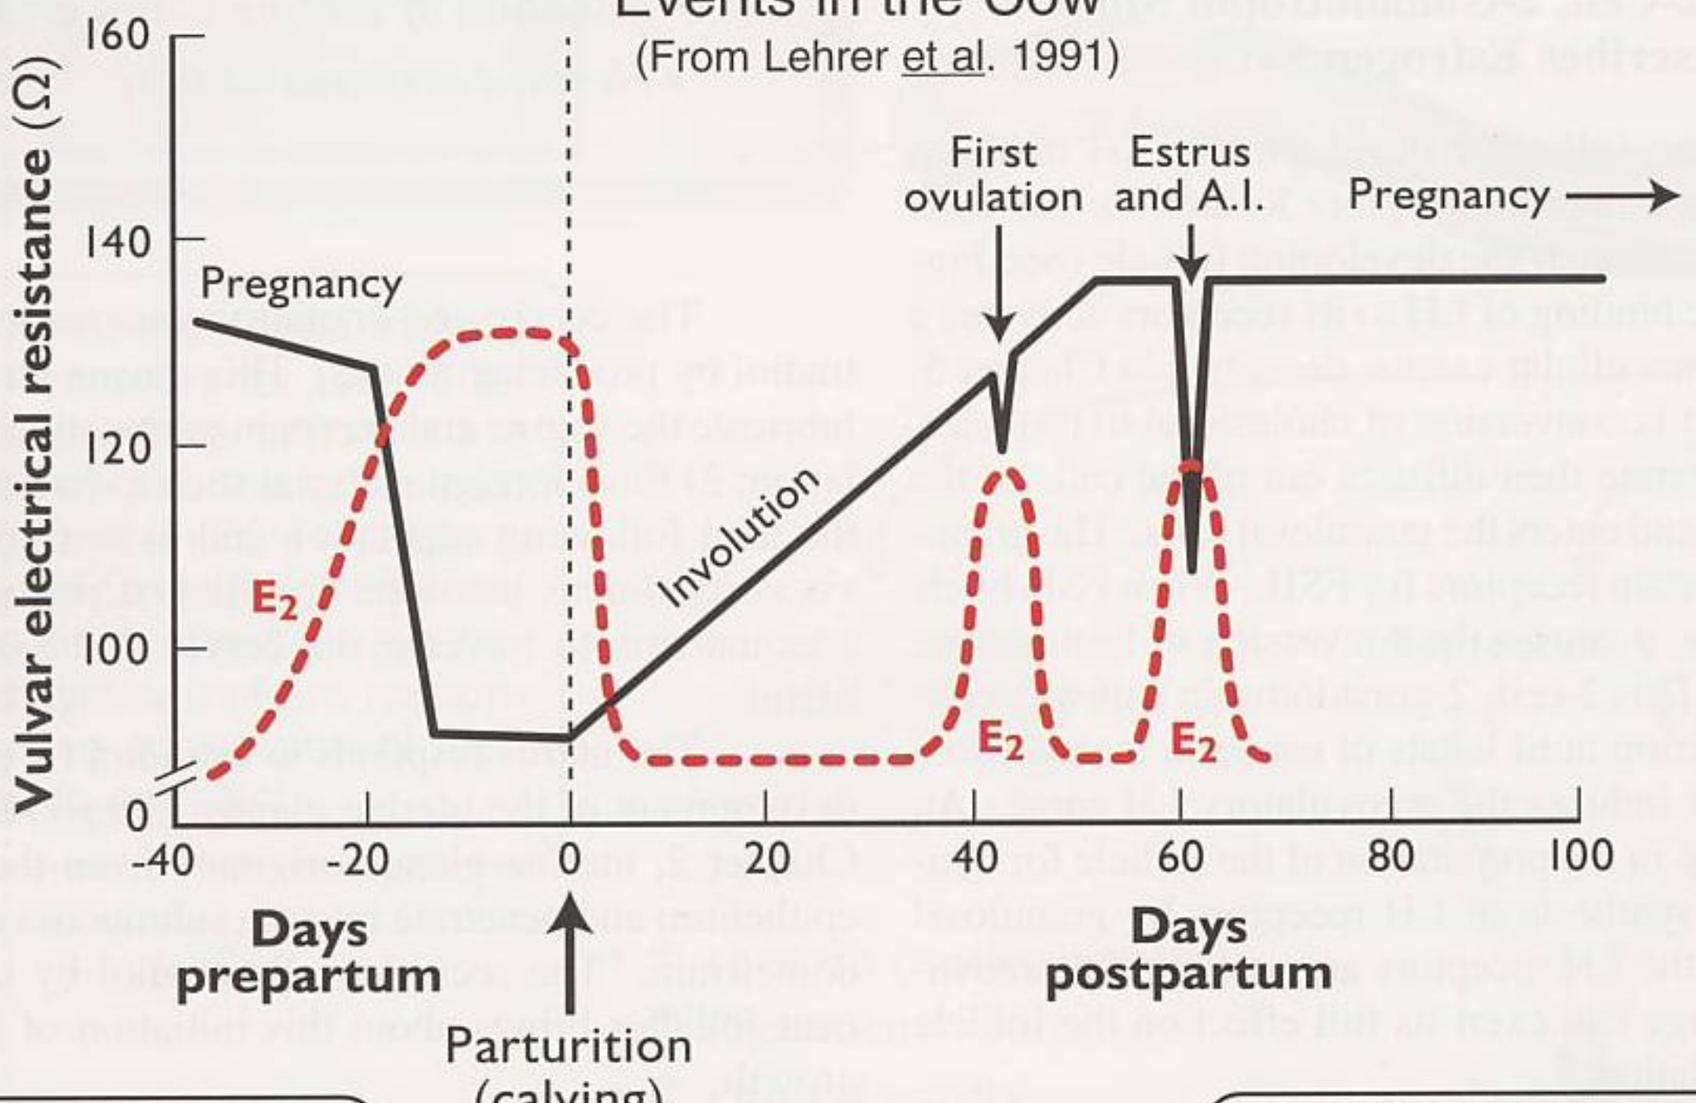
(From Lehrer et al. 1991)



During most of gestation, progesterone is high and estradiol is low. However, near the time of parturition estradiol increases dramatically. This dramatic increase in estradiol is accompanied by a dramatic decrease in vulvar electrical resistance.

After parturition, the reproductive tract undergoes gradual repair (involution). As involution occurs, the electrical resistance begins to increase slowly until about 40 days postpartum. When the first postpartum dominant follicle develops, estradiol increases and thus the first ovulation (usually silent) is accompanied by a decrease in electrical resistance.

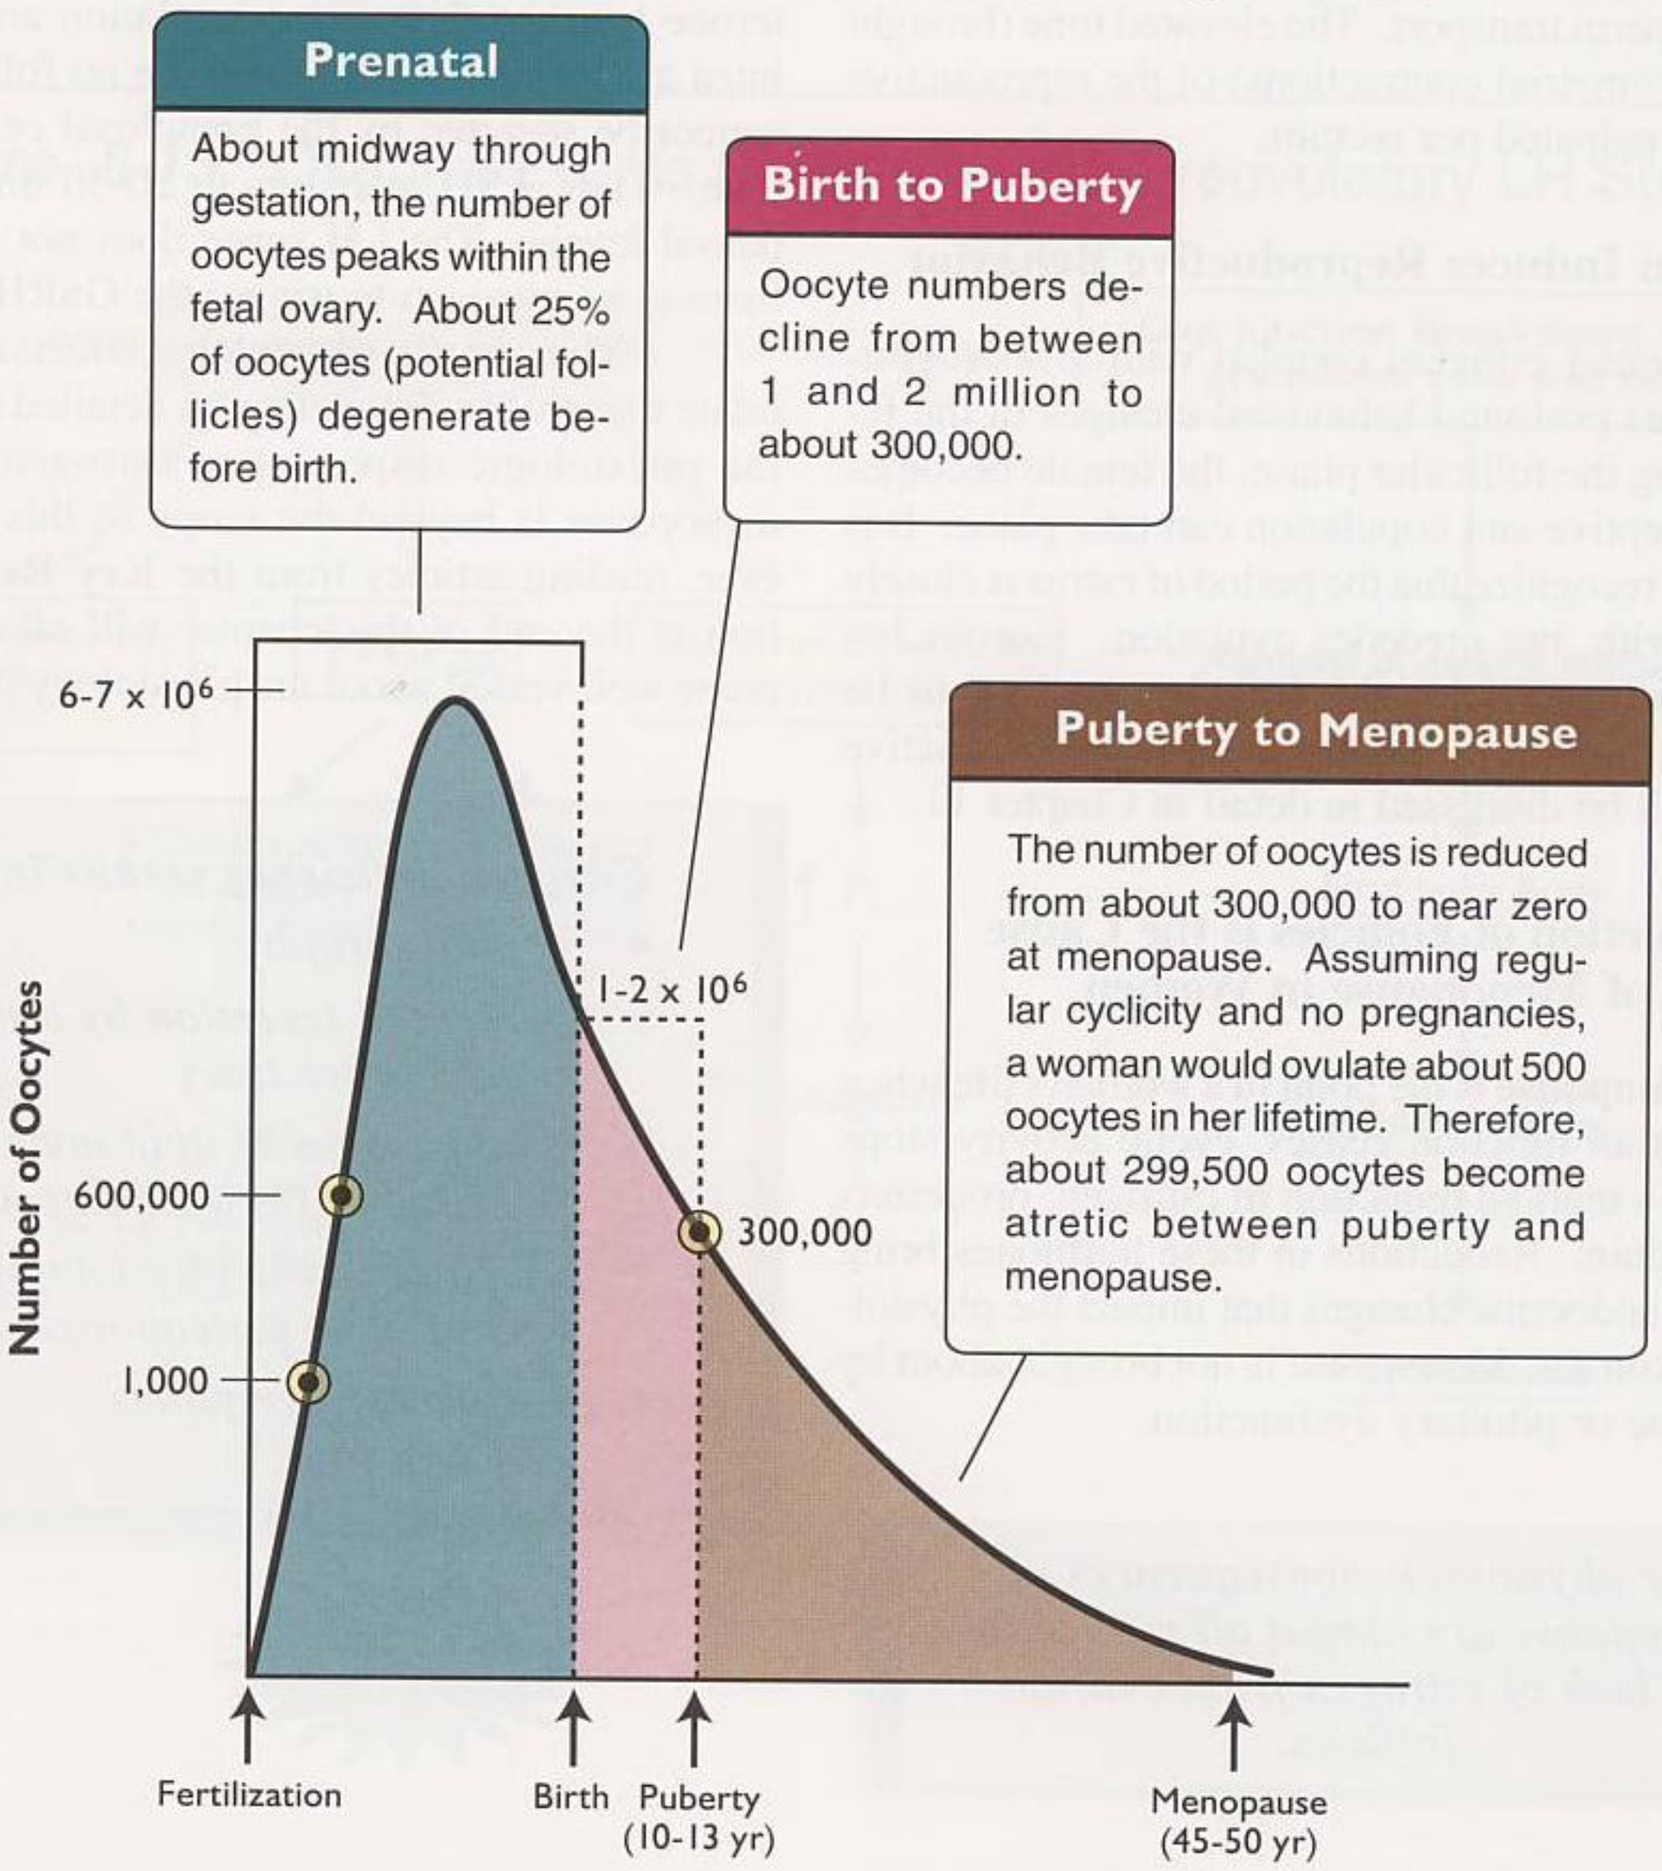
The first behavioral estrus after parturition also has high estradiol levels and electrical resistance decreases dramatically. If the animal becomes pregnant, electrical resistance will remain high because progesterone is also high. The more dramatic decrease in resistance at the second ovulation is because the tract has undergone complete involution and healing.

tract including the uterus and the oviduct. In addition to facilitating secretory activity, hyperemia plays two other important roles. First, it allows for delivery of leukocytes into the submucosal region of the reproductive tract so that invading foreign materials (including sperm) may be phagocytized after copulation. This influx of leukocytes into the tissue and the lumen of the reproductive tract is referred to as **leukocytosis**. One of the diagnostic features of estrus in most species is swelling (edema) of the external genitalia. Swelling of the vulva is brought about also by elevated blood flow that increases the local capillary pressure and causes lymph to buildup in the external genitalia (edema). While not definitive, this vulvar edema may serve as a diagnostic indicator of estrus.

Changes in the tissue fluid content of the reproductive tract alters its electrical conductivity (impedance). Implanting electrodes into the reproductive tract allows monitoring of this change in a manner that can predict the stage of cycle in cows. As estradiol increases the electrical resistance (impedance) within the vulva decreases. Researchers in Israel and at Virginia Tech (Blacksburg, VA) have developed an implantable impedance meter that can convert electrical resistance measurements into a radio signal. The radio signal can be transmitted from the cows to a remote radio receiver. This technique was used to describe the relationship between ovarian hormones and changes in tissue impedance (See Figure 8-10).

Figure 8-12. Changes in Oocyte Numbers Throughout the Life-span of the Human Female

(Modified from Palter and Olive in *Novak's Gynecology*, 11th Ed.)



It is important to recognize that repeated measurements of electrical resistance within a given female are needed to accurately diagnose estrus because there is significant variation among females with regard to impedance changes. While this technology has yet to become cost-effective the concept holds significant promise for describing reproductive and endocrine function in the cow. Figure 8-11 illustrates the changes in vulvar electrical resistance that occurs from late gestation through the subsequent pregnancy in cows. The ability to monitor reproductive function and health is an exciting feature of this technology. The change in impedance is predictable depending on the levels of estradiol and this has been used as a diagnostic indicator of the onset of estrus, particularly in cattle. As implant technology continues to develop, it is conceivable that the described approach can be made cost-effective and functional under practical conditions.

Estradiol causes increased tone and motility of the muscularis in all regions of the reproductive tract. This increase in tone and motility is responsible, at least in part, for sperm transport. The elevated tone (brought about by myometrial contractions) of the reproductive tract can be palpated per rectum.

Estrogen Induces Reproductive Behavior

Elevated estradiol coupled with low progesterone induces profound behavioral changes in the female. During the follicular phase, the female becomes sexually receptive and copulation can take place. It is important to recognize that the period of estrus is closely associated with, but precedes ovulation. Estrous behavior culminates with the female standing to be mounted by the male. The physiology of reproductive behavior will be discussed in detail in Chapter 11.

Depletion of Follicles is the Cause of Menopause in Women

Menopause is the point in a woman's life when normal ovarian function ceases, cyclic activity stops and there is a marked reduction in estrogen, progesterone and inhibin. Reductions in these hormones bring about other endocrine changes that impact the physiology of the woman. Menopause is not brought about by hypothalamic or pituitary dysfunction.

The physiologic consequences of menopause are almost all related to the lack of estrogen from ovarian follicles.

Describing follicular dynamics in the human female is quite difficult because it is almost impossible to perform daily observations of the ovaries in adequate numbers to generate good data about how groups of follicles develop to dominance and/or become atretic. Therefore, the assumption is made that the follicular dynamics in women is fundamentally the same as those in domestic animals. In the woman, there is a single follicular wave during the follicular phase of the menstrual cycle. There are no follicular waves during the luteal phase. However, the number of follicular waves per cycle and the duration of each of the processes (recruitment, selection, dominance and atresia) are not known. There are however, sufficient data to make definitive descriptions of the dramatic decline in follicular/oocyte numbers in the ovary over the lifetime of a woman. This decline is illustrated in Figure 8-12.

The net effect of follicular depletion is declining blood levels of estrogen. In addition to lack of estradiol, there is also a substantial decline in progesterone because there is no ovulation and no corpora lutea are formed. Since there are no follicles, inhibin cannot be secreted by the granulosal cells of the follicle. Thus, FSH increases to 20-30 times premenopausal levels. The LH surge does not exist because there is no estrogen to trigger the GnRH surge.

The primary physiologic effects of menopause relate to estrogen deficiency. A detailed description of the physiologic responses to estrogen reduction at menopause is beyond the scope of this book. However, reading articles from the **Key References** section at the end of this chapter will allow you to become well versed about the physiology of menopause.

Estrogen deficiency results in:

- ***genital atrophy***
- ***decreased secretion by the reproductive tract***
- ***modification of lipid metabolism and of the vascular walls***
- ***increase in the physiological loss of bone (osteoporosis)***
- ***vasomotor symptoms ("hot flashes")***

The term **menopause** means the termination of menses. Since non-primate mammals have no menses, reproductive senescence is used to imply the cessation or the decline of reproductive function. Because of the high rate of follicular atresia among all mammals studied, it is likely that oocytes can be depleted completely during the lifetime of the female. Therefore, probably all mammals will experience "menopause" if they live long enough.

Ovulation Results from a Cascade of Events Starting with the LH Surge

The preovulatory surge of LH is critically important because it sets in motion a series of biochemical events that lead to ovulation. Ovulation is a complicated process that involves purposeful destruction of follicular tissue. The main events of the ovulatory cascade resulting from the LH surge are shown in Figure 8-13.

Hyperemia (local elevated blood flow) is believed to be controlled at the tissue level by histamine and prostaglandin E_2 (PGE_2). Blood flow to the ovary has been shown to increase 7-fold after an injection of human chorionic gonadotropin (hCG), an LH-like hormone. In addition, there is elevated local blood flow to dominant follicles. Accompanying this local hyperemia, the theca interna becomes edematous because of increased vascular permeability brought about by histamine. This edematous condition causes elevated hydrostatic pressure around the follicle that may facilitate its eventual rupture. In addition to increased blood flow brought about by histamine and PGE_2, dominant follicles are thought to produce **angiogenic factors** (substances that promote the growth of new blood vessels). Angiogenic factors have been found in follicular fluid and this implies that the dominant follicle can potentially control its own blood flow. The net effect of elevated blood flow is to ensure that the dominant preovulatory follicle is provided with the necessary hormonal and metabolic ingredients for final maturation.

Figure 8-13. Ovarian Events Caused by the Preovulatory LH Surge

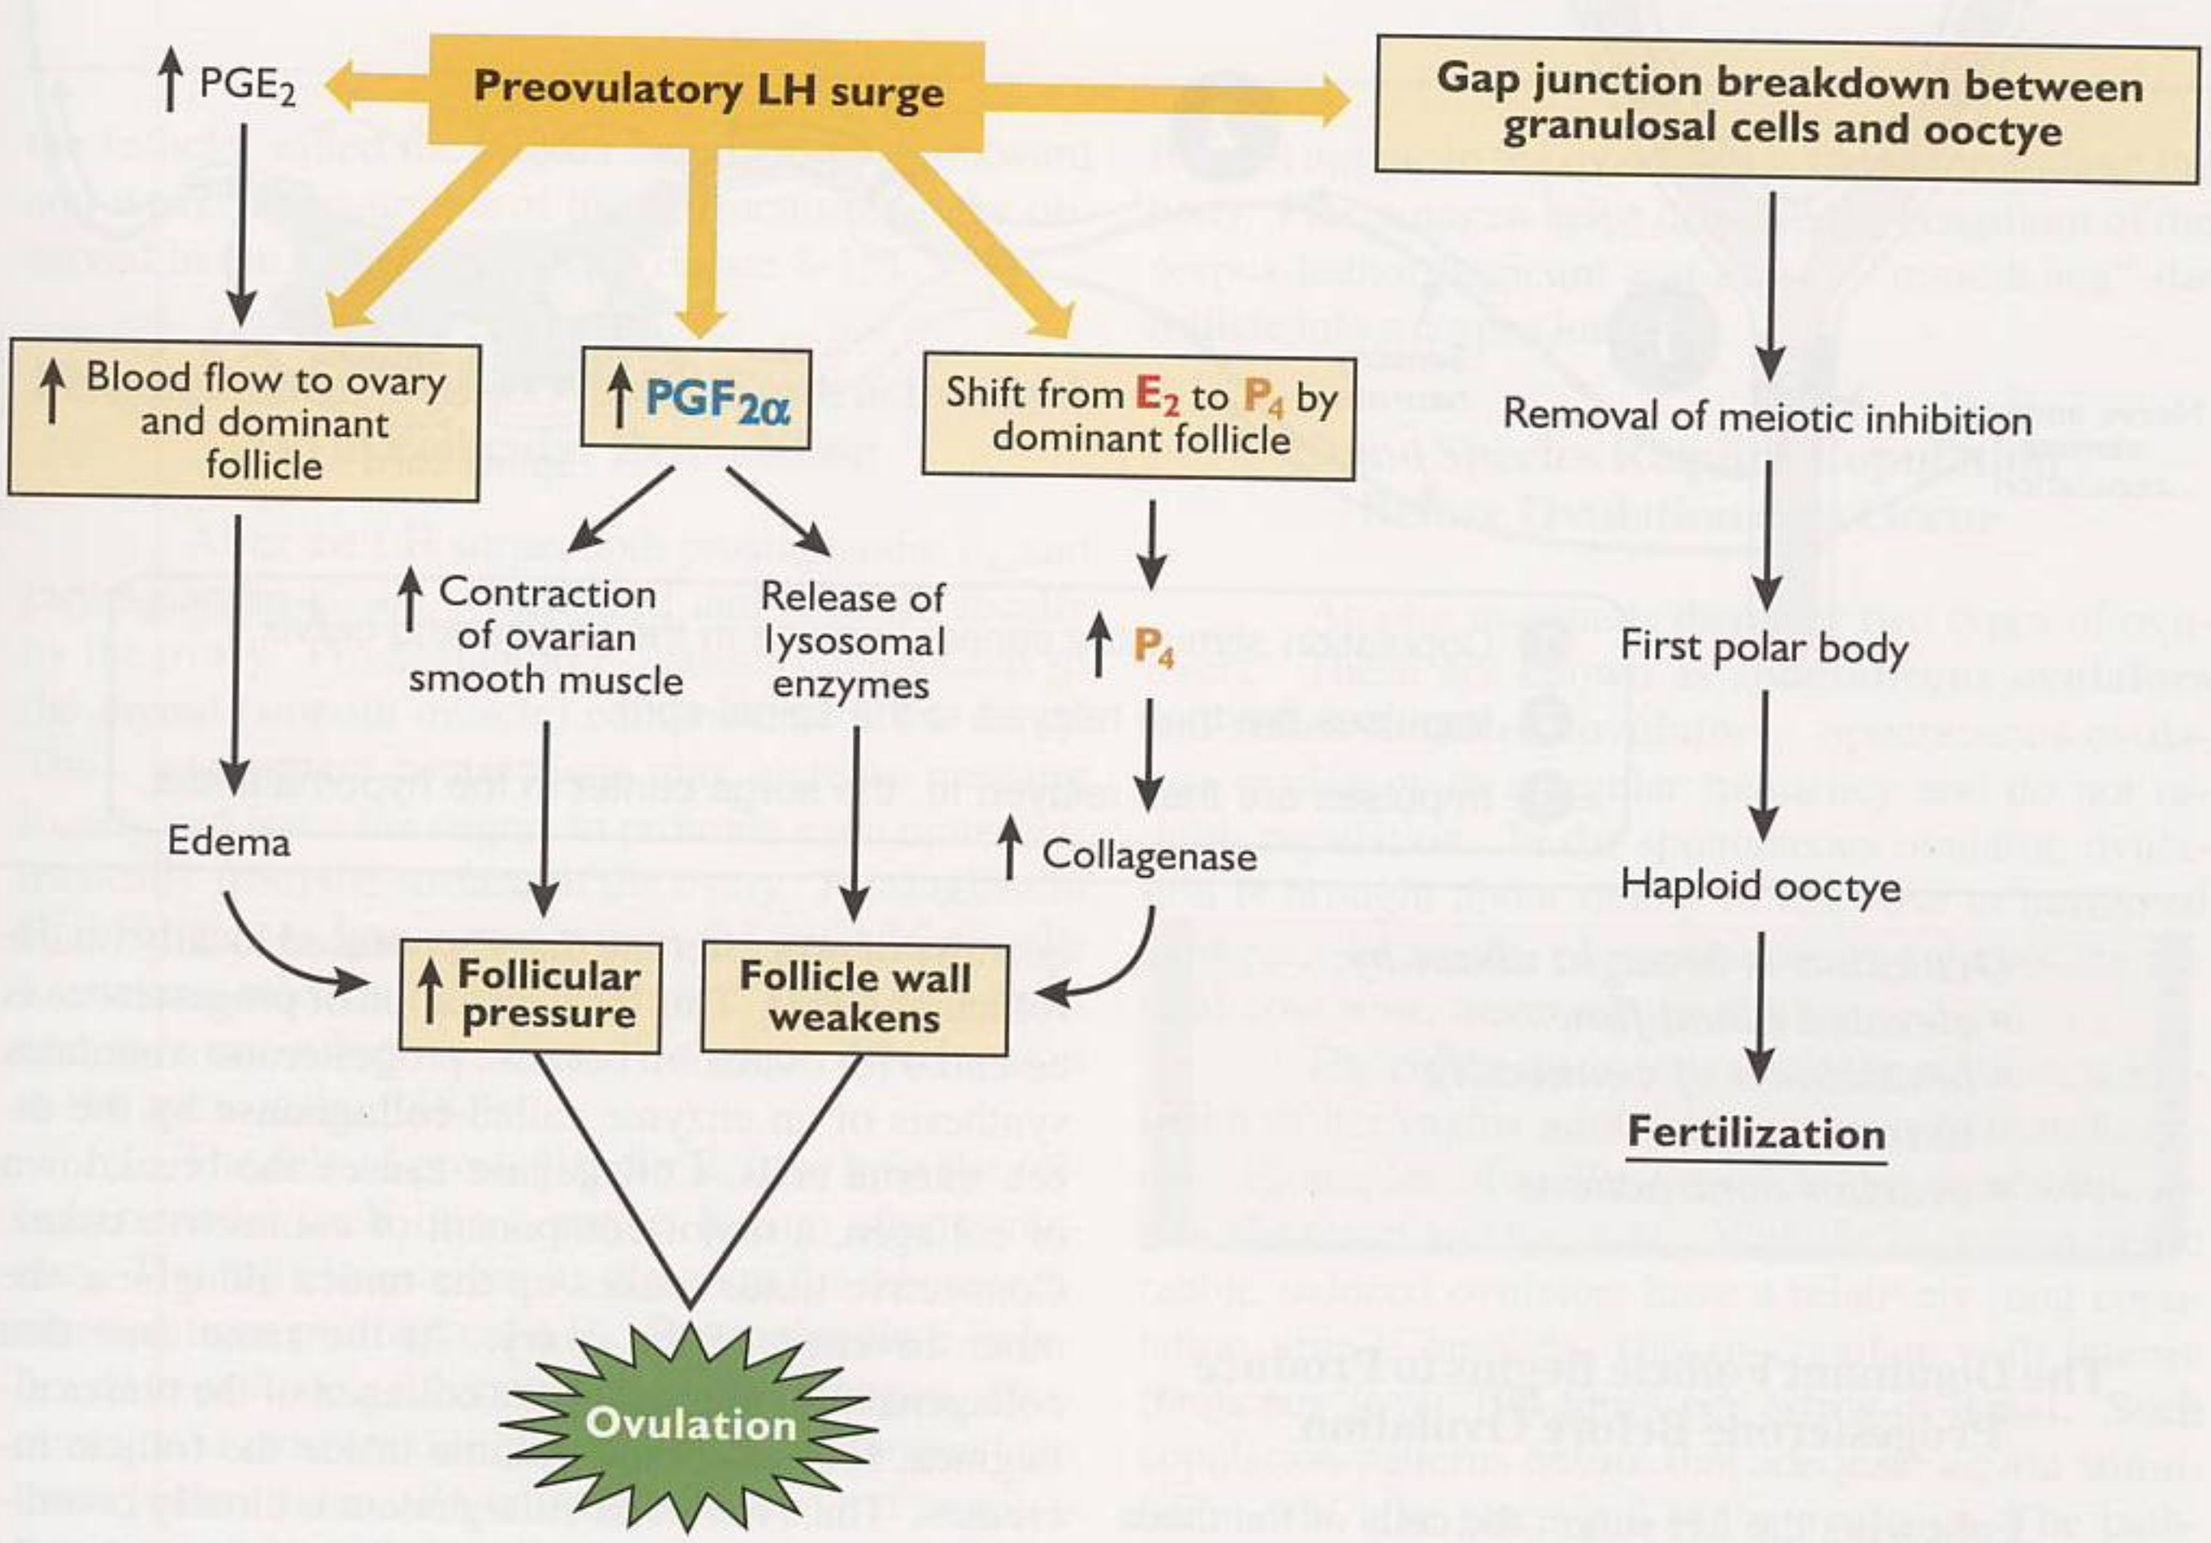


Figure 8-14. The Pathway for Induced Ovulation

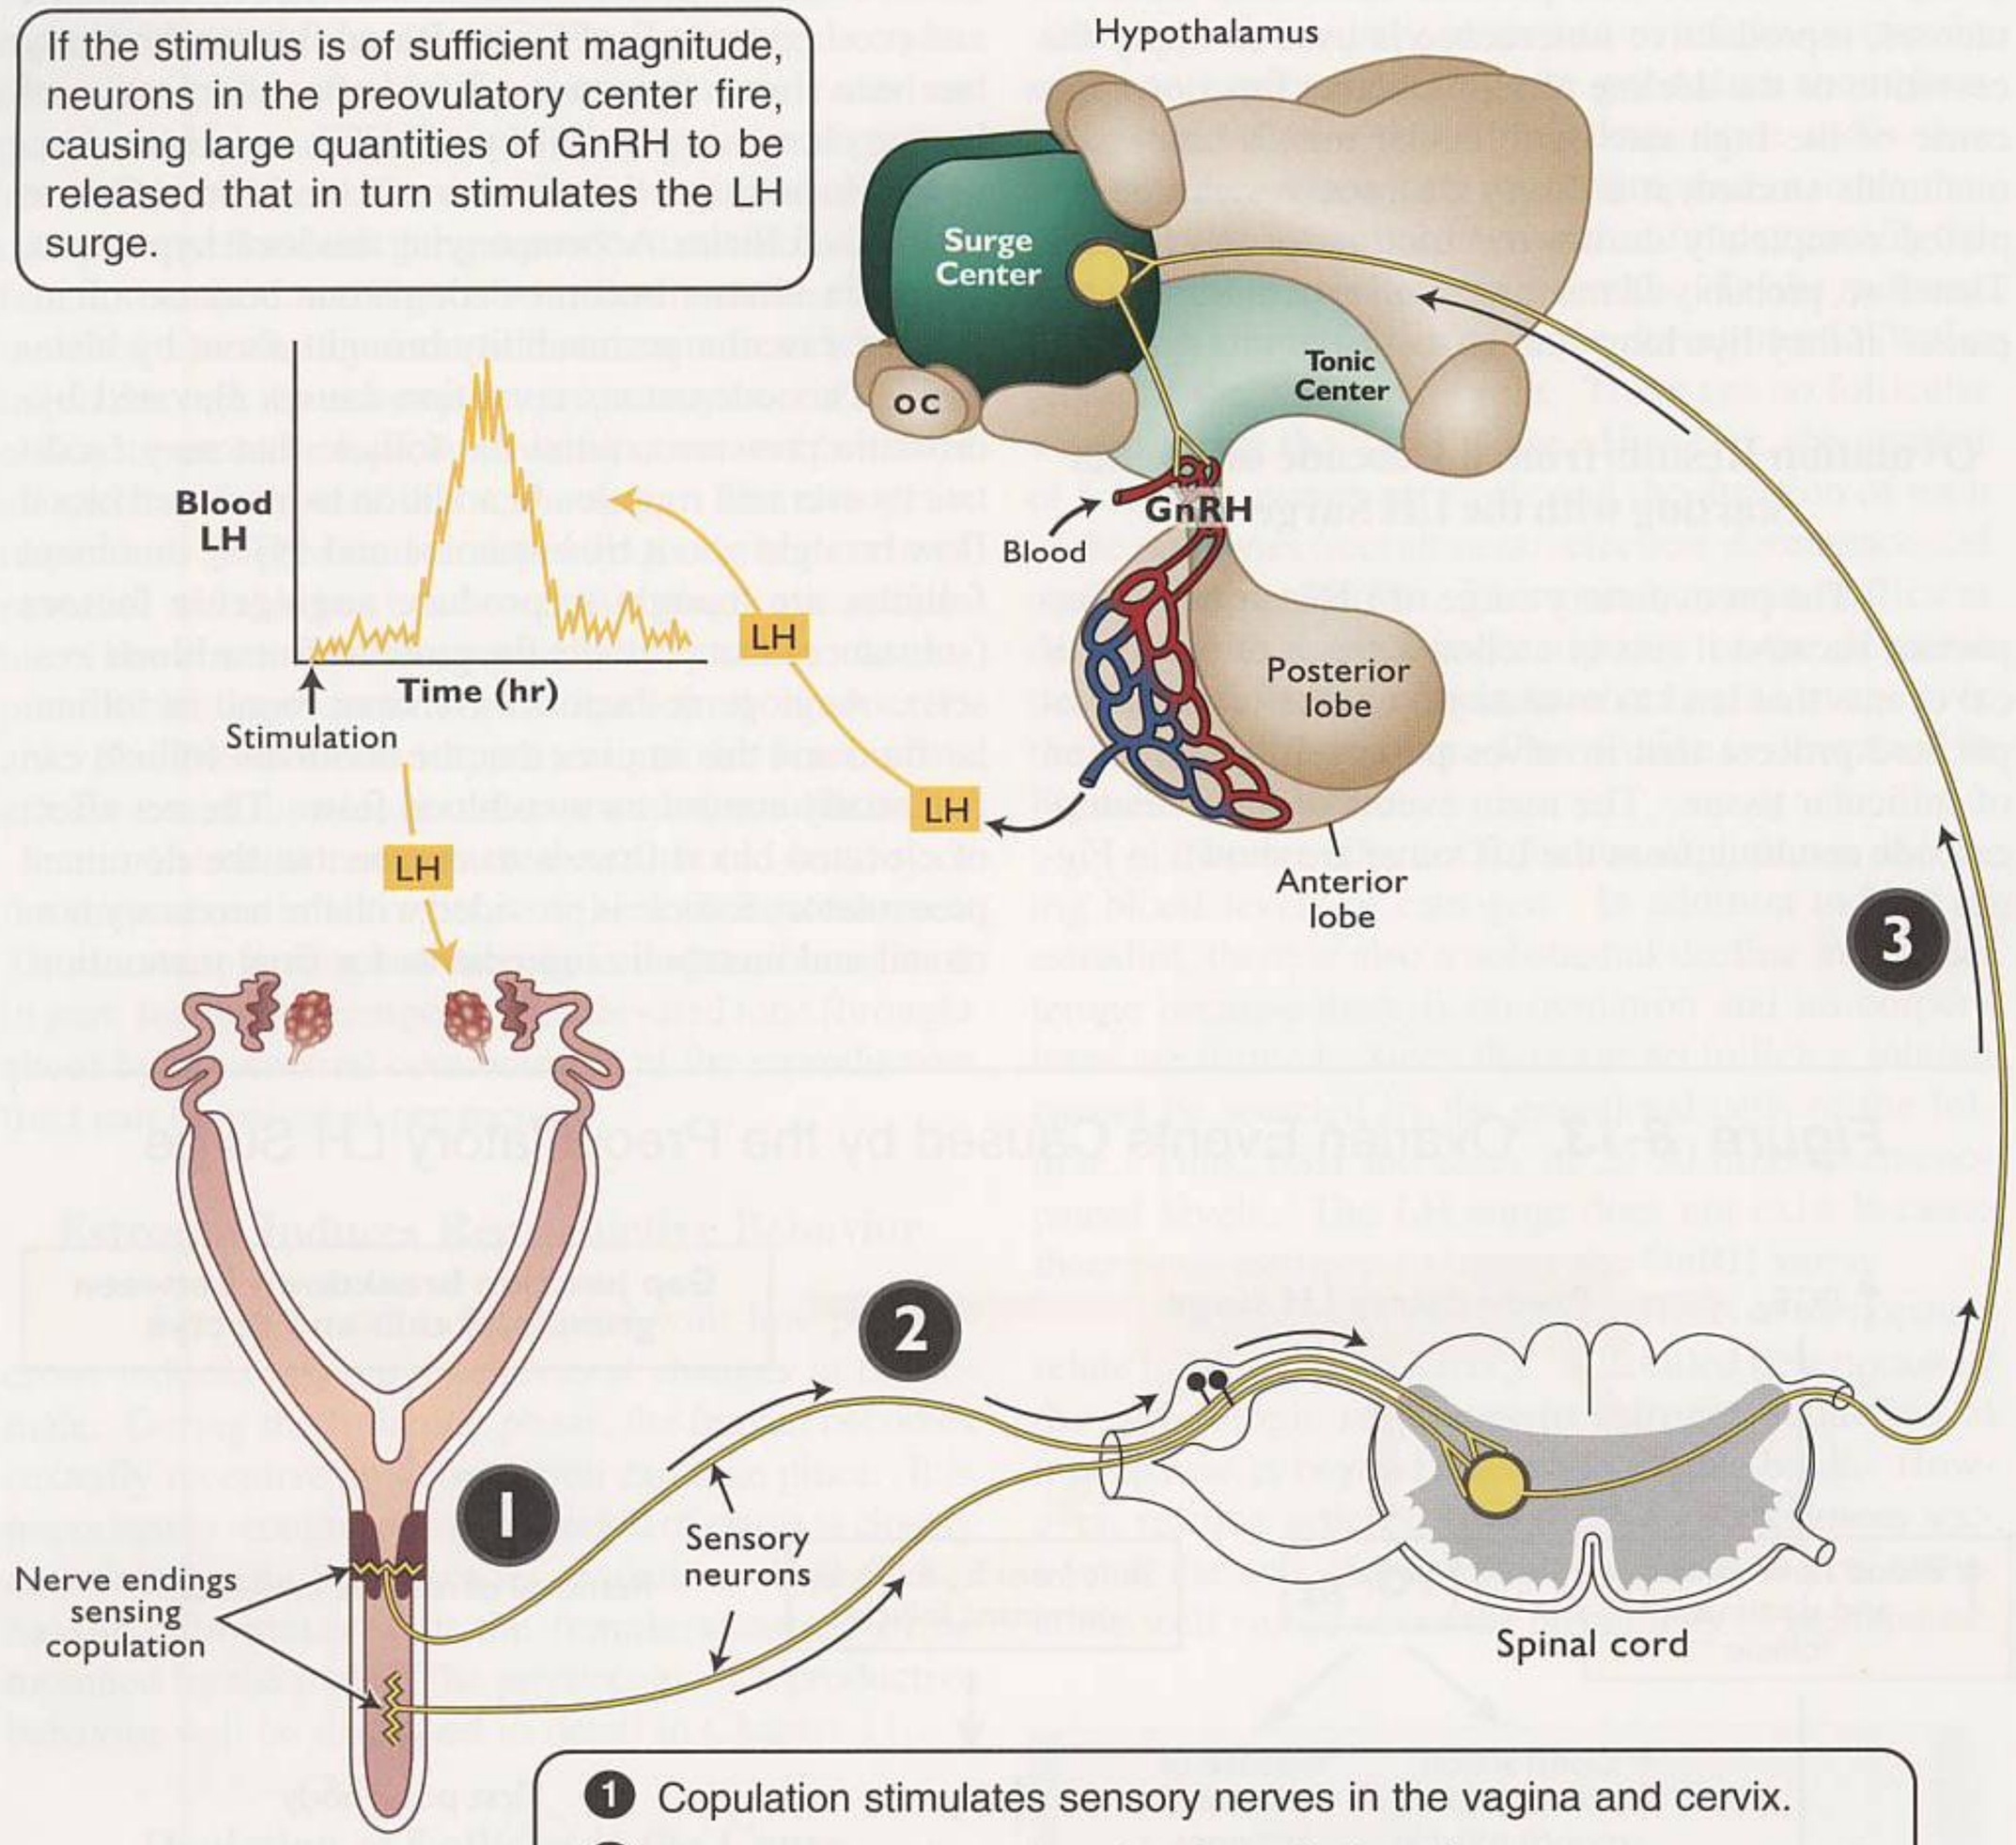
If the stimulus is of sufficient magnitude, neurons in the preovulatory center fire, causing large quantities of GnRH to be released that in turn stimulates the LH surge.



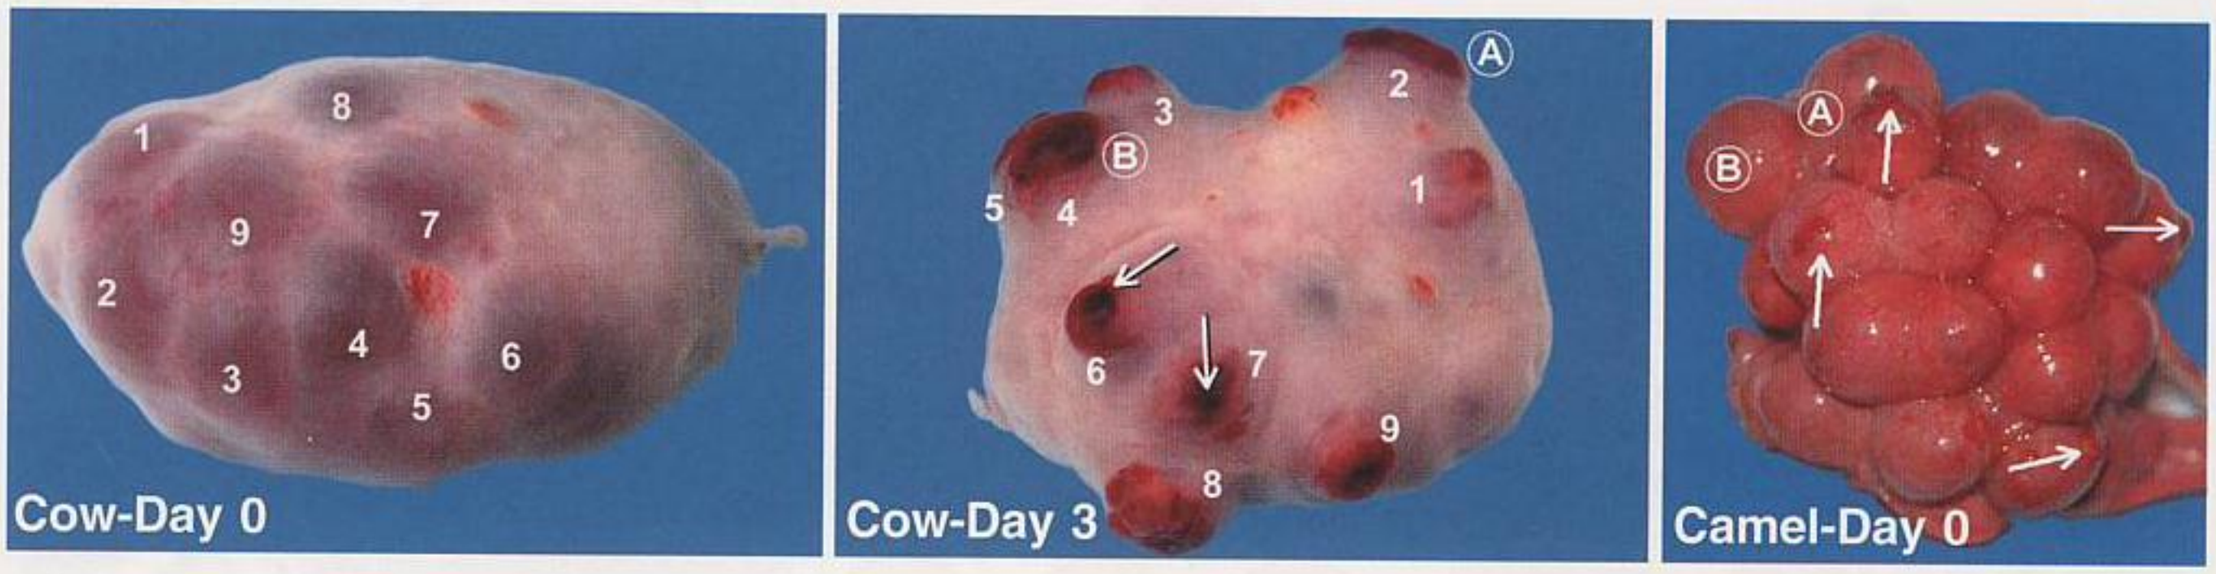
1. Copulation stimulates sensory nerves in the vagina and cervix.
2. Impulses are then relayed to the spinal cord.
3. Impulses are then relayed to the surge center in the hypothalamus.

Ovulation is brought about by:
- ***elevated blood flow***
- ***breakdown of connective tissue***
- ***ovarian contractions***

The Dominant Follicle Begins to Produce Progesterone Before Ovulation

Following the LH surge, the cells of the theca interna begin to produce progesterone instead of testosterone. At first, this transition involves only a small quantity of progesterone that is produced locally (at the follicular level). This local elevation of progesterone is essential for ovulation because progesterone stimulates synthesis of an enzyme called **collagenase** by the theca interna cells. Collagenase causes the breakdown of collagen, a major component of connective tissue. Connective tissue makes up the tunica albuginea, the outer covering of the ovary. At the same time that collagenase is "digesting" the collagen of the tunica albuginea, follicular fluid volume inside the follicle increases. Thus, follicular enlargement is closely coordinated with the enzymatic degradation of the tunica albuginea. As these two processes advance, the apex of

Figure 8-15. Superstimulated Ovaries



This cow ovary was hyperstimulated with gonadotropins. Ovariectomy was performed on the day of estrus. There are 9 preovulatory follicles visible (all numbered). (Specimen courtesy of Dr. Brad R. Lindsey, Minitube of America, *www.minitube.com*)

This superovulated cow ovary has 9 corpora hemorraghica (all numbered) indicating individual ovulation sites. Ovariectomy was performed 3 days after estrus. Notice the points of follicular rupture and the blood clots at the apex (arrows). Two corpora hemorrhagica (A and B) are larger than the others because the follicles ovulated sooner. (Specimen courtesy of Dr. Brad R. Lindsey, Minitube of America, *www.minitube.com*)

This hyperstimulated camel ovary was exteriorized through an incision in the lumbar fossa. The camel was in estrus. There are 13 follicles approaching ovulation. Four follicles recently ovulated as judged by the small points of rupture (arrows) at the apex of the follicle. Notice the thinning at the apex of follicles A and B. These are very near ovulation. (Photograph courtesy of Dr. Ahmed Tibary, Washington State University, College of Veterinary Medicine)

the follicle, called the **stigma** begins to push outward and weaken. Examples of these structures can be observed in the camel ovary (See Figure 8-15).

Prostaglandins Cause Ovarian Contraction and Aid in Follicular Remodeling

After the LH surge, both prostaglandin $F_{2\alpha}$ and prostaglandin E_2 are synthesized and released locally by the ovary. Prostaglandin $F_{2\alpha}$ causes contractions of the myoid (smooth muscle) components of the ovary. Thus, intermittent contractions may increase pressure locally and force the stigma to protrude even more dramatically from the surface of the ovary. Prostaglandin $F_{2\alpha}$ also causes **lysosomes** within the granulosal cells to rupture, releasing their enzymes. These lysosomal enzymes cause further connective tissue deterioration at the apex of the follicle.

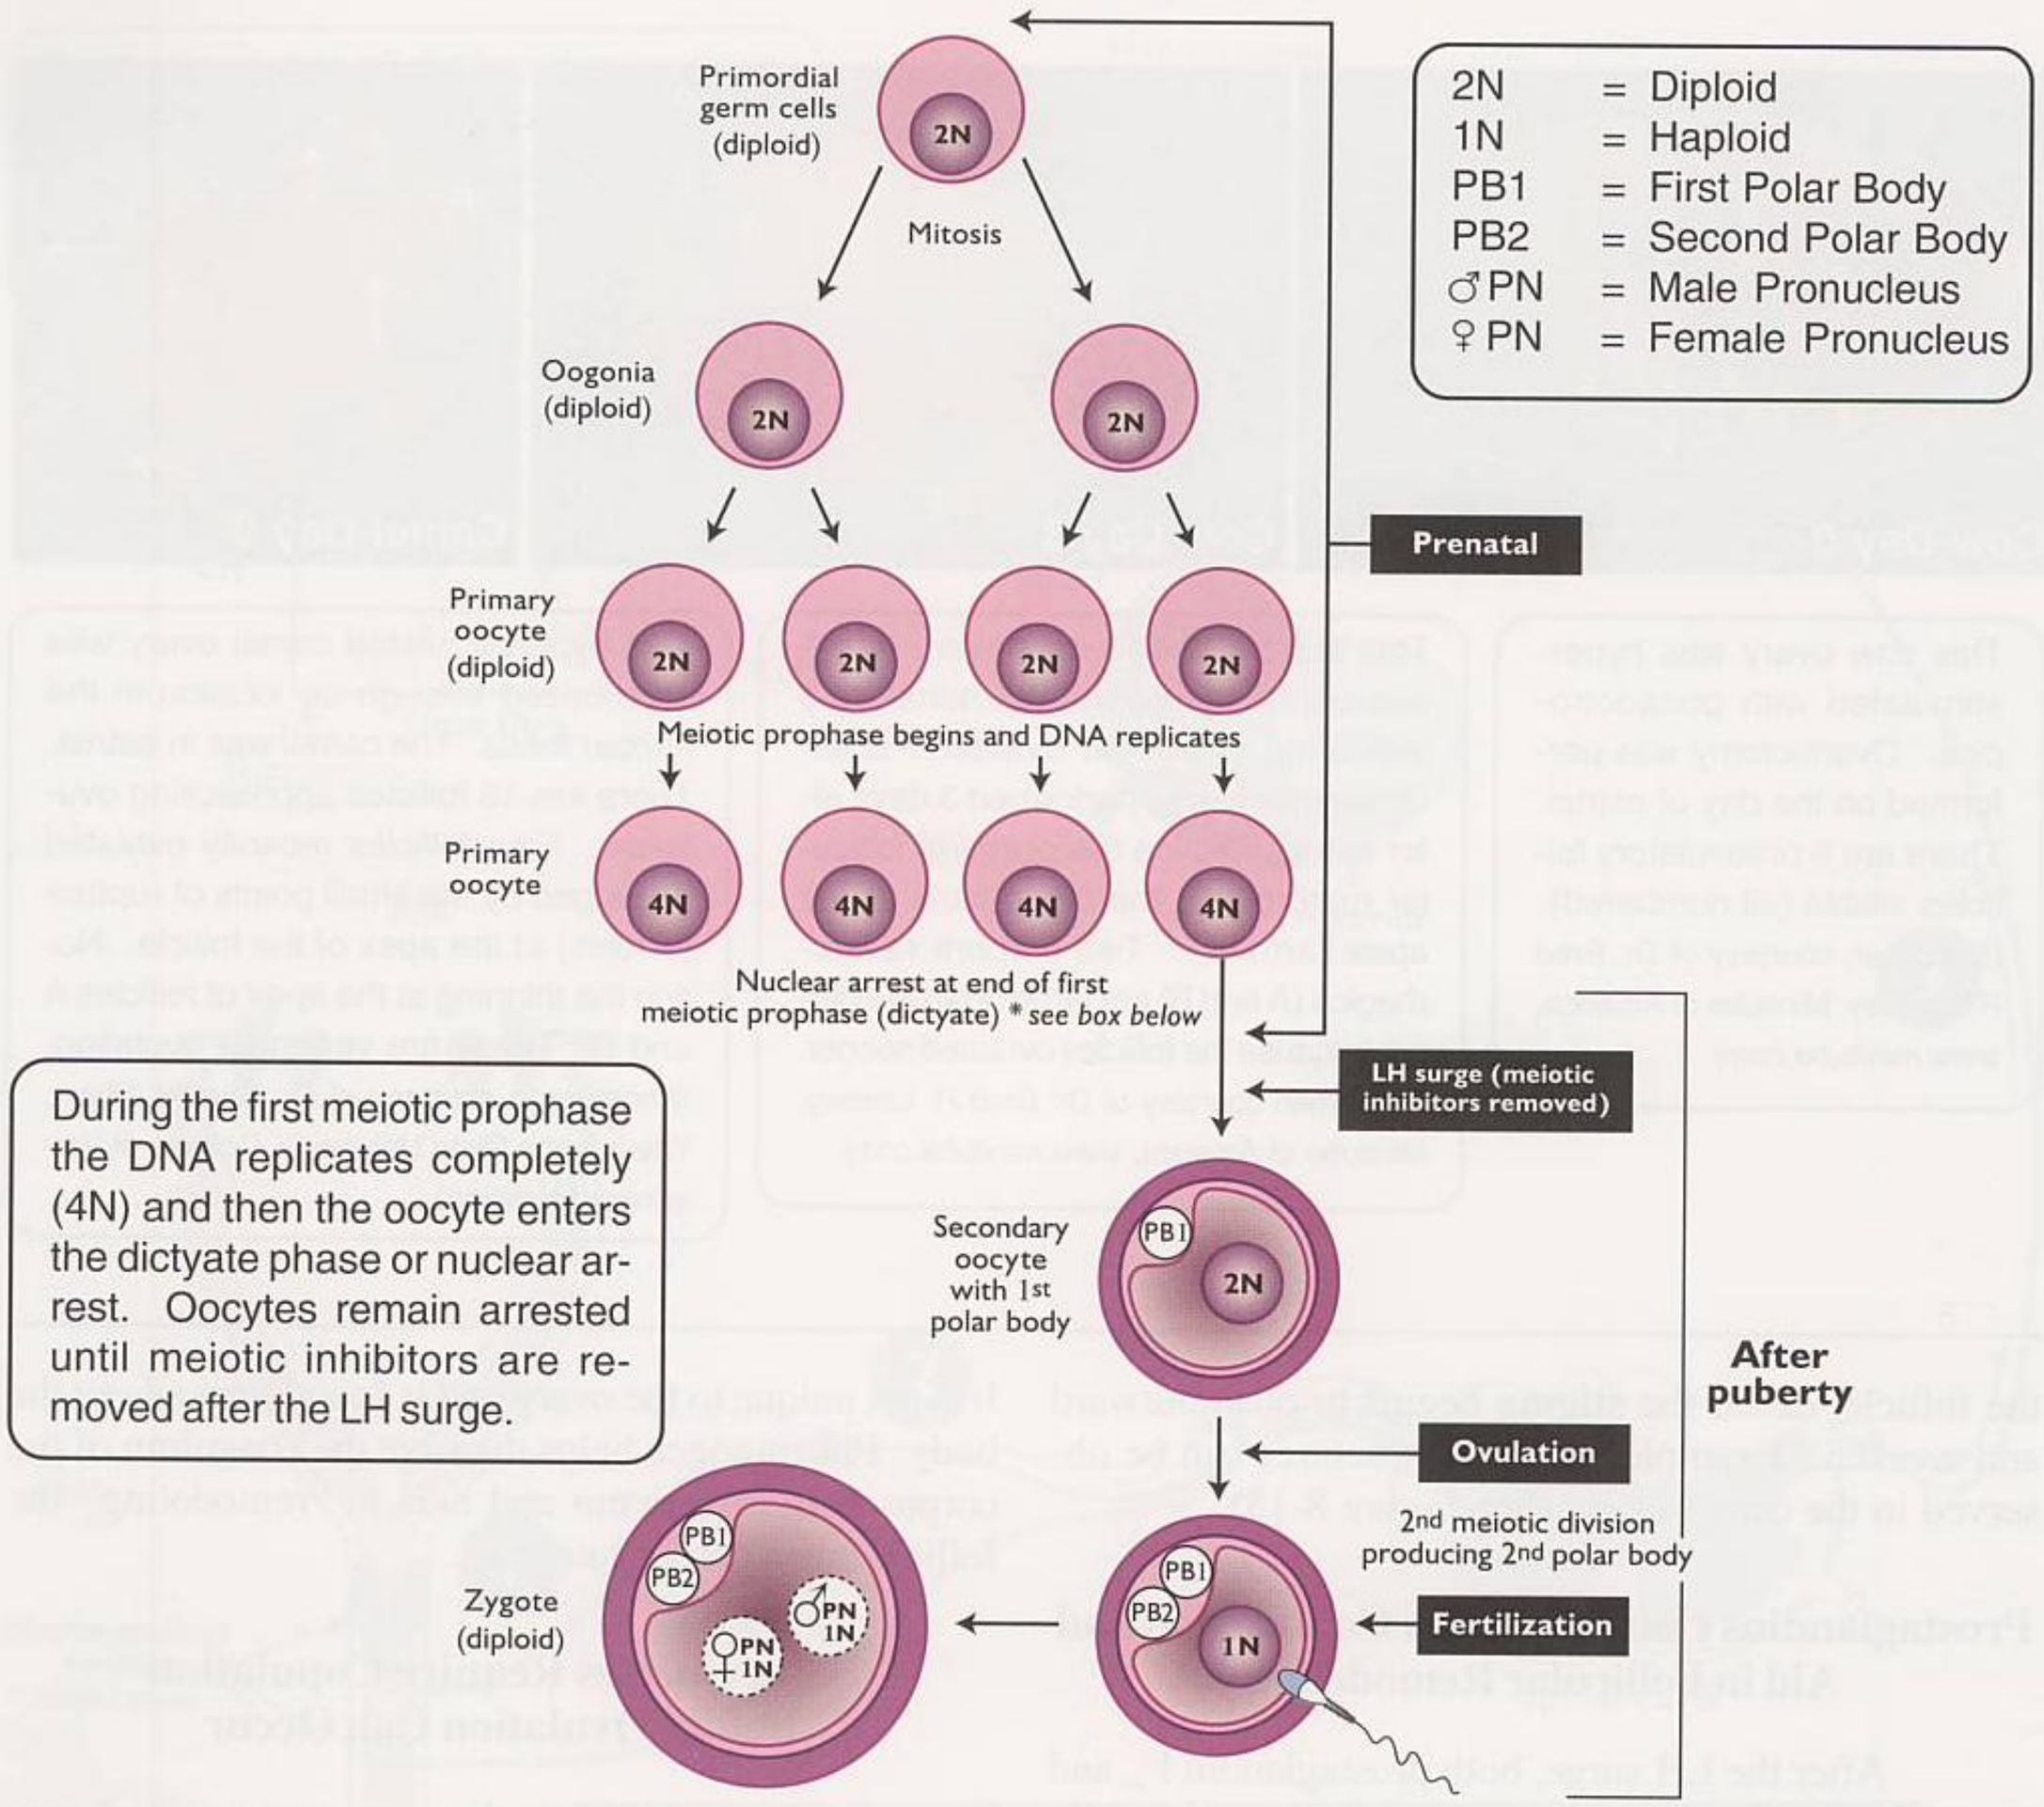
The role of prostaglandin E_2 is to help the follicle remodel itself into a corpus luteum after ovulation. The follicle receives its direction for this reorganization from prostaglandin E_2. Prostaglandin E_2 is believed to activate a substrate called plasminogen. Plasminogen is converted to plasmin by plasminogen activator (either tissue, tPA or urokinase, uPA). Plasmin is the active enzyme that participates in tissue remodeling. It is not unique to the ovary and is found throughout the body. Plasminogen helps dissolve the coagulum of the corpus hemorrhagicum and aids in "remodeling" the follicle into a corpus luteum.

Some Species Require Copulation Before Ovulation Can Occur

Among mammals there are two types of ovulators. These are known as **spontaneous ovulators** and **reflex (induced) ovulators**. Spontaneous ovulators ovulate with a regular frequency and do not require copulation. In the spontaneous ovulator, ovulation is brought about totally in response to hormonal changes. Examples of spontaneous ovulators are the cow, sow, ewe, mare and the woman.

The **reflex (induced) ovulator** requires stimulation of the vagina and/or cervix for ovulation to occur. Examples of reflex ovulators are the rabbit, felids, the ferret and the mink. With the exception of the rabbit, induced ovulators have a relatively long copulation time (Camelids; 1hr) or copulate with intense frequency (over 100 times per estrus in lions). Such copulation patterns ensure that adequate neural stimulation will take place and cause ovulation. The pathway for induced ovulation is illustrated in Figure 8-14.

Figure 8-16. The Major Steps of Oogenesis



During the first meiotic prophase the DNA replicates completely (4N) and then the oocyte enters the dictyate phase or nuclear arrest. Oocytes remain arrested until meiotic inhibitors are removed after the LH surge.

8

Females that are reflex ovulators can be induced artificially using electrical or mechanical stimulation. The tactile stimulation associated with copulation is converted into action potentials that travel through a pathway from the vagina and/or cervix to the spinal cord. Afferent pathways innervate the hypothalamus. The elevated frequency of action potentials in the sensory nerves in the vagina and cervix causes increased firing of hypothalamic neurons that then results in a preovulatory surge of GnRH. This release of GnRH in turn causes LH to be released, prompting the cascade of events leading to ovulation. In cats, a single copulation will induce ovulation about 50% of the time. Multiple copulations cause a much higher LH surge amplitude than single copulations. Reflex ovulators, particularly the rabbit, make excellent experimental models, since the time of ovulation relative to the onset of reproductive tract stimulation can be controlled. In the rabbit, the timing of ovulation is quite precise relative to stimulation. Thus, if one has the desire to recover embryos or oocytes from the reproductive tract, a higher degree of precision (relative to the stage of early embryo development) can be achieved in the reflex ovulator than with the spontaneous ovulator.

Some spontaneous ovulators (cow) apparently have some residual neural input from the reproductive tract that can alter the timing of the LH surge. For example, research has shown that when heifers (but not cows) are artificially inseminated and the insemination is accompanied by clitoral massage, the LH surge shifts toward the time of clitoral stimulation. This manipulation of the LH surge by neural stimulation suggests that the time of ovulation can be altered to some degree in spontaneous ovulators.

Camelids Appear to be Modified Induced Ovulators

In camelids (camels, alpacas and llamas) the presence of seminal plasma in the female reproductive tract appears to be more important for inducing ovulation than tactile stimulation (like in felids). There appears to be an "ovulation inducing factor" present in seminal plasma that acts through a hormonal pathway. This factor is GnRH-like because when seminal plasma from camels (Bactrian) was injected into rabbits an LH surge followed. A similar response (LH surge) in camels was observed when seminal plasma was deposited into the skeletal muscle, vagina, cervix or uterus. Seminal plasma appears to be important as an ovulation inducer in these species. However, biochemical characterization of the material within seminal plasma has not been reported.

Folliculogenesis and Ovulation can be Artificially Induced Using Various Hormones

Understanding the basic hormonal requirements for follicular dynamics and ovulation has enabled the manipulation of the timing of ovulation for management and convenience purposes. Two main approaches have been developed. These are hormonally induced ovulation (generally coupled with induced estrus) and **superovulation**. Hormonally induced ovulation requires premature luteolysis. Premature luteolysis can be accomplished using the administration of exogenous prostaglandin $F_{2\alpha}$. Prostaglandin $F_{2\alpha}$ causes luteolysis and therefore causes a decline in blood progesterone. This allows endogenous GnRH to be released, thus stimulating the release of FSH and LH from the anterior lobe of the pituitary. The applications of superovulation to embryo transfer will be presented in Chapter 13.

Superovulation is due to an abnormally high number of follicles that are selected followed by ovulation. It requires the administration of exogenous gonadotropins that cause abnormally high numbers of follicles to be selected (See Figure 8-15). Superovulated females ovulate abnormally high numbers of ova. Methods of superovulation usually include injections of equine chorionic gonadotropin (eCG) or FSH followed by administration of LH, GnRH or human chorionic gonadotropin (hCG) several days later to induce ovulation. The principle of superovulation involves providing the female with higher than normal levels of FSH so that greater numbers of follicles are recruited and selected. Dosages of exogenous gonadotropins required to induce superovulation vary both among and within species.

The four phases of oocyte maturation are:

- ***mitotic division of primordial germ cells (prenatal)***
- ***nuclear arrest (dictyotene)***
- ***cytoplasmic growth***
- ***resumption of meiosis***

Oocyte maturation is not limited to the follicular phase, but occurs throughout the lifetime of the female conceptus. Maturation of oocytes occurs in four phases beginning during embryonic development of the female and continuing throughout her reproductive lifetime.

Mitotic divisions occur prenatally (See Chapter 4) and ensure that the female is born with a complete supply of germ cells that will provide a future follicular reservoir. Further mitotic activity does not take place postnatally except for a few postnatal days in the rabbit. The last mitotic division from the oogonia to the primary oocyte constitutes an important step because the primary oocyte enters the first meiotic prophase (See Figure 8-16). The meiotic prophase is then arrested and the nucleus of the oocyte becomes dormant and will remain so until stimulated by gonadotropins after puberty. The oocyte remains arrested for a prolonged period of time from late fetal life through birth and puberty. Oocytes remain in the period of arrest until ovulation occurs or even later in some species. The purpose of this nuclear arrest is to inactivate the DNA in the female gamete so that it may not be vulnerable to possible insult during the lifetime of the female. Insults, or damage to DNA of the female gamete could compromise reproduction because embryo death would likely occur after fertilization.

Oocyte Growth Involves Formation of a Large Cytoplasm and the Zona Pellucida

The neonatal female enters a period of somatic growth and development in that body growth increases but the gonad remains relatively dormant. During this period of growth, however, some of the primary oocytes begin to accumulate larger volumes of cytoplasm and develop a translucent band around this cytoplasm known as the **zona pellucida** that is formed during the secondary follicle stage. An important development during this stage of maturation is the establishment of **junctional complexes** between neighboring follicular cells and the oocyte that permit ionic and electronic coupling between different cell types. These cell contacts are important for communication between the oocyte and the adjacent granulosal cells. These junctions are known as **gap junctions** and are illustrated in Figure 8-17. Their presence is especially important after the formation of the zona pellucida because it would serve as a barrier limiting diffusion of materials needed for growth of the oocyte.

Oocyte growth is believed to be mediated primarily by granulosal cells of the follicle. Indeed, *in vitro* experiments have shown that oocytes cannot develop unless follicular cells and functional gap junctions are present. Gap junctions between granulosal cells and the plasma membrane of the oocyte remain intact until the time of the preovulatory LH surge. During the growth phase, the volume of oocyte cytoplasm increases about 50 times. Presumably, the ability of the oocyte cytoplasm to develop is a direct function of the ability of the cell to maintain functional contact with the granulosal cell.

It was once thought that the zona pellucida was formed exclusively by the follicle cells adjacent to the oocyte. It is now evident that the oocyte itself is primarily responsible for the synthesis of the zona pellucida. The precursors for this **mucopolysaccharide** material are synthesized by the oocyte itself and then transferred out of the oocyte to form the thick, translucent layer surrounding the cytoplasm. At the time of antrum formation in the follicle, the oocyte has attained its full cytoplasmic size and these oocytes presumably have the potential to undergo a nuclear maturation provided that atresia has not been initiated.

Final Maturation and Resumption of Meiosis Occur Near the Time of Ovulation

Once the follicle has entered the dominance phase, the oocyte becomes poised to resume meiosis. It is believed that when the oocyte reaches a critical minimum size, it gains the ability to resume meiosis

when the ovulatory LH discharge occurs. Shortly after the LH surge, the gap junctions between the granulosal cells and the oocyte deteriorate. This deterioration precedes meiotic resumption and it is thought that this disruption of communication between the granulosal cells and the oocyte cytoplasm may remove the inhibition upon meiosis. The timing of the deterioration of gap junctions varies among species. Therefore, the resumption of meiosis cannot be explained totally by the breakdown of these cellular junctions.

The nuclear arrest must be interrupted to permit final oocyte maturation. The preovulatory discharge of gonadotropins is necessary to release the oocyte from inhibitors, presumably provided by the granulosal cells. Cyclic AMP (cAMP) provided by granulosal cells is proposed as the primary inhibitor of meiotic resumption. When granulosal projections dissociate from the cytoplasm of the oocyte, cAMP is no longer available to inhibit the oocyte. Another substance called **oocyte meiotic inhibitor** (OMI) has been implicated in controlling the resumption of meiosis. However, this substance has not been purified and its exact role remains uncertain. Once these inhibitors have been removed, the oocyte is free to proceed with the first meiotic division. For example, in the sheep, pig, mouse and hamster the relationship between the follicle cells and the oocyte is the main factor controlling resumption of meiosis. It is clear that this event takes place in the dominant follicle just prior to ovulation in most mammals. In the dog and the fox, ovulation occurs before meiosis is resumed.

The resumption of meiosis is complex and can be described using a number of criteria. In the dominant follicle, the nucleus of the oocyte begins to migrate towards the periphery and flattens against the oocyte plasma membrane. The peripheral migration of the nucleus constitutes an early morphologic sign of the initiation of final oocyte maturation. This migration takes place after the ovulatory surge of LH in rodents and carnivores. In ruminants, the nucleus becomes polymorphic with many folds. This lobulation is then followed by a dissociation of the nuclear membrane. The bivalent chromosomes then line up and the chromatids are then separated by a microtubule system that pulls the chromosome apart, forming the **first polar body**. This meiotic division generally occurs slightly before ovulation. After fertilization, the second meiotic division will occur, producing the **second polar body**. In some cases, the first polar body will divide, producing two additional "daughter" polar bodies. In this case, three polar bodies can be observed.

Further PHENOMENA *for* Fertility

Aristotle reported that "Camels copulate with the female in a sitting posture and the male straddles over and covers her...and they pass the whole day long in the operation." The practical significance of this relates to the use of camels as pack animals during military operations. Aristotle reported that camels were spayed (removal of ovaries) to prevent pregnancy. An equally important reason for spaying the female camel was to prevent estrus so that excessive time spent copulating would not interfere with military operations. Tribesmen also discovered that placing stones in the uterus prevented copulation during traveling and wars.

During estrus (2 to 4 days), lions can copulate more than a hundred times, with mating occurring every 15 minutes. It has been estimated that lions copulate 3,000 times for every cub that survives to the yearling stage. One male copulated 157 times in 55 hours with 2 different females. (Lions are induced ovulators.)

In the domestic chicken, ovarian progesterone induces the preovulatory surge of LH, not estradiol.

The elephant shrew and tenrec are natural superovulators. In fact, in the tenrec more than 40 follicles may ovulate, but litters of greater than 10 have not been observed. About 75% of the embryos die and are reabsorbed during gestation.

Female elephants in estrus attract males by releasing a pheromone that is excreted in the urine. This pheromone is potent and can attract bull elephants from miles away.

The female canary must hear her male partner's song in order for her ovaries to develop. The more he sings, the more her ovaries are stimulated and the eggs develop. Here is a case where there appears to be a link between the auditory sense and the GnRH neurons in the hypothalamus.

Female Old World monkeys have a "sex skin" (perianal skin). Under the influence of estrogen the "sex skin" becomes hyperemic and swells. This serves as a visual signal to males, "announcing" the optimum time for copulation.

The Guinness Book of World Records reported that Mrs. R.A. Kistler gave birth to a baby girl when she was 57 years, 4 months and 5 weeks old.

One observer noted that a male lion copulated 84 times in 24 hours. In the following 24 hours he copulated an additional 62 times, eventually ending with a tally of 157 copulations in 55 hours. After the primary male becomes satiated, another male usually takes over and copulates with the lioness. The lioness (like all felids) is an induced ovulator.

In Papua New Guinea, a small group of people (about 2,000) called Sambia practice extensive rituals that they believe promote the onset of puberty in the male. Rituals in the female are not practiced because they believe the female attains reproductive competence through natural means. Up to six intermittent "manhood" initiation rituals are performed. One taboo contends that the reproductive development of the male is compromised by the sustained presence of the mother. Boys are traumatically separated from their mothers (and wiped clean of female contaminants) so that puberty can develop. They further believe the young male can produce semen only after long series (years) of homosexual fellatio inseminations following removal of the mother. They believe this "injection of semen" is obligatory for the formation of male reproductive capacity.

There are several examples of males being forced to leave their family group when they reach puberty to avoid inbreeding. Some of these encounters can be rather brutal, with the maternal faction ganging up on the newly pubertal males to "kick them out." Examples of this behavior are found in lions and elephants.

In ancient Greece (1200-300 BC) women placed sea sponges-sometimes doused with lemon juice or vinegar- inside the vagina as a barrier against semen.

In more than 20 African countries and some parts of Asia, young women may undergo clitoridectomy (female circumcision). The clitoris is bisected or cut out entirely and all or part of their labia is sliced off. Their vulvas may also be stitched together, a process called infibulation. This practice was begun in an effort to control a woman's sexuality by eradicating their ability to derive sexual pleasure from intercourse.

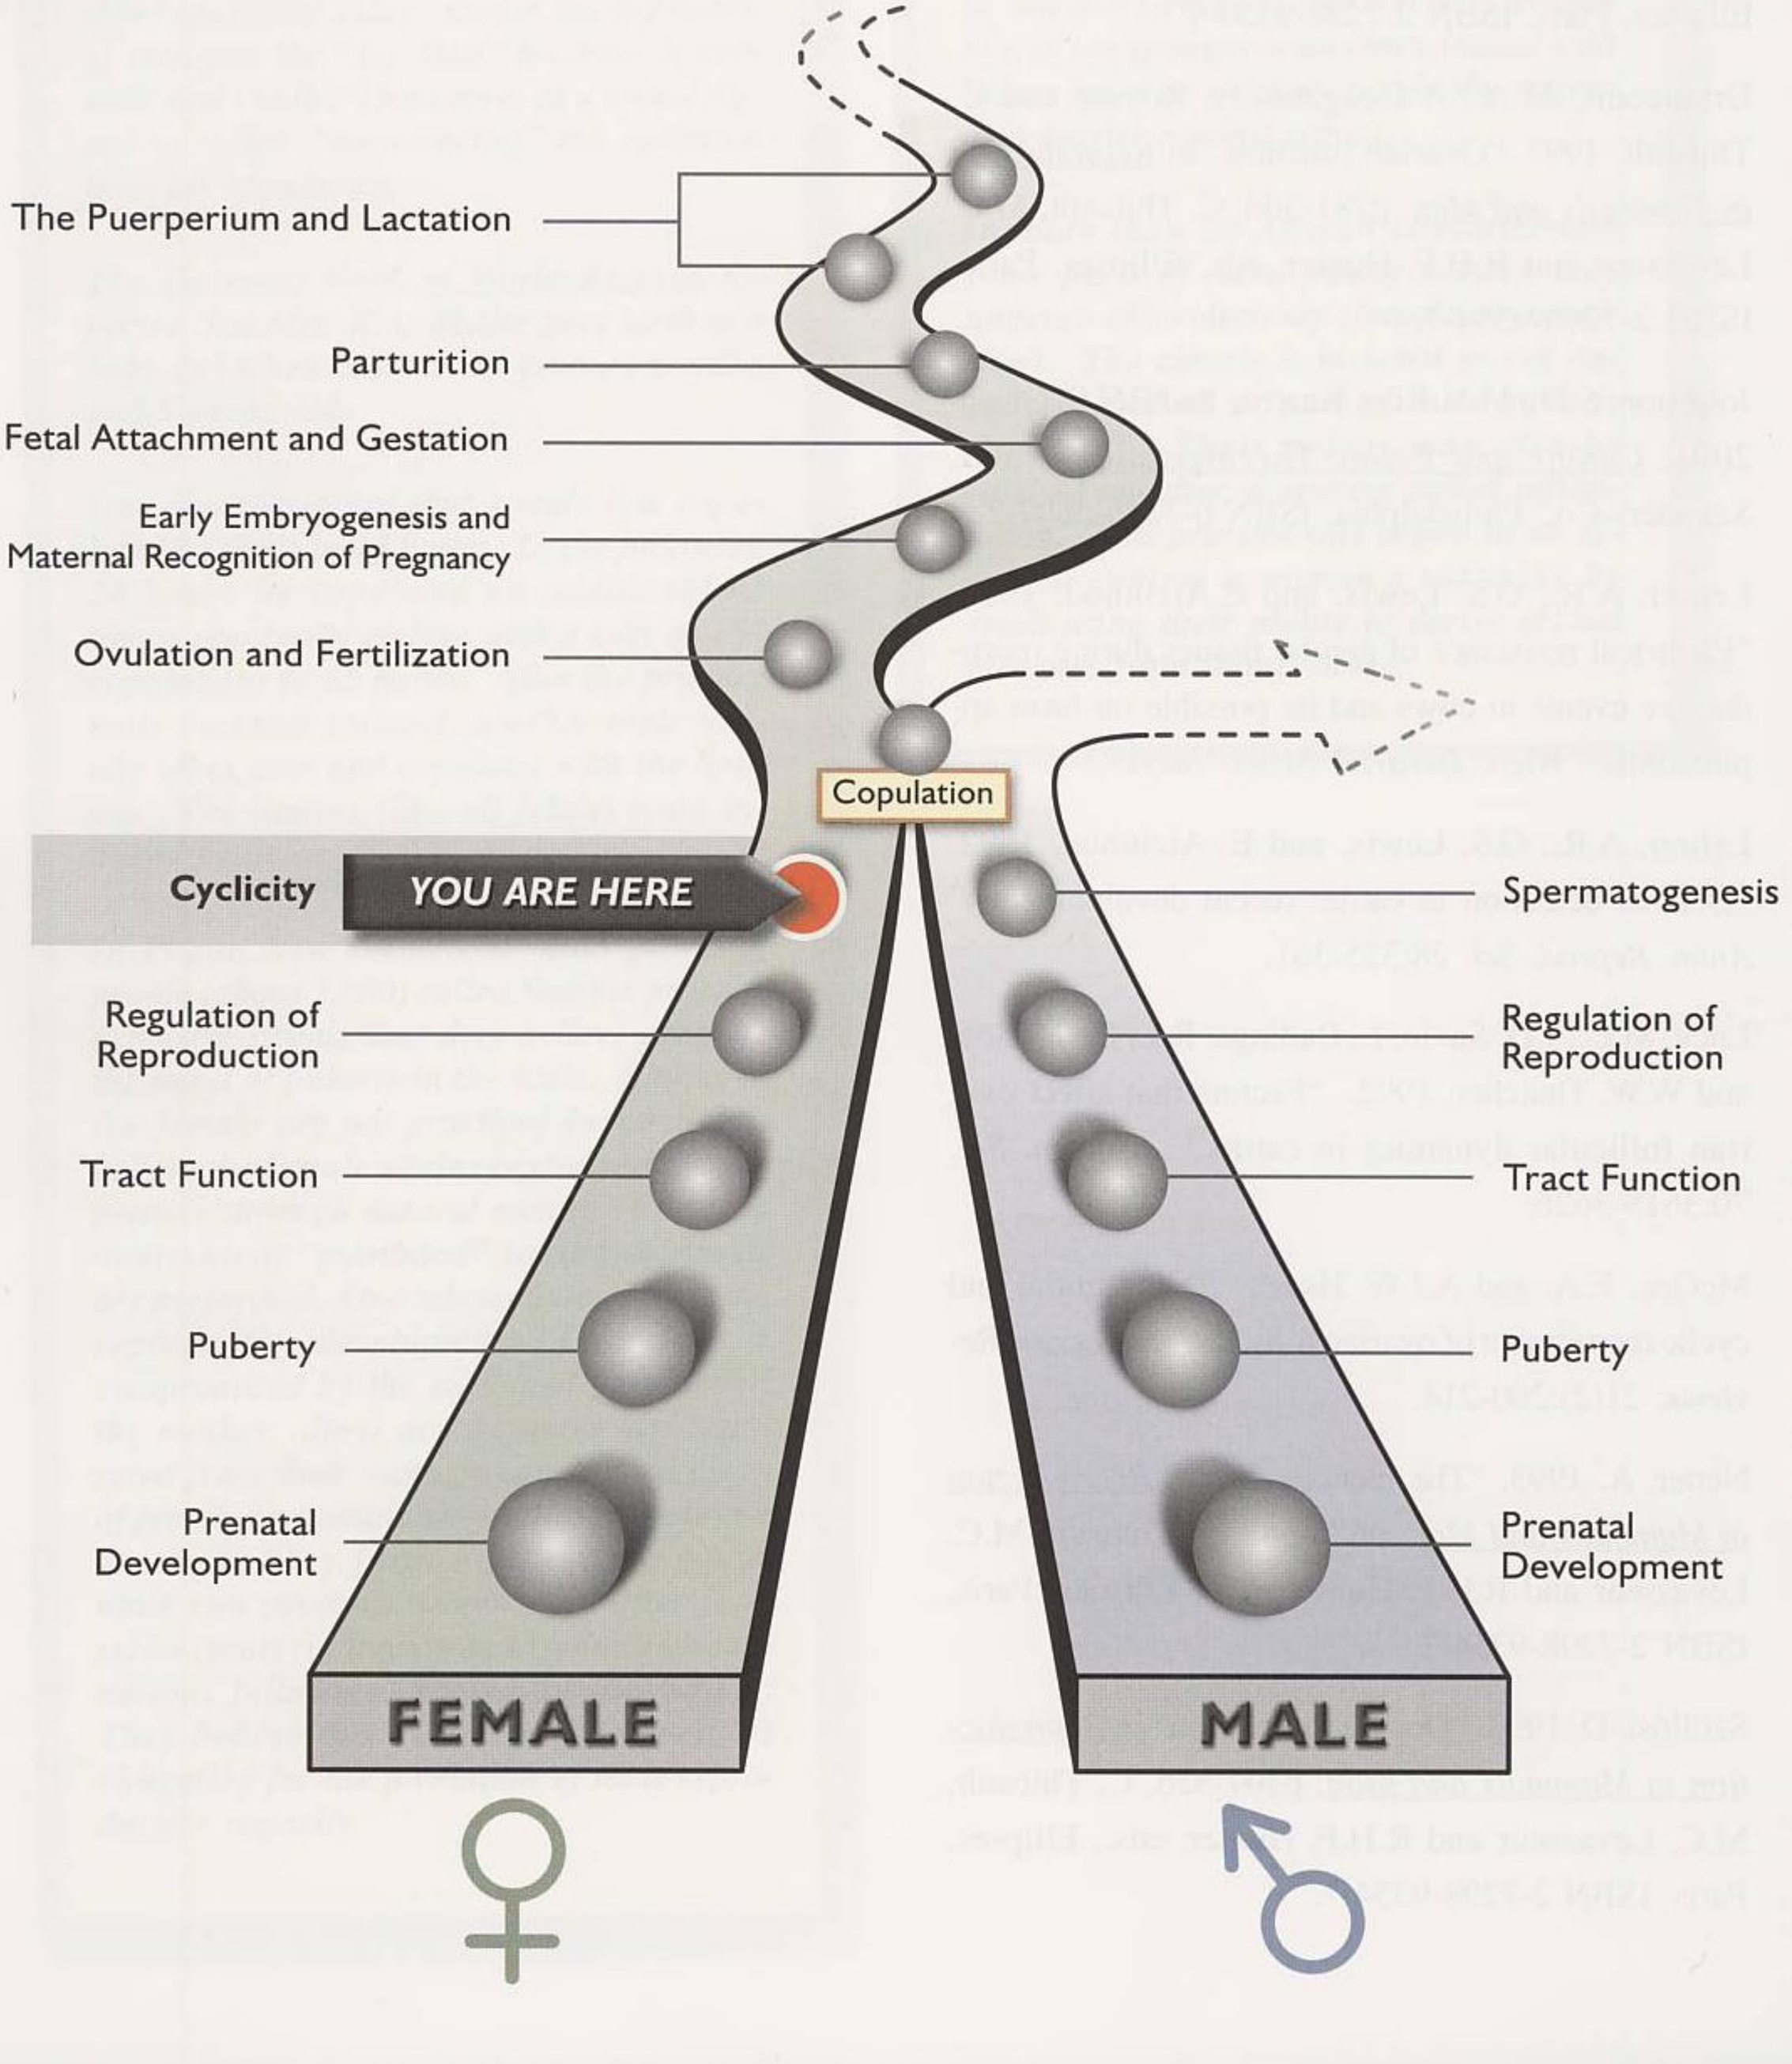
CHAPTER 9

Reproductive Cyclicity - The Luteal Phase



Take Home Message

The luteal phase consists of three major processes. They are: 1) the transformation of follicle cells into luteal cells after ovulation (luteinization); 2) growth and development of the corpus luteum so that it produces high quantities of progesterone (diestrus); 3) destruction of the corpus luteum (luteolysis) resulting in a subsequent follicular phase. Lysis of corpora lutea is brought about by prostaglandin $F_{2\alpha}$ that is produced by the uterine endometrium in most mammals and by the ovary in humans. Lysis of corpora lutea is followed by a marked reduction in progesterone. The negative feedback exerted by progesterone on the hypothalamus is removed and the female enters a new follicular phase because the pulse frequency and amplitude of GnRH increases thus causing FSH and LH to increase. In humans, luteolysis causes the initiation of menstruation that is followed by another follicular phase.

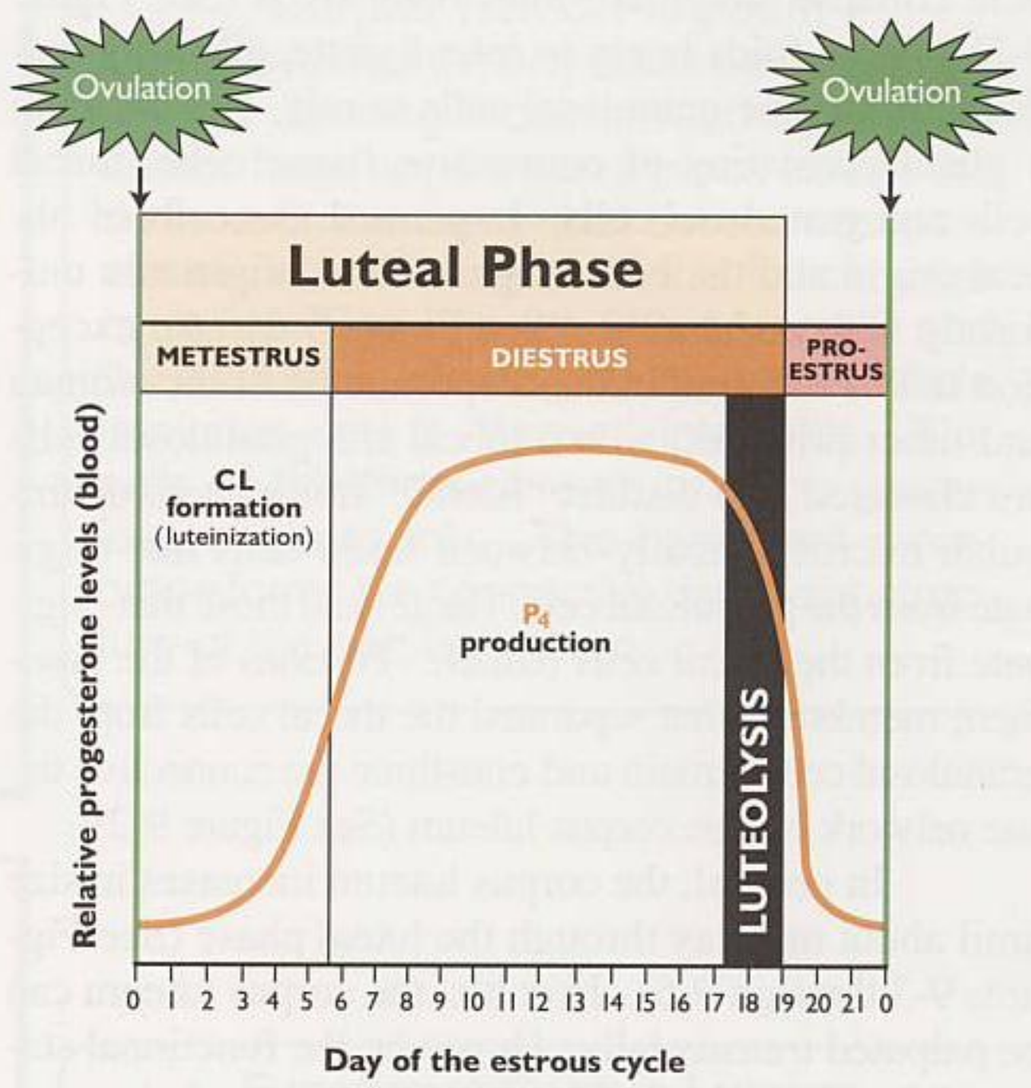
The luteal phase lasts from the time of ovulation until regression (**luteolysis**) of the corpus luteum (CL) near the end of the estrous cycle. It includes **metestrus** and **diestrus** (See Figure 9-1). The dominant ovarian hormone during the luteal phase is progesterone.

The luteal phase consists of:

- ***corpora lutea formation (luteinization)***
- ***production of progesterone***
- ***luteolysis***

When the follicle ruptures at ovulation, blood vessels within the follicular wall also rupture. This vascular breakage results in a structure with a "bloody" clot-like appearance. This structure is called the **corpus hemorrhagicum** because of its hemorrhagic (bloody) appearance when viewed from the surface of the ovary. Corpora hemorrhagica can be observed from the time of ovulation until about day 1 to 3 of the estrous cycle (See Figures 9-3 through 9-6). Immediately after ovulation, corpora hemorrhagica appear as small, pimple-like structures on the surface of the ovary. At about day 3 to 5, the CL begins to increase in size and lose its hemorrhagic appearance. It increases in mass until the middle of the cycle, when its size is maximal and coincides with the maximum production of progesterone during diestrus. Near the end of the luteal phase, luteolysis occurs and the CL loses its functional integrity and decreases in size. Luteolysis causes an irreversible structural degradation of the corpus luteum. A lysed corpus luteum will become a corpus albicans.

Figure 9-1. The Luteal Phase



The luteal phase begins immediately after ovulation. During the early luteal phase, the corpus luteum (CL) develops (luteinization) and progesterone begins to increase. During the mid-luteal phase (diestrus) the corpus luteum is fully functional and progesterone (P_4) plateaus at high concentrations. During the last 2-3 days of the luteal phase, destruction of the corpus luteum occurs (luteolysis) and the luteal phase terminates. Following luteolysis, proestrus is initiated.

In general, a corpus albicans can be observed for a substantial period of time (several estrous cycles) after luteolysis. This remnant of the corpus luteum appears as a white scar-like structure because of the connective tissue that remains after the glandular tissue disappears.

The corpus luteum originates from the ovulatory follicle.

After ovulation the **theca interna** and the **granulosal cells** of the follicle undergo a dramatic transformation known as **luteinization**. Luteinization is the process whereby cells of the ovulatory follicle are transformed into luteal tissue. This transformation is governed by LH. Shortly before ovulation the basement membrane of the follicle undergoes partial disintegration and the physical separation of the thecal and granulosal cells disappears (See Figure 9-2). Immediately after ovulation the walls of the follicle collapse (implode) into many folds (See Figure 9-2). These folds begin to interdigitate, allowing thecal cells and the granulosal cells to mix, thus forming a gland consisting of connective tissue cells, thecal cells and granulosal cells. In general, the cells of thecal origin and the cells of granulosal origin mix uniformly with one another (See Figure 9-2). An exception to this is found in the corpora lutea of the woman and other primates, where thecal and granulosal cells are clustered into distinct "islets". It is easy to distinguish microscopically between luteal cells that originate from the granulosal cells (large) and those that originate from the thecal cells (small). Portions of the basement membrane that separated the thecal cells from the granulosal cells remain and constitute the connective tissue network of the corpus luteum (See Figure 9-2).

In general, the corpus luteum increases in size until about midway through the luteal phase (See Figures 9-3 through 9-6). In cattle, the corpus luteum can be palpated transrectally. However, the functional status of the corpus luteum is difficult to ascertain by transrectal palpation because the palpable size of the corpus luteum is not always related to its progesterone producing ability. For example, a skilled examiner can almost always determine whether a corpus luteum is present or absent in cows. In mares, it is almost impossible to ascertain the presence or absence of the corpus luteum because it does not protrude from the surface of the ovary.

In the cow, palpation cannot predict with accuracy the degree to which a corpus luteum is functional. In four separate studies cows were transrectally palpated by experienced diagnosticians. Corpora lutea were classified as functional (producing high quantities of progesterone) or nonfunctional (regressing or producing low levels of progesterone) by the diagnosticians. Using measurements of blood progesterone as the indicator of corpus luteum function, it was found that 25% to 39% of cows classified as having a functional corpus luteum were not producing high amounts of progesterone. Furthermore, 15% to 21% of cows classified as having a nonfunctional corpus luteum had high blood progesterone. Clearly, the use of transrectal palpation to assess the functional status of the corpus luteum has limitations. From a practical reproductive management perspective, this problem limits the effectiveness of treating animals with luteolytic agents to induce estrus and ovulation. In other words, administering luteolytic agents (prostaglandin $F_{2\alpha}$) on the basis of transrectal palpation alone usually will provide suboptimal results.

Luteal tissue consists of large and small luteal cells:

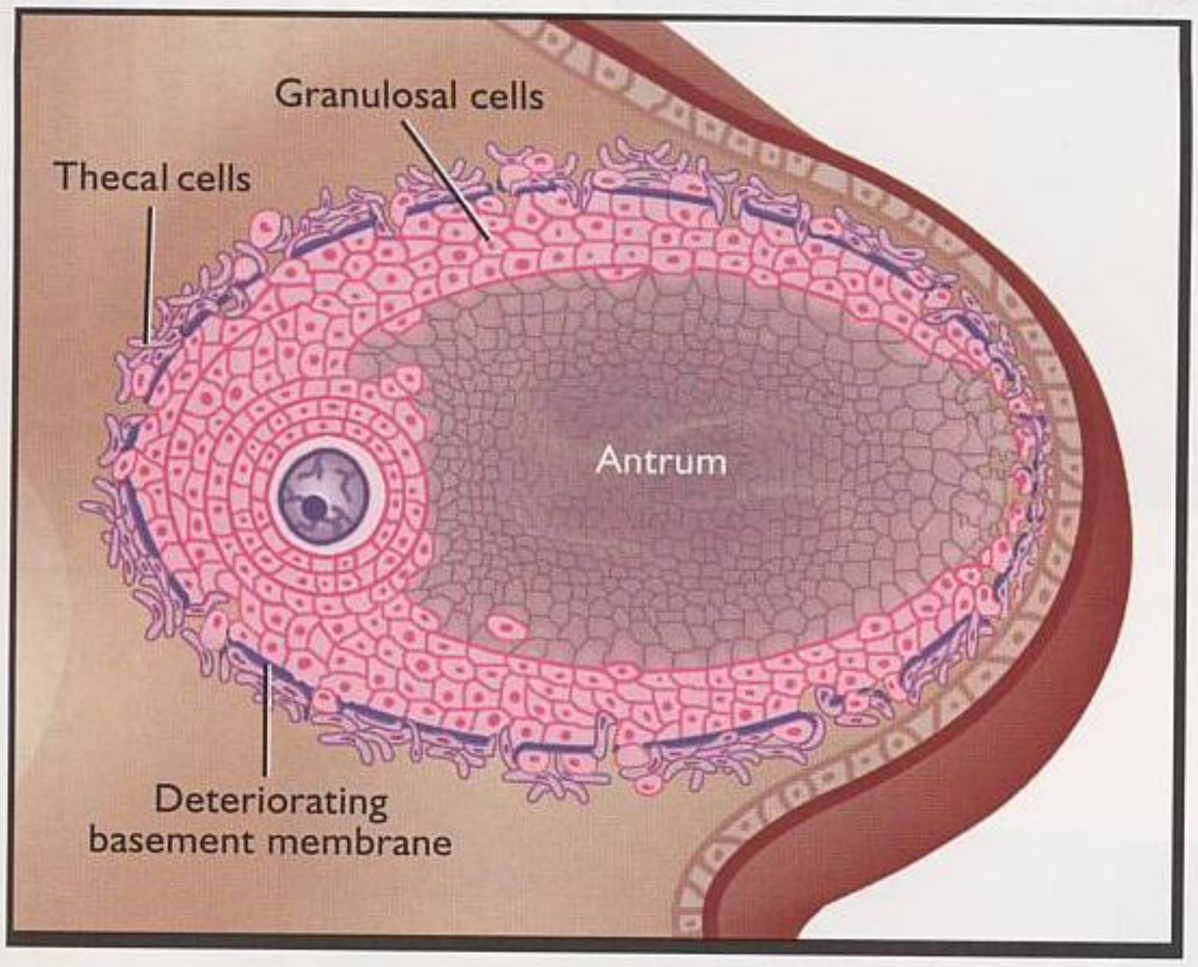
- ***large cells originate from the granulosal cells***
- ***small cells originate from the cells of the theca interna***

Recently, the use of real-time ultrasonography has proven effective for the examination of corpora lutea, as well as ovarian follicles. Progesterone concentration in blood is correlated with the diameter of the corpus luteum as measured by ultrasonography. Veterinarians routinely use this technique in cows and mares to evaluate ovarian status.

Large luteal cells (sometimes called granulosal-lutein cells) vary in diameter from 20-40 micrometers (μm), depending on species. In some species (ruminants), there are a large number of dense secretory granules close to the plasma membrane (See Figure 9-7B). These secretory granules contain **oxytocin** in the corpus luteum of the cycle and are believed to contain **relaxin** in the corpus luteum of pregnancy.

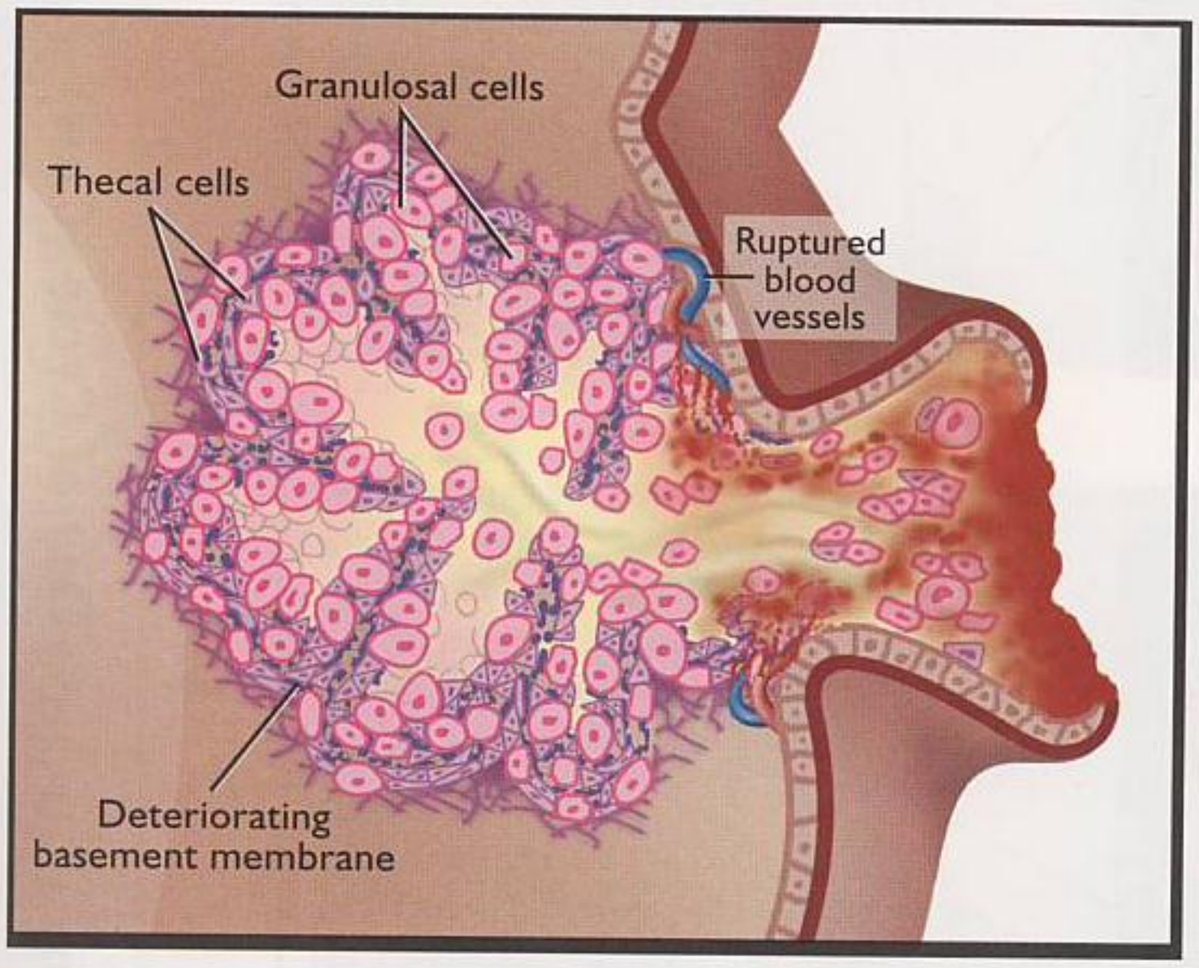
Small luteal cells (sometimes called thecal-lutein cells) are less than 20 μm in diameter, have an irregular shape and possess numerous lipid droplets in their cytoplasm (See Figure 9-7). They do not contain secretory granules as do the large luteal cells. Both small and large luteal cells are **steroidogenic** (possessing the ability to produce steroids), in this case progesterone.

Figure 9-2. Formation of the Corpus Luteum



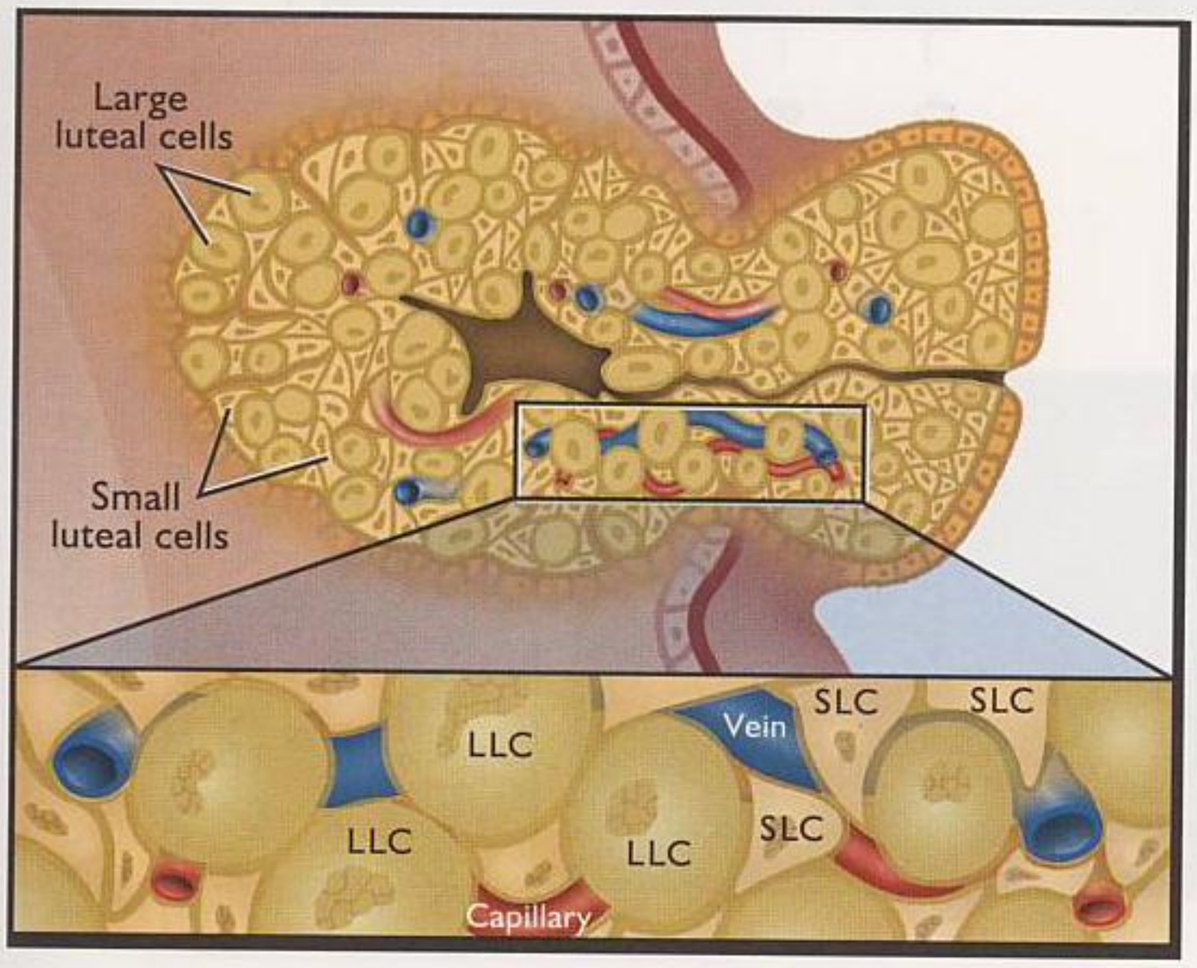
Preovulatory Follicle

The preovulatory follicle consists of granulosal cells that line the antrum. The basement membrane, separating the granulosal cells from the cells of the theca interna begins to deteriorate prior to ovulation because of the action of collagenase. Complete separation between the granulosal cells and the theca interna no longer exists and the cells can begin to intermingle.



Corpus Hemorrhagicum

During ovulation, many small blood vessels rupture causing local hemorrhage. This hemorrhage appears as a blood clot on the surface of the ovary that sometimes penetrates into the center of the follicle after ovulation (See Figures 9-3, 1A and B and 9-4,1A and B). During ovulation the follicle implodes and is "thrown" into folds. The cells of the theca interna and the granulosa begin to mix. The basement membrane forms the connective tissue substructure of the corpus luteum.



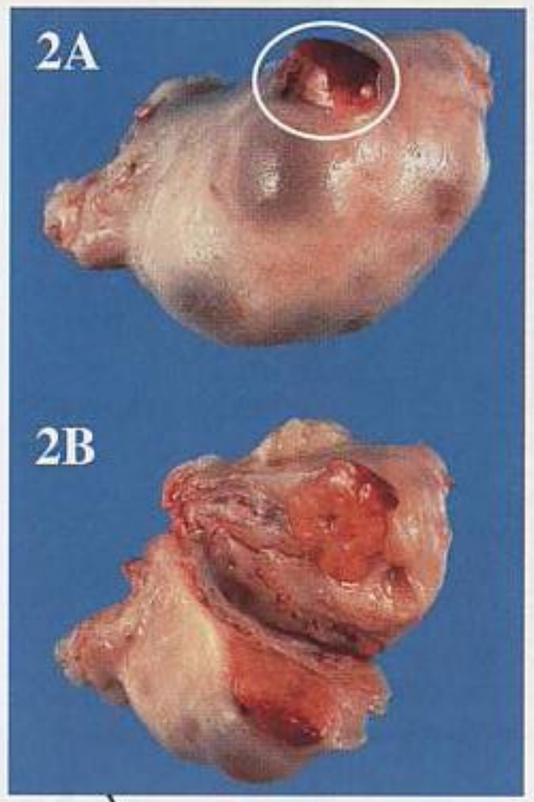
Functional Corpus Luteum

The corpus luteum is now a mixture of large luteal cells, LLC (formerly granulosal cells) and many small luteal cells, SLC (formerly thecal cells). In some cases, there is a remnant of the follicular antrum that forms a small cavity in the center of the corpus luteum (See Figures 9-3, 3B and 9-4, 2B; 9-6, 3B).

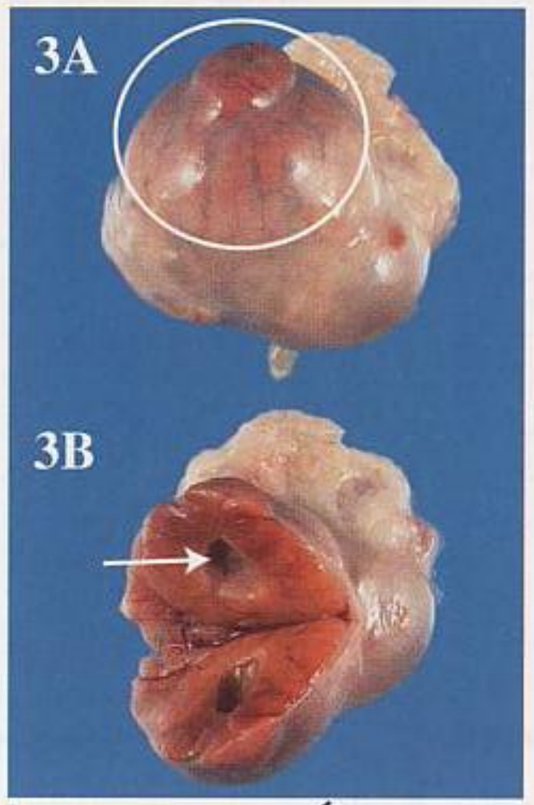
Figure 9-3. Luteal Anatomy in Relation to Progesterone Secretion During the Estrous Cycle in the Cow

2A
The area designated by the circle represents a developing corpus luteum.
2B
The corpus luteum has been sliced in half. Notice the increase in size when compared to that shown in 1B.

Late Metestrus

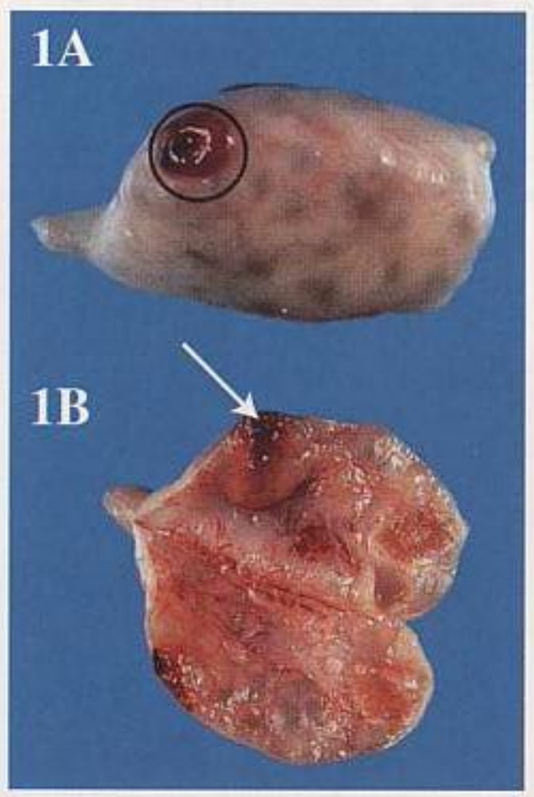


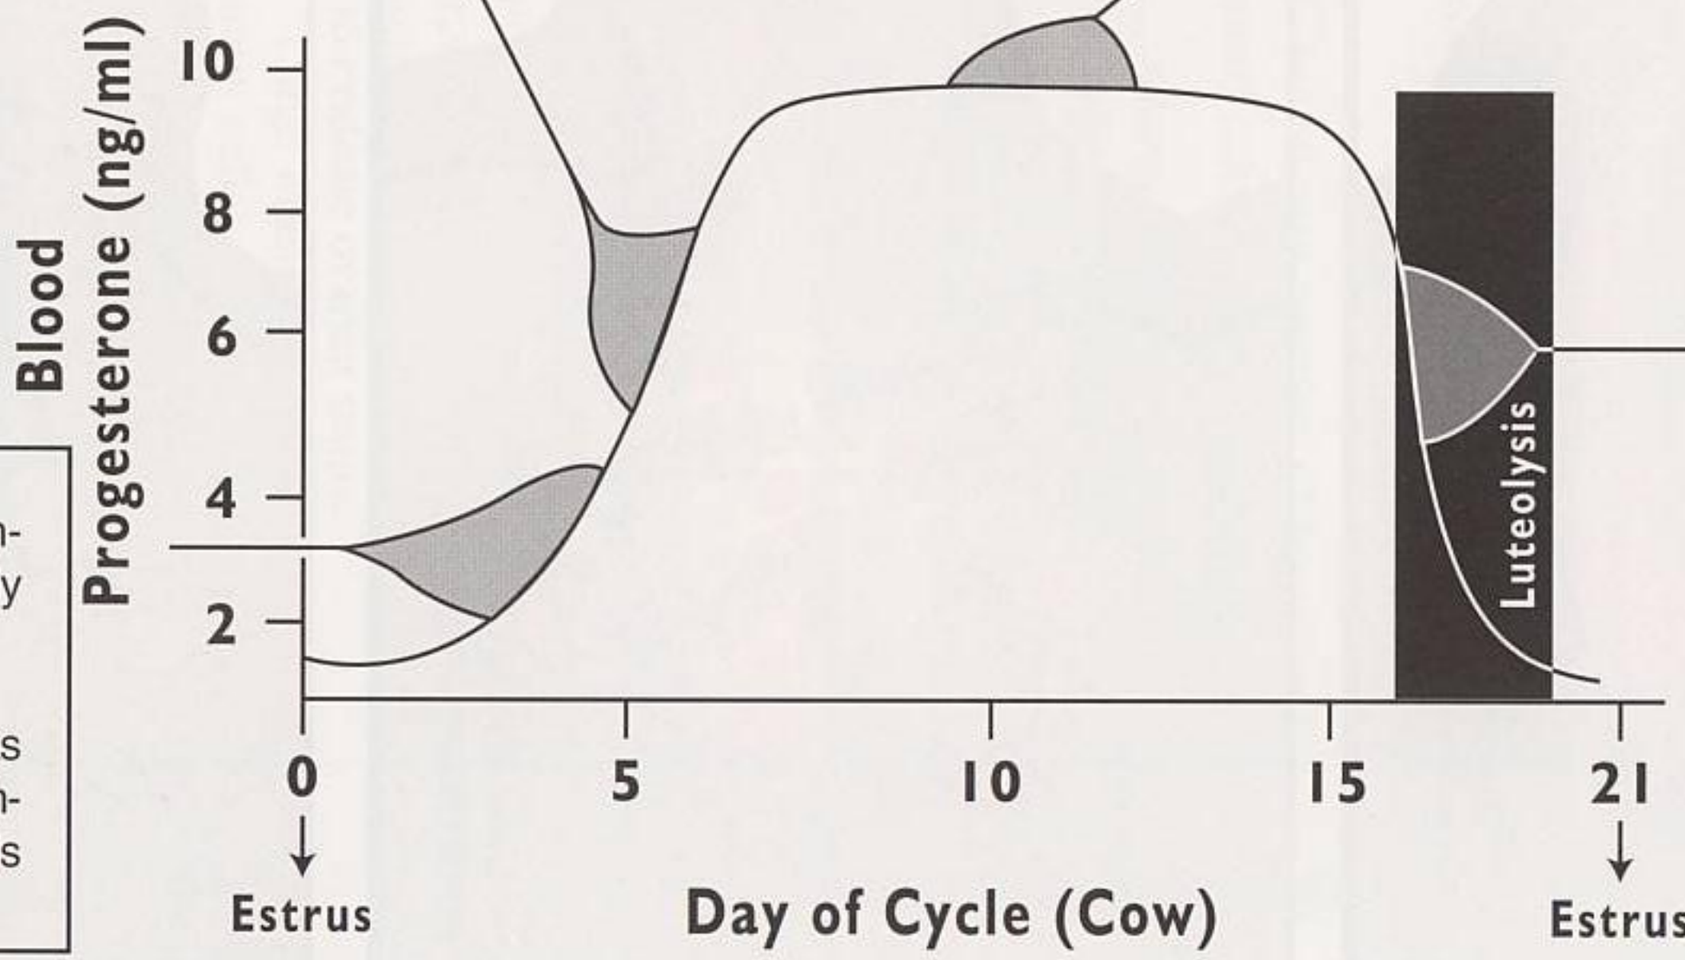
Diestrus



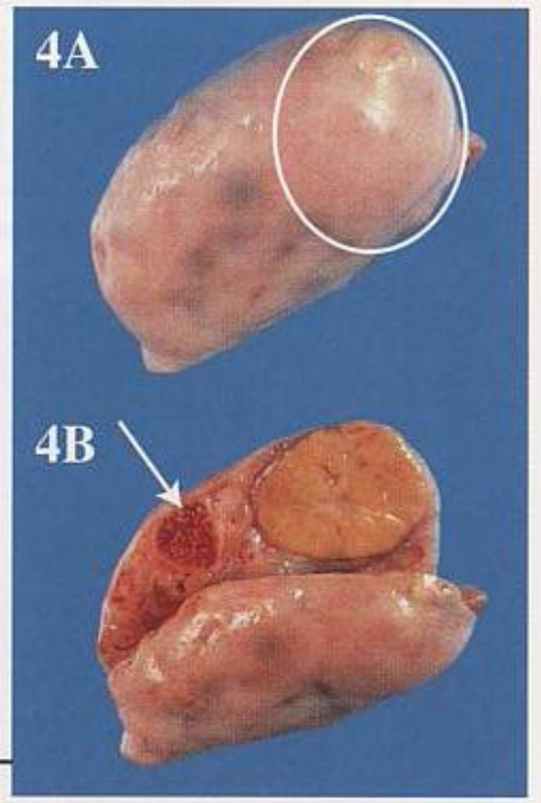
3A
A corpus luteum (circle) at peak progesterone production.
3B
A large mass of orange tissue can be seen when the CL is sliced in half. The orange color reflects the high content of β-carotene. The central cavity (arrow) is a remnant of the follicular antrum. A central cavity does not exist in every CL.

Early Metestrus





Proestrus



1A
Circled area is a corpus hemorrhagicum. Notice the bloody appearance at the apex.
1B
The corpus hemorrhagicum has been sliced in half. Notice the remnant of the follicular lumen that is filled with a blood clot (arrow).

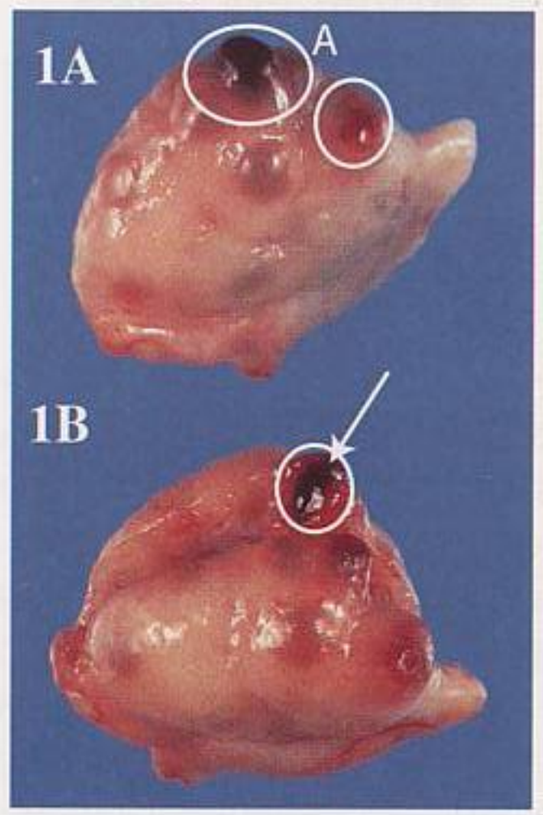
4A
The circle indicates the approximate area of the regressing corpus luteum.
4B
The corpus luteum has changed in color and in size. The secretory component of the tissue has decreased significantly as a result of luteolysis. Arrow designates regressing CL from a previous cycle.

Figure 9-4. Luteal Anatomy in Relation to Progesterone Secretion During the Estrous Cycle in the Ewe

2A
Circles A and B indicate developing corpora lutea.

2B
Corpus luteum B has been sliced in half. Notice the developing luteal tissue (circle) that surrounds a small cavity (arrow) that is the remnant of the follicular antrum. Notice that the hemorrhagic appearance is no longer present.

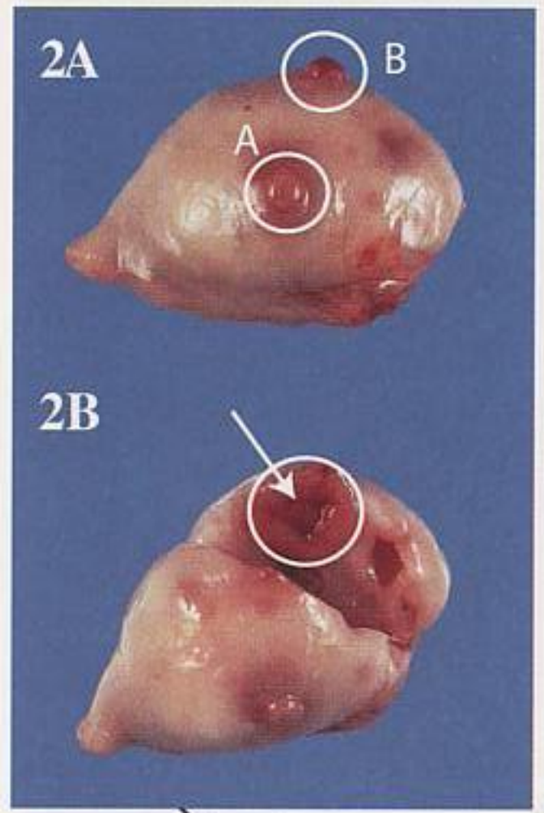
Early Metestrus



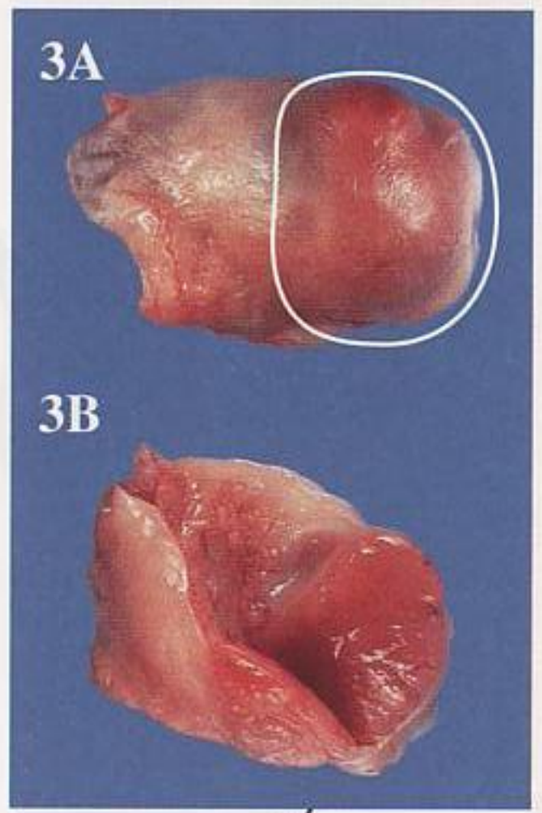
1A
Circles indicate two corpora hemorrhagica. Structure A likely ovulated first, since it contains less coagulated material.

1B
Circled area shows the corpus hemorrhagicum sliced in half. The clot is indicated by the arrow.

Late Metestrus



Diestrus



3A
A corpus luteum (circle) during the peak luteal phase.

3B
The luteal tissue (sliced in half) is a relatively large mass of secretory tissue.

Proestrus

4A
The circle indicates the surface of a regressing corpus luteum.

4B
The corpus luteum has become pale and the secretory tissue mass has decreased in size.

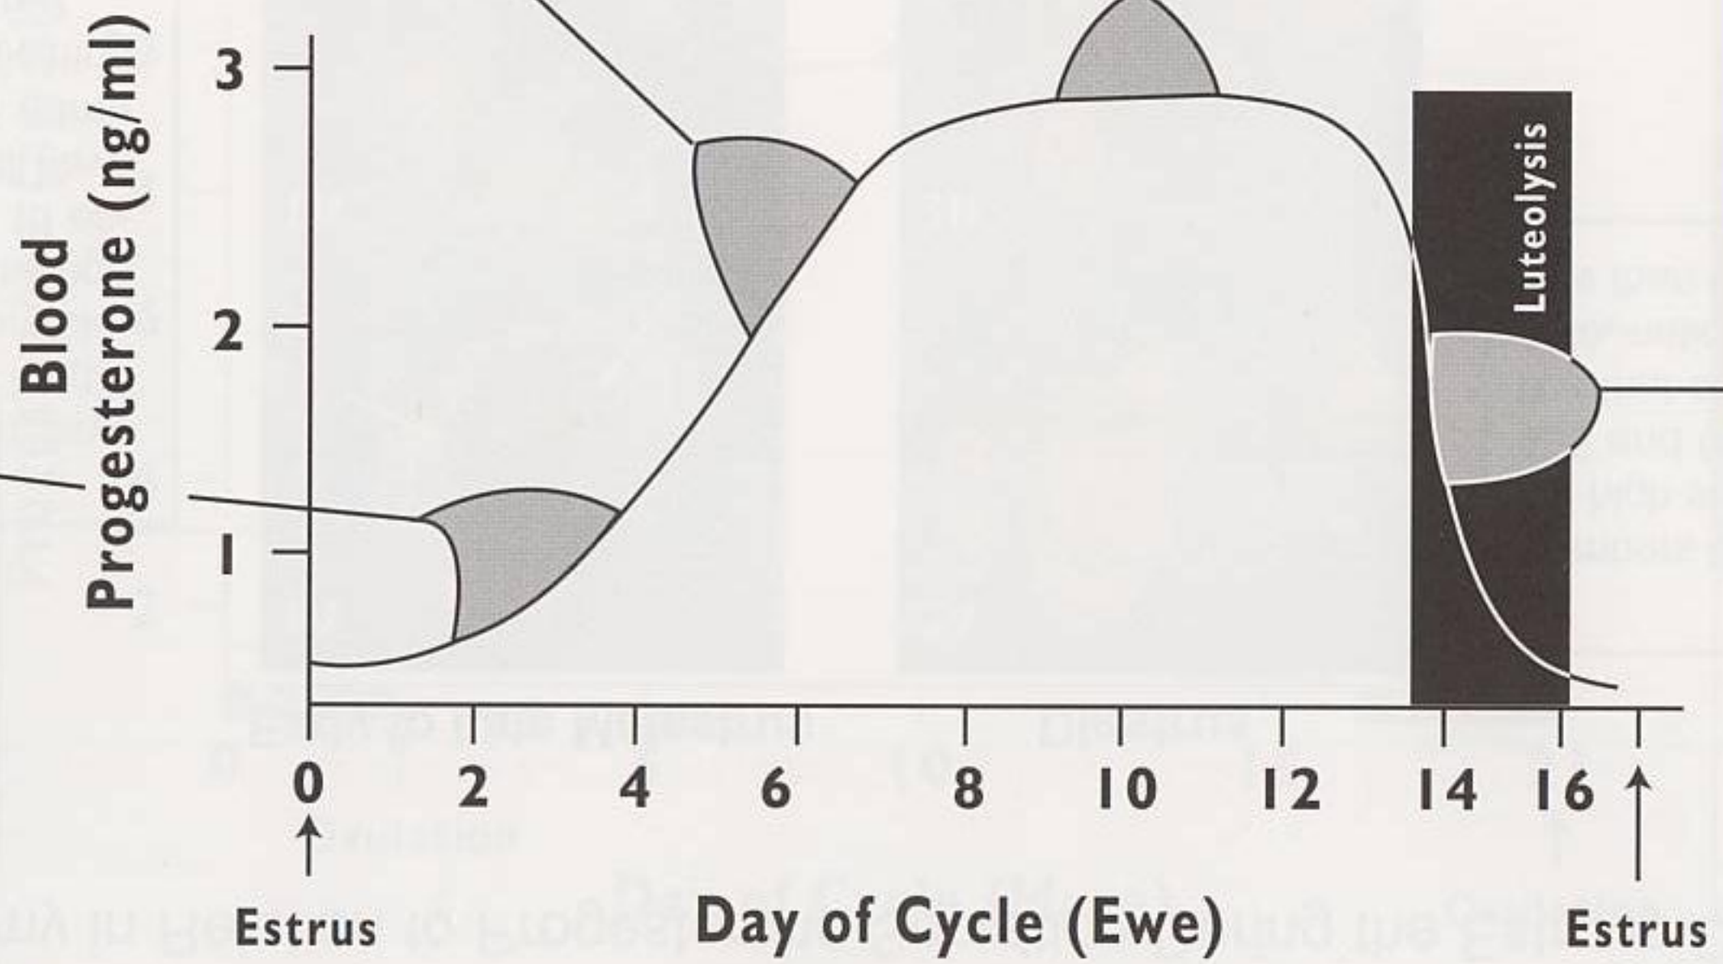


Figure 9-5. Luteal Anatomy in Relation to Progesterone Secretion During the Estrous Cycle in the Sow

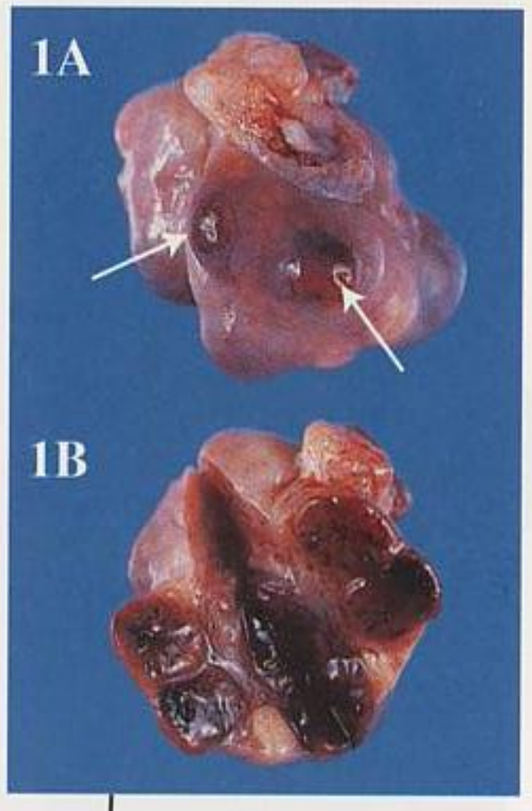
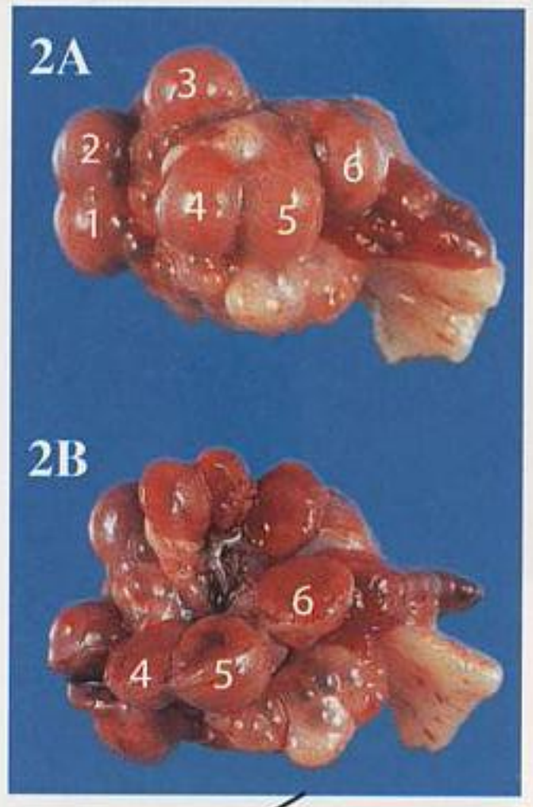
1A and 1B
Developing corpora lutea between days 3 and 6. Because of variation in length of the cycle and the time of ovulation relative to the stage of the cycle, precise age of these corpora lutea is difficult to establish. Notice that all structures still have a hemorrhagic appearance and some have a visible stigma (arrows) indicating the point at which ovulation occurred.

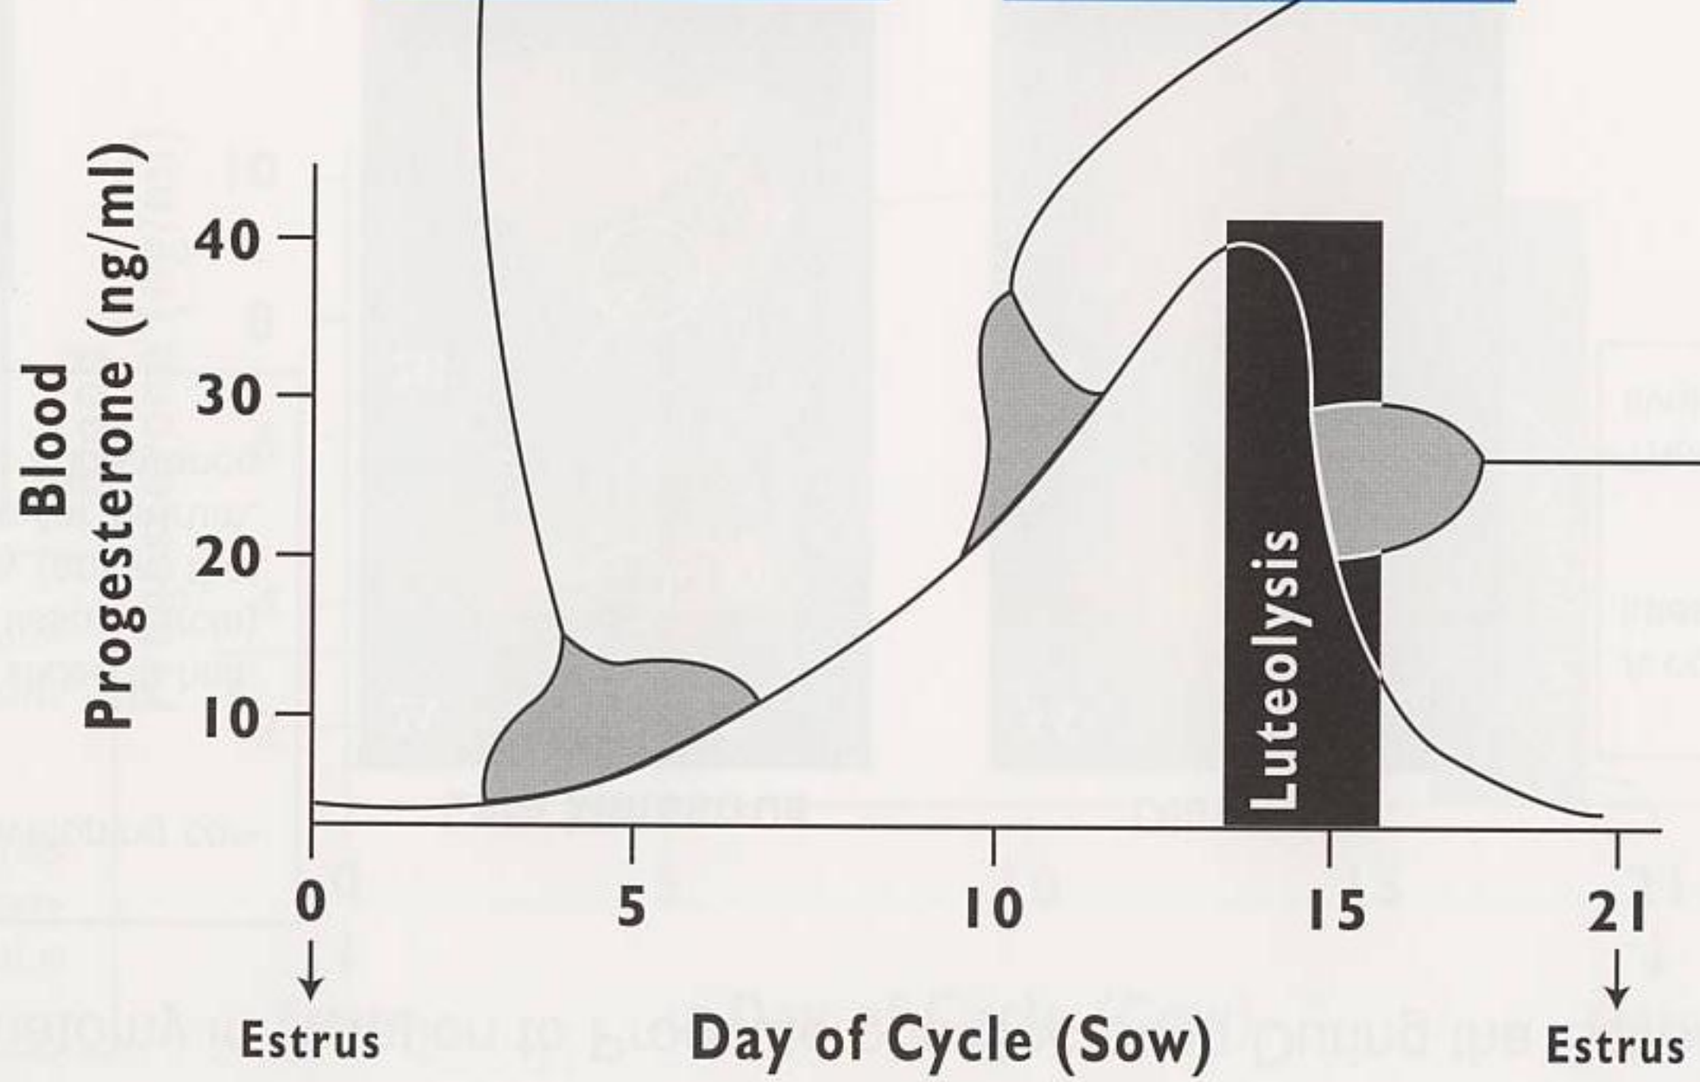
Early to Late Metestrus



Diestrus



2A and 2B
Numbers designate six corpora lutea during high secretory activity. Corpora lutea 4, 5 and 6 have been sliced in half. Notice that corpus luteum 5 has an antrum. Also, notice that P_4 is much higher in the sow than in the cow, ewe and mare.



Proestrus

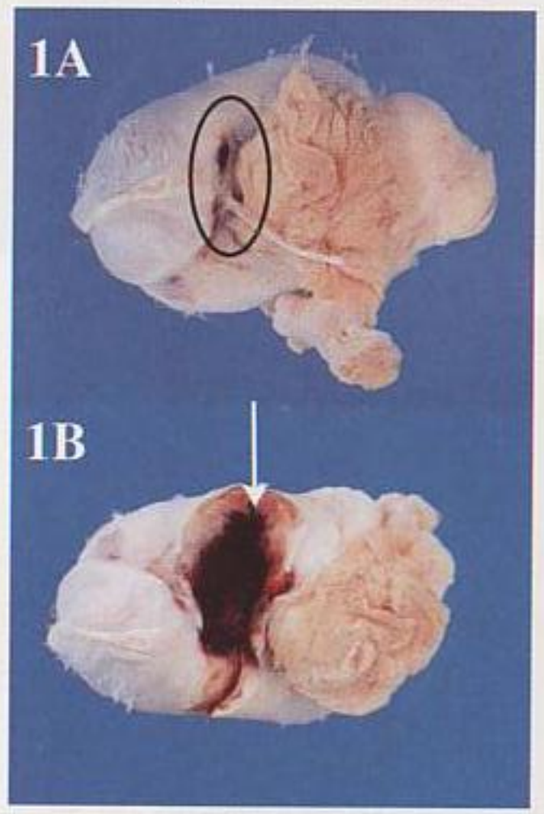
3A and 3B
Regressing corpora lutea. Notice the pale color. The interval from luteolysis to estrus is longer than other species.

Figure 9-6. Luteal Anatomy in Relation to Progesterone Secretion During the Estrous Cycle in the Mare

2A
Area designated by the arrow is the developing corpus luteum.

2B
The corpus luteum seen in 2A has been sliced in half. The arrow indicates a follicle that was sliced.

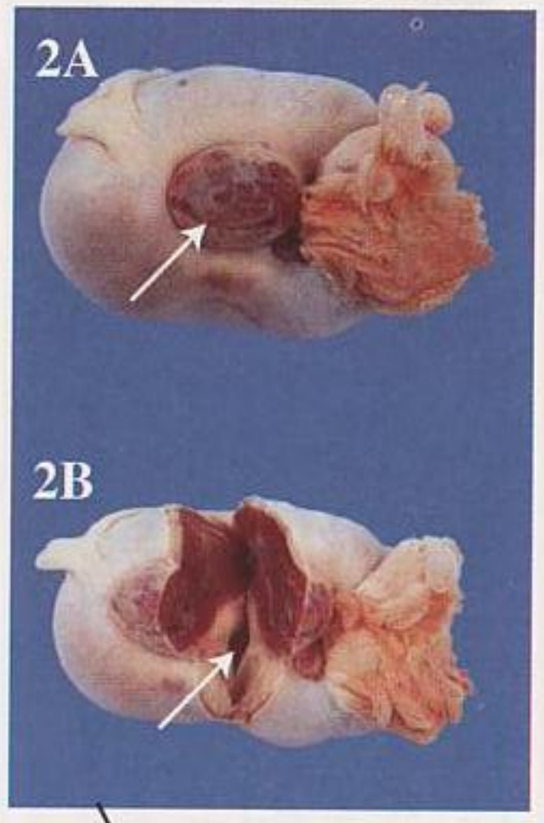
Early Metestrus



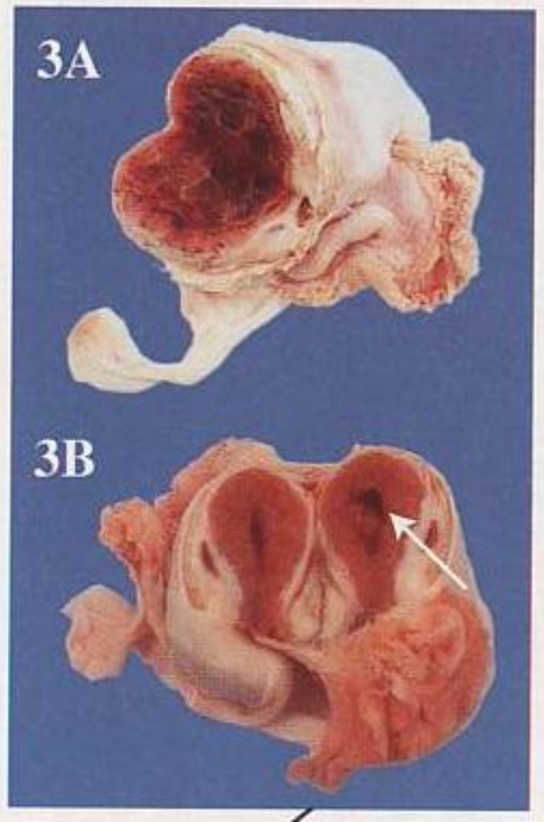
1A
The corpus hemorrhagicum is within the circle. It is not highly visible from the exterior as in other species.

1B
Arrow indicates the hemorrhagic tissue within the wall of the newly ovulated follicle that has been sliced in half.

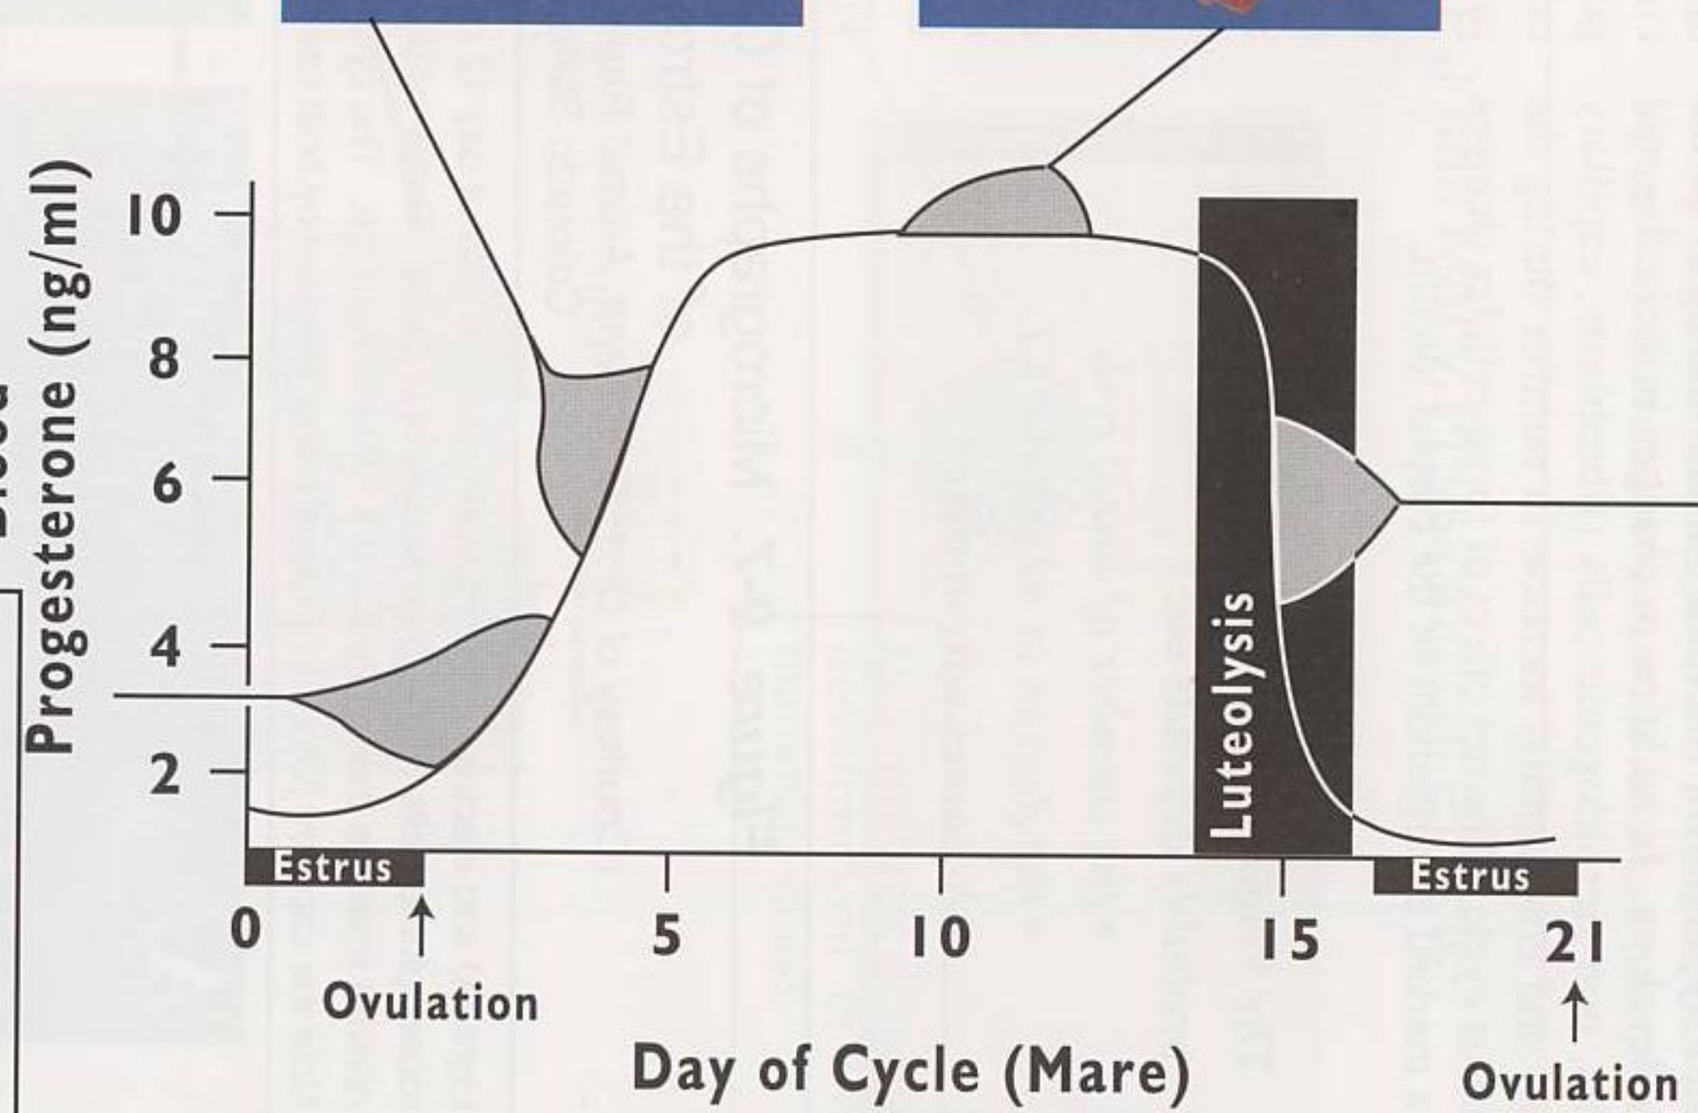
Late Metestrus



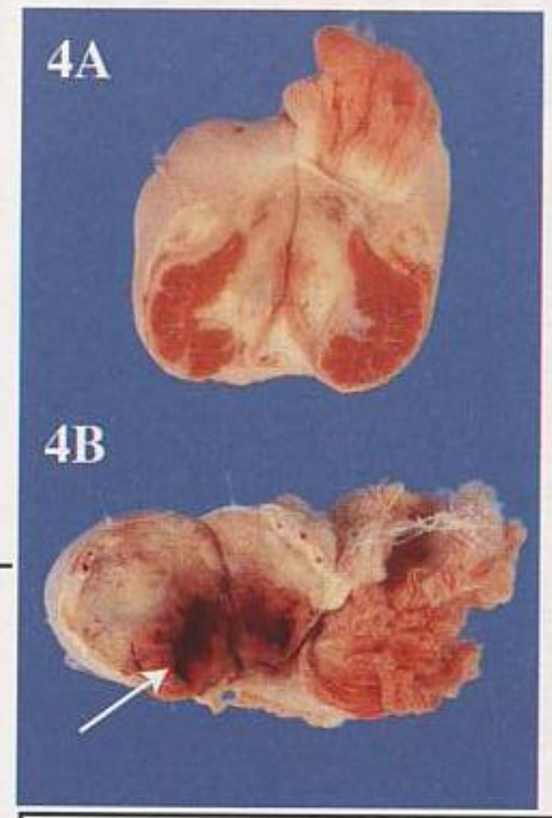
Diestrus



3A and 3B
In both examples the structures are sliced in half to expose the inner tissue mass of the corpus luteum. Two distinct types of corpora lutea can be seen during the peak luteal phase. In some, there is a homogeneous mass of tissue without a central cavity (3A), while in others a central cavity (arrow) exists (3B).
In almost all cases, corpora lutea in the mare are "buried" within the ovarian cortex and are very difficult to palpate per rectum. In cases where a cavity exits, ultrasonography easily identifies a corpus luteum.



Proestrus



4A and 4B
Two examples of regressing corpora lutea. Specimens were sliced in half. Notice that the size has decreased. Arrow in 4B indicates a residual blood clot within the corpus luteum.

Large luteal cells rarely multiply after ovulation. Therefore, the total number of granulosal cells "donated" by the follicle determines the number of large luteal cells in the newly-formed CL. Luteal function may in-part be related to the vigor (as judged by the number of granulosal cells) of the follicle prior to ovulation. In the ewe (and presumably other species), an increase in corpus luteum size and weight is due to a threefold increase in volume of large luteal cells coupled with a fivefold increase in the number of small luteal cells. Thus, large luteal cells undergo **hypertrophy** (increase in size), while small luteal cells undergo **hyperplasia** (increase in cell numbers) as the CL develops. In addition to changes in steroidogenic cells, non-steroidogenic cells (fibroblasts, capillary cells and eosinophils) increase in number during the estrous cycle. The net effect of these cellular changes is a marked enlargement of the corpus luteum.

The "vigor" of the corpus luteum probably depends on:

- ***the number of luteal cells***
- ***the degree to which the CL becomes vascularized***

The functional capability (ability to produce progesterone) of the newly developed corpus luteum may also depend on the degree of vascularity in the cellular layers of the follicle. The ability of the corpus luteum to vascularize may relate to its ability to synthesize and deliver hormones. As presented in the previous chapter, follicular fluid contains angiogenic factors. The degree to which these angiogenic factors promote vascularization of the corpus luteum is probably related to the quantity of angiogenic factors present in the follicular tissue.

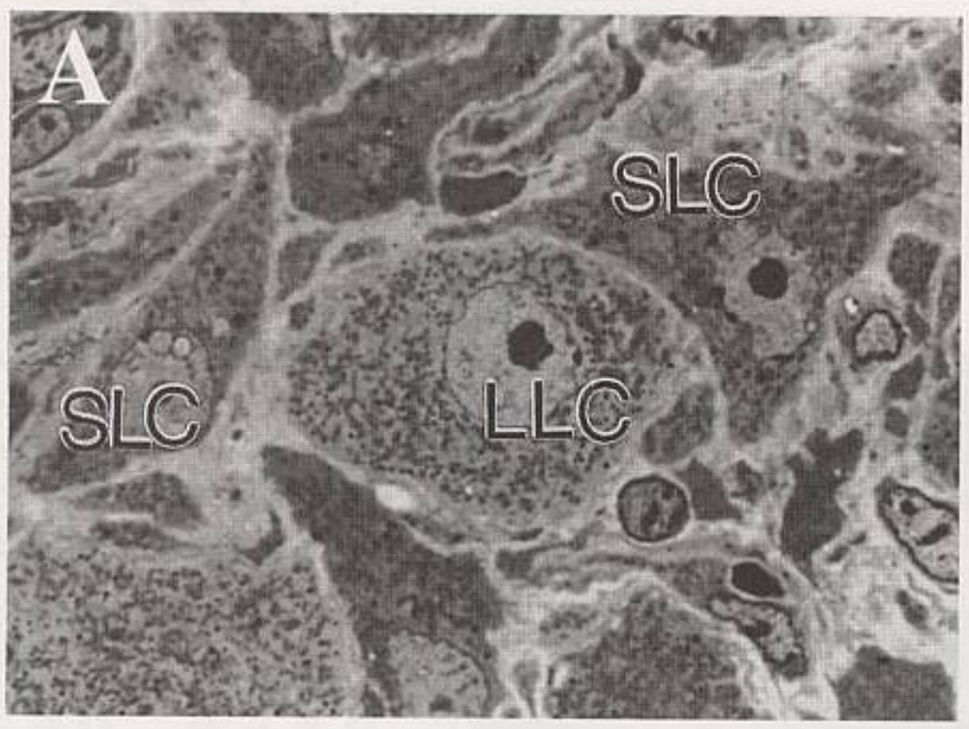
Insufficient luteal function (poor progesterone synthesis and secretion) is believed to be an important contributor to reproductive failure in mammals. A corpus luteum producing suboptimal levels of progesterone probably results in the inability of the dam's uterus to support development of the early embryo.

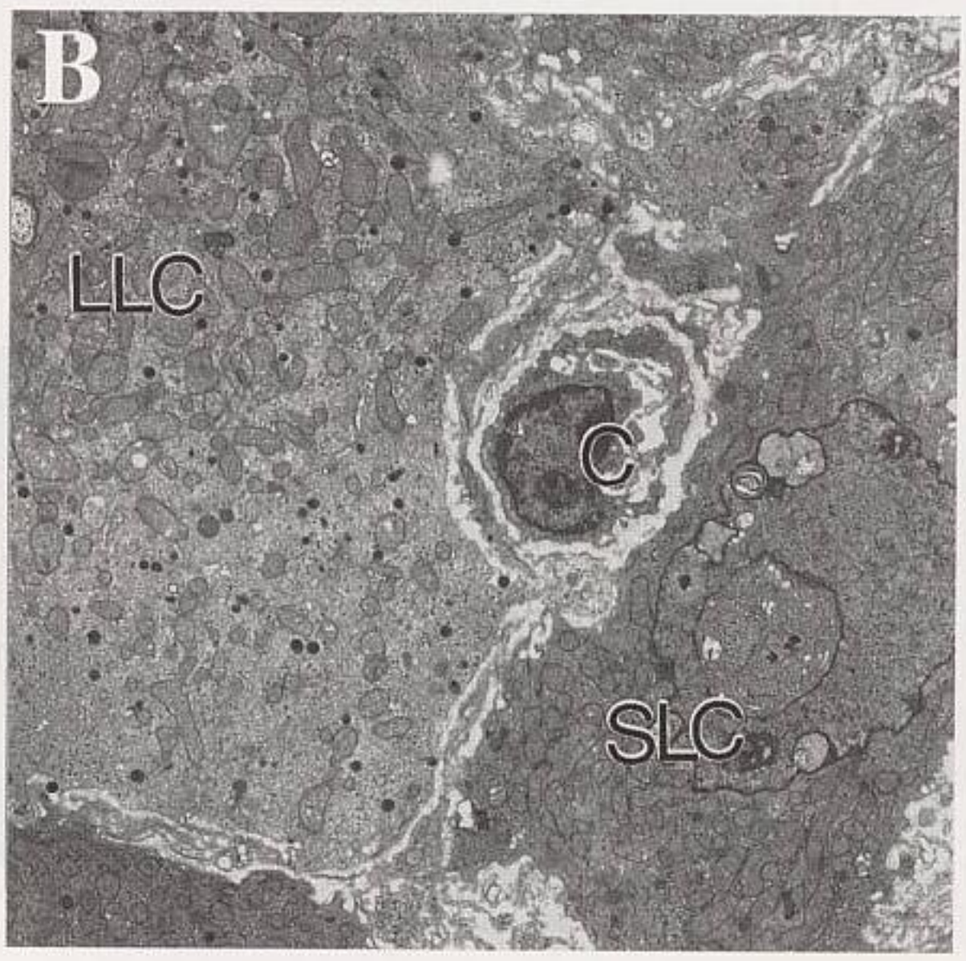
The primary target organs for progesterone are the hypothalamus, the uterus and the mammary gland (See Figure 9-8). The uterus has two target components. These two uterine tissues are the glandular endometrium and the muscular myometrium. Progesterone stimulates maximal secretion by the endometrial glands. Secretory products from the endometrial glands contribute to an environment that supports the development of the "free-floating" conceptus after it enters the uterine lumen. An important inhibitory role of progesterone is to reduce the motility (contractions) of

Figure 9-7. Micrographs of Ovine Luteal Cells at Day 12 of the Estrous Cycle

(Courtesy of Dr. H.R. Sawyer, Animal Reproduction and Biotechnology Laboratory, Colorado State University)

Light (A) and electron micrograph (B) of luteal cells at day 12 of the estrous cycle in the ewe. Large luteal cells (LLC) are round, plump cells with a large spherical nucleus. These cells are derived from granulosal cells. Small luteal cells (SLC), derived from the theca interna, are stellate in shape. The cytoplasm of small luteal cells is darker than in the large cells. Note the capillary (C) in B. Progesterone secreted by both cell types has ready access to the blood.





