Chapter 109 - Sarsaparilla species

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

Smilax aristolochiifolia (family: Liliaceae)
Synonym: *Smilax medica*
Common name: Mexican sarsaparilla

Smilax officinalis (family: Liliaceae)
Synonym: *Smilax regelii*
Common name: Honduras sarsaparilla

GENERAL DESCRIPTION

Sarsaparilla is a tropical American perennial plant. Its long slender root and short thick rhizomes produce a vine which trails on the ground and climbs by means of tendrils growing in pairs from the petioles of the alternate, obicular to ovate, evergreen leaves. The root is the part of the plant utilized for medicinal purposes.

CHEMICAL COMPOSITION

Sarsaparilla contains 1.8–2.4% steroid saponins, including:

- sarsaponin
- smilasaponin
- sarsaparilloside and its aglycones sarsapogenin(see [Fig. 109.1](#)), smilagenin, pollinastanol.

Other constituents include starch, resins, and a trace of volatile oil.^[1]

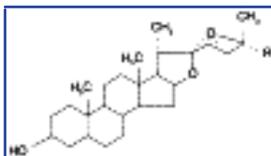

Figure 109-1 Sarsasapogenin.

940

HISTORY AND FOLK USE

Sarsaparilla's medicinal use has been as a tonic and blood purifier. Tonics are defined as agents:^[2]

... which permanently exalt the energies of the body at large, without vitally affecting any one organ in particular. ... In short, tonics tone the whole system.

A blood purifier or depurative refers to an agent which cleanses and purifies the system.^[2] Sarsaparilla's reputation in this regard probably stems from its importation from the Caribbean and South America to Europe in the 16th century for the treatment of syphilis.^[3]

Historical use in the treatment of syphilis

A French physician, Nicholas Monardes, published a comprehensive account of sarsaparilla and several other "new" drugs in the treatment of syphilis in 1574. Many Europeans at the time believed that syphilis had come to Europe from the West Indies with Columbus' sailors, and since there was a general belief that whatever disease was native to a country might be cured by the medicinal herbs growing in that region, it was only natural for sarsaparilla to become a popular remedy. Furthermore, the standard treatment for syphilis, mercury, often resulted in greater morbidity and mortality than the disease itself.

Sarsaparilla was a welcome alternative, but despite initial excitement, Monardes' sarsaparilla cure sank in favor. This was probably due to other aspects of the cure, which included confinement to a warm room for 30 days, followed by 40 days of abstinence from both wine and sexual intercourse.^[3]

However, sarsaparilla continued to be used in the treatment of syphilis. During military operations in Portugal in 1812, a British Inspector General of Hospitals noted that the Portuguese soldiers suffering from syphilis who used sarsaparilla recovered much faster and more completely than their British counterparts who were treated with mercury.^[3]

Sarsaparilla was also used by the Chinese in the treatment of syphilis. Clinical observations in China demonstrated that sarsaparilla is effective, according to blood

tests, in about 90% of acute cases and 50% of chronic cases.^{[1] [4]}

Although sarsaparilla was clearly more beneficial in the treatment of syphilis, it was mercury that established itself as the standard treatment for over four and a half centuries. It has been stated that “the use of mercury in the treatment of syphilis may have been the most colossal hoax ever perpetrated” in the history of medicine. Mercury represented a new kind of medicine, one formulated and prepared in a laboratory using the new techniques of chemistry. It helped to prepare the way for the future use of drugs rather than herbal medicines.^[3]

An interesting note is that sarsaparilla species have been used all over the world in many different cultures for the same conditions, namely gout, arthritis, fevers, digestive disorders, skin disease, and cancer.^[1]

PHARMACOLOGY

The mechanism of action of sarsaparilla is largely unknown, although the plant does contain several saponins and has been shown to be clinically effective in the treatment of psoriasis.^{[1] [5] [6]} This evidence points to a possible effect on binding of cholesterol and bacterial toxins in the intestines.

Endotoxin binding

Evidence seems to support sarsaparilla as an endotoxin binder. Endotoxins are cell wall constituents of bacteria that are absorbed from the gut. Normally, the liver plays a vital role by filtering these, and other, gut-derived compounds before they reach the general circulation. If the amount of endotoxin absorbed is excessive or if the liver is not functioning adequately, the liver can become overwhelmed, and endotoxins will spill into the blood.

If endotoxins are allowed to circulate, activation of the alternate complement system occurs. This system plays a critical role in aggravating inflammatory processes, and activation of complement is responsible for much of the inflammation and cell damage that occurs in many diseases, including gout, arthritis, and psoriasis. Historically, these conditions have been treated with sarsaparilla.

In further support of sarsaparilla’s effect as a binder of endotoxin is its historical use in the treatment of fever, as absorbed endotoxins produce fever. Sarsaparilla also exhibits some antibiotic activity, but this is probably secondary to its endotoxin-binding action.^[1]

CLINICAL APPLICATION

Sarsaparilla’s medicinal action appears to be a result of its binding of bacterial endotoxins in the gut, which makes them unabsorbable. This greatly reduces the stress on the liver and other organs and is probably responsible for sarsaparilla’s historical use as a tonic and blood purifier. This ability to bind endotoxins is also the probable reason

why sarsaparilla is effective in many cases of psoriasis, gout, and arthritis.

Psoriasis

Individuals with psoriasis have been shown to have high levels of circulating endotoxins. Binding of endotoxin in the gut is associated with clinical improvement in

941

these individuals. In a controlled study of 92 patients, an endotoxin-binding saponin (sarsaponin) from sarsaparilla greatly improved the psoriasis in 62% of the patients and resulted in complete clearance in 18%.^[6]

DOSAGE

- Dried root: 1–4 g or by decoction three times/day
- Liquid extract (1:1): 8–15 ml three times/day
- Solid extract (4:1): 250 mg three times/day.

TOXICOLOGY

Although no adverse effects have been reported, it is possible that problems could arise if large doses are used over a long period of time.

Chapter 110 - *Serenoa repens* (saw palmetto)

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

Serenoa repens (family: Arecaceae)
Common names: saw palmetto, palmetto scrub, sabal serrulata

GENERAL DESCRIPTION

Serenoa repens is a small palm tree native to the West Indies and the Atlantic coast of North America from South Carolina to Florida. The plant grows from 6– 10 feet high, with a crown of large, 2–4 feet high spiny-toothed leaves which form a circular, fan-shaped outline. The berries of the plant are the components used for medicinal purposes. The deep red-brown to black berries are wrinkled, oblong, and 0.5–1 inch long with a diameter of 0.5 inch.^[1]

CHEMICAL COMPOSITION

The saw palmetto berries contain about 1.5% of a fruity-smelling oil containing saturated and unsaturated fatty acids and sterols.^[1] About 63% of this oil is composed of free fatty acids including capric, caprylic, caproic, lauric, palmitic, and oleic acids. The remaining portion is composed of ethyl esters of these fatty acids and sterols, including beta-sitosterol and its glucoside. The lipid-soluble compounds are thought to be the major pharmacological components. Other components of the berries include carotenes, lipase, tannins, and sugars.

The purified fat-soluble extract is used medicinally and contains between 85 and 95% of fatty acids and sterols. It is made up predominantly of a complex mixture of saturated and unsaturated free fatty acids, their methyl- and ethyl-esters (approximately 7%), long chain alcohols in free and esterified form, and various free and esterified sterol derivatives.

The free fatty acids in this extract are identified by gas chromatography and mass spectrometry as:

- caproic acid (C6)
 - capric acid (C8)
-

944

- caprylic acid (C10)
- lauric acid (C12)
- myristic acid (C14)
- isomyristic acid (C14)
- palmitic acid (C16)
- oleic acid (C18:1)
- stearic acid (C18).

Lauric and myristic acid are the major fatty acids, accounting for approximately 30% of the fatty acid content.

The identified alcohols include those with *n*-C22, *n*-C23, *n*-C24, *n*-C26, *n*-C28, and *n*-C30 chains, phytol, farnesol, and geranylgeraniol, in addition to high molecular weight unsaturated polyphenols.

The sterolic fraction is composed of beta-sitosterol, stigmasterol, cycloartenol, lupeol, lupenone, and 24-methylcycloartenol. Many of these sterols are esterified with the fatty acids of the extract.

HISTORY AND FOLK USE

The American Indians, and later Eclectic and Naturopathic physicians, used saw palmetto berries in the treatment of genitourinary tract disturbances and as a tonic to support the body nutritionally.^{[2] [3]} It was used in men to increase the function of the testicles and relieve irritation in mucous membranes, particularly those of the genitourinary tract and prostate. It has been used in women with disorders of the mammary glands; long-term use was reputed to cause the breasts to enlarge slowly.^[2] Many herbalists have considered it to be an aphrodisiac.^[1]

PHARMACOLOGY

A standardized liposterolic (fat-soluble) saw palmetto berry extract has demonstrated numerous pharmacological effects relating to its primary clinical application in the treatment of the common disorder of the prostate gland, benign prostatic hyperplasia (BPH). BPH is thought to be caused by an accumulation of testosterone in the prostate. Once within the prostate, testosterone is converted to the more potent hormone dihydrotestosterone (DHT). This compound stimulates the cells to multiply excessively,

eventually causing the prostate to enlarge.

The primary therapeutic action of saw palmetto extract in the treatment of BPH has been thought to be a result of inhibition in the intraprostatic conversion of testosterone to dihydrotestosterone (DHT) and inhibition of its intracellular binding and transport.^[4] ^[5] However, more recent research has suggested additional mechanisms of action, including anti-estrogenic and receptor site-binding effects.^[6]

Estrogen contributes to BPH because it inhibits the hydroxylation and subsequent elimination of DHT. Serenoa appears to inhibit the activity of estrogen in the prostate. For example, in a double-blind study of 35 men with BPH, 18 were given the saw palmetto extract at 160 mg twice daily and 17 were given placebo.^[4] At the end of the 90 day study, androgen, estrogen, and progesterone receptors from prostate tissue samples were evaluated by two different techniques. The men receiving the saw palmetto extract had significantly lower cytosol and receptor values for estrogen and progesterone compared with the placebo group. Since the progesterone receptor content is linked to estrogenic activity, the results of the evaluation imply that at least part of the efficacy of the saw palmetto extract is through its anti-estrogenic effect.

The results from the androgen receptor analysis were quite interesting: there was no change in the number of cytosol androgen receptors, but the number of nuclear androgen receptors was significantly lower in the saw palmetto group (60% of the placebo group were positive for the nuclear receptor compared with 10% in the saw palmetto group). These results indicate that the saw palmetto extract probably competitively blocks the translocation of the cytosol androgen receptor to the nucleus.

The overall results of the study indicate that the standardized extract of saw palmetto exerts both anti-androgenic and anti-estrogenic activities. Preliminary analysis of the extract indicate that separate fractions are responsible for these effects. Researchers in this study concluded:

It cannot be excluded, however, that the primary effect is antiestrogenic and that the inactivation of androgen receptors and progesterone receptors and of the 5-alpha-reductase activity is secondary to the estrogen receptor blockade.

The standardized extract has also demonstrated anti-edematous effects and the polysaccharide components have demonstrated immunostimulatory effects.^[7] ^[8]

CLINICAL APPLICATION

Currently, the primary clinical application of saw palmetto berries (specifically the fat-soluble extract) is in the treatment of benign prostatic hyperplasia (BPH). Based on its pharmacology, this extract may also be of benefit in conditions of androgen excess in women, such as hirsutism and polycystic ovarian disease.

Benign prostatic hyperplasia

In the United States, between 50 to 60% of men between the ages of 40 and 59 years have BPH. This disorder is characterized by increased urinary frequency, night-time awakening to empty the bladder, and reduced force and caliber of urination (see [Ch. 138](#)). These major symptoms have been shown to be significantly improved in over

a dozen double-blind, placebo-controlled clinical trials (summarized in [Table 110.1](#)). ^[9]
^[10] ^[11] ^[12] ^[13] ^[14] ^[15] ^[16] ^[17] ^[18] ^[19] ^[20]

In one of the larger studies involving 110 patients with BPH, impressive clinical results were reported: nocturia decreased by over 45%, flow rate (ml/s) increased by over 50%, and post-micturition residue (ml) decreased by 42% in the group receiving the serenoa extract.^[18] In contrast, those on placebo showed no significant improvement in nocturia or flow rate, and post-micturition residue actually worsened.

Significant improvements were also noted in self-rating by the patients and global rating by the physicians. Of the 50 treated subjects completing the 30 day study, physicians rated 14 greatly improved, 31 improved, and only five unchanged or worsened. In contrast, no subjects in the placebo group had greatly improved, 16 showed some improvement, and 28 remained unchanged or worsened.

Although the saw palmetto extract has shown excellent results in numerous double-blind, placebo-controlled clinical trials, results from a recent open, multicenter study are perhaps the most revealing.^[21] The results corroborate those from numerous double-blind, controlled studies showing that the liposterolic extract of saw palmetto (*Serenoa repens*) standardized to contain 85–95% fatty acids and sterols is an effective treatment for benign prostatic hyperplasia (BPH). While drugs like finasteride (Proscar) typically take up to a year to produce significant benefit, the saw palmetto extract produces better results in a much shorter period of time. Most patients achieve some relief of symptoms within the first 30 days of treatment with the saw palmetto extract. In this study, 305 men were given a dosage of 160 mg twice daily. The subjective evaluations of treatment made by patients after 45 and 90 days of treatment were quite

favorable. After 45 days, 83% of patients estimated that the drug was effective. After 90 days, the percentage increased to 88%. Similarly, global evaluations made by physicians after 45 and 90 days demonstrated 81 and 88% effectiveness, respectively. The objective evaluations demonstrated remarkable improvements in all measurements. Maximum urinary flow increased from 9.8 to 12.2 ml/s, mean urinary flow rate increased from 5.8 to 7.4 ml/s, prostatic volume decreased from 40,348 to 36,246 mm³; and the international prostate symptom score decreased from 19.0 to 12.4. No serious adverse reactions were reported.

While these results are impressive, perhaps the most impressive changes occurred in the quality of life scores as shown in [Table 110.2](#). These improvements in quality of life scores demonstrate just how powerful an effect improving bothersome symptoms such as nocturia can have on an individual's mental outlook. Another important finding was that the saw palmetto extract had no demonstrable effect on serum prostatic specific antigen levels.

A recently reported study has now evaluated the long-term efficacy of saw palmetto. This 3 year, multicenter,

TABLE 110-2 -- Quality of life scores

| Evaluation | Day 0 | Day 90 |
|-------------------|--------------|---------------|
| Delighted | 0.6% | 5.4% |
| Happy | 2.3% | 24.0% |
| Satisfied | 9.7% | 36.8% |
| Mitigated | 22.7% | 20.9% |
| Unsatisfied | 43.8% | 9.5% |
| Unhappy | 18.5% | 2.4% |
| Hopeless | 2.3% | 1.0% |

open-label study evaluated 160 mg of a standardized extract (Strogen[®]) in 435 men (aged 41–89 years) with stage I or II BPH. By the end of the study, 120 patients had withdrawn – 12 due to lack of efficacy, 41 due to the need for surgery, 41 lost to follow-up and eight due to adverse reactions. In the remaining 315, the following were reported:

- nocturia normalized or improved in 73%
- daytime frequency improved in 54%
- feeling of incomplete emptying improved in 75%
- rectal examination revealed improvement in prostate congestion in 55%

- average residual volume decreased from 64 to 38 ml
- peak urine flow increased by an average of 6.1 ml/s.

A total of 14.7% of the men experienced a continued deterioration of their prostate function. The primary adverse events were mild gastrointestinal disturbance.

DOSAGE

The dosage for the liposterolic extract of saw palmetto berries (containing 85–95% fatty acids and sterols) is 160 mg twice daily. A similar dose using fluid extracts and tinctures would require extremely large quantities of alcohol and therefore cannot be recommended. Dosages are as follows:

- crude berries: 10 g twice daily
- liposterolic extract (standardized at 85–95% fatty acids and sterols): 160 mg twice daily.

TOXICOLOGY

No significant side-effects have been reported in the clinical trials of the saw palmetto berry extract or with saw palmetto berry ingestion.

Chapter 111 - *Silybum marianum* (milk thistle)

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

Silybum marianum (family: Compositae)
Synonym: *Carduus marianum*
Common names: milk thistle, marian thistle, St Mary's thistle

GENERAL DESCRIPTION

Silybum marianum is a stout, annual or biennial plant, found in dry rocky soils in southern and western Europe and some parts of the United States. The branched stem grows 1–3 feet high and bears alternate, dark green, shiny leaves with spiny, scalloped edges that are markedly streaked with white along the veins. The solitary flower heads are reddish-purple with bracts ending in sharp spines. Flowering season is from June to August. The seeds, fruit, and leaves are used for medicinal purposes.

CHEMICAL COMPOSITION

Silybum marianum contains silymarin, a mixture of flavanolignans, consisting chiefly of silibin, silydianin, and silychristine.^{[1] [2] [3]} The concentration of silymarin is highest in the fruit, but it is also found in the seeds and leaves. Other flavanolignans are contained in silybum, including silandrin, silyhermin, silymonin, and neosilyhermin.^[1] Silibin is the silymarin component which yields the greatest degree of biological activity (see [Fig. 111.1](#)).

HISTORY AND FOLK USE

Perhaps the most widespread folk use of this plant has

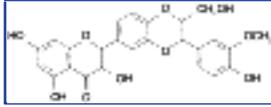

Figure 111-1 Silibin.

been in assisting the nursing mother in the production of milk. It was also used in Germany for curing jaundice and biliary derangements. It is interesting to note that the discovery of the liver-protecting flavanolignans in *Silybum marianum* was not the result of systemic pharmacological screening, but rather of investigation of silybum's empirical effects in liver disorders.^[1]

PHARMACOLOGY

Silybum marianum extracts (usually standardized to contain 70% silymarin) are currently widely used in European pharmaceutical preparations for hepatic disorders. Silymarin is one of the most potent liver-protecting substances known.^{[1] [2] [3] [4] [5] [6] [7] [9]}

Hepatoprotection effects

Free radical scavenging

Silybum's ability to prevent liver destruction and enhance liver function is due largely to silymarin's inhibition of the factors that are responsible for hepatic damage, i.e. free radicals and leukotrienes, coupled with its ability to stimulate liver protein synthesis.

Silybum components prevent free radical damage by acting as antioxidants.^{[1] [2] [3] [4]} Silymarin is many times more potent in antioxidant activity than vitamin E.

Effects on hepatic glutathione

Silymarin prevents the depletion of glutathione (GSH) induced by alcohol and other liver toxins. Even in normals, it increases the basal GSH level of the liver by 35% over controls.

Protection from liver-damaging chemicals and drugs

The protective effect of silybum against liver damage has been demonstrated in a number of experimental and clinical studies. Experimental liver damage in animals can be produced by such diverse toxic chemicals as carbon tetrachloride, galactosamine, ethanol, and praseodymium nitrate. Silymarin has been shown to protect the liver from all of these toxins.^{[1] [2] [3] [4] [7]}

Perhaps the most impressive of silymarin's protective effects is against the severe

poisoning of *Amanita phalloides* (the deathcap or toadstool mushroom), an effect which has long been recognized in folk medicine.^{[5] [6] [7]} Ingestion of *Amanita phalloides* or its toxins causes severe poisoning and, in approximately 30% of victims, death.

Among the experimental models for measuring protection against liver damage, those based on amanitin or phalloidin toxicity are the most important, because these two peptides from *Amanita phalloides* are the most powerful liver-damaging substances known. Silymarin has demonstrated impressive results in these experimental models. When silymarin was administered before amanita toxin poisoning, it was 100% effective in preventing toxicity.^{[5] [7]} Even if given 10 minutes after the amanita toxin, it completely counteracted the toxic effects.

Two cases reported in the literature found that silymarin still prevents death and greatly reduces the amount of liver damage as long as 24 hours after ingestion.^[6] This study reported on a husband and wife who ate toxic mushrooms and developed gastrointestinal symptoms 18 hours later. Despite initial conventional treatment with gastric emptying, intravenous fluids, activated charcoal and a duodenal tube, both patient's laboratory work showed deteriorating liver and renal function. One patient developed mild hepatic encephalopathy. Treatment with intravenous silibinin at a dose of 20 mg/kg of body weight, penicillin and glucose for 3 days resulted in reversal of both the organ failures and encephalopathy.

Silymarin may also be of great value as an adjunct for patients receiving long-term drug therapy. A very interesting study found that providing psychiatric patients receiving phenothiazines or butyrophenones with the unusually high dose of 800 mg/day of silymarin resulted in significant protection of the liver as measured by malondialdehyde serum liver enzyme levels.^[10] The silymarin did not interfere with the efficacy of the antidepressants.

Stimulation of hepatic protein synthesis

Perhaps the most interesting effect of silybum components on the liver is their ability to stimulate protein synthesis.^{[4] [11] [12]} This results in an increase in the production of new liver cells to replace the damaged old ones. It has been suggested that:^[12]

silibinin imitates in some way a physiological regulator in animal cells, so that the structure fits into a specific binding site on the polymerase and in such a way causes the observed effects on rRNA synthesis making the drug from *Silybum marianum* indeed interesting for liver therapy.

Interestingly enough, silybinin does not have a stimulatory effect on malignant hepatic tissue.^[11]

Anti-inflammatory effects

Leukotrienes, key chemical mediators of inflammation, produced by the transfer of oxygen to polyunsaturated fatty acids (a reaction catalyzed by the enzyme

lipoxygenase) can also damage the liver. Silymarin has been shown to be a potent inhibitor of this enzyme, thereby inhibiting the formation of damaging leukotrienes.^[13]

Silymarin has also been shown to inhibit prostaglandin synthesis during inflammation.^[14] Free radical damage to membrane structures due to organic disease or intoxication results in increased release, by lipolysis, of fatty

acids. This leads, among other things, to increased prostaglandin and leukotriene synthesis. Silymarin counteracts this deleterious process by suppressing the pathological decomposition of membrane lipids and inhibiting prostaglandin formation.^[14] As leukotrienes and inflammatory prostaglandins are also involved in the damage of the liver by toxins, their neutralization by silybin is another mechanism for its protection of the liver.

Other pharmacological actions

Silymarin has demonstrated several other physiologic effects. It is a strong inhibitor of cyclic AMP phosphodiesterase: 13–50 times more active than theophylline and one to three times more active than papaverine.^[15] Silymarin has also been shown to prevent the toxic effects of a variety of compounds, e.g. hemolysis induced by phenylhydrazine, X-radiation-induced damage, and brain edema induced by triethyltin sulfate (TZS).^[16] ^[17] ^[18] Presumably, these effects are related to silymarin's significant membrane-stabilizing and antioxidant actions. Its action in increasing the osmotic resistance of RBCs is also quite significant.^[19]

CLINICAL APPLICATIONS

Silymarin's primary use is as an aid to the liver, although additional clinical applications are regularly being discovered. It can be used to support detoxification reactions or in the treatment of more severe liver disease. In numerous clinical studies, silymarin has been shown to have positive effects in treating several types of liver disease, including:

^[20] ^[21] ^[22] ^[23] ^[24] ^[25] ^[26] ^[27] ^[28] ^[29] ^[30] ^[31] ^[32] ^[33] ^[34] ^[35] ^[36] ^[37] ^[38]

- cirrhosis
- chronic hepatitis
- fatty infiltration of the liver (chemical- and alcohol-induced fatty liver)
- subclinical cholestasis of pregnancy
- cholangitis and pericholangitis.

The therapeutic effect of silymarin in these disorders has been confirmed by histological, clinical, and laboratory data. Silymarin may also be useful in improving the solubility of the bile in the treatment of gallstones and in psoriasis.

Chemical-induced liver damage

In one of the first extensive double-blind clinical trials investigating silymarin's therapeutic effect in liver disorders, silymarin demonstrated impressive results for 129 patients with toxic metabolic liver damage, fatty degeneration of the liver of various origin, or chronic hepatitis, as compared with a control group comprised of 56 patients. The results might have been even more impressive if the study had lasted longer than 35 days.^[20]

A follow-up study of patients with liver damage due to alcohol, diabetes viruses, or toxic exposure demonstrated even more striking results. Patients were followed for a long period of time (e.g. 7 weeks). Not only were clinical findings markedly improved in the silymarin-treated groups, but laboratory and liver biopsy data improved as well. Highly significant results were obtained in bromsulphalein retention, SGPT, iron, and cholesterol levels. There were remarkable tissue restorative effects as evidenced by biopsy. Upon completion of silymarin therapy, the liver showed restitution of normal cell structure even in severely damaged livers. These effects on the tissue level correlated well with improvements in blood chemistry.^[21]

Another study highlighted the benefit of silymarin in individuals exposed to toxic chemicals. In this study, abnormal results of liver function tests (elevated levels of AST, ALT activity) and/or abnormal hematological values (low platelet counts, increased white blood cell counts, and a relative increase of lymphocytes compared with other white blood cells) were observed in 49 of 200 workers exposed to toxic toluene and/or xylene vapors for 5–20 years.^[33] Thirty of the affected workers were treated with silymarin, and the remaining 19 were left without treatment. Under the influence of silymarin, the liver function tests and the platelet counts significantly improved. The white blood counts also showed a tendency towards improvement.

Cirrhosis

As described above, silymarin is quite effective in treating alcohol-related liver disease. There is a tremendous range in severity of alcohol-related liver disease from relatively mild to serious damage, such as cirrhosis. Even in this severe state, silymarin has shown benefit. Perhaps the most significant benefit is extending the life span of these patients.

In one study, 87 cirrhotics (46 with alcoholic cirrhosis) received silymarin, while 83 cirrhotics (45 with alcoholic cirrhosis) received a placebo.^[34] The mean observation period was 41 months. In the treatment group, there were 24 deaths with 18 related to liver disease while, in the controls, there were 37 deaths with 31 related to liver disease. The 4-year survival rate was 58% in the treatment group compared with 39% in the controls.

Silymarin can also improve immune function in patients with cirrhosis.^[35] Whether this effect is involved in the hepatoprotective action or a result of improved liver function has

yet to be determined.

Viral hepatitis

Silymarin is useful in helping reverse viral-induced liver damage. It is effective in both acute and chronic viral

950

hepatitis. In one study of acute viral hepatitis, 29 patients treated with silymarin showed a definite therapeutic influence on the characteristic increased serum levels of bilirubin and liver enzymes compared with a placebo group.^[36] The laboratory parameters in the silymarin group had regressed more than in the placebo group by the fifth day of treatment. The number of patients attaining normal liver values after 3 weeks of treatment was significantly higher in the silymarin group than in the placebo group.

In a study in chronic viral hepatitis, silymarin was shown to result in dramatic improvement. Used at a high dose (420 mg of silymarin) for periods of 3–12 months, silymarin resulted in a reversal of liver cell damage (as noted by biopsy), an increase in protein level in the blood, and a lowering of liver enzymes. Common symptoms of hepatitis (e.g. abdominal discomfort, decreased appetite, and fatigue) were all improved.^[37]

Gallstones

Silymarin may help to prevent or treat gallstones via its ability to increase the solubility of the bile. In one study, the composition of the bile was assayed in 19 patients with a history of gallstones (four) or removal of the gall bladder due to gallstones (15) before and after silymarin (420 mg/day for 30 days) or placebo. Silymarin treatment led to significant reduction in the biliary cholesterol concentration and bile saturation index.^[38]

Psoriasis

Correction of abnormal liver function is indicated in the treatment of psoriasis. Silymarin has been reported to be of value in the treatment of psoriasis, and this may be due to its ability to inhibit the synthesis of leukotrienes, and improve liver function.^[39]

The connection between the liver and psoriasis relates to one of the liver's basic tasks – filtering the blood. Psoriasis has been shown to be linked to high levels of circulating endotoxins, such as those found in the cell walls of gut bacteria. If the liver is overwhelmed by an increased number of endotoxins or chemical toxins, or if the liver's functional ability to filter and detoxify is decreased, the psoriasis is aggravated.

Another factor in psoriasis is excessive production of leukotrienes. Silymarin has been shown to reduce leukotriene formation by inhibiting lipoxigenase.^[13] Therefore, silymarin

would inhibit one of the causes of the excessive cellular replication.

Silymarin has other effects of value in patients with psoriasis. Most of these effects revolve around correcting the abnormal cAMP to cGMP ratio observed in the skin of patients with psoriasis. The ratio of these two cellular control agents controls cellular replication. In psoriasis, cGMP levels are high relative to cAMP levels. Silymarin works to lower cGMP levels while raising cAMP levels.^[15]

Protection against chemical-induced renal damage

Recent research has indicated that the anti-toxin, free radical scavenging effects of silymarin may be of value in protecting the kidneys.^[40] In a very provocative study, female rats were given the anti-cancer drug cisplatin either with or without silibinin (300 mg/kg). Compared to the drug-only group, the silibinin-treated group lost significantly less weight, experienced no loss in creatinine clearance, no changes in urea level or magnesium excretion, and only slight degenerative changes in the glomerulus and tubules. Considering the significant problem of serious nephrotoxicity from cisplatin and other chemotherapeutic agents, silibinin may be of great value as an adjunct in the treatment of cancer.

Silibin bound to phosphatidylcholine

In the past decade, a new form of silymarin has emerged that may provide the greatest benefit. The new form binds silybin to phosphatidylcholine. Preliminary research indicates that phosphatidylcholine-bound silybin is better absorbed and produces better clinical results.

Absorption studies

Several human and animal studies have shown phosphatidylcholine-bound silybin is better absorbed. In one study, the excretion of silybin, the major component of silymarin, in the bile was evaluated in patients undergoing gall bladder removal (cholecystectomy). A drainage tube, the T-tube, was used to sample the bile. Patients were given either a single oral dose of the silybin–phosphatidylcholine complex or silymarin. The amount of silybin recovered in the bile in free and conjugated form within 48 hours was 11% for the silybin–phosphatidylcholine group compared with 3% for unmodified silybin.^[41]

One of the significant features of this study is the fact that silymarin has been shown to improve the solubility of the bile. Since more silybin is being delivered to the liver and gall bladder when the phosphatidylcholine-bound silybin is used, this form is the ideal form for individuals with gallstones or fatty infiltration of the liver, two conditions characterized by decreased bile solubility.

In another study, plasma silybin levels were determined after administration of single oral doses of silybin–phosphatidylcholine complex and a similar amount of silymarin to nine healthy volunteers. Although absorption was rapid with both preparations, the

bioavailability of the silybin–phosphatidylcholine complex was much

greater than that of silymarin, as indicated by higher plasma silybin levels at all sampling times after intake of the complex. The authors concluded that complexation with phosphatidylcholine greatly increases the oral bioavailability of silybin, probably by facilitating its passage across the gastrointestinal mucosa.^[42]

Clinical studies

Several clinical studies have shown phosphatidylcholine-bound silybin to be more effective. In one study, eight patients with chronic viral hepatitis (three with hepatitis B, three with both hepatitis B and hepatitis C, and two with hepatitis C) were given one capsule of phosphatidylcholine-bound silybin (equivalent to 140 mg silymarin) between meals for 2 months.^[43] After treatment, serum malondialdehyde levels (an indicator of lipid peroxidation) decreased by 36% and the quantitative liver function evaluation, as measured by galactose elimination capacity, increased by 15%. A statistically significant reduction of liver enzymes was also seen: AST decreased 17% and ALT decreased 16%.

In another study designed primarily to evaluate the dose–response relationship of phosphatidylcholine-bound silybin, positive effects were again displayed.^[44] In this study, patients with chronic hepatitis due to either a virus or alcohol were given different doses: 20 patients received 80 mg twice daily, 20 patients received 120 mg twice daily, and 20 patients received 120 mg three times daily for 2 weeks. At all tested doses, phosphatidylcholine-bound silybin produced a remarkable and statistically significant decrease of mean serum and total bilirubin levels. When used at the dose of 240 or 360 mg/day, it also resulted in a remarkable and statistically significant decrease in ALT and GGTP liver enzymes. These results indicate that even short-term treatment of viral or alcohol-induced hepatitis with relative low doses of phosphatidylcholine-bound silybin can be effective, but for the best results higher doses are indicated.

DOSAGE

The standard dose of milk thistle is based on its silymarin content (70–210 mg three times daily). For this reason, standardized extracts are preferred. The best results are achieved at higher dosages, i.e. 140–210 mg of silymarin three times daily.

The dosage for silybin bound to phosphatidylcholine is 120–240 mg twice daily.

Alcohol-based extracts are virtually always contraindicated in liver disease, as a relatively large amount of alcohol is administered in order to obtain an adequate dose of silymarin.

TOXICITY

Silymarin preparations are widely used medications in Europe, where a considerable body of evidence points to very low toxicity.^[1] When used at high doses for short periods of time, silymarin given by various routes to mice, rats, rabbits, and dogs has shown no toxic effects. Studies in rats receiving silymarin for protracted periods have also demonstrated a complete lack of toxicity.^[1]

As silymarin possesses choleric activity, it may produce a looser stool as a result of increased bile flow and secretion. If higher doses are used, it may be appropriate to use bile-sequestering fiber compounds (e.g. guar gum, pectin, psyllium, oat bran, etc.) to prevent mucosal irritation and loose stools. Because of silymarin's lack of toxicity, long-term use is feasible when necessary.

Chapter 112 - Soy isoflavones and other constituents*

Kathi Head ND

INTRODUCTION

In the past several years, soy and its constituents have received considerable attention, from both researchers and health practitioners. Epidemiological data which indicated that people from Asian cultures have lower rates of certain cancers, including cancer of the breast, prostate and colon, sparked an interest in soy as a contributing factor. While soy constituents, including saponins, lignans, phytosterols, protease inhibitors, and phytates, have come under investigation, the constituents which seem to hold the most promise from a therapeutic standpoint are the two isoflavones, genistein and daidzein. Numerous epidemiological, human, animal, and in vitro studies have demonstrated that soy isoflavones are effective chemopreventive agents for certain types of cancer. Mechanisms involved include:

- antiangiogenesis
- estrogen receptor binding
- modulation of sex hormone binding globulin (SHBG)
- anti-inflammatory and antioxidant effects
- inhibition of the enzymes protein tyrosine kinase (PTK) and 5 alpha-reductase.

Interaction with many other enzymes has been suggested. Evidence also points to the beneficial effects of soy, particularly the isoflavones, in prevention of cardiovascular disease. Isoflavones appear to inhibit platelet-activating factor and thrombin formation. They also increase HDL cholesterol and decrease triglycerides, LDL, VLDL, and total cholesterol. Other potential health benefits of soy include prevention of osteoporosis, via the phytoestrogen effects of isoflavones, and prevention of neovascularization in ocular conditions, via inhibition of angiogenesis.

* Reprinted with permission from *Alternative Medicine Review* 1997; 2: 433–450

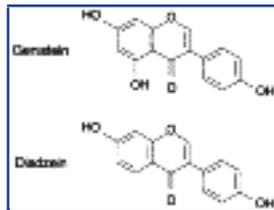

Figure 112-1 Structure of genistein and daidzein.

CHEMICAL COMPOSITION

Recent interest in the constituents of soybeans, particularly the isoflavones, has catapulted soy to the status of a promising nutraceutical with potentially significant health benefits. The principal isoflavones in soy are genistein (4',5,7-trihydroxyisoflavone), daidzein (4',7-dihydroxyisoflavone) (see [Fig. 112.1](#)), and their metabolites. In addition, soy products are a source of lignans, coumestans, saponins, plant sterols, phytates (inositol hexaphosphate), and protease inhibitors, all of which are also receiving attention for their health-promoting benefits.^[1]

Isoflavones

Classification

Flavonoids are a subgroup of the larger group of plant constituents, the polyphenols. Flavonoids are further differentiated into isoflavonoids, with isoflavones a subcategory of isoflavonoids (see [Fig. 112.2](#)). Isoflavonoids differ from other classes of flavonoids by their greater structural variability, their frequent presence in plants in their free form, rather than as a glycoside, and by the greater frequency of isoprenoid substitution. They are not as ubiquitous in nature as some of the other flavonoids, such as flavones and flavonols, being found primarily in one subfamily of Leguminosae, the Papilionoideae.^[2] Approximately 600 isoflavonoids have been identified. They are divided into subclasses depending on the oxidation level of the central pyran ring. Isoflavones are the most abundant of the subclasses of isoflavonoids. Genistein and daidzein are two important isoflavones in soy. As can be seen in [Figure 112.1](#), genistein has a hydroxy group in the 5 position, giving it three hydroxy groups, while

Figure 112-2 Polyphenol classification.

daidzein has just two. Due to the fact that the 5 hydroxy group on the genistein binds to the 4 ketonic oxygen, genistein is a more hydrophobic molecule than daidzein. This affords genistein some of its unique therapeutic effects.

Absorption, metabolism and excretion

Isoflavones undergo extensive metabolism in the intestinal tract prior to absorption. Genistein is formed from biochanin A, and daidzein from formononetin.^[1] Genistein and daidzein also occur in soy products in the form of their glycosides, genistin and daidzin. In the case of the glycosides, intestinal bacterial glucosidases cleave the sugar moieties, releasing the biologically active isoflavones, genistein and daidzein. In adults, these are further transformed by bacteria to specific metabolites: equol, O-desmethylandrogenesis, dihydrogenistein, and p-ethylphenol. Due to soy intake by livestock, isoflavone metabolites are also consumed indirectly in a diet high in dairy products and meat.^[3]

In at least one study, genistein was found to be well-absorbed in the small intestines by human subjects fed a soy beverage.^[4] After absorption, the isoflavones are transported to the liver where they are removed from the portal blood. However, a percentage of the isoflavones in the portal blood can escape uptake by the liver and enter the peripheral circulation. The effectiveness of this hepatic first-pass clearance influences the amount which reaches peripheral tissues.^[4] The isoflavones are then eliminated, primarily via the kidneys, similar to endogenous estrogens.^[5]

After examining plasma, fecal and urinary concentrations of isoflavones in healthy volunteers, Xu et al^[6] concluded that the bioavailability of soy isoflavones is influenced by an intact, healthy gut, with microflora capable of converting these isoflavones to their active forms. Wheat fiber appears to decrease the bioavailability of genistein. A small cross-over study of seven healthy women found that a more fiber-rich diet resulted in 55% less plasma genistein 24 hours after soy intake and a 20% reduction in total urinary genistein. The researchers postulated that fairly insoluble wheat fiber reduced the absorption of genistein by its bulking effect and hydrophobic binding.^[7] Karr et al^[8] found urinary excretion of isoflavones to be reflective of the type and amount of soy ingested. A study conducted on healthy male subjects between the ages of 20 and 40 found that urinary excretion of genistein and daidzein was greater after consumption of 112 g of tempeh, a fermented soy product, than after 125 g of unfermented soy pieces.^[9] This finding seems to indicate that fermentation of soy products increases bioavailability of the isoflavones. Plasma levels of soy isoflavones are also increased after consumption of soy and certain other leguminous plants, such as clover.^[10]

Levels in soy products

Fukutake et al^[11] analyzed soy products for genistein and genistin (the glycoside of genistein) content. The results are outlined in [Table 112.1](#). In general, they found that

fermented soy products contain more genistein than soybeans, soy milk and tofu. Alcohol extraction, a process used in the production of many soy protein concentrates and isolates (used in soy protein powders), results in the removal of up to 90% of the isoflavones.^[12] The isoflavone content of soybeans varies considerably depending on the variety of soybean (there are over 10,000 varieties of soybeans), the year harvested, geographic location, and the plant part in question.^[13] Non-soy legumes, such as lentils and other beans, do not contain appreciable amounts of isoflavones.^[14]

Other soy constituents

Protease inhibitors

Researchers have looked with interest at protease inhibitors (PI) and their potential anti-cancer and antiinflammatory effects. Two prominent protease inhibitors from soybeans are Bowman–Birk inhibitor (BBI) and Kunitz–Trypsin inhibitor (KTI). BBI is a 71-residue inhibitor which has two independent inhibitory sites involving binding with the proteases, trypsin and chymotrypsin.^[15] BBI has been found to inhibit expression of certain oncogenes in irradiated animal models^[16] and to inhibit chemically induced carcinogenesis.^[17] ^[18] Both in vitro and in vivo animal models have demonstrated that BBI appears to exert its effects directly on the target organ rather than by a non-specific effect on metabolism.^[19] ^[20]

TABLE 112-1 -- Levels of genistein and its glycoside, genistin, in soy foods^[11]

| | Genistein | Genistin |
|---|-----------------------------|--------------------------------|
| Soybeans, soy nuts, soy powder | 4.6–18.2 mcg/g [*] | 200.6–968.1 mcg/g [*] |
| Soy milk, tofu | 1.9–13.9 mcg/g | 94.8–137.7 mcg/g |
| Fermented soy miso and natto [†] | 38.5–229.1 mcg/g | 71.7–492.8 mcg/g |
| Calculated daily Japanese dietary intake | 1.5–4.1 mg/day | 6.3–8.3 mg/day |

* mcg/g raw food.

† Soy sauce contains both genistein and genistin, but at lower levels than other fermented soy products.

Some researchers have hypothesized that the dietary intake of exogenous PIs indirectly increases endogenous PI formation.^[21] Other researchers have questioned the concept that PIs contribute significantly to the anti-cancer effects of soy. This is due, in part, to the fact that both raw and cooked soy products are equally effective in reducing cancer incidence, even though heating virtually destroys all protease activity.^[22] Another reason for skepticism is that ingested PIs (such as purified BBI) are very poorly absorbed from the digestive tract.^[22] Some researchers have postulated that the formation of these protease:protease inhibitor complexes might interfere with protein absorption, offering

some cancer protection (epidemiological studies indicate that high-fat and high-protein diets increase cancer risk).^[23]

Protease inhibitors in soy products have been implicated in pancreatic hypertrophy and hyperplasia in animal models.^[24] Whether it is the protease inhibitors and whether this hyperplasia contributes to increased rates of pancreatic cancer in these animals are still subjects of debate.

Lignans

Lignans are capable of exerting a phytoestrogenic effect in humans. In addition, they exhibit antitumor and antiviral activity.^[2] The most prevalent lignans in mammals are enterolactone and enterodiol, formed by gut bacteria, from the plant precursor lignans, matairesinol and secoisolariciresinol, respectively.^[3] Oil seeds, such as flaxseed, contain about 100 times the lignan content of other plants. Other sources of lignans in descending order of importance are dried seaweed, whole legumes (including soy), cereal bran, legume hulls, whole grain cereals, vegetables, and fruit.^[4] Gender differences in urinary lignan excretion have been observed, with men excreting more enterolactone and less enterodiol than women. The researchers felt this implied a difference in colonic bacterial metabolism of lignans between the genders.^[25] Administration of antibiotics nearly completely eliminates the formation of these mammalian lignans from their precursors.^[3]

Phytosterols

Phytosterols, such as β -sitosterol, are found in high concentrations in soy products. Although poorly absorbed, they bind cholesterol in the gut.^[22] Dietary content of phytosterols differs widely among populations. The typical Western diet contains about 80 mg/day, while the traditional Japanese diet contains approximately 400 mg/day.^{[26] [27]}

Coumestans

The phytoestrogen, coumesterol, and other coumestan isoflavonoids have been found by some researchers in significant quantities in soy foods of all types, including:^[28]

- soybeans
- soy flour
- soy flakes
- isolated soy protein
- tofu
- soy drinks
- soy sprouts.

On the other hand, Adlercreutz & Mazur^[3] reports its presence only in soy sprouts. The most abundant source is mung bean sprouts. It is also found in significant quantities in other members of the Leguminosiae family, including *Trifolium* and *Medicago* spp.^[2]

Saponins

Saponins are distributed widely in the plant kingdom, including in soybeans. They appear to have anti-cancer properties by virtue of their antioxidant and anti-mutagenic properties.^[29] They also bind cholesterol and bile acids in the gut.^[22] An in vitro study demonstrated that saponins isolated from soybeans exhibited potent antiviral effects on the HIV virus. Saponin B1 completely inhibited HIV-induced cytopathic changes and virus-specific antigen expression within 6 days of infection. Saponin B2 exhibited similar, although less potent, effects.^[30]

Phytates

Although phytic acid (inositol hexaphosphate) has been implicated in blocking the absorption of minerals, the phytate content of plants, including soy, seems to be responsible for some of the anti-cancer properties of vegetable-based foods. Phytic acid is a highly charged antioxidant, capable of scavenging hydroxyl radicals and chelating metal ions such as the pro-oxidant, iron. Graf & Eaton^[31] reported the iron-chelating ability of phytate to be more important than the fiber in dietary colon cancer prevention. Vucenik et al^[32] reported antitumor effects of phytic acid both in vitro and in animal models. Phytates also appear to enhance natural killer cell activity.^[33] Rao et al^[34] found these potent antioxidant effects to protect against cardiac ischemia and reperfusion injury in animal models. For a summary of soy constituents and their functions, see [Table 112.2](#).

PHARMACOLOGY

Soy constituents have been shown to have estrogenic, anti-estrogenic, antiviral,^[35] anticarcinogenic,^[36] ^[37] ^[38] bacteriocidal, and antifungal^[39] effects. Isoflavones also have anti-mutagenic,^[37] antioxidant,^[40] ^[41] mild anti-inflammatory,^[42] antihypertensive,^[42] and antiproliferative effects.^[36] ^[43] This

TABLE 112-2 -- Soy constituents and their functions

| Constituent | Function |
|---|---|
| Protease inhibitors (Bowman–Birk inhibitor, Kunitz–Trypsin inhibitor) | Inhibit oncogene expression |
| | Inhibit chemically induced carcinogenesis |
| | Implicated in pancreatic hypertrophy (animal studies) |

| | |
|---|--|
| Lignans (enterolactone, enterdiol) | Phytoestrogen effects (agonistic/antagonistic) |
| | Antitumor |
| | Antiviral |

| Isoflavones (genestein, daidzein and their metabolites) | Phytoestrogen effects (agonistic/antagonistic) |
| | Anti-mutagenic |
| | Antioxidant |
| | Anti-inflammatory |
| | Antiproliferative |
| | Antihypertensive |
| | Angiogenesis inhibition |

chapter focuses primarily on isoflavones as these are the constituents found in greatest quantity in soy products. Brief reference will be made to other beneficial constituents.

Hormonal effects

Infants

Recent advances in understanding the phytoestrogen content of soy foods have led researchers to examine the isoflavone content in commonly consumed infant formulas. A recent study examined the isoflavone content of 25 randomly selected samples from five major brands of soy-based infant formulas. There were significant levels of isoflavones, particularly in the form of the glycosides of genistein and daidzein, in all samples tested. The plasma concentrations of genistein and daidzein were compared in 4-month-old infants fed exclusively soy formula, cow's milk formula, and breast milk. A 4-month-old infant consuming soy milk was estimated to be ingesting between 4.5 and 8.0 mg/kg body weight per day of total isoflavones. This is a proportionately greater

concentration per body weight than that found in adults consuming soy foods.

Additionally, the researchers estimated the daily exposure of infants to soy isoflavones was 6–11 times higher, with body weight factored into the equation, than the typical dose necessary to exert hormone-like effects in adults. They found negligible concentrations of isoflavones in breast milk and cow's milk.^[5] There was some evidence of the daidzein metabolite, equol, in the infants who were fed cow's milk, confirming previous observations that cow's milk also contains some isoflavones. In this study, the plasma concentration of isoflavones in breast-fed babies was 1/200 the level in soy-formula fed babies. Franke & Custer,^[44] on the other hand, reported in 1996 that human breast milk from mothers consuming soy foods provided significant levels of isoflavones. Some researchers have concluded that the isoflavone content of human breast milk appears to be a reflection of the mother's diet.

These findings have raised some interesting questions and stimulated lively debate. Adverse effects of phytoestrogens on development and reproductive capacity of livestock, wildlife and experimental animals have been reported.^[45] There has been very little clinical experience with human infants and phytoestrogens, however. In animal models, phytoestrogens have had effects similar to other estrogens, included interfering with normal reproductive system development.^[46] On the other hand, phytoestrogenic isoflavones have been found to possess some important anti-cancer properties. Genistein, given in only three doses to newborn mice, decreased breast cancer incidence and tumor numbers significantly.^[44] Although millions of Asians have consumed large quantities of soy foods for hundreds of years without any apparent health risk and seemingly with health benefits, long-term studies are needed to clarify the safety of using soy-based infant formulas and to assess the potential beneficial or adverse effects of consuming phytoestrogens in the form of soy isoflavones early in life.

Adults

Plant lignan and isoflavonoid glycosides are converted by gut bacteria in the intestines to compounds with molecular weights and structures similar to steroid hormones (see [Fig. 112.3](#)). The pattern of isoflavonoid and lignan excretion in the urine is similar to endogenous estrogens.^[47] Studies of the effects of phytoestrogens on hormone levels are conflicting.

Lu et al^[48] found that the consumption of soy products by premenopausal women resulted in decreased circulating ovarian steroids and adrenal androgens, as well as increased length of the menstrual cycle. Six healthy females, aged 22–29, were given 12 ounces of soy milk three times daily with meals for 1 month. Daily isoflavone intake was approximately 100 mg each of daidzein and genistein (in the form of their glycosides, daidzin and genistin). The estradiol levels decreased by 31% on days 5–7 of the cycle, 81% on days 12–14, and 49% on days 20–22. Luteal phase progesterone levels decreased by 35%, and DHEA sulfate levels decreased progressively during the

month by 14–30%. The length of the menstrual cycle increased during the soy feeding month from 28.3 ± 1.9 to 31.8 ± 5.1 days.

In another study, also on premenopausal women, Lu et al found that 60 g of soy protein, with 45 mg of isoflavones daily, resulted in the suppression of midcycle surges of FSH and LH. Plasma concentrations of estradiol increased during the follicular phase in the soy group, while cholesterol decreased by 9.6%. The researchers noted that a similar effect occurs in women given tamoxifen. There were no significant differences in estradiol levels between the soy and control groups at midcycle or during the luteal phase.^[49] At least one study found soy protein isolate to have a stimulatory effect on breast tissue in premenopausal women, characterized by increased breast secretions, epithelial cell hyperplasia, and elevated levels of serum estradiol.^[50]

Wang et al^[51] found that genistein competed with estradiol binding to estrogen receptors, with 50% inhibition occurring at 5×10^{-7} M. A study of soy-supplemented postmenopausal women found a small estrogenic effect on vaginal cytology. However, no difference between soy-supplemented subjects and controls, with regard to serum FSH, LH, sex hormone binding globulin, endogenous estradiol or body weight, was observed.^[52]

Many studies on phytoestrogens focus on the use of coumestrol, as it has more potent phytoestrogenic effects than lignans, genistein and daidzein. In vitro studies have found that both genistein and coumestrol inhibit the conversion of estrone to 17-beta estradiol. Coumestrol exhibited the strongest inhibition.^[53] An in vitro study monitoring the expression of the estrogen-responsive protein pS2 in breast cancer cell MCF-7 tissue culture, to assess the estrogenic response of various plant substances, found that the following substances elicited estrogen-like activity:

- daidzein
- equol
- nordihydroguaiaretic acid
- enterolactone
- kaempferol.

The substances tested that did not appear to have estrogen-like activity were quercetin and enterodiol.^[54]

The effects of phytoestrogens vary greatly depending on the species of animal, the particular phytoestrogen compound being tested, the age of the animal, the length

Figure 112-3 Structure of soy isoflavones compared with estrogens.

of time of ingestion, the presence or absence of exogenous estrogen, the target tissue in question, and the dosage used. The phytoestrogen, coumestrol, was found to have an estrogenic effect, as demonstrated by changes in uterine and brain tissue, when given to prepubescent rats; however, when given to adult female rats, ovarian cycling was inhibited. When given for 10 days to neonatal rats, there was no effect on estrous cycling, but when given for 21 days, it interfered with normal cycling once the rats reached adulthood. The females exhibited persistent estrous and lack of an LH surge, while the males demonstrated a decrease in sexual behavior.^[55]

Historically, the consumption of soy products in Asian cultures, from a very young age, has not resulted in any apparent negative effects related to hormone imbalances. It is unlikely that animal studies are effective at predicting the effects of phytoestrogens in the human model.^[56]

The mechanisms for the anti-estrogenic effect of phytoestrogens are largely unknown, but some experts believe it is unlikely to be a direct receptor-mediated effect.^[3] One mechanism of action of lignans and isoflavonoids is to stimulate sex hormone-binding globulin (SHBG) (also known as sex steroid-binding protein (SBP)) synthesis in the liver. SHBG binds to cell surface receptors, resulting in regulation of bioavailability and activity of hormones.^[3] In vitro, in MCF-7 human breast cancer cells, SHBG has been found to downregulate estradiol.^[57]

It appears that phytoestrogens exert mild agonistic and antagonistic effects on estrogen, depending on the level of endogenous estrogen present and on the tissue being tested. In vitro studies demonstrate an estrogenic effect in the absence of endogenous estrogen, and an anti-estrogenic effect in the presence of estrogen.^[3] Much research in this area remains to be done.

Much of the effect of phytoestrogens might be due to enzyme inhibitions. It appears that phytoestrogens have an inhibitory effect on many enzymes involved in the biosynthesis and metabolism of steroid hormones. The effect on enzymes is further discussed below.

Mechanism of action of soy isoflavones

Soy's inhibition of cancer cell growth does not seem to be entirely estrogen-dependent.^[58] There are many proposed mechanisms for the therapeutic effects of isoflavones. The mechanisms include:

- inhibition of protein tyrosine kinase (PTK)
- binding of estrogen receptors (although soy's inhibition of cancer cell growth does not seem to be entirely estrogen-dependent)^[58]
- inhibition of production of reactive oxygen species^[59]
- induction of DNA strand breakage resulting in apoptosis or cell death^[58]
- inhibition of angiogenesis^[60]

- modulation of sex steroid-binding protein^[61]
- inhibition of 5-alpha-reductase^[62]
- inhibition of P-form phenolsulfotransferase (PST)-mediated sulfation^[63]
- inhibition of thrombin formation and platelet activation^[64]
- increased LDL receptor activity.^[65]

The therapeutic implications of each of these mechanisms is elaborated below.

CLINICAL APPLICATIONS

Cancer

The first clues that soy diets might provide protection from cancer came from epidemiological studies, in which people from Asian cultures eating a diet high in soy foods, such as tofu, demonstrated lower rates of several types of cancers, including types not typically considered to be hormone- or diet-related. Messina et al^[66] reviewed 21 epidemiological studies which evaluated the effect of soy diets on 26 different cancer sites. An evaluation of the effect of non-fermented soy products in these studies found that 10 showed decreased risks for rectal, stomach, breast, prostate, colon, and lung cancers, while 15 showed no significant effect. Only one, in which fried bean curd was evaluated, showed an increased risk for esophageal cancer. On the other hand, the effects of fermented soy products – miso soup and soybean paste – were much less consistent. In 21 studies evaluating fermented soy products, involving 25 cancer sites, an increased cancer risk was found in four, mixed results were obtained in four, no significant effects were found in 14, and a decreased risk was found in three. The increased risks of cancer from consumption of fermented soy products appear to involve primarily the gastrointestinal tract – esophageal, stomach, colorectal, and pancreatic cancers.^[66] These studies are summarized in Table 112.3 (Table Not Available) .

To put the epidemiological studies into some perspective, Adlercruetz et al^[67] found high urinary excretion of the soy isoflavones, equol, daidzein, and O-desmethylangolensin, in both men and women living in rural Japan. Most soy foods contain about 1–2 mg/g of genistein. In Asian cultures people tend to consume 20–80 mg/day. The usual dietary intake of genistein in Western cultures is 2–3 mg/day. Messina et al^[66] examined 26 animal studies and reported that 17 (65%) of them demonstrated a protective effect of soy from experimental carcinogenesis.

There are many proposed mechanisms for the anti-cancer benefits of soy-based foods. Inhibition of PTK activity has been proposed as a major mechanism in the prevention of carcinogenesis. While synthetic PTK inhibitors have been proposed for the treatment of cancer, expected toxicity has restricted their development. In

TABLE 112-3 -- Summary of epidemiological studies of soy and cancer (From Messina et al^[66])

(Not Available)

1987, genistein was discovered to be a natural PTK inhibitor.^[58] Tyrosine kinase inhibition results in the inhibition of leukotriene production, (products of inflammation which have been implicated in the stimulation of tumor growth). In vitro studies found that pretreatment of cancer cell lines with genistein completely inhibited leukotriene production.^[68]

Influence on a number of other enzymes has been suggested as a possible mechanism for the anti-cancer properties of isoflavones. Some of these enzymes include DNA topoisomerases,^[69] ribosomal S6 kinase activity,^[71] phospholipase C-gamma,^[72] phosphatidylinositol kinases,^[73] and mitogen-activated protein kinase.^[74] In addition, genistein demonstrated in vitro inhibition of phenolsulfotransferase, an enzyme involved in sulfation-induced carcinogenesis.^[63]

In vitro studies have found genistein to be a very potent inhibitor of neovascularization or angiogenesis, one of the proposed mechanisms for cancer growth inhibition.^[60] Isoflavone effects on hormone regulation, expression and metabolism have been elaborated above and are discussed further below in the sections on breast and prostate cancer.

At issue in the study of soy isoflavones in the treatment of cancer is whether the concentration achieved by dietary consumption of soy products is enough to influence tumor growth. Studies on human volunteers consuming soy beverages, which provided 42 mg genistein and 27 mg daidzein daily, resulted in peripheral blood concentrations of 0.5–1.0 μM ,^[4] a concentration much lower than that necessary to inhibit growth of cultured cancer cells.^[75] However, these same researchers found non-transformed mammary epithelial cell cultures to be much more sensitive to genistein, with inhibition of growth stimulation occurring in the range of 1–2 μM . This suggests a role of isoflavones as chemopreventive rather than chemotherapeutic agents.

Breast cancer

Case-controlled, epidemiological, in vitro, and animal studies point to effectiveness of soy isoflavones in the

prevention of breast cancer. A recent case-controlled study, examined the effect of phytoestrogens on breast cancer risk. One hundred and forty-four women with early diagnosed breast cancer were paired with age- and area-of-residency-matched controls. Prior to treatment, a questionnaire, and 72 hour urine and blood tests were administered. Urine was assayed for the isoflavones daidzein, genistein, and equol, and the lignans enterodiol, enterolactone, and matairesinol. Adjustments were made for age

at menarche, parity, and alcohol and total fat intake. Increased excretion of daidzein, equol, and enterolactone was associated with a reduction in the risk for development of breast cancer. The most significant correlation was between the levels of the soy isoflavone, equol, and the risk of breast cancer, with those in the highest quartile of equol excretion exhibiting only one-quarter the risk of those in the lowest quartile – a fourfold reduction in risk. The lignan, enterolactone, and the isoflavone, daidzein, were associated with a threefold reduction in risk. The daidzein results were insignificant, after correcting for confounding variables. Similar trends were noted for both pre- and postmenopausal groups. Unfortunately, no reliable data for genistein were available due to instability of the derivative of genistein being tested and interference by an unknown compound.^[76] Two case-controlled studies, one in Singapore^[77] and one in Japan,^[78] found significant protection from soy intake for pre- but not postmenopausal women.

Epidemiological studies demonstrate an inverse relationship between soy intake and incidence of breast cancer (see Table 112.3 (Table Not Available)). Americans have two to three times the breast cancer rate of Asians eating a traditional diet.^[79] An epidemiological study of Asian-American women found tofu intake to correlate inversely with breast cancer incidence, after adjustment for other dietary, menstrual and reproductive factors.^[80] This effect was observed in both pre- and postmenopausal women. In summary, all four of the human studies examined seemed to indicate a protective effect of soy against breast cancer in premenopausal women. The effect on postmenopausal women was significant in two of the four studies.

In vitro experiments with human breast cancer cells confirm genistein to be a potent inhibitor of cell growth, regardless of estrogen receptor status. Other isoflavones, daidzein and biochanin A, demonstrated weaker growth inhibition.^[81] ^[82] ^[83] Pagliacci et al^[84] reported that the in vitro inhibition of MCF-7 human breast cancer cells occurred through blocks at critical points in cell cycle control as well as via induction of apoptosis. Wang et al^[51] found that genistein produced a concentration-dependent effect on breast cancer cell cultures. At lower concentrations (10^{-8} – 10^{-6} M), genistein stimulated growth, while higher concentrations ($>10^{-5}$) inhibited growth. They concluded that the effect of genistein at the lower concentrations appeared to be estrogen receptor-mediated, while effects at higher concentrations were independent of estrogen receptors.

Genistein, when administered to neonatal^[85] or prepubescent rats,^[86] suppressed the development of chemically induced mammary tumors without causing toxicity to the development of the endocrine or reproductive systems. Barnes et al^[87] found that soy in the form of raw soybeans as well as soy protein isolate inhibited mammary tumors in experimental models.

Prostate cancer

Epidemiological evidence points to the benefits of soy constituents in the prevention of prostate cancer. Japanese men who consume a low-fat, high-soy diet have low mortality rates from prostate cancer. Isoflavones in the plasma of Japanese men were between seven and 110 times higher than in Finnish men, with genistein present in the highest concentrations.^[88] Mechanisms suggested include genistein-induced prostate cancer cell adhesion, direct growth inhibition, and induction of apoptosis. Growth inhibition appears

to be independent of genistein's estrogenic effects.^[89] An in vitro study indicated that the isoflavones genistein, biochanin A, and equol were potent inhibitors of 5-alpha-reductase,^[62] the enzyme necessary for the conversion of testosterone to dihydrotestosterone (implicated in prostate cancer).

Studies have found that animals fed soy isolates high in the isoflavones, genistein and daidzein, demonstrated a lower incidence of prostate cancer and a 27% longer disease-free period after exposure to chemical carcinogens than animals fed a soy isolate low in isoflavones.^[90] This not only points to the potential chemoprotective effects of soy, but seems to point to the importance of the isoflavones over other soy constituents. Peterson & Barnes^[91] found that the isoflavones, genistein and biochanin A, but not daidzein, inhibited several human prostate cancer cell lines.

NIH recommendations

The committee of the National Institutes of Health (NIH) studying chemoprevention from soy products made the following recommendations:

- Future dietary studies involving soybeans should be carried out using soy products rather than isolated compounds, since soybeans appear to contain several potential anticarcinogens.
- Standardized and improved analytical methods are needed so that the contents of all soy-based materials employed in soybean research, whether soybean fractions or soy products, can be accurately described.
- Basic research in the absorption, metabolism, and physiology of potential anticarcinogens in humans should be conducted.

Cardiovascular disease

Lipid effects

A large meta-analysis of 38 controlled studies of the effects of soy diets, with animal protein diets serving as the controls, found a statistically significant decrease in serum lipids in the soy group. The changes were most significant in hypocholesterolemic subjects^[92] (see [Table 112.4](#)). The intake of energy, fat, saturated fat, and cholesterol was similar between the two groups. Gooderham et al^[93] reported no effect on platelet aggregation or serum lipid levels in healthy, normocholesterolemic men fed soy protein compared with casein.

One of the proposed mechanisms for the hypolipidemic effect involves an increase in LDL receptor activity in both humans and animals.^[65] Other metabolic changes which have been noted in animals and humans on soy diets include increased cholesterol and bile acid synthesis, increased apolipoprotein B and E receptor activity, and decreased hepatic secretion of lipoproteins (associated with increased clearance of cholesterol

from the bloodstream).^[94] Proposals for the specific constituents involved include the amino acid profile, saponins, phytic acid, fiber, as well as the effects of isoflavones discussed below.^[94]

In one study, monkeys were fed soy isolates high in isoflavones and compared in a cross-over trial with a soy isolate in which the isoflavones had been removed via alcohol extraction. LDL, VLDL, and total cholesterol:HDL ratios were significantly lowered, while HDL was significantly elevated in the group on the isoflavone-rich diet.^[12] No lipid-lowering effect occurred in the group on the casein diet.

TABLE 112-4 -- Results of a meta-analysis of the effects on serum lipids of soy diet compared with meat protein diet^[92]

| | | |
|-------------------|-------------------------|----------------|
| Total cholesterol | 23.2 md/dl decrease | 9.3% decrease |
| LDL cholesterol | 21.7 mg/dl decrease | 12.9% decrease |
| Triglycerides | 13.3 mg/dl decrease | 10.5% decrease |
| HDL cholesterol | 1.2 mg/dl increase (NS) | 2.4% increase |

Effects on the atherosclerotic process

Arterial thrombus formation is generally initiated by an injury to the endothelial cells lining the blood vessels. One of the first events after an injury is thrombin formation. This leads to a cascade of events including platelet activation, resulting in thrombus formation. Genistein has been found to inhibit thrombin formation and platelet activation.^[64] The pathogenesis of atherosclerotic plaque formation also involves, in addition to lipid accumulation, the infiltration of monocytes and T-lymphocytes into the artery wall, contributing to the thickening of the wall and occlusion of the vessel. Monocytes and lymphocytes are able to adhere to the endothelial cell surfaces via the expression of certain “adhesion molecules”. The infiltration and proliferation appear to be controlled by peptide growth factors. Increased levels of isoflavones, genistein in particular, appear to alter the growth factor activity, and inhibit cell adhesion and proliferation, all activities necessary for lesion formation in the intima of the blood vessels (see [Fig. 112.4](#)).^[95]

Cardioprotective effects

Animal studies with monkeys have confirmed the cardioprotective effects of soy. Soy protein diets, when compared with casein diets, resulted in significant improvements in lipid profiles, insulin sensitivity, and a decrease in arterial lipid peroxidation.^[96] Furthermore, animal studies also indicate the isoflavone content of the soy is an important factor.

Other potential therapeutic benefits

While research on the health benefits of soy constituents has focused primarily on the

chemopreventive effects for cancer and cardiovascular disease, there are a few other conditions which might benefit from the addition of soy isoflavones to the diet.

Figure 112-4 Impact of soy on atherosclerotic plaque formation.

Osteoporosis

Animal studies indicate that soy isolates enhance bone density. Ovariectomized rats fed a high-soy diet demonstrated enhanced bone density of the vertebral bodies and femoral bone compared with the group fed a casein diet. While there was considerable bone turnover in the soy-fed group, bone densities suggest that formation exceeded resorption.^[97] Further studies on the use of soy isoflavones for the prevention and treatment of osteoporosis are warranted.

Eye disorders

Neovascularization complicates many eye disorders, such as proliferative diabetic retinopathy, and is responsible for corneal transplant rejection. Substances which exhibit the capacity to inhibit angiogenesis could play an important role in preventing this vascularization. An animal study demonstrated that genistein, when injected subconjunctivally, inhibited corneal neovascularization.^[98] While this was not a human study with the use of oral doses, this study has opened the door for future investigation.

CONCLUSION

Research indicates that soy and its individual constituents have several potential health benefits. The primary isoflavones, genistein and daidzein, as well as their metabolites, exert a wide array of effects which appear to offer protection against cancer, cardiovascular disease, osteoporosis, and ocular neovascularization. Many of the studies to date have been epidemiological, animal, or in vitro. Further controlled human trials are needed to confirm the preliminary findings reported in these studies. Soy constituents, particularly the isoflavones, have come under scrutiny, due to their phytoestrogen effects. Because in some cases they act as estrogen agonists, and at other times as antagonists, the use of these isoflavones in cancer patients and in infant formulas is controversial. Further study to determine whether their use in these situations is harmful or beneficial is indicated.

Chapter 113 - *Tabebuia avellanedae* (LaPacho, Pau D'Arco, Ipe Roxo)

Terry Willard PhD

Tabebuia avellanedae (family: Bignoniaceae)

Tabebuia ipe

Tabebuia cassinoides

Tecoma ochracea

Common names: LaPacho, Pau D'Arco, Ipe Roxo

INTRODUCTION

The taxonomical division of plants with medicinal uses in the Bignoniaceae family is confused. The literature often interchanges the genera of *Tecoma* and *Tabebuia*. At least four species have been called LaPacho:

- *Tecoma ochracea*
- *Tecoma ipe*
- *Tabebuia cassinoides*
- *Tabebuia avellanedae*.

This chapter considers the *Tabebuia* genus.

GENERAL DESCRIPTION

The tree from which LaPacho is obtained is a member of the Bignoniaceae family known as *Tabebuia avellanedae* or *Tabebuia ipe*. This tropical tree, native to Brazil, can grow up to 125 feet tall and has rose to violet-colored flowers which bloom in profusion

just before the new leaves appear.

There are about 100 species of these evergreen trees or shrubs, native to tropical America. The leaves are opposite, long-petiolate, digitately five- or seven-foliolate. The leaflets are entire or toothed; the flowers large in terminal cymes or panicles; the calyx tubular or campanulate, closed in bud, variously cleft or toothed in anthesis; the corolla tubes ampliate, the limb somewhat bilate; the stamens four; the capsule slender-cylindric, suterete; and the seeds broadly winged.

The trees of this genus are very showy when in flower as they usually blossom when leafless. Because the taxonomy of these plants is so difficult, it is quite possible that there is confusion among even trained gatherers.

968

One specific way to distinguish the species is at the seedling stage. The four-leaf clover-like cotyledons are distinctively deeply cleft.^[1]

CHEMICAL COMPOSITION

Many of the studies and chemical analyses on *Tabebuia* spp. have been performed on the heart wood, while the bark is the product available in the market place and the part utilized in folklore. The major components of *Tabebuia avellanae* are 16 quinones (mostly with C₁₅ skeleton) containing both naphthoquinones (seven, C₁₀–C₅) and anthraquinones (nine, C₁₄–C₁). Both of these groups of quinones rarely occur in the same plant. The lapachol content is usually 2–7%. The quinones are listed in [Table 113.1](#).

Other compounds found in the heart wood include lapachenole, quercetin, and *o*- and *p*-hydroxybenzoic acids.^[2]

Lapachol content can be estimated by study of the yellowish flaky powder found on the surface of the fractured wood chips or bark. If the lapachol content is over 1–2%, mixing with dilute (5%) NaOH generates, due to a litmus-type reaction, a red-brown solution. There is no color if the content is below 0.5%. Exact concentration can be determined by titrating the NaOH reaction or by chromatography.^[3]

A recent analysis of 10 products found in the market place showed that only one contained lapachol (and only in trace amounts) and the other nine had none. This suggests that many of the products now present on the market are not truly *Tabebuia* spp., that the wrong part of the plant is being marketed, or that processing and transportation have damaged the product. This might explain the variation in results practitioners have experienced. Standardization of LaPacho products for lapachol or naphthoquinone content is needed to solve this problem.

TABLE 113-1 -- Quinones in *Tabebuia avellanedae*

Naphthoquinones

- Lapachol
 - Menaquinone-I
 - Deoxylapachol
 - Beta-lapachone
 - Alpha-lapachone
 - Dehydro-alpha-lapachone
-

Anthraquinones

- 2-Methylantraquinone
 - 2-Hydroxymethylantraquinone
 - 2-Acetoxymethylantraquinone
 - Anthraquinone-2-aldehyde
 - 1-Hydroxyanthraquinone
 - 1-Methoxyanthraquinone
 - 2-Hydroxy-3-methylquinone
 - Tabebuin (a newly discovered compound)
-

HISTORY AND FOLK USE

The native Indians of Brazil also refer this tree as Pau D'Arco or Ipe Roxo. The inner bark has been used for medicinal purposes for centuries as a folk remedy for a wide variety of afflictions, including:^[4] ^[5] ^[6] ^[7]

- boils
- chlorosis
- colitis
- diarrhea
- dysentery
- enuresis
- fever
- pharyngitis
- snakebite
- syphilis
- wounds
- ulcers
- respiratory problems
- arthritis
- cystitis

- constipation
- prostatitis
- poor circulation
- constipation
- cancer of the esophagus, head, intestine, lung, prostate and tongue.

It is reported to be alexiteric, analgesic, anodyne, antidotal, antimicrobial, diuretic, and fungicidal.^[4]

PHARMACOLOGY

During the past century, LaPacho has been subjected to scientific scrutiny. The first active constituent to be studied, lapachol, was isolated by Paterno in 1882 (see [Fig. 113.1](#)). Its structure was determined by Hooker in 1896. In 1927, Fieser synthesized lapachol. It has since been studied by numerous researchers.

It is interesting to note that many of the scientific studies have found LaPacho and lapachol to be more effective in treating malaria and cancerous tumors through oral ingestion rather than intravenous or intramuscular injection.^[8]

An herbalist's interpretation would be that the body's recuperative powers are more effectively stimulated

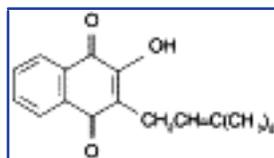

Figure 113-1 Lapachol.

969

by the more natural route of nutrient plant material absorption through the digestive tract. Although most of the studies are on individual chemicals, some show significantly better results with the whole extract and diminishing effectiveness as the extracts are refined or individual chemicals are tested.^[8]

Antimicrobial activity

Antibacterial activity

In 1956, a research team at the Universidade do Recife in Brazil reported that lapachol isolated from the *Tabebuia avellanedae* tree exhibited antimicrobial activity against Gram-positive and acid-fast bacteria, and *Brucella* sp.^[9]

It is important to note that the research team found that progressive purification reduced the antimicrobial activity of the extract. This led to the conclusion that there was more than one active substance present in the original extract.

Later that year the researchers published a paper proclaiming a new antibiotic substance from *Tabebuia avellanedae* which demonstrated “strong anti-*Brucella* activity and fungistatic behavior”.^[10] They eventually found that, along with lapachol, the extract of the *Tabebuia* tree contained alpha-lapachone, beta-lapachone, and a newly discovered quinone which they named xyloidone.

In 1967, another group of researchers discovered seven naphthoquinones, nine anthraquinones, lapachenole, quercetin and *o*- and *p*-hydroxybenzoic acids in the heartwood of the tree.^[11] Several of these exhibit strong microbicidal and fungicidal activities (see [Table 113.2](#)). Naphthoquinones are highly effective against *Candida albicans* and *Tricophyton mentagrophytes*.^[12]

Lapachol has been shown to have both antimicrobial and antiviral activity.^{[13] [14] [15]} Beta-lapachone shows diversified antiparasitic activity as well as antiviral action.^{[16] [17]} Alpha-lapachone is also active against certain parasites, and xyloidone is active against numerous bacteria and fungi.^{[18] [19]} Another LaPacho component, the flavonoid quercetin, is cytotoxic for certain parasites.^[20]

Xyloidone is effective against a wide array of organism, such as *Staphylococcus aureus* and the *Brucella* species. The causative agents of tuberculosis, dysentery, and anthrax are also inhibited by xyloidone. In addition to its activity against a variety of bacteria, this quinone inhibits several species of fungus (including *Candida albicans*, *C. kruzei*, and *C. neoformans*).

Mechanism of action

Lapachol, like many naphthoquinones, acts as a respiratory poison by interfering with electron transport in microbes.^[21] Research showed in 1946 that drug suppression of malarial parasites could usually be correlated with the inhibition of their oxygen uptake.^[22] In 1947, lapachol was found, at concentrations of 100 mg/L, to inhibit O₂ uptake by *Plasmodium knowles* by 74% and succinate oxidase systems by 26%.^[23] In the following year, lapachol was found to exhibit antimalarial activity against *Plasmodium lophurae*,^[24] suggesting respiratory poisoning as a likely mechanism.

Mitochondrial respiration is inhibited by 50% at a lapachol concentration of less than 110 μmol/L.^[25] Increasing doses of lapachol produced progressive respiratory inhibition in tumor cells isolated from animals. Oxygen consumption and oxygen metabolite production

TABLE 113-2 -- Antimicrobial activity of *Tabebuia avellanedae**

| Microorganism | Lapachol | Chorohidro-lapachol | Alpha-lapachone | Beta-lapachone |
|---------------|----------|---------------------|-----------------|----------------|

* Minimum concentration of inhibition (mcg/ml).

are inhibited in neutrophils upon administration of lapachol.^[26]

The exact site at which lapachol acts has been the subject of some controversy. Some researchers have concluded that 2-hydroxy-3-alkyl-1,4 naphthoquinones, such as lapachol, act just after cytochrome c in the respiratory chain,^[27] while others suggest that lapachol exhibited an oligomycin-like action in mitochondria, acting just after cytochrome b.^[21] It has been hypothesized that naphthoquinones either prevent an interaction between cytochromes b and c, or act directly on an unknown enzyme between the two.^[28] The inhibitory action can be reversed by the addition of 2,4-dinitrophenol,

suggesting that lapachol may act on energy conservation reactions.^[18]

Lapachol has now been shown to act as an uncoupler of oxidative phosphorylation. Lapachol prevents ATP synthesis by stimulating respiration in the absence of a phosphate acceptor. This effect is most pronounced at a high pH level where lipid solubility is the lowest.^[29]

Hadler & Moreau^[25] studied lapachol in combination with showdomycin and demonstrated that lapachol exposes a mitochondrial thiol group which occupies a pivotal position between the cycle that meshes with the respiratory chain and the cycle that meshes with ATP. They believe the side chain acts as a swinging arm while the remainder of the lapachol molecule is embedded in a lipid matrix.^[30]

In addition to inhibiting cellular respiration and uncoupling oxidative phosphorylation, lapachol inhibits certain enzymes. In particular, it is a competitive inhibitor of glycolase I in erythrocytes. The side chain is again thought to be significant in this action. Lapachol also demonstrates non-competitive inhibition of alpha-keto-aldehyde dehydrogenase, leading to the accumulation of toxic alpha-ketoaldehydes.^[30] Lapachol demonstrated 64% inhibition of 3-alpha-hydroxysteroid mediated transhydrogenase at a concentration of 10^{-5} M (well within dosage range).^[31]

Antiviral activity

Lapachol has proven to be active against certain viral strains, including herpes virus hominis types I and II.^[31] Hydroxynaphthoquinone has been shown to effectively inhibit four influenza viruses. Lapachol also significantly inhibits poliovirus and vesicular stomatitis virus.^[14]

Studies of beta-lapachone's antiviral activity have offered insights into the mechanism of this powerful quinone. In experiments with viruses, beta-lapachone demonstrated its ability to inhibit certain enzymes, such as DNA and RNA polymerases.^[32] Beta-lapachone was tested against avian myeloblastosis virus and Rauscho murine leukemia virus and found to inhibit retrovirus reverse transcriptase.^[33] In the presence of dithioreitol, beta-lapachone inhibits eukaryotic DNA polymerase-alpha activity. Although the mechanism of action for enzyme inhibition is complex, it may be related to superoxide production.^[32] This in turn may aid in explaining the structural changes in the DNA of the epimastigotes. The site of action appears to be the enzyme protein. This has great significance for possible treatment of both HIV and HLBV (the implicated viruses in AIDS and Epstein-Barr syndrome).

Beta-lapachone also inhibits Friend virus and was the only substance among a number tested which prolonged survival time of chickens infected intraperitoneally with Rous sarcoma virus.^[34]

Antiparasitic activity

The trematode *Schistosoma mansoni* is the causative agent of the common tropical

disease schistosomiasis. The cercariae of this blood fluke live in water and enter the host by penetrating the skin. This debilitating disease, a serious problem in many tropical areas, causes weakening of the host and increases susceptibility to a variety of other pathogens, some of which may be fatal.

Lapachol has been tested as a topical barrier to the cercariae and has been found to be highly effective at preventing its penetration.^[32] ^[35] Oral lapachol was also tested and found to significantly reduce penetration. After being consumed, the lapachol was secreted onto the skin, apparently by the sebaceous glands, where it again acted as a topical barrier. The cercariae seek to penetrate the host through or near the sebaceous glands, which suggests that dietary administration of lapachol would be an efficient means of protecting against infection. Although the mechanism for this anti-schistosomal activity is relatively unknown, Pinto thought that the side chain was involved, and noted that effective barriers are liposoluble.

Alpha-lapachone and beta-lapachone, also components of LaPacho, both exhibited activity against *S. mansoni*.^[13] The activity of beta-lapachone against viruses and parasites has been studied in an attempt to understand the mechanism by which this quinone works. Beta-lapachone is notably effective against *Trypanosoma cruzi*, a zoomastigote responsible for trypanosomiasis, or Chaga's disease. This disease occurs in both acute and chronic forms and has no known cure.

Beta-lapachone causes complete inhibition of *T. cruzi* at concentrations of 0.8–5.0 µg/mL and progressively inhibits motility with increasing concentrations. When *T. cruzi* epimastigotes were incubated with the quinone, they were subject to nuclear, mitochondrial, endoplasmic reticular, and cytoplasmic membrane damage, and underwent alterations in the chromatin distribution. Respiration rates were lowered, the mitochondria became swollen, and glucose and pyruvate oxidation was inhibited.

Lipid peroxidation was stimulated, which resulted in decreased cell viability.

In addition, in vitro testing resulted in the rapid decay of DNA, RNA, and protein, and DNA breakage in *T. cruzi*. This was accompanied by inhibition of DNA, RNA, and protein synthesis and instigation of “unscheduled” DNA synthesis.^[36]

It is thought that this toxic action against parasites is at least partly due to superoxide production.^[37] Both O_2^- and H_2O_2 are intermediates of oxygen reduction and both are toxic to living organisms. When beta-lapachone is introduced to *T. cruzi*, it rapidly enters the epimastigote and is reduced to its semiquinone form in the mitochondria and microsomes of the pathogen.^[38] Superoxide is produced by the reduction of molecular oxygen, which is facilitated by auto-oxidation of the semiquinone free radical. Superoxide is then converted to hydrogen peroxide via SOD (superoxide dismutase). Stimulation of lipid peroxidation follows and the cell degenerates.

Anti-neoplastic effects

Due to the folklore information surrounding the tumor-reducing qualities of the herb LaPacho, it underwent extensive study by the National Cancer Institute (NCI). After initial positive results, it was felt that lapachol was the most active anti-neoplastic agent. Lapachol entered phase I clinical trials at NCI in 1968, based on its activity against Walker 256 tumors (with over a 90% confidence rate). During these trials it was difficult to obtain therapeutic blood levels of lapachol without some mild toxic side-effects such as nausea, vomiting, and anti-vitamin K activity. This is quite hard to understand, as latter studies found the toxicity to be very low, with an LD₅₀ of 487 mg, about the same as caffeine.^[4] The IND (investigative new drug status) for the drug was closed in 1970.^[39]

It has been shown, however, that some of the anthraquinones in LaPacho have vitamin K activity, and therefore use of the whole herb would compensate for lapachol's effect on vitamin K.^[40]

An analog, dichloroallyl lawsone, which had a better in vivo activity in the Walker 256 system, was selected to replace lapachol with IND approval in 1975. It was found, as was lapachol, to be an inhibitor of oxidative phosphorylation. In Rhesus monkeys it was observed to have some cardiac toxicity. It was decided subsequently that there was little point to any further analog development and the case was closed.^[41]

The approach described above indicates a flaw in the underlying philosophy of the pharmaceutical sciences and the NCI program. Since the initial studies came from a whole plant, the detailed studies should have been undertaken on the whole plant: some of the other quinones have also been shown to have anti-neoplastic activities. Was it too complex to consider the chemical reactions of the over 20 components found in the LaPacho? Or was the standard economic/political incentive for patenting an analog an impediment to the investigation of a plant species?

Lapachol is rapidly absorbed through the gastrointestinal tract after oral administration to rats bearing W-256 tumors. It is taken up by all tissues except the brain and blood cells. A significant amount appears in the tumor after 6 hours, with most of the drug disappearing from the other body tissue. The half-life of i.v. lapachol in mice is 33 minutes (75 minutes in dogs). Lapachol is extensively metabolized and excreted mostly in the feces.^[1] Most other analogs had little effect on cancer.^[42]

The theories on how lapachol works as an anti-neoplastic agent vary considerably. One of the most prominent involves redox cycle capabilities. The redox function of lapachol was known as early as 1936.^[43] In 1947, Ball et al^[44] studied the respiratory poison mechanism of naphthoquinones in the i.v. killing of malarial parasites. In 1966, lapachol was shown to stimulate mitochondrial ATPase activity (in the general fashion of uncouplers), while being without effect on ATPase stimulation by dinitrophenol. Its maximum activity is at a high pH where lipid solubility might be expected to be lowest.^[10] Lapachol was found to be an in vivo inhibitor of respiration at chemotherapeutic doses.^[7] Later, lapachol was shown to augment the flow of electrons from reduced

NADP to form oxygen-related free radicals. These seem to be site-specific free radicals that bind to the cancerous DNA or RNA producing either superoxides or free hydroxyl radicals.^[45] ^[46]

There seems to be a redox potential which is important for the inhibition of electron transfer in coenzyme Q₁₀.^[47] It is argued by Bennett et al^[48] that this respiration poisoning is not the mechanism of antitumor activity. Lapachol was shown to significantly reduce the pool of uridine triphosphate (UTP), the largest pool of the pyrimidine nucleotides (exposure time was very short, 2–4 hours).

Lapachol is theorized to be like dichloroallyl lawsone (DCL) in that it blocks pyrimidine biosynthesis through inhibition of dihydroorotate dehydrogenase.^[21] It is also believed that the anti-neoplastic activities of lapachol might stem from its interaction with nucleic acids^[49] and it is proposed that interaction of the naphthoquinone moiety between base pairs of the DNA helix occurs with subsequent inhibition of DNA replication and/or RNA synthesis. Free amino groups in the sugar moiety are necessary for DNA binding.^[49]

Beta-lapachone was shown to decrease the viability of sarcoma cells by stimulating lipid peroxidation. This was accomplished through:^[37]

- reduction of lapachone at the mitochondrial and microsomal membranes with generation of the semiquinone form
-

972

- autooxidation to produce O₂
- production of H₂ O₂ via SOD.

Anti-inflammatory activity

Extracts of the bark from *Tabebuia avellanedae* demonstrate clear anti-inflammatory activity with low toxicity.^[50] Tampons soaked in an alcoholic extract of LaPacho have been shown to be very successful against a wide range of inflammations, such as cervicitis and cervicovaginitis.^[2] ^[33]

Quercetin

Quercetin is a highly active flavonoid which inhibits a wide range of enzymes and suppresses the synthesis of DNA, RNA, and proteins.^[51] Quercetin's cytotoxicity may be due to the fact that it inhibits mitochondrial electron transport.^[52] Hodnick et al have noted that quercetin produced a substrate-independent, KCN-insensitive, respiratory burst in mitochondria. Other flavonoids which demonstrated this activity produced O₂⁻ and H₂ O₂, suggesting that quercetin may also generate these cytotoxic chemicals.

Among the enzymes inhibited by quercetin are:^[36] ^[37] ^[53]

- NADH oxidase
- phosphodiesterase
- cAMP-independent protein kinases
- Ca²⁺ phospholipid-dependent protein kinase
- tyrosine protein kinases.

Shapiro et al suggested that the cytotoxicity of quercetin may be due to its chelating abilities.^[20] It is trypanocidal to *Trypanosoma brucei*, a livestock parasite belonging to the same genus as *Trypanosoma cruzi*. Soon after the parasite enters the host, the host's unsaturated iron-binding proteins remove iron from the hemoflagellate. Since the parasite is unable to synthesize heme, it encounters a shortage of iron. By chelating the host's iron, quercetin blocks utilization by the parasite, yet does not adversely affect the host. This flavonoid is also cytotoxic against *Crithidia fasciculata*. The fact that it is small and lipophilic seems to be significant to its activity.

Like lapachol, quercetin inhibited O₂ consumption and H₂O₂ production in neutrophils.^[28]

Many flavonoids exhibit antiviral activity. When mice that had been intracerebrally infected with attenuated viruses, including rabies, were given quercetin in their diet, a prophylactic effect was observed.^[54] Quercetin inactivates the following viruses:

- herpes simplex type 1
- respiratory syncytial virus
- pseudorabies/Aujeszky's virus
- poliovirus type 1
- parainfluenza type 3
- Sindbis virus
- potato virus X.

(Inactivation is defined as reducing viral infectivity tenfold.)

CLINICAL APPLICATION

The spectrum of clinical applications of *Tabebuia avellanedae* is quite broad. Current use has focused on LaPacho's anti-neoplastic and antimicrobial activity. Its use is extremely popular in the treatment of intestinal candidiasis and vaginal candidiasis (topically and internally). There are also many anecdotal reports of remission of different forms of cancer from use of this botanical.^[28]

Unfortunately, due to lack of quality control and confusion about the portion of the plant to use (any of the studies and chemical analyses have been done on the heart wood, while the bark is the product available in the market place and discussed in the folklore), it is highly likely that most practitioners are not using effective materials. This could

explain varying clinical results.

DOSAGE

The usual form of administration of LaPacho is as a decoction, with the standard dose being 1 cup of decocted bark two to eight times/day. The decoction is made by boiling 1 tsp of LaPacho for each cup of water for 5–15 minutes.

A more precise dosage based on a lapachol content of 2–4% would be 15–20 g of bark boiled in 500 ml or 1 pint of water for 5–15 minutes three to four times daily.

Dosages of other forms (aqueous extract, fluid extract, solid extract) should be based on lapachol content, providing a daily lapachol intake of 1.5–2.0 g/day.

A tampon which has been soaked in the decoction or fluid extract is used in the treatment of vaginitis and cervicitis. The tampon is inserted vaginally and changed every 24 hours until resolution.

TOXICOLOGY

Although anti-vitamin K activity has been reported for lapachol, the presence of several vitamin K-like substances in the whole plant suggests this is not a problem. Lapachol has been reported to have an oral LD₅₀ of 1.2–2.4 g/kg in albino rats and 487–621 mg/kg in mice.^[55] In comparison, the oral LD₅₀ of caffeine is 192 mg/kg in rats and 620 mg/kg in mice.^[5]

Chronic administration of lapachol at a dose of 0.0625–0.25 g/kg per day to monkeys produces moderate to severe anemia. The anemia was most pronounced during the first 2 weeks of treatment. Death occurred in monkeys after six doses of lapachol at 0.5 g/kg per day and after five doses of 1.0 g/kg per day.^[8]

There have been no reports in the literature of human toxicity when the whole bark as a decoction is used.

Chapter 114 - *Tanacetum parthenium* (feverfew)

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

Tanacetum parthenium (family: Compositae)
Synonym: *Chrysanthemum parthenium*
Common names: feverfew, featherfew

GENERAL DESCRIPTION

Feverfew (*Tanacetum parthenium*) is a composite plant that is cultivated in flower gardens throughout Europe and the United States. The round, leafy, branching stems bear alternate, bipinnate leaves with ovate, hoary-green leaflets. The flowers are small and daisy-like, with yellow disks and from 10 to 20 white, toothed rays. The name feverfew is a corruption of the word febrifuge used to signify its tonic and fever-dispelling properties.

CHEMICAL COMPOSITION

The major active chemicals in the plant are sesquiterpene lactones, principally parthenolide. The flowering herb also contains 0.02–0.07% essential oils (L-camphor, L-borneol, terpenes, and miscellaneous esters).^{[1] [2]}

HISTORY AND FOLK USE

Feverfew has been used for centuries as a febrifuge and for the treatment of migraines and arthritis. Other historical uses of feverfew have been in the treatment of anemia, earache, dysmenorrhea, dyspepsia, trauma, and intestinal parasites.^[1] It has also been used as an abortifacient, and in gardens to control noxious pests (its pyrethrin component is an effective insecticide and herbicide).

PHARMACOLOGY

Feverfew has demonstrated some remarkable pharmacological effects in experimental studies. Its long folk history of use in the treatment of inflammatory conditions such as fever, arthritis, and migraine suggests that

976

it acts in a fashion similar to that of the more common non-steroidal anti-inflammatory agents (NSAIDs), such as aspirin. Extracts of feverfew have been shown to inhibit the synthesis of compounds which promote inflammation, including inflammatory prostaglandins, leukotrienes, and thromboxanes. Unlike aspirin and other NSAIDs, inhibition by feverfew at the initial stage of synthesis is more like that of cortisone than NSAIDs.^[3]

Feverfew also has a favorable effect on the behavior of blood platelets.^[3] ^[4] The favorable effects include inhibition of platelet aggregation and the secretion of inflammatory and allergic mediators like histamine and serotonin. Parthenolide components also exert a tonic effect on vascular smooth muscle.^[5]

The combined effect on smooth muscle and platelets is probably the factor responsible for feverfew's effect in preventing and treating migraine headaches.

CLINICAL APPLICATIONS

Feverfew has been used for centuries to relieve fever, migraines and arthritis. The only condition with confirmed scientific documentation at the present time is in the prevention and treatment of migraine headache.

Migraine headache

Physician John Hill, in his book *The family herbal* (1772) noted: "In the worst headache this herb exceeds whatever else is known." Recently, there has been tremendous increase in the interest in feverfew for migraine headache. This renewed interest began in 1970s in Britain. Increased public awareness of the herb led to scientific investigation. A 1983 survey found that 70% of 270 migraine sufferers who had eaten feverfew daily for prolonged periods claimed that the herb decreased the frequency and/or intensity of their attacks.^[6] Many of these patients had been unresponsive to orthodox medicines. This prompted two clinical investigations of the therapeutic and preventive effects of feverfew in the treatment of migraine.

The first double-blind study was done at the London Migraine Clinic, using patients who reported being helped by feverfew.^[6] Those patients who received the placebo (and as a result stopped using feverfew) had a significant increase in the frequency and severity

of headache, nausea, and vomiting during the 6 months of the study, while patients taking feverfew showed no change in the frequency or severity of their symptoms. Two patients in the placebo group who had been in complete remission during self-treatment with feverfew leaves developed recurrence of incapacitating migraine and had to withdraw from the study. The resumption of self-treatment led to renewed remission of symptoms in both patients.

The second double-blind study was performed at the University of Nottingham.^[7] The results of the study clearly demonstrated that feverfew was effective in reducing the number and severity of migraine attacks. In the study, 72 patients were randomly allocated to receive either one capsule of dried feverfew leaves (82 mg) daily or placebo. After 4 months, patients were transferred to the other treatment for another 4 months. Treatment with feverfew was associated with a reduction in the mean number and severity of attacks and in the degree of vomiting; duration of single attacks was unaltered. The efficacy of feverfew in the prevention of migraine headaches has now been demonstrated in several controlled studies.^[8]

Rheumatoid arthritis

Inflammatory compounds released by white blood cells and platelets contribute greatly to the inflammation and cellular damage found in rheumatoid arthritis. The inhibition of the release of inflammatory particles by feverfew is much greater than that achieved by NSAIDs like aspirin.^[4] This, coupled with many of feverfew's other effects, indicates that feverfew could greatly reduce inflammation in rheumatoid arthritis.

Although a double-blind, placebo-controlled study demonstrated no apparent benefit from oral feverfew in rheumatoid arthritis, the dosage used was small (76 mg dried, powdered feverfew leaf corresponding to two medium-sized leaves), the level of parthenolide was not determined in the product, and patients continued to take NSAIDs, a practice that has been suggested to reduce the efficacy of feverfew.^[9] Therefore, the benefit of feverfew in rheumatoid arthritis has not yet been determined.

DOSAGE

The effectiveness of feverfew is dependent upon adequate levels of parthenolide, the active principle. Unfortunately, recent analyses of the parthenolide content of over 35 different commercial preparations indicate a wide variation in the amount of parthenolide.^[10] The majority of products contained no parthenolide or only traces.

The preparations used in successful clinical trials had a parthenolide content of 0.4–0.66%. In order to achieve the benefits noted in the migraine studies, the dosage of parthenolide must be similar. The dosage of feverfew used in the London Migraine Clinic study was one capsule containing 25 mg of the freeze-dried pulverized leaves twice daily. In the Nottingham study it was one

capsule containing 82 mg of dried powdered leaves once daily. Therefore, the daily dosage of parthenolide which may be effective in the prevention of a migraine headache is roughly 0.25–0.5 mg.

While these low dosages may be effective in preventing an attack, a higher dose (1–2 g) is necessary during an acute attack:

- dried pulverized leaves: 25–50 mg two times/day.

TOXICITY

There were no reports of toxic reactions in patients taking feverfew in the 6 month migraine study. Feverfew has been used by large numbers of people for many years without reports of toxicity. Chewing the leaves, however, may result in aphthous ulcerations, and some sensitive persons will develop an exudative dermatitis from external contact.^[11]

Chapter 115 - *Taraxacum officinale* (dandelion)

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

Taraxacum officinale (family: Compositae)
Common names:

- English: dandelion, wet-a-bed, Lion's tooth
- French: dent-de-lion, pissenlit
- German: lowenzahn, pfaffenrohrlein
- Spanish: diente de leon
- Italian: tarassaco
- Chinese: p'u kung ying, Ching p'o po, Chiang-nou-ts'ao, Huang-hua-tii-ting

GENERAL DESCRIPTION

Dandelion (*Taraxacum officinale*) is a member of the Compositae family and is closely related to chicory.^[1] Several origins have been attributed to the name *Taraxacum*, among them the most likely being from the Greek *taraxo* (disorder, disturbance) and *akos* (remedy), *akeoma* (I heal) and from *tharakhcharkon*, possibly a derivative of a Persian-Arabic word for "edible" and the name by which the plant is referred to in a 13th-century Arabian botanical work.

Taraxacum is known around the world by a variety of names. In English speaking countries, dandelion (from the French *dent-de-lion*, referring to the plant's lion's tooth leaves) is its most common name. It is also known as wet-a-bed (after its diuretic action), Lion's tooth, fairy clock, priest's crown, swine's snout, blowball, milk gowan, wild endive, white endive,^[4] cankerwort,^[5] puffball, and Irish daisy.^[1]

Dandelion is a variable perennial, growing to a height of 12 inches. Its spatula-like leaves are deeply toothed, shiny, and hairless, and are arranged in a ground level rosette. The yellow flowers bloom for most of the year, are sensitive to light and weather – opening at daybreak and closing at night fall, and opening in dry weather and closing in wet (a closed dandelion flower signals rain). When the flower matures, it closes up,

the petals wither, and it forms into a puffball containing seeds which are dispersed by the breeze.

980

The rosette formation of grooved leaves channels rainwater into its center and down to a taproot which is thick, dark brown and almost black on the outside. The root is cylindrical, tapering, and somewhat branched. It has a slight odor and a sweetish taste. The inside of dried dandelion root is yellowish, very porous and without pith.

It is believed that the plant originated in Central Asia and spread throughout most of the world, preferring the cooler climates.^[1] Although *Taraxacum* is very adaptable, it prefers moist nitrogen-rich soils at altitudes less than 6,000 feet. Most species occur in the temperate zones of the northern hemisphere, with the greatest concentration in north-west Europe.

The portion of the plant that is most commonly used is the root; however, the leaves and whole plant can also be used. In addition to its medicinal use, dandelion is also used as a nutritious food and beverage. Tender leaves are used raw in salads and sandwiches, or lightly cooked as a vegetable. Tea is made from the leaves, coffee substitute from the roots, and wine and schnapps from the flowers.

CHEMICAL COMPOSITION

The primary therapeutic actions of dandelion are believed to be due to the bitter principle taraxacin, various terpenoids, inulin, and its high concentration of nutrients. Other constituents of dandelion which may contribute to its pharmacology include resins, pectin, taraxanthin (a carotenoid pigment in the flowers), fatty acids, and flavonoids.

Many studies show that dandelion is a rich source of vitamins and minerals.^[1] The leaves have the highest vitamin A content (14,000 IU/100 g raw) of all greens, as well as ample amounts of vitamins D, B complex, C and minerals such as iron silicon, magnesium, sodium, potassium, zinc, manganese, copper and phosphorus.^[1] ^[2] Dandelion also contains relatively high amounts of choline, an important nutrient for the liver.^[3]

Taraxacum officinale roots contain the triterpenes β -amyrin, taraxasterol, taraxerol and the sterols sitosterin, stigmasterin and phytosterin ([Figs 115.1](#) and [115.2](#)).^[4]

More recent research is now eliciting several compounds which are likely to be clinically significant. Three

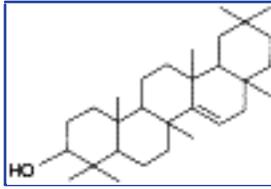

Figure 115-1 Taraxerol.

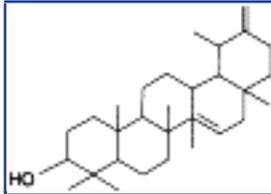

Figure 115-2 Taraxasterol.

flavonoid glycosides – luteolin 7-glucoside and two luteolin 7-diglucosides – have been isolated from dandelion flowers and leaves together with free luteolin and chrysoeriol in the flower tissue. Three hydroxycinnamic acids – chicoric acid, monocaffeoyltartaric acid and chlorogenic acid – have been found throughout the plant, and the coumarins, cichoriin and aesculin, have been identified in leaf extracts. Chicoric acid and the related monocaffeoyltartaric acid were found to be the major phenolic constituents in flowers, roots, leaves and involucre bracts and also in the medicinal preparations tested.^[5]

HISTORY AND FOLK USE

While many individuals may consider the common dandelion an unwanted weed, herbalists all over the world have revered this valuable herb. Generally regarded as a liver remedy, dandelion has a long history of folk use throughout the world. In Europe, dandelion was used in the treatment of:

- fevers
- boils
- eye problems
- diarrhea
- fluid retention
- liver congestion
- heartburn
- various skin problems.

In China, dandelion has been used to treat:

- breast problems (cancer, inflammation, lack of milk flow, etc.)
- liver diseases
- appendicitis
- digestive ailments.

Dandelion's use in India, Russia, and most other parts of the world revolved primarily around its action on the liver.

PHARMACOLOGY

The primary pharmacological activities relate to digestion, liver function, and diuresis.

981

Digestive effects

Bitter herbs like dandelion are used to aid digestion based on the belief that bitter principles stimulate the initial phase of digestion including the secretion of salivary and gastric juices. Dandelion goes beyond this initial stimulation by stimulating the release of bile by the liver and gall bladder.

Liver effects

Studies in humans and laboratory animals have shown that dandelion root enhances the flow of bile, improving such conditions as liver congestion, bile duct inflammation, hepatitis, gallstones, and jaundice.^{[6] [7] [8]} Dandelion's action on increasing bile flow is twofold: it has a direct effect on the liver, causing an increase in bile production and flow to the gall bladder (choloretic effect), and a direct effect on the gall bladder, causing contraction and release of stored bile (cholagogue effect). The high choline content of the root may be a major factor in dandelion's ability to act as a "tonic" to the liver. Historically, dandelion's positive effect on such a wide variety of conditions is probably closely related to its ability to improve the functional ability of the liver.

Diuretic and weight-loss effects

The leaves of dandelion have confirmed diuretic activity. In one study in mice, dandelion exerted a diuretic activity comparable to furosemide (Lasix).^[9] Because dandelion replaces potassium lost through diuresis, it does not have the potential side-effects of furosemide such as hepatic coma and circulatory collapse. The dose given was 8 ml/ kg body weight of the aqueous fluid extract of the leaves. This dose produced a 30% loss of body weight in mice and rats in a 30 day period. Much of the weight loss was attributed to the significant diuretic effects.

Hypoglycemic effects

Dandelion and inulin have demonstrated experimental hypoglycemic activity in animals.^[10] Since inulin is composed of fructose chains, it may act to buffer blood glucose levels, thus preventing sudden and severe fluctuations.

CLINICAL APPLICATIONS

Although dandelion's specific action is on the liver, as an alterative or tonic it benefits the body as a whole. It is often used as:

- a diuretic
- a laxative
- a cholagogue
- a general stimulant for the urinary system
- a choloretic
- a depurative (purifier)
- a hypoglycemic
- an antitumor agent.

Liver conditions

Two human studies have demonstrated the liver-healing properties of dandelion. In a 1938 study in Italy, 12 patients with severe liver imbalances, many exhibiting classical symptoms of loss of appetite, low energy and jaundice, were treated with dandelion extract (one 5 ml injection per day for 20 days).^[1] Eleven of the 12 patients showed a considerable drop in blood cholesterol. In the other study, dandelion extract was shown to successfully treat hepatitis, swelling of the liver, jaundice and dyspepsia with deficient bile secretion.^[6]

Dandelion's effects on the liver, particularly its lipotropic effects, may be put to good use in the treatment of premenstrual syndrome. Decreased clearance of estrogen and other hormones by the liver is believed to be responsible for these symptoms in some women. If dandelion can improve the liver's ability to detoxify these hormones, symptoms may be likewise improved.

Cancer

A Japanese study in 1979 found that dandelion alcoholic extract administered to mice for 10 days markedly inhibited the growth of inoculated Ehrlich ascites cancer cells within a week of treatment.^[11] A freeze-dried warm-water extract of the root for use as an antitumor agent was patented by the Japanese in 1979, and TOf-CFr, a glucose polymer isolated by Japanese researchers in 1981, was found to have antitumor properties in laboratory mice.^[1] These findings lend support to the Chinese use of dandelion for breast cancers.

Kidney stones

One study, using female Wistar rats, evaluated seven botanicals historically used to prevent and treat stone kidney formation:

- *Verbena officinalis*
- *Lithospermum officinale*
- *Taraxacum officinale*

- *Equisetum arvense*
- *Arctostaphylos uva-ursi*
- *Arctium lappa*
- *Silene saxifraga*.

Variations of the main urolithiasis risk factors – citraturia, calciuria, phosphaturia, pH and diuresis – were measured. The researchers concluded that the beneficial effects caused by these herbal infusions on urolithiasis can be attributed to some disinfectant action, and, tentatively, to the presence of saponins.^[12]

982

DOSAGE

As a general tonic and mild liver remedy, the root can be used at the following dosages three times/day:

- dried root: 2–8 g by infusion or decoction
- fluid extract (1:1): 4–8 ml (1–2 tsp)
- tincture: alcohol-based tinctures of dandelion are not recommended because of the extremely high dosage required
- juice of fresh root: 4–8 ml (1–2 tsp)
- powdered solid extract (4:1): 250–500 mg.

Preparations of the leaves can be used as a mild diuretic and weight-loss agent at the following dosages three times/day:

- dried leaf: 4–10 g by infusion
- fluid extract (1:1): 4–10 ml.

TOXICITY

No toxic or adverse effects have been reported, for either external or internal use. It is considered safe to use, even in large amounts.^[4]

Chapter 116 - *Taxus brevifolia* (Pacific yew)

Cathy Flanagan ND

Taxus brevifolia (family: Taxaceae)
Common names: Pacific yew, taxol, paclitaxel

GENERAL DESCRIPTION

Paclitaxel (also known as taxol) and taxotene (docetaxel) are a complex diterpenoid taxanes extracted from *Taxus brevifolia*, the Pacific yew. They have been cited as some of the most promising plant compounds tested for anti-cancer properties to date.^[1] First collected in 1962 by a USDA team in Washington state as part of the large natural products screening program of the US National Cancer Institute, confirmed activity against the KB cell line in tissue culture was reported in 1964. Isolation studies began in 1965 and by 1971 Wall and co-workers at the Research Triangle Institute (Durham, NC) identified taxol as the active constituent.^[2] Taxol became big news in 1989, when investigators at the Johns Hopkins Oncology Center in Baltimore reported a 30% response rate in cases of refractory ovarian cancer, a remarkable rate for this type of cancer.^[3] Taxanes used in conjunction with chemotherapy and radiation have demonstrated improved results to either therapy alone along with improved tolerance to the therapies.

Yews are evergreen trees or shrubs which produce a seed surrounded by an edible red fleshy aril. The yew is difficult to class taxonomically as its appearance is similar to conifers, but because of the absence of cones and resin ducts, it is placed in a separate order.

Although the yew appears to be tenacious, it is slow to reproduce. The species is dioecious, with female trees producing relatively scarce fruits. Seedlings are rare. Most often, new yew trees come from offshoots of a “mother tree”, which is why they are usually found in clusters. They grow best on deep, moist, rich rocky or gravelly soils. The largest known living Pacific yew is in Lewis County, Washington, near Mount Rainier. It stands 21.3 m tall, has a girth of 4.5 m, and is estimated to be 1,000 years

old.^[2]

Although taxol is found in species other than the

984

Pacific yew, its concentration is too low to warrant the extensive extraction processing required. Initially, it was thought that the most consistently stable and highly active constituent came from bark isolates, followed by root isolates. Currently, taxol and another compound, baccatin III (from the English yew, *T. baccata*), are being extracted from needles and twigs of 3- to 5-year-old cuttings being grown for this purpose. Taxol, a complex molecule, can be synthesized from baccatin III, but to date eludes efforts at total synthesis.^[4] ^[5]

Harvesting of a sufficient natural source is unrealistic for long-term use, as the Pacific yew, an inhabitant of old-growth stands, is in limited supply. The demand for taxol is estimated at 50–200 kg/patient, which would require 500,000–635,000 kg of bark yearly. One 200-year-old tree, with a 25 cm diameter yields only 2.7 kg of bark.^[2] The National Cancer Institute had requested 340,200 kg of dried bark in 1991 for 25 kg to be used in clinical trials alone. Environmentalists are concerned about the decimation of the little old-growth habitat which has survived logging efforts. Ironically, the Pacific yew had been previously regarded as a trash tree, left behind or burnt after logging operations. Now it is sought for its bark, and accessible stands are being harvested for maximum yield.

The future of taxol as a viable anti-cancer agent depends either on it, or a molecule similar enough to retain the therapeutic properties, being synthetically produced or on improved harvesting and extraction techniques that will maximize yield while perpetuating the natural source. Researchers at Stanford University have overcome many hurdles in the synthesis, but have not yet been totally successful. Extraction from needles looks promising, as it takes only 27.2 kg of foliage (produced from one tree) versus 4.1 kg of bark (consuming three trees) to obtain 2 g of taxol, the necessary dose for one patient. Harvesting trees in a manner that allows for sprouting of new trees is another way to sustain a supply and the survival of the species.

A collaborative research and development agreement between the National Cancer Institute and the Bristol-Myers Squibb Company has made it possible for taxol to be the first drug available through the treatment referral center to designated comprehensive cancer centers for eligible patients before being commercially available.^[3] The National Cancer Institute announced (newsletter, September 1992) that taxol had been reclassified as a group C drug, making it available with Medicare reimbursement to women with refractory ovarian cancer.

CHEMICAL COMPOSITION

Yew is poisonous because of at least 11 alkaloids, known collectively as taxines. The

structure of only two of the alkaloid constituents is known: taxine A, which accounts

Figure 116-1 Paclitaxel.

for 30%, and taxine B, which accounts for 2%. Paclitaxel ([Fig. 116.1](#)) is a pseudoalkaloid, but not a constituent of taxine since its nitrogen is acylated with benzoic acid and has no basic principle. The concentration of paclitaxel in yew bark is low, only 0.01%.

Taxenes have now been found in species other than the Pacific yew, but at lower concentrations. The harvesting of 500,000–635,000 kg/year of the bark is required to provide the estimated paclitaxel needed. Therefore, development of analogs synthesized from natural terpenes are important for long-term use.

In the search for precursors for paclitaxel synthesis, the much more prevalent yew needles have been analyzed for paclitaxel analogs. Several have been identified (e.g. 10-deacetyltaxol III, cephalmannine, 10-deacetyltaxol, 10-deacetylcephalomannine, and baccatin-III). As all yew species contain these highly oxygenated diterpenoids based on the unique taxane skeleton, most of the over 100 yew varieties are being screened, as are other members of the *Taxus* species. Other analogs, like docefaxel, are made by altering compounds extracted from the yew tree needles.

Paclitaxel is synthesized from cyclization of the universal diterpenoid precursor, geranylgeranyl diphosphate to taxa-4(5),11(12)-diene. This olefin is hydroxylated via cytochrome P450 catalysts to taxa-4(20),11(12)-dien-5 alpha-ol. Then this alcohol is converted via an acetylCoA-dependent process to the corresponding

acetate ester. Further genetic identification and isolations are targeted to improve the yield of taxol from the *Taxus* species. ^[6]

HISTORY AND FOLK USE

Historically, the yew has been highly valued for its dense, resilient, decay-resistant, tight-grained wood, and its medicinal properties. The Greeks named the yew *toxus* in reference to its use for making strong bows (toxon), and its poisonous nature (toxikon).^[2] It was used as an animal and fish poison by primitive cultures, as well as for murder

and suicide. In the 1st century AD, Claudius suggested its use as an antidote for viper bites. Europeans used it as an abortifacient, and for heart ailments and hydrophobia.^[2] Native Americans used the yew for many ailments such as:

- rheumatism
- lung ailments
- colds
- fever
- pain
- scurvy
- numbness
- paralysis
- stomach ache
- bowel ailments
- dysmenorrhea
- clots
- gonorrhoea.

Women ate yew berries to prevent conception. Youths rubbed smooth sticks of yew on their developing bodies to gain its strength. Both the bark and the leaves have been brewed for tea, and powders made from the bark alone. The fleshy red aril (berry) that surrounds the seed is not poisonous, although the seed itself is.^[7]

There is a lot of folklore about the yew's supernatural powers. As it is a slow-growing, long-lived tree, it was associated with immortality. It was used in spells to raise the dead.^[8] Because it was regarded as among the most potent of trees for protection against evil, it was considered unlucky to cut down or damage a yew tree. Many were planted in churchyards/graveyards and alongside homes for protection. Specimens survive today in spite of main trunks being hollowed out from decay following hundreds of years of existence.

PHARMACOLOGY

Paclitaxel's anti-cancer action is unique in that it inhibits cell division by promoting the formation of microtubules, the rod-like structures that function as a cell skeleton, making cells more stable and resistant to depolymerization. In contrast, other anti-cancer phytoagents (i.e. colchicine and vinca alkaloids) induce polymerization of microtubules. In addition, under the influence of paclitaxel, the microtubules polymerize independently of the microtubule-organizing center (MTOC), which is in a perinuclear area, and instead localize predominantly in the cell periphery.^[9] This interferes with the mitotic spindle and selectively blocks cells in the G₂ and M phases of the cell cycle, the most radiosensitive phases. Additionally, paclitaxel induces the formation of abnormal spindle asters that do not require centrioles for enucleation and are reversible following treatment.^{[10] [11]} Discovery of this unique mechanism of action by Horowitz and co-workers in 1979 kindled interest in paclitaxel, despite the inherent problems in the utilization of a scarce natural product.^{[12] [13]}

In addition, paclitaxel has demonstrated, in vivo, an ability to activate a local release of

an apoptosis-inducing cytokine.^[14] Studies on cancer cell lines induced with *gmi*, a novel gene, demonstrated a marked increase in sensitivity to paclitaxel via apoptosis. An assay for *gmi* expression could serve as a clinically useful predictor of chemotherapeutic sensitivity.^[15]

Docetaxel (taxotene) manifests its maximum inhibitory effect against cells that are in S phase.^[46] Other analogs (particularly IDN5109) are showing anti-proliferative activity 20- to 30-fold higher than paclitaxel in multi-drug-resistance-positive cancer cells.^[16]

CLINICAL APPLICATION

Paclitaxel has demonstrated a broad spectrum of antitumor activity. Phase I trials, which began in 1983, demonstrated paclitaxel's anti-neoplastic activity against several tumor types, such as:^{[17] [18] [19] [20] [21] [22] [23] [24]}

- melanoma
- adenocarcinoma of unknown origin
- refractory ovarian carcinoma
- small-cell and non-small-cell lung carcinoma
- gastric, colon, prostate, breast, head and neck carcinomas
- lymphoblastic and myeloblastic leukemias.

Trials are also being conducted with impressive results, using paclitaxel in combination with other anti-neoplastic agents, such as cisplatin.^[25] The Gynecology Oncology Group (GOG) reports a 33% response rate in patients who were previously resistant to cisplatin, when they are treated with the combination of cisplatin and paclitaxel.^[26] Trials are being conducted on small-cell and non-small-cell lung, renal, gastric, breast, advanced ovarian, colon, and cervical carcinomas; head and neck cancers; small cell lung and prostate carcinomas and low-grade non-Hodgkin's lymphoma.^[27] [Table 116.1](#) lists the short-term partial or complete response rates of various types of cancer to paclitaxel alone or in combination with other chemotherapeutic drugs.

TABLE 116-1 -- Results of clinical trials of paclitaxel or paclitaxel combinations^[28]

| Cancer type | Response range (%) |
|-----------------|--------------------|
| Ovarian cancer | 20–50 |
| Breast cancer | 56–62 |

TOXICITY

Human poisoning from the deliberate consumption of yew leaves or seeds is now rare. Recently published cases, from psychiatric patients and prisoners, describe the first symptoms of intoxication as appearing 1 hour after ingestion. The manifestations include mydriasis, nausea, vomiting, abdominal cramping and arrhythmia. Death occurs from cardiac arrest 3–24 hours after ingestion.^[28] The lethal dose in humans is approximately four or five handfuls of leaves, corresponding to 150 needles. No specific antidote is known.

Paclitaxel binds 95–98% with plasma proteins, yet is readily eliminated through hepatic metabolism, biliary excretion, and/or extensive tissue binding. Total urinary excretion has been insignificant, indicating that renal clearance contributes minimally to systemic clearance.^{[24] [29] [30] [31]} Hepatic metabolism via cytochrome p450 (CYP) is involved for both paclitaxel and docetaxel. However, the former is hydroxylated by CYP2C8 while the latter is hydroxylated by CYP3A4.^[32]

Toxicity in clinical trials manifests as:

- bone marrow suppression
- hypersensitivity
- cardiovascular abnormalities
- neurotoxicity
- arthralgias and myalgias
- alopecia
- gastrointestinal upset.

Junctional tachycardia via conduction block rather than direct primary toxicity on myocytes has been suggested.^[33] Hypersensitivity, skin reactions and accumulated fluid retention syndrome are minimized with a 3–5 day corticosteroid regime prior to paclitaxel infusions.^[34]

Leukemia patients treated with high doses of paclitaxel exhibited mucositis, which also appeared in response to lower, cumulative dosing. An accumulation of epidermal cells with paclitaxel-induced asters has been evident in ulcerated mucosa, indicating that the cell cycle was arrested in mitosis.^[35]

Paclitaxel has been known to inhibit neurite growth and induce prominent morphological effects, such as microtubule bundles in neurons, in satellite cells and in Schwann cells in organotypic dorsal root ganglion cultures.^{[36] [37] [38] [39] [40] [41]} Clinically, the most common symptoms have been glove-and-stocking paresthesia and perioral numbness. Distal sensory loss to large- (proprioception, vibration) and small-fiber (pin-prick, temperature) modalities and lost or decreased distal deep tendon reflexes have been noted, although motor nerves seem to be spared. In general, the clinical incidence and

severity of peripheral neurotoxicity have been dose-related. Patients with a history of substantial alcohol use have appeared to be more predisposed to the development of neurosensory toxic effects of cisplatin and paclitaxel.^{[17] [18] [19] [20] [42] [43] [44]}

The development of a suitable clinical formulation has been hampered by paclitaxel's poor aqueous solubility. Cremophor is being used as the vehicle for administration and has been implicated in side-effects such as type 1 hypersensitivity reactions.^[45] Neutropenia is the principle dose-limiting toxic effect of paclitaxel and resolves rapidly (15–21 days) after treatment is stopped.^[42] The major clinical risk factor for neutropenia seems to be the extent of prior myelotoxic chemotherapy and/or irradiation.

Bradyarrhythmias, which have been noted as transient and asymptomatic, have been reported during paclitaxel infusions in at least 29% of ovarian cancer patients, as reported by McGuire et al.^[42] This appears to be more related to paclitaxel, as other agents formulated with Cremophor have not been associated with similar arrhythmias. Atypical chest pains during paclitaxel infusion have been observed, but they are believed to be a manifestation of a hypersensitivity reaction.^{[29] [43]}

Other paclitaxel or Cremophor-related side-effects include sudden and complete alopecia – often occurring in a single day – local venous toxic effects such as erythema, tenderness and cellulitis in areas of dermal extravasation, fatigue, headaches, taste perversions, significant elevations in serum triglyceride levels, and minor elevations in hepatic and renal functions.^[24]

Lipid-coated microbubbles may be an effective way of providing selective affinity for tumor cells, thus reducing systemic effects while maintaining antitumor actions.^[46] Additional precautions may be necessary with

TABLE 116-2 -- Medications which interact with paclitaxel^[47]

-

Chapter 117 - *Uva ursi* (bearberry)

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

Arctostaphylos uva ursi (family: Ericaceae)
Common names: bearberry, upland cranberry

GENERAL DESCRIPTION

Uva ursi is a small evergreen shrub found in the northern US and in Europe. A single long, fibrous main root sends out several prostrate or buried stems 4–6 inches high. The bark is dark brown, the leaves are obovate to spatulate 0.5–1 inch long, the flowers are pink or white growing in sparse terminal clusters, and the fruit is a bright red or pink.

CHEMICAL COMPOSITION

Uva ursi's most active ingredient is arbutin, which typically composes 7–9% of the leaves. Other constituents include:

- tannins (6–7%)
- flavonoids (quercetin)
- allantoin
- gallic and ellagic acids
- volatile oils
- a resin (urvone). ^[1] ^[2]

HISTORY AND FOLK USE

This plant has a long history of use for its diuretic and astringent properties. Conditions for which it was used include chronic cystitis, nephritis, kidney stones, and bronchitis. ^[1]

PHARMACOLOGY

Antimicrobial

Although pharmacological research has primarily focused on arbutin, the pharmacology of the whole plant is different from that of just arbutin alone. The crude plant extracts are much more effective medicinally than the

990

isolated constituent arbutin. This appears to be related to the activity of gallic acid, which prevents the splitting of arbutin by such enzymes as beta-glucosidase.^[2] Arbutin undergoes hydrolysis to produce its aglycone, hydroquinone, which has urinary antiseptic properties.^[3] This hydrolysis of arbutin is responsible for much of the therapeutic effect of *uva ursi*.^[1] ^[3] By preventing the splitting of arbutin, the flavonoid components allow more arbutin to be hydrolyzed than when arbutin is administered as an isolated component.

Arbutin alone has been reported to be an effective urinary antibiotic, but only if taken in large doses and if the urine is alkaline (once again documenting the value of whole plant medicines).^[1] It is reported to be active against *Candida albicans* and *S. aureus*, and especially active against *E. coli*.^[4] *Uva ursi* also has diuretic properties.^[1]

Anti-inflammatory effects

Some early animal research is now showing that arbutin, and possibly other constituents of *uva ursi*, potentiate the activity of commonly prescribed anti-inflammatory drugs. One study found that an aqueous extract increased the inhibitory activity of dexamthasone in allergic and inflammatory models without increasing any of the side-effects.^[5] Similar results have been demonstrated with isolated arbutin when combined with indomethacin.^[6]

Inhibition of melanin synthesis

Another recently discovered property of *uva ursi* is the inhibition of tyrosinase by a 50% alcoholic extract.^[7] This effect impairs melanin synthesis, which leads the authors to suggest it could be used as a whitening agent for the skin. However, no clinical trials have been reported.

CLINICAL APPLICATIONS

Crude extracts are widely used in Europe as components in certain diuretic and laxative products, but the major use of *uva ursi* is as a urinary disinfectant in cases of urinary

tract infection.^[1]

Uva ursi is reported to be especially active against *E. coli*.^[3] It can be used in both the acute treatment and the prevention of recurrent cystitis. In one double-blind study, the prophylactic effect of a standardized *uva ursi* extract compared to a placebo on recurrent cystitis was evaluated in 57 women.^[3] At the end of one year, 5/27 women in the placebo group had a recurrence while 0/30 women receiving *uva ursi* extract had a recurrence. No side-effects were reported in either group. These impressive results indicate that regular use of *uva ursi* is a safe and effective measure to prevent recurrent cystitis.

DOSAGES

- Dried leaves or as an infusion: 1.5 to 4.0 g (1 to 2 tsp)
- Freeze-dried leaves: 500 to 1,000 mg
- Tincture (1:5): 4 to 6 ml (1 to 1.5 tsp)
- Fluid extract (1:1): 1 to 2 ml (¼ to ½ tsp)
- Powdered solid extract (10% arbutin): 250 to 500 mg

TOXICOLOGY

The toxicology of *uva ursi* is proportional to the conversion of arbutin to hydroquinone. Hydroquinone has been shown to be toxic at 1 g (equivalent to approximately 0.5 ounce of the fresh leaves), with signs and symptoms of:^[2]

- tinnitus
- nausea
- vomiting
- sense of suffocation
- shortness of breath
- cyanosis
- convulsions
- delirium
- collapse.

Chapter 118 - *Vaccinium myrtillus* (bilberry)

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

Vaccinium myrtillus (family: Ericaceae)
Common names: bilberry, huckleberry, European blueberry, whortleberry, blueberry

GENERAL DESCRIPTION

The genus *Vaccinium* in the family Ericaceae comprises nearly 200 species, most of which are found in the Northern Hemisphere. This chapter focuses on *Vaccinium myrtillus* and the medicinal use of extracts of its fruit.

Vaccinium myrtillus, or bilberry, is a shrubby perennial plant that grows in the sandy areas of the northern US and in the woods and forest meadows of Europe. The angular, green, branched stem grows from a creeping rootstock to a height of 1–1.5 feet. The 0.5–1.0 inch long leaves are oval, slightly dentate, and bright green, while the flowers are reddish- or greenish-pink and bell-shaped. The flowering season is April–June. The fruit is a blue-black berry.^[1]

CHEMICAL COMPOSITION

The pharmacologically active constituents of bilberries are its flavonoid components, specifically its anthocyanosides. Anthocyanosides are composed of an aglycone (e.g. anthocyanidin) bound to one of three glycosides (arabinoside, glucoside, or galactoside). Over 15 different anthocyanosides originate from the five aglycones found in *Vaccinium myrtillus* (see [Fig. 118.1](#)).^[2] Other members of the genus *Vaccinium*, as well as *Ribes nigrum* (black- currant) and *Vitis vinifera* (grape), contain similar anthocyanosides.^[3] Extracts of these fruits are also used for medicinal purposes in Europe.

The concentration of anthocyanosides in the fresh fruit is approximately 0.1–0.25%,

while concentrated extracts of *Vaccinium myrtillus* are produced which yield an anthocyanidin content of 25%.^[2] An extract with an anthocyanidin content of 25% actually contains about 37% anthocyanosides due to the conjugation of the anthocyanidin with a glycoside. (For analytical purposes, the

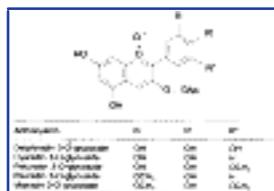

Figure 118-1 Structures of *V. myrtillus* anthocyanins^[2] Glyc. = arabinoside, glucoside or galactoside

anthocyanosides content should always be expressed in terms of anthocyanidin.) Only very small amounts of free anthocyanidins exist in nature and in *V. myrtillus* extracts.

HISTORY AND FOLK USE

Bilberries have, of course, been used as food and for their high nutritive value. Medicinally, they have been utilized in the treatment of scurvy and urinary complaints (including infection and stones).^[1] The dried berries have been used primarily for their astringent qualities in the treatment of diarrhea and dysentery. Decoctions of the leaves have been used in the treatment of diabetes.^[1]

PHARMACOLOGY

The pharmacology of *Vaccinium myrtillus* is discussed almost entirely in relationship to its anthocyanoside content, as research has focused primarily on the anthocyanosides.

Collagen-stabilizing action

Anthocyanosides possess significant collagen-stabilizing action.^{[4] [5] [6] [7] [8] [9] [10]} Collagen, the most abundant protein of the body, is responsible for maintaining the integrity of “ground substance” as well as tendons, ligaments, and cartilage. Collagen is destroyed during the inflammatory processes that occur in rheumatoid arthritis, periodontal disease, and other inflammatory conditions involving bones, joints, cartilage, and other connective tissue.

Anthocyanidins, proanthocyanidins and other flavonoids are remarkable in their ability to prevent collagen destruction. The anthocyanidins in *Vaccinium myrtillus* extracts have been shown to affect collagen metabolism in several ways:

- Anthocyanosides cross-link collagen fibers, resulting in strengthening of the natural cross-linking of collagen that forms the collagen matrix of connective tissue (ground substance, cartilage, tendon, etc.).^{[4] [5] [6] [7] [8]}
- Anthocyanosides prevent free radical damage with their potent antioxidant and free radical scavenging action.^{[4] [5] [6] [7] [9]}
- Anthocyanosides inhibit enzymatic cleavage of collagen by enzymes secreted by leukocytes during inflammation.^{[4] [5] [6] [8] [9] [10]}
- Anthocyanosides and other flavonoid components of *V. myrtillus* prevent the release and synthesis of compounds that promote inflammation, such as histamine, serine proteases, prostaglandins, and leukotrienes.^{[4] [5] [6] [11] [12]}
- Anthocyanosides promote mucopolysaccharide and collagen biosynthesis and stimulate reticulation of collagen fibrils.^{[13] [14] [15]}

Normalization of capillary permeability

Anthocyanosides have strong “vitamin P” activity.^[4] Included in their effects are an ability to increase intracellular vitamin C levels and to decrease capillary permeability and fragility.^{[4] [5] [6]} Their effect in reducing capillary fragility and permeability is roughly twice that of rutin, in both intensity and duration of action.^[16]

Vaccinium myrtillus extracts have been widely used in Europe in the treatment of various arterial, venous, and capillary disorders. Clinical studies have demonstrated a positive effect in the treatment of:^{[17] [18] [19] [20] [21] [22]}

- capillary fragility
- blood purpuras
- various encephalic circulation disturbances (similar to *Ginkgo biloba*)
- venous insufficiency
- varicose veins
- microscopic hematuria caused by diffused and kidney capillary fragility.

V. myrtillus's efficacy in the treatment of a variety of venous disorders relates to the ability of anthocyanosides to protect altered veins (postphlebotic veins as well as varicose veins) via two mechanisms:^[15]

- increasing the endothelium barrier-effect through stabilization of the membrane phospholipids
- increasing the biosynthesis of the acid mucopolysaccharides of the connective ground substance, thus restoring the altered mucopolysaccharide pericapillary sheath.

This latter effect leads to a marked increase in newly formed capillaries and collagen fibrils.

One interesting effect of the normalization of collagen structures and capillaries is the demonstration that anthocyanosides from *Vaccinium myrtillus* decrease the permeability

of the blood–brain barrier. ^[8] ^[23] Increased

blood–brain permeability has been linked to autoimmune diseases of the central nervous system, schizophrenia, “cerebral allergies”, and a variety of other CNS disorders. Presumably, the anthocyanosides inhibit both enzymatic and non-enzymatic degradation of the basement membrane collagen of brain capillaries, thus helping to maintain or restore the brain’s protection from drugs, pollutants, naturally occurring degradation products, and other cerebral toxins. ^[7] ^[8] ^[9] ^[10] ^[23]

Another recent study further demonstrates the remarkable efficacy of bilberry in protecting and strengthening the capillaries and microcirculation. In this study, the effects of anthocyanidins on hamster cheek microcirculation were investigated after ischemia and reperfusion. The treated group had decreased adherence of leukocytes to the venules after reperfusion, resulting in prevention of the markedly increased capillary permeability seen in the placebo group. ^[24]

Anti-aggregation effect on platelets

Anthocyanosides, like many other flavonoids, have been shown to possess significant anti-aggregation effects on platelets. ^[25] ^[26] ^[27] Their action in vivo appears to be direct anti-aggregation effects on the platelets and an indirect effect via prostacyclin-like action. ^[25] ^[26] ^[27] Prostacyclin (PGI₂) is a potent stimulator of adenylyl cyclase, the enzyme which catalyzes the production of cAMP from ATP. cAMP prevents platelets from aggregating and adhering to the endothelial surface.

Smooth muscle relaxing activity

Anthocyanoside extracts have demonstrated significant vascular smooth muscle-relaxing effects in a variety of experimental models. ^[28] ^[29] ^[30] The clinical application of this research may be in the treatment of dysmenorrhea, for which a preliminary study has demonstrated positive effects. ^[31]

CLINICAL APPLICATIONS

The primary clinical application of bilberry extracts has been in the prevention and treatment of a diverse group of disorders of the eye and vision. However, the same mechanisms of action which benefit the eye are of value to other health problems, especially those involving capillary dysfunction or inflammation.

Ophthalmological applications

Night vision

Perhaps the most significant clinical applications for *Vaccinium myrtillus* extracts are in the field of ophthalmology. Interest in *V. myrtillus* anthocyanosides was first aroused when it was observed that the administration of bilberry extracts to healthy subjects resulted in improved night-time visual acuity, quicker adjustment to darkness, and faster restoration of visual acuity after exposure to glare.^[32] ^[33]

Further studies confirmed these results.^[34] ^[35] ^[36] ^[37] Results were most impressive in individuals with pigmentary retinitis and hemeralopia. (Hemeralopia refers to “day blindness” or an inability to see as distinctly in bright light as in dim light.)

It appears that, in addition to their effect on capillaries, *V. myrtillus* anthocyanosides have an affinity for the pigmented epithelium of the retina, which composes the optical or functional part of the retina.^[38] This is consistent with several of the clinical effects observed.

Anthocyanoside extracts of *V. myrtillus* appear to be of great value in both poor night vision and poor day vision.

Glaucoma

Vaccinium myrtillus may play a significant role in the prevention and treatment of glaucoma via its effect on collagen structures in the eye. In the eye, collagen provides tensile strength and integrity to the tissues, i.e. cornea, sclera, lamina cribosa, trabecular meshwork, vitreous, etc.

Morphological changes in the collagen of the eye precede clinically detectable abnormalities. These changes may result in elevated intraocular pressure (IOP) readings or, perhaps more significantly, the progression of peripheral vision loss. Changes in collagen structure would explain why there is:

- similar peripheral vision loss in patients with normal and elevated IOP
- cupping of the optic disc even at low IOP levels
- no apparent anatomical reason for decreased aqueous outflow (see [Ch. 153](#) for complete discussion and references).

Therefore, primary prevention of glaucoma involves maintaining ground substance and collagen framework integrity. It appears the prevention of collagen matrix breakdown is important here, as it is in other conditions involving collagen abnormalities, i.e. atherosclerosis, rheumatoid arthritis, and periodontal disease.

Vaccinium myrtillus consumption may offer significant protection against the development of glaucoma, due to its collagen-enhancing actions. In addition, anthocyanosides may be of benefit in the treatment of chronic glaucoma, as rutin has been demonstrated to lower IOP when used as an adjunct in patients unresponsive to

miotics alone.^[39] *V. myrtillus* anthocyanosides are, in general, much more biologically active than rutin.^[16]

Cataracts and retinal degeneration

Vaccinium myrtillus anthocyanosides may offer significant protection against the development of retinal (macular) degeneration and cataracts, particularly diabetic retinopathy and cataracts. Both the rate of retinal degeneration and the occurrence of cataracts in rats can be retarded by changing their diet from a commercial laboratory chow to a “well-defined diet”.^[40] ^[41] Preliminary research suggests that flavonoid components in the well-defined diets may be responsible for the protective effects against cataracts and retinal degeneration.^[42] Limited research has shown that, when combined with vitamin E, bilberry significantly slowed the progression of senile cataracts in humans.^[43]

Vaccinium myrtillus anthocyanoside extracts are widely used in Europe in the prevention of diabetic retinopathy.^[43] ^[44] ^[45] The positive effects noted in clinical trials may be due to improved capillary integrity as well as inhibition of sorbitol production (see [Ch. 147](#)). Flavonoids have been shown to be potent in vitro and in vivo inhibitors of sorbitol accumulation. In laboratory experiments they have been shown capable of inhibiting the development of diabetic cataracts.^[46] ^[47] ^[48]

Other clinical applications

Diabetes mellitus

A decoction of blueberry leaves has a long history of folk use in the treatment of diabetes. This use is supported by research, which has shown that oral administration reduces hyperglycemia in normal and depancreatized dogs, even when glucose is concurrently injected intravenously.^[45] ^[49]

The anthocyanoside myrtillin (3-glucoside of delphinidin) is apparently the most active hypoglycemic component of *V. myrtillus*. Upon injection, it is somewhat weaker than insulin, but it is also less toxic, even at 50 times the 1 g/day therapeutic dose. It is of interest to note that a single dose can produce beneficial effects lasting for several weeks.^[45]

The most important benefits from use of anthocyanosides in the treatment of diabetes, however, relate to their ability to improve collagen integrity and capillary permeability. Benefit also possibly derives from their ability to inhibit sorbitol accumulation, thus providing protection from the serious vascular and neurological sequelae of diabetes.

Vaccinium myrtillus anthocyanosides have also been shown to have a protective effect

on capillary fragility in diabetics and to reduce serum cholesterol and triglyceride levels in primary dyslipidemia.^[50]

Although studies in rabbits have not confirmed a cholesterol-lowering effect, the anthocyanosides significantly decrease the proliferation of the intima, extracellular matrix production, and calcium and lipid deposition found in the aorta of untreated atherosclerotic rabbits. Presumably, this is a result of increasing collagen cross-linking, thus diminishing the permeability in small, as well as in large, blood vessels.^[51]

Inflammatory joint disease

The effects of anthocyanosides on collagen structures and their potent antioxidant activity make *V. myrtillus* anthocyanoside extracts very useful in the treatment of a wide variety of inflammatory conditions, most notably rheumatoid arthritis. Bioflavonoids have been found to increase collagen synthesis and inhibit collagen catabolism in rats with adjuvant-induced arthritis (a chronic progressive polyarthritis with some similarities to rheumatoid arthritis).^[13]

Blueberries, like cherries, are particularly indicated in the treatment of gout, as their flavonoid components are able to reduce both uric acid levels and tissue destruction (see [Ch. 154](#)).^[52]

Microscopic hematuria

The effect of *V. myrtillus* in the reduction of microscopic hematuria may be reflective of its tissue distribution. Pharmacokinetic studies in rats have demonstrated an affinity for the skin and kidneys.^[53] Anthocyanosides' affinity for these tissues reflects the high concentration of collagen and mucopolysaccharides in the skin and kidneys and the fact that they are excreted via the kidneys.

DOSAGE

The standard dose for *V. myrtillus* is based on its anthocyanoside content, as calculated by its anthocyanidin percentage. Widely used pharmaceutical preparations in Europe are typically standardized for a 25% anthocyanidin content. Dosages are as follows:

- anthocyanosides (calculated as anthocyanidin): 20–40 mg three times/day
- *Vaccinium myrtillus* (25% extract): 80–160 mg three times/day
- fresh berries: 55–115 g three times/day.

TOXICOLOGY

Extensive toxicological investigation has demonstrated that *V. myrtillus* anthocyanoside extracts are devoid of toxic effects. Administration to rats of dosages as high as 400 mg/kg produces no apparent side-effects, and excess levels are quickly excreted

SUMMARY

Vaccinium myrtillus anthocyanosides exhibit significant pharmacological activity, particularly on collagen structures. Research has demonstrated a positive effect in the treatment of:

- capillary fragility
- blood purpuras
- various encephalic circulation disturbances
- venous insufficiency
- varicose veins
- microscopic hematuria caused by diffused and kidney capillary fragility
- poor night vision
- hemeralopia
- diabetic retinopathy.

Experimental studies indicate that anthocyanoside should also be useful in most inflammatory or degenerative conditions involving connective tissues (e.g. osteoarthritis, gout, rheumatoid arthritis, periodontal disease, etc.), glaucoma, diabetes, cataracts, retinal degeneration, and schizophrenia.

Chapter 119 - *Valeriana officinalis* (valerian)

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

Valeriana officinalis (family: Valerianaceae)
Common names: valerian, all heal

GENERAL DESCRIPTION

Valerian is a perennial plant native to North America and Europe. The yellow-brown tuberous rootstock produces a flowering stem 2–4 feet high. The stem is round, but grooved and hollow, with leaves arranged in pairs. The small rose-colored flowers are in bloom from June to September. The rootstock is the portion used medicinally.

CHEMICAL COMPOSITION

The important active compounds of valerian are the valepotriates (iridoid molecules; see [Fig. 119.1](#)) and valerenic acid. These compounds are found exclusively in valerian. Originally it was thought that just the valepotriates were responsible for valerian's sedative effects, but recently an aqueous extract of valerian has also been shown to have a sedative effect. Since the valepotriates are not soluble in water, it was concluded that valerenic acid also possesses sedative action and is the chemical factor responsible for the sedative effect noted in human clinical trials with aqueous extracts of valerian root (see below).

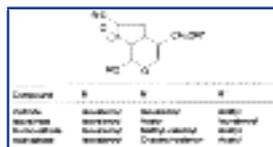

Figure 119-1 Valepotriates in *Valeriana officinalis*.

Moreover, because the safety of valepotriates was questioned after studies demonstrated mutagenicity, most commercial extracts feature water-soluble extracts standardized for valerenic acids.^{[1] [2] [3]}

Other components of valerian include a volatile oil (0.5–2%), choline (3%), flavonoids, sterols, and several alkaloids (actinidine, valerianine, valerine, and chatinine).^[4]

HISTORY AND FOLK USE

Valerian's primary traditional use has been as a sedative for the relief of insomnia, anxiety, and conditions associated with pain. Specific conditions for which it was used include migraine, insomnia, hysteria, fatigue, intestinal cramps, and other nervous conditions.

PHARMACOLOGY

Valerian has demonstrated a number of pharmacological effects including:^{[4] [5] [6] [7]}

- normalizing of the central nervous system (it acts as a sedative in states of agitation and a stimulant in cases of extreme fatigue)
- lowering of blood pressure
- enhancement of the flow of bile (choleric effect)
- relaxing intestinal muscles
- antitumor and antibiotic activity.

Its prime pharmacological effect, however, is consistent with its historical use as a sedative.

A recent pharmacological study indicated that both valepotriates and valerenic acid are capable of binding to GABA receptors in a similar fashion to benzodiazepines.^[8] However, valerian does not appear to act in a similar fashion, in that side-effects such as impaired mental function, morning hangover, and dependency have not been reported with valerian. In addition, valerian compounds which do not bind to GABA receptors have also been shown to produce sedative effects.

CLINICAL APPLICATIONS

The primary clinical application for valerian is as a sedative in the treatment of insomnia. It can also be used in the treatment of stress and anxiety.

Insomnia

Several recent clinical studies have substantiated valerian's ability to improve sleep quality and relieve insomnia.^{[9] [10] [11] [12] [13]}

The first studies were performed on subjects who did not have insomnia. In the first double-blind study involving 128 subjects, an extract of valerian root improved subjective ratings for sleep quality and sleep latency (the time required to go to sleep) but left no "hangover" the next morning.^[9]

In another study, the effects of valerian on sleep were studied in two groups of healthy young subjects.^[10] One group slept at home, the other in a sleep laboratory. Sleep was evaluated on the basis of questionnaires, self-rating scales and night-time motor activity. Under home conditions, both doses of an aqueous valerian extract (450 and 900 mg) reduced perceived sleep latency and wake time after sleep onset. Night-time motor activity was enhanced in the middle third of the night and reduced in the last third. The data suggest a dose-dependent effect. In the sleep laboratory, where only the higher dose of valerian was tested, no significant differences from placebo were obtained. However, the direction of the changes in the subjective and objective measures of sleep latency and wake time after sleep onset, as well as in night-time motor activity, corresponded to that observed under home conditions. There was no evidence for a change in sleep stages and EEG spectra. The results indicate that the aqueous valerian extract exerts a mild sedative effect.

While these two studies demonstrated that valerian could improve sleep quality in normal subjects, they failed to answer the question whether valerian could improve sleep patterns in people suffering from insomnia. In a follow-up to these two preliminary studies, valerian extract was shown to significantly reduce sleep latency, improve sleep quality, and reduce night-time awakenings in sufferers of insomnia.^[11] This study, performed under strict laboratory conditions, demonstrated that valerian is as effective in reducing sleep latency as small doses of barbiturates or benzodiazepines. However, while these latter compounds also increase morning sleepiness, valerian usually reduces morning sleepiness.

In another study of insomniacs, subjects received either a valerian preparation placebo.^[12] Compared with the placebo, valerian showed a significant effect, with 44% reporting perfect sleep and 89% reporting improved sleep.

And finally, in another double-blind study of insomniacs, 20 subjects received a combination of valerian root (160 mg) and *Melissa officinalis* (80 mg), a benzodiazepine (triazolam 0.125), or placebo.^[13] In the insomniac group, the valerian preparation showed an effect comparable to that of the benzodiazepine, as well as an increase in deep sleep stages 3 and 4. The valerian preparation did not, however, cause daytime sedation and there was no evidence of diminished concentration based on the Concentration Performance Test or impairment of physical performance.

DOSAGE

As a mild sedative, valerian may be taken at the following dosages 30–45 minutes before retiring:

- dried root (or as tea): 1–2 g
 - tincture (1:5): 4–6 ml (1–1.5 tsp)
-

999

- fluid extract (1:1): 1–2 ml (0.5–1 tsp)
- solid (dry powdered) extract (4:1): 250–500 mg
- valerian extract (1.0–1.5% valtrate or 0.5% valerenic acid): 150–300 mg.

For the rare patient with increased morning sleepiness, reducing the dosage will eliminate the problem. For best results, eliminate dietary factors such as caffeine and alcohol which disrupt sleep (see [Ch. 164](#)).

TOXICITY

Valerian is generally regarded as safe and is approved for food use by the United States Food and Drug Administration.^[14] A major concern for any sedative or anti-anxiety medication is its potential to affect a person's ability to drive or operate potentially dangerous machinery. A randomized, placebo-controlled, double-blind study evaluated the impact of a valerian/lemon balm preparation on psychomotor and mental performance tests.^[15] No impact was found on reaction time, concentration or attentiveness.

One case of valerian overdose has been reported in the literature.^[16] The patient presented with mild symptoms, all of which disappeared within 24 hours after taking an overdose of approximately 20 times the recommended therapeutic dose.

Since the safety of the valepotriates have been questioned, until there is better information, the best choice is to use water-soluble extracts standardized for valerenic acid content.

Chapter 120 - *Viscum album* (European mistletoe)

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

Viscum album L. (family: Loranthaceae)
Common names: European mistletoe, all-heal, birdlime, devil's fuge

GENERAL DESCRIPTION

Viscum album or European mistletoe is an evergreen, semi-parasitic plant found on the branches of deciduous trees in Europe and northern Asia. The roots of the plant penetrate through the bark into the wood of the host tree. The green branches are 1–2 feet long and form pendent bushes with leaves that are opposite, leathery, yellow-green and narrowly obovate. Inconspicuous pale yellow or green flowers appear from March to May, the female developing into sticky white berries which ripen from September to November.^{[1] [2]}

Viscum is most commonly seen on old apple, ash, and hawthorn trees. Traditionally, mistletoe from oak has been the most widely used, although it does not grow as well on oak as the previously mentioned trees.^{[1] [2]}

CHEMICAL COMPOSITION

Viscum album contains a variety of pharmacologically active substances including alkaloids, polysaccharides, phenylpropanes, lignins, lectins, and viscotoxins.^{[3] [4] [5] [6] [7] [8] [9] [10]} Specific compounds found in *viscum* include: ^{[2] [5] [6] [10]}

- a wide range of carbohydrates, including simple sugars as well as polysaccharides
- phenolic compounds such as flavonoids, caffeic acid, syringin, and eleutherosides
- sterols, including beta-sitosterol, stigmasterol, and triterpenes
- various amino acids as well as vasoactive amines, including tyramine, phenylethylamine, and histamine

- fatty acids such as linoleic, palmitic, and oleic acids.

The alkaloids isolated from *viscum* appear to be related to those found in the host plant.^[3] ^[4] For example,

1002

mistletoes growing on solanaceae shrubs contain nicotine alkaloids like hyoscine, anabasine, and isopelletierine; cardiac glycosides have been found in mistletoe growing on *Nerium oleander*; strychnine has been found in mistletoe growing on *Strychnos* sp.; and caffeine in mistletoe growing on coffee plants.

Since pharmacologically active compounds appear to be concentrated within the mistletoe, different host trees, providing diverse chemical constituents, could be used for different therapeutic action.

Also of importance is the fact that the proteins/lectins are present only in aqueous extracts, indicating that therapeutic activity would differ from the alcoholic/ aqueous extracts. The alcoholic/aqueous extracts also demonstrate considerably less toxicity.

HISTORY AND FOLK USE

Mistletoe was held in great reverence by the Druids who, dressed in white robes, would search for the sacred plant. When some was discovered, a great ceremony would ensue, culminating in the mistletoe's separation from the oak with a golden knife. The Druids believed that mistletoe protected them from all evil, and that the oaks on which it was seen growing were to be respected because of the wonderful cures which the priests were able to produce with it.^[1]

Mistletoe's use has been recorded in the Middle East, Africa, India, and Japan, and it was mentioned as an anti-cancer drug by Pliny, Dioscorides, and Galen.^[3]

In 1720, an English physician, Sir John Colbatch, extolled the virtues of *viscum* in a pamphlet entitled *The treatment of epilepsy by mistletoe*. For many years, mistletoe was used in the treatment of a variety of nervous system disorders, including convulsions, delirium, hysteria, neuralgia, and nervous debility.^[1] ^[3] It has been used in naturopathic medicine in the treatment of hypertension and vascular disorders of the uterus, bladder, and intestines.

Probably due to its potential toxicity, *viscum* use appeared to fall into some disrepute shortly after Colbatch's work. For many years it was used only in external preparations for the treatment of dermatitis. Then in 1906 a study demonstrating *viscum*'s hypotensive effect in animals and humans was published. This appears to have restored *viscum*'s medical prestige, initially in France and eventually throughout

Europe.^[3]

PHARMACOLOGY

Viscum album exhibits diverse pharmacological actions. The herb and various extracts have demonstrated the following activities:

- hypotensive
- vasodilating
- cardiac depressant
- sedative
- antispasmodic
- immunostimulatory
- anti-neoplastic.

It is interesting to note that purified mistletoe lectins are, in general, not as active in experimental studies as crude preparations.^[21]^[22] Presumably, there are a number of compounds in viscum which act synergistically. It has also been proposed that alkaloidal components are responsible for the maintenance of lectin structure and activity.^[5] During isolation and purification procedures, alkaloidal linkages are cleaved from the lectins, resulting in a loss of specificity for target molecules. Unfermented viscum preparations typically demonstrate a greater direct cytotoxicity to tumor cells due to higher concentrations of the viscotoxin ML I.^[14]^[23]^[24]

Cardiovascular effects

Viscum has exhibited a variety of effects on components of the cardiovascular system.^[3]^[11] In particular, viscum has repeatedly demonstrated hypotensive action in animal studies. The mechanism of action for its hypotensive effect is still not entirely clear, and no recent investigations have been published. Viscum has been shown to inhibit the excitability of the vasomotor center in the medulla oblongata and to possess cholinomimetic activity.^[11]

The hypotensive activity may be dependent on the form in which the mistletoe is administered and the host tree from which it was collected. Studies indicate that aqueous extracts are more effective; the highest hypotensive activity was demonstrated by a macerate of leaves of mistletoe parasitizing on willow and gathered in January.^[11]

Viscum's non-protein components, e.g. flavonoids, phenol carboxylic acids, phenylpropanes, and lignins, have been shown to possess hypotensive action. Alcoholic solutions (tinctures and fluid extracts) contain these compounds, but not viscotoxins or lectins. However, as stated above, aqueous extracts appear to be more effective.

Currently, in Europe, several viscum preparations for hypertension exist. In fact, in Britain alone over 150 different mistletoe preparations can be found in the marketplace.^[3] These preparations typically have small amounts of viscum in combination with other botanicals with hypotensive action, e.g. garlic, *Crataegus*

oxyacantha, and *Tilia platyphyllos*.

Anti-neoplastic and immunostimulatory effects

Viscum preparations have been used clinically in Europe for the treatment of cancer since 1926 when Iscador, a

1003

fermented product made from the crude pressed juice, was introduced as an immunotherapeutic agent for cancer. This work was carried out under the direction of Rudolph Steiner. Since that time, numerous studies have shown that Iscador, and other viscum preparations and components, are effective anti-neoplastic and immunostimulatory agents.^{[12] [13] [14] [15] [16] [17] [18] [19] [20] [21] [22] [23] [24] [25] [26] [27] [28] [29] [30] [31]}

Iscador and other fermented viscum preparations differ from non-fermented extracts in their greater effectiveness and their decreased toxicity.^[12] Specifically, the major viscotoxin, ML I, is not found in Iscador.^[13] It is thought, that fermentation transforms ML I to its A and B chains, which have important immunological properties.^[14] The A chain has mitogenic effects and the B chain stimulates macrophages and the release of lymphokines. In addition, there is a rapid decrease of lectin concentration during fermentation.

The pharmacological activity of Iscador has been shown to be due to its viscum components, rather than to other constituents such as lactobacilli, which possess adjuvant activity. The lectins have been clearly demonstrated to be the viscum components largely responsible for Iscador's adjuvant activity. Although in vitro unfermented plant juice has demonstrated a 10-fold greater cytotoxicity to tumor cells than Iscador, fermented Iscador contains a great number of substances which may act synergistically. In vivo studies in mice have demonstrated Iscador to be of greater adjuvant activity than purified mistletoe lectin, and without secondary toxic effects.^{[15] [16]}

Viscum's adjuvant activity is demonstrable in both delayed-type hypersensitivity and antibody responses of mice to sheep red blood cells.^{[15] [16]} Similar to other adjuvants (BCG, levamisole, muramyl dipeptide, bacterial and yeast components, etc.), Iscador is most effective when administered near the tumor, although systemic administration has also yielded positive results. Upon local administration, an inflammatory process ensues which promotes WBC infiltration and an encapsulation of the tumor.

The non-specific host defense factors stimulated by *Viscum album* include:

- enhanced macrophage phagocytic and cytotoxic activity^{[12] [16]}
- increased neutrophil production^[12]
- increased thymic weight and enhanced cortical thymocyte activity and proliferation^{[17] [19]}
- enhanced natural killer cell activity^{[12] [18] [20]}

- increased antibody-dependent, cell-mediated cytotoxicity.^{[12] [18]}

Iscador's effects on these immunological parameters have been confirmed in patients with cancer.^{[12] [18]}

Iscador's effect on stimulating the thymus gland has been demonstrated in several studies.^{[17] [19]} Its ability to induce hyperplasia of the thymic cortex and to accelerate the regeneration of hematopoietic cells following X-irradiation is much greater than any other agent re-ported to date.^[17] In addition, thymic lymphocytes became 29 times more responsive to concanavalin A as a result of Iscador administration.

In summary, *Viscum album* exhibits numerous cytotoxic, adjuvant, and immunostimulatory effects which indicate a therapeutic effect in human cancer. These effects have been confirmed in vivo against murine tumors, Lewis lung carcinoma, colon adenocarcinoma 38, and C3H mammary adenocarcinoma 16/C.^[4]

CLINICAL APPLICATIONS

Cancer

The only clinical application with any significant scientific documentation is the use of viscum preparations as adjuncts in cancer therapy. It must be pointed out that the route of the administration of viscum preparations used in published studies as adjuncts in cancer treatments is subcutaneous or intravenous. It is not known to what degree (if any) the effects noted for Iscador, as well as other preparations and viscum compounds, can be achieved with oral administration.

Early clinical investigations of viscum preparations, i.e. Iscador, were not very well documented. Due to the shortage of acceptable controlled clinical trials, the use of Iscador and other viscum preparations as a cancer treatment in Europe has remained controversial, even though positive effects with Iscador in the postoperative treatment of lung, breast, colon, and cervical carcinomas has been shown in several controlled studies.^[25] The problem is that the methodological criteria in these studies are quite poor. Until their benefits are better documented, at this time, mistletoe preparations appear most useful as adjuncts to standard therapy.

A new generation of mistletoe preparations standardized on mistletoe lectin I (e.g. Eurixor) is emerging. This greater standardization offers significant advantages. Mistletoe lectin I is a potent inducer of cytokines like interleukin 1, interleukin 6, and tumor necrosis factor. Its cytotoxic effects are also related to its ability to induce apoptosis (programmed cell death).^[26]

In one study, the effect of Eurixor was examined in 40 patients with advanced carcinoma of the breast. Along with standard chemotherapy (VEC regimen), 21 patients were assigned to receive mistletoe (treatment group) while 19 patients were given a placebo (control group).^[27] After the fourth cycle of chemotherapy, the treatment group had statistically significantly higher leukocyte levels ($P < 0.001$) compared with the

control group. The treatment group had an average white blood cell count of 3,000, while the control group had an average count

1004

of 1,000. Furthermore, the parameters of the quality of life and anxiety strain revealed significantly better values in the treatment group than in the control group. These results show that the adjuvant treatment with mistletoe extracts, in this case Eurixor, is a valuable addition to standard chemotherapy for advanced breast cancer patients. These results are quite important as advanced breast cancer carries with it a very poor prognosis. Similar results have been shown in advanced pancreatic cancer.^[28] These results in better designed studies are quite encouraging.

Clearly, additional investigations into the pharmacology of *Viscum album* are needed. Specifically, it must be determined whether the effects noted both in vitro and in vivo in animals, as well as in patients receiving injectable viscum preparations, can be attained by oral administration.

In addition, greater clarification is needed to determine optimal viscum preparations. What host tree should be selected for which condition? What is the optimal harvesting time? In what form should the viscum be administered – crude herb, aqueous or alcoholic extract, fermented or non-fermented?

Viscum is undoubtedly one of the most complex botanicals, yet, after examining currently available data, it can be said with much confidence that the future medicinal use of *Viscum album* is quite promising.

DOSAGE

The standard dose of *Viscum album*, based on the *British herbal pharmacopoeia*, is as follows:^[32]

- dried leaves: 2–6 g (or by infusion) three times/day
- tincture 1:5 (45% alcohol): 1–3 ml three times/day
- fluid extract 1:1 (25% alcohol): 0.5 ml three times/day
- dried aqueous extract 4:1: 100–250 mg three times/day.

TOXICITY

Viscum album possesses significant toxicity. Historically, the berries have been regarded as being considerably more toxic than the leaves and stems despite the fact they both contain similar toxic compounds. The reason the toxicity of the berries is considered to be greater probably stems from fatal poisonings of children resulting from ingestion of the berries.

Lethal doses of viscum lectins administered by various routes to mice produce two types of toxicity:

- a typical type characterized by death after 3–4 days with marasmus-like symptoms
- an atypical type characterized by immediate death from respiratory paralysis.^[19]

In mice, the LD₅₀ of the plant juice administered intraperitoneally is 32 mg (dry weight)/kg body weight.^[29]

The LD₅₀ values of orally administered *Viscum album* or extracts of *Viscum album* have not yet been determined. As stated earlier, alcohol-based extracts contain virtually no viscum proteins. This would imply significantly less toxicity with these preparations. However, this would also imply loss of activity, as much of the pharmacology of viscum relates to its protein content, especially immuno-enhancing activity.

It is interesting to note that the toxicity of Korean mistletoe, *Viscum album coloratum*, appears to be lower than that of European mistletoe.^{[30] [31]} This species has also demonstrated anti-cancer effects, but the effects appear to be due to highly cytotoxic alkaloids rather than to lectins.^{[5] [30]} Studies comparing Korean viscum extracts with European extracts, as well as their alkaloid components, have demonstrated that the Korean mistletoe has greater activity in inhibiting cancer cells. In addition, fresh Korean mistletoe extracts exhibited greater activity compared with fermented extracts.^{[5] [30]} In the future Korean mistletoe may prove to be superior to European mistletoe.

Chapter 121 - Vitamin A

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

INTRODUCTION

Vitamin A was the first fat-soluble vitamin to be recognized. Although identified as a necessary growth factor in 1913, it was not chemically characterized until 1930. The initial discovery of vitamin A was made almost simultaneously by two groups of research workers, McCollum & Davis at the University of Wisconsin, and Osborne & Mendel at Yale University. They found that young animals fed a diet deficient in natural fats became very unhealthy, as evidenced by their inability to grow and poor immune function. These researchers also noted that the animals' eyes would become severely inflamed and infected on the restricted diet and that this could be quickly relieved by the addition to the diet of either butterfat or cod liver oil. Once known as the "anti-infective vitamin", vitamin A has recently regained recognition as a major determinant of immune status.

NOMENCLATURE

When isolated in its pure form, vitamin A is a pure, lipid-soluble, yellow crystal with a condensed formula of $C_{20}H_{29}OH$. Vitamin A is termed retinol, signifying that it is an alcohol that is intricately involved in the function of the retina of the eye. All-*trans* retinol is found in nature primarily as long-chain retinyl esters. The aldehyde form of all-*trans* retinol is commonly designated retinaldehyde or retinal, while the acidic form is termed retinoic acid. It has been suggested that retinol serves only as a precursor to these two active forms of vitamin A – retinal being primarily involved with vision and reproduction, while retinoic acid is important in other somatic functions, such as growth and differentiation.

Synthetic derivatives of retinoic acid have been developed to treat many dermatological conditions and, more recently, certain forms of cancer. Isotretinoin (13-*cis* retinoic acid) is used in treating severe cystic acne and disorders of keratinization, such as Darier's

disease and lamellar ichthyosis. Etretinate, an aromatic derivative

1008

of retinoic acid, has no appreciable activity against acne, but is claimed to be more potent than isotretinoin in the treatment of psoriasiform diseases. These compounds, however, are not without side-effects.^{[1] [2]}

RECOMMENDED DIETARY ALLOWANCE (RDA)

Vitamin A was originally measured in international units, with 1 IU being defined as 0.3 mcg of crystalline all-*trans* retinol or 0.6 mcg beta-carotene. In 1967, an FAO/WHO Expert Committee recommended that vitamin A activity be referred to in terms of retinol equivalents rather than in IU, with 1 mcg of retinol being equivalent to 1 retinol equivalent (RE). The amount of beta-carotene required for 1 RE is 6 mcg, while the amount required for other provitamin A carotenoids is 12 mcg. In 1980, The Food and Nutrition Board of the NRC/NAS adopted this recommendation, and the 1980 RDA for vitamin A is stated in mcg and RE. For the adult male the RDA is set at 1000 RE (750 as retinol and 250 as beta-carotene, 5000 IU), while the RDA for women is lower at 800 RE (4000 IU). Children need 400–1000 RE (2000–5000 IU), increasing from infancy to 14 years.^{[1] [2] [3]} The RDAs for different age groups are shown in [Table 121.1](#).

DIETARY SOURCES

The most concentrated sources of preformed vitamin A are liver, kidney, butter, whole milk, and fortified skim milk, while the leading sources of provitamin A are dark green leafy vegetables (collards and spinach), and yellow-orange vegetables (carrots, sweet potatoes, yams, and squash) (see [Table 121.2](#)). Ingestion of excessive amounts of liver, i.e. 2.7–11 kg/week, has been reported to cause hypervitaminosis A.^[4]

DEFICIENCY

Vitamin A deficiency may be due to inadequate dietary intake (primary deficiency) or some secondary factor that interferes with the absorption, storage, or transportation

TABLE 121-1 -- Recommended dietary allowances

| Group | Retinol equivalents | International Units |
|-----------|---------------------|---------------------|
| Infants | | |
| 0–1 year | 375 | 1,875 |
| Children | | |
| 1–3 years | 400 | 2,000 |
| 4–6 years | 500 | 2,500 |

| | | |
|-------------------------|-------|-------|
| 7–10 years | 700 | 3,500 |
| Young adults and adults | | |
| Males 11+ years | 1,000 | 5,000 |
| Females 11+ years | 800 | 4,000 |
| Pregnancy | 800 | 4,000 |

TABLE 121-2 -- Food sources of Vitamin A^[4]

| Food | Portion size | IU/portion |
|-----------------------|---------------------|-------------------|
| <i>Meats</i> | | |
| Beef liver, fried | 100 g | 50,375 |
| Calf liver, cooked | 100 g | 26,872 |
| Chicken liver, cooked | 2 livers | 25,760 |
| <i>Vegetables</i> | | |
| Sweet potatoes, baked | 1 medium | 14,600 |
| Carrots, raw | 1 large | 11,000 |
| Spinach, raw | 100 g | 8,100 |
| Carrots, cooked | ½ cup | 8,000 |
| Pumpkin, cooked | ½ cup | 8,000 |
| Spinach, cooked | ½ cup | 7,300 |
| Collard greens | ½ cup | 5,400 |
| Broccoli, cooked | ½ cup | 1,900 |
| <i>Fruits</i> | | |
| Watermelon | 1/16 melon | 5,310 |
| Cantaloupe | ¼ melon | 3,400 |
| Apricots, dried | 4 halves | 2,275 |
| Apricots, raw | 2–3 medium | 2,700 |
| Nectarines, raw | 1 medium | 1,650 |

of vitamin A. Some factors known to induce a vitamin A deficiency include:

- malabsorption due to bile acid or pancreatic insufficiency
- protein-energy malnutrition
- liver disease
- zinc deficiency

- abetalipoproteinemia.

Immune system effects

Immune system abnormalities associated with a vitamin A deficiency include impaired ability to mount an effective antibody response, decreased levels of helper T-cells, and alterations in the mucosal linings of the respiratory and gastrointestinal tract. Vitamin A-deficient individuals are more susceptible to infectious diseases and have higher mortality rates. It appears that while a vitamin A deficiency may predispose an individual to an infection, during the course of an infection vitamin A stores are severely depleted. Thus, a vicious cycle ensues. Infectious conditions associated with vitamin A deficiency include the measles, chicken pox, respiratory syncytial virus (RSV), AIDS, and pneumonia.

Other effects

Prolonged vitamin A deficiency results in the characteristic signs of follicular hyperkeratosis (build-up of cellular debris in the hair follicles giving the skin a goose bump appearance, which occurs most often at the back of the upper arm), night blindness, and increased rate of infection. As the condition worsens, the mucous

1009

membranes of the respiratory tract, gastrointestinal tract, and genitourinary tract also become affected, and the classic eye disease known as xerophthalmia due to vitamin A deficiency ensues. Even a mild vitamin A deficiency is associated with a significant increase in mortality. This is extremely significant, as vitamin A deficiency is particularly widespread in developing countries, especially in Asia where as many as 10 million children develop xerophthalmia every year.^{[1] [2] [5]}

Xerophthalmia

The term xerophthalmia is generally used to cover all the ocular manifestations of vitamin A deficiency. Blindness is one of the most serious consequences of vitamin A deficiency. Although it rarely occurs in the United States, it is the major preventable cause of blindness in Asia. The xerophthalmia of vitamin A deficiency is staged, as shown in [Table 121.3](#) .

In an effort to prevent vitamin A deficiency in underdeveloped countries, large prophylactic doses (200,000 IU) are given by the World Health Organization to children every 6 months.

Determination of deficiency

The rapid dark adaptation test (see [Ch. 26](#)) is perhaps the most sensitive of the

currently available tests designed to determine vitamin A deficiency. Measurement of serum retinol levels is usually not useful, since they may not become lowered until marked deficiency occurs. Deficiency in the United States and other developed countries is usually secondary to malabsorption, liver disease, or proteinuria.^{[1] [2]}

METABOLISM

Absorption

A variety of factors are known to influence the absorption efficacy of vitamin A and carotenoids. Although

TABLE 121-3 -- The staging of the xerophthalmia

| Stage | Diagnosis | Signs and symptoms |
|-------|------------------------|---|
| XO | Night blindness | Poor dark adaptation |
| X1A | Xerosis of conjunctiva | Dryness with “lackluster” appearance, thickening, wrinkling, and diffuse pigmentation of conjunctiva |
| X1B | Bitot’s spots | Usually triangular-shaped collections of desquamated keratinized epithelial cells and mucus |
| X2 | Xerosis of cornea | Dryness of cornea leading to keratinization and a hazy milky appearance |
| X3 | Keratomalacia | Ulceration, distortion, and softening of the cornea with eventual perforation and iris prolapse and infection |

retinol does not require bile acids to facilitate absorption, carotenoids do. Other factors that affect vitamin A and carotenoid absorption include:

- the presence of fat, protein, and antioxidants in the food
- the presence of bile and a normal complement of pancreatic enzymes in the intestinal lumen
- the integrity of the mucosal cells.

The absorption efficiency of dietary vitamin A is usually quite high (80–90%), with only a slight reduction in efficiency at high doses. In contrast, beta-carotene’s absorption efficiency is much lower (40–60%), and it decreases rapidly with increasing dosage.^{[1] [2]} Carotene supplements are better absorbed than the carotenes from foods.^[6]

Transformation in the intestinal mucosa

The majority of absorbed retinol is esterified with palmitic acid or another free fatty acid within the intestinal mucosal cells. It is then incorporated, along with triglycerides, phospholipids, and cholesterol esters, into chylomicra. The chylomicron is transported through the lymphatic channels into the general circulation and eventually is removed

from the circulation by the liver.

Transport, storage and excretion

Upon reaching the liver, vitamin A is stored primarily in special perisinusoidal lipocytes (Ito cells), while the hepatocytes contain only a minor fraction of the total vitamin A stored in the liver. Although small amounts of vitamin A are found in most tissues (see [Table 121.4](#)), more than 90% of the total body vitamin A content is stored in the liver. It is stored as a lipoglycoprotein complex consisting of 96% retinyl esters and 4% unesterified retinol. The retinyl esters are hydrolyzed by a tightly bound retinyl ester hydrolase which transfers the released all-*trans* retinol to intracellular retinol binding protein (RBP). The bound retinol is then processed through the Golgi apparatus and secreted into the plasma where it forms a reversible 1:1 molar complex with prealbumin.^{[1] [2]}

TABLE 121-4 -- Distribution of vitamin A in some human tissues (mcg/kg)

| Tissue | Vitamin A |
|----------|-------------|
| Adrenal | 10.4 ± 7.1 |
| Liver | 149 ± 132 |
| Testis | 1.14 ± 1.23 |
| Fat | 1.46 ± 1.55 |
| Pancreas | 0.52 ± 0.28 |
| Spleen | 0.89 ± 0.88 |
| Lung | 0.91 ± 1.89 |
| Thyroid | 0.43 ± 0.33 |

Adequate dietary protein and zinc are necessary for proper retinal mobilization. The half-lives of RBP and prealbumin are less than 12 hours, making them particularly likely to be deficient during protein-calorie malnutrition or other situations in which protein metabolism is abnormal. A zinc or vitamin E deficiency will also severely impair vitamin A metabolism, as these two nutrients function synergistically in many physiological processes of vitamin A metabolism (absorption, transport, and mobilization in particular).^[2]

Retinol is transferred into the cell after RBP binds to a cell surface receptor. The retinol is then quickly bound by cellular retinol binding protein (CRBP) in the cell cytosol.

Retinoic acid is metabolized differently from retinol. It is absorbed through the portal system and transported in the plasma bound to albumin. It does not accumulate in the

liver or other tissues in any appreciable amounts. It is metabolized quite rapidly to more polar oxygenated compounds. Intracellularly, it is bound to the cellular retinoic acid binding protein (CRABP).^[1]

Vitamin A metabolites are excreted mainly through the feces (via the bile) and the urine. During periods of deficiency there appears to be an adaptation in utilization, as evidenced by a reduction in the rate of vitamin A catabolism.^[1] ^[2]

PHYSIOLOGICAL ROLES OF VITAMIN A

Vision

The best understood physiological role of vitamin A is its effects on the visual system. The human retina has four kinds of vitamin A-containing photopigments:

- rhodopsin, present in the rods (maximum absorption at 498 nm)
- three iodopsins, present in the cones
 - blue cones (maximum absorption 420 nm)
 - green cones (maximum absorption 534 nm)
 - red cones (maximum absorption 563 nm).

The vitamin A form found in these pigments is the 11-*cis* isomer of vitamin A aldehyde (retinal). When a photon of light strikes the dark-adapted retina, the 11-*cis* configuration is converted to the all-*trans* form of the retinaldehyde and split from the rhodopsin molecule to yield opsin and all-*trans* retinol. This leads to a change in membrane potential and subsequent visual excitation. During light adaptation, as the visual processes are largely dependent on the cone cells, the released all-*trans* retinal or retinol from the rod cells is transported to pigment epithelial cells and stored as retinyl palmitate. During dark adaptation these processes are reversed, and, in addition, the retinal is isomerized to the 11-*cis* form. As the rod cells are particularly sensitive to vitamin A deficiency, night blindness or poor dark adaptation is an early consequence of vitamin A deficiency (see [Ch. 26](#)).^[1] ^[2]

Growth and development

Vitamin A is believed to affect growth and development by its necessary role in the synthesis of many glycoproteins (e.g. mucus), some of which may control cellular differentiation, and by its function as CRBP in controlling gene expression.^[1] ^[2]

The adhesion between cells is apparently related to glycoprotein synthesis, which is markedly depressed in vitamin A deficiency. Consequently, during deficiency there is a loss of normal stimuli for cellular growth and differentiation. CRBP is transferred directly into the nucleus and may function in a fashion similar to some of the steroid hormones. The effects of a vitamin A deficiency most readily seen at the cellular level are in those

differentiating tissues that have a rapid turnover rate, i.e. epithelial cells of the oral cavity, respiratory tract, urinary tract, and ducts of secretory glands.^{[1] [2]}

Epithelial tissue development and maintenance

The role of vitamin A and carotenoids in the development and maintenance of epithelial tissue cannot be overstated. Vitamin A status determines whether mucin or keratin is synthesized in epidermal cells – the presence of adequate vitamin A results in mucin production, while a lack results in hyperkeratinization of the skin, cornea, upper respiratory tract, and genitourinary tract. Mucopolysaccharide synthesis also appears to be dependent on adequate vitamin A status.^{[1] [2] [8]}

Reproduction

The requirement of vitamin A for reproductive functions in higher animals has been known since 1922.^[2] Beta-carotene has also been reported to have a specific effect in fertility distinct from its role as a precursor to vitamin A.^{[9] [10] [11]} In bovine nutritional studies, cows fed beta-carotene-deficient diets exhibited delayed ovulation and an increase in the number of follicular and luteal cysts.^{[9] [10]} The corpus luteum has the highest concentration of beta-carotene of any organ measured.^[11] The carotene cleavage activity changes with the ovulation cycle, with the highest activity occurring during the midovulation stage. It has been speculated that a proper ratio of carotene to retinol must be maintained to ensure proper corpus luteum function.

As the corpus luteum produces progesterone, inadequate corpus luteum function could have significant deleterious effects. Inadequate corpus luteum secretory function is one of the characteristic features of infertile

1011

and/or irregular menstrual cycles.^[12] Furthermore, an increased estrogen to progesterone ratio has been implicated in a variety of clinical conditions, including ovarian cysts, premenstrual tension syndrome, fibrocystic breast disease, and breast cancer.^[13] Since supplemental beta-carotene given to cows significantly reduced the incidence of ovarian cysts (42% in control group vs. 3% in the beta-carotene group), it may have a similar effect in humans.^{[10] [11]} Another bovine condition that benefited from increased dietary beta-carotene levels is cystic mastitis.^[12] It appears that farmers have a greater appreciation of beta-carotene than do many nutritionists. Of course, there are significant financial reasons, as the annual monetary loss from bovine mastitis in the United States has been estimated to be at least \$1.5–2.0 billion and ovarian cysts represent the major cause of infertility in cattle.

Immune system

Vitamin A is absolutely essential to proper immune function. The first way in which vitamin A affects the immune system is that it plays an essential role in maintaining the

epithelial and mucosal surfaces and their secretions. These systems constitute a primary non-specific host defense mechanism. Furthermore, vitamin A has been shown to stimulate and/or enhance numerous immune processes, including induction of antitumor activity, enhancement of white blood cell function, and increased antibody response.^[14] These effects are not due simply to a reversal of vitamin A deficiency, since many of these effects are further enhanced by (supposedly) excessive amounts of vitamin A. Retinol has also demonstrated significant antiviral activity and has prevented the immunosuppression induced by glucocorticoids, severe burns, and surgery. Some of these effects are probably related to vitamin A's ability to prevent stress-induced thymic involution and to promote thymus growth. As carotenes are better antioxidants, they may turn out to be even better in protecting the thymus gland than vitamin A, since the thymus gland is particularly susceptible to free radical and oxidative damage. The clinical uses of vitamin A and beta-carotene in infectious diseases are discussed below.

CLINICAL APPLICATIONS

Adequate tissue vitamin A levels are vital for optimum health. In addition, this nutrient can be used beyond its "physiological" role in the treatment of various conditions. Supplemental vitamin A is used primarily to enhance the immune system in viral illnesses and in the treatment of numerous skin disorders.

Natural vitamin A is available either as retinol or retinyl-palmitate. Absorption may be improved via either micellization or emulsification. Micellization is the process of making the fat-soluble vitamin A into very small droplets (micelles) so that the material is dispersed in water. Emulsification is the process of emulsifying the vitamin A with another chemical (such as lecithin) so that it can mix with water. Despite manufacturers' claims, it is important to remember that regular vitamin A is absorbed at a rate of 80–90%.

Viral illnesses

As discussed above, vitamin A is absolutely critical to a healthy functioning immune system. Vitamin A-deficient individuals are more susceptible to infectious diseases in general, but especially viral infections. While vitamin A deficiency may predispose an individual to an infection, during the course of an infection vitamin A stores are severely depleted.

Measles

Vitamin A deficiency is a major problem in many developing countries as 5–10 million children in these countries exhibit severe vitamin A deficiency. Recently, a number of well-designed studies have confirmed an effect first noted in 1932 – vitamin A supplementation can significantly reduce infant mortality among measles patients by at least 50%. Typically the dosage of vitamin A in double-blind studies has been 200,000–400,000 IU administered only once or twice to replenish body stores.^{[15] [16]}

The benefits of vitamin A supplementation in the treatment of measles is not limited to

developing countries. A study of “well nourished” children in Long Beach, California, suffering from measles indicated that 50% were deficient in vitamin A.^[17] This finding supports the use of vitamin A supplementation even in the US.

Infants with RSV infections

Wide-scale immunization programs have reduced the risk of measles in children. However, vitamin A therapy appears appropriate for other childhood viral illnesses. One of the more common viruses is the respiratory syncytial virus (RSV), a common cause of severe respiratory disease in young children. Studies have shown that children with RSV have low serum vitamin A levels. Furthermore, the lower the vitamin A level, the greater the severity of the disease, similar to the relationship shown in measles. Because vitamin A supplementation diminishes the morbidity and death caused by measles, a group of researchers decided to determine vitamin A's safety and absorption pattern in RSV as a first step in determining the therapeutic effectiveness.^[18]

Twenty-one children with a mean age of 2.3 months

1012

(range, 1–6 months) with mild RSV infection were treated with 12,500–25,000 IU of oral micellized vitamin A. Baseline vitamin A levels were shown to be low, but within 6 hours of receiving 25,000 IU, but not 12,500 IU, of vitamin A normal levels were re-established. Despite the young age, none of the children experienced any obvious signs or symptoms of vitamin A toxicity. Although the study was not designed as a therapeutic trial, the subjects receiving vitamin A had hospital stays that were shorter than those of children with a similar severity of illness who were not enrolled in the study.

Although vitamin A supplementation is an attractive treatment of RSV infections, due to its low cost, wide availability, and ease of administration, recent placebo-controlled trials are suggesting it may be of value only in the most severe cases. A placebo-controlled study of 180 children in Chile with RSV provided 50–200,000 IU of retinyl palmitate (according to age) within 2 days of admission.^[19] Supplementation resulted in no significant benefit, except for those children suffering from hypoxemia. These children experienced substantial benefit – a more rapid resolution of tachypnea and shortening of their hospital stay from 9.3 to 5.5 days.

AIDS

Another viral illness that may benefit from vitamin A supplementation is AIDS. It was recently shown that a vitamin A deficiency is quite common during HIV infection and that vitamin A deficiency is clearly associated with a decreased level of circulating helper T-cells, one of the hallmark features of AIDS.^[20]

Analysis of vitamin A levels, helper T-cells, and other blood parameters in HIV

individuals indicated that more than 15% had low serum vitamin A levels. When vitamin A levels were low, helper T-cell levels were much lower than the levels in HIV-infected individuals who had normal levels of vitamin A. Vitamin A deficiency was also shown to be associated with a higher rate of mortality due to HIV.

Increasing beta-carotene may be the preferred form of vitamin A for supplementation in HIV patients as there is concern that retinoic acid, the active form of vitamin A, may actually increase HIV replication in humans. Low beta-carotene levels are common in AIDS, presumably as a result of fat malabsorption. Low beta-carotene levels are associated with greater impairment of immune function.^[21]

Skin disorders

The use of high-dose vitamin A therapy for acne and other skin disorders was introduced in dermatology in the late 1930s. It is still used by a few dermatologists, although, since the advent of the synthetic retinoids, this type of therapy is not as popular as it once was. Vitamin A therapy has been shown to be quite effective in treating skin conditions associated with excessive formation of keratin (hyperkeratosis), a skin protein which can clog the pores of the skin to produce a “goose bump” effect. Examples of some skin conditions associated with hyperkeratosis include acne, psoriasis, ichthyosis, lichen planus, Darier’s disease, palmoplantar keratoderma, and pityriasis rubra pilaris. The dosages of vitamin A used to treat these conditions have typically been quite high (300,000–500,000 IU/day for 5–6 months in the treatment of acne, and 1–3.5 million IU/day for 1–2 weeks for the other conditions).^{[22] [23] [24] [25]} The use of these high dosages usually results in the development of significant toxicity (see below). Although there is some evidence that carotenes may be more useful, and less toxic, in some of these conditions, the pharmacological activity responsible for the effects of vitamin A in hyperkeratosis are believed to result when serum retinol levels exceed serum retinol binding protein capacity, causing destabilization of membranes and destruction of the keratin-producing cells.^[21]

In monitoring for vitamin A toxicity, laboratory tests appear unreliable until obvious toxicity symptoms are apparent. The first significant toxic symptom is usually headache followed by fatigue, emotional instability, and muscle and joint pain. Chapped lips (cheilitis) and dry skin (xerosis) will generally occur in the majority of patients, particularly in dry weather. Because high doses of vitamin A during pregnancy can cause birth defects, women of child-bearing age should use effective birth control during vitamin A treatment and for at least 1 month after discontinuation.

High doses of vitamin A may not be necessary if other nutritional factors like zinc and vitamin E are included. These nutrients work with vitamin A in promoting healthy skin. A safe and effective recommendation for vitamin A in the treatment of acne is less than 25,000 IU/day.

Dry eyes

Dry-eye disorders are a complex group of diseases characterized by a localized water deficiency in the tear ducts; a mucin deficiency; or a combination of the two. Despite the

diversity of underlying causes, the changes in the conjunctiva of the eye are similar in all cases, i.e. loss of goblet cells (mucin-producing cells), abnormal enlargement of non-goblet epithelial cells, and an increase of cellular layers and keratin deposition, stratification and keratinization.

Apart from topical vitamin A therapy, all other non-surgical therapies of dry eye, i.e. the frequent application of artificial tears, lubricants, or slow-releasing polymers, and the therapeutic use of soft contact lenses, are not

1013

directed toward reversing the underlying process, but rather toward alleviating the symptoms.

The hypothesis that a localized vitamin A deficiency in the lining of the outer eye may be responsible for dry eye, considering vitamin A's vital role in epithelial tissue, seems obvious. Clinical studies featuring commercial vitamin A eye drops (Viva-Drops from Vision Pharmaceuticals) have yielded impressive clinical results in the treatment of dry eyes.^[26] ^[27]

DOSAGE

Dosage ranges for vitamin A reflect the intent of use. For general health purposes, a dosage of 5,000 IU for men and 2,500 IU for women appears reasonable. During an acute viral infection, a single oral dosage of 50,000 IU for 1 or 2 days appears to be safe even in infants (note, however, that women who might be pregnant must not use vitamin A supplements; beta-carotene is fine). For the treatment of acne and hyperkeratotic skin disorders, high-dose therapy may be useful but should be monitored closely by a physician.

TOXICITY

Vitamin A supplementation must be avoided during pregnancy. Vitamin A in large doses has been shown to be teratogenic. Unfortunately, the safe dosages for pregnant women have not yet been determined. According to recent studies, dosages greater than 10,000 IU during pregnancy (specifically during the first 7 weeks after conception) have probably been responsible for one out of every 57 cases of birth defects in the United States. Women who are at risk of becoming pregnant should keep their supplemental vitamin A levels below 5,000 IU or, better yet, look to carotenes.^[28]

Acute toxicity with vitamin A is most often seen in children as a result of the accidental ingestion of a single large dose of vitamin A (100,000–300,000 IU) and manifests as:^[1]

- raised intracranial pressure with vomiting
- headache

- joint pain
- stupor
- occasionally papilledema.

Symptoms rapidly subside upon withdrawal of the vitamin, and complete recovery always results.^[1]

Vitamin A toxicity may occur in adults when taking an excess of 50,000 IU/day for several years. Smaller daily doses may produce toxicity symptoms if there are defects in storage and transport of vitamin A such as occurs in cirrhosis of the liver, hepatitis, or protein calorie malnutrition, and in children and adolescents.^{[29] [30]} Signs of vitamin A toxicity generally include:

- dry, fissured skin
- brittle nails
- alopecia
- gingivitis
- cheilosis
- anorexia
- irritability
- fatigue
- nausea.

Serum levels of vitamin A of 250–6,600 IU/dl are typical of toxicity. Prolonged, severe hypervitaminosis A will result in bone fragility and thickening of the long bone.

Toxicity is typically encountered during high-dose vitamin A therapy for various skin conditions. Although dosages below 300,000 IU/day for a few months rarely cause toxicity symptoms, early recognition is still very important. Cheilitis (chapped lips) and xerosis (dry skin) will generally appear in the majority of patients, particularly in dry weather. The first significant toxicity symptom is usually headache, followed by fatigue, emotional lability, and muscle and joint pain. Laboratory tests are of little value in monitoring toxicity, as serum vitamin A levels correlate poorly with toxicity, and SGOT and SGPT are elevated only in symptomatic patients.^[21]

Interactions

Vitamin E and zinc are particularly important to the proper function of vitamin A. A deficiency of zinc, vitamin C, protein, or thyroid hormone will impair the conversion of provitamin A carotenes to vitamin A.