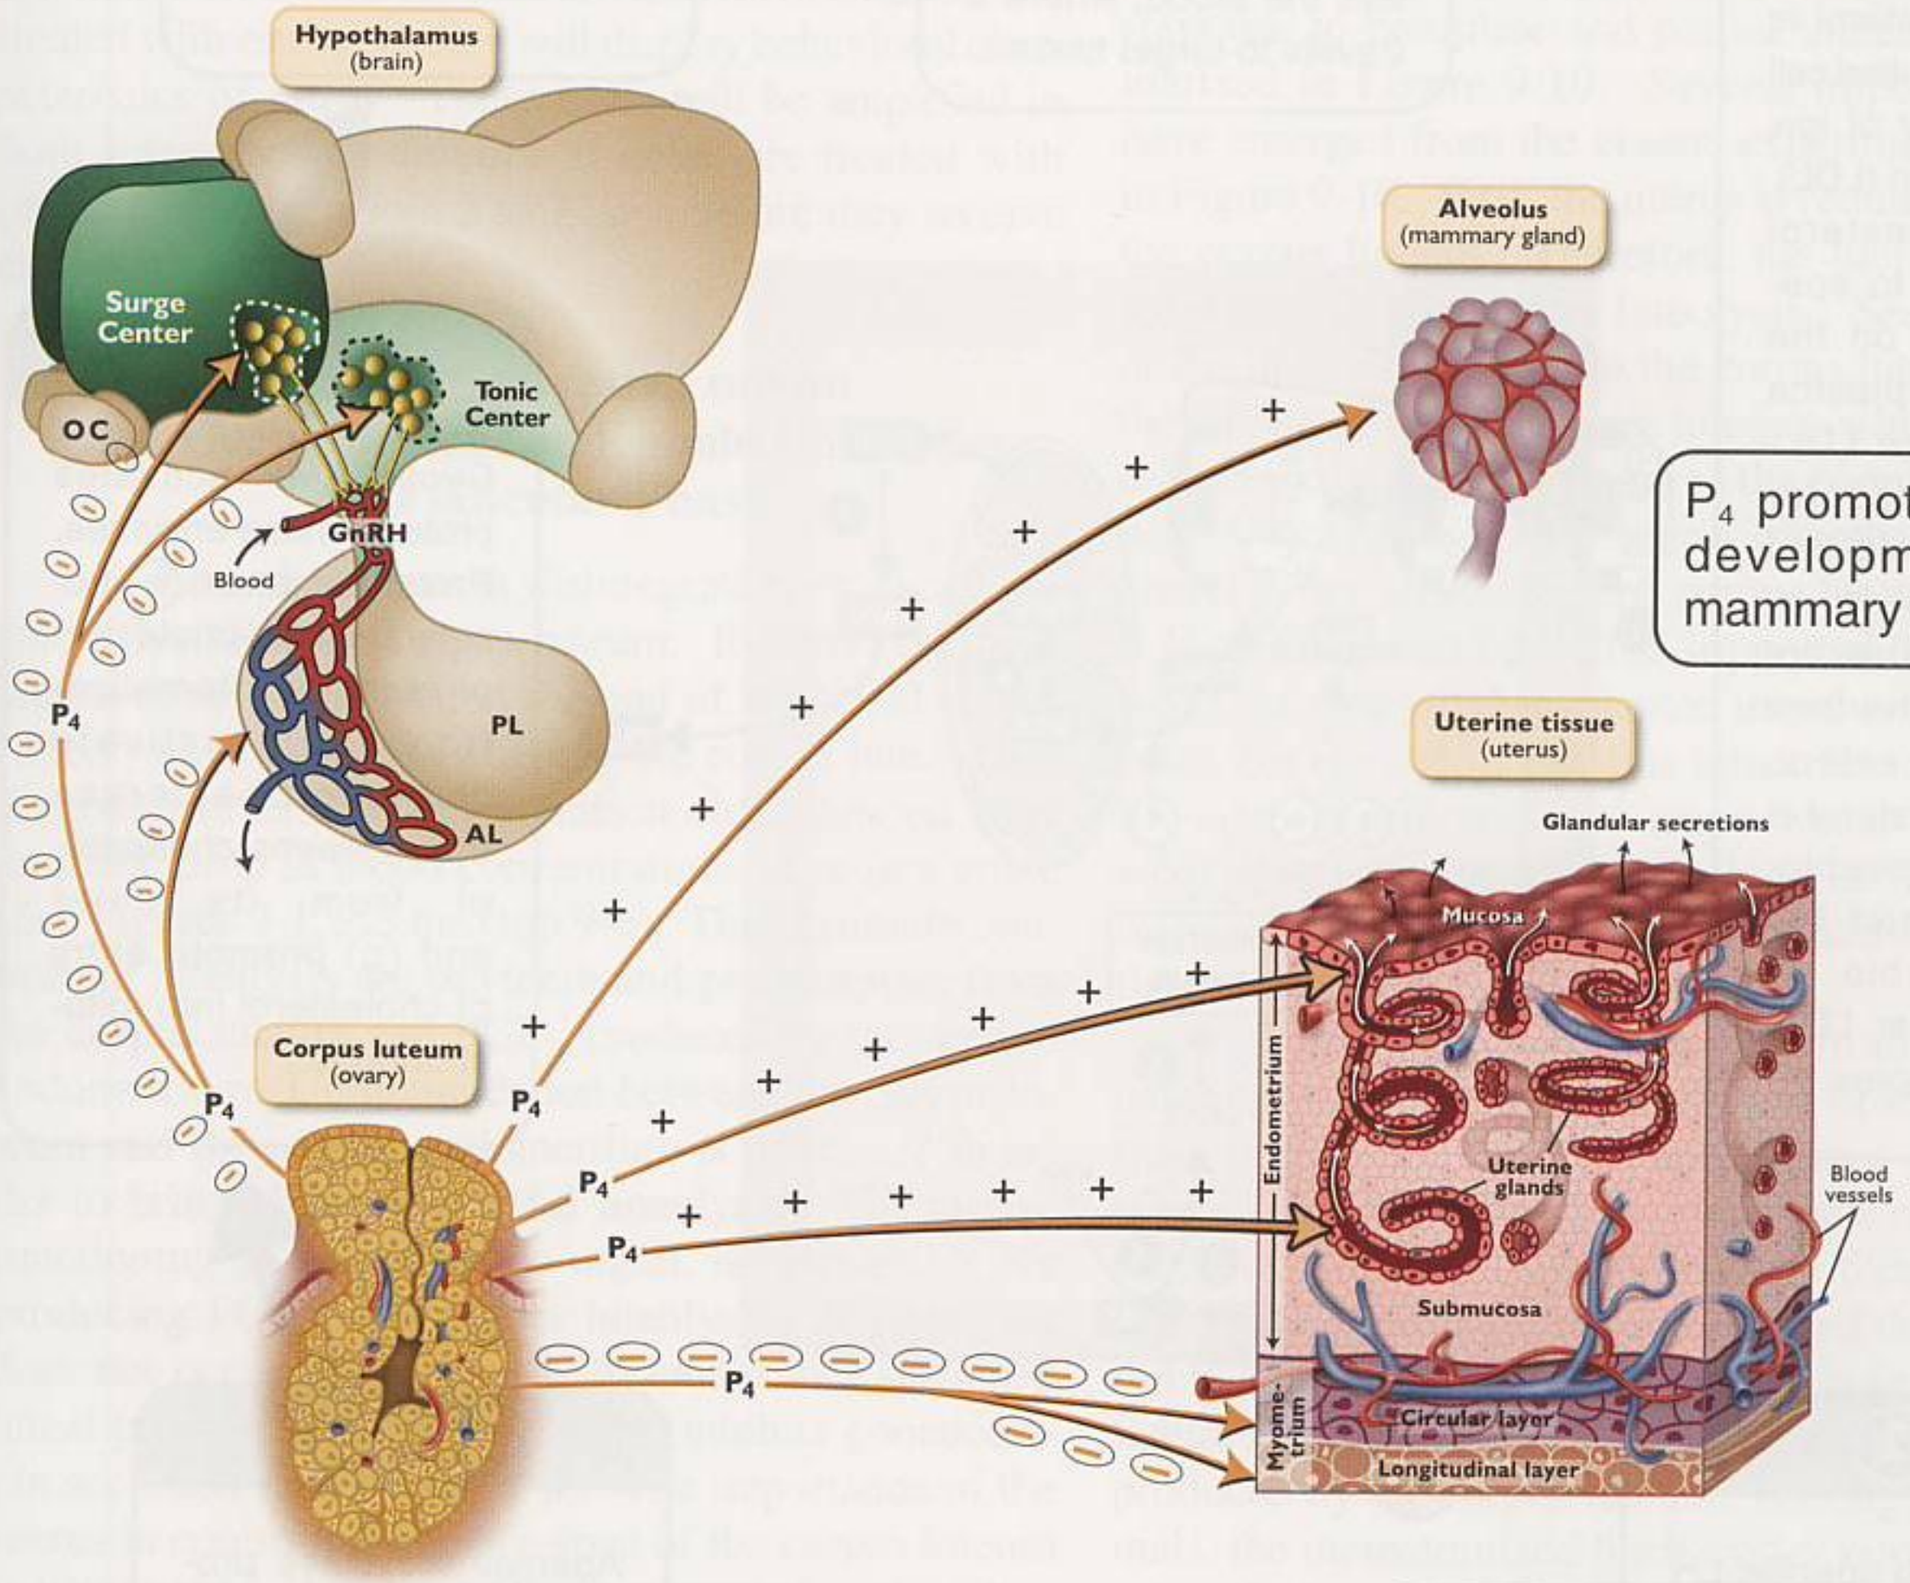
the myometrium. Such a role causes a "quieting" effect on the myometrium in the cow, pig and ewe. In the mare, myometrial motility is not inhibited to the same degree so that the conceptus is moved around the uterus but not expelled (See Chapter 13). Myometrial inhibition is believed to be important because it provides a set of "calm" conditions for attachment of the conceptus to the uterine endometrium. In the mare, the conceptus is moved about in the uterine lumen by contractions of the myometrium. This phenomenon will be discussed in more detail in Chapter 13. Progesterone causes final alveolar development of the mammary gland prior to parturition, thereby allowing initiation of lactation.

Progesterone Synthesis Requires Cholesterol and LH

The presence of basal (tonic) LH and cholesterol is necessary for progesterone to be produced by luteal cells. The mechanism whereby LH causes production of progesterone in luteal cells is illustrated in Figure 9-9. In order to fully understand progesterone synthesis, you should carefully read the explanation of each step in the boxes provided in Figure 9-9.

Progesterone is of major importance in the endocrine control of reproduction because it exerts a strong **negative feedback** on the hypothalamus (See Figure 9-8). Elevated progesterone reduces the frequency

Figure 9-8. Progesterone (P_4) has Many Physiological Effects



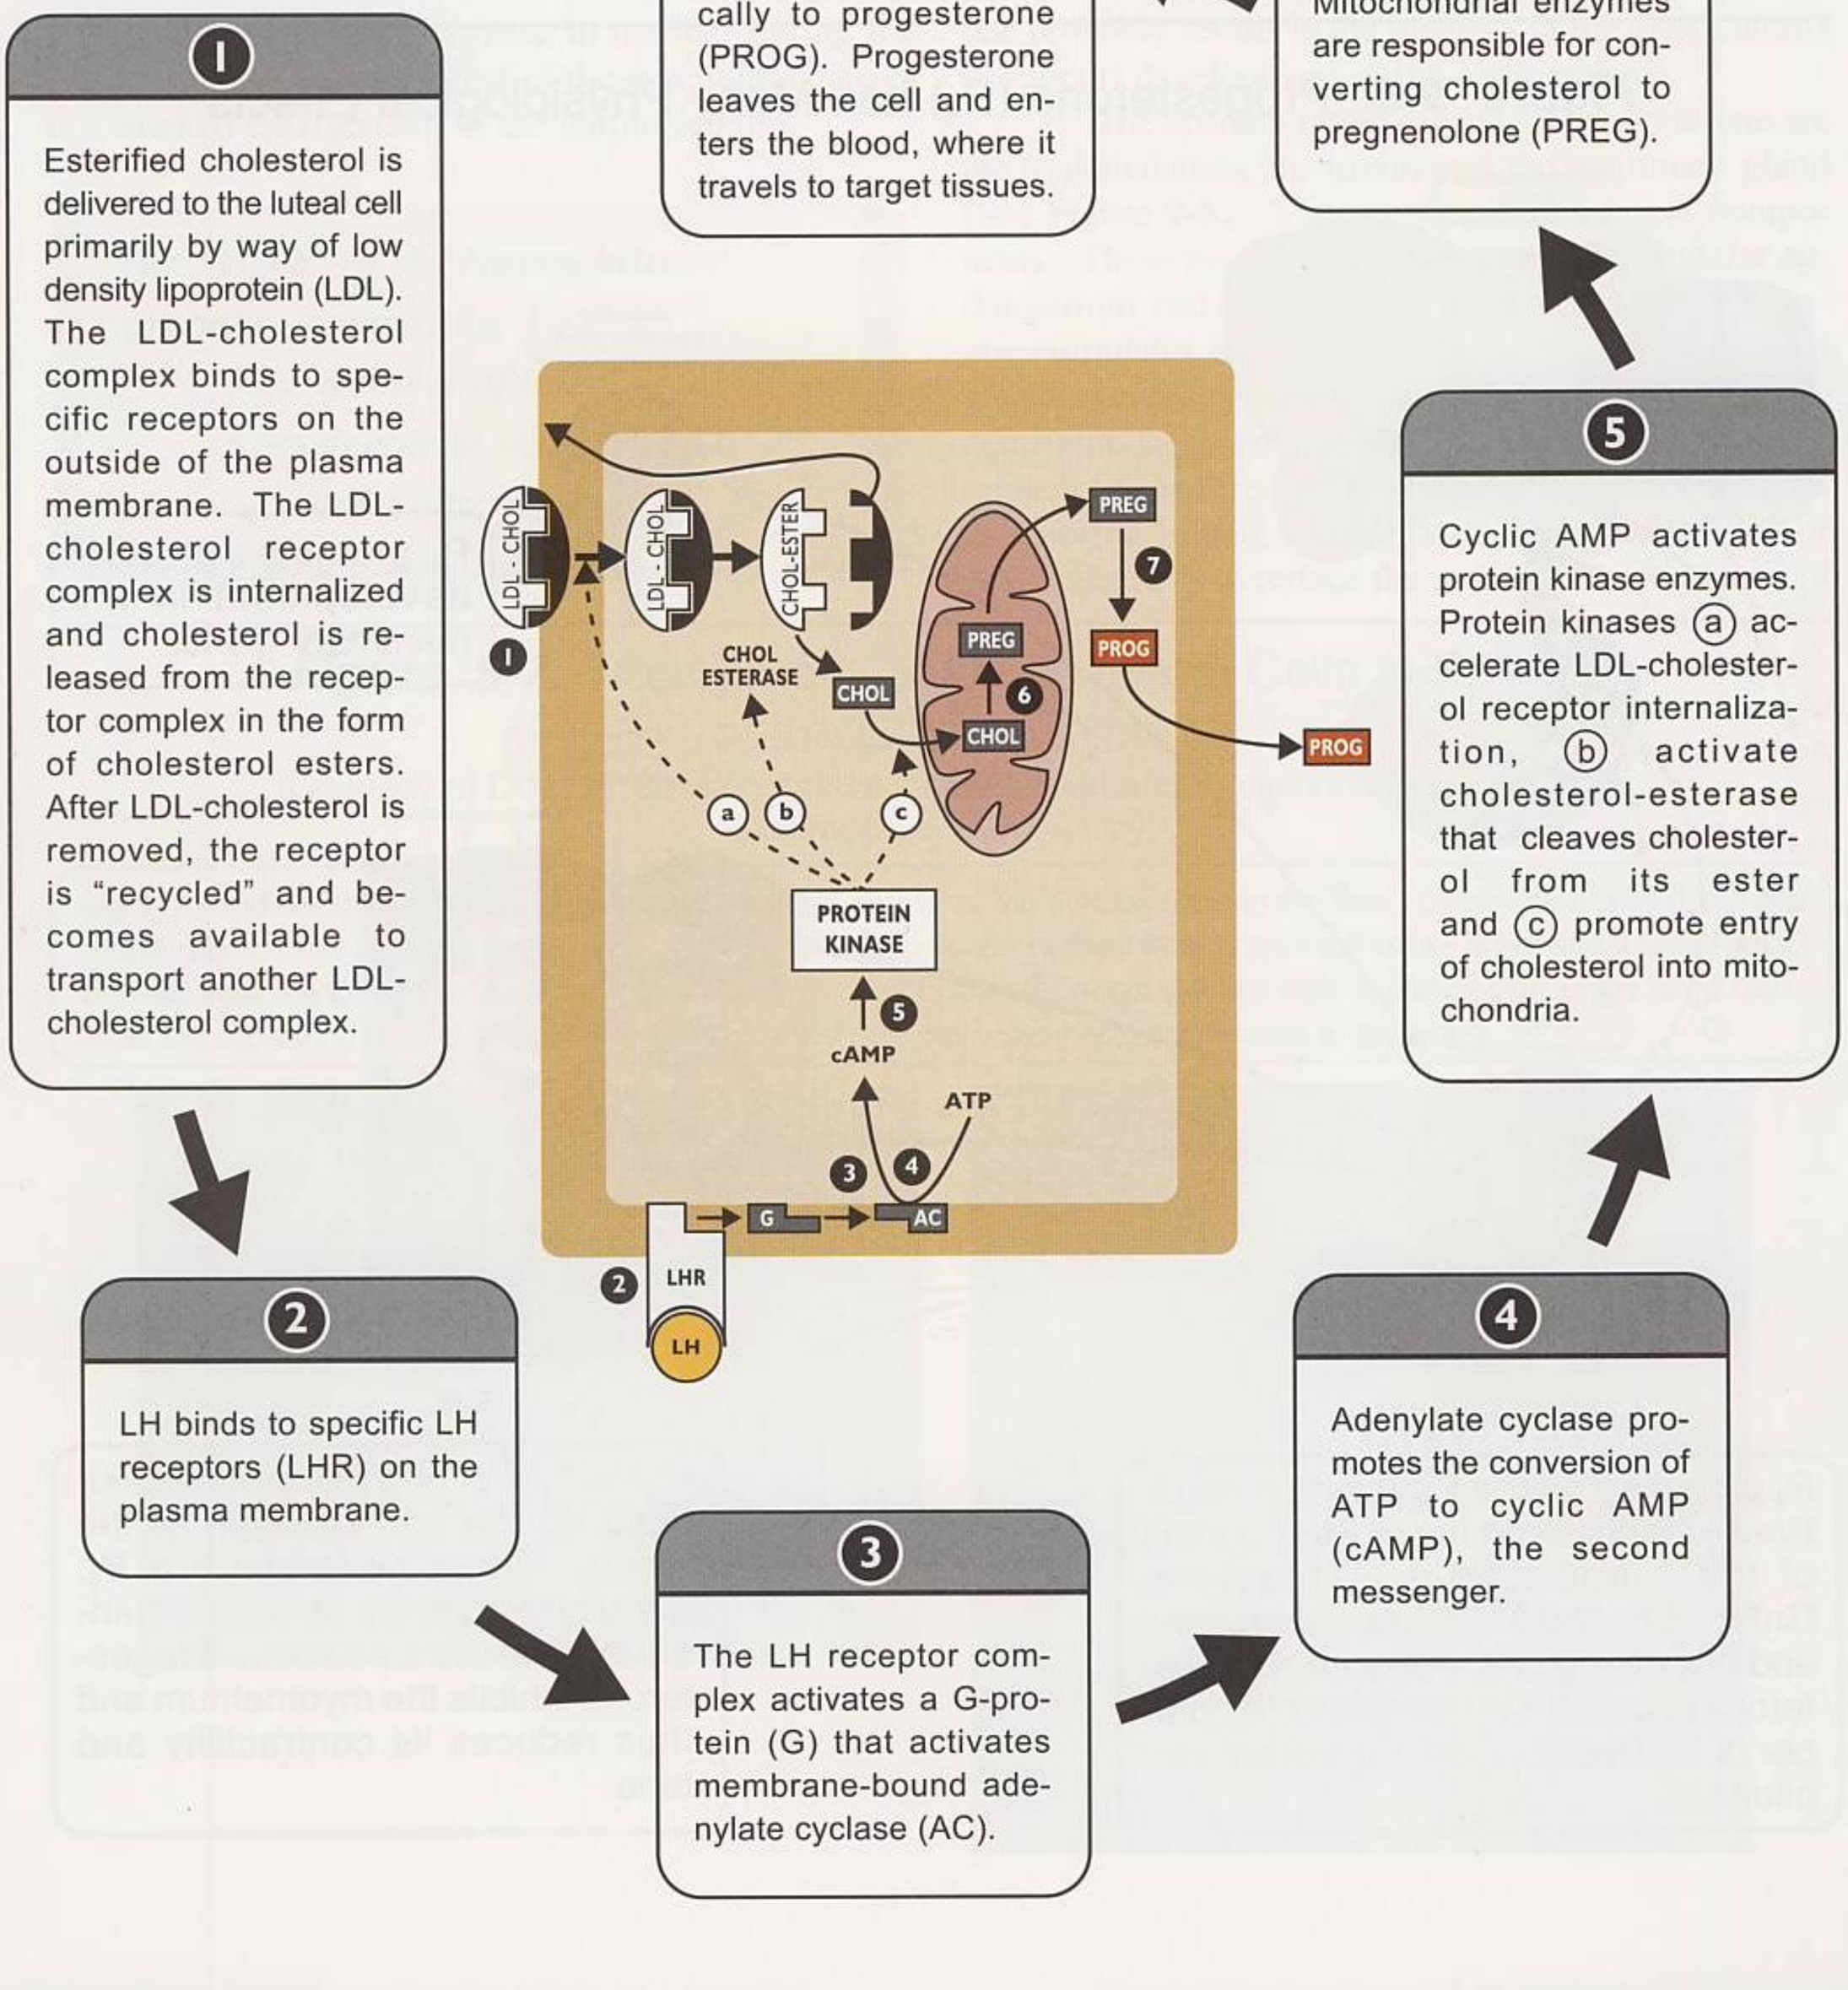
P_4 promotes alveolar development in the mammary gland.

P_4 produced by the CL exerts a negative (-) feedback on the GnRH neurons of the hypothalamus. Therefore, GnRH, LH and FSH are suppressed and little estrogen is produced. Progesterone is thought to decrease the number of GnRH receptors on the anterior pituitary.

P_4 exerts a strong positive (+) influence on the endometrium of the uterus. Under the influence of P_4, the uterine glands secrete materials into the uterine lumen. Progesterone inhibits the myometrium and thus reduces its contractility and tone.

of the basal episodic secretion of GnRH by the tonic GnRH center in the hypothalamus. However, the amplitude of the LH pulses is still relatively high. Such a pattern of LH secretion along with tonic FSH secretion allows follicles to develop during the luteal phase. These follicles do not reach preovulatory status until progesterone decreases and the frequency of LH pulses increases. High progesterone therefore prevents development of preovulatory follicles, production of estrogen, behavioral estrus and the preovulatory surge of GnRH and LH.

Figure 9-9. Mechanism of Progesterone Synthesis by Luteal Cells



Progesterone is an inhibitor because it:

- ***reduces basal GnRH amplitude and frequency***
- ***prevents behavioral estrus***
- ***stops the preovulatory LH surge***
- ***reduces myometrial tone***

Progesterone almost totally inhibits estrual behavior. In general, females under the influence of progesterone do not display estrus and will not accept the male for copulation. However, as pointed out in Chapter 7, progesterone exerts a positive priming effect on the brain to enhance the behavioral effects of estrogen after progesterone is reduced. For example, if females are **ovariectomized** (removal of ovaries) and treated with estrogen, they will display behavioral characteristics of estrus. These traits will be amplified in both intensity and duration if cows are treated with progesterone for about 5 to 7 days before they receive estrogen.

Lysis of the Corpus Luteum Must Occur Before the Female Can Enter the Follicular Phase

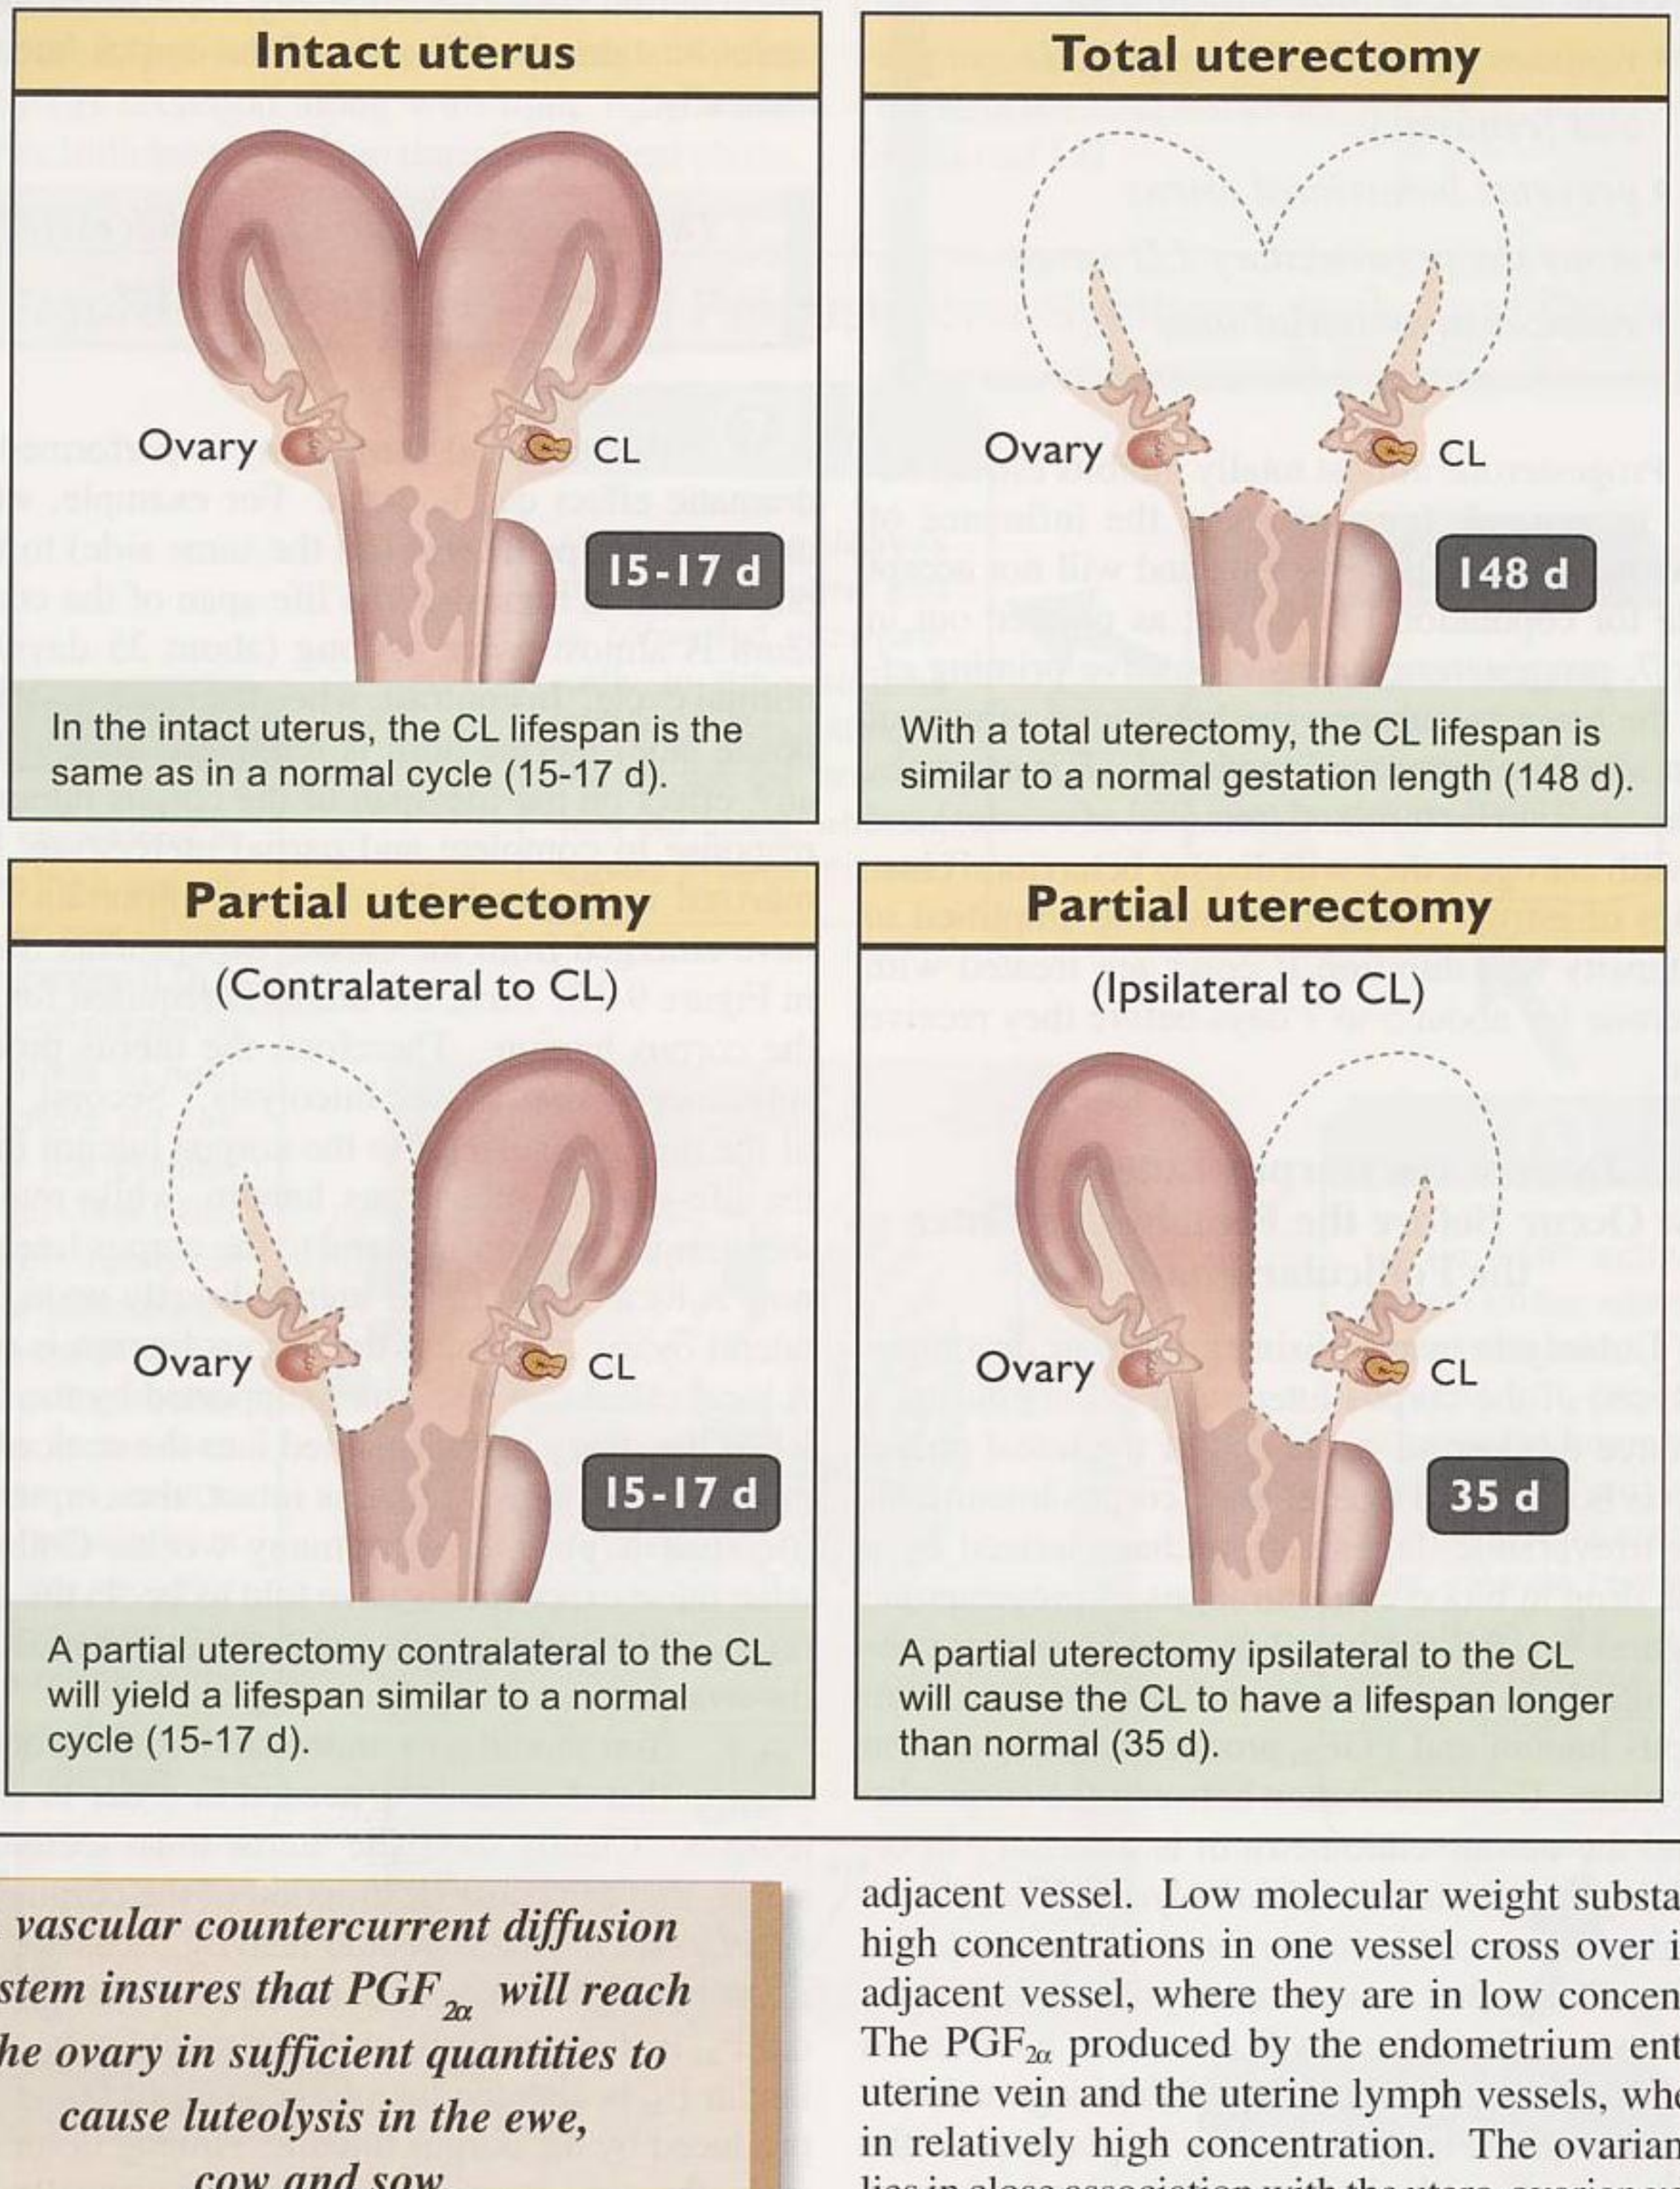
Luteolysis means disintegration or decomposition (lysis) of the corpus luteum. It occurs during a one-to-three day period at the end of the luteal phase. Luteolysis is a process whereby the corpus luteum undergoes irreversible degeneration characterized by a dramatic drop in blood concentrations of progesterone (See Figures 9-1, 9-3 through 9-6). The hormones controlling luteolysis are oxytocin and progesterone from the corpus luteum and $PGF_{2\alpha}$ produced by the uterine endometrium. Communication between the corpus luteum and the uterine endometrium is necessary in order to bring about successful luteolysis. The uterus, functioning as an endocrine organ, is responsible for producing $PGF_{2\alpha}$ that causes luteolysis. If luteolysis does not occur, the animal will remain in a sustained luteal phase because progesterone inhibits gonadotropin secretion (See Figure 9-8). The importance of the uterus in controlling the life-span of the corpus luteum is illustrated in Figure 9-10. In mammals, other than primates, complete removal of the uterus (**uterectomy**) after ovulation causes the corpus luteum to be maintained just as if the female were pregnant. For example, in ewes with an intact uterus the life-span of the corpus luteum is identical to that seen in the normal cycle (17 days). However, when the entire uterus is removed (total uterectomy), the life-span of the corpus luteum is prolonged for months and is similar to a normal gestation period (148 days). Clearly, removal of the entire uterus sustains the life-span of the corpus luteum dramatically.

The uterus is required for successful luteolysis in many species.

When partial uterectomy is performed, a less dramatic effect can be seen. For example, when the uterine horn **ipsilateral** (on the same side) to the corpus luteum is removed, the life-span of the corpus luteum is almost twice as long (about 35 days) as the normal cycle. In contrast, when the **contralateral** (opposite side) uterine horn is removed, there is little, if any, effect on the life-span of the corpus luteum. The response to complete and partial uterectomy is summarized in Figure 9-10. Several important findings have emerged from the classic experiments illustrated in Figure 9-10. First, the uterus is required for lysis of the corpus luteum. Therefore, the uterus produces a substance(s) that causes luteolysis. Second, removal of the uterus ipsilateral to the corpus luteum increases the life-span of the corpus luteum, while removal of the uterine horn contralateral to the corpus luteum does not. A local effect of the uterus directly upon the ipsilateral ovary containing the corpus luteum is obvious. A local effect can be further supported by the fact that when the ovary is transplanted into the neck of the female, but the uterus remains intact, the corpus luteum life-span is prolonged by many weeks. Collectively, what these experiments have told us is: 1) the uterus is responsible for luteolysis and 2) the uterus must be near the ovary.

You should now understand from the above discussion that the uterus is needed in order to cause luteolysis. Clearly then, the uterus must secrete a substance that can cause destruction of the corpus luteum. After years of intensive and heavily focused research, it has been conclusively demonstrated that prostaglandin $F_{2\alpha}$ is the luteolysin in domestic animals. Prostaglandin $F_{2\alpha}$ is also the luteolytic agent in humans but is produced by the corpus luteum. Among domestic animals, the uterectomized bitch cycles normally and has a luteal phase of normal duration suggesting that the uterus has little or no influence upon luteal function.

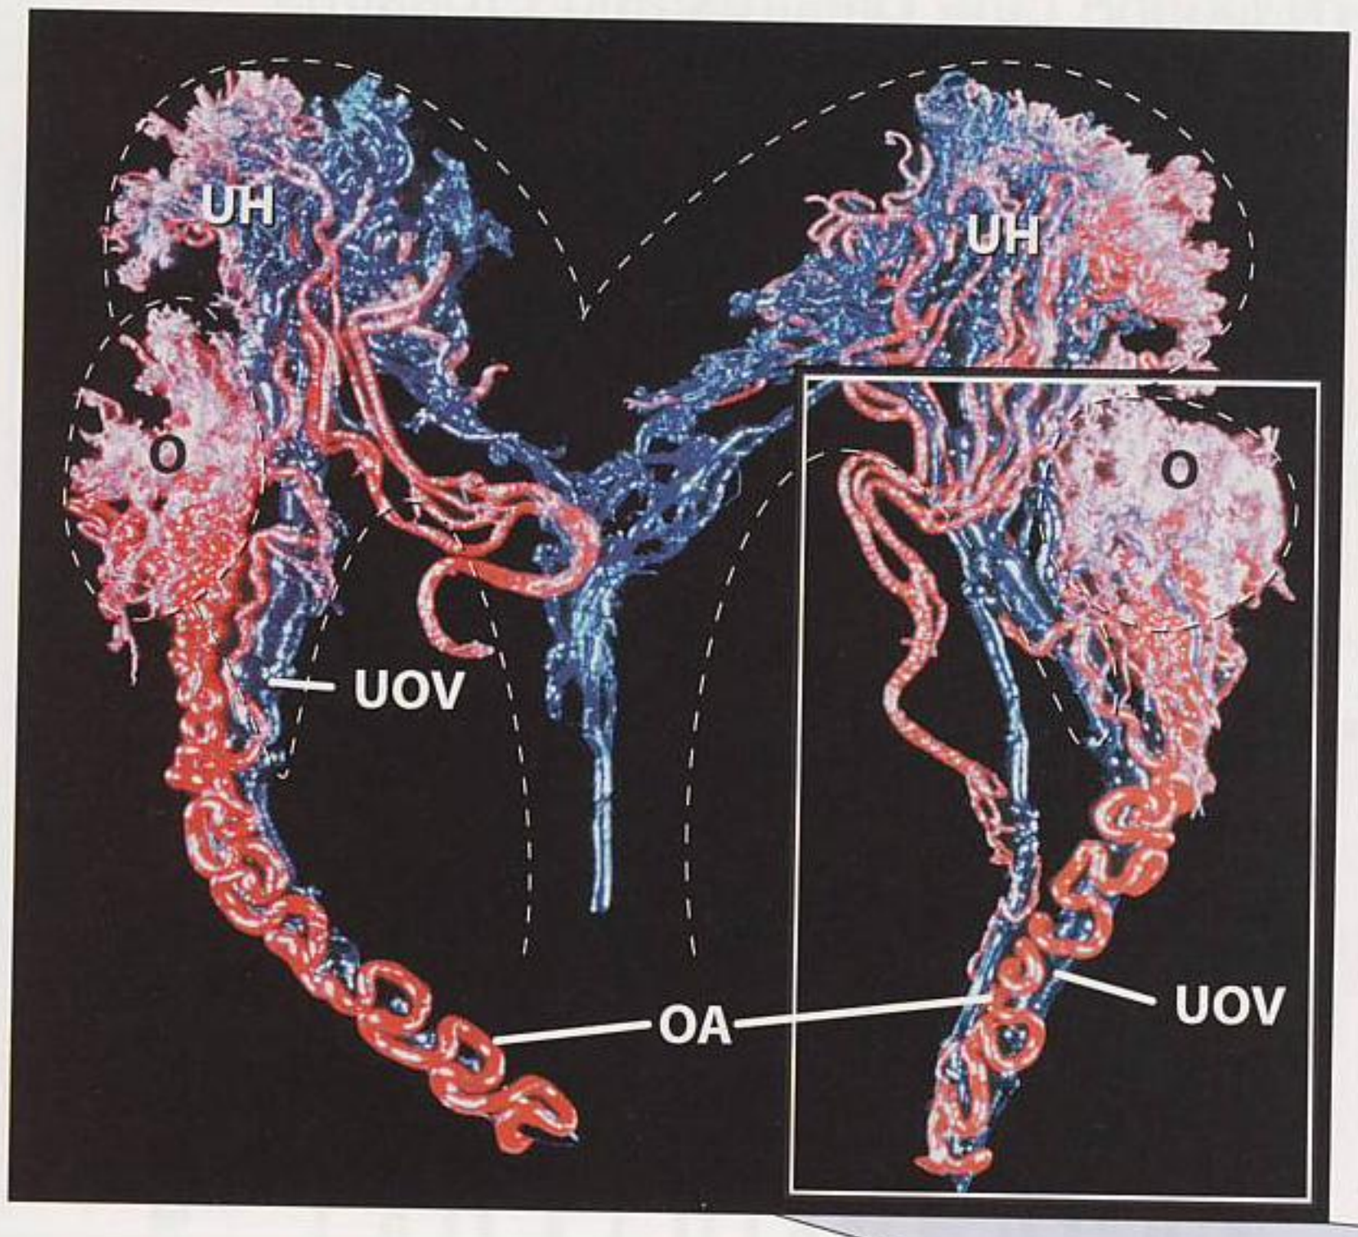
Figure 9-10. Effect of Uterectomy upon Estrous Cycle Duration in the Ewe



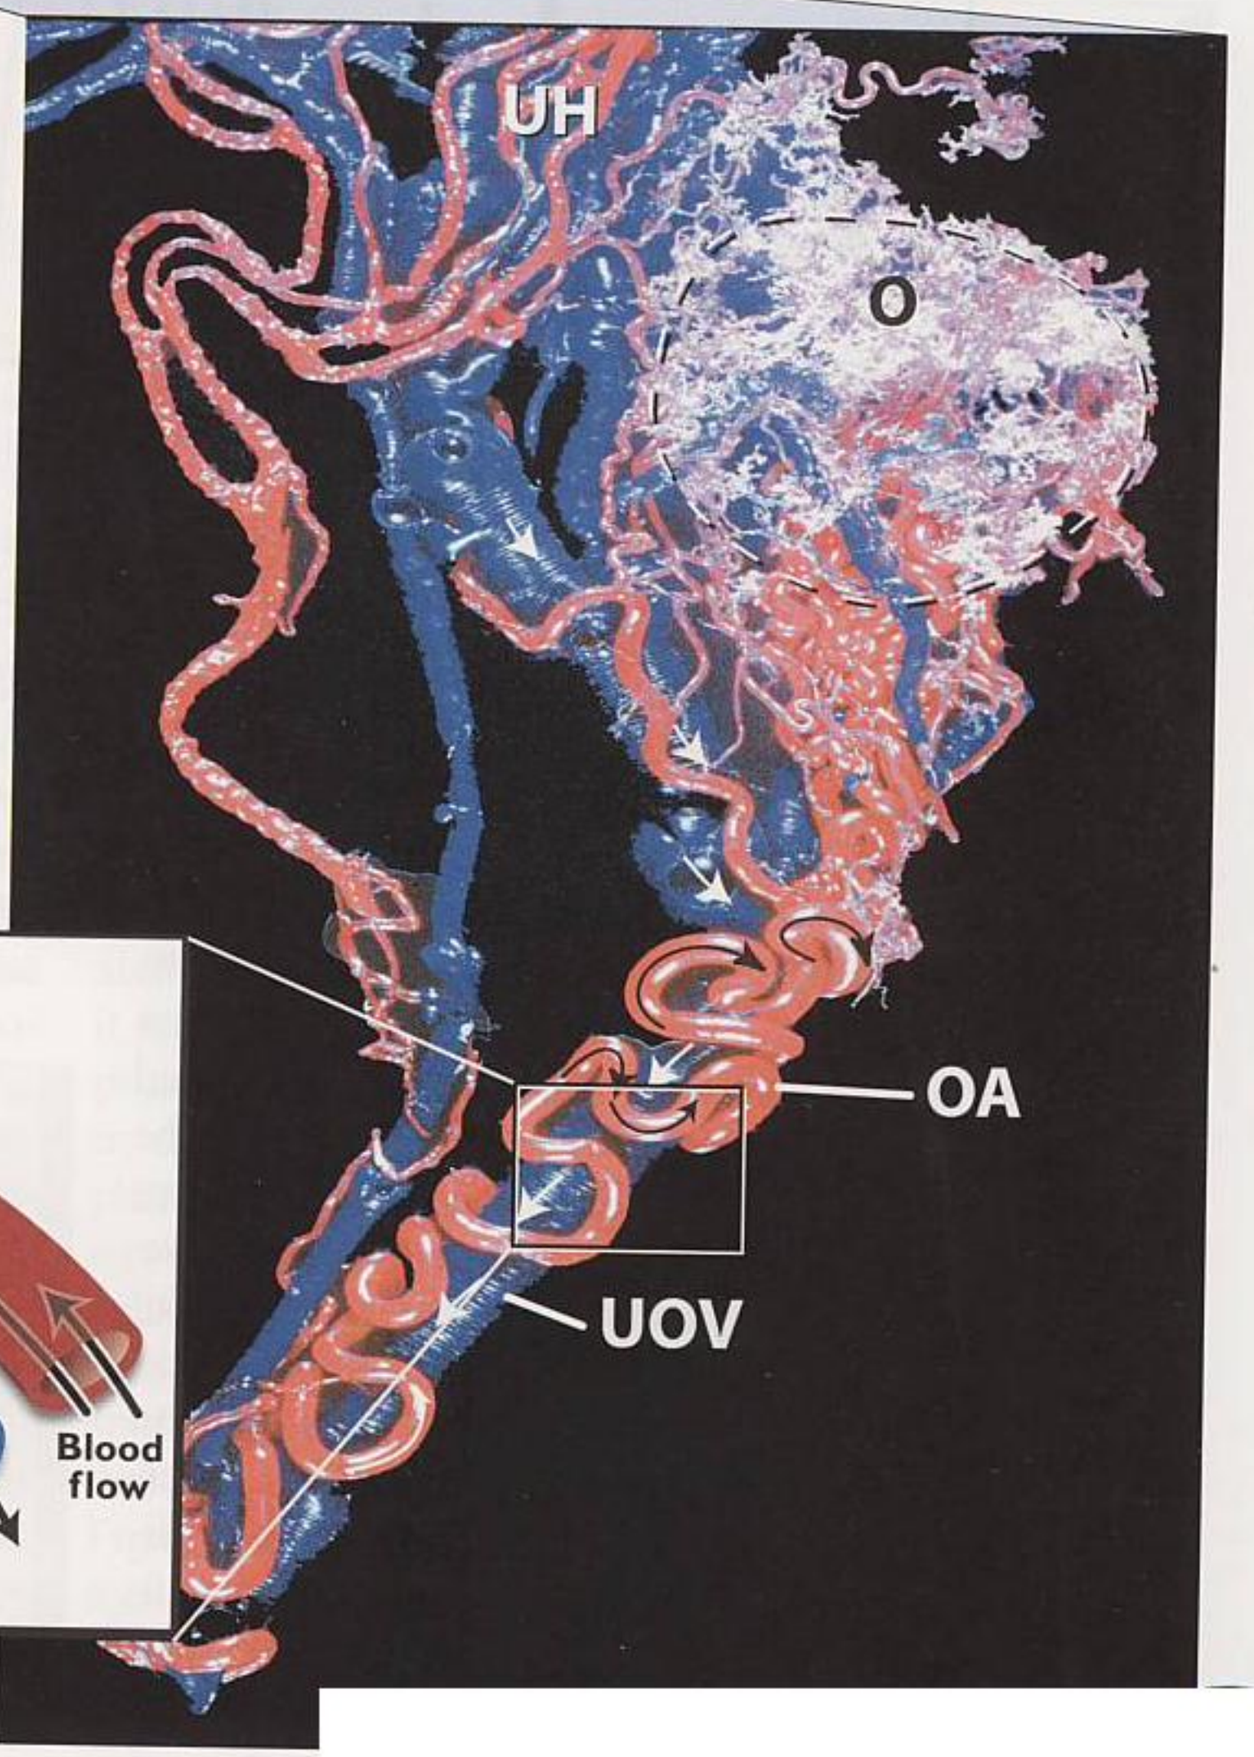
A vascular countercurrent diffusion system insures that $PGF_{2\alpha}$ will reach the ovary in sufficient quantities to cause luteolysis in the ewe, cow and sow.

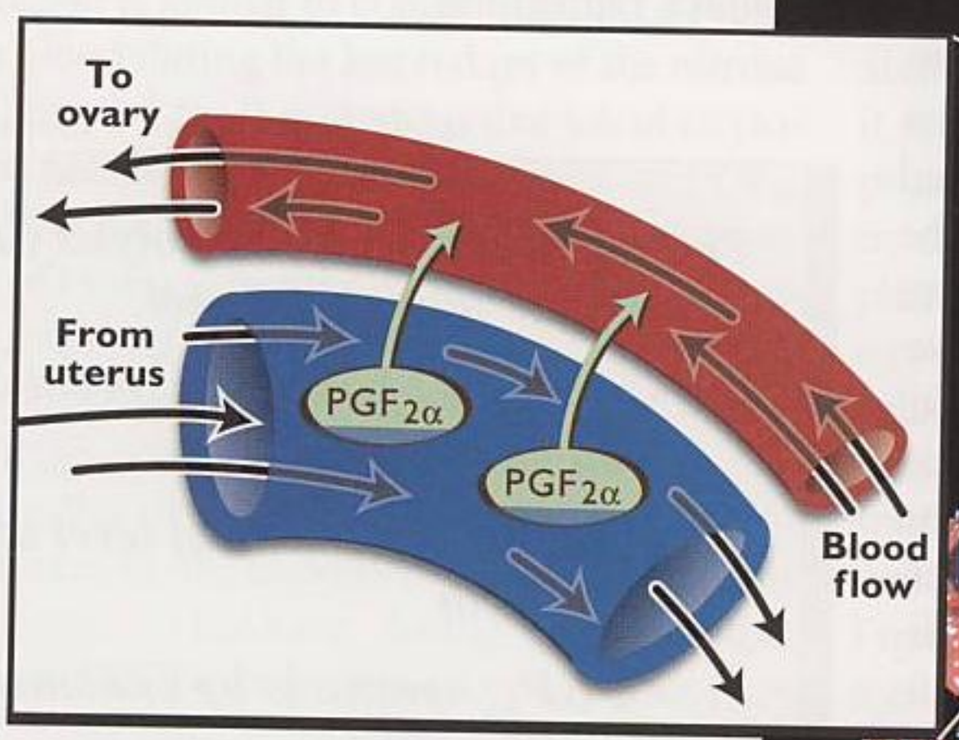
How does $PGF_{2\alpha}$ get from the uterus to the ovary, where it causes luteolysis? Prostaglandin $F_{2\alpha}$ from the uterus is transported to the ipsilateral ovary through a **vascular countercurrent exchange mechanism**. A countercurrent exchange system involves two closely associated blood vessels in which blood from one vessel flows in the opposite direction to that of the adjacent vessel. Low molecular weight substances in high concentrations in one vessel cross over into the adjacent vessel, where they are in low concentration. The $PGF_{2\alpha}$ produced by the endometrium enters the uterine vein and the uterine lymph vessels, where it is in relatively high concentration. The ovarian artery lies in close association with the utero-ovarian vein (See Figure 9-11). By countercurrent exchange, $PGF_{2\alpha}$ is transferred across the wall of the uterine vein into the blood of the ovarian artery by passive diffusion. This special anatomical relationship ensures that a high proportion of the $PGF_{2\alpha}$ produced by the uterus will be transported directly to the ovary and the corpus luteum without dilution in the systemic circulation. This mechanism is particularly important because much of $PGF_{2\alpha}$ is denatured during one circulatory pass through

Figure 9-11. The Utero-Ovarian Vascular Countercurrent Diffusion System



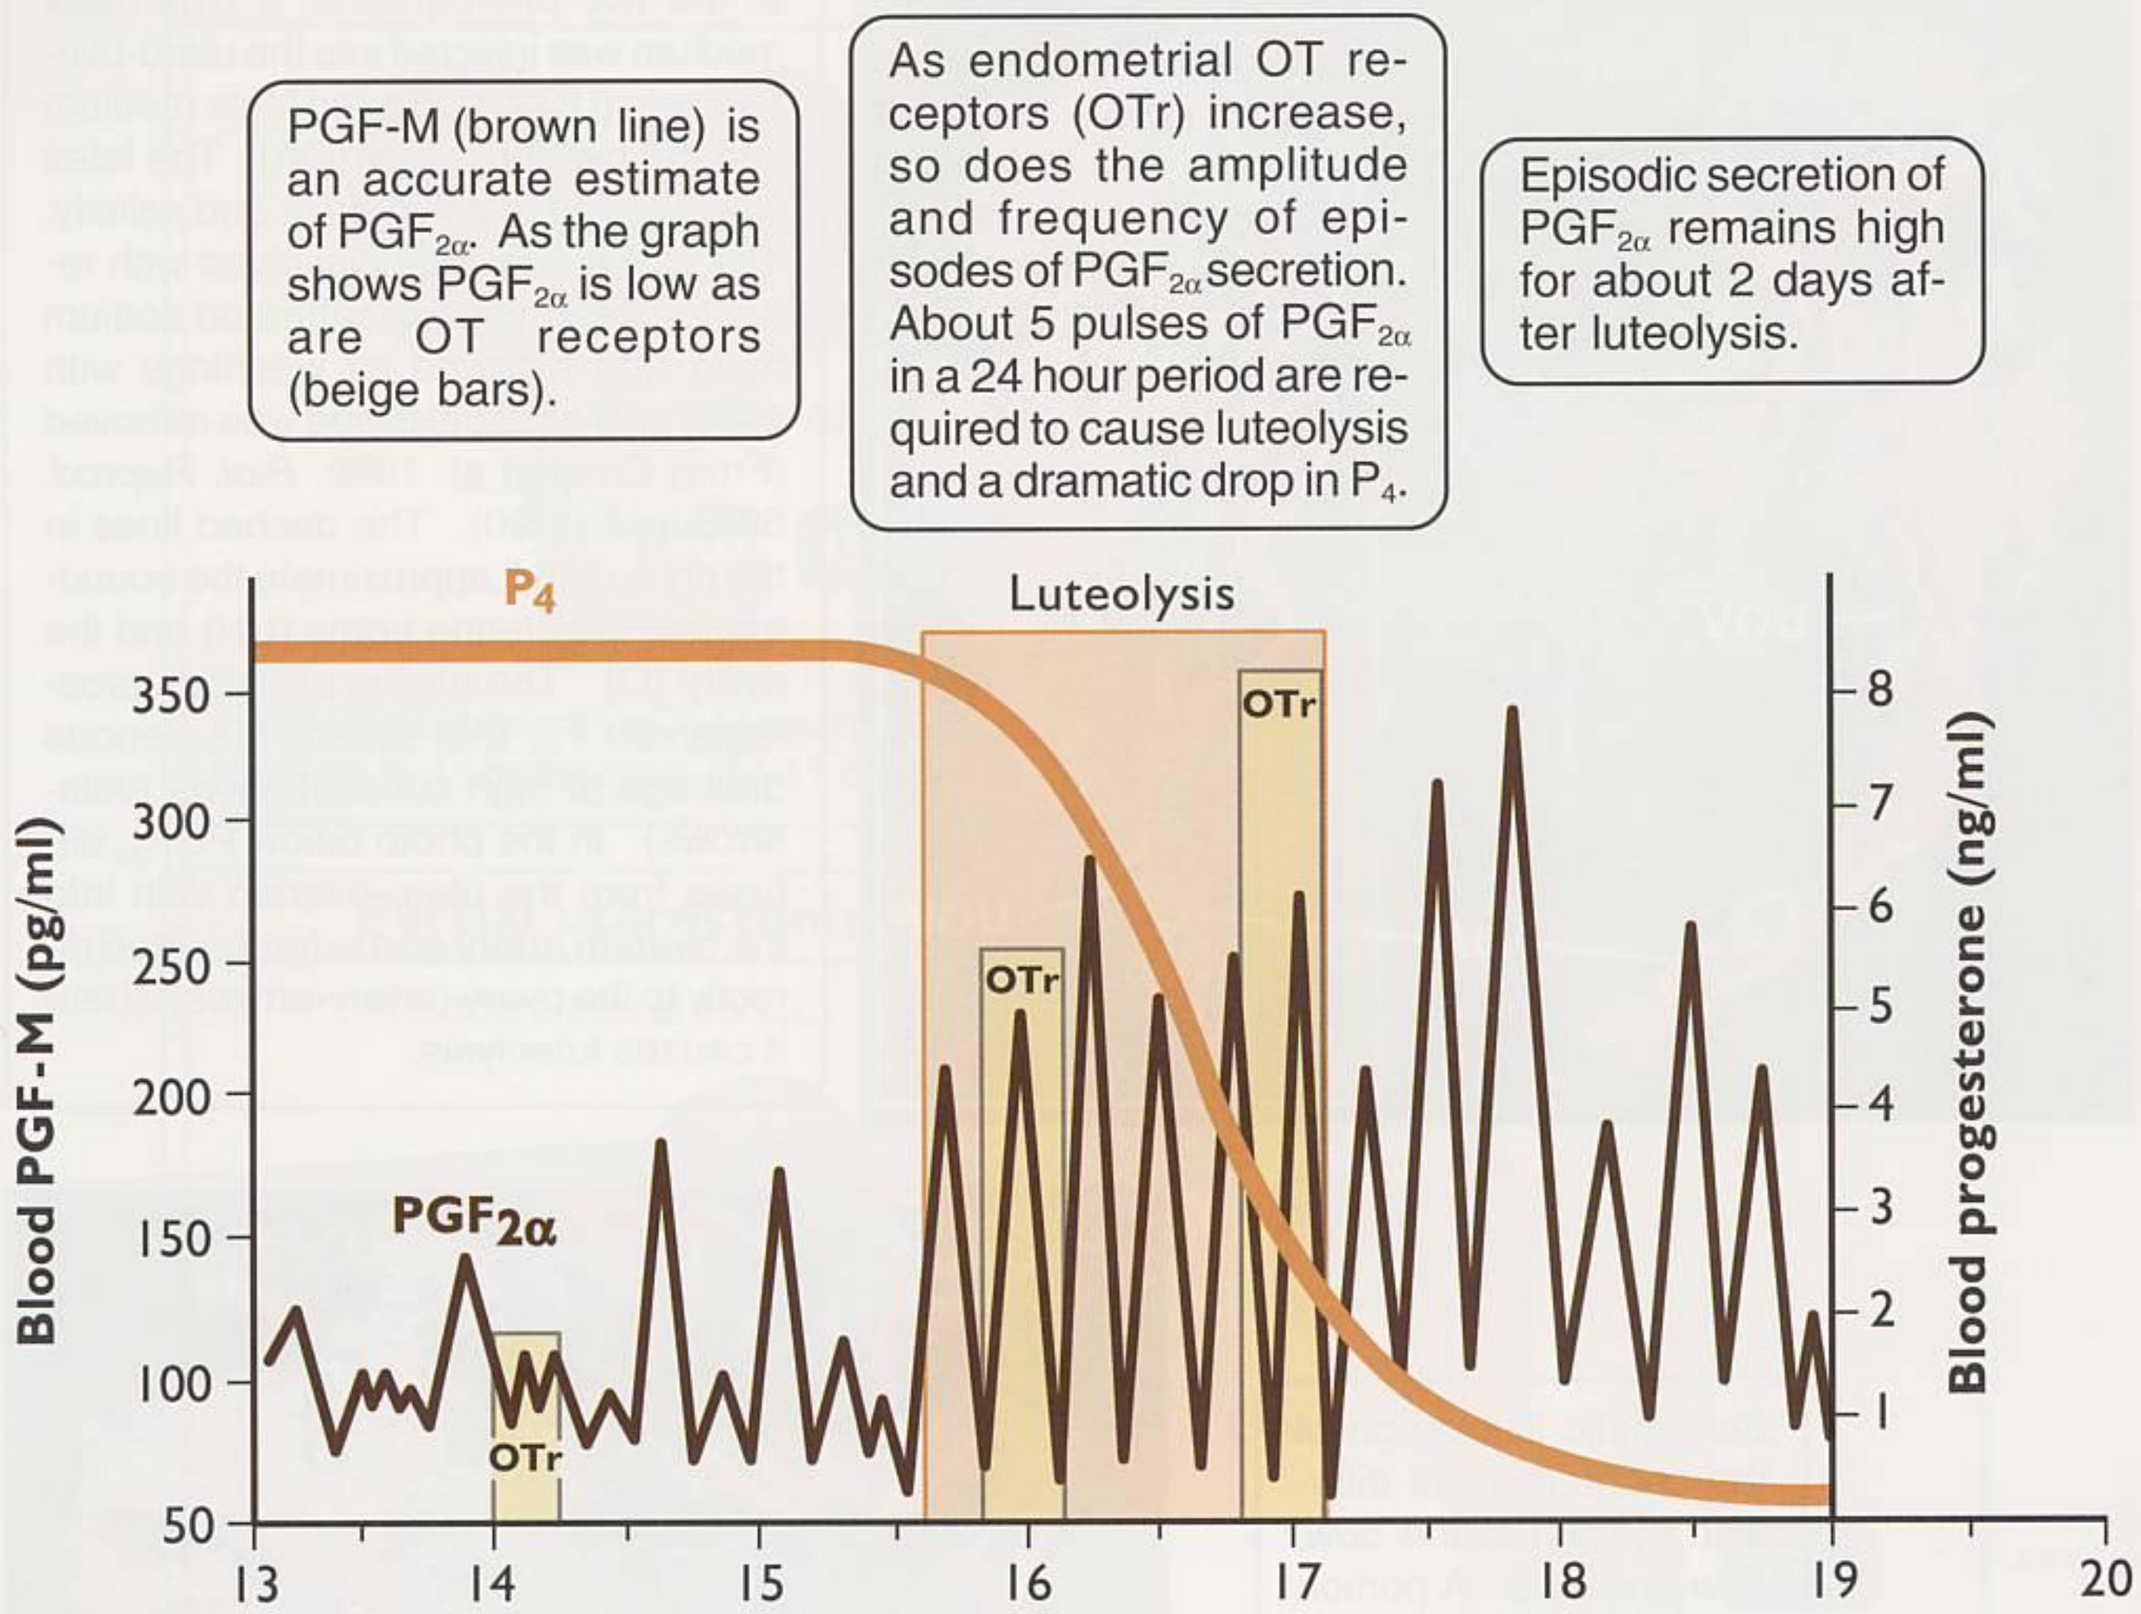
In the two photographs, a blue latex medium was injected into the utero-ovarian vein (UOV) and a red latex medium into the ovarian artery (OA). The latex was allowed to polymerize and solidify. The tissue was then dissolved with repeated treatments of saturated sodium hydroxide followed by washings with water until all of the tissue was removed (From Cody et al. 1999. *Biol. Reprod.* 60(Suppl 1): 90). The dashed lines in the photo at left approximate the boundaries of the uterine horns (UH) and the ovary (O). The uterus produces prostaglandin $F_{2\alpha}$ that enters the venous drainage at high concentrations (vein-arrows). In the photo below $PGF_{2\alpha}$ diffuses from the utero-ovarian vein into the ovarian artery and is transported directly to the ovary (artery-arrows) where it causes luteolysis.





Schematic illustration of the countercurrent diffusion system in the cow, sow and ewe. A portion of uterine $PGF_{2\alpha}$ diffuses directly from the utero-ovarian vein into the ovarian artery where it has a direct lytic effect on the corpus luteum.

Figure 9-12. Changes in PGF Metabolite (PGF-M), Oxytocin (OT) and Oxtocin Receptors (OTr) During Late Diestrus and Proestrus



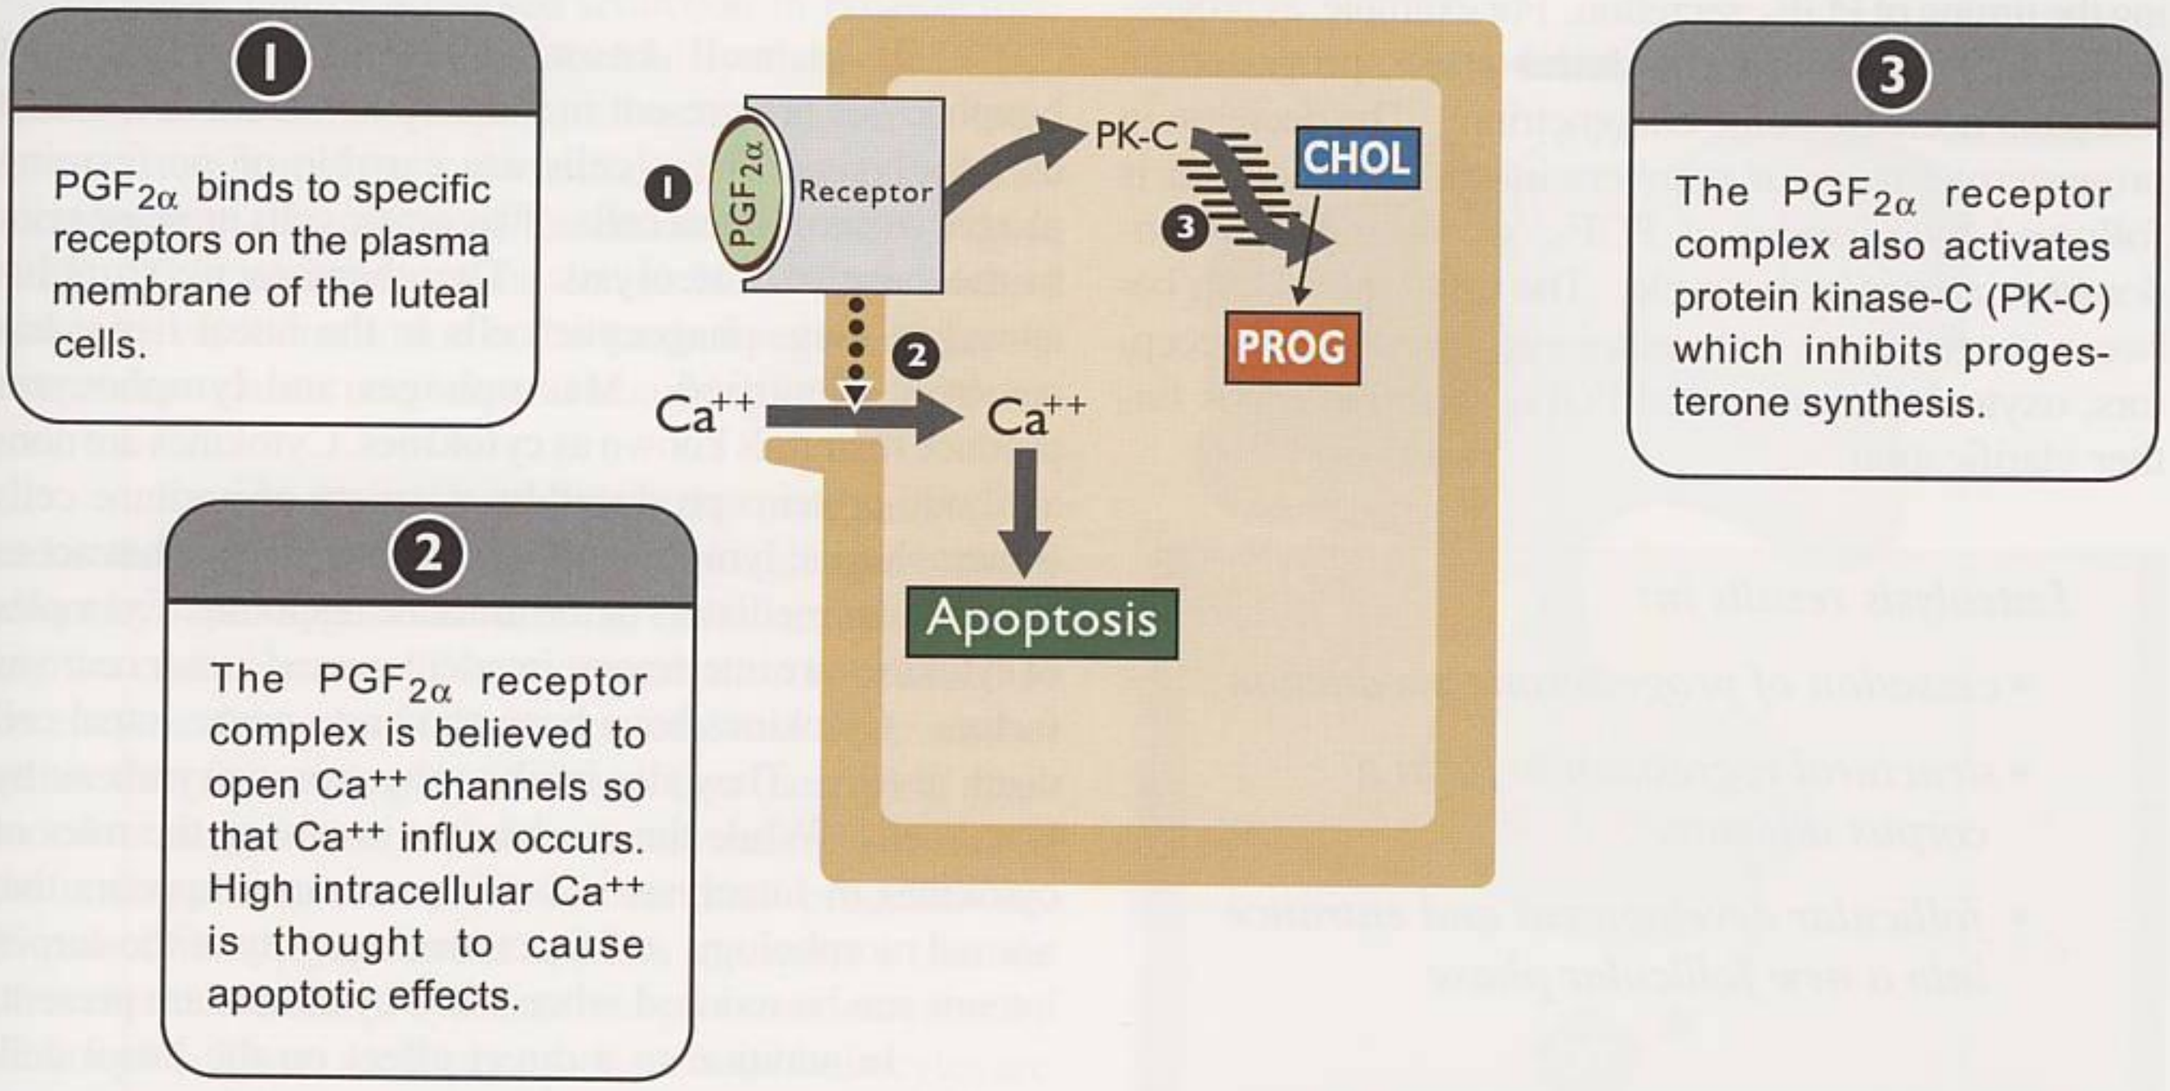
the pulmonary system in the ewe and the cow (around 90%). In the sow, only about 40% of the $PGF_{2\alpha}$ is denatured in the pulmonary circulation. By entering the ovarian artery, $PGF_{2\alpha}$ can exert its lytic effect directly on the corpus luteum before it enters the systemic circulation. The countercurrent diffusion system is present in the cow, sow and ewe, but not in the mare. The mare does not metabolize $PGF_{2\alpha}$ as rapidly as other species, so the need for a local transport specialization is not important in the mare. In addition, the mare CL is believed to be more sensitive to $PGF_{2\alpha}$ than the CL of the cow, sow and ewe.

Exogenous $PGF_{2\alpha}$ causes luteolysis during about 60% of the cycle in most species. For example, it exerts its most potent effect after day six of the cycle and will almost always cause luteolysis if administered after this time in the cow. In contrast, $PGF_{2\alpha}$ has a negligible effect during the first two to four days after ovulation. In the pig, the corpus luteum does not become responsive to the luteolytic action of a single dose of $PGF_{2\alpha}$ until day 12 to 14 of the cycle. Prostaglandin $F_{2\alpha}$, as well as its analogs, is used widely to cause regression of the corpus luteum and thus synchronize estrus and ovulation to induce abortion and sometimes to induce parturition.

The requirements for luteolysis (in subprimate mammals) are:

- ***presence of oxytocin receptors on endometrial cells***
- ***presence of a critical level of oxytocin***
- ***$PGF_{2\alpha}$ synthesis by endometrium***

Figure 9-13. Proposed Steps Resulting in the Loss of Progesterone Production from Steroidogenic Cells



What stimulates the production of $PGF_{2\alpha}$ during the late luteal phase? In addition to progesterone, large luteal cells synthesize and secrete oxytocin. In fact, in the cow and the ewe the corpus luteum contains very large quantities of oxytocin. Luteal oxytocin is stored in secretory granules analogous to those observed in the nerve terminals of the posterior pituitary gland. When oxytocin is injected into ewes near the end of the luteal phase, $PGF_{2\alpha}$ appears in the circulating blood in response to these injections. In contrast, immunization against oxytocin (developing antibodies that destroy oxytocin) increases the duration of the luteal phase in the ewe. Luteal oxytocin has been shown to be synthesized by the same messenger RNA that is found in the nerves of the posterior pituitary gland. The pattern of luteal oxytocin secretion is similar to concentrations of $PGF_{2\alpha}$ metabolite in blood during the last 6 days of the estrous cycle (See Figure 9-12). It is obvious that luteal oxytocin pulses are nearly coincident with pulses of $PGF_{2\alpha}$ metabolites. The reason metabolites of $PGF_{2\alpha}$ are measured instead of $PGF_{2\alpha}$ is that the metabolites are longer-lived and are easier to measure. In general, concentrations of the metabolites of $PGF_{2\alpha}$ in the blood are a close reflection of $PGF_{2\alpha}$ concentration.

During the first-half of the luteal phase, prostaglandin secretion by the endometrium of the uterus is almost nonexistent. However, during the late luteal phase, secretion of $PGF_{2\alpha}$ begins to occur in pulses (See Figure 9-12). The pulses increase in frequency and amplitude as the end of the luteal phase approaches. It has been established that a critical number of $PGF_{2\alpha}$ pulses within a given time-span are required to induce complete luteolysis. The exact number of pulses required has not been defined for all species. However, based on data from the ewe, about five pulses in a 24 hour period are required to induce complete luteolysis. Pulsatile release of $PGF_{2\alpha}$ is apparently not required under conditions of exogenous $PGF_{2\alpha}$ administration.

The exact stimulus that initiates $PGF_{2\alpha}$ secretion is controversial. One school of thought maintains that the uterus must be exposed to elevated progesterone for a period of days before it can synthesize and release $PGF_{2\alpha}$ in sufficient quantities to cause luteolysis. During the first half of the estrous cycle progesterone prevents secretion of $PGF_{2\alpha}$ by blocking the formation of oxytocin receptors in the uterus. After 10 to 12 days progesterone loses its ability to block formation of oxytocin receptors, although it is not known how this occurs. During the late luteal phase exogenous oxytocin causes the secretion of $PGF_{2\alpha}$ by the uterus. Injections of $PGF_{2\alpha}$ during the late luteal phase lead to a rapid release of ovarian oxytocin. Thus, oxytocin and $PGF_{2\alpha}$ stimulate each other in a positive feedback manner. In the ewe, oxytocin episodes precede $PGF_{2\alpha}$ episodes. At this time during the luteal phase uterine responsiveness to oxytocin is increased by the rise in the number of oxytocin receptors in the endometrium (See Figure 9-12). The higher the number of endometrial oxytocin receptors, the greater the ability of oxytocin to stimulate the synthesis of $PGF_{2\alpha}$.

It should be emphasized that our understanding of the precise luteolytic mechanism is not complete. Progesterone is believed to play a major role in regulating the timing of $PGF_{2\alpha}$ secretion. For example, as progesterone increases during the luteal phase, progesterone receptors decrease in the endometrium. The decrease in progesterone receptor numbers in the endometrium is followed by episodes of $PGF_{2\alpha}$ secretion by the endometrium later in the cycle. The exact interaction between progesterone concentrations, progesterone receptors, oxytocin secretion and $PGF_{2\alpha}$ secretion needs further clarification.

Luteolysis results in:

- ***cessation of progesterone production***
- ***structural regression to form a corpus albicans***
- ***follicular development and entrance into a new follicular phase***

The intracellular mechanisms that cause luteolysis have been the subject of intense research during the last 10 years. One of the original theories to explain the demise of the corpus luteum was that $PGF_{2\alpha}$ caused reduction in blood flow to the corpus luteum by causing vasoconstriction (contraction) of arterioles supplying the luteal tissue. While blood flow to the corpus luteum does decrease during luteolysis, blood flow to the corpus luteum is still 5 to 20 times greater than to the surrounding ovarian tissue. Thus, **ischemia** (reduced blood flow) as a primary mode for luteolysis seems unlikely. It is known that capillaries in the corpus luteum undergo degeneration during luteolysis. It is possible that this capillary degeneration is more responsible for reducing blood flow than vasoconstriction associated with $PGF_{2\alpha}$. Nevertheless, a degree of circulatory disruption is associated with the luteolytic process. However, it is unlikely that this disruption to the luteal vasculature can totally account for luteolysis.

A second line of thinking is the theory that $PGF_{2\alpha}$ binds to specific receptors on large luteal cells and triggers a cascade of events resulting in the death of these cells and, thus, cessation of steroidogenesis. These events are presented in Figure 9-13.

The Immune System May Be Involved in Structural Regression of the Corpus Luteum

It is well known that macrophages and lymphocytes are present in the corpus luteum at the time of luteolysis. These cells are capable of performing phagocytosis of luteal cells. Phagocytic cells increase prior to the onset of luteolysis. The chemotactic stimulus attracting these phagocytic cells to the luteal tissue has not been identified. Macrophages and lymphocytes produce materials known as **cytokines**. Cytokines are non-antibody proteins produced by a variety of immune cells (macrophages, lymphocytes and granulocytes) that act as intercellular mediators of the immune response. Examples of cytokines are interferons, interleukins and tumor necrosis factors. Cytokines have been shown to cause luteal cell death *in vitro*. They also inhibit progesterone synthesis by luteal cells. While the mechanism involving the roles of cytokines in luteolysis is far from clear, it appears that normal morphologic and functional integrity of the corpus luteum can be reduced when these cytokines are present.

In addition to a direct effect on the luteal cell, cytokines may serve as triggering agents for a process called apoptosis. **Apoptosis** (pronounced "a-pa-toe-sis") is a phenomenon that has been described as "programmed cell death". It is quite normal for cells throughout the body to die on a daily basis. Cell death occurs by one of two processes. The first, cell **necrosis,** is brought about by pathologic damage. The second type of cell death, apoptosis, is an ordered biochemical process. This process involves distinct biochemical and morphologic changes in the cell. The process of apoptosis is probably the final step resulting in the death of the luteal cell. Final destruction and "clean-up" of the luteal cells *per se* is probably performed by macrophages that phagocytize damaged luteal cells. Over time the luteal cells disappear completely, leaving only connective tissue behind. Thus, the scar-like **corpus albicans** is formed.

Luteolysis in Women is an Intra-Ovarian Event. The Uterus is not Required

Uterectomy in the woman does not influence ovarian cyclicity. In other words, the normal pattern of folliculogenesis, CL development and luteolysis occurs in a rhythmic fashion every 28 days after the removal of the uterus. A proposed mechanism for luteolysis in primates is presented in Figure 9-14. Even though traces of luteal oxytocin have been identified, it is believed that oxytocin from the posterior pituitary acts on ovarian oxytocin receptors to generate small amounts of intraovarian prostaglandin $F_{2\alpha}$. Luteolysis is believed to be a local effect and therefore only small amounts of prostaglandin $F_{2\alpha}$ are

required to lyse the CL. As a result of oxytocin receptors binding oxytocin, the synthetic pathway for prostaglandin $F_{2\alpha}$ is activated and this causes luteolysis. Luteolysis therefore causes a marked reduction in progesterone that is believed to cause endometrial synthesis of $PGF_{2\alpha}$. Endometrial $PGF_{2\alpha}$ is important because it causes local vasoconstriction of the endometrial arterioles and initiates menstruation (sloughing of the endometrium-See Figure 9-15). This significant reduction in blood flow brought about by vasoconstriction in the luminal region of the endometrium causes necrosis and sloughing of the endometrial tissue.

Recent research studying the mechanisms of menstruation suggest that endometrial sloughing is brought about by rapid degeneration of the basal lamina supporting the endometrium. Tissue degeneration is believed to be enzyme-driven and is the cause of tissue degeneration rather than the result of vasoconstriction (necrosis). Current data suggest that an inflammatory reaction occurs in the endometrium as a result of decreased progesterone. The decline in progesterone appears to trigger a cascade of events that initiates cytokine and protease secretion by leukocytes. These secretory products from leukocytes are thought to initiate endometrial degeneration. The relative roles of $PGF_{2\alpha}$, vasoconstriction and inflammation in the initiation of menstruation is under current investigation and more knowledge will undoubtedly be available soon.

Exogenous Administration of Progesterone Results in Manipulation of the Estrous and Menstrual Cycles

Now that you understand the mechanisms that control progesterone synthesis, secretion and luteolysis, an understanding of how progesterone is used to control/manipulate cyclicity will provide you with practical knowledge that is based on the physiologic principles.

As you know, progesterone provides negative feedback on the hypothalamus to suppress GnRH. This fact has been applied to the development of many applications designed to manipulate the reproductive cycles in both domestic animals and women. The administration of progesterone serves as an "artificial corpus luteum".

Exogenous progesterone suppresses estrus and ovulation. However, when the exogenous progesterone is removed or withdrawn, the animal will enter proestrus and estrus within two to three days after progesterone removal. This approach enables estrus to be synchronized in large groups of females so that artificial insemination can be accomplished within a few days. This application is intended to increase the convenience of artificial insemination programs and to facilitate fertility (higher pregnancy rates). In contrast, the use of exogenous progesterone in humans is intended to block ovulation and minimize the likelihood of pregnancy.

Figure 9-14. Proposed Mechanism of Luteolysis in Primates

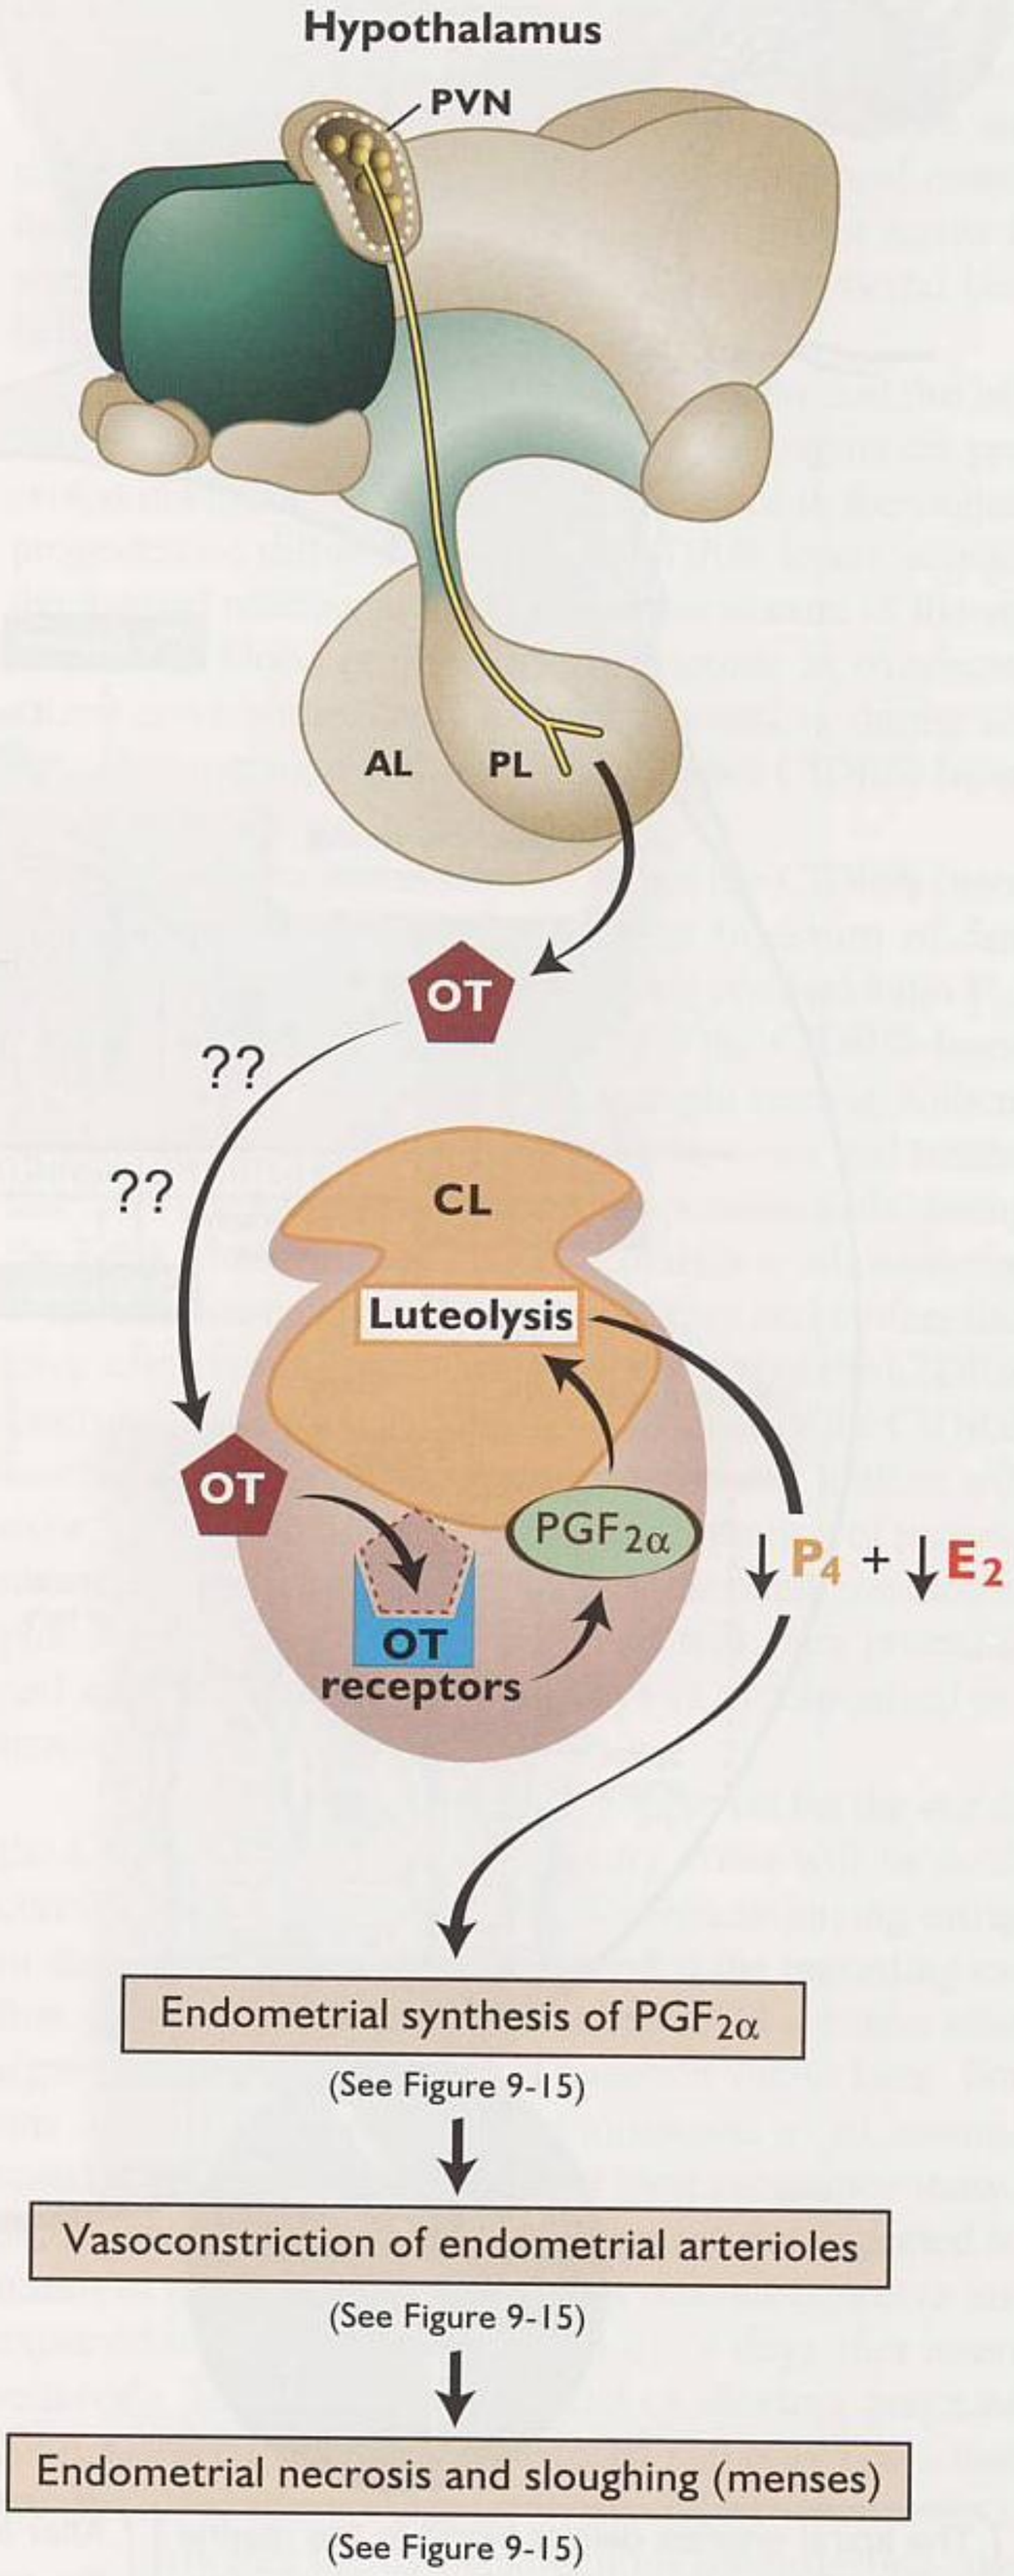


Figure 9-15. Luteolysis as the Initiator of Menses

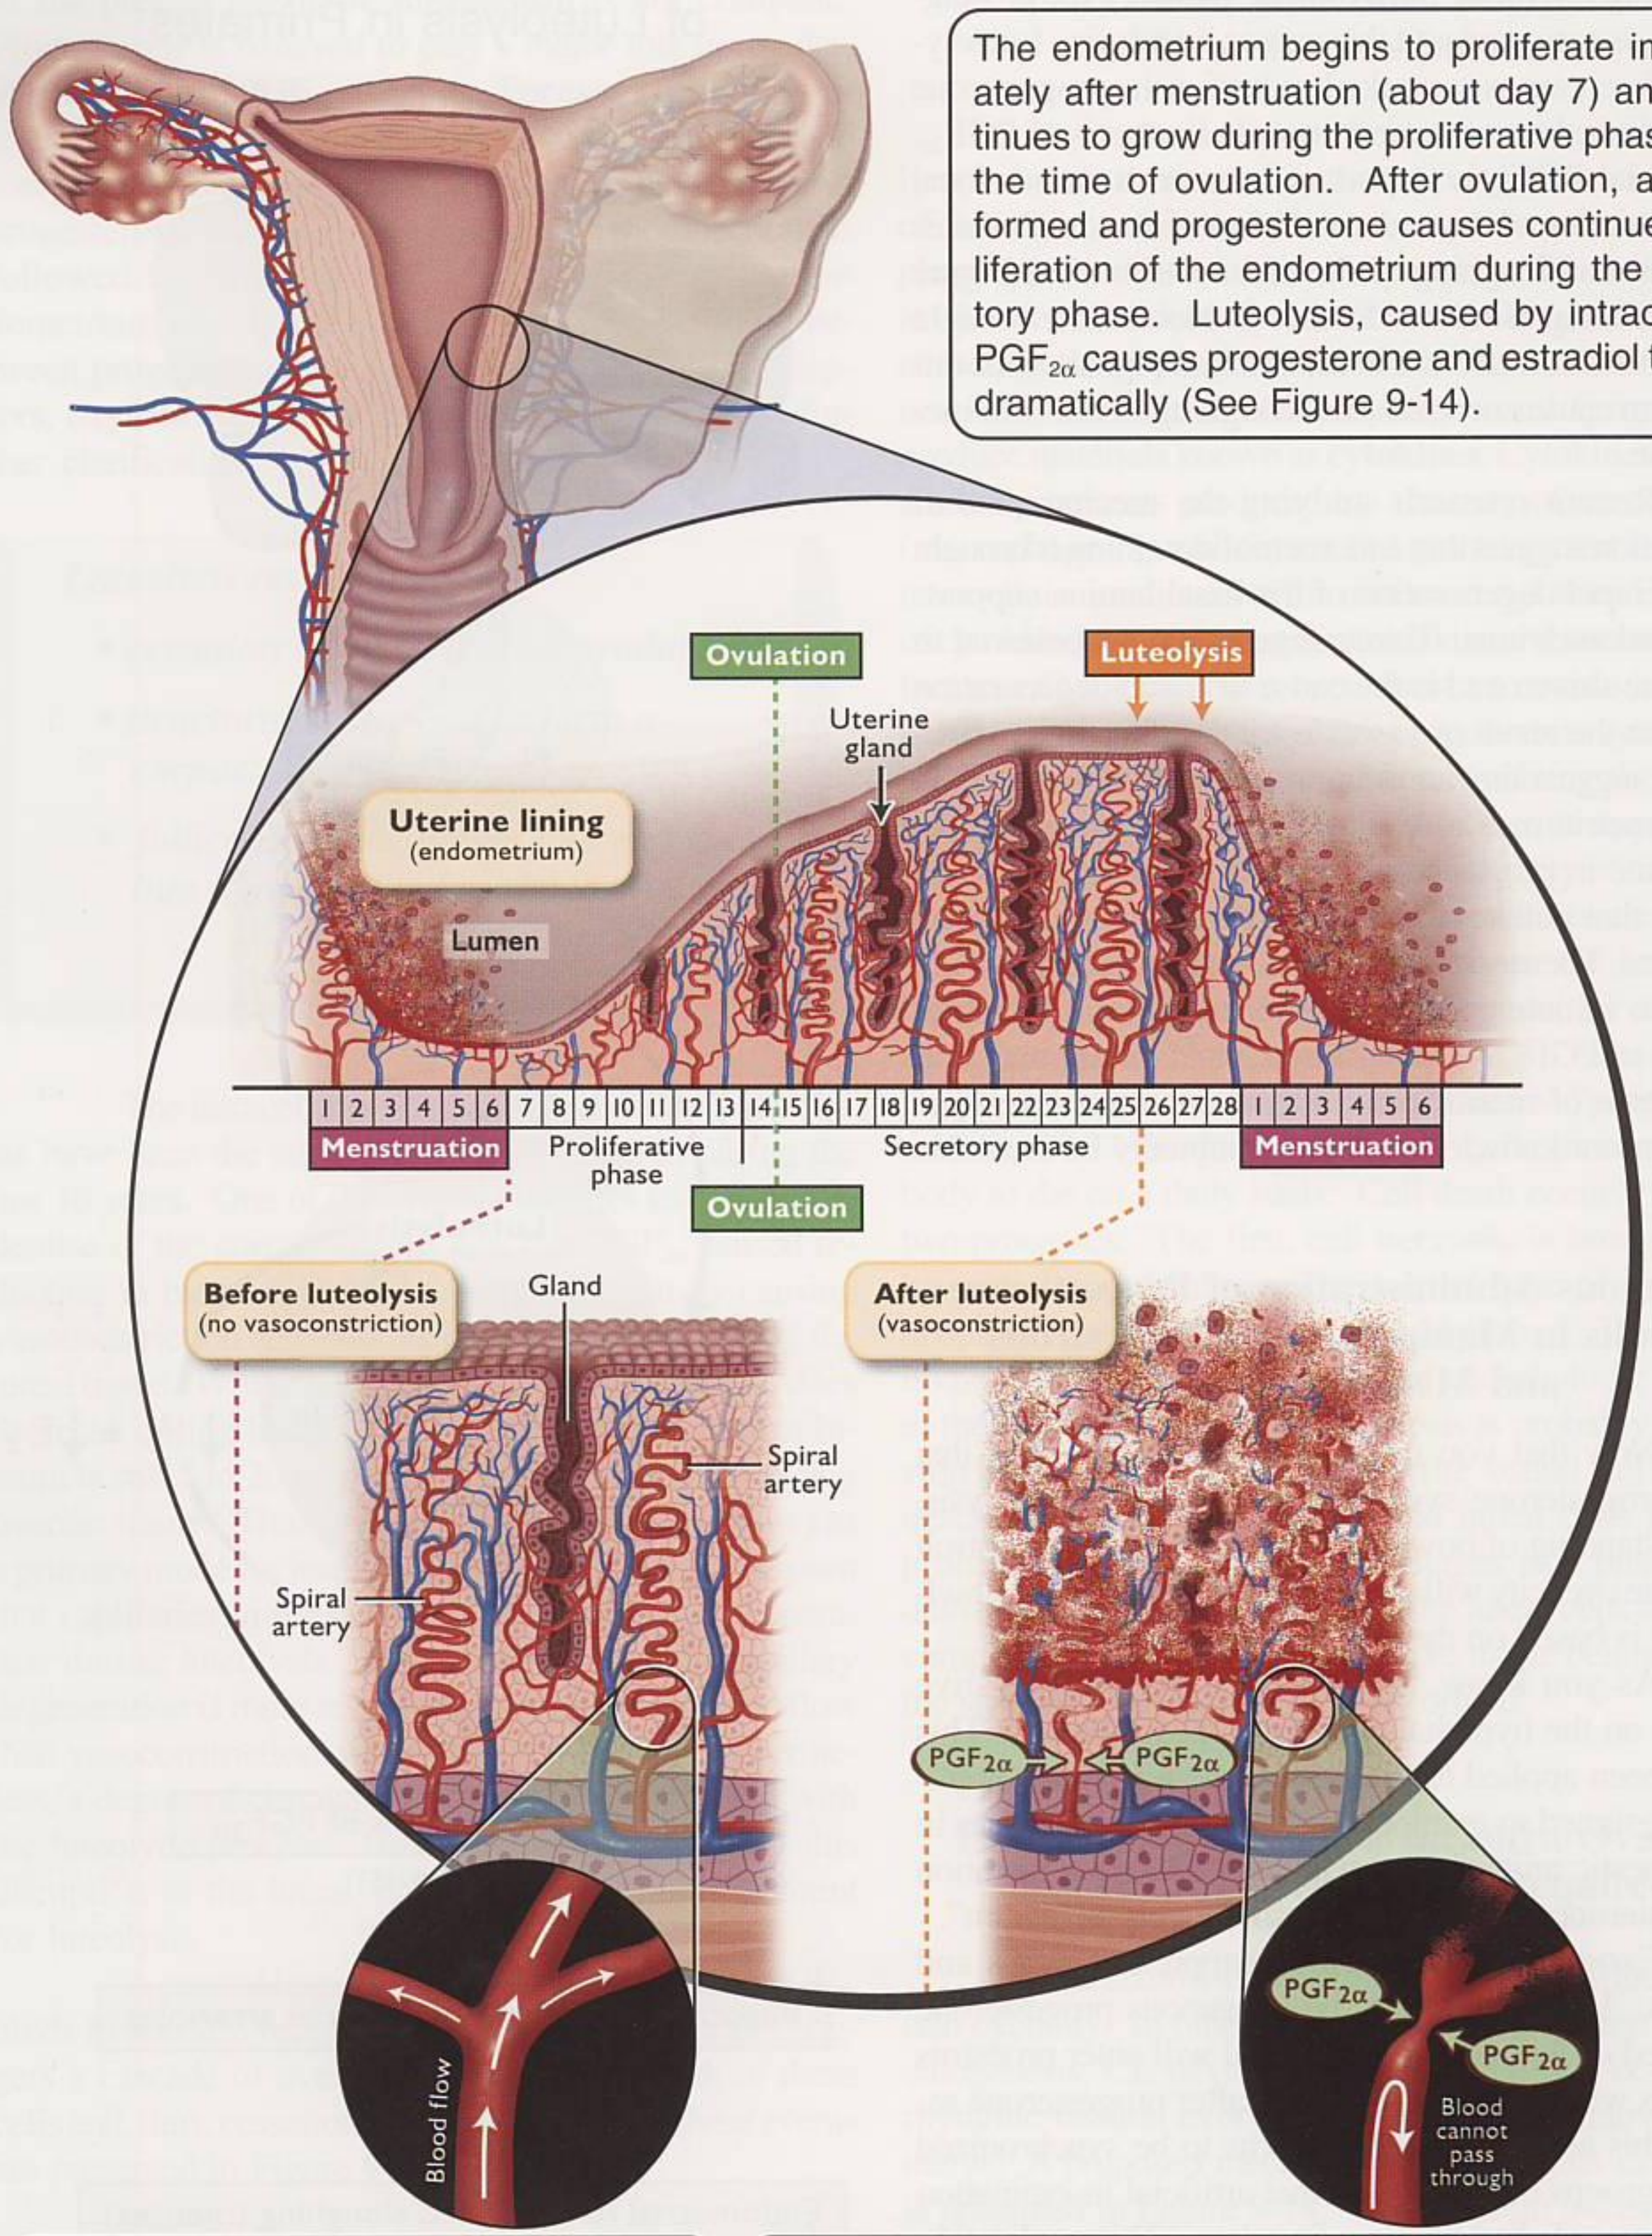
The endometrium begins to proliferate immediately after menstruation (about day 7) and continues to grow during the proliferative phase until the time of ovulation. After ovulation, a CL is formed and progesterone causes continued proliferation of the endometrium during the secretory phase. Luteolysis, caused by intraovarian $PGF_{2\alpha}$ causes progesterone and estradiol to drop dramatically (See Figure 9-14).



The spiral arteries deliver blood to the uterine glands during the proliferative and secretory phases before luteolysis. A high blood flow to the endometrium facilitates secretion by the uterine glands.

After luteolysis, the dramatic drop in P_4 promotes $PGF_{2\alpha}$ synthesis by the endometrium that causes sustained vasoconstriction in the spiral arteries. Sustained vasoconstriction causes ischemia and the endometrium undergoes necrosis and sloughs into the uterine lumen. Endometrial sloughing (menstruation) lasts from 2 to 6 days.

Intravaginal Progesterone is Effective at Synchronizing Estrus in Cattle

Recently, the EAZI-BREED™ CIDR® Cattle Insert (CIDR Insert; an intravaginal progesterone insert) was approved by the Food and Drug Administration (FDA) for synchronization of estrus in beef cattle and dairy heifers. In addition to synchronization of estrus, the product was approved for advancing first estrus in anestrus postpartum beef cows and in prepubertal beef heifers.

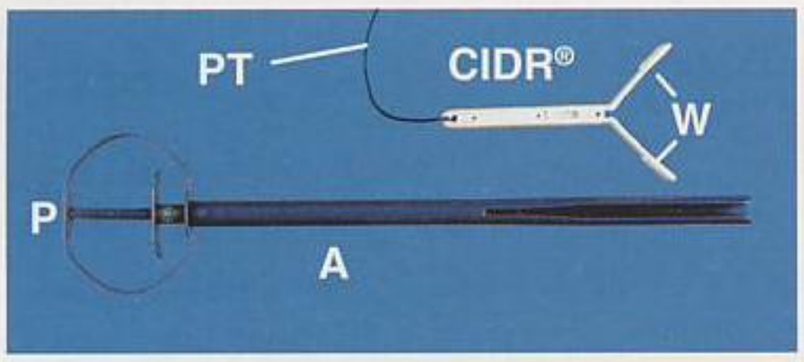
The techniques for administration and the orientation of the CIDR® Insert within the vagina are presented in Figure 9-17. During its residence in the vagina, progesterone diffuses out of the CIDR® Insert, crosses the vaginal mucosa and enters the vasculature of the vagina. The blood profiles of progesterone in ovariectomized cows immediately following insertion, during a 7 day administration and immediately after CIDR® Insert removal are shown in Figure 9-16.

For synchronization of estrus the CIDR® Insert is administered for 7 days with an injection of 5ml LUTALYSE® Sterile Solution (25mg prostaglandin $F_{2\alpha}$) on the sixth day. Progesterone from the CIDR® Insert suppresses GnRH release, gonadotropin release, follicular development and ovulation in those cows and heifers that have corpora lutea that regress spontaneously during the 7 day administration period. Lutalyse is administered to initiate luteal regression in those cows and heifers that have a functional corpus luteum at the end of the CIDR® Insert administration period. Upon removal of the CIDR® Insert and injection of Lutalyse, cows and heifers will experience a rapid decline in the concentration of progesterone followed by elevated GnRH, elevated gonadotropins and follicular development and will enter proestrus and estrus within two to three days (a synchronized estrus).

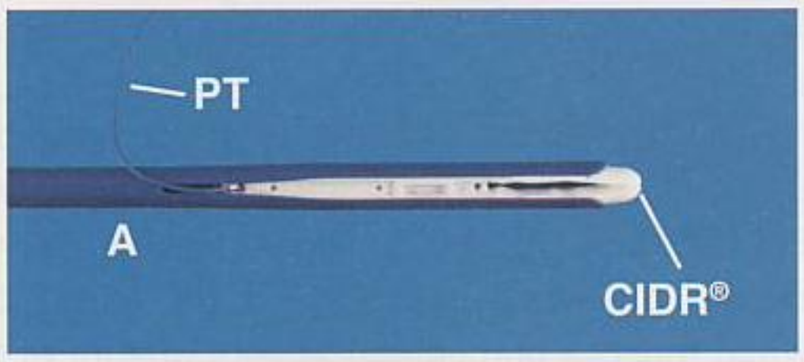
It is anticipated that FDA approval for the use of the CIDR® Insert in lactating dairy cows will be forth coming. The anticipated use is for synchronizing estrus in dairy cows that were inseminated at the preceding estrus. The CIDR® Insert is administered 14 ± 1 days after a previous insemination and is removed 7 days later. For this use CIDR® Inserts are administered to all inseminated cows without knowledge of their pregnancy status. Upon insert removal, pregnant cows are not expected to return to estrus whereas cows that did not conceive are expected to return to estrus within 2 to 4 days after insert removal. To prevent the potential of aborting pregnant cows **Lutalyse is not administered** and only cows that are observed in standing estrus would be inseminated.

Another use of an exogenous progesterone-like compound is in mares. A material with the trade name Regu-Mate® is used to control cyclicity. The active ingredient in Regu-Mate® is a synthetic progestin

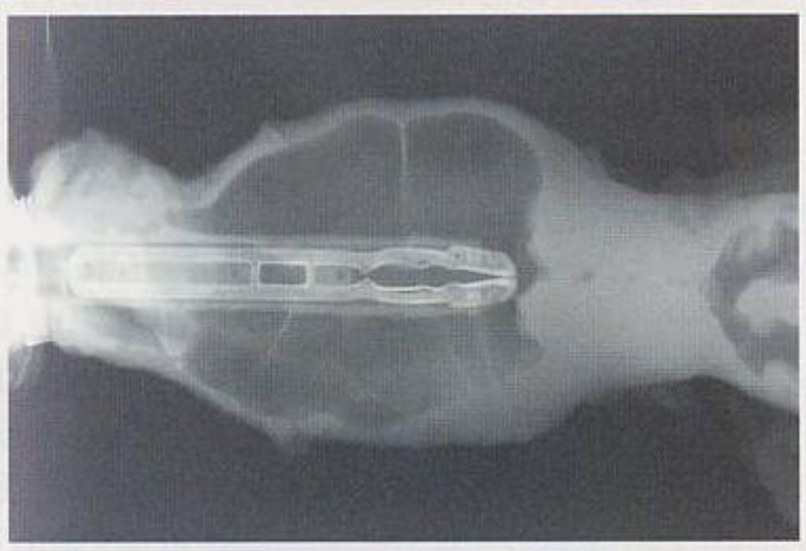
Figure 9-17. The CIDR® as an Artificial Corpus Luteum in Cattle



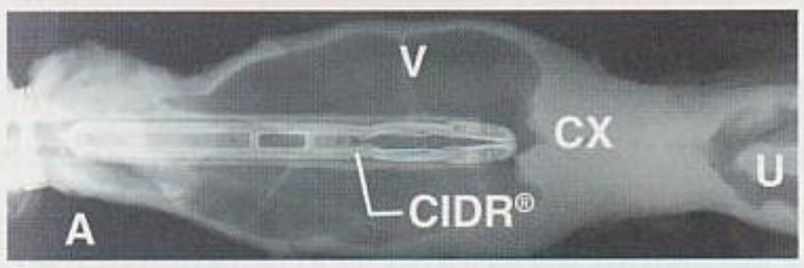
The CIDR® is a "Y" shaped flexible device containing 1.38g of progesterone. The polyester "tail" (PT) allows retrieval of the CIDR® after seven days. The low tension spring-like "wings" (W) provide gentle pressure to hold the CIDR® in the vagina. The applicator (A) is a flexible plastic, syringe-like device with a plunger (P), that when depressed, inserts the CIDR® into the vagina of the cow.



The "wings" of the CIDR® are folded back and the CIDR® is inserted into the tip of the applicator (A).



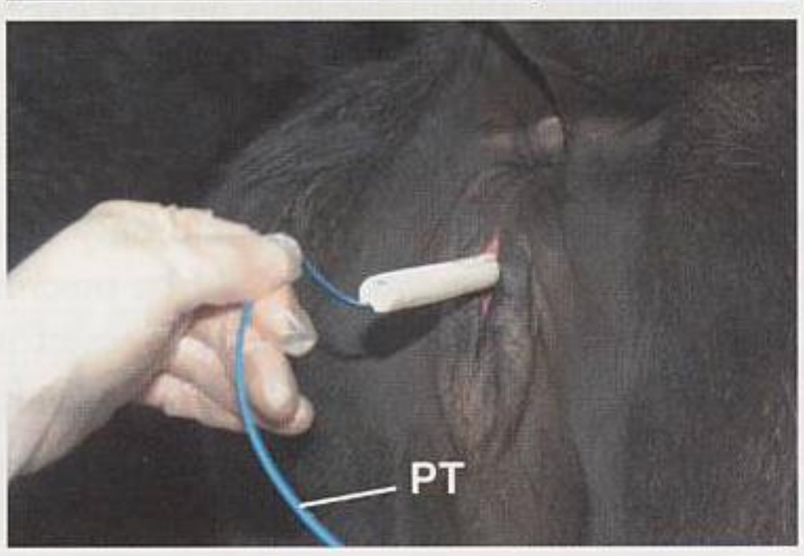
The lubricated applicator is inserted gently into the vagina.



Radiograph showing the applicator containing the CIDR® after insertion into the vagina (V). The plunger of the applicator (A) has not been depressed and the "wings" of the CIDR® are still folded inside the applicator (CX = cervix; U = uterus).

The plunger of the applicator is being depressed allowing the CIDR® to be deposited into the vagina.

Radiograph showing the CIDR® inside the vagina (V) with the "wings" expanded to prevent loss after insertion. (CX = cervix; U = uterus).



After seven days, the CIDR® is removed by gently pulling on the polyester "tail" (PT).

Note: for more details see *www.cidr.com.*

called altrenogest. The physiologic action of altrenogest is the same as progesterone. It is used in mares for the following reasons: 1) to induce regular cyclicity in mares making the transition from winter anestrus to the breeding season, 2) to suppress undesired estrous behavior and 3) allow for scheduled breeding during the breeding season.

Altrenogest is administered by placing the appropriate dose on the posterio-dorsal surface of the mare's tongue or is applied to the grain ration. It is given daily for 15 consecutive days. During the time that altrenogest is being administered GnRH is suppressed, no follicular development occurs and behavioral estrus and ovulation do not occur. After cessation of the treatment, mares will display estrus four to five days later.

Progesterone is the primary hormone in human contraception. The four strategies for its use are:

- ***oral administration***
- ***transdermal administration***
- ***injectable administration***
- ***implants***

In humans, exogenous progesterone (many are synthetic progestins) is intended to block ovulation so that conception cannot occur. There are four primary strategies for using progesterone as a contraceptive in women. These are presented and explained in Figure 9-18.

It is beyond the scope of this text to describe all of the specific variations for use of progesterone in human contraception. However, the principles for use of progesterone as a contraceptive hormone are common to all applications. Progesterone inhibits cyclicity for the same reasons (negative feedback) as in other mammals. The duration of this inhibition depends on the duration of progestin administration. For example, oral contraception inhibits ovulation but does not inhibit the onset of the menstrual period. Monthly withdrawal of progesterone mimics luteolysis and initiates menstruation. Oral contraception usually involves a combination of both progesterone and estrogen. Estrogen is added for two reasons. First, at low doses, estrogen (like P_4) has a negative feedback on the hypothalamus and inhibits GnRH secretion. Second, estrogen stimulates the reproductive tissues so that their secretory function "waxes and wanes" thus, approximating the secretory activity during the normal menstrual cycle. Progestin injections and implants last for months to several years and blood levels remain high for the period that the progestin is administered (See Figure 9-18).

Exogenous Prostaglandin $F_{2\alpha}$ is a Potent Luteolysin and Can Synchronize Estrus

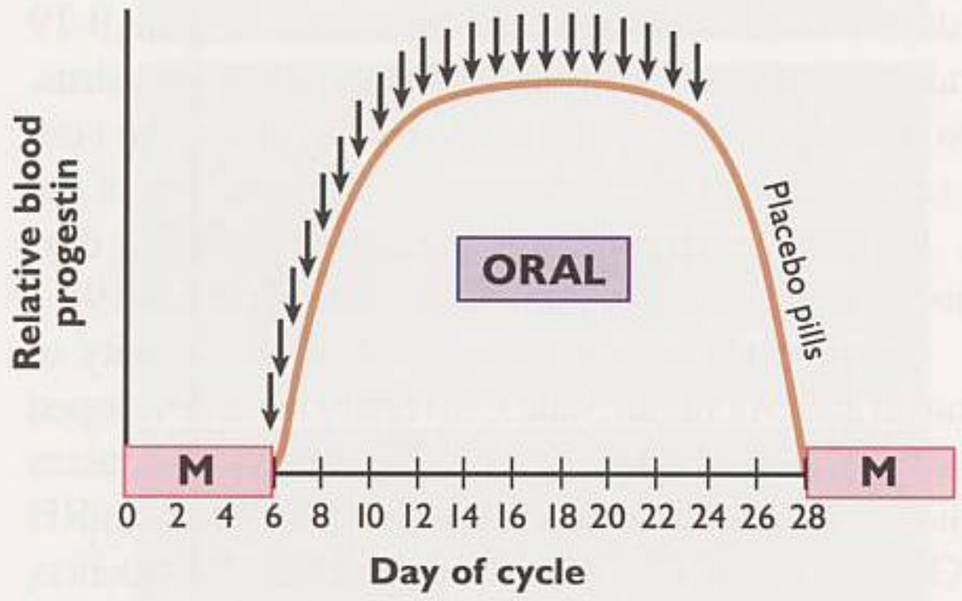
Following the discovery that $PGF_{2\alpha}$ was the luteolysin, a major research emphasis was placed on using this hormone to shorten the estrous cycle and induce estrus in cattle. Injections of $PGF_{2\alpha}$ between day seven and day 18 will cause the cow to begin to show estrus in about three days (60-80 hours after the injection). Figure 9-19 illustrates the effect of prostaglandin for inducing estrus. It must be emphasized that the corpus luteum of the cow is not sensitive to $PGF_{2\alpha}$ between days one and six of the cycle. In other words, injecting the cow with $PGF_{2\alpha}$ during this time will not have an effect (See Figure 9-19).

Reproductive physiologists at the University of Wisconsin and Michigan State University have developed an innovative use of GnRH and $PGF_{2\alpha}$ that synchronizes ovulation. This protocol is named Ovsynch. When GnRH and $PGF_{2\alpha}$ are used together in the proper timed-sequence, visual detection of estrus can be eliminated and timed artificial insemination (TAI) can be performed. This program is now being used effectively as a reproductive management tool in the dairy industry. The Ovsynch innovation incorporates the mechanisms of follicular dynamics described in Chapter 8 and the mechanisms of luteolysis (described earlier in this chapter) into a practical application of physiologic principles. A solid understanding of these mechanisms will translate into understanding of the Ovsynch protocol described below.

The basic strategy for the Ovsynch program is presented in the steps that follow. **Step 1**- GnRH is injected randomly into cows that are eligible to be inseminated (fully recovered from their last parturition). The random GnRH injection causes one of two events to take place. First, if there is a dominant follicle on the ovary (a follicle that is greater than 10mm and has an adequate population of LH receptors) the cow will ovulate in response to GnRH. A CL will then form. Second, if the cow does not have a dominant follicle (an immature follicle that has few LH receptors), GnRH will promote continued follicular growth. In this case, there is a CL present from the previous ovulation; **Step 2**- An injection of $PGF_{2\alpha}$ seven days after GnRH causes luteolysis and the cow will enter the follicular phase; **Step 3**- A second injection of GnRH 48 hours later causes the cow to ovulate. **Step 4**- The cow can then be inseminated without detection of estrus 16 hours after the second GnRH injection.

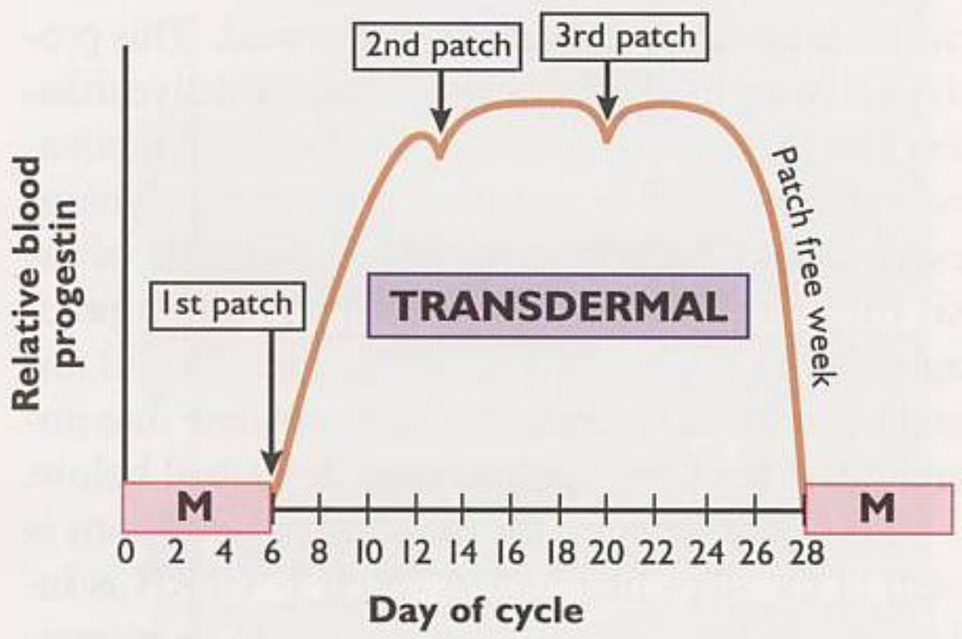
This strategy, when properly applied in commercial dairy herds has resulted in acceptable conception rates without detection of estrus in lactating dairy cows. The Ovsynch strategy will enable almost 100% of the cows to be inseminated after the designated postpartum waiting period (called the "voluntary wait period"). The first

Figure 9-18. Relative Blood Progesterone in Women Utilizing Various Hormonal Contraception Strategies (M = menses)



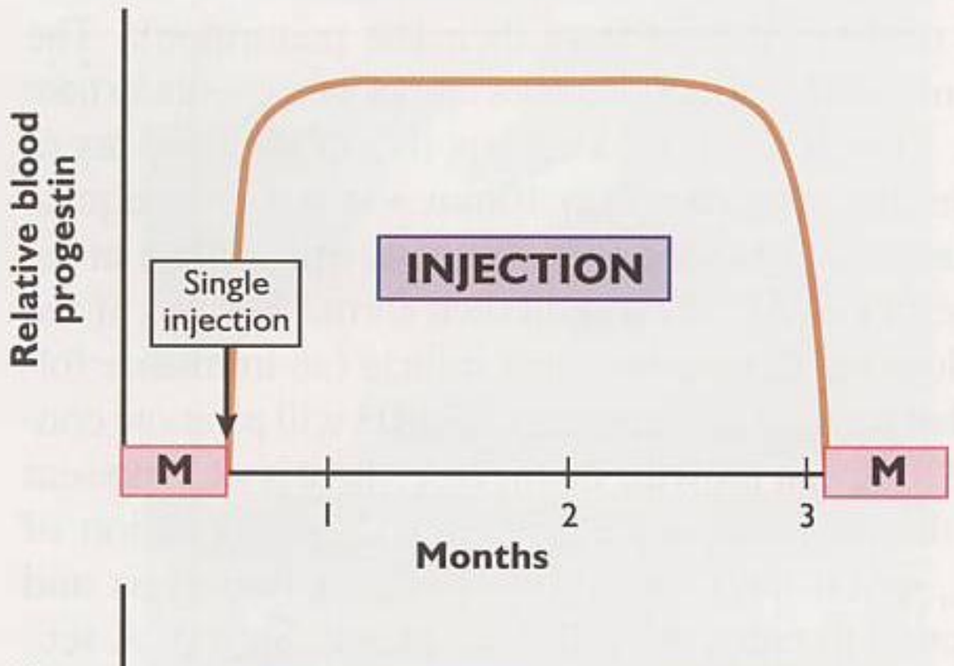
ORAL

Oral contraception requires oral ingestion of a tablet containing progesterone (many contain some estrogen). The progesterone/estrogen pills are taken for 21 consecutive days. During the time that the pills are taken, blood progesterone concentrations mimic those produced by the corpus luteum and provide negative feedback to the hypothalamus thus suppressing GnRH and preventing ovulation. The first pill is taken at the end of menses. After the 21st hormone pill, placebo pills (no hormone) are taken and progesterone concentrations drop, mimicking luteolysis. Menstruation will follow. After the last placebo pill, hormone-containing pills are again taken.



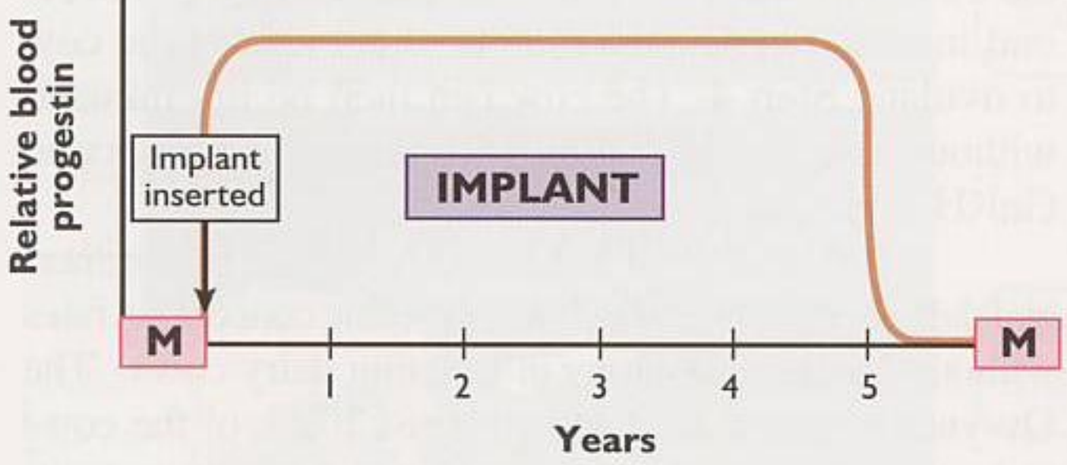
TRANSDERMAL

Transdermal hormonal administration is accomplished by attaching a patch containing progesterone/estrogen to the skin of the buttock, abdomen, arm or upper torso. Hormones diffuse from the patch into the vasculature of the skin. Progesterone then provides negative feedback on the hypothalamus. Patches are designed to provide a one week supply of progesterone (equivalent of seven pills). Transdermal administration of progesterone is attractive because daily pills do not need to be taken. After the third patch is removed (21 days), a patch-free week mimics luteolysis.



INJECTION

Progesterone injections are designed to provide negative feedback for about three months. The injection site is either the buttock or the arm. Injections do not contain estrogen and completely inhibit cyclicity for about three months. After three months, the menstrual period will be initiated if further injections are not administered.



IMPLANT

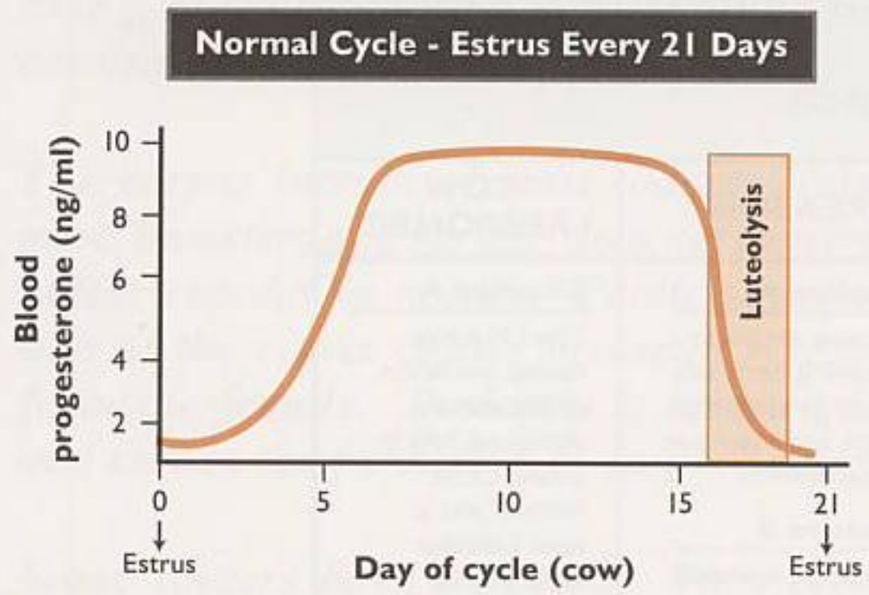
This technology is designed to inhibit cyclicity for up to five years. Implant technology provides a slow release of progesterone from the implants for a sustained period of time and therefore the woman maintains high progesterone concentrations and sustained negative feedback occurs. The implant can be removed (sometimes with difficulty) and cyclicity will be initiated.

GnRH injection in the Ovsynch program is given at random (without knowledge of the specific day of the cycle). This can result in several problems. If cows are not cycling, GnRH will not initiate cyclicity in all of them. Those that do ovulate in response to GnRH have reduced conception. Some GnRH-treated cows will recruit follicles from the second or third follicular wave and the follicle may not ovulate. Therefore, the $PGF_{2\alpha}$ injection is not totally effective (because there is no CL present) in these cows.

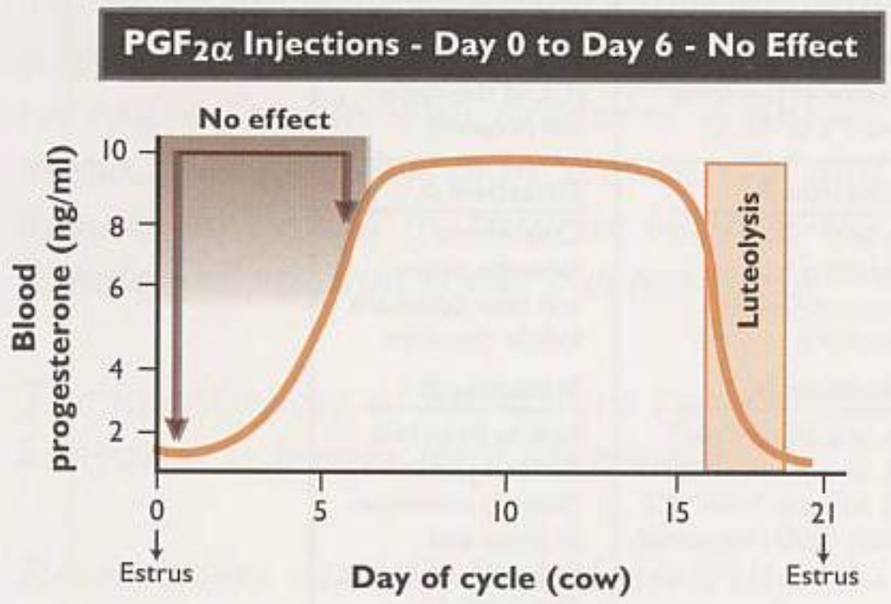
In order to help minimize the above problems, a strategy has been developed that is called Presynch. The Presynch program begins 26 days prior to the first GnRH injection. At random, all cows are given $PGF_{2\alpha}$. Fourteen days later a second $PGF_{2\alpha}$ injection is given. Remember, the first $PGF_{2\alpha}$ will lyse an existing corpus luteum if it is between days 7 and 17. Obviously, all cows will not fall into this range and the second $PGF_{2\alpha}$ lyses all corpora lutea that are present because they are in the "sensitive window" between days 7 and 17 Twelve days after the prostaglandin injection, GnRH is injected. GnRH may cause a new follicle to ovulate, forming a new CL as per the original Ovsynch protocol. Figure 9-20 summarizes the Presynch and Ovsynch protocols and provides the rationale and response for each.

More detail about each method can be obtained from the **Key References** section at the end of the chapter.

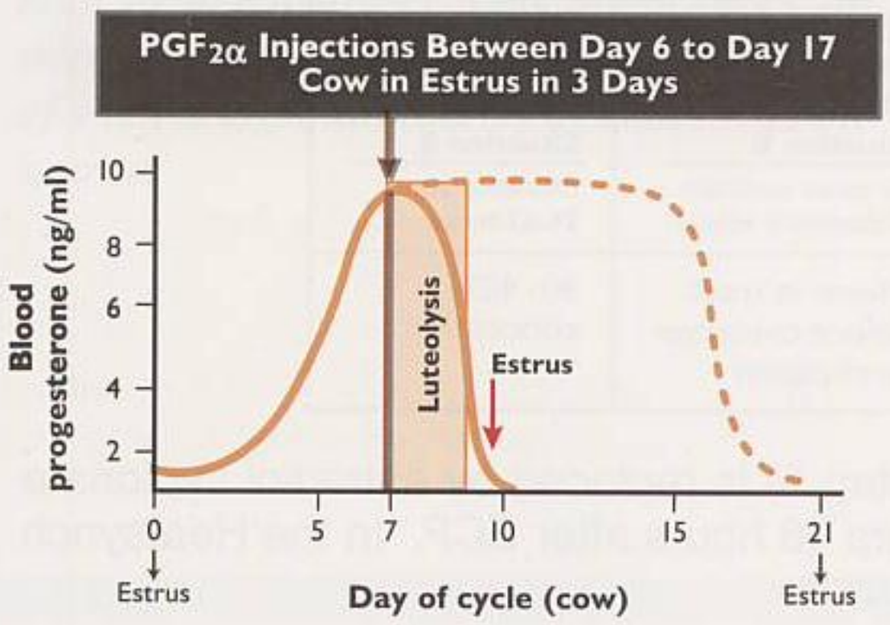
Figure 9-19. Influence of Prostaglandin $F_{2\alpha}$ Upon Cycle Length in the Cow



In the normal cycling cow estrus and ovulation occurs every 21 days. Luteolysis (induced naturally by $PGF_{2\alpha}$ from the uterus) causes the animal to enter a new follicular phase and subsequent estrus.

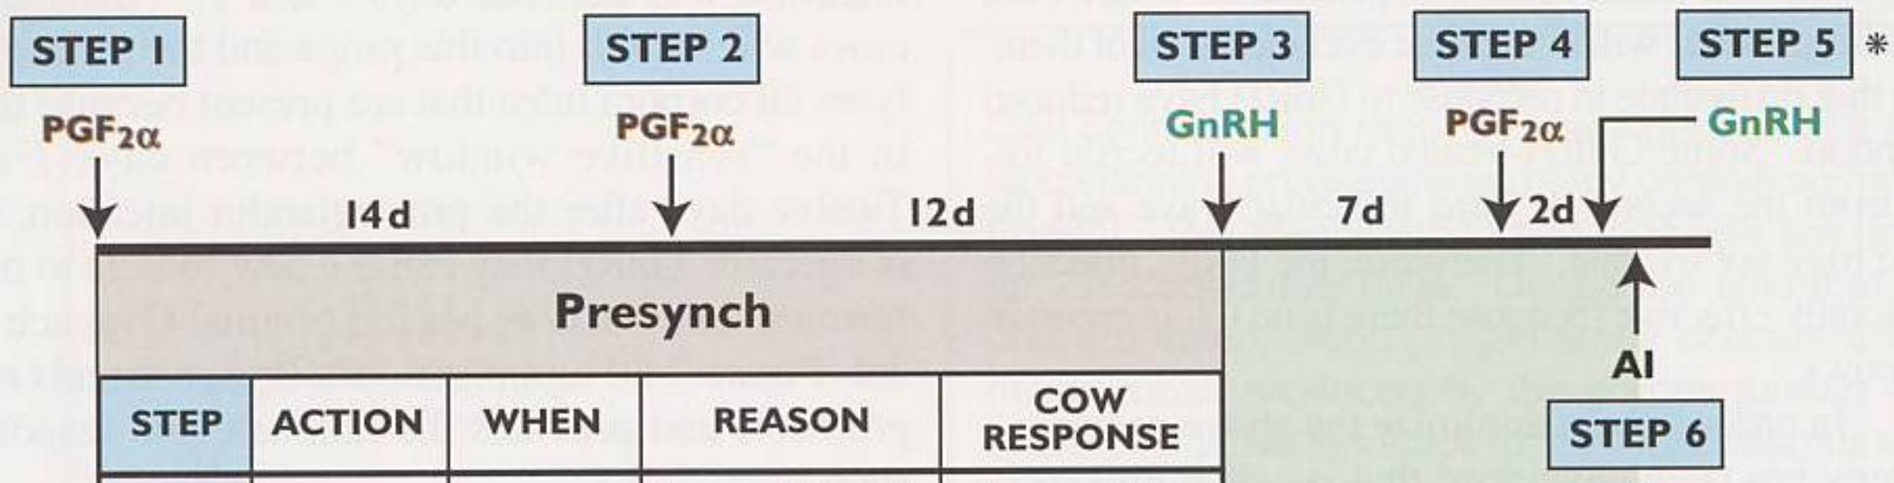


If a single injection of $PGF_{2\alpha}$ is given between day zero and about day six, luteolysis will not occur and the cycle will be of normal length. This is because the corpus luteum must reach a certain stage of development before it is sensitive to $PGF_{2\alpha}$.



If $PGF_{2\alpha}$ is injected on day 7-17, luteolysis will occur. Progesterone will drop and the animal will come into estrus in about three days after the injection. Such a strategy is used to synchronize estrus in large groups of animals.

Figure 9-20. Presynch and Ovsynch as Methods to Synchronize Ovulation in Cows



STEP	ACTION	WHEN	REASON	COW RESPONSE
1	$PGF_{2\alpha}$	Anytime	Lyse existing CL and induce new ovulation	Cow ovulates and produces "new" CL
2	$PGF_{2\alpha}$	14 days after 1st $PGF_{2\alpha}$	Lyse "new" CL. In cows not responding to 1st $PGF_{2\alpha}$ injection - lyse "old" CL.	New follicular phase (↓ P_4)

Ovsynch

STEP	ACTION	WHEN	REASON	COW RESPONSE
3	GnRH	12 days after last $PGF_{2\alpha}$	**Situation A** To cause ovulation in existing dominant follicle (greater than 10mm and that have LH receptors) **Situation B** To cause continued growth of existing immature follicles (few LH receptors). A CL from the current cycle is present at the same time ("old" CL).	**Situation A** The LH surge causes ovulation of the existing dominant follicle, a new CL is formed and a new follicular wave starts. **Situation B** Continued follicular growth towards follicular dominance (CL of the cycle still present)
4	$PGF_{2\alpha}$	7 days after last GnRH	**Situation A** To lyse "new" CL (resulting from previous GnRH injection) **Situation B** To lyse either "old" CL or both the "old" CL and the "new" CL (from GnRH injection)	**Situation A** Cow enters follicular phase and new dominant follicle develops **Situation B** Follicle from first GnRH injection (Step 3) continues to grow and becomes dominant. The "old" CL is lysed.
5	GnRH	2 days after last $PGF_{2\alpha}$	**Situation A** To cause ovulation of dominant follicle **Situation B** To cause ovulation of dominant follicle	**Situation A** Ovulation in 24-32 hours **Situation B** Ovulation in 24-32 hours
6	Insemination	16 hours after GnRH	Sperm in tract before ovulation fertilization	30-40% conception

*In another strategy, called Heatsynch, the GnRH (step 5) is replaced by estradiol cypionate (ECP) 24 hours after $PGF_{2\alpha}$ (Step 4). Timed AI occurs 48 hours after ECP. In the Heatsynch strategy, exogenous estradiol promotes the GnRH surge.

Further PHENOMENA *for* Fertility

Female elephants have a uniquely long estrous cycle (16 weeks) and a gestation of 22 months. What does this say about elephant CL?

The regression of the corpus luteum in humans and other primates is not controlled by the uterus. However, $PGF_{2\alpha}$ will induce luteolysis in primates. It is believed that $PGF_{2\alpha}$ of ovarian origin is responsible for causing luteal regression.

The corpus luteum of most rodents (rats, mice, hamsters and gerbils) does not develop unless copulation occurs. Penile stimulation of the cervix causes prolactin release from the female. Prolactin is luteotropic and causes the formation of corpora lutea.

Some spiders have no penis. They eject sperm from their abdomen onto their web. The male spider picks up the ejaculate with a special set of antennae and searches for a receptive female who produces a pheromone. The male has to be very careful and deposit the semen by surprise because the female will eat him if she catches him.

The luteal phase of the estrous cycle of the kangaroo is longer than pregnancy.

Researchers at N.C. State University observed a sow that had 128 corpora lutea on both of her ovaries. This is ten times the normal number of corpora lutea. The cause of such a high number of ovulations is unknown.

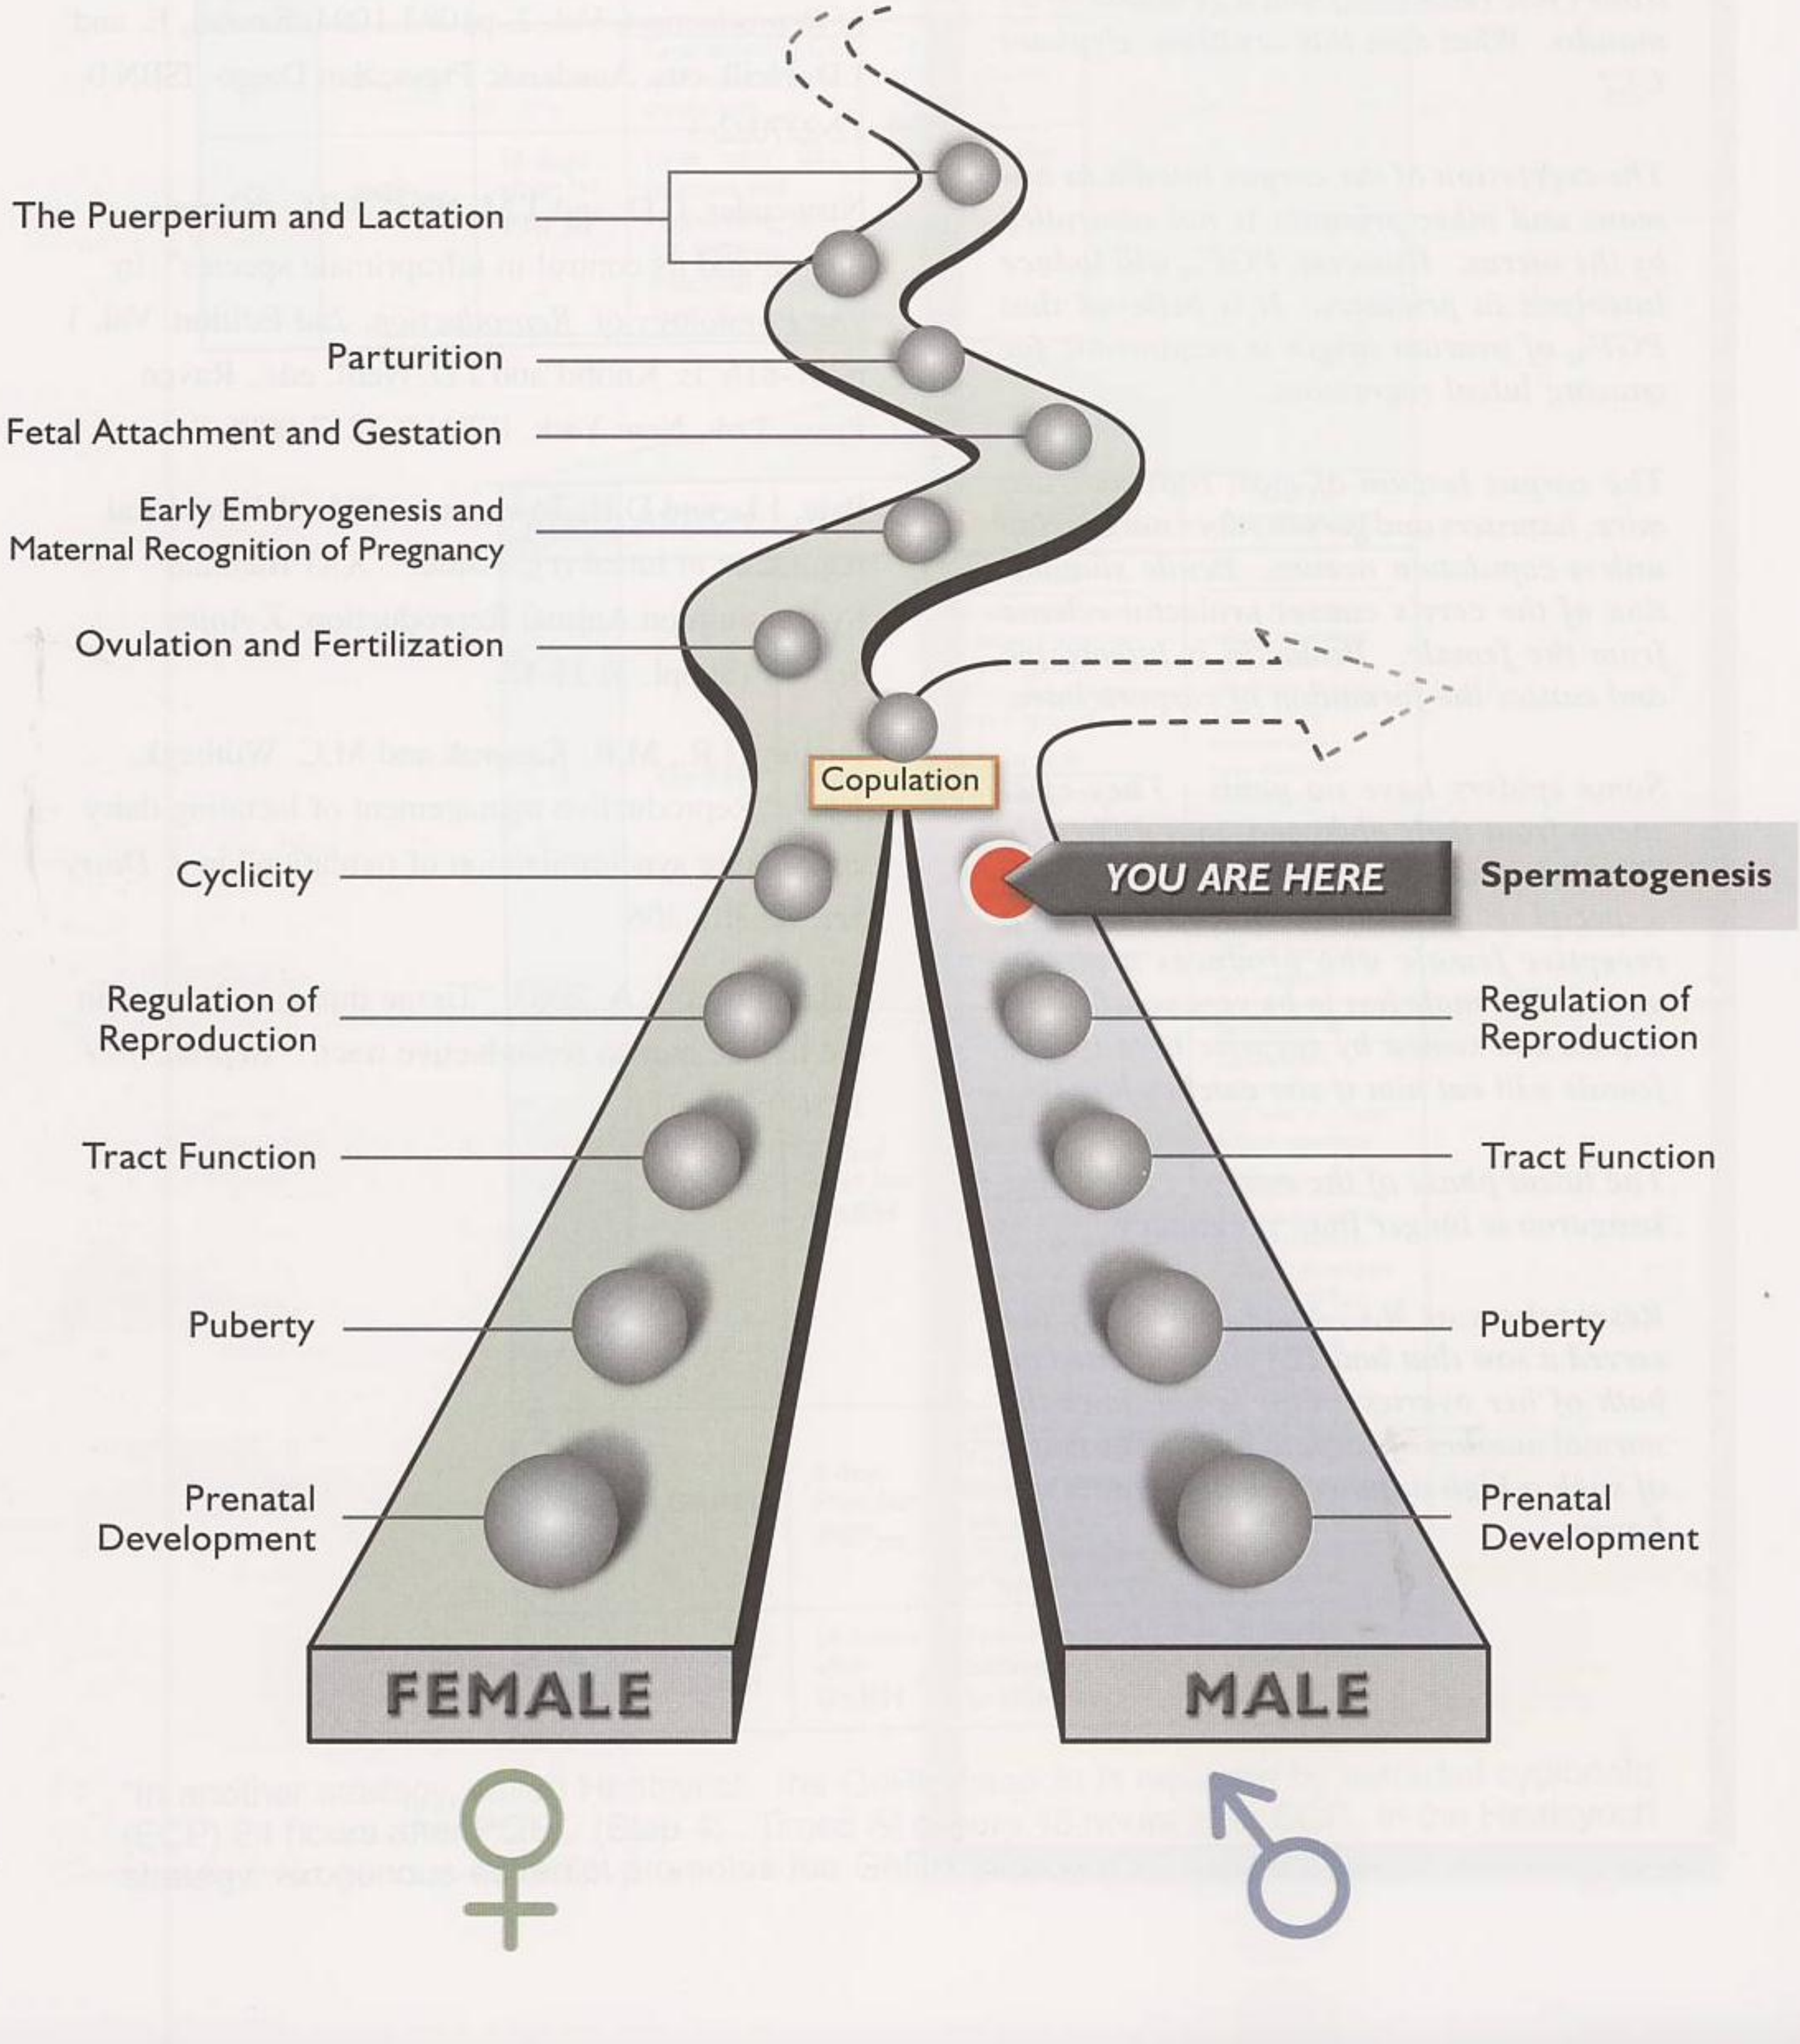
CHAPTER 10

Endocrinology of the Male and Spermatogenesis



Take Home Message

In the adult male, GnRH, LH and testosterone are released in pulses that occur every several hours. Follicle stimulating hormone is released in smaller pulses of longer duration. Spermatozoa are produced by the testes by a process called spermatogenesis that requires 5 to 9 weeks, depending on the species. The number of sperm produced each day is independent of the number ejaculated and spermatozoa are released constantly from the testes. Spermatogenesis is a process involving sequential mitotic and meiotic divisions and concludes after differentiation of spherical spermatids into highly specialized spermatozoa. Spermatozoa are released continually from the seminiferous epithelium.

Endocrine Control/Regulation is Different than in the Female

Before spermatozoa can be produced, certain endocrine requirements must be met. They are: 1) adequate secretion of GnRH from the hypothalamus; 2) FSH and LH secretion from the anterior lobe of the pituitary and 3) secretion of gonadal steroids (testosterone and estrogen). Recall from Chapter 6 that the hypothalamus in the male does not develop a surge center. In the female, basal release is followed by a preovulatory surge of GnRH every few weeks. The discharge of GnRH from the hypothalamus in the male occurs in frequent, intermittent bursts that occur throughout the day and night. These bursts of GnRH last for a few minutes and cause discharges of LH that follow almost immediately after the GnRH episode. The episodes of LH last from 10 to 20 minutes and occur between 4 to more than 8 times every 24 hours. Concentrations of FSH are lower, but the pulses are of longer duration than LH (See Figure 10-1) because of the relatively constant secretion of inhibin by the adult testis and the longer half-life of FSH.

Luteinizing hormone acts on the **Leydig cells** within the testes. These cells, named after the German anatomist Franz von Leydig, are analogous to the cells of the theca interna of antral follicles in the ovary. They contain membrane-bound receptors for LH. When LH binds to their receptors, Leydig cells produce progesterone, most of which is converted to testosterone. The production of testosterone takes place by the same intracellular mechanism as in the female (See Chapters 5 and 8). The Leydig cells synthesize and secrete testosterone less than 30 minutes after the onset of an LH episode. Blood LH is elevated for about 30 to 75 minutes. The response (testosterone secretion) by Leydig cells is short and secretion is pulsatile, lasting for a period of 20 to about 60 minutes (See Figure 10-2).

Leydig cells are the male equivalent of the follicular theca interna cells.

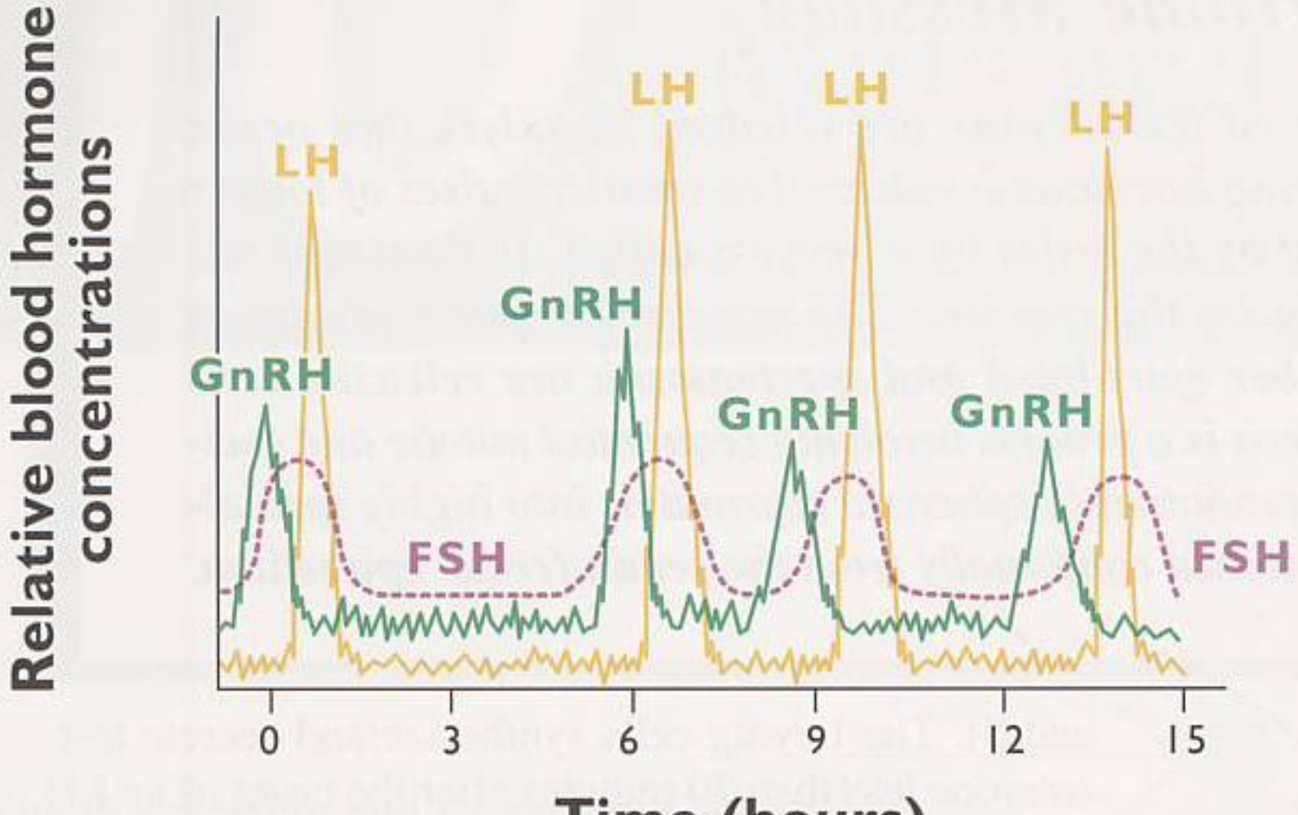
Sertoli cells are the male equivalent of the follicular granulosal cells.

It is believed that the pulsatile discharge of LH is important for two reasons. First, high concentrations of testosterone within the seminiferous tubule are essential for spermatogenesis. Second, Leydig cells become **refractory** to sustained high levels of LH. In fact, continual high concentrations of LH result in reduced secretion of testosterone. From a physiologic perspective the term refractory means unresponsive, or not yielding to treatment. The refractory condition brought about by sustained high concentrations of LH is believed to be caused by a reduction in the number of LH receptors in the Leydig cell. Thus, there is a marked reduction in testosterone secretion when LH remains high for a sustained period. Intratesticular levels of testosterone are 100-500 times higher than that of systemic blood. However, testicular testosterone

Production of normal numbers of fertile spermatozoa requires:

- ***endocrine regulation of the testis***
- ***mitotic divisions of spermatogonia***
- ***meiotic divisions resulting in haploid spermatids***
- ***morphologic transformation of spermatids into spermatozoa***

Figure 10-1. Relationship Between GnRH, LH and FSH in the Male



GnRH causes the release of LH and FSH. Episodes of all three hormones occur between 4 and 8 times in 24 hours. The lower FSH profile, when compared to LH, is due to inhibin secretion by Sertoli cells. Also, the greater duration of the FSH episode is probably due to its longer half-life (100 min) when compared to LH (30 min).

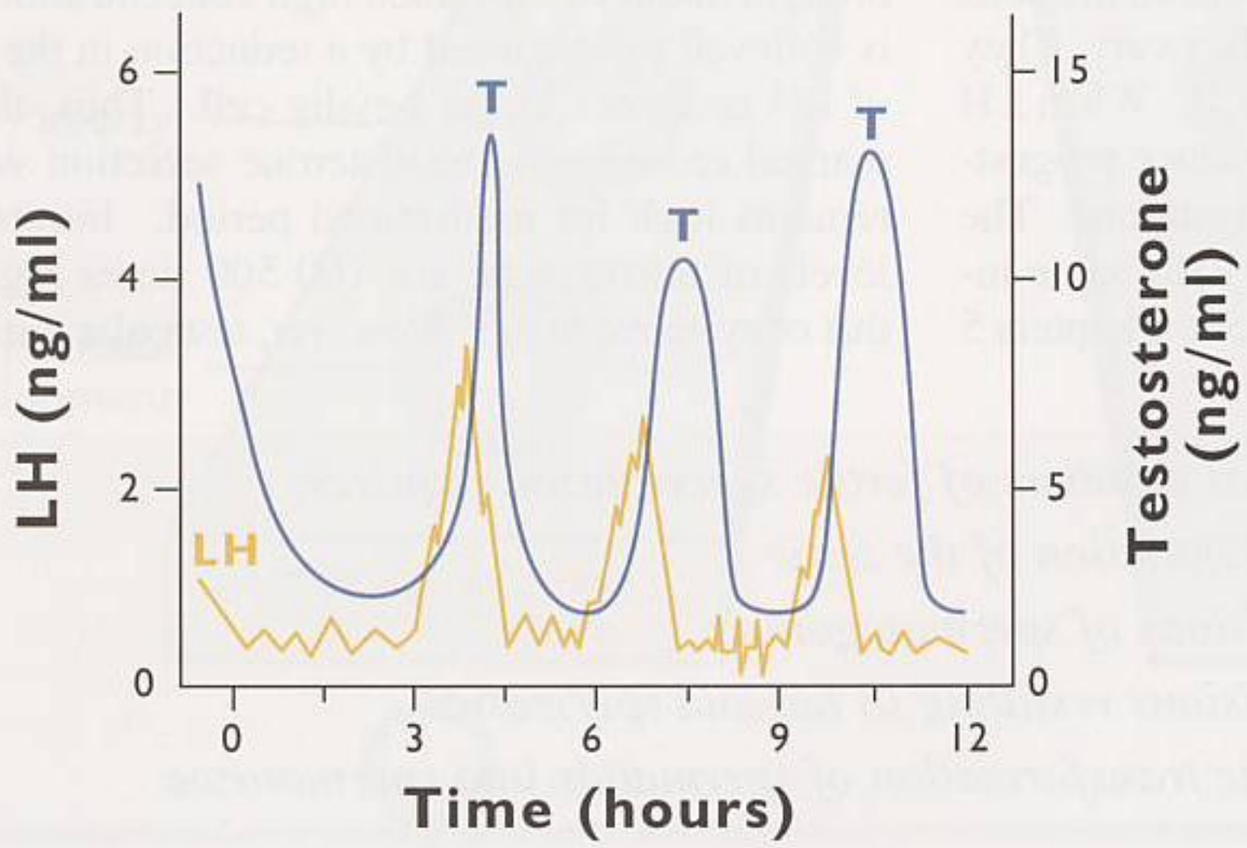
is diluted over 500 times when it reaches the peripheral blood. Dilution coupled with the relatively short half-life of testosterone keeps systemic concentrations well below that which would cause down-regulation of the GnRH/LH feedback system. For example, if the LH pulses were long (hours), the Leydig cells would produce testosterone for hours rather than minutes. This would likely result in a metabolic failure to clear testosterone from the systemic blood and testosterone would exert sustained negative feedback on the GnRH neurons in the hypothalamus. Such a sustained negative feedback would eventually stop LH secretion and therefore stop testosterone secretion. Spermatogenesis therefore would not occur.

The role of the pulsatile nature of testosterone is not fully understood. It is believed that chronically high systemic concentrations of testosterone suppress FSH secretion. Sertoli cell function is FSH dependent. Thus, their function is compromised when FSH is reduced. The periodic reduction in testosterone allows the negative feedback on FSH to be removed (See Figure 10-3).

In addition to production of testosterone by the Leydig cells, the testes also produce estradiol and other estrogens. The stallion and the boar secrete large amounts of estrogens (both free and in conjugated form). In fact, urinary estrogens in the male are significantly higher than urinary estrogens in pregnant mares and sows. These high concentrations of estrogen seem to be of little consequence, since they are secreted as molecules with low physiologic activity.