Studies have demonstrated a link between exposure to toxic chemicals and vitamin A nutrition. Administration of compounds such as polybrominated biphenyls, dioxin, and other toxic chemicals to rats results in a decrease in the hepatic content of vitamin A. Administration of vitamin A concurrently with the xenobiotics partially prevents the symptoms of toxicity. Exposure to these compounds results in an increased vitamin A

requirement due to the enhanced degradation of vitamin A in the liver.^[31] ^[32]

Chapter 122 - Vitamin toxicities and therapeutic monitoring

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

INTRODUCTION

When nutrients such as vitamins are being used at high doses for pharmacological effects, the physician must be vigilant for possible toxicity or side-effects. In general, vitamin therapy is virtually “non-toxic” and the small risk of developing any toxicity can be further reduced by careful monitoring of the patient. The physician should also be aware of toxicity resulting from self-administered vitamins. The primary signs and symptoms of vitamin toxicity are listed in [Tables 122.1](#) and [122.2](#), which are complemented by a more detailed discussion of toxicity and guidelines for monitoring selected vitamins.

VITAMIN TOXICITY

Lipid-soluble vitamins

Vitamin A

The majority of the cases of hypervitaminosis A involve acute ingestion by young children.^{[1] [2]} Adverse reactions to acute ingestion are usually transient. Chronic ingestion in children, usually a result of administration by a parent, may result in long-lasting changes in bone formation.

When large doses of vitamin A are being given, careful monitoring is necessary. Rather than using sudden large doses, a gradual stepwise increase in dosage is indicated, with a symptom evaluation made before increasing the dose. Usually, the first recognized symptom of hypervitaminosis is frontal headache. If signs or symptoms appear, supplementation should be discontinued until they disappear. Therapy may be carefully

resumed at a lesser dose. Periodic liver enzyme levels should be determined to check for hepatic damage. Typically, SGOT levels are the first to be affected. ^{[1] [2] [3] [4]}

As vitamin A has been shown to have teratogenic effects in animals (e.g. resorption of fetus, cleft palate, spina bifida, anencephaly, etc.), supplementation above the RDA is not warranted in pregnant, or potentially pregnant, women. According to recent studies (see [Ch. 121](#)),

TABLE 122-1 -- Toxic doses and side-effects of lipid-soluble vitamins

| Vitamin | Toxic dose | Toxic signs and symptoms |
|----------------|-------------------------------|---|
| Carotene | Chronic: none | No apparent toxicity, even at large doses (250 mg/day); synthetic form may be a problem for heavy smokers not taking other antioxidants |
| Vitamin A | Acute | |
| | —infants: 75–300,000 IU | Anorexia, bulging fontanelles, hyperirritability, vomiting |
| | —adults: 2–5 million IU | Headache, drowsiness, nausea, vomiting |
| | Chronic | |
| | —infants: 18–60,000 IU/day | Premature epiphyseal bone closing, long bone growth retardation |
| | —adults: 100,000 IU/day | Anorexia, headache, blurred vision, loss of hair, bleeding lips, cracking and peeling skin, muscular stiffness and pain, severe hepatic damage and enlargement, anemia, teratogenesis |
| Vitamin D | Acute: 1–3,000 IU/kg | Anorexia, nausea, vomiting, diarrhea, headache, polyuria, polydipsia |
| | Chronic: 10–50,000 IU/day | Weight loss, pallor, constipation, fever, hypercalcemia, calcium deposits in soft tissues |
| Vitamin E | Chronic: >800 IU/day | Severe weakness, fatigue, exacerbation of hypertension, potentiation of anticoagulants |
| Vitamin K | Chronic: none | Phylloquinone (K ₁), unlike menadione (K ₃), is not associated with side-effects when given orally |

TABLE 122-2 -- Toxic doses and side-effects of water-soluble vitamins

| | Toxic dose | Toxic signs and symptoms |
|-------------------------|------------------------------|---|
| Ascorbic acid | Acute: usually >10 g | Nausea, diarrhea, flatulence |
| | Chronic: >3 g/day | Increased urinary oxalate and uric acid levels in extremely rare cases, impaired carotene utilization, chelation and resultant loss of minerals may occur |
| Biotin | Chronic: >10 mg/day | No side-effects from oral administration at therapeutic doses have been reported |
| Folic acid | Chronic: 15 mg/day | Abdominal distension, anorexia, nausea, sleep disturbances (see discussion) |
| Niacin | Acute: >100 mg | Transient flushing, headache, cramps, nausea, vomiting |
| | Chronic: 3–7 g/day | Anorexia, abnormal glucose tolerance, increased plasma uric acid levels, gastric ulceration, elevated liver enzymes |
| Niacinamide | Chronic: >1,000 mg/day | Same as for niacin |
| Pantothenic acid | Chronic | Occasional diarrhea |
| Pyridoxine | Acute | No acute effects are noted at therapeutic doses |
| | Chronic: 300 mg/day | Sensory and motor neuropathy |
| Riboflavin | Chronic | No toxic effects have been noted |
| Thiamin | Chronic | No toxic effects noted for humans after oral administration |
| Vitamin B ₁₂ | Chronic | No side-effects from oral administration have been reported |

dosages greater than 10,000 IU during pregnancy (specifically during the first 7 weeks after conception) have probably been responsible for one out of every 57 cases of birth defects in the United States.

Carotenoids

Carotenoids appear to be without toxic effects at the therapeutic doses usually used and are therefore more appropriate than vitamin A for most conditions. The only effect of large dosages is an apparently benign yellowing of the skin.

Three large, recent, widely publicized therapeutic trials with synthetic beta-carotene

have found that it appears to increase the risk of cancer for heavy smokers. However, several factors complicate the interpretation of these results. The significance of these trials is fully discussed in [Ch. 121](#) .

Vitamin D

Large doses of vitamin D are rarely used clinically; self-administration is the usual cause of toxicity. Vitamin D has great potential to cause toxicity. Dosages greater than 1,000 IU/day are certainly not recommended. Toxicity is characterized by hypercalcemia, deposition of calcium into internal organs, and kidney stones. It has also been suggested that long-term overconsumption of vitamin D₂ in fortified foods contributes to atherosclerosis and heart disease, possibly as a result of decreasing magnesium absorption.^[5]

Vitamin E

Although vitamin E is a fat-soluble vitamin it has an excellent safety record. Recent clinical trials of vitamin E supplementation at doses as high as 3,200 IU/day in a wide variety of subjects for periods of up to 2 years have not shown any unfavorable side-effects. Detailed safety assessments have been carried out in several studies. For example, in one double-blind trial in 32 elderly (>60 years old) people, the effect of daily supplementation of 800 IU of D,L- α -tocopheryl acetate for 30 days was assessed by measuring general health, nutrient status, liver and kidney function, metabolism, blood cell status, blood nutrient and antioxidant status, thyroid hormones, and urinary function.^[6] The only significant effect noted was an increase in serum vitamin

1017

E levels. Vitamin E at this dose was extremely well-tolerated and no side-effects were reported. The results of this study are not surprising and are consistent with a large body of knowledge demonstrating that vitamin E supplementation is extremely safe.

Vitamin K

Large doses of the synthetic, water-soluble vitamin K₃ (menadione), when administered to infants, may cause hemolytic anemia, hyperbilirubinemia, hepatomegaly, and possibly death. Adults with G6PD deficiency may show hemolytic reactions.^[7] The natural vitamin K₁ (phytadione or phylloquinone) does not appear to have any toxicity when given orally, until huge doses (200 mg) are given.^[8]

Water-soluble vitamins

Ascorbic acid

Vitamin C has been reported to have perhaps the lowest toxicity of all vitamins. Diarrhea and intestinal distension or gas are the most common complaints at higher dosages. High doses have been shown to:

- increase the urinary excretion of calcium, iron and manganese
- increase the absorption of iron
- increase urinary oxalate or uric acid levels, but only in an extremely small subgroup of the population
- alter many routine laboratory tests, i.e. serum B₁₂, aminotransferases, bilirubin, glucose, stool occult blood.

It is necessary to take these effects into consideration when supplementing with mega-doses of vitamin C.

The primary concern with high dosages of vitamin C often cited in the medical literature is the development of calcium oxalate kidney stones. However, numerous studies have now demonstrated that in persons not on hemodialysis or suffering from recurrent kidney stones, severe kidney disease, or gout, high dosage vitamin C therapy will not cause kidney stones. Vitamin C administration of up to 10 g/day has not shown any effect on urinary oxalate levels.^[9] ^[10]

There have been reports that abrupt cessation of high dosage vitamin C intake leads to “rebound scurvy”, or in pregnant women to the presence of rebound scurvy after birth in their babies. However, other studies do not support the existence of rebound scurvy with sudden cessation or after pregnancy with high doses of vitamin C. While the existence of rebound scurvy is controversial (some experts question its existence), it is better to err on the side of caution. At this time a safe recommendation to pregnant women would be a daily dosage of 500 mg.

Folic acid

It has been reported that eight out of 14 healthy human subjects who consumed 15 mg/day of folic acid for 1 month developed abdominal distension, flatulence, nausea, anorexia, sleep disturbances with vivid dreams, malaise, and irritability.^[11] This, however, has not been confirmed in a double-blind clinical study^[12] and other investigations.^[13] ^[14] ^[15] Folic acid supplementation appears to be without side-effects, even at high doses (e.g. 15 mg/ day).

Niacin

The acute side-effects of niacin are well known. The most common and bothersome is the skin flushing that typically occurs 20–30 minutes after the niacin is taken. Long-term consequences of niacin therapy include gastric irritation, nausea, and liver damage. In an attempt to combat the acute reaction of skin flushing, several manufacturers began marketing “sustained-release”, “timed-release” or “slow-release” niacin products. These formulations allow the niacin to be absorbed gradually, thereby reducing the flushing

reaction. However, while these forms of niacin reduce skin flushing, they have actually proven to be more toxic to the liver. In a recent study, it was strongly recommended that the use of sustained-release niacin be restricted because of the high percentage (78%) of patient withdrawal due to side-effects – 52% of the patients taking the sustained-release niacin developed liver damage, compared with none of the patients taking immediate-release niacin.^[16]

Because niacin can impair glucose tolerance, it should probably not be used in diabetics unless they are under close observation. Niacin should also not be used in patients with pre-existing liver disease or elevation in liver enzymes, gout, or peptic ulcers.

Side-effects can occur with any form of niacin, including niacinamide. Although niacinamide does not cause the acute flushing of the skin, it can cause liver damage. Inositol hexaniacin is the safest form of niacin currently available. Both short- and long-term studies have shown it to be virtually free of side-effects other than an occasional mild gastric upset or mild flushing of the skin.

Regardless of the form of niacin being used, periodic checking (at least every 3 months) of liver function tests are indicated when high-dose (i.e. 2–6 g/day) niacin, inositol hexaniacinate, or niacinamide therapy is being used.

Pyridoxine

Vitamin B₆ is one of the few water-soluble vitamins that is associated with some toxicity when taken in large doses or moderate dosages for long periods of time.

1018

Large doses of vitamin B₆ are currently being used for a wide variety of conditions.

Doses greater than 2,000 mg/day can produce symptoms of nerve toxicity (tingling sensations in the feet, loss of muscle coordination, and degeneration of nerve tissue) in some individuals. Chronic intake of dosages greater than 500 mg/day can be toxic if taken daily for several months.^[17] There are also a few rare reports of toxicity occurring at chronic long-term dosages as low as 150 mg/day.^{[18] [19] [20]} The toxicity is thought to be a result of supplemental pyridoxine overwhelming the liver's ability to add a phosphate group to produce the active form of vitamin B₆ (pyridoxal-5-phosphate). As a result, it is speculated either that pyridoxine is toxic to the nerve cells or that it actually acts as an anti-metabolite by binding to pyridoxal-5-phosphate receptors thereby creating a relative deficiency of vitamin B₆. It appears to make sense to limit dosages to 50 mg. If more than 50 mg are desired, then the dosages should be spread throughout the day.

LABORATORY TESTS FOR VITAMIN TOXICITY

Only a limited number of routine laboratory tests are available for detecting vitamin toxicity. These are presented in [Table 122.3](#).

TABLE 122-3 -- Laboratory tests for vitamin toxicity

| Vitamin | Laboratory test |
|-----------|-------------------------------|
| Vitamin A | SGOT, serum vitamin A |
| Vitamin D | Serum calcium |
| Niacin | SGOT, SGPT |
| Vitamin C | Urinary oxalate and uric acid |

Chapter 123 - *Vitex agnus castus* (chaste tree)

Donald J. Brown ND

Vitex agnus castus (family: Verbenaceae)
Common name: chaste tree

GENERAL DESCRIPTION

Vitex agnus castus, also known as chaste tree, is a shrub with finger-shaped leaves and slender violet flowers. *Vitex agnus castus* grows in creek beds and on river banks in valleys and lower foothills in the Mediterranean and central Asia. The plant blooms in high summer and, after pollination, develops dark-brown to black fruit the size of a peppercorn. The fruit possess a pepper-like aroma and flavor. The ripe, dried fruit of *Vitex agnus castus* is the part of the plant used in medicinal preparations today.^[1]

CHEMICAL COMPOSITION

The fruit of *Vitex* contains essential oils, iridoid glycosides, and flavonoids.^[2] The essential oils include limonene, 1,8 cineole, and sabinene.^[3] The primary flavonoids include castican, orientin, and isoVitexin. The two isolated iridoidglycosides are agnuside and aucubin (see [Figs 123.1](#) and [123.2](#)).^[4] Agnuside serves as a reference material for quality control in the manufacture of *Vitex* extracts.

One study found delta-3-ketosteroids in the flowers and leaves of *Vitex*. The authors reported (albeit in a somewhat vague manner) that this fraction of the leaves and flowers “probably” contained progesterone and 17-hydroxyprogesterone. Testosterone and epitestosterone were also presumed to be present.^[5] Additional research is needed.

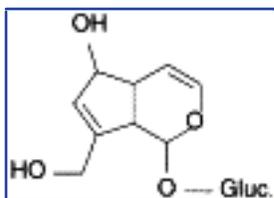

Figure 123-1 Aucubin.

1020

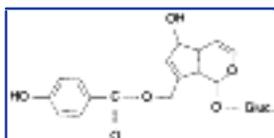

Figure 123-2 Agnuside.

HISTORY AND FOLK USE

The genus name *Vitex* is derived from the “vitilium” which means plaiting. The flexible, but tough and hard, branches were used for construction of wattle fences. Plinius, 1st century AD, has the earliest reference to the plant as *Vitex*. The species name *agnus castus* originates from the Latin “castitas” (chastity) and the equating of the Greek “agnos” with the Latin “agnus” (lamb).

Vitex agnus castus belonged to the official medicinal plants of antiquity and is mentioned in the works of Hippocrates, Dioscorides, and Theophrast. The first specific medicinal indications can be found in the writings of Hippocrates, 4th century BC. He recommends the plant for injuries, inflammation, and swelling of the spleen, and the leaves in wine for hemorrhages and the “passing of afterbirth”. In the *Corpus Hippocraticum* he states:

If blood flows from the womb, let the woman drink dark red wine in which the leaves of the chaste tree have been steeped. A draft of chaste leaves in wine also serves to expel a chorion held fast in the womb.

Dioscorides attributed to the fruit a hot and astringent activity and recommended it for wild animal bites, swelling of the spleen, and dropsy. Decoctions of the fruit and plant were used as sitz baths for diseases of the uterus.

The English name for *Vitex agnus castus*, “chaste tree”, is derived from the belief that the plant would suppress libido in women taking it. In Greek cities, festivals in the honor of Demeter included a vow of chastity by the local women. The Catholic church in Europe developed a variation on this theme by placing the blossoms of the plant in the clothing of novice monks to supposedly suppress libido. It is interesting to note that another common name for *Vitex agnus castus*, “monk’s pepper”, derived from the fact that monks in southern Europe commonly used the fruit as a spice in their cooking.

PHARMACOLOGY

According to Dr Rudolf Fritz Weiss, Vitex acts on the diencephalohypophyseal system. Vitex increases LH production (see [Fig. 123.3](#)). The result is a shift in the ratio of estrogen to progesterone, in favor of progesterone. This

Figure 123-3 Impact of Vitex on pituitary hormone secretion.

is, in fact, a corpus luteum-like hormone effect.^[6] The ability of Vitex to increase or modulate progesterone levels in the body is therefore an indirect effect and not a direct hormonal action.^[7] This is in contrast to other phytomedicines, like Black cohosh, frequently used in gynecology, which directly bind to estrogen receptors through their content of phytoestrogens.^[8]

Vitex also modulates the secretion of prolactin from the pituitary gland. Early animal studies indicated an increase in lactation and enlargement of the mammary gland following administration of Vitex.^[7]

Current research with Vitex indicates usefulness in hyperprolactinemia. In studies with rats, Vitex was shown to inhibit prolactin release by the pituitary gland – particularly under stress. The mechanism of action appears to involve the ability of Vitex to directly bind dopamine receptors and subsequently inhibit prolactin release in the pituitary.^{[9] [10]} Slight hyperprolactinemia is commonly associated with corpus luteum insufficiency.^[11]

CLINICAL APPLICATIONS

The causes of menstrual disorders are multifaceted and can vary greatly in their manifestation. Frequently, therapeutic interventions must be used on a trial and error basis over the duration of a number of menstrual cycles to determine their efficacy. Nutritional interventions like vitamin B₆, magnesium, and vitamin E, as well as phytomedicines such as dong quai and evening primrose oil, have all shown greater efficacy when used over time periods of several months. This reflects the gradual balancing effect that many of these interventions have on the female hormonal system. Vitex certainly fits this mould.

The majority of clinical studies completed with Vitex have been non-controlled studies with large populations

of female patients in European gynecology practices. Vitex, which has a Commission E Monograph in Germany, is frequently used in these practices as an initial intervention in a number of menstrual disorders, including:

- premenstrual syndrome
- hypermenorrhea
- polymenorrhea
- anovulatory cycles
- secondary amenorrhea
- infertility
- hyperprolactinemia.

Many of these cases can be linked to corpus luteum insufficiency. Vitex is also used in cases of poor lactation, uterine fibroids, and climacteric.

Corpus luteum insufficiency

Corpus luteum insufficiency (also referred to as luteal phase defect) is a manifestation of suboptimal ovarian function. In laboratory terms, corpus luteum insufficiency is usually defined as an abnormally low progesterone level 3 weeks after the onset of menstruation (serum progesterone below 10–12 ng/ml). This state is normal during puberty and at menopause. However, it is usually considered abnormal when occurring in women between the ages of 20 and 40 years.^[12]

Corpus luteum insufficiency points to abnormal formation of ovarian follicles, an abnormality that may be so pronounced that no secondary or tertiary follicles are produced, with a resulting lack of ovulation (anovulation). Corpus luteum insufficiency also leads to a relative deficiency of progesterone. Insufficient levels of progesterone may also result in the formation of ovarian cysts.

Corpus luteum insufficiency may result in a myriad different menstrual abnormalities. [Table 123.1](#) lists the most common clinical conditions in 1,592 women diagnosed with corpus luteum insufficiency. Foremost are hypermenorrhea (heavy periods), polymenorrhea (abnormally frequent periods), and persistent anovulatory bleeding. It is interesting to note that secondary amenorrhea (lack of a period) may sometimes be observed in women with corpus luteum insufficiency.

Disturbances of other hormones may also be associated with corpus luteum insufficiency. One study found hyperprolactinemia in 70% of cases.^[13] Also noted is an exaggerated response to the thyroid-releasing hormone (TRH) test which is associated with manifest or latent hypothyroidism.

Premenstrual syndrome

Premenstrual syndrome (PMS) is one of the most frequent complaints found in gynecology practices. According to

TABLE 123-1 -- The most common clinical conditions in 1,592 women diagnosed with corpus luteum insufficiency

| Diagnosis | No. of patients | Percentage of total |
|---------------------------------|-----------------|---------------------|
| Hypermenorrhea | 418 | 26.3 |
| Polymenorrhea | 369 | 23.2 |
| Persistent anovulatory bleeding | 216 | 13.6 |
| Secondary amenorrhea | 202 | 12.7 |
| Dysmenorrhea | 186 | 11.7 |
| Anovulatory cycles | 175 | 11.0 |
| Involuntary sterility | 145 | 9.1 |
| Oligomenorrhea | 69 | 4.3 |
| Menorrhagia/metrorrhagia | 66 | 4.1 |
| Irregular menstrual cycles | 32 | 2.0 |
| Primary amenorrhea | 1 | 0.1 |

some estimates, 30–40% of menstruating women are affected by PMS.^[14] [Table 123.2](#) lists the different categories for PMS and the symptoms associated with them.

Two monitoring surveys of gynecology practices in Germany examined the effect of Vitex on 1,542 women with a diagnosis of PMS.^[15] The mean age of the patients was 34.7 with a range of 13–62 years. Additional diagnoses noted with these patients included corpus luteum insufficiency ($n = 1016$) and uterine fibroids ($n = 170$). Patients were placed on a proprietary Vitex liquid extract known as “Agnolyt®” and were instructed to take 40 drops daily. The average duration of treatment was 166 days. The efficacy of treatment was assessed by both patients and their physicians. These assessments are listed in [Table 123.3](#). In over 90% of the cases, symptoms were completely relieved, with a report of side-effects in only 2% of the patients (listed in [Table 123.3](#)). Only 17 of the 1,542 women studied had to stop treatment due to side-effects. Improvement in symptoms began after an average treatment duration of 25.3 days. After completion on the monitoring period, 562 patients continued taking Agnolyt.

Another study with 36 patients with a diagnosis of

TABLE 123-2 -- PMS subgroups

| Subgroup | Symptoms | Prevalence |
|----------|----------|------------|
|----------|----------|------------|

| | | |
|-------|---------------------|--------|
| PMS-A | Anxiety | 75–80% |
| | Nervous tension | |
| PMS-H | Irritability | 60–70% |
| | Fluid retention | |
| | Weight gain | |
| | Swollen extremities | |
| | Abdominal bloating | |
| | Breast tenderness | |
| PMS-C | Increased appetite | 35–40% |
| | Sweet craving | |
| | Headache | |
| | Fatigue | |
| | Fainting spells | |
| PMS-D | Depression | 30–35% |

| | Forgetfulness | |

1022

TABLE 123-3 -- Efficacy of Vitex

| Outcome | Percentage of patients |
|-----------------------------|-------------------------------|
| <i>Patient assessment</i> | |
| Improved | 57% |
| Relieved | 33% |
| No change | 4% |
| No data | 5% |
| <i>Physician assessment</i> | |
| Very good/good | 71% |
| Satisfactory | 21% |
| Unsatisfactory | 4% |
| No data | 3% |

PMS used 40 drops of Vitex liquid extract (Agnolyt®) daily over 3 cycles. A reduction was noted in physical symptoms (headaches, pressure and tenderness in the breasts, bloating and fatigue) and psychological changes (increased appetite, craving for sweets, nervousness/restlessness, anxiety, irritability, lack of concentration, depression, mood swings, and aggressiveness). Additionally, the interval of the luteal phase was normalized from an average of 5.4 days to one of 11.4 days and a diphasic cycle was established.^[16]

A recent study compared the efficacy of Vitex (3.5– 4.2 mg/day of dried fruit extract – Agnolyt®) with vitamin B₆ (200 mg/day) in 175 women with premenstrual tension syndrome.^[17] While both were effective (symptom scale decreased from 15.2 to 5.1 in the Vitex group and from 11.9 to 5.1 in the B₆ group), 24.5% reported excellent results, compared with only 12.1% with B₆. However, over twice as many women (12) reported side-effects from Vitex than from B₆ (5).

Abnormal menstrual cycles

The first major clinical study on Vitex was published in 1954. Fifty-seven women suffering from a variety of menstrual disorders were given Vitex on a daily basis. Fifty patients developed a cycle in phase with menses while seven women did not respond. Of the 50 women, six with secondary amenorrhea demonstrated one or more cyclic menstruations. Of nine with oligomenorrhea (scant or infrequent menstrual flow), six experienced a shortening of the menstrual interval and an increase in bleeding.

Most striking was a dramatic improvement in menstrual regularity among 40 patients with cystic hyperplasia of the endometrium. This condition is associated with a relative deficiency of progesterone and is characterized by dysfunctional uterine bleeding. No side-effects were observed with Vitex treatment.^[18]

An observational study of 126 women with menstrual disorders utilized 15 drops of Vitex liquid extract three times daily over several cycles. In 33 women suffering from polymenorrhea, the duration between periods lengthened, on average, from 20.1 days to 26.3 days. In 58 patients with menorrhagia, a statistically significant shortening of menses was achieved. Fourteen patients became pregnant during the study; among them were three women with primary infertility over 2, 3, and 8 years, as well as two patients with secondary infertility over 4 and 15 years.^[19]

Twenty patients with secondary amenorrhea were admitted to a 6 month study using Vitex liquid extract at 40 drops daily. Laboratory monitoring of progesterone, FSH, LH, and pap smears were performed at pre-study, 3 months, and 6 months. At the end of the 6 month study, data were available in 15 patients. The onset of cycles with menstruation was observed with Vitex treatment in 10 out of 15 patients. The hormone values showed increased values for progesterone and LH, while FSH values either did not change or decreased slightly.^[20]

Two non-blind uncontrolled trials studied the effect of Vitex on corpus luteum function in 48 infertile women between 23 and 39 years of age. The inclusion criteria were normal

prolactin levels (below 20 ng/ml), normal results in the prolactin and thyroid-stimulating hormone (TSH) stimulation tests and an abnormally low serum progesterone (below 12.0 ng/ml on the 20th day of the cycle). Treatment consisted of Vitex liquid extract, 40 drops daily, without any other medication for 3 months. Forty-five women completed the studies (three were excluded because of concurrent hormone use). The outcome of therapy was assessed by the normalization of the midluteal progesterone level and by correction (lengthening) of any pre-existing shortening of the phases of the cycle. Treatment was deemed successful in 39 of the 45 patients. Seven women became pregnant, serum progesterone was restored to normal (>12 ng/ml) in 25 patients and there was a trend toward normalization of progesterone levels in seven cases.^[21]

Hyperprolactinemia

As mentioned previously, Vitex has shown a modulating effect on prolactin. A double-blind, placebo-controlled study examined the effect of a proprietary Vitex preparation (“Strotan[®]”) on 52 women with luteal phase defects due to latent hyperprolactinemia. The daily dose of the Vitex extract was 20 mg and the study lasted for 3 months. Hormonal analysis was performed at days 5–8 and day 20 of the menstrual cycle before and after 3 months of therapy. After 3 months of therapy, 37 cases were available for analysis (20 placebo and 17 Vitex). Prolactin release was significantly reduced in the Vitex group. Shortened luteal phases were normalized and deficits in progesterone production were normalized. No side-effects were noted and two women in the Vitex group became pregnant.^[22]

Potential indications

Anecdotal clinical reports have indicated a potential use for Vitex in the management of climacteric (hot flashes) in the early stages of menopause.^[24] Uterine fibroids which are embedded into the muscle or are subserous may have their growth arrested by use of Vitex. Submucosal fibroids, however, are not likely to respond. Mild cases of endometriosis for which progesterone therapy are indicated also may respond to Vitex.

DOSAGE

The majority of clinical studies with *Vitex agnus castus* (Vitex) have been performed with a tincture of the fruit. Most medicinal texts, as well as monographs in Europe, list the entire preparation as “medicinally active”.^[1] This is an indication that the medical activity of the fruit is examined as a whole and that specific “active constituents” have not been individually isolated.

Since the early 1950s, the standard Vitex extract used for clinical research and treatment in Europe has been an alcohol-based tincture of the fruits of the plant known as Agnolyt[®]. A 100 ml amount of the solution is standardized to contain 9 g of the fruit. The recommended dosage is 40 drops with some liquid in the morning over several

months without interruption. It is recommended that treatment with this extract be continued over several weeks after relief of symptoms is determined. The recent development of a solid extract equivalent of the tincture has allowed use by alcohol-sensitive women. The capsules, which contain 4.2 mg of the dried extract, have a one-a-day recommendation also.

It is important to note that Vitex is not a fast-acting medication. In cases of anovulatory cycles and infertility, treatment duration may be as long as 5–7 months before inception occurs. For secondary amenorrhea of more than 2 years' duration, Vitex should be administered for at least 1.5 years. In other conditions mentioned, however, first indications of efficacy with Vitex are usually seen within one or two cycles. Extensive or complete freedom of symptoms usually occurs after 4–6 months of treatment.

TOXICOLOGY

Human and animal studies have determined Vitex to be safe for most women of menstruating age. Vitex should not be used during pregnancy, but it is safe for use during lactation. Safety has not been determined in children. Vitex is not recommended in women taking hormone replacement therapy.

Side-effects noted in one large population study are listed in [Table 123.4](#). Side-effects noted in other clinical observations have included itching and an occasional rash. Again, these side-effects are rare and have been noted in only 1–2% of the patients monitored on Vitex. Some women also report that menstrual flow increases during Vitex treatment. This is often an indication of therapeutic efficacy.

TABLE 123-4 -- Side-effects from Vitex in 1,542 women

| Side effect | No. of patients reporting |

Chapter 124 - *Zingiber officinale* (ginger)

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

Zingiber officinale (family: Zingiberaceae)
Common name: ginger

GENERAL DESCRIPTION

Ginger is an erect perennial herb with thick tuberous rhizomes (underground stems) from which the aerial stem grows to a height of 2–4 feet. Grass-like alternate leaves, 6–12 inches long and 0.75 inch wide, shoot off from the aerial stem. Wild ginger will produce a beautiful flower, but cultivated ginger rarely flowers.

Although ginger is native to southern Asia, it is now extensively cultivated throughout the tropics (e.g. India, China, Jamaica, Haiti, and Nigeria). Jamaica is the major producer, with exports to all parts of the world amounting to more than 2,000,000 lb annually.

The knotted and branched rhizome, commonly called the “root”, is the portion of ginger used for culinary and medicinal purposes. Extracts and the oleoresin are produced from dried unpeeled ginger, as peeled ginger loses much of its essential oil content.^{[1] [2]} Ginger oil is produced from the fresh ginger via steam distillation.

CHEMICAL COMPOSITION

The following compounds have been isolated from ginger:^{[1] [2]}

- starch (up to 50%)
- protein (~ 9%)
- lipids (6–8%) composed of triglycerides, phosphatidic acid, lecithins, and free fatty acids

- a protease (2%)
- volatile oils (1–3%), the principal components of which are sesquiterpenes (bisabolene, zingiberene and zingiberol) and various “pungent” principles, aromatic ketones, known collectively as gingerols vitamins (especially niacin and vitamin A)
- resins.

The pungent principles are thought to be the most

1026

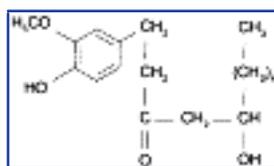

Figure 124-1 Gingerol.

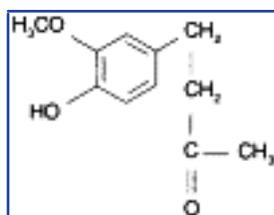

Figure 124-2 Zingerone.

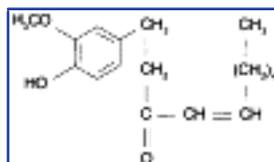

Figure 124-3 Shogaol.

pharmacologically active components of ginger. Gingerol and its derivatives can be found in concentrations as high as 33% in ginger oleoresin (see [Fig. 124.1](#)). The fresh oleoresin will have a higher percentage of the more pungent gingerol, as gingerol can be dehydrated during storage to form shogaol or have its fatty acid moiety cleaved to form zingerone (see [Figs 124.2](#) and [124.3](#)). The oleoresin is made by extracting the oily and resinous materials with the aid of a solvent (alcohol, hexane, or acetone).

HISTORY AND FOLK USE

Ginger has been used for thousands of years in China for medicinal purposes. Chinese records dating from the 4th century BC indicate that it was used to treat numerous conditions:^[1]

- stomach ache

- diarrhea
- nausea
- cholera
- hemorrhage
- rheumatism
- toothache.

It was used by Eclectic physicians in the US in the late 1800s as a carminative, diaphoretic, appetite stimulant, and local counter-irritant.^[3]

Ginger is widely used as a spice, especially in Asian and Indian dishes. It is also used in many baked goods, beverages (ginger ale), candy, liqueurs, and cosmetic products (perfumes, soaps, creams, etc.).

PHARMACOLOGY

Ginger possesses numerous pharmacological properties, the most relevant are:

- its antioxidant effects
- inhibition of prostaglandin, thromboxane, and leukotriene synthesis
- inhibition of platelet aggregation
- cholesterol-lowering actions
- choleric effects
- cardiogenic effects
- gastrointestinal actions
- thermogenic properties
- antibiotic activities.

Antioxidant effects

Ginger's strong antioxidant properties have led to its being investigated for preventing the development of rancidity in meat products.^[4] Ginger has been shown to prolong the shelf life of fresh, frozen, and pre-cooked pork patties. Since the use of many synthetic antioxidants is prohibited by law, ginger may one day be used commercially to extend the shelf life of meats and other foods.

Presumably the antioxidant components of ginger are absorbed in vivo where they undoubtedly contribute greatly to the pharmacology of ginger. In comparison, curcumin is about 30 times more potent in preventing lipid peroxidation than zingerone.^[5]

Effects on prostaglandin and leukotriene metabolism

Numerous constituents in ginger have been shown to be potent inhibitors of prostaglandin and leukotriene synthesis.^{[6] [7] [8]} The most potent components appear to be the pungent principles, although the aqueous extract has also demonstrated inhibition. Inhibition of prostaglandin and leukotriene formation could explain some of ginger's historical use as an anti-inflammatory agent. However, ginger and its extracts

also have strong antioxidant activities, and fresh ginger contains a protease that may have similar action to other plant proteases (e.g. bromelain, ficin, papain, etc.) on inflammation.^[1]

Effects on platelets

Ginger, like garlic and onions, is an inhibitor of platelet aggregation. However, ginger's effects may be far more

1027

powerful. In a comparison, an aqueous extract of ginger was shown to exert greater inhibitory effects on platelet aggregation than aqueous garlic and onion extracts.^[9] Ginger was shown to produce a greater inhibition on thromboxane formation and pro-aggregatory prostaglandins. Ginger, but not onion or garlic, also significantly reduced platelet lipid peroxide formation.

The superiority of ginger over onions was also demonstrated in a controlled study.^[10] Female volunteers given either 70 g raw onions or 5 g raw ginger demonstrated that ginger has a pronounced effect in lowering platelet thromboxane production while onion actually produced a mild elevation (pooled results).

Cholesterol-lowering and hepatic effects

Ginger has been shown to significantly reduce serum and hepatic cholesterol levels in cholesterol-fed rats by impairing cholesterol absorption as well as stimulating cholesterol-7-alpha-hydroxylase, the rate-limiting enzyme of bile acid synthesis.^{[11] [12] [13]} In addition, ginger has also been shown to increase bile secretion.^[14] Therefore, ginger works to lower cholesterol by promoting excretion and impairing absorption.

Cardiotonic and hypotensive properties

Gingerol has shown potent cardiotonic activity (positive inotropic and chronotropic effects) on isolated guinea pig left atria.^{[15] [16]} These effects are a result of acceleration of calcium uptake by the sarcoplasmic reticulum. Gingerol was the first substance shown to produce these effects.

Individuals with heart problems or high blood pressure are probably better off using fresh ginger rather than the dried preparation. This recommendation is based not only on the fact that gingerol is the more potent cardiotonic, but also because shogaol has been shown to produce a blood pressure-elevating effect in animals.^[17] Gingerol is found predominantly in fresh ginger while shogaol is rarely found in fresh ginger.

Analgesic effects

Ginger has demonstrated analgesic effects in experimental studies in animals.^[18] This effect is thought to be a result of shogaol inhibiting the release of substance P in a similar fashion to capsaicin, the pungent principle of red pepper (*Capsicum frutescens*).

Gastrointestinal smooth muscle effects

One interesting aspect of ginger is its ability to simultaneously improve gastric motility while exerting antispasmodic effects. This is consistent with its use as a gastrointestinal tonic. A lipophilic ginger extract was shown in one study to enhance gastric motility, as evidenced by increased intestinal transport of a charcoal meal fed to rats,^[19] and various fat-soluble components of ginger, such as galanolactone, demonstrated antagonism of serotonin receptor sites.^[20] This latter mechanism may be responsible for ginger's antispasmodic effects on visceral and vascular smooth muscle. Ginger has been shown to inhibit serotonin-induced diarrhea.^[21]

Anti-ulcer effects

Ginger has demonstrated significant anti-ulcer effects in a variety of animal models.^[22]^[23]^[24] Ginger prevents ulcer formation due to ethanol, indomethacin, aspirin, and other common ulcerogenic compounds. The pungent principles appear to be responsible for this effect. Interestingly, in one study, roasted ginger demonstrated inhibition of ulcer formation in three gastric ulcer models while dry ginger had no such effect.^[25]

Thermogenic properties

Ginger is noted for its apparent ability to subjectively warm the body and has historically been used as a diaphoretic. In animal studies, ginger has been shown to help maintain body temperature and to inhibit serotonin-induced hypothermia.^[21]^[26]

Crude extracts and the pungent components of ginger have been shown to increase oxygen consumption, perfusion pressure, and lactate production in the perfused rat hind limb.^[27] These effects signify increased thermogenesis. Gingerol is the most potent thermogenic component of ginger. A human study demonstrated that consuming a ginger sauce (containing unspecified amounts of ginger principles) with a meal produced no significant effect on metabolic rate.^[28] However, there were two problems with this study: (1) the concentration of gingerol in the preparation used was probably low or zero; and (2) the effective concentration range of gingerol for its thermogenic effects is quite narrow.

Given ginger's historical use as a "warming" substance, these scientific investigations appear to support its use as a diaphoretic and thermogenic aid, although confirmation in humans is still lacking.

Antibiotic activity

Ginger, shogaol, and zingerone have been shown to be strongly inhibitory against

Salmonella typhi, *Vibrio cholerae*, and *Tricophyton violaceum*, while aqueous extracts at 2.5, 5, and 25% concentration have been shown to be effective against *Trichomonas vaginalis*.^[29]

CLINICAL APPLICATIONS

Ginger is widely used as a condiment for its unique flavors, but from the above-described pharmacology it obviously has important medicinal effects as well. In general, like many other culinary herbs and spices such as garlic and onions, ginger provides many health-promoting effects. Specifically, ginger provides benefit to many body systems including the digestive, hepatobiliary, and cardiovascular systems.

Historically, the majority of complaints for which ginger was used concerned the gastrointestinal system. A clue to ginger's efficacy in alleviating gastrointestinal distress is offered in several recent double-blind studies in motion sickness, hyperemesis gravidum, and postoperative nausea and vomiting. Human studies have also shown a positive effect in arthritis and migraine headaches.

Motion sickness

Ginger was first shown to be effective in treating motion sickness by Mowrey & Clayson in 1982.^[30] In their study, ginger (940 mg) was shown to be far superior to Dramamine (100 mg) in relieving symptoms of nausea and vomiting. Since this initial study, several better designed follow-up studies have evaluated the effectiveness of ginger as a motion sickness medication.

The appearance of motion sickness trials using ginger prompted an interest in ginger by NASA, which subsequently funded a study at Louisiana State University. This study compared ginger, both fresh and dried powdered, with scopolamine by measuring the number of head movements experimental subjects could make in a rotating chair until they reached an end-point of motion sickness short of vomiting. Ginger was not shown to produce any protection against motion sickness in this model or in two additional protocols (vestibular stimulation only and combined vestibular-visual stimulation).^[31] However, in perhaps a more "real life" test, ginger (1 g) given to naval cadets, unaccustomed to sailing in heavy seas, was shown to reduce the tendency to vomiting and cold sweating compared with a placebo in a double-blind trial.^[32]

Mowrey & Clayson proposed that the anti-motion sickness effects of ginger were due to local gastrointestinal tract effects rather than to central nervous system effects. Although ginger's mechanism of action in alleviating gastrointestinal distress has yet to be fully elucidated, there is evidence to support this hypothesis. Ginger has been shown to partially inhibit the excessive gastric motility characteristic of motion sickness.^[31] To further support a gastric versus a CNS mechanism of action, one study clearly demonstrated that neither the vestibular nor the oculomotor system, both of which are of

critical importance in the occurrence of motion sickness, was influenced by ginger (1 g).^[33] However, in a double-blind cross-over placebo-controlled study, ginger (1 g) was shown to produce significant reductions in induced vertigo, but not nystagmus.^[34] These results suggest that ginger may dampen the vestibular impulses to the autonomic centers of the brain.

The overall effectiveness of ginger in motion sickness has yet to be determined. Issues that the studies have raised include the variability in the quality of commercial ginger preparations and the time required for ginger to produce its effects. Commercial preparations vary widely in chemical composition and often contain adulterants, and in the ginger study conducted at sea, ginger only reduced symptoms of cold sweating and vomiting at the end of 4 hours. In other words, it appears that ginger may prove to be more effective when well-defined preparations are given at least 4 hours prior to experiencing motion.

Nausea and vomiting

Ginger's anti-emetic actions has been studied in hyperemesis gravidum, the most severe form of pregnancy-related nausea and vomiting. This condition usually requires hospitalization. In a double-blind randomized cross-over trial, ginger root powder at a dose of 250 mg four times a day brought about a significant reduction in both the severity of the nausea and the number of attacks of vomiting in 19 of 27 cases of early pregnancy (less than 20 weeks).^[35] These clinical results, along with the safety and the relatively small dose of ginger required and the problems (e.g. teratogenicity) with anti-emetic drugs in pregnancy, support the use of ginger in nausea and vomiting in pregnancy. This is becoming a well-accepted prescription even in orthodox obstetrical practices – ginger (as well as vitamin B₆) was recommended as an effective treatment of early nausea and vomiting of pregnancy in a 1992 review of current drug therapy during pregnancy published in the medical journal *Current Opinion in Obstetrics and Gynecology*.

The anti-emetic action of ginger was also observed in women who had undergone major gynecological surgery. In a double-blind study, 500 mg of dry powdered ginger root was shown to significantly reduce the incidence of nausea compared with placebo in a manner similar to the drug metoclopramide.^[36]

Inflammatory conditions

Ginger's ability to inhibit the formation of inflammatory prostaglandins, thromboxanes, and leukotrienes, along with its strong antioxidant activities and protease component, suggests a possible benefit in inflammatory conditions. To test this hypothesis, a preliminary clinical

study was conducted on seven patients with rheumatoid arthritis, in whom conventional

drugs had provided only temporary or partial relief.^[37] One patient took 50 g/day of lightly cooked ginger while the remaining six took either 5 g of fresh or 0.1–1 g of powdered ginger daily. All patients reported substantial improvement, including pain relief, increased joint mobility, and decreased swelling and morning stiffness.

In the follow-up to this study, 28 patients with rheumatoid arthritis, 18 with osteoarthritis, and 10 with muscular discomfort who had been taking powdered ginger for periods ranging from 3 months to 2.5 years were evaluated.^[38] Based on clinical observations, Srivastava & Mustafa reported that 75% of the arthritis patients and 100% of the patients with muscular discomfort experienced relief in pain or swelling. The recommended dosage was 500–1,000 mg/day, but many patients took three to four times this amount. Patients taking the higher dosages also reported quicker and better relief.

Srivastava & Mustafa^[39] have also reported ginger to be beneficial in migraine headache. Given ginger's effects on platelets, eicosanoids, and serotonin inhibition, this recommendation makes sense.

DOSAGE

There remain many questions concerning the best form of ginger and the proper dosage. Most research studies have utilized 1 g of dry powdered ginger root. Practically speaking, this is a small dose of ginger. For example, ginger is commonly consumed in India at a daily dose of 8–10 g. Furthermore, although most studies have used powdered ginger root, fresh (or possibly freeze-dried) ginger root or extracts concentrated for gingerol at an equivalent dosage may yield even better results because they may deliver higher levels of gingerol as well as the active protease.

In the treatment of nausea and vomiting due to motion sickness, pregnancy, or postoperatively, a dosage of 1–2 g of dry powdered ginger may be effective. This would be equivalent to approximately 10 g or one-third of an ounce of fresh ginger root, roughly a quarter-inch slice. For inflammatory conditions like rheumatoid arthritis, the dosage should be double this amount.

For ginger extracts standardized to contain 20% gingerol and shogaol, an equivalent dosage in treating motion sickness or nausea and vomiting would be 100–200 mg. For inflammatory conditions like rheumatoid arthritis, the dosage is 100–200 mg three times daily.

TOXICOLOGY

Ginger does not appear to produce any toxicity problems when used at normal dosages. Although ginger extracts and several components in ginger have been shown to possess potent mutagenic activity, ginger also contains several equally potent anti-mutagenic substances.^[40] ^[41] The significance of this mutagenicity (the study was conducted in *E. coli* not the Ames test) has not been entirely determined, but the long historic use and lack of carcinogenic or toxic effect in animals suggest that it is not a

problem.

In acute toxicity tests in mice, ginger extract administered as a lavage was tolerated up to 2.5 g/kg with no mortality or side-effects during a 7 day trial period.^[42] Increasing the dosage to 3.0–3.5 g/kg resulted in a 10–30% mortality. In comparison, 0.6 g/kg of aspirin produced mortality in 25%, stomach ulcers in 40%, and hypothermia in 60% of subjects.

Some individuals consuming high doses, i.e. greater than the equivalent of 6 g of dried powdered ginger alone on an empty stomach, may experience some gastrointestinal discomfort. Administration of 6 g of dried powdered ginger has been shown to increase the exfoliation of gastric surface epithelial cells in human subjects.^[43] This may cause some gastric distress and ultimately could lead to ulcer formation. Therefore, it is recommended that dosages on an empty stomach be less than 6 g.

Chapter 125 - Acne vulgaris and acne conglobata

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

DIAGNOSTIC SUMMARY

- Open comedones – dilated follicles with central dark, horny plugs (blackheads)
- Closed comedones – small follicular papules with (red papules) or without (whiteheads) inflammatory changes
- Superficial pustules – collections of pus at follicular opening
- Nodules – tender collections of pus deep in dermis
- Cysts – from nodules that fail to discharge contents to the surface
- Large deep pustules – from nodules that break down adjacent tissue leading to scars.

GENERAL CONSIDERATIONS

Acne is the most common of all skin problems. Acne vulgaris is characterized as a pilosebaceous disease with comedones, papules, and pustules, while acne conglobata is a more severe form, with cyst formation and subsequent scarring. The lesions occur predominantly on the face and, to a lesser extent, on the back, chest, and shoulders. It is more common in males and onset is typically at puberty (somewhat later for conglobata form).

In acne vulgaris the onset reflects an increase in pilosebaceous gland size and sebum secretion due to androgenic stimulation. The severity and progression are determined

by a complex interaction between hormones, keratinization, sebum, and bacteria.

The lesions begin in the upper portion of the follicular canal, with hyperkeratinization being the first microscopic change. This leads to blockage of the canal, resulting in dilation and thinning. Eventually a comedo is formed. The formation of open or closed comedones appears to be related to the degree of keratinization and the level of blockage of the duct.

Despite a large amount of purulent exudate in pustular and cystic lesions, the only bacteria commonly cultured

1034

are normal skin species: *Propionibacterium acnes* (*Corynebacterium acnes*) and *Staphylococcus albus*. *P. acnes* is believed to release lipases that hydrolyze sebum triglycerides into free fatty acid lipoperoxides, thus promoting an inflammatory cascade.

Acne-like lesions can occur in response to a variety of compounds: corticosteroids, halogens, isonicotinic acid, diphenylhydantoin, and lithium carbonate. Exposure to various industrial pollutants also causes acne: machine oils, coal tar derivatives, and chlorinated hydrocarbons. Cosmetics, pomades, over-washing, and repetitive rubbing can produce acne.

Endocrinological aspects

Acne is considered to be an androgen-dependent condition, and androgen excess, either systemic or local, is associated with more severe forms of the disease. Androgens control sebaceous gland secretion and exacerbate the development of abnormal keratinizing follicular epithelium. Endocrine disorders producing excess androgens are important etiological factors: idiopathic adrenal androgen excess, partial defect in 21-hydroxylase, and polycystic ovarian syndrome. Free testosterone, dihydroepiandrosterone, dehydroepiandrosterone sulfate, and low sex-hormone-binding globulin levels have all been implicated.^{[1] [2] [3]} The skin of acne patients shows greater activity of 5-alpha-reductase, the enzyme converting testosterone to the more potent androgen, dihydrotestosterone.^{[4] [5]} This increased activity is independent of systemic levels of androgens and may explain the poor correlation between systemic levels of androgens and the severity of the acne lesions.

THERAPEUTIC CONSIDERATIONS

Effective treatment of acne is a significant clinical challenge. Success can only be obtained by a rigorous, comprehensive application of dietary, nutritional, and botanical interventions.

Nutrition

Diet

Subjects fed a high-protein diet (44% protein, 35% carbohydrate, and 21% fat) show substantially less 5-alpha-reduction of testosterone and enhanced cytochrome P450 hydroxylation of estradiol, both therapeutic goals.^[6] A high carbohydrate diet (10% protein, 70% carbohydrate, and 20% fat) had the opposite effect.

Foods high in iodine should be eliminated, and milk consumption (due to high hormone content) should be limited.^[7] *Trans*-fatty acids and high-fat foods should also be eliminated.

Sugar, insulin, and chromium

Many dermatologists have reported that insulin is effective in the treatment of acne, suggesting impaired cutaneous glucose tolerance and/or insulin insensitivity.^[8] ^[9] The insulin was either given systemically (5–10 units two to three times a week) or injected directly into the lesion.

One study comparing the results of oral glucose tolerance tests in acne patients showed no differences from controls. However, repetitive skin biopsies revealed that the acne patients' skin glucose tolerance was significantly impaired.^[10] One researcher of the role of glucose tolerance in acne coined the term "skin diabetes" to describe the disorder of acne.^[11] Considering the known immunosuppressive effects of sugar (see [Ch. 53](#)), all concentrated carbohydrates should be strictly eliminated.

High-chromium yeast is known to improve glucose tolerance and enhance insulin sensitivity^[12] and has been reported in an uncontrolled study to induce rapid improvement in patients with acne.^[13]

Vitamin A

Retinols, including oral vitamin A, have been shown in many studies to reduce sebum production and the hyperkeratosis of sebaceous follicles. Retinol has been shown to be effective in treating acne when used at high, and potentially toxic, dosages, i.e. 300,000–400,000 IU per day for 5–6 months.^[14]

Vitamin A toxicity. Although dosages of vitamin A below 300,000 IU/day for a few months rarely cause toxicity symptoms,^[14] early recognition is important. Cheilitis (chapped lips) and xerosis (dry skin) will generally occur in the majority of patients, particularly in dry weather.

The first significant toxic symptom is usually headache followed by fatigue, emotional lability, and muscle and joint pain. Laboratory tests appear unreliable for monitoring

toxicity, since serum vitamin A levels correlate poorly with toxicity, and SGOT and SGPT are elevated only in symptomatic patients. Of far greater concern is the teratogenicity of massive dosages of vitamin A. Women of child-bearing age should use effective birth control during treatment and for at least 1 month after discontinuation.

It is the authors' opinion that massive doses should be reserved for intractable cases and retinol therapy should not be used alone. The major problem with many of the clinical studies using retinol and retinol analogues has been their simplistic use as isolated agents. As noted below, many other factors are of critical importance.

Zinc

Zinc is vitally important in the treatment of acne. It is involved in local hormone activation, retinol-binding

1035

protein formation, wound healing, immune system activity, and tissue regeneration.

Zinc supplementation in the treatment of acne has been the subject of much controversy and many double-blind studies. The inconsistency of the results may be due to the differing absorbability of the various zinc salts used. For example, studies using effervescent zinc sulphate show efficacies similar to tetracycline, with fewer side-effects from chronic use,^[15] while those using plain zinc sulfate have shown less beneficial results.^[16] The majority of patients required 12 weeks of supplementation before good results were demonstrated, although some showed dramatic improvement immediately.

In the most recent study, 66 patients with inflammatory acne were given zinc gluconate (30 mg elemental zinc) or placebo for 2 months.^[17] Based upon the number and severity of lesions, an "inflammatory score" was attributed to each patient. In the placebo group the inflammatory score dropped from 58 to 47 in the 2 month period, while in the treatment group the score dropped from 49 to 27. Physicians rated 24 of 32 patients in the zinc group as responders compared with only eight of 34 in the placebo group.

This latest study utilized a common form of zinc, but unfortunately there have been no studies to date using zinc picolinate or zinc monomethionine, two better absorbed forms of zinc.

The importance of zinc to normal skin function is well recognized, especially in light of the zinc-deficient syndrome acrodermatitis enteropathica. Zinc is essential for retinol-binding protein and thus for serum retinol levels.^[18] Although low levels of zinc increase 5-alpha-reduction of testosterone, high concentrations significantly inhibit this reaction.^[19] Serum zinc levels are lower in 13- and 14-year-old males than in any other

age group.^[20]

Vitamin E and selenium

Serum vitamin A levels in rats on a vitamin E-deficient diet remain low regardless of the amount of oral or intravenous vitamin A supplementation. Serum levels return to normal after vitamin E is restored to the diet. Vitamin E has been shown to regulate retinol levels in humans.

Male acne patients have significantly decreased levels of erythrocyte glutathione peroxidase, which normalizes with vitamin E and selenium treatment. The acne of both men and women improves with this treatment.^[21] This improvement is probably due to inhibition of lipid peroxide formation, and suggests the use of other free-radical quenchers.

Pyridoxine

Women with premenstrual aggravation of acne are often responsive to vitamin B₆ supplementation, reflecting its role in the normal metabolism of steroid hormones.^[24] In rats, a vitamin B₆ deficiency appears to cause an increased uptake and sensitivity to testosterone.^[25]

In some patients, thyroid therapy has resulted in marked improvement.^[26]

Pantothenic acid

Pantothenic acid, which is physiologically active in the synthesis of cholesterol and steroid hormones, may be of value at high dosages in the treatment of acne. This was evaluated in a study of 100 Chinese (45 males and 55 females) between 10 and 30 years of age (80% were between the ages of 13 and 23) with varying ranges of acne lesions. They were provided 10 g/day of pantothenic acid in four divided doses and a cream consisting of 20% by weight pantothenic acid was applied four to six times a day. Within 1 or 2 days of starting, there was a noticeable decrease in sebum secretion. Within 1–2 weeks, the frequency of new acne eruptions began to decline and existing lesions started to regress. No side-effects were noted.^[27]

Miscellaneous factors

One study showed that 50% of patients with severe acne had a positive microclot test, indicating circulating endotoxins.^[22] This is important since circulating endotoxins have been shown to cause an increased copper:zinc ratio,^[23] and to enhance tissue destruction via activation of the alternate complement pathway and formation of fibrin.

Topical treatments

A variety of topical gels, ointments, and creams containing natural products are

available which can be used in the treatment of acne. The goal of these preparations is the same as benzoyl peroxide, i.e. to reduce the bacteria level and reduce inflammation. Although there are many possibilities to choose from, the most popular formulas are those which feature either tea tree oil or azelaic acid.

Tea tree oil

Melaleuca alternifolia or “tea tree” is a small tree native to only one area of the world: the north-east coastal region of New South Wales, Australia. The leaves, the portion of the plant that is used medicinally, are the source of a valuable therapeutic oil.

Tea tree oil possesses significant antiseptic properties and is regarded by many as the ideal skin disinfectant. This claim is supported by its efficacy against a wide range of organisms (including 27 of 32 strains of *P. acnes*),^[28] and its good penetration and lack of irritation to the skin. The therapeutic uses of tea tree oil are based largely on its antiseptic and antifungal properties.

1036

In a study conducted at the the Royal Prince Hospital in New South Wales, Australia, a 5% tea tree oil solution was shown to demonstrate similar beneficial effects as 5% benzoyl peroxide in acne, but with substantially fewer side-effects.^[29] However, this 5% tea tree oil solution is probably not strong enough for moderate to severe acne. Stronger solutions (up to 15%) should provide even better results. Numerous studies have shown that tea tree oil is extremely safe for use as a topical antiseptic, but it can occasionally produce contact dermatitis.

Azelaic acid

This naturally occurring nine-carbon dicarboxylic acid has exerted numerous pharmacological activity, including antibiotic activity against *P. acnes*. Clinical studies with 20% azelaic acid creams have shown it to produce results equal to those achieved with benzoyl peroxide, retinoin, and oral tetracycline.^[30] It has been shown to be effective in all of the different forms of acne. In order to achieve benefits, azelaic acid must be applied to affected areas twice daily continuously for a period of at least 4 weeks. Treatment usually has to be continued for at least 6 months to maintain the benefits produced after the first month.

A recent review article found topical cream containing 20% azelaic acid to be as effective as 5% benzoyl peroxide, 4% hydroquinone cream, 0.05% tretinoin, 2% erythromycin and 0.5–1 g/day oral tetracycline in ameliorating comedonal, papulopustular and nodulocystic acne, but less effective than oral isotretinoin at a dose of 0.5–1 mg/kg per day in reducing conglobate acne. The authors suggested that the few side-effects of topical azelaic acid and lack of overt systemic toxicity made it a better choice for chronic use than other agents. The lower incidence of allergic sensitization, exogenous ochronosis, and residual hypopigmentation offer a clear

advantage over conventional drugs.^[31]

THERAPEUTIC APPROACH

Acne is a multifactorial disease requiring an integrated therapeutic approach in order to avoid supplement toxicity while attaining the desired clinical results. Patients should be checked for treatable causes and underlying hormonal abnormalities before specific therapies are initiated. Also, considering the widespread use of long-term broad-spectrum antibiotics, systemic candidiasis must be ruled out (see [Ch. 48](#)).

Diet

Eliminate all refined and/or concentrated carbohydrates, and limit high-fat and high-carbohydrate foods. Avoid foods containing *trans*-fatty acids and iodine.

Supplements

- Vitamin A: 100,000 IU/day for 3 months
- Vitamin E: 400 IU/day
- Vitamin C: 1000 mg/day
- Zinc: 50 mg/day (picolinate is best^[23])
- Selenium: 200 µg/day
- Yeast (brewer's) – 1 tbs two times/day (if patient is susceptible to gout, use chromium supplement instead).

Physical medicine

Sun or UV lamp.

Topical treatment

- Tea tree oil (5–15%) preparations
- Azelaic acid (20%) preparations
- Thorough daily cleansing with calendula soap
- Drain comedones with comedo extractor.

Chapter 126 - Affective disorders

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

DIAGNOSTIC SUMMARY

Depression

The official definition of clinical depression, according to the American Psychiatric Association in its *Diagnostic and statistical manual of mental disorders (DSM-IV)*, is based upon the following eight primary criteria:

- Poor appetite with weight loss, or increased appetite with weight gain
- Insomnia or hypersomnia
- Physical hyperactivity or inactivity
- Loss of interest or pleasure in usual activities, or decrease in sexual drive
- Loss of energy and feelings of fatigue
- Feelings of worthlessness, self-reproach or inappropriate guilt
- Diminished ability to think or concentrate
- Recurrent thoughts of death or suicide.

The presence of five of these eight symptoms definitely indicates clinical depression; the individual with four is probably depressed. According to the *DSM-IV*, the symptoms must be present for at least 1 month to be called depression. Clinical depression is also referred to as major depression or unipolar depression.

Dysthymia

Like clinical depression, dysthymia is diagnosed according to *DSM-IV* criteria. In order to be officially diagnosed as dysthymic, a patient must be depressed most of the time for at least 2 years (1 year for children or adolescents) and have at least three of the following symptoms:

- Low self-esteem or lack of self-confidence
 - Pessimism, hopelessness, or despair
 - Lack of interest in ordinary pleasures and activities
 - Withdrawal from social activities
 - Fatigue or lethargy
 - Guilt or ruminating about the past
-

1040

- Irritability or excessive anger
- Lessened productivity
- Difficulty in concentrating or making decisions.

Manic phase

- The mood is typically elation, but irritability and frank hostility are not uncommon
- Inflated self-esteem, grandiose delusions, boasting, racing thoughts, decreased need for sleep, psychomotor acceleration, weight loss due to increased activity and lack of attention to dietary habits.

Seasonal affective disorder

- Regularly occurring winter depression frequently associated with summer hypomania.

INTRODUCTION

Affective disorders are disturbances in mood. Used in this context, mood is a prolonged emotional tone dominating an individual's outlook. Normal, typically transient, moods (sadness, grief, elation, etc.) are a part of every-day life, making the demarcation between "normal" and "pathological" often difficult to determine. Depression and mania, either alone or in alternation, are the most common affective disorders, with depression alone being much more common.

In order to separate states of depression which alternate with mania from the more common types of depression, i.e. those uncomplicated by mania, the terms "unipolar" and "bipolar" are commonly used. A unipolar depressive suffers from depression alone, while the bipolar depressive suffers from either mania alone or mania alternating with depression. Many nutritional, environmental, and lifestyle factors are discussed in this chapter, and it is important to recognize that they have a much broader scope of clinical application than simply to depression and mania. This chapter is really a compilation of many chapters that address factors associated with mood disturbance.

As the biochemistry of mood and behavior have become better understood, many conditions once thought of as having a psychological or sociological etiology are now

being shown to have a physiological or biochemical basis as well. There appear to be at least eight factors that modify the functional state of the brain, thus affecting mood and behavior:

- the individual genetic make-up
- the particular age of neuronal development, which results in age-specific variability
- the functional plasticity of the brain during development, which contributes to the functional and structural shaping of the system
- the motivational state, affected by various biological drives, which channels behavior toward specific goals by setting priorities or prejudicing the context of particular types of incoming information
- the availability of memory-stored information and related processing strategies
- the environment, which can adjust the incoming information depending on its momentary significance
- disease or lesion of the brain, which could cause aberrant functional states
- conditions of the metabolic/hormonal system or the internal biochemical environment of the CNS.

This chapter focuses on the nutritional, environmental, and lifestyle factors which contribute to affective disorders as well as specific therapies to alter brain neurotransmitter levels.

DEPRESSION

Obviously, there is a spectrum of clinical depression that ranges from mild feelings of depression to serious considerations of suicide. Mild depression is also known as dysthymia. Dysthymia is a term coined in the 1980s that replaced the term depressive neurosis which was used in the 1950s and the term depressive personality which was used in the 1970s.

GENERAL CONSIDERATIONS

Depression is a major problem in the United States. Approximately 17 million Americans suffer true clinical depression each year and over 28 million Americans take antidepressant drugs or anxiolytics. The obvious question is: "Why are so many Americans depressed?". Five basic theoretical models of depression attempt to answer this question:

- The "aggression-turned-inward" construct, which although apparent in many clinical cases, has no substantial proof
- The "loss model," which postulates that depression is a reaction to the loss of a person, thing, status, self-esteem, or even a habit pattern
- The "interpersonal relationship" approach, which utilizes behavioral concepts, i.e. the person who is depressed uses depression as a way of controlling other people (including doctors). It can be an extension and outgrowth of such simple behavior as pouting, silence, or ignoring something or someone. It fails to serve the need and the problem worsens

- The “learned helplessness” model, which theorizes
-

1041

that depression is the result of habitual feelings of pessimism and hopelessness

- The “biogenic amine” hypothesis, which stresses biochemical derangement characterized by imbalances of biogenic amines.

Although the biogenic amine model of depression is the dominant medical model of depression, there is much value to counseling, especially in clear cases of psychological etiology. Of the various psychological theories of depression, the one that we feel has the most merit is the learned helplessness model developed by Martin Seligman PhD. During the 1960s, Dr Seligman discovered that animals could be trained to be helpless. His animal model provided a valuable clue to human depression as well as serving as a model to test antidepressant drugs.^[1]

The learned helplessness model

Seligman’s early experiments were performed on three groups of dogs. The first group of dogs was given an escapable electrical shock. The dogs could turn off the shock by simply pressing a panel with its nose. This group of dogs would thus have control. The second group of dogs was “yoked” to the first group. They would get exactly the same shocks as the first group, but would be unable to turn off the shock. The shock would cease only when the “yoked” dog in the first group would press its nose to the panel. Thus, the second group had no control over the degree of shock they received. The third group of dogs received no shocks at all.

Once the dogs went through this first part of the experiment, they would be placed in what is known as a shuttle box – a box separated in the middle by a small barrier that the dogs could jump over. The dogs would be electrically shocked, but they would be able to escape the shock by simply jumping over the barrier to the other side. Seligman hypothesized that the first and third groups would quickly figure this out, but that the second group of dogs would have learned to be helpless in that they would believe that nothing they would do mattered. Seligman thought that the dogs in the second group would simply lie down and accept the shock.

As predicted, the first and third groups of dogs learned within seconds that they could avoid the shock by jumping over the barrier, while the dogs in the second group would simply lie down and not even make an effort to jump over the barrier though they could see the shock-less side of the shuttle box. Seligman and his colleagues went on to show that many humans react in an identical fashion to animals in these experiments.

The adoption of Seligman’s model was revolutionary in psychopharmacology as it became an effective experiment to test antidepressive drugs. Basically, when animals that had learned to be helpless were given antidepressant drugs, they would unlearn helplessness and start exerting control over their environment. Researchers discovered that when animals learned to be helpless it resulted in alteration of brain monoamine

content. The drugs would restore proper monoamine balance and alter the animal's behavior. Researchers also discovered that when animals with learned helplessness were taught how to gain control over their environment their brain chemistry also normalized. The alteration in brain monoamine content in the animals with learned helplessness mirrors the altered monoamine content in human depression.

While most physicians quickly look to drugs to alter brain chemistry, helping the patient to gain greater control over their life will actually produce even greater biochemical changes. One of the most powerful techniques to produce the necessary biochemical changes in the brains of depressed individuals is to teach them to be more optimistic.

Outside the laboratory setting, Seligman discovered that the determining factor on how a person would react to uncontrollable events, either "bad" or "good", was their explanatory style – the way in which they explained events. Optimistic people were immune to becoming helpless and depressed. However, individuals that were pessimistic were extremely likely to become depressed when something went wrong in their lives. Seligman and other researchers also found a direct correlation between an individual's level of optimism and the likeliness of developing not only clinical depression but other illnesses as well.^{[2] [3]} In one of the longer studies, patients were followed for a total of 35 years. While optimists rarely got depressed, pessimists were extremely likely to battle depression and other psychological disturbances.

THERAPEUTIC CONSIDERATIONS

Modern psychiatry focuses on manipulating neurotransmitter levels in the brain rather than identifying and eliminating the psychological factors which are responsible for producing the imbalances in serotonin, dopamine, GABA, and other neurotransmitters. Depression can often be due to an underlying organic or physiological cause (see [Table 126.1](#)). Identification and elimination of the underlying cause should be the primary therapy. The depressed individual needs a comprehensive clinical evaluation.

The basic clinical approach to a person suffering from depression is to ascertain what nutritional, environmental, social and psychological factors are involved in the disease process. After the diagnosis of depression has been made, it is important to rule out the simple organic factors which are known to contribute to the depression, i.e.:

- nutrient deficiency or excess
 - drugs (prescription, illicit, alcohol, caffeine, nicotine, etc.)
-

- hypoglycemia
- consumption
- hormonal derangement
- allergy
- environmental factors

- microbial factors.

TABLE 126-1 -- Organic and physiological causes of depression

| |
|-----------------------------------|
| • Pre-existing physical condition |
| —diabetes |
| —heart disease |
| —lung disease |
| —rheumatoid arthritis |
| —chronic inflammation |
| —chronic pain |
| —cancer |
| —liver disease |
| —multiple sclerosis |
| • Prescription drugs |
| —antihypertensives |
| —anti-inflammatory agents |
| —birth control pills |
| —antihistamines |
| —corticosteroids |
| —tranquilizers and sedatives |
| • Premenstrual syndrome |
| • Stress/low adrenal function |
| • Heavy metals |
| • Food allergies |
| • Hypothyroidism |
| • Hypoglycemia |
| • Nutritional deficiencies |
| • Sleep disturbances |

Each of these is discussed below. Regardless of whether there is an underlying organic cause, counseling is always recommended for the depressed individual.

Counseling

There are a number of counseling techniques that can be quite useful. The therapy that has the most merit and support in the medical literature is cognitive therapy. In fact, cognitive therapy has been shown to be as effective as antidepressant drugs in treating moderate depression.^[4] ^[5] However, while there is a high rate of relapse of depression when drugs are used, the relapse rate for cognitive therapy is much lower. People taking drugs for depression tend to have to stay on them for the rest of their lives. That is not the case with cognitive therapy because the patient is taught new skills to deal with depression.^[6]

Psychologists and other mental health specialists trained in cognitive therapy seek to change the way the depressed person consciously thinks about failure, defeat, loss, and helplessness. Cognitive therapists employ five basic tactics.

First they help patients recognize the negative automatic thoughts that flit through the consciousness at the times when the patient feels the worst. The second tactic is disputing the negative thoughts by focusing on contrary evidence. The third tactic is teaching the patient a different explanation to dispute the negative automatic thoughts. The fourth tactic involves learning how to avoid rumination (the constant churning of a thought in one's mind) by helping the patient better control their thoughts. The final tactic is questioning depression-causing negative thoughts and beliefs, and replacing them with empowering positive thoughts and beliefs.

Cognitive therapy does not involve the long, drawn-out process of psychoanalysis. It is a solution-oriented psychotherapy designed to help the patient learn skills to improve the quality of his or her life.

Hormonal factors

Many hormones are known to influence mood; however, it is beyond the current scope of this text to address all of them. Instead, the focus will be on the effects of the thyroid and adrenal hormones.

Thyroid function

Depressive illness is often a first or early manifestation of thyroid disease, as even subtle decreases in available thyroid hormone are suspected of producing symptoms.^[7] ^[8] The link between hypothyroidism and depression is well known, but whether the thyroid hypofunction is a result of depression-induced hypothalamic-pituitary-thyroid (HPT) dysfunction, or of thyroid hypofunction, remains to be definitively determined. It is probably a combination. Depressed patients should be screened for hypothyroidism, particularly if they complain of fatigue or have any other symptoms suggestive of hypothyroidism.

Stress and adrenal function

Like the thyroid gland, dysfunction of the adrenal gland is closely associated with

depression. Often this dysfunction is the result of stress – a major factor to consider in the depressed individual. The patient's level of, and response to, stress can be measured with the adrenal stress index. This test measures the level of the cortisol and dehydroepiandrosterone (DHEA) in the saliva. The typical pattern found in depression is an elevated morning cortisol level and a decreased DHEA level.

That elevations in cortisol reflect a disturbance in the hypothalamic-pituitary-adrenal (HPA) axis is the basis of the dexamethasone suppression test (discussed below). Defects in HPA regulation seen in affective disorders include excessive cortisol secretion which is independent of stress responses, abnormal nocturnal release of cortisol, and inadequate suppression by dexamethasone.^[9]

The CNS effects of increased endogenous release of

1043

cortisol mirror the effects of exogenous cortisol: depression, mania, nervousness, insomnia, and, at high levels, schizophrenia. The effects of glucocorticoids on mood are related to their induction of tryptophan oxygenase (see [Fig. 126.2](#) below). This results in shunting of tryptophan to the kynurenine pathway at the expense of serotonin and melatonin synthesis.^[10]

Tests of hypothalamic-pituitary function

The two tests widely used as aids in classifying psychiatric conditions are the dexamethasone suppression test (DST) and the thyroid stimulation test.^{[11] [12]} The basic function of these tests is to determine if the condition is a result of hypothalamic dysfunction and to categorize the psychiatric illness, e.g. severe major affective disorders versus severe psychotic disorders.

It is generally held that the DST is of little clinical value as a screening test and it is debatable whether it offers more information than urinary free cortisol.

Since thyroid hormone assays are not able to detect all cases of thyroid hypofunction, they are not an effective screening procedure. The thyroid stimulation test (TRH) is significantly more sensitive in diagnosing "subclinical hypothyroidism".^[12] A grading system for hypothyroidism as determined by the TRH test has been proposed as follows:

- *Grade 3 (subclinical hypothyroidism – 4%).* Patients are usually without classic signs of thyroid failure, have normal T₃ RU, T₄, and TSH levels, but definitely abnormal TSH response to the TRH test.
- *Grade 2 (mild hypothyroidism – 3.6%).* Patients may have mild isolated clinical signs or symptoms of hypothyroidism, but demonstrate normal T₃ RU and T₄ levels. Baseline TSH levels are elevated, and there is an abnormal TRH test.

- *Grade 1 (overt hypothyroidism – 1%).* Patients demonstrate signs and symptoms of classical hypothyroidism along with abnormal laboratory values, i.e. reduced T₃ RU and T₄ levels, increased TSH levels, and abnormal TRH response.

The TRH test may have wide clinical utility as dysfunction of the thyroid gland is implicated in many conditions.

Environmental toxins

Heavy metals (lead, mercury, cadmium, arsenic, nickel, and aluminum) as well as solvents (cleaning materials, formaldehyde, toluene, benzene, etc.), pesticides, and herbicides have an affinity to nervous tissue. As a result, a variety of psychological and neurological symptoms can occur, including:^{[13] [14] [15]}

- depression
- headaches
- mental confusion
- mental illness
- tingling in extremities
- abnormal nerve reflexes
- other signs of impaired nervous system function.

(See [Chs 18](#) and [37](#) for further discussion.)

Detailed medical history and hair mineral analysis are good screening mechanisms for environmental toxicity. If the hair mineral analysis is inconclusive, a more sensitive indicator is the 8 hour lead mobilization test. This test employs the chelating agent EDTA (edetate calcium disodium) and measures the level of lead excreted in the urine for a period of 8 hours after the injection of EDTA.

Lifestyle factors

A health-promoting lifestyle and diet are very important in the treatment of depression. Particularly important is the cessation of smoking, excessive alcohol consumption, and the intake of caffeine. These lifestyle changes coupled with regular exercise and a healthful diet are more than likely to produce better clinical results than Prozac, with no side-effects and no cost.

Smoking

Cigarette smoking is one of the major factors contributing to premature death in the United States. Cigarette smoking is also a significant factor in depression. Central to the effect of nicotine is the stimulation of adrenal hormone, including cortisol, secretion. Elevated cortisol levels are a well-recognized feature of depression.^[3] One of the key effects of cortisol (and stress) on mood is activation of tryptophan oxygenase, resulting in less tryptophan being delivered to the brain. Since the level of serotonin in the brain is

dependent upon the amount of tryptophan delivered to the brain, cortisol dramatically reduces the level of serotonin and melatonin.^[10] In addition, cortisol also “down-regulates” serotonin receptors in the brain, making them less sensitive to the serotonin that is available.

Cigarette smoking also leads to a relative vitamin C deficiency as the vitamin C is utilized to detoxify the cigarette smoke. Low levels of vitamin C in the brain can result in depression and hysteria.^[16]

Alcohol

Alcohol, a brain depressant, increases adrenal hormone output, interferes with many brain cell processes, and disrupts normal sleep cycles. Alcohol ingestion also leads to hypoglycemia. The resultant drop in blood sugar produces a craving for sugar because it can quickly

1044

elevate blood sugar. Unfortunately, increased sugar consumption ultimately aggravates the hypoglycemia. Hypoglycemia aggravates the mental and emotional problems of the alcoholic.

Caffeine

Although caffeine is a well-known stimulant, the intensity of response to caffeine varies greatly, with people prone to feeling depressed or anxious tending to be especially sensitive to caffeine. The term “caffeinism” is used to describe a clinical syndrome similar to generalized anxiety and panic disorders which includes such symptoms as depression, nervousness, palpitations, irritability, and recurrent headache.^[17]

Several studies have looked at caffeine intake and depression. For example, one study found that, among healthy college students, moderate and high coffee drinkers scored higher on a depression scale than did low users. Interestingly, the moderate and high coffee drinkers also tended to have significantly lower academic performance.^[18] Several other studies have shown that depressed patients tend to consume fairly high amounts of caffeine (e.g. greater than 700 mg/day).^{[19] [20]} In addition, the intake of caffeine intake has been positively correlated with the degree of mental illness in psychiatric patients.^{[21] [22]}

The combination of caffeine and refined sugar seems to be even worse than either substance consumed alone. Several studies have found an association between this combination and depression. In one of the most interesting studies, 21 women and two men responded to an advertisement requesting volunteers “who feel depressed and don’t know why, often feel tired even though they sleep a lot, are very moody, and generally seem to feel bad most of the time”.^[23] After baseline psychological testing, the subjects were placed on a caffeine- and sucrose-free diet for 1 week. The subjects who

reported substantial improvement were then challenged in a double-blind fashion. The subjects took either a capsule containing caffeine and a Kool-Aid drink sweetened with sugar or a capsule containing cellulose and a Kool-Aid drink sweetened with Nutrasweet. Each challenge lasted up to 6 days. About 50% of test subjects became depressed during the test period with caffeine and sucrose.

Another study using a similar format as the Kool-Aid study described above found that seven of 16 depressed patients were found to be depressed with the caffeine and sucrose challenge, but became symptom-free during the caffeine- and sucrose-free diet and cellulose and Nutrasweet test period.^[24]

The average American consumes 150–225 mg of caffeine daily, or roughly the amount of caffeine in one to two cups of coffee. Although most people appear to tolerate this amount, some people are more sensitive to the effects of caffeine than others. Even small amounts of caffeine, as found in decaffeinated coffee, are enough to affect some people adversely. Patients with depression or any psychological disorder should be advised to avoid caffeine completely.

Exercise

Regular exercise may be the most powerful natural antidepressant available. In fact, many of the beneficial effects of exercise noted in the prevention of heart disease may be related just as much to its ability to improve mood as to its improvement of cardiovascular function.^[25] Various community and clinical studies have clearly indicated that exercise has profound antidepressive effects.^[26] These studies have shown that increased participation in exercise, sports, and physical activities is strongly associated with decreased symptoms of anxiety, depression, and malaise. Furthermore, people who participate in regular exercise have higher self-esteem, feel better, and are much happier than people who do not exercise.

Much of the mood-elevating effects of exercise may be attributed to the fact that regular exercise has been shown to increase the level of endorphins, which are directly correlated with mood.^[27] One of the most interesting studies that examined the role of exercise and endorphins in depression compared the beta-endorphin levels and depression profiles of 10 joggers with those of 10 sedentary men of the same age. The 10 sedentary men tested were more depressed, perceived greater stress in their lives, and had a higher level of cortisol and lower levels of beta-endorphins. As the researchers stated, this “reaffirms that depression is very sensitive to exercise and helps firm up a biochemical link between physical activity and depression”.^[28]

At least 100 clinical studies have now evaluated the efficacy of an exercise program in the treatment of depression. In an analysis of the 64 studies prior to 1980, physical fitness training was shown to relieve depression and improve self-esteem and work behavior.^[29]

Unfortunately, the quality of many of the studies was less than ideal. However, because of the good results noted in the analysis of these studies, there was a flurry of well-designed studies conducted in the 1980s to better determine how effective exercise

could be as a therapy. These studies utilized stricter scientific criteria than the earlier ones, yet they produced similar results. It was concluded that exercise can be as effective as other antidepressants, including drugs and psychotherapy.^[30] More recently, even stricter studies have further demonstrated that regular exercise is a powerful antidepressant.^{[31] [32] [33]}

The best exercises are either strength training (weight lifting) or aerobic activities such as walking briskly, jogging, bicycling, cross-country skiing, swimming, aerobic dance, and racquet sports.

1045

Nutrition

A deficiency of any single nutrient can alter brain function and lead to depression, anxiety and other mental disorders (see [Table 126.2](#)). However, the role of nutrient deficiency is just the tip of the iceberg with regard to the role of nutrient effects on the brain and mood. According to Melvin Werbach MD:^[34]

It is clear that nutrition can powerfully influence cognition, emotion, and behavior. It is also clear that the effects of classical nutritional deficiency diseases upon mental function constitute only a small part of a rapidly expanding list of interfaces between nutrition and the mind. ... Even in the absence of laboratory validation of nutritional deficiencies, numerous studies utilizing rigorous scientific designs have demonstrated impressive benefits from nutritional supplementation.

A high potency multiple provides a good nutritional foundation upon which to build. When selecting a multiple vitamin and mineral formula it is important to make sure that it provides the full range of vitamins and minerals at high potency levels. Deficiencies of a number of nutrients are quite common in depressed individuals. The most common deficiencies are folic acid, vitamin B₁₂ and vitamin B₆. The significance of these deficiencies is discussed below.

Dietary guidelines

Since the brain requires a constant supply of blood sugar, hypoglycemia must be avoided. Symptoms of hypoglycemia can range from mild to severe and include:

- depression, anxiety, irritability, and other psychological disturbances
- fatigue
- headache
- blurred vision
- excessive sweating
- mental confusion

- incoherent speech
- bizarre behavior
- convulsions.

TABLE 126-2 -- Behavioral effects of some vitamin deficiencies

| Deficient vitamin | Behavioral effects |
|--------------------------|--|
| Thiamin | Korsakoff's psychosis, mental depression, apathy, anxiety, irritability |
| Riboflavin | Depression, irritability |
| Niacin | Apathy, anxiety, depression, hyperirritability, mania, memory deficits, delirium, organic dementia, emotional lability |
| Biotin | Depression, extreme lassitude, somnolence |
| Pantothenic acid | Restlessness, irritability, depression, fatigue |
| B ₆ | Depression, irritability, sensitivity to sound |
| Folic acid | Forgetfulness, insomnia, apathy, irritability, depression, psychosis, delirium, dementia |
| B ₁₂ | Psychotic states, depression, irritability, confusion, memory loss, hallucinations, delusions, paranoia |
| Vitamin C | Lassitude, hypochondriasis, depression, hysteria |

Several studies have shown hypoglycemia to be very common in depressed individuals.^{[35] [36] [37] [38]} Simply eliminating refined carbohydrate from the diet is occasionally all that is needed for effective therapy in patients who have depression due to reactive hypoglycemia.

The dietary guidelines for depression are identical to the dietary guidelines for optimal health. It is now a well-established fact that certain dietary practices cause, while others prevent, a wide range of diseases. Quite simply, a health-promoting diet provides optimal levels of all known nutrients and low levels of food components which are detrimental to health, such as sugar, saturated fats, cholesterol, salt, and food additives. A health-promoting diet is rich in whole "natural" and unprocessed foods. It is especially high in plant foods, such as fruits, vegetables, grains, beans, seeds and nuts, as these foods contain not only valuable nutrients but also additional compounds which have remarkable health-promoting properties.

Folic acid and vitamin B₁₂

Folic acid and vitamin B₁₂ function together in many biochemical processes. Folic acid deficiency is the most common nutrient deficiency in the world. In studies of depressed patients, 31–35% have been shown to be deficient in folic acid.^{[39] [40] [41] [42]} In elderly

patients this percentage may be even higher. Studies have found that among elderly patients admitted to a psychiatric ward, the number with folic acid deficiency ranges from 35 to 92.6%.^[43] ^[44] Depression is the most common symptom of a folic acid deficiency. Vitamin B₁₂ deficiency is less common than that of folic acid deficiency, but it can also cause depression, especially in the elderly.^[45] ^[46] Correcting the folic acid and/or vitamin B₁₂ deficiency results in a dramatic improvement in mood.

Folic acid, vitamin B₁₂, and a form of the amino acid methionine known as SAM (S-adenosyl-methionine) function as “methyl donors” ([Fig. 126.1](#)). They carry and donate methyl molecules to important brain compounds including neurotransmitters. SAM is the major methyl donor in the body. The antidepressant effects of folic acid appear to be a result of raising brain SAM content.

One of the key brain compounds dependent on methylation is tetrahydrobiopterin (BH₄). This compound functions as an essential coenzyme in the activation of enzymes which manufacture monoamine neurotransmitters like serotonin and dopamine from their corresponding amino acids. Patients with recurrent depression have been shown to have reduced BH₄ synthesis, probably as a result of low SAM levels. BH₄ supplementation

Figure 126-1 Relationship between folate cycle, SAM and transmethylation.

has been shown to produce dramatic results in these patients.^[47] ^[48] Unfortunately, BH₄ is not currently available commercially. However, since BH₄ synthesis is stimulated by folic acid, vitamin B₁₂, and vitamin C, it is possible that increasing these vitamin levels in the brain may stimulate BH₄ formation and the synthesis of monoamines like serotonin.^[49]

There is evidence to support the contention that supplementing the diet with folic acid, vitamin C, and vitamin B₁₂ can increase BH₄ levels. In addition, the folic acid supplementation and the promotion of methylation reactions have been shown to increase the serotonin content.^[50] ^[51] ^[52] The serotonin-elevating effects are undoubtedly responsible for much of the antidepressive effects of folic acid and vitamin B₁₂.

Typically the dosages of folic acid in the antidepressant clinical studies have been very high: 15–50 mg. High-dose folic acid therapy is safe (except in patients with epilepsy)

and has been shown to be as effective as antidepressant drugs.^[53]

A dosage of 800 mcg of folic acid and 800 mcg of vitamin B₁₂ should be sufficient in most circumstances to prevent deficiencies. Folic acid supplementation should always be accompanied by vitamin B₁₂ supplementation to prevent folic acid from masking a vitamin B₁₂ deficiency.

Vitamin B₆

B₆ levels are typically quite low in depressed patients, especially women taking birth control pills or Premarin.^{[54] [55] [56] [57] [58]} Considering the many functions of vitamin B₆ in the brain, including the fact that vitamin B₆ is absolutely essential in the manufacture of all monoamines, it is likely that many of the millions of people who are taking Prozac may be suffering depression simply as a result of low vitamin B₆. Patients with low B₆ status usually respond very well to supplementation. The typical effective dosage is 50–100 mg.

Omega-3 fatty acids

An insufficiency of omega-3 oils has been linked to depression.^[59] This may be related to the impact of dietary fatty acids on the phospholipid composition of neurological cell membranes. While it is thought that the cell is programmed to selectively incorporate the different fatty acids it needs to maintain optimal function, the lack of essential fatty acids (particularly the omega-3 oils) and excess of saturated fats and animal fatty acids lead to the formation of cell membranes which are much less fluid than normal.

A relative deficiency of essential fatty acids in cellular membranes substantially impairs cell membrane function. Since the basic function of the cell membrane is to serve as a selective barrier that regulates the passage of molecules into and out of the cell, a disturbance of structure or function disrupts homeostasis. Because the brain is the richest source of phospholipids in the human body and proper nerve cell function is critically dependent on proper membrane fluidity, alterations in membrane fluidity impact behavior, mood, and mental function. Studies have shown that the biophysical properties, including fluidity, of brain cell membranes directly influence neurotransmitter synthesis, signal transmission, uptake of serotonin and other neurotransmitters, neurotransmitter binding, and the activity of monoamine oxidase. All of these factors have been implicated in depression and other psychological disturbances.

Researchers have concluded that omega-3 fatty acids may reduce the development of depression just as they reduce the development of coronary artery disease.^[59] This conclusion was based on several factors:

- Recent studies have suggested that lowering plasma cholesterol by diet and medications increases suicide, homicide, and depression.
- The quantity and type of dietary fats consumed influence serum lipids and alter the biophysical and biochemical properties of cell membranes.

- Dietary advice to lower cholesterol levels tends to increase the ratio of omega-6 to omega-3 fatty acids and decreases the level of the essential omega-3 fatty acid, docosahexanoic acid.
- Epidemiological studies in various countries and the United States have indicated that decreased consumption of omega-3 fatty acids correlates with increasing rates of depression.
- There is also a consistent association between depression and coronary artery disease.

Food allergies

Depression and fatigue have been linked to food allergies for over 65 years. In 1930, Rowe coined the term “allergic toxemia” to describe a syndrome that included the

1047

symptoms of depression, fatigue, muscle and joint aches, drowsiness, difficulty in concentration, and nervousness.^[60] Although the term allergic toxemia is not used anymore, food allergies still play a major role in many people with depression.^[61]

Monoamine metabolism and precursor therapy

The use of monoamine (MA) precursors, particularly tryptophan, 5-hydroxytryptophan (5-HTP), and tyrosine, has offered a more “natural way” of influencing MA metabolism than monoamine oxidase inhibitors or tricyclic antidepressants.

The tryptophan catastrophe

For more than 30 years, L-tryptophan was used by millions of people in the US and around the world safely and effectively for insomnia and depression. But in October 1989, some people taking tryptophan started reporting strange symptoms to physicians – severe muscle and joint pain, high fever, weakness, swelling of the arms and legs, and shortness of breath.^[62] The syndrome was dubbed EMS (eosinophilia-myalgia syndrome).

Laboratory studies showed that the blood of subjects with EMS contained a very high level of eosinophils. In patients with EMS, eosinophil levels rose to greater than 1,000/mm³, roughly double the normal level, and the percentage of eosinophils often increased to levels above 30%.

The problem with such severe elevations in eosinophils is that these white blood cells contain packets that have high levels of histamine and other allergic and inflammatory compounds. When these compounds are released by eosinophils, this leads to intense symptoms of an allergic and inflammatory nature, e.g. severe muscle and joint pain, high fever, weakness, swelling of the arms and legs, skin rashes, and shortness of

breath – the same symptoms as those experienced by people with EMS. What was suspected was that one or more newly introduced contaminants which activated eosinophils and other white blood cells had to be the reason behind EMS because L-tryptophan had been used successfully by over 30 million people worldwide without side-effect.

Detailed analysis of all the evidence by the Centers for Disease Control (CDC) led to the conclusion that the cause of the EMS epidemic could be traced to one Japanese manufacturer, Showa Denko.^[63] ^[64] Of the six Japanese companies which supplied L-tryptophan to the United States, Showa Denko was the largest, supplying 50–60%. The L-tryptophan was used not only as a nutritional supplement, but also in infant formulas and nutrient mixtures used for intravenous feeding.

The L-tryptophan produced from October 1988 to June 1989 by Showa Denko became contaminated with substances now linked to EMS due to changes in the bacteria being used to produce the L-tryptophan and in the filtration process. The change in the filtration process resulted in the L-tryptophan being contaminated with impurities linked to EMS. Examination of the pre-filtered material indicated that it had no detectable levels of the impurities linked to EMS. Somehow the filtration process produced the contaminants.

While the epidemic of EMS during the last half of 1989 was clearly related to the contaminated L-tryptophan produced by Showa Denko, there have been a handful of other reported cases of EMS in people who never took L-tryptophan and in people who took L-tryptophan prior to the contaminated batch manufactured by Showa Denko hitting the shelves. It is likely that in these earlier reports of EMS-like illnesses among L-tryptophan users, the subjects were also using contaminated L-tryptophan and they also had a predisposition to EMS (discussed below).^[65] ^[66] This conclusion is based upon the fact that uncontaminated tryptophan 5-HTP has never produced EMS. Clearly it is absolutely essential that non-contaminated L-tryptophan be used to avoid the possibility of EMS.

The total number of reported cases of EMS in the United States eventually reached 1,511. Included in this number were 36 deaths attributed to L-tryptophan. In Europe the total number of cases was 171 and there were no deaths.^[63] ^[64] ^[65] ^[66] The difference between the US and the European experiences is that the dominant L-tryptophan supplement in Europe was Optimax[®], a product marketed by Merck, the largest pharmaceutical company in the world. The supplier of the tryptophan used in the Merck product was Ajinomoto.

One of the interesting aspects of the entire L-tryptophan catastrophe is that it did not affect more people. Based on very detailed studies, it was concluded that EMS affected 144 out of every 100,000 men and 268 out of every 100,000 women taking L-tryptophan.^[67] If 50% of these L-tryptophan users were taking Showa Denko supplied L-tryptophan, we can assume that EMS affected 144 out of every 50,000 men, and 268 out of every 50,000 women, taking *contaminated* L-tryptophan. In other words, roughly one out of every 250 people who took the contaminated L-tryptophan developed EMS.

The obvious question is: “Why didn’t everyone taking the contaminated L-tryptophan experience EMS?”. The answer appears to be that only those with an abnormal activation of the kynurenine pathway reacted to the contaminant.^[68] Kynurenine and its metabolites (especially quinolic acid) are also linked to other EMS-related illnesses including the toxic oil syndrome, one of the largest food-related epidemics that has occurred to date. This syndrome occurred in Spain during the month of May in 1991. It affected more than 20,000 people and caused over 12,000 hospitalizations. It was caused by the ingestion of canola oil contaminated with a compound very similar

1048

to one of the contaminants in the contaminated Showa Denko L-tryptophan.^[69]

One of the interesting findings from studies conducted by researchers from the CDC was that people who took a multiple vitamin preparation were extended some protection against EMS.^[70] When regular vitamin users did develop EMS, it was less severe than the EMS experienced in non-vitamin users. A likely explanation for this occurrence is that either the vitamins (particularly vitamin B₆ and niacin) shunted tryptophan metabolism away from the kynurenine pathway or the contaminants are somehow metabolized by vitamin-dependent enzymes.

L-Tryptophan

The basic theory of tryptophan supplementation in depression (and insomnia) is that it will increase the level of serotonin and melatonin in the brain. This theory is supported by the considerable evidence that many depressed individuals have low tryptophan and serotonin levels. Unfortunately, supplementation with L-tryptophan in depressed patients has produced mixed results in the published clinical trials. In only two out of eight studies comparing L-tryptophan with a placebo was L-tryptophan shown to be more effective than the placebo. But interestingly, nine out of 11 studies comparing L-tryptophan with conventional antidepressant drugs showed no difference.^{[71] [72] [73] [74] [75] [76]}

There are many factors to consider when looking at these studies, such as study size, severity of depression, duration, and dosage. In addition, a number of factors, such as hormones like estrogen and cortisol, as well as tryptophan itself, stimulate the activity of tryptophan oxygenase which results in tryptophan being converted to kynurenine and less tryptophan being delivered to the brain ([Fig. 126.2](#) shows the metabolism of tryptophan).

In summary, L-tryptophan is only modestly effective in the treatment of depression when used alone. In order to gain any real benefit from L-tryptophan, it must be used along with vitamin B₆ and the niacinamide form of vitamin B₃ to help block the kynurenine

its enhancement of catecholamine synthesis or possibly its stimulation of thyroid hormone synthesis. The largely negative results using L-dopa alone in affective disorders tend to substantiate this assumption.^[81] Central norepinephrine turnover, however, is decreased in depressed patients. This may be a result of the low serum tyrosine levels seen in some depressed individuals.^[83]

Like tryptophan, the brain tyrosine content is best determined by the ratio of serum tyrosine concentration to the sum of its brain-uptake competitors, i.e. leucine, isoleucine, valine, tryptophan, and phenylalanine. Tyrosine ratios are increased by high-protein meals. Tyrosine

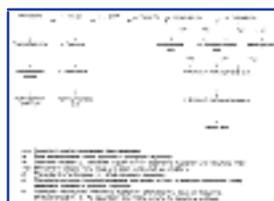

Figure 126-3 Catecholamine metabolism.

1050

supplementation results in increased levels of 3-methoxy-4-hydroxyphenethylene glycol (MHPG) in the urine. This compound is believed to be the principal breakdown product of norepinephrine in the CNS and may provide a biochemical marker for determining which amino acid to supplement.

[Table 126.3](#) summarizes clinical studies using phenylalanine and/or tyrosine for depression. These results indicate that phenylalanine and tyrosine supplementation offer encouraging alternatives to tricyclics and MAO inhibitors.

In the early 1970s, van Praag et al discovered that about one out of five patients who responded well to 5-HTP tended to relapse after 1 month of treatment. The antidepressant effects of 5-HTP in these subjects began to wear off gradually after the first month despite the fact that the level of 5-HTP in the blood, and presumably the level of serotonin in the brain, remained at the same level as when they were experiencing benefit.^[81] These researchers discovered that while serotonin levels appeared to stay at the same levels after 1 month of treatment, the levels of other the other important monoamine neurotransmitters, dopamine and norepinephrine, declined.^[84] These patients responded to supplemental tyrosine.

S-Adenosyl-methionine (SAM)

SAM was discussed briefly above with vitamin B₁₂ and folic acid in its methylation role ([pp. 1045](#)). SAM is involved in the methylation of monoamines, neurotransmitters, and phospholipids like phosphatidylcholine and phosphatidylserine. Normally, the brain manufactures all the SAM it needs from the amino acid methionine. However, SAM

synthesis is impaired in depressed patients. Supplementing the diet with SAM in depressed patients results in increased levels of serotonin, dopamine, and phosphatides, and improved binding of neurotransmitters to receptor sites, resulting in increased serotonin and dopamine activity and improved brain cell membrane fluidity, and thus significant clinical improvement.^{[85] [86] [87]}

The results of a number of clinical studies suggest that SAM is one of the most effective natural antidepressants.^{[88] [89] [90] [91]} Unfortunately, its use is still limited due to its high price. [Tables 126.4](#) and [126.5](#) summarize double-blind studies comparing SAM with either a placebo or a tricyclic drug such as imipramine.

The studies cited in these tables utilized injectable SAM. However, more recent studies using a new oral preparation at a dosage of 400 mg four times daily (1,600 mg total) have demonstrated that SAM is just as effective orally as it is when given intravenously.^{[92] [93] [94] [95]} SAM is better tolerated and has a quicker onset of antidepressant action than tricyclic antidepressants.

A recent study compared SAM with the tricyclic desipramine. In addition to clinical response, the blood level of SAM was determined in both groups. At the end of the 4 week trial, 62% of the patients treated with SAM and 50% of the patients treated with desipramine had significantly improved. Regardless of the type of treatment, patients with a 50% decrease in their Hamilton Depression Scale (HAM-D) score showed a significant increase in plasma SAM concentration. These results suggest that one of the ways in which tricyclic drugs exert antidepressive effects is by raising SAM levels.^[96]

No significant side-effects have been reported with oral SAM. However, because SAM can cause nausea and vomiting in some people, it is recommended that it be started at a dosage of 200 mg twice daily for the first day, increased to 400 mg twice daily on day 3, then to 400 mg three times daily on day 10, and finally to the full dosage of 400 mg four times daily after 20 days.

Individuals with bipolar (manic) depression should not take SAM. Because of SAM's antidepressant activity, these individuals are susceptible to experiencing hypomania or mania. This effect is exclusive to some individuals with bipolar depression.

TABLE 126-3 -- Phenylalanine and tyrosine in depression

| Reference | Number of patients | Dose (mg/day) | Duration (days) | Clinical effects and comments |
|----------------------|--------------------|---------------|-----------------|--|
| Yaryura et al (1974) | 15 | 200–400 | 14 | (D,L-P) 10 severely depressed patients responded |
| Fischer et al (1975) | 23 | 100 | 1–13 | (D, or D,L-P) A complete response was observed in 17 patients previously unresponsive to tricyclics and MAO inhibitors |

| | | | | |
|----------------------|----|---------|---------|---|
| Beckman et al (1977) | 20 | 75–200 | 20 | (D,L-P) Eight complete remissions, four showed marked improvement; used Hamilton Depression Scale and von Zerssen self-rating questionnaire |
| Heller (1978) | 55 | 100–400 | 60–180 | (D-P) 73% recovered completely after 15 days, 23% had marked improvement, 4% failed to respond |
| Heller (1978) | 60 | 100 | 30 | (D-P) Complete remission and improvement in 83% for the phenylalanine group compared with 73% for the imipramine group; double-blind controlled study – no diagnostic criteria or rating scales were reported |
| Beckman (1979) | 27 | 200 | 30 | (D,L-P) No significant difference between phenylalanine and imipramine groups |
| Gibson et al (1983) | 9 | 300 | Ongoing | (T) Double-blind, placebo-controlled study; tyrosine demonstrated a rate of response (60–70%) typical of most major antidepressants without side-effects |

References are from Beckman^[83] and Gibson & Gelenberg.^[82]

P = phenylalanine; T = tyrosine.

TABLE 126-4 -- Double-blind clinical studies with SAM vs. placebo in depression*

| Authors | SAM responders | Placebo responders | Conclusion |
|-------------------------|-----------------------|---------------------------|--|
| Fazio et al (1973) | Not quantified | | SAM superior to placebo based on Hamilton Depression Scale |
| Agnoli et al (1976) | 20/20 | 1/10 | SAM superior to placebo |
| Muscettola et al (1982) | 4/10 | 0/10 | SAM superior to placebo |
| Janicak (1982) | 5/7 | 0/5 | SAM superior to placebo |

| | | | |
|---------------------|----------------|-----------|--|

Botanical medicines

Hypericum perforatum

Extracts of St John's wort standardized for hypericin are the most thoroughly researched natural antidepressants. A total of 1,592 patients have been studied in 25 double-blind controlled studies (15 compared with placebo, 10 compared with antidepressant drugs including five studies comparing St John's wort extract with tricyclics: two vs. imipramine, two vs. amitriptyline, and one vs. desipramine).^[97] ^[98] ^[99]

In these studies, St John's wort extract was shown to produce improvements in many psychological symptoms, including:

- depression
- anxiety
- apathy
- sleep disturbances
- insomnia
- anorexia
- feelings of worthlessness.

The main advantage of St John's wort extract over antidepressant drugs was not so much a difference in therapeutic outcome, but rather a significant advantage in terms of side-effects, cost and patient. For example, in a study of 102 patients there were slightly better results obtained with maprotiline (a tetracyclic) in the HAM-D, D-S, and CGI, but when side-effects and patient tolerance were added to the equation, St John's wort was considered superior.^[100] Maprotiline treatment resulted in the typical side-effects of tricyclics, e.g. tiredness, mouth dryness, and heart complaints. For more information on St John's wort, consult [Chapter 93](#).

Piper mythicum

Kava extracts, like St John's wort, are gaining in popularity in Europe in the treatment of anxiety and depression. Several European countries (e.g. Germany, the United Kingdom, Switzerland, and Austria) have approved kava preparations in the treatment of nervous anxiety, insomnia, depression, and restlessness on the basis of detailed pharmacological data and favorable clinical studies. In fact, kava extract compares quite favorably with benzodiazepines in effectiveness, but does not possess the major drawbacks of these drugs (impaired mental acuity, addictiveness, etc.).^[101] ^[102] ^[103] These

approved kava preparations are extracts standardized for kavalactone content (usually 30–70%). Kava appears most

useful in cases of depression with severe anxiety (for more information on kava, see [Ch. 104](#)).

Ginkgo biloba

The extract of *Ginkgo biloba* leaves standardized to contain 24% ginkgo flavonglycosides and 6% terpenoids exerts good antidepressant effects, especially in patients over the age of 50 years. Researchers became interested in the antidepressive effects of *Ginkgo biloba* extract as a result of the improvement in mood reported by patients suffering from cerebrovascular insufficiency who were treated with ginkgo in double-blind studies.^{[104] [105] [106] [107]} These observations led to several double-blind studies of the efficacy of ginkgo in depression. In one of the more recent double-blind studies, 40 older patients (age range, 51–78 years) with depression who had not benefited fully from standard antidepressant drugs were given either 80 mg of *Ginkgo biloba* extract three times daily or a placebo.^[108] By the end of the fourth week of the study, the total score on the Hamilton Depression Scale was reduced on average from 14 to 7. At the end of the 8 week study, the total score in the *Ginkgo biloba* extract group had dropped to 4.5. In comparison, the placebo group only dropped from 14 to 13. This study indicates that *Ginkgo biloba* extract can be used with standard antidepressants and it may enhance their effectiveness, particularly in patients over 50 years of age.

In addition to human studies, *Ginkgo biloba* extract has also demonstrated antidepressant effects in a number of animal models including the learned helplessness model. The most interesting of these studies demonstrated that *Ginkgo biloba* extract was able to counteract one of the major changes in brain chemistry associated with aging – the reduction in the number of serotonin receptor sites.^[109] Typically, with aging there is a significant reduction in the number of serotonin receptor sites on brain cells. As a result, the elderly are more susceptible to depression, impaired mental function, insomnia, and sleep disturbances. The study was designed to determine whether *Ginkgo biloba* extract could alter the number of serotonin receptors in old (24-month-old) and young (4-month-old) rats. At the beginning of the study, the older rats had a 22% lower number of serotonin binding sites compared with the younger rats. The results of chronic treatment with *Ginkgo biloba* extract for 21 consecutive days demonstrated that there was no change in receptor binding in young rats, but in the older rats there was a statistically significant increase (by 33%) in the number of serotonin binding sites. These results indicate that *Ginkgo biloba* extract may counteract at least some, if not all, of the age-dependent reductions of serotonin binding sites in the aging human brain as well.

The exact mechanism of *Ginkgo biloba* extract's effect on increasing serotonin receptors

has not yet been determined; however, *Ginkgo biloba* extract may address two major reasons why serotonin receptors decline with age: impaired receptor synthesis, or changes in cerebral neuronal membranes or receptors as a result of free radical damage. *Ginkgo biloba* extract has demonstrated an ability to increase protein synthesis. In addition, *Ginkgo biloba* extract is known to be a potent antioxidant. The most likely explanation is that it is a combination of these two effects (and others) rather than one single mechanism (see [Ch. 88](#) for further discussion).

THERAPEUTIC APPROACH

Treatment is largely dependent upon accurate determination of which factors are contributing to the patient's depression; balancing of errant neurotransmitter levels; and optimizing the patient's nutrition, lifestyle, and psychological health.

Diet

Increase the consumption of fiber-rich plant foods (fruits, vegetables, grains, legumes, and raw nuts and seeds). Avoid the intake of caffeine, nicotine, other stimulants, and alcohol. Identify and control food allergies. Increase the consumption of cold water fish to at least twice per week.

Lifestyle

- Either refer the patient to a counselor or help them to develop a positive, optimistic mental attitude. This can be accomplished by helping the patient to set goals, use positive self-talk and affirmations, identify self-empowering questions and find ways to inject humor and laughter into his or her life.
- Regular exercise: at least 30 minutes at least three times a week.
- Relaxation/stress reduction technique: 10–15 minutes each day.

Supplements

- High potency multiple vitamins and minerals
- Vitamin C: 500–1,000 mg three times/day
- Vitamin E: 200–400 IU/day
- Flaxseed oil: 1 tbsp/day
- 5-HTP: 100–200 mg three times/day
- Folic acid and vitamin B₁₂ : 800 mcg of each daily.

Botanical medicines

If under the age of 50, St John's wort extract (0.3% hypericin) should be used at a dosage of 300 mg three times daily. In severe cases, St John's wort extract can be used in combination with 5-HTP.

If over the age of 50, *Ginkgo biloba* extract (24% ginkgo flavonglycosides) should be used at a dosage of 80 mg three times daily. In severe cases, this can be used in combination with St John's wort and/or 5-HTP.

If anxiety is a significant factor, kava extract standardized for kavalactone content should be used at a dosage of 45–70 mg kavalactones three times daily.

BIPOLAR (MANIC) DEPRESSION AND HYPOMANIA

GENERAL CONSIDERATIONS

Bipolar depression is a disorder characterized by periods of major depression alternating with periods of elevated mood. If the elevated mood is relatively mild and lasts for 4 days or less it is referred to as hypomania. Mania is longer and more intense. To be diagnosed as a bipolar depressive, an individual would be expected to have at least three of the following symptoms:

- excessive self-esteem or grandiosity
- reduced need for sleep
- extreme talkativeness, excessive telephoning
- extremely rapid flight of thoughts along with the feeling that the mind is racing
- inability to concentrate, easily distracted
- increase in social or work-oriented activities, often with a 60–80 hour working week
- poor judgment, as indicated by sprees of uncontrolled spending, increased sexual indiscretions, and misguided financial decisions.

A full-blown manic attack requires hospitalization. Manic people have lost control, and they may hurt themselves or others. The standard treatment of bipolar depression is lithium. Lithium stabilizes mood. It is especially useful in preventing the manic phase. Lithium is used either alone or in combination with an antidepressant like Prozac. However, because Prozac and other antidepressant drugs can occasionally induce mania and hypomania, it is often very difficult to effectively control the lows in bipolar depressives with drug therapy.

THERAPEUTIC CONSIDERATIONS

Patients experiencing a manic syndrome usually require hospitalization to prevent impulsive and aggressive behavior from ruining their careers or injuring themselves or others. Lithium has become the drug of choice for these patients. Typically, manic patients are initially hospitalized for 2 weeks and kept under sedation with antipsychotic drugs until lithium levels reach acceptable blood levels. Referral seems warranted for most cases until mood can be stabilized.

Many of the principles outlined in the discussion of depression are applicable to mania as well. However, due to the seriousness of this condition, it is more appropriate to use nutritional therapy as an adjunct, rather than as the primary therapy. Also, as serotonin reuptake inhibitors like Prozac, Zoloft, and Paxil are often helpful when used in combination with lithium, 5-HTP and botanical medicines such as St John's wort extract may prove useful as adjuncts to lithium as well but without the side-effects.

Tryptophan

Although patients have responded to tryptophan supplementation, the effective doses were generally quite large, i.e. 12 g/day L-tryptophan. [\[110\]](#) [\[111\]](#) A better choice appears to be 5-HTP, which has been shown to be helpful in the treatment of bipolar depression when used in combination with lithium at a much lower dosage (e.g. 100 mg three times/day) than L-tryptophan. [\[112\]](#) [\[113\]](#)

Phosphatidylcholine

Supplementation with large amounts of phosphatidylcholine (15–30 g/day in both the pure form and as lecithin) has shown better results than monoamine precursors in the treatment of mania. [\[114\]](#) [\[115\]](#) [\[116\]](#) Lithium is believed to promote increased CNS cholinergic activity via inhibition of choline flux across the blood–brain barrier. [\[117\]](#) [\[118\]](#) There is evidence that mania is associated with a reduced CNS cholinergic activity. [\[117\]](#) [\[118\]](#) The use of phosphatidylcholine to increase CNS choline may result in significant improvement or amelioration of symptoms in some patients. [\[114\]](#) [\[115\]](#) [\[116\]](#) Details of the basic defect in the one-carbon cycle and the cholinergic system need to be worked out, but it appears to be a valuable clue to the etiology of mania.

Vanadium

Vanadium's role in mania has been researched primarily by Naylor and colleagues. [\[119\]](#) [\[120\]](#) [\[121\]](#) Increased levels of vanadium are found in hair samples from manic patients, and these values fall towards normal levels with recovery. [\[119\]](#) In contrast, depressed patients typically have normal hair concentrations, while whole blood and serum vanadium levels are elevated. [\[119\]](#) Their levels also return to normal upon recovery. Vanadium, as the vanadate ion, is a strong inhibitor of Na⁺, K⁺ ATPase. Lithium has been reported to reduce this inhibition. [\[119\]](#) [\[120\]](#) [\[121\]](#)

Therapies designed to reduce vanadate to the less inhibitory vanadyl form have used ascorbic acid, methylene blue, and EDTA separately and in combination. [\[120\]](#) [\[121\]](#) Ascorbic acid (3 g/day) has been shown in a doubleblind cross-over study to result in significant clinical improvement. [\[120\]](#)

The use of a “low-vanadium diet” has also been advocated by Naylor. However, his dietary suggestions for low vanadium intake are not consistent with the vanadium content of foods, as determined by flameless atomic absorption spectroscopy.^[122] Using this method, low-vanadium foods (1–5 ng/g) include fats, oils, fresh fruits, and vegetables. Whole grains, sea food, meat, and dairy products are in the range of 5–30 ng/g, while prepared foods, such as peanut butter, white bread, and breakfast cereals, range from 11 to 93 ng/g.^[122] The benefit of the low-vanadium diet used in Naylor’s study was probably due to his simultaneous administration of EDTA.

If Naylor’s hypothesis is correct, perhaps other factors which are known to affect Na⁺, K⁺ ATPase activity are involved in some cases. Those factors associated with decreased activity would include uremia, hypothyroidism, and catecholamine insensitivity. From a therapeutic aspect, correction of these underlying factors may be of some aid. Vitamins E and B₆ have been demonstrated to increase Na⁺, K⁺ ATPase activity in vitro, and vitamin E stabilizes membranes as well.^[123]

Circadian rhythms

Manic depressive patients have disturbed circadian rhythms, seasonal patterns of exacerbations, and supersensitivity to light, suggesting that alteration of circadian light–dark cycles through light therapy may be of clinical utility (see “Seasonal affective disorder” below).^[124]

THERAPEUTIC APPROACH

In general, the same dietary and lifestyle guidelines given in the section on depression are appropriate here.

Diet

A low-vanadium diet is recommended. This entails eliminating all refined and processed foods and promoting the consumption of fresh fruits and vegetables.

Supplements

- Phosphatidylcholine: 10–25 g/day (note that phosphatidylcholine may induce depression in some patients;^[125] if this occurs, discontinue immediately)
- Vitamin C: 3–5 g/day in divided doses
- Vitamin E: 400–800 IU/day
- Pyridoxine: 100 mg/day.

SEASONAL AFFECTIVE DISORDER

GENERAL CONSIDERATIONS

Seasonal affective disorder (SAD) is associated with winter depression and summer hypomania. Typically, these individuals feel depressed, they slow down, and generally oversleep, overeat, and crave carbohydrates in the winter. In the summer, these same patients feel elated, active, and energetic.

THERAPEUTIC CONSIDERATIONS

Melatonin

Although many variables may be responsible for SAD, light exposure appears the most logical explanation. Many mammals exhibit seasonal variation in activity level, sleep patterns, and appetite, and are extremely sensitive to changes in day length. The key hormonal change may be a reduced secretion of melatonin from the pineal gland and an increased secretion of cortisol by the adrenal glands. Melatonin supplementation may improve SAD because it not only increases brain melatonin levels, but also may suppress cortisol secretion.^[126]

Light therapy

The antidepressive effects of full-spectrum light therapy have been demonstrated in well-monitored, controlled studies not only in SAD, but also in clinical depression.^[127] ^[128] ^[129] The antidepressant effect of light therapy is probably due to restoring proper melatonin synthesis and secretion by the pineal gland leading to re-establishment of the proper circadian rhythm.

Light therapy consists of using full-spectrum lighting (Vitalite is a popular brand). The typical protocol used in clinical studies involved placing full-spectrum fluorescent tubes in regular fluorescent fixtures (eight tubes total). Patients were then instructed to sit 3 feet away from the light from 5.00 a.m. to 8.00 a.m. and again from 5.30 p.m. to 8.30 p.m. They were free to engage in activities as long as they glanced at the light at least once per minute. Obviously, to adopt this treatment protocol would greatly restrict social activities. Something that may work just as well is simply replacing standard light bulbs with full-spectrum light bulbs.

Hypericum perforatum

St John's wort extract, standardized to contain 0.3% hypericin (see [Ch. 93](#)), at a dosage of 300 mg three times daily has been shown to improve SAD.^[130] However, although effective on its own, St John's wort extract is more effective when used in combination with light therapy. This was demonstrated in a double-blind study where patients with SAD were randomized in a 4 week treatment study with 900 mg/day of St John's wort extract (0.3% hypericin content) combined with either bright (3000 lux, $n =$

10) or dim light (<300 lux therapy). There was a significant reduction in the Hamilton

Depression Scale in both groups (72 and 60%, respectively), demonstrating that the efficacy of St John's wort extract in SAD is enhanced with light therapy.

THERAPEUTIC APPROACH

Since the cause of SAD appears to be light-related, the treatment goal is to extend the light exposure on winter days. This can be accomplished by using full-spectrum lighting as described above. However, it may be unrealistic to expect most patients to comply fully. Therefore, have the patient introduce full-spectrum lighting throughout their indoor environment and prescribe conjunctive therapy with night-time melatonin (3 mg 45 minutes before retiring) and daytime St John's wort or 5-HTP.

Chapter 127 - Alcoholism

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

DIAGNOSTIC SUMMARY

- Alcohol dependence manifested when alcohol is withdrawn: tremulousness, convulsions, hallucinations, delirium
- Alcoholic binges, benders (48 hours or more of drinking associated with failure to meet usual obligations), or blackouts
- Evidence of alcohol-induced illnesses: cirrhosis, gastritis, pancreatitis, myopathy, polyneuropathy, cerebellar degeneration
- Physical signs of excess alcohol consumption: alcohol odor on breath, flushed face, tremor, ecchymoses
- Psychological/social signs of excess alcohol consumption: depression, loss of friends, arrest for driving while intoxicated, surreptitious drinking, drinking before breakfast, frequent accidents, unexplained work absences.

GENERAL CONSIDERATIONS

Alcoholism has been defined by the World Health Organization as alcohol consumption by an individual that exceeds the limits accepted by the culture or injures health or social relationships. As can be seen from [Table 127.1](#), the health, social, and economic consequences of alcoholism are alarming.

Current estimates indicate that 18 million persons in the US are alcoholics, making alcoholism one of the most serious health problems facing the physician today.⁽¹⁾ The total number of Americans affected, either directly or indirectly, is much greater when one considers disruption of family life, automobile accidents, crime, decreased productivity, and mental and physical disease.

Doctors should consider alcoholism when the information provided by the patient and the doctor's own analysis seem to indicate a missing factor. Often, alcoholism is a

“hidden” disease. The natural consequences of the alcoholic’s behavior may be disguised by sympathetic family and friends. This allows the alcoholic to

TABLE 127-1 -- Consequences of alcoholism^[1]

Increased mortality

- 10–12 year decrease in life expectancy
 - Double the usual death rate in men, triple in women
 - Six times greater suicide rate
 - Major factor in the four leading causes of death in men between the ages of 25 and 44: accidents, homicides, suicides, cirrhosis
-

Economic toll (yearly)

- Lost production: \$14.9 billion
 - Health care costs: \$8.3 billion
 - Accident and fire losses: \$5.0 billion
 - Cost of violent crime: \$1.5 billion
 - Total costs (health care, accidents, violence, lost productivity): \$136 billion
-

Health effects

- Metabolic damage to every cell
 - Intoxication
 - Abstinence and withdrawal syndromes
 - Nutritional diseases
 - Cerebellar degeneration
 - Cerebral atrophy
 - Psychiatric disorders
 - Esophagitis, gastritis, ulcer
 - Increased cancer of mouth, pharynx, larynx, esophagus
 - Pancreatitis
 - Liver fatty degeneration and cirrhosis
 - Arrhythmias
 - Myocardial degeneration
-

- Hypertension

- Angina

- Hypoglycemia

- Decreased protein synthesis

- Increased serum and liver triglycerides

- Decreased serum testosterone

- Myopathy

- Osteoporosis

- Rosacea, spiders

- Coagulation disorders

Effects on fetus

- Growth retardation

- Mental retardation

- Fetal alcohol syndrome

- Teratogenicity

target other factors as the “real problem” without identifying his or her drinking behavior (see [Table 127.3](#) for an alcoholism-screening questionnaire).

The etiology of alcoholism remains obscure. It represents a multifactorial condition with genetic, physiological, psychological, and social factors, all seemingly equally important. However, recent research indicates genetic factors may be most important.^[2] The finding of a genetic marker for alcoholism could result in the diagnosis of the disease in its initial and most reversible stage.

A number of studies have shown that the incidence of alcoholism is four to five times more common in the biological children of alcoholic parents than those of non-alcoholic parents.^[2] This suggests that a biological marker may not be necessary for the implementation of a relatively innocuous primary prevention program. The genetic basis of alcoholism has been supported by:

- genealogical studies showing that alcoholism is a family condition
- studies of adopted children of alcoholic parents raised by foster parents demonstrating continued higher risk of alcoholism
- twin studies showing differences between identical and non-identical twins
- association with genetic markers: color vision, non-secretor ABH, HLA-B₁₃, and low platelet MAO
- biochemical studies showing the importance of alcohol dehydrogenase polymorphism in racial susceptibility to alcoholism.^[2]

INTOXICATION AND WITHDRAWAL

The signs of alcoholic intoxication are typical of a central nervous system depressant: drowsiness, errors of commission, disinhibition, dysarthria, ataxia, and nystagmus. Fifteen milliliters of pure alcohol (the equivalent of 1 ounce of whiskey, 4 ounces of wine, or 10 ounces of beer) raise the blood level of alcohol by 25 mg/dl in a 70 kg person. [Table 127.2](#) shows the effects of varying blood levels of alcohol.

Withdrawal symptoms usually occur 1–3 days after the last drink. They typically range from anxiety and tremulousness to mental confusion, tremor, sensory hyperactivity, visual hallucinations, autonomic hyperactivity,

TABLE 127-2 -- Effects of varying levels of blood alcohol

| Blood level (mg/dl) | Effect |
|---------------------|---|
| <50 | No significant motor dysfunction |
| 100 | Mild intoxication – decreased inhibitions, slight visual impairment, slight muscular incoordination, slowing of reaction time |
| | Legally intoxicated in most jurisdictions |
| 150 | Ataxia, dysarthria, slurring of speech, nausea and vomiting |
| 350 | Marked muscular incoordination, blurred vision, approaching stupor |
| 500 | Coma and death |

TABLE 127-3 -- The brief Michigan alcoholism screening test (MAST)^[1]

| | | |
|--|------------|-----------|
| 1. Do you feel you are a normal drinker? | Yes (0) | No (2) |
| 2. Do friends or relatives think you are a normal drinker? | Yes (0) | No (2) |
| 3. Have you ever attended a meeting of Alcoholics Anonymous (AA)? | Yes (5) | No (0) |
| 4. Have you ever lost friends or girlfriends or boyfriends because of drinking? | Yes (2) | No (0) |
| 5. Have you ever gotten into trouble at work because of drinking? | Yes (2) | No (0) |
| 6. Have you ever neglected your obligations, your family, or your work for 2 or more days in a row because you were drinking? | Yes (2) | No (0) |
| 7. Have you ever had delirium tremens (DTs), severe shaking, heard voices, or seen things that weren't there after heavy drinking? | Yes (2) | No (0) |

| | | |
|--|------------|-----------|
| 8. Have you ever gone to anyone for help about your drinking? | Yes (5) | No (0) |
| 9. Have you ever been in a hospital because of drinking? | Yes (5) | No (0) |
| 10. Have you ever been arrested for drunk driving or driving after drinking? | Yes (2) | No (0) |

Note: alcoholism is indicated by a score of greater than 5.

1061

diaphoresis, dehydration, electrolyte disturbances, seizures, and cardiovascular abnormalities.

METABOLIC EFFECTS OF ALCOHOL AND ALCOHOLISM

Ethanol metabolism

The primary metabolic processes that regulate the rate of alcohol catabolism in normal individuals are:^[3]

- the rate of ethanol absorption
- the concentration and activity of liver alcohol dehydrogenase (ADH) and aldehyde dehydrogenase (ALDH)
- the NADH/NAD⁺ ratio in the liver mitochondria.

It is generally accepted that the availability and regeneration of NAD⁺ are the dominant rate-limiting factors for ethanol oxidation.^[4] Ethanol is converted to acetaldehyde by ADH, with NAD⁺ as a necessary cofactor.

The aldehyde product of ethanol metabolism is believed to be responsible both for many of the harmful effects of alcohol consumption, and for the addictive process itself. Higher than normal blood aldehyde levels have been found in alcoholics and their relatives after alcohol consumption.^[4] This suggests either increased ADH activity or depressed ALDH activity in people susceptible to alcoholism. Acetaldehyde is converted by ALDH to acetate with little entering the Krebs cycle; most is converted to long-chain fatty acids.^[3]

Fatty liver

All active alcoholics display fatty infiltration of the liver, with the severity roughly proportional to the duration and degree of alcohol excess. Even moderate doses of ethanol may produce both acute and chronic fatty liver infiltrates. The pathogenesis is

due to:^[3] ^[5]

- increased endogenous fatty acid synthesis
- diminished triglyceride utilization
- impaired lipoprotein excretion
- direct damage to endoplasmic reticulum by free radicals produced by ethanol metabolism
- the high-fat diet of the alcoholic (as is typical of the average American diet).

Hypoglycemia

Alcohol induces reactive hypoglycemia. The resultant drop in blood sugar produces a craving for food, particularly foods which quickly elevate blood sugar, i.e. sugar and alcohol. Increased sugar consumption aggravates the reactive hypoglycemia, particularly in the presence of alcohol, due to alcohol-induced impairment of gluconeogenesis.^[3] Hypoglycemia aggravates the mental and emotional problems of the alcoholic and the withdrawing alcoholic with such symptoms as:^[4]

- sweating
- tremor
- tachycardia
- anxiety
- hunger
- dizziness
- headache
- visual disturbance
- decreased mental acuity
- confusion
- depression.

THERAPEUTIC CONSIDERATIONS

Nutrition

While many of the nutritional problems of alcoholics relate directly to the effects of alcohol, a major contributing factor is that alcoholics tend not to eat. They substitute alcohol for food. As a result, the alcoholic not only has to deal with nutritional deficiencies caused by excessive alcohol consumption, but also true nutritional deficiencies due to inadequate intake.

Zinc

One of the key nutrients involved in the metabolic handling of alcohol is zinc, as both ADH and ALDH are zinc-dependent enzymes, with the latter being more sensitive to deficiency.^[6] Both acute and chronic alcohol consumption result in zinc deficiency.^[6] ^[7] Several factors contribute to the development of zinc deficiency in alcoholics:

- decreased dietary intake
- decreased ileal absorption (probably due to interference with the zinc-binding ligand, picolenic acid, and non-specific mucosal damage)
- hyperzincuria.

Low serum zinc levels are associated with impaired alcohol metabolism, a predisposition to cirrhosis, impaired

1062

testicular function, and other complications of alcohol abuse.^[6] ^[8] Zinc supplementation, particularly when combined with ascorbic acid, greatly increases alcohol detoxification and survival in rats.^[9]

Vitamin A

A vitamin A deficiency is also common in alcoholics and appears to work synergistically with the zinc deficiency to produce the major complications of alcoholism.^[5] ^[8] The mechanism has been hypothesized as follows: reduced intestinal absorption of zinc and vitamin A, in conjunction with impaired liver function (reduced extraction of zinc, mobilization of retinol binding protein [RBP], and storage of vitamin A), results in reduced blood levels of zinc, vitamin A, RBP, and transport proteins, and a shift to non-protein ligands. These cause, in the tissues, reduced concentrations of zinc and vitamin A, abnormal enzyme activities and glycoprotein synthesis, and impaired DNA/RNA metabolism; and in the kidney, increased loss of zinc. These metabolic abnormalities then lead to the common disorders of alcoholism:^[8]

- night blindness
- skin disorders
- cirrhosis of the liver
- reduced skin healing
- decreased testicular function
- impaired immune function, etc.

Vitamin A supplementation inhibits alcohol consumption in female, but not male, rats, and the effect is inhibited by testosterone administration.^[10] Other research on rats further supports the significance of the endocrine system on alcohol preference. Ovariectomized and adrenalectomized rats show decreased preference for alcohol, while corticosterone injections increase alcohol preference.^[11]

Vitamin A supplementation in the alcoholic has produced correction of vitamin A deficiency as noted by improvements in night blindness and sexual function.^[5] Despite the importance and benefits to the alcoholic, great care must be employed when recommending vitamin A supplementation. Excessive amounts of vitamin A are contraindicated due to the fact that a liver damaged by excessive alcohol consumption significantly loses its ability to store vitamin A. As a result, the alcoholic is at great risk

for developing vitamin A toxicity when supplemented at dosages above the recommended dietary allowance of 5,000 IU.

Antioxidants

Ethanol consumption causes an increase in lipid peroxidation in humans, resulting in increased lipoperoxide levels in both the liver and serum. Matters are made even worse by the fact that alcoholics are typically deficient in key antioxidant nutrients, particularly vitamin E, selenium, and vitamin C.^[12] There is a significant correlation between serum lipid peroxide levels, SGOT activity, and liver cell necrosis.^[13] Antioxidant administration, either prior to or simultaneous with ethanol intake, inhibits lipoperoxide formation and prevents fatty infiltration of the liver.^[14] Effective antioxidants include vitamins C and E, zinc, selenium, and cysteine.

Carnitine

Although the use of lipotropic agents appears warranted in treating alcoholic fatty liver disease, many commonly used lipotropic agents, e.g. choline, niacin, and cysteine, appear to have little value.^{[15] [16]} One lipotropic agent, carnitine, does significantly inhibit alcohol-induced fatty liver disease. It has been suggested that chronic ethanol consumption results in a functional deficiency in carnitine.^{[17] [18] [19]} Since carnitine normally facilitates fatty acid transportation and oxidation in the mitochondria, a high liver carnitine level may be needed to handle the increased fatty acid load produced by alcohol consumption. Supplemental carnitine reduces serum triglycerides and SGOT levels while elevating HDL cholesterol.^[17]

Amino acids

Amino acid chromatography patterns are aberrant in alcoholics; restoration to normal levels greatly aids the alcoholic patient.^{[20] [21] [22] [23]} Since the liver is the primary site for amino acid metabolism, it is not surprising that alcoholics develop abnormal amino acid patterns. Normalization of plasma amino acids is particularly indicated in those patients showing signs or symptoms of hepatic cirrhosis or depression. The branched-chain amino acids (BCAA), i.e. valine, isoleucine and leucine, inhibit the hepatic encephalopathy and increased protein catabolism that are common sequelae of cirrhosis.^[23] Derangement of neurotransmitter profiles, particularly due to the very low plasma levels of tryptophan typically seen in withdrawing alcoholics, will result if not normalized, leading to depression, encephalopathy, and coma.^{[20] [22]} These problems are aggravated by the low-protein diet used as standard therapy for cirrhosis, but can be avoided through the use of free form amino acids without the risk of hepatic encephalopathy.^{[20] [22]} (See "Depression" on [p. 1064](#) for further discussion of amino acid imbalances.)

Although there are some characteristic amino acid abnormalities in alcoholics, an individual approach is indicated, due to differences in nutritional status, biochemistry, and the amount of liver damage. Correction of the imbalances probably requires amino

acid chromatography for best results.

Vitamin C

In one study, a deficiency of ascorbic acid (AA) was found in 91% of patients with alcohol-related diseases.^[24] Supplemental AA helped ameliorate the effects of acute and chronic ethanol toxicity in experimental studies involving humans and guinea pigs, two species unable to synthesize their own AA.^[9] ^[25] There is a direct correlation between leukocyte ascorbic acid levels (a good index of actual body AA status), the rate of ethanol clearance from the blood, and the activity of hepatic ADH.^[9] The evidence suggests that AA, a strong reducing agent, can function as an electron donor similar to NAD in ethanol metabolism, thereby increasing the conversion of ethanol to acetaldehyde and the further catabolism of acetaldehyde.^[9] ^[25]

B vitamins

Alcoholics are classically deficient in most of the B vitamins.^[1] ^[5] ^[24] These deficiencies result from a variety of mechanisms:

- low dietary intake
- deactivation of the active form
- impaired conversion to the active form by ethanol or acetaldehyde
- impaired absorption
- decreased storage capacity.

A thiamin deficiency is both the most common (55% in one study^[24]) and the most serious of the B-vitamin deficiencies, since a deficiency causes beri-beri and the Wernicke–Korsakoff Syndrome. In addition, recent evidence indicates that a thiamin deficiency results in greater intake of alcohol, suggesting that thiamin deficiency is a predisposing factor for alcoholism.

A functional pyridoxine deficiency is also common in alcoholics, due not so much to inadequate intake as to impaired conversion to its active form, pyridoxal-5-phosphate, and enhanced degradation.^[27] In addition to inhibiting conversion to more active forms, alcohol also decreases the absorption and utilization by the liver, and/or increases the urinary excretion of many B vitamins, especially folic acid.^[5] ^[28]

Magnesium

A magnesium deficiency is common in alcoholics. In fact, hypomagnesemia is present in as many as 60% of alcoholics and is strongly linked to delirium tremens.^[29] It is thought to be the major reason for the increased cardiovascular disease noted in alcoholics.^[30] This deficiency is due primarily to a reduced magnesium intake coupled

with alcohol-induced renal hyperexcretion of magnesium,^[1] ^[29] which continues during withdrawal despite low serum magnesium levels. Alcoholic cardiomyopathy, often associated with thiamine deficiency, may instead be due to a magnesium deficiency.

Essential fatty acids

Ethanol has been shown to interfere with essential fatty acid (EFA) metabolism and as a result may produce symptoms of EFA deficiency if consumed in excess.^[31]

Glutamine

Glutamine supplementation (1 g/day) has been shown to reduce voluntary alcohol consumption in uncontrolled human studies and experimental animal studies.^[32] ^[33] ^[34] ^[35] Despite the fact that this research is over 40 years old now, there has never been any follow-up to these preliminary studies. This situation is unfortunate as the results were quite promising, safe, and the supplement relatively inexpensive.

Psychosocial aspects

Psychological and social measures are critical in the treatment of the alcoholic patient. It is important for the physician to maintain a non-judgmental, but not passive, attitude towards the patient. Alcoholism should be viewed as a chronic, progressive, addictive, and potentially fatal disease, although many aspects of the alcoholic's behavior may make it difficult to maintain this objectivity.^[1]

Social support for both patient and family is very important, and success often appears proportional to the involvement of Alcoholics Anonymous (AA), counselors and other social agencies. Since most physicians have not had adequate training or experience in handling the psychosocial aspects of this problem, it is important to establish a close working relationship with an experienced counselor and AA. Al-Anon and Ala-Teen are useful resources for family members.

Successful initiation of treatment requires:

- the patient's agreement that they have an alcohol problem
- education of the patient and their family about the physical and psychosocial effects of alcoholism
- immediate involvement of the patient in a treatment program.

Successful programs (such as AA) usually include strict control of drinking and replacement of the alcohol addiction with another addiction that is non-chemical, time-consuming, and heavily supported by family, friends, and peers. Although strict abstinence may not be absolutely necessary, at this time it appears the safest and most effective choice.^[1]

Depression

Depression is common in alcoholics and is known to lead to the high suicide rate. Many alcoholics are depressed first and later become alcoholic (primary depressives), while others become alcoholic first and later develop a depressive condition in the context of their alcoholism (secondary depressives). Alterations in the metabolism of serotonin and the availability of its precursor, tryptophan, have been implicated in some forms of depression, while other forms have been linked to alterations in catecholamine metabolism and tyrosine availability.

Alcoholics have severely depleted levels of tryptophan, which may explain both the depression and sleep disturbances common in alcoholism, since brain serotonin levels are dependent on circulating tryptophan levels.^[36] Ethanol impairs tryptophan transport into the brain. The enzyme tryptophan pyrolyase, considered to be rate-limiting in tryptophan catabolism, is more active in rats during alcohol withdrawal.^[21] In one study, five of six chronic alcoholics had no detectable plasma tryptophan upon withdrawal.^[20] The tryptophan levels returned to normal after 6 days of treatment and abstinence.

Another factor influencing tryptophan uptake into the brain is competition from amino acids which share the same transport – tyrosine, phenylalanine, valine, leucine, isoleucine, and methionine – many of which are elevated in malnourished alcoholics.^[20] Alcoholics have significantly depressed ratios of tryptophan to these amino acids when compared with normal controls, with depressed alcoholics having the lowest ratios.^[21]

The major amino acids, whose elevated levels help to lower this ratio, are the catecholamine precursors, tyrosine and phenylalanine. Elevated plasma catecholamine levels are common in alcoholics and may contribute to the depression.^[37] An interesting finding is that taurine is also low in depressed alcoholics, with the lowest levels being reported in psychotic alcoholics.^[20]

Miscellaneous factors

Intestinal flora

The intestinal microflora is severely deranged in alcoholics.^[38] Colonization of the small intestine by endotoxin-producing bacteria may lead to malabsorption of fats, carbohydrates, protein, folic acid, and vitamin B₁₂. This is probably the cause of the abnormalities of the small intestine commonly found in alcoholics. Alcohol ingestion also increases intestinal permeability to endotoxins and macromolecules, allowing increased toxic and antigenic effects.^[39] The ensuing allergic reactions and deposition of immune complexes probably contribute to the many complications of alcoholism, and, considering the addictive tendency of food allergies, may also contribute to alcoholic

cravings.

Exercise

The involvement of the alcoholic patient in a graded, individually tailored fitness program has been shown to improve the likelihood of maintaining abstinence.^[40] Research has shown that regular exercise is effective in alleviating anxiety and depression and enables individuals to respond better to stress. Improved fitness may allow more effective responses to emotional upset, thereby reducing the likelihood of resorting to alcohol when involved in conflict.

Silybum marianum

The flavonoid complex of milk thistle (silymarin) appears to be very useful for the alcoholic, especially in the presence of considerable liver involvement or cirrhosis. Silymarin has been shown to be effective in the treatment of the full spectrum of alcohol-related liver disease from relatively mild to serious cirrhosis. Perhaps the most significant benefit is extending the life span of these patients. In one study, 87 cirrhotics (46 with alcoholic cirrhosis) received silymarin, while 83 cirrhotics (45 with alcoholic cirrhosis) received a placebo.^[41] The mean observation period was 41 months. In the treatment group, there were 24 deaths with 18 related to liver disease, while in the controls, there were 37 deaths with 31 related to liver disease. The 4 year survival rate was 58% in the treatment group, compared with 39% in the controls.

Silymarin can also improve immune function in patients with cirrhosis.^[42] Whether this effect is involved in the hepatoprotective action or a result of improved liver function has yet to be determined.

THERAPEUTIC APPROACH

Alcoholism is a difficult disease to treat. Although many therapeutic regimens have been attempted, there has been little documented long-term success, except for that of Alcoholics Anonymous (and even the overall success of this program is highly controversial). The approach presented here is unique in that we have attempted to develop an integrated, whole-person, stage-oriented program.

The treatment of the alcoholic patient must be optimized for the four stages of alcoholism: active alcohol consumption, withdrawal, recovery, and recovered. The recovery stage is defined here as the period between withdrawal and full re-establishment of normal metabolic function. All alcoholics, at whatever stage, need a number of common counselling, lifestyle, and metabolic balancing therapies. Following are the recommended therapies in the usual context, with additional recommendations for each stage. Also, a complete diagnostic work-up is necessary, due to the high risk that the alcoholic patient will develop a wide variety of clinical and subclinical diseases.

Diet

Stabilization of blood sugar levels is critical to successful treatment. Although a strict hypoglycemic diet may not be warranted, most of the dietary guidelines must be followed. These include elimination of all simple sugars (foods containing added sucrose, fructose or glucose; fruit juice; dried fruit; and low-fiber fruits such as grapes and citrus fruits), limitation of processed carbohydrates (white flour, instant potatoes, white rice, etc.), and an increase in complex carbohydrates (whole grains, vegetables, beans, etc.).

Supplements

- Vitamin A: 25,000 IU/day
- Vitamin B complex: 20 times the RDA
- Vitamin C: 1 g two times/day
- Vitamin E: 400 IU/day (D-alpha-tocopherol)
- Magnesium: 250 mg two times/day
- Selenium: 200 ug/day
- Zinc: 30 mg/day (picolenate)
- Carnitine: 500 mg two times/day (L-carnitine)
- Glutamine: 1 g/day
- *Lactobacillus acidophilus*: 1 tsp/day.

Exercise

Establish a graded program using heart rate response to determine intensity. The patient should exercise five to seven times per week, for 20–30 minutes, at an intensity sufficient to raise the heart rate to 60–80% of maximum for the age group.

Counselling

Establish a good working relationship with AA and an experienced counselor who has particular expertise in working with alcoholics.

Additional recommendations for the four stages**Active alcohol consumption**

Work with family, peers, social group and whoever else is involved with the patient to elicit the patient's recognition of his/her alcohol problem and willingness to enter a treatment program.

Additional supplements

- Pyridoxal-5-phosphate: 20 mg/day
- Riboflavin: 100 mg/day
- Vitamin A: 50,000 IU/day
- Zinc: 30 mg/day.

Withdrawal

Severity of symptomatology varies widely, although it is usually proportional to the degree of physiological dependence and the duration of the disease. Milder cases usually start within a few hours after cessation of drinking and typically resolve within 48 hours. More severe cases usually occur only in patients over 30 years of age and usually develop after about 48 hours of abstinence. These patients should be admitted to an in-patient facility. Some institutions may not allow the use of supplements; this should be checked before a patient is admitted.

Additional supplements

- Tryptophan: 3 g/day
- Riboflavin: 100 mg/day
- Electrolyte replacement as necessary.

Recovering

Establish a strong network of caring family, friends, and peers to regularly support the patient. Get the patient involved and busy with intense, people-oriented activities. Help the patient recognize that alcohol is no answer to the stresses of life; aid him/her in developing more effective ways of handling adversity.

Additional supplement

- Flaxseed oil: 1 tbsp three times/day.

Recovered

The patient's support group must always be maintained. Continued total abstinence is the best policy, although carefully controlled drinking may be possible. Slowly reduce supplement doses, after a period of 6 months of abstinence, to 25% of the above.

Chapter 128 - Alzheimer's disease

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

DIAGNOSTIC SUMMARY

- Progressive mental deterioration, loss of memory and cognitive functions, inability to carry out activities of daily life
- Characteristic symmetrical, usually diffuse, EEG pattern
- Diagnosis usually made by exclusion
- Definitive diagnosis can be made only by postmortem biopsy of brain, demonstrating atrophy, senile plaques, and neurofibrillary tangles.

GENERAL CONSIDERATIONS

Alzheimer's disease (AD) is a neurodegenerative disorder which clinically manifests itself as a progressive deterioration of memory and cognition or dementia. In the United States, 5% of the population over 65 suffer from severe dementia, while another 10% suffer from mild to moderate dementia. With increasing age there is a rise in frequency. For example, in people over the age of 80, the frequency rate for dementia is over 25%. Postmortem studies have shown that 50–60% of all cases of dementia, in both the senile and presenile period, are the result of Alzheimer's disease (AD). The tremendous increase (10-fold) of AD in this century in the US population over the age of 65 is one reason why AD is referred to as "the disease of the 20th century". Many believe that AD will reach epidemic proportions by the end of this century.

Neuropathology

Alzheimer's disease has distinctive neuropathological features, including:^[1]

- plaque formation
- amyloid deposition
- neurofibrillary tangles

- granulovacuolar degeneration
 - the massive loss of telencephalic neurons.
-

1068

These findings are particularly evident in the cerebral cortex and hippocampal formation.

The clinical features of AD are believed to be related to cholinergic dysfunction due to appreciable reductions in the activity of the enzyme choline acetyltransferase, the enzyme that synthesizes acetylcholine, and the neuronal transfer of choline.

Etiology

The etiology of AD is being extensively researched. Genetic factors play a major role with several genes being linked to AD: the amyloid precursor protein on chromosome 21 (explaining the close association between Down's syndrome and AD); the presenilin genes on chromosomes 14 and 1; and the apolipoprotein E (ApoE) gene on chromosome 19. The first two mutations are rare and associated with symptoms developing before the age of 50. The most significant genetic finding is the link with the ApoE. One form of ApoE, the e4-type, is linked to a significantly greater risk for AD; another, the e2-type, is associated with significant protection.

Although genetics plays a very significant role in determining susceptibility to AD, like most chronic degenerative disease, environmental factors also play a significant role. Traumatic injury to the head, chronic exposure to aluminum and/or silicon, exposure to neurotoxins from environmental sources, and free radical damage have all been implicated as causative factors. Like other chronic degenerative diseases there is considerable evidence that increased oxidative damage plays a central role in the pathophysiology. Therapies designed to support antioxidant mechanisms (discussed below) may be quite helpful in the prevention of AD.^[2]

Aluminum

Considerable attention has been focused on the association of aluminum concentration in the neurofibrillary tangle (NFT). Whether the aluminum concentration develops in response to AD or whether it initiates the lesions has not yet been determined, but significant evidence shows that it contributes, possibly very significantly, to the disease.

Aluminum has a very strong affinity for the paired helical filament tau (PHFt) which is involved in the formation of the neurofibrillary tangles. In fact, the latest study has demonstrated that aluminum is the cofactor along with this tau filament in the formation of the neurofibrillary tangles.^[3] The aluminum selectively binds to PHFt, induces PHFt to aggregate, and retards the brain's ability to break down PHFt.

There is a great deal of circumstantial evidence linking chronic aluminum exposure to AD. Increasing aluminum concentrations in the brain could explain why AD increases with increasing age. A study of 356 healthy people has shown that serum aluminum concentration increases as people age.^[4] Those with Alzheimer's disease have significantly higher aluminum levels than both normal people and patients with other types of dementias, such as those from alcohol, atherosclerosis, and stroke. Trying to remove the aluminum appears to help some, but it is probably too late after the disease is well established. For example, intramuscular injections of desferrioxamine (a chelating agent for the removal of iron and aluminum) over a 2 year period showed a significant slowing of the rate of decline in 48 Alzheimer's disease patients.^[5]

Even in those without mental disease, elevated aluminum levels are associated with poorer mental function. For example, in a study of dialysis patients, the 13 patients who had a positive aluminum deferoxamine test (a measure of the amount of aluminum in the body) were compared with 13 who had a negative test. Subjecting the entire group to four attention tests and two memory tests revealed that those with higher levels of aluminum had a moderate to considerable disturbance of mental function.^[5]

The aluminum appears to come from the water supply, food, antacids, and deodorants. The most significant source is probably drinking water, as the aluminum in water is in a more bioavailable, and thus potentially toxic, form. Researchers measured the aluminum absorption of tap water by adding a small amount of soluble aluminum in a radioactive form to the stomach of animals. They discovered that the trace amounts of aluminum from this single exposure immediately entered the animal's brain tissue. The frightening news is that aluminum in water not only occurs naturally, but is also added (in the form of alum) to treat some water supplies.^[6]

DIAGNOSTIC CONSIDERATIONS

Since only about 50% of patients with dementia actually have Alzheimer's disease, a comprehensive diagnostic work-up is paramount in the approach to the demented patient. The diagnosis of AD chiefly depends upon clinical judgment.

Complete evaluation of a patient who may have dementia includes:

- a detailed history
 - neurological and physical examination
 - psychological evaluation with particular attention to depression
 - a general medical evaluation with emphasis on the detection of subtle metabolic, toxic, or cardiopulmonary disorders that can precipitate confusion, especially in the elderly
-

- a series of neurophysiology tests to document the type and severity of cognitive impairment

- evaluation by a social worker or other qualified individual who can mobilize community resources
- appropriate laboratory studies, including an EKG, EEG, and CT scan.

The diagnostic process in AD is one of exclusion. The first step is to diagnose dementia. Error rates of 10–50% have been reported when the diagnosis of dementia is based only on the first evaluation.^[7] ^[8] Most of these misdiagnosed patients are found, on further evaluation, to have a pseudodementing functional illness.^[7] Depression, which can mimic dementia in the elderly, is common. Possible causes are listed in [Table 128.1](#).

A careful neurological examination is required for every subject suspected of dementia.^[1] The examinaion will reveal one of the following:

1. clear evidence of focal, circumscribed brain disease
2. clear evidence of diffuse, bilateral brain dysfunction
3. no evidence of neurological dysfunction.

The “routine” neurological examination described in most physical diagnosis textbooks is designed to effectively recognize “1” and “3” above, but it will not accurately assess diffuse brain dysfunction, the evidence for which is subtle.

The diagnosis of diffuse brain dysfunction is made through careful attention to the patient’s level of consciousness, attentiveness to the examiner, comprehension, and performance of tasks. Note is also made of facial expressions, quality of speech, posture, respiratory rhythm, and gait.

Specific signs of diffuse brain dysfunction include:

- persistence of glabella-tap response (light tapping above the bridge of the nose produces a blink which normally fatigues rapidly)
- corneomandibular reflex (ipsilateral strong blink and contralateral movement of the chin in response to a firm stimulus applied quickly to the cornea)
- sucking reflex
- snout reflex
- palmomental reflex (ipsilateral contraction of mentalis muscle in response to stimulation of the thenar eminence)
- grasp reflex.

TABLE 128-1 -- Causes and mechanisms of development of senile dementia

| Etiology | Pathogenesis |
|------------------------------|---|
| <i>Degenerative etiology</i> | Disturbances of gene expression, and thus of protein metabolism |
| Altered genetic code | Disturbance of the synthesis of specific proteins |

| | |
|--|---|
| Alzheimer's disease | Reduction in acetylcholine synthesis resulting from decreased ChAc activity |
| Huntington's chorea | Disturbance of the GABAergic system |
| Idiopathic dementia | |
| Localized form | Decline in cognitive function |
| Parkinson's disease | Reduction in dopamine turnover |
| Pick's disease | Reduction in cholinergic activity |
| Loss of neuronal redundancy | Disturbance of cerebral metabolism following infection or trauma |
| | Reduction in cholinergic activity caused by loss of neurons and synapses |
| Cerebrovascular disease | |
| Chronic meningitis | |
| Tuberculous, mycotic | |
| Encephalomyelitis | |
| Encephalopathy following head injury (boxers) | |
| Epileptic dementia | |
| Virus encephalopathy | |
| <i>Nutritive etiology</i> | |
| Chronic alcoholism | |
| Diabetes mellitus | |
| Disturbances of electrolyte metabolism | |
| Hypoglycemia | Insulin, starvation |
| Hyponatremia | Diuretics |
| Hypothyroidism | |
| Korsakoff syndrome | Thiamine transketolase deficiency |
| Nicotinamide deficiency | |
| Vitamin B deficiency | Disturbances of energy formation |
| <i>Toxic etiology</i> | |
| Addiction to barbituates, psychotropic drugs, etc. | |
| Chronic CO intoxication | |

| | |
|--------------------------------------|--|
| Chronic CS ₂ intoxication | |
| Mycotoxins | |
| Renal/hepatic encephalopathy | |
| Vincristine intoxication | |

1070

TABLE 128-2 -- Recommended laboratory tests in dementia

| Test | Rationale |
|---|----------------------------|
| CBC | Anemia, infection |
| VDRL | Syphilis |
| Electrolytes | Metabolic dysfunction |
| Liver function tests | Hepatic dysfunction |
| BUN | Renal dysfunction |
| TSH, T ₄ , T ₃ , T ₃ U | Thyroid dysfunction |
| Serum B ₁₂ and RBC folate | Deficiency |
| Urinalysis | Renal/hepatic dysfunction |
| Hair mineral analysis | Heavy metal intoxication |
| EKG | Heart function |
| EEG | Focal vs. diffuse |
| CT scan | Atrophy, intracranial mass |

Recognizing reversible causes

Once the diagnosis of dementia is made, the next step is to rule out reversible causes of dementia. The most common reversible cause is drug toxicity. Other important causes are metabolic and nutritional disorders, such as hypoglycemia, thyroid disturbances, and vitamin B₁₂, folate, or thiamine deficiency. Also to be considered are neurosyphilis and a number of disorders which can cause dementia: Huntington's Chorea, cerebral vascular disease, normal pressure hydrocephalus, and intracranial masses. Recommended tests are listed in [Table 128.2](#).

The electroencephalogram (EEG) is an important diagnostic tool in differentiating dementia. Although a normal EEG does not rule out the diagnosis of dementia,

particularly in its early stages, it does provide valuable information. AD is associated with a characteristic symmetrical, usually diffuse, slowing of the EEG. More importantly, the EEG differentiates focal (e.g. intracranial mass or vascular disease) versus diffuse (e.g. metabolic disorders or normal pressure hydrocephalus) brain dysfunction.

The CT scan is included in the diagnostic protocol due to the high incidence (4–5%) of silent brain tumors or other masses (e.g. subdural hematoma) in patients seen for the diagnosis of dementia. The CT scan is of limited usefulness in AD, since atrophy of the brain is part of the “normal” aging process.

Fingerprint patterns

Abnormal fingerprint patterns are associated with both Alzheimer’s disease and Down’s syndrome.^[9] Compared with the normal population, Alzheimer’s and Down’s patients show an increased number of ulnar loops on the fingertips, with a concomitant decrease in whorls, radial loops, and arches. Ulnar loops (loop pointing toward the ulnar bone, away from the thumb) are frequently found on all 10 fingertips. Radial loops (loops pointing towards the thumb), when they do appear, tend to be shifted away from the index and middle fingers – where they most commonly occur – to the ring and little fingers. In patients with this fingerprint pattern characteristic of Alzheimer’s disease, it is recommended that an aggressive preventive approach be instituted immediately.

THERAPEUTIC CONSIDERATIONS

The primary areas of intervention from a natural medicine perspective involve prevention by addressing suspected pathophysiology and using natural measures to improve mental function in the early stages of the disease. In the advanced stages of AD, natural measures will provide only limited benefit.

Estrogen

Estrogen is being promoted to offer protective and possibly therapeutic benefits in AD. However, the epidemiological and clinical evidence to support the potential benefits of estrogen is very weak, especially as there is little evidence of major sex differences in the rate or severity of AD.^[10]

Twelve population-based studies indicate that women on hormone replacement therapy (HRT) have a lower rate of AD.^{[10] [11] [12] [13]} The problem with these studies is that women taking hormone replacement therapy are much healthier prior to taking the hormones.^[14] This situation has clouded much of the research on HRT, not only in its role against AD, but also in its role against cardiovascular disease. If women taking estrogens have a lower risk for AD prior to taking HRT, it is difficult to fully evaluate the protective role of HRT, especially in light of a possible increased risk for breast cancer.

In clinical trials, estrogen therapy has been shown to improve mental function in some studies, but not in others.^{[10] [11] [12] [13]} It is likely that estrogen produces some benefits, but several natural products discussed in this chapter exert greater benefit without the

potential side-effects of estrogens.

The benefits of estrogen in AD could be related to many different factors, but the one that appears most likely is its antioxidant effect.^[14] However, a safer and probably better recommendation for this effect is vitamin E. The protective role of vitamin E against heart disease, for example, is greater than that offered by hormone replacement therapy (see [Ch. 133](#)).

Aluminum

It certainly seems appropriate to encourage the avoidance of all known sources of aluminum – aluminum-containing antacids, aluminum-containing anti-perspirants, cooking in aluminum pots and pans, wrapping food with aluminum foil, and non-dairy creamers. Aluminum

1071

is also found in baking powder and table salt, as it is added to keep them from becoming lumpy. In addition, citric acid as well as calcium citrate supplements appear to increase the efficiency of absorption of aluminum (but not lead) from water and food.^[15] Aluminum absorption can be decreased by magnesium, because magnesium competes with aluminum for absorption, not only in the intestines but also at the blood–brain barrier.^[16] A diet rich in magnesium is recommended. Have the patient focus on unprocessed foods, avoid milk and dairy products, and increase the consumption of vegetables, whole grains, nuts and seeds – all good sources of magnesium.

Nutritional considerations

Nutritional status is directly related to cognitive function in the elderly.^[17] Given the frequency of nutrient deficiency in the elderly population, it is likely that many cases of impaired mental function may have a nutritional etiology.

Antioxidants

There is considerable evidence that oxidative damage plays a major role in the development and progression of AD.^[2] ^[18] ^[19] There is also epidemiological evidence suggesting that antioxidant nutrients offer significant protection against AD.^[20] There is tremendous need for good studies evaluating the role of antioxidant nutrients in preventing AD.^[21] Undoubtedly researchers will show that antioxidant nutrients, especially vitamin E, may help to prevent AD in the same way that they help against heart disease, cancer, Parkinson's disease, and other diseases linked to excessive oxidation.

Antioxidant nutrients like vitamin C and E have been shown to be quite effective in slowing the progression of Parkinson's disease in those patients not yet on medications.

These results have led to a pilot trial of high-dose vitamins C and E in early Parkinson's disease as well as a large study of high-dose vitamin E and the drug Deprenyl.^[22] High dosages are required because it is more difficult to increase antioxidant levels in brain tissue compared with other body compartments.

In a vitamin C and E pilot study beginning in 1979, 21 patients with early Parkinson's disease were given 3,000 mg/day of vitamin C and 3,200 IU/day of vitamin E.^[23] The patients were followed closely for a period of 7 years. Although all patients eventually required drug treatment (Sinemet or Deprenyl), the progression of the disease as determined by the need for medication was considerably delayed in those receiving the nutritional antioxidants. Dividing the patients in both groups into younger-onset and older-onset patients, those not receiving antioxidants required medication at 40 and 24 months, respectively, after the onset of the disease. In contrast, the two age groups in the pilot study were able to delay the need for drug therapy for 65.3 and 59.2 months, respectively. Thus, the patients receiving the vitamins were effectively able to delay the need for medication for up to 2–3 years longer. These results are quite promising and offer some hope in slowing down the progression of this dreaded disease.

Only one intervention trial of antioxidant nutrients in AD has been published to date. In the study, 341 patients with moderately severe AD received either the monoamine oxidase inhibitor selegiline (10 mg/day), vitamin E (2,000 IU/day), a combination of selegiline and vitamin E, or a placebo for 2 years. One of the key parameters was survival. Compared with the placebo group, the median survival was 230 days for vitamin E, 215 for the selegiline, and 145 days for the combination. The percentages of participants who had to be institutionalized among the four groups were: vitamin E, 26%; selegiline, 33%; combination, 35%; and placebo, 39%. While these results are not outstanding, vitamin E clearly provides some benefit for patients with moderately severe dementia. Better results are likely to be obtained if antioxidant therapy is started earlier in the disease process and by using a combination of antioxidants.

Thiamin

Although severe thiamin deficiency is relatively uncommon (except in alcoholics), many Americans do not consume even the RDA of 1.5 mg, especially the elderly. In an attempt to gauge the prevalence of thiamin deficiency in the geriatric population, 30 unselected consecutive outpatients visiting a university outpatient clinic in Tampa, Florida, were tested for thiamin levels. Depending upon the thiamin measurement (plasma vs. red blood cell thiamin), low levels (defined as a level below the lowest reference range for younger aged groups) were found in 57 and 33%, respectively.^[24]

In addition to its role as a nutrient, thiamin also demonstrates some pharmacological effects on the brain. Specifically it mimics the important neurotransmitter involved in memory – acetylcholine. Thiamin has been shown to potentiate and mimic the effects of acetylcholine in the brain.^[25] This effect explains the positive clinical results that have been noted for thiamin (3–8 g/day) in improving mental function in Alzheimer's disease and age-related impaired mental function (senility).^[26] ^[27] High-dosage thiamin supplementation exerts its benefits without side-effects.

These results highlight the growing body of evidence that a significant percentage of the geriatric population is deficient in one or more of the B vitamins. Given the essential role of thiamin and other B vitamins to normal human physiology, especially cardiovascular and brain function, routine B vitamin supplementation appears to

be worthwhile in this age group. Alzheimer's disease may simply be the result of chronic low intake of essential nutrients – key among these nutrients are the B vitamins.

Vitamin B₁₂

Another key B vitamin linked to Alzheimer's disease is vitamin B₁₂. A vitamin B₁₂ deficiency will result in impaired nerve function which can cause numbness, paresthesias, or a burning feeling in the feet, as well as impaired mental function which in the elderly can mimic Alzheimer's disease. Vitamin B₁₂ deficiency is thought to be quite common in the elderly and is a major cause of depression in this age group. Determination of vitamin B₁₂ deficiency is best achieved by measuring the level in the blood (serum cobalamin) or the level of methylmalonic acid in the urine. In addition, measuring the level of plasma homocysteine is emerging as a method to determine the status of both vitamin B₁₂ and folate.

Several investigators have found that the level of vitamin B₁₂ declines with age and that vitamin B₁₂ deficiency is found in 3–42% of persons aged 65 and over. It is very important to diagnose cobalamin deficiency early in the elderly because it is easily treatable and, if left untreated, can lead to impaired neurological and cognitive function.^{[28] [29]} In a recent study, among 100 consecutive geriatric outpatients who were seen in office-based settings for various acute and chronic medical illnesses but not for vitamin B₁₂ deficiency-related diseases like pernicious anemia, 11 patients had serum cobalamin levels at 148 pmol/L or below; 30 patients had levels between 148 to 295 pmol/L; and 59 patients had levels above 296 pmol/L.^[30] After the initial cobalamin determination, the subjects were followed for up to 3 years. The patients with cobalamin levels below 148 pmol/L were treated and not included in the analysis of declining cobalamin levels. The average annual serum cobalamin level decline was 18 pmol/L for patients who had higher initial serum cobalamin levels (actual range, from 224 to 292 pmol/L). For patients with lower initial cobalamin levels, the average annual serum cobalamin decline was much higher, at 28 pmol/L.

These results indicate that measuring the level of vitamin B₁₂ in the blood (serum cobalamin), or measuring the urinary excretion of methylmalonic acid or the level of homocysteine as a screening test for vitamin B₁₂ deficiency appears to be indicated in the elderly given the positive cost–benefit ratio.^{[31] [32]} Of these three tests, the urinary methylmalonic acid assay is perhaps the best, in that it is sensitive as well as being

non-invasive and relatively convenient for the patient. Correction of an underlying vitamin B₁₂ deficiency can improve mental function and the quality of life in these patients quite significantly.

The importance of detailed examination in elderly patients with mental symptoms is highlighted by results from a recent study which analyzed the plasma homocysteine, serum cobalamin, and blood folate in 296 consecutive patients referred to a geriatric psychiatric ward in Sweden for diagnosis of mental disease.^[33] Patients who were found to be deficient in vitamin B₁₂ or folic acid, or who had elevated levels of homocysteine, were given vitamin B₁₂ (dosage not specified) and/or folic acid (10 mg/day). When individuals with low cobalamin levels were supplemented with vitamin B₁₂, significant clinical improvements were noted.

In other studies, supplementation with vitamin B₁₂ has shown tremendous benefit in reversing impaired mental function as a result of low levels of vitamin B₁₂.^[28] In one large study, a complete recovery was observed in 61% of cases of mental impairment due to low levels of vitamin B₁₂.^[34] The fact that 39% did not respond is probably a result of long-term low levels of vitamin B₁₂. Several studies have shown that the best clinical responders are those who have been showing signs of impaired mental function for less than 6 months.^[12] In one study, 18 subjects with low serum cobalamin levels and evidence of mental impairment were given vitamin B₁₂. Only those patients who had symptoms for less than 1 year showed improvement.^[35] The importance of diagnosing and correcting low vitamin B₁₂ levels in the elderly cannot be overstated.

Serum vitamin B₁₂ levels are significantly low, and vitamin B₁₂ deficiency is significantly common in Alzheimer's disease patients.^{[28] [36] [37]} Supplementation of B₁₂ and/or folic acid may result in complete reversal in some patients, but generally there is little improvement in patients who have had Alzheimer's symptoms for greater than 6 months. It has been hypothesized that prolonged low levels of vitamin B₁₂ may lead to irreversible changes that will not respond to supplementation.

Vitamin B₁₂ is available in several forms. The most common form is cyanocobalamin; however, vitamin B₁₂ is active in the human body in only two forms: methylcobalamin and adenosylcobalamin. While methylcobalamin and adenosylcobalamin are active immediately upon absorption, cyanocobalamin must be converted to either methylcobalamin or adenosylcobalamin by removing the cyanide molecule and adding either a methyl or adenosyl group. This conversion may be reduced with aging and may be another factor responsible for the vitamin B₁₂ disturbances noted in the elderly population.

Zinc

Zinc deficiency is one of the most common nutrient deficiencies in the elderly and has been suggested to be a major factor in the development of Alzheimer's disease.^[38]

are most enzymes involved in DNA replication, repair, and transcription. It has been suggested that dementia, possibly because of a long-term zinc deficiency, may represent the long-term cascading effects of error-prone or ineffective DNA-handling enzymes in nerve cells.^[39] In addition, zinc is required by many antioxidant enzymes including superoxide dismutase. The end result could be the destruction of nerve cells and the formation of neurofibrillary tangles and plaques. The levels of zinc in the brain and cerebrospinal fluid in patients with Alzheimer's disease are markedly decreased and there is a strong inverse correlation between serum zinc levels and the senile plaque count.^[40]

Zinc supplementation is demonstrating good benefits in Alzheimer's disease. In one study, 10 patients with Alzheimer's disease were given 27 mg/day of zinc (as zinc aspartate). Only two patients failed to show improvement in memory, understanding, communication, and social contact. In one 79-year-old patient, the response was labeled "unbelievable" by both medical staff and family.^[41] Unfortunately, there does not seem to be much interest in the scientific community in following up these impressive results with zinc therapy.

This might be due to a conflicting theory that zinc may be problematic for Alzheimer's patients as, in vitro, it accelerates the formation of insoluble beta-amyloid peptide.^[42] While zinc is neurotoxic at high concentrations and accumulates at sites of degeneration, total tissue zinc is markedly reduced in the brains of Alzheimer's patients. Other research has shown a much higher concentration of copper-zinc superoxide dismutase in and around the damaged brain tissue of AD patients.^[43] This suggests that the increased concentration of zinc in the damaged areas is due to the body's efforts to neutralize free radicals through the increased local production of dismutases. A possible corollary is that the higher focal levels of zinc result in increased amyloid formation when the free radical scavenging mechanisms have been inadequate.

Phosphatidylcholine

Since dietary phosphatidylcholine can increase acetylcholine levels in the brain in normal patients, and since Alzheimer's disease is characterized by a decrease in cholinergic transmission, it seems reasonable to assume that phosphatidylcholine supplementation would be of benefit to Alzheimer patients. However, the basic defect in cholinergic transmission in Alzheimer's disease relates to impaired activity of the enzyme acetylcholine transferase. This enzyme combines choline (as provided by phosphatidylcholine) with an acetyl molecule to form acetylcholine, the neurotransmitter. Since providing more choline will not necessarily increase the activity of this key enzyme, phosphatidylcholine supplementation will not be beneficial in the majority of patients with Alzheimer's disease. Not surprisingly, clinical trials using phosphatidylcholine have largely been disappointing. Studies have shown inconsistent

improvements in memory from choline supplementation in both normal and Alzheimer's patients.^{[44] [45] [46]} The studies have been criticized for small sample size, low dosage of phosphatidylcholine, and poor design.

In a patient with mild to moderate dementia, the use of a high-quality phosphatidylcholine preparation may be worth a try. A dosage of 15–25 g/day of phosphatidylcholine is required. If there is no noticeable improvement within 2 weeks, supplementation should be discontinued.

Phosphatidylserine

Phosphatidylserine is the major phospholipid in the brain where it plays a major role in determining the integrity and fluidity of cell membranes. Normally, the brain can manufacture sufficient levels of phosphatidylserine, but a deficiency of methyl donors like S-adenosylmethionine (SAM), folic acid, and vitamin B₁₂ or essential fatty acids may inhibit the production of sufficient phosphatidylserine. Low levels of phosphatidylserine in the brain are associated with impaired mental function and depression in the elderly.

The primary use of phosphatidylserine is in the treatment of depression and/or impaired mental function in the elderly, including Alzheimer's disease. To date, the 11 double-blind published studies have all reported the successful use of phosphatidylserine in the treatment of age-related cognitive decline, Alzheimer's disease or depression.^{[47] [48] [49] [50] [51] [52] [53] [54] [55] [56]} In the largest study, a total of 494 elderly patients (aged between 65 and 93 years), with moderate to severe senility, were given either phosphatidylserine (100 mg three times daily) or a placebo for 6 months.^[56] The patients were assessed for mental performance, behavior, and mood at the beginning and the end of the study. Statistically significant ($P < 0.01$) improvements were noted in mental function, mood, and behavior for the phosphatidylserine group.

L-Acetylcarnitine

A great deal of research has been conducted over the last decade with L-acetylcarnitine (LAC) in the treatment of Alzheimer's disease, senile depression, and age-related memory defects. LAC is composed of acetic acid and L-carnitine bound together. This reaction occurs naturally in the human brain, and therefore it is not exactly known how much greater of an effect is achieved with LAC vs. L-carnitine. However, LAC is thought to be substantially more active than these other forms of carnitine in conditions involving the brain.^{[57] [58]}

The close structural similarity between LAC and acetylcholine led to the interest in the use of LAC in

Alzheimer's disease. Research has now shown that LAC does mimic acetylcholine and

is of benefit not only in patients with early-stage Alzheimer's disease, but also in elderly patients who are depressed or who have impaired memory.^[58] It has also been shown to act as a powerful antioxidant within the brain cell, stabilize cell membranes, and improve energy production within the brain cell, as well as enhancing or mimicking the function of acetylcholine.^[59]

The results in delaying the progression of Alzheimer's disease have been very promising.^{[23] [57] [60] [61]} For example, in one study LAC (2 g twice daily) or placebo was given to 130 patients with Alzheimer's disease over the course of 1 year.^[23] The patients were evaluated by 14 different outcome measures such as assessment scales, cognitive function tests, memory tests, and physician evaluations. The group receiving the LAC showed better results on all outcome scores.

The memory impairment need not be as severe as in Alzheimer's disease in order for LAC to demonstrate benefit.^{[62] [63] [64]} In one double-blind study of 236 elderly subjects with mild mental deterioration, as evidenced by detailed clinical assessment, the group receiving 1,500 mg/day of LAC demonstrated significant improvement in mental function, particularly in memory and constructional thinking.^[64]

Other therapies

DHEA

DHEA (dehydroepiandrosterone) is the most abundant hormone in the bloodstream and is found in extremely high concentrations in the brain. As DHEA levels decline dramatically with aging, low levels of DHEA in the blood and brain are thought to contribute to many symptoms associated with aging, including impaired mental function.

Although DHEA itself has no known function, it does serve as the source for all other steroid hormones in the body including sex hormones and corticosteroids. Therefore, the function of DHEA seems to be supplying the body with what it needs to maintain optimum levels and balance of all the steroid hormones that regulate the body's activities.

Over the last decade it has been demonstrated that declining levels of DHEA are linked to such conditions as diabetes, obesity, elevated cholesterol levels, heart disease, arthritis and other age-related diseases. In addition, DHEA shows promise in enhancing memory and improving cognitive function.^{[65] [66] [67]}

The levels of DHEA necessary to improve brain power in men over the age of 50 appears to be 25–50 mg/day. For women, a dosage of 15–25 mg appears to be sufficient in most cases. As men and women reach their seventies, they may require higher levels (e.g. 50–100 mg). Excessive dosages of DHEA can cause acne and, in women, menstrual irregularities. While most of the elderly probably need DHEA, laboratory assessment before prescription provides better assessment to determine needed dosages.

Ginkgo biloba extract

The *Ginkgo biloba* extract (GBE) standardized to contain 24% ginkgo flavonglycosides is showing great benefit in many cases of senility including Alzheimer's disease. In addition to GBE's ability to increase the functional capacity of the brain via the mechanisms described above, it has also been shown to normalize the acetylcholine receptor in the hippocampus of aged animals, to increase cholinergic transmission, and to address many of the other major elements of Alzheimer's disease^{[68] [69]} (see [Ch. 88](#) for a full discussion).

Although preliminary studies in established Alzheimer's patients are quite promising, at this time it appears that GBE only helps to reverse or delay mental deterioration in the early stages of Alzheimer's disease. This improvement may help to enable the patient to maintain a normal life and avoid a nursing home.

The benefits of GBE in early-stage Alzheimer's disease are quite evident when looking at the results of two recent double-blind studies. In the first study, 216 patients with Alzheimer's disease or multi-infarct dementia were given either 240 mg/day of GBE or placebo for 24 weeks.^[70] Improvements were noted in several clinical parameters including the Clinical Global Impressions (CGI) scale, as shown in [Table 128.3](#).

The second study, published in *JAMA*, was the first clinical study on GBE conducted in the United States.^[71] The study was conducted at six research centers, with the design of the study being approved by the Harvard Medical School and the New York Institute for Medical Research. In the study, 202 patients with Alzheimer disease were given either a modest dose of GBE (120 mg/day) or a placebo for 1 year. GBE not only stabilized Alzheimer's disease, but also led to significant improvements in mental function in 64% of the patients. There were no side-effects with GBE.

In addition to offering benefit in early-stage Alzheimer's disease, if the mental deficit is due to vascular insufficiency

TABLE 128-3 -- Clinical Global Impression ratings: GBE vs. placebo

| | GBE | Placebo |
|--------------------|------------|----------------|
| Very much improved | 3% | 1% |
| Much improved | 29% | 16% |
| Slightly improved | 41% | 38% |
| Unchanged | 28% | 30% |
| Moderately worse | 0% | 14% |
| Much worse | 0% | 1% |

or depression and not Alzheimer's disease, GBE will usually be effective in reversing the deficit.^{[23] [60] [61]}

It must be pointed out that GBE should be taken consistently for at least 12 weeks in order to determine effectiveness. Although some people with AD report benefits within a 2–3 week period, most will need to take GBE for a longer period of time.

Huperzine A. Huperzine A is an alkaloid isolated from the moss *Huperzia serrata* – long used in China to treat primarily fever and inflammation. Although it has been shown to have no antipyretic or anti-inflammatory properties in experimental models, Huperzine A has been shown to be a potent inhibitor of acetyl-cholinesterase. In fact, it is significantly more selective and substantially less toxic than the acetyl-cholinesterase inhibitors currently used in conventional medicine (physostigmine, tacrine, and donepezil). Toxicity with synthetic acetyl-cholinesterase inhibitors has been a major drawback in their clinical use. In contrast, Huperzine A, purified from *Huperzia serrata*, has been used as a prescription drug in China since the early 1990s, and has reportedly been used by over 100,000 people with no serious adverse effect.^[72]

Clinical studies conducted in China have shown considerable benefit in the treatment of dementia. One double-blind clinical study found that Huperzine A at a dose of 200 mcg twice daily produced measurable improvements in memory, cognitive function, and behavioral factors in 58% of Alzheimer's patients.^[73] In contrast, in the placebo group 36% showed improvement. No significant side-effects occurred in either group.

THERAPEUTIC APPROACH

The primary therapeutic goal is prevention or beginning therapy as soon as any dementia is noted.

Dietary and lifestyle recommendations

- Avoid aluminum (found in many anti-perspirants, antacids, and cookware)
- General healthful dietary and lifestyle plan.

Supplements

- High potency multiple vitamin and mineral supplement according to guidelines given in [Chapter 44](#)
- Vitamin C: 500–1,000 mg three times/day
- Vitamin E: 400–800 IU/day
- Flaxseed oil: 1 tbs/day
- Thiamin: 3–8 g/day
- Phosphatidylserine: 100 mg three times/day

- L-Acetylcarnitine: 500 mg three times/day
- Methylcobalamin: 1,000 mcg twice daily.

Botanical medicine

- *Ginkgo biloba* extract (24% ginkgo flavonglycosides): 80 mg three times/day
- Huperzine A: 200 mcg twice daily.

Chapter 129 - Angina

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

DIAGNOSTIC SUMMARY

- Squeezing or pressure-like pain in the chest appearing immediately after exertion. Other precipitating factors include emotional tension, cold weather, or a large meal. Pain may radiate to the left shoulder blade, left arm, or jaw. The pain typically lasts for only 1–20 minutes.
- Stress, anxiety, and high blood pressure are typically present.
- The majority will demonstrate an abnormal electrocardiographic reading (transient ST segment depression) in response to light exercise (stress test).

GENERAL CONSIDERATIONS

Angina pectoris results when the supply of oxygen, and occasionally other nutrients, is inadequate to meet the metabolic needs of the heart muscle. The primary cause is atherosclerosis, although platelet aggregation, coronary artery spasm, non-vascular mechanisms such as hypoglycemia, and increased metabolic need (such as in hyperthyroidism) can also be important.

The primary lesion of atherosclerosis is the atheromatous plaque, which progressively narrows, and ultimately blocks, the coronary artery, resulting in a decreased supply of blood and oxygen to the heart tissue. Symptoms typically begin to appear after a major coronary artery is blocked by more than 50%.

Blood flow to the heart may also be compromised by transient platelet aggregation (discussed in more detail in [Ch. 133](#)) and coronary artery spasm. Prinzmetal's variant angina, the most commonly recognized form of coronary artery spasm, is not due to plaque in the coronary arteries and is more apt to occur at rest or at odd times during the day or night. It is more common in women under age 50. Magnesium insufficiency-induced coronary artery spasm, more common in men than women, is now

recognized as an important cause of myocardial infarction and may be of significance in angina pectoris.

1078

DIAGNOSTIC CONSIDERATIONS

The diagnosis of angina is frequently made by history alone. Clinical evaluation of all patients with angina should include an electrocardiogram at rest and a chest X-ray. Since more than one-half of patients with typical angina and confirmed coronary atherosclerosis have normal 12-lead electrocardiogram readings at rest, diagnosis must often be confirmed using electrocardiographic stress testing or 24 hour Holter monitoring (ambulatory electrocardiography).

The most common diagnostic electrocardiographic changes associated with angina are evidence of previous myocardial infarction, and ST-segment and T-wave changes that occur *during* attacks of pain. The most characteristic change is displacement of the ST segment, with or without T-wave inversion. Complicating diagnosis, however, is the observation that hypoglycemia-induced angina does not manifest with rate or ST-segment abnormalities.^[1]

THERAPEUTIC CONSIDERATIONS

Angina is a serious condition that requires careful treatment and monitoring. In the severe case, as well as in the initial stages in the mild to moderate patient, prescription medications may be necessary. Eventually the condition should be able to be controlled with the help of natural measures. If there is significant blockage of the coronary artery, intravenous EDTA chelation therapy, angioplasty or coronary artery bypass may be appropriate.

From a natural perspective, there are two primary therapeutic goals in the treatment of angina: improving energy metabolism within the heart and improving the blood supply to the heart. These goals are interrelated, as an increased blood flow means improved energy metabolism and vice versa.

The heart utilizes fats as its major metabolic fuel. It converts free fatty acids to energy in much the same way as an automobile utilizes gasoline. Defects in the utilization of fats by the heart greatly increase the risk of atherosclerosis, heart attacks, and angina pains. Specifically, impaired utilization of fatty acids by the heart results in accumulation of high concentrations of fatty acids within the heart muscle. This then makes the heart extremely susceptible to cellular damage which ultimately leads to a heart attack.

Carnitine, pantethine and coenzyme Q₁₀ are essential compounds in normal fat and energy metabolism and are of extreme benefit to sufferers of angina. These nutrients prevent the accumulation of fatty acids within the heart muscle by improving the

conversion of fatty acids and other compounds into energy.

Coronary angiogram, artery bypass surgery and angioplasty

An angiogram (cardiac catheterization) is an X-ray procedure where dye is injected into the coronary arteries to determine blockages. These blockages are then most often opened with balloon angioplasty or and/or coronary artery bypass surgery.

Angiograms, bypass surgery, and angioplasty are a big business. Over a million heart angiograms are performed each year for a total cost of over \$10 billion, but based upon extensive analysis it appears that most of this money is wasted.

Several studies have now challenged the widespread recommendation for an angiogram given by most cardiologists.^[2] One study evaluated 168 patients who were told they needed to have an angiogram to determine the degree of blockage and consequent need for bypass surgery or angioplasty. Using non-invasive tests, such as the exercise stress test, the echocardiogram, and the Holter heart monitor that is worn for 24 hours, the researcher determined that 134, or 80% did not need the catheterization.

These 168 patients experienced only a 1.1% annual fatal heart attack rate over a 5 year period. This rate is much lower than the mortality rates associated with either coronary artery bypass surgery (5–10%) or angioplasty (1–2%). The researcher concluded: “in a large fraction of medically stable patients with coronary disease who are urged to undergo coronary angiography (heart catheterization), the procedure can be safely deferred”. Non-invasive testing to determine the functional state of the heart is far more important in determining the type of therapy that is needed than the dangerous search for blocked arteries. If the heart is not functioning well, *then* the angiogram may be needed to see if surgery should be done.

Furthermore, the blockages found by the angiogram are usually not relevant to the patient’s risk of heart attack. For instance, in the most sophisticated study of bypass surgery, the Coronary Artery Surgery Study (CASS), it was demonstrated that heart patients with healthy hearts, but with one, two, or all three of the major heart vessels blocked, did surprisingly well without surgery.^[3] ^[4] ^[5] Regardless of the number or severity of the blockages, each group had the same very low annual death rate of 1%. That same year, the average death rate from bypass surgery was 10.1%, or about one death for every 10 operations. In other words, the operation being recommended supposedly to save lives was about five to 10 times more deadly than the disease. The best that can be said about bypass surgery and balloon angioplasty is that they are irrelevant to the course of the disease in all but the most serious cases. Patients electing not to have the surgery live just as long, or longer, than those having surgery.^[6]

The severity of blockage does not estimate reduction in blood flow in the artery. In one

study, Iowa researchers measured blood flow in over 44 blockages demonstrated by angiogram.^[7] Much to their surprise, they found no correlation between blood flow and the severity of the heart artery blockage. In other words, the angiogram did not provide clinically relevant information.

The researchers found that “the majority of coronary artery with a 96% blockage had one of the most brisk blood flows while similar artery, with only 40% blockage, had severe blood flow restriction”. The authors concluded that the blockages found on the heart catheterization simply do not correlate with blood flow restriction. The researchers also commented that “the results of these studies should be profoundly disturbing ... information cannot be determined accurately by conventional angiographic approaches”.

The bottom line is this: when patients are recommended to have a coronary angiogram, chances are 8 out of 10 that do not need it. The critical factor in whether a patient needs coronary artery bypass surgery or angioplasty is how well the left ventricular pump is working, not the degree of blockage or the number of arteries affected. Bypass is only helpful when the ejection fraction is less than 40%.^[8] Up to 90% of all bypass procedures are done when the ejection fraction is greater than 50%, which is adequate for circulatory needs. In other words, as many as 90% of all bypass procedures may be unnecessary.

When coronary artery bypass surgery and/or angioplasty is necessary based on these accepted criteria, they definitely increase long-term survival and give relief of symptoms for 85%. However, the surgery is not without risk. Complications arising from coronary bypass operations are common, as this surgery represents one of the most technically difficult procedures in modern medicine. In one study, 61% of the patients having coronary artery bypass surgery suffered nervous system disorders as a result.^[9] Another study found that 2–5% of individuals having coronary bypass surgery die during or soon after the operation and 10% have myocardial infarctions.^[10]

Considering the cost of the procedure, the lack of long-term survival benefit, and the high level of complications, it appears that electing to have this surgery is very unwise for the majority of patients.

This is particularly true in light of the availability of effective “natural” alternatives to coronary bypass surgery. Numerous studies have shown that dietary and lifestyle changes can significantly reduce the risk of heart attacks and other causes of death due to atherosclerosis (see [Ch. 133](#)). Simple dietary changes, such as decreasing the amount of saturated fat and cholesterol, and increasing the amount of dietary fiber, complex carbohydrates, fish oils, and magnesium in the diet, along with eliminating alcohol consumption and cigarette smoking and reducing high blood pressure, would greatly reduce the number of coronary bypass operations performed in Westernized countries. In addition, several nutritional supplements and botanical medicines have been shown in clinical studies to improve heart function in even the most severe angina cases. Another important alternative is intravenous EDTA chelation therapy. Although controversial, considerable clinical research has proven its efficacy (discussed below).

When an angiogram is unavoidable

When cardiac catheterization cannot be prevented, the goal is then to prevent the damaging effects produced by this procedure. This can be accomplished by prescribing a high potency multiple vitamin and mineral formula along with additional vitamin C (minimum 500 mg three times daily) and CoQ₁₀ (300 mg daily 2 weeks prior to surgery and for 3 months after). Note that it is generally recommended that garlic supplementation and high dosages of vitamins (greater than 200 IU) should be avoided prior to any surgery due to their ability to inhibit platelet aggregation.

Vitamin C supplementation is rarely employed in hospitals, despite the fact that it may provide significant benefits, and low vitamin C status is quite common in hospitalized patients. In a study analyzing the vitamin C status of patients undergoing coronary artery bypass, the plasma concentration of vitamin C was shown to plummet by 70% 24 hours after coronary artery bypass surgery and persisted in most patients for up to 2 weeks after surgery.^[11] In contrast, vitamin E and carotene levels did not change to any significant degree presumably because they are fat-soluble and are therefore retained in the body for longer periods of time. Given the importance of vitamin C, the serious depletion of vitamin C may deteriorate defense mechanisms against free radicals, infection, and wound repair in these patients. Supplementation appears to be essential in patients recovering from heart surgery, or any surgery for that matter.

CoQ₁₀ is recommended in an attempt to prevent oxidative damage during reperfusion. Return of blood flow after coronary artery bypass surgery results in oxidative damage to the vascular endothelium and myocardium, and thus increases greatly the risk for subsequent coronary artery disease. CoQ₁₀ prevents reperfusion injury in patients undergoing coronary artery bypass surgery or angioplasty. In one study, 40 patients undergoing elective surgery received either 150 mg of coenzyme Q₁₀ each day for 7 days before the surgery or served in the control group.^[12] The concentrations of lipid peroxides and an enzyme (creatine kinase) indicating myocardial damage were significantly lower in patients receiving coenzyme

Q₁₀ than in the control group. The treatment group also showed a statistically significant lower incidence of ventricular arrhythmias during the recovery period. These results clearly demonstrate that pretreatment with coenzyme Q₁₀ can play a protective role during routine bypass surgery by reducing oxidative damage.

In addition to vitamin C and CoQ₁₀, a mixture of highly purified bovine-derived glycosaminoglycans naturally present in the aorta, including dermatan sulfate, heparan sulfate, hyaluronic acid, chondroitin sulfate, and related hexosaminoglycans, is also of benefit in preventing reperfusion injury and restoring proper structure, integrity, and function of the coronary vascular endothelium.^[13] The dosage of purified aortic GAGs is

100 mg daily.

Nutritional supplements

Carnitine

Carnitine, a vitamin-like compound, stimulates the breakdown of long-chain fatty acids by the energy-producing units in cells – the mitochondria. Carnitine is essential in the transport of fatty acids into the mitochondria. A deficiency in carnitine results in a decrease in fatty acid concentrations in the mitochondria and reduced energy production.

Normal heart function is critically dependent on adequate concentrations of carnitine. While the normal heart stores more carnitine than it needs, if the heart does not have a good supply of oxygen, carnitine levels quickly decrease. This leads to decreased energy production in the heart and increased risk for angina and heart disease. Since angina patients have a decreased supply of oxygen, carnitine supplementation makes good sense.

Several clinical trials have demonstrated that carnitine improves angina and heart disease.^{[14] [15] [16] [17] [18]} Supplementation with carnitine normalizes heart carnitine levels and allows the heart muscle to utilize its limited oxygen supply more efficiently. This translates to an improvement in cases of angina. Improvements have been noted in exercise tolerance and heart function. The results indicate that carnitine is an effective alternative to drugs in cases of angina.

In one study of patients with stable angina, oral administration of 900 mg of L-carnitine increased mean exercise time and the time necessary for abnormalities to occur on a stress test (6.4 minutes in the placebo group compared with 8.8 minutes in the carnitine-treated group).^[18]

These results indicate that carnitine may be an effective alternative to other anti-anginal agents such as beta-blockers, calcium-channel antagonists, and nitrates, especially in patients with chronic stable angina pectoris.

Carnitine, by improving fatty acid utilization and energy production in the heart muscle, may also prevent the production of toxic fatty acid metabolites. These compounds are extremely deleterious as they activate various phospholipases and disrupt cellular membrane structures. The changes in the properties of cardiac cell membranes induced by fatty acid metabolites are thought to contribute to impaired heart muscle contractility and compliance, increased susceptibility to irregular beats, and eventual death of heart tissue. Supplemental carnitine increases heart carnitine levels and prevents the production of toxic fatty acid metabolites. This has been demonstrated clinically where the early administration of L-carnitine (40 mg/kg per day) in patients having heart attacks was found to considerably reduce heart damage.^[19]

Pantethine

Pantethine is the stable form of pantetheine, the active form of pantothenic acid, which is the fundamental component of coenzyme A (CoA). CoA is involved in the transport of fatty acids to and from cells, and to the mitochondria. The synthetic pathway from pantethine to CoA is much shorter than that of pantothenic acid, making pantethine the preferred therapeutic substance. In addition, pantethine has significant lipid-lowering activity while pantothenic acid has very little (if any) effect in lowering cholesterol and triglyceride levels.

The standard dose for pantethine is 900 mg/day. Like carnitine, pantothenic acid has been shown in clinical trials to significantly reduce serum triglyceride and cholesterol levels while increasing HDL cholesterol levels.^[20] ^[21] ^[22] Its lipid-lowering effects are most impressive when its toxicity (virtually none) is compared with that of conventional lipid-lowering drugs. Its mechanism of action is due to inhibiting cholesterol synthesis and accelerating fatty acid breakdown in the mitochondria.

Pantethine is well indicated in angina. Like carnitine, heart pantethine levels decrease during times of reduced oxygen supply. Demonstrated effects in animals indicate that it would greatly benefit individuals with angina.^[23]

Coenzyme Q₁₀

Coenzyme Q₁₀ (CoQ₁₀), also known as ubiquinone, is an essential component of the mitochondria, where it plays a major role in energy production. Like carnitine and pantethine, CoQ₁₀ can be synthesized within the body. Nonetheless, deficiency states have been reported. Deficiency can be a result of impaired CoQ₁₀ synthesis due to nutritional deficiencies, a genetic or acquired defect in CoQ₁₀ synthesis, or increased tissue needs.^[24]

Cardiovascular diseases including angina, hypertension, mitral valve prolapse, and congestive heart failure are examples of diseases which require increased tissue

levels of CoQ₁₀.^[24] In addition, many of the elderly may have increased CoQ₁₀ requirements: the decline of CoQ₁₀ levels that occurs with age may be partly responsible for the age-related deterioration of the immune system.

CoQ₁₀ deficiency is common in individuals with heart disease. Heart tissue biopsies in patients with various heart diseases show a CoQ₁₀ deficiency in 50–75% of cases.^[24] One of the most metabolically active tissues in the body, the heart may be unusually

susceptible to the effects of CoQ₁₀ deficiency. Accordingly, CoQ₁₀ has shown great promise in the treatment of heart disease.

In one study, 12 patients with stable angina pectoris were treated with CoQ₁₀ (150 mg/day for 4 weeks) in a double-blind, cross-over trial.^[25] Compared with placebo, CoQ₁₀ reduced the frequency of anginal attacks by 53%. In addition, there was a significant increase in treadmill exercise tolerance (time to onset of chest pain and time to development of electrocardiogram abnormalities) during CoQ₁₀ treatment. The results of this study and others suggest that CoQ₁₀ is a safe and effective treatment for angina pectoris.

Carnitine, pantethine, and coenzyme Q₁₀ should be considered in all heart disorders, not just angina.

Magnesium

Magnesium deficiency may play a major role in angina, including Prinzmetal's variant. A magnesium deficiency has been shown to produce spasms of the coronary arteries and is thought to be a cause of non-occlusive heart attacks.^[26] Furthermore, it has been observed that men who die suddenly of heart attacks have significantly lower levels of heart magnesium, as well as potassium, than matched controls.^[27]

It has been suggested that it should become the treatment of choice for angina due to coronary artery spasm.^{[27] [28] [29]} Magnesium administration has also been found to be helpful in the management of arrhythmias and in angina due to atherosclerosis. Its benefit in all of these situations is presumably via the same mechanisms responsible for its effects in an acute myocardial infarction.

Since the mid-1980s, there have been eight well-designed studies involving over 4,000 patients demonstrating that intravenous magnesium supplementation during the first hour of admission to hospital for an acute MI produces a favorable effect in reducing immediate and long-term complications as well as death rates.^{[30] [31] [32]}

The beneficial effects of magnesium in an acute MI relate to its ability to:

- improve energy production within the heart
- dilate the coronary arteries resulting in improved delivery of oxygen to the heart
- reduce peripheral vascular resistance resulting in reduced demand on the heart
- inhibit platelets from aggregating and forming blood clots
- reduce the size of the infarct (blockage)
- improve heart rate and arrhythmias.

Botanical medicines

Crataegus species

Hawthorn berry and flowering tops extracts are widely used in Europe for their cardiovascular activity. They exhibit a combination of effects that are of great value to patients with angina and other heart problems. Studies have demonstrated that hawthorn extracts are effective in reducing angina attacks as well as in lowering blood pressure and serum cholesterol levels.^[33] ^[34] ^[35]

The beneficial effects in the treatment of angina are due to improvement in the blood and oxygen supply of the heart resulting from dilation of the coronary vessels, as well as improvement of the metabolic processes in the heart.^[33] ^[34] ^[35] ^[36]

Crataegus' ability to dilate coronary blood vessels has been repeatedly demonstrated in experimental studies.^[33] ^[34] ^[35] In addition, crataegus extracts have been shown to improve cardiac energy metabolism in human and experimental studies. This combined effect is extremely important in the treatment of angina as it results in improved myocardial function with more efficient use of oxygen. The improvement is a result not only of increased blood and oxygen supply to the heart muscle, but also of hawthorn flavonoids interacting with key enzymes to enhance myocardial contractility (see [Ch. 79](#) for a comprehensive discussion of this important botanical).

Ammi visnaga

Khella is an ancient medicinal plant native to the Mediterranean region where it has been used in the treatment of angina and other heart ailments since the time of the pharaohs. Several of its components have demonstrated effects in dilating the coronary arteries. Its mechanism of action appears to be very similar to the calcium-channel blocking drugs.

Since the late 1940s, there have been numerous scientific studies on the clinical effect of khella extracts in the treatment of angina. More specifically, khellin, a derivative of the plant, was shown to be extremely effective in relieving angina symptoms, improving exercise tolerance, and normalizing electrocardiographic tests. This is evident by the concluding statements in a study by Osher et al^[36] in 1951:

The high proportion of favorable results, together with the striking degree of improvement frequently observed, has led us to the conclusion that khellin, properly used, is a safe and effective drug for the treatment of angina pectoris.

At higher doses (120–150 mg/day), pure khellin was associated with mild side-effects such as anorexia, nausea, and dizziness. Although most clinical studies used high

dosages, several studies show that as little as 30 mg of khellin per day appears to offer as good results with fewer side-effects.^[37] ^[38]

Rather than using the isolated compound khellin, khella extracts standardized for khellin content (typically 12%) are the preferred form. A daily dose of such an extract would be 250–300 mg. Khella appears to work very well with hawthorn extracts.

Intravenous EDTA chelation therapy

EDTA chelation therapy is an alternative to coronary artery bypass surgery and angioplasty which may prove to be more effective and is definitely safer and less expensive. While a coronary artery bypass surgery or angioplasty usually costs between \$40,000 and \$100,000, EDTA chelation therapy is an in-office procedure that usually costs less than \$2,500 for a full set of treatments.

EDTA (ethylenediaminetetraacetic acid) is an amino acid-like molecule that, when slowly infused into the bloodstream, binds with minerals such as calcium, iron, copper, and lead, and carries them to the kidney where they are excreted. EDTA chelation has been commonly used for lead poisoning, but in the late 1950s and early 1960s it was found to help patients with atherosclerosis.

The discovery of EDTA chelation therapy in the treatment of angina and other conditions associated with atherosclerosis happened accidentally. In 1956, a battery worker whom Dr Norman Clarke was treating with EDTA for lead poisoning noticed that his symptoms of angina disappeared. Dr Clarke and others began using EDTA chelation therapy in patients with angina, cerebral vascular insufficiency, and occlusive peripheral vascular disease.

In a series of 283 patients treated by Dr Clarke and his colleagues from 1956 to 1960, 87% showed improvements in their symptoms. Heart patients got better and patients with blocked arteries in the legs, particularly those with diabetes, avoided amputation.^[39]
^[40]

It was originally thought that EDTA opened blocked arteries by chelating out the calcium deposits in the cholesterol plaque. However, it now seems more related to chelating out excess iron and copper, minerals which, in the presence of oxygen, stimulate free radicals. Free radicals damage the cells in the artery and are a primary reason for atherosclerosis.

In a review of the progression and regression of atherosclerosis, the authors write that the process of atherosclerosis is “dependent on the presence of some metals (copper and iron) and can be completely inhibited by chelating agents such as EDTA”.^[41]

In spite of obvious benefits to heart patients, EDTA fell out of favor in the mid-1960s. Advocates believe this occurred for two reasons: the lucrative surgical approach to heart and vessel disease was on the rise; and the patent on EDTA that was held by Abbott Laboratories expired so there was no financial interest for drug companies to fund any

research.

Fortunately, in 1972 a small group of practicing physicians using EDTA chelation therapy founded an organization now called the American College for the Advancement of Medicine to continue education and research in this important area.

In the early days of EDTA chelation therapy, several serious problems were discovered. Giving too much of the EDTA or giving it too fast was soon noted to be dangerous. In fact, there were several deaths attributed to kidney failure caused by toxicity to EDTA. Fortunately, additional research resulted in more appropriate protocols and EDTA chelation therapy as used now is very safe. There have not been any deaths or significant adverse reactions in well over 500,000 patients who have undergone EDTA chelation therapy. Because EDTA chelation improves blood flow throughout the body, the “side-effects” are usually beneficial and only a few adverse effects are noticed.

There now exists a substantial body of scientific evidence on the use of EDTA chelation therapy in the treatment of angina, peripheral vascular disease, and cerebral vascular disease.^[42] Since 1987, numerous FDA approved studies have demonstrated some rather impressive results.^{[42] [43] [44] [45] [46]}

THERAPEUTIC APPROACH

The primary therapy for angina is prevention since angina is usually secondary to atherosclerosis. Once angina has developed, restoring proper blood supply to the heart and enhancing energy production within the heart are necessary. Particularly important nutrients for accomplishing these results are carnitine, pantethine, coenzyme Q₁₀, and magnesium. Magnesium is of additional benefit because of its ability to relax spastic coronary arteries and improve heart function.

Hawthorn berries or extracts offer a number of benefits to individuals with angina, including coronary artery dilation and improved heart muscle metabolism.

Patients with unstable angina pectoris (characterized by a progressive increase in the frequency and severity of pain, increased sensitivity to precipitating factors, progression of symptoms over several days, and prolonged coronary pain) should be hospitalized.

Diet

An increase of dietary fiber is recommended, especially the gel-forming or mucilaginous

fibers (flaxseed, oat bran, pectin, etc.). Onions and garlic (both raw and cooked), vegetables, and fish should also be increased, while reducing the consumption of saturated fats, cholesterol, sugar, and animal proteins. All fried foods and food allergens should be avoided. Patients with reactive hypoglycemia should eat regular meals and carefully avoid simple carbohydrates of all forms (sugar, honey, dried fruit, fruit juice, etc.).

Lifestyle

The individual with angina should stop smoking and drinking alcohol and coffee. Stress should be decreased by using stress management techniques such as progressive relaxation, meditation or guided imagery. A carefully graded, progressive, aerobic exercise program (30 minutes three times/week) is a necessity. Walking is a good exercise with which to start.

Nutritional supplements

- Coenzyme Q₁₀ : 150–300 mg daily.
- L-Carnitine: 500 mg three times/day
- Pantethine: 300 mg three times/day
- Magnesium, preferably bound to aspartate, citrate, or other Krebs cycle intermediate): 200–400 mg three times/day.

Botanical medicines

- *Crataegus oxyacantha* (three times/day)
 - berries or flowers (dried): 3–5 g or as a tea
 - tincture (1:5): 4–6 ml (1–1.5 tsp)
 - fluid extract (1:1): 1–2 ml (0.25–0.5 tsp)
 - solid extract (10% procyanidins or 1.8% vitexin-4'-rhamnoside): 100–250 mg
- *Ammi visnaga* (three times/day)
 - dried powdered extract (12% khellin content): 100 mg three times/day.

Chapter 130 - Aphthous stomatitis

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

DIAGNOSTIC SUMMARY

- Single or clustered, shallow, painful ulcers found anywhere in the oral cavity.
- Lesions are from 1–15 mm in diameter, have fairly even borders, are surrounded by an erythematous border, and are often covered by a pseudomembrane.
- Lesions usually resolve in 7–21 days, but are often recurrent.

GENERAL CONSIDERATIONS

Aphthous stomatitis (also called common canker sore and ulcerative stomatitis) is a common condition, estimated to affect 20% of the population. Histological studies show lesions similar to those of Behcet's syndrome – lymphomononuclear infiltrate and hemagglutination antibodies against oral mucosa – and suggest an autoimmune mechanism. The etiology, based on studies of initiating factors, appears to be related to food sensitivities (especially gluten sensitivity), stress, and/or nutrient deficiency.

THERAPEUTIC CONSIDERATIONS

Food and environmental allergens

The oral cavity is obviously the first site of contact for ingested, and many inhaled, allergens. The histological appearance of the lesions and the association of recurrent aphthous stomatitis (RAS) with increased serum antibodies to food antigens and atopy strongly suggest that an allergic reaction is involved.^[1] Furthermore, IgE-bearing lymphocytes are significantly increased in aphthous lesions, and mast cells are increased in tissue sections from prodromal stages of recurrent ulcers.^[2] Mast cell degranulation plays an important role in the production of the aphthous lesion.^[3] An elimination diet has been shown to have good therapeutic results.^[4]

The allergen doesn't necessarily have to be a food. Frequent allergens inducing RAS include:^[5]

- benzoic acid
- cinnamaldehyde
- nickel
- parabens
- dichromate
- sorbic acid.

Elimination of allergens usually brings complete resolution or significant improvement.

Gluten sensitivity

There is considerable evidence that sensitivity to gluten is the primary cause of RAS in many cases. The incidence of RAS is increased in patients with celiac disease.^[6] ^[7] ^[8] ^[9] Jejunal biopsy of 33 patients with RAS showed eight to have the villous atrophy typical of celiac disease along with histological signs of immunological reactions to food antigens.^[6] The remaining patients also exhibited these types of signs, but to a lesser degree. Although villous atrophy is a prerequisite for the diagnosis of celiac disease, gluten sensitivity may take other forms: gluten may act directly on the oral mucosa or produce functional changes in the small intestine by immunological or other mechanisms that are distinct from those causing the characteristic abnormalities of celiac disease.^[8] An underlying gluten-sensitive enteropathy would also contribute to nutritional deficiencies. Withdrawing gluten from the diet results in complete remission of RAS in patients with celiac disease and some improvement in the rest of the patients.^[6] ^[7] ^[8] ^[9]

Even with the absence of villous atrophy, gluten sensitivity can definitely produce RAS. For example, in one small study, three out of four gluten-sensitive patients identified by positive antibodies to alpha-gliadin, but with normal small intestinal biopsy, responded dramatically to a gluten-free diet.^[10]

We strongly recommend measuring alpha-gliadin antibodies in any patient presenting with RAS.

Stress

Stress is often a precipitating factor in recurrent aphthous stomatitis, suggesting a breakdown in normal host protective factors.^[11]

Nutrient deficiency

The oral cavity is often the first place nutritional deficiency becomes visible to the physician because of the high turnover rate of the mucosal epithelium. Although a number of nutrient deficiencies can lead to aphthous stomatitis, thiamin appears to be the most significant. In one study seeking to examine whether thiamin deficiency is associated with recurrent aphthous stomatitis, the levels of transketolase (a thiamin-dependent enzyme) was determined in 70 patients with RAS and 50 patients from a control group.^[12] Low levels of transketolase were found in 49/70 patients with recurrent aphthous stomatitis compared with only 2/50 in the control. These results clearly demonstrate an association between low thiamin levels and recurrent aphthous stomatitis.

There are several other studies showing that nutrient deficiencies are much more common in RAS sufferers. For example, a study of 330 patients with RAS found that 47 (14.2%) were deficient in iron, folate or vitamin B₁₂, or a combination of these nutrients.^[13] In another study of 60 patients, 28.2% were deficient in thiamin, riboflavin, or pyridoxine.^[14] When these patients' deficiencies were corrected, the majority had complete remission. Other studies have shown similar deficiency rates for the same nutrients and equally good response to supplementation.^[15]

Quercetin

Quercetin is known to inhibit mast cell degranulation, basophil histamine release, and the formation of other mediators of inflammation.^[16] The anti-allergy drug di-sodium cromoglycate, a compound very similar in structure and function to quercetin, has been shown to be effective in the treatment of RAS, resulting in an increase in the number of ulcer-free days and in mild symptomatic relief.^[17] Other flavonoids (acacetin, apigenin, chrysin and phloretin, but not catechin, flavone, morin, rutin or taxifolin) have also shown anti-allergy effects similar to di-sodium cromoglycate.^[16]

Deglycyrrhizinated licorice (DGL)

DGL may be effective in promoting healing of RAS. In one study, 20 patients were instructed to use a solution of DGL as a mouthwash (200 mg powdered DGL dissolved in 200 ml warm water) four times daily.^[18] Fifteen of the 20 (75%) experienced 50–75% improvement within 1 day, followed by complete healing of the ulcers by the third day. DGL in tablet form may be more convenient and effective.

THERAPEUTIC APPROACH

These data suggest that no single factor is solely responsible for the initiation of the aphthous lesion in any specific patient. However, an underlying tendency to ulceration may be present, the expression of which is facilitated by these factors. Considerable evidence suggests that the underlying problem may be a gluten

sensitivity. In addition, nutrient deficiencies need to be corrected, and anti-inflammatory nutrients prescribed.

Diet

The patient's diet should be low in animal products, high in complex carbohydrates, and free of known allergens and all gluten sources (i.e. grains).

Supplements

- Vitamin C: 1,000 mg/day
- High potency multiple vitamin and mineral according to guidelines given in [Ch. 44](#)
- DGL: one to two 380 mg chewable tablets 20 minutes before meals.

Chapter 131 - Ascariasis

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

DIAGNOSTIC SUMMARY

- Intestinal phase: vague upper abdominal discomfort, occasional vomiting, abdominal distention, and, rarely, intestinal obstruction^[1]
- Pulmonary phase: transient cough, dyspnea, wheezing, urticaria, and transient pulmonary infiltrates
- Diagnosis of *Ascaris* pneumonia may be confirmed by finding larvae and eosinophils in the sputum or gastric aspirate
- Diagnosis of intestinal infection is usually confirmed by finding the characteristic *Ascaris* ova in the stool, although some patients will discover the worms when passed through the mouth, nose or rectum
- Eosinophilic leukocytosis (up to 50%) may be present, particularly during larval migration, but infrequently during chronic intestinal infection.

GENERAL CONSIDERATIONS

Ascariasis is a parasitic infection by *Ascaris lumbricoides*, the largest and most common intestinal roundworm. (The term roundworm refers to worms of the class *Nematoda*, including *Ancylostoma duodenale*, *Ascaris lumbricoides*, *Enterobius vermicularis*, and *Strongyloides stercoralis*.) *Ascaris* are large nematode worms, reaching 6–16 inches in length, which are found in warm, moist climates where soil pollution is common. It has been estimated that 25% of the world's population, including 4 million Americans (especially in the south-east), are infected with roundworms. In the developing areas of the world, where sanitary facilities are lacking, infection in children is almost universal.

In 1987, state diagnostic laboratories evaluated over 200,000 stool specimens. Parasites were found in 20.1% of the stools. The incidence of the various parasites are listed in [Table 131.1](#).

TABLE 131-1 -- Incidence of parasites in 200,000 stool samples²¹

| Organism | Incidence | Notes |
|---|-----------|---|
| Protozoans | | |
| <i>Giardia lamblia</i> | 7.2% | Significant increase from the 4% found in 1979; more than 9% of the specimens, were located around the Great Lakes or in the north-west |
| <i>Entamoeba coli</i> and <i>Endolimax nana</i> | 4.2% | |
| <i>Blastocystis hominis</i> | 2.6% | |
| <i>Entamoeba histolytica</i> | 0.9% | |
| <i>Cryptosporidium</i> species | 0.2% | |
| Nematodes | | |
| Hookworm | 1.5% | |
| <i>Trichuris trichiura</i> | 1.2% | |
| <i>Ascaris lumbricoides</i> | 0.8% | |
| <i>Clonorchis</i> and <i>Opisthorchis</i> species | 0.6% | |
| <i>Strongyloides stercoralis</i> | 0.4% | |
| <i>Hymenolepis nana</i> | 0.4% | |
| <i>Enterobius vermicularis</i> | 0.4% | Tape tests positive for 11.4% of 9,597 specimens |
| <i>Taenia</i> species | 0.1% | |

Etiology

Infection with *Ascaris* is found only in humans. The worms are most often spread as a result of the contamination of food and fingers by human fecal matter containing mature eggs, particularly in areas of the world where human feces is used as a fertilizer. When the eggs are swallowed, the motile larvae hatch in the stomach and small intestine, penetrate the wall of the small intestine, and commence a journey through the mesenteric venules and lymphatics to the heart and then through the blood to the lungs. There they burrow through the alveoli and migrate into the trachea and throat, where

they are swallowed and return to the jejunum, where they develop into mature nematode worms. Within 2–3 months, the female matures and begins production of enormous numbers of eggs which are excreted in the feces. The eggs become infective after 2–3 weeks in the soil, where they can survive up to seven years. The adult worm may live for one year or more.

Pathophysiology and symptomatology

As the worms pass through the lungs, they cause capillary and alveolar damage. This may result in a bronchopneumonia with fever, cough, dyspnea, wheezing and eosinophilic leukocytosis. Chronic intestinal infection may be asymptomatic if the infection is light. Heavy infection may cause abdominal discomfort, with pain or distention and fullness, vomiting, weight loss, weakness, constipation, and diarrhea. The common symptom picture in children may also include:

- convulsions, fits or spasms
- nervousness
- irritability
- twitching in various parts of the body
- itching of the nose or the anus
- anal irritation
- oral pallor
- anorexia
- ravenous appetite
- restlessness at night
- bruxism
- frequent micturition
- dry cough.

Often malabsorption of fat, protein, carbohydrates, and vitamins occurs, which can lead to anemia and growth retardation. The worm may become entangled and cause blockages in the intestinal tract, gall bladder or appendix. Pulmonary infiltrates (Löffler's syndrome) can develop in previously sensitized hosts. During the pulmonary phase, eosinophilia may reach as high as 30–50% and may persist as long as 1 month.

Malnutrition

Ascaris is often associated with malnutrition, but it is difficult to determine whether they are causally related, as both ascariasis and malnutrition are common in areas of poverty and poor sanitation. It has long been suspected that *Ascaris* may interfere with the host's food utilization, but investigations of nutrient absorption before and after drug therapy have yielded conflicting results.^{[3] [4]} Most studies clearly show that *Ascaris* infection is associated with growth retardation in malnourished children (or in those with marginally adequate protein intake) and that deworming improves nitrogen absorption, fat absorption, and growth.^{[3] [5] [6]} It has been suggested that failure of anti-*Ascaris* treatment to enhance growth in one prominent study may have been due to the absence of severe malnutrition in the subjects, adequate dietary protein, possible low worm load,

and/or failure to eradicate the *Ascaris* infection.^[4]

1091

Children infected with *Ascaris* have also been demonstrated to have decreased D-xylose absorption, lactose tolerance and mucosal lactase activity, and impaired absorption of vitamin A, which suggests that *Ascaris* could contribute to xerophthalmia if the diet is poor in vitamin A.^{[3] [6] [7]}

The mechanism of apparent malnutrition in ascariasis is unclear^{[6] [8]} and radiological examination has found no abnormality of the intestines.^[9] It has been suggested that malnutrition could be due to:^{[5] [8] [9]}

- a functional alteration of the intestinal mucosa leading to malabsorption (inflammation, direct mucosal surface blockage)
- the nutritional metabolic demands of large worms depriving the host of nutrients, especially during his/her growth cycle
- anorexia and vomiting adversely affecting the host's food intake.

Ascarids also produce large amount of ascarase, which has an antitryptic effect, to protect the parasite from being damaged by proteolytic enzymes. The ascarase could cause poor digestion of protein in the host by interfering with trypsin activity.^[10]

Asthma

Several studies have indicated a possible association between *Ascaris* infection and asthma in children.^{[11] [12]} The *Ascaris* polysaccharide antigen strongly stimulates IgE antibody formation, and repeated seasonal proliferation of *Ascaris* larvae may result in allergic respiratory disease.^[12] Allergic reactions to *Ascaris* larvae as they pass through the lungs^[11] or increased sensitivity to common inhaled allergens caused by exposure to *Ascaris* antigen could account for the enhanced tendency to bronchoconstriction found in susceptible individuals with ascariasis.^{[11] [12]}

Environmental toxicity

A growing body of evidence is suggesting that heavy metal toxicity may not only increase susceptibility to parasite infestation but also inhibit the body's attempts to limit the infection and allow increased migration of worms throughout the body.

One study looked at the short-term effects of industrial heavy metal emissions (Hg, Cu, Pb, Zn), collected at 5 km from a mercury-producing plant, on T- and B-lymphocytes and peritoneal macrophages of guinea pigs with experimental ascariasis (*Ascaris suum*). Administration of the emission for 5 days showed a significant decrease in T- and B-cell population and in macrophage phagocytic ability during the migration phase of *Ascaris suum* when compared with an infected but untreated group of animals. This

was also manifested by a remarkable eightfold increase in the density of migrating *Ascaris* larvae into the lungs. The most striking decrease in the immunological responses was observed in guinea pigs that were given emission but were not infected.^[13]

Other studies by some of the same researchers looked specifically at the independent effects of cadmium and mercury on guinea pigs with experimental ascariasis. Cadmium chloride given orally for 28 days caused a considerable suppression of T- and B-cells in the lymphoid organs and of the metabolic activity of their peritoneal macrophages and a moderate decline in the level of complement from day 1 to day 28 of the experiment. After a subsequent infection of the subchronically intoxicated guinea pigs, the values for both the cell populations and the macrophage metabolic activity remained considerably suppressed, compared with infected control animals. Compared with the controls, the mean intensity of infection with *Ascaris* larvae migrating in the lungs of intoxicated animals increased by 20%.^[14]

Mercury given for 28 days to guinea pigs infected with *Ascaris suum* resulted in significantly reduced T- and B-cell populations in the lymphoid organs and the phagocytic ability of peritoneal macrophages. The mean intensity of infection with migrating *Ascaris* larvae in HgCl₂-treated animals increased by 15% compared with controls.^[15]

THERAPEUTIC CONSIDERATIONS

Diet

Diet and nutritional factors, although slow in action, are helpful in preventing reinfection following therapy. Clinicians report that a diet high in unrefined carbohydrates and raw green vegetables and moderate in protein, with no meat, dairy, or sugar, provides high resistance to worm infections.^[16] Roundworms prefer an environment that is acidic, sweet, and constipated, so an alkaline diet low in sugar and high in fiber is recommended. A healthy diet also prevents worm infection by improving immunity and preventing exposure through proper preparation and cooking of food.

Fasting

Fasting for the elimination of parasites is an intriguing concept, but with no human research. Some light is shed by experiments conducted on the fasting on 40 young cross-bred growing pigs naturally infected with *Ascaris suum* and *Oesophagostomum* spp. In one experiment, 10 pigs were fasted and offered water ad libitum for 6 days, and in another experiment for 10 days. Subsequently, these pigs, together with 10 non-fasted control pigs per experiment were slaughtered, and worm numbers, worm location, sex, developmental stage and female worm

fecundity were determined. Pigs fasted for 10 but not for 6 days had decreased numbers of *A. suum* and *Oesophagostomum* spp. at slaughter vs. controls, and worms were found in more distal locations in the gastrointestinal tract. Fasting for both 6 and 10 days significantly lowered the fecundity of both worm species.^[17]

Botanical medicines

Traditional botanicals

There are several botanicals effective in treating *Ascaris*. Extracts of garlic, onion, pomegranate rind, turmeric (*Curcuma longa*), and various citrus rinds have all been shown to possess anthelmintic properties against *Ascaris*.^[18] ^[19] Bromelain and papain, like certain other proteolytic enzyme complexes,^[20] are useful in dissolving the outer layer of the worms that shields them from proteases. Fig powder is also helpful, presumably for its laxative effect. *Lactobacillus* supplementation may be recommended because the lactic acid it produces inhibits the growth of pathogens, decreases any tendency to constipation, and generally promotes healthy bowel activity which prevents reinfection.

Some of the traditional anthelmintic botanicals, such as *Spigelia marilandica* (pinkroot), *Chenopodium ambrosoides* (wormseed), *Tanacetum vulgare* (tansy), and santonin (from the flowers of *Artemisia maritima* and *Artemisia cina*), are in most cases either too toxic or ineffective when administered within the dosage range considered safe.^[21] ^[22] ^[23] *Artemisia absinthium* (wormwood), *Inula helenium* (elecampane), and *Picraena excelsa* (quassia) are less toxic vermifuges specific for *Ascaris*.^[21] ^[24] ^[25] ^[26] Elecampane is recommended as the safest for children. Elecampane's vermifuge activity appears to be due to helenin (also called alantolactone), which is similar to santonin (but better and less toxic)^[27] and has been found to have a paralyzing effect on the worm's central nervous system.^[24] Wormwood and elecampane also have bitter properties which, due to their tonic effect on the gastrointestinal tract, may enhance their anthelmintic activity. The comparative toxicity of anthelmintic botanicals is shown in [Table 131.2](#) .

Papaya latex

The anthelmintic activity of papaya latex (*Carica papaya*) against natural infection of *Ascaris suum* was investigated

TABLE 131-2 -- Comparative toxicity of anthelmintic botanicals^[28] ^[29]

| Botanical | Therapeutic dose | Toxic dose | Toxic symptoms |
|-----------|------------------|------------|----------------|
| | | | |

| | | | |
|--|-----------------------------------|-------------------------|---|
| <i>Artemesia absinthium</i> (wormwood) | 1–5 drops oil | 15 ml oil | <i>Acute</i> – headache, trembling, then stupor, followed by clonic convulsions, death |
| | | | <i>Chronic</i> – disturbed rest, disagreeable dreams, morning nausea and vomiting, epileptoid attacks, physical and mental force impaired, impotence or premature menopause, hyperesthesia of the hypogastrium |
| | | | <i>HB</i> – restlessness, insomnia, nightmares, vomiting, vertigo, tremor, convulsions |
| Santonin crystals (<i>Artemesia maritima</i>) | 0.1–4 grains | 5 grains fatal in child | Excessive alkalinity in intestines increases absorption and toxicity |
| | | | Abdominal cramps, nausea and vomiting, coldness and pallor, headache, vertigo, generalized asthenia, anuria, diarrhea, profuse sweating, flushed face, foaming at the mouth, xanthopsia or chromatopsia, urine changes color from yellow to saffron (if alkaline) to reddish-purple, dilated pupils, decreased blood pressure, bradycardia, twitching eyes and head, clenching of teeth, convulsions, tetany or cramps, unconsciousness and death by respiratory paralysis; if non-fatal, aphasia or blindness may result |
| | | | <i>HB</i> – vomiting, diarrhea, yellow vision, convulsions, death |
| <i>Artemesia cina</i> (Levent wormseed) | Same as <i>Artemesia maritima</i> | | As above |
| <i>Chenopodium ambrosoides</i> (wormseed) | 5–16 drops oil | | Burning sensation in throat and mouth, nausea, vomiting, headache, tinnitus, drowsiness, sleep, deafness, decrease in visual acuity, decreased respiration, varied heart rate, gastric ulcers, constipation, prostration, nephritis, decreased blood pressure and CNS activity, spinal cord depression (paralysis), death by respiratory paralysis |
| | | | <i>HB</i> – vomiting, diarrhea, blindness, deafness, convulsions, coma |
| <i>Inula helenium</i> (elecampane) | 1–2 g root (child) | | |

| | | | |
|---|-----------------------------|--------------------|---|
| <i>Picraena excelsor</i> (quassia [Jamaican]) | 1–2 g wood | | Diarrhea, vomiting, collapse |
| <i>Spigelia marilandica</i> (pinkroot) | 4–8 g root | | Increased cardiac action, cerebral disturbance, dizziness, dimness of vision, dilated pupils, facial and palpebral spasms, general convulsions and stupor, purgation |
| | 5–60 drops fluid extract | | |
| <i>Tanacetum vulgare</i> (tansy) | 1–10 drops oil | 15 drops oil | Gastrointestinal irritation, nausea, vomiting, diarrhea, mydriasis, increased pulse rate, weak pulse, convulsions, paralysis, spasms, frothing from mouth, also coma and death by respiratory paralysis |
| | | 4 ml fatal | |

1093

in pigs.^[30] Sixteen naturally infected pigs were, on the basis of fecal egg counts and body weight, allocated into four groups, each of four pigs. Three groups (groups B, C, and D) were given papaya latex per os at dose levels of 2, 4, and 8 g of papaya latex/kg body weight, respectively. The fourth group (group A) served as a non-treated control. Results of postmortem counts on day 7 post-treatment revealed worm count reductions of 39.5, 80.1 and 100% in groups B, C, and D, respectively. Some of the pigs receiving the highest dose of the latex showed mild diarrhea on the day following treatment. Otherwise, no clinical or pathological changes were observed in the treated animals. This is a very promising result, requiring follow-up in humans.

THERAPEUTIC APPROACH

In general, vermifuges are toxic agents and can be very dangerous in material doses. As a fundamental precept of naturopathic medicine is to avoid doing harm with extreme measures, effective simple and relatively less toxic therapies should first be given the opportunity to succeed. It is also important to recognize that a light *Ascaris* infection is common in childhood, is frequently not symptomatic, and need not necessarily be considered a serious disease requiring heroic measures in otherwise healthy children. The drugs typically used for deworming are not only highly toxic, but may, in a heavily infected individual, induce the adult worm to migrate out of the intestines into other body tissues with potentially serious results.

Since nematode reproduction requires that a portion of its life cycle be outside of the body, continuing infection almost certainly implies improper hygiene. Prevention and treatment greatly depend on proper disposal of waste matter, good hygiene, and proper washing of fruits and vegetables.

When the infection is heavy, there is likely to be some underlying cause in the host

providing either a suitable habitat for the worms, susceptibility for infection, and/or repeated exposure. In such cases simple removal of the worms alone will not cure the disease or prevent reinfection. Important factors to consider are living conditions; hygiene, diet and nutritional status; general state of health; heavy metal or other toxin exposure; and the integrity of stomach, bowels (such as constipation), and mucous membranes. As a child's poor hygiene may result in infestation of other members of the family, and daycare and school classmates, all of a child's close associates should be examined.

Upon completion of an apparently effective treatment program, re-examination of the feces after 2 weeks and a few months is crucial to ensure that no new eggs have hatched. Also of importance is the fact that other intestinal parasites are frequently found in association with *Ascaris* infection. Heavy *Ascaris* infection may mask the presence of other ova and parasites in the stool resulting in false-negative laboratory reports. Repeat stool examinations after 3 months will occasionally reveal other parasites. Anthelmintic drugs should be used for patients who do not respond to the recommended therapy.

The basic protocol, besides careful attention to hygiene, is to provide an inhospitable diet, botanical medicines to stun or poison, and a purgative to expel the helminth. As most botanical anthelmintics do not affect the eggs, repeat treatments are needed to ensure newly hatching larvae from existing eggs are cleared from the body.

Days 1–3

Eat nothing but 3–5 ounces of pumpkin seeds, plus three to eight cloves of raw garlic per day. On an empty stomach, the patient should take the following dosages three times/day:

- bromelain (1,200 MCU): 500 mg
- papain: 500–1,000 mg
- pancreatin (8x USP): 500 mg
- fig powder: 1 tsp.

Take one botanical therapy three times/day:

- Children
 - Inula helenium* (elecampane)
 - powdered root: 1–2 g
 - fluid extract (1:1): 1–2 ml
- Adults
 - Artemisia absinthium* (wormwood)
 - oil: 1–5 drops

- infusion: 0.5–1 tsp/cup
- powdered root: 1–2 g
- fluid extract (1:1): 2–4 ml
- Picraena excelsor* (quassia)
- powdered wood: 1–2 g.

Day 4

Administer a purging dose of licorice root (children), magnesium citrate, *Senna*, or *Cascara sagrada*. Licorice root or coriander may be added to strong laxatives to make them more palatable and/or milder in action if desired. Soaked raisins may be taken on day 4 prior to the purge. The sweetness will help to lure any remaining worms out of hiding and enhance their expulsion.

Two weeks later

Repeat the entire 4 day program two more times: 2 weeks later, and once more after an additional week later. In between, maintain the recommended preventive diet while continuing the same quantities of pumpkin seeds and garlic.

Chapter 132 - Asthma

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

DIAGNOSTIC SUMMARY

- Recurrent attacks of dyspnea, cough, and expectoration of tenacious mucoid sputum
- Prolonged expiration phase with generalized wheezing and musical rales
- Eosinophilia, increased serum IgE, positive food and/or inhalant allergy tests.

GENERAL CONSIDERATIONS

Bronchial asthma is a hypersensitivity disorder characterized by bronchospasm, mucosal edema, and excessive excretion of a viscous mucus that can lead to ventilatory insufficiency. Its prevalence is approximately 3% of the US population, and although it occurs at all ages, it is most common in children under 10. There is a 2:1 male-to-female ratio in children, which equalizes by the age of 30.

Major factors involved in asthma are:

- hypersensitivity of the airways
- beta-adrenergic blockade
- cyclic nucleotide imbalance in airway smooth muscle
- release of inflammatory mediators from mast cells.

The rate of asthma in the United States is rising rapidly, especially in children. Reasons often given to explain the rise in asthma include:

- increased stress on the immune system due to factors such as greater chemical pollution in the air, water, and food
- earlier weaning and earlier introduction of solid foods to infants
- food additives

- genetic manipulation of plants resulting in food components with greater allergenic tendencies.

Pertussis vaccine

An evaluation of health criteria in a total of 448 children and adolescents in Britain who had received only breast

1096

milk for the first 6 months of life, and in particular on the first day after birth, produced some interesting findings. All of the children were weaned after 1 year of age and were older than 4 years at the time the parents responded. The mean age was 7.87 years.

To the question “Has your child ever been diagnosed as asthmatic?” there were 30 positive answers (6.72%). The surprise came when the researchers classified the respondents according to whether or not they received the pertussis vaccine.^[1]

Among the 243 immunized children, 26 were diagnosed as having asthma (10.69%). In contrast, of the 203 children who had not been immunized only four had asthma (1.97%). The relative risk of developing asthma from the pertussis vaccine was 5.43 in this study. The significance of this finding was at the $P = 0.0005$ level.

Even though all of the children who received the pertussis vaccine received other vaccinations, the researchers felt the statistical evidence focused on pertussis. Among the children who did not receive the pertussis vaccine, most had received some other vaccination. Of the 91 subjects of the study who received no vaccines, only one had asthma, compared with three with asthma in the 112 who had other vaccinations. Therefore, the relative risk of developing asthma is about 1% in children receiving no immunizations, 3% in those receiving vaccinations other than pertussis, and 11% for those receiving pertussis. Another finding to weigh, in the group not immunized to pertussis, is that 16 developed whooping cough compared with only one in the immunized group.

Major categories

Asthma has typically been divided into two categories: extrinsic and intrinsic. Extrinsic or atopic asthma is generally considered an immunologically mediated condition with a characteristic increase in serum IgE. Intrinsic asthma is associated with a bronchial reaction that is due, not to antigen–antibody stimulation, but rather to such factors as chemicals, cold air, exercise, infection, agents that activate the alternative complement pathway, and emotional upset.

Mediators

Both extrinsic and intrinsic factors trigger the release of mast cell-derived chemical mediators. These mediators are responsible for the signs and symptoms in the majority of cases. They are either preformed within granules or generated from membrane-bound phospholipids. The preformed mediators include histamine, various chemotactic peptides, such as eosinophilic factor (ECF) and high-molecular weight neutrophil chemotactic factor (NCF), proteases, glycosidases and heparin proteoglycan. The membrane-derived agents include lipoxygenase products, such as leukotrienes (LT) and the so-called slow-reacting substance of anaphylaxis (SRS-A), prosta-glandins (PG), thromboxanes (TX) and platelet-activating factor (PAF).

These mediators are diverse in chemical composition and modes of action and account for many of the signs and symptoms of asthma. The actions include bronchial smooth muscle constriction (histamine, LTC₄, LTD₄ and LTE₄, PGF_{2α}, PGD₂, and PAF), mucosal edema (increased permeability histamine, LTC₄, LTD₄, and PAF), vasodilation (PGD₂ and PGE₂), mucous plugging (histamine, HETEs, and LTC₄), inflammatory cell infiltrate (NCF, ECF-A, HETEs, LTB₄, and PAF), and desquamation of epithelium (proteases and glycosidases, together with lysosomal enzymes and basic proteins derived from neutrophils and eosinophils).

Mild episodic asthma differs from moderate to severe sustained asthma in that the latter is largely dependent on a subacute/chronic inflammation of the bronchi with infiltration of eosinophils, neutrophils and mononuclear cells, while episodic asthma is due primarily to bronchial smooth muscle contraction.

Lipoxygenase products

The most potent chemical mediators in asthma are the lipoxygenase products, i.e. leukotrienes (see [Fig. 132.1](#)). The leukotrienes composing SRS-A (LTC₄, LTD₄, LTE₄) are 1,000 times more potent as stimulators of bronchial constriction than is histamine. It has been observed that asthmatics have an imbalance in arachidonic acid metabolism, leading to a relative increase in lipoxygenase products.^[2] Platelets from asthmatic patients show a 40% decrease in cyclooxygenase-derived metabolites and a 70% increase in lipoxygenase products. This pathophysiological alteration is further aggravated in “aspirin-induced asthma”. Aspirin and other non-steroidal anti-inflammatory drugs (NSAID), e.g. indomethacin and phenylbutazone, inhibit cyclooxygenase while promoting lipoxygenase.^[3] ^[4] The net result is a shunting of arachidonic acid towards the lipoxygenase pathway and the production of excessive levels of leukotrienes.

Tartrazine (yellow dye no. 5) is also a cyclooxygenase inhibitor and known inducer of asthma, particularly in children.^[3] Tartrazine is ubiquitous in processed foods and can even be found in vitamin preparations and anti-asthma prescription drugs (e.g. aminophylline). Tartrazine may also indirectly support the asthmatic process via its role as an anti-metabolite of vitamin B₆ (see tryptophan discussion below).

Autonomic nervous system

The relationship between the autonomic nervous system and bronchial asthma represents an interaction between

1097

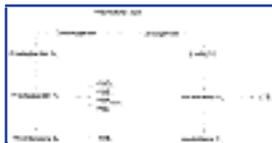

Figure 132-1 Arachidonic acid metabolism.

parasympathetic and sympathetic innervation and beta-2-adrenergic receptors (which are localized in lung tissue and which react to circulating catecholamines).^[5] Stimulation of the parasympathetic vagus nerve results in airway constriction. This vagal mechanism involves the following: release of acetylcholine at the synapse, subsequent binding to its receptor on smooth muscle tissue, and subsequent formation of cyclic guanosine monophosphate (cGMP). Accumulation of cGMP and/or a relative deficiency in cyclic adenosine monophosphate (cAMP) result in constriction of the airway smooth muscle as well as degranulation of mast cells and basophils. Decreased sympathetic activity or diminished beta-2 receptor numbers or sensitivity also promote the cyclic nucleotide imbalance. Some of the mediators discussed above block beta-2-receptors and both directly and indirectly elevate cGMP levels.

Adrenal gland

The activity of the adrenal gland is important in asthma due to its hormones cortisol and epinephrine. Cortisol is a very effective prime activator of beta receptors, and epinephrine is considered to be the prime stimulator of beta receptors. It has been suggested that during asthmatic attacks there is a relative deficiency of cortisol and epinephrine (which stimulates beta-2 receptors to catalyze the formation of cAMP from AMP). This leads to a decrease in the cAMP:cGMP ratio, resulting in bronchial constriction.

THERAPEUTIC CONSIDERATIONS

As with many complex diseases, the initial cause(s) of asthma, e.g. hypochlorhydria, may initiate a sequence of events that become self-propagating, e.g. hypochlorhydria-induced food allergies leading to increased intestinal permeability and then to increased susceptibility to food allergy. Effective treatment requires control of both the initiating cause(s) and the induced physiological abnormalities.

General

Hypochlorhydria

Fractional gastric analyses in 200 asthmatic children by Bray in 1931 showed that 80% of them had gastric acid secretions below normal levels.^[6] This high occurrence suggests that decreased gastric acid output may predispose these children to food allergies, has a major impact on the success of rotation and/or elimination diets, and, if not corrected, on the development of additional food allergies.

Increased intestinal permeability

The presence of food allergies is thought to be responsible for asthmatics having been shown to have a “leaky gut”.^[7] As a result of this increased gut permeability, there is increased antigen load on the immune system. This subsequently overwhelms the immune system, increasing the likelihood of developing additional allergies as well as increasing bronchoconstrictive compounds into the circulation. It is essential to identify offending foods as soon as possible to avoid the development of further allergies.

Candida albicans

An overgrowth of the common yeast, *Candida albicans*, in the gastrointestinal tract has been implicated as a causative factor in allergic conditions including asthma. Apparently the acid protease produced by *C. albicans* is the responsible allergen.^[8] Appropriate anti-*Candida* therapy may result in significant clinical improvement of asthma in many cases.

Food additives

Vitaly important in the control of asthma is the elimination of food additives.^[9] Artificial dyes and preservatives are widely used in foods, beverages, and drugs. The most common coloring agents are azo dyes – tartrazine (orange), sunset yellow, amaranth and the new coccine (both red) – and the non-azo dye pater blue. The most commonly used preservatives in food are sodium benzoate, 4-hydroxybenzoate esters, and sulfur dioxide. Various sulfites are commonly used in prepared foods.

Tartrazine, benzoates, sulfur dioxide and, in particular, sulfites have been reported to cause asthma attacks in susceptible individuals.^{[9] [10]} It is estimated that 2–3 mg of sulfites are consumed each day by the average US citizen, while an additional 5–10 mg are ingested by wine and beer drinkers.^[10] The largest sources are the salads, vegetables (particularly potatoes), and avocado dip served in restaurants. A customer

can ingest 25–100 mg of metabisulfite in as little as one restaurant meal.

It has been postulated that a molybdenum deficiency may be responsible for sulfite sensitivity.^[11] Sulfite oxidase, the enzyme responsible for neutralizing sulfites, is molybdenum-dependent.

Salt

There is strong evidence indicating that an increased intake of salt increases bronchial reactivity and mortality from asthma.^[12] ^[13] The degree of bronchial reactivity to histamine is positively correlated with the 24 hour urinary sodium excretion and rises with increased dietary sodium. Since the severity of asthma correlates with the degree of bronchial reactivity, it is clear that the severity of asthma can be influenced by alterations in dietary sodium consumption.

DHEA

Decreased levels of DHEA have been shown to be quite common in postmenopausal women with asthma compared with matched controls.^[14] Whether DHEA produces any therapeutic benefit in asthma remains to be demonstrated; however, given its importance to proper immune function, an ability to produce positive effects is certainly possible.

Diet

Food allergy

Many studies have indicated that food allergies play an important role in asthma (see [Ch. 51](#)).^[15] ^[16] ^[17] ^[18] ^[19] Adverse reactions to food may be immediate or delayed. Double-blind food challenges in children have shown that immediate onset sensitivities are usually due (in decreasing order of frequency) to egg, fish, shellfish, nuts, and peanuts, while foods most commonly associated with delayed onset include (in decreasing order of frequency) milk, chocolate, wheat, citrus, and food colorings.^[17] Elimination diets have been successful in identifying allergens and treating asthma, and are a particularly valuable diagnostic and therapeutic tool in infants.^[20] Elimination of common allergens during infancy (first 2 years) has been shown to reduce allergic tendencies in high risk children (e.g. strong familial history).^[21]

Vegan diet

A long-term trial of a vegan diet (elimination of all animal products) provided significant improvement in 92% of the 25 treated patients who completed the study (nine dropped out).^[22] Improvement was determined by a number of clinical variables, including vital capacity, forced expiratory volume at 1 second, and physical working capacity, and by biochemical indices, such as haptoglobin, IgM, IgE, cholesterol, and triglyceride levels in the blood. The researchers also found a reduction in the tendency to infectious disease. It is important to recognize, however, that while 71% of the patients responded within 4

months, 1 year of therapy was required before the 92% level was reached.

The diet excluded all meat, fish, eggs, and dairy products. Drinking water was limited to spring water (chlorinated tap water was specifically prohibited), and coffee, ordinary tea, chocolate, sugar, and salt were excluded. Herbal spices were allowed, and water and herbal teas were allowed up to 1.5 L/day. Vegetables used freely were lettuce, carrots, beets, onions, celery, cabbage, cauliflower, broccoli, nettles, cucumber, radishes, Jerusalem artichokes, and all beans except soya and green peas. Potatoes were allowed in restricted amounts. A number of fruits were also used freely: blueberries, cloudbberries, raspberries, strawberries, black currants, gooseberries, plums, and pears. Apples and citrus fruits were not allowed, and grains were either very restricted or eliminated.

The beneficial effects of this dietary regime are probably related to three areas:

- elimination of food allergens
- altered prostaglandin metabolism
- increased intake of antioxidant nutrients and magnesium.

The importance of avoiding food allergies was discussed above. In regards to altered prostaglandin metabolism, the avoidance of dietary sources of arachidonic acid (derived from animal products) appears to be quite significant. The prostaglandins and leukotrienes derived from arachidonic acid contribute very significantly to the allergic reaction in asthma. Decreasing the availability

of arachidonic acid as a substrate of these inflammatory compounds appears to explain some aspects of the efficacy of the vegan diet. The beneficial effects of altering prostaglandin metabolism is further discussed below, as is the role of increased dietary antioxidants in preventing asthma.

Perhaps the most significant effect noted in the trial of the vegan diet, besides the patients' improvement in health, was the great reduction in health care costs (the patients had been receiving corticosteroids and other drugs and therapies for an average of 12 years) and, according to the authors, the changed attitude towards increased responsibility for their own health.

Nutrition

Omega-3 essential fatty acids

Epidemiological studies have shown that children who eat fish more than once a week have one-third the risk for asthma of children who do not eat fish regularly.^[23] Several clinical studies have shown that increasing the intake of omega-3 fatty acids through

supplementation with fish oils containing eicosapentaenoic acid (EPA) and docosahexanoic acid (DHA) offers significant benefits in asthma as noted by improvements in airway responsiveness to allergens as well as improvements in respiratory function.^{[24] [25]} These benefits are related to increasing the ratio of omega-3 to omega-6 fatty acids in cell membranes, thereby reducing the availability of arachidonic acid. In particular, omega-3 fatty acid ingestion leads to a significant shift in leukotriene synthesis from the extremely inflammatory 4-series to the less inflammatory 5-series leukotrienes. This shift is directly related to improvements in asthma symptoms.^[26] The benefits may take as long as 1 year before they are apparent, as it appears to take time to turn over cellular membranes in favor of the omega-3 fatty acids.

Tryptophan metabolism and pyridoxine supplementation

Children with asthma have been shown to have a metabolic defect in tryptophan metabolism and reduced platelet transport for serotonin.^{[27] [28]} Tryptophan is converted to serotonin, a known bronchoconstricting agent in asthmatics. High serotonin levels in the blood and sputum are common findings in asthmatics and are reflected by an elevated urinary level of 5-hydroxyindole acetic acid (5-HIAA), the breakdown product of serotonin. The levels of 5-HIAA in the urine correlate well with the severity of asthmatic symptoms. Double-blind clinical studies have shown that patients benefit from either a tryptophan-restricted diet^[27] or pyridoxine supplementation^{[28] [29]} to correct the blocked tryptophan metabolism.

Pyridoxine may also be of direct benefit to asthmatic patients. In one study, plasma and erythrocyte pyridoxal phosphate (PLP) levels in 15 adult patients with asthma were significantly lower than in 16 controls.^[28] Oral supplementation with 50 mg of pyridoxine twice daily to seven of the patients failed to produce a substantial elevation of these low levels. However, all patients reported a dramatic decrease in frequency and severity of wheezing and asthmatic attacks while taking the supplements. In a study of 76 asthmatic children, pyridoxine at a dosage of 200 mg daily produced significant reductions in symptoms and dosages of bronchodilators and corticosteroids. However, a double-blind study failed to demonstrate any significant improvement with B₆ supplementation in patients who were dependent upon steroids for control of symptoms.^[30]

While vitamin B₆ supplementation may not help patients on steroids, it is definitely indicated in asthmatics being treated with the drug theophylline. Theophylline significantly depresses pyridoxal-5-phosphate levels.^[31] In addition, another study has shown that vitamin B₆ supplementation can significantly reduce the typical side-effects of theophylline (headaches, nausea, irritability, sleep disorders, etc.).^[32]

It appears that the tryptophan load test (see [Ch. 28](#)) could be utilized to determine the appropriateness and level of pyridoxine supplementation needed. Urinary excretion of kynurenic and xanthurenic acids will be increased in patients who will respond to pyridoxine.

Antioxidants

The substantial increase in the prevalence of asthma over the past 20 years can be partially explained by the reduced dietary intake of antioxidant nutrients like beta-carotene and vitamins A, C, and E as well as the mineral cofactors essential for antioxidant defense mechanisms such as zinc, selenium, and copper.^[33] Antioxidants are thought to provide important defense mechanisms for maintaining the redox state of the lung. This protection is significant because oxidizing agents can both stimulate bronchoconstriction and increase hyperactivity to other agents. Asthma appears to be another disease process that is influenced greatly by antioxidant mechanisms.

Vitamin C

Especially important to the health of the lung is vitamin C as it is the major antioxidant substance present in the extracellular fluid lining the airway surfaces.^[34] Vitamin C intake in the general population appears to correlate with asthma, indicating that low vitamin C (in the diet and the blood) is an independent risk factor for asthma. Additional support is offered by the fact that children of smokers have a higher rate of asthma (cigarette smoke is known to deplete respiratory vitamin C and E levels)

1100

and symptoms of ongoing asthma in adults appear to be increased by exposure to environmental pro-oxidants and decreased by vitamin C supplementation.

Nitrogen oxides are examples of oxidants that can arise from both endogenous and exogenous sources. Vitamin C has been shown to offer significant protection against nitrogen oxide damage in the lungs in animal models.^[35]

Both treated and untreated asthmatic patients have been shown to have significantly lower levels of ascorbic acid in serum and leukocytes.^[35] From a clinical perspective it appears that asthmatics have a higher need for vitamin C. Since 1973 there have been 11 clinical studies of vitamin C supplementation in asthma.^[36] Seven of these studies showed significant improvements in respiratory measures and asthma symptoms as a result of supplementing the diet with 1–2 g of vitamin C daily. This dosage recommendation appears extremely wise based on the increasing exposure to inhaled oxidants along with the growing appreciation on the antioxidant function of vitamin C in the respiratory system.

High-dose vitamin C therapy may also help asthma by lowering histamine levels.^[37] The importance of vitamin C as a natural antihistamine has emerged for several reasons, including concern over the safety of antihistamine medications and recently recognized immune-suppressing effects of histamine. In the initial stages of an immune response, histamine amplifies the immune response by increasing capillary permeability and smooth muscle contraction, thus enhancing the flow of immune factors to the site of

infection. Subsequently, histamine exerts a suppressive effect on the accumulated white blood cells in an attempt to contain the inflammatory response.

Vitamin C exerts a number of effects against histamine. Specifically it prevents the secretion of histamine by white blood cells and increases the detoxification of histamine. A recent study examined the antihistamine effect of acute and chronic vitamin C administration and its effect on white blood cell (neutrophil) function in healthy men and women. In the chronic study, 10 subjects ingested a placebo during weeks 1, 2, 5, and 6, and 2 g/day of vitamin C during weeks 3 and 4. Fasting blood samples were collected after the initial 2 week period (baseline) and at the end of weeks 4 and 6. Blood vitamin C levels rose significantly following vitamin C administration, while blood histamine levels fell by 38% during the weeks vitamin C was given. The ability of white blood cells to move to respond to an infection (chemotaxis) increased by 19% during vitamin C administration, and fell 30% after vitamin C withdrawal. However, these changes were linked to histamine concentrations. Chemotaxis was greatest when histamine levels were the lowest. In the part of the study looking at the acute effects of vitamin C, blood histamine concentrations and chemotaxis did not change 4 hours after a single dose of vitamin C. This result suggests that vitamin C will only lower blood histamine if taken over a period of time. Individuals prone to allergy or inflammation are encouraged to increase their consumption of vitamin C through supplementation.^[37]

Flavonoids

Flavonoids appear to be key antioxidants in the treatment of asthma. Various flavonoids, chief among them being quercetin, have been shown to inhibit:^{[38] [39] [40] [41]}

- histamine release from mast cells and basophils when stimulated by antigens and other ligands
- phospholipase A₂ in neutrophils
- lipoxygenase
- anaphylactic contraction of smooth muscle
- phosphodiesterase in the lung (resulting in increased cAMP levels)
- biosynthesis of SRS-A
- calcium influx.

In addition, quercetin has both a vitamin C-sparing effect and a direct stabilizing effect on membranes, including mast cells. Flavonoids are also extremely effective antioxidants.

Quercetin can be used, or flavonoid-rich extracts such as those from grape seed, pine bark, green tea, or *Ginkgo biloba* may prove even more helpful in the treatment of asthma due to their better bioavailability. In particular, the proanthocyanidins from grape seed or pine bark extracts appear to have an affinity for the lungs (for more information, see [Ch. 106](#)).

Carotenes

Carotenes are powerful antioxidants which may increase the integrity of the epithelial lining of the respiratory tract, and act as substrates for lipoxygenase, possibly competing with arachidonic acid, thereby decreasing leukotriene formation.^[42]

Vitamin E

Vitamin E's activity as an antioxidant, lipoxygenase inhibitor, and phospholipase inhibitor makes it a useful agent in asthma treatment.^[43]

Selenium

Reduced selenium levels have been demonstrated in asthma patients.^[44] ^[45] ^[46] Glutathione peroxidase, a selenium-dependent metalloenzyme, is very important for reducing hydroperoxy-eicosatetraenoic acid (HPETE) to hydroxy-eicosatetraenoic acid (HETE), thereby reducing leukotriene formation. Reduced levels of glutathione

1101

peroxidase have also been reported for asthmatics.^[44] Supplemental selenium appears warranted to address any deficiency of glutathione peroxidase. In addition, supplemental selenium may reduce the production of leukotrienes by ensuring optimal activity of glutathione peroxidase.

Vitamin B₁₂

Jonathan Wright MD believes that "B₁₂ therapy is the mainstay in childhood asthma".^[47] In one clinical trial, weekly 1,000 mcg intramuscular injections produced definite improvement in asthmatic patients.^[48] Of 20 patients, 18 showed less shortness of breath on exertion, as well as improved appetite, sleep, and general condition. Vitamin B₁₂ appears to be especially effective in sulfite-sensitive individuals. It offers the best protection when given orally (1–4 mcg) prior to challenge, compared with other pharmacological agents (e.g. cromolyn sodium, atropine, and doxepin).^[49] The mode of action is the formation of a sulfite–cobalamin complex, which blocks sulfite's effect.

Magnesium

In 1912, Trendelenburg demonstrated that magnesium relaxed bovine bronchial smooth muscle in vitro.^[50] Later, uncontrolled clinical studies revealed magnesium's beneficial effect in the treatment of patients with acute attacks of bronchial asthma.^[51] Unfortunately, this promising line of research was dropped as antihistamines and bronchodilators became available. However, the advent of calcium-channel blockers for the treatment of asthma generated renewed interest in the therapeutic use of magnesium for asthma. In fact, intravenous magnesium (2 g of magnesium sulfate

infused every hour up to a total of 24.6 g magnesium sulfate) is now a well-proven and clinically accepted measure to halt an acute asthma attack as well as acute exacerbations of COPD.^{[52] [53] [54] [55] [56]}

While these studies have utilized injectable magnesium therapy, it must be pointed out that it has been demonstrated that injectable magnesium is not necessary to restore magnesium status (except in the case of an emergency situation such as an acute heart attack or acute asthma attack).^[57] Oral magnesium therapy is an effective measure to raise body magnesium stores, but it will usually take 6 weeks to achieve significant elevations in tissue magnesium concentrations. Supplementation appears to be warranted, as dietary magnesium intake is independently related to lung function and asthma severity.^[58]

Botanical medicines

The most popular historical herbal treatment of asthma involved the use of *Ephedra sinensis* (Ma huang) in combination with herbal expectorants. Example of commonly used expectorants include:

- *Glycyrrhiza glabra* (licorice)
- *Grindelia camporum* (grindelia)
- *Euphorbia hirta* (euphorbia)
- *Drosera rotundifolia* (sundew)
- *Polygala senega* (senega).

This approach appears to have considerable merit as ephedra and its alkaloids have proven effective as bronchodilators for the treatment of mild to moderate asthma and hay fever.^{[59] [60]} The peak bronchodilation effect occurs in 1 hour and lasts about 5 hours after administration. In addition to this approach, several other botanical medicines deserve mention.

Glycyrrhiza glabra

Licorice root has a long history of use as an antiinflammatory and anti-allergic agent, actions which have now been documented in the scientific literature (see [Ch. 90](#)). The primary active component of licorice root in this application is glycyrrhetic acid, a compound which has shown cortisol-like activity. In particular, glycyrrhetic acid has been shown to inhibit phospholipase A₂, the enzyme responsible for cleaving arachidonic acid from the phospholipid membrane pool and initiating eicosanoid synthesis.^[61] Licorice is also an expectorant, a useful action in asthma.

Lobelia inflata

Indian tobacco contains the alkaloid lobeline, a very efficient expectorant. Although it has a long history of use in asthma, it does promote bronchoconstriction and is a respiratory stimulant in vitro.^[62] Although this suggests a cholinergic effect in the respiratory system, it also binds to nicotine acetylcholine receptors in ganglions, thus

promoting the release of epinephrine and norepinephrine. It is this action on adrenal hormone secretion that is responsible for lobelia's therapeutic effects.^[63] Although effective when used alone, it has traditionally been used in combination with other botanical agents such as *Capsicum frutescens* and *Symphlocarpus factida*.

Capsicum frutescens

Experimental evidence has shown that capsaicin, cayenne pepper's major active component, induces long-lasting desensitization of airway mucosa to various mechanical and chemical irritants.^[64] This effect is probably due to capsaicin-induced depletion of substance P (which normally increases vascular permeability and flow) in the respiratory tract nerves. Substance P is an undecapeptide associated with "neurogenic inflammation" via a

1102

direct effect, and a synergistic action with histamine, on the peripheral nervous system.^[65] The respiratory and gastrointestinal tracts have large numbers of substance P-containing neurons. Because of its location and physiological action, it is believed to play an important role in atopic conditions such as asthma and atopic dermatitis. Therefore depletion of substance P may be desirable in these conditions.

Zizyphi fructus

The jujube plum has been used extensively in Chinese medicine for the treatment of asthma and allergic rhinitis.^[66] It contains 100–500 nmol/g of dry weight, a concentration 10 times greater than that of any other plant or animal tissue thus far reported in the literature.^[67] It also contains a beta-adrenergic receptor stimulator which also raises cAMP levels. These experimental findings, in conjunction with zizyphi's long historical use, strongly support its clinical use.

Thea sinensis

Green tea is useful as an adjunctive in asthma treatment due to its methylxanthine and antioxidant components (see [Ch. 70](#)).

Allium family

Onions and garlic inhibit lipoxygenase and cyclooxygenases which generate TxA_2 , PGD_2 and PGE_2 .^[68] Oral pretreatment of guinea pigs (who were sensitized to ovalbumin) with 1 ml of an alcohol/onion extract markedly reduced the asthmatic response to allergen inhalation challenges. Onion contains quercetin, which may account for some of its pharmacological effect,^[69] but the major protective actions appear to be related to its content of benzyl and other isothiocyanates (mustard oils).^[70] Although the mechanism of action is unknown, it has been suggested that it is due to

inhibition of the biosynthesis of arachidonic acid metabolites.

Tylophora asthmatica

The leaves of *Tylophora asthmatica* have been used extensively in Ayurvedic medicine in asthma and other respiratory tract disorders. The mode of action of tylophora is unknown, but is thought to be due to the alkaloids, especially tylophorine, which have been reported to possess antihistamine and antispasmodic activity as well as inhibition of mast cell degranulation.^[71]^[72] However, a more central mechanism may be responsible for the clinical effects in asthma.

Several double-blind clinical studies have shown tylophora to produce good results.^[73]^[74]^[75]^[76] In one study of 135 patients, those given 200 mg of tylophora leaves twice daily for 6 days demonstrated improvements in symptoms and respiratory function during the treatment period and for up to 2 weeks after treatment.^[73] Symptom score, FEV₁, and PEFR were used as parameters. Side-effects, such as nausea and vomiting, occurred in 9.8% in the tylophora group and 14% in the placebo group.

In another double-blind study of 103 patients, those receiving 40 mg of the dry alcoholic extract of *T. indica* daily for only 6 days demonstrated significant improvement in symptoms of asthma compared with a placebo group.^[75] At the end of the first week, 56% had complete to moderate improvement, as compared with 31.6% of the 92 patients receiving the placebo. At the end of 4 weeks, the respective figures were 32 and 23.8%; at 8 weeks, 23.8 and 8.4%; and at 12 weeks, 14.8 and 7.2%. The incidence of side-effects such as nausea, partial diminution of taste for salt, and slight mouth soreness was 16.3% in the tylophora group and 6.6% in the placebo group. These results, as well as the results from an additional study, indicate that the benefits of tylophora are short-lived.^[76]^[77]

Ginkgo biloba

Ginkgo biloba contains several unique terpene molecules known collectively as ginkgolides that antagonize platelet-activating factor (PAF), a key chemical mediator in asthma, inflammation, and allergies. Ginkgolides compete with PAF for binding sites and inhibit the various events induced by PAF. The anti-asthmatic effects of orally administered or inhaled ginkgolides have been shown to produce improvements in respiratory function and reduce bronchial reactivity in several double-blind studies.^[77]^[78] Treatment consisted of 120 mg of the pure ginkgolides daily – a dosage that is currently very expensive to achieve using the 24% ginkgo flavonglycoside and 6% total terpenoid *Ginkgo biloba* extract.

Aloe vera

Administration of *Aloe vera* preparations may be effective for patients who are not dependent upon corticosteroids. In one study, the oral administration of an extract of *Aloe vera* for 6 months was shown to produce good results in the treatment of asthma in some individuals of various ages.^[79] The extract was produced from the supernatant of

fresh leaves stored in the dark at 4°C for 7 days. Subjecting the leaves to dark and cold results in an increase in the polysaccharide fraction. One gram of the crude extract obtained from leaves stored in cold and dark produced 400 mg of neutral polysaccharide compared with only 30 mg produced from leaves not subjected to cold or dark. The dosage was 5 ml of a 20% solution of the *Aloe vera* extract in saline twice daily for 24 weeks; 11

1103

of 27 patients (40%) without corticosteroid dependence felt very much better at the study's conclusion. The mechanism of action is thought to be via restoration of protective mechanisms, followed by augmentation of the immune system.

Coleus forskohlii

Coleus forskohlii extracts may be particularly useful in asthma, as increasing intracellular levels of cAMP result in relaxation of bronchial muscles and relief of respiratory symptoms. Forskolin has been shown to have remarkable effects in relaxing constricted bronchial muscles in asthmatics (see [Ch. 77](#)).^[80] ^[81] However, these studies utilized inhaled doses of pure forskolin. Whether orally administered forskolin in the form of *C. forskohlii* extract would produce similar bronchodilatory effects is yet to be determined. However, based on the plant's historical use and additional mechanisms of action, it appears likely.

THERAPEUTIC APPROACH

The effective treatment of asthma requires the consideration and control of many aspects. In particular, the specific underlying defects and initiating factors must be determined, since many different defects and metabolic abnormalities result in the same clinical picture of asthma. Otherwise, only a much less successful "shotgun" approach is possible. The development of an appropriate treatment plan includes the following five steps:

1. determining and rectifying the underlying defect that allows the development of sensitization
2. determining and balancing the underlying metabolic defect that causes an excessive inflammatory response
3. finding the allergens, and developing a lifestyle, diet, and environment that allow the allergens to be avoided
4. modulating the inflammatory process to limit the severity of the response
5. preparing an effective treatment for the bronchoconstriction of the acute attack.

Environment

Air-borne allergens such as pollen, dander, and dust mites, are often difficult to avoid

entirely, but measures can be taken to reduce exposure. Eliminating dogs and cats, and carpets, rugs, upholstered furnitures and other surfaces where allergens can collect is a great first step. If this can't be done entirely, make sure that the bedroom is as allergy proof as possible. Have the patient encase the mattress in an allergen-proof plastic; wash sheets, blankets, pillow cases, and mattress pads every week; consider using bedding material made from Ventflex, a special hypoallergenic synthetic material; and install an air purifier. The best mechanical air purifiers are HEPA (high-efficiency particulate arresting) filters which can be attached to central heating and air-conditioning systems. These units are available from suppliers of heating and air-conditioning units.

Diet

Eliminate all food allergens and food additives, and bananas if they aggravate the condition. The patient who has many food allergies may need to utilize a 4 day rotation diet. In the early stages of treatment, mild tryptophan reduction (see [Appendix 5](#)) should be useful, but not critical, unless there is a metabolic defect in tryptophan metabolism. Garlic and onions should be liberally used unless the patient reacts to them. If the patient is willing, or his/her asthma is unresponsive to this recommended therapy, a vegan diet should be tried (for a minimum of 4 months) with the possible exception of cold-water fish.

Supplements

- Vitamin B₆ : 25–50 mg two times/day
- Vitamin B₁₂ : 1,000 mcg/day (oral) or weekly injection; evaluate for efficacy after 6 weeks
- Vitamin C: 10–30 mg for every kg body weight in divided dosages
- Vitamin E: 200–400 IU daily
- Magnesium: 200–400 mg three times/day
- Quercetin: 400 mg 20 minutes before meals
- Grape seed extract (95% PCO content): 50–100 mg. three times/day
- Carotenes: 25,000–50,000 IU/day
- Selenium: 200 mcg/day.

(These are all adult doses. Carefully determine the content of all supplements to assure avoidance of any allergens.)

Botanical medicines

Ephedra sinica. The optimum dosage of ephedra depends on the alkaloid content in the form used. The ephedra dose should have an ephedrine content of 12.5–25.0 mg and be taken two to three times daily. For the crude herb, this dosage would most likely be 500–1,000 mg three times/day. Standardized preparations are often preferred as they have more dependable therapeutic activity. Ephedra can be combined with herbal expectorants as described above.

Glycyrrhiza glabra

- Powdered root: 1–2 g
- Fluid extract (1:1): 2–4 ml
- Solid (dry powdered) extract (4:1): 250–500 mg.

Camellia sinensis. Liberal use (green tea only).

1104

Tylophora asthmatica. Use 200 mg of tylophora leaves or 40 mg of the dry alcoholic extract twice daily.

Coleus forskolii. Use the extract standardized to contain 18% forskolin: 50 mg (9 mg of forskolin) two to three times daily.

Counselling

For patients who respond to emotional crisis with asthmatic attacks, counseling is very important. It is also important for children with moderate to severe asthma, who may develop behavioral problems.

In acute attack

An acute asthma attack can be a medical emergency. If unable to administer intravenous magnesium, refer patient to emergency room immediately.

Chapter 133 - Atherosclerosis

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

DIAGNOSTIC SUMMARY

- Characteristically associated with high blood pressure, weak pulse, and wide pulse pressure
- Symptoms and signs depend on arteries involved and degree of obstruction: angina, leg cramps (intermittent claudication), gradual mental deterioration, weakness or dizziness; may also be without symptoms
- Diagonal ear lobe crease.

GENERAL CONSIDERATIONS

Atherosclerosis and its complications are the major causes of death in the United States and have reached epidemic proportions throughout all of the Western world. "Heart disease" is a term that is often used to describe atherosclerotic disease of the coronary arteries. Heart disease accounts for 36% of all deaths in the US and ranks as the number one killer; strokes, another complication of atherosclerosis, are the third most common cause of death. All together, atherosclerosis is responsible for at least 43% of all deaths in the US. In light of the fact that atherosclerosis is largely a disease of diet and lifestyle, it appears that many of these deaths could be significantly delayed through a healthful diet and lifestyle.^[1]

Understanding atherosclerosis

To fully understand the important ways that the various natural measures described in this chapter impact the health of the artery and the treatment of cardiovascular disease, it is necessary to examine closely the structure of an artery and the process of atherosclerosis.

Structure of an artery

An artery is divided into three major layers:

- The *intima* represents the endothelium or internal
-

1108

lining of the artery. It consists of a layer of endothelial cells. Glycosaminoglycans (GAGs) line the exposed endothelial cells to protect them from damage as well as promoting repair. Beneath the surface cells is the internal elastic membrane composed of a layer of GAGs and other ground substance compounds which provides support to the endothelial cells as well as separating the intima from the smooth muscle layer.

- The *media* consists primarily of smooth muscle cells. Interposed among the cells are GAGs and other ground substance structures which provide support and elasticity to the artery.
- The *adventitia* or external elastic membrane consists primarily of connective tissue, including GAGs, providing structural support and elasticity to the artery.

The process of atherosclerosis

No single theory of the development of atherosclerosis has been formulated which satisfies all investigators. However, the most widely accepted explanation theorizes that the lesions of atherosclerosis are initiated as a response to injury to the cells lining the inside of the artery, the arterial endothelium. The progression of atherosclerosis via this process is detailed below:

1. The initial step in the development of atherosclerosis is a weakening of the GAG layer which protects the endothelial cells. As a result, the endothelial cell is exposed to damage by free radicals. Immune, physical, mechanical, viral, chemical, and drug factors have all been shown to induce damage to the endothelial cells that can lead to plaque development.
2. Once the endothelial lining has been damaged, sites of injury become more permeable to plasma constituents, especially lipoproteins. The binding of lipoproteins to glycosaminoglycans leads to a breakdown in the integrity of the ground substance matrix and causes an increased affinity for cholesterol. Once significant damage has occurred, monocytes and platelets adhere to the damaged area where they release growth factors which stimulate smooth muscle cells to migrate from the media into the intima and replicate.
3. The local concentration of lipoproteins, monocytes, and platelets leads to the migration of smooth muscle cells from the media into the intima, where they undergo proliferation. The smooth muscle cells dump cellular debris into the intima, leading to further development of plaque.
4. The formation of a fibrous cap (consisting of collagen, elastin, and glycosaminoglycans) over the intimal surface occurs. Fat and cholesterol deposits

accumulate.

5. The plaque continues to grow until eventually it blocks the artery. Blockage is usually around 90% before symptoms of atherosclerosis are apparent.

Causative factors

Reducing the risk for heart disease and strokes involves reducing, and when possible eliminating, various risk factors associated with premature death due to a heart attack or stroke. The various risk factors are divided into two primary categories: major risk factors and other risk factors. The major risk factors are listed in [Table 133.1](#). Risk for a heart attack increases with the number of major risk factors as shown in [Table 133.2](#).

In addition to these well-accepted major risk factors, there are numerous other factors which on occasion have been shown to actually be more significant than the “major” risk factors. [Table 133.3](#) lists these additional risk factors.

Determining a patient’s risk

To help determine a patient’s overall risk for having a heart attack or stroke, we have designed the following risk determinant scale. While there are several other important factors that this risk assessment does not take into consideration (such as the level of lipoprotein(a), fibrinogen, and coping style), the score provides a good indication of a patient’s risk for a heart attack or stroke (see [Table 133.4](#)).

TABLE 133-1 -- Major risk factors for atherosclerosis

TABLE 133-2 -- Association of risk factors with incidence of atherosclerosis

| Major risk factors | Increase in incidence |
|---|-----------------------|
| Presence of one of the major risk factors | 30% |
| High cholesterol and high blood pressure | 300% |
| High cholesterol and a smoker | 350% |
| High blood pressure and a smoker | 350% |
| Smoker, high blood cholesterol, and high blood pressure | 720% |

TABLE 133-3 -- Other risk factors for atherosclerosis

- Low antioxidant status
- Low levels of essential fatty acids
- Low levels of magnesium and potassium
- Increased platelet aggregation
- Increased fibrinogen formation
- Elevated levels of homocysteine
- “Type A” personality

1109

TABLE 133-4 -- Risk determinate scale for heart disease and strokes

| | Scale of risk | | | | |
|---|---------------|---------|---------|---------|-------|
| | 1 | 2 | 3 | 4 | 5 |
| Blood pressure (systolic) | <125 | 125–134 | 135–149 | 150–164 | =165 |
| Blood pressure (diastolic) | <90 | 90–94 | 95–104 | 105–114 | =115 |
| Smoking (cigarettes/day) | None | 1–9 | 10–19 | 20–29 | =30 |
| Heredity I [±] | None | >65 | 50–64 | 35–49 | <35 |
| Heredity II [±] | 0 | 1 | 2 | 4 | =4 |
| Diabetes duration (years) | 0 | 1–5 | 6–10 | 11–15 | >15 |
| Total cholesterol (mg/dl) | <200 | 200–224 | 225–249 | 250–274 | =275 |
| HDL cholesterol (mg/dl) | =75 | 65–74 | 55–64 | 35–54 | <35 |

Risk = sum of all five columns.

- * , Age of patient when he or she had a heart attack or stroke.
- + , Number of immediate family members having a heart attack before the age of 50.
- #, Divide the value of the total cholesterol by the value of the HDL cholesterol.

Clinical evaluation

The complete cardiovascular assessment can include the tests listed in [Table 133.5](#) .

Risk factors

Smoking

According to a report from the US Surgeon General: “Cigarette smoking should be considered the most important risk factor for coronary heart disease.”^[2] Statistical evidence reveals a three- to fivefold increase in the risk of coronary artery disease in smokers as compared with non-smokers. The more cigarettes smoked and the longer the period of years a person has smoked, the greater the risk of dying from a heart attack or stroke. Overall, the average smoker dies 7–8 years sooner than the non-smoker.

In addition to heart disease, cigarette smoking is the single major cause of cancer death in the United States. Cigarette smokers have total overall cancer death

rates twice that of non-mokers. The greater the number of cigarettes smoked, the

greater the risk.

Tobacco smoke contains more than 4,000 chemicals, of which more than 50 substances have been identified as carcinogens. These chemicals are extremely damaging to the cardiovascular system. Specifically, these chemicals are carried in the bloodstream on LDL cholesterol where they either damage the lining of the arteries directly or they damage the LDL molecule which then damages the arteries. An elevated cholesterol level makes the effect of smoking on the cardiovascular system even worse, because more cigarette toxins will be carried through the vascular system. Smoking also contributes to an elevated cholesterol presumably by damaging feedback mechanisms in the liver which control how much cholesterol is being manufactured.^[3] Smoking also promotes platelet aggregation and elevated fibrinogen levels, two other important independent risk factors for heart disease and strokes. In addition, it is a well-documented fact that cigarette smoking is a contributing factor to high blood pressure.^[4]

Even passive exposure to cigarette smoke is damaging. Convincing evidence links environmental (second-hand or passive) smoke to heart disease mortality and morbidity. Analysis of 10 epidemiological studies indicates a consistent dose–response effect related to exposure.^[5] Evidence indicates that non-smokers appear to be more sensitive to smoke, including its deleterious effects on the cardiovascular system. Environmental tobacco smoke actually has a higher concentration of some toxic constituents. Pathophysiological and biochemical data after short- and long-term environmental tobacco smoke exposure show changes in the lining of the arteries and platelet function as well as exercise capacity similar to

those in active smoking. In summary, passive smoking is a relevant risk factor for heart disease. In the United States it is estimated that more than 37,000 coronary heart disease deaths each year are attributed to environmental smoke.

Those exposed to second-hand smoke can help to mitigate the effects through the use of antioxidant nutrients such as vitamin C (500 mg/day) and vitamin E (400 IU/day).

Various measures, including nicotine-containing skin patches or chewing gum, acupuncture and hypnosis have all been shown to provide some benefit in helping patients to quit smoking, but not much. In a systematic review of the efficacy of interventions intended to help people to stop smoking, data were analyzed from 188 randomized controlled trials.^[6] Encouragement to stop smoking by physicians during a routine office call resulted in a 2% cessation rate after 1 year. Supplementary measures such as follow-up letters or visits had an additional effect. Behavioral modification techniques such as relaxation, rewards and punishment, and avoiding trigger situations in group or individual sessions led by a psychologist had no greater effect than the 2% rate achieved by simple advice from a physician. Eight studies with acupuncture have produced an overall effectiveness rate of roughly 3%. Hypnosis has been judged to be

ineffective even though trials have shown a success rate of 23%. The reason hypnosis was judged to be ineffective was because no biochemical marker was used to accurately determine effectiveness. Nicotine replacement therapy (gum or patch) is effective in about 13% of smokers who seek help in quitting. All together these results are not very encouraging. It appears the best results occur when people quit “cold turkey”. [Table 133.6](#) lists 10 tips to help patients stop smoking.

TABLE 133-6 -- Tips to help patients stop smoking

-
- List all the reasons why you want to quit smoking and review them daily
-
- Set a specific day to quit, tell at least 10 friends that you are going to quit smoking, and then ... DO IT!
-
- Throw away all cigarettes, butts, matches, and ashtrays
-
- Use substitutes. Instead of smoking, chew on raw vegetables, fruits, or gum. If your fingers seem empty, play with a pencil
-
- Take one day at a time
-
- Realize that 40 million Americans have quit. If they can do it, so can you!
-
- Visualize yourself as a non-smoker with a fatter pocketbook, pleasant breath, unstained teeth, and the satisfaction that comes from being in control of your life
-
- Join a support group. Call the local American Cancer Society and ask for referrals. You are not alone
-
- When you need to relax, perform deep breathing exercises rather than reaching for a cigarette
-
- Avoid situations that you associate with smoking
-
- Each day, reward yourself in a positive way. Buy yourself something with the money you've saved or plan a special reward as a celebration for quitting

Elevated blood cholesterol levels

The evidence overwhelmingly demonstrates that elevated cholesterol levels greatly increase the risk of death due to heart disease. It is currently recommended that the total blood cholesterol level be less than 200 mg/dl. In addition, it is recommended that the LDL cholesterol be less than 130 mg/dl, the HDL cholesterol greater than 35 mg/dl, and triglyceride levels less than 150 mg/dl.

Cholesterol is transported in the blood by lipoproteins. The major categories of lipoproteins are very low-density lipoprotein (VLDL), low-density lipoprotein (LDL), and high-density lipoprotein (HDL). Since VLDL and LDL are responsible for transporting fats (primarily triglycerides and cholesterol) from the liver to body cells while HDL is responsible for returning fats to the liver, elevations of either VLDL or LDL are associated with an increased risk for developing atherosclerosis, the primary cause of a heart attack or stroke. In contrast, elevations of HDL are associated with a low risk of

heart attacks.

The ratio of total cholesterol to HDL cholesterol and the ratio of LDL to HDL are referred to as the cardiac risk factor ratios because they reflect whether cholesterol is being deposited into tissues or broken down and excreted. The total cholesterol to HDL ratio should be no higher than 4.2 and the LDL to HDL ratio should be no higher than 2.5. The risk for heart disease can be reduced dramatically by lowering LDL cholesterol while simultaneously raising HDL cholesterol levels: for every 1% drop in the LDL cholesterol level, the risk for a heart attack drops by 2%. Conversely, for every 1% increase in HDL levels, the risk for a heart attack drops 3–4%.^[7]

Further refinement of determining risk. Although LDL cholesterol is referred to as “bad cholesterol”, the “worst cholesterol” is lipoprotein(a) or Lp(a). Lp(a) is a plasma lipoprotein whose structure and composition closely resemble that of LDL (low-density lipoprotein), but with an additional molecule of an adhesive protein called apolipoprotein(a). Several studies have indicated that elevated plasma levels of Lp(a) are an independent risk factor for coronary heart disease, particularly in those patients with elevated LDL cholesterol levels.^{[8] [9]} In fact, a high level of Lp(a) has been shown to carry with it a 10 times greater risk for heart disease than an elevated LDL cholesterol level. That is because LDL on its own lacks the adhesive apolipoprotein(a). As a result, LDL does not easily stick to the walls of the artery. Actually a high LDL cholesterol level carries less risk than a normal or even low LDL cholesterol with a high Lp(a). Levels of Lp(a) below 20 mg/dl are associated with a low risk for heart disease; levels between 20–40 mg/dl are associated with a moderate risk; and levels above 40 mg/dl are associated with an extremely high risk for heart disease.

Inherited elevations of cholesterol and triglycerides. Elevations of blood cholesterol and/or triglycerides can

1111

be due to genetic factors. These conditions are referred to as familial hypercholesterolemia (FH), familial combined hyperlipidemia (FCH), and familial hypertriglyceridemia (FT). Relatively speaking these disorders are among the most common inherited disease as they affect about one in every 500 people.

The basic problem in FH is a defect in the receptor protein for LDL in the liver. Under normal situations the LDL receptor is responsible for removing cholesterol from the blood. When the liver cell takes up the LDL after it has bound to the receptor, it signals the liver cell to stop making cholesterol. In FH the defect in the LDL receptor results in the liver not receiving the message to stop making cholesterol.

Damage to the LDL receptor occurs with normal aging and in several disease states, with diabetes being chief among them. As a result of LDL receptor damage, cholesterol levels tend to rise as one gets older and in diabetics. In addition, a diet high in saturated fat and cholesterol decreases the number of LDL receptors, thereby reducing the

feedback mechanism which tells the liver cell that no more cholesterol is needed.

Fortunately, lifestyle and dietary changes can increase the function and/or number of LDL receptors. The most dramatic effects will be in people without inherited causes of elevated cholesterol and/or triglycerides, but even people with FH can see benefit.

Familial combined hyperlipidemia (FCH) and familial hypertriglyceridemias (FT) result in similar defects to FH. In FCH the basic defect appears to be an accelerated production of very-low-density lipoprotein (VLDL) in the liver. These individuals may have only a high blood triglyceride level, or only a high cholesterol level, or both. In FT there is only an elevation in blood triglyceride levels, and HDL cholesterol levels tend to be low. The defect in FT is that the VLDL particles made by the liver are larger than normal and carry more triglycerides. FT is made worse by diabetes, gout, and obesity.

The recommendations given below will also help FCH and FT, although these conditions will usually require more aggressive support.

Other risk factors

In addition to the major risk factors for heart disease, there are a number of other factors which, on occasion, have been shown to be more significant than the so-called major risk factors:

- elevated blood pressure (see [Ch. 159](#))
- diabetes (see [Ch. 147](#))
- low thyroid function (see [Ch. 162](#))
- physical inactivity
- low antioxidant status
- low levels of essential fatty acids
- low levels of magnesium and potassium
- increased platelet aggregation
- increased fibrinogen formation
- elevated levels of homocysteine
- “type A” personality.

Several of these are discussed below.

THERAPEUTIC CONSIDERATIONS DIRECTED TO LOWERING CHOLESTEROL LEVELS

Prevention of a heart attack or stroke involves reducing risk factors. The significant risk factors are discussed below, including natural measures to address the risk factor.

Diet

The most important approach to lowering a high cholesterol level is a healthful diet and

lifestyle. The dietary guidelines are straightforward:

- decreased consumption of saturated fat and cholesterol by reduction or elimination of animal products in the diet
- increased consumption of fiber-rich plant foods (fruits, vegetables, grains, and legumes)
- weight reduction (if appropriate).

The lifestyle factors include regular aerobic exercise, not smoking, and reducing or eliminating the consumption of coffee (both caffeinated and decaffeinated). [Table 133.7](#) provides an overview of the key dietary changes needed.

Dietary saturated fat, cholesterol, and total fat

A great deal of research links a diet high in saturated fat and cholesterol to numerous cancers, heart disease, and strokes. Both the American Cancer Society and the American Heart Association have recommended a diet containing less than 30% of calories as fat. The best and easiest way for most people to achieve this goal is to eat fewer animal products and more plant foods. With

TABLE 133-7 -- Food choices for lowering cholesterol

| Decrease consumption of: | Substitute with: |
|--|---|
| Red meats | Fish and white meat of poultry |
| Hamburgers and hot dogs | Soy-based alternatives |
| Eggs | Egg beaters and similar products, tofu |
| High fat dairy products | Low fat or non-fat dairy products |
| Butter, lard, and other saturated fats | Vegetable oils |
| Ice cream, pies, cake, cookies, etc. | Fruits |
| Refined cereals, white bread, etc. | Whole grains, whole wheat bread |
| Fried foods, fatty snack foods | Vegetables, fresh salads |
| Salt and salty foods | Low-sodium, light salt |
| Coffee and soft drinks | Herbal teas, fresh fruit and vegetable juices |

the exception of nuts and seeds, most plant foods are very low in fat. With regard to nuts and seeds, while they do contain high levels of fat calories, the calories are derived largely from polyunsaturated essential fatty acids.

Margarine and other foods containing trans-fatty acids and partially hydrogenated oils (see [Table 133.8](#))

Many researchers and nutritionists have been concerned about the health effects of margarines since they were first introduced. Although many Americans believe margarine is better than butter and saturated fats, the opposite is true. Margarine and other hydrogenated vegetable oils not only raise LDL cholesterol, they also lower HDL cholesterol, interfere with essential fatty acid metabolism, and are suspected of being causes of certain cancers.^[10] Although butter may be better than margarine, the bottom line is that they both need to be restricted in a healthy diet while natural polyunsaturated oils like canola, safflower, soy, fish and flaxseed oils should be used to meet essential fatty acid requirements. The requirement for essential fatty acids is not high – just 1 tablespoon of a high quality flaxseed oil will provide more than enough in most cases.

Cold-water fish and flaxseed oil

Cold water fish like salmon, mackerel, herring, and halibut are good sources of the longer chain omega-3 fatty acids eicosapentaenoic acid (EPA) and docosahexanoic acid (DHA). These fatty acids are also available in capsules and have been shown in hundreds of studies to lower cholesterol and triglyceride levels.^[11] However, since it has been shown that commercially available fish oils contain very high levels of lipid peroxides and greatly stress antioxidant defense mechanisms, at this time it makes the most sense to rely on consumption of cold-water fish and flaxseed oil for the omega-3 oils rather than fish oil capsules.^{[12] [13]} Flaxseed oil contains alpha-linolenic acid, an omega-3 oil which the body can convert to EPA.^[14]

Vegetables and fruits

Many health care experts and departments of the US Government, including the US National Academy of Science, the US Department of Agriculture, the US Department of Health and Human Services, the National Research Council, and the National Cancer Institute, are recommending that Americans consume two to three servings of fruit and three to five servings of vegetables per day in an attempt to reduce the risk of developing heart disease, cancer, and other chronic degenerative diseases. Unfortunately, less than 10% of the population are meeting even the lowest recommendation of five servings of a combination of fruits and vegetables.

Numerous population studies have repeatedly demonstrated that a high intake of carotene-rich and flavonoid-rich fruits and vegetables reduces the risk of heart disease and strokes.^[15] Carotenes represent the most widespread group of naturally occurring pigments in nature. They are a highly colored (red and yellow) group of fat-soluble compounds. Over 600 carotenoids have been characterized, including 30–50 that the body can transform into vitamin A. Beta-carotene has been termed the most active of the carotenoids, due to its higher provitamin A activity, but several other carotenes exert greater antioxidant effects.

The best dietary sources of carotenes are green leafy vegetables and yellow-orange colored fruits and vegetables, e.g. carrots, apricots, mangoes, yams, and squash. Red and purple vegetables and fruits – such as tomatoes, red cabbage, berries, and plums – contain a large portion of non-vitamin-A active pigments, including flavonoids. Legumes, grains, and seeds are also significant sources of carotenoids (see [Ch. 67](#) for further discussion).

The flavonoids are another group of plant pigments providing remarkable protection against heart disease and strokes. These compounds are largely responsible for the colors of fruits and flowers. Flavonoids act as powerful antioxidants in providing protection against oxidative and free radical damage. The practical aspect of this antioxidant activity is highlighted by the results of a study in 805 men designed to determine the effect of dietary flavonoids on protecting against heart disease.^[16] The study demonstrated an inverse correlation between flavonoid intake and death from a heart attack. Good dietary sources of flavonoids include citrus fruits, berries, onions, parsley, legumes, green tea, and red wine. The average daily intake in the United States for flavonoids is estimated to be somewhere between 150 and 200 mg (for further discussion see [Ch. 87](#)).

Dietary fiber and complex carbohydrates

The term “dietary fiber” refers to the components of plant cell wall as well as the

indigestible residues. Dietary fiber, particularly the soluble fiber found in legumes,

TABLE 133-9 -- Impact of various sources of fiber on serum cholesterol levels

| Fiber | Dosage (g) | Typical reduction in total cholesterol |
|-----------------|------------|--|
| Oat bran (dry) | 50–100 | 20% |
| Guar gum | 9–15 | 10% |
| Pectin | 6–10 | 5% |
| Psyllium | 10–20 | 10–20% |
| Vegetable fiber | 27 | 10% |

fruit, and vegetables, is very effective in lowering cholesterol levels.^[17] Specifically, a significant reduction in the level of serum total cholesterol was found in 68 of the 77 (88%) studies reviewed.^[17] The effect of fiber, particularly soluble fiber, was clearly dose-dependent. [Table 133.9](#) shows the average doses and reductions noted in clinical trials with soluble fiber supplements.

Many of the studies featured oat preparations containing either oat bran or oatmeal.^[18] The overwhelming majority of these studies demonstrated that individuals with high cholesterol levels will see significant reductions with frequent oatmeal or oat bran consumption. In contrast, individuals with normal or low cholesterol levels will see little change. In individuals with high cholesterol levels (above 220 mg/dl), the consumption of the equivalent of 3 g of soluble oat fiber typically lowers total cholesterol by 8–23%. This is highly significant as with each 1% drop in serum cholesterol level there is a 2% decrease in the risk of developing heart disease. Three grams of fiber is provided by approximately one bowl of ready-to-eat oat bran cereal or oat meal. Although oatmeal's fiber content (7%) is less than that of oat bran (15–26%), it has been determined that the polyunsaturated fatty acids contribute as much to the cholesterol-lowering effects of oats as the fiber content. Although oat bran has a higher fiber content, oatmeal is higher in polyunsaturated fatty acids.

In an effort to lower cholesterol with dietary fiber, have patients try to achieve a daily intake of 35 g of fiber from the fiber-rich foods, a full listing of which can be found in [Chapter 57](#).

Dietary animal protein

One of the key recommendations of the National Research Council's Committee on Diet and Health was that Americans need to reduce protein intake to moderate levels.^[1] Americans consume much more protein than is required. Excess protein intake has been linked to several chronic diseases including cancer, osteoporosis, and heart

disease. Reducing protein intake is best done by reducing meat and dairy consumption.

In the United States, approximately 72% of protein in the diet is from animal products – specifically, 49% from meat, fish, and poultry; 18% from dairy; and 4% from eggs. In contrast, plant foods account for only 28% of the protein intake. Fruits and vegetables provide about 8%, legumes about 3%, and grain products 18%.^[1]

It is often difficult to separate the effects of animal protein from the effects of animal fats, because they are so highly correlated. Despite this obstacle, there is much evidence that the reliance on animal proteins to meet protein requirements is linked to the development of several chronic degenerative diseases. There is evidence that the body handles animal proteins differently from plant proteins. Population studies comparing vegetarians with omnivores as well as animal studies indicate that it is not simply a matter of protein quantity that is important; the source of the protein is equally important. A high intake of animal protein is linked to heart disease, many cancers, high blood pressure, kidney disease, osteoporosis, and kidney stones. In contrast, a vegetarian diet is associated with a reduced risk of these diseases. At the very least, the intake of animal protein should be limited to no more than 4–6 ounces/day, with fish, skinless poultry, and lean cuts being preferred to the fat-laden choices.

Olive and canola oil

Most experts now agree that the best oils for cooking are canola and olive oil. These oils are composed chiefly of oleic acid, a mono-unsaturated oil that is more resistant to the damaging effects of heat and light compared with highly polyunsaturated oils like corn, safflower, and soy. When the polyunsaturated oils are exposed to heat or light, the chemical structure of the essential fatty acids are changed to toxic derivatives known as lipid peroxides.

When LDL cholesterol is largely composed of oleic acid due to a higher intake of olive oil or canola oil, it is less susceptible to peroxidation. As a result, population studies routinely show a reduced risk for heart disease when the intake of oleic acid is high.

Refined carbohydrates

There is substantial evidence that refined sugar intake is a significant factor in the development of atherosclerosis.^[19] Although a high sugar intake leads to elevations in triglyceride and cholesterol levels, the real culprit may be the elevations of insulin. When high-sugar foods are eaten alone, blood sugar levels rise quickly, producing a strain on blood sugar control and elevations in insulin. Elevated insulin levels are associated with elevations in cholesterol, triglycerides, blood pressure, and risk of death from cardiovascular disease. Currently, more than half of the carbohydrates consumed in the United States are in the form of sugars added to foods as sweetening agents.

Sources of refined sugar should be limited. Have patients read food labels carefully for clues on sugar

content. Instruct them that if the words sucrose, glucose, maltose, lactose, fructose, corn syrup, or white grape juice concentrate appear on the label, extra sugar has been added.

The importance of breakfast. An evaluation of data from the National Health and Nutrition Examination Survey II (a national survey of the nutritional and health practices of Americans) disclosed that serum cholesterol levels are lowest among adults eating whole grain cereal for breakfast.^[20] Although those individuals who consumed other breakfast foods had higher blood cholesterol levels, levels were highest among those who typically skipped breakfast. Healthy breakfast choices include whole grain cereals, muffins, and breads, along with fresh whole fruit or fresh fruit juice. Cereals, both hot and cold, and preferably from whole grains, may be the best food choices for breakfast.

Nutritional supplements

In many cases dietary therapy, while very important, is not sufficient alone to reduce lipid levels to the desired ranges. Fortunately, there are several natural compounds which can lower cholesterol levels and other significant risk factors for coronary artery disease. In fact, when all factors are considered (cost, safety, effectiveness, etc.), the natural alternatives presented here offer significant advantages to the standard drug therapy.

Niacin

Despite the fact that niacin has demonstrated better overall results in reducing the risk for coronary heart disease compared with other cholesterol-lowering agents, physicians are often reluctant to prescribe niacin.^[21] The reason is a widespread perception that niacin is a difficult and somewhat dangerous medicine. There is much confusion about the benefits vs. the risks in patients taking niacin. In contrast, most physicians are unaware of the considerable risks and limited benefits of commonly used prescription cholesterol-lowering agents. In addition, since niacin is a widely available “generic” agent, no pharmaceutical company stands to generate the huge profits that the other lipid-lowering agents have enjoyed. As a result, niacin does not enjoy the intensive advertising that the HMG CoA reductase inhibitors and gemfibrozil enjoy. Despite the advantages of niacin over other lipid-lowering drugs, it accounts for only 7.9% of all lipid-lowering prescriptions.

The benefits of niacin compared with the drugs. The lipid-lowering activity of niacin was first described in the 1950s. It is now known that niacin does much more than lower total cholesterol. Specifically, niacin has been shown to lower LDL cholesterol, Lp(a) lipoprotein, triglyceride, and fibrinogen levels while simultaneously raising HDL cholesterol levels.^[22]

The famed Coronary Drug Project demonstrated that niacin was the only lipid-lowering

agent to actually reduce overall mortality.^[21] Its effects are long-lasting, as demonstrated in a 15-year follow-up study to the Coronary Drug Project which showed that the long-term death rate for patients treated with niacin was still 11% lower than the group receiving a placebo, even though the treatment had been discontinued in most patients many years earlier. In contrast, patients treated with drugs (clofibrate and/or cholestyramine) actually experienced an increased mortality.^[23] Clofibrate was associated with a 36% higher mortality rate. Presumably both clofibrate and cholestyramine lowered cholesterol and reduced the mortality rate for coronary artery disease, but increased the risk of dying prematurely from cancer, complications from gall bladder surgery (clofibrate causes gallstones), and from other conditions.

Clofibrate and, to a lesser extent, bile-sequestering resins have been replaced by the HMG CoA reductase inhibitors (the “statin” family of drugs) and gemfibrozil (a newer fibric acid derivative). Preliminary studies are showing some benefits. For example, a 5 year safety and efficacy study of lovastatin in 745 patients with severe hypercholesterolemia (total cholesterol levels greater than 360 mg/dl) demonstrated effectiveness over time, no increase in mortality, and good patient tolerance.^[24] Longer-term studies with larger patient populations are now in progress with all of the statin drugs, but the results will not be available for several years. In the meantime, millions of Americans are being placed on these drugs.

Comparative studies: lovastatin vs. niacin. Several recent head-to-head studies have compared niacin with the new lipid-lowering drugs. In the first published clinical study, niacin was compared with lovastatin directly in 136 subjects with LDL cholesterol levels greater than 160 mg/dl and with coronary heart disease and/or with more than two coronary heart disease risk factors; or in patients with LDL cholesterol levels greater than 190 mg/dl and without coronary heart disease or less than two coronary heart disease risk factors.^[25] The controlled, randomized, open-label 26 week study was performed at five lipid clinics. Patients were first placed on a 4 week diet run-in period after which eligible patients were randomly assigned to receive treatment with either lovastatin (20 mg/day) or niacin (1.5 g/day). On the basis of the LDL cholesterol response and patient tolerance, the doses were sequentially increased to 40 and 80 mg/day of lovastatin or 3 and 4.5 g/day of niacin after 10 and 18 weeks of treatment, respectively. In the two patient groups, 66% of patients treated with lovastatin and 54% of patients treated with niacin underwent full dosage titration. The results are shown in [Table 133.10](#) .

These results indicate that while lovastatin produced a greater LDL cholesterol reduction, niacin provided

TABLE 133-10 -- Comparison of niacin to lovastatin

| Lipoprotein | Group | Week 10 | Week 18 | Week 26 |
|-------------|-------|---------|---------|---------|
|-------------|-------|---------|---------|---------|

| | | | | |
|-----------------------------|------------|-----|-----|-----|
| LDL cholesterol reduction | Lovastatin | 26% | 28% | 32% |
| | Niacin | 5% | 16% | 23% |
| HDL cholesterol increase | Lovastatin | 6% | 8% | 7% |
| | Niacin | 20% | 29% | 33% |
| Lp(a) lipoprotein reduction | Lovastatin | 0 | 0 | 0 |
| | Niacin | 14% | 30% | 35% |

better overall results despite the fact that fewer patients were able to tolerate a full dosage of niacin because of skin flushing. The percentage increase in HDL cholesterol, a more significant indicator for coronary heart disease, was dramatically in favor of niacin (33 vs. 7%). Equally as impressive was the percentage decrease in Lp(a) for niacin. While niacin produced a 35% reduction in Lp(a) lipoprotein levels, lovastatin did not produce any effect. Niacin's effect on Lp(a) in this study confirmed a previous study which showed that niacin (4 g/ day) reduced Lp(a) levels by 38%.^[26]

Another comparative study evaluated the lipoprotein responses to niacin, gemfibrozil, and lovastatin in patients with normal total cholesterol levels but low levels of HDL cholesterol.^[27] The first phase of the study compared lipoprotein responses to lovastatin and gemfibrozil in 61 middle-aged men with low levels of high-density lipoproteins. In the second phase, 37 patients agreed to take niacin; 27 patients finished this phase at a dose of 4.5 g/day. In the first phase, gemfibrozil therapy increased high-density lipoprotein cholesterol levels by 10% and lovastatin by 6%. In the second phase, niacin therapy was shown to raise HDL cholesterol by 30%.

The side-effects of niacin. The side-effects of niacin are well known. The most common and bothersome side-effect is the skin flushing that typically occurs 20–30 minutes after the niacin is taken. Other occasional side-effects of niacin include gastric irritation, nausea, and liver damage. In an attempt to combat the acute reaction of skin flushing, several manufacturers began marketing “sustained-release”, “timed-release”, or “slow-release” niacin products. These formulations allow the niacin to be absorbed gradually, thereby reducing the flushing reaction. However, while these forms of niacin reduce skin flushing, they have actually been proven to be more toxic to the liver. In a recent study, it was strongly recommended that sustained-release niacin be restricted from use because of the high percentage (78%) of patient withdrawal due to side-effects; 52% of the patients taking the sustained-release niacin developed liver toxicity while none of the patients taking immediate-release niacin developed liver toxicity.^[28]

Because niacin can impair glucose tolerance, it should be used with close observation in patients with diabetes. Niacin should not be used in patients with pre-existing liver disease or elevation in liver enzymes. For these patient groups, gugulipid, garlic, or pantethine are recommended.

The safest form of niacin at present is inositol hexaniacinate. This form of niacin has long been used in Europe to lower cholesterol levels and also to improve blood flow in

intermittent claudication. It yields slightly better clinical results than standard niacin, but is much better tolerated, in terms of both flushing and, more importantly, long-term side-effects.^{[29] [30] [31]}

Regardless of the form of niacin being used, periodic checking (minimum every 3 months) of cholesterol and liver function tests are indicated. This statement is particularly true if sustained-release preparations are being used.

Niacin dosage recommendations. If pure crystalline niacin is being used, start with a dose of 100 mg three times a day and carefully increase the dosage over a period of 4–6 weeks to the full therapeutic dose of 1.5–3 g daily in divided dosage. If inositol hexaniacinate is being used, begin with 500 mg three times daily for 2 weeks and then increase to 1,000 mg. With either crystalline niacin or inositol hexaniacinate, it is best if they are taken with meals.

Niacin – drug of first choice. Because of its low cost and proven efficacy, niacin should be considered the premier lipid-lowering agent. Although regarded by most experts as a “drug of first choice” in patients with mixed or combined hyperlipidemia as well as for patients with mild-to-modest elevation of LDL cholesterol accompanied by low levels of HDL cholesterol, niacin accounts for only 7.9% of all prescriptions for these conditions. The problems with niacin (e.g. skin flushing, other side-effects, and patient compliance) can be avoided by using inositol hexaniacinate.

Pantethine

Pantethine is the stable form of pantetheine, the active form of vitamin B₅ or pantothenic acid. Pantothenic acid is the most important component of coenzyme A (CoA). This enzyme is involved in the transport of fats to and from cells, as well as to the energy-producing compartments within the cell. Without coenzyme A, the cells' fats could not be metabolized to energy.

For some reason, pantethine has significant lipid-lowering activity while pantothenic acid has very little (if any) effect in lowering cholesterol and triglyceride levels. Pantethine administration (standard dose 900 mg/day) has been shown to reduce significantly serum triglyceride (-32%), total cholesterol (-19%), and LDL cholesterol (-21%) levels while increasing HDL cholesterol (+23%) levels.^{[32] [33]} It appears to be especially useful in lowering blood lipids in diabetics.^{[34] [35] [36]}

The lipid-lowering effects of pantethine are most impressive when its toxicity (virtually none) is compared with conventional lipid-lowering drugs. Its mechanism

of action is due to inhibited cholesterol synthesis and acceleration of the utilization of fat as an energy source.

Vitamin C

Dozens of observational and clinical studies have shown that vitamin C levels correspond to total cholesterol and HDL cholesterol.^{[37] [38] [39] [40]} In one of the best designed studies, it was shown that the higher the vitamin C content of the blood, the lower the total cholesterol and triglycerides, and the higher the HDL cholesterol.^[40] The benefits on HDL were particularly impressive. For each 0.5 mg/dl increase in vitamin C content of the blood, there was an increase in HDL cholesterol of 14.9 mg/dl in women and 2.1 mg/dl in men. This study and others demonstrate that the association of vitamin C and HDL levels persists even in well-nourished individuals with normal levels of vitamin C in their blood who supplement their diets with additional vitamin C. The most significant effect of high-dosage vitamin C therapy in reducing the risk for heart disease may turn out to be a reduction in Lp(a) and its antioxidant activity.

Botanical medicines

Allium sativum and *Allium cepa*

Garlic appears to be an important protective factor against heart disease and strokes via its ability to impact the process of atherosclerosis at so many steps.

Foremost in garlic's significant protection against heart disease and strokes is its ability to improve cholesterol levels.^{[41] [42] [43] [44]} According to the results from numerous double-blind, placebo-controlled studies in patients with initial cholesterol levels greater than 200, supplementation with commercial preparations providing a daily dose of at least 10 mg alliin or a total allicin potential of 4,000 mcg can lower total serum cholesterol levels by about 10–12%; LDL cholesterol will decrease by about 15%, HDL cholesterol levels will usually increase by about 10%, and triglyceride levels will typically drop by 15%.

Although the effects of supplemental garlic preparations on cholesterol levels are not phenomenal, the combination of lowering LDL and raising HDL can greatly improve the LDL:HDL ratio – a significant goal in trying to prevent heart disease and strokes. In addition, garlic preparations standardized for alliin content exert several other beneficial effects in preventing heart disease and strokes (discussed below).

Individuals with high cholesterol levels should also eat more onions, as increased dietary garlic and onion consumption can also lower cholesterol levels.^{[45] [46]} In a 1979 population study, researchers studied three populations of vegetarians in the Jain community in India who consumed differing amounts of garlic and onions.^[47]

TABLE 133-11 -- Effects of garlic and onion consumption on serum lipids under carefully matched diets

| Garlic/onion consumption | Cholesterol (mg/dl) | Triglyceride (mg/dl) |
|------------------------------------|---------------------|----------------------|
| Garlic 50 g/week, onion 600 g/week | 159 | 52 |

| | | |
|------------------------------------|-----|-----|
| Garlic 10 g/week, onion 200 g/week | 172 | 75 |
| No garlic or onions | 208 | 109 |

Numerous favorable effects on blood lipids, as shown in [Table 133.11](#), were observed in the group that consumed the largest amount. Blood fibrinogen (discussed below) levels were highest in the group eating no onions or garlic. The study is quite significant because the subjects had nearly identical diets, except for the quantity of garlic and onion ingestion.

Dosage recommendations for commercial garlic preparations. The majority of studies showing a positive effect of garlic and garlic preparations are those which deliver a sufficient dosage of allicin. Since allicin is the component in garlic that is responsible for its easily identifiable and, to some, offensive odor, several manufacturers have developed highly sophisticated methods in an effort to provide the full benefits of garlic without odor. They provide “odorless” garlic products concentrated for alliin because alliin is relatively “odorless” until it is converted to allicin in the body. Products concentrated for alliin and other sulfur components provide all of the benefits of fresh garlic, but are more “socially acceptable”. Based on a great deal of clinical research, the dosage of a commercial garlic product should provide a daily dose of at least 10 mg alliin or a total allicin potential of 4,000 mcg. The German Commission E recommends the equivalent of 4,000 mg of fresh garlic – roughly one to four cloves (see [Chs 62](#) and [63](#) for further discussion of these useful herbs/foods.)

Gugulipid

Gugulipid is the standardized extract of the mukul myrrh tree (*Commiphora mukul*) which is native to India. The active components of gugulipid are two compounds, Z-guggulsterone and E-guggulsterone. Several clinical studies have confirmed that gugulipid has an ability to lower both cholesterol and triglyceride levels.^[48]^[49] Typically, total cholesterol levels will drop 14–27% in a 4–12 week period, while LDL cholesterol and triglyceride levels will drop from 25 to 35% and 22 to 30%, respectively. HDL cholesterol levels will typically increase by 16–20%.

The effect of gugulipid on cholesterol and triglyceride levels is comparable to that of lipid-lowering drugs. While those drugs are associated with some degree of toxicity, gugulipid is without side-effects. Safety studies in rats, rabbits, and monkeys have demonstrated it to be non-toxic. It is also considered safe to use in pregnancy.

The mechanism of action for gugulipid cholesterol-lowering action is its ability to increase the liver’s metabolism of LDL cholesterol; guggulsterone increases the uptake of LDL cholesterol from the blood by the liver.^[48]

In addition to lowering lipid levels, gugulipid has been shown to prevent the formation of

atherosclerosis and aid in the regression of pre-existing atherosclerotic plaques in animals. This implies that it may have a similar effect in humans. Gugulipid also has a mild effect in inhibiting platelet aggregation and promoting fibrinolysis, implying that it may also prevent the development of a stroke or embolism.^[49]

The dosage of gugulipid is based on its guggulsterone content. Clinical studies have demonstrated that gugulipid extracts standardized to contain 25 mg of guggulsterone per 500 mg tablet given three times per day are an effective treatment for elevated cholesterol levels, elevated triglyceride levels, or both. No significant side-effects have been reported with purified gugulipid preparations; however, crude guggul preparations like gum guggul are associated with side-effects (skin rashes, diarrhea, etc.; see [Ch. 78](#) for further discussion).

Comparing natural cholesterol-lowering agents

There are a number of natural compounds which can effectively improve cholesterol and triglyceride levels. Of the several described above, niacin in the form of inositol hexaniacinate produces the best overall effect. However, the others do have a place in the clinical management of hyperlipidemia and atherosclerosis prevention (see [Table 133.12](#)).

Typically, along with the dietary and lifestyle recommendations, niacin (1,000 mg three times daily) will produce reductions in total cholesterol of 50–75 mg/dl in patients with initial total cholesterol levels above 250 mg/dl within the first 2 months. In patients with initial cholesterol levels above 300 mg/dl, it may take 4–6 months before cholesterol levels begin to reach recommended levels. Once cholesterol levels are reduced below 200 mg/dl, reduce the dosage of niacin to 500 mg three times daily for 2 months. If the cholesterol levels creep up above 200 mg/dl, then the dosage of niacin is raised back up to 1,000 mg three times daily. If the cholesterol level remains below 200 mg/dl, then the niacin is withdrawn completely and the cholesterol

TABLE 133-12 -- Comparative effects on blood lipids of several natural compounds

| | Niacin | Garlic | Gugulipid | Pantethine |
|--------------------------------|---------------|---------------|------------------|-------------------|
| Total cholesterol (% decrease) | 18 | 10 | 24 | 19 |
| LDL cholesterol (% decrease) | 23 | 15 | 30 | 21 |
| HDL cholesterol (% increase) | 32 | 31 | 16 | 23 |
| Triglycerides (% decrease) | 26 | 13 | 23 | 32 |

levels are rechecked in 2 months, with niacin therapy re-instituted if levels have crept up over 200 mg/dl.

Gugulipid can be added to the above protocol if after 4 months the total cholesterol remains above 250 mg/dl. Gugulipid is also suitable for the rare patient who cannot tolerate inositol hexaniacinate.

Pantethine is recommended primarily to patients who have hypertriglyceridemia. Pantethine is also preferred to niacin in cases of hyperlipidemia in diabetics. Although there are no data concerning the possible adverse effects of inositol hexaniacinate, niacin is known to adversely affect blood sugar control in some diabetics. As stated above, pantethine has demonstrated excellent effects in diabetics. It not only improves cholesterol and triglyceride levels, it also normalizes platelet lipid composition and function, and blood viscosity.^[15]

With regard to elevations in Lp(a), both niacin and vitamin C have shown an ability to reduce Lp(a) levels dramatically (35 and 27% reductions, respectively). In addition, it is important to rule out low thyroid function (hypothyroidism) in all cases of elevated blood lipids, especially Lp(a).

It is well-established that patients with overt hypothyroidism are prone to coronary artery disease because of increased LDL cholesterol and decreased HDL cholesterol. What is not so well-established is the significance of “subclinical” hypothyroidism in terms of risk for cardiovascular mortality. A recent study indicates that the risk may be greater than previously suspected. The study demonstrated that patients with subclinical hypothyroidism (defined in this study as normal T3 and FTI with a raised TSH) were shown to have not only significantly elevated levels of LDL cholesterol, but also elevated lipoprotein(a).^[50] These results question the dominant medical view that there is no reason to treat subclinical hypothyroidism. For more information, see [Chapter 162](#).

GENERAL THERAPEUTIC CONSIDERATIONS

Antioxidant status

Antioxidant nutrients like beta-carotene, selenium, vitamin E , and vitamin C have been shown to be very important in protecting against the development of heart disease, cancer, and other chronic degenerative diseases. In addition, antioxidants are also thought to slow down the aging process.

Fats and cholesterol are particularly susceptible to free radical damage. When damaged, fats and cholesterol form lipid peroxides and oxidized cholesterol which can then damage the artery walls as well as accelerate the progression of atherosclerosis. Antioxidants block the formation of these damaging compounds.

Based on extensive data, it appears that a combination

of antioxidants will provide greater antioxidant protection than any single nutritional antioxidant. The two primary antioxidants in the human body are vitamin C and vitamin E. Vitamin C is an “aqueous phase” antioxidant while vitamin E is a “lipid phase”

antioxidant (see [Ch. 99](#) for a more comprehensive discussion).

Vitamin E

Of all the antioxidants, vitamin E may offer the greatest protection against the oxidation of LDL cholesterol because of its ability to be easily incorporated into the LDL molecule (see [Table 133.13](#)). Furthermore, there is a clear-cut dosage effect, i.e. the higher the dosage of vitamin E, the greater the degree of protection against oxidative damage to LDL cholesterol. Although dosages as low as 25 mg are effective in offering some protection, it appears that doses of greater than 400 IU are required to produce clinically significant effects.^[51] Dosages of 200 IU do not provide the same degree of protection as 400–800 IU, especially in smokers and people exposed to greater oxidative stress.^{[51] [52] [53]}

Vitamin E provides significant additional benefit in protecting against heart disease and strokes by its ability to:

- reduce LDL cholesterol peroxidation and increase plasma LDL breakdown
- inhibit excessive platelet aggregation
- increase HDL cholesterol levels
- increase fibrinolytic activity.

Improvements have also been noted in insulin sensitivity and plasma lipids in non-insulin-dependent diabetics.

Several large population studies have demonstrated that vitamin E levels may be more predictive of developing a heart attack or stroke than total cholesterol levels.^{[54] [55] [56] [57]} In one study, low vitamin E levels were shown to be a far better predictive factor of heart disease than the factors most people associated with heart disease.^[57]

TABLE 133-13 -- Effect of increasing doses of vitamin E on oxidation parameters

| Dose (mg/day) | Lag time | Propagation rate |
|---------------|----------|------------------|
| 0 | 94 | 7.8 |
| 25 | 99 | 8.0 |
| 50 | 100 | 7.9 |
| 100 | 106 | 7.7 |
| 200 | 111 | 7.5 |
| 400 | 116 | 6.8 |
| 800 | 120 | 6.5 |

Lag time = the time before oxidation occurs after the addition of an oxidizing agent. The higher the number, the greater the beneficial effect.

Propagation rate = the rate at which lipid peroxidation progresses. The lower the number, the greater the beneficial effect.

High blood cholesterol was predictive 29% of the time and high blood pressure 25% of the time. But low levels of vitamin E in the blood were shown to be predictive of a heart attack almost 70% of the time. While the consumption of red wine has been suggested as the reason behind the “French paradox”, i.e. why the French have a lower rate of heart disease and strokes despite a higher cholesterol and fat intake, higher vitamin E levels provide at least as good an explanation.^[54] ^[57]

Two large-scale studies with relatively low dosages of vitamin E supplements have shown a significant reduction in the risk of dying of a heart attack or a stroke. One study of 87,245 nurses concluded that nurses who took 100 IU of vitamin E daily for more than 2 years had a 41% lower risk of heart disease compared with non-users of vitamin E supplements.^[58] Another study of 39,910 male health care professionals found similar results: a 37% lower risk of heart disease with the intake of more than 30 IU of supplemental vitamin E daily.^[59]

A recent study has demonstrated more clearly the benefits of even “low dosage” vitamin E supplementation in preventing heart disease. The study utilized the extensive dietary and nutritional supplement database collected in the Cholesterol Lowering Atherosclerosis Study. A total of 156 men aged 40–59 years with previous coronary artery bypass graft surgery were studied. The main outcome was the change per subject in the percentage of vessel diameter obstructed because of hardening of the artery, as determined by angiography after 2 years of randomized therapy of a cholesterol-lowering diet and either a cholesterol-lowering drug (colestipol-niacin combination) or placebo in association with supplemental antioxidant vitamins.^[60] Overall, the study found that only subjects in the group taking 100 IU or greater of vitamin E demonstrated significantly less coronary artery lesion progression than did subjects taking less than 100 IU. No benefit of vitamin E supplementation could be demonstrated in the placebo group. These results indicate that vitamin E supplementation, even at a relatively low dosage (100 IU), can reduce the progression of coronary artery disease when used in conjunction with cholesterol-lowering therapy (preferably natural).

In addition to offering protection against cardiovascular disease, vitamin E supplementation also plays a major role in the treatment of heart disease, recovery from stroke, and peripheral vascular diseases like intermittent claudication. The “mecca” for vitamin E research in cardiovascular disease is the Shute Institute and Medical Clinic in London, Ontario, Canada. The Shute Institute has been active in the use of vitamin E therapy since the 1940s. The Shute brothers, Drs Evan and Wilfred Shute, were instrumental in bringing to light many of the now substantiated cardiovascular benefits of vitamin E. It was the Shute brothers’ contention that

vitamin E is vital to cardiovascular health and that it is important to supplement the diet with high doses of vitamin E in many health conditions, especially those involving the cardiovascular system. Once scorned in mainstream medical circles, the Shute brothers have now been vindicated. Over half a century, the Shute Institute has successfully treated over 60,000 patients with vitamin E and other natural therapies. Vitamin E has been at the center stage in their treatment programs.

Vitamin C

Vitamin C works as an antioxidant in aqueous (water) environments in the body – both outside and inside human cells. It is the first line of antioxidant protection in the body. Its primary antioxidant partners are vitamin E and carotenes, as these antioxidants are fat-soluble. Vitamin C also works along with antioxidant enzymes such as glutathione peroxidase, catalase, and superoxide dismutase. Vitamin C is also responsible for regenerating oxidized vitamin E in the body, thus potentiating the antioxidant benefits of vitamin E.^[61] Vitamin C has been shown to be extremely effective in preventing LDL cholesterol from being oxidized, even in smokers.

A high dietary vitamin C intake has been shown to significantly reduce the risk of death from heart attacks and strokes (as well as all other causes including cancer) in numerous population studies.^{[62] [63]} One of the most detailed studies providing the most insight analyzed the vitamin C intake of 11,348 adults over 5 years and divided it into three groups: (1) less than 50 mg daily; (2) greater than 50 mg daily dietary intake with no vitamin C supplementation; and (3) greater than 50 mg dietary intake plus vitamin C supplementation (estimated to be 300 mg or more).^[62]

Analysis showed that the standardized mortality ratio (SMR), a comparison to the average death rate, was up to 48% lower in the high vitamin C intake group than in the low intake group for cardiovascular disease and overall mortality. These differences correspond to an increase in longevity of 5–7 years for men and 1–3 years for women.

Vitamin C lowers the risk for cardiovascular disease by:^{[62] [63] [64] [65] [66] [67]}

- acting as an antioxidant
- strengthening the collagen structures of the arteries
- lowering total cholesterol, Lp(a), and blood pressure
- raising HDL cholesterol levels
- inhibiting platelet aggregation.

Red wine

Several studies have shown that frequent red wine ingestion offers protection against heart disease and stroke.

TABLE 133-14 -- Antioxidant effects of red and white wine compared with vitamin C

| | Percentage increase in SAOC | |
|------------|-----------------------------|------------|
| | At 1 hour | At 2 hours |
| White wine | 4 | 7 |
| Red wine | 18 | 11 |
| Vitamin C | 22 | 29 |

Because the French consume more saturated fat than the populations in the United States and the United Kingdom, yet have a lower incidence of heart disease, red wine consumption has been suggested to be the reason behind the “French paradox”. Presumably this protection is the result of flavonoids in red wine protecting against oxidative damage to LDL cholesterol.

To better determine the antioxidant capacity of red wine, a study was conducted comparing the effects of red wine, white wine, and vitamin C on the serum antioxidant capacity. The serum antioxidant capacity (SAOX) was determined in nine subjects after consuming one glass (300 ml) of red wine and compared with nine subjects consuming one glass of white wine and four subjects consuming 1,000 mg of vitamin C.^[68] As shown in [Table 133.14](#), significantly better protection is offered by consuming 1,000 mg of vitamin C than one glass of either red or white wine.

Grape seed and pine bark extracts

One of the most beneficial groups of plant flavonoids are the proanthocyanidins (also referred to as procyanidins). The most potent proanthocyanidins are those bound to other proanthocyanidins. Collectively, mixtures of proanthocyanidin dimers, trimers, tetramers, and larger molecules are referred to as procyanidolic oligomers, or PCOs for short. Although PCOs exist in many plants as well as in red wine, commercially available sources of PCO include extracts from grape seeds and the bark of the maritime (Landes) pine.

The primary uses of PCO extracts are in the treatment of venous and capillary disorders including venous insufficiency, varicose veins, capillary fragility, and disorders of the retina, e.g. diabetic retinopathy and macular degeneration. Good clinical studies have shown positive results in the treatment of these conditions.^[69]

The potent antioxidant activity of PCO extracts suggests value in the prevention of heart disease and strokes. Since PCO has a greater antioxidant effect compared with vitamins C and E, it is only natural to assume it could offer greater protective effects than these antioxidant vitamins. In addition to preventing damage to cholesterol and the lining of the artery, PCO extracts have been shown in animal studies to lower blood cholesterol

levels and shrink the size of cholesterol deposits in the artery.^[70] ^[71] Additional mechanisms of PCO useful in preventing atherosclerosis include inhibition of platelet aggregation and inhibition of vascular constriction.^[72] ^[73] Presumably PCO extracts may exert similar benefits in humans.

Platelet aggregation

Excessive platelet aggregation is another independent risk factor for heart disease and strokes. Once platelets aggregate, they release potent compounds which dramatically promote the formation of the atherosclerotic plaque or they can form a clot which can lodge in small arteries and produce a heart attack or stroke. The adhesiveness of platelets is determined largely by the type of fats in the diet and the level of antioxidants. While saturated fats and cholesterol increase platelet aggregation, omega-3 oils have the opposite effect.

Essential fatty acids

Researchers and physicians are finding that by manipulating the type of dietary oils they can dramatically alter many aspects of metabolism, including the tendency for platelet aggregation. The omega-3 oils are showing the greatest promise in this regard.

Population studies have demonstrated that people who consume a diet rich in omega-3 oils from either fish or vegetable sources have a significantly reduced risk of developing heart disease.^[74] ^[75] Furthermore, results from autopsy studies have shown that the highest degree of coronary artery disease is found in individuals with the lowest concentration of omega-3 oils in their fat tissues. Conversely, individuals with the lowest degree of coronary artery disease had the highest concentration of omega-3 oils.^[76] Omega-3 fatty acids lower LDL cholesterol levels and triglycerides, inhibit excessive platelet aggregation, lower fibrinogen levels, and lower both systolic and diastolic blood pressure in individuals with high blood pressure.

The two populations with the lowest rate of heart attacks have a relatively high intake of alpha-linolenic acid (the essential omega-3 fatty acid): the Japanese who inhabit Kohama Island and the inhabitants of Crete.^[77] ^[78] Typically, Cretans have a threefold higher concentration of alpha-linolenic acid than members of other European countries, owing to their frequent consumption of walnuts and purslane.^[77] Another important dietary factor in both the Kohamans and Cretans is their use of oleic acid-containing oils – canola and olive oil. LDL cholesterol largely composed of oleic acid is less susceptible to peroxidation. Although the oleic content of the diet offers some degree of protection, the rate of heart attacks in the Kohamans and Cretans is much lower than in populations that consume only oleic acid sources and little alpha-linolenic acid. The intake of alpha-linolenic acid is viewed as a more significant protective factor.^[77] ^[78]

In addition to the omega-3 fatty acids, antioxidant nutrients, and flavonoids, vitamin B₆

also inhibits platelet aggregation (as well as lowering blood pressure and homocysteine levels).^[79] ^[80] In a recent study, the effect of vitamin B₆ (pyridoxine HCl) supplementation on platelet aggregation, plasma lipids, and serum zinc levels was determined in 24 healthy male volunteers (19–24 years old) given either pyridoxine at a dosage of 5 mg/kg body weight or a placebo for 4 weeks.^[80] Results demonstrated that pyridoxine inhibited platelet aggregation by 41–48%, while there was no change in the control group. Pyridoxine prolonged both bleeding and coagulation time, but not over the physiological limits. It had no effect on platelet count. Pyridoxine was also shown to lower total plasma lipids and cholesterol levels considerably from pretreatment levels. Total plasma lipids were reduced from 593 to 519 mg/dl and total cholesterol was reduced from 156 to 116 mg/dl. HDL cholesterol increased from 37.9 to 48.6 mg/dl. Serum zinc levels increased from 96 to 138 ug/dl. These results provide further evidence concerning the possible role of vitamin B₆ supplementation in reducing the risk of atherosclerotic mortality.

Garlic preparations standardized for alliin content as well as garlic oil have also demonstrated inhibition of platelet aggregation. In one study, 120 patients with increased platelet aggregation were given either 900 mg/ day of a dried garlic preparation containing 1.3% alliin or a placebo for 4 weeks.^[81] In the garlic group, spontaneous platelet aggregation disappeared, the microcirculation of the skin increased by 47.6%, plasma viscosity decreased by 3.2%, diastolic blood pressure dropped from an average of 74 to 67 mmHg and fasting blood glucose concentration dropped from an average of 89.4 to 79 mg/dl.

Fibrinogen formation

Elevated fibrinogen levels are a major primary risk factor for cardiovascular disease. Early clinical studies stimulated detailed epidemiological investigations into the possible link between fibrinogen and cardiovascular disease.^[82] The first such study was the Northwick Park Heart Study in the UK. This large study involved 1,510 men aged 40–64 years who were randomly recruited and tested for a range of clotting factors, including fibrinogen. At 4 years follow-up there was a stronger association between cardiovascular deaths and fibrinogen levels than that for cholesterol. This association has now been confirmed in at least five other prospective epidemiological studies.

Natural therapies (e.g. exercise, omega-3 oils, niacin, and

garlic) designed to promote fibrinolysis offer significant benefit in the prevention of heart attacks and strokes.

Elevated levels of homocysteine

Homocysteine is an intermediate in the conversion of the amino acid methionine to

cysteine. If a person is functionally deficient in folic acid, vitamin B₆, or vitamin B₁₂, there will be an increase in homocysteine. This compound has been implicated in a variety of conditions including atherosclerosis. Homocysteine is thought to promote atherosclerosis by directly damaging the artery and reducing the integrity of the vessel wall, and by interfering with the formation of proper collagen.

Elevated homocysteine levels are an independent risk factor for developing a heart attack, stroke, or peripheral vascular disease. Elevations in homocysteine are found in approximately 20–40% of patients with heart disease.^{[83] [84]} It is estimated that folic acid supplementation (400 mcg daily) alone would reduce the number of heart attacks suffered by Americans each year by 10%. However, given the importance of vitamin B₁₂ and B₆ to proper homocysteine metabolism, all three should be used together.^{[85] [86] [87]}

The prevalence of suboptimal levels of these nutrients in men with elevated homocysteine levels were 56.8, 59.1, and 25% for folic acid, vitamin B₁₂, and B₆, respectively, indicating that folic acid supplementation alone would not lower homocysteine levels in many cases.^[86] In other words, folic acid supplementation will only lower homocysteine levels if there are adequate levels of vitamin B₁₂ and B₆.

“Type A” personality

“Type A” behavior is characterized by an extreme sense of time urgency, competitiveness, impatience, and aggressiveness. This behavior carries with it a twofold increase in coronary heart disease compared with non-type A behavior.^{[88] [89]} Particularly damaging to the cardiovascular system is the regular expression of anger.^[90]

In one study, the relationship between habitual anger coping styles, especially anger expression, and serum lipid concentrations were examined in 86 healthy subjects. Habitual anger expression was measured on four scales: aggression, controlled affect, guilt, and social inhibition. A positive correlation between serum cholesterol level and aggression was found. The higher the aggression score, the higher the cholesterol level. A negative correlation was found between the LDL/HDL ratio and controlled affect score – the greater the ability to control anger, the lower the LDL/HDL ratio. In other words, those who learn to control anger experience a significant reduction in the risk for heart disease, while an unfavorable lipid profile is linked to a predominantly aggressive (hostile) anger coping style.

Here are 10 tips to improve coping strategies.

Tip 1. Don't starve your emotional life. Foster meaningful relationships. Provide time to give and receive love in your life.

Tip 2. Learn to be a good listener. Allow the people in your life to really share their feelings and thoughts uninterrupted. Empathize with them, put yourself in their shoes.

Tip 3. Don't try to talk over somebody. If you find yourself being interrupted, relax; don't try and out talk the other person. If you are courteous and allow them to speak,

eventually (unless they are extremely rude) they will respond likewise. If they don't, point out to them that they are interrupting the communication process. You can only do this if you have been a good listener.

Tip 4. Avoid aggressive or passive behavior. Be assertive, but express your thoughts and feelings in a kind way to help improve relationships at work and at home.

Tip 5. Avoid excessive stress in your life as best you can be avoiding excessive work hours, poor nutrition, and inadequate rest. Get as much sleep as you can.

Tip 6. Avoid stimulants like caffeine and nicotine. Stimulants promote the fight or flight response and tend to make people more irritable in the process.

Tip 7. Take time to build long-term health and success by performing stress-reduction techniques and deep breathing exercises.

Tip 8. Accept gracefully those things over which you have no control. Save your energy for those things that you can do something about.

Tip 9. Accept yourself. Remember that you are human and will make mistakes along the way to learn from.

Tip 10. Be more patient, and tolerant of other people. Follow the Golden Rule.

Other nutritional factors

Magnesium and potassium

Magnesium and potassium are absolutely essential to the proper functioning of the entire cardiovascular system. Their critical roles in preventing heart disease and strokes are now widely accepted. In addition, there is a substantial body of knowledge demonstrating that magnesium and/or potassium supplementation is effective in treating a wide range of cardiovascular diseases including angina, arrhythmias, congestive heart failure, and high blood pressure. In many of these applications magnesium and/or potassium supplementation has been used for over 50 years.^{[91] [92] [93]}

Since the role of potassium on the cardiovascular system is described in detail in [Chapter 159](#), the focus here will be on magnesium. Most Americans do not consume enough of this important mineral. The average intake of magnesium by healthy adults in the US ranges between 143 and 266 mg/day. This level is well below even the RDA of 350 mg for men and 300 mg for women. Food choices are the main reason. Since magnesium occurs abundantly in whole foods, most nutritionists and dietitians assume that most Americans get enough magnesium in the diet. But most Americans are not eating whole, natural foods. They are consuming large quantities of processed foods. Since food processing refines out a very large portion of magnesium, most Americans are not getting the RDA for magnesium.

The best dietary sources of magnesium are tofu, legumes, seeds, nuts, whole grains, and green leafy vegetables. Fish, meat, milk, and most commonly eaten

1122

fruit are quite low in magnesium. Most Americans consume a low magnesium diet because their diet is high in low magnesium foods such as processed foods, meat, and dairy products.

People dying of a heart attack have been shown to have lower heart magnesium levels than people of the same age dying from other causes.^[94] Intravenous magnesium therapy has now emerged as a valued treatment measure in acute myocardial infarction (MI).^{[95] [96] [97]} The major obstacle to it becoming the preferred method for saving a person's life may be financial interests. Magnesium is cheap compared with new, high-tech, high-priced, genetically engineered drugs currently being promoted by the drug companies. The treatment of acute myocardial infarctions is a big business in the United States. Each year in the US over 1.5 million Americans will experience an acute MI. While many other parts of the world are now utilizing magnesium therapy of an acute MI because of its effectiveness, low cost, safety, and ease of administration, in the US it plays second fiddle to the high-tech drugs.

During the past decade, eight well-designed studies involving over 4,000 patients have demonstrated that intravenous magnesium supplementation during the first hour of admission to a hospital for an acute MI produces a favorable effect in reducing immediate and long-term complications as well as death rates.^{[95] [96] [97]}

The beneficial effects of magnesium in an acute MI relate to its ability to:

- improve energy production within the heart
- dilate the coronary arteries, resulting in improved delivery of oxygen to the heart
- reduce peripheral vascular resistance, resulting in reduced demand on the heart
- inhibit platelets from aggregating and forming blood clots
- reduce the size of the infarct (blockage)
- improve heart rate and arrhythmias.

Preventing a recurrent heart attack

People who have experienced a heart attack or stroke and live through it are extremely likely to experience another. The primary prevention of subsequent cardiovascular events is to control the major cardiac risk factors (e.g. hyperlipidemia, hypertension, cigarette smoking, diabetes, and physical inactivity). The most popular "secondary" recommendation to reduce the risk of a subsequent heart attack being given by most physicians is low-dose aspirin (e.g. 325 mg/day). However, there are significant

problems with this advice.

Aspirin

There have been seven prospective, randomized, placebo-controlled trials involving almost 15,000 survivors of heart attacks which have examined the use of aspirin to reduce the incidence of recurrent heart attack and death. These trials have used several doses of aspirin ranging from 325 to 1,500 mg/day and enrolled patients at various intervals after infarction ranging from 4 weeks to 5 years. None of the studies demonstrated a statistically significant reduction in mortality with aspirin use. However, when all the results from these studies were pooled, aspirin was shown to produce a reduction in mortality rate from all causes and cardiovascular deaths. The mortality rate for all causes in the aspirin group was 5.8% compared with 8.3% in the placebo group, indicating a reduction in mortality by 30% with aspirin.^[98]

Although it is becoming popular to recommend dosages of aspirin lower than 325 mg (e.g. 50–150 mg daily), these lower dosages have not been tested in properly designed trials.

Aspirin and other NSAIDs are associated with a significant risk of peptic ulcer. However, most studies documenting the relative frequency of peptic ulcers as a consequence of aspirin and NSAIDs have focused on their use in the treatment of arthritis and headaches. Recently the risk of gastrointestinal bleeding due to peptic ulcers was evaluated for aspirin at daily dosages of 300, 150, and 75 mg.

The study concluded that there is an increased risk of gastrointestinal bleeding due to peptic ulcer at all dosage levels. However, the dosage of 75 mg/day was associated with a 40% reduction in ulcers compared with 300 mg/day, and 30% compared with 150 mg/day. The researchers concluded: “No conventionally used prophylactic aspirin regimen seems free of the risk of peptic ulcer complications.”^[99]

Given the fact that it is not known whether 75 mg/day of aspirin is at all helpful in preventing a second heart attack, most physicians recommend at least 300 mg. For the prevention of stroke, the dosage necessary appears to be 900 mg. These dosage recommendations carry with them a significant risk for developing a peptic ulcer, but may be appropriate for high-risk patients unwilling to adopt the natural approach.

Natural alternatives to aspirin

The best approach to preventing subsequent heart attacks may not be low-dose aspirin, especially in aspirin-sensitive patients. The first alternative to aspirin to examine is one too often overlooked by many physicians – diet. Several studies have shown that dietary modifications are not only more effective in preventing heart attack recurrence than aspirin, but also can reverse the blockage of clogged arteries. The most famous of the three studies showing this effect is the Lifestyle Heart Trial conducted by Dean Ornish.^[100] In this study, subjects with heart disease were divided into a control group

and an experimental group. The control group received regular medical care while the experimental group was asked to eat a low-fat vegetarian diet for at least 1 year. The diet included fruits, vegetables, grains, legumes, and soybean products. Subjects were allowed to consume as many calories as they wished. No animal products were allowed except egg white and 1 cup/day of non-fat milk or yogurt. The diet contained approximately 10% fat, 15–20% protein, and 70–75% carbohydrate which was predominantly complex carbohydrate from whole grains, legumes, and vegetables.

The experimental group was also asked to perform stress reduction techniques such as breathing exercises, stretching exercises, meditation, imagery, and other relaxation techniques for an hour each day and to exercise at least 3 hours/week. At the end of the year, the subjects in the experimental group showed significant overall regression of atherosclerosis of the coronary blood vessels. In contrast, subjects in the control group who were being treated with regular medical care and following the standard American Heart Association diet actually showed progression of their disease. Ornish states: “This finding suggests that conventional recommendations for patients with coronary heart disease (such as a 30% fat diet) are not sufficient to bring about regression in many patients.”

Two other studies showing that diet can prevent further heart attacks in patients suffering a first heart attack highlight the importance of omega-3 fatty acids and again show the ineffectiveness of the American Heart Association’s dietary recommendations.

As stated previously, numerous population studies have demonstrated that people who consume a diet rich in omega-3 oils from either fish or vegetable sources have a significantly reduced risk of developing heart disease.^[101] Furthermore, results from autopsy studies have shown that the highest degree of coronary artery disease is found in individuals with the lowest concentration of omega-3 oils in their fat tissues. Conversely, individuals with the lowest degree of coronary artery disease had the highest concentration of omega-3 oils.^[102]

In the Dietary and Reinfarction Trial (DART) it was only when the intake of omega-3 fatty acids (from fish) was increased that future heart attacks were reduced.^[103] In another study, the Lyon Diet Heart Study, increasing the intake of omega-3 fatty acids from plant sources (alpha-linolenic acid) was found to offer the same degree of protection as increased fish intake.^[104] The diet used in the Lyon Heart Study is often referred to as the Mediterranean or Cretan diet. Compared with the standard American diet (the SAD diet), the Cretan diet consists of more bread, more root vegetables, more green vegetables, more fish, less meat (beef, lamb, and pork are replaced with poultry), no day without fruit, and butter and cream replaced with canola and olive oil. Compared with the control group, the group consuming the Cretan diet had a 60% reduction in overall mortality.

Glycosaminoglycans

A mixture of highly purified bovine-derived glycosaminoglycans naturally present in the aorta, including dermatan sulfate, heparan sulfate, hyaluronic acid, chondroitin sulfate, and related hexosaminoglycans, has been shown to inhibit platelet aggregation as well as protecting and promoting normal artery and vein function. Over 50 clinical studies have shown an orally administered complex of aortic GAGs to be effective in a number of vascular disorders including:

- cerebral and peripheral arterial insufficiency
- venous insufficiency and varicose veins
- hemorrhoids
- vascular retinopathies including macular degeneration
- post-surgical edema.

Significant improvements in both symptoms and blood flow have been noted.^{[105] [106] [107] [108] [109]}

Aortic GAGs appear to be of value primarily for patients recovering from heart attack or stroke, and those who have had angiograms, coronary artery bypass surgery, or angioplasty. The dosage of aortic GAGs is 100 mg/day. Similar, but not nearly as impressive, results to aorta extracts in the treatment of atherosclerosis have been noted with chondroitin sulfate at a daily dose of 3 g (1 g with meals, three times daily).^[110]

Preventing a subsequent stroke

To prevent a subsequent stroke, as well as to promote recovery from a stroke, *Ginkgo biloba* extract should be added to the program given above for preventing a subsequent heart attack. The extract of *Ginkgo biloba* leaves standardized to contain 24% ginkgo flavonglycosides and 6% terpenoids has been the subject of over 300 published scientific papers and over 40 double-blind studies in the treatment of decreased blood supply to the brain (cerebral vascular insufficiency). It is currently the third most widely prescribed drug of all kinds in Germany. *Ginkgo biloba* extract has demonstrated remarkable effects in improving many symptoms associated with aging, including short-term memory loss, depression, dizziness, ringing in the ears, and headache. *Ginkgo biloba* extract has also been shown to enhance stroke recovery.^{[111] [112] [113] [114]}

Other considerations

Angiography, coronary artery bypass surgery or angioplasty

A significant challenge for the clinician is determining when a patient should be referred for angiography,

coronary artery bypass surgery, or angioplasty. As is fully discussed in [Chapter 129](#), these procedures are utilized far more frequently than is justified by objective evaluation of their appropriateness and efficacy.^[115] [Chapter 129](#) also gives advice for patient care when angiogram, coronary artery bypass surgery, or angioplasty is unavoidable.

Intravenous EDTA chelation therapy

The clinician will also be asked for recommendations concerning the efficacy of the far less invasive intravenous EDTA chelation therapy. This useful, yet controversial, procedure is also discussed fully in [Chapter 129](#).

Ear lobe crease

The presence of a diagonal ear lobe crease has been recognized as a sign of cardiovascular disease since 1973. Since then, over 30 studies have been reported in the medical literature, with the largest to date involving 1,000 unselected patients. The ear lobe is richly vascularized, and a decrease in blood flow over an extended period of time is believed to result in collapse of the vascular bed. This leads to a diagonal crease.^{[116] [117]}

In one study, angiographs performed on 205 consecutive patients showed an 82% accuracy in predicting heart disease, with a false-positive rate of 12% and a false-negative rate of 18%. In another study of 112 consecutive patients, the ear lobe crease was highly correlated with demonstrable heart disease and, less strongly, with previous myocardial infarction.^[116]

The crease is seen more commonly with advancing age, until the age of 80, when the incidence drops dramatically. However, the association with heart disease is age-independent.

In conclusion, the ear lobe crease appears to be a better predictor of heart disease than any other known risk factor, including age, smoking, sedentary lifestyle, hyperlipidemia, and others. While the presence of an ear lobe crease does not prove heart disease, it strongly suggests it, and examination of the ear lobe should be a useful screening procedure. The correlation does not hold true with Orientals, native Americans, and children with Beckwith's syndrome.^[116]

THERAPEUTIC APPROACH

There is no doubt that in most cases atherosclerosis is a disease directly related to diet and lifestyle. Treatment and prevention include reducing all known risk factors. For many patients this goal requires a major change in diet and lifestyle. Since so many factors are known to be involved in atherosclerosis, any treatment plan must be

individualized to assure optimal results. What follows is a general approach which needs to be tailored according to the clinical picture and patient's willingness.

Dietary and lifestyle recommendations

- Eat less saturated fat and cholesterol by reducing or eliminating the amounts of animal products in the diet
- Increase the consumption of fiber-rich plant foods (fruits, vegetables, grains, legumes, and raw nuts and seeds)
- Achieve ideal body weight
- Obtain regular aerobic exercise
- Do not smoke
- Eliminate the consumption of coffee (both caffeinated and decaffeinated)
- Drink at least 1.4 litres of water daily.

Supplements

- High potency multiple vitamin and mineral formula
- Vitamin C: 500–1,000 mg three times/day
- Vitamin E: 400–800 IU/day
- Flaxseed oil: 1 tbsp/day
- Inositol hexaniacinate: 500 mg three times/day with meals for 2 weeks, then increase dosage to 1,000 mg three times/day with meals
- Garlic preparation: dosage to provide 4,000 mcg allicin.

Note. For diabetics recommend pantethine: 300 mg three times daily.

Chapter 134 - Atopic dermatitis (eczema)

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

DIAGNOSTIC SUMMARY

- Chronic, pruritic, inflammatory skin condition
- Skin is dry and hyperkeratotic
- Lesions include excoriations, papules, eczema (patches of erythema, exudation, and scaling with small vesicles formed within the epidermis), and lichenification (hyperpigmented plaques of thickened skin with accentuated furrows)
- Scratching and rubbing lead to lichenification, most commonly in the antecubital and popliteal flexures
- Personal or family history of atopy.

GENERAL CONSIDERATIONS

Atopic dermatitis (eczema) is a very common condition with a prevalence of 2.4–7% of the population. Current research indicates that atopic dermatitis is, at least partially, an immediate hypersensitivity disease:^[1]

- serum IgE is elevated in 80% of patients
- all patients have positive skin, RAST, and other allergy tests
- there is a positive family history in two-thirds of eczema patients
- many eventually develop allergic rhinitis and/or asthma
- most improve with an elimination diet.

Atopic dermatitis is also characterized by a variety of physiological and anatomical abnormalities of the skin. The type of abnormality determines the manner in which atopic dermatitis is manifested in each patient. The major abnormalities (with possible mechanism) are:

- a lowered threshold to itch stimuli (substance P excess?)

- hypersensitivity to alpha-adrenergic agonists and cholinergic agents which may be due to a partial beta-adrenergic blockade (receptor site insensitivity)
- dry, hyperkeratotic skin, which has decreased water-holding capacity (dry – zinc or thyroid deficiency; hyperkeratotic – vitamin A deficiency?)

1128

- a marked tendency to lichenify in response to rubbing and scratching (membrane fragility?)
- a tendency of the skin to be heavily colonized by bacteria, especially coagulase-positive *Staphylococcus aureus* (immune dysfunction).^[2]

Other aspects of possible significance are Dennie's sign (an accentuated double pleat below the margin of the lower eyelid) and a tendency towards vasoconstriction which can be provoked by physical pressure (also called white dermatographism).^[2]

Immunological abnormalities

Leukocytes from patients with atopic dermatitis have decreased cyclic AMP levels due to increased cyclic AMP-phosphodiesterase activity and a decreased level of prostaglandin precursors.^[3] The lack of intracellular cAMP results in increased histamine release (see [Fig. 134.1](#)) and decreased bactericidal activity.

One of the key immunological abnormalities in atopic serum is a defect in serum bactericidal activity, a reaction dependent on the integrity of the alternate complement pathway (ACP).^[4] The historic use of inulin-containing herbs such as burdock root (*Arctium lappa*) and dandelion root (*Taraxacum officinale*) appears to have some scientific validity, since inulin activates the ACP.^[5] This activation could possibly result in restoration of bactericidal activity and increased levels of cAMP.

These defects in immune function, coupled with scratching and the predominance of pathogenic *Staphylococcus aureus* in the skin flora in 90% of patients with atopic dermatitis, lead to the increased susceptibility to *Staphylococcus* infections. There are also cell-mediated immunity defects which lead to increased susceptibility to cutaneous herpes simplex, vaccinia, molluscum contagiosum, and verruca vulgaris infections. The local immune response is further compromised by reduced delayed-type hypersensitivity, cutaneous anergy, and a decreased in vitro lymphocyte reactivity to mitogens and antigens. It is interesting to note that these cell-mediated defects normalize during clinical remission and become abnormal again during recurrences of the dermatitis.^[4]

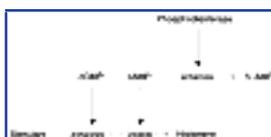

Figure 134-1 cGMP, cAMP, and histamine.

THERAPEUTIC CONSIDERATIONS

Food allergy

Many studies have documented the major role of food allergy in atopic dermatitis (also see [Ch. 51](#)). Studies have also shown that breast feeding offers significant prophylaxis against atopic dermatitis (as well as allergies in general).^[3] If infants who are breast fed develop atopic dermatitis it usually is the result of transfer of allergic antigens in the breast milk, in which case mothers should be instructed to avoid the common food allergens (especially milk, eggs, and peanuts, and to a lesser extent, fish, soy, wheat, citrus, and chocolate).^[6] Maternal avoidance of these common allergens is associated with complete resolution in the majority of cases.

In older or formula-fed infants, milk, eggs, and peanuts appear to be the most common food allergen inducing atopic dermatitis. In one study, these three foods account for roughly 81% of all cases of childhood atopic dermatitis,^[7] while in another study 60% of children with severe atopic dermatitis have a positive food challenge to one or two of egg, cow's milk, peanut, fish, wheat or soybean. However, virtually any food can be the offending agent.^[2]

Diagnosis of food allergy is usually best achieved via the elimination diet and challenge method. This approach is especially useful in childhood eczema. A simple elimination of milk products, eggs, peanuts, tomatoes, and artificial colors and preservatives results in significant improvement in at least 75% of cases.^{[2] [7] [8]} If laboratory methods are used to identify food allergies in eczema, the most useful method appears to be ELISA IgE and IgG₄ (see [Ch. 15](#)).^[9]

The presence of food allergies is thought to be responsible for children with atopic dermatitis having been shown to have a "leaky gut".^[10] As a result of this increased gut permeability, there is increased antigen load on the immune system which subsequently overwhelms the immune system, increasing the likelihood of developing additional allergies. It is essential to identify offending foods as soon as possible to avoid the development of further allergies. Trying to deal with multiple food allergies is often a very difficult task for the patient as the diet is often unrealistically restrictive. Elimination of allergenic foods appears to stop the development of new allergies.^[11]

Patients should be encouraged to find out that if they can avoid offending foods for a period of up to 1 year – in many cases they will "lose" or "outgrow" their allergy. Loss rate of food allergy in patients with atopic dermatitis after 1 year was 26% for the five major allergens (egg, milk, wheat, soy, and peanut) and 66% for other food allergies.^[12]

Candida albicans

An overgrowth of the common yeast, *Candida albicans*, in the gastrointestinal tract has been implicated as a

causative factor in allergic conditions including atopic dermatitis. Elevated levels of anti-*Candida* antibodies are common in atopic individuals. Furthermore, the severity of lesions tends to correlate with the level of IgE antibodies to *Candida* antigens. Appropriate anti-*Candida* therapy (see [Ch. 48](#)) may result in significant clinical improvement of atopic dermatitis. ^[13]

Essential fatty acids and prostaglandin metabolism

Patients with atopic dermatitis appear to have altered essential fatty acid (EFA) and prostaglandin metabolism. For example, several analyses of fatty acids in plasma, red blood cells, and monocytes in patients with atopic dermatitis demonstrated a tendency for linoleic acid levels to be increased while longer-chain polyunsaturated fatty acids such as gamma-linolenic acid, arachidonic acid, and the long-chain omega-3 oils, eicosapentaenoic acid (EPA) and docosahexanoic acid (DHA), tend to be relatively low. ^{[14] [15]}

Initially it was thought that patients with atopic dermatitis may have a defect in delta-6-desaturase, the zinc-dependent enzyme that converts linoleic acid to gamma-linolenic acid. If such a defect exists, supplementing the diet with evening primrose, borage, or blackcurrant oil (commercial sources of gamma-linolenic acid) may prove helpful. In fact, several double-blind studies with evening primrose oil have shown benefit (studies with evening primrose oil showing benefit have typically used dosages of at least 3,000 mg of evening primrose oil daily, providing 270 mg of GLA). ^{[16] [17] [18]} However, overall the results appear to more favorable with omega-3 oil supplementation than with evening primrose oil, and less expensive. Several studies with evening primrose oil failed to demonstrate any benefit over a placebo. In the largest and highest methodological quality of these studies, no benefit of evening primrose oil could be demonstrated. ^[19]

In general, treatment with omega-3 oils appears to produce better results, as they deal more effectively with the prostaglandin abnormalities. ^[20] In the most recent study analyzing the fatty acid patterns in atopic dermatitis, the proportions of linoleic acid in total plasma lipids and phospholipids were significantly greater, and those of oleic acid were lower, in patients with atopic dermatitis than in age-matched healthy controls. ^[21] However, even more significant was the fact that the ratio of omega-3 to omega-6 fatty acids was significantly lower in patients with atopic dermatitis. Furthermore, no significant decreases in the proportions of dihomo-gamma-linolenic acid and arachidonic acid were observed in plasma lipids of atopic patients, suggesting that delta-6-desaturase activity is not impaired in atopic patients. This analysis seems to provide an answer as to why clinical studies with omega-3 fatty acids tend to be more favorable in atopic dermatitis than those with evening primrose oil.

Dietary enrichment with “fish oil” supplements providing EPA and DHA or simply eating more fatty fish (e.g. mackerel, herring, and salmon) results in significant incorporation of

omega-3 fatty acids into the membrane phospholipid pools. Although flaxseed oil, which contains alpha-linolenic acid, the precursor omega-3 fatty acid, may provide some benefit to patients with atopic dermatitis, since the degree of clinical improvement correlates with the increase in the concentration of DHA in serum phospholipids and since fish oils tend to be more effective in raising DHA levels than flaxseed oil, supplementation with EPA/DHA or increasing the consumption of cold-water fish is likely to produce better overall results in atopic dermatitis than flaxseed oil.^[22]

Inhibition of excess histamine release

As can be seen in [Fig. 134.1](#), agents which stimulate cAMP production and/or inhibit cAMP phosphodiesterase reduce the inflammatory process in atopic dermatitis by reducing the shunting to histamine.

Coleus forskolii is a strong cAMP stimulant,^[23] and many botanicals have been shown to inhibit diesterase, with licorice (*Glycyrrhiza glabra*) showing marked activity.^[24]

A number of flavonoids also inhibit cAMP phosphodiesterase, with maximal activity from the flavonols quercetin and hyperoside, the flavones orientin and vitexin, and the flavanone naringenin.^[25] However, the common flavanol, rutin, has less than one-tenth the activity of quercetin, which has been shown to greatly increase the level of cAMP in human platelets.^[26] Flavonoid extracts from *Vaccinium myrtillus*, *Rosa damascena*, *Ruta graveolens*, *Prunus spinosa* and *Crataegus pentagyna* were the most potent inhibitors, according to one study.^[27] These flavonoids are also potent inhibitors of mast cell degranulation.^[28] Flavonoid-rich extracts such as those from grape seed, pine bark, green tea, or *Ginkgo biloba* may prove helpful in the treatment of atopic dermatitis.

In addition to flavonoids, *Ginkgo biloba* extract contains several unique terpene molecules known collectively as ginkgolides that antagonize platelet-activating factor (PAF), a key chemical mediator in atopic dermatitis. PAF plays a central role in many inflammatory and allergic processes, including neutrophil activation, increasing vascular permeability, smooth muscle contraction including bronchoconstriction, and reduction in coronary blood flow. Ginkgolides compete with PAF for binding sites and inhibit the various events induced by PAF. Preliminary studies have indicated that mixtures of ginkgolides (BN 52063) as well as the *Ginkgo biloba* extract standardized to contain 24% ginkgo flavonglycosides and 6% terpenoid are capable of demonstrating clinically significant anti-allergy effects.^[29] ^[30]

Zinc

Zinc supplementation appears to be very much indicated in atopic dermatitis given that low zinc levels are common in atopic dermatitis and given its importance to proper essential fatty acid metabolism (zinc is required for delta-6-desaturase, the enzyme that

is responsible for converting linoleic acid to gamma-linolenic acid).^[28]

Botanical medicines

The use of botanical medicines in atopic dermatitis can be generally divided into two categories: internal and external. Licorice (*Glycyrrhiza glabra*) appears to be useful in either application. Internally, licorice preparations can exert significant anti-inflammatory and anti-allergic effects (see [Ch. 90](#)). These benefits are perhaps best exemplified in several recent double-blind studies featuring a licorice-containing Chinese herbal formula.^[31] In addition to licorice, the formula contained:

- *Ledebouriealla seseloides*
- *Potentilla chinensis*
- *Clematis chensis*
- *Clematis armandi*
- *Rehmania glutinosa*
- *Paeonia lactiflora*
- *Lophatherum gracile*
- *Dictamnus dasycarpus*
- *Tribulus terrestris*
- *Schizonepeta tenuiflora*.

Interest in this formula by a group of researchers began after one of their patients with atopic dermatitis experienced tremendous improvement after taking a decoction prescribed by a Chinese doctor.

Several double-blind studies have confirmed this benefit. In one study, 40 adult patients with long-standing, refractory, widespread, atopic dermatitis were randomized to receive 2 months' treatment of either the active formula or placebo decoction, followed by a cross-over to the other treatment after a 4 week washout period.^[32] The treatment group demonstrated significant superiority over the placebo in clinical evaluation. In addition, of the 31 patients completing the study, 20 preferred the active formula while only four patients preferred the placebo. There was also a subjective improvement in itching and sleep during the active treatment phase. No side-effects were reported, although many complained about the unpalatability of the decoction.

Similar results were demonstrated in a double-blind study in children.^[33] These positive preliminary studies will hopefully be followed by more extensive investigations to determine proper dosages and perhaps different forms of administration (e.g. pills, tablets, or capsules versus unpalatable decoctions).

Licorice undoubtedly plays a major role in the effectiveness of the Chinese herbal formula. At this time, until the benefits of the other components can be confirmed, it makes the most sense to base the dosage level upon the level of delivered licorice.

With regard to using licorice topically, the best results are likely to be obtained by using commercial preparations featuring pure glycyrrhetic acid. Several studies have shown

glycyrrhetic acid to exert an effect similar to that of topical hydrocortisone in the treatment of eczema, contact and allergic dermatitis, and psoriasis. In one study, nine of 12 patients with intractable eczema noted marked improvement and two patients noted mild improvements when an ointment containing glycyrrhetic acid was applied topically. In a another study in patients with eczema, 93% of the patients applying glycyrrhetic acid demonstrated improvement compared with 83% using cortisone.^[34]

Miscellaneous factors

Hypothyroid patients with eczema respond well to thyroid.^[35]

Itching is extremely detrimental in atopic dermatitis because it breaks the skin, which aids bacterial ingress, and promotes lichenification. Factors which limit itching, therefore, promote healing and prevent recurrence.

Emotional tension can provoke and aggravate itching in patients with atopic dermatitis; and, according to a number of studies, atopic dermatitis patients show higher levels of anxiety, hostility, and neurosis than matched controls.^[36]

THERAPEUTIC APPROACH

Effective management requires relief from, and prevention of, itching while treating the underlying metabolic abnormalities. The food and environmental allergens must be detected and controlled; prostaglandin metabolism should be normalized; and it is essential that immune system abnormalities be balanced.

Diet

Start by using a 4 day rotation diet and eliminating all major allergens (milk, eggs, and peanuts account for the offending food in approximately 81% of cases). As the patient improves, slowly reintroduce allergens and reduce stringency of rotation diet. Limit animal products and add fatty fish such as salmon, mackerel, herring, and halibut.

Supplements

Vitamin A: 50,000 IU/day

Vitamin E: 400 IU/day (mixed tocopherols)

Zinc: 50 mg/day (decrease as condition clears)

Quercetin: 200–400 mg three times/day (5–10 minutes before meals)

EPA and DHA: 540 and 360 mg daily or flaxseed oil 10 g daily

Evening primrose oil: 3,000 mg/day.

Botanicals

The doses are three times/day dosages.

Arctium lappa* or *Taraxacum officinale

- Dried root: 2–8 g by infusion or decoction
- Fluid extract (1:1): 4–8 ml (1–2 tsp)
- Tincture: alcohol-based tinctures of dandelion are not recommended because of the extremely high dosage required
- Juice of fresh root: 4–8 ml (1–2 tsp)
- Powdered solid extract (4:1): 250–500 mg.

Coleus forskolii. Extract standardized to contain 18% forskolin: 50 mg (9 mg of forskolin) two to three times daily.

Glycyrrhiza glabra

- Powdered root: 1–2 g
- Fluid extract (1:1): 2–4 ml
- Solid (dry powdered) extract (4:1): 250–500 mg.

Topical treatment

Glycyrrhetic acid-containing commercial preparations may be helpful. Also, chamomile preparations (see [Ch. 184](#)) and witch hazel preparations are also quite popular and have support for their use in the scientific literature. ^[37] ^[38]

In addition:

- avoid sweating and rough-textured clothing
- wash clothing with mild soaps only and rinse thoroughly
- avoid exposure to chemical irritants and any other agent which might cause skin irritation.

Local application of soothing lotions ameliorates itching (zinc oxide works well), but greasy preparations should not be used for extended periods since they block the sweat ducts.

Psychological

Determine if the patient has significant levels of anxiety, hostility, or neurosis. If present, assist the patient in their resolution or refer the patient to a counselor for more extensive

assistance.

Chapter 135 - Attention deficit disorders (hyperactivity and childhood learning disorders)

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

DIAGNOSTIC SUMMARY

Hyperactivity (attention deficit disorder with hyperactivity)

- The child displays signs of inattention, impulsiveness, and hyperactivity inappropriate for mental and chronological age.

Learning disability (attention deficit disorder without hyperactivity)

- The child displays developmentally inappropriate brief attention span and poor concentration for mental and chronological age.

GENERAL CONSIDERATIONS

Attention deficit disorder (ADD) is the current term that encompasses a wide variety of terms used in the past to describe similar disorders, e.g. hyperkinetic reaction of childhood, hyperkinetic syndrome, hyperactive child syndrome, minimal brain damage, minimal brain dysfunction, minimal cerebral dysfunction, and minor cerebral dysfunction.

Three separate ADD disorders exist:

- ADD without hyperactivity
- ADD with hyperactivity
- ADD, residual type.

The first two disorders are considered individually below. The discussion of hyperactivity is concerned largely with the role of food additives, food allergies, and sucrose, while

the discussion of attention deficit disorder without hyperactivity focuses on heavy metals. Residual attention deficit disorder (patient 18 years or older) is viewed primarily as a continuation of the process.

Although these two syndromes are discussed separately, it is important to recognize that the factors discussed under one may be equally relevant to the other. Another important consideration is otitis media (see [Ch. 178](#)), given the fact that frequent ear infections and antibiotic

1134

use are associated with a greater likelihood of developing ADD.

HYPERACTIVITY (ATTENTION DEFICIT DISORDER WITH HYPERACTIVITY)

The incidence of this disorder has been reported to be from 4 to 20% of school-age children. Over 2 million American children (mostly boys) take the drug methylphenidate (Ritalin). A more widely accepted conservative figure of 3% is probably more accurate, due to improved diagnostic criteria.^[1] Clinical observation and epidemiological surveys report a substantially greater incidence in boys than girls (10:1). Onset is usually by the age of 3, although diagnosis is not generally made until later when the child is in school.

The characteristics of this disorder cited in order are:

- hyperactivity
- perceptual motor impairment
- emotional lability
- general coordination deficit
- disorders of attention (short attention span, distractibility, lack of perseverance, failure to finish things off, not listening, poor concentration)
- impulsiveness (action before thought, abrupt shifts in activity, poor organizing, jumping up in class)
- disorders of memory and thinking
- specific learning disabilities
- disorders of speech and hearing
- equivocal neurological signs and electroencephalographic irregularities.

These characteristics are frequently associated with difficulties in school, in both learning and behavior. Although other factors may be involved in the etiology, considerable evidence points towards food additives, food sensitivities, and sucrose consumption as being responsible for the majority of hyperactivity in this country.

Food additives

The term food additives covers a wide range of chemicals (5,000 additives are used in the USA), such as:

- anticaking agents (e.g. calcium silicate)
- antioxidants (e.g. BHT, BHA)
- bleaching agents (e.g. benzoyl peroxide)
- colorings (e.g. artificial azo dye derivatives)
- flavorings
- emulsifiers
- mineral salts
- preservatives (e.g. benzoates, nitrates, sulfites)
- thickeners
- vegetable gums.

The 1985 per capita daily consumption of food additives is approximately 13–15 g, with the total annual consumption of food colors alone being approximately 100 million pounds for the entire population.^[2] The hypothesis that food additives induce hyperactivity, commonly referred to as the “Feingold hypothesis”, stemmed from the research of Benjamin Feingold MD.

According to Feingold, many hyperactive children, perhaps 40–50%, are sensitive to artificial food colors, flavors, and preservatives and to naturally occurring salicylates and phenolic compounds.^[3] Feingold’s claims were based on his experience with over 1,200 cases in which food additives were linked to learning and behavior disorders. Since Feingold’s presentation to the American Medical Association in 1973, the role of food additives in the etiology of hyperactivity has been hotly debated in the scientific literature.^{[4] [5] [6] [7] [8] [9] [10] [11] [12] [13] [14] [15] [16]} In actuality however, researchers have focused on only 10 food dyes versus the 3,000 food additives with which Feingold was concerned.

At first glance, it appears that the majority of the double-blind studies designed to test the hypothesis have shown essentially negative results.^{[4] [5] [6] [7] [8] [9]} However, upon closer examination of these studies and further investigation into the literature, it becomes evident that food additives do in fact play a major role in hyperactivity.^{[10] [11] [12] [13] [14] [15] [16]} This is somewhat in opposition to the final report filed by the National Advisory Committee on Hyperkinesis and Food Additives to the USA Nutrition Foundation in 1980. However, the US National Institutes of Health, Consensus Conference on Defined Diets and Childhood Hyperactivity agreed to reconsider the Feingold diet in the amelioration of hyperkinesis.^{[17] [18]} The reason for this reconsideration is largely due to the overwhelming evidence produced in several studies^{[8] [9] [10] [13] [14]} and to the fact that, despite major inadequacies in the negative studies, about 50% of those who tried the Feingold diet in these studies displayed a decrease in symptoms of hyperactivity.^{[4] [7]}

Schauss^[11] and Rippere^[12] have reviewed much of the literature concerning food additives and hyperactive children and have formulated guidelines and recommendations for future research designs that we hope will be utilized. Rippere’s

review is primarily a critique of C. Keith Conners' studies and book, *Food additives and hyperactive children*. Conners has been the primary researcher refuting the Feingold hypothesis.^[4] ^[5] ^[6] Rippere's major criticisms of Conners' work focused on six areas:

- *Type of placebo*. In Conners' studies the placebo used was a chocolate cookie. In [Table 135.1](#), it can be seen that in double-blind studies of reactions to foods in hyperkinetics, chocolate produced a reaction in 33% in one
-

1135

study and 59% in another. Conners himself acknowledges that reaction to the placebo was not uncommon. Furthermore, Conners reports that at a 2 year follow-up 21% of the mothers whose children took part in the diet trials mentioned that chocolate is a food that appeared to affect behavior adversely. When the other constituents of the cookie are also taken into consideration, e.g. cow's milk, sugar, wheat, corn, yeast, and other additives besides artificial colors, this placebo can hardly be termed inert.

- *Adequacy of challenge dosages*. The dose of mixed food dyes in these challenge trials was based on erroneous information, being far below the average daily intake based on FDA data. The dose given in Conners' studies was 13 mg twice daily, compared with a daily dose of 150 mg estimated to be at the 90th percentile for children from 5 to 12 years of age (average daily dose for children between 5 and 12 years of age is estimated at 76.5 mg). Swanson & Kinsbourne^[13] confirmed Conners' results when a daily dose of 26 mg of mixed food dyes was given; however, they demonstrated that doses of 75, 100 and 150 mg produced significant impairment of learning performance in 17 of the 20 subjects. These results were consistent with other researchers' demonstrations of severe behavioral effects provoked by administration of mixed dyes, even at the low concentrations used by Conners.^[14]

- *Length of dose interval*. The doses of food dyes were given at relatively long intervals. This, combined with the inadequate dosage, indicates that the model fell far short of real-life exposure experienced by these victims of the technicolor breakfast cereal generation.

- *Type of blood test for allergy determination*. Conners' use of the cytotoxic test for allergy is irrelevant, as is his logic in manipulating information from this test to make erroneous statements. The test has a high rate of false-positives and -negatives, and Feingold's hypothesis does not require an allergic basis for the reactions to the various additives.

- *Outcome measures*. Conners' main outcome measure, an a priori standardized rating procedure using subjective judgements and administered at less than daily intervals in the majority of studies, in conjunction with a group design, is potentially insensitive to true effects. Behavioral changes were not adequately detected, due to inappropriateness of the conventional drug reaction scales being used.

- *Bias in the presentation of other investigators' data*. Conners consistently minimizes and discounts findings which support Feingold's hypothesis, including even his own findings. In the two major double-blind studies assessing the Feingold diet (Conners' and Harley's), parental scores revealed positive behavioral changes for the Feingold diet.^[4] ^[7] The fact that teacher ratings failed to improve may indicate

that other environmental factors were having an effect. In particular, it has been demonstrated that standard cool-white fluorescent lighting increases hyperactive behavior, while full-spectrum light with radiation shields decreases hyperactivity.^[21]

It is interesting to note that, while the US studies have been largely negative, the reports from Australia and Canada have been more supportive.^{[8] [10] [14] [22] [23]} Feingold has contended that there is a conflict of interest on the part of the Nutrition Foundation, an organization supported by the major food manufacturers – Coca Cola, Nabisco, General Foods, etc. It appears significant that the Nutrition Foundation has financed most of the negative studies.^{[21] [24]} Feingold contends that the conflict of interest arises because these companies would suffer economically if food additives were found to be harmful. Other countries have significantly restricted the use of artificial food additives because of the possible harmful effects.^[25]

Several more recent studies have been designed to determine the effect of the common yellow dye tartrazine on behavior in hyperactive children. In the largest study, 200 children were included in a 6 week open trial of a diet free of synthetic food coloring.^[26] The parents of 150 children reported behavioral improvement with the diet, and deterioration of behavior on the introduction of foods containing artificial colors. Thirty-four children (23 suspected reactors, 11 uncertain reactors) and 20 control subjects, aged 2–14 years, were studied in the double-blind, placebo-controlled portion of the study.

Placebo or one of six dose levels of tartrazine (1, 2, 5, 10, 20, and 50 mg) were administered randomly each morning, and behavioral ratings were recorded by parents at the end of each day.

The study identified 24 children as clear reactors (19 of 23 “suspected reactors”, three of 11 “uncertain reactors,” and two of 20 “control subjects”). Reactors displayed irritability, restlessness, and sleep disturbances. A clear dose–response effect was obtained. With doses greater than 10 mg, the duration of effect was prolonged.

These results once again support the Feingold hypothesis. Not surprisingly, the study was not performed in the United States. The study was conducted at the Royal Children’s Hospital, University of Melbourne, Australia.

The other two recent studies also found that food additives and food allergies are common causes of ADD. In one study, 19/26 children with ADHD responded favorably to an elimination diet.^[27] In the other study, 59/78 children responded.^[28] In both studies, double-blind, placebo-controlled food challenge confirmed the negative effects of provoking agents on behavior and mental performance.

Sucrose

There appears to be an interrelationship between sucrose consumption and artificial food dyes. Prinz et al^[29]

demonstrated that destructive-aggressive and restless behavior significantly correlated with the amount of sucrose consumed.

In addition to the above incriminating evidence connecting sucrose with negative effects on behavior, there are the Langseth & Dowd^[30] findings. These researchers performed 5 hour oral glucose tolerance tests on 261 hyperactive children, with the result that 74% displayed abnormal glucose tolerance curves. The predominant abnormality was a low, flat curve. Hypoglycemia would obviously promote hyperkinesis via increased catecholamine secretion. Refined carbohydrate appears to be the major factor in promoting reactive hypoglycemia.^[31]

Food allergies (sensitivities)

The contention that food allergies provoke hyperactivity in children is another popular notion in lay publications. There are, however, much more consistent results in double-blind studies that examined the relationship between food and food additive allergies and behavior.^{[19] [20] [32] [33]} While artificial colorings and preservatives are the most common provoking substances in two of these studies, no child was sensitive to these alone.^{[19] [20]} This suggests that, since food sensitivities provoke psycho-logical symptoms, elimination of just food additives from the diet is inadequate.

Egger et al,^[19] in a large controlled trial, treated 76 severely hyperactive children with an oligoantigenic diet (lamb, chicken, potatoes, rice, banana, apple, brassica family vegetable, calcium gluconate 3 g/day, and a multiple vitamin). After a 4 week trial, 82% (62) improved, and a normal range of behavior was achieved in 21 of these. Other symptoms, such as headaches, abdominal pains, and fits, also improved.^[19] Reintroduction of the foods to which the child was sensitive led to reappearance of symptoms and hyperactive behavior. No mention was made of the possibility that non-responders were reacting to foods on the oligoantigenic diet or perhaps the vitamins, although it was noted that somatic complaints were reduced in the non-responders as well. [Table 135.1](#) summarizes the results of two studies on food sensitivities and hyperactivity (see [Ch. 51](#) for further discussion). It is also significant that, in a retrospective study, 86% of hyperactive children had elevated eosinophils.^[30]

Eggers et al have since reproduced his results in a larger study of 185 children with established hyperkinetic syndrome. The children were put on an oligoantigenic diet treatment for 4 weeks. The diet consisted of two meats (lamb and chicken), two carbohydrates (potatoes and rice), two fruits (banana and pears), vegetables (cabbage, sprouts, cauliflower, broccoli, cucumber, celery, and carrots), and water. They were supplemented with calcium, magnesium, zinc and some basic

TABLE 135-1 -- Food allergy reactions in hyperactive children*

| Item | Percentage reacting ^[20] | Percentage reacting (no. of patients*) ^[19] |

NT, not tested.

Fifteen patients were tested for each food in O'Shea & Porter.^[20] The number tested in Egger et al^[19] are in parentheses after the percentage who reacted.

vitamins. Behavior in 116 of these children responded and provoking foods were identified by sequential reintroduction.^[32] Other researchers have found similar improvements. For example, one double-blind study of 26 children who met the criteria for attention deficit hyperactivity disorder found that 19 responded favorably to an oligoantigenic diet which also eliminated food additives.^[33]

THERAPEUTIC APPROACH

Despite the controversy about the significance of food additives in hyperactivity, careful reading of the published studies yields some clear conclusions:

- Virtually every study, both negative and positive, demonstrated that some

hyperactive children consistently react with behavioral problems when challenged by specific food additives.

- On a statistical basis, virtually every study, both those that are supportive and critical of the hypothesis, is marred by significant experimental design defects.
- Critics of the hypothesis are misusing the apparently inconsistent statistical group results to ignore the significance of the clear (reproducible under double-blind conditions) individual results.

Although the best approach would be to eliminate all food additives, practical realities make this difficult. Ultimately, the best results will depend upon accurate identification of the offending agents, preferably with behavioral, rather than laboratory measurements.

Considering the importance of food allergy, recognition

1137

and control of the offending allergens are critical. The oligoantigenic diet (preferably individualized to the patient) for a period of 4 weeks, followed by reintroduction/challenge of suspected foods (full servings at least once a day, one food introduced per week), is the most sensible and economical approach. If symptoms recur or worsen upon reintroduction/challenge, the food should be withdrawn. If there is no improvement on the oligoantigenic diet, it is possible that the child is reacting to something in the diet or environment. Further testing may be indicated in these patients.

All refined sugars should be eliminated from the diet, and a general multivitamin and mineral supplement should be used (with special care to ensure that the child is not allergic to the product used).

Also, the factors discussed below under “Learning disability” (below) should be considered. For example, hyperactive children have been shown to have increased lead levels.^[34] ^[35]

LEARNING DISABILITY (ATTENTION DEFICIT DISORDER WITHOUT HYPERACTIVITY)

Three factors appear to be particularly relevant to learning disabilities:

- otitis media
- nutrient deficiency
- heavy metals.

Otitis media

Children with moderate to severe hearing loss tend to have impaired speech and language development, lowered general intelligence scores, and learning difficulties.^[36]

[37] Current and early incidence of otitis media have been reported to be twice as common in learning-disabled children as in non-learning-disabled children.[37] This reconfirms the necessity of dealing with otitis media from a preventive standpoint (see Ch. 178), since many of the factors associated with hyperactivity are also associated with otitis media.

Nutrient deficiency

Virtually any nutrient deficiency can result in impaired CNS function.[2] [38] [39] Iron deficiency is the most common nutrient deficiency in American children.[2] [39] Iron deficiency is associated with:[2] [39] [40] [41]

- markedly decreased attentiveness
- less complex or purposeful, narrower attention span
- decreased persistence
- decreased voluntary activity that is usually responsive to supplementation.

Several investigators have demonstrated that correction of even subtle nutritional variables exerts a substantial influence on learning and behavior, while “megavitamin” supplementation is generally of limited value.[38] [42] [43] [44]

Heavy metals

Numerous studies have demonstrated a strong relationship between childhood learning disabilities (and other disorders including criminal behavior) and body stores of heavy metals, particularly lead.[34] [35] [45] [46] [47] [48] [49] Learning disabilities seem to be characterized by a general pattern of high hair levels of mercury, cadmium, lead, copper, and manganese.[42] [43] Poor nutrition and elevation of heavy metals usually go hand in hand, due to decreased consumption of food factors known to chelate these heavy metals or decrease their absorption (see Ch. 18). Table 135.2 summarizes the results of several studies examining hair heavy metal levels in learning-disabled subjects.

Screening for lead toxicity is an essential process when evaluating a child with symptoms of ADD or developmental delay (DD). However, results from a recent study did not find significantly higher lead levels in children with ADD and DD than in normal controls.[50] This study would seem to refute the need for lead status evaluation in ADD and DD; however, the study used blood lead levels as an indicator of body lead burden. The problem with blood lead measurements is that they reflect recent exposure and do not accurately evaluate lead concentration in the brain. Hair mineral analysis or EDTA challenge has provided entirely different results.

TABLE 135-2 -- Summary of literature on heavy metals and learning disability (LD)[42] [48] [51]

| Study | Minerals | | | | Subjects |
|-------|----------|----|----|----|----------|
| | Cd | Pb | Hg | Cu | |
| | | | | | |

| | | | | | |
|-------------------------|----|----|----|----|---|
| Cameron et al (1980) | + | ++ | ++ | ++ | 66 LD |
| Colgan (1983) | ++ | ++ | + | 0 | 16 LD |
| Ely et al (1981) | + | | - | | 77 LD males |
| Hansen et al (1980) | | + | | | 20 LD vs. controls |
| Moore et al (1975) | | ++ | | | 45 LD |
| Pihl et al (1977) | ++ | ++ | 0 | 0 | 35 LD vs. 22 controls |
| Rasmussen (1976) | | + | | + | 200 LD |
| Thatcher et al (1982) | ++ | ++ | | | 141 children, IQ and achievement scores |
| Rudolph (1977) | 0 | + | | ++ | 53 LD vs. 1,347 controls |
| Tuthill ^[51] | | ++ | | | 277 first graders |

++, significant positive relationship; +, weak positive relationship; 0, no relationship; -, weak negative relationship.

THERAPEUTIC APPROACH

The treatment plan involves the elimination of any underlying otitis media (see [Ch. 178](#)), detection and elimination of any heavy metal toxicity (see [Ch. 18](#)), and establishment of optimum nutrition for these children. Counseling is also indicated in most cases, and for the best results should involve the whole family.

Chapter 136 - Autism

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

DIAGNOSTIC SUMMARY

- A syndrome of early childhood (first diagnosed no later than 30 months) characterized by:
 - profound failure to develop social relationships
 - language disorder with impaired understanding, echolalia, and pronominal reversal
 - rituals and compulsive phenomena
 - general retardation in intellectual development (in most cases)
- Male to female ratio 4:1.

GENERAL CONSIDERATIONS

Autism was originally thought to be primarily a psychiatric condition. However, recent biochemical and genetic studies have led to the hypothesis that the disorder is due to an organic defect in brain development. Specifically, autism is thought to be a result of abnormal serotonin metabolism in the brain.^[1]

The prognosis of the autistic child is quite poor: typically only one in 20 will show any improvement by adulthood.^[2] The prognosis appears to be related to the results of IQ testing. Autistic children are difficult to test but, in the hands of an experienced examiner, an accurate assessment can be made.^[3] Typically about half of those children with an IQ over 50 can do moderately well, some even attaining normal adjustment, particularly when appropriate behavioral therapy, psychotherapy, and special schooling is available. In those children with IQ scores under 50, temporal lobe

epilepsy eventually manifests.

There is no specific medical treatment for autism. Phenothiazines are used to control severe forms of aggressive and self-destructive behavior, but do not abort the psychosis.^[3] Although not effective for all autistic children, vitamin B₆ and magnesium, when used in combination, have been shown in a number of studies to greatly help a significant portion.

1140

THERAPEUTIC CONSIDERATIONS

Serotonin

As stated earlier, patients with autism appear to have a defect in serotonin metabolism. The abnormalities that have been documented include:^[1]

- abnormal release and uptake of serotonin by platelets
- abnormal kynurenine metabolism
- increased serum serotonin and free tryptophan levels
- abnormal urinary 5-hydroxyindolacetic acid (5-HIAA) levels
- abnormal urinary serotonin metabolites.

The basic defect appears to be a decrease in CNS serotonin activity despite elevated free tryptophan levels in the serum.