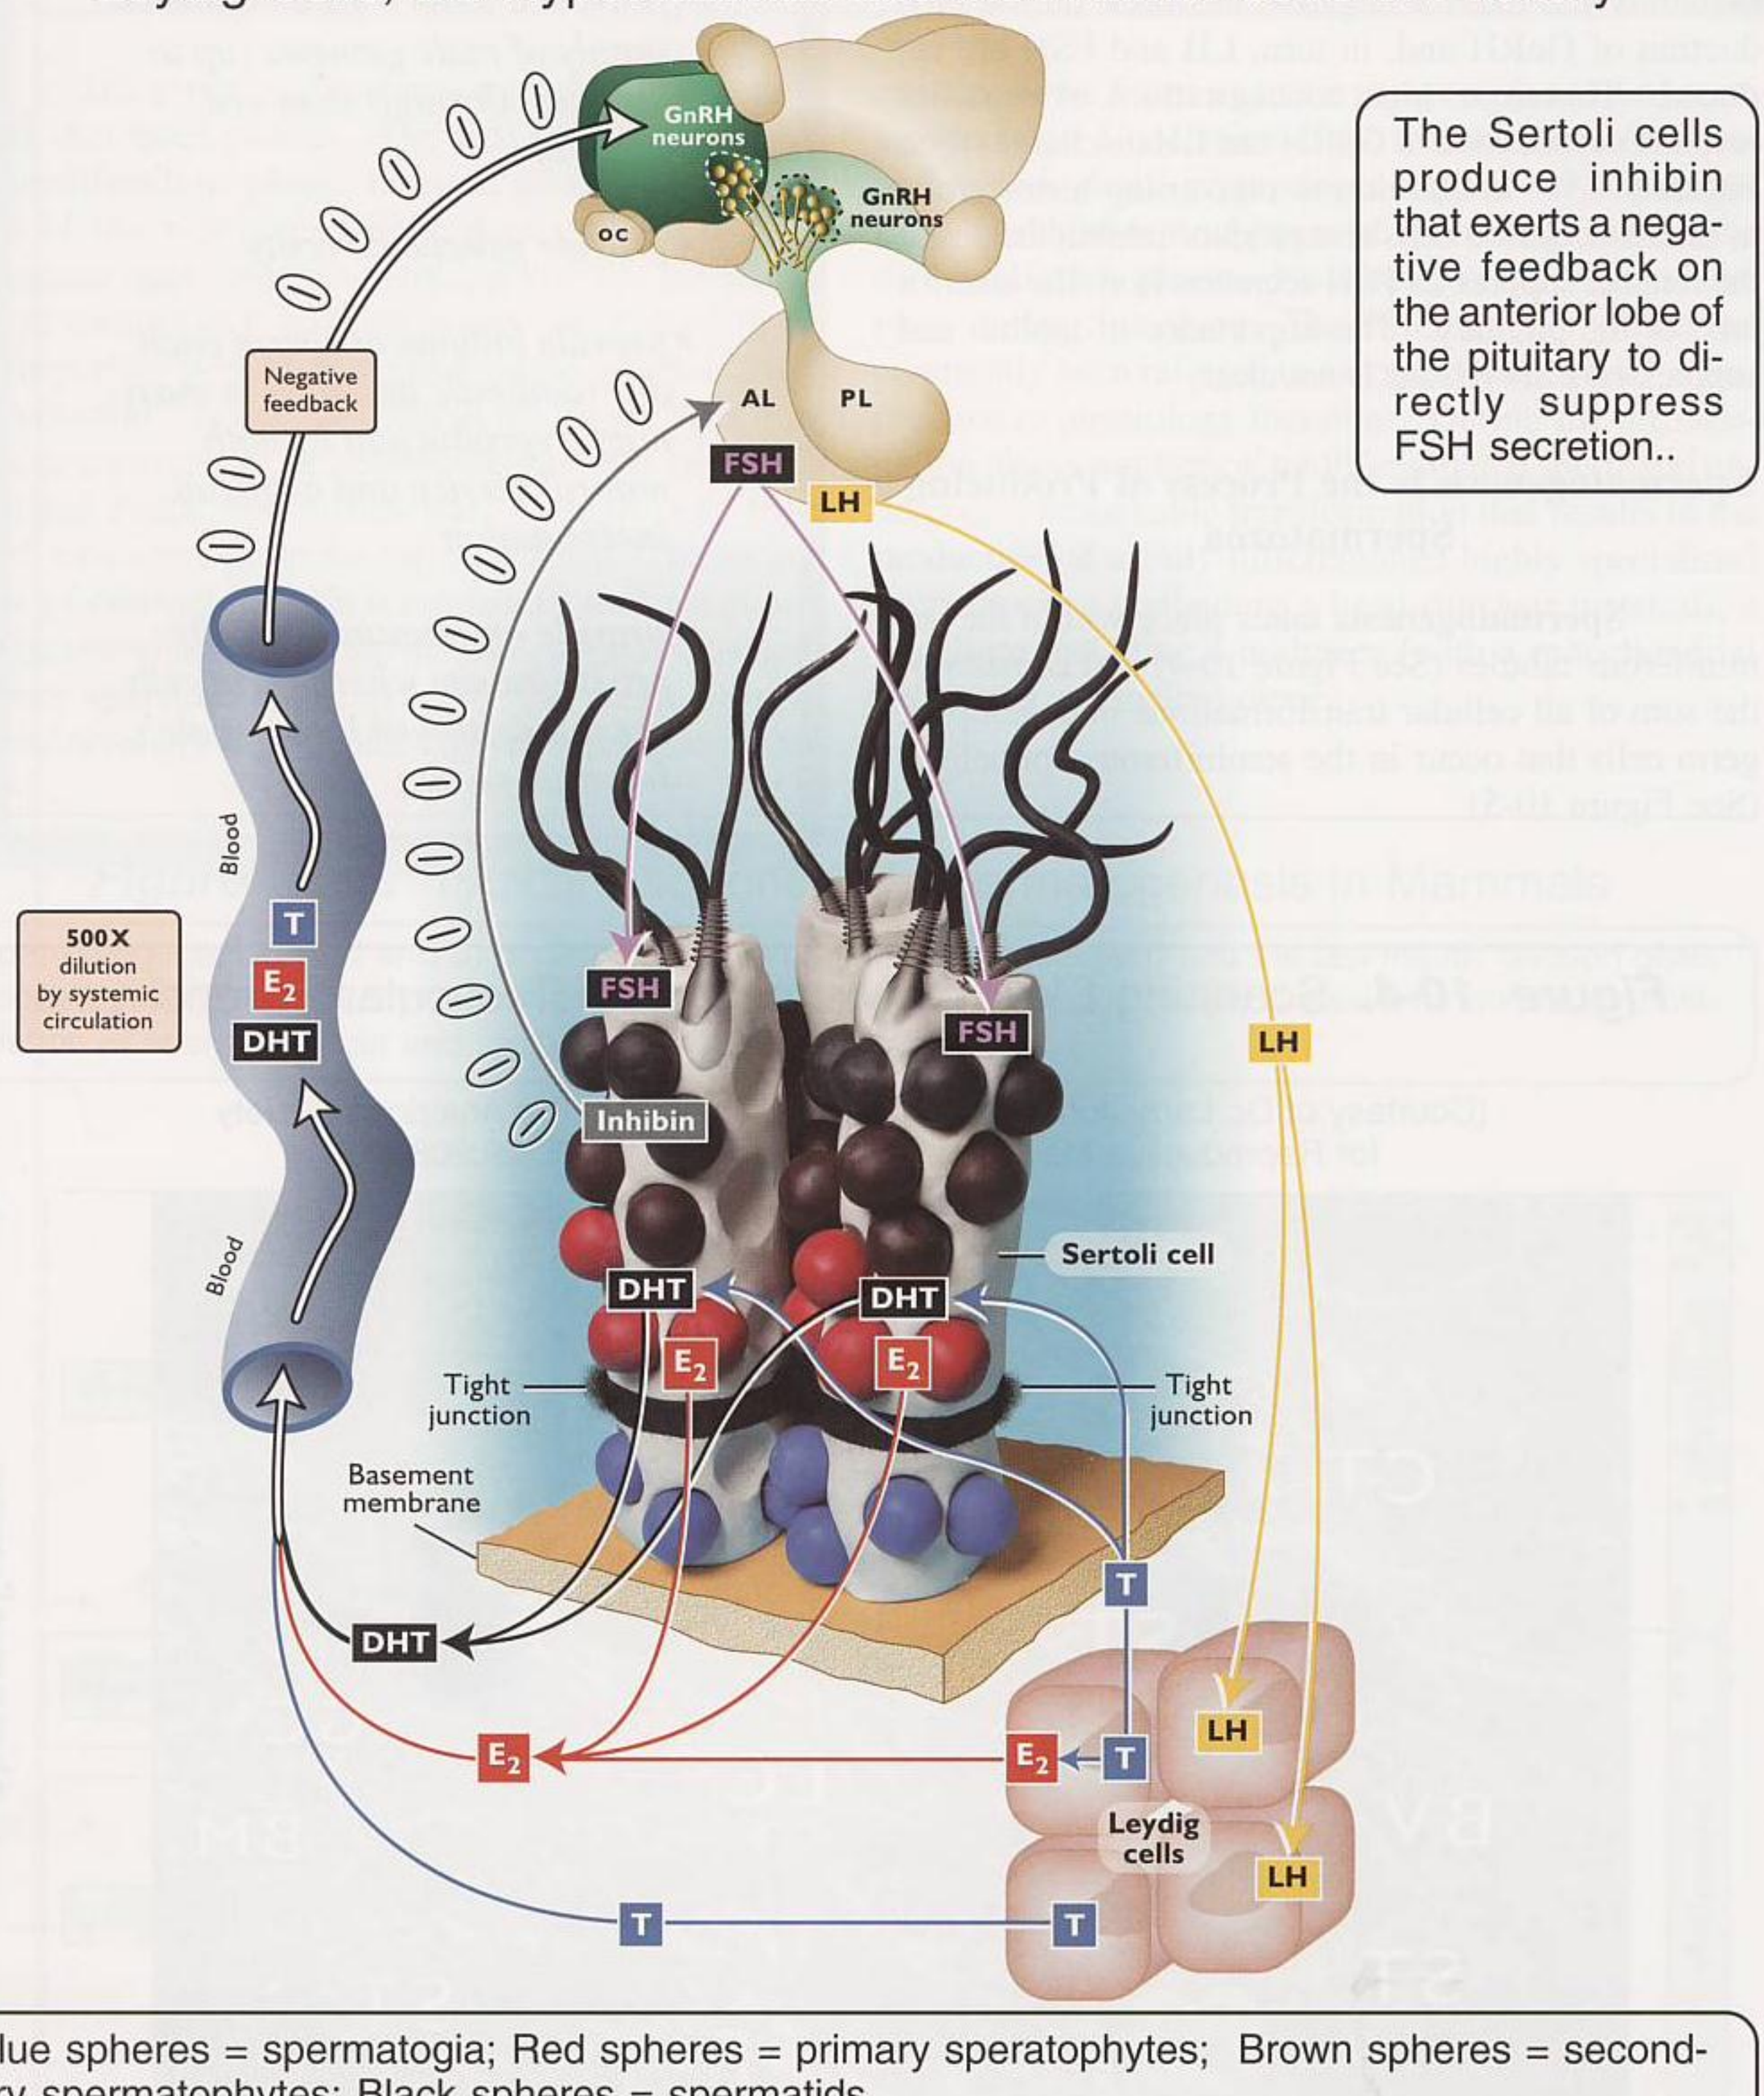
Sertoli cells convert testosterone to estradiol utilizing a mechanism identical to the granulosal cells of the antral follicle in the female. The exact role of estradiol in male reproduction is poorly understood, but there is little doubt that this hormone has a

Figure 10-2. Typical Peripheral Concentrations of Blood LH and Testosterone (T) in the Male



LH is elevated for a period of 0.5 to 1.25 hours, while the subsequent testosterone (T) episode lasts for 0.5 to 1.5 hours.

Figure 10-3. Interrelationships Among Hormones Produced by Sertoli Cells, Leydig Cells, the Hypothalamus and the Anterior Lobe of Pituitary



The Sertoli cells produce inhibin that exerts a negative feedback on the anterior lobe of the pituitary to directly suppress FSH secretion..

Blue spheres = spermatogia; Red spheres = primary speratophytes; Brown spheres = secondary spermatophytes; Black spheres = spermatids

Testosterone (T) produced by the Leydig cells is transported into the Sertoli cells where it is converted to dihydrotestosterone (DHT) and also estrogen (E_2). Testosterone and E_2 are transported by the blood to the hypothalamus where they exert a negative feedback on the GnRH neurons.

LH binds to receptors in the interstitial cells of Leydig and FSH binds to Sertoli cells. Leydig cells produce testosterone that is transported to the adjacent vasculature and the Sertoli cells where T is converted to DHT.

negative feedback role on the hypothalamus. Testosterone and estradiol in the blood act on the hypothalamus and exert a negative feedback on the production of GnRH and, in turn, LH and FSH are reduced. Therefore, high concentrations of estradiol result in suppression of GnRH and LH discharges (See Figure 10-3). In addition to converting testosterone to estradiol, Sertoli cells also produce inhibin that, as in the female, suppresses FSH secretion from the anterior lobe of the pituitary. The importance of inhibin and suppressed FSH release is not clear.

The goals of spermatogenesis are to:

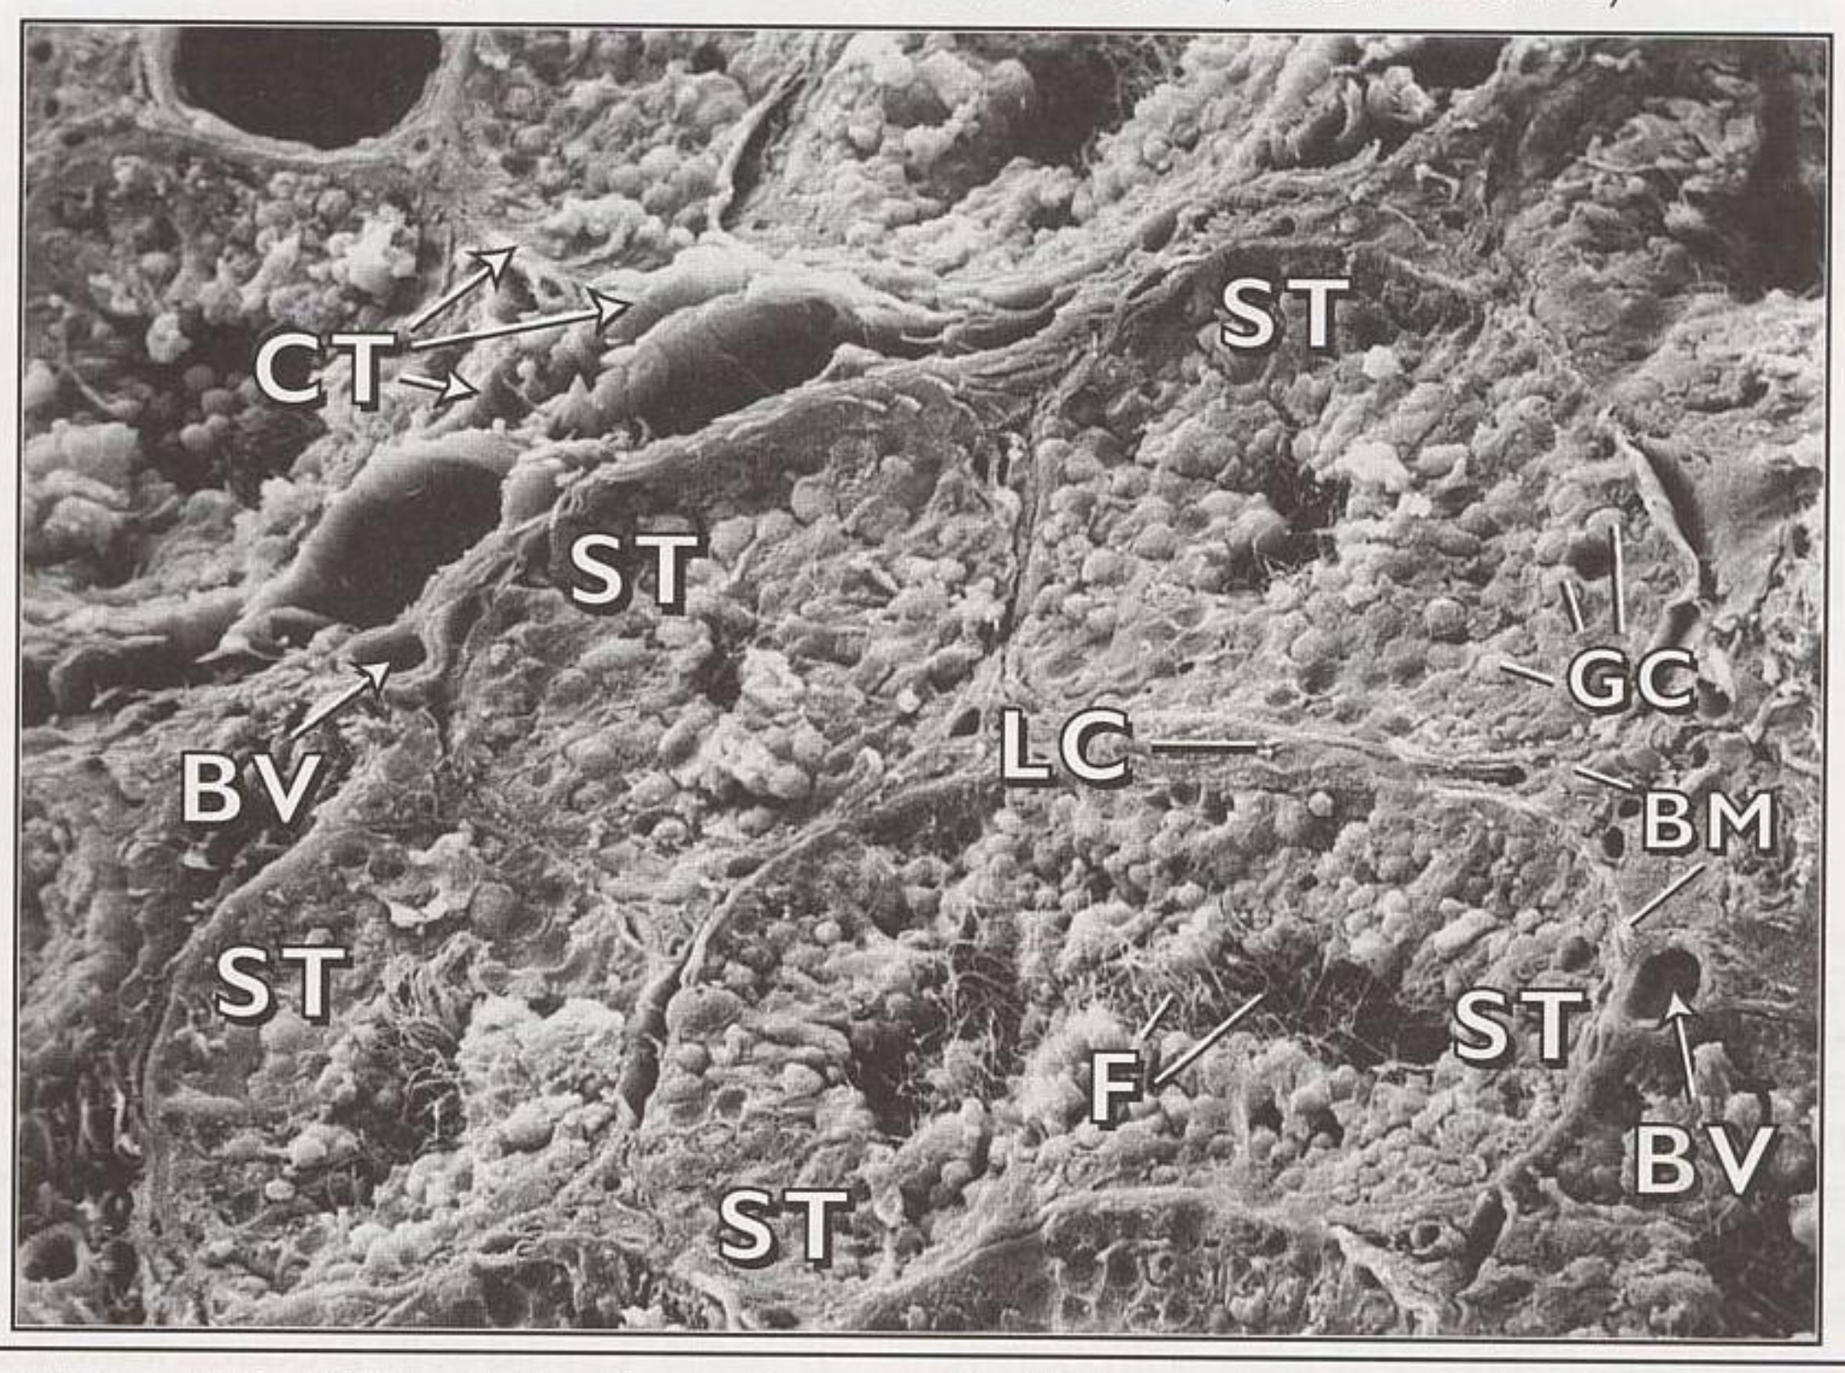
- *provide a male with a continual supply of male gametes (up to decades) through stem cell renewal*
- *provide genetic diversity*
- *provide billions of sperm each day (domestic animals) to maximize reproduction by both natural service and artificial insemination*
- *provide an immunologically privileged site where germ cells are not destroyed by the male's immune system*

Spermatogenesis is the Process of Producing Spermatozoa

Spermatogenesis takes place within the seminiferous tubules (See Figure 10-4) and consists of the sum of all cellular transformations in developing germ cells that occur in the seminiferous epithelium (See Figure 10-5).

Figure 10-4. Scanning Electron Micrograph of Testicular Parenchyma in the Stallion

(Courtesy of Dr. Larry Johnson, Texas A&M University, The American Society for Reproductive Medicine. *Fertil. and Steril.*, 1978. 29:208-215)



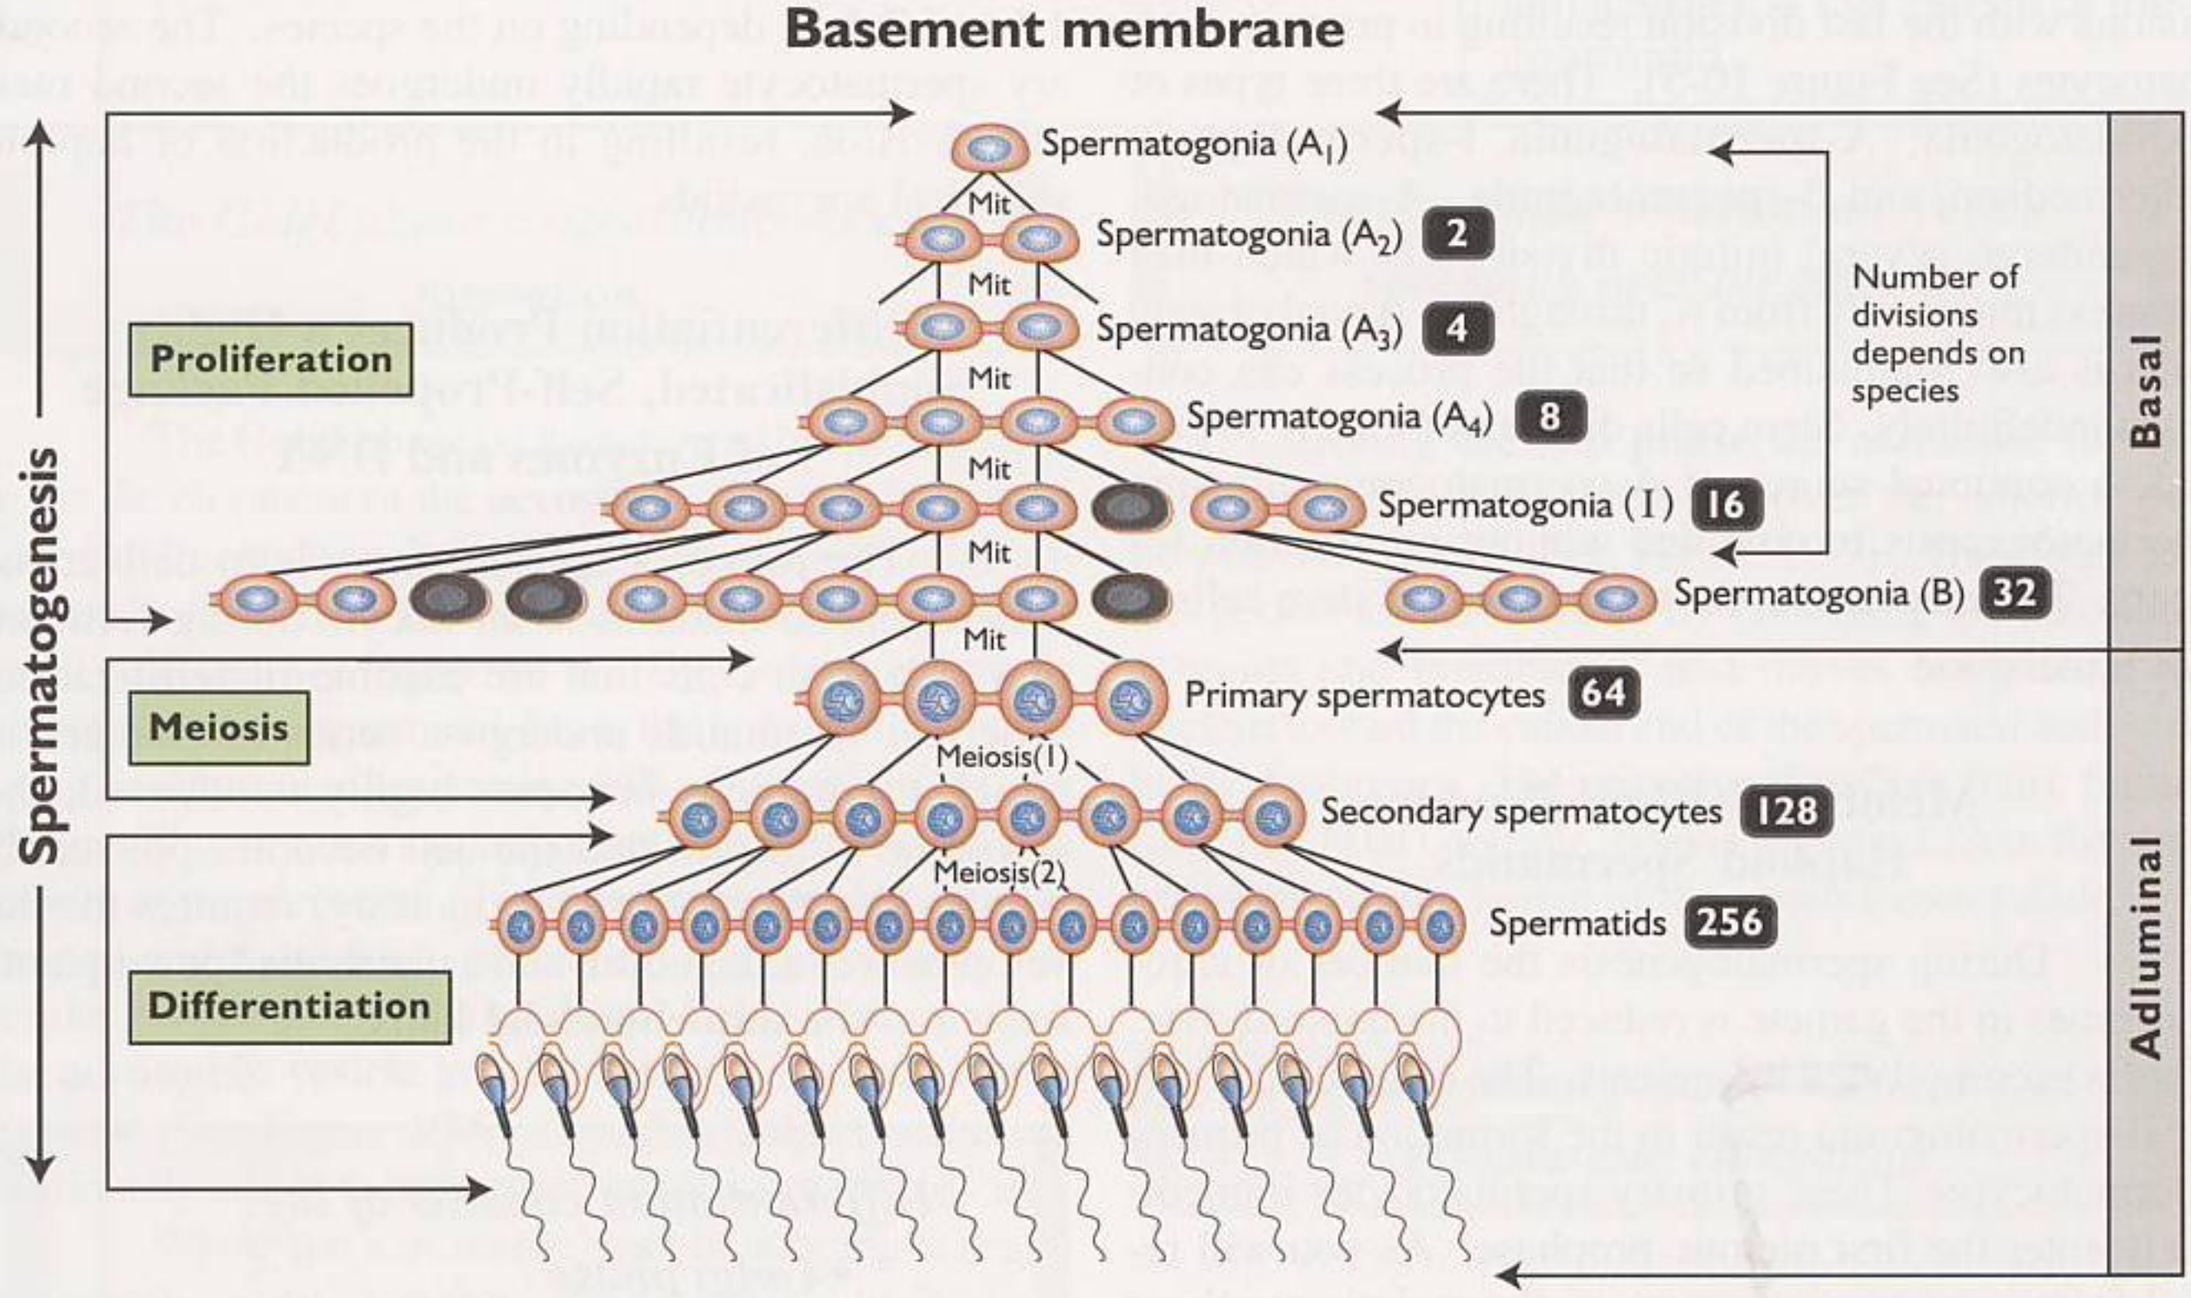
Seminiferous tubules (ST) containing developing germ cells (GC) are surrounded by a basement membrane (BM). Flagella (F) from developing spermatids can be observed protruding into the lumen of some tubules. The interstitial compartment contains Leydig cells (LC), blood vessels (BV) and connective tissue (CT).

Spermatogenesis = proliferation + meiosis + differentiation

The process of spermatogenesis can be subdivided into three phases. The first phase, designated the **proliferation phase**, consists of all mitotic divisions of spermatogonia. Several generations of spermatogonia each undergo mitotic divisions, generating a large number of B-spermatogonia (See Figure 10-5). An important part of the proliferation phase is **stem cell renewal**. Some spermatogonia revert back to a more primitive type of spermatogonia thus providing continual replacement (renewal) of stem cells from which new spermatogonia can be derived. The second phase of spermatogenesis is termed the **meiotic phase**. The second or meiotic phase involves **primary** and **secondary spermatocytes**. During the meiotic phase, genetic diversity is guaranteed by DNA replication and crossing over. From a genetic perspective no two sperm are identical. Conclusion of the meiotic phase (the second meiotic division) produces haploid (1N) **spermatids**. The third or final phase of spermatogenesis is the **differentiation phase**. No further cell divisions take place during this phase. The differentiation phase has commonly been referred to as **"spermiogenesis"** in reproductive physiology literature. During the differentiation phase, a spherical undifferentiated spermatid undergoes a remarkable transformation that results in the production of a fully differentiated highly specialized spermatozoon containing a head (nuclear material), a flagellum including a midpiece (with a mitochondrial helix) and a principal piece.

Figure 10-5. Typical Sequence of Spermatogenesis in Mammals

Spermatogonia (A_1-A_4, I and B) undergo a series of mitotic divisions (Mit) and the last mitotic division gives rise to primary spermatocytes that enter meiosis. This series of mitotic divisions allows for continual proliferation of spermatogonia and replacement of A_1 spermatogonia.



After meiosis, haploid spherical spermatids differentiate into spermatozoa. Meiosis and differentiation take place in the adluminal compartment. Notice that each generation of cells is attached by intercellular cytoplasmic bridges. Thus, each generation divides synchronously in cohorts. Some cells (black) degenerate during the process. Numbers indicate the theoretical number of cells generated by each division.

The most immature germ cells (spermatogonia) are located at the periphery of a seminiferous tubule near the basement membrane. As these germ cells proliferate and mature they move toward the lumen. The cell types in the seminiferous epithelium are illustrated in Figure 10-5. Developing germ cells are connected by **intercellular bridges**. Groups of spermatogonia, spermatocytes or spermatids are connected by intercellular bridges, so that the cytoplasm of an entire cohort (groups of cells of the same type) is interconnected. The exact number of germ cells that are interconnected is not known, but might approach 50. The significance of these intercellular bridges is not fully understood. However, they do provide communication between cells and this might contribute to synchronized development of a cohort.

Proliferation Generates Spermatogonia that are Committed to Become More Advanced Cell Types

The most primitive cells encountered in the seminiferous epithelium are the spermatogonia. These specialized diploid (2N chromosomal content) cells are located in the **basal compartment** of the seminiferous epithelium. Spermatogonia undergo several mitotic divisions with the last division resulting in primary spermatocytes (See Figure 10-5). There are three types of spermatogonia: **A-spermatogonia**, **I-spermatogonia** (intermediate) and **B-spermatogonia**. A-spermatogonia undergo several mitotic divisions in which they progress mitotically from A_1 through A_4. A pool of stem cells is also maintained so that the process can continue indefinitely. Stem cells divide mitotically to provide a continual source of A-spermatogonia allowing spermatogenesis to continue without interruption for years. The mechanism for the renewal of stem cells is not understood.

10

Meiotic Divisions Produce Haploid Spermatids

During spermatogenesis the number of chromosomes in the gamete is reduced to the haploid state. This is accomplished by meiosis. The mitotic divisions of B-spermatogonia result in the formation of primary spermatocytes. These primary spermatocytes immediately enter the first meiotic prophase. As you will recall from your previous courses, the meiotic prophase consists of five stages: preleptotene, leptotene, zygotene, pachytene and diplotene. Each of these stages represents a different step in the progression of DNA synthesis and replication. Primary spermatocytes must progress from interphase (immediately after their division) through this series of changes before the first meiotic division can occur. The important event of the preleptotene phase is complete DNA replication forming tetrads without separation. These tetrads then fuse at random points known as chiasmata and **crossing-over** of DNA material later takes place. The term "crossing-over" refers to segments of one chromosome crossing-over to a homologous chromosome when the chromatids separate. Crossing-over results in a random assortment of different segments of each chromosome. Thus, the prophase of the first meiotic division insures that genetic heterogeneity exists and that each secondary spermatocyte and spermatid will be genetically unique. Recognize that the prophase of the first meiotic division is a relatively long process. In fact, the lifespan of the primary spermatocyte is the longest of all germ cell types found in the seminiferous epithelium. For example, in the bull the lifespan of the primary spermatocyte is 18 to 19 days. The total duration of spermatogenesis in bulls is 61 days. Thus, the prophase of the first meiotic division (primary spermatocyte) occupies about 30% of the time required for the entire spermatogenic process.

After the first division of meiosis the primary spermatocyte becomes a secondary spermatocyte. The secondary spermatocyte is short-lived, existing for only 1.1 to 1.7 days depending on the species. The secondary spermatocyte rapidly undergoes the second meiotic division, resulting in the production of haploid spherical spermatids.

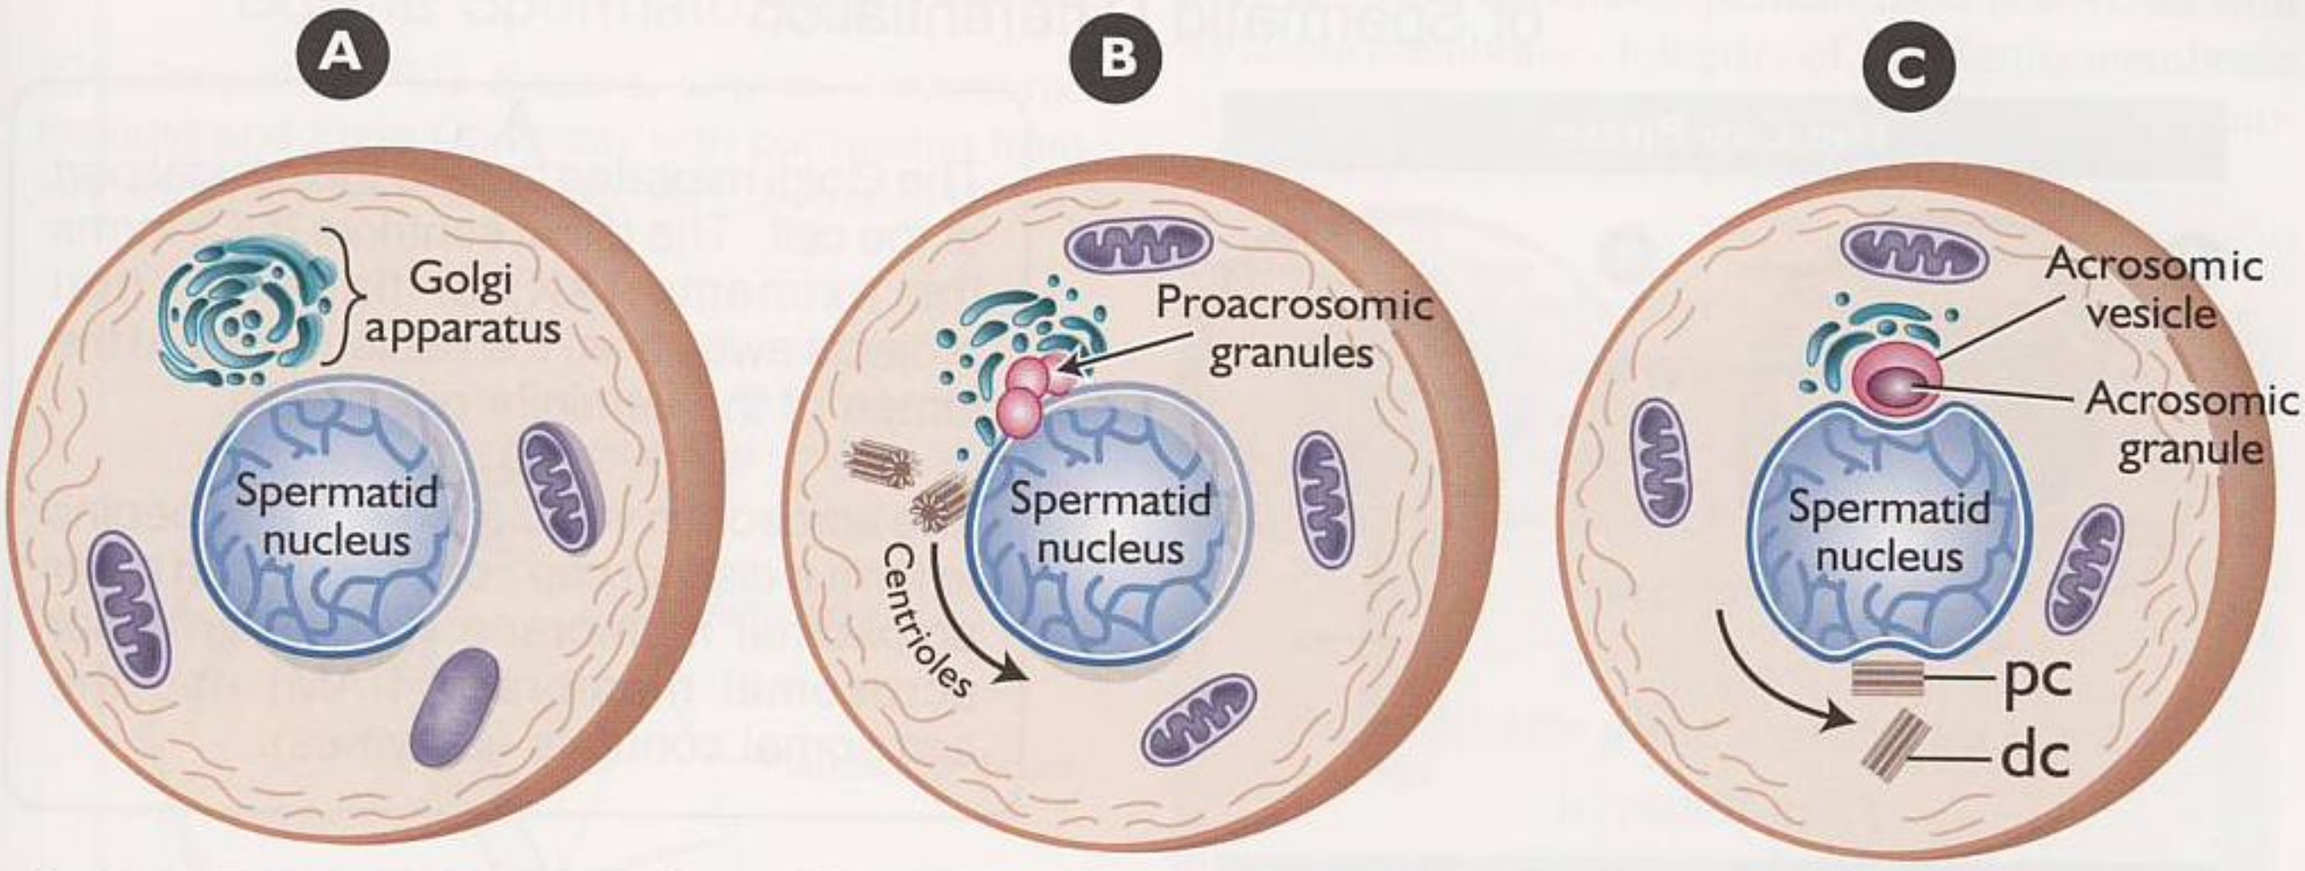
Differentiation Produces a Highly Sophisticated, Self-Propelled Package of Enzymes and DNA

The role of a spermatozoon is to deliver the male's genetic material to an oocyte during fertilization. To form cells that are capable of fertilization, spherical spermatids undergo a series of changes in which the nucleus becomes highly condensed, the acrosome is formed and the cell becomes potentially motile. The ability to swim (motility) requires the development of a **flagellum** and a metabolic "powerplant" known as the **mitochondrial helix**.

Differentiation consists of the:

- ***Golgi phase***
- ***cap phase***
- ***acrosomal phase***
- ***maturation phase***

Figure 10-6. The Golgi Phase of Spermatid Differentiation



The newly formed spermatid is almost perfectly spherical and has a well developed Golgi apparatus.

Small vesicles of the Golgi fuse, giving rise to larger secretory granules called pro-acrosomic granules. The centrioles start to migrate to a position beneath the nucleus that is opposite the acrosomic vesicle.

Vesicle fusion continues until a large acrosomic vesicle is formed that contains a dense acrosomic granule. The proximal centriole (PC) will give rise to the attachment point of the tail. The distal centriole (DC) will give rise to the developing axoneme (central portion of the tail) inside the cytoplasm of the spermatid.

The Golgi phase = acrosomic vesicle formation

The **Golgi phase** is characterized by the first steps in the development of the **acrosome**. The newly formed spermatid contains a large, highly-developed Golgi apparatus located near the nucleus that consists of many small vesicles (See Figure 10-6). The Golgi apparatus is not unique to the spermatid, but is the intracellular "packaging" system in all secretory cells. In a spermatid, the Golgi will give rise to an important subcellular organelle known as the acrosome. First, proacrosomic vesicles are formed and these fuse, generating a larger vesicle that resides on one side of the nucleus. This vesicle is called the **acrosomic vesicle** and contains a dense **acrosomic granule** (See Figure 10-6). Smaller Golgi vesicles are continually added to the larger vesicle increasing its size.

While the acrosomic vesicle is being formed, the centrioles migrate from the cytoplasm to the base of the nucleus (See Figure 10-6). The proximal centriole will give rise to an implantation apparatus that allows the flagellum to be anchored to the nucleus (See Figure 10-9). The distal centriole gives rise to the developing **axoneme**. The axoneme is the central portion of a flagellum, in this case the sperm tail.

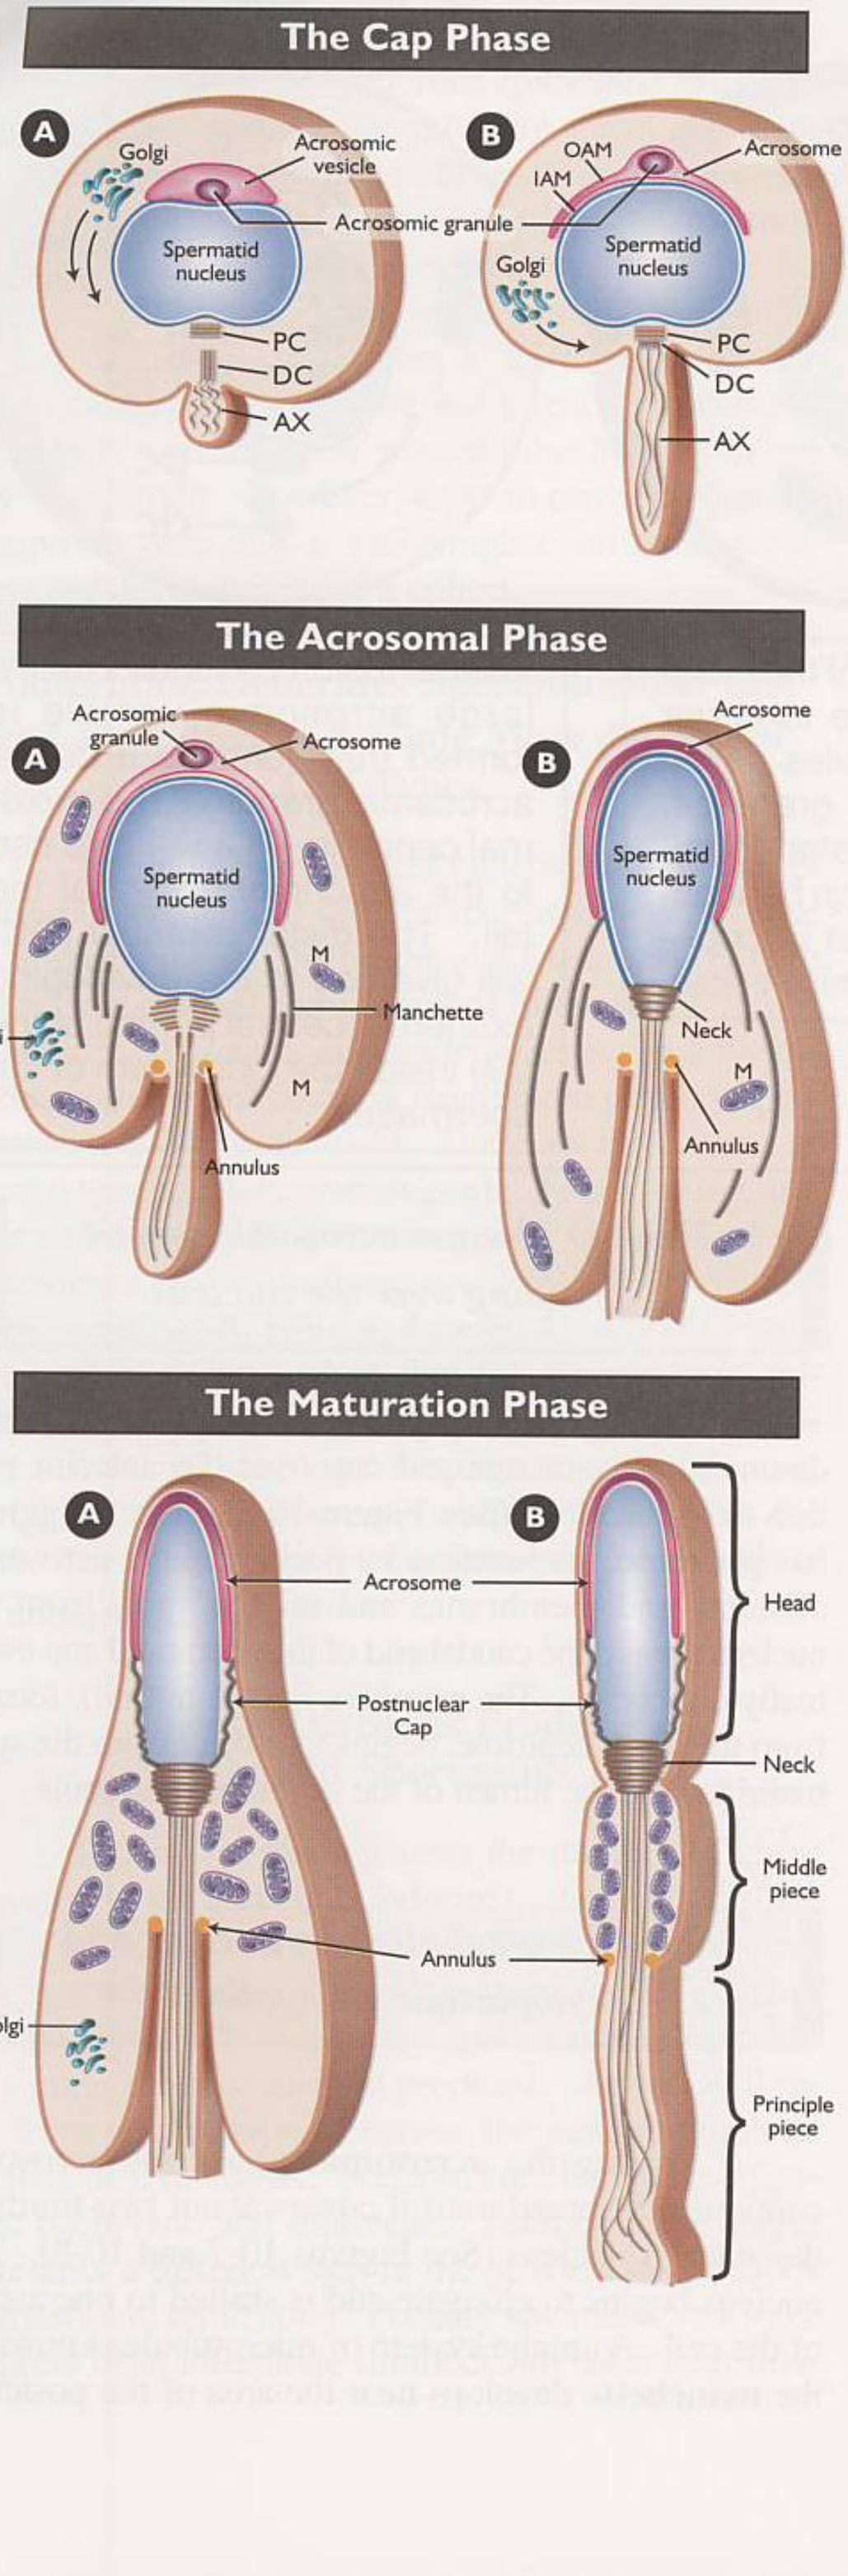
The cap phase = acrosomic vesicle spreading over the nucleus

During the **cap phase** the acrosome forms a distinct, easily recognized cap over the anterior portion of the nucleus (See Figure 10-7). The Golgi now has performed its function by packaging the acrosomal contents and membranes and moves away from the nucleus toward the caudal end of the spermatid and eventually disappears. The primitive flagellum (tail), formed from the distal centriole, begins to project from the spermatid toward the lumen of the seminiferous tubule.

The acrosomal phase = nuclear and cytoplasmic elongation

During the **acrosomal phase** the acrosome continues to spread until it covers about two-thirds of the anterior nucleus (See Figures 10-7 and 10-8). The nucleus begins to elongate and is shifted to one aspect of the cell. A unique system of microtubules known as the **manchette** develops near the area of the posterior

Figure 10-7. The Cap, Acrosomal and Maturation Phases of Spermatid Differentiation



A

The Golgi migrates toward the caudal part of the cell. The distal centriole (DC) forms the axoneme (AX) or flagellum that projects away from the nucleus toward the lumen of the seminiferous tubule.

B

The acrosomic vesicle flattens and begins to form a distinct cap consisting of an outer acrosomal membrane (OAM), an inner acrosomal membrane (IAM) and the acrosomal contents (enzymes).

A

The spermatid nucleus begins to elongate and the acrosome eventually covers the majority of the anterior nucleus. The manchette forms in the region of the caudal half of the nucleus and extends down toward the developing flagellum.

B

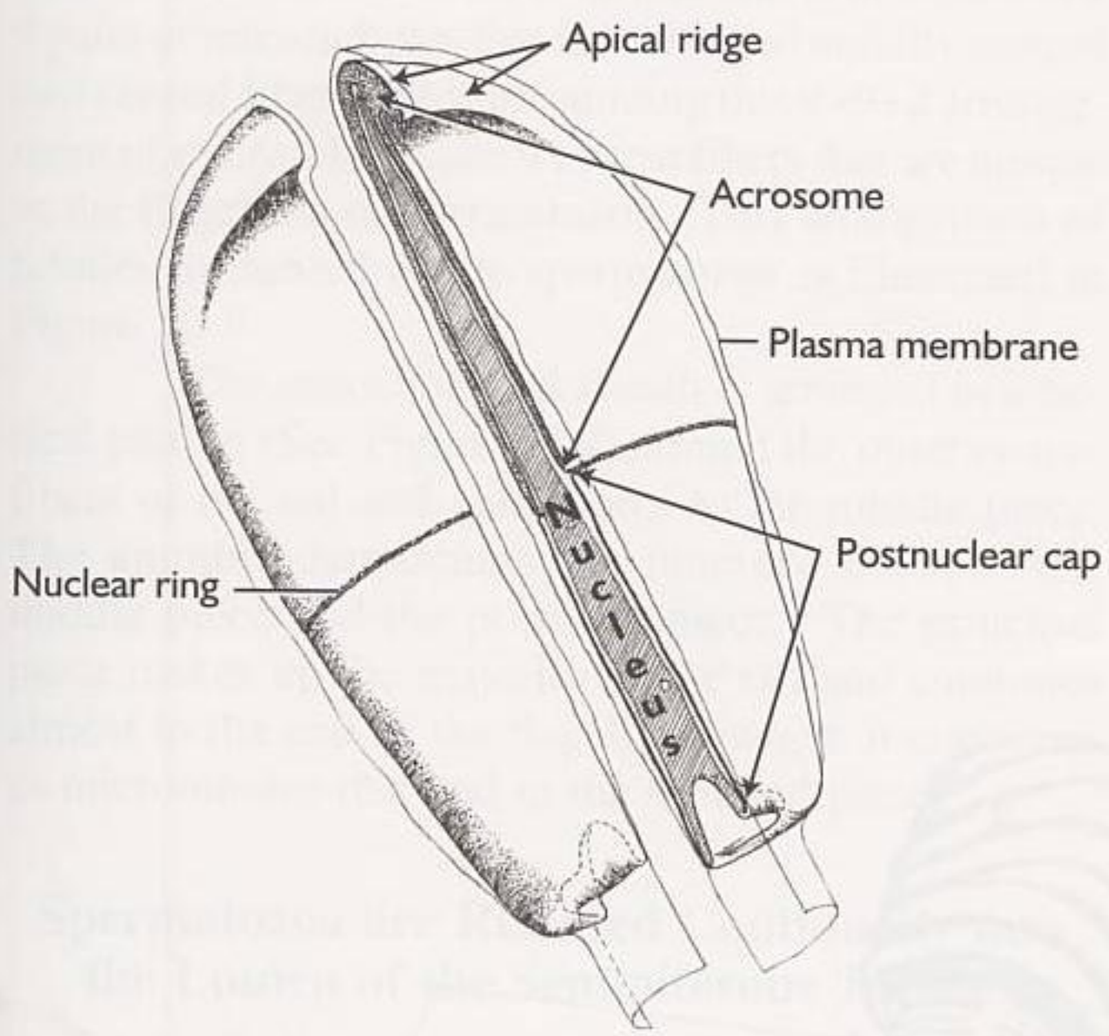
The neck and the annulus are formed and the later will become the juncture between the middle piece and the principal piece. Notice that all components of the developing spermatid are completely surrounded by a plasma membrane. M = mitochondria.

A and B

Mitochondria form a spiral assembly around the flagellum that defines the middle piece. The postnuclear cap is formed from the manchette microtubules. The annulus forms the juncture between the middle piece and the principal piece.

Figure 10-8. The Head of the Bovine Spermatozoon

(Courtesy of Dr. R.G. Saacke, Virginia Polytechnic Institute and State University with permission from John R. Wiley and Sons, Inc. *Am. J. Anat.* 115:143)



nucleus. Portions of the manchette attach to the region of the nucleus just posterior to the acrosome (See Figure 10-7). Some of the **microtubules** of the manchette will become the **postnuclear cap**. During the acrosomal phase, spermatids become deeply embedded in Sertoli cells with their tails protruding toward the lumen of the seminiferous tubule (See Figure 10-4).

The maturation phase = final assembly that forms a spermatozoon

During the **maturation phase** portions of the manchette migrate toward the tail and begin to disappear, while portions of it remain to form the postnuclear cap. Mitochondria migrate toward and cluster around the flagellum in the region posterior to the nucleus. Mitochondria are quickly assembled around the flagellum from the base of the nucleus to the anterior one-third of the tail. They are assembled in a spiral fashion (See Figure 10-9) and form the middle piece in fully differentiated spermatozoa. Dense outer fibers of the flagellum and the fibrous sheath are produced and final assembly is complete. It should be emphasized that, as in any cell, the entire spermatozoon is covered with a plasma membrane. Integrity of the plasma membrane is required for the survival and function of spermatozoa as you will see later in the chapter.

Spermatozoa = head + tail

Head = nucleus + acrosome + post-nuclear cap

Tail = middle piece + principal piece + terminal piece

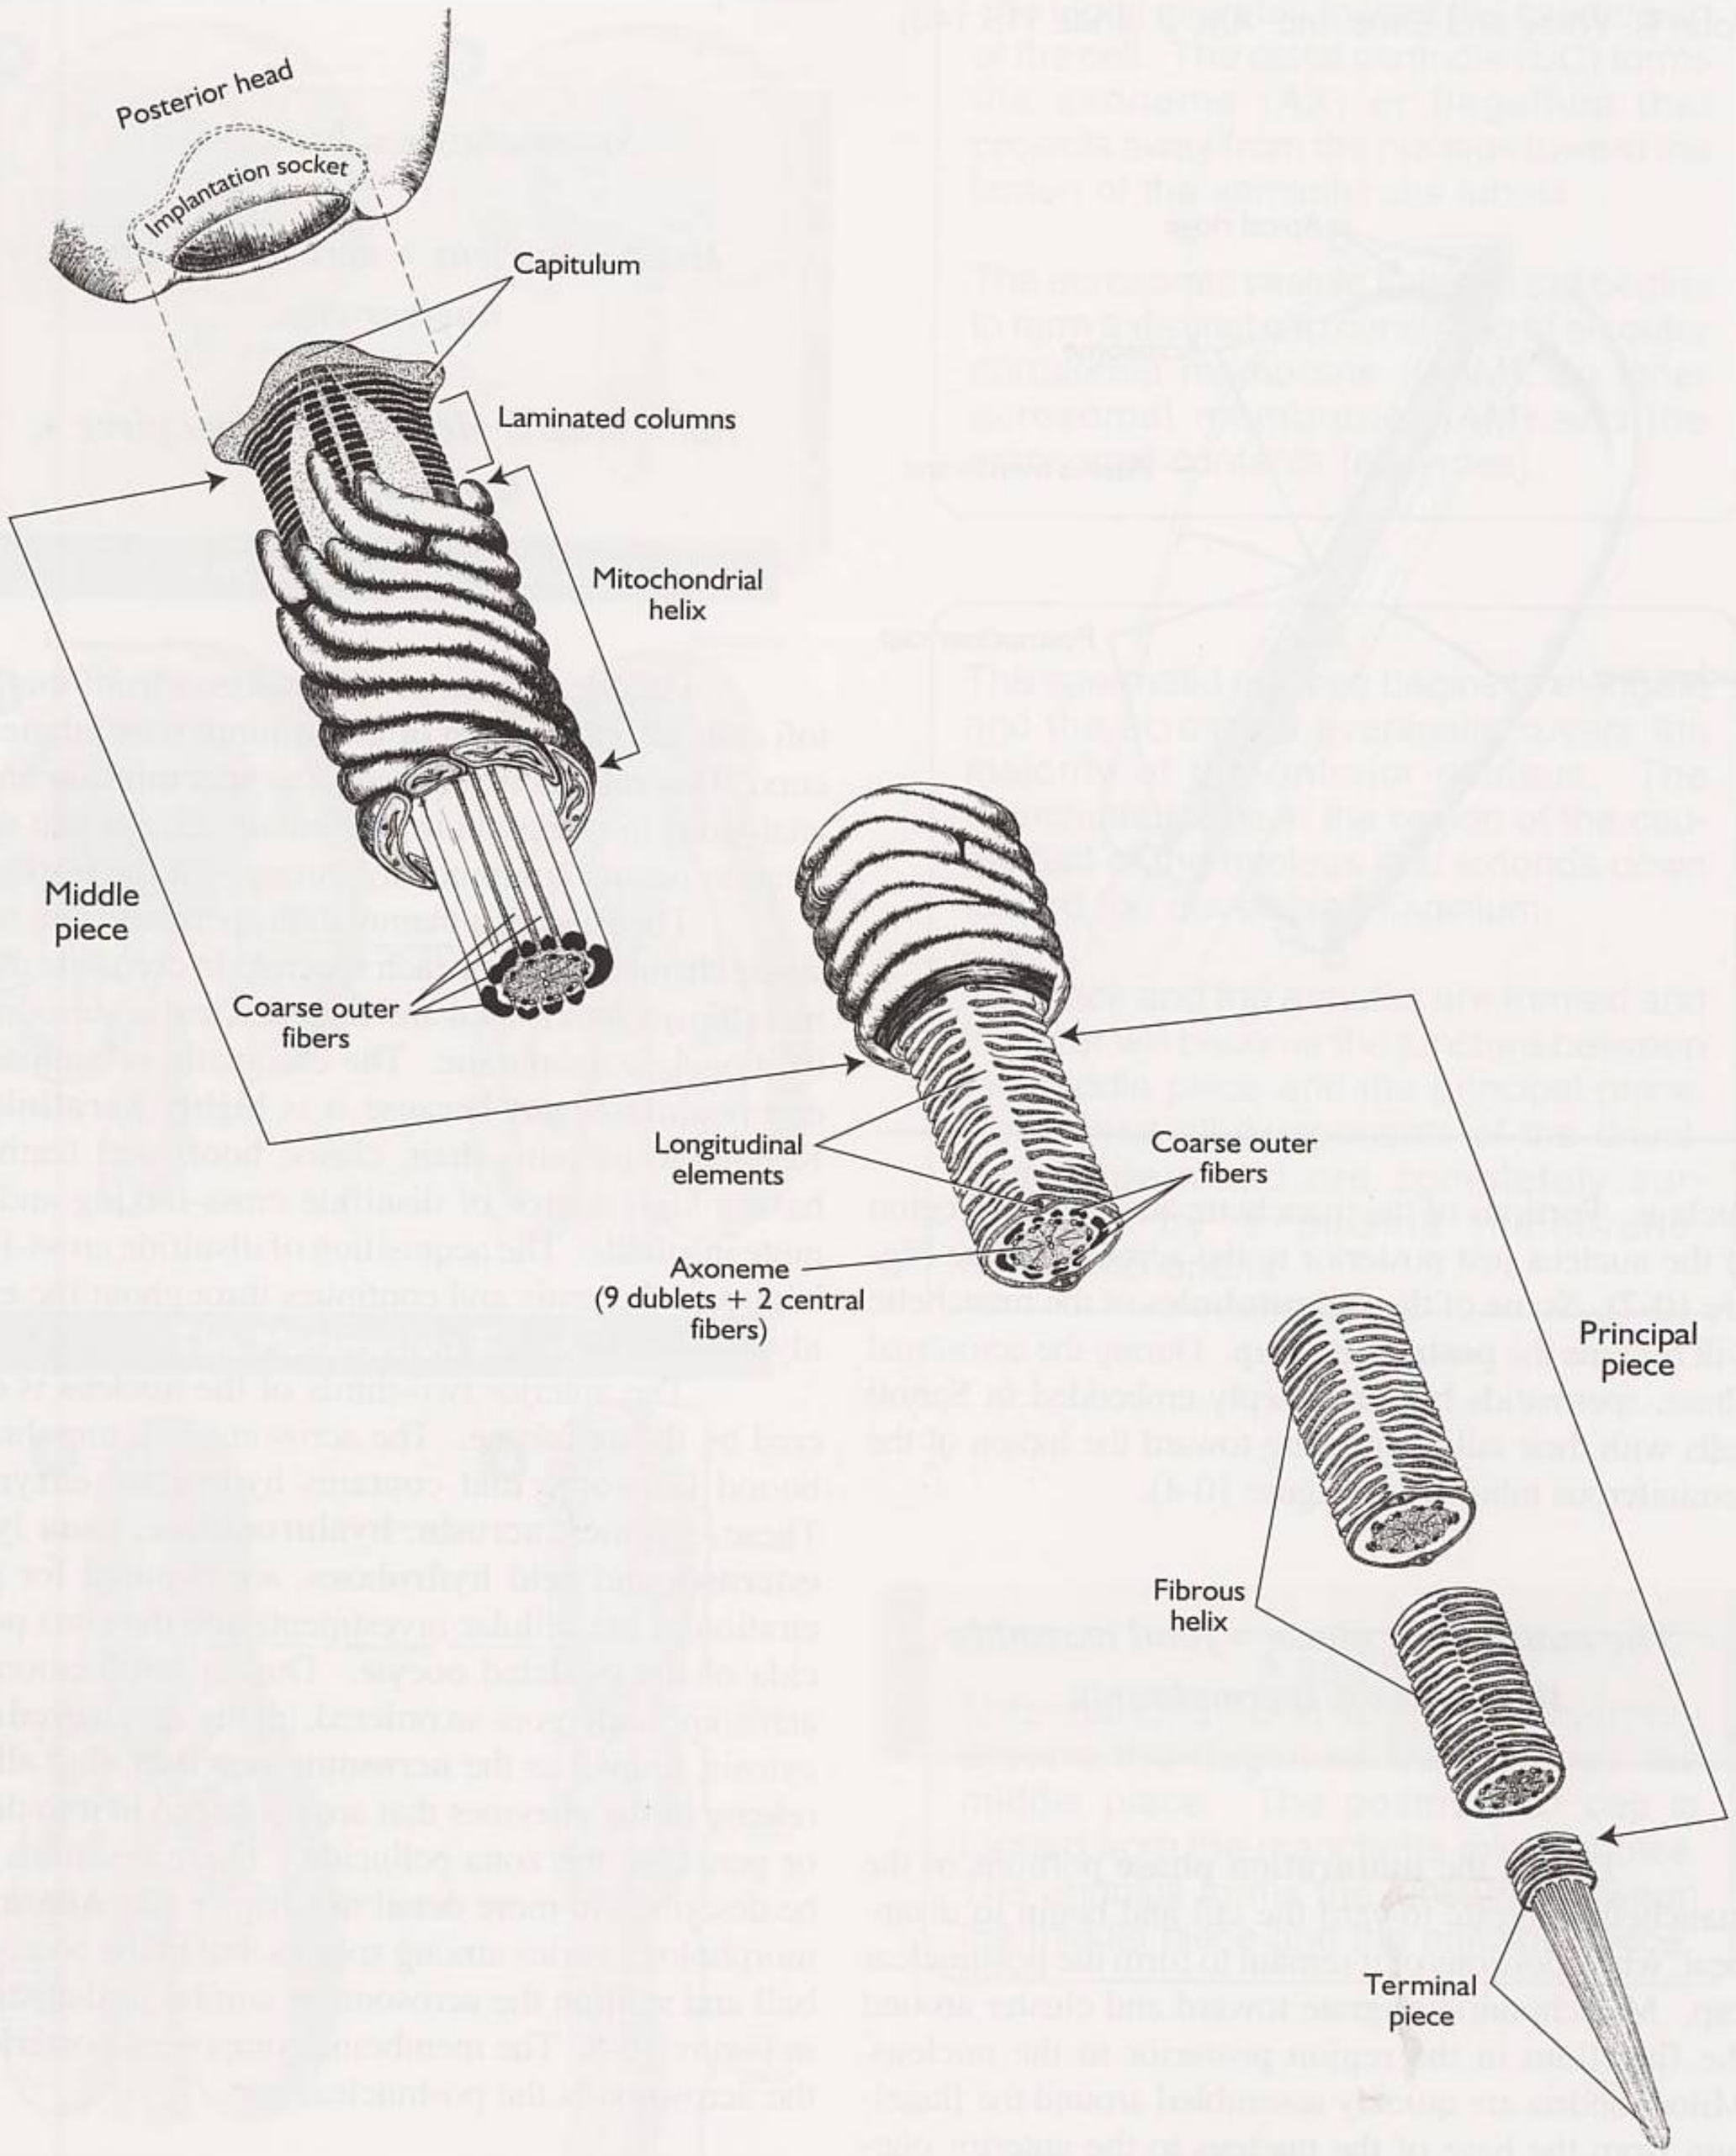
Finally, release of spermatozoa from the Sertoli cells into the lumen of the seminiferous tubule occurs. This release is referred to as **spermiation** and is analogous to ovulation in the female, except that spermiation occurs continuously throughout the testis.

The head of a mammalian spermatozoon has a shape characteristic for each species. In domestic mammals the nucleus is oval and flattened and is surrounded by a nuclear membrane. The chromatin is compacted and is almost inert because it is highly **keratinized**. Keratinoid proteins (hair, claws, hoofs and feathers) have a high degree of disulfide cross-linking and are quite insoluble. The acquisition of disulfide cross-links begins in the testis and continues throughout the epididymis (See Chapter 3).

The anterior two-thirds of the nucleus is covered by the acrosome. The acrosome is a membrane-bound lysosome that contains hydrolytic enzymes. These enzymes, **acrosin**, **hyaluronidase**, **zona lysin**, **esterases** and **acid hydrolases**, are required for penetration of the cellular investments and the zona pellucida of the ovulated oocyte. During fertilization the acrosome undergoes an ordered, highly specialized exocytosis, known as the **acrosome reaction**, that allows release of the enzymes that are packaged in it to digest or penetrate the zona pellucida. These reactions will be described in more detail in Chapter 12. Acrosomal morphology varies among species, but in the boar, ram, bull and stallion the acrosome is similar to that shown in Figure 10-8. The membrane component posterior to the acrosome is the postnuclear cap.

The sperm tail is a self-powered flagellum.

Figure 10-9. The Tail of the Bovine Spermatozoon
(Courtesy of Dr. R.G. Saacke, Virginia Polytechnic Institute and State University with permission from John R. Wiley and Sons, Inc. *Am. J. Anat.* 115:163)



The tail is composed of the **capitulum**, the **middle piece**, the **principal piece** and the **terminal piece**. The capitulum fits into the implantation socket, a depression in the posterior nucleus. The anterior portion of the tail consists of laminated columns that give the neck region flexibility when it becomes motile, so the tail can move laterally from side-to-side during the flagellar beat. The axonemal component of the tail originates from the distal centriole and is composed of 9 pairs of microtubules that are arranged radially around two central filaments. Surrounding this 9+9+2 arrangement of microtubules are 9 coarse fibers that are unique to the flagellum of spermatozoa. This arrangement of tubules in the tail of the spermatozoa is illustrated in Figure 10-9.

The mitochondrial sheath is arranged in a helical pattern (See Figure 10-9) around the outer coarse fibers of the tail and contributes to the middle piece. The annulus demarcates the juncture between the middle piece and the principal piece. The principal piece makes up the majority of the tail and continues almost to the end of the flagellum, where it continues as microtubules that end in the terminal piece.

Spermatozoa are Released Continually into the Lumen of the Seminiferous Tubules

One of the major differences between gamete production in the female and the male is that the female's gamete supply is produced entirely before birth. After puberty, she begins to produce oocytes that will undergo meiosis and ovulate every 3-4 weeks. Thus, maturation, meiosis and release of female gametes is pulsatile. In contrast, the male produces gametes continually and uniformly throughout his reproductive lifespan. An exception to this is the seasonal breeder that produces spermatozoa during the breeding season only. Understanding the mechanisms responsible for the continual production of spermatozoa by the seminiferous epithelium represents a major challenge for students of reproductive physiology.

Appreciating the spermatogenic process is necessary for a complete understanding of reproductive physiology. But the importance of this understanding goes beyond the academic. From a clinical perspective, evaluation of sperm numbers in the ejaculate does not always accurately reflect normal or abnormal spermatogenesis. Therefore, the fate of males being evaluated is often fraught with error and thus bad decisions are made. One needs to understand that there is a 2 to 4 week delay before the effects of deleterious events (heat stress, shipping, fever, exposure to certain toxins) can be observed by monitoring changes in the ejaculate characteristics. Furthermore, 6 to 12 weeks are required before restoration of normal spermatogenesis can be accomplished after these events. Therefore, clinical interpretations of ejaculate characteristics requires specific knowledge of the timing of spermatogenesis in the species being evaluated. Seasonal spermatogenesis requires that the germinal epithelium "turn-on" and "turn-off" as a function of environmental influences. More and more emphasis is being placed on "saving and managing" endangered species. For these efforts to be successful, the timing and sperm producing potential of the male must be understood so that sufficient male gametes are available for reproductive manipulation (artificial insemination, *in vitro* fertilization, etc.). As of yet, a practical, cost-effective male contraceptive is not available for humans. We need to learn how to temporarily "turn-off" and later "turn-on" spermatogenesis without altering the behavior of the male. Our ability to manipulate male gamete production will play a major part in the ability to manipulate reproduction in the future.

In order to comprehend the cycle of the seminiferous epithelium you must first understand:

- ***cellular generations***
- ***stages of the cycle***
- ***duration of one cycle***
- ***how the cycle is repeated***

The **cycle of the seminiferous epithelium** is the progression through a complete series of cellular associations (stages) at one location along a seminiferous tubule. The time required for this progression is the duration of the cycle of the seminiferous epithelium and is unique for each species.

Germ cell generations are cells of the same type located at one site within the seminiferous epithelium.

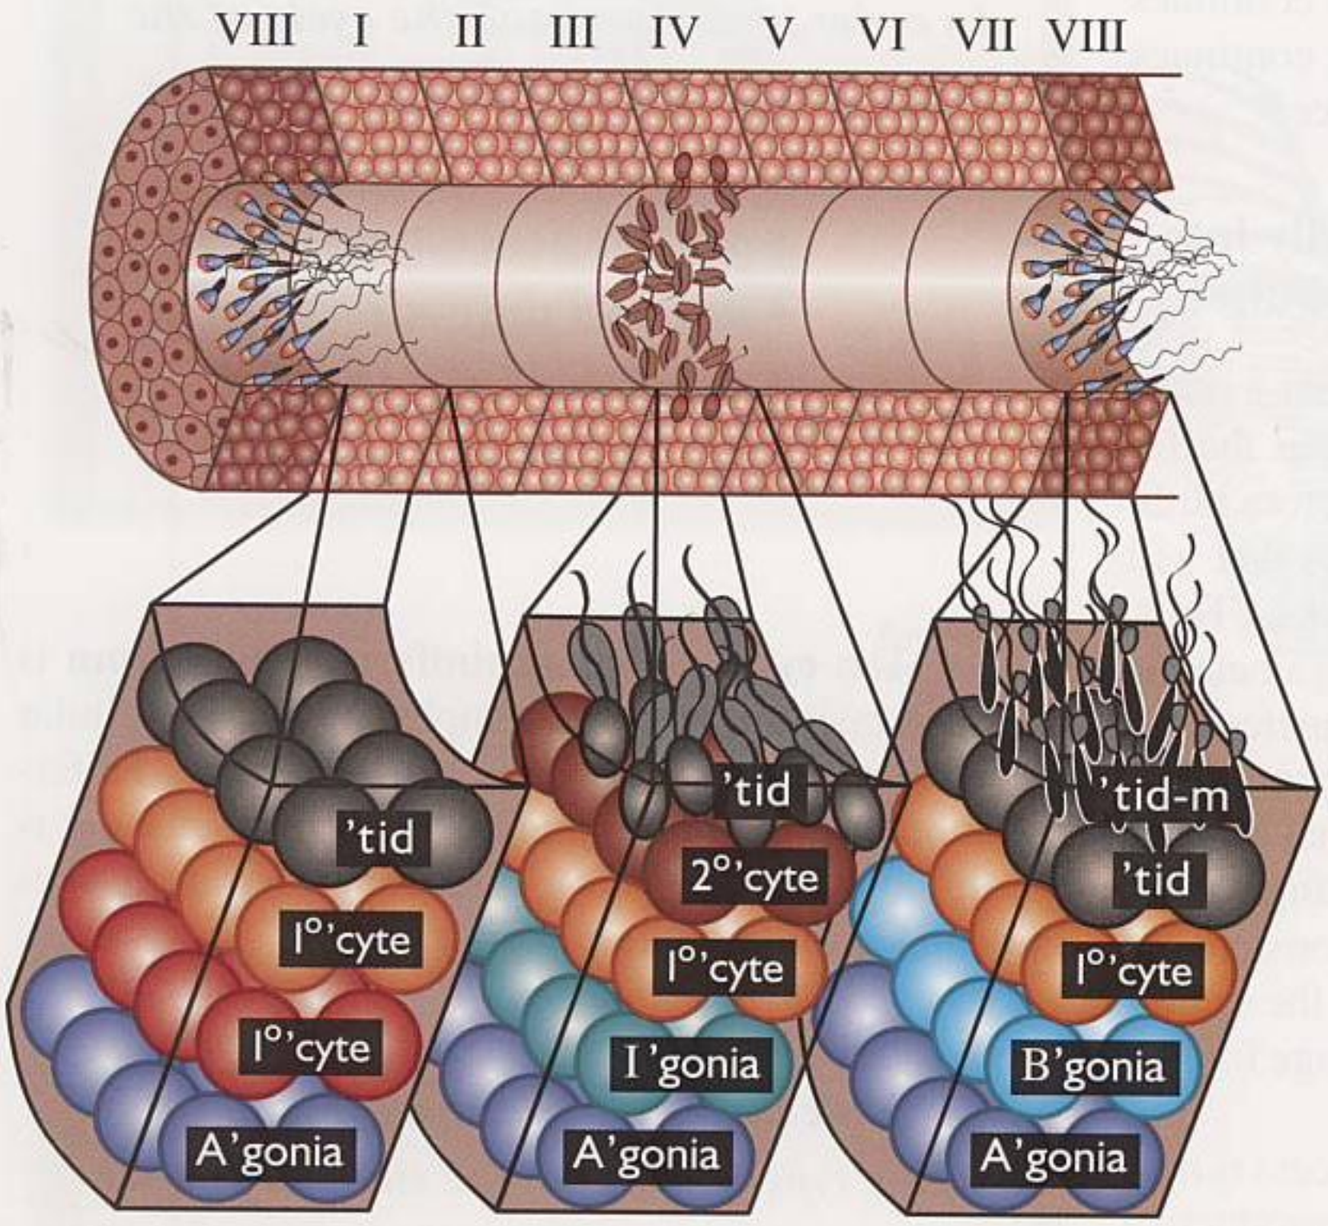
Within any given microscopic cross-section of a seminiferous tubule, one can observe four or five concentric "layers" of germ cells. Cells in each layer comprise a generation. A generation is a cohort of cells that develops as a synchronous group. Each generation of cells (each concentric layer) has a similar appearance and function. Cross-sections along the length of a seminiferous tubule will have a different appearance but the entire cross-section at a given location

will usually appear similar. For example, while viewing cross-section I (stage I) in Figure 10-10, you will observe four generations of germ cells. Each generation will give rise to a succeeding, more advanced generation. Observe in Figure 10-10 that there is a generation of A-spermatogonia near the basement membrane in the section of the tubule labeled Stage I. Just above the A-spermatogonia is a young generation of primary spermatocytes. Above it lies a third generation consisting of more mature primary spermatocytes. Finally, near the lumen, is a fourth generation of cells. This generation consists of spherical immature spermatids. Remember that the more immature cell types are generally located near the basement membrane (basal compartment) and the more advanced cell types reside in the adluminal compartment.

In cross-section IV (stage IV) of Figure 10-10, there are five generations of germ cells. You will observe a generation of A-spermatogonia, one generation of intermediate spermatogonia, one generation of primary spermatocytes, one generation of secondary spermatocytes and one generation of spermatids. The spermatids in stage IV are elongated and, thus are more advanced than the spermatids in stage I.

In cross-section VIII (stage VIII), there are also five generations of germ cells. Observe two generations of spermatogonia (one generation of A and one generation of B-spermatogonia), one generation of primary

Figure 10-10. Associations of Developing Germ Cells That Represent Various Stages of the Cycle of the Seminiferous Epithelium



At any given cross-sectioned location along a seminiferous tubule, one can observe different stages of the cycle of the seminiferous epithelium. In this example, we see three stages (I, IV, and VIII).

'gonia = spermatogonium
1° cyte = primary spermatocyte
2° cyte = secondary spermatocyte
'Tid = immature spermatid
'Tid-m = mature spermatid

Stage I

A stage I tubule consists of 1 generation of A-spermatogonia, 2 generations of primary spermatocytes (1° cyte) and 1 generation of immature spermatids ('Tid).

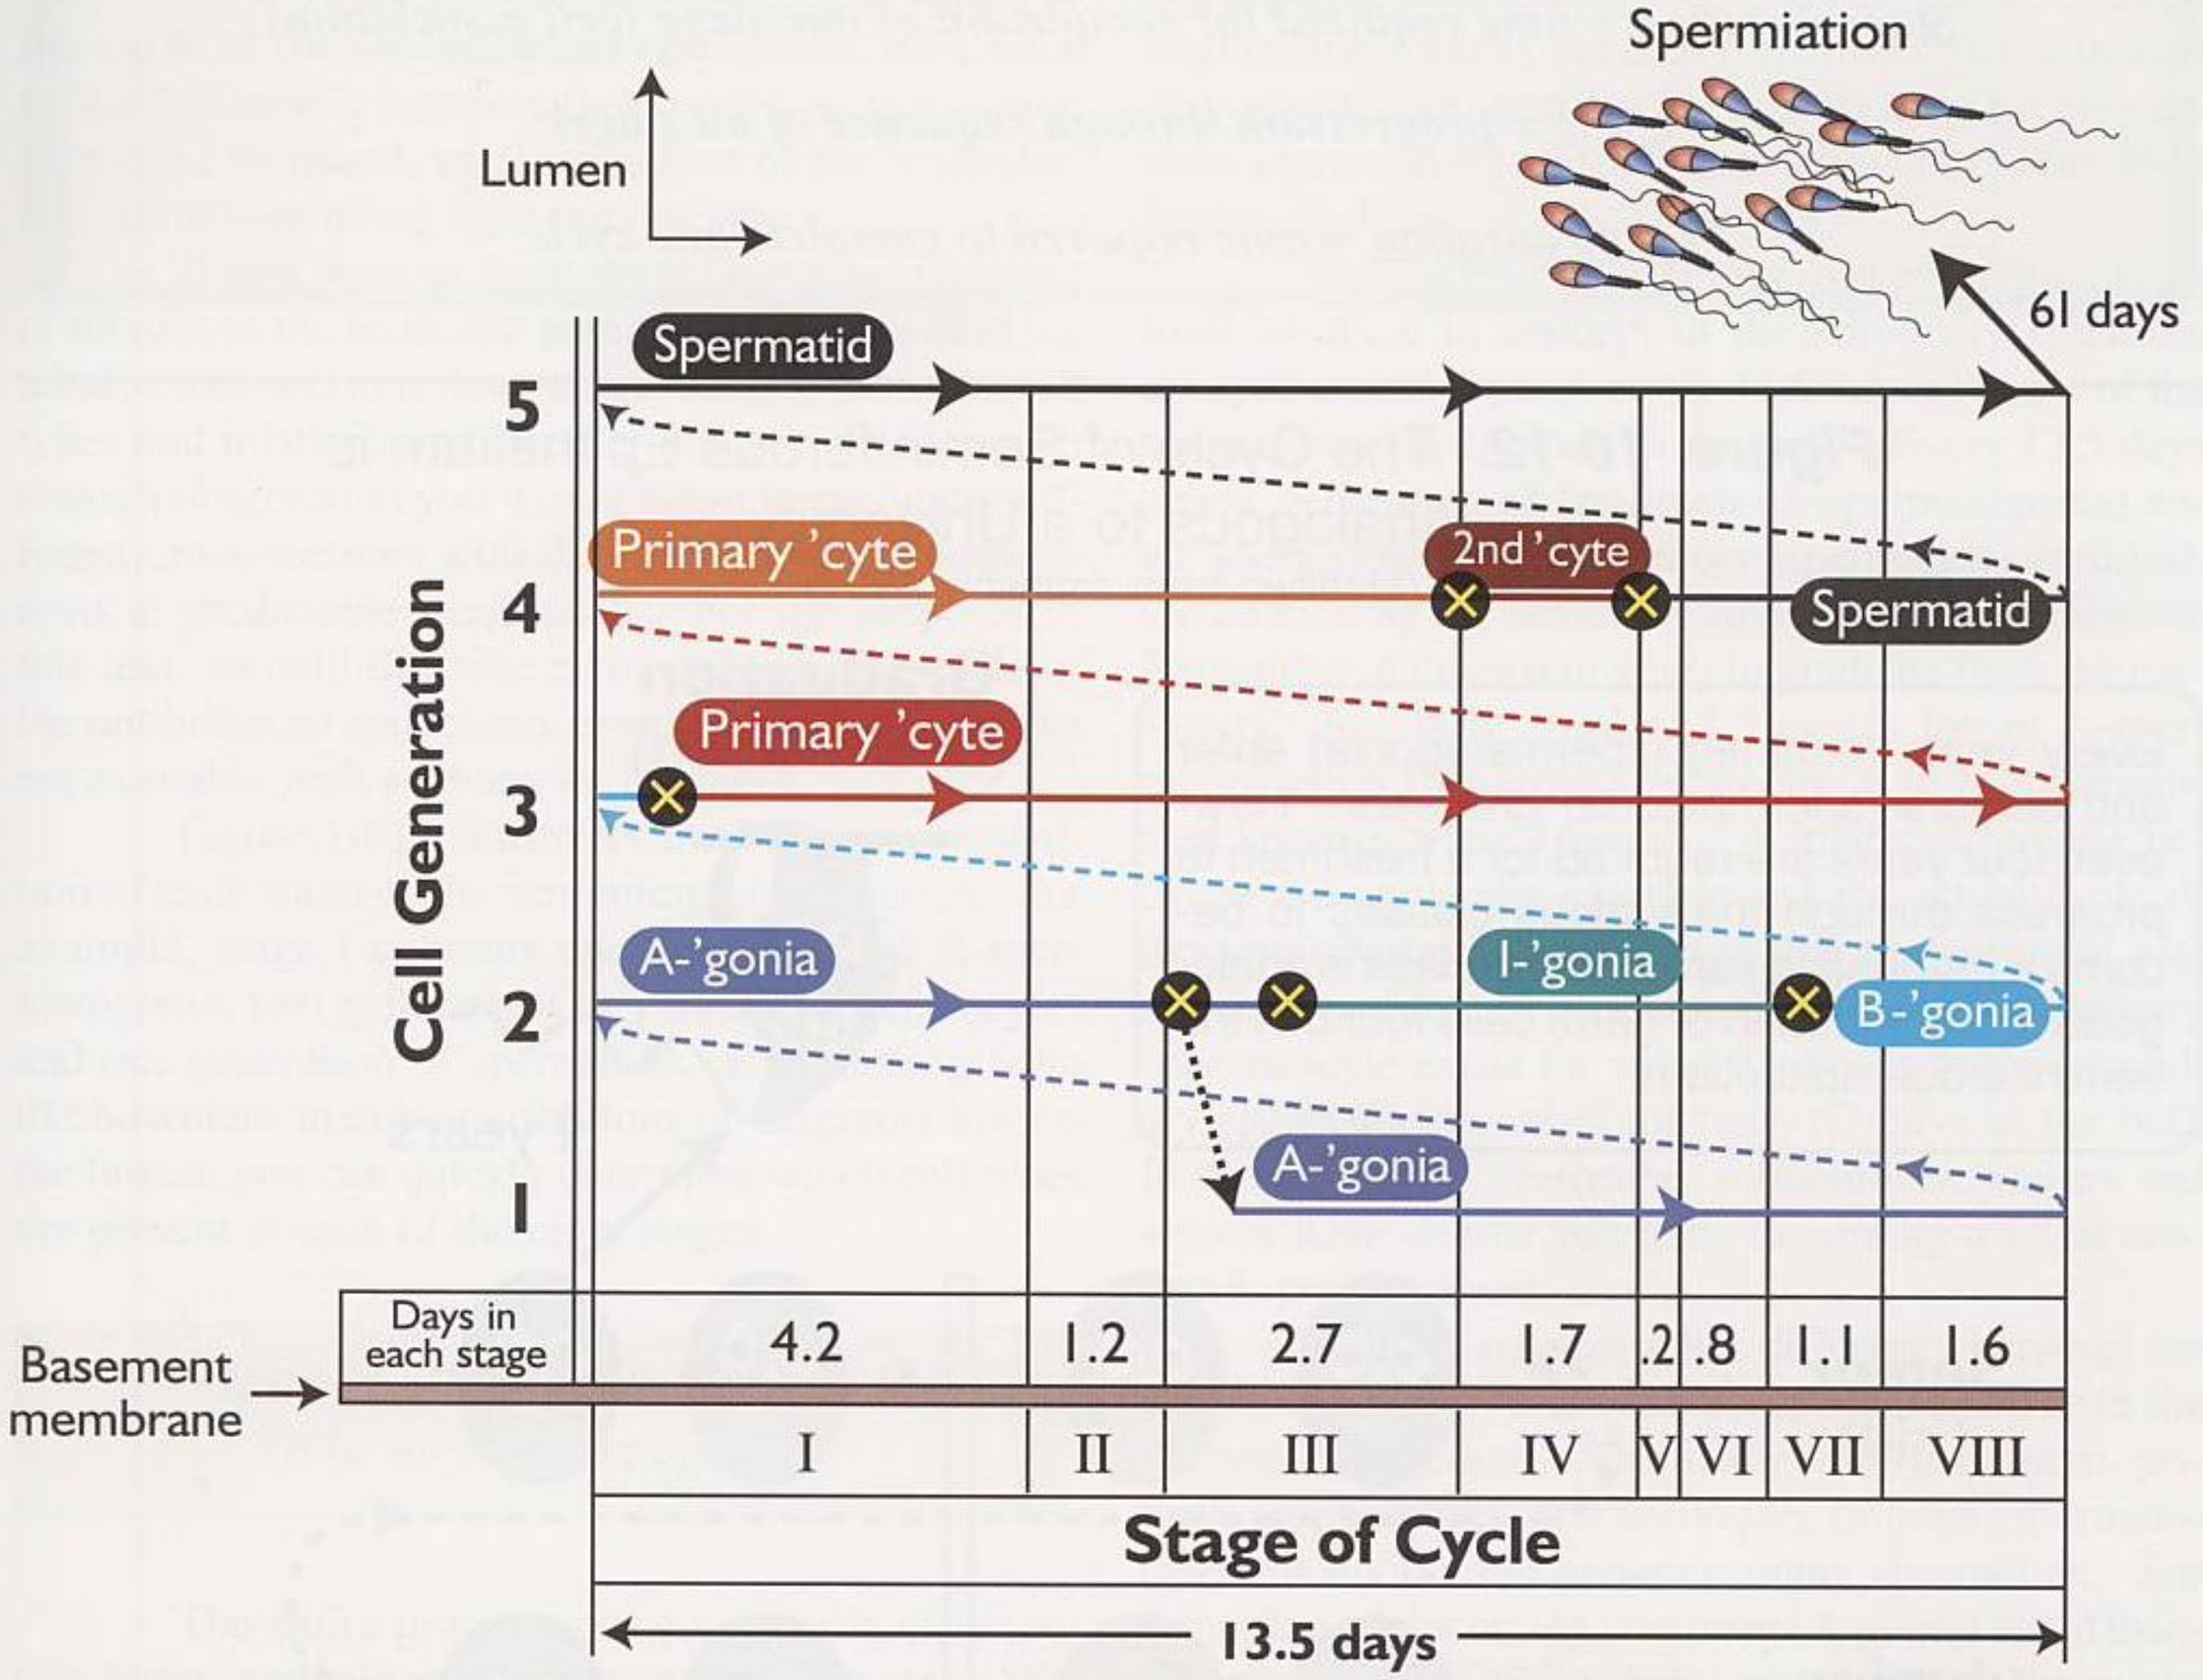
Stage IV

A stage IV tubule consists of 2 generations of spermatogonia (A+I), 1 generation of primary spermatocytes (1° cyte), 1 generation of secondary spermatocytes (2° cyte) and 1 generation of immature spermatids ('Tid).

Stage VIII

A stage VIII tubule consists of 2 generations of spermatogonia (A+B), 1 generation of primary spermatocytes (1° cyte) and 2 generations of spermatids ('Tid). The young generation of spermatids ('Tid) have formed only a few days earlier and are quite immature. The second generation of spermatids are mature ('Tid-m) and are about to be released into the lumen.

Figure 10-11. Cycle of the Seminiferous Epithelium in the Bull
(Modified from Amann, R.P. *Am. J. Anat.* 110:69)



- **Horizontal axis** = Stage of cycle and days spent in each stage.
- **Vertical axis** = Cell generations in each stage i.e. type of cell seen from the basal level to the luminal level within a cross section of a seminiferous tubule.
- **Horizontal line** = Developmental pathway from spermatogonia to spermatozoa (61 days).
- The release of spermatozoa from the Sertoli cells occurs in stage VIII and is called spermiation. It occurs 61days after A-spermatogonia are formed at the beginning of Stage III.
- ⊗ Cell division (mitotic for 'gonia, meiotic for primary and secondary 'cytes).
- In the bull, it takes about 4.5 cycles of the seminiferous epithelium to complete spermatogenesis (4.5 cycles x 13.5 days/cycle = 61 days).

spermatocytes and two generations of spermatids. One generation of spermatids is rather immature and spherical, while the more advanced generation consists of mature spermatids ready for release from Sertoli cells into the lumen of the seminiferous tubule.

At one instance in time, three cross-sections at different locations along the seminiferous tubule show different generations of cells. Cells in each section are actively engaged in spermatogenesis, but only one cross-section (VIII) is ready to release spermatozoa into the lumen. Thus, along the length of any seminiferous tubule there are only certain zones (cross-sections) where spermatozoa are released each second. All other zones or stages are preparing to release spermatozoa, but the cells in those zones have not reached the appropriate stage of maturity for spermiation to occur.

Stages of the cycle are arbitrarily defined cellular associations that transition one to the next at predictable intervals.

Stage = specific cellular associations

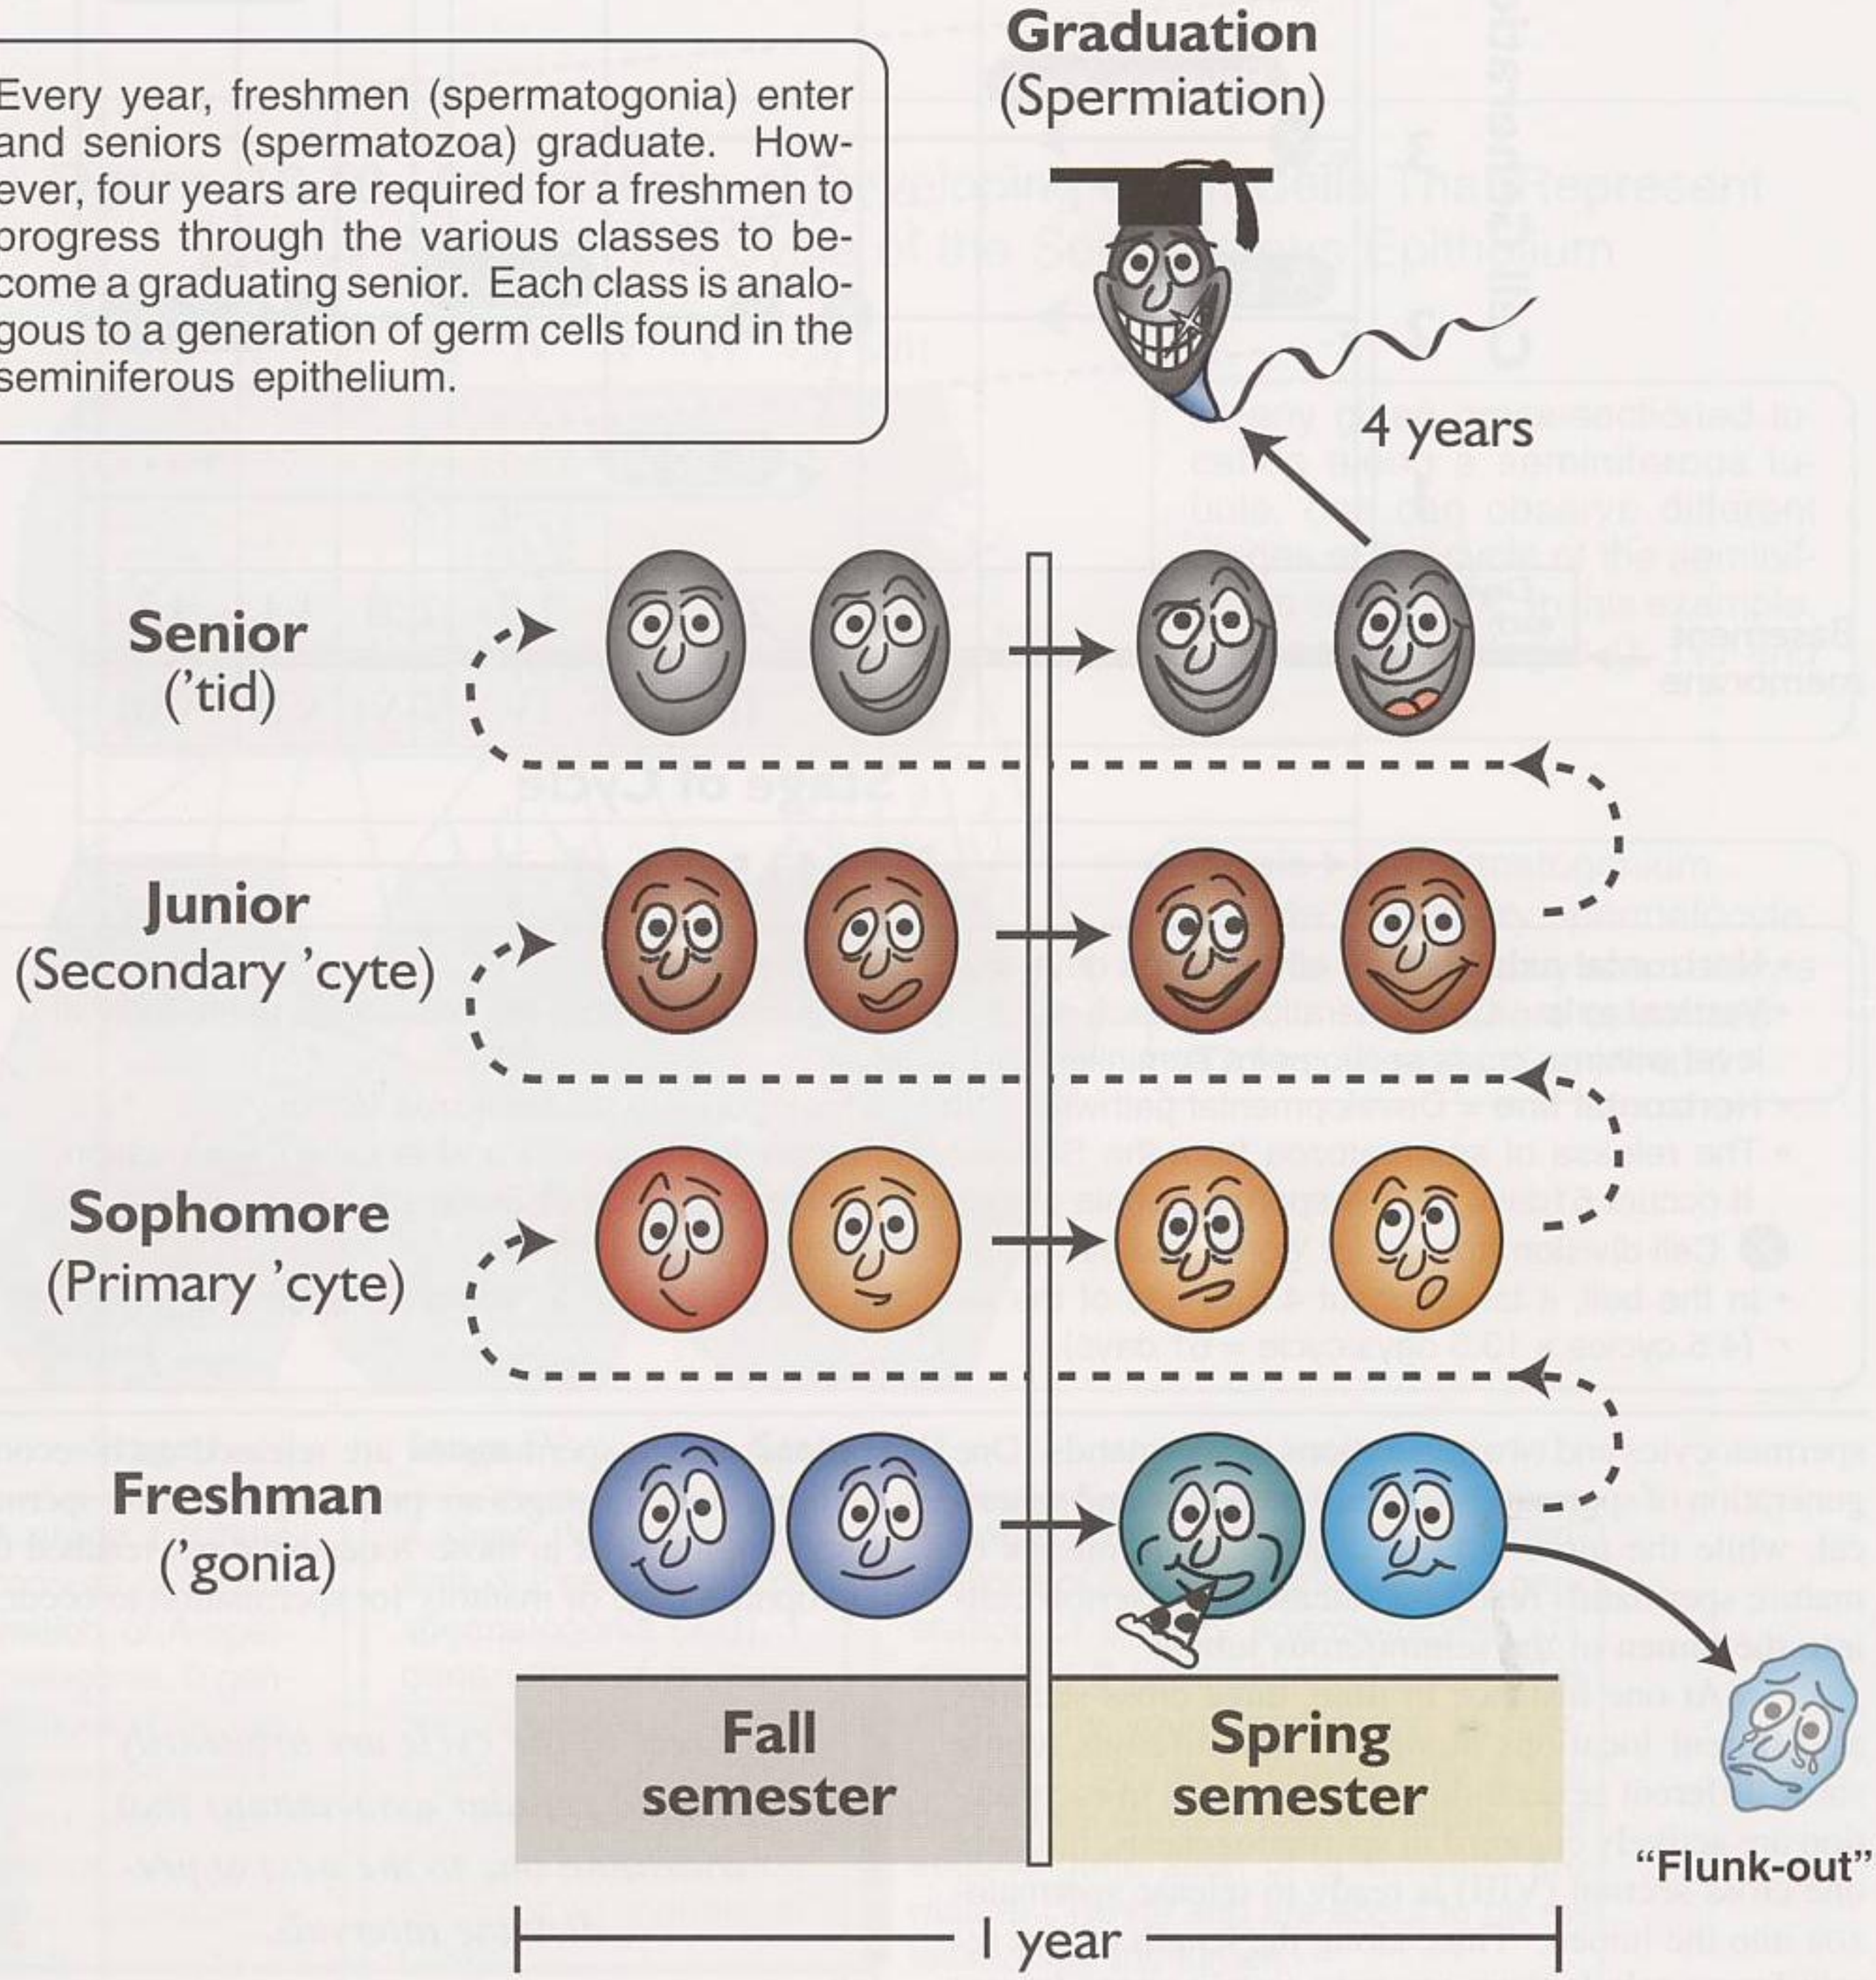
Stage duration = time required for completion of one stage (cell association)

Cycle = progression through sequence of all stages

Cycle duration = time required to complete one cycle

Figure 10-12. The Cycle of Seminiferous Epithelium is Analogous to a University
(Modified from Johnson, 1991)

Every year, freshmen (spermatogonia) enter and seniors (spermatozoa) graduate. However, four years are required for a freshmen to progress through the various classes to become a graduating senior. Each class is analogous to a generation of germ cells found in the seminiferous epithelium.



As previously explained, sections or zones along a seminiferous tubule contain different cellular associations. These cellular associations, or **stages of the cycle of the seminiferous epithelium**, have been defined arbitrarily by researchers who have made thousands and thousands of observations of the seminiferous epithelium using light microscopy.

If you were to microscopically scan a number of tubules in the testicular parenchyma, you would see tubule cross-sections that contain exactly the same cell types and relationships as other tubules. In fact, with enough observation you would begin to encounter different cross-sections with definable cellular compositions at predictable frequencies. For the purposes of this text, we will describe eight stages in the cycle of the seminiferous epithelium, even though other schemes are available with as many as 14 stages.

Figure 10-11 illustrates the cellular composition of each stage of the seminiferous epithelium. For example, stage I contains one generation of A-spermatogonia, two generations of primary spermatocytes and one generation of spermatids. By scanning from the basement membrane (bottom of diagram) toward the lumen, you can quickly determine which cell types are present at each of the eight stages.

Lifespan of cells and duration of the cycle vary among species.

The entire progression of one cycle of the seminiferous epithelium from stage I through stage VIII requires 13.5 days in the bull (for other species see Table 10-1). That is, if you could observe one cross-section of a seminiferous tubule continually, starting at the beginning of stage I, it would require 13.5 days before you would observe spermiation (the end of stage VIII). After spermiation (end of stage VIII), the cross section you were observing would again have the same cellular association as it did on the day you started watching (stage I). Thus, one cycle of the seminiferous epithelium would have been completed.

The complete process of spermatogenesis from A-spermatogonia to the formation of fully differentiated spermatozoa takes 61 days in the bull. During the 61 days, cells at a given area of the seminiferous epithelium proceed through 4.5 cycles of the seminiferous epithelium (13.5 days/cycle X 4.5 cycles = 61 days).

This process is analogous to a traditional university. Every year a new class of freshmen enters the university in the fall. These freshmen are analogous to committed A-spermatogonia entering the spermatogenic pathway. The freshmen (A-spermatogonia) undergo noticeable changes during the first year, and after one year they become sophomores. Sophomores are analogous to primary spermatocytes. The sophomores (primary spermatocytes) also undergo maturational changes and become juniors (secondary spermatocytes; although they actually are short-lived). Finally, they become seniors (spermatids) and graduate after four years (See Figure 10-12).

The cycle of the seminiferous epithelium is almost identical in concept to the university situation, except the school year is only 13.5 days (1 cycle of the seminiferous epithelium in the bull). Every 13.5 days a new generation of freshmen (A-spermatogonia) enter and a generation of seniors (spermatids) graduate. Graduation by the seniors is analogous to spermiation. Remember, it takes four years to graduate from the university. Similarly, it takes 4.5 cycles for an A-spermatogonium (freshman) to become a fully differentiated spermatozoon (senior). A major difference between the university example and the actual cycle of the seminiferous epithelium is that the germinal elements have different lifespans. For example, a primary spermatocyte exists for about 21 days while a secondary spermatocyte exists for only 1.7 days in the bull. In the university, freshmen, sophomores, juniors and seniors have similar lifespans (assuming a basal academic performance).

There is another major difference between the university analogy and what actually takes place in the germinal epithelium. Spermatogonia (freshmen), primary (sophomores) and secondary (juniors) spermatocytes all divide and generate many spermatids. For example each incoming freshmen (A-gonia) could theoretically produce 256 seniors (spermatids). Obviously, such multiplication does not take place with university students. In the university, a significant proportion of entering freshmen "flunk-out" and never graduate, so there are always more freshmen than graduating seniors. Similarly, during spermatogenesis many proliferating spermatogonia die and never become primary spermatocytes. Therefore, the number of primary spermatocytes generated per committed A-spermatogonium is closer to 20-30 than the theoretical 64 as depicted in Figure 10-5. There also is death of primary spermatocytes, although most spherical spermatids do form a spermatozoon. In contrast from a university where each student can choose their pace throughout the years, to amass 120 credits, in the testis of a given species, the pace through spermatogenesis is essentially identical and is not affected by environment.

The spermatogenic wave is the sequential ordering of stages along the length of the seminiferous tubule.

Table 10-1. Duration of the Stages of the Cycle of the Seminiferous Epithelium in Various Species

Stage	Bull	Ram	Boar	Stallion	Rabbit
I	4.2	2.2	1.1	2.0	3.1
II	1.2	1.1	1.4	1.8	1.5
III	2.7	1.9	0.4	0.4	0.8
IV	1.7	1.1	1.2	1.9	1.2
V	0.2	0.4	0.8	0.9	0.5
VI	0.8	1.3	1.6	1.7	1.7
VII	1.1	1.1	1.0	1.6	1.3
VIII	1.6	1.0	0.8	1.9	0.9
TOTAL[A]	13.5	10.1	8.3	12.2	11.0
SPERMATOGENESIS[B]	61	47	39	55	48

[A]Total days required for 1 cycle of the seminiferous epithelium
[B]Approximate days to complete spermatogenesis (spermatogonia to spermatozoa)

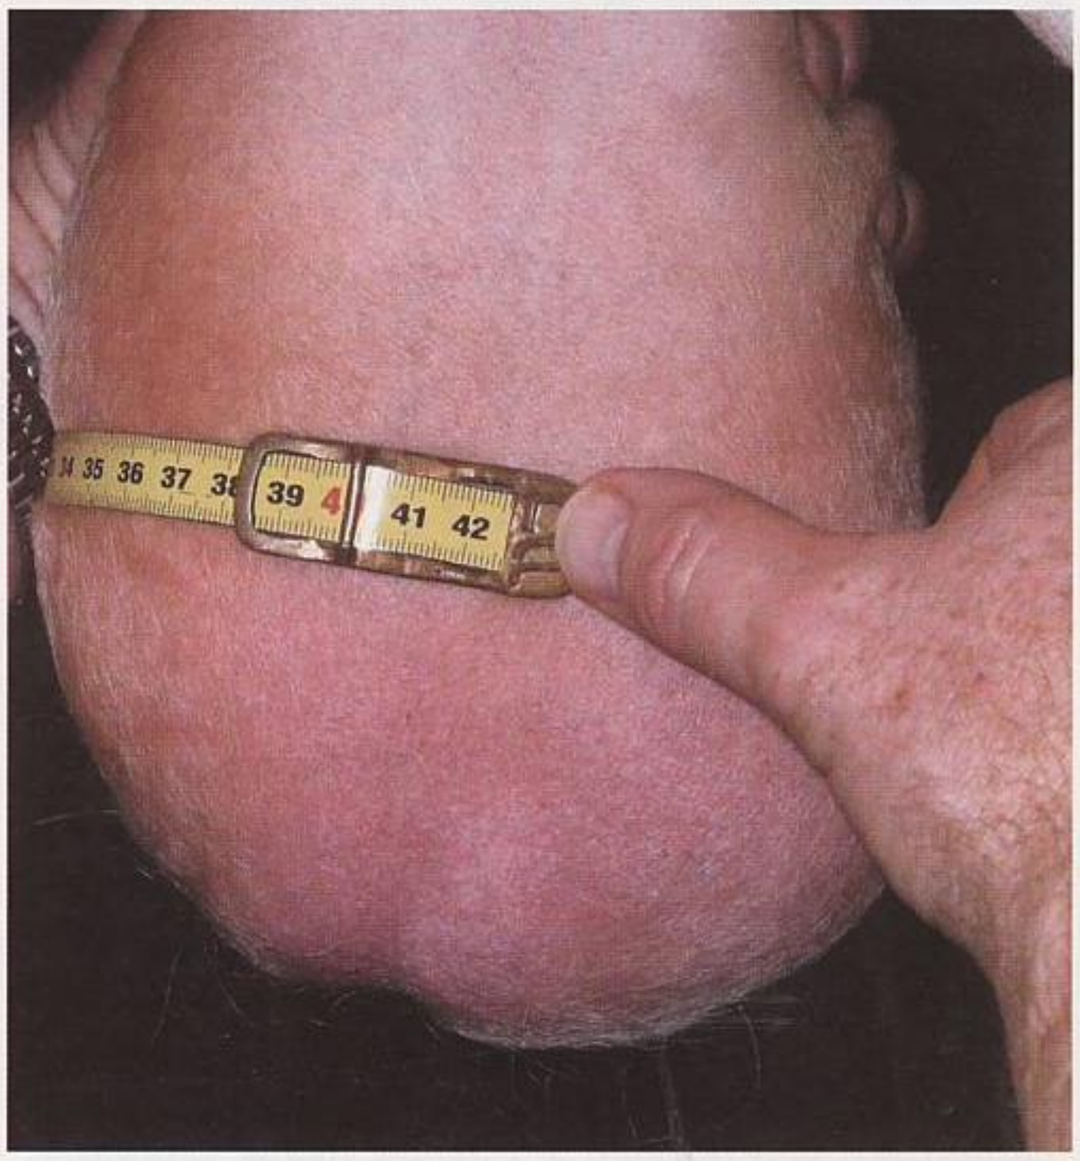
The duration of each stage of the cycle of the seminiferous epithelium varies with species, as does the length of the cycle of the seminiferous epithelium. Variations in stage, cycle length and total time required for spermatogenesis are presented in Table 10-1.

The **spermatogenic wave** refers to the differences at any given instant in time along the length of the seminiferous tubule. Imagine that you could run down the lumen of the seminiferous tubule. As you run down the tubule, you will encounter zones that are near spermiation (stage VIII). The distance between these spermiation sites is relatively constant. During the wave, each stage of the seminiferous epithelium transitions to a successively more advanced stage. For example, a stage I tubule will later become a stage II and stage II will later become a III and so on. Thus, the site of spermiation along the tubule is constantly changing, creating a "wave" of sperm release down the length of the tubule. This "wave" is like the wave conducted by football fans in a stadium. When the fans stand up, they mimic spermiation. They sit back down and don't stand up again until they have had a period of rest. The time spent sitting (stages I-VII) is much longer than the time spent standing. As the wave in the stadium continues, repeated standing and sitting takes place at a relatively constant rate. So does spermiation. The physiologic importance of the spermatogenic wave is to provide a relatively constant supply of spermatozoa to the epididymis, creating a pool for ejaculation.

Daily sperm production (DSP) is defined as the total number of spermatozoa produced per day by both testicles of the male. Accurate measurement of DSP requires removal of all or a portion of the testicle and thus, DSP cannot be measured using noninvasive techniques. However, noninvasive measures

Figure 10-13. Scrotal Circumference Measurements are Good Indicators of Sperm Producing Ability

(Photograph courtesy of Select Sires, Inc. Plain City, Ohio, *www.selectsires.com*)



Accurate scrotal circumference measurements require that both testicles be pushed ventrally by applying pressure to the spermatic cord. A specially designed tape is then placed around the scrotum at its widest point and a measurement is taken (in this case, 40cm).

Table 10-2. Testicular Characteristics and Sperm Production Estimates of Sexually Mature Mammals

Species	Gross weight of paired testes (grams)	Sperm produced per gram of testicular parenchyma	Daily spermatozoal production
Beef Bull	650	$11x10^6$	$6x10^9$
Boar	750	$23x10^6$	$16x10^9$
Cat	21	$16x10^6$	$32x10^6$
Dairy Bull	725	$12x10^6$	$7.5x10^9$
Dog (16 kg body weight)	31	$17x10^6$	$0.50x10^9$
Man	35	$4x10^6$	$0.13x10^9$
Rabbit	6	$25x10^6$	$0.20x10^9$
Ram*	550	$21x10^6$	$10x10^9$
Rooster***	25	$100x10^6$	$2.5x10^9$
Stallion**	340	$16x10^6$	$5x10^9$

*in breeding season (shortening-day length), ** in breeding season (increasing day length), ***varies greatly with management and strain

such as total number of spermatozoa ejaculated into an artificial vagina with daily ejaculations for 2-3 weeks gives a good estimate of DSP. Interspecies variation in testicular weights, sperm produced per gram of testicular parenchyma and daily sperm production is presented in Table 10-2. The number of spermatozoa produced per day per gram of testicular parenchyma is referred to as **efficiency of sperm production**. Daily sperm production is dependent, at least in part, on the number of Sertoli cells populating the testes. For example, the higher the number of Sertoli cells, the higher the spermatozoal production rates. Numbers of Sertoli cells also have been positively correlated with spermatogonial and spermatid numbers. The exact reason that Sertoli cells control spermatozoal production rates is not understood.

Assuming that a male can develop an erect penis, mount and ejaculate in the female, his potential fertility is determined by:

- ***his sperm producing ability***
- ***the viability of his spermatozoa***
- ***the number of morphologically abnormal spermatozoa that he ejaculates***
- ***the number of functionally normal spermatozoa that he ejaculates***

Testicular Size is a Good Estimator of Sperm Producing Ability

To determine a given male's sperm producing capability, it is necessary to collect ejaculates from the animal for a period of time. This enables one to accurately estimate how many spermatozoa the animal can produce per unit time. If collection of semen is not possible, a good estimate of sperm producing capability can be made by measuring the circumference of both testicles (See Figure 10-13). The greater the testicular circumference, the greater the sperm producing capability, in other words, "the bigger the factory, the greater the output." Because of the non-pendular scrotum in the boar and stallion, scrotal width or length is used as the measurement.

Spermatozoal Viability is Judged by Evaluating Motility

Even though a male can produce large quantities of spermatozoa, it is important that these sperm are alive and highly motile. Motility is generally described as the ability of sperm to swim progressively forward. Motility is the most commonly used assessment of viability. It is expressed as an estimate of the percentage of sperm that are swimming in a linear fashion within a given environment as determined microscopically. Unfortunately, the relationship between percentage of motile sperm and fertility is not a good one. However, if few spermatozoa within a series of

Figure 10-14. Some Common Abnormalities in Bovine Sperm as Observed With Differential-Interference Contrast Microscopy
(Courtesy of R.G. Saacke, Virginia Polytechnic Institute and State University)

Note: A vast amount of information is available for bulls because of intense scrutiny given to abnormal sperm by commercial AI organizations. For details on the incidence, causes and their effects on fertility of abnormal sperm shown here (and other types as well) see Barth and Oko, 1998 in the **Key References** section at the end of the chapter. Most descriptions in the bull apply to other mammals as well.

ejaculates are motile, the assumption can be made correctly that sperm in the ejaculate are not alive and therefore cannot fertilize the egg. There are many ways to tell if a spermatozoon is alive. These include oxygen consumption, exclusion of certain dyes by the plasma membrane (live-dead stains) and examination by flow cytometry. However, the simplest and most common is to determine if a cell moves forward in a progressive manner (motile) when examined at 37°C. Evaluating motility at temperatures below 37°C is not a good practice because motility stops at about 18°C. The use of a phase-contrast microscope (essential to clearly visualize sperm) and a heated stage (to allow sperm to display their potential to swim) is the most practical way to evaluate motility of sperm. Decisions about motility should never be based solely on one ejaculate.

There are Many Types of Abnormal Spermatozoa

As you might imagine, a process that potentially produces up to 20 billion sperm per day (over 200,000 per second) will have errors. These errors are expressed as abnormal spermatozoa some of which can be detected on the basis of abnormal shape. Morphologically abnormal sperm can be defined as any shape characteristic deviating from normal. Every ejaculate will contain between 5 and 15% abnormal sperm and these levels are generally considered acceptable. Reduced fertility may result when morphologically abnormal sperm exceed 20% of sperm in the ejaculate. Some morphologic abnormalities have a severe effect on fertility while others have little or no

effect. In general, morphologic abnormalities either originate in the testes because of faulty differentiation or in the epididymis because of faulty epididymal transit and/or maturation. The latter results in the presence of cytoplasmic droplets (See Chapter 3). Morphologically abnormal sperm of testicular origin are generally classified as either head abnormalities or tail abnormalities.

Potential fertility of the male can be related to the percentage of morphologically abnormal sperm within an ejaculate. Some common abnormalities in bull sperm are shown in Figure 10-14. Some abnormalities are heritable and result in sterility. Males possessing these abnormalities should be eliminated from the gene pool.

Evaluation of the proportion of abnormal sperm in an ejaculate requires a microscope. For most laboratories, a phase-contrast microscope and a skilled observer will yield satisfactory diagnoses. For laboratories examining large numbers of ejaculates, a **differential-interference contrast microscope** is preferred because of the high resolution and the cellular detail generated with this optical system. A differential-interference contrast microscope transforms gradients in intracellular density into an optical image that appears as a relief or an indentation in the cell. Thus, abnormalities of both the head and tail can be observed and quantitated with a high degree of precision. All of the micrographs presented in Figure 10-14 were generated with a differential-interference contrast microscope. A description of each type of abnormality that one can encounter within a series of ejaculates is beyond the scope of this text.

It must be recognized that morphologic abnormalities represent only one characteristic among a myriad of possibilities for abnormal function. For example, abnormal nuclear composition (faulty DNA), abnormal biochemical composition, surface protein deficiency and faulty response to stimuli within the female tract represent only a few possibilities that may limit the function of spermatozoa.

Artificial Insemination is the Single Most Important Physiological Technology Ever Devised for Acceleration of Genetic Improvement

The components of artificial insemination (AI) in the fact box, will be presented in the chapters that discuss the physiology of each process. For example, collection of semen involves behavioral issues requiring specific stimuli for mounting and ejaculation (See Chapter 11). Preservation and extension of semen is an issue associated with providing an optimum in-vitro environment to preserve sperm viability (Current Chapter). Finally, insemination of the female delivers sperm to the female reproductive tract so that adequate numbers are present and fertilization can be accomplished (See Chapter 12). Successful AI can be accomplished in any species provided the criteria are met.

The major steps of artificial insemination are:

- ***collection of semen from the male (See Chapter 11)***
- ***preservation and extension of sperm (See Below)***
- ***insemination of the female (See Chapter 12)***

Artificial insemination is a common practice in some species. For example, over 7 million dairy cows and about 2 million beef cows are artificially inseminated annually in the United States. All turkey hens in commercial flocks (over 300 million) are artificially inseminated because the toms have such a broad breast that they cannot mount and copulate. The use of AI in swine has exploded during the past 10 years. For example, about 4.5 million sows are artificially inseminated at least once per year, resulting in over 35 million pigs sired by artificial insemination annually. Overall, about 75% of the sows and gilts in the USA are artificially inseminated; Artificial insemination is also common for horses. In addition, many species in zoos have been artificially inseminated to avoid inbreeding and facilitate reproduction in exotic and endangered species. In fact, during 2002 the first baby elephant was produced by artificial insemination at the National Zoo in Washington D.C. Artificial insemination is used routinely in assisted reproductive techniques in humans, allowing pregnancies to occur that otherwise would not be possible.

Immediately after collection, the following information is needed:

- ***ejaculate volume***
- ***concentration of spermatozoa in the ejaculate***
- ***percentage of motile sperm***

In Vitro Preservation is Obligatory for Successful AI

After semen has been collected successfully, *in vitro* preservation of sperm for a period of time must be accomplished before successful delivery of sperm to the female can take place. Preservation and dilution of sperm requires an environment that minimizes death of sperm. It also requires knowledge about the volume of the ejaculate, the concentration of sperm in the ejaculate and their motility.

Having the above information is necessary to determine the appropriate dilution rate of the sperm so that multiple females can be inseminated with sperm from the same ejaculate. Where multiple females are to be inseminated, one must know the concentration of sperm in the ejaculate so that each female can be inseminated with a threshold number (minimum number) of spermatozoa to maximize the probability of a pregnancy.

Evaluation of Semen is Needed Before Dilution

Immediately after the collection of the ejaculate seminal evaluation is conducted. First, ejaculate volume must be determined. Second, the percentage of sperm displaying progressive motility (swimming in a linear fashion) is estimated by viewing live smears at 37°C with a phase-contrast microscope. Third, the concentration of spermatozoa in the ejaculate is determined by comparing optical density of a standard volume of neat semen with reference values. The greater the sperm concentration, the greater the optical density. The sperm concentration is determined from a standard curve where optical density is plotted against concentration.

10

The ejaculate volume and concentration of spermatozoa are important elements of seminal evaluation because the volume multiplied by the concentration equals the total number of sperm in the ejaculate as shown in the equation below.

Total Sperm in Ejac. = Ejac. Vol. x Sperm/ml

Knowing the total number of sperm in the ejaculate enables the laboratory technician to determine how many insemination doses are potentially available within each ejaculate.

A high percentage of motile sperm (60% or more) indicates good quality. An ejaculate containing few motile sperm (less than 50%) is a candidate for discard especially if sperm are to be frozen and later thawed to inseminate females.

Information for determining the number of insemination doses contained in a typical ejaculate for the bull is presented below. These calculations apply in principle to other species except that the values (volume, concentration and motility) may vary significantly from species-to-species and from male-to-male.

Ejaculate volume = 6 ml

Sperm concentration = 1.0×10^9 sperm/ml (1 billion)

Total sperm in ejaculate = 6 ml x 1.0×10^9 sperm/ml = 6×10^9 (6 billion)

Progressive motility = 70%

Total motile sperm = $6.0 \times 10^9 \times .7 = 4.2 \times 10^9$ motile sperm/ejaculate

Desired concentration = 15×10^6/dose (1 insemination)

Number of doses = $4.2 \times 10^9 / 15 \times 10^6$ = **280 doses**

To determine the number of doses a single ejaculate will generate, one must divide the total number of sperm by the desired number of sperm in each dose. For example, the ejaculate illustrated above contains 4.2 billion motile sperm. If a dose of semen is intended to contain 15 million motile sperm (15×10^6) then we divide 4.2×10^9 sperm by 15×10^6 sperm. By the computation in the box above, this ejaculate will produce 280 doses (units) of semen after dilution.

Good seminal extenders must:

- ***be isotonic***
- ***be good buffers***
- ***minimize cold damage ("cold shock")***
- ***provide appropriate nutrients***
- ***prevent microbial growth***
- ***maintain viability***
- ***be relatively low in cost***

Seminal Extenders Extend Both Sperm Viability and Numbers

After it has been determined that the ejaculate is of sufficient quality (volume, % motile spermatozoa and concentration of spermatozoa) the sperm must be preserved so that they can be used to inseminate females over an extended period of time (e.g. several days to one week). To inseminate many females with a single ejaculate the neat semen must be extended so that each inseminate dose contains less sperm than the entire ejaculate. Typically, the solution into which spermatozoa are diluted is referred to as an **extender** because it not only "extends" the number of sperm in the original ejaculate, but it "extends" their functional life. Extenders may be purchased from commercial sources or they can be prepared in the laboratory.

The Extender Must be Isotonic

You will recall from your basic biology class that when a cell is in an isotonic solution there is no net movement of water into or out of the cell. A **hypotonic** solution is a solution in which the medium contains fewer osmotically active particles than the cell and water rushes into the cell and the cell membrane ruptures (**cell lysis**). In contrast, a **hypertonic** solution contains more osmotically active particles than does the inside of the cell and water moves out of the cell and it dehydrates. Providing the proper osmotic pressure of the seminal extender is obligatory for survival of spermatozoa.

An Extender Must be a Good Buffer

A **buffer** is a material that prevents marked changes in pH (hydrogen ion concentration). High concentrations of hydrogen ions (high acids) results in death of a cell. Likewise, highly alkaline solutions (high hydroxide ion concentrations) damage and kill spermatozoa. Typical buffers used in seminal extenders are tris, sodium citrate and sodium phosphate.

The cell membrane of a spermatozoon is quite sensitive to sudden drops in temperature ("cold shock"). Care must be taken to prevent sudden declines in temperature so that the cell membrane and motile apparatus of the sperm do not become damaged. In neat semen, particular care must be taken to prevent damage to the spermatozoa. The design of the artificial vagina is important so that "cold shock" can be prevented (See Chapter 11). Slow, controlled cooling of sperm is important because it lowers the temperature gradually and minimizes stresses on the cell membrane. A low storage temperature reduces metabolism by about 50% for each 10°C decline. Sperm are analogous to a battery. They have no option but to "run down." Unfortunately, recharging sperm cells after ejaculation is not possible.

Where the goal is to extend the semen for a sustained period of time (1 week to years), a **cryoprotectant** in the extender is required. Cryoprotectants are materials that protect the cells against cold damage that would occur between 0 and -50°C. In general, cyroprotectants can be classified as cell-penetrating (glycerol, DMSO) and non-penetrating (milk protein and egg yolk lipoprotein). Depending on species, one or a combination of types of cryoprotectants may be optimum. Common cryoprotectants are **glycerol** and **dimethyl sulfoxide** (DMSO) with glycerol being the dominant cryoprotectant for frozen sperm. Physiologic fluids are used frequently as extender ingredients. These include hen's egg yolk and cow's milk. These provide lipoproteins that minimize cold damage and they also provide nutrients.

The rate of temperature decline and the ultimate storage temperature is important depending on species. For example, a slow decline in temperature is important in the bull and the stallion but is of much less importance to the dog and human. The influence of holding temperatures for unfrozen sperm also vary among species. For example, bull and stallion semen can be stored effectively at 5°C while boar semen requires 18°C for best preservation. These differences are due, at least in part, to differences in lipid composition of the sperm membranes.

Spermatozoa have no **anabolic** capability. In other words, spermatozoa are incapable of synthesizing materials for energy and repair. Therefore, the viability of sperm is totally dependent on the environment in which they are suspended. Nutrients need to be supplied in adequate quantities so that metabolism can be maintained for the appropriate duration of time. The major nutrients for sperm metabolism are **fructose** and **glucose**. Sperm are capable of converting glucose to fructose and metabolizing it to fuel their motility.

Ejaculated Semen is Not Sterile

Bacteria are present in the sheath and on the penis of the male and occasionally in the urethra and vesicular glands and therefore semen contains a variety of microorganisms. Seminal plasma and extender are ideal mediums for microbial growth and steps must be taken to minimize this growth. Antibiotics typically are added to the neat semen and extender to prevent microbial growth. Antibiotics such as penicillin, liquamycin, linco-spectin and streptomycin may be added in some combination to neat semen and to extenders.

Preservation of spermatozoa can be accomplished using two methods. For relatively short term use, fresh liquid semen is used after the semen has been extended. In most species, liquid semen can be cooled and stored at near freezing temperature (5°C) for several days to about one week. In swine, 17-18°C is optimum. When widespread distribution and long-term usage is a requirement, frozen semen is the preferred method of preservation. When frozen semen is used careful attention to freezing and thawing techniques must be practiced. Freezing and thawing compromises spermatozoal viability in all species. However, the degree to which viability and fertility are affected depends on the individual male and species.

Sex of the Conceptus is Determined by the Sperm Because Each Spermatozoon Contains Either an X or a Y Chromosome

As you already know, each secondary spermatocyte produces two haploid daughter spermatids. Each spermatid contains either an X or a Y chromosome. Sperm containing the **X chromosome** that fertilize an oocyte will generate a female. Sperm containing the **Y chromosome** will generate a male (See Figure 10-15).

The desire to separate the X and Y bearing sperm is driven by the fact that one sex has significantly more economic value than the other in certain species. For example, in the dairy industry, bull calves are of little value since about 80% of all cows in the U.S. (and higher on a worldwide basis) are artificially inseminated. Thus, relatively few bulls are required to inseminate the cows in the national dairy herd. The cow, the source of milk, is the primary income generator for a dairy business. It would be advantageous to have a high percentage of female offspring since lactation is limited to the female. In other food producing animals, it might be more desirable to produce higher percentage males since these animals grow faster and have more desired meat characteristics.

It is known that the X and Y chromosome contain different quantities of DNA. For example, an X bearing sperm contains 2.8-4.2% more DNA (depending on the species) than does a Y bearing sperm. Based on this difference, it is possible to separate the X and Y bearing sperm into two subpopulations. The separation procedure requires the uptake of a DNA stain or dye (called a **flourochrome**) into both living and dead spermatozoa. Those sperm that contain the X chromosome "take-up" more DNA dye than do sperm containing the Y chromosome. Vital dyes used to stain sperm produce emissions of light at a specific wavelength when excited or activated by light at a specific wavelength.

The technology utilized for separation of X and Y bearing spermatozoa is referred to as flow cytometry (sometimes called "cell sorting"). Figure 10-15 highlights the major steps for separation of the X and Y bearing spermatozoa using flow cytometry.

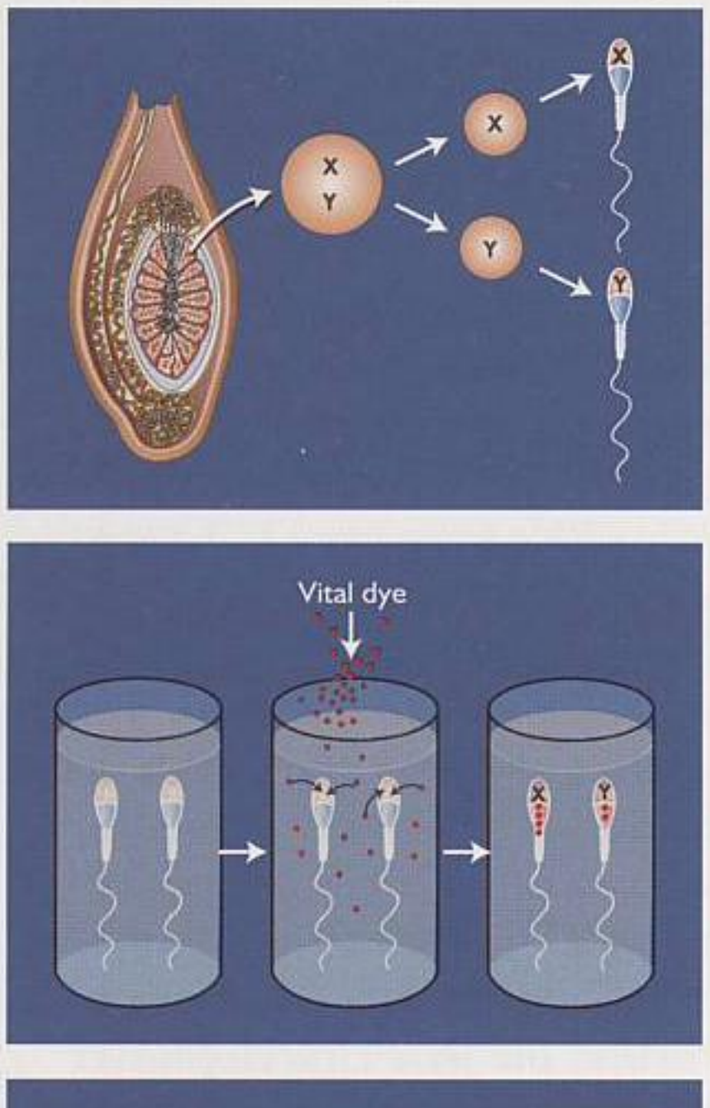
Experimental evidence clearly shows the success of this technology for separating the X and Y bearing spermatozoa from common mammals and most experiments have yielded 80-90% successful separation for either males or females in cattle, swine and rabbits (See Table 10-3). There are several factors that have prevented this technology from receiving widespread application. Limitations to this technique include the high cost of equipment. In addition to the cost, a flow cytometer separates sperm at a slow rate.

Regardless of the problems associated with separating the X and Y bearing spermatozoa, it is inevitable that improvement of the technology will occur. Thus, it is reasonable to expect that separation of X and Y bearing spermatozoa eventually will be commonplace. Manipulation of the sex ratio under controlled conditions could greatly impact the efficiency of food animal production.

Table 10-3. Offspring Ratios of Spermatozoa Sorted for the X and Y Chromosome

Species	Sorted for Y Chromosome		Sorted for X Chromosome	
	% Male	% Female	% Male	% Female
Cattle	81	19	11	89
Rabbit	81	19	6	94
Swine	75	25	10	90

Figure 10-15. Major Steps for Separation of X and Y Bearing Spermatozoa by Flow Cytometry

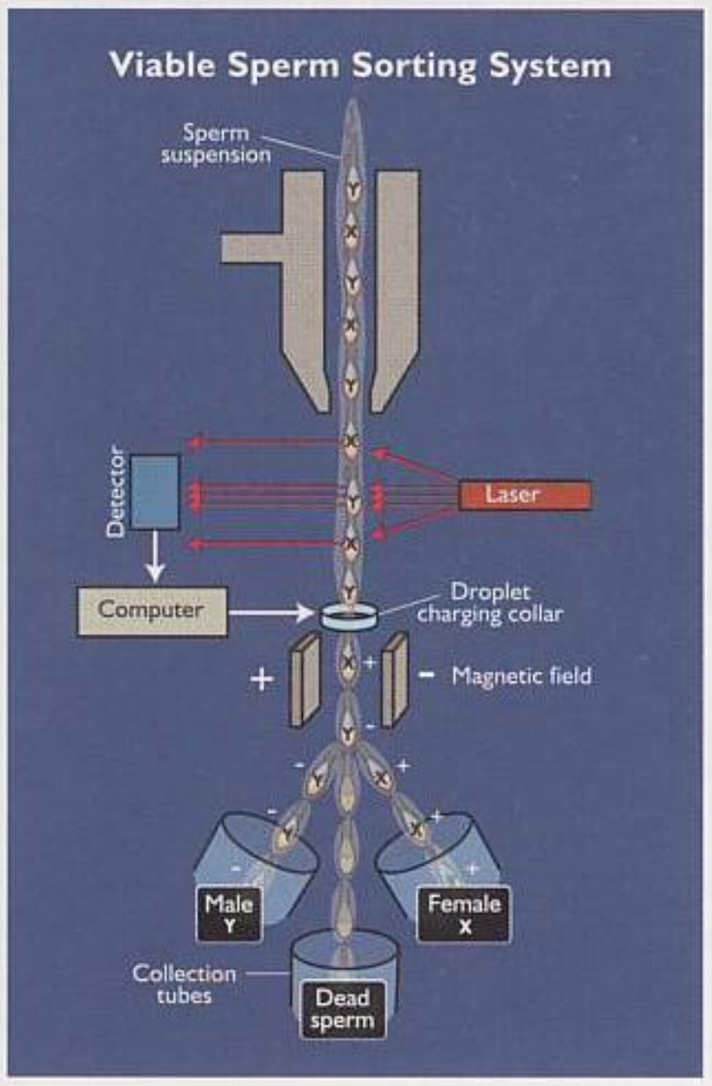


Step 1

X and Y bearing spermatozoa are produced by the testis and ejaculated by the male.

Step 2

Ejaculated spermatozoa are treated with a DNA dye (fluorochrome). X bearing sperm absorb more dye than Y bearing sperm. They therefore emit more intense light when excited by a laser. Sperm also are treated with a dye that greatly suppresses the signal from dead sperm. Dead sperm are therefore identified and rejected.



Step 3

Once spermatozoa enter the flow cytometer chamber, they pass single-file through a small nozzle. At a region just outside the nozzle, an excitation laser beam activates the fluorescent dye in each sperm and each live sperm produces an emission with an intensity that is directly related to the quantity of DNA within the sperm head. X-bearing live sperm produce more intensity. A light sensing device is coupled to a computer that determines the intensity of light emission by each sperm and the order of passage of each sperm through a column below the nozzle. When the sperm pass by charged plates, they are assigned either a positive or negative charge depending on their DNA content (X or Y chromosome). When the microdroplet containing a single sperm passes through an electromagnetic field the computer applies an appropriate charge and directs the droplet (and sperm) to one side or the other. Dead sperm are discarded into the center tube. Thus, at the conclusion of the separation process there are three vessels that contain sperm. One contains a high proportion of X, one contains a high proportion of Y chromosome bearing sperm and one contains dead sperm.

Further PHENOMENA for Fertility

Spermatozoa of the American opossum are ejaculated in doublets. They are formed in the seminiferous epithelium as single cells with an acrosome. During epididymal transit the acrosome of two spermatozoa attach to each other, so that a pair of spermatozoa exists. These doublets apparently have more progressive motility than do single cells. When motility ceases they apparently separate.

In Greek Mythology, when Priapus was in the womb of his mother Aphrodite, Hera put a spell on him to make him ugly. When he was born, he was of small stature and very ugly but possessed an extremely large penis that was always erect. The name Priapus gave rise to the medical term "priapism", which is defined as a persistent (sometimes painful) erection of the penis, associated with some form of pathology (blood clot in cavernous tissue) and not sexual excitation. Priapus became known as the Greek God of Fertility in most species, including plants, animals and humans. As the source of fertility, statues of Priapus were kept in gardens to ensure fertile crops and to scare away thieves. He has also been thought to be a cure for impotence.

In some regions of the world, testes are prized as gourmet treats. In Japan, testicles of dolphins are highly valued hors d'oeuvres. In Spain, bull testicles are served at social events surrounding the occasion of a bull fight. Bull testicles are also consumed by hungry American cowboys at castration time. In all cases, they are cooked.

The bulls at a leading AI organization produce a lot of sperm. The annual semen production from the bulls collected is as follows:

- *42-43,000 ejaculations per year*
- *205 trillion spermatozoa per year*
- *454 lbs. (206kg) neat semen per year*
- *10,282,759 0.5-ml straws per year*
- *12,196 lbs. (6.1 tons) of extended semen per year*

It is rumored that during the early stages of Christianity, the church had succeeded in getting the pagans to give up worship of all the old gods except Priapus (the Greek God of Fertility with a huge penis). No matter what the threats or enticements were, the loyal worshipers of Priapus would not give up reverence for their favorite god. The expression of this unwavering reverence included the baking of bread in the shape of a penis on every available celebratory occasion, including church holidays. Unable to dissuade the people from this rather un-Christian practice, the wise church fathers sanctified the loaves, providing each had three crosses carved into its top. This was the reported beginning of hot crossed buns.

The ancient Greeks thought that spermatozoa from the left testicle produced girls and spermatozoa from the right testicle produced boys. This myth apparently stood the "test of time" because as late as the 1700s, French noblemen would have their left testicle removed in an attempt to sire boys only. The author proposes that the modern day declaration by males, "I would give my left testicle for a ---", is a sexist comment that devalues the left testicle because it was once thought to produce females only. Have you ever heard a male say he was willing to give-up his right testicle for something?

Lazzaro Spallanzani was a mathematician and philosopher. He was also a priest who conducted experiments with sperm and eggs. His religious beliefs prevented him from collecting and working with human sperm. He wondered, though, if every human sperm in an ejaculate had a soul and, if so, what happened to the millions of souls in wasted semen. If every sperm had its own soul, then masturbation and contraception were serious sins. In Spallanzani's era (1700s) many biologists believed in "remote fertilization," in which the egg could

be stimulated to develop without contact with semen. They thought if an egg were exposed to invisible "spermatic vapor" it would develop into an embryo. Since "spermatic vapor," like a ghost, could not be seen there was some worry that this ghostly vapor, once released from an ejaculate, might waft-up the legs of some unsuspecting female, causing an unwanted pregnancy. No one knows how many unmarried women of Spallanzani's era may have credited their pregnancies to "spermatic vapor." Spallanzani believed in these sperm ghosts but wanted to test his belief. He attached freshly laid toad eggs to a watch glass and inverted it over another watch glass containing toad seminal fluid. He thus had an enclosed system in which the eggs and seminal fluid were separated, and where the invisible "spermatic vapor" could migrate to stimulate the eggs. Nothing happened. But when the eggs were mixed directly into seminal fluid, the physical contact produced tadpoles. How did Spallanzani obtain frog semen? He dressed male frogs in tiny taffeta trousers and placed them with a female frog (without clothes). He waterproofed the pants with a light coating of candle wax. Aroused, the males mounted the females and ejaculated in their pants. Spallanzani then collected the semen. These experiments might have been the forerunners to in vitro fertilization because tadpoles developed. Spallanzani was one of the first scientists to achieve artificial collection of semen in a laboratory under controlled conditions.

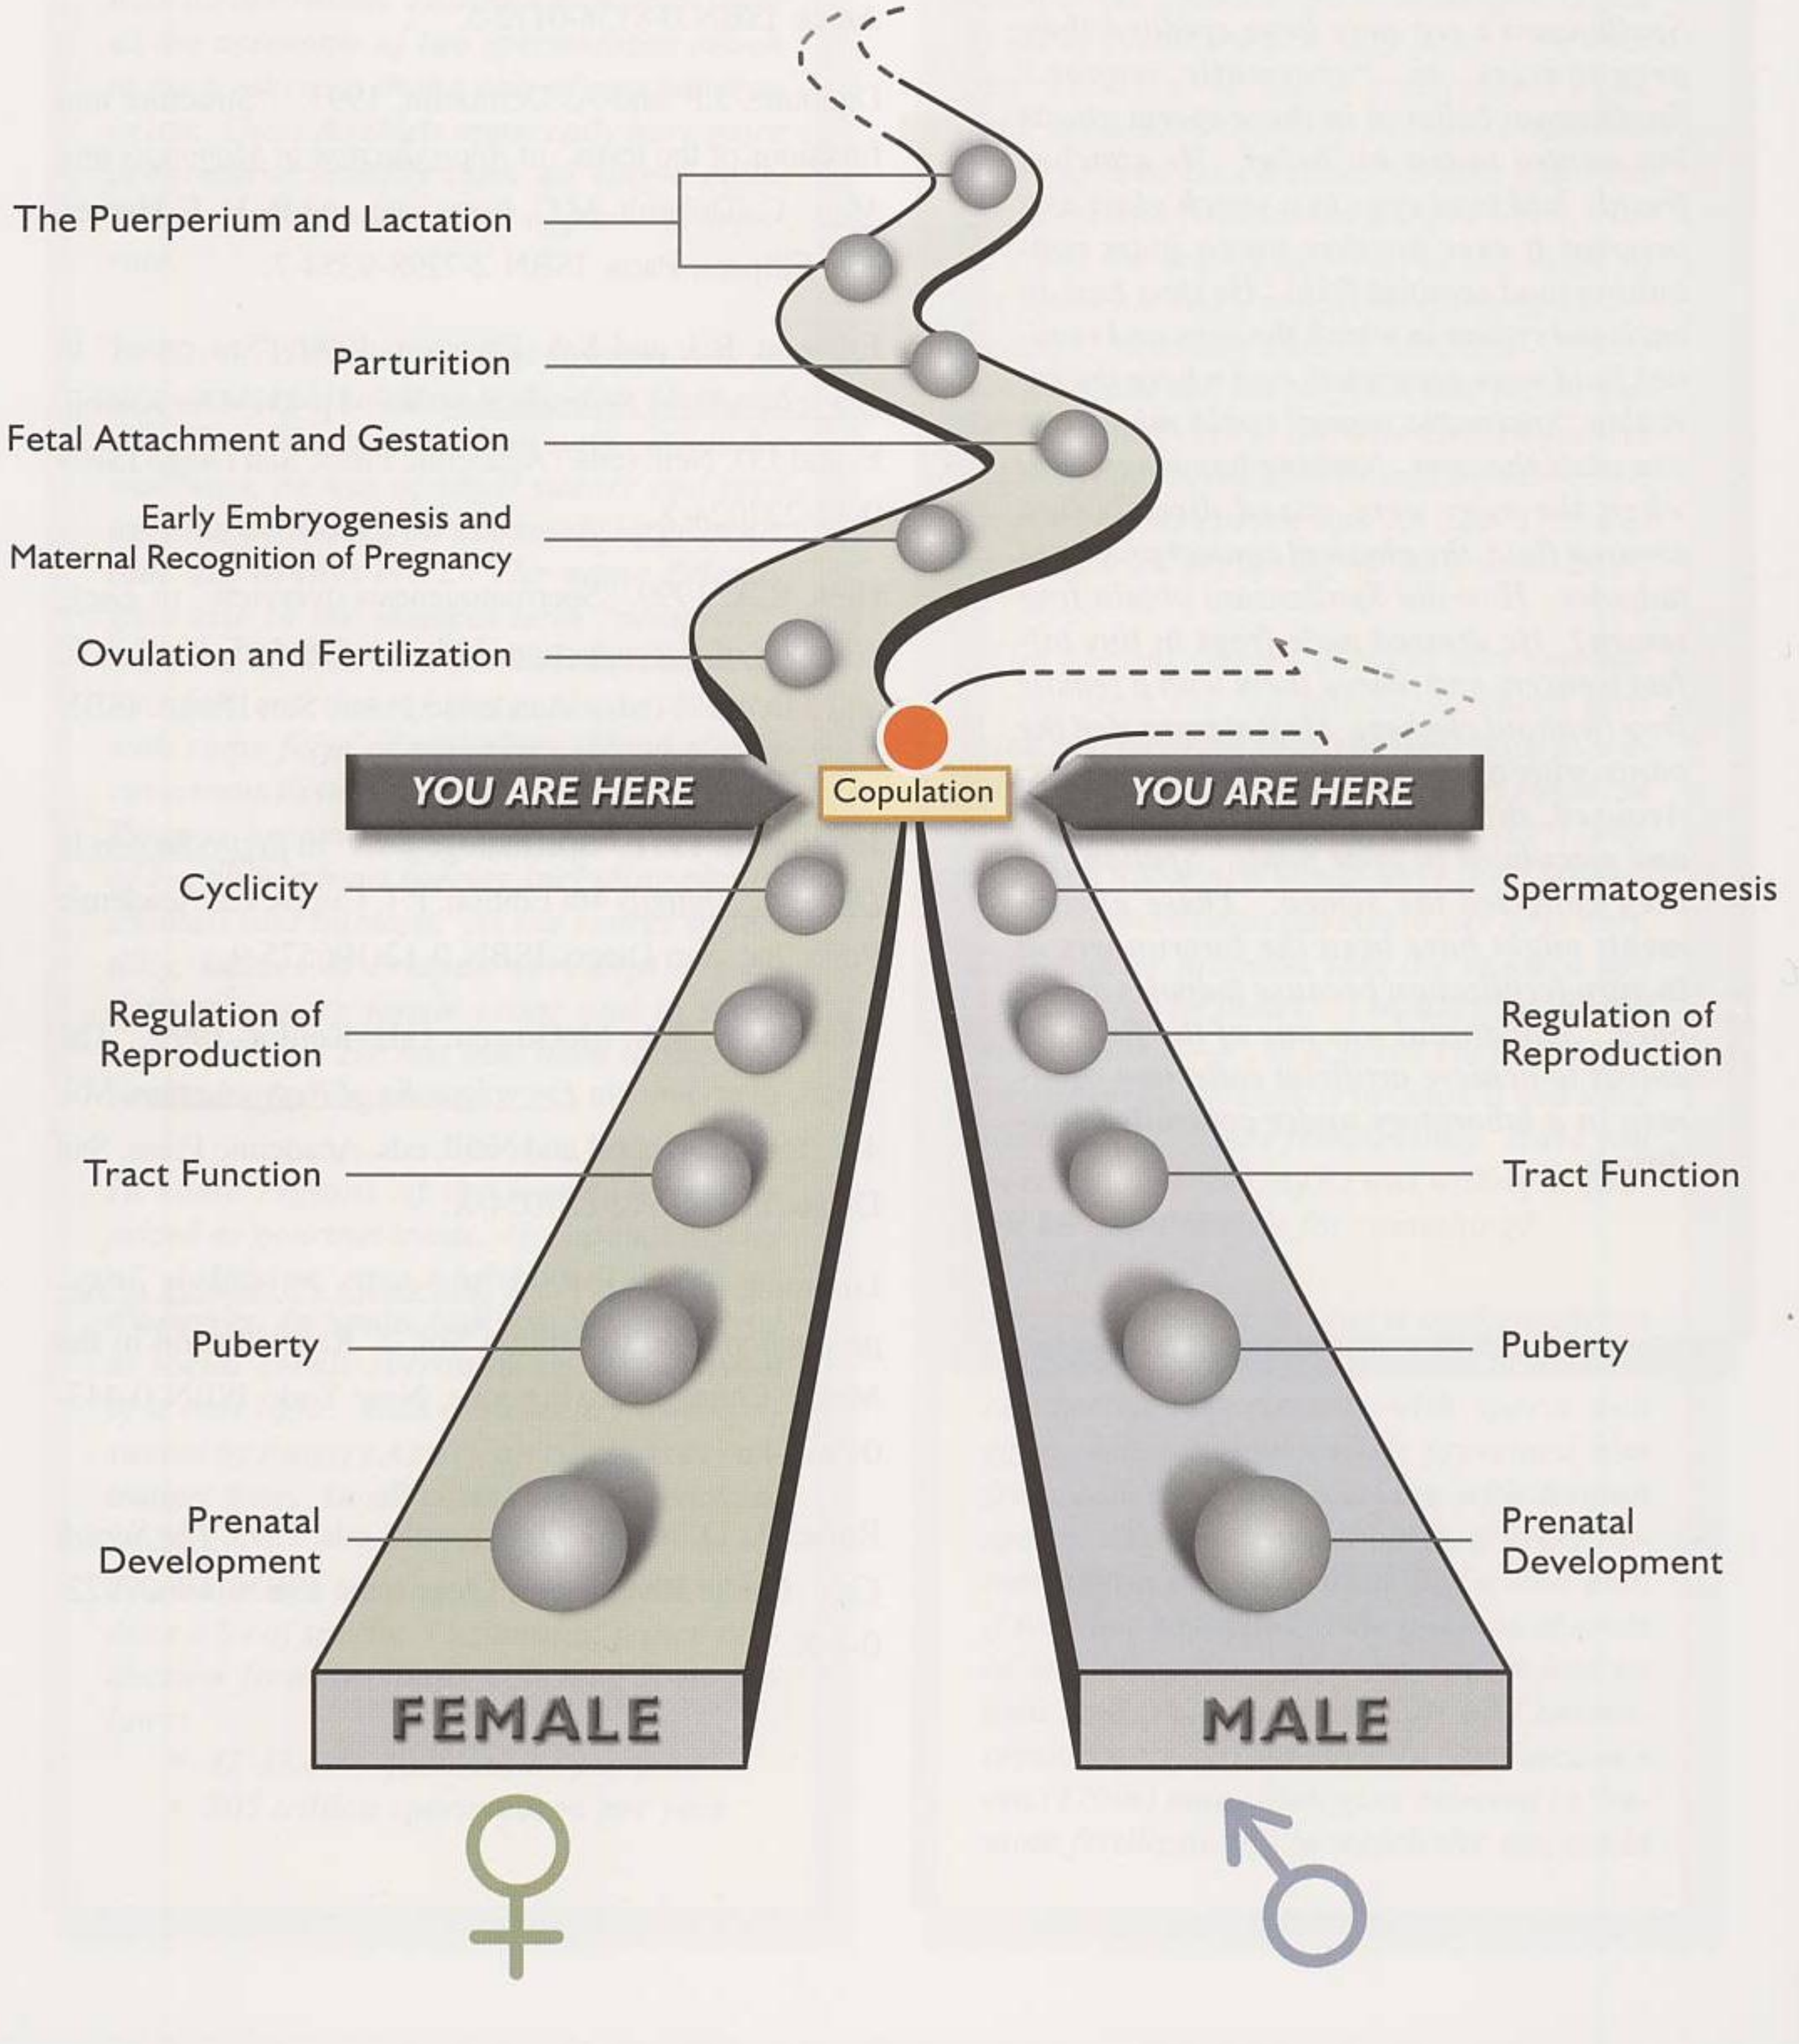
CHAPTER 11

Reproductive Behavior



Take Home Message

Reproductive behavior is an obligatory component of the reproductive process. It consists of precopulatory, copulatory and postcopulatory stages. In the female sexual receptivity occurs only during estrus and is characterized by distinct behavior and mating posture (lordosis). In the male, reproductive behavior can occur potentially any time. Sexual arousal in the male involves a cascade of endocrine and neural events that result in erection of the penis, mounting of the sexually receptive female, intromission and ejaculation. Erection of the penis involves specific neural and biochemical events that culminate in penile vasodilation. Ejaculation is a reflex that is initiated by stimulation of the glans penis and concludes with expulsion of semen.

Reproductive behavior has evolved as one of the strongest drives in the animal kingdom and usually takes precedence over all other forms of activity such as eating, resting and sleeping. The purpose of reproductive behavior is to promote the opportunity for copulation and thus increase the probability that the sperm and the egg will meet. The ultimate goal of copulation is pregnancy, successful embryogenesis and parturition.

Reproductive behavior in the male consists of three distinct stages:

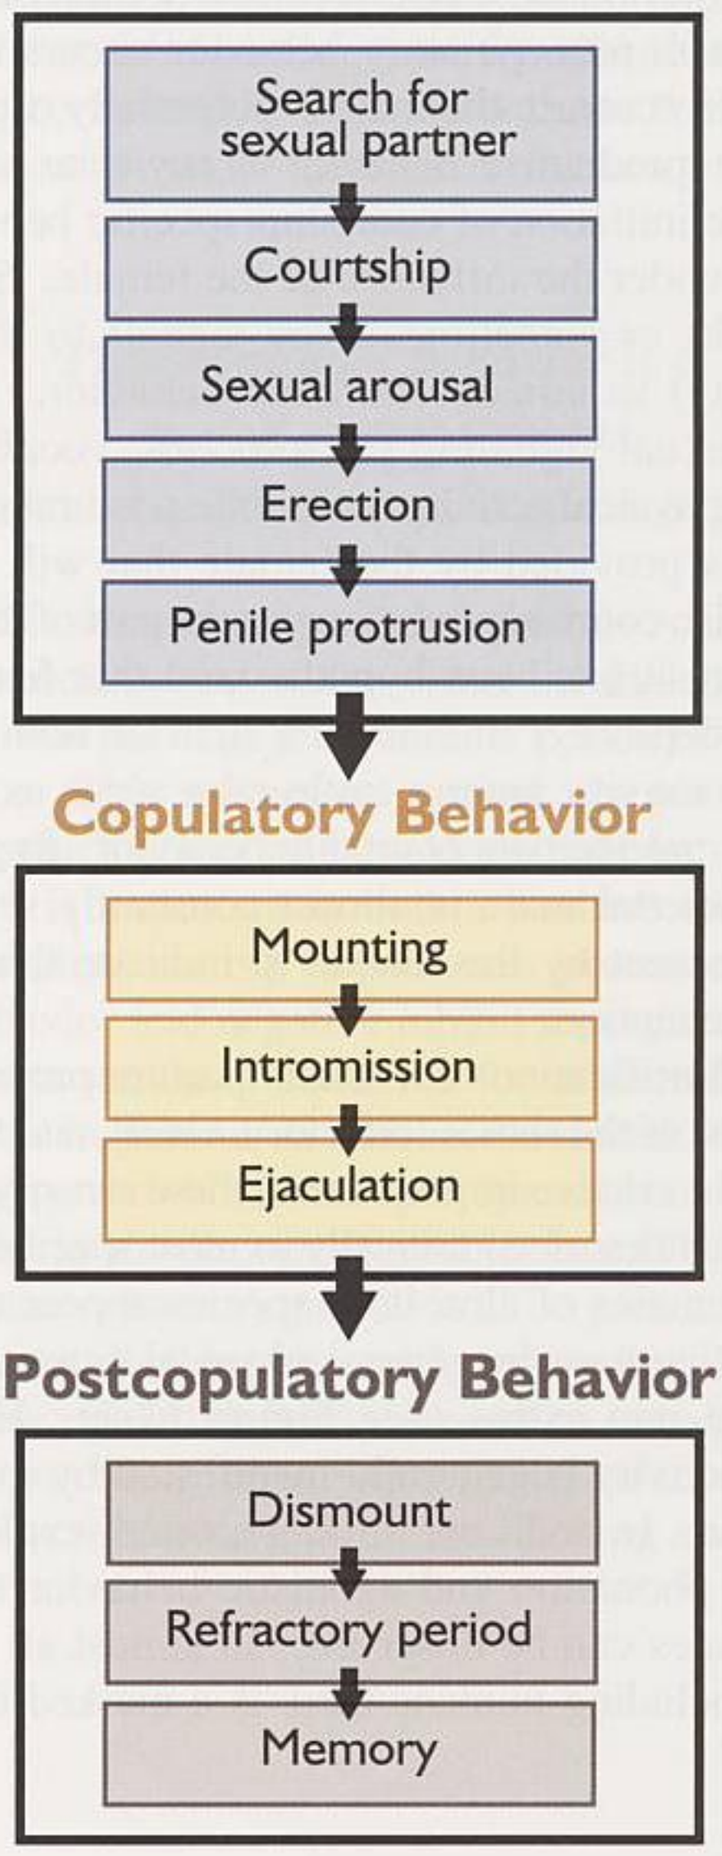
- ***the precopulatory stage***
- ***the copulatory stage***
- ***the postcopulatory stage***

Reproductive behavior in the male can be divided into three distinct stages. These stages are: the **precopulatory stage**; the **copulatory stage**; and the **postcopulatory stage**. The specific events that occur during each of these stages are presented in Figure 11-1.

Reproductive behavior in the female can be considered to serve the following functions:

- ***attractivity***
- ***proceptivity***
- ***receptivity***

Figure 11-1. Stages of Male Reproductive Behavior and Specific Events in Each Stage



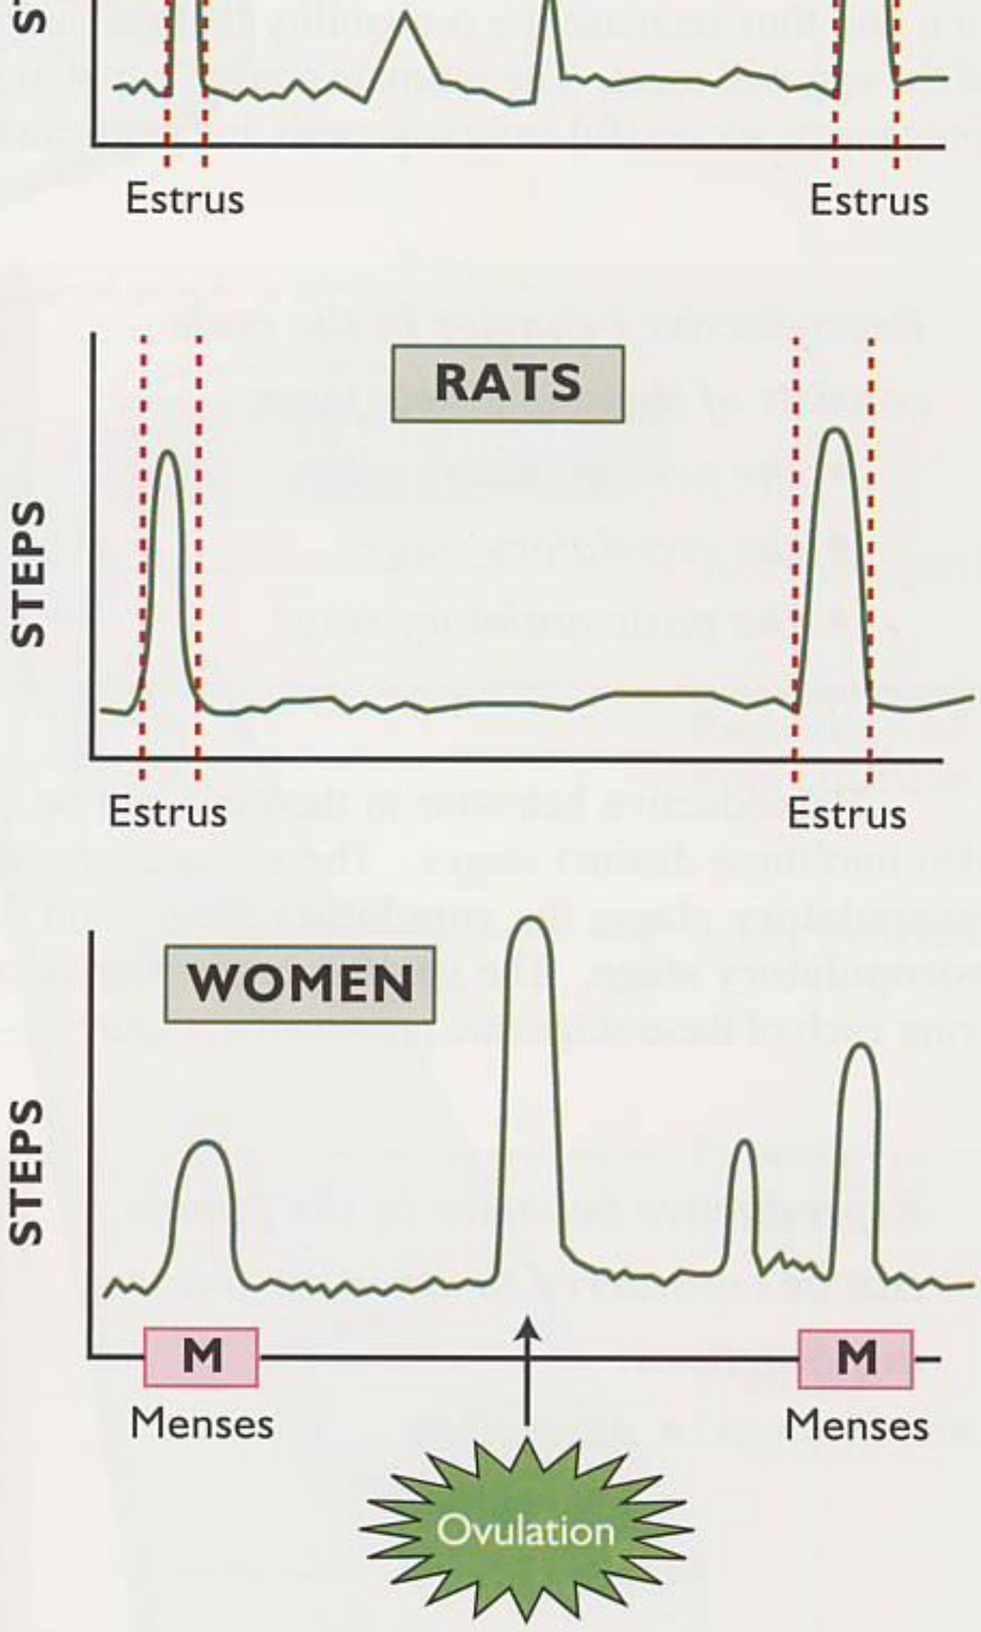
Precopulatory, copulatory and postcopulatory behaviors in the female can be considered as serving the functions of: attractivity, proceptivity and receptivity. **Attractivity** refers to behaviors and other signals that serve to attract males. This can include postures, vocalizations, behaviors and chemical cues such as pheromones that attract the male to approach and engage in precopulatory behavior. **Proceptivity** refers to the behaviors exhibited by females toward males that stimulate the male to copulate or that reinitiate sexual behavior after copulation. For example, head butting of the male and mounting the male are two of the most common proceptive behaviors exhibited by females. Proceptivity may also include behaviors among females, such as female-female mounting that sexually stimulate males. Finally, **receptivity** is the copulatory behavior of females that ensures insemination. This may include the immobility or standing response (lordosis) as well as tail deviation or backing-up toward the male.