The following possible mechanisms have been suggested to explain the brain serotonin hypoactivity seen in autism:

1. Reduced tryptophan hydroxylase or L-aromatic amino acid decarboxylase activity results in impaired serotonin synthesis and, via feedback control, leads to increased serum free tryptophan levels.
2. Increased tryptophan oxygenase activity results in high levels of kynurenine which reduces the available tryptophan for serotonin synthesis and inhibits tryptophan transport across the blood–brain barrier. In turn, increased free tryptophan levels result in increased tryptophan oxygenase activity, thus setting up a positive feedback cycle.
3. There is increased degradation of serotonin by MAO or other enzymes.
4. Abnormal blood levels of albumin and non-esterified fatty acids are directly involved in the variation of serum levels of free tryptophan.
5. There is lowered sensitivity of serotonin receptors on neurons, resulting in increased serotonin synthesis through a feedback cycle.

The first and second postulates are the most plausible and the ones with the most support in the scientific literature. These will be discussed below in conjunction with

therapeutic approaches that have been shown to normalize the aberrations. The metabolic pathways of tryptophan, serotonin, and their metabolites are shown in [Figure 136.1](#).

Folic acid, vitamin B₁₂ and vitamin C

If the defect is due to a decrease in tryptophan hydroxylase activity (a tetrahydrobiopterin [BH₄] dependent enzyme), supplementation with folic acid, ascorbic acid and B₁₂ may increase the activity of tryptophan hydroxylase by increasing BH₄.^[4] Although no studies have been

Figure 136-1 The metabolic pathways of tryptophan, serotonin, and their metabolites.

done with autistic children, increasing CNS BH₄ levels has offered some benefit in patients with affective disorders and Parkinson's disease.^[5]

Pyridoxine

If the defect is in decarboxylation or abnormal kynurenine metabolism, pyridoxine supplementation is indicated.^{[1] [6] [7] [8] [9]} Pyridoxine supplementation of autistic children has been investigated in several double-blind clinical studies.^{[6] [7] [8] [9]} The results indicate that there is a subgroup that improves with B₆ supplementation and shows significantly reduced levels of urinary HVA.^{[6] [7] [8] [9]} However, on the average, only about 20% will show moderate improvement in symptom scores, while about 10% will demonstrate dramatic clinical improvement.^{[6] [7] [8] [9]} It has also been observed that B₆ supplementation had a greater effect when used in combination with magnesium.^{[8] [9]}

A 1985 study of 60 autistic children used four crossed-sequential, double-blind therapeutic trials. The children were divided into two groups and given various combinations

of vitamin B₆, magnesium, and placebo. Therapeutic effects were measured using behavioral rating scales, urinary excretion of homovanillic acid (HVA), and evoked potential recordings (EP). The combination of B₆ and magnesium resulted in significant

improvement in behavior that was closely associated with decreases in HVA excretion and a normalized EP amplitude and morphology. However, magnesium and vitamin B₆ were not significantly effective when used alone.^[10]

The tryptophan load test may be indicated as a screening test for B₆-responsive patients and as a monitor of B₆ dosage (see [Ch. 28](#)). Although B₆ may not result in a cure for autism, sufficient evidence exists to support a clinical trial in which improvement may be noted.^{[6] [7] [8] [9]} According to Rimland^[11] (who pioneered the use of pyridoxine in treating autistic children): "... anywhere from a quarter to half of the children are significantly helped, with about 20% showing dramatic improvement".

Other factors contributing to central serotonin defects are discussed in [Chapter 126](#).

Serotonin metabolites

The abnormal serotonin metabolites seen in autistic children may significantly contribute to their mental dysfunction. LSD, psilocybin, ergot, and other hallucinogens are serotonin analogs and a number of serotonin metabolites are known to be hallucinogens.^[12] It is also interesting to note that serotonin and its metabolites are produced in, and absorbed from, the intestines.

Food allergies and intestinal permeability

Food allergies may be contributory to the behavioral disorders. Sensitivity to gluten and milk are thought to be the major food allergens in these patients. In one study, 19 children with autistic syndromes were treated with either gluten-free and milk-reduced diets, or milk-free and gluten-reduced diets.^[13] Before treatment five of the 15 fully studied patients had increased levels of IgA antibodies to casein or gluten. After following the diet for 1 year, improvement was noted in increased social contact, decreased stereotypy, an end to self-mutilation like head banging, and a decrease in "dreamy state" periods. These improvements were accompanied by a significant decrease in urinary peptide excretion. The possible mechanism is that children with autism suffer from one or more peptidase defects that fail to break down "exorphins" (exogenous opioids) found in milk and wheat. These exorphin peptides then gain entry into the brain where they significantly disrupt brain chemistry.

The presence of other food allergies should be determined, as food allergies are likely the factor responsible for the increased intestinal permeability noted in these patients.^[14]

In fact, increased gut permeability has been suggested as a possible causative factor for autism.

THERAPEUTIC APPROACH

Clearly, the information for developing an effective therapeutic approach to autism is incomplete at best. More research needs to be done. Despite these limitations, the following suggestions may offer some improvement in the condition. Electroconvulsive

therapy, however, should be discouraged.

Diet

Eliminate those factors that play a role in aggravating CNS dysfunction in children (see [Ch. 135](#)). General bowel detoxification diet and assessment for intestinal permeability ([Ch. 21](#)) should be implemented.

Supplements

Tailor doses according to age and size of patient. The doses given below are general levels suitable for children between the ages of 2 and 6 years:

- vitamin C: 1 g/day
- pyridoxal phosphate: 5–20 mg/day
- pyridoxine: 25–100 mg/day
- folic acid: 500 mcg/day
- vitamin B₁₂ : 500 mcg/day
- magnesium: 75–100 mg/day.

Counseling

This condition requires specialized behavioral and psycho-logical attention. Referral to a counselor experienced in working with autistic children is warranted.

Chapter 137 - Bacterial sinusitis

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

DIAGNOSTIC SUMMARY

- History of acute viral respiratory infection, dental infection, or nasal allergy
- Nasal congestion and purulent discharge
- Fever, chills, and frontal headache
- Pain, tenderness, redness, and swelling over the involved sinus
- Transillumination shows opaque sinus
- Chronic infection may produce no symptoms other than mild postnasal discharge, a musty odor, or a non-productive cough.

GENERAL CONSIDERATIONS

The most common predisposing factor in acute bacterial sinusitis is viral upper respiratory infection (the common cold). Allergic rhinitis and other factors which interfere with normal protective mechanisms may precede the viral infection and, therefore, are the more likely predisposing factors. Any factor which induces edema of the mucous membranes may result in obstruction of meatal drainage. The transudate which is produced serves as a suitable medium for bacterial overgrowth, with streptococci, pneumococci, staphylococci, and *Haemophilus influenzae* being most commonly cultured.

In chronic sinusitis an allergic background is commonly present, and in 25% of chronic maxillary sinusitis there is an underlying dental infection. Although vasoconstrictors and antihistamines cause transient relief, their chronic use is contraindicated, since there is usually a reflex reaction following continual administration.

THERAPEUTIC CONSIDERATIONS

Antibiotics

Although antibiotic therapy is the dominant treatment of acute and chronic bacterial sinusitis, it is of limited value. The effectiveness of antibiotic therapy of acute sinusitis in adults is quite controversial. A recent detailed analysis

1144

to determine the evidence for the effectiveness of antibiotic treatment in acute maxillary sinusitis in adults by assessing the methodological quality of placebo-controlled double-blind randomized trials concluded: "The effectiveness of antibiotic treatment in acute maxillary sinusitis in a general practice population is not based sufficiently on evidence."^[1] Nonetheless, in severe or unresponsive cases, antibiotics may be appropriate. Newer, more potent antibiotics (e.g. lactam antibiotics) appear to be more effective than penicillin, amoxicillin, and other less potent antibiotics.^[2]

In children, there is even less evidence that antimicrobial therapy is of significant benefit. Overuse of antibiotics in children with sinusitis or otitis media is a growing concern as it is leading to antibiotic-resistant strains of bacterial pathogens. According to a 1997 review article:^[3] "To date, no definitive trials of bacteriologic efficacy in children have been published."

In chronic sinusitis, antibiotics are of little or no benefit.^[4] Clearly, addressing the underlying cause of chronic sinusitis (e.g. respiratory or food allergens) along with supportive therapy (e.g. saline nasal sprays, immune-enhancing herbs, and natural decongestants) appears to be the most rational approach.

Allergy

Studies have found that between 25 and 70% of the cases of allergies are associated with sinusitis.^[5] Patients with chronic sinusitis that does not respond to immune support and antibiotics should be aggressively worked up for environmental and food allergies.

Environmental control requires the elimination of dust mites (warm water washing at a temperature of least 58°C), use of air-filtering vacuum cleaners, installation of an air cleaner with a HEPA filter, and whatever methods are needed to maintain the humidity at under 50%. Some particularly sensitive patients may need to have all pets removed, along with carpeting and feather bedding.^[6]

Sick building syndrome

In addition to allergens, chemicals in the environment can be a problem for patients with chronic sinusitis. For example, some of the main complaints of sick building syndrome,

such as lethargy, headache, and blocked or runny nose, are signs of chronic sinusitis.^[7]

Helicobacter pylori

An interesting study evaluated 275 atopic patients with symptoms of peptic ulcer and showed that urticaria, sinusitis and exercise-induced anaphylaxis were increased when they were positive for *Helicobacter pylori*. Fifty-two patients showed *H. pylori*-specific IgE and IgG reactivity, with 29 being IgE-positive and IgG-negative and 23 being both IgG- and IgE-positive. Endoscopy confirmed *H. pylori* in the stomachs or sinuses of patients with *H. pylori* antibodies. Antibiotic therapy for *H. pylori*-induced ulcers resolved allergy symptoms in a significant number of these patients.^[8]

THERAPEUTIC APPROACH

In acute sinusitis, the therapeutic goals are to re-establish drainage and clear the acute infection. Various measures can be used: local application of heat, local use of volatile oils and botanicals with antibacterial properties, and immune system support (see [Ch. 53](#)).

Since chronic sinusitis is often associated with allergy, long-term control is dependent on isolation and elimination of the food or airborne allergens and correction of the underlying problem which allowed the allergy to develop (see [Ch. 51](#) for a more thorough discussion). During the acute phase, elimination of the common food allergens (milk, wheat, eggs, citrus, corn, and peanut butter) is indicated until a more definitive diagnosis can be made.

Local applications of heat have been shown to be very effective in alleviating both short- and long-term symptoms of allergic rhinitis.^[9]

Supplements

- Vitamin C: 500 mg every 2 hours
- Bioflavonoids: 1,000 mg/day
- Vitamin A: 5,000 IU/day or
Beta-carotene: 25,000 IU/day
- Zinc: 30 mg/day
- Thymus extract: the equivalent to 120 mg pure polypeptides with molecular weights less than 10,000 or roughly 500 mg of the crude polypeptide fraction.

Botanicals

- *Echinacea* sp.
 - dried root (or as tea): 0.5–1 g
 - freeze-dried plant: 325–650 mg
 - juice of aerial portion of *E. purpurea* stabilized in 22% ethanol: 2–3 ml

—tincture (1:5): 2–4 ml

—fluid extract (1:1): 2–4 ml

—solid (dry powdered) extract (6.5:1 or 3.5% echinacoside): 150–300 mg

- *Hydrastis canadensis* – the dosage should be based on berberine content. As there is a wide range of quality in goldenseal preparations, standardized extracts are recommended. Three times a day dosages are as follows:
-

1145

—dried root or as infusion (tea): 2–4 g

—tincture (1:5): 6–12 ml (1.5–3 tsp)

—fluid extract (1:1): 2–4 ml (0.5–1 tsp)

—solid (powdered dry) extract (4:1 or 8–12% alkaloid content): 250–500 mg.

Local treatment

- Intranasal douche with hydrastis tea
- Swab passages with oil of bitter orange
- Menthol or eucalyptus packs over sinuses (care should be taken to avoid irritation).

Physical therapy

- Local applications of hot packs
- Diathermy: 30 minutes (discontinue if pain increases without drainage).

Chapter 138 - Benign prostatic hyperplasia

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

DIAGNOSTIC SUMMARY

- Symptoms of bladder outlet obstruction (progressive urinary frequency, urgency and nocturia, hesitancy and intermittency with reduced force and caliber of urine)
- Enlarged, non-tender prostate
- Uremia if prolonged obstruction.

GENERAL CONSIDERATIONS

Benign prostatic hyperplasia (BPH, also known in the past as benign prostatic hypertrophy) affects over 50% of men in their lifetime. The actual incidence increases with advancing age from approximately 5–10% at age 30 to over 90% in men over 85 years of age.^[1]

BPH represents an androgen-dependent disorder of metabolism reflecting the many significant changes in steroid levels in aging men. Testosterone (T) and, in particular, free testosterone levels decrease with age after the fifth decade. Prolactin, estradiol, sex hormone-binding ligand, luteinizing hormone (LH), and follicle-stimulating hormone (FSH) levels are all increased. The ultimate effect of these changes is an increased intraprostatic concentration of dihydrotestosterone (DHT), the potent androgen derived from testosterone. This increase is largely due to a decreased rate of removal combined with an increase in the activity of the enzyme 5-alpha-reductase, the enzyme that converts T to DHT.^[2] T and DHT are extensively metabolized by hydroxylation, which decreases the normally high affinity of the cytosolic receptor proteins for these hormones, thereby allowing their excretion. Estrogens inhibit this hydroxylation. The prostatic androgen receptors have a fivefold greater affinity for DHT than T, and BPH tissue has a three- to fourfold greater net ability to increase tissue levels of DHT.

DIAGNOSTIC CONSIDERATIONS

BPH originates in the periurethral and transition zones of

1148

the prostate in a microscopic (histologically identifiable) state as early as the third decade of life. With advancing age and the presence of androgens, microscopic BPH will develop into macroscopic (palpably enlarged prostate) BPH. However, symptoms will develop in only 50–60% of men with an enlarged prostate gland. Many men will develop symptoms without macroscopic enlargement as the hyperplasia will go to the area of least resistance – the lumen of the urethra.^[1]

In other words, about one-half of men with a palpably enlarged prostate will have symptoms and roughly one-half of men with a normal sized prostate will experience symptoms. What all this means is that relying on digital palpation for diagnosis is unreliable.

Prostate-specific antigen

Because the symptoms of BPH and prostate cancer can be quite similar, measurement of prostate-specific antigen (PSA) is often used to differentiate BPH from the more serious prostate cancer. The PSA test is a highly accurate and sensitive marker for prostate cancer. The normal value for PSA is less than 4 ng/ml. An elevation above 10 is highly indicative of prostate cancer.

There has been concern that the use of PSA as a screening test for prostate cancer is not reliable enough. Although an elevated level indicates prostate cancer in about 90% of cases, it must be kept in mind that mid-range elevations in PSA can be caused by BPH and that in some instances there may be prostate cancer without elevation of PSA levels. Factors such as prostatitis, urinary retention, ejaculation, and exercise can also lead to elevations in PSA.

Despite the fact that the PSA test is not perfect, it is a simple, relatively non-invasive test that can provide valuable information. PSA screening has been endorsed by the American Cancer Society, the American Urological Association, and other physicians' groups.

For men over the age of 50, where there is a family history (any immediate relative – father, brother, or uncle) of prostate cancer, an annual prostate examination and PSA test are strongly recommended.

THERAPEUTIC CONSIDERATIONS

If left untreated, BPH will eventually obstruct the bladder outlet, resulting in the retention of urine and eventually kidney damage. As this situation is potentially life-threatening, proper treatment is crucial. In the past, medical treatment involved a procedure known as a TURP (trans-urethral resection of the prostate). Because this surgery is associated with a high rate of morbidity and will often make matters worse, it should be avoided unless absolutely necessary.

Nutritional factors

Diet appears to play a critical role in the health of the prostate. It is particularly important to avoid pesticides, increase the intake of zinc and essential fatty acids, and keep cholesterol levels below 200 mg/dl.

High-protein diet

A high-protein diet (total calories: 44% protein, 35% carbohydrate, 21% fat) inhibits 5-alpha-reductase, while a low protein diet (10% protein, 70% carbohydrate, and 20% fat) stimulates the enzyme.^[3] Since a high-protein diet has not actually been used in the treatment of men with BPH, its use is speculative.

Zinc

Paramount to an effective BPH treatment plan is adequate zinc intake and absorption. Zinc supplementation has been shown to reduce the size of the prostate – as determined by rectal palpation, X-ray, and endoscopy – and to reduce symptomatology in the majority of patients in studies conducted in the 1970s.^[4] ^[5] The clinical efficacy of zinc is probably due to its critical involvement in many aspects of androgen metabolism. Intestinal uptake of zinc is impaired by estrogens, but enhanced by androgens. Since estrogen levels are increased in men with BPH, zinc uptake may be low.

Although zinc levels and 5-alpha-reductase activity do not consistently correlate in hyperplastic tissue, zinc has been shown to inhibit the activity of 5-alpha-reductase, the enzyme that irreversibly converts T to DHT.^[6] ^[7] ^[8] ^[9] ^[10] Zinc also inhibits specific binding of androgens to the cytosol and nuclear androgen receptors.^[6]

Zinc has also been shown to inhibit prolactin secretion.^[11] ^[12] Prolactin has been shown to increase the uptake of testosterone by the prostate, thereby leading to increased levels of DHT by providing more substrate.^[12] Prolactin antagonists, such as bromocriptine, have been shown to reduce many of the symptoms of prostatic hyperplasia. However, these drugs have severe side-effects and are of limited value.^[13] Beer (but not pure alcohol), tryptophan, and stress all increase prolactin secretion and may therefore be aggravating factors.^[14] ^[15]

Alcohol

While only beer raises prolactin levels, higher alcohol intake is definitely associated with

BPH. In a 17 year study of 6,581 men in Hawaii, it was noted that an alcohol intake of at least 25 ounces/month was directly correlated with the diagnosis of BPH.^[16] The association was most significant for beer, wine, and sake, and less for distilled spirits.

Essential fatty acids

The administration of an essential fatty acid (EFA) complex containing linoleic, linolenic, and arachidonic acids has resulted in significant improvement for many BPH patients.^[17] All 19 subjects in an uncontrolled study showed diminution of residual urine, with 12 of the 19 having no residual urine by the end of several weeks of treatment. These effects appear to be due to the correction of an underlying EFA deficiency, since these patients' prostatic and seminal lipid levels and ratios are often abnormal.^{[18] [19]}

Amino acids

The combination of glycine, alanine, and glutamic acid (in the form of two 6 grain capsules administered three times daily for 2 weeks and one capsule three times daily thereafter) has been shown in several studies to relieve many of the symptoms of BPH. In a controlled study of 45 men, nocturia was relieved or reduced in 95%, urgency reduced in 81%, frequency reduced in 73%, and delayed micturition alleviated in 70%.^[20] These results have also been reported in other controlled studies.^[21] The mechanism of action is unknown, but is likely related to the amino acids acting as inhibitory neurotransmitters and reducing the feelings of a full bladder. In other words, amino acid therapy is only palliative.

Cholesterol

Cholesterol metabolites are cytotoxic and carcinogenic and have been shown to accumulate in the hyperplastic or cancerous human prostate. Epoxycholesterols initiate degeneration of epithelial cells, leading to the increased regeneration seen in BPH. Hypocholesterolemic drugs have been shown to have a favorable influence on BPH, preventing the accumulation of cholesterol in the prostatic cells and limiting subsequent formation of epoxycholesterols.^[22] Every effort should be made to decrease cholesterol levels by utilizing the principles outlined in [Chapter 133](#) .

Soy

Soybeans are especially rich in phytosterols, especially beta-sitosterol. The cholesterol-lowering effects of phytosterols are well documented.^[23] Phytosterols have also been shown to improve BPH. The latest double-blind study consisted of 200 men receiving beta-sitosterol (20 mg) or placebo three times daily.^[24] The beta-sitosterol produced an increase in maximum urine flow rate from a baseline of 9.9 ml/s to 15.2 ml/s, and a decrease in mean residual urinary volume of 30.4 ml from 65.8 ml. No changes were observed in the placebo group. A 3.5 ounce serving of soybeans, tofu, or

other soyfood provides approximately 90 mg of beta-sitosterol.

An increased consumption of soy and soyfoods is associated with a decrease in the risk of prostate cancer.^[25] Much of this protection is due to the isoflavonoids genistein and daidzein, the so-called phytoestrogens of soy.^[25] ^[26] However, in addition to acting on estrogen receptors, these compounds inhibit 5-alpha-reductase. Obviously, this action could have beneficial effects in the treatment of BPH.

Drugs and pesticides

The diet should be as free as possible from pesticides and other contaminants, since many of these compounds (e.g. dioxin, polyhalogenated biphenyls, hexachlorobenzene, and dibenzofurans) increase 5-alpha reduction of steroids.^[3] Diethylstilbestrol (DES) produces changes in rat prostates histologically similar to BPH.

Cadmium

Although cadmium is a known antagonist of zinc and increases the activity of 5-alpha-reductase, its concentration in, and effects on, the prostate are unclear. Several studies have produced conflicting results.^[27] ^[28]

Botanical medicines

According to a recent review article published in the *British Journal of Urology*, plant-based medicines are much more popular prescriptions in Europe than their synthetic counterparts.^[29] Specifically in Germany and Austria botanical medicines are considered "first-line" treatments for BPH and account for greater than 90% of all drugs in the medical management of BPH. In Italy, plant extracts account for roughly 50% of all medications prescribed for BPH, while alpha-blockers and 5-alpha-reductase inhibitors account for only 5.1 and 4.8%, respectively.^[29]

There are about 30 different plant-based compounds currently available in Europe for the treatment of BPH. At least 15 of them contain *Serenoa repens* (saw palmetto) extract. Other popular botanical medicines include *Pygeum africanum*, *Urtica dioica* (stinging nettles), and Cernilton, a special flower pollen extract. Based upon careful examination of the published literature we would rate the relative effectiveness of these agents as follows:

serenoa > Cernilton > pygeum > urtica.

However, in certain situations one herbal approach may be more effective than another. In other words, even though we rate urtica lowest, in some cases urtica may produce better results than serenoa. Each plant has a slightly different mechanism of action.

The chance of clinical success with any of the botanical treatments of BPH appears to be determined by the degree of obstruction as indicated by the residual urine content. For levels less than 50 ml, the results are usually excellent. For levels between 50 and 100 ml, the results are usually quite good. Residual urine levels between 100 and 150 ml will be tougher to produce significant improvements in the customary 4–6 week period. If the residual urine content is greater than 150 ml, saw palmetto extract and other botanical medicines are not likely to produce any significant improvement on their own.

Serenoa repens (saw palmetto)

The liposterolic extract of the fruit of this palm tree (also known as *Sabal serrulata*), native to Florida, has been shown to significantly improve the signs and symptoms of BPH in numerous clinical studies (see [Ch. 110](#)). The mechanism of action is related to inhibition of DHT binding to both the cytosolic and nuclear androgen receptors, inhibition of 5-alpha-reductase, and interference with intraprostatic estrogen receptors. As a result of these multitude of effects, excellent results have been produced in numerous double-blind clinical studies. The results from these studies are discussed in [Chapter 110](#). In summary, it can be stated that roughly 90% of men with mild to moderate BPH experience some improvement in symptoms during the first 4–6 weeks of therapy. All major symptoms of BPH are improved, especially nocturia.

Cernilton

Cernilton, an extract of flower pollen, has been used to treat prostatitis and BPH in Europe for more than 35 years.^[30] It has been shown to be quite effective in several double-blind clinical studies in the treatment of BPH.^[31] ^[32] The overall success rate in patients with BPH is about 70%.^[31] Patients who respond typically have reductions of nocturia and diurnal frequency of around 70% as well as significant reductions in residual urine volume.^[32] The extract has been shown to exert some anti-inflammatory action and produce a contractile effect on the bladder while simultaneously relaxing the urethra. In addition, Cernilton contains a substance which inhibits the growth of prostate cells.^[33]

In the most recent study, the clinical efficacy of Cernilton in the treatment of symptomatic BPH was examined over a 1 year period.^[30] Seventy-nine males of an average age of 68 years (range 62–89), with a mean baseline prostatic volume of 33.2 cm, were administered 63 mg Cernilton pollen extract twice daily for 12 weeks. Average urine maximum flow rate increased from 5.1 to 6.0 ml/s. Average flow rate increased from 9.3 to 11 ml/s. Residual urine volume decreased from 54.2 ml to less than 30 ml. Clinical efficacy, based on symptoms, was as follows:

- urgency or discomfort – improved by 76.9%
- dysuria – improved by 71.4%

- nocturia – improved by 56.8%
- incomplete emptying – improved by 66.2%
- prolonged voiding – improved by 64.1%
- delayed voiding – improved by 62.2%
- intermittency – improved by 60.6%
- post-void dribbling – improved by 42.7%.

Overall, 85% of the test subjects experienced benefit: 11% reporting “excellent”, 39% reporting “good”, 35% reporting “satisfactor”, and 15% reporting “poor” as a description of their outcome.

Pygeum africanum

Pygeum is an evergreen tree native to Africa whose bark has historically been used in the treatment of urinary tract disorders. The major active components of the bark are fat-soluble sterols and fatty acids. Virtually all of the research on pygeum has featured a pygeum extract standardized to contain 14% triterpenes including beta-sitosterol and 0.5% *n*-docosanol. This extract has been extensively studied in both experimental animal studies and clinical trials in humans (see [Ch. 107](#)).

Numerous clinical trials in over 600 patients have demonstrated pygeum extract to be effective in reducing the symptoms and clinical signs of BPH, especially in early cases.^[34] However, in a double-blind study which compared the pygeum extract with the extract of saw palmetto, the saw palmetto extract produced a greater reduction of symptoms and was better tolerated.^[35] In addition, the effects on objective parameters, especially urine flow rate and residual urine content, are better in the clinical studies with saw palmetto. However, there may be circumstances where pygeum is more effective than saw palmetto. For example, saw palmetto has not been shown to produce some of the effects that pygeum has produced on prostate secretion. Of course, as the two extracts have somewhat overlapping mechanisms of actions, they can be used in combination.

Urtica dioica (stinging nettles)

Extracts of *Urtica dioica* have also been shown to be effective in the treatment of BPH. Fewer studies have been done with urtica extract compared with the other botanical medicines discussed. Two double-blind studies have shown it to be more effective than a placebo.^[35] ^[36] However, like pygeum, the results with urtica are less impressive than those with saw palmetto extract (or Cernilton). Like the extract of *Serenoa repens*, urtica extracts appear to interact with binding of DHT to cytosolic and nuclear receptors.^[37]

THERAPEUTIC APPROACH

Therapeutic goals for BPH are to:

- normalize prostate nutrient levels
- restore steroid hormones to normal levels
- inhibit excessive conversion of T to DHT
- inhibit DHT receptor binding
- limit promoters of the hyperplastic process, e.g. prolactin.

Severe BPH resulting in significant acute urinary retention may require catheterization for relief, and a sufficiently advanced case may not respond rapidly enough to therapy and may require the short-term use of an alpha-1 antagonist (e.g. Hytrin or Cordura) or surgical intervention.

Diet

Since there have been no clinical trials of the use of diet in the treatment of BPH, the following recommendations are somewhat speculative. Initially the diet should be high in protein, low in carbohydrate, low in animal fats, and high in unsaturated oils. After the patient responds, a more normal diet can be used. The patient should limit alcohol, avoid drug-, pesticide- and hormone-contaminated foods, and limit cholesterol-rich foods. Soy foods should be used regularly.

Supplements

- Zinc: 50 mg/day (picolinate preferred, maximum of 6 months; monitor copper status)
- Flax oil: 1 tbsp two times/day
- Glycine: 200 mg/day
- Glutamic acid: 200 mg/day
- Alanine: 200 mg/day.

Botanicals

- Liposterolic extract (standardized at 85–95% fatty acids and sterols): 160 mg two times/day
- Flower pollen extract (e.g. Cernilton): 63 mg two to three times/day.

Chapter 139 - Carpal tunnel syndrome

Douglas C. Lewis ND

DIAGNOSTIC SUMMARY

- Patient complains of numbness, tingling and/or burning pain on the palmar surfaces of the first three digits of the hand
- Positive Tinel's sign (tingling or shock-like pain on volar wrist percussion)
- Positive Phalen's sign (appearance of exacerbation of symptoms caused by flexion of the wrist for 60 seconds and relieved by extension).

GENERAL CONSIDERATIONS

Carpal tunnel syndrome (CTS) may be defined as unior bilateral paresthesia in the palmar aspect of the first three digits and the lateral half of the fourth digit of the hand due to median nerve compression within the carpal tunnel. Pain may be felt in the wrist, palm, and/or forearm proximal to the area of compression. There may be loss of strength in abduction and opposition of the thumb and atrophy of the opponens pollicis muscle may develop.

Etiology

Any condition which increases the volume of the structures within the carpal tunnel or causes a narrowing of the tunnel itself can result in impingement upon the median nerve. Conditions which may decrease the volume in the tunnel include deformity from subluxation of the carpals, separated distal radius and ulna, Colles' fracture, arthritic spurs, tumor, or thickening of the flexor retinaculum. Those conditions which may increase the volume of the contents of the carpal tunnel include fluid retention, fat deposition, carpal synovitis, or tenosynovitis. A large percentage of cases are idiopathic. Within these idiopathic cases some researchers have found decreased vitamin B₆ levels,^[1]^[2] while others have seen evidence of collagen dysplasia.^[3]

Risk factors and frequency of occurrence

Traumatic injury and occupational injury through repetitive use are the most obvious causes of CTS. A recent study of 501 participants (156 of whom were diagnosed with CTS) showed the following risk factors: repetitive activities with a flexed or extended wrist, hysterectomy without oophorectomy, and last menstrual period in menopausal women 6–12 months earlier.^[4] Others have found an increased incidence in pregnant women, women taking oral contraceptives, menopausal women, or patients on hemodialysis.^[5] CTS is more prevalent among women and occurs frequently between the ages of 40 and 60 years.

DIAGNOSTIC CONSIDERATIONS

Most commonly the patient will complain of pain and tingling or numbness in the hand. Symptoms are often worse at night and will awaken the patient. Patients regularly claim that relief is gained from shaking or rubbing the hand (or hands if the condition is bilateral). Occasionally patients will complain of clumsiness due to an inability to hold or feel an object.

Physical examination

Examination will reveal impaired sensation in the distribution of the median nerve. If the condition has existed for a prolonged period, atrophy of the thenar eminence and weakness of the thumb abductor will also be present. Tinel's and Phalen's tests have been the accepted tests for diagnosing CTS in the general office.

Tinel's sign is tingling in the distribution of the median nerve when tapping the nerve in the middle of the palm over the transverse carpal ligament. Phalen's test is positive when symptoms are reproduced by holding the wrist in forced flexion for 60–90 seconds.

Katz & Stirrat^[6] have devised a self-administered hand diagram that has shown an 80% sensitivity and a 90% specificity for classic or probable CTS. Other diagnostic tests include nerve conduction tests, CT scan, and MR imaging.

Differential diagnosis

The paresthesia of CTS may be confused with the paresthesia of the brachial plexus found in thoracic outlet syndrome or with paresthesia of either the radial or ulnar nerves. Likewise, a patient might complain of hand pain which may be the presenting feature of reflex sympathetic dystrophy (shoulder–hand syndrome). Impingement of the median nerve may occur below the elbow where the nerve passes under the pronator teres muscle. The specific dermatome pattern of CTS, without proximal dysfunction, should

lead the practitioner to the particular history and tests needed to establish a diagnosis of CTS. When left-sided, CTS may be confused with angina pectoris.

THERAPEUTIC CONSIDERATIONS

The majority of patients respond well to nutritional and conservative physical medicine approaches. While a few will require surgical intervention, nutritional support continues to be needed to address the underlying metabolic weakness.

Nutrition

Vitamin B supplementation

Ellis and Folkers (and co-workers) ^[1] ^[7] ^[8] ^[9] repeatedly demonstrated the efficacy of vitamin B₆ supplementation in the treatment of CTS. B₆ in the amount of 50 mg initially and increased to 200–300 mg as needed has been shown to be significantly effective in the treatment of CTS in these studies. Another study has shown vitamin B₂ to be useful in the treatment of CTS, with an even greater effect seen when B₆ and B₂ are given together.^[7] This is most likely due to riboflavin-containing enzymes which convert pyridoxine to its more active form, pyridoxal 5'-phosphate. This may support the use of this form of B₆ in the treatment of CTS. The therapeutic response may require up to 3 months of supplementation.

The increased incidence of CTS since its initial description by Phalen in 1950 parallels the increased presence of pyridoxine anti-metabolites in the environment. These include the hydrazine dyes (FD&C yellow no. 5) and drugs (INH and hydralazine), dopamine, penicillamine, oral contraceptives, and excessive protein intake.

In an attempt to determine if there is a relationship between vitamin B₆ status and symptoms of carpal tunnel syndrome (CTS), researchers measured vitamin B₆ levels, assessed ulnar and median nerve function in their wrists and hands, and noted CTS symptoms in 125 randomly selected employees at an auto parts plant.^[10] About one-third of the employees reported CTS, a quarter had median nerve dysfunction, and 10 had vitamin B₆ deficiency. After statistical analysis, researchers found no correlation between employees' blood levels of vitamin B₆ and the presence of or improvement in CTS symptoms.

The study did not analyze the effectiveness of vitamin B₆ therapy, yet several reports in the popular press and *JAMA* stated that we should “forget the vitamin B₆” in the treatment of CTS. Vitamin B₆ therapy may prove to be effective in some cases of CTS regardless of the patient's vitamin B₆ status. Despite the lack of clinical evaluation, the authors of the study concluded that

“empiric treatment for CTS with vitamin B₆ supplementation is not warranted”. Given the safety and positive clinical studies with vitamin B₆ in reasonable dosages (e.g. 25–50 mg three times daily), a trial of vitamin B₆ should still be utilized (especially before opting for surgery).

Physical medicine

Hydrotherapy

Inflammation and edema are present in CTS, causing compression of the local capillaries with resultant decreased nutrition to the median nerve, thus making the nerve fibers hyperexcitable.^[11] Contrast hydrotherapy provides a simple, efficient way to increase circulation to the area. Immersion in hot water for 3 minutes followed by immersion in cold water for 30 seconds, repeated three to five times, will increase local circulation, thereby increasing local nutrition, eliminating waste, and decreasing pain.

Immobilization

According to Cailliet,^[11] splinting of the wrist in a neutral position is required day and night for several weeks. Night-time splinting only when symptoms appear is ineffective.

Manual manipulation

Manipulation of subluxation of the carpals or separation of the distal radius and ulna may relieve pressure in the carpal tunnel, thereby relieving impingement of the median nerve.

Acupuncture

In a study of the acupuncture treatment of CTS, a positive response was demonstrated in 35 of 36 patients (14 of whom were previously treated unsuccessfully with surgery).^[12] Treatment involved puncture of PC-7 and PC-6 on the affected side.

Stretching

In 92 patients, 81 of whom had carpal tunnel syndrome compared with controls, it was found that the mean tunnel pressure was double in those with carpal tunnel syndrome. After 1 minute of stretching–loading exercises, intratunnel pressures dropped to normal levels where they remained for more than 20 minutes. Exercise includes flexing the wrists and fists with the arms extended for 5 minutes. This slow, sustained movement helps to prepare the carpal tunnel nerve for repetitive actions. These exercises should be done before work starts and during every break. The researchers suggested that

these exercises might reduce the need for surgery by 50%.^[13]

Surgery

If all other attempts at treatment fail, surgery may be a last resort. In the past, an incision has been made through the skin overlying the transverse carpal ligament. Chow^[14] has developed a less invasive endoscopic technique with a high success rate and decreased morbidity compared with the more commonly performed surgical techniques.

THERAPEUTIC APPROACH

Whenever possible, prevention is obviously best. The patient should be instructed to avoid activities which cause trauma to the median nerve through repeated wrist flexion and extension, as well as activities which cause direct trauma to the wrist. All professions that require extensive use of the hands are ones that put the patient at risk. Protecting the hands from injury, as well as maintaining wrist posture, may help in avoiding the onset of CTS.

A conservative approach to treatment should be instituted as soon as possible to avoid long term or permanent damage to the median nerve or its associated muscles. All sources of hydrazines should be avoided. If, after several months of treatment, the therapies recommended here do not produce the desired clinical effects, endoscopic surgery should be considered.

Anti-inflammatory agents have shown some usefulness in CTS and should be considered as a part of an overall treatment protocol.

Diet

Avoid foods containing yellow dyes and limit daily protein intake to a maximum of 0.75 g/kg body weight.

Supplements

- Pyridoxine: 50–200 mg/day – use pyridoxal 5'-phosphate if there is no response within 6 weeks
- Riboflavin: 10 mg/day.

Physical medicine

Contrast hydrotherapy. Immerse for 3 minutes in hot water followed by a 30 second immersion in cold water, three to five times/day. Perform daily.

Manipulation. Manipulate carpals and ensure proper spacing of distal radius and ulna.

Acupuncture. Needle PC-7 and PC-6 on the affected side.

Splint. For severe or unresponsive cases, splint the wrist in the neutral position night and day.

Regular wrist exercises.

Chapter 140 - Celiac disease

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

DIAGNOSTIC SUMMARY

- A chronic intestinal malabsorption disorder caused by an intolerance to gluten
- Bulky, pale, frothy, foul-smelling, greasy stools with increased fecal fat
- Weight loss and signs of multiple vitamin and mineral deficiencies
- Increased levels of serum gliadin antibodies
- Diagnosis confirmed by jejunal biopsy.

GENERAL CONSIDERATIONS

Celiac disease, also known as non-tropical sprue, gluten-sensitive enteropathy, or celiac sprue, is characterized by malabsorption and an abnormal small intestine structure which reverts to normal on removal of dietary gluten. The protein gluten and its polypeptide derivative, gliadin, are found primarily in wheat, barley, and rye grains. Symptoms most commonly appear during the first 3 years of life, after cereals are introduced into the diet. A second peak incidence occurs during the third decade. Breast feeding appears to have prophylactic effect, and breast-fed babies have a decreased risk of developing celiac disease.^{[1] [2] [3]} The early introduction of cow's milk is also believed to be a major etiological factor.^{[1] [2] [3] [4]} Research in the past few years has clearly indicated that breast feeding, along with delayed administration of cow's milk and cereal grains, are primary preventive steps that can greatly reduce the risk of developing celiac disease.

Epidemiology and genetics

Precise epidemiological data on celiac disease is unavailable, due in part to the fact that asymptomatic disease makes ascertainment of true prevalence rates difficult. Celiac disease appears to have a genetic etiology, as evidenced by an increased frequency of

types.^{[3] [5]} The HLA-B₈ antigen has been found in 85–90% of these celiac patients, as compared with 20–25% in normal subjects. The HLA-B₈ gene locus is believed to be linked to the immunologic recognition of antigens and specific T-cell-regulated immune responses.

There is a low prevalence of HLA-B₈ within long-standing agrarian populations, while the frequency in northern and central Europe and the north-west Indian subcontinent is much higher.^{[3] [6]} Wheat cultivation in these high HLA-B₈ areas is a relatively recent development (1000 BC). The prevalence of celiac disease is much higher in these areas compared with other parts of the world (e.g. 1:300 in south-west Ireland compared with 1:2,500 in the United States [estimated]).

Chemistry of grain proteins

Gluten, a major component of the wheat endosperm, is composed of gliadins and glutenins. Only the gliadin portion has been demonstrated to activate celiac disease. In rye, barley, and oats, the proteins that appear to activate the disease are termed secalins, hordeins, and avenins, respectively, and prolamines collectively. Cereal grains belong to the family Gramineae. The closer a grain's taxonomic relationship to wheat, the greater is its ability to activate celiac disease. Rice and corn, two grains that do not appear to activate celiac disease, are further removed taxonomically from wheat.^{[3] [7]} The taxonomic relationship of the grains is shown in [Figure 140.1](#).

Gliadins are single polypeptide chains that range in molecular weight from 30,000 to 75,000, with a very high glutamine and proline content. Gliadins have been divided into four major electrophoretic fractions: alpha-, beta-, gamma-, and omega-gliadin. Alpha-gliadin is believed to be the fraction most capable of activating celiac disease, although beta- and gamma-gliadin are also capable. Omega-gliadin does not appear to activate the disease, although it has the highest content of glutamine and proline. Gliadin that has been subjected to complete hydrolysis does not activate celiac disease in susceptible individuals, suggesting a possible relation to deficient brush border peptidase or similar defect in some other factor involved with protein digestion.^[3]

Opioid activity

Pepsin hydrolysates of wheat gluten have demonstrated opioid activity.^{[8] [9]} This activity is believed to be the factor responsible for the association between wheat consumption and schizophrenia.^{[10] [11] [12]} The hypothesis that gluten is a pathogenic factor in the development of schizophrenia is substantiated by epidemiological, clinical, and

experimental studies.^{[10] [11] [12]}

Pathogenesis

Various hypotheses have been proposed to explain the pathogenesis of celiac disease. Currently, the most likely relates to abnormalities in the immune response rather than some “toxic” property of gliadin.^[13] Sensitization to gliadin occurs both in humoral and cell-mediated immunity and it appears that T-cell dysfunction is the main factor responsible for the enteropathy.^[14] Cell-mediated mechanisms can produce in animals the characteristic lesions seen in celiac disease, i.e. crypt hyperplasia, villous atrophy, and intraepithelial lymphocyte infiltration and mitosis. Although patients with celiac disease have high titers of serum antibodies to gliadin and other food proteins, it appears that these titers are probably secondary to the increased intestinal permeability which is the result of the enteropathy produced by the T-cell defect.^[14] Of course, these immune complexes (e.g. antibody + gliadin) also contribute to the enteropathy through antibody-dependent cell-mediated cytotoxicity and activation of complement.^[3]

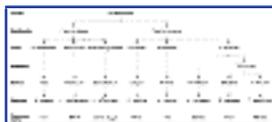

Figure 140-1 Taxonomic relationship of major cereal grains.^{[3] [24]}

Clinical aspects

The histologic lesions of celiac disease are often indistinguishable from those changes caused by tropical sprue, food allergy, diffuse intestinal lymphoma, and viral gastroenteritis. Furthermore, celiac disease will often lead to a disaccharidase deficiency, causing lactose intolerance, and the increased intestinal permeability usually results in multiple food allergies. As stated earlier, cow’s milk intolerance may precede celiac disease.^{[1] [2] [3] [4]}

Associated conditions

Conditions such as thyroid abnormalities, insulin-dependent diabetes mellitus, psychiatric disturbances (including schizophrenia), dermatitis herpetiformis, and urticaria have also been linked to gluten intolerance.^[3] A more ominous association is the increased risk for malignant neoplasms seen in celiac patients.^{[3] [15] [16]} This may be a result of decreased vitamin and mineral absorption, particularly vitamin A and carotenoids (see [Chs 67](#) and [121](#)). However, it may also be a result of gliadin-activated suppressor cell activity.^[17] Alpha-gliadin has demonstrated suppressor cell activation on the cells of celiac patients but has no effect on those of healthy controls or patients with Crohn’s disease. Two other dietary antigens, casein and beta-lactoglobulin, have failed to produce suppressor cell activation in similar experimental settings. This depression in

the immune response makes these patients more susceptible to infection and neoplasm.

Diagnosis

Jejunal biopsy is the definitive diagnostic procedure. However, the presence of the characteristic symptoms along with a positive titer for antibodies against gliadin (anti-alpha-gliadin antibodies) spares the patient the rigor of a small intestine biopsy. The ELISA test for alpha-gliadin antibodies has a diagnostic sensitivity of 100% and a diagnostic specificity of 97%.^[18] The fluorescent immunosorbent test has yielded similar impressive results (100% sensitivity and 84% specificity).^[19] It appears that both IgA and IgG gliadin antibody levels should be taken into consideration rather than relying on just one antibody assay. Anti-endomysium antibodies are now also reliable markers for celiac disease.^[20]

THERAPEUTIC CONSIDERATIONS

Diet

Once the diagnosis has been established, a gluten-free diet is indicated. This diet does not contain any wheat, rye, barley, triticale, or oats. Buckwheat and millet are often excluded as well. Although buckwheat is not in the grass family, and millet appears to be more closely related to rice and corn, they do contain prolamines with similar antigenic activity to the alpha-gliadin of wheat. A recent study of 52 adults with celiac disease suggests that modest amounts of oats may be tolerated without adverse side-effects.^[21]

In addition, other foods should be rotated, and milk and milk products should be eliminated until the patient redevelops an intestinal structure and function returns to normal.

Patient response

Usually clinical improvement will be apparent within a few days or weeks (30% respond within 3 days, another 50% within 1 month, and 10% within another month). However, 10% of patients only respond after 24–36 months of gluten avoidance.^[22]

If the patient does not appear to be responding, the following should be considered:^[3] ^[23]

- incorrect diagnosis
- the patient is not adhering to the diet or is being exposed to hidden sources of gliadin
- the presence of an associated disease or complication, such as zinc deficiency.

The latter highlights the importance of multivitamin and mineral supplementation in these patients. In addition to treating any underlying deficiency, supplementation

provides the necessary cofactors for growth and repair. Celiac disease will be refractive to dietary therapy if an underlying zinc deficiency is present.^[3] ^[23]

Pancreatic enzymes

The effect of pancreatic enzyme substitution therapy in the 2 months following the initial diagnosis of celiac disease (gluten enteropathy) was investigated in a recent double-blind study. The study sought to clarify the benefit of pancreatic enzyme therapy because previous studies had shown pancreatic insufficiency in 8–30% of celiac patients. The standard treatment of celiac disease is a gluten-free diet. In the study, patients followed a gluten-free diet and received either two capsules of pancreatic enzymes with each meal (six to 10 capsules a day with each capsule containing lipase 5,000 IU, amylase 2,900 IU, and protease 330 IU) or two placebo capsules with meals. Complete nutritional and anthropomorphic evaluations were conducted at days 0, 30, and 60. Results indicated that pancreatic enzyme supplementation enhanced the clinical benefit of a gluten-free diet during the first 30 days, but did not provide any greater benefit than the placebo after 60 days. These results support the use of pancreatic enzyme preparations

1160

in the first 30 days after diagnosis of celiac disease (see [Ch. 101](#) for a complete discussion).^[24]

THERAPEUTIC APPROACH

The therapeutic approach is quite straightforward: eliminate all sources of gliadin (see [Appendix 5](#)), eliminate dairy products initially, correct underlying nutritional deficiencies, treat any associated conditions, and determine and eliminate all food allergens. If the patient does not begin to respond within 1 month, reconsider the diagnosis and search for hidden sources of gliadin.

Maintenance of a strict gluten-free diet is quite difficult in the United States, due to the ubiquitous distribution of gliadin and other activators of celiac disease in processed foods. Patients must be encouraged to read labels carefully in order to avoid hidden sources of gliadin, such as is found in some brands of soy sauce, modified food starch, ice cream, soup, beer, wine, vodka, whisky, malt, etc. Patients should also be encouraged to consult resources for patient education and information on gluten-free recipes (see below for a list of patient education resources).

Chapter 141 - Cellulite

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

DIAGNOSTIC SUMMARY

- Demonstration of the “mattress phenomena”, i.e. pitting, bulging and deformation of the skin
- 90–98% of cases occur in women
- Symptoms may include feeling of tightness and heaviness in areas affected (particularly the legs)
- Tenderness of the skin is quite apparent when the skin is pinched, pressed upon, or vigorously massaged.

GENERAL CONSIDERATIONS

The term *cellulite* is used to describe a cosmetic defect that is cause for great distress among millions of European and American women. This French word was adopted by the lay public in the United States before American physicians and medical literature were educated in a condition that European physicians had been treating for over 150 years.^[1]

The correct English translation would be *cellulitis*. However, in the United States, cellulitis is used solely to describe a diffuse, inflammatory or infectious process involving the connective tissue, most commonly of the skin and subcutaneous structures. In cellulite there is no inflammatory or infectious process occurring. This difference in meaning in the translated term was just one source of confusion for American physicians.

Researchers have suggested that the terms *dermo-panniculois deformans* or *adiposis edematosa* be used to designate the clinical condition.^[2] In this chapter, however, the term cellulite will be used.

Histological features

The subcutaneous tissue is disturbed in cellulite. Since the thighs are the prime area of involvement, the structure of the subcutaneous tissue of the thighs is discussed here in greatest detail.

The subcutaneous tissue of the thighs is composed of

1162

Figure 141-1 The anatomical basis of cellulite.

three layers of fat, with two planes of connective tissue (ground substance) between them. The basic construction of the subcutaneous tissue of the thigh differs in men and women, as shown in [Figure 141.1](#) .

In women, the uppermost subcutaneous layer consists of what are termed large “standing fat-cell chambers”, which are separated by radial and arching dividing walls of connective tissue anchored to the overlying connective tissue of the skin (corium). In contrast, the uppermost part of the subcutaneous tissue in men is thinner and has a network of criss-crossing connective tissue walls. In addition, the corium (the connective tissue structure between the dermis and subcutaneous tissue) is thicker in men than in women.^{[1] [2]}

These basic differences in subcutaneous tissue structure are the reason cellulite is seen almost exclusively in women. A simple test to illustrate these differences is the “pinch test”. Pinching the skin and subcutaneous tissue of the thighs of women will result in the “mattress phenomenon”, i.e. pitting, bulging, and deformation of the skin, while in most men the skin will fold or furrow, but will not bulge or pit. These structural differences between men and women are responsible for most women producing the mattress phenomenon in response to the pinch test, as illustrated in [Figure 141.2](#) .^{[1] [2]}

As women age, the corium (see [Figure 141.1](#)), which is already thinner in women than in men, becomes progressively thinner and looser.^[3] This allows fat cells to migrate into this layer. In addition, the connective tissue walls between the fat-cell chambers also become thinner, allowing the fat-cell chambers to enlarge excessively (hypertrophy). The breaking down or thinning of connective tissue structures is a major contributor to the

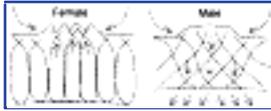

Figure 141-2 The “pinch” test.

development of cellulite and is responsible for the granular “buck-shot” feel of cellulite.^[1]
^[2]

The “mattress phenomenon” is brought about by alternating depressions and protrusions in the upper compartment systems of fat tissue. The vertical orientation of women’s fat-cell compartments, in conjunction with the weakening of the tissues noted above, is apparently what allows the protrusion of the fat cells into the lower corium.^[1] The anatomical differences between men and women are summarized in [Table 141.1](#) .

Histological examination also reveals distension of the lymphatic vessels of the upper corium and a decrease in the number of subepidermal elastic fibers.

CLINICAL FEATURES

The basic clinical features of cellulite are well known and are described above as the “mattress phenomenon”. Women comprise 90–98% of the cases, reflecting histological differences between men and women. Symptoms of cellulite include feeling of tightness and heaviness in areas affected (particularly the legs). Tenderness of the skin is quite apparent when the skin is pinched, pressed upon, or vigorously massaged.^[1] ^[2]

The areas of the body involved are typically the gluteal and thigh regions, and, to a lesser extent, the lower part of the abdomen, the nape of the neck, and the upper parts of the arms. These are the areas of the body usually affected in gynecoid (female) obesity.

Cellulite is classified in four major stages:

- *Stage 0* – the skin on the thighs and buttocks has a smooth surface when the subject is standing or lying. When the skin is pinched (pinch test), it folds and

1163

furrows but does not pit or bulge. This stage is the “normal” stage of most men and slim women.

- *Stage 1* – the skin surface is smooth while a subject is standing or lying, but the pinch test is clearly positive for the mattress phenomenon (pitting, bulging, and deformity of the affected skin surfaces). This is normal for most females, but in a male may be a sign of deficiency of androgenic hormones.
- *Stage 2* – the skin surface is smooth while a subject is lying, but when standing there is pitting, bulging, and deformity of the affected skin surfaces. This stage is common in women who are obese or over 35–40 years of age.
- *Stage 3* – the mattress phenomenon is apparent when a subject is lying or

standing. It is very common after menopause and in obesity.

TABLE 141-1 -- Sex-typical differences of the skin of the lateral thighs of men and women (16–50 years old)^[2]

| Cutis and subcutis | Men | Women |
|--|--|--|
| Epidermis | Thicker (58–77 u) | Thinner (47–62 u) |
| Corium | Thicker (1159–1798 u) | Thinner (994–1349 u) |
| Border zone of corium and subcutis | Fewer papillae adiposae | More papillae adiposae |
| Subcutis | Variably thinner | Variably thicker |
| Upper zone | Small polygonal fat-cell chambers with criss-crossing septa of connective tissue | Large, standing fat-cell chambers with radially running septa of connective tissue |
| Status protrusio cutis (so-called mattress phenomenon) | Does not develop | Develops |

Although most women consider stage 0 the cosmetic ideal, stage 1 is the best classification most can expect, due to structural predisposition.

THERAPEUTIC CONSIDERATIONS

As usual, the best approach is prevention. However, since the number and size of fat cells an individual has are largely determined by maternal prenatal nutritional status, many people have a significant predisposition. The next step is maintaining a slim subcutaneous fat layer. This is best done by exercising and maintaining a normal body weight throughout life. Slim women and female athletes have little or no cellulite.^{[1] [2]}

Lifestyle

Weight reduction and exercise

Weight reduction and exercise can be employed in the treatment of cellulite, and they should always form the primary mode of treatment. However, weight reduction should be gradual, especially in women over the age of 40. A rapid loss of weight in individuals whose skin and connective tissues are already undergoing changes from aging will often make the mattress phenomena more apparent.

Massage

Massage is very beneficial, particularly self-administered massage with the hand or brush. The physical and mechanical effects of massage improve circulation of blood and lymph. The direction of the massage should always be from the periphery to the heart.

Botanical medicines

Many cosmetic formulas and herbal preparations on the market claim to be effective in “curing” cellulite. However, the majority of these formulas have no scientific basis to support their use. In addition, long-term double-blind studies of some of the more popular cellulite treatments (e.g. Thiomucase, Nemectron, and Alec Eden-Slendertone) demonstrated them to be no more effective than placebo.^[3] ^[4] However, several botanical compounds do have confirmed effects in the treatment of cellulite.

The comprehensive herbal treatment of cellulite involves both the oral and topical administration of botanical medicines which enhance connective tissue structures. As stated earlier, the breaking down or thinning of connective tissue structures is a major contributor to the development of cellulite.

Centella asiatica

An extract of centella containing 70% triterpenic acids (asiatic acid and asiaticoside) has demonstrated impressive clinical results when given orally in the treatment of cellulite, venous insufficiency of the lower limbs, and varicose veins.^[5] ^[6] ^[7] ^[8] ^[9]

Several experimental studies have demonstrated that centella exerts a normalizing action on the metabolism of connective tissue. Specifically, it enhances connective tissue integrity by stimulating glycosaminoglycan synthesis without promoting excessive collagen synthesis or cell growth.^[5] Glycosaminoglycans are the major components of the amorphous intercellular matrix (ground substance) in which collagen fibers are embedded. The net outcome is the development of normal connective tissue that is rich in glycosaminoglycans.

The effect of centella in the treatment of cellulite appears to be related to its ability to enhance connective tissue structure and reduce sclerosis, while its action in venous insufficiency and varicose veins is a combination of its connective tissue effects and its ability to improve the blood flow through the affected limbs.

Escin

Escin is a compound isolated from the seeds of the *Aesculus hippocastanum* (horse chestnut). It has anti-inflammatory and anti-edema properties, and it decreases capillary permeability by reducing the number and size of the small pores of the capillary walls.^[10] ^[11] ^[12] Investigators have also demonstrated that escin has venotonic activity.^[13] This has been confirmed in clinical trials that demonstrate a positive effect in the treatment of varicose veins and thrombophlebitis.^[11] ^[14]

In the treatment of cellulite, escin can be given orally, or an escin/cholesterol complex can be applied topically. The topical application of escin is also of benefit in the treatment of bruises, due to escin's ability to decrease capillary fragility and swelling.

1164

Fucus vesiculosus

Fucus vesiculosus (bladderwrack) is a seaweed that has been used in the treatment of obesity since the 17th century. Its high iodine content is thought to stimulate thyroid function. Bladderwrack has also been used in toiletries and cosmetics for its soothing, softening, and toning effects.^[15]

Another major topical application of bladderwrack has been in the treatment of cellulite. Its effects in this application have not been confirmed by scientific investigation, but bladderwrack does possess general actions (soothing, softening, and toning effects) which may be of benefit in the treatment of cellulite.

Cola species

Cola is a very rich source of caffeine and related compounds. These compounds potentiate the effect of catecholamine-induced lipolysis. Topical administration of caffeine is preferable to oral administration in the treatment of cellulite, since its effects will be primarily local.

THERAPEUTIC APPROACH

It must be kept in mind that cellulite is not a disease per se. Instead, it is primarily a cosmetic disorder due to anatomical changes. Excessive subcutaneous adipose tissue or degeneration of subcutaneous connective tissue leads to fat chamber enlargement and greater visibility of the "mattress phenomenon". The basic therapeutic approach is straightforward, i.e. reduce subcutaneous fat and enhance connective tissue integrity.

Varicose veins are often found in conjunction with cellulite, and the two conditions share much in common. In particular, both appear to result largely from a loss of integrity of supporting connective tissue (see [Ch. 193](#) for further discussion).

It must be stated again that demonstration of the "mattress phenomenon" in men is a highly probable sign of androgen deficiency.^[2] This may be due to either primary or secondary hypogonadism.

Diet

A diet high in complex carbohydrates and low in refined carbohydrates and fats is very important. Weight loss should be promoted in obese individuals.

Physical measures

- Exercise: 20–30 minutes of aerobic exercise a minimum of 5 days/week
- Massage: regular self-massage of the affected area.

Botanical medicines

Oral administration

- Centella asiatica extract (70% triterpenic acid content): 30 mg three times/day
- *Aesculus hippocastanum*
 - bark of root: 500 mg three times/day
 - escin: 10 mg three times/day.

Topical application of salve, ointment, etc. (two times/ day)

- Cholesterol/escin complex: 0.5–1.5%
- Cola vera extract (14% caffeine): 0.5–1.5%
- *Fucus vesiculosus*: 0.25–75%.

Chapter 142 - Cervical dysplasia

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

DIAGNOSTIC SUMMARY

- Abnormal Papanicolaou smear (stages II–IV)
- Positive Schiller test.

GENERAL CONSIDERATIONS

Cervical dysplasia is generally regarded as a precancerous lesion with risk factors similar to those of cervical cancer.^[1] That being the case, this discussion focuses on the lifestyle and nutritional factors that appear to play a prominent role in the etiology of cervical carcinoma. These include:

- early age of first intercourse
- multiple sexual partners
- herpes simplex type II and papilloma viruses
- lower socioeconomic class
- smoking
- oral contraceptive use
- many nutritional factors.^[1] ^[2]

All risk factors appear to be closely related, as in other multifactorial diseases.

Epidemiology

Although the death rate due to invasive cervical cancer has dropped remarkably in the past 40 years (due primarily to improved screening via the Papanicolaou cytologic test; see [Table 142.1](#)), cervical cancer still accounts for approximately 7,500 deaths per year.^[1] Approximately 16,000 cases of invasive cervical cancer and 45,000 case of carcinoma in situ occur annually in the United States. Cervical cancer is still the second

most common malignancy found in women between the ages of 15 and 34 (although it can occur at any age).^[1] The peak incidence of invasive lesions occurs at age 45, while in situ lesions peak at around age 30. In contrast to invasive carcinoma, the incidence of carcinoma in situ is increasing dramatically, probably as a result of the

TABLE 142-1 -- Classification systems for Papanicolaou smears

| Numerical | Dysplasia | CIN | Bethesda system |
|------------------|--------------------------|--------------------------|------------------------|
| I | Benign | Benign | Normal |
| II | Benign with inflammation | Benign with inflammation | Normal |
| III | Mild dysplasia | CIN I | Low-grade SIL |
| III | Moderate dysplasia | CIN II | Low-grade SIL |
| III | Severe dysplasia | CIN III | High-grade SIL |
| IV | Carcinoma in situ | CIN III | High-grade SIL |
| V | Invasive cancer | Invasive cancer | Invasive cancer |

CIN, cervical intraepithelial neoplasia; SIL, squamous epithelial lesion.

increase in risk factors (e.g. early age at first intercourse, multiple sexual partners, oral contraceptive use, and cigarette smoking).

Histological considerations

Ninety-five percent of cervix cancers originate in the squamocolumnar junction of the cervical os.^[1] In adolescence, glandular epithelium covers much of the exocervix, but as adolescence progresses the columnar epithelium is gradually replaced by squamous cells. This actively growing area seems to be more susceptible to multiple insults and cancer-causing substances, probably due to the metaplastic nature of the conversion process.

Risk factors (see [Table 142.2](#))

Sexual activity

Early age at first intercourse and/or multiple sexual contacts are associated with an increased risk of cervical dysplasia/carcinoma.^{[1] [2]} From this and other evidence, it has been suggested that cervical cancer is a venereal disease, in the sense that the implicated infectious agents appear to be sexually transmitted. Furthermore, an arginine-rich histone or protamine, as well as other substances released by sperm

during degradation, could be the transmissible oncogenic agent.^[2]

TABLE 142-2 -- Risk factors in cervical dysplasia/cancer*

| Risk factor | Relative risk |
|---|----------------------|
| Smoking (10+ cigarettes/day) | 3.0 ^[6] |
| Multiple sexual partners (2–5) | 3.4 ^[6] |
| Age at first intercourse (<18) | 2.7 ^[6] |
| Oral contraceptive use (5–8 years) | 3.6 ^[6] |
| Deficient dietary beta-carotene (<5,000 IU/day) | 2.8 ^[14] |
| Deficient dietary vitamin C (<30 mg/day) | 6.7 ^[17] |

* The actual values for the absolute risk of the various risk factors are as yet somewhat controversial. The numbers listed here represent the authors' summarization of the literature. These risks are not linearly additive, since they are usually closely related, and more involved multivariate analysis is necessary to determine the actual relative risk of each.

Viruses

Two classes of virus are currently suspected of playing a causative role in cervical cancer: herpes simplex type II (HSV-II) and the human papillomavirus (HPV). The relationship between HSV-II and cervical cancer has been demonstrated in many studies, using a variety of methods:

- In one study, 23% of women with herpes infection had cervical dysplasia or cancer, compared with 2.6% of those without infection.
- HSV-II antibody titers are significantly higher in women with cervical cancer or dysplasia than in controls.
- Women with herpetic cervicitis have a four- to 16-fold increase in risk of cervical cancer/dysplasia. HPV, the etiological agent in condyloma acuminata (venereal warts), has been detected by various techniques in the cervix in patients with cervical dysplasia.

Although these agents have been shown to be related to cervical dysplasia, it has not been determined whether they reflect decreased host resistance or whether they are, themselves, the causative agents.^{[1] [2]}

Smoking

A major risk factor for cervical cancer and/or cervical dysplasia is cigarette smoking: smokers have a two- to threefold increased incidence compared with non-smokers (one study^[3] showed the increase to be as high as 17-fold in women aged 20–29).^{[3] [4] [5] [6]}

Many hypotheses have been proposed to explain this association:

- Smoking may depress immune functions, allowing a sexually transmitted agent to promote abnormal cellular development, leading to the onset of cervical dysplasia.
 - Smoking induces vitamin C deficiency, as vitamin C levels are significantly depressed in smokers.^[7]
 - Vaginal or endometrial cells may concentrate carcinogenic compounds from inhaled smoke and secrete these compounds.
 - There may be unrecognized associations between smoking and sexual behavior.^[3]
- ^[4] ^[5] ^[6]
-

1167

Oral contraceptives

The long-term use of oral contraceptives (OCs) is associated with increased risk of hospitalization for thromboembolic disease, gall bladder disease, myocardial infarction, mental illness, hyperthyroidism, and hypertension, as well as cancer of the cervix.^[6] ^[7] ^[8] ^[9] ^[10] OCs are known to potentiate the adverse effects of cigarette smoking and decrease numerous nutrient levels, including vitamins C, B₆ and B₁₂, folic acid, riboflavin, and zinc.^[11]

THERAPEUTIC CONSIDERATIONS

Nutrition

Numerous nutritional factors have been implicated in the etiology of cervical dysplasia, cancer of the cervix and other epithelial cancers (such as skin, buccal cavity, pharynx, esophagus, colon, rectum, lung, etc.). Although many single nutrients may play a significant role (particularly beta-carotene and retinoids, folic acid, pyridoxine, and vitamin C), it is important to recognize that a large proportion (67%) of patients with cervical cancer have abnormal anthropometric or biochemical parameters. Significant abnormalities have been found in height-to-weight ratios, triceps skin fold thickness, mid-arm muscle circumference, serum albumin levels, total iron-binding capacity, hemoglobin levels, creatinine height index, prothrombin time, and lymphocyte count. Many other patients have marginal but “normal” nutritional status as determined by these cursory evaluations.^[12] These suggest that multiple nutrient deficiencies are probably the rule rather than the exception.

Vitamin assessment by biochemical evaluation (plasma and red cell folate; serum beta-carotene, vitamin A, B₁₂, and C; erythrocyte transketolase for thiamin determination; erythrocyte glutathione reductase for riboflavin determination; and erythrocyte aspartate transaminase for pyridoxine determination) in patients with untreated cervical cancer shows that at least one abnormal vitamin level was present in 67% of patients, while 38% display multiple abnormal parameters.^[13] If mineral levels

are also included, it is clear that nutritional aspects play a major role in the onset of cervical dysplasia/carcinoma.

General dietary factors are also important. A high-fat intake has been associated with increased risk for cervical cancer, while a diet rich in fruits and vegetables is believed to offer significant protection against carcinogenesis, probably due to the higher intake of fiber, beta-carotenes, and vitamin C.^[5]

Vitamin A and beta-carotene

There appears to be a minor association between dietary retinoids and cervical cancer/dysplasia risk and a strong inverse correlation between beta-carotene intake and the risk of cervical cancer/dysplasia.^{[14] [15] [16]} While only 6% of patients with untreated cervical cancer have below normal serum vitamin A levels, 38% have stage-related abnormal levels of beta-carotene.^[13] Low serum beta-carotene levels are associated with a threefold greater risk for severe dysplasia,^[16] and serum vitamin A and beta-carotene levels are significantly lower in patients with cervical dysplasia than in a control group (54 vs. 104 mg/dl for vitamin A, and 21.3 vs. 13.9 mcg/dl for beta-carotene).^{[17] [18]}

Carotenes and retinols offer several types of protection. They improve the integrity and function of the epithelial tissues, provide antioxidant properties and enhance immune system function (see [Ch. 53](#)). As with other diseases, it appears that beta-carotene is more advantageous than retinoids, possibly due to greater antioxidant properties, immune-enhancing effects and its tendency to be concentrated in epithelial tissues.

Vitamin C

There is a significant decrease in vitamin C intake and plasma levels in patients with cervical dysplasia, and it has been documented that inadequate vitamin C intake is an independent risk factor for the development of premalignant cervical disease and carcinoma in situ.^{[19] [20]} Vitamin C is known to:^[11]

- act as an antioxidant
- strengthen and maintain normal epithelial integrity
- improve wound healing
- enhance immune function
- inhibit carcinogen formation.

Folic acid

Cervical cytological abnormalities related to folic acid deficiency precede hematological abnormalities by many weeks.^{[21] [22]} As folic acid is the most common vitamin deficiency in the world, and quite common in women who are pregnant or taking oral contraceptives,^{[11] [23]} it is probable that many abnormal cytological smears reflect folate deficiency rather than “true” dysplasia.^{[19] [22] [24] [25]} This is particularly applicable to cases

in which patients are taking oral contraceptives (OCs).

It has been hypothesized that oral contraceptives induce a localized interference with folate metabolism and, although serum levels may be increased, tissue levels at end-organ targets, such as the cervix, may be deficient.^{[24] [25]} This is consistent with the observation that tissue status as measured by erythrocyte folate is typically decreased (especially in those with cervical dysplasia), while serum levels may be normal or even increased.^[26] OCs are believed to induce the synthesis of a macromolecule that inhibits folate uptake by cells.

1168

Low red blood cell folate status has been shown to enhance the effect of the other risk factors for cervical dysplasia, especially human papillomavirus (HPV) infection. In other words, low RBC folate appears to be a major risk factor for HPV infection of the cervix.^{[27] [28]}

Folic acid supplementation (10 mg/day) has resulted in improvement or normalization of cytological smears in patients with cervical dysplasia in controlled clinical studies.^{[24] [27] [28]} Regression rates for patients with untreated cervical dysplasia are typically 1.3% for mild and 0% for moderate dysplasia. When treated with folic acid, the regression-to-normal rate, as determined by colposcopy/ biopsy examination, was observed to be 20% in one study,^[28] 63.7% in another,^[27] and 100% in yet another.^[24] Furthermore, the progression rate of cervical dysplasia in untreated patients is typically 16% at 4 months, a figure matched in the placebo group in one study, while the folate-supplemented group had a 0% progression rate.^[25] These figures were achieved despite the fact that the women remained on the OCs.

Since the median time required for progression from cervical dysplasia to carcinoma in situ in untreated patients ranges from 86 months for patients with very mild dysplasia to 12 months for patients with severe dysplasia, and regression is very uncommon, it is suggested that a trial of folate supplementation (along with other considerations discussed) be instituted in mild-to-moderate dysplasia, with a follow-up Pap smear and colposcopy at 3 months. Vitamin B₁₂ supplementation should always accompany folate supplementation to rule out the possibility of folate supplementation masking an underlying vitamin B₁₂ deficiency.

Pyridoxine

Vitamin B₆ status, as determined by erythrocyte transaminase, is decreased in one-third of patients with cervical cancer.^[29] Decreased pyridoxine status would have a significant effect on the metabolism of estrogens and tryptophan, as well as impairing immune response.

Selenium

Serum, dietary, and soil selenium levels have been shown to be inversely correlated with all epithelial cancers,^[30] and to be significantly lower in patients with cervical dysplasia.^[17] Increased glutathione peroxidase activity resulting from increased selenium intake is believed to be the factor responsible for selenium's anti-carcinogenic effect, although other factors may be of equal significance. Many toxic elements, such as lead, cadmium, mercury, and gold, possess selenium-antagonistic properties.^[30] The role these heavy metals may play in cervical disease has not been determined.

Copper:zinc ratio, zinc, retinol

An increase in the serum copper:zinc ratio is a non-specific reaction to inflammation or malignancy. Recently, in a study involving gynecologic cancer, it was suggested that serum copper:zinc ratio "is clinically of utmost importance, since it constitutes a tool with which to establish the extent of the cancer".^[31] A ratio above 1.95 indicated malignancy in 90% of the patients in that study. Elevated ratios are also seen in a variety of conditions, including:

- oral contraceptive use
- pregnancy
- acute and chronic infections
- chronic liver disease
- inflammatory conditions.

Therefore, the serum Cu:Zn ratio should not be used to predict malignancy in patients with these conditions. A decrease in available zinc may be the reason retinol binding protein was either absent or undetectable in 80% of dysplastic tissue samples as compared with 23.5% in normal tissue. A large study of 206 women found an inverse relationship between serum levels of both retinol and zinc and the incidence of cervical dysplasia.^[32]

Miscellaneous considerations

Vaginal depletion pack

The vaginal depletion pack (or vag pack) has a long history of effective use by naturopathic and eclectic physi-cians in the treatment of cervical dysplasia. Although its mechanism of action has not yet been elucidated, it is thought to work by promoting the sloughing of the super-ficial cervical cells, particularly those which are abnormal. It is effective in most cases of cervical dysplasia (see, Appendix 12 for a complete description of this technique).

THERAPEUTIC APPROACH

If the patient has a class IV Pap, proper treatment of cervical dysplasia involves first ascertaining if carcinoma in situ is present. Since this can be determined only through biopsy, a good relationship with a gynecologist or surgeon is recommended. (A class III Pap should also be biopsied if the patient has had recurrent abnormal Paps, has significant risk factors, or has been unresponsive to therapy.) Patients with carcinoma in situ, or a class V Pap, should undergo conization.

The basic approach is to eliminate all factors known to be associated with cervical dysplasia and to optimize the patient's nutritional status. In particular, eliminate smoking and oral contraceptive use and supplement with folic acid, beta-carotenes, and vitamin C. For most patients, the vaginal depletion pack will accelerate the rate of normalization of the cervix. For those patients

1169

who undergo conization, treatment is still necessary since the causes of cervical dysplasia are not treated by this approach. Pap smears should be repeated every 1–3 months, according to severity.

Diet

Animal product consumption should be decreased, particularly animal fats and exogenous estrogens. High-fiber foods should be encouraged.

Supplements

- Folic acid: 10 mg/day for 3 months, then 2.5 mg/day
- Pyridoxine: 50 mg three times/day
- Vitamin B₁₂ : 1 mg/day
- Beta-carotene: 200,000 IU/day
- Vitamin C: 1 g/day
- Vitamin E: 200 IU four times/day
- Selenium: 400 mcg/day
- Zinc: 30 mg/day.

Vaginal depletion pack

The vag pack should be used weekly until the Pap normalizes (unless the patient has had conization; see Appendix 12 for formulation directions).

Chapter 143 - Chlamydial genital infections

Nancy Roberts ND

DIAGNOSTIC SUMMARY

Non-gonococcal urethritis and cervicitis

- Mucopurulent discharge
- Dysuria
- Urinary frequency
- Negative cultures for *Neisseria gonorrhoea* and *Ureaplasma urealyticum* (unless concomitant infection)
- Positive direct immunofluorescent test in smears of urethral or cervical tissue
- Examination of Gram's stain of discharge at 1,000 × magnification in oil shows 4 WBC per field in urethritis and 10 WBC per field in cervicitis.

Pelvic inflammatory disease

- Dyspareunia
- Leukorrhea
- Moderate cramp-like, non-radiating lower abdominal pain
- Adnexal tenderness
- Slight elevation in temperature
- Slight elevation in white count and sedimentation rate
- May be relatively asymptomatic.

GENERAL CONSIDERATIONS

Chlamydiae are a large group of obligate intracellular parasites closely related to Gram-negative bacteria. The genus *Chlamydia* has two species: *psittaci* and *trachomatis*.^[1]^[2] *Chlamydia psittaci* is considered subhuman, usually infecting birds and domestic and wild animals.^[3] While animals are the favored hosts, humans can be infected, with the organisms typically populating the alveoli and reticuloendothelial cells.

The resulting pneumonitis (psittacosis or ornithosis) has a prolonged recovery period, and protracted infectious states have been reported to last as long as 8 years.^[4] Infected animals are very contagious, as the transmission to humans is

TABLE 143-1 -- Diseases associated with chlamydial infection

| System/disease | Serotype |
|---------------------------|--------------------------------|
| Genital tract | |
| Non-gonococcal urethritis | D–K |
| Cervicitis | D–K |
| Salpingitis | D–K |
| Lymphogranuloma venereum | L ₁ –L ₃ |
| Proctitis | D–K |
| Epididymitis | D–K |
| Eye | |
| Trachoma | A, B, Ba, C |
| Paratrachoma | D–K |
| Inclusion conjunctivitis | D–K |
| Respiratory tract | |
| Pneumonitis | |

by inhalation, and animal survivors will become healthy carriers.

Trachomatis, the human species of *Chlamydia*, has been differentiated into 15 immunotypes. Genital serotypes are D–K, with lymphogranuloma venereum (LGV) being caused by chlamydial L₁–L₃. Trachoma is caused by serotypes A, B, Ba, C.^[5] ^[6] The diseases associated with chlamydial infections are listed in [Table 143.1](#).

Epidemiology

Genital chlamydial infection

Annually, about 4 million cases of genital chlamydial infection are reported in the United States.^[7] Worldwide, it is sexually estimated that there are more than 50 million new cases making it the most common transmitted disease (STD) in developed countries.^[8] Since chlamydial infection is commonly asymptomatic,^[9] the actual incidence is probably

much higher.^[10] The primary site of infection is the urethra in men and the cervix in women.^{[11] [12] [13]} The incubation period for these genital infections is 7–28 days.^[12]

LGV comprises the most invasive strains. LGV occurs as an important STD in the tropics, but is rare in more developed countries.^[12] Symptoms involve the genitalia and inguinal lymph nodes, where the typically unilateral lymphadenopathy can be severe. The nodes can rupture and, if there is scarring of the nodes, elephantiasis of the lower extremities can develop.

The serotypes of the genital strain are also responsible for half of the pneumonias in infants.^{[12] [14]} The baby is afebrile with a slow onset in the second or third month. Respiratory rate is increased with rales and a protracted staccato cough.^[14]

Trachoma

Chlamydia trachomatis infection of the ocular epithelial cells is not sexually transmitted, but passed on by direct eye–hand–eye contact or through infected vectors such as flies.^[4] Trachoma is the leading cause of blindness in the world, affecting an estimated 500 million people.^[3] The *Chlamydia trachomatis* infection deforms the eyelids by causing them to turn under; the consequent abrasion of cornea leads to blindness.^[6]

Trachoma is not to be confused with chlamydial conjunctivitis in neonates transmitted by the genital infections of the mothers. This infection has been designated as paratrachoma by some authors.^[15]

Incubation for this form is 3–14 days. If untreated, it can last for a month.^{[12] [16]} The course of conjunctivitis with serotypes D–K is typically benign, although chronic cases can lead to permanent changes in the conjunctiva or cornea. Although blindness does not occur, effective treatment is important, and the neonate is quite infectious, requiring careful hygiene.

Microbiology

In China, *Chlamydia* was recognized over 2,000 years ago.^{[6] [13]} In Europe, chlamydial infections were described in the Middle Ages. In 1907, Halberstaedter and von Prowazek thought the organism a protozoan and called it Chlamydozaceae, or “mantled animal”. The species was first isolated and classified in the 1950s.^[17]

Chlamydia trachomatis has previously been labeled as both a bacteria and a virus. Viruses are 15–350 nm in diameter while bacteria are 300–3000 nm. *Chlamydia trachomatis* has a size of 350 nm and is considered to be a bacteria because:

- it contains both DNA and RNA
- it possesses a cell wall
- it is susceptible to sulfonamides and broad spectrum antibiotics.

It inhabits the columnar and pseudostratified columnar epithelium. Thus, *Chlamydia* has

been called a parasite of mucosal surfaces and also an energy parasite. *Chlamydia* is unable to synthesize adenosine triphosphate (ATP) and guanosine triphosphate (GTP).^[3]

The organism has a fascinating and complex life cycle, in which multiplication is possible only inside host cells, where the chlamydial invader uses the cells' energy processes. The life cycle of *Chlamydia* is represented by two phases, which are identified microscopically as elementary bodies (EB) and reticulate bodies (RB), also known as initial bodies. EBs do not multiply; they are for extracellular travel and entry into new host cells.^[18] RBs are non-infectious and responsible for multiplication within the cell. Once attachment and entry into a host cell has taken place, the EBs reorganize as RBs and reproduce by binary fission. The RBs then convert into EBs and are released from the cell to begin the cycle again. The complete cycle takes 48–72 hours.^[12]

1173

When in the reticulate body form, the organism is in a cytoplasmic vacuole which has a membrane composed, at least in part, from components of the host cell's membrane. This bit of treachery may protect the *Chlamydia* from host defenses and contribute to the low levels of antibodies and chronicity typically found. Of possibly greater concern is the suggestion that this membrane modification could trigger an autoimmune reaction.^[3]

Non-infectious impacts of chlamydial infections

A growing body of evidence is showing a connection between chlamydial infections and overgrowth in the intestines and several chronic diseases which had not been previously associated with infections. For example, chlamydial infection has now been associated with rheumatoid arthritis in some patients,^[19] Reiter's syndrome,^[20] and coronary artery disease.^[21]

DIAGNOSIS

Clinical

The diagnosis of chlamydial infection is difficult and somewhat obscure. In *Chlamydia*-positive women, roughly 50% are symptomatic, and the remaining will have only increased vaginal secretions as the most reported symptom.^[17] ^[22] Mucopurulent cervical discharge is the most frequently found sign of *Chlamydia*. This "mucopurulence" may actually, however, be a normal response to the influence of increased progesterone rather than a sign of chlamydial infection (increased polymorphonuclear leukocytes in the cervical mucus is common in women taking exogenous progesterone).^[23] Nevertheless, a mucopurulent discharge from the cervical os is an important sign of chlamydial infection.^[24]

Other symptoms are urinary frequency and abdominal pain.^[25] Thick cervical discharge is considered more suspicious than thin, yellow or greenish discharge more suspicious than clear, although 10% of one study population of *Chlamydia*-positive women had clear mucus with an increased amount of lactobacillus.^[17] Concomitant presence of other sexually transmitted infections as well as bacterial vaginosis is common.^[17] Exposure to a *Chlamydia*-positive sexual partner is valid grounds to expect infection.

It is imperative that the clinical picture be competently scrutinized, since as many as 60% of women with tubal infertility and serologic evidence of previous chlamydial infection have no history of acute salpingitis.^[26]

Laboratory

Laboratory confirmation of *Chlamydia* has been as confused as the clinical work-up. Problems of expense, laboratory expertise, and collection techniques and transport have been serious barriers to reliable reporting.^[27] In a recent issue of *College of American Pathologists Today*, it was noted that there are 27 commercial tests available for testing chlamydia in the US.^[8] The general categories of tests are:

- culture
- DNA probes
- direct fluorescent antibody (DFAs)
- immunohistochemical detection of antigen (EIAs, Chlamydiazyme, rapid tests)
- polymerase chain reaction (PCR or LCR).

The culture is still the gold standard and is the only test admissible for legal purposes. Most recently, nucleic acid amplification technologies have been developed. These tests are more sensitive while the cultures are relatively insensitive (70–85%). The cultures have a 100% specificity. An advantage of the culture is that the organism is preserved for additional studies. The CDC recommends the culture for female urethral specimens, asymptomatic men, nasopharyngeal specimens from infants, all rectal specimens and vaginal sources of prepubertal girls.

To select a testing method, parameters of age, gender, symptomatology and legal issues must be considered. There is also patient consent to consider; a person may not consent to a urogenital collection, but may consent to a urine test. Collection techniques vary with each test and gender. For the culture in women, the endocervix is the best location. Because blood will interfere, brushes are not advised. The pooling of a urethral swab with the endocervix will increase the culture sensitivity. Swab types used for the male urethra area are also used in females. For the females, the swab is inserted 1 cm and rotated once. For the male, the anterior urethra is best; the male should not urinate an hour prior to testing as this washes away the cells. The dry swab is inserted 3–4 cm and rotated. A necessity in specimen collection is the inclusion of host cells that harbor the organism. The secretions and exudate is insufficient (see [Table 143.2](#)).

The EIAs and DNA probes are listed as good screens but these non-culture tests must

be confirmed in low prevalence populations if positive and the person is asymptomatic. The PCR and LCR on endocervical

TABLE 143-2 -- Procedure for the laboratory diagnosis of chlamydial infections of the genital tract

| |
|--|
| 1. Use a cotton-tipped swab with an aluminum or plastic stick |
| 2. Wipe the cervix and urethra clean of discharge |
| 3. Take the urethra sample by inserting the swab 3–5 cm and rotating it vigorously. Take the cervical sample from the endocervical canal, leaving the swab in for at least 30 seconds; carefully remove it without touching the vaginal wall |
| 4. Transport to the laboratory in plastic |
| 5. Order the fluorescein-labeled monoclonal antibody smear test (Microtrak) |

1174

specimens are the most sensitive and specific; they are also the most expensive.

Laboratory assessments for *Chlamydia* are evolving and changing so rapidly that it will be best to check with your laboratory. It is hoped that the information presented will create an awareness of the various issues that must be considered and evaluated.

The male

Chlamydia trachomatis has been isolated from the male urethra, epididymis, prostate, and rectum. Rectal *Chlamydia* has been reported as asymptomatic and is considered relatively innocuous.^[4] Non-gonococcal urethritis (NGU) is twice as common as gonococcal urethritis, and approximately half of all NGU has a chlamydial etiology.^{[12] [28]} It has been estimated that more than 800,000 cases of symptomatic chlamydial urethritis occur annually in men.^[29] Other causes are *Ureaplasma urealyticum*, herpes simplex, and *Trichomonas vaginalis*.^[30] Approximately 45% of patients with gonococcal urethritis have concomitant chlamydial infection.^{[28] [31]} The urethral signs and symptoms of chlamydia are also indistinguishable from gonorrhea (discharge and/or pyuria/dysuria). If symptoms present, it will be 1–3 weeks following exposure. Sexual partners should be named and treated.^{[22] [32]} However, 25% are asymptomatic.^[26]

THERAPEUTIC CONSIDERATIONS

Alternative therapies for *Chlamydia trachomatis* are rarely found in the scientific literature. Recurrence of *Chlamydia* in men and women who have received antibiotic regimens is a significant problem. Although there is always the question of reinfection rather than recurrence of the previous infection, at least one study of antibiotic-treated women found reappearance to be due strictly to recurrence, not reinfection.^{[31] [33]} This

suggests the use of non-drug or adjunctive therapeutic approaches.

Immune support

Establishment of effective immune function is tremendously important in the treatment of chlamydial infections. This topic is thoroughly discussed in [Chapter 53](#) and will not be duplicated here. Particularly important nutrients are zinc and vitamin E, both of which have been shown to boost immune function and to be effective in the treatment of chlamydial infections.^[34] ^[35]

Berberine

To specifically target *Chlamydia trachomatis*, local and oral applications of berberine-containing herbs are very important. Berberine has been shown to be very effective in the treatment of ocular *Chlamydia trachomatis* (see [Ch. 91](#)).^[36] ^[37] Although apparently there have been no studies of the use of berberine in genital *Chlamydia trachomatis* infections, it is reasonable to expect it to be equally effective. Local application can be accomplished using berberine-containing douches and the vaginal depletion pack (see Appendix 12). Oral treatment can be in the form of tinctures, powdered dried root, and fluid and solid extracts of *Hydrastis canadensis*, *Berberis vulgaris*, and *Berberis aquifolium*.

Providone iodine

Betadyne, or other sources of providone iodine, has been shown to be an effective antichlamydial agent.^[38] It can be used to clean the cervix and in a douche.

Lactobacilli

Women who do not have vaginal lactobacilli are more likely to have vaginal *Chlamydia trachomatis*.^[39] Vaginal suppositories with H₂ O₂ -positive lactobacilli are likely to prevent recurrence and reinfection. Unfortunately, most commercially available products contain lactobacilli that do not produce H₂ O₂ or strains derived from dairy foods, which are unable to bind to vaginal epithelial cells.

THERAPEUTIC APPROACH

Reinfection is a common complication, thus making the identification and treatment of possibly infected sexual partners mandatory for effective treatment. Abstinence is recommended until mutual treatment is complete. As discussed above, since the infection may become asymptomatic, and recurrence after therapy is common, careful laboratory monitoring is important to ensure eradication of the infection. Patient follow-up and education are particularly important with this microbe. For complete directions on support of the immune system, see [Chapter 53](#) .

Supplements

- Vitamin C: 1,000 mg four times/day
- Vitamin E: 400 IU/day
- Beta-carotene: 200,000 IU/day
- Zinc: 30 mg/day (picolinate form).

Botanical medicine

Hydrastis canadensis dosages:

- dried root: 2.0–3.0 g three times/day
- tincture (1:5): 6–12 ml three times/day
- fluid extract (1:1): 1.0–2.0 ml three times/day
- solid extract (4:1): 250 mg three times/day.

1175

Additionally, for women:

- vaginal depletion pack: three times/week until negative cultures and then once a week as appropriate (see Appendix 12)
- betadyne douche: 2 tbsp/quart of water alternating with vag packs.

Note. Since *Chlamydia trachomatis* is responsible for up to 50% of all cases of acute salpingitis, and ineffective treatment and undiagnosed infection often lead to tubal fibrosis and infertility, effective and timely care is very important. If the patient does not rapidly respond to treatment, if there is significant PID, or if repeat direct immunofluorescence shows continued infection, the patient should be treated with antibiotics in addition to the therapies suggested here.

Chapter 144 - Congestive heart failure

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

DIAGNOSTIC SUMMARY

- Left ventricular failure – exertional dyspnea, cough, fatigue, orthopnea, cardiac enlargement, rales, gallop rhythm, and pulmonary venous congestion
- Right ventricular failure – elevated venous pressure, hepatomegaly, dependent edema
- Both left and right ventricular failure – combinations of the above
- Diagnosis confirmed by echocardiograph.

GENERAL CONSIDERATIONS

Congestive heart failure (CHF) refers to an inability of the heart to effectively pump enough blood. The contractile function of the heart is governed by five primary factors:

- the contractile state of the myocardium
- the pre-load of the ventricle
- end-diastolic volume
- the impedance to left ventricular ejection
- the heart rate.

Chronic CHF is most often due to long-term effects of high blood pressure, previous myocardial infarction, disorder of a heart valve, cardiomyopathy, or chronic lung disease. These conditions produce CHF by impacting one or more of the primary determinants of myocardial contractile function (precipitating or exacerbating factors in CHF are presented in [Table 144.1](#)).

One of the most serious consequences of reduced cardiac output is reduction in renal blood flow and glomerular filtration rate, which in turn leads to sodium and fluid retention. Adding more stress is activation of the renin–angiotensin–aldosterone system,

leading to an increase in peripheral vascular resistance, increased ventricular afterload, and increased levels of circulating vasopressin which also serves as a vasoconstrictor and antidiuretic.

TABLE 144-1 -- Precipitating or exacerbating factors in CHF

| |
|---------------------------------|
| • Increased demand |
| —anemia |
| —fever |
| —infection |
| —fluid overload |
| —increased sodium intake |
| —high environmental temperature |
| —renal failure |
| —hepatic failure |
| —thyrotoxicosis |
| —arteriovenous shunt |
| —respiratory insufficiency |
| —emotional stress |
| —pregnancy |
| —obesity |
| • Arrhythmias |
| • Pulmonary embolism |
| • Ethanol ingestion |
| • Nutrient deficiency |
| • Uncontrolled hypertension |
| • Drugs |
| —beta-adrenergic blockers |
| —anti-arrhythmic drugs |
| —sodium-retaining drugs: |
| —steroids |

—non-steroidal anti-inflammatory drugs

In an attempt to compensate for the reduced cardiac output, several compensatory mechanisms occur: tachycardia, increased sympathetic nervous system activation, ventricular dilation, and hypertrophy. These mechanisms are a bit of a mixed blessing. For example, while the increase in sympathetic activity increases cardiac output by increasing heart rate and force of contraction, it also leads to increased vascular resistance.

The signs and symptoms of CHF depend upon which ventricle has failed. The clinical symptoms of left ventricular failure are dominated by symptoms of pulmonary congestion and edema, while right ventricular failure is characterized by signs of systemic venous congestion and peripheral edema. Weakness, fatigue, and shortness of breath are common to both right and left ventricular failure as well as biventricular failure.

DIAGNOSTIC CONSIDERATIONS

CHF is most effectively treated via natural measures in the early stages. Hence, early diagnosis and prevention by addressing causative factors are imperative. The first symptom of CHF is usually shortness of breath. A chronic non-productive cough may also be the first presenting symptom. Patients suspected of having CHF should have an extensive cardiovascular evaluation, including a complete physical examination, to look for the characteristic signs of CHF (peripheral signs of heart failure, enlarged and sustained left ventricular impulse, diminished first heart sound, gallop rhythm, etc.), electrocardiogram, and echocardiogram.

TABLE 144-2 -- Stages of congestive heart failure as defined by the New York Heart Association

| Stage | Symptoms |
|-----------|---|
| Stage I | Patient is symptom-free at rest and with treatment |
| Stage II | Patient experiences impaired heart function with moderate physical effort. Shortness of breath with exertion is common. There are no symptoms at rest |
| Stage III | Even minor physical exertion results in shortness of breath and fatigue. There are no symptoms at rest |
| Stage IV | Symptoms such as shortness of breath and signs such as lower extremity edema are present when the patient is at rest |

THERAPEUTIC CONSIDERATIONS

In the initial stages of CHF, natural measures designed to address the underlying cause (e.g. hypertension) or improve the metabolic functions of the myocardium (described

below, as well as measures described in [Ch. 129](#)) are often quite effective. In later stages, however, medical treatment involving the use of diuretics and angiotensin-converting enzyme (ACE) inhibitors and/or digitalis glycosides is indicated in most cases. The measures described here can be used as adjunctive therapy in these more severe cases. The New York Heart Association staging system for CHF can be used in an effort to better clarify likely respondents to natural therapy alone (see [Table 144.2](#)). In general, excellent clinical results can be expected in stages I and II with the use of the natural measures described below.

Nutritional supplements

The natural approach focuses on improving myocardial energy production as CHF is always characterized by an energy depletion status. This impaired energy production is often the result of nutrient or coenzyme deficiency (e.g. magnesium, thiamin, coenzyme Q₁₀ , and carnitine). The dietary recommendations given in [Chapter 159](#) are appropriate for most patients with CHF, especially if the CHF is due to long-term hypertension. Of particular importance is a diet low in sodium and high in potassium. A high intake of sodium greatly exacerbates the hemodynamic aspects of CHF. Sodium intake should be restricted to below 1.8 g daily.

Magnesium

Low magnesium levels (particularly white blood cell magnesium) are common findings in patients with CHF. This association is extremely significant as magnesium levels have been shown to correlate directly with survival rates. In one study, CHF patients with normal levels of magnesium had 1 and 2 year survival rates of 71 and

61%, respectively, compared with rates of 45 and 42%, respectively, for patients with lower magnesium levels.^[1] These results are not surprising, considering that magnesium deficiency is associated with cardiac arrhythmias, reduced cardiovascular prognosis, worsened ischemia, and increased mortality in acute myocardial infarction.

The magnesium deficiency is probably due to a combination of inadequate intake and increased wasting due to overactivation of the renin–angiotensin–aldosterone system, as commonly seen in patients with heart failure.

In addition to providing benefits of its own in CHF, magnesium supplementation also prevents the magnesium depletion caused by the conventional drug therapy for CHF, i.e. digitalis, diuretics, and vasodilators (beta-blockers, calcium channel-blockers, etc.). Magnesium supplementation has even been shown to produce positive effects in CHF patients receiving conventional drug therapy, even if serum magnesium levels are normal.^[2] Finally, magnesium is a critical nutrient for the production of ATP.

Typical dosages are 200–400 mg three times per day of magnesium in the citrate form.

Thiamin

Interest has recently risen regarding the potential role of thiamin deficiency in congestive heart failure (CHF). Thiamin was the first B vitamin discovered, hence its designation as vitamin B₁. It is well established that thiamin deficiency can result in the cardiovascular manifestations of “wet beri-beri”, sodium retention, peripheral vasodilation, and heart failure. It is also well-established that furosemide (Lasix), the most widely prescribed diuretic, has been shown to cause thiamin deficiency in animals and patients with CHF.

Although severe thiamin deficiency is relatively uncommon (except in alcoholics), many Americans do not consume the RDA of 1.5 mg, especially elderly patients in hospitals or nursing homes. In an attempt to gauge the prevalence of thiamin deficiency in the geriatric population, 30 unselected consecutive outpatients visiting a university outpatient clinic in Tampa, Florida, were tested for thiamin levels. Depending upon the thiamin measurement, plasma vs. red blood cell thiamin, low levels (defined as a level below the lowest reference range for younger aged groups) were found in 57 and 33%, respectively.^[3]

These results highlight the growing body of evidence that a significant percentage of the geriatric population is deficient in one or more of the B vitamins. Given the essential role of thiamin and other B vitamins to normal human physiology, especially cardiovascular and brain function, routine B vitamin supplementation appears to be worthwhile in this age group.

The association between thiamin deficiency and long-term furosemide use was discovered in 1980 when it was shown that after only 4 weeks of furosemide use, thiamin concentrations and the activity of the thiamin-dependent enzyme transketolase was significantly reduced. The first study looking at thiamin as a potential adjunct in the treatment of CHF showed only modest benefits. However, several subsequent studies have shown that daily doses of 80–240 mg of thiamin daily improved the clinical picture as measured by a 13–22% increase of left ventricular ejection fraction.^[4] This is quite significant as an increase in ejection fraction is associated with a greater survival rate in patients with CHF.

Given the possible benefit, lack of risk, and low cost of thiamin supplementation, administration of 200–250 mg of thiamin daily appears warranted in patients with CHF.

Carnitine

Normal heart function is critically dependent on adequate concentrations of carnitine and coenzyme Q₁₀ (discussed below). These compounds are essential in the transport of fatty acids into the myocardium and mitochondria for energy production. While the

normal heart stores more carnitine and coenzyme Q₁₀ than it needs, if the heart does not have a good supply of oxygen, carnitine and coenzyme Q₁₀ levels quickly decrease. Both of these agents have shown benefit in the treatment of CHF.

Several double-blind clinical studies have shown carnitine supplementation to improve cardiac function in patients with CHF.^[5] ^[6] ^[7] In one double-blind study, only 1 month of treatment (500 mg three times daily), was needed to cause significant improvement in heart function.^[6] The longer carnitine was used, the more dramatic was the improvement. After 6 months of use, the carnitine group demonstrated an increase in the maximum exercise time of 25.9% and a 13.6% increase in ventricular ejection fraction. In another double-blind study in similar patients, at the end of 6 months of treatment maximum exercise time on the treadmill increased 16.4% and the ejection fraction increased by 12.1%.^[7]

Coenzyme Q₁₀

Numerous studies have also shown CoQ₁₀ supplementation to be extremely effective in the treatment of CHF. Most of these studies utilized CoQ₁₀ as an adjunct to conventional drug therapy. In one of the early studies, 17 patients with mild congestive heart failure received 30 mg/day of CoQ₁₀.^[8] All patients improved and nine (53%) became asymptomatic after 4 weeks. In another early study, 20 patients with congestive heart failure due to either atherosclerosis or high blood pressure were treated with CoQ₁₀ at a dosage of 30 mg/day for 1–2 months.^[9] Fifty-five per cent of the patients reported

subjective improvement; 50% showed a decrease in New York Heart Association (NYHA) classification; and 30% showed a “remarkable” decrease in chest congestion as seen on chest X-ray. Patients with mild disease tended to improve more often than those with more severe disease. Subjective improvements in these patients were confirmed by various objective tests, including increased cardiac output, stroke volume, cardiac index, and ejection fraction. These results were consistent with CoQ₁₀ producing an increased force of heart muscle contraction (a positive inotropic effect) similar to, but less potent than, digitalis.^[10] ^[11]

Three more recent studies have also shown CoQ₁₀ to be effective in significantly improving heart function in patients with CHF. In a double-blind Scandinavian study of 80 patients, participants were given either CoQ₁₀ (100 mg/day) or placebo for 3 months and then crossed. The improvements noted with CoQ₁₀ were found to be actually more positive than those obtained from conventional drug therapy alone.^[12] In another double-blind study, 641 patients with CHF received either CoQ₁₀ (2 mg/kg body weight) or a placebo for 1 year.^[13] The number of patients requiring hospitalization or

experiencing serious consequences due to CHF was significantly reduced in the CoQ₁₀ group compared with the placebo group.

In the most recent, and largest, study to date, a total of 2,664 patients in New York Heart Association (NYHA) classes II and III were enrolled in an open study in Italy.^[14] The daily dosage of CoQ₁₀ was 50–150 mg orally for 90 days, with the majority of patients (78%) receiving 100 mg/day. After 3 months of CoQ₁₀ treatment, the proportions of patients with improvement in clinical signs and symptoms were as follows:

- cyanosis – 78.1%
- edema (fluid retention) – 78.6%
- pulmonary edema – 77.8%
- enlargement of liver area – 49.3%
- venous congestion – 71.81%
- shortness of breath – 52.7%
- heart palpitations – 75.4%
- sweating – 79.8%
- subjective arrhythmia – 63.4%
- insomnia – 66.2%
- vertigo – 73.1%
- night-time urination – 53.6%.

Improvement of at least three symptoms occurred in 54% of patients, indicating a significantly improved quality of life with CoQ₁₀ supplementation. The results also showed a low incidence of side-effects – only 36 patients (1.5%) reported mild side-effects attributed to CoQ₁₀.

Arginine

Another amino acid of value in CHF is arginine, although via a totally different mechanism from other nutrients. One of the experimental findings in patients with CHF is that they are less able to achieve peripheral vasodilation during exercise. Since the body makes the natural vasodilator nitric acid from arginine, several researchers have evaluated its efficacy in improving CHF. The first study of orally administered arginine has shown promising results. In a randomized, double-blind, placebo-controlled study of 5.6–12.6 g/day of oral L-arginine, peripheral blood flow was found to increase by 29%, 6 minute walking distance increased by 8% and arterial compliance increased 19%.^[15]

Botanical medicines

***Crataegus oxyacantha* (Hawthorne)**

Preparations of *Crataegus* sp. appear to be quite useful in CHF, especially in the early stages as a sole agent and in the latter stages in combination with digitalis cardioglycosides. The effectiveness of crataegus in CHF has been repeatedly

demonstrated in double-blind studies.^[16] ^[17] ^[18] In one of the most recent studies, 30 patients with congestive heart failure (NYHA stage II) were assessed in a randomized double-blind study.^[17] Treatment consisted of a crataegus extract standardized to contain 15 mg procyanidin oligomers per 80 mg capsule. Treatment duration was 8 weeks, and the substance was administered at a dose of one capsule taken twice a day. The group receiving the crataegus extract showed a statistically significant advantage over placebo in terms of changes in heart function as determined by standard testing procedures. Systolic and diastolic blood pressures were also mildly reduced. Like all other studies with crataegus extracts, no adverse reactions occurred.

In another study, 78 patients with CHF (NYHA stage II) were given either 600 mg of standardized crataegus extract or placebo daily.^[18] The parameter used to measure effectiveness was the patient's working capacity on a bicycle ergometer. After 56 days of treatment, the crataegus group had a mean increase of 25 watts compared with the placebo group's increase of only 5 watts. In addition, the crataegus group also experienced a mild, but significant, reduction in systolic blood pressure (drop from 171 to 164 mmHg) and heart rate (115 to 110 beats/minute). There was no change in blood pressure or heart rate with the placebo group.

Terminalia arjuna

A traditional Ayurvedic botanical for cardiac failure has recently been shown to be very effective in a controlled clinical study. Twelve patients with severe refractory congestive heart failure (class IV NYHA) received an extract (500 mg every 8 hours) from the bark or placebo

for 2 weeks. Those receiving the medicinal plant experienced, according to echocardiogram evaluation, statistically significant improvement in several parameters of cardiac function, such as end-systolic volume and left ventricular ejection fractions. A second, uncontrolled, phase of the study utilizing a combination of *Terminalia arjuna* with conventional medication found that, after 2 years, nine patients showed a remarkable improvement to NYHA class II with the other three improving to class III.^[19]

THERAPEUTIC APPROACH

Treatment with diet and the natural agents described above is effective in early stages of CHF, i.e. NYHA stages I and II. In latter stages, adjunct drug therapy is usually necessary. Treatment is designed to address underlying pathophysiology and to improve myocardial function through improved energy production.

Diet

Achieve ideal body weight, restrict sodium intake (below 1.8 g daily), increase the consumption of plant foods in the diet; reduce the intake of saturated fat, and follow the

other dietary guidelines given for lowering blood pressure.

Nutritional supplements

Magnesium: 200–400 mg three times daily

Thiamin: 200–250 mg daily

L-Carnitine: 300–500 mg three times daily

Coenzyme Q₁₀ : 150–300 mg daily.

Botanical medicines

- Hawthorn extract (1.8% vitexin-4'-rhamnoside or 10% procyanidin content): 100–200 mg three times daily.

Chapter 145 - Cystitis

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

DIAGNOSTIC SUMMARY

- Burning pain on urination
- Increased urinary frequency, nocturia
- Turbid, foul-smelling, or dark urine
- Lower abdominal pain
- Urinalysis shows significant pyuria and bacteriuria.

GENERAL CONSIDERATIONS

Bladder infections in women are surprisingly common: 10–20% of all women have urinary tract discomfort at least once a year, 37.5% of women with no history of urinary tract infection will have one within 10 years, and 2–4% of apparently healthy women have elevated levels of bacteria in their urine, indicative of an unrecognized urinary tract infection. Women with a history of recurrent urinary tract infections will typically have an episode at least once every year.^[1] Recurrent bladder infections can be a significant problem for some women since 55% will eventually involve the upper urinary tract, i.e. the kidneys. Recurrent kidney infection can cause progressive damage, resulting in scarring and, for some, kidney failure.

Urinary tract infections are much less common in males than females, except infants, and in general indicate an anatomical abnormality, a prostate infection or rectal intercourse. Incidence by age and sex is listed in [Table 145.1](#).

TABLE 145-1 -- Incidence of urinary tract infection according to age and sex^[2]

| Age group | Incidence | Male:female ratio |
|-----------|-----------|-------------------|
| Neonatal | 1.0 | 1.5:1 |

| | | |
|------------------|---------|-------|
| Preschool age | 1.5–3.0 | 1:10 |
| School age | 1.2 | 1:30 |
| Reproductive age | 3–5 | 1:50 |
| Geriatric | 10–30 | 1:1.5 |

1184

Causes

Urine, as it is secreted by the kidneys, is sterile until it reaches the urethra which transports it from the bladder to the urethral opening. Bacteria can reach the urinary tract by ascending from the urethra or, much less commonly, through the bloodstream. Bacteria are introduced into the urethra from fecal contamination or, in women, vaginal secretions. Important factors in aiding or perpetuating an ascending infection are anatomical or functional obstructions to flow (allowing pooling of urine) and immune system dysfunction. Free flow, large urine volume, complete emptying of the bladder, and optimal immune function are important antibacterial defenses.

The body has several defenses against bacterial growth in the urinary tract:^[4]

- urine flow tends to wash away bacteria
- the surface of the bladder has antimicrobial properties
- the pH of the urine inhibits the growth of many bacteria
- in men the prostatic fluid has many antimicrobial substances
- the body quickly secretes white cells to control the bacteria.

Many factors are associated with increased risk of bladder infections: pregnancy (twice as frequent), sexual intercourse (nuns have 1/10 the incidence), homosexual activity (in males), mechanical trauma or irritation, and perhaps most important, structural abnormalities of the urinary tract which block the free flow of urine.

Reflux of infected urine from the bladder into the upper urinary tract is important in the development of kidney infections and the establishment of recurrent infections. [Table 145.2](#) lists the types and frequencies of abnormalities associated with chronic urinary tract infections.

DIAGNOSIS

The diagnosis of bladder infection is imprecise since clinical symptoms and the presence of significant

TABLE 145-2 -- Results of urologic evaluation of women with persistent bacteria in their urine, recurrent urinary infections, or kidney infections^[1]

| Diagnosis | Percentage of subjects |
|---|------------------------|
| Normal | 60 |
| Abnormalities of unknown significance | 10–20 |
| Kidney structural abnormalities or scarring | 15 |
| Kidney stones | 2–8 |
| Reflex of urine | 20 (children) |
| | 5 (adults) |
| Hydronephrosis | <1 |
| Bladder outlet obstruction | <1 |
| Miscellaneous urinary tract lesions | <1 |

TABLE 145-3 -- Results of women presenting with typical urinary tract infection symptoms and no fever, vaginal symptoms, or toxicity^[3]

| Diagnosis | Percentage of subjects |
|--------------------------------------|------------------------|
| Upper urinary tract infection | 20 |
| Bladder infection | 40 |
| Low levels of bacteria in urethra | 16 |
| Urethral chlamydia | 8 |
| Unsuspected vaginitis | 4 |
| Other (herpes, gonorrhea, PID, etc.) | 12 |

amounts of bacteria in the urine do not correlate well. As can be seen from [Table 145.3](#), only 60% of women with the typical symptoms of urinary tract infection actually have significant levels of bacteria in their urine. Equally important, however, is the fact that 20% have the more potentially serious involvement of the upper tract.

In general, the diagnosis is made according to signs and symptoms and urinary findings. Microscopic examination of the infected urine will show high levels of white blood cells and bacteria. Culturing the urine will determine the quantity and type of bacteria involved. As shown in [Table 145.4](#), *E. coli* (from the colon) are by far the most common. The presence of fever, chills, and low back pain can indicate involvement of the kidneys. Those with recurrent infections should be examined by intravenous urogram to determine if a structural abnormality is present.

Collection of urine specimen for culture

The optimal clinical method for obtaining a urine sample is the voided midstream specimen. It involves cleaning the urethral meatus or vaginal vestibule before collecting

the sample. A satisfactory technique for the female consists of spreading the labia and cleansing the area with two gauze sponges moistened with a cleansing solution and a dry gauze sponge. The washing is accomplished by making a single front-to-back motion with

TABLE 145-4 -- Bacteriologic findings in outpatients and inpatients with urinary tract infections²

| Bacteria species | Outpatients | Inpatients |
|-----------------------------------|--------------------|-------------------|
| <i>Escherichia coli</i> | 89.2 | 52.7 |
| <i>Proteus miribili</i> | 3.2 | 12.7 |
| <i>Klebsiella pneumonia</i> | 2.4 | 9.3 |
| <i>Enterococci</i> | 2.0 | 7.3 |
| <i>Enterobacter aerogenes</i> | 0.8 | 4.0 |
| <i>Pseudomonas aeruginosa</i> | 0.4 | 6.0 |
| <i>Proteus sp.</i> | 0.4 | 3.3 |
| <i>Serratia marcescens</i> | 0 | 3.3 |
| <i>Staphylococcus epidermidis</i> | 1.6 [*] | 0.7 |
| <i>S. aureus</i> | 0 | 0.7 |

* Recent evidence suggests that this may be more prevalent than is currently thought – in sexually active college-age women it may account for as much as 20% of asymptomatic urinary tract infections.

each of the two moist sponges and then the dry sponge. While the labia are still held apart, a small amount of urine is allowed to pass into the toilet (or bedpan); then a midstream specimen is collected in a sterile container and immediately closed.

Occasionally the urine will have to be collected via catheterization. This is more invasive to the patient and carries with it a 1–2% chance of initiating a urinary tract infection as a result of introducing microorganisms into the bladder. Suprapubic aspiration is the most accurate method of urine collection, but obviously it is the most invasive as well.

Examination of the collected urine

Several methods are routinely employed in the detection of bacteria in the urine. They range from the use of dipsticks to microscopic examination and culture. For most accurate determinations, the urine should be examined within one hour. If examination must be delayed, refrigeration at 5°C will preserve the urine for most routine

examinations. However, culturing requires that the urine not be refrigerated for more than 8 hours.

Dipstick methods

The modern examination of urine specimens typically involves the use of reagent strips which are dipped into urine and removed. Parts of the dipstick are impregnated with chemicals that react with specific substances in the urine to produce various colors. Color standards are provided against which the color can be compared. Careful attention must be paid to match the dipstick to the color standard at the appropriate time. Instructions accompany commercially prepared dipsticks.

Dipsticks are invaluable for qualitative and rough quantitative analysis. Typically, they provide information on pH, protein, glucose, ketones, bilirubin, hemoglobin, nitrite, and urobilinogen. Some dipsticks also allow for detection of white blood cells and bacteria (including semi-quantitative cultures).

As many common organisms contain enzymes which reduce nitrate in the urine to nitrite (see [Table 145.5](#)), measuring urinary nitrite provides an inexpensive and

TABLE 145-5 -- Organisms which reduce nitrates to nitrites

| Organisms which reduce | Organisms which do not |
|-----------------------------------|-------------------------------|
| <i>Citrobacter</i> spp. | <i>Gonococcus</i> |
| <i>Escherichia coli</i> | <i>Streptococcus faecalis</i> |
| <i>Klebsiella pneumonia</i> | <i>Tuberculosis</i> |
| <i>Proteus</i> spp. | |
| <i>Pseudomonas</i> spp. | |
| <i>Serratia marcescens</i> | |
| <i>Shigella</i> | |
| <i>Staphylococcus</i> spp. (most) | |

rapid detection of significant bacteriuria, but it should be confirmed by culture.

Microscopic examination

Microscopic examination should be performed within the first hour after collection. A drop of fresh urine or a drop of resuspended sediment from centrifuged fresh urine is placed on a microscope slide, covered with a cover glass, and examined with the high-dry objective under reduced illumination. The presence of more than 10 bacteria per field in an unstained specimen suggests a bacteria count of over 100,000/ml of urine. Smears may be also made using a Gram stain and examined under the oil immersion objective. The presence of white blood cells further indicates an infectious process. The presence of large quantities of protein and/or WBC casts in the

micrographic examination may be indicative of renal involvement, most commonly pyelonephritis.

Urine culture

Typically, only quantitative cultures are used. After introduction of diluted urine to the suitable medium and incubation, the colonies are counted and multiplied by the dilution factor to yield the bacterial count/ml. Bacteriuria is considered significant if it is over 100,000/ml, but even the presence of 1,000 colonies/ml is considered clinically significant in the presence of symptoms characteristic of urinary tract infection. Most physicians are now employing semi-quantitative tests using dipsticks or glass slides coated with culture media. Colonies are counted or appearance is compared as soon as 12–24 hours later. For recurrent or chronic infection, sensitivity studies are often performed.

In more than 95% of urinary tract infections, a single bacterial species is the problem. When mixed bacterial species are grown, the probability of contamination is high.^[2] *Staphylococcus epidermidis*, diphtheroids and lactobacilli are commonly found in the distal urethra but rarely cause urinary tract infections.

THERAPEUTIC CONSIDERATIONS

The primary goal in the natural approach to treating infectious cystitis is enhancing normal host protective measures against urinary tract infection. Specifically this refers to enhancing the flow of urine by achieving and maintaining proper hydration, promoting a pH which will inhibit the growth of the organism, preventing bacterial adherence to the endothelial cells of the bladder, and enhancing the immune system. In addition, there are several botanical medicines with antimicrobial activity that can be employed.

Chronic interstitial cystitis

In chronic interstitial cystitis, a persistent form of cystitis not due to infection, in addition to the general measures given below, the focus is on enhancing the integrity of the interstitium along with the lining of the bladder wall. Eliminating food allergies appears to be a valid goal even though the association of food allergies and cystitis is not well established. Food allergies have been shown to produce cystitis in some patients.^{[5] [6] [7]} Repeated ingestion of a food allergen could easily explain the chronic nature of interstitial cystitis. *Centella asiatica* appears to address some of the other pathological features of chronic interstitial cystitis. Specifically, centella extracts have been shown to improve the integrity of the connective tissue that composes the interstitium as well as healing ulcerations of the bladder.^{[8] [9]} For a complete discussion of the pharmacology, see [Chapter 74](#) .

General measures

Increasing urine flow

Increasing urine flow can be easily achieved by increasing the amount of liquids consumed. Ideally, the liquids should be in the form of pure water, herbal teas, and fresh fruit and vegetable juices diluted with at least an equal amount of water. The patient should be encouraged to drink at least 2 litres of liquids from this group, with at least half of this amount being water. The patient should also be advised to avoid such liquids as soft drinks, concentrated fruit drinks, coffee, and alcoholic beverages.

Cranberry juice

Of particular benefit in the treatment of urinary tract infections are cranberries and cranberry juice, which have been shown to be quite effective in several clinical studies.^{[10] [11] [12]} In one study, 0.5 litres/day of cranberry juice was shown to produce beneficial effects in 73% of the subjects (44 females and 16 males) with active urinary tract infections.^[10] Furthermore, withdrawal of the cranberry juice in the people who benefited resulted in recurrence of bladder infection in 61%.

Many believe the action of cranberry juice is due to acidifying the urine and the antibacterial effects of a cranberry component hippuric acid.^{[13] [14]} However, these are probably not the major mechanisms of action. In order to acidify the urine, at least 1 litre of cranberry juice would have to be consumed at one sitting.^[13] In addition, the concentration of hippuric acid in the urine as a result of drinking cranberry juice is insufficient to inhibit bacteria.^{[13] [14]} As 0.5 litres/day of cranberry juice have been shown to be effective in the treatment of bladder infection, another mechanism is more likely.^[5]

Recent studies have shown components in cranberry juice to reduce the ability of *E. coli* to adhere to the lining of the bladder and urethra.^{[15] [16]} In order for bacteria to infect, they must first adhere to the mucosa. By interfering with adherence, cranberry juice greatly reduces the likelihood of infection and helps the body to fight off infection. This is the most likely explanation of cranberry juice's positive effects in bladder infections.

In one study of seven juices (cranberry, blueberry, grapefruit, guava, mango, orange, and pineapple), only cranberry and blueberry contained this inhibitor.^[16] Blueberry juice is a suitable alternative to cranberry juice in bladder infections.

It must be pointed out that most cranberry juices on the market contain one-third cranberry juice mixed with water and sugar. Since sugar has such a detrimental effect on the immune system,^{[17] [18] [19]} use of sweetened cranberry juice cannot be recommended. Fresh cranberry (sweetened with apple or grape juice) or blueberry juice is preferred. Cranberry extracts are also available commercially in pill form.

Acidify or alkalinize?

Although many practitioners believe acidifying the urine is the best approach in addressing cystitis, several arguments can be made for alkalinizing the urine. First, it is often difficult to acidify the urine. Many popular methods of attempting to acidify the urine, such as ascorbic acid supplementation and the drinking of cranberry juice, have very little effect on pH at commonly prescribed doses.

The best argument for alkalinizing the urine is that it appears to be more effective, especially in women without pathogenic bacteria in their urine. The best method for alkalinizing the urine appears to be the use of citrate salts, e.g. potassium citrate and sodium citrate. These salts are rapidly absorbed and metabolized without affecting gastric pH or producing a laxative effect. They are excreted partly as carbonate, thus raising the pH of the urine.

Potassium citrate and/or sodium citrate have long been employed in the treatment of lower urinary tract infections. They are often used as a “holding exercise” until the results of a urine culture are available. There are some clinical studies to support this practice. For example, in one study, women presenting with symptoms of a urinary tract infection were given a 4 g dose of sodium citrate every 8 hours for 48 hours.^[20] Of the 64 women evaluated, 80% of the women had relief of symptoms, 12% had deterioration of symptoms, and 91.8% of the women rated the treatment as acceptable. Of the 64 women, 19 were shown to have positive bacterial cultures. There was more variation in response to treatment in the group of women with proven bacterial

1187

infection, with those with symptoms of urethral pain (seven of 10) and dysuria (13 of 18) improving more than those with symptoms of frequency (nine of 17) and urgency (six of 13). These results were similar to a previous study that demonstrated significant symptomatic relief in 80% of the 159 women studied who were abacteriuric.^[21]

Because of these positive results, it has been suggested that urine culture could be restricted to those women who fail to respond to alkalinization therapy. Restricting urine cultures to non-responders would lower health care costs.

There is one more possible advantage to alkalizing rather than acidifying the urine. Many of the herbs used to treat urinary tract infections, such as *Hydrastis canadensis* and *Arctostaphylos uva ursi*, contain antibacterial components which work most effectively in an alkaline environment.

Enhancing immune function

The recommendations given in [Chapter 53](#) are appropriate to employ during a bladder or lower urinary tract infection.

Botanical medicines

Many herbs have been used through the centuries in the treatment of urinary tract infections. The following are several which have both folk and scientific support for their use.

Arctostaphylos uva ursi

Most research has focused on *uva ursi*'s (bearberry or upland cranberry) urinary antiseptic component, arbutin, which typically composes 7–9% of the leaves. Arbutin is hydrolyzed to hydroquinone and glucose in the body. Hydroquinone is most effective in an alkaline urine. However, crude plant extracts are more effective medicinally than isolated arbutin.^[22] *Uva ursi*, reported to be especially active against *E. coli*, also has diuretic properties.^[23]

The prophylactic effect of a standardized *uva ursi* extract on recurrent cystitis was evaluated in a double-blind study in 57 women.^[24] At the end of 1 year, 5/27 women in the placebo group had a recurrence, while 0/30 women receiving *uva ursi* extract had a recurrence. No side-effects were reported in either group. These impressive results indicate that regular use of *uva ursi*, like cranberry, may prevent bladder infections.

A more recent, large, double-blind, placebo-controlled study evaluated the efficacy of 300 ml of cranberry juice in 153 women (average age 78.5) with confirmed bacteriuria (10^5 /ml urine).^[25] Even this small an amount dramatically decreased the level of bacteria in the women's urine and the frequency of recurrence of infection. Interestingly, the researchers used saccharin-sweetened juice.

Care must be taken to avoid excessive dosages of *uva ursi* – as little as 15 g (0.5 ounce) of the dried leaves has been shown to produce toxicity in susceptible individuals. Toxic signs include:^[22]

- ringing in the ears
- nausea
- vomiting
- sense of suffocation
- shortness of breath
- convulsions
- delirium
- collapse.

Allium sativum

Garlic has been shown to have antimicrobial activity against many disease-causing organisms, including those associated with urinary tract infections:^[26] ^[27] ^[28]

- *Escherichia coli*

- *Proteus* sp.
- *Klebsiella pneumonia*
- *Staphylococcus* sp.
- *Streptococcus* sp.

Hydrastis canadensis

Goldenseal is one of the most effective of the herbal antimicrobial agents. Its long history of use by herbalists and naturopathic physicians for the treatment of infections is well documented in the scientific literature. Of particular importance here is its efficacy against *Escherichia coli*, *Proteus* sp., *Klebsiella* sp., *Staphylococcus* sp., *Enterobacter aerogenes* (requires large dosage), and *Pseudomonas* sp.^[29] ^[30] Berberine, like hydroquinone from

TABLE 145-6 -- Bacteriologic susceptibility to nutrients and botanical medicines

| Bacteria species | Agent |
|-------------------------------------|-----------------------------|
| Abacterial | Citrates |
| <i>Enterobacter aerogenes</i> | |
| <i>Enterococci</i> | |
| <i>Escherichia coli</i> | <i>Allium sativum</i> |
| | <i>Hydrastis canadensis</i> |
| | <i>Uva ursi</i> |
| <i>Klebsiella pneumonia</i> | <i>Allium sativum</i> |
| | <i>Hydrastis canadensis</i> |
| <i>Proteus miribili</i> | <i>Allium sativum</i> |
| | <i>Hydrastis canadensis</i> |
| <i>Pseudomonas aeruginosa</i> | <i>Hydrastis canadensis</i> |
| <i>Staphylococcus saprophyticus</i> | <i>Allium sativum</i> |
| | <i>Hydrastis canadensis</i> |

uva ursi, works better in an alkaline urine (see [Ch. 91](#) for a full discussion).

THERAPEUTIC APPROACH

Although most cases of cystitis are relatively benign, it is extremely important that the patient be properly diagnosed, treated, and monitored. Proper monitoring includes

having the patient notify the physician of any change in their condition. If the original culture was positive, it is appropriate to follow up with another culture 7–14 days after treatment was started. Citrates can be used to ameliorate symptoms.

While the occasional acute bladder infection is easily treated, treating the women with chronic cystitis can be a significant challenge. Long-term success requires determining the underlying cause: structural abnormalities, excessive sugar consumption, food allergies, nutritional deficiencies, chronic vaginitis, local foci of infection (e.g. prostate, kidneys), current or childhood sexual abuse – all potential causes must be evaluated and resolved.

General measures

Drink large amounts of fluids (at least 2 litres/day) including at least 0.5 litres of unsweetened cranberry or 0.25 litres of blueberry juice per day.

Urinate after intercourse. Women who develop bladder infections after intercourse should wash their labia and urethra with a strong tea of *Hydrastis canadensis* (2 tsp/cup) both before and after. If this is inadequate, a dilute solution of providone-iodine will usually prove effective.

Diet

Avoid all simple sugars, refined carbohydrates, full-strength fruit juice (diluted fruit juice is acceptable), and food allergens. Restrict calories and eat liberal amounts of garlic and onions.

Nutritional supplements

- Vitamin C: 500 mg every 2 hours
- Bioflavonoids: 1,000 mg/day
- Vitamin A: 25,000 IU/day
- Beta-carotene: 200,000 IU/day
- Zinc: 30 mg/day
- Choline: 1,000 mg/day.

Botanical medicines

Dosages are three times daily quantities:

- *Uva ursi*
 - dried leaves or as a tea: 1.5 to 4.0 g (1–2 tsp)
 - freeze-dried leaves: 500 to 1,000 mg
 - tincture (1:5): 4 to 6 mL (1 to 1.5 tsp)

—fluid extract (1:1): 1.0 ml (¼ to ½ tsp)
—powdered solid extract (10% arbutin): 250–500 mg.

- *Hydrastis canadensis*

—dried root (or as tea): 1–2 g

—freeze-dried root: 500–1,000 mg

—tincture (1:5): 4–6 ml (1–1.5 tsp)

—fluid extract (1:1): 0.5–2.0 ml (1 ¼ to ½ tsp)

—powdered solid extract (8% alkaloid): 250–500 mg

- Sandalwood oil: 1–2 drops.

Chapter 146 - Dermatitis herpetiformis

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

DIAGNOSTIC SUMMARY

- Pruritic, blistering rash usually on the extensor surfaces
- Occurs most commonly in middle-aged Caucasian males, although it may be present in individuals of any age
- IgA deposits in the papillary skin; confirmed by immunofluorescence
- Asymptomatic “celiac” disease (gluten-sensitive enteropathy) in 75–90% of patients.

GENERAL CONSIDERATIONS

Dermatitis herpetiformis (DH) is a dermatological condition that is almost certainly due to a gastrointestinal immunological disorder. Jejunal biopsy in DH patients shows villous atrophy characteristic of celiac disease, although gastrointestinal symptoms are rare.^[1]^[2]^[3] Absorption studies (see [Ch. 21](#)) can be used to assess the degree of enteropathy. The average age of onset of the rash is 7.2 years, with a predilection for the elbows, knees, and buttocks. Skin biopsy shows granular IgA deposits.

THERAPEUTIC CONSIDERATIONS

Gluten

The most important factor in the treatment of patients with DH is the elimination of all sources of gluten. Frazer’s criteria for the diagnosis of gluten-sensitive enteropathy (improvement on a gluten-free diet and relapse after reintroduction) have been used in many studies and have shown conclusively that the rash and villous atrophy of DH are largely gluten-dependent.^[1]^[2]^[3]^[4]^[5]^[6] Gluten elimination results in improvement in virtually all patients, including the elimination of the reticulins and gluten antibodies found

in patients with DH.

Further study of the wheat connection has shown that the gliadin polypeptide of gluten is most likely the key antigen. Indirect immunofluorescence shows antibodies

1192

to gliadin in the sera of 45% of patients with DH, and the titer and correlation increase with increasing severity of the disease; 81% of patients with severe jejunal abnormalities show antibodies to gliadin.^[7]

Despite the published benefits of a gluten-free diet in the treatment of DH, it is virtually never mentioned in dermatology or medical textbooks. The advantages of a gluten-free diet over drugs like dapsons (the most widely prescribed drug for DH) is quite obvious as this drug is often associated with severe side-effects while on the gluten-free diet:

- most patients (well over 65%) experience complete resolution and the rest are substantially improved
- there is complete resolution of the enteropathy associated with DH
- harsh medications can be eliminated or substantially reduced
- most patients experience an improved sense of well-being.

Also of interest is the fact that those who utilized a gluten-free diet rather than drugs appear also to be protected against developing lipomas.^[8]

Food allergy

Although gluten control is critical in the treatment of patients with DH, some patients (about 35%) are not adequately helped. In particular, only half the patients totally eliminate the cutaneous IgA deposits and develop normal jejunal tissue. This is probably due to the presence of other food allergies which, although probably not initiating, developed as a result of the increased leakage of macromolecules across the damaged gastrointestinal membranes. Milk, in particular, has been found to be significant in some patients.^[9] ^[10] Using a sensitive enzyme-linked immunoassay (ELISA), 75% of DH patients were shown to have serum antibodies reactive against gliadin, bovine milk, or ovalbumin.^[11] These results indicate that other food sensitivities can also induce DH. An elemental diet followed by careful food reintroduction usually produces better results than simply a gluten-free diet.^[12]

PABA

Para-aminobenzoic acid has been used successfully in the control of DH, even in those not controlling the gluten content of their diet.^[13] However, since its use is only for symptom control and probably does not result in repair of the villous atrophy, it is not recommended as the treatment of choice, but rather as an adjunct in unresponsive

cases or to help in particularly severe cases.

THERAPEUTIC APPROACH

After all sources of gluten and gliadin have been eliminated (see [Appendix 5](#) for the gluten content of foods), a careful search should be made for other food allergies (for more detail see [Ch. 15](#)). Once the allergens are under control, a therapeutic regimen similar to that for atopic dermatitis (see [Ch. 134](#)) should be utilized. Patience is necessary since response may take several weeks to 6 months.

Diet

Utilize a normal, healthy, unprocessed diet free of all grains and allergic foods.

Supplements

- PABA: 5 g/day until remission (maximum of 3 months).

Chapter 147 - Diabetes mellitus

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

DIAGNOSTIC SUMMARY

- The National Diabetes Data Group of the National Institutes of Health recommends the following criteria in diagnosing diabetes:
 - fasting (overnight): venous plasma glucose concentration greater than or equal to 140 mg/dl on at least two separate occasions
 - following ingestion of 75 g of glucose: venous plasma glucose concentration greater than or equal to 200 mg/dl at 2 hours post-ingestion and at least one other sample during the 2 hour test
- Classic symptoms of polyuria, polydipsia, and polyphagia.

GENERAL CONSIDERATIONS

Diabetes is a chronic disorder of carbohydrate, fat, and protein metabolism characterized by fasting elevations of blood sugar (glucose) levels and a greatly increased risk of heart disease, stroke, kidney disease, and loss of nerve function. Diabetes can occur when the pancreas does not secrete enough insulin, or if the cells of the body become resistant to insulin; hence, the blood sugar cannot get into the cells which then leads to serious complications.

The classic symptoms of diabetes are frequent urination, and excessive thirst and appetite. Because these symptoms are not very serious, many with diabetes do not seek medical care. In fact, of the more than 10 million Americans with diabetes, fewer than half know that they have diabetes or ever consult a physician.

Classification

Diabetes is divided into two major categories: type I and type II. Type I or insulin-dependent diabetes mellitus (IDDM) occurs most often in children and adolescents. Type II or non-insulin dependent diabetes mellitus (NIDDM) usually has an onset after 40 years of age.

TABLE 147-1 -- Comparison of type I and type II diabetes

| Features | Type I | Type II |
|-----------------------------|------------------|------------------|
| Age at onset | Usually under 40 | Usually over 40 |
| Percentage of all diabetics | Less than 10% | Greater than 90% |
| Seasonal trend | Fall and winter | None |
| Family history | Uncommon | Common |
| Appearance of symptoms | Rapid | Slow |
| Obesity at onset | Uncommon | Common |
| Insulin levels | Decreased | Variable |
| Insulin resistance | Occasional | Often |
| Treatment with insulin | Always | Not required |
| Beta-cells | Decreased | Variable |
| Ketoacidosis | Frequent | Rare |
| Complications | Frequent | Frequent |

[Table 147.1](#) presents a comparison between these two types of diabetes.

Insulin-dependent diabetes mellitus

IDDM is associated with complete destruction of the beta-cells of the pancreas which manufacture the hormone insulin. IDDM patients require life-long insulin for the control of blood sugar levels. The type I diabetic must learn how to manage his or her blood sugar levels on a day-by-day basis, modifying insulin types and dosage schedules as necessary, according to the results of regular blood sugar testing. About 10% of all diabetics are type I.

Although the exact cause of type I diabetes is unknown, current theory suggests it is due to injury to the insulin-producing beta-cells coupled with some defect in tissue regeneration capacity. Type I diabetes appears to have an autoimmune component at its origin as antibodies for beta-cells are present in 75% of all cases of type I diabetes,

compared with 0.5–2.0% of normals. It is probable that the antibodies to the beta-cells develop in response to cell destruction due to other mechanisms (chemical, free radical, viral, food allergy, etc.). It appears that normal individuals either do not develop as severe an antibody reaction, or are better able to repair the damage once it occurs.

Non-insulin dependent diabetes mellitus

About 90% of all diabetics are type II. Insulin levels are typically elevated, indicating a loss of sensitivity to insulin by the cells of the body. Obesity is a major contributing factor to this loss of insulin sensitivity, with approximately 90% of individuals with type II diabetes being obese. Achieving ideal body weight in these patients is associated with restoration of normal blood sugar levels in most cases.

In type II diabetes, diet is of primary importance and should be implemented diligently before a drug is used. Most type II diabetics can be controlled by diet alone. Despite a high success rate with dietary intervention, physicians often use drugs or insulin instead.

Other types of diabetes

Other types of diabetes include:

- secondary diabetes – a form of diabetes that is secondary to certain conditions and syndromes such as pancreatic disease, hormone disturbances, drugs, and malnutrition
- gestational diabetes – refers to glucose intolerance occurring during pregnancy
- impaired glucose tolerance – a condition that includes prediabetic, chemical, latent, borderline, subclinical, and asymptomatic diabetes.

Individuals with impaired glucose tolerance have blood glucose levels and GTT that are intermediate between normal and those that are clearly abnormal. In addition, many practitioners consider reactive hypoglycemia as a prediabetic condition.

Incidence and epidemiology

The incidence of DM in the United States is estimated at approximately 4.5%, of which 90% are NIDDM and the rest IDDM.^[1] In 1992, while diabetics accounted for only 4.5% of the US population, its care required roughly 14.6% of the total US health care expenditures (\$105 billion).^[2]

The prevalence of DM is rising and it is now the seventh leading cause of death in the US. At the current rate of increase (6%/year), the number of diabetics will double every 15 years. Epidemiologically, DM has been linked to the Western lifestyle and is uncommon in cultures consuming a more “primitive” diet.^[3] ^[4] As cultures switch from their native diets to the “foods of commerce”, their rate of DM increases, eventually reaching the same proportions seen in Western societies.

The hypoglycemia–diabetes link

Blood sugar problems are strongly associated with the so-called “Western diet”.^[3] ^[4] This diet is rich in refined sugar, fat, and animal products, and low in dietary fiber. It is widely accepted that refined carbohydrates are among the most important contributing factors to diabetes and reactive hypoglycemia (as well as obesity). Refined sugars are quickly absorbed into the bloodstream, causing a rapid rise in blood sugar. The body’s response to this is to greatly increase the secretion of insulin by the pancreas. The excessive secretion of insulin drives the blood sugar down and often causes the symptoms of hypoglycemia to appear.

In response to the rapid fall in blood glucose levels, the

1195

adrenal glands secrete epinephrine (adrenaline) which causes a rapid increase in the blood glucose level. In time, the adrenal glands become “exhausted” by the repeated stress and cannot mount an appropriate response. This lack of response leads to reactive hypoglycemia. If blood sugar control mechanisms are further stressed, the body will eventually become insensitive to insulin or the pancreas will also become “exhausted”, and the reactive hypoglycemia will turn into diabetes.

DIAGNOSIS

Fasting blood glucose level

The standard method of diagnosing diabetes involves the measurement of blood glucose levels. The normal fasting blood glucose level is between 70 and 105 mg/dl. A fasting blood glucose measurement greater than 140 mg/dl on two separate occasions is diagnostic of diabetes. Levels below 50 mg/dl indicate fasting hypoglycemia.^[1]

The glucose tolerance test

A more functional test of blood sugar control is the oral glucose tolerance test (GTT). The GTT is a very sensitive test for DM. However, it is also very stressful to the patient and has a relatively low specificity. The National Diabetes Data Group recommends giving a 75 g glucose dose, dissolved in 300 ml of water, for adults (1.75 g/kg ideal body weight for children) after an overnight fast in subjects who have been consuming at least 150 g of carbohydrate daily for 3 days prior to the test. The patient is considered normal if the 2 hour plasma glucose is less than 140 mg/dl and no value exceeds 200 mg/dl. A confirmatory diagnosis of DM requires that plasma levels be above 200 mg/dl both at 2 hours and at least once between zero time and 2 hours (see [Table 147.2](#)).

Medications that impair glucose tolerance (diuretics, glucocorticoids, nicotinic acid, and

phenytoin) may invalidate the results.

The glucose-insulin tolerance test

Relying on blood sugar levels alone is often not adequate in diagnosing blood sugar disorders. Several studies have shown that the glucose-insulin tolerance test (G-ITT) is more sensitive in the diagnosis of both hypoglycemia and diabetes than the standard GTT. The test criteria are given in [Table 147.3](#) .

The G-ITT uses a standard 6 hour glucose tolerance test coupled with measurements of insulin levels. The G-ITT appears to be one of the best diagnostic indicators for faulty sugar metabolism. As many as two-thirds of subjects with suspected diabetes or hypoglycemia who have normal glucose tolerance tests will demonstrate abnormal insulin tolerance tests. The down-side to this test is that it is costly. For example, the glucose-insulin tolerance test (G-ITT) costs around \$200 while a standard GTT is usually less than \$30. Despite the high price, the G-ITT and other diagnostic tests are often appropriate.

Skin tags

Skin tags (fibroepithelial papillomas) are frequently found in diabetic men. The presence of multiple, large, hyperpigmented, lateral skin tags in a male patient may be suggestive of diabetes and warrants laboratory testing to rule out the disease.

TABLE 147-2 -- Glucose tolerance test response criteria

| Type | Criteria |
|-----------------------|---|
| Normal | No elevation greater than 160 mg |
| | Below 150 mg at the end of first hour |
| | Below 120 mg at the end of second hour |
| | Flat |
| | No variation more than ± 20 mg from fasting value |
| Pre-diabetic | Over 120 mg at the end of second hour |
| Diabetic | Over 180 mg during the first hour |
| | 200 mg or higher at the end of first hour |
| | 150 mg or higher at the end of second hour |
| Reactive hypoglycemia | Normal response for the first 2 or 3 hours |
| | A decrease of 20 mg or more from the fasting level during the final hours |

| | |
|--------------------------------|---|
| Probable reactive hypoglycemia | Normal response for the first 2 or 3 hours |
| | A decrease of 10–20 mg from the fasting level during the final hours |
| Flat hypoglycemia | An elevation of 20 mg or less, followed by a decrease of 20 mg or more below fasting level |
| Pre-diabetic hypoglycemia | A 2 hour response like the pre-diabetic |
| | Hypoglycemic response during the final 3 hours |
| Hyperinsulinism | A marked hypoglycemic response, with a value of less than 50 mg during the third, fourth, or fifth hour |

1196

TABLE 147-3 -- Glucose-insulin tolerance test criteria

| Pattern | Description |
|----------------|---|
| Pattern 1 | Normal fasting insulin 0–30 units |
| | Peak insulin at 0.5–1 hour |
| | The combined insulin values for the second and third hours is less than 60 units. This pattern is considered normal |
| Pattern 2 | Normal fasting insulin |
| | Peak at 0.5–1 hour with a delayed return to normal |
| | Second and third hour levels between 60 and 100 units usually is associated with hypoglycemia and is considered borderline for diabetes; values greater than 100 units considered to be definite diabetes |
| Pattern 3 | Normal fasting insulin |
| | Peak at second or third hour instead of 0.5–1 hour. Definite diabetes |
| Pattern 4 | High fasting insulin. Definite diabetes |
| Pattern 5 | Low insulin response |
| | All tested values for insulin less than 30 |
| | When associated with elevated blood sugar levels, it indicates probable insulin-dependent diabetes (juvenile pattern) |

CAUSES OF DIABETES

Genetic considerations

IDDM and NIDDM are genetically substantially different. HLA-antigen analyses in IDDM patients show significant positive associations with HLA-DR₃, HLA-DW₃, HLA-DR₄, HLA-B₈ and HLA-B₁₅, and significant negative associations with HLA-B₇ and HLA-DR₂₁. Approximately 50% of juvenile diabetics are HLA-B₈.

Although these correlations are not seen in patients with NIDDM, extensive studies of monozygotic twins indicate that genetic factors play an even greater role in these patients. When twins under the age of 40 were studied, there was a concordance rate of 20–50% in identical twins and 5% in fraternal twins with IDDM as contrasted with a concordance rate approaching 100% in identical twins and only 10% in fraternal twins with NIDDM.

Although genetics appear important in susceptibility to diabetes, environmental factors are important in its induction. Many have been identified. A diet high in refined, fiber-depleted carbohydrate is believed to be diabetogenic in susceptible phenotypes, while a high intake of high-fiber, complex carbohydrate-rich foods is protective.^[3] ^[4]

Obesity is another significant environmental factor, as 90% of NIDDM types are obese.^[1] Even in normal individuals, significant weight gain results in carbohydrate intolerance, higher insulin levels, and insulin insensitivity in fat and muscle tissue. The progressive development of insulin insensitivity (which will be discussed in more detail later) is believed to be the underlying factor in the genesis of NIDDM. Weight loss alone can correct all of these abnormalities and either significantly improves the metabolic disturbances of DM or converts overt diabetes into subclinical diabetes.^[5]

Etiological factors in IDDM

Insulin dependent diabetes mellitus is generally recognized to be due to an insulin deficiency.^[1] Although the exact cause is unknown, current theory suggests an hereditary beta-cell predisposition to injury coupled with some defect in tissue regeneration capacity. Causes of injury are most likely hydroxyl and other free radicals, viral infection, and autoimmune reactions. Alloxan, the uric acid derivative used to induce experimental diabetes in animals, is a potent beta-cell toxin, causing destruction via hydroxyl radical formation.

Streptozotocin

The *N*-nitroso derivative of glucosamine has now replaced alloxan as the preferred agent for destruction of beta-cells in the induction of experimental diabetes.^[6] Circumstantial epidemiologic evidence suggests that dietary intake of the *N*-nitroso compounds found in smoked/cured meats is diabetogenic in susceptible individuals, producing beta-cell damage by the same mechanism as streptozotocin.^[7] Many other

chemicals, such as rodenticide vacor, have also been implicated in beta-cell damage.^[8]

Viral infection

Recent epidemiological and experimental evidence has strengthened the hypothesis of a viral etiology of IDDM in some cases.^[6] ^[9] A viral etiology was initially suspected due to the seasonal variation in the onset of the disease (October–March). During these months, viral diseases, such as mumps, hepatitis, infectious mononucleosis, congenital rubella, and Coxsackie virus infections are much more prevalent. Viruses are capable of infecting pancreatic beta-cells and inducing DM.

1197

Autoimmunity

Autoimmune factors may also be etiological in many cases, especially HLA-B₈ individuals. Antibodies to pancreatic cells (all types) are present in 75% of all cases of IDDM compared with 0.5–2.0% of normals.^[6] The antibody levels decline progressively after the first few weeks of the disease, suggesting beta-cell destruction and depletion of antigenic stimulus. It is probable that the antibodies to the islet cells develop in response to cell destruction due to other mechanisms (chemical, viral, etc.) when normally concealed cellular antigens are exposed. It appears that normal individuals either do not develop as severe an antibody reaction, or are more able to repair the damage once it occurs.

Early weaning and cow's milk exposure

Recent studies have provided some strong evidence that exposure to a protein in cow's milk (bovine albumin peptide) in neonates may trigger the autoimmune process and subsequent type I diabetes. Although animal and laboratory evidence exists to justify these concerns, studies involving humans and clinical end-points have generated conflicting results.^[9]

A critical review and analysis of all relevant citations in the medical literature indicated that early cow's milk exposure may, in fact, be an important determinant of subsequent type I diabetes and may increase the risk about 1.5 times.^[9] In case-controlled studies, patients with type I diabetes were more likely to have been breast-fed for less than 3 months and to have been exposed to cow's milk or solid foods before 4 months.

Etiological factors in NIDDM

Central to the pathogenesis of NIDDM is insulin insensitivity as evidenced by typically high levels of circulating insulin and the reversibility of hyperglycemia by dietary changes and/or weight loss sufficient to restore insulin sensitivity.

Obesity

Obesity plays a major role in the etiology of NIDDM for many patients.^{[1] [5] [10] [11] [12]} As stated earlier, obesity is associated with insulin insensitivity, and adipose size and distribution also seem to be important.

The heterogeneity of human obesity has resulted in an attempt to identify subgroups. Using cellular criteria, two types have been identified: hypertrophic obesity (enlarged fat cells) and hyperplastic obesity (increased number of fat cells). The hypertrophic form is more closely associated with the metabolic complications associated with obesity, i.e. diabetes, hyperinsulinemia, glucose intolerance, hypertension, hyperlipidemia, etc. Another system is based on fat distribution and also results in two subgroups: android type (deposition in the upper body, i.e. abdomen, typical in the obese male) and gynecoid type (with distribution in the lower body, i.e. gluteal and femoral, most common in the obese female). Activity of the abdominal adipocyte is affected by metabolic variables, such as plasma insulin and triglyceride levels, while the gluteal and femoral adipocytes are more sensitive to certain steroidal hormones such as corticosteroids and estrogen. The incidence of DM is higher in both men and women with the hypertrophic, android-type obesity.

Weight loss, in particular a significant decrease in body fat percentage, is a prime objective in treating the majority of NIDDM patients since it improves all aspects of diabetes and may result in cure.

Dietary fat

The percentage of calories from fat, especially saturated fat, in the diet has been shown to be associated with NIDDM as well as to predict the conversion from impaired glucose tolerance to NIDDM.^{[13] [14]} These results suggest that a high-fat, low-carbohydrate diet increases the risk of subsequently developing NIDDM. Ironically, such a diet was used in the past for the dietary management of diabetes.

Chromium deficiency

Considerable experimental and epidemiological evidence now indicates that chromium levels are a major determinant of insulin sensitivity.^{[15] [16] [17] [18] [19] [20]} Chromium, an essential micronutrient, functions as a cofactor in all insulin-regulating activities. Its deficiency is widespread in the US. Trivalent chromium (Cr^{3+}) is the only form of chromium that exhibits biological activity^[17] and is an integral component of the so-called "glucose tolerance factor" (GTF). This low molecular weight compound also contains two molecules of nicotinic acid plus cysteine, glutamine, and glycine.

Supplemental chromium has been shown to significantly improve glucose tolerance, decrease fasting glucose, cholesterol and triglyceride levels, and increase the HDL cholesterol level by increasing insulin sensitivity in normal, elderly and NIDDM

patients.^[15] ^[16] ^[17] ^[18] ^[19] ^[20] Chromium is not, however, a panacea for NIDDM.

Uremia

Uremia is a potent inhibitor of insulin sensitivity due to a circulating small molecular weight peptide unique to patients with kidney failure. Renal function should be assessed and monitored in all diabetics.

1198

Prenatal factors

Recent epidemiological evidence supports the concept that prenatal malnutrition, in particular hyperglycemia, may be a promoter of both types I and II DM later in life. Studies done in Berlin have shown that adults born during the “hypocaloric war and post-war period (1941–48)” have significantly less DM than those born during the relatively hypercaloric years before and after. This is not a minor correlation; the data show a greater than 50% drop in the incidence of DM!^[21]

Another study shows a significantly lower incidence of childhood diabetes during periods in which maternal hyperglycemia was carefully controlled and the fetus protected from hyperinsulinism.^[22] Although the data in this study are based on a number of suppositions, they again indicate a greater than 50% drop in the incidence of childhood DM.

MONITORING THE DIABETIC PATIENT

There appears to be a causal relationship between hyperglycemia and the development of the complications of diabetes. Therefore, monitoring and controlling the degree of hyperglycemia are critical to the prevention of the major diabetic complications. The adequacy of control can be determined by several simple laboratory techniques.

Urinary glucose

Measurement of urinary glucose is an archaic and insufficient measure of diabetic control since diabetics have a higher renal threshold for glucose than the normal 180 mg/dl.

Home glucose monitoring

The advent of home glucose monitoring, using reagent strips and capillary blood, has brought about major improvement in the care of diabetes. A sample can be obtained by the use of a simple spring-triggered device equipped with a disposable lancet. The best sites are the lateral sides of the distal phalanges (taking care to avoid the nail beds). Glucose levels are then determined by placing the sample on a reagent strip and

measuring the color change using a commercially available reflectance meter. There are also reagent strips that give satisfactory values by visual inspection using a dual-color scale.

Glycosylated hemoglobin

Proteins that have glucose molecules attached to them (glycosylated peptides) are elevated several-fold in diabetics. The measurement of the level of glycosylated hemoglobin (HgbA1c) is used for monitoring blood sugar levels over a long period. Normally about 5–7% of hemoglobin is combined with glucose. Mild elevations in blood sugar result in an HgbA1c concentration of 8–10%, while severe elevations may result in concentrations up to 20%.

Since the average life span of a red blood cell is 120 days, the HgbA1c assay represents time-averaged values for blood glucose over the preceding 2–4 months, thus providing a simple, useful method for assessing treatment effectiveness and patient compliance. HgbA1c determination can also be used in some cases to diagnose diabetes. Although the oral glucose tolerance test is more sensitive than the HgbA1c assay in the diagnosis of diabetes, it is also more stressful to the patient. Because an elevated HgbA1c level almost always indicates diabetes, many physicians will simply measure the HgbA1c level rather than, or before, subjecting patients, particularly pregnant women, to the stress of a GTT.

In general, measuring glycosylated hemoglobin (and possibly other glycosylated proteins) is an important and useful test for diabetic control and the prevention of complications.

CONVENTIONAL MEDICAL TREATMENT

IDDM

There is no question that a type I diabetic requires insulin. Insulin preparations have been used in the treatment of diabetes since 1922. Since insulin is not absorbed orally, it must be injected. Insulin preparations come in concentrations of 100 units/ml (U-100) and 500 units/ml (U-500), but can differ in their source (beef, pork, or human synthetic insulin), duration of action (rapid, intermediate, and long-acting), and solubility (crystalline vs. soluble). The human synthetic insulin is gaining wider acceptance as the preferred source.

Conventional insulin therapy involves administering crystalline insulin, usually a mixture of rapid- and intermediate-acting insulin, once or twice daily. This method is being replaced by intensified insulin therapy where the insulin is given in increasingly sophisticated and complex regimens. Increasing evidence is demonstrating that intensified insulin therapy significantly reduces the development of the chronic complications of diabetes (discussed below).^[23] Intensified insulin therapy is designed to mimic as closely as possible the continuous variations in plasma insulin levels produced

by a healthy pancreas.

Intensified insulin therapy is implemented through either multiple daily injections (three to five injections daily) or the use of the “insulin pump” to administer a continuous supply of insulin. The insulin pump method

1199

involves the filling of a syringe with soluble insulin. The syringe, which looks like a ballpoint pen, is connected via a hollow flexible hose to a needle which is inserted into a site on the abdomen. The unit must be worn 24 hours a day. The plunger of the syringe is pressed slowly and constantly by a small pump so that a constant trickle of soluble insulin is delivered. Fifteen minutes prior to a meal, the diabetic can press the pump manually to release a burst of insulin.

The insulin pump which approximates the natural levels of insulin is the best of currently available techniques, but is not without drawbacks. The device must be worn constantly and can be an irritation; the patient must be highly motivated to monitor blood sugar levels quite closely; the risk for hypoglycemia is greater; and not all physicians are familiar enough with the method. Regardless of the type of insulin therapy used, the proper care of diabetes must include appropriate diet and lifestyle.

NIDDM

When type II diabetes cannot be controlled satisfactorily with diet therapy, oral hypoglycemic agents or, when necessary, insulin are utilized for additional support. Since most type II diabetics are obese and secrete large amounts of insulin each day to try to overcome the resistance to the action of insulin by the cells of the body, additional insulin is usually of only limited value. While healthy individuals secrete approximately 31 units of insulin daily, the obese type II diabetic secretes an average of 114 units daily. This amount is nearly four times the normal amount. In contrast to obese type II individuals, lean type II individuals produce about 14 units daily and individuals with type I diabetes secrete only 4 units of insulin daily. If a diabetic is over-producing insulin, it makes more sense to work on increasing the sensitivity to insulin by following the recommendations given below.

The other drug treatment of type II diabetes utilizes oral hypoglycemic agents. These agents are sulfa drugs (sulfonylureas) which appear to stimulate the secretion of additional insulin by the pancreas as well as enhancing the sensitivity of body tissues to insulin. Some common examples of this class of drugs are listed in [Table 147.4](#) .

As a group, these drugs are not very effective. After 3 months of continual treatment at an adequate dosage, only about 60% are able to control blood sugar levels

TABLE 147-4 -- Oral hypoglycemic agents

-
- Chlorpropamide (Diabinese)
-
- Glipizide (Glucotrol)
-
- Glyburide (DiaBeta, Micronase)
-
- Tolazamide (Tolinase)
-
- Tolbutamide (Orinase)

using these drugs. Furthermore, these agents generally lose their effectiveness over time. After an initial period of success, these drugs will fail to produce a positive effect in about 30% of cases. The overall rate of achieving adequate control by long-term use of sulfonylureas is 20–30% at best.

In addition to being of limited value, there is evidence to indicate that these drugs actually produce harmful long-term side-effects. For example, in a famous study conducted by the University Group Diabetes Program (UDGP) on the long-term effects of tolbutamide, it was shown that the rate of death due to a heart attack or stroke was 2.5 times greater than the group controlling their type II diabetes by diet alone.^[24]

The major side-effect of sulfonylureas is hypoglycemia. Other possible side-effects include allergic skin reactions, headache, fatigue, indigestion, nausea and vomiting, and liver damage. Due to the high risk of side-effects, these drugs have to be used with caution. They should not be used in the following situations:

- pregnancy
- known allergy to sulfa drugs
- during infection, injury, or surgery
- during long-term corticosteroid use.

In addition, oral hypoglycemics must be used with extreme caution in treating the elderly, alcoholics, those taking multiple drugs, and those with impaired liver or kidney function.

COMPLICATIONS OF DIABETES

Diabetes gives rise to the development of numerous complications due to hyperglycemia. The likelihood of developing complications, whether acute or chronic, is ultimately a reflection of the level of blood sugar control. A large body of evidence indicates that good blood sugar control significantly reduces the development of complications. Therefore, as mentioned before, monitoring and controlling the degree of hyperglycemia is critical to the prevention of the major diabetic complications.

Acute complications

Diabetics are susceptible to three major acute complications:

- hypoglycemia
- diabetic ketoacidosis (primarily affects type I diabetics)
- non-ketogenic hyperosmolar syndrome (primarily affects type II diabetics).

Hypoglycemia

The problem of hypoglycemia is much more common in type I than type II DM because the type I diabetic

1200

is injecting insulin. Taking too much insulin, missing a meal, or over-exercising can result in hypoglycemia. It is imperative that a good relationship exists between the patient and the physician prescribing the insulin so that dosages can be gauged correctly.

Daytime hypoglycemic episodes are usually recognized by the following symptoms: sweating, nervousness, tremor, and hunger. Night-time hypoglycemia may be without symptoms or manifest as night sweats, unpleasant dreams, or early morning headache.

In response to the hypoglycemia, secretion of several hormones which raise blood glucose levels – epinephrine, norepinephrine, growth hormone, and cortisol – is increased. As a result, blood sugar levels will rebound and often lead to hyperglycemia. This phenomenon is commonly referred to as the Somogyi phenomenon. It is very important to recognize this response when monitoring insulin needs. The Somogyi phenomenon should be suspected whenever there are wide swings in blood glucose over short periods of time during the day. For example, a blood glucose of 70 mg/dl before breakfast and 400 mg/dl before lunch suggests early morning hypoglycemia with post-breakfast hyperglycemia due to increased counter-regulatory hormone activity. The advent of the improved insulin therapy, the insulin pump, and home glucose monitors has led to better blood sugar control and a decreased frequency of the Somogyi phenomenon.

Diabetic ketoacidosis

Another acute complication more likely to occur in the type I diabetic is ketoacidosis, a condition caused by a lack of insulin leading to a build-up of ketoacids. If progressive, ketoacidosis can result in numerous metabolic problems and even coma. Since ketoacidosis is potentially a medical emergency, prompt recognition is imperative. The coma is usually preceded by a day or more of increased urination and thirst as well as marked fatigue, and nausea and vomiting. A simple urine dipstick can be used at home by diabetics to measure the level of ketones in the urine.

Non-ketogenic hyperosmolar syndrome

With a mortality rate of over 50%, non-ketogenic hyperosmolar syndrome constitutes a true medical emergency. It is usually the result of profound dehydration secondary to deficient fluid intake or precipitating events such as pneumonia, burns, stroke, a recent operation, or certain drugs such as phenytoin, diazoxide, glucocorticoids, and diuretics.

The onset of the syndrome may be insidious over a period of days or weeks, with symptoms of weakness, increased urination and thirst, and progressively worse signs of dehydration (weight loss, loss of skin elasticity, dry mucous membranes, rapid heart beat, and low blood pressure).

Chronic complications

On a long-term basis, the diabetic's health condition is complicated by repeated elevations in blood glucose levels. Five major chronic complications of diabetes are discussed here:

- atherosclerosis
- diabetic retinopathy
- diabetic neuropathy
- diabetic nephropathy
- diabetic foot ulcers.

There are two primary mechanisms behind the development of most chronic complications of diabetes: glycosylated proteins and the intracellular accumulation of sorbitol.

Glycosylated proteins and diabetic complications

The binding of glucose to proteins, a process referred to as glycosylation, leads to changes in the structure and function of many body proteins. For example, glycosylated LDL molecules (found in high levels in diabetics) do not bind to LDL receptors or shut off endogenous cholesterol synthesis. In diabetes, excessive glycosylation also occurs with the proteins of the red blood cell, lens, and myelin sheath.

Excessive non-enzymatic glycosylation has many adverse effects:^[25]

- inactivation of enzymes
- inhibition of regulatory molecule binding
- cross-linking of glycosylated proteins
- trapping of soluble proteins by glycosylated extracellular matrix
- decreased susceptibility to proteolysis
- abnormalities of nucleic acid function
- altered macromolecular recognition

- increased immunogenicity.

Sorbitol and diabetic complications

Sorbitol is a by-product of glucose metabolism formed within the cell through the action of aldose reductase. In non-diabetics, once sorbitol is formed it is metabolized by polyol dehydrogenase to fructose. This conversion to fructose allows the sorbitol to be excreted from the cell. Unfortunately, in the diabetic with frequent hyperglycemia, sorbitol accumulates and plays a major role in the development of the chronic complications of diabetes (see [Fig. 147.1](#)).

1201

Figure 147-1 Production of polyols.

The mechanism by which sorbitol is involved in the development of diabetic complications is best understood by considering its involvement in cataract formation. Although the lens does not have any blood vessels, it is an actively metabolizing tissue that continuously grows throughout life. Hyperglycemia results in shunting of glucose to the sorbitol pathway. Since the lens membranes are virtually impermeable to sorbitol and lack the enzyme polyol dehydrogenase, sorbitol accumulates to high concentrations which persist even if glucose levels return to normal. This accumulation creates an osmotic gradient that draws water into the cells to maintain osmotic balance. The cells also release small molecules like amino acids, inositol, glutathione, niacin, vitamin C, magnesium and potassium to maintain osmotic balance. Since these latter compounds function to protect the lens from damage, their loss results in increased susceptibility to damage. As a result, the delicate protein fibers within the lens become opaque and a cataract forms.

Intracellular accumulation of polyols is a major factor in the development of the majority of the complications of DM. Elevated sorbitol levels are found in high concentrations in the tissues commonly involved in the major diabetic complications: the lens epithelium, the Schwann cell of the peripheral nerve, the papilla in the kidney, the islets of Langerhans in the pancreas, and the mural cell of the retinal blood vessels.

Measurement of the erythrocyte sorbitol concentration may become a valuable indicator of diabetic control, since RBC and nerve cell sorbitol concentrations correlate well.^[26]

Atherosclerosis

The diabetic has a two- to threefold higher risk of dying prematurely of atherosclerosis than a non-diabetic individual.

TABLE 147-5 -- Recommended blood cholesterol and triglyceride levels

| | |
|-------------------|-----------------------|
| Total cholesterol | Less than 200 mg/dl |
| LDL cholesterol | Less than 130 mg/dl |
| HDL cholesterol | Greater than 35 mg/dl |
| Triglycerides | 50–150 mg/dl |

Therefore, the physician and diabetic patient must be aggressive in reducing the risk factors linked to heart attacks and strokes. Foremost is the reduction of LDL cholesterol levels and triglycerides while increasing HDL cholesterol levels. The recommended blood cholesterol and triglyceride levels are given in [Table 147.5](#) .

The most important approach to lowering a high cholesterol level is to follow a healthy diet and lifestyle. The dietary recommendations are straightforward:

- instruct the patient to eat less saturated fat and cholesterol by reducing or eliminating the amounts of animal products in the diet
- increase the consumption of fiber-rich plant foods (fruits, vegetables, grains, and legumes)
- lose weight, if necessary.

The lifestyle changes include getting regular aerobic exercise, stopping smoking, and reducing or eliminating the consumption of coffee (both caffeinated and decaffeinated).

Diabetic neuropathy

Diabetic neuropathies are among the most frequent complications of long-term diabetes. Loss of peripheral nerve function, tingling sensations, numbness, loss of function, pain, and muscle weakness may occur as a result of diabetic neuropathies. Occasionally, the neuropathy can affect deeper nerves and result in impaired heart function, alternating bouts of diarrhea and constipation, inability to empty the bladder, and impotence.

The earliest and best measured signs of diabetic neuropathy are decreased sensory and nerve conduction velocities. There is substantial evidence that diabetic neuropathy is also due to sorbitol accumulation.^{[1] [27]} In rats, increasing the sorbitol concentration in the sciatic nerve is directly related to decreasing nerve conduction velocity, possibly as a result of decreased myoinositol concentrations.^[28] Sorbitol accumulation leads to myoinositol loss. Although some studies have shown inositol supplementation to improve nerve conduction velocity, addressing the underlying accumulation of sorbitol is

of greater importance.^[26]

Diabetic retinopathy

Diabetic retinopathy is a serious eye disease that can result in blindness. In fact, diabetic retinopathy is still the leading cause of blindness in the United States. One

1202

in 20 type I and one in 15 type II diabetics develop retinopathy.^[1]

The retinopathic lesions are divided into background or “simple” retinopathy (consisting of microaneurysms, hemorrhages, exudates, and retinal edema) and proliferative or “malignant” retinopathy (with newly formed vessels, scarring, retinitis proliferens, vitreous hemorrhage, and retinal detachment).

The development of laser photocoagulation therapy will probably reduce the prevalence of diabetes-induced blindness. Patients with the following signs should be referred to an ophthalmologist trained in this technique:

- moderate or severe growth of new vessels on or within one disc diameter of the optic disc
- mild growth of new vessels on or within one disc diameter of the optic disc if fresh hemorrhage is present
- moderate or severe growth of new vessels elsewhere if fresh hemorrhage is present.

Laser photocoagulation is probably not indicated in milder forms of retinopathy since the occasional side-effects (vitreous hemorrhage, vitreous contraction with retinal detachment, macular edema, and visual field loss) may outweigh the benefits.^[1]

Diabetic neuropathy

Diabetic neuropathy is usually limited to the peripheral nerves, the most common being peripheral polyneuropathy.^{[1] [10]} Typically bilateral, this condition is characterized by paresthesias, severe hyperesthesias, and pain. The neurological examination reveals dulled perception of vibration, pain and temperature, particularly in the lower extremities. Bilateral atrophy of the first interosseous muscle of the hand is characteristic. Nerve conduction is delayed and there may be a delayed response of the Achilles reflex similar to that seen in hypothyroidism.

Occasionally, autonomic neuropathy is present in DM. This can present in a variety of ways, such as postural hypotension, decreased cardiovascular response to the Valsalva maneuver, resting tachycardia, alternating bouts of diarrhea and constipation, inability to

empty the bladder, and impotence.

This is a common complication and a leading cause of death in DM.^[1] Four types of possibly overlapping lesions develop:

- glomerulosclerosis
- arteriosclerosis of the efferent and afferent arterioles
- arteriosclerosis of the renal artery and its intrarenal branches
- peritubular deposits of glycogen, fat, and mucopolysaccharides.

The glomerular lesions have received the most attention, with nodular glomerulosclerosis being the classical Kimmelsteil–Wilson lesion. The Kimmelsteil–Wilson syndrome refers to the presence of edema, hypertension, proteinuria, and renal failure seen as a complication of DM. Periodic monitoring of a diabetic patient's kidney function (BUN, uric acid, creatinine, and creatinine clearance) is important.

Diabetic foot ulcers

Ischemia and peripheral neuropathy are the key factors in the development of diabetic foot ulcers. The incidence of gangrene of the feet is 20 times that of matched controls.^[10] However, foot ulcers are largely preventable through proper foot care, the avoidance of injury and tobacco in any form, and employing methods to improve local circulation. Proper foot care includes keeping the feet clean, dry, and warm and wearing only well-fitted shoes. Tobacco constricts the peripheral blood vessels and can cause Buerger's disease. Circulation can be improved by avoiding sitting with the legs crossed or in other positions that compromise circulation, and by massaging the feet lightly upwards and carefully applying hydrotherapy (see [Ch. 42](#)). *Ginkgo biloba* extract (discussed below) may also be helpful in improving vascular flow.

THERAPEUTIC CONSIDERATIONS

Proper and effective treatment of the diabetic patient requires the careful integration of a wide range of therapies and patients who are willing to substantially alter their diet and lifestyle. The diabetic individual must be monitored carefully, particularly if he/she is on insulin or has relatively uncontrolled diabetes. Careful attention to symptoms, home glucose monitoring, and other blood tests are essential in monitoring the progress of the diabetic individual. It is important to recognize that as the diabetic individual employs some of the suggestions described in this chapter, drug dosages will have to be altered.

Diet

Dietary modification and treatment is fundamental to the successful treatment of diabetes, whether it be type I or II. Since diabetics have a higher incidence of death from cardiovascular disease (60–70% versus 20–25% in matched non-diabetic controls), most of the dietary recommendations given in [Chapters 57](#) and [133](#) are equally appropriate here. As stated in these chapters, the incidence of DM is highly

correlated with the fiber-depleted, high-refined carbohydrate diet of “civilized” humans.^[3]
Re-establishing a traditional diet and lifestyle

1203

reverses the carbohydrate and lipid metabolism abnormalities associated with the “foods of commerce” and eventually results in a low prevalence of DM. The epidemiological evidence indicting the Western diet and lifestyle as the ultimate etiological factor in DM is overwhelming.^[3] ^[30]

Although there are several commonly recommended diets in the management of diabetes, the best is not the one promoted by the American Diabetes Association (ADA), but rather one popularized by Dr James Anderson.^[31] The diet he recommends is high in cereal grains, legumes, and root vegetables and restricts simple sugar and fat intake. It is called the high-complex carbohydrate, high-fiber diet or HCF diet for short.

Clinical trials of dietary treatment with a more primitive diet high in plant cell-wall materials and complex carbohydrates and low in fat and animal products have consistently demonstrated superior therapeutic effects over oral hypoglycemic agents, insulin (when less than 30 units/day), and other previously recommended dietary regimens (carbohydrate restriction, high protein, and the ADA diet).^[31] ^[32] ^[33] ^[34] ^[35] ^[36]

The ADA diet

The diet recommended by the American Diabetes Association and the American Dietetic Association is clearly inferior to the HCF and MHCF diets (presented below). Nonetheless, it is presented here for historical purposes, and the exchange system is a useful concept and, as the diet is in common use by the typical physician, familiarity is necessary. It offers some palliative support to many, especially if supplemented with dietary fiber (guar at 15–30 g/day or pectin at 30–45 g/day).^[4] ^[37]

A resurgence of interest in diet therapy resulted from the Universal Group Diabetes Program (UGDP) report which, in 1970, cast serious doubt on the efficacy and safety of oral hypoglycemic drugs.^[24] Prior to the report, the ADA diet consisted of high-protein, high-cholesterol, and high-fat foods. This diet obviously exacerbated the already atherogenic state of DM and contributed to greater insulin insensitivity. In 1971, a revised ADA diet was developed based on the exchange system, a very useful concept for diabetic diets.

The exchange system recognizes six groups of foods: milk, vegetables, fruit, bread, meat, and fat. The composition of the typical exchange is listed in [Table 147.6](#) . Exchange lists for meal planning have been developed and are available through the ADA (2 Park Ave, New York, NY, 10016). They are very useful since they help to promote patient compliance by providing flexibility, choice, and relative ease of use. Unfortunately, the ADA exchange plan does not place a strong enough focus on the

quality of food choices.

The Healthy Exchange System presented in [Appendix 6](#)

TABLE 147-6 -- Composition of food exchanges

| Exchange | Calories | CHO (g) | Fat (g) | Protein (g) |
|-----------------|-----------------|----------------|----------------|--------------------|
| Milk | 170 | 12 | 10 | 8 |
| Vegetables | 35 | 7 | 0 | 2 |
| Fruit | 40 | 10 | 0 | 0 |
| Bread | 70 | 15 | 0 | 2 |
| Meat | 75 | 0 | 5 | 7 |
| Fat | 45 | 0 | 5 | 0 |

is a better version because it emphasizes healthier food choices and focuses on unprocessed, whole foods. The diet is prescribed by allotting a specific number of exchanges per list per day. Although there are seven exchange lists, the milk and meat lists should be considered optional.

The current ADA diet stresses the major goal of caloric restriction as a means of achieving and maintaining ideal weight, an approach known to benefit diabetics. The major changes recommended here include the restriction of fat intake to 35% or less of total calorie intake; the reduction of saturated fats to one-third of the fat intake by substituting poultry, veal, and fish for red meats; and the reduction of cholesterol to less than 300 mg/day. The carbohydrate content is 40–50% of total calories, and unrefined carbohydrates are recommended (supplying 15–20 g/day of fiber) to the exclusion of refined and simple carbohydrates.

Although easy to use, the ADA diet suffers from significant limitations: it is not as effective as the other diets presented here, a large percentage of the recommended calories is still derived from fat, and the fiber content is much too low.

The HCF diet

The high-carbohydrate, high plant-fiber (HCF) diet popularized by James Anderson MD has substantial support and validation in the scientific literature as the diet of choice in the treatment of DM. ^{[31] [32] [33] [34] [35] [36]} It is high in cereal grains, legumes, and root vegetables and restricts simple sugar and fat intake. The caloric intake consists of 70–75% complex carbohydrates, 15–20% protein, and 10–25% fat, and the total fiber content is almost 100 g/day. The positive metabolic effects of the HCF diet are many:

- reduced postprandial hyperglycemia and delayed hypoglycemia
- increased tissue sensitivity to insulin
- reduced cholesterol and triglyceride levels with increased HDL cholesterol levels

- progressive weight reduction.

Adding further support to the superiority of the HCF over the ADA diet is the fact that, when type I

1204

diabetics following the HCF resume a conventional ADA diet, their insulin requirements return to prior levels.

Anderson basically promotes two HCF diets:

- one for the initial treatment of the hospitalized patient which provides 70% of total calories from carbohydrate, 19% protein, and 11% fat, 50 mg/day of cholesterol and 35–49 g/day of dietary fiber per 1,000 kcal
- a home use, or maintenance, diet that provides 55–60% of total calories from carbohydrate, 20% protein, and 20–25% fat, 75–200 mg/day of cholesterol and 50 g/day of dietary fiber (approximately 25g/1,000 kcal).

Anderson claims fair to good compliance in 90% of patients.

On the home HCF diet, available carbohydrate calories come from grain products (50%), fruits and vegetables (48%), and skim milk (2%). Protein is provided by fruits and vegetables (50%), grain products (36%), and skim milk and lean meat (14%). The fat is derived from grain products (60%), fruits and vegetables (20%), and skim milk and meat (12%). The HCF diet is also based on the exchange system with more information and dietary guidelines available from the HCF Diabetes Research Foundation (1872 Blairmore Rd, Lexington, KY 40502). A representative menu for the maintenance HCF diet is shown in [Table 147.7](#).

Some researchers have shown that despite liberal instructions to increase carbohydrate intake from unrefined sources, patients still only manage to average 36% of their energy intake from carbohydrates, even lower than the ADA recommendation.^[37] One study found that when patients on a complex carbohydrate diet were allowed free selection in their choice of carbohydrate-rich foods, even though their fiber intake was the recommended 50 g/day, their selections resulted in a disappointing 51% simple and 49% complex carbohydrates.^[37]

Serum triglyceride concentrations appear to be the most sensitive indicators of dietary compliance: when the patient deviates, serum triglyceride levels rise. Average serum cholesterol levels are 180 mg/dl.

Type I patients have also benefited from the HCF diet. In one representative study, when 16 type I patients were treated with HCF diets, their average insulin requirements dropped by 38% and they demonstrated significantly lower fasting, postprandial and

urinary glucose levels than matched patients on control diets.^[35]

Modified high-fiber content diet (MHCF)

In general, the HCF diet^[38] and/or the Pritikin diet^[39] are adequate for the treatment of diabetes mellitus. However, improvements can be made, primarily by substituting more natural (i.e. primitive or unprocessed) foods wherever possible in the HCF diet and avoiding some foods that have deleterious effects. The MHCF diet is higher in leguminous fibers than any of the other diets, limits processed grains, and excludes fruit juices, low-fiber fruits, skimmed milk and margarine. A typical menu plan for the MHCF diet is presented in [Table 147.7](#). A comparison of the nutrient content of the ADA, HCF and MHCF diets is shown in [Table 147.8](#).

There is substantial rationale for these modifications. Legumes are low in fat and high in complex carbohydrates and fiber and are proven effective in treating DM. Fruit juices, low fiber juices, and processed grains

TABLE 147-7 -- Typical menus for the HCF and MHCF diets

| HCF diet | MHCF diet |
|---------------------------------------|------------------------------|
| <i>Breakfast</i> | |
| Whole oats, 1 cup | |
| Whole-wheat bread, 2 slices | Oat bran cereal, 1 cup |
| Skimmed milk, 1 cup | Yogurt, plain low fat, 1 cup |
| Grapefruit, ½ | Blueberries, ½ cup |
| Margarine, 2 pats | |
| <i>Snack (morning or afternoon)</i> | |
| Whole grain flat bread cracker, 2 | |
| Yogurt, ½ cup | |
| Fresh strawberries, 1 cup | Apple, 1 medium |
| <i>Lunch</i> | |
| Whole wheat bread, 2 slices | Brown rice, cooked, ¾ cup |
| Kidney bean and rice casserole, 1 cup | Lentil soup, ½ cup |
| Kale, cooked, 1 cup | —carrot, 1 large |
| Cucumber and onion salad | —celery, ½ large |
| Potatoes, boiled, ½ cup | —onion, 1 cup |
| Margarine, 4 pats | —garlic, 1 clove |
| <i>Dinner</i> | |

| | |
|-----------------------------|----------------------------|
| Whole wheat bread, 2 slices | Whole grain bread, 1 slice |
| Blackberries, ¾ cup | |
| Lima beans, 1 cup | Green beans, ¾ cup |
| Peas, ¾ cup | |
| Tomato, 1 small | Tossed salad, 2 cups |
| Asparagus, steamed, 1 cup | Broccoli, ¾ cup |
| Squash, winter, 1 cup | |
| Beef, roast, 115 g | Salmon, 115 g |
| Margarine, 4 pats | Butter, 1 pat |

TABLE 147-8 -- Composition of the ADA, HCF and MHCF diets (all values in g except ratios)

| Nutrient | ADA | HCF | MHCF |
|---------------------|------|------|------|
| Protein | 98 | 96 | 90 |
| Carbohydrate | 215 | 351 | 370 |
| Simple (S) | 100 | 94 | 70 |
| Complex (C) | 115 | 257 | 300 |
| S/C ratio | 0.87 | 0.37 | 0.23 |
| Fat | 83 | 23.5 | 20 |
| Saturated (S) | 19 | 4.7 | 4.0 |
| Monounsaturated (M) | 43 | 9.5 | 7 |
| Polyunsaturated (P) | 15 | 6.9 | 8 |
| P/S ratio | 0.79 | 1.47 | 2.0 |
| Cholesterol | 0.47 | 0.04 | 0.05 |
| Fiber | 27 | 82 | 100 |
| Soluble (S) | 15 | 67 | 80 |
| Insoluble (I) | 12 | 15 | 20 |
| S/I ratio | 1.25 | 4.47 | 5.0 |

(i.e. flour) induce a rapid elevation of serum glucose and insulin levels, and the casein in skimmed milk appears to raise cholesterol levels. The *trans*-fatty acids in margarine

(and other synthetically saturated fats) also have significant injurious effects.

The importance of dietary fiber

Population studies, as well as clinical and experimental research, show diabetes to be one of the diseases most clearly related to inadequate dietary fiber intake.^[3] ^[4] These results indicate that while the intake of refined sugars should be curtailed, the intake of complex carbohydrate sources that are rich in fiber should be increased.

The term “dietary fiber” refers to the components of the plant cell wall as well as the indigestible residues from plant foods. Different types of fibers possess different actions. The types of fiber that exert the most beneficial effects on blood sugar control are the water-soluble forms. Included in this class are hemicelluloses, mucilages, gums, and pectin substances. These types of fiber are capable of slowing down the digestion and absorption of carbohydrates, thereby preventing rapid rises in blood sugar; increasing the sensitivity of tissues to insulin, thereby preventing the excessive secretion of insulin; and improving uptake of glucose by the liver and other tissues, thereby preventing a sustained elevation of blood sugar.

Fortunately, the majority of fiber in most plant cell walls is water-soluble. Particularly good sources of water-soluble fiber are legumes (beans), oat bran, nuts, seeds, psyllium seed husks, pears, apples, and most vegetables. The optimal diet for diabetics includes a large amount of plant foods to ensure adequate levels of dietary fiber. A daily intake of 50 g is a reasonable goal.

Recommending frequent consumption of legumes is particularly important since a high carbohydrate, legume-rich, high-fiber diet has been shown to improve all aspects of diabetic control.^[35]

Fiber supplementation vs. a high fiber diet

Supplementation with the plant fibers (e.g. guar gum at a dosage of 5 g/meal and pectin 10 g/meal; see [Table 147.9](#) for dietary fiber content of selected foods) has demonstrated a positive impact on diabetic control. These fiber supplements are now being used, along with the standard ADA diet, by many experts in diabetes.^[4] For example, Jenkins and colleagues developed a palatable crisp bread containing guar gum.^[36] ^[40] When diabetic patients ate between 14 and 26 g/day of guar, they required less insulin and had less glycosuria.^[36] ^[40] It is interesting to note that these beneficial effects are maximized in patients consuming a diet containing at least 40% complex carbohydrates.

TABLE 147-9 -- Dietary fiber content of selected foods

| Food | Serving | Calories | Fiber (g) |
|-------------------|----------|----------|-----------|
| <i>Fruits</i> | | | |
| Apple (with skin) | 1 medium | 81 | 3.5 |

| | | | |
|---------------------------|----------|-----|-----|
| Banana | 1 medium | 105 | 2.4 |
| Cantaloupe | ¼ melon | 30 | 1.0 |
| Cherries, sweet | 10 | 49 | 1.2 |
| Grapefruit | ½ medium | 38 | 1.6 |
| Orange | 1 medium | 62 | 2.6 |
| Peach (with skin) | 1 | 37 | 1.9 |
| Pear (with skin) | ½ large | 61 | 3.1 |
| Prunes | 3 | 60 | 3.0 |
| Raisins | ¼ cup | 106 | 3.1 |
| Raspberries | ¼ cup | 35 | 3.1 |
| Strawberries | 1 cup | 45 | 3.0 |
| <i>Vegetables, raw</i> | | | |
| Bean sprouts | ½ cup | 13 | 1.5 |
| Celery, diced | ½ cup | 10 | 1.1 |
| Cucumber | ½ cup | 8 | 0.4 |
| Lettuce | 1 cup | 10 | 0.9 |
| Mushrooms | ½ cup | 10 | 1.5 |
| Pepper, green | ½ cup | 9 | 0.5 |
| Spinach | 1 cup | 8 | 1.2 |
| Tomato | 1 medium | 20 | 1.5 |
| <i>Vegetables, cooked</i> | | | |
| Asparagus, cut | 1 cup | 30 | 2.0 |
| Beans, green | 1 cup | 32 | 3.2 |
| Broccoli | 1 cup | 40 | 4.4 |
| Brussels sprouts | 1 cup | 56 | 4.6 |
| Cabbage, red | 1 cup | 30 | 2.8 |
| Carrots | 1 cup | 48 | 4.6 |
| Cauliflower | 1 cup | 28 | 2.2 |
| Corn | ½ cup | 87 | 2.9 |
| Kale | 1 cup | 44 | 2.8 |
| Parsnip | 1 cup | 102 | 5.4 |
| Potato (with skin) | 1 medium | 106 | 2.5 |

| | | | |
|---------------------------------|------------|-----|-----|
| Potato (without skin) | 1 medium | 97 | 1.4 |
| Spinach | 1 cup | 42 | 4.2 |
| Sweet potatoes | 1 medium | 160 | 3.4 |
| Zucchini | 1 cup | 22 | 3.6 |
| <i>Legumes</i> | | | |
| Baked beans | ½ cup | 155 | 8.8 |
| Dried peas, cooked | ½ cup | 115 | 4.7 |
| Kidney beans, cooked | ½ cup | 110 | 7.3 |
| Lima beans, cooked | ½ cup | 64 | 4.5 |
| Lentils, cooked | ½ cup | 97 | 3.7 |
| Navy beans, cooked | ½ cup | 112 | 6.0 |
| <i>Rice, breads, and pastas</i> | | | |
| Bran muffins | 1 muffin | 104 | 2.5 |
| Bread, white | 1 slice | 78 | 0.4 |
| Bread, whole wheat | 1 slice | 61 | 1.4 |
| Crisp bread, rye | 2 crackers | 50 | 2.0 |
| Rice, brown, cooked | ½ cup | 97 | 1.0 |
| Rice, white, cooked | ½ cup | 82 | 0.2 |
| Spaghetti, cooked | ½ cup | 155 | 1.1 |
| Spag, whole wheat, cooked | ½ cup | 155 | 3.9 |
| <i>Breakfast cereals</i> | | | |
| All-Bran | ? cup | 71 | 8.5 |
| Bran Chex | ? cup | 91 | 4.6 |
| Corn Bran | ? cup | 98 | 5.4 |
| Cornflakes | 1¼ cup | 110 | 0.3 |
| Grape-Nuts | ¼ cup | 101 | 1.4 |
| Oatmeal | ¾ cup | 108 | 1.6 |
| Raisin Bran-type | ? cup | 115 | 4.0 |
| Shredded Wheat | ? cup | 102 | 2.6 |
| <i>Nuts</i> | | | |
| Almonds | 10 nuts | 79 | 1.1 |
| Filberts | 10 nuts | 54 | 0.8 |

Despite these beneficial results, fiber-supplemented diets are not as effective as the HCF diet and are reserved for the type II patient who is unwilling to implement the more difficult dietary change and who will settle for palliative results. The insulin dosages of diabetics on fiber-supplemented diets can usually be reduced to one-third those used on control (ADA) diets, while the HCF diet has led to discontinuation of insulin therapy in approximately 60% of NIDDM patients, and significantly reduces doses in the other 40%.^[4] ^[32] ^[33]

For a more complete discussion of the effects of fiber, see [Chapter 57](#).

The glycemic index

The “glycemic index” was developed by David Jenkins in 1981 to measure the rise of blood glucose after eating a particular food.^[40] The standard value of 100 is based on the rise seen after the ingestion of glucose. The glycemic index ranges from about 20 for fructose and whole barley to about 98 for a baked potato. The insulin response to carbohydrate-containing foods is similar to the rise in blood sugar.

The glycemic index is used as a guideline for dietary recommendations for people with either diabetes or hypoglycemia (see [Table 147.10](#)). Basically, people with blood sugar problems are advised to avoid foods with high values and choose instead carbohydrate-containing foods with lower values. However, the glycemic index should not be the only dietary guideline. For example, while high fat foods like ice cream and sausage may have a low glycemic index because a diet high in fat has been shown to impair glucose uptake, these foods are not good food choices for people with hypoglycemia or diabetes.

Fruits and fructose

Many physicians have recommended that individuals with diabetes or hypoglycemia avoid fruits and fructose. However, recent research challenges this approach. Fructose does not cause a rapid rise in blood sugar levels. Because fructose must be changed to glucose in the liver in order to be utilized by the body, blood glucose levels do not rise as rapidly after fructose consumption as they do with other simple sugars. While most diabetics and hypoglycemics cannot tolerate sucrose, most can tolerate moderate amounts of fruits and fructose without loss of blood sugar control. In fact, fructose and fruits are not only much better tolerated than white bread and other refined carbohydrates, but they also produce less sharp elevations in blood sugar levels compared with most sources of complex carbohydrates (starch).^[41] As a bonus, fructose has actually been shown to enhance the sensitivity to insulin by 34% when fed to

non-insulin-dependent diabetics over 4 weeks.

TABLE 147-10 -- Glycemic index of some common foods

| Food | Glycemic index |
|----------------------|-----------------------|
| <i>Sugars</i> | |
| Glucose | 100 |
| Maltose | 105 |
| Honey | 75 |
| Sucrose | 60 |
| Fructose | 20 |
| <i>Fruits</i> | |
| Apples | 39 |
| Bananas | 62 |
| Oranges | 40 |
| Orange juice | 46 |
| Raisins | 64 |
| <i>Vegetables</i> | |
| Beets | 64 |
| Carrot, raw | 31 |
| Carrot, cooked | 36 |
| Potato, baked | 98 |
| Potato (new), boiled | 70 |
| <i>Grains</i> | |
| Bran cereal | 51 |
| Bread, white | 69 |
| Bread, whole grain | 72 |
| Corn | 59 |
| Cornflakes | 80 |
| Oatmeal | 49 |
| Pasta | 45 |
| Rice | 70 |
| Rice, puffed | 95 |
| Wheat cereal | 67 |

Legumes

| | |
|--------------------|----|
| Beans | 31 |
| Lentils | 29 |
| Peas | 39 |
| <i>Other foods</i> | |
| Ice cream | 36 |
| Milk | 34 |
| Nuts | 13 |
| Sausages | 28 |

Nutritional supplements

The treatment of diabetes requires nutritional supplementation, as these patients have a greatly increased need for many nutrients. Supplying the diabetic with additional key nutrients has been shown to improve blood sugar control as well as helping to prevent or ameliorate many of the major complications of diabetes.