As you have already learned, sexual activity of the postpubertal female is confined to estrus (heat). This short period of sexual receptivity limits the time during which precopulatory behavior occurs in most females. In contrast, the male is potentially capable of initiating reproductive behavior at any time after puberty. The initiation of courtship-specific behavior is generally under the influence of the female. She will send subtle, or sometimes overt signals to the male (attractivity) to initiate courtship behavior. Factors such as sexual signaling pheromones, vocalization, increased physical activity and subtle postural changes are signals provided by the female that will initiate more intense courtship behavior on the part of the male. In addition, it has been hypothesized that female-female (proceptivity) interactions such as homosexual mounting activity among cattle may serve as signals to initiate male-female courtship behavior. In general, the postpubertal male is almost constantly searching for signals sent by the female to indicate that she is sexually receptive.

Identification of a sexual partner probably requires most of the senses (olfactory, visual, auditory and tactile). The relative importance of these sensory stimuli has not been described critically in most species.

Females of almost all species appear to show a marked increase in general physical activity when they come into estrus (See Figure 11-2). Elevated physical activity is generally manifested by increased locomotion. In addition, milling around, exploration, increased phonation and agonistic behavior towards other females can be observed. In almost all species studied, including humans there is a marked increase

Figure 11-2. Relationship Between Physical Activity and Reproductive Cycles in Various Female Mammals



Physical activity increases significantly around the time of ovulation.

in physical activity that accompanies the time of ovulation. Presumably, this physical activity is associated with searching for a mate. This increased physical activity can be measured by equipping females with pedometers. Pedometers are devices that monitor and quantitate steps taken by the animal and are currently used in commercial dairy enterprises for detection of estrus.

Courtship-specific behavior is initiated after a sexual partner has been identified.

Once a sexual partner has been identified, a series of highly specific courtship behaviors begin. Courtship-specific behaviors include sniffing of the vulva by the male, urination by the female in the presence of the male, exhibiting **flehmen** behavior (See Figure 11-5), chin resting, circling and increased phonation. In many species the sense of sight appears to be the most important with regard to sexual arousal in the male. This should not be interpreted to mean that other stimuli, such as auditory or olfactory are not important.

Copulatory behavior varies significantly among species with regard to duration.

Lordosis (mating posture) by the female (receptivity) triggers significant sexual arousal behavior on the part of the male. Once the male discovers that the female will display lordosis, he becomes sexually stimulated. It should be emphasized that lordosis is a highly specific female motor response associated with the "willingness" to mate.

Sexual arousal is followed by erection and penile protrusion.

Following exposure to the appropriate stimuli, erection and protrusion of the penis occur. These highly specific motor events are controlled by the central nervous system. The mechanisms of penile protrusion and erection will be presented later. Typical behavior during search, courtship and sexual arousal for domestic animals is presented in Table 11-1.

After significant sexual stimulation, mounting, intromission and ejaculation follow. In general, mammals can be classified as sustained copulators or short copulators. The bull, ram, buck and tom are short copulators while the boar, dog and camelids are sustained copulators. The stallion is intermediate with regard to duration of copulation.

Mounting behavior requires immobilization on the part of the female and elevation of the front legs of the male to straddle the posterior region of the female (See Figure 11-10). **Intromission** is entrance of the penis into the vagina. **Ejaculation** is expulsion of semen from the penis into the female reproductive tract.

Copulatory behavior on the part of the male is learned. Past sexual experiences are important in order for the male to develop appropriate reproductive behavior. For example, negative experiences during the precopulatory and copulatory stages will generally result in less enthusiasm on the part of the male. From a practical standpoint, management of the breeding male should always be directed towards providing the male with totally positive stimuli. Utilizing non-estrus females to collect semen from stallions, boars, rams and bulls should be avoided because these females do not willingly stand to be mounted. Injury to both the female and the male can occur under these circumstances.

Postcopulatory behavior is a period of refractivity.

Postcopulatory behavior involves dismounting and a period during which either the male, the female or both will not engage in another period of copulatory behavior. This **refractory period** is a period of time during which a second copulation will not take place. Memory is important in both a positive and negative way. Positive mating experiences promote reproductive behavior and negative inhibit reproductive behavior. When semen is collected for artificial insemination, it is important to reduce the duration of the refractory period when multiple ejaculations need to be collected in the shortest possible time. Techniques to reduce the refractory period will be presented later in the chapter. Both males and females often display specific postcopulatory behavior such as vocal emissions, genital grooming, changing postural relationships and various tactile behaviors, such as licking and nuzzling.

Table 11-1. Typical Behavior During Search, Courtship and Consummation by Female and Male Domestic Animals

Species	Search	Courtship	Consummation
FEMALE			
Cow	Increased locomotion, increased vocalization, twitching & elevation of the tail	Increased grooming, mounting attempts with other females	Homosexual mounting & standing to be mounted
Mare	Increased locomotion, tail erected ("flagging")	Urination stance, urination in presence of stallion	Presents hindquarters to male, clitoral exposure by labial eversion, pulsatile contractions of labia
Ewe	Short period of restlessness ram "seeking"	Urination in presence of ram	Immobile stance
Sow	Mild restlessness	Immobile stance	Immobile stance
Bitch	Roaming	Immobile stance	Tail deflected to one side Urination in presence of male affectionate head rubbing
Queen	Vocalization (calling)	Crouching, affectionate head rubbing, rolling	Elevation of rear quarters and hyper-extension of back (lordosis), presentation of vulva, tail deviation
MALE			
Bull	Approach sexually active group of females testing for lordosis, flehmen	Nuzzling and licking of perineal region: chin resting, testing for lordosis	Penile protrusion with dribbling of seminal fluid with few sperm-atozoa, erection and attempted mounts
Stallion	Visual search, flehmen	High degree of excitement	Penile protrusion with no preejaculatory expulsion of seminal fluid
Ram	Sniffing and licking of ano-genital region, nudging ewe, flehmen	Neck outstretched and head held horizontally	Repeated dorsal elevation of scrotum, penile protrusion with no dribbling of seminal fluid
Boar	Moving among females	Nuzzling, grinding of teeth, foams at mouth	Penile protrusion, shallow pelvic thrusts, attempted mounting
Dog	Roaming around territory	Sniffing, licking of the vulva	Erection, protrusion of penis, mounting
Tom	Prowling	Biting queen on dorsal neck	Mounting

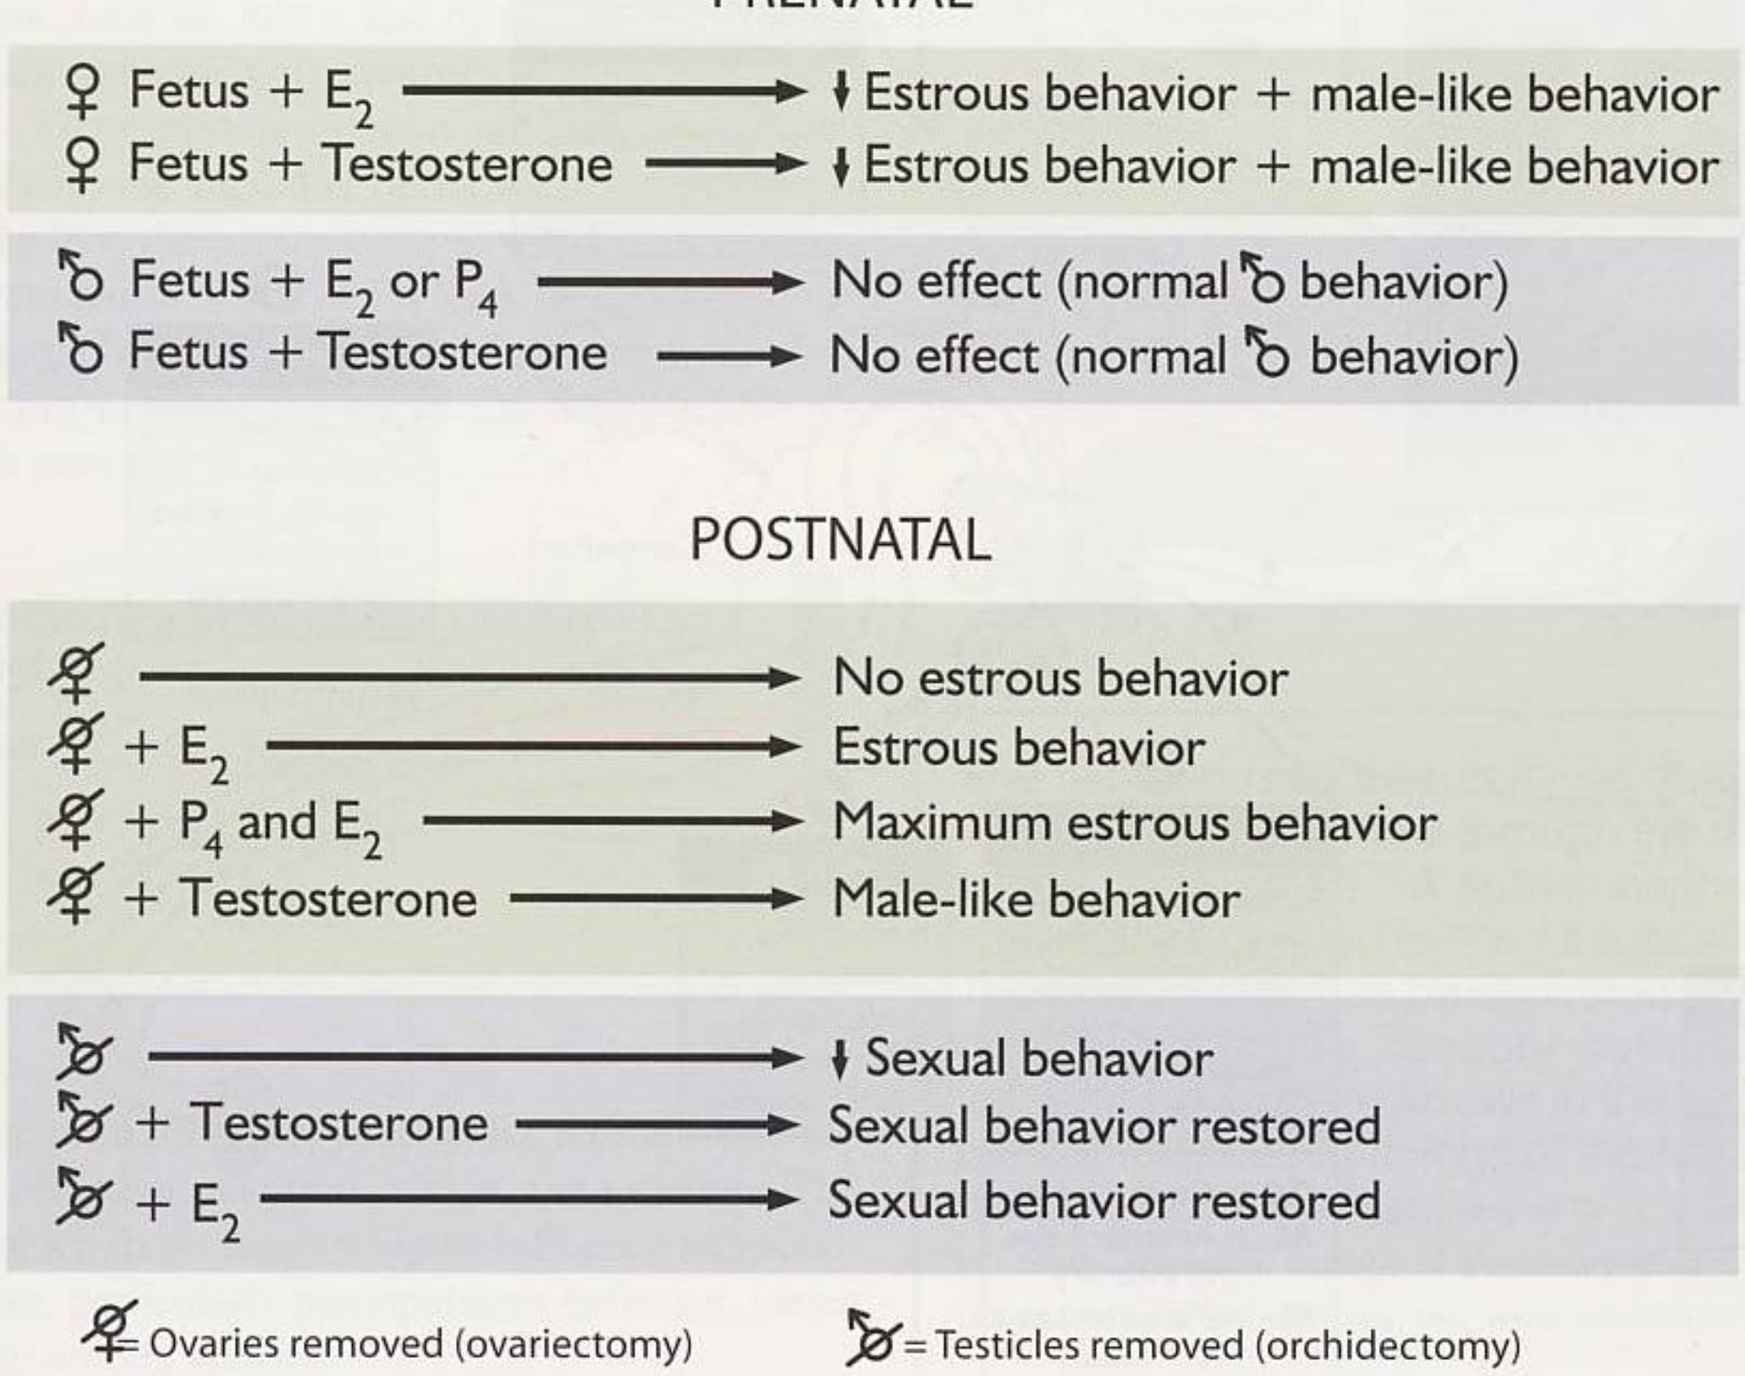
Reproductive Behavior is Programmed During Prenatal Development

During embryogenesis, sexual differentiation occurs, during which the brain is programmed to be either male or female. Recent findings suggest that the very early embryo is neutral with regard to sex (gender). Under the influence of extremely small quantities of estradiol the brain becomes feminized. **Feminization** is the development of female-like behavior. As you learned in Chapter 6, during fetal development, α-fetoprotein is produced that prevents most fetal and maternal estradiol from crossing the blood-brain barrier and entering the brain. When α-fetoprotein prevents estradiol from entering the brain, the embryo becomes "fully feminized," because it has not been exposed to estrogen (See Chapter 6). Alpha-fetoprotein does not bind to testosterone, which can then enter the brain and be converted to estradiol. In developing males this high concentration of estradiol in the brain causes **defeminization** and **masculinization** of the brain. Defeminization reduces the likelihood that the animal will express female-like behavior postpubertally. Masculinization results in the potential of the animal to develop male-like behavior postpubertally.

Sex differences in specific brain structures for the control of reproductive behavior have been observed. For example, in the male, the preoptic area of the hypothalamus is larger than in females. In the male, the size of neurons, the neuron nuclei and the dendritic arborizations are greater. In the female, the ventromedial hypothalamus is more important with regard to reproductive behavior.

In most mammals, reproductive behaviors are sexually differentiated. For example, mounting, erection and ejaculation are typically male behaviors, while standing to be mounted (lordosis), crouching and elevated locomotion are typically female behaviors. These behaviors are endocrine controlled. For example, sequential treatment with progesterone and estradiol induces sexual receptivity in ovariectomized females and testosterone will restore reproductive behavior in castrated males. In some species, injections of testosterone into castrated females will even induce male-like reproductive behavior. Female fetuses exposed to androgens prenatally will display significantly reduced female behavior (defeminized) and acquire male-like behavior postnatally (masculinized). In contrast, males exposed to estrogen or progesterone prenatally are unaffected. A classic example illustrating the

Figure 11-3. Influence of Various Steroid Treatments Upon Reproductive Behavior



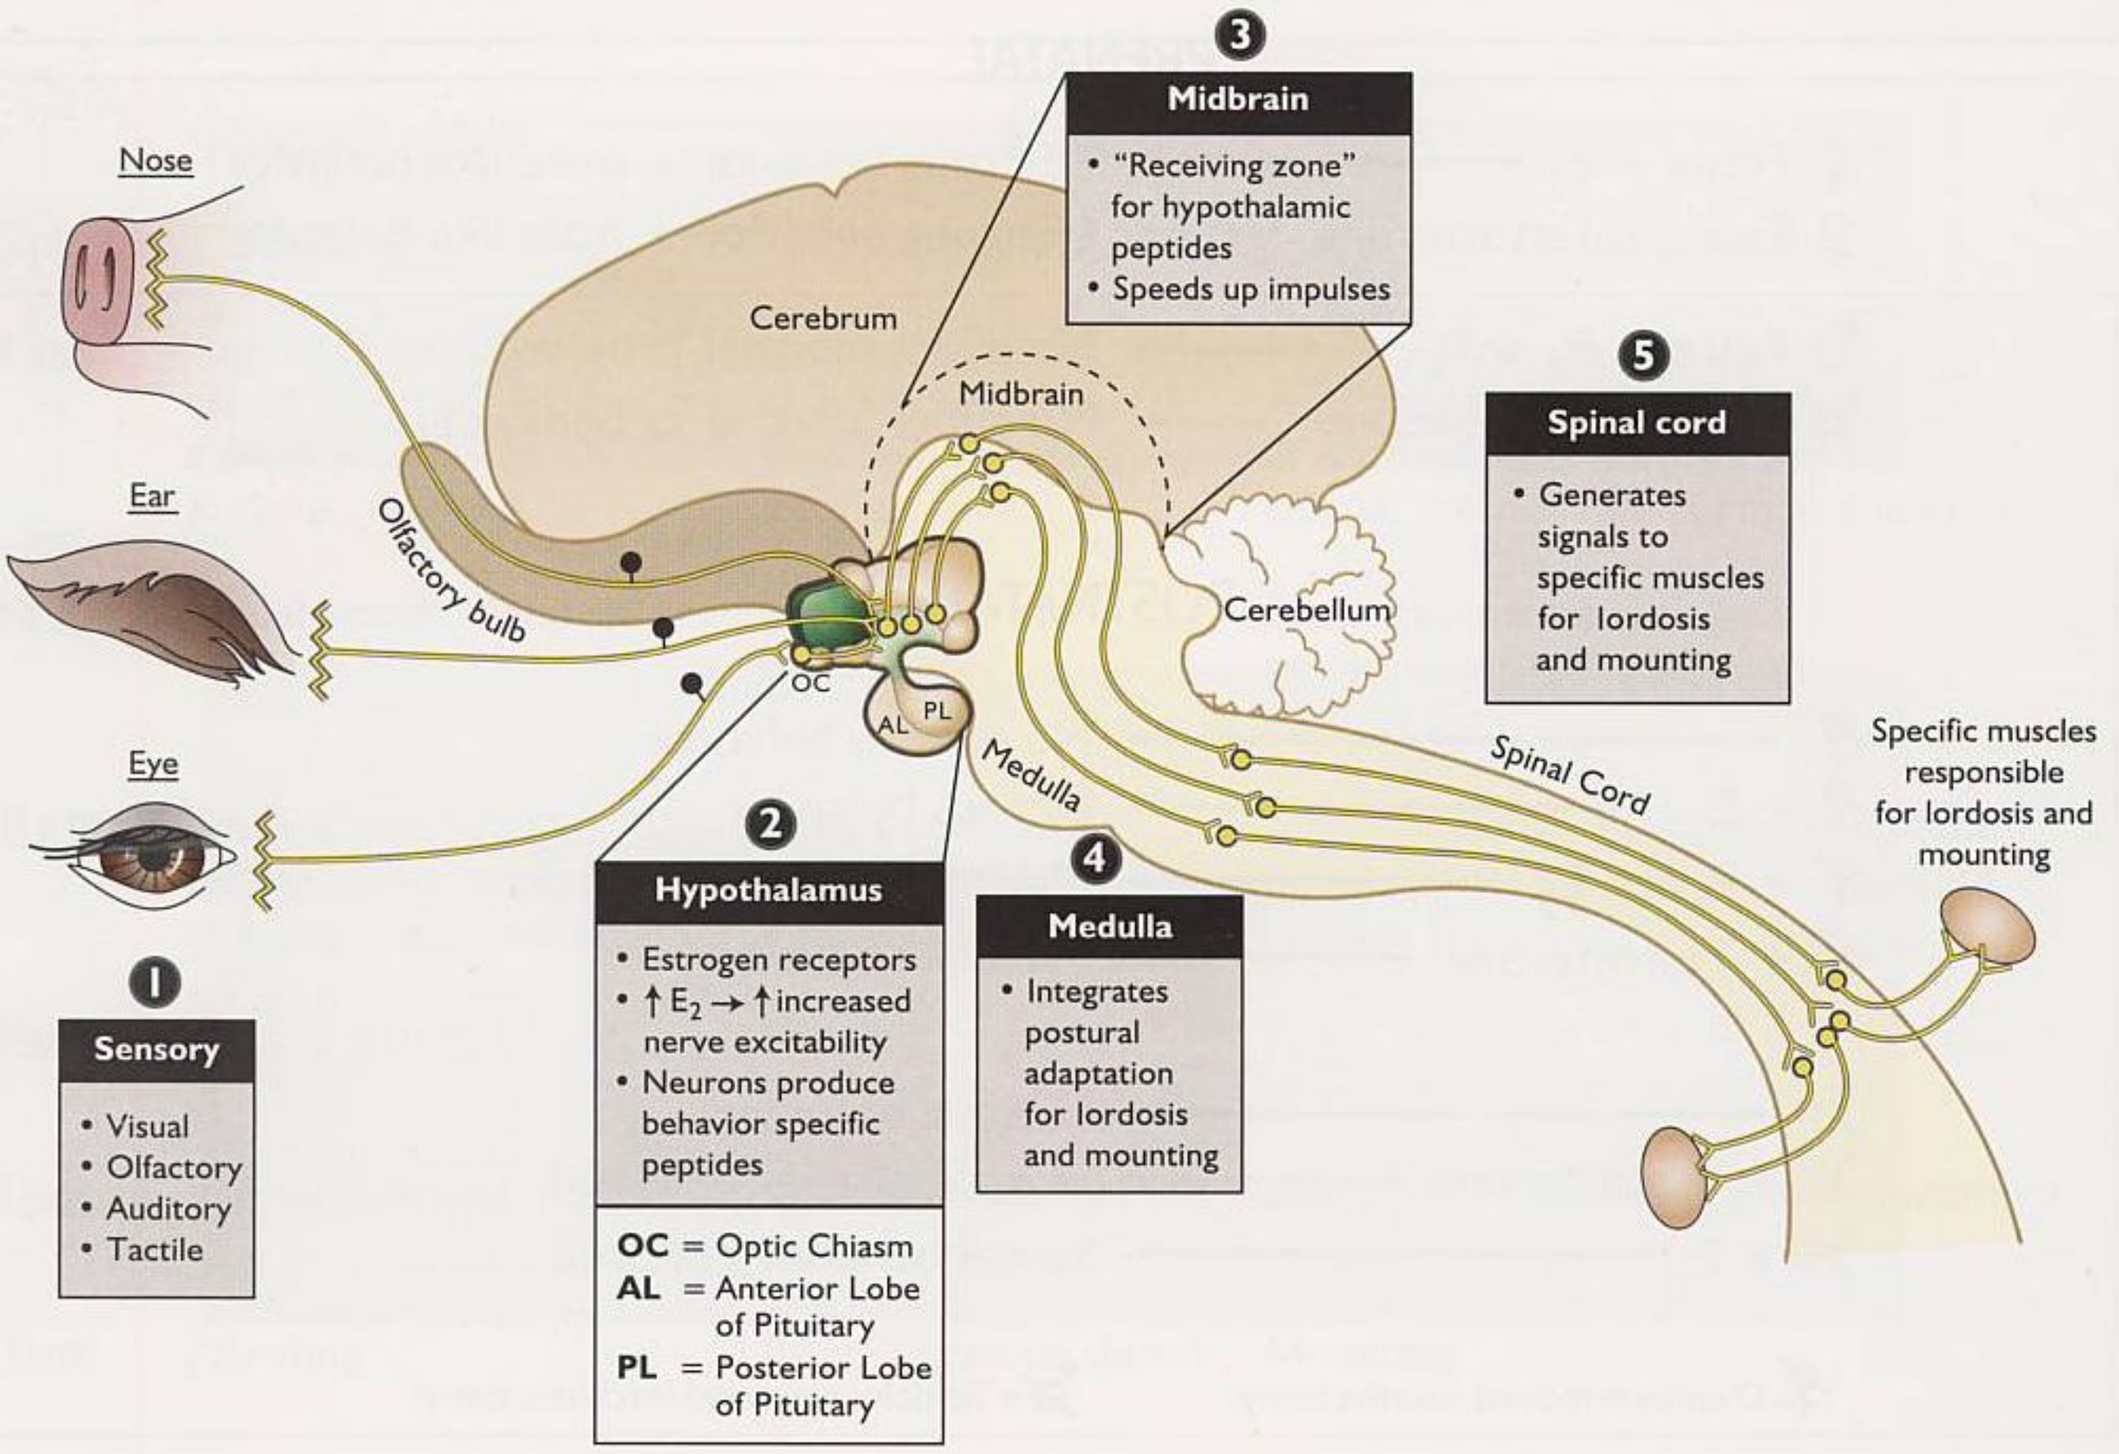
behavioral manifestations of prenatal exposure to androgens is the freemartin heifer. As previously discussed (See Chapter 4), this animal has abnormal development of the reproductive tract for two reasons. First, from a genetic perspective freemartins are chimeras that are XX/XY and therefore they have an ovitestis. Second, androgen exposure per se causes abnormal development of the female tract. In addition, the freemartin displays more male-like behavior than do her normal heifer counterparts. Figure 11-3 summarizes the influence of reproductive steroids on behavior in the male and the female.

The presence of gonadal steroids (estrogen and testosterone) is obligatory for normal reproductive behavior in both the male and the female. For example, ovariectomized females display no estrous behavior (See Figure 11-3). Likewise, castrated males have significantly reduced reproductive behavior. But, the abolition of reproductive behavior depends on the duration of time between castration and the opportunity to copulate. For example, males that have reached puberty and established a sustained pattern of reproductive behavior require a longer period of time between abolition of sexual behavior after castration than do males that have not established a sustained pattern of reproductive behavior.

Females will display male reproductive behavior following injections of testosterone.

When ovariectomized females receive injections of estradiol, estrous behavior is reestablished, but at a less than maximum level. Among farm animals, ovariectomized females that are treated first with progesterone (to mimic the luteal phase of the cycle) and then treated with estradiol display maximum estrous behavior. In other species estradiol must precede progesterone to produce maximal behavior. It is not clear why progesterone "priming" of the central nervous system for maximal stimulation is necessary. Ovariectomized females that are treated with testosterone develop male-like behavior. They will even develop secondary sex characteristics (reduced pitch of voice, hump on the back of the neck and atrophy of the female reproductive tract).

Figure 11-4. Hypothetical Nervous Pathway Eliciting Reproductive-Specific Motor Behavior



Reproductive Behavior is Controlled by the Central Nervous System

The neural pathways and key anatomical components for the control of reproductive behavior are presented in Figure 11-4. Reproductive behavior can take place only if the neurons in the hypothalamus have been sensitized to respond to sensory signals. Testosterone in the male is aromatized to estradiol in the brain and estradiol promotes reproductive behavior. Recall that testosterone is produced in small episodes every 4 to 6 hours. Therefore, there is a relatively constant supply of testosterone and thus estradiol, to the hypothalamus in the male. This allows the male to initiate reproductive behavior at any time. In contrast, the female experiences high estradiol during the follicular phase only and will display sexual receptivity during estrus only.

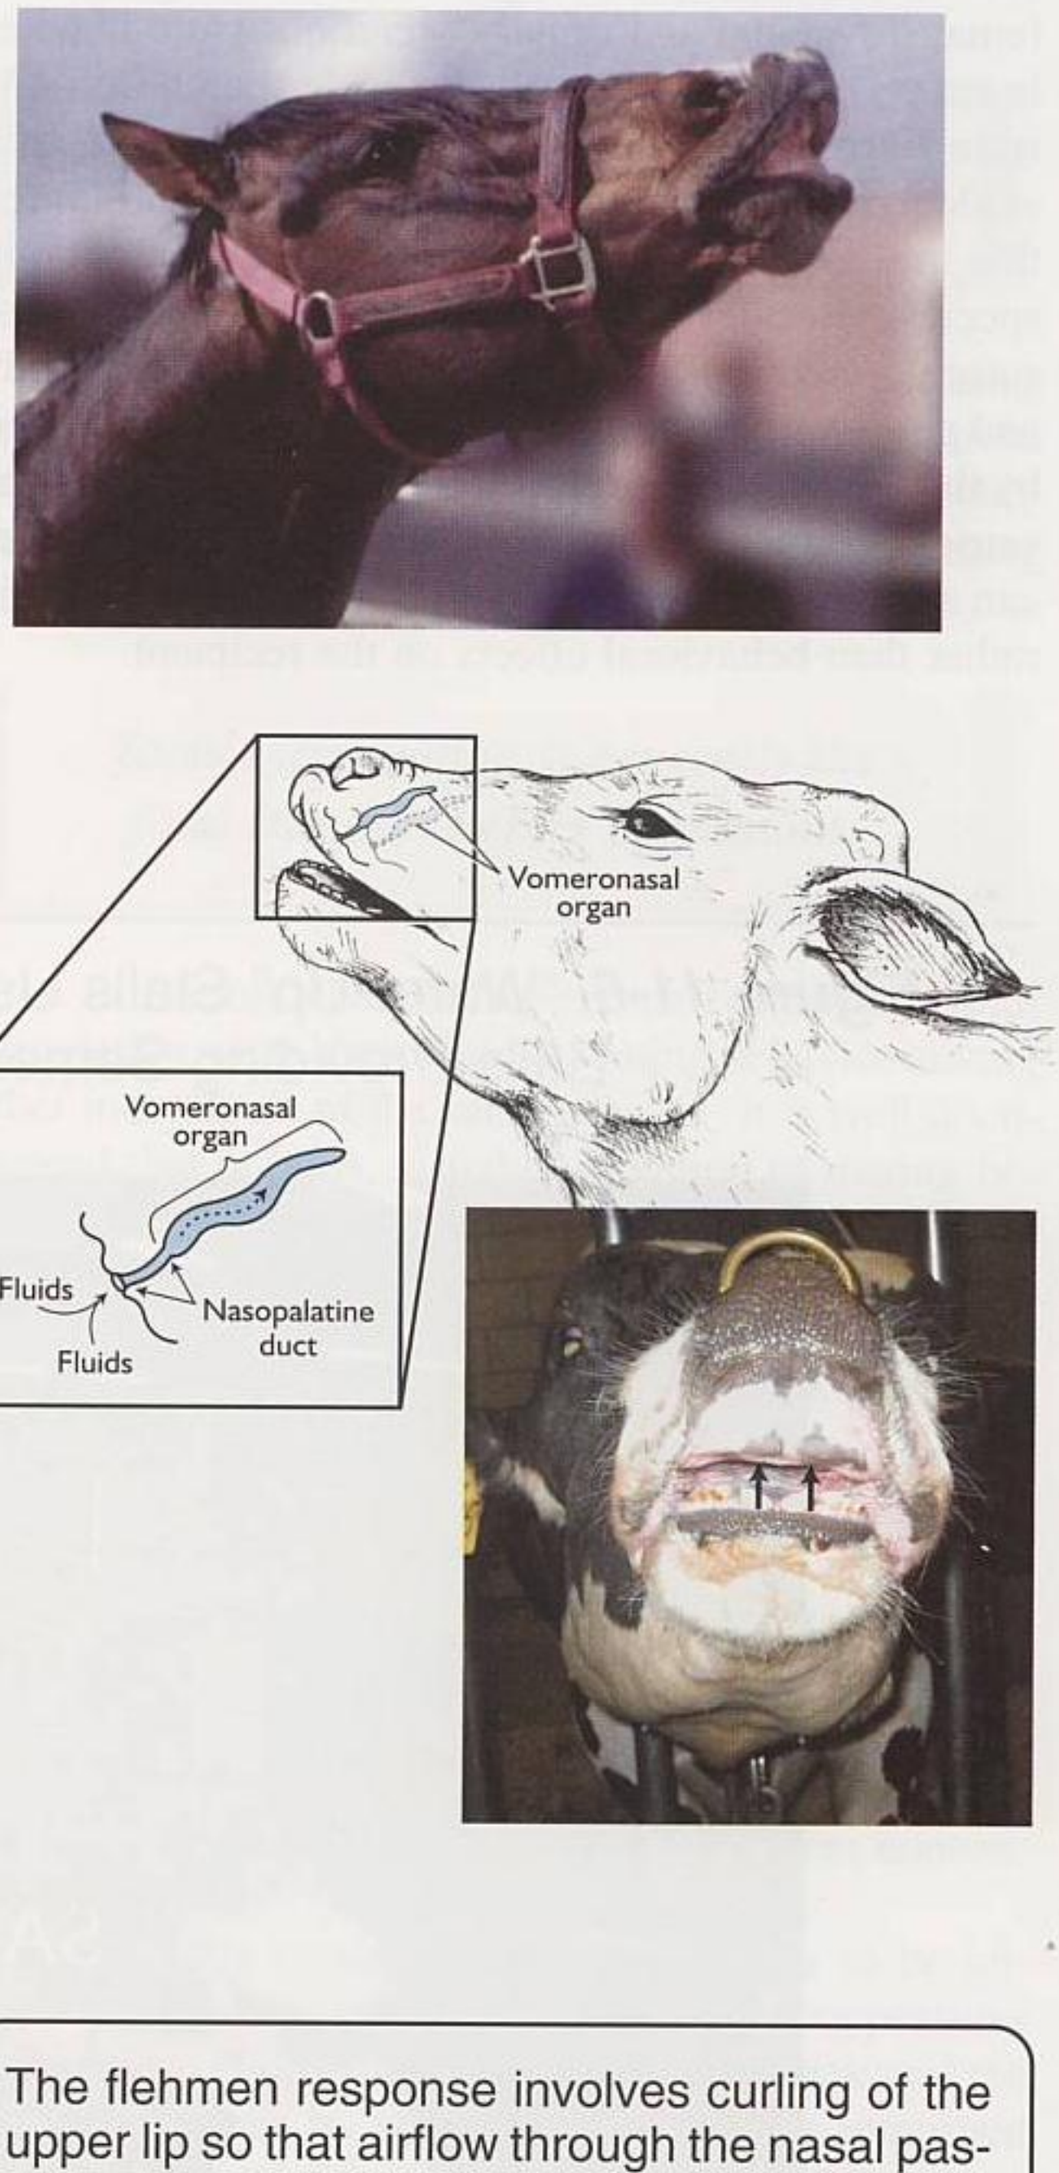
Figure 11-4 outlines a generic neural pathway for sexual behavior. Under the influence of estrogen, sensory inputs such as olfaction, audition, vision and tactility send neural messages to the hypothalamus. These neurons synapse directly on neurons in the ventromedial hypothalamus as well as the preoptic and anterior hypothalamic regions. These sensory inputs cause neurons in the hypothalamus to release behavior specific peptides that serve as neurotransmitters. These neurotransmitters act on neurons in the midbrain. The neurons in the midbrain serve as receiving zones for the peptides produced by the hypothalamic neurons. The midbrain translates neuropeptide signals released by hypothalamic neurons into a fast response. Neurons in the midbrain synapse with neurons in the brain stem (medulla). These nervous signals are integrated in the medulla. From the medulla, nerve tracts extend to the spinal cord where the nerves synapse with motor neurons that innervate muscles that cause lordosis and mounting. It should be emphasized that the model presented in Figure 11-4 does not account for all of the nerve pathways involved in reproductive behavior.

Reproductive behavior is initiated by:

- ***olfaction***
- ***vision***
- ***audition***
- ***tactility***

The primary sensory inputs for reproductive behavior are olfaction, audition, vision and tactility. The degree to which these sensory inputs influence reproductive behavior, particularly precopulatory behavior, varies significantly among species.

Figure 11-5. Flehmen Response in the Stallion and Bull and the Vomeronasal Pathway



The flehmen response involves curling of the upper lip so that airflow through the nasal passages is restricted. A subatmospheric pressure is thus created in the nasopalatine duct. Therefore, fluids can be aspirated through the duct and into the sensory surfaces of the vomeronasal organ. Arrows in the bull indicate the approximate openings of the nasopalatine ducts. (Photo of stallion courtesy of Dr. A. Tibary, Washington State University, College of Veterinary Medicine; Photo of bull courtesy of Select Sires, Inc. *www.selectsires.com*)

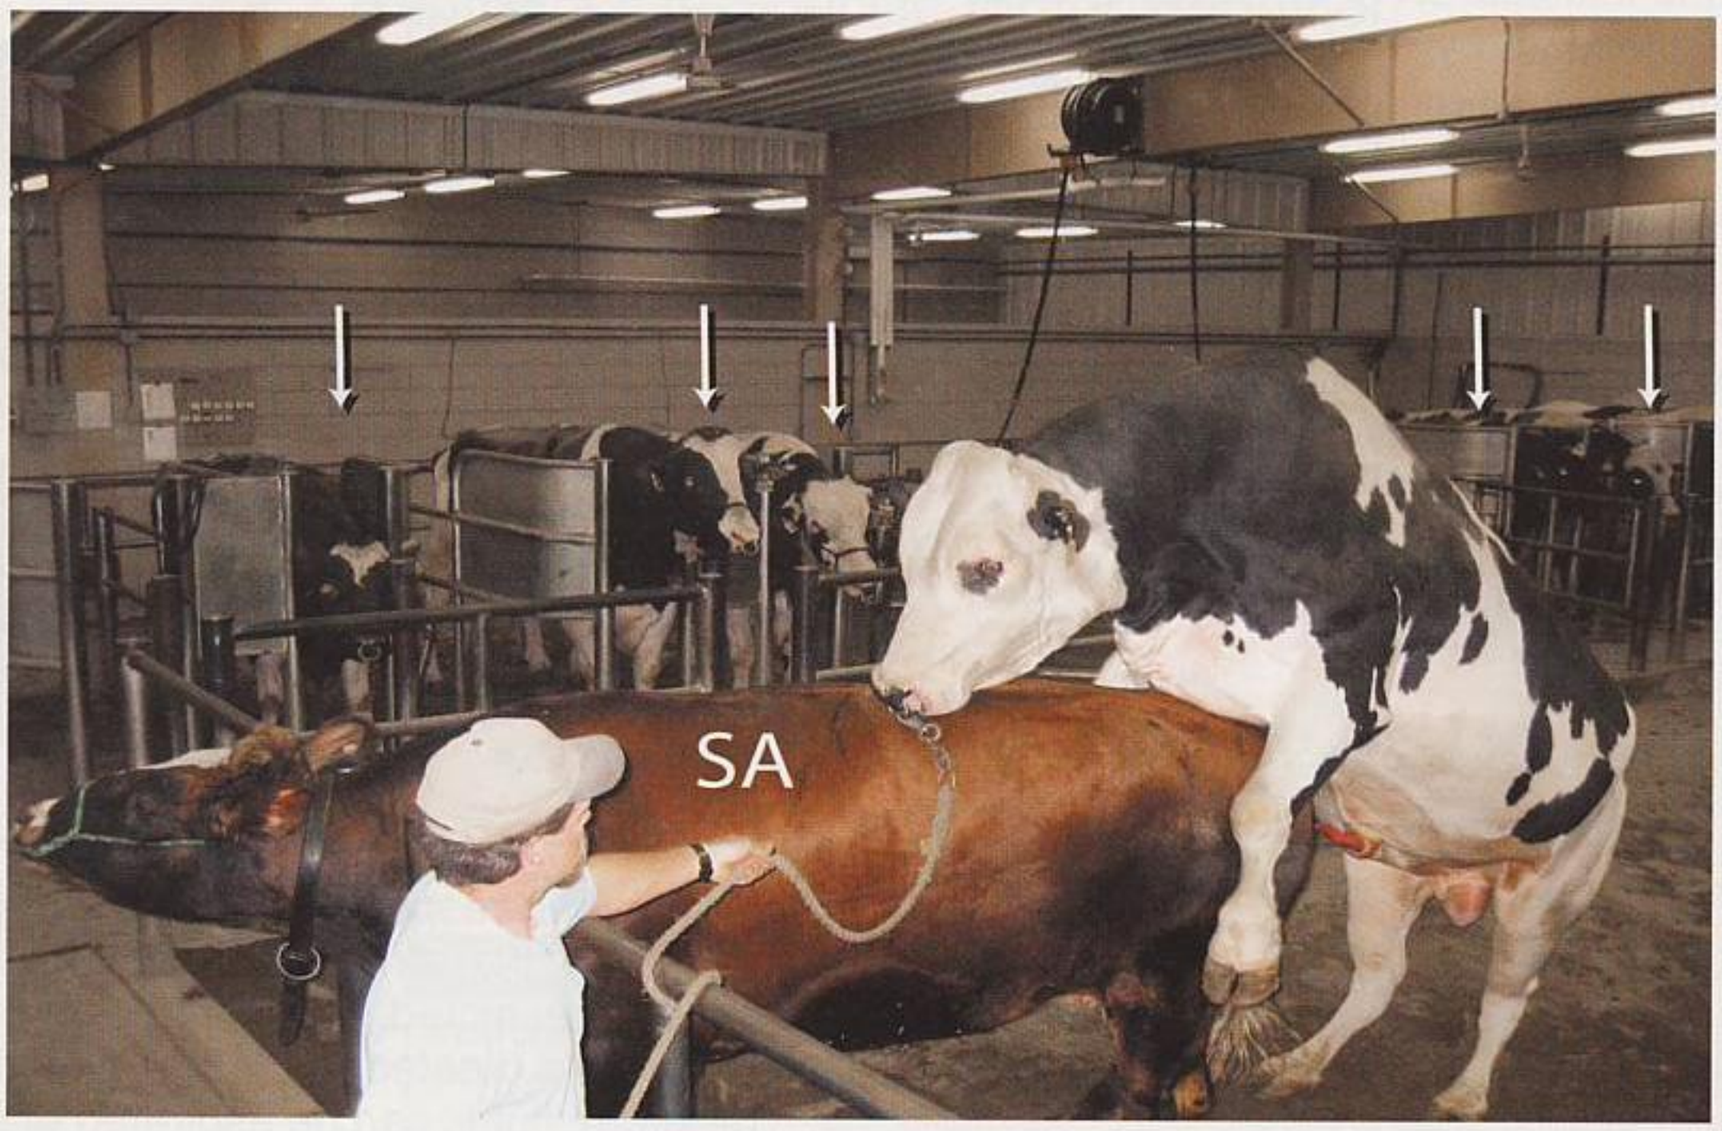
The Olfactory and Vomeronasal Systems Respond to Pheromones that Trigger Reproductive Behavior

Secretions from the female reproductive tract serve to sexually stimulate and attract the male to the female. Vaginal and urinary secretions from females in estrus smell different to the male than secretions from females not in estrus. There is good scientific evidence that females produce pheromonal substances that are identifiable both within species and among species. Recall that a **pheromone** is a volatile substance secreted or released to the outside of the body and perceived by the olfactory system and/or activated by the vomeronasal organ. Releasing pheromones can cause specific behavior in the recipient. Pheromones can also be priming pheromones that have physiologic rather than behavioral effects on the recipient.

Males also produce sex pheromones that attract and stimulate females. Among food producing animals, the best documentation for a male sex pheromone is in swine. Boars produce specific substances that cause sows and gilts to become sexually aroused when they are in estrus. Two sexual attractants are produced by boars. One of these attractants is a preputial pouch secretion. The second pheromonal-like substance is present in saliva secreted by the submaxillary salivary glands. During sexual excitement and precopulatory interactions, the boar produces copious quantities of foamy saliva. The active components in saliva are the androgen metabolites 3α-androstenol and 5α-androstenone. Both compounds have a musk-like odor.

It has been demonstrated that dogs have the ability to identify cows in estrus by olfactory discrimination. In addition, rats can be trained to press a lever in response to air bubbled through urine from cows in estrus. Rats did not press the lever when air was bubbled through urine from nonestrous cows. Clearly, urine from cows in estrus contains a material that can be identified by olfaction by other species (dogs and rats).

Figure 11-6. "Warm-Up" Stalls Used for Stimulating Sexual Behavior in Bulls Providing Semen for Artificial Insemination



Bulls waiting to be ejaculated (arrows) watch mounting and ejaculatory behavior of another bull. Such a practice "prestimulates" bulls and reduces stimulation time when they enter the collection arena. A false-mount is being performed by the bull mounting the stimulus animal (SA). (Photo courtesy of Select Sires, Inc., *www.selectsires.com)*

Flehmen Behavior is a Close-Range Investigative Behavior

Some pheromones appear to be less volatile and need to be detected by the **vomeronasal organ** in the bull, ram, stallion and to some extent, the boar. The male needs to closely approach the source of pheromones and he will nuzzle the genital region of the female. The vomeronasal organ (See Figure 11-5) is an accessory olfactory organ. It is connected to two small openings in the anterior roof of the mouth just behind the upper lip. Fluid-borne, less volatile chemicals can enter the vomeronasal organ through the oral cavity by means of the **nasopalatine** (incisive) **ducts**. Many species, such as bulls, rams and stallions, perform a special investigative maneuver when in close proximity to a female. Vaginal secretions and urine evoke an investigative behavior known as the **flehmen response**. Flehmen behavior allows less volatile materials to be "examined" by sensory neurons in the vomeronasal organ. Flehmen behavior is characterized by head elevation and curling of the upper lip (See Figure 11-5). Curling of the upper lip closes the nostrils and allows a negative pressure to form in the nasopalatine duct. Thus, less volatile materials (like mucous and urine) can be aspirated through the duct into the vomeronasal organ where they can be "evaluated" by sensory neurons in the organ. Olfactory bulbectomy in goats inhibits the flehmen response. Flehmen behavior in males is likely to be performed whether the material is from an estrus or nonestrus female. It is believed that the flehmen behavior is used to help a male identify mating opportunities. Flehmen is occasionally performed by females during sexual encounters with males. Cows will frequently perform the maneuver when sniffing other cows that are in estrus or proestrus. As in the male, females will display flehmen to novel compounds, including fluids associated with the placenta, newborn animals and other volatile materials. Flehmen is frequently displayed by post-parturient females as they make identity discriminations between their own versus other's neonates.

Auditory stimulation can serve as a long-range signal.

In many species, sexual readiness is accompanied by some form of unique vocalization or "mating calls". For example, cows are known to increase their bellowing during the time of estrus. Sows display a characteristic grunting sound associated with estrus. Queens often "yeow" repeatedly to call the tom. By comparison, mares and ewes are relatively silent. Elevated vocalization serves to alert or send a signal to males that sexual readiness is imminent. The auditory stimulus is more useful in long-range discrimination, rather than close discrimination. The classic example of reproductive driven phonation is bugling of the bull elk during rut (the breeding season).

Visual signals are valuable for close encounters.

All females display a form of sexual posturing that can be perceived by males. While posturing can be quite subtle especially to human observers, the identification of postures probably takes place easily among members of the same species.

Tactile stimulation is generally the final stimulus before copulation.

Almost all males experience a degree of sexual stimulation when they observe mating behavior among other individuals of the same species. It is well documented that in bulls, visual observation of mating behavior enhances sexual stimulation. This observation has led to the common practice of placing bulls used for artificial insemination in "warm-up" stalls (See Figure 11-6). Bulls are brought to the "warm-up" stalls and are allowed to observe the mounting behavior and collection of semen from other bulls prior to entering the collection area themselves. This causes an elevated level of sexual excitement and reduces the time required for final sexual stimulation and collection of semen. This is important because labor requirements for semen collection are significant. This procedure is also important because it tends to increase sperm concentration in the ejaculate.

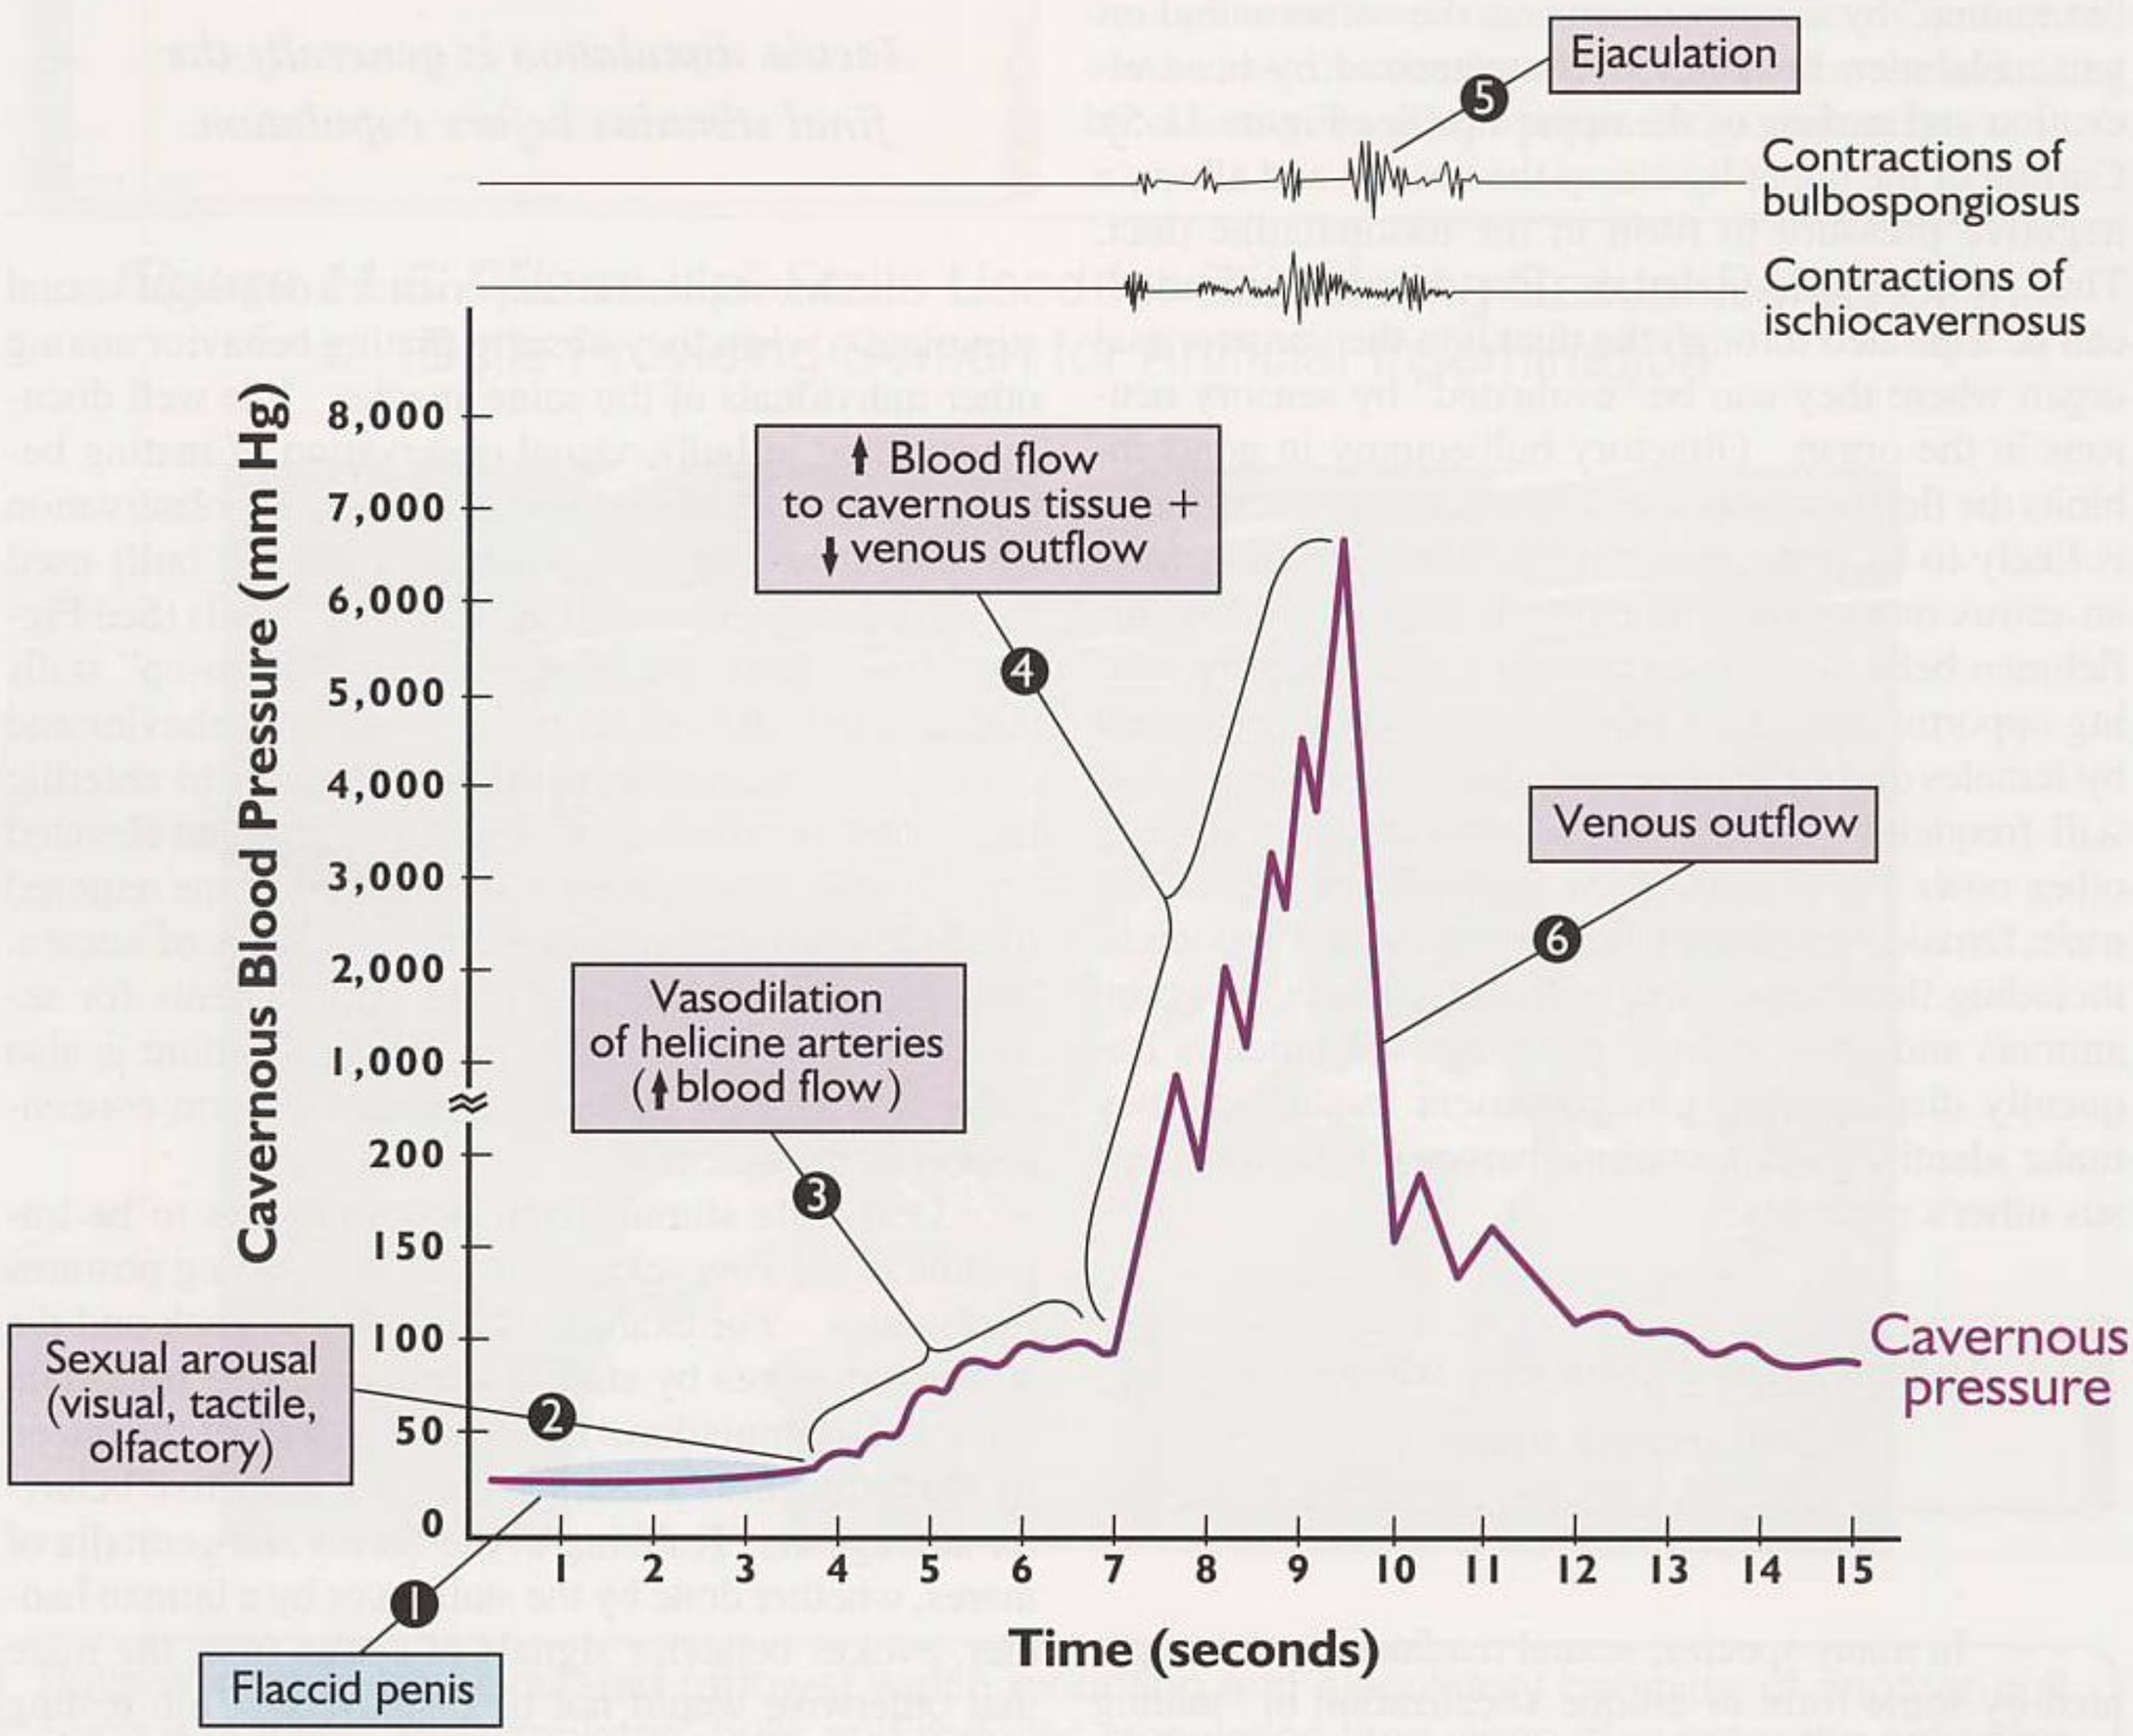
Tactile stimuli from males appears to be important in evoking sexual postures or standing postures by females. For example, biting on the neck and the withers of mares by stallions appears to be important for sexual stimulation. Biting of the neck of the queen by the tom is also a characteristic reproductive behavior among cats. Rubbing of the flanks and genitalia of mares, whether done by the stallion or by a human handler, evokes behavior signals of estrus from the mare that otherwise would not be displayed. Chin resting by a bull on the back of a cow just prior to mounting may have some stimulatory effect on the cow.

Penile Erection and Protrusion Completes the Precopulatory Phase of Reproductive Behavior

When sexual receptivity of a female is established and sufficient arousal is accomplished in the male, erection and protrusion of the penis ensue. Successful penile erection requires a complex series of neural and vasomotor (blood vessel) reactions. Erection of the penis is necessary for copulation and deposition of semen in the female reproductive tract. Erection is characterized by a marked increase in the rigidity of the penis. The increased rigidity is the result of a marked increase in arterial inflow of blood when compared to the venous outflow of blood. Erection requires that blood be trapped within the cavernous sinuses of the penis. Increased blood flow to the penis is brought about by vasodilation of the arterioles supplying it. In the bull, ram and boar erection not only involves increased blood flow and a subsequent in-

Figure 11-7. Steps in Penile Erection as They Relate to Cavernous Blood Pressure and Contraction of the Bulbospongiosus and Ischiocavernosus Muscles

(Modified from Beckett, et al. 1972. *Biol. of Reprod.* 7:359)



crease in pressure, but a simultaneous relaxation of the retractor penis muscles. Thus, erection and protrusion also involve straightening of the penis to eliminate the sigmoid flexure. The penis of the bull, boar and ram is fibroelastic in nature and therefore does not increase significantly in diameter during erection and protrusion. In contrast, the penis of the stallion increases significantly in diameter during erection. The stallion has a retractor penis muscle that, as in other species, relaxes during erection. However, the stallion does not have a sigmoid flexure. Engorgement with blood plays a much more significant role in the highly vascular penis of the stallion, dog and man than in the bull, ram, boar and camelids.

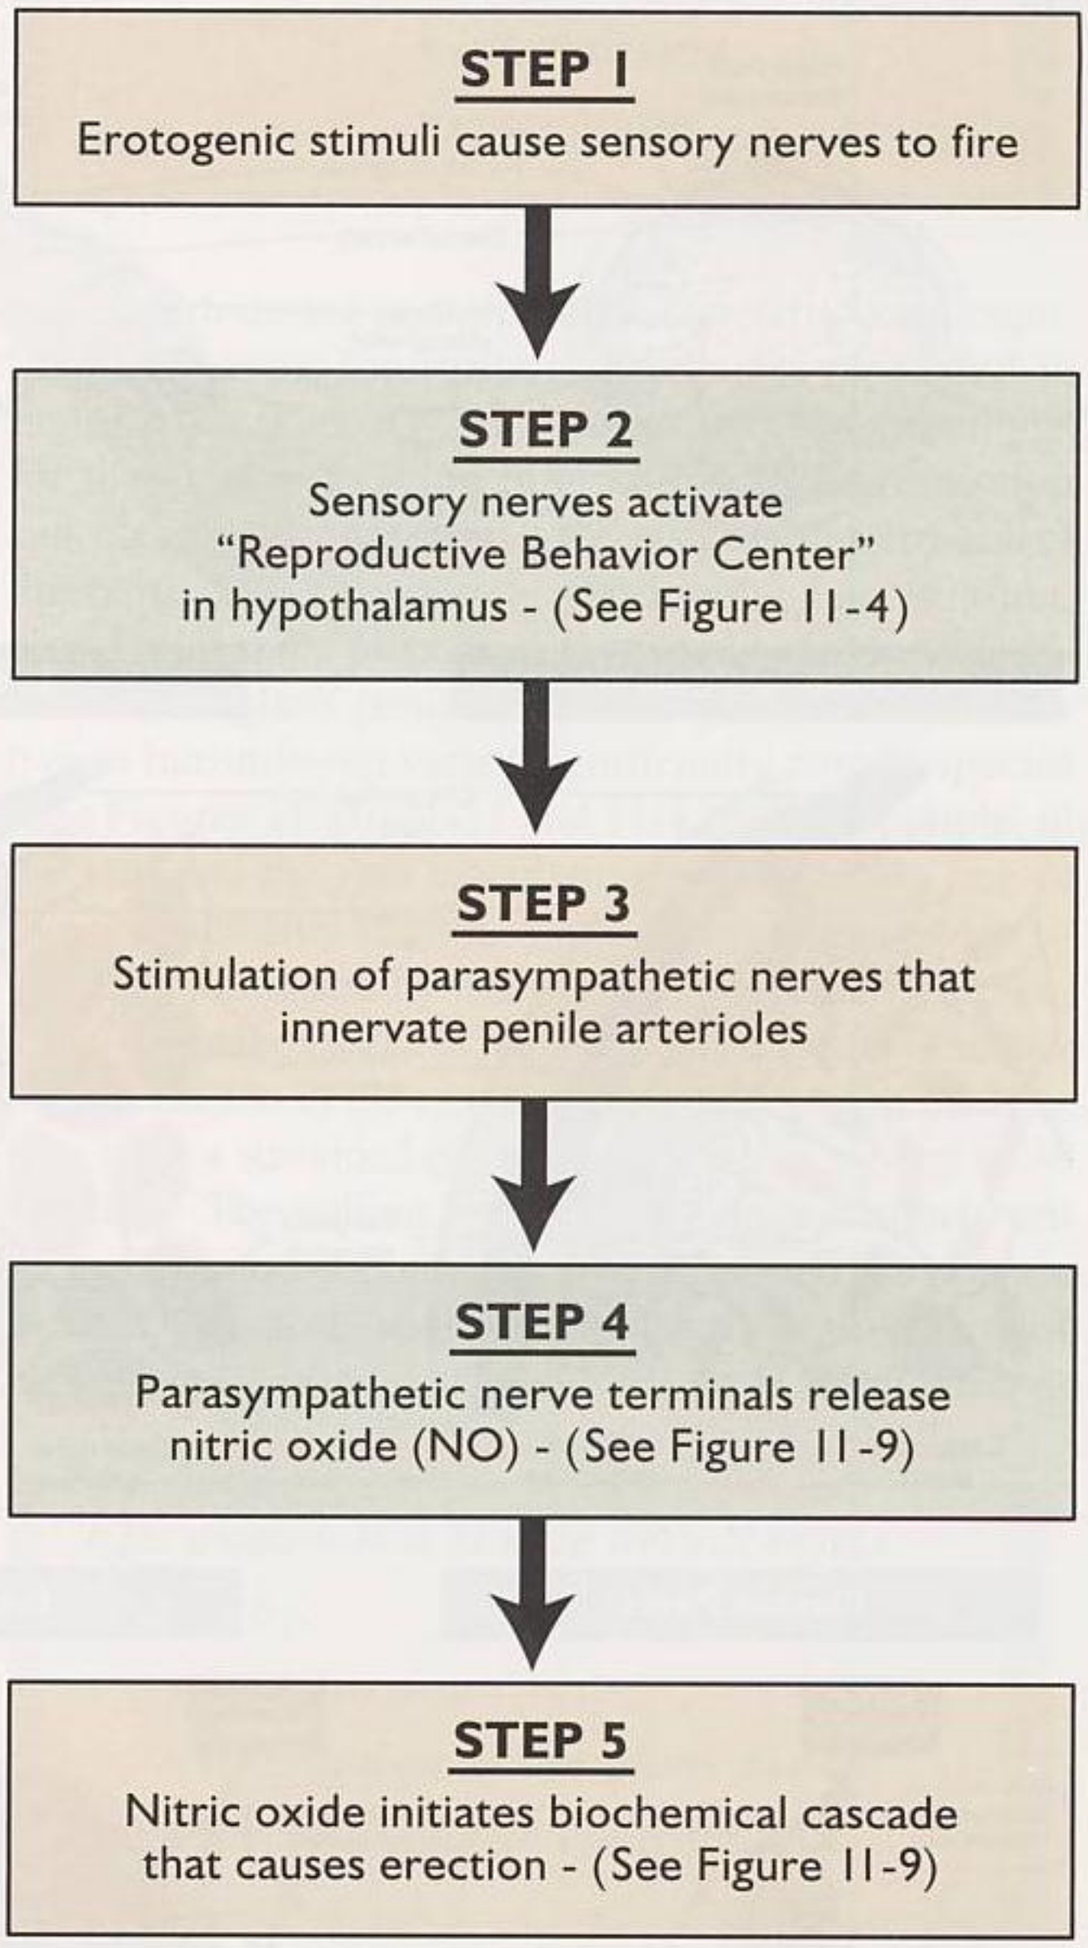
Erection of the penis requires:

- ***elevated arterial blood inflow***
- ***dilation of corporal sinusoids***
- ***restricted venous outflow***
- ***elevated intrapenile pressure***
- ***relaxation of the retractor penis muscle***

Engorgement of the cavernous tissues causes a blockage of venous return from the penis. Contractions of the ischiocavernosus muscles cause compression of the penile veins. As you will recall, the ischiocavernosus muscles surround the two crura. Intermittent contractions of the muscles creates a pump-like action at the base of the penis. These contractions result in a buildup of blood within the corpus cavernosum of the penis and exceptionally high pressures result. For example, during the final stages of erection, the pressures within the cavernous tissue of the goat penis can reach 7,000 mm Hg (See Figure 11-7). When the penis is flaccid, pressures within the corpus cavernosum are only 19 mm Hg. Pressures in the bull penis are around 1,700 mm Hg during peak erection and about 30 mm Hg when the cavernous spaces are collapsed. Figure 11-7 summarizes the steps of penile erection and intrapenile pressures as they relate to contraction of the ischiocavernosus and bulbospongiosus muscles.

One of the most publicized pharmaceuticals ever introduced is a material called Sildenafil Citrate (Viagra®). This pharmaceutical provides a therapy for erectile dysfunction in men. Erectile dysfunction is defined as the inability to achieve and maintain a penile erection (**tumescence**). Reports indicate that 10% of men between the ages 40 and 70 years old are afflicted by complete erectile failure. Other reports have estimated that up to 30 million men in the United States may have some form of erectile dysfunction. Erectile dysfunction is rare among domestic animals because such males are rapidly eliminated from the gene pool by artificial selection (culling) or by natural selection (no erection-no copulation-no offspring).

Figure 11-8. Basic Steps in the Erectile Process

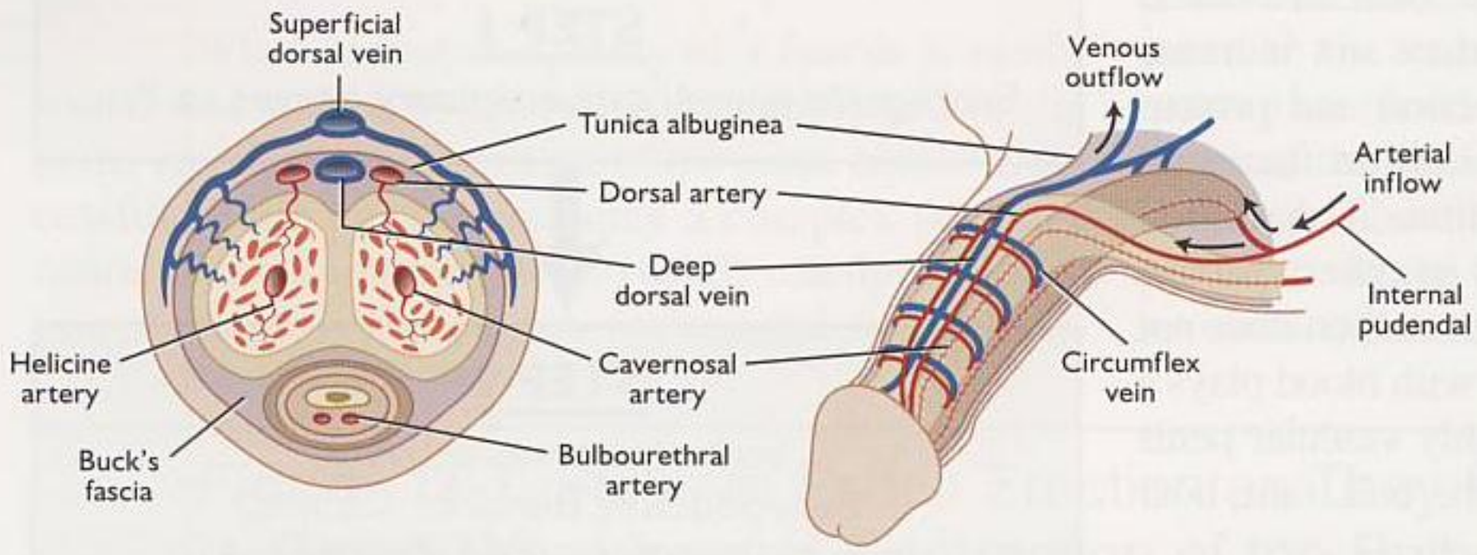


Erection of the Penis Requires Sensory Input and a Local Vascular Response

As mentioned earlier in the chapter, penile erection is a complex series of neural and vasomotor events. These events can be broadly subdivided into a nervous component (cerebral and spinal) and a local vascular component within the penis. The nervous component

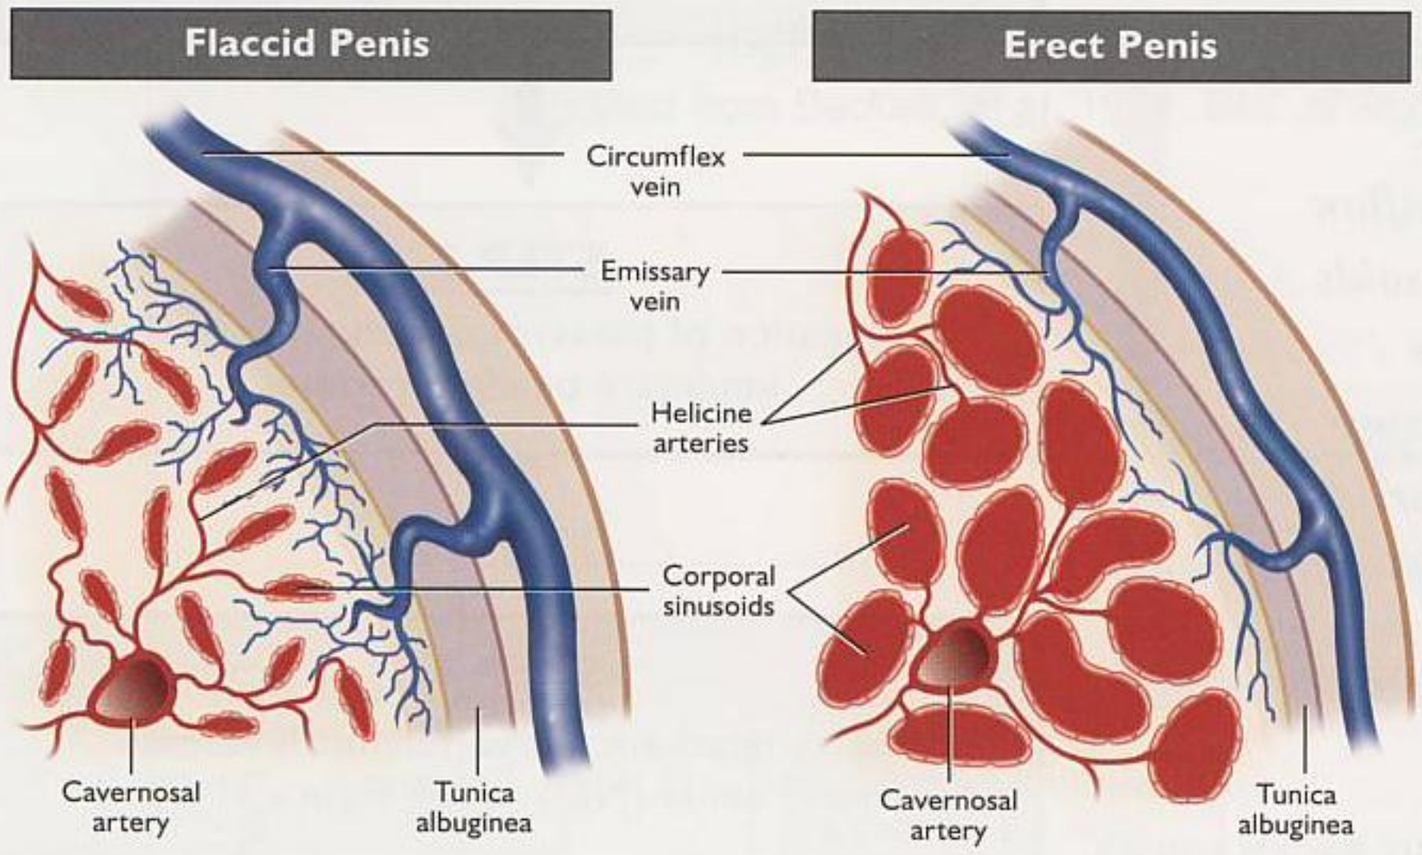
Figure 11-9. Vascular and Biochemical Control of the Erection

(Modified from Korenman. 1998. *Am. J. Med.* 105:135.)



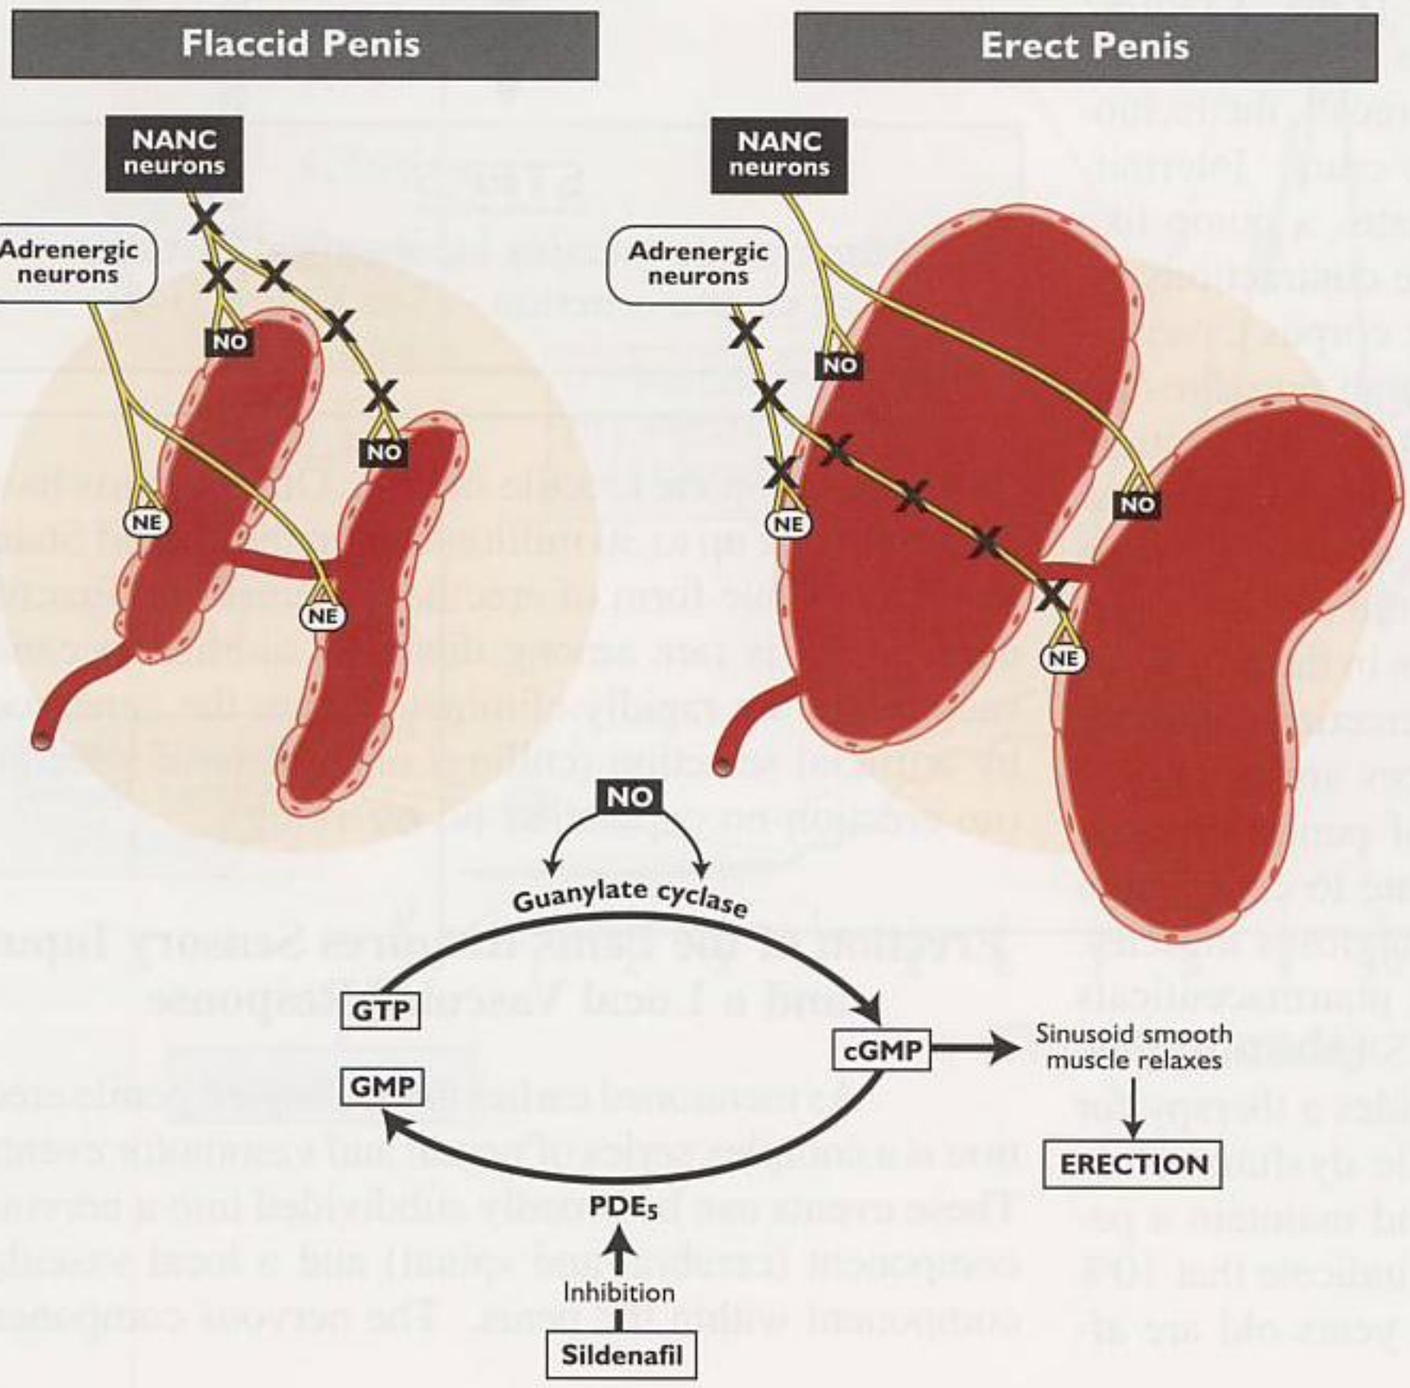
Anatomy

The shaft of the penis consists of two dorso-lateral corpora cavernosa and the corpus spongiosum. Arterial blood is supplied by the internal pudendal artery that supplies the dorsal and deep cavernosal arteries. Corporal sinusoids are supplied by helicine arteries. The deep dorsal vein and superficial dorsal vein drain the erectile tissues.



Flaccid penis

The sinusoids are flattened because adrenergic nerves secrete norepinepherine that causes vasoconstriction. Blood flow to the cavernous tissue therefore is quite low for the majority of the time. Since no erotogenic stimuli are present, nonadrenergic noncholinergic (NANC) parasympathetic neurons do not fire and thus do not release nitric oxide (NO). Therefore, vasoconstriction takes precedence over vasodilation.



Erect penis

When erotogenic stimuli are present the NANC neurons fire and release nitric oxide (NO) from their terminals. When NO is released, it activates an enzyme called guanylate cyclase. This enzyme converts guanylate triphosphate (GTP) to cyclic guanyosine monophosphate (cGMP) and causes the smooth muscle of the corporal sinusoids to relax (vasodilatation). The cavernous sinusoids engorge with blood and intracorporal pressure increases dramatically. This compresses the venules through which blood exits the penis. Blood is then trapped within the penis causing an erection.

is arousal-driven. For example, there must be appropriate sensory stimuli (tactile, visual, auditory and olfactory) in order for the central nervous system to be appropriately stimulated so that efferent neural events can cause an erection. These extrinsic stimuli are called **erotogenic stimuli**. As shown in Figure 11-4, these stimuli cause afferent sensory nerves to fire. Their terminals synapse with neurons in the so-called "behavior center" in the hypothalamus. These hypothalamic neurons synapse with parasympathetic and sympathetic efferent neurons that control penile vascular smooth muscle (vascular tone). The basic steps in the erectile process are outlined in Figure 11-8.

It is known that erection is caused by the firing of nonadrenergic, noncholonergic (NANC) parasympathetic neurons that release nitric oxide (NO), a gas, from their terminals. Nitric oxide is the principal neurotransmitter that "drives" the erectile process. Nitric oxide causes its effect by stimulating an enzyme, guanylate cyclase, to convert guanylate triphosphate (GTP) to cyclic guanosine monophosphate (cGMP). Cyclic guanosine monophosphate causes corporal smooth muscle relaxation (vasodilation) and an erection results.

Under nonerotogenic conditions, cGMP is acted upon by PDE_5 (Phosphodiesterase 5) and this enzyme promotes the conversion of cGMP to GMP. This breakdown causes increased vascular tone resulting in outflow of blood from the corpora cavernosa and loss of an erection. Sildenafil blocks the action of PDE_5 thus prolonging the vasodilation effect of cGMP and an erection develops that can be maintained for a sustained period of time. It should be emphasized that without nitric oxide production by the parasympathetic nerve terminals Sildenafil can have no effect because nitric oxide must be present for cGMP to be produced. The usual flaccid state of the penis (contracted corporal arteries) results from a tonic contraction of the arterial and corporal smooth muscles mediated by sympathetic adrenergic neurons. Such vasoconstriction keeps penile blood flow to a minimum under non-erotogenic conditions.

When the corporal smooth muscles relax because of cGMP, the resistance to blood flow by the penile arterioles and corporal sinusoids decreases and blood flow to the penis triples or quadruples when the appropriate erotogenic stimuli are present. When an erection occurs, the sinusoid pressure is so great that the emissary veins are collapsed. Therefore, blood cannot return through them because venous outflow is blocked. Penile erection can be maintained for as long as vasodilation of the corporal smooth muscle takes place. These reactions are summarized in Figure 11-9.

Copulatory behavior includes:

- ***mounting***
- ***intromission***
- ***ejaculation***

Mounting postures and characteristics of copulatory behavior for various species are presented in Figures 11-10 and 11-11. The purpose of mounting is for the male to position himself so that **intromission** can occur. Intromission is the successful entrance of the penis into the vagina. Following intromission, ejaculation takes place in response to sensory stimulation of the glans penis. The time of ejaculation relative to intromission varies significantly among species (See Figures 11-10, 11-11 and 11-12). For example, in the bull and the ram ejaculation occurs within one or two seconds after intromission. In these species ejaculation is stimulated by the warm temperature of the vagina. Vaginal pressure is relatively unimportant in inducing ejaculation in the ram and bull. In contrast, the boar may have a sustained ejaculation for periods of up to 30 minutes. The stallion has a mating duration of between 30 seconds and one minute. The llama and the dog are perhaps the most sustained copulators with reports of copulation occuring continually for up to 50 minutes.

Ejaculation is a simple neural reflex caused by:

- ***intromission***
- ***stimulation of the glans penis***
- ***forceful muscle contraction***

Ejaculation is defined as the reflex expulsion of spermatozoa and seminal plasma from the male reproductive tract. The basic mechanism for ejaculation of semen is quite similar among all mammals. Expulsion of semen is the result of sensory stimulation, primarily to the glans penis that causes a series of coordinated muscular contractions. Once intromission has been achieved, reflex impulses are initiated. These neural impulses are derived mainly from sensory nerves in the glans penis. Upon threshold stimulation, impulses are transmitted from the glans penis by way of the internal pudendal nerve to the lumbosacral region of the spinal cord (See Figure 11-13). The sensory impulses result in firing of nerves in the spinal cord and the forcing of semen into the urethra is accomplished by nerves in the hypogastric plexus that innervate the target

Figure 11-10. Characteristics of Copulation, Site of Seminal Deposition and Number of Ejaculations to Satiation and Exhaustion in the Ram, Bull, Stallion and Boar

Mating pair	Duration of Copulation	Volume of Ejaculate (Range)	Site of Semen Deposition	Average Number of Ejaculations to Satiation	Maximum Number of Ejaculations to Exhaustion
	1 to 2 seconds (1 pelvic thrust with foreleg clasp)	.8 to 1ml (.1 to 2ml)	external cervical os	10	30 to 40
	1 to 3 seconds (1 pelvic thrust with foreleg clasp)	3-5ml (.5 to 12ml)	fornix vagina	20	60 to 80
	20 to 60 seconds (multiple pelvic thrusting, flagging of tail followed by inactive phase)	75-120ml	external cervical os but semen enters uterus at high pressure	3	20
	5 to 20 minutes (rapid pelvix thrusting to engage penis in cervix) When penis is engaged, thrusting stops and ejaculation commences that is accompanied by somnolence)	200-250ml	cervix and uterus	3	8

muscles. Of primary importance for ejaculation are the urethralis muscle (that surrounds the pelvic urethra), the ischiocavernosus and the bulbospongiosus muscles.

Figure 11-13 summarizes the nerve pathways resulting in **emission** and ejaculation. It should be emphasized that emission is defined as the movement of seminal fluids from the accessory sex glands into the pelvic urethra so they can mix with spermatozoa. Emission occurs before and during ejaculation. In some species, such as the boar, stallilon and dog, emission occurs in a sequence resulting in an ejaculate that consists of various fluid fractions (See Chapter 12).

Postcopulatory behavior involves refractivity and recovery.

Following ejaculation, all males experience a refractory period before a second ejaculation can occur. The length of time of this refractory period depends on several factors. These factors are: degree of sexual rest prior to copulation, age of the male, species of the male, degree of female novelty and number of previous ejaculations. The postcopulatory refractory period is sometimes erroneously referred to as sexual exhaustion. The refractory period should be considered as part of satiation rather than exhaustion. With natural service, it is quite normal for a male to copulate repeatedly with the same female. For example, a stallion will breed a mare in heat 5 to 10 times during one estrus period. Rams are noted to remate with the same ewe 4 to 5 times. Bulls also remate with estrous cows repeatedly. In fact, it has been noted in most species that if more than one female is in heat at the same time, some males will generally copulate preferentially with one and sometimes will not copulate with a second female. Boars normally serve sows several times over a period of 1 to 2 days.

Sexual satiation refers to a condition in which further stimuli will not cause immediate responsiveness or motivation under a given set of stimulus conditions. Restimulation may occur after the refractory period. Figures 11-10 and 11-11 compare the normal number of ejaculations to satiety and the number of ejaculations to exhaustion among species. Exhaustion is the condition whereby no further sexual behavior can be induced even if sufficient stimuli are present. As you can see from Figures 11-10 and11-11, there is a large variation in the behavioral reserves (the behavioral capacity, or **libido**) among species. There is also a large variation in libido within species. For example, beef bulls have significantly lower behavioral reserves than dairy bulls. While the factors that

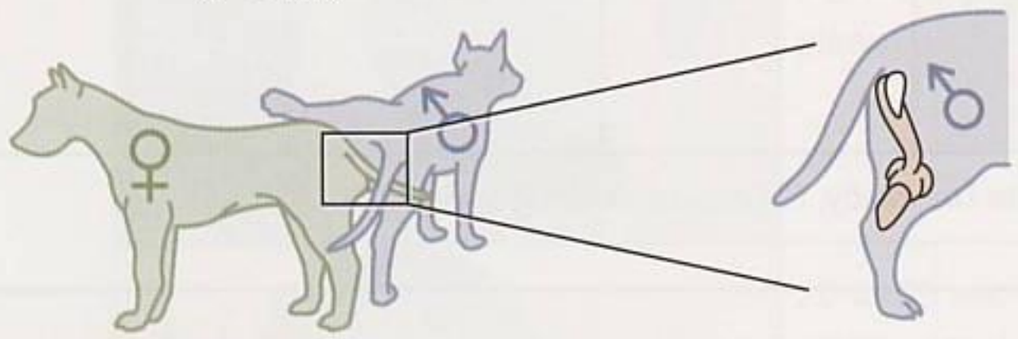
First Stage Coitus
(1-2 min)

First Stage Coitus

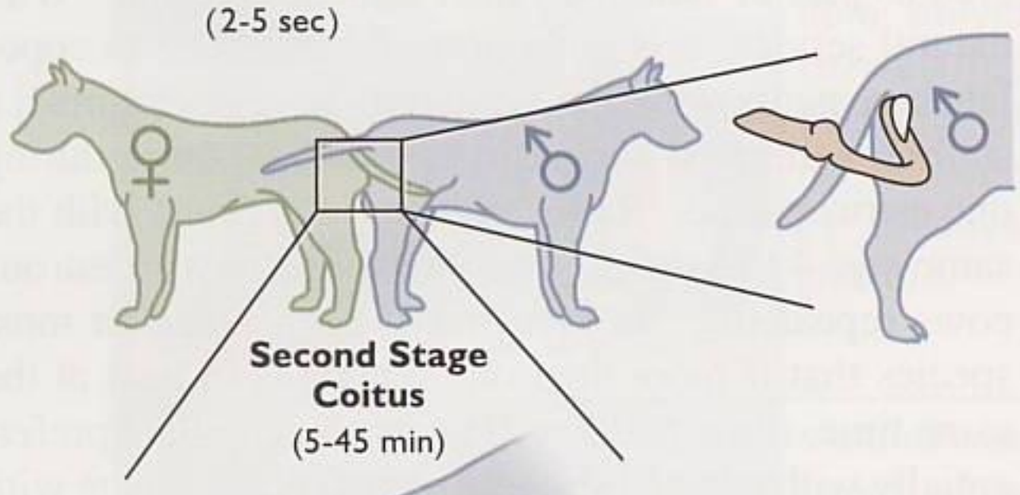
The male mounts the female in a manner typical of a quadraped. The female holds the tail to one side and the penis is introduced into the vagina by a few thrusting movements. This stage of copulation lasts for only 1-2 minutes. The first and second fractions of semen are ejaculated during the first stage coitus.



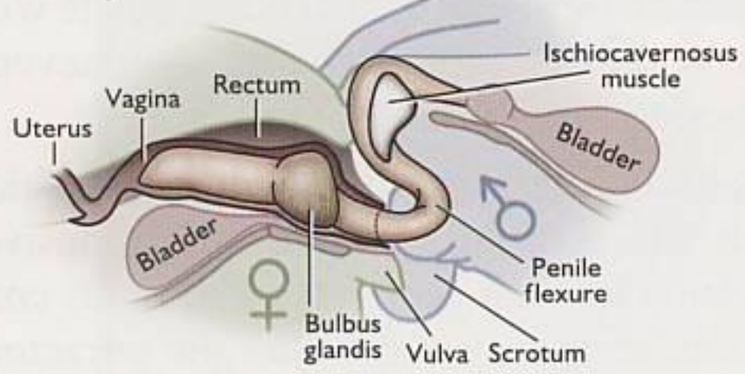
The Turn
(2-5 sec)

The Turn

This is the transition between first stage and second stage coitus. Shortly after ejaculation, the dog dismounts and turns around while lifting one hind leg over the bitch.



Second Stage Coitus
(5-45 min)

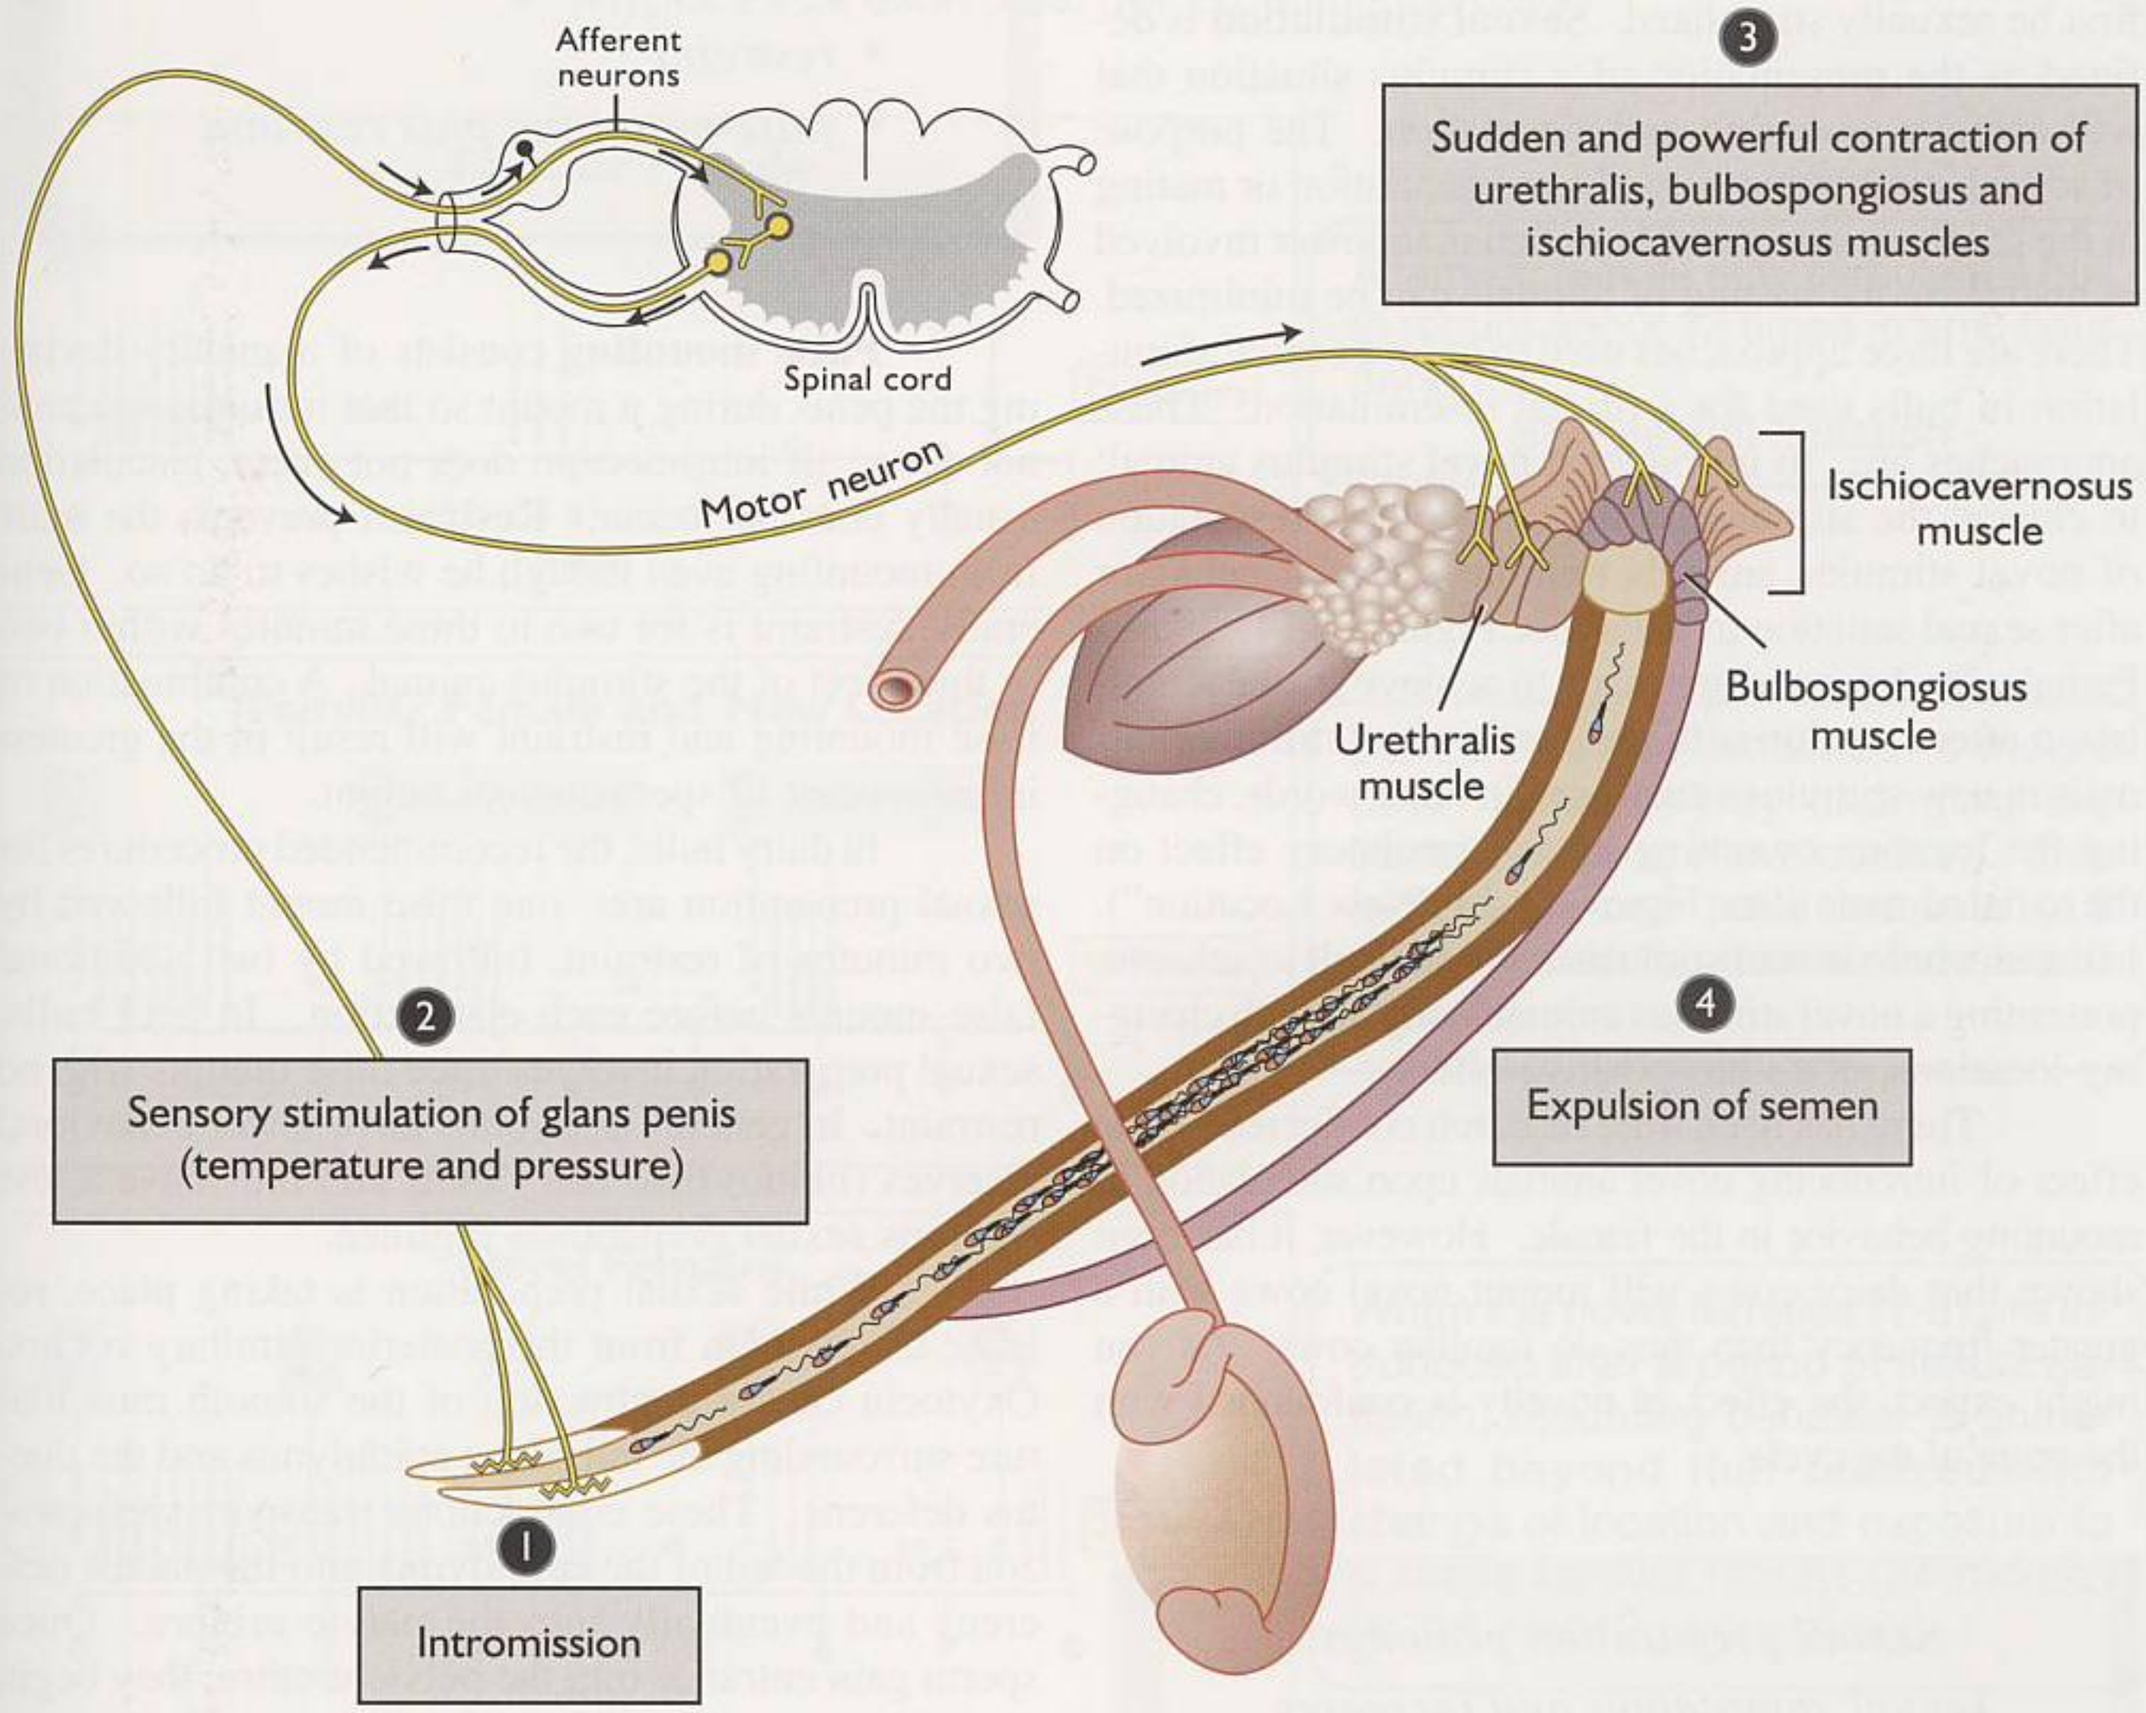


Second Stage Coitus

After the turn, the animals stand with their hind quarters in contact and their heads facing opposite directions. The third fraction of semen is ejaculated during this stage. Second stage coitus may last from 5-45 minutes. It is believed that the purpose of second stage coitus is to encourage uterine rather than vaginal insemination. Turning around discourages detumescence of the penis and therefore maintains high intravaginal pressure. The dog steadily ejaculates up to 30-ml of seminal fluid that is delivered through the cervix into the uterus. This phenomenon tends to force the sperm-rich fraction into the uterus. The copulatory behavior described here is perfectly natural. Unfortunately this behavior is often interpreted as being unnatural and attempts to break the "tie" are often made by the uninformed. Such intervention compromises fertility because delivery of semen to the uterus over a sustained period of time is reduced.

The male and female remain "tied" together because the bulbus glandis of the penis remains engorged with blood after the turn. Contractions of the muscles near the base of the penis prevent venous outflow of blood from the bulbus glandis. Also, the sphincter muscles of the vulva constrict thus compressing the dorsal veins of the penis preventing blood from leaving. (Figures modified from Grandage. 1972. *Vet. Rec.* 91:141)

Figure 11-13. Major Steps in Ejaculation



control the degree of reproductive behavior among males are poorly understood, they are almost certainly governed by genetic factors as well as environmental factors.

Reproductive behavior can be enhanced by:

- ***introducing novel stimulus animals***
- ***changing stimulus settings***

Reproductive Behavior and Spermatozoal Output can be Manipulated

The degree of novelty of both the copulatory partner and the copulatory environment can be of great importance when managing reproductive behavior in breeding males. Under conditions of artificial insemination, where repeated seminal collection is necessary to maximize the harvest of spermatozoa, understanding the influence of novelty and mating situations is important. The "**Coolidge Effect**" is defined as the restoration of mating behavior in males (that have reached sexual satiation) when the original female is replaced by a novel female. In other words, a sexually satiated male can be restimulated if exposed to a novel female. (For derivation of the term "Coolidge Effect" see ***Further Phenomena for Fertility***)

In bulls, semen collection can occur as frequently as 4 to 6 ejaculations per week. In order for this collection frequency to be successful, the male must first be sexually stimulated. **Sexual stimulation** is defined as the presentation of a stimulus situation that will achieve mounting and ejaculation. The purpose of sexual stimulation is to obtain ejaculation or mating in the shortest time possible so that manpower involved in managing the mating of animals can be minimized. There are three approaches used to induce sexual stimulation in bulls used for artificial insemination. These approaches are: to introduce a novel stimulus animal; to change the stimulus setting; or both. Presentation of novel stimulus animals reinitiates sexual behavior after sexual satiation in bulls (See Figure 11-14, "Novel Females"). A second approach to achieve sexual stimulation after satiation is to present familiar stimulus animals in new stimulus situations. In other words, changing the location or setting has a stimulatory effect on the satiated male (See Figure 11-14 "New Location"). In cases where sexual stimulation is difficult to achieve, presenting a novel stimulus animal, coupled with changing locations, often has positive effects.

There has been little research conducted on the effect of introducing novel animals upon stimulation of mounting behavior in the female. However, it has been shown that dairy cows will mount novel cows with a greater frequency than they do familiar cows. As you might expect, the effect of novelty is confounded with the stage of the cycle.

Sexual preparation prolongs sexual stimulation and increases spermatozoa per ejaculation.

In order to maximize the output of spermatozoa per ejaculate, sexual preparation is necessary. **Sexual preparation** is extending the period of sexual stimulation beyond that needed for mounting and ejaculation. Sexual preparation prolongs the precopulatory stage of reproductive behavior. The purpose of sexual preparation is to collect semen containing the greatest possible number of spermatozoa per ejaculation. Figure 11-15 illustrates the physiologic mechanisms believed to be responsible for enhancing spermatozoal numbers in the ejaculate. Three approaches are used to sexually prepare a male. These are: false-mounting, restraint and false-mounting plus restraint.

Sexual preparation may include:

- ***false-mounting***
- ***restraint***
- ***false-mounting plus restraint***

False mounting consists of manually deviating the penis during a mount so that intromission cannot occur. If intromission does not occur, ejaculation usually does not occur. **Restraint** prevents the male from mounting even though he wishes to do so. Generally, restraint is for two to three minutes within two or three feet of the stimulus animal. A combination of false mounting and restraint will result in the greatest improvement of spermatozoal output.

In dairy bulls, the recommended procedures for sexual preparation are: one false mount followed by two minutes of restraint, followed by two additional false mounts before each ejaculation. In beef bulls, sexual preparation involves three false mounts with no restraint. In general, beef bulls have lower behavioral reserves (libido) than dairy bulls and thus have a less rigorous sexual preparation regimen.

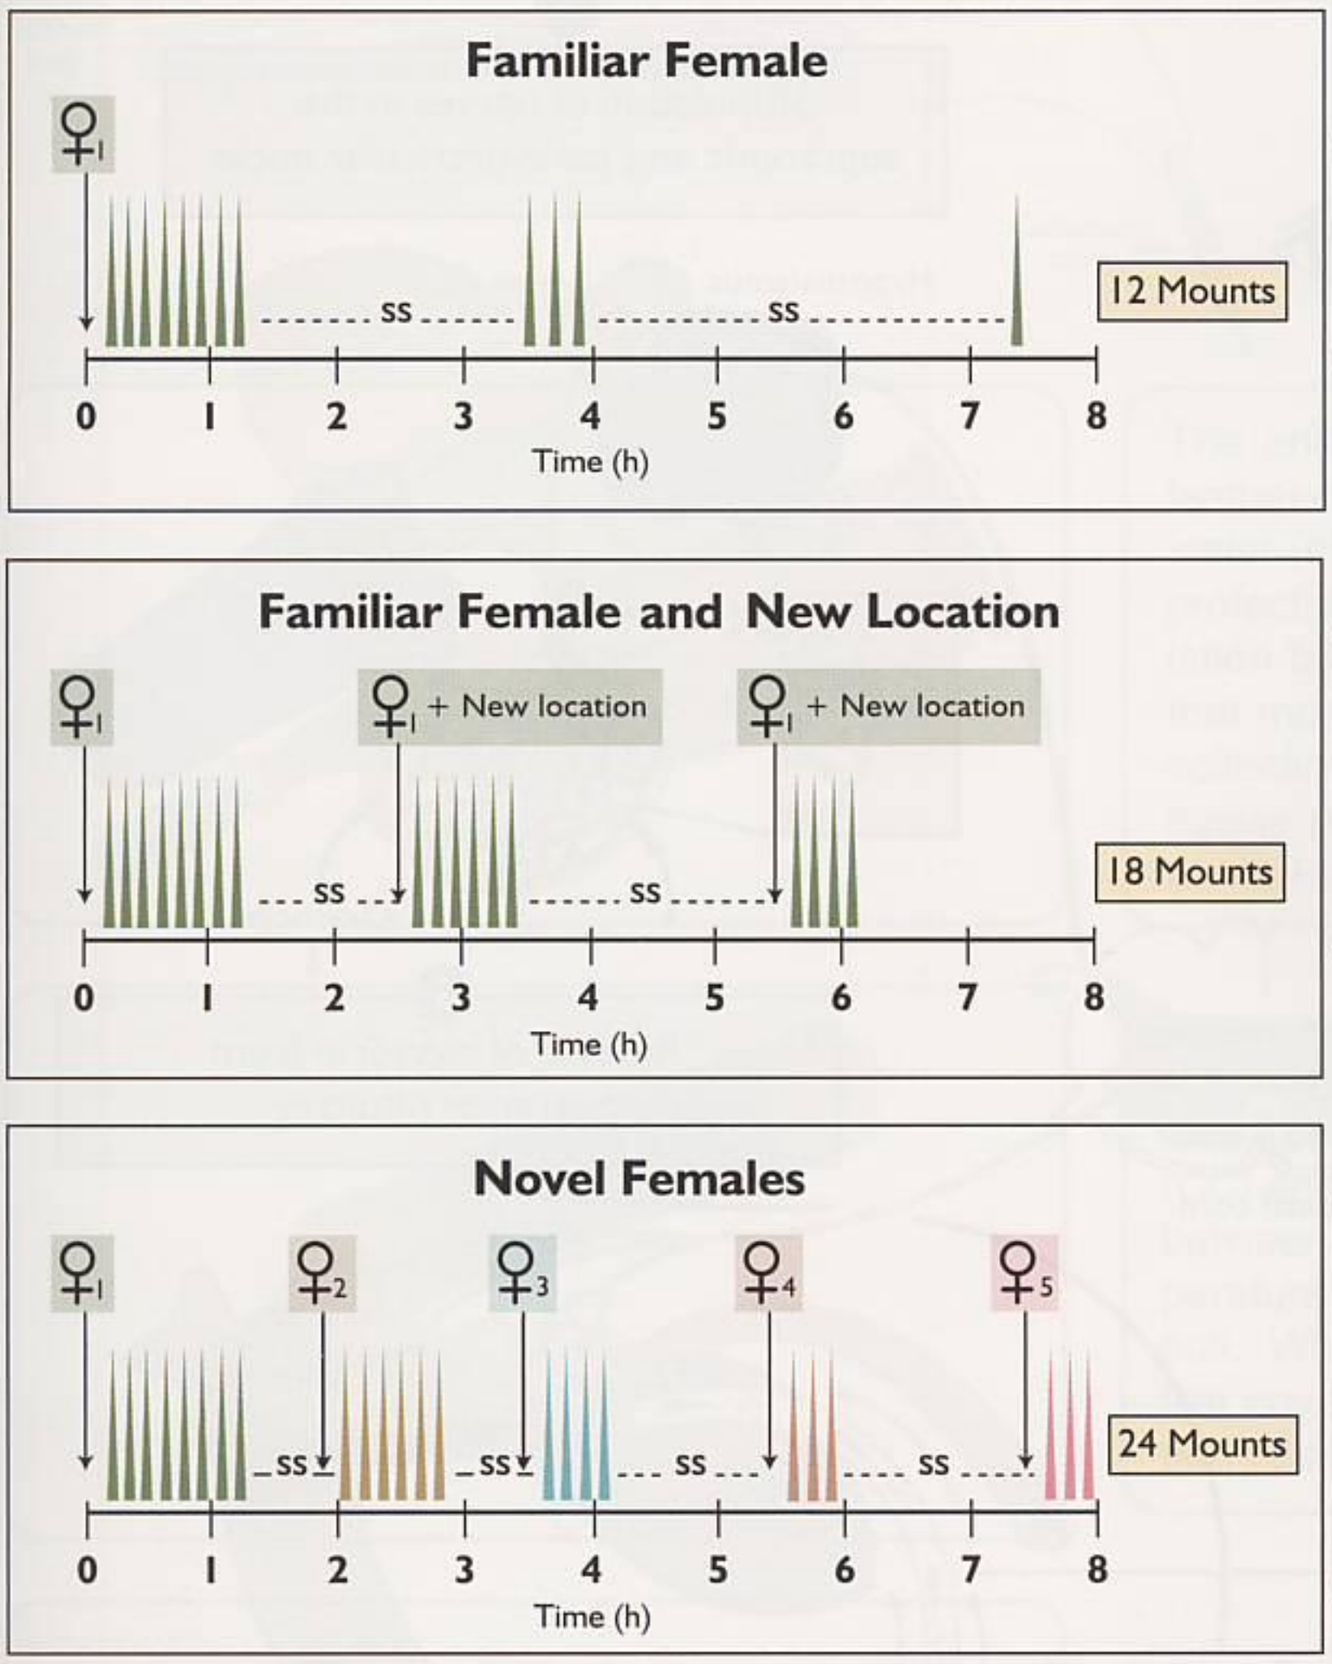
While sexual preparation is taking place, release of oxytocin from the posterior pituitary occurs. Oxytocin causes contraction of the smooth musculature surrounding the tail of the epididymis and the ductus deferens. These contractions transport spermatozoa from the tail of the epididymis into the ductus deferens and eventually into the pelvic urethra. Once sperm gain entrance into the pelvic urethra, they begin to mix with secretions from the accessory sex glands.

Homosexual-like Behavior

Homosexual-like behavior is common among domestic animals and is particularly common in cattle. The term homosexuality implies a sexual preference for same-sex partners. In animals, there is not a preference, but rather indiscriminate orientation or same-sex directed behavior. Thus, an alternative term that is applicable to sub-primate animals would be homosexual-like behavior. Cows and bulls exhibit strong homosexual-like behavior. Similar behavior is seen in sheep and dogs and to a lesser extent in swine and horses. Such behavior has profound usefulness for detecting cattle in estrus. When a female stands to be mounted by another cow, this alerts the management team that the cow is in estrus and artificial insemination can be performed. A favorite question of managers and students of reproductive physiology alike is, "What is the evolutionary advantage of animals displaying this kind

Figure 11-14. Introduction of Novel Females and a Change of Locations has a Positive Effect on Mounting Behavior

(Hypothetical examples, not experimental data)



A familiar female may stimulate a bull to mount about 12 times in an 8 hour period.

SS= sexual satiation

Bulls can be restimulated to mount (after satiation) by changing the stimulus setting (new location). This induces more total mounts (18 mounts) than the familiar female (12 mounts).

When the novel females (1-5) are introduced after a period of sexual satiation, mounting behavior is stimulated beyond that realized with change of location and exposure to a single familiar female (24 mounts vs. 18 and 12 respectively).

of behavior?" While a definitive answer is not known, two theories exist to explain female-female mounting behavior in cattle.

The first explanation theorizes that cows mounting one another provide a visual signal that attracts a bull to the cow in estrus. In other words, when a bull sees cows mounting one another he will further investigate and if the cow is in standing estrus, he will breed her.

The second theory explaining the evolution of homosexual-like behavior among cows involves inadvertent genetic selection by man for this behavior. It has been proposed that cattle of European descent were selected by humans for their estrous behavior. In Medieval Europe, cattle husbandry involved the use of a few cows by each peasant farmer for three purposes: draft, milk and meat. Peasant farmers could not afford to maintain a bull for breeding purposes since the bulls gave no milk, gave birth to no calves and had obnoxious behavior that made them unsuitable for everyday management. In addition, most bulls apparently were owned by wealthy land holders who probably controlled the breeding, as well as the financial aspects of cattle management. Since most cows were kept in groups without intact males, the herdsmen needed some sign to tell him when his cows should be bred. Obviously, the cow that showed the most intense mounting behavior was the one most likely to be observed by the peasant and most likely to be bred by the nobleman's bull. Those that showed little mounting behavior did not become pregnant in a reasonable amount of time. This theory suggests that cows with a high degree of mounting behavior were inadvertently selected because they were noticed by man and offered a greater opportunity to become pregnant. Thus, this behavioral trait was transmitted to their offspring.

Figure 11-15. Major Steps in Sexual Preparation Resulting in Transport of Spermoatozoa from the Tail of the Epididymis into the Pelvic Urethra

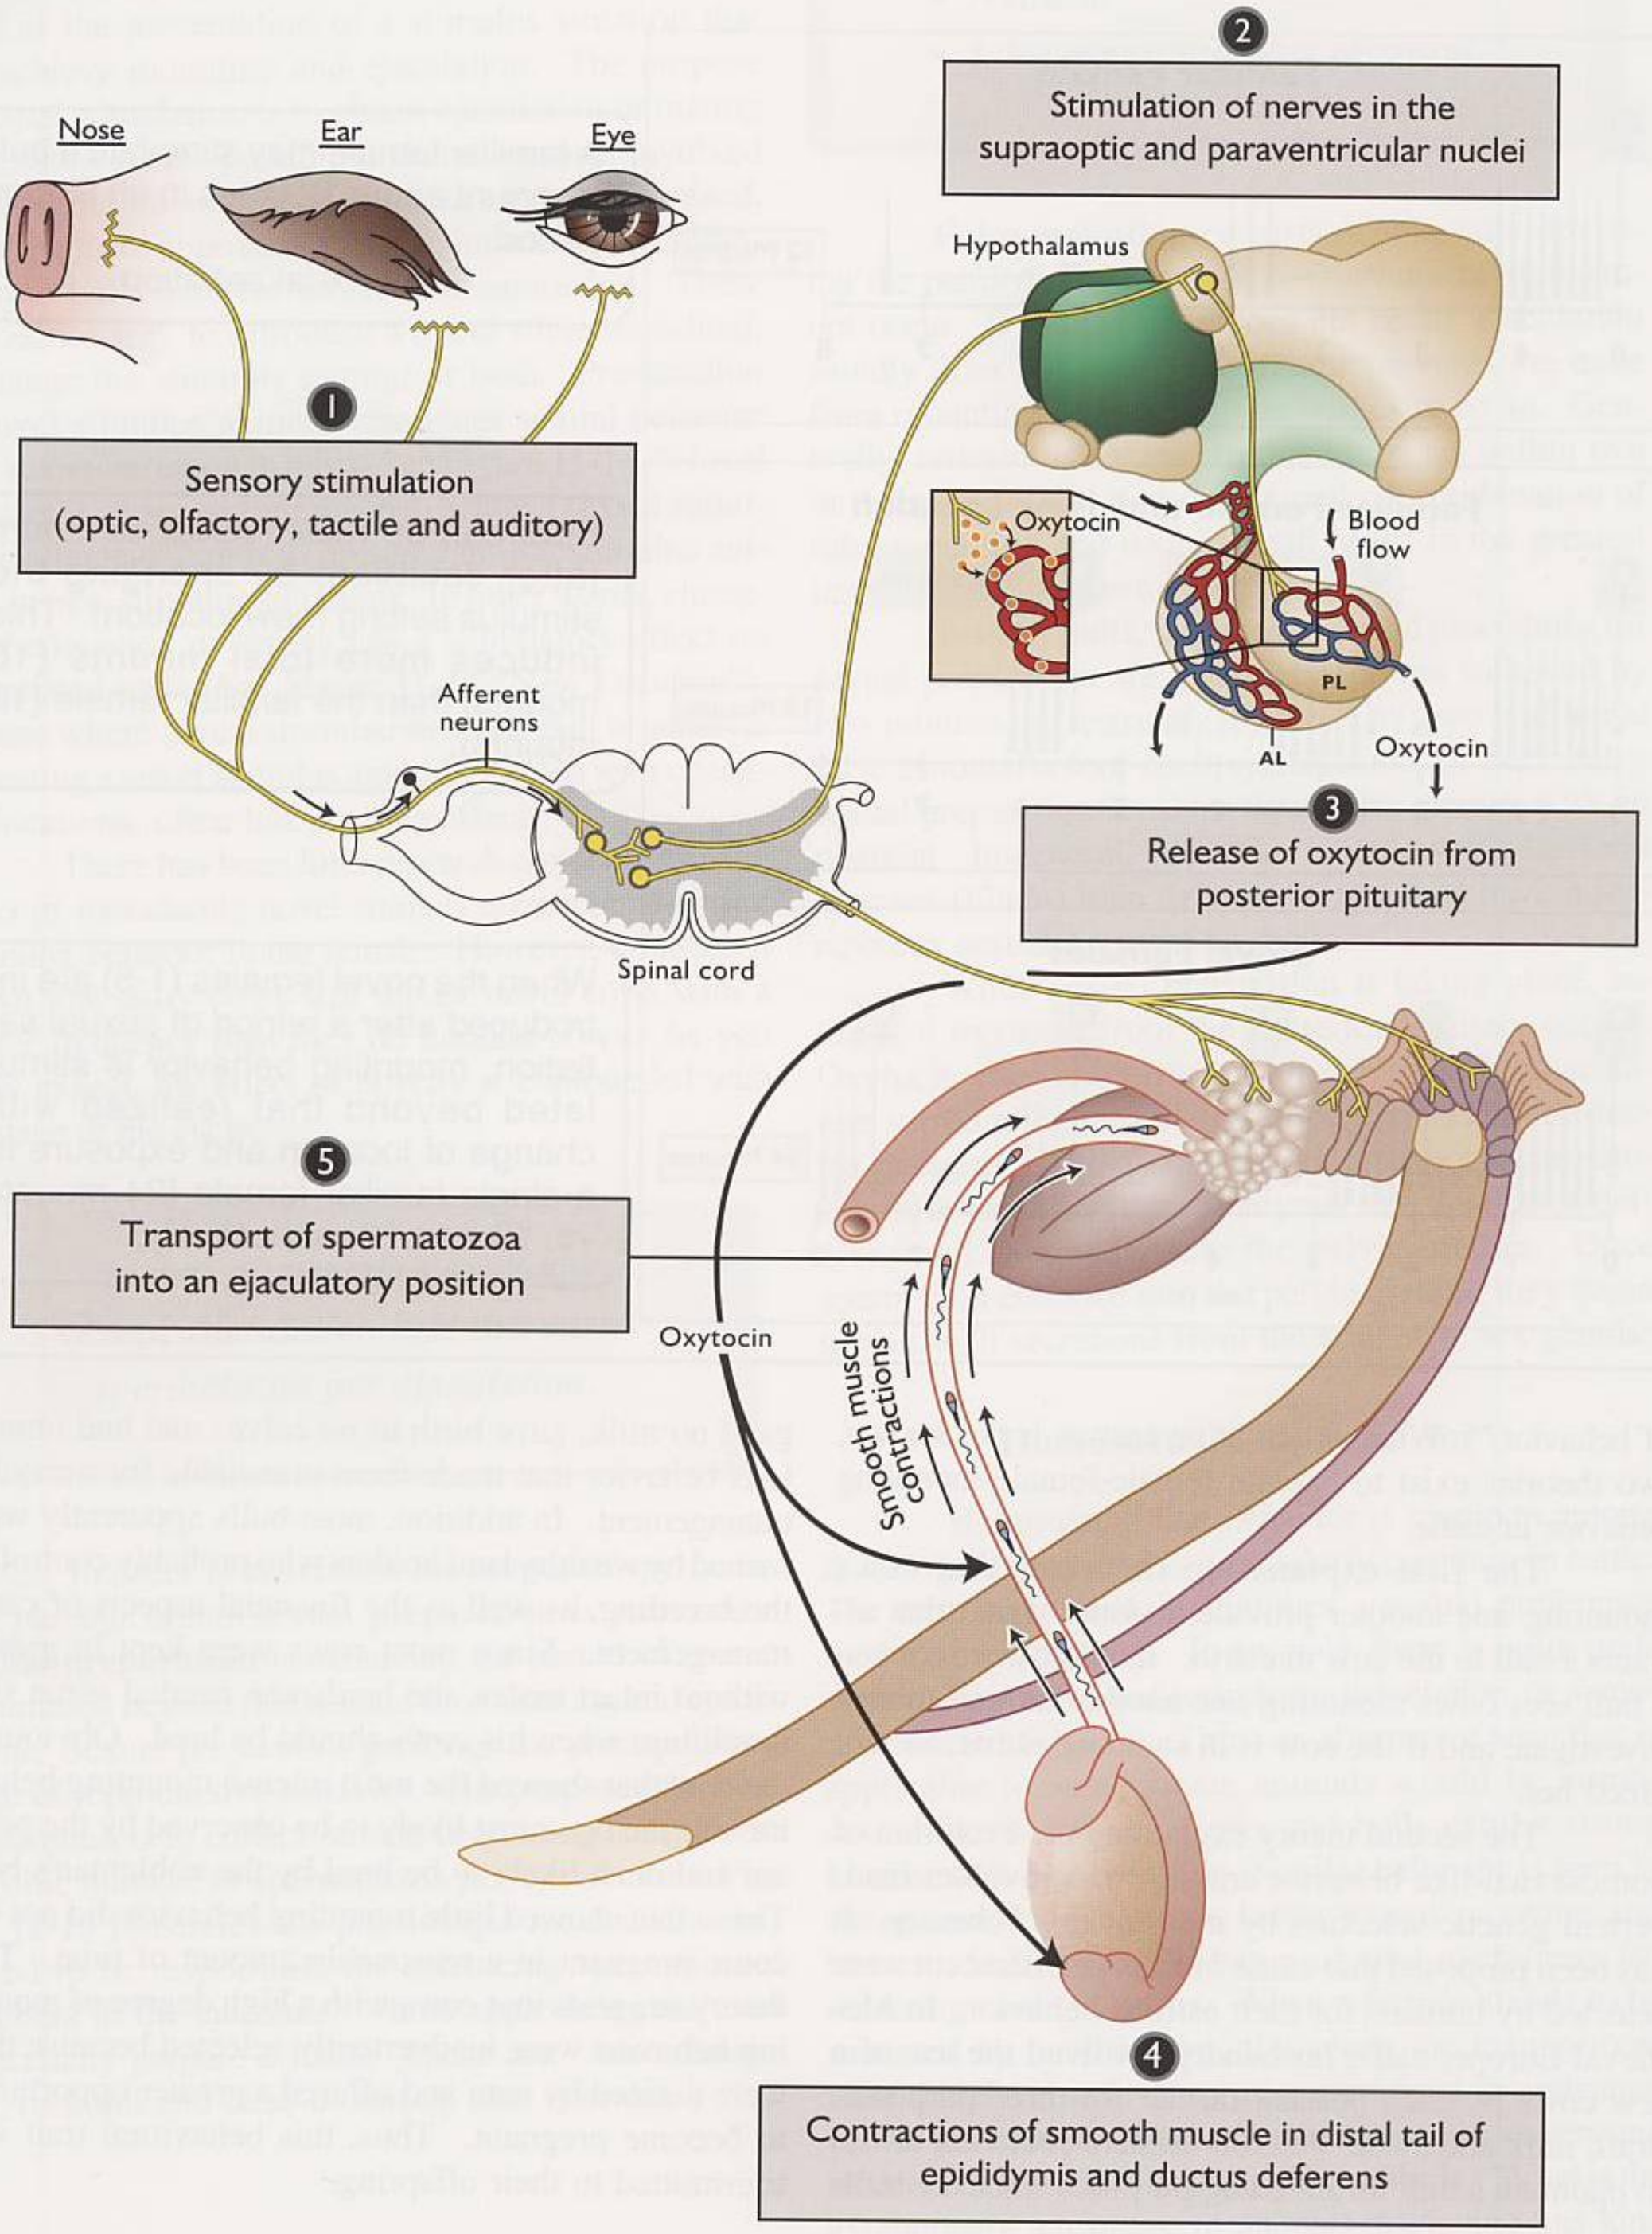


Figure 11-16. Artificial Vaginas for Various Animals

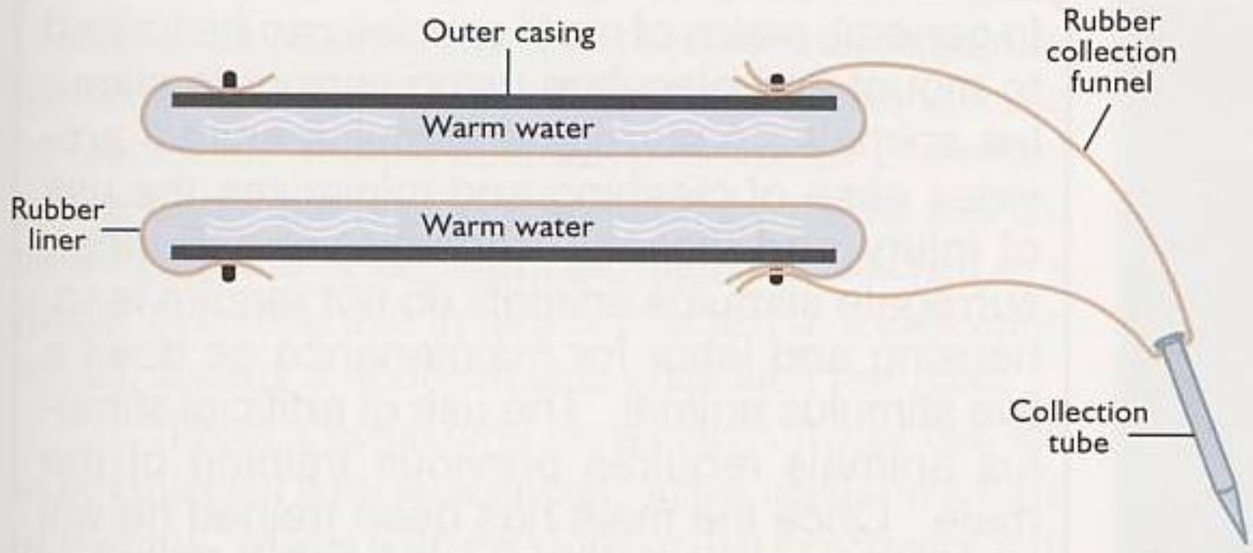
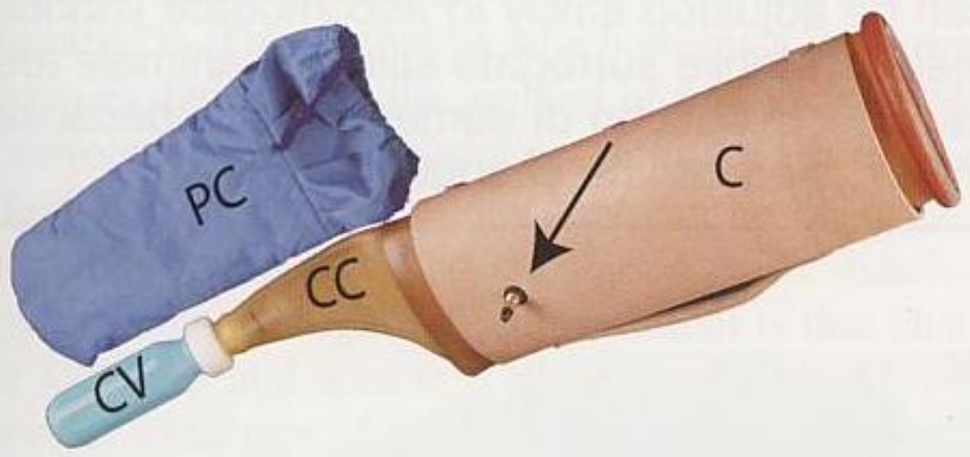
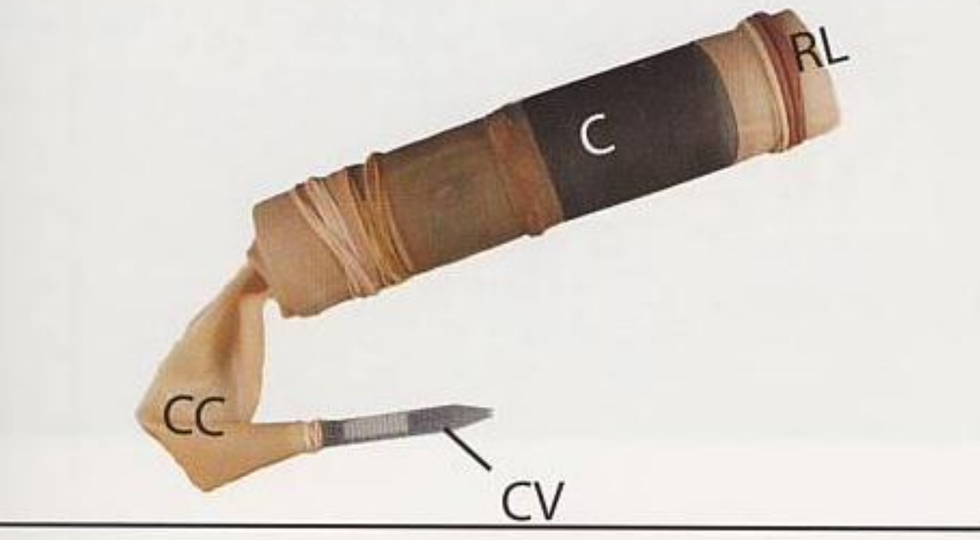


The typical artificial vagina consists of a sturdy outer casing, a rubber liner, a chamber filled with warm water, a rubber collection funnel and a collection tube.

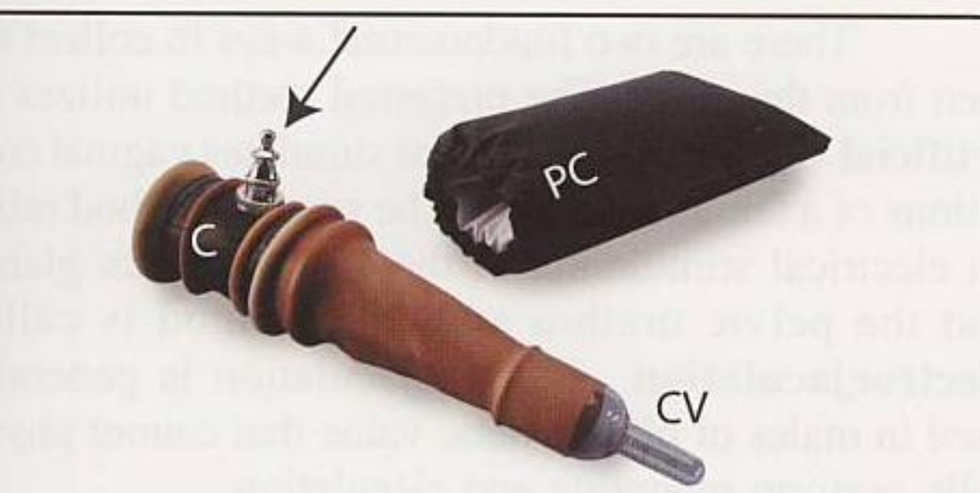


The artificial vagina for the stallion consists of a leather outer casing (C) equiped with a port to drain water (arrow). The collection vessel (CV) and the protective covering (PC) are shown. Ideally, ejaculation takes place in the collection cone (CC) so that most of the semen will drain directly into the collection vessel. (Artificial vagina courtesy of Northwest Equine Reproduction Laboratory, University of Idaho, *www.avs.uidaho.edu/nerl)*



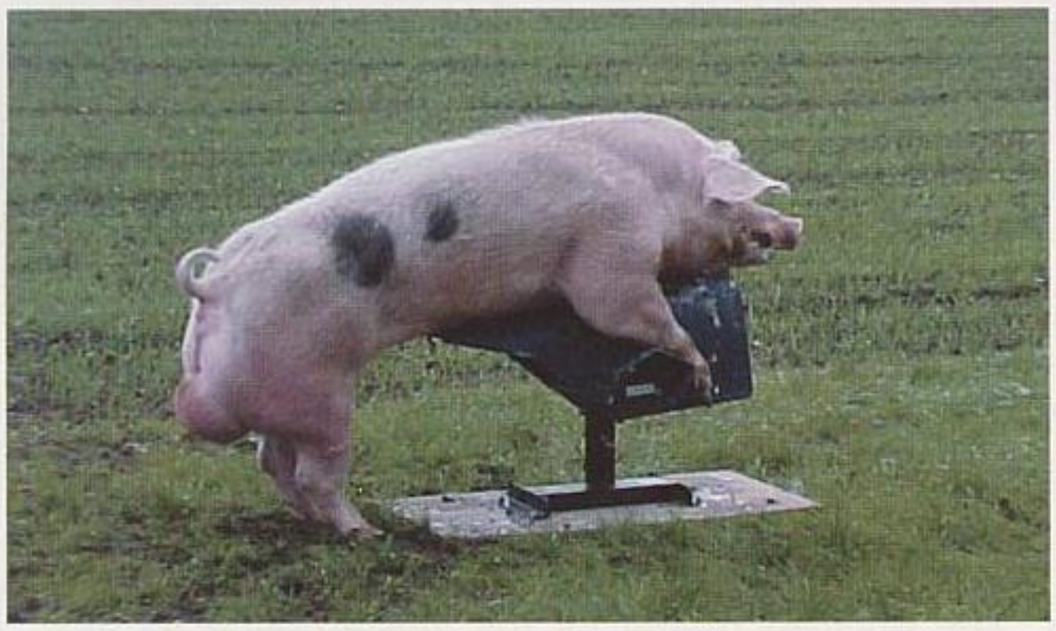
The artificial vagina for the bull consists of a black casing (C), a rubber liner (RL) a collection cone (CC) and a collection vessel (CV). Water is placed between the casing and the liner. The proper temperature is critical for successful ejaculation in the bull. While not shown in the photograph a protective covering is placed over the cone and collection vessel to prevent cold shock of the semen.

The artificial vagina for the boar consists of a bulb that can apply pressure to the artificial vagina. High pressure is obligatory for stimulation of the glans penis and ejaculation in the boar. The artificial vagina for the boar also consists of an outer casing (C), a liner (L) and a protective covering (PC) that houses the collection vessel. (Photograph courtesy of Minitüb Germany, *www.minitüb.de)*



The artificial vagina for collection of semen from rams and bucks consists of a rubber casing (C) with a valve (arrow) through which water can be added or emptied, a rubber liner and a collection vessel (CV). The protective covering (PC) is shown above the artificial vagina. (Photograph courtesy of Minitüb Germany, *www.minitüb.de*)

Figure 11-17. Surrogate Stimulus Animals for Semen Collection



In general, males of most species can be trained to mount and ejaculate using surrogate stimulus animals. A surrogate stimulus animal provides ease of cleaning and minimizes the risk of injury and disease transmission. Further, surrogate stimulus animals do not require feed, housing and labor for maintenance as does a live stimulus animal. The use of artificial stimulus animals requires previous training of the male. Once the male has been trained he will generally mount the "dummy" readily. The size can be adjusted easily to accomodate various males. Mobile surrogate stimulus animals are used for collection of semen in bulls because the location can be changed with ease.

"Phantom" for Stallion Semen Collection

The surrogate stimulus animal used to collect semen from the stallion is generally referred to as a "phantom". The "phantom" contains a biting belt (arrow) to provide the stallion with a surface to bite during mounting thus providing a means for natural behavior. All of the devices shown have a built-in artificial vagina in which the temperature and pressure can be controlled. (Photographs courtesy of Minitüb Germany, *www.minitüb.de)*

The design of an artificial vagina should accomplish the following:

- *provide a suitable environment for stimulation of the glans penis*
- *provide an environment that prevents damage to the penis*
- *provide an environment that maximizes sperm recovery and minimizes sperm insult*

Artificial Insemination Requires an Understanding of Reproductive Behavior and Physiology

There are two fundamental ways to collect semen from the male. The preferred method utilizes an **artificial vagina** or a device that simulates vaginal conditions of a female in estrus. The second method relies on electrical stimulation of the accessory sex glands and the pelvic urethra and this method is called **electroejaculation**. Electroejaculation is generally used in males of high genetic value that cannot physically perform mounting and ejaculation.

Typical artificial vaginas for domestic animals is shown in Figure 11-16. In general, artificial vaginas consist of an outer casing fashioned of reinforced rubber and a liner that is generally made of rubber that can be lubricated. Temperature and pressure are controlled by the water that is placed between the casing and the liner. One end of the artificial vagina is attached to a funnel-like cone that in turn is attached to a collection vessel, usually a nonbreakable graduated test tube.

From a behavioral perspective, males that are to be collected with an artificial vagina need some form of training. Males with previous sexual experience will readily mount a surrogate animal (artificial animal or "dummy"). The degree to which animals will mount dummies depends on the amount of training provided. A surrogate stimulus animal provides the advantage of safety, reduced expense and they can be designed to accomodate males of various stature. The disadvantage of using surrogate stimulus animal is that changing locations and teasers is difficult. Figure 11-17 illustrates examples of surrogate animals for semen collection.

Sometimes it is difficult to train animals to mount either a stimulus animal or a surrogate stimulus animal. In this event, semen can be collected by placing a condom-like structure inside the vagina of the female in estrus. When the male mounts the female and ejaculates, the semen is deposited inside the vessel. Such techniques are valuable when animals have not been adequately trained.

Further PHENOMENA *for* Fertility

One day President and Mrs. Coolidge were visiting a government farm. Soon after their arrival they were taken off on separate tours. When Mrs. Coolidge passed the chicken pens, she paused to ask the man in charge if the rooster copulated more than once each day. "Dozens of times," was the reply. "Please tell that to the President," Mrs. Coolidge requested. When the President passed the pens and was told about the rooster, he asked, "Same hen every day?" "Oh no, Mr. President, a different one each time." The President nodded slowly and then said, "Please tell that to Mrs. Coolidge."

The praying mantis has unusual reproductive behavior. As soon as the male mounts the female and accomplishes intromission, the female bites his head off. She immediately eats the top half of his body while intromission is still taking place. The reason for this behavior is because ejaculation is permanently inhibited in the male and can take place only after the head has been removed. It is not known whether the slang phrase "bite-your-head-off" was derived from this behavior.

To mate, the queen bee leaves the hive and performs a mating flight in an area where drones are congregated. The fastest drone is the first to copulate with the queen. Copulation is an in-flight event that lasts from 1 to 3 seconds. When the copulating bees separate, the entire male genitalia is ripped from the male and stays with the queen. The male soon dies and another male will then mate with the queen. Up to 17 matings in one mating flight have been observed.

Some male insects (certain flies and mosquitoes) have evolved unusual adaptations to insure that their genetics will be passed on. Males have a sharp, specialized penis that can enter a pupa. The male inseminates the unborn female.

Females of some species are quite choosy about who gets to fertilize their eggs. In these cases, mate choice is determined by nuptial gifts presented by the male. The female black-tipped hangfly accepts nuptial gifts in the form of food in exchange for copulation. When edible food is presented by the male, the duration of copulation is dependent on the size of the gift. If the gift is small and can be consumed in 5 minutes or less, the female will not allow mating. If the gift is large (cannot be consumed in 20 minutes), the female will allow mating to take place. If the gift provides a meal of only 12 minutes she will leave the gift-giver prematurely and seek another gift-giver as a mate.

Satin bowerbirds build their nests only with blue objects. Males gather blue flowers, pen caps, berries and ribbons and arrange them under bushes or in other cozy spots. If a female "likes" what she sees, she will choose the nest's decorator as her mate.

A male newt begins his courtship by jumping on the back of the female and rubbing his jaw against her snout. This releases a scent that drives the female newt "crazy with desire."

When female rhinoceri are in heat they will run away from a male, then suddenly turn and fight him horn-to-horn, sometimes for longer than a day. Only if he is fit enough to pursue will she submit. There are no "wimp genes" in the rhinocerous gene pool.

During courtship the female balloon fly will eat the male if given the chance. To achieve copulation and keep from getting eaten, the male will present the female with a balloon-shaped cocoon as a "present". Unwrapping this "present" keeps the female occupied long enough for the male to mate her and fly off.

When a grey squirrel comes into estrus, up to a dozen males noisily chase her through the trees. This chase is necessary, because the female will not ovulate without it.

When box turtles copulate, the male mounts the female and remains in an upright position in order to facilitate insemination. The pair may remain in this position for hours to ensure adequate insemination. At the conclusion of the event the female will suddenly move away, sometimes causing the male to fall precariously on his back where he may remain until his death if he can't right himself.

Roman snails shoot love darts at one another before copulation to determine if they are both members of the same species.

Most frogs and toads copulate in the dark. They are often so eager to mate that the male will try to mount anything that passes by. They have been observed keeping a firm grip on strange objects and even other small animals in the hope that they might turn out to be females.

The long neck of the giraffe plays an important role in their reproductive behavior. First the male samples the female's urine to ascertain whether she is in estrus. If so, the two giraffes then indulge in a form of sexual preparation by entwining and rubbing their necks together. Physiologically, this behavior is like a false-mount and no doubt causes the release of oxytocin that moves sperm in the distal tail of the epididymis into an ejaculatory position.

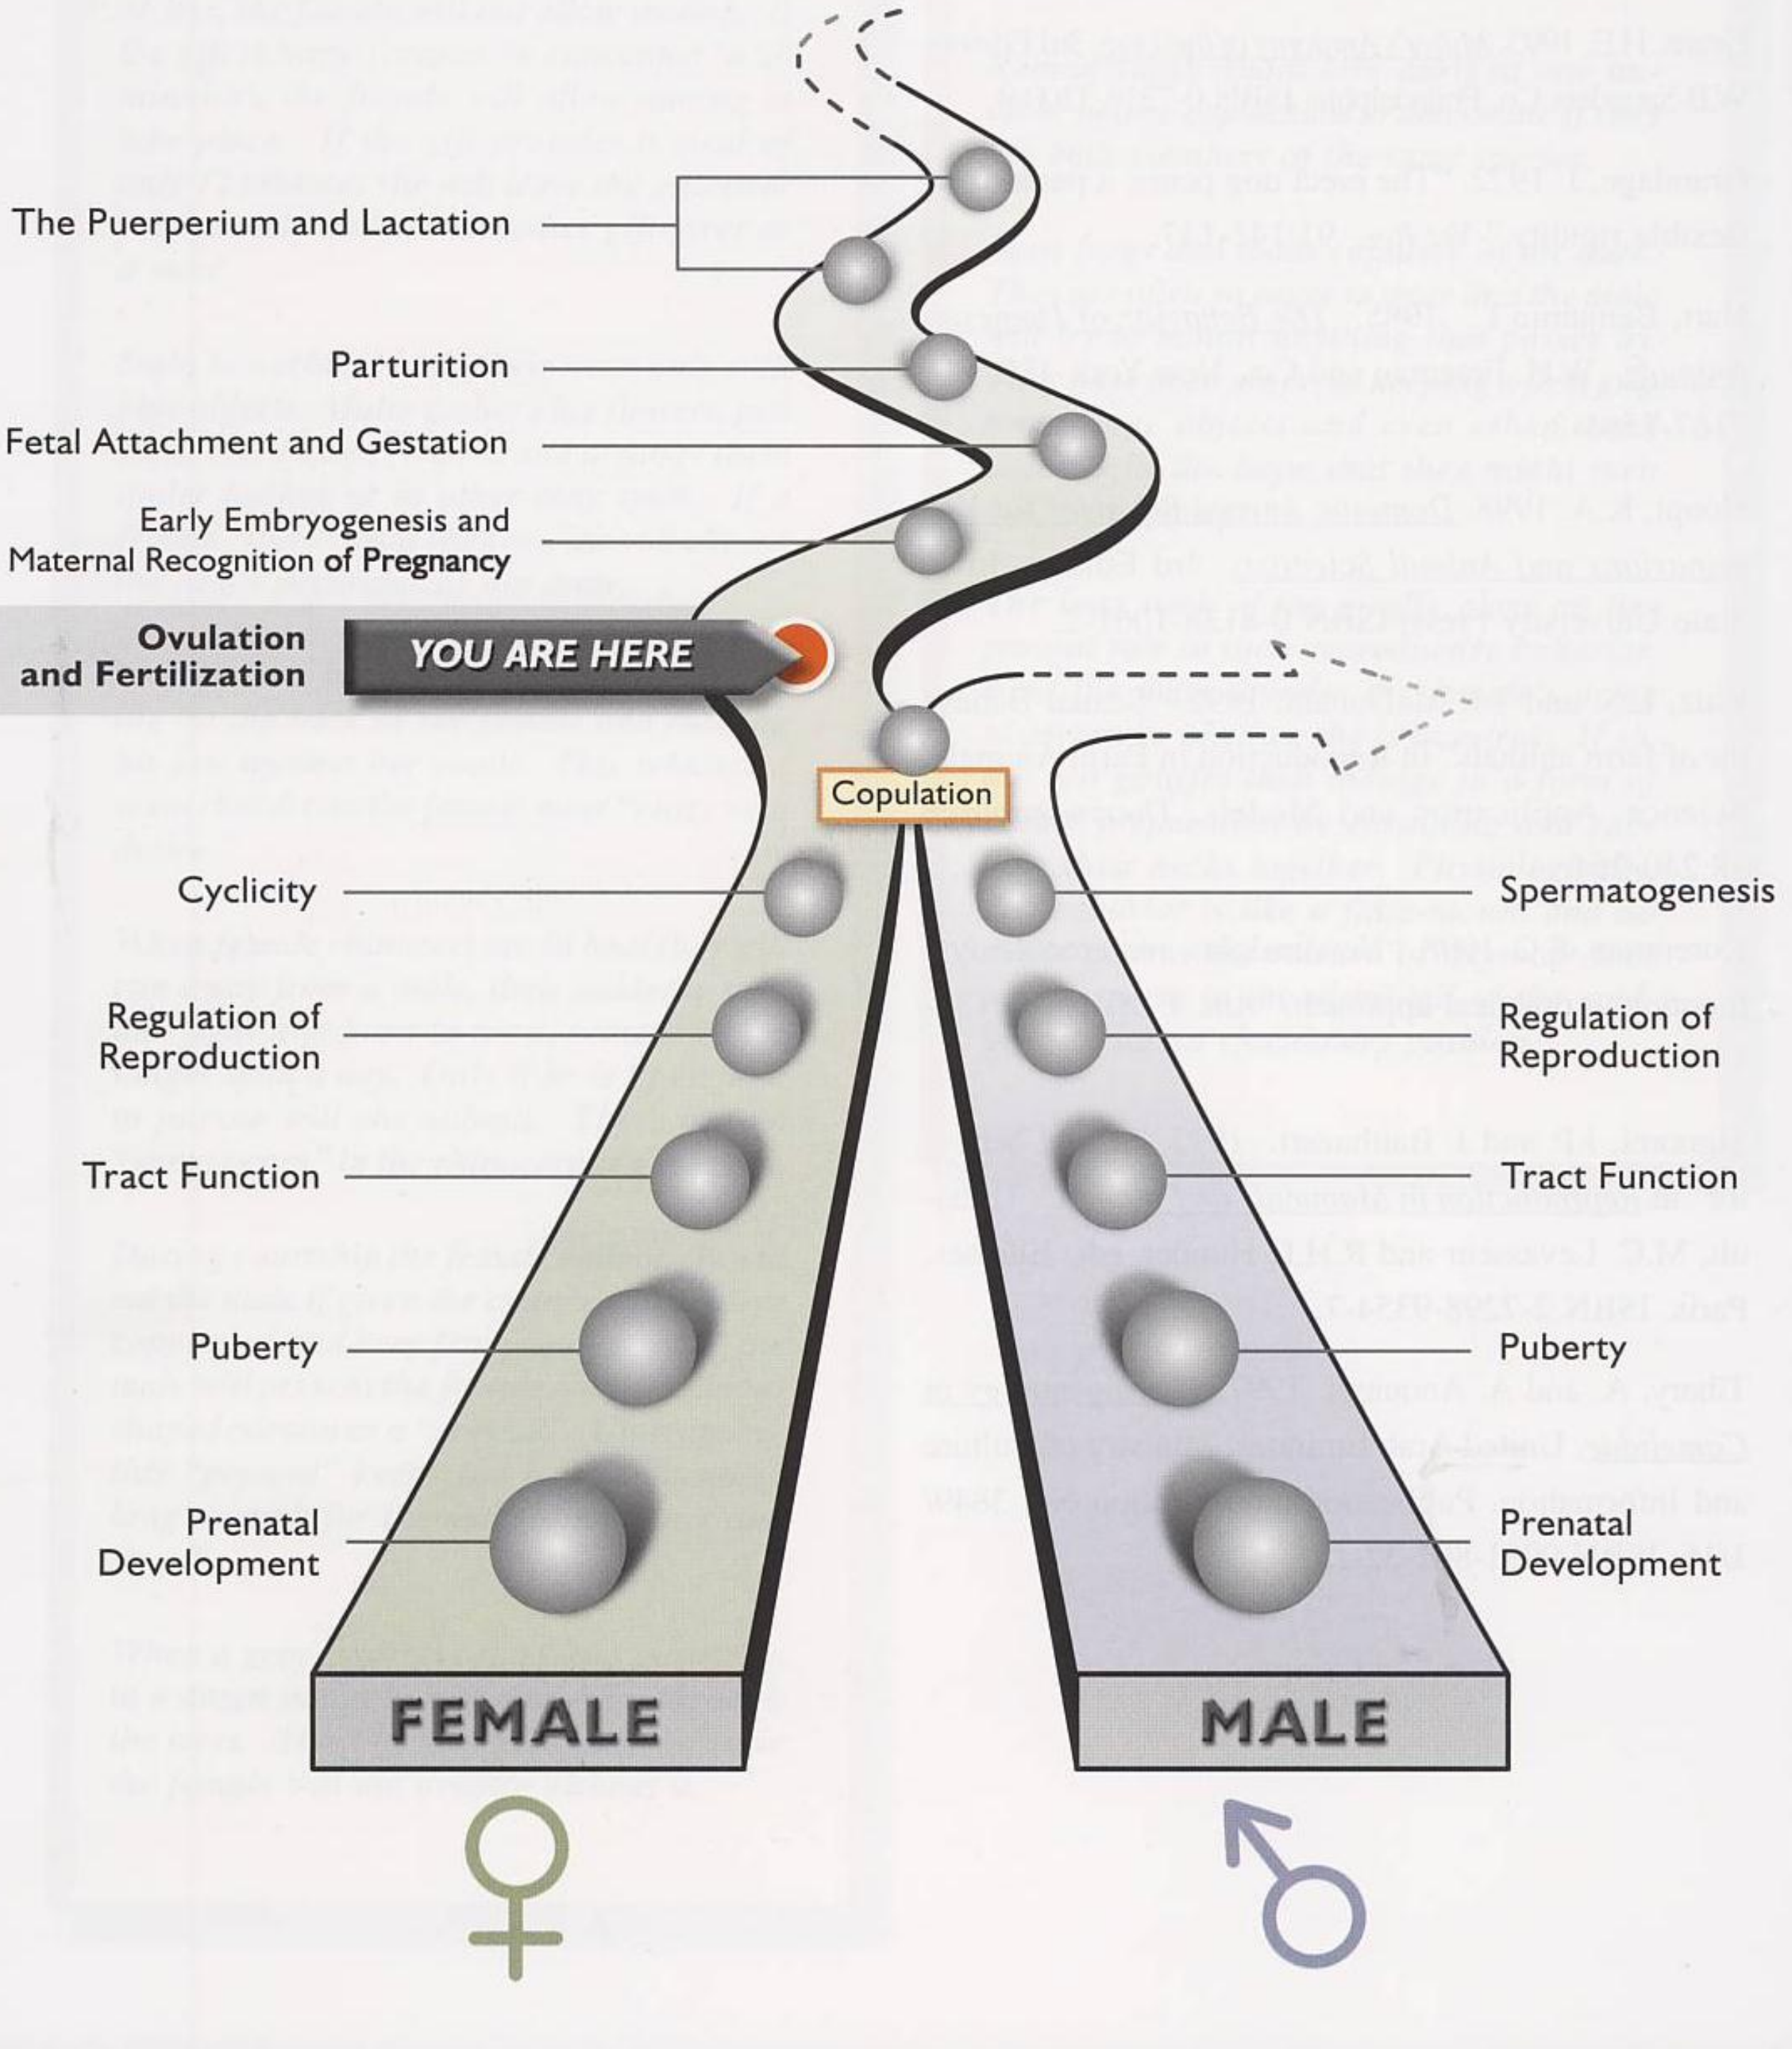
CHAPTER

12 Spermatozoa in the Female Tract

Transport, Capacitation & Fertilization

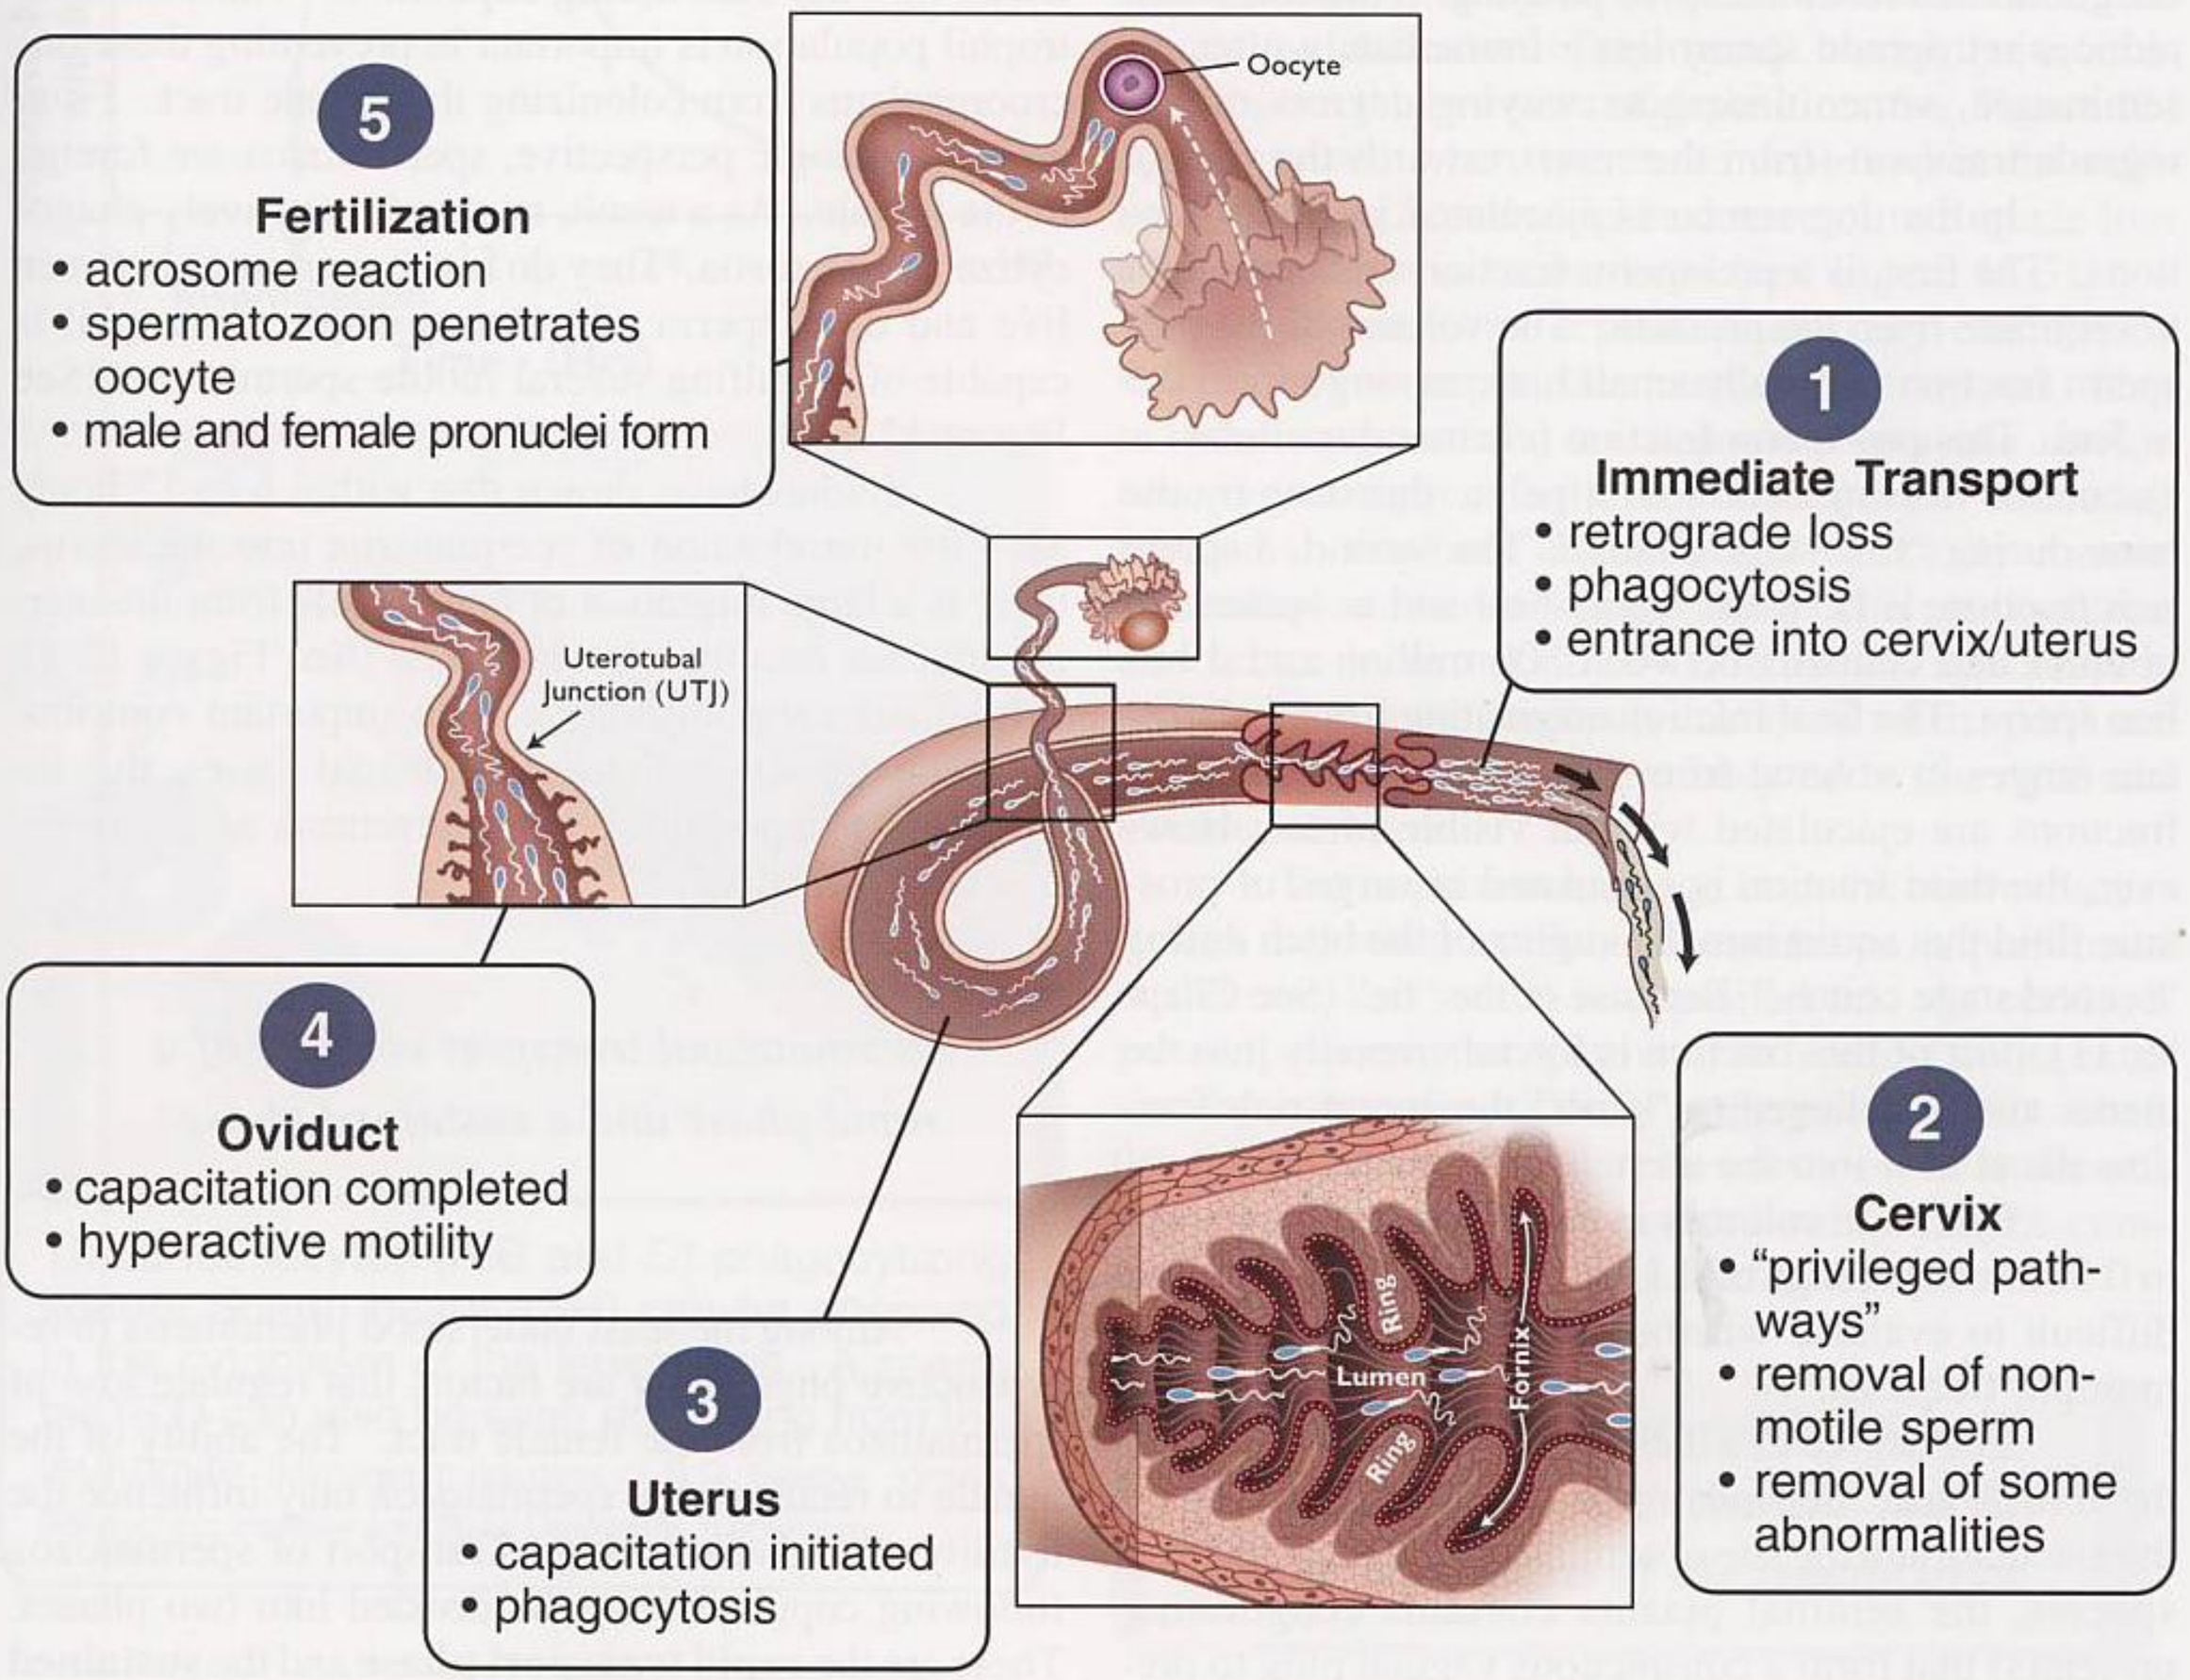


Take Home Message

Following insemination, viable spermatozoa that are retained in the female reproductive tract must: 1) transverse the cervix, 2) be transported through the uterus to the oviduct, 3) undergo capacitation, 4) bind to the oocyte, 5) undergo the acrosome reaction and 6) penetrate the zona pellucida and fuse with the oocyte plasma membrane. After fusion with the plasma membrane, the fertilizing spermatozoon enters the oocyte cytoplasm and its nucleus decondenses. The male pronucleus is formed. This signifies successful fertilization.

Following deposition of semen during copulation, spermatozoa are exposed to a series of different environments that significantly alter their numbers and their function. After insemination, spermatozoa are lost from the female reproductive tract by retrograde transport and many are phagocytized by leukocytes within the female tract. The remaining spermatozoa must traverse the cervix, enter and traverse the uterus and enter the oviduct. They must undergo capacitation before they can fertilize the oocyte. When sperm encounter the egg they undergo the acrosome reaction and fertilization takes place. This series of events is summarized in Figure 12-1.

Figure 12-1. Major Sequence of Events Following Deposition of Spermatozoa in Female Tract



In some animals (cow, sheep, rabbit, primates, dog and cat), the male ejaculates the semen into the cranial vagina. In others, (pigs, horses and camelids) semen is either deposited directly into the cervix (pig) or is squirted through the cervical lumen during copulation (horse). In the dog, pig and the horse most of the ejaculate gains entrance into the uterine lumen.

The stallion ejaculates in a series of "jets" in which a sperm-rich fraction is ejaculated first in a series of 3 to 4 high pressure squirts. This fraction contains about 80% of the spermatozoa. The last 5 to 8 "jets" are of lower pressure and contain fewer sperm. The seminal plasma in the final "jets" is highly viscous and may serve to minimize retrograde sperm loss from the mare's tract.

Because of the large volume (200 to 400 ml) of boar ejaculate, most of the semen flows from the cervix into the uterine lumen. As in the stallion, the boar ejaculates a series of seminal fractions with different characteristics as ejaculation progresses. The first fraction consists of accessory fluids and gelatinous pellets. This fraction contains few sperm. The second fraction is rich in spermatozoa and this sperm-rich fraction is followed by a final fraction that forms a coagulum that resembles rice pudding. This coagulum reduces retrograde sperm loss. Immediately after insemination, semen undergoes varying degrees of retrograde transport (from the cervix towards the vulva).

In the dog semen is ejaculated in three fractions. The first, is a pre-sperm fraction that is thought to originate from the prostate. The volume of the pre-sperm fraction is usually small but can range from 0.5 to 5ml. This pre-sperm fraction (clear and acellular) is ejaculated in conjunction with pelvic thrusting by the male during "first stage coitus." The second, a sperm rich fraction, is between 1 and 4 ml and is opalescent in color and contains between 300 million and 2 billion sperm. The final fraction originating from the prostate ranges in volume from 1 to 80ml. The first two fractions are ejaculated without visible force. However, the third fraction is ejaculated in surges of prostatic fluid that squirt into the vagina of the bitch during "second stage coitus." Because of the "tie" (See Chapter 11) most of this fraction is forced cranially into the uterus and is believed to "push" the sperm-rich fraction ahead of it into the uterus.

Ejaculate volumes in the tom average only 0.2 to 0.3ml with a range of 0.1 to 0.7ml and it is therefore difficult to evaluate whether the ejaculate consists of multiple fractions.

The degree to which spermatozoa are lost from the female tract depends upon the physical nature of the ejaculate and the site of seminal deposition. In some species, the seminal plasma contains coagulating protein(s) that form a conspicuous vaginal plug to prevent spermatozoa from undergoing retrograde flow to the exterior. Female rodents (mice and rats) have a relatively solid vaginal plug that is externally visible following copulation. The presence of the vaginal plug can be used to determine when mating occurred. Domestic animals do not have a conspicuous vaginal plug.

Spermatozoa are lost from the female tract by:

- ***phagocytosis by neutrophils***
- ***retrograde transport***

When the female reproductive tract is under the influence of estradiol during estrus, neutrophils (powerful phagocytic white blood cells) sequester in the mucosa of the tract, especially in the vagina and uterus. These neutrophils are poised to attack foreign materials that are introduced into the female reproductive tract at insemination. It should be recognized that, in addition to spermatozoa, microorganisms are introduced into the tract during copulation. Thus, the neutrophil population is important in preventing these microorganisms from colonizing the female tract. From an immunologic perspective, spermatozoa are foreign to the female. As a result, neutrophils actively phagocytize spermatozoa. They do not discriminate between live and dead sperm. In fact, a single neutrophil is capable of engulfing several motile spermatozoa (See Figure 12-2).

Studies have shown that within 6 to 12 hours after the introduction of spermatozoa into the uterus, there is a large migration of neutrophils from the uterine mucosa into the uterine lumen (See Figure 12-2). While leukocyte infiltration is an important contributor to post-insemination spermatozoal losses, this infiltration is important for the prevention of reproductive tract infection.

Spermatozoal transport consists of a rapid phase and a sustained phase.

Among the least understood phenomena in reproductive physiology are factors that regulate loss of spermatozoa from the female tract. The ability of the female to retain viable spermatozoa may influence the fertility of a given mating. Transport of spermatozoa following copulation can be divided into two phases. These are the **rapid transport phase** and the **sustained**

transport phase. Within a few minutes after copulation, spermatozoa can be found in the oviducts. The rapid phase of transport was once considered to be important because it delivered spermatozoa to the site of the fertilization very shortly after copulation, where they "postured" themselves for the arrival of oocytes. However, further research has shown that spermatozoa arriving in the oviducts within minutes after copulation were not viable. The functional importance of the rapid phase of sperm transport is not obvious. It may simply represent a burst of transport activity brought about contraction of the muscularis of the female tract in conjunction with copulation.

The more important component of transport is the sustained phase in which spermatozoa are transported to the oviducts in a "trickle-like" effect from so-called reservoirs in the cervix and the uterotubal junction. The sustained sperm transport phase delivers spermatozoa to the ampulla of the oviduct in a more uniform manner over a sustained period of time.

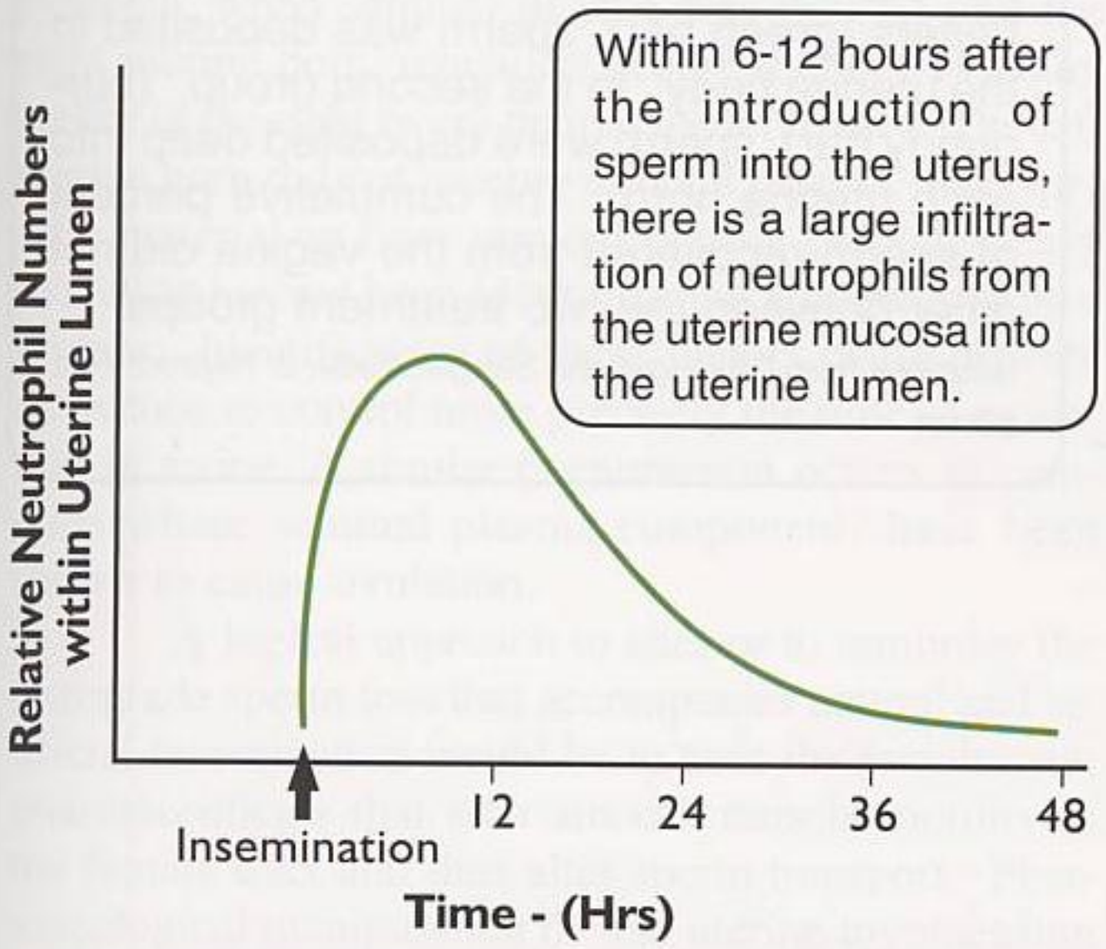
It had been erroneously assumed for years that most spermatozoa ascend toward the oviduct soon after they are deposited in the cow uterus by artificial insemination. However, recent studies have shown that a high proportion of spermatozoa deposited in the uterus of the cow or ewe are lost from the tract by retrograde transport. In most cows, over 60% of spermatozoa artificially inseminated into the uterus are lost to the exterior of the tract within 12 hours after deposition. Given these findings, a logical interpretation would be that artificial insemination of spermatozoa deep into the uterus would result in reduced retrograde loss. This assumption is not true because when sperm are deposited deep into both uterine horns (as opposed to the uterine body) the degree of sperm recovered from the vagina (an indication of retrograde loss) is quite similar between the two sites of deposition (See Figure 12-3). However, when sperm are deposited in the mid-cervix, a significantly higher degree of retrograde loss of spermatozoa is encountered (See Figure 12-3).

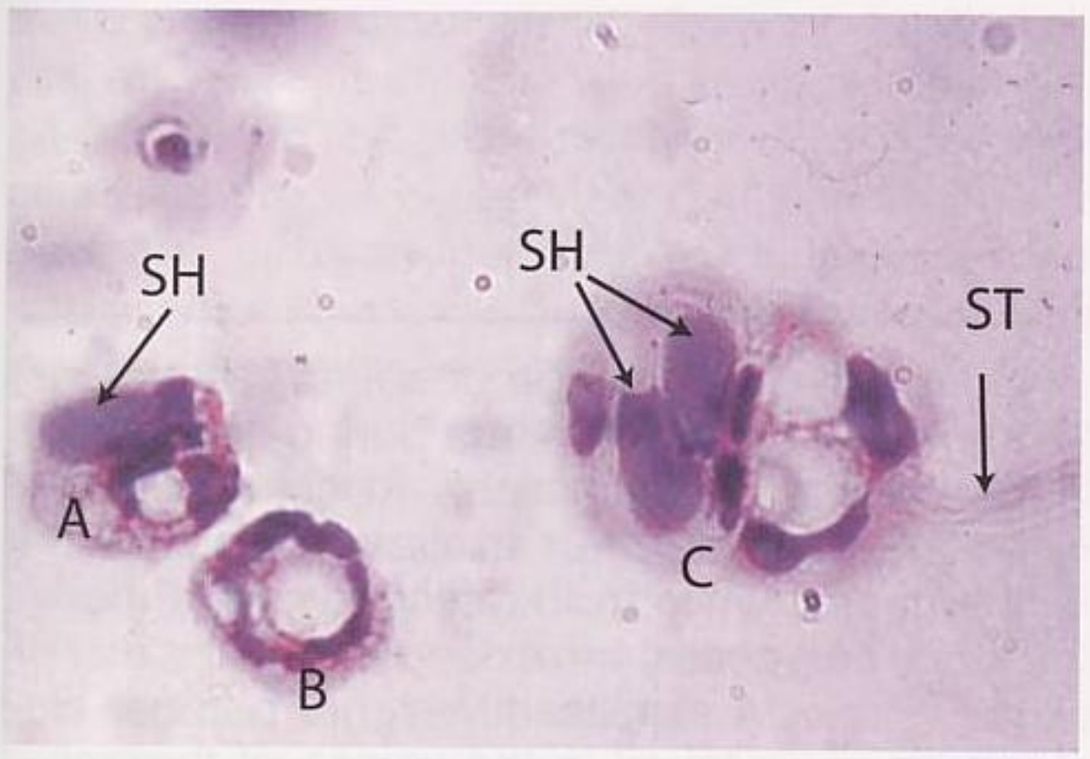
Spermatozoa deposited into only one uterine horn of the cow experience intercornual transport. That is, when spermatozoa are deposited into one uterine horn (either right or left), they subsequently are redistributed so that both uterine horns eventually contain substantial numbers of spermatozoa. This phenomenon also occurs in swine. In cows, fertility is not compromised and in some studies is enhanced when sperm are deposited within the uterine body or in the right and left uterine horns.

The important message from the above discussion is that when artificial insemination is performed in the cow and semen is deposited into the cervix, a greater proportion of spermatozoa are lost to the exterior than when deposition is in the uterus. Thus, when the insemination procedure involves cervical deposition (a serious technique error), fertility may be compromised because of greater spermatozoal loss.

Transport of spermatozoa is primarily the result of elevated tone and motility of the muscularis of the female tract.

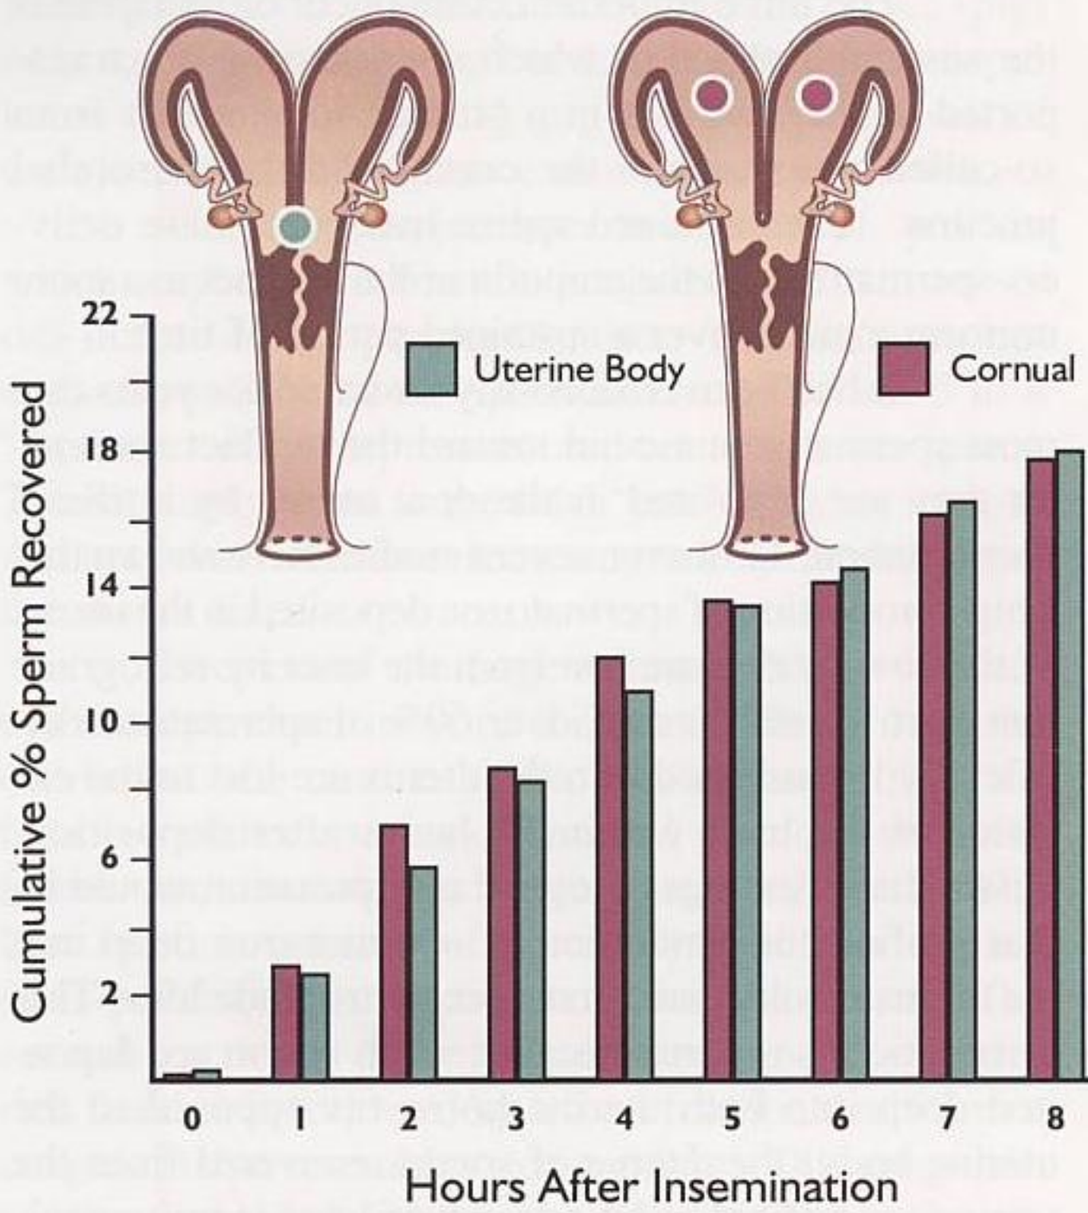
Figure 12-2. Leukocyte Infiltration Helps Prevent Reproductive Tract Infections





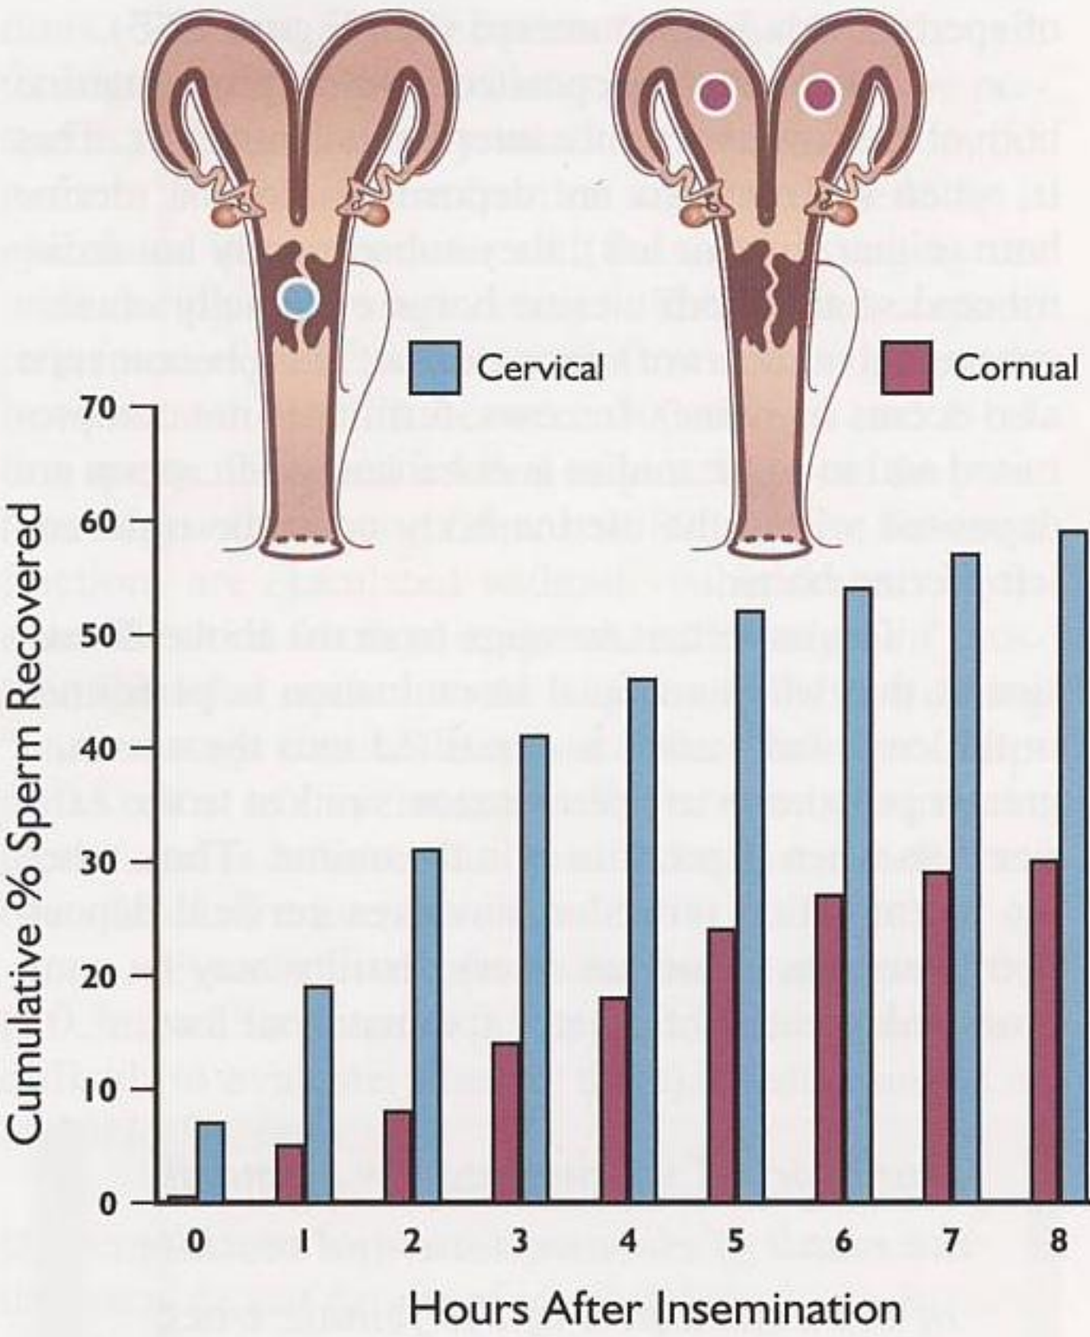
Three leukocytes (A,B and C) phagocytizing sperm. Sperm heads (SH) can be observed in the cytoplasm of the leukocytes. A sperm tail (ST) can also be seen protruding from the leukocyte (Micrograph courtesy of R.G. Saacke, Virginia Polytechnic Institute and State University, Blacksburg)

Figure 12-3. Insemination into the Uterine Horns Can Reduce Sperm Loss



Cumulative percentage of sperm recovered from the vagina of heifers during an 8 hour period after insemination. In one group of heifers (green bar), sperm was deposited in the uterine body. In the second group (burgundy bar), sperm were deposited deep into each uterine horn. The cumulative percent of sperm recovered from the vagina did not differ between the two treatment groups.

(Modified from Gallahger and Senger, 1989, *J. Reprod. Fert.* 86:19)



Cumulative percentage of sperm recovered from the vagina of heifers during an 8 hour period after insemination. In one group of heifers (blue bar) sperm were deposited in the cervix, while in the second group (burgundy bar) sperm were deposited in the uterine horns. A significantly higher number of sperm were found in the vagina of the animals that were inseminated at midcervix indicating retrograde sperm transport.

(Modified from Gallagher and Senger, 1989, *J. Reprod. Fert.* 86:19)

As you already know, estradiol is high during the follicular phase when insemination occurs. Estradiol stimulates contractions of the muscularis, particularly the myometrium. Also, prostaglandins in semen ($PGF_{2\alpha}$ and PGE_1) cause increased tone and motility of the uterus and/or the oviduct. Intermittent contractions of the muscularis propel spermatozoa in both a cranial and a caudal direction. Fluids secreted into the lumen of the female tract also serve as a vehicle for transport. Control of directionality, while not understood, is probably under the collective influence of muscular contractions and fluid distribution and characteristics.

In addition to alteration of tract motility, seminal plasma from boars has been shown by German researchers to advance the time of ovulation in gilts. For example, when seminal plasma was infused into the right uterine horn, ovulation occurred about 11 hours earlier in the right ovary than in the left ovary. The left uterine horn did not receive seminal plasma. The specific material in boar seminal plasma inducing early ovulation has not been identified, but it appears to be a protein. Identification of these factors could provide an avenue to control more precisely the time of ovulation in swine. A similar phenomenon occurs in camelids where seminal plasma components have been shown to cause ovulation.

A logical approach to alter or to minimize the retrograde sperm loss that accompanies natural and artificial insemination would be to treat the female with pharmaceuticals that alter smooth muscle motility in the female tract and thus alter sperm transport. Pharmacological manipulation of the uterine myometrium may represent an avenue whereby fewer numbers of spermatozoa can be inseminated with acceptable fertility.

In one test, when rabbits were injected with phenylephrine or ergonovine, two smooth muscle stimulants, the number of sperm reaching the oviducts was significantly elevated. In does inseminated with very low sperm numbers (around 90,000), an intramuscular injection of either phenylephrine or ergonovine resulted in a significantly increased fertilization rate when compared to controls that received neither phenylephrine nor ergonovine (See Figure 12-4). This finding suggests that a reduction in numbers of spermatozoa, if accompanied by proper stimulators of uterine smooth muscle motility, can result in acceptable fertilization rates. This would be particularly important if pharmaceuticals could be added to semen used in artificial insemination. If "transport conservation" could be accomplished, fewer sperm could be used in each dose of semen and spermatozoa from genetically superior sires could be distributed on a wider basis. Further, the problem of low sperm numbers following X-Y cell sorting described in Chapter 10 might be minimized using this approach.

Figure 12-4. Smooth Muscle Stimulants Increase Fertilization Rate in Rabbits

The number of spermatozoa that reached the oviducts was significantly increased in rabbits that were injected with phenylephrine (P) or ergonovine (E) (both smooth muscle stimulants). Even when inseminated with low sperm numbers (~90,000), an intramuscular injection of smooth muscle stimulants significantly increased fertilization rates.

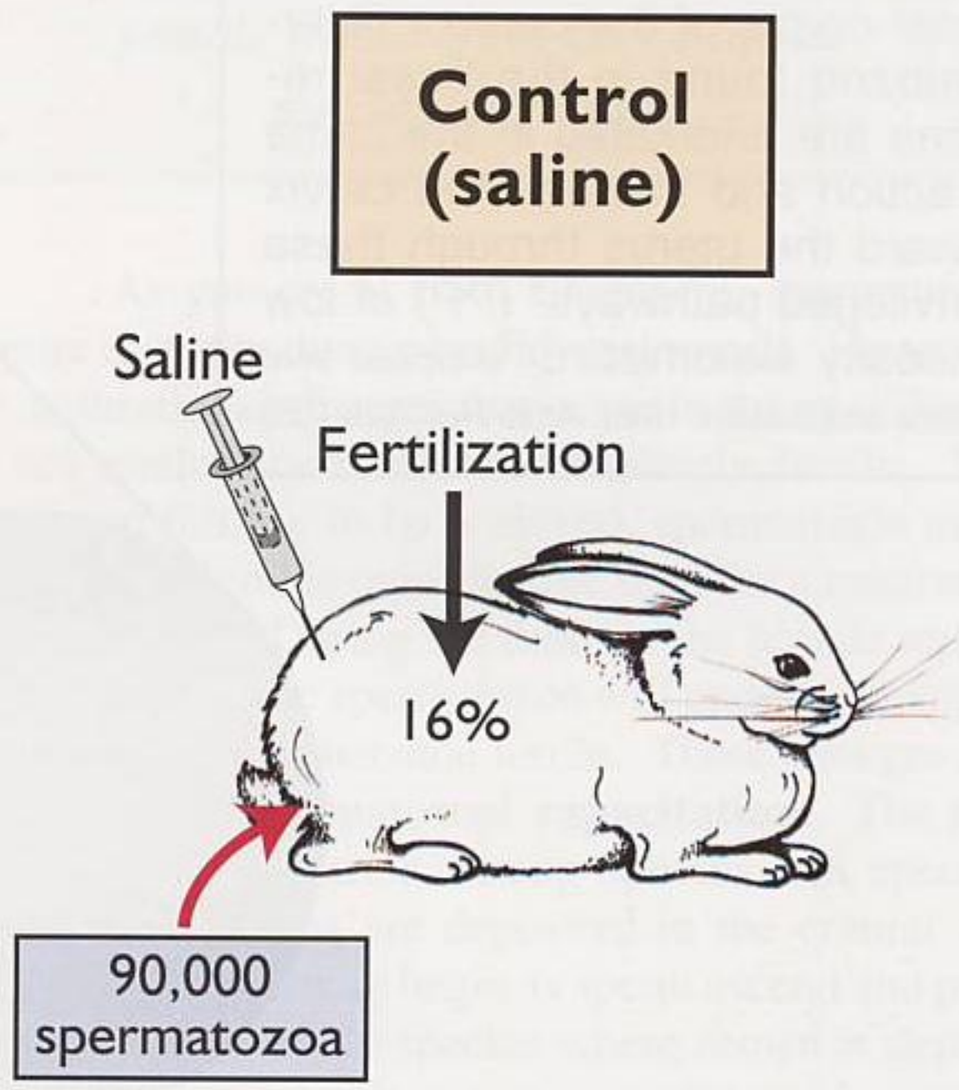


Figure 12-5. Spermatozoa Travel Through "Privileged Pathways" in the Cow

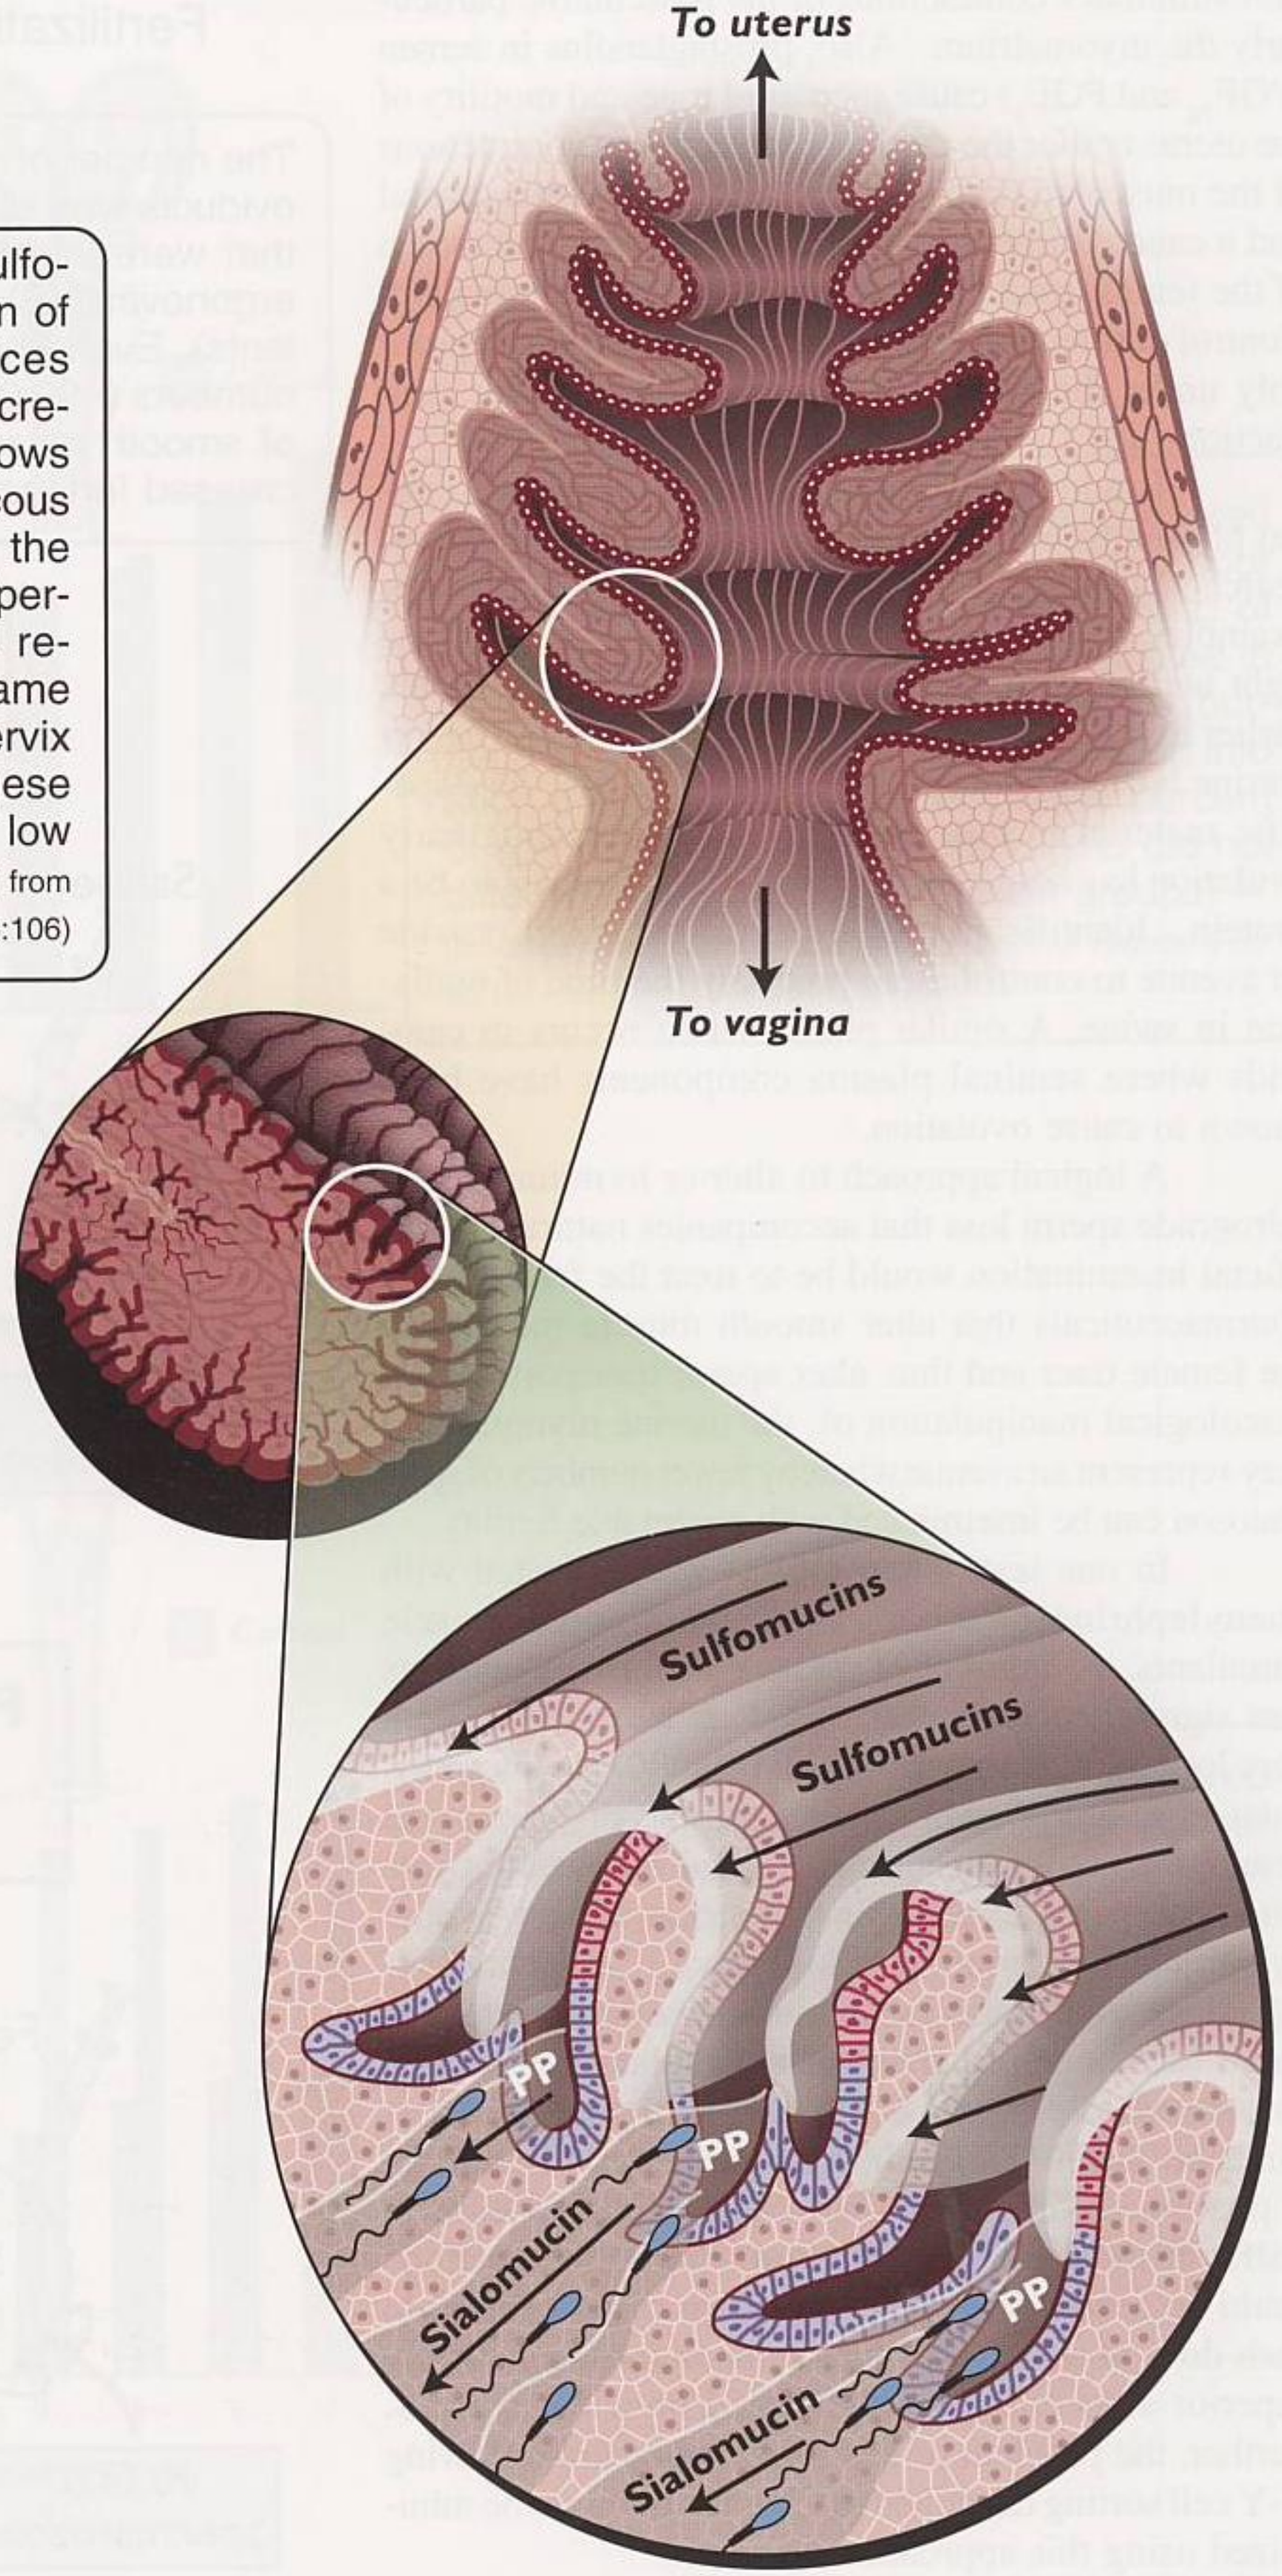
During estrus secretion of sulfomucins from the apical portion of the cervical mucosa produces sheets of viscous mucus. Secretion is toward the lumen and flows in a caudal direction. Less viscous sialomucins are produced in the basal crypts of the cervix. Spermatozoa found in the basal regions are orientated in the same direction and traverse the cervix toward the uterus through these "privileged pathways" (PP) of low viscosity sialomucin. (Modified from Mullins and Saacke 1989, *Anat. Rec.* 225:106)



The cervix is a major barrier to spermatozoal transport and it can also serve as a reservoir for spermatozoa.

Following natural service in the cow and ewe and, to some degree, the mare, spermatozoa must negotiate the highly convoluted system of grooves within the cervix (See Figure 12-5). During estrus, the cervix produces mucus. In the cow cervical mucus consists of two types. One type is a **sialomucin**, a mucus of low viscosity. It is produced by cells in the basal areas of the cervical crypts (See Figure 12-5). A second type, **sulfomucin** is produced in the apical portions of the cervical epithelium covering the tips of the cervical folds. This type of mucus is quite viscous. The production of two types of mucus (one of low viscosity and one of high viscosity) creates two distinct environments within the cervix. Spermatozoa encountering the viscous sulfomucin are washed out of the tract. Those that encounter the low viscosity sialomucin in the environment of the crypts of the cervix swim into it. Thus, the low viscosity environment of the deeper cervical crypts creates "privileged pathways" through which spermatozoa can move.

The ability of spermatozoa to traverse these "privileged pathways" is believed to depend on their ability to swim through the basal channels (crypts) of the cervix. In this context, the cervix may be a filter that eliminates non-motile spermatozoa. The time required for motile sperm to gain access and traverse these "privileged pathways" probably contributes significantly to the time required for the sustained phase of sperm transport. The specific role of the cervix in spermatozoal transport and/or retention awaits further clarification in the sow and the mare, where a high proportion of spermatozoa are ejaculated into the uterus.

Delivery of Semen to the Proper Anatomical Region of the Female Tract is Required for Successful Artificial Insemination

Artificial insemination technique requires that spermatozoa be deposited in the reproductive tract of the female by artificial means. In general, semen is delivered using a pipette to penetrate and bypass the cervix (See Figure 12-6). This type of insemination is referred to as **transcervical insemination**. In the sow, the insemination pipette is positioned within the cervix and semen is delivered into the cranial half of the cervix and flows directly into the uterine horns. This type of insemination is referred to as **intracervical insemination** (See Figure 12-7). In dogs and cats semen is deposited in the cranial vagina. This type of insemination is referred to as **intravaginal insemination** (See Figure 12-7).

In cases where sperm are in very limited supply, surgical insemination can be performed by exteriorizing the reproductive tract and injecting sperm directly into the uterus or uterotubal junction region. Also, use of laparoscopy enables insemination to be performed without laparotomy (an abdominal incision). In bulls, X-Y sorted semen are in short-supply. Therefore, a technique has been developed to "thread" the tip of an insemination pipette near the uterotubal junction. Such a technique has been reported to generate excellent results.

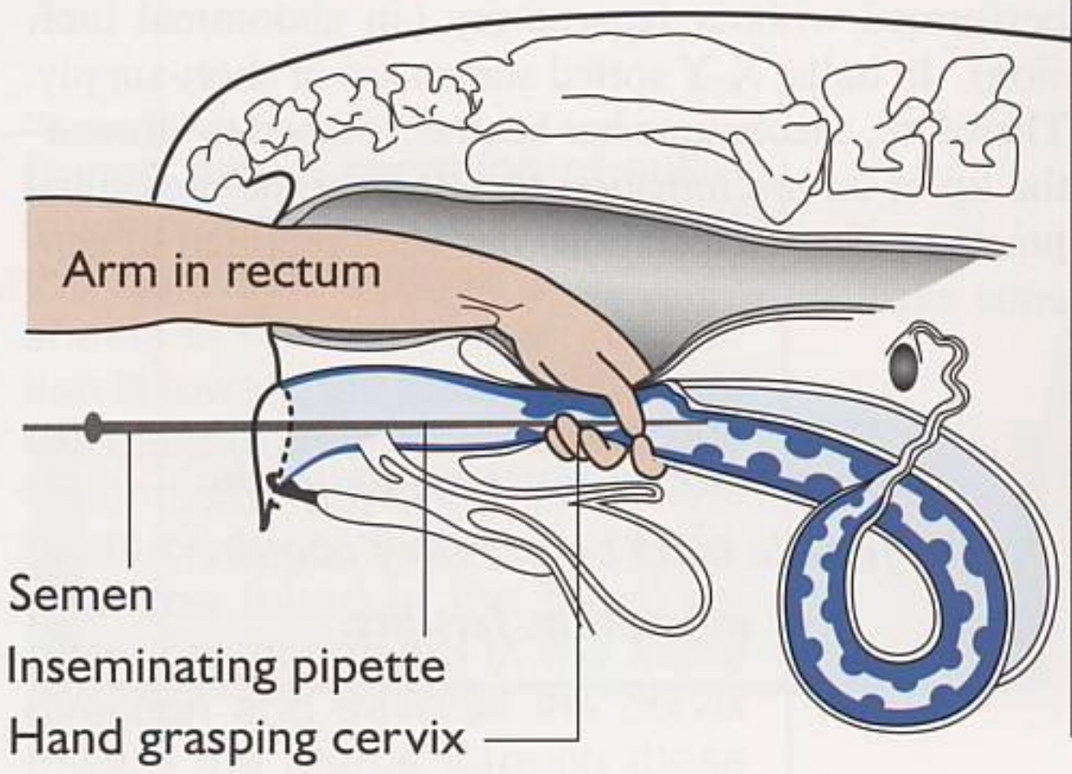
Spermatozoa must reside in the female tract before they acquire maximum fertility.

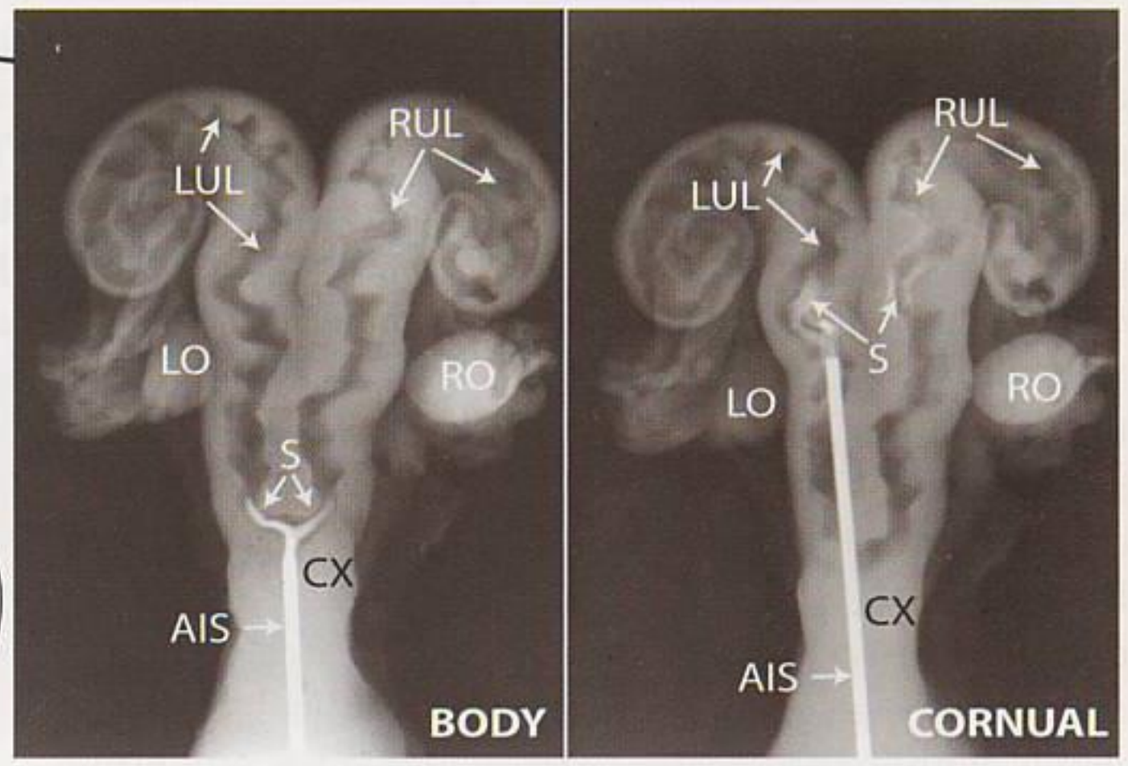
As you recall from Chapter 3, spermatozoa acquire maturity during epididymal transit. However, the maturational changes that occur in the epididymis do not render spermatozoa completely fertile. For maximum fertility to be achieved, spermatozoa must reside in the female reproductive tract for a minimum period of time. During the time in the female reproductive tract, some spermatozoa will undergo changes that allow them to become fertile. These changes are referred to as spermatozoal **capacitation**. The site for capacitation varies among species. In species where spermatozoa are deposited in the cranial vagina, capacitation may begin as sperm ascend and pass through the cervix. In species where semen is deposited into the mid-cervix (sow) or caudal cervix (mare) and immediately enters the uterus, capacitation is probably initiated within the uterus and completed in the isthmus of the oviduct. All spermatozoa are not capacitated at the same rate. Instead, they are capacitated over a relatively long period of time (several hours) and this reflects individual sperm differences as well as location within the tract. Capacitation can occur in fluids other than those found in the luminal compartment of the female reproductive tract. For example, *in vitro* capacitation has been accomplished in a wide variety of species using blood serum, a variety of commercial tissue culture media, Krebs Ringer solution and Tyrodes solution. No single *in vitro* environment will support capacitation for all species.

There is little doubt that the plasma membrane of the sperm (particularly the head) undergoes marked biochemical changes during capacitation. One way to envision the process of capacitation is presented in Figure 12-8. During mixing of sperm with seminal plasma the sperm become coated with various proteins. The coating of seminal plasma proteins is

Figure 12-6. Artificial Insemination Technique in the Cow and Mare

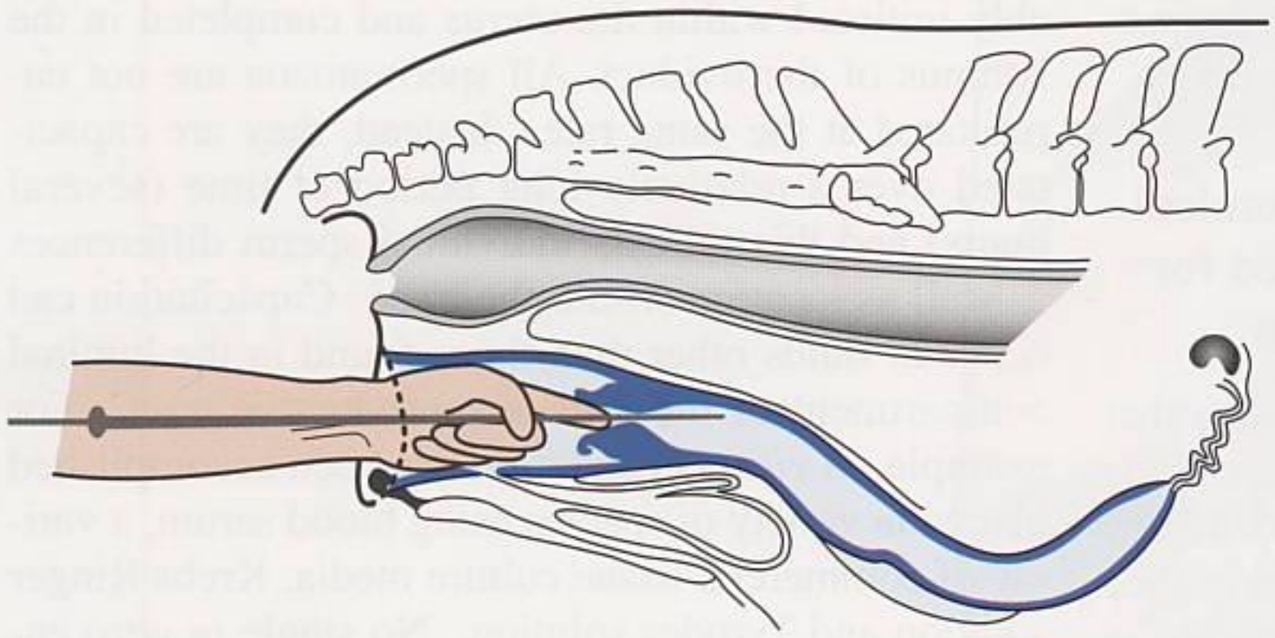
Cow

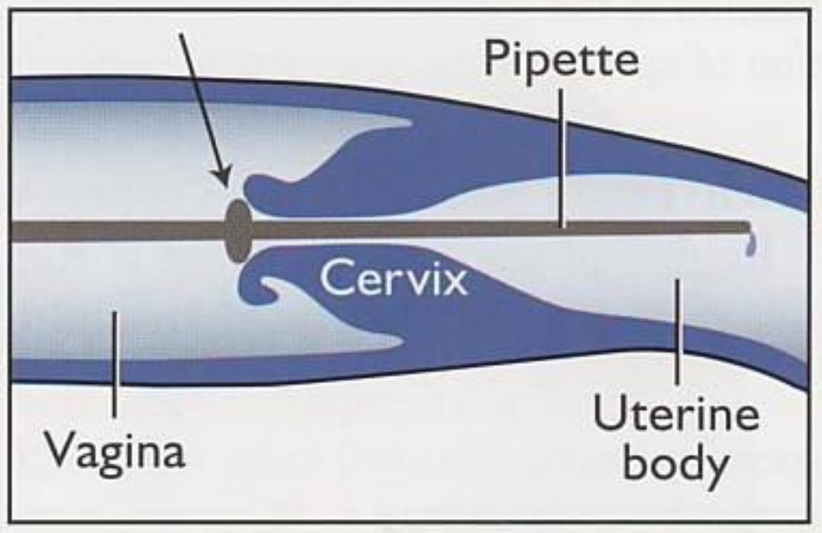




The radiographs above are from extirpated cow reproductive tracts (dorsal view). In cornual insemination, one-half of the semen is deposited in each uterine horn. In both examples, the inseminant volume is 0.5-ml. Cornual insemination minimizes the possibility of cervical deposition that results in significant retrograde loss of spermatozoa (See Figure 12-3). RUL= Right Uterine Lumen; LUL= Left Uterine Lumen; RO= right ovary; LO= left ovary; S= semen; AIS= artificial insemination syringe; CX= cervix

Mare

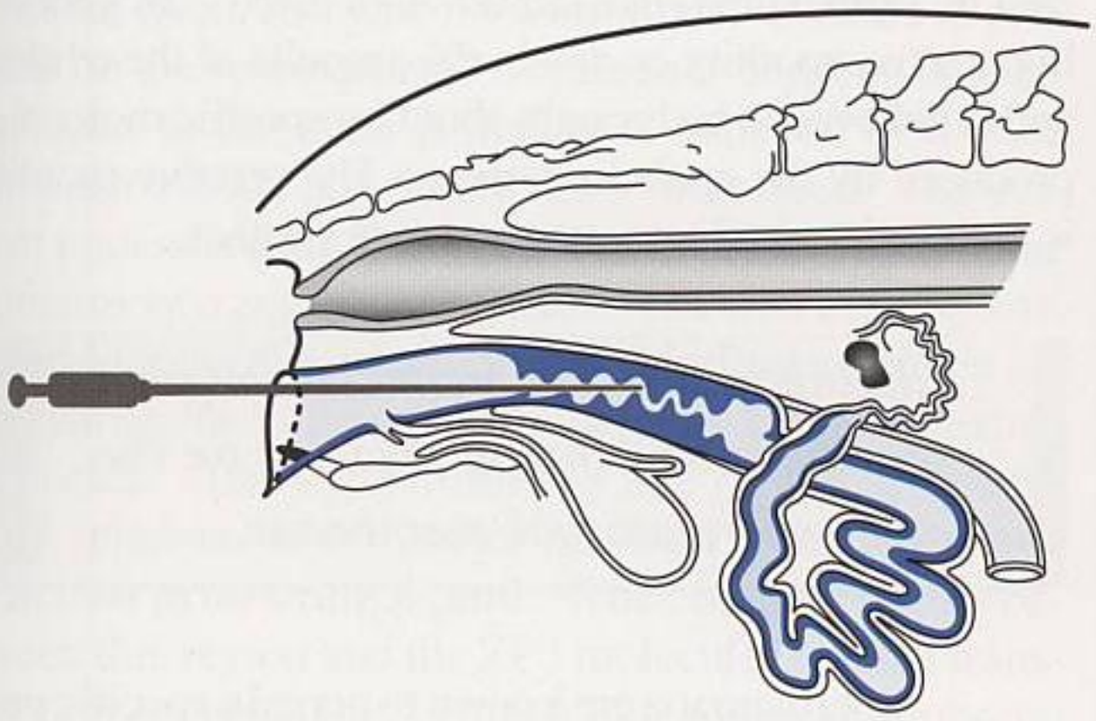


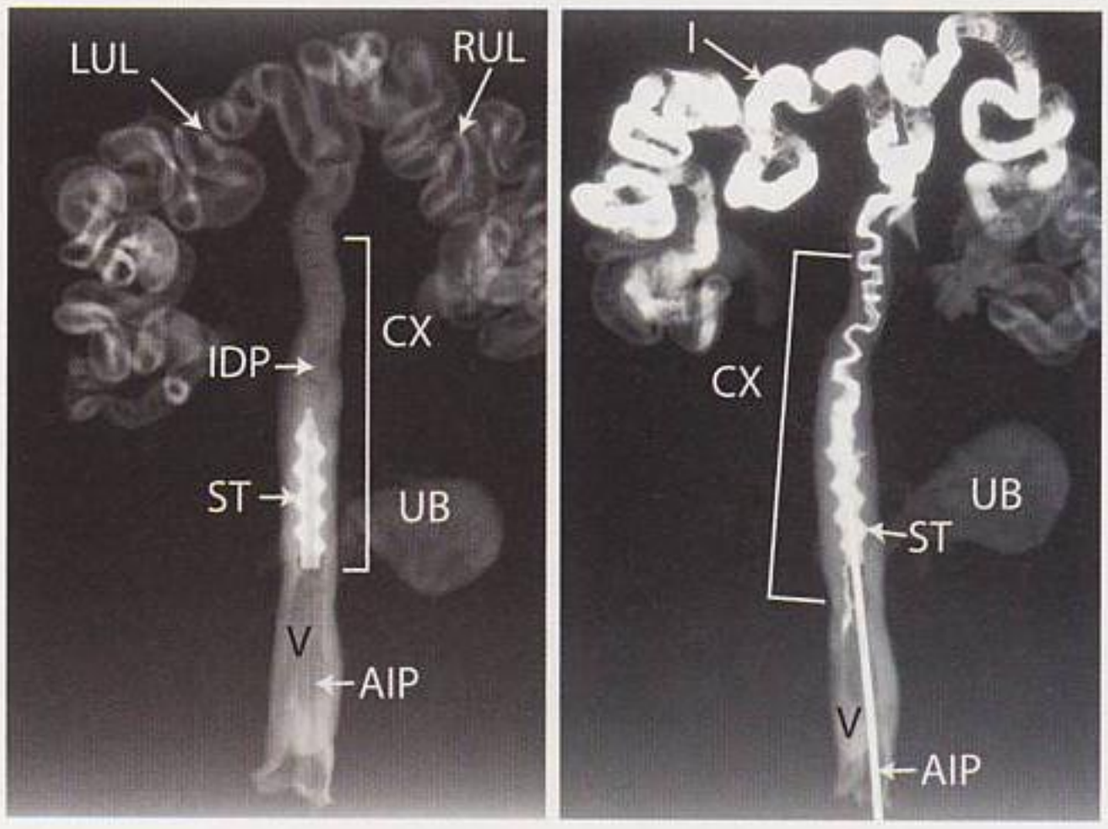


In the mare, the gloved lubricated hand is inserted directly into the vagina and the index finger is used to guide the insemination pipette into the cervical lumen. A marker (arrow) is used to gauge the depth of insemination.

Figure 12-7 Artificial Insemination Technique in the Sow and Bitch

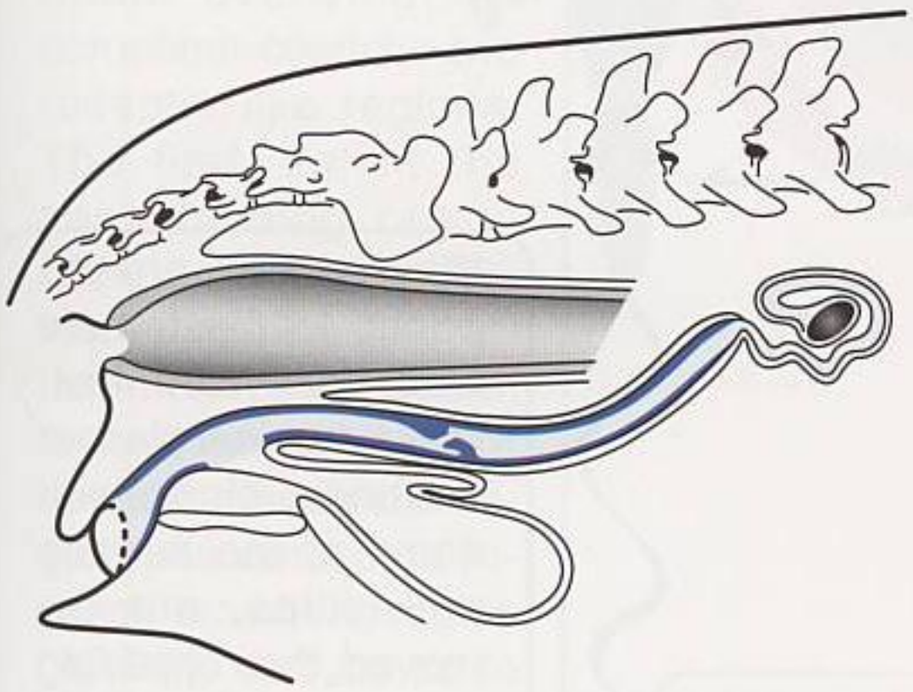
Sow

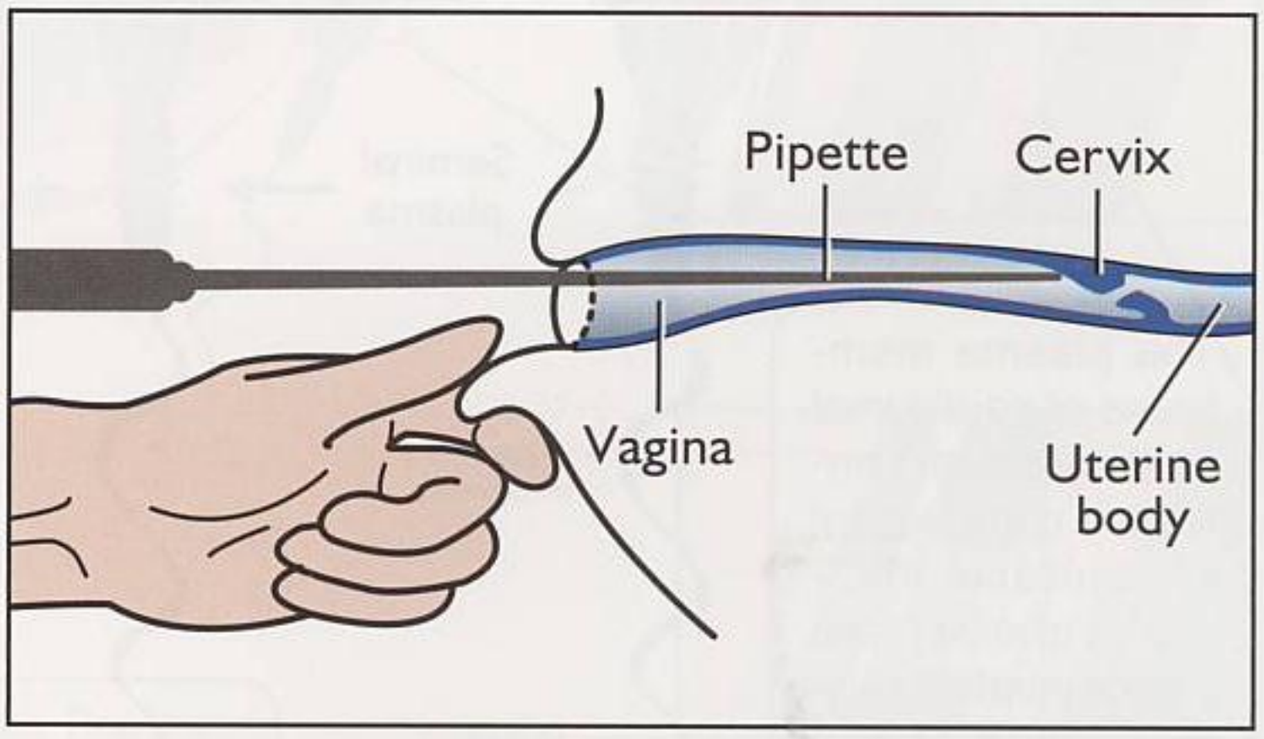




Radiographs of an extirpated sow reproductive tracts (dorsal view). An artificial insemination pipette (AIP) consists of a spiral tip (ST) that is designed so that it can snugly penetrate the interdigitating prominences (IDP) of the cervix (CX). In the photograph to the right, about 80-ml of radiopaque contrast medium was infused into the reproductive tract to mimic the inseminant (I). Notice that the semen becomes distributed within both uterine horns. High volumes (about 80-ml) are necessary to maximize pregnancies in sows. The vagina (V) and the urinary bladder (UB) can be visualized. LUL= Left Uterine Lumen; RUL= Right Uterine Lumen.

Bitch





The vulva is elevated manually so that the ventral "tilt" of the vestibule is removed. This allows the insemination pipette to be inserted with relative ease. The hindquarters of the bitch should be elevated for about 5 minutes after deposition of the semen to allow pooling in the cranial vagina and caudal cervix.

"stripped" away by the female tract environment. The exact nature of the "stripping process" of capacitation is not understood.

An important concept with regard to capacitation is that the process can be reversed by returning capacitated spermatozoa to seminal plasma. For example, when capacitated spermatozoa are removed from the female reproductive tract and returned to seminal plasma, they become **decapacitated** and require additional capacitation time in the female reproductive tract before they can regain their fertility. It appears that the seminal plasma components coat the plasma membrane with surface substances that prevent or inhibit interaction of spermatozoa with the egg.

Fertilization is a Complex Process and Involves a Cascade of Events

The process of fertilization involves a series of specific interactions between spermatozoa and the oocyte. These are outlined in Figure 12-9.

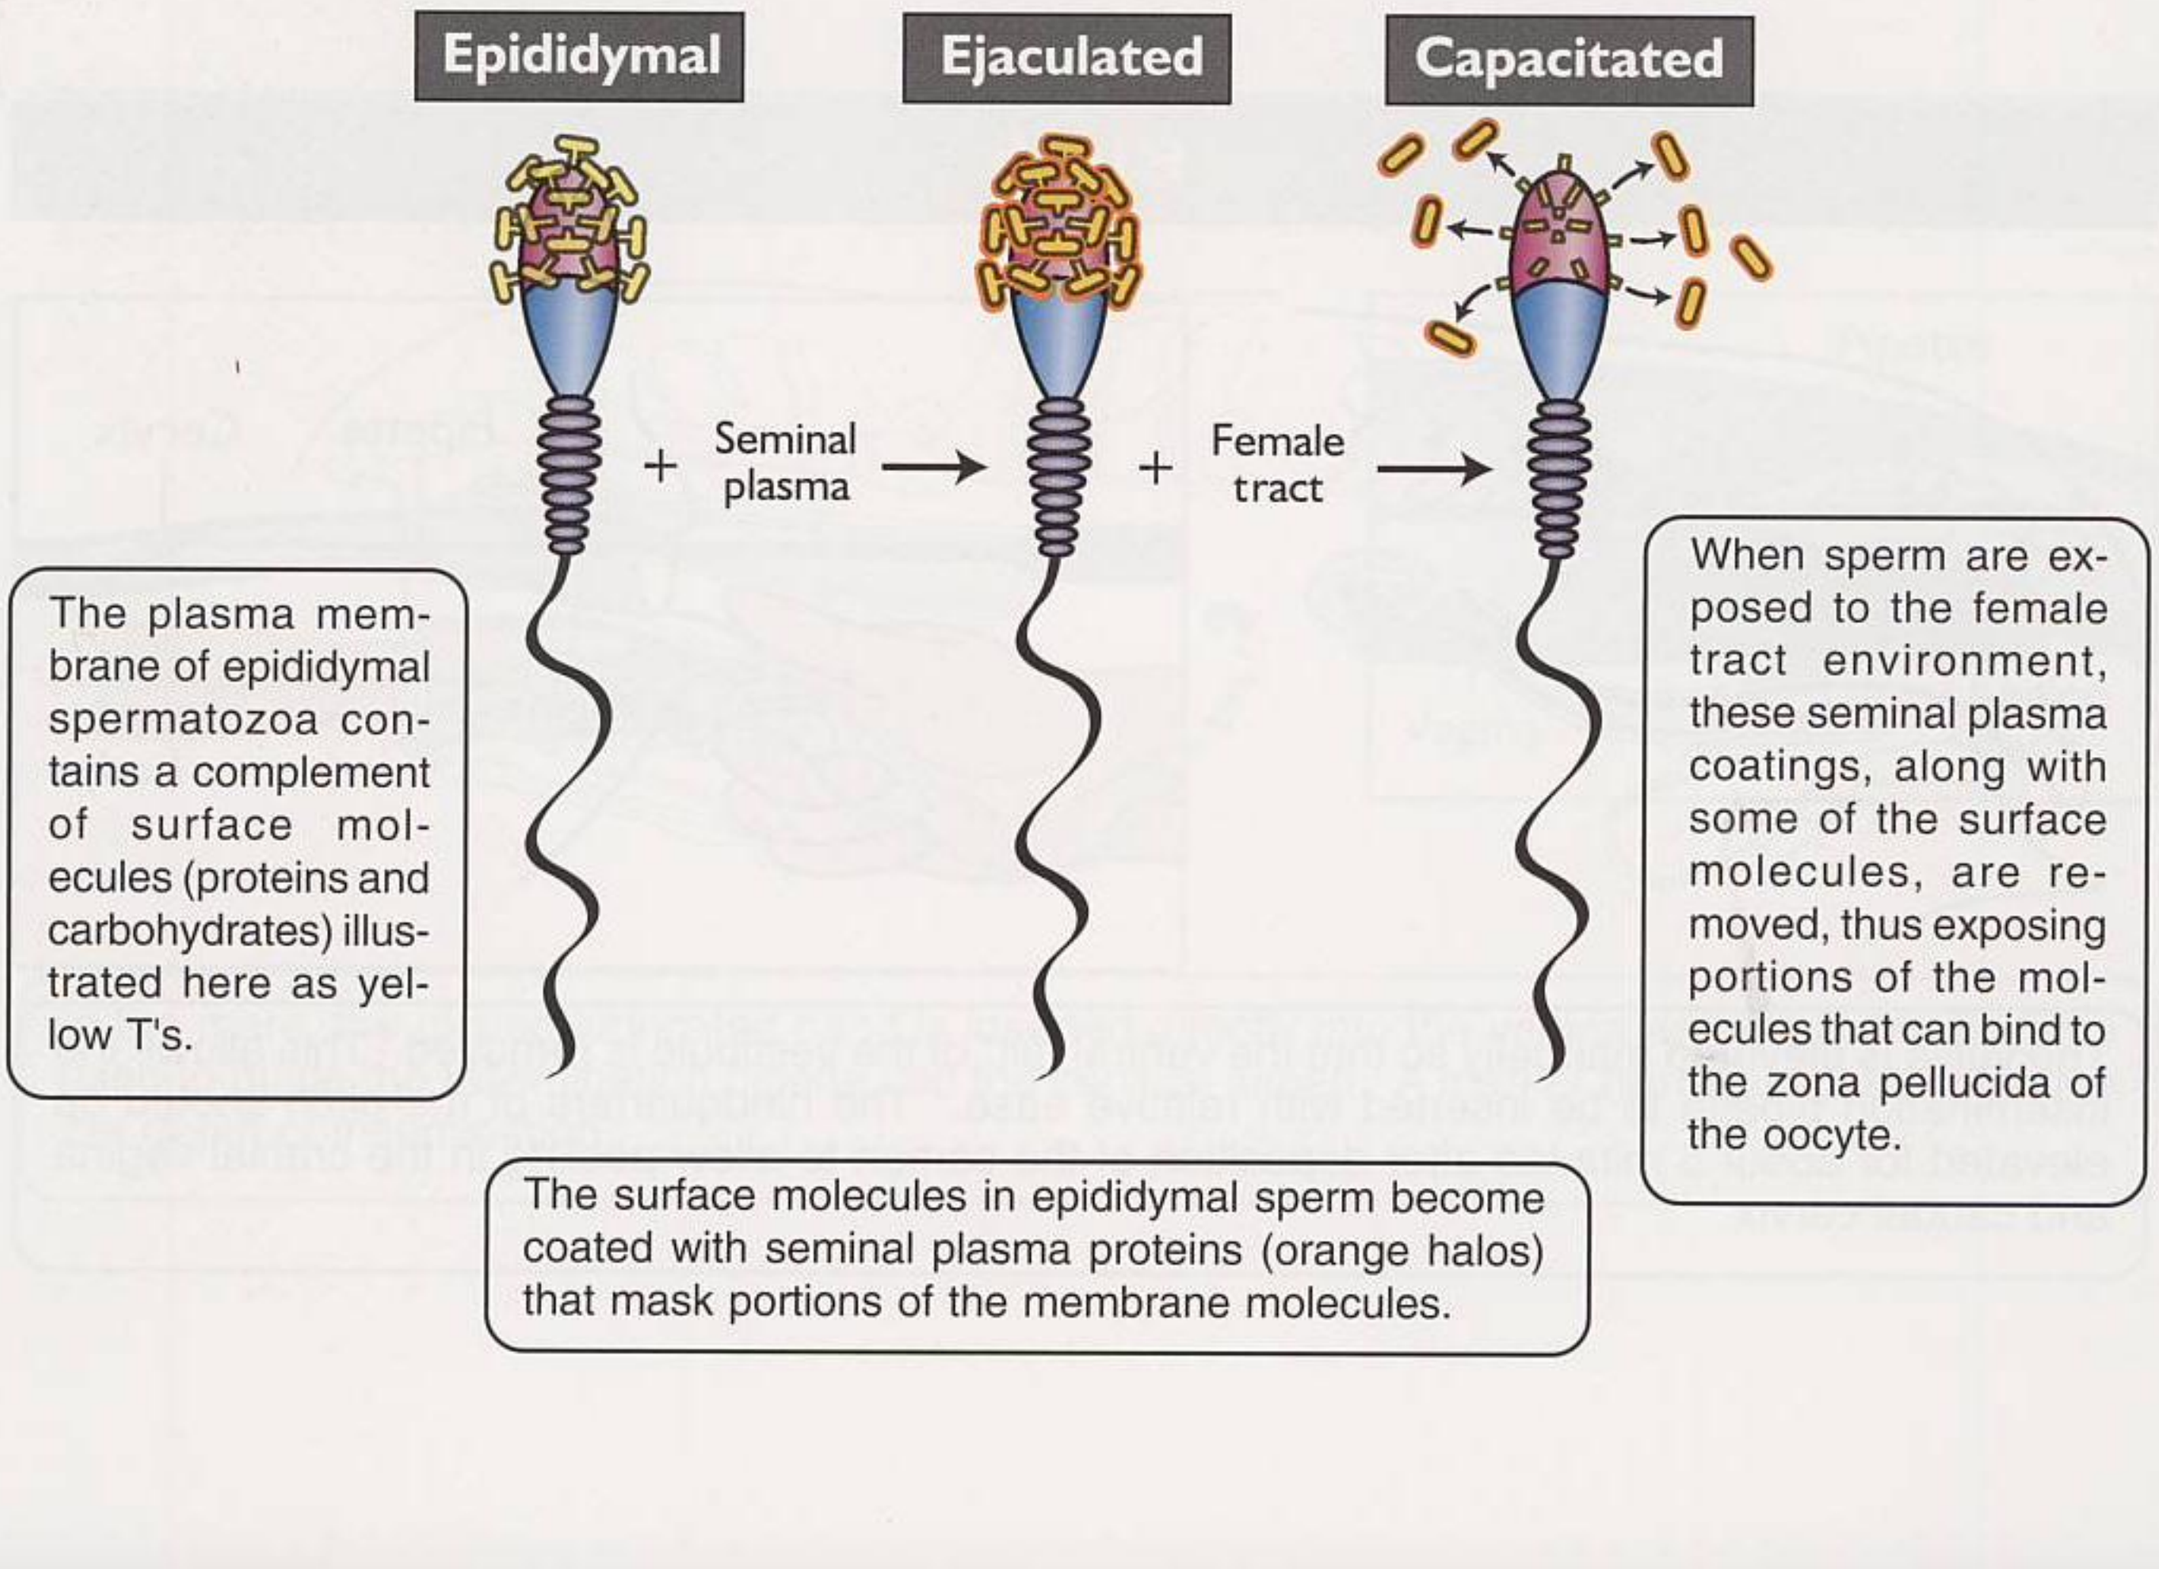
Acquisition of hyperactive motility occurs in the oviduct.

In the oviduct the motility patterns of spermatozoa become hyperactive. The motility pattern changes from a progressive, linear motility in which they swim in a relatively straight line (like an Olympic swimmer), into a frenzied, dancing motion that is not linear and is localized in a small area (like dancers in a disco). In general, hyperactive motility occurs in the ampulla of the oviduct and is believed to be brought about by specific molecules produced by the epithelium there. Hyperactive motility is believed to facilitate sperm-oocyte contact.

Binding to the zona pellucida requires specific zona-binding proteins on the spermatozoal membrane.

Spermatozoa are known to contain specific proteins on their plasma membrane surfaces overlying the acrosome that bind specifically to zona pellucida proteins. These zona binding proteins on the plasma membrane must be exposed during the capacitation process before binding to the zona pellucida can occur. Before zona binding can be understood fully, the molecular makeup of the zona must be described.

Figure 12-8. Conceptual Version of Mammalian Capacitation



The zona pellucida of the oocyte consists of three glycoproteins. These glycoproteins have been named **zona proteins 1**, **2** and **3** (**ZP1**, **ZP2** and **ZP3**). Zona proteins 1 and 2 are structural proteins providing the structural integrity of the zona. Zona protein 3 is much like a receptor for a hormone. It binds to proteins on the spermatozoal membrane. Binding of spermatozoa to the zona pellucida is believed to require between 10,000 and 50,000 ZP3 molecules. The current understanding is that the sperm plasma membrane contains two zona binding sites. The first binding site, referred to as the **primary zona binding region** is responsible for adherence of spermatozoa to the zona pellucida. The second binding site on the spermatozoal plasma membrane is believed to be **acrosome reaction promoting ligand**. When binding occurs between this region and the ZP3 molecule, a signal transduction occurs. This is much like a typical hormone-receptor binding complex. Binding initiates the acrosomal reaction. The relationship between ZP3 and the spermatozoal plasma membrane during binding is illustrated in Figure 12-10.

Figure 12-9. Postcapacitation Sequence of Events Leading to Fertilization

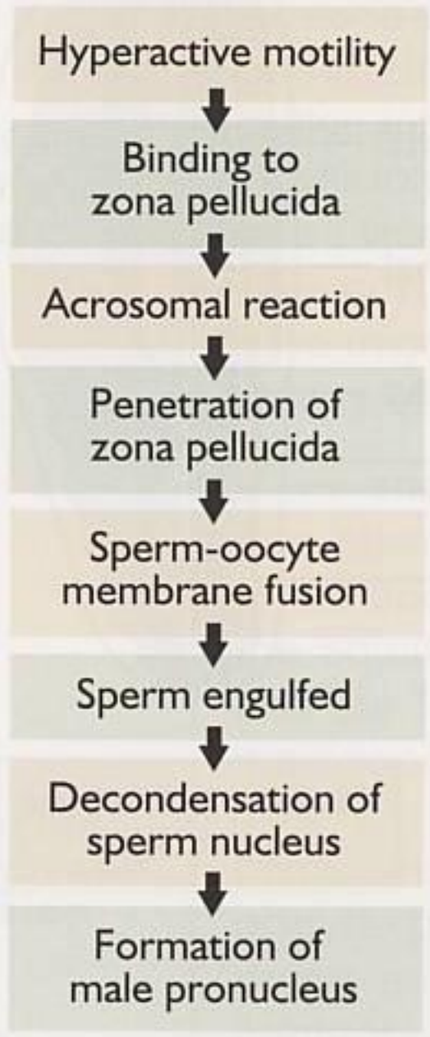


Figure 12-10. Zona Binding by Sperm and Initiation of the Acrosomal Reaction

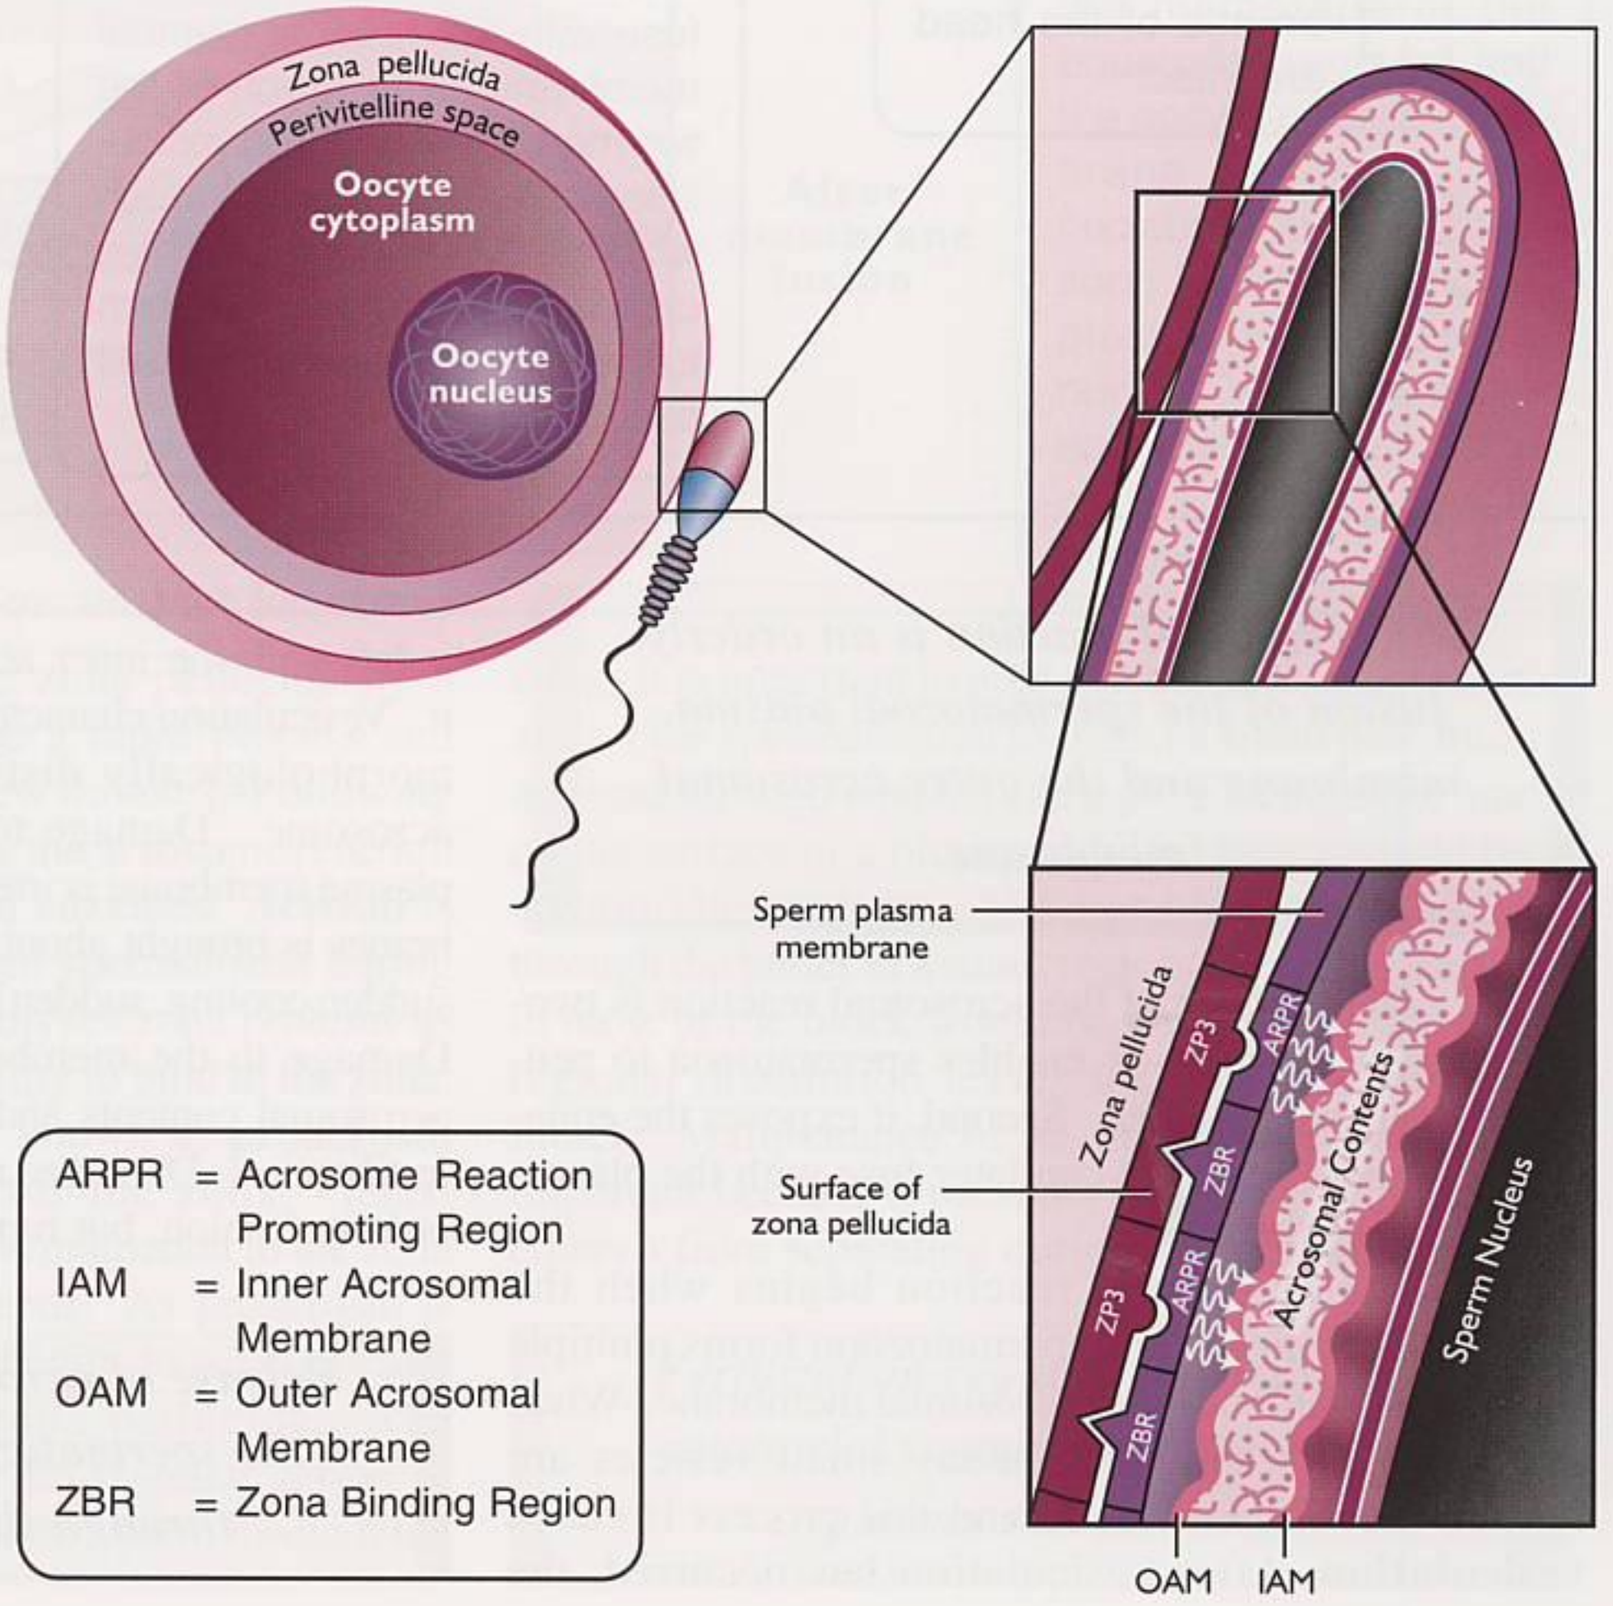
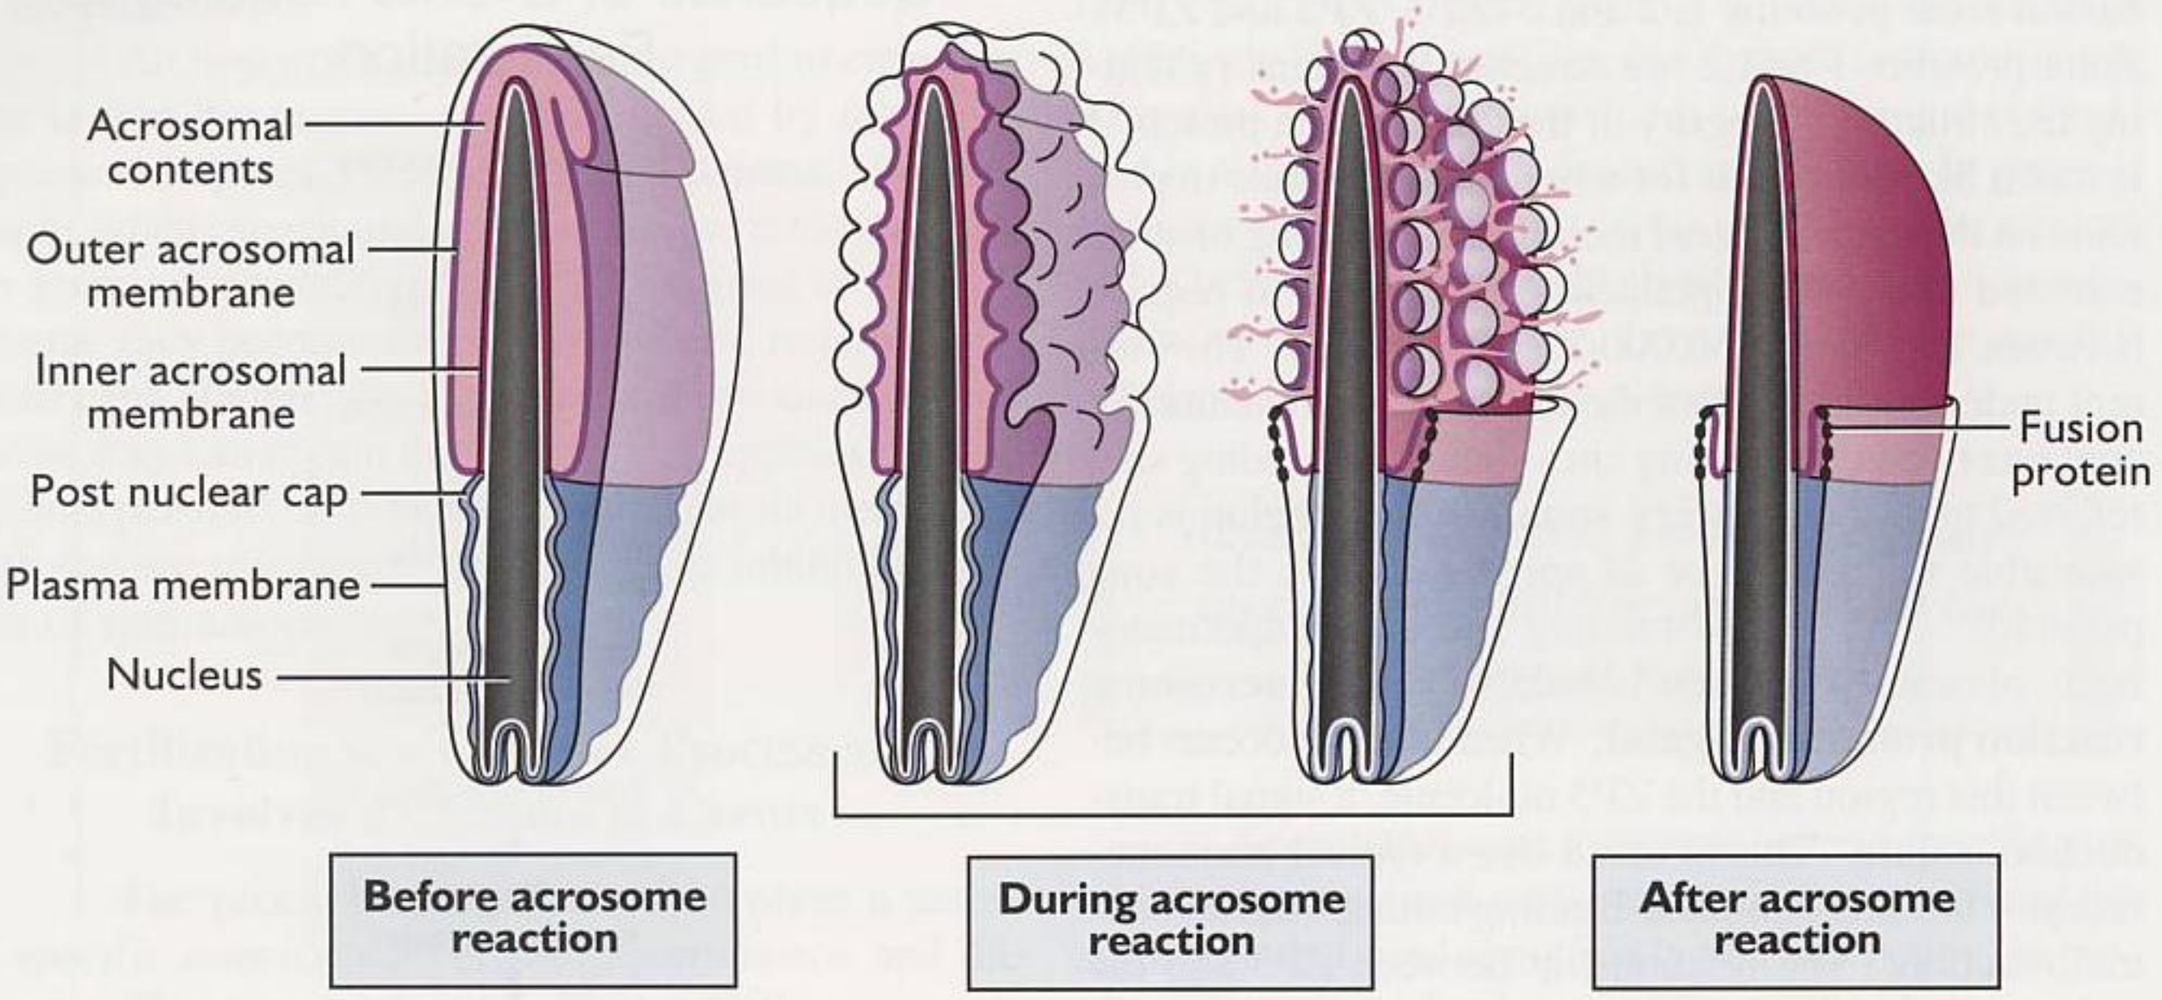
Proposed model for zona binding and the initiation of the acrosomal reaction in mammalian spermatozoa. The sperm plasma membrane overlying the acrosome contains two receptor-like regions. The first, called the zona binding region (ZBR), reacts with ZP3 to cause physical attachment of the sperm to the zona pellucida. A second membrane region, the acrosome reaction promoting region (ARPR), also binds to ZP3 and initiates the acrosome reaction by causing the sperm plasma membrane to fuse (arrows) to the outer acrosomal membrane.



ARPR = Acrosome Reaction Promoting Region
IAM = Inner Acrosomal Membrane
OAM = Outer Acrosomal Membrane
ZBR = Zona Binding Region

Figure 12-11. Schematic Illustration of the Acrosomal Reaction



Before Acrosomal Reaction
Before the reaction begins, all membranes of the head are intact.

During Acrosomal Reaction
During the reaction, the plasma membrane overlying the acrosomal membrane begins to fuse with the outer acrosomal membrane. The fusion of the two membranes leads to vesiculation that creates pores through which the acrosomal enzymes can pass. This allows the sperm to penetrate through the zona pellucida.

After Acrosomal Reaction
After the reaction, the vesicles are sloughed, leaving the inner acrosomal membrane, the equatorial segment and the post nuclear cap intact.

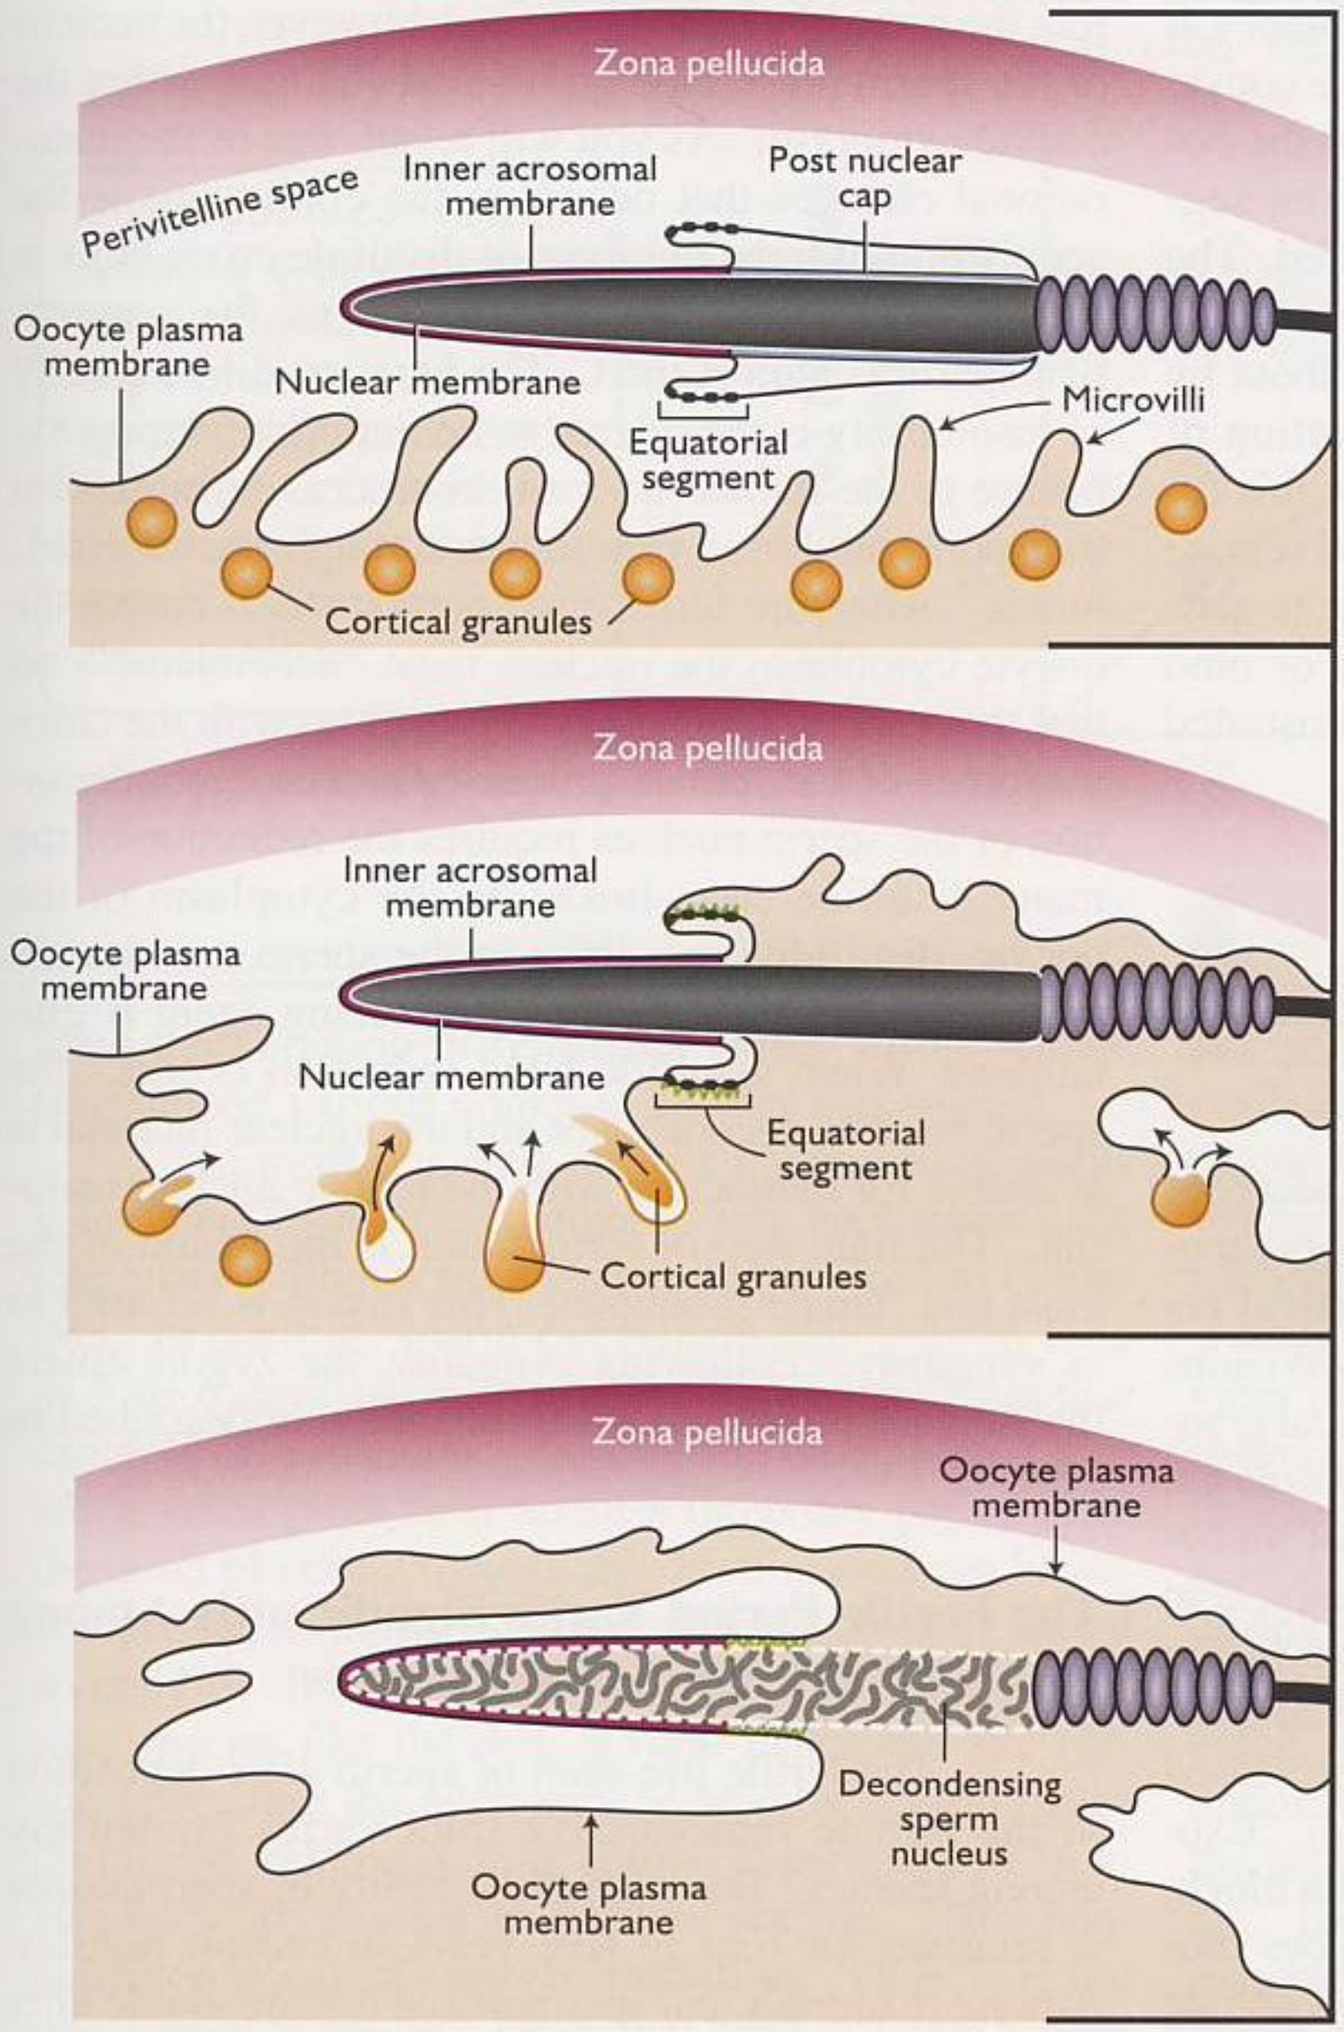
The acrosomal reaction is an orderly fusion of the spermatozoal plasma membrane and the outer acrosomal membrane.

The purpose of the acrosomal reaction is twofold. First, the reaction enables spermatozoa to penetrate the zona pellucida. Second, it exposes the equatorial segment so that it can later fuse with the plasma membrane of the oocyte.

The acrosomal reaction begins when the plasma membrane of the spermatozoon forms multiple fusion sites with the outer acrosomal membrane. When the two membranes fuse, many small vesicles are formed (See Figure 12-11) and this process is called **vesiculation**. After vesiculation has occurred, the acrosomal contents are dispersed and the sperm nucleus is left with the inner acrosomal membrane surrounding it. Vesiculation characterizes the acrosomal reaction and morphologically distinguishes it from a damaged acrosome. Damage to the acrosome membrane and plasma membrane is irreversible. Damage to these membranes is brought about by changes in osmotic pressure, sudden cooling, sudden heating or marked changes in pH. Damage to the membranes causes premature loss of acrosomal contents and such sperm cannot accomplish fertilization. Damaged acrosomes do not vesiculate in an orderly fashion, but rupture all-at-once.

Release of acrosomal enzymes allows the spermatozoon to digest its way through the zona pellucida.

Figure 12-12. Illustration of Sperm-Oocyte Fusion



Before membrane fusion

When the spermatozoon completely penetrates the zona and reaches the perivitelline space, it settles into a bed of microvilli formed by the oocyte plasma membrane. The cortical granules have migrated to the periphery of the oocyte.

During membrane fusion

The plasma membrane of the oocyte fuses with the equatorial segment and the fertilizing spermatozoon is engulfed. The cortical granule membrane fuses with the oocyte plasma membrane and the cortical contents are released into to perivitelline space by exocytosis.

After membrane fusion

After the fusion between the membrane of the equatorial segment and the oocyte plasma membrane occurs, the nucleus of the spermatozoon is within the cytoplasm. The sperm nuclear membrane disappears and the nucleus of the sperm decondenses.

The penetration of the zona pellucida by a spermatozoon is believed to be a rapid process and probably takes no more than a few minutes. Following attachment to the zona pellucida, the acrosome reaction allows the release of a variety of enzymes. **Acrosin** is one enzyme that is released from spermatozoa during the acrosomal reaction. It hydrolyzes zona proteins as well as enhances the sperm's ability to bind to the zona. In the inactive form, acrosin is known as **proacrosin** which has a strong affinity for the zona. Thus, proacrosin aids in binding the spermatozoon to the zona as the acrosomal reaction proceeds. As proacrosin is converted to acrosin, the sperm begins to penetrate and make its way through the zona pellucida. The mechanical force generated by the flagellar action of the tail may be sufficient to push the sperm through the zona. It is important to note that the acrosomal reaction allows the spermatozoon to digest a small hole through the zona through which it can pass. Placing a hot marble on the surface of a block of chilled butter would be an appropriate analogy. The hot marble would move through the butter in a small regional hole, but the butter in most of the block would be unchanged. This small regional dissolution leaves the zona predominately intact. Maintenance of an intact zona pellucida is important because it prevents blastomeres in the early embryo from separating during embryogenesis.

Fertilization requires fusion of the equatorial segment and the oocyte plasma membrane.

When the spermatozoon completely penetrates the zona and reaches the perivitelline space (the space between the zona and the oocyte plasma membrane), it settles into a bed of microvilli formed from the oocyte plasma membrane. The plasma membrane of the oocyte fuses with the membrane of the equatorial segment and the fertilizing spermatozoon is engulfed. The actual fusion of the oocyte plasma membrane with the equatorial segment is believed to be brought about by a so-called **fusion protein** located on this portion of the membrane. Prior to the acrosome reaction, this fusion protein is inactive. After vesiculation and release of the acrosomal contents, the fusion protein is activated, enabling the sperm membrane to fuse or bind with the oocyte membrane. This process is illustrated in Figure 12-12.

The cortical reaction prevents penetration by additional spermatozoa.

After membrane fusion, the oocyte undergoes a series of changes that prepare it for early embryogenesis. The most easily recognizable is the **cortical reaction**. During the first and second meiotic divisions of oogenesis, small, dense granules called cortical granules move to the periphery of the oocyte cytoplasm. The contents of the cortical granules consist of mucopolysaccharides, proteases, plasminogen activator, acid phosphatase and peroxidase. After membrane fusion between the oocyte and spermatozoon, the cortical granules undergo **exocytosis** and their contents are released into the perivitelline space (See Figure 12-12). Exocytosis of the cortical granules results in the **zona block**, a process whereby the zona pellucida undergoes biochemical changes so that further sperm cannot penetrate it. **Polyspermy** is prevented by the zona block.

Pronuclei formation allows the male and female DNA to form a single nucleus.

Polyspermy is the fertilization of an oocyte by more than one spermatozoon which results in embryo death. In addition to alteration of the zona pellucida, the cortical reaction is believed to reduce the ability of the oocyte plasma membrane to fuse with additional spermatozoa, thus causing the **vitelline block**, another mechanism that prevents polyspermy. Some species have both a zona block as well as a vitelline block, while others have either a zona or a vitelline block.

After the sperm nucleus has entered the cytoplasm of the egg, it becomes the male pronucleus. Before the pronucleus can be formed, however, the nucleus of the sperm must undergo marked changes within the oocyte cytoplasm. As you will recall, one of the maturational changes that occurs in the epididymis is the acquisition of large numbers of disulfide cross-links in the sperm nucleus. Thus, the nucleus of the mammalian sperm is almost inert. The keratinoid-like quality of insolubility is considered to be important during exposure to the female tract environment, during sperm transport and during penetration through the zona pellucida. After the fertilizing spermatozoon enters the oocyte cytoplasm the nucleus must "decondense" so that the male chromosomes may pair up with the chromosomes of the female pronucleus. The decondensation of the sperm nucleus requires the reduction of the many disulfide cross-links. In the cytoplasm of the oocyte, disulfide cross-links in the sperm nucleus are reduced quickly. The primary reducing agent is glutathione. When disulfide bond reduction occurs, the sperm nucleus decondenses and the nuclear material is available for interaction with the female nuclear material. The final step of fertilization is the fusion of the male and female pronuclei. This fusion is referred to as **syngamy**. Following syngamy, the zygote enters the first stages of embryogenesis that are described in Chapter 13.

The Fertile Period Varies Significantly Among Mammalian Females

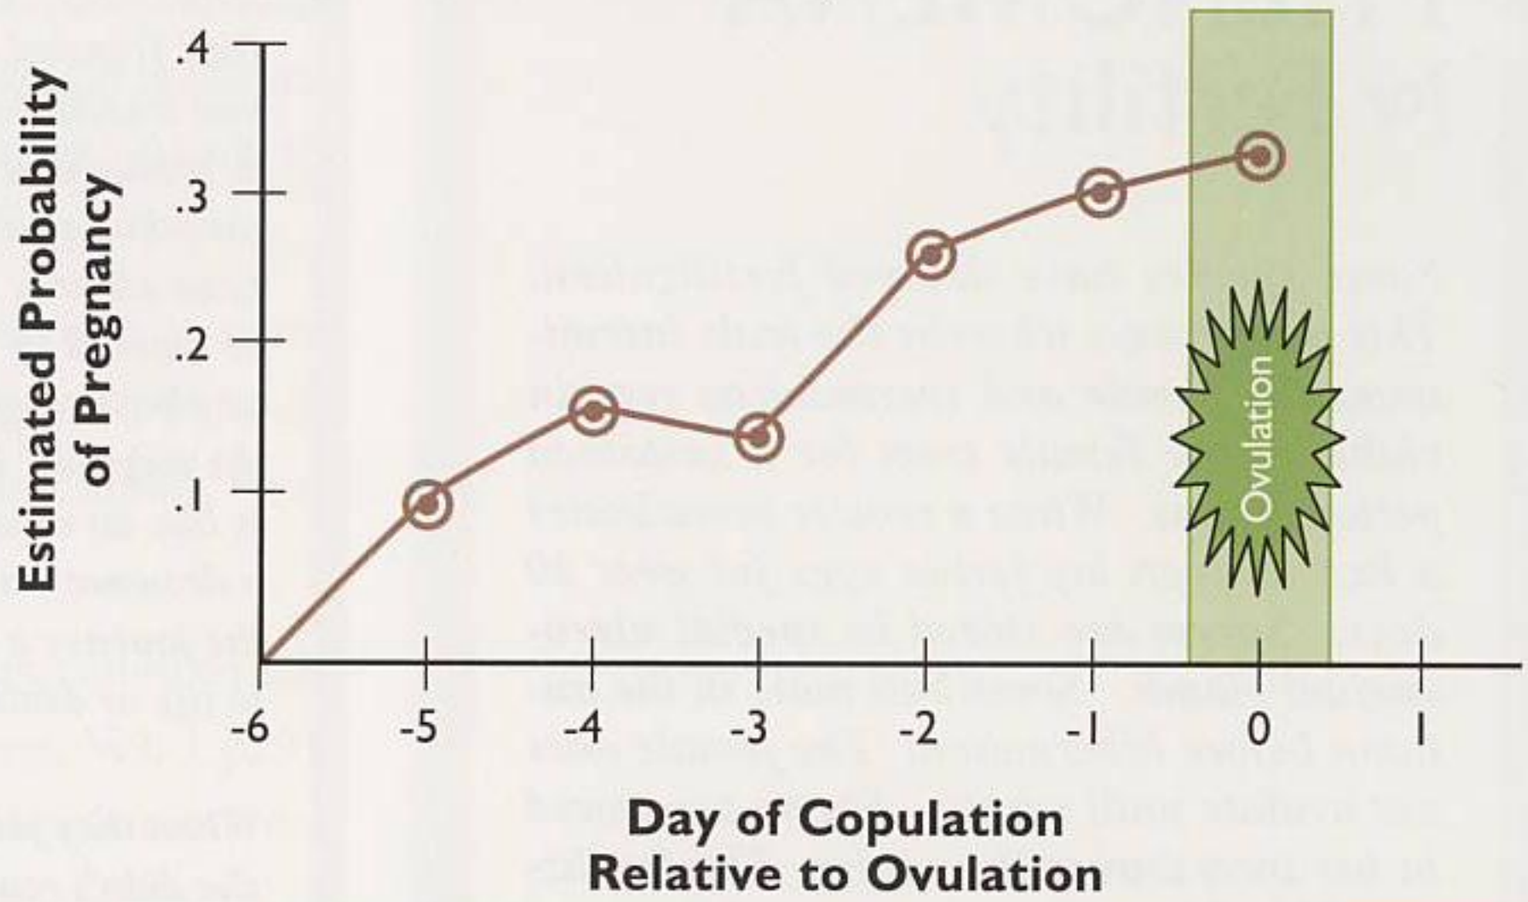
The fertile life-span of sperm after deposition in the female reproductive tract varies immensely among species. For example, fertility of spermatozoa is retained for four to five years in certain reptiles. Among mammals, bat spermatozoa remain viable after insemination in the female tract for up to 4-5 months before the female ovulates. In general, retention of fertilizing capacity among domestic animals and humans lasts only a few days. Values in Table 12-1 docu-

Table 12-1. Duration of Fertilizing Ability of Sperm Within the Female Reproductive Tract of Various Species

Species	Fertile Life (days)
Bitch	9-11
Camelids (camel, llama, alpaca)	4-5
Cow	1.5-2
Mare	4-5
Woman	5-6

Figure 12-13. Probability of Conception When Copulation Occurred on Specific Days Relative of Ovulation in Women
(From Wilcox et al. 1995. *NEJM* 333:1517)

Conception can occur within a 6-day window prior to ovulation. At 5 days prior to ovulation, the probability of conception was 0.11 and the probability increases to about 0.33 two days before ovulation.



ment the variation in fertilizing ability in the female tract among various domestic species and women.

In most domestic species the period of estrus is less than 24 hours. In other words, copulation must take place within a time-period that is close to ovulation. In contrast, sperm can remain viable for as long as 5 to 6 days before ovulation in women. Another example of a sustained fertile period is the bitch. Ovulation takes place over about a three day period after the onset of sexual receptivity. Fertilization can be accomplished as long as six days after the onset of sexual receptivity. It should be pointed out that in a multiparous species like the dog, several males can sire offspring because the bitch may be bred by several males during her relatively long estrus. Spermatozoa from all males are eligible to fertilize oocytes. This phenomenon is called **superfecundation**. Thus, it is not uncommon to observe litters that have different breeds of puppies.

It should be emphasized that the long fertile period in women coupled with a high frequency of copulation predisposes humans to unwanted pregnancies and a high global birth rate. Since the woman does not have a definite period of sexual receptivity, copulation taking place within 5-6 days of ovulation can result in a pregnancy. Where a poor understanding of the cycle exists, the probability of pregnancy becomes quite high because almost one-fourth of the menstrual cycle has the potential to generate a pregnancy.

The question is often asked as to whether the number of copulations can influence the chance of pregnancy within a given mating period. In spontaneous ovulators the answer is "probably not". In induced ovulators (especially in felids), there appears to be a threshold number of copulations required to optimize the chance of ovulation and therefore pregnancies. The probability of conception (pregnancy) is about 0.33 per cycle in women. This means if mating takes place among fertile individuals there is a one-in-three chance that the woman will become pregnant every cycle (if mating takes place within 2 days of ovulation as Figure 12-13 shows). It is like a batting average. If your favorite baseball player had a batting average of 0.333 for the season, he had a one in three chance to get a base-hit during each at-bat. Each at-bat is equivalent to the fertile period of an estrous or menstrual cycle. On average, your favorite hitter needs 3 at-bats to get a hit (a pregnancy). It makes no difference how many times the batter swings (number of matings) during each "at-bat," his batting average will still be 0.333. Similarly, assuming a threshold number of sperm are deposited during the first copulation, the number of matings during each fertile period (an "at bat") will not influence the probability of pregnancy.

Batting Averages and Pregnancies are Similar:

- ***Each "at-bat" = 1 opportunity to achieve pregnancy***
- ***The batting average = probability of becoming pregnant***
- ***A swing = 1 mating***
- ***A good "at-bat" = many swings (but depletes extragonadal reserves)***

Further PHENOMENA for Fertility

Some species have delayed fertilization. This is a process whereby the male inseminates the female and spermatozoa remain viable in the female tract for a sustained period of time. When a rooster inseminates a hen she can lay fertile eggs for over 20 days. Sperm are stored in special utero-vaginal glands. Some bats mate in the autumn before hibernation. The female does not ovulate until spring. Sperm are stored in her tract during the winter. The fertilizing life of bat sperm is reported to range from 68 to 198 days depending on the species of bat. Snakes are reported to store sperm that are fertile for up to 6 years.

The bifurcation of the glans penis of the opossum led to the widespread Appalachian folk belief that opossums mated through the nose, with one fork of the glans penis penetrating each nostril. Little scientific consideration was given to the issues of sperm transport.

Male mammals deliver sperm to the female in seminal plasma. However, many lower forms of animals make use of special packages for delivering spermatozoa to the female reproductive tract. These packages are called spermatophores. These spermatophores are produced within the male reproductive tract and are stored there until copulation. In some cephalopods (octopus and squid) the male deposits the spermatophore in the female tract or into the buccal cavity (cheek pouch), from which it can be conveniently transferred to the female tract. In some annelids, spermatophores are "injected" subcutaneously, after which the spermatozoa spread throughout the female's body before contacting eggs.

A Spermatozoon Race
by Cheryl A. Dudley

Half frenzied, thick and slick
and treacherous, through vast dark tunnels,
as motile and penetratingly
zona-bound as any race ever,
none other is so victim-laden,
so masked by drunken seizures
or pleasures of full-bodied assaults,
the tadpoles' mad dash
is like an escaped madman,
a drowner driven to oxygen,
the journey a seas-width heat
to life or death

When they jolted over the barrier
she didn't realize a race was on,
yet in her own primordial way
she cheered for them, provided secret
privileged pathways through crypts
too difficult for most, whose dead,
flat-floating bodies cluttered the way.
The lone victor slithered through, sensed
the trophy ahead-the zona seducing him to dip
in her warm waters, melt into her soft globe.
(The courtship was only long enough for him
to work his way through her pellucida.)

A quivering union formed
primitive cords that proliferated
time and time and time again,
swelling to fill the primed pear-palmed
womb where the victor celebrated,
And a genesis began.

Cheryl Dudley typed the 1st Edition of Pathways to Pregnancy and Parturition from the author's dictation. She has since graduated Cum laude in English from the University of Idaho and is now a graduate student in the Department of English at that university.

Motility of trout spermatozoa is induced by the fresh water into which it is ejaculated. Motility lasts for only about 30 seconds. During this time the sperm must locate a single tiny hole in the egg (called a micropyle) through which it enters before fertilization can occur. All this happens while being swept about by moving water.

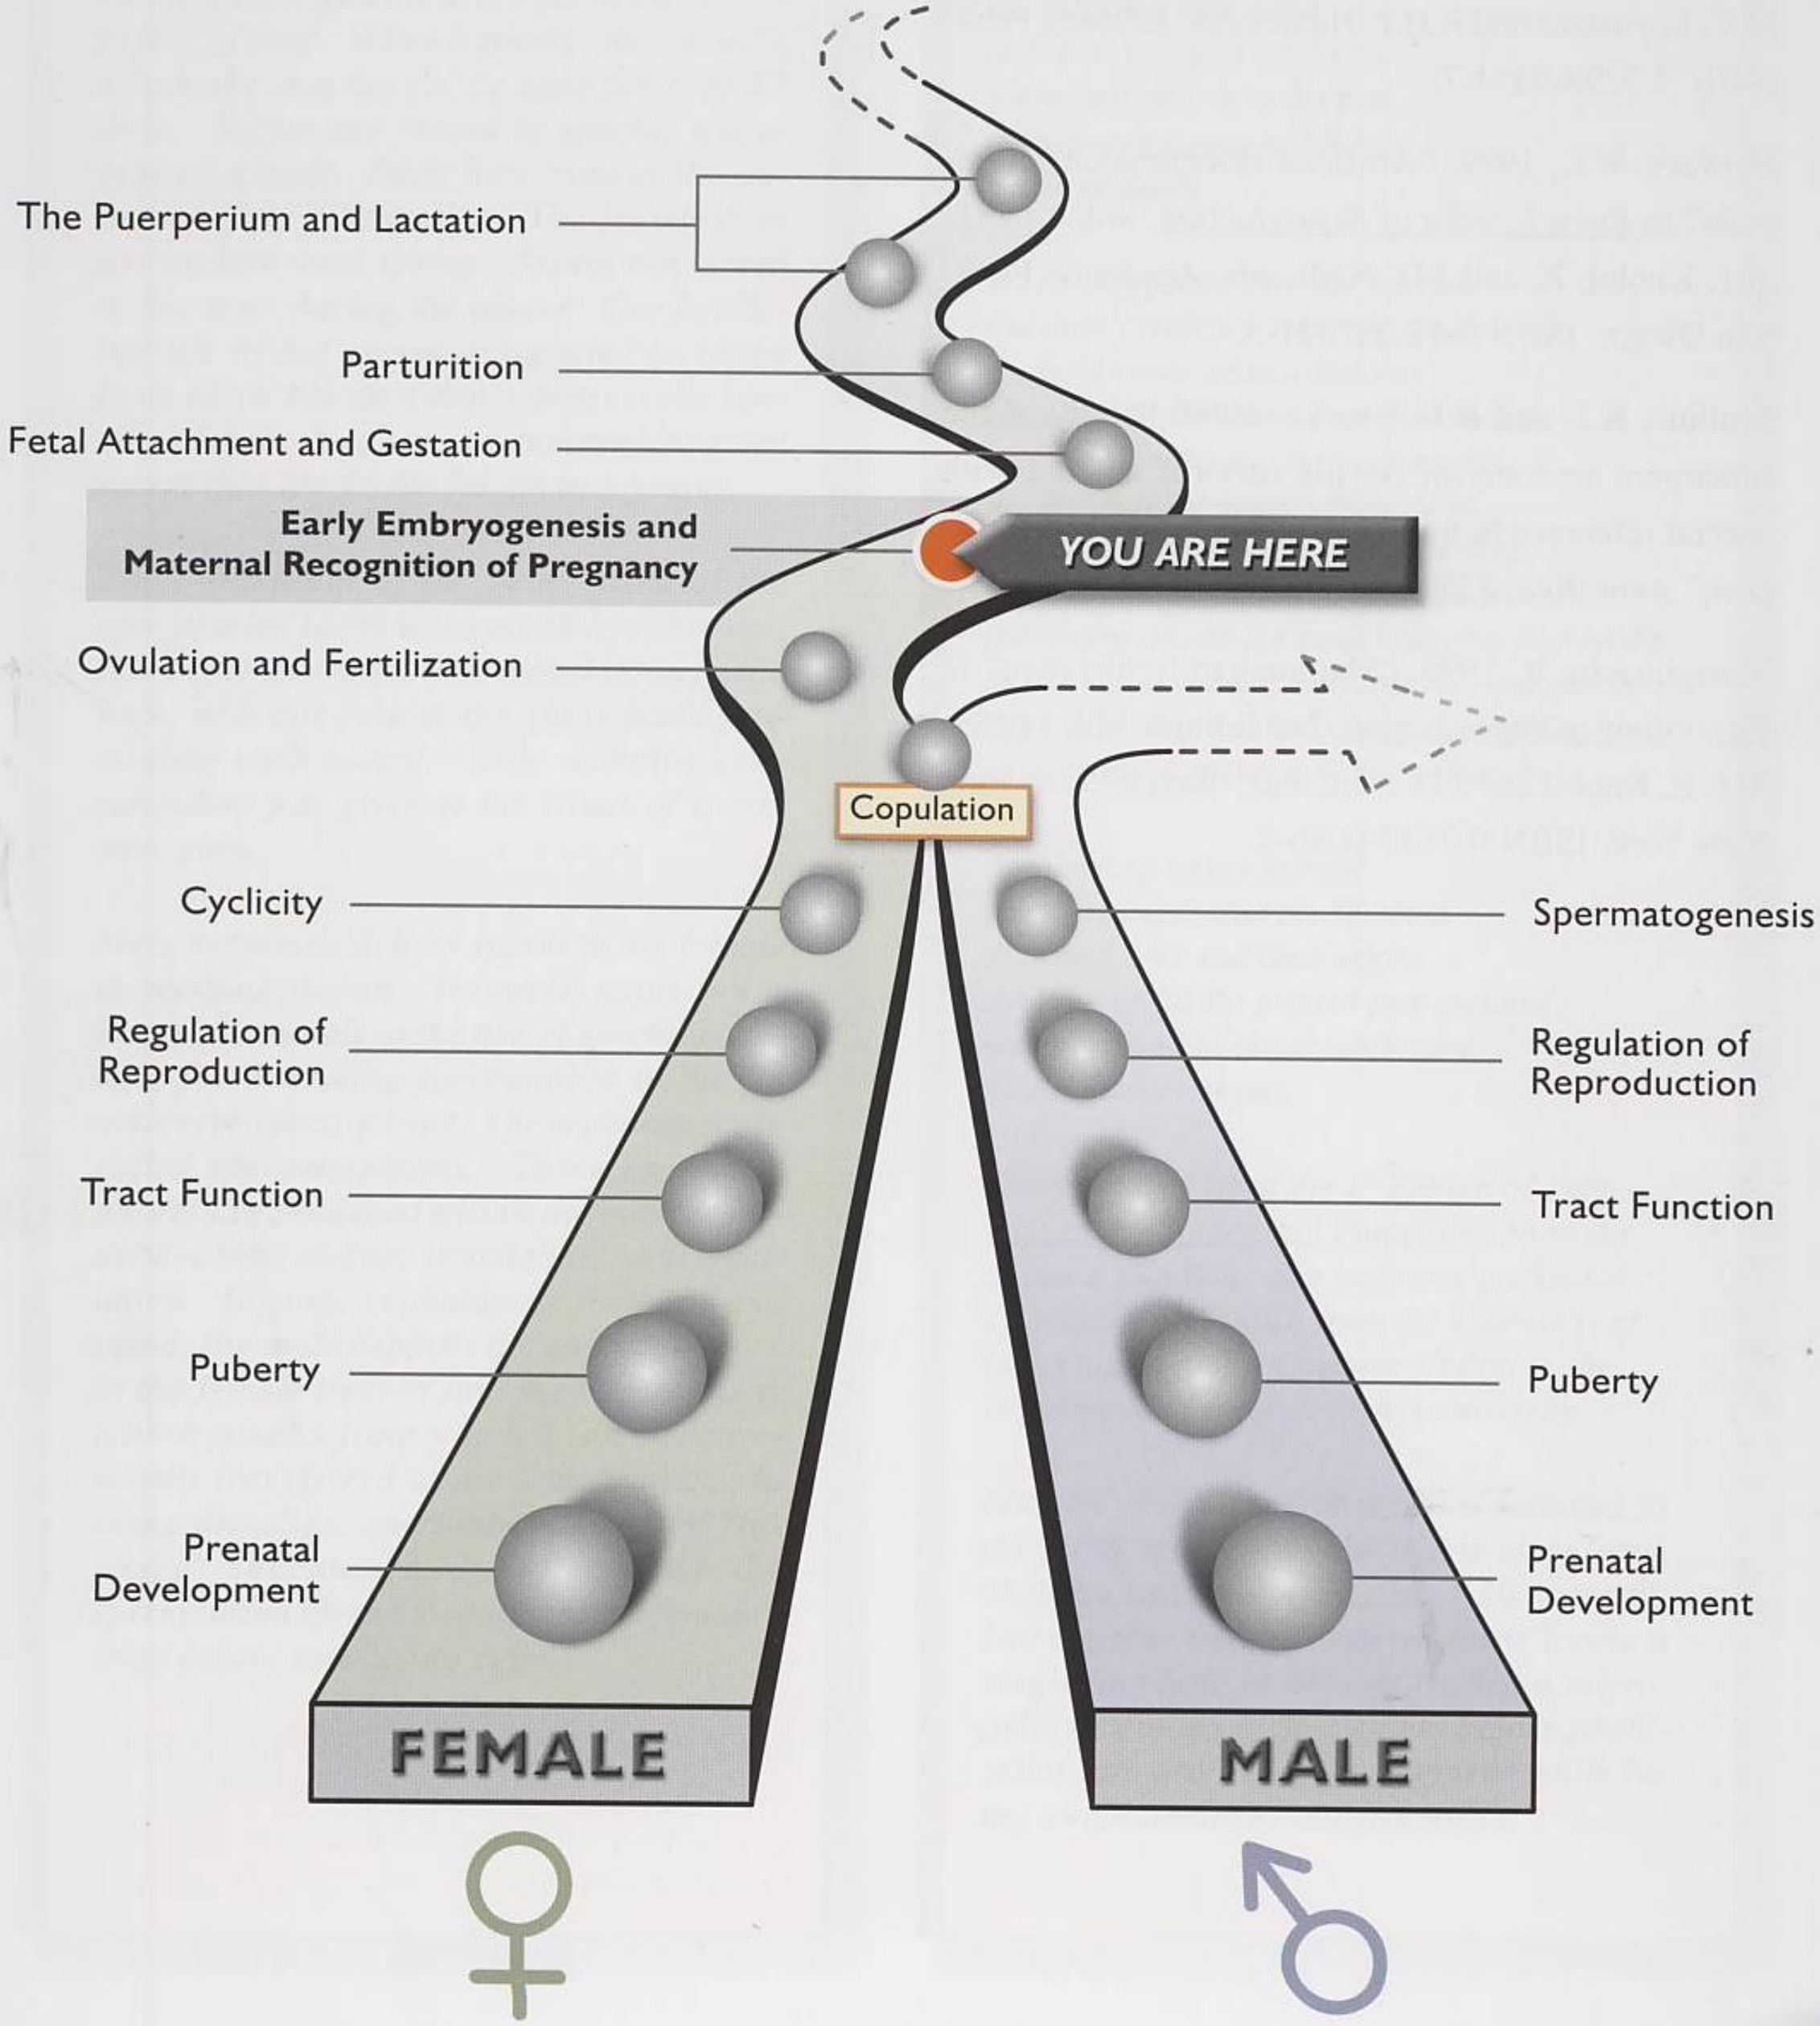
CHAPTER 13

Early Embryogenesis and Maternal Recognition of Pregnancy



Take Home Message

A successful preattachment pregnancy requires that the embryo develop into a blastocyst, hatch from the zona pellucida and develop a functional trophoblast. The early embryo must produce materials that prevent luteolysis or that enhance luteal function to maintain pregnancy.

Before describing the important events of early embryogenesis, several potentially confusing terms with overlapping meanings need to be defined. These terms have subtly different uses depending on the species and the context in which they are used. After **syngamy** (fusion of the male and female pronuclei), the zygote becomes an **embryo**. An embryo is defined as an organism in the early stages of development. In general, an embryo has not acquired an anatomical form that is readily recognizable in appearance as a member of the specific species. For example, at early stages of development, the pig embryo cannot be distinguished from the cow embryo except by skilled embryologists. As a matter of fact, at certain stages, the human embryo cannot be distinguished from the embryos of lower species.

A **fetus** is defined as a potential offspring that is still within the uterus, but is generally recognizable as a member of a given species. Most physiologists think of a fetus as the more advanced form of an embryo. The terms embryo, conceptus and fetus are often used interchangeably to describe the developing organism.

A **conceptus** is defined as the product of conception. It includes: 1) the embryo during the early embryonic stage, 2) the embryo and extraembryonic membranes during the preimplantation stage and 3) the fetus and placenta during the post-attachment phase.

After fertilization, four important developmental events must occur before the embryo attaches to the uterus. Only after these milestones are achieved will the embryo be eligible to develop a more intimate, semipermanent relationship with the uterus.

Four steps must be achieved before the embryo can attach to the uterus. They are:

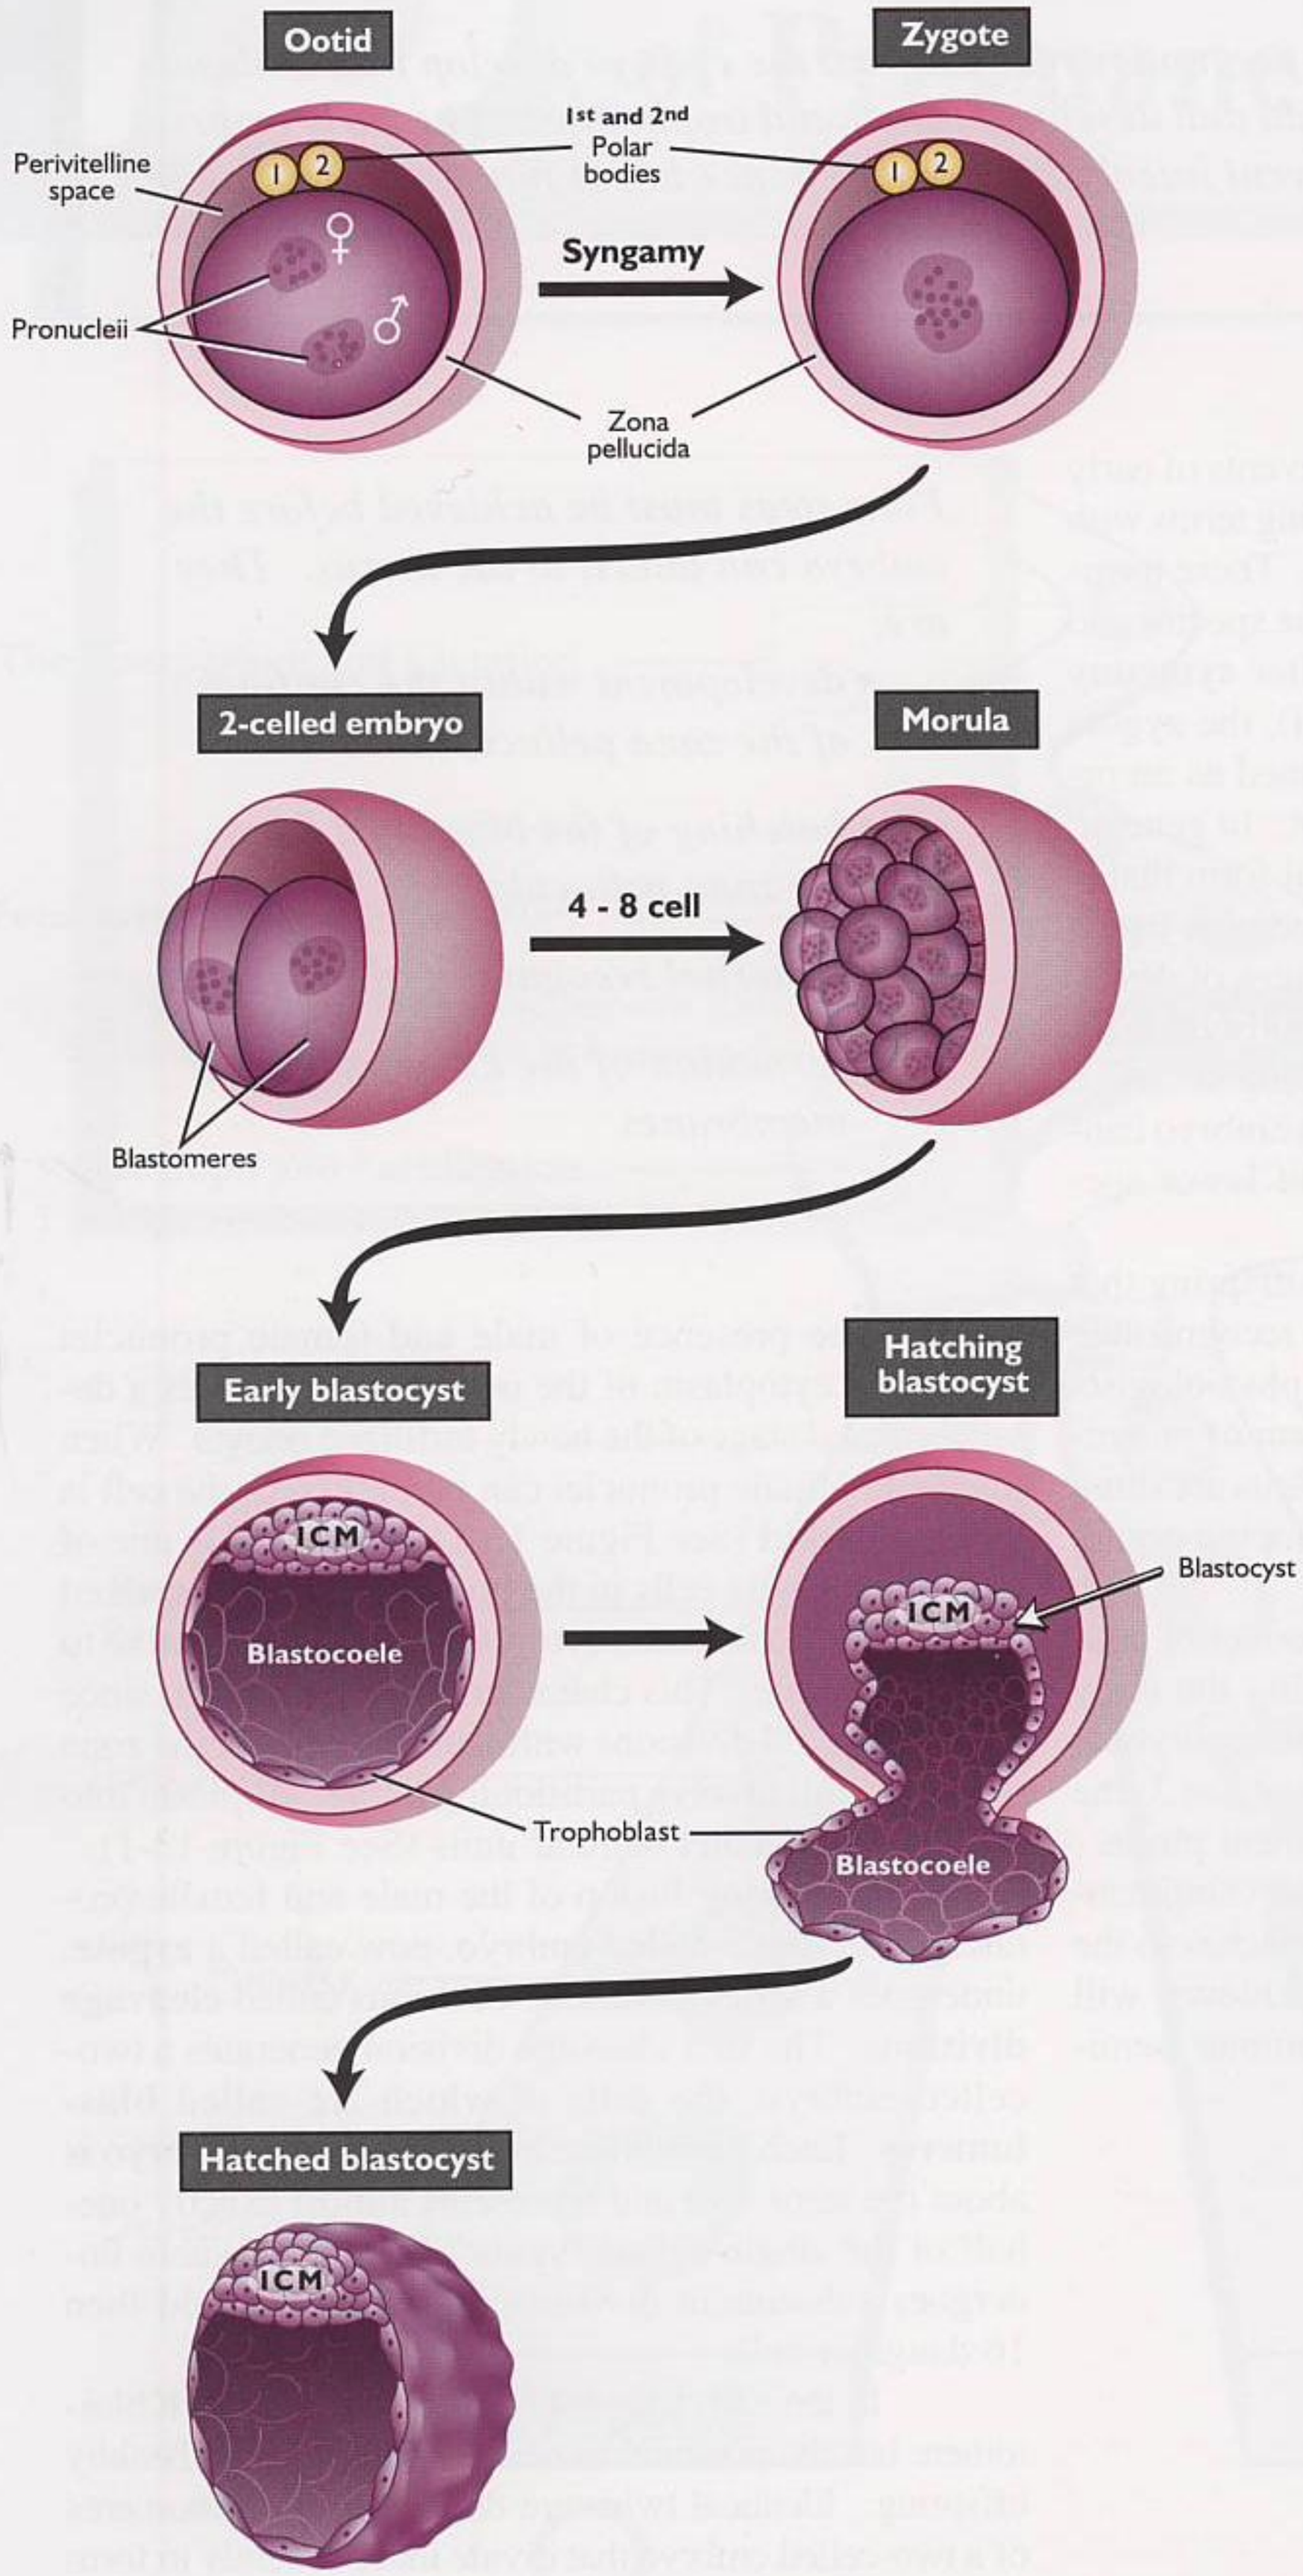
- ***development within the confines of the zona pellucida***
- ***hatching of the blastocyst from the zona pellucida***
- ***maternal recognition of pregnancy***
- ***formation of the extraembryonic membranes***

The presence of male and female pronuclei within the cytoplasm of the oocyte characterizes a developmental stage of the newly fertilized oocyte. When male and female pronuclei can be observed, the cell is called an **ootid** (See Figure 13-1). The ootid is one of the largest single cells in the body and is characterized by having an enormous cytoplasmic volume relative to nuclear volume. This characteristic is important, since subsequent cell divisions within the confines of the zona pellucida will involve partitioning of the cytoplasm into smaller and smaller cellular units (See Figure 13-1).

Following fusion of the male and female pronuclei, the single-celled embryo, now called a **zygote**, undergoes a series of mitotic divisions called **cleavage divisions**. The first cleavage division generates a two-celled embryo, the cells of which are called **blastomeres**. Each blastomere in the two-celled embryo is about the same size and represents almost exactly one-half of the single-celled zygote. Each blastomere undergoes subsequent divisions, yielding 4, 8 and then 16 daughter cells.

In the early stages of embryogenesis, each blastomere has the potential to develop into separate healthy offspring. Identical twins are derived from blastomeres of a two-celled embryo that divide independently to form

Figure 13-1. Preattachment Development of the Embryo

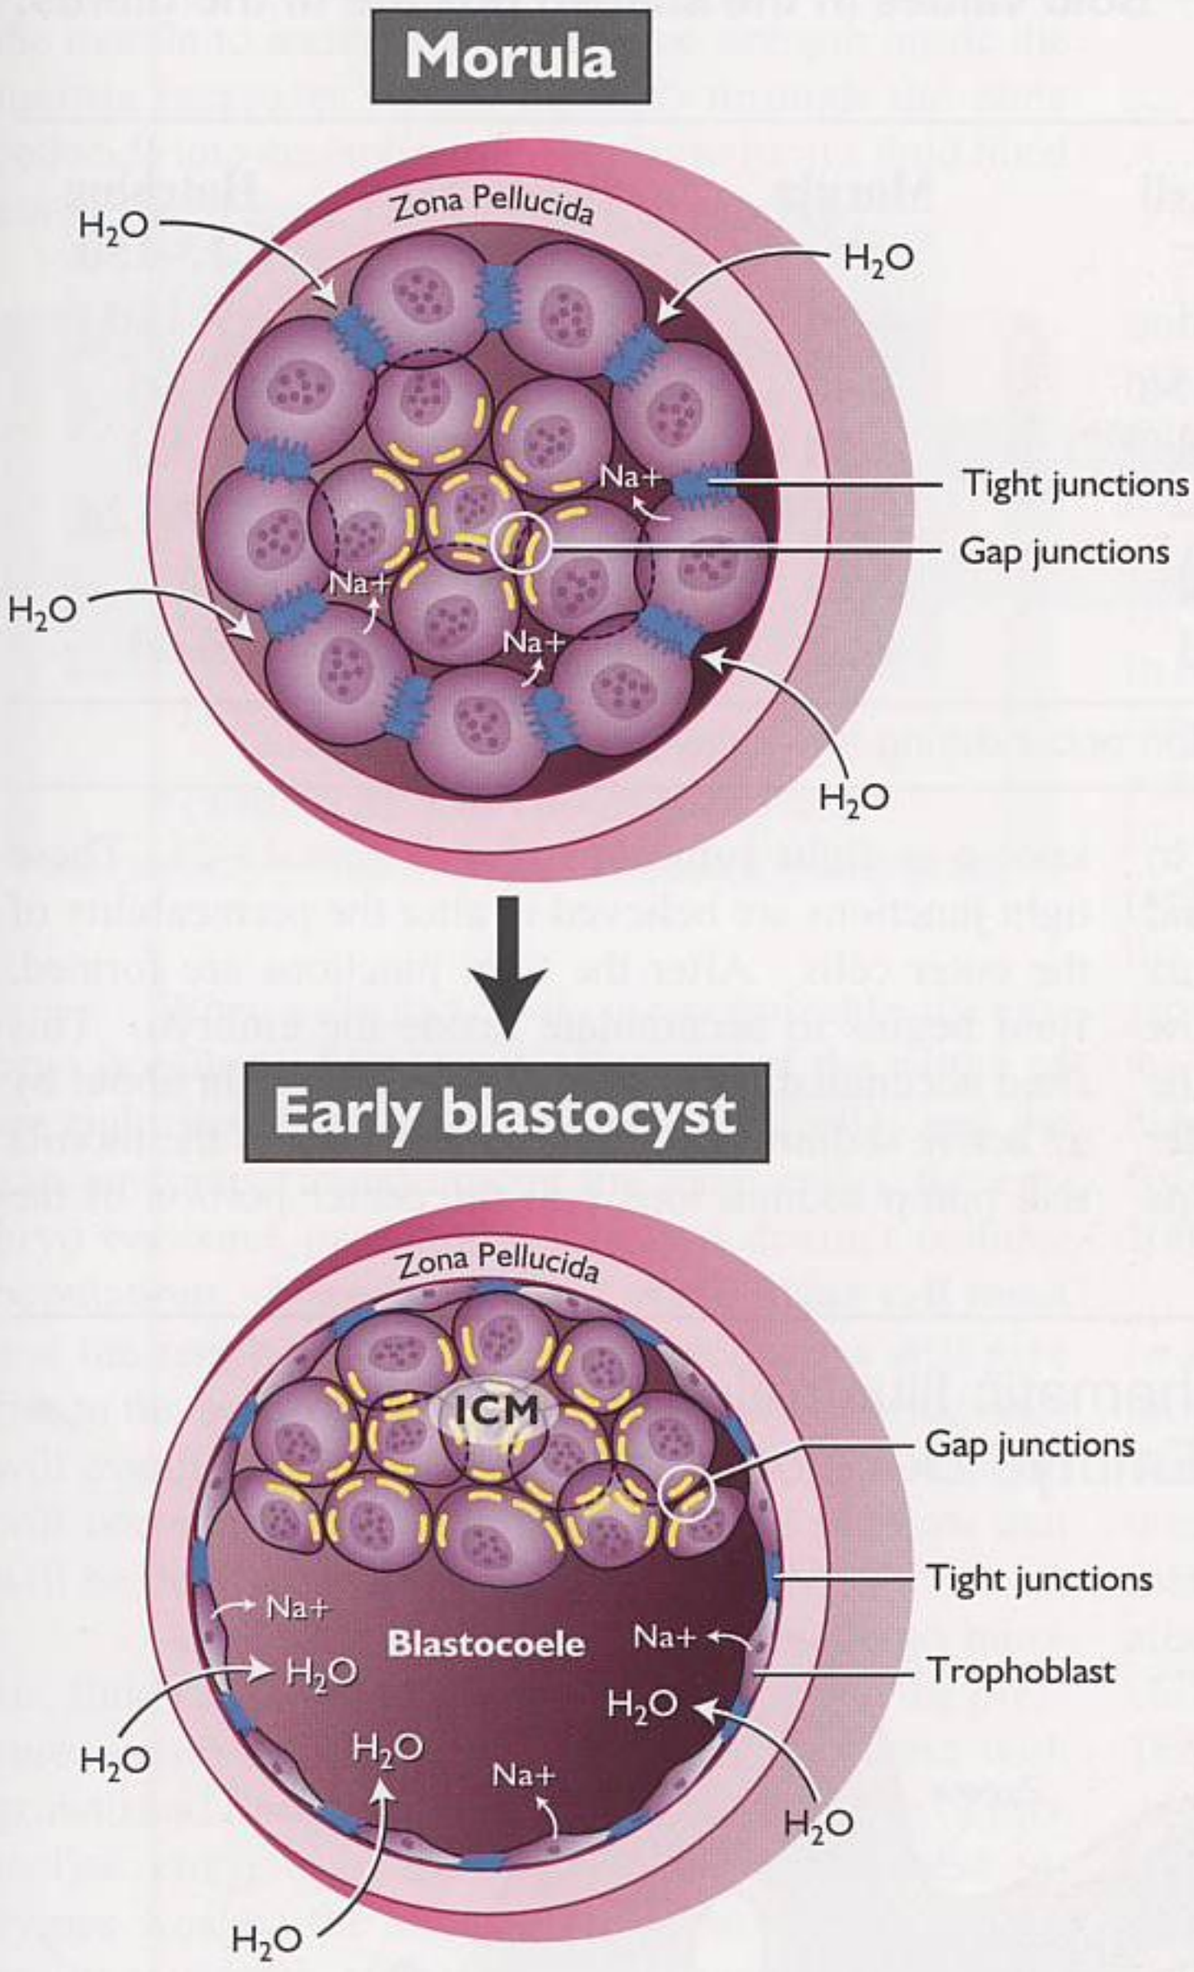


In the ootid, male and female pronuclei along with the first and second polar bodies are present. Fusion of the male and female pronuclei into a single diploid nucleus constitutes syngamy. Shortly thereafter, the zygote undergoes cleavage (mitotic divisions) and gives rise to daughter cells called blastomeres.

Cleavage divisions continue. A four-celled embryo gives rise to an eight-celled embryo. After the eight-celled stage, a ball of cells is formed and this embryonic stage is referred to as a morula.

Cells of the morula continue to divide and a blastocyst develops. It consists of an inner cell mass (ICM), a cavity called the blastocoele and a single layer of cells called the trophoblast. Finally, the rapidly growing blastocyst "hatches" from the zona pellucida and forms a "hatched" blastocyst that is free-floating within the uterus.

Figure 13-2. Transition of a Morula into an Early Blastocyst



Tight junctions form between the outer cells of the morula. Gap junctions form between the inner cells thus creating two groups of cells. Sodium is pumped into the intercellular spaces by the outer cells of the morula and water follows osmotically. Therefore, fluid begins to accumulate within the morula.

As fluid accumulates, the outer cells become flattened and a cavity known as the blastocoele is formed. The gap junctions connecting the inner cells of the morula allow these cells to polarize as a group. As a result two separate cellular components emerge. These are, the inner cell mass (ICM) and the trophoblast.

two separate embryos. Blastomeres from the 2-, 4- and 8- celled embryos are **totipotent**. Totipotency is a term used to describe the ability of a single cell (blastomere) to give rise to a complete, fully formed individual. Identical twins can be artificially produced in the laboratory by separating individual blastomeres, placing each blastomere inside a surrogate zona pellucida and allowing it to develop within the uterus of a host female. The individual blastomeres isolated from 4- and 8- celled stages can develop into normal embryos in the rabbit (doe), mare, cow and ewe. Totipotency has not been demonstrated when whole blastomeres beyond the 16-cell stage are used. Recently, nuclei from somatic cells from adult sheep have been transplanted into enucleated oocytes. These oocytes have developed into normal lambs. Therefore, it appears that all cells may have the potential for totipotency if exposed to the appropriate environmental conditions.

The mitotic divisions of each blastomere generally occur simultaneously but are unique in that with each division, two cells are produced (from each blastomere) but there is no net change in cytoplasmic mass. The unique mitotic divisions are called cleavage divisions and occur between the 1-cell and the blastocyst stages. As a result of the cleavage divisions an embryo gains cell number but still contains the same total mass of cytoplasm it had when it was a 1-cell zygote. All of the cleavage divisions take place inside the zona pellucida that maintains a fixed volume throughout the process.