Although the following discussion of specific nutrients documents their usefulness, they are used as part of a comprehensive approach where diet is the primary focus. Good blood sugar control combined with nutritional supplementation will go a long way in helping to prevent many of the major complications of diabetes.

Chromium

Chromium was briefly discussed above. Chromium is vital to proper blood sugar control as it functions as

1207

a key constituent of the “glucose tolerance factor”. Chromium works closely with insulin in facilitating the uptake of glucose into cells. Without chromium, insulin’s action is blocked, and glucose levels are elevated.^[19]

Clinical studies in diabetics have shown that supplementing the diet with chromium to decrease fasting glucose levels improves glucose tolerance, lowers insulin levels, and decreases total cholesterol and triglyceride levels, while increasing HDL cholesterol levels.^{[19] [20]} Although some studies have not shown chromium to exert much effect in improving glucose tolerance in diabetes, there is no doubt that it is an important mineral in blood sugar metabolism.

A recent large study clearly documented the benefit of chromium for NIDDM patients. In this study, 180 type II diabetics were placed in one of three groups. The first group was a placebo group; the second received 100 µg of chromium as chromium picolinate two times a day; and the third group received 500 µg of chromium picolinate two times per day. The patients continued their normal medication. There were significant dose- and time-dependent decreases in glycosylated hemoglobin, fasting glucose, 2 hour postprandial glucose levels, fasting and 2 hour postprandial insulin values, and total serum cholesterol.^[15]

Reversing a chromium deficiency by supplementing the diet with chromium has also been demonstrated to lower body weight while increasing lean body mass. All of the effects of chromium appear to be due to increased insulin sensitivity. A chromium deficiency may be an underlying contributing factor to the large number of Americans suffering from diabetes, hypoglycemia, and obesity. There is evidence that marginal chromium deficiency is common in the United States.

Although no RDA has been established for chromium, at least 200 mcg/day appears necessary for optimal sugar regulation. Chromium levels can be depleted by refined sugars, white flour products, and lack of exercise. In addition to the regular consumption of chromium-rich foods, the diabetic and hypoglycemic should supplement the diet with chromium polynicotinate, chromium picolinate, and chromium-enriched yeast.

Vitamin C

A primary function of vitamin C is the manufacture of collagen, the main protein substance of the human body. Since collagen is such an important protein for connective tissue, vitamin C is vital for wound repair, healthy gums, and the prevention of excessive bruising. In scurvy or severe vitamin C deficiency, the classic symptoms are bleeding gums, poor wound healing, extensive bruising, increased susceptibility to infection, hysteria, and depression. In addition to its role in collagen metabolism, vitamin C is also critical to immune function, the manufacture of certain nerve transmitting substances and hormones, and the absorption and utilization of other nutritional factors.

Since the transport of vitamin C into cells is facilitated by insulin, many diabetics do not have enough intracellular vitamin C. Therefore, a relative vitamin C deficiency exists in many diabetics despite adequate dietary consumption.^[42] A chronic, latent vitamin C deficiency will lead to a number of problems for the diabetic, including an increased tendency to bleed (increased capillary permeability), poor wound healing, microvascular disease, elevations in cholesterol levels, and a depressed immune system.

Vitamin C at high doses (e.g. 2,000 mg/day) has been shown to reduce the accumulation of sorbitol in the erythrocytes of diabetics and to inhibit the glycosylation of proteins.^{[43] [44]} As discussed previously, sorbitol accumulation and glycosylation of proteins are linked to many complications of diabetes, especially eye and nerve diseases. The attempt to prevent sorbitol accumulation with drugs designed specifically to inhibit aldose reductase has produced equivocal results in human clinical trials along with consistent side-effects. Vitamin C may be able to accomplish what these drugs

could not – safe and effective inhibition of sorbitol accumulation.

A recent study provides further support for this possibility.^[45] In this research, 100 or 600 mg vitamin C was supplemented daily for 58 days in young adults with insulin-dependent diabetes. RBC sorbitol was measured at baseline and again at 30 and 58 days. The baseline results indicated that RBC sorbitol levels were nearly doubled in these patients despite “adequate” dietary intakes of vitamin C as determined by diet diaries. Vitamin C supplementation at both dosages normalized RBC sorbitol within 30 days. This correction of sorbitol accumulation was independent of changes in diabetic control as monitored by fasting glucose, glycosylated hemoglobin, and glycosuria. In fact, overall diabetic control during the study was moderate to poor. The researchers concluded:

Vitamin C supplementation is effective in reducing sorbitol accumulation in the erythrocytes of diabetics. Given its tissue distribution and low toxicity, we suggest a superiority for vitamin C over pharmaceutical ARIs [aldose reductase inhibitors].

Although lower levels of vitamin C achieved normal RBC sorbitol levels, supplementation with a minimum of 2 g/day of vitamin C in diabetes appears warranted due to its other important effects. While vitamin C supplementation will be necessary to ensure this level of intake, patients should be encourage not to rely exclusively on supplements to meet all of their vitamin C requirements. Vitamin C-rich foods are rich in flavonoids and carotenes which enhance the effects of vitamin C

1208

as well as exerting favorable effects of their own. Good dietary sources of vitamin C are:

- broccoli
- peppers
- potatoes
- Brussels sprouts
- citrus fruits.

Niacin and niacinamide

Niacin (vitamin B₃)-containing enzymes play an important role in energy production; fat, cholesterol, and carbohydrate metabolism; and the manufacture of many body compounds including sex and adrenal hormones. Niacin, like chromium, is an essential component of the glucose tolerance factor, making it a key nutrient for hypoglycemia and diabetes.^[46]

Supplementing the diet of diabetics with niacin in the form of niacinamide has been shown to exert many favorable effects. Foremost is its possible application in preventing

the development of type I diabetes.^{[47] [48] [49] [50]} Niacinamide, also called nicotinamide, has been shown to prevent the development of diabetes in experimental animals. This observation led to several pilot clinical trials which suggest that niacinamide can prevent type I diabetes from developing, or, if given soon enough at the onset of diabetes, help restore beta-cells or at least slow down their destruction. There have been several studies of niacinamide treatment in recent onset IDDM or IDDM of less than 5 years, duration and residual beta-cell mass. Six of these studies used a double-blind placebo-controlled format. Of these six, three studies showed a positive effect in terms of prolonged non-insulin-requiring remission, lower insulin requirements, improved metabolic control, and increased beta-cell function. Some newly diagnosed type I diabetics have experienced complete resolution of their diabetes with niacinamide supplementation.^[9] The main difference between the positive and negative studies in recent onset IDDM seems to be the older age and higher baseline fasting C-peptide in positive studies.

In the spring of 1993, a large multicenter study involving 18 European countries, Israel, and Canada was started to follow up these encouraging preliminary findings. Other clinical trials are also in progress or have been proposed.

The mechanism of action appears to be inhibition of macrophage- and interleukin-1-mediated beta-cell damage, inhibition of nitric oxide production, along with niacinamide's antioxidant role.^[51] The daily dose of nicotinamide is based on body weight, 25 mg/kg. The studies in children used 100–200 mg/day.

Niacin in the form inositol hexaniacinate can also be used in both type I and type II diabetes to lower elevated blood lipids. Niacin or nicotinic acid has long been used to lower cholesterol levels. In fact, niacin is recommended by the National Cholesterol Education Program as the first “drug” to use.^[52] Unlike many cholesterol-lowering drugs which have actually been shown to reduce life expectancy, niacin has been shown to lower cholesterol levels safely and extend life. Niacin was the only substance to demonstrate a decreased mortality in the famed Coronary Drug Project.^[53] Its effects are long-lasting, as demonstrated in a follow-up study to the Coronary Drug Project which showed that the long-term death rate for patients treated with niacin was 11% lower than the group receiving a placebo, even though in most patients the treatment had been discontinued many years earlier.^[54]

Because the dose of niacin required (1 g three times/day) to lower cholesterol levels often results in flushing of the skin, stomach irritation, ulcers, liver damage, fatigue, and other side effects, many people do not tolerate niacin very well. The acute reaction of skin flushing after taking niacin can be alleviated by taking “sustained-release”, “timed-release”, or “slow-released” niacin products. These formulations allow the niacin to be absorbed gradually, thereby reducing the flushing reaction. However, while these forms of niacin reduce skin flushing, they are more toxic to the liver.^[55]

A better and safer form of niacin is inositol hexaniacinate, composed of one molecule of inositol (an unofficial B vitamin) and six molecules of niacin. This form of niacin has long been used in Europe to lower cholesterol levels and also to improve blood flow in patients with intermittent claudication. It yields slightly better clinical results than

standard niacin, including improved sugar level regulation, and is much better tolerated.^[56] ^[57] ^[58] In one study of 153 patients treated with inositol hexaniacinate at dosages ranging from 600–1,800 mg/day, no patients reported any side-effects or adverse reaction.^[56]

In cases of hyperlipidemia, a dosage of 600–1,000 mg three times daily is usually sufficient to produce an 18% reduction in total cholesterol, a 26% reduction in triglycerides, and an increase of 30% in HDL cholesterol levels.

Because niacin can disrupt blood sugar control in diabetics, patients taking any form of niacin including inositol hexaniacinate must closely monitor blood sugar levels and discontinue treatment in the event of worsening of diabetic control.

Biotin

Biotin functions in the manufacture and utilization of carbohydrates, fats, and amino acids. Since biotin is manufactured in the intestines by gut bacteria, it is not often discussed as a needed nutrient. A vegetarian diet has been shown to alter the intestinal bacterial flora in such a manner as to enhance the synthesis and promote the absorption of biotin.

Biotin supplementation has been shown to enhance insulin sensitivity and increase the activity of the enzyme

1209

glucokinase, the enzyme responsible for the first step in the utilization of glucose by the liver. Glucokinase concentrations in diabetics are very low. In one study, 16 mg/day of biotin resulted in significant lowering of fasting blood sugar levels and improvements in blood glucose control in type I diabetics.^[59] In a study in type II diabetics, similar effects were noted with 9 mg/day of biotin.^[60]

If high-dose biotin is used in type I diabetics, insulin requirements must be adjusted.

Vitamin B₆

Vitamin B₆ supplementation appears to offer significant protection against the development of diabetic neuropathy, as diabetics with neuropathy have been shown to be deficient in vitamin B₆ and to benefit from supplementation.^[61] Individuals with long-standing diabetes or who are developing signs of peripheral nerve abnormalities should definitely be supplemented with vitamin B₆. The standard dose for this application is 150 mg. It is interesting to note that the neuropathy of a vitamin B₆ deficiency is indistinguishable from diabetic neuropathy.

Vitamin B₆ may also prove to be important in preventing other diabetic complications because it inhibits glycosylation of proteins.^[62] Vitamin B₆ supplementation should be tried as a safe treatment for gestational diabetes. In one study of 14 women with gestational diabetes, taking 100 mg of vitamin B₆ for 2 weeks resulted in eliminating the diagnosis in 12 of the 14 women.^[63]

Vitamin B₁₂

A vitamin B₁₂ deficiency is characterized by numbness of the feet, pins and needles sensations, or a burning feeling, i.e. symptoms typical of diabetic neuropathy.^[64] ^[65] Vitamin B₁₂ supplementation has been used with some success in treating diabetic neuropathy. It is not clear if this is due to the correcting of a deficiency state or the normalization of the deranged vitamin B₁₂ metabolism seen in diabetics.^[66] Absence of megaloblastic anemia is not an adequate criteria for ruling out a deficiency. A deficit within the nerve cells will usually precede anemia, often by several years. Measuring blood levels is more reliable in diagnosing vitamin B₁₂ deficiency.

Oral supplementation with 1,000–3,000 mcg/day may be sufficient, but intramuscular vitamin B₁₂ may be necessary in many cases.

Vitamin E

Diabetics appear to have an increased requirement for vitamin E. High-dose vitamin E (e.g. 900 IU) not only improves insulin action, but also exerts a number of beneficial effects that may aid in preventing the long-term complications of diabetes.^[67]

Vitamin E appears to play a significant role in the prevention of diabetes. A prospective study followed 944 men, 42–60 years of age, who did not have diabetes at baseline. Forty-five men developed diabetes during the 4 year follow-up. A low lipid standardized plasma vitamin E concentration was associated with 3.9-fold risk of incidence of diabetes. A decrement of 1 µmol/L of serum vitamin E was associated with an increment of 22% in the risk of diabetes.^[68]

Magnesium

Magnesium is involved in several areas of glucose metabolism and there is considerable evidence that diabetics need supplemental magnesium. The reasons are that magnesium deficiency is common in diabetics and magnesium may prevent some of the complications of diabetes, such as retinopathy and heart disease.^[69] Magnesium levels are lowest in those with severe retinopathy.

The RDA for magnesium is 350 mg/day for adult males and 300 mg/day for adult females. The diabetic may need twice this amount. While ideally the magnesium should be derived from the diet, the average intake of magnesium by healthy adults in the US

ranges only between 143 and 266 mg per day. While magnesium occurs abundantly in whole foods, food processing refines out a large portion of magnesium. The best dietary sources of magnesium are:

- tofu
- legumes
- seeds
- nuts
- whole grains
- green leafy vegetables.

Fish, meat, milk, and most commonly eaten fruit are quite low in magnesium. As most Americans consume a diet high in refined foods, meat, and dairy products, low magnesium is common.

In addition to eating a diet high in magnesium-rich foods, supplementation with 300–500 mg of magnesium as aspartate or citrate is recommended. Also, diabetics should take at least 50 mg/day of vitamin B₆, as the level of intracellular vitamin B₆ appears to be intricately linked to the magnesium content of the cell. In other words, without vitamin B₆, magnesium will not get inside the cell.

Potassium

There are several reasons why diabetics should eat a high-potassium diet:^[70] ^[71]

- potassium supplementation yields improved insulin sensitivity, responsiveness and secretion
 - insulin administration induces a loss of potassium
-

1210

- a high potassium intake reduces the risk of heart disease, atherosclerosis, and cancer.

However, there are some concerns with potassium supplementation in diabetics.

The estimated safe and adequate daily dietary intake of potassium, as set by the Committee on Recommended Daily Allowances, is 1.9–5.6 g. If body potassium requirements are not being met through diet, supplementation is essential to good health. This is particularly true for the diabetic as well as for the elderly and the athlete. Potassium salts are commonly prescribed by physicians in the dosage range of 1.5–3.0 g/day. However, potassium salts can cause nausea, vomiting, diarrhea, and ulcers. These effects are not seen when potassium levels are increased through the diet only. This highlights the advantages of using vegetable juices, foods, or food-based potassium supplements to meet the human body's potassium requirements.

While most people can handle any excess of potassium, those with diabetes and kidney disease do not handle potassium normally and are more likely to experience heart disturbances and other consequences of potassium toxicity. Individuals with kidney disorders usually need to restrict their potassium intake. Most diabetics can consume a high-potassium diet, but their kidney function should be properly evaluated before prescribing a potassium supplement.

Manganese

Manganese is a cofactor in many enzyme systems involved in blood sugar control, energy metabolism, and thyroid hormone function.^[72] ^[73] In guinea pigs, a deficiency of manganese results in diabetes and the frequent birth of offspring who develop pancreatic abnormalities or who have no pancreas at all. Diabetics have been shown to have only one-half the manganese of normal individuals. A good daily dose of manganese for a diabetic is 30 mg.

Zinc

Zinc is involved in virtually all aspects of insulin metabolism: synthesis, secretion, and utilization. Zinc also has a protective effect against beta-cell destruction and has well-documented antiviral effects. Diabetics typically excrete excessive amounts of zinc in the urine and therefore require supplementation,^[74] which has been shown to improve insulin levels in both type I and type II diabetes.^[75] In addition, zinc helps to improve the poor wound healing observed in diabetics.^[76] Zinc is found in good amounts in whole grains, legumes, nuts, and seeds. The recommended level of zinc supplementation for diabetics is at least 30 mg/day.

Flavonoids

Flavonoids appear to normalize the body's reaction to allergens, viruses, and carcinogens as evidenced by their anti-inflammatory, anti-allergic, antiviral, and anti-carcinogenic properties. Recent research also suggests that flavonoids may be useful in diabetes.^[77] ^[78] ^[79] Flavonoids, such as quercetin, promote insulin secretion and are potent inhibitors of sorbitol accumulation. These effects may help to explain the favorable effects of many botanical medicines, many of which are high in flavonoids, traditionally used in the treatment of diabetes. The nutritional effects of flavonoids include: the increase of intracellular vitamin C levels, a decrease in the leakiness and breakage of small blood vessels, the prevention of easy bruising, and immune system support, all of which are of benefit in diabetes.^[79] In addition to consuming a diet rich in flavonoids, the diabetic should take an extra 1–2 g/day of mixed flavonoids.

Essential fatty acids

Both omega-6 and omega-3 fatty acids have shown benefit in various aspects of diabetes. In particular, the omega-6 gamma-linolenic acid (18:3n6) has been shown to offer significant protection against the development of diabetic neuropathy while the

omega-3 oils offer significant protection against atherosclerotic processes and augment insulin secretion in NIDDM. It appears the best approach in diabetics is to:

- increase the consumption of cold-water fish such as salmon, herring, mackerel, and halibut
- supplement the diet with 480 mg of gamma-linolenic acid as provided from evening primrose, borage, or blackcurrant oil
- consume 1 tbs (roughly 10 g) of flaxseed oil daily.

Omega-6 fatty acids. Both human and experimental diabetes are associated with a substantial disturbance in essential fatty acid (EFA) metabolism.^[80] As a result, a variety of microvascular, hemorrhological, and other abnormalities are produced which ultimately lead to reduced blood flow and neuronal hypoxia. Endoneural hypoxia impairs axonal transport, produces demyelination, and reduces neural ATPase activity. Much of this disturbance in EFA metabolism is likely due to intracellular deficiencies of key nutrients involved in EFA metabolism (e.g. vitamin C, magnesium, vitamin B₆, and zinc).

One of the key disturbances is the impairment in the process of converting linoleic acid to gamma-linolenic (GLA), dihomo-gamma-linolenic (DHGLA), and arachidonic acids.^[80] As a result, providing GLA in the form of borage, evening primrose, or black currant oils may offer a method to bypass some of this disturbance.

To test the hypothesis, a large multicenter trial was designed. The Gamma-Linolenic Acid Multicenter Trial enrolled 111 patients with mild diabetic neuropathy from seven centers into a randomized, double-blind, placebo-controlled parallel study of GLA at a dose of 480 mg/day for 1 year.^[81] The source of GLA used in the study was evening primrose oil. Patients in the treatment group took 12 capsules containing 40 mg of GLA per day.

Sixteen different parameters were assessed, including conduction velocities and amplitudes, hot and cold thresholds, sensation, tendon reflexes, and muscle strength. After 1 year, all 16 parameters improved, 13 of which were statistically significant. Treatment was more effective in relatively well-controlled than in poorly controlled diabetic patients. The latter finding highlights the need for a comprehensive approach in controlling blood sugar levels rather than expecting a single physiological aid (i.e. GLA) to compensate for poor control.

Omega-3 fatty acids. The omega-3 fatty acid-rich oils have been shown in hundreds of studies to lower cholesterol and triglyceride levels, including many studies in diabetics.^[82] The omega-3 fatty acids are being recommended to treat or prevent not only high cholesterol levels, but also high blood pressure, other cardiovascular diseases, cancer, autoimmune diseases like multiple sclerosis and rheumatoid arthritis,

allergies and inflammation, eczema, psoriasis, and many others (see [Ch. 86](#)).

In diabetics, omega-3 fatty acids have been shown to lower total cholesterol, LDL cholesterol, and triglyceride levels while simultaneously raising HDL cholesterol levels.^[82] Additional benefits observed in diabetics are:

- decreased platelet reactivity
- decreased blood viscosity
- increased plasma levels of tissue plasminogen activator
- reduced endothelial permeability
- improved insulin.

However, all of the studies have not yielded positive effects (discussed below). In fact, some studies have shown deterioration of blood sugar control and elevations in blood lipids.^[82] Although there is no obvious explanation for these contradictory findings, proper dosage and antioxidant support (e.g. vitamin E) appear to be critical to produce beneficial rather than deleterious effects.

The initial enthusiasm for the use of fish oils in diabetes was modified by reports of potentially deleterious effects, including increased levels of plasma glucose, total cholesterol, LDL cholesterol, and serum apolipoprotein B. The magnitude of these adverse effects was relatively small, but nonetheless their occurrence raised doubts regarding the safety of fish oil supplementation in diabetes. These adverse effects occurred at larger doses, usually 4–10 g/day of EPA and DHA. Subsequent studies using lower doses (2.5 g of omega-3 fatty acids) or highly purified EPA (1,800 or 900 mg/day) have led to a better understanding of the potential problems with fish oils.^[83] ^[84]

Specifically, dosage appears to be a critical element. At the lower dosage of 2.5 g of omega-3 fatty acids, fish oil supplementation inhibited platelet aggregation and thromboxane A₂ production, reduced elevated systolic blood pressure, reduced triglyceride levels, and caused small, but statistically significant, increases in HBA1c and total cholesterol.^[83] The benefits were retained and the deleterious effects reduced at the lower dosage.

In another study, a 96% pure EPA product at a dose of 900 mg/day for 8 weeks reduced platelet aggregation due to platelet-activating factor, but had little effect on diabetes regulation, lipid levels, and blood rheology.^[84] In contrast, 1,800 mg/day for 8 weeks reduced platelet aggregation, but LDL cholesterol increased significantly. These results again suggest that there is a threshold of benefit with EPA. At dosages above 900 mg/day, negative effects on blood sugar control, and possibly blood lipids, begin to appear.

Altogether, these studies seem to suggest caution when prescribing fish oils in diabetics. One of the reasons fish oil products may be negatively affecting diabetes is the high level of lipid peroxides in these preparations coupled with their effects on depleting antioxidant nutrients when ingested. A better approach to gaining the benefits of omega-3 oils in diabetics may be through fish consumption and/or the use of flaxseed

oil, neither of which is associated with negative effects in diabetes.

Increased consumption of cold-water fish has been shown to produce effects equal or superior to fish oil supplementation. For example, in one study, 25 men with high cholesterol levels were studied over a 5 week period, comparing the effects of eating an equivalent amount of fish oil from whole fish with those of a fish oil supplement.^[85] Although total cholesterol levels were unchanged in both groups, both fish and fish oil supplements lowered triglycerides and raised HDL cholesterol. However, dietary fish produced some additional benefits over the fish oil supplements. These findings suggest that while both fish consumption and fish oil supplementation produce desirable effects on lipids and lipoproteins, fish consumption is more effective in improving several other factors involved in cardiovascular disease.

Another study demonstrated an inverse correlation between fish intake and impaired glucose tolerance and diabetes. A mean daily intake of 24.2 g was associated with a significantly lower incidence of glucose intolerance.^[86] In addition, mortality was lower in fish consumers (20.6/1,000 person-years) than in those who did not eat fish (31.2/1,000 person-years).

These studies, along with additional epidemiological

studies showing a low prevalence of both IDDM and NIDDM in cultures consuming cold-water fish, indicate that omega-3 fatty acids may offer some protection against the development of diabetes (see [Ch. 86](#)).^[82]

Although the majority of studies on omega-3 oils have utilized fish oils (eicosapentaenoic acid [EPA] and docosahexanoic acid [DHA]), flaxseed oil may offer similar benefits because it contains alpha-linolenic acid (ALA), an omega-3 oil which the body can convert to EPA. Linolenic acid exerts many of the same effects as EPA as well as several on its own.^[87]

Flaxseed oil supplementation may avoid some of the problems associated with EPA supplementation in diabetics. In the presence of omega-6 fatty acids, ALA is not as effective in increasing tissue concentrations of EPA and lowering tissue concentrations of arachidonic acid.^[88] In contrast to EPA, this moderate effect of flaxseed oil in the presence of omega-6 oils may not compromise the already disturbed EFA metabolism of the diabetic. In addition, given the fact that encapsulated fish oils (1) have been shown to contain very high levels of lipid peroxides; (2) deplete body stores of antioxidant nutrients; and (3) are expensive to use at therapeutic dosages (1.8 g/day EPA for most clinical applications), flax oil will more than likely emerge as the preferred source of omega-3 fatty acids in the treatment of diabetes as well as in atherosclerosis, high blood pressure, and inflammatory conditions such as psoriasis, rheumatoid arthritis, eczema, multiple sclerosis, and ulcerative colitis.

In summary, diabetics can benefit from omega-3 oils. At this time the best recommendation may be to increase the amount of cold-water fish in the diet and use flaxseed oil. An average daily intake of 30 g/day of fish is appropriate. This amount works out to roughly two 100 g servings/week. For flaxseed oil, a daily dosage of 1 tablespoon (roughly 10 g) is recommended for diabetics.

Carnitine

Carnitine supplementation of diabetic patients has resulted in significantly decreased total serum lipid and increased HDL cholesterol levels.^[89] In addition, it increases α -oxidation of fatty acids, possibly playing a role in preventing diabetic ketoacidosis.

Inositol

As mentioned above, inositol supplementation has shown some success in the treatment of experimental animal diabetic neuropathy, since it helps to re-establish normal myoinositol levels in the deficient neuron.^[6] The neuronal myoinositol deficiency is believed to be due to a combination of glucose competition with myoinositol for active transport and accumulation of sorbitol within the cell, resulting in the loss of intracellular myoinositol. Oral supplementation in human diabetics has not, however, resulted in significant clinical improvement.^[26]

Botanical medicines

Before the advent of insulin, diabetes was treated with plant medicines. In 1980, the World Health Organization urged researchers to examine whether traditional medicines produced any beneficial clinical results. In the last 10–20 years, scientific investigation has, in fact, confirmed the efficacy of many of these preparations, some of which are remarkably effective. Covered here are those plants that appear most effective, are least toxic, and have substantial documentation of efficacy.

Even though the herbs discussed possess blood sugar-lowering effects, proper and effective natural treatment of the diabetic patient requires the careful integration of diet, nutritional supplements, lifestyle, and botanical medicine.

Allium cepa and Allium sativum

Onions and garlic have demonstrated blood sugar-lowering action in several studies.^[90]^[91] The active principles are believed to be sulfur-containing compounds, allyl propyl disulfide (APDS) and diallyl disulfide oxide (allicin), respectively, although other constituents such as flavonoids may play a role as well.

Experimental and clinical evidence suggests that APDS lowers glucose levels by competing with insulin (also a disulfide) for insulin-inactivating sites in the liver.^[91] This results in an increase of free insulin. ADPS administered in doses of 125 mg/kg to fasting humans causes a marked fall in blood glucose levels and an increase in serum

insulin. Allicin at doses of 100 mg/kg produces a similar effect.

Graded doses of onion extracts (1 ml of extract = 1 g of whole onion) at levels sometimes found in the diet, i.e. 1–7 ounces of onion, reduce blood sugar levels in a dose-dependent manner as measured by oral and intravenous glucose tolerance tests, i.e. the higher the dose, the greater the effect. The effects are similar in both raw and boiled onion extracts.^[91]

The cardiovascular effects of garlic and onions, i.e. cholesterol- and blood pressure-lowering actions, further substantiate the value of liberal intake of garlic and onions by the diabetic patient.

Momordica charantia

Bitter melon, also known as balsam pear, is a tropical fruit widely cultivated in Asia, Africa and South America. A green cucumber-shaped fruit covered with gourd-like bumps, bitter melon looks like an ugly cucumber. In

1213

addition to the unripe fruit being eaten as a vegetable, bitter melon has been used extensively in folk medicine as a remedy for diabetes. The blood sugar-lowering action of the fresh juice or extract of the unripe fruit has been clearly established in human clinical trials as well as experimental models.^{[92] [93]}

Bitter melon is composed of several compounds with confirmed anti-diabetic properties. Charantin, extracted by alcohol, is a hypoglycemic agent composed of mixed steroids that is more potent than the oral hypoglycemic drug tolbutamide. Momordica also contains an insulin-like polypeptide, polypeptide-P, which lowers blood sugar levels when injected subcutaneously into type I diabetics.^[94] Since it appears to have fewer side-effects than insulin, it has been suggested as a replacement for some patients.

The oral administration of bitter melon preparations has shown good results in clinical trials in patients with type II diabetes.^{[92] [93]} In one study, glucose tolerance was improved in 73% of type II diabetics given 57 g of the juice.^[92] The pooled area under the glucose tolerance curves of the patients responding to the bitter melon was 187.0 cm², much lower than the baseline level of 243.6 cm². In another study, 15 g of the aqueous extract of bitter melon produced a 54% decrease in postprandial blood sugar level and a 17% reduction in glycosylated hemoglobin in six patients.^[93]

Unripe bitter melon is available primarily at Asian grocery stores. Commercial suppliers and health food stores may have bitter melon extracts, but the fresh juice is probably the best as this traditional form was used in some of the studies. Bitter melon juice is very difficult to make palatable since, as its name implies, it is quite bitter. When using this effective plant medicine, instruct the patient to simply plug his or her nose and quickly drink the 57 g shot of the juice. The dosage of other forms should approximate this

dose.

Gymnema sylvestre

Gymnema sylvestre, a plant native to the tropical forests of India, has long been used as a treatment for diabetes. Recent scientific investigation has upheld its effectiveness in both type I and type II diabetes.^[95] ^[96]

Gymnema sylvestre appeared on the US market a few years ago; originally it was hyped as a “sugar blocker”. Manufacturers erroneously claimed that *Gymnema* could block the absorption of sugar in the gastrointestinal tract and allow the sugar to pass through the intestinal tract unabsorbed. Ridiculous advertisement claims were made such as “how to cut down on sugar calories without cutting down on sugar”.

When applied to the tongue, *Gymnema* components, like gymnemic acid, block the sensation of sweetness. Clinically this has shown some significance. Subjects that had *Gymnema* extracts applied to their tongue have been shown to eat fewer calories at a meal compared with controls. Consumption of capsules or tablets has not been shown to produce the same effect.

Gymnema extracts have been shown to enhance glu-cose control in diabetic dogs and rabbits. Interestingly, in animals that have their pancreas removed, *Gymnema* possesses no apparent effects, suggesting that *Gymnema* enhances the production of endogenous insulin. There is evidence in animal studies that it accomplishes this through regeneration of the insulin-producing beta-cells in the pancreas. Studies in humans with both types of diabetes also seem to support the possibility of pancreas regeneration.^[95] ^[96]

Gymnema extract has shown positive clinical results in both type I and type II diabetes. An extract of the leaves of *Gymnema sylvestre* given to 27 patients with type I diabetes on insulin therapy was shown to reduce insulin requirements and fasting blood sugar levels, and to improve blood sugar control.^[95] In type I diabetes, *Gymnema* appears to enhance the action of insulin. In a study of type II diabetics, 22 were given *Gymnema* extract along with their oral hypoglycemic drugs. All patients demonstrated improved blood sugar control; 21 out of the 22 were able to reduce their drug dosage considerably; and five subjects were able to discontinue their medication and maintain blood sugar control with the *Gymnema* extract alone.^[96]

The dosage for *Gymnema sylvestre* extract is 400 mg/day in both type I and type II diabetes. It is interesting to note that *Gymnema* extract given to healthy volunteers does not produce any blood sugar-lowering or hypoglycemic effects.^[96] No side-effects have been reported from *Gymnema* extract.

Trigonella foenumgraecum

Fenugreek seeds have demonstrated significant anti-diabetic effects in experimental and clinical studies. The active principle is in the defatted portion of the seed and

contains the alkaloid trigonelline, nicotinic acid, and coumarin.

Administration of the defatted seed (in daily doses of 1.5–2 g/kg) to both normal and diabetic dogs reduces fasting and postprandial blood levels of glucose, glucagon, somatostatin, insulin, total cholesterol and triglycerides, while increasing HDL cholesterol levels.^[97]

Human studies have confirmed these effects. Defatted fenugreek seed powder given twice daily at a 50 g dose to insulin-dependent diabetics resulted in significant reduction in fasting blood sugar and improved glucose tolerance test results.^[98] There was also a 54% reduction in 24 hour urinary glucose excretion and significant reductions in LDL and VLDL cholesterol and triglyceride values. In non-insulin diabetics, the addition of 15 g of

1214

powdered fenugreek seed soaked in water significantly reduced postprandial glucose levels during the meal tolerance test.^[99] These results indicate that fenugreek seeds or defatted fenugreek seed powder should be included in the diet of the diabetic.

Atriplex halimu

Salt bush is a branchy woody shrub native to the Mediterranean, North Africa, and southern Europe. Salt bush is especially common around the Jordan valley in inundated saline depressions and oases. Researchers began investigating the possible therapeutic benefits of atriplex in humans when it was noticed that, if sand rats switched from a diet rich in atriplex to standard rat chow, they would typically develop severe diabetes. Restoring atriplex to the diet brought about a quick reversal of the condition.

Human studies conducted in Israel demonstrated improved blood glucose regulation and glucose tolerance in patients with type II diabetes.^{[100] [101]} Atriplex is rich in fiber, protein, and numerous trace minerals including chromium. The dosage used in the human studies was 3 g/day.

Pterocarpus marsupium and epicatechin-containing plants

Pterocarpus has a long history of use in India as a treatment for diabetes. The flavonoid, (-)-epicatechin, extracted from the bark of this plant, has been shown to prevent beta-cell damage in rats. Further, both epicatechin and a crude alcohol extract of *Pterocarpus marsupium* have been shown to actually regenerate functional pancreatic beta-cells in diabetic animals.^{[102] [103]}

The different forms of catechin and epicatechin, and their glycosides and esters, constitute an interesting and clinically valuable group of flavanols. These flavan-3-ols readily undergo epimerization (interconversion between chemically identical but

sterically different forms) during which interconversion of the (+) and (-) forms is possible. These compounds are very strong antioxidants, particularly against the hydroxyl radical-induced lipoperoxidation characteristic of alloxan-induced diabetes and many hepatotoxins.^[104] It is quite probable that most flavan-3-ols have anti-diabetic properties.^[105]

In addition to *Pterocarpus*, the dry weight percentage of epicatechin is very high in a number of other plants, most notably *Camellia chinensis* (green tea) – 1 to 3% – and *Acacia catechu* (burma catch) – 5%. These plants are also good sources of other flavan-3-ols, including catechins, gallo-catechins and epigallocatechins.

As commercial sources of *Pterocarpus* are lacking in the United States, green tea may be a suitable alternative. The recommended dosage is at least two cups of green tea per day or roughly 240 mg of green tea polyphenols.

Vaccinium myrtillus

Bilberry or European blueberry is a shrubby perennial plant that grows in the woods and forest meadows of Europe. The fruit is a blue-black berry that differs from an American blueberry in that its meat is also blue-black. Bilberry leaf tea has a long history of folk use in the treatment of diabetes. This use is supported by research which has shown that oral administration reduces hyperglycemia in normal and diabetic dogs, even when glucose is concurrently injected intravenously.^[106]^[107] Although this research is interesting, it is thought that the berries or extracts of the berries offer even greater benefit.

The anthocyanoside myrtillin, extracted with a slightly acidic ethanol solution, is apparently the most active constituent. Upon injection, while it is somewhat weaker than insulin, it is less toxic, even at 50 times the 1 g/day therapeutic dose. It is of great interest to note that a single dose can produce beneficial effects lasting for several weeks.

Vaccinium myrtillus anthocyanosides provide other benefits in diabetics. Specifically, they have been shown to increase intracellular vitamin C levels, decrease the leakiness and breakage of small blood vessels, prevent easy bruising, and exert potent antioxidant effects. These effects are of particular value in dealing with the microvascular abnormalities of diabetes.

Interest in bilberry anthocyanosides began when it was observed during World War II that British Royal Air Force pilots reported improved night-time visual acuity on bombing raids after consuming bilberries. Subsequent studies showed that the administration of bilberry extracts to healthy subjects resulted in improved night-time visual acuity, quicker adjustment to darkness, and faster restoration of visual acuity after exposure to glare.

It appears that anthocyanosides have an affinity for the blood vessels of the eye and the retina, especially the macula, and improve circulation to the retina.^[108]^[109]^[110] This

affinity is consistent with several of the clinical effects observed, including positive results in diabetic retinopathy, macular degeneration, cataracts, retinitis pigmentosa, and night-blindness.^[108] ^[111] Bilberry extracts have been prescribed for diabetic retinopathy in France since 1945.

The standard dose for bilberry extracts is based on its anthocyanoside content, as calculated by its anthocyanidin percentage. Widely used pharmaceutical preparations in Europe are standardized for anthocyanidin content (typically 25%). These extracts are also available in the US. The standard dose is 80–160 mg three times daily.

1215

Ginkgo biloba

Although the primary clinical application of *Ginkgo biloba* extract (GBE) is cerebral vascular insufficiency,^[112] ^[113] GBE has also been shown to improve the blood flow to peripheral tissues like the arms, legs, fingers, and toes. This is an important effect, as peripheral vascular insufficiency is quite common in diabetes. In several double-blind trials in patients with intermittent claudication, ginkgo was shown to be quite active and superior to placebo.^[114] ^[115] ^[116] Not only were measurements of pain-free walking distance and maximum walking distance dramatically increased, but ultrasound measurements demonstrated increased blood flow through the affected limb.

The significance of demonstrating measurable improvement in blood flow through the affected areas is great. While conventional medical treatment of these patients (muscular rehabilitation and the elimination of risk factors, e.g. smoking, excess weight, etc.) results in clinical improvement, such as increased walking tolerance, it has not shown improved perfusion of the limbs, and the results are limited over time. Therefore, the muscular rehabilitation and elimination of risk factors, while valuable therapies, are not satisfactory alone.

Ginkgo is clearly an important medicine in the treatment of peripheral vascular disease due to diabetes. *Ginkgo biloba* extract has also been shown to prevent diabetic retinopathy in diabetic rats, suggesting it may have a protective effect in human diabetics.^[116]

The dosage of the *Ginkgo biloba* extract standardized to contain 24% ginkgo flavoglycosides is 40 mg three times a day.

Ginseng

In a double-blind controlled study, 36 non-insulin-dependent diabetic patients were treated for 8 weeks with ginseng extract at 100 or 200 mg or with a placebo. Ginseng elevated mood, improved psychophysiological performance, and reduced fasting blood sugars and body weight. The 200 mg dose improved glycated hemoglobin, serum

aminoterminalpropeptide concentrations, and physical activity.^[117]

Exercise

An appropriate exercise training program is vitally important in a DM treatment plan.^[39]^[40] ^[41] ^[42] ^[43] Exercise improves many parameters and is indicated in both IDDM and NIDDM. Physically trained diabetics experience many benefits:^[118] ^[119] ^[120]

- enhanced insulin sensitivity with a consequent diminished need for exogenous insulin
- improved glucose tolerance
- reduced total serum cholesterol and triglycerides with increased HDL levels that result in a more anti-atherogenic state
- improved weight loss (in obese diabetics).

However, a physical fitness program does present some risk to the diabetic and must be carefully adapted to the fitness of the patient. Exercise should be avoided during periods of hypoglycemia.

Besides its well-known and well-documented value, exercise may have a more specific beneficial effect for diabetics: exercise increases tissue levels of chromium (in rats)^[121] and increases the number of insulin receptors in IDDM patients.^[122] It is possible, then, that many of the beneficial effects of exercise are directly related to improved chromium metabolism.

THERAPEUTIC APPROACH

Effective treatment of the diabetic patient requires the careful integration of a wide range of therapies and patients who are willing to substantially improve their lifestyles. Type II diabetes is usually the end result of many years of chronic metabolic insult and, although treatable with the natural metabolic approach presented here, its ultimate resolution will take persistence. Although much of the information presented in this chapter has focused on NIDDM, it is equally appropriate for the IDDM patient, with the exception that, according to current information, the type I diabetic will always require insulin.

The first step in the therapy of either IDDM or NIDDM is a thorough diagnostic work-up. Of particular importance is identifying any of the complications of DM. The patient's diet, environment, and lifestyle should be carefully studied to rule out any exposure to agents that may be inducing his/her glucose intolerance.

Then a diet, exercise, and supplement program should be developed that meets the individual needs of the patient and his/her current glucose tolerance. For maximum efficacy, the patient's weight must be normalized (see [Ch. 175](#) for specific therapeutic recommendations).

When treating patients with severe or uncontrolled diabetes, a high level of awareness

of the acute diabetic complications must be maintained. The clinician should be aware of the early signs and symptoms of diabetic acidosis and hyperosmolar non-ketogenic coma and have the patient hospitalized at the first signs.

Finally, the patient must be monitored carefully, particularly if he/she is on insulin or has relatively uncontrolled diabetes. As discussed above, the Somogyi phenomenon can give misleading fasting and urinary glucose levels which can lead to inappropriate therapeutic actions and serious, life-threatening effects for the patient. Patient symptomatology, home glucose monitoring, and the HgbA1c test are, at this time, the

1216

best ways to monitor the progress of the patient. It is important to recognize that as these therapies take effect, the patient's drug dosages will have to be altered and that a good working relationship with the prescribing doctor will greatly aid the healing process. The ultimate goal is to re-establish normal glycemia and prevent the development of (or ameliorate) the complications of DM.

Note. Under no circumstances should a patient be suddenly taken off diabetic drugs, especially insulin. According to current information, an IDDM patient will never be able to stop taking insulin.

Diet

The HCF diet modified to incorporate more natural foods is clearly the diet of choice. All simple, processed and concentrated carbohydrates must be avoided. Complex-carbohydrate, high-fiber foods should be stressed, and fats should be kept to a minimum. Legumes, onions and garlic are particularly useful, and should be encouraged.

Supplements

- Chromium: 200–400 mcg/day
- Vitamin C: >2,000 mg/day
- Biotin
 - 16 mg/day (IDDM)
 - 9 mg/day (NIDDM)
- Pyridoxine: 150 mg/day
- Vitamin E: 900 IU/day
- Selenium: 200 mcg/day
- Magnesium: 300–500 mg/day
- Manganese: 30 mg/day
- Zinc (preferably picolinate): 25 mg/day
- Mixed flavonoids: 1,000–2,000 mg/day

- Fiber (guar, pectin, or oat bran): 20–30 g/day.

Botanical medicines

- *Momordica charantia*: 30–60 ml fresh juice three times/day
- *Gymnema sylvestre extract*: 200 mg two times/day
- Defatted fenugreek powder: 50 g/day
- *Atriplex halimus*: 3 g/day
- Green tea: two 120 ml cups daily or 200–300 mg of green tea polyphenols
- *Ginkgo biloba* extract (24% ginkgo flavoglycosides): 40 mg three times/day.
- *Panax ginseng* extract (5% ginsenosides): 100 mg one to three times/day.

Exercise

A graded exercise program should be developed which is both cognizant of the patient's fitness and interest, and elevates heart rate at least 50% for half an hour three times a week.

Chapter 148 - Epididymitis

Nancy Roberts ND

DIAGNOSTIC SUMMARY

- Acute or chronic, painful, tender swelling of the epididymis
- Usually accompanied by fever, chills, pain in the groin, and leukocytosis
- Usually secondary to other infections of the genitourinary tract.

GENERAL CONSIDERATIONS

Epididymitis is an inflammatory process in the scrotum which causes the afflicted male much misery and concern. Acute epididymitis is self-limited and, with good immune support and appropriate medical care, will resolve without complications. Chronic epididymitis is uncommon and is generally seen as an irreversible end stage of a severe acute attack which has not been treated or has not responded, and has been followed by frequent mild attacks.^[1]

In the average adult male, the epididymis is 5–7 cm long and 1 cm in diameter. The structure is C-shaped, tapers downward, and hugs the posterior border of the testis. The epididymis contains a tortuous tubule which has pseudostratified columnar epithelial lining. The epididymis continues on as the vas deferens which joins the spermatic cord in the inguinal canal. Eventually it joins the ejaculatory duct.^{[1] [2]}

The sperm mature within the epididymis.^[3] The exact nature of the process is unknown, but the epididymis makes a critical contribution since without it the spermatozoa cannot develop the ability to fertilize.^[4] It is known that the epididymis has two functions: one is to promote ability of the sperm to swim out of the seminal plasma and negotiate cervical passage to the uterotubal junction; the other prevents the expression of these abilities in the male tract. Reduced forward progression of the sperm is accomplished by the secretion of viscous proteins and tight packing of the sperm.^[5]

The particular pain in epididymitis is caused by

1220

pressure against the inelastic casing of the tunica albuginea. As the inflammation spreads up the vas, the pain is intensified by the constricting action of the external inguinal ring, which, by not allowing swelling, increases the pressure.^[2] Infection may spread through the lumen of the ducts, lymphatics, and blood vessels or directly through tissues and along the membranes.^{[6] [7] [8] [9] [10]} Ligation of the vas deferens, but not the lymphatics, does not prevent epididymitis.^[7]

Rows of tight junctions form a blood–testis barrier.^[11] Large molecules are prevented access while smaller molecules freely permeate the lumen, although much of the transport is stereospecific. (Most testing of these barriers has been done on animal species; human studies in this regard are not available.)

DIAGNOSIS

There are a variety of diseases (listed in [Table 148.1](#)) which must be considered in the differential diagnosis of the acute scrotum.

Epididymitis

With classic epididymitis, there is usually sudden onset of severe scrotal pain and swelling. There may also be a history of gradual onset of swelling and pain.^[10] This pain may radiate along the spermatic cord and can become flank pain. Visible swelling follows the pain, and testicles can quickly double in size. Early in the sequence the epididymis can be distinguished within the scrotal sac but within hours the testis and the epididymis become one mass. The physician can elicit tenderness over the groin or the lower abdominal quadrant of the same side. If the epididymis is palpable, the structure will be indurated, enlarged and painful. Inflammation will be unilateral, with the left and right sides being equally represented.^[8] A slight elevation in temperature will be observed in only half of the patients.

A urinalysis (UA) is recommended, but frequently

TABLE 148-1 -- Diseases to consider in the differential diagnosis of the acute scrotum

- Intrascrotal torsion

- extravaginal torsion

- intravaginal torsion

- twisting of a testicular appendage

- Mumps

- Scrotal tumor

- Tubercular epididymitis

- Henoch–Schönlein purpura

- Inguinal hernia

- Hydrocele

- Idiopathic scrotal edema

- Spermatoceles

- Chemical epididymitis

- Sexually transmitted diseases

will be negative. Follow with a culture if bacteria are present in the UA. Pyuria is the most frequent finding. To improve sensitivity, do a prostatic massage and collect the first 20–30 ml of the urine. Cleanse the penis before massage and urine collection.

Intravenous urography has, in the past, been employed diagnostically in epididymitis. This is not recommended. Studies conclusively demonstrate that findings do not alter the method of care. The procedure is expensive, has significant risks, and is a poor clinical choice unless tuberculosis is suspected and there are abnormal chest films.^[12] ^[13]

It is interesting to note that the method of making a diagnosis has become more conservative over the years. In the 1950s exploratory surgeries and wedge biopsies were commonplace. So, too, were week-long hospital stays. In the 1960s epididymis washings were frequently performed. Exploratory procedures are now virtually never recommended in epididymitis and aspirates have been found to be of little value.

Intrascrotal torsion

In children, various forms of torsion should be suspected. Intrascrotal torsion is a rotational twisting of the vascular pedicle which leads to venous and arterial insufficiency.^[14] The damage is in proportion to the duration of the ischemia. When this duration is 8 hours or less, there is usually 100% recovery, while 24 hours of ischemia results in only a 50% chance of total recovery. There are three types of torsion:

- Extravaginal torsion is seen in newborns and will present as an asymptomatic, firm, discolored mass.
- Intravaginal torsion is most common in children (although it has been observed in post-teen young adults^[10]) and is a congenital problem with abnormal testicular suspension. Pain is the presenting complaint and, in addition to the acute scrotal inflammation, there is nausea and vomiting.
- Torsion resulting from a twisting of a testicular appendage. There will be point tenderness on the superior aspect of the testis and it is sometimes possible to palpate a firm, pea-sized nodule. This torsion is precipitated by human chorionic

gonadotropin in puberty. The appendage enlarges and infarcts.

There are several procedures, summarized in [Table 148.2](#), which are helpful in differentiating torsion from epididymitis. The spermatic cord is twisted in torsion so the testis is often elevated and rotated such that the epididymis is not in its normal position. Prehn's sign (elevation of the testis) will give relief in epididymitis but not in torsion. In epididymitis, the skin adheres to the epididymis on the affected side. There is no adherence

1221

TABLE 148-2 -- Differentiation of epididymitis and intrascrotal torsion

| | Epididymitis | Torsion |
|--------------------|---------------------|------------------|
| Testis height | Normal | Elevated |
| Prehn's sign | Relief | No relief |
| Skin | Adheres | No adherence |
| Cremasteric reflex | Present | Absent |
| Pyuria | Usually present | Unusual |
| Doppler | Increased sounds | Decreased sounds |

of the skin to the epididymis in torsion.^[10] The cremasteric reflex (elicited by stroking the medial thigh and observing testicular retraction) is usually absent in torsion.^[14] If there is pyuria, the diagnosis of torsion is more difficult. Conversely, a normal urinalysis in a child makes epididymitis unlikely. Inspection with a Doppler will reveal reduced sounds with torsion as there is less spermatic blood flow. Epididymitis will have the sounds of increased blood flow typical of inflammation.

Mumps

Epididymo-orchitis occurs in approximately 20% of postpubertal males with mumps and is usually unilateral. When parotitis is present, diagnosis is simple. When parotitis is not present, other associated clinical syndromes of obscure etiology (aseptic meningitis, encephalitis, pancreatitis, or arthritis) may help in the diagnosis.^[15]

Tubercular epididymitis

Tubercular epididymitis is rarely associated with pain or fever. There may be beading of the vas and induration of the prostate. Tubercular involvement should be suspected where there is no sexual contact or a sexually transmitted disease (STD) is unlikely and there is no bacteriuria or pyuria (with bacteriuria or pyuria and sexual contact, an association with non-gonococcal urethritis (NGU) rather than tuberculosis is more

likely).^[16] When TB is suspected, a chest film should be ordered before more elaborate testing is initiated. Tuberculosis of the testis and epididymis is almost invariably secondary to infection in some other part of the body, most often the genitourinary tract.^[6]

Scrotal tumors

With scrotal tumors, the swelling tends to be painless, although hemorrhage can cause painful distention against the tunica albuginea. With a tumor, the prostate and UA are normal. Diagnosis is made through ultrasonography and laboratory tests for tumor marker glycoproteins (alpha-fetoprotein and human chorionic gonadotropin). Biopsy should never be performed since it greatly increases the risk of lymphatic spread. Testicular cancer is the most common cancer in young men. Neoplasm should be particularly suspected when epididymitis fails to respond to adequate treatment.

Trauma

Trauma is a rare cause of epididymitis as the scrotum will “roll away” from injuries.^[17] This etiology should be reserved for cases with objective evidence of trauma and absence of infection of the urine or prostate.^[18] Trauma will illicit discoloration, while infection does not. Scrotal trauma is usually obvious from the history.

Henoch–Schönlein purpura

Henoch–Schönlein purpura will present with scrotal involvement 15–38% of the time.^[14]^[18] ^[19] It will tend to mimic torsion more than epididymitis and there is an associated diffuse systemic vasculitis. Rarely will this disorder present with only scrotal symptoms.

Inguinal hernia

An inguinal hernia or hydrocele will generally not look like an acute scrotum, except when the hernia is incarcerated. The focus is above the scrotum and one can palpate the spermatic thickening between the vas and the inguinal ring.

Idiopathic scrotal edema

Idiopathic scrotal edema is generally seen in children. This scrotal enlargement will tend to be bilateral and symmetrical. The etiology may be allergic and the redness can extend past the scrotum to the perineum or the inguinal region. There is no deep tenderness, the pain coming from skin or subcutaneous layers.

Spermatoceles

Spermatoceles arise from the epididymis. Spermatoceles are translucent, which is sufficient to differentiate them from epididymitis.^[17]

Chemical epididymitis

There is vigorous debate in the literature about “chemical epididymitis”. This form of epididymitis has a non-pathogenic basis and is triggered by the reflux of sterile urine into the epididymis.^{[9] [20] [21] [22]} Chemical epididymitis has been induced in laboratory models but such research has not eliminated the controversy. Many researchers insist that reflux is in fact impossible.^{[7] [17]} If reflux is occurring, the urine follows the urethra back through the ejaculatory ducts into the vas deferens. There are

1222

studies which demonstrate an idiopathic epididymitis with sterile cultures of epididymal washings.^[21] It is thought that strenuous exercise or straining with a full bladder causes a “retrograde urination” into the vas.^{[16] [23]}

Sexually transmitted diseases

The physician must always consider STDs with suspected epididymitis. Organisms associated with epididymitis are listed in [Table 148.3](#). The existence of a urethral discharge and sexual exposure are important parts of the history. The data from one recent study suggest that *Chlamydia trachomatis* is now the major cause of acute epididymitis in men under 35 years of age in Seattle.^[24] Epididymitis from an STD will generally present with urethritis. In these cases a urethral culture is more beneficial than a urine culture. In older men the epididymitis tends to be due to urinary tract abnormalities or sequelae from instrumentation rather than STDs.^[25] Epididymitis not arising from an STD and in elderly men is usually from an Enterobacteriaceae or *Pseudomonas* infection. Generally, chlamydial epididymitis tends to have more discharge and inguinal pain, while the coliforms have prominent scrotal edema and erythema.^[24] As might be expected, a recent study found that homosexual men with acute epididymitis were found to have infections from coliforms rather than *Chlamydia*. The study hypothesizes that the prevalence of *E. coli* could be due to urethral exposure to enteric bacteria during anal intercourse.^[26]

THERAPEUTIC CONSIDERATIONS

Bromelain

Bromelain is a good all-purpose therapy for epididymitis. As the kinins and prostaglandins are inhibited by the action of bromelain, the decreased inflammation reduces recovery time. Antibacterial agents should be combined with the bromelain except where trauma is clearly the etiology. With trauma, bromelain, bedrest, ice and support are recommended. Bromelain may enhance the efficacy of the antibacterial herbs by increasing the permeability of the blood–testis barrier.^{[27] [28] [29]}

TABLE 148-3 -- Organisms associated with epididymitis

- *Chlamydia trachomatis*

- *Cryptococcus neoformans* (primarily in immunocompromised hosts)

- *Hemophilus influenzae* (rare)

- Mumps

- *Mycobacterium tuberculosis*

- *Neisseria gonorrhoea*

- *Neisseria meningitidis*

- *Salmonella typhi* (rare)

- Various filaria (tropical regions only)

Berberine

Berberine-containing herbs are effective antibacterial agents. Since berberine has been shown to inhibit *Chlamydia trachomatis*, berberine with bromelain is an excellent choice for “idiopathic epididymitis”. For a more complete discussion of berberine-containing botanicals, see [Chapter 91](#).

THERAPEUTIC APPROACH

Treatment is straightforward. Bedrest and local ice for the first 48 hours are very beneficial. An athletic supporter will further relieve pain once normal activity is resumed. When a positive urine culture has identified an organism, it can be specifically treated and, as with all infections, the immune system should be supported (see [Ch. 53](#) for more information). If the man is 18–37 years old or is sexually active in a new or non-monogamous relationship, *Chlamydia* should be highly suspected. Sexual partners should also be tested for *Chlamydia* (see [Ch. 143](#) for more details on treatment).

The patient should be advised to empty his bladder prior to strenuous activity, and counseled to interrupt strenuous activity if there is a sensation of a full bladder.^{[17] [20]} The pain of epididymitis is very motivating and patients, once informed, will follow these guidelines.

The patient should be instructed to return immediately if there are recurring signs and symptoms of epididymitis. Pain and swelling can be relieved within 2 weeks, but it typically takes 4 weeks, and as long as 3 months, for the scrotum to return to normal size.^[10] All treatments (except ice and bedrest) need to be continued for at least 1 week after the scrotum has returned to normal size.

Supplements

- Vitamin C: 1,000 mg four times/day
- Beta-carotene: 200,000 IU/day
- Bromelain: 250 mg four times/day (between meals).

Botanical medicines

- *Hydrastis canadensis*
 - dried root: 0.5–1.0 g three times/day
 - tincture (1:10): 6–12 ml three times/day
 - fluid extract (1:1): 1.0–2.0 ml three times/day
 - solid extract (4:1): 250 mg three times/day
- *Echinacea angustifolia*
 - dried root: 1–2 g three times/day
 - tincture (1:10): 8–12 ml three times/day
 - fluid extract: 1.5–3.0 ml three times/day
 - solid extract (6.5:1): 250 mg three times/day.

Hydrotherapy

Ice packs for the first 2 days.

Exercise

Bedrest for the first 2 days. Restricted activity until there is no pain.

Note. Men, and their partners, with STDs must be effectively treated as soon as possible. If the patient does not immediately respond to therapy, or the physician is inexperienced in this area, the patient should be referred for antibiotics. Repeat cultures are necessary to ensure resolution of the infection.

Chapter 149 - Epilepsy

Gaetano Morello ND

DIAGNOSTIC SUMMARY

- Recurrent seizures
- Characteristic electroencephalographic changes accompanying seizures
- Mental status abnormalities or focal neurologic symptoms may persist for hours postictally.

GENERAL CONSIDERATIONS

Epilepsy is not a disease in itself, but rather a symptom of disease. The epilepsies are a group of disorders characterized by sudden, recurrent, and episodic changes in neurologic function caused by abnormalities in the electrical activity of the brain.^{[1] [2] [3] [4]} Each episode of neurologic dysfunction is called a seizure. Seizures are termed “convulsive” when accompanied by motor manifestations or “non-convulsive” when accompanied by sensory, cognitive, or emotional events. Epilepsy can occur due to a number of abnormalities such as neurologic injuries, structural brain lesions, or some systemic diseases. Epilepsy is termed “idiopathic” when there is neither a history of neurologic insult nor other apparent neurologic dysfunction.^[3] Whatever the etiology, the common denominator in all these conditions is the epileptic attack or seizure.

Epidemiology

The reported incidence and prevalence rates of epilepsy have varied widely because of uncontrolled methodological factors.^[5] According to the best available data, the prevalence of chronic, recurrent epilepsy is about 10 per 1,000, and it has been estimated that 2–5% of the population will have a non-febrile seizure at some point in life. An additional 2–5% of children will experience febrile convulsions during the first several years of life. About 10% of these children, especially those in whom the febrile seizure is prolonged, will develop epilepsy later in life.^[1]

The role of genetic factors in the pathogenesis is complex due to the diversity of conditions that lead to the common symptom of seizures. In general, the prevalence of seizures in close relatives is three times that of the overall population.^[4]

Etiology

Epilepsy is classified etiologically as symptomatic or idiopathic, symptomatic implying that a probable cause has been identified.^[4] Research has shown that 70–80% of all cases of epilepsy are idiopathic. Probable causes can be determined by age of onset of seizures as shown in [Table 149.1](#) . The most common etiological factors are listed in [Table 149.2](#) .

Classification

The current classification of epileptic seizures is based on clinical and electroencephalographic criteria proposed by the International League Against Epilepsy. [Table 149.3](#) lists the clinical features.

DIAGNOSIS

Differentiating between partial or focal seizures and generalized seizures is of great clinical significance. Partial seizures begin focally with a specific sensory, motor, or psychic aberration that reflects the affected part of the cerebral hemisphere.^[5] These types of seizure may remain

TABLE 149-1 -- Presumptive causes of epilepsy according to age of onset of first seizure^{[3] [4]}

| Age of onset | Presumptive causes |
|-------------------|--|
| Birth to 2 years | Birth injury, degenerative brain disease |
| 2–19 years | Congenital birth injury, febrile thrombosis, head trauma, infection (meningitis or encephalitis) |
| 20–34 years | Head trauma, brain neoplasm |
| 35–54 years | Brain neoplasm, head trauma, stroke |
| 55 years and over | Stroke, brain neoplasm |

TABLE 149-2 -- The most common etiologic factors in epilepsy

- Brain damage before or at birth (congenital malformations, anemia, fetal infection)

- Head trauma significant enough to injure the brain and gliosis

- CNS infections such as meningitis, encephalitis, brain abscess, neurosyphilis, rabies, tetanus, falciparum malaria, toxoplasmosis, and cysticercosis of the brain

- Metabolic disorders: hypocalcemia, hypoglycemia, hypoparathyroidism, phenylketonuria, and withdrawal from alcohol and drugs

- Brain tumors and other space-occupying lesions

- Stroke and other vascular disorders

- Degenerative brain disease

- Genetic disease

- Toxic conditions

- Idiopathic

TABLE 149-3 -- Classification of epileptic seizures in adults^[1]

Partial (focal, local) seizures

- Simple partial seizures (consciousness not impaired)
 - motor signs
 - somatosensory or special sensory symptoms
 - autonomic symptoms or signs
 - psychic symptoms
- Complex partial (consciousness impaired)
 - simple partial onset followed by impaired consciousness
 - consciousness impaired at onset
- Partial seizures evolving to generalized seizures (tonic, clonic, or tonic-clonic)
 - simple partial seizures evolving to generalized seizures
 - complex partial seizures evolving to generalized seizures
 - simple partial seizures evolving to partial seizures evolving to generalized seizures

Generalized seizures (convulsive or non-convulsive)

- Absence seizures
 - typical (brief stare, eye flickering, no emotion)
 - atypical (associated with movement)
- Myoclonic seizures
- Clonic seizures
- Tonic seizures

- Tonic-clonic seizures
 - Atonic seizures
-

Unclassified seizures

localized, whereas generalized seizures appear to generalize from their onset and usually affect both consciousness and motor function.^{[2] [3] [4] [5]} Differentiation is important since partial seizures are usually indicative of focal brain disorders, such as tumors or gliosis, while generalized seizures rarely have a definable etiology (although some studies now implicate metabolic disorders).

An eyewitness account of a typical attack can be of great value in classifying a seizure. Past trauma, infections, and the use of drugs and alcohol should be fully explored, as should the family history. A complete neurological examination should be performed as a preliminary screen for neoplasms. Laboratory work should include:^[4]

- serum glucose and calcium
- CBC
- liver and kidney function tests
- serologic test for syphilis
- skull X-rays
- an electroencephalogram (EEG)
- a CT scan (in all cases of adult onset seizures).

Cerebrospinal fluid examination is indicated if infection or meningeal neoplasm is suspected.^[1]

Epilepsy should not be diagnosed on the basis of a solitary seizure. The recurrence rate after a single seizure is approximately only 27% over 3 years.^[6]

PATHOPHYSIOLOGY

The hallmark of the altered physiologic state of epilepsy is a rhythmic and repetitive, synchronous discharge

1227

of many neurons in a localized area of the brain.^[3] This discharge pattern is easily recorded on the electroencephalogram during an attack. However, the cause of the abnormal discharges is still not known. Research shows that the synchronous depolarization of masses of neurons is the result of a combination of increased excitatory mechanisms and decreased inhibitory mechanisms.^[7]

Seizures can be induced in experimental models by blocking inhibitory mechanisms. For example, agents which block the action of the inhibitory neurotransmitter

gamma-aminobutyric acid (GABA) are potent convulsants in humans. Conversely, the anti-epileptic drugs phenobarbital and benzodiazepines enhance GABA, thus supporting the inhibitory mechanism. In some forms of chronic focal epilepsy, inhibitory terminals on neurons in areas around cortical gliotic lesions are in fact diminished.

Other research demonstrates the instability of the nerve cell membranes in epileptics. During seizure activity, intracellular Ca^{2+} stored in the cell organelles is released and moves towards the inner cell membranes where it binds to specific Ca^{2+} -receptive proteins, causing conformational changes in the protein's structure. These changes cause the transmembranal Ca^{2+} , K^{+} , and Na^{+} channels to pathologically remain open, potentiating the excitatory state and, hence, the convulsive activity.^{[1] [2]}

The earliest symptomatology, or aura, that is generated by a focal discharge provides the best clue to the localization and, occasionally, to the characterization of the responsible lesion. For example, a generalized seizure following an aura of a peculiar abdominal sensation or ill-defined odor indicates a lesion in the temporal lobe. A Jacksonian seizure beginning in the fingers and spreading up the arm before becoming generalized and producing a coma indicates a focal lesion in the convexity of the opposite motor cortex.^[1]

THERAPEUTIC CONSIDERATIONS

Environmental toxins

Heavy metals

Heavy metals such as lead, mercury, cadmium, and aluminum can induce seizures by disrupting neural function.^[8] Heavy metal toxicity should be ruled out as a possible cause in all seizures. A hair mineral analysis provides the most cost-effective screening method for the detection of heavy metals (see [Ch. 17](#)), although other procedures may at times be more appropriate (see [Ch. 18](#)).

Neurotoxic chemicals

Many neuron-, axon-, and myelin-toxic chemicals have now been released into the environment. Despite efforts to decrease their release, the levels of many in the environment continues to increase. The impact of these neurotoxins is discussed in [Chapter 37](#).

Dietary considerations

Hypoglycemia

Some researchers believe that hypoglycemia is the most important metabolic cause of seizures.^[8] Researchers have found that:^{[8] [9] [10] [11] [12]}

- serum glucose levels are unusually low prior to a seizure
- 50–90% of epileptics have constant or periodic low blood sugar
- 70% or more of epileptics have abnormal glucose tolerance tests.

Although the correlation of blood sugar abnormalities and epilepsy seems well documented, the mechanism of action is unknown. It has been suggested that low blood sugar could impair ATP production in nerve cells, reducing the efficacy of the sodium ATPase pump. A defective sodium pump allows increased intracellular sodium concentrations, which depolarize the cell membrane, thus lowering the firing threshold.

Single measurements of serum glucose levels are inadequate to determine glycemic status – only an extended glucose tolerance test will give a complete picture.

Ketogenic diet

The ketogenic diet has a long history of use for the reduction of seizure activity.^{[13] [14] [15]} The diet consists of large amounts of fat and minimal amounts of protein and carbohydrate. The low carbohydrate intake inhibits fat metabolism, resulting in the production of excessive levels of ketone bodies (acetone, aceto-acetic acid, and beta-hydroxybutyric acid), the intermediary oxidation products. Presumably the beneficial effects of such a diet are due to its induction of metabolic acidosis which corrects an underlying tendency of epileptics towards spontaneous development of alkalosis.^{[13] [14] [15]} This acidification is thought to normalize nerve conductivity, irritability, and membrane permeability.

Recent research is continuing to document the efficacy of this dietary therapy. For example, one study of 27 children aged 1–16 years found that 40% experienced a reduction of seizures of more than 50%, with 25% becoming seizure-free.^[16] However, 35% discontinued the diet due to difficulty in following the rigorous guidelines. A recent review article stated that the ketogenic diet’s success rate “greatly exceeds that of the medications” and that its side-effects were fewer and the therapy cheaper.^[17]

Although the ketogenic diet is effective it is not without side-effects. The long-term risks of a high-fat diet are well

known, and a ketogenic diet is unhealthy for a growing child. Also, children should not be allowed to eat very large meals, as these may predispose them to seizures.

Food allergy

There has been little research into the correlation between food allergy and epilepsy; only anecdotal case histories,^{[18] [19]} single-case double-blind, placebo-controlled

studies,^[20] ^[21] and uncontrolled studies having been reported. It is postulated that epileptic patients may have allergic reactions in the brain that are similar to the swelling, anoxia, and inflammatory chemical reactions seen at other sites of local allergic reactions.^[18]

One uncontrolled study evaluated oligoantigenic diets in 63 children with epilepsy. Of 45 children with recurrent headaches, hyperkinetic behavior, or abdominal symptoms, 25 ceased to have seizures and 11 had fewer seizures during diet therapy. Headaches, abdominal pains and hyperkinetic behavior ceased in all patients whose seizures ceased and in some of those whose seizures did not cease. Reintroduction of foods reproduced symptoms. Eighteen of 24 children with generalized epilepsy recovered or improved, as did 18 of 21 children with partial epilepsy. In double-blind provocation, 15 of 16 children experienced recurrence of symptoms including seizures in eight, while none improved in the placebo group. Eighteen other children who had epilepsy alone had no improvement with dietary change.^[22] This study suggests that food allergy should be suspected in epileptics who suffer from multiple other symptoms of food allergy (see [Chs 15](#) and [51](#)).

Another study evaluated two females, 5 and 23 years old, who had focal occipital epilepsy with cerebral calcifications and were not responding well to anti-epileptic therapy. Both had celiac disease as well as documented folic acid deficiency (a common side-effect of most anti-epileptic drugs). A gluten-free diet combined with supplementation with folic acid (dosage not reported) led to complete normalization of the EEG in the 5-year-old and cessation of seizures. The 23-year-old experienced significant improvement in her EEG, and enhanced seizure control. Folic acid returned to the normal range within several months.^[23]

A larger study looked more closely at the association between celiac disease and epilepsy. Forty-three patients (15 male) between 4 and 31 years of age were evaluated for the association between celiac disease, epilepsy, and cerebral calcifications. Intestinal biopsy on the 31 patients with cerebral calcifications of unexplained origin and epilepsy found a flat intestinal mucosa in 24, suggesting celiac disease. CAT scanning showed cerebral calcifications in five of the 12 patients with celiac disease and epilepsy. Antibodies to gluten and folic acid serum concentrations were measured, and HLA typing was done in most patients. Only two patients with cerebral calcifications and epilepsy had gastrointestinal symptoms at the time of biopsy. A gluten-free diet in epilepsy was found to be inversely related to the duration of epilepsy before the diet, and to the age at the beginning of the diet. The authors strongly recommended that celiac disease be considered in all cases of epilepsy and cerebral calcifications of unexplained origin, especially when the epilepsy is characterized by occipital seizures and the calcification is located bilaterally in the posterior regions.^[24]

Nutritional considerations

Pyridoxine

There are two known types of vitamin B₆ -related seizures in newborns and infants less

than 18 months of age: B₆ -deficient and B₆ -dependent. They have similar neurological symptoms, EEG abnormalities, and a prognosis of mental retardation if not treated.^[25]

The diagnosis of pyridoxine dependency should be suspected in every infant with convulsions in the first 18 months of life. Certain clinical features may be especially suggestive, including:

- seizures of unknown origin in a previously normal infant without an abnormal gestational or perinatal history
- a history of severe convulsive disorders
- the occurrence of long-lasting focal or unilateral seizures, often with partial preservation of consciousness
- irritability, restlessness, crying, and vomiting preceding the actual seizure.

Since atypical presentations of pyridoxine responsive seizures have been reported, it has been recommended that an empiric trial of parenteral pyridoxine be done on any neonate or infant with long-lasting convulsions, especially when no clear-cut etiology is present.^{[25] [26]} A 100–200 mg intravenous dose or 20 mg dose every 5 minutes to a total of 200 mg is recommended. If the seizures stop, it is likely that the child has pyridoxine-responsive seizures.^{[25] [26]} The chance to identify a pyridoxine-responsive seizure is lost if pyridoxine is given together with, or after, most anticonvulsant drugs.^[26]

While B₆ -deficient seizures are promptly corrected by the administration of dietary amounts of pyridoxine, B₆ -dependent seizures require continuous high-dose supplementation in the range of 25–50 mg/day.^{[25] [26] [27] [28]}

Although the mechanism by which pyridoxine decreases seizure activity is not fully understood, it is undoubtedly related to its role as a necessary cofactor in the metabolism of a variety of neurotransmitters whose production is dependent on amino acid decarboxylation. Once absorbed, pyridoxine is phosphorylated to pyridoxal-5-phosphate,

Figure 149-1 The conversion of glutamic acid to GABA.

a coenzyme in the reaction converting glutamic acid to gamma-aminobutyric acid (GABA) (see [Fig. 149.1](#)). GABA, as mentioned earlier, is an important inhibitory neurotransmitter.

One proposed mechanism for pyridoxine dependency is that pyridoxal phosphate does not bind with its usual affinity to glutamic acid decarboxylase, resulting in reduced GABA production. In these patients, higher than normal levels of pyridoxine are required for the

activity of this enzyme.^{[25] [26] [27] [28]}

One uncontrolled study of infants and children with uncontrollable infantile spasms or their sequelae found improvement in 2–14 days using oral pyridoxine phosphate (20–50 mg/kg). Three had complete relief, six showed transient relief, and eight showed marked reduction in seizures and improvement in their EEGs.^[28] Some adverse reactions were seen: elevated transaminases, nausea, and vomiting.

Administration of vitamin B₆ to epileptics must be strictly monitored. Although some improvements have been noted, daily doses in the range of 80–400 mg have been shown to interfere with commonly used anticonvulsants.^[29]

Folic acid

Low blood and cerebrospinal fluid levels of folic acid are commonly found in patients using the anticonvulsants phenytoin, primidone, and phenobarbital. These drugs interfere with the intestinal uptake of folic acid at the mucosal level.

It has been suggested that some of anti-epileptic activity of these drugs is mediated by their antifolate action. Conflicting clinical evidence supporting and against this suggestion can be found in the literature.^{[30] [31] [32]}

At this time it appears that, although extremely rare, folic acid supplementation may exacerbate seizure control in some individuals. Administration of a single intravenous dose of 110 mEq folic acid in drug-treated epileptic patients undergoing continuous EEG monitoring has produced seizures in two of 25 subjects.^{[31] [32]}

Experimentally induced seizures also cause a decrease in total brain folate, suggesting that folate metabolism may be involved in the epileptic process.^[30] However, since several clinical studies have shown that supplementation with folic acid does not lead to any significant clinical improvement^[30] and can decrease serum vitamin B₁₂ levels,^[33] it appears that supplementation with folic acid is probably contraindicated in the absence of demonstrated deficiency.

Thiamin

In an interesting study, 16 of 50 consecutive neurologic patients with a diagnosis of thiamin deficiency showed epileptic manifestations. It is possible that thiamin deficiency may promote epileptic episodes in those who have a subclinical predisposition for seizures. For example, the stimulation of nerve fibers in vitro causes them to lose significant amounts of thiamin pyrophosphate in the surrounding fluid, suggestive of a significant role for thiamin in nerve to nerve conduction. In addition, thiamin deficiency may be accompanied by low concentrations of GABA, which, as noted above, is significant in seizure disorders. The authors suggested that, in patients with late-onset epilepsy, thiamin deficiency may be considered one of the possible causes.^[34]

Taurine

Taurine is one of the most abundant amino acids in the mammalian brain.^{[35] [36]} It is involved in hyperpolarizing neurons by changing ion permeability and may mimic the effects of GABA and glycine.

Since the early 1970s, considerable clinical and experimental evidence has accumulated supporting the anticonvulsive activity of the amino acid taurine.^{[35] [36] [37] [38] [39] [40] [41] [42] [43] [44] [45] [46] [47] [48]} The primary mode of action responsible for taurine's anti-epileptic effects is its membrane-stabilizing effects, i.e. it seems to normalize the flow of Na⁺, K⁺, and Ca²⁺ into and out of the cell.^{[35] [36] [37]}

In addition to acting as a GABA-like neurotransmitter,^{[35] [36] [37] [38]} taurine may also help to decrease seizure activity by increasing GABA levels through enhancement of the action of glutamic acid decarboxylase.

Epileptics have been shown to have significantly lower levels of taurine in platelets than control patients.^[39] Although several studies have shown lower taurine levels in the plasma, serum, and urine of epileptics, other research has yielded disparate results.^{[40] [41] [42] [43]} Cellular concentration of taurine as determined by platelet level is thought to be of much greater significance.

The first clinical trials of taurine were undertaken by Barbeau & Donaldson^[44] in 1973 and Bergamini et al^[45] in 1974. The results were encouraging and several additional reports have confirmed taurine's anticonvulsant effects.^{[35] [37] [44] [45] [46] [47] [48] [49] [50]} However, the rate of effectiveness of taurine is far below the level where taurine could be recommended as a standard "drug" treatment for epilepsy. At this time, there is no consensus on the seizure types for which taurine is most suitable, nor is there agreement on appropriate dose.

Taurine, at a daily oral dose of 0.05–0.3 g/kg in one study and 750 mg in another, has demonstrated efficacy in some cases of intractable epilepsy, decreasing seizures by more than 30% in 11 of 34 subjects.^{[49] [50]} This is highly significant since these patients were unresponsive to any

other anticonvulsants. Patients with partial epilepsy demonstrated the best results, with those achieving the highest taurine concentrations showing the best response.

The positive clinical response of some epileptic patients to supplemental taurine and the apparent cellular deficiency of taurine suggest that taurine supplementation be tried in most patients. Therapeutic monitoring of platelet or plasma taurine levels may prove

useful.

Magnesium

Epileptics have been shown to have significantly lower serum magnesium levels as compared with normals, with seizure severity correlating with the level of hypomagnesemia.^[51] ^[52] ^[53] Although the mechanism of action is not fully understood, magnesium has been shown, in uncontrolled trials, to be of benefit in the control of seizures.^[54] ^[55]

Pfeiffer^[54] found that a magnesium deficiency induces muscle tremors and convulsive seizures, and reported success in controlling the seizure activity of 30 epileptic patients with 450 mg/day of magnesium.

Manganese

The link between epilepsy and manganese was first suggested in 1963 when Hurley et al^[56] observed that manganese-deficient rats were more susceptible to seizures than manganese-replete animals, and that manganese-deficient animals exhibit an epileptic-like EEG. This prompted researchers to measure manganese concentrations in epileptics. Low whole blood and hair manganese levels have been found in epileptics, with those with the lowest levels typically having the highest seizure activity.^[57] ^[58] ^[59] ^[60] ^[61]

Manganese plays a significant role in cerebral function as it is a critical cofactor for glucose utilization within the neuron, adenylate cyclase activity, and neurotransmitter control. Obviously, optimal central nervous system function requires proper manganese levels. Manganese supplementation may be helpful in controlling seizure activity for some patients.^[62]

Zinc

Children with epilepsy have been found to have significantly lower levels of serum zinc, especially those with the West or Lennox syndromes.^[53] ^[63] More importantly, it appears that epileptics may have an elevated copper-to-zinc ratio.^[63] Seizures may be triggered when zinc levels fall, as in the absence of adequate taurine. Although the exact role of zinc or the copper-to-zinc ratio is not clearly understood, it appears to involve either the storage or binding of GABA.^[63]

Zinc supplementation appears to be warranted, especially in light of the observation that anticonvulsants may cause zinc deficiency.^[64]

Choline, betaine, dimethylglycine, and sarcosine

Choline, betaine (*N,N,N*-trimethylglycine), dimethylglycine (DMG), and sarcosine have exhibited some anticonvulsant activity in human and animal studies. Choline is converted to betaine when it acts as a methyl donor, while betaine is converted to DMG

when it donates a methyl group. This is most evident in the transformation of homocysteine to methionine. Supplemental betaine has also been shown to be very effective in preventing a variety of induced seizures in rats and in alleviating seizures in humans with homocystinuria.^[65] ^[66] ^[67] ^[68] ^[69]

Dimethylglycine (DMG) has also been shown to block induced seizures in rats and mice.^[67] ^[68] Roach & Carlin^[70] reported a striking decrease in seizure frequency in a patient with long-standing mental retardation when 90 mg of DMG was administered twice daily. Despite treatment with phenobarbital and carbamazepine, the patient had an average of 16–18 generalized seizures each week. Within 1 week of starting DMG, seizure frequency dropped to three per week. Two attempts to withdraw the DMG caused dramatic increases in seizure frequency.

It has been suggested that glycine and betaine may act indirectly on glycine metabolism and glycine-mediated neuronal inhibition, enhance GABA activity, or simply have a non-specific effect on biological membranes.

Vitamin D

The association of anticonvulsant drugs with disorders of mineral metabolism, including hypocalcemia, rickets, and osteomalacia, is well-documented.^[71] Conflicting results have been published concerning the serum levels of vitamin D in patients with epilepsy. Studies have reported increased,^[72] normal,^[73] and decreased levels.^[74]

Supplemental vitamin D intake is recommended when climatic conditions or the patient's lifestyle do not allow adequate exposure to sunlight.^[75] Supplementing the diet of 23 epileptics with 4,000–16,000 IUs of vitamin D resulted in a significant decrease in the number of seizures, indicating a possible therapeutic effect.^[76] Doses of this magnitude can, however, be quite toxic, requiring careful monitoring.

Vitamin E and selenium

Vitamin E and selenium function synergistically in many physiological functions. Vitamin E deficiency is known to produce seizures,^[77] and anti-epileptic drugs have been shown to decrease vitamin E levels.^[78] Studies have shown both nutrients to be low in epileptic patients.^[77] ^[79] Supplementation with vitamin E and selenium may result in improved control of seizures.^[77]

For example, a double-blind placebo-controlled study of 24 epileptic children not responding to anti-epileptic drugs found that supplementing with 400 IU/day of vitamin E provided a significant reduction of seizures in 10 out of 12 children. The two unresponsive children were non-compliant. All the children continued their normal dosages of anti-epileptic drugs. There was no benefit in the 12 placebo children, and, as

expected, no negative side-effects from the vitamin E therapy.^[80]

One report described four children with reduced glutathione peroxidase activity, intractable seizures, multiple infections and resistance to anticonvulsant treatment. All had seizures within their first 6 months of life. There was no evidence of known inborn errors of metabolism; however, all four patients had low intracellular glutathione peroxidase levels. Two had normal whole-blood selenium while the other two had low levels. Discontinuing anticonvulsant therapy and administering selenium resulted in clinical improvement in all patients.^[81]

Botanical medicines

Chinese herbal medicine

Botanical medicines have played a significant role in the treatment of epilepsy in both the Eastern and Western healing arts. Recently, Western scientific methodologies have been used to evaluate the efficacy of a Chinese herbal medicine combination, Saiko-Keishi-To (SK).^[82] SK demonstrated dramatic therapeutic effects on some difficult cases of epilepsy which had long been unsuccessfully treated with standard allopathic anticonvulsive drugs. SK is a combination of nine botanical drugs:

- *Bupleuri radix* (5.0 g)
- *Scutellaria radix* (3.0 g)
- *Pinelliae tuber* (5.0 g)
- *Paeoniae radix* (6.0 g)
- *Cinnamon cortex* (2.0 g)
- *Zizyphi fructus* (4.0 g)
- *Ginseng radix* (30.0 g)
- *Glycyrrhizae radix* (1.5 g)
- *Zingiber rhizoma* (2.0 g).

In one experiment, seizure-like activity was induced in snail neurons by the drug pentylenetetrazol (PTZ).^[83] ^[84] SK was found to:

- inhibit the intracellular shift of Ca^{2+} towards the cell membrane
- inhibit the binding of Ca^{2+} to Ca^{2+} -receptive membrane proteins and the Ca^{2+} -calmodulin complex
- inhibit the conformational changes of the Ca^{2+} -receptive membrane proteins
- inhibit the pathologic transmembrane current of Na^+ , K^+ , and Ca^{2+} .

The researchers presumed that SK's experimental effects are similar to its mode of action in humans. It is interesting to note that when an attempt was made to isolate purified chemicals from the component herbs, the crude drug's efficacy was lost. This suggests a synergistic effect between the component botanical agents.

More recent clinical research has shown some benefit in epileptic patients. One study reported that eight out of 28 epileptics experienced a 25% decrease in number of

seizures after 8 weeks of treatment.^[84]

Coleus forskolii

Research showing that the cyclic nucleotides are involved in the pathophysiology of seizures has elucidated a possible mechanism for the action of several botanical medicines used in the treatment of seizure activity.^[85] Cyclic AMP has been demonstrated to depress electrical activity in cat hippocampal slices, while cGMP can produce seizure-like discharge in the same tissues.^[86] In addition, cAMP inhibits Ca²⁺ from binding to intracellular proteins like calmodulin, resulting in a decrease in the extrusion of neurotransmitters into the synapse.

The botanical *Coleus forskolii*, an important plant medicine in the Ayurvedic treatment of epilepsy, activates adenylate cyclase, thus increasing the levels of cAMP.^[87] ^[88] This action is thought to be due to forskolin, a diterpine, which has been found to increase adenylate cyclase activity by 530%.^[88] This is the greatest activity found in 100 plants studied for the ability to increase cAMP. The same study found that seven – *Bupleuri radix*, *Cinnamon cortex*, *Glycyrrhizae radix*, *Paeoniae radix*, *Ginseng radix*, *Scutellaria radix*, and *Zingiber rhizoma* – of the nine botanicals in Saiko-Keishi-To were found to display significant cAMP enhancement, either by enhancing adenylate cyclase or by inhibiting cAMP phosphodiesterase.^[88] *Bupleuri radix*, a key component of the SK formula, was found to increase cAMP by 170%.

THERAPEUTIC APPROACH

Epileptic patients should be advised to avoid situations that could be dangerous if further seizures occur. Also, they should be made aware of state laws regarding epilepsy and driving. Epileptics should avoid known initiators of seizure activity, e.g. bright flashing lights, sudden loud sounds, etc.. Therapy should continue at full dosages until the patient has been seizure-free for at least 2 years. Dosage reduction should then be gradual over a period of several months. Epileptics who are not controlled with natural therapies require drug therapy.

Eliminate pyridoxine antagonists: isoniazid, cycloserine, hydralazine, dopamine, penicillamine, oral contraceptives, alcohol, and hydrazine dyes (FD&C yellow #5).

Note. Status epilepticus is a medical emergency that

inevitably results in serious neurological damage or death if untreated. Immediate hospitalization is required, preferably with ambulance or aid car transport, with the necessary equipment to maintain the patient's airway, assist in ventilation, and administer intravenous glucose and anti-epileptic drugs.

Diet

All sugar and other refined carbohydrates should be eliminated and protein levels should be moderate. Food allergens should be identified and eliminated. If a ketotic effect is desired, all carbohydrates should be strictly limited and fat intake increased (such a diet should only be used sparingly and rarely for children).

Nutritional supplements

(The following are adult doses; reduce proportionately for children.)

- Vitamin B₆ : 50 mg three times/day
- Vitamin E: 400 IU/day
- Taurine: 500 mg three times/day
- Magnesium: 300 mg three times/day
- Manganese: 10 mg three times/day
- Selenium: 100 µg/day
- Zinc: 25 mg/day.

Botanical medicine

- Saiko-Keishi-To: 300 ml before bedtime.

Chapter 150 - Erythema multiforme

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

DIAGNOSTIC SUMMARY

- Sudden onset of symmetric, erythematous, edematous, macular, papular, urticarial, bullous or purpuric skin lesions
- Evolves into “target lesions” (lesions with clear centers and concentric erythematous rings)
- Characteristic first site: dorsum of hand
- Characteristic distribution: extensor surfaces of extremities with relative sparing of head and trunk
- Tendency to recur in spring and fall.

GENERAL CONSIDERATIONS

Erythema multiforme (EM) can occur as a primary skin disorder or as a skin manifestation of systemic infection or chronic inflammatory disease. Often it is a manifestation of a hypersensitivity reaction to a variety of drugs, with penicillin, sulfonamides, and barbiturates being the most common. *Vaccinia*, BCG, and poliomyelitis vaccines; herpes simplex; food allergy; and various infectious organisms have all induced EM. Evidence clearly points to hypersensitivity as the common factor, and the tissue damage is caused by the release of highly reactive, polynuclear leukocyte-derived, oxygen intermediates.^[1]

THERAPEUTIC CONSIDERATIONS

Potassium iodide

Potassium iodide has historically been used to treat a variety of erythematous disorders, including:

- erythema multiforme
- erythema nodosum
- nodular vasculitis
- acute febrile neutrophilic dermatosis
- subacute nodular migratory panniculitis.

Recent clinical studies have documented dramatic success.^{[2] [3] [4]} The mechanism is apparently related to the suppression of the generation of oxygen intermediates,

1236

such as hydrogen peroxide and hydroxyl radical, by stimulated PMNs.^[5] It is important to recognize, however, that iodine therapy has occasionally been associated with various adverse skin reactions and gastrointestinal discomfort, and should never be utilized in pregnant women in the last trimester due to suppression of the fetal thyroid.^[6]

Zinc

Zinc sulphate (0.025–0.05%) has been used locally at the site of herpetic infection and to prevent the relapse of post-herpetic erythema multiforme.^[7]

THERAPEUTIC APPROACH

A careful search should be made to determine the initiating factor. Underlying infections should be treated, all unnecessary medications should be stopped, and an anti-inflammatory program should be initiated.

Supplements

- Potassium iodide: 100 mg three times/day for 4–6 weeks. Discontinue if there are adverse reactions
- Zinc sulphate: 0.025–0.05% solution locally if post-herpetic.

Chapter 151 - Fibrocystic breast disease

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

DIAGNOSTIC SUMMARY

- Very common: 20–40% of premenopausal women
- Pain or premenstrual breast pain and tenderness common, although condition often asymptomatic
- Characteristically cyclic and bilateral with multiple cysts of varying sizes giving the breast a nodular consistency.

GENERAL CONSIDERATIONS

Benign fibrocystic breast disease (FBD), also known as cystic mastitis, is usually a component of the premenstrual syndrome (PMS) and is considered a risk factor for breast cancer. It is not, however, as significant a factor as the classical breast cancer risk factors, i.e. family history, early menarche, and late or no first pregnancy.

The pathogenesis of FBD is apparently due to an increased estrogen-to-progesterone ratio. During each menstrual cycle there is a recurring biphasic stimulation of the breast – first the proliferation of breast tissue by estrogens, then of alveolar secretory activity by progesterone – followed by a period of involution. In many women these changes are so slight, clinical signs or symptoms do not appear. In others, however, significant inflammatory processes occur.

Histologically, FBD is characterized by proliferation and hyperplasia of the alveolar epithelium, increased secretory activity, ectasia of milk ducts, and periductal fibrosis. These effects may be due to an increased prolactin level, which is significantly elevated in women with FBD,^{[1] [2]} although not sufficiently to cause amenorrhea. Estrogen, both endogenous and exogenous, causes an increase in prolactin secretion while prolactin inhibits luteal function.

DIFFERENTIAL DIAGNOSIS

FBD cannot be definitively differentiated from breast cancer or fibroadenoma of the breast on clinical criteria

1238

alone. Pain, cyclic variations in size, high mobility, and multiplicity of nodules are indicative of FBD. Non-invasive procedures, such as ultrasonography and thermo-graphy, help to aid differentiation further. However, definitive diagnosis depends upon biopsy.

THERAPEUTIC CONSIDERATIONS

[Chapter 183](#) contains a much more comprehensive discussion on the many factors involved in FBD; the reader is encouraged to read it first. The factors discussed here were chosen since they are not covered in depth in the PMS chapter and are particularly relevant to FBD.

Methylxanthines

Epidemiologically,^[3] experimentally,^{[4] [5] [6]} and clinically,^{[4] [5] [6]} there is strong evidence supporting an association between methylxanthine consumption and FBD. Caffeine, theophylline and theobromine are all known to inhibit the action of cAMP and cGMP phosphodiesterase and to significantly elevate their levels in breast tissue.^{[4] [5] [6]} In turn, increased levels of these cyclic nucleotides excessively stimulate protein-kinase activities and cause the overproduction of cellular products, such as fibrous tissue and cyst fluid. Excessive levels of cyclic nucleotides within the breast are one of the biochemical findings in breast cancer, and caffeine has been shown to promote carcinogenesis in the mammary gland of rats.^[7]

In one study, limiting methylxanthines (coffee, tea, cola, chocolate, and caffeinated medications) in the diet resulted in improvement in 97.5% of the 45 women who completely abstained, and in 75% of the 28 who limited their consumption. Those who continued with little change in their methylxanthine consumption showed little improvement.^[4] According to this study, women may have varying thresholds of response to methylxanthines. Stress may also play an important role, since fibro-cystic breasts appear more responsive to epinephrine, the presence of which increases adenylate cyclase activity and, hence, cAMP production.

Vitamin E

Alpha-tocopherol has been shown to relieve many PMS symptoms, particularly FBD, as evidenced by several double-blind clinical studies.^{[8] [9]} The mode of action remains

obscure, although it has been shown to normalize circulating hormones in PMS and FBD patients.^[8] ^[9] ^[10] Vitamin E supplementation (600 IU/day) also normalizes the elevated FSH and LH levels commonly seen in FBD patients.^[10]

Vitamin A

After 3 months of high dose supplementation with vitamin A, five of the nine patients (150,000 IU/day) who completed the study had complete or partial remission of their FBD.^[11] However, some patients developed mild side-effects, resulting in two of the original 12 withdrawing due to headaches, and one patient having her dosage reduced. Beta-carotene would appear to be a more appropriate source of retinol due to its greatly decreased toxicity and similar activity in ovarian and inflammatory disorders (see [Chs 122](#) and [183](#)).

Thyroid and iodine

Hypothyroidism and/or iodine deficiency are associated with a higher incidence of breast cancer. Experimental iodine deficiency in rats results in a mammary dysplasia histologically similar to human FBD.^[12] Thyroid hormone replacement therapy in hypothyroid, and some euthyroid, patients may result in clinical improvement.^[12] ^[13] Research has shown that thyroid supplementation (0.1 mg/day Synthroid) decreases mastodynia, serum prolactin levels, and breast nodules in, supposedly, euthyroid patients. These results suggest that subclinical hypothyroidism and/or iodine deficiency may be an etiological factor in FBD.

Iodine (specifically iodine caseinate) may be an effective treatment for FBD.^[14] It is theorized that an absence of iodine renders the epithelium more sensitive to estrogen stimulation. This hypersensitivity can produce excess secretions over the limit of absorption, thus distending the breast ducts to produce small cysts and later fibrosis (hardening of the tissue due to the deposition of fibrin similar to the formation of scar tissue).

In studies in rats, it was shown that there is a hierarchical response to the type of iodine compound in correcting the abnormalities in mammary tissue due to iodine deprivation. While iodides correct the cystic spaces and partially correct the excessive cellular reproduction, iodine in its elemental form corrects the entire disease process. Thus, it appears that elemental iodine is the preferential form of iodine for breast metabolism. Also, oral iodine supplementation is known to have significant anti-inflammatory and antifibrotic effects, in both acute and chronic experimental models.^[15]

Human studies also indicate that elemental iodine may be more effective than iodides. Since 1975 three clinical trials have been performed on women with FBD:^[14]

- an uncontrolled study with sodium iodide and protein-bound iodide
- a prospective, controlled, crossover study from iodide to molecular iodine
- a prospective, controlled, double-blind study with molecular iodine.

Results from these studies indicate that while treatment with iodides was effective in about 70% of subjects, it was associated with a high rate of side-effects (e.g.

1239

altered thyroid function in 4%, iodism in 3%, and acne in 15%). Results with elemental iodine were about the same, but were not associated with significant side-effects. The most significant side-effect with molecular iodine was short-term increased breast pain which seemed to correspond to a softening of the breast and disappearance of fibrous tissue plaques on physical examination.

The dosage of molecular iodine was 70–90 mcg/kg body weight. This dosage appears to be a safe and effective treatment for FBD. Unfortunately, at the time of writing (August 1997) the forms of iodine supplement used in the studies (iodine caseinate and liquid iodine) were not yet available on the marketplace.

Liver function

Since the liver is the primary site for estrogen clearance, any factor (e.g. cholestasis, “toxic liver syndrome”, environmental pollution) that interferes with proper liver function may lead to estrogen excess. Adequate levels of lipotropic factors and B vitamins are necessary for estrogen conjugation.

Colon function

Breast disease has been linked to the Western diet and bowel function. There is an association between epithelial dysplasia in nipple aspirates of breast fluid and the frequency of bowel movements.^[16] Women having fewer than three bowel movements per week have a risk of FBD 4.5 times greater than women having at least one a day.

This association is probably due to the bacterial flora in the large intestine transforming endogenous and exogenous sterols and fatty acids into a variety of toxic metabolites, including polycyclic carcinogens and mutagens.^[17] Fecal microorganisms are capable of synthesizing estrone, estradiol, and 17-methoxyestradiol, as well as metabolizing estrogen sulphate and glucuronate conjugates,^[18] resulting in absorption of bacteria-derived estrogens and reabsorption of previously conjugated estrogen. Diet plays a major role in the colon microflora, transit time, and the concentration of absorbable metabolites.^[18]

Women on a vegetarian diet excrete two to three times more conjugated estrogens than women on an omnivorous diet who also reabsorb more estrogens.^[18] Furthermore, omnivorous women have 50% higher mean levels of unconjugated estrogens. *Lactobacillus acidophilus* supplementation has been shown to lower fecal

beta-glucuronidase.^[19]

Fiber

A comparison between the diet of 354 women with benign proliferative epithelial disorders of the breast and that of 354 matched controls and 189 unmatched controls found an inverse association between dietary fiber and the risk of benign, proliferative, epithelial disorders of the breasts.^[20] An increased intake of dietary fiber may be associated with a reduced risk to both benign breast disease and breast cancer.

THERAPEUTIC APPROACH

Unless a woman has pure FBD, the therapeutic approach outlined in [Chapter 183](#) will more definitively meet her individual needs. The therapy recommended here includes key factors discussed in that chapter.

Diet

The diet should be primarily vegetarian with large amounts of dietary fiber. All methylxanthines should be eliminated until symptoms are alleviated. They can then be reintroduced in small amounts. Exogenous estrogens should be avoided (oral contraceptives, high estrogen containing animal products, etc.). The diet should emphasize whole, unprocessed foods (whole grains, legumes, vegetables, fruits, nuts, and seeds). Recommend the patient drink at least 48 ounces of water daily.

Supplements

- B-complex: 10 times the RDA
- Lipotropic factors
 - choline: 500–1,000 mg/day
 - methionine: 500–1,000 mg/day
- Vitamin B₆: 25–50 mg three times/day
- Vitamin C: 500 mg three times/day
- Vitamin E: 400–800 IU/day of D-alpha tocopherol
- Beta-carotene: 50,000–300,000 IU/day
- Iodine (molecular iodine): 70–90 mcg of iodine per kilogram body weight
- Zinc: 15 mg/day
- Flaxseed oil: 1 tbsp/day
- *Lactobacillus acidophilus*: 1–2 billion live organisms/day.

Chapter 152 - Gallstones

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

DIAGNOSTIC SUMMARY

- May be asymptomatic or cause biliary colic with irregular pain-free intervals of days or months
- Real-time ultrasonography provides definitive diagnosis.

GENERAL CONSIDERATIONS

Gallstones are another example of a “Western diet”-induced disease. In the United States, autopsy studies have shown that gallstones exist in approximately 20% of the women and 8% of the men over age 40. Conservative estimates suggest that about 20 million Americans have gallstones. Each year 1 million more develop gallstones. More than 300,000 gall bladders are removed each year in the US due to the presence of gallstones.^{[1] [2] [3] [4]}

The bile components include bile salts; bilirubin; cholesterol, phospholipids, and fatty acids; water; electrolytes; other organic and inorganic substances.^[5] [Table 152.1](#) shows the characteristics of the major bile components. Gallstones arise when a normally solubilized component of bile becomes supersaturated and precipitates. Gallstones can be divided into four major categories:

- pure cholesterol
 - pure pigment (calcium bilirubinate)
-

- mixed – containing cholesterol and its derivatives along with varying amounts of bile salts, bile pigments, and inorganic salts of calcium

- stones composed entirely of minerals.

TABLE 152-1 -- Characteristics of the major bile components^[5]

| Component | Percentage of bile | Water solubility | Physiochemical properties |
|--------------|--------------------|---|--|
| Cholesterol | 5% | Very poor | Will precipitate from aqueous solutions |
| Bile salts | 65–90% | Soluble; have polar and non-polar regions | Capable of solubilizing cholesterol and phospholipid in aqueous phase |
| Phospholipid | 2–25% | Poor | Fits between bile salt molecules, thus increasing their capacity to solubilize cholesterol |

Pure stones, either cholesterol or calcium bilirubinate, are extremely rare in the US. Recent studies indicate that in the US, approximately 80% of the stones are of the mixed variety. The remaining 20% of the stones is composed entirely of minerals, principally calcium salts, although some stones contain oxides of silicon and aluminum.^{[1] [2] [3]}

PATHOGENESIS

The formation of gallstones has been divided into three steps:

- bile supersaturation
- nucleation and initiation of stone formation
- enlargement of the gallstone by accretion.

Cholesterol and mixed stones

The requisite step in cholesterol and mixed stone formation is cholesterol supersaturation of bile within the gall bladder. Bile solubility, as well as bile supersaturation, is based on the relative molar concentrations of cholesterol, bile acids, phosphatidylcholine (lecithin) and water. Since free cholesterol is water-insoluble, it must be incorporated into a lecithin-bile salt micelle (see [Fig. 152.1](#)). Using triangular coordinates, it is possible to demonstrate the solubility of cholesterol in bile (see [Fig. 152.2](#)).

As illustrated above, either an increase in cholesterol secretion or a decrease in bile acid or lecithin secretion will result in the bile becoming supersaturated. Once the bile is supersaturated, stone formation is initiated by such

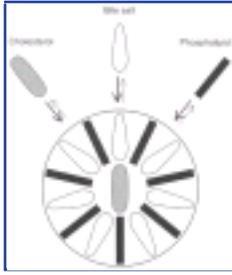

Figure 152-1 Mixed micelle.

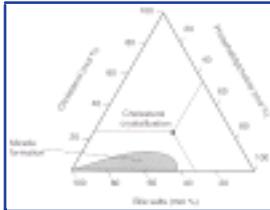

Figure 152-2 Cholesterol solubility in bile.

factors as biliary stasis, infection and, perhaps, mucin. Once the stone begins to form, its radius increases at an average rate of 2.6 mm/year, eventually reaching a size of a few millimeters to over a centimeter. Symptoms typically occur an average of 8 years after formation begins. Cholelithiasis is present in 95% of patients with cholecystitis.^[5]

Risk factors for cholesterol and mixed stones

The major risk factors for the development of cholesterol and mixed gallstones include:^[1]
^[2] ^[3]

- diet
- sex
- race
- obesity
- high caloric intake
- estrogens
- gastrointestinal diseases (especially Crohn's disease and cystic fibrosis)
- drugs
- age.

The role of a low-fiber, high-fat diet in the development of gallstones, as well as other dietary factors, is discussed under "Therapeutic considerations" ([p. 1243](#)), while the other factors are briefly discussed here.

Sex

The frequency of gallstones is two to four times greater in women than in men. Women are thought to be predisposed to gallstones because of either increased cholesterol synthesis or suppression of bile acids by estrogens. Pregnancy, use of oral contraceptives or other causes of elevated estrogen levels greatly increase the

incidence of gallstones.

1243

Genetic and ethnic

The prevalence of gallstones appears to have some genetic aspects. Gallstones are the most common in Native American women over the age of 30. Nearly 70% of this group have gallstones. In contrast, only 10% of black women over 30 have gallstones.

The difference in the prevalence rate between different ethnic and genetic groups reflects the extent of cholesterol saturation of the bile. The extent to which dietary factors impact this value probably outweighs genetic factors.^[6]

Obesity

Obesity causes an increased secretion of cholesterol in the bile as a result of increased cholesterol synthesis. Therefore, obesity is associated with a significantly increased incidence of gallstones due to biliary cholesterol saturation.

It is important to recognize that during active weight reduction, biliary cholesterol saturation initially increases.^[3] The secretion of all biliary lipids is reduced during weight loss but the secretion of bile acids decreases more than that of cholesterol. Once the weight is stabilized, bile acid output returns to normal levels, while the cholesterol output remains low. The net effect is a significant reduction in cholesterol saturation.

Gastrointestinal tract diseases

Malabsorption of bile acids from the terminal ileum disturbs the enterohepatic circulation, thereby reducing the bile acid pool and the rate of secretion of bile. Diseases associated with this phenomenon include Crohn's disease and cystic fibrosis.

Drugs

In addition to oral contraceptives and other estrogens, drugs which increase the risk of gallstones include clofibrate and possibly other lipid-lowering drugs. Clofibrate lowers serum lipids but greatly increases the development of gallstones by increasing cholesterol secretion in the bile.

Age

Gallstones have been reported from fetus to extreme old age, but the average patient is 40–50 years old. The incidence increases with age.

Risk factors for pigmented gallstones

Risk factors for pigmented gallstones are not related to diet as much as they are to geography, sun exposure and severe diseases. Pigmented gallstones are more common in the Orient due to the higher incidence of parasitic infection of the liver and gall bladder by a variety of organisms including the liver fluke *Clonorchis sinensis*. Bacteria and protozoa can cause stasis or act as nucleating agents. In the United States, pigmented stones are usually caused by chronic hemolysis or alcoholic cirrhosis of the liver.

THERAPEUTIC CONSIDERATIONS

Gallstones are easier to prevent than to reverse. Primary treatment, therefore, involves reducing the controllable risk factors discussed above. Once gallstones have formed, therapeutic intervention involves avoiding aggravating foods and employing measures which increase the solubility of cholesterol in bile. If symptoms persist or worsen, cholecystectomy should be considered.

A number of dietary factors are important in the prevention and treatment of gallstones. Foremost is the elimination of foods which can produce symptoms. Also important are increasing dietary fiber, eliminating food allergies, and reducing the intake of animal protein.

Other treatment measures involve the use of nutritional lipotropic compounds, herbal cholagogues, and other natural compounds in an attempt to increase the solubility of bile.

It should be noted that biliary cholesterol concentration and serum cholesterol levels do not seem to correlate.^[7] Although some authors have reported an inverse correlation between HDL cholesterol and bile saturation and a direct correlation between LDL and bile saturation,^{[8] [9]} more detailed research does not appear to support these correlations.^[7] There does, however, seem to be an association between increased serum triglyceride levels and bile saturation.^[10]

Asymptomatic gallstones

The natural history of silent or asymptomatic gallstones supports the contention that elective cholecystectomy is not warranted. While there is a cumulative chance for developing symptoms – 10% at 5 years, 15% at 10 years, and 18% at 15 years – if controllable risk factors are eliminated or reduced, a patient should never experience discomfort.^[2]

Diet

Dietary fiber

The hypothesis that the main cause of gallstones is the consumption of fiber-depleted refined foods has considerable research support.^{[3] [4]} As mentioned earlier, gallstones are associated with the “Western diet” in

1244

population studies. Such a diet, high in refined carbohydrates and fat, and low in fiber, leads to a reduction in the synthesis of bile acids by the liver and a lower bile acid concentration in the gall bladder.

Another way in which fiber may prevent gallstone formation is by reducing the absorption of deoxycholic acid.^{[3] [4]} This compound is produced from bile acids by bacteria in the intestine. Deoxycholic acid greatly lessens the solubility of cholesterol in bile.

Dietary fiber has been shown both to decrease the formation of deoxycholic acid and to bind deoxycholic acid and promote its excretion in the feces. This greatly increases the solubility of cholesterol in the bile. A diet high in fiber, especially those fibers capable of binding to deoxycholic acid, i.e. predominantly the water-soluble fibers found in vegetables and fruits, pectin, oat bran, and guar gum, is extremely important in both the prevention and reversal of most gallstones.^[4]

Interestingly, diets rich in legumes with high concentrations of water-soluble fibers are associated with an increased risk for gallstones.^[6] Chileans, Pima Indians, and other North American Indians have the highest prevalence rates for cholesterol gallstones. All consume a diet rich in legumes. Evidently legume intake increases biliary cholesterol saturation as a result of their saponin content.^[6] It is therefore recommended that legume intake be restricted in individuals with gallstones.

Vegetarian diet

A vegetarian diet has been shown to be protective against gallstone formation.^{[4] [11]} A recent study in England compared a large group of healthy non-vegetarian women with a group of vegetarian women. Ultrasound diagnosis showed that gallstones occurred significantly less frequently in the vegetarian group.

While this may simply be a result of the increased fiber content of the vegetarian diet, other factors may be equally important. Animal proteins, such as casein from dairy products, have been shown to increase the formation of gallstones in animals, while vegetable proteins, such as soy, were shown to be preventive against gallstone formation.^{[3] [4] [12]}

Food allergies

Since 1948, Dr J. C. Breneman, author of *Basics of Food Allergy*, has used a very successful therapeutic regimen to prevent gall bladder attacks: allergy elimination diets. There is some support in the scientific literature for the idea that food allergies cause gall bladder pain.^[13] ^[14] ^[15] ^[16] A 1968 study revealed that 100% of a group of patients were free from symptoms while they were on a basic elimination diet (beef, rye, soybean, rice, cherry, peach, apricot, beet, and spinach).^[13]

Foods inducing symptoms, in decreasing order of their occurrence, were:

- egg
- pork
- onion
- fowl
- milk
- coffee
- citrus
- corn
- beans
- nuts.

Adding eggs to the diet caused gall bladder attacks in 93% of the patients.

Several mechanisms have been proposed to explain the association of food allergy and gall bladder attacks. Dr Breneman believes the ingestion of allergy-causing substances causes swelling of the bile ducts, resulting in impairment of bile flow from the gall bladder.

Sugar

A 4 year study evaluated 111 cases of biliary tract cancer and compared them with 480 controls for a variety of dietary parameters including sugar intake. The major finding was an increased risk associated with the intake of sugars, either monosaccharides or disaccharides, independent of other energy sources. Sugar may be a risk factor for biliary tract cancer based on the relationship between sugars, blood lipids, and gallstone formation. The author also noted an association between the intake of sugar and gallstones. Diets high in refined carbohydrates have been found to be associated with increased cholesterol saturation of the bile.^[17] A 25 year follow-up study of 860 men, 54 of whom developed symptomatic gallstones, also found a positive association between sugar consumption and gallstones.^[18]

Caloric restriction

In a case-controlled study which compared 200 patients with gallstones with 98 controls, total calorie and carbohydrate intake and serum triglyceride levels were higher in the gallstone patients. Dietary intake of refined carbohydrates was higher in the female patients with gallstones, while male patients with gallstones had an increased fat

intake.^[19]

However, caloric restriction must be instituted very carefully as rapid weight loss^[20] and fasting^[21] increase the risk of gallstones. For example, in 179 obese patients, 9% of whom had pre-existing gallstones, a very low calorie (605 kcal) diet resulted in 11% of the patients developing gallstones either during or within 6 months of completing the diet.^[20] Another study of a 925 kcal diet found that

1245

12.8% of the 47 women patients displayed gallstones at week 17 as determined by sonography. Those who developed gallstones had significantly higher baseline triglyceride and total cholesterol levels than those who didn't. They also had a significantly greater rate of weight loss.^[22]

Coffee

Patients with gallstones should be advised to avoid coffee until their stones are resolved as coffee induces gall bladder contractions. In an interesting study, 400 ml of regular coffee, and 165 ml of regular and decaffeinated coffee were assessed for their effect on cholecystokinin secretion. Both regular coffee at both dosages and decaffeinated coffee caused significant gall bladder contractions as compared with the control sodium chloride in six healthy, regular coffee drinkers.^[23]

Nutritional factors

Lecithin (phosphatidylcholine)

A low lecithin concentration in the bile may be a causative factor for many individuals with gallstones. For example, a pure bile salt micelle requires 50 molecules to enclose a single molecule of cholesterol, while a mixed bile salt/phospholipid micelle requires only seven molecules.^[5] Studies have shown that taking as little as 100 mg of lecithin three times per day will increase the concentration of lecithin in the bile, while larger doses (up to 10 g) produce even greater increases.^{[24] [25]} This is significant as an increased lecithin content of bile usually increases the solubility of cholesterol. However, no significant effects on gallstone dissolution have been obtained using lecithin supplementation alone.

Nutrient deficiencies

Deficiencies of either vitamins E or C have been shown to cause gallstones in experimental studies in animals.^{[26] [27]}

Olive oil

A very popular lay remedy for gallstones is the so-called olive oil “liver flush”. There are several variations. A typical one involves drinking 1 cup of unrefined olive oil with the juice of two lemons in the morning for several days.

Many people tell tales of passing huge stones while on the liver flush. However, what they think are gallstones are simply a soft saponified complex of minerals, olive oil, and lemon juice produced within the gastrointestinal tract.

The olive oil liver flush is probably undesirable for patients with gallstones for several reasons. First, consuming a large quantity of any oil will result in contraction of the gall bladder which may increase the likelihood of a stone blocking the bile duct. This may result in a cholecystitis, requiring immediate surgery to prevent death. Second, oleic acid, the main component of olive oil, has been shown to increase the development of gallstones in rabbits and rats by increasing the content of cholesterol in the gall bladder.^[28] ^[29] Although this effect has not yet been observed in humans, the animal research suggests it is unwise to use an olive oil liver flush as a treatment of gall bladder disease.^[30] This recommendation is not meant to obviate the use of the liver flush as a viable method of liver detoxification. Rather it is a caution against its use in patients with gallstones.

Fish oils

Although human studies appear to not be available at this time, some provocative animal studies exist. For example, one study compared a diet high in lard with a diet high in fish oils in 21 male African green monkeys. One group was fed 0.8 mg cholesterol/kcal and 42% of the calories as fat, with half of the fat calories derived from lard, while the other group was fed a similar diet with an isocaloric substitution of menhaden oil instead of the lard. After 2–3 years, necropsies were performed and it was found that 67% of the animals fed the lard diet had cholesterol gallstones compared with 22% of the animals fed the fish oil. The cholesterol saturation index of the gall bladder bile was also higher in the lard-fed group although there was no difference in bile acids. There was a significantly greater biliary phospholipid secretion rate in the fish oil-fed animals compared with lard-fed animals.^[31]

A more recent study found similar effects in a prairie dog model using a diet more typical of human habits. Twelve animals consumed a standard control diet while 16 consumed a lithogenic 1.2% cholesterol diet. One-half of the animals in each group were supplemented with 200 mg/kg per day of omega-3 fatty acids from eicosapentaenoic and docosahexaenoic acids. After 14 days, those fed the diet with added fish oil showed an inhibition of gallstone formation accompanied by significant decrease in biliary calcium and total protein concentration. This antilithogenic effect may be due to an enhancement in the stability of biliary phospholipid-cholesterol vesicles.^[32]

Lipotropic factors and botanical cholagogues

The naturopathic approach to the treatment of gallstones has typically involved the use

of lipotropic and choleric formulas. Lipotropic factors are, by definition, substances that hasten the removal or decrease the deposit of fat in the liver through their interaction with fat metabolism.

1246

Compounds commonly employed as lipotropic agents include choline, methionine, betaine, folic acid, and vitamin B₁₂.

Often these nutritional factors are used with herbal cholagogues and choleric. Cholagogues stimulate gall bladder contraction to promote bile flow, while choleric increase bile secretion by the liver.

Many of the herbal choleric have a favorable effect on the solubility of bile. The choleric which are appropriate to use in the treatment of gallstones include: *Taraxacum officinale*, silymarin from *Silybum marianum*, *Cynara scolymus*, and *Curcuma longa*. In addition, *Peumus boldo* contains alkaloids such as boldine which are quite useful in the treatment of gallstones.

Chemical dissolution of gallstones

Several successful non-surgical alternatives for the treatment of gallstones now exist. These entail using a complex of plant terpenes alone or, preferably, in combination with oral bile acids. As the formation of the stone is dependent on either increased accumulation of cholesterol or reduced levels of bile acids or lecithin, decreasing gall bladder cholesterol levels and/or increasing bile acid or lecithin levels should result in dissolution of the stone. Chemical dissolution is especially indicated in the treatment of gallstones in the elderly who cannot withstand the stress of surgery and in other cases where surgery is contraindicated.

Bile acids

Promoting increased cholesterol solubility through oral chenodeoxycholic acid therapy alone (750 mg/day) has resulted in complete dissolution of gallstones in 13.5% and partial dissolution in 27% of patients.^[33] However, this therapy often takes several years and is associated with mild diarrhea and possible liver damage. Ursodeoxycholic acid appears to be somewhat more effective and has fewer side-effects.^[34]

Terpenes

Gallstone dissolution by a natural terpene combination (i.e. menthol, menthone, pinene, borneol, cineol, and camphene) has been demonstrated in several studies.^{[35] [36] [37] [38] [39]} This non-surgical approach to gallstone removal offers an effective alternative to surgery and has been demonstrated to be safe even when it has been consumed for

prolonged periods of time (up to 4 years).

Combined therapy

Although terpenes are effective alone, the best results appear to be achieved when plant terpene complexes are used in combination with bile acid therapy.^[39]^[40]^[41]^[42] This combined approach offers better results than either bile acids or plant terpenes used alone.^[40]^[41]^[42] Furthermore, since a lower dose of bile acid can be used, there is a significant reduction in the risk of complications or side-effects, and in the cost of bile acid therapy. As menthol is the major component of this formula, peppermint oil, especially enteric-coated, may offer similar results.

Lifestyle

Sunbathing

As almost all cholesterol gallstones contain a central, pigmented nucleus with radial or lamellar pigmented bands, alternating with layers of crystalline cholesterol, a researcher speculated that the activation of the pigmentary system by ultraviolet light might lead to increased concentrations of indole metabolites in the bile, triggering their polymerization. In a case-controlled study of 206 white-skinned individuals, a positive attitude towards sunbathing was associated with twice the risk of cholelithiasis, compared with those with a negative attitude. When the effect of sun attitude was considered for individual skin pigmentation types, the association was found to be almost entirely restricted to those who always burn after long sunbathing. In this group, the relative risk was a remarkable 25.6 for a positive attitude towards sunbathing versus a negative one.^[43]

THERAPEUTIC APPROACH

As is typical of most diseases, gallstones are much easier to prevent than to reverse. The risk factors and causes of gallstones are well known, and in most cases a healthy diet rich in dietary fiber will be adequate prevention.

Once gallstones have developed, measures to avoid gall bladder attacks and increase the solubility of the bile are necessary. To limit the incidence of symptoms, intolerant/allergic foods must be determined (see [Ch. 15](#)) and, along with fatty foods, avoided. The solubility of the bile can be increased by following the dietary guidelines and utilizing the nutritional and herbal supplements recommended below.

Diet

Increase intake of vegetables, fruits and dietary fiber, especially the gel-forming or mucilaginous fibers (flaxseed, oat bran, guar gum, pectin, etc.). Reduce consumption of saturated fats, cholesterol, sugar, and animal proteins. All fried foods should be

avoided.

An allergy elimination diet can be used to reduce gall bladder attacks (see [Ch. 51](#) for a description of elimination diets).

1247

Water

Consumption of six to eight glasses of water is necessary each day to maintain the water content of bile.

Nutritional supplements

- Vitamin C: 1–3 g/day
- Vitamin E: 200–400 IU/day
- Phosphatidylcholine: 500 mg/day
- Choline: 1 g/day
- L-Methionine: 1 g/day
- Fiber supplement (guar gum, pectin, psyllium, or oat bran): minimum of 5 g/day.

Botanical medicines

- *Taraxicum officinale* (three times/day)
 - dried root: 4 g
 - fluid extract (1:1): 4–8 ml
 - solid extract (4:1): 250–500 mg
- *Peumus boldo* (three times/day)
 - dried leaves (or by infusion): 250–500 mg
 - tincture (1:10): 2–4 ml
 - fluid extract (1:1): 0.5–1.0 ml
- *Silybum marianum*
 - sufficient dosage according to form to yield 70–210 mg of silymarin three times/day
- *Cynara scolymus*
 - extract (15% cynarin): 500 mg three times/day
- *Curcuma longa*
 - use liberally as a spice

- Curcumin: 300 mg three times/day.

Gallstone dissolving formula:

- Menthol: 30 mg
- Menthone: 5 mg
- Pinene: 15 mg
- Borneol: 5 mg
- Camphene: 5 mg
- Cineol: 2 mg
- Citral: 5 mg
- Phosphatidylcholine: 50 mg
- Medium chain triglycerides: 125 mg
- Chenodeoxycholic acid: 750 mg.

Dosage. Once three times daily if used in combination with meals.

Note. Peppermint oil in an enteric-coated capsule can be used instead at a dosage of 1–2 capsules (0.2 ml/capsule) three times daily between meals.

Chapter 153 - Glaucoma: acute (angle closure) and chronic (open-angle)

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

DIAGNOSTIC SUMMARY

Acute glaucoma

- Increased intraocular pressure, usually unilateral
- Severe throbbing pain in eye with markedly blurred vision
- Pupil moderately dilated and fixed
- Absence of pupillary light response
- Nausea and vomiting are common.

Chronic glaucoma

- Persistent elevation of intraocular pressure associated with pathological cupping of optic discs
- Asymptomatic in the early stages
- Gradual loss of peripheral vision resulting in tunnel vision
- Insidious onset in older individuals.

GENERAL CONSIDERATIONS

Glaucoma refers to increased intraocular pressure (IOP) as a result of an imbalance between production and outflow of the aqueous humor. Obstruction to outflow is the main factor responsible for this imbalance in closed-angle glaucoma. Acute glaucoma can occur only with the closure of a pre-existing narrow anterior chamber angle, while in chronic open-angle glaucoma the anterior chamber appears normal.

In the USA there are approximately 2 million people with glaucoma, 25% of which is

undetected.^[1] Ninety per cent is of the chronic open-angle type, i.e. there appears to be no consistent anatomical basis for the condition. Histologically, however, there is a strong correlation between the content and composition of collagen and the glaucomatous eye.^[2]

Collagen is the most abundant protein in the body, including the eye. In the eye it provides tensile strength and integrity to the tissues, i.e. cornea, sclera, lamina cribosa, trabecular meshwork, vitreous, etc. Inborn errors

1250

of collagen metabolism (e.g. osteogenesis imperfecta, Ehlers–Danlos syndrome, Marfan’s syndrome) are often associated with ocular complications: glaucoma, myopia, retinal detachment, ectopia lentis, and blue sclera.^[3] Morphological changes in the lamina cribosa (the scleral area that is pierced by the optic nerve fibers and blood vessels), trabecular meshwork (the connective tissue network the aqueous humor must pass through to reach the canal of Schlemm), and papillary blood vessels in the eye have all been observed in glaucomatous eyes.^{[2] [4] [5] [6]} These changes may result in elevated intraocular pressure (IOP) readings or, perhaps more significantly, may lead to the progression of peripheral vision loss. Changes in collagen structure would explain why there is:^{[2] [4] [5] [6]}

- similar peripheral vision loss in patients with normal and elevated IOP
- cupping of the optic disc even at low IOP levels
- no apparent anatomical reason for decreased aqueous outflow.

DIAGNOSIS

Patients with open-angle glaucoma initially have no symptoms, which is why this disease can be so insidious. Physical examination may reveal slight cupping of the optic disc and narrowing of the visual fields. Tonometry is key to confirmation of the diagnosis.

The key challenge with acute glaucoma is early recognition as delay in referral for surgical intervention increases the risk of blindness. [Table 153.1](#) provides an overview of the differential diagnosis of the inflamed eye.

THERAPEUTIC CONSIDERATIONS

Treatment and prevention of both acute and chronic glaucoma are dependent upon reduction of IOP and improvement of collagen metabolism, particularly in the optic disc and trabecular meshwork.

The optic disc is composed of the lamina cribosa, the optic nerve fibers, and the blood vessels. The lamina cribosa is a mesh-like network rich in collagen through which the

optic nerves and blood vessels must pass. The morphological changes in the collagen of the eye (i.e. lamina cribosa, papillary vessels, and trabecular meshwork) precede pressure changes. Therefore, primary prevention of ground substance and collagen framework breakdown is important here, as it is in other conditions involving collagen abnormalities, i.e. atherosclerosis, rheumatoid arthritis, and periodontal disease.

Corticosteroids

The importance of collagen destruction in the etiology of glaucoma is very apparent in corticosteroid-induced glaucoma.^{[1] [2]} Corticosteroid use should be discouraged in the glaucoma patient, as it is known to inhibit the biosynthesis of collagen and glycosaminoglycans, thereby causing glaucoma to develop.^{[1] [2]}

Nutrition

Vitamin C

Of foremost importance in achieving collagen integrity are optimal tissue concentrations of ascorbic acid (AA). Furthermore, AA has been demonstrated to lower IOP levels in many clinical studies.^{[7] [8] [9] [10] [11]} A daily dose of 0.5 g/kg body weight, whether in single or divided doses, reduces the IOP by an average of 16 mmHg.^[11] Almost normal tension levels were achieved in some patients unresponsive to acetazolamide (a carbonic anhydrase inhibitor) and 2% pilocarpine (a miotic agent).^[11]

TABLE 153-1 -- Differential diagnosis of the inflamed eye^[1]

| | Acute conjunctivitis | Acute iritis | Acute glaucoma | Corneal trauma or infection |
|------------------------|-----------------------------|---------------------|-----------------------|------------------------------------|
| Incidence | Very common | Common | Uncommon | Common |
| Discharge | Moderate to copious | None | None | Watery or purulent |
| Vision | No effect | Slightly blurred | Markedly blurred | Usually blurred |
| Pain | None | Moderate | Severe | Moderate to severe |
| Conjunctival injection | Diffuse, mostly fornices | Circumcorneal | Diffuse | Diffuse |
| Cornea | Clear | Usually clear | Steamy | Clarity may change |
| Pupil size | Normal | Small | Dilated and fixed | Normal |
| Pupil light response | Normal | Poor | None | Normal |
| Intraocular pressure | Normal | Normal | Elevated | Normal |

| | | | | |
|----------------------|---------------------|---------------|-----------------------|---|
| Anterior chamber | | Normal depth | Very shallow | Normal depth |
| Iris | Normal | Dull, swollen | Congested and bulging | Normal unless infected |
| Smear | Causative organisms | No organisms | No organisms | Causative organisms if there is infection |
| Cornea | Clear | Usually clear | Steamy | Clarity may change |
| Pupil size | Normal | Small | Dilated and fixed | Normal |
| Pupil light response | Normal | Poor | None | Normal |
| Intraocular pressure | Normal | Normal | Elevated | Normal |
| Anterior chamber | Normal depth | Normal depth | Very shallow | Normal depth |
| Iris | Normal | Dull, swollen | Congested and bulging | Normal unless infected |
| Smear | Causative organisms | No organisms | No organisms | Causative organisms if there is infection |

1251

The hypotonic action of AA on the eye is long-lasting if supplementation is continued, and intravenous administration results in an even greater initial reduction in IOP.^{[7] [9] [10] [11]} Patient monitoring is required to determine the appropriate individual dose, as some patients respond to as little as 2 g/day, while others will respond only to extremely high doses, i.e. 35 g/day.^{[7] [8] [9] [10] [11]} Abdominal discomfort when using high doses is common, but usually resolves after 3–4 days.^[11]

The proposed mechanisms by which AA lowers IOP include:

- increased blood osmolarity
- diminished production of aqueous fluid by the ciliary epithelium
- improved aqueous fluid outflow.

In light of recent research, however, its role in collagen formation may be key to its antiglaucomatous action.

Bioflavonoids

To further aid normal collagen metabolism, bioflavonoids should be supplemented, particularly the anthocyanosides (the blue-red pigments found in berries). These compounds elicit an AA sparing effect, improve capillary integrity, and stabilize the collagen matrix by preventing free radical damage, inhibiting enzymatic cleavage of the collagen matrix, and cross-linking with collagen fibers directly to form a more stable collagen matrix.^[12] ^[13] ^[14] *Vaccinium myrtillus* (European bilberry) extract is particularly rich in these flavonoid and anthocyanidin compounds and has been used in Europe with good results in reducing myopia, improving nocturnal vision, and reversing diabetic retinopathy.^[15] Rutin has also been demonstrated to lower IOP when used as an adjunct in patients unresponsive to miotics alone.^[16]

Allergy

The successful treatment of chronic glaucoma by antiallergy measures has been reported in the literature.^[17] In one study, any of the 113 patients demonstrated an immediate rise in intraocular pressure of up to 20 mm (in addition to other typical allergic symptoms) when challenged with the appropriate allergen, whether food borne or environmental. The author speculated that the known allergic responses of altered vascular permeability and vasospasm could result in the congestion and edema characteristic of glaucoma.

Magnesium

Since channel-blocking drugs offer benefits for some glaucoma patients, a group of researchers at the University Eye Clinic in Basel, Switzerland, decided to evaluate the effect of supplemental magnesium which has been referred to as “nature’s physiological calcium-channel blocker”. Ten glaucoma patients (six with primary open-angle glaucoma, four with normal-tension glaucoma) participated in the trial. All patients had a digital cold-induced vasospasm. Magnesium was given at a dose of 121.5 mg twice daily for 1 month. After 4 weeks of treatment, the visual fields improved as noted by a decrease in the mean defect and square root of loss variance scores. All three nailfold-capillaroscopic para-meters improved, as well as digital temperature. These results demonstrate that magnesium supplementation improves the peripheral circulation and seems to have a beneficial effect on the visual field in patients with glaucoma.^[18]

Chromium

A case-controlled study of 400 consecutive eye patients, of which 52 had ocular hypertension and/or glaucoma, found that primary open-angle glaucoma was strongly associated with a deficiency of erythrocyte chromium, habitual daily intake of ascorbic acid, and elevations of erythrocyte vanadium which is chromium’s principal antagonist.

Ascorbic acid and chromium potentiate insulin receptors that help to sustain strong

ciliary-muscle eye-focusing activity. Deficiencies of either ascorbic acid or chromium were associated with elevated intraocular pressure which tends to stretch the normal eye, thereby reducing the capacity for focusing power.^[19]

Fish oil

In an interesting speculative study, feeding rabbits food soaked with cod liver oil resulted in a 25 mmHg drop in intraocular pressure to 11 mmHg. Intramuscular injections of cod liver oil produced a dose-dependent reduction in intraocular pressure. When the animals were taken off cod liver oil, their intraocular pressure returned to baseline. Control animals given liquid lard or safflower oil experienced no change in intraocular pressure.^[20]

THERAPEUTIC APPROACH

Acute closed-angle glaucoma is an ocular emergency and should be referred immediately to an ophthalmologist.

Unless adequately treated within 12–48 hours, the patient will become permanently blind within 2–5 days. An asymptomatic eye with a narrow anterior chamber angle may convert spontaneously to angle-closure glaucoma. The process can be precipitated by anything that dilates the pupil, such as atropine and epinephrine-like drugs. Typical signs and symptoms include extreme

1252

pain, blurring of vision, conjunctivitis, and a fixed and dilated pupil.^[4]

Agents which dilate the pupils must be strictly avoided in any patient suspected of glaucoma.

Supplements

- Vitamin C: 0.1–0.5 g/kg per day in divided doses
- Bioflavonoids (mixed): 1,000 mg/day
- Magnesium: 200 mg/day
- Chromium: 100 µg/day.

Botanical medicines

- *Vaccinium myrtillus* extract (25% anthocyanidin content): 80 mg three times/day.

Chapter 154 - Gout

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

DIAGNOSTIC SUMMARY

- Acute onset, frequently nocturnal, of typically monarticular joint pain, involving the metatarsophalangeal joint of the big toe in about 50% of cases
- Elevated serum uric acid level
- Asymptomatic periods between acute attacks
- Identification of urate crystals in joint fluid
- Aggregated deposits of monosodium urate monohydrate (tophi) chiefly in and around the joints of the extremities, but also in subcutaneous tissue, bone, cartilage, and other tissues
- Uric acid kidney stones
- Familial disease; 95% males.

GENERAL CONSIDERATIONS

Gout is a common type of arthritis caused by an increased concentration of uric acid (the final breakdown product of purine metabolism) in biological fluids. In gout, uric acid crystals (monosodium urate) are deposited in joints, tendons, kidneys, and other tissues, where they cause considerable inflammation and damage.^{[1] [2]} Gout is a condition characterized biochemically by increased serum uric acid levels, leukotriene levels, and neutrophil accumulation. Gout may lead to debilitation due to the tophaceous deposits around the joints and tendons, and renal involvement may result in kidney failure due to either parenchymal disease or urinary tract obstruction.

Gout is associated with affluence and is often called the “rich man’s disease”. Throughout history, the sufferer of gout has been depicted as a portly, middle-aged man sitting in a comfortable chair with one foot resting painfully on a soft cushion as he consumes great quantities of meat and wine. In fact, the traditional picture does have some basis in reality, as meats, particularly organ meats, are high purine foods, while

alcohol inhibits uric acid secretion by the kidneys. Furthermore, even today,

1254

gout is primarily a disease of adult men; over 95% of sufferers of gout are men over the age of 30.^[1] ^[2] The incidence of gout is approximately three adults in 1,000, although as many as 10–20% of the adult population have hyperuricemia.^[4]

Causes of gout

Gout is classified into two major categories: primary and secondary. Primary gout accounts for about 90% of all cases, while secondary gout accounts for only 10%. Primary gout is usually idiopathic, i.e. the underlying metabolic defect is unknown. There are, however, several genetic defects in which the exact cause of the elevated uric acid is known.^[1] ^[2] The synthesis and degradation of purines is summarized in [Figure 154.1](#) .

Secondary gout refers to those cases in which the elevated uric acid level is secondary to some other disorder, such as excessive breakdown of cells or some form of renal disease. Diuretic therapy for hypertension and low-dose aspirin therapy are also important causes of secondary gout since they cause decreased uric acid excretion.^[1] ^[2]

The increased serum uric acid level observed in primary idiopathic gout can be divided into three categories:

- increased synthesis of uric acid, found in a majority of individuals
- reduced ability to excrete uric acid, typical of a smaller group (about 30%)
- overproduction of uric acid as well as underexcretion of uric acid – a small minority.

Although the exact metabolic defect in gout is not known in the majority of cases, gout is one of the most controllable metabolic diseases.^[1] ^[2] The causes of gout are summarized in [Table 154.1](#) .

About 200–600 mg of uric acid are excreted daily in the urine of an adult male. This is two-thirds of the amount produced, the rest being excreted in the bile and other gastrointestinal tract secretions. The dietary component of uric acid is usually 10–20%, but in an individual with significant hyperuricemia, 1 mg/100 ml may be added to the serum concentration of uric acid through the diet, enough to increase precipitation into the tissues if the individual is near the saturation threshold.^[4]

Almost all of the plasma urate is filtered at the glomerulus: only the small amount bound to protein is not filtered. Renal excretion is peculiar in that about 80% of the filtered uric acid is reabsorbed in the proximal tubule of the nephron. Actually, the distal tubule secretes most of the uric acid found in the urine. Distal to this site, some post-secondary reabsorption occurs.^[4] These events are summarized in [Figure 154.2](#) .

Uric acid is a highly insoluble molecule, and at pH 7.4 and body temperature, the serum is saturated at 6.4–7.0 mg/100 ml. Although higher concentrations do not necessarily result in urate deposition (some unknown factor in serum appears to inhibit urate precipitation), the chance of an acute attack is greater than 90% when

Figure 154-1 Purine synthesis and degradation.^[4]

1255

TABLE 154-1 -- Causes of hyperuricemia^{[3] [4]}

| <i>Metabolic</i> |
|---|
| • Increased production of purine (primary) |
| • Idiopathic |
| • Specific enzyme defects (e.g. Lesch–Nyhan syndrome, glycogen storage disease) |
| • Decreased enzyme activity (e.g. hypoxanthine-guanine phosphoribosyltransferase is decreased in 1–2% of adult gouty individuals) |
| • Increased enzyme activity (e.g. phosphoribosylpyrophosphate synthetase) |
| • Increased production of purine (secondary) |
| —increased turnover of purines |
| —myeloproliferative disorders |
| —lymphoproliferative disorders |
| —carcinoma and sarcoma (disseminated) |
| —chronic hemolytic anemia |
| —cytotoxic drugs |
| —psoriasis |
| • Increased de novo synthesis (e.g. glucose-6-phosphatase deficiency) |
| • Increased catabolism of purines |
| —fructose ingestion or infusion |
| —exercise |

Renal

- Decreased renal clearance of uric acid (primary)
 - intrinsic kidney disease
- Decreased renal clearance of uric acid (secondary)
- Functional impairment of tubular secretion
 - drug-induced (e.g. thiazides, probenecid, salicylates, ethambutol, pyrazinamide)
- Hyperlacticemia (e.g. lactic acidosis, alcoholism, toxemia of pregnancy, chronic beryllium disease)
- Hyperketoacidemia (e.g. diabetic ketoacidosis, fasting, starvation)
- Diabetes insipidus
- Bartter’s syndrome
- Chronic lead intoxication
- Glucose-6-phosphatase deficiency

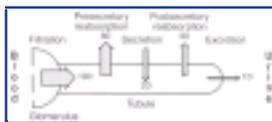

Figure 154-2 Normal uric acid excretion.^[4]

the level is above 9 mg/100 ml (see [Table 154.2](#)). Lower temperatures decrease the saturation point of uric acid, which may explain why urate deposits tend to form in areas such as the pinna of the ear, where the temperature is lower than the mean body temperature (see [Table 154.3](#)). Uric acid is insoluble below pH 6.0 and can precipitate as the urine is concentrated in the collecting ducts and passed to the renal pelvis.

TABLE 154-2 -- Prevalence of gouty arthritis by maximum urate level^[5]

| Serum urate | Men (%) | Women (%) |
|--------------|---------|-----------|
| <6 mg/100 ml | 0.6 | 0.08 |
| 6.0–6.9 | 1.9 | 3.3 |
| 7.0–7.9 | 16.7 | 17.4 |
| 8.0–8.9 | 25.0 | 0 |
| 9+ | 90.0 | 0 |

TABLE 154-3 -- Solubility of urate ion as a function of temperature in 140 mM Na⁺⁵

| Temperature (°C) | Maximum solubility (mg/100 ml) |
|------------------|--------------------------------|
| 37 | 6.8 |

| | |
|----|-----|
| 35 | 6.0 |
| 30 | 4.5 |
| 25 | 3.3 |
| 20 | 2.5 |
| 15 | 1.8 |
| 10 | 1.2 |

Signs and symptoms

The first attack of gout is characterized by intense pain, usually involving only one joint. The first joint of the big toe is affected in nearly half of the first attacks and is at some time involved in over 90% of individuals with gout. If the attack progresses, fever and chills will appear. The first attacks usually occur at night and are usually preceded by a specific event such as dietary excess, alcohol ingestion, trauma, certain drugs, or surgery.^[2]

The classic description of gout was by an English physician, Sydenham, who suffered from gout in 1683. Little has changed in the clinical picture of gout in over 300 years. Sydenham's classic description was as follows:

The victim goes to bed and sleeps in good health. About two o'clock in the morning he is awakened by a severe pain in the

1256

great toe; more rarely in the heel, ankle, or instep. The pain is like that of a dislocation, and yet parts feel as if cold water were poured over them. Then follows chills and shivers, and a little fever. The pain which at first was moderate, becomes more intense. With its intensity the chills and fever increase. After a time this comes to a height, accommodating itself to the bones and ligaments of the tarsus and metatarsus. Now it is a violent stretching and tearing of the ligaments – now it is a gnawing pain and now a pressure and tightening. So exquisite and lively meanwhile is the feeling of the part affected, that it cannot bear the weight of bedclothes nor the jar of a person walking in the room. The night is passed in torture, sleeplessness, turning the part affected, and perpetual change of posture; the tossing about of the body being as incessant as the pain of the tortured joint, and being worse as the fit comes on. Hence the vain effort by change of posture, both in the body and the limb affected, to obtain an abatement of pain.

Subsequent attacks are common, with the majority having another attack within 1 year. However, nearly 7% never have a second attack. Chronic gout is extremely rare, due to the advent of dietary therapy and drugs that lower uric acid levels. Some degree of

kidney dysfunction occurs in nearly 90% of subjects with gout, and there is a higher risk of kidney stones.^[2]

THERAPEUTIC CONSIDERATIONS

The current standard medical treatment of acute gout is administration of colchicine, the anti-inflammatory drug originally isolated from the plant *Colchicum autumnale* (autumn crocus, meadow saffron).^[2] Colchicine has no effect on uric acid levels; rather it stops the inflammatory process by inhibiting neutrophil migration into areas of inflammation.

Over 75% of patients with gout show major improvement in symptoms within the first 12 hours after receiving colchicine. However, as many as 80% of patients are unable to tolerate an optimal dose because of gastrointestinal side-effects, which may precede or coincide with clinical improvement.^[2]

Colchicine may also cause bone marrow depression, hair loss, liver damage, depression, seizures, respiratory depression, and even death. Other anti-inflammatory agents are also used in acute gout, including: indomethacin, phenylbutazone, naproxen, and fenoprofen.^[2]

Once the acute episode has resolved, a number of measures are taken to reduce the likelihood of recurrence:^[2]

- drugs to keep uric acid levels within a normal range
- controlled weight loss in obese individuals
- avoidance of known precipitating factors, such as heavy alcohol consumption or a diet rich in purines
- low doses of colchicine to prevent further acute attacks.

Several dietary factors are known to be causes of gout: consumption of alcohol, high purine-containing foods (organ meats, meat, yeast, poultry, etc.), fats, and refined carbohydrates, and overconsumption of calories.^{[6] [7]} Individuals with gout are typically obese, prone to hypertension and diabetes, and at a greater risk for cardiovascular disease. Obesity is probably the most important dietary factor.^{[6] [7]}

In concept, the naturopathic approach for chronic gout does not differ substantially from the standard medical approach:

- Dietary and herbal measures are employed instead of drugs to keep uric acid levels within the normal range.
- Obese individuals are put on a careful weight loss program.
- Known precipitating factors, such as heavy alcohol consumption and numerous dietary factors, are controlled.
- Nutritional substances are used to prevent further acute attacks.

Lead toxicity

An additional item of concern relates to lead toxicity. A secondary type of gout, sometimes called saturnine gout, can result from lead toxicity.^[7] ^[8] ^[9] Historically, saturnine gout was due to the consumption of alcoholic beverages stored in containers containing lead.^[9] An unexpected and fairly common source of lead appears to be leaded crystal, as port wine elutes lead when stored in a crystal decanter.^[10] Lead concentration increases with storage time, reaching toxic levels after several months. Even a few minutes in a crystal glass results in a measurable increase in the level of lead in the wine. The mechanism of action is related to a decrease in renal urate excretion.

Dietary considerations

The dietary treatment of gout involves the following guidelines:

- elimination of alcohol intake
- low-purine diet
- achievement of ideal body weight
- liberal consumption of complex carbohydrates
- low fat intake
- low protein intake
- liberal fluid intake.

Alcohol

Alcohol increases uric acid production by accelerating purine nucleotide degradation, and reduces uric acid excretion by increasing lactate production (a result of ethanol oxidation) which impairs kidney function. The net effect is a significant increase in serum uric acid levels. This explains why alcohol consumption is often a precipitating factor in acute attacks of gout. Elimination

1257

of alcohol is all that is needed to reduce uric acid levels and prevent gouty arthritis in many individuals.^[9] ^[7] ^[11]

Low-purine diet

A low-purine diet has been the mainstay of the dietary therapy of gout for many years. However, with the advent of potent drugs that lower uric acid levels, many physicians “lower the serum urate levels without subjecting the patient to the inconvenience and deprivation associated with a purine-free diet”. Dietary restriction of purines is, however, recommended to reduce metabolic stress. Foods with high purine levels should be entirely omitted. These include organ meats, meats, shellfish, yeast (brewer’s and baker’s), herring, sardines, mackerel, and anchovies. Foods with moderate levels of

protein should be curtailed as well. These include dried legumes, spinach, asparagus, fish, poultry, and mushrooms.^[6] ^[7]

Weight reduction

Excess weight is associated with an increased rate of gout.^[12] Weight reduction in obese individuals significantly reduces serum uric acid levels. Weight reduction should involve the use of a high-fiber, low-fat diet, as this type of diet will help to manage the elevated cholesterol and triglycerides which are also common in obesity. This diet is also an alkaline ash diet, recommended in the dietary treatment of gout, since a more alkaline pH increases uric acid solubility.

Carbohydrates, fats, and protein

Refined carbohydrates and saturated fats should be kept to a minimum, as the former increase uric acid production while the latter increase uric acid retention.^[6] ^[7] ^[13] ^[14]

Protein intake should not be excessive (i.e. greater than 0.8 g/kg body weight), as it has been shown that uric acid synthesis may be accelerated in both normal and gouty patients by a high protein intake.^[6] Adequate protein is necessary (0.8 g/kg body weight), however, as amino acids decrease resorption of uric acid in the renal tubules, thus increasing uric acid excretion and reducing serum uric acid concentrations.^[7]

Fluid intake

Liberal fluid intake keeps the urine dilute and promotes the excretion of uric acid. Furthermore, dilution of the urine reduces the risk of kidney stones.^[6]

Nutritional supplements

Eicosapentaenoic acid

Eicosapentaenoic acid (EPA) supplementation is very useful in the treatment of gout. EPA limits the production of the proinflammatory leukotrienes, which are the mediators of much of the inflammation and tissue damage observed in gout.^[15] ^[16]

Vitamin E

Vitamin E is indicated in the treatment of gout since it also (mildly) inhibits the production of leukotrienes and acts as an antioxidant.^[17] Selenium functions synergistically with vitamin E.

Folic acid

Folic acid has been shown to inhibit xanthine oxidase, the enzyme responsible for producing uric acid.^[18] The drug allopurinol, used in the medical treatment of gout, is a

potent inhibitor of this enzyme. Research has demonstrated that a derivative of folic acid is an even greater inhibitor of xanthine oxidase than allopurinol, suggesting that folic acid at pharmacological doses may be an effective treatment in gout.^[19] Positive results in the treatment of gout have been reported, but the data are incomplete and uncontrolled.^[20]

Bromelain

The proteolytic enzyme of pineapple has been demonstrated to be an effective anti-inflammatory agent in both clinical human studies and experimental animal models.^[21] It is a suitable alternative to stronger prescription anti-inflammatory agents used in the treatment of gout. For best results, bromelain should be taken between meals (for further discussion of this useful anti-inflammatory agent, see [Ch. 83](#)).

Quercetin

The bioflavonoid quercetin has demonstrated several effects in experimental studies that indicate its possible benefit to individuals with gout.^[22] ^[23] ^[24] ^[25] Quercetin may offer significant protection by inhibiting:

- xanthine oxidase in a similar fashion to the drug allopurinol,^[22]
- leukotriene synthesis and release,^[24]
- neutrophil accumulation and enzyme release.^[23]

For best results, quercetin should be taken with bromelain between meals (bromelain is believed to enhance the absorption of quercetin and other medications^[25]).

Alanine, aspartic acid, glutamic acid, and glycine

These amino acids have been shown to lower serum uric acid levels, presumably as a result of decreasing uric acid resorption in the renal tubule. This results in an increase in uric acid excretion.^[6] ^[12]

Vitamin C

Megadoses of vitamin C are probably contraindicated in individuals with gout as vitamin C may increase uric acid levels in a small number of individuals.^[26]

Niacin

High doses of niacin, i.e. above 50 mg/day, are probably contraindicated in the

treatment of gout, as niacin competes with uric acid for excretion.^[27]

Botanical medicines

Cherries

Consuming one-half pound of fresh or canned cherries per day has been shown to be very effective in lowering uric acid levels and preventing attacks of gout.^[28] Cherries, hawthorn berries, blueberries, and other dark red-blue berries are rich sources of anthocyanidins and proanthocyanidins. These compounds are flavonoid molecules, which give these fruits their deep red-blue color, and are remarkable in their ability to prevent collagen destruction.^{[29] [30]}

Anthocyanidins and other flavonoids affect collagen metabolism in many ways:

- They have the unique ability to actually cross-link collagen fibers, resulting in reinforcement of the natural cross-linking of collagen that forms the collagen matrix of connective tissue (ground substance, cartilage, tendon, etc.).^{[29] [30] [31]}
- They prevent free radical damage through their potent antioxidant and free radical scavenging action.^{[29] [30] [31] [32]}
- They inhibit enzymatic cleavage of collagen by enzymes secreted by leukocytes during inflammation.^{[31] [32]}
- They prevent the release and synthesis of compounds that promote inflammation, such as histamine, serine proteases, prostaglandins, and leukotrienes.^[32]

These effects on collagen structures make flavonoids extremely useful in the treatment of a wide variety of inflammatory conditions, including gout, rheumatoid arthritis, and periodontal disease.

Harpagophytum procumbens (Devil's claw)

Devil's claw has been used in folk medicine for the treatment of a variety of diseases, including gout and rheumatoid arthritis. Clinical research in Europe appears to indicate Devil's claw may be of benefit in the treatment of gout. In addition to relieving joint pain, clinical trials found that Devil's claw also reduced serum cholesterol and uric acid levels.^[33]

Several pharmacological studies utilizing experimental models of inflammation in animals have reported that Devil's claw possesses an anti-inflammatory and analgesic effect comparable to the potent drug phenylbutazone.^[34] However, other studies have indicated that Devil's claw has little, if any, anti-inflammatory activity.^{[35] [36]}

The equivocal research results found in experimental models may reflect a mechanism of action that is inconsistent with current anti-inflammatory drugs or a lack of quality control (standardization) of the preparations used. Further clinical research is needed to clarify these inconsistencies.

At this time it can be stated that Devil's claw may be useful in the short-term management of gout. However, since gout can be successfully prevented and treated by following simple dietary changes in most instances, the use of Devil's claw in the long-term management of gout is probably unnecessary.

THERAPEUTIC APPROACH

As stated earlier, the naturopathic approach to the prevention and treatment of gout does not differ substantially from the standard medical approach. The basic approach involves:

- dietary and herbal measures which maintain uric acid levels within the normal range
- controlled weight loss in obese individuals
- avoidance of known precipitating factors (such as heavy alcohol consumption and a high-purine diet)
- the use of nutritional substances to prevent further acute attacks
- the use of herbal and nutritional substances to inhibit the inflammatory process.

Diet

Eliminate alcohol intake, maintain a low-purine diet, increase consumption of complex carbohydrates and decrease consumption of simple carbohydrates, maintain a low fat intake, optimize protein intake (0.8 g/kg body weight), and consume liberal quantities of fluid. Urinary 24 hour uric acid levels can be used to monitor compliance with purine-free diet (maintain below 0.8 g/day).

In addition, liberal amounts (250–500 g/day) of cherries, blueberries, and other anthocyanoside-rich, i.e. red-blue, berries (or extracts), should be consumed.

Nutritional supplements

- EPA: 1.8 g/day
- Vitamin E: 400–800 IU/day
- Folic acid: 10–40 mg/day
- Bromelain: 125–250 mg three times/day between meals
- Quercetin: 125–250 mg three times/day between meals.

Botanical medicine

- *Harpagophytum procumbens*
—dried powdered root: 1–2 g three times/day

—tincture (1:5): 4–5 ml three times/day

—dry solid extract (3:1): 400 mg three times/day

- Anthocyanoside extracts (e.g. *Vaccinium myrtillus*): equivalent to 80 mg anthocyanoside content daily.

Chapter 155 - Hemorrhoids

David K. Shefrin ND

DIAGNOSTIC SUMMARY

- Abnormally large or symptomatic varices of vessels or conglomerates of supporting tissues and overlying mucous membrane or skin of the anorectal area
- Bright red bleeding on the surface of the stool, on the toilet tissue, and/or in the toilet bowl
- Anemia is an uncommon complication.

GENERAL CONSIDERATIONS

In the United States, as well as other industrialized countries, hemorrhoidal disease is extremely common. Although most individuals may begin to develop hemorrhoids in their twenties, hemorrhoidal symptoms usually do not become evident until the thirties.^[1]

Estimates have indicated that 50% of persons over 50 years of age have symptomatic hemorrhoidal disease and up to one-third of the total US population have hemorrhoids to some degree.^[3]

Etiological considerations

The causes of hemorrhoidal disease are similar to those of varicose veins. Like varicose veins, genetic weakness of the veins, excessive venous pressure, pregnancy, long periods of standing or sitting, and heavy lifting are considered the major factors.

Because the portal venous system contains no valves, factors which increase venous congestion in the perianal region can precipitate hemorrhoid formation. This includes increasing intra-abdominal pressure (e.g. defecation, pregnancy, coughing, sneezing, vomiting, physical exertion, and portal hypertension due to cirrhosis), a low-fiber diet-induced increase in straining during defecation, and standing or sitting for

prolonged periods of time.

Classification of hemorrhoids

Hemorrhoids are typically classified according to location and degree of severity.

1262

External hemorrhoids

External hemorrhoids occur below the anorectal line, the point in the 3 cm long anal canal at which the skin lining changes to mucous membrane. They may be either thrombotic or cutaneous. A thrombotic hemorrhoid is produced when a hemorrhoidal vessel has ruptured and formed a thrombus, while a cutaneous hemorrhoid consists of fibrous connective tissue covered by anal skin. Cutaneous hemorrhoids can be located at any point on the circumference of the anus. Typically, they are caused by the resolution of a thrombotic hemorrhoid, i.e. the thrombus becomes organized and replaced by connective tissue.

Internal hemorrhoids

Internal hemorrhoids occur above the anorectal line. Occasionally an internal hemorrhoid will enlarge to such a degree that it will prolapse and descend below the anal sphincter.

Internal-external hemorrhoids

Internal-external, or mixed, hemorrhoids are a combination of contiguous external and internal hemorrhoids that appear as baggy swellings. The following types occur:

- without prolapse – bleeding may be present, but there is no pain
- prolapsed – characterized by pain and possibly bleeding
- strangulated – the hemorrhoid has prolapsed to such a degree and for so long that its blood supply is occluded by the anal sphincter's constricting action. Strangulated hemorrhoids are very painful and usually become thrombosed.

CLINICAL SYMPTOMATOLOGY

The symptoms most often associated with hemorrhoids include:

- itching
- burning
- pain
- inflammation

- irritation
- swelling
- bleeding
- seepage.

Itching is rarely due to hemorrhoids, except when there is mucous discharge from prolapsing internal hemorrhoids. The common causes of pruritus ani include tissue trauma secondary to excessive use of harsh toilet paper, *Candida albicans*, parasitic infections, and allergies. Pain does not usually occur unless there is acute inflammation of external hemorrhoids. As there are no sensory nerves ending above the anorectal line, uncomplicated internal hemorrhoids rarely cause pain. Bleeding is almost always associated with internal hemorrhoids and may occur before, during or after defecation. When bleeding occurs from an external hemorrhoid, it is due to rupture of an acute thrombotic hemorrhoid. Bleeding hemorrhoids can produce severe anemia due to chronic blood loss.

Large hemorrhoids of long duration may have associated local lesions such as anal fissures and hypertrophied papillae. Internal hemorrhoids are not palpable unless they are thrombosed, fibrosed (long-standing), and/or recently injected with a sclerosing agent.

Note. Many patients attribute all rectal symptoms to hemorrhoids. Worse, some doctors treat rectal symptoms without examination; more than one rectal cancer has gone undetected in this way. More serious lesions should always be ruled out by sigmoidoscopy.

THERAPEUTIC CONSIDERATIONS

Nutrition

Diet

In contrast to the United States and the United Kingdom, hemorrhoids are rarely seen in parts of the world where high-fiber, unrefined diets are consumed.^[3] A low-fiber diet, high in refined foods, contributes greatly to the development of hemorrhoids.

Individuals consuming a low-fiber diet tend to strain more during bowel movements, since their smaller and harder stools are more difficult to pass. This straining increases the pressure in the abdomen, which obstructs venous return. The increased pressure will increase pelvic congestion and may significantly weaken the veins, causing hemorrhoids to form.

A high-fiber diet is perhaps the most important component in the prevention of hemorrhoids. A diet rich in vegetables, fruits, legumes, and grains promotes peristalsis; and many fiber components attract water and form a gelatinous mass which keeps the feces soft, bulky, and easy to pass. The net effect of a high-fiber diet is significantly less straining during defecation. The importance of fiber is discussed in more detail in

[Chapters 57](#) and [193](#) .

Another important, but only recently recognized, dietary factor is breakfast. An age, sex and pregnancy matched case–control study carried out in an outpatient clinic found a remarkable 7.5-fold increase in the odds of suffering from hemorrhoids or anal fissures in matched subjects who did not eat breakfast!^[4]

Fiber supplements

Natural bulking compounds can be used to reduce fecal

1263

straining. These fibrous substances, particularly psyllium seed and guar gum, possess mild laxative action due to their ability to attract water and form a gelatinous mass. They are generally less irritating than wheat bran and other cellulose fiber products. Several double-blind clinical trials have demonstrated that supplementing the diet with bulk-forming fibers can significantly reduce the symptoms of hemorrhoids (bleeding, pain, pruritus, and prolapse) and improve bowel habits.^{[5] [6]}

A recent randomized, placebo-controlled study evaluated the efficacy of fiber supplements in 50 patients with bleeding internal hemorrhoids. Patients in the study group were treated with a commercially available preparation of *Plantago ovata* and those in the control group were treated with a placebo. Endoscopy was performed on every patient before and after treatment to establish the degree of hemorrhoidal prolapse, the number of congested hemorrhoidal cushions and contact bleeding hemorrhoids. During the first 15 days of treatment, the average number of bleeding episodes was 4.8 ± 3.8 for the study group versus 6.4 ± 3 for the control group (NS). During the following 15 days, it decreased to 3.1 ± 2.7 in the study group versus 5.5 ± 3.2 ($P < 0.05$) in the control group, and in the last 10 days of treatment a further reduction to 1.1 ± 1.4 was found in the study group versus 5.5 ± 2.9 ($P < 0.001$). The number of congested hemorrhoidal cushions diminished from 2.6 ± 1 to 1.6 ± 2.2 after fiber treatment ($P < 0.01$) and no differences were found in the control group. In the fiber group, hemorrhoids bled on contact in five out of 22 patients before treatment and in none after treatment; no differences were found in the control group. No modification of the degree of prolapse was observed after treatment.^[7] While the effect took a few weeks to develop, the final results were very impressive.

Flavonoids

Flavonoid preparations have been shown to be beneficial in the prevention and treatment of hemorrhoids due to their strengthening effect on venous tissues. While early studies primarily utilized rutin, more recent research has used hydroxyethylrutosides (HER). These are discussed fully in [Chapter 87](#) .

Several of the studies have been performed in pregnant women where HER was shown

to be of great benefit in helping to relieve hemorrhoidal signs and symptoms. In one study, 90% of the women given HER (1,000 mg daily for 4 weeks) had improved symptoms, compared with only 12% in the placebo group.^[8] Similar results in hemorrhoids not associated with pregnancy have been reported.^[9] ^[10] A recent study provided a micronized flavonoid combination (diosmin 90% and hesperidin 10%) for a median of 8 weeks before delivery and 4 weeks after delivery to 50 pregnant women with acute hemorrhoids. Their therapy was very successful, with 66% reporting relief from symptoms by the fourth day of treatment and fewer suffering relapses during the antenatal period.^[11] Treatment was well accepted, and did not affect pregnancy, fetal development, birth weight, infant growth or feeding.

Topical therapy

Topical therapy, in most circumstances, will only provide temporary relief. Topical treatments involve the use of suppositories, ointments, and anorectal pads. Many over-the-counter products for hemorrhoids contain primarily natural ingredients, such as:

- witch hazel (*Hamamelis* water)
- shark liver oil
- cod liver oil
- cocoa butter
- Peruvian balsam
- zinc oxide
- live yeast cell derivative
- allantoin.

Botanical medicines

The botanicals described in [Chapter 193](#) (*Centella asiatica*, *Aesculus hippocastanum*, and *Ruscus Aculeatus*) are useful for enhancing the integrity of the venous structures of the rectum.

Hydrotherapy

The warm Sitz bath (see [Ch. 42](#)) is an effective non-invasive treatment for uncomplicated hemorrhoids.^[2]

Surgical treatment

Surgical methods of treating hemorrhoids include:

- the injection of sclerosing agents
- rubber band ligation
- the dilatation of the anal canal and lower rectum
- cryosurgery
- hemorrhoidectomy

- infrared coagulation.^[2]

Monopolar direct current therapy

The monopolar direct current technique for hemorrhoid management is becoming a significant treatment of choice in the United States. According to an article in *Gastrointestinal Endoscopy*:^[12]

This painless outpatient treatment of all grades of hemorrhoids is effective and safe. This methodology warrants consideration as the treatment of choice of hemorrhoidal disease.

1264

The first published work on monopolar direct current (also called inverse galvanism) was *Obliteration of Hemorrhoids with Negative Galvanism* by Wilbur E. Keesey MD of Chicago.^[13] Dr Keesey dated the first use of this approach to 1897, although the technical problems (producing a smooth uninterrupted galvanic current source) were not worked out until approximately 1925. The technique then began to be used in general practice. However, it should be noted that without the naturopathic medical schools teaching this technique over the last 60 years, and its use by a number of highly skilled NDs and DCs, it is very possible that this irreplaceable technique would have been lost to the healing arts.

A recent study also relieved the chronic anal fissures often associated with internal hemorrhoids. All 10 of the patients in the reported study experienced relief of chronic anal pain within two treatments and anal fissures healed in nine within 4 weeks. One patient developed a perianal abscess and fistula requiring surgery. There were no recurrences in 20 months (mean) of follow-up.^[14]

The monopolar direct current technique is purely an office procedure. No anesthetic is needed, except local anesthetic for the occasional hypersensitive or nervous patient (in such instances, a 2% procaine solution is injected directly into the hemorrhoid). To date, there have been no reported cases of stricture or metastatic abscesses, which speaks well for the procedure's safety.

The chemico-physiological action which causes the absorption and destruction of a vein is responsible for the permanency of the cure. The mechanism of action of monopolar direct current is well understood. When introduced into the interior of the hemorrhoid, the negative pole of the galvanic current makes contact with the water of the blood and generates hydrogen gas and hydroxide ions. The hydroxide destroys the organized structure of the hemorrhoid and its capillary circulation. This produces first a hydrolysis and then a hardening of the hemorrhoid.

The final disappearance of the hemorrhoid is brought about in one of two ways. It will either absorb in a manner similar to absorption of any bodily contusion, or, if the

hemorrhoid is large, it will rupture, causing a discharge of the thrombosed elements into the rectum, followed by a contraction of the residual hemorrhoidal tissues.

For optimal results, the physician must be thoroughly familiar with the anatomy and physiology of the rectum and its surrounding structures.

No pre-operative preparation is necessary.

Special equipment

- Slotted anoscope
- Needle (27g, 3 cm length) and 3 cc syringe
- 2% procaine
- Galvanic generator with timer and on/off foot switch
- Dilute electrolyte solution
- A ground pad (positive electrode) with 10 × 20 cm sponge
- Specially constructed rectal needle electrodes.

Technique

1. Have needed instruments readily accessible.
2. Lay patient on the examination table on his/her left side in the Sims position.
3. Thoroughly moisten the ground pad with the electrolyte solution and connect it to the positive pole of the generator.
4. Place the positive ground pad under the patient's left thigh.
5. Lubricate the anoscope and then gently dilate the anus with the index finger.
6. Insert the anoscope with the slot facing the hemorrhoid area to be treated and then remove the obturator.
7. Test the hemorrhoidal mucosa with a cotton-tipped applicator: if it is loose and rucks up, inject 0.5–1 cc of 2% procaine directly into the hemorrhoid.
8. Insert the negative galvanic needle electrode at a point at least 5 mm above the dentate line in the longitudinal axis of the vein at a very slight angle to the rectal canal. If current is directed below the dentate line, a painful burning sensation will be produced at once, and an anal fissure may be produced. Care must be taken to keep the point of the electrode away from the wall of the rectum. Failure to do so may result in sloughing and ulceration of the rectal mucosa. The needle electrode must always be inserted into the mucosa, never the skin or mucocutaneous junction.
9. Slowly turn on the current until the current meter registers 10–15 mA, using the tolerance of the patient as a guide.
10. Continue the current for up to 10 minutes, at which time dark red rings, which coalesce to dusky red (in some cases nearly black) appearance, will have formed.
11. Slowly shut off the current.
12. Withdraw the needle electrode.
13. The patient may be freely ambulant after completion of the procedure (have the patient place an absorbant pad in his or her underwear to absorb any resulting secretions).

14. The hemorrhoid will disappear in 3–7 days after the treatment.

Treat each separate hemorrhoid in the same manner. Larger hemorrhoids will need to be treated more than once. It is not a good policy to treat more than one, or at the uppermost two, hemorrhoids at the same time. Internal hemorrhoids, which are uppermost in the rectum, should be treated first, after which many of the so-called external hemorrhoids will retract into the rectum.

1265

Since the hemorrhoidal tissue is devoid of sensory nerves, the whole procedure, including insertion of the needle, should be painless. When the treatment is properly applied, the most a patient will notice is a slight feeling of warmth. If the patient complains of any burning or stinging pain, the needle electrode has entered sensitive tissue and is most likely touching the rectal wall. In such a case, shift the needle point to another angle. If this does not give relief, it is best to shut off the current and reinsert the electrode at a new site. If treatment is continued with an improperly inserted electrode, a rectal ulcer or fissure may result.

There should be an interval of 3–7 days between each office treatment.

Note. The needle electrode should always be inserted before the current is turned on, and the current should always be turned off before the electrode is withdrawn. Any pain indicates that the electrode is not properly aligned.

THERAPEUTIC APPROACH

As with all diseases, the primary treatment of hemorrhoids is prevention. This involves reducing those factors which may be responsible for increasing pelvic congestion: straining during defecation, sitting or standing for prolonged periods of time, or underlying liver disease. A high-fiber diet is crucial for the maintenance of proper bowel activity, and nutrients and botanical substances which enhance the integrity of venous structures may also be of benefit.

Warm Sitz baths and topical preparations are useful to ameliorate the discomfort, but have only transient results.

When indicated, the monopolar direct current method, specifically designed for hemorrhoid treatment, will give permanent results. This technique is especially useful in advanced hemorrhoidal disease.

Diet

A high-complex carbohydrate diet rich in dietary fiber is indicated. The diet should contain liberal amounts of proanthocyanidin- and anthocyanidin-rich foods, such as

blackberries, cherries, blueberries, etc. to strengthen vein structures.

Supplements

- Vitamin A: 10,000 IU/day
- Vitamin B-complex: 10–100 mg/day
- Vitamin C: 500–3,000 mg/day
- Vitamin E: 200–600 IU/day
- Bioflavonoids: 100–1,000 mg/day
- Zinc: 15–30 mg/day.

Botanical medicines

See [Chapter 193](#) for specific recommendations.

Physical medicine

- Monopolar direct current therapy: as outlined above
- Hydrotherapy: warm Sitz baths to relieve uncomplicated hemorrhoids.

Chapter 156 - Hepatitis

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

DIAGNOSTIC SUMMARY

- Prodrome of anorexia, nausea, vomiting, fatigue, flu-like symptoms that can occur 2 weeks to 1 month before liver involvement depending upon the incubation period of the virus
- Symptoms may occur abruptly or rather insidiously
- Fever; enlarged, tender liver; jaundice
- Dark urine
- Normal to low white blood cell count, markedly elevated aminotransaminases, elevated bilirubin levels.

GENERAL CONSIDERATIONS

Hepatitis can be caused by many drugs and toxic chemicals, but in most instances it is caused by a virus, with types A, B, and C being the most common. Hepatitis A occurs sporadically or in epidemics, and is transmitted primarily through fecal contamination. Hepatitis B, accounting for 50% of viral cases in the US, is transmitted through infected blood or blood products as well as through sexual contact (the virus is shed in saliva, semen, and vaginal secretion). Hepatitis C (formerly known as hepatitis non-A, non-B) has its primary route of transmission through blood transfusion. In fact, it is responsible for roughly 90% of all cases of hepatitis through blood transfusions (about 10% of people receiving blood transfusions in the past developed hepatitis C). However, only 4% of cases of hepatitis C are a result of transfusions. Most cases are due to intravenous drug use, but in others the source of infection is unclear. Mortality rate (1–12%) is much higher than for the other forms. Other viral causes of hepatitis include hepatitis viruses D, E, and G, as well as herpes simplex, cytomegalovirus, and Epstein–Barr virus.

Acute viral hepatitis can be an extremely debilitating disease requiring bedrest and anything from 2 to 16 weeks for recovery. Most patients recover completely (usually by

9 weeks for type A and 16 weeks for B, C, D, and G). However, about one in 100 will die, and 10% of

hepatitis B and 10–40% of hepatitis C cases now develop into chronic viral hepatitis forms (hepatitis C contracted from a transfusion is associated with a 70–80% development of chronic hepatitis). The symptoms of chronic hepatitis vary from virtually non-existent to chronic fatigue, serious liver damage, and even death.

DIAGNOSTIC CONSIDERATIONS

Diagnosis is suspected when the typical signs and symptoms (see [Table 156.1](#)) are present. Diagnosis is confirmed by blood tests for elevated liver enzymes and the presence of viral antigens or virus-specific antibodies. The type of virus involved is determined by identifying specific viral antigens or antibodies in the blood.

In cases of chronic hepatitis B or C, it is necessary to perform serological evaluation to monitor progression or clearance. In addition to liver enzymes, hepatitis C is monitored by the presence of hepatitis C viral RNA by polymerase chain reaction (HCV-RNA[PCR]). Hepatitis B serological findings and their interpretation are listed in [Table 156.2](#).

THERAPEUTIC CONSIDERATIONS

Hepatitis is a disease that is greatly benefited by

TABLE 156-1 -- Incidence of symptoms in viral hepatitis^[1]

| Symptom | Percentage of patients |
|----------------------|------------------------|
| Dark urine | 94 |
| Fatigue | 91 |
| Loss of appetite | 90 |
| Nausea | 87 |
| Fever | 76 |
| Vomiting | 71 |
| Headache | 70 |
| Abdominal discomfort | 65 |
| Light stools | 52 |
| Muscle pain | 52 |

| | |
|--------------|----|
| Drowsiness | 49 |
| Irritability | 43 |
| Itching | 42 |
| Diarrhea | 25 |
| Joint pain | 21 |

natural therapies. Several nutrients and herbs have been shown to inhibit viral reproduction, improve immune system function, and greatly stimulate regeneration of the damaged liver cells. General therapies to protect and support the liver are discussed in more detail in [Chapter 50](#). Those recommendations can be used in conjunction with the more specific recommendations given in this chapter.

With regard to chronic hepatitis, it is absolutely essential to be aggressive in the treatment of this condition, due to the increased risk for hepatocellular carcinoma and cirrhosis. If cirrhosis is present in chronic hepatitis B, for example, the 5 year survival rate is only 50–60%.

Prevention of hepatitis B

Primary prevention of hepatitis B involves vaccination. Vaccination is a good idea for high-risk occupations such as members of the medical and dental fields who are regularly exposed to blood and other body fluids.

In the case of acute exposure to the hepatitis B virus (HBV), hyperimmune globulin (HBIG) is administered i.m. and is a concentrated solution of immune globulins specific to HBV. It is given to individuals who are known to be exposed to HBV. It confers immediate, but short-lived, passive immunity which lasts for 3 months. Two doses of HBIG are given within 2 weeks of the exposure and it is said to confer adequate protective immunity to 75% of exposed individuals.

HBIG administration is recommended for individuals exposed to HBV surface antigen-contaminated material via mucous membranes or through breaks in the skin. Newborns with HBsAg-positive mothers should also receive the vaccine (0.5 ml shortly after birth and at ages 3 and 6 months).

Nutritional considerations

Diet

During the acute phase, the focus should be on replacing fluids through consumption of vegetable broths, diluted

TABLE 156-2 -- Serological patterns and their interpretations in hepatitis B

| HbsAg | Anti-HBS | Anti-HBc | HBeAg | Anti-HBe | Interpretation |

1269

vegetable juices (diluted with 50% water), and herbal teas. Solid foods should be restricted to brown rice, steamed vegetables, and moderate intake of lean protein sources.

In chronic cases, follow the dietary recommendations given in [Chapter 50](#). The diet should be low in saturated fats, simple carbohydrates (sugar, white flour, fruit juice, honey, etc.), oxidized fatty acids (fried oils), and animal products. A diet which focuses on plant foods (i.e. a high-fiber diet) has been shown to increase the elimination of bile acids, drugs and toxic bile substances from the system.

Vitamin C

According to Robert Cathcart MD, acute hepatitis is one of the easiest diseases for vitamin C to cure.^{[2] [3]} Cathcart demonstrated that high dosages of vitamin C (40–100 g orally or i.v.) were able to greatly improve acute viral hepatitis in 2–4 days and to clear jaundice within 6 days.^[3] Other studies demonstrated similar benefits.^{[4] [5] [6]} A controlled study found that 2 g/day or more of vitamin C was able to dramatically prevent hepatitis B in hospitalized patients. While 7% of the control patients (receiving less than 1.5 g/day of vitamin C) developed hepatitis, none of the treated patients did.^[7]

Liver extracts

The oral administration of liver extracts has been used in the treatment of many chronic liver diseases since 1896. Numerous scientific investigations into the therapeutic efficacy of liver extracts have demonstrated that these extracts promote hepatic regeneration and are quite effective in the treatment of chronic liver disease, including chronic active hepatitis.^{[8] [9] [10]} For example, in one double-blind study, 556 patients with

chronic hepatitis were given either 70 mg of a liver extract or a placebo three times daily.^[10] At the end of 3 months of treatment, the group receiving the liver extract were shown to have far lower liver enzyme (aminotransaminases) levels. Since the level of liver enzymes in the blood reflect damage to the liver, it can be concluded that the liver extract is effective in chronic hepatitis via an ability to improve the function of damaged liver cells as well as prevent further damage to the liver.

Thymus extracts

There is good clinical data to support the effectiveness of orally administered bovine thymus extracts in acute and chronic viral hepatitis (see [Ch. 53](#) for additional information on the thymus gland). The effectiveness of the thymus extract in viral hepatitis is reflective of broad-spectrum immune system enhancement presumably mediated by improved thymus gland activity. Several double-blind studies in both acute and chronic cases of type B viral hepatitis have shown thymus extracts to be effective. In these studies, therapeutic effect was noted by accelerated decreases of liver enzymes (transaminases), elimination of the virus, and a higher rate of seroconversion to anti-HBe, signifying clinical remission.^{[11] [12]}

Botanical medicines

Several plant medicines have been investigated for their effects in viral hepatitis. The two with the most positive documentation are licorice (*Glycyrrhiza glabra*) and silymarin (the flavonoid complex from milk thistle [*Silybum marianum*]). A third, catechin (from *Uncaria gambii*), is effective but is associated with potentially serious side-effects in rare cases (see [Ch. 73](#)). A fourth, *Phyllanthus amarus*, sparked considerable excitement based upon preliminary results, but detailed follow-up studies showed it to provide no benefit.

Glycyrrhiza glabra

Licorice exerts many pharmacological actions beneficial in the treatment of acute and chronic hepatitis, including:

- antihepatotoxic effects
- immune-enhancing actions
- potentiation of interferon
- antiviral effects
- acting as a choloretic.

Clinical studies with a glycyrrhizin-containing product in Japan have shown excellent results in the treatment of acute and chronic hepatitis.^{[13] [14] [15] [16] [17]} The product, Stronger Neominophagen C (SNMC), consists of 200 mg glycyrrhizin, 100 mg cysteine and 2,000 mg glycine in 100 ml of physiological saline solution. It is administered intravenously (oral administration may be just as effective, as discussed below).

SNMC has demonstrated impressive results in treating chronic hepatitis due to either B

or C viruses.^{[13] [14] [15] [16] [17]} With either form, approximately 40% of patients will have complete resolution – a statistic that compares quite favorably with alpha-interferon's 40–50% clearance rate. Like SNMC, alpha-interferon administration has been shown to lead to similar dramatic reductions in the risk for hepatocellular carcinoma.^[18] However, it is expensive and associated with side-effects (primarily fever, joint pain, nausea, and flu-like symptoms). In the latest study, of 453 patients diagnosed with chronic hepatitis C at a hospital in Japan between 1979 and 1984, 84 patients were treated with SNMC at a dosage of 100 ml/day for 8 weeks followed by treatments of two to seven times weekly for periods up to 16 years.^[17] The rates of cumulative hepatocellular carcinoma (HCC) and cirrhosis in

1270

year 10 were 7 and 12%, respectively; in year 15 they were 12 and 21%, respectively. The numbers compare quite favorably with alpha-interferon's success rates in both patients with early stages of the disease (0.6%/year progression to HCC with alpha-interferon and 0.7%/year for SNMC) and patients with advanced stages (1.5%/year progression to HCC in alpha-interferon-treated patients compared with 1.3% for SNMC).

Although the studies with SNMC utilized injectable glycyrrhizin, intravenous administration may not be necessary as glycyrrhizin is readily absorbed from licorice. The goal is to achieve a high level of glycyrrhizin in the blood without producing side-effects. The dosages given in the "Treatment approach" section (p. 1271) provide roughly 50% of the dosage of glycyrrhizin used in the studies with SNMC. The main hazard of licorice administration is the production of its aldosterone-like effects. If ingested regularly, licorice root (greater than 3 g/day for more than 6 weeks) or glycyrrhizin acid (>100 mg/day) may cause sodium and water retention, hypertension, hypokalemia, and suppression of the renin–aldosterone system. Monitoring of blood pressure and electrolytes and increasing dietary potassium intake are suggested.^{[19] [20]}

There is a great individual variation in the susceptibility to the symptom-producing effects of glycyrrhizin. Adverse effects are rarely observed at levels below 100 mg/day, while they are quite common at levels above 400 mg/day.^[19]

Prevention of the side-effects of glycyrrhizin may be possible by following a high-potassium, low-sodium diet. Although no formal trial has been performed, patients who normally consume high-potassium foods and restrict sodium intake, even those with high blood pressure and angina, are free from the aldosterone-like side-effects of glycyrrhizin. Nonetheless, licorice should probably not be used in patients with a history of hypertension or renal failure, or a current use of digitalis preparations.

Silybum marianum

Milk thistle contains silymarin, a mixture of flavanolignans, consisting chiefly of silybin, silidianin, and silichristine. Silymarin is one of the most potent liver-protecting

substances known. Silymarin inhibits hepatic damage by:

- acting as a direct antioxidant and free radical scavenger
- increasing the intracellular content of glutathione and superoxide dismutase
- inhibiting the formation of leukotrienes
- stimulating hepatocyte regeneration.

Silymarin is effective in both acute and chronic viral hepatitis. In one study of acute viral hepatitis, 29 patients treated with silymarin showed a definite therapeutic influence on the characteristic increased serum levels of bilirubin and liver enzymes compared with a placebo group.^[21] The laboratory parameters in the silymarin group regressed more than in the placebo group by the fifth day of treatment. The number of patients attaining normal liver values after 3 weeks' treatment was significantly higher in the silymarin group than in the placebo group.

In a study in chronic viral hepatitis, silymarin was shown to result in dramatic improvement. Use at a high dose (420 mg of silymarin) for periods of 3–12 months resulted in a reversal of liver cell damage (as noted by biopsy), an increase in protein level in the blood, and a lowering of liver enzymes. Common symptoms of hepatitis (e.g. abdominal discomfort, decreased appetite, and fatigue) were all improved.^[22]

Recently, a new form of silymarin has emerged that may provide even greater benefit. The new form binds silymarin to phosphatidylcholine (referred to as silymarin phytosome). A growing body of scientific research indicates that phosphatidylcholine-bound silymarin is better absorbed and produces better clinical results than unbound silymarin.^{[23] [24] [25] [26] [27] [28]} These benefits were demonstrated in one study involving 232 patients with chronic hepatitis (viral, alcohol, or chemically induced) treated with silymarin phytosome at either 120 mg twice daily or 120 mg three times daily for up to 120 days.^[28] Liver function tests were compared with a group of controls (49 treated with a commercially available unbound silymarin; 117 untreated or given placebo). Liver function returned to normal faster in all patients and subtypes given silymarin phytosome compared with both the commercially available silymarin and placebo.

Silymarin has a very low toxicity and is well tolerated. However, as it does possess choleric activity, it may produce a looser stool as a result of increased bile flow and secretion. If higher doses are used, it may be appropriate to use bile-sequestering fiber compounds (e.g. guar gum, pectin, psyllium, oat bran, etc.) to prevent mucosal irritation and loose stools. Because of silymarin's lack of toxicity, long-term use is feasible when necessary. (*Silybum marianum* is discussed in more detail in [Ch. 111.](#))

Phyllanthus amarus

Phyllanthus amarus is an Asian herb with a long history of use in liver disorders. A preliminary report in 1988 demonstrated that 59% of patients with hepatitis B had lost the hepatitis B surface antigen when tested 15–20 days after treatment with a preparation of *Phyllanthus amarus* (200 mg of the dried, powdered, sterilized plant in capsules three times daily).^[29] This report was met with a great deal of excitement.^[29] In

this double-blind

1271

study only 1/23 (4%) of placebo-treated controls tested negative. Unfortunately, these results have not been confirmed by other researchers.^{[30] [31] [32] [33]}

For example, in one double-blind study, 59 and 57 carriers of hepatitis B virus received 400 mg of *P. amarus* three times daily and placebo, respectively, for 30 days and were evaluated on days 15, 30, 60, and 180. HBsAg was detected during treatment and follow-up in every case but one in each group at day 180.^[30]

To rule out the possibility that poor-quality herbal material was responsible for the poor response, the latest double-blind study performed in New Zealand utilized a *Phyllanthus amarus* extract in a capsule standardized to contain 20 mg geraniin per 290 mg of extract.^[33] The dosage used was three capsules daily for 2 months. No effect was noted in the 52 patients receiving the extract. Specifically, clinical symptomatology as well as hepatitis B surface and core antigen levels did not change.

These results indicate that either the type of extract used is not effective or *phyllanthus* itself is not effective. Given the benefits of thymus extracts, licorice, and silymarin in the treatment of chronic hepatitis B as demonstrated in several double-blind studies, it simply does not seem warranted to use *Phyllanthus amarus* at this time.

THERAPEUTIC APPROACH

Bedrest is important during the acute phase of viral hepatitis, with slow resumption of activities as health improves. Strenuous exertion, alcohol and other liver-toxic drugs and chemicals should be avoided. During the contagious phase (2–3 weeks before symptoms appear to 3 weeks after), careful hygiene and avoiding close contact with others is important. In particular, once diagnosis is made, work in a day care center, restaurant, or other similar occupations is not recommended.

Diet

A natural diet, low in natural and synthetically saturated fats, simple carbohydrates (sugar, white flour, fruit juice, honey, etc.), oxidized fatty acids (fried oils), and animal fat and high in fiber is recommended.

Nutritional supplements

Follow the recommendations given in [Chapter 50](#) .

- Vitamin C: to bowel tolerance (10–50 g/day) in acute cases; 1,000 mg three times/day in chronic cases

- Liver extracts: 500–1,000 mg/day of crude polypeptides
- Thymus extracts: equivalent to 120 mg pure polypeptides with molecular weights less than 10,000 or roughly 750 mg of the crude polypeptide fraction.

Botanical medicines

- *Glycyrrhiza glabra* (licorice)
 - powdered root: 1–2 g three times/day
 - fluid extract (1:1): 2–4 ml (1–2 g) three times/day
 - solid (dry powdered) extract (5% glycyrrhetic acid content): 250–500 mg three times/day
- *Silybum marianum* (milk thistle). The standard dose of milk thistle is based on its silymarin content (70–210 mg three times/day). For this reason, standardized extracts are preferred. The best results are achieved at higher dosages, i.e. 140–210 mg of silymarin three times daily. The dosage for silybin bound to phosphatidylcholine is 120 mg two to three times daily between meals.

(Note that if licorice is to be used over a long period of time it is necessary to increase the intake of potassium-rich foods.)

Chapter 157 - Herpes simplex

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

DIAGNOSTIC SUMMARY

- Recurrent viral infection of the skin or mucous membranes characterized by the appearance of single or multiple clusters of small vesicles on an erythematous base frequently occurring about the mouth (herpes gingivostomatitis), lips (herpes labialis), genitals (herpes genitalis), and conjunctiva and cornea (herpes keratoconjunctivitis)
- Incubation period 2–12 days, averaging 6–7
- Vesicle scraping stained with Giemsa's stain gives a positive Tzanck's test
- Regional lymph nodes may be tender and swollen
- Outbreak may follow minor infections, trauma, stress (emotional, dietary, and environmental), and sun exposure.

GENERAL CONSIDERATIONS

More than 70 viruses compose the *Herpes viridae*. Of these, four are important in human disease: herpes simplex (HSV), varicella zoster (VZV), Epstein–Barr (EBV), and cytomegalovirus (CMV). Serological methods have distinguished two types of HSV, which have been designated HSV-1 and HSV-2. Current estimates indicate that 20–40% of the US population have recurrent HSV infections. Serological studies have shown that 30–100% of adults have been infected with one or both HSV types, with the greatest incidence among the lower socioeconomic groups. HSV-1 is primarily isolated from extragenital sites, while genital infections are primarily by HSV-2 (10–40% are due to HSV-1).

Recurrence rate

HSV-1 genital lesions have a recurrence rate of 14%, while the HSV-2 recurrence rate is 60%. Men seem more susceptible to recurrences. After resolution of the primary

infection, HSV probably becomes a dormant inhabitant within sensory and/or autonomic ganglia.

1274

Recurrences develop at or near the sites of primary infection and may be precipitated by many different stimuli:

- sunburn
- sexual activity
- menses
- stress
- food allergy
- drugs
- certain foods.

The risk of clinical herpes infection after sexual contact with an individual with active lesions is estimated to be 75%.