When a solid ball of cells is formed and individual blastomeres can no longer be counted accurately, the early embryo is called a **morula** (See Figure 13-1). When the morula is formed, the outer cells begin to be compacted more than the cells in the

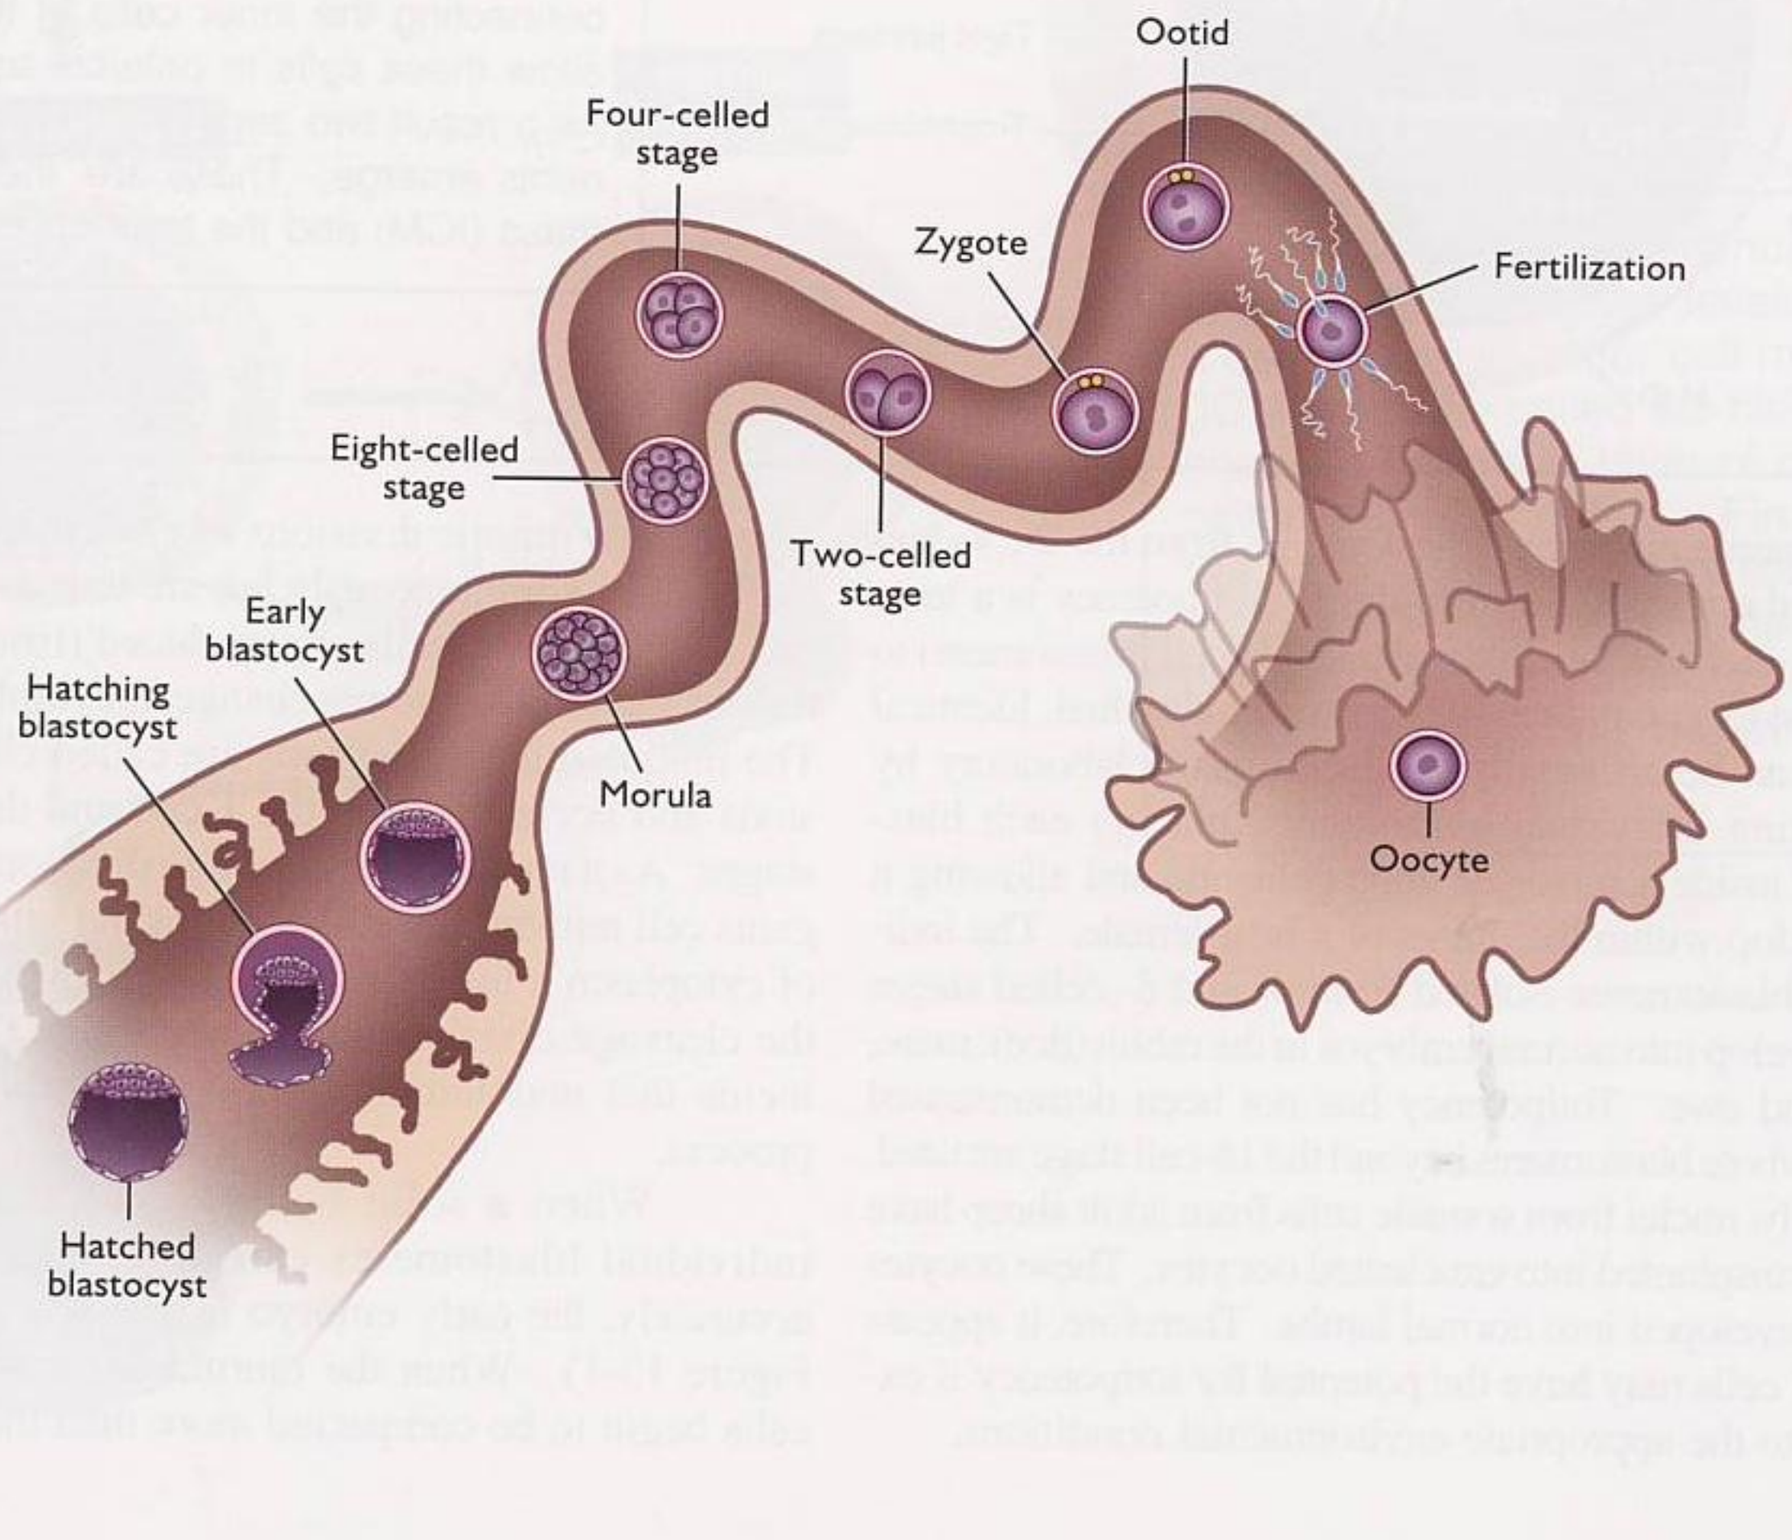
Table 13-1. Timing of preattachment embryogenesis relative to ovulation within females of various species. Non-bolded values are in the oviduct. **Bold values in the shaded box are in the uterus; (—) = no data.**

Species	2-cell	4-cell	8-cell	Morula	Blastocyst	Hatching
bitch*	3-7d	—	—	—	—	**13-15d**
cow	24h	1.5d	3d	**4-7d**	**7-12d**	**9-11d**
ewe	24h	1.3d	2.5d	**3-4d**	**4-10d**	**7-8d**
mare	24h	1.5d	**3d**	**4-5d**	**6-8d**	**7-8d**
queen	—	—	—	**5d**	**8d**	**10-12d**
sow	14-16h	1.0d	**2d**	**3.5d**	**4-5d**	**6d**
woman	24h	2d	3d	**4d**	**5d**	**5-6d**

*Recall from Figure 7-4 that ovulation and fertilization occur during a 6-7 day period during estrus.

center. Thus, during the morula stage, cells begin to separate into two distinct populations, the inner and outer cells. Cells in the inner portion of the morula develop **gap junctions** (See Figure 13-2) that allow for intercellular communication and may enable the inner cells to remain in a defined cluster. The outer cells of the morula develop cell-to-cell adhesions known as **tight junctions** (See Figure 13-2). These tight junctions are believed to alter the permeability of the outer cells. After the tight junctions are formed, fluid begins to accumulate inside the embryo. This fluid accumulation is believed to be brought about by an active sodium pump in the outer cells of the morula that pump sodium ions into the center portion of the

Figure 13-3. Schematic Illustration of Preattachment Embryo Development



morula. This buildup of ions causes the ionic concentration of the fluid surrounding the inner cells of the morula to increase. As the ionic strength inside the morula increases, water diffuses through the zona pellucida into the embryo and begins to form a fluid filled cavity (See Figure 13-2) called a **blastocoele**.

Hatching of the blastocyst is governed by three forces. They are:

- ***growth and fluid accumulation within the blastocyst***
- ***production of enzymes by the trophoblastic cells***
- ***contraction of the blastocyst***

When a distinct cavity is recognizable, the embryo is called a **blastocyst**. Because of the nature of the tight junctions (found in the outer cells) and the gap junctions (found among the inner cells), the embryo becomes partitioned into two distinct cellular populations. These are known as the **inner cell mass** and the **trophoblast**. The inner cell mass will give rise to the body of the embryo. The trophoblastic cells will eventually give rise to the **chorion**. The chorion will become the fetal component of the placenta that will be described later.

As the blastocyst continues to undergo mitosis, fluid continues to fill the blastocoele and the pressure within the embryo increases. Concurrent with growth and fluid accumulation is the production of proteolytic enzymes by the trophoblastic cells. These enzymes weaken the zona pellucida so that it ruptures easily as growth of the blastocyst continues. Finally, the blastocyst itself begins to contract and relax. Such behavior causes intermittent pressure pulses. These pressure pulses coupled with continued growth and enzymatic degradation cause the zona pellucida to rupture.

When a small crack or fissure in the zona pellucida develops, the cells of the blastocyst squeeze out of the opening, escaping from their confines (See Figure 13-1). The blastocyst now becomes a free-floating embryo within the lumen of the uterus and is totally dependent on the uterine environment for survival. In this context, early embryo survival is dependent on adequate luteal function, adequate progesterone synthesis and responsiveness of the uterus to progesterone. Figure 13-3 illustrates the anatomical location of the various preattachment stages of the embryo. The timing and species variation is presented in Table 13-1.

Development of the Extraembryonic Membranes Represents an "Explosion" of Embryonic Tissue Growth Prior to Attachment

After hatching, the conceptus undergoes massive growth. For example, in the cow at day 13 the blastocyst is about 3 mm in diameter. During the next four days, the cow blastocyst will become 250 mm in length (about the vertical length of the printed portion of this page) and will appear as a filamentous thread. By day 18 of gestation, the blastocyst occupies space in both uterine horns. While the blastocyst of the cow (and the ewe) grows quite rapidly during this early preattachment stage, the development of the pig blastocyst is even more dramatic. On day 10 of pregnancy, pig blastocysts are 2 mm spheres. During the next 24 to 48 hours, these 2 mm blastocysts will grow to about 200 mm in length (about the width of the printed portion of this page). This means that the blastocyst is growing at a rate of 4 to 8 mm per hour. By day 16, the pig blastocyst reaches lengths of 800 to 1000 mm.

Mammalian embryos can be subdivided into two primary groups. In the first group (that includes most domestic animals), the preattachment period within the uterus is long (several weeks). During this time, extensive extraembryonic membranes form by a folding process that generates the amnion, chorion and allantochorion. In the second group (primates) the blastocyst implants very soon after it enters the uterus. The extraembryonic membranes form after implantation or attachment. In this text, we will deal exclusively with the first group. For details about implantation of the human blastocyst please consult the reference by Larsen in **Key References**.

The extraembryonic membranes of the preattachment embryo consist of the:

- ***yolk sac***
- ***chorion***
- ***amnion***
- ***allantois***

The dramatic growth of the conceptus is due largely to the development of a set of membranes called the **extraembryonic membranes**. The pig, sheep and cow are characterized as having filamentous or

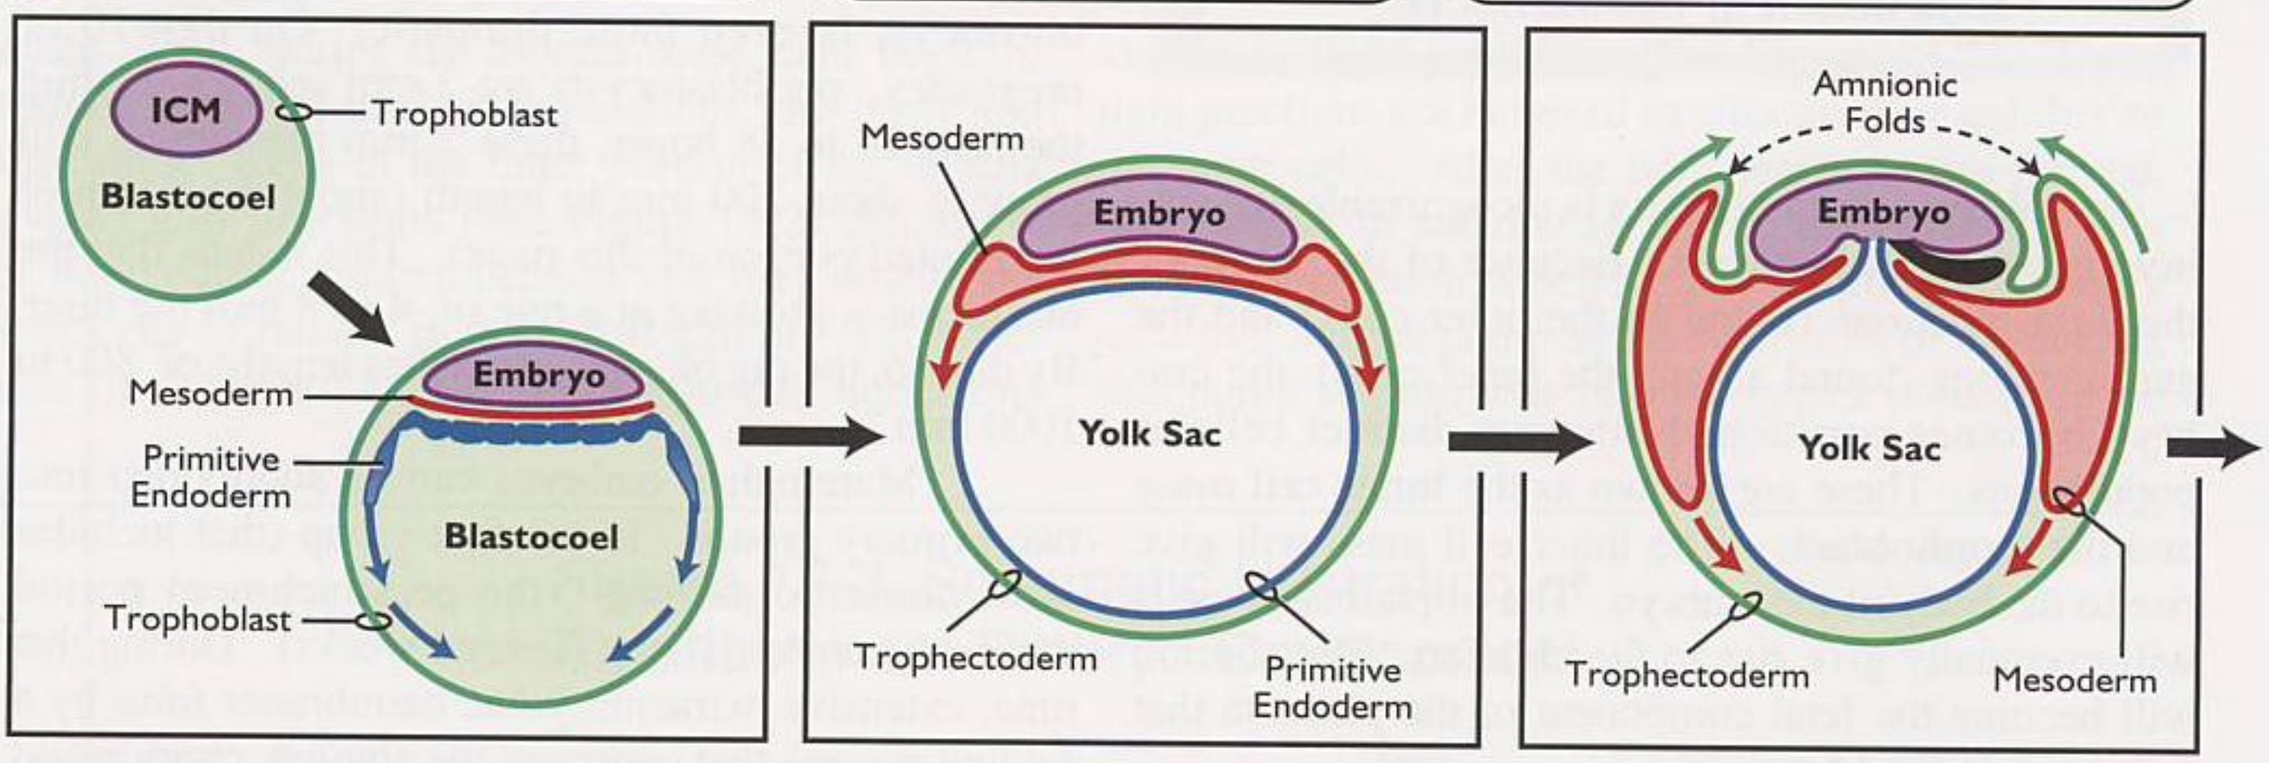
Figure 13-4. Schematic Diagram Illustrating the Typical Development of Extraembryonic Membranes in Mammals

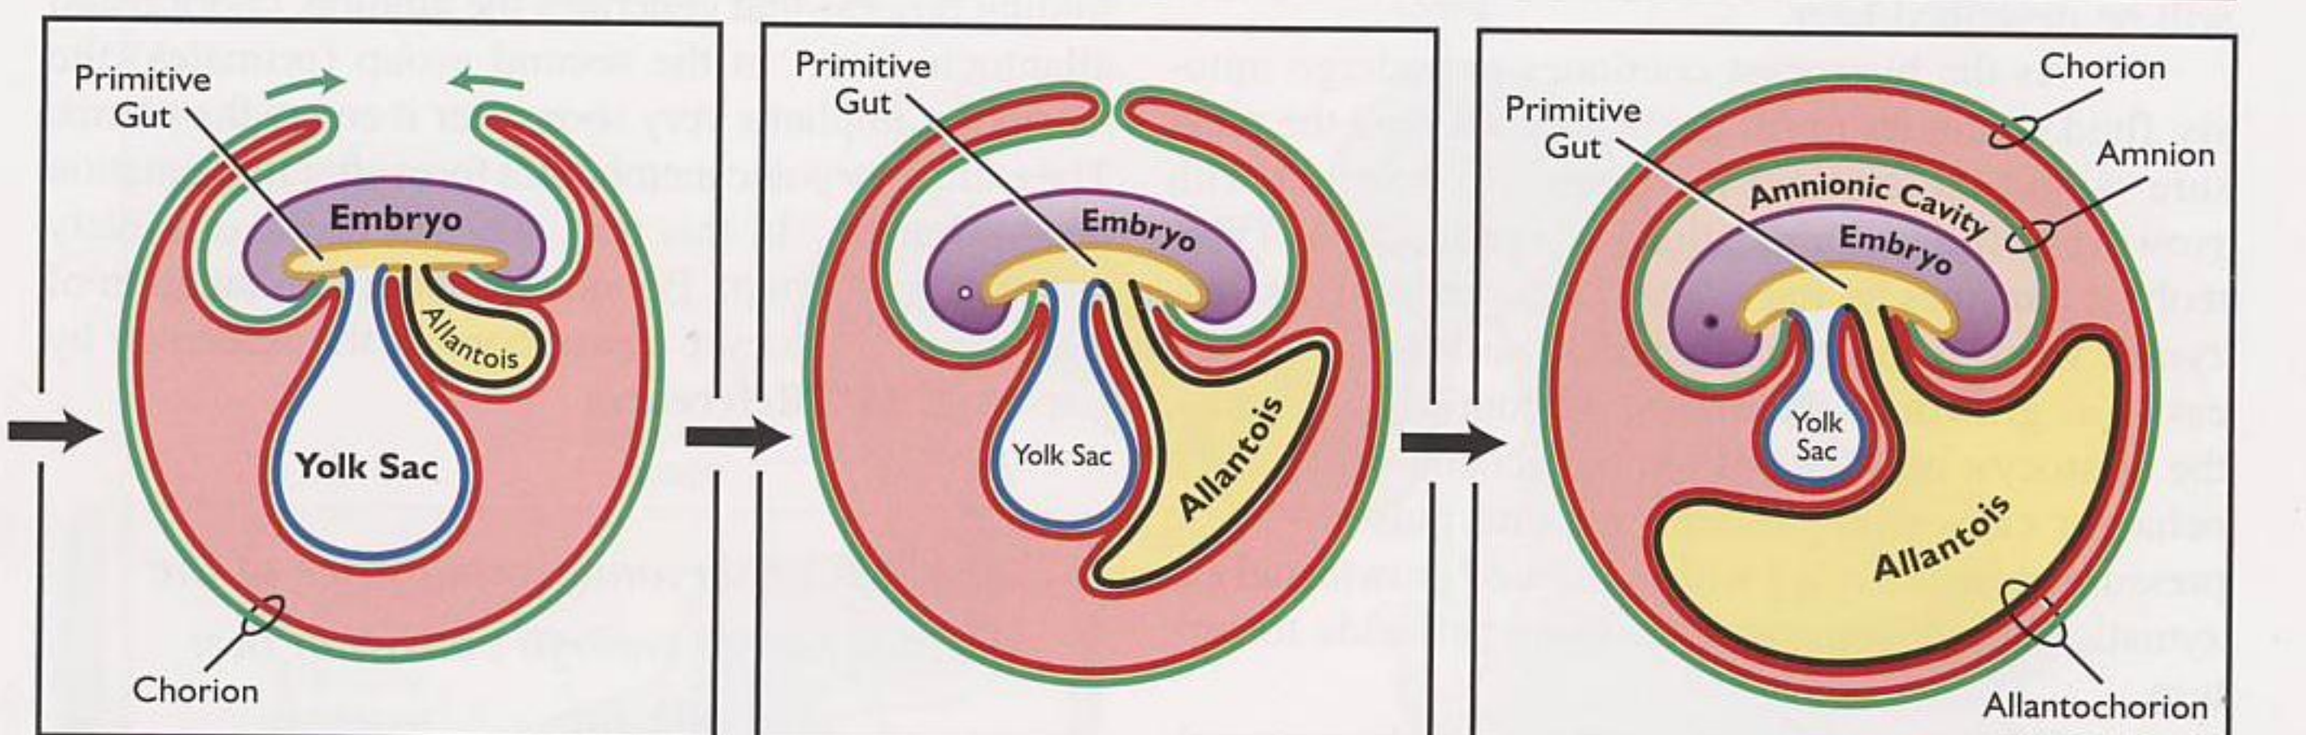
(This developmental sequence must occur before attachment to the endometrium can take place)

The hatched blastocyst consists of the inner cell mass (ICM), the trophoblast and the blastocoele. Very early in embryonic development, the primitive endoderm (blue layer) begins to form beneath the inner cell mass and grows downward forming a lining on the inner surface of the trophoblast. At the same time, the mesoderm (red layer) begins to develop between the primitive endoderm and the embryo.

When the primitive endoderm completes its growth, it forms a cavity called a yolk sac. This cavity does not contain yolk but is so named because it is analogous to the yolk sac in avian embryos.

The mesoderm continues to grow, forming a sac that surrounds the yolk sac and pushes against the trophectoderm (previously the trophoblastic cells). The newly formed mesodermal sac pushes against the trophectoderm and begins to fold upward forming "wing-like" structures called amnionic folds.





The mesoderm now completely surrounds the yolk sac and the developing allantois. The allantois is a diverticulum from the primitive gut that collects embryonic wastes. The mesoderm continues to fuse with the cells of the trophectoderm to form the chorion. The amnionic folds continue to grow upward around the embryo.

The yolk sac begins to regress but the allantois continues to grow and expand. The amnionic folds almost completely surround the embryo. The leading edges of the amnionic folds will eventually fuse.

The amnionic folds have completely fused resulting in the formation of a double sac around the embryo. The inner sac consists of trophectoderm and mesoderm and is called the amnion. It creates the amnionic cavity. The chorion completely surrounds the entire conceptus. The allantois continues to expand and begins to fill-in the spaces of the cavity. Eventually, the allantois and the chorion will fuse forming the allantochorion. The yolk sac continues to regress.

threadlike blastocysts prior to attachment. In the mare, however, blastocysts do not change into a threadlike structure but remain spherical.

Formation of the extraembryonic membranes is an obligatory step in the acquisition of the embryo's ability to attach to the uterus of the dam. The extraembryonic membranes are a set of four anatomically distinct membranes that originate from the trophoblast, endoderm, mesoderm and the embryo.

The trophoblast, along with the **primitive endoderm** and **mesoderm**, give rise to the **chorion** and the **amnion** (See Figure 13-4). The yolk sac develops from the primitive endoderm. The chorion will eventually attach to the uterus, while the amnion will provide a fluid-filled protective sac for the developing fetus.

As the hatched blastocyst begins to grow, it develops an additional layer just beneath, but in contact with the inner cell mass. This layer of cells is called the primitive endoderm (See Figure 13-4) and will continue to grow in a downward direction, eventually lining the trophoblast. At the same time the primitive endoderm is growing to become the inside lining of the trophoblast, it also forms an evagination at the ventral portion of the inner cell mass. This evagination forms the yolk sac (See Figure 13-4). The yolk sac in domestic animal embryos is a transient extraembryonic membrane that regresses in size as the conceptus develops. In spite of its regression, you will recall (See Chapter 4) that the yolk sac contributes the primitive germ cells that migrate to the genital ridge.

As the blastocyst continues to expand, the newly formed double membrane (the trophoblast and mesoderm) becomes the chorion. As it develops, the chorion pushes upward in the dorsolateral region of the conceptus and begins to surround it. As the chorion begins to send "wing-like" projections above the embryo, the amnion begins to form (See Figure 13-4). When the chorion fuses over the dorsal portion of the embryo, it then forms a complete sac around the embryo. This sac is the amnion. The amnion is filled with fluid and serves to hydraulically protect the embryo from mechanical perturbations. The amnionic fluid serves as an anti-adhesion material to prevent tissues in the rapidly developing embryo from adhering to each other. The amnionic vesicle can be palpated in the cow between days 30 and 45 and feels like a small, turgid balloon inside the uterus. The embryo, however, is quite fragile during this early period and amnionic vesicle palpation should be performed with caution.

During the same time that the amnion is developing, a small evagination from the posterior region of the primitive gut begins to form (See Figure 13-4). This sac-like evagination is referred to as the **allantois**. The allantois is a fluid-filled sac that collects liquid waste from the embryo. As the embryo grows, the allantois continues to expand and eventually will make contact with the chorion. When the allantois reaches a certain volume, it presses against the chorion and eventually fuses with it. When fusion takes place the two membranes are called the **allantochorion** (See Figure 13-4). The allantochorionic membrane is the fetal contribution to the **placenta** and will provide the surface for attachments to the endometrium. Details about the anatomy and function of the placenta will be presented in Chapter 14.

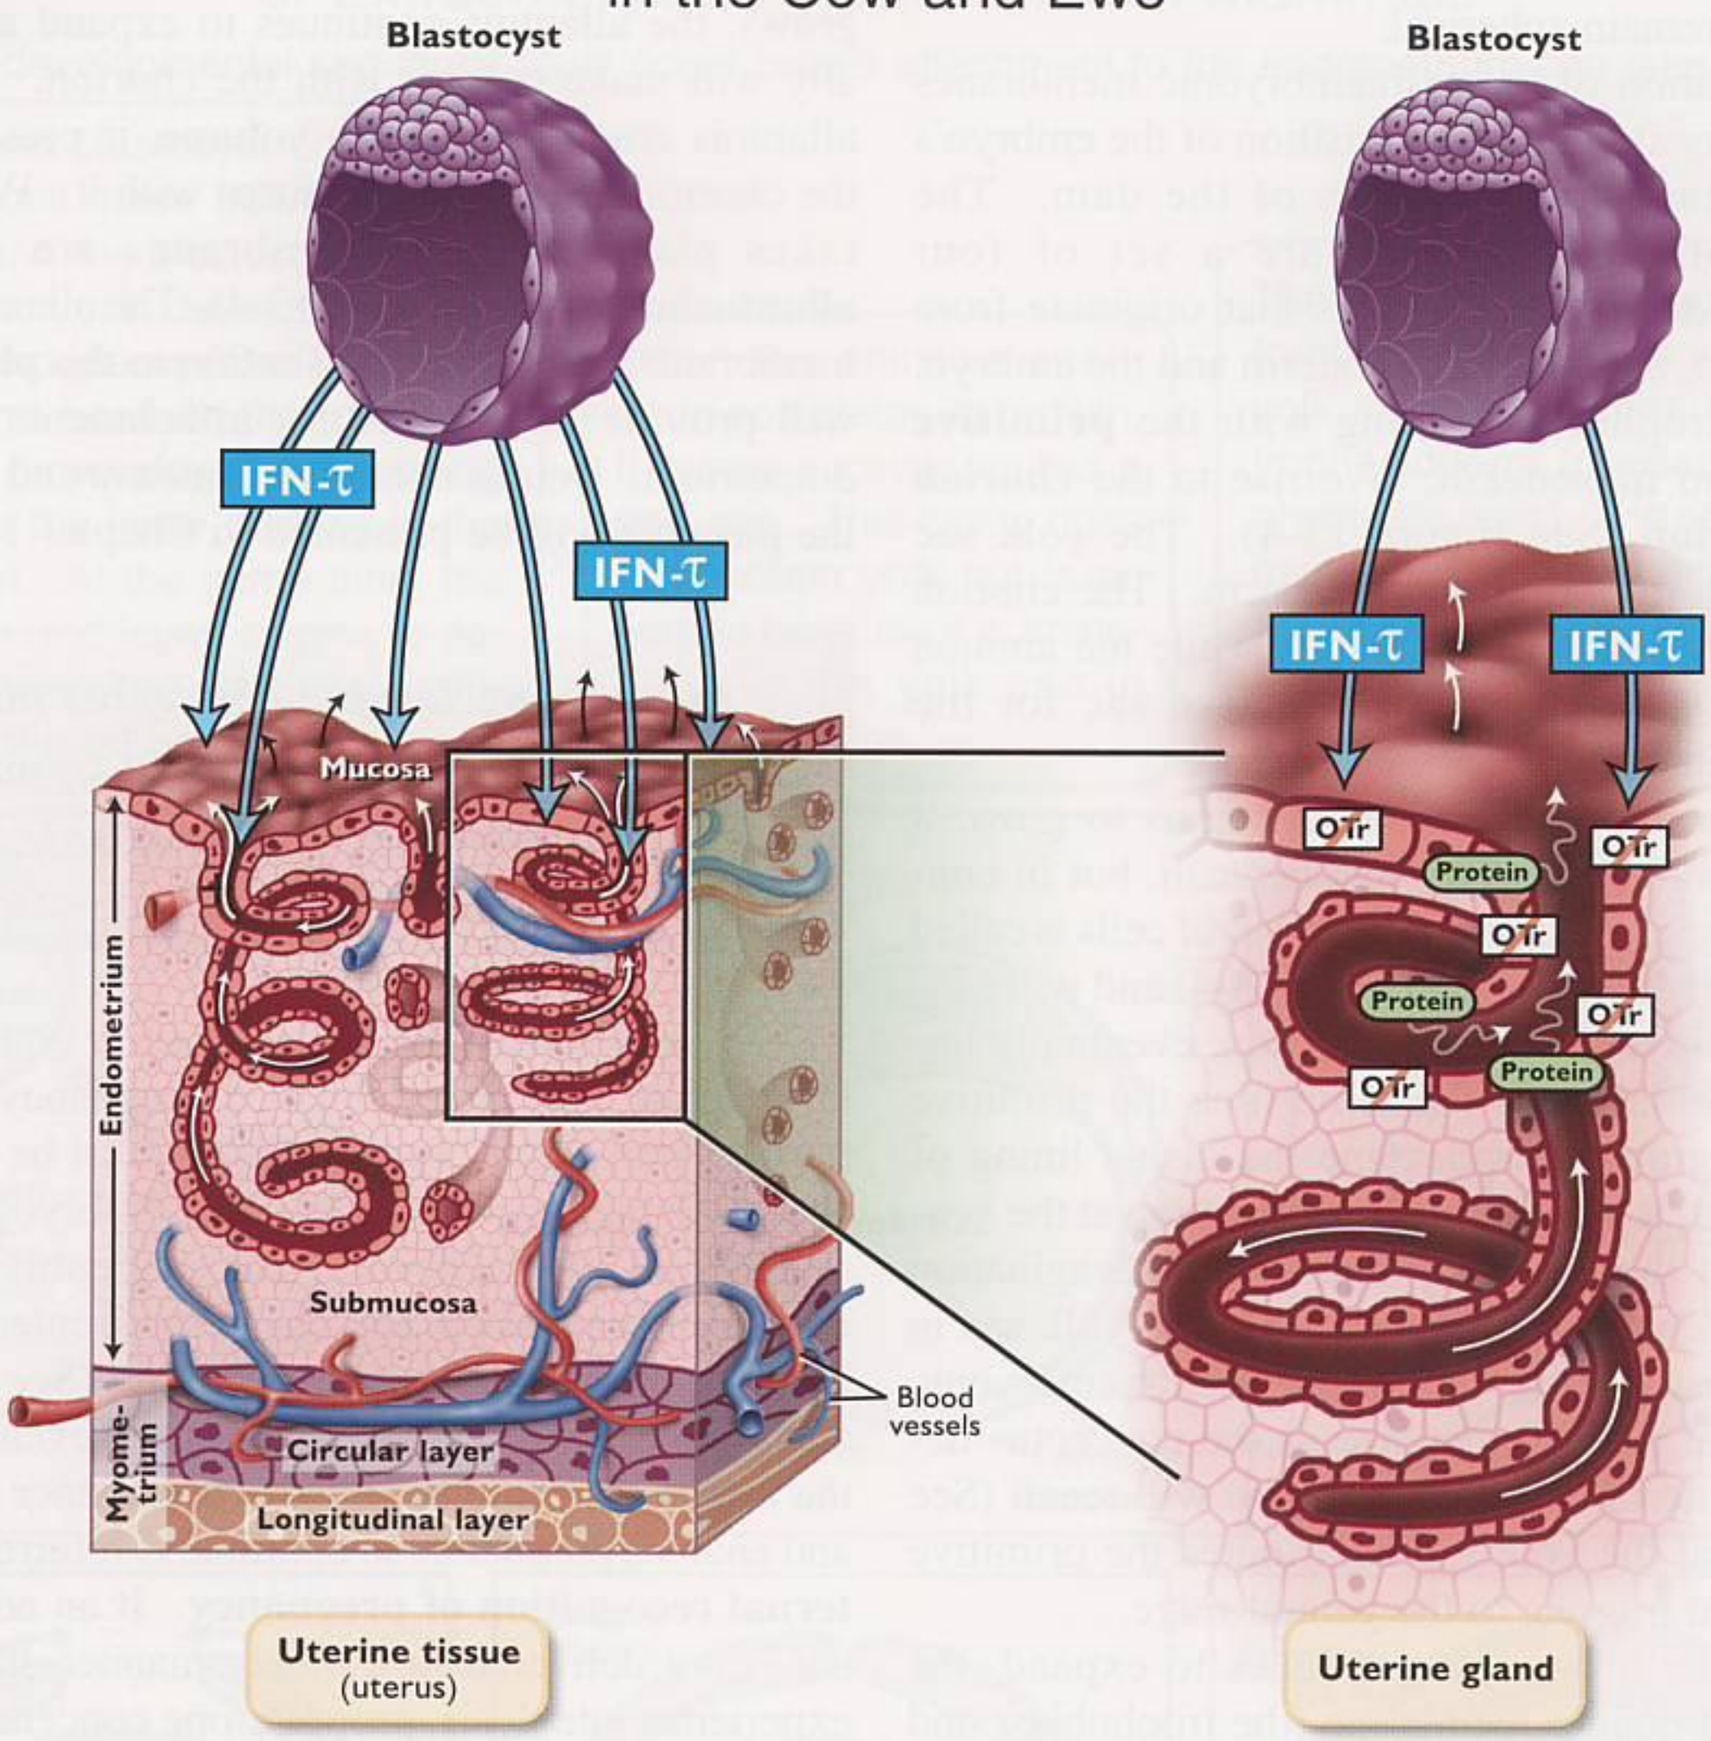
In most species, the conceptus must provide a timely biochemical signal or the pregnancy will terminate.

In order for the events of early embryogenesis to continue into an established pregnancy, luteolysis must be prevented. Progesterone must be maintained at sufficiently high levels so that embryogenesis and attachment of the developing conceptus to the endometrium can take place. The embryo enters the uterus between days 2 and 5 after ovulation (See Table 13-1 and Figure 13-3). The critical series of events by which the conceptus initially signals its presence to the dam and enables pregnancy to continue is referred to as **maternal recognition of pregnancy**. If an adequate signal is not delivered in a timely manner, the dam will experience luteolysis, progesterone concentrations will decline and pregnancy will be terminated. Recognition factors as they relate to the critical recognition period are presented in Table 13-2.

Maternal recognition of pregnancy must occur prior to luteolysis.

Recall from Chapter 9 that the corpus luteum of ruminants produces oxytocin that stimulates endometrial cells to synthesize $PGF_{2\alpha}$. The production of $PGF_{2\alpha}$ is dependent upon a threshold number of oxytocin receptors that are synthesized by endometrial cells at a critical time during the estrous cycle. When these receptors are available in sufficient numbers, pulsatile secretion of $PGF_{2\alpha}$ occurs in response to luteal oxytocin secretion and luteolysis follows (See Figure 13-5). Clearly, this mechanism must be prevented if a successful pregnancy is to proceed.

Figure 13-5. IFN-τ From the Conceptus Prevents Luteolysis in the Cow and Ewe



IFN-τ is produced by the trophoblastic cells of the blastocyst (cow and ewe). IFN-τ acts on the endometrial cells of the uterus to inhibit the production of oxytocin receptors so that oxytocin cannot stimulate $PGF_{2\alpha}$ synthesis. In addition, IFN-τ causes production of proteins from the uterine glands. The arrows from the uterine glands indicate the movement of products that are secreted into the uterine lumen to nourish the conceptus.

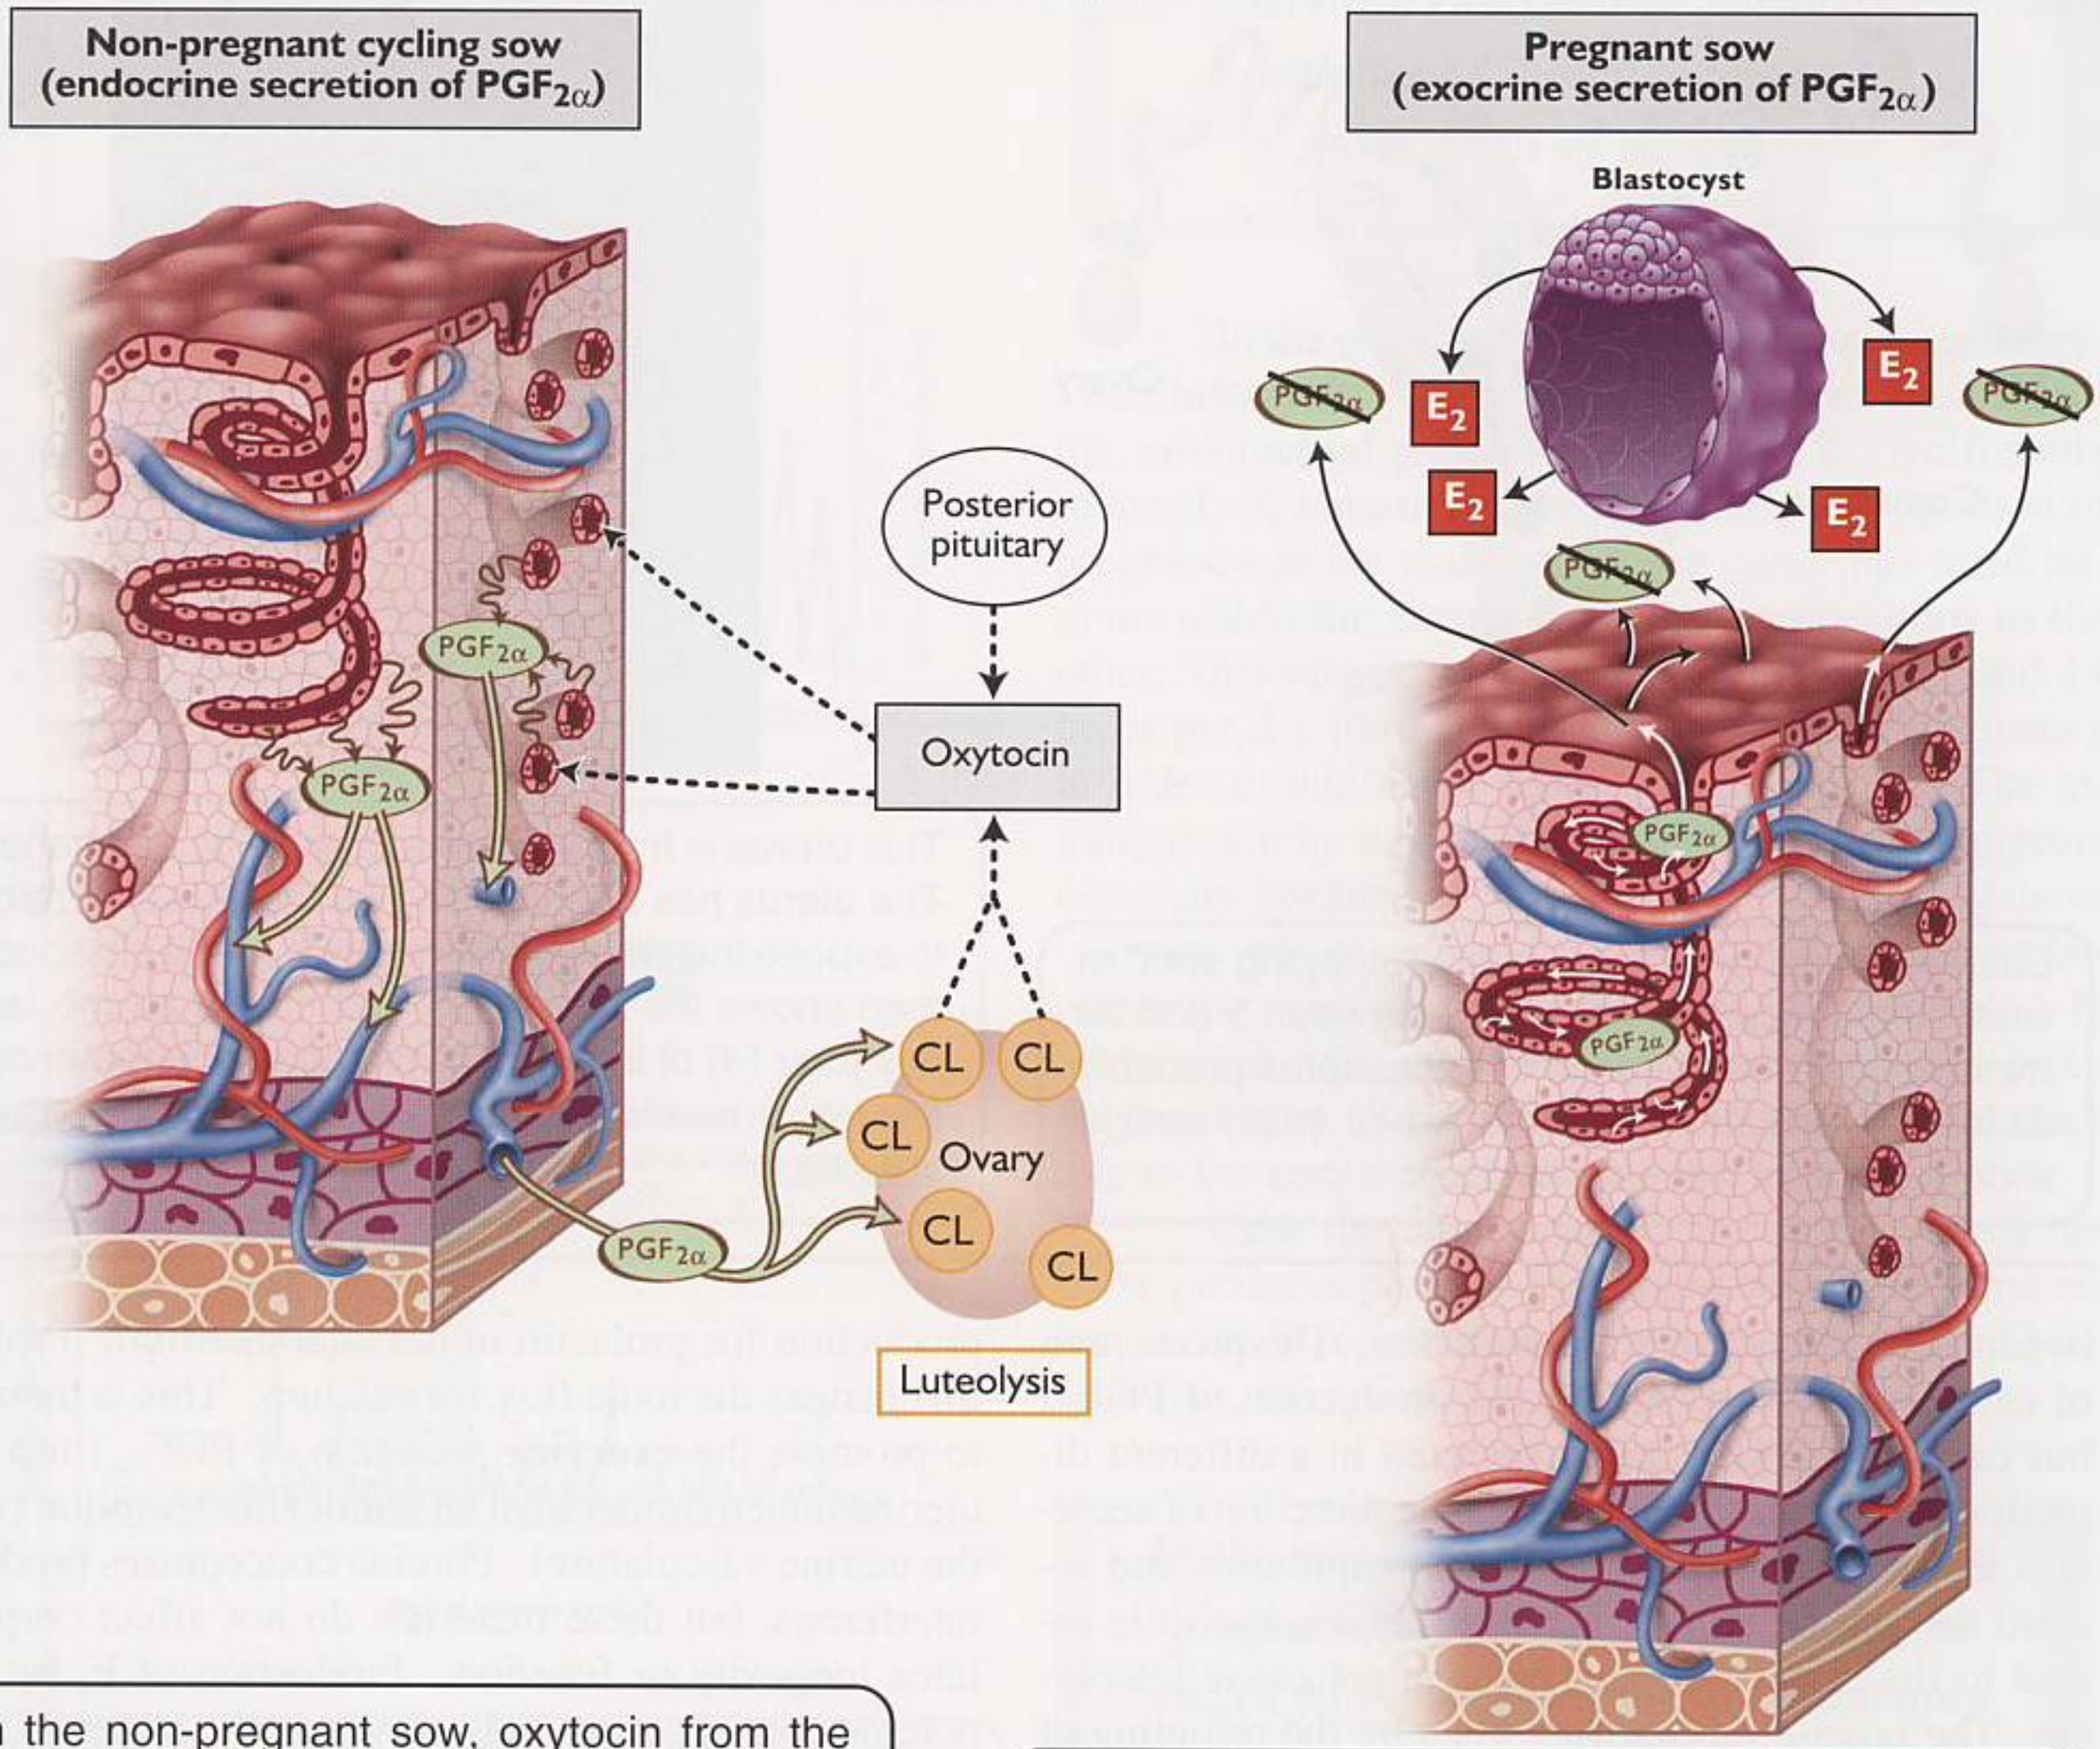
13

In the ewe and cow, the blastocyst secretes materials that block the synthesis of uterine oxytocin receptors.

In the ewe and the cow the free-floating blastocyst produces specific proteins that provide the signal for prevention of luteolysis. The specific proteins were once called **ovine trophoblastic protein 1** (oTP-1) and **bovine trophoblastic protein 1** (bTP-1). Both of these proteins belong to a class of materials known as **interferons.** Most interferons are nonspecific glycoproteins produced by leukocytes, fibroblasts, lymphocytes and trophoblastic cells. Interferons have antiviral action and alter the function of target cells. Because trophoblastic proteins (oTP-1 and bTP-1) constitute a separate class of interferons, they are now referred to as **ovine Interferon τ (oIFN-τ)** and **bovine Interferon τ (bIFN-τ)**. The use of the Greek letter τ designates the trophoblastic origin of these proteins.

A relatively small protein (18,000 to 20,000 daltons), oIFN-τ is produced by the trophoblastic cells of the blastocyst and is present in the uterus from about

Figure 13-6. Estradiol Reroutes $PGF_{2\alpha}$ to Prevent Luteolysis in the Sow



In the non-pregnant sow, oxytocin from the endometrium, posterior pituitary lobe and CL promotes $PGF_{2\alpha}$ synthesis by the uterine endometrium. $PGF_{2\alpha}$ diffuses by concentration gradient towards the endometrial capillaries where it drains into the uterine vein, is transported to the ovary and causes luteolysis.

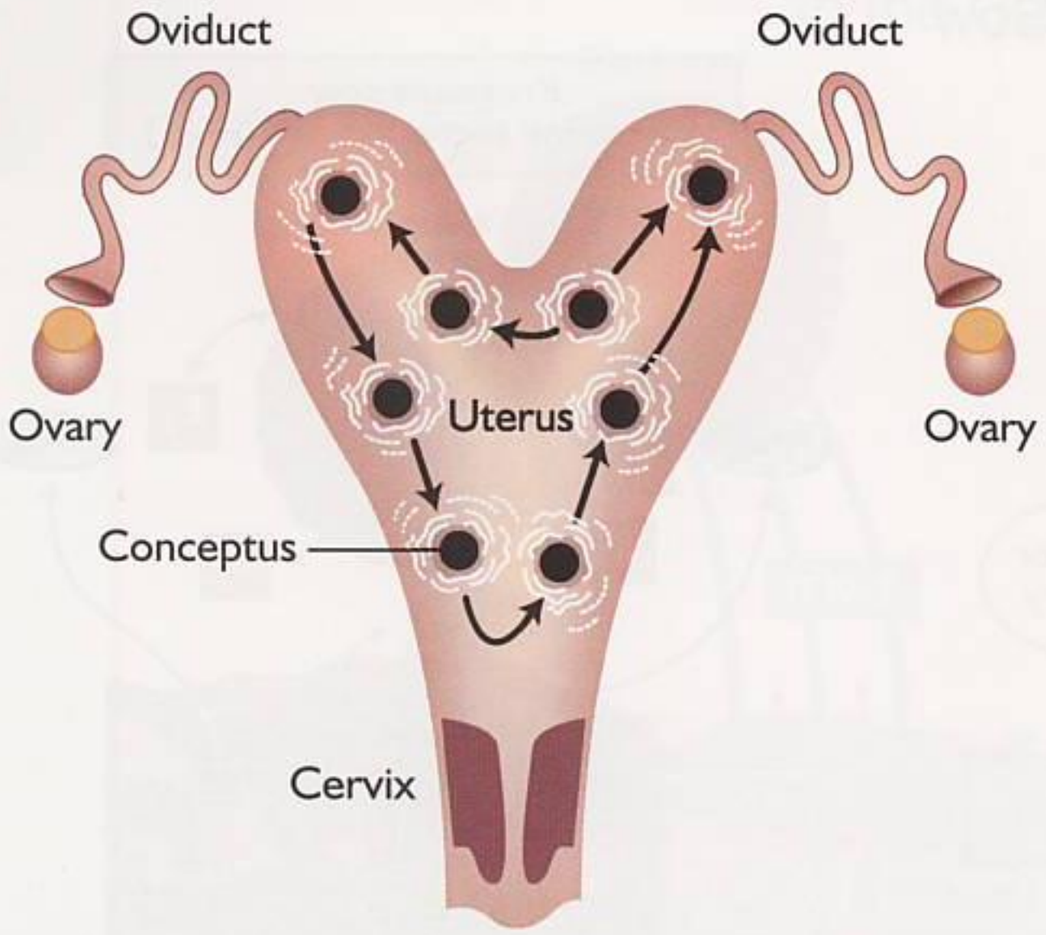
In the pregnant sow, the blastocyst produces estradiol that causes the $PGF_{2\alpha}$ to be rerouted into the uterine lumen, where it is destroyed, thus preventing luteolysis. Like the cycling cow, oxytocin is also produced by the CL and posterior pituitary lobe in the pregnant sow.

day 13 to 21 after ovulation. Production of progesterone by the corpus luteum cannot be enhanced by oIFN-τ and therefore it is not luteotrophic. Instead, oIFN-τ binds to the endometrium and inhibits oxytocin receptor synthesis by endometrial cells. Figure 13-5 summarizes the proposed effect of oIFN-τ and bIFN-τ on endometrial production of oxytocin receptors. In addition to blocking oxytocin receptor synthesis, IFN-τ also binds to the apical portion (See Figure 13-5) of the uterine glands and promotes protein synthesis believed to be critical to preimplantation embryonic survival.

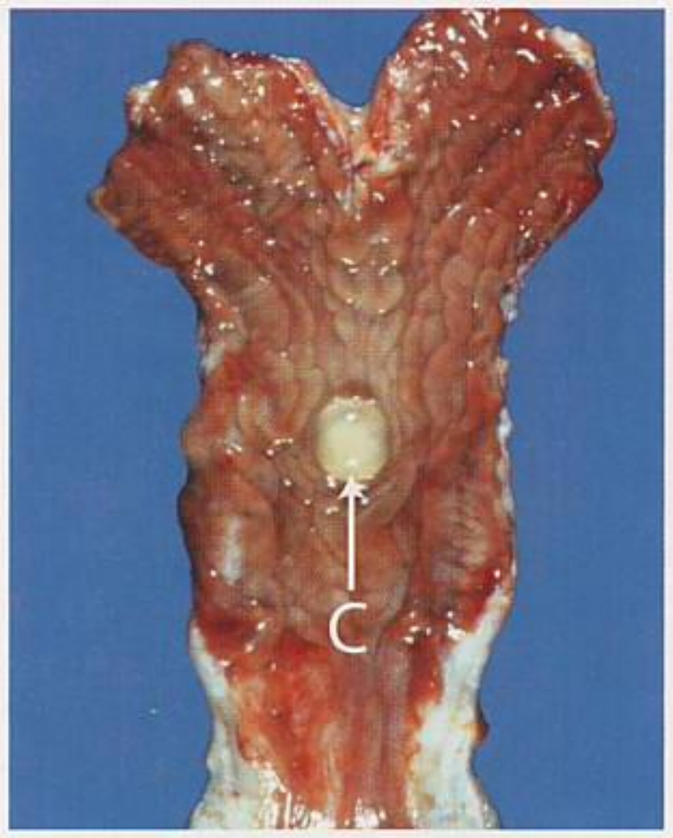
In the sow, estradiol reroutes $PGF_{2\alpha}$ secreted by the endometrium.

In the sow, two major differences exist in maternal recognition of pregnancy, compared to the ewe and cow. First, the conceptus of the pig produces estradiol that serves as the signal for maternal recognition of pregnancy. Second, $PGF_{2\alpha}$ is produced in significant quantities, but is rerouted into the uterine lumen. The conceptus begins to produce estradiol be-

Figure 13-7. Transuterine Migration of the Equine Conceptus



Each black sphere represents a "stopping spot" in which the conceptus will spend between 5 and 20 minutes. The migration of the conceptus probably distributes pregnancy factors (white lines) over a wide surface of the endometrium.



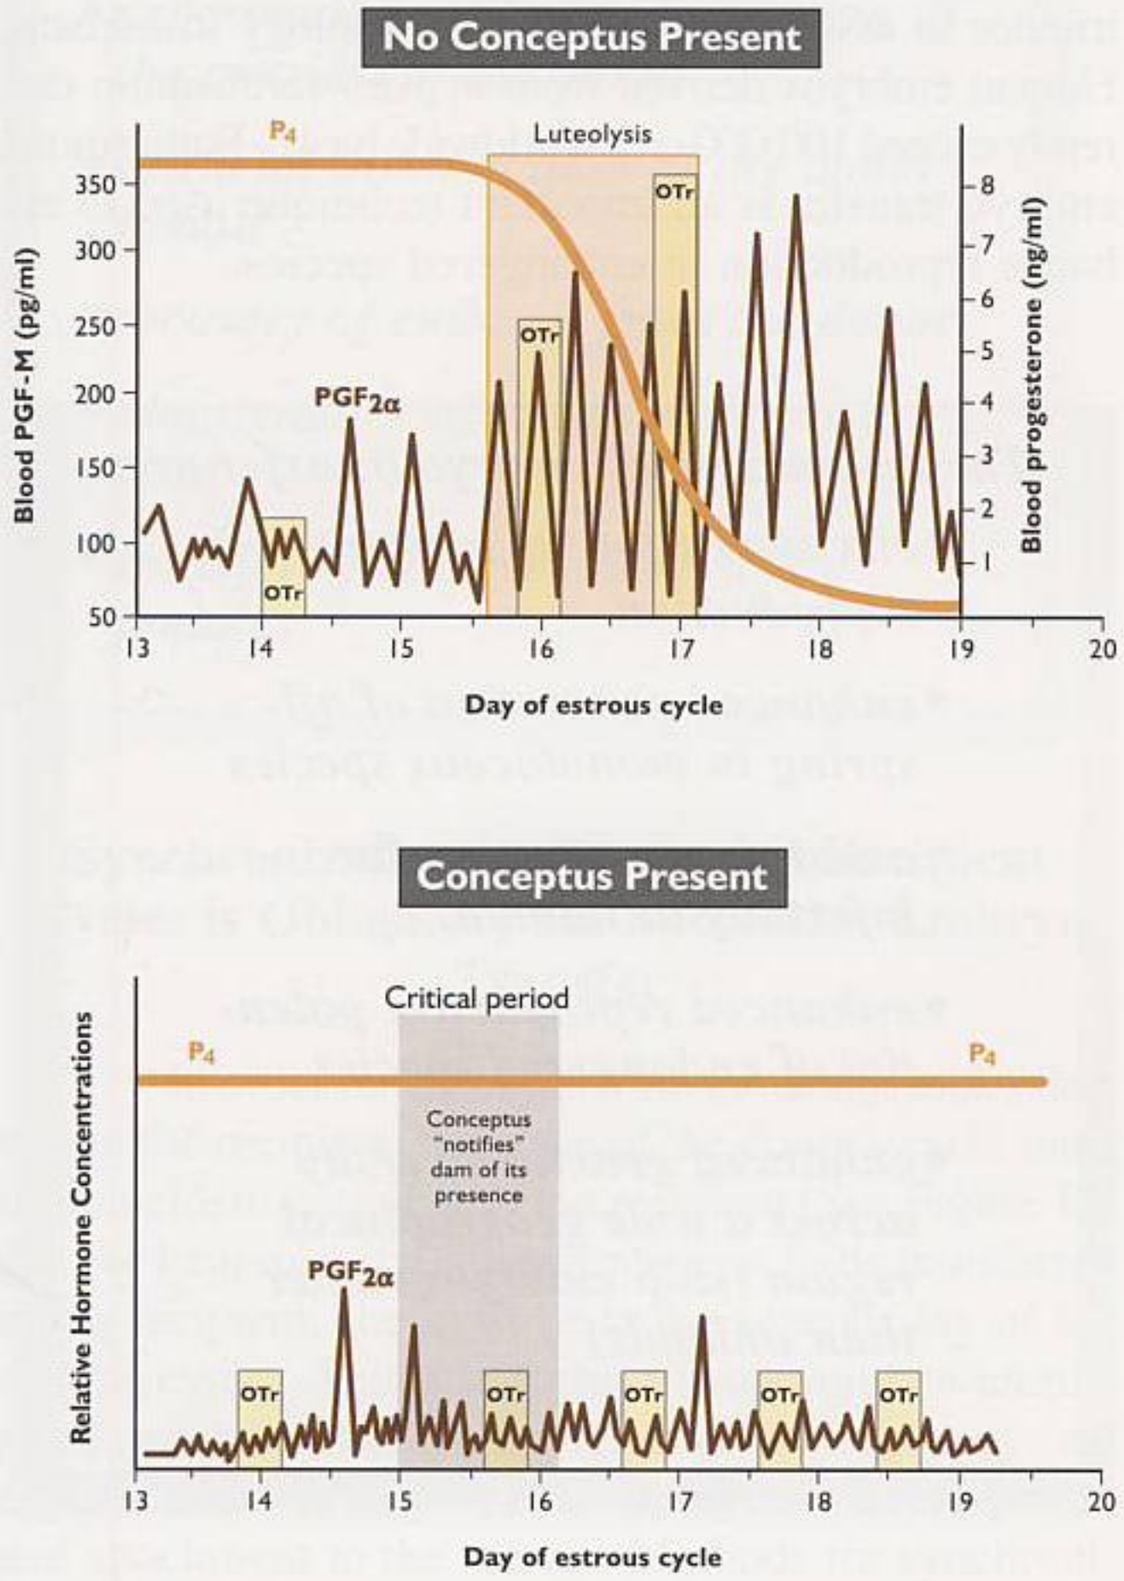
This uterus is from a mare at day 14 of pregnancy. The uterus has been incised on the dorsal surface to expose the spherical conceptus (C). This specimen shows the conceptus and uterus on the last day (day 14) of the uterine migration phenomenon. (Photograph courtesy of Dr. O.J. Ginther, *Reproductive Biology of the Mare*)

tween days 11 and 12 after ovulation. The production of estrogen does not inhibit the production of $PGF_{2\alpha}$, but causes the $PGF_{2\alpha}$ to be secreted in a different direction than in the cycling sow. The direction of secretion is away from the submucosal capillaries and toward the uterine lumen. Luminal $PGF_{2\alpha}$ has little access to the circulation and thus cannot cause luteolysis. The precise mechanism whereby the rerouting of $PGF_{2\alpha}$ occurs is not completely understood. However, it is believed that estrogen causes increased receptor production for prolactin in the endometrium. Prolactin changes the ionic flux for calcium. This is thought to promote the **exocrine** secretion of $PGF_{2\alpha}$ (into the uterine lumen) rather than an **endocrine** secretion (into the uterine vasculature). Porcine conceptuses produce interferons, but these materials do not affect corpora lutea longevity or function. Production of E_2 by the porcine conceptus not only serves as the maternal signal to prevent luteolysis, but also probably serves to stimulate contractions of the myometrium to distribute conceptuses with the proper spacing along the uterine horn.

Table 13-2. Pregnancy recognition factors, critical days of pregnancy recognition and time of conceptus attachment in mammals

Species	Pregnancy Recognition Factors	Critical Period for Recognition (days after ovulation)	Time of Attachment (days after ovulation)
Bitch	none needed	—	—
Cow	bIFN-τ (bTP-1)	15-16	18-22
Ewe	oIFN-τ (oTP-1)	13-14	15-18
Mare	3 Proteins/Estrogens = ?	12-14	36-38
Queen	none needed	—	—
Sow	Estradiol (E_2)	11-12	14-18
Woman	hCG	7-12	9-12

Figure 13-8. Maternal Recognition Must Occur Prior to Luteolysis



Comparison between the endocrine condition of the female (timing shown here is for the cow) with no conceptus present and with conceptus present. Notice that in the pregnant animal (conceptus present), episodes of $PGF_{2\alpha}$ that cause luteolysis do not occur. These are blocked because endometrial oxytocin receptor synthesis is blocked. This is called maternal recognition. Maternal recognition must occur prior to the onset of luteolysis if the pregnancy is to be maintained.

Another important feature of maternal recognition of pregnancy in the sow is that there must be at least two conceptuses present in each uterine horn for pregnancy to be maintained. If conceptuses are not present in one uterine horn, $PGF_{2\alpha}$ will be secreted in an endocrine fashion, luteolysis will occur and the pregnancy will be terminated. Figure 13-6 summarizes the proposed mechanism for maternal recognition of pregnancy in the sow.

The equine conceptus must migrate over the endometrial surface to initiate and complete maternal recognition of pregnancy.

In the mare, the presence of the conceptus prevents luteolysis. Also, in the presence of the conceptus, endometrial production of $PGF_{2\alpha}$ is significantly reduced. A unique feature of maternal recognition of pregnancy in the mare is that the conceptus must migrate within the uterus from one uterine horn to the other. This migration must occur between 12 and 14 times per day during days 12, 13 and 14 of pregnancy in order to inhibit $PGF_{2\alpha}$ (See Figure 13-7). The intrauterine migration of the equine conceptus appears necessary because the conceptus does not elongate as in other species. Therefore, there is less contact between the conceptus and the endometrial surface. In other words, the migration of the conceptus is probably necessary to distribute pregnancy recognition factors to the endometrial cells.

Like the other species, the conceptus of the horse produces proteins that apparently have some effect on the recognition of pregnancy (See Table 13-2). However, the specific roles are yet unknown.

In the woman, maternal recognition of pregnancy is provided by a hormone called human chorionic gonadotropin (hCG).

At about the time of implantation (day 7-9 after ovulation) the human conceptus begins to secrete a hormone called human chorionic gonadotropin (hCG). This is an LH-like hormone that acts on the corpus luteum to inhibit intraovarian luteolysis (See Chapter 9). The precise mechanism whereby hCG blocks luteolysis is not known. Regardless, the luteotrophic effect of hCG is sufficient to allow for implantation and maintenance of pregnancy.

Maternal recognition of pregnancy in the dog and the cat probably does not require a signal from the conceptus.

In the bitch, the CL of pregnancy and the CL of the cycle have similar lifespans. Therefore, under normal cyclic conditions, the CL is long-lived. When luteolysis does occur it is near the end of the normal gestation period. In other words, the period of diestrus is quite similar to the gestation period and thus, the corpus luteum is not lysed under normal conditions until the gestation period is complete.

As you recall, the queen is an induced ovulator. If mating does not occur, corpora lutea are not formed and a "post estrous" period of several days (8-10) exists before another estrus. In the queen that has been bred, a CL forms and the duration is the same as gestation (about 60 days). Like the bitch, a signal from the conceptus is not needed because corpora lutea are not lysed before a pregnancy is established. Please see Chapter 7 for graphic illustrations of this concept.

A successful pregnancy requires maintenance of high blood progesterone concentrations.

Regardless of whether or not specific pregnancy recognition signals are provided, progesterone concentrations in the blood of the dam must be maintained at sufficiently high concentrations so that the conceptus will grow and develop. The extraembryonic membranes will form an attachment with the endometrium to provide a semipermanent link between the dam and the fetus. This semipermanent link is known as the **placenta** and will be discussed in the next chapter.

Embryo Transfer Technology Provides Avenues for Reproductive and Genetic Enhancement

Embryo transfer requires a set of procedures that allows removal of pre-attachment embryos from the reproductive tract of a **donor female** and transfers them into the reproductive tract of a **recipient female**. Embryo transfer is a valuable research technique. It is commercially available in some species to increase the productivity of females with desired traits. The first successful embryo transfer procedure was performed in a rabbit in 1890. Since that time embryo transfer techniques have been used in many species and countless offspring have been produced using this technique. In principle, embryo transfer can be performed in any mammalian species. However, its widest application is in cattle and more embryos are transferred in this species per year than in all other species combined. The main advantage of embryo transfer in cattle is to amplify the number of offspring that donor females with desired genetic traits can produce. A single donor cow is capable of producing 10 to 20 offspring annually. Embryo transfer has been a contributor to assisted reproductive technology in humans. Human embryos derived from *in vitro* fertilization currently exceed 100,000 on a worldwide basis. Futhermore, embryo transfer is an important technique used to enhance reproduction in endangered species.

The advantages of embryo transfer are:

- ***circumvention of seasonal reproduction***
- ***enhanced generation of offspring in monotocous species***
- ***assisted reproduction for infertility in humans***
- ***enhanced reproductive potential of endangered species***
- ***enhanced genetic diversity across a wide geographical region (ship embryos rather than animals)***

A major advantage of embryo transfer is the ability to transport germ plasm from one geographical area to another. For example, embryos collected in North America can be shipped to any country in the world. This is particularly important in large animals (cows, horses, exotic species) because transportation of the animal over long distances is inefficient, expensive and can transmit diseases. Embryo transfer offers significant biosecurity advantages over animal transport. In addition to the above contributions, embryo transfer is an essential step in many experimental techniques in the production of clones and transgenic animals.

Successful embryo transfer involves:

- *synchronizing the cycles of donors and recipients*
- *superovulation (hyperstimulation of the ovaries) of the donor*
- *artificial insemination of the donor female*
- *recovery of embryos from the donor*
- *maintenance of viable embryos in vitro*
- *transfer of embryos to recipient females*

Synchronization of Donor and Recipient Cycles is Obligatory for Successful Embryo Transfer

In order for embryos from the donor to develop within the recipient, the stage of the donor's cycle must be coincident with that of the recipient (See Figure 13-9). For example, if a 7-day embryo is to be transferred into a recipient, she must be in the seventh day of her estrous cycle. This allows for the appropriate uterine environment, maternal recognition of pregnancy and establishment of appropriate embryonic development and attachment to the uterus. Methods for synchronization of estrous are presented in Chapter 9.

Superovulation Results from Hyperstimulation of the Ovaries with Gonadotropins

Superovulation is the treatment of a female with gonadotropins (typically FSH) to increase the number of oocytes that are selected to become dominant follicles and to ovulate (See Figure 13-9). Among monotocous animals, superovulation is used to increase the number of potential offspring from donor females possessing traits of high economic value. Superovulation is also used in humans (even though only one offspring is usually desired) to compensate for imperfections in embryo transfer techniques.

In monotocous species, ovulation rates of 5-10 times normal occur. In polytocous species, ovulation rates of only 2-3 times normal are experienced. There is a wide variation in the individual's response to gonadotropin stimulation. Because a commercial embryo transfer industry exists in cattle, there are significant data available describing this variation. For example, a typical response in cattle would be 8 to 10 ovulations, producing 5 to 7 viable embryos. But, about 30% of the cows respond by producing one or fewer viable embryos. About 2% of the cows may produce as many as 30 embryos or more. The physiologic reasons for this wide variation in ovarian response to hyperstimulation are not known.

Recovery of oocytes from ovaries can be accomplished by:

- *surgically exposing the ovary and aspirating follicles*
- *non-surgically aspirating follicles utilizing ultrasonography*
- *aspirating follicles postmortem in an abattoir*

Recovery of Embryos from the Donor Females may be Accomplished in Several Ways

Most frequently, donor females are bred utilizing artificial insemination with semen from a male possessing highly desired traits. After insemination, embryos can be recovered by a variety of methods.

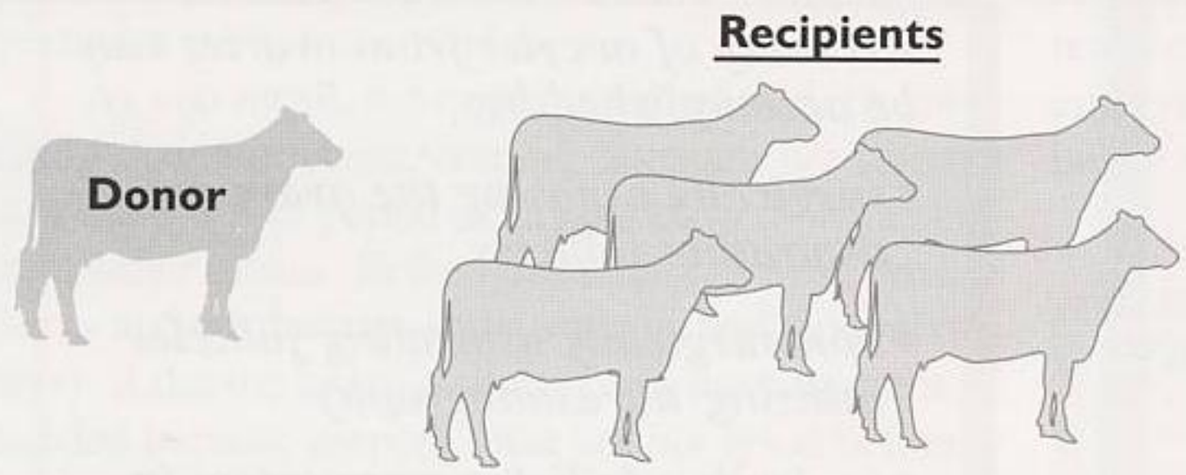
Recovery of embryos from the oviduct requires surgery in all species. Recovery of embryos from the uterus is accomplished surgically in small species and non-surgically in large species. In cows and mares transrectal palpation and introduction of catheters for removal of embryos by flushing with various culture media is a routine procedure (See Figure 13-9).

Oocytes can be recovered directly from the ovary using aspiration with a hypodermic needle. In horses and cattle, a common technique for recovery of oocytes by aspiration involves inserting a needle through the wall of the rectum and with the use of ultrasonography, identifying dominant follicles and aspirating the oocytes into a special apparatus (See Figure 13-10). The purpose of follicular aspiration is to recover oocytes from dominant follicles and perform *in vitro* fertilization (See Figure 13-10). In the case of the postmortem recovery, large numbers of ovaries are available from cattle immediately after exsanguination from slaughter facilities. Oocytes remain viable for relatively long periods after exsanguination, typically 9-12 hours in most species. Therefore these serve as valuable sources of oocytes for experimental purposes. Even though cows have not received ovarian stimulation by gonadotropins numerous antral follicles are normally present on ovaries and provide a ready source of viable oocytes for *in vitro* fertilization procedures.

Figure 13-9. Major Steps of Embryo Transfer in Mammals-Cow Model

STEP 1

Sychronization of recipients with donor



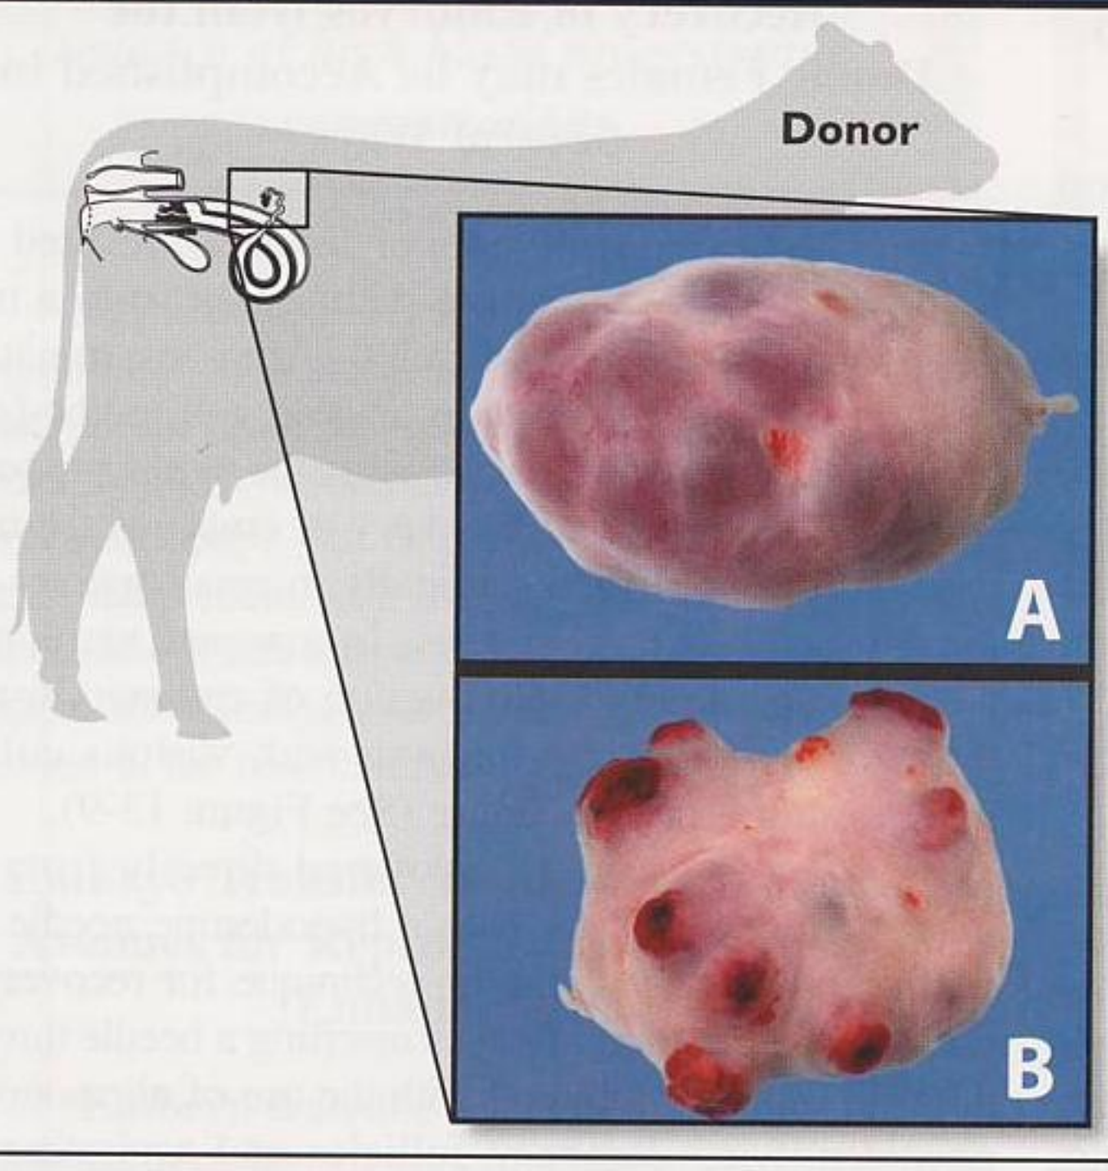
Goal: To synchronize the donor and recipient to be in the same stage of the estrous cycle.

Reason: To prepare the uterus of the recipient to support preattachment embryogenesis.

How: Treat recipient with hormonal regime that induces estrus to occur at the same time as the donor.

STEP 2

Superovulation of donor



Goal: To hyperstimulate ovaries with gonadotropins.

Reason: To provide higher than normal numbers of follicles that reach dominance and ovulate.

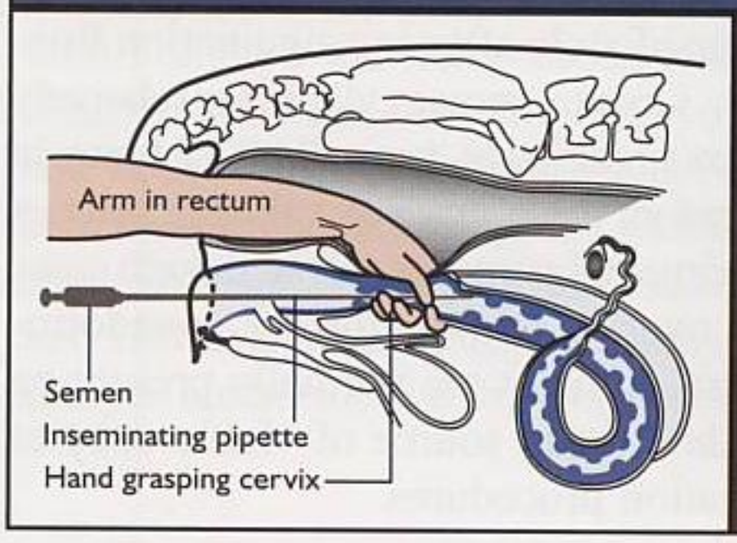
How: Inject donor with gonadotropins to hyperstimulate follicular development. Generally, FSH (or one of its analogs) is used.

Ovary A- Hyperstimulated ovary. There are 9 follicles visible in this ovary. The donor is in estrus.

Ovary B- 1 day after estrus. There are 9 corpora hemorrhagica visible on this specimen.

STEP 3

Inseminate donor with semen from genetically superior bull



Goal: To generate the best fertilization rates and genetic combinations possible.

Reason: Enhance rate of genetic progress.

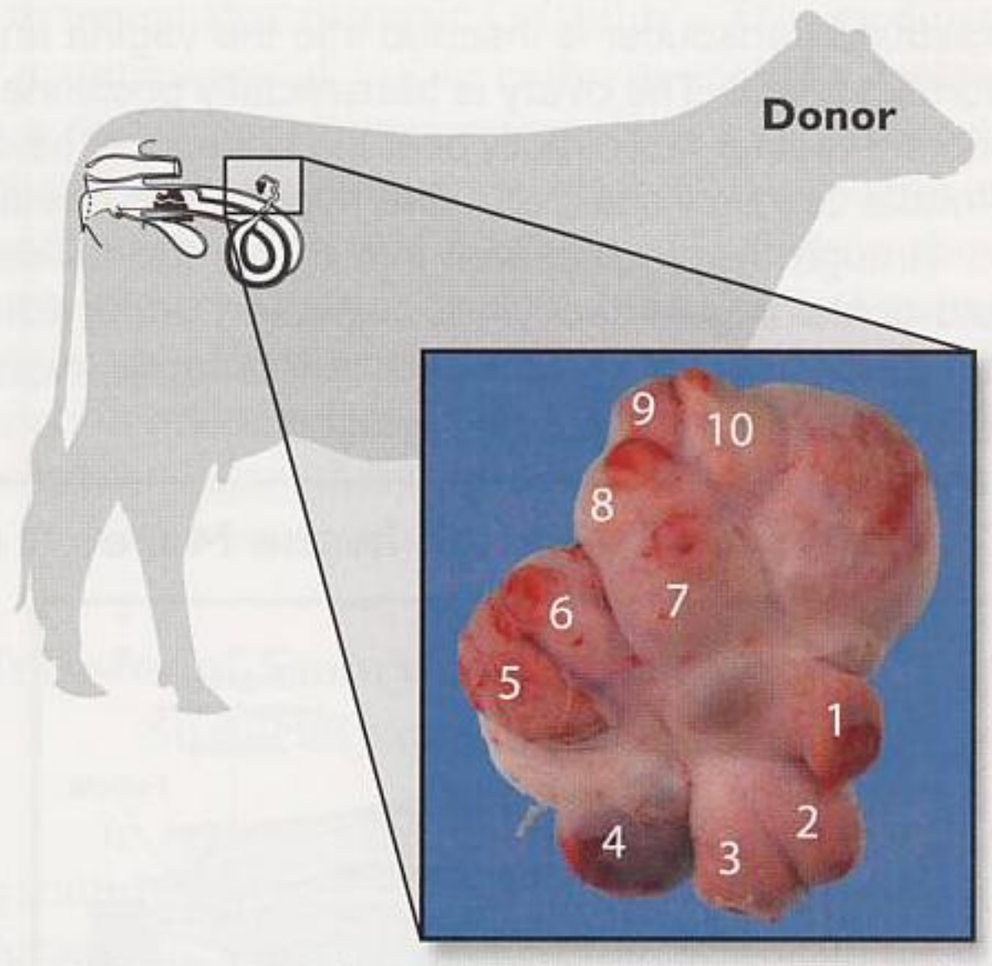
How: Utilize highly fertile semen and well-trained, experienced inseminators.

AIP = AI Pipette, S = Semen, RO = Right Ovary, LO = Left Ovary, RUH = Right Uterine Horn, LUH = Left Uterine Horn

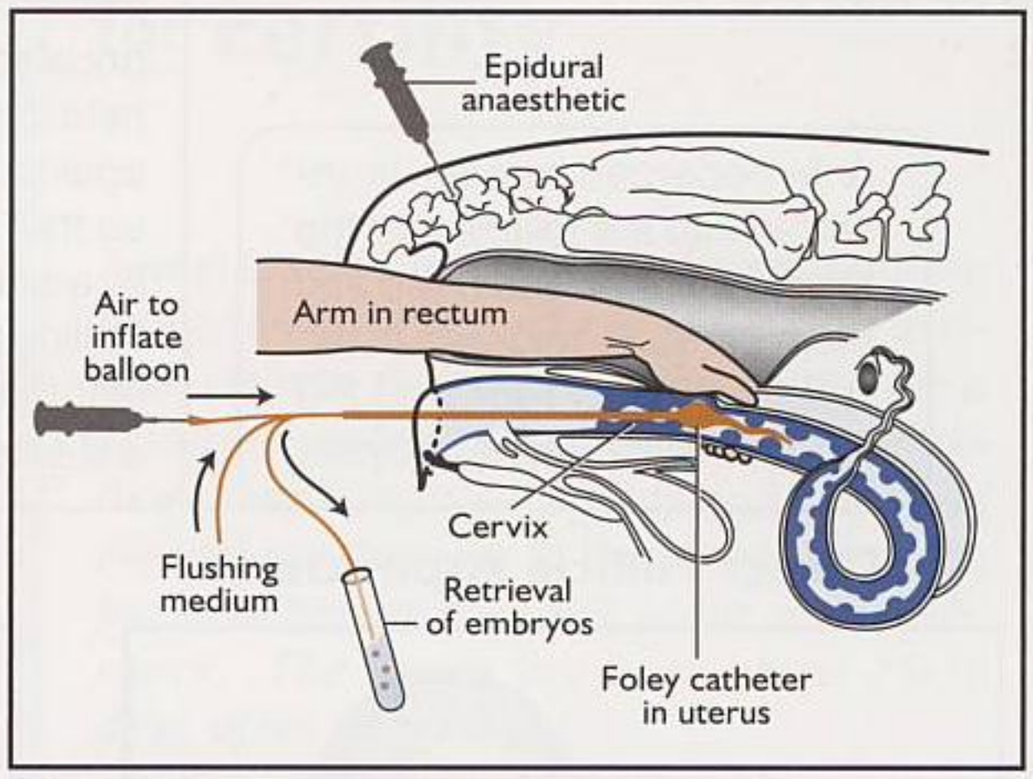
(Ovarian specimens courtesy of Dr. B.R. Lindsey, Minitube of America, *www.minitube.com)*

STEP 4

Recovery and indentification of viable embryos



Goal: To nonsurgically collect (flush) embryos from the donor for transfer.
Reason: To recover viable embryos.

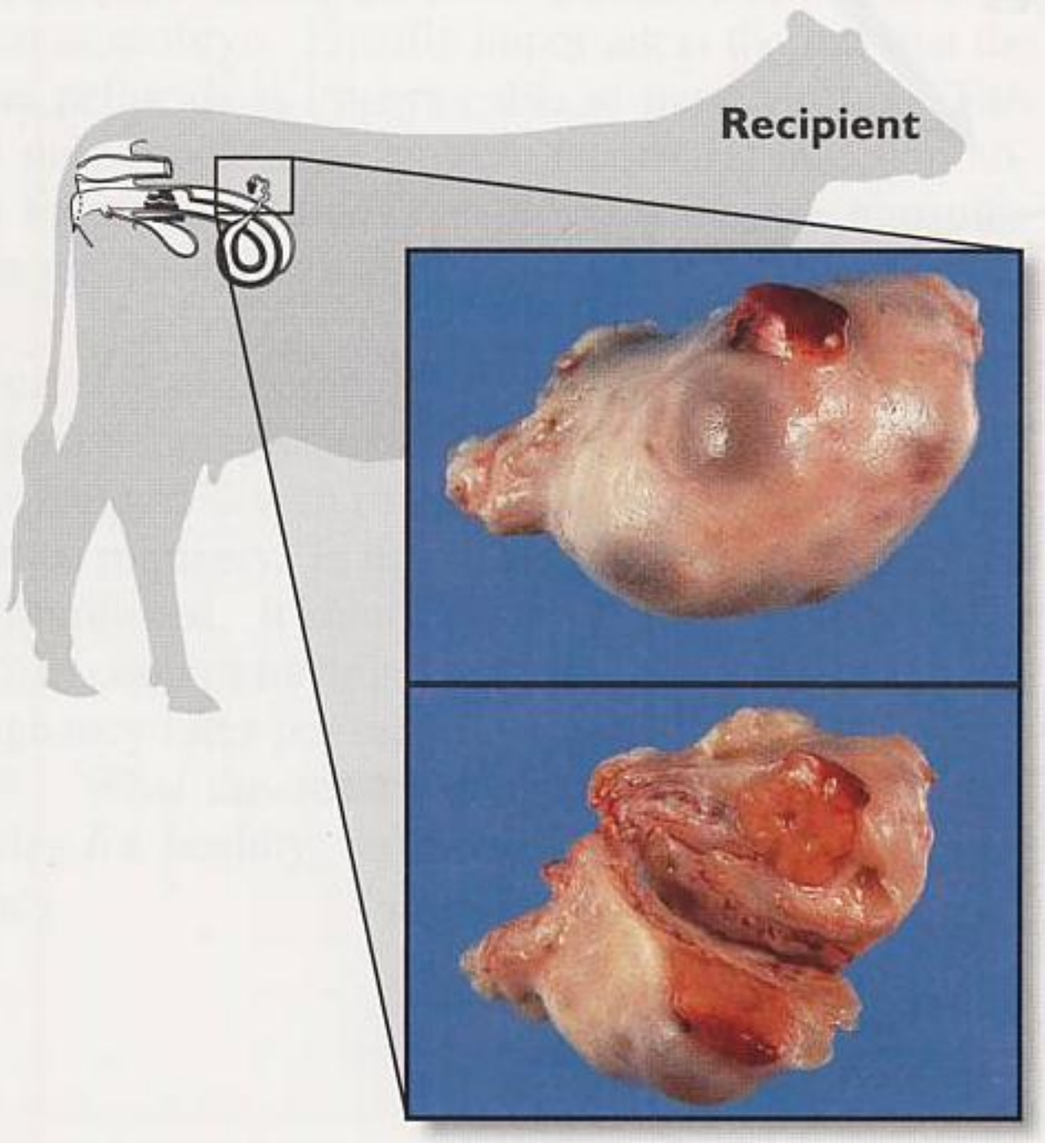


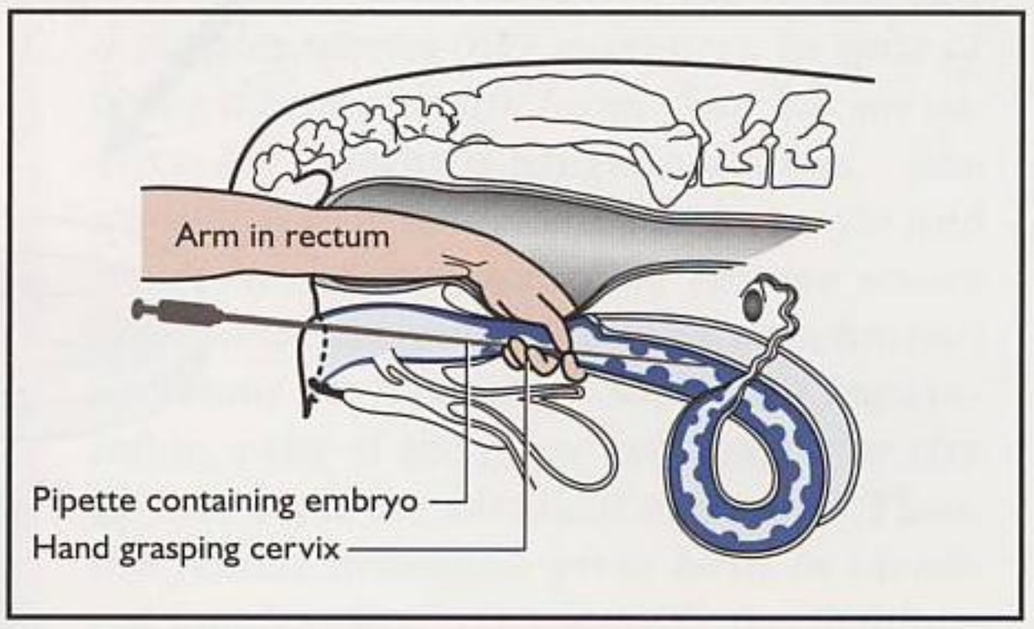
How: Before the procedure is started a local anesthetic is injected to cause relaxation of the rectum. At day 6-8 a specialized catheter is inserted into the uterus. The catheter has a small balloon that can be inflated to prevent retrograde flow of the flushing medium. A flushing medium is then introduced into the uterus, lavaged and then returned through the catheter to a collection vessel. The ovary in the photo has ten-7 day CL.

(Ovarian specimens courtesy of Dr. B.R. Lindsey, Minitube of America, *www.minitube.com)*

STEP 5

Transfer of viable embryos into synchronized recipients





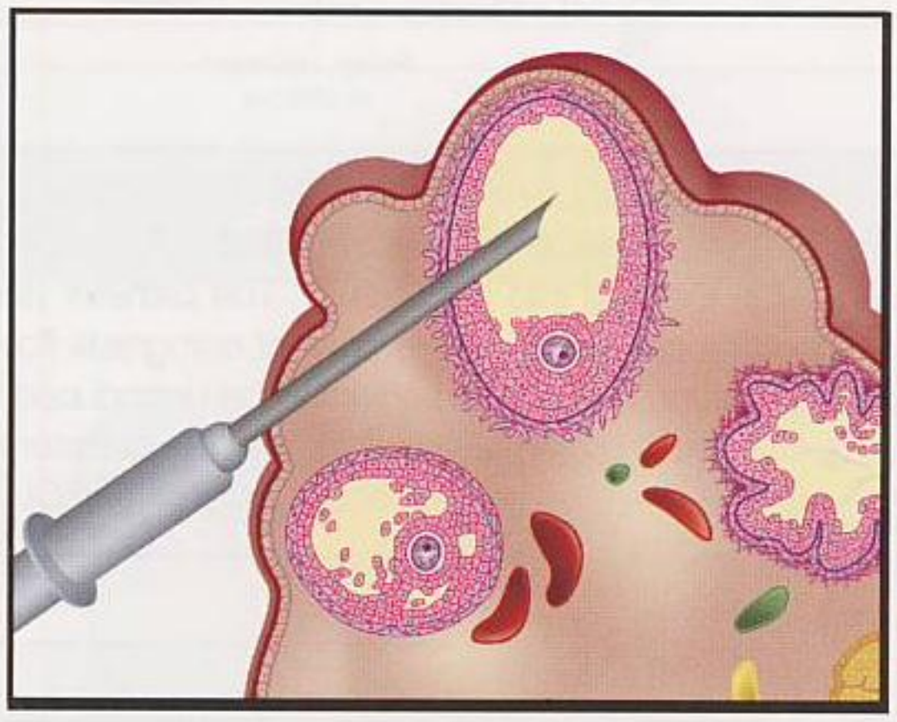
Goal: To deposit a potentially viable embryo into the uterine horn of each recipient.
Reason: To achieve pregnancy in each recipient.
How: A single embryo is placed into the uterine horn using a transfer pipette. Note that both the donor (step 4) and recipient here have CL at similar stages of leutinization. Thus, the uterine environment in the donor and recipient are quite similar.

Figure 13-10. Oocyte Collection from Ovarian Follicles for *In Vitro* Fertilization

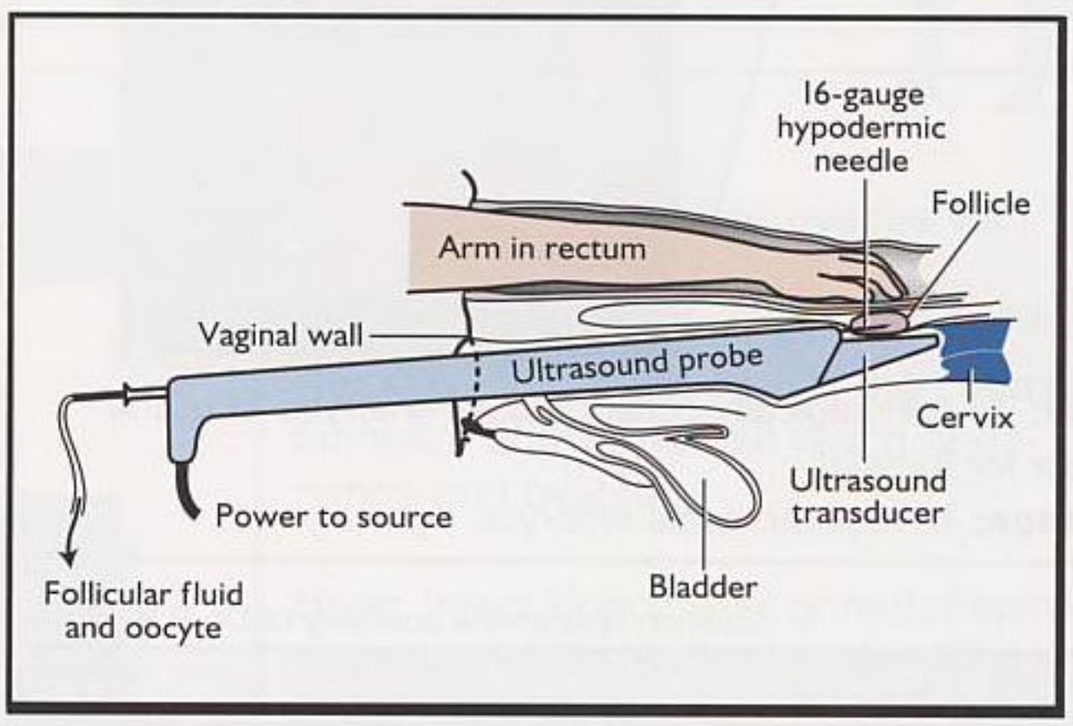
A hypodermic needle is inserted into the follicle and the follicular fluid is aspirated and then forcefully returned to the follicle. This is repeated 2-3 times to dislodge the oocytes.

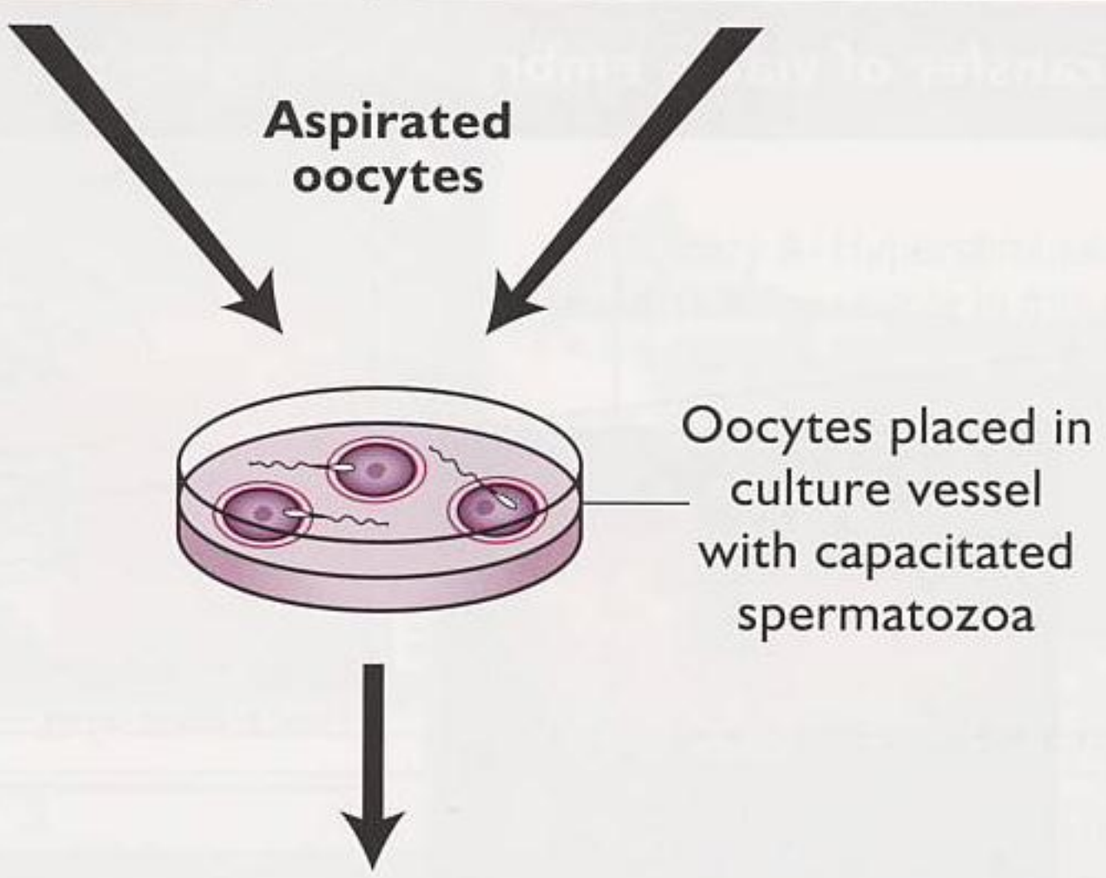
Prior to performing the procedure, mares are injected with propatheline bromide (a sedative) to relax the rectum. The lubricated ultrasound transducer is inserted into the vagina and held in the fornix vagina. The ovary is transrectally positioned against the dorsal vaginal wall directly over the transducer head so that the follicle can be visualized. The hypodermic needle is advanced through the vaginal wall into the antral follicle. Follicular fluid containing the oocyte is aspirated under constant vacuum (Graphic modified with permission from *Ultrasonic Imaging and Animal Reproduction: Horses Book 2*. 1995 by O.J. Ginther).

Direct Follicle Aspiration



Transvaginal Aspiration in the Mare





Embryo Viability Must be Maintained *In Vitro*

In order for embryos to be transferred successfully into recipient females they must be stored in an environment that maintains viability. The conditions for maintenance of viable embryos include: maintenance of appropriate temperature (near or at body temperature), exposure to the appropriate atmospheric environment (5% CO_2 and 5-8% O_2), pH slightly above neutral and the absence of microorganisms. A culture medium should also contain the appropriate ionic configuration and the appropriate energy sources for metabolism and growth by the young embryo. Embryos can be frozen successfully for long term storage.

Transfer of Embryos can be Accomplished Surgically or Non-Surgically

In general, embryos can be transferred non-surgically into the recipients in almost any species. This is because the embryos can be recovered from the donor at a stage that allows them to be transferred directly into the uterus of the synchronized recipient. Transferring the embryos into the uterus involves passing a pipette through the vagina and cervix and depositing the embryos into the appropriate uterine horn (ipsilateral to the CL).

The zona pellucida is an important component of the early embryo. First, it houses the blastomeres so that they do no separate and can develop together to form an embryo. Equally important is the fact that the zona pellucida is impermeable to most viruses. This not only protects the embryo from viral infection under natural conditions but prevents disease transmission via the embryo after transfer.

Embryo transfer procedures have become very successful. In commercial embryo transfer programs with cattle, pregnancy rates of 70% with unfrozen embryos and 65% with frozen embryos have been accomplished routinely. In humans, 30% pregnancy rates are accomplished. It should be emphasized that in young human couples having regular copulatory patterns, the pregnancy rates per reproductive cycle are only about 35%. What this means is, it takes an average of 3.3 cycles for healthy, fertile couples to achieve a pregnancy.

Further PHENOMENA *for* Fertility

Some species have delayed implantation (attachment to the uterus) in which a viable embryo floats within the uterus for a sustained period of time. Martens (a mink-like animal) copulate in July or August and the embryo develops to the blastocyst stage, but attachment does not occur until February. The young are born about 26-30 days after attachment.

The presence of the marsupial embryo within the uterus does not interrupt the estrous cycle. Therefore, pregnancy recognition in this species is apparently not caused by a substance(s) produced by the embryo. Instead, the semipermanent attachment of the prematurely born fetus to the teat provides a pregnancy recognition mechanism, because it arrests cyclicity.

The female nine-banded armadillo has several unique features. First, the female has a simplex uterus (like primates), in spite of being a primitive life form. She has no vagina, but retains a urogenital sinus. She spontaneously ovulates a single oocyte and mates in the summer. The embryo enters embryonic diapause (delayed attachment) for about 3 to 4 months. Soon after implantation, cells of the inner cell mass give rise to four separate identical embryos. Thus, the female armadillo gives birth to identical quadruplets. The genetic implications of identical offspring in this species are not known.

The human blastocyst (along with guinea pigs, hedgehogs and chimpanzees) first attaches to the endometrial epithelium, passes through and becomes completely imbedded. Thus, the embryo is isolated from the uterine lumen. Knowledge of this phenomenon led to the term "implantation". True implantation does not occur in domestic animals.

In rodents, a successful pregnancy can be terminated if an alien male (one that did not cause the pregnancy) shows up and hangs-out with the pregnant female. This is known as the "Bruce Effect".

The Apostlebird of Eastern Australia derived its name from the fact that it does everything in groups of twelve. During the mating season, nests are built on horizontal branches of trees. The females lay eggs in each other's nests. All members share the task of incubating the eggs and rearing the young.

A pair of Indian Pythons have been observed copulating for 180 days.

After copulation, the male garter snake plugs the female's cloaca with a material made from renal secretions. This natural chastity belt prevents any further sexual activity, insuring that the offspring are sired by the first male to breed her.

Cantharidin is derived from beetles known as "blister beetles". The material has been erroneously nicknamed "Spanish Fly". This material developed a reputation as being a "medical wonder" including being a powerful sexual stimulant. Cantharidin irritates the urogenital tract, causing a tingling and burning sensation that is felt in both the male genitalia and female genitalia because of vasodilation. This vasodilation of the labia made women more aware of their genitals and it was thought to build erotic passion and cause sexual excitement. Occasionally, cantharidin caused persistent erections (priapism) in males. Priapism was generally not associated with sexual pleasure and could cause vascular damage to the penis. Cantharidin has been illegal since the 1800's and is currently not for sale over-the-counter. In significant doses, cantharidin can cause health problems. It has been reported in the French literature that "Spanish Fly" had been incorporated into a pate of pears that was consumed by the groom on his wedding night. "When the night came, the husband embraced his wife so much that she began to suffer exhaustion." These delights quickly changed to misfortune because "the man began to experience the effects of cantharidin inflammation by midnight. He had difficulty urinating, saw a discharge from his penis, became frightened and fainted more than once. Considerable effort was made to restore his health."

The Chinese apparently have been searching throughout the course of history for a Viagra-like compound. For example, ashes from hornets or wasps' nests were mixed with water and wine and ingested. This mixture was also applied to the penis for sexual stimulation to cure erectile dysfunction and to increase daily sperm output.

Dragonflies and silkworms were believed to increase penile turgidity and prevent ejaculation. The latter effect was believed to lengthen the duration of copulation.

Scale insects and stinkbugs were considered by the Chinese as aphrodisiacs. Consumption of scale insects was also believed to be a cure for amenorrhea.

The Chinese believed egg cases from the praying mantis had several beneficial effects such as prevention of nocturnal emissions, premature ejaculation, male weakness and impotence.

The word "aphrodisiac" is derived from the name of the Greek goddess of love, Aphrodite.

In 1848, a physician named Frederick Hollick published a book entitled, <u>The Male Generative Organs-Health and Disease from Infancy to Old Age</u> that undoubtedly received more attention than the reproductive physiology books of the day. It was marketed "For Every Man's Private Use". Not only did this book deal with the anatomy and physiology of the male genitalia, it dealt extensively with recipes and concoctions that would facilitate male genital function.

Based on clay tablets dated 12th Century B.C., it was found that castration was the punishment for several male sex offenders. Hence, they apparently knew that the testes were the source of mating behavior in human males. Castration (performed without anesthesia) was likely the first survivable surgery in humans.

Aristotle drew an analogy between the epididymis/ductus deferens, testis and a weaver's string being held tight by an attached rock. Aristotle thought that the function of the testis was only as a weight (like a rock attached to a string) to keep the "kinks" out of the ductus deferens.

Peppermint shrimp begin their life as males, but most change into a female-with a slight twist. The "female" shrimp maintain their male ducts, produce sperm and fertilize other female-phase shrimp even when incubating their own embryos. They can do it all.

On average, the bilaterally castrated man lives 12 years longer than intact men. The possible reason? There is no energy spent trying to copulate. The energy spent copulating is minuscule compared to the energy expended trying to convince the female partner to copulate. If no testes are available, there is no energy expenditure.

In Cephalopods (squids, cuttlefishes and octopi) the male deposits a special sperm package called a spermatophore in the female body cavity by way of an artificial penis. This artificial penis is known as a hectocotylus and it is a specially modified tentacle. Some species have developed a detachable penis that they can leave behind in the female's body.

Spiders (arachnids) also have an artificial penis. In their case it is a leg that doubles as a penis and is known scientifically as a maxillary palp. It is not known whether the detachable penis has the ability to grow back. Mr. Bobbit would like to know more about this possibility.

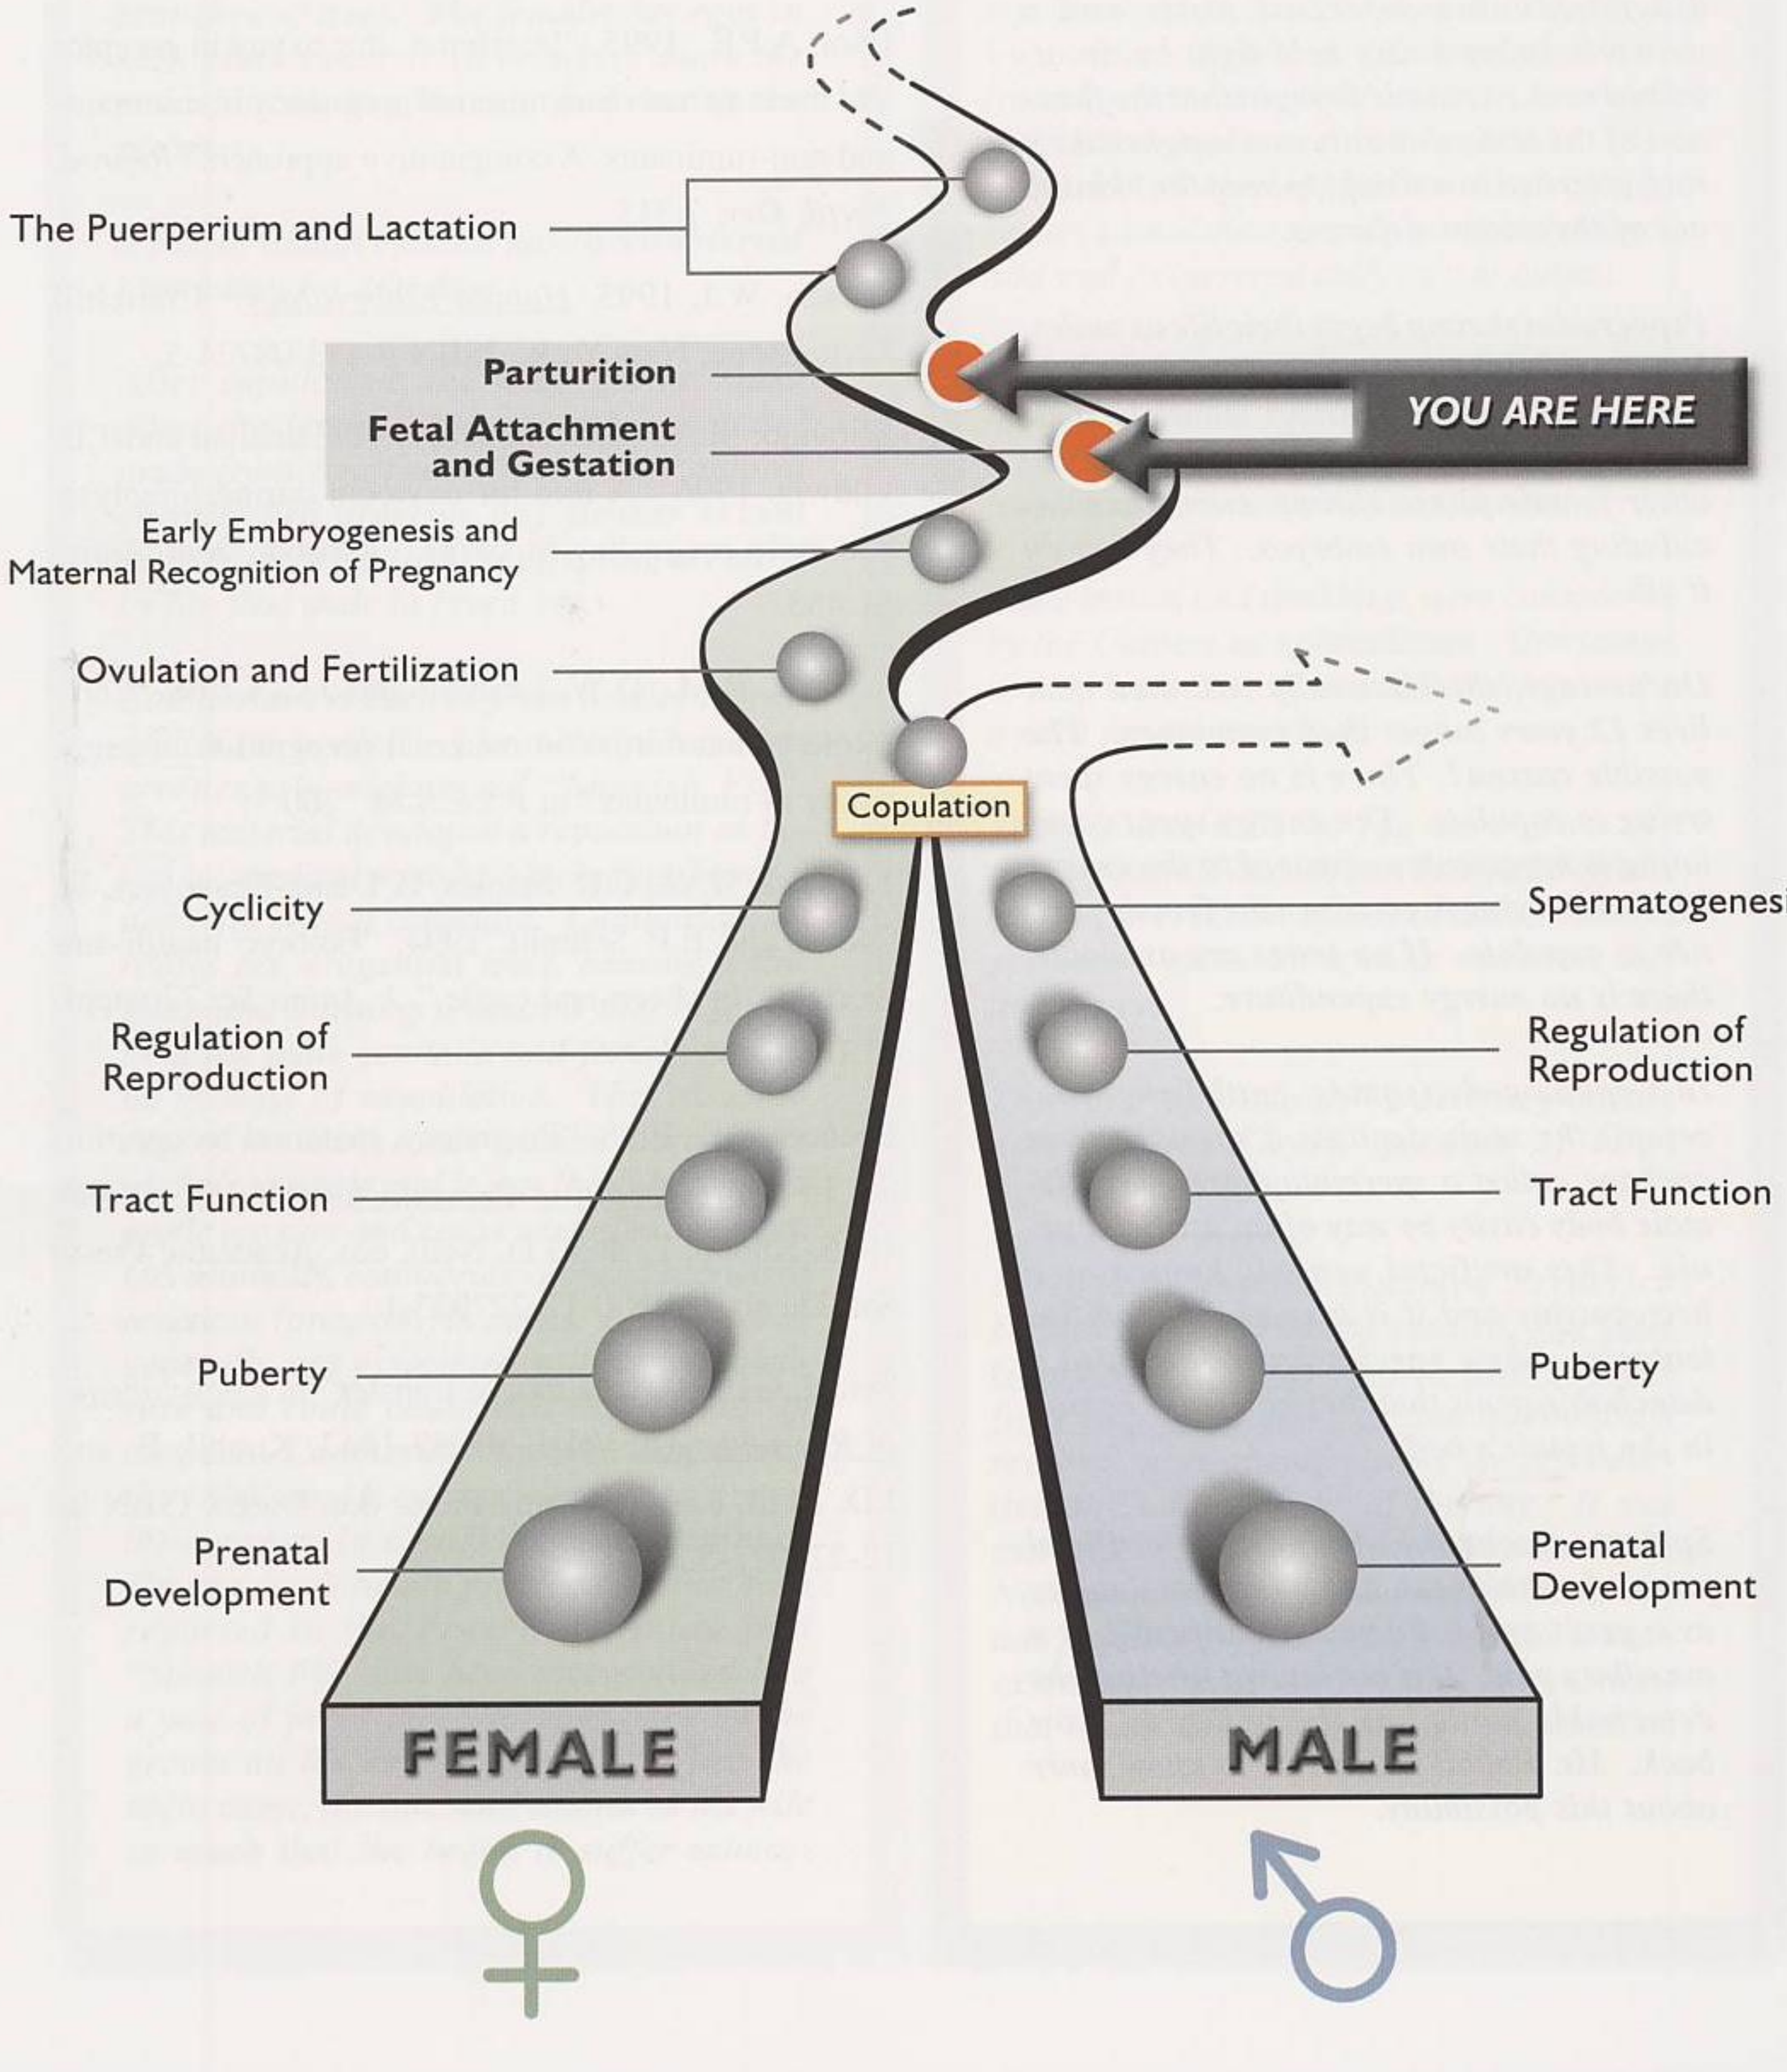
CHAPTER

14 Placentation, the Endocrinology of Gestation and Parturition



Take Home Message

The placenta is a transient organ of pregnancy that provides an interface for metabolic exchange between the dam and the fetus. Placentas are described morphologically according to the distribution of villi on the chorionic surface and the degree of separation between maternal and fetal blood. The placenta is a transitional endocrine organ that produces hormones responsible for: 1) maintenance of pregnancy; 2) stimulation of the maternal mammary gland and 3) promotion of fetal growth. Parturition is brought about by production of fetal corticoids and requires removal of the progesterone block. Parturition consists of three stages. They are: 1) initiation of myometrial contractions; 2) expulsion of the fetus and 3) expulsion of the fetal membranes.

Attachment of the conceptus to form an intimate, but temporary, relationship with the uterus is an evolutionary step that provides significant advantage to the conceptus. The phenomenon of intrauterine development ensures that the developing conceptus will receive adequate nutrition and protection during its development. In contrast, lower forms of animals lay eggs (**oviparous**). The survival of potential offspring of oviparous animals is jeopardized because the female cannot completely protect the eggs from environmental and predatory danger. Thus, **eutherian mammals** (mammals with a placenta), have a strong reproductive advantage over oviparous animals.

The final prepartum steps of reproduction are:

- ***formation of a placenta***
- ***acquisition of endocrine function of the placenta***
- ***initiation of parturition***

The term **implantation** is often used to mean **attachment** of the placental membranes to the endometrium in most animals. Actually, true implantation is a phenomenon in rodents and humans in which the conceptus "buries" itself into the uterine endometrium. The conceptus temporarily disappears beneath the surface. In most other species, the conceptus does not truly implant, but rather attaches to the endometrial surface and never disappears from the luminal compartment.

The **placenta** is a transient organ of metabolic interchange between the conceptus and the dam. It is also a transient endocrine organ. The placenta is composed of a fetal component derived from the chorion and a maternal component derived from modifications of the uterine endometrium. The discrete regions of contact between the chorion and the endometrium form specific zones of metabolic exchange. The placenta also produces a variety of hormones. This transient endocrine function is important for the maintenance of pregnancy and the induction of parturition.

Parturition (giving birth to young) is the step in the reproductive process that immediately precedes lactation, uterine involution and return to cyclicity. It is initiated by the fetus and involves a complex cascade of endocrine events that promote myometrial contractions, dilation of the cervix, expulsion of the fetus and expulsion of the extraembryonic membranes.

Placentas Have Different Distributions of Chorionic Villi

As you have learned in the previous chapter, the conceptus consists of the embryo and the extraembryonic membranes (amnion, allantois and chorion). The chorion is the fetal contribution to the placenta. The functional unit of the fetal placenta is the **chorionic villus**. Chorionic villi are small, finger-like projections that are on the surface of the chorion. These tiny villi protrude away from the chorion toward the uterine endometrium. Placentas are classified according to the distribution of chorionic villi on their surfaces, giving each placental type a distinct anatomical appearance. Placentas may also be classified by number of tissue layers separating maternal and fetal blood.

Placentas are classified according to the distribution of chorionic villi. These classifications are:

- *diffuse*
- *zonary*
- *discoid*
- *cotyledonary*

The diffuse placenta of the pig has a velvet-like surface with many closely spaced chorionic villi that are distributed over the entire surface of the chorion (See Figure 14-1). Initial attachment occurs around day 12 and is well established by day 18 to 20 after ovulation (See Chapter 13).

Diffuse placentas have uniform distribution of chorionic villi that cover the surface of the chorion.

The mare placenta is also classified as diffuse, however it is characterized by having many specialized "microzones" of chorionic villi known as **microcotyledons** (See Figure 14-1). These microcotyledons are microscopically discrete regions at the fetal-maternal interface. As in the pig, they are also distributed over the entire chorionic surface.

The mare placenta also contains unique transitory structures known as **endometrial cups**. These are discrete areas that range from a few millimeters to several centimeters in diameter. The endometrial cups are of both trophoblastic and endometrial origin. There are 5 to 10 endometrial cups distributed over the surface of the placenta (See Figure 14-6). Endometrial cups produce **equine chorionic gonadotropin (eCG)** and develop between days 35 and 60 of pregnancy. Following day 60, the endometrial cups are sloughed into the uterine lumen and are no longer functional. Attachment of the conceptus to the endometrium is initiated at about day 24 and becomes well established by 36 to 38 days (See Chapter 13).

Zonary placentas have a band-like zone of chorionic villi.

The **zonary placenta** (found in dogs and cats) includes a prominent region of exchange that forms a broad zone around the chorion near the middle of the conceptus (See Figure 14-2). A second region consists of a highly pigmented ring at either end of the central zone. This pigmented zone consists of small hematomas (blood clots). The pigmented zone is also referred to as the **paraplacenta** and is thought to be important in iron transport from the dam to the fetus. The function of this zone is not well understood. A third region is the transparent zone on the distal ends of the chorion that has poor vascularity. This zone may be involved in absorption of materials directly from the uterine lumen.

Discoid placentas form a regionalized disc.

The **discoid** placenta (See Figure 14-2) is found in rodents and primates. It is characterized by having one or two distinct adjacent discs. These discs contain chorionic villi that interface with the endometrium and provide the region for nutrient and metabolic waste exchange.

Cotyledonary placentas have numerous, discrete button-like structures called cotyledons.

Ruminants have a **cotyledonary** placenta (See Figure 14-3). A cotyledon is defined as a placental unit of trophoblastic origin consisting of abundant blood vessels and connective tissue. In sheep, there are between 90 and 100 cotyledons distributed across the surface of the chorion and, in cattle, 70 to 120 cotyledons have been observed. The **placentome** (point of interface) in the cotyledonary placenta consists of a **fetal cotyledon** contributed by the chorion and a **maternal cotyledon**, originating from the **caruncular regions** of the uterus. At about day 16 in sheep and day 25 in cattle the chorion initiates attachment to the caruncles of the uterus. Prior to this time the placenta is essentially diffuse. During the formation of the placentomes, chorionic villi protrude into crypts in the caruncular tissue. Attachment is well established by day 30 in ewes and day 40 in cows (See Chapter 13).

In the cow, the placentomes form a convex structure, while in the ewe they are concave (See Figure 14-3). During gestation, the cotyledons will increase many-fold in diameter. In fact, cotyledons in

the cow near the end of gestation may measure 5 to 6 centimeters in diameter. Such growth provides enormous surface area to support placental transfer of nutrients from the dam and metabolic wastes from the fetus.

Placental Classification by Microscopic Appearance is Based on the Number of Placental Layers that Separate the Fetal Blood from the Maternal Blood

The nomenclature for describing placental intimacy is derived by first describing the tissues of the maternal placenta in the prefix of the word. The tissues of the fetal placenta constitute the suffix. Exchange can occur through as many as six tissue layers and as few as three. The name of the prefix and suffix of each type of placenta changes depending on the number of tissue layers that exist.

Prefix ***=maternal side*** ***Suffix*** ***=fetal side***
"epithelio" ***"chorial"***
epitheliochorial

The **epitheliochorial** placenta (See Figure 14-5) is the least intimate among the placental types. In the epitheliochorial placenta, both the endometrial epithelium (maternal side) and epithelium of the chorionic villi are intact. In other words, there is a complete intact layer of epithelium in both the maternal and fetal components. The epitheliochorial placenta is found in the sow and the mare. Recall that the placentas of the sow and the mare are diffuse and villi occupy a large proportion of the surface area of the chorion.

Ruminants also have an epitheliochorial placenta. However, the endometrial epithelium transiently erodes and then regrows, causing intermittent exposure of the maternal capillaries to the chorionic epithelium. This type of placenta has been termed **syndesmochorial**.

In addition to the feature of partial erosion of the endometrial epithelium, a unique cell type is found in the ruminant placenta. These cells are called **binucleate giant cells**. As their name implies, they are characterized as being quite large and have two nuclei. Binucleate giant cells appear at about day 14 in the sheep and between days 18 and 20 in the cow. These cells originate from trophoblast cells and are believed to be formed continuously throughout gestation. Binucleate giant cells constitute around 20% of the fetal placenta. During development, the binucleate giant cells migrate from the chorionic epithelium and invade the endometrial epithelium (See Figure 14-4). The binucleate giant cells are believed to transfer complex molecules from the fetal to the maternal placenta. There is evidence that they secrete **placental lactogen**. Also, these cells secrete **pregnancy specific protein B** (**PSPB**) that are also called pregnancy associated glycoproteins (PAG). These proteins are unique to pregnancy in ruminants. The binucleate giant cells are also important sites of steroidogenesis, producing progesterone and estrogen. These cells will no doubt emerge as increasingly important "players" in the function of the ruminant placenta with further research.

The **endotheliochorial placenta** is characterized as having complete erosion of the endometrial epithelium and underlying interstitium. Thus, maternal capillaries are directly exposed to epithelial cells of the chorion (See Figure 14-5). The chorionic epithelium packs around the vessels on the maternal side. Note in Figure 14-5 that this type of placenta is more intimate than the epitheliochorial placenta because the endometrial epithelium no longer exists. Dogs and cats possess endotheliochorial placentation.

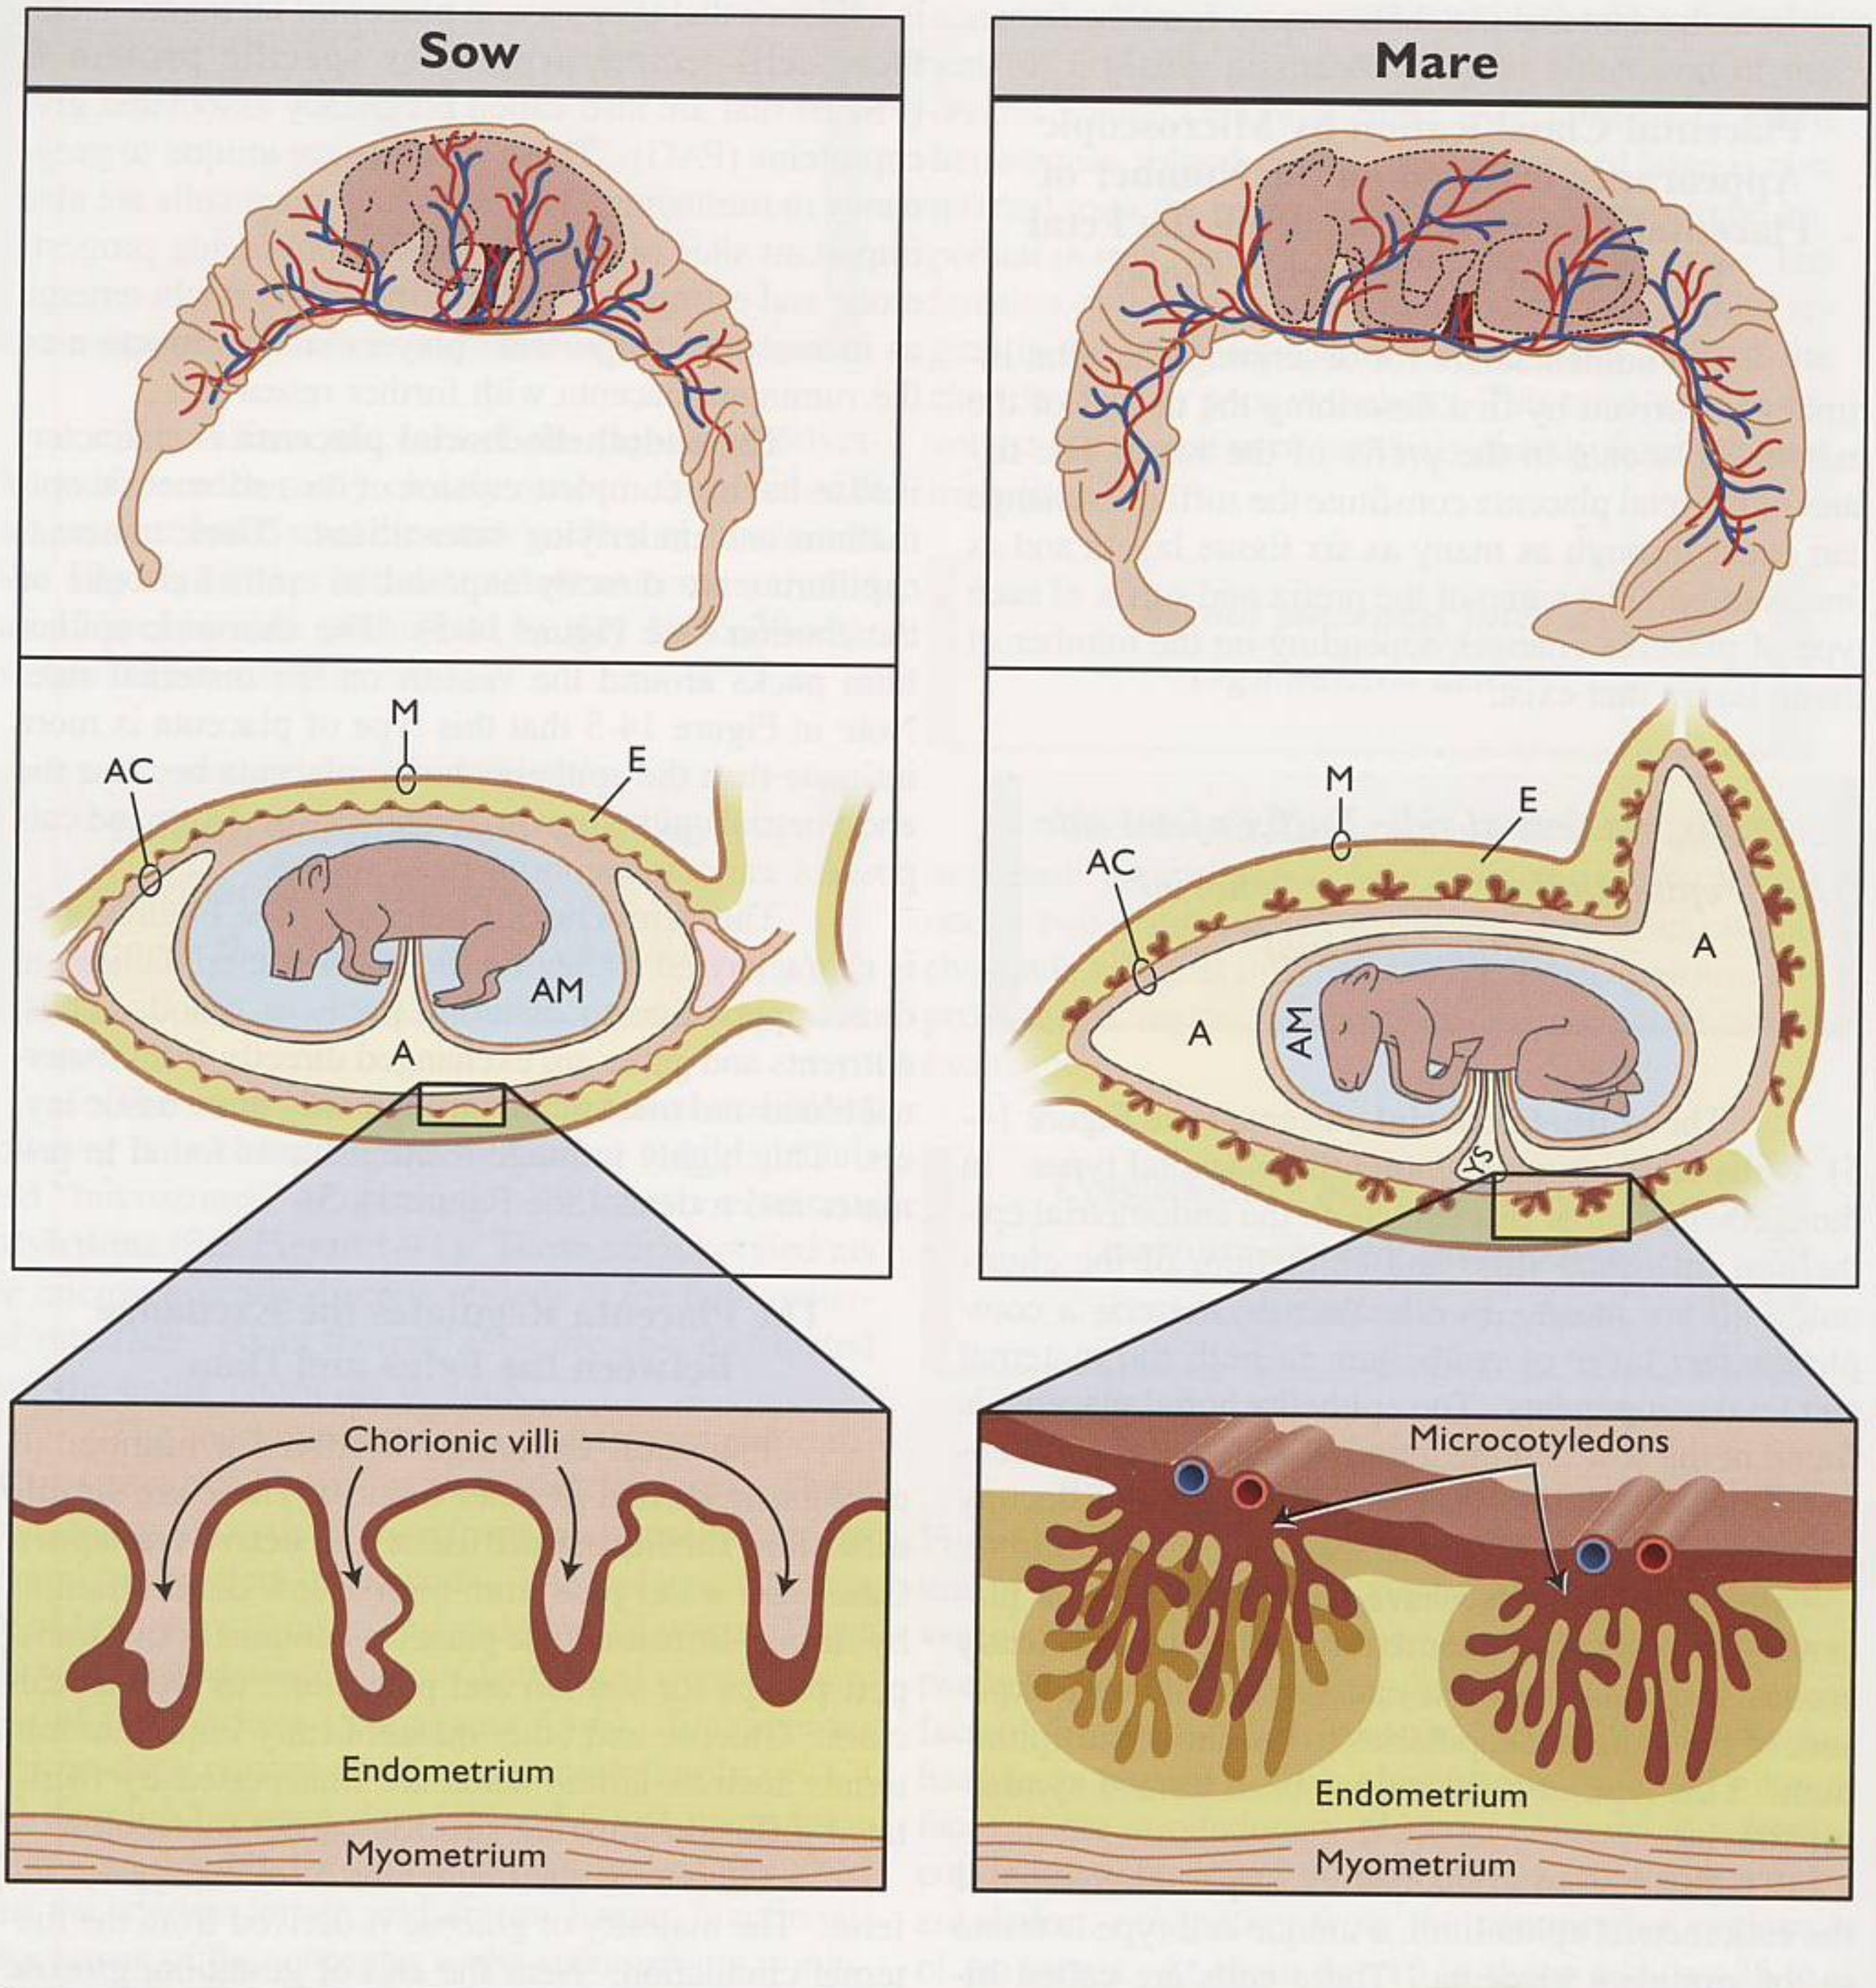
The **hemochorial placenta** (See Figure 14-5) is characterized as having the chorionic epithelium in direct apposition to maternal pools of blood. Thus, nutrients and gases are exchanged directly from maternal blood and must move through only three tissue layers. This highly intimate relationship is found in primates and rodents (See Figure 14-5).

The Placenta Regulates the Exchange Between the Fetus and Dam

Placental exchange involves a number of mechanisms found in other tissues. These are **simple diffusion**, **facilitated diffusion** and **active transport**. Gases and water pass from high to low concentrations by simple diffusion. The placenta contains active transport pumps for sodium and potassium, as well as calcium. Glucose and other metabolically important materials such as amino acids are transported by facilitated diffusion utilizing specific carrier molecules.

Glucose is the major source of energy for the fetus. The majority of glucose is derived from the maternal circulation. Near the end of gestation, glucose consumption by the fetus is exceptionally high and can lead to a metabolic drain of glucose away from the dam. Such a glucose drain favors the development of ketosis in the dam. Ketosis results from the metabolism of body fat that generate ketones for energy when glucose is limited. Periparturient ketosis is common in dairy cows where postpartum metabolic demands are exceptionally high because of high milk production. Some materials cannot be transported across the

Figure 14-1. The Diffuse Placenta

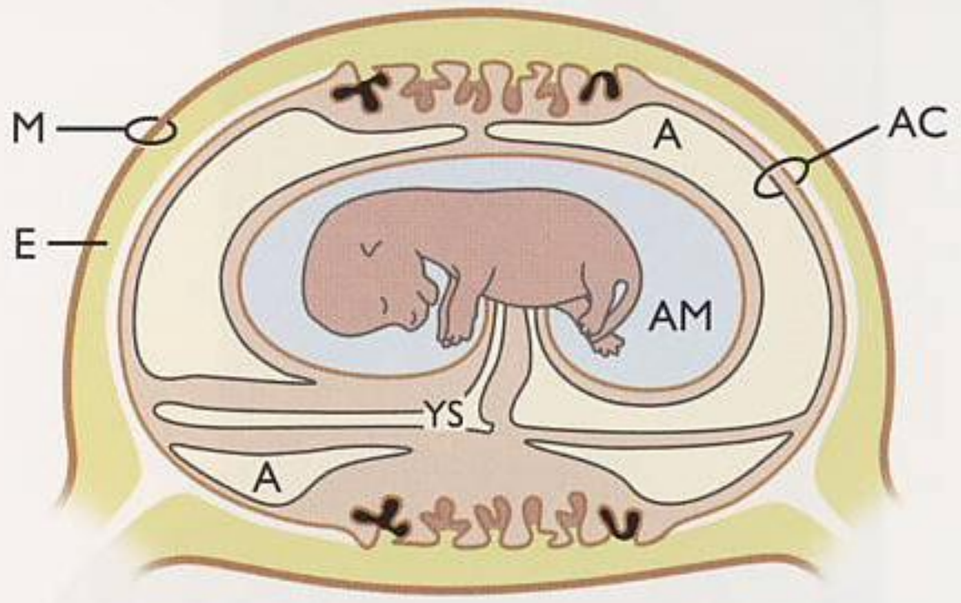


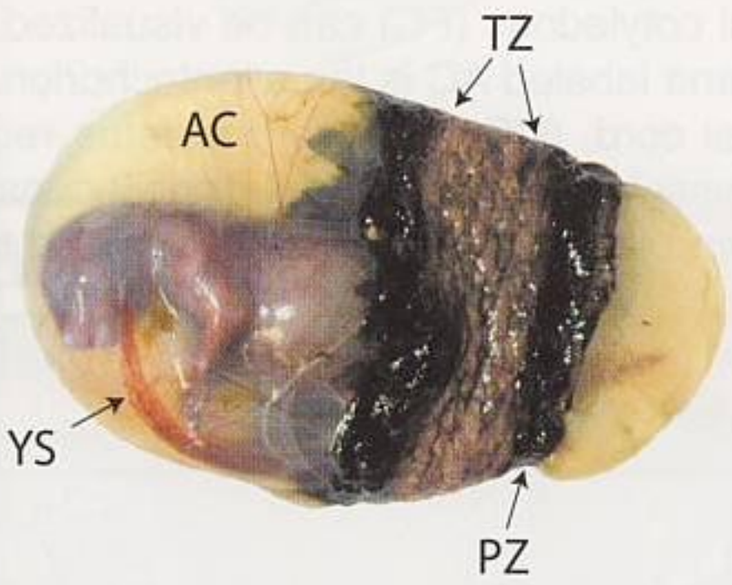
The diffuse placenta of the sow consists of many chorionic villi distributed over the entire surface of the chorion. They penetrate into the endometrium forming the fetal-maternal interface. Vessels from each chorionic villus merge and eventually form large vessels that enter the umbilical cord. A= Allantois, AC= Allantochorion, AM= Amnionic Cavity, E= Endometrium, M= Myometrium

The diffuse placenta of the mare consists of many microcotyledons distributed over the entire surface of the chorion. These microcotyledons are the site of fetal-maternal exchange. A= Allantois, AC= Allantochorion, AM= Amnionic Cavity, E= Endometrium, M= Myometrium, YS= Yolk Sac

Figure 14-2. The Zonary and Discoid Placentas

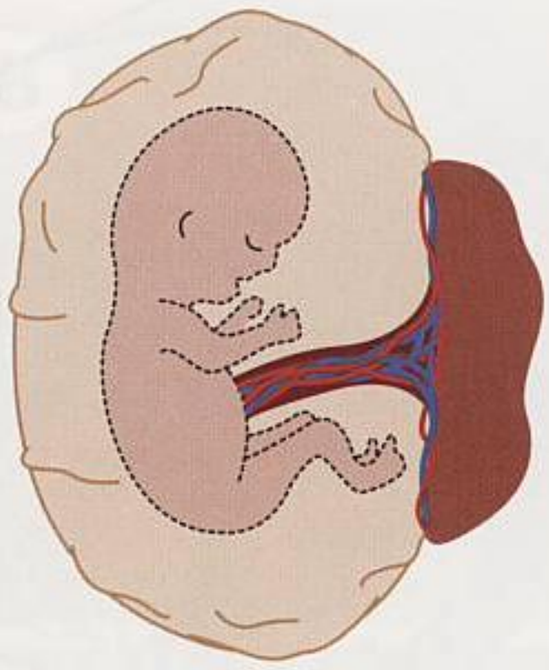
Bitch

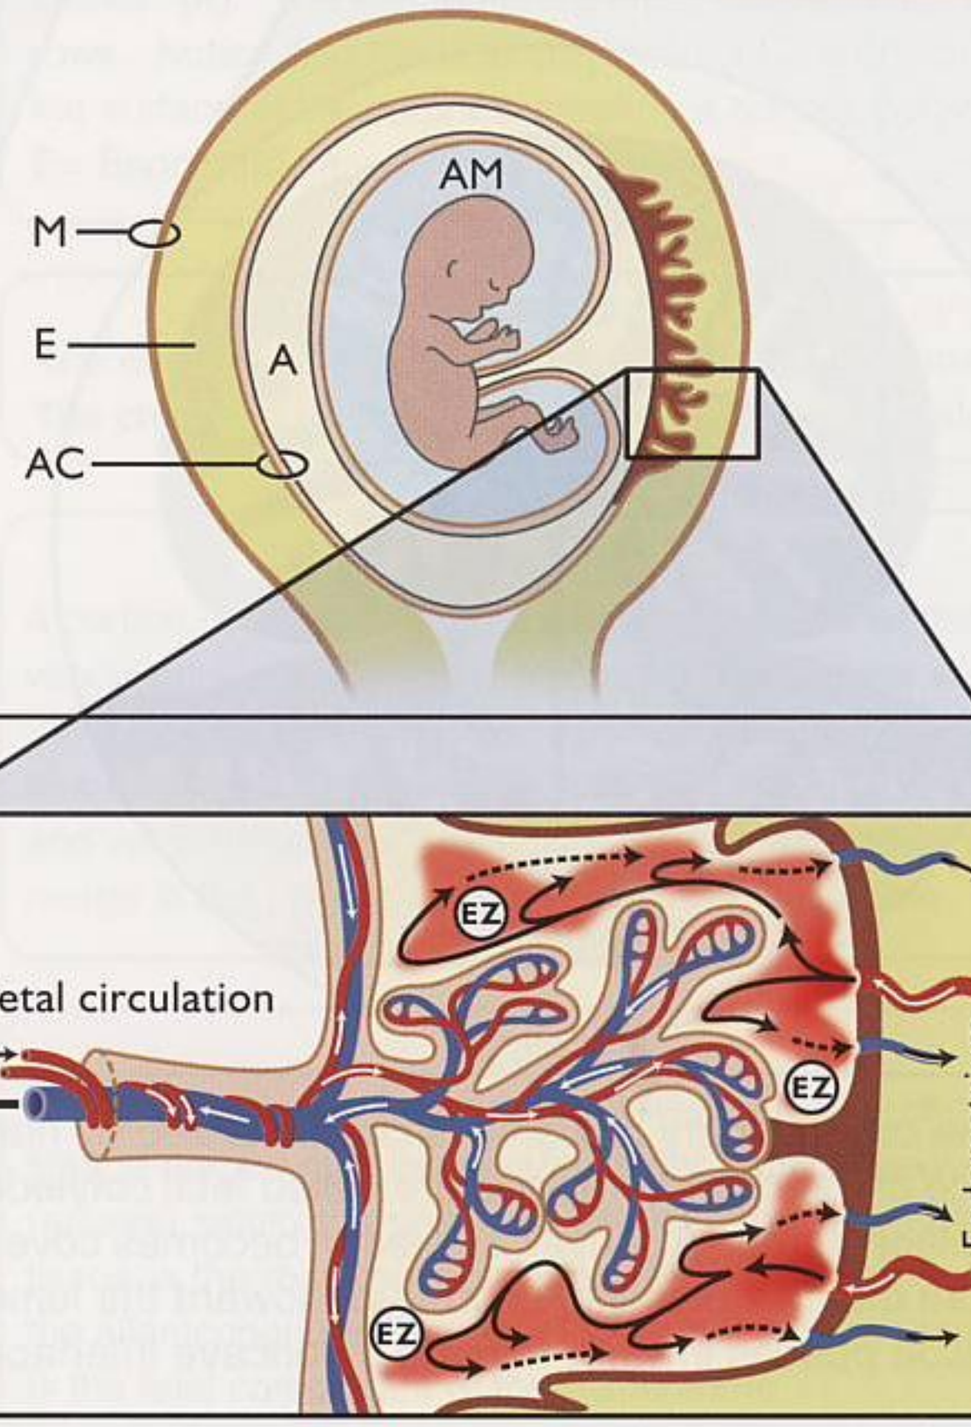




The zonary placenta consists of three distinct zones; a transfer zone (TZ), a pigmented zone (PZ) and a relatively nonvascular zone, the allantochorion (AC). In the zonary placenta, a band of tissue forms around the conceptus where nutrient transfer occurs. The pigmented zone (PZ) or paraplacenta represents local regions of maternal hemorrhage and necrosis.
A= Allantois, AC= Allantochorion, AM= Amnionic Cavity, E= Endometrium, M= Myometrium, YS= Yolk Sac

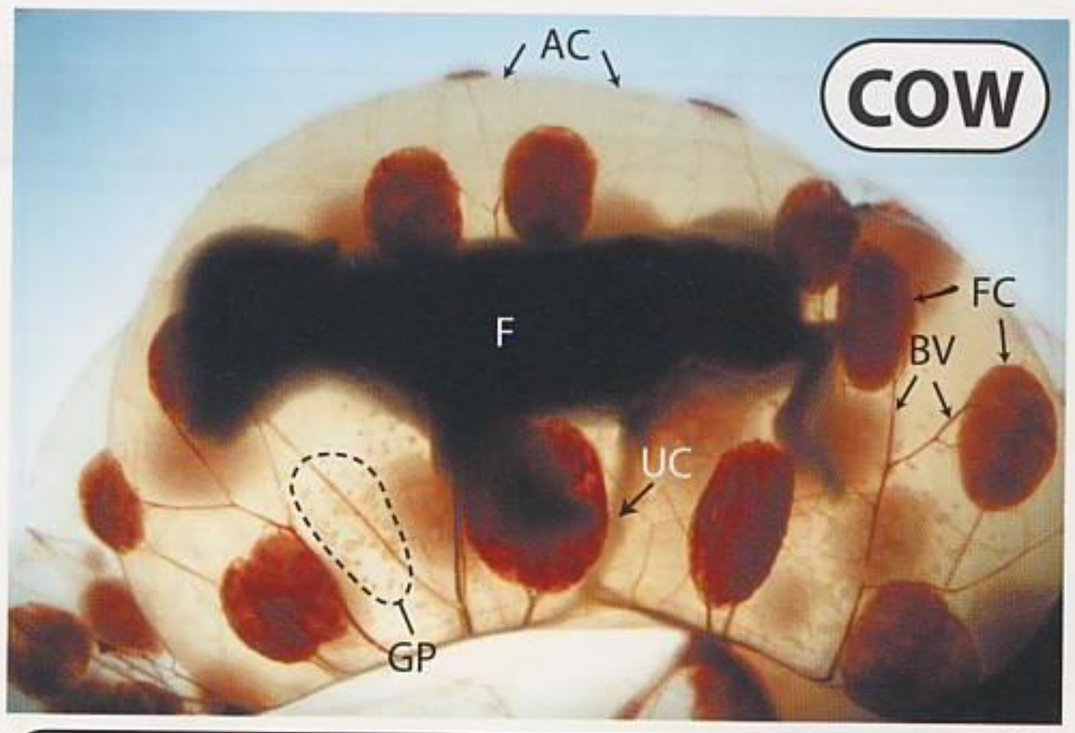
Primates



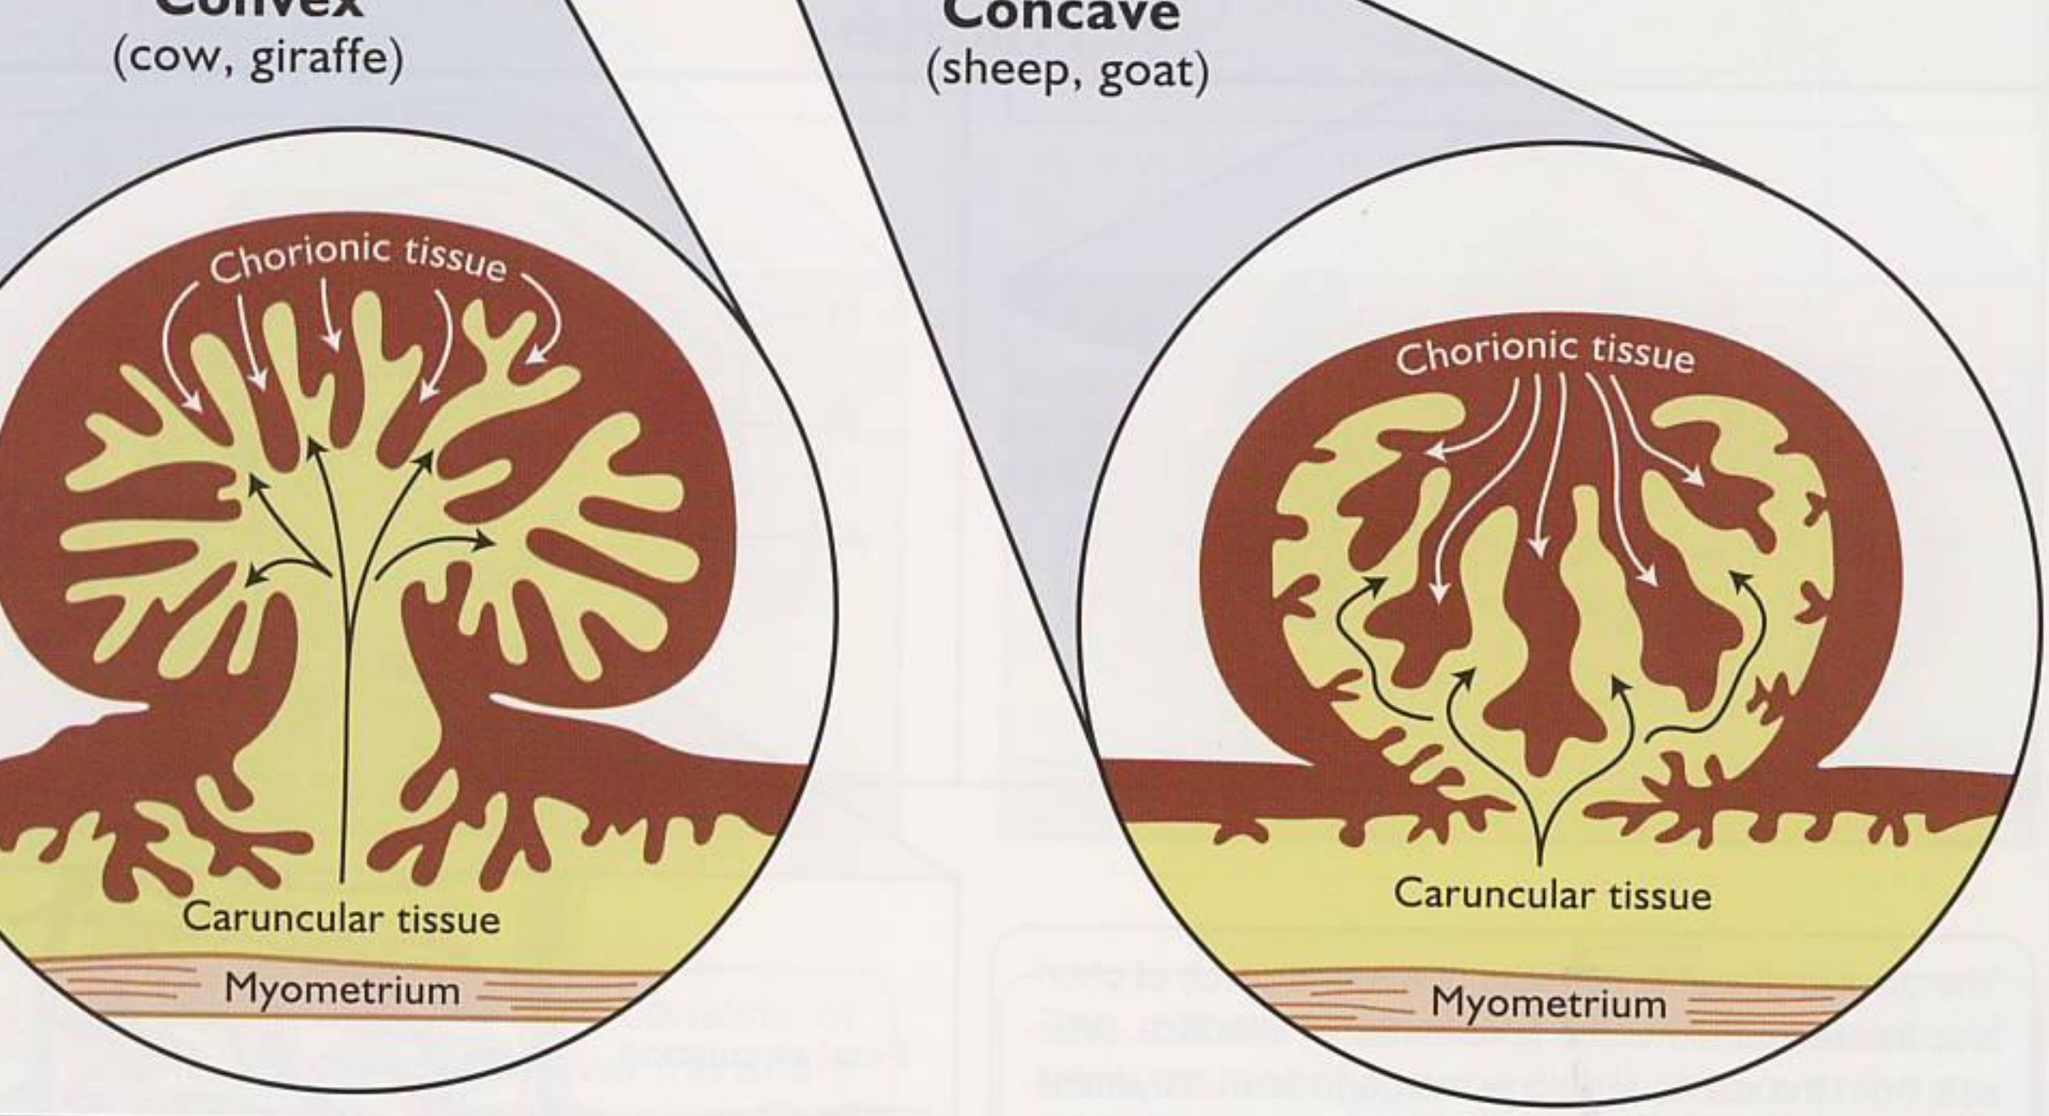


The discoid placenta consists of a round patch of chorionic tissue that forms the fetal-maternal interface. Vessels from the exchange zone merge to form the umbilical vessels that supply the fetus with blood. The vasculature of the chorion (within the disc) is immersed in pools of blood where metabolic exchange takes place.
A = Allantois, AC = Allantochorion,
AM = Amnionic Cavity, E = Endometrium,
EZ = Exchange Zone, M = Myometrium

Figure 14-3. The Cotyledonary Placenta

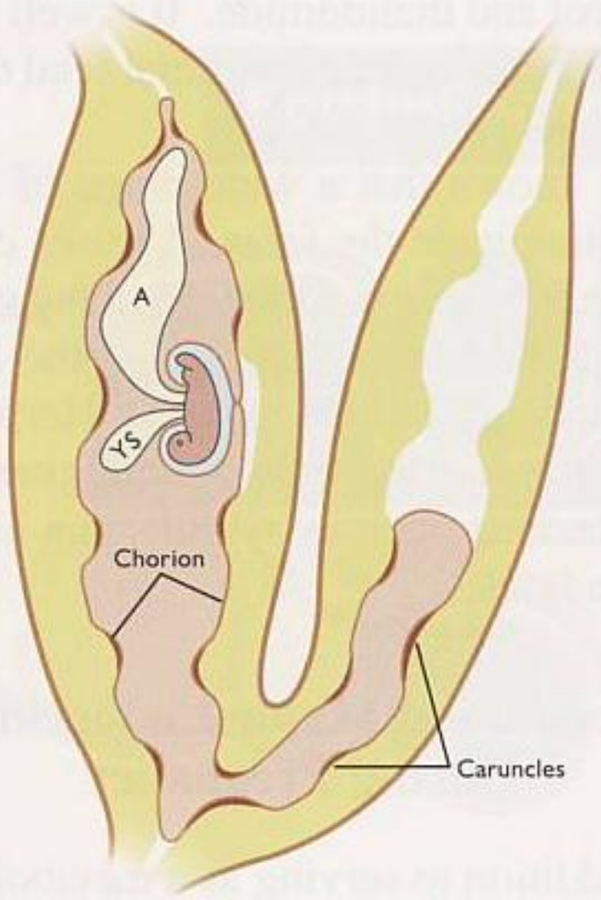


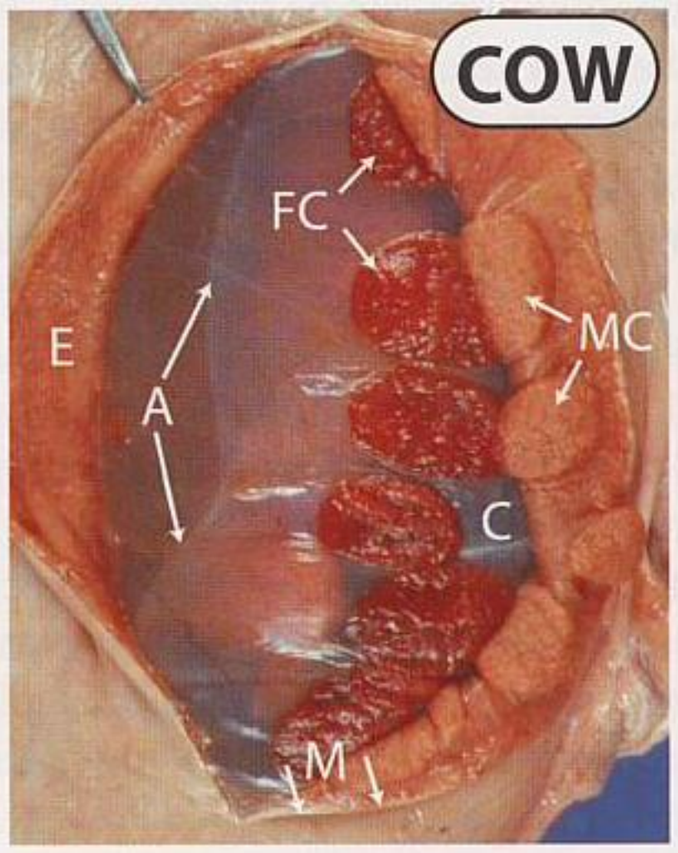
In the photograph above, the fetal membranes and the fetal cotyledons (FC) can be visualized. The membrane labeled AC is the allantochorion. The umbilical cord, (UC-arrow) of the fetus receives blood vessels (BV) from the fetal cotyledons (FC). Glycogen plaques (GP) can be visualized on the surface of the chorion and the amnion. These plaques are localized squamous proliferations called verrucae.