Immunological aspects

Since not everyone exposed to HSV develops clinical infection, it appears that the host defense mechanisms are paramount in protecting against HSV infection. Chronic, persistent labial and genital infections are seen in immunosuppressed individuals. The cell-mediated immune system is undoubtedly the major factor in determining the outcome of herpes exposure: resistance, latent infection, or clinical disease. Athymic nude mice are overcome by HSV and do not develop neutralizing antibodies, reflecting a deficiency of the T-helper cells. HSV-neutralizing antibody is found in saliva and is decreased during active recurrence. It is an IgG immunoglobulin which may be significant, since IgA is the major immunoglobulin in saliva.

THERAPEUTIC CONSIDERATIONS

Enhancement of the host's immunological status is key to the control of herpes infection. There is some evidence that a defect of specific cell-mediated immunity is present even in apparently normal subjects with recurrent HSV infection.^[1] In addition to general immune support (for a complete discussion, see [Ch. 53](#)), one of the key natural measures to strengthen cell-mediated immunity is the use of bovine thymus extracts. Thymus extracts have been shown to be effective in preventing both the number and severity of recurrent infections in immune-suppressed individuals.^[2] The thymus extract appears to increase the lymphoproliferative response to HSV, natural killer cell activity, and interferon production. The thymus extract, therefore, appears to prevent viral activation by potentiating cell-mediated immune responses.

Zinc

Oral supplementation with zinc (50 mg/day) has been shown to be effective in clinical studies.^[3] Although zinc is an effective inhibitor of HSV replication in vitro, its effect in vivo is probably related to its role in enhancing cell-mediated immunity. The topical application of 0.01–0.025% zinc sulphate solutions has also been shown to be effective in both ameliorating symptoms and inhibiting recurrences of HSV infection.^[4]

Vitamin C

Both oral consumption and topical application of vitamin C increase the rate of healing of herpes ulcers. In a randomized, double-blind study, an ascorbic acid-containing pharmaceutical formulation (Ascoxal) applied with a soaked cotton wool pad three times daily for 2 minutes resulted in patients reporting fewer days with scabs and fewer cases of worsening of symptoms. Cultures yielded herpes complex viruses significantly less frequently in the treatment group.^[5] In another study, 20 patients with herpes labialis were treated with a complex of 600 mg of water-soluble bioflavonoids and 600 mg of vitamin C given in equal increments three times daily. Twenty episodes of herpes labialis were treated with a complex of 1,000 mg of water-soluble bioflavonoids and 1,000 mg of vitamin C in equal increments five times daily. Ten episodes were treated with a lactose preparation. This approach was maintained for 3 days after the recognition of symptoms. The water-soluble bioflavonoid–vitamin C complex was shown to reduce vesiculation and to prevent the disruption of the vesicular membrane. The therapy was most beneficial when initiated at the beginning of the disease. Those treated with the 1,000 mg regimen experienced 4.4 days for the blister to heal compared with 10 days for the placebo group.

Lysine and arginine

A lysine-rich/arginine-poor diet has become a popular treatment for HSV infections. This approach came from research showing that lysine has antiviral activity in vitro due to antagonism of arginine metabolism.^[6] HSV replication requires the synthesis of arginine-rich proteins, and arginine itself is suggested to be an operon coordinate inducer.^[6] ^[7] A preponderance of lysine over arginine is believed to act as either an allosteric enzyme inhibitor or an operon coordinate repressor.

Double-blind studies on the effectiveness of lysine supplementation with uncontrolled avoidance of arginine-rich foods have shown inconsistent results.^[7] ^[8] ^[9] ^[10] These results may be due to the relatively low levels of lysine used (1200 mg/day) and the severity of the cases in some of the studies (placebo and treated groups had lesions for 40% of the time in one negative study).^[7] ^[8] In the most recent study, lysine was given at a larger dosage (1 g three times/day) along with dietary restriction of nuts, chocolate, and gelatin.^[9] At 6 months, lysine

was rated as effective or very effective in 74% of those receiving lysine compared with only 28% for those receiving the placebo. The mean number of outbreaks was 3.1 in the lysine group compared with 4.2 in the placebo group.

From a theoretical perspective this approach should be effective, since in vitro studies have shown that HSV replication is dependent on adequate levels of arginine and low levels of lysine.^[11] As dibasic amino acids, they compete with each other for intestinal transport, and rats fed a lysine-rich diet displayed a 60% decrease in brain arginine levels, although there was no change in serum levels.^[7] Since HSV is believed to reside in the ganglia during latency, lysine supplementation and arginine avoidance seem appropriate. However, this approach is not curative – it only inhibits recurrences. In some patients, withdrawal from lysine is followed by relapse within 1–4 weeks.^[11]

Topical preparations

One of the most widely used topical preparations in the treatment and prevention of herpes outbreaks is a concentrated extract (70:1) of *Melissa officinalis* (lemon balm). Rather than any single antiviral chemical, the melissa contains several components that work together to prevent the virus from infecting human cells. When the melissa cream was used in patients with the initial herpes infection, results from comprehensive trials from three German hospitals and a dermatology clinic demonstrated that not a single recurrence occurred.^[11] In other words, by using the cream not a single patient with a first herpes outbreak developed another cold sore.

Furthermore, it was noted in these studies that the melissa cream produced a rapid interruption of the infection and promoted healing of the herpes blisters much quicker than normal. The control group receiving other topical creams had a healing period of 10 days while the group receiving the melissa cream were completely healed within 5 days.

The melissa cream was also studied in patients suffering from recurrent cold sores. Researchers found that if subjects used the melissa cream regularly, they would either stop having recurrences or experience a tremendous reduction in the frequency of recurrences (an average cold sore-free period of greater than 3.5 months).

The melissa cream should be applied to the lips two to four times a day during an active recurrence. It can be applied fairly thickly (1–2 mm). Detailed toxicology studies have demonstrated that it is extremely safe and suitable for long-term use.

Another popular topical treatment for preventing and treating herpes outbreaks is to use preparations containing glycyrrhetic acid. This triterpenoid component of *Glycyrrhiza glabra* (licorice root) inhibits both the growth and cytopathic effects of herpes simplex, as well as vaccinia, Newcastle's disease, and vesicular stomatitis viruses.^[12] Topical glycyrrhetic acid has been shown in clinical studies to be quite helpful in reducing the

healing time and pain associated with cold sores and genital herpes.^[13] ^[14]

THERAPEUTIC APPROACH

The therapeutic aim is to shorten the current attack and prevent recurrences. Support of the immune system is of primary importance, necessitating control of food allergens and optimizing nutrients necessary for cell-mediated immunity. Inhibition of HSV replication through manipulation of the lysine/arginine ratio in the diet seems well indicated. Although no curative methodology is known, strengthening the immune system can be very effective at reducing the frequency, duration, and severity of recurrences.

Diet

Develop a diet which avoids major food allergens and arginine-rich foods while promoting lysine-rich foods (see [Appendix 5](#)). The foods with the worst arginine/ lysine ratio are chocolate, peanuts, and almonds.

Supplements

- Vitamin C: 2,000 mg/day
- Bioflavonoids: 1,000 mg/day
- Zinc: 25 mg/day
- Lysine: 1,000 mg three times/day
- Thymus extract: the equivalent to 120 mg pure polypeptides with molecular weights less than 10,000 or roughly 500 mg of the crude polypeptide fraction.

Topical treatment

- Ice: 10 min on, 5 min off during prodrome
- Zinc sulphate solution: 0.025% solution three times/day
- Melissa cream: apply twice daily
- Glycyrrhetic acid: apply twice daily.

Chapter 158 - HIV/AIDS: naturopathic medical principles and practice

Leanna J. Standish ND PhD
John F. Ruhland ND
Beth DiDomenico ND
Kjersten Gmeiner MD

DIAGNOSTIC SUMMARY

- Positive test for the antibody against the human immunodeficiency virus
- Onset may be sudden or insidious, or may present first as an opportunistic infection such as thrush (oral candidiasis) or *Pneumocystis carinii* pneumonia
- Sudden onset (duration of up to 14 days) of fevers, sweats, malaise, fatigability, joint and muscle pain, headaches, sore throat, diarrhea, generalized swelling of lymph glands, and/or rash on the trunk
- Insidious onset may present as unexplained progressive fatigue, weight loss, fever, diarrhea, and/or generalized swelling of the lymph glands
- Advanced stages will show neurological changes, including dementia and loss of nerve function (e.g. partial paralysis, vertigo, visual disturbances, etc.).

INTRODUCTION

Acquired immune deficiency (AIDS) is a complex multifactorial disease that has both immunodeficiency and autoimmune inflammatory aspects which involve multiple systems of the body (immune, gastrointestinal, genitourinary, endocrine, dermatologic and nervous systems). Conventional medical management of HIV/AIDS revolves around two treatment principles:

- inactivate or slow replication of HIV
- provide antibiotic prophylaxis for patients with abnormally low CD4 lymphocyte counts.

Naturopathic medical management revolves around nine treatment principles that should guide the physician in assisting patients in optimizing their health, slowing disease progression, improving quality of life, and possibly improving immune function.

Focus of chapter

This chapter is written for the naturopathic physician, although conventionally trained physicians may find the

1278

perspective, treatment principles, and some of the treatment suggestions useful. The field of HIV/AIDS medicine is rapidly changing. A dramatic change in the management of patients with HIV infection occurred in March 1996 when combination anti-retroviral pharmaceutical therapy that included protease inhibitors was introduced. Deaths due to AIDS have decreased dramatically in the last two years with the introduction of what is, for some patients, highly active anti-retroviral drug therapy. While conventional medical research has produced a breakthrough in drug therapy that lowers HIV replication as measured by reduction in HIV RNA viral load levels, little progress has been made in developing therapies that restore immune function to pre-HIV infection levels. Naturopathic medicine and naturopathic medical research may have an impact on this as yet unsolved problem in HIV disease and AIDS.

While the International AIDS Conference was dominated in 1996 by the exciting news that combination therapy with protease inhibitors was producing significant clinical benefits, interest in alternative medicine was high. Concerns were expressed about the inaccessibility to the expensive protease inhibitors in combination with other anti-retroviral drugs by more than 90% of the world's HIV+ people. Considerable interest and political action was focused on looking carefully at less expensive, more accessible alternative treatments such as herbal medicines. This view was expressed from both the audience and the speakers at a special conference satellite meeting on alternative therapies for HIV/AIDS where Bastyr University presented information about our nationwide outcomes study of alternative medicine in HIV+ patients.

Health care worker risk of HIV infection

Some health care providers new to the field of HIV/AIDS health care have concerns about their safety. For those naturopathic physicians who have yet to treat HIV-infected patients, it is important to know that the risk of HIV infection from accidental needle sticks in the routine care of your HIV+ patients is minimal. Prospective studies indicate that the estimated risk for HIV infection after a percutaneous exposure to HIV-infected blood is approximately 0.3%.¹⁴ This is substantially less than the incidence of hepatitis C virus (HCV) seroconversion in health care workers reporting an occupational exposure. From January 1992 through December 1993, 331 (51%) hollow-bore needlesticks, 105 (16.5%) suture needle or sharp object injuries, 85 (13%) mucous membrane

contaminations, and 125 (19.5%) skin contaminations were reported. Four HCV seroconversions were observed after hollow-bore needlesticks (1.2%; 95% CI, 0.3–3.0%); no seroconversions occurred after other routes of exposure.^[2]

NATUROPATHIC TREATMENT PRINCIPLES

1. Reduce oxidative stress using antioxidants.
2. Optimize nutritional status by improving gastrointestinal nutrient absorption and mucosal immunity, eliminating food allergens; optimize gastrointestinal ecology health, removing GI parasites and providing optimal therapeutic and dietary nutrition.
3. Eliminate cofactors (sexually transmitted disease and their residual, possibly miasmatic effects, yeast, and viral cofactors).
4. Botanical and hydrotherapeutic antiviral therapy.
5. Immunomodulation through botanical medicine and exercise.
6. Increase oxidation of tissues through exercise.
7. Opportunistic infection prophylaxis.
8. Recommend or provide psychoneuroimmunological support.
9. Provide support for patients receiving pharmaceutical drugs (prophylactic antibiotics and anti-retroviral drugs).

DIAGNOSIS AND WORK-UP

History

In addition to the standard medical history, it is important to obtain information about the factors listed in [Table 158.1](#) .

TABLE 158-1 -- Additional historic information required

| |
|---|
| • History of sexually transmitted diseases in chronological order, e.g. syphilis, gonorrhea, hepatitis B, human papilloma virus |
| • History of mononucleosis |
| • History of antibiotic courses for childhood and adult infections including STDs |
| • Vaccination history and adverse reactions to vaccines |
| • History of cofactor viruses in chronological order (EBV; herpes I, II, 6 and 8; hepatitis A, B, C or E; HPV; CMV) |
| • History of vaginal and GI yeast infections |
| • History of genital or anal warts and abnormal pap smears |
| • Detailed 24 hour diet history (“Choose a typical day and tell me exactly what you ate and drank.”) |
| • Exercise pattern |
| • History of psychoemotional trauma and issues (abuse history, anxiety, depression) |

- Nature of the patient's spiritual life, if any, and the felt purpose of the patient's life
-

TABLE 158-2 -- Essential laboratory assessments

-
- CBC with platelet count and ESR
-
- Full fasting chemistry and lipid panel (triglycerides, HDL, LDL)
-
- T/B/NK cell subsets (immune panel that includes CD3, CD4, CD8, CD19 and CD56 subsets)
-
- HIV RNA viral load
-
- DHEA (serum)
-
- Urinalysis with microscopic analysis (especially important in patients who are taking certain protease inhibitors)
-
- Serum *Candida* antibodies (IgA, IgG, IgM) and *Candida* antigen when available
-
- For women, a recent pap read by a thorough cytopathologist, i.e. in pathologist should look for and report koilocytotic changes as well addition to the standard classification of cervical cells, the as assessment of bacterial dysbiosis

Laboratory assessment

[Table 158.2](#) lists the tests that are essential for a full naturopathic evaluation of each HIV+ patient.

In addition, the tests listed in [Table 158.3](#) are recommended if the history indicates problems in the associated area.

THERAPEUTIC CONSIDERATIONS

For each of the naturopathic treatment principles, therapeutic suggestions are described below to attain each goal, including the scientific rationale for each treatment recommendation. This is not a protocol list, but suggestions only. Clinical management of HIV/AIDS is a rapidly changing field, and new ideas emerge and old ideas disappear rather quickly. One must individualize treatment. While we have attempted to avoid naming specific products or companies, occasionally this is unavoidable since the product is unique and available only by trade name through a particular manufacturer. Names of dependable natural products companies and their phone numbers are found on the last page.

Core protocol

While individualized treatment is essential to naturopathic management, patients are typically started on a core protocol that includes the following:

TABLE 158-3 -- Additional, history-specific laboratory assessments

-
- Complete digestive stool analysis
-
- Serum and antibody titers of cofactor viruses present in the history
-
- Serum food allergy panels that evaluate the IgE and IgG reactivity against panels of common foods. This is especially helpful in evaluating chronic sinusitis
-
- Thyroid panel
-
- Ferritin if anemia is present
-
- Serum vitamin B₁₂ and folate
-
- Toxoplasmosis IgG
-
- Mycobacterium avian intracellular (MAI) blood culture if CD4 count is lower than 100 cells/ml
-
- beta-carotene: 150,000 IU/day
 - vitamin C: 2,000 mg three times/day
 - vitamin E: 400 IU twice daily
 - cod liver oil: 1 tbsp/day
 - multiple vitamin and mineral supplement: two capsules twice daily with breakfast and lunch; if HIV viral load is high, vitamin supplementation without iron is thought to be wise
 - aerobic exercise: minimum 20 minutes three times/week
 - coenzyme Q₁₀ : 30 mg three times/day between meals
 - SPV-30: one capsule three times/day if HIV viral load is detectable and/or the patient has refused anti-retroviral therapy
 - maitake mushroom extract: 10 drops twice daily
 - *Glycyrrhiza glabra* (licorice) solid extract: 0.25–0.5 tsp twice daily between meals.

The scientific rationale for each item in the core protocol is provided in sections that follow.

Treatment principle 1: antioxidant therapy to reduce oxidative stress

Oxidative stress may contribute to several aspects of HIV disease pathogenesis and progression, such as:

- viral replication
- inflammation

- decreased immune cell proliferation
- loss of immune function
- apoptosis
- weight loss
- increased drug toxicities.

Since HIV-infected people are immunosuppressed, they are susceptible to inflammatory responses induced by oxidative stress resulting from exposure to viral and opportunistic pathogens and drugs. Inflammation is associated with the formation of reactive oxygen intermediates (ROIs), cytokines such as IL-1, IL-2 and IL-6, granulocyte-macrophage colony stimulating factor (GM-CSF) and tumor necrosis factor (TNF- α or β). Evidence for oxidative damage in HIV-infected patients is provided by the finding that malondialdehyde, a by-product of lipid peroxidation, is increased in HIV infection.^[3] HIV-infected patients have been demonstrated to have increased levels of TNF- α and IL-6 in their serum.^[4] Even asymptomatic HIV+ patients show elevated sedimentation rates.^[5] The goal of antioxidant therapy is to quench free radicals or ROIs produced by inflammation.

Beta-carotene

Dosage: 150,000 IU b.i.d.

Research review:

- A significant depletion has been found in HIV+
-

1280

patients of plasma levels of all the carotenoids, including lutein, cryptoxanthin, lycopene, alpha-carotene and beta-carotene as well as vitamin C and cholesterol.^[6]

- There is a dramatic serum beta-carotene deficiency in HIV-infected children. It is even more pronounced in children with AIDS.^[7]
- Selenium and beta-carotene improve the function of the enzymatic antioxidant system in blood and glutathione status in HIV-infected patients.^[8]
- Greater than five times the RDA of B₁, greater than five times the RDA of B₂ and B₃; greater than two times the RDA of B₆; and beta-carotene are all associated with increased survival in HIV-1-infected people. Any quantity of zinc was associated with poorer survival.^[9]
- Serum vitamin A and beta-carotene are decreased in HIV-1-infected pregnant women in the first trimester who have CD4 counts lower than 200.^[10]
- Even asymptomatic patients present a severe beta-carotene deficiency. Carotene deficit and associated increase in free radicals are potentially harmful, suppressing HIV latency in infected macrophages, stimulating viral replication and decreasing cellular immunity.^[11]
- Beta-carotene, 180 mg/day, increased CD4 counts by 17% in 4 weeks in a randomized controlled trial in HIV+ patients.^[12]

- Supplementation decreases fever, nocturnal sweating, diarrhea, weight loss and improved mean CD4 counts.^[13]
- Low blood levels of vitamins A (18%), E (27%), riboflavin (26%), B₆ (53%), and B₁₂ (23%), together with copper (74%) and zinc (50%), were documented in HIV-1-seropositive subjects. With the exception of riboflavin, zinc, and copper, a similar prevalence of abnormalities among HIV-1-seronegative controls was not observed.^[14]
- Mean serum levels were significantly lower for vitamin A, folate, and carotene in patients with the HIV wasting syndrome than in non-wasting patients with comparable CD4 cell counts.^[226]

Note. Recent data indicate that synthetic beta-carotenoids may increase risk of lung cancer in smokers.^[15] There is now controversy about the safety of beta-carotene. Given these uncertainties, we use only natural carotenoids and inform our patients, particularly those who smoke, of the possible risks of taking beta-carotene. For patients who have doubt about the safety of taking supplemental beta-carotene, we recommend two glasses of freshly juiced carrot juice instead.

Co-enzyme Q₁₀

Dosage: 30–100 mg t.i.d.

Research review:

- AIDS patients had a blood deficiency of CoQ₁₀ compared with non-HIV+ controls. This deficiency was greater than that seen in ARC patients.^[16]
- CoQ₁₀ (100 mg/day) increased CD4+/CD8+ ratios in non-HIV subjects.^[17]

Vitamin C

Dosage: 2,000 mg t.i.d. between meals.

Research review:

- Despite the fact that vitamin C is commonly taken in high doses by HIV+ individuals, no controlled studies have been done to date in humans.
- Some in vitro work suggests that ascorbate can suppress HIV replication in both chronically and acutely infected T-lymphocytes.^[18]
- Ascorbate saturation by lymphocytes has been linked to enhanced immunocompetence.^[19]

Notes. Some of the antiviral protease inhibitors such as Indinavir can induce nephrolithiasis. Although there have been no specific studies addressing the question of whether vitamin C adds to the risk of kidney stones in patients taking Indinavir, there is

some concern about adding excessive levels of ascorbic acid to the regimen of a patient taking this particular protease inhibitor.

Health care providers differ in recommendation regarding vitamin C dosing for HIV+ patients. Some recommend a slow increase in oral dosing until bowel tolerance (6–20 g/day) is attained. We have noticed that those patients with GI dysbiosis will experience diarrhea from even the lowest dose recommended. This may indicate a need to perform a complete digestive stool test to assess gastrointestinal candidiasis and/or inflammation.

More information about vitamin C in its role as an antiviral may be found in the section on “Naturopathic antiviral therapy” ([p. 1286](#)).

Vitamin E

Dosage: 400 IU/day.

Research review:

- Vitamin A, E, and B₁₂ deficiency accelerated the development of AIDS.^[20]
 - Supplementation at high levels can modulate cytokine production by thymocytes.^[21]
 - Vitamin E restores retrovirus-suppressed splenocyte proliferation and natural killer cell cytotoxicity.^[22]
 - Vitamin E partially reverses the myelosuppressive action of AZT in HIV-infected patients.^[23]
 - The hazard of AIDS decreased as consumption increased for all 11 micronutrients; this relationship was statistically significant for iron, vitamin E, and riboflavin, in a sample of 296 HIV-seropositive men.^[24]
 - Vitamin E has demonstrated immune-enhancing, and antioxidant properties.^[25]
-

1281

- Reduced blood levels of vitamin E and polyunsaturated fatty acids of phospholipids (PUFA-PL) favor the onset and the development of AIDS.^[26]

Selenium

Dosage: 200–600 mcg/day.

Research review:

- Selenium deficiency is common in HIV infection and AIDS.^[27]
- Selenium and beta-carotene improve the function of the enzymatic antioxidant

system in blood and glutathione status in HIV-infected patients.^[8]

- In vitro dose-dependent inhibition by selenium of NF-kappa β controlled gene expression in HIV-1 replication.^[28]
- Latency period in HIV infection may be attributed to the period of time it takes to deplete the body of selenium storage.^[31]
- Stimulation of glutathione peroxidase activity with selenium decreases HIV-1 activation after oxidative stress.^[30]
- An adequate supply of selenium and of antioxidant vitamins has been proposed as a measure to reduce the probability of the placental transmission of HIV in pregnancy.^[32]
- Measurements of plasma antioxidants and fatty acid (FA) composition of erythrocyte membranes and plasma antioxidants in HIV+ patients show that selenium is lower in patients with less than 400 CD4 cells/mm³, vitamin A is lower in the HIV+ regardless of the CD4 cell count, and that saturated FAs are higher and polyunsaturated FAs lower than in controls.^[32]

N-acetylcysteine

Dosage: 1,000 mg b.i.d.

Research review:

- NAC (10 mmol/L) caused less than twofold inhibition of HIV, and conferred a synergistic effect (approximately eightfold inhibition) when tested simultaneously with vitamin C (0.426 mmol/L).^[33]
- NAC reduced HIV-1 replication in stimulated T-cells. However, NAC and glutathione-enhanced acute HIV-1 replication in monocyte-derived macrophages in vitro.^[34]
- Oral administration reversed loss in CD4 count associated with change from optimal intracellular levels of glutathione and cysteine in HIV+ individuals.^[35]
- A series of clinical studies and laboratory investigations suggests that the AIDS syndrome may be the consequence of a virus-induced cysteine deficiency.^[36]
- The relationship between HIV-induced cysteine deficiency and T-cell dysfunction provides a rationale for treatment with *N*-acetylcysteine.^[37]
- Treatment with *N*-acetylcysteine improved cysteine and glutathione deficiency in AIDS patients.^[36] Note that orally administered glutathione is hydrolyzed in the stomach, and is thus not absorbable. Supplementing NAC and glutamine increases serum glutathione levels.
- NAC is a potent suppressor of human immunodeficiency virus transcription in persistently infected cells.^[38]
- NAC fully replenishes depleted GSH in in vitro studies.^[39]
- NAC appears to modulate HIV-1 replication in both chronically and acutely infected lymphocytes that produce high virus levels independently from cytokine activation. In both cases, NAC doses of 0.12 and 0.25 mM decreased, whereas doses of 0.5–2 mM increased the infectious HIV-1 yield.^[40]
- Oral *N*-acetylcysteine increases serum glutathione.^[41]

Lipoic acid (lipoate, alpha-lipoic acid, dihydrolipoic acid, thioctic acid)

Research review:

- Alpha-lipoic acid is unique in its ability to act as an antioxidant in fat- and water-soluble tissues in both its reduced and oxidized forms.^[42]
- Alpha-lipoic acid increases intracellular glutathione in human T-lymphocyte cells.^[43]
- Alpha-lipoic acid is a biological antioxidant; it prevents HIV activation, and reacts with reactive oxygen species.^[44]
- Lipoic acid prevents gene expression of HIV virus.^[45]
- Of all the compounds tested, thiamine disulfide, alpha-lipoic acid, and *N*-acetylcysteine significantly depressed HIV-1 Tat activity.^[46]
- The inhibitory action of alpha-lipoic acid was found to be very potent as only 4 mM was needed for a complete inhibition, whereas 20 mM was required for *N*-acetylcysteine. These results indicate that alpha-lipoic acid may be effective in AIDS therapeutics.^[47]
- Alpha-lipoic acid inhibits HIV replication.^[48]
- Lipoate increased plasma ascorbate (nine of 10 patients), total glutathione (seven of seven patients), total plasma thiol groups (eight of nine patients), T-helper lymphocytes and T-helper/suppressor cell ratio (six of 10 patients).^[49]
- Increases antioxidant recycling and reduces activation of HIV virus by reducing the NF-kappa β transcription factor.^[50]

Notes. Alpha-lipoic acid was originally classified as a vitamin, but later was found to be synthesized by animals and humans.

1282

Treatment principle 2: improve nutritional status (GI nutrient absorption and mucosal immunity)

Lactobacillus acidophilus

Dosage: 2 capsules b.i.d. away from food (Thorne HMF).

Research review:

- Effect of *Bifidobacterium bifidum* and *Lactobacillus acidophilus* on gut mucosa and peripheral blood B-lymphocytes.^[54]
- May influence survival of HIV in female genital tract.^[52]
- Persists in stomach longer than other bacteria and may be useful in managing conditions associated with altered GI flora.^[53]

- Review of literature on *Lactobacillus acidophilus*.^[54]

Nystatin

Prescribe if *Candida* antigen is positive and/or there are abnormally high levels of *Candida* antibodies, even if the patient is asymptomatic. *Candida* is both a result and the cause of HIV-related health problems. Nystatin appears safe since it is not absorbed into the circulation from the gut).

Dosage: 500,000 units t.i.d. × 30 days.

Research review:

- Nystatin is efficacious in oral and gut antifungal prophylaxis.^[55]
- It is effective in reducing yeast contamination in neonates.^[56]
- It is effective in eradicating systemic candidiasis.^[57]

Capryllic acid

Dosage: swish and swallow for thrush.

Research review:

- Capryllic acid is effective in the treatment of candidiasis.^[58]
- It is readily absorbed in the intestines.^[59]

Phytostan

Dosage: 2 tablets t.i.d. (NF formula – capryllic acid, grapefruit seed extract, beta-carotene, rosemary, thymus vulgaris, glutamic acid).

Research review:

- Grapefruit seed extract significantly inhibits commonly pathogenic bacteria while reserving the normal flora.^[60]
- Constituents of rosemary found to be effective HIV protease inhibitors.^[61]

Butyric acid

Dosage: 2 caps t.i.d. with meals.

Research review:

- Butyric acid is a source of energy for colonic epithelial cells which are critical in mucosal immunity.^[62]
- It acts therapeutically in the treatment of colitis.^[63]
- It is a luminal trophic factor for the cecal epithelium.^[64]

Digestive enzymes

Dosage: 1–2 t.i.d. with major meals. (See [Ch. 5](#) , Pancreatic enzymes, for a full discussion of dosages and forms.)

Research review:

- An increase in serum enzymes, commonly found in HIV, is associated with pancreatic damage.^[65]
- The pancreas is often infected or neoplastic during HIV infection.^[66]
- Pancreatitis is a common cause of morbidity in patients with AIDS.^[67]

Notes. Complete digestive stool analyses often detect poor pancreatic output in many patients with digestive complaints, including HIV+ patients. Digestive enzymes taken with meals can assist enzymatic degradation of foods necessary for absorption.

Garlic

Dosage: 2 capsules b.i.d. (600–1,000 mg b.i.d.).

Research review:

- Garlic is effective in hypermotile intestinal disorders.^[68]
- It acts as an antioxidant.^[69]
- It increases serum insulin and improves liver glycogen storage.^[70]

Glutamine

Research review:

- Glutamine deficiency is hypothesized to be a causal factor in HIV-associated wasting.^[71]
- Glutamine is useful in slowing malabsorption.^[72]
- Deficiency of L-glutamine is associated with atrophy and degeneration of the small

intestine.^[73]

Carnitine

Dosage: 2,000 mg/day in wasting and high serum triglycerides.

Research review:

- Deficiencies in carnitine can lead to critical metabolic dysfunctions.^[74]
-

1283

- Carnitine improves lymphocyte proliferation in response to mitogens.^[75]
- AIDS patients with a deficiency are at risk for alterations in fatty-acid oxidation and energy supply.^[51]

Permeability factors

Dosage: 2 caps t.i.d. away from food (Tyler – 1,500 mg L-glutamine, 750 mg *n*-acetyl-D-glycosamine, 400 mg gamma-linolenic acid, 200 mg oryzanol).

Research review:

- Localized protection of GI mucosa by oryzanol may be an effect of its potent antioxidant activity.^[76]
- Gamma-linolenic acid prevents and treats GI mucosal inflammation (see cod liver oil).
- Localized protection of GI mucosa by oryzanol may be an effect of its potent antioxidant activity (see oryzanol, and rice bran).

Saccharomyces boulardii

Dosage: 2 capsules t.i.d. away from food.

Research review:

- *Saccharomyces boulardii* significantly reduces antibiotic associated diarrhea.^{[77] [78]}
- It stimulates secretory IgA with oral administration.^[79]

Ultra Clear Sustain

Dosage: 2 scoops b.i.d. as fruit smoothie or in water, rice, or soy milk (Metagenics and HealthComm).

Research review:

- Fructo-oligosaccharides and inulin promote proliferation of *Bifidobacteria* and *Lactobacillus* in the digestive tract.^[80]
- Oligoantigenic diets that provide GI nutrition are associated with reduced GI symptoms and potentially toxic bacterial metabolites.^[81]
- Deficiencies of vitamins and minerals are well documented in HIV.^[82]

Treatment principle 2: improve nutritional status (therapeutic and dietary nutrition)

Assume food sensitivities and try therapeutic trial of elimination diet – eliminate all gluten/gliadin grains, all milk and dairy, and food allergies/sensitivities for at least 2 weeks to observe the change in symptoms.

Whole foods

Reduce simple sugars; ensure essential fatty acids; emphasize protein; and clean fresh fruits and vegetables; increase variety; eliminate caffeine and alcohol.

Protein powder smoothie

Dosage: 2 scoops of protein powder with 1 cup of nuts/nut butter (not peanuts), 1 cup yogurt, 1 cup fresh fruit/berries, 1 tbsp honey, 1 tbsp flaxseed oil; thin with rice milk/juice to make 24 fluid ounces; drink 8 oz t.i.d.

Flaxseed oil or cod liver oil

Dosage: 1 tbsp 1–2 times/day.

Research review:

- Gamma linolenate selectively kills HIV-infected cells.^[83]
- It increases superoxide production of stimulated macrophages in mice.^[84]
- It increases plasma essential fatty acids and decreases urinary excretion of prostaglandin E₂.^[85]
- Formula fortified with alpha-linolenic acid (1.8 g/day), arginine (7.8 g/day), and RNA (0.75 g/day) resulted in a weight gain (+2.9 kg in 4 months vs. -0.5 kg in 4 months with the control formula, $P < 0.05$), whereas no changes in CD4+ lymphocyte counts

were observed.^[86]

- Gamma-linolenic acid prevents and treats GI mucosal inflammation.^[87]
- Fatty acid (FA) composition of erythrocyte membranes in HIV+ patients showed that saturated FAs are higher and polyunsaturated FAs lower than in controls.^[88]
- Reduced blood levels of polyunsaturated fatty acids of phospholipids (PUFA-PL) favor the onset and the development of AIDS.^[26]
- A deficiency in dietary gamma-linolenic and/or eicosapentaenoic acids may determine individual susceptibility to AIDS.^[89]

Oat bran

Dosage: add 1–2 tbsp to other foods.

Research review:

- Oat bran is rich in glutamine, water-soluble, and a fermentable-fiber beta-glucans; it provides gastrointestinal surface protection and mucosa reconditioning.^[90]

Multiple vitamin and mineral with or without iron

Dosage: 2 caps b.i.d. (pediatric liquids useful in wasting and malabsorption – 1 tbsp b.i.d.).

Research review:

- Dietary vitamin and mineral analysis revealed that 88% of AIDS patients, 88% of HIV-seropositive patients, and 89% of ARC patients were ingesting less than 50% RDA for at least one nutrient. The mean number of deficiencies per patient was 1.8.^[91]
 - Low blood levels of vitamins A (18%), E (27%), riboflavin (26%), B₆ (53%), and B₁₂ (23%), together with copper (74%) and zinc (50%), were documented in HIV-1-seropositive
-

subjects. With the exception of riboflavin, zinc, and copper, a similar prevalence of abnormalities among HIV-1-seronegative controls was not observed.^[14]

- Of a sample of 30 HIV-1(+) subjects in the study, percentages with below normal plasma concentrations include: zinc (30%), calcium (27%), magnesium (30%), carotenes (31%), total choline (50%), and ascorbate (27%). Percentages with above normal values include: folate (37%) and carnitine (37%). Some subjects with above normal values for plasma vitamins reported self-supplementation, usually with large doses.^[92]
- Intake of greater than five times the RDA of B₁; greater than five times the RDA of

B₂ and B₃ ; greater than two times the RDA of B₆ , and beta-carotene are all associated with increased survival in HIV-1-infected people. Any quantity of zinc was associated with poorer survival.^[9]

- Deficiencies of vitamin B₁₂ , folate and thiamin may contribute to neurological impairment in HIV.^[93]
- Daily multivitamin use is associated with a reduced hazard of AIDS.^[24]

Copper (may be excessively low or elevated)

Research review:

- Copper (40%) and long-chain polyunsaturated fatty acids (21%) were higher in the non-AIDS group than the micronutrient levels in HIV-1-infected children.^[94]
- Low blood levels of vitamins A (18%), E (27%), riboflavin (26%), B₆ (53%), and B₁₂ (23%), together with copper (74%) and zinc (50%), were documented in HIV-1-seropositive subjects. With the exception of riboflavin, zinc, and copper, a similar prevalence of abnormalities among HIV-1-seronegative controls was not observed.^[14]

Folate

Dosage: 400 mcg/day if there is macrocytic anemia or after folate antagonist drugs have been used.

Research review:

- There is an increased incidence of bone marrow toxicity in patients on AZT when folic acid levels are low.^[95]
- Absorption of folate is significantly impaired in HIV.^[96]

Vitamin B₁ (thiamin)

Dosage: up to 50 mg b.i.d.

Research review:

- Greater than five times the RDA of B₁ ; greater than five times the RDA of B₂ and B₃ ; and greater than two times the RDA of B₆ , and beta-carotene are all associated with increased survival in HIV-1-infected people. Any quantity of zinc was associated with poorer survival.^[9]
- Highest levels of total intake (from food and supplements) of vitamins C and B₁ and niacin were associated with a significantly decreased progression rate to AIDS.^[97]

- Thiamin disulfide is a potent inhibitor of HIV virus (type-1) production.^[46]

Vitamin B₁₂ (hydroxycobalamin)

Dosage: 1,000 mcg i.m. one to two times/week in macro-cytic anemia, peripheral neuropathy, and depression.

Research review:

- Low serum vitamin B₁₂ concentrations are associated with faster HIV-1 disease progression.^[98]
- Vitamin A, E, and B₁₂ deficiency accelerated the development of AIDS.^[20]
- Development of deficiency of vitamin A or vitamin B₁₂ was associated with a decline in CD4 cell count, while normalization of vitamin A, vitamin B₁₂, and zinc was associated with higher CD4 cell counts in 108 HIV-1(+) men.^[99]
- Decreased cobalamin levels were frequently found in HIV disease.^[100]
- Cobalamins inhibit HIV-1 infection of normal blood monocytes and lymphocytes.^[101]
- Subnormal serum B₁₂ levels are common in HIV disease and occur at an early stage. B₁₂ levels fall in most patients with time and may help to predict those patients whose disease will progress most rapidly.^[102]
- Vitamin B₁₂ levels were low in 39% of 36 HIV-infected patients with chronic diarrhea.^[103]
- Low blood levels of vitamins A (18%), E (27%), riboflavin (26%), B₆ (53%), and B₁₂ (23%), together with copper (74%) and zinc (50%), were documented in HIV-1-seropositive subjects. With the exception of riboflavin, zinc, and copper, a similar prevalence of abnormalities among HIV-1-seronegative controls was not observed.^[14]

High dilutional IGF-1 (200C)

Orally administered high dilutional IGF-1 was hypothesized to be the high dilutional growth factor responsible for weight gain observed in those HIV+ patients receiving IGF-1 200C.^[225]

DHEA (see previous section)

Testosterone

Androgen deficiency combined with classical growth hormone resistance may contribute to the critical loss of lean body and muscle mass in hypogonadal men with the AIDS wasting syndrome.^[226]

Intravenous nutrition

If wasting, consider intravenous nutrition (e.g. vitamin C i.v., cachexia formula, Myers cocktail, and/or total parenteral nutrition).

1285

Research review:

- See review article that posits on the possibility that the use of vitamin C infusion treatment may be beneficial in the clinical management of AIDS.^[104]
- Improvement of motor disability in patients with HTLV-I-associated myelopathy was 82% in high-dose vitamin C.^[105]

Cachexia formula

Dosage: administer over 2–4 hours.

- Total volume – 558.6 cc
- Sterile water – 350 cc
- ACE – 6 cc
- Boron – 2 mg
- Calcium gluconate – 4 g
- Chromium – 200 mcg
- Copper – 1 mg
- Freamine or Travasol – 100 cc
- Lithium – 5 mg
- Manganese – 1 mg
- Magnesium sulfate – 2 g
- Molybdenum – 200 mcg
- Potassium – 20 meq
- Rubidium – 100 mcg
- Selenium – 200 mcg
- Strontium – 1 mg
- Vanadium – 5 mcg
- Vitamin A – 10,000 IU
- Vitamin B₆ – 300 mcg
- Vitamin B₁₂ – 3000 mcg
- Vitamin B-complex – 3 cc
- Zinc – 0.5 mg.

Myers cocktail

Dosage. Draw up cocktail into one syringe, add 10–20 ml sterile water to reduce hypertonicity, and inject slowly over 5–15 min through a 25G butterfly needle.

- Magnesium chloride hexahydrate (20%) – 2–5 cc
- Calcium gluconate (10%) – 2–4 cc
- Hydroxocobalamin (1,000 mcg/cc) – 1 cc
- Pyridoxine hydrochloride (100 mg/cc) – 1 cc
- Dexpanthenol (250 mg/cc) – 1 cc
- B-complex 100 – 1 cc
- Vitamin C (222 mg/cc) – 1–20 cc.

Treatment principle 3: clear drug, STD, yeast, and viral cofactors

Acupuncture detoxification auricular program

Research review:

- Acupuncture heroin detoxification is effective in a single-blind clinical trial.^[106]
- Traditional acupuncture increases both the concentrations of B-endorphins in mononuclear cells and T-lymphocyte proliferation.^[107]

Homeopathic

- Clear concurrent viral cofactors (HSV, HHV-6, HZ., EBV, CMV, HPV) with nosodes (Staufen Pharma)
- Homeopathic marijuana, cocaine, amphetamines, LSD, heroin, amyl nitrate, etc.
- Consider homeopathic miasmatic polychrests (sulfur, psorinum, medorrhinum, syphilinum, mercurius, HIV when available; also phosphorus, lycopodium, calcarea, baryta, etc.).

Research review:

- In 129 asymptomatic HIV+ patients treated in India with constitutional homeopathy, 12 became ELISA-seronegative after 3–16 months.^[108]
- In 34 HIV+ cases, homeopathic treatment increased CD4+ lymphocytes in 23 out of 34 cases.^[260]

Helpful tips for classical homeopathic prescribing. Several homeopaths have indicated remedies they commonly use for people with AIDS. Dr P. K. Mishra, an Indian homeopathic physician and recent WHO Research Fellow at the Bastyr University AIDS Research Center, observed HIV+ patients receiving care at the Bastyr University HIV/AIDS Integrated Care Clinic, an outpatient clinic which provides integrated naturopathic medicine, Chinese medicine, and nutrition. After 10 weeks of observation,

he arrived at the following conclusions regarding effective homeopathic prescribing. Dr Mishra recommends consideration of the following homeopathic drugs, but not excluding others which fit the individual's constitution:

- When skin symptoms predominate, consider: Sulfur, Psorinum, HSV nosode (for Herpes infection).
 - If growths such as warts or condylomata are the predominant symptoms, consider: *Thuja*, Nitric acid, Medorrhinum.
 - When GI symptoms predominate, consider: Lycopodium, including Hepar sulph, Mercurius (for liver symptoms).
 - When neurological symptoms predominate, consider: Arsenicum alba, Aurum metallicum, Bufo, Calcarea c, Cannabis i, Causticum, Kali phosphorus, Lachesis, Lycopodium, Mercurius sol., Nux vomica, Natrum muriaticum, Opium, Phosphorus, Phosphoricum ac, Silicea, Staphysagria, Stramonium, Sulfur, Syphlinum, Tarentual c, *Thuja occ*, Thyroidinum.
 - When respiratory & wasting symptoms predominate, consider: Aurum m, Arsenicum a, Tuberculinum, Iodum, Arsenicum iod., Phosphoricum ac.
 - STD related AIDS cases, consider using Medorrhinum & Mercurius sol intercurrently.
 - For harmful effects of chemotherapy, steroids, AZT, combination drugs, consider X-ray.
-

1286

Glycyrrhiza glabra (licorice root)

Broad-spectrum antiviral botanical (see “Antiviral” section).

Herpes tincture

(*Hydrastis canadensis*, 2; *Lomatium dissectum*, 2; *Passiflora incarnata*, 1; *Taraxacum officinale*, 2; *Astragalus membranous*, 1; *Gelsemium*, 15)

Dosage: tincture 30–60 gtt q 2 hours during prodrome; q.i.d. during outbreak.

Research review:

- *Passiflora incarta* has antibacterial activity.^[109]
- *Astragalus membranous* injections enhance antibody response to a T-dependent antigen (see “*Astragalus*” in Treatment principle 4 below).
- See *Lomatium dissectum* in Treatment principle 4 below.

HPV tincture

Lomatium dissectum and *Thuja occidentalis*.

Research review:

- *Lomatium* inhibits HIV replication, and is suppressive during acute HIV-1 infections.^[110]
- *Lomatium* constituents shown to have significant antiviral activity.^[111]
- *Thuja* induces CD4+ fraction of human peripheral blood T-cell subset, as well as IL-1 beta, IL-2, IL-3, IL-6, gamma-IFN, G-CSF, GM-CSF and TNF-β production.^[112]

Silymarin (in milk thistle and artichoke)

Dosage: 160 mg t.i.d.

Research review:

- Silymarin-phosphatidylcholine complex improved liver function indices in patients with chronic active hepatitis.^[113]
- Silymarin increased the SOD and antioxidant activity of blood cells of patients with liver disease.^[114]

Note. Drug addictions can be related to deficiencies in amino acids essential for optimal neurochemical function. Consider combination amino acid supplementation when a history of drug use is present.

Treatment principle 4: provide antiviral therapy

With the advent of highly effective antiretroviral combination drug therapy, it is important to inform your patients that pharmaceutical antiretroviral therapy (ART) is effective in lowering HIV viral load and, in many patients, modestly increasing CD⁺ cells. With each passing year developments in ART are generating better drug combinations with fewer side-effects. Many HIV/AIDS conventional clinicians urge HIV+ patients to initiate ART early in the course of their disease. Others recommend waiting until HIV viral load rises to moderate levels (depending on the clinician 5,000–30,000 copies/ml). It is important for the naturopathic physician to know and communicate that at this time there exists no highly effective natural antiviral therapy for HIV/AIDS. What follows is a summary of botanical and nutritional therapies that may contribute to slowing viral replication. However, none of these natural therapies have been thoroughly evaluated in clinical trial.

Our approach has been to explain to patients the benefits and risks of ART, and refer to MDs experienced in HIV care for consultation regarding initiation of ART. For patients who wish to try natural antiviral approaches, we recommend getting a baseline HIV RNA

viral load, then prescribing concurrent multiple naturopathic antiviral medicines at adequate doses. A follow up HIV RNA viral load should be repeated at 1–3 months after initiation of natural antiviral therapy. If viral load has not dropped by a factor of 5 (or 0.3 log units) you may conclude that the natural antiviral combination has not produced the intended benefit. You should then reintroduce the decision to initiate ART.

Glycyrrhiza glabra (licorice root)

Dosage: 2 caps t.i.d. or 0.25–0.5 tsp solid extract as tea q.d. or b.i.d. (monitor blood pressure) – also helpful for adrenal fatigue as indicated by low DHEA (< 250 ng/dl).

Research review:

- Glycyrrhizin (GL) has an inhibitory effect on several viruses including HIV-1 and varicella zoster virus (VZV). In addition, some therapeutic and prophylactic effects on chronic active viral hepatitis have been claimed for GL. In one study, 0.2% GL dissolved in saline (2 mg/ml), supplemented with 2% glycine and 0.1% cysteine (Stronger Neo-Minophagen C, SNMC), was administered intravenously in a dose of 50 ml/day for a period of more than 1 week to three infants with cytomegalovirus (CMV) infection who exhibited abnormal liver function or hepatomegaly. Liver function had become normal at the end of the course of SNMC. These findings suggest that GL might have therapeutic effects on liver dysfunction associated with CMV infections.^[115]
- Inhibition of HIV-1 replication in vivo has been demonstrated.^[116]
- GL inhibits giant cell formation of HIV-infected cells.^[117]
- *Glycyrrhiza* showed significant effect over placebo in a double-blind study.^[118]

1287

Hypericin perforatum (St John's wort)

Dosage: 3 capsules (300 mg each) q.i.d. M&T, or 2–10 mg/day “HY” (Pacific Biologics).

Research review:

- Incubation with HIV rendered the virus non-infectious.^[119]
- Inhibits binding and entry of HIV into host cells.^[120]
- St John's wort has the ability to cross the blood–brain barrier, which is important considering the fact that HIV virus often attacks the brain.^[121]

Note. It is difficult to achieve sufficiently high blood levels of Hypericin via oral administration to produce antiviral activity. It is highly recommended, however, as an antidepressant for HIV+ patients. Be aware that Hypericum can produce

photosensitivity. Patients will tan and burn more rapidly. Recommend sun block.

Buxus sempervirens (evergreen boxwood)

Dosage: 100 mg t.i.d. (SPV-30).

Research review:

- An extract of evergreen boxwood (SPV-30) is being evaluated in an open-label trial conducted by Mestman & Stokes (SPV-30 Progress Report #2, unpublished data, October 1995). As of October 1995, 500 HIV+ people had enrolled. Results thus far indicate stability of CD4, a slight rise in CD8 and a drop in HIV RNA (69% decrease) after 2 months.
- A 1 year open-label evaluation of SPV-30 in 173 HIV+ patients found that 63% of participants experienced a 0.3 log unit decrease in viral load after 6 months. Average CD4 counts appeared to stabilize and CD8 counts rose slightly over the 6 months.^[122]

Curcuma longa (curcumin)

Research review:

- There is significant inhibition of HIV-1 by integrase inhibition.^[123] ^[124]
- Curcumin results in inhibition of directed transcription.^[125]
- Curcumin results in inhibition of HIV-2 protease.^[126]

Whole-body hyperthermia

Dosage: core temperature increased to 102°F for 20 min, two times/week for 3 weeks.

Research review:

- Elevating the temperature to 42°C sensitized HIV-infected cells in vitro to subsequent oxidative stress by H₂O₂, demonstrating the importance of hyperthermia, often associated with opportunistic infections, in the development of immunodeficiency. In this case, selenium induced partial protection against the sensitizing effect of hyperthermia.^[31]
- Whole-body hyperthermia coinciding with beta-carotene supplementation in patients with AIDS decreased HIV viral load and improved subjective life quality in small study.^[127]
- Fever has antiviral effects.^[128]
- Systemic hyperthermia is useful in controlling HIV and related malignancy.^[129]
- Hyperthermia caused marked regression in Kaposi's sarcoma and a 5% rise in T4

count was seen in a single HIV+ patient after hyperthermia treatments.^[130]

Momordica charantia (bitter melon)

Research review:

- Antiviral plant protein inactivates viral DNA.^[131]
- Proteins have been shown to have abortifacient, antitumor, ribosome inactivating and immunomodulatory activities.^[132]
- Recombinant protein of *Momordica charantia* found to have anti-HIV activity.^[133]

N-acetylcysteine (NAC)

Research review:

- NAC (10 mmol/L) caused a nearly twofold inhibition of HIV, and conferred a synergistic effect (approximately eightfold inhibition) when tested simultaneously with vitamin C (0.426 mmol/L).^[33]
- It reduces HIV-1 replication in stimulated T-cells.^[34]
- It causes a relative increase in CD4 cells in humans, in spite of decreasing GSH.^[35]
- A series of clinical studies and laboratory investigations suggests that AIDS may be the consequence of a virus-induced cysteine deficiency.^{[36] [37]}
- NAC is a potent suppressor of HIV transcription in persistently infected cells.^[38]

Aloe vera

Dosage: 1 oz b.i.d. or Acemannan capsules (Carrington Labs).

Research review:

- Extracts of aloe have been shown to inactivate herpes simplex virus type I.^[134]
- Acemannan is an antiviral agent with immune enhancement capabilities.^[135]
- There is concentration-dependent inhibition of HIV virus replication and pathogenesis by Acemannan in vitro.^[134]

Allium sativa (garlic)

Research review:

- Alliin and thiosulfinates present in *Allium sativa*
-

show antiviral activity in vitro against several viruses, including HSV I and II.^[136]

- Garlic extract inhibits cytomegalovirus replication in vitro.^[137]

Quercetin (derived from yellow onion)

Dosage: 2,000 mg/day.

Research review:

- Quercetin exhibits antiviral activity against herpes simplex I and II.^[138]
- It is a strong inhibitor of HIV-reverse transcriptase.^[139]
- It is a potent HIV-integrase inhibitor.^[140]
- It is a potent inhibitor of DNA polymerase B and RNA polymerase.^[141]

Vitamin A

Dosage: 25,000–100,000 IU/day.

Research review:

- Detection of vaginal HIV-1 DNA in pregnant women was associated with severe vitamin A deficiency.^[142]
- Reduced levels of vitamin A in women experiencing hypertension of pregnancy may place them at increased risk for mother–child transmission of the HIV-1 virus.^[143]
- Serum vitamin A and beta-carotene are decreased in HIV-1-infected pregnant women in the first trimester with CD4 counts lower than 200.^[140]
- Vitamin A, E, and B₁₂ deficiency accelerated the development of AIDS.^[24]
- Development of deficiency of vitamin A or vitamin B₁₂ was associated with a decline in CD4 cell count, while normalization of vitamin A, vitamin B₁₂ and zinc was associated with higher CD4 cell counts in 108 HIV-1(+) men.^[144]
- Vitamin A supplementation for children of HIV-infected women appeared to be beneficial, reducing morbidity. The benefit was observed particularly in children experiencing diarrhea.^[145]
- Vitamin A deficiency is predictor of mortality in HIV-infected injection drug users.^[146]
- Regardless of intake, patients with AIDS may represent a population at considerable risk of vitamin A deficiency, as 27% of those with “adequate intake” had serum retinol levels below the normal range.^[147]
- Vitamin A deficiency is associated with decreased circulating CD4 T-cells and increased mortality.^[148]
- HIV+ men require vitamin A intake far greater than the RDA to achieve normal

plasma levels.^[99]

- Severe vitamin A deficiency (< 20 mcg/dl) was associated with a 20-fold increased risk of having HIV-1 DNA in breast milk among women with < 400 CD4 cells/mm³.^[149]
- Maternal vitamin A status inversely correlates with vertical transmission of HIV.^[150]
- Vitamin A deficiency is a risk factor for disease progression during HIV-1 infection.^[148]
- Vitamin A is lower in the HIV+ regardless of the CD4 cell count.^[32]
- Low blood levels of vitamins A (18%), E (27%), riboflavin (26%), B₆ (53%), and B₁₂ (23%), together with copper (74%) and zinc (50%), were documented in HIV-1-seropositive subjects. With the exception of riboflavin, zinc, and copper, a similar prevalence of abnormalities among HIV-1-seronegative controls was not observed.^[14]

Note. Watch carefully for vitamin A toxicity symptoms, such as headaches, body aches, excessively dry skin.

Vitamin B₃ (niacin)

Dosage: up to 250 mg b.i.d.

Research review:

- Greater than five times the RDA of B₁, greater than five times the RDA of B₂ and B₃, greater than two times the RDA of B₆ and beta-carotene are all associated with increased survival in HIV-1-infected people.^[9]
- HIV induces a state of intracellular pellagra which is reversed by the administration of nicotinamide. Nicotinamide, the amide form of niacin, inhibits HIV-1 infection in cell culture.^[151]
- In vitro models of acute and chronic HIV infection are inhibited by nicotinamide, but not nicotinic acid, in a dose-dependent manner.^[152]
- Highest levels of total intake (from food and supplements) of vitamins C and B₁ and niacin were associated with a significantly decreased progression rate to AIDS.^[99]
- HIV infection may cause chronic loss of tryptophan, thus causing decreases in niacin, which in turn may cause cachexia, dementia, diarrhea, and possibly immuno-suppression of AIDS patients.^[153]

Vitamin C

Dosage: to bowel tolerance.

Research review:

- Ascorbate exerts a post-translational inhibitory effect on HIV by causing impairment

of enzymatic activity.^[154]

- Highest levels of total intake (from food and supplements) of vitamins C and B₁ and niacin were associated with a significantly decreased progression rate to AIDS.^[99]
 - Vitamin C significantly enhances NK cell activity.^[155]
 - Ascorbate diminishes HIV viral protein production in infected cells.^[18]
 - Vitamin C suppresses the extracellular level of newly induced virus in unstimulated and latently infected cell lines.^[155]
 - It supports the potent antiviral activity of ascorbate
-

1289

and is suggested to work synergistically in controlling HIV infection in combination with NAC.^[33]

- Vitamin C (2–3 g p.o. in humans) significantly enhances neutrophil chemotaxis.^[261]

Vitamin E

Dosage: 400 IU b.i.d.

Research review. Vitamin E acetate or alpha-tocopheryl succinate exhibited a concentration-dependent inhibition of NF-kappa B activation.^[156]

Substances to be further investigated

Ozone

Dosage: rectal insufflation.

Research review:

- Ozone, being a strong oxidizer, can stimulate increased production of cellular antioxidant enzymes, eventually inhibiting the oxidative stress.^[157]
- Three of four patients with AIDS or ARC, with intractable diarrhea of unknown etiology, who were treated with daily colonic insufflations of medical ozone, experienced complete resolution, and one patient had marked improvement.^[158]
- There is inactivation of HIV type 1 by ozone in vitro.^[159]
- Ozone inactivates HIV at noncytotoxic concentrations.^[160]

Olea (olive leaf)

Dosage: 1 capsule t.i.d. to q.i.d. (Allergy Research).

Research review. Olea is reported to increase NK cell function, to be anti-retroviral, and to be effective against HIV and herpes viruses.^[161]

Treatment principle 5: immunomodulation

Adrenal glandular

Dosage: 2 caps b.i.d.

Note. Use caution when employing glandular products in the age of prions and cross-species viral contamination. See also “*Eleutherococcus senticosus*” and “*Glycyrrhiza glabra*”, both of which are purported to help in “adrenal fatigue”.

Astragalus membranous

Astragalus injections enhance antibody response to a T-dependent antigen.^[162]

Co-enzyme Q₁₀

Dosage: 30–100 mg t.i.d.

Research review:

- CoQ₁₀ increases blood levels of CD4 lymphocytes when administered at 100 mg/day.^[163]
- It significantly increases levels of IgG in AIDS patients.^[163]
- It has been shown to protect against tumor growth and to enhance viral immunity in animals.^[164]

Constitutional acupuncture

Dosage: see *Treating AIDS with Chinese Medicine* (Shattuck & Ryan^[166]) for a comprehensive discussion of TCM in the treatment of HIV/AIDS.

Research review:

- Diu^[167] explores the possibility of treating AIDS by acupuncture.
- In a 12 week randomized, double-blind, placebo-controlled clinical trial, 30 adults with symptomatic HIV infection with CD4+ counts of 200–499 received a combination of 31 Chinese herbs or placebo. Outcome measures included quality of life, symptoms, weight and CD4+ count. No differences between treatment groups attained statistical significance, but there were trends toward greater improvement among herb-treated subjects on all symptom subscales except dermatologic.^[168]
- An uncontrolled outcomes study reported that a 3 month treatment course of acupuncture and Chinese herbal therapy in HIV+ patients statistically decreased

symptom severity and improved quality of life.^[169]

- A study of 31 HIV+ patients with peripheral neuropathy showed that acupuncture alleviated pain or tingling in 38% of the patients.^[170]
- One clinician, after treating 112 HIV/AIDS patients with a Chinese herbal formula called Glyke (60 mg b.i.d., p.o.) for 3–6 months, reported improvements in CD4 counts and reduction in symptoms (Wei B, personal communication).

Note. Acupuncture may help with depression, and other symptoms.

Constitutional homeopathy

Research review:

- A 34 case trial showed an increase in the CD4+ count in 23 subjects, and no change in four subjects.^[171]
- Of 129 HIV-infected patients treated constitutionally, 12 have since sero-converted to negative using the ELISA.^[108]

Constitutional hydrotherapy

Research review:

- The skin plays a significant role in immune function.^[172]
-

1290

- Alpha-2 macroglobulins and complement factor C3 were increased after hydrotherapy treatments.^[173]
- Hydrotherapy helps to maximize circulation of well-oxygenated, nutrient-rich, and toxin-low blood.^[174]

DHEA

Supplement if serum levels are low.

Dosage: 5–10 p.o. mg/day in women, and 15–50 mg/day in men.

Research review:

- An epidemiological study showed decreased levels of serum DHEA, a predictor for progression to AIDS in asymptomatic HIV-infected men.^[175]
- Both DHEA levels and CD4 counts are independent predictors of disease

progression in HIV-infected men.^[175]

- A correlational study of CD4 counts and serum cortisol and DHEA-sulfate showed a positive relationship between immune status as measured by CD4 count and DHEA, supporting an hypothesis that DHEA deficiency may worsen immune status in HIV-infected patients.^[176]
- A phase I study evaluated the effects of oral administration of DHEA in 13 HIV+ patients with baseline CD4 counts of 250–600 cells/mm³. Five patients treated with the highest of three doses (750 mg/day) had CD4+ cell increases at 8 weeks from a mean of 373/μl pre-treatment to 463/μl after 8 weeks.^[177]
- In another open-label, uncontrolled study in 12 HIV+ patients, DHEA therapy (75 mg/day) increased CD4 and CD8 cell counts in the majority of patients.^[178]
- A subsequent study evaluated escalating oral doses of DHEA (750 mg/day up to 2,250 mg/day) for 16 weeks in 31 HIV+ patients with baseline CD4 counts between 250 and 600 cells/μl. Dose proportionality was not evidenced by serum DHEA nor by DHEA-sulfate. No sustained increases in CD4 counts or decreases in serum p24 antigen or beta-2-microglobulin levels were observed. However, serum neopterin levels decreased transiently by 23–40% at 8 weeks.^[264]
- Low levels of DHEA may cause immunological deficits via deficient IL-2 production in lymphocytes. Abnormal levels of DHEA were associated with low levels of serum IL-2.^[265]
- Direct murine lymphocyte exposure to DHEA at low concentrations (10^{-10} – 10^{-7} M) enhanced secretion of IL-2 following immunological challenge.^[179]
- DHEA is a modest selective inhibitor of HIV-1 replication in human lymphocytes and macrophages. The antiviral mechanism does not appear to be mediated through reverse transcriptase inhibition since DHEA did not inhibit HIV-1 RT enzymatic activity when tested up to 100 μM. Acute infection of normal human lymphocytes was also inhibited by DHEA at 10–100 μM.^[180] In another in vitro experiment, 50% inhibition of macrophage HIV p24 expression occurred at concentrations of 3–30 μg/ml.^[180]
- DHEA is frequently prescribed to, and self-prescribed by, many HIV+ patients in the US. Caution may be appropriate given that high serum DHEA levels have also been implicated in the pathogenesis of Kaposi's sarcoma (KS) in HIV/AIDS. DHEA levels were significantly higher, as were testosterone and androstenedione in 34 HIV+ patients with KS vs. 35 HIV+ controls without KS.^[181]
- In a small open-label trial with 20 HIV+ people, DHEA as monotherapy at fairly high doses of 600 mg twice a day was shown to reduce viral load by 0.6 log unit in HIV patients with baseline CD4 counts of 50–300.^[182]

Note. The adrenal steroid hormone, dehydroepiandrosterone (DHEA), is an intermediate compound in the synthesis of testosterone and other steroid reproductive hormones. Use with caution in women who are at risk for hormone-sensitive malignancies such as breast cancer.

Echinacea sp.

Dosage: 0.5 tsp tincture q.i.d. for acute viral symptoms; not for chronic use.

Research review:

- *Echinacea* increases the number of polymorphonucleocytes and monocytes, induces C-reactive proteins, and elevates ESR.^[183]
- It stimulates macrophages in vivo.^[184]
- Prophylactic treatment results in a decreased number and severity of infections.^[185]

Eleutherococcus senticosus

Dosage: 10 gtt b.i.d. (Maxim-L from Omega).

Research review. *Eleutherococcus* increases T-helper cells, as well as cytotoxic and natural killer cells in vitro.^[186]

Note. It is helpful in cases of adrenal fatigue.

Lentinus edodes (shiitake mushroom)

Dosage: 3 caps t.i.d. (Lentinan active constituent).

Research review:

- Lentinan increases host resistance to various bacterial, viral and parasitic infections, including HIV.^[187]
- It manifests marked antitumor and antimetastatic activity, and prevents chemical and viral carcinogenesis.^[188]
- With IL-2, Lentinan stimulates CD8+ cytotoxic T-lymphocyte antitumor activity in vitro.^[189]

Corifolia frondosa (maitake mushroom)

Dosage: 3 caps t.i.d.

Research review:

- Activities of macrophage, killer cells, and cytotoxic T-cells are increased in vitro. Significant immune-stimulating activity is confirmed even with oral administration, including increased antitumor activity in vivo as well as anti-HIV activity in vitro.^[190]

N-acetylcysteine (see “Treatment principle 4”)

Thymic fractions

Dosage: 2 caps b.i.d. (use caution when using glandular products in the age of prions and cross-species viral contamination).

Research review:

- Thymic hormone (of which zinc is an essential cofactor) stimulation may be important in AIDS.^[192]
- It improves clinical symptoms and T-cell defects in the early stages of HIV infection.^[193]
- Thymostimulin increases CD4 lymphocytes.^[194]
- It regulates differentiation of T-cell precursors, normalizing the ratio between helper and suppressor subsets.^[195]

Vitamin B₆ (pyridoxine)

Dosage: up to 100 mg b.i.d.

Research review:

- Greater than five times the RDA of B₁ ; greater than five times the RDA of B₂ and B₃ ; and greater than two times the RDA of B₆ , and beta-carotene are all associated with increased survival in HIV-1-infected people. Any quantity of zinc was associated with poorer survival.^[9]
- Deficiency of pyridoxine induces atrophy of lymphoid organs, marked reduction in lymphocyte numbers, and impairs antibody responses and IL-2 production.^[196]
- For HIV+ men, immunodeficiency was associated with consumption of vitamin B₆ and zinc at the RDA level.^[99]
- Low blood levels of vitamins A (18%), E (27%), riboflavin (26%), B₆ (53%), and B₁₂ (23%), together with copper (74%) and zinc (50%), were documented in HIV-1-seropositive subjects. With the exception of riboflavin, zinc, and copper, a similar prevalence of abnormalities among HIV-1-seronegative controls was not observed.^[14]
- Impaired immune responsiveness in HIV-1-infected patients with compromised vitamin B₆ status.^[198]
- Vitamin B₆ status in HIV-1-infected subjects was significantly associated with functional parameters of immunity.^[198]

Zinc

Dosage: not generally recommended. Recommend foods high in zinc (pumpkin seeds, oysters, etc.) instead of supplements.

Research review:

- Greater than five times the RDA of B₁ ; greater than five times the RDA of B₂ and B₃ ; and greater than two times the RDA of B₆ ; and beta-carotene are all associated with increased survival in HIV-1-infected people. Any quantity of zinc was associated with poorer survival.^[9]
- Thymic hormone (of which zinc is an essential cofactor) stimulation very important in AIDS.^[192]
- Low blood levels of vitamins A (18%), E (27%), riboflavin (26%), B₆ (53%), and B₁₂ (23%), together with copper (74%) and zinc (50%), were documented in HIV-1-seropositive subjects. With the exception of riboflavin, zinc, and copper, a similar prevalence of abnormalities among HIV-1-seronegative controls was not observed.^[14]
- Serum copper levels were higher in HIV-1-seropositive progressors than the seropositive non-progressors and the seronegatives. Conversely, serum zinc levels were lower in the seropositive progressors than the seropositive non-progressors and the seronegatives. Furthermore, higher serum copper and lower serum zinc predicted progression to AIDS independently of baseline CD4+ lymphocyte level, age, and calorie-adjusted dietary intakes of both nutrients.^[199]
- Of a sample of 30 HIV-1(+) subjects, some of whom were found to have below normal plasma concentrations included: zinc, 30%; calcium, 27%; magnesium, 30%; carotenes, 31%; total choline, 50%; and ascorbate, 27%. Percentages with above normal values included: folate, 37%; and carnitine, 37%. Some subjects with above normal values for plasma vitamins reported self-supplementation, usually with large doses.^[91]

Promising substances to be further investigated

Melatonin. Regulates not only neuroendocrine functions but also has immunoenhancing and antitumor effects.^[200]

Testosterone. Supplement if levels are low.

Dosage: 5–10 mg/day for women; 50–100 mg/day for men.

Ganoderma lucidum mushrooms (reishi)

Amino acids. Deficiency of cysteine, methionine, phenylalanine, threonine, tryptophan,

tyrosine, or valine may result in reduced humoral antibody response.

Treatment principle 6: increase oxidation of tissues through exercise and breathing disciplines

Physical fitness program

Research review:

- Positive relationships between hardiness and perception of physical, emotional, and spiritual health; participation in prayer and meditation; and participation in exercise and the use of special diets.^[201]
-

1292

- Individuals undergoing aerobic training reported no increases in anxiety and depression in response to notification of a positive HIV-1 serologic status. An aerobic exercise training program may enhance certain critical components of cellular immunity as well as acting as a buffer for the detrimental mood changes that typically accompany stress.^[202]
- Long-term survivors with AIDS generally engage in physical fitness/exercise programs.^[203]
- Exercise intervention attenuates emotional distress and natural killer cell decrements following notification of positive serologic status for HIV-1.^[204]
- During the non-acute stage of AIDS, progressive resistance exercise induced physiologic adaptation that improved muscle function and increased body dimensions and mass.^[205]

Treatment principle 7: opportunistic infection: prophylaxis and treatment – viral/bacterial/protozoal/yeast

Bacterial infections

Zinc. Hypozincemia in 228 HIV+ patients was associated with an increased incidence of concomitant systemic bacterial infections, but not PCP, viral, or fungal infections.^[206]

CMV, Candida, Cryptococcus, herpes, Mycobacteria, Mycoplasma, tuberculosis

Garlic

Dosage: 4 caps/day.

Research review:

- There is antiviral activity of the extract against CMV.^[207]
- Garlic is effective against herpes virus, and cryptococcal, mycobacterial, and candidal organisms.^{[208] [209] [210] [211] [212] [213]}
- It enhances natural killer cell activity in AIDS patients.^[214]

Colloidal silver

Dosage: 1 tsp b.i.d. of 3 ppm solution.

Research review: Electrochemical Ag⁺ solutions exhibit antimicrobial effectiveness against *E. coli*, *P. aeruginosa*, *C. albicans* and *A. niger*.^[215]

SSKI (super saturated potassium iodide)

Dosage: 8 gtt/day.

Vitamin D₃

Dosage. Supplements are not recommended for most patients, unless they have TB, MAI or psoriasis (exposure of skin to sunlight produces vitamin D, and in moderation is a healthy source).

Research review:

- Vitamin D has been shown to be useful in treating/preventing tuberculosis, but excessive dosages can compromise B- and T-lymphocyte efficiency.^[216]
- AIDS patients with *Mycobacterium avium* complex infection had severely decreased serum vitamin D levels.^[217]
- The hormonal form of vitamin D, 1,25(OH)₂ D₃, is involved in the regulation of the immune system.^[218]
- HIV-related psoriasis responded to a topical vitamin D analog.^[219]

Fungal infections

Thuja occidentalis* (cedar), *Melaleuca alternifolia* (tea tree oil), *Calendula officinalis

Dosage: ointment applied locally.

Kaposi's sarcoma

Unsaturated fatty acids. Essential fatty acids formulated to increase the tissue levels of dihomo-gamma-linolenic acid (DGLA) relative to arachidonic acid (AA) cause a

regression in early Kaposi's sarcoma.^[266]

Chelidonium majus. Extract given as 10 mg i.v. every other day for 10 injections made KS lesions diminish in size, thickness, and color, and no new lesions were noted. Experimental group did significantly better compared with controls.^[220]

Vitamin A. This may be useful in treating KS.

Parasites

Pancreatin

Dosage: If CDSA is abnormal, prescribe two 1,400 mg tablets after meals.

***Artemesia absiunthium* (worm wood).** This is anecdotally reported to be useful in treating GI parasites.

Pneumocystis carinii **pneumonia**

Ginkgo biloba

Dosage: 2 caps b.i.d.–t.i.d.

Research review:

- The extract has a slightly anti-inflammatory effect.^[221]
- *Ginkgo* increases cerebral blood flow in 70% of patients evaluated.^[222]
- It shows in vitro and in vivo activity against *Pneumocystis carinii*.^[223]

Zinc. Zinc was found to be an effective treatment in 12 patients for infections due to *Pneumocystis carinii* and *Candida*, but not for cytomegalovirus and *Toxoplasma* infections.^[224]

Cryptosporidiosis

Hyperimmune bovine colostrum. Hoerr and Bostwick at Galagen, the research division of Land o' Lakes, have

developed a treatment for AIDS-related cryptosporidial diarrhea. Colostrum from cows immunized against cyptosporidium is lyophilized and given orally in 10 g doses reconstituted in water four times a day. Bastyr University and the University Health

Clinic (Standish as clinical investigator) have been two of the national clinical sites evaluating the efficacy of hyperimmune bovine colostrum (Sporidin-G™) in cryptosporidial diarrhea. In six patients treated for 20–40 days, four had resolution of diarrhea and elimination of detectable cryptosporidium oocysts in follow-up stool samples.

Treatment principle 8: psychoneuroimmunology

Cranioelectrical stimulation (CES)

Dosage: 0.1 mA, 100 Hz, 20 min b.i.d.; or Alpha Stim.

Research review:

- CES decreases anxiety and insomnia.^[228]
- It is effective in treating depression.^[229]

Individual psychotherapy, support groups

Research review:

- There is a significantly elevated physical healthrisk among gay men who conceal their homosexual identity.^[230]
- Support groups reduce depression, hostility, and somatization.^[231]
- Long-term coping skills are fostered in HIV+ support groups.^[232]
- Participation in an AIDS support group decreases levels of anxiety and hopelessness.^[233]

Hypericum (St John's wort)

In 23 randomized trials with a total of 1,757 patients on *Hypericum*, the botanical was more effective than placebo and similarly effective to standard antidepressants but with fewer adverse events.^[267]

Magnesium

Dosage: slowly increase dose up to 1,000 mg/day.

Research review:

- Fifty-nine per cent of HIV+ patients had low concentrations of magnesium compared with 9% of controls. It may be particularly relevant to HIV-related

symptoms of fatigue, lethargy, and impaired mentation.^[234]

- The absolute number of T4 cells was directly correlated with the serum magnesium concentration.^[235]

Meditation

Research review:

- Used as part of a stress management program, medication effected significant improvement by all dependent measures.^[236]
- It demonstrated positive relationships between hardiness and perception of physical, emotional, and spiritual health; participation in prayer and meditation; and participation in exercise and the use of special diets.^[201]
- Increase in corticotropin-releasing hormone immuno-reactivity follows meditation.^[237]

Spiritual practice

Research review:

- There is a positive correlation between hardiness and a patient's perception of spiritual health and participation in prayer and meditation.^[201]
- Health of terminally ill patients is based more on spirituality and ability to relate to others than on pathology.^[238]

Vitamin B₆ (pyridoxine) and tryptophan

Research review. Psychological distress declined with normalization of vitamin B₆ status from inadequate to adequate ($P < 0.02$). A decrease in psychological distress was also observed with increased tryptophan intake in subjects whose vitamin B₆ status was adequate.^[239]

Vitamin B₁ (thiamin)

Research review:

- Wernicke's encephalopathy (WE) is a neuropsychiatric disorder caused by thiamin deficiency and may be found in undernourished AIDS patients. The triad of confusion, ataxia and ophthalmoplegia may be present. However, it should be recognized that these three symptoms are not always present at the same time.^[240]
- Thiamin deficiency was found in 9/39 (23%) patients with AIDS or ARC, with no history of alcohol abuse.^[241]
- Thiamin deficiency was identified as the cause of Wernicke's encephalopathy in

two non-alcoholic patients with AIDS.^[242]

Vitamin B₁₂

Dosage: oral dosing or 1,000 mcg i.m./week for a course of 6 weeks.

Research review:

- Normalization of plasma cobalamin inadequacy in HIV-1 disease may provide significant improvement in memory.^[243]
 - There was reversal of apparent AIDS dementia complex in one patient following treatment with vitamin B₁₂.^[244]
-

1294

- Concurrent vitamin B₁₂ deficiency may be a cofactor in subtle cognitive changes observed in the asymptomatic stages of HIV-1 infection.^[245]
- Most B₁₂-deficient HIV-infected patients with neurological dysfunction had a therapeutic response with B₁₂ supplementation.^[246]

Yoga, qi gong

Research review:

- Yoga produces increased perceptions of mental and physical energy and feelings of alertness and enthusiasm.^[247]
- Yoga participants report decreased tension, fatigue, confusion, depression, and anger as measured by mood and personality inventories.^[248]
- Storing of qi gong energy in various materials and drugs (qi gongnization): its clinical application for the treatment of pain, circulatory disturbance, bacterial or viral infections, heavy metal deposits, and related intractable medical problems is by selectively enhancing circulation and drug uptake.^[249]

Promising substances to be further investigated

Methyl donors [N-dimethylglycine (betaine), methionine, and S-adenosylmethionine (SAME)] (see also "Glutathione" above)

Research review:

- Deficiencies of folate and vitamin B₁₂ have been found to reduce CNS SAME concentrations. Deficiency of either folate or vitamin B₁₂ may cause similar

neurological and psychiatric disturbances, including depression, dementia, myelopathy and peripheral neuropathy. S-AdoMet has a variety of pharmacological effects in the CNS, especially on monoamine neurotransmitter metabolism and receptor systems. S-AdoMet has antidepressant properties, and preliminary studies indicate that it may improve cognitive function in patients with dementia.^[250]

- Cerebrospinal fluid S-adenosylmethionine (S-AdoMet) and glutathione concentrations are decreased in HIV infection.^[251]
- HIV-infected patients had lower concentrations of methionine in plasma.^[252]

Note. Betaine is found in beet, and is similar to choline, but instead of CH₃ at A, it is at the B position.

Treatment principle 9: support for patients taking pharmaceutical drugs

AZT-induced myopathy and immune suppression

Carnitine

Research review:

- Tissue depletion of L-carnitine by zidovudine induces myopathies and impaired lymphocyte function.^[253]
- A marked decrease in total and free carnitine was observed in 21 (72%) AIDS subjects on zidovudine.^[254]

Vitamin B₁₂

Research review:

- Decreased cobalamin levels are found frequently in HIV disease, especially among those treated with zidovudine.
- Evidence of B₁₂ malabsorption is found among those with more advanced disease and gastrointestinal symptoms. Serum homocysteine levels were significantly higher in patients with subnormal cobalamin levels.^[100]

AZT-induced bone marrow suppression

Vitamin E. Tocopherol partially reverses the myelosuppressive action of AZT in HIV-positive patients.^[23]

Zinc

Research review:

- Zidovudine-treated subjects demonstrated alterations in hematological and

nutritional parameters.^[23]

- A large proportion of the AZT-treated participants exhibited decreased levels of zinc and copper along with a significant increase in red cell folate. The level of plasma zinc appeared to be particularly important in maintaining immune function in the AZT-treated group.^[254]

Crixivan/Indinavir

Kidney tonic tea should be given to those on Indinavir to prevent kidney stones (decoction of *Arctostaphylos uva ursi*, *Zea mays*, *Eupatorium perfoliatum*, *Equisetum arvense*, *Symphytum radix*, *Verbascum thapsus*, *Barosma betulina* in equal proportions).

ddl and isoniazid

Research review:

- In the absence of any disease-induced pathology, ddl and isoniazid can induce neuropathy. Myelin splitting and intramyelin edema were the most frequent abnormalities observed in the sciatic nerves of ddl-dosed rats, whereas whorls, extracellular debris, macrophages, and reduced myelinated axon number were seen following chronic isoniazid administration. Isoniazid also resulted in myelinopathy of the CNS.^[255]
- The use of omega-3 oils may be helpful in mitigating the inflammation associated with neuropathy (GLA500 mg b.i.d.).

Hepatoprotection

Silymarin (see “Treatment principle 3”)

Research review. Silymarin, an antioxidant flavonoid

1295

isolated from artichoke, could be a useful antitumor-promoting agent capable of ameliorating the tumor-promoting effects of a wide range of tumor promoters.^[256]

Lipoic acid. See previous section.

Hypersensitivity reaction to sulfa drugs (e.g. TMP or Bactrim or Septra)

Alka selzer gold

Dosage: take as directed on package.

Quercetin

Dosage: 2 capsules four to five times/day.

Vitamin C

Dosage: 2 g q 2 hours.

Peripheral neuropathy

Peripheral neuropathy, usually presenting with lower limb and feet tingling, burning or numbness, usually bilateral, can be a side-effect of several of the pharmaceutical anti-retroviral drugs and can also appear in the absence of causative drug treatment. Often the following treatment will help.

Vitamin B₁₂

Dosage: 1 ml (1,000 mcg/cc) two times/week for 6 weeks.

Cod liver oil

Dosage: 1 tbsp b.i.d.

Sphingomyelin

Dosage: myelin basic protein 1,000 mg t.i.d. (Sphingolin is the trade name; made by Cardiovascular Research).

Acupuncture

Dosage: one to three treatments/week for 6 weeks.

IS NATUROPATHIC MEDICAL TREATMENT EFFECTIVE?

The scientific basis for the treatments suggested in the preceding compendium of clinical recommendations is based almost exclusively on what some call “borrowed” science. Scientific evidence for the naturopathic medical approach described in the preceding pages comes from in vitro studies, animal studies, epidemiologically reported associations, uncontrolled clinical and, rarely, randomized controlled clinical trials (RCTs). To date, there has not been a single RCT that addresses the question of whether naturopathic medical care slows or halts disease progression, or improves clinical, laboratory or quality of life outcomes for HIV+ patients. Even the uncontrolled

clinical outcomes data are limited, and it is currently unclear as to whether naturopathic or other kinds of “holistic care” produce similar, poorer or superior health outcomes to standard conventional therapy. There are three published uncontrolled studies that support some of what is proposed in the treatment guidelines.^[5] ^[257] ^[268]

Holistic providers and comprehensive health care programs

Published uncontrolled studies

A comprehensive 1 year treatment program of naturopathic medicine was evaluated in an uncontrolled trial in 16 asymptomatic HIV+ men.^[5] Treatment modalities included botanical and nutritional medicine, whole-body hyperthermia, homeopathy, physical medicine and psychological counseling. Symptomatic and neuropsychological improvement were observed and morbidity and mortality rates compared favorably with results in similar patients treated with zidovudine. Absolute CD4 cell counts rose transiently at 3 months, then subsequently declined to below baseline levels by month 12. The slope of CD4 decline was lower than in recently published AZT studies looking at survival rates in similar patients. In two published AZT studies, only 18% were still alive in the 26th month follow-up period, whereas 40% of the naturopathically treated cohort were still alive 54 months later.

In Los Angeles, Joan Priestley MD treated 225 HIV+ patients at various stages of the disease with a protocol that employed both conventional pharmaceutical anti-retroviral therapy and prophylaxis and nutritional supplementation (p.o. and i.v.). She released some preliminary data from which she concludes that maintenance of a stable body weight is influenced by the use of nutrient supplementation therapy. Even once CD4 cell counts dropped below 50, 58% of the patients on the protocol survived for at least another year. She also suggested that survival rates appear to be higher among the group who had never taken AZT than among the group who had taken AZT.

Jon Kaiser MD described outcome data from his large HIV+ practice in Los Angeles in his 1993 book *Immune Power: a Comprehensive Treatment Program for HIV*. Dr Kaiser’s treatment included:

- anti-retroviral therapy
- antibiotic prophylaxis combined with botanical and nutritional supplementation
- moderate exercise
- abstinence from cigarettes, drugs and alcohol
- stress reduction techniques
- participation in an emotional support group and moderate exercise.

He has released data based on his private practice files during a surveillance period of 4.25 years (March 1987–June 1991). He reports that of 134 patients tracked (asymptomatic, symptomatic, and AIDS), 119 remained stable or improved their diagnosis during the 4.25 years with an overall survival rate of 98%. Kaiser compares the survival rates of his patients after AIDS diagnosis with data published in *JAMA* and

Disease Control (CDC) data. Kaiser's patients showed an 80% survival at 27.3 months (1987–1992), while the *JAMA* reports 50% survival at 12.5 months (1981–1987) and CDC reports 50% survival at 22 months (1985–1990). Kaiser reports on 10 HIV+ asymptomatic patients with mean CD4 counts at intake of 406 and a 96% preservation of mean CD4 count at the completion of a 30 month study period. He compares this to a CD4 cell count drop of 18% in a comparison group receiving only conventional therapy during the same period.

US National Institutes of Health Office of Alternative Medicine, Bastyr University HIV/AIDS Research Center

These three studies of clinical outcomes in HIV+-treated patients suggest that comprehensive care that is concordant with several naturopathic principles may be valuable in the clinical management of the HIV+ patient. However, more research will need to be done to provide more certainty about which therapies in the field of alternative medicine are truly useful, and those that are not – or, even worse, those that are harmful. For this reason, the Bastyr University AIDS Research Center was established in 1994 through a 3 year cooperative agreement grant with the NIH's Office of Alternative Medicine and administered through the National Institute of Allergy and Infectious Disease's office of AIDS.

We have now analyzed approximately 10% of our entire data set of 2 years of observations of HIV+ men and women who utilize a diverse range of alternative medicine and their clinical, laboratory, and quality of life outcomes.^[267] We began recruiting for this study in October 1995 and have enrolled 1,689 patients as of November 1997. A preliminary analysis has been completed on the first 500 patients enrolled in the study for whom we have information about treatments, both alternative and conventional, clinical status, and laboratory markers. Preliminary results indicate that HIV+ men and women who use complementary and alternative medicine exclusively do not fare as well over 6 months as those who utilize both conventional drug therapy and complementary and alternative medicine. Ongoing data analysis from a collaborative study with Johns Hopkins University will tell us if alternative medicine use in addition to conventional drug therapy is associated with improved outcomes relative to those who utilize only conventional drug therapy.

In the meantime, we urge physicians to apply the principles of naturopathic medicine in the care of their HIV+ patients. These principles make theoretic sense and many of the naturopathic therapies utilized rest on sound preliminary in vitro, animal and, in some cases, preliminary human clinical data.

Chapter 159 - Hypertension

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

DIAGNOSTIC SUMMARY

- Borderline high blood pressure: 120–160/90–94
- Mild high blood pressure: 140–160/95–104
- Moderate high blood pressure: 140–180/105–114
- Severe high blood pressure: 160+/115+.

GENERAL CONSIDERATIONS

An elevated blood pressure is a major risk factor for a heart attack or stroke. In fact, it is generally regarded as the most significant risk factor for a stroke. Over 60 million Americans have high blood pressure, including more than half (54.3%) of all Americans aged 65–74 years and almost three-quarters (71.8%) of all American blacks in the same age group.

Hypertension is divided into several levels:

- borderline (120–160/90–94)
- mild (140–160/95–104)
- moderate (140–180/105–114)
- severe (160+/115+).

Individuals with a normal diastolic pressure (< 82 mmHg) but elevated systolic pressure (>158 mmHg), i.e. an increased pulse pressure, have a twofold increase in cardiovascular death rates when compared with individuals with normal systolic pressures (< 130 mmHg).

THERAPEUTIC CONSIDERATIONS

Since over 80% of patients with hypertension are in the borderline to moderate range, most cases of hypertension can be brought under control through changes in diet and lifestyle. In fact, in head-to-head comparisons, many non-drug therapies, such as diet, exercise, and relaxation therapies, have proved superior to drugs in cases of borderline to mild hypertension.

Conventional antihypertensive drugs

An increasing body of evidence is indicating that drugs

1304

may be doing more harm than good. Several well-designed, long-term clinical studies have found that people taking antihypertensive drugs (most often diuretics and/or beta-blockers) suffer from several side-effects including an *increased* risk for heart disease.

Virtually every medical authority (textbook, organization, journal, etc.) including the Joint National Committee on Detection, Evaluation and Treatment of High Blood Pressure, has recommended that non-drug therapies be used in the treatment of borderline to mild hypertension in place of drugs. The drugs carry with them no benefit, yet possess significant risks. The two most definitive trials, the Australian and Medical Research Council trials, as well as five other large trials, including the Multiple Risk Factor Intervention Trial (MRFIT), have shown that these drugs offer no benefit in protecting against heart disease in borderline to moderate hypertension.^{[1] [2] [3] [4] [5] [6] [7]} Opposed to these seven negative trials, there are two that found treatment was somewhat effective.^{[8] [9]} However, upon further examination, both of these studies were shown to be flawed. The European Working Party on Hypertension in the Elderly Trial was relatively small and in the Hypertension Detection and Follow-up Program there was an inadequate control group.

The most important aspect of these studies is that they compared drug treatment to no treatment (placebo). If the natural alternatives outlined in this chapter were compared with standard drug treatment in borderline to moderate hypertension in clinical trials, there is little doubt that the non-drug approach would yield substantial benefit. As was well stated by researchers in the field:^[10]

Few patients with uncomplicated marginal hypertension require drug treatment ... there is little evidence these patients (with marginal hypertension) will achieve enough benefit to justify the costs and adverse effects of antihypertensive drug treatment.

Despite this substantial evidence and medical opinion, blood pressure-lowering drugs are still among the most widely prescribed. The possible explanation is as follows: "Treatment of hypertension has become the leading reason for visits to physicians as

well as for drug prescriptions.”^[11] Yearly sales of blood pressure medications are estimated to be greater than \$10 billion. Since approximately 50% of patients with high blood pressure are in the borderline to mild range, prescribing the non-drug protocols described here could mean health care system savings of greater than \$5 billion.

Dietary and lifestyle factors

Hypertension is closely related to lifestyle and dietary factors. Some of the important lifestyle factors which may cause hypertension include coffee consumption, alcohol intake, lack of exercise, stress, and smoking. The most important dietary factors include:

- obesity
- high sodium-to-potassium ratio
- low-fiber, high-sugar diet
- high-saturated fat and low-essential fatty acids intake
- a diet low in calcium, magnesium and vitamin C.

Several of these dietary and lifestyle factors are discussed in [Chapter 133](#) since the health of the artery is critical to maintaining normal blood pressure.

Diet

Next to attaining ideal body weight, perhaps the most important dietary recommendation is to increase the proportion of plant foods in the diet. Vegetarians generally have lower blood pressure levels and a lower incidence of hypertension and other cardiovascular diseases than non-vegetarians.^[12] While dietary levels of sodium do not differ significantly between these two groups, a vegetarian’s diet typically contains more potassium, complex carbohydrates, essential fatty acids, fiber, calcium, magnesium, and vitamin C, and less saturated fat and refined carbohydrate, all of which have a favorable influence on blood pressure.

The most useful foods for people with hypertension include:

- celery
- garlic and onions
- nuts and seeds or their oils for their essential fatty acid content
- cold-water fish (salmon, mackerel, etc.)
- green leafy vegetables for their rich source of calcium and magnesium
- whole grains and legumes for their fiber
- foods rich in vitamin C, like broccoli and citrus fruits.

Celery is a particularly interesting recommendation for hypertension. It contains a 3-*n*-butyl phthalide which has been found to lower blood pressure. In animals, a very small amount of this compound lowered blood pressure by 12–14% and cholesterol by about 7%. The equivalent dose in humans can be supplied in about four ribs of celery. The research was prompted by the father of one of the researchers, who after eating a quarter-pound of celery every day for 1 week observed that his blood pressure had

dropped from 158/96 to 118/82.

Garlic and onions are also important foods for lowering blood pressure. Although most recent research has focused on the cholesterol-lowering properties of garlic and onions, both have also been shown to lower blood pressure in hypertension.^[13] In addition, commercial garlic supplements may also be of benefit. The usual response when using garlic is fairly modest, roughly 8–11 mmHg

1305

for the systolic and 5–8 mmHg for the diastolic (see [Chs 62](#) and [63](#) for full discussion and dosages).

Potassium and sodium

A diet low in potassium and high in sodium is associated with hypertension. Just as important as the dietary total potassium content of food is the sodium-to-potassium ratio. Numerous studies have demonstrated that a low-potassium, high-sodium diet plays a major role in the development of cancer and cardiovascular disease (heart disease, hypertension, strokes, etc.).^{[14] [15]} Conversely, a diet high in potassium and low in sodium is protective against these diseases, and, in the case of hypertension, can be therapeutic.^{[1] [16] [17] [18]}

It is a well-established fact that excessive consumption of dietary sodium chloride, coupled with diminished dietary potassium, is a common cause of high blood pressure, especially in “salt-sensitive” individuals. Numerous studies have shown that sodium restriction alone does not improve blood pressure control in most people – it must be accompanied by a high potassium intake.^{[1] [16] [17]} In a typical Western diet only 5% of sodium intake comes from the natural constituents in food. Prepared foods contribute 45% of the sodium intake, 45% is added during cooking, and another 5% is added as a condiment.

Most Americans have a potassium-to-sodium (K:Na) ratio of less than 1:2. Epidemiological and experimental research suggests a dietary potassium-to-sodium ratio of greater than 5:1 is necessary to maintain health. However, even this level may not be optimal. A natural diet rich in fruits and vegetables can produce a K:Na ratio greater than 100:1, as most fruits and vegetables have a K:Na ratio of at least 50:1.

Many studies have now shown that increasing dietary potassium intake can lower blood pressure.^{[1] [19]} In addition, there are now several studies which show that potassium supplementation alone can produce significant reductions in blood pressure in hypertensive subjects. Typically these studies have utilized dosages ranging from 2.5 to 5.0 g/day of potassium. Significant drops in both systolic and diastolic values have been achieved.^{[19] [20] [21] [22] [23] [24]}

In one study, 37 adults with mild hypertension received either 2.5 g/day of potassium,

2.5 g/day of potassium plus 480 mg/day of magnesium, or a placebo for 8 weeks, and then they were crossed over to receive one of the other treatments for another 8 weeks and then again in another 8 weeks.^[23] The potassium supplementation lowered systolic blood pressure an average of 12 mmHg and diastolic blood pressure an average of 16 mmHg. Interestingly, the additional magnesium offered no further reduction in blood pressure; nonetheless magnesium supplementation has been shown to be helpful in other studies (discussed below).

Potassium supplementation may be especially useful in the treatment of hypertension in persons over the age of 65, who often do not fully respond to antihypertensive drugs. In one double-blind study, 18 untreated elderly patients (average age 75 years) with a systolic blood pressure of greater than 160 mmHg and/or a diastolic blood pressure of greater than 95 mmHg were given either potassium chloride (2.5 g of potassium) or a placebo each day for 4 weeks.^[24] After this relatively short treatment period, the group receiving the potassium experienced a drop of 12 mmHg in the systolic and 7 mmHg in the diastolic. These results compare quite favorably with the reduction of blood pressure produced by drug therapy, but without the negative effects and side-effects.^[25]

The estimated safe and adequate daily dietary intake of potassium, as set by the Committee on Recommended Daily Allowances, is 1.9–5.6 g.

Potassium supplements are available by prescription as well as over the counter (OTC). However, the FDA restricts the amount of potassium available in OTC potassium supplements to a mere 99 mg/dose because of problems associated with high-dosage prescription potassium salts, yet so-called salt substitutes such as the popular brands NoSalt and Nu-Salt are in fact potassium chloride and provide 530 mg of potassium per 1/6 teaspoon! The prescription and OTC supplements are either potassium salts (chloride and bicarbonate), potassium bound to various mineral chelates (e.g. aspartate, citrate, etc.), or food-based potassium sources. Potassium chloride preparations are the most popular by prescription and are available in a vast array of formulations (timed-release tablets, liquids, powders, and effervescent tablets) and flavors. Potassium salts are commonly prescribed in the dosage range of 1.5–3.0 g/ day. However, potassium salts can cause nausea, vomiting, diarrhea, and ulcers when given in pill form at high dosage levels. These effects are not seen when potassium levels are increased through the diet only. This difference highlights the advantages of using foods or food-based potassium supplements to meet the human body's high potassium requirements rather than pills.

Potassium supplementation is relatively safe, except for patients with kidney disease. Their inability to maintain appropriate potassium homeostasis may result in heart arrhythmias and other consequences of potassium toxicity. Potassium supplementation is also contraindicated when using a number of prescription medications, including digitalis, potassium-sparing diuretics, and the angiotensin-converting enzyme inhibitor class of antihypertensive drugs.

Magnesium

Potassium interacts in many body systems with magnesium, and low intracellular

potassium levels may be the

1306

result of low magnesium intake. It is therefore appropriate to supplement magnesium (400 mg–1,200 mg/day in divided dosages) along with potassium. This suggestion may also lower blood pressure. For example, in one double-blind clinical study, 21 male patients with hypertension were given 600 mg/day of magnesium (as magnesium oxide) or placebo.^[26] Mean blood pressure (the average between the systolic and diastolic) decreased from 111 to 102 mmHg. The patients who responded the best were those with reduced red blood cell potassium. After therapy with magnesium, the levels of intracellular sodium, potassium, and magnesium normalized, suggesting that one of the ways in which magnesium lowers blood pressure is through activation of the cellular membrane pump which pumps sodium out of, and potassium into, the cell.

There is considerable evidence that a high intake of magnesium is associated with lower blood pressure in population studies. The principal source of magnesium in early studies was water. Water that is high in minerals like magnesium is often referred to as “hard water”. Numerous studies have demonstrated an inverse correlation between water hardness and high blood pressure.^[27]

These early studies gave way to more extensive dietary studies looking at the association of magnesium with hypertension. These dietary studies found the same results as the hard water studies. In one of the most extensive studies – the Honolulu Heart Study – systolic blood pressure was 6.4 mmHg lower and diastolic blood pressure 3.1 mmHg lower in the highest magnesium intake group compared with the lowest magnesium intake group.^[28]

The studies of magnesium supplementation in the treatment of hypertension have yielded mixed results. The hypertensive patients who respond appear to be those taking a diuretic, with a high level of renin, with low RBC magnesium, and/or with elevated intracellular sodium or a decreased intracellular potassium.

The ideal intake for magnesium appears to be approximately 6 mg/kg body weight, while the therapeutic dose is twice as high.

Magnesium is available in several different forms. While most are equally well absorbed, magnesium bound to aspartate or the Krebs cycle intermediates (malate, succinate, fumarate, and citrate) is usually preferable to magnesium oxide, gluconate, sulfate, and chloride. Absorption studies indicate that magnesium is easily absorbed orally, especially when it is bound to citrate (and presumably aspartate and other members of the Krebs cycle).^[29] ^[30] In addition, magnesium bound to aspartate or Krebs cycle intermediates may also help with fatigue. Aspartate feeds into the Krebs cycle, the final common pathway for the conversion of glucose, fatty acids, and amino acids to chemical energy (ATP), while citrate, fumarate, malate, and succinate are actual components of Krebs cycle. Minerals chelated to the Krebs cycle intermediates are

better absorbed, utilized, and tolerated compared with inorganic or relatively insoluble mineral salts, including magnesium chloride, oxide, or carbonate. In addition, while inorganic magnesium salts often cause diarrhea at higher dosages, organic forms of magnesium generally do not.

In general, magnesium is very well tolerated. Magnesium supplementation can sometimes cause a looser stool, particularly magnesium sulfate (Epsom salts), hydroxide, or chloride. Magnesium supplementation must be used with great care in patients with kidney disease or severe heart disease (such as high-grade atrioventricular block).

Stress

Stress can be the causative factor of hypertension in many instances. Relaxation techniques such as deep breathing exercises, biofeedback, autogenics, transcendental meditation, yoga, progressive muscle relaxation, and hypnosis have all been shown to have some value in lowering blood pressure.^[31] Although the effect is only modest, a stress reduction technique is a necessary component in a natural blood pressure-lowering program.

One of the most powerful methods of producing less stress and more energy in the body is diaphragm breathing. A recent study has shed some light on the effect of breathing in hypertension.^[32] Volunteers with normal blood pressure were taught how to breath very shallow. Measurement of the amount of sodium and potassium excreted in the urine indicated that shallow breathing led to the retention of sodium in the body. It was suggested that this breathing pattern may play a causative role in some cases of hypertension due to the retention of sodium.

Vitamin C

Population-based and clinical studies have shown that the higher the intake of vitamin C, the lower the blood pressure. Several preliminary studies have shown a modest blood pressure-lowering effect (e.g. a drop of 5 mmHg) of vitamin C supplementation in people with mild elevations of blood pressure.^[33]

One of the mechanisms by which vitamin C exerts this antihypertensive effect is by promoting the excretion of lead. Chronic exposure to lead from environmental sources, including drinking water, is associated with hypertension and increased cardiovascular mortality.^[34] Areas with a soft water supply have an increased lead concentration in drinking water due to the increased acidity of the water, and people living in these areas may be predisposed to hypertension. It should be noted that soft water is also, of course, low in calcium

and magnesium, two minerals which have also been shown to protect against

hypertension.

Vitamin B₆

Vitamin B₆ supplementation has been shown to lower blood pressure. In one study, vitamin B₆ supplementation at a single oral dosage of 5 mg/kg body weight for 4 weeks in 20 people with hypertension demonstrated significant reductions in systolic and diastolic blood pressures as well as serum norepinephrine levels. The effects on blood pressure were significant: systolic pressure dropped from 167 to 153 mmHg and the diastolic pressure dropped from 108 to 98 mmHg.^[35]

Calcium

Population-based studies have suggested a link between hypertension and a low intake of calcium.^[36] However, the association is not as strong as the one for magnesium and potassium. In addition to the epidemiological data, several clinical studies have demonstrated that calcium supplementation can lower blood pressure in hypertension, but the results have been inconsistent.^[36]

To clarify the effectiveness of calcium supplementation in patients with hypertension, a recent double-blind placebo controlled cross-over study was performed on 46 patients with either salt-sensitive or salt-resistant hypertension.^[37] During the calcium supplementation phase, patients received 1.5 g/day of calcium (as calcium carbonate) for 8 weeks. The calcium supplementation was found to effectively reduce blood pressure in blacks and in patients who are salt-sensitive, but not in patients who have salt-resistant hypertension. Better results have been found for calcium citrate vs. calcium carbonate.^[38]

Another group that appears to respond to calcium supplementation are elderly hypertensives. One study used 24 hour monitoring of blood pressure to evaluate the effect of calcium supplementation on mild to moderate essential hypertension in elderly hospitalized patients. The mean systolic and diastolic blood pressures over a period of 24 hours declined by 13.6 mmHg and 5.0 mmHg, respectively, in patients whose diet was supplemented with 1 g of elemental calcium.^[39]

Coenzyme Q₁₀

Coenzyme Q₁₀ (CoQ₁₀), also known as ubiquinone, is an essential component of the mitochondria. Although CoQ₁₀ can be synthesized within the body, deficiency states have been reported. In hypertension, CoQ₁₀ deficiency has been shown to be present in 39% of patients. This finding alone suggests a need for CoQ₁₀ supplementation. However, CoQ₁₀ appears to provide benefits beyond correction of a deficiency. In several studies, CoQ₁₀ has actually been shown to lower blood pressure in patients with hypertension.^{[40] [41] [42]} However, the effect of CoQ₁₀ on blood pressure is usually not seen until after 4–12 weeks of therapy. Thus, CoQ₁₀ is not a typical blood

pressure-lowering drug; rather, it seems to correct some metabolic abnormality, which in turn has a favorable influence on blood pressure. Typical reductions in both systolic and diastolic blood pressures with CoQ₁₀ therapy in patients with hypertension are in the 10% range.

While the mechanism of action of CoQ₁₀ in angina is well understood (see [Ch. 129](#)), the mechanism in hypertension remains a mystery, as the physiological factors known to be associated with hypertension do not appear to be affected. For example, when 10 patients with hypertension were given 100 mg/day of CoQ₁₀ for 10 weeks, systolic blood pressure dropped from 161.5 to 142 mmHg and diastolic pressure dropped from 98.5 to 83 mmHg, but there were no changes in renin, sodium, or aldosterone levels.^[40] Cholesterol levels decreased from 227 to 204 mg/dl and peripheral vascular resistance in the arteries of the arms and legs improved significantly.

Omega-3 oils

Increasing the intake of omega-3 fatty acids can lower blood pressure. Over 60 double-blind studies have demonstrated that either fish oil supplements or flaxseed oil are very effective in lowering blood pressure.^{[43] [44] [45] [46]} Although the fish oils have typically produced a more pronounced effect than flaxseed oil, because the dosage of fish oils used in the studies was quite high (e.g. equal to 10 fish oil capsules daily), flaxseed oil may be the better choice for lowering blood pressure, especially when cost-effectiveness is considered.

Along with reducing the intake of saturated fat, 1 tbsp/day of flaxseed oil should reduce both the systolic and diastolic readings by up to 9 mmHg.^[45] One study found that for every absolute 1% increase in body alpha-linolenic acid content there was a decrease of 5 mmHg in the systolic, diastolic, and mean blood pressures.^[46]

Botanical medicines

Crataegus sp.

Extracts of hawthorn berries as well as of the flowering tops are widely used by physicians in Europe because of their cardiovascular activities. Several studies have demonstrated that hawthorn extracts are effective in lowering blood pressure and improving heart function. However the blood pressure-lowering effect of hawthorn is very mild.^{[47] [48]} It usually requires at least 2–4 weeks before it begins to exert any effect.

Allium sativum and Allium cepa

As discussed above, garlic and onion are useful antihypertensive additions to the diet as are various garlic extracts. A recent large, long and double-blind cross-over study has

provided the strongest documentation of the efficacy of garlic as an antihypertensive agent. Aged garlic (7.2 g/day) administered for 10 months reduced systolic blood pressure in hypertensives by 3.1%.^[49] Unfortunately, the high dosage would be quite expensive for the average patient. The beneficial effects of these foods/botanicals are discussed in detail in [Chapters 62](#) and [63](#).

Viscum album

Viscum exhibits hypotensive action in animal studies. The mechanism of action for its hypotensive effect is not, however, fully understood and no recent investigations have been published. *Viscum* has been shown to inhibit the excitability of the vasomotor center in the medulla oblongata and to possess cholinomimetic activity.^[50]

The hypotensive activity may be dependent on the form in which the mistletoe is administered and the host tree from which it was collected. Studies indicate that aqueous extracts are more effective; the highest hypotensive activity was demonstrated by a macerate of leaves of mistletoe parasitizing on willow and gathered in January (see [Ch. 120](#) for further discussion).

THERAPEUTIC APPROACH

Mild hypertension (140–160/90–104)

- Reduce excessive weight.
- Eliminate salt (sodium chloride) intake.
- Follow a healthy lifestyle. Avoid alcohol, caffeine, and smoking. Exercise and use stress reduction techniques.
- Follow a high-potassium diet rich in fiber and complex carbohydrates.
- Increase dietary consumption of celery, garlic, and onions.
- Reduce or eliminate the intake of animal fats while increasing the intake of vegetable oils.
- Supplement the diet with the following:
 - high potency multiple vitamin and mineral formula
 - vitamin C: 500–1,000 mg three times/day
 - vitamin E: 400–800 IU/day
 - magnesium: 800–1,200 mg/day
 - garlic: the equivalent of 4,000 mg/day of fresh garlic
 - flaxseed oil: 1 tbsp/day.

If after following the above recommendations for a period of 3–6 months blood pressure has not returned to normal, antihypertensive medications are appropriate to bring the

blood pressure down. When a prescription drug is necessary, calcium channel blockers or ACE inhibitors appear to be the safest.

Moderate hypertension (140–180/105–114)

- Employ all the measures above.
- Coenzyme Q₁₀ : 50 mg two to three times/day
- Take hawthorn extract (10% procyanidins or 1.8% vitexin-4'-rhamnoside): 100–250 mg three times daily.

Follow these guidelines for 1–3 months. If the blood pressure has not dropped below 140/105, you will need to work with a physician to select the most appropriate medication.

Severe hypertension (160+/115+)

Drug intervention is required. Employ all the measures above. When satisfactory control over the high blood pressure has been achieved, have the patient taper off the medication gradually.

Chapter 160 - Hyperthyroidism

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

DIAGNOSTIC SUMMARY

- Weakness, sweating, weight loss, nervousness, loose stools, and heat intolerance, irritability, fatigue
- Tachycardia; warm, thin, moist skin; stare; and tremor
- Diffuse, non-painful goiter
- Increased T_4 , free T_4 , and free T_4 index
- Failure of thyroid suppression with T3 administration
- In Graves' disease: goiter (often with bruit), ophthalmopathy.

GENERAL CONSIDERATIONS

Hyperthyroidism, also known as thyrotoxicosis, denotes a group of clinical disorders characterized by increased levels of free thyroxine, also known as tetraiodothyronine (T_4), and/or triiodothyronine (T_3). The autoimmune disorder, Graves' disease, accounts for up to 85% of all cases of hyperthyroidism. It is much more common in women than men (ratio 8:1) and typically begins between the ages of 20 and 40. Diffuse non-painful goiter with hyperthyroidism is the most common presentation of Graves' disease. Other less common signs and symptoms include exophthalmos, pretibial myxedema and other skin changes, nail changes (acropachy) and even paralysis in some groups.^[1]

Although no single immunological abnormality explains all of the clinical features of the disease, the common denominator is the presence of antibodies against thyroid-stimulating hormone (TSH) receptors. The exophthalmos and skin changes can progress independently from thyroid dysfunction (euthyroid Graves' disease), making it difficult to predict the course of the disease in a given individual.

There are definite patterns of susceptibility in autoimmune disease in general, and in Graves' disease in particular. Many of these patterns have been recognized by common

observation, while others have come to light only with careful study.

1312

Gender

The most obvious pattern is that of gender. Practically all the original cases described by Parry, von Basedow, and Graves were women. The female to male ratio in published series is 7:1 to 10:1, but the ratio in those with ophthalmic complications is about 1:1.^[2]

Stress

Recent stress has been recognized as a precipitating factor since Graves' disease was first recognized. In fact, the most common precipitating event is an "actual or threatened separation from an individual upon whom the patient is emotionally dependent".^[3] Studies now support the long-held observation that the onset of Graves' often follows some kind of emotional shock, in particular some sort of loss such as divorce, death, or difficult separations.^[4]

Genetics

Genetic susceptibility to Graves' is apparently significant in some people. Graves' is statistically more prevalent in some HLA haplotypes such as HLA-B₈ and HLA-DR₃ in Caucasians, HLA-Bw₃₅ in the Japanese, and, in the Chinese, HLA-Bw₄₆.^[5] HLA identical twins have a 50% chance of manifesting Graves' if one twin is affected, and a 9% chance for fraternal twins.^[5] Some haplotypes appear to offer protection from manifesting Graves'.^[6] Genetic haplotype does not seem to affect the clinical course of Graves' disease or the response to treatment.

Additional evidence, but not proof, for a genetic etiology comes from an interesting case of bone marrow transplantation between siblings in which the sister donated her bone marrow to her brother 8 years prior to her diagnosis with Graves' disease. His bone marrow genotype was 98% 46, XX 8 years after the transplant. He contracted Graves' 2 months after his sister's subtotal thyroidectomy.^[7] The authors, while admitting that the manifestation of Graves' disease in both siblings could be due to chance, propose that the brother passively acquired a clone of programmed or activated lymphocytes from his sister and that his hyperthyroidism was not primarily dependent on any exposure to a specific thyroid-derived antigen.^[7]

Left-handedness

One study showed a statistically significant trend for left-handed people to manifest Graves' and other autoimmune diseases. Wood & Cooper,^[8] using only male subjects, found that 70% of the Graves' patients had some degree of left-handedness as compared with only 24% of controls. They also found some evidence for a higher rate of

dyslexia in Graves' patients.

Smoking

A statistically significant correlation exists between smoking and Graves' disease, especially in patients with ophthalmic complications.^[9] The risk estimate is comparatively less for smoking (1.5) than that associated with heredity (3.6) and negative life events (6.3). There is little immunological evidence to support an immunological role for smoking in Graves' disease. The group at the highest increase in risk for severe endocrine ophthalmopathy are those who already have some eye manifestation and who continue to smoke.^{[10] [11]}

Iodine supplementation

An interesting study evaluated the effects of mandatory consumption of iodized salt in a whole population of 267,330 inhabitants of Galicia. The incidence of thyrotoxicosis, diagnosed as elevated T₄ and suppressed TSH levels, increased throughout the whole study period, with 4.89 new cases per 100,000 population. The rate of increase for females (8.03) was much greater than for males (1.34). The increased incidence of thyrotoxicosis comprised both nodular and diffuse goiters. The authors conclude that dietary iodine supplementation in iodine-sufficient areas can increase the incidence of thyrotoxicosis in susceptible individuals.^[12]

Mercury and cadmium exposure

Animal research has shown that exposure to toxic levels of cadmium or mercury will induce an immediate hyperthyroidism.^[13] Similar effects have been reported in a 13-year-old boy who had played with liquid mercury in his small bedroom with closed windows during cold weather for approximately 2 weeks. One month after exposure he began to have extremity pain which became so severe that he was hospitalized. He had cold extremities that were cyanotic, with red palms and soles, a maculopapular rash across his trunk, tremors and hypertension, and he perspired heavily. Raised mercury levels were found in the blood and urine and a diagnosis of acrodynia was made. A thyroid nodule was noted and a thyroid test indicated possible hyperthyroidism. A thyroid scan found an enlargement of the gland and the increased uptake of the isotope.^[14] Chelating agents returned his mercury levels to normal and carbimazole treatment alleviated symptoms after 4 weeks.

Drugs

In older patients with hyperthyroidism, a toxic reaction to prescription drugs must be considered. The most common cause of hyperthyroidism in the elderly is a low intake of iodine and higher use of aminodarone, an antihypertensive drug.^[15] In addition, symptoms of

hyperthyroidism vary somewhat in older adults, with apathy, tachycardia and weight loss being more common.

DIAGNOSIS

Clinical presentation

The typical clinical presentation of Graves' disease is a young adult female complaining of:

- nervousness
- irritability
- sweating
- palpitations
- insomnia
- tremor
- frequent stools
- weight loss despite a good appetite.

Physical examination will often reveal a smooth, diffuse, non-tender goiter; tachycardia, especially after exercise; loud heart sounds (often a systolic murmur); mild proptosis, lid retraction, lid lag, and tremor.

Other signs and symptoms include muscle weakness and fatigue, anxiety, heat intolerance, and pretibial myxedema. However, in atypical cases, especially in elderly patients, any or all of the above symptoms may be absent. This presentation is known as apathetic thyrotoxicosis and has been known to present in the elderly with the only symptom being depression. Special care must be taken to avoid missing the diagnosis with this presentation. A screening laboratory test for suppressed TSH is helpful in these patients. Also it is useful to keep in mind that an increase in thyroid hormone can present as a worsening of already present cardiac symptoms such as angina pectoris, congestive heart failure, and atrial fibrillation.

The skin can show characteristic changes, becoming moist, warm, and finely textured. Perspiration increases as a response to the increased body temperature. Pigment changes such as vitiligo can be associated with Graves' as well as increased pigmentation of areas such as skin creases and the knuckles. Hair may thin or fall out in patches or altogether (alopecia). Nails may separate prematurely from the nail bed (onycholysis). Localized non-pitting edema typically occurs along the shins (myxedema), but may occur elsewhere, generally on the extensor surfaces, and is often pruritic and red.

Other symptoms can be associated with Graves', including osteoporosis, dyspnea, polyurea and polydipsia, myopathy, paralysis, Parkinsonian or choreoathetoid affect,

and others.^[1]

Differential diagnosis

Graves' disease is the most common diagnosis of hyperthyroidism, but several other conditions present with a similar symptom picture. Several types of thyroiditis will cause hyperthyroidism, including Hashimoto's thyroiditis (early stage), subacute thyroiditis, painless thyroiditis, and radiation thyroiditis. Hyperthyroidism can also result from exogenous causes, including iatrogenic hyperthyroidism, factitious hyperthyroidism (often seen in dieters who are taking thyroxine for weight loss), and iodine-induced hyperthyroidism (Jod–Basdow disease).

Toxic nodular goiters are another source of hyperthyroidism. These include toxic adenoma and multinodular goiter. Other rare causes of hyperthyroidism include thyroid carcinoma, ectopic hyperthyroidism, trophoblastic tumors (i.e. hydatidiform mole, choriocarcinoma, embryonic carcinoma of the testis), excessive thyroid-stimulating hormone (i.e. pituitary adenoma, non-neoplastic pituitary secretion of TSH), and struma ovarii.

[Table 160.1](#) indicates the relative frequency of the various causes of hyperthyroidism.

Laboratory diagnosis

The laboratory is where the definitive diagnosis is made, and quite a number of tests are available to the physician to assess thyroid function and functional anatomy.

While many tests are available, for the vast majority of cases a few simple tests will confirm the diagnosis. Serum T_3 , T_4 , thyroid resin uptake, and free thyroxine are usually all elevated. A reliable, sensitive TSH assay

TABLE 160-1 -- Relative frequency of primary causes of hyperthyroidism

| Etiology | Relative frequency* |
|--|---|
| Graves' disease | 70–85% |
| Toxic multinodular goiter | 5–15% |
| Toxic uninodular goiter | 3–30% |
| Thyroiditis (including so-called hashitoxicosis) | 4–23% |
| Drug-induced | Common in the elderly; rare in the young (except in cases where I-administered to population) |
| Post-radiation | |

* Overall frequency; relative frequency may be altered in certain populations, e.g. the elderly, and in regions of endemic goiter.

will show low levels, except in rare cases. TSH receptor antibodies (TSH-R Ab) are present in 80% of cases.

If a nodular goiter is present, a thyroid scan should be performed to help rule out cancer and to guide treatment. Determining serum antibodies can also be useful in ruling out cancer in patients with lobular firm goiters. High antibody levels suggest chronic thyroiditis in these cases.

THERAPEUTIC CONSIDERATIONS

The chief objective of the natural treatment of Graves' disease and hyperthyroidism is to reduce symptoms while trying to re-establish normal thyroid status. Unfortunately, the natural approach has not received much research attention. Nonetheless, here are some general measures which should be employed followed by a description of additional modalities which may offer some benefit.

Reduce risk factors, i.e. stress, smoking, and excess iodine intake and increase rest. Stress control is the single most important action the patient can take to assist normalization of the thyroid. The patient should avoid anything that will excite him or her and increase agitation. Counseling can and should be used to prevent a return to stress-generating life strategies. Rest should be increased, including a daily nap after lunch as well as a full night's sleep.^[16]

Diet

Balanced whole foods diet

The diet should be high in calories to compensate for the increase in metabolism, and eaten in the form of small, frequent meals. Protein should be supplemented if the patient is nutritionally depleted.^[16] Evidence concerning iodine in the diet is conflicting, but none should be taken as a supplement. Caffeine-containing foods and other stimulants should be avoided.

Dietary goitrogens

Some foods contain goitrogenic substances which prevent the utilization of iodine. These compounds are primarily isothiocyanates which are similar in action and structure to propylthiouracil. They are found in such foods as turnips, cabbage, rutabagas, mustard, rapeseeds, cassava root, soybeans, peanuts, pine nuts and millet. However, these foods are unreliable in the treatment of hyperthyroidism as:

- their goitrogen content is quite low, especially when compared with the dosages of PTU required in hyperthyroidism (100–200 mg three to four times/day)
- cooking inactivates the goitrogens
- there is no substantial documentation that these naturally occurring goitrogens interfere with thyroid function to any significant degree when dietary iodine levels are adequate.

It is interesting to note that goitrogens are transmitted from cow's milk to humans.^[17]

Despite these shortcomings, practitioners may want to use naturally occurring goitrogens in mild cases instead of PTU and related drugs. In order to achieve clinical results, large amounts of these foods must be consumed in their raw state, and iodine intake must be restricted. The highest levels of isothiocyanates are found in raw soymilk (0.46–2.5 mg/dl). Of the brassica family, rutabagas, cabbage, and turnips usually contain the highest levels. However, the quantity will vary considerably according to climatic and soil factors. Anecdotally, a half head of raw cabbage per day is the typical prescription. Iodine is found in kelp and other seaweeds, vegetables grown near the ocean, seafood, iodized salt, and nutritional supplements.

Nutritional supplements

Vitamin A

Vitamin A in large amounts has an inhibitory effect on thyroid function and has been shown to ameliorate the symptoms of Graves' disease.^[18] The exact mechanism is unknown, but evidence suggests that iodine metabolism is altered.^[17] Animal studies have shown an alteration in cellular uptake of thyroxin, capacity of nuclear T₃ receptors, and thyroid hormone metabolism.^{[19] [20] [21]}

Vitamin C

Early in this century, a considerable amount of research was conducted attempting to elicit the effects of hyperthyroidism on ascorbate metabolism. Experimental administration of thyroid, thyroxin or thyrotrophic hormone results in a reduction in the ascorbic acid content of the serum, blood, liver, adrenal, thymus, and kidney.^{[22] [23]} Somewhat surprising was the observation that antithyroid drugs such as thiourea and thiouracil caused the same effect.^[22] Research in hyperthyroid humans found a decreased excretion of ascorbate.^[24] While supplemental vitamin C does not appear to directly affect the course of this disease, supplementation seems warranted to help ameliorate the symptoms and metabolic effects.

Vitamin E

Some evidence exists that this antioxidant may protect the patient from the oxidative damage of hyperthyroidism.^[25] In a rat model of hyperthyroid-induced animals, vitamin E

helped to prevent the lipid peroxidation

1315

that is associated with hyperthyroidism. It is not known whether vitamin E supplementation of hyperthyroid patients would be beneficial in protecting against oxidative damage.^[26]

Calcium

Calcium metabolism is altered in hyperthyroidism, and Graves' patients are more susceptible to osteoporosis than normals.^[15]

Iodine

Worldwide, iodine deficiency continues to be a problem, but in developed countries, iodine excess is more common. Sources of iodine include additives to food products (e.g. salt and iodine used to sterilize pipes in dairies) and in medical products (e.g. betadine washes, iodine-containing drugs such as aminodarone, radiographic dyes).^[27]

The effects of iodine in patients with hyperthyroidism are as follows:

- It temporarily reduces symptoms by stopping hormone synthesis (Wolff–Chaikoff effect).
- The thyroid can remain suppressed or can eventually resume hormone synthesis at a reduced, former, or even increased rate (escape from Wolff–Chaikoff).^[28]
- Excess iodine can trigger hyperthyroidism (Jod–Basedow disease) in an euthyroid person or can trigger an overactive thyroid to return to normal.

From the brief description of these three possibilities it is clear that, aside from the initial suppression of thyroid function, the action of iodine is unpredictable.

Zinc

RBC zinc is decreased in patients with hyperthyroidism. Treatment with antithyroid drugs normalizes RBC zinc levels but not until 2 months after T_4 and T_3 levels normalize. As RBC zinc during the 12 weeks prior to treatment shows that the T_4 and T_3 levels correlated with RBC zinc levels, zinc RBC concentrations in hyperthyroid patients apparently reflect a patient's mean thyroid hormone level over the preceding several months, just as glycosylated hemoglobin indicates mean glucose levels in diabetic patients.^[29]

The oral zinc tolerance test (done by obtaining a baseline zinc level after a 10 hour fast followed by an oral dose of 165 mg of zinc sulfate heptahydrate – 37.5 mg zinc –

dissolved in 20 ml deionized water with blood samples drawn at 30 minute intervals over the next 3 hours) shows that hyperthyroid patients have a basal serum zinc concentration similar to euthyroid individuals, but with greater urinary zinc excretion, which suggests zinc depletion from tissues to the bloodstream caused by catabolism from the hyperthyroid state. Hyper-thyroidism also caused lower zinc assimilation by tissues after ingestion.^[30]

Botanical medicines

[Table 160.2](#) lists medicinal plants that have been used traditionally in the treatment of hyperthyroidism. Unfortunately, these plants have not been adequately evaluated in clinical studies.

LycopusSpp., *Lithospermum officinale* and *Melissa officinalis*

Aqueous, freeze-dried extracts of *Lycopus* spp., *Lithospermum officinale* and *Melissa officinalis* have been studied both in vivo and in vitro, with preliminary results supporting their use in the treatment of Graves' disease. However, additional clinical research is needed before these plants can be relied upon clinically.

Effects noted for these three plants include an ability to inhibit the effects of exogenous TSH on the thyroid glands of rats, to block the effects of TSH on the TSH receptor sites located on thyroid membranes, to inhibit the peripheral deiodination of T₄ to T₃, and to block the effects of antithyroid immunoglobulins on TSH receptors.^{[33] [34] [35] [36]} Eight isolated compounds, mainly oxidation products of derivatives of 3,4-dihydroxycinnamic acid, were found to be responsible for most of these effects. The blocking effects of the isolated compounds of the TSH receptors were reversible and none of the compounds combined irreversibly, damaged or altered the TSH receptors in situ.

An alcohol extract of *Lycopus europeus* administered orally to rats caused a long-lasting decrease in T₃ levels, presumably due to reduced peripheral T₄ deiodination. A pronounced reduction in TSH was also observed 24 hours later, as was a drop in lutenizing hormone and testosterone.^[37] Water extracts did not have as strong an effect, explaining the lack of results in some earlier

TABLE 160-2 -- Medicinal plants traditionally used in the treatment of hyperthyroidism^[31]
^[32]

| Medicinal plant | Traditional indications |
|-------------------------------|--------------------------------------|
| <i>Valerian officinalis</i> | Nervine effect |
| <i>Scutellaria laterflora</i> | Nervine effect |
| <i>Cactus grandiflora</i> | Heart tonic; use with elevated pulse |
| <i>Iris versicolor</i> | Traditional use for hyperthyroidism |

| | |
|--------------------------------|--|
| <i>Fucus</i> spp. | Use with caution as a high iodine content can improve symptoms at first then later cause aggravation |
| <i>Lycopus</i> spp. | Blocks the TSH receptors; blocks peripheral conversion of T ₄ to T ₃ |
| <i>Lithospermum officinale</i> | Blocks the TSH receptors |
| <i>Melissa officinalis</i> | Blocks the TSH receptors |

1316

studies. This is consistent with the observation that the active constituents are the unoxidized phenolic compounds which are not present in the aqueous extract.

These findings offer some support for the traditional use of these plants for patients with hyperactive thyroids. Unfortunately, there is no research on the clinical use of these plants or documented guidelines for dosage recommendations. Although it is not known how effective the historical dosage schedules for these plants are, the dosage recommendations from the British Herbal Pharmacopoeia for *Lycopus* spp. and *Melissa officinalis* (no mention is made of *Lithospermum officinale*) are given below.^[38]

Other therapies

Hydrotherapy

The traditional approach is to use calming hydrotherapy such as neutral baths, particularly before bed.^[39] A cold compress to the throat 15 minutes a day has been reported to improve symptoms. Also, an ice bag over the heart will reduce the heart rate but should not be overused.

Acupuncture

Acupuncture has been reported as an effective treatment for hyperthyroidism.^[40]

THERAPEUTIC APPROACH

Acute Graves' disease is not easily treated by naturopathic methods. In severe cases, there is no guarantee that natural treatments will alleviate the symptoms adequately. Thyroid storm is a potentially fatal complication and should be treated very aggressively with antithyroid drugs and/or iodine. In mild cases, natural therapeutics can manage the patients' symptoms well but must be monitored carefully to avoid sudden exacerbation of the illness. Patients will often do well for a time and then relapse. Mild cases should be treated symptomatically and allowed to return to a euthyroid status if possible. If iodine is used, then some sort of ablative treatment should be scheduled, as the risk of

escape (with a potential for a return to even more intense symptoms) increases with time.

The allopathic treatment of Graves' disease is unusual in that there are three relatively equal treatments to choose from. As physicians, we need to do our best to educate our patients about the advantages and disadvantages of each treatment option and allow our patients to decide which treatment best fits their needs. It is important to note that for many patients, decision-making will be difficult while in a thyrotoxic state. For these patients, symptomatic relief must be rendered before a decision is made.

Antithyroid drugs can manage symptoms indefinitely while waiting for a possible return to euthyroid status. If drugs are not tolerated well, then ablative therapies must be considered. Surgery has a higher rate of euthyroid results than radioactive iodine but carries a greater risk of serious complications. Regardless of the treatment selected, supportive treatment can and should be rendered.

Diet

A whole-foods diet with increased levels of calories, micronutrients, and protein is recommended to meet the increased metabolic needs of the hyperthyroid patient. In mild cases, consumption of large amounts of raw brassica family foods and raw soy products may be adequately combined with restricted iodine consumption to control symptoms.

Supplements

- Vitamin A: 50,000 IU/day
- Vitamin C: 2,000 mg b.i.d.
- Vitamin E: 800 IU/day.

Botanical medicines

- *Lycopus* spp., *Lithospermum officinale* and/or *Melissa officinalis*
- Dried herb: 1–3 g or by infusion three times/day
- Tincture (1:5): 2–6 ml three times/day
- Fluid extract (1:1): 1–3 ml three times/day.

Hydrotherapy

Cold packs are placed over the thyroid three times/day.

Chapter 161 - Hypoglycemia

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

DIAGNOSTIC SUMMARY

- Blood glucose level below 50 mg/dl
- A normal response curve during the first 2–3 hours of a glucose tolerance test followed by a decrease of 20 mg or more below the fasting glucose level during the final hours of the test, with symptoms developing during the decrease.

INTRODUCTION

Both low and high blood glucose levels can cause significant physiological dysfunction. Normally, the body maintains blood sugar levels within a narrow range through the coordinated effort of several glands and their hormones. If these control mechanisms are disrupted, hypoglycemia (low blood sugar) or diabetes (high blood sugar) may result.

The beta-cells of the pancreas respond to the rise in blood glucose levels after meals by secreting the hormone insulin which lowers blood glucose by increasing the rate at which glucose is taken up by cells throughout the body. Reductions in blood glucose, such as occur during food deprivation or exercise, cause the release of the hormone glucagon by the alpha-cells of the pancreas. Glucagon stimulates the release of glucose stored in body tissues as glycogen, especially the liver. Rapidly falling blood sugar levels, anger, fright, and stress may stimulate the release of epinephrine and corticosteroids by the adrenal glands. These hormones provide quicker breakdown of stored glucose for extra energy during a crisis or increased need.

Americans overstress these control mechanisms through improper diet and lifestyle. As a result, diabetes and hypoglycemia are common diseases.

Hypoglycemia is divided into two main categories: reactive hypoglycemia and fasting

hypoglycemia. Reactive hypoglycemia, the most common, is characterized by the development of symptoms of hypoglycemia 3–5 hours after a meal. Reactive hypoglycemia may also

TABLE 161-1 -- Oral hypoglycemic drugs

-
- Chlorpropamide (Diabinese)

 - Glipizide (Glucotrol)

 - Glyburide (DiaBeta, Micronase)

 - Tolazamide (Tolinase)

 - Tolbutamide (Orinase)

result from the use of oral hypoglycemic drugs. These sulfa drugs (sulfonylureas) appear to stimulate the secretion of additional insulin by the pancreas, as well as enhancing the sensitivity of body tissues to insulin. Common examples of this class of drugs are listed in [Table 161.1](#) .

Some researchers, however, are recommending that, for many patients, this syndrome instead be designated idiopathic postprandial syndrome (IPPS), because, although symptoms do exist and are related to rapid drops in blood glucose, the absolute glucose levels are not reliable indicators of the syndrome. Many asymptomatic controls have glucose levels below 50, while many symptomatic patients have normal postprandial glucose levels.^{[1] [2] [3]}

Fasting hypoglycemia is rare as it usually appears only in severe disease states such as pancreatic tumors, extensive liver damage, prolonged starvation, and various cancers, or as a result of excessive exogenous insulin in diabetics.

Because glucose is the primary fuel for the brain, low levels affect the brain first. Symptoms of hypoglycemia can range from mild to severe, including:

- headache
- depression, anxiety, irritability, and other psychological disturbances
- blurred vision
- excessive sweating
- mental confusion
- incoherent speech
- bizarre behavior
- convulsions.

DIAGNOSTIC CONSIDERATIONS

The standard methods of diagnosing hypoglycemia, as well as diabetes, involve the measurement of blood glucose levels. The normal fasting blood glucose level is between 70 and 105 mg/dl. A fasting blood glucose measurement greater than 140 mg/dl on two separate occasions is diagnostic of diabetes. At levels below 50 mg/dl, the diagnosis is fasting hypoglycemia.^[4]

The glucose tolerance test

A more functional test of blood sugar control is the oral glucose tolerance test (GTT). It is used in the diagnosis of both reactive hypoglycemia and diabetes, although it is rarely required for the latter. After fasting for at least 12 hours, a baseline blood glucose measurement is made. Then the subject is given a liquid containing glucose to drink. The amount consumed is based on body weight, 1.75 g/kg body weight. Blood sugar levels are measured at 30 minutes, 1 hour, and then hourly for up to 6 hours. Basically, blood sugar levels greater than 200 mg/dl indicate diabetes. Levels below 50 mg/dl indicate reactive hypoglycemia. [Table 161.2](#) provides greater explanation on interpreting results from a GTT.

The glucose-insulin tolerance test

Relying on blood sugar levels alone is often not enough to diagnose hypoglycemia, as it is now widely recognized

TABLE 161-2 -- Glucose tolerance test response criteria

| Diagnosis | Response |
|--------------------------------|---|
| Normal | No elevation greater than 160 mg |
| | Below 150 mg at the end of first hour |
| | Below 120 mg at the end of second hour |
| | Never lower than 20 mg below fasting |
| Flat | No variation more than ± 20 mg from fasting value |
| Pre-diabetic | Over 120 mg at the end of second hour |
| Diabetic | Over 180 mg during the first hour |
| | 200 mg or higher at the end of first hour |
| | 150 mg or higher at the end of second hour |
| Reactive hypoglycemia | A normal 2 or 3 hour response curve followed by a decrease of 20 mg or more from the fasting level during the final hours |
| Probable reactive hypoglycemia | A normal 2 or 3 hour response curve followed by a decrease of 10–20 mg from the fasting level during the final hours |

| | |
|---------------------------|---|
| Flat hypoglycemia | An elevation of 20 mg or less, followed by a decrease of 20 mg or more below the fasting level |
| Pre-diabetic hypoglycemia | A 2 hour response identical to the pre-diabetic, but showing a hypoglycemic response during the final 3 hours |
| Hyperinsulinism | A marked hypoglycemic response, with a value of less than 50 mg during the third, fourth or fifth hour |

1321

TABLE 161-3 -- Glucose-insulin tolerance test criteria

| Pattern | Response |
|-----------|---|
| Pattern 1 | Normal fasting insulin 0–30 units. Peak insulin at 0.5–1 hour. The combined insulin values for the second and third hours is less than 60 units. This pattern is considered normal |
| Pattern 2 | Normal fasting insulin. Peak at 0.5–1 hour with a “delayed return to normal”. Second and third hour levels between 60 and 100 units are usually associated with hypoglycemia and are considered borderline for diabetes; values greater than 100 units considered definite diabetes |
| Pattern 3 | Normal fasting insulin. Peak at second or third hour instead of 0.5–1 hour. Definite diabetes |
| Pattern 4 | High fasting insulin. Definite diabetes |
| Pattern 5 | Low insulin response. All tested values for insulin less than 30. If this response is associated with elevated blood sugar levels, it probably indicates insulin-dependent diabetes (“juvenile pattern”) |

that the signs and symptoms of hypoglycemia can occur in individuals having blood glucose levels well above 50 mg/dl and there is a wide overlap between symptomatic patients and asymptomatic controls.^[1] Many of the symptoms linked to hypoglycemia appear to be a result of increases in insulin or epinephrine. Therefore, it has been recommended that insulin or epinephrine (adrenaline) be measured during a GTT since symptoms often correlate better with elevations in these hormones than with glucose levels.^{[5] [6]} Several studies have shown that the glucose-insulin tolerance test (G-ITT) leads to a greater sensitivity in the diagnosis of both hypoglycemia and diabetes than the standard GTT.^{[6] [7]}

The G-ITT uses a standard 6 hour glucose tolerance test coupled with measurements of insulin levels. The G-ITT appears to be one of the best diagnostic indicators for faulty sugar metabolism.^[7] As many as two-thirds of subjects with suspected diabetes or hypoglycemia who have normal glucose tolerance tests will demonstrate abnormal

insulin tolerance tests. [Table 161.3](#) lists the various patterns seen with the G-ITT.

The down-side to this test is that it tends to be costly. For example, the glucose-insulin tolerance test (G-ITT) costs the patient around \$200 while a standard GTT is usually less than \$30.

The hypoglycemic index

Another laboratory parameter that can aid in the diagnosis of hypoglycemia, especially in the borderline case, is the so-called “hypoglycemic index”. This value is determined by calculating the fall in blood glucose levels during the 90 minute period before the lowest point divided by the value of the lowest point. A hypoglycemic index greater than 0.8 usually indicates reactive hypoglycemia.

The hypoglycemia questionnaire

When all is considered (especially cost to the patient), the most useful measure of diagnosing hypoglycemia in many cases remains assessing symptoms. In general, when symptoms appear 3–4 hours after eating and disappear with the ingestion of food, hypoglycemia should be considered. The questionnaire shown in [Table 161.4](#) is an excellent screening method for hypoglycemia.

GENERAL CONSIDERATIONS

In the 1970s, hypoglycemia was a popular “self-diagnosis” for a long list of symptoms; every symptom on the hypoglycemia questionnaire in [Table 161.4](#) was linked to hypoglycemia. Although all of these symptoms may be due to hypoglycemia, there are obviously other causes in many cases. The tremendous public interest in hypoglycemia and sugar intake was fueled by a number of popular books like *Sugar blues* by William Duffy, *Hope for hypoglycemia* by Broda Barnes, and *Sweet and dangerous* by John Yudkin. The popularity of these books and the diagnosis of hypoglycemia was met by much skepticism in the medical community. Editorials in the *Journal of the American Medical Association* and the *New England Journal of Medicine* during the 1970s denounced this public interest in hypoglycemia and tried to invalidate the concept of hypoglycemia.^{[8] [9]}

TABLE 161-4 -- Hypoglycemia questionnaire

| | No | Mild | Moderate | Severe |
|--|----|------|----------|--------|
| Crave sweets | 0 | 1 | 2 | 3 |
| Irritable if a meal is missed | 0 | 1 | 2 | 3 |
| Feel tired or weak if a meal is missed | 0 | 1 | 2 | 3 |
| Dizziness when standing suddenly | 0 | 1 | 2 | 3 |
| Frequent headaches | 0 | 1 | 2 | 3 |

| | | | | |
|--|---|---|---|---|
| Poor memory (forgetful) or concentration | 0 | 1 | 2 | 3 |
| Feel tired an hour or so after eating | 0 | 1 | 2 | 3 |
| Heart palpitations | 0 | 1 | 2 | 3 |
| Feel shaky at times | 0 | 1 | 2 | 3 |
| Afternoon fatigue | 0 | 1 | 2 | 3 |
| Vision blurs on occasion | 0 | 1 | 2 | 3 |
| Depression or mood swings | 0 | 1 | 2 | 3 |
| Overweight | 0 | 1 | 2 | 3 |
| Frequently anxious or nervous | 0 | 1 | 2 | 3 |
| Total | | | | |
| <i>Scoring:</i> | | | | |
| <5, hypoglycemia is not likely a factor | | | | |
| 6–15, hypoglycemia is a likely factor | | | | |
| >15, hypoglycemia is extremely likely. | | | | |

Research in the past decade has provided an ever-increasing amount of new information concerning the role that refined carbohydrates and faulty blood sugar control play in many disease processes. New terminology and descriptions are now used to describe the complex hormonal fluxes that are largely a result of the ingestion of too much refined carbohydrate. For example, the term “syndrome X” has been introduced to describe a cluster of abnormalities that owe their existence largely to a high intake of refined carbohydrate leading to the development of hypoglycemia, excessive insulin secretion, and glucose intolerance, followed by diminished insulin sensitivity leading to high blood pressure, elevated cholesterol levels, obesity, and, ultimately, type II diabetes. Syndrome X is discussed in greater detail below.

Hypoglycemia (or IPPS) is, without question, a valid clinical entity. There exists a substantial amount of information that hypoglycemia is caused by an excessive intake of refined carbohydrates.^{[10] [11]} While most medical and health organizations, as well as the US Government, have recommended that no more than 10% of the total caloric intake be derived from refined sugars that are added to foods, added sugar accounts for roughly 30% of the total calories consumed by most Americans.^[12] The average American consumes over 100 pounds of sucrose and 40 pounds of corn syrup each year. This sugar addiction plays a major role in the high prevalence of ill health and chronic disease in the US.

Health impacts of hypoglycemia

Hypoglycemia and the brain

The brain is dependent on glucose as an energy source. When glucose levels are low, as occurs during hypoglycemia, the brain dysfunction results in dizziness, headache, clouding of vision, blunted mental acuity, emotional instability, confusion, and abnormal behavior.

The association between hypoglycemia and impaired mental function is well known. What is not as well known is the effect that hypoglycemia plays in various psychological disorders. For example, despite numerous studies of depressed individuals showing a high percentage of abnormal glucose or insulin tolerance tests, rarely is hypoglycemia considered and rarely are depressed individuals prescribed dietary therapy.^[13] ^[14] There is no explanation for this oversight by so many physicians, especially since dietary therapy (usually simply eliminating refined carbohydrate from the diet) is occasionally all that is needed for effective therapy in patients who suffer from depression due to reactive hypoglycemia.

Aggressive and criminal behavior

There is a strong, yet controversial, link between hypoglycemia and aggressive or criminal behavior. Several controlled studies in psychiatric patients, and habitually violent and impulsive criminals have shown that reactive hypoglycemia (as determined by an oral glucose tolerance test) is a common finding.^[15] ^[16] Furthermore, during the GTT, abnormal and sometimes emotionally explosive behavior is often observed. In one study, reactive hypoglycemia was shown to induce fire-setting behavior in arsonists.^[17]

Several large studies involving over 6,000 inmates in 10 penal institutions in three states have now evaluated the effect of dietary intervention, i.e. the elimination of refined sugar, on antisocial or aggressive behavior.^[18] ^[19]

In the first study, 174 incarcerated juvenile delinquents were placed on a sugar-restricted diet while another 102 offenders were placed on a control diet.^[18] During the 2 year study the number of incidents of antisocial behavior was reduced by 45% in the treatment group. The most significant changes were in the reduction of assaults (83%), theft (77%), "horseplay" (65%), and refusal to obey an order (55%). Antisocial behavior changed the most in those charged with assault, robbery, rape, aggravated assault, auto theft, vandalism, child molestation, arson, and possession of a deadly weapon.

In the largest study, 3,999 incarcerated juveniles were studied over a period of 2 years.^[19] This study limited the dietary revisions to replacing sugary soft drinks with fruit juices and high-sugar snacks with non-refined carbohydrate snacks (for example, replacing a candy bar with popcorn). When the 1,121 young men on the sugar-restricted diet were compared with the 884 on the control diet, there were

significant differences: suicide attempts were reduced 100%; the need for restraints to prevent self-injury was reduced 75%; disruptive behavior was reduced 42%; and assaults and fights were reduced by 25%. Interestingly, the dietary changes did not seem to affect the behavior of female subjects. This lack of effect seems to indicate that men may react to hypoglycemia in a different manner from women. From an anthropological and evolutionary view this makes sense. Low blood sugar levels were undoubtedly an internal signal for men to hunt for food.

The link between hypoglycemia and aggressive behavior also extends to men without a history of criminal activity. In one study, a glucose tolerance test was given to a group of men who did not have a history of aggressive behavior or hypoglycemia.^[11] In these subjects a significant correlation was found between the tendency to become mildly hypoglycemic and scores on questionnaires used to measure aggression. These results indicated that aggressiveness often coincided with hypoglycemia.

Premenstrual syndrome

The premenstrual syndrome (PMS) is a recurrent condition of women characterized by troublesome, yet often

1323

ill-defined, symptoms that usually appear 7–14 days before menstruation. The syndrome affects about one-third of women between 30 and 40 years of age, about 10% of whom may have a significantly debilitating form.

An authority on PMS, Guy Abraham MD, attempted to clarify the different forms, by subdividing PMS into four distinct subgroups (A, C, D, and H).^[20] Each subgroup is linked to specific symptoms, hormonal patterns, and metabolic abnormalities (see [Ch. 183](#) for further information).

PMS-C is associated with increased appetite, craving for sweets, headache, fatigue, fainting spells, and heart palpitations. Glucose tolerance tests on PMS-C patients during the 5–10 days before their menses typically displayed a flattening of the early part of the curve and reactive hypoglycemia, whereas during other parts of the menstrual cycle their GTT was normal. A flat early part of the GTT curve usually implies excessive secretion of insulin in response to sugar consumption. This excessive secretion appears to be hormonally regulated, but other factors may also be involved.^[21] Sodium chloride ingestion enhances insulin response to sugar ingestion, and decreased magnesium levels in the pancreas can result in increased secretion of insulin in response to glucose. Regardless of the cause, women with PMS-C appear to be extremely sensitive to hypoglycemia.

Migraine headaches

Migraine headaches are probably caused by excessive dilation (expansion) of a blood

vessel in the head (see [Ch. 172](#)). Migraines are a surprisingly common disorder, affecting 15–20% of men and 25–30% of women at some time in their lives. More than half of the patients have a family history of the illness. Hypoglycemia has been shown to be a common precipitating factor in migraine headaches since 1933.^[22]

Several studies have found that eliminating refined sugar from the diet of migraine sufferers with confirmed hypoglycemia results in significant improvement. In one study of 48 migraine sufferers with reactive hypoglycemia, 27 (56%) showed a greater than 75% improvement in symptoms, 17 (35%) showed a greater than 50% improvement, and four (8%) showed a greater than 25% improvement.^[23]

Atherosclerosis, intermittent claudication and angina

There is substantial evidence that reactive hypoglycemia or impaired glucose tolerance is a significant factor in the development of atherosclerosis. Although a high sugar intake leads to elevations in triglyceride and cholesterol levels, the real culprit may be the elevations of insulin.^[24] Abnormal glucose tolerance tests and elevations in insulin secretion are common findings in patients with heart disease.^{[25] [26]}

In addition to playing a role in atherosclerosis, high sugar consumption and reactive hypoglycemia can be a cause of angina and intermittent claudication.^{[27] [28]}

Syndrome X

Syndrome X is a term used to describe a set of cardiovascular risk factors including glucose or insulin disturbances, high blood cholesterol and triglyceride levels, elevated blood pressure, and android obesity. Other terms to describe this syndrome include “the metabolic cardiovascular risk syndrome (MCVS)”, Reaven’s syndrome, insulin resistance syndrome and “atherothrombogenic syndrome”. While there is a push to abandon the term “syndrome X”, it has nonetheless persisted.^{[29] [30]}

The underlying metabolic denominator in syndrome X is elevated insulin levels. There is little doubt about what contributes to these elevations: an elevated intake of refined carbohydrate. An increased simple sugar intake leads first to hypoglycemia and later to diabetes. Adding support to the contention that prolonged consumption of refined sugars and the resulting elevations in insulin eventually lead to type II diabetes are the results from a recent 25 year study where the development of type II diabetes was shown to be preceded by elevations of serum insulin values and insulin insensitivity.^[5] In most cases these defects presented themselves decades before the development of diabetes.

Hypoglycemia, increased insulin secretion, syndrome X, and type II diabetes can be viewed as a progression of the same illness – maladaptation to the “Western diet”. The human body was not designed to handle the amount of refined sugar, salt, saturated fats, and other harmful food compounds that many people in the United States and other “Western” countries feed it. The result is that a metabolic syndrome emerges – elevated insulin levels, obesity, elevated blood cholesterol and triglycerides, and high

blood pressure.

THERAPEUTIC CONSIDERATIONS

Dietary factors

Diet control is fundamental to the successful treatment of hypoglycemia. Basically, the dietary guidelines given in [Chapter 147](#) apply here as well. A high-complex carbohydrate, high-fiber, low-sugar diet has substantial support and validation in the scientific literature as the diet of choice in the treatment of both diabetes and hypoglycemia.^[31]

Dietary carbohydrates play a central role in the cause, prevention, and treatment of hypoglycemia. Simple carbohydrates, or sugars, are quickly absorbed by the body, resulting in a rapid elevation in blood sugar, stimulating a corresponding excessive elevation in serum insulin levels. It is thought by some that the assortment

1324

of natural, simple sugars in fruits and vegetables have an advantage over sucrose and other refined sugars in that they are balanced by a wide range of nutrients that aid in the utilization of the sugars. However, of greater importance is the fact that in whole, unprocessed foods the sugars are more slowly absorbed as they are contained within cells and are associated with fiber and other food elements. Problems with carbohydrates begin when they are refined, which strips them of associated nutrients and increases their rate of absorption. Virtually all of the vitamin and trace mineral content has been removed from white sugar, white breads and pastries, and many breakfast cereals. When high sugar foods are eaten alone, blood sugar levels rise quickly, producing a strain on blood sugar control. Eating foods high in simple sugars in any form, i.e. sucrose, honey, or maple syrup, is harmful to blood sugar control. Large amounts of fruit juice and even vegetable juice may be a problem for hypoglycemics as the cell disruption characteristic of juicing increases the rate of the sugars in the juices.

Currently, more than half of the carbohydrates consumed in the US are in the form of sugars added to processed foods as sweetening agents.^[12] Patients should be instructed to read food labels carefully for clues to sugar content. Inform them of the variety of words used to describe refined simple carbohydrates; any of the following might appear on the label: sucrose, glucose, maltose, lactose, fructose, corn syrup, or white grape juice concentrate.

A closer look at simple carbohydrates

Glucose is not particularly sweet-tasting compared with fructose and sucrose. It is found in abundant amounts in fruits, honey, sweet corn, and most root vegetables. Glucose is

also the primary repeating sugar unit of most complex carbohydrates.

Fructose or fruit sugar is the primary carbohydrate in many fruits, maple syrup, and honey. Fructose is very sweet, roughly 1.5 times sweeter than sucrose. Although fructose has the same chemical formula as glucose, its structure is quite different. In order to be utilized by the body, fructose must be converted to glucose within the liver.

Many physicians have recommended that individuals with diabetes or hypoglycemia avoid fruits and fructose. However, recent research challenges this. Fructose does not cause a rapid rise in blood sugar levels. Since fructose must be changed to glucose in the liver in order to be utilized by the body, blood glucose levels do not rise as rapidly after fructose consumption as they do with other simple sugars. For example, the ingestion of sucrose results in an immediate elevation in the blood sugar level. While most diabetics and hypoglycemics cannot tolerate sucrose, most can tolerate moderate amounts of fruits and fructose without loss of blood sugar control. In fact, fructose and fruits are not only much better tolerated than white bread and other refined carbohydrates, but they also produce less sharp elevations in blood sugar levels compared with most sources of complex carbohydrates (starch).^[32] As a bonus, fructose has actually been shown to enhance the sensitivity to insulin.^[33]

Regular fruit consumption also may help to control sugar cravings and promote weight loss in overweight individuals. While studies have shown aspartame (Nutrasweet), glucose, and sucrose to increase the appetite, fructose has actually been shown to decrease the amount of calories and fat consumed in several double-blind studies. Typically, subjects will be given food or drink containing an equivalent caloric amount of fructose or other sweetener 30 minutes to 2.5 hours before allowing them to consume as much food as they desire at a dinner buffet. Consistently, subjects receiving the fructose sweetened food or drink will eat substantially fewer calories and fat compared with the groups receiving aspartame, sucrose, or glucose.^[34] ^[35] ^[36]

The glycemic index

The “glycemic index” was developed in 1981 to express the rise of blood glucose after eating a particular food.^[37] The standard value of 100 is based on the rise seen with the ingestion of glucose. The glycemic index ranges from about 20 for fructose and whole barley to about 98 for a baked potato. The insulin response to carbohydrate-containing foods is similar to the rise in blood sugar.

The glycemic index is used as a guideline for dietary recommendations for people with either diabetes or hypoglycemia (see [Table 161.5](#)). People with blood sugar problems are advised to avoid foods with high values and choose carbohydrate-containing foods with lower values. However, the glycemic index should not be the only dietary guideline. For example, while high fat foods like ice cream and sausage may have a low glycemic index because a diet high in fat has been shown to impair glucose tolerance, these foods are not good food choices for people with hypoglycemia or diabetes.

The importance of fiber

Population studies, as well as clinical and experimental data, show blood sugar disorders to be clearly related to inadequate dietary fiber intake.^{[12] [39]} These results indicate that while the intake of refined sugars should be curtailed, the intake of complex carbohydrate sources that are rich in fiber should be increased.

The term “dietary fiber” refers to the components of the plant cell wall as well as the indigestible residues from plant foods. Different types of fibers possess different actions. The water-soluble forms exert the most

1325

TABLE 161-5 -- Glycemic index of isocaloric amounts of some common foods^[38]

| | Food | Glycemic index |
|------------|----------------------|-----------------------|
| Sugars | Glucose | 100 |
| | Maltose | 105 |
| | Honey | 75 |
| | Sucrose | 60 |
| | Fructose | 20 |
| Fruits | Apples | 39 |
| | Bananas | 62 |
| | Oranges | 40 |
| | Orange juice | 46 |
| | Raisins | 64 |
| Vegetables | Beets | 64 |
| | Carrot, raw | 31 |
| | Carrot, cooked | 36 |
| | Potato, baked | 98 |
| | Potato (new), boiled | 70 |

| | | |
|-------------|--------------------|----|
| Grains | Bran cereal | 51 |
| | Bread, white | 69 |
| | Bread, whole grain | 72 |
| | Corn | 59 |
| | Cornflakes | 80 |
| | Oatmeal | 49 |
| | Pasta | 45 |
| | Rice | 70 |
| | Rice, puffed | 95 |
| | Wheat cereal | 67 |
| Legumes | Beans | 31 |
| | Lentils | 29 |
| | Peas | 39 |
| Other foods | Ice cream | 36 |
| | Milk | 34 |
| | Nuts | 13 |
| | Sausages | 28 |

beneficial effects on blood sugar control. Included in this class are hemicelluloses, mucilages, gums, and pectin substances. These types of fiber are capable of:

- slowing down the digestion and absorption of carbohydrates, thereby preventing rapid rises in blood sugar
- increasing cell sensitivity to insulin, thereby preventing the excessive secretion of insulin
- improving uptake of glucose by the liver and other tissues, thereby preventing a sustained elevation of blood sugar.

(For a full discussion of the importance of fiber, see [Ch. 57.](#))

The majority of fiber in most plant cell walls is water-soluble. Particularly good sources of water-soluble fiber are legumes, oat bran, nuts, seeds, psyllium seed husks, pears, apples, and most vegetables. Patients should be advised to consume a large amount of plant foods to obtain adequate levels of dietary fiber. A daily intake of 50 g is a healthful goal.

Chromium

Chromium is vital to proper blood sugar control as it functions in the body as a key

constituent of the “glucose tolerance factor”. Without chromium, insulin’s action is blocked and glucose levels are elevated. A chromium deficiency may be an underlying contributing factor to the tremendous number of Americans who have hypoglycemia or diabetes, or are obese.^[40] There is evidence that marginal chromium deficiency is quite common in the United States and may be responsible for many cases of reactive hypoglycemia.^[41]

In one double-blind cross-over study of eight female patients, 200 mcg of chromium (as chromium chloride) given twice daily for 3 months alleviated hypoglycemic symptoms and the glucose nadir at 2–4 hours after a glucose load.^[41] In addition, insulin binding improved and the number of insulin receptors increased.^{[42] [43]}

Lifestyle factors

Alcohol

Alcohol consumption severely stresses blood sugar control and is often a contributing factor to hypoglycemia. Alcohol induces reactive hypoglycemia by interfering with normal glucose utilization as well as increasing the secretion of insulin. The resultant drop in blood sugar produces a craving for food, particularly foods which quickly elevate blood sugar, as well as a craving for more alcohol. The increased sugar consumption aggravates the reactive hypoglycemia, particularly in the presence of more alcohol, again due to alcohol-induced impairment of normal glucose utilization and increased secretion of insulin.

Hypoglycemia is an important complication of acute and chronic alcohol abuse. Hypoglycemia aggravates the mental and emotional problems of the alcoholic and the withdrawing alcoholic with such symptoms as:^[4]

- sweating
- tremor
- rapid heart beat
- anxiety
- hunger
- dizziness
- headache
- visual disturbance
- decreased mental function
- confusion
- depression.

Although acute alcohol ingestion induces hypoglycemia, in the long run it leads to hyperglycemia and diabetes. Eventually the body becomes insensitive to the augmented insulin release caused by the alcohol. In addition, alcohol itself can cause insulin resistance even in healthy individuals.^[44] There is also evidence from large population studies that alcohol intake is strongly correlated with diabetes.^{[12] [45]} The

higher the alcohol intake, the more likely it is that an individual will have diabetes.

1326

Exercise

An appropriate exercise training program is an important part of a hypoglycemia treatment and prevention plan. Regular exercise has been well documented to prevent type II diabetes, and regular exercise improves many aspects of glucose metabolism, including enhancing insulin sensitivity and improving glucose tolerance in existing diabetics. Some of the effects of exercise on blood sugar control may stem from the fact that exercise increases tissue chromium concentrations.^[46]

THERAPEUTIC APPROACH

The primary treatment of hypoglycemia is the use of dietary therapy to stabilize blood sugar levels. Reactive hypoglycemia is not a disease, it is simply a complex set of symptoms caused by faulty carbohydrate metabolism induced by an inappropriate diet.

Diet

All simple, processed and concentrated carbohydrates must be avoided, while the consumption of complex-carbohydrate, high-fiber foods should be emphasized. Legumes should be consumed regularly. Frequent small meals may be more effective in stabilizing blood sugar levels. Alcohol must be avoided as it can cause hypoglycemia.

Supplements

The recommendations for the daily intake levels of vitamins and minerals given in [Chapter 108](#) are especially important in hypoglycemia as there are many essential nutrients critical to proper carbohydrate metabolism. The recommended levels are most easily attained by taking a multiple vitamin–mineral formula. Critically important is chromium: 200–400 µg/day.

Exercise

A graded exercise program should be developed which is appropriate to the individual's fitness level and interest, yet which elevates heart rate at least 60% of maximum for half an hour three times a week. For a full discussion, see [Chapter 38](#).

Chapter 162 - Hypothyroidism

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

DIAGNOSTIC SUMMARY

- Depression
- Difficulty in losing weight
- Dry skin
- Headaches
- Lethargy or fatigue
- Menstrual problems
- Recurrent infections
- Sensitivity to cold.

GENERAL CONSIDERATIONS

Since the hormones of the thyroid gland regulate metabolism in every cell of the body, a deficiency of thyroid hormones can affect virtually all body functions. The degree of severity of symptoms in the adult range from mild deficiency states which are not detectable with standard blood tests (subclinical hypothyroidism) to severe deficiency states which can be life-threatening (myxedema).^{[1] [2] [3] [4]}

Deficiency of thyroid hormone may be due to lack of stimulation by the pituitary gland, defective hormone synthesis or impaired cellular conversion of T_4 to T_3 . The pituitary gland regulates thyroid activity through the secretion of thyroid-stimulating hormone (TSH). The combination of low thyroid hormone and elevated TSH blood levels usually indicates defective thyroid hormone synthesis, which is defined as primary hypothyroidism. When TSH and thyroid hormone levels are both low, the pituitary gland is responsible for the low thyroid function, a situation termed secondary hypothyroidism. Normal blood thyroid hormone and TSH blood levels combined with low functional thyroid activity (as defined by a low basal metabolic rate) suggest cellular

hypothyroidism.

Most estimates on the rate of hypothyroidism are based on the levels of thyroid hormones in the blood. This may result in a large number of people with mild hypothyroidism going undetected. Nonetheless, using blood levels of thyroid hormones as the criteria, it is estimated that between 1 and 4% of the adult population have

1330

moderate to severe hypothyroidism, and another 10–12% have mild hypothyroidism.^{[1] [2] [3] [4] [5] [6] [7]} The rate of hypothyroidism increases steadily with advancing age.

Using only blood tests, thyroid function is commonly low in older adults. One study evaluated 370 elderly subjects, 60–97 years of age. About 18% of the patients already had an established history of past or current thyroid disease. Another 5.4% had a history of thyroid surgery. Of the remaining 283 patients with no history of thyroid disease, 14.6% of the women and 15.4% of the men had subclinical hypothyroidism. In other words, 40% of these elderly had current or past problems with their thyroid.^[8]

Some writers of popular books using medical history, physical examination, and basal body temperatures along with the blood thyroid levels as the diagnostic criteria estimate the rate of hypothyroidism in the general adult population to be as high as 40%.^{[9] [10]} It is likely that the true rate of hypothyroidism using these criteria is somewhere near 25% of the adult population and significantly higher in the elderly.

Causes of hypothyroidism

Overt hypothyroidism

About 95% of all cases of overt hypothyroidism are primary. In the past, the most common cause of hypothyroidism was iodine deficiency. The thyroid gland adds iodine to the amino acid tyrosine to create the thyroid hormones. Iodine deficiency leads to hypothyroidism and/or the development of an enlarged thyroid gland, i.e. a goiter.

Goiters are estimated to affect over 200 million people the world over. In all but 4% of these cases, the cause is an iodine deficiency. Iodine deficiency is now quite rare in the US and other industrialized countries due to the addition of iodine to table salt. Adding iodine to table salt began in Michigan, where in 1924 the goiter rate was an incredible 47%.

Few people in the US are now considered iodine-deficient, yet some still develop goiters. These goiters are probably a result of the excessive ingestion of goitrogens – foods which block iodine utilization. These include such foods as:

- turnips

- cabbage
- mustard
- cassava root
- soybean
- peanuts
- pine nuts
- millet.

Cooking usually inactivates goitrogens.

Currently, the most frequent cause of overt hypothyroidism in the US is the autoimmune disorder Hashimoto's disease. In this disease antibodies are formed that bind to the thyroid (specifically against the thyroid peroxidase enzyme, thyroglobulin, and TSH receptors) and prevent the manufacture of sufficient levels of thyroid hormone. In addition to binding to thyroid tissue, these antibodies may also bind to the adrenal glands, pancreas, and acid-producing cells of the stomach (parietal cells).

Functional hypothyroidism

If thyroid activity is measured by a functional test such as that developed by Broda Barnes, rather than blood thyroid hormone levels, the incidence is a surprising 25%.^[9] There are several reasons functional tests show a far greater incidence of low thyroid than blood tests. The most important is that the typical blood tests measure thyroxine (T_4), which accounts for 90% of the hormone secretion by the thyroid. However, the form that affects the cells the most is T_3 (triiodothyronine) which cells make from T_4 . If the cells are not able to convert T_4 to the four times more active T_3 , a person can have normal levels of thyroid hormone in the blood, yet be thyroid-deficient. Blood tests for T_3 were medically popular for a while, but research found they missed low thyroid function in 50% of patients.

A better way of assessing thyroid function is to measure its effects on the body. This is done by measuring a person's resting metabolic rate, which is controlled by the thyroid gland. Barnes found that measuring basal body temperature was a good way of assessing basal metabolic rate and thus the body's response to thyroid hormones, regardless of their blood level.

DIAGNOSTIC CONSIDERATIONS

Before the use of blood measurements, it was common to diagnose hypothyroidism based on basal body temperature (the temperature of the body at rest) and Achilles reflex time (reflexes are slowed in hypothyroidism). With the advent of sophisticated laboratory measurement of thyroid hormones in the blood, these "functional" tests of thyroid function fell by the wayside. However, it is now known that the routine blood tests may not be sensitive enough to diagnose milder forms of hypothyroidism in all cases. As mild hypothyroidism is the most common form of hypothyroidism, many people with hypothyroidism are going undiagnosed. The basal body temperature is

perhaps the most sensitive functional test of thyroid function.^[9] ^[10]

Clinical symptomatology

Metabolic

A lack of thyroid hormones leads to a general decrease in the rate of utilization of fat, protein, and carbohydrate.

1331

Moderate weight gain combined with sensitivity to cold weather (demonstrated by cold hands or feet) is a common finding.

Cholesterol and triglyceride levels are increased in even the mildest forms of hypothyroidism. This elevation greatly increases the risk of serious cardiovascular disease. Studies have shown an increased rate of heart disease due to atherosclerosis in individuals with hypothyroidism.^[12]

Hypothyroidism also leads to increases in capillary permeability and slow lymphatic drainage. Often this will result in swelling of tissue (edema).

Endocrine

A variety of hormonal symptoms can exist in hypothyroidism. Perhaps the most common is a loss of libido (sexual drive) in men and menstrual abnormalities in women. Women with mild hypothyroidism have prolonged and heavy menstrual bleeding, with a shorter menstrual cycle. Infertility may also be a problem. If the hypothyroid woman does become pregnant, miscarriages, premature deliveries, and stillbirths are common. Rarely does a pregnancy terminate in normal labor and delivery in the overtly hypothyroid woman.

Skin, hair, and nails

Dry, rough skin covered with fine superficial scales is seen in most hypothyroid individuals while the hair is coarse, dry, and brittle. Hair loss can be quite severe. The nails become thin and brittle and typically show transverse grooves.

Psychological

The brain appears to be quite sensitive to low levels of thyroid hormone. Depression along with weakness and fatigue are usually the first symptoms of hypothyroidism.^[13] ^[14]
^[15] Later the hypothyroid individual will have difficulty concentrating and be extremely

forgetful.

Muscular and skeletal

Muscle weakness and joint stiffness are predominate features of hypothyroidism.^[16] Some individuals with hypothyroidism may also experience muscle and joint pain, and tenderness.^[17]

Cardiovascular

Hypothyroidism is thought to predispose one to hardening of the arteries (atherosclerosis) due to the increase in cholesterol and triglycerides.^{[12] [13] [14]} Hypothyroidism can also cause hypertension, reduce the function of the heart, and reduce heart rate.

Other manifestations

Shortness of breath, constipation, and impaired kidney function are some of the other common features of hypothyroidism.

Several diseases have been shown to be associated with low thyroid function, even some which seem to have no apparent relationship. For example, one study compared the thyroid function of 56 patients suffering from dermatitis herpetiformis with that of 26 control subjects. The patients with dermatitis herpetiformis had significantly increased abnormalities of thyroid function tests (32% vs. 4%), with significant hypothyroidism being the most common abnormality affecting 12 of the 56 patients.^[18]

Laboratory evaluation

The diagnosis of hypothyroidism by laboratory methods is primarily based on the results of total T_4 , free T_4 , T_3 , and TSH levels (see [Table 162.1](#) for normal levels). The diagnosis is straightforward in overt cases. In subclinical cases the diagnosis is not so clear. An elevation in TSH with a normal T_4 level is generally considered as subclinical. The accepted normal range is extremely broad, 0.35–5.50 $\mu\text{IU/ml}$. In conventional circles, treatment is not recommended unless the TSH is greater than 10 $\mu\text{IU/ml}$. Given the importance of adequate thyroid hormone to human health, our recommendation is more aggressive. If the patient does not respond to nutritional intervention, we recommend low-dose thyroid hormone therapy (detailed below) in patients with TSH values greater than 2.5 $\mu\text{IU/ml}$ – slightly higher than the accepted level of 2.0 $\mu\text{IU/ml}$ demonstrating disturbance of the thyroid–pituitary axis – especially in the presence of anti-thyroid antibodies.

Functional assessment

Functional thyroid activity, as indicated by basal metabolic rate, can be estimated by measuring basal body temperature. According to Barnes, the normal basal body

temperature is 97.6–98.2°F. However, Barnes' approach can also be in error, as a low basal metabolic rate could also indicate nutritional deficiencies, inadequate physical activity, etc., while fever from an infection or other disease can result in an inaccurately high body temperature.

TABLE 162-1 -- Serum thyroid hormone normal values

| | |
|---------------------|------------------|
| T ₄ | 4.8–13.2 µg/dl |
| Free T ₄ | 0.9–2 ng/dl |
| T ₃ | 80–220 ng/dl |
| TSH | 0.35–5.50 µIU/ml |

1332

Patient instructions for taking basal body temperature are provided in [Appendix 8](#).

THERAPEUTIC CONSIDERATIONS

[Figure 162.1](#) provides an algorithm for managing hypothyroid patients that combines clinical evaluation, basal body temperature, and laboratory evaluation.

Nutritional considerations

It is important to nutritionally support the thyroid gland by ensuring adequate intake of key nutrients required in the manufacture of thyroid hormone and by avoiding goitrogens.

Iodine, tyrosine, and goitrogens

Thyroid hormones are made from iodine and the amino acid tyrosine. The recommended dietary allowance (RDA) for iodine in adults is quite small, 150 mcg. The average intake of iodine in the United States is estimated to be over 600 mcg/day. Too much iodine can actually inhibit thyroid gland synthesis. For this reason and because the only function of iodine in the body is for thyroid hormone synthesis, it is recommended that dietary levels or supplementation of iodine not exceed 600 mcg/day for any length of time.

Deficiencies of iodine intake are rare since the addition of iodine to salt. However, goitrogens can induce an iodine deficiency by combining with the iodine and making it unavailable to the thyroid. These foods include brassica family foods (turnips, cabbage, rutabagas, mustard greens, radishes, horseradishes), cassava root, soybeans, peanuts, pine nuts, and millet.^[19] In general, cooking inactivates these goitrogens. This is not to suggest that these foods should not be eaten, but rather that they should not be eaten in

excess.

Vitamins and minerals

Zinc, vitamin E and vitamin A function together in many body processes including the manufacture of thyroid

Figure 162-1 Hypothyroidism diagnosis flowchart.

1333

hormone. A deficiency of any of these nutrients would result in lower levels of active thyroid hormone being produced. Low zinc levels are common in the elderly, as is hypothyroidism.^[20] There may be a correlation. The B vitamins riboflavin (B₂), niacin (B₃), and pyridoxine (B₆), and vitamin C are also necessary for normal thyroid hormone manufacture.

The trace minerals zinc, copper, and selenium are the required cofactors for iodothyronine iodine, the enzyme which converts T₄ to the far more active T₃. There are several different forms of this enzyme, each requiring a different trace mineral. Supplementation with zinc (the second most common mineral deficiency) has been shown to re-establish normal thyroid function in hypothyroid patients who were zinc-deficient, even though they had normal serum T₄ levels.^[21]

Similarly, selenium supplementation may be important, as those living in areas of the world where selenium is deficient have a greater incidence of thyroid disease.^[22] Of particular significance is the fact that while a selenium deficiency does not decrease the conversion of T₄ to T₃ in the thyroid or the pituitary, it does result in a great decrease in this conversion in the other cells of the body.^[23] People with a deficiency of selenium have elevated levels of T₄ and TSH. Supplementation with selenium results in a decrease in T₄ and TSH and normalization of thyroid activity.^[24] Selenium is deficient in about 50% of people's diets, which may account for the large number of people with low thyroid activity.^[25] This research appears to clearly demonstrate that a selenium deficiency results in low thyroid activity in the cells even though hormone levels are normal or even elevated, and provides some support for Barnes' contentions.

Exercise

Exercise is particularly important in a treatment program for hypothyroidism. Exercise stimulates thyroid gland secretion and increases tissue sensitivity to thyroid hormone. Many of the health benefits of exercise may be a result of improved thyroid function.

The health benefits of exercise are especially important in overweight hypothyroid individuals who are dieting. A consistent effect of dieting is a decrease in the metabolic rate as the body strives to conserve fuel. Exercise has been shown to prevent the decline in metabolic rate in response to dieting.^[26]

Thyroid hormone replacement

If nutritional and lifestyle intervention are inadequate to re-establish normal thyroid activity, prescription of thyroid hormones is necessary. Although synthetic hormones have become popular, many physicians (particularly naturopathic physicians) still prefer the use of desiccated natural thyroid, complete with all thyroid hormones, not just thyroxine.

Several thyroid hormone preparations are available, each with advantages and disadvantages. The advantages of preparations containing only T_4 (e.g. Synthroid, Levothyroid, etc.) are that it provides consistent potency and prolonged duration of action. T_3 is rarely used alone as thyroid hormone replacement therapy, as it is roughly four times more potent with a shorter duration of action than T_4 , making it difficult to work with. The advantage of desiccated thyroid is that it provides both T_4 and T_3 , and relevant amino acids and micronutrients. The main drawback with natural thyroid is that it lacks consistency. However, according to the *United States Pharmacopoeia (USP)*, these preparations must contain not less than 85% and not more than 115% of the labeled amount of T_4 , and not less than 90% and not more than 110% for T_3 . The labeled amount is 38 mcg of T_4 and 9 mcg T_3 per grain (65 mg). Synthetic mixtures of T_4 and T_3 (e.g. Liotrix, Thyrolar) in similar ratios are available which provide the consistency that whole, natural desiccated thyroid is thought to lack.

The equivalencies of the thyroid agents based on clinical response are as follows:

- 100 mcg of T_4 (e.g. Synthroid)
- 20–25 mcg T_3 (e.g. Cytomel)
- 1 grain desiccated thyroid
- 12.5 mcg T_4 + 50 mcg T_4 (e.g. Thyrolar).

These values for the different forms of thyroid hormones will be referred to below as 1 “thyroid unit”. Therefore, 0.5 thyroid units would be equal to 50% of the values shown in the list.

THERAPEUTIC APPROACH

Treatment of hypothyroidism should begin with optimization of the nutrients needed not only for thyroid hormone production, but also for the critical cellular conversion of T_4 to T_3 . If, after a few months, the patient does not respond, then thyroid hormone replacement is indicated.

Diet

The diet should be low in goitrogens and high in foods rich in the trace minerals needed for thyroid hormone production and activation. Goitrogens to be limited include brassica family foods (turnips, cabbage, rutabagas, mustard greens, radishes, horseradishes), cassava root, soybeans, peanuts, pine nuts, and millet. When eaten, these foods should be cooked to break down their goitrogenic constituents. Good sources of iodine include sea fish, sea vegetables (kelp, dulse, arame, hijiki, nori, wakame, kombu) and iodized salt. Good sources of zinc include

1334

seafood (especially oysters), beef, oatmeal, chicken, liver, spinach, nuts, and seeds. Copper is found in liver and other organ meats, eggs, yeast, beans, nuts, and seeds. Finally, the best sources of the B vitamins are yeast, whole grains, and liver. The best source of selenium is Brazil nuts, especially those that are unshelled. Organically grown foods should be recommended due to their higher levels of trace minerals.

Supplements

- Zinc: 25 mg/day
- Copper: 5 mg/day
- Selenium: 200 mcg/day.

Thyroid hormones

Treatment should begin at levels ranging from 0.5 to 2 thyroid units (see above) daily based upon the patient's size and serum hormone levels. Re-evaluation of basal body temperature, TSH, T_4 , T_3 , and free T_4 levels 4–6 weeks after initiating therapy is recommended, with the treatment goal being to normalize basal body temperature as well as serum hormone levels. After stabilization of dosage, periodic evaluations are based on the individual patient's needs or are recommended to be carried out at least once a year.

In the treatment of subclinical hypothyroidism, the dosage should be no more than 0.5

thyroid units daily for at least the first 3 months of treatment.

Thyroid hormone replacement therapy is recommended to be taken on an empty stomach to increase absorption. The patient should avoid taking thyroid at the same time as other medications and supplements (especially those containing iron) which may affect absorption. Once-a-day dosage generally produces stable increases in thyroid hormone levels.

The dosage of thyroid hormone during pregnancy will likely have to be increased due to the effects that estrogens have on increasing serum thyroid hormone binding globulin – thereby reducing the level of free thyroxine. Careful monitoring is required during pregnancy. Typically, dosage requirements increase by 30–50% during pregnancy and return to pre-pregnancy levels shortly after delivery.

Chapter 163 - Inflammatory bowel disease (Crohn's disease and ulcerative colitis)

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

DIAGNOSTIC SUMMARY

Crohn's disease

- Intermittent bouts of diarrhea, low-grade fever, and right lower quadrant pain
- Anorexia, weight loss, flatulence, and malaise
- Abdominal tenderness, especially in the right lower quadrant, with signs of peritoneal irritation and an abdominal or pelvic mass
- X-rays show abnormality of the terminal ileum.

Ulcerative colitis

- Bloody diarrhea with cramps in the lower abdomen
- Mild abdominal tenderness, weight loss, and fever
- Rectal examination may show perianal irritation, fissures, hemorrhoids, fistulas, and abscesses
- Diagnosis confirmed by X-ray and sigmoidoscopy.

GENERAL CONSIDERATIONS

Definition

Inflammatory bowel disease (IBD) is a general term for a group of chronic inflammatory disorders of the bowel. It is divided into two major categories: Crohn's disease and ulcerative colitis. Clinically, IBD is characterized by recurrent inflammatory involvement of specific intestinal segments resulting in diverse clinical manifestations.

Crohn's disease

Crohn's disease is characterized by a granulomatous inflammatory reaction throughout the entire thickness of the bowel wall. In approximately 40% of cases, however, the granulomas are either poorly developed or totally absent. The original description in 1932 by Crohn and colleagues localized the disease to segments in the ileum. However, the same granulomatous process may involve the buccal mucosa, esophagus, stomach, duodenum,

1336

jejunum, and colon. Crohn's disease of the small intestine is also known as regional enteritis, while involvement of the colon is known as Crohn's disease of the colon or granulomatous colitis. The latter term is less accurate as only a portion of the patients develop granulomatous lesions.

Ulcerative colitis

In ulcerative colitis there is a non-specific inflammatory response limited largely to the colonic mucosa and submucosa. Well-developed granuloma formation does not occur. Crohn's disease and ulcerative colitis do share many common features and, where appropriate, will be discussed together. Otherwise they will be discussed as separate entities.

Common features shared by Crohn's disease and ulcerative colitis

- The colon is frequently involved in Crohn's disease and is invariably involved in ulcerative colitis.
- Although rare, patients with ulcerative colitis who have total colon involvement may develop a so-called "backwash ileitis". Thus, both conditions may cause changes in the small intestine.
- Patients with Crohn's disease often have close relatives with ulcerative colitis, and vice versa.
- When there is no granulomatous reaction in Crohn's disease of the colon, the two lesions may resemble each other clinically as well as pathologically.
- There are many epidemiological similarities between the two diseases, including age, race, sex, and geographic distribution.
- Both conditions are associated with similar extraintestinal manifestations.
- There appear to be etiological parallels between the two conditions.
- Both conditions are associated with an increased frequency of colonic carcinoma.

Etiology

The epidemiological and etiological data on ulcerative colitis and Crohn's disease are

quite similar.^{[1] [2]} The incidence and prevalence of the two diseases differ slightly, with most studies showing ulcerative colitis to be more common. The current estimate of the incidence of ulcerative colitis in western Europe and the United States is approximately six to eight cases per 100,000, and the estimated prevalence is approximately 70–150 cases per 100,000. The estimate for the incidence of Crohn's disease is approximately two cases per 100,000, while the prevalence is estimated at 20–40 per 100,000. The incidence of Crohn's disease is increasing in Western cultures.^{[3] [4]}

IBD may occur at any age, but most often it occurs between the ages of 15 and 35. Females are affected slightly more frequently than males. Caucasians develop the disease two to five times more often than Blacks or Orientals, while Jews have a three- to sixfold higher incidence compared with non-Jews.^{[1] [2] [3] [4]}

Theories about the etiology of IBD can be divided into several groups:^{[1] [2]}

- genetic predisposition
- infectious agent or agents
- immunologic abnormality
- dietary factors
- an assortment of miscellaneous concepts implicating psychosomatic, vascular, traumatic, and other mechanisms.

Genetic predisposition

Although the search for a specific genetic marker for IBD has been futile, several factors suggest a genetic predisposition. As already mentioned, IBD is two to four times more common in Caucasians than in non-Caucasians, and four times more common in Jews than in non-Jews. In addition, multiple members of a family have Crohn's disease or ulcerative colitis in 15–40% of the cases.^{[1] [2]}

Infectious etiology

Many microorganisms have been hailed as putative causes of IBD, but in spite of numerous attempts to confirm a bacterial, mycobacterial, fungal, or viral etiology, the idea that a transmissible agent is responsible for IBD is still a hotly debated subject. Viruses, such as rotavirus, Epstein–Barr virus, cytomegalovirus, and an uncharacterized RNA intestinal cytopathic virus, and mycobacteria continue to be favored candidates. Other candidates include:^{[1] [2] [5] [6] [7]}

- *Pseudomonas*-like organisms
- enteric anaerobes
- *Chlamydia*
- *Yersinia enterocolitica*.

Antibiotic exposure

Antibiotic exposure is being linked to Crohn's disease.^[1] Prior to the 1950s, Crohn's

disease was found in selected groups with a strong genetic component. Since this time there has been a rapid climb in developed countries, particularly in the United States, and in countries that previously had virtually no reported cases. In fact, since

1337

1950 Crohn's disease has spread like an epidemic. Are antibiotics to blame? Penicillin and tetracycline have been available in oral form since 1953. The annual increase in prescriptions of antibiotics parallels the increase in the annual incidence of Crohn's disease. Comparative statistics have shown that wherever antibiotics are used early and in large quantities, the incidence of Crohn's disease is now quite high.

Over the years researchers have sought to identify Crohn's disease as an infectious process. The problem may be that the infectious agent may be a component of the normal intestinal flora which suddenly produces immunostimulatory toxins or becomes invasive as a direct result of sublethal doses of antibiotics. Administration of sublethal amounts of antibiotics has been shown to induce a capacity for toxin production in intestinal organisms. When microbes are not given a full lethal dose, their usual response is to adapt and become even stronger in virility and numbers.

Immune mechanisms

An overwhelming amount of evidence points to immunologic derangements in IBD, but whether they are causal or secondary phenomena remains unclear. Theories relating humoral mechanisms, immunological deficiencies, and cell-mediated reactions in the etiology of IBD have all been proposed, but the current evidence seems to indicate that these derangements are probably secondary to the disease process.^{[1] [2]}

Dietary factors

Despite the fact that a dietary etiology of Crohn's disease is hardly considered (if mentioned at all) in most standard medical and gastroenterology texts, several lines of evidence strongly support dietary factors as being the most important etiologically.^{[8] [9] [10] [11] [12] [13] [14] [15] [16] [17] [18] [19] [20]}

The incidence of Crohn's disease is increasing in cultures consuming the "Western" diet, while it is virtually non-existent in cultures consuming a more primitive diet.^{[8] [9] [10] [11] [12] [13]} As food is the major factor in determining the intestinal environment, the considerable change in dietary habits over the last century could explain the rising incidence. Several studies which analyzed the pre-illness diet of patients with Crohn's disease have found that people who develop Crohn's disease habitually eat more refined sugar, and less raw fruit and vegetables and dietary fiber than healthy people.^{[8] [9] [10] [11] [12]} In one study, the pre-illness intake of refined sugar in Crohn's disease patients was nearly twice that of controls (122 g/day versus 65 g/day).^[12] One researcher found that before the onset of disease, Crohn's disease patients had eaten corn flakes more frequently than controls.^[21] Although other researchers could not verify

this specific finding, corn flakes are high in refined carbohydrates and are derived from a very common allergen (corn).

Much of controversy over the role of pre-illness diet in the etiology of Crohn's disease is largely due to the fact that the only way to assess this diet is from post-diagnostic interviews. Studies where the interview has taken place within the first 6 months of diagnosis tend to be more supportive than studies done more than 7 months after diagnosis. In contrast, patients with ulcerative colitis do not show an increased consumption of refined carbohydrate when compared with controls.^[22]

Another important dietary factor that is entirely overlooked in the standard texts is the role of food allergy. Support for this hypothesis is offered in clinical studies which have utilized an elemental diet, total parenteral nutrition, or an exclusion diet with great success in the treatment of IBD.^{[14] [15] [16] [17] [18] [19]} The role of food allergy is discussed in greater detail in the "Therapeutic considerations" section ([p. 1338](#)), as is the effect of dietary fiber in the etiology and treatment of IBD.

A reduced intake of omega-3 oils and an increased intake of omega-6 oils is also being linked to the growing rise of Crohn's disease in Japan. Since the genetic background of the Japanese is relatively homogenous, this increased incidence is most likely due to the incorporation of "Western" foods in the diet. To examine the role of diet in contributing to the increased incidence of Crohn's disease in Japan, the incidence and daily intake of a number of dietary components was compared annually from 1966 to 1985. The analysis showed that the increased incidence of Crohn's disease was strongly correlated with increased dietary intake of total fat, animal fat, omega-6 fatty acids, animal protein, milk protein, and the ratio of omega-6 to omega-3 fatty acids. It was less correlated with intake of total protein, was not correlated with fish protein, and was inversely correlated with vegetable protein. Multivariate analysis showed that increased intake of animal protein was the strongest independent factor followed by an increased ratio of omega-6 to omega-3 fatty acids.^[20] Correction of this increased ratio by reducing the intake of omega-6 while increasing omega-3 oils may lead to significant clinical benefit by impacting eicosanoid metabolism (discussed below).

Miscellaneous factors

Psychosomatic factors, primary vascular disease within mural arteries or arterioles, and chronic trauma have received consideration in the etiology of IBD, but at present are not considered significant pathogenic mechanisms.^{[1] [2]} While there is little evidence directly relating psychological factors to the initiation of IBD, there is little doubt that emotional factors are important in modifying the course of the disease.

THERAPEUTIC CONSIDERATIONS

Inflammatory bowel disease is the end result of a complex interplay of several factors.

The following is a discussion of the key nutritional, microbial, and toxic issues which must be addressed for the successful management of this difficult disease.

Control of causative factors

Natural history of Crohn's disease

Little is known concerning the natural course of Crohn's disease, as virtually all patients with the disease undergo standard medical care (drugs and/or surgery) or alternative therapy. The only exceptions are those patients in clinical trials who are assigned to the placebo group.^{[23] [24] [25]} However, even these patients do not represent the natural course of the disease, since they are frequently seen by physicians and other members of a health care team and are taking medication, even if it is only in the form of a placebo. If proper evaluation of therapies for IBD is to occur, there must be a greater understanding of its natural history. This is particularly important for alternative practitioners, as it is commonly believed that standard medical care often interferes with the normal efforts of the body to restore health. Some aspects of the "natural" course of Crohn's disease support this idea, especially when coupled with the limited efficacy of current medications and surgery and their known toxicity. However, heroic measures do have their place in many instances and should be used when appropriate.

Researchers in the National Cooperative Crohn's Disease Study (NCCDS) reviewed 77 patients who received placebo therapy in part 1 of the 17 week study.^{[23] [24]} They all had active disease, as defined by a Crohn's disease activity index (CDAI) (see [Appendix 3](#)), of above 150. Of the patients completing the study:

- none died
- only seven (9%) suffered a major worsening of their disease (i.e. either they developed a major fistula or required abdominal surgery)
- 25 (32%) suffered a lesser worsening (increase in the CDAI to >450 or presence of fever of 100°F for 2 weeks)
- 25 (32%) were considered failures, as their CDAI remained >150
- 20 patients (26%) achieved clinical remission.