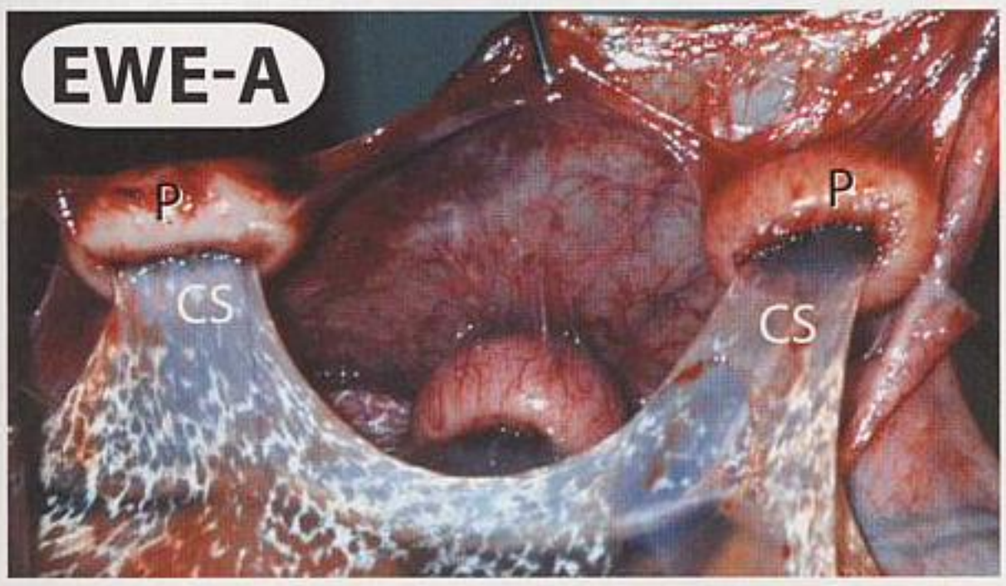


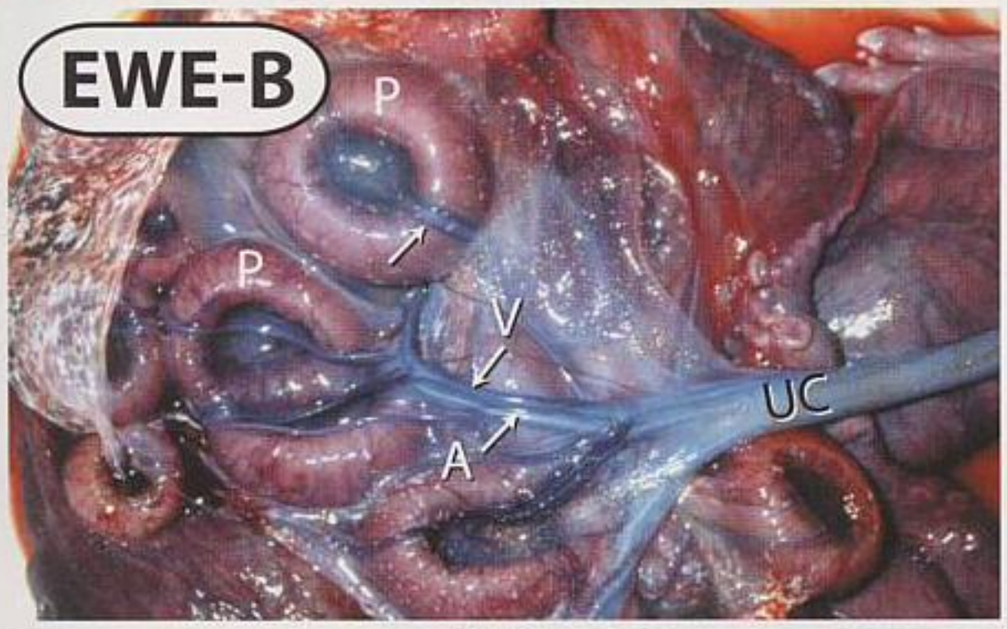
The cotyledonary placenta is characterized by numerous "button-like" structures distributed across the surface of the chorion. These are called fetal cotyledons. When they join with the maternal caruncle they form a placentome. A convex cotyledon becomes covered with the chorion. Many finger-like villi (red) originating from the chorionic tissue protrude toward the lumen of the uterus. In the concave cotyledon, the chorionic tissue pushes inward, forming a concave interface between the chorion and the maternal caruncle.

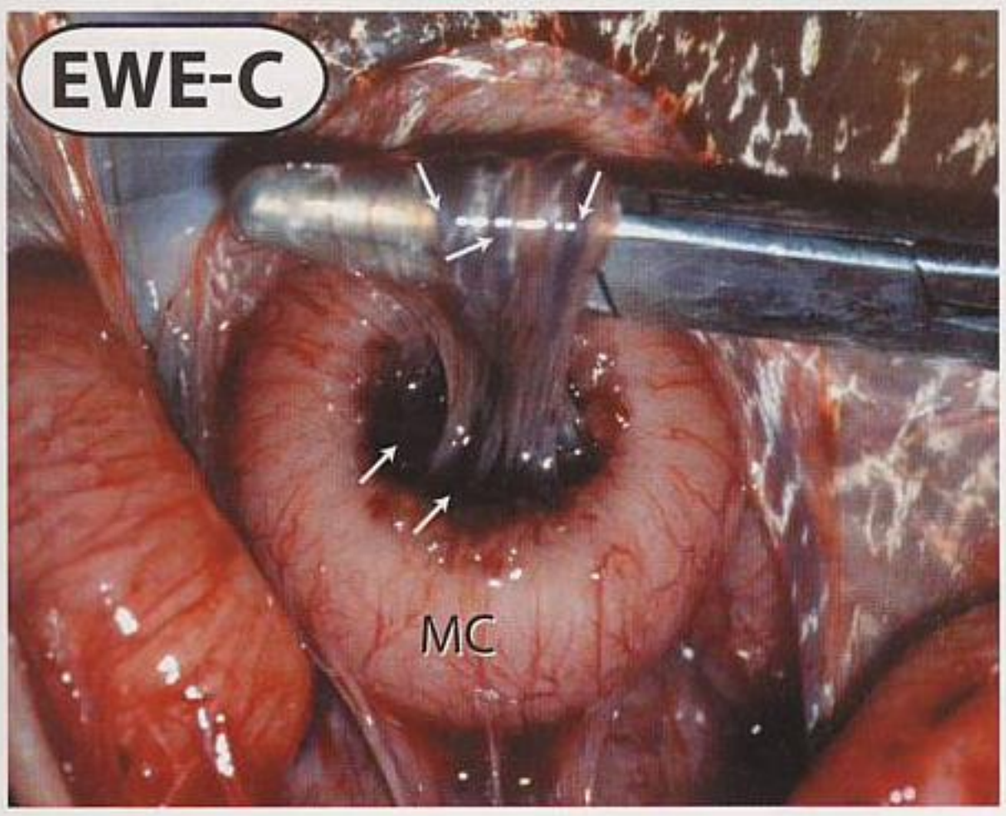
Figure 14-3. The Cotyledonary Placenta











The diagram in the upper left illustrates the distribution of the extraembryonic membranes prior to complete attachment. The extraembryonic membranes consist of the amnion (blue sac), yolk sac (YS) and the allantois (A). Even though the fetus is located in one uterine horn, the chorion invades the contralateral uterine horn and forms placentomes.

Cow

Some fetal cotyledons (FC) have been partially separated from maternal cotyledons (MC). The chorion (C) is the outer fetal membrane. Arrows indicate the border of the amnion (A). The myometrium (M) is indicated by the arrows. Notice that the fetal cotyledon (FC) is attached to the surface of the caruncle creating a convex cotyledon. E= Endometrium

Ewe-A

The chorion can be seen entering the placentome (P). The chorionic stalk (CS) contains the fetal vasculature.

Ewe-B

A portion of the chorion has been incised so that the fetal vasculature can be visualized clearly. The fetal vessels (arrow) and chorionic tissue "push" into the caruncular tissue forming a concave cotyledon. A set of arteries (A) and veins (V) emerge from each cotyledon and eventually merge in the umbilical cord (UC). P= Placentome

Ewe-C

A concave placentome is clearly visible. The chorionic stalk is draped over the needle holder. Notice the vessels (arrows) within the chorionic tissue. The reddish-beige tissue is the maternal cotyledon (MC) that is covered by the allantochorion. The dark tissue in the center (arrows) is the fetal component of the placentome.

placenta. With the exception of some immunoglobulins, maternal proteins do not cross the placental barrier. Immunoglobulins can be transported from the maternal to the fetal side in a hemochorial or an endotheliochorial placenta. However, the fetus synthesizes the majority of its own proteins from amino acids contributed by the dam. Lipids do not cross the placenta. Instead, the placenta hydrolyzes triglycerides and maternal phospholipids and synthesizes new lipid materials to be used by the fetus. Large peptide hormones such as thyroid stimulating hormone, adrenal cortical stimulating hormone, growth hormone, insulin and glucagon do not cross the placenta. Smaller molecular weight hormones such as steroids, thyroid hormone and the catecholamines (epinephrine and norepinephrine) cross the placenta with relative ease. Vitamins and minerals are transferred to the fetus at variable rates. Fat soluble vitamins do not cross the placenta with ease, while water soluble vitamins (B and K) pass across the placenta with relative ease. Nutrients are also transferred by pinocytosis and phagocytosis. Areolae from the chorion form over the openings of the uterine glands and are thought to absorb secretions from these glands.

Of significant importance is the ability of the placenta to transfer toxic and potentially pathogenic materials. Many toxic substances easily cross the placental barrier. These include ethyl alcohol, lead, phosphorus and mercury. Also, opiate drugs and numerous common pharmaceuticals such as barbiturates and antibiotics can cross the placental barrier. Some substances may be highly **teratogenic**. Teratogenic means inducing abnormal development (birth defects). These substances include LSD, amphetamines, lithium, diethylstilbestrol and thalidomide. It is well documented that these materials induce abnormal fetal development and cause serious birth defects.

It is known that a wide range of microorganisms can contaminate the fetus. Viruses can cross the placental barrier with ease and thus many viral diseases can be transmitted from the dam to the fetus. Such human diseases as German measles, Herpes virus and HIV can be transmitted from the pregnant mother to the fetus. Bacteria such as syphilis can also be transmitted to the fetus.

The Placenta is a Major Endocrine Organ During Pregnancy

In addition to serving as a metabolic exchange organ, the placenta serves as a transitory endocrine organ. Hormones from the placenta gain access to both the fetal and the maternal circulation.

The placenta produces hormones that can:

- ***stimulate ovarian function***
- ***maintain pregnancy***
- ***influence fetal growth***
- ***stimulate mammary function***
- ***assist in parturition***

The placenta of the mare produces a gonadotropin called **equine chorionic gonadotropin (eCG)**. Equine chorionic gonadotropin is also called **pregnant mare's serum gonadotropin (PMSG)**. Equine chorionic gonadotropin is produced by the endometrial cups of the placenta. Endometrial cups are a transient placental endocrine gland. They begin producing eCG at the time of attachment of the conceptus to the endometrium. The relationship between the formation of the endometrial cups in the mare and the synthesis of eCG is presented in Figure 14-6. As you can see, the production of eCG is closely related to the weight of the endometrial cups.

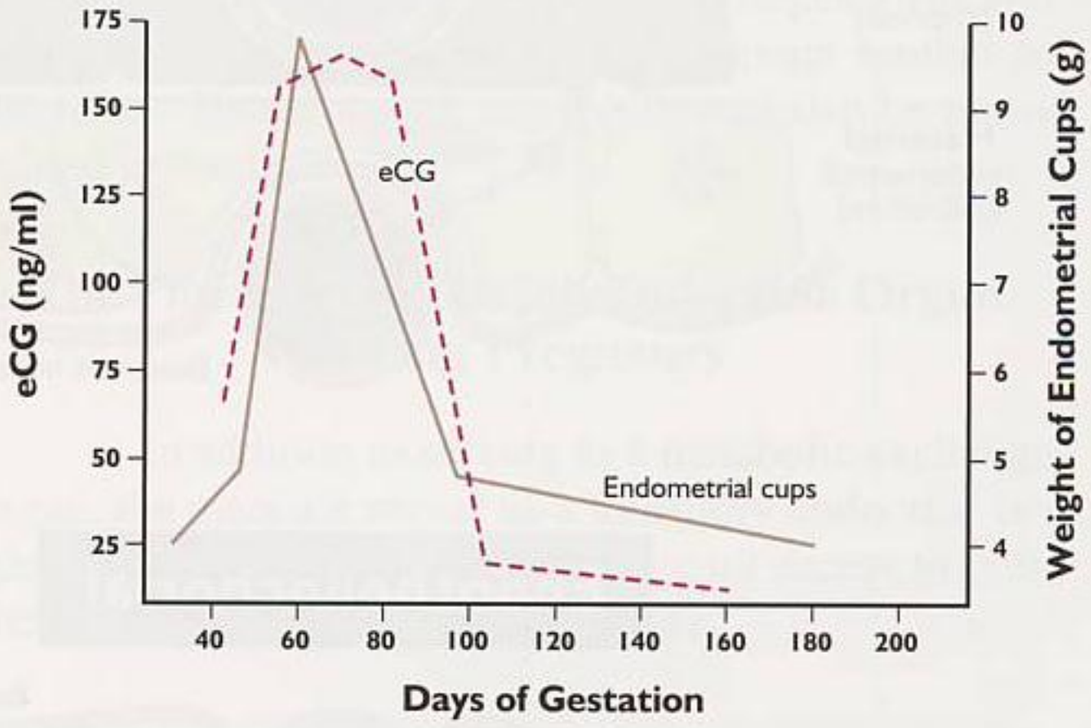
Equine chorionic gonadotropin acts as a luteotropin and provides a stimulus for maintenance of the **primary corpus luteum**. The primary corpus luteum in the mare is defined as the corpus luteum formed from the ovulated follicle. In addition, eCG is responsible for controlling the formation and maintenance of **supplementary (accessory) corpora lutea**. As eCG increases, the pregnant mare will often ovulate, thus generating accessory corpora lutea. The eCG-induced ovulations occur between days 40 and 70 of pregnancy. Luteinization (promoted by eCG) also occurs in antral follicles that do not ovulate. Thus, eCG has a significant positive impact on the ability of the ovary to produce progesterone. Indeed, if one examines the progesterone profile, it can be seen that there is a close relationship between the concentrations of progesterone and the production of accessory corpora lutea (See Figure 14-7).

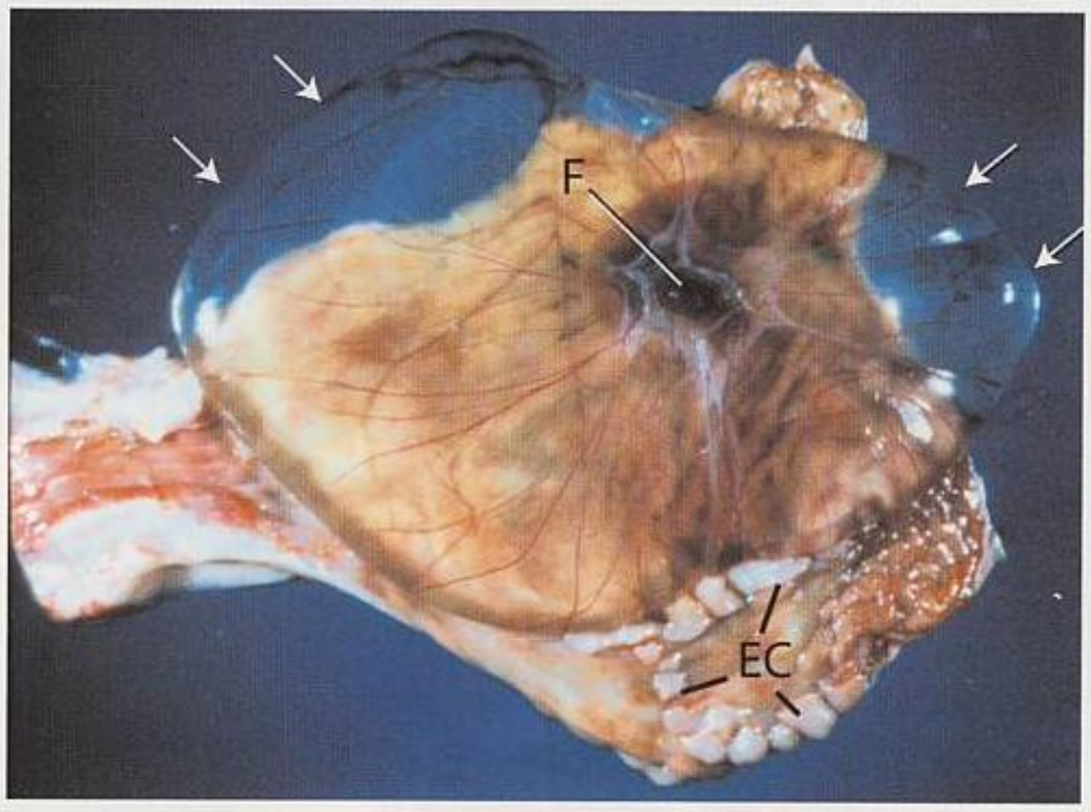
In addition to its luteotropic action, eCG has powerful FSH-like actions when administered to females of other species. In fact, eCG will cause marked follicular development in most species. It is used commonly to induce superovulation where embryo transfer is performed (cow, sheep, rabbit). In mares, however, eCG does not exert significant FSH-like action.

The second major gonadotropin of placental origin is **human chorionic gonadotropin (hCG)**. This hormone is not only found in the human but in many other primates. Often hCG (and eCG) may simply be referred to as "CG". It originates from the trophoblastic cells of the chorion and is secreted as soon as the blastocyst hatches from the zona pellucida. Human chorionic gonadotropin can be detected in the blood and urine of the pregnant woman as early as days 8 to 10 of gestation. It increases rapidly in the urine of the pregnant woman, reaching a maximum value at about 2.5 months (See Figure 14-8). Its presence in the urine constitutes the basis for over-the-counter pregnancy diagnosis kits.

The primary role of hCG during early pregnancy is to provide a luteotropic stimulus for the ovulatory corpus luteum as it transitions into the CL of

Figure 14-6. Production of Equine Chorionic Gonadotropin (eCG) is Closely Related to the Weight of the Endometrial Cups
(Modified from Ginther, *Reproductive Biology of the Mare*)





Endometrial cups (EC) are seen here in a U-shaped configuration. The fetus (F) is surrounded by the amnion (not visible). The membrane indicated by arrows is the allantochorion. This specimen was removed from a mare at 50 days of gestation. (Photograph courtesy of Dr. O.J. Ginther from *Reproductive Biology of the Mare, 2nd Ed.*)

Figure 14-7. Luteal Progesterone Output During the First Half of Gestation in the Mare

(Modified from Ginther, *Reproductive Biology of the Mare*)

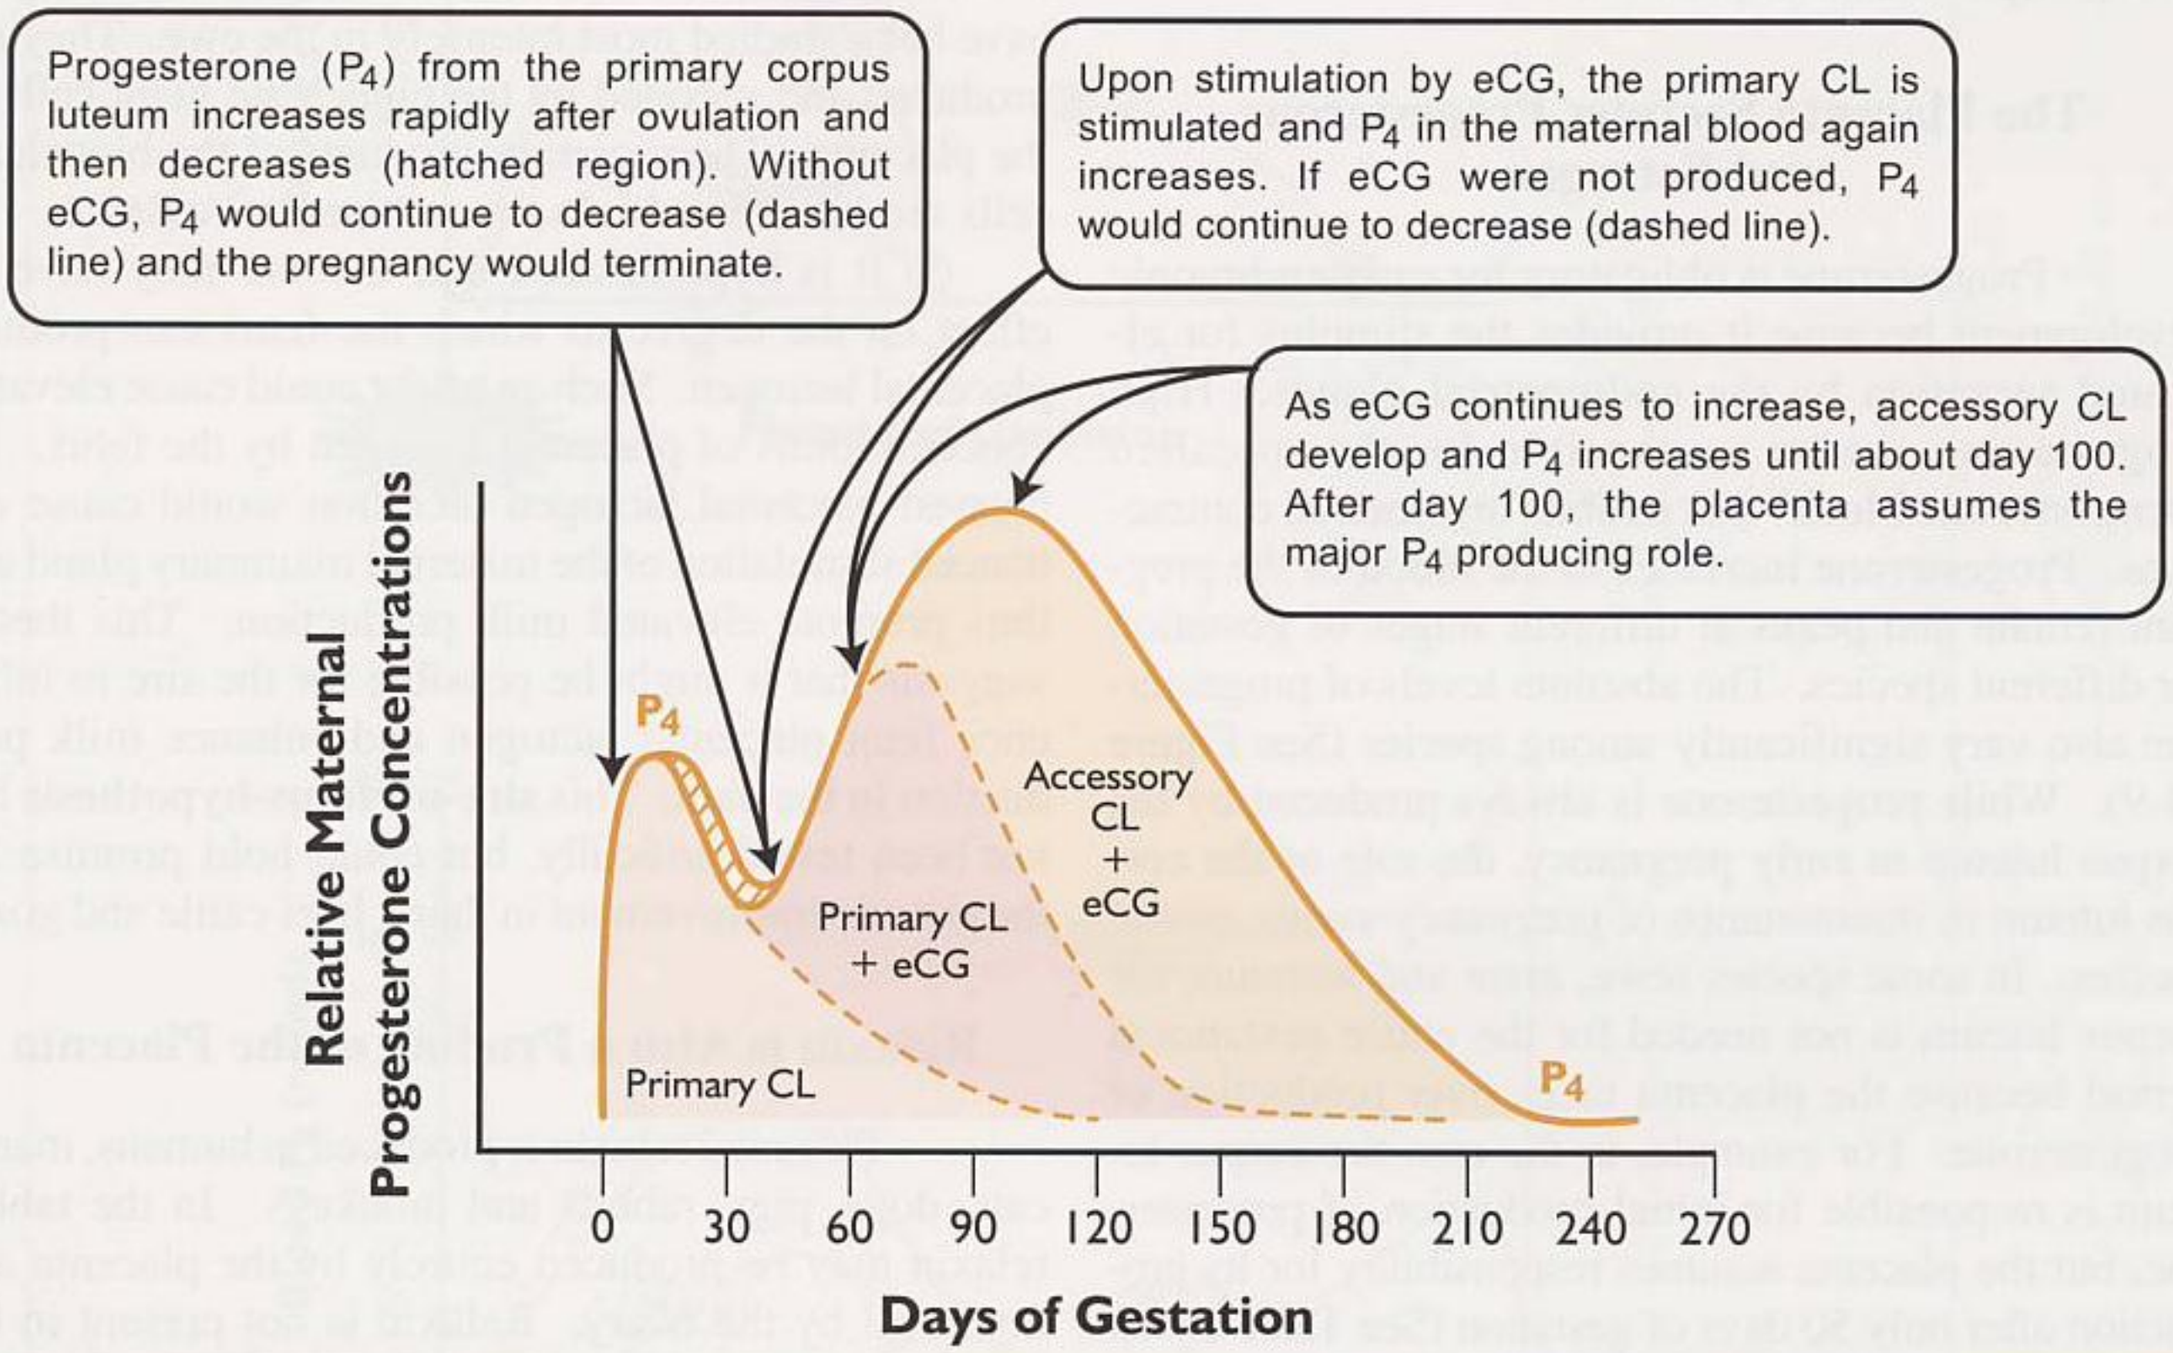


Figure 14-8. The Production of hCG and Progesterone During Gestation in the Pregnant Woman

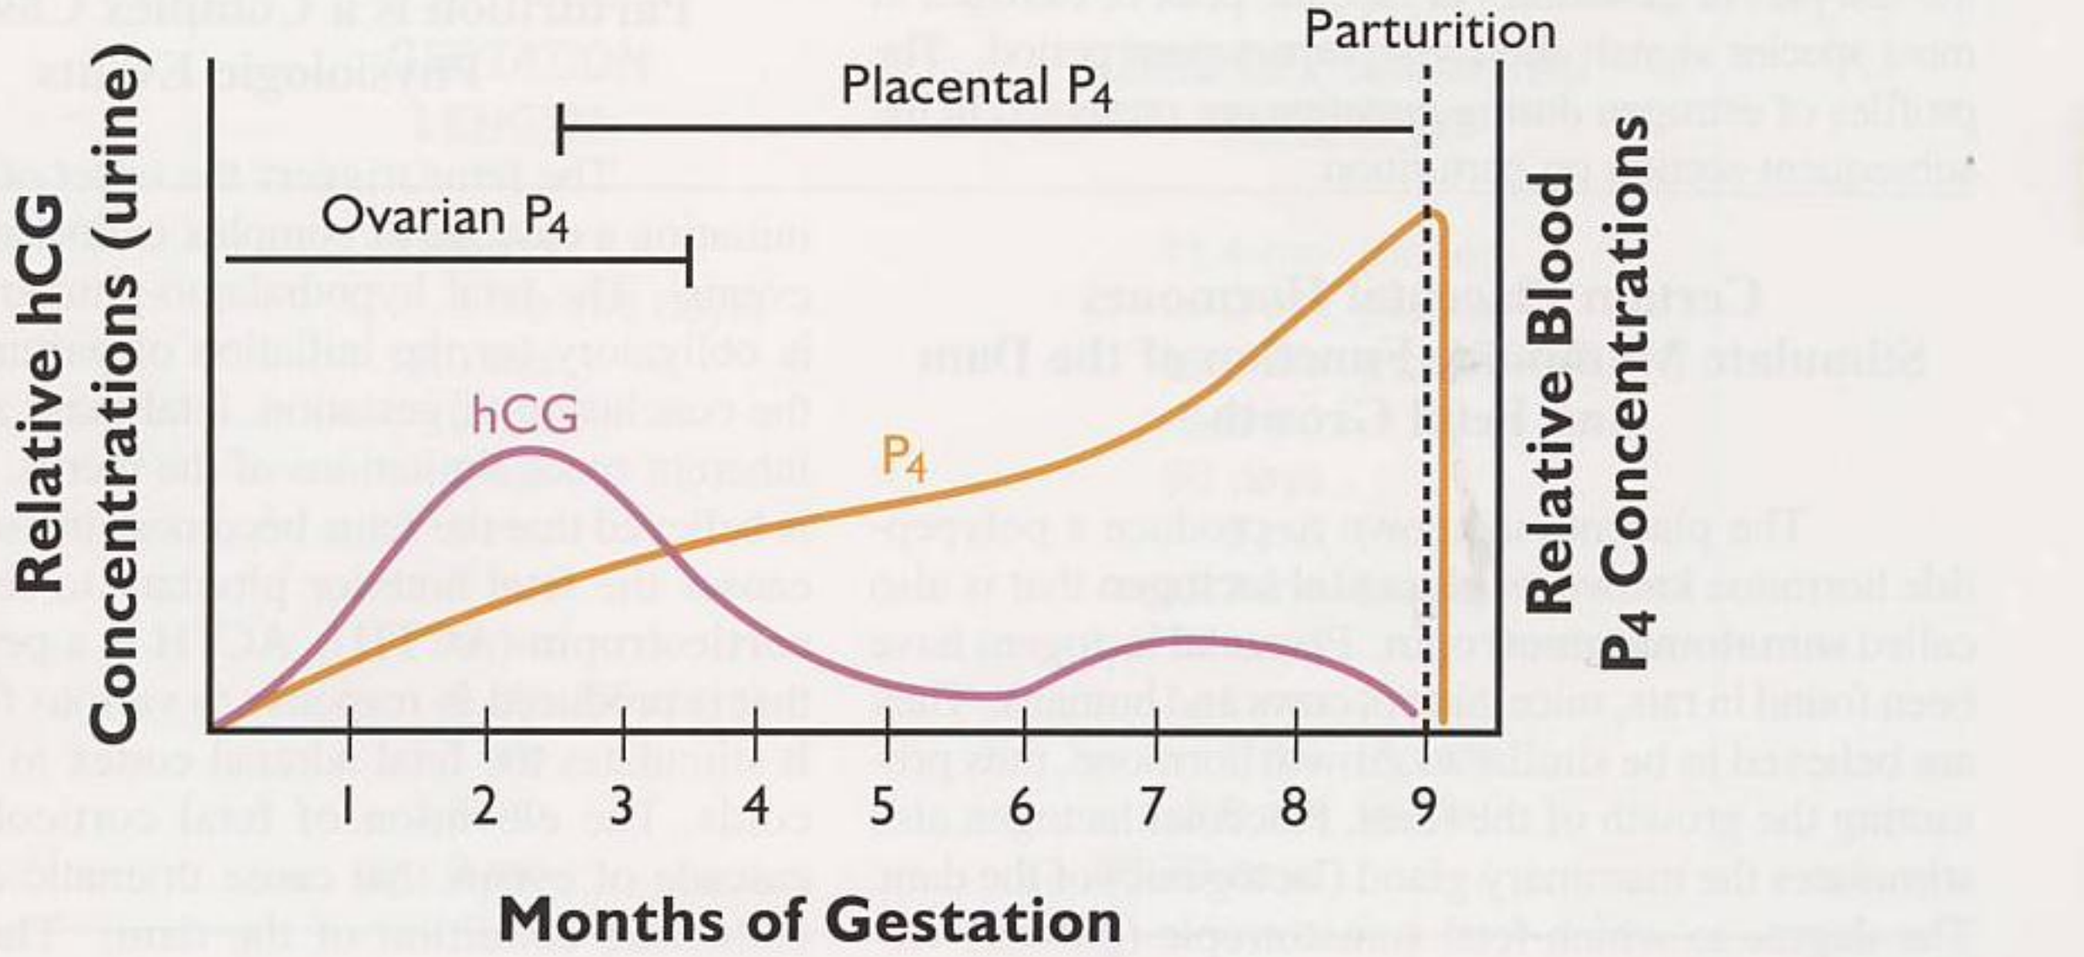
Human chorionic gonadotropin peaks at about 2.5 months of gestation and then declines. This period of time is critical for maintenance of pregnancy because the corpus luteum assumes primary responsibility for progesterone secretion.

At about 2.5 to 3 months of gestation the placenta begins to assume the primary responsibility for progesterone secretion and continues this role until the time of parturition. hCG increases slightly between months 6 and 9 because of the increased placental mass.



pregnancy. Luteal LH receptors also bind hCG resulting in sustained progesterone production. Administration of hCG to non-primate females can cause ovulation. In fact, hCG is used commonly to induce ovulation in superovulation protocols.

The Placenta Secretes Progesterone and Estrogen

Progesterone is obligatory for early embryonic development because it provides the stimulus for elevated secretion by the endometrial glands. High progesterone is also responsible for the so-called "**progesterone block**" that inhibits myometrial contractions. Progesterone increases in the blood of the pregnant female and peaks at different stages of gestation for different species. The absolute levels of progesterone also vary significantly among species (See Figure 14-9). While progesterone is always produced by the corpus luteum in early pregnancy, the role of the corpus luteum in maintenance of pregnancy varies among species. In some species (ewe, mare and woman), the corpus luteum is not needed for the entire gestational period because the placenta takes over production of progesterone. For example, in the ewe the corpus luteum is responsible for initial production of progesterone, but the placenta assumes responsibility for its production after only 50 days of gestation (See Table 14-1). In other species, lutectomy (surgical removal of corpora lutea) will terminate pregnancy regardless of when this occurs during gestation (sow or rabbit). Lutectomy in the cow up to 8 months of gestation will result in abortion. It should be pointed out that even though the placenta takes over for the corpus luteum of pregnancy, the corpus luteum produces progesterone throughout gestation.

In addition to progesterone, estrogens are also an important product of the placenta, particularly during the last part of gestation. In fact, the peak of estrogen in most species signals the early preparturient period. The profiles of estrogen during gestation are presented in the subsequent section on parturition.

Certain Placental Hormones Stimulate Mammary Function of the Dam and Fetal Growth

The placenta is known to produce a polypeptide hormone known as **placental lactogen** that is also called **somatomammotropin**. Placental lactogens have been found in rats, mice, sheep, cows and humans. They are believed to be similar to growth hormone, thus promoting the growth of the fetus. Placental lactogen also stimulates the mammary gland (lactogenic) of the dam. The degree to which fetal somatotropic (growth) versus lactogenic effects occur depends on the species (See Figure 14-10). For example, in the ewe **ovine placental lactogen (oPL)** has a more potent lactogenic activity than somatotropic activity. A similar condition exists in humans, but not in the cow. Placental lactogens have been studied most intensely in the ewe. They are produced and secreted by the binucleate giant cells of the placenta. The secretory products of the binucleate cells are transferred into the maternal circulation.

It is hypothesized that the sire may have an effect on the degree to which the fetus can produce placental lactogen. Such an effect could cause elevated concentrations of placental lactogen by the fetus. Increased placental lactogen secretion would cause enhanced stimulation of the maternal mammary gland and thus promote elevated milk production. This theory suggests that it might be possible for the sire to influence fetal placental lactogen and enhance milk production in the dam. This **sire-on-fetus-hypothesis** has not been tested critically, but could hold promise for the genetic improvement in dairy, beef cattle and goats.

Relaxin is Also a Product of the Placenta

Placental relaxin is produced in humans, mares, cats, dogs, pigs, rabbits and monkeys. In the rabbit, relaxin may be produced entirely by the placenta and not at all by the ovary. Relaxin is not present in the bovine placenta during any stage of gestation. It is likely (with the exception of the rabbit) that relaxin, during the time of parturition, originates from both the ovary and the placenta. A possible exception to this may be the cow, because ovariectomy does not result in calving difficulties. The role of relaxin is therefore questionable in the cow. Maternal blood relaxin levels are the basis for a commercial pregnancy detection test at about 30 days of gestation in the bitch.

Parturition is a Complex Cascade of Physiologic Events

The fetus triggers the onset of parturition by initiating a cascade of complex endocrine/biochemical events. The fetal hypothalamo-pituitary-adrenal axis is obligatory for the initiation of parturition. During the conclusion of gestation, fetal mass approaches the inherent space limitations of the uterus. As a result, it is believed that the fetus becomes stressed. Such stress causes the fetal anterior pituitary to release **adrenal corticotropin (ACTH)**. ACTH is a peptide hormone that is produced in response to various forms of stress. It stimulates the fetal adrenal cortex to produce corticoids. The elevation of fetal corticoids initiates a cascade of events that cause dramatic changes in the endocrine condition of the dam. These endocrine

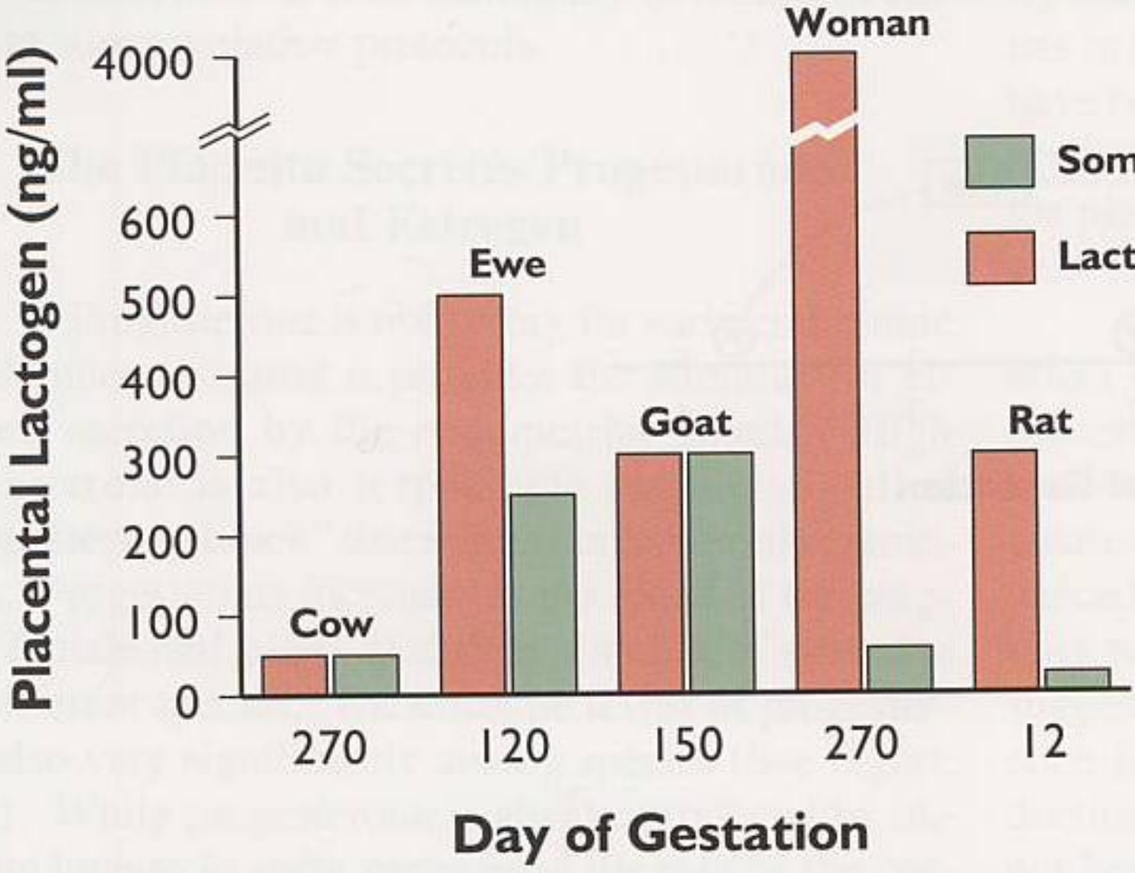
Figure 14-10. Placental Lactogen in Blood Near Termination of Gestation

(From Martal in *Reproduction in Man and Mammals*)



Placental lactogen has both lactogenic actions and somatotrophic actions. The lactogenic activity of placental lactogen promotes mammary function in the dam, while the somatotropic activity promotes fetal growth.

changes cause two major events to occur: 1) removal of the myometrial "progesterone block," enabling myometrial contractions to begin and 2) increased reproductive tract secretions, particularly by the cervix.

The three stages of parturition are:

- ***<u>stage I</u>: initiation of myometrial contractions (removal of progesterone block)***
- ***<u>stage II</u>: expulsion of the fetus***
- ***<u>stage III</u>: expulsion of the fetal membranes***

Removal of the "progesterone block" occurs because fetal cortisol promotes the synthesis of three enzymes that convert progesterone to estradiol. The conversion pathway is illustrated in Figure 14-11. Progesterone, that is high at the placental interface, is converted to 17α-hydroxyprogesterone by the enzyme 17α-hydroxylase. Fetal cortisol also triggers the enzyme 17-20 desmolase to convert 17α-hydroxyprogesterone to androstenedione. Androstenedione is converted to estrogen by activation of an aromatase enzyme. This involves aromatization of the A ring of the steroid and removal of the 19 carbon. The conversion of progesterone to estradiol accounts, at least in part, for the dramatic drop in progesterone and dramatic elevation of estradiol. The relationship between progesterone and estradiol during gestation is presented in Figure 14-12.

In addition to converting progesterone to estradiol, fetal corticoids also cause the placenta to synthesize $PGF_{2\alpha}$. The synthesis of $PGF_{2\alpha}$ helps abolish the "progesterone block." As both estradiol and prostaglandin become elevated, the myometrium becomes increasingly more active and begins to display noticeable contractions. Also, $PGF_{2\alpha}$ causes the CL of pregnancy to regress, facilitating the decline in progesterone. The drop in progesterone in some species is brought about both by the conversion of progesterone into estradiol and by the luteolytic process brought about by $PGF_{2\alpha}$. Endocrine events associated with parturition are summarized in Figures 14-13 and 14-14.

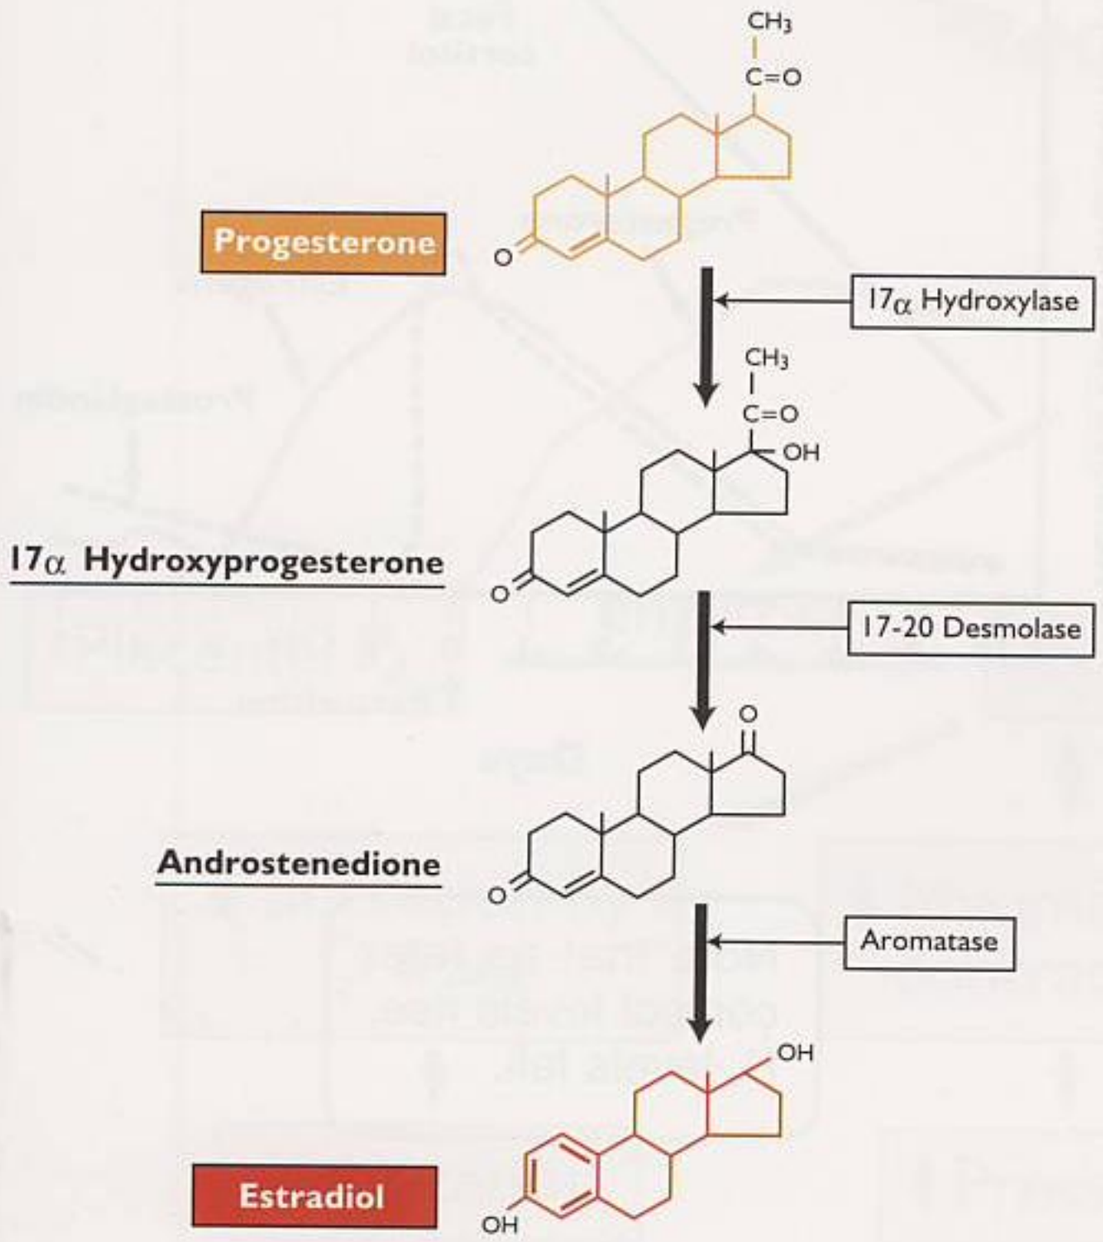
The fetus initiates stage I of parturition.

As the pressure inside the uterus continues to increase, the fetus in the cow, mare and ewe rotates so that the front feet and head are positioned to the posterior of the dam (See Figure 14-15). Such a rotation is important to insure a proper delivery. If the fetus fails to position itself correctly, **dystocia** (difficult birth) may occur.

As the levels of estradiol increase, coupled with the elevation in levels of $PGF_{2\alpha}$, the contracting uterus begins to push the fetus toward the cervix, applying pressure to the cervix. The endocrine events that promote the first stage of parturition (dilation of the cervix and entry of the fetus into the cervical canal) are summarized in Figure 14-14.

Figure 14-11. Conversion of Progesterone to Estradiol as Parturition Nears

Corticoids from the fetus activate 17α-hydroxylase, 17-20 desmolase and aromatase that convert progesterone to estradiol. This conversion removes the "progesterone block" to myometrial activity.

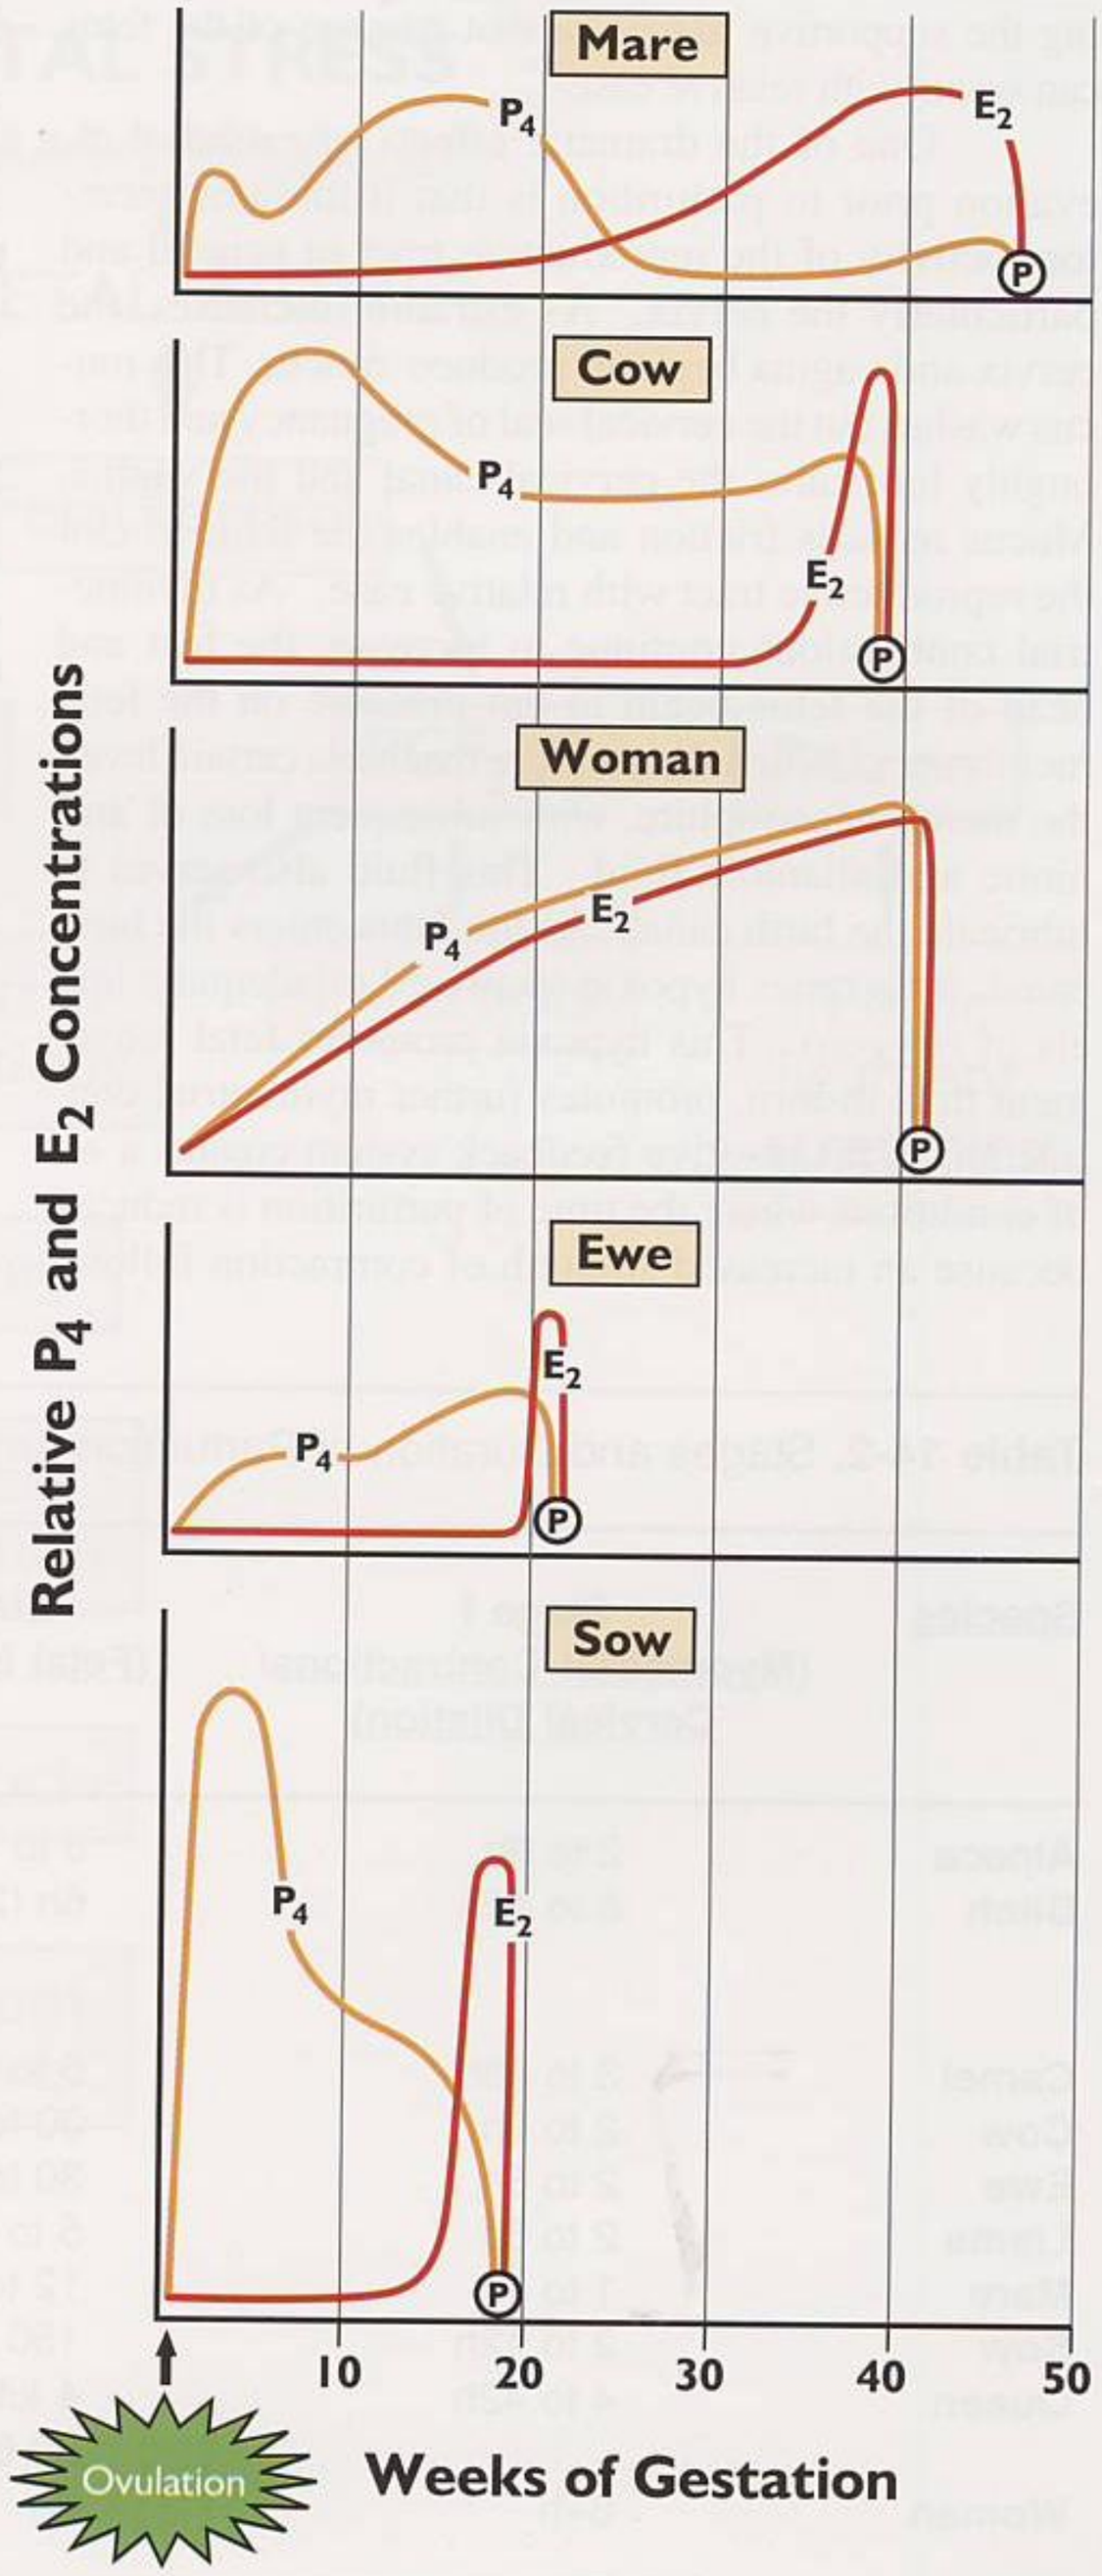


Pressure on the cervix brought about by increased myometrial contractions activates pressure-sensitive neurons located in the cervix that synapse in the spinal cord and eventually synapse with oxytocin producing neurons in the hypothalamus (See Figure 14-15). Oxytocin, released into the systemic circulation, acts to facilitate the myometrial contractility initiated by estradiol and by $PGF_{2\alpha}$. As the pressure against the cervix continues to increase, so does the oxytocin secretion, and thus the force of contraction of the myometrial smooth muscle begins to peak. When this occurs, the fetus enters the cervical canal and the first stage of parturition is complete.

Expulsion of fetus (stage II) requires strong myometrial and abdominal muscle contractions.

Figure 14-12. Estrogen and Progesterone Profiles During Gestation in the Mare, Cow, Woman, Ewe and Sow

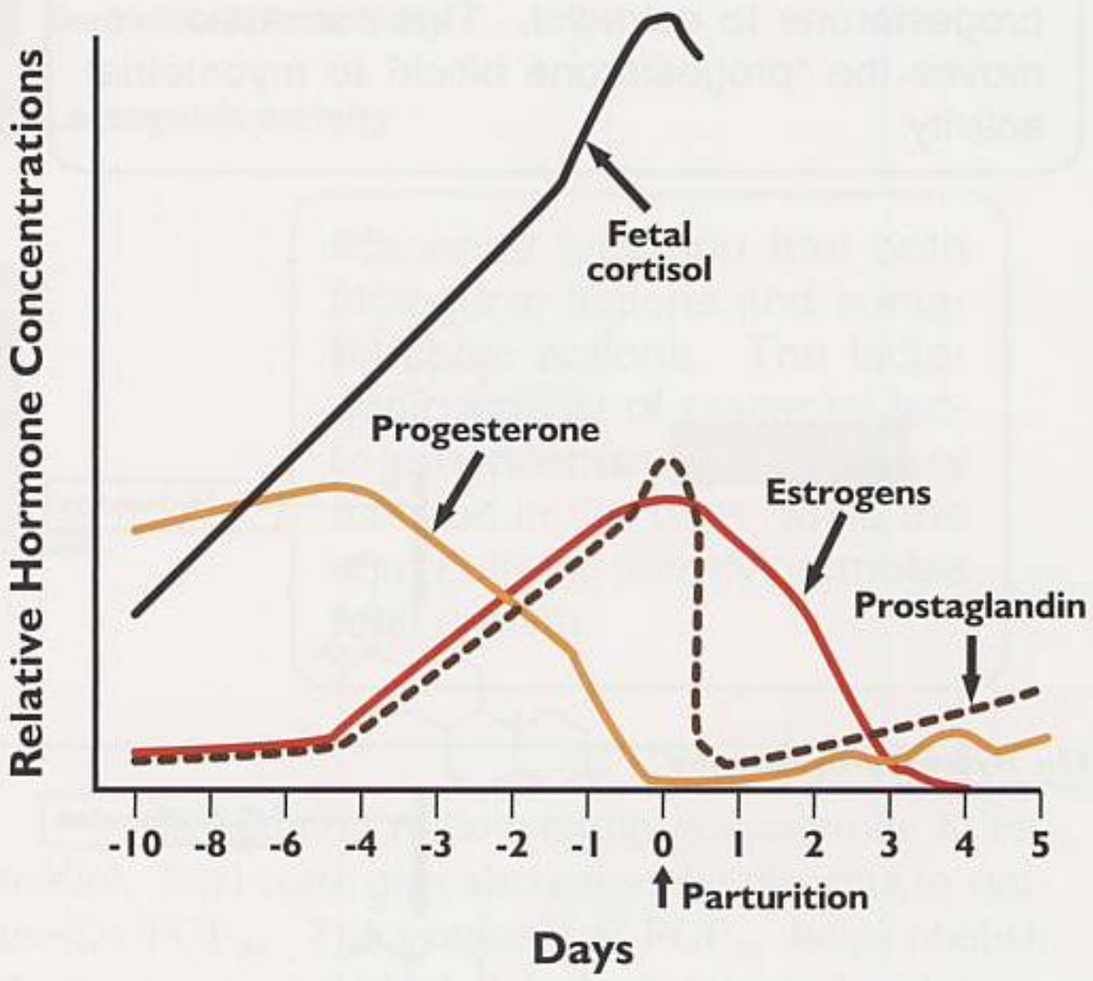
(P = Parturition)



Another important hormone involved in successful parturition is **relaxin**. Relaxin is a glycoprotein that is produced by either the corpus luteum or the placenta, depending upon the species. The synthesis of relaxin is stimulated by $PGF_{2\alpha}$. Relaxin causes a softening of the connective tissue in the cervix and promotes elasticity of the pelvic ligaments. Thus, this hormone prepares the birth canal by loosening the supportive tissues so that passage of the fetus can occur with relative ease.

One of the dramatic effects of estradiol elevation prior to parturition is that it initiates secretory activity of the reproductive tract in general and particularly the cervix. As estradiol increases, the cervix and vagina begin to produce mucus. This mucus washes out the cervical seal of pregnancy and thoroughly lubricates the cervical canal and the vagina. Mucus reduces friction and enables the fetus to exit the reproductive tract with relative ease. As myometrial contractions continue to increase, the feet and head of the fetus begin to put pressure on the fetal membranes. When the pressure reaches a certain level, the membranes rupture, with subsequent loss of amniotic and allantoic fluid. This fluid also serves to lubricate the birth canal. As the fetus enters the birth canal, it becomes hypoxic (deprived of adequate levels of oxygen). This hypoxia promotes fetal movement that, in turn, promotes further myometrial contraction. This positive feedback system creates a set of conditions where the time of parturition is reduced because an increased strength of contraction follows

Figure 14-13. Relative Hormone Profiles in the Cow During the Periparturient Period



Note that as fetal cortisol levels rise, P_4 levels fall.

Table 14-2. Stages and Duration of Parturition Among Various Species

Species	Stage I (Myometrial Contractions/ Cervical Dilation)	Stage II (Fetal Expulsion)	Stage III (Fetal Membrane Expulsion)
Alpaca	2 to 6h	5 to 90 min	45 to 180 min
Bitch	6 to 12h	6h (24h in large litters)	most placentas pass with neonate or within 15min of birth
Camel	3 to 48h	5 to 45 min	40 min
Cow	2 to 6h	30 to 60 min	6 to 12h
Ewe	2 to 6h	30 to 120 min	5 to 8h
Llama	2 to 6h	5 to 90 min	45 to 180 min
Mare	1 to 4h	12 to 30 min	1h
Sow	2 to 12h	150 to 180 min	1 to 4h
Queen	4 to 42h	4 kittens/litter, 30-60 min/kitten	most placentas pass with neonate
Woman	8+h	2h	1h or less

Figure 14-14. Cascade of Events Prompted by Fetal Cortisol

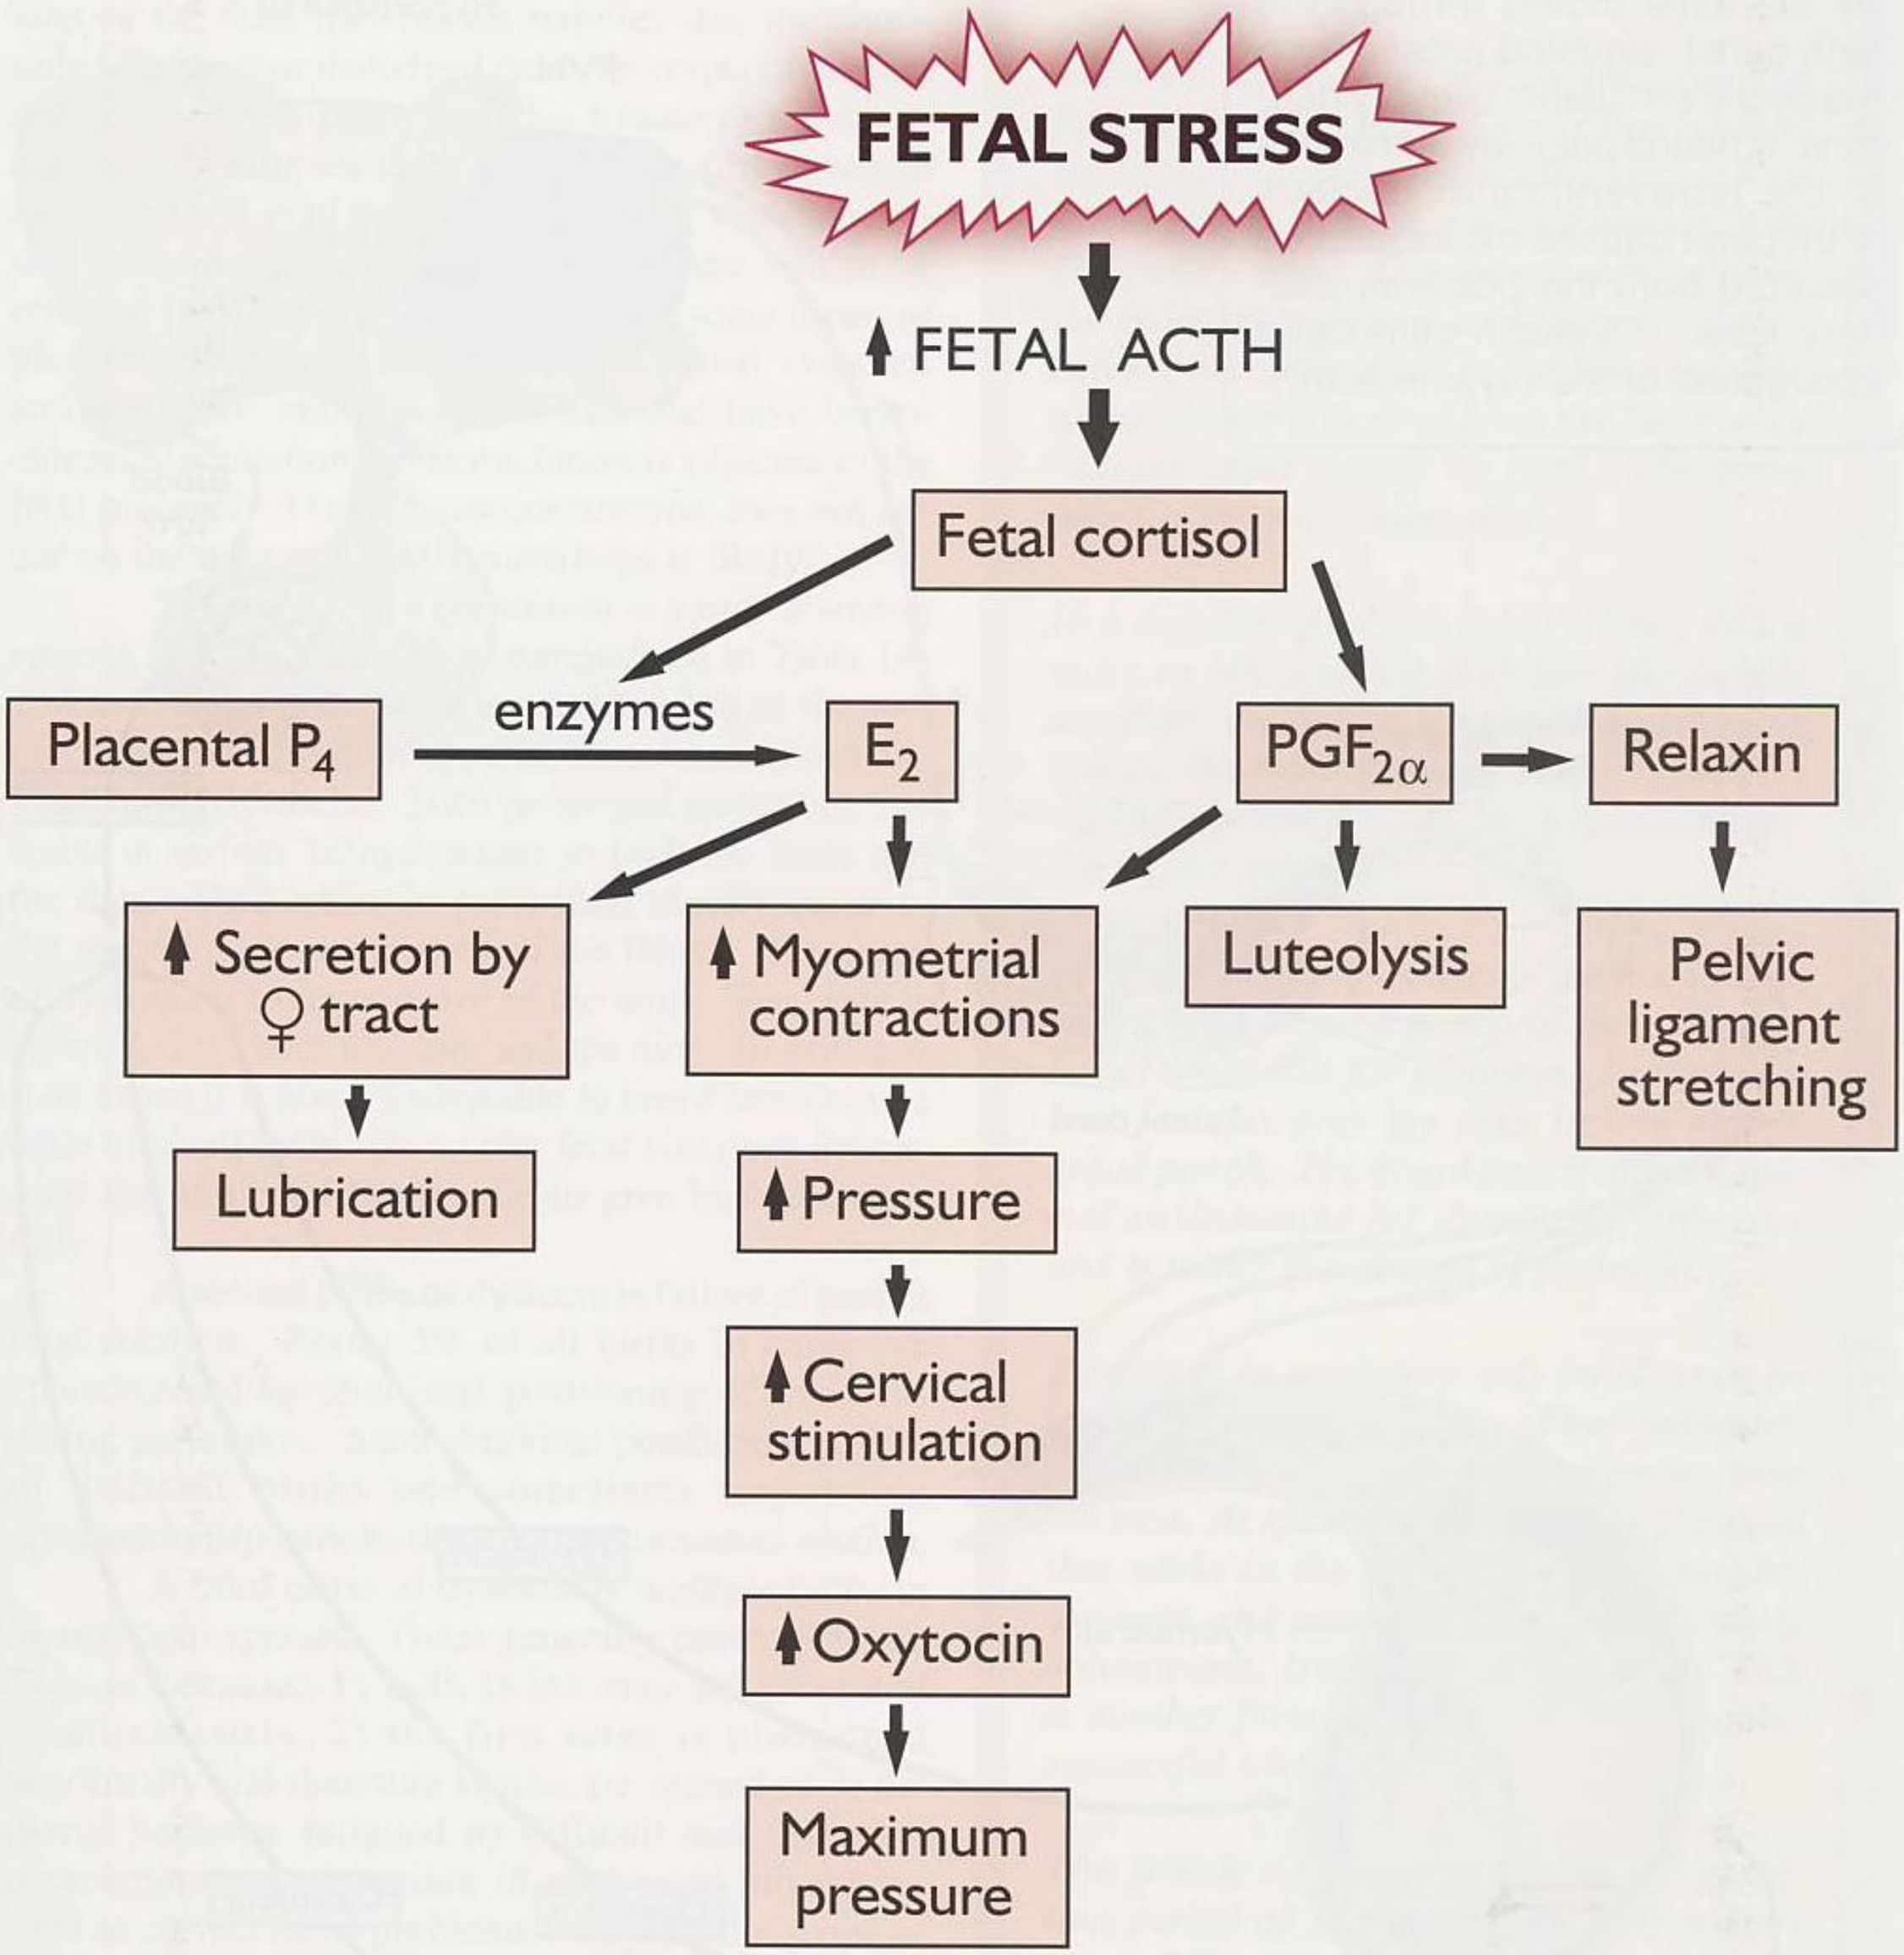


Figure 14-15. Pressure on the Cervix Causes Oxytocin Release and Subsequent Myometrial Contractions

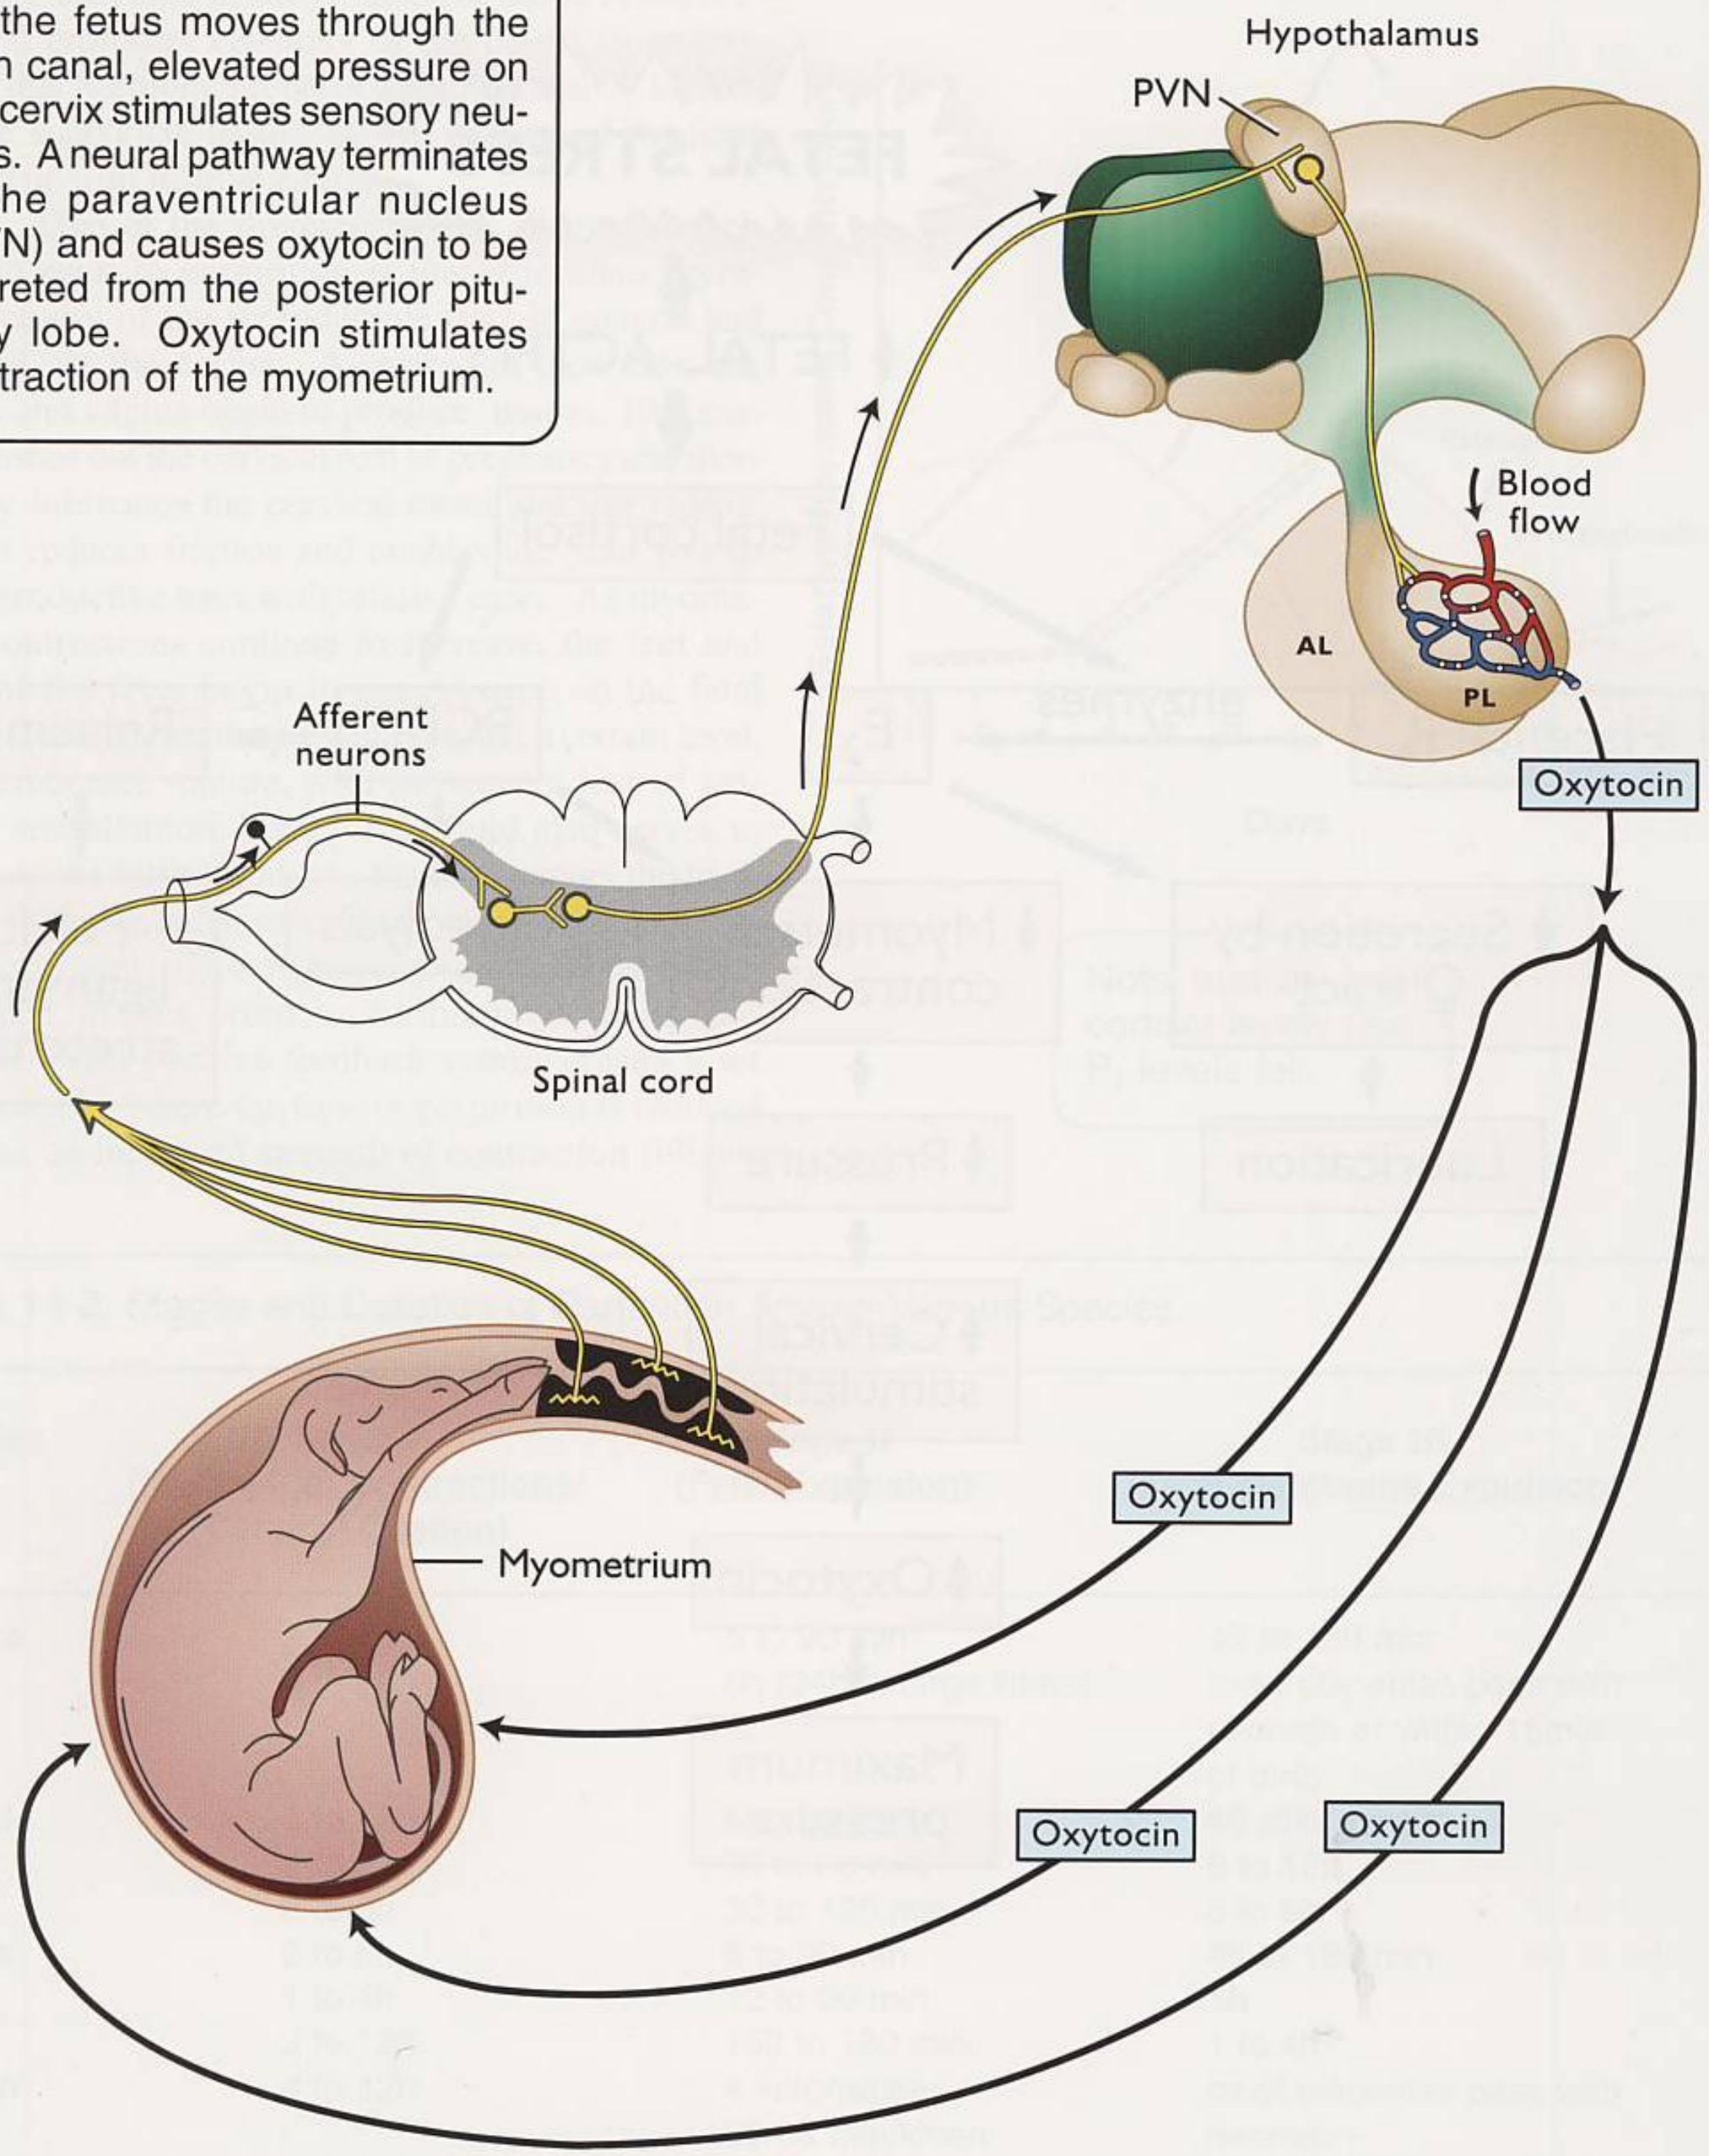
As the fetus moves through the birth canal, elevated pressure on the cervix stimulates sensory neurons. A neural pathway terminates in the paraventricular nucleus (PVN) and causes oxytocin to be secreted from the posterior pituitary lobe. Oxytocin stimulates contraction of the myometrium.



fetal movement. In a sense, the fetus is controlling its exit from the uterus. The uterine contractions are accompanied by abdominal muscle contractions of the dam that further aid in expulsion of the fetus.

In most species, expulsion of the fetal membranes quickly follows expulsion of the fetus. Expulsion of the fetal membranes requires that the chorionic villi become dislodged from the crypts of the maternal side of the placenta. This release of the chorionic villi is believed to be brought about by powerful vasoconstriction of arteries in the villi. Vasoconstriction reduces pressure and thus allows the villi to be released from the crypts. Obviously in some forms of placentation, there must be some maternal vasoconstriction. For example, in animals that have hemochorial placentation, maternal blood is adjacent to the fetal placenta. Thus, if vasoconstriction does not occur on the maternal side, hemorrhage is likely.

The duration of parturition is variable among species and this variation is summarized in Table 14-2. Extension beyond what is considered to be the normal upper-end duration of parturition constitutes a difficult birth (**dystocia**). Such prolonged parturition can result in serious complications to both the fetus and the dam. Difficulties in parturition usually occur in the second stage (expulsion of the fetus). One cause of dystocia is excessive size of the fetus. Fetal size is controlled by both the dam and the sire. In primiparous dams, it is always advisable to breed females to a male of small body size so that fetal size does not exceed the ability of the female to give birth successfully.

A second cause of dystocia is failure of proper fetal rotation. About 5% of all births in cattle are characterized by abnormal positioning of the fetus during parturition. Such abnormal positioning results in difficult births and sometimes impossible presentations/positions that require caesarean section.

A third cause of dystocia is multiple births in monotocous species. Twins generally cause dystocia. This is because: 1) both twins may be presented simultaneously, 2) the first fetus is positioned abnormally and therefore blocks the second or 3) the uterus becomes fatigued by difficult and sustained contractions. A discussion of obstetrical procedures used to correct these problems is beyond the scope of this book, but can be researched by consulting the appropriate references at the conclusion of this chapter.

Further PHENOMENA *for* Fertility

The term "caesarean" was derived from the false notion that Julius Caesar was born by removing him from his mother through an incision in the abdominal and uterine wall. His family name, Caesar was derived from the belief that Julius' ancestors (centuries before him) were born in such a way. The name Caesar is derived from the Latin word "caesus" that means "to cut". The name also fits the way Julius died.

In a number of teleost fishes (fishes with a more or less ossified skeleton) the female incubates the eggs in her mouth and in some species the male does the same. The term "keep your mouth shut" has a special meaning in this species.

In pipe fishes and sea horses the female lays her eggs in a brood pouch of the male and he is responsible for gestation. In fact, several females may lay eggs in one male's brood pouch. The brood pouch offers a special environment for developing offspring and is under the control of prolactin.

Lampreys (a predatory eel) build nests in sandy bottomed streams. They assemble rock walls to slow the water running over the nest. At spawning, they stir up the sand that sticks to the eggs. The sand weights the eggs and prevents them from floating downstream. It also reduces predation. This is another form of attachment that enables successful embryogenesis.

The female African elephant has a gestation period of 1.8 years. The calf weighs about 300 pounds at birth and nurses for about three years.

The female pigeon can't lay eggs when she's alone. She needs either another pigeon or her own reflection in a mirror to do that task.

When comparing the size of bird eggs to the sizes of the birds that produce them, ostrich eggs are among the smallest and hummingbird eggs are among the largest.

Infant kangaroos in their mother's pouches nurse from two nipples, and two babies of different ages commonly nurse at the same time. So, the mother kangaroo produces two kinds of milk- on one side, fully rich for the younger and on the other side, a sort of skim for the elder.

The most prolific mammal in existence is the tiny rodent known as the multimammate rat. One female is capable of producing up to 120 offspring a year if conditions are favorable. This is because she has 24 teats, the most of any female mammal. It is rare that all of them are used but when they are a multimammate population explosion can occur.

The alpine black salamander has the longest gestation period known. Interestingly, it depends on altitude. When they live more than 4,600 feet above sea level, the infant develops within the mother for over three years.

The nesting behavior of the Silvery-Cheeked Hornbill adds new meaning to the term "cabin fever". When the time comes to incubate the eggs, the female finds a suitable hole in a tree and goes inside. The male then brings mud to his spouse who "plasters" herself inside for over three months. She leaves a narrow opening so that the male can deliver food for her and the chicks.

The female Egyptian spiny mouse acts as a midwife to other females. She bites through the umbilical cord and licks the neonates while the mother continues to deliver the litter.

During the 19th Century, adultery was so feared that the chastity belt was invented. Such belts were devices that were locked around the woman's genitalia to prevent copulation. It has been recorded that a faithful wife locked into a chastity belt discovered that she was pregnant some months after her husband had left on a crusade. Her husband had the only key. Her pregnancy progressed and eventually the village blacksmith had to be called in to remove the chastity belt.

During the Middle Ages, prostitution was considered to be an honest and essential profession. This was because prostitution was considered as a means to prevent adultery, homosexual behavior and masturbation. The Church actually condoned prostitution for this reason.

The Mayans believed in a maize god. Since corn was a nutritional staple for these people, they revered it and believed that corn was symbolic of both the male and female. From a nutritional perspective they believed that corn was nurturing like a woman's breast and that each individual kernel had powerful fertilizing capabilities like spermatozoa. Once the seeds were planted in the earth and the mature corn was produced, the cob represented the penis and the husk represented the vagina. Thus, the ear of corn was also symbolic of copulation.

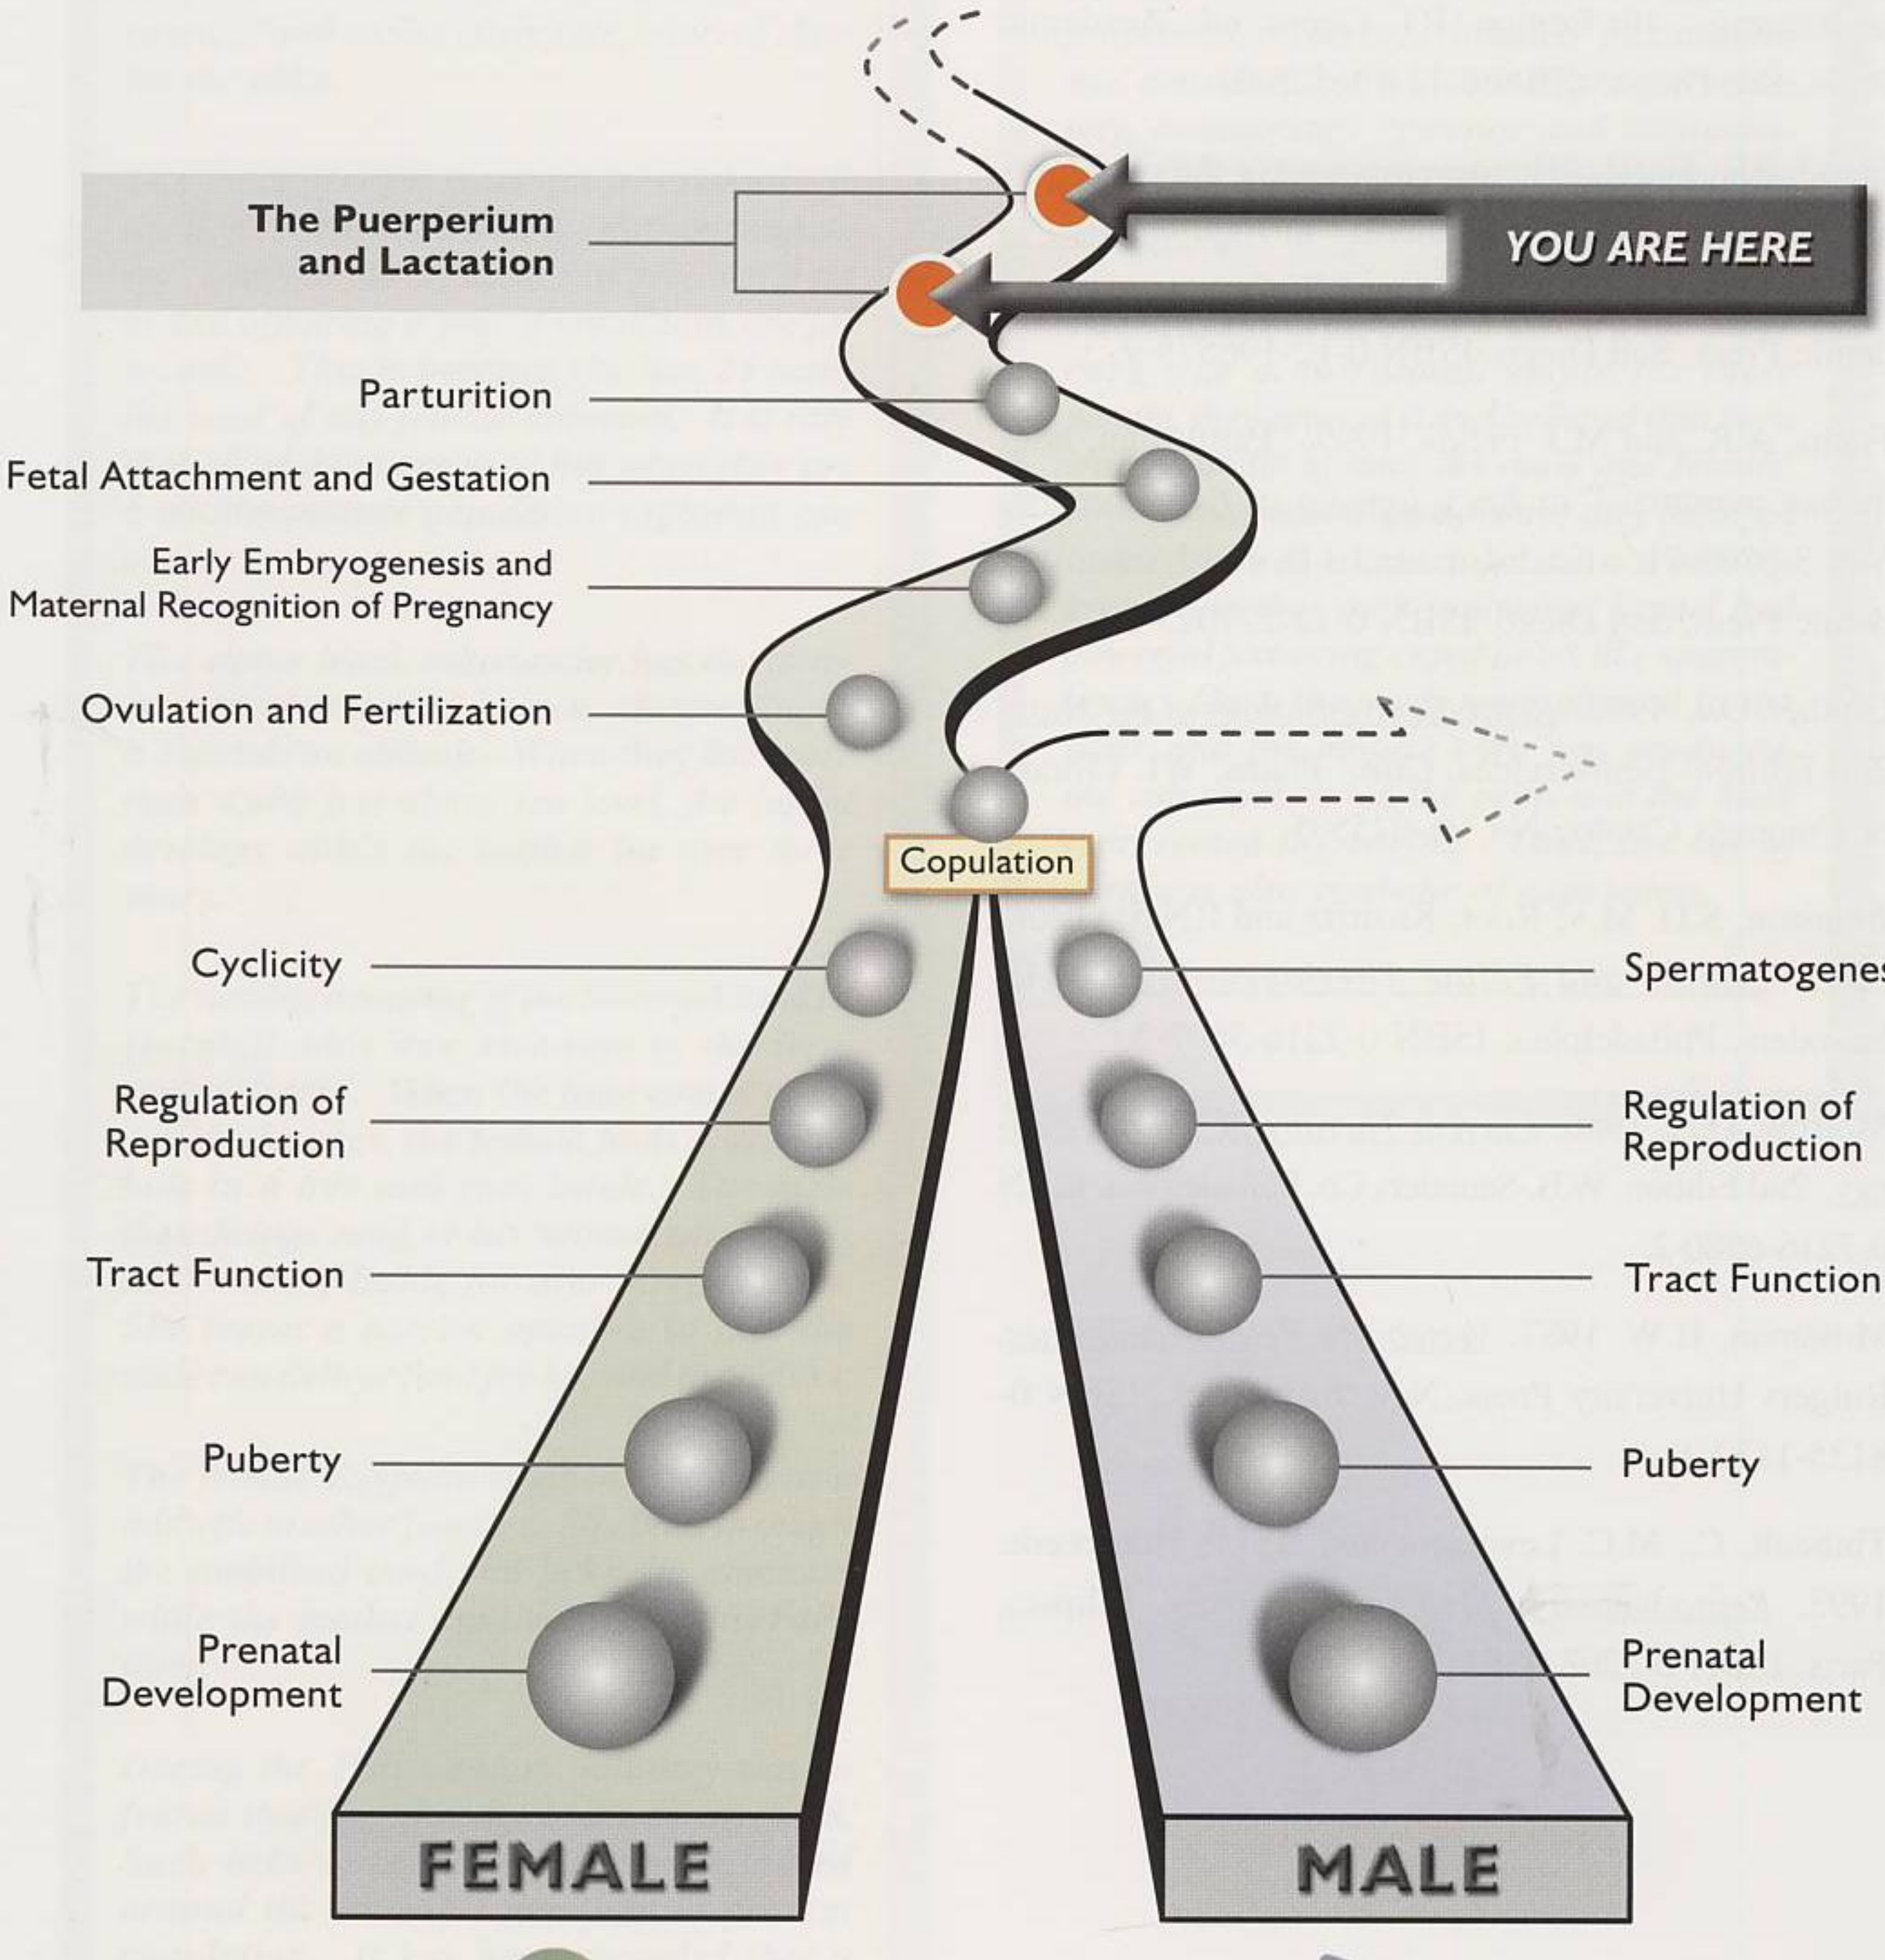
CHAPTER 15

The Puerperium and Lactation



Take Home Message

Immediately following parturition, the female begins to lactate and enters a period of reproductive repair called the puerperium. For a period of time these two processes overlap. During the puerperium uterine involution and return of ovarian function occurs. Involution is the reduction in size and "remodeling" of the endometrium so that the uterus can initiate and sustain another pregnancy.

Mammary gland development is initiated prenatally in the female fetus and continues through puberty and pregnancy. The anatomy and distribution of mammary glands is diverse among mammals. Secretion of milk does not begin until shortly before parturition (hours). Lactation provides the neonate with the opportunity to nurse and be nourished with minimal expenditure of energy. It also provides immunoprotection for the neonate because initial mammary secretions called colostrum contain antibodies that provide passive immunity. Lactation continues until the neonate is weaned. After weaning, the mammary glands undergo involution and return to a non-secretory state.

The puerperium and lactation are initiated immediately after parturition and for a period of time these processes occur simultaneously. **Lactation** is the synthesis, secretion and removal of milk from the mammary gland. The **puerperium** is the period after parturition when the reproductive tract returns to its non-pregnant condition so that the female may become pregnant again. This chapter will describe the basics of these two important processes. Parturition results in loss of placental function and deterioration of the maternal placenta during and after expulsion of the fetus and fetal membranes. Tissue damage results. During the puerperium damaged reproductive tissues are repaired and ovarian function returns.

The Puerperium

The puerperium begins immediately after parturition and lasts until reproductive function is restored so that another pregnancy can occur. The time required for complete uterine involution (repair) and ovarian activity to resume in the postpartum female varies significantly among species (See Table 15-1).

The four major events of the puerperium are:

- ***myometrial contractions and expulsion of lochia***
- ***endometrial repair***
- ***resumption of ovarian function***
- ***elimination of bacterial contamination of the reproductive tract***

It must be emphasized that in many polyestrous animals, the shortest possible puerperium is desirable because eligibility for a subsequent pregnancy is of high economic importance. For example, in dairy cows frequent pregnancies are required for maximum lifetime milk yield. In swine and beef cows, the shorter the interval between pregnancies the more offspring are produced and the more efficient the production of meat becomes. Conversely, the longer the puerperium, the longer the delay of a subsequent pregnancy and the less efficient the production process becomes. Figure 15-1 summarizes the events that occur from parturition to the subsequent pregnancy. These events will be described in more detail below.

Reduction in Uterine Size and Volume is Brought About by Myometrial Contractions

Immediately after parturition, the myometrium undergoes strong repeated contractions. The purpose of these contractions is threefold. First, they facilitate discharge of fluids and tissue debris from the uterus. Secondly, the contractions compress the uterine vasculature and help minimize the possibility of hemorrhage. Third, myometrial contractions reduce the overall size of the uterus. Of the species presented in this text, timely uterine involution is most important in the postpartum dairy cow. In most species, frequent postpartum suckling occurs and oxytocin is secreted (See Figure 15-13). In suckled animals, uterine contractions occur on a frequent basis. In the dairy cow however, the calf is usually removed within 24 hours after parturition and milking takes place only two or three times per day. Consequently, oxytocin episodes are

Figure 15-1. Major Events From Parturition to Subsequent Conception

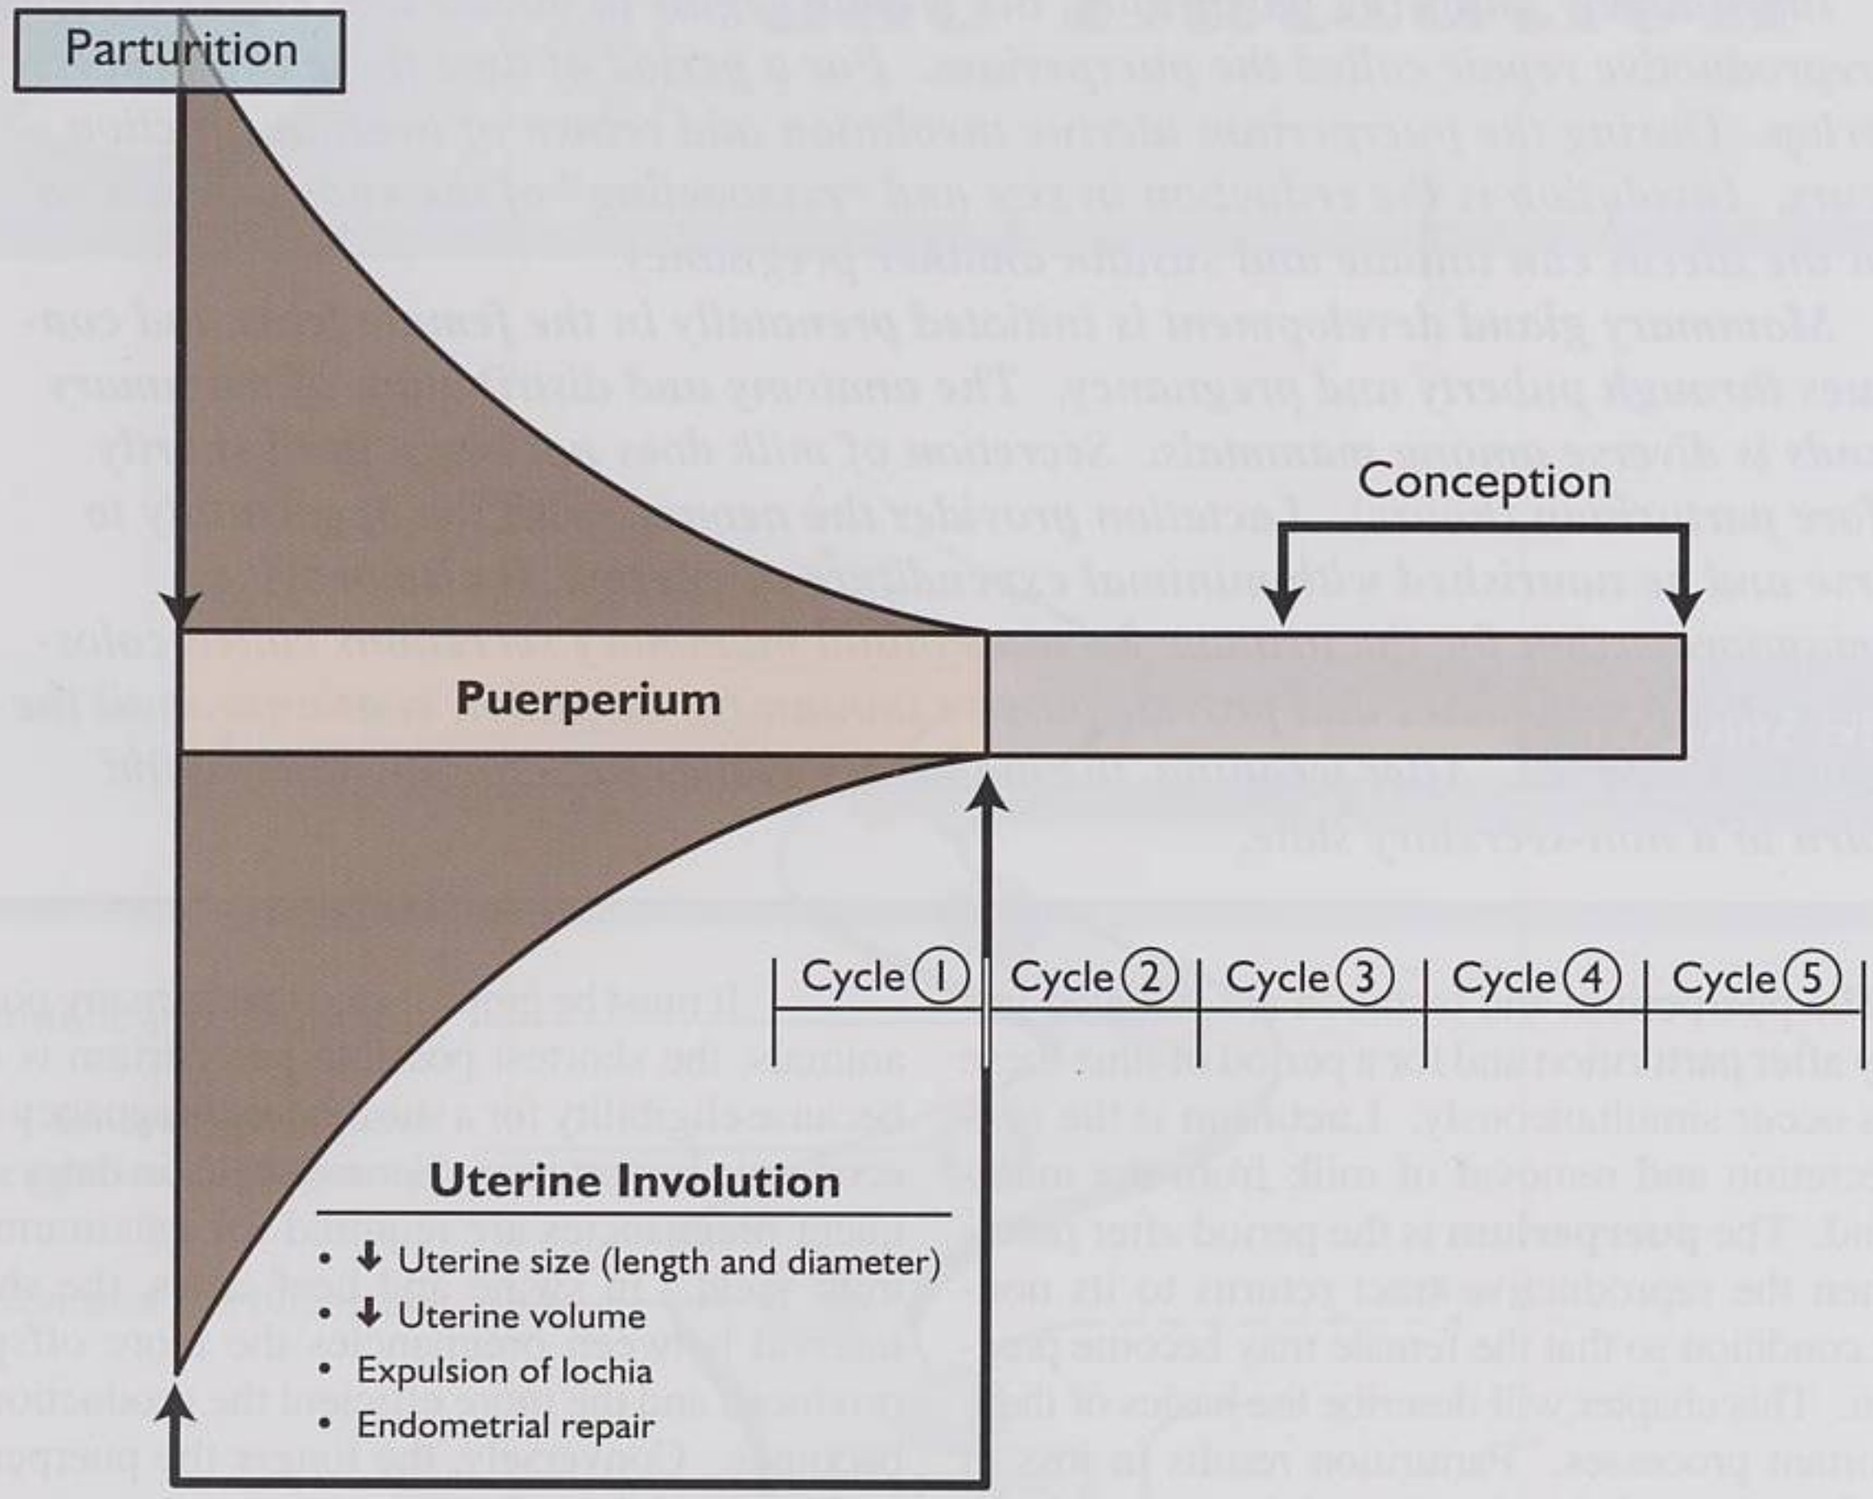


Table 15-1. Time Required for Uterine Involution and Resumption of Ovarian Activity in Various Species

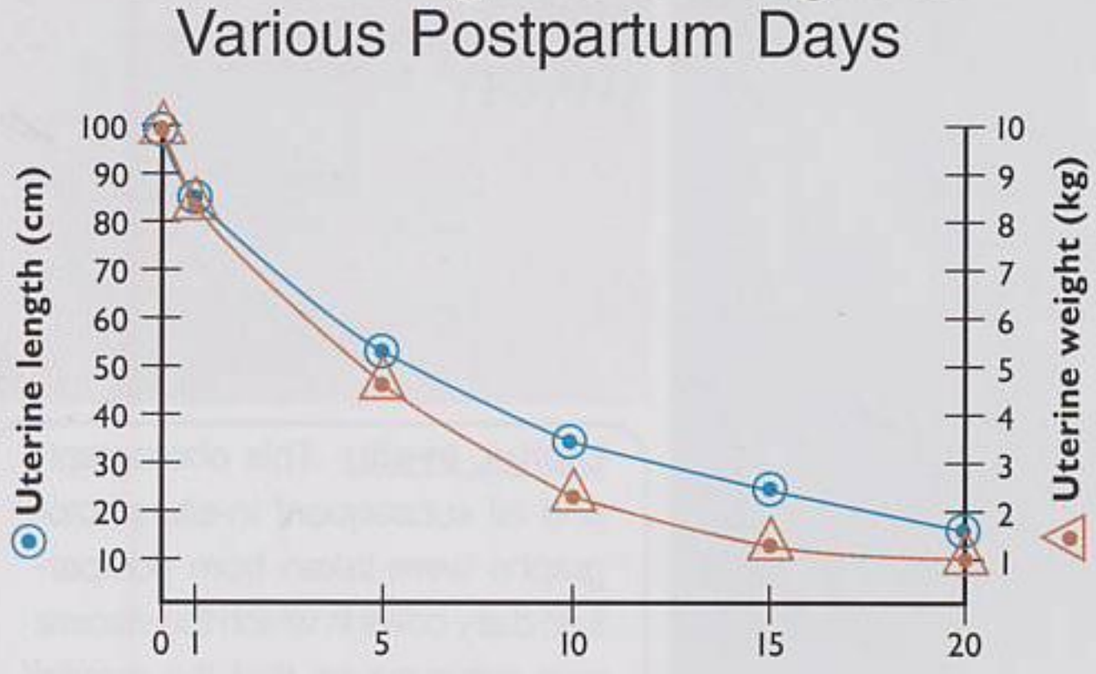
Species	Time Required for Complete Uterine Involution	Time Required for Resumption of Ovarian Activity
Alpaca	20d	5-10d
Beef Cow	30d	50-60d (L)
Bitch	90d	150d (A)
Camel	30-50d	25-40d or up to 1 yr (L)
Dairy Cow	45-50d	18-25d
Ewe	30d	180d (SDB)
Llama	20d	5-10d
Mare	21-28d	5-12d
Queen	30d	30d
Sow	28-30d	7d (L)
Woman	40-45d	6-24mo (L) (See Chapter 7)

L = Lactation inhibits ovarian activity (See Chapter 7)
SDB = Short Day Breeder- ewes giving birth in the spring will not cycle until fall
A = Long natural postpartum anestrus (See Chapter 7)

reduced, myometrial contractions are not as frequent and uterine involution can be delayed. In this light, much of the material presented on uterine involution will focus on the dairy cow since delayed uterine involution is an important factor limiting fertility in this animal.

Immediately after parturition the uterus undergoes rapid but highly coordinated atrophy so that in a relatively short period of time the uterine mass is reduced to its nonpregnant size. In all species, marked size reduction occurs during the first several days after parturition. In fact, in the dairy cow, myometrial cell size decreases from 700µm on the first day after parturition to 200µm a few days later. In most species, myometrial contractions occur in three to four minute intervals for the first several postpartum days. These strong, high frequency myometrial contractions subside within several days. The exact time that these contractions stop depends on the species. The dramatic postpartum size reduction of the uterus in the dairy cow is illustrated in Figure 15-2.

Figure 15-2. Changes in Uterine Length and Weight at Various Postpartum Days



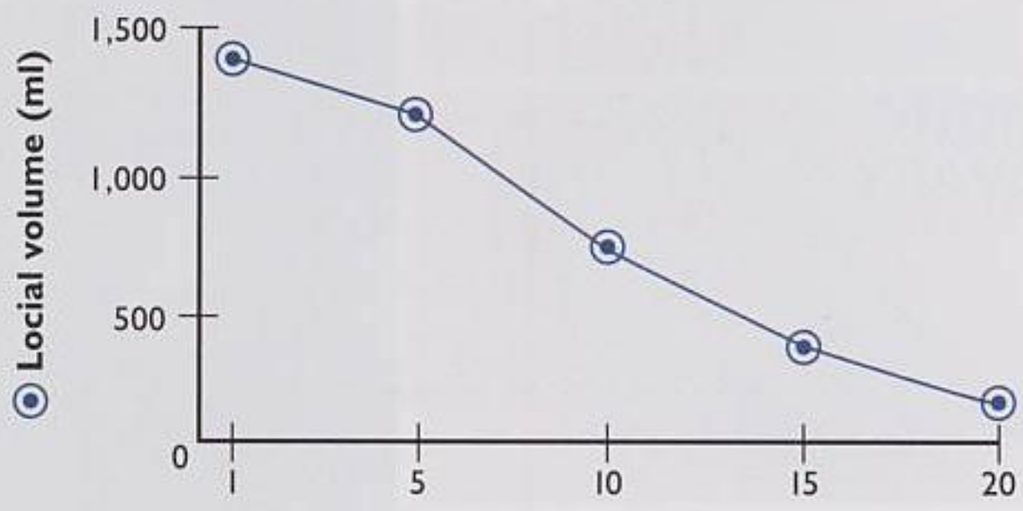
The uterine length values here are used in Figures 15-4 through 15-8 to illustrate approximate size changes. (From Gier, H.T. and G.B. Marion, 1968. *Amer. J. Vet. Res.* 29: 83-96)

During and After Myometrial Contractions a Bloody Fluid is Discharged from the Tract

Shortly after parturition, a discharge called **lochia** is expelled from the vulva. Lochia is typically a blood-tinged fluid containing remnants of the fetal placenta and endometrial tissue. Lochial discharge occurs between 2 and 9 days in postpartum dairy cows. An increase in blood and tissue debris in the lochia is normal and occurs between 5 and 10 days. This is due to the sloughing of caruncular surfaces that leaves vascular "stubs" that leak blood. Lochial discharge is physiologically normal in all species. However, it is often interpreted by observers to be the result of uterine pathology (especially in the dairy cow). Therefore, the first "instinct" of the reproductive management team is to treat the animal for nonexistent pathology. Unwarranted treatment is financially wasteful, not effective and often prolongs uterine involution especially if the uterine lumen is invaded (infusion of antibiotics, various solutions or to remove manually retained fetal membranes).

Obviously, with significant myometrial contractions occurring for the first 7 to 10 days there will be a reduction in the volume of lochia within the uterus. In the dairy cow, up to 2000ml of lochia can be expelled from the uterus during the first two to three days after parturition. By 14 to 18 days, lochial discharge is almost nonexistent in most cows (See Figure 15-3).

Figure 15-3. Changes in Lochial Volume at Various Postpartum Days



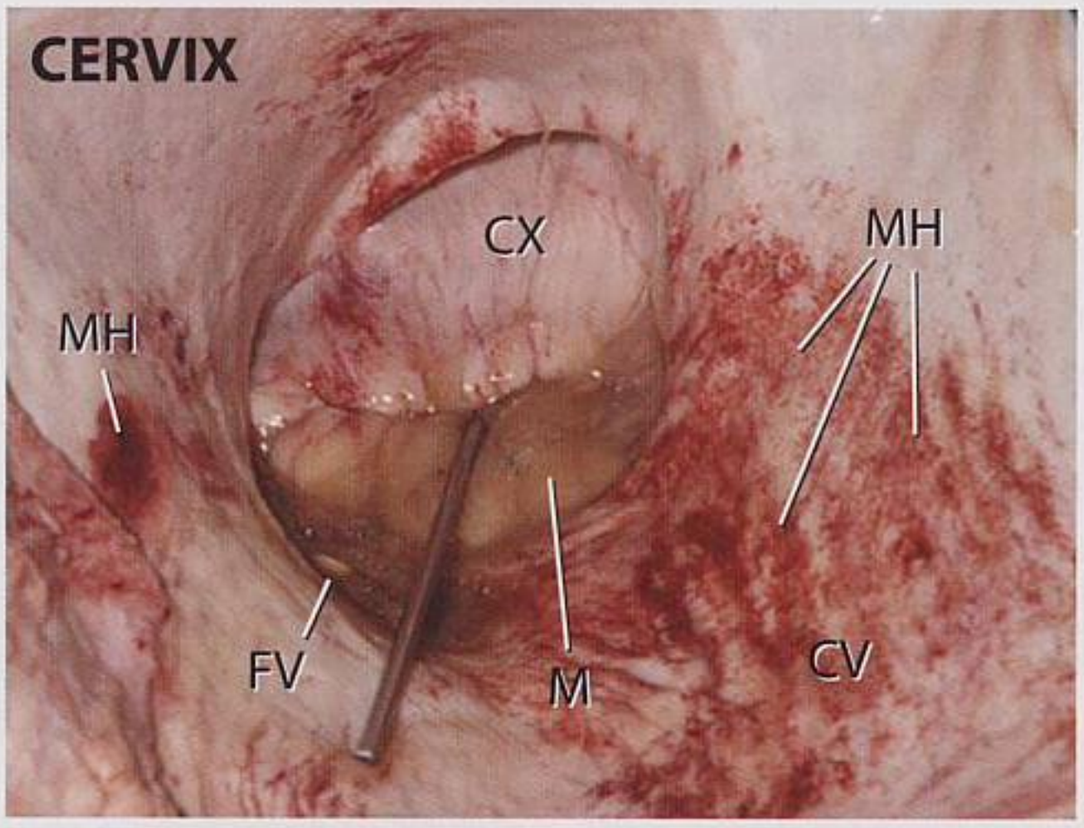
(From Gier, H.T. and G.B. Marion, 1968. *Amer. J. Vet. Res.* 29: 83-96)

Caruncular Repair RequiresVasoconstriction, Necrosis and Sloughing of Tissues Followed by Growth of Surface Epithelium

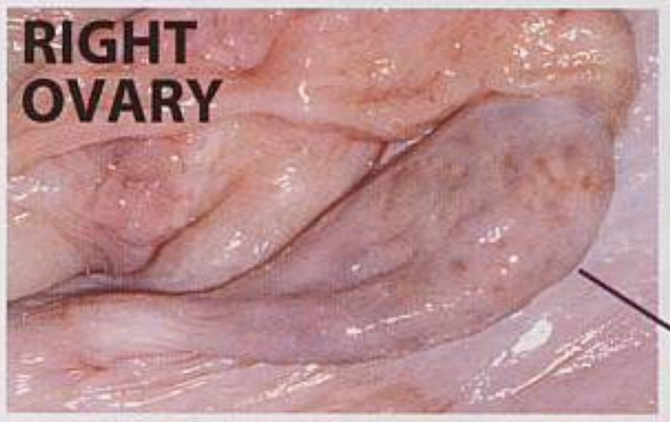
After separation of the fetal cotyledons from the maternal caruncle (within 8-12 hours after delivery of the neonate) vasoconstriction takes place in the stalk of the maternal caruncle. Necrosis of the caruncular tissue follows. Necrosis is irreversible cell death that leads to sloughing of the caruncular mass leaving necrotic tissue in the lochial fluid inside the uterus. Some blood is released from the caruncular stalk generating a blood-tinged fluid. About 5 days after parturition, the caruncles begin to lose their cellular organization and integrity. This results in chunks of the caruncles detaching from the surface of the caruncle leaving remnants of blood vessels exposed to the surface. After

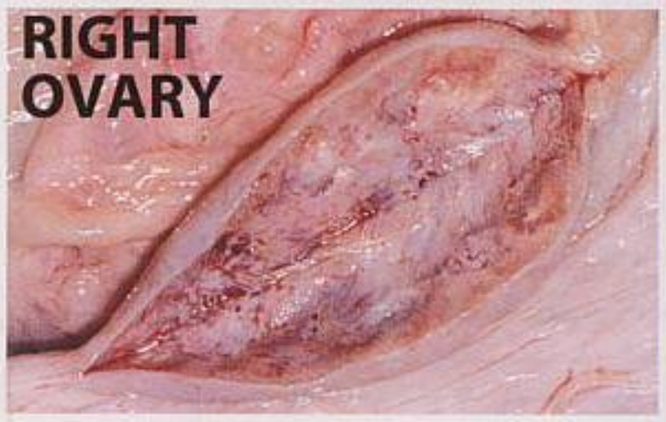
Figure 15-4. Bovine Reproductive Organs- Day 1 Postpartum

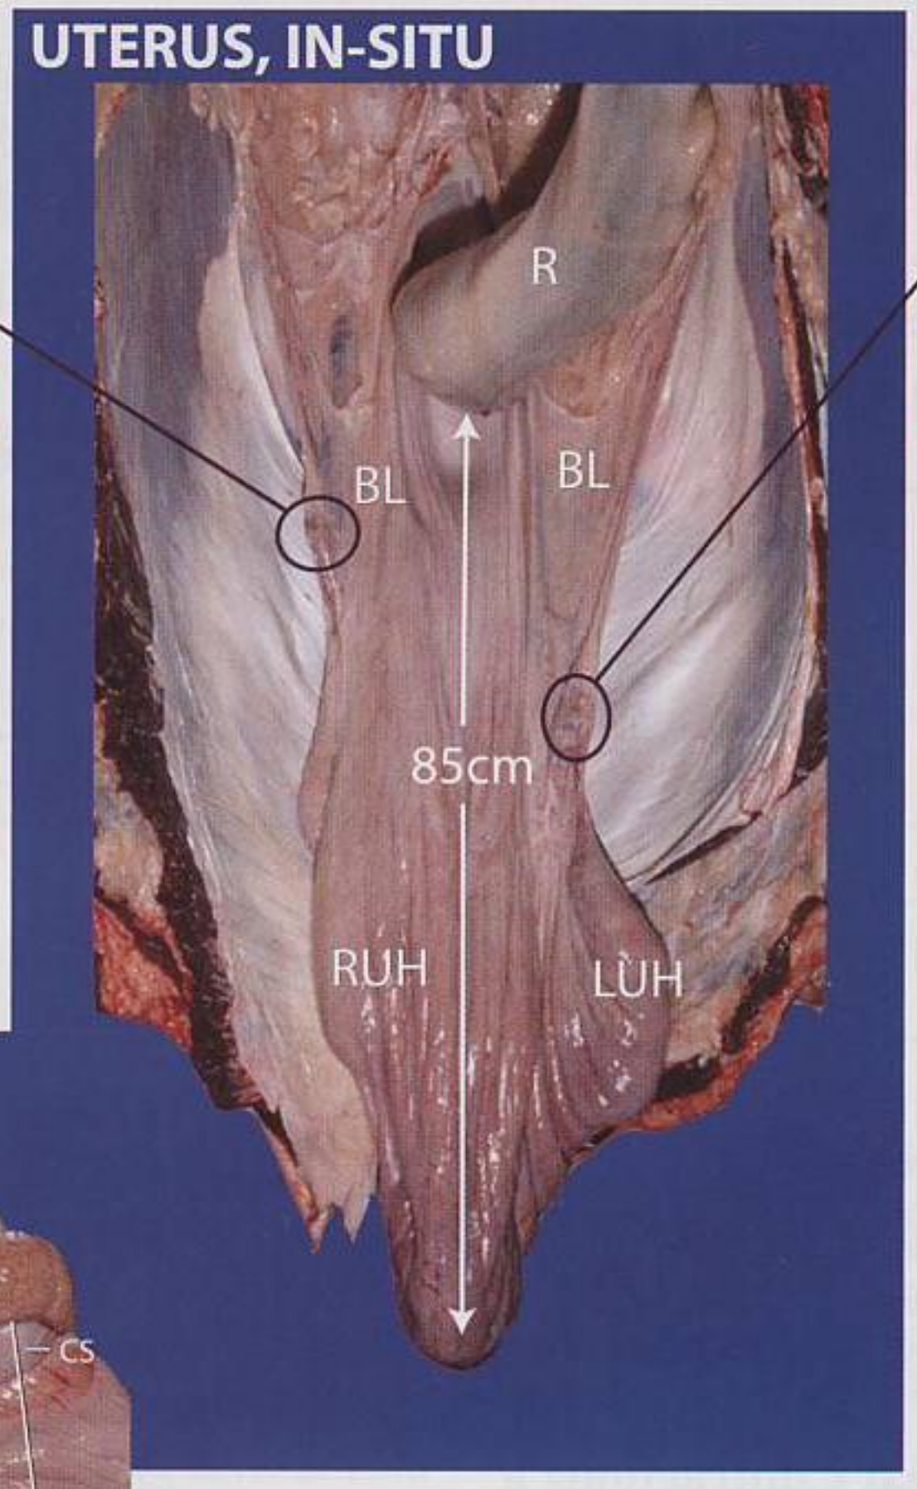
Ovaries- There are no functional structures on the right ovary. The left ovary contains two corpora lutea (arrows 1 and 2) indicating a double ovulation. Only one conceptus developed. There is no evidence of follicular development on either ovary.

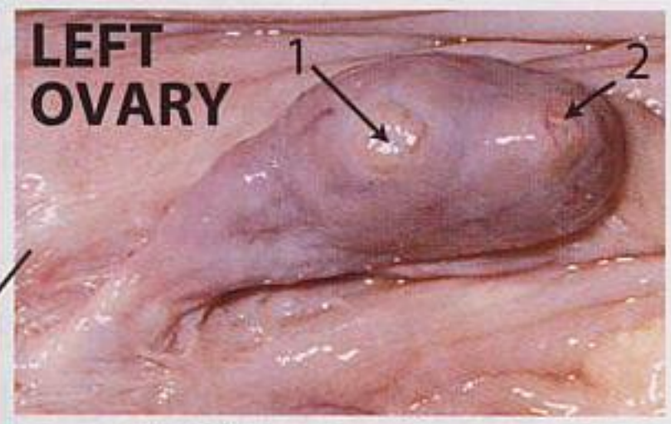


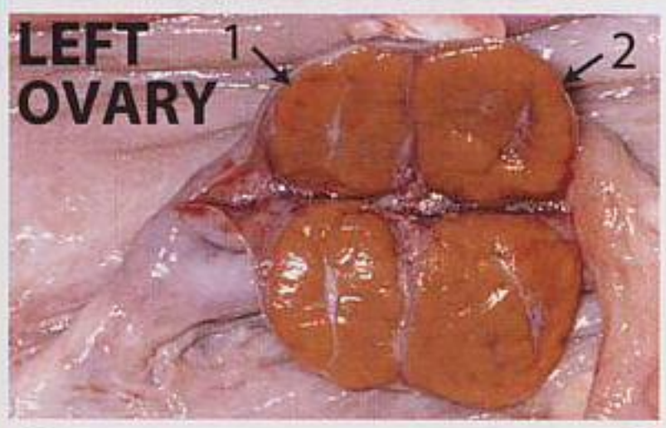
Cervix (cranial view)- The brownish mucus (M) is a remnant of the cervical seal of pregnancy. Mucosal hemorrhaging (MH) has resulted from abrasive trauma to the cranial vagina (CV), fornix vagina (FV) and portions of the cervix (CX) during expulsion of the fetus. A stainless steel rod has been positioned in the cervical canal to provide spatial reference in Figures 15-4 through 15-8.



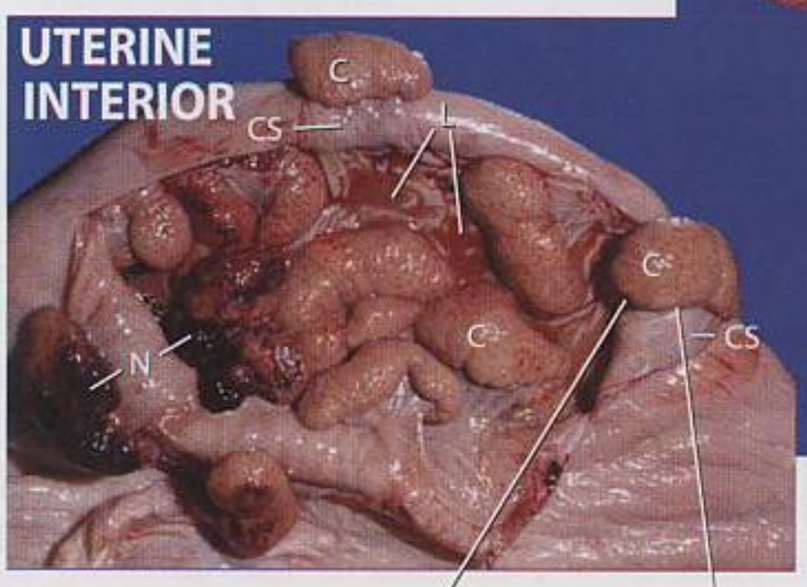


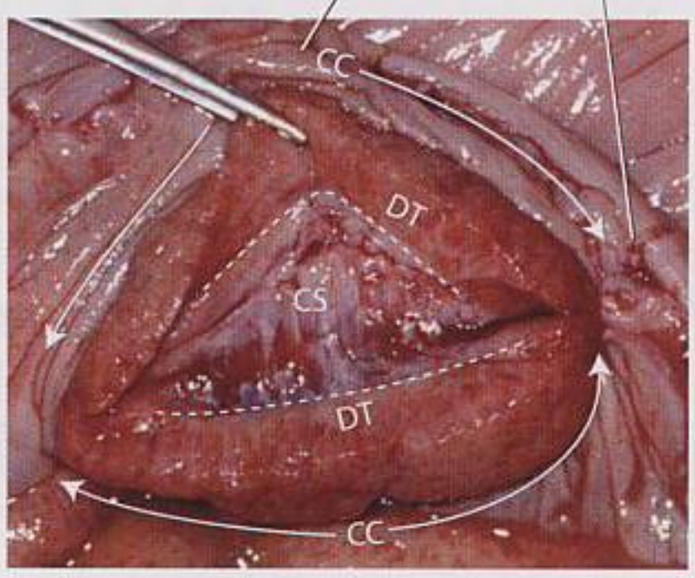






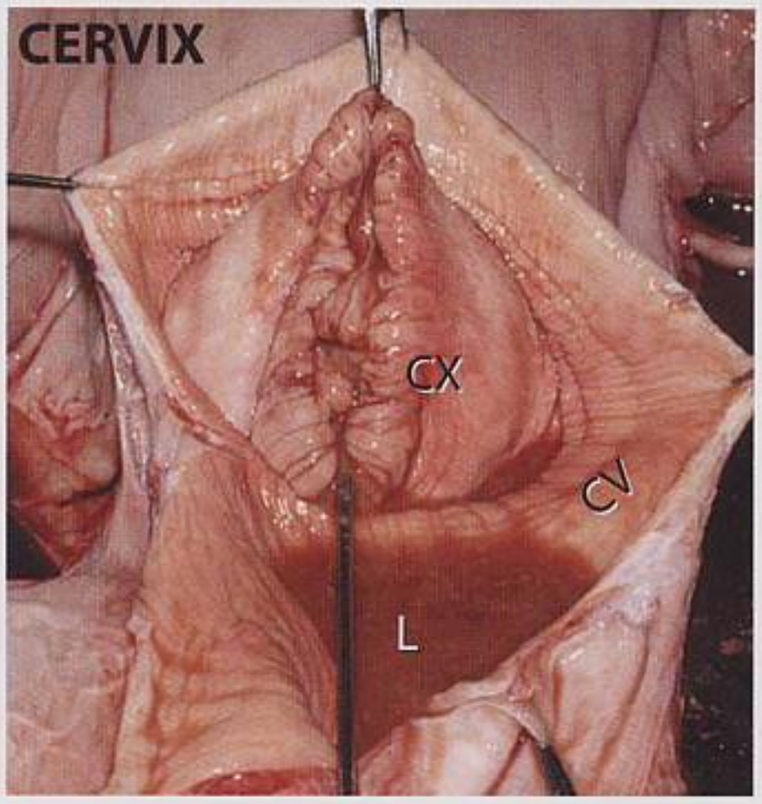
Uterus, in-situ- This photograph and all subsequent in-situ photographs were taken from postpartum dairy cows in which the viscera was removed so that the cranial surface of the reproductive tract can be viewed. Here, the approximate overall length of the uterus is 85cm. The right uterine horn (RUH) is larger than the left uterine horn (LUH) because the right uterine horn housed the fetus. The broad ligament (BL) and rectum (R) are obvious.



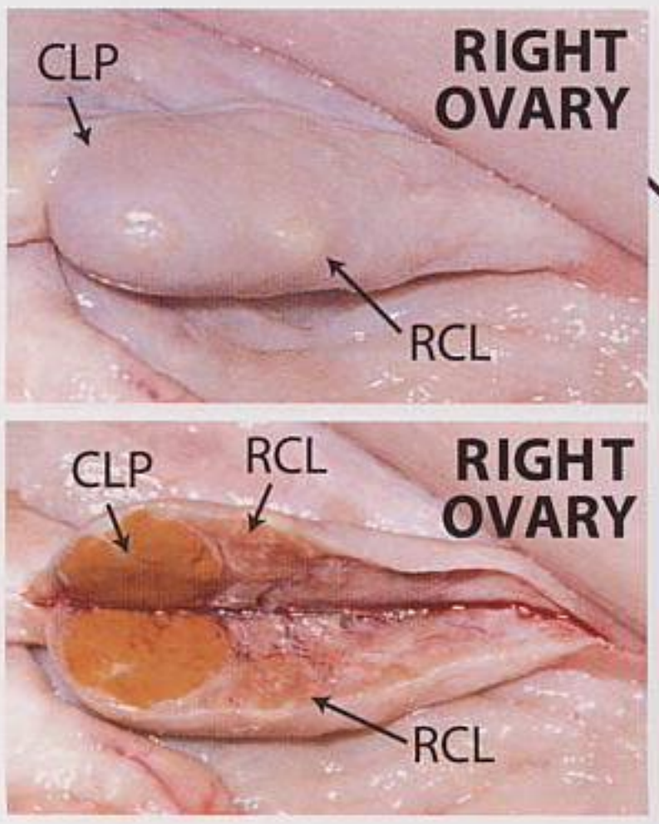


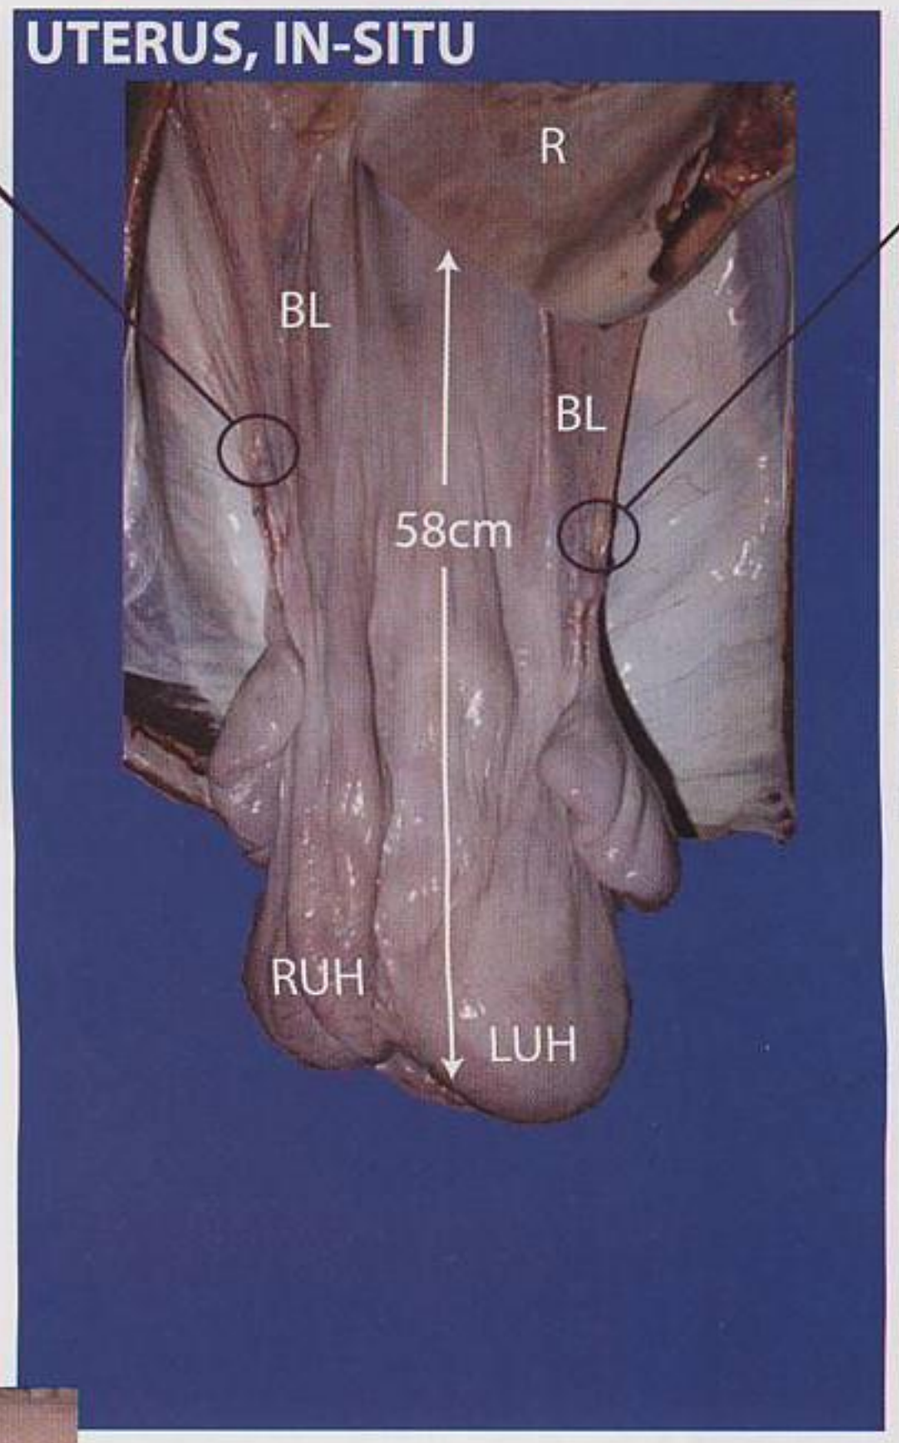
Uterine Interior- The uterus contains many large caruncles (C) that consist of intact tissue. Only a few caruncles have started to undergo necrosis (N) as judged by the blackened regions. There is very little lochia (L) present. The caruncular stalks (CS) are quite long and house the vasculature that supplied the maternal cotyledon with blood during pregnancy. The enlarged photograph illustrates a caruncular crown (CC) that has been sliced open. The incision has extended into the center of the caruncular stalk (CS). The entire layer of decidual tissue (DT) will soon slough into the uterine lumen because of vasoconstriction of the caruncular arterioles.

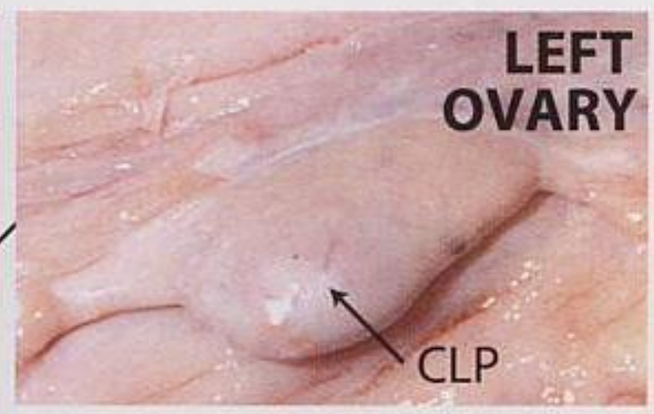
Figure 15-5. Bovine Reproductive Organs- Day 4 Postpartum

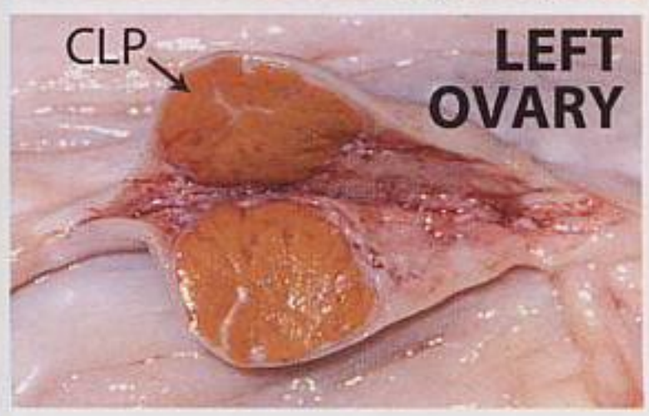


Cervix (cranial view)- Lochia (L) has been expelled through the cervix (CX) and it has pooled in the ventral region of the cranial vagina (CV) here. In the live cow, lochia would be discharged to the exterior.

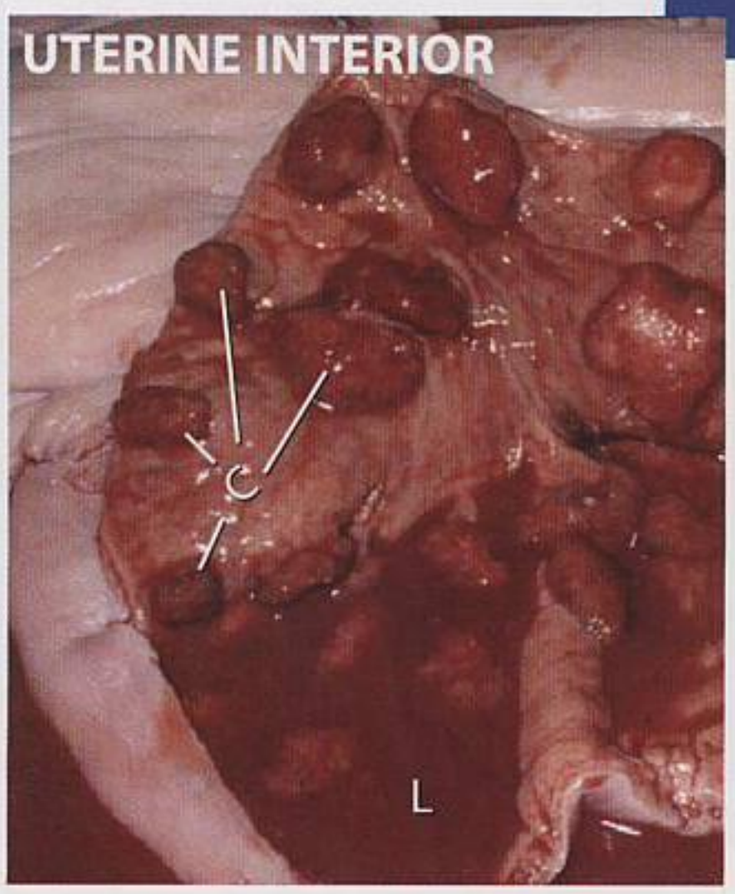








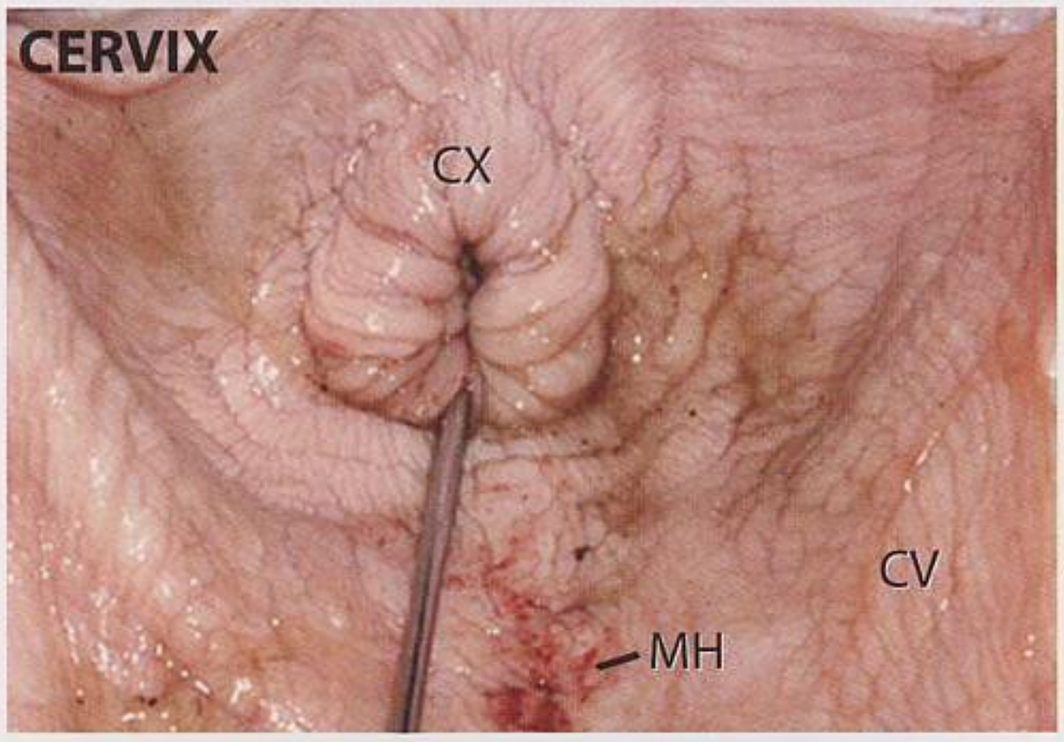
Ovaries- A regressing CL from the pregnancy (CLP) is present on each of the right and left ovaries indicating a double ovulation. Only one conceptus developed. A regressing CL (RCL) from a cycle prior to the pregnancy is present on the right ovary. There is no evidence of follicular development in either ovary.



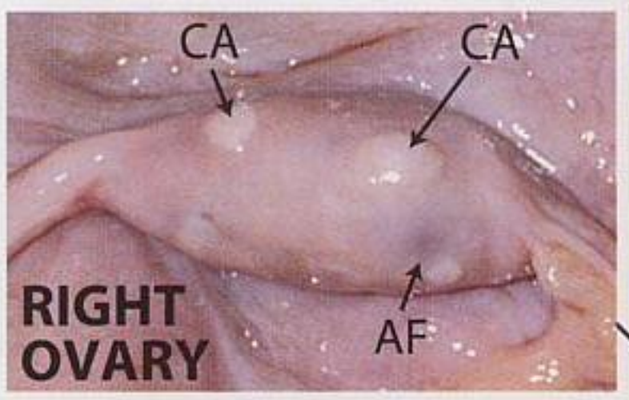
Uterus, in-situ- The most dramatic reduction in uterine size occurred between day 1 and day 5. Uterine length is reduced from about 85cm (day 1) to 58cm (day 4). The left uterine horn (LUH) housed the conceptus during pregnancy and is larger than the right uterine horn (RUH). The broad ligament (BL) and rectum (R) can be observed.

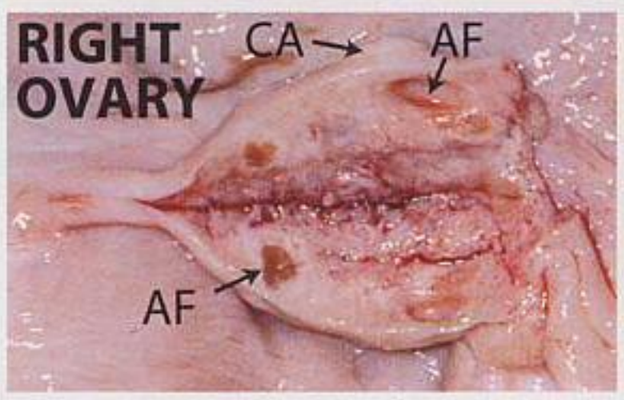
Uterine Interior- Much of the decidual tissue of the caruncles (C) has sloughed into the uterine lumen along with blood and other fluids forming lochia (L). This material is normally expelled from the uterus. The presence of lochia (L) in the uterus and its discharge from the vulva is normal.

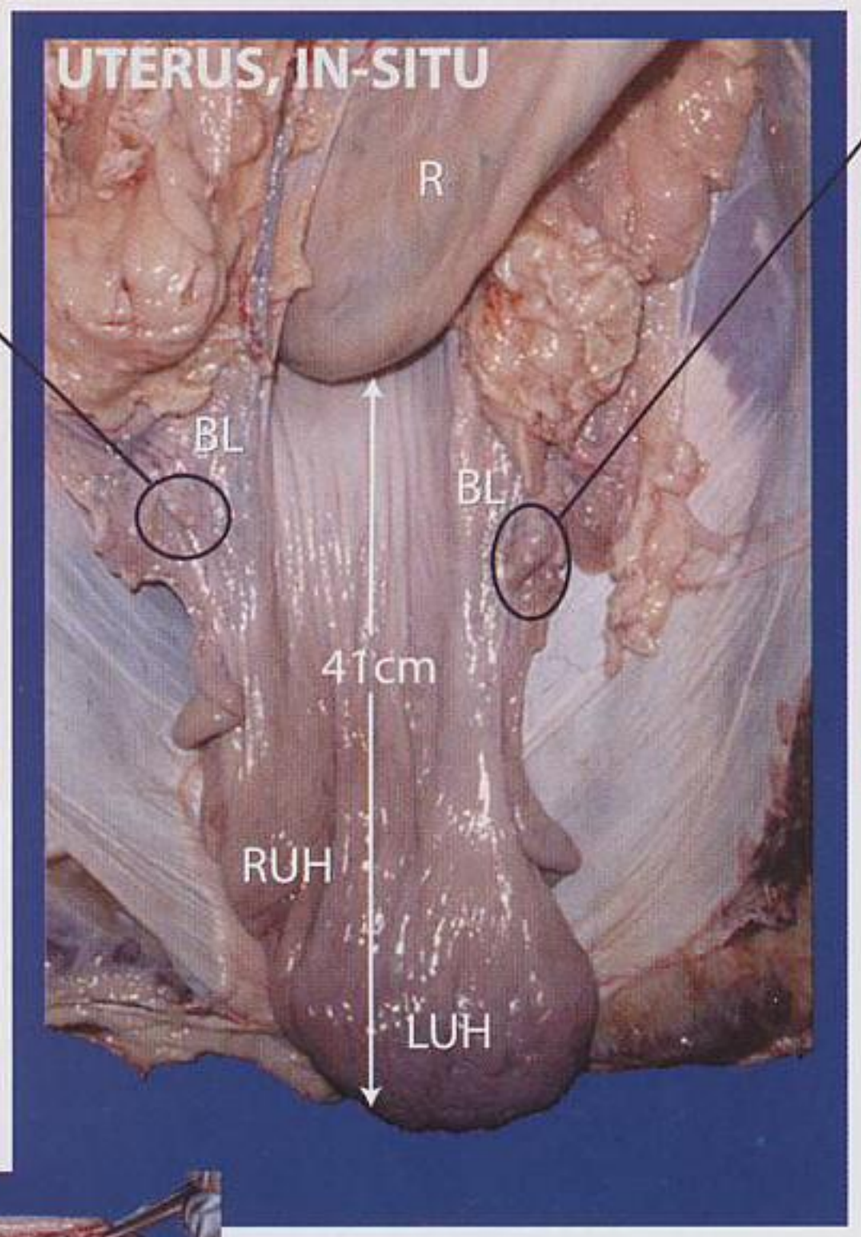
Figure 15-6. Bovine Reproductive Organs- Day 10 Postpartum

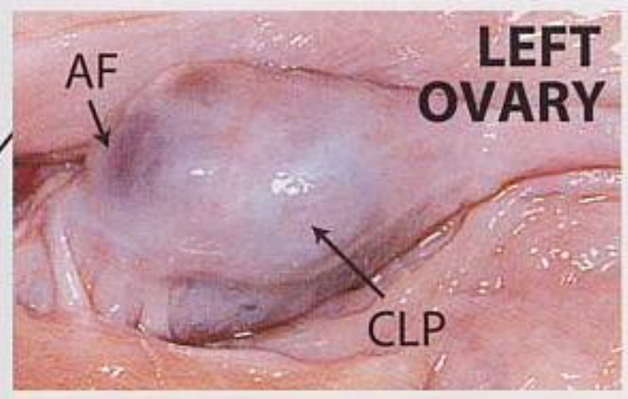


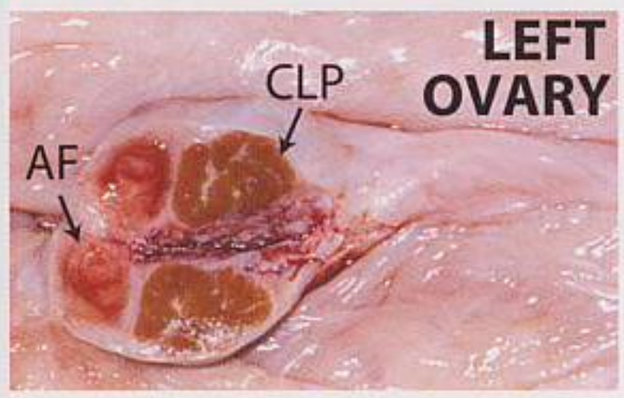
Cervix (cranial view)- Sites of mucosal hemorrhaging (MH) are still apparent in the floor of the cranial vagina (CV) in this cow. The cervix (CX) has decreased in diameter because its overall tone has increased.