On at least one occasion during the 17 weeks of therapy, 49% of the patients were found to have a CDAI of <150.

The patients who responded favorably to the placebo continued to be observed on placebo therapy for up to 2 years (part 1, phase 2). It is interesting to note that while none of these patients' X-rays worsened during phase 1 or phase 2, 18% showed improvement on their intestinal X-rays. Of the patients responding to placebo (20; 26% of the 77), the majority (70%) remained in remission at one year, and a fair number (45%) remained in remission at 2 years. These results indicate that many patients will undergo spontaneous remission, approximately 20% at 1 year and 12% at 2 years. However, when another factor is considered, the "success" of placebo therapy rises dramatically. In patients having no previous history of steroid therapy, 41% achieved remission after 17 weeks. In addition, 23% of this group continued in remission after 2

years, compared with only 4% of the group with a prior history of steroid use.

The European Cooperative Crohn's Disease Study (ECCDS), although different in some methodological details, is quite similar to the NCCDS.^{[23] [25]} In the ECCDS, 110 patients constituted the placebo group, 68 patients with prior treatment and 42 patients with no prior treatment. The results of the study indicated that 55% of the total placebo group achieved remission by 100 days, 34% remained in remission at 300 days, and 21% remained in remission at 700 days. Like the NCCDS, the ECCDS demonstrated that patients with no prior therapy have an increased likelihood of remission.

While one group of researchers did not advocate placebo therapy, they did carefully point out that once remission is achieved, 75% of the patients will continue in remission at the end of 1 year and up to 63% by 2 years, regardless of the maintenance therapy used. These results would suggest that the key is achieving remission, which, once attained, can be maintained by conservative non-drug therapy rather than the "medicines we are currently using with their limited efficacy and known toxicity".^[23]

Eicosanoid metabolism in IBD

Prostaglandin levels are greatly increased in the colonic mucosa, serum, and stools of patients with IBD. Specifically, these patients show an increase in the synthesis of the lipoxygenase products, leukotrienes, and mono HETEs.^{[26] [27] [28] [29]} These compounds are produced by neutrophils and are known to amplify the inflammatory process and cause smooth muscle contraction. Release of lipoxygenase products is promoted by activation of the alternative complement pathway. The therapeutic efficacy of sulfasalazine and corticosteroids is due to their effect on eicosanoid metabolism. Sulfasalazine is an inhibitor of both cyclooxygenase and neutrophil lipoxygenase, while corticosteroids inhibit phospholipase A₂ and thus block the release of arachidonic acid from the membrane phospholipid pool. Sulfasalazine also inhibits the degranulation of mast cells. Several naturally occurring compounds, such as the flavonoid quercetin, also interact with these enzymes.

The formation of these inflammatory compounds can be decreased by reducing or eliminating the consumption of meat and dairy while increasing the consumption of omega-3 fatty acids by increasing the intake of cold-water

fish like salmon, mackerel, herring, and halibut. These fish are good sources of the longer-chain omega-3 fatty acids eicosapentaenoic acid (EPA) and docosahexanoic acid (DHA). Double-blind studies with fish oil supplements (2.7–5.1 g total omega-3 oils) have demonstrated an ability to prevent or delay relapses in both Crohn's disease and ulcerative colitis.^{[30] [31]} Flaxseed oil is also of value. Flaxseed oil contains alpha-linolenic acid, the essential omega-3 fatty acid which the body can convert to EPA.^[32]

Mucin defects in ulcerative colitis

Mucins are an ill-defined class of high molecular weight, carbohydrate-rich (85% by weight of *N*-acetylgalactosamine, galactose, sialic acids, *N*-acetylglucosamine, and fucose) glycoproteins that are thought to be largely responsible for the viscous and elastic characteristics of secreted mucus. Alterations in mucin composition and content in the colonic mucosa have been reported in patients with ulcerative colitis.^{[32] [33] [34] [35]} The factors responsible for this appear to be a dramatic decrease in the mucous content of the goblet cells (proportional to the severity of the disease) and a decrease in the major sulfomucin subfraction (designated species IV according to DEAE-cellulose differentiation). In contrast, these abnormalities are not found in patients with Crohn's disease. It is significant that while the mucin content of the goblet cells returns to normal during remission, the sulfomucin deficiency does not. The specific components of the sulfomucin and the cause of its lower concentration have not yet been determined. These mucin abnormalities are also thought to be a major factor in the increased risk of colon cancer in these patients.

Many of the herbs used historically in the treatment of ulcerative colitis are demulcents, i.e. agents that soothe irritated mucous membranes and promote the secretion of mucus. This effect appears to be very much indicated and supports the use of demulcents in ulcerative colitis.

Intestinal microflora

The intestinal microflora is extraordinarily complex and contains over 400 distinct microbial species.^{[5] [6]} Accurate simultaneous quantification of all possible species is not possible with current conventional culture techniques. In addition, measurement techniques such as stool cultures do not indicate bacterial metabolic activity, locations of growth within the gastrointestinal tract, or turnover rates. These latter factors may prove to be the more important determinants of the role of the intestinal bacterial flora in IBD than the actual numbers of specific bacterial species. In an effort to describe a non-specific (qualitative or quantitative) alteration in the intestinal flora, the term dysbiosis is often used (see [Chs 7](#) and [9](#) for a full discussion of this important topic).^[5]

The fecal flora of patients with IBD has been found to contain higher numbers of Gram-positive anaerobic coccoid rods and *Bacteroides vulgatus*, a Gram-negative rod.^[5] Studies have indicated that these alterations in fecal flora are not secondary to the disease, and alterations in the metabolic activity of the various bacteria are thought to be more important than alterations in the number of bacteria *per se*. In addition, it is thought that specific bacterial cell components (which vary even within the same species) are responsible for promoting lymphocyte cytotoxic activity against the colonic epithelial cells.^{[5] [6]}

Carrageenan

It is very interesting to note that researchers investigating the intestinal flora of

ulcerative colitis often use the carrageenan (a sulfated polymer of galactose and D-anhydrogalactose extracted from red seaweeds, principally *Eucheuma spinosum* or *Chondrus crispus*) model to experimentally induce the disease in animals. In the initial experiments reported by Marcus & Watt^[36] in 1969, 1 and 5% carrageenan solutions were provided as the exclusive source of oral fluids for guinea pigs. Over a period of several days the animals lost weight, developed anemia, and had bloody diarrhea. Gross anatomical studies after sacrifice at 20 and 45 days revealed a loss of haustral folds, mucosal granularity, pseudopolyps, and strictures, while microscopic examination revealed crypt abscesses, lymphocytic infiltration, capillary congestion of the lamina propria, and gross ulcerations. These results have since been confirmed by numerous investigators and in studies involving other animal species, including primates.^{[5] [37] [38] [39]}

In its native state this polymer has a molecular weight of 100,000–800,000, but in the studies it is degraded by mild acidic hydrolysis to yield products with weights in the vicinity of 30,000. Carrageenan compounds are used by the food industry as stabilizing and suspending agents, with different molecular weight polymers being used for a variety of purposes. Typically, carrageenans used in the food industry have a molecular weight greater than 100,000. Carrageenan is widely used in milk and chocolate milk products (ice cream, cottage cheese, milk chocolate, etc.) due to its ability to stabilize milk proteins.

As suggestive as the animal studies are in linking ulcerative colitis with carrageenan, and despite the increased consumption of carrageenan in Western diets, there appears to be no correlation between human consumption of carrageenan and development of ulcerative colitis at this time. No lesions of IBD were observed in healthy human subjects fed enormous quantities of degraded carrageenan.^[40] However, differences in intestinal bacterial flora are probably responsible for this discrepancy, as germ-free animals do not display carrageenan-induced damage.

Upon further examination, it was discovered that

the bacteria that has been linked to facilitating the carrageenan-induced damage in animals is a strain of *Bacteroides vulgatus*.^[5] As mentioned earlier, this organism is found in much higher concentrations (six times as high) in the fecal cultures of patients with IBD. When all the data are evaluated, they appear to imply that while carrageenan can be metabolized into non-damaging components in most human subjects, those individuals with an overgrowth of *Bacteroides vulgatus* may be at risk. Strict avoidance of carrageenan appears warranted at this time for patients with IBD until further research clarifies its safety for these patients.

Aspirin and intestinal permeability

A very interesting study evaluated 30 patients with Crohn's disease and 37 first-degree relatives of the patients with Crohn's disease for intestinal permeability using the

lactulose–mannitol ratio. First-degree relatives had a 110% increase in intestinal permeability after acetylsalicylic acid compared with an increase of 57% in the controls. Thirty-five percent were hyper-responders.^[94] A familial permeability defect would be a significant predisposing factor for Crohn's disease as a leaky gut is associated with increased incidence of food allergy and increased absorption of intestinal toxins (see [Ch. 21](#)).

Endotoxemia and the alternative complement pathway

Endotoxemia is associated with both Crohn's disease and ulcerative colitis.^{[41] [42]} Endotoxemia-induced activation of the alternative complement pathway could explain some of the extra-gastrointestinal manifestations of IBD (discussed below). Whole gut irrigation significantly reduces the endotoxin pool in the gut and has been shown to have a very beneficial anti-endotoxemia effect.^[43] Colonic irrigation may offer similar benefit. However, colon irrigation during an acute inflammatory flare may be contraindicated.

Extra-gastrointestinal manifestations

Over 100 disorders, known as extraintestinal lesions (EILs), constitute a diverse group of systemic complications of IBD.^{[2] [44] [45]} The most common EIL in adults is arthritis, which is found in about 25% of patients. Two types are typically described, the more common being peripheral arthritis affecting the knees, ankles, and wrists. Arthritis is more frequently found in patients with colon involvement. Severity of symptoms is typically proportional to disease activity.^{[2] [44] [45]}

Less frequently, the arthritis affects primarily the spine. Symptoms are low back pain and stiffness, with eventual limitation of motion. This EIL occurs predominantly in males with HLA-B₂₇ and is fairly indistinguishable from typical ankylosing spondylitis. In fact, it may antedate the bowel symptoms by several years. There is probably a consistent underlying factor in both the progression of ankylosing spondylitis and IBD.^{[2] [44] [45]}

Skin manifestations are also common, being seen in approximately 15% of patients. Typical lesions are erythema nodosum, pyoderma gangrenosum, and aphthous ulcerations. Recurrent aphthous stomatitis occurs in approximately 10% of the patients.^{[2] [44] [45]}

Serious liver disease (i.e. sclerosing cholangitis, chronic active hepatitis, cirrhosis, etc.) is also a common EIL, affecting 3–7% of the patients with IBD. This probably relates to the increased endotoxin load associated with IBD. If patients are demonstrating liver enzyme abnormalities, hepatoprotection appears indicated, with substances such as *Glycyrrhiza glabra*, *Silybum marianum*, catechin, and curcumin.^{[46] [47] [48]}

Other common EILs are:^{[2] [44] [45]}

- thrombophlebitis
- finger clubbing
- ocular manifestations (episcleritis, iritis, and uveitis)

- nephrolithiasis
- cholelithiasis
- (in children) failure to grow, thrive, and mature normally.

Malnutrition

Many nutritional complications occur during the course of IBD.^{[49] [50] [51]} As these can have a significant influence on the morbidity, and perhaps also the mortality, of these patients, every effort should be made to ensure optimal nutritional status. The major mechanisms that contribute to nutritional depletion in these patients are listed in [Table 163.1](#).

A decreased food intake is the most important mechanism of nutritional deficiency in these patients, and a deficient calorie intake is the most common nutritional deficit in patients requiring hospitalization. Often the patient feels significant pain, diarrhea, nausea, and/or

TABLE 163-1 -- Causes of malnutrition in inflammatory bowel disease

| |
|--|
| • Decreased oral intake |
| —disease-induced (pain, diarrhea, nausea, anorexia) |
| —iatrogenic (restrictive diets without supplementation) |
| • Malabsorption |
| —decreased absorptive surface due to disease or resection |
| —bile salt deficiency after resection |
| —bacterial overgrowth |
| —drugs (e.g. corticosteroids, sulfasalazine, cholestyramine) |
| • Increased secretion and nutrient loss |
| —protein-losing enteropathy |
| —electrolyte, mineral, and trace mineral loss in diarrhea |
| • Increased utilization and increased requirements |
| —inflammation, fever, infection |
| —increased intestinal cell turnover |

other symptoms after a meal, resulting in a subtle diminution in dietary intake. Weight loss is prevalent in 65–75% of IBD patients.^[49]

Malabsorption can be anticipated in patients with extensive mucosal involvement of the

small intestine and in patients who have had resection of segments of the small intestine. Particularly common is fat malabsorption, resulting in significant caloric loss and loss of fat-soluble vitamins and minerals. Involvement of the ileum or resection of that area typically results in bile acid malabsorption. Because of the cathartic effect of bile acids on the colon, this may result in a chronic watery diarrhea. Electrolyte and trace mineral deficiency should be suspected in patients with a history of chronic diarrhea, while calcium and magnesium deficiency may be a result of chronic steatorrhea.

Increased secretion and nutrient loss due to the exudative and inflammatory nature of IBD often occur. In particular, there is a significant loss of plasma proteins across the damaged and inflamed mucosa. The loss of protein may exceed the ability of the liver to replace plasma proteins, despite a high protein intake. The chronic loss of blood often leads to iron depletion and anemia.

The most common drugs used in the allopathic treatment of IBD are corticosteroids and sulfasalazine, both of which increase nutritional needs. Corticosteroids are known to:

- stimulate protein catabolism
- depress protein synthesis
- decrease the absorption of calcium and phosphorus
- increase the urinary excretion of ascorbic acid, calcium, potassium, and zinc
- increase blood glucose, serum triglycerides, and serum cholesterol
- increase the requirements for vitamin B₆, ascorbic acid, folate, and vitamin D
- decrease bone formation
- impair wound healing.

Sulfasalazine has been shown to:^[52]

- inhibit the absorption and transport of folate
- decrease serum folate and iron
- increase the urinary excretion of ascorbic acid.

The last consideration in the causes of nutrient deficiency in IFB patients is the nutritional consequences of a chronic inflammatory and/or infectious disease. This topic has not been fully investigated, and the only conclusion that currently can be made is that protein requirement may be increased in patients with acute exacerbations of IBD. An elevated sedimentation rate signifies an increase in both protein breakdown and synthesis. Typically, patients with IBD require perhaps as much as 25% more protein than the usual recommended allowance.^{[49] [50] [51]}

TABLE 163-2 -- Prevalence of nutritional deficiency in hospitalized patients with inflammatory bowel disease^[49]

| Deficiency | Prevalence (%) |
|-----------------|----------------|
| Hypoalbuminemia | 25–80 |
| Anemia | 60–80 |

| | |
|-----------------------------------|-------|
| Iron deficiency | 40 |
| Low serum vitamin B ₁₂ | 48 |
| Low serum folate | 54–64 |
| Low serum magnesium | 14–33 |
| Low serum potassium | 6–20 |
| Low serum retinol | 21 |
| Low serum ascorbate | 12 |
| Low serum 25-OH-vitamin D | 25–65 |
| Low serum zinc | 40–50 |

Prevalence of nutritional deficiencies

As shown in [Table 163.2](#), the prevalence of nutritional deficiencies is quite high in hospitalized patients with IBD. Although it is generally agreed that a greater prevalence of nutritional deficiencies exists in hospitalized patients than in outpatients (as these patients typically have a more severe condition), a great number of ambulatory patients with Crohn's disease display one or more nutrient deficiencies as well.^[53] In addition to the deficiencies listed in [Table 163.2](#), low levels of vitamin K, copper, niacin, and vitamin E have been reported.^[49]

Diet

The importance of correcting nutritional deficiencies in patients with IBD cannot be overstated. Nutrient deficiencies, both macro- and micro-, lead to altered gastrointestinal function and structure, which may result in the patient entering a vicious cycle, i.e. the secondary effects of malnutrition on gastrointestinal tract function and structure may lead to a further increase in malabsorption, further decreasing nutrient status. Foremost in nutritional therapy is providing adequate caloric intake. It should be assumed that the majority of patients suffer from micronutrient deficiency, although often the deficiency is subclinical and can only be detected by appropriate laboratory investigation.

In general, patients with inflammatory bowel disease should be placed on therapeutic vitamin supplements of at least five times the RDA. Several minerals may also need to be supplemented at equally high levels. Dietary treatment involves the use of either an elemental or an elimination diet (described below).

Elemental diets

The elemental diet has been shown to be an effective non-toxic alternative to corticosteroids as the primary treatment of acute IBD.^{[14] [15] [16] [17]} An elemental diet is

one that is purported to contain all essential nutrients, with

1342

protein being provided only as predigested or free-form amino acids. The improvements noted on an elemental diet are, however, probably not primarily related to nutritional improvement. Although the improvement could be a result of alterations in the fecal flora (which have been noted to occur in patients consuming an elemental diet), a stronger case could be made for a secondary immune mechanism being bypassed during elemental feeding: the elemental diet is serving as an allergy elimination diet.

The main drawback of the widespread use of elemental diets is their unpalatability and their hyperosmolality, which often results in diarrhea. In addition, hospitalization is often required for satisfactory administration, and relapse is quite common when patients resume normal eating. An elimination diet, rather than an elemental diet, may be a more acceptable alternative in the treatment of acute IBD, particularly when treating chronic IBD.

Elimination (oligoantigenic) diets

Although food allergy has long been considered an important etiologic factor in the pathogenesis of IBD, it is only recently that there have been studies utilizing an elimination diet in the treatment of IBD (elimination diets are described in [Ch. 15](#)).^[18]^[19]^[20] These studies demonstrate that an elimination is the primary therapy of choice in the treatment of chronic IBD. The most common offending foods were found to be wheat and dairy products.

An alternative approach is to determine the actual allergens by laboratory methods, preferably a method that measures both IgG- and IgE-mediated reactions. The allergens are then avoided or a rotary diversified diet is used as appropriate (see [Chs 51](#) and [58](#)).

High-complex carbohydrate, high-fiber (HFC) diet

Treatment with an HCF diet has been shown to have a favorable effect on the course of Crohn's disease.^[13] This is in direct contrast to one of the oldest allopathic dietary treatments of IBD, i.e. a low-fiber diet. Although some foods may be too "rough" to handle, the dietary treatment of IBD should utilize an unrefined carbohydrate, fiber-rich diet combined with an avoidance or rotary-diversified diet. This latter combination is much more effective than just a high-fiber diet alone.^[19] Dietary fiber has a profound effect on the intestinal environment and is thought to promote a more optimal intestinal flora composition.^[54] However, considering the high degree of intolerance to wheat found in patients with IBD, and the known roughness of wheat bran, supplemental wheat bran is not the fiber of choice for these patients.

Minerals

Zinc

Zinc deficiency, a well-known complication of Crohn's disease, occurs in approximately 45% of Crohn's disease patients.^[55] Low serum zinc concentrations, low hair zinc levels, malabsorption of zinc, altered urinary excretion of zinc, and impaired taste acuity are commonly found in Crohn's disease patients.^{[49] [55]} It is due to low dietary intake, poor absorption, and excess fecal losses.^{[49] [50] [51] [55]} Many of the complications of the disease may be a direct result of zinc deficiency:^{[55] [56] [57]}

- the complications of poor healing of fissures and fistulas
- skin lesions (acrodermatitis)
- hypogonadism
- growth retardation
- retinal dysfunction
- depressed cell-mediated immunity
- anorexia.

Many patients will not respond to oral or intravenous zinc supplementation, as there appears to be a defect in tissue transport. Intravenous supplementation results in a tremendous increase in urinary zinc excretion, but insignificant clinical results. Several clinical trials using oral zinc sulfate have shown the same lack of results.^[58]

Supplying zinc as a picolinate may be more advantageous, possibly improving both intestinal absorption and tissue transport, although one study displayed no significant difference in zinc absorption between zinc sulfate and zinc picolinate in patients with pancreatic insufficiency.^[59] Zinc citrate may also be an appropriate alternative. In any event, every attempt should be made to ensure that adequate tissue stores of zinc are maintained, as disease activity is correlated with zinc deficiency. This may necessitate parenteral administration in some cases. Although less than ideal, intravenous zinc is often the only way to attain even marginal zinc levels in patients with Crohn's disease.^[58]

Magnesium

Magnesium deficiency is quite prevalent in patients with IBD.^{[49] [60] [61]} However, a poor correlation exists between serum levels, which may be decreased in only a few patients, and intracellular magnesium levels, which are commonly decreased in patients with IBD.^[49] Patients with low intracellular magnesium levels may present with:^[49]

- weakness
 - anorexia
 - hypotension
 - confusion
-

- hyperirritability
- tetany
- convulsions
- electrocardiographic or electroencephalographic abnormalities.

These symptoms are responsive to parenteral magnesium supplementation.

A daily intravenous dose of 200–400 mg elemental magnesium may be necessary for those not responding to oral supplementation. Patients with IBD may require this route of supplementation due to magnesium's somewhat cathartic action and poor absorption in patients with a short bowel. Oral supplementation should be with magnesium chelates (i.e. citrate, aspartate, etc.), rather than inorganic magnesium salts (i.e. carbonate).

Iron

Iron deficiency anemia is very frequent in IBD, largely because of chronic blood loss through the gut.^[49] Serum ferritin levels are the most useful indices of iron status. A concentration greater than 55 ng/ml indicates adequate bone marrow iron reserves, while a ferritin concentration of less than 18 ng/ml is highly predictive of iron deficiency (see [Ch. 24](#) for further discussion). There should be an attempt to increase iron stores by improving absorption, as with supplemental vitamin C, rather than through direct iron supplementation, since iron promotes intestinal infection.^[62]

Calcium

Patients with IBD are also at risk of developing calcium deficiency. This is probably due to several factors:^[49]

- loss of absorptive surfaces
- steatorrhea
- corticosteroid use
- vitamin D deficiency.

Potassium

Diarrheal diseases are often associated with potassium and other electrolyte deficiencies. Although symptoms of potassium deficiency are quite rare in patients with IBD, levels are probably below optimum. In one study, nutritional support to correct potassium deficiency resulted in significantly reduced rates of surgical complications.^[63]

Vitamins

Vitamin A

Low serum retinol levels are found in approximately 20% of Crohn's disease patients and are correlated with the activity of the disease.^{[49] [57]} Vitamin A can profoundly affect the metabolism and differentiation of the intestinal epithelial mucosa, since it can increase the number of goblet cells, increase the production of mucins, increase the secretion of mucus, and restore normal barrier function. Preliminary case reports have indicated that vitamin A may be useful therapeutically in Crohn's disease.^{[64] [65]} However, long-term controlled trials have indicated that vitamin A (50,000 IU twice daily) had no therapeutic effect in the majority of Crohn's disease cases.^{[66] [67]} It should be kept in mind, however, that certain patients may respond to vitamin A therapy, and that zinc supplementation will often normalize disturbances of vitamin A metabolism, as zinc is a necessary component of retinol-binding protein (RBP).^[57]

Vitamin D

There is evidence that vitamin D deficiency is quite common in IBD patients, particularly in those patients with other signs of nutritional deficiency.^{[49] [68]} This is probably a result of decreased absorption of 25-hydroxy-vitamin D. Patients with IBD are at an increased risk for the development of metabolic bone diseases, such as osteoporosis and osteomalacia. This relates to previously mentioned factors regarding calcium.

Vitamin E

Vitamin E deficiency can occur in IBD, as observed in one case report.^[69] The patient had a 25 year history of Crohn's disease, with multiple small bowel resections. Presenting symptoms relating to vitamin E deficiency included:

- bilateral visual field scotomata
- generalized motor weakness
- a broad-based gait with marked ataxia
- brisk reflexes
- a bilateral Babinski response.

Serum vitamin E concentration was 0.03 mg/dl (normal 0.8–1.2 mg/dl) and in vitro peroxide hemolysis was 100% (normal <10%). Supplementation with 270 IU/day eventually brought complete recovery over a period of 2 years.

Vitamin E supplementation is also indicated due to its ability to inhibit leukotriene formation and reduce free radical damage.^[70]

Vitamin K

Vitamin K deficiency, resulting in the formation of abnormal prothrombin (deficient in

gamma-carboxyglutamic acid), is quite common in patients with IBD.^{[71] [72]}

1344

Folic acid

Low serum concentrations of folic acid are quite common in IBD, with reports of occurrence ranging between 25 and 64%.^{[49] [73] [74] [75]} The drug sulfasalazine exacerbates the condition by interfering with folate-dependent enzymes and with the intestinal folate transport system.^[52] A folate deficiency promotes further malabsorption due to altered structure of the intestinal mucosal cells.^[76] These cells have a very rapid turnover (1–4 days) compared with RBCs (3–4 months), and therefore deficiency affects these cells much earlier than the RBC.

Vitamin B₁₂

A significant correlation exists between vitamin B₁₂ absorption and the extent of terminal ileal disease and/or resection.^{[49] [77]} Overall, abnormal Schilling tests are found in 48% of patients with Crohn's disease. When ileal resection exceeds 90 cm, the Schilling test is abnormal in all patients and does not improve with time. If the length of the resection is less than 60 cm, or the extent of the inflammatory lesion is less than 60 cm, adequate absorption may occur.

Ascorbic acid

A low vitamin C intake is common in patients with IBD, particularly in those patients on a low-fiber diet.^{[49] [78]} Serum and leukocyte ascorbic acid levels are significantly lower in patients with Crohn's disease than in matched controls.^{[49] [78]} Vitamin C is thought to be particularly important in the prevention of fistula formation. It has been shown that patients with fistulas have lower ascorbic acid levels than patients without fistulas.^[79]

Other nutrients

Obviously, patients with IBD are at risk of developing any nutrient deficiency, including nutrients not discussed above. However, there is probably no real need for laboratory investigation to determine micronutrient deficiencies, other than for those nutrients discussed above.^[49]

Recommend a high-potency multiple vitamin and mineral formula

It is absolutely essential that patients with IBD take a high-potency multiple vitamin and mineral supplement providing all of the known vitamins and minerals. [Table 163.3](#) lists recommendations for an optimum intake range.

In addition to taking a high-potency multiple vitamin and mineral formula, patients with IBD will need to take additional antioxidants. Increased oxidative stress and decreased antioxidant defenses in the mucosa are

TABLE 163-3 -- Optimal range of nutrients

| Nutrient | Range for adults |
|-------------------------------------|---|
| <i>Vitamins</i> | |
| Vitamin A (retinol) | 5,000 IU (women of child-bearing age should not take more than 2,500 IU/day of retinol due to the possible risk of birth defects if becoming pregnant is a possibility) |
| Vitamin A (from beta-carotene) | 5,000–25,000 IU |
| Vitamin D | 100–400 IU |
| Vitamin E (d-alpha tocopherol) | 100–200 IU |
| Vitamin K (phytonadione) | 60–300 mcg |
| Vitamin C (ascorbic acid) | 100–1,000 mg |
| Vitamin B ₁ (thiamin) | 10–100 mg |
| Vitamin B ₂ (riboflavin) | 10–50 mg |
| Niacin | 10–100 mg |
| Niacinamide | 10–30 mg |
| Vitamin B ₆ (pyridoxine) | 25–100 mg |
| Biotin | 100–300 mcg |
| Pantothenic acid | 25–100 mg |
| Folic acid | 400 mcg |
| Vitamin B ₁₂ | 400 mcg |
| Choline | 10–100 mg |
| Inositol | 10–100 mg |
| <i>Minerals</i> | |
| Boron | 1–6 mg |
| Calcium | 250–500 mg |

| | |
|------------|--|
| Chromium | 200–400 mcg |
| Copper | 1–2 mg |
| Iodine | 50–150 mcg |
| Iron | 15–30 mg (men and post-menopausal women rarely need supplemental iron) |
| Magnesium | 250–500 mg |
| Manganese | 10–15 mg |
| Molybdenum | 10–25 mcg |
| Potassium | 200–500 mg |
| Selenium | 100–200 mcg |
| Silica | 1–25 mg |
| Vanadium | 50–100 mcg |
| Zinc | 15–45 mg |

hallmark features of IBD.^[80] This association provides a strong rationale for therapeutic modulation with antioxidants. The two primary antioxidants in the human body are vitamin C and vitamin E. Vitamin C is an “aqueous phase” antioxidant while vitamin E is a “lipid phase” antioxidant. Recommended dosages in patients with IBD are as follows:

| | |
|----------------------------------|-----------------|
| • vitamin E (D-alpha-tocopherol) | 400–800 IU |
| • vitamin C (ascorbic acid) | 1,000–3,000 mg. |

Botanical medicines

Quercetin

The plant flavonoid quercetin appears to be particularly indicated in the treatment of IBD. Flavonoids, in general, are considered natural biological response modifiers.^{[81] [82]} Quercetin, as perhaps the most pharmacologically active flavonoid, has remarkable effects on a variety of enzyme systems.^{[81] [82]} Many of the enzymes affected by quercetin

are important in the secretory, contractile, and motility processes associated with the inflammatory response, i.e. the release of histamine and other inflammatory mediators from mast cells, basophils, neutrophils, and macrophages; migration and infiltration of leukocytes; and smooth muscle contraction.

Quercetin's effect on these enzymes and processes is likely due to a common action, i.e. antagonizing calmodulin.^[83] When calcium is bound to calmodulin it activates a great variety of enzymes, including those involved in cyclic nucleotide metabolism, protein phosphorylation, secretory function, muscle contraction, microtubule assembly, glycogen metabolism, and calcium flux. Quercetin is believed to interact directly with calmodulin and calcium channels. This has been shown in many experimental studies and would explain quercetin's effect on such a wide number of enzymes.

Quercetin and many other flavonoids have been shown to be potent inhibitors of mast cell and basophil degranulation.^{[84] [85] [86] [87]} A generally accepted hypothesis for this action is that quercetin inhibits receptor-mediated calcium influx, thereby inhibiting the primary signal for degranulation. However, quercetin is also active under conditions in which the calcium-channel mechanism is not operative, indicating that other mechanisms are responsible as well.

Quercetin has been shown to inhibit many of the inflammatory processes attributed to activated neutrophils.^[88] This is probably due to its membrane-stabilizing action, potent antioxidant effect (which prevents the production of free radicals and inflammatory leukotrienes), and inhibition of the enzyme hyaluronidase (thus preventing the breakdown of the collagen matrix of connective tissue and ground substance). Quercetin's membrane-stabilizing effect could also account for its action in preventing mast cell and basophil degranulation. This effect also inhibits inflammation by decreasing neutrophil lysosomal enzyme secretion.^[88] (Neutrophils and monocytes contain lysosomes that, upon secretion of their contents, contribute greatly to the inflammatory process.)

Quercetin has been shown to inhibit many steps in eicosanoid metabolism. Probably of most significance in IBD is its inhibition of phospholipase A₂ and lipoxygenase enzymes (see [Fig. 149.1, p. 1229](#)).^{[81] [82] [89]} The net result is a significant reduction in the formation of leukotrienes. Excessive leukotriene formation has been linked to asthma, psoriasis, atopic dermatitis, gout, and possibly cancer, as well as IBD.^{[90] [91]} The leukotrienes C₄, D₄, and E₄ (composing the slow-reacting substances of anaphylaxis (SRS-A)) are derived from arachidonic acid and are 1,000 times as potent as histamine in promoting inflammation. Leukotrienes promote inflammation by causing vasoconstriction (thereby increasing vascular permeability) and other smooth muscle contraction, and by promoting WBC chemotaxis and aggregation. The reduction of leukotriene formation has significant anti-inflammatory effects, particularly in IBD. (For more information on quercetin, see [Ch. 87.](#))

Bastyr's formula (modified Robert's formula)

Although no research has been done to document its efficacy, an old naturopathic remedy, Robert's formula, has a long history of use in IBD (see [Table 163.4](#)). It is composed of several botanical medicines:

- *Althea officinalis* (also known as marshmallow root) – a demulcent with soothing

properties on the mucous membranes

- *Baptisia tinctora* (also known as wild indigo) – used for gastrointestinal infections
- *Echinacea angustifolia* (also known as purple coneflower) – it is antibacterial and used to promote normalization of the immune system; see [Chapter 82](#)
- *Geranium maculatum* – a gastrointestinal hemostatic
- *Hydrastis canadensis* (also known as goldenseal) – inhibits the growth of many enteropathic bacteria; see [Chapter 91](#)
- *Phytolacca americana* (also known as poke root) – used for healing ulcerations of the intestinal mucosa
- *Symphytum officinale* (also known as comfrey) – it is anti-inflammatory, and promotes tissue growth and wound healing
- *Ulmus fulva* (also known as slippery elm) – it has a demulcent effect.

The cabbage powder is used because of its documented ability to heal gastrointestinal ulcers (see [Ch. 108](#)); pancreatin is used to assist in the digestive process (see [Ch. 101](#)); niacinamide is used for its anti-inflammatory effects; and duodenal substance is used because it too heals gastrointestinal ulcers.

Butyrate enemas in ulcerative colitis

Short-chain fatty acids and colon function

The short-chain fatty acids (SCFAs), mainly acetate, propionate, and butyrate, arise in the colon as end-products

TABLE 163-4 -- Composition of Bastyr's formula

-
- Eight parts *Althea officinalis*

 - Four parts *Baptisia tinctora*

 - Eight parts *Echinacea angustifolia*

 - Eight parts *Geranium maculatum*

 - Eight parts *Hydrastis canadensis*

 - Eight parts *Phytolacca americana*

 - Eight parts *Ulmus fulva*

 - Eight parts cabbage powder

 - Two parts pancreatin

 - One part niacinamide

 - Two parts duodenal substance
-

of bacterial carbohydrate fermentation. These SCFAs function as primary energy sources for the luminal colon cells, especially in the distal segments. Decreased levels or decreased utilization of SCFAs leading to impaired cellular energetics have been hypothesized to play a major role in ulcerative colitis. Based upon this hypothesis, several clinical trials have been conducted with enemas providing SCFAs (usually composed of either butyrate as a sole agent in concentrations ranging from 80 to 100 mmol/L, or SCFA combinations composed of acetate 60 mmol/L, propionate 25 mmol/L, and butyrate 40 mmol/L). Excellent preliminary results in pilot studies led to a well-designed double-blind study.^[52] ^[70]

In this study, 47 patients with distal ulcerative colitis randomly received either a combination of SCFAs, butyrate, or a placebo in an enema form twice daily and retained for 30 minutes.^[70] The primary end-point in the study was the disease activity index composed of stool frequency, rectal bleeding, mucosal appearance, and physician's rating of disease activity as well as endoscopic examination. After 8 weeks of therapy, there was a drop in activity in all three groups, with the butyrate group demonstrating the lowest disease activity. Endoscopic examination demonstrated less pathology in the butyrate and SCFA combination groups. Complete remission occurred in 47% receiving SCFAs, 38% receiving butyrate, and 25% receiving placebo. This study and others indicate that butyrate and SCFA enemas may prove useful adjuncts in the treatment of ulcerative colitis.

THERAPEUTIC MONITORING AND EVALUATION

Crohn's disease activity index (CDAI)

The Crohn's disease activity index was developed as a monitoring tool in the National Cooperative Crohn's Disease Study.^[92] It met the basic requirements necessary for the study, i.e. it provided uniform clinical parameters which could be assessed, and produced a consistent numerical index for recording the results of the study of several centers over a period of several years.

The CDAI is calculated by adding together eight variables (see [Table 163.5](#)). It incorporates both subjective and objective information in determining relative disease activity. A form is provided in [Appendix 3](#) which may be photocopied and given to patients. When the patient returns with the completed form, the calculation of disease activity can be completed. In general, CDAI scores below 150 indicate a better prognosis than higher scores. The CDAI is a very useful way to monitor therapeutic progress.

Monitoring of the pediatric patient

The pediatric patient with IBD presents a particularly difficult problem in that it is often very difficult to

TABLE 163-5 -- Independent variables and formula used to calculate the CDAI^[90]

| | |
|----------------|---|
| X ₁ | Number of liquid or very soft stools in 1 week |
| X ₂ | Sum of seven daily abdominal pain ratings: 0 = none, 1 = mild, 2 = moderate, 3 = severe |
| X ₃ | Sum of seven daily ratings of general well-being: 0 = well, 1 = slightly below par, 2 = poor, 3 = very poor, 4 = terrible |
| X ₄ | Symptoms or findings presumed related to Crohn's disease: —arthritis or arthralgia —iritis or uveitis —erythema nodosum, pyoderma gangrenosum, aphthous stomatitis —anal fissure, fistula, or perirectal abscess —other bowel-related fistula —febrile episode >100°F during past week Add 1 for each category corresponding to patient's symptoms |
| X ₅ | Taking Lomotil or opiates for diarrhea: 0 = no, 1 = yes |
| X ₆ | Abdominal mass: 0 = none, 0.4 = questionable, 1 = present |

| X ₈ | 100 × (standard weight – body weight)/standard weight |

$$\text{CDAI} = 2 \times X_1 + 5 \times X_2 + 7 \times X_3 + 20 \times X_4 + 30 \times X_5 + 10 \times X_6 + 6 \times X_7 + X_8$$

achieve normal growth and development. Growth failure occurs in 75% of Crohn's disease pediatric patients, while ulcerative colitis causes growth failure in 25%.^[51] The pediatric patient with IBD should be evaluated at least twice yearly. Evaluation should include a pertinent history, clinical anthropometry, Tanner staging, and appropriate laboratory testing. [Table 163.6](#) outlines the necessary components of a comprehensive bi-yearly nutritional evaluation in pediatric patients with IBD. An aggressive nutritional program should be instituted, including supplements (it may be necessary to use enteral or parenteral methods in some patients), which is similar to the approach outlined for the adult patient, with the the doses adjusted as appropriate.

The CDAI is not as accurate in monitoring the disease in children as it is in adults. To overcome this shortcoming, Lloyd-Still & Green^[93] devised a clinical scoring system for IBD in children. The scoring system is divided into five major divisions (the maximum score is in parentheses): general activity (10), physical examination and clinical complications (30), nutrition (20), X-rays (15), and laboratory (25). An elevated score

(i.e. scores in the 80s) represents good status, while scores in the 30s and 40s represent severe disease. [Table 163.7](#) outlines the determination of clinical score.

THERAPEUTIC APPROACH

It is important to recognize that in some patients these are life-threatening diseases which at times require

1347

| | 3 | Mild stomatitis |
| | 4 | Erythema nodosum, pyoderma, severe stomatitis, uveitis |

Nutrition

| | | |
|--------|----|--------------------------------------|
| Height | 10 | >2 inches/year |
| | 5 | <optimal % |
| | 1 | No growth |
| X-rays | 15 | Normal |
| | 10 | Ileitis |
| | 5 | Total colon or ileocecal involvement |
| | 1 | Toxic megacolon or obstruction |

Laboratory

| | | |
|-----|---|--------|
| HCT | 5 | >40 |
| | 3 | 25–35 |
| | 1 | <25 |
| ESR | 5 | Normal |
| | 3 | 20–40 |
| | 1 | >40 |

| | | |
|---------|----|-----------|
| WBC | 5 | Normal |
| | 3 | <20,000 |
| | 1 | >20,000 |
| Albumin | 10 | Normal |
| | 5 | 3.0 g/dl |
| | 1 | <2.5 g/dl |

emergency treatment. A small percentage of patients who have severe colitis may experience severe exacerbations requiring hospitalization. This is more common in patients with ulcerative colitis who typically present with a fever of 101°F or higher; profuse, constant, loose, bloody stools; anorexia; apathy and prostration; and, although abdominal signs may be normal, physical examination will reveal a distended abdomen, tympany, absent bowel sounds, and even rebound tenderness.

For the typical patient, IBD is a chronic disease requiring long-term therapy and follow-up. The first step is to identify and remove all factors which may be initiating or aggravating the inflammatory reaction, i.e. food allergens and carrageenan. The patient is put on a diet which maximizes macro- and micronutrients while minimizing aggravating foods/non-foods.

A broad-based individualized nutritional supplementation plan is necessary for all patients with IBD. Particularly important are the nutrients zinc, magnesium, folic acid, and vitamin A. As appropriate, nutritional supplements are utilized to correct deficiencies, normalize the inflammatory process, and promote healing of the damaged mucosa. Botanical medicines are used to promote healing and normalize the intestinal flora.

Diet

All allergens, wheat, corn, and dairy products, and carrageenan-containing foods should be eliminated. The diet should be high in complex carbohydrates and fiber, and low in sugar and refined carbohydrates.

Supplements

- Multivitamin and mineral supplement
- Magnesium: 200 mg/day

- Zinc picolinate: 50 mg/day
- Vitamin A: 50,000 iu/day
- Vitamin E: 200 iu/day

- Fish oil: 3 g/day.

Botanical medicines

- Quercetin: 400 mg 20 minutes before meals
- Bastyr's formula: two to three "00" capsules with each meal.

Chapter 164 - Insomnia

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

DIAGNOSTIC SUMMARY

- Difficulty falling asleep (sleep-onset insomnia)
- Frequent or early awakening (maintenance insomnia)
- Affects one out of every four people in the United States.

GENERAL CONSIDERATIONS

Insomnia represents one of the most common complaints seen by physicians, and is a symptom that can have many causes. [Table 164.1](#) summarizes some of the more common of these.

Insomnia is an extremely common complaint. Within the course of a year, up to 30% of the population suffers from insomnia.^[1] Many use over-the-counter medications to combat the problem, while others seek stronger sedatives. Each year 4–6 million people in the US receive prescriptions for sedative hypnotics.^[2] Psychological factors account for 50% of all insomnias evaluated in sleep laboratories.^[1] Insomnia is closely associated with affective disorders (see [Ch. 126](#)) and may be the presenting symptom in patients with another, sometimes more serious, condition.^[2]

A thorough history and examination are indicated in the patient presenting with insomnia. This also includes a detailed recreational, prescription and non-prescription

TABLE 164-1 -- Causes of insomnia^{*}

| Sleep-onset insomnia | Sleep-maintenance insomnia |
|----------------------|----------------------------|
| Anxiety or tension | Depression |
| Environmental change | Environmental change |

| | |
|------------------------|---------------------|
| Emotional arousal | Sleep apnea |
| Fear of insomnia | Nocturnal myoclonus |
| Phobia of sleep | Hypoglycemia |
| Disruptive environment | Parasomnias |
| Pain or discomfort | Pain or discomfort |
| Caffeine | Drugs |
| Alcohol | Alcohol |

* The boundary between the categories is not entirely distinct.

drug usage history along with a dietary and beverage history to determine if the patient is consuming any stimulants or other agents known to interfere with sleep, such as:

- thyroid preparations
- oral contraceptives
- beta-blockers
- marijuana
- alcohol
- coffee
- tea
- chocolate.

Among serious diseases to be considered in the differential diagnosis are narcolepsy and sleep apnea syndromes.

Normal sleep patterns

Human sleep is perhaps one of the least understood physiological processes. Its value to human health and proper functioning is without question. Sleep is absolutely essential to both the body and the mind. Impaired sleep, altered sleep patterns, and sleep deprivation impair mental and physical function.

Normal adult sleep–wake patterns repeat themselves on an approximately 24 hour cycle, of which sleep constitutes one-third. Exactly how much sleep is required by an individual varies from one person to the next. Although sleep tends to decrease with age, whether this is a normal or abnormal progression is unknown. A 1-year-old baby requires about 14 hours of sleep a day, a 5-year-old about 12 hours, and adults about 7–9 hours. Women tend to require more sleep than men. The elderly tend to sleep less

at night, but doze more during the day than younger adults.

Based upon observation of eye movement and electroencephalographic (EEG) recordings, sleep is divided into two distinct types of sleep – REM (rapid eye movement) and non-REM (non-rapid eye movement) sleep. During REM sleep the eyes move rapidly and dreaming takes place. When people are awakened during non-REM sleep, they will report that they were thinking about everyday matters but rarely report dreams.

Non-REM is divided into four stages graded 1–4 based upon level of EEG activity and ease of arousal. As sleep progresses there is a deepening of sleep and slower brain wave activity until REM sleep when suddenly the brain becomes much more active. In adults, the first REM sleep cycle is usually triggered 90 minutes after going to sleep and lasts about 5–10 minutes. After the flurry of activity, brain wave patterns will return to non-REM sleep for another 90 minute sleep cycle.

Each night most adults experience five or more sleep cycles. REM sleep periods grow progressively longer as sleep continues; the last sleep cycle may produce a REM sleep period that can last about an hour. Non-REM sleep lasts approximately 50% of this 90 minute sleep cycle in infants and about 80% in adults. As people age, in addition to less REM sleep, they tend to awaken at the transition from non-REM to REM sleep.

The importance of adequate sleep

Adequate sleep is absolutely necessary for long-term health and regeneration. While many different physiological processes occur during sleep, perhaps the most important are the increased secretion of growth hormone and the scavenging of free radicals in the brain.

Many of the benefits of sleep are probably mediated through growth hormone. As an anabolic hormone, it has been called, by some, the “anti-aging” hormone. Several research projects are now studying its rejuvenating effects when it is injected. The reason for the excitement is that it stimulates tissue regeneration, liver regeneration, muscle building, breakdown of fat stores, normalization of blood sugar regulation, and a whole host of other beneficial processes in the body. In other words, it helps convert fat to muscle. While small amounts are secreted at various time during the day, essentially all its secretion occurs during sleep.

Sleep functions as an antioxidant for the brain as free radicals are removed during this time. Sleep is required to ensure there is minimal neuronal damage due to free radical accumulation during waking. Most people can tolerate a few days without sleep and fully recover. However, chronic sleep deprivation appears to accelerate aging of the brain, as animal research shows that prolonged periods of sleep deprivation cause neuronal damage.^[3]

THERAPEUTIC CONSIDERATIONS

Since insomnia is largely due to psychological and physiological factors, these should

considered and handled before simply inducing sleep pharmacologically. Counseling and/or stress reduction techniques (including biofeedback and hypnosis) may be indicated in many cases. The following topics are discussed as they relate to promoting sleep:

- exercise
 - progressive relaxation
 - nocturnal glucose levels
 - serotonin precursor and cofactor therapy
 - 5-HTP
 - cofactors for serotonin synthesis
 - melatonin
 - restless legs syndrome and nocturnal myoclonus
 - botanicals with sedative properties.

1353

Exercise

Regular physical exercise is known to improve general well-being as well as to promote improvement in sleep quality.^[1] Exercise should be performed in the morning or early evening, not before bedtime, and should be of moderate intensity. Usually 20 minutes of aerobic exercise at a heart rate between 60 and 75% of maximum (approximately 220 – age in years) is sufficient.

Progressive relaxation

There are numerous techniques which can promote relaxation and prepare the body and mind for sleep. One of the most popular and easy-to-use techniques is progressive relaxation. The technique is based on a very simple procedure of comparing tension with relaxation. Many people are not aware of the sensation of relaxation. In progressive relaxation an individual is taught what it feels like to relax by comparing relaxation with muscle tension. The muscle will first be asked to contract forcefully for a period of 1–2 seconds and then give way to a feeling of relaxation. Since the procedure goes progressively through all the muscles of the body, eventually a deep state of relaxation will result. The procedure begins with contracting the muscles of the face and neck, holding the contraction for a period of at least 1–2 seconds and then relaxing the muscles. Next the upper arms and chest are contracted and then relaxed, followed by the lower arms and hands. The process is repeated progressively down the body, i.e. the abdomen, the buttocks, the thighs, the calves, and the feet. This whole practice is repeated two or three times, or until sleep is produced.

Nocturnal glucose levels

Low nocturnal blood glucose levels are an important cause of maintenance insomnia. The brain is highly dependent on glucose as an energy substrate and a drop in blood

glucose level promotes awakening via the release of glucose regulatory hormones, i.e. epinephrine, glucagon, cortisol, and growth hormone. Hypoglycemia must be ruled out in maintenance type insomnia (see [Ch. 161](#)).

Serotonin precursor and cofactor therapy

Serotonin is an important initiator of sleep. The synthesis of CNS serotonin is dependent on tryptophan availability (this is discussed in more detail in [Ch. 126](#)). L-Tryptophan has shown modest effects in the treatment of insomnia.^{[4] [5] [6] [7] [8]} It is certainly not a panacea; however, excellent results have been reported even in severe cases. Although not every patient has responded to L-tryptophan in the clinical trials, those that have responded have experienced dramatic relief. It is generally more effective in sleep-onset insomnia and less effective in sleep-maintenance insomnia. The key advantage of L-tryptophan over over-the-counter and prescription pills is that, unlike these drugs, L-tryptophan does not produce any significant distortions of normal sleep processes whether it is given one time, for a prolonged period, or upon withdrawal. Dosages less than 2,000 mg are generally ineffective.

Current knowledge on the sleep-inducing effects of L-tryptophan are consistent with its effectiveness being somewhat limited to sleep-onset insomnia.^{[7] [8]} While it is often thought that the sleep-promoting effect is the result of enhanced serotonin synthesis, there is evidence to suggest that other mechanisms may also be responsible or contributory, including L-tryptophan-enhanced melatonin synthesis. L-Tryptophan administration causes a massive elevation of plasma melatonin levels.^[9] While L-tryptophan reduces sleep latency, in normal subjects it exerts effects that are at odds with the serotonin system such as reducing REM and increasing non-REM sleep.^{[10] [11]} Drugs which prevent the conversion of tryptophan to serotonin enhance these effects. From this information it is concluded that some of L-tryptophan's effects on sleep do not involve the serotonin or melatonin system. As discussed in [Chapter 92](#) , the effects of L-tryptophan can be negated by the conversion via the kynurenine pathway. This can be partially inhibited by niacin (30 mg is an appropriate dosage), thereby enhancing the effects of L-tryptophan.

It appears that the insomnia-relieving and sleep-promoting actions of L-tryptophan are cumulative, in that it often takes a few nights for L-tryptophan to start working. For example, let us examine the results from one of the double-blind studies. In the study, the effects of 3 g L-tryptophan on sleep, performance, arousal threshold, and brain electrical activity during sleep were assessed in 20 male, chronic sleep-onset insomniacs.^[12] Following a sleep laboratory screening night, all subjects received placebo for three consecutive nights, 10 subjects received L-tryptophan, and 10 received placebo for six nights. All subjects received placebo on two withdrawal nights. There was no effect of L-tryptophan on sleep latency during the first three nights of administration. However, on nights 4–6 of administration, sleep latency was significantly reduced. Consistent with other studies, unlike sleeping pills (benzodiazepines especially), L-tryptophan did not alter sleep stages, impair performance, or alter brain electrical activity during sleep. What can be learned from this study is that L-tryptophan should be used for a minimum of 1 week to gauge effectiveness in chronic insomnia. L-Tryptophan does exert good sleep-promoting effects with a single administration, as

giving L-tryptophan to subjects who regularly experience insomnia when sleeping in a “strange place” is often very effective.

1354

High-dosage L-tryptophan (4 g) administration during the day can promote sleep. This research information indicates that consumption of high tryptophan-containing foods during the day may contribute to daytime sleepiness. Conversely, an evening meal which is high in tryptophan in relationship to competing amino acids may promote sleep.

5-HTP

5-Hydroxytryptophan (5-HTP) is one step closer to serotonin than L-tryptophan and is not dependent upon a transport system for entry into the brain. Several clinical studies have shown 5-HTP to produce dramatically better results than L-tryptophan in promoting and maintaining sleep.^{[13] [14] [15] [16]}

One of the key benefits with 5-HTP is its ability to increase REM sleep (typically by about 25%) while simultaneously increasing deep sleep stages 3 and 4 without increasing total sleep time.^{[10] [11]} The sleep stages that are reduced to compensate for the increases are non-REM stages 1 and 2 – the least important stages of sleep.

The dosage recommendation to take advantage of the sleep-promoting effects of 5-HTP is 100–300 mg 30–45 minutes before retiring. Have the patient start with the lower dose for at least 3 days before moving up.

Cofactors for serotonin synthesis

The important cofactors vitamin B₆, niacin, and magnesium should be administered along with the tryptophan to ensure its conversion to serotonin. Also, since other amino acids compete with tryptophan for transport into the CNS across the blood–brain barrier and insulin increases tryptophan uptake by the CNS, protein consumption should be avoided near administration and a carbohydrate source such as fruit or fruit juice should accompany tryptophan administration.^[4]

Niacin has been reported to have a sedative effect, probably due to its peripheral dilating action and shunting of tryptophan metabolism towards serotonin synthesis.

Melatonin

One of the best aids for sleep is melatonin. Supplementation with melatonin has been shown in several studies to be very effective in helping to induce, and maintain, sleep in both children and adults and in those with normal sleep patterns as well as those suffering from insomnia. However, it appears the sleep-promoting effects of melatonin are most apparent only if melatonin levels are low.^[17] In other words, melatonin is not

like taking a sleeping pill or even 5-HTP. It will only produce a sedative effect when melatonin levels are low. When melatonin is given just before going to bed in normal subjects or in patients with insomnia who have normal melatonin levels, it produces no sedative effect. This is because normally just prior to going to bed there is a rise in melatonin secretion. Melatonin supplementation is only effective as a sedative when the pineal gland's own production of melatonin is very low. Melatonin appears to be most effective in treating insomnia in the elderly as low melatonin levels are quite common in this age group.^[18]

In one of the most interesting studies, 26 elderly insomniacs with lower than normal melatonin levels were given 1–2 mg of melatonin 2 hours prior to the desired bedtime for 1 week. Rapid- and slow-release melatonin preparations were used. Both sleep latency and sleep quality were evaluated. While there was no discernible difference in sleep onset and sleep efficiency (time asleep as a percentage of total time in bed) between the two forms, the timed-release form yielded better results on sleep maintenance.^[19]

A dosage of 3 mg at bedtime is more than enough as dosages as low as 0.1 and 0.3 mg have been shown to produce a sedative effect when melatonin levels are low.^[20] Although there appear to be no serious side-effects at recommended dosages, conceivably melatonin supplementation could disrupt the normal circadian rhythm. In one study, a daily dosage of 8 mg/day for only 4 days resulted in significant alterations in hormone secretions.^[21]

Restless legs syndrome and nocturnal myoclonus

These disorders are significant causes of insomnia. The restless legs syndrome is characterized during waking by an irresistible urge to move the legs. Almost all patients with restless legs syndrome have nocturnal myoclonus.^[1] Nocturnal myoclonus is a neuromuscular disorder characterized by repeated contractions of one or more muscle groups, typically of the leg, during sleep. Each jerk usually lasts less than 10 seconds. The patient is normally unaware of the myoclonus and only complains of either frequent nocturnal awakenings or excessive daytime sleepiness, but questioning the sleep partner often reveals the myoclonus.

If there is a family history of restless legs syndrome (about one-third of all patients with this syndrome), high-dosage folic acid 35–60 mg daily therapy can be helpful.^[22] Dosages in this range will require a prescription as the FDA limits the amount available per capsule to 800 mcg. In cases of familial restless legs syndrome, there appears to be a higher need for folic acid. Restless legs syndrome is also a common finding in patients with malabsorption syndromes.^[22]

If there is no family history, measure serum ferritin levels. Serum ferritin is the best method for measuring

iron stores. The association between low iron levels and the restless legs syndrome was documented in clinical studies more than 30 years ago. A recent study reproduced these observations, finding serum ferritin levels to be reduced in the 18 patients with the restless legs syndrome compared with 18 control subjects.^[23] Serum iron, vitamin B₁₂, folic acid, and hemoglobin levels did not differ between the two groups. A rating scale with a maximum score of 10 was used to assess the severity of restless legs syndrome symptoms. Serum ferritin levels were inversely correlated with the severity of restless legs syndrome symptoms. Fifteen of the patients with restless legs syndrome were treated with iron (ferrous sulfate) at a dosage of 200 mg three times daily for 2 months. The severity of restless legs syndrome improved by an average of 4 points in six patients with an initial ferritin less than 18 mcg/L, by 3 points in four patients with ferritin levels between 18 and 45 mcg/L, and by 1 point in five patients with ferritin levels between 45 and 100 mcg/L.

The conclusion of the study, “Iron deficiency, with or without anemia”,^[23] is an important contributor to the development of RLS (restless legs syndrome) in elderly patients, and iron supplements can produce a significant reduction in symptoms.

In addition to the restless legs syndrome, low serum ferritin levels have been found in psychiatric patients experiencing a condition called “akathisia”, coming from the Greek word meaning “can’t sit down”. Akathisia is a drug-induced state of agitation. The most common drugs producing akathisia are antidepressant drugs such as Prozac, Zoloft, and Paxil. The level of iron depletion correlates with the severity of akathisia. If you suffer from drug-induced akathisia, please ask your physician to perform a serum ferritin assessment. If serum ferritin levels are below 35 mcg/L, recommend 30 mg of iron bound to either succinate or fumarate twice daily between meals. If this recommendation results in abdominal discomfort, recommend 30 mg with meals three times daily.

For nocturnal myoclonus as well as muscle cramps occurring at night, magnesium (250 mg at bedtime) and/or vitamin E (400–800 IU/day) may be helpful. If the patient is over the age of 50, *Ginkgo biloba* extract (80 mg three times daily) may also be used.

Botanicals with sedative properties

Numerous plants have sedative action. Plants commonly prescribed as aids in promoting sleep include:^[24] ^[25]

- *Passiflora incarnata*
- *Humulus lupulus*
- *Valeriana officinalis*
- *Scutellarea latriflora*
- *Matricaria chamomilla*.

Passiflora and valerian, which have research supporting their use, are discussed below.

***Passiflora incarnata* (passion flower).** Passion flower was widely used by the Aztecs as a diaphoretic, sedative, and analgesic. Its constituents include harmol, harman, harmine, harmalol, harmaline, and passicol. Harmine was originally known as telepathine because of its peculiar ability to induce a contemplative state and mild euphoria. It was later used by the Germans in World War II as “truth serum”. Harma alkaloids are monoamine oxidase inhibitors, and therefore their use with tryptophan or 5-HTP would have an additive effect.^[25]

***Valeriana officinalis* (valerian).** This plant has also been widely used in folk medicine as a sedative and antihypertensive.^[9] An early study involving 128 subjects demonstrated that an aqueous extract of valerian root significantly improved sleep quality.^[26] This double-blind study compared the effects of the aqueous extract versus a placebo and an over-the-counter preparation of valerian from Switzerland in both good and poor sleepers. From the results using sleep latency, night awakenings, subjective sleep quality, and sleepiness the next morning, the following conclusions can be made:

- The aqueous extract of valerian had its most significant effect among people who considered themselves poor or irregular sleepers (particularly women), smokers, and people with long sleep latencies.
- The over-the-counter valerian product at a daily dose of 400 mg produced very little sedative effect compared with placebo.
- The use of the commercially available product produced a significant increase in the degree of sleepiness the next morning compared with the aqueous extract or the placebo.

Several other clinical studies have substantiated valerian’s ability to improve sleep quality and relieve insomnia.^{[27] [28] [29] [30]} In one study, the effects of valerian on sleep was studied in two groups of healthy young subjects.^[27] One group slept at home, the other in a sleep laboratory. Sleep was evaluated on the basis of questionnaires, self-rating scales and night-time motor activity. Under home conditions, both 450 and 900 mg doses of an aqueous valerian extract reduced perceived sleep latency and wake time after sleep onset. Night-time motor activity was enhanced in the middle third of the night and reduced in the last third. In the sleep laboratory, where only the higher dose of valerian was tested, no significant differences from placebo were obtained. However, the direction of the changes in the subjective and objective measures of sleep latency and wake time after sleep onset, as well as in night-time motor activity, corresponded to that observed under home conditions. There was no evidence for a change in sleep stages

and EEG spectra. The results indicate that the aqueous valerian extract exerts a mild sedative effect.

While the two studies described above demonstrated that valerian could improve sleep quality in normal subjects, they failed to answer the question as to whether valerian could improve sleep patterns in people suffering from insomnia. In a follow-up to these two preliminary studies, valerian extract was shown to significantly reduce sleep latency, improve sleep quality, and reduce night-time awakenings in sufferers of insomnia.^[28] This study, performed under strict laboratory conditions, demonstrated that valerian is as effective in reducing sleep latency as small doses of barbiturates or benzodiazepines. However, while these latter compounds also increase morning sleepiness, valerian usually reduces morning sleepiness.

In another study of insomniacs, subjects received either a valerian preparation or placebo.^[29] Compared with the placebo, valerian showed a significant effect, with 44% reporting perfect sleep and 89% reporting improved sleep.

And finally, in another double-blind study of insomniacs, 20 subjects received a combination of valerian root extract (160 mg) and *Melissa officinalis* extract (80 mg), benzodiazepine (triazolam 0.125 mg), or placebo.^[30] In the insomniac group, the valerian preparation showed an effect comparable to that of the benzodiazepine as well as an ability to increase deep sleep stages 3 and 4. The valerian preparation did not, however, cause daytime sedation and there was no evidence of diminished concentration based on the Concentration Performance Test or impairment of physical performance.

THERAPEUTIC APPROACH

The treatment should be as conservative as possible and should include some means of dealing with psychological factors contributing to the insomnia. Metabolically, foremost is the elimination of those factors known to disrupt normal sleep patterns, such as:

- stimulants (e.g. coffee, tea, chocolate, coffee-flavored ice cream, etc.)
- alcohol
- hypoglycemia
- stimulant-containing herbs (e.g. ephedra, guarana)
- marijuana and other recreational drugs
- numerous over-the-counter medications
- prescription drugs.

If this approach produces no response, more aggressive measures can be taken. Once a normal sleep pattern has been established, the recommended supplements and botanicals should be slowly decreased. If the patient suffers from restless leg syndrome, add 5–10 mg/day of folic acid. Nocturnal myoclonus can be aided by 400 IU/day of natural vitamin E.

Lifestyle

Institute a regular exercise program that elevates heart rate 50–75% for at least 20 minutes a day.

Supplements

These should be taken 45 minutes before bedtime:

- Niacin: 100 mg (decrease dose if uncomfortable flushing interferes with sleep induction)
- Vitamin B₆: 50 mg
- Magnesium: 250 mg
- Tryptophan: 3–5 g; or 5-HTP: 100–300 mg
- Melatonin: 3 mg.

Botanical medicines

These should also be taken 45 minutes before bedtime:

- *Valeriana officinalis*
 - dried root (or as tea): 2–3 g
 - tincture (1:5): 4–6 ml (1–1.5 tsp)
 - fluid extract (1:1): 1–2 ml (0.5–1 tsp)
 - dry powdered extract (0.8% valerenic acid): 150–300 mg
- *Passiflora incarnata*
 - dried herb (or as tea): 4–8 g
 - tincture (1:5): 6–8 ml (1.5–2 tsp)
 - fluid extract (1:1): 2–4 ml (0.5–1 tsp)
 - dry powdered extract (2.6% flavonoids): 300–450 mg.

Chapter 165 - Irritable bowel syndrome

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

DIAGNOSTIC SUMMARY

- A functional disorder of the large intestine with no evidence of accompanying structural defect
- Characterized by some combination of:
 - abdominal pain
 - altered bowel function, constipation, or diarrhea
 - hypersecretion of colonic mucus
 - dyspeptic symptoms (flatulence, nausea, anorexia)
 - varying degrees of anxiety or depression
- Less acceptable synonyms include nervous indigestion, spastic colitis, mucous colitis, and intestinal neurosis. The splenic flexure syndrome is a variant of the irritable bowel syndrome in which gas in the bowel leads to pain in the lower chest or the left shoulder.

GENERAL CONSIDERATIONS

The irritable bowel syndrome (IBS) is the most common gastrointestinal disorder seen in general practice, and represents 30–50% of all referrals to gastroenterologists.^{[1] [2]} Determining incidence or prevalence figures is virtually impossible, as many sufferers never seek medical attention. It has, however, been estimated that approximately 15% of the population has complaints of IBS, with women predominating two to one (it is likely that an equal number of males have IBS but that they do not report symptoms as often). The etiology of the increased colonic motility seen in IBS has been attributed to

physiological, psychological, and dietary factors.

While IBS is often a diagnosis of exclusion, clinical judgment must be used to determine the needed extent of the diagnostic process. A detailed history and physical examination have been shown to eliminate much of the vagueness involved in diagnosing IBS.^[3] Distension, relief of pain with bowel movements, and the onset of loose or more frequent bowel movements with pain seem to correlate best with the diagnosis of IBS (any three $P = 0.84$, just one $P = 0.25$).^[1]

1360

TABLE 165-1 -- Conditions which may mimic IBS^[2]

-
- Gastrogenic dietary factors such as excessive tea, coffee, carbonated beverages, and simple sugars

 - Infectious enteritis such as amebiasis and giardiasis

 - Inflammatory bowel disease

 - Lactose intolerance

 - Laxative abuse (an easy test to eliminate this possibility is to add a few drops of sodium hydroxide solution to a stool specimen; since most laxatives contain phenolphthalein, the stool will turn red)

 - Intestinal candidiasis

 - Disturbed bacterial microflora as a result of antibiotic or antacid usage

 - Malabsorption diseases such as pancreatic insufficiency and celiac disease

 - Metabolic disorders such as adrenal insufficiency, diabetes mellitus, and hyperthyroidism

 - Mechanical causes such as fecal impaction

 - Diverticular disease

 - Neoplasm

In most cases, a comprehensive stool and digestive analysis (see [Ch. 9](#)), complete blood count, erythrocyte sedimentation rate, and serum protein concentration should be performed to determine the diagnosis. If no discernible cause can be identified, sigmoidoscopy is indicated. Conditions which may mimic IBS are shown in [Table 165.1](#).

THERAPEUTIC CONSIDERATIONS

Once other conditions have been ruled out, there appear to be three major treatments

to consider when formulating a therapeutic regimen:

- increasing dietary fiber
- eliminating allergic/intolerant foods
- controlling psychological components.

These are discussed below. In addition, please consult [Chapters 51](#) , [55](#) and [101](#) .

Dietary fiber

The treatment of irritable bowel syndrome by increasing dietary fiber has a long, though irregular, history.^[1] Patients with constipation are much more likely to respond to dietary fiber than those with diarrhea. One problem that has not been addressed in studies on the therapeutic use of dietary fiber is the role of food allergy. The type of fiber often used in both research and clinical practice is wheat bran.^[4] As wheat and other grains are among the most commonly implicated foods in malabsorptive and allergic conditions, the use of wheat bran is usually contraindicated since food allergy is a significant etiological factor in this condition.

Increasing dietary fiber from fruit and vegetable sources rather than cereal sources may offer more benefit in some individuals, although in one uncontrolled clinical study there was no significant difference in improvement when a diet composed of 30 g of fruit and vegetable fiber and 10 g of cereal fiber was compared with one with the opposite ratio.^[5] Although both diets resulted in similar significant improvement in abdominal pain, bowel habits, and state of well-being, the presence of large quantities of potentially allergic cereal fiber in both diets would probably have obscured any differences.

In certain cases, fiber may aggravate diarrhea and is therefore contraindicated. For a more detailed explanation on dietary fiber, see [Chapter 57](#) .

Food allergy

The importance of food allergies in the etiology of IBS has been recognized since the early 1900s.^[6] ^[7] More recent studies have further documented the association between food allergy and the irritable bowel.^[8] ^[9] ^[10] ^[11] The type of food allergy most significant in IBS is believed to be non-immunological, so food intolerance rather than food allergy may be a more appropriate diagnosis (see [Ch. 51](#) for definitions and further discussion). According to double-blind challenge methodologies, the majority of patients with IBS (approximately two-thirds) have at least one food intolerance, and some have multiple intolerances.^[8] The most common allergens are dairy products (40–44%) and grains (40–60%).^[10] Since in most cases the reaction appears to be related to prostaglandin synthesis or IgG- rather than IgE-mediated reactions, skin tests and the IgE-RAST are poor indicators of food intolerance in these patients. The ELISA ACT or ELISA IgE/IgG₄ may be better indicators (see [Chs 10](#) and [15](#) for further discussion), although many sensitivities may still be undetectable by currently available laboratory procedures.^[12] Many patients have noted marked clinical improvement when using elimination diets.^[8] ^[9]

[10] [11]

It is interesting to note that many IBS patients have associated symptoms suggestive of vasomotor instability (such as palpitation, hyperventilation, fatigue, excessive sweating, and headaches), which is consistent with food allergy/intolerance reactions.

Sugar

Meals high in refined sugar can contribute to IBS as well as small intestinal bacterial overgrowth by decreasing intestinal motility.^[13] When blood sugar levels rise too

1361

rapidly, a gastrointestinal tract peristalsis slows down. Since glucose is primarily absorbed in the duodenum and jejunum, the message affects this portion of the gastrointestinal tract the strongest. The result is that the duodenum and jejunum become atonic. A diet high in refined sugar may be the most important reason IBS is such a common condition in the United States.

Enteric-coated volatile oils

Peppermint oil and presumably similar volatile oils inhibit gastrointestinal smooth muscle action in both laboratory animal preparations and humans. Clinically, it has been used to reduce colonic spasm during endoscopy,^[14] and an enteric-coated peppermint oil capsule has been used in the treatment of IBS.^[15] Enteric coating is believed to be necessary, as menthol (the major constituent of peppermint oil) and other plant monoterpenes in peppermint oil are rapidly absorbed.^[16] This rapid absorption tends to limit its effects to the upper intestine, resulting in relaxation of the cardioesophageal sphincter and common side-effects, such as esophageal reflux and heartburn, after administration. A transient hot burning sensation in the rectum during defecation, due to unabsorbed menthol, has been noted in some patients taking the enteric-coated peppermint oil.

Most of the studies have utilized enteric-coated peppermint oil at a dosage of 0.2 ml twice daily between meals.^[16] The most recent, and perhaps the best-designed, study with enteric-coated peppermint oil involved 110 patients with symptoms of IBS.^[17] The patients took one capsule of either enteric-coated peppermint oil (0.2 ml) or a placebo three to four times daily, 15–30 minutes before meals, for one month. The results on the major symptoms of IBS are given below:

| Parameter | ECPO | Placebo |
|----------------------|------|---------|
| Abdominal pain | 79% | 43% |
| Abdominal distension | 83% | 29% |

| | | |
|-----------------|-----|-------|
| Stool frequency | 83% | 33% |
| Borborygmi | 73% | 31% |
| Flatulence | 79% | 22.5% |

These results are quite impressive, especially given the safety of enteric-coated peppermint oil. Only two cases of side-effects were reported – one patient developed heartburn (because of chewing the tablet) and one patient developed a transient skin rash.

Enteric-coated peppermint oil is thought to work by improving the rhythmic contractions of the intestinal tract and relieving intestinal spasm. An additional benefit of these volatile oils is their efficacy against *Candida albicans*.^[18] This is of use in IBS as an overgrowth of *C. albicans* may be an underlying factor, especially in cases that do not respond to dietary advice and in those who consume large amounts of sugar. Administration of nystatin (600,000 IU/day for 10 days) to patients who were unresponsive to an elimination diet produced dramatic clinical improvement.^[9]

Psychological factors

Mental/emotional problems, e.g. anxiety, fatigue, hostile feelings, depression, and sleep disturbances, are reported by almost all patients with IBS.^[19] Symptom severity and frequency tend to correlate with these psychological factors. Especially significant is sleep quality – poor sleep quality results in an increase in symptom severity.^[20]

There are several theories that link psychological factors to the symptoms of IBS. The “learning model” holds that when exposed to stressful situations some children learn to develop gastrointestinal symptoms to cope with the stress. Another theory holds that IBS is a manifestation of depression or chronic anxiety, or both. Personality assessments of IBS sufferers have shown them to have higher anxiety levels and a greater feeling of depression.^[21] However, these studies were based on post-morbid personality assessments, and it has since been determined by pre-morbid personality assessment that IBS sufferers have normal personality profiles. Therefore, many of the psychological symptoms may be either secondary to the bowel disturbances (particularly malabsorption) or the result of a common etiological factor, e.g. stress, food allergy, or candidiasis.

Increased colonic motility during exposure to stressful situations has been shown to occur in both normal subjects and those suffering from IBS.^[22] This apparently accounts for the increased abdominal pain and irregular bowel functions seen in patients with IBS and normal subjects during periods of emotional stress. Some researchers believe that IBS sufferers have difficulty adapting to life events, although this has not been well demonstrated in clinical studies. Psychotherapy, in the form of relaxation therapy,^[23] biofeedback,^[24] hypnosis,^[24] counseling,^[25] or stress management training,^[26] has been shown to reduce symptom frequency and severity and enhance the results of standard medical treatment of IBS. In contrast, the use of anxiolytic drugs, a combination of

tranquilizers and antispasmodics, or antidepressants has not yielded effective results.

Miscellaneous considerations

Although probably significant, the role of altered microbial flora in IBS has not been investigated. Some of the beneficial effects attributed to increasing dietary fiber may be mediated by alterations in colon bacteria concentrations. *Lactobacillus acidophilus* supplementation appears to be indicated in IBS (see [Ch. 105](#)).

1362

Although no research has been done to document its efficacy, an old naturopathic remedy, Robert's formula, has a long history of use in this condition (see [Ch. 180](#) for a full description).

An increase in physical exercise also appears helpful for these patients. Many find that daily leisurely walks markedly reduce symptoms, probably due to the known stress reduction effects of exercise.

THERAPEUTIC APPROACH

As a multifactorial disease, the approach to the patient with IBS requires the consideration and integration of many factors:

- dietary fiber
- determination and elimination of food allergies/intolerances
- stress reduction
- exercise.

As necessary, peppermint oil and Robert's formula may be used to temporarily ameliorate symptoms. Also, since the diagnosis is typically made by exclusion, a careful diagnostic work-up is always indicated.

Diet

Increase fiber-rich foods (see [Ch. 57](#)) and eliminate allergenic, refined sugar, and highly processed foods.

Supplements

- *Lactobacillus acidophilus* 1–2 billion live organisms/day.

Botanical medicine

- Enteric-coated volatile oil preparations (e.g. peppermint oil): 0.2–0.4 ml twice daily between meals.

Physical therapy

Take daily, leisurely 20 minute walks.

Counseling

Aid the patient in developing an effective stress reduction program. Biofeedback may be particularly useful for these patients.

Chapter 166 - Kidney stones

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

DIAGNOSTIC SUMMARY

- Usually asymptomatic
- Diagnosed adventitiously or by acute symptoms of urinary tract obstruction
- Excruciating intermittent radiating pain originating in the flank or kidney
- Nausea, vomiting, abdominal distension
- Chills, fever, and urinary frequency if infection.

GENERAL CONSIDERATIONS

Stone formation in the urinary tract has been recognized for thousands of years, but during the last few decades the pattern and incidence of the disease have changed markedly. In the past, stone formation was almost exclusively in the bladder, while today most stones form in the upper urinary tract. Over 10% of all males experience a renal stone during their lifetime, with an annual incidence of 0.1–6.0% of the general population. In the US, one out of every 1,000 hospital admissions is for kidney stones. The incidence has been steadily increasing, paralleling the rise in other diseases associated with the so called “Western diet”, i.e. ischemic heart disease, cholelithiasis, hypertension, and diabetes.

In the western hemisphere, kidney stones are usually composed of calcium salts (75–85%), uric acid (5–8%), or struvite (10–15%). The incidence varies geographically, reflecting differences in environmental factors, diet, and components of drinking water. Males are affected more than females, and most patients are over 30 years of age.

Human urine is supersaturated with respect to calcium oxalate, uric acid, and phosphates. They normally remain in solution, due to pH control and the secretion of inhibitors of crystal growth.

A number of primary and secondary metabolic diseases cause kidney stones and must be ruled out early in the clinical process:

- hyperparathyroidism
- cystinuria

1364

- vitamin D excess
- milk-alkali syndrome
- destructive bone disease
- primary oxaluria
- Cushing's syndrome
- sarcoidosis.

TABLE 166-1 -- Causes of excessive excretion of relatively insoluble urinary constituents

| Constituent | Cause of excess excretion | Laboratory findings |
|----------------------|---|---|
| Calcium | (>250 mg/day excreted) | |
| | Absorptive hypercalciurea | Low serum PO ₄ |
| | | 30–40% of all stone formers |
| | Renal hypercalciuria (renal tubular acidosis) | High serum PTH |
| | | High urinary cAMP |
| | Primary hyperparathyroidism | High serum calcium |
| | | High 1,25(OH) ₂ D ₃ |
| | Hyperthyroidism | |
| | High vitamin D intake | High serum calcium |
| | Excess intake of milk and alkali | |
| | Aluminum salt intake | Low serum phosphate |
| | | High 1,25(OH) ₂ D ₃ |
| | Destructive bone disease | |
| | Sarcoidosis | |
| Prolonged immobility | | |

| | | |
|-----------|---------------------------------------|--|
| Oxalate | Familial oxaluria | Rare |
| | Ileal disease, resection, or bypass | |
| | Steatorrhea | |
| | High oxalate intake | |
| | Ethylene glycon poisoning | |
| | Vitamin C excess (extremely unlikely) | Vitamin B ₆ deficiency or abnormal oxalate metabolism |
| | Methoxyflurane anesthesia | |
| Uric acid | (>750 mg/day excreted) | |
| | Gout | |
| | Idiopathic hyperuricosuria | |
| | Excess purine intake | |
| | Anti-cancer drugs | Rapid cell destruction |
| | Myeloproliferative disease | |
| Cystine | Hereditary cystinuria | |

DIAGNOSTIC CONSIDERATIONS

Stone formation

Conditions favoring stone formation can be divided into two groups: factors increasing the concentration of stone crystalloids; and factors favoring stone formation at normal urinary concentrations. The first group includes reduction in urine volume (dehydration) and an increased rate of excretion of stone constituents. The second group of factors is related to urinary stasis, pH changes, foreign bodies, and reduction of normal substances which solubilize stone constituents. See [Tables 166.1](#) and [166.2](#) for an outline of the diagnostic possibilities.

THERAPEUTIC CONSIDERATIONS

Stone composition

Diagnosing the type of stone is critical to determining the

TABLE 166-2 -- Physical changes in the urine and kidney

| Condition | Possible cause |
|-----------|----------------|
|-----------|----------------|

| | |
|----------------------------|---|
| Increased concentration | Dehydration |
| | Stasis |
| | Obstruction |
| | Foreign body concretions |
| Urinary pH | Low – uric acid, cystine |
| | High – calcium oxalate and PO ₄ |
| Infection | Proteus – struvite |
| Uricosuria | Crystals of uric acid initiate precipitation of calcium oxalate from solution |
| Nuclei for stone formation | Cells, bacteria, blood clots, etc. initiate precipitation |
| | Sponge kidney |
| Deformities of kidney | Horseshoe kidney |
| | Caliceal obstruction or defect |

appropriate therapy. Careful evaluation of the following criteria will usually determine the composition of the stone, if one is not available for chemical analysis:

- diet
- underlying metabolic or disease factors
- serum and urinary calcium, uric acid, creatinine, and electrolyte levels
- urinalysis
- urine culture.

[Table 166.3](#) summarizes the findings in the major types of kidney stones.

TABLE 166-3 -- Chemical and physical characteristics of urinary stones

| Composition | Crystal name | Frequency | X-ray appearance | Urine characteristics | Crystal characteristics |
|-----------------|--------------|-----------|------------------|-----------------------|--|
| Calcium oxalate | Whewellite | 30–35% | Opaque | Non-specific | Small, hempseed or mulberry-shaped, brown or black color |

| | | | | | |
|-------------------------------------|------------------|-------|-------------|-----------|--|
| Calcium oxalate + calcium phosphate | | 30–35 | Opaque | pH >5.5 | Small, hempseed or mulberry-shaped, brown or black color |
| Calcium phosphate | Apatite | 6–8 | Opaque | pH >5.5 | Staghorn configuration, light color |
| Magnesium ammonium phosphate | Struvite | 15–20 | Opaque | pH >6.2 | Staghorn configuration, light color |
| | Triple phosphate | | | Infection | |
| Uric acid | | 6–10 | Translucent | pH <6.0 | Ellipsoid, tan or red-brown |
| Cystine | | 2–3 | Opaque | pH <7.2 | Multiple, faceted, maple sugar color |

Dietary factors

Calcium-containing stones are composed of calcium oxalate, calcium oxalate mixed with calcium phosphate, or, very rarely, calcium phosphate alone. The high incidence of calcium-containing stones in affluent societies is directly associated with the following dietary patterns:

- low fiber^[1]
- highly refined carbohydrates ^[2] ^[3]
- high alcohol consumption^[4]
- large amounts of animal protein^[4] ^[5]
- high fat^[6]
- high calcium-containing food
- high vitamin D-enriched food.

The classification of most stones as either caused by “idiopathic” hypercalciuria or just “idiopathic” is reflective of ignorance of dietary factors that induce hyperuricemia, hypercalciuria, and stone formation. The cumulative effect of these dietary factors is undoubtedly the reason for the rising incidence of kidney stones.

As a group, vegetarians have a decreased risk of developing stones.^[5] Studies have shown that even among meat eaters those who ate higher amounts of fresh fruits and vegetables had a lower incidence of stones.^[7] Bran supplementation, as well as the simple change from white to whole wheat bread, has resulted in lowering urinary

calcium.^[1]

Weight and carbohydrate metabolism

Weight control and correction of carbohydrate metabolism are important, since excess weight and insulin insensitivity lead to hypercalciuria and are high-risk factors for stone formation.^{[8] [9]} This is particularly relevant, because following glucose ingestion there is a rise in urinary calcium along with a decreased phosphate reabsorption. This leads to a low plasma phosphate which stimulates 1,25-dihydroxycholecalciferol production and results in increased intestinal absorption of calcium and, concurrently, hypercalciuria. The ingestion of sucrose and other simple sugars causes an exaggerated increase in the urinary calcium oxalate content in approximately 70% of recurrent kidney stone formers.^[10]

Magnesium and vitamin B₆

A magnesium-deficient diet accelerates renal tubular calcium deposition in rats.^[11] Magnesium has been shown to increase the solubility of calcium oxalate and inhibit the precipitation of both calcium phosphate and calcium oxalate.^{[11] [12] [13]} A low urinary magnesium:calcium ratio is an independent risk factor in stone formation,^[14] and supplemental magnesium alone has been shown to be effective in preventing recurrences of kidney stones.^{[12] [13] [14]} However, when used in conjunction with vitamin B₆ an even greater effect is noted.^{[15] [16]}

Pyridoxine is known to reduce the endogenous production and urinary excretion of oxalates,^{[17] [18] [19]} and patients with recurrent oxalate stones show abnormal EGPT, EGOT, UGPT, and UGOT activation levels, indicating clinical insufficiency of vitamin B₆ and impaired glutamic acid synthesis. These levels return to normal after 3 months of treatment.^[19] Induced pyridoxine deficiency in rats has been shown to produce oxaluria and calcium oxalate lithiasis (which is prevented by magnesium supplementation).^[18]

Glutamic acid

Depressed levels of glutamic acid (due to vitamin B₆ deficiency or other reasons) is significant in the formation of kidney stones, since an increased concentration of glutamic acid in the urine induces calcium oxalate precipitation. Glutamic acid supplementation in rats significantly reduces the incidence of calculi, and it may do so in humans as well.^[20] Supplementation with glutamic acid may, however, be superfluous if adequate vitamin B₆ levels are attained.

Calcium

Most doctors tell their patients to avoid calcium supplements, as calcium restriction actually enhances oxalate

absorption. In other words, when calcium intake is restricted oxalate absorption is increased and calcium oxalate stones still form. A recent study has also shown that calcium supplementation actually reduces oxalate excretion.^[21]

The study measured the urinary oxalate excretion after calcium supplementation and the administration of oxalic acid. Calcium was given in the form of calcium carbonate or calcium citrate malate at a dosage of 300 mg elemental magnesium. Compared with baseline assessment, calcium supplementation significantly reduced oxalate absorption and excretion, indicating that calcium supplementation (300–1,000 mg daily) may prove to be an effective preventative measure against calcium oxalate kidney stones.

Citrate

While urinary calcium will rise in patients consuming calcium citrate, some of citrate's effects inhibit the formation of kidney stones. Specifically citrate has the ability to reduce urinary saturation of calcium oxalate and calcium phosphate, and to retard the nucleation and crystal growth of calcium salts. The use of potassium or sodium citrate in the treatment of recurrent calcium oxalate has been shown to be quite effective in clinical studies, ceasing stone formation in nearly 90% of the subjects.^[22] ^[23] For example, in one study, 31 mmol/day of potassium citrate provided to recurrent stone formers who were also hypocitraturic resulted in a drop of stone formation from 0.7 to 0.13/year.^[23] However, rather than use potassium or sodium citrate, it appears that magnesium citrate would offer the greatest benefit.

Vitamin K

The urinary glycoprotein that is a powerful inhibitor of calcium oxalate monohydrate growth requires post-transcription carboxylation of glutamic acid to form gamma-carboxyglutamic acid. Vitamin K is an essential factor for this carboxylation to occur.^[24] Impairment of glutamic acid formation or a vitamin K deficiency will reduce the formation of this glycoprotein. The presence of vitamin K in green leafy vegetables may be one reason vegetarians have a lower incidence of kidney stones.^[25]

Uric acid metabolism

The level of dietary purine consumption is linearly related to the rate of urinary uric acid excretion;^[26] this is important, since hyperuricosuria is a causative factor in recurrent calcium oxalate stones. High levels of supplemental folic acid promote purine scavenging and xanthine oxidase inhibition, resulting in decreased excretion of uric acid (see [Ch. 154](#)).

Botanicals

Anthraquinones isolated from the *Rubia*, *Cassia*, and *Aloe* species bind calcium and significantly reduce the growth rate of urinary crystals when used in oral doses lower than the laxative dose.^[27] ^[28] *Rubia tinctoria*, *Rumex*, *Rheum*, *Polygonum aviculare*, *Aloe*,^[29] *Senna*, *Rhamnus alnus*, and *Mitchella repens* are sources of these anthraquinones and may be used to prevent formation and, during acute attacks, to reduce the size of the stone.

The furanocoumarin-containing herb, *Ammi visnaga*, has been shown to be unusually effective in relaxing the ureter and allowing the stone to pass.^[30] This action is due to its calcium channel-blocking capabilities which act primarily upon the ureters. Atropine and papaverine have similar, but less active, smooth muscle-relaxing effects. *Peucedanum*, *Leptotania*, *Ruta graveolens*, and *Hydrangea* contain similar furanocoumarins that also promote smooth muscle relaxation, and all of these herbs have historical uses in the treatment of kidney stones.

Miscellaneous

Hair mineral analysis may be of value, since many heavy metals (mercury, gold, uranium, and cadmium) are nephrotoxic. Cadmium, in particular, has been shown to greatly increase the incidence of kidney stones. A prospective study of coppermiths showed a 40% incidence of kidney stones, which correlated with elevated serum cadmium levels.^[31]

Vitamin C is often cited in the medical literature as a potential factor in the development of calcium oxalate kidney stones. However, numerous studies have now demonstrated that in persons not on hemodialysis or suffering from recurrent kidney stones, severe kidney disease, or gout, high-dosage vitamin C therapy will not cause kidney stones. Vitamin C administration of up to 10 g/day has not shown any effect on urinary oxalate levels.^[32] ^[33]

Another possible intervention is to decrease sodium chloride consumption. Urinary calcium excretion increases approximately 1 mmol (40 mg) for each 100 mmol (2,300 mg) increase in dietary sodium in normal adults. Renal calcium stone formers with hypercalcemia have a greater increase in urinary calcium per 100 mmol increase in salt intake.^[34]

THERAPEUTIC APPROACH

Effective treatment requires accurate differentiation between the various stone types and the recognition and control of any underlying metabolic diseases or structural abnormalities of the urinary tract. [Tables 166.1](#) and [166.2](#) list diagnosable causes of kidney stones.

Prevention of recurrence is the therapeutic aim in the

treatment of kidney stones. Since dietary management is effective, inexpensive, and free from side-effects, it is the treatment of choice. The specific treatment is determined by the type of stone and may include:

- reducing urinary calcium
- reducing purine intake
- avoiding high oxalate-containing foods
- increasing foods with a high magnesium:calcium ratio
- increasing vitamin K-rich foods.

For all types of stones, increasing urine flow to dilute the urine is vital. Enough fluids should be consumed to produce a urine with a specific gravity lower than 1.015 and urinary volume of at least 2,000 ml.

Acute obstruction

(Surgical removal or lithotripsy may be necessary.)

- *Ammi visnaga* extract (12% khellin content): 250 mg three times daily
- *Rubia tinctora*, *Rumex crispus*, or *Aloe vera* at below laxative doses.

Calcium stones

Diet

Increase fiber, complex carbohydrates, and green leafy vegetables, and decrease simple carbohydrates and purines (meat, fish, poultry, yeast). Increase high magnesium:calcium ratio foods (barley, bran, corn, buckwheat, rye, soy, oats, brown rice, avocado, banana, cashew, coconut, peanut, sesame seed, lima beans, potato). If they are oxalate stones, reduce oxalate foods (black tea, cocoa, spinach, beet leaves, rhubarb, parsley, cranberry, nuts). Limit dairy products.

Supplements

- Vitamin B₆ : 25 mg/day
- Vitamin K: 2 mg/day
- Magnesium: 600 mg/day
- Calcium: 300–1,000 mg/day.

Botanicals

Use any of the following in a dose below the laxative effect:

- *Rubia tinctoria*
- *Rumex crispus*
- *Aloe vera*.

Miscellaneous

Avoid aluminum compounds and alkalis.

Uric acid stones

Diet

Decrease purines (list above).

Supplements

- Folic acid: 5 mg/day.

Miscellaneous

- Alkalinize urine: citrate, bicarbonate.

Magnesium ammonium phosphate stones

Miscellaneous

- Eradicate infection: see [Chapter 53](#)
- Acidify urine: ammonium chloride (100–200 mg t.i.d.).

Cystine stones

Diet

Avoid methionine-rich foods (soy, wheat, dairy products [except whole milk], fish, meat, lima beans, garbanzo beans, mushrooms, and all nuts except coconut, hazelnut, and sunflower seeds).

Miscellaneous

- Alkalinize urine: optimal pH is 7.5–8.0.

Chapter 167 - Leukoplakia

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

DIAGNOSTIC SUMMARY

- Adherent white patch or plaque appearing anywhere on the oral mucosa
- Asymptomatic until ulceration, fissuring, or malignant transformation
- Diagnosis confirmed by biopsy.

GENERAL CONSIDERATIONS

Leukoplakia is a clinical term signifying a white plaque-like lesion occurring anywhere on the oral mucosa. It is generally a reaction to irritation, such as cigarette smoking or tobacco or betel nut chewing, and an early sign in HIV infection. It appears most frequently in men aged 50–70 years. In 90% of the cases, it represents epithelial hyperkeratosis and hyperplasia.^[1] In the remaining 10% of cases there is also epithelial dysplasia; these lesions are considered precancerous.

Oral cancer is among the most common malignant neoplasms, with nearly 50,000 new cases and 12,000 deaths reported in the United States alone each year. Survival rates with chemotherapy, radiation, and surgical procedures are unchanged in the past few decades. Success in preventing mortality is through prevention. Abstinence from tobacco and an increased intake of antioxidant nutrients are the primary preventive measures.

THERAPEUTIC CONSIDERATIONS

Treatment of leukoplakia includes removal of all irritants. Electrodessication, cryosurgery, and proteolytic enzymes have not given predictably favorable results.^[2]

Vitamin A and beta-carotene

Historically, vitamin A supplementation and, more recently, beta-carotene have been found to be clinically effective in the treatment of leukoplakia.^{[3] [4] [5] [6] [7] [8]} Stich et al,^{[7] [8]} using the micronucleus test to monitor the efficacy, were

1370

among the first to look at vitamin A and beta-carotene. The micronucleus test is a useful indicator of the cancerous tendency of epithelial cells, since it provides immediate information on genotoxic damage. Micronuclei are formed during chromatid or chromosomal breakage, with the rate of formation tied closely to carcinogenesis in the oral cavity. It is a good predictor of cancer, which typically takes years or decades to develop clinically recognizable signs. Based on the results using the micronucleus test, Stich et al found that these two dietary factors, particularly beta-carotene, were quite effective in decreasing the mean proportion of cells with micronuclei on the buccal mucosa in Asian betel nut and tobacco chewers.^{[7] [8]} These subjects continued to chew betel nut and tobacco during the study.

The epidemiological and experimental data documenting the protective effect of carotenoids and retinoids against epithelial cancers are overwhelming (see [Chs 67](#) and [121](#)). The inverse relationship between serum retinol and carotene levels and cancer incidence holds true for oral carcinomas as well.^{[9] [10]}

Clinical studies which tested vitamin A in the treatment of leukoplakia used dosages which were generally quite high (i.e. 150,000–900,000 IU/day), but extremely effective.^{[3] [4] [5] [6]} Since it appears that beta-carotene is as effective as retinol in decreasing micronuclei levels and has a much higher therapeutic index, it is suggested that beta-carotene be the treatment of choice for this condition. (Note: vulvar leukoplakia is also responsive to retinol, and could therefore respond to beta-carotene as well.)^{[11] [12]}

More recent studies have focused on the use of beta-carotene in the treatment of leukoplakia. To date, there have been seven clinical trials showing that beta-carotene produces regression of leukoplakia.^[9] The results of these studies are given in [Table 167.1](#) .

TABLE 167-1 -- Beta-carotene trials

| Author | Dosage | Response rate |
|-------------------------------|-------------|---------------|
| Stich et al ^[7] | 180 mg/week | 15% |
| Stich et al ^[8] | 180 mg/week | 27% |
| Garewal et al ^[13] | 30 mg/day | 71% |
| Brandt et al ^[14] | 90 mg/day | 60% |

| | | |
|-------------------------------|-----------|-----|
| Toma et al ^[15] | 90 mg/day | 44% |
| Malaker et al ^[16] | 30 mg/day | 50% |
| Garewal et al ^[17] | 60 mg/day | 56% |

Other antioxidants

In addition to beta-carotene, other antioxidants may be helpful. For example, studies have shown vitamin E (400 mg/day) to produce a 65% response rate.^[18] However, it makes the most sense to utilize a combination of antioxidant nutrients, given their interactions and limitations, as monotherapy. Preliminary results using a combination of vitamin C (1,000 mg/day), beta-carotene (30 mg/day), and vitamin E (400 mg/day) are encouraging.^[19]

THERAPEUTIC APPROACH

Since leukoplakia is due to a combination of excessive carcinogenic irritation in the context of marginal or low levels of vitamin A, the approach is simple: eliminate all sources of irritation and establish optimal vitamin A, beta-carotene, and antioxidant levels. Particularly significant irritation results from tobacco smoking and chewing, betel nut chewing, and ultraviolet exposure.

Supplements

- Vitamin A: 5,000 IU/day
- Beta-carotene: 30–90 mg/day
- Vitamin C: 1,000–3,000 mg/day
- Vitamin E: 400 IU/day.

Chapter 168 - Macular degeneration

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

DIAGNOSTIC SUMMARY

- Progressive visual loss due to degeneration of the macula
- Ophthalmological exam may reveal spots of pigment near the macula and blurring of the macular borders.

GENERAL CONSIDERATIONS

The macula, the area of the retina where most images focus, is the portion of the eye responsible for fine vision. Degeneration of the macula is the leading cause of severe visual loss in the United States and Europe in persons aged 55 years or older and is second to cataracts as the leading cause of decreased vision in persons over 65 years of age. It is estimated that over 150,000 Americans are legally blind from age-related macular degeneration, with 20,000 new cases occurring each year.^{[1] [2]}

The major risk factors for macular degeneration are smoking, aging, atherosclerosis, and hypertension.^{[1] [2] [3]} Apparently, the degeneration is a result of free radical damage similar to the type of damage that induces cataracts (see [Ch. 188](#)). However, decreased blood and oxygen supply to the retina is the harbinger of macular degeneration.

Types of macular degeneration

The two most common types of age-related macular degeneration are the atrophic (“dry”) form, by far the more frequent, and the neovascular (“wet”) form.^{[2] [3]} In either form, patients may experience blurred vision. The patient may note that straight objects appear distorted or bent; the presence of a dark spot near or around the center of the visual field; and, while reading, that parts of words are missing.

Dry ARMD

Between 80 and 95% of people with ARMD have the dry form of the disease. The primary lesions are atrophic

1374

changes in the retinal pigmented epithelium (RPE) which composes the innermost layer of the retina. Apparently beginning in early life, and continuing throughout life, cells of the RPE gradually accumulate sacs of cellular debris (lipofuscin). The lipofuscin bodies are either remnants of incompletely degraded abnormal molecules from damaged RPE cells or derivatives of phagocytized rod and cone membranes. Progressive engorgement of the RPE cells with lipofuscin is associated with the extrusion of tissue components like hyaline, sialomucin, and cerebroside.^{[1] [2] [3]} The hallmark excrescences beneath the RPE apparent upon ophthalmoscopic examination are referred to as “drusen”.

The disease progresses slowly and only central vision is lost, as peripheral vision remains intact. It is rare for anyone to become totally blind from dry ARMD.^{[1] [2] [3]} Currently there is no standard medical treatment for this common form of ARMD.

Wet ARMD

The other form of ARMD is the wet or neovascular form. This form affects 5–20% of those with ARMD. It is characterized by the growth of abnormal blood vessels. Unlike the dry form, wet ARMD can be treated quite effectively, in the early stages, with laser photocoagulation therapy. Because the disease can rapidly progress to a point where surgery cannot be utilized, the surgery should be performed as soon as possible.^{[1] [2] [3]}

THERAPEUTIC CONSIDERATIONS

The treatment of the wet form of ARMD is straightforward: laser photocoagulation. The treatment of the dry form and prevention of the wet form involve the use of antioxidants and natural substances which correct the underlying pathophysiology, i.e. free radical damage and poor oxygenation of the macula. This can be accomplished by reducing the risk factors for atherosclerosis, increasing dietary intake of fresh fruits and vegetables, and supplementing with nutritional and botanical antioxidants.

Reducing and preventing atherosclerosis

Although atherosclerosis is a well-accepted risk factor for macular degeneration, this association was unconfirmed until 1995.^[3] In the confirmation study, 104 subjects with, and 1,324 subjects without, macular degeneration were evaluated for atherosclerosis by ultrasound determination of the intima-media thickness and by assessment of the

presence of atherosclerotic plaque in the carotid arteries as well as by measuring the ankle:arm systolic blood pressure ratio (an indicator of peripheral atherosclerosis). The results indicated that in subjects younger than 85 years, plaques in the carotid bifurcation were associated with a 4.7 times increased prevalence of macular degeneration. Lower extremity atherosclerosis was associated with a 2.5 times greater risk.

These results indicate that measures designed to reduce the risk of atherosclerosis are of great significance in the prevention (and treatment) of macular degeneration (see [Ch. 133](#) for a comprehensive program for prevention and reversal).

Dietary fruits and vegetables

A diet rich in fruits and vegetables is associated with a lowered risk for ARMD. Presumably this protection is the result of increased intake of antioxidant vitamins and minerals.^[4]^[5]^[6] However, various “non-essential” food components such as the non-provitamin A carotenes lutein, zeaxanthin, and lycopene and flavonoids are proving to be even more significant in protecting against ARMD than traditional nutritional antioxidants. The macula, especially the central portion of the macula, the fovea, owes its yellow color to its high concentration of lutein and zeaxanthin. These yellow carotenoids function in preventing oxidative damage to the area of the retina responsible for fine vision and obviously a central role in protecting against the development of macular degeneration.^[7]

For example, one study compared patients with soft drusen, retinal pigment abnormalities, age-related macular degeneration and/or neovascular or exudative macular degeneration with controls. Individuals with lycopene in the lowest quintile were twice as likely to have age-related macular degeneration.^[6]

Nutritional supplements

In addition to recommending a diet high in antioxidants, supplementation with nutritional antioxidants like vitamin C, selenium, beta-carotene, and vitamin E is certainly important in the treatment and prevention of macular degeneration. A combination of these nutrients will likely produce better results than any single nutrient alone as studies have shown that none of these antioxidants alone accounts for the impaired antioxidant status in ARMD. Instead, the decreased antioxidant status reflects decreases in a combination of nutrients.^[4]

There have been a couple of studies utilizing various commercially available broad-based antioxidant formulas that have shown promising results. For example, a 1.5 year study demonstrated that the progression of dry ARMD could be halted (but not reversed) with Ocuguard.^[8]^[9] A retrospective study of a nutritional supplement called ICAPS Plus (which contains beta-carotene, vitamins C and E, zinc, copper, manganese, selenium, and riboflavin) compared the 38 who used

the preparation regularly with the 37 who used only one bottle, who served as controls. Fifteen of the treated patients improved their vision by one line or more compared with only six of the control group. In addition, three of the 38 in the treatment group lost one line or more of vision, compared with 13 in the control group.^[10] In a second prospective blinded clinical trial reported in the same review, vision and contrast sensitivity were evaluated. After 6 months, visual acuity was the same or better in 36 of 61 controls compared with 168 of 192 treated patients.

Zinc

Zinc plays an essential role in the metabolism of the retina and the elderly are at high risk for zinc deficiency. A 2 year, prospective, randomized, double-blind, placebo-controlled trial involving 151 subjects with dry ARMD demonstrated that the group taking 200 mg/day of zinc sulfate (approximately 80 mg of elemental zinc) had significantly less visual loss than the placebo group.^[11] These results were not confirmed, however, in a more recent double-blind study in 112 patients with wet ARMD.^[12]

Although these results are viewed as “inconclusive” until further studies are performed, given the importance of zinc to the human eye, supplementation certainly seems justifiable.

Flavonoid-rich extracts

Flavonoid-rich extracts of bilberry (*Vaccinium myrtillus*), *Ginkgo biloba*, or grape seed (*Vitis vinifera*) offer significant benefits in the prevention and treatment of ARMD. In addition to possessing excellent antioxidant activity, all three extracts have been shown to exert positive effects on retinal blood flow and function. Clinical studies in humans have demonstrated that all three are also capable of halting the progressive visual loss of dry ARMD and possibly even improving visual function.^{[13] [14] [15] [16]} Of the three extracts, bilberry extracts standardized to contain 25% anthocyanidins appear to be the most useful. The anthocyanosides of *Vaccinium myrtillus* have a very strong affinity for the retinal pigmented epithelium which composes the optical or functional portion of the retina, reinforcing the collagen structures of the retina and preventing free radical damage. Since the RPE is the portion of the eye affected in ARMD, it appears that *Vaccinium myrtillus* anthocyanosides are ideal therapeutic agents in the disorder. However, the *Ginkgo biloba* extract with a 24% ginkgo flavonglycoside content is perhaps a better choice if the patient is also demonstrating signs of cerebrovascular insufficiency. Grape seed extract may be the most useful when there is significant photophobia or poor night vision.

Lifestyle

As oxidant exposure is a major factor in macular degeneration, it is not surprising that

smoking increases the risk of macular degeneration in both men and women.^[17] ^[18] For example, in a 12 year study of 31,843 registered female nurses, those who currently smoked 25 or more cigarettes per day had a relative risk of 2.4 for age-related macular degeneration compared with those who had never smoked. Past smokers of 25 cigarettes or more per day still had a twofold increased risk relative to never-smokers. Risk did not return to the control until after quitting smoking for 15 years.^[18]

THERAPEUTIC APPROACH

As with most diseases, prevention or treatment at an early stage is most effective. The treatment of the wet form of ARMD is clearly laser photocoagulation, applied as soon as possible. Since free radical damage and lack of blood and oxygen supply to the macula appear to be the primary causes of macular degeneration, consumption of antioxidants and promotion of retinal blood flow are the keys to effective treatment.

Any patient 55 years or older complaining of visual loss should be referred to an ophthalmologist for complete evaluation, especially if the visual loss is progressing rapidly.

Diet

Avoid fried and grilled foods, and other sources of free radicals. Increase consumption of legumes (high in sulfur-containing amino acids), yellow vegetables (carotenes), flavonoid-rich berries (blueberries, blackberries, cherries, etc.) and vitamin E- and vitamin C-rich foods (fresh fruits and vegetables).

Supplements

- Vitamin C: 1 g three times/day
- Vitamin E: 600 to 800 IU/day
- Selenium: 400 mcg/day
- Beta-carotene (mixed carotenoids recommended): 50,000 IU/day
- Lutein: 5 mg/day.

Botanical medicines (choose one)

- *Ginkgo biloba* extract (24% ginkgo heterosides): 40–80 mg three times/day
- *Vaccinium myrtillus* (bilberry) extract (25% anthocyanidin content): 40–80 mg three times/day
- Grape seed extract (95% procyanidolic content): 150–300 mg/day.

Chapter 169 - Male infertility

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

DIAGNOSTIC SUMMARY

- Inability to conceive a child after 6 months of unprotected sex in the absence of female causes
- A total sperm count less than 5 million/ml
- The presence of greater than 50% abnormal sperm
- Inability of sperm to impregnate egg as determined by the postcoital or hamster egg penetration tests.

GENERAL CONSIDERATIONS

In the United States, it is estimated that as many as 15% of all couples have difficulty conceiving a child. In about one-third of the cases of infertility, it is the man who is responsible; in another one-third, both the male and female are responsible; and in another one-third, it is the female who is responsible. Current estimates suggest about 6% of men between the ages of 15 and 50 are infertile.^[1]

Most causes of male infertility reflect an abnormal sperm count or quality. Although it only takes one sperm to fertilize an egg, in an average ejaculate a man will eject nearly 200 million sperm. However, because of the natural barriers in the female reproductive tract only about 40 sperm will ever reach the vicinity of an egg. There is a strong correlation between the number of sperm in an ejaculate and fertility.

In about 90% of the cases of low sperm count, the reason is deficient sperm production. Unfortunately, in about 90% of cases, the cause for the decreased sperm formation cannot be identified and the condition is labeled “idiopathic oligospermia or azospermia”.^[2] Oligo-spermia means a low sperm count while azospermia is defined as a complete absence of living sperm in the semen. Other causes of male infertility include ductal obstruction, ejaculatory dysfunctions, and infections or disorders of

accessory glands (see [Table 169.1](#)).

Since the overwhelming majority of men who are infertile suffer from deficient sperm production, this will be the major focus of this chapter.

TABLE 169-1 -- Causes of male infertility

-
- Deficient sperm production

 - Ductal obstruction
 - congenital defects

 - post-infectious obstruction

 - cystic fibrosis

 - vasectomy

 - Ejaculatory dysfunction
 - premature ejaculation

 - retrograde ejaculation

 - Disorders of accessory glands
 - infection

 - inflammation

 - antisperm antibodies

 - Coital disorders
 - defects in technique

 - premature withdrawal

 - erectile dysfunction

Review of the male sexual system

The male sexual system is composed of the scrotal sac, testes, genital ducts, accessory glands, and penis. The scrotal sac performs an important role in maintaining the testes at a temperature about 2°C below the temperature of the internal organs so that sperm formation can occur. The cremasteric muscles help to maintain the appropriate scrotal temperature by pulling the testes close to the body when they get too cold and dropping them loose when the temperature rises too high. In addition to serving the function as

the location for sperm formation, the testes are also responsible for hormonal output.

Each testicle is surrounded by a thick, sturdy capsule of connective tissue known as the tunica albuginea which serves as a protective shield for this somewhat exposed organ. Inside the testis are about 250 compartments known as testicular lobules, with each lobule being composed of one to four tubules called seminiferous tubules. Each tubule is 1.5–2 feet long if straightened out.

Inside the seminiferous tubule, sperm formation takes place with the aid of nutrient-providing cells called Sertoli cells. Sertoli cells are known to have at least four main functions:

- the support, protection, and nutritional regulation of the developing sperm
- the breaking down of cellular debris cast off by developing sperm
- the secretion of a fluid that is utilized for sperm transport
- the excretion of estrogen and a binding protein for testosterone.

The seminiferous tubules are immersed in a web of blood and lymphatic vessels, loose connective tissue, nerves, and Leydig cells. These cells are responsible for the production and secretion of testosterone. Leydig cells are almost non-existent in the testes during childhood, but are numerous and quite active in the newborn male infant and in the adult male after puberty, the two times when the testes secrete large quantities of testosterone.

The fully developed sperm (spermatozoa) is produced via a process known as spermatogenesis. Sperm production usually begins around puberty as a result of the release of the pituitary hormones leutinizing hormone (LH) and follicle-stimulating hormone (FSH). LH stimulates the Leydig cells to produce testosterone, while FSH stimulates the Sertoli cells to produce sperm. Other hormones are also critical, especially testosterone, which is essential for the growth and division of the germinal cells in the production of sperm. Estrogens, formed from testosterone by the Sertoli cells, are also critical to sperm function.

Genital ducts

The genital ducts function by transporting the sperm produced in the testis out of the body. The first passageway is the epididymis, one long, highly tortuous tube about 20 feet in length. As the sperm make the passage through the epididymis, they begin to mature. After being in the epididymis for 18–24 hours, the sperm become more motile (inhibitory fluids secreted by the epididymis prevent full motility until after ejaculation).

From the epididymis, the sperm travel up through the ductus (vas) deferens, a straight tube with thick walls. Before the vas penetrates the prostate it dilates, forming a region known as the ampulla. At the final portion of the ampulla, the seminal vesicles join. Upon entering the prostate, the duct is called the ejaculatory duct before it empties into the urethra.

Accessory glands

It was previously thought that the sperm was stored in the seminal vesicles, hence their name. We now know the primary function of the seminal vesicles is the secretion of a fluid that provides nutrients to sperm and increases sperm motility. Substances secreted by the seminal vesicles include fructose, which nourishes the sperm, and large quantities of prostaglandins and fibrinogen. Prostaglandins are thought to aid fertilization by reacting with the mucus of the vagina and cervix to make it more receptive to sperm and possibly causing contractions in the uterus and fallopian tubes to move the sperm toward the ovaries. The fibrinogen combines with prostatic secretions to form a weak coagulate, which holds the semen together after ejaculation, allowing it deeper penetration into the vagina. The coagulate also limits sperm motility, but as the coagulate dissolves 15–20 minutes after ejaculation, the sperm become highly motile.

About 60% of the volume of semen is composed of secretions from the seminal vesicles. The remainder

1379

of the semen is composed of prostatic fluid (30% of the total volume) and secretions from the vas deferens including sperm and fluid (10% of total volume).

The prostate, a doughnut-shaped gland about the size of a walnut lying below the bladder and surrounding the urethra, secretes a thin, milky, alkaline fluid which lubricates the urethra to prevent infection and increases sperm motility. The alkaline nature of the prostatic secretion is extremely important to successful fertilization of the egg, because the fluid of the vas deferens as well as the vaginal secretions are relatively acidic. Sperm do not become optimally mobile until the pH of the surrounding fluids rises to approximately 6–6.5. Consequently, the prostatic fluid plays an important role in promoting sperm motility by neutralizing the acid and raising the pH of semen to 7.5.

The final accessory sexual glands are the bulbourethral glands, pea-sized formations located below the prostate and around the urethra. The bulbourethral glands produce a thin, milky secretion that lubricates the urethra and prepares the urethra for the transport of the semen.

The penis

The penis consists primarily of erectile tissue, the urethra, and blood vessels, all surrounded externally by skin. The penis is divided into two distinct sections, the shaft and the head (glans penis). The glans is the most important source of nerve impulses to signal the sexual response. The shaft of the penis contains erectile tissue that is housed in three cylindrical masses. Two of the masses, the corpus cavernosum, are located around central arteries while the other, the corpus cavernosum or spongiosum,

surrounds the urethra.

Erection is the result of dilation of the arteries in the penis combined with the filling of the erectile tissue. In simple terms, an erection requires that the volume of blood entering the penis exceed the volume leaving it. The erectile tissue is really nothing more than large, cavernous, blood storage compartments, which are normally relatively empty but which become dilated when arterial blood flows rapidly into them under pressure and the outflow is partially occluded. The erectile tissue is surrounded by a strong membrane composed of hard fibers, which greatly increases the pressure within the ballooning erectile tissue; thus the penis becomes hard and elongated.

DIAGNOSTIC CONSIDERATIONS

Semen analysis is the most widely used test to estimate fertility potential in the male. The semen is analyzed for concentration of sperm and sperm quality. The total sperm count as well as sperm quality of the general male population has been deteriorating over the last

TABLE 169-2 -- Possible causes of falling sperm counts

few decades. In 1940, the average sperm count was 113 million/ml; by 1990 that value had dropped to 66 million.^[3] Adding to this problem, the amount of semen fell almost 20% from 3.4 to 2.75 ml. Altogether, these changes mean that men are now supplying about 40% of the number of sperm per ejaculate compared with 1940 levels ([Table 169.2](#) presents possible causes for this fall).

The downward trend in sperm counts has led to speculation that environmental, dietary, or lifestyle changes in recent decades may be interfering with a man's ability to

manufacture sperm. Although controversial, there is substantial evidence that supports this speculation. This evidence and methods for improving sperm quality are discussed in greater detail below.

In diagnosing male infertility on the basis of sperm concentration, it is important to point out that as sperm counts in the general population have declined, there has also been a parallel reduction in the accepted line differentiating between infertile and fertile men, from 40 million/ml, to 20 million/ml, to 10 million/ml, to 5 million/ml. One of the key reasons these values have dropped so drastically is that researchers are learning that quality is more important than quantity (see [Table 169.3](#)). A high sperm count means absolutely nothing if the percentage of healthy sperm is not also high.

Whenever the majority of sperm are abnormally shaped, or are entirely or relatively non-motile, a man can be infertile despite having a normal sperm concentration. Conversely, a low sperm count does not always mean a man is infertile ([Table 169.4](#)). Numerous pregnancies have occurred with men having very low sperm counts. For example, in studies at fertility clinics, 52% of

couples whose sperm counts were below 10 million/ml achieved pregnancy and 40% of

those with sperm counts as low as 5 million/ml are able to achieve pregnancy.^[1] Because of these confirmed successes in men with low sperm counts, it is recommended that conventional semen analysis be interpreted with caution regarding the likelihood of conception and that more sophisticated functional tests should be used, especially when screening couples for in vitro fertilization.

Until recently, pregnancy was the only proof of the ability of sperm to achieve fertilization. Now there are several functional tests in use (see [Table 169.5](#)). The postcoital test measures the ability of the sperm to penetrate the cervical mucus after intercourse. In vitro variants of this test are also available. One of the most encouraging tests is based on the discovery that human sperm can, under appropriate conditions, penetrate hamster eggs. It was established that fertile males exhibit a range of penetration of 10–100% and that penetration less than 10% is indicative of infertility. The hamster egg penetration test is considered to predict fertility in 66% of the cases compared with about 30% for conventional semen analysis.^[1]

Another important test in the diagnosis of infertility is the detection of antisperm antibodies. These antibodies, when produced by the man, usually attack the tail of the sperm, thereby impeding the sperm's ability to move and penetrate the cervical mucus. In contrast, the antisperm antibodies produced by women are typically directed against the head. The presence of antisperm antibodies in semen analysis is usually a sign of past or current infection in the male reproductive tract.

THERAPEUTIC CONSIDERATIONS

Standard medical treatment of oligospermia can be quite effective when the cause is known, e.g. increased scrotal temperature, chronic infection of male sex glands, prescription

TABLE 169-5 -- Male fertility tests

| Test | Fertility prediction accuracy |
|------------------------------|--------------------------------------|
| Semen analysis | 30% |
| Hamster egg penetration test | 66% |

medicines, and endocrine disturbances (including hypogonadism and hypothyroidism). However, as stated above, in about 90% of the cases of oligospermia, the cause is unknown (idiopathic oligospermia). With regard to azoospermia, if the cause is ductal obstruction, new surgical techniques are showing some good results.^[1]

In the treatment of idiopathic oligospermia or azoospermia, the rational approach is to focus on enhancing those factors which promote sperm formation. In addition to scrotal temperature, sperm formation is closely linked to nutritional status. Therefore, it is critical that men with low sperm counts have optimal nutritional intake. In addition to consuming a healthful diet, there are several nutritional factors that deserve special mention:

- vitamin C and other antioxidants
- fats and oils
- zinc
- folate
- vitamin B₁₂
- arginine
- carnitine.

In addition, it appears important for men with low sperm count to avoid dietary sources of estrogens.

Some herbs, especially *Panax ginseng* and *Eleutherococcus senticosus*, are known to increase sperm counts. And finally, another popular natural treatment of male infertility involves the use of glandular therapy. The concept behind this therapy is discussed below.

Controlling sperm-damaging factors

Scrotal temperature

The scrotal sac normally keeps the testes at a temperature of between 94 and 96° Fahrenheit.^[2] At temperature above 96°F, sperm production is greatly inhibited or stopped completely. Typically, the mean scrotal temperature of infertile men is significantly higher than that of fertile men. Reducing scrotal temperature in infertile men will often be enough make them fertile. This temperature reduction is best done by not wearing tight-fitting underwear or tight jeans, and avoiding hot tubs.

In addition, the following exercises can raise scrotal temperature, especially if a man is wearing synthetic fabrics, exceptionally tight shorts, or tight bikini underwear: rowing machines, simulated cross-country ski machines, treadmills, and jogging. After exercising, a man should allow his testicles to hang free to allow them to recover from heat build-up.

Infertile men should wear boxer-type underwear and periodically apply a cold shower or ice to the scrotum. They can also choose to use a device called a testicular hypothermia device or “testicle cooler” to reduce scrotal

temperatures. Still in its somewhat primitive stage, the testicle cooler looks like a jock strap from which long, thin tubes have been extended. The tubes are attached to a small fluid reservoir filled with cold water that attaches to a belt around the waist. The fluid reservoir is also a pump that causes the water to circulate. When the water reaches the surface of the scrotum, it evaporates and keeps the scrotum cool. Because of the

evaporation, the reservoir must be filled every 6 hours or so. It is recommended that the testicle cooler must be worn daily during waking hours. Most users claim that it is fairly comfortable and easy to conceal.^[4]

Increased scrotal temperature can be due to the presence of a varicocele. A large varicocele can cause scrotum temperatures high enough to inhibit sperm production and motility. Surgical repair may be necessary, but scrotal cooling should be tried first.

Infections and infertility

Infections in the male genitourinary tract, including infections of the epididymis, seminal vesicles, prostate, bladder, and urethra, are thought to play a major role in many cases of infertility.^[5] The exact extent of the role they play is largely unknown because of the lack of suitable diagnostic criteria coupled with the asymptomatic nature of many infections. The presence of antisperm antibodies is considered to be a good indicator of a chronic infection in the absence of other clinical findings.

There are a wide number of bacteria, viruses, and other organisms which can infect the male genitourinary system. It is beyond the scope of this chapter to discuss every type of infection, and therefore the discussion will be limited to *Chlamydia trachomatis*. Chlamydia is now recognized as the most common as well as the most serious of infections in the male genitourinary tract.^[5]

Chlamydia is considered a sexually transmitted disease. In women, chlamydia infection can lead to pelvic inflammatory disease (PID) and scarring of the fallopian tubes. Previous chlamydia infection accounts for a large number of cases of female factor infertility. In men, chlamydia infection can lead to equally disabling effects. Chlamydia is the major cause of acute non-bacterial prostatitis and urethritis. Typically the symptoms will be pain or burning sensations upon urination or ejaculation. More serious is chlamydia infection of the epididymis and vas deferens. The resultant damage to these organs parallels the tubal damage in women. Serious scarring and blockage can occur. During an acute chlamydia infection, antibiotics are essential. Chlamydia is sensitive to tetracyclines and erythromycin. Unfortunately, because chlamydia lives within human cells it may be difficult to totally eradicate the organism with antibiotics alone.

While acute chlamydial infections are usually associated with severe pain, chronic infections of the urethra, seminal vesicles, or prostate can go on with little or no symptoms. It is estimated that 28–71% of infertile men have evidence of a chlamydial infection.^[5] Because of the possible link between chlamydia and low sperm counts, there have been several double-blind studies on the effects of antibiotics on sperm counts. These studies have shown only limited improvements in sperm count and sperm quality.^[5] However, there have been isolated cases of tremendous increases in sperm counts and sperm quality after antibiotic treatment. If electing this form of treatment, both partners should take the antibiotic. However, it should be used only if there is reason to believe a chronic infection is present and after the recommendations given in [Chapter 148](#) have been employed for at least 3 months. The presence of antisperm antibodies may indicate a chronic chlamydia infection. In the absence of a positive culture, rectal ultrasonography and the detection of antibodies directed against

chlamydia can confirm the diagnosis.

Avoiding estrogens

According to experts on the impact of the environment and diet on fetal development, we now live in an environment that can be viewed as “a virtual sea of estrogens”.^{[6] [7]} Increased exposure to estrogens during fetal development, as well as during the reproductive years, is suggested to be a major cause of the tremendous increase in the disorders of development and function of the male sexual system.

The relationship between estrogens and male sexual development is best viewed by examining the effects of the synthetic estrogen, diethylstilbestrol (DES). Between 1945 and 1971 several million women were treated with DES. By 1970, the side-effects of DES became more known. DES is now recognized to have led to substantial increases in the number of men suffering from developmental problems of the reproductive tract as well as decreased semen volume and sperm counts.^[5] As well as being used in humans, DES and other synthetic estrogens were used for 20–30 years in the livestock industry to fatten the animals and help them grow faster.

Although many synthetic estrogens like DES are now outlawed, many livestock and poultry are still hormonally manipulated, especially dairy cows. Cow's milk contains substantial amounts of estrogen due to modern farming techniques. The rise in dairy consumption since the 1940s inversely parallels the drop in sperm counts. Avoidance of hormone-fed animal products and milk products are important for male sexual vitality, especially in men with low sperm counts or low testosterone levels.

There are reports that estrogens have been detected in drinking water.^{[6] [7]} Presumably the estrogens are recycled

from excreted synthetic estrogens (birth control pills) at water treatment plants. These estrogens may be harmful to male sexual vitality as they are more potent since they do not bind to sex-hormone-binding-globulin (SHBG). Purified or bottled water may be a suitable option to prevent exposure.

There are other sources of estrogen from the environment (food, water, and air) that can weaken male sexual vitality. For example, many of the chemicals that we have contaminated our environment with in the past 50 years are weakly estrogenic. Most of these chemicals, like PCBs, dioxin, and DDT, are resistant to biodegradation and are recycled in our environment until they find a safe haven in our bodies. For example, even though DDT has been banned for nearly 20 years, it is still often found in the soil and root vegetables such as carrots and potatoes. These toxic chemicals are known to interfere with spermatogenesis, but their effects during sexual development may be more important.

All of the estrogenic factors discussed above are thought to have their greatest impact during fetal development. Based on animal studies, these estrogens inhibit the multiplication of the Sertoli cells. The number of Sertoli cells is directly proportional to the amount of sperm that can be produced, as each Sertoli cell can only support a fixed number of germ cells that will develop into sperm.

Sertoli cell multiplication occurs primarily during fetal life and before puberty. It is controlled by follicle-stimulating hormone (FSH). In animal studies, estrogens administered early in life inhibit FSH secretion, resulting in a reduced number of Sertoli cells and, in adult life, reduced sperm counts. Evidence exists to indicate that the same events occur in humans.^[6] The best example are the sons of women exposed to DES during pregnancy, who, like the animals exposed to estrogens, show reduced sperm counts. Even if a mother did not take DES she may have followed the typically low-fiber, high-fat diet of most Americans. Such a diet is associated with higher levels of estrogens because, without the fiber, excreted estrogens are reabsorbed.

If testosterone levels are low or marginal, or if estrogen levels are elevated, a diet rich in legumes (beans), especially soy foods, may be of benefit. Soy is a particularly good source of isoflavonoids. These compounds are also known as “phytoestrogens”, signifying their mild estrogenic activity. The isoflavonoids in soybeans have about 0.2% of the estrogen activity of estradiol, the principal human estrogen. Isoflavones actually bind to estrogen receptors. Their weak estrogenic action is in actuality an anti-estrogenic effect as it prevents the binding of the body’s own estrogen to the receptor. In addition, phytoestrogens may reduce the effects of estrogens on the body by stimulating the production of SHBG so that the estrogen is bound.^[8] Soy, as well as other legumes, nuts, and seeds, is also a good source of phytosterols which may aid in the manufacture of steroid hormones including testosterone.

Heavy metals

Sperm are also particularly susceptible to the damaging effects of heavy metals such as lead, cadmium, arsenic, and mercury. A hair mineral analysis for heavy metals should be performed on all men with reduced sperm counts to rule out heavy metals as a cause.

Nutritional considerations

Vitamin C and other antioxidants

Free radical or oxidative damage to sperm is thought to be responsible for many cases of idiopathic oligospermia, with high levels of free radicals found in the semen of 40% of infertile men.^{[9] [13]} Three factors combine to render sperm particularly susceptible to free radical damage:

- a high membrane concentration of polyunsaturated fatty acids
- active generation of free radicals

- a lack of defensive enzymes.

All of these factors combine to make the health of the sperm critically dependent upon antioxidants. Although most free radicals are produced during normal metabolic processes, the environment contributes greatly to the free radical load. Men exposed to increased levels of sources of free radicals are much more likely to have abnormal sperm and sperm counts.^{[1] [9] [10] [11] [12]}

Sperm are extremely sensitive to free radicals because they are so dependent upon the integrity and fluidity of their cell membrane for proper function. Without proper membrane fluidity, enzymes are activated, which can lead to impaired motility, abnormal structure, loss of viability, and ultimately death of the sperm.^[9] The major determinant of membrane fluidity is the concentration of polyunsaturated fatty acids, particularly omega-3 fatty acids like docosahexanoic acid, which are very susceptible to free radical damage. The sperm have a relative lack of superoxide dismutase and catalase which can prevent or repair oxidative damage. Adding to this more susceptible state is the fact that sperm generate high quantities of free radicals to help break down barriers to fertilization.

A common source of oxidants is cigarette smoking, which is associated with decreased sperm counts and sperm motility as well as an increased frequency of abnormal sperm.^[12] Cigarette smoking, as well as the increase in environmental pollution, is thought to be a major contributor to the decrease in sperm counts seen in many industrialized nations during the past few decades.

1383

Antioxidants such as vitamin C, beta-carotene, selenium, and vitamin E have been shown to be very important in protecting the sperm against damage. Vitamin C plays an especially important role in protecting the sperm's genetic material (DNA) from damage. Ascorbic acid levels are much higher in seminal fluid compared with other body fluids, including the blood. When dietary vitamin C was reduced from 250 to 5 mg/day in healthy human subjects, the seminal fluid ascorbic acid decreased by 50% and the number of sperm with damage to their DNA increased by 91%.^[14] These results indicated that dietary vitamin C plays a critical role in protecting against sperm damage and that low dietary vitamin C levels were likely to lead to infertility.

It is now well-documented that cigarette smoking greatly reduces vitamin C levels throughout the body. Even the Food and Nutrition Board, the organization which calculates the recommended dietary allowances (RDAs) acknowledges that smokers require at least twice as much vitamin C than non-smokers.^[15] In one study, men who smoked one pack of cigarettes a day received either 0, 200, or 1,000 mg of vitamin C. After 1 month, sperm quality improved proportional to the level of vitamin C supplementation.^[16]

Non-smokers also appear to benefit from vitamin C as much as smokers. In one study,

30 infertile but otherwise healthy men received either 200 or 1,000 mg vitamin C or placebo daily.^[17] There were weekly measurements of sperm count, viability, motility, agglutination, abnormalities, and immaturity. After 1 week, the 1,000 mg group demonstrated a 140% increase in sperm count, the 200 mg group a 112% increase, and the placebo group no change. After 3 weeks both vitamin C groups continued to improve, with the 200 mg group catching up to the improvement of the 1,000 mg group. One of the key improvements was observed in the number of agglutinated sperm. Sperm become agglutinated when antibodies produced by the immune system bind to the sperm. Antibodies to sperm are often associated with chronic genitourinary tract or prostatic infection. When more than 25% of the sperm are agglutinated, fertility is very unlikely. At the beginning of the study all three groups had over 25% agglutinated sperm. After 3 weeks, the agglutinated sperm in the vitamin C groups dropped to 11%. Although this result is significant, the most impressive result of the study was that at the end of 60 days, all of the vitamin C group had impregnated their wives, compared with none of the placebo group. It can be concluded from these results that vitamin C supplementation can be very effective in treating male infertility, particularly if the infertility is due to antibodies against sperm.

Other dietary antioxidants, such as vitamin E, selenium, and beta-carotene, are also important and should be supplemented. Vitamin E supplementation appears to be especially warranted as it is the main antioxidant in various cell membranes, including sperm membranes. Vitamin E has been shown to play an essential role in inhibiting free radical damage to the unsaturated fatty acids of the sperm membrane.^[18] In addition, vitamin E has been shown to enhance the ability of sperm to fertilize an egg in test tubes. In one study, supplementation with vitamin E was found to decrease malondialdehyde concentration in sperm pellet suspensions. Even more important, however, 11 of 52 treated infertile men impregnated their spouses.^[19] Supplementation appears to be indicated based on its physiological effects alone. Vitamin E may prove to exert more beneficial effects on sperm counts or motility when given at higher levels (600–800 IU/day).

Fats and oils

Considering the effects of fats and oils on agglutination and cell membrane dynamics, certain fats are best avoided in infertile men while others should be increased. Saturated fats, hydrogenated oils, *trans*-fatty acids, and cotton, coconut and palm oil should be avoided. Coconut and palm oils are primarily saturated fat, while cotton seed may contain toxic residues, due to the heavy spraying of cotton and its high levels of gossypol, a substance known to inhibit sperm function. In fact, gossypol is being investigated as the “male birth control pill”. Its use as an antifertility agent began after studies demonstrated that men who had used crude cotton seed oil as their cooking oil were shown to have low sperm counts followed by total testicular failure.^[20] Excessive consumption of saturated fats combined with inadequate intake of essential fatty acids changes the fatty acid composition of the sperm membranes, thus decreasing fluidity and interfering with sperm motility. The patient must be informed to read food labels carefully and avoid all sources of cotton seed oil and other damaging oils.

While the intake of saturated and hydrogenated fats must be eliminated, the intake of

polyunsaturated oils should be increased. These oils function in all aspects of sexual function including sperm formation and activity.

Zinc

Zinc is perhaps the most critical trace mineral for male sexual function. It is involved in virtually every aspect of male reproduction including the hormone metabolism, sperm formation, and sperm motility.^[21] Among many other problems, zinc deficiency is characterized by decreased testosterone levels and sperm counts. Zinc levels are typically much lower in infertile men with low sperm counts, indicating that a low zinc status may be the contributing factor to the infertility.

1384

Several studies have evaluated the effect of zinc supplementation on sperm counts and motility.^[22]^[23]^[24] The results from all of the studies support the use of zinc supplementation in the treatment of oligospermia, especially in the presence of low testosterone levels. The effectiveness of zinc is best illustrated by a study in 37 men with infertility of greater than 5 years' duration whose sperm counts were less than 25 million/ml.^[24] Blood testosterone levels were also measured. The men received a supplement of zinc sulfate (60 mg elemental zinc daily) for 45–50 days. In the 22 patients with initially low testosterone levels, mean sperm count increased significantly from 8 to 20 million. Testosterone levels also increased and nine out of the 22 wives became pregnant during the study. This result is quite impressive given the long-term nature of the infertility and the rapidity of the results. In contrast, in the 15 men with normal testosterone levels, although sperm count increased slightly, there was no change in testosterone level and no pregnancies occurred.

Optimal zinc levels must be attained if optimum male sexual vitality is desired. Although severe zinc deficiency is quite rare in this country, many men consume a diet that does not provide the RDA for zinc (15 mg). Zinc is found in whole grains, legumes, nuts, and seeds. In addition to eating these zinc-containing foods, recommending supplementary zinc (45–60 mg/day) appears warranted.

Vitamin B₁₂

Vitamin B₁₂ is involved in cellular replication. A deficiency of B₁₂ leads to reduced sperm counts and sperm motility. Even in the absence of a vitamin B₁₂ deficiency, supplementation appears to be worthwhile in men with sperm counts less than 20 million per mL or a motility rate of less than 50%. In one study, 27% of men with sperm counts less than 20 million given 1,000 mcg/day of vitamin B₁₂ were able to achieve a total count in excess of 100 million.^[25] In another study, 57% of men with low sperm counts given 6,000 mcg/day demonstrated improvements.^[26]

Arginine

The amino acid arginine is required for the replication of cells, making it essential in sperm formation. Arginine supplementation is often, but not always, an effective treatment of male infertility. The critical determinate appears to be the level of oligospermia. If sperm counts are less than 20 million/ml, arginine supplementation is less likely to be of benefit. In order to be effective, it appears that the dosage of L-arginine be at least 4 g/day for 3 months. In perhaps the most favorable study, 74% of 178 men with low sperm counts had significant improvements in sperm counts and motility.^[27] L-Arginine therapy should be reserved for use after other nutritional measures have been tried.

Carnitine

Carnitine is essential in the transport of fatty acids into the mitochondria. A deficiency of carnitine results in a decrease in fatty acid concentrations in the mitochondria and reduced energy production. Carnitine concentrations are extremely high in the epididymis and sperm, suggesting a role for carnitine in male reproductive function. The epididymis derives the majority of its energy requirements from fatty acids, as do the sperm, during transport through the epididymis. After ejaculation, the motility of sperm correlates directly with carnitine content. The higher the carnitine content, the more motile are the sperm. Conversely, when carnitine levels are low, sperm development, function and motility are drastically reduced. One clinical study found an increase in sperm count and mobility in 37 of 47 men with idiopathic asthenospermia.^[28]

Supplementing the diet with L-carnitine may be useful in restoring male fertility in some cases. The optimal dosage is 300–1,000 mg of L-carnitine three times daily. However, because L-carnitine tends to be relatively expensive, the other nutritional measures should be tried first.

Botanical medicines

Ginseng

Current scientific investigation suggests that both *Panax ginseng* (Chinese or Korean ginseng) and *Eleutherococcus senticosus* (Siberian ginseng) are likely to be effective in the treatment of male infertility. Both botanicals have a long history of use as male “tonics”. Although human clinical studies are lacking, *Panax ginseng* has been shown to promote the growth of the testes, increase sperm formation and testosterone levels, and increase sexual activity and mating behavior in studies with animals (see [Ch. 100](#) for references). Siberian ginseng has also shown some benefit to the male reproductive function in animal studies as it has been shown to increase reproductive capacity and sperm counts in bulls (see [Ch. 83](#) for references). These results seem to support the use of either ginseng as a fertility and virility aid.

In general, *Panax ginseng* is regarded as being more potent in its effects (particularly

stimulant effects) than *Eleutherococcus senticosus*. Although Siberian ginseng contains no ginsenosides and is not a true ginseng, it does possess many of the same effects that *Panax ginseng* exerts, but it is generally regarded as being milder.

1385

Pygeum africanum

Pygeum may be effective in improving fertility in cases where diminished prostatic secretion plays a significant role. Pygeum has been shown to increase prostatic secretions and improve the composition of the seminal fluid.^{[29] [30] [31]} Specifically, pygeum administration to men with decreased prostatic secretion has led to increased levels of total seminal fluid plus increases in alkaline phosphatase and protein. Pygeum appears to be most effective in cases where the level of alkaline phosphatase activity is reduced (i.e. less than 400 IU/cm³) and where there is no evidence of inflammation or infection (i.e. absence of white blood cells or IgA). The lack of IgA in the semen is a good indicator of clinical success. In one study, the patients with no IgA in the semen demonstrated an alkaline phosphatase increase from 265 to 485 IU/cm³.^[29] In contrast, those subjects with IgA showed only a modest increase from 213 to 281 IU/cm³.

Pygeum extract has also shown an ability to improve the capacity to achieve an erection in patients with BPH or prostatitis as determined by nocturnal penile tumescence in a double-blind clinical trial.^[32] BPH and prostatitis are often associated with erectile dysfunction and other sexual disturbances. Presumably, by improving the underlying condition, pygeum can improve sexual function.

Glandular therapy

For almost as long as historic records have been kept, glandular therapy has been an important form of medicine. The basic concept underlying the medicinal use of glandular substances from animals is that "like heals like". In the case of low testosterone levels or low sperm counts, extracts of bovine (beef) orchic or testicular tissues are often recommended by physicians practicing glandular therapy. It is well established that a number of glandular preparations are effective orally because of active hormones (e.g. thyroid, adrenal, and thymus). Presumably, orchic or testicular products may also be of benefit. Unfortunately, dosage, as well as effectiveness, may vary from one manufacturer to another.

THERAPEUTIC APPROACH

Male infertility is most often due to an abnormal sperm count or semen quality. Referral to a urologist or fertility specialist for a complete evaluation is often necessary. As elevated scrotal temperature is a common cause of infertility, scrotal cooling through the use of loose underwear made of cotton, avoidance of activities which elevate testicular temperature (e.g. hot tubs) and application of cold water to the testes should be utilized.

Nutritional status should be optimized (especially antioxidants and zinc), environmental pollutants identified and eliminated, and fertility-enhancing botanicals such as the ginsengs consumed.

General measures

- Maintain scrotal temperatures between 94 and 96°F
- Avoid exposure to free radicals
- Identify and eliminate environmental pollutants
- Stop or reduce all drugs, especially antihypertensives, anti-neoplastics such as cyclophosphamide, and anti-inflammatory drugs such as sulfasalazine.

Diet

- Avoid dietary sources of free radicals, saturated fats, hydrogenated oils, *trans*-fatty acids, and cottonseed oil
- Increase consumption of legumes, especially soy (high in phytoestrogens and phytosterols), good dietary sources of antioxidant vitamins, carotenes, and flavonoids (dark-colored vegetables and fruits), and essential fatty acids and zinc (nuts and seeds)
- Recommend the daily consumption of eight to 10 servings of vegetables, two to four servings of fresh fruits, and half a cup of raw nuts or seeds.

Nutritional supplements

- Multiple vitamin and mineral
- Vitamin C: 1,000–3,000/day in divided doses
- Vitamin E: 600–800 IU/day
- Beta-carotene: 100,000–200,000 IU/day
- Folic acid: 400 µg/day
- Vitamin B₁₂: 1,000 µg/day
- Zinc: 30–60 mg/day.

Botanical medicines

- *Panax ginseng* (three times/day dosages)
 - high quality crude ginseng root: 1.5–2 g/day
 - standardized extract (5% ginsenosides): 500 mg
- *Eleutherococcus senticosus*
 - dried root: 2–4 g
 - tincture (1:5): 10–20 mL
 - fluid extract (1:1): 2.0–4.0 mL

—solid (dry powdered) extract (20:1): 100–200 mg.

The dosage of ginseng is related to the ginsenoside content. The typical dose (taken one to three times daily) should contain a saponin content of at least 25 mg of ginsenosides with a ratio Rb1 to Rg1 of 2:1. For example, for a high-quality ginseng root extract containing 5% ginsenosides, the dose would be 500 mg.

1386

As each individual's response to ginseng is unique, care must be taken to observe possible ginseng toxicity (see [Ch. 100](#)). It is best to begin at lower doses and to increase gradually. The Russian approach for long-term administration of either Panax or Siberian ginseng is to use ginseng cyclically for a period of 15–20 days followed by a 2 week interval without any ginseng. This recommendation appears prudent.

Chapter 170 - Menopause

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

DIAGNOSTIC SUMMARY

- Cessation of menstruation in older women for 6–12 months
- Average age of onset is 51 years
- Hot flashes in 65–80%
- Atrophic vaginitis
- Frequent bladder infections in 15%.

INTRODUCTION

Menopause denotes the cessation of menstruation in women, which usually occurs when a woman reaches the age of 50. Six to 12 months without a period is the commonly accepted rule for diagnosing menopause. The time period prior to menopause is referred to as perimenopausal while the time period after menopause is referred to as postmenopausal. During the perimenopausal period, many women ovulate irregularly due to either inadequate secretion of estrogen or resistance of the remaining follicles to ovulatory stimulus.

The current medical view of menopause is as a disease rather than as a normal physiological process. This is in stark contrast to the perspective of many cultures in which menopause is a natural part of the life process and a positive event in a woman's life. In fact, in many cultures of the world, most women do not experience the symptoms associated with menopause. This observation raises some interesting questions about menopause being a sociocultural event.

With the prolongation of life expectancy, the menopausal and postmenopausal periods are becoming more significant in a woman's life. In fact, today's average woman can expect to live at least one-third of her life in the postmenopausal phase.

Current medical treatment of menopause primarily involves hormone replacement therapy, utilizing a combination of estrogen and progesterone. The obvious question is: “Is hormone replacement therapy necessary?” The goal of this chapter is to answer this question and

1388

provide a natural approach to menopause and the postmenopausal period.

GENERAL CONSIDERATIONS

Causes of menopause

Menopause is thought to occur when there are no longer any eggs left in the ovaries. This “burning out” of the ovaries reflects the natural course of events. At birth, there are about 1 million eggs (ova). This number drops to 300,000–400,000 at puberty; however, only about 400 of these ova will actually mature during reproductive years. By the time a woman reaches the age of 50, few eggs remain.

With menopause, the absence of active follicles results in reduced production of estrogen and progesterone level. In response to this drop in estrogen, the pituitary increases secretion of FSH and LH. After menopause, FSH and LH are secreted in large and continuous quantities.

Although there are no longer any follicles to stimulate in the postmenopausal woman, LH and FSH cause the ovaries as well as the adrenal glands to secrete increased amounts of androgens which can be converted to estrogens by the fat cells of the hips and thighs. Converted androgens account for most of the circulating estrogen in postmenopausal women, but the total estrogen levels are still far below the levels in women with reproductive function.

Menopause as a social construct

The biomechanical model of health that most physicians adhere to leaves little room for other explanatory models. In the case of menopause, the biomechanical model focuses on the physiological processes resulting from ovarian decline, ignoring the psychological and cultural aspects of menopause. In Western society, menopause is viewed as a deficiency disease.

While there is undeniably a physiological process involved in menopause, menopause is much more than simply a biological event. Social and cultural factors contribute greatly to how women react to menopause.^[1] Modern society has placed great value on the allure of everlasting youth, resulting in a cultural devaluing of older women. This devaluation is deeply entrenched in our mental programming, as it is found in our

children's books, fairy tales, television programs, and movies. Advocates of a social and cultural explanation of menopause often point to this cultural devaluing of older women as the root of the negativity associated with achieving menopause.

In contrast, in many cultures of the world, women look forward to menopause because it brings with it greater respect. Achieving an advanced age is viewed as a sign of divine blessing and great wisdom. Studies of menopausal women in many traditional cultures demonstrate that most will pass through menopause without hot flashes, vaginitis, and other symptoms common to menopausal women in developed countries. Even osteoporosis is extremely rare, despite the fact that the average woman in many traditional societies lives at least 30 years after menopause.

Cross-cultural research clearly demonstrates that the cultural view of menopause is directly related to the symptoms of menopause.^[2] If the cultural view of menopause is largely negative, as in the United States, symptoms are quite common. In contrast, if menopause is associated with little negativity or viewed in a positive light, symptoms are far less frequent.

One of the most detailed studies on the cultural effects on menopause involved studying rural Mayan Indians.^[2] Detailed medical histories and examinations which included physical examination, hormone level measurement, and bone density studies were performed on 52 postmenopausal women. According to these results, no woman experienced hot flashes or any other menopausal symptom and not one single woman showed evidence of osteoporosis, despite the fact that their hormonal patterns were identical to postmenopausal women living in the United States.

The researchers of this study felt that the attitude of the Mayan women towards menopause was responsible for their symptomless passage. The Mayan women saw menopause as a positive event that would provide them with acceptance as respected elders as well as relief from child-bearing. This attitude is very different from the dominant attitude towards menopause common to industrialized societies. If our society adopted a different cultural view of older women, it is likely that the symptoms of menopause would cease to exist.

The Western view of menopause: feminine forever?

In 1966, Robert A. Wilson MD introduced, in his landmark book, *Feminine Forever*, the theory that menopause is an estrogen deficiency disease that needs to be treated with estrogen to compensate for the normal decline of estrogen with aging.^[3] According to Wilson, without estrogen replacement therapy, women are destined to become sexless "caricatures of their former selves ... the equivalent of a eunuch".

Wilson's theory of menopause as a disease is now the dominant medical view of menopause. This places women entering menopause in a difficult dilemma: should they pass through this period of time naturally or should they remain "forever feminine"? Before a woman can be counseled, the benefits and the risks of estrogen replacement

therapy must be considered, as well as the natural alternatives.

Estrogen replacement therapy

The evolution of estrogen replacement therapy

During the 1940s and 1950s, estrogen became a popular prescription for ameliorating the symptoms of menopause. By the 1970s, estrogen replacement therapy became firmly entrenched as the medical treatment of choice for women in menopause. Unfortunately, the consequences of long-term estrogen therapy were not well understood.

It is now well established that estrogen replacement therapy is associated with a four to 13 times increased risk of developing endometrial cancer.^[4] To combat the link between estrogen and endometrial cancer, drug companies and physicians began recommending that estrogen be combined with progesterone. Estrogen replacement therapy thus became hormone replacement therapy (HRT). The combination of estrogen with progesterone (or more accurately a progestin) appears to have reduced the risk of endometrial cancer, but still carries with it the risk of causing other cancers (discussed below).^[5] This stigma looms very large in the minds of many women and some physicians.

The benefits of HRT

Hormone replacement therapy (HRT) results in several undeniable benefits: relief of hot flashes and other menopausal symptoms and a significant reduction in osteoporosis. Furthermore, while early studies showed an increased risk for cardiovascular disease with estrogen use, more recent studies are indicating that the estrogen may offer some protection against heart disease and strokes.^{[6] [7]}

However, dietary, exercise, and lifestyle factors have also been shown to offer identical benefits without the risks. Furthermore, the use of short-term (less than 6 months) HRT for menopausal symptoms only provides temporary relief. It is not a permanent cure; it only delays the inevitable. Long-term HRT is not justified in most women due to the risks outweighing the benefits. The exception is women who are at high risk of developing osteoporosis.

Since both estrogen and progesterone have been shown to exert beneficial effects against bone loss and, in women with established bone loss, actually to increase bone mass, estrogen–progesterone combinations are preferred to estrogen alone.^{[6] [7]} The exception is in women at high risk for breast cancer or women with a disease aggravated by estrogen, such as breast cancer, active liver diseases, and certain

cardiovascular diseases, in which case progesterone alone should be used.

HRT and cancer

The cancer-causing potential of HRT is a serious concern. Unfortunately, while there have been over 50 studies seeking to determine the cancer risk of HRT, the results have not been clear.^{[8] [9] [10] [11]}

The most likely form of cancer adversely affected by HRT is breast cancer, the most common cancer in women. Current estimates are that one in nine women in the United States will develop breast cancer in her lifetime. Since estrogens play a critical role in the development of most breast cancers, it only makes sense that additional estrogens may promote breast cancer.

Several studies in postmenopausal women taking estrogen have shown an increased risk for breast cancer. When all are examined collectively, experts have calculated that estrogen replacement therapy is associated with a 1–30% increase in the risk of breast cancer.^{[9] [10] [11]} Most of the positive studies were conducted in European countries and seem to suggest an association that increases with age and length of use. In comparison, only a few studies in the United States have shown that HRT increases the risk of breast cancer. Several hypotheses have been suggested to explain this surprising difference: American researcher bias; and the fact that since American women are already at such a high risk for breast cancer, the effect is difficult to measure. American researcher defensiveness about the positive findings in the European studies makes resolution of this issue difficult, as does the years-long United States medical establishment's enthusiastic recommendation of estrogen and HRT.

Based on the current evidence, and until the issue of whether HRT increases the risk of breast cancer is cleared up, it can be concluded that well-intentioned physicians and their female patients are probably better off avoiding HRT, except in specific cases such as serious osteoporosis.

Other side-effects of HRT

The *Physicians' Desk Reference* and package inserts for estrogen and progesterone products provide a long list of side-effects. In addition to the risk of cancer, estrogen and progesterone increase the risk of developing gallstones and blood clots and are absolutely contraindicated during the first 4 months of pregnancy.

Other side-effects of estrogen and progesterone include:

- nausea
- breast tenderness
- symptoms similar to premenstrual tension syndrome (PMS)
- depression
- liver disorders
- enlargement of uterine fibroids

- fluid retention
-

1390

- blood sugar disturbances
- headaches.

However, these side-effects are most often linked to estrogen and progesterone-containing birth control pills. Since the doses of estrogen and progesterone used in menopause are much lower than the doses used in oral contraception, these side-effects are usually not as common when used in menopausal women.

A newly recognized side-effect was discovered through the evaluation of the more than 23,000 women in the Nurses' Health Study. Women taking postmenopausal hormones were found to be over twice as likely to suffer adult-onset asthma than women who never took hormones.^[12] The researchers also found that the effect was dose-related. This finding could help explain why severe adult-onset asthma afflicts more women than men. This is not surprising since the number of asthma cases in women soars at the onset of puberty.

Types of HRT

If after weighing all the evidence, a woman elects to utilize HRT for short-term relief or if she requires long-term therapy because of a high risk for osteoporosis, it is important that she participates in choosing the right combination and dosage pattern for her needs. There is no well-accepted "best program" among many experts. However, based on the current evidence, a strong case could be made for what is known as combined continuous HRT as being the best in terms of benefits to risk.^{[6] [7]}

When estrogen is given alone without a progestin, it is known as unopposed estrogen therapy. This regimen carries with it the high risk for endometrial cancer and possibly other cancers, including breast cancer. Unopposed estrogen can either be given continuously (every day) or during 25 day cycles separated by 3–6 days without estrogen.

In an effort to reduce the risk of endometrial cancer, estrogen is often given in combination with a progestin-like progesterone. The hormones can be given either in a cyclical fashion or continuously. The cyclical fashion involves taking estrogen for 25 days and progestin for the last 10–12 days of the cycle. A 3–6 day hormone-free interval follows, during which planned bleeding occurs. In other words, with cyclical administration, menstruation continues in about 90% of women.

In order to prevent monthly bleeding, estrogen and progesterone can be given every day without a hormone-free interval. This regimen is known as combined continuous HRT. As shown in [Table 170.1](#), when administered according to recommended guidelines (the lowest dose of estrogen possible along with 2.5 mg of

medroxy-progesterone acetate), combined continuous HRT offers several advantages over other regimens.

TABLE 170-1 -- Advantages of combined continuous hormone replacement therapy

-
- Avoidance of cyclical bleeding
-
- Continuous protection of the endometrium against the cancer-causing effects of estrogen
-
- Lower daily and cumulative amounts of progestins are required
-
- Avoidance of symptoms of premenstrual syndrome which often accompany estrogen
-
- Prolongation of the synergistic effects of estrogen and progesterone on bone integrity
-
- Regression of uterine fibroids
-
- Prevention of rare conceptions by promoting endometrial atrophy
-
- Greater convenience and patient compliance

As for the best type of estrogen to use, “natural-type” estrogens are preferred to synthetic versions. Examples of natural estrogens commonly used in HRT include:

- conjugated estrogens (Premarin, Genesis)
- esterified estrogens (Evex, Menest)
- micronized 17-beta-estradiol (Estrace)
- transdermal 17-beta-estradiol (Estraderm, System).

The most commonly used forms are the conjugated estrogens like Premarin. Conjugated estrogens are metabolized in the body to active forms of estrogen like 17-beta-estradiol. Unfortunately, the liver catabolizes much of the active estrogens before they have the opportunity to produce their effects. Therefore, relatively large amounts of conjugated estrogens have to be given, especially since the most active estrogen, 17-beta-estradiol, is not absorbed well orally. It is, however, absorbed very well through the skin and is the form of estrogen used in the newer estrogen patches as well as vaginal creams.

Estrogen patches are preferable to conjugated estrogens for several reasons, but primarily because they approximate more accurately the female body’s own natural estrogen secretions by delivering 17-beta-estradiol into the bloodstream in a slow, sustained manner. Estrogen-containing patches appear to be safer than oral estrogens. The patches are applied to the skin and changed twice per week.

With regard to the best form of progesterone, the natural derivative, medroxyprogesterone acetate, is preferred to synthetic versions like megestrol, norethindrone, and norgestrel. Examples of medroxyprogesterone products are Provera, Cycrin, and Amen.

THE MAJOR SYMPTOMS

The most common complaints of menopause are:

- hot flashes
 - headaches
 - atrophic vaginitis
 - frequent urinary tract infections
 - cold hands and feet
-

1391

- forgetfulness
- an inability to concentrate.

Hot flashes

Hot flashes are the most common symptoms of menopause. A hot flash refers to peripheral vasodilation which leads to a rise in skin temperature and flushing of the skin. In the typical hot flash, the skin, especially of the head and neck, becomes red and warm for a few seconds to 2 minutes with cold chills thereafter. Hot flashes can be accompanied by other symptoms, including increased heart rate, headaches, dizziness, weight gain, fatigue, and insomnia.

In the United States, 65–80% of menopausal women experience hot flashes to some degree. Hot flashes are often the first sign that menopause is approaching as they may begin prior to the cessation of menses. In most cases, hot flashes are most uncomfortable in the first to second years after menopause. As the body adapts to decreased estrogen levels, hot flashes typically subside.

Atrophic vaginitis

After menopause, the vaginal lining may become thin and dry due to the lack of estrogen. As a result, menopausal and postmenopausal women may experience painful intercourse, an increased susceptibility to infection, and symptoms of vaginal itching or burning.

Women with atrophic vaginitis should try to avoid substances which tend to dry the mucous membranes, including antihistamines, alcohol, caffeine, and diuretics. In addition, it is critical that the body stays well hydrated.

Clothes made from natural fibers, particularly cotton, are often recommended as they allow the skin to breathe, thus decreasing the incidence of vaginal infections.

Regular intercourse is beneficial as it increases blood flow to vaginal tissues which

helps to improve tone and lubrication. However, good lubrication, e.g. with oil or K-Y Jelly, must be maintained.

Bladder infections

About 15% of menopausal women experience frequent bladder infections. Apparently, there is a breakdown in the natural defense mechanisms which protect against bacterial growth in the urinary tract. The primary goal in the natural approach to treating bladder infections is enhancing normal host protective measures against urinary tract infection. Specifically, this refers to enhancing the flow of urine by achieving and maintaining proper hydration, promoting a pH which will inhibit the growth of the organism, and preventing bacterial adherence to the endothelial cells of the bladder. In addition, there are several botanical medicines that can be employed (see [Ch. 145](#) for further information).

Cold hands and feet

Cold hands and feet are common to women in general, not just menopausal women. In most instances, there are three major causes of cold hands and feet: hypothyroidism, low iron levels in the body, and poor circulation. The basal body temperature test (see [Appendix 8](#)) should be performed to evaluate functional thyroid activity. Serum ferritin levels, the best indicator of body iron stores, along with a CBC (complete blood count) and chemistry panel, including LDL/HDL cholesterol levels, should also be performed. A complete physical examination is also required, paying particular attention to any other signs of vascular insufficiency. Once the cause is identified, the treatment is straightforward.

Forgetfulness

Forgetfulness and an inability to concentrate are common symptoms of menopause. Often these symptoms are simply a result of decreased oxygen and nutrient supply to the brain. The brain is highly dependent on a constant supply of oxygen and nutrients. Although weighing only 1.36 kg, the brain utilizes about 20% of the oxygen supply of the entire body. In dealing with the forgetfulness of menopause, the goal is to improve the supply of blood, oxygen, and nutrients to the brain.

The role of the hypothalamus and endorphins

Many of the symptoms of menopause, especially hot flashes, appear to be a result of altered function of the hypothalamus, which serves as the bridge between the nervous system and the hormonal (endocrine) system. The hypothalamus is responsible for the control of many body functions, including:

- body temperature
- metabolic rate
- sleep patterns
- reactions to stress

- libido
- mood
- the release of pituitary hormones.

Critical to proper functioning of the hypothalamus are the endorphins.

Several natural measures are thought to exert some of their beneficial effects by enhancing endorphin output. Most notable are exercise and acupuncture.

THERAPEUTIC CONSIDERATIONS

Rather than use estrogens to artificially counteract the symptoms of menopause, the natural approach focuses on improving physiology. This improvement can be

1392

accomplished through diet, exercise, nutritional supplementation, and the use of botanical medicines.

The baseline evaluation of the menopausal woman should include:

- detailed personal and family medical history
- breast examination and instructions on self-examination of the breasts
- pelvic examination
- laboratory tests
 - complete blood count
 - blood chemistry panel
 - cholesterol evaluation, including HDL, LDL, and VLDL
 - thyroid function panel, including T₃, T₄, and TSH
- baseline mammography (if indicated)
- baseline bone densitometry.

After this initial evaluation, these tests should be repeated every year. The bone density studies can be used as a gauge to whether HRT is necessary.

Diet

The most important dietary recommendation may be to increase the amount of plant foods, especially those high in phytoestrogens, while reducing the amount of animal foods in the diet. There is also a protective effect with consumption of fruit and

vegetables.

Phytoestrogen-containing foods

Fennel, celery, and parsley are members of the *Umbelliferous* plant family. Foods of this family typically contain phytoestrogens. Fennel is particularly high in these compounds and possesses confirmed estrogenic action.^[13]

Other foods high in phytoestrogens include soy, nuts, whole grains, apples, and alfalfa. A high intake of phytoestrogens is thought to explain why hot flashes and other menopausal symptoms rarely occur in cultures consuming a predominantly plant-based diet. Several lignans and isoflavonoids are converted by intestinal bacteria to diphenolic estrogenic compounds which decrease hot flashes, increase maturation of vaginal cells and may inhibit osteoporosis. In addition, such a diet results in a decreased incidence of breast, colon, and prostate cancer.^[14]

Soy

An especially important dietary recommendation in the relief of atrophic vaginitis and prevention of breast cancer is to increase the consumption of soy foods. The isoflavones (e.g. genistein) and phytosterols of soybeans produce a mild estrogenic effect. One cup of soybeans provides approximately 300 mg of isoflavone. This level would be the equivalent of about 0.45 mg of conjugated estrogens or one tablet of Premarin.^[15] However, while estrogen replacement therapy may increase the risk for cancer, the consumption of soy foods is associated with a significant reduction in the risk of cancer.^{[14] [15]}

In a study of postmenopausal women, those women consuming enough soyfoods to provide about 200 mg of isoflavone demonstrated signs of estrogenic activity when compared with a control group.^[15] Specifically, the women consuming the soyfoods demonstrated an increase in the number of superficial cells which line the vagina. This increase offsets the vaginal drying and irritation that is common in postmenopausal women.

The soybean plant (*Glycine max*) is native to China where it has been cultivated for food for well over 13,000 years. The ancient Chinese considered the soybean their most important crop and a necessity for life. The soybean, thanks largely to the United States which accounts for over 50% of the world's production, is now the most widely grown and utilized legume as it accounts for well over 50% of the world's total legume production.

The increase in soyfood consumption is attributed to a number of factors, including economics, health benefits, and environmental concerns.^[16] Interestingly, the lower the protein content, the higher the level of isoflavonoids. Products made from whole soybeans are higher in isoflavonoid content than those produced from soy protein concentrates. Therefore, in dealing with the symptoms of menopause, lower protein content products made from soy flour and whole soy are superior to high protein

isolates.

Another useful effect of soy is its protection of LDL cholesterol from oxidation, an effect of great significance for the prevention of cardiovascular disease.^[14]

Dietary fat

There was a clear positive correlation between breast cancer risk and saturated fat intake in postmenopausal women.^[17] Total caloric intake is apparently not associated with an increased risk to breast cancer.

Nutritional supplements

Several nutrients have been shown to be effective in relieving hot flashes and atrophic vaginitis in clinical studies, including vitamin E, hesperidin in combination with vitamin C, and gamma-oryzanol.

Vitamin E

In the late 1940s, several clinical studies found vitamin E to be effective in relieving hot flashes and menopausal vaginal complaints when compared with a placebo.^[18] ^[19] ^[20] Unfortunately, there have been no further clinical investigations.

1393

In one study, vitamin E supplementation was shown to improve not only the symptoms, but also the blood supply to the vaginal wall when taken for at least 4 weeks.^[18] A follow-up study published in 1949 demonstrated that vitamin E (400 IU/day) was effective in about 50% of postmenopausal women with atrophic vaginitis.^[19]

Vitamin E oil, creams, ointments, or suppositories can be used topically to provide symptomatic relief of atrophic vaginitis. Vitamin E is usually quite effective in relieving the dryness and irritation of atrophic vaginitis as well as other forms of vaginitis.^[3]

Hesperidin and vitamin C

Like many other flavonoids, hesperidin is known to improve vascular integrity and relieve capillary permeability. Combined with vitamin C, hesperidin and other citrus flavonoids may be effective in relieving hot flashes.

In one clinical study, 94 women suffering from hot flashes were given a formula containing 900 mg of hesperidin, 300 mg of hesperidin methyl chalcone (another citrus flavonoid), and 1,200 mg of vitamin C daily.^[21] At the end of 1 month, symptoms of hot flashes were relieved in 53% of the patients and reduced in 34%. Improvements were also noted in nocturnal leg cramps, nose bleeds, and easy bruising. The only side-effect

noted was a slightly offensive body odor with a tendency for the perspiration to discolor the clothing.

Gamma-oryzanol

Gamma-oryzanol (ferulic acid) is a growth-promoting substance found in grains and isolated from rice bran oil. In the treatment of hot flashes, its primary action is to enhance pituitary function and promote endorphin release by the hypothalamus. Gamma-oryzanol was first shown to be effective in menopausal symptoms, including hot flashes, in the early 1960s.^[22] Subsequent studies have further documented its effectiveness.^[23]

In one of the earlier studies, eight menopausal women and 13 women who had their ovaries surgically removed were given 300 mg/day of gamma-oryzanol. At the end of the 38 day trial, over 67% of the women had a 50% or greater reduction in their menopausal symptoms.^[22] In a more recent study, the benefit of a 300 mg/day dose of gamma-oryzanol was even more effective as 85% of the women reported improvement in their symptoms.^[23]

Gamma-oryzanol is an extremely safe natural substance. No significant side-effects have been produced in experimental and clinical studies. In addition to being helpful in improving the symptoms of menopause, gamma-oryzanol has also been shown to be quite effective in lowering blood cholesterol triglyceride levels.^[24]

Botanical medicines

Many plants have been shown to exert a tonic effect on the female glandular system. As a class, these botanicals are often referred to as “uterine tonics”. Much of their effect is thought to be a result of phytoestrogens in the plants as well as the plant’s ability to improve blood flow to the female organs. The botanicals work to nourish and tone the female glandular and organ system rather than exerting a drug-like effect. This non-specific mode of action makes many botanicals useful in a broad range of female conditions.

Phytoestrogens are found in many medicinal herbs with a historical use in conditions which are now treated by estrogens. Phytoestrogen-containing herbs offer significant advantages over the use of estrogens in the treatment of menopausal symptoms. While both synthetic and natural estrogens may pose significant health risks, phytoestrogens have not been associated with these side-effects. In fact, epidemiological data and experimental studies in animals have demonstrated that phytoestrogens are extremely effective in inhibiting mammary tumors, not only because they occupy estrogen receptors, but also by other unrelated anti-cancer mechanisms.^[14] ^[25]

Phytoestrogens in herbs are capable of exerting estrogenic effects, although their activity compared with estrogen is only 2% as strong at the most.^[26] However, because of this low activity, phytoestrogens have a balancing action on estrogen effects. If estrogen levels are low, since phytoestrogens have some estrogenic activity, they will

cause an increase in estrogen effect. If estrogen levels are high, since phytoestrogens bind to estrogen receptor binding sites, thereby competing with estrogen, there will be a decrease in estrogen effects.^[27]

Because of the balancing action of phytoestrogens on estrogen effects, it is common to find the same plant recommended for conditions of both estrogen excess (e.g. premenstrual syndrome) and estrogen deficiency (e.g. menopause, menstrual abnormalities).

The four most useful herbs in the treatment of hot flashes are:

- *Angelica sinensis*
- *Glycyrrhiza glabra*
- *Vitex agnus-castus*
- *Cimicifuga racemosa*.

These herbs have been used historically to lessen a variety of female complaints including hot flashes.

Angelica sinensis

In Asia, angelica's (also known as Dong Quai) reputation is perhaps second only to ginseng. Predominantly regarded as a "female" remedy, angelica has been used in menopausal symptoms (especially hot flashes), as well

1394

as in such conditions as dysmenorrhea, amenorrhea and metrorrhagia, and to assure a healthy pregnancy and easy delivery (see [Ch. 65](#) for a full discussion).

Angelica has demonstrated good uterine tonic activity, causing an initial increase in uterine contraction followed by relaxation.^[28] In addition, administration of angelica to mice resulted in an increase of uterine weight and of glucose utilization by the liver and uterus.^[29] These effects reflect estrogenic activities.

Its effectiveness in relieving hot flashes may be a combination of angelica's mild estrogenic effects and other components acting to stabilize blood vessels.^[30]

Glycyrrhiza glabra

The medicinal use of licorice root in both Western and Eastern cultures dates back several thousand years (see [Ch. 90](#) for a full discussion).

Licorice is particularly useful in premenstrual syndrome or PMS. PMS has been attributed to an increase in the estrogen:progesterone ratio. Licorice is believed to lower

estrogen while simultaneously raising progesterone levels. For menopause, it is thought that the estrogen-like activity of licorice is responsible for many of its beneficial effects, but its effects on progesterone may also be important.^[31] ^[32]

Vitex agnus-castus

The chaste tree is native to the Mediterranean. Its berries have long been used for female complaints. As its name suggests, chaste berries were used in suppressing the libido. Scientific investigation has shown chaste berry has profound effects on pituitary function.^[33] It is possible that its beneficial effects in menopause are due to altering LH and FSH secretion (see [Ch. 123](#) for a full discussion).

Cimicifuga racemosa

Black cohosh was widely used by the American Indians and later by American colonists for the relief of menstrual cramps and menopause. Recent scientific investigation has upheld the use of black cohosh in both dysmenorrhea and menopause.

A special extract of *Cimicifuga racemosa* standardized to contain 1 mg of triterpenes calculated as 27-deoxyacteine per tablet (tradename = Remifemin) is the most widely used and thoroughly studied natural alternative to hormone replacement therapy in menopause. Clinical studies have shown this cimicifuga extract to relieve not only hot flashes, but also depression and vaginal atrophy.^[34] For more information see [Chapter 75](#).

Most patients report noticeable benefits within 4 weeks after the onset of cimicifuga therapy. After six to eight weeks complete resolution of symptoms are achieved in most patients. Cimicifuga is very well tolerated and only 7–10% of patients report mild transitory stomach complaints or other mild side-effects. Because there are no contraindications or limitations of use, cimicifuga offers a suitable natural alternative to hormone replacement therapy for menopause, especially where hormone replacement therapy is contraindicated, e.g., women with a history of cancer, unexplained uterine bleeding, liver and gallbladder disease, pancreatitis, endometriosis, uterine fibroids, or fibrocystic breast disease.

Ginkgo biloba

Ginkgo biloba extract is often indicated in menopausal and postmenopausal women for its effects on the vascular system. It may be especially useful in improving both cold hands and feet, and the forgetfulness which often accompany menopause. *Ginkgo biloba* extract has also been shown to improve blood flow to the hands and feet in human clinical trials and has been shown to be effective in the treatment of peripheral vascular disease of the extremities, including Raynaud's syndrome, a disease characterized by extremely cold fingers or toes.^[35] ^[36] ^[37]

Ginkgo biloba extract has repeatedly been used to improve mental health in patients with cerebral vascular insufficiency and may exert similar effects in menopause. *Ginkgo*

biloba extract appears to work not only by increasing blood flow to the brain, but also by enhancing energy production within the brain, increasing the uptake of glucose by brain cells, and actually improving the transmission of nerve signals.^[35]

Improving the transmission rate of the nerve signal is critically important to memory. Memory is directly related to the speed at which the nerve impulse can be transmitted. Although the effect of *Ginkgo biloba* extract on the forgetfulness of menopause has not been studied in a controlled fashion, there is ample evidence to suggest that it is worth a clinical trial in the menopausal woman with forgetfulness and/or an inability to concentrate. Ginkgo has been shown in double-blind studies to significantly improve memory in elderly as well as college-aged women.^{[38] [39] [40] [41]}

It must be pointed out that in the treatment of cerebral vascular insufficiency, *Ginkgo biloba* extract should be taken consistently for at least 12 weeks in order to determine effectiveness. Although most report benefits within a 2–3 week period, some individuals may take longer to respond. It seems that the longer the treatment is continued, the more obvious and lasting the result.

Lifestyle factors

Exercise

The hypothesis that impaired endorphin activity within the hypothalamus is a major factor in provoking hot

TABLE 170-2 -- Health benefits of regular exercise in menopause

- Relief from hot flashes
- Decreased bone loss
- Improved heart function
- Improved circulation
- Reduced blood pressure
- Decreased blood cholesterol levels
- Improved ability to deal with stress
- Improved oxygen and nutrient utilization in all tissues
- Increased self-esteem, mood, and frame of mind
- Increased endurance and energy levels

flashes led researchers in Sweden to design a study to determine the effect of regular

physical exercise on the frequency of hot flashes.^[42] In the study, the frequency of moderate and severe hot flashes was investigated in 79 postmenopausal women who took part in physical exercise on a regular basis and compared with a control group of 866 postmenopausal women between 52 and 54 years old.

The study clearly demonstrated that regular physical exercise definitely decreased the frequency and severity of hot flashes: the women in the exercising group passed through a natural menopause without the use of HRT and the physically active women who had no hot flashes whatsoever spent an average of 3.5 hours/week exercising, while women who exercised less than this amount were more likely to have hot flashes. Similar results, including mood elevation in pre-, peri- and postmenopausal exercising versus sedentary women have been reported in other studies.^[43] The benefits of exercise were experienced in women both on and off HRT.

Given the many benefits of regular exercise (see [Table 170.2](#)) on mood and the health of bone and the cardiovascular system, along with these positive results in reducing the frequency and severity of hot flashes, it is clear that regular physical exercise is a key component of menopause care.

Cigarette smoking

Cigarette smoking significantly increases the risk of early menopause, as smokers have approximately double the risk of menopause between the ages of 44 and 55. Those who were former smokers had a lowered risk, showing there could be a partial reversal of the effect.^[44]

THERAPEUTIC APPROACH

Many natural measures can help to alleviate the most common symptoms of menopause. In most cases, HRT is not necessary. However, in women at high risk for osteoporosis and women who have already experienced significant bone loss, HRT may be indicated. For the immediate treatment of atrophic vaginitis, prescribe topical vitamin E preparations. If the woman is smoking, facilitate a smoking cessation program.

Diet

Increase the amount of phytoestrogens in the diet by consuming more soyfoods; fennel, celery, and parsley; high-lignin flaxseed oil; and nuts and seeds.

Supplements

- Vitamin E: 800 IU/day until symptoms have improved, then 400 IU/day
- Hesperidin: 900 mg/day
- Vitamin C: 1,200 mg/day
- Gamma-oryzanol: 300 mg/day.

Botanical medicines

All dosages are t.i.d.

- *Angelica sinensis*
 - powdered root or as tea: 1–2 g
 - tincture (1:5): 4 ml (1 tsp)
 - fluid extract: 1 ml (¼ tsp)
- *Glycyrrhiza glabra*
 - powdered root or as tea: 1–2 g
 - fluid extract (1:1): 4 ml (1 tsp)
 - solid (dry powdered) extract (4:1): 250–500 mg
- *Vitex agnus-castus*
 - powdered berries or as tea: 1–2 g
 - fluid extract (1:1): 4 ml (1 tsp)
 - solid (dry powdered) extract (4:1): 250–500 mg
- *Cimicifuga racemosa*

The dosage of cimicifuga is based on its content of 27-deoxyacteine which serves as an important biochemical marker to indicate therapeutic effect. The dosage of the cimicifuga extract used in the majority of clinical studies has been 2 mg of 27-deoxyacteine twice daily. Here are the approximate dosage recommendations using other forms (non-standardized) of *Cimicifuga racemosa*:

 - Powdered rhizome: 1–2 g
 - Tincture (1:5): 4–6 ml
 - Fluid extract (1:1): 3–4 ml (1 tsp)
 - Solid (dry powdered) extract (4:1): 250–500 mg
- *Ginkgo biloba* extract
 - 24% ginkgo flavonglycoside content: 40 mg.

Lifestyle

Facilitate a regular exercise program – at least 30 minutes three times a week.

Chapter 171 - Menorrhagia

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

DIAGNOSTIC SUMMARY

- Excessive menstrual bleeding, i.e. blood loss greater than 80 ml, occurring at regular cyclical intervals (cycles are usually, but not necessarily, of normal length)
- Often caused by local lesions, e.g. uterine myomas (fibroids), endometrial polyps, endometrial hyperplasia, adenomyosis, and endometritis.

GENERAL CONSIDERATIONS

The complaint of menorrhagia is largely subjective, as objective measurement of blood loss is rarely done. Furthermore, there is a poor correlation between measured blood loss and a patient's assessment of her bleeding (discussed in more detail below). Studies that have measured blood loss have demonstrated that patients with menorrhagia have a considerable increase in menstrual blood flow during the first 3 days (up to 92% of their total menses being lost at this time). This suggests that the mechanisms responsible for cessation of menstruation are as effective in women who have menorrhagia as in normal women, despite the very high blood loss.

Etiology

As with any disease, proper determination of the etiology is essential for effective treatment. The appropriate methodology for ruling out pathological causes is beyond the scope of this text and can be found in any good text on gynecology. [Table 171.1](#) lists typical causes of menorrhagia.

Abnormalities in prostaglandin metabolism

The etiology of functional menorrhagia is currently believed to involve abnormalities in

the biochemical processes of the endometrium which control the supply

1398

TABLE 171-1 -- Pathological causes of menorrhagia^[1]

| Cause | Possible etiology |
|---------------------------------|---------------------------------|
| Anovulation | Excessive estrogen |
| | Failure of midcycle surge of LH |
| | Hypothyroidism |
| | Hyperprolactinemia |
| | Polycystic ovarian disease |
| Intrauterine structural defects | Fibroids |
| | Polyps |
| | Cancer |
| | Ectopic pregnancy |
| | Intrauterine devices |
| Bleeding disorders | See Table 171.2 |

of arachidonic acid for prostaglandin synthesis.^{[2] [3]} Menorrhagic endometrium incorporates arachidonic acid into neutral lipids to a much greater extent than normal, while incorporation into phospholipids is decreased. The increased arachidonic acid release during menstruation results in increased production of series 2 prostaglandins, which are thought to be the major factor both in the excessive bleeding seen at menstruation and in the symptoms of dysmenorrhea. The excessive bleeding during the first 3 days appears to be due to the vasodilatory properties of PGE₂ and PGI₂ and the anti-aggregating activity of PGI₂, while the pain of dysmenorrhea is due to the overproduction PGF_{2α}.

Other factors believed to contribute to menorrhagia are:

- iron deficiency
- hypothyroidism
- vitamin A deficiency
- intrauterine devices
- various local factors, e.g. uterine myomas, endometrial polyps, adenomyosis, endometrial hyperplasia, salpingitis, and endometritis.

Estimating menstrual blood loss

Physicians often feel they can assess menstrual blood loss by asking the patient to estimate the number of pads used during each period and the duration of the period. However, studies have demonstrated that there is no correlation between measured blood loss and these assessments.^{[1] [4] [5]} A woman's assessment of her blood loss is extremely subjective, as demonstrated by one study which found that 40% of women with a menstrual blood loss exceeding 80 ml considered their periods only moderately heavy or scanty, while 14% of those with a measured loss of less than 20 ml judged their periods to be heavy.^[5]

Serum ferritin levels may be the best indicator of excessive menstrual blood loss from a clinical perspective.

THERAPEUTIC CONSIDERATIONS

Psychological

As the complaint of menorrhagia is largely subjective, it is possible that a psychological component may at times be the etiological factor.^[6] However, while it is known that, as a group, women complaining of menorrhagia are more likely to have received antidepressant medication at some time in the past (and are more likely to have a hysterectomy),^[7] the role of iron deficiency and thyroid insufficiency as factors contributing to this association has never been assessed. (The role these can play in disturbances of mood is discussed in [Ch. 126](#), while their role in menorrhagia is discussed below.) It is the authors' opinion that women have often been subjected to needless hysterectomy, uterine curettage, and/or antidepressant medication when appropriate diagnostic and therapeutic measures would have revealed the underlying cause. While psychological factors may play a major role in the complaint of menorrhagia, organic factors must always be ruled out first.

Iron deficiency

A menstrual blood loss above 60 ml per period is associated with negative iron balance in most cases.^[8] Although menstrual blood loss is well recognized as a major cause of iron deficiency anemia in fertile women, it is not as well known that chronic iron deficiency can be a cause of menorrhagia. Taymor et al^[9] have suggested this to be the case, based on several observations:

- response to iron supplementation alone in 74 of 83 patients (in whom organic pathology had been excluded)
-

- high rate of organic pathology (fibroids, polyps, adenomyosis, etc.) in the patients

who failed to respond to iron supplementation

- associated rise in serum iron levels in 44 of 57 patients
- decreased response to iron therapy when initial serum iron levels were high
- correlation of menorrhagia with depleted tissue iron stores (bone marrow) irrespective of serum iron level
- a significant double-blind placebo-controlled study displaying improvement in 75% of those on iron supplementation, compared with 32.5% for the placebo group.

TABLE 171-2 -- Acquired generalized hemorrhagic disorders^[15]

| Factor | Possible cause |
|--|--|
| Deficiency of vitamin K | Low intake, impaired absorption, antimicrobial inhibition of gut flora that synthesize vitamin K |
| Drug-induced hemorrhage | Heparin, warfarin |
| Dysproteinemias | Myeloma, macroglobinemia |
| Disseminated intravascular coagulation | |
| Severe hepatic disease | |
| Circulating inhibitors of coagulation | |
| Primary fibrinolysis | |

Hematological screening and serum ferritin determination (which will be the first to indicate decreased iron levels) should be performed for patients complaining of menorrhagia. In one study, menorrhagic women (based on subjective information) displayed significantly lower serum ferritin levels than controls, while hemoglobin concentration, mean corpuscular volume, and mean corpuscular hemoglobin were not significantly different between the two groups.^[10] (It was erroneously stated by the authors that these women do not require prophylactic iron supplementation since no hematological abnormalities appeared, despite significantly reduced iron stores.)

Iron supplementation, at a daily dose of 100 mg elemental iron, has been recommended as a prophylactic therapy by several researchers, since it appears that chronic iron deficiency may promote menorrhagia, and iron-containing enzymes are depleted before hematological changes are observed. A decreased serum ferritin level is a good indication of the need for iron supplementation.^{[8] [9]}

Vitamin A

In one study, serum retinol levels were found to be significantly lower in 71 women with menorrhagia than in healthy controls. After 40 of these were given 25,000 IU of vitamin A twice a day for 15 days, blood loss returned to normal in 23 and was reduced in 14,

i.e. 92.5% of these women had either complete relief or significant improvement.^[11]

Vitamin C and bioflavonoids

Capillary fragility is believed to play a role in many cases of menorrhagia. Supplementation with vitamin C (200 mg t.i.d.) and bioflavonoids (quantity not specified) has been shown to reduce menorrhagia in 14 out of 16 patients.^[12] One of the patients failing to respond had endometriosis and the other had metrorrhagia.

As vitamin C is known to significantly increase iron absorption, its therapeutic effect could be also due to enhanced iron absorption.

Vitamin E

One group of investigators has suggested that free radicals have a causative role in endometrial bleeding, particularly in the presence of an intrauterine device.^[13] Vitamin E supplementation (100 IU every 2 days) resulted in improvement in all patients by the end of 10 weeks.^[13] Although vitamin E may have produced its effects via its antioxidant activity, it is equally plausible that it affected prostaglandin metabolism in a manner that would reduce bleeding.

Vitamin K and chlorophyll

Although bleeding time and prothrombin levels in women with menorrhagia are typically normal, the use of vitamin K (historically in the form of crude preparations of chlorophyll) has clinical and limited research support.^[14] Also, some women will be found to have an inherited or acquired bleeding disorder. [Table 171.2](#) lists some causes of acquired hemorrhagic disorders.

Thyroid abnormalities

The association of overt hypothyroidism or hyperthyroidism with menstrual disturbances is well known. However, even minimal thyroid dysfunction, particularly minimal, subclinical insufficiency (as determined by the thyroid stimulation (TRH) test) may be responsible for menorrhagia and other menstrual disturbances.^[15] Patients with minimal thyroid insufficiency and menorrhagia have responded dramatically to thyroxine.^[15] It has been recommended that patients with long-standing menstrual dysfunction (who have no obvious uterine pathology) should be considered for TRH testing. This is preferable to the empirical use of thyroid hormone.

Essential fatty acids

Since it now appears that the majority of tissue arachidonic acid is derived from the diet,^[17] it is possible that reducing the intake of animal products and/or increasing intake of linoleic, linolenic and di-homo-gamma-linolenic acid could curtail blood loss by

decreasing the availability of arachidonic acid.

Botanicals

Numerous botanicals have been used in the treatment of menorrhagia, including:

- *Geranium maculatum*
 - *Trillium pendulum*
-

1400

- *Areca catechu*
- *Caulophyllum thalictroides*
- *Hamamelis virginiana*
- *Capsella bursa pastoris*.

The latter (shepherd's purse) has a long history of use in the management of obstetric and gynecologic hemorrhage. Intravenous and intramuscular injections have been found to be effective (in uncontrolled studies) in menorrhagia due to functional abnormalities and fibroids.^{[18] [19]} Its hemostatic action is believed to be a result of its high concentration of oxalic and dicarboxylic acids.^{[18] [19]}

The use of botanicals should be reserved for intractable cases of menorrhagia, those cases where immediate cessation of blood loss is desired, and/or as a short-term adjunct to above-mentioned therapies.

THERAPEUTIC APPROACH

The first step in treating a woman with menorrhagia is to rule out serious pathological causes (see [Table 171.1](#)). When the excessive bleeding has been determined to be functional, prothrombin time, hematological status, and thyroid function should be determined, and any abnormalities corrected. In order to accurately determine the efficacy of therapy, some relatively quantitative method of measuring blood loss should be worked out with the patient. Serum ferritin levels can be used to help monitor the patient's progress.

Diet

The diet should be relatively low in sources of arachidonic acid (animal fats) and high in linolenic and linoleic acids (vegetable oil sources). Green leafy vegetables and other sources of vitamin K should be eaten freely.

Supplements

- Vitamin C: 1,000 mg/day

- Bioflavonoids: 250 mg/day
- Vitamin A: 25,000 IU/day
- Vitamin E: 200 IU/day
- Chlorophyll: 25 mg/day (use a crude form)
- Iron: 25 mg/day.

Botanical medicine

- *Capsella bursa pastoris*: 1 tsp/cup three times/day, if needed to control very heavy bleeding.

Chapter 172 - Migraine headache

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

DIAGNOSTIC SUMMARY

- Recurrent, paroxysmal attacks of headache
- Headache is typically pounding and unilateral, but may become generalized
- Attacks often preceded by psychological or visual disturbances; accompanied by anorexia, nausea, and gastrointestinal upset; and followed by drowsiness.

GENERAL CONSIDERATIONS

Migraine headaches are caused by excessive dilation of a blood vessel in the head. Migraines are a surprisingly common disorder, at some time in their life affecting 15–20% of men and 25–30% of women.^[1] More than half of the patients have a family history of the illness.

Although many migraines come without warning, many migraine sufferers have warning symptoms (auras) before the onset of pain. Typical auras last a few minutes and include:

- blurring or bright spots in the vision
- anxiety
- fatigue
- disturbed thinking
- numbness or tingling on one side of the body.

In vascular headaches, like migraine headaches, the pain is characterized by a throbbing or pounding sharp pain. In non-vascular headaches, like tension headaches, the pain is characterized as a steady, constant, dull pain that starts at the back of the head or in the forehead and spreads over the entire head, giving the sensation of pressure or as if a vise grip has been applied to the skull (see [Table 172.1](#) for primary

classifications of headaches).

The pain of a headache comes from outside the brain because the brain tissue itself does not have sensory nerves. Pain arises from the meninges and from the scalp and its blood vessels and muscles when these structures are stretched or tensed.

The most common non-vascular headache is the

1402

TABLE 172-1 -- Primary classifications of headache

| —temporomandibular joint (TMJ) dysfunction |
| • Increased or decreased intracranial pressure |

- Brain tumors

- Sinus infections

- Dental infections

- Inner or middle ear infections

tension headache. This headache is usually caused by tightening in the muscles of the face, neck, or scalp as a result of stress or poor posture. The tightening of the muscles results in pinching of the nerve or its blood supply which results in the sensation of pain and pressure. Relaxation of the muscle usually brings about immediate relief.

Classification and diagnosis

Migraine headache has been subdivided into several types, based on the presence or absence of preceding or concomitant neurological manifestations and the nature of the manifestations. Although there are several subtypes, the three most common (*common*, *classic*, and *complicated*) comprise the vast majority of patients, and differentiation, while important, does not at this time have any therapeutic significance. The differentiation and diagnosis of these types are summarized in [Table 172.2](#).

Cluster headache was once considered a migraine-type headache, since vasodilation is a key component, but it is now separately classified. Also referred to as histamine cephalgia, Horton's headache, or atypical facial neuralgia, it is much less common than migraine.