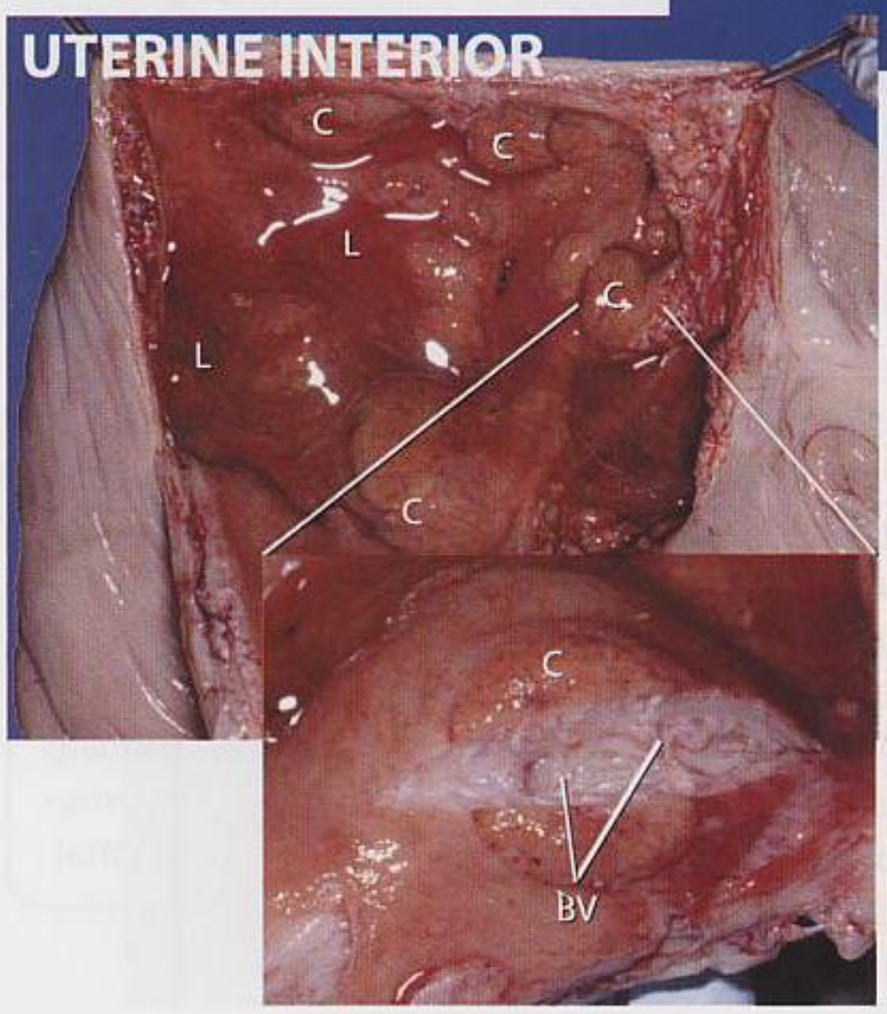






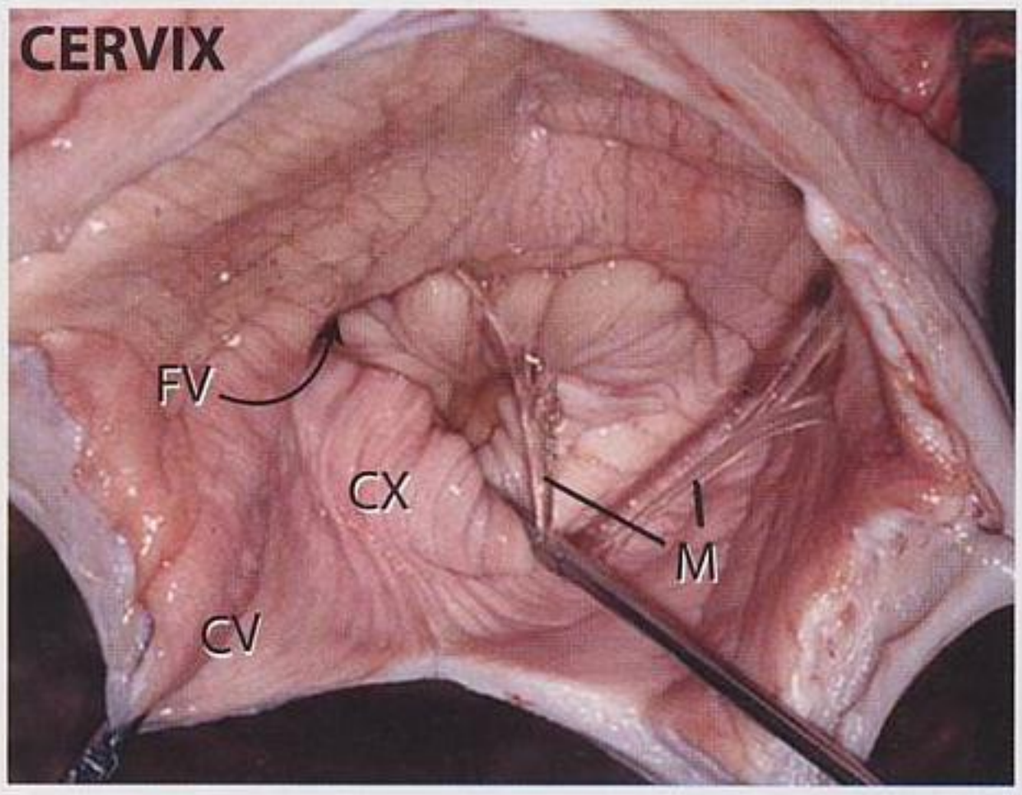


Ovaries- The right ovary contains several corpora albicantia (CA) and a few antral follicles (AF). The left ovary contains the regressing corpus luteum of pregnancy (CLP). It also contains an antral follicle (AF) indicating that a new follicular phase is beginning.

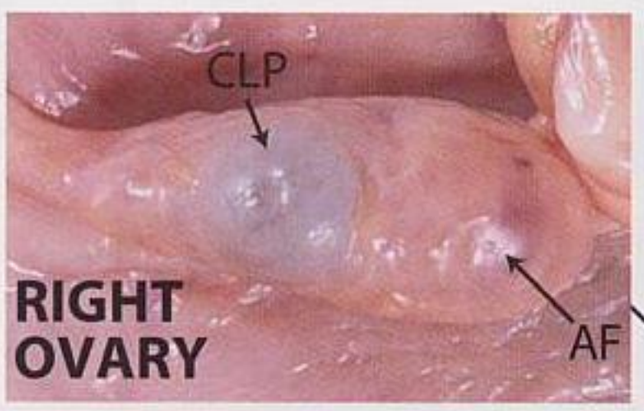


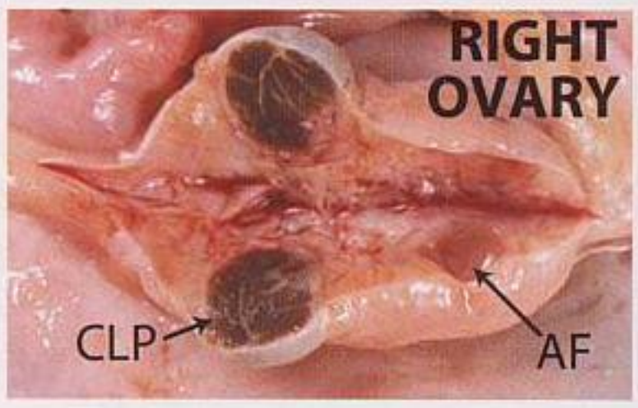
Uterus, in-situ- The uterus continues to undergo a reduction in size (41cm). The left uterine horn (LUH) remains larger than the right uterine horn (RUH) because the left uterine horn housed the conceptus. The rectum (R) and broad ligament (BL) are visible.
Uterine Interior- The decidual tissue of each caruncle has been sloughed into the uterine lumen. Some lochia (L) is still present but it is more viscous and mucus-like. The endometrial and caruncular epithelium is now beginning to cover the surface. The enlarged photograph illustrates the marked reduction in size of the caruncle (compare to days 1 and 4). The caruncular stalk is nonexistent. This size reduction is a function of vasoconstriction of the caruncular blood vessels (BV).

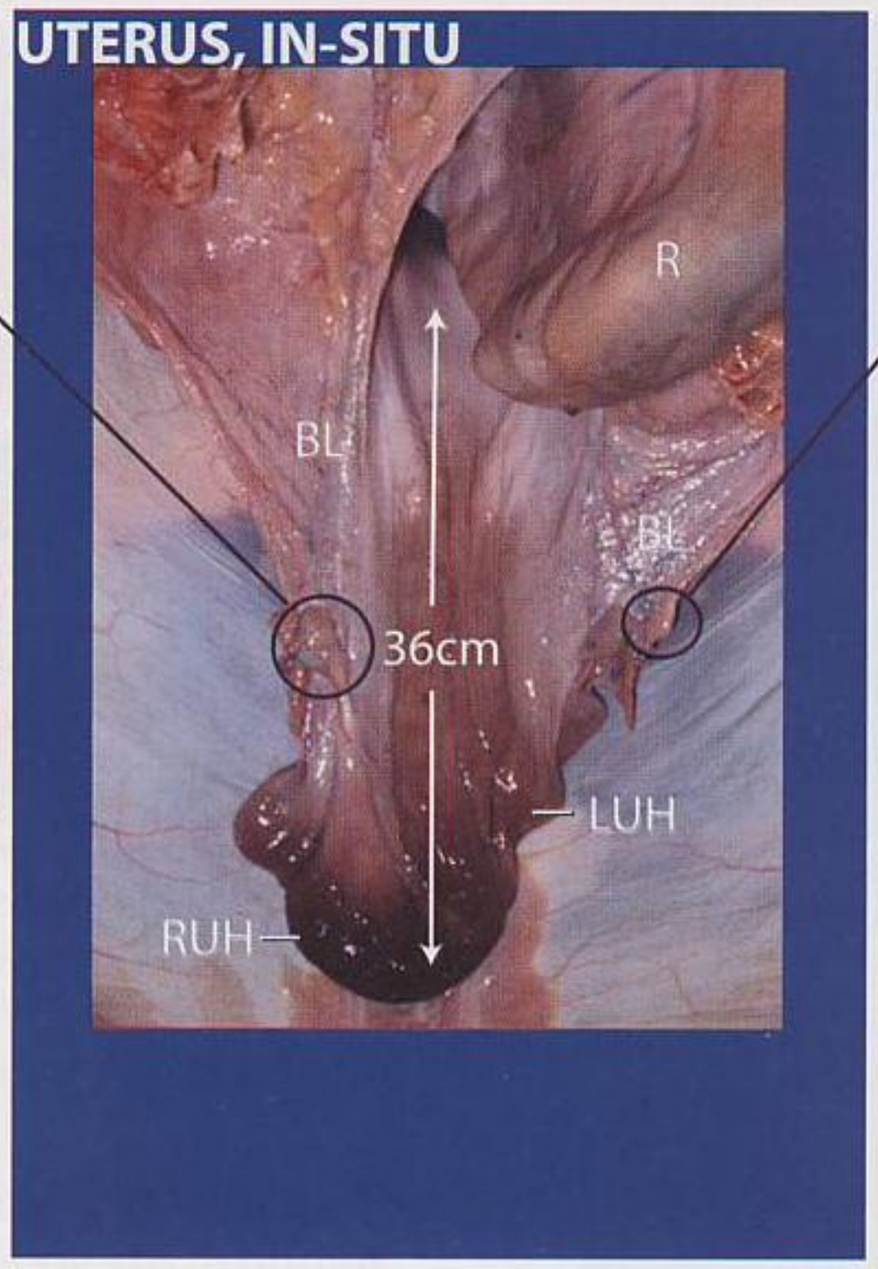
Figure 15-7. Bovine Reproductive Organs- Day 15 Postpartum

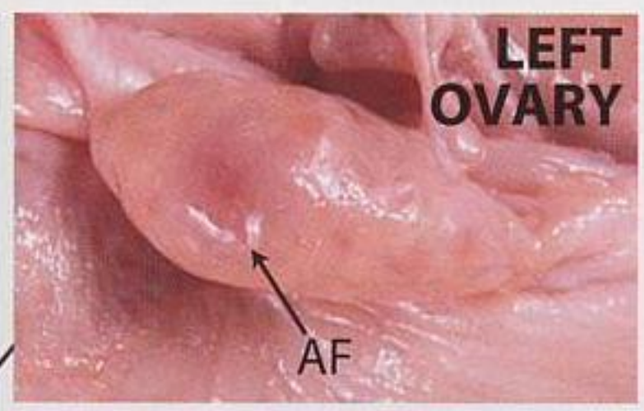


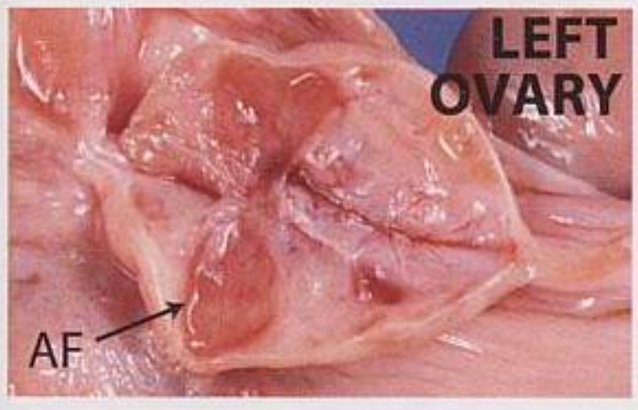
Cervix (cranial view)- Strands of clear mucus (M) secreted by the cervix (CX) and cranial vagina (CV) indicate that this cow is entering her first follicular phase after parturition (See ovaries). FV = Fornix vagina.



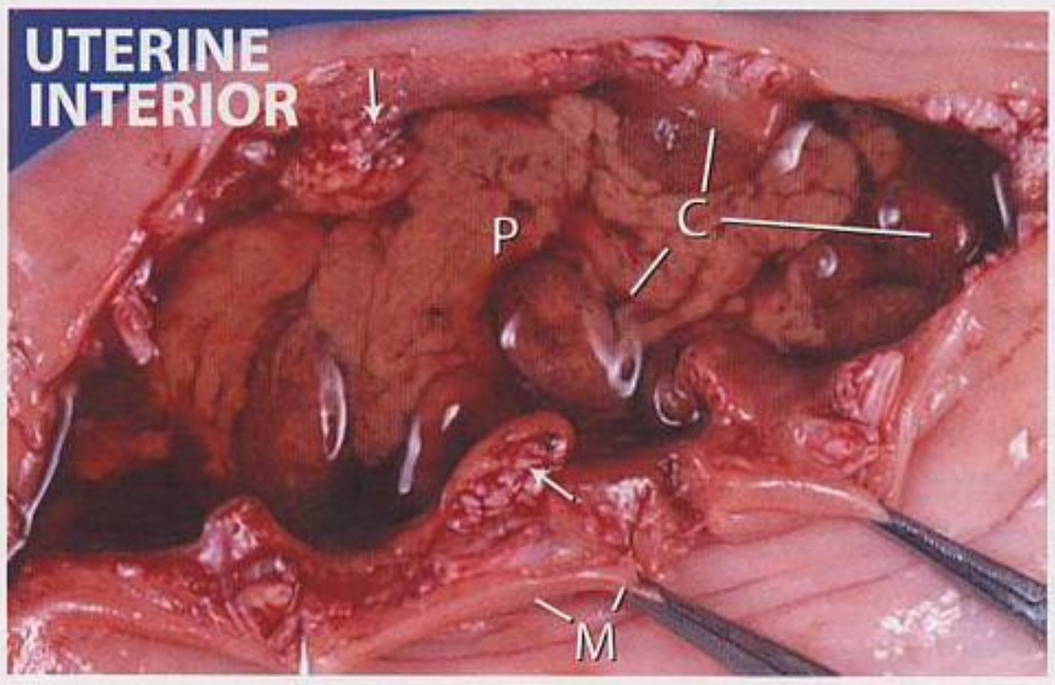








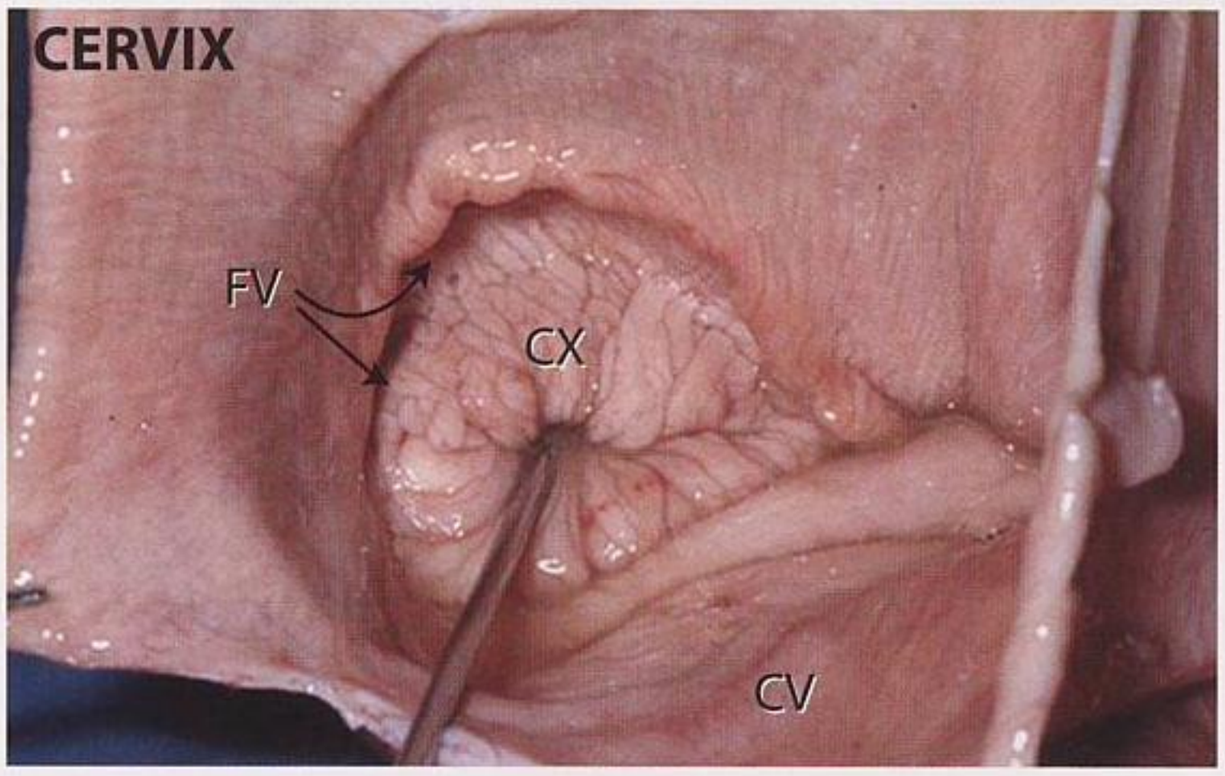
Ovaries- The right ovary contains the regressing corpus luteum of pregnancy (CLP). It also contains a developing antral follicle (AF). The left ovary contains a large antral follicle (AF) indicative of the first postpartum follicular phase. The follicles present produce estradiol that causes secretion of mucus by the cervix and cranial vagina.



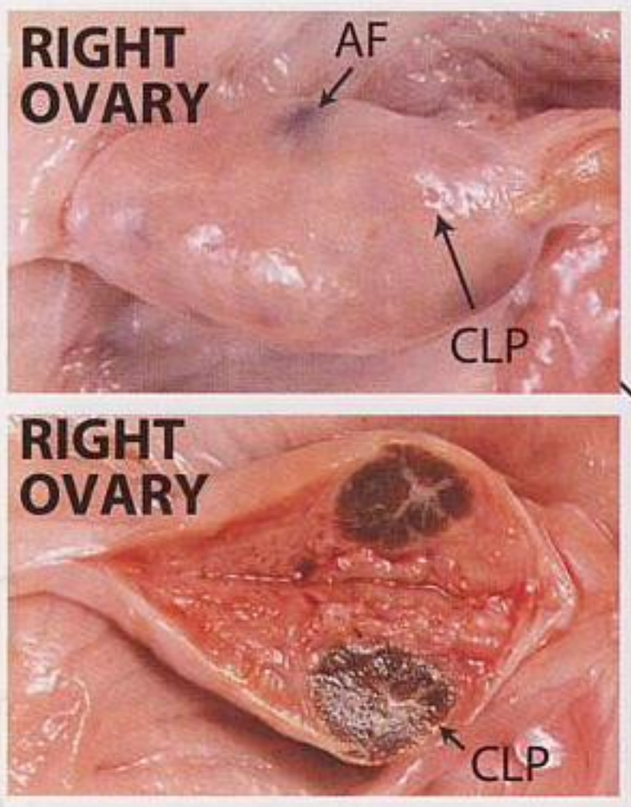
Uterus, in-situ- The right uterine horn (RUH) housed the conceptus and is larger than the left uterine horn (LUH). Continued reduction in size is evident. The broad ligament (BL) and the rectum (R) can be observed. The dark coloration at the tips of the uterine horns represents pooling of blood following exsanguination of the cow.

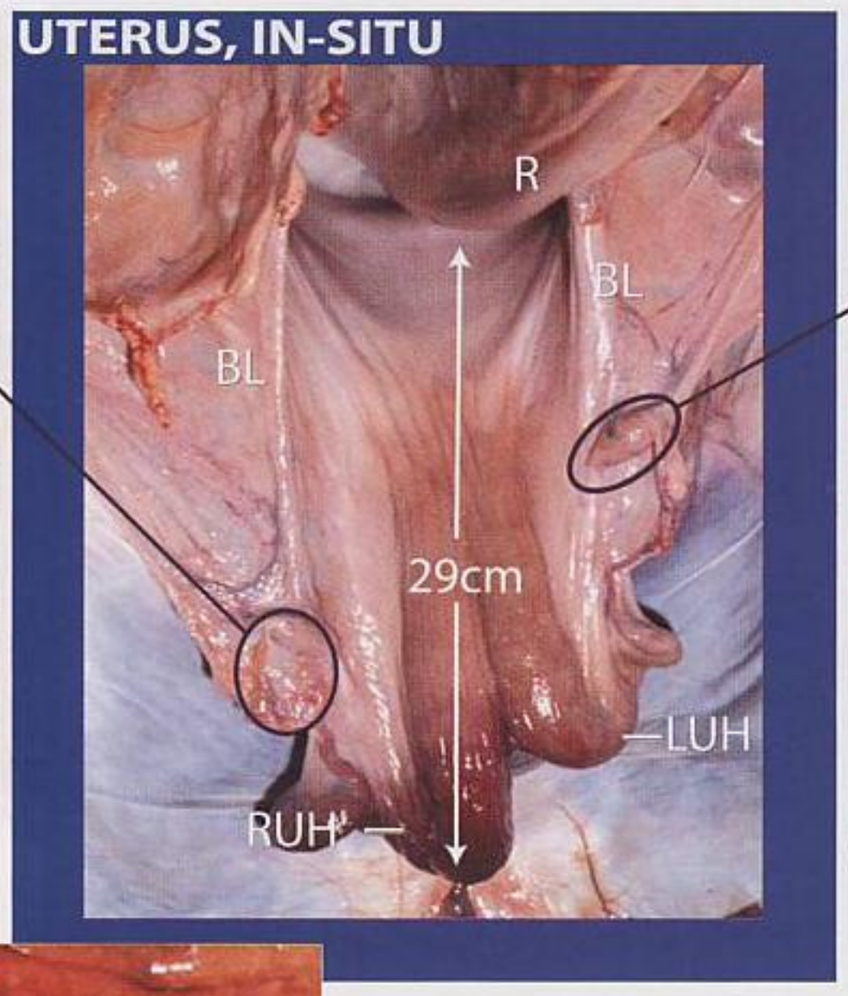
Uterine Interior- The caruncles (C) have decreased further in size and are almost completely covered in mucus. Lochia is almost nonexistent and a puss-like material (P) is present in localized areas. The presence of puss is normal and reflects phagocytosis of deteriorating tissue by leukocytes. Caruncular blood vessels (arrows) can be seen as small knot-like structures in the incised caruncles. M = Myometrium.

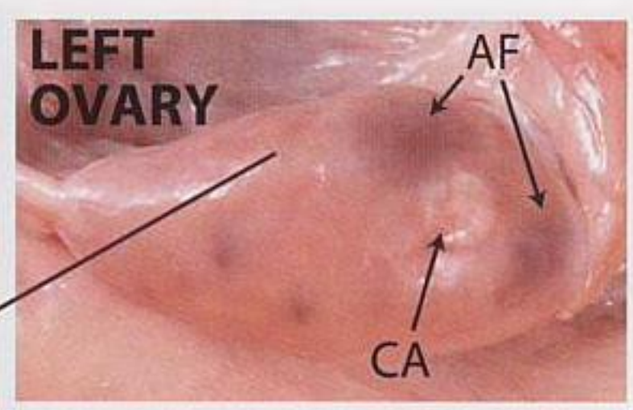
Figure 15-8. Bovine Reproductive Organs- Day 20 Postpartum

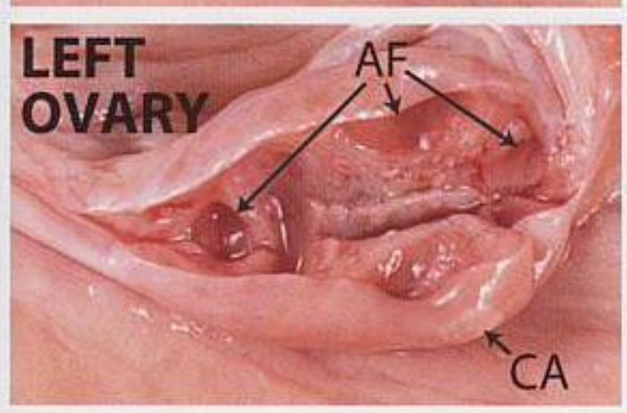


Cervix (cranial view)- The cranial vagina (CV) and fornix vagina (FV) are free of hemorrhagic foci. The color, diameter and tone of the cervix (CX) are normal. Mucus is present coating the mucosal surfaces.

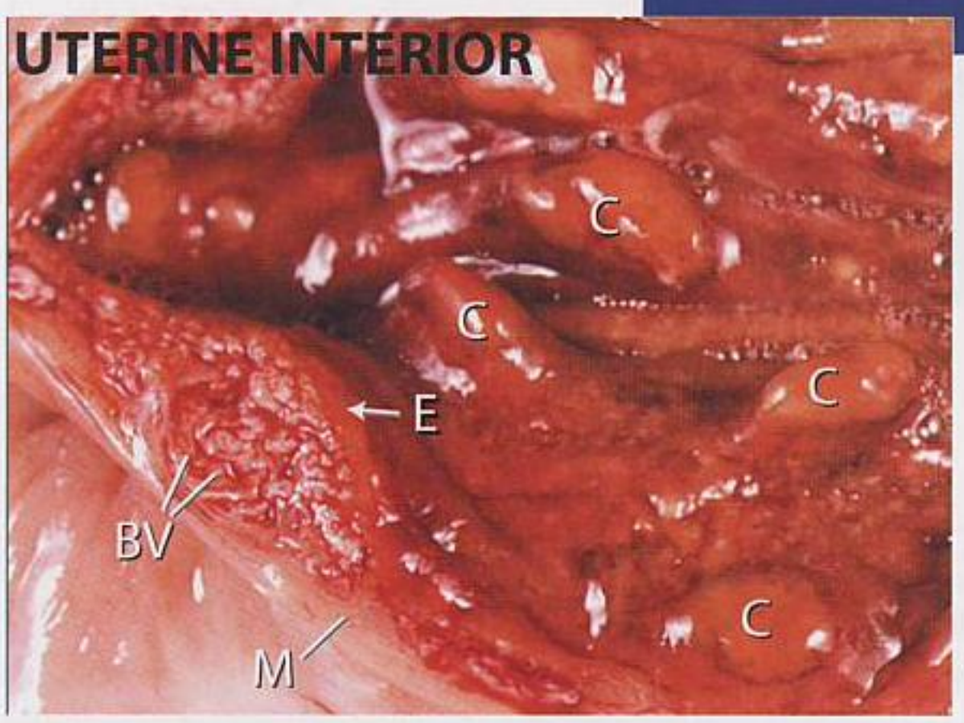








Ovaries- The right ovary contains the regressing corpus luteum of pregnancy (CLP) and an antral follicle (AF). The antral follicle is not observed in the incised ovary because it is out of the plane of section. The left ovary contains several antral follicles (AF) indicating this cow is entering her first postpartum follicular phase. A corpus albicans (CA) represents a corpus luteum from a cycle prior to the previous pregnancy.

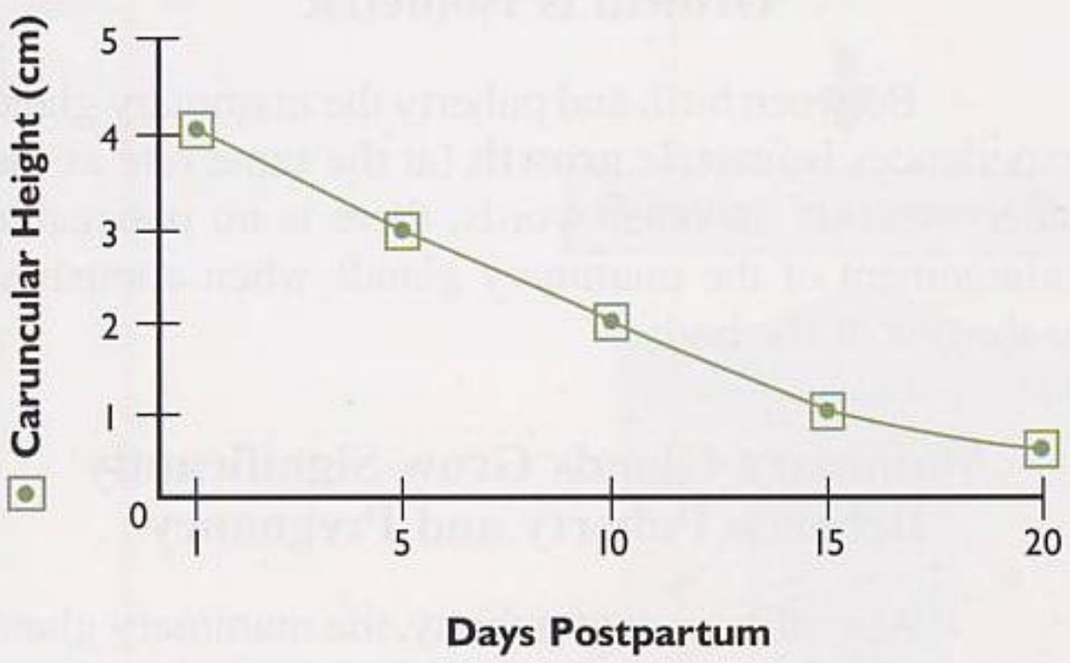


The photographs in Figures 15-4 through 15-8 were part of an Honors Thesis entitled "A Full Color Photographic Description of Postpartum Uterine Involution in the Dairy Cow" submitted to Washington State University Honors College by Christina M. Davis, Spring 2002. The Honors project was sponsored by Current Conceptions, Inc.

Uterus, in-situ- The uterine horns continue to decrease in size and have almost returned to their normal nonpregnant size. The right uterine horn (RUH) remains larger than the left uterine horn (LUH) because the right uterine horn housed the conceptus. The broad ligament (BL) and the rectum (R) can be readily observed. **Uterine Interior**- Caruncles (C) are approaching the size of those normally seen within the nonpregnant uterus. A cross-section of an incised caruncle shows the mass of blood vessels (BV) between the myometrium (M) and the epithelium (E) covering the caruncle. The fluid within the uterine lumen is predominantly mucus.

the decidual tissue of the caruncle has sloughed into the uterine lumen the caruncle begins to undergo repair and is eventually covered again with endometrial epithelium.

Figure 15-9. Changes in Caruncular Height at Various Postpartum Days



(From Salisbury et al. 1978)

At the same time caruncular repair is taking place, the intercaruncular endometrial surfaces also undergo repair. In general, the epithelium of the intercaruncular area of the endometrium repairs at a faster rate than do the caruncles. The repair of the intercaruncular endometrium is generally complete by the eighth postpartum day. The delay in caruncular repair, when compared to the intercaruncular epithelium is associated with the large mass of the caruncular tissue that must undergo necrosis and sloughing before surface epithelial repair can take place.

Postpartum Bacterial Contamination of the Uterus is Common in Most Domestic Animals

Generally, parturition in domestic animals occurs in a non-sterile environment. As a result, bacterial contamination of the reproductive tract, especially the uterus is an inevitable sequela to parturition. The postpartum reproductive tract (containing lochia) is an ideal environment for the growth of bacteria. Even though myometrial contractions tend to remove the large volume of lochia produced in some species, bacterial growth can continue. It must be emphasized that bacterial contamination is not always associated with pathology. Normal postpartum events tend to eliminate the bacterial flora within a reasonable time. As you recall, elevated estradiol promotes leukocytosis in the uterus and elsewhere in the reproductive tract. Thus, a high degree of phagocytosis can be observed in the postpartum reproductive tract as a result of relatively high postpartum estradiol concentrations that exist for a few days.

In some instances, high numbers of bacteria can overwhelm the natural defense mechanisms resulting in postpartum uterine infection. Conditions that predispose the uterus to infections are: retained fetal membranes, dystocia and delay in lochial expulsion brought about by weak myometrial contractions. Regardless of the cause, failure to eliminate bacterial contamination will: 1) prolong uterine involution; 2) prolong the puerperium and 3) delay subsequent pregnancies. Treatment of uterine infections is controversial. There is little evidence that supports the effectiveness of infusing the uterus with various pharmaceuticals in dairy cows. The single most important natural factor that aids in elimination of bacterial contamination is a return to cyclicity (estrus) so that estradiol concentrations will be elevated.

Photographic descriptions of the changes that occur in the uterus, caruncles, cervix and ovaries of the dairy cow during the first 20 days of the puerperium are presented in Figures 15-4 through 15-8. The specimens were obtained from cows that were defined as clinically normal as judged by palpation per rectum by the veterinarian servicing the herd. All cows gave birth to a single calf. To compare these various days of involution to completely involuted organs, please consult the figures in Chapter 2.

Lactation

Lactation ensures that the neonatal mammal does not have to obtain food on its own. Instead, the dam is responsible for consuming all of the nutritional raw materials and transforming these into a highly nutritious secretion called **milk**. The neonate benefits from this synthetic and secretory process because its only behavioral requirement in the early postnatal period is suckling the dam. Some animals have been domesticated and selected so they produce quantities of milk that far exceed that needed to nourish the young. The dairy cow is the dominant producer of milk for human consumption. However, goats, sheep, water buffalo, camels and mares are also considered important for their milk producing ability in some parts of the world. The immense milk producing ability of the modern dairy cow has provided a huge variety of dairy products that contribute to a multi-billion dollar industry in the western world. In this light, much of the information provided in this section will be about the dairy cow. However, the basic principles apply to most mammals. The development of the mammary gland (**mammogenesis**), anatomical diversity and **milk ejection** from the gland will be the priority topics in the remainder of this chapter.

Mammary Glands are Sophisticated Sweat Glands

Mammary glands arise in the developing embryo along two lateral lines on the ventral surface of the developing conceptus. These lines are slightly thickened ridges of epidermis (skin) and are called **mammary ridges** (See Figure 15-10). The mammary ridges extend from the axillary region (armpit) of the conceptus to the inguinal region. The number of mammary glands that develop from the mammary ridges depends on the species. For example, animals like the pig, dog and cat have a series of individual glands that develop at predictable positions along the entire path of the mammary ridges. In contrast, animals like the human and elephant have paired mammary glands that develop from the thoracic portion of the mammary ridges. Animals like the cow, mare and goat have mammary glands that develop from the inguinal region of the mammary ridge. The diversity among mammals in gland number, anatomic location and teat morphology is presented in Figure 15-11.

The thickened epidermal epithelium creating the mammary ridges gives rise to the **primary mammary bud** (See Figure 15-10). The primary mammary bud pushes into the underlying dermis as it grows. Continued growth results in **secondary mammary buds** that form bud protrusions away from the primary bud. These secondary buds then lengthen and branch throughout the remainder of embryonic development. Finally, these branched buds begin to **canalize** forming tiny ducts in the center of each bud. Each bud then becomes a duct with a lumen. At birth, the mammary glands consist of **lactiferous ducts** that open into larger ducts and empty to the exterior of the mammary gland (See Figure 15-10).

Postnatal changes in the mammary gland occur:

- ***between birth and puberty***
- ***between puberty and pregnancy***
- ***during pregnancy***
- ***during lactation***
- ***during involution***

Postnatal Growth of the Mammary Gland is Endocrine Mediated

Complete anatomical development of the mammary gland coupled with the ability to synthesize and secrete milk does not occur until the female has reached puberty, becomes pregnant and gives birth to offspring.

Between Birth and Puberty, Mammary Growth is Isometric

Between birth and puberty the mammary gland experiences **isometric growth** (at the same rate as the other tissues). In other words, there is no noticeable enlargement of the mammary glands when compared to the rest of the body.

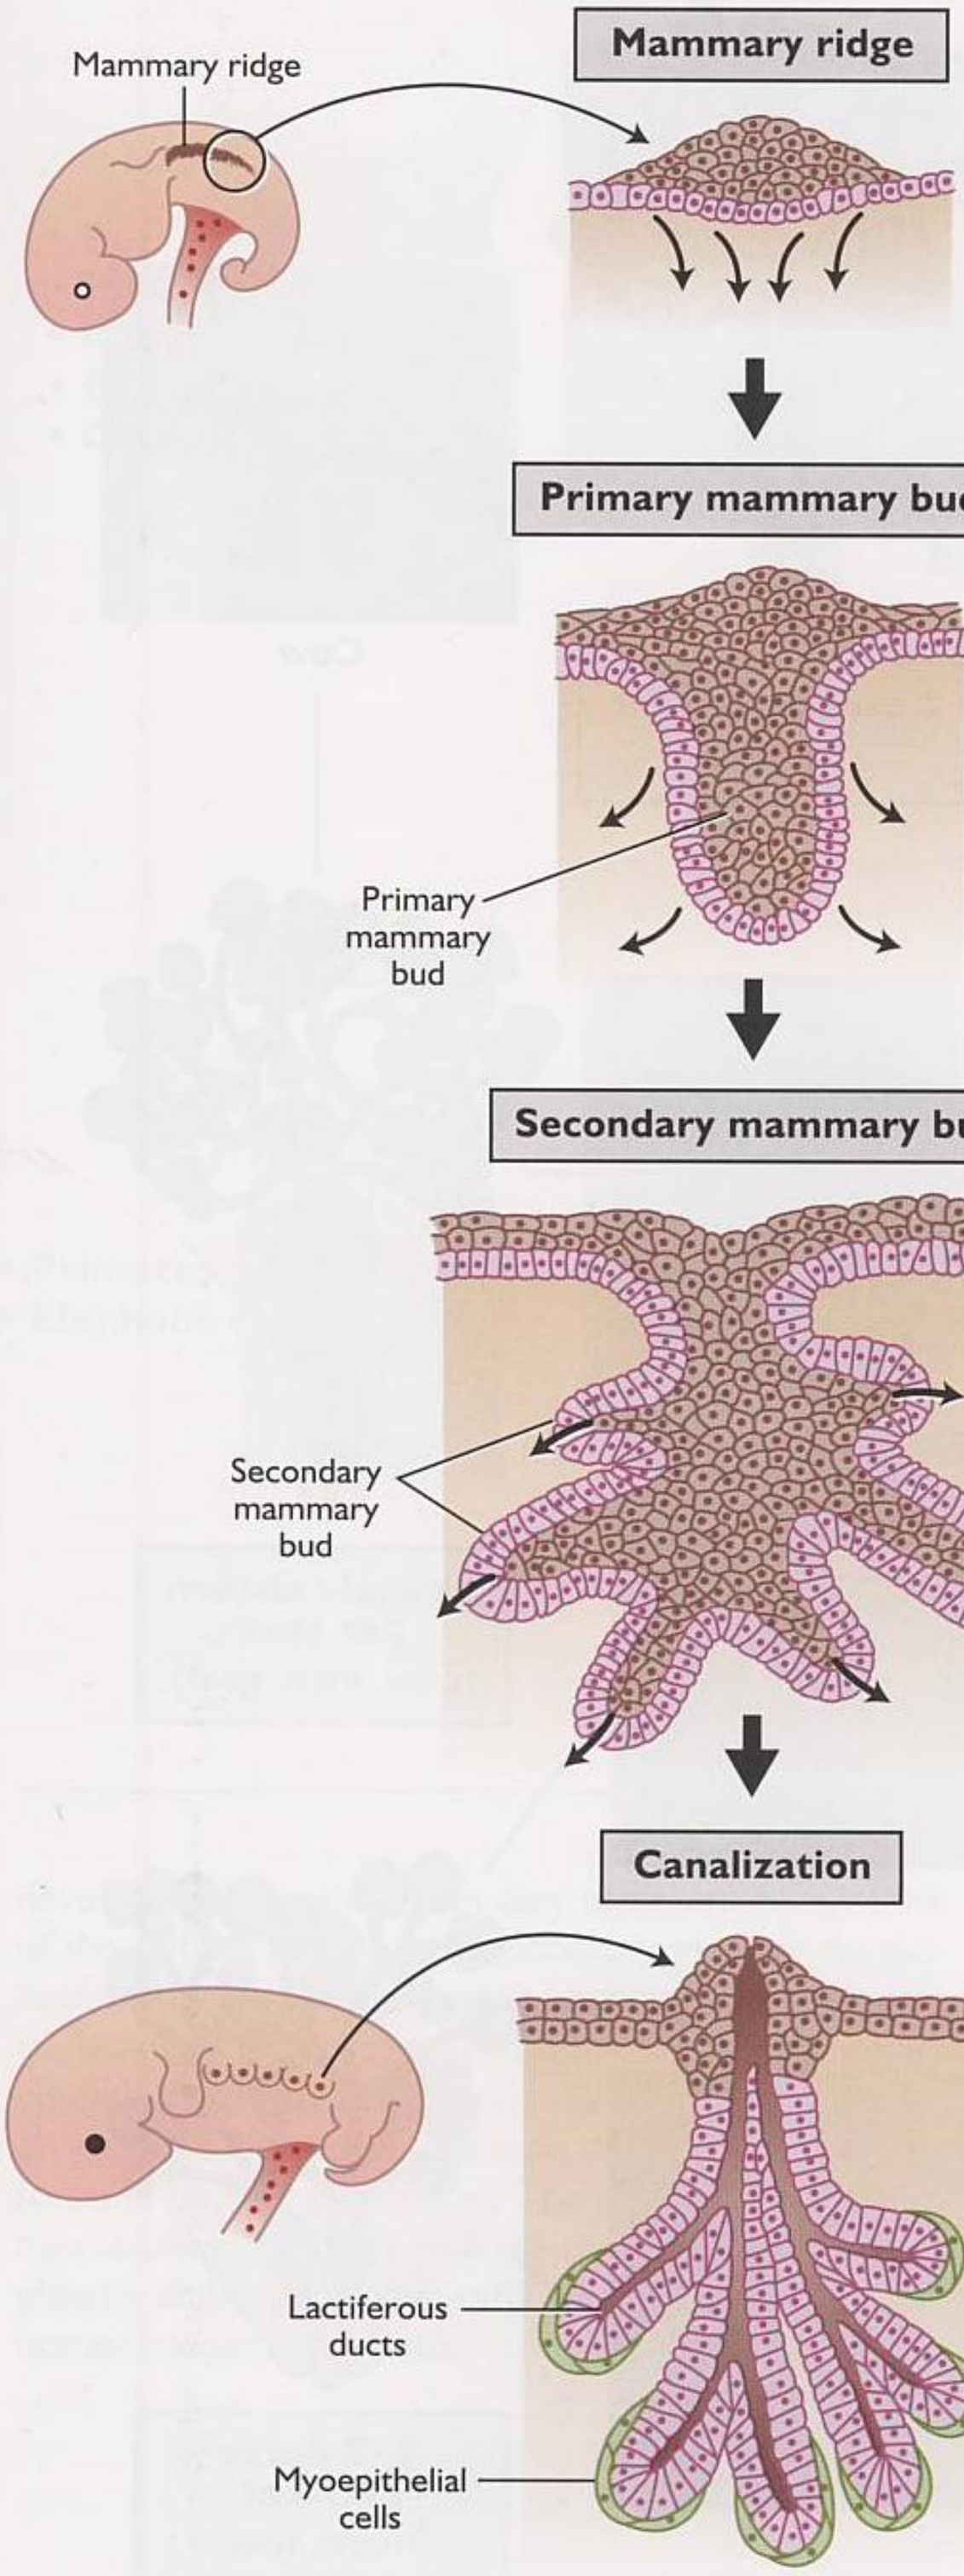
Mammary Glands Grow Significantly Between Puberty and Pregnancy

After the onset of puberty, the mammary gland begins to grow at a rate that is disproportionately faster than normal body growth. This type of growth is referred to as **allometric growth**. During repeated estrous cycles, a duct and alveolar framework is constructed within the mammary gland. This framework provides the cellular basis for future milk synthesis. During the first several estrous (or menstrual) cycles, the ducts begin to branch and their diameter increases under the influence of estrogen. Under the influence of progesterone (during the luteal phase), the terminal portions of each branch begin to form the initial portions of the alveoli. The alveoli form the functional secretory elements of the mammary gland (See Figure 15-13). Estrogen alone will cause some duct development but more complete and rapid duct development occurs in the presence of **prolactin** and **growth hormone** (somatotropin). Both of these hormones increase during the onset of puberty. Repeated cyclic exposure of the mammary cells to estrogen and progesterone can stimulate mammogenesis to proceed only so far. The mammary framework formed between puberty and pregnancy needs future endocrine input during the gestational period for complete development.

Final Mammary Development Occurs During Pregnancy

Complete alveolar development in the dam takes place during the last trimester of pregnancy. During this time the terminal alveoli begin to grow into bunches called **lobules**. A lobule would be analogous to a group of grapes on a single stem among an entire bunch of grapes (See Figure 15-13). During the final trimester of pregnancy, the **lobulo-alveolar structures**

Figure 15-10. Prenatal Mammogenesis



Mammary Ridges
Mammary ridges are thickened epidermal tissue that give rise to the mammary gland.

Primary Mammary Bud
The thickened epidermal tissue begins to develop inward and penetrate into the mesenchyme (dermis).

Secondary Mammary Bud
The primary mammary bud begins to send out branches that further penetrate into the dermis.

Canalization
The fingerlike secondary buds begin to lengthen and branch out. Finally they begin to form canals or channels (canalization) that will form the duct system of the gland. Myoepithelial cells surround the terminal portions of the developing gland.

develop to the point where they represent nearly 90% of the cellular mass of the mammary gland at parturition. Prolactin, adrenal cortical hormones and placental lactogen are important in allowing the mammary epithelium to synthesize milk. As seen in Chapter 14, all of these hormones increase dramatically just before the time of parturition. The induction of parturition is carefully timed with the onset of the mammary gland's ability to secrete milk so that the neonate has immediate access to milk.

Lactation Provides Immunoprotection and Nutrition for the Neonate

The first secretions from the mammary gland (called colostrum) are critical to neonatal survival because the milk from the dam contains immunoglobulins (antibodies). These immunoglobulins are ingested by the neonate and are transported unaltered into the cells of the gut mucosa to provide passive immunity. In ruminants (and other animals) with an epitheliochorial placenta maternal immunoglobulins cannot be transferred in-utero because the placenta is a barrier. Thus, ingestion of colostrum soon after birth provides

necessary immunologic protection for the newborn. In contrast, humans and other animals with hemochorial placentation have placental transfer of immunoglobulins from the dam to the fetus. The fetus is thus born with at least partial passive immunity. Immunoglobulins in milk are still important to neonatal immunoprotection in primates. Colostrum is provided for a brief period (2 to 3 days) and then milk composition remains relatively constant for the remainder of the lactation. During the course of lactation, milk synthesis increases and then peaks shortly after parturition. After the secretory peak, the synthetic rate decreases and this generally coincides with the time of weaning. It is important to recognize that growth of the neonate is directly proportional to milk production by the dam. In some instances, failure of the neonate to grow can be due to mastitis (inflammation of the mammary gland) or agalactia (failure to synthesize milk). It should be emphasized that in some breeds of sheep and goats the reproductive goal is to produce triplets and quadruplets. This goal conflicts with the anatomy/lactation ability of the dam since these species have only two teats. Nutrition of the neonate may thus be compromised since there may not be enough milk to serve the nutritional demands of the offspring.

Involution is the Return to a Nonsecretory State

As the need for milk as the sole nutritional source begins to decrease, the neonate begins to suckle less frequently. Consequently, there is a buildup of pressure within the mammary gland causing the secretory cells to become less and less functional. This phenomenon is called **pressure atrophy**. Pressure atrophy is such a powerful force that milk synthesis can be stopped in just a few days if the intramammary pressure is allowed to buildup suddenly. The milk synthesis occurring in the alveolar epithelium decreases to the point that the cells undergo almost complete atrophy. Secretory cells will remain nonfunctional until a subsequent pregnancy. With a subsequent pregnancy, prolactin, adrenal cortical hormones and placental lactogen will restimulate alveolar cells to produce milk for another lactation.

During involution, immune cells such as lymphocytes and macrophages invade the mammary tissue. These immune cells will participate in the production of important immunoglobulins in the subsequent lactation. Mammary involution is a critical process because it allows the mammary gland to recover and develop new secretory tissue for a subsequent lactation. Changes in the tissue mass of the mammary gland as a function of reproductive stage are presented in Figure 15-12.

Milk Contains Hormones and Growth Factors

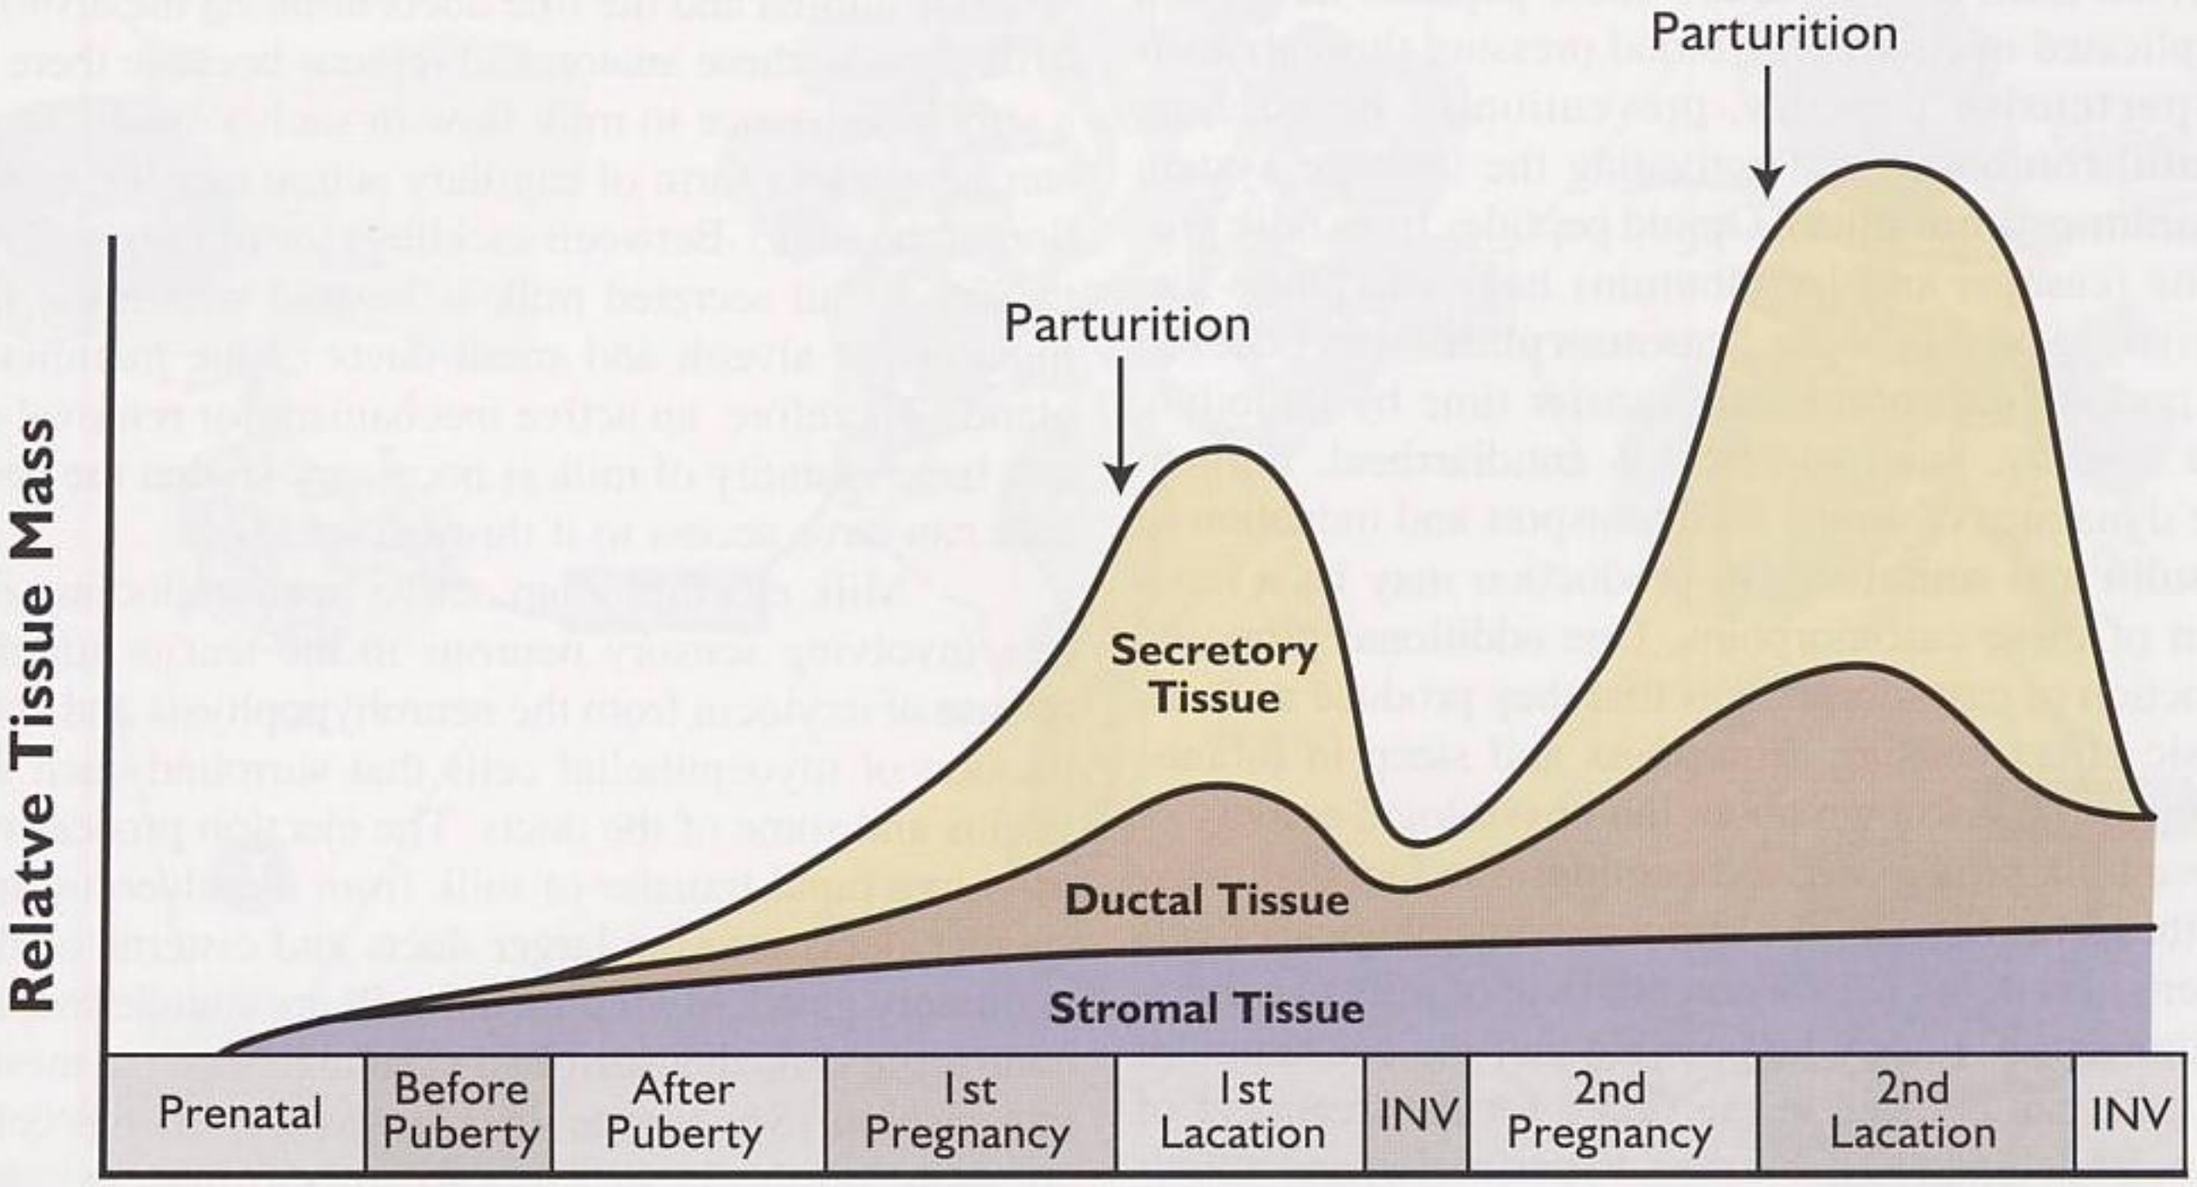
Many substances that are found in blood can also be found in milk. Thus, milk naturally contains hormones and growth factors that are derived from the blood of the lactating female. Also, exogenous materials such as alcohol, drugs, antibiotics, etc. can be found in milk if they are consumed by the dam. Before the advent of controlled nutrition in dairy cattle, it was not uncommon for milk to have an onion-like flavor in the spring because cows grazed in pastures and consumed wild onions growing there. Chemicals causing the onion flavor pass directly into the milk because they are lipid soluble.

The appearance of hormones in milk relates to two transfer mechanisms. First, cells of the alveolar epithelium have receptors for various hormones. Therefore, these hormones can be internalized into the alveolar cells. As a result, the hormone can be secreted into the milk. The primary hormone secreted in this manner is the pituitary hormone prolactin. Prolactin produced by the anterior lobe of the pituitary enters the blood and is transferred into mammary cells and into milk. Other hormones such as GnRH, growth hormone (somatotropin), thyroid hormone (thyroxine) and their releasing factors have been identified in milk. It should be emphasized that protein hormones have little or no physiological effect on the neonate (or the consumer) because they are hydrolyzed into amino acids in the gastrointestinal tract and therefore lose their biologic activity.

Ovarian steroids (estrogens and progesterones) diffuse directly from the blood into the milk by passive diffusion because they are lipid soluble. All steroid hormones can be found in milk. The concentration of estrogen and progesterone in milk reflects cyclic hormone production by the ovaries and is highly correlated with blood concentrations. Such a phenomenon enables steroids (particularly progesterone) to be easily assayed in milk to determine the reproductive status of the female. Cowside ELISA technology enables progesterone concentrations in milk to be determined. Procedures to assay progesterone at each milking through the use of "in-line" assay technology in the milking parlor is a worthy research and development pursuit. The concept would utilize a small sensor in each milking machine that can transduce the progesterone concentration into an electrical signal that could be transferred to the computer. The development of such technology would enable the producer to determine whether a cow is cycling, the stage of the estrous cycle, the pregnancy status and some forms of ovarian pathology (e.g. cystic ovarian disease) for each cow on a daily basis. The availability of such technology would revolutionize reproductive management of dairy cows.

Figure 15-12. Changes in the Mammary Gland as a Function of Reproductive Stage

(Modified from Mepham. 1987. *Physiology of Lactation*)



The mammary gland undergoes continuous change from prenatal life through subsequent lactations. During pubertal onset the ductal and secretory tissue of the mammary gland increases. During the first pregnancy these tissues continue to increase but at a faster rate. At the time of parturition, the secretory tissue mass is high and continues to increase until it peaks shortly after parturition during the first lactation. At the conclusion of the first lactation (either weaning or drying-off in the dairy cow) the secretory tissue mass decreases significantly (mammary involution, INV). During the second pregnancy and lactation secretory tissue and ductal tissue increases significantly. Following lactation a second involution (INV) takes place.

Growth Factors in Milk May Provide New Insights to Neonate Health

It is known that a number of growth factors are present at high levels in **colostrum**. Colostrum is the first milk produced after parturition and contains antibodies to provide the neonate with passive immunity. These growth factors mirror the profile of immunoglobulins secreted into the colostrum. Researchers have hypothesized that the accumulation of growth factors in colostrum evolved to promote neonatal growth and development. Examples of growth factors found in colostrum are Insulin Like Growth Factors 1 & 2 (IGF1&2), Epidermal Growth Factor (EGF) and Transforming Growth Factor a and b (TGF-a, TGF-b). Most of the discoveries related to the presence of these growth factors in milk are relatively recent. Since growth factors are present in milk and have significant biologic activity, two outcomes could be important. First, the discovery that these growth factors exist opens a new avenue of study implicating mammary secretions in neonatal health and development that go beyond simply meeting nutritional needs. Secondly, there must be some molecular protection mechanism for these growth factors that prevents digestion by the gastrointestinal tract. Better understanding in both areas could open doors regarding neonatal health and growth and protection mechanisms for various proteins.

Peptides are Physiologically Derived from Milk Proteins

Over 15 physiologically active peptides are derived from milk proteins. These peptides have been implicated in controlling blood pressure through **antihypertensive** peptides, prevention of blood clots (**antithrombotic**) and activating the immune system (**immunostimulation**). Opioid peptides from milk proteins (caseins and lactalbumin) have morphine-like activity. Some of these "**casomorphins**" are believed to prolong gastrointestinal transfer time by inhibiting gut motility. Such an effect is antidiarrheal. Further, the dynamics of amino acid transport and induction of **insulin** and **somatostatin** production may be a function of these casomorphins. One additional proposed function of casomorphins is that they produce an analgesic effect causing drowsiness and sleep in infants. While little is known about the physiologic activity of these milk protein derived peptides, the fact that many of these materials have distinct pharmacological effects opens new doors for the potential use of milk in a therapeutic sense. It may be possible that the consumption of milk can be used in the future for the treatment of mineral deficiencies, diarrhea, hypertension and immunodeficiencies. By employing genetic engineering techniques, it may be possible to "genetically engineer" a mammary gland that would produce materials that can have significant therapeutic effects on the consumer beyond the known nutritional effects of milk.

Milk ejection requires:

- ***sensory activation (teat stimulation, auditory, tactile and visual)***
- ***neural activation of the hypothalamus***
- ***oxytocin release into the blood***
- ***contraction of the myoepithelial cells***
- ***mechanical transfer of milk from alveoli into large ducts and finally into the teat/nipple***

15

Milk Ejection Transfers Milk from the Mammary Alveoli into the Ducts

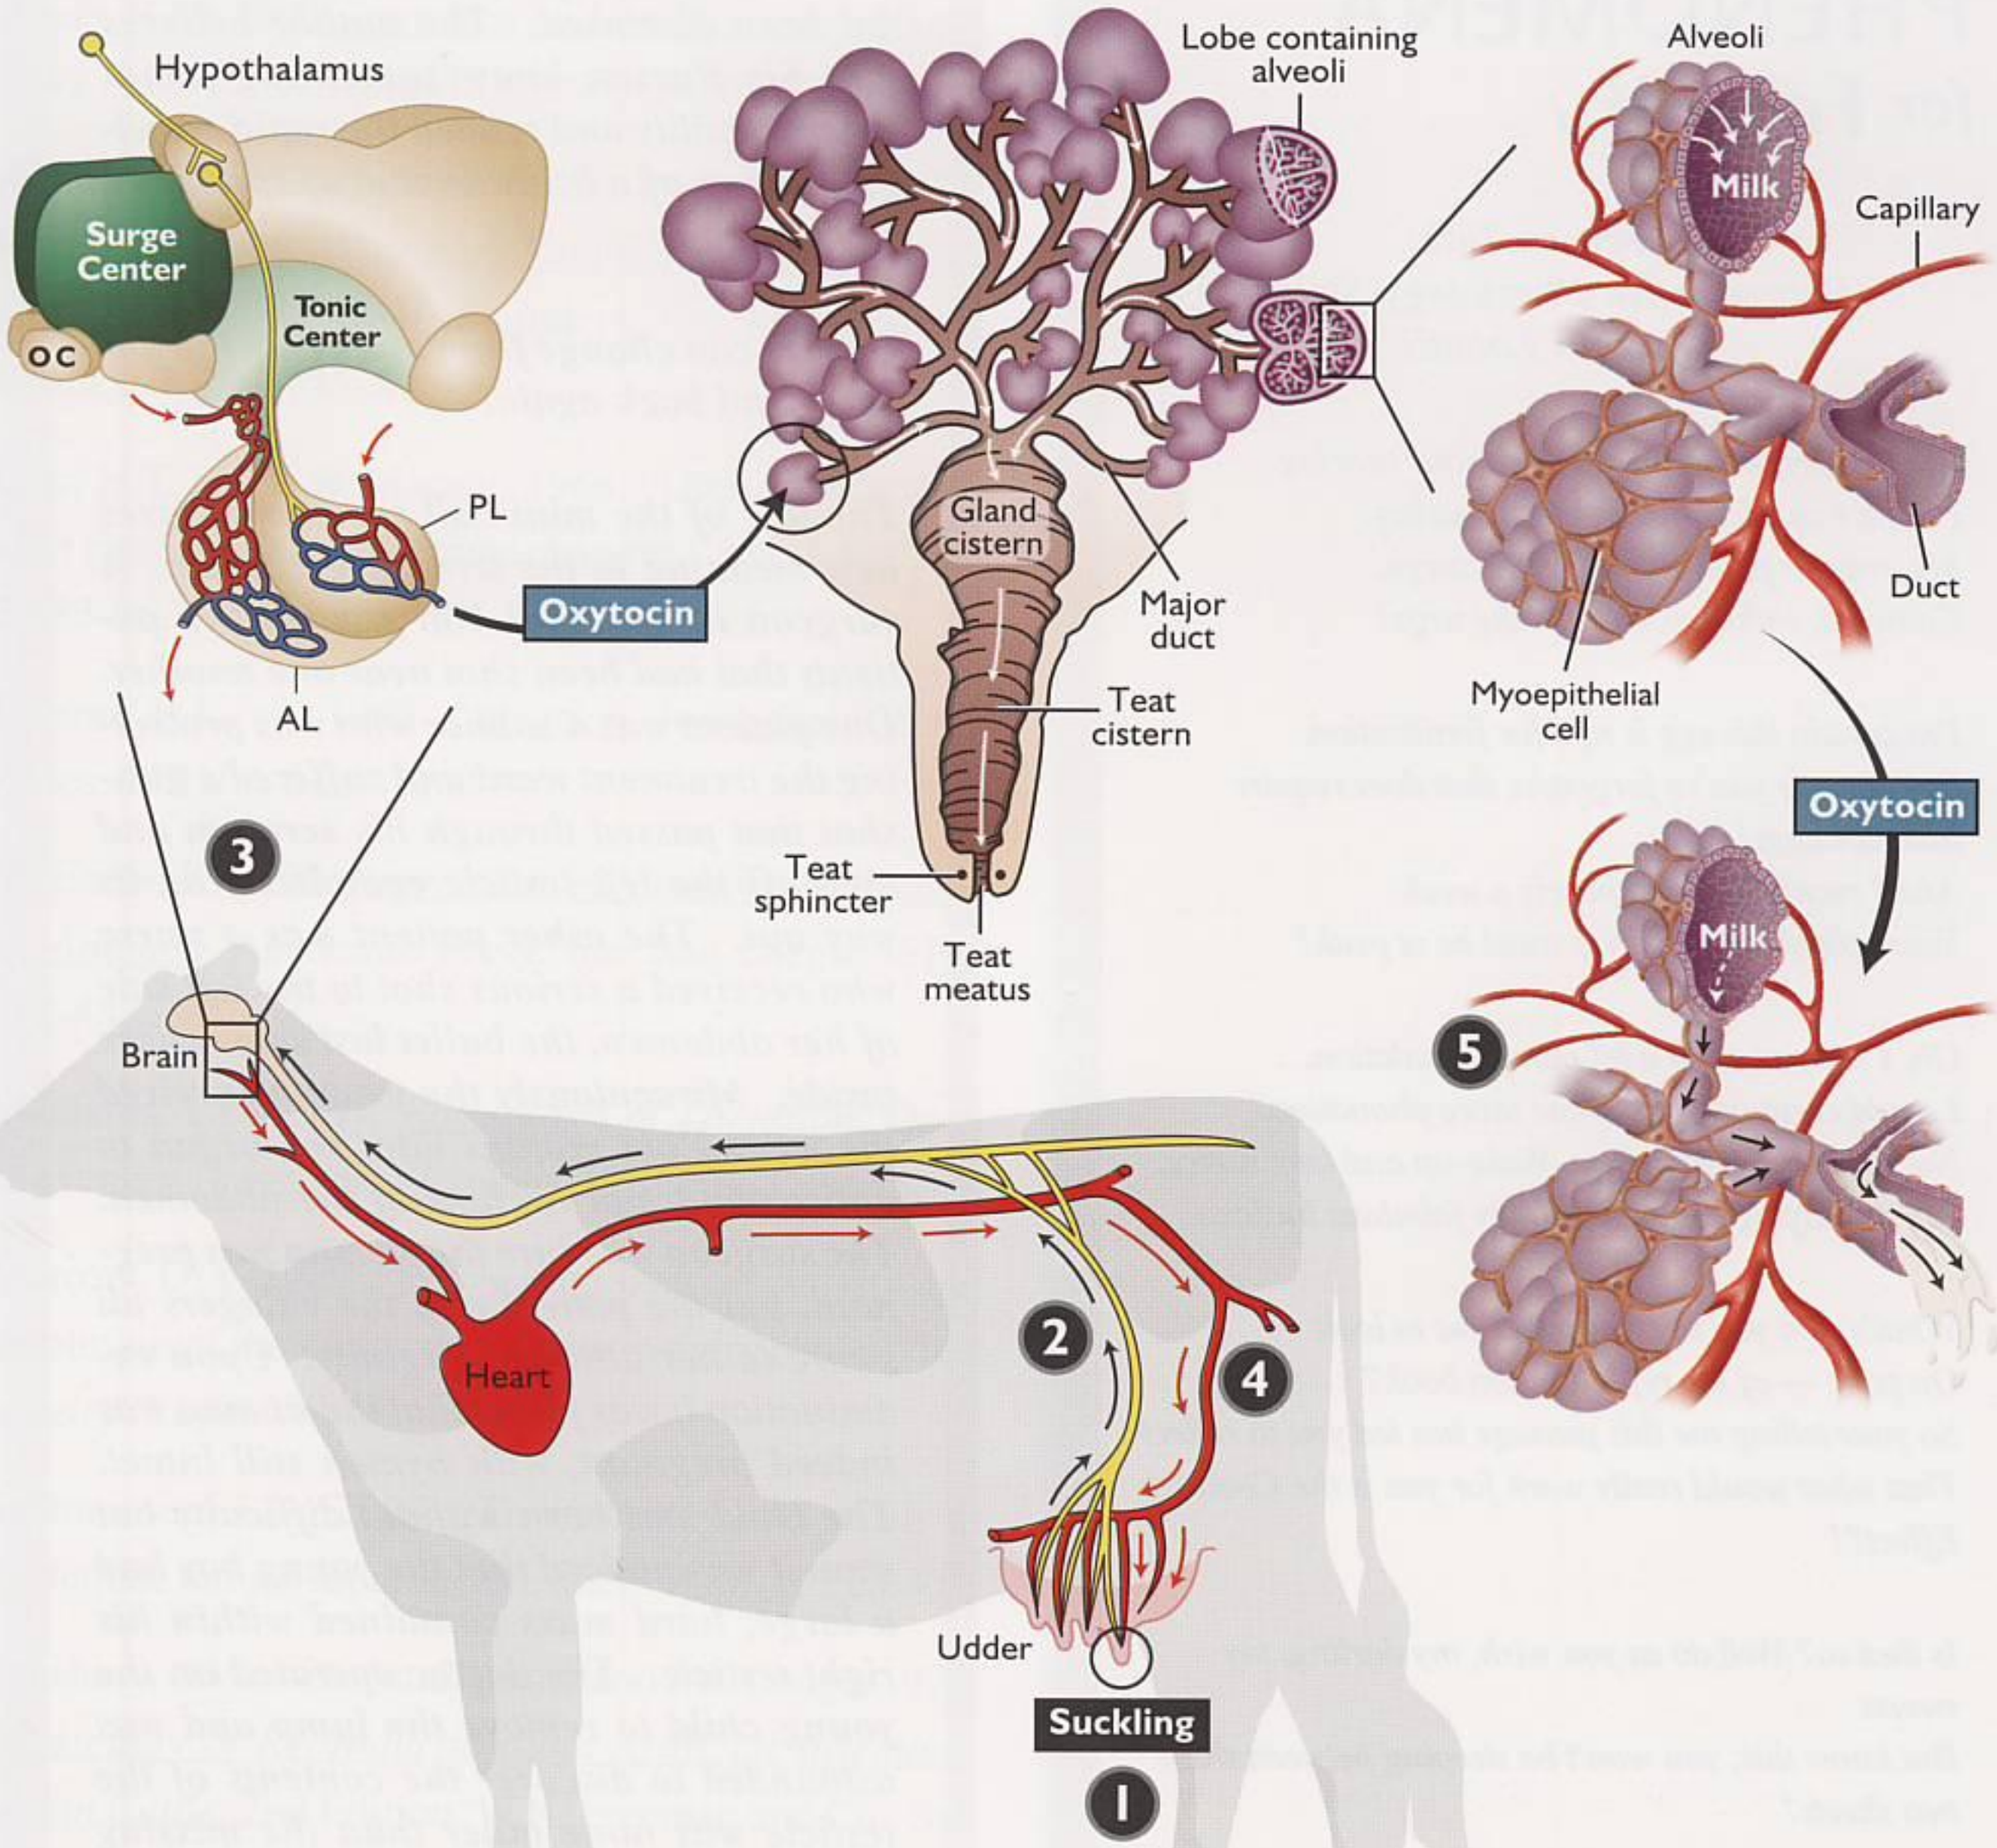
Milk ejection is the active transfer of milk from the alveoli and alveolar ducts into the larger mammary ducts, the cisterns and into the teat or nipples where it can be removed by the suckling neonate. Milk ejection should not be confused with milk secretion. Secretion is the synthesis of milk by the alveolar cell and its transfer from the alveolar cell into alveolar lumina. Prior to suckling (or milking) milk is predominately located in alveolar lumina and the fine ducts draining the alveoli. Milk stays in these anatomical regions because there is a strong resistance to milk flow in such a small diameter network (a form of capillary action causing retention of the milk). Between sucklings (or milkings) 70% to 80% of all secreted milk is located within the lumina of the alveoli and small ducts of the mammary gland. Therefore, an active mechanism for removal of this large quantity of milk is necessary so that the neonate can have access to it through suckling.

Milk ejection is an active neuroendocrine reflex involving sensory neurons in the teat or nipple, release of oxytocin from the neurohypophysis and contraction of myoepithelial cells that surround each alveolus and some of the ducts. The ejection process results in a rapid transfer of milk from the alveolus and smaller ducts into the larger ducts and cisterns of the mammary gland. Myoepithelial cells are spindle shaped contractile cells that surround each alveolus in a mesh-like fashion (See Figure 15-13). Myoepithelial cells are quite similar in structure to smooth muscle cells. The process of milk ejection is often referred to as "milk letdown." Efficient and timely removal of milk from the mammary gland is not only important for extraction of milk by the neonate, but also is an important part of the milk harvest to prevent pressure atrophy. In general, the more frequently milk is removed, the less the pressure atrophy and greater the quantity of milk that can be secreted.

Tactile stimulation of the teat or nipple is the primary sensory "driver" for milk ejection. In addition to direct tactile stimulation of the teat or nipple, sounds of the neonate (or the milking parlor), visual sight of the newborn or a milking facility can stimulate release of oxytocin from the neurohypophysis. Release of oxytocin is brought about by afferent nerve fibers that synapse with oxytocin synthesizing neurons in the paraventricular and the supraoptic nuclei. When sufficient frequency of stimulation has been accomplished, nerves in the two nuclei begin to fire and release oxytocin from their terminals located in the neurohypophysis. Oxytocin is then secreted into the blood and enters the systemic circulation of the dam. The physiology of milk ejection is presented in Figure 15-13.

The **myoepithelial cells** within the mammary gland have receptors to oxytocin and contract immediately upon exposure to it. When myoepithelial cells contract they cause the diameter of the alveolus to be greatly reduced. Thus, milk is ejected into larger ducts and is transferred into the larger spaces and finally into the teat or nipple.

Figure 15-13. The Anatomy and Physiology of Milk Ejection



The milk ejection mechanism is initiated by suckling (1). The teat contains sensory neurons and impulses from these neurons travel through afferent nerves (2) to the hypothalamus. Nerves in the paraventricular nuclei are stimulated by these afferent neurons and the terminals in the posterior lobe of the pituitary (3) release oxytocin. Oxytocin then enters the blood and is delivered to the mammary gland (4). The target cells for oxytocin are the myoepithelial cells that surround the alveolus. Contraction of the myoepithelial cells (5) causes milk to be "squeezed" out of each individual alveolus into small ducts and then into larger ducts. The net effect of simultaneous contraction of the myoepithelial cells throughout the entire mammary gland is to deliver milk to the large ducts and the gland cistern so that it is available for removal by the neonate.

Further PHENOMENA for Fertility

"BedroomTalk:
Reproductive Physiology Style"
by Ruth Loomis

Hey honey, wake-up and quit your snoring
I think I can feel my E_2 levels soaring.
My ovary is primed for the LH surge,
Come on, wake-up, I've got the urge!

I'm certain this egg is ripe for fertilization,
But, in case you've forgotten, that does require insemination!
And I recall, it's been nearly a week
Your epididymal reserves must be at peak!

Oh, I see you need a bit more stimulation.
I could continue with some more phonation?
No, don't close your eyes. Wake-up and take notice.
I'm displaying some absolutely fabulous lordosis!

What's that you say, you want me to look
On page --- of my reproduction book?
So your telling me this passage has led you to reflect
That what would really work for you is the Coolidge Effect?!

Is that so? Well do as you wish, my darling, my sweets
But know this, you won't be sleeping between these two sheets!

Ruth Loomis was a student in Animal Reproductive Physiology at Washington State University in the spring of 2002 and based the poem above on the nomenclature she learned in the reproduction course. She graduated from Washington State University with a BA in English Literature. She is now in the College of Veterinary Medicine at WSU (Class of 2006).

The 19th Century British explorer, Sir Richard Burton, developed a recipe that he believed enhanced sperm production and viability. Such a recipe would result in an increased probability of conception. He used a mixture of honey, opium, spices and a small lizard. The purpose of the lizard has not been disclosed. The author believes that Sir Burton knew something about sperm motility and related the rapid crawling motion of a lizard to that of spermatozoa.

Oysters can change from one gender to another and back again.

The tale of the mini ball pregnancy gives new meaning to the term target tissue. A surgeon in the Civil War treated two patients that had been shot near one another. One patient was a soldier who was protecting the treatment ward and suffered a gunshot that passed through his scrotum and took off the left testicle completely on its way out. The other patient was a nurse who received a serious shot to the left side of her abdomen, the bullet lost somewhere inside. Miraculously the woman survived the wound but months later she began to notice abnormal swelling of her abdomen. The surgeon was sure the woman was pregnant, but the patient and the villagers all swore to her absolute virginity. Upon examination it was found that the woman was indeed pregnant, with hymen still intact. The child was born without difficulty but soon it was noticed that the young boy had a large, hard mass contained within his right testicle. The doctor operated on the young child to remove the lump and was astounded to discover the contents of the testicle was none other than the missing mini ball that wounded the mother nine months before. The solution to this mysterious conception? The surgeon thought that this mini ball must have been the same one to have mutilated the soldier's testicle, carrying sperm with it into the uterus of the nurse after the bullet left the first victim, where it remained and functioned to fertilize one of her eggs! How could the ball get into the scrotum of the neonate? What parts of this narrative are absolutely false and which could be true? A great final exam question!

Glossary

A

accessory sex glands. Glands of the male reproductive system surrounding the pelvic urethra that produce seminal plasma. The accessory sex glands are the vesicular glands (seminal vesicles), prostate, bulbourethral glands (Cowper's Glands) and ampullae.

acid hydrolases. Hydrolytic enzymes within the acrosome that aid in sperm penetration of the zona pellucida.

acrosin. A proteolytic enzyme specific to the acrosome of spermatozoa. Acrosin causes zona pellucida dissociation during sperm penetration.

acrosomal granule. An intracellular granule within the young spermatid resulting from the condensation of Golgi products within the confines of the acrosomal membrane that will give rise to the acrosomal contents. (See Figure 10-6)

acrosomal phase. A specific developmental phase of spermatid differentiation in which the acrosome extends toward the posterior of the nucleus. (See Figure 10-7)

acrosomal reaction. An orderly fusion of the spermatazoal plasma membrane with the outer acrosomal membrane. This fusion initiates the release of acrosomal enzymes from the acrosome that allow the sperm to penetrate the zona pellucida. (See Figure 12-11)

acrosomal reaction promoting ligand/region. One of two binding sites found on the sperm plasma membrane that binds with the zona pellucida (ZP3). Binding of this ligand to ZP3 initiates the acrosomal reaction. (See Figure 12-10)

acrosomal vesicle. An intracellular vesicle within the young spermatid resulting from fusion of smaller Golgi vesicles; the precursor to the acrosome. (See Figures 10-6, 10-7)

acrosome. A membrane-bound organelle of the spermatozoon that covers the anterior one-third to one-half of the nucleus. It contains proteolytic enzymes required for penetration of the zona pellucida. (See Figure 10-7)

action potential. The rapid, all-or-none depolarization of a nerve cell membrane that is propagated from a nerve cell body to the axon and to another nerve or to an effector organ.

active transport. Transport of materials across a cell membrane against a concentration gradient (from low concentration to high); requires energy in the form of ATP.

activin. A protein hormone that stimulates follicle stimulating hormone (FSH) secretion. Activin belongs to a broader family of proteins that modify tumor growth and cell differentiation.

adeno-. A prefix designating a glandular organ or tissue. For example, the adenohypophysis is the glandular portion of the hypophysis.

adenohypophysis. The anterior lobe of the pituitary gland.

adenosine triphosphate (ATP). The energy source of the cell. It is synthesized from adenosine diphosphate (ADP). (See Figure 5-14)

adenylate cyclase. A membrane-bound enzyme activated by a hormone-receptor complex, and by G-protein. Adenylate cyclase promotes conversion of ATP to cyclic AMP. (See Figure 5-14)

adipocyte. A fat cell.

adluminal compartment. The compartment or zone of a seminiferous tubule defined at its lower boundary by the tight junctions of Sertoli cells and at its upper boundary by the lumen of the seminiferous tubule. (See Figure 3-16)

adrenal corticoids. A class of steroid hormones produced by the adrenal cortex that govern mineral metabolism, induce parturition and mediate response to stress.

adrenal corticotropin (ACTH). A glycoprotein hormone produced by the anterior lobe of the pituitary that controls the release of adrenal corticoids.

agonist. Any substance capable of binding to receptors for the native substance and that causes action identical to the native substance. Degree of response varies depending on the agonist.

allantochorion. The extraembryonic membrane resulting from the fusion of the chorion and the allantois. (See Figure 13-4)

allantois. One of the extraembryonic membranes formed from the embryonic ectoderm that serves as a liquid waste storage reservoir for the developing fetus. (See Figure 13-4)

allometric growth. Growth of an organ or tissue that is disproportionately faster than the growth in the remainder of the body.

alpha fetoprotein (AFP). A fetal protein that binds estradiol and prevents it from crossing the blood-brain barrier.

alpha subunit. The protein subunit of a glycoprotein hormone common to all gonadotropins. (See Figure 5-8)

amenorrhea. Absence of or abnormal cessation of cyclicity as manifested by lack of menses.

amnion. One of the extraembryonic membranes formed from the chorion that surrounds and encloses the fetus. It is filled with fluid and serves to protect the embryo against mechanical damage and to prevent tissue adhesions. (See Figure 13-4)

amniotic cavity. The fluid filled cavity surrounding the embryo and contained by amnionic membrane.

ampulla (pl. ampullae). In the female, the ovarian one-third of the oviduct characterized by a large diameter and many mucosal folds. In the male, enlargements in the ductus deferens that open directly into the pelvic urethra.

ampullary-isthmic junction. The region of the oviduct where the ampulla makes an anatomical transition into the isthmus.

anabolic. Relating to or promoting the growth, buildup or accretion of body organs and/or tissues.

anabolism. Building-up of complex tissues/organs from simple compounds.

analog (analogue). A substance having a similar structure to a native hormone and causes a similar or opposite physiologic response.

androgen binding protein (ABP). A protein secreted by Sertoli cells. It binds testosterone in the seminiferous tubules and delivers testosterone to the epididymis.

androgens. A class of substances (usually steroids) that promote development of male secondary sex characteristics and function of the male reproductive tract.

andrology. Study of the male reproductive system with emphasis on reproductive dysfuction in human and animals.

anestrous. Relating to anestrus.

anestrus, apparent. Failure to observe estrus or failure to recognize pregnancy that is erroneously interpreted as true anestrus.

anestrus, true. A condition where a female does not cycle due to insufficient hormonal stimuli.

anestrus. A condition in a female when she does not display estrus. Anestrus may result from pregnancy, poor nutrition, negative energy balance, lactation and/or season.

angiogenic factors. Substances that promote angiogenesis (the growth of blood vessels).

anosmic. Without the sense of smell.

antagonist. A material that blocks or inhibits the action of a hormone.

anterior hypothalamic area. Hypothalamic region just dorsal to the optic chiasm that is part of the GnRH surge center.

anterior lobe of the pituitary (adenohypophysis). The glandular portion of the pituitary that is derived from the stomodeal ectoderm of the embryo. The anterior lobe of the pituitary produces gonadotropins (FSH and LH), adrenocorticotropin (ACTH), thyroid stimulating hormone (TSH), growth hormone (GH) and prolactin.

antidiuretic hormone (ADH). A hormone synthesized within the cell bodies of neurons of the hypothalamus and released from the posterior lobe of the pituitary. ADH promotes the reabsorption of water in the distal tubule and collecting duct of the kidney.

anti-hypertensive. A drug or mode of treatment that reduces blood pressure of hypertensive individuals.

antimüllarian hormone (AMH). A hormone produced by embryonic Sertoli cells in the male. It causes degeneration of the paramesonephric ducts (Müllerian ducts) and probably causes the differentiation of Leydig cells within the fetal testis.(See Figure 4-6)

antithrombotic. Any substrate that inhibits or prevents the effects of thrombin in such a manner that prevents coagulation/clotting.

antral follicle (tertiary follicle). An ovarian follicle that contains an antrum (cavity). Antral follicles consist of an oocyte, follicular fluid, granulosal cells, the theca interna and the theca externa. (See Figure 2-11)

antrum. A cavity or chamber.

anuclear squamous cells. Scale-like cells with distinct epithelial borders with or without nuclei.

apoptosis. A process of organized cell death distinguishable from necrosis because it involves nuclear control of cell degeneration.

apparent anestrus. The erroneous interpretation that anestrus exists. Such an interpretation might exist because of failure to detect pregnancy or observe estrus.

arcuate nucleus. A hypothalamic nucleus located directly medial to the ventromedial nucleus that contributes to the tonic GnRH center.

artificial vagina. Device that simulates vaginal conditions of a female in estrus used for collection of semen. (See Figure 11-16)

aseptic. Free of microorganisms.

aspiration. Removal of gas or fluid through negative pressure.

atresia. Degeneration and resorption of ovarian follicles before ovulation.

atretogenic. Promoting or causing atresia.

atrophy. A wasting or decrease in size of a cell, tissue or organ.

attachment, conceptus. The formation of a transient relationship between the chorion of the conceptus and the endometrium of the uterus.

attractivity. Female behaviors or signals that serve to attract males, e.g. phonation, postures and pheromonal cues.

axoneme. The core of the spermatozoal flagellum consisting of a complex of hollow fibrils arranged in a 9+9+2 architecture typical of all flagella. Two single fibrils are centrally positioned and are surrounded by 9 pairs of fibrils. (See Figure 10-9)

B

basal compartment. The compartment of the seminiferous tubule containing spermatogonia between the basement membrane and the tight junctions of adjacent Sertoli cells. (See Figure 3-16)

base of penis. The proximal portion of the penis that is attached to the floor of the pelvis by a suspensory ligament in larger species.

beta subunit. The protein subunit of a glycoprotein hormone that gives the hormone its specificity or uniqueness. (See Figure 5-8)

bicornuate uterus. A uterus consisting of distinct uterine horns (cornua). (See Figure 2-15)

binucleate giant cells. Cells originating in the chorion of the ruminant placenta that migrate toward the endometrial epithelium and produce pregnancy-specific substances. (See Figure 14-4)

blastocoele. The cavity in the central portion of the blastocyst.

blastocyst. An early embryo consisting of an inner cell mass, a blastocoele and a trophoblast.

blastomere. A cell produced by the cleavage divisions of the early embryo.

blood-testis barrier. The specialized permeability barrier consisting primarily of multiple junctional complexes (tight junctions) between Sertoli cells that divides the seminiferous epithelium into the basal compartment and the adluminal compartment. Two separate environments exist between these two compartments.

bovine interferon tau (bIFN-τ). A glycoprotein produced by the preimplantation bovine conceptus that allows maternal recognition of pregnancy by inhibiting oxytocin receptor synthesis by the endometrial cells.

bovine trophoblastic protein 1. See bovine Interferon τ.

broad ligament. The ligament (continuous with the peritoneum) that supports the female reproductive tract consisting of the mesometrium, the mesosalpinx and the mesovarium.

buffer. A mixture of an acid and its conjugate base that when present in solution, minimizes any changes in pH when acid or alkali are added and thus helps maintain the pH of physiologic fluids so that cell viability is maintained.

bulbospongiosus muscle. A thick, circular, striated muscle that is continuous with the urethralis muscle at the position of the bulbourethral glands. It covers the bulb of the penis and attaches to the proximal shaft of the penis. In the stallion, it extends on the ventrolateral surface of the penis to the glans penis.

bulbourethral glands (Cowper's glands). Paired glands that lie on the dorsal surface of the caudal end of the pelvic urethra. These glands are so named because they are associated with the bulb of the penis and the pelvic urethra.

bursa (pl. bursae). A sac or saclike cavity that may contain a fluid and usually located in areas subject to friction. The ovarian bursa is a saclike structure that will completely (bitch) or partially (sow) surround the ovary.

C

canalize. To furnish with, or convert to a canal or canals.

canalization. Formation of canals or tube-like structures within a tissue.

cap phase. The phase of spermatid differentiation in which the acrosomic vesicle begins to spread over the anterior portion of the spermatid nucleus. (See Figure 10-7)

capacitation. The process whereby spermatozoa acquire fertility in the female reproductive tract. (See Figure 12-8)

caput epididymis. The head of the epididymis.

caruncle. In ruminants, a button-like area of the uterine endometrium that will form the maternal side of the cotyledonary placenta.

caruncular regions. Highly vascular and non-glandular regions of the ruminant uterus that protrude from the endometrial surface. They will form the maternal cotyledon, the maternal contribution to the placentome.

casomorphins. Opioid peptides from milk proteins that have morphine-like activity.

cauda epididymis. The tail of the epididymis; the primary sperm storage reservoir of the extragonadal duct system.

cell lysis. Rupturing of the cell membrane resulting in cell death.

cervical seal of pregnancy. A highly viscous plug that cements the folds of the cervix together during pregnancy, thus isolating the developing fetus from the exterior environment.

cervix. A structure consisting of dense connective tissue with varying degrees of folding and protrusion of the mucosal epithelium. The cervix connects the uterus to the vagina.

chorion. The outermost extraembryonic membrane, derived from the trophoblastic ectoderm. It will develop villi that will form the fetal sites of placental attachment.

chorionic girdle. A specialized region of the chorion in the equine fetus that forms the initial attachment to the endometrium.

chorionic gonadotropins. Glycoprotein hormones produced by the trophoblastic cells of the placenta that cause stimulation of the ovary in the pregnant female.

chorionic villus (villi). Small, finger like projections found on the surface of the chorion that interface with the maternal placenta. The functional unit of the fetal placenta.

CIDR®. Controlled Intravaginal Drug Release in this case progesterone. That is used for synchronization of estrus in beef and dairy cattle (See Figure 9-17).

cistern of the teat. A holding area or reservoir for milk within the teat. (See Figure 15-13)

cleavage divisions. The series of mitotic divisions of the early embryo within the confines of the zona pellucida giving rise to equally sized daughter cells, called blastomeres.

clitoral fossa. A longitudinal depression or cavity below the surface of the vulva housing the clitoris (especially developed in the bitch and mare).

clitoris. A small body of highly innervated erectile tissue located in the posterior extremity of the ventral vaginal floor. It is the homologue of the penis.

cohort. A group united through/for a common purpose, or a group having certain similarities.

coitus (copulation). The sexual union of male and female during mating that involves intromission. Copulation.

collagenase. An enzyme that breaks down collagen.

colostrum. The first milk produced after parturition that contains antibodies to provide the neonate with passive immunity.

columnar epithelium. An epithelial type consisting of cells that are taller than they are wide, thus resembling columns. (See Figures 2-19 and 2-22)

commissure. A seam or a line resulting from the site of union of two components of an organ system. (See Figures 2-23 and 2-24)

conceptus. The products of conception, including the embryo, the extraembryonic membranes and the placenta.

constrictor vulvae. The bundles of skeletal muscle embedded in the labia that maintain closure of the labial commissure.

contralateral. The opposite side.

Coolidge effect. Renewal of sexual stimulation in the sexually satiated male by the introduction of a novel female into the stimulus setting. (See Figure 11-14)

copulatory stage. The second stage of reproductive behavior consisting of mounting, intromission and ejaculation.

cornua. A structure resembling a horn.

cornual insemination. A technique of artificial insemination where the semen is deposited into the horns of the uterus. (See Figures 12-3 and 12-6)

corpus albicans (pl. corpora albicantia). A white scar-like fibrous ovarian structure that represents advanced regreassion of the corpus luteum. (See Figure 2-11)

corpus cavernosum. The cavernous erectile tissue in the central portion of the penis that allows for influx of blood during erection of the penis. (See Figure 3-21)

corpus epididymis. The body of the epididymis. (See Figures 3-15 and 3-18)

corpus hemorrhagicum. A small, blood clot that results from rupture of blood vessels during ovulation. (See Figures 9-2, 9-3, 9-4, and 9-6)

corpus luteum (CL) (pl. corpora lutea). An orange to yellow colored transient endocrine structure formed after ovulation from granulosal and thecal cells of the ovarian follicle. The corpus luteum is responsible for producing progesterone and oxytocin. (See Figures 2-11, 9-2, 9-3, 9-4, 9-6, and 9-8)

corpus prostate. The body of the prostate, located dorsal to the cranial pelvic urethra. (See Figure 3-4)

corpus spongiosum. The portion of erectile tissue in the penis that surrounds the penile urethra. (See Figure 3-21)

cortical reaction. A reaction following spermatozoal penetration of the oocyte in which the membrane surrounding the cortical granule in the oocyte cytoplasm fuses with the oocyte plasma membrane. Their contents are expelled into the perivitelline space. The cortical reaction is believed to prevent polyspermy. (See Figure 12-12)

corticoids. A class of steroid hormones secreted by the adrenal cortex.

cortisol (hydrocortisone). An anti-inflammatory steroid secreted by the adrenal cortex.

cotyledonary. A term referring to the presence of cotyledons (found in ruminants) as the functional unit of the placenta.

cotyledons. The points of attachment between the fetal and maternal placenta, consisting of a maternal cotyledon contributed by the caruncular areas of the uterus and the fetal cotyledon contributed by the chorion of the conceptus. (See Figure 14-3)

countercurrent heat exchanger. Network of the testicular artery and vein in which heat passively diffuses between vessels separating the two streams so that at the end the fluid leaving is the same temperature as the fluid entering the system. (See Figure 3-9)

cranial. Relating to the cranium or head; in the direction of the cranium.

cremaster muscle. A striated muscle continuous with the internal oblique muscle that partially surrounds the spermatic cord and attaches to the parietal vaginal tunic. (See Figures 3-2, 3-3, 3-4, 3-5 and 3-7)

crossing-over. When segments of one chromosome crossover and attach to a homologous chromosome during the pachytene stage of the first meiotic prophase. When the chromatids separate (during anaphase I) crossing-over results in a random assortment of different segments of each chromosome thus assuring genetic heterogeneity.

crus penis. The posterior attached portion of the corpus cavernosum penis. (See Figures 3-3, 3-4, 3-5, 3-6 and 3-7)

cryoprotectant. A material that protects the cell membrane against damage during cooling and freezing.

cryptorchid. An individual in which the testes have failed to descend into the scrotum and remain in the abdominal cavity.

cycle of seminiferous epithelium. The progression through a complete series of cellular associations at one location along a seminiferous tubule. (See Figure 10-11)

cyclic AMP. Cyclic adenosine monophosphate; a cyclic nucleotide that serves as a "second messenger" for protein hormone action. (See Figure 5-14)

cyclic recruitment. Follicular recruitment after puberty that results from elevated FSH (follicle stimulating hormone).

cyclicity. The condition in which a female displays estrus (or menstrual) cycles with a predictable duration.

cyclopentanoperhydrophenanthrene. The common nucleus of steroid hormones consisting of three 6-membered rings (A, B and C) and one 5-membered ring (D). (See Figure 5-9)

cytokines. Messenger proteins released by immune cells that act as intercellular mediators of the immune response.

D

daily sperm production (DSP). The quantity of spermatozoa produced by both testicles in one day.

dartos muscle. See tunica dartos.

decapacitation. The exposure of spermatozoa to seminal plasma after capacitation has occurred, thus requiring additional capacitation time before fertility can again be acquired.

defeminization. Failure to promote the development of female appearance and/or behavior.

depolarization. A change in nerve cell electrical potential caused by sodium influx.

descendin. A material believed to be produced by the fetal testis that promotes rapid growth of the gubernaculum, thus promoting descent of the testis into the scrotum.

diastolic pressure. The minimum arterial blood pressure reached during the diastolic phase (relaxation) of the cardiac cycle.

dictyotene phase. A phase of meiosis unique to the primary oocyte in which the nuclear material is arrested or rendered inactive until final stages of oogenesis. Oocytes remain in the dictyotene phase in the fetal ovary until final folliculogenesis.

diestrus. The stage of the estrous cycle characterized by a dominance of progesterone from the corpora lutea and periods of relative quiescence of reproductive behavior.

differential-interference contrast microscope. A microscope that transforms differences in intracellular density into an image that gives the appearance of surface relief (See Figure 10-14; ruffled acrosome; knobbed acrosome) or cratering (See Figure 10-14; crater defect).

differentiation. The development of structure and function that is more specialized than the original cells or tissue.

differentiation phase. The final phase of spermatogenesis where a spermatid becomes a fully differentiated spermatozoon.

diffuse placenta. A placenta characterized by uniform distribution of chorionic villi across the surface of the chorion (e.g. pig, mare). (See Figure 14-1)

dimethyl sulfoxide (DMSO). A cryoprotectant used for protecting living cells against damage caused by freezing and thawing.

discoid. Placenta characterized by a regional disk that attaches to the endometrium. Primates have a discoid placenta. (See Figure 14-2)

disseminate prostate. Prostatic tissue diffusely distributed within the walls of the pelvic urethra.

distal cytoplasmic droplet. A remnant of cytoplasm located just posterior to the middle piece of the spermatozoon.

disulfide cross-linking. A covalent linkage between two cystein residues on two different proteins or on two different regions on the same protein. Disulfide cross-linking increases integrity and insolubility. The chromatin in the head of sperm and the structural components of the flagellum have high degrees of disulfide cross-linking. (See Figure 3-18)

diverticulum (pl. diverticula). A blind tube, or outpocketing that diverts from a main tubular organ or cavity.

dominance (follicular). The condition of a large antral follicle in the final stages of maturation. Dominant follicles become atretic when LH levels are low and ovulate when LH levels are high.

dominant follicle. The final maturational structure during folliculogenesis that produces relatively high concentrations of estradiol and inhibin. (See Figure 8-6)

donor female. A female that contributes (donates) oocytes or embyos for embryo transfer. (See Figure 13-19)

down-regulation. Reduced receptor density.

ductus deferens. The duct derived from the mesonephric duct that connects the tail of the epididymis to the ampulla and transports sperm into the pelvic urethra.

duplex uterus. A uterus containing two cervices (rabbit). (See Figure 2-15)

dystocia. Abnormal or difficult parturition.

E

ectoderm. The outer layer of cells in the embryo.

efferent ducts. Ducts that are embryologically derived from the mesonephric tubules connecting the rete testis to the head of the epididymis.

efferent neurons. Neurons originating in the central nervous system and travelling to effector organs. (See Figure 5-1)

ejaculation. The expulsion of semen from the pelvic and penile urethra. (See Figure 11-13)

electroejaculation. Electrical stimulation of the accessory sex glands and pelvic urethra resulting in ejaculation.

elongated blastocyst. A blastocyst that has undergone rapid growth after hatching from the zona pellucida but before attachment to the uterus to form a long, filamentous structure.

embryo. An animal in the early stages of development that has not taken an anatomical form that is recognizable as a member of a species.

embryo transfer. A procedure used to transfer embyos from a donor female to a group of recipient females generally used to amplify the genetic characteristics of the donor female. (See Figure 13-9)

embryogenesis. The formation and growth of an embryo.

emission. The discharge of accessory sex gland secretions into the pelvic urethra.

endocrine. Pertaining to the secretion of hormones by an internal gland that are secreted into the blood.

endocrine gland. Any of various glands such as thyroid, adrenal, pituitary, ovary, testis and placenta that secrete hormones directly into the blood.

endocrine system. The endocrine glands of the body and the internal secretion of hormones.

endoderm. The innermost layer of cells in the embryo.

endometrial cups. Discrete raised areas (ranging from a few millimeters to a few centimeters) found in the gravid uterine horn of the mare that produce equine chorionic gonadotropin (eCG). These structures slough from the endometrial surface at about day 100 of gestation.

endometrium. The mucosal lining of the uterus.

endotheliochorial placenta. A form of placenta found in dogs and cats in which the endometrial epithelium has completely eroded and the maternal capillaries are almost directly exposed to the chorionic epithelium. (See Figure 14-5)

enzyme-linked immunosorbent assay (ELISA). A method of detecting and quantifying hormones utilizing an enzyme-linked antibody that produces an identifying color in the presence of the appropriate substrates. (See Figure 5-19)

epididymal duct. See epididymis.

epididymal transit. The transport of spermatozoa from the proximal head of the epididymis to the distal tail.

epididymal transit time. The time required for spermatazoa to be transported from the proximal head of the epididymis to the distal tail of the epididymis. Epididymal transit time is relatively constant within species and cannot be significantly altered by high ejaculation frequencies. (See Table 3-1)

epididymis (ductus epididymis). A duct derived embryologically from the mesonephric duct that connects the efferent ducts to the ductus deferens. It serves as a transport, storage and maturation site for spermatozoa.

episodic. A pattern of secretion in which a hormone is released in bursts of varying duration and quantity.

epitheliochorial placenta. A form of placenta found in the sow and mare in which the endometrial epithelium is directly apposed to the epithelium of the chorion. (See Figure 14-5)

equine chorionic gonadotropin (eCG). A luteotropic hormone produced by the endometrial cups of the mare. It also has powerful FSH-like actions when administered to females of other species.

erection. The rigid state of the penis caused when blood enters the cavernous tissue of the penis. (See Figure 11-9)

erotogenic stimuli. Stimuli capable of causing sexual excitement or arousal.

esterases. A generic classification of enzymes that catalyze the hydrolysis of esters.

estradiol. The predominant estrogen produced by the dominant follicles during the follicular phase of the estrus cycle.

estrogen. A class of steroid hormones (natural or synthetic) that exerts physiologic effects on the female reproductive and mammary systems.

estrous. Adjective used to describe phenomena associated with the estrous cycle.

estrous cycle. The reproductive cycle of nonprimate females, generally defined as the period from one estrus (heat) to the next. Ovulation can also signify the beginning and/or the end of the estrous cycle. The estrous cycle consists of the follicular phase and the luteal phase.

estrual. An adjective used to describe phenomena associated with estrus (heat).

estrus. The period of sexual receptivity in the female.

eutherian mammal. Mammals characterized by having a highly developed placenta; all mammals except marsupials and monotromes.

excitatory neurotransmitter. A neurotransmitter that causes increased sodium permeability in the membrane of postsynaptic neurons.

excurrent duct system (extragonadal duct system). The efferent ducts, the epididymal duct and the ductus deferens. These ducts (continuous with one another) transport spermatozoa from the efferent ducts into the pelvic urethra. (See Figure 3-15)

exocrine. A glandular secretion that is delivered to a surface, into a lumen or through a duct.

exocytosis. Process whereby secretory materials too large to diffuse through the cell membrane are released from the cell. During exocytosis the membrane surrounding the secretory product fuses with the plasma membrane of the cell and releases the contents to the exterior.

exogenous. Originating or produced outside the body.

extender. A medium added to semen to increase its volume and to extend the time of in-vitro viability.

external genitalia. Portion of the male or female reproductive tract that can be viewed externally.

external uterine bifurcation. The external point of separation (forking) of the two uterine horns.

extra-abdominal gubernaculum. The portion of the gubernaculum located outside of the body cavity.

extracellular domain. The portion of a hormone receptor that protrudes from the surface of the plasma membrane and binds the hormone. (See Figure 5-13)

extraembryonic membranes. Membranes formed by the embryo and that are outside of it. The three extraembryonic membranes are the amnion, the chorion and the allantois.

extragonadal spermatozoal reserves (EGR). The spermatozoa stored within the epididymis, ductus deferens and ampulla.

F

facilitated diffusion. A type of diffusion requiring a carrier molecule that moves materials across a plasma membrane from a region of high concentration to a region of low concentration.

fallopian tube. The oviduct.

false mount. A mount in which intromission is purposely prevented. (See Figure 11-6)

fascia. Sheets of fibrous connective tissue that connect and support other tissues.

feminization. The promotion of the development of female appearance and behavior.

fetal cortisol. A hormone secreted from the adrenal cortex of the fetus as a result of stress on the fetus near parturition. Fetal cortisol causes a dramatic cascade of events that change the endocrine status of the dam, thus initiating parturition.

fetal cotyledon. See cotyledon.

fetus. The unborn young of a eutherian mammal that has developed identifiable features of a given species.

fimbria (pl. fimbriae). A fringe-like structure at the distal end of the infundibulum of the oviduct.

first polar body. See polar body.

flagellum (pl. flagella). A whip-like appendage of the spermatozoa responsible for propelling it.

Flehmen response. A specific investigative behavior seen in both the male and the female cattle, sheep, goats and horses in which the upper lip is curled upward to restrict airflow through the nostrils creating a subatmospheric pressure in the nasopalantine duct. This reduced pressure allows fluids to be aspirated into the duct and onto the surface of the vomeronasal organ. (See Figure 11-5)

fluorochrome. A fluorescent dye used to stain specific subcellular components.

follicle. A spherical structure within the ovary that contains an oocyte. Follicles may be primordial, primary, secondary, antral or atretic. (See definitions for each follicle type) (See Figure 2-11)

follicle stimulating hormone (FSH). A glycoprotein hormone secreted by the anterior lobe of the pituitary in response to GnRH. FSH promotes follicular development in the female and Sertoli cell function in the male.

follicular aspiration. Aspiration of an oocyte by inserting a needle directly into an antral follicle. (See Figure 13-10)

follicular dynamics. The sum of the intraovarian processes involved in follicular development and degeneration.

follicular fluid. A fluid produced by the granulosal cells that fills the antrum of the follicle.

follicular phase. The phase of the estrous cycle characterized by the presence of a dominant follicle that produces estradiol. Females display behavioral estrus and ovulate during the follicular phase.

follicular selection. The emergence of ovulatory follicles from a cohort of previously recruited antral follicles. (See Figure 8-8)

folliculogenesis. The process whereby ovarian follicles develop from primary into secondary and eventually into antral follicles that become eligible for ovulation.

fornix vagina. The cranial portion of the vagina that forms a crypt extending cranially to the cervix.

freemartin. The sterile heifer twin to a bull. It has incomplete development of the reproductive tract and male-like behavior.

fructose. A naturally occurring D-isomer sugar ($C_6H_{12}O_6$) that is the result of sucrose hydrolysis. Fructose is a major substrate for sperm metabolism.

fusion protein. A protein believed to be located on the equatorial segment of a spermatozoon that allows the oocyte plasma membrane to fuse with the equatorial segment.

G

G-protein. A membrane-bound protein that responds to a hormone-receptor complex by activating membrane-bound adenylate cyclase. (See Figure 5-14)

gap junctions. The membrane specializations that provide continuity between two adjacent cells, allowing passage of small molecular weight materials from one cell to another.

Gartner's cysts (ducts). The remnants of the mesonephric ducts that can be found in the vagina as blind cysts or ducts.

genital ridge. The swellings in the dorsal body wall of the developing embryo into which primordial germ cells migrate; these form the gonad.

germ cells. Spermatozoa or oocytes.

germ layers. The ectoderm, mesoderm and endoderm. These are the earliest recognizable forms of tissue structure in the early embryo.

germinal epithelium. The epithelium of the seminiferous tubule that produces spermatozoa.

gestation. Pregnancy. The period that a female is pregnant between conception and parturition.

glans penis. The anatomically specialized, highly sensitive distal end of the penis.

glucose. A monosaccharide found widely in animal tissue; the main form of sugar that circulates in the blood. Glucose is also a major nutrient in sperm metabolism.

glucuronide. A metabolite of steroid hormones excreted in the urine. Glucuronic acid is attached to the steroid rendering it water soluble so that it can be excreted in the urine.

glycerol. A liquid that may be used as a solvent, antifreeze, plasticizer, and a sweetener. It is also a common cryoprotectant used in freezing mammalian spermatozoa.

glycoprotein. A type of protein characterized as having carbohydrate molecules attached to the main protein chain.

glycosylation. The process of attaching carbohydrate moieties to a protein. The degree of glycosylation of glycoprotein hormones is believed to influence the half-life of the hormone.

glycosylation sites. Regions along a protein hormone to which carbohydrate moieties attach. Attachment of carbohydrates to a protein changes it to a glycoprotein. (See Figure 5-8)

goitrogen. A substance that inhibits thyroid function.

Golgi phase. The phase of spermiogenesis in which the Golgi vesicles fuse to form larger vesicles that reside on one side of the nucleus. (See Figure 10-6)

gonadal hormones. Any hormone produced by the male or female gonad.

gonadotroph. A cell type in the anterior pituitary that produces gonadotropins.

gonadotropin. The hormones (FSH and LH) of anterior pituitary origin that stimulate gonadal function.

gonadotropin releasing hormone (GnRH). A decapeptide released from terminals of neurons in the surge and tonic centers of the hypothalamus that causes the release of gonadotropins from the anterior lobe of the pituitary.

Graafian follicle. A large, dominant preovulatory follicle.

granulosal cells. (Granulosal cell layer, or membrana granulosa). Cells that line the antrum of an antral follicle that play a major role in oocyte development, steroidogenesis and follicular fluid secretion. After ovulation granulosal cells give rise to large luteal cells of the corpus luteum. (See Figure 9-2)

growth hormone (somatotropin). A hormone produced by the anterior lobe of the pituitary. It promotes growth and lactogenesis.

gubernaculum. A connective tissue cord attaching the testes to the base of the scrotum. It governs testicular descent. (See Figure 4-8)

gynecology. A specialty of human medicine focusing on normal function and pathology of the female reproductive system.

H

half-life. The period of time required for one-half of a substance to be destroyed or removed from the body.

heat. See estrus.

hemochorial placenta. A placenta characterized as having the chorionic epithelium in direct apposition to pools of maternal blood. (See Figure 14-5)

hilus. A region housing blood and lymphatic vessels and nerves that enter and leave an organ. (See Figure 2-13)

hormone. A substance produced by one or more glands that is transported by the blood to exert a specific effect upon another organ.

hormone receptor. A highly specific molecule found in the plasma membrane or the nucleus of a target cell. A receptor has affinity for a specific hormone. When the hormone binds to its receptor, a response from the cell in the target tissue occurs. (See Figure 5-12)

human chorionic gonadotropin (hCG). A hormone produced by the human placenta that has strong luteotropic activity.

hyaluronidase. A group of enzymes that hydrolyze hyaluronic acid. One or more of these enzymes is present in the acrosome of the spermatozoa.

hyperemia. Excessive blood flow to an organ or region of the body.

hyperplasia. An increase in the number of cells in a tissue or organ.

hypertonic. Solutions containing solute concentrations greater than intracellular fluids. Cells in hypertonic solutions dehydrate and shrink.

hypertrophy. An increase in organ or gland size not related to elevated cell numbers, but due to increased individual cell size.

hypothalamic hormones. Hormones produced by neurons located in the hypothalamus.

hypothalamic nuclei. Anatomically specific groupings or clusters of nerve cell bodies in the hypothalamus.

hypothalamo-hypophyseal portal system. A unique circulatory network that delivers minute quantities of releasing hormones from the pituitary stalk directly to the anterior lobe of the pituitary without dilution by the systemic circulation. (See Figure 5-5)

hypotonic. Solutions containing solute concentrations less than intracellular fluids. Water diffuses into cells in hypotonic solutions and they swell and may lyse.

hysterectomy. Surgical removal of the uterus. (uterectomy)

I

immunostimulation. Stimulation of the immune system.

implantation. See attachment.

incisive duct. The duct that connects the oral cavity to the nasal cavity and receives the ducts of the vomeronasal organ. (See Figure 11-5)

induced ovulation. See reflex ovulation.

infrared thermography. A technique that enables the surface temperature of a physical body to be determined. (See Figure 3-12)

infundibulum. A hollow funnel-shaped structure or passage. (oviduct - See Figures 2-12, 2-13, 2-14, and 2-16 pituitary - See Figure 4-3)

inguinal. Of, relating to, or located in the groin.

inguinal hernia. An abnormal condition where abdominal contents pass through the inguinal canal and enter the vaginal cavity. (See Figure 4-11)

inhibin. A glycoprotein hormone produced by Sertoli cells in the male and granulosal cells in the female that specifically inhibit the release of FSH from the anterior lobe of the pituitary.

inhibitory neuron. A neuron producing a neurotransmitter that causes hyperpolarization of a postsynaptic neuron.

inhibitory neurotransmitter. A specific chemical released by an inhibitory neuron causing the post synaptic membrane to become more permeable to potassium, thus lowering the resting membrane potential.

initial recruitment phase. The continuous recruitment of primordial follicles into a growing follicle pool that terminates in atresia. (See Figure 8-7)

inner cell mass. A cluster of cells located at one pole of the blastocyst from which the embryo will develop. (See Figure 13-4)

insulin. A polypeptide hormone secreted from the pancreas that promotes glucose utilization and protein synthesis.

intercellular bridges. The connections between adjacent developing male germ cells that form a cohort of cells of similar developmental type.

interferons (IFN). Glycoproteins produced by a variety of cells that exert antiviral, antiproliferative and immunosuppressant effects. They are classified as α (from leukocytes), β (from fibroblasts), γ (from lymphocytes), and τ . IFN-τ is produced by the trophoblast of the ruminant embryo. It is antiluteolytic in addition to possessing characteristics of the other classes of IFNs.

interneurons. Neurons found in the central nervous system between afferent (sensory neuron) and efferent neurons (motor neuron). Interneurons can be either excitatory or inhibitory.

interstitial compartment. The compartment of the testicular parenchyma that surrounds the seminiferous tubules. (See Figure 3-16)

intracellular domain. The component of a hormone receptor located inside the cell that is attached to the transmembrane domain of the receptor. (See Figure 5-13)

intracervical insemination. Insemination in which the semen is deposited into the cervix (sow). (See Figure 12-3)

intravaginal insemination. Insemination in which the semen is deposited into the cranial vagina.

intromission. The insertion of one part into another. The insertion of the penis into the vagina.

involution, mammary. The process whereby alveolar cells stop secreting milk and become similar in structure to a nulliparous female. (See Figure 15-12)

involution, uterine. The process whereby the uterus returns to its normal nonpregnant size and function following parturition. (See Figure 15-1)

ipsilateral. On the same side.

ischemia. A local reduction in blood flow resulting in accumulation of metabolites in the tissue.

ischiocavernosus muscle(s). Paired, powerful, striated muscles originating on the medial surface of the ischium, covering the crura of the penis and inserting on the proximal shaft of the penis. (See Figures 3-4, 3-5, 3-6, 3-7, 3-8, 3-19 and 3-20)

isometric growth. Growth in which body components enlarge at the same rate.

isotonic. Solutions containing solute concentration similar to intracellular fluids. There is no net diffusion of water.

isthmus. A narrow passage connecting two larger cavities. The isthmus of the oviduct is of small diameter and connects the large diameter ampulla of the oviduct to the uterus.

J

junctional complexes. The specialized regions of cell-to-cell attachment consisting of tight junctions, intermediate junctions, gap junctions or desmosomes.

K

keratinization. The synthesis of an insoluble protein (keratin) containing a high degree of disulfide cross-links found in hair, feathers, nails, sperm heads and tails.

L

labia. The lip-shaped structures forming the lateral boundaries of the female external genitalia. (See Figures 2-23 and 2-24)

labial commissure. The point of junction between the two labia of the female external genitalia.

lactation. Formation and/or secretion of milk by the mammary glands.

lactational anestrus. A lack of cyclicity brought about by nursing and presence of the young. (See Figure 7-8)

lactiferous ducts. Ducts that produce, secrete or convey milk. (See Figure 15-13)

lactogenic. Stimulation of lactation.

lateral ventricle. A cavity within the brain through which cerebral spinal fluid moves. Lateral ventricles are attached to the third ventricle. (See Figure 5-4)

leptin. Material produced by adipocytes that correlates directly with the amount of body fat. Leptin may influence GnRH secretion from the hypothalamus.

leukocyte. A white blood cell produced by myeloid or lymphoid tissue that fights infection and disease (neutrophils, basophils, eosinophils, lymphocytes and monocytes).

Leydig cells. Cells found in the interstitial compartment of the testis that produce testosterone. (See Figure 10-3)

libido. The behavioral drive associated with the desire to copulate.

ligand. A small molecule that binds to a larger molecule. For example, a hormone (ligand) binding to a receptor.

lobulation. Subdivided into lobules or lobes.

lobules. A small lobe or subdivision of a lobe.

lobulo-alveolar structures. Structures formed in the mammary gland during the final trimester of pregnancy that consist of ductules and apocrine glands that secrete milk. (See Figure 15-13)

lochia. Normal uterine discharge consisting of blood, necrotic tissue and mucus after parturition. (See Figures 15-5 and 15-6)

long-day breeder. A seasonal breeder in which reproductive activity and cyclicity peaks during long photoperiods (spring and summer). (See Figure 7-1)

lordosis. A condition in which the lumbar spine is flexed, forming a convex or hollowed-out appearance. The lumbar curvature is characteristic as a mating posture of females in estrus.

luteal phase. The phase of the estrous cycle characterized by progesterone dominance and the presence of a functional corpus luteum. The luteal phase begins immediately after ovulation and ends after lysis of the corpus luteum.

luteinization. The process whereby granulosal and thecal cells are transformed into luteal cells. Luteinization is brought about by the hormone LH.

luteinizing hormone (LH). A glycoprotein hormone secreted by the anterior lobe of the pituitary that causes ovulation and subsequent development and maintenance of the corpus luteum. In the male, it causes Leydig cells to produce testosterone.

luteolysis. The process whereby luteal tissue undergoes regression and cell death.

luteolytic. A material that promotes luteolysis.

lysin. A substance capable of causing destruction or dissolution of cellular elements.

lysis. The destruction of cells or tissue. In tissues/organs (like corpora lutea) "destruction" and loss of function. In blood cells usually associated with rupture of the cell.

lysosomes. Intracellular vesicles that contain digestive enzymes.

M

mammary ridges. Two longitudinal ridges of slightly thickened epithelium on the ventral surface of the conceptus that give rise to the mammary glands. (See Figure 15-10)

mammogenesis. Development of the mammary gland. (See Figure 15-10)

manchette. The specialized microtubules that appear in the cytoplasm of developing spermatids around the posterior portion of the nucleus. They become closely apposed to the nuclear membranes and contribute to the postnuclear cap region. (See Figure 15-7)

masculinization. A process that promotes the development of male appearance and behavior.

maternal cotyledon. The maternal contribution to a cotyledonary placenta derived from the uterine caruncles.

maternal recognition of pregnancy. The process whereby the female physiologically recognizes the presence of a conceptus and therefore luteolysis does not occur. (See Figures 13-5, 13-6)

maturation phase. The final phase of spermiogenesis in which the developing spermatid resembles a spermatozoon. During this phase the flagellum is completely formed and the mitochondria cluster around the flagellum to form a middle piece. (See Figure 10-7)

median eminence. The most ventral part of the hypothalamus that forms a stalk connecting the hypothalamus to the pituitary. Nerve terminals from neurons originating in various hypothalamic nuclei populate this region and secrete releasing hormone into the primary capillaries of the hypothalamo-hypophyseal portal system. (See Figure 5-5)

mediastinum. The connective tissue core of the testes that houses the rete tubules. (See Figure 3-15)

meiosis. The cell divisions occurring in developing germ cells in which the daughter cell nucleus receives half the number of chromosomes (haploid) found in somatic cells.

meiotic phase. The phase of spermatogenesis involving primary and secondary spermatocytes that produce haploid spermatids.

meiotic prophase. The first stage of meiosis in which the nuclear or chromosomal material duplicates. Meiotic prophase occurs in primary spermatocytes.

melatonin. A hormone secreted by the pineal gland predominantly during darkness that alters GnRH and gonadotropin secretion. (See Figure 7-7)

menopause. Permanent cessation of menses; termination of menstrual cycles brought about by depletion of ovarian follicles. (See Figure 8-12)

menses (menstruation). The periodic endometrial sloughing and hemorrhagic discharge to the exterior lasting 5-7 days in most women; the time of menstruation. (See Figure 9-15)

menstrual cycle. The reproductive cycle of the woman that consists of the physiologic events during and between menstrual periods (lasting about 28 days). There are three phases in the menstrual cycle; menses, the proliferative phase and secretory phase. (See Figure 7-10)

menstrual period. Time of menses.

mesoderm. The middle germ layer of the embryo. (See Figure 4-1 and Table 4-1)

mesometrium. The portion of the broad ligament that supports the uterus and is continuous wiht the perimetrium.

mesonephric ducts (Wolffian ducts). The ducts that provide an outlet for the fluid produced by the mesonephros in the developing embryo. They will be retained and form the epididymis and the ductus deferens in the male or will become vestigial in the female. (See Figures 4-7, 4-13)

mesonephric kidney (mesonephros). One of three renal systems appearing in the mammalian embryo. The mesonephros undergoes regression and does not serve an excretory function in the postnatal animal. (See Figure 4-5)

mesonephric tubules. The tubules of the mesonephric kidney that connect the capillary tufts of the mesonephros to the mesonephric duct. These tubules will be retained as the efferent ducts in the male. (See Figure 4-7)

mesosalpinx. A portion of the broad ligament that surrounds and supports the oviduct. (See Figures 2-13, 2-14)

mesovarium. A portion of the broad ligament that attaches the ovary to the mesometrium. (See Figures 2-13, 2-14)

metabolic hormones. Hormones that a regulate metabolic function, e.g. thyroxin, adrenal corticoids and somatotropin.

metanephros kidney. The most advanced form of the three renal types found in the developing mammalian embryo that is retained and becomes the permanent and functional kidney. (See Figure 4-5)

metestrus. A stage of the estrous cycle between ovulation and formation of a functional corpus luteum. (See Figure 7-3)

microcotyledons. Unique forms of chorionic villi that characterize the mare placenta. (See Figure 14-1)

microtubules. Cylindrical cytoplasmic elements associated with mitosis and meiosis and related to the movement of chromosomes on the nuclear spindle during cell division.

middle piece (midpiece). A portion of the sperm flagellum around which the mitochondrial helix is entwined. (See Figure 10-9)

milk. A whitish liquid containing proteins, fats, lactose and various vitamins and minerals produced by the mammary glands of mammalian females after parturition.

milk ejection. The process whereby milk is moved from the alveolar lumen into the ducts so that it can easily be removed by the suckling neonate. The process is brought about by oxytocin induced contractions of myoepithelial cells. (See Figure 15-13)

mitochondrial helix. The helical arrangement of mitochondria around the flagellum of mammalian sperm. (See Figure 10-9)

monoestrus. Animals that display only one period of sexual receptivity (estrus) during a year.

monotocous. Mammals that typically give birth to a single offspring at a time.

morula. A stage of early embryonic development within the confines of the zona pellucida characterized by a round mass of blastomeres resulting from cleavage divisions of the zygote. (See Figures 13-1, 13-2)

motility. The ability to move or contract (sperm motility, swimming; uterine motility, contracting).

mucopolysaccharide. A protein-polysaccharide complex that functions as a protective coating.

mucosa. An epithelial lining or coating of a structure. (See Figure 2-1)

Müllerian ducts. See paramesonephric ducts.

multiparous. A female that has had at least one previously successful pregnancy and parturition.

muscularis. The smooth muscular layer covering a tubular or hollow organ. (See Figure 2-1)

myoepithelial cells. Cells within the mammary glands that have receptors for oxytocin and upon stimulation contract to cause milk ejection. (See FIgure 15-13)

myoid layer. A smooth muscle layer (e.g. surrounding the seminiferous tubule, epididymis or oviduct).

myometrium. The smooth muscle layer of the uterus consisting of an inner circular layer and an outer longitudinal layer. (See Figures 2-16, 2-17 and 2-18)

N

nasopalatine ducts. See incisive ducts.

neat semen. Unadulterated, unaltered semen.

necrosis. The death of cells, tissues or organs, usually resulting from damage to the tissue or from ischemia.

negative feedback. The set of conditions whereby a hormone exerts an inhibitory effect on another gland or organ suppressing the level of hormone secretion. For example, progesterone exerts a negative feedback on the hypothalamus and thus limits the release of GnRH.

nervous system. The system consisting of the brain, spinal cord and peripheral nerves that regulate the body's response to internal and external stimuli.

neuroendocrine reflex. A reflex initiated by stimulation of sensory neurons that causes the release of a neurohormone from neurosecretory cells. (See Figure 5-1)

neurohormone. A hormone that is synthesized and secreted by neurons.

neurohypophysis. The posterior lobe of the pituitary gland.

neuropeptides. A variety of regulatory molecules produced by neurons that exert specific effects on other neurons or tissues.

neurosecretory cell. A neuron that secretes a substance into the blood.

neurotransmitter. A specific chemical released from the terminal boutons of neurons that causes either excitation or inhibition of postsynaptic neurons. (See Figure 5-1)

nuclear receptors. The specialized molecules within the nucleus of the cell that combine with a drug, steroid hormone or chemical mediator to alter the metabolism of the cell. (See Figure 5-15)

nulliparous. A female that has not become pregnant.

O

obstetrics. A specialty of human and veterinary medicine focusing on the care of the female during pregnancy, parturition and the puerperium.

oestrous. British spelling of estrous.

oestrus. British spelling of estrus (heat).

olfactory. Relating to, or contributing to the sense of smell.

oocyte meiotic inhibitor (OMI). Substance implicated in controlling the resumption of meiosis in the oocyte just before or after ovulation.

ootid. The oocyte after the first meiotic division in which the first polar body is present. (See Figure 13-1)

ostium. A small opening in a tubular organ such as the cervix or oviduct.

ovarian cortex. The outer portion of the ovary that contains developing and atretic follicles as well as functional and regressing corpora lutea. (See Figure 2-11)

ovarian follicles. Spherical structures that contain an oocyte. Follicles are classified as primary, secondary or antral, depending on the number and type of cellular layers present. (See Figure 2-11)

ovarian medulla. The inner portion of the ovary that houses blood vessels, lymphatics and nerves. (See Figure 2-11)

ovariectomy. Surgical removal of one or both ovaries.

ovary. The female gonad.

oviducts. The small, usually convoluted ducts (Fallopian tubes or uterine tubes) originating embryologically from the paramesonephric ducts that transport ova and sperm. The oviduct consists of the ampullary and isthmic regions.

ovine interferon τ (oIFN-τ). A specific protein produced by the ovine trophoblast that is antiluteolytic. It contributes to maternal recognition of pregnancy in the ewe. (See Figure 13-5)

ovine placental lactogen. A placental lactogen produced by the ewe that has higher lactogenic effects than somatotrophic effects.

ovine trophoblastic protein 1. See ovine Interferon τ.

oviparous. Animals that produce eggs that are hatched outside the body of the ovulatory animal, as in birds.

ovulation fossa. A conspicuous depression in the ovarian surface that is the site of each ovulation in the mare.

oxytocin. A peptide synthesized by neurons in the hypothalamus and released by nerve terminals in the posterior lobe of the pituitary. It is also produced by the corpus luteum. It causes contractions in smooth muscle in the male and female reproductive tract and regulates luteolysis.

P

pampiniform plexus. A specialized venous plexus beginning in the spermatic cord and terminating on the dorsal pole of the testis. It consists of the testicular vein that elaborately intertwines around the testicular artery. The pampiniform plexus provides a countercurrent heat exchange mechanism for the testes. (See Figure 3-9)

paramesonephric ducts (Müllerian ducts). The ducts that originate lateral to the mesonephric ducts in the female embryo. They develop into the oviducts, uterus, cervix and portions of the cranial vagina. (See Figures 4-13, 4-17)

paraplacenta. The pigmented area at the distal borders of a zonary placenta that consists of hematomas (blood clots) that is thought to be involved in iron transport from the dam to the fetus. (See Figure 14-2)

parenchyma. The functional cells of a gland or organ supported by a connective tissue framework. (See Figure 3-15)

parietal vaginal tunic. The layer of peritoneum that defines the outermost (peripheral) boundary of the vaginal cavity in the male. (See Figure 3-15)

parturition. To give birth.

pelvic urethra. The region of the urethra within the pelvis that extends to the base of the penis. Surrounding the pelvic urethra is a specialized muscle known as the urethralis muscle. The accessory sex glands that secrete their products via ducts directly into the pelivc urethra. (See Figures 3-3, 3-4, 3-6, 3-7, 3-8, 3-19 and 3-20)

penile protrusion. The forward positioning or projection of the penis; protrusion of an erect penis is an indicator of sexual stimulation and is obligatory for intromission.

penile urethra. The portion of the urethra inside the penis.

penis. The male organ of copulation consisting of a shaft and the glans penis.

peptide. A compound of two or more amino acids in which a carboxyl group of one amino acid is united with an amino group of another, resulting in the elimination of a molecule of water and formation of a peptide bond.

perimetrium. The serous outer covering of the uterus that is continuous with the peritoneum.

perineum. The external surface surrounding the vulva and the anus in the female and between the scrotum and the anus in the male.

peritoneum. A thin, serous, semitransparent connective tissue that lines the abdominal cavity and surrounds most of the viscera. (See Figure 2-2, 4-8)

pheromone. A volatile material secreted externally that is recognized by the olfactory system. Pheromones stimulate or inhibit reproduction.

photoperiod. The period of time during the day when there is daylight. (See Figure 7-7)

pineal gland. A neural structure on the dorsal surface of the midbrain that secretes melatonin in response to changing photoperiods. (See Figure 7-7)

pinealocyte. The cells of the pineal gland that secretes melatonin. (See Figure 7-7)

pituitary hormone. Any hormone secreted into the blood from the anterior or posterior lobes of the pituitary. The primary reproductive hormones secreted from the anterior lobe of the pituitary are follicle stimulating hormone (FSH), luteinizing hormone (LH) and prolactin. Oxytocin is secreted from the posterior lobe of the pituitary.

placenta. The organ of metabolic exchange between the fetus and the dam consisting of a portion of embryonic origin (chorion) and a portion of maternal origin (endometrium). The placenta is also a temporary endocrine organ. Placentas are classified according to the distribution of chorionic villi or the intimacy of the maternal-fetal tissue interface.

placental lactogen (somatomammotropin). A hormone produced by the placenta that stimulates lactogenesis in the dam and fetal growth.

placentation. The structural organization and physical relationship of the fetal membranes to the endometrium that provides the site of metabolic exchange between the dam and the fetus.

placentome. The specific anatomical region or zone of attachment between the fetal and maternal placenta.

plasmin. An enzyme that dissolves blood clots by converting fibrin into soluble products.

plasminogen. An inactive precursor to plasmin found in blood plasma.

polar body. A small portion of oocyte cytoplasm containing one-half of the female genetic material. It is removed by exocytosis into the perivitelline space during the first (first polar body formation) and second (second polar body formation) meiotic divisions. (See Figure 8-16)

polyestrus. Animals that display estrous cycles uniformly distributed throughout the year without marked seasonal influence. (See Figure 7-1)

polyspermy. A condition in which more than one spermatozoon fertilizes the oocyte.

polytocous. Mammals that give birth to multiple offspring. (litter-bearers)

positive feedback. A condition whereby a hormone exerts a stimulatory effect on another gland or tissue.

postcopulatory stage. The third (last) stage of reproductive behavior consisting of a dismount, a refractory period and memory.

posterior lobe of the pituitary (neurohypophysis). The portion of the pituitary gland that originates from the infundibulum of the brain during embryogenesis. The posterior lobe of the pituitary is neural tissue that houses terminals from neurons located in specific hypothalamic nuclei.

postestrus. An interestrus period that follows behavioral estrus in the queen that has not been induced to ovulate by copulation. (See Figure 7-5)

postnuclear cap. The membranous portion surrounding the posterior one-half to one-third of the sperm cell. The postnuclear cap originates from the manchette during spermiogenesis. (Figure 10-7)

postpartum recovery. See puerperium.

postsynaptic neuron. A neuron onto which the terminals of presynaptic neurons synapse.

precopulatory stage. The first stage of reproductive behavior consisting of search, courtship, sexual arousal, erection and penile protrusion.

pregnancy. A condition of the female mammal in which the conceptus (future offspring) develops in the uterus. The duration of pregnancy (gestation) varies greatly among species. (See Table 14-1)

pregnancy maintenance hormones. A group of hormones responsible for the maintenance of pregnancy, e.g. progesterone, estradiol, bIFτ, oIFτ, hCG, eCG. (See Figure 14-4)

pregnancy specific protein B (PSPB). A protein unique to pregnancy in ruminants that is produced by binucleate giant cells in the chorion.

pregnant mare's serum gonadotropin (PMSG). See equine chorionic gonadotropin.

prenatal. Preceding birth.

preoptic nucleus. Hypothalamic nucleus located rostral to the optic chiasm that is part of the GnRH surge center.

preovulatory GnRH center (surge center). A group of specific hypothalamic nuclei in the female that respond to high levels of estradiol by secreting high concentrations of GnRH during a relatively short period of time. (See Figure 8-3)

preovulatory GnRH surge. A series of high amplitude, high frequency episodes of GnRH released from the hypothalamic surge center that cause the preovulatory LH surge.

pressure atrophy. The build-up of pressure usually from secretory products within a secretory organ that results in the decrease or the cessation of secretion.

presynaptic neuron. A neuron that secretes neurotransmitters that cause excitation or inhibition in the postsynaptic neuron.

primary corpus luteum. The corpus luteum formed from the ovulatory follicle in the mare.

primary follicle. An ovarian follicle characterized as having a single layer of spindle shaped cells surrounding the oocyte. The nucleus of the oocyte contained within the primary follicle is arrested in the dictyate stage (dictyotene). (See Figure 2-11)

primary mammary bud. The primary embryonic stage of mammary gland development in which future mammary tissue pushes into the dermis. (See Figure 15-10)

primary portal plexus. The arterial capillary plexus of the hypothalamo-hypophyseal portal system into which releasing hormones are secreted. (See Figure 5-5)

primary spermatocyte. The daughter cells of spermatogonia that enter the first meiotic prophase and will give rise to a secondary spermatocyte. (See Figures 3-16, 10-5, 10-10 and 10-11)

primary zona binding region. One of the binding sites found on the sperm plasma membrane that is believed to be responsible for adherence of spermatozoa to the zona pellucida. (See Figure 12-10)

primiparous. Referring to the first parity or pregnancy of a female.

primitive endoderm. A tissue layer that is formed very early in development that lines the trophoblast and will eventually give rise to the yolk sac. (See Figure 13-4)

primitive gut. The embryonic precursor to the gastrointestinal tract. (See Figure 13-4)

primitive sex cords. Cords of cells that penetrate to the interior of the male embryonic gonad that incorporate primordial germ cells. These cords will give rise to the seminiferous tubules. (See Figure 4-4)

primordial follicles. The most primitive stage of the ovarian follicle. (See Figure 2-11)

principal piece. The portion of the sperm tail that extends from the middle piece to the terminal piece. (See Figure 10-9)

proacrosin. An inactive form of acrosin found in the acrosome of mammalian spermatozoa.

proceptivity. Female behaviors toward males that stimulate the male to copulate, e.g. headbutting and mounting the male.

proestrus. The stage of the estrus cycle between luteolysis and the onset of estrus.

progesterone. A steroid hormone produced by corpora lutea and the placenta that is required for the maintenance of pregnancy.

progesterone block. The inhibition (block) of myometrial contractions brought about by high levels of progesterone during pregnancy.

progestin. Any substance that produces an effect similar to progesterone.

prolactin. A hormone secreted by the anterior lobe of the pituitary that stimulates lactogenesis and initiates maternal behavior.

proliferation phase. (Spermatogenesis) The phase of spermatogenesis that consists of all spermatogonial mitotic divisions, resulting in increasing numbers of spermatogonia (proliferation). (See Figure 10-5)

proliferative phase. (Mentrual cycle) Phase of the menstrual cycle in which the endometrium begins to grow and increase in thickness in response to rising estrogen levels. (See Figure 9-15)

pronephros. The most primitive form of kidney found in developing mammalian embryos that degenerates and gives way to the mesonephros.

prostaglandin (PG). A class of physiologically active substances (designated as PGE, PGF, PGA and PGB) that are present in most tissues of the body. Prostaglandins are derived from arachidonic acid and have a wide variety of functions.

prostaglandin $F_{2\alpha}$. A hormone that causes luteolysis. It is secreted from the uterus in most animals, and secreted by the ovary and uterus in the human.

prostate gland. One of the accessory sex glands of the male consisting of a body (sometimes paired) that is outside of the pelvic urethra and/or a disseminate portion that forms a glandular layer in the wall of the pelvic urethra. (See Figures 3-3, 3-4, 3-5, 3-6, 3-19 and 3-20)

protein kinases. A class of control enzymes that phosphorylate proteins. (See Figure 5-14)

proximal cytoplasmic droplet. A cytoplasmic remnant in the neck region of a newly formed spermatozoon.

puberty. A developmental process in which endocrine and morphologic changes transform the animal into an individual capable of reproducing. Puberty is the acquisition of gonadotropin secretion, gametogenesis, gonadal steroid secretion, reproductive behavior and development of secondary sex characteristics.

puerperium. The period between parturition and return to the normal cycling state of the ovaries and uterus.

pulsatile secretion. A secretory pattern in which the secretions are released in a relatively predictable rhythmic fashion.

pulse pressure eliminator. The blood within the testicular artery has a very low pulse pressure (about 10mmHg) when compared to other systemic arteries (about 40mmHg). It is believed that the long torturous highly compliant testicular artery greatly reduces the pulse pressure. The physiological significance is not known.

R

radioimmunoassay (RIA). An immunologic assay that quantifies hormones or other immunogenic substances using radiolabeled hormones.

rapid transport phase. The short burst of spermatozoal transport activity during and soon after copulation brought about by muscular contractions of the female tract; functional importance not known.

Rathke's pocket (pouch). An invagination of the stomodeal ectoderm in the developing embryo that gives rise to the anterior lobe of the pituitary. (See Figure 4-3)

receptivity. Specific behavior in the female that promotes copulation, e.g. lordosis, tail deviation and backing toward males.

receptor domains. The regions of specific receptor proteins of the plasma membrane consisting of the extracellular, transmembrane and intracellular domains.

recipient female. A female into which embryos are transferred (generally into the uterus) from a donor female with the goal of generating a pregnancy that progresses to term.

recruitment (follicular). The process whereby a cohort of antral follicles are recruited and begin to grow from a pool of FSH sensitive antral follicles. (See Figure 8-7)

rectogenital pouch. The pouch (space) between the rectum and the reproductive organs.

rectus. Straight; lacking curvature.

reflex ovulation (induced). A condition whereby the female must experience cervical and/or vaginal stimulation (usually in the form of mating) before ovulation can occur.

refractory. Temporarily unresponsive to nervous or sexual stimuli.

refractory period (postcopulatory). The period of time after copulation where neither the male nor the female will engage in another copulation.

relaxin. A polypeptide hormone secreted by the placenta and/or the corpus luteum of pregnancy that causes the cervix to dilate and softens the ligaments in the pelvic region, thus tending to widen the birth canal during parturition. (See Figure 14-14)

releasing hormones. Small peptides produced by neurons in hypothalamic nuclei that cause the release of anterior pituitary hormones.

renewable stem cells. Cells in the seminiferous epithelium that provide a continual supply of stem cells so that spermatogenesis can continue indefinitely.

restraint, sexual. A maneuver used to prolong sexual stimulation by preventing a sexually stimulated male from mounting a stimulus animal or device.

rete fluid. Fluid located within the rete testis that contains spermatozoa and secretions from the seminiferous epithelium.

rete testis. A network of tubules housed within the mediastinum of the testis that are connected to the straight portions (tubuli recti) of the seminiferous tubules and merging into the efferent ducts. (See Figure 3-15)

rete tubules. The tubules found in the mediastinum of the testes that transport or allow spermatazoa and fluid from the seminiferous tubules to the efferent ducts. (See Figure 3-15)

retractor penis muscles. A pair of smooth muscles originating on the ventral surface of the first few caudal vertebrae. The muscle(s) circumvent the rectum and continue to their attachment on the lateral and urethral surfaces of the penis. Relaxation of this muscle is required for full penile protrusion and erection.

retrograde loss of sperm. The loss of sperm to the exterior of the female after insemination.

retroperitoneal. Located behind or outside of the peritoneum. The reproductive tracts of both the male and the female are retroperitoneal.

S

salpinx. Oviduct.

scrotum. A sac consisting of skin, sweat glands, a layer of smooth muscle (tunica dartos) and connective tissue that houses the testis. (See Figures 3-11 and 3-12)

season. A term used in reference to the breeding season in females, or referring to estrus as, "in season".

seasonal anestrus. A period of anestrus induced by either long (ewe) or short (mare) photoperiods.

seasonal polyestrus. A condition in which females exhibit multiple estrous cycles during a specific season of the year. (See Figure 7-1)

second messenger. An intracellular material that responds to a hormone-receptor complex and initiates a specific set of intracellular reactions. (See Figure 5-14)

second polar body. See polar body.

secondary follicle. An ovarian follicle characterized by having two or more cell layers surrounding the oocyte but without an antrum. (See Figure 2-11)

secondary mammary bud. An early stage of embryonic mammary gland development in which the primary mammary bud begins to produce numerous additional buds that penetrate the dermis. (See Figure 15-10)

secondary spermatocyte. The daughter cells of primary spermatocytes that will complete the second meiotic division and give rise to spermatids. (See Figures 10-5, 10-10 and 10-11)

secretory phase. Phase of the menstrual cycle in which the endometrial glands gain full secretory activity in response to progesterone and estrogen. (See Figure 9-15)

selection (follicular). The process by which a cohort of antral follicles are selected from the previously recruited antral follicles. (See Figure 8-7)

sella turcica. A vault-like depression in the sphenoid bone that houses the anterior and posterior lobes of the pituitary. (See Figure 4-3)

seminal plasma. The noncellular liquid portion of semen produced by the accessory sex glands.

seminiferous epithelium. The epithelium between the basement membrane and the lumen of the seminiferous tubules consisting of developing germ cells and Sertoli cells.

seminiferous tubules. The highly tortuous tubules within the testes that produce spermatozoa. (See Figures 3-15 and 10-10)

serosa. A serous membrane making up the outermost covering of an organ or serving as a lining of a cavity. (See Figure 2-1)

Sertoli cells. Somatic cells in the seminiferous epithelium that are believed to govern spermatogenesis. Sertoli cells contain FSH receptors and produce a wide variety of materials and hormones. They are named after the famous Italian scientist Enrico Sertoli. (See Figure 10-3)

sexually indifferent stage. The stage of embryogenesis when the sex of the embryo cannot be determined based on morphologic features.

sexual stimulation. A set of stimulus conditions in the male that will result in arousal, mounting and ejaculation.

shaft of penis. The portion of the penis between the base and the glans.

short-day breeders. Females that begin to exhibit estrous cycles during times of short photoperiods (short days). (See Figure 7-1)

short scrotumed bull. A bull who's scrotum has been artificially shortened to hold the testes next to the body resulting in elevated testicular temperature that inhibits spermatogenesis.

sialomucin. A mucus of low viscosity produced by the mucosa of the basal cervical crypts. (See Figure 12-5)

sigmoid flexure. The s-shaped curvature of the flaccid fibroelastic penis when it is retracted into the body. During sexual excitation and erection, the sigmoid flexure disappears when the penis straightens. (See Figure 3-4)

silent ovulation. A condition whereby ovulation occurs without behavioral estrus. Silent ovulation frequently occurs in the first postpartum estrous cycle of dairy cows and the first estrous cycle after seasonal anestrus in ewes. (See Figure 7-6)

simple diffusion. The movement of materials from high concentration to low concentration without active expenditure of energy.

simple neural reflex. The mechanism by which external stimuli trigger a response without cognition. The components are the afferent sensory neuron, an interneuron (located in the spinal cord) and an efferent neuron that leaves the spinal cord and innervates an effector organ. (See Figures 5-1, 5-2)

simplex uterus. A uterus found in primates consisting of a large uterine body without uterine horns. (See Figure 2-15)

sire-on-fetus-hypothesis. A theory that suggests that it may be possible for the sire to influence placental lactogen secretion by the placenta and thus enhance milk production of the dam.

slough. The separation of necrotic tissue from living tissue.

smooth muscle. A type of muscle without striations that surrounds most organs of the reproductive tract often referred to as the muscularis.

somatomammotropin. See placental lactogen.

somatostatin. A hormone secreted by the hypothalamus and pancreas that inhibits the secretion of somatotropin, insulin, gastrin and other hormones.

spay. The removal of the ovaries (ovariectomy).

spermatic cord. A cord-like collection of tissues containing the testicular artery and vein, lymphatics, the pampiniform plexus, nerves, the cremaster muscle, the ductus deferens and the vaginal tunics. (See Figures 3-2, 3-4, 3-5, 3-6, 3-7, and 3-8)

spermatids. Haploid male germ cells derived from secondary spermatocytes that undergo a transformation from a spherical cell to a fully specialized and differentiated spermatozoon with a head and a tail. (See Figures 10-5, 10-10, and 10-11)

spermatocytes. The male germ cells derived from the final mitotic division of spermatogonia (primary spermatocyte). They give rise to secondary spermatocytes. (See Figures 10-5, 10-10 and 10-11)

spermatogenesis. The process whereby spermatozoa are formed. It consists of proliferation (mitosis), meiosis and differentiation. (See Figure 10-5)

spermatogenic efficiency. The number of spermatozoa produced per gram of testicular parenchyma. (See Figures 10-1 and 10-2)

spermatogenic wave. A sequential ordering of the stages of the cycle of the seminiferous epithelium along the length of the seminiferous tubule.

spermatogonia. The most primitive of the adult male germ cells located in the basal compartment of the seminiferous tubule that give rise to primary spermatocytes after a series of mitotic divisions. Spermatogonia proliferate through a series of histologically definable types generally accepted to be A, I and B spermatogonia. (See Figures 10-5, 10-10, and 10-11)

spermatozoa. The male gamete consisting of a head (nucleus) and a tail (flagellum) that exhibits motility when exposed to the appropriate physiologic environment. (See Figure 10-9)

spermiation. The release of mature spermatozoa from Sertoli cells into the lumen of the seminiferous tubule. (See Figure 10-11)

spermiogenesis. A subcategory of spermatogenesis during which spermatids undergo morphologic transformation into highly specialized spermatozoa. Spermiogenesis consists of the Golgi phase, the cap phase, the acrosomal phase and the maturation phase. (See Figures 10-6 and 10-7)

sphenoid bone. A bone forming the floor of the cranium that houses the sella turcica into which the hypophysis fits. (See Figure 4-3)

spontaneous ovulation. A condition whereby ovulation is brought about by changing endocrine conditions without the need for cervical or vaginal stimulation.

standing estrus. A female behavioral characteristic of estrus in which the female remains immobile allowing the male to mount her.

stem cell renewal. The process during the proliferative phase of spermatogenesis whereby differentiation of spermatogonia into more mature spermatogonia does not occur.

steroid. A generic term referring to closely related compounds that contain a common ring structure. (See Figures 5-9 and 5-10)

steroidogenic. Producing or synthesizing steroid hormones.

stigma. The small protrusion at the apex of a follicle that represents a site of deterioration of the follicular wall prior to ovulation.

stomodeal ectoderm. A layer lining the stomodeum or embryonic mouth (oral cavity). (See Figure 4-3)

stomodeum. A depression in the oral region of the embryo that will form the mouth and become continuous with the gut. (See Figure 4-3)

stratified squamous epithelium. A type of epithelium characterized by irregular flattened cells in multiple layers lining portions of the vagina and covering the glans penis. (See Figure 2-22)

submucosa. A general region of tissue lying just beneath the mucosal layer housing the vasculature, nerve supply and lymphatics. (See Figures 2-1, 2-12, 2-16 and 2-22)

suburethral diverticulum. An outpocketing of tissue located just beneath the urethra that forms a blind pouch with probably no functional significance.

sulfate salt. An end product of the metabolism of testosterone that is excreted in urine. (See Figure 5-17)

sulfated glycoproteins 1 and 2. The products of Sertoli cells believed to be related to fertility acquisition (SGP-1) and provides a detergent effect that allows spermatozoa and fluids to move through the tubular network of the testis with ease (SPG-2).

sulfomucin. A type of mucus characterized as being highly viscous and produced by cells that line the lumen in the bovine cervix. (See Figure 12-5)

superfecundation. Fertilization of two or more ova during the same estrus by sperm from different males. For example, since the bitch has an estrus of several days, mating can occur during this time by several males. Thus, it is common for a bitch to deliver a litter containing offspring sired by several males.

superfetation. The presence of fetuses of different ages (not twins) resulting from fertilization of oocytes ovulated in successive periods of estrus.

superior cervical ganglion. The ganglion where neurons from the suprachiasmatic nucleus synapse with neurons that innervate the pineal gland to control melatonin release.

superior hypophyseal artery. The primary artery supplying the hypothalamo-hypophyseal portal system.

superovulation. Ovulation of abnormally high numbers of ova.

supplemental (accessory) corpora lutea. Corpora lutea that form as a result of eCG secretion from the endometrial cups in the mare. These corpora lutea produce progesterone that helps maintain pregnancy when the reduction in progesterone secretion by the primary corpus luteum occurs and before the onset of placental secretion of progesterone. (See Figure 14-7)

supplementary corpora lutea. The corpora lutea produced by the pregnant mare as a result of ovulation and/or luteinization induced by equine chorionic gonadotropin. (See Figure 14-7)

suprachiasmatic nucleus. A hypothalamic nucleus located just above the optic chiasm that is believed to be part of the GnRH surge center.

surge center. See preovulatory GnRH center.

sustained transport phase. Phase in which spermatozoa are transported to the ampulla of the oviducts in a "trickle-like" effect from the cervix and/or uterotubal junction.

synapse. The functional junction between two nerve cells characterized by close apposition of the membrane of the presynaptic terminal (teledendrite) with the postsynaptic membrane (dendrite). Nerve terminals can also synapse with blood vessels, in the case of the hypothalamic portal system, or in the case of oxytocin producing neurons in the posterior lobe of the pituitary.

synchronization of estrus (ovulation). Hormonal intervention designed to interrupt the luteal phases or to stimulate the onset of the follicular phase so that a group of females will display estrus and ovulate at similar times. (See Figures 9-19 and 9-20)

syncytiotrophoblast. Cells comprising the outer layer of the trophoblast that make contact with the endometrium of the uterus forming attachment with the endometrium.

syndesmochorial placenta. A type of epitheliochorial placenta in which the endometrial epithelium locally erodes, causing intermittent exposure of the maternal capillaries to the chorionic epithelium.

syngamy. The fusion of the male and female pronuclei within the cytoplasm of the newly fertilized oocyte, giving rise to the zygote.

systolic pressure. Blood pressure occurring during ventricular systole (contraction). Systolic pressure is the highest pressure during the cardiac cycle.

T

target tissue. A tissue containing receptors to a specific hormone or neurotransmitter.

teratogenic. Causing physical defects in the developing conceptus.

terminal piece. The terminal portion (end) of the flagellum of mammalian spermatozoa. (See Figure 10-9)

tertiary follicle. See antral follicle. (See Figure 2-11)

testicular artery. The vessel that provides the arterial blood supply to the testes. It originates from the abdominal aorta, passes through the inguinal canal and becomes quite torturous in the spermatic cord and provides the surface for the venous pampiniform plexus. In most species the testicular artery is highly convoluted on the surface of the testes and then enters the interior of it. (See Figures 3-2, 3-9 and 3-10)

testicular capsule. The tunica albuginea and visceral vaginal tunic. (See Figure 3-15)

testis (pl. testes). One of the two male gonads.

testis determining factor (TDF). A substance synthesized by the primitive sex cords of the male embryo that causes the development of the male gonad and the male reproductive tract. The absence of TDF results in the development of the female reproductive tract. (See Figure 4-6)

testosterone. The male sex hormone and the most potent naturally occurring androgen produced by the interstitial cells of Leydig. (See Figure 5-10)

theca externa. The outermost layer of an antral follicle that provides structural integrity and support for the follicle. (See Figure 9-2)

theca interna. The layer of flattened spindle-shaped cells just outside the basement membrane of an antral follicle with receptors to LH. (See Figures 2-11, 8-9)

theriogenology. A specialty of veterinary medicine focusing on the physiology and pathology of the reproductive system of animals.

third ventricle. One of the ventricles of the brain that is attached to the right and left lateral ventricles and to the cerebral aqueduct. It is surrounded by the hypothalamus. (See Figures 5-3, 5-4)

threshold. The minimal stimulus required to elicit a response.

thyroxin. Hormone produced by the thyroid gland that governs metabolic rate.

tight junctions. Specialized intracellular junctions that prevent materials from gaining access to the adluminal compartment of the seminiferous epithelium. (See Figures 3-16 and 10-3)

tonic GnRH center. A term used to describe the hypothalamic nuclei that control the tonic release of GnRH. The tonic center collectively consists of the ventromedial nucleus, the arcuate nucleus and the median eminence. (See Figures 5-3, 5-5 and 5-6)

totipotency. The ability of a single cell to differentiate and develop into a complete organism.

transcervical insemination. Technique of artificial insemination in which the semen is deposited into the uterus using a pipette to penetrate and bypass the cervix (cow and mare). (See Figure 12-3)

transduce. To convert from one form of energy into another form of energy.

transferrin. A plasma globulin responsible for transporting iron. Some transferrin is produced by Sertoli cells. Relatively high concentrations are found in fluid of the seminiferous tubules and the rete tubules.

translocating cytoplasmic droplet. The residual cytoplasm from spermiogenesis that is relocating from the neck to the distal middle piece of the spermatozoa. Sperm containing translocating droplets are characterized as having the flagellum bent back toward the head of the sperm forming a crook containing the droplet. (See Figure 3-18)

transmembrane domain. The portion of a hormone receptor within the plasma membrane that connects the extracellular and intracellular domains. (See Figure 5-13)

transuterine migration. The mechanism for maternal recognition of pregnancy in the mare via the movement of the conceptus through both uterine horns for a defined period of time. In other species, the migration of the conceptus from one uterine horn to the other. (See Figure 13-7)

transvaginal follicular aspiration. A non-surgical technique used to recover oocytes from mares and cows in which an ultrasound guided hypodermic needle is inserted through the vaginal wall into a dominant follicle and the follicular fluid containing the oocyte is aspirated. (See Figure 13-10)

trophectoderm. The cell layer from which the trophoblast differentiates. (See Figure 13-4)

trophoblast. The cell layer covering the blastocyst that will form the chorion. (See Figure 13-4)

-tropin. A suffix referring to nourishment or having an affinity for.

true anestrous. A condition where a female does not cycle due to insufficient hormonal stimuli.

tubular compartment. The compartment of the testicular parenchyma consisting of the seminiferous tubules.

tubulus contortus. The highly convoluted tortuous component of a seminiferous tubule contributing to the majority of its length. It is attached to a straight portion (tubulus rectus) that connects to the rete tubule. The tubulus contortus is the primary site of spermatogenesis. (See Figure 3-15)

tumescence. A swelling or enlarging as in penile erection.

tunica albuginea. A dense, white connective tissue covering an organ (testis, ovary, penis). (See Figures 2-11, 3-14, 3-15 and 11-9)

tunica dartos. The layer of smooth muscle that is a component of the scrotum that controls contraction and relaxation of the scrotum. (See Figure 3-15)

tunica vasculosa. A layer well supplied with blood vessels. The vascular lining of the connective tissue septa within the testes. (See Figure 3-15)

U

umbilical cord. A cord-like structure that connects the developing fetus to the placenta. It contains two arteries and one vein that bring nutrients to the fetus and transports fetal wastes to the dam. (See Figure 14-2)

up-regulate. An increase in receptor density.

urethral gland. See disseminate prostate.

urethral tubercle. An elevated nodule located dorsal to the urethra in the vagina of the bitch. (See Figure 2-9)

urethralis muscle. The striated, circular muscle surrounding the pelvic urethra, the contractions of which cause semen to move into the penile urethra. (See Figures 3-2, 3-3, 3-4, 3-6, 3-7, 3-8, 3-19 and 3-20)

urogenital sinus. An embryonic cavity in the caudal portion of the animal that will give rise to the bladder, the pelvic urethra (male), the vagina (female) and the external genitalia of both the male and female. (See Figure 4-14)

uterectomy. Complete removal of the uterus; also known as a hysterectomy. (See Figure 9-10)

uterine horns (cornua). The portions of the uterus that are the result of the incomplete fusion of paramesonephric ducts. (See Figures 2-2, 2-3, 2-4, 2-7, 2-8, 2-9, and 2-10)

uterine involution. The acquisition of normal uterine size and function in the postpartum female. (See Figure 15-1)

utero-ovarian ligament. A portion of the broad ligament that attaches the ovary to the uterus. (See Figure 2-13)

uterotubal junction. The site where the oviduct joins the uterus.

uterus. A hollow, tubular organ surrounded by smooth muscle and lined with epithelium that connects the cervix to the oviducts. It is responsible for sperm transport, early embryonic development, formation of maternal placenta, housing the fetus throughout gestation and parturition. The uterus produces prostaglandin $F_{2\alpha}$.

V

vagina. The female copulatory organ that connects the external genitalia to the cervix. (See Figures 2-4, 2-5, 2-6, 2-7, 2-8, 2-9, and 2-10b)

vaginal cavity. The space that separates the visceral vaginal tunic from the parietal vaginal tunic of the descended testicle. (See Figure 4-8)

vaginal process. The space (cavity) formed between the visceral and parietal vaginal tunics during descent of the testes. (See Figure 4-8)

vas deferens. (See ductus deferens).

vascular countercurrent exchange. A process whereby exchange of substances and/or heat occurs between an artery and a vein that are intimately associated. (See Figures 3-9, 9-11)

ventromedial nucleus. A hypothalamic nucleus located in the medial floor of the hypothalamus that contributes to the tonic GnRH center.

vesicular glands. Paired accessory sex glands located lateral to the ductus deferens and dorsal to the pelvic urethra. They secrete a portion of the seminal plasma into the pelvic urethra. (See Figures 3-4, 3-5, 3-6, 3-19, and 3-20)

vesiculation. A process whereby membrane vesicles are formed. Vesiculation occurs during the acrosome reaction

when the plasma membrane of the sperm fuses with the outer acrosomal membrane, forming many small vesicles. (See Figure 12-11)

vestibular glands. Mucous secreting glands located in the wall of the vestibule. The secretion from these glands lubricates the vestibule at copulation and at parturition. The odor of the secretions has a sexually stimulating effect on the male in some species.

vestibule. The portion of the vagina cranial to the clitoris extending to and including the urethral opening. It is common to both the urinary and reproductive systems. (See Figures 2-5, 2-7, and 2-9)

visceral vaginal tunic. The layer of peritoneum that defines the inside boundary of the vaginal cavity in the male. This layer is tightly adherent to the tunica albuginea of the testis. (See Figure 3-15)

vital dye. Staining material for living cells that does not result in cell death.

vitelline block. A phenomenon that prevents polyspermy by rendering the plasma membrane of the oocyte incapable of further binding with the sperm membrane.

vomeronasal organ. An accessory olfactory organ consisting of a pair of blind ducts located ventral to the nasal cavity. The ducts open into the oral cavity through the incisive duct. They are believed to be associated with identification of nonvolatile pheromones. (See Figure 11-5)

vulva. The external genitalia of the female. (See Figures 2-23 and 2-24)

W

Wolffian duct. See mesonephric duct.

X

X chromosome. Female somatic chromosome.

Y

Y chromosome. Male somatic chromosome.

yolk sac. An extraembryonic structure that develops from the primitive endoderm and regresses in size as the conceptus develops. In mammals the yolk sac does not contain yolk. However, it does contribute primitive germ cells that migrate to the genital ridge, and also produces erythrocytes and alpha fetoprotein. (See Figures 4-4, 13-4)

Z

zona block. A mechanism to prevent polyspermy that renders the zona pellucida incapable of binding additional spermatozoa.

zona lysin. An enzyme in the acrosome that aids in penetration of the zona pellucida.

zona pellucida. A thick, translucent mucoprotein surrounding the oocyte and early embryo. (See Figures 2-11, 12-10, 12-12 and 12-13)

zona proteins (ZP). Specific proteins of the zona pellucida that provide structure (ZP1 and ZP2) and bind spermatozoa (ZP3). (See Figure 12-10)

zonary placenta. A placenta of dogs and cats in which chorionic villi attach to the uterus in a well defined zone or band. (See Figure 14-2)

zygote. The diploid cell resulting from the fusion of the male and female pronuclei. (See Figure 13-1)

SECOND REVISED EDITION

The best professionals are great teachers. They transfer relevant knowledge that allows their students/clientele to proceed with greater competence. The 2nd Edition of **Pathways to Pregnancy and Parturition** is your instrument for understanding, reviewing or teaching the basic concepts of reproductive physiology.