Another headache to be considered in this chapter is chronic daily headache (CDH). Approximately 40% of patients seen in headache clinics suffer from CDH. Other terms used to describe CDH by doctors include:

- chronic tension headache
- migraine with interparoxysmal headache
- transformed migraine
- evolutive migraine
- mixed headache syndrome
- tension-vascular headache.

To simplify matters, CDH has now been divided into four major types (see [Table 172.3](#)).

Pathophysiology

Considerable evidence supports an association between migraine headache and vasomotor instability, but the mechanisms are not yet known. Although most clinicians and researchers believe that the sequence of events is excessive intracranial arterial constriction (causing brain ischemia) followed by rebound dilation of the extracranial vessels (the headache phase), sophisticated studies of sequential cerebral blood flow

before, during, and after are inconsistent in their support of this hypothesis.^{[2] [3]}

Vasomotor instability

It is a well-known clinical observation that superficial temporal vessels are visibly dilated and local compression of these vessels or the carotid artery temporarily relieves migraine pain.^[4] However, other types of extracranial vasodilation (e.g. heat- or exercise-induced) are not associated with migraine. Despite the extracranial vasodilation, the patient appears pale during the headache, suggesting constriction of the small vessels. This is supported by the observation of lower skin temperature on the affected side.

The clinical manifestations of focal or diffuse cerebral or brain stem dysfunction have been attributed to intracranial vasoconstriction. A majority, but not all, of the studies measuring cerebral blood flow have confirmed

TABLE 172-2 -- Migraine classification

| | Common | Classic | Complicated |
|----------------------|------------------------|--|--|
| Incidence | 80% | 10% | 10% |
| Pain | Frontal, uni/bilateral | Unilateral | Unpredictable, may be absent |
| Aura | Unusual | 0.5 hour, striking | Neurological aura, vertigo, syncope, diplopia, hemiparesis |
| Duration of headache | 1–3 days | 2–6 hours | Unpredictable |
| Physical examination | Unhappiness | Pallor, vomiting cranial nerve III palsy | Mild neurological signs, speech disorder, hemiparesis, unsteadiness, |

TABLE 172-3 -- The four types of chronic daily headache

 - drug-induced
 - non-drug-induced
- Chronic tension-type headache
- New daily persistent headache
- Post-traumatic headache

a reduction of blood flow, sometimes to very low and critical levels, during the prodromal stage. This is followed by a stage of increased blood flow that can persist for more than 48 hours. There is significant decrease in regional cerebral blood flow in classic, but not common, migraine.^[6] The abnormal blood flow appears confined to the cerebral cortex, while deeper structures are perfused normally.

There is some evidence that migraine patients have an inherited abnormality of vasomotor control. Migraine patients suffer from orthostatic symptoms more often than normal people, and they seem to be abnormally sensitive to the vasodilatory effects of physical and chemical agents.

Platelet disorder

The migraine platelet shows significant differences from the normal platelet both during and between headaches.^[6] These differences include a significant increase in spontaneous aggregation, highly significant differences in the manner of serotonin release, and significant differences in platelet composition.

The major proponent of the platelet hypothesis is Hanington,^[6] who starts with the observation that the most common precipitant of migraine is some type of stressor. This results in a rise in plasma catecholamine levels which triggers the release of serotonin and resultant platelet aggregation and vasoconstriction.

The platelets of migraine sufferers aggregate more readily than normal platelets, both spontaneously and when exposed to serotonin (and to adenosine diphosphate and catecholamines). The increase in spontaneous aggregation is similar to that reported in patients suffering from transient cerebral ischemic attacks (TIAs). This is significant, considering the close resemblance of the symptomatology of TIAs and the prodromal phase of the migraine headache.

The onset of an attack is accompanied by a significant rise in plasma serotonin levels, followed by an increase in urinary 5-hydroxyindoleacetic acid, the breakdown product of serotonin metabolism. All of the serotonin normally in the blood is stored in the platelets and is released by platelet aggregation and in response to various stimuli, such as catecholamines. There is no difference in total serotonin content between normal platelets and the platelets of migraine patients. However, the quantity of serotonin released by the platelets of the migraine patient in response to serotonin stimulation, while normal (or even subnormal) immediately after an attack, becomes progressively higher as the next attack approaches.^[6]

The platelet hypothesis is strengthened by the observation that patients with classic migraine have a twofold increase in incidence of mitral valve prolapse.^[7] Using careful clinical and echocardiographic criteria and matched controls, the researchers found in the migraine patients definite mitral prolapse in 16% and possible prolapse in 15%. The controls had 7 and 8%, respectively. This is of significance, since the prolapsing mitral valve is known to damage platelets and increase their aggregation. This work has been

confirmed in several studies.^{[8] [9]}

Neuronal disorder

A third major hypothesis is that the nervous system plays a role in initiating the vascular events in migraine.^[1] It has been suggested that the trigeminovascular neurons, which innervate the pial arteries, release peptide substance P either in direct response to the various initiators or secondarily to changes in the central nervous system.^[10] Substance P is an important mediator of pain, and its release into the arteries is associated with vasodilation, mast cell degranulation, and increased vascular permeability. It is thought that the endothelial cells of the arteries respond to substance P by releasing vasoactive substances, such as arachidonic acid metabolites, purine compounds, or molecules containing carbonyl groups.

This theory suggests that functional changes within the noradrenergic system constitute the threshold for migraine activation, and it is through modulation of sympathetic activity that potentiators exert their effect.^[10] Chronic stress is thought to be an important potentiator in this model.

Migraine as a “serotonin deficiency” syndrome

The final hypothesis is that migraine headache represents a serotonin deficiency state. The story of serotonin and headaches began in the 1960s when researchers found that there was an increase in the serotonin breakdown product 5-hydroxyindoleacetic acid (5-HIAA) in the urine during a migraine.^[11] Initially it was thought that serotonin excess was the culprit; however, newer information indicates that the factor responsible for the increase in 5-HIAA is more likely the increased breakdown of serotonin as a result of increased activity of monoamine oxidase (MAO).^{[12] [13]} Because migraine sufferers actually have low levels of serotonin in their tissues, it led researchers to refer to migraine as a “low serotonin syndrome”.^[14]

Low serotonin levels are thought to lead to a decrease

in the pain threshold in patients with chronic headaches. This contention is strongly supported by over 35 years of research, including positive clinical results in double-blind studies with the serotonin precursor 5-hydroxytryptophan (5-HTP). For more information on the clinical studies with 5-HTP in migraine headaches, see [Chapter 92](#) .

The link between low serotonin levels and headache is the basis of many prescription drugs for the treatment and prevention of migraine headaches. For example, the serotonin agonist drug sumatriptan (Imitrex) is now among the most popular migraine prescriptions. In addition to sumatriptan, monoamine oxidase inhibitors (which increase serotonin levels) have also been shown to prevent headaches. The bottom line is that there is considerable evidence that increasing serotonin levels leads to relief from

chronic migraine headaches.

The effects that 5-HTP, sumatriptan, and other drugs exert on the serotonin system are extremely complex because of the multiple types of serotonin receptors. The manner in which many substances produce their effects on cells is by first binding to receptor sites on the cell membrane. Some serotonin receptors are involved in triggering migraines and others prevent them. This situation is quite clear by looking at the different effects that various drugs exert when binding to these different serotonin receptors. Drugs which bind to serotonin receptors designated as 5-HT_{1c} trigger migraines, while drugs like methysergide that inhibit 5-HT_{1c} are used to prevent migraines.^[15] In addition, the serotonin receptor 5-HT_{1d} may prevent migraine headaches since drugs like sumatriptan which bind to these receptors and mimic the effects of serotonin are quite effective in the acute treatment of migraine.^[16]

5-HTP supplementation affects these different receptors in several ways. For example, some serotonin receptors appear to undergo desensitization when exposed to higher levels of serotonin. It is thought that by increasing serotonin levels, 5-HT_{1c} lose their ability or affinity to bind serotonin, resulting in more serotonin binding to the 5-HT_{1d} receptor. In other words, it is thought that what is occurring with 5-HTP in the preventive treatment of migraine headache is that the higher levels of serotonin produced over time result in a decrease in the sensitivity of the 5-HT_{1c} receptors and an increased sensitivity for 5-HT_{1d} receptors.^[17] As a result, there would be a lowered tendency to experience headache. One of the key pieces of evidence to support this concept is the fact that 5-HTP is more effective over time (better results are seen after 60 days of use than after 30).

Unified hypothesis

The mechanism of migraine can be described as a three-stage process: initiation, prodrome, and headache.

TABLE 172-4 -- Factors that trigger migraine headaches

| |
|---|
| • Low serotonin levels |
| —genetics |
| —shunting of tryptophan into other pathways |
| • Foods |
| —food allergies |
| —histamine-releasing foods |
| —histamine-containing foods |
| • Alcohol, especially red wine |
| • Chemicals |

—nitrates

—MSG (monosodium glutamate)

—nitroglycerin

- Withdrawal from caffeine or other drugs which constrict blood vessels

- Stress

- Emotional changes, especially let-down after stress, and intense emotions, such as anger

- Hormonal changes, e.g. menstruation, ovulation, birth control pills

- Too little or too much sleep

- Exhaustion

- Poor posture

- Muscle tension

- Weather changes, e.g. barometric pressure changes, exposure to sun

- Glare or eyestrain

Although a particular stressor may be associated with the onset of a specific attack, it appears that initiation is dependent on the accumulation over time of several stressors. These stressors ultimately affect serotonin metabolism (see [Table 172.4](#)). Once a critical point of susceptibility (or threshold) is reached, a cascade event is initiated. This susceptibility is probably a combination of decreased tissue serotonin levels, changes in the platelet, alteration in the responsiveness of key cerebrovascular end-organs, increased sensitivity of the intrinsic noradrenergic system of the brain, and the build-up of histamine, arachidonic acid metabolites, or other mediators of inflammation. The platelet changes include increased adhesiveness, enhanced tendency to release serotonin, and increased levels of arachidonic acid in the membranes. Once the platelet is stimulated to secrete serotonin, platelet aggregation, vasospasm, and inflammatory processes result in local cerebral ischemia. This is followed by rebound vasodilation and the release of peptide substance P and other mediators of pain. These events are summarized in [Figure 172.1](#).

THERAPEUTIC CONSIDERATIONS

Modern pharmacological treatment of headache, whether migraine or tension, is ultimately doomed because it fails to address the underlying cause. The first step in treating migraine headache is identifying the precipitating factor. Although food intolerance/allergy is the most important, many other factors must be considered as either primary causes or contributors to the migraine process. In particular, it is very important to assess the

Figure 172-1 The pathogenesis of migraine.

role that headache medications may be playing, especially in chronic headaches.

Drug reaction

Several clinical studies have estimated that approximately 70% of patients with chronic daily headaches suffer from drug-induced headaches.^[18] There are two main forms of drug-induced chronic daily headaches: analgesic rebound headache and ergotamine rebound headache.^[19] Withdrawal of medication results in prompt clinical improvement in most cases. In one study (summarized in [Table 172.5](#)) of 200 patients suffering from analgesic-rebound headache, discontinuation of these symptomatic medications resulted in 52% improvement in the total headache index, improvements in headache frequency and severity, general well-being, sleep patterns, and a reduction in irritability, depression, and lethargy.^[19]

These 200 patients were typical in that they sought relief from a variety of drugs. [Table 172.6](#) lists the types

TABLE 172-5 -- Profile of 200 patients with chronic daily headache

| Medications | Average no. of tablets/week | Range of no. | No. of patients of tablets/week | Percentage of patients |
|--|-----------------------------|--------------|---------------------------------|------------------------|
| Butalbital/aspirin, acetaminophen/caffeine with or without codeine | 30 | 14–86 | 84 | 42 |
| Codeine | 28 | 10–84 | 80 | 40 |
| Aspirin or acetaminophen with caffeine | 42 | 14–108 | 50 | 25 |
| Ergotamine | 15 mg | 6–42 mg | 44 | 22 |
| Acetaminophen | 52 | 15–105 | 34 | 17 |

| Nasal decongestants and antihistamines | 14 | 6–30 | 24 | 12 |

Aspirin

| 28

| 10–64 | 8

| 4

TABLE 172-6 -- Commonly used drugs to prevent migraine headaches

| Drug | Adult daily dosage | Common side-effects |
|---|---------------------------|--|
| Aspirin | 650–1950 mg | Gastric irritation, ulcer formation |
| Propranolol | 80–240 mg | Fatigue, lassitude, depression, insomnia, nausea, vomiting, constipation |
| Amitriptyline and imipramine | 10–150 mg | Drowsiness, dry mouth, constipation, weight gain, blurred vision, water retention |
| Sertraline | 50–200 mg | Anxiety, insomnia, sweating, tremor, gastrointestinal disturbances |
| Fluoxetine | 20–60 mg | Similar to those of sertraline |
| Ergonovine maleate | 0.6–2 mg | Nausea, vomiting, abdominal pain, diarrhea |
| Cyproheptadine | 12–20 mg | Sedation, dry mouth, gastrointestinal disturbances |
| Clonidine | 0.2–0.6 mg | Dry mouth, drowsiness, sedation, headache, constipation |
| Methysergide | 4–8 mg | Nausea, vomiting, diarrhea, abdominal pain, cramps, weight gain, insomnia, edema, decreased blood flow to extremities, heart and lung fibrosis |
| Calcium-channel blockers (verapamil, nifedipine, diltiazem, etc.) | 80–160 mg | Headache, low blood pressure, flushing, water retention, constipation |

1406

of drugs used for symptomatic relief. Most of these patients took at least three of these preparations at the same time.

Analgesic-rebound headache

In the early 1980s, it began to be quite apparent in the medical literature that headache medications increase the tendency for headache and perpetuate chronic headache. Early reports were labeled “paradoxical” in that heavy analgesic users experienced headaches of much greater frequency and intensity. For example, in one study it was found that sufferers of migraine headaches who took more than 30 analgesic tablets per

month had twice as many headache days per month as those who took fewer than 30 tablets.^[20] This finding led to the recommendation that analgesic use should be restricted in patients with chronic daily headaches.

In another study, 70 patients with daily headaches who were consuming 14 or more analgesic tablets per week were told to discontinue their use.^[21] One month later, 66% of the patients were improved. At the end of the second month, this percentage had grown to 81%.

Analgesic-rebound headaches should be suspected in any patient with chronic headaches who is taking large quantities of analgesics and who is experiencing daily predictable headache. The critical dosage which can lead to analgesic-rebound headache is estimated to be 1,000 mg of either acetaminophen or aspirin.

Analgesic medications typically contain substances in addition to the analgesic such as caffeine or a sedative like butabarbital. These substances further contribute to the problem and may lead to withdrawal headache and related symptoms such as nausea, abdominal cramps, diarrhea, restlessness, sleeplessness, and anxiety. Withdrawal symptoms typically start at 24–48 hours, and in most cases subside in 5–7 days.

Ergotamine-rebound headache

Ergotamine is the most widely used drug in the treatment of severe acute migraine and cluster headaches. Ergotamine works by constricting the blood vessels of the head, thereby preventing or relieving the excessive dilation of the blood vessels that is responsible for the pain of migraine and cluster headaches. Ergotamine is administered intramuscularly, by inhalation or by suppository since it is poorly absorbed when given orally.

Although usually quite effective, ergotamine is also associated with some significant side-effects. Symptoms of acute poisoning include:

- vomiting
- diarrhea
- dizziness
- rise or fall of blood pressure
- slow, weak pulse
- dyspnea
- convulsions
- loss of consciousness.

Symptoms of chronic poisoning include two types of manifestations: those resulting from blood vessel contraction and reduced circulation – numbness and coldness of the extremities, tingling, pain in the chest, heart valve lesions, hair loss, decreased urination, and gangrene of the fingers and toes – and those resulting from nervous system disturbances – vomiting, diarrhea, headache, tremors, contractions of the facial

muscles, and convulsions.

Regular use of ergotamine in migraine headaches is also associated with a dependency syndrome characterized by severe chronic headache with an increase in headache intensity upon cessation of medication. Because most migraine headaches rarely occur more than once or twice a week, the presence of an almost daily migraine-type headache in individuals taking ergotamine is a good clue for ergotamine-rebound headache. Dosage of ergotamine can also be a clue. In most cases of ergotamine-rebound headache, individuals take weekly dosages in excess of 10 mg. In some cases, patients may be taking dosages as high as 10–15 mg daily.

Stopping ergotamine causes predictable, protracted, and extremely debilitating headache usually accompanied by nausea and vomiting. These symptoms usually appear within 72 hours and may last for another 72 hours. Improvement after stopping the medication is very common. Ginger (discussed below) may lessen ergotamine withdrawal symptoms.

Diet

Food allergy/intolerance

There is little doubt that food allergy/intolerance plays a role in many cases of migraine headache. Many double-blind, placebo-controlled studies have demonstrated that the detection and removal of allergic/intolerant foods will eliminate or greatly reduce migraine symptoms in the majority of patients. What is unclear is the percentage of migraine patients for whom food control is the most important factor. [Table 172.7](#) summarizes the results of several clinical studies. As can be seen, success ranges from 30 to 93%, with the majority of studies showing a remarkably high degree of success.^[21]
^{[22] [23] [24] [25] [26] [27]}

A possible explanation for the large difference between the results of Mansfield et al^[21] and the others is that the Mansfield design was carefully selected for food allergy only, while the others included food intolerance. These studies found the incidence of food allergy to be similar for the three major types of migraine. The foods most

TABLE 172-7 -- Food allergy/intolerance and migraine headache

| Study | Percentage responding | Method |
|---------------------------------|-----------------------|--------------------------------|
| Mansfield et al ^[21] | 30 | Elimination |

| Monro et al ^[25] | 70 | RAST, elimination, sodium cromoglycate |
| Grant ECG ^[26] | 85 | Elimination |

commonly found to induce migraine headaches are listed in [Table 172.8](#) .

The mechanism by which food allergy/intolerance induces a migraine attack is still unknown. Several theories have been proposed:

- idiopathic response to a pharmacologically active substance, such as tyramine
- monoamine oxidase deficiency
- platelet phenolsulfotransferase deficiency; immunologically mediated food allergy
- platelet abnormalities, etc.

TABLE 172-8 -- Foods which most commonly induce migraine headaches

Egger et al^[24] suggested that migraine headache may result from chronic alteration of the non-specific responsiveness of cerebral vascular end-organ as a result of long-term antigenic stimulation. This mechanism would be analogous to the response in asthma of the bronchioles to exercise or cold after antigen contact. Allergic reactions to foods are known to cause platelet degranulation, with resultant serotonin release.^[27]

There are several methods which can be used to detect food allergies, most of which are described in [Chapter 15](#) . Although laboratory procedures are probably the most convenient for the patient, challenge testing is thought to be the most reliable. Unfortunately, challenge testing has limitations: some foods evoke a delayed response, which may require several days of repeated challenge to elicit recognizable symptoms; also, ingestion of large amounts of several foods may be necessary to detect those that are marginally reactive. The recommended procedure for the diagnosis and management of food allergy/ intolerance is described in the section on “Therapeutic approach” ([p. 1411](#)).

Dietary amines

Foods such as chocolate, cheese, beer and wine precipitate migraine attacks in many

people because they contain histamine and/or other vasoactive compounds which can trigger migraines in sensitive individuals by causing blood vessels to expand (see [Table 172.9](#)).^[28]^[29]^[30] Red wine is much more likely than white wine to cause a headache because it contains 20–200 times the amount of histamine and also stimulates the release of vasoactive compounds by platelets.^[6]^[29]^[31] It is also much higher in flavonoids – the antioxidant components shown to help prevent heart disease. These compounds can also inhibit the enzyme (phenolsulfotransferase) which normally breaks down

TABLE 172-9 -- Factors involved with histamine-induced headaches

| |
|--|
| <i>Histamine levels increased by:</i> |
| • Histamine in alcoholic beverages (particularly red wine) |
| • Histamine in food |

| • Vitamin B ₆ |
| • Vitamin C |

serotonin and other vasoactive amines in platelets. Many migraine sufferers have been found to have significantly lower levels of this enzyme.^[32] Since red wine contains substances which are potent inhibitors of this enzyme, it often triggers migraines in these individuals, especially if consumed along with high vasoactive amine foods like

cheese or chocolate. The standard treatment of histamine-induced headache is the histamine-free diet along with vitamin B₆ supplementation.^{[29] [30]}

The activity of the enzyme diamine oxidase, which breaks down histamine in the lining of the small intestine before it is absorbed into the circulation, appears to play a major role in determining whether or not a person is going to react to dietary histamine. Individuals sensitive to dietary histamine have lower levels (about half) of this enzyme in their tissues compared with control subjects.^[29] Diamine oxidase is a vitamin B₆-dependent enzyme. Not surprisingly, compounds which inhibit vitamin B₆ also inhibit diamine oxidase.^[29] These inhibiting factors include food coloring agents (specifically the hydrazine dyes like FD&C yellow #5), some drugs (isoniazid, hydralazine, dopamine, and penicillamine), birth control pills, alcohol, and excessive protein intake. Yellow dye #5 (tartrazine) is often consumed in greater quantities (per capita intake of 15 g/day) than the RDA for vitamin B₆ of 2.0 mg for males and 1.6 mg for females.

Vitamin B₆ supplementation (usually 1 mg/kg body weight) has been shown to improve histamine tolerance, presumably by increasing diamine oxidase activity.^{[29] [32]} Women have lower levels of diamine oxidase which may explain their higher incidence of histamine-induced headaches. Women are also much more frequently unable to tolerate red wine.^[29] Interestingly, the level of diamine oxidase in a woman increases by over 500 times during pregnancy.^{[33] [34]} It is very common for women with histamine-induced headaches to experience complete remission of their headaches during pregnancy.

Nutritional supplements

5-HTP

The role of 5-HTP in preventing migraine headaches by increasing serotonin levels was discussed above. In addition to this mechanism of action, 5-HTP also increases endorphin levels. The use of 5-HTP in the prevention of migraine headache offers considerable advantages over drug therapy. Although a number of drugs have been shown to be useful in the prevention of migraine headaches, all of these currently used drugs carry with them significant side-effects. 5-HTP is at least as effective as other pharmacological agents used in the prevention of migraine headaches and is certainly much safer and better tolerated. While some studies have used a dosage of 600 mg/day, equally impressive results have been achieved at a dosage as low as 200 mg/day. The clinical studies with 5-HTP in migraine headaches are discussed in [Chapter 92](#).

EFA's and arachidonic acid

The role of essential fatty acids in the pathogenesis of migraine may be quite important but does not appear to have received much research attention. Considering the significance of platelet aggregation and arachidonic acid metabolites in the mediation of the events leading to the prodromal cerebral ischemia of migraine, manipulation of

dietary EFAs may be very useful. It has been well demonstrated that reducing the consumption of animal fats and increasing the consumption of fish will significantly change platelet and membrane EFA ratios and decrease platelet aggregation.^[35] ^[36] ^[37]

Riboflavin

Another hypothesis for explaining migraine headaches is that they are caused by a reduction of energy production within the mitochondria of cerebral blood vessels. If this hypothesis is true, riboflavin, which has the potential of increasing mitochondrial energy efficiency, might have preventive effects against migraine. To test this hypothesis, 49 patients suffering from migraine were treated with a very large dose (400 mg daily) of riboflavin for at least 3 months.^[38] Overall improvement after therapy was 68.2% in the riboflavin group as determined by the migraine severity score used in the study. No side-effects were reported. The results from this preliminary study suggest high-dose riboflavin could be an effective, low-cost preventive treatment of migraine.

Magnesium

Low magnesium levels may also play a significant role in many cases of headaches as several researchers have provided substantial links between low magnesium levels and both migraine and tension headaches based on both theory and clinical observations.^[39] ^[40] ^[41] A magnesium deficiency is known to set the stage for the events that can cause a migraine attack as well as a tension headache. Low brain and tissue magnesium concentrations have been found in patients with migraines, indicating a need for supplementation since one of magnesium's key functions is to maintain the tone of the blood vessels as well as preventing overexcitability of nerve cells.^[39] ^[40] ^[41] ^[42]

Unfortunately, two recent double-blind studies have given conflicting results in the prevention of migraines in people prone to recurrent migraine headaches. In the first study, 250 mg of magnesium or placebo was given twice daily to 69 patients (35 received magnesium, 34 the placebo) for 12 weeks.^[43] The number of responders was

10 in each group (28.6% under magnesium and 29.4% under placebo). There was no benefit with magnesium compared with placebo in the number of migraine days or migraine attacks.

In the other double-blind study, 81 patients suffering from recurrent migraines were given either 600 mg of oral magnesium daily for 12 weeks or placebo.^[44] By the ninth week, the attack frequency was reduced by 41.6% in the magnesium group compared with only 15.8% in the placebo group. The number of days with migraine and the drug consumption for symptomatic treatment per patient also decreased significantly in the magnesium group. Side-effects with magnesium supplementation included diarrhea (18.6%) and gastric irritation (4.7%).

It appears that magnesium supplementation may only be effective in those individuals with low tissue or low ionized levels of magnesium. Low tissue levels of magnesium are common in patients with migraine, but most cases go unnoticed because most physicians rely on serum magnesium levels to indicate magnesium levels, a very unreliable indicator as most of the body's store of magnesium lies within cells, not in the serum. A low magnesium level in the serum reflects end-stage deficiency. More sensitive tests of magnesium status are the level of magnesium within the red blood cell (erythrocyte magnesium level) and the level of ionized magnesium (the most biologically active form) in serum.

Another possible benefit of magnesium in migraine sufferers may be its ability to improve mitral valve prolapse. Mitral valve prolapse is linked to migraines because it leads to damage to blood platelets, causing them to release vasoactive substances like histamine, platelet-activating factor, and serotonin.^{[7] [8] [9]} Since research has shown that 85% of patients with mitral valve prolapse have chronic magnesium deficiency, magnesium supplementation is indicated.^[45] This recommendation is further supported by several studies showing that oral magnesium supplementation improves mitral valve prolapse.

Magnesium bound to citrate, malate, aspartate, or some other Krebs cycle compound is better absorbed and better tolerated than inorganic forms, such as magnesium sulfate, hydroxide, or oxide, which tend to produce a laxative effect.^[46] If magnesium produces a loose stool or diarrhea, advise the patient to cut back to a level that is tolerable. Also, it is a good idea to prescribe at least 50 mg of vitamin B₆ daily as this B vitamin has been shown to increase the intracellular accumulation of magnesium.^[47]

Intravenous magnesium for acute migraine headaches

Intravenous magnesium has been shown to be an extremely effective treatment in some cases of acute migraine, tension, and cluster headaches in three studies. A dosage of 1–3 g of intravenous magnesium (over a 10 minute period) typically resulted in a nearly 90% success rate in patients with low ionized magnesium levels.^{[48] [49] [50]}

In the first study, the efficacy of intravenous infusion of 1 g of magnesium sulfate (MgSO₄) was evaluated in 40 patients (16 patients had migraines without aura, nine had cluster headaches, four had chronic tension-type headaches, and 11 had chronic migraine headaches).^[48] Complete elimination of pain was observed in 32 (80%) patients within 15 minutes of infusion of MgSO₄. No recurrence or worsening of pain was observed within 24 hours in 56% of the patients. Patients treated with MgSO₄ observed complete elimination of migraine-associated symptoms such as sensitivity to light and sound as well as nausea. No side-effects were observed, except for a brief flushed feeling. The eight non-responders exhibited significantly elevated serum ionized magnesium levels compared with responders prior to the infusion of MgSO₄.

In a study of migraine sufferers only, the hypothesis that patients with an acute attack of

migraine headache and low serum levels (< 0.54 mmol/L) of ionized magnesium are more likely to respond to an intravenous infusion of magnesium sulfate (MgSO_4) than patients with higher serum ionized magnesium levels was tested.^[49] Serum ionized magnesium levels were drawn immediately before infusion of 1 g of MgSO_4 in 40 consecutive patients with an acute migraine headache. Pain reduction of 50% or more, as measured on a headache intensity verbal scale of 1–10, occurred within 15 min of infusion in 35 patients. In 21 patients, at least this degree of improvement or complete relief persisted for 24 hours or more. Pain relief lasted at least 24 hours in 18 of 21 patients (86%) with serum ionized magnesium levels below 0.54 mmol/L, and in three of 19 patients (16%) with ionized magnesium levels at or above 0.54 mmol/L. The average ionized magnesium level in patients with relief lasting for at least 24 hours was significantly lower than that in patients with no relief or brief relief.

The final study involved patients with cluster headaches.^[50] Because previous studies reported that low serum ionized magnesium levels are common in patients with cluster headaches, researchers examined the possibility that patients with cluster headaches and low ionized magnesium levels may respond to an intravenous infusion of magnesium sulfate. Infusions of magnesium sulfate given to 22 patients with cluster headaches produced meaningful improvement in nine (41%) of them – not great numbers, but certainly worth the effort and certainly much safer than the drugs used in the treatment of acute cluster headaches such as ergotamine.

Physical medicine

Many forms of physical medicine have been used in the treatment of migraine headache. Although most have

been shown to be effective in shortening the duration and decreasing the intensity of an attack, they appear relatively ineffective in actually curing this disorder. Although very effective for headaches which have a significant muscular contraction component, these methods appear to have more limited success in reducing the frequency of attacks of true migraine.

Cervical manipulation

In a 6 month trial in Australia, 85 patients were studied to determine the efficacy of manipulation of the cervical spine by a chiropractor in the treatment of migraine headache. The study was controlled by comparing chiropractic manipulation with manipulation by a medical practitioner or physiotherapist and with simple cervical mobilization. Although the study found no difference in frequency of recurrence, duration, or disability, the chiropractic patients reported greater reduction in the pain associated with the attacks.^[51]

Temporomandibular joint dysfunction syndrome

Some researchers and clinicians have claimed that a substantial portion of headaches diagnosed as classic or common migraine are in reality the symptoms of temporomandibular joint dysfunction syndrome (TMJ). However, a careful investigation found that the incidence of migraine in patients with TMJ is similar to that in the general population, while the incidence of headache due to muscle tension is much higher.^[52] These results suggest that, while correction of TMJ dysfunction may be of use in the treatment of migraine headaches, it is far more important in muscle tension headaches.

Transcutaneous electrical stimulation

Transcutaneous electrical stimulation (TENS) has been shown in a placebo-controlled trial to be effective in the treatment of patients with migraine and muscle tension headaches (55% responded to treatment vs. an 18% placebo response).^[53] However, the study also found that inappropriately applied TENS, i.e. TENS applied below perception threshold, was ineffective.

Acupuncture

The use of acupuncture in the treatment of migraine headache has received considerable research attention. However, assessing its efficacy is difficult since the studies have not been blind, migraine patients were seldom studied separately, and most of the research has been reported in foreign languages, with only summaries available in English.

Despite these limitations, sufficient evidence exists to support use of acupuncture to relieve migraine pain.^{[54] [55] [56]} It is interesting to note that the mechanism of relief is apparently not endorphin-mediated. One study found that the injection of saline or naloxone did not affect the efficacy of the therapy,^[57] and another found that, while acupuncture increased endorphin levels in controls, the low levels of serum endorphins found in migraine patients did not increase with treatment.^[58] The mechanism of action may instead be through normalization of serotonin levels. One study found that acupuncture was effective in relieving pain when it normalized serotonin levels, but was ineffective in relieving pain and in raising serotonin levels in those patients with very low levels of serotonin.^[59]

Acupuncture appears to have some success in reducing the frequency of migraine attacks, although, as mentioned above, limitations in experimental design make interpretation difficult. One study found that 40% of the subjects experienced a 50–100% reduction in severity and frequency.^[57] Although the authors used a double-blind, cross-over design, the patients were only followed for 2 months. Another (uncontrolled) study found that five treatments (over a period of 1 month) decreased recurrence in 45% of the patients over a period of 6 months.^[60]

Biofeedback and relaxation therapy

The most widely used non-drug therapy for migraine headaches is thermal biofeedback and relaxation training. Thermal biofeedback utilizes a feedback gauge to monitor the temperature of the hands. The patient is then taught how to raise (or lower) the temperature of the hand by the device providing feedback as to what is affecting the temperature. Relaxation training involves teaching patients techniques designed to produce the “relaxation response” – a term used to describe the physiological state that is the opposite of the stress response. This term was originally coined by Harvard professor and cardiologist Herbert Benson MD in his best-selling book, *The relaxation response* (William Morrow 1975).

The effectiveness in reducing the frequency and severity of recurrent migraine headaches with biofeedback and relaxation training has been the subject of over 35 clinical studies.^[61] When the results from these studies were compared with studies using the beta-blocking drug Inderal (propranolol), it was apparent that the non-drug approach was as effective as the drug approach, but was without side-effect (see [Table 172.10](#)).

TABLE 172-10 -- Biofeedback/relaxation compared with propranolol – average percentage improvement per patient

| | |
|------------------------|-------|
| Biofeedback/relaxation | 56.4% |
| Propranolol | 55.2% |
| Placebo | 14.3% |
| Untreated | 3.2% |

Botanical medicines

Botanical medicines have a long history of use as folk cures for migraine headache. Although many botanicals have been used, few have received careful evaluation. Feverfew (*Tanacetum parthenium*) and ginger (*Zingiber officinalis*) are discussed here, as they have the most scientific documentation.

Tanacetum parthenium

Perhaps the most popular preventive treatment of migraine headaches is the herb feverfew. Scientific interest in feverfew began when a 1983 survey found that 70% of 270 migraine sufferers who had eaten feverfew daily for prolonged periods claimed that the herb decreased the frequency and/or intensity of their attacks.^[62] Many of these patients had been unresponsive to orthodox medicines. This survey prompted several

clinical investigations of the therapeutic and preventive effects of feverfew in the treatment of migraine.^[62] ^[63] ^[64] ^[65]

The first double-blind study was done at the London Migraine Clinic, using patients who reported being helped by feverfew.^[62] Those patients who received the placebo (and as a result stopped using feverfew) had a significant increase in the frequency and severity of headache, nausea, and vomiting during the 6 months of the study, while patients taking feverfew showed no change in the frequency or severity of their symptoms. Two patients in the placebo group who had been in complete remission during self-treatment with feverfew leaves developed a recurrence of incapacitating migraine and had to withdraw from the study. The resumption of self-treatment led to renewed remission of symptoms in both patients. The second double-blind study, performed at the University of Nottingham, demonstrated that feverfew was effective in reducing the number and severity of migraine attacks.^[63]

Follow-up studies to the clinical results have shown that feverfew works in the treatment and prevention of migraine headaches by inhibiting the release of blood vessel-dilating substances from platelets, inhibiting the production of inflammatory substances, and re-establishing proper blood vessel tone.^[64] The effectiveness of feverfew is dependent upon adequate levels of parthenolide, the active principle.^[65]

Zingiber officinalis

The common ginger root has been shown to exert significant effects against inflammation and platelet aggregation.^[66] ^[67] Unfortunately, in relation to migraine headache, there is much anecdotal information but little clinical evidence. For example, a 1990 article described a 42-year-old woman with a long history of recurrent migraines who discontinued all medications for a 3-month period prior to a trial of ginger.^[68] For the trial, 500–600 mg of dried ginger was taken mixed with water at the onset of the migraine and repeated every 4 hours for 4 days. Improvement was evident within 30 minutes and there were no side-effects. The woman subsequently began to use uncooked fresh ginger in her daily diet. Migraines became less frequent and, when they did occur, they were at a “much lower intensity” than previously.

There remain many questions concerning the best form of ginger and the proper dosage. The most active anti-inflammatory components of ginger are found in fresh preparations and the oil.

THERAPEUTIC APPROACH

Migraine headache is a multifaceted disease, and indeed could be accurately described as a symptom rather than as a disease. The challenge for the clinician is to determine which of the several factors discussed here are responsible for each patient’s migraine process. Identification of the precipitating factors, and their avoidance, is important in reducing the frequency of headaches. Avoidance of initiators is particularly significant, considering that they are cumulative in effect.

Due to the high incidence (80–90%) of food allergy/ intolerance in patients with migraine headache, diagnosis and management begins with 1 week of careful avoidance of all foods to which the patient may be allergic or intolerant. This can be accomplished through either a pure water fast or the use of an elemental diet (an oligoantigenic diet may be used but is less desirable, since significant allergens may be inadvertently included). All other possible allergens, e.g. vitamins, unnecessary drugs, herbs, etc., should also be avoided. During this procedure, food-sensitive patients will exhibit a strong exacerbation of symptoms early in the week, followed by almost total relief by the end of the fast/modified diet. This sequence is due to the addictive characteristic of the reactive foods. Once the patient is symptom-free, one new food is reintroduced (and eaten several times) each day while symptoms are carefully recorded. Some authors recommend reintroduction on a 4 day cycle. Suspected foods (symptom onset ranges from 20 minutes to 2 weeks) are eliminated, and apparently safe foods are rotated through a 4 day cycle (see [Ch. 58](#)). Once a symptom-free period of at least 6 months has been established, the 4 day rotation diet should no longer be necessary.

Diet

As discussed above, all food allergens must be eliminated and a 4 day rotation diet utilized until the patient is symptom-free for at least 6 months. Foods containing

1412

vasoactive amines should initially be eliminated. After symptoms have been controlled they can be carefully reintroduced. The primary foods to eliminate are alcoholic beverages, cheese, chocolate, citrus fruits, and shellfish. The diet should be low in sources of arachidonic acid (land animal fats) and high in foods which inhibit platelet aggregation, e.g. vegetable oils, fish oils, garlic, and onion.

Supplements

- Magnesium: 250–400 mg three times/day
- Vitamin B₆ : 25 mg three times/day
- 5-HTP: 100–200 mg three times/day.

Botanical medicines

- *Tanacetum parthenium*: 0.25–0.5 mg parthenolide twice daily
- Ginger (*Zingiber officinalis*)
 - fresh ginger: approximately 10 g/day (6 mm slice)
 - dried ginger: 500 mg four times/day
 - extract standardized to contain 20% of gingerol and shogaol 100–200 mg three

times/day for prevention and 200 mg every 2 hours (up to six times daily) in the treatment of an acute migraine.

Physical medicine

- TENS to control secondary muscle spasm
- Acupuncture to balance meridians
- Biofeedback:
 - The Association for Applied Psychophysiology and Biofeedback

DIAGNOSTIC SUMMARY

- Sudden, transient motor and sensory disturbances including impaired vision
- Diffuse neurologic signs, with remissions and exacerbations
- Diagnosis is made almost entirely on characteristic clinical presentation.

GENERAL CONSIDERATIONS

The syndrome of progressive diffuse neurological disturbances occurring early in adult life, known as multiple sclerosis, has been recognized since its description by Charcot in 1868. Multiple sclerosis (MS) is an intriguing condition in that, despite considerable research, no coherent theory accounts for all the evidence about the epidemiology, etiology, and pathogenesis of MS. Mainstream medicine has focused on finding a viral etiology for this demyelinating disease, although most current work suggests immune disturbances and autoimmunity. The pathologic hallmark of the disorder consists of zones of demyelination (plaques) that vary in size and location. Symptoms correspond in a general way to the distribution of the plaques.

This discussion attempts to encompass all relevant factors in the development and progression of this often debilitating illness.

Epidemiology

In about two-thirds of the cases, onset is between ages 20 and 40 (rarely is the onset after 50) and women have a slight preponderance over males (60% female:40% male). One of the more interesting features of MS is the geographic distribution of the disease. Areas with the highest prevalence are all located in the higher latitudes, in both the northern and southern hemispheres (50–100 cases/100,000 vs. 5–10/100,000 in the

tropics). These high-risk areas include the northern United States,

1416

Canada, Great Britain, Scandinavia, northern Europe, New Zealand, and Tasmania. There are interesting exceptions to this geographic distribution, as the disease is uncommon in Japan.^{[1] [2]}

It appears that the initial event in the development occurs in early life. This statement is based on the observation that people who move from a low-risk area to a high-risk area before age 15 acquire a high risk of developing MS, whereas those who make the same move after adolescence retain their low risk.^[2] The incidence of MS appears to be increasing.

There are many possible reasons for the geographic distribution of MS, such as solar exposure, genetics, diet, and other environmental factors. These are discussed below.

Etiology

The cause of MS remains to be definitively determined. Many causative factors have been proposed, but the data supporting these postulates are fragmentary and indirect. The following etiologies represent only a fraction of the possible explanations of the cause of MS. MS may be the epitome of a multifactorial disease.

Virus infection

Viruses cause several demyelinating diseases in humans and animals that are quite similar to MS. The virus-associated demyelinating disease seen most commonly is postinfectious encephalomyelitis. This disease starts 10–40 days after an acute viral infection or after an immunization. Progressive multifocal leukoencephalopathy and subacute sclerosing panencephalitis are other human demyelinating diseases caused by the human papovavirus and the measles virus, respectively. In animals, many viruses are capable of producing demyelination.^{[1] [2] [3]}

The studies, when considered collectively, have clearly demonstrated that demyelination can occur as a result of viral infection. The demyelination may be direct viral lysis of the myelin-producing cells, or viral infection leading to autoimmunity. In addition, a viral infection may lead to alteration in the balance of suppressor to helper T-cells which may promote immune-mediated demyelination. This information has suggested to many researchers that MS has a viral etiology. However, the viruses that have actually been isolated from cultures of material from patients with multiple sclerosis most likely have represented contamination or were adventitious, rather than causal, agents. Isolated viruses include:^{[1] [2] [3]}

- rabies virus

- herpes simplex virus
- scrapie virus
- parainfluenza virus
- subacute myelo-optic neuropathy virus
- measles virus
- coronavirus.

Serological evidence has also pointed to several viruses, particularly the measles virus. As early as 1962, researchers reported that the sera of patients with multiple sclerosis had elevated measles antibody titers. Subsequent studies confirmed this association and also demonstrated that patients with MS had CNS synthesis of measles antibody. Based on this data, MS was at one time believed to be due to an ongoing measles infection. This view has been modified by more recent studies indicating that a high percentage of patients with MS have elevated cerebrospinal fluid antibody titers to two or more viruses. More importantly, studies have shown that the measles-specific antibody in MS patients accounts for only a small percentage of the total IgG.^{[1] [2] [3]}

The cerebrospinal fluid of most MS patients contains an elevated level of IgG, the electrophoretic pattern of which is characteristic of an infectious process. One hypothesis states that this pattern is in fact due to an unrecognized infectious agent that causes MS. This hypothesis has been termed the “sense antibody” hypothesis. An alternative hypothesis states that MS is not an infectious disease and that all the IgG in the CNS is non-specific or “non-sense antibody”. At present, the data available do not appear to support a common infectious agent as the antigen for the increased IgG. Hyperactivity of circulating B-cells during acute attacks is thought to be the factor responsible for the excessive IgG production within the CNS.^{[1] [2] [3]}

Autoimmune reaction

The lesions of MS are mimicked by those of experimental allergic encephalomyelitis (EAE), an autoimmune disease induced in animals after immunization with myelin. However, in EAE, T-lymphocyte sensitivity is to a single antigen, i.e. myelin basic protein, while in MS, sensitivity to myelin basic protein cannot be demonstrated. This indicates that if MS is an autoimmune disease, it is due to some other antigen. Attempts to find an antigen to which only MS patients react have failed.^{[1] [2]}

A variety of immune system abnormalities have been reported in MS patients that would seem to support an autoimmune etiology. During acute episodes, suppressor T-cell levels have been shown to fall just prior to an attack and to rise when the attack ends.^{[1] [2]} Loss of suppressor cell activity could permit a latent autoimmune condition to become active. However, if this were the case, evidence of other autoimmune diseases

would be expected to manifest at this time as well. An alternative explanation is that the changes in the T-cell suppressor activity during acute attacks may be secondary to viral

suppression.^[1]

Diet

Many researchers have attempted to correlate various dietary patterns and the geographic distribution of MS. Diets high in gluten^[4] and milk^[5] ^[6] are much more common in areas where there is a high prevalence of MS. As intriguing as these associations are, the majority of research concerning nutrition and MS has focused on the role that dietary fat plays in the epidemiology and etiology of MS.^[7] ^[8] ^[9] ^[10]

Some of the first investigations into diet and MS centered around trying to explain why inland farming communities in Norway had a higher incidence than areas near the coastline.^[10] It was discovered that the diets of the farmers were much higher in animal and dairy products than the diets of the coastal dwellers, and the latter's diet had much higher levels of cold-water fish. Since animal and dairy products are much higher in saturated fatty acids and lower in polyunsaturated fatty acids than fish, researchers explored this association in greater detail. Subsequent studies have upheld a strong association between a diet rich in animal and dairy products and the incidence of MS.^[7]

Epidemiologic evaluation based on 36 countries between 1983 and 1989 of the relationship between the mortality rates from multiple sclerosis showed that saturated fatty acids, animal fat, animal minus fish fat, and latitude correlated independently and positively with multiple sclerosis mortality. The ratio of polyunsaturated fatty acids to saturated fatty acids (P/S ratio) and the ratio of unsaturated fatty acids to saturated fatty acids correlated independently and negatively with multiple sclerosis mortality.^[8]

It is interesting to note that the incidence of MS is quite low in Japan, where consumption of marine foods, seeds, and fruit oil is quite high. These foods contain abundant polyunsaturated fatty acids, including the omega-3 oils (alpha-linolenic, eicosapentaenoic, and docosahexanoic acids). Deficiencies of the omega-3 oils are thought to interfere with lipid elongation and permanently impair formation of normal myelin.^[11] Individuals with MS are thought to have a defect in essential fatty absorption and/or transport, which results in a functional deficiency state. In addition, consumption of saturated fats increases the requirements for the essential fatty acids, creating a relative deficiency state in some individuals. This is probably significant in patients with MS. The role of diet in the etiology and pathogenesis of MS is discussed further in "Therapeutic considerations" below.

Excessive lipid peroxidation

Many studies have demonstrated reduced glutathione peroxidase (GSH-Px) activity in the erythrocytes and leukocytes of patients affected by multiple sclerosis.^[12] ^[13] ^[14] ^[15] As GSH-Px is intricately involved in the protection of cells from free radical damage, decreased activity level would leave the myelinated sheath particularly sensitive to lipid peroxidation. GSH-Px is found in two forms, a selenium-dependent enzyme and a non-selenium-dependent enzyme. Since low-selenium areas often overlap high-prevalence areas for MS, it is natural to speculate that there may be a correlation between selenium levels, GSH-Px activity, and MS. Initial studies seemed to support

this correlation.^[12] ^[16] However, subsequent studies indicated that the reduced GSH-Px activity found in MS patients is independent of the selenium concentration and is probably due more to genetic factors.^[13] ^[14] ^[15]

There appears to be genetic polymorphism for GSH-Px. In patients with MS, there appears to be an increased occurrence in individuals who inherently possess low GSH-Px activity (GSH-PxL), compared with individuals who possess high GSH-Px activity (GSH-PxH).^[13] These studies have utilized erythrocyte GSH-Px activity, but it is not known how this correlates with oligodendrocyte GSH-Px activity. A decreased GSH-Px activity in the myelin-producing cells would render these cells extremely susceptible to lipid peroxidation.

DIAGNOSTIC CONSIDERATIONS

Multiple sclerosis is a difficult disease to diagnose early, when it is most effectively treated. The initial symptoms may occur alone or in combination, and they occur in varying frequencies (see [Table 173.1](#)). Typically, they develop over a few days, remain stable for a few weeks, and then recede. Recurrences are common, although the course of the disease is extremely variable.

Although multiple sclerosis is diagnosed primarily

TABLE 173-1 -- Early symptoms of multiple sclerosis

| Type | Frequency | Symptoms |
|---------------|-----------|--|
| Motor | 42% | Feeling of heaviness, weakness, leg dragging, stiffness, tendency to drop things, clumsiness |
| Sensory | 18% | Tingling, “pins and needles” sensation, numbness, dead feeling, band-like tightness, electrical sensations |
| Visual | 34% | Blurring, fogginess, haziness, eyeball pain, blindness, double vision |
| Vestibular | 7% | Light-headedness, feeling of spinning, sensation of drunkenness, nausea, vomiting |
| Genitourinary | 4% | Incontinence, loss of bladder sensation, loss of sexual function |

on clinical grounds, some laboratory procedures provide support for the diagnosis. These include measurement of components of the patient’s cerebral spinal fluid and evoked-potential studies. The concentration of IgG in the cerebral spinal fluid is elevated in 80–90% of patients with MS, and agarose electrophoresis reveals the presence of oligoclonal bands in 90%. Unfortunately, these abnormalities are not specific for MS. Assessment of nerve fiber conduction in the visual, auditory, and somatosensory

pathways shows abnormalities in 94% of patients with established disease, and 67% of patients with suspected disease. During the past decade, magnetic resonance imaging has become a useful tool for assessing the level of lesions in the nervous system.

Essential fatty acid analysis (see [Ch. 13](#)) for early recognition of lipid abnormalities will result in better therapeutic results, and aids in the determination of the efficacy of fatty acid supplementation.

THERAPEUTIC CONSIDERATIONS

From a natural therapeutic standpoint, there appear to be three major approaches:

- dietary therapy
- nutritional supplements
- physical therapy.

Obviously, including all three provides the most comprehensive treatment plan.

Diet

The Swank diet

Dr Roy Swank, Professor of Neurology, University of Oregon Medical School, has provided convincing evidence that a diet low in saturated fats, maintained over a long period of time, tends to retard the disease process and reduce the number of attacks.^[9]^[17] Swank began successfully treating patients with his low-fat diet in 1948. Swank's diet recommends:^[9] ^[17]

- a saturated fat intake of no more than 10 g/day
- a daily intake of 40–50 g of polyunsaturated oils (margarine, shortening, and hydrogenated oils are not allowed)
- at least 1 tsp of cod liver oil daily
- a normal allowance of protein
- the consumption of fish three or more times a week.

A diet low in saturated fats significantly restricts many animal sources of protein. The patient will have to derive protein from other sources, e.g. legumes, grains, and vegetables. While meat consumption is contraindicated, fish appears to be particularly indicated due to its excellent protein content and, perhaps more importantly, its oil content. Cold-water fish such as mackerel, salmon, and herring are rich in the beneficial oils eicosapentaenoic and docosahexanoic acid (omega-3 oils). These oils are important in maintaining normal neural function and myelin production.^[11] They are incorporated into the myelin sheath where they may increase fluidity and improve neural transmission.

Swank's diet was originally thought to help patients with MS by overcoming an essential

fatty acid deficiency. Currently, it is thought that the beneficial effects are probably a result of:^[18] ^[19]

- decreasing platelet aggregation
- decreasing an autoimmune response
- normalizing the decreased essential fatty acid levels found in the serum, erythrocytes, and, perhaps most importantly, the cerebrospinal fluid in patients with MS.

Swank's diet significantly reduces the platelet adhesiveness and aggregation that is observed in atherosclerotic processes as well as in multiple sclerosis. Excessive platelet aggregation and microemboli are thought to result in the following abnormalities observed in MS: damage to the blood–brain barrier, alterations in the microcirculation of the CNS, spontaneous and induced subcutaneous hemorrhage, and cerebral ischemia.^[20] ^[21]

MS patients have been shown to have an abnormal blood–brain barrier, presumably as a result of excessive platelet adhesiveness and aggregation.^[21] ^[22] Damage to the blood–brain barrier may allow the influx into the cerebral spinal fluid of plasma constituents, such as bacteria, viruses, antibodies, toxic chemicals, and other compounds, that are toxic to myelin. Ischemia may also be a contributing factor in demyelination, by promoting both the release of lysosomal enzymes and cellular death.^[23]

The effect of diet on platelets is important in MS, but probably of greater importance is the effect that fatty acids have on the activity of the immune system. Immunosuppressive compounds such as adrenal steroids, cyclophosphamide, and various antimetabolites have yielded good short-term benefits, but are of limited value due to their high risk and lack of demonstrable long-term efficacy.^[1] ^[3] Currently, new immunosuppressive drugs are being tested for use in MS. However, considering the lack of toxicity, Swank's dietary approach and supplementation with linoleic acid appear to be more appropriate and safer ways of modulating the immune response.

Food allergy

The role of food allergies in the pathogenesis and treatment of MS has been popularized.^[24] As mentioned earlier, the consumption of two common allergens,

gluten and milk, has been implicated in the etiology of MS. Jejunal biopsy in a small group of MS patients indicated an increased frequency of significant villous atrophy similar to that which occurs in celiac disease and food allergies.^[25] Clinical evidence for the efficacy of a gluten-free diet is, however, minimal. A clinical trial of a gluten-free diet in 40 patients with MS indicated that the relapse rate was no better than average.^[26] Another study demonstrated the absence of gluten antibodies in 35 out of 36 MS

patients.^[27] While there is no convincing evidence that gluten-free or allergy elimination diets are universally beneficial in the management of MS, it certainly is generally healthful to eliminate food allergens (as long as other dietary measures are also included, i.e. the Swank diet), and there is anecdotal evidence that specific individuals have been helped.

Nutritional supplements

Linoleic acid

Linoleic acid supplementation for the treatment of MS has been investigated in at least three double-blind trials.^[28] ^[29] ^[30] Although the results of the studies were mixed (two showed an effect and one did not), combined analysis indicated that patients supplementing with linoleic acid had a smaller increase in disability, and reduced severity and duration of relapses compared with controls.^[31] ^[32] These studies used a sunflower seed oil emulsion at a sufficient dosage to provide a daily supplementation of 17.2 g of linoleic acid. Other vegetable oils which primarily contain linoleic acid include safflower and soy. Better results would probably have been attained in the double-blind studies if dietary saturated fatty acids had been restricted, larger amounts of linoleic acid had been used (at least 20 g/day),^[29] and the studies had been of longer duration (one study found that normalization of erythrocyte fatty acid levels required at least 2 years of supplementation).^[33]

The effectiveness of linoleic acid supplementation in MS is thought to be due to immunosuppression. As mentioned earlier, MS bears a strong resemblance to experimental allergic encephalomyelitis (EAE), an autoimmune disease induced in animals by immunization with myelin.^[34] ^[35] Linoleic acid has been shown to greatly inhibit the severity of EAE in animals with less severe forms of the disease, paralleling the effect of linoleic acid supplementation in humans with MS, i.e. individuals with minimal disability respond better than those with severe disability. Polyunsaturated free fatty acids are known to significantly influence cell-mediated immunity.^[36] ^[37]

Evidence exists to show that the beneficial effects of essential fatty acid supplementation are mediated by prostaglandins and a splenic factor. Inhibitors of prostaglandin synthesis (such as aspirin and similar non-steroidal anti-inflammatory agents) and splenectomy have been shown to prevent the protective effect of linoleic acid in EAE.^[38] ^[39] The spleen is considered to be the major site for the production and release of immunologically active prostaglandins. Non-steroidal anti-inflammatory agents and splenectomy should be avoided in patients with MS.

If the effect of essential fatty acid supplementation is related to correcting the lipid composition of oligodendrocytes, Schwann cells, and other myelin-producing cells, several years of supplementation may be required before complete therapeutic benefits are observed. Electrophoretic mobility studies of erythrocytes from subjects with MS indicate that treatment with unsaturated fatty acids must continue for at least 2 years before they regain normal reactivity.^[33] Presumably, since myelin-producing cells have a much longer half-life than erythrocytes, it could take several years before the total

benefit of supplementation would be observed.

Flax and marine oils

Better results may be attained by using flaxseed oil, as this oil contains both linoleic and alpha-linolenic acid (an omega-3 oil). Linolenic acid has a greater effect on platelets^[40] and is required for normal CNS composition.^{[11] [41]}

It has been suggested that gamma-linolenic acid, as found in evening primrose oil, is more effective than linoleic acid alone, due to its easier incorporation into brain lipids and its possibly greater effect on immune function.^[42] However, due to its cost and the fact that relatively large amounts of the product would have to be consumed to exert a therapeutic effect, supplementation with evening primrose oil may not be indicated at this time. One study demonstrated that daily supplementation with only 340 mg of gamma-linoleic and 2.92 g of linoleic acid (the ratio found in evening primrose oil) had no effect on the clinical course in MS patients.^[29] In the same study, those receiving 23 g of linoleic acid demonstrated reduced frequency and severity of acute attacks, even though the study was only 24 months long.

There appears to be a strong rationale for supplementation with eicosapentaenoic acid (EPA) and DHA, the so-called “marine lipids”, in the treatment of MS, although no direct clinical investigation has been reported. EPA greatly inhibits platelet aggregation,^[43] and DHA is present in large concentrations in lipids of the brain.^[44] This is consistent with Swank’s protocol, which included the liberal consumption of fish and supplementation with cod liver oil, a rich source of EPA and DHA.^{[9] [17]} Supplements may be used to increase EPA and DHA, particularly in areas where the availability of cold-water fish is limited.

Selenium and vitamin E

Selenium’s role as the mineral portion of glutathione peroxidase is discussed above with regard to the increased lipid peroxidation observed in patients with MS. While selenium supplementation will not increase the activity of glutathione peroxidase in the majority of patients with MS, it is a relatively inexpensive supplement that may benefit some. Vitamin E supplementation is definitely indicated, due to the increased lipid peroxidation previously mentioned and the increased consumption of polyunsaturated fats, which increases vitamin E requirements.

One study reported that supplementation of 18 MS patients with 6 mg/day of sodium selenite, 2 g/day of vitamin C, and 480 mg/day of vitamin E for 5 weeks increased GSH-Px fivefold.^[44] Unfortunately, clinical parameters were not evaluated.

Vitamin B₁₂

Acquired deficiency of vitamin B₁₂ as well as inborn errors of metabolism involving this vitamin are well-known causes of demyelination of nerve fibers in the central nervous system (CNS). There are several reports in the medical literature that vitamin B₁₂ levels in the serum, red blood cells, and CNS are low in multiple sclerosis. The coexistence of a vitamin B₁₂ deficiency in MS may aggravate the disease or promote another cause of progressive demyelination.^{[45] [46] [47]}

Recently, researchers in Japan sought to clarify the state of vitamin B₁₂ metabolism in 24 Japanese patients with MS, and to determine if vitamin B₁₂ in massive doses provided any therapeutic benefit in chronic progressive MS.^[48] The researchers found that the level of vitamin B₁₂ in the serum was normal, but that there was a significant decrease in the unsaturated vitamin B₁₂ binding capacities in the patients with MS, indicating a defect in the transport of vitamin B₁₂ into cells. In six patients with severe chronic progressive MS, the oral administration of 60 mg/day of vitamin B₁₂ (methylcobalamin) improved both visual and brain-stem auditory evoked potentials by nearly 30%. Motor function did not improve, indicating that afferent pathways benefit from vitamin B₁₂ while efferent pathways do not.

The results produced are on a par with those produced by the combination of high-dose intravenous cyclophosphamide and steroids. However, while this drug combination is associated with profound immunosuppression and toxicity, no side-effects have been attributed to high doses of vitamin B₁₂. The form of vitamin B₁₂ used in this study was methylcobalamin rather than the standard cyanocobalamin. Hydroxocobalamin was tried in an earlier MS study with no apparent benefit.^[49] Methylcobalamin is the main form in the body and is directly related to the function of vitamin B₁₂ in methylation reactions.

Evaluation of vitamin B₁₂ in CSF and blood levels of 16 MS patients, 20–63 years of age (12 females), revealed that mean values in MS patients were significantly lower than in healthy subjects. Mean homocysteine levels in the serum and CSF in MS patients were significantly higher than in healthy subjects, an indication of impaired B₁₂ nutriture (see [Ch. 52](#)).^[50] However, another study of 38 patients with MS found no differences in the blood levels of B₁₂ or homocysteine.^[51] They did not test CSF.

Pancreatic enzymes

Like other autoimmune diseases, MS is associated with an increased level of circulating immune complexes. Experimental and clinical studies have shown that protease enzyme preparations are effective in reducing circulating immune complex levels in several of these diseases. Furthermore, clinical improvements correspond with decreases in immune complex levels. In the treatment of multiple sclerosis, pancreatic

enzyme preparations have been shown to produce good effects in reducing the severity and frequency of symptom flare-ups.^[52] Especially good results were noted in cases of visual disturbance, urinary bladder and intestinal malfunction, and sensory disturbances. However, it should be pointed out that little effect on spasticity, dizziness, or tremor was reported.

Other considerations

Malabsorption

A significant number of those with MS may have some degree of malabsorption.^[25] ^[53] In one study, 42% of MS patients were shown to have fat malabsorption, 42% were shown to have high levels of undigested meat fibers in their feces, 27% had an abnormal D-xylose absorption, and 12% had malabsorption of vitamin B₁₂.^[53] Malabsorption appears to be an important factor to consider, since multiple subclinical deficiency may result.

Physical therapy

The patient should be encouraged to lead as normal and active a life as possible. Exercise is physically and psychologically beneficial; however, the patient should avoid overwork and fatigue. Passive movement and massage are indicated for weakened spastic limbs, both for comfort and circulation.

Natural alpha-interferon

Recombinant beta-interferon is emerging as a popular medical treatment for multiple sclerosis. However,

naturally derived alpha-interferon from leukocytes may prove to be as (or more) advantageous. In three preliminary, sequential series conducted between 1987 and 1991, natural leukocyte alpha-interferon was evaluated in 49 multiple sclerosis patients.^[54] In the study, patients received 5–30 million international units per week for 3–12 months and were observed for 2 years after their first injection. Although no major toxicity was observed, 13 of the 49 patients initially reported fatigue, flu-like symptoms, or myalgias. These symptoms tended to abate after 1 month of treatment.

In the first year, 80% of the patients improved or stabilized, and in the second year 76% remained improved or stabilized. Better results were seen with higher dosages for longer periods of time. The 83% remission rate in relapsing/remitting patients reported in this study is better than the 30% rate reported for beta-interferon. Further studies with larger patient populations using a double-blind format are needed.

Ginkgo biloba extract

The increased levels of lipid peroxides and other indicators of free radical damage in the central nervous system in patients with MS suggest the need for antioxidant support.^[55] *Ginkgo biloba* extract (GBE) demonstrates impressive results as an antioxidant, exerts positive effects on platelet function, and has been shown to enhance nerve cell functions (see [Ch. 88](#)). This has now been assessed in a clinical study.

This was a randomized, double-blind, placebo-controlled trial in 104 patients for 7 days. Forty-three received a placebo, 29 received 240 mg/day of ginkgolide B, and 32 received 360 mg/day of ginkgolide B. There was no statistically significant difference between the three groups for changes in functional scores. There was, however, a trend in favor of the groups treated with ginkgolide for a change of the Rankin AI scores.^[56] While this study seems to demonstrate that ginkgo is not of value for acute exacerbations, it is of far too short a duration to evaluate the value of ginkgo for MS.^[56]

Hyperbaric oxygen

Early reports described promising results from the use of hyperbaric oxygen (HBO) in the treatment of MS.^[57] ^[58] ^[59] However, these reports were largely anecdotal or from uncontrolled clinical trials. In 1970, one study reported a small, transient improvement in 16 of 26 patients treated with HBO.^[57] Another small study, in 1978, reported an improvement in 11 patients treated with HBO.^[58] One year later, a large study found minimal to dramatic improvement in 91% of 250 patients treated with HBO.^[59] Several other researchers published similarly encouraging results.

The first double-blind, placebo-controlled trial of HBO indicated an apparently beneficial effect in the treatment of MS.^[60] Objective improvement was noted in 12 of 17 in the study group, compared with only one of 20 in the placebo group. Although the improvements were mild and transient in most of the patients, it appeared that patients with milder forms of MS and a shorter duration of disease derived a more pronounced and longer-lasting benefit. This was an encouraging preliminary study, yet it was criticized for its small sample and short follow-up period.

Subsequently, the Multiple Sclerosis Society commissioned further trials to be performed on a larger number of subjects, with longer periods of follow-up.^[61] ^[62] The results showed no significant improvement, apart from a subjective improvement in bowel and bladder functions in one of the studies. The results from these larger well-designed studies cast substantial doubt on the efficacy of HBO treatment of MS.

Recently, a study was published which evaluated the results of 14 controlled trials of hyperbaric oxygen treatment. Of the eight trials considered of reasonably high quality, only one showed favorable results. The patients in the trials had chronic progressive or chronic stable multiple sclerosis. In most of the trials, hyperbaric oxygen was supplied at pressures of 1.75–2 ATA during 20 sessions of 90 minutes over a period of 4 weeks.

Side-effects were generally minor but included ear and visual problems.^[63]

Oral antigen therapy

Perhaps the most exciting new therapy for MS is oral antigen therapy. Because of the striking similarity between the clinical and histopathological features of MS and the experimentally induced disease, experimental autoimmune encephalomyelitis (EAE) researchers began studying oral administration of myelin basic protein (MBP) in humans. EAE is induced by the injection of adjuvants. Oral administration of MBP has been shown to exert a profoundly suppressive effect on EAE induced in the rats.^[64] This MBP-induced oral tolerance is characterized by an inhibition of EAE clinical neurologic signs, reduced CNS histopathologic changes, a significant decrease in the T-lymphocyte proliferative response specific for the fed antigen, and a decrease in serum antibody specific for MBP.

Preliminary results in humans look equally impressive.^[65] However, at this time oral antigen therapy of MS is still in the investigational phase. Hopefully these preliminary results will be confirmed in subsequent studies.

Exercise

Whereas in the past conventional physicians cautioned against exercise, it has now been shown to significantly

improve fitness and have a positive impact on quality-of-life factors of multiple sclerosis patients. In an interesting study, 54 MS patients were assigned to either an exercise or a non-exercise group for 15 weeks. Aerobic training consisted of three 40 minute sessions per week of combined arm and leg ergometry. The exercise group improved in all measures of physical function, social interaction, emotional behavior, home management, total sickness impact profile score and recreation. There was no benefit on fatigue score.^[66]

Electromagnetic fields

Extracerebral applications of picotesla low-frequency electromagnetic fields have been suggested as a way of rapidly reversing the conduction blocks in demyelinating fibers. Reversal of the conduction block is believed to change the axonal sodium and potassium channels and synaptic nerve transmitter release, which may account for the immediate improvement in vision and other neurologic deficits reported in MS patients following this therapy.^[67] While this therapy may have value (immediate improvements in fine and large muscle control, speech, balance, fatigue, body image, cataplexy, and mood), evaluation is impossible at this time as all the published reports are small in number (one to five patients), uncontrolled, authored by a single clinician, and published

in a single journal.

THERAPEUTIC APPROACH

Treatment of MS with diet, lifestyle modification, and supplementation should begin as soon as possible, as the earlier in the disease process this therapy is initiated, the better the results will be. Several non-specific measures are important, including avoidance of excessive fatigue, emotional stress, and marked temperature changes.

The natural therapy of MS, while not proven to be highly effective, will help, and poses no threat to the patient's health. In fact, it is quite healthful, since the recommendations decrease the risk of atherosclerosis and other degenerative diseases. However, once MS has progressed to significant disability, it is unlikely to be affected to any great degree by these measures.

Diet

Swank's dietary protocol is recommended:

- saturated fat intake should be no more than 10 g/day
- daily intake of polyunsaturated oils should be 40–50 g (margarine, shortening, and hydrogenated oils are not allowed)
- normal amounts of protein are recommended
- fish should be eaten three or more times per week.

Fresh whole foods should be emphasized and animal foods (with the exception of cold-water fish) should be reduced, if not completely eliminated.

Supplements

- EPA: 1.8 g/day; or flaxseed oil: 1 tbsp/day
- Selenium: 200 mcg/day
- Vitamin E: 800 IU/day
- Vitamin B₁₂ (methylcobalamin): 60 mg/day
- Pancreatin (10X): 350–700 mg three times/day (on an empty stomach).

Botanical medicines

- *Ginkgo biloba* extract (24% ginkgo flavonglycosides): 40 to 80 mg three times/day.

Chapter 174 - Nausea and vomiting of pregnancy

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

DIAGNOSTIC SUMMARY

- Morning or evening nausea and vomiting occurring during the first trimester of pregnancy.

GENERAL CONSIDERATIONS

Many physiologic and psychogenic mechanisms have been proposed to explain the high incidence of nausea and vomiting during pregnancy (morning sickness). It has been estimated that 50% of women complain of these symptoms at some time during pregnancy. Considering the multitude of hormonal and metabolic changes which occur during pregnancy, the existence of these symptoms is not surprising; nonetheless, emotional factors undoubtedly contribute to the perceived, and actual, severity of the nausea and vomiting. Effective psychological support is paramount to any effective metabolic therapy.

THERAPEUTIC CONSIDERATIONS

Pyridoxine

Vitamin B₆ is often recommended in the treatment of nausea and vomiting of pregnancy. A pyridoxine deficiency, coupled with estrogen-mediated alterations in tryptophan metabolism, may be the etiologic factor in many cases of nausea and vomiting of pregnancy (for further discussion, see [Ch. 183](#)).

Support for the use of vitamin B₆ in nausea and vomiting of pregnancy in the medical literature prior to the 1990s consisted primarily of uncontrolled studies in the 1940s.^{[1] [2]} In 1979, the American Medical Association Council on Drugs went so far as to say that

“there was no solid evidence that vitamin B₆ is effective against nausea”. Two double-blind studies in the 1990s appear to provide the necessary support for this popular (and seemingly effective) recommendation to pregnant women. In the first study, 59 women were randomly assigned to receive either 25 mg of vitamin B₆ every 8 hours or a

1426

placebo. After 72 hours, only eight of 31 B₆ treated patients had nausea compared with 15 of 28 in the placebo group.^[3]

In the other, more recent, double-blind study, 342 pregnant women (less than 17 weeks gestation) were randomized to receive either 30 mg of vitamin B₆ or placebo in a double-blind fashion.^[4] Patients graded the severity of their nausea by a visual analog scale and recorded the number of vomiting episodes over the previous 24 hours before treatment and again during five consecutive days on treatment. Compared with the placebo group, there was a statistically significant reduction in nausea scores and vomiting episodes. Vitamin B₆ was recommended as a first-line treatment of nausea and vomiting of pregnancy.

Although a positive effect was reported in the trial, the results were not all that impressive. More than one-third of the patients still experienced vomiting and significant nausea with B₆ supplementation. Perhaps a larger dosage would have been more effective. Or perhaps ginger is a better recommendation (alone or in combination with vitamin B₆).

Vitamins K and C

Vitamins K and C, when used together, have shown considerable clinical efficacy, with 91% of patients in one study showing complete remission within 72 hours.^[5] The mechanism for this effect is unknown, and both vitamins administered alone show little effect.

Zingiber officinale (Ginger)

Ginger has a long tradition of being very useful in alleviating the symptoms of gastrointestinal distress, including the nausea and vomiting typical of pregnancy. Although the mechanism of action has yet to be elucidated, current thought is that it is due more to its aromatic and carminative effects on the gastrointestinal tract than to any CNS effects.^[6]

Ginger's anti-emetic actions have been studied in hyper-emesis gravidum, the most severe form of pregnancy-related nausea and vomiting. This condition usually requires hospitalization. In a double-blind, randomized cross-over trial, ginger root powder at a

dose of 250 mg four times a day brought about a significant reduction in both the severity of the nausea and the number of attacks of vomiting in 19 of 27 cases of early pregnancy (less than 20 weeks).^[7] These clinical results, along with the safety and the relatively small dose of ginger required and the problems (e.g. teratogenicity) with anti-emetic drugs in pregnancy, support the use of ginger in nausea and vomiting in pregnancy. This recommendation is becoming a well-accepted prescription even in orthodox obstetrical practices: ginger (as well as vitamin B₆) was recommended as an effective treatment of early nausea and vomiting of pregnancy.

Psychological aspects

Many studies have been performed in an attempt to understand why 50% of normal women experience no nausea and vomiting during pregnancy and why in some women this symptom continues beyond the first trimester.^[8] Although many theories have been proposed, the lack of consistent data has hampered the development of a widely accepted viewpoint.

There appears to be general agreement that mild symptoms of nausea and vomiting during the first trimester have a strong physiological basis (linked to hormone changes during pregnancy) and are predictive of positive pregnancy adjustment and outcome. More serious or longer-lasting symptoms are thought more likely to have a psychological component.

A prospective study of 86 pregnant women showed a significant increase in both nausea and vomiting in the first trimester in women who reported more unplanned, undesired pregnancies and negative relationships with their own mothers. Those with problems continuing into the third trimester were also significantly more negative in their assessment of their relationships with their mothers.^[9]

Acupressure

A prospective, controlled clinical trial examined the efficacy of acupressure therapy for morning sickness, using a two-group, random assignment, cross-over design. Subjects in group 1 ($n = 8$) used acupressure wristbands for 5 days, followed by 5 days without therapy. Subjects in group 2 ($n = 8$) had no therapy for 5 days, followed by 5 days' use of wristbands. The Multiple Affect Adjective Checklist and Sickness Impact Profile were used, and extent of nausea was assessed at baseline, day 5, and day 10. Use of acupressure wristbands relieved morning sickness for 12 of 16 subjects. Acupressure therapy also resulted in statistically significant ($P < 0.05$) reductions in anxiety, depression, behavioral dysfunction, and nausea.^[10]

THERAPEUTIC APPROACH

Diet

- Small, frequent meals

- Dry toast immediately after rising.

Supplements

- Vitamin B₆: 25 mg two to three times/day
 - Vitamin C: 250 mg two to three times/day
 - Vitamin K: 5 mg/day.
-

1427

Botanical medicines

Zingiber officinale (Ginger). There remain many questions concerning the best form of ginger and the proper dosage. Most research studies have utilized 1 g of dry powdered ginger root, a relatively small dose. For example, ginger is commonly consumed in India at a daily dose of 8–10 g. Furthermore, although most studies have used powdered ginger root, fresh (or possibly freeze-dried) ginger root or extracts concentrated for gingerol at an equivalent dosage may yield even better results.

In the treatment of nausea and vomiting of pregnancy, a dosage of 1–2 g of dry powdered ginger or as a decoction may be effective. For ginger extracts standardized to contain 20% gingerol and shogaol, an equivalent dosage would be 100–200 mg.

Counseling

Women who are having an unplanned or undesired pregnancy or who report a poor relationship with their own mother should be referred to a qualified counselor for assistance in resolving these conflicts.

Chapter 175 - Obesity

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

DIAGNOSTIC SUMMARY

Obesity is defined as:

- Being greater than 10% above “normal” weight
- Having a body fat percentage greater than 30% for women and 25% for men.

GENERAL CONSIDERATIONS

According to the results of The National Health and Nutrition Examination Survey III, the frequency of obesity (defined as greater than 20% above the ideal weight for height) in adults living in the United States is now greater than one in three.^[1] Even more alarming is the number of obese children – the number doubled from 1960 to 1991.^[2] This situation is serious as the odds are 4:1 against a child ever achieving normal weight as an adult if they enter their teenage years obese, and 28:1 if they end their teenage years obese.

Obesity is such a problem for American adults as most eat a diet high in fat and sugar, and are physically inactive. Increased television viewing and decreased physical activity are thought to be primary causes of the growing number of obese children.^[2]

Obesity defined

The simplest definition of obesity is an excessive amount of body fat. It must be distinguished from overweight, which refers to an excess of body weight relative to height. A muscular athlete may be overweight, yet have a very low body fat percentage. With this in mind, it is obvious that using body weight alone as an index of obesity is not entirely accurate. Nonetheless, obesity is classically identified as being of a weight greater than 20% more than the average desirable weight for men and women of a

given height (see the Metropolitan Life tables in [Ch. 44](#)).

In terms of body fat percentage, obesity is defined as a body fat percentage greater than 30% for women and 25% for men.^[1]

TABLE 175-1 -- Indirect methods of analyzing body fat composition

- Visual observation (somatotypes)
 - anthropometric measurements
 - height and weight
 - circumferences and diameters
 - skinfold thickness
- Isotope or chemical dilution
- Body water
- Body potassium
- Body fat
- Body density and body volume
- Conductivity
 - Total body electrical conductivity
 - Bioelectric impedance
 - Neutron activation
 - Imaging techniques
 - Ultrasound
 - Computer tomography
 - Nuclear magnetic resonance
 - Nuclear magnetic spectroscopy

DETERMINATION OF BODY COMPOSITION

The significance of accurately determining body fat composition and classifying obesity cannot be overstated as it offers valuable monitoring, prognostic, and therapeutic information. Since direct analysis of body composition cannot at this time be performed on live subjects, indirect methods must be employed, such as those listed in [Table](#)

Visual observation

Superficial visual observation is often all that is required for a qualitative analysis of obesity. One popular way of classifying body types is somatotyping, a physical anthropological classification of physique based on body size and proportion:

- The *endomorph* has a relatively large body and short arms and legs.
- The *mesomorph* has a large muscular chest that dominates over the abdomen and has prominent bony joints.
- The *ectomorph* has a relatively small frame (a slender and delicate bone structure) and long arms and legs.

The endomorph is at greatest risk of developing obesity, the mesomorph is at moderate risk, and the ectomorph is extremely unlikely to develop obesity.

The distribution of body fat is also important in the classification of obesity. Two basic distribution patterns exist: gynecoid and android or female and male patterned obesity. These types are discussed in greater detail under “Classification of obesity” ([p. 1431](#)).

Anthropometric measurements

Anthropometric measurements involve measurements of height and weight, various body circumferences or diameters (waist, chest, or hip circumferences and distances between the iliac crests, greater trochanters or acromioclavicular joints), and skinfold thickness.

Height and weight

Height and weight indices are the most common measurements made in the determination of obesity. The indices in widest use are the tables of desirable weights for height provided by the Metropolitan Life Insurance Company (see [Ch. 44](#)).

The Metropolitan tables are often criticized for three major shortcomings:

- the stated weight ranges merely reflect the weights of those with lowest mortality of *insurea* persons, which may not reflect the US population
- weight ranges for lowest mortality do not necessarily reflect optimal healthy weight for height
- the standard values make it difficult to assess degree of obesity, e.g. a person within the proper weight range may have excess body fat and lower than optimal lean body mass, or an individual with increased muscular development may be “overweight” despite having a low body fat percentage.

Again, it is important to recognize that weight alone is a poor reflector of body fat

composition.

In addition to the Metropolitan table, the Fogarty table of desirable weights for height is also widely used. It is simply a modification of the Metropolitan data, i.e. it represents an adaptation of the table in which the mean weight for the medium frame size is used as a reference point, with acceptable body weight ranging between the lowest level for the small frame and the highest level for the large frame.

Body mass indices

Body mass indices (BMIs) are often calculated for more precise estimates of adiposity. A number of body mass indices have been developed from weight and height measurements. The most popular BMIs include the weight–height ratio (W/H), Quetelet index (W/H^2), Khosla-Lowe index (W/H^3), and Benn index (W/H^P). These indices are widely used in large epidemiologic and health investigations due to the simplicity of their computation and their cost-effectiveness.

The Quetelet index is the most widely accepted method and generally correlates well with skinfold thickness measurements of body fat (see below). Quetelet's index, W/H^2 (W = weight in kg; H = height in meters), has been found to have the least correlation with body height and the highest correlation with independent measures of body fatness.^[3] ^[4] A Quetelet value of 27 or greater

for either sex is indicative of obesity, while a score of between 24 (for females) or 25 (for males) and 27 is considered to indicate that the person is overweight.

It should be kept in mind, once again, that measures of relative weight are generally unable to distinguish between adiposity, muscularity, and edema, but the Quetelet index correlates well with hydrostatic and skinfold measurements.

Skinfold thickness

The amount of total body fat can be estimated by measuring the thickness of the subcutaneous fat (skinfold or fatfold thickness). Skinfold thickness is measured with skinfold calipers at several sites on the body to improve accuracy. The most common measurement sites are the triceps, biceps, subscapular, and suprailiac skinfolds.

While skinfold thickness measurements are easy to obtain and are generally accurate in estimating body fat percentage, there are some limitations, including the inability to control inter- and intra-subject variation in skinfold compressibility, the inability to palpate the fat–muscle interface, and the impossibility of obtaining interpretable measurements on very obese individuals. Additionally, interobserver variability, as well

as the use of different types of skinfold calipers, may contribute to measurement errors.

However, for most clinical purposes, skinfold measurements provide the easiest and least expensive method for estimating body fat percentage. For more precise estimations, other methods (e.g. bioelectrical impedance, ultrasound, total body electrical conductivity [TOBEC], and hydrostatic weighing) offer significant advantages.

Body density

Measurement of body density provides a quantitative technique for measuring body fat. Density is determined from the specific gravity, which is calculated through measuring the different weight of the body in and out of water. In this procedure, individuals are weighed under water and out of water, taking into account the residual volume of the lungs. This information is used to fractionate the body into its fat and non-fat components, since fat is lighter than water and other tissues are heavier than water. The method is relatively easy if appropriate facilities are available. However, with the advent of more sophisticated body composition analyzers, the procedure has generally fallen out of favor, although many experts still consider it to be the “gold standard” of body composition determination.

The major limitation of hydrostatic weighing is that it requires considerable subject cooperation. The test subject must exhale completely and then submerge totally under water up to 10 times, making the method impossible for use with the elderly, the ill, or hospitalized patients.

Bioelectric impedance

The bioelectrical impedance method for determining body composition is based on measuring the conduction of an applied electrical current through body tissues. In biological structures, application of a constant low-level alternating current results in an impedance to the flow of the current that is frequency-dependent, according to the type of tissue. Intracellular and extracellular fluids behave as electrical conductors, while the cell membranes act as electrical condensers. At low frequencies, such as 1 kHz, the current mainly passes through the extracellular fluids, whereas at higher frequencies, such as 500–800 kHz, it penetrates the intra- and extracellular fluids. Thus body fluids and electrolytes function as electrical conductors, while cell membranes behave as capacitors. Since fat-free mass has a much greater conductivity than does fat, there is a strong relationship between conductance and lean body mass. Body composition analysis, as determined by bioelectrical impedance, is a safe non-invasive procedure that provides rapid measurement. Home scales equipped with bioelectrical impedance units to assess body fat percentage at the same time as weight are now available. These scales typically cost between \$150 and \$200.

TYPES OF OBESITY

Obesity is divided into several different categories based on the size and number of fat cells and also on how the fat is distributed in the body (e.g. in the abdomen versus the

hips).

Hyperplastic obesity

In hyperplastic obesity, there is an increased number of fat cells throughout the body. The number of fat cells that a person has is primarily dependent on the diet of the mother while the person was still in the womb as well as early infant nutrition. An excess of calories during these early stages of development can lead to the formation of an increased number of fat cells for the rest of the baby's life. Because it is harder to develop new fat cells in adulthood, hyperplastic obesity usually begins in childhood. Fortunately, hyperplastic obesity tends to be associated with fewer serious health effects compared with other types of obesity.

Hypertrophic obesity is characterized by an increase in the size of each individual fat cell and is linked to diabetes, heart disease, high blood pressure, and other serious disturbances of metabolism.^[5] Usually with hypertrophic obesity the fat distribution is around the waist. This fat cell distribution is referred to as male-patterned

1432

or android since it is typically seen in the obese male. If the waist is larger than the hips, a person is said to have android obesity. If the hips are larger, then a person has female-patterned or gynecoid obesity.

In hyperplastic–hypertrophic obesity there is an increase in both the number and size of fat cells.

CAUSES OF OBESITY

There are basically two areas on which to focus in trying to understand what causes obesity: psychological factors and physiological factors.

Psychological factors

In the past, psychological factors were thought largely responsible for obesity. A popular theory proposed that overweight individuals were insensitive to internal signals for hunger and satiety while simultaneously being extremely sensitive to external stimuli (sight, smell, and taste) which can increase the appetite. One source of external stimuli that has definitely been shown to be associated with obesity is watching television.

Watching television has been demonstrated to be linked to the onset of obesity, and there is a dose-related effect. In addition to leading to childhood obesity,^[5] television viewing also contributes to being overweight in adults. In one study of 4,771 adult women, the relationship between time spent watching television per week and obesity demonstrated that twice as many women who reported 3 or more hours of television

viewing per day were obese compared with the reference group of women who watched less than 1 hour of television per day.^[6]

Although watching television fits very nicely with the psychological theory (increased sensitivity to external cues), there are also several physiological effects of watching television that promote obesity, such as reducing physical activity and the actual lowering of resting (basal) metabolic rate to a level similar to that experienced during trance-like states. These factors clearly support the physiological view.

Physiological factors

While the psychological theories primarily propose that obese individuals have a decreased sensitivity to internal cues of hunger and satisfaction, an emerging theory of obesity states almost the opposite: obese individuals appear to be extremely sensitive to specific internal cues.^[4] The physiological theories of obesity are tied to:

- brain serotonin levels
- diet-induced thermogenesis
- the activity of the sympathetic nervous system
- the metabolism of the fat cells
- sensitivity to the hormone insulin.

All of these models (discussed below) support the theory that obesity is not just a matter of overeating, and explain why some people can consume very large quantities of calories and not increase their weight substantially, while for others just the reverse is true.

The low serotonin theory

A considerable body of scientific evidence demonstrates that brain serotonin plays a major role in influencing eating behavior. Much of the initial research was conducted at the Massachusetts Institute of Technology by Judith Wurtman PhD and her husband, Richard Wurtman PhD. These pioneers in brain chemistry have made many valuable contributions to the understanding of the effects of amino acids (including melatonin) on mood and behavior.

The Wurtmans and other researchers have shown that when animals and humans are fed diets deficient in tryptophan, appetite is significantly increased, resulting in binge eating of carbohydrates.^{[7] [8]} The diet low in tryptophan leads to low brain serotonin levels, a condition the brain interprets as starvation, resulting in the stimulation of the appetite control centers. This stimulation results in a preference for carbohydrates. Feeding animals or humans a carbohydrate meal leads to increased tryptophan delivery to the brain, resulting in the elevated manufacture of serotonin. This scenario has led to the idea that low serotonin levels leads to “carbohydrate craving” and plays a major role in the development of obesity.

Furthermore, it has been demonstrated that concentrations of tryptophan in the

bloodstream and subsequent brain serotonin levels plummet with dieting.^[9] In response to severe drops in serotonin levels, the brain simply puts out such a strong message to eat that it cannot be ignored. This situation sets up the scenario to explain why most diets do not work.

Cravings for carbohydrate due to low serotonin levels can be very mild or quite severe. They may range in severity from the desire to nibble on a piece of bread or a cookie to uncontrollable binging. At the upper end of the spectrum of carbohydrate addiction is bulimia, a potentially serious eating disorder characterized by binge eating and purging of the food through forced vomiting or the use of laxatives. The medical consequences of bulimia can be quite severe, e.g. rupture of the stomach, erosion of the dental enamel, and heart disturbances due to loss of potassium.

The set point theory

The “set point” is the weight that a body tries to maintain by regulating the amount of food and calories consumed. Research with animals and humans has found that

1433

each person has a programmed “set point” weight.^[4] It has been postulated that individual fat cells control this set point: when the fat cell becomes smaller, it sends a powerful message to the brain to eat. Since the obese individual often has both more and larger fat cells, the result is an overpowering urge to eat.

The existence of this set point helps to explain why most diets do not work. While the obese individual can fight off the impulse to eat for a time, eventually the signal becomes too strong to ignore. The result is rebound overeating with individuals often exceeding their previous weight. In addition, their set point is now set at a higher level, making it even more difficult to lose weight. This effect has been termed the “ratchet effect” and “yo-yo dieting”.

The set point seems to be tied to fat cell insulin sensitivity. When cells become insensitive to insulin, not only is transport of blood sugar (glucose) into the cells impaired, but there is also impaired burning of fat for energy. Both obesity and diabetes are strongly linked to the Western diet, presumably due to the negative effects saturated fats and refined carbohydrates have on internal mechanisms that control blood sugar levels (see [Ch. 147](#)).

The key to overcoming the fat cell’s set point appears to be increasing the sensitivity of the fat cells to insulin. This sensitivity apparently can be improved, and the set point lowered, by exercise, a specially designed diet, and several nutritional supplements which are discussed below. The set point theory suggests that a diet that does not improve insulin sensitivity will most likely fail to provide long-term results.

Increasing the body’s sensitivity to insulin results in less insulin being secreted. This

effect is very important as elevated insulin levels increase the transport of fatty acids into fat cells and, when the fat cells are replete with high levels of fat, triggers the body to manufacture more fat cells. While the body is able to add new fat cells, it is impossible to reduce the number of existing fat cells via natural means.

The set point of the fat cells not only predisposes an individual to be overweight, it also leads to an increased susceptibility to gain weight following weight loss, due to the ratchet effect. It is this physiology that is largely responsible for the “ratchet effect” and “yo-yo dieting”; however, the loss of muscle mass (the prime burner of fat in the body) caused by dieting is also a factor.

Diet-induced thermogenesis

A certain amount of excess consumed calories is converted immediately to heat, a process labeled “diet-induced thermogenesis”. There is some evidence that the level of diet-induced thermogenesis determines an individual’s susceptibility to weight gain. In lean individuals a meal may stimulate up to a 40% increase in heat production. In contrast, overweight individuals often display only a 10% or less increase in heat production. The excess food energy is stored instead of being converted to heat.^[10]

A major factor for the decreased thermogenesis in overweight people is, once again, insulin insensitivity.^[11] Therefore, enhancing insulin sensitivity may go a long way to re-establishing normal thermogenesis as well as resetting the set point in overweight individuals.

Another cause of the decreased thermogenesis in overweight individuals is impaired sympathetic nervous system activity.^[12] Several natural plant stimulants, described below, can activate the sympathetic nervous system, thereby increasing the metabolic rate and thermogenesis.

Researchers have also shown that even after weight loss has been achieved, individuals predisposed to obesity will still have decreased diet-induced thermogenesis compared with a lean individual.^[13] It is therefore important to continue to support insulin sensitivity and proper metabolism indefinitely if weight loss is to be maintained.

In addition to insulin insensitivity and reduced sympathetic nervous system activity, another factor determines diet-induced thermogenesis – the amount of brown fat. Most fat in the body is “white fat”, consisting of an energy reserve containing triglycerides stored in a single compartment. Tissue composed of white fat will look white or pale yellow. Brown fat cells contain multiple fat storage compartments. The triglycerides are localized in smaller droplets surrounding numerous mitochondria. An extensive blood vessel network and the density of the mitochondria give the tissue its brown appearance as well as its increased capacity to metabolize fatty acids.^[14]

Brown fat does not metabolize fatty acids to ATP as efficiently as other tissues of the body, including white fat. This inefficiency results in increased heat production. Brown

fat plays a major role in diet-induced thermogenesis.

Some theories suggest that lean people have a higher ratio of brown fat to white fat than overweight individuals. There is evidence to support this theory. The amount of brown fat in modern humans is extremely small (estimates are 0.5–5% of total body weight), but because of its profound effect on diet-induced thermogenesis, as little as 1 ounce of brown fat (0.1% of body weight) could make the difference between maintaining body weight or putting on an extra 10 pounds/year.^[14]

Lean individuals also tend to respond differently to excess calories than overweight individuals. In one experiment, lean individuals were overfed to increase their weight. In order to maintain the excess weight, they had to increase their caloric intake by 50% over their previous intake.^[15] The opposite appears to be the

1434

case in overweight and formerly overweight individuals. In addition to requiring fewer calories to gain and maintain their weight, studies have shown that in order to maintain a reduced weight, formerly obese persons must restrict their food intake to approximately 25% less than a lean person of similar weight and body size.^[16]

Individuals predisposed to obesity because of decreased diet-induced thermogenesis have been shown to be extremely sensitive to marked weight gain when consuming a high-fat diet compared with lean individuals.^[17] These individuals are not only more sensitive to the weight gain-promoting effects of a high-fat diet, they tend to consume much more dietary fat than lean individuals and they tend to exercise less.

THERAPEUTIC CONSIDERATIONS

Long-term, successful control of obesity is one of the greatest clinical challenges. Few people want to be overweight, yet only 5% of markedly obese individuals are able to attain and maintain “normal” body weight, while 66% of those just a few pounds or so overweight are able to do the same.

The successful program for obesity is consistent with the basic foundations of good health – a positive mental attitude, a healthy lifestyle (especially important is regular exercise), a health-promoting diet, and supplementary measures. All of these components are interrelated, creating a situation where no single component is more important than the other. Improvement in one facet may be enough to result in some positive changes, but impacting all components yields the greatest results.

There are literally hundreds of diets and diet programs that claim to be the answer to the problem of obesity. Dieters are constantly bombarded with new reports of a “wonder” diet to follow. However, the basic equation for losing weight never changes. In order for an individual to lose weight, energy intake must be less than energy expenditure. This goal can be achieved by de-creasing caloric intake or by increasing the rate at which

calories are metabolized.

To lose 1 pound, a person must consume 3,500 fewer calories than he or she expends. The loss of 1 pound each week requires a negative caloric balance of 500 calories/day. This can be achieved by decreasing the amount of calories ingested or by exercise. Reducing a person's caloric intake by 500 calories is often difficult, as is increasing metabolism by an additional 500 calories/day by exercise (accomplished by a 45 minute jog, playing tennis for an hour, or a brisk walk for 1.25 hours). The most sensible approach to weight loss is to both decrease caloric intake and increase energy expenditure through exercise.

Most individuals will begin to lose weight if they decrease their caloric intake below 1,500 calories/day and do aerobic exercise for 15–20 minutes three to four times per week. Starvation and crash diets usually result in rapid weight loss (largely muscle and water), but cause rebound weight gain. The most successful approach to weight loss is gradual weight reduction (0.5–1 pound/week) through adopting long-standing dietary and lifestyle habits that promote health and the attainment and maintenance of ideal body weight.

There are several natural weight loss aids that can be very useful in helping either to reduce appetite or to enhance metabolism. In decreasing order of efficacy, we rate these items as follows:

- 5-hydroxytryptophan
- thermogenic formulas
- fiber supplements
- chromium
- medium-chain triglycerides
- hydroxycitrate
- coenzyme Q₁₀
- thyroid hormone.

5-HTP

Over two decades ago, researchers demonstrated that administering 5-HTP to rats who were genetically bred to overeat and be obese resulted in a significant reduction in food intake.^[6] Further research revealed that these rats have decreased activity of tryptophan hydroxylase, which converts tryptophan to 5-HTP, itself subsequently converted to serotonin. In other words, these rats are fat as a result of a genetically determined low level of activity of the enzyme that starts the manufacture of serotonin from tryptophan. As a result, these rats never get the message to stop eating until they have consumed far greater amounts of food than normal rats. There is much circumstantial evidence that many humans are genetically predisposed to obesity. This predisposition may involve the same mechanism as rats genetically predisposed to obesity, i.e. decreased conversion of tryptophan to 5-HTP and, as a result, decreased serotonin levels. By providing preformed 5-HTP, this genetic defect is bypassed and more serotonin is

manufactured. (For a complete discussion of this interesting nutrient, see [Ch. 92.](#))

The early animal studies with 5-HTP as a weight loss aid have been followed by a series of three human clinical studies in overweight women.^{[18] [19] [20]} The first study showed that 5-HTP was able to reduce calorie intake and promote weight loss despite the fact that the women made no conscious effort to lose weight.^[18] The average amount of weight loss during the 5 week period of 5-HTP supplementation was a little more than 3 pounds.

The second study sought to determine if 5-HTP helped overweight individuals adhere to dietary recommendations.^[19]

1435

TABLE 175-2 -- Impact of 5-HTP on weight loss

| | Placebo | 5-HTP group |
|----------------------------|----------------|--------------------|
| Weight (pounds) | | |
| Baseline | 207.68 | 229.46 |
| After 6 weeks | 206.58 | 225.94 |
| After 12 weeks | 205.4 | 219.12 |
| Total weight loss (pounds) | | |
| After 6 weeks | 1.1 | 3.52 |
| After 12 weeks | 2.28 | 10.34 |

The 12 week study was divided into two 6 week periods. For the first 6 weeks there were no dietary recommendations, and for the second 6 weeks the women were placed on a 1,200 calorie diet. As shown in [Table 175.2](#) , the women taking the placebo lost 2.28 pounds, while the women taking the 5-HTP lost 10.34 pounds.

Like the previous study, 5-HTP appeared to promote weight loss by promoting satiety, leading to fewer calories being consumed at meals. Every women taking 5-HTP reported early satiety.

The third study with 5-HTP was similar to the second study: for the first 6 weeks there were no dietary restrictions, and for the second 6 weeks the women were placed on a diet of 1,200 calories/day.^[20] The group receiving the 5-HTP lost an average of 4.39 pounds after the first 6 weeks and an average of 11.63 pounds after 12 weeks. In comparison, the placebo group lost an average of only 0.62 pounds after the first 6 weeks and 1.87 pounds after 12 weeks. The lack of weight loss during the second 6 week period in the placebo group obviously reflects the fact that the women had

difficulty adhering to the diet.

Early satiety was reported by 100% of the subjects during the first 6 week period. During the second 6 week period, even with severe caloric restriction, 90% of the women taking 5-HTP reported early satiety. Many of the women receiving the 5-HTP (300 mg three times daily) reported mild nausea during the first 6 weeks of therapy. However, the symptom was never severe enough for any of the women to drop out of the study. No other side-effects were reported.

Thermogenic formulas

When properly combined, plant stimulants like ephedrine and caffeine can activate the sympathetic nervous system, thereby increasing the metabolic rate and diet-induced thermogenesis. This results in weight loss by helping to normalize a possible underlying defect in metabolism. These formulas must be used in a rational manner and not abused, as they are not panaceas, not for everyone, and may induce side-effects.

Although ephedrine has demonstrated an appetite-suppressing effect, its main mechanism for promoting weight loss appears to be increasing the metabolic rate of adipose tissue.^{[21] [22]} Its weight-reducing effects are greatest in those individuals with a low basal metabolic rate and/or decreased diet-induced thermogenesis.

The thermogenic effects of ephedrine can be enhanced by methylxanthines. Botanicals rich in these active ingredients can be used in a similar fashion to the isolated principles. Good methylxanthine sources include coffee (*Coffea arabica*), tea (*Camellia sinensis*), cola nut (*Cola nitida*), and guarana (*Paullinea cupana*). The optimum dosage of the crude plant preparation or extract depends on their content of active constituents. Standardized preparations may produce more dependable results.

Although more recent studies have used a daily dosage of 60 mg of ephedrine and 600 mg of caffeine, these high dosages may not be necessary.^{[21] [22] [23] [24] [25] [26]} In one study, a daily dosage of 22 mg ephedrine, 30 mg caffeine and 50 mg theophylline was shown to greatly increase the basal metabolic rate and diet-induced thermogenesis.^[27]

One of the key benefits of thermogenic formulas appears to be their ability to promote fat breakdown and not loss of lean muscle mass. For example, in one study of 16 obese women on a weight-reducing diet given either a combination of ephedrine (20 mg) and caffeine (200 mg) twice daily or a placebo, no real significant differences in overall weight loss were demonstrated.^[28] However, upon closer examination it was determined that the ephedrine-caffeine group lost 9.9 pounds more body fat and 6.16 pounds less lean body mass compared with the placebo group. These results indicate that ephedrine and caffeine combinations promote fat loss and preserve lean body mass during weight reduction diets. As an added bonus, subjects in the study taking the ephedrine-caffeine combination had higher energy levels and burned more calories than the placebo group.

Although effective, these formulations are not without side-effects. Thermogenic formulas containing ephedrine and caffeine combinations can produce increased blood

pressure, increased heart rate, insomnia, and anxiety.

The FDA advisory review panel on non-prescription drugs recommended that ephedrine should not be taken by patients with heart disease, high blood pressure, thyroid disease, diabetes, or difficulty in urination due to enlargement of the prostate. In addition, ephedrine should not be used by patients on antihypertensives or antidepressants.

There is tremendous variation in the response to ephedrine and caffeine. Some people can tolerate high levels quite easily while others (most likely with slow liver phase I detoxification – see [Ch. 16](#)) are extremely sensitive to the CNS stimulatory effects.

The side-effects reported in the studies using a daily dosage of 60 mg of ephedrine and 600 mg of caffeine tend to decrease with time, suggesting tolerance or

1436

induction of liver phase I detoxification. Although at week 4, 60% of subjects taking the ephedrine–caffeine combination typically reported side-effects such as dizziness, headache, insomnia, heart palpitations, and headache, by week 8 the rate of side-effects was substantially reduced to the same as the placebo group.

A significant concern with this dosage schedule is an elevation of blood pressure. Surprisingly, systolic and diastolic blood pressure actually decreased, indicating that the effect of weight loss more than compensated for any increase in blood pressure caused by the ephedrine and caffeine. Blood glucose, triglycerides, and cholesterol levels also decreased with weight loss and were not affected by ephedrine and caffeine.

Fiber supplements

Increasing the amount of dietary fiber promotes weight loss. The best fiber sources for weight loss are psyllium, chitin, guar gum, glucomannan, gum karaya, and pectin, because they are rich in water-soluble fibers. When taken with water before meals, these fiber sources bind to the water in the stomach to form a gelatinous mass which induces a sense of satiety. As a result, individuals will be less likely to overeat.

The benefits of fiber go well beyond this mechanical effect, however. Fiber supplements have been shown to enhance blood sugar control, decrease insulin levels, and reduce the number of calories absorbed by the body.^[29] In some of the clinical studies demonstrating weight loss, fiber supplements were shown to reduce the number of calories absorbed by 30–180 calories/day. While modest, this reduction in calories would, over the course of a year, result in a 3–18 pound weight loss.

There are two important recommendations to make to patients to assist their choice of

fiber supplements:

- avoid products that contain a lot of sugar or other sweeteners to camouflage the taste
- be sure to drink adequate amounts of water when taking any fiber supplement, especially if it is in a pill form.

The most impressive results in weight loss studies have been achieved with guar gum, a water-soluble fiber obtained from the Indian cluster bean (*Cyamopsis tetragonoloba*) (see [Table 175.3](#)). In one study, nine women weighing between 160 to 242 pounds were given 10 g of guar gum immediately before lunch and dinner. They were told not to consciously alter their eating habits. After 2 months, the women reported an average weight loss of 9.4 pounds. Reductions were also noted for cholesterol and triglyceride levels.^[30]

Studies with soluble fiber in the treatment of elevated cholesterol levels have shown a dose-dependent effect.^[29] Dietary fiber supplements appear to exert a dose-dependent effect in weight loss studies as well. Therefore, to achieve the greatest benefit, the dosage should be as high as possible.

As water-soluble fibers are fermented by intestinal bacteria, a great deal of gas can be produced, leading to increased flatulence and abdominal discomfort. Advise the patient to start out with a dosage between 1 and 2 g before meals and at bedtime and gradually increase the dosage to 5 g.

Chromium

One of the key goals for enhancing weight loss is to increase the sensitivity of the cells throughout the body to insulin. Chromium plays a key role in cellular sensitivity to insulin. Chromium has lately gained a great deal of lay attention as an aid to weight loss. The importance of this trace mineral in human nutrition was not discovered until 1957 when it was shown that it was essential to proper blood sugar control. Although there is no recommended dietary allowance (RDA) for chromium, health requires a dietary intake of at least 200 mcg/day.

TABLE 175-3 -- Clinical studies with dietary fiber supplements

| Fiber | No. of subjects | Length of study | Dosage (g/day) | Calorie restriction | Average weight loss (fiber, lbs) | Average weight loss (placebo) | Reference |
|-------|-----------------|-----------------|----------------|---------------------|----------------------------------|-------------------------------|--------------------|
| Guar | 9 | 2 months | 20 | None | 9.4 | No placebo group | 30 |

| | | | | | | | |
|---------------|----|------------|------|------|------|---------------------------|--------------------|
| Guar | 7 | 1 year | 20 | None | 61.9 | No placebo group | 31 |
| Guar | 21 | 2.5 months | 20 | None | 15.6 | No placebo group | 32 |
| Guar | 33 | 2.5 months | 15 | None | 5.5 | 0.9 lbs in placebo group | 33 |
| Glucomannan | 20 | 2 months | 3 | None | 5.5 | Weight gain of 1.5 lbs | 34 |
| Glucomannan | 20 | 2 months | 3 | None | 8.14 | 0.44 lbs in placebo group | 35 |
| Citrus Pectin | 14 | 4 weeks | 5.56 | Yes | 12.8 | No placebo group | 36 |
| Mixture A | 60 | 12 weeks | 5 | Yes | 18.7 | 14.7 lbs in placebo group | 37 |
| Mixture A | 89 | 11 weeks | 10 | Yes | 13.9 | 9.2 lbs in placebo group | 38 |
| Mixture B | 45 | 3 months | 7 | Yes | 13.6 | 9 lbs in placebo group | 39 |
| Mixture B | 97 | 3 months | 7 | Yes | 10.8 | 7.3 lbs in placebo group | 40 |
| Mixture B | 52 | 6 months | 7 | Yes | 12.1 | 6.1 lbs in placebo group | 41 |

Mixture A = 80% fiber from grains, 20% fiber from citrus; mixture B = 90% insoluble and 10% soluble fiber from beet, barley, and citrus fibers.

Chromium levels can be depleted by refined sugars, white flour products, and lack of

exercise.^[42]

In some clinical studies in diabetics, supplementing the diet with chromium has been shown to decrease fasting glucose levels, improve glucose tolerance, lower insulin levels, and decrease total cholesterol and triglyceride levels, while increasing HDL-cholesterol levels.^[43] Obviously chromium is a critical nutrient in diabetes, but it is also very important in hypoglycemia. In one study, eight female patients with hypoglycemia given 200 mcg/day for 3 months demonstrated alleviation of their symptoms.^[44] In addition, glucose tolerance test results were improved and the number of insulin receptors on red blood cells were increased.

Chromium supplementation has been demonstrated to lower body weight yet increase lean body mass, presumably as a result of increased insulin sensitivity.^[45] In one study, patients were given chromium bound to picolinic acid (chromium picolinate) in one of three doses daily for 2.5 months: placebo, 200 mcg, or 400 mcg.^[46] Patients taking the 200 and 400 mcg doses lost an average of 4.2 pounds of fat. The group taking the placebo lost only 0.4 pounds. Even more impressive was the fact that the chromium groups gained more muscle (1.4 vs. 0.2 pounds) than those taking the placebo. The results were most striking in elderly subjects and in men. The men taking chromium picolinate lost more than seven times the amount of body fat as those taking the placebo (7.7 vs. 1 pound). The 400 mcg dose is more effective than the 200 mcg dose (see [Table 175.4](#)).

The results of these preliminary studies with chromium are encouraging. Particularly interesting is the fact that in these initial studies chromium picolinate promoted an increase in lean body weight percentage, as it led to fat loss but also to muscle gain.^[47] Greater muscle mass means greater fat burning potential.

All of the effects of chromium appear to be due to increased insulin sensitivity. There is evidence that marginal chromium deficiency is quite common in the United States. Chromium supplementation will often not only improve blood sugar control, but also lower cholesterol and triglyceride levels.^[48]

There are several forms of chromium available on the market. Chromium picolinate, chromium polynicotinate, chromium chloride, and chromium-enriched yeast are each touted by their respective suppliers to provide the greatest benefit. There is no firm evidence to indicate that one is a significantly better choice than another, although there was one small study of six women and six men given either 400 mcg of chromium picolinate or chromium polynicotinate. The test subjects were enrolled in an aerobics class for 3 months. Those taking the chromium picolinate increased muscle mass by three times as much as those taking chromium polynicotinate (women: 4 vs. 1.3 pounds; men: 4.6 vs. 1.5 pounds).^[22]

Medium-chain triglycerides

Medium-chain triglycerides (MCTs) are saturated fats (extracted from coconut oil) that range in length from 6 to 12 carbon chains. MCTs are used by the body differently from the long-chain triglycerides (LCTs) which are the most abundant fats found in nature.

LCTs are the storage fats for both humans and plants that range in length from 18 to 24 carbons. This difference in length makes a substantial difference in how MCTs and LCTs are metabolized. Unlike regular fats, MCTs appear to promote weight loss rather than weight gain.

MCTs may promote weight loss by increasing thermogenesis.^[49] In contrast, the LCTs are usually stored in the fat deposits, and since their energy is conserved, a high fat diet tends to decrease the metabolic rate. In one study, the thermogenic effect of a high calorie diet containing 40% fat as MCTs was compared with one containing 40% fat as LCTs.^[50] The thermogenic effect (calories wasted 6 hours after meal) of the MCTs was almost twice as high as the LCTs – 120 vs. 66 calories. The researchers concluded that the excess energy provided by fats in the form of medium-chain triglycerides would not be efficiently stored as fat, but rather would be wasted as heat. A follow-up study demonstrated that MCT oil given over a 6 day period can increase diet-induced thermogenesis by 50%.^[50]

In another study, researchers compared single meals of 400 calories composed entirely of MCTs or LCTs.^[51] The thermic effect of MCTs over 6 hours was three times greater than that of LCTs. In addition, while the LCTs elevated blood fat levels by 68%, MCTs had no effect on the blood fat level. Researchers concluded that substituting MCTs for LCTs would produce weight loss as long as the calorie level remained the same.

In order to gain the benefit from MCTs, a diet must remain low in LCTs. MCTs can be used as an oil for salad dressing, a bread spread, or simply taken as a supplement. A good dosage recommendation for MCTs is 1–2 tablespoons/day.

TABLE 175-4 -- Effects of 200 vs. 400 mcg/day for 2.5 months

| Dosage | Fat loss | Muscle gain | Total weight loss |
|-----------------------------|-----------------|--------------------|--------------------------|
| 200 mcg chromium picolinate | -3.3 lbs | +1.5 lbs | -1.8 lbs |
| 400 mcg chromium picolinate | -4.6 lbs | +1.1 lbs | -3.5 lbs |

Diabetics and individuals with liver disease should be monitored very closely when using MCTs as they may develop ketoacidosis.

Hydroxycitrate

Hydroxycitrate is a natural substance isolated from the fruit of the Malabar tamarind (*Garcinia cambogia*). The Malabar tamarind is a yellowish fruit that is about the size of an orange, with a thin skin, and deep furrows similar to an acorn squash. It is native to southern India where it is dried and used extensively in curries. The dried fruit contains about 30% hydroxycitric acid.

Hydroxycitrate has been shown to be a powerful lipogenic inhibitor in animals.^[52] ^[53] Whether or not it demonstrates this effect in humans has not yet been proven. The weight loss-promoting effects in animals are perhaps best exemplified in a study that shows hydroxycitrate producing a “significant reduction in food intake, and body weight gain” in rats.^[54] Hydroxycitrate may not only be a powerful inhibitor of fat production; it may also suppress appetite. It is critical when using a hydroxy-citrate formula that a low-fat diet be maintained as it only inhibits the conversion of carbohydrates into fat.

By itself, hydroxycitrate may offer a safe, natural aid for weight loss when taken at a dosage of 500 mg three times daily. However, combining it with chromium and a thermogenic formula should produce a greater effect because in addition to inhibiting the production of fat, fat catabolism would increase.

Coenzyme Q¹⁰

Coenzyme Q₁₀ is an essential compound required in the transport and breakdown of fatty acids into energy. Clinical studies have shown that CoQ₁₀ may help to promote weight loss. For example, in one study CoQ₁₀ levels were found to be low in 52% (14 of 27) of overweight subjects tested.^[55] Nine subjects (five with low CoQ₁₀ levels, and four with normal levels) were given 100 mg/day of CoQ₁₀ along with a low-calorie diet. After 9 weeks, mean weight loss in the CoQ₁₀ -deficient group was 29.7 pounds, compared with 12.8 in those with initially normal levels of CoQ₁₀ .

THERAPEUTIC APPROACH

A successful program for weight loss must be consistent with the four cornerstones of good health:

- proper diet
- adequate exercise
- a positive mental attitude
- the right support for the body through natural measures.

All of these components are critical and interrelated.

Diet

Follow the recommendations given in [Chapter 44](#) .

Psychological support

Consider referral for counseling. The overweight individual tends to suffer a great deal

of assaults on their self-esteem and self-image.

Lifestyle

Exercise is absolutely critical to an effective weight loss program. Follow the recommendations given in [Chapter 38](#).

Supplements

Follow the recommendations given in [Chapter 44](#).

- 5-HTP: begin at 50–100 mg 20 minutes before meals for 2 weeks and then double the dosage (to a maximum of 300 mg) if weight loss is less than 1 pound/week. Higher dosages of 5-HTP (e.g. 300 mg) are associated with nausea, but this symptom disappears after 6 weeks of use
- Chromium: 200–400 mcg/day
- Medium-chain triglycerides: incorporate 1–2 tbsp into the diet
- Hydroxycitrate: 500 mg three times/day
- Coenzyme Q₁₀ : 100–300 mg/day.

Botanical medicines

Combinations of an ephedrine source such as *Ephedra sinica* with a methylxanthine source such as coffee (*Coffea arabica*), tea (*Camellia sinensis*), cola nut (*Cola nitida*), or guarana (*Paullinea cupana*) can be used at a dosage to provide 20–30 mg/day of ephedrine and 80–100 mg/day of methylxanthines.

Chapter 176 - Osteoarthritis

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

DIAGNOSTIC SUMMARY

- *Clinical symptoms*– mild early-morning stiffness, stiffness following periods of rest, pain that worsens on joint use, and loss of joint function
- *Clinical signs* – local tenderness, soft tissue swelling, joint crepitus, bony swelling, restricted mobility, Heberden’s (proximal interphalangeal joints) and/or the less common Bouchard’s (distal interphalangeal joints) nodes, and other signs of degenerative loss of articular cartilage
- *X-ray findings* – narrowed joint space, osteophytes, increased density of subchondral bone, subchondral sclerosis, bony cysts, soft tissue swelling, and periarticular swelling.

GENERAL CONSIDERATIONS

Osteoarthritis or degenerative joint disease is characterized by joint degeneration, loss of cartilage, and alterations of the subchondral bone. The most common form of arthritis, osteoarthritis (OA) probably has the highest morbidity rate of any illness.^[1]

Although primarily seen in the elderly, there is a 35% incidence in the knee as early as age 30 (often diagnosed as chondromalacia patellae).^[2] Its incidence increases dramatically with age. Surveys have indicated that over 40 million Americans have osteoarthritis, including 80% of persons over the age of 50. Under the age of 45, osteoarthritis is much more common in men, while after age 45 it is much more common in women.^[1] [Table 176.1](#)

TABLE 176-1 -- Diseases thought to be osteoarthritis of specific joints

| Joint | Disease |
|-------|---------------------------------|
| Hands | Heberden’s and Bouchard’s nodes |

| | |
|-------------------|--|
| Hip | Malum coxae sinilis |
| Temporomandibular | Costen's syndrome |
| Knee | Chondromalacia patellae |
| Spine | Ankylosing hyperostosis (interstitial skeletal hyperostosis) |

1442

lists some of the diseases which are now thought to be osteoarthritis of specific joints.

The weight-bearing joints and peripheral and axial articulations are the joints principally affected by the degenerative changes associated with osteoarthritis. There is much hyaline cartilage destruction followed by hardening and the formation of large bone spurs (calcified osteophytes) in the joint margins. Pain, deformity, and limitation of joint motion result from this degeneration. Inflammation is usually minimal.^[1]

Osteoarthritis is divided into two categories, primary and secondary. In primary osteoarthritis, the degenerative “wear-and-tear” process occurs after the fifth and sixth decades, with no apparent predisposing abnormalities. The cumulative effects of decades of use lead to the degenerative changes by stressing the collagen matrix of the cartilage. Damage to the cartilage results in the release of enzymes that destroy collagen components. With aging, the ability to restore and synthesize normal collagen structures decreases.^{[1] [2] [3]}

Secondary osteoarthritis is associated with some predisposing factor which is responsible for the degenerative changes. Predisposing factors in secondary osteoarthritis include:

- congenital abnormalities in joint structure or function (e.g. hypermobility and abnormally shaped joint surfaces)
- trauma (obesity, fractures along joint surfaces, surgery, etc.)
- crystal deposition
- presence of abnormal cartilage
- previous inflammatory disease of joint (rheumatoid arthritis, gout, septic arthritis, etc.).

The many factors involved in the pathogenesis of OA are summarized in [Table 176.2](#) .

DIAGNOSIS

The onset of osteoarthritis can be subtle. Morning joint stiffness is often the first symptom. As the disease progresses, there is pain on motion of the involved joint that is made worse by prolonged activity and relieved by rest. There are usually no signs of

inflammation.^[1]

TABLE 176-2 -- Multifactorial etiology of osteoarthritis

| |
|--|
| • Hypermobility/joint instability |
| • Age-related changes in collagen matrix repair mechanisms |
| • Hormonal and sex factors |
| • Altered biochemistry |
| • Genetic predisposition |
| • Inflammation |
| • Fractures and mechanical damage |
| • Inflammatory joint disease |
| • Acromegaly |
| • Others |

The specific clinical picture varies with the joint involved. Disease of the hands leads to pain and limitation of use. Knee involvement produces pain, swelling, and instability. Osteoarthritis of the hip causes local pain and a limp. Spinal osteoarthritis (which is very common) may result in compression of nerves and blood vessels, causing pain and vascular insufficiency.^[1]

The classic presentation of OA is easy to distinguish from other arthritides, especially rheumatoid arthritis which is usually associated with much more inflammation of surrounding soft tissues. After a detailed medical history and physical examination, the best diagnostic tool to confirm the diagnosis of osteoarthritis is an X-ray of the suspected joint. The classic finding in joints affected with osteoarthritis is joint space narrowing, loss of cartilage, and the presence of bone spurs (osteophytes).^[1] Important causes of misdiagnosis of osteoarthritis are given in [Table 176.3](#).

Pain

One of the most interesting clinical features of osteoarthritis is the lack of correlation between severity of osteoarthritis as determined by X-ray and the degree of pain. In some cases the joint will appear normal, with little if any joint space narrowing, yet the pain can be excruciating. Conversely, there are cases where there

TABLE 176-3 -- Important causes of misdiagnosis of osteoarthritis

| |
|--|
| <i>The source of the pain is not osteoarthritis, but:</i> |
| • Arthritis of other origin |
| • Pathological changes of the adjacent bone (tumor, osteomyelitis, metabolic bone disease, etc.) |

- Mechanical injuries
- Pathological fractures
- Referred pain of neuritis, neuropathy, or radiculopathy
- Other neurological disorders causing stiffness of joints

The source of the pain is osteoarthritis, but not at the joint suspected

- OA of the hip, pain localized to the knee
- OA of the cervical spine, causing pain in the shoulder
- OA of the lumbar spine, causing pain in the hip, knee, or ankle
- OA of the shoulder, causing pain in the elbow

The source of pain is caused by secondary soft tissue alterations of OA

- Tendonitis or ligamentitis (especially of the knee)
- Enthesopathy, tendinopathy, due to joint contracture
- Bursitis

Misinterpretation of deformity

- Pseudohypertrophic osteoarthropathy
- Psoriatic arthritis
- Flexion contracture of the joints
- Mucopolysaccharidoses
- Neurogenic arthropathies
- Calcium pyrophosphate dihydrate crystal deposition disease
- Genu varum and valgum

Misinterpretation of X-ray films

- Arthritis with previous OA changes
- Initial stage of osteoarthritis; may have normal X-ray
- Flexion contracture can cause a virtual loss of joint space width
- Neurogenic and metabolic arthropathies

TABLE 176-4 -- Potential causes of pain in osteoarthritis

- Bone

—periosteal elevation by osteophytes

—trabecular microfractures

—pressure on subchondral bone

—hypertension in bone marrow

- Articular

—synovial inflammation

—pinching of synovial villi

—joint capsule distension

- Periarticular

—ligament damage

—muscle spasm

—bursitis

- Psychological factors

—anxiety

—depression

—lack of social support

—secondary gain

- Physical demands

—occupational

—obesity

- Neuromuscular integrity

—protective reflexes

—muscle weakness

is tremendous deformity, yet very little if any pain. In fact, about 40% of individuals with the worst X-ray classification for osteoarthritis are pain-free.^[3] The exact cause of the pain in osteoarthritis is still not well-defined, but there are numerous potential causes ([Table 176.4](#)). Depression and anxiety appear to increase the experience of the pain of osteoarthritis.

THERAPEUTIC CONSIDERATIONS

Data collected from the earliest lesions to the most advanced stages of clinical OA suggest that cellular and tissue response is purposeful and is aimed at repair of the anatomic defects. The process contributing to OA appears to be arrestable, and sometimes reversible.^[2] The major therapeutic goal appears to be enhancing collagen

matrix repair and regeneration by the connective tissue cells.

Several studies have attempted to determine the “natural course” of OA.^{[2] [4]} One group of researchers studied the natural course of OA of the hip over a 10-year period. All subjects had pseudocystic changes suggestive of advanced osteoarthritis, yet the researchers reported marked clinical improvement and radiologic recovery of the joint space in 14 of 31 hips.^[4] The authors purposely applied no therapy and regarded their results as reflecting the natural course of the disease.

These results, as well as others, raise the serious concern that medical intervention may actually promote disease progression.

Aspirin and nonsteroidal anti-inflammatory drugs

The first drug generally employed in the allopathic treatment of osteoarthritis is aspirin. It is often quite effective in relieving both the pain and inflammation. It is also relatively inexpensive. However, since the therapeutic dose required is relatively high (2–4 g/day), toxicity often occurs. Tinnitus (ringing in the ears) and gastric irritation are early manifestations of toxicity.^{[1] [2]}

Other non-steroidal anti-inflammatory drugs (NSAIDs) are often used as well, especially when aspirin is ineffective or not tolerated. The following are representative of this class of drugs:

- ibuprofen (Motrin)
- fenoprofen (Nalfon)
- indomethacin (Indocin)
- naproxen (Naprosyn)
- tolmetin (Tolectin)
- sulindac (Clinoril).

These drugs are associated with such side-effects as gastrointestinal upset, headaches, and dizziness, and are therefore recommended for only short periods of time.

While these drugs provide short-term symptomatic relief, unexpected side-effects may be increasing the rate of degeneration of the joint cartilage. Experimental studies have shown that aspirin and other NSAIDs inhibit collagen matrix synthesis and accelerate cartilage destruction.^[5] Retrospective clinical studies have shown that NSAID use is associated with acceleration of osteoarthritis and increased joint destruction.^{[6] [7] [8] [9]}

Simply stated, NSAIDs appear to suppress the symptoms but accelerate the progression of osteoarthritis.

Hormonal considerations

There is a considerable amount of evidence that endocrine forces may initiate or accelerate the development of OA by altering the chondrocyte’s microenvironment.

Virtually all hormones act, directly or indirectly, on connective tissue cells: fibroblasts, osteoblasts and chondrocytes.^[2]

Estrogen

The higher prevalence of OA in women suggests that estrogens may play a role. Estradiol worsens, and tamoxifen, an anti-estrogen drug, improves experimental OA by decreasing erosive lesions. This suggests a therapeutic role for estrogen blockade. Several botanicals (e.g. *Glycyrrhiza glabra* and *Medicago sativa*) commonly used in the treatment of OA contain compounds with phytoestrogen activity capable of binding to estrogen receptors and acting as estrogen antagonists. However, although phytoestrogen-containing herbs may be of value in osteoarthritis, perhaps the best way to increase the intake of phytoestrogens is to increase the intake of food sources of phytoestrogens. Good food sources of

1444

phytoestrogens include soy, fennel, celery, parsley, nuts, whole grains, and apples.

Insulin growth hormone and somatomedin

Diabetic patients have a greater incidence and more severe form of OA than non-diabetics.^[2] Diabetes is characterized by insulin insensitivity or deficiency, increased growth hormone levels, and decreased somatomedin levels (somatomedins are insulin-like growth factors secreted by the liver in response to growth hormone).

Insulin stimulates chondrocytes to increase the synthesis and assembly of proteoglycans.^[2] As the most prominent early change seen in the articular cartilage is a decrease in both proteoglycan content and state of aggregation, insulin insensitivity or deficiency predisposes to OA.

Excessive growth hormone has detrimental effects on bone and joint structures, as demonstrated by the increased incidence of OA in acromegaly. Women with primary osteoporosis have been shown to have significantly higher basal growth hormone levels than controls.^[10] Growth hormone appears to be detrimental to chondrocytes, while somatomedins appear to mediate normal chondrocyte activity.^[2]

Impaired hepatic function, diabetes, malnutrition, and other metabolic abnormalities suppress the liver's secretion, in response to growth hormone, of somatomedin. This could lead to increased risk of developing OA.

Thyroid

Patients with hypothyroidism have been shown to have an increased risk of OA compared with age- and sex-matched population samples.^[2] Clearly, correction of

underlying endocrine imbalance or liver dysfunction is of critical importance in normalizing chondrocyte function.

Dietary considerations

Dietary therapy primarily involves the achievement of normal body weight, as excess weight means increased stress on weight-bearing joints affected with osteoarthritis.^{[11] [12]} A general healthy diet, rich in complex carbohydrates and dietary fiber, is recommended (for further discussion see [Ch. 175](#)).

Nightshade vegetables

Childers, a horticulturist, popularized a diet that treated osteoarthritis by eliminating foods from the genus Solanaceae (nightshade family). He arrived at this method after finding that this simple dietary elimination cured his own osteoarthritis.^[13] Childers developed a theory that genetically susceptible individuals might develop arthritis, and other complaints, from long-term, low-level consumption of the solanum alkaloids found in tomatoes, potatoes, eggplant, peppers, and tobacco. Presumably, these alkaloids inhibit normal collagen repair in the joints or promote inflammatory degeneration of the joint. Although as yet unproven, this diet has been of benefit to some individuals (the authors have seen osteoarthritis in several patients respond well to such a diet) and is certainly worth a try.

Antioxidant nutrients

Results from the Framingham Osteoarthritis Cohort Study indicate that a high intake of antioxidant nutrients, especially vitamin C, may reduce the risk of cartilage loss and disease progression in people with osteoarthritis.^[14] A threefold reduction in the risk of osteoarthritis progression was found in both the middle tertile and highest tertile of vitamin C intake. These results highlight the importance of a diet rich in plant-based antioxidant nutrients protecting against chronic degenerative diseases including osteoarthritis.

Nutritional supplements

Glucosamine sulfate

Glucosamine is a simple molecule composed of glucose and an amine. The main physiological function of glucosamine on joints is to stimulate the manufacture of glycosaminoglycans.^{[15] [16]} Glucosamine also promotes the incorporation of sulfur into cartilage. It appears that as some people age, they lose the ability to manufacture sufficient levels of glucosamine. The result is that cartilage loses its gel-like nature and ability to act as a shock absorber. The inability to manufacture glucosamine may be the major factor leading to osteoarthritis.

The clinical benefits of glucosamine sulfate in the treatment of osteoarthritis are impressive. In one of the more recent studies comparing glucosamine sulfate with a

placebo, 252 patients with osteoarthritis of the knee were given either a placebo or 500 mg glucosamine sulfate three times daily for 4 weeks.^[17] Glucosamine sulfate was significantly more effective than the placebo in improving pain and movement after only 4 weeks of use. Previous studies have shown that the longer glucosamine sulfate is used, the more obvious the therapeutic benefit. The rate and severity of side-effects with glucosamine did not differ from the placebo. These results are consistent with other double-blind studies versus a placebo.^{[18] [19] [20] [21] [22]}

Head-to-head double-blind studies have shown glucosamine

1445

sulfate to produce better long-term results than NSAIDs in relieving the pain and inflammation of osteoarthritis despite the fact that glucosamine sulfate exhibits very little direct anti-inflammatory effect and no direct analgesic or pain-relieving effects.^{[23] [24] [25]} While NSAIDs offer purely symptomatic relief and may actually promote the disease process, glucosamine sulfate appears to address the cause of osteoarthritis. By treating the root of the problem through the promotion of cartilage synthesis, glucosamine sulfate not only improves the symptoms, including pain, but also helps the body to repair damaged joints. The clinical effect is impressive, especially when glucosamine's safety and lack of side-effects are considered.

In one of the earlier comparative studies, glucosamine sulfate (1,500 mg/day) was compared with the common anti-inflammatory drug ibuprofen (1,200 mg/day). While pain scores decreased faster in the first 2 weeks in the ibuprofen group, by week 4 the group receiving the glucosamine sulfate improved more than the ibuprofen group.^[23] Physicians rated the overall response as good in 44% of the glucosamine sulfate-treated patients as compared with only 15% of the ibuprofen group.

Two more recent studies designed to further evaluate the comparative effectiveness of glucosamine sulfate to NSAIDs provide even better evidence. The first study consisted of 200 subjects with osteoarthritis of the knee given either glucosamine sulfate (500 mg three times daily) or ibuprofen (400 mg three times daily) for 4 weeks.^[24] Consistent with previous studies, the ibuprofen group experienced quicker pain relief. However, by the end of the second week the group taking glucosamine sulfate experienced as good results as the ibuprofen group with one major exception – while the rate of side-effects with glucosamine were mild and only affected 6% of the group, ibuprofen produced more significant side-effects much more frequently, with 35% of the group experiencing side-effects.

In the second study, 329 patients were given one of 1,500 mg glucosamine sulfate; 20 mg piroxicam; both compounds; or a placebo for 90 days.^[25] The main efficacy variable was represented by the Lequesne index, a common assessment of disease activity. The results of the study were strikingly in favor of glucosamine sulfate alone. These impressive results with glucosamine sulfate were achieved without side-effects. In fact, patients on glucosamine sulfate had fewer side-effects than the placebo and no

drop-outs.

In addition to showing benefit in double-blind studies, oral glucosamine sulfate was shown to offer significant benefit in an open trial involving 252 doctors and 1,506 patients in Portugal.^[26] The patients received 500 mg of glucosamine sulfate three times daily over a mean period of 50 days. Symptoms of pain at rest, on standing, and on exercise and limited active and passive movements improved steadily throughout the treatment period. Objective therapeutic efficacy was rated by doctors as “good” in 59% of patients, and “sufficient” in an additional 36%. Therefore, a total of 95% of patients achieved benefit from glucosamine sulfate. The results with glucosamine sulfate were rated by both doctors and patients as being significantly better than those obtained with previous treatment including NSAIDs, vitamin therapy, and cartilage extracts. Glucosamine sulfate produced good benefit in a significant portion of patients who had not responded to any other medical treatment.

In the study, obesity was associated with a significant shift from good to fair. This finding may indicate that higher dosages may be required for obese individuals or that oral glucosamine is not enough to counteract the stress of obesity on the joints. Patients with peptic ulcers and individuals taking diuretics were also associated with a shift from good to sufficient in efficacy, as well as tolerance. Individuals with current peptic ulcers should try to take glucosamine sulfate with foods. Individuals taking diuretics may need to increase the dosage to compensate for the reduced effectiveness.

The improvement with glucosamine lasted for a period of 6–12 weeks after the end of treatment. This result indicates that glucosamine may have to be taken for long periods of time or in repeated short-term courses. Given the safety and excellent tolerability of glucosamine, it is suitable for long-term use, even if continuous. (For additional discussion about the physiological effects and clinical efficacy of glucosamine sulfate, see [Ch. 89.](#))

Chondroitin sulfate

Chondroitin sulfate, as well as shark cartilage, bovine cartilage extracts, and sea cucumber, contains a mixture of intact or partially hydrolyzed GAGs of molecular weights ranging from 14,000 to over 30,000. Chondroitin sulfate is composed of repeating units of derivatives of glucosamine sulfate with attached sugar molecules. While the absorption rate of glucosamine sulfate is 90–98%, the absorption of intact chondroitin sulfate is estimated to be anywhere from 0 to 13%.^{[27] [28] [29]} The difference in absorption is largely due to the difference in size. Chondroitin sulfate is at least 50–300 times larger than glucosamine sulfate, too large to pass the normal intact intestinal barrier. If chondroitin sulfate molecules were absorbed intact or partially digested, they are still unlikely to produce any significant benefit as the chondroitin sulfate molecules are too large to be delivered to cartilage cells.

One of the key reasons why glucosamine sulfate is so effective is that its small molecular size allows it to penetrate the joint cartilage and be delivered to the chondrocyte and stimulate GAG synthesis. It would be nearly impossible for large

to produce this effect. Furthermore, chondroitin sulfate levels are typically *elevated* in the synovial tissues in patients with osteoarthritis.^[30] These absorption problems suggest that any direct effect of these compounds in osteoarthritis is highly unlikely.

Any clinical benefit from chondroitin sulfate is most likely due to the absorption of sulfur or smaller GAG molecules broken down by the digestive tract.^[23] However, even this is controversial as in one human study, 1 g of chondroitin sulfate failed to increase serum GAG concentration at all based on a highly sensitive measure of intact or depolymerized GAG absorption. These results prompted the researchers to conclude: “We suggest that chondroprotection by orally administered chondroitin sulfate is a biologically and pharmacologically unfounded theory.”^[28] In a further analysis, these experts on chondroitin sulfate further concluded:^[31]

Pooled literature on chondroitin sulfate biochemistry offers enough information to assert that neither intact, nor polymerized chondroitin sulfate is absorbed by the mammalian gastrointestinal tract. Therefore, any *direct* action of orally administered chondroitin sulfate on cartilage and chondrocytes is not possible.

The few clinical studies that have been done with orally administered chondroitin sulfate demonstrate that it is less effective than glucosamine sulfate.^{[32] [33] [34] [35]} Far more impressive results have been achieved with glucosamine sulfate. Glucosamine sulfate is faster acting and provides much greater overall benefit.

Niacinamide

In the 1940s and 1950s, Dr William Kaufman, and later Dr Abram Hoffer, reported very good clinical results in the treatment of hundreds of patients with rheumatoid arthritis and osteoarthritis using high-dose niacinamide (i.e. 900–4,000 mg/day in divided doses).^{[36] [37]} Dr Kaufman documented improvements in joint function, range of motion, increased muscle strength and endurance, and reduction in the sedimentation rate. Most patients achieved noticeable benefits within 1–3 months of use, with peak benefits noted between 1 and 3 years of continuous use.

These clinical results were recently evaluated in a well-designed double-blind, placebo-controlled trial.^[38] Seventy-two patients with osteoarthritis were randomized for treatment with niacinamide (3,000 mg daily in six divided dosages) or placebo for 12 weeks. Outcome measures included global arthritis impact and pain, joint range of motion and flexibility, erythrocyte sedimentation rate (ESR), complete blood count, liver function tests, serum cholesterol, serum uric acid, and fasting blood sugar. The researchers found that niacinamide produced a 29% improvement in global arthritis impact compared with a 10% worsening in the placebo group. Pain levels did not

change, but those on niacinamide reduced their NSAID use. Niacinamide supplementation reduced the ESR by 22% and increased joint mobility by 4.5° over controls (8° vs. 3.5°), otherwise there were no other changes in blood chemistry. Side-effects, primarily mild gastrointestinal complaints, were more common in the niacinamide group, but could be effectively managed by recommending the pills be taken with food or fluids.

Niacinamide at this high dose can result in significant side-effects (e.g. glucose intolerance and liver damage) and therefore requires strict supervision.

Methionine

S-Adenosylmethionine (SAM) is an important physiological agent formed in the body by combining the essential amino acid methionine to adenosyl-triphosphate (ATP). A deficiency of SAM in the joint tissue, just like a deficiency of glucosamine, leads to loss of the gel-like nature and shock-absorbing qualities of cartilage. SAM appears to be useful in the treatment of osteoarthritis.

SAM has been shown to be very important in the manufacture of cartilage components.^[39] In one double-blind study, supplemental SAM increased cartilage formation, as determined by magnetic resonance imaging (MRI), in 14 patients with osteoarthritis of the hands.^[40] In addition to this effect, SAM has also demonstrated some mild pain-relieving and anti-inflammatory effects in animal studies.

A total of 21,524 patients with osteoarthritis have been treated with SAM in published clinical trials. In double-blind trials, SAM has demonstrated similar reductions in pain scores and clinical symptoms to NSAIDs like ibuprofen, indomethacin, naproxen, and piroxicam.

In one double-blind study, SAM was compared with the popular drug ibuprofen (Advil, Motrin, Nuprin, etc.).^[41] The 36 subjects with osteoarthritis of the knee, hip, and/or spine received a daily oral dose of 1,200 mg of SAM or 1,200 mg of ibuprofen for 4 weeks. Morning stiffness, pain at rest, pain on motion, swelling, and limitation of motion of the affected joints were assessed before and after treatment. The total score of the individual clinical parameters improved to the same extent in patients treated with SAM or ibuprofen. In two other studies SAM was shown to produce slightly better results than ibuprofen.^[42] ^[43]

SAM has been compared with naproxen (Naprosyn) in several studies. In one double-blind study, 20 patients with osteoarthritis of the knee were given either SAM or naproxen for 6 weeks.^[44] During the first week, SAM was administered at a dose of 400 mg three times daily and afterwards at a dose of 400 mg twice daily, whereas the dose of naproxen during the first week was 250 mg three times daily and subsequently 250 mg twice daily. During the first 2 weeks, the patients were allowed to

take the drug paracetamol as an additional analgesic if the pain was severe. The patients were examined at the beginning of the study and after 2, 4, and 6 weeks. The parameters tested were: pain, joint swelling, circumference of joint, extent of motility and walking time over 10 m. At the end of the sixth week no statistically significant difference between the two patient groups treated was found; both groups exhibited a marked improvement on all parameters.

Another double-blind study compared SAM with both naproxen and placebo in the treatment of osteoarthritis of the hip, knee, spine, and hand.^[45] The study involved 33 rheumatologic and orthopedic medical centers and a total of 734 subjects. SAM administered orally at a dose of 1,200 mg daily was shown to exert the same analgesic (pain-relieving) activity as naproxen at a dose of 750 mg daily. However, SAM was significantly more effective than naproxen, both in terms of physicians' and patients' judgments and in terms of the number of patients with side-effects. In fact, SAM was better tolerated than the placebo. Ten patients in the SAM group and 13 in the placebo group withdrew from the study because of intolerance to the drug.

Other double-blind studies have shown SAM to offer the pain-relieving and anti-inflammatory benefit of drugs like indomethacin (Indocin and Indometh) and piroxicam (Feldene), but it is generally much better tolerated than these potent NSAIDs.^[46] ^[47]

Perhaps the most meaningful study of SAM in the treatment of osteoarthritis was a long-term multicenter open 2 year trial of 97 patients with osteoarthritis of the knee, hip, and spine.^[48] The patients received 600 mg of SAM for the first 2 weeks and thereafter 400 mg daily until the end of the 24th month of treatment. Separate evaluations were made for osteoarthritis of the knee, hip, cervical spine, and dorsal/lumbar spine. The severity of the clinical symptoms (morning stiffness, pain at rest, and pain on movement) was assessed using scoring before the start of the treatment, at the end of the first and second weeks of treatment, and then monthly until the end of the 24 month period. Clinical improvement was evident after the first week of treatment and continued to the end of the 24th month. Non-specific side-effects occurred in 20 patients, but in no case did therapy have to be discontinued. Most side-effects disappeared during the course of therapy. Moreover, during the last 6 months of treatment, no adverse effect was recorded. Detailed laboratory tests carried out at the start and after six, 12, 18, and 24 months of treatment showed no pathologic changes. SAM administration also helped to relieve the depression often associated with osteoarthritis.

The largest study evaluated 20,641 patients with osteoarthritis of the knee, hip, and spine and also with osteoarthritic polyarthrititis of the fingers over an 8 week period.^[49] The patients were given 400 mg three times of SAM daily for the first week, 400 mg twice daily for the second week, and 200 mg twice daily from the third week on. No additional analgesic/anti-inflammatory treatment was allowed. The efficacy of SAM was comparable to results achieved with NSAIDs. Efficacy was described as very good or good in 71% of cases, moderate in 21%, and poor in 9% of cases. The tolerance was

assessed as very good or good in 87%, moderate in 8%, and poor in 5% of cases.

All of these studies indicate that SAM appears to offer significant advantages over NSAIDs. While the drugs are associated with a significant risk of toxicity, side-effects, and actual promotion of the disease process in osteoarthritis, SAM offers similar benefits without risk or side-effect.

Superoxide dismutase

Intra-articular injections of superoxide dismutase (SOD) have demonstrated significant therapeutic effects in the treatment of OA.^[50] ^[51] Whether oral SOD preparations are absorbed orally is yet to be determined. Preliminary indications are that they probably are not.^[52]

Vitamin E

A clinical trial using 600 IU of vitamin E in patients with osteoarthritis demonstrated significant benefit.^[53] The benefit was thought to be due to vitamin E's antioxidant and membrane-stabilizing actions. In vitro studies have shown that vitamin E has an ability to inhibit the activities of lysosomal enzymes and stimulate increased deposition of proteoglycan.^[54]

Vitamin C

Deficient intake of vitamin C is common in the elderly, resulting in altered collagen synthesis and compromised connective tissue repair.^[54] Several in vitro studies have demonstrated that vitamin C has an anabolic effect on cartilage.^[55] ^[56] Research has confirmed the importance, indeed necessity, for an excess of ascorbic acid in human chondrocyte protein synthesis.^[57] One in vivo study of experimental OA in guinea pigs found that cartilage erosion was much less and the overall histologic and biochemical changes in and around the OA joint much milder in animals kept on high doses of vitamin C.^[54] Vitamins C and E appear to possess synergistic effects.^[54] The researchers concluded:

Thus, both vitamins E and C appear to enhance the stability of sulfated proteoglycans in the complex structure comprising articular cartilage. Judicious use of these vitamins in the treatment of osteoarthritis, either alone or in combination with other therapeutic means, may thus be of great benefit to the patient population by retarding the erosion of cartilage.

Pantothenic acid

Acute deficiency of pantothenic acid in the rat causes a pronounced failure of cartilage

growth and eventually produces lesions similar to osteoarthritis. Clinical improvement in OA symptomatology with the administration of 12.5 mg pantothenic acid has been reported.^[58] ^[59] Results often did not manifest until 7–14 days. However, a larger, double-blind study in patients with primarily rheumatoid arthritis displayed no significant benefit from administration of 500 mg of pantothenic acid.^[60]

Vitamins A and E, pyridoxine, zinc, copper, and boron

These nutrients are required for the synthesis of collagen and maintenance of normal cartilage structures. A deficiency of any one of these would allow accelerated joint degeneration. In addition, supplementation at appropriate levels may promote cartilage repair and synthesis. For example, boron supplementation has been used in the treatment of osteoarthritis in Germany since the mid-1970s. This use was recently evaluated in a small double-blind clinical study and an open trial. In the double-blind study, of the patients given 6 mg of boron (as sodium tetraborate decahydrate), 71% improved compared with only 10% in the placebo group.^[61] In the open trial, boron supplementation (6–9 mg daily) produced effective relief in 90% of arthritis patients including patients with osteoarthritis, juvenile arthritis and rheumatoid arthritis.^[62] The preliminary indication is that boron supplements are of value in arthritis with many people with osteoarthritis experiencing complete resolution.

Physical therapy

Various physical therapy modalities (exercise, heat, cold, diathermy, ultrasound, etc.) are often beneficial in improving joint mobility and reducing pain in OA, especially when administered regularly ([Table 176.5](#)). Much of the benefit of physical therapy is thought to be a result of achieving proper hydration within the joint capsule.

Clinical and experimental studies seem to indicate that

TABLE 176-5 -- Non-pharmacological approaches to pain in osteoarthritis

| • Weight loss |

short-wave diathermy may be of the greatest benefit.^[63] ^[64] ^[65] Combining short-wave diathermy therapy with periodic ice massage, rest, and appropriate exercises appears to be the most effective approach. Ultrasound and laser therapy have also been shown to be helpful.^[66] ^[67]

The best exercises are isometrics and swimming. These types of exercises increase circulation to the joint and strengthen surrounding muscles without placing excess strain on joints. Increasing quadriceps strength has been shown to improve the clinical features and reduce pain in osteoarthritis of the knee.^[68] Walking programs help to improve functional status and relieve pain in patients with osteoarthritis of the knee.^[69]

Botanical medicines

Many herbs have historically been used in the treatment of osteoarthritis. When inflammation is present, those botanicals and nutritional factors possessing anti-inflammatory activity are indicated. Examples include bromelain, curcumin, and ginger.

Yucca

A double-blind clinical trial found that a saponin extract of yucca demonstrated a positive therapeutic effect.^[70] Results were of gradual onset and no direct joint effects of the yucca saponin were noted. The researchers suggested that the clinical improvement was due to indirect effects on the gastrointestinal flora. This is an interesting suggestion, since bacterial lipopolysaccharides (endotoxins) have been shown to depress the biosynthesis of proteoglycans.^[71] It is entirely possible that yucca decreases bacterial endotoxin absorption and thus reduces this inhibition of proteoglycan synthesis. If this is the mechanism of action, then other saponin-containing herbs, and other ways of reducing endotoxin load, may be useful.

Harpagophytum procumbens (Devil's claw)

Several pharmacological studies utilizing experimental animal models of inflammation have reported that Devil's claw possesses an anti-inflammatory and analgesic effect comparable to phenylbutazone.^[72] However, other studies have indicated that Devil's claw has little, if any, anti-inflammatory activity in experimental inflammation.^[73] ^[74]

The equivocal research results may reflect a mechanism of action that is inconsistent with current anti-inflammatory models or a lack of quality control (standardization) of the preparations used. Since the main components of Devil's claw are saponins, its therapeutic effect in OA may be similar to that observed for yucca.

Boswellia serrata

Another herb historically used in the treatment of osteo-arthritis is *Boswellia serrata*, a large branching tree native to India. *Boswellia* yields an exudative gum resin known as salai guggul. Although salai guggul has been used for centuries, newer preparations concentrated for the active components (boswellic acids) are giving better results.

Boswellic acid extracts have demonstrated anti-arthritic effects in a variety of animal models. There are several mechanisms of action including inhibition of inflammatory mediators, prevention of decreased glycosaminoglycan synthesis, and improved blood supply to joint tissues.^[75] ^[76] Clinical studies using herbal formulas with *Boswellia* have yielded good results in both osteoarthritis and rheumatoid arthritis.^[77] The standard dosage for boswellic acids in arthritis is 400 mg three times daily. No side-effects due to boswellic acids have been reported.

THERAPEUTIC APPROACH

Although there appear to be several worthwhile approaches to control of OA through natural therapies, a direct clinical study of a comprehensive, integrated program has yet to be conducted. The therapeutic approach recommended here is based on reducing joint stress and trauma, promoting collagen repair mechanisms, and eliminating foods and other factors which may inhibit normal collagen repair. All diseases or predisposing factors (see [Table 176.1](#)) should, of course, be controlled. Non-steroidal anti-inflammatory drugs, such as aspirin, should be avoided as much as possible. If aspirin must be used, deglycyrrhizinated *Glycyrrhiza glabra* (or Robert's formula) should be used to help protect the gastrointestinal tract from its damaging effects and its use should be discontinued as soon as possible.

Diet

All simple, processed, and concentrated carbohydrates must be avoided; complex-carbohydrate, high-fiber foods should be emphasized; and fats should be kept to a minimum. Plants of the Solanaceae family should be eliminated (tomatoes, potatoes, eggplant, peppers, and tobacco). Liberal consumption of flavonoid-rich berries or extracts is also important.

Supplements

- Glucosamine sulfate: 1,500 mg/day
- Niacinamide: 500 mg six times/day (under strict supervision – liver enzyme must be regularly assayed)
- Vitamin E: 600 IU/day
- Vitamin A: 5,000 IU/day
- Vitamin C: 1,000–3,000 mg/day
- Vitamin B₆ : 50 mg/day
- Pantothenic acid: 12.5 mg/day

- SAM: 400 mg three times/day
- Zinc: 45 mg/day
- Copper: 1 mg/day
- Boron: 6 mg/day.

Botanical medicines

- *Medicago sativa*: equivalent to 5–10 g/day
- *Yucca* leaves: 2–4 g three times/day
- *Harpagophytum procumbens*
 - dried powdered root – 1–2 g three times/day
 - tincture (1:5) – 4–5 ml three times/day
 - dry solid extract (3:1) – 400 mg three times/day
- *Boswellia serrata*: equivalent to 400 mg boswellic acids three times/day.

Physical therapy and exercise

Physical activity that induces physiologic or traumatic strain, such as occupational or recreational overuse of a joint, must be avoided. Normalization of posture and orthopedic correction of structural abnormalities should be utilized to limit joint strain. Daily non-traumatic exercise (isometrics and swimming) is important, but should be carefully monitored. Short-wave diathermy, hydrotherapy, and other PT modalities which improve joint perfusion are indicated.

Chapter 177 - Osteoporosis

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

DIAGNOSTIC SUMMARY

- Usually asymptomatic until severe backache
- Most common in postmenopausal white women
- Spontaneous fractures of the hip and vertebra
- Decrease in height
- Demineralization of spine and pelvis as confirmed by X-ray techniques.

GENERAL CONSIDERATIONS

Osteoporosis literally means porous bone. Normally there is a decline in bone mass after the age of 40 in both sexes (about 2% loss/year), but women are at a much greater risk for osteoporosis because of lower bone density prior to the age of 40. Many factors can result in excessive bone loss and different variants of osteoporosis exist, but postmenopausal osteoporosis is the most common form of osteoporosis. Approximately one in four postmenopausal women has osteoporosis (see [Table 177.1](#) for other major risk factors in women).^[1] Osteoporosis affects more than 20 million people in the United States.

Although the entire skeleton may be involved in postmenopausal osteoporosis, bone loss is usually greatest

TABLE 177-1 -- Major risk factors for osteoporosis in women

- | |
|---------------------------|
| • Postmenopausal |
| • White or Asian |
| • Premature menopause |
| • Positive family history |

- Short stature and small bones

- Leanness

- Low calcium intake

- Inactivity

- Nulliparity

- Gastric or small-bowel resection

- Long-term glucocorticosteroid therapy

- Long-term use of anticonvulsants

- Hyperparathyroidism

- Hyperthyroidism

- Smoking

- Heavy alcohol use

1454

in the spine, hips, and ribs. Since these bones bear a great deal of weight, they are then susceptible to pain, deformity or fracture. At least 1.5 million fractures occur each year as a direct result of osteoporosis, including 250,000 hip fractures, the most catastrophic of fractures. Hip fracture is fatal in 12–20% of cases and precipitates long-term nursing home care for half of those who survive. Nearly one-third of all women and one-sixth of all men will fracture their hips in their lifetime.^[2]

Etiology

Osteoporosis involves both the mineral (inorganic) and the non-mineral (organic matrix composed primarily of protein) components of bone. This basic physiology clearly indicates that there is more to osteoporosis than simply a lack of dietary calcium. In fact, lack of dietary calcium in the adult results in a separate condition known as osteomalacia or “softening of the bone”. The two conditions, osteomalacia and osteoporosis, are different in that in osteomalacia there is only a deficiency of calcium in the bone. In contrast, in osteoporosis there is a lack of both calcium and other minerals as well as a decrease in the non-mineral framework (organic matrix) of bone. Little attention has been given to the important role that this organic matrix plays in maintaining bone structure.

Bone is dynamic living tissue that is constantly being broken down and rebuilt, even in adults. Normal bone metabolism is dependent on an intricate interplay of many nutritional and hormonal factors, with the liver and kidney having a regulatory effect as well. Although over two dozen nutrients are necessary for optimal bone health, it is generally thought that calcium and vitamin D are the most important nutritional factors.

However, hormones are also critical, as the incorporation of calcium into bone is dependent upon the estrogen.

Gastric acid

The absorption of calcium is dependent on becoming ionized in the intestines. The poor ionization of calcium has been the major problem with calcium carbonate, which is the most widely utilized form of calcium for nutritional supplementation. In order for calcium carbonate to be absorbed, it must first be solubilized and ionized by stomach acid.

In studies with postmenopausal women, it has been shown that about 40% are severely deficient in stomach acid.^[3] It has been shown that patients with insufficient stomach acid output can only absorb about 4% of an oral dose of calcium as calcium carbonate, while a person with normal stomach acid can typically absorb about 22%.^[3] Patients with low stomach acid secretion need a form of calcium that is already in a soluble and ionized state, such as calcium citrate, calcium lactate, or calcium gluconate. About 45% of the calcium is absorbed from calcium citrate in patients with reduced stomach acid compared with 4% absorption for calcium carbonate.^[4]

This difference in absorption clearly demonstrates that ionized soluble calcium is much more beneficial than insoluble calcium salts like calcium carbonate in patients with reduced stomach acid secretion. It has also been demonstrated that calcium is more bioavailable from calcium citrate than from calcium carbonate in normal subjects.^[5]

Vitamin D

It is well known that vitamin D stimulates the absorption of calcium. Since vitamin D can be synthesized by the action of sunlight on 7-dehydrocholesterol in the skin, many experts consider it more of a hormone than a vitamin. The sunlight changes the 7-dehydrocholesterol into vitamin D₃ (cholecalciferol). It is then transported to the liver and converted into 25-hydroxycholecalciferol (25-(OH)D₃) which is five times more potent than cholecalciferol (D₃). The 25-hydroxycholecalciferol is then converted by the kidneys to 1,25-dihydroxycholecalciferol (1,25-(OH)₂D₃), which is 10 times more potent than cholecalciferol and the most potent form of vitamin D₃ (see [Table 177.2](#)).

Disorders of the liver or kidneys result in impaired conversion of cholecalciferol to more potent vitamin D compounds. Many patients with osteoporosis have a high level of 25-OH-D₃ but quite a low level of 1,25-(OH)₂D₃. This signifies an impairment of the conversion of 25-(OH)D₃ to 1,25-(OH)₂D₃ within the kidneys in people with osteoporosis.^[6] ^[7] Many theories have been proposed to account for this decreased conversion, including relationships to estrogen and magnesium deficiency. Recently, the trace mineral boron has been theorized to play a role in this conversion. All of these theories are discussed below.

Hormonal factors

The concentration of calcium in the blood is strictly maintained within very narrow limits. If levels start to decrease, there is an increase in the secretion of parathyroid

TABLE 177-2 -- Relative activities of vitamin D forms

| Form | Relative activity |
|---------------------------------------|-------------------|
| Vitamin D ₃ | 1 |
| Vitamin D ₂ | 1 |
| 25-(OH)D ₃ | 2–5 |
| 25-(OH)D ₂ | 2–5 |
| 1,25-(OH) ₂ D ₃ | 10 |
| 1,25-(OH) ₂ D ₂ | 10 |

1455

hormone by the parathyroid glands and a decrease in the secretion of calcitonin by the thyroid and parathyroids. If calcium levels in the blood start to increase, there is a decrease in the secretion of parathyroid hormone and an increase in the secretion of calcitonin. An understanding of how these hormones increase (parathyroid hormone) and decrease (calcitonin) serum calcium levels is necessary in understanding osteoporosis.

Parathyroid hormone increases serum calcium levels primarily by increasing the activity of the osteoclast catabolism of bone, although it also decreases the excretion of calcium by the kidneys and increases the absorption of calcium in the intestines. In the kidneys, parathyroid hormone increases the conversion of 25-(OH)D₃ to 1,25-(OH)₂ D₃.

One of the theories relating bone loss to estrogen deficiency is that an estrogen deficiency makes the osteoclasts more sensitive to parathyroid hormone, resulting in increased bone breakdown and thereby raising blood calcium levels. This elevation in blood calcium leads to a decreased parathyroid hormone level that results in diminished levels of active vitamin D and increased calcium excretion as well. This theory appears to best explain the hormonal effects in osteoporosis.

DIAGNOSTIC CONSIDERATIONS

Osteoporosis is best diagnosed by bone densitometry. There are several different techniques, but the one with the greatest support and popularity is dual energy X-ray

absorptiometry (DEXA).^[9] There are other methods (some of which are promising because they indicate not only bone density but also bone quality and structure, such as some of the computerized tomography [CT] scans), but DEXA is currently considered the gold standard. In addition to providing the most reliable measurement of bone density, the DEXA test requires less radiation exposure than other X-ray procedures for measuring bone density. Usually the DEXA examination measures both the hip and the lumbar spine densities. We recommend that women of high risk get a baseline bone density measurement and then monitor the rate of bone loss by urine tests that measure breakdown products of bone such as cross-linked N-telopeptide of type I collagen or deoxypyridium.

These tests of bone resorption can be used to monitor the rate of bone loss and success (or failure) of therapy. They provide quicker feedback compared to DEXA which can take up to 2 years to detect a therapeutic response. The DEXA test is best used to measure bone density, while urinary bone resorption assessments can be used to measure the rate of bone loss. Reducing urinary levels of these markers of bone breakdown over a 2-year period has produced increases in bone density measurements.^[9]

THERAPEUTIC CONSIDERATIONS

Recently, there has been considerable public advocacy of an increase in dietary calcium to prevent osteoporosis. While this appears to be sound medical advice for many, osteoporosis is much more than simply a lack of dietary calcium. It is a complex condition involving hormonal, lifestyle, nutritional, and environmental factors. A comprehensive plan that addresses these factors offers the greatest protection against developing osteoporosis.

The primary goals in the treatment and prevention of osteoporosis are:

- to preserve adequate mineral mass
- to prevent loss of the protein matrix and other structural components of bone
- to assure optimal repair mechanisms to remodel damaged areas of bone.

Hormone replacement therapy

One of the most publicized effects of hormone replacement therapy (combination of estrogen and progesterone) in menopause is its role in maintaining bone health and preventing osteoporosis. The research clearly demonstrates that the benefits of hormonal therapy significantly outweigh its risks in women who are susceptible to osteoporosis and women who have already experienced significant bone loss.

Since both estrogen and progesterone exert beneficial effects against bone loss and, in women with established bone loss, actually increase bone mass, estrogen–progesterone combinations are preferred to estrogen alone. The exception is in women at high risk for breast cancer or women with a disease aggravated by estrogen, including breast cancer, active liver diseases, and certain cardiovascular diseases, in

which case progesterone alone should be used.

Lifestyle factors

Certain lifestyle factors significantly impact bone health. For example, coffee, alcohol, and smoking cause a negative calcium balance and are associated with an increased risk of developing osteoporosis, while regular exercise reduces the risk.^{[10] [11]} In fact, as important as hormonal and dietary factors are, exercise is more critical for maintaining healthy bones.

Numerous studies have demonstrated that physical fitness is the major determinant of bone density. Physical exercise consisting of 1 hour of moderate activity three times a week has been shown to prevent bone loss and actually increase bone mass in postmenopausal women.^{[11] [12] [13] [14] [15] [16]} In contrast to exercise, immobilization doubles the rate of urinary and fecal calcium excretion, resulting in a significant negative calcium balance.^[17]

1456

Although nutritional factors are important, the most effective practice for strengthening bones is physical activity.

General dietary factors

Many dietary factors have been suggested as a cause of osteoporosis, a few of which are:^{[18] [19]}

- low calcium-high phosphorus intake
- high protein diet
- high acid-ash diet
- high salt intake
- trace mineral deficiencies, to name a few.

A vegetarian diet (both lacto-ovo and vegan) is associated with a lower risk of osteoporosis.^{[20] [21]} Although bone mass in vegetarians does not differ significantly from omnivores in the third, fourth, and fifth decades, there are significant differences in the later decades. These findings indicate that the decreased incidence of osteoporosis in vegetarians is not due to increased initial bone mass, but rather to decreased bone loss.

Several factors are probably responsible for the decrease in bone loss observed in vegetarians. The most important of these is probably a lowered intake of protein. A high-protein diet or a diet high in phosphates is associated with increased excretion of calcium in the urine. Raising daily protein from 47 to 142g doubles the excretion of calcium in the urine.^[22] A diet this high in protein is common in the United States and may be a significant factor in the increased number of people suffering from

osteoporosis in this country.^[23]

Another dietary factor which increases the loss of calcium from the body is refined sugar. Following sugar intake, there is an increase in the urinary excretion of calcium.^[24] Considering that the average American consumes, in 1 day, 125 g of sucrose, 50 g of corn syrup plus other refined simple sugars, and a glass of a carbonated beverage loaded with phosphates, along with the high amount of protein, it is little wonder that there are so many suffering from osteoporosis in this country.

Soft drinks

Soft drink consumption may be a major factor for osteoporosis as they are high in phosphates but contain virtually no calcium. This leads to lower calcium levels and higher phosphate levels in the blood. The United States ranks first among countries for soft drink consumption with a per capita consumption of approximately 15 ounces/day.

The link between soft drink consumption and bone loss is going to be even more significant as children practically weaned on soft drinks reach adulthood. Soft drink consumption in children poses a significant risk factor for impaired calcification of growing bones. Since there is such a strong correlation between maximum bone mineral density and the risk of osteoporosis, the rate of osteoporosis may reach even greater epidemic proportions.

The severe negative impact that soft drinks exert on bone formation in children was clearly demonstrated in a study that compared 57 children, aged 18 months to 14 years, with low blood calcium to 171 matched controls of children with normal calcium levels.^[25] The goal of the study was to assess whether the intake of at least 1.5 quarts/week of soft drinks containing phosphates is a risk for the development of low blood calcium levels. Of the 57 children with low blood calcium levels, 38 (66.7%) drank more than four bottles (12–16 ounces) per week, but only 48 (28%) of the 171 children with normal serum calcium levels drank as many soft drinks. For all 228 children, a significant inverse correlation between serum calcium level and the number of bottles of soft drink consumed each week was found.^[26]

Green leafy vegetables

Consumption of green leafy vegetables (kale, collard greens, parsley, lettuce, etc.) offers significant protection against osteoporosis. These foods are a rich source of a broad range of vitamins and minerals important to maintaining healthy bones, including calcium, vitamin K₁, and boron.

Vitamin K₁ is the form of vitamin K that is found in plants. A function of vitamin K₁ that is often overlooked is its role in converting inactive osteocalcin to its active form. Osteocalcin, the major non-collagen protein in bone, anchors calcium molecules into the protein matrix.^[27]

A deficiency of vitamin K leads to impaired mineralization of bone due to inadequate

osteocalcin levels. Very low blood levels of vitamin K₁ have been found in patients with fractures due to osteoporosis.^[28] The severity of fracture strongly correlated with the level of circulating vitamin K. Other studies have shown that the lower the level of circulating vitamin K, the lower the bone density.^[29] This evidence clearly indicates the importance of vitamin K₁. The richest sources of vitamin K₁ are dark green leafy vegetables, broccoli, lettuce, cabbage, spinach, and green tea. Good sources are asparagus, oats, whole wheat, and fresh green peas.

In addition to vitamin K₁, the high levels of many minerals like calcium and boron in green leafy vegetables may also be responsible for this protective effect. Boron is a trace mineral gaining recent attention as a protective factor against osteoporosis (see [Ch. 68](#)).^[30] Supplementing the diet of postmenopausal women with 3 mg/day of boron reduced urinary calcium excretion by 44% and dramatically increased the levels of 17-beta-estradiol,

1457

the most biologically active estrogen. It appears boron is required to activate certain hormones, including estrogen and vitamin D. Boron is also apparently required for the conversion of vitamin D to its most active form (1,25-(OH)₂ D₃) within the kidney. A boron deficiency may contribute greatly to osteoporosis as well as menopausal symptoms.

As fruits and vegetables are the main dietary sources of boron, diets low in these foods may be deficient in boron. Typically, the standard American diet is severely deficient in these foods. According to several large surveys, including the US Second National Health and Nutrition Examination, fewer than 10% of Americans met the minimum recommendation of two fruit servings and three vegetable servings per day, and only 51% ate one serving of vegetables per day.^[31]

In order to guarantee adequate boron levels, supplementing the diet with a daily dose of 3–5 mg of boron is indicated. Boron has been shown to mimic some of the effects of estrogen therapy in postmenopausal women.^[32]

Nutritional supplements

As stated several times previously, but worth repeating, osteoporosis involves much more than calcium. Bone is dependent on a constant supply of many nutrients. A deficiency of any one of these nutrients will adversely affect bone health. In addition to vitamin K and boron (discussed above), there are other key nutrients critical to bone health, which are discussed below.

Calcium

Supplementation of calcium has been shown to be effective in reducing bone loss in

postmenopausal women.^[33] ^[34] ^[35] ^[36] ^[37] ^[38] ^[39] Although, by itself, calcium supplementation does not completely halt calcium loss, it does slow the rate down by at least 30–50% and offers significant protection against hip fractures. Combined with exercise and the dietary recommendations given above, calcium is clearly part of an effective treatment for most women. While menopausal and postmenopausal women are often told that without hormone replacement therapy they will most definitely get osteoporosis, several studies provide strong evidence of the inaccuracy of this commonly held view.

In one study, 118 healthy white women who had experienced the onset of menopause 3–6 years previously were randomly allocated to receive either 1,700 mg of calcium as calcium carbonate, a placebo, or Premarin with 1,700 mg of calcium.^[38] The nearly 3-year-long study indicated that calcium supplementation alone significantly prevented bone loss. Using a more absorbable form of calcium like calcium citrate or calcium bound to other Krebs cycle intermediates may have provided greater benefit compared with calcium carbonate due to enhanced absorption (discussed below). Although calcium alone was less effective than the Premarin– calcium combination, because calcium supplementation carries with it no significant health risks this study reinforces the opinion that hormone replacement therapy should definitely be reserved for women at significant risk for osteoporosis.

In another study, 86 postmenopausal women received, for 4 years, either 1 g of elemental calcium from an effervescent form containing 5.24 g calcium-lactate-gluconate and 0.8 g calcium carbonate or a placebo of an identical effervescent tablet containing no calcium.^[39] Clinical status, calcium intake, physical activity, and bone mineral density were assessed at baseline and every 6 months. The study found that continued calcium supplementation produces a sustained reduction in the rate of loss of total bone mineral density in healthy postmenopausal women. As a result, the incidence of bone fractures was far lower in the group taking calcium (two out of 38) compared with the placebo (nine out of 40).

And finally, in another 4 year study, the long-term effect of calcium supplementation on bone density was determined in 84 elderly women (54–74 years) more than 10 years past the menopause.^[35] A placebo group who did not take calcium supplements at all during the 4 year study served as a comparison. Changes in bone density at the lumbar spine, hip, and ankle sites, current calcium intake and activity were monitored. Over the 4 years, the calcium supplement group (average calcium intake of nearly 2,000 mg/day) did not lose bone at the hip and ankle sites. The control group (average calcium intake, 950 mg/day) lost significantly more bone than the calcium supplement group at all sites of the hip and ankle. No overall bone loss was seen at the spine, in either group, over the 4 years of this study.

There is a strong correlation between premenopausal bone density and the risk of osteoporosis. That being the case, building strong bones should be a lifelong goal, beginning in childhood. However, most women probably are not concerned about osteoporosis until a few years before menopause. Fortunately, calcium supplementation does improve bone density in perimenopausal women.

In a 2 year study, 214 perimenopausal women received either 1,000 or 2,000 mg of calcium provided in an effervescent mixture as described above.^[40] While the control group actually lost 3.2% of the bone density of their spine, the calcium-treated groups increased their density by 1.6% (there was no difference between the two calcium groups). These results highlight the importance of calcium supplementation prior to menopause in the battle against osteoporosis.

The best form of calcium is certainly neither oyster shell nor bone meal. Studies have indicated that these

calcium supplements may contain substantial amounts of lead.^[41] (For a discussion of the toxic effects of lead in children and adults, see [Chs 18](#) , [37](#) , and [135](#) .)

In 1981, the FDA cautioned the public to limit their intake of calcium s derived from either dolomite or bone meal because of the potentially high lead levels in these calcium supplements. More recent studies have shown that other calcium sources such as carbonate (from oyster shells) and various chelates may also contain high amounts of lead.^[41] One study measured the lead level in 70 brands of calcium supplements and found some forms and brands to have high levels.^[41] The 70 products were divided into five categories:

- refined calcium carbonate produced in a laboratory ($n = 17$)
- unrefined calcium carbonate derived from limestone or oyster shells ($n = 25$)
- calcium bound to various organic chelates such as citrate, gluconate, lactate, etc. ($n = 13$)
- dolomite ($n = 9$)
- bone meal ($n = 6$).

The results (lead content in mcg/800 mg calcium) are listed in [Table 177.3](#) .

None of the products tested in the dolomite and bone meal groups, and only two out of 25 in the unrefined calcium carbonate group, had lead levels below the recommended level of 1 mcg/800 mg of calcium. The group that displayed the greatest range of lead content was the unrefined calcium carbonate group (the source was oyster shells) – while two products contained very little lead, most contained higher levels, and one product contained 25 mcg of lead per 800 mg of calcium, a cause for great concern.

As the total tolerable daily intake of lead for children aged 6 years and under is less than 6 mcg/day, young children should utilize refined calcium carbonate or chelated calcium products as calcium sources for supplementation. Since chelated calcium, especially calcium citrate, is better absorbed than calcium carbonate, the best recommendation for calcium supplementation are products which feature calcium bound to citrate, gluconate, or some other organic molecule. This recommendation is appropriate for

older children and adults as well.

Natural oyster shell calcium, dolomite, and bone meal

TABLE 177-3 -- Lead content of calcium supplements

| Supplement | Lead content |
|-----------------------------|---------------------|
| Refined calcium carbonate | 0.92 |
| Calcium chelate | 1.64 |
| Dolomite | 4.17 |
| Unrefined calcium carbonate | 6.05 |
| Bone meal | 11.33 |

products should be avoided unless the manufacturer can provide reasonable assurance that lead levels are below acceptable levels. Refined calcium carbonate has the lowest lead content, but calcium chelates are better absorbed, especially in women with low gastric acid output.

Calcium bound to citrate and other Krebs cycle intermediates such as fumarate, malate, succinate, and aspartate is probably the best form. The Krebs cycle intermediates fulfill every requirement for an optimum calcium chelating agent:

- they are easily ionized
- they are almost completely degraded
- they have virtually no toxicity
- they have been shown to increase the absorption of not only calcium, but other minerals as well.

One popular calcium supplement is calcium hydroxyapatite – basically a purified bone meal. It is interesting to note that among calcium supplements tested for absorption, this form tested at 20% absorption compared with 30% for either calcium carbonate or calcium citrate.^[42]

Vitamin D

In addition to studies that utilized calcium supplementation alone, there have been several studies that used calcium in combination with vitamin D (usually vitamin D₃) as well as vitamin D alone. One study using vitamin D₃ alone found that supplementation with 700 IU/day will reduce the annual rate of hip fracture from 1.3 to 0.5% – nearly a 60% reduction.^[43] In another study, 348 women aged 70 and older received either 400 IU/day of vitamin D₃ or a placebo for 2 years.^[44] Bone density at the hip (femoral neck) increased by 1.9% in the left hip and 2.6% in the right hip in the vitamin D-treated group. In comparison, the placebo group demonstrated decreases of 0.3% in the left hip and 1.4% in the right hip. Studies that combined vitamin D with calcium produced slightly better results. For example, in one study of 3,270 elderly women living in nursing

homes, the hip fracture rate in those receiving 1,200 mg/day of calcium and 800 IU/day of vitamin D₃ was reduced by 43% compared with the placebo group. [45]

In another study, the effects of 3 years of dietary supplementation with calcium and vitamin D₃ on bone mineral density and the incidence of hip fractures in 176 men and 213 women aged 65 years or older who were living at home was evaluated. [46] The participants received either 500 mg/day of calcium plus 700 IU/day of vitamin D₃ (cholecalciferol) or placebo. Bone mineral density was measured by DEXA, and cases of hip fracture were ascertained by means of interviews and verified using hospital records. The average changes in bone mineral density in the calcium–vitamin D group were

1459

+0.5% for the hip, +2.12% for the spine, and +0.06% for the whole body. In contrast, the values for the placebo group were -0.70, +1.22, and -1.09%, respectively. Of 37 subjects who had hip fractures, 26 were in the placebo group and 11 were in the calcium–vitamin D group.

These studies imply that vitamin D can be helpful, especially in elderly people living in nursing homes, people living further away from the equator, and those who do not regularly get outside. We recommend a dosage of 400 IU/day of vitamin D₃ rather than higher dosages, as the level of active vitamin D does not differ substantially from 400–800 IU. Taking higher dosages offers no significant benefit and may adversely affect magnesium levels.

Magnesium

Magnesium supplementation may turn out to be as important as calcium supplementation in the prevention and treatment of osteoporosis. Women with osteoporosis have lower bone magnesium content and other indicators of magnesium deficiency than people without osteoporosis. [47] [48] In human magnesium deficiency, there is a decrease in the serum concentration of the most active form of vitamin D (1,25-(OH)₂ D₃) which has been observed in osteoporosis. [49] This finding could be due either to the enzyme responsible for the conversion of 25-(OH)D₃ to 1,25-(OH)₂ D₃ being dependent on adequate magnesium levels, or to magnesium's ability to mediate parathyroid hormone and calcitonin secretion.

The benefits of magnesium supplementation were investigated in a small 2 year trial in 31 postmenopausal women. [50] The women received an initial dosage of either 250 mg of magnesium (as magnesium hydroxide) or a placebo. Dosages were increased to a maximum of 750 mg for the first 6 months followed by a maintenance dosage of 250 mg for the remaining 18 months of the trial. After 1 year, the women in the magnesium-treated group showed a slight improvement in the bone density. In contrast, the placebo group showed a slight decrease in bone density. Hopefully there will be

follow-up studies to this preliminary study to better assess the benefits of magnesium in osteoporosis.

Vitamin B₆, folic acid, and vitamin B₁₂

Low levels of these nutrients are quite common in the elderly population and may contribute to osteoporosis. These vitamins are important in the conversion of the amino acid methionine to cysteine. If deficient in these vitamins or if a defect exists in the enzymes responsible for this conversion, there will be an increase in homocysteine. This compound has been implicated in a variety of conditions, including atherosclerosis and osteoporosis (see [Ch. 52](#) for a complete discussion).

Increased homocysteine concentrations in the blood have been demonstrated in postmenopausal women and are thought to play a role in osteoporosis by interfering with collagen cross-linking leading to a defective bone matrix. Since osteoporosis is known to be a loss of both the organic and inorganic phases of bone, the homocysteine theory has much validity as it is one of the few theories that addresses both factors.

Folic acid supplementation has been shown to reduce homocysteine levels in postmenopausal women even though none of the women were deficient in folic acid according to standard folic acid laboratory criteria.^[51] Vitamins B₆ and B₁₂ are also necessary in the metabolism of homocysteine. Combinations of these vitamins will produce better results than either one of them alone.^[52]

Silicon

Silicon is necessary for cross-linking collagen strands, thereby contributing greatly to the strength and integrity of the connective tissue matrix of bone.^[53] Since silicon concentrations are increased at calcification sites in growing bone, recalcification in bone remodeling may be dependent on adequate levels of silicon. It is not known whether the typical American diet provides adequate amounts of silicon. In patients with osteoporosis or where accelerated bone regeneration is desired, silicon requirements may be increased and therefore supplementation may be indicated.

Fluoride

Fluoride administration is a popular therapy in many parts of the world, but its validity is still in question. Early studies showed that fluoride is largely ineffective.^[54] Fluoride's predominant effects are stimulation of osteoblastic activity and positive calcium balance. Fluoride is incorporated into the crystalline structure of bone as fluoroapatite, but the bone matrix is poorly formed and weak, and long-term excessive exposure typically results in more fragile bones.

The therapeutic index for fluoride is quite narrow, and at the recommended daily dose of 60–75 mg, sodium fluoride causes side-effects in 33–50% of patients. Joint pain is the most common, but stomach aches, nausea, and vomiting also occur, although they are

less troublesome if the fluoride is taken with meals.

Newer sodium fluoride preparations, i.e. enteric-coated and timed-release to prevent digestion in the stomach, are showing better results in terms of both fewer side-effects and better clinical results.^[55] However, at this time we do not recommend fluoride supplementation in the treatment of osteoporosis.

Phytoestrogens

Plant estrogenic substances or “phytoestrogens” are components of many medicinal herbs with a historical use in conditions which are now treated with synthetic estrogens. They may be suitable alternatives to estrogens in the prevention of osteoporosis in menopausal women (see [Ch. 170](#) for further description).

A semi-synthetic isoflavonoid similar in structure to soy isoflavonoids has been approved in Japan, Hungary, and Italy for the treatment and prevention of osteoporosis.^[56] The compound, ipriflavone, has shown impressive results in a number of clinical studies. For example, in one study, ipriflavone (200 mg three times daily) increased bone density measurements by 2 and 5.8% after 6 and 12 months, respectively, in 100 women with osteoporosis.^[57] In another 1 year study in women with osteoporosis, ipriflavone (600 mg/day) produced a 6% increase in bone mineral density after 12 months, while the bone density of the placebo group was reduced by 0.3%.^[58] Longer-term studies are showing equally promising results given the safety and apparent efficacy of ipriflavone.^[59] ^[60] The effectiveness of ipriflavone suggests that naturally occurring isoflavonoids like genistein and diadzein in soy may exert similar benefits. Given the benefits of soy isoflavonoids against breast cancer alone, the regular consumption of soyfoods is encouraged. The mechanism of action appears to be due to enhancement of calcitonin effects (see above) on calcium metabolism as ipriflavone exerts no estrogen-like effects.^[61]

THERAPEUTIC APPROACH

Osteoporosis is a preventable illness if appropriate dietary and lifestyle measures are followed. Women of all ages, from the very young to the very old, should make building healthy and strong bones a lifelong priority. This involves avoiding those dietary and lifestyle practices that leach calcium from the bone and choosing those dietary and lifestyle factors which promote bone health.

Although calcium intake is highlighted by most physicians, strong bones require much more than this important mineral. Bone is dynamic, living tissue that requires a constant supply of high-quality nutrition and regular stimulation (exercise).

The primary goal in the treatment of osteoporosis is prevention. In severe cases of osteoporosis, the recommendations given in this chapter should be used in conjunction

with appropriate medical care, which may include the use of a variety of prescription drugs. Although drugs like Fosamax, as well as natural hormonal therapies like calcitonin, have side-effects, the benefits (prevention of hip fracture) usually outweigh these side-effects in severe cases.^[62] ^[63]

Diet

Follow the guidelines given in [Chapter 44](#) . Recommend that patients avoid those dietary factors that promote calcium excretion such as salt, sugar, protein, and soft drinks.

Supplements

- High potency multiple vitamin and mineral formula
- Calcium: 800–1,200 mg/day
- Vitamin D: 400 IU/day
- Magnesium: 400–800 mg/day
- Boron (as sodium tetraborate): 3–5 mg/day.

Chapter 178 - Otitis media

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

DIAGNOSTIC SUMMARY

Acute otitis media

- Earache or irritability
- History of recent upper respiratory tract infection or allergy
- Red, opaque, bulging ear drum with loss of the normal features
- Fever and chills.

Chronic or serous otitis media

- Painless hearing loss
- Dull, immobile tympanic membrane.

GENERAL CONSIDERATIONS

Otitis media occurs as a result of inflammation, swelling, or infection of the middle ear. There are basically two types of otitis media: chronic and acute.

Acute otitis media is usually preceded by an upper respiratory infection or allergy. The organisms most commonly cultured from middle ear fluid during acute otitis media include *Streptococcus pneumoniae* (40%) and *Haemophilus influenzae* (25%). Chronic otitis media – also known as serous, secretory, or non-suppurative otitis media; chronic otitis media with effusion; and “glue ear” – refers to a constant swelling of the middle ear.

Acute otitis media affects two-thirds of American children by 2 years of age, and chronic otitis media affects two-thirds of children under the age of 6.^[1] Otitis media is the most

common diagnosis in children and accounts for over 50% of all visits to pediatricians. It has been conservatively estimated that approximately \$8 billion are spent annually on medical and surgical treatment of earache in the United States.

Standard medical treatment

The standard medical approach to otitis media in children is antibiotics, analgesics (e.g. acetaminophen),

1464

and/or antihistamines. If the ear infection is long-standing and unresponsive to the drugs, surgery is performed. The surgery involves the placement of a tiny plastic myringotomy tube through the ear drum to assist the normal drainage of fluid into the throat via the Eustachian tube. It is not a curative procedure as children with myringotomy tubes in their ears are in fact more likely to have further problems with otitis media.

Myringotomies are currently being performed on nearly 1,000,000 American children each year. It appears that the unnecessary surgery of the past, the tonsillectomy, has been replaced by this new procedure. In fact there is a direct correlation between the decline of the tonsillectomy and the rise of the myringotomy. Over 2 million myringotomy tubes are inserted into children's ears each year, along with 600,000 tonsillectomies and adenoidectomies. These surgeries are unnecessary for most children.

A 1994 evaluation of the appropriateness of myringotomy tubes in children under 16 years of age in the United States found that only 42% were judged as being appropriate.^[2] These results mean that several hundred thousand children are subjected to a procedure that will do them little good and possibly significant harm.

A number of well-designed studies have demonstrated that there are no significant differences in the clinical course of acute otitis media when conventional treatments were compared with placebo. Specifically, no differences were found between non-antibiotic treatment, ear tubes, ear tubes with antibiotics, and antibiotics alone.^[3] ^[4] ^[5] ^[6] ^[7] Interestingly, in some studies, children not receiving anti-biotics did have fewer recurrences than those receiving antibiotics. This reduced recurrence rate is undoubtedly a reflection of the suppressive effects antibiotics have on the immune system as well as disturbing the normal flora of the upper respiratory tract.

Although some reviews showed a slight benefit with antibiotics, in the most recent analysis, a group of eight international experts from the United States, Britain, and the Netherlands reported that antibiotics are not recommended for the otitis media in most children.^[7] Their extensive review of the scientific literature on the value of antibiotics in the treatment of otitis media over the past 30 years led to the following conclusions:

We conclude that the benefit of routine antimicrobial use for otitis media,

judged by either short-term or long-term outcomes, is unproven.

We conclude that existing research offers no compelling evidence that children with acute otitis media routinely given antimicrobials have a shorter duration of symptoms, fewer recurrences, or better long-term outcomes than those who do not receive them.

Although preventing mastoiditis and meningitis is a rationale for antimicrobial treatment, little evidence exists that routine treatment is effective for this purpose.

Antimicrobials did not improve outcome at 2 months, and no differences in rates of recovery were found for either antimicrobial type or duration.

These results are not likely to be readily accepted by most pediatricians in the United States, who rely heavily on antibiotics to treat otitis media. Instead of antibiotics, this group of experts recommended using analgesics (e.g. acetaminophen) and close observation by the parent, as over 80% of the children with acute otitis media will respond to a placebo within 48 hours.

In addition to not being very effective in otitis media, the widespread use and abuse of antibiotics is becoming increasingly alarming for many other reasons, including the near-epidemic proportion of sufferers of chronic candidiasis as well as the development of “superbugs” that are resistant to currently available antibiotics. According to many experts as well as the World Health Organization, we are coming dangerously close to arriving at a “post-antibiotic era” where many infectious diseases will once again become almost impossible to treat because of an over-reliance on antibiotics (see [Ch. 53](#) for further information).^[9]

The risks and failure with antibiotics, when coupled with the high rate of recurrent otitis media following insertion of ear tubes, suggest that conservative (non-antibiotic, non-surgical) treatment alone would reduce the frequency rate and decrease the yearly financial costs of otitis media.

Although standard antibiotic and surgical procedures may not be statistically effective, each child must be evaluated individually before a decision not to use these procedures is taken.

Causes

The primary risk factors for otitis media are:^[4]

- day care attendance
- wood-burning stoves
- parental smoking or exposure to other second-hand smoke
- food allergies

- not being breast-fed.

All of these factors share a common mechanism – abnormal Eustachian tube function, the underlying cause in virtually all cases of otitis media. The Eustachian tube regulates gas pressure in the middle ear, protects the middle ear from nose and throat secretions and bacteria, and clears fluids from the middle ear. Swallowing causes active opening of the Eustachian tube due to the action of the surrounding muscles. Infants and small children are particularly susceptible to Eustachian tube problems since it is smaller in diameter, and more horizontal.

Obstruction of the Eustachian tube leads first to fluid build-up and then, if the bacteria present are pathogenic

1465

and the immune system is impaired, to bacterial infection. Obstruction results from collapse of the tube (due to weak tissues holding the tube in place and/or an abnormal opening mechanism), blockage with mucus in response to allergy or irritation, swelling of the mucous membrane, or infection.

THERAPEUTIC CONSIDERATIONS

The primary treatment goals are to ensure patency of Eustachian tubes and to promote drainage by identifying and addressing causative factors. In addition, it is very important to support the immune system. The recommendations given below are to be used along with those recommendations given in [Chapter 53](#).

Bottle feeding

Recurrent ear infection is strongly associated with early bottle feeding, while breast-feeding (minimum of 4 months) has a protective effect.^[9] Whether this is due to cow's milk allergy or to the protective effect of human milk against infection has not yet been conclusively determined. It is probably a combination of both.

In addition, bottle feeding while a child is lying on his or her back (bottle propping) leads to regurgitation of the bottle's contents into the middle ear and should be avoided.

Whatever the "causative" organism in otitis media – viral (respiratory syncytial virus or influenza A) or bacterial (*Streptococcus pneumoniae* or *Haemophilus influenzae*) – human milk offers protection due to its high antibody content which helps to inhibit infectious agents.^[10] Breast-fed infants also have a thymus gland (the major organ of the immune system) roughly 20 times larger than formula-fed infants (see [Ch. 53](#) for further information).^[11]

Food allergy

The role of allergy as the major cause of chronic otitis media has been firmly established in the medical literature.^{[12] [13] [14] [15] [16] [17]} Most studies show that 85–93% of these children have allergies: 16% to inhalants only, 14% to food only, and 70% to both.

One of the ways in which prolonged breast-feeding prevents otitis media may be by the avoidance of food allergies, particularly if the mother avoids sensitizing foods (i.e. those to which she is allergic) during pregnancy and lactation. In addition to breast-feeding, also of value is the exclusion or limited consumption of the foods to which children are most commonly allergic – wheat, egg, fowl, and dairy – particularly during the first 9 months.

Since a child's digestive tract is quite permeable to food antigens, especially during the first 3 months, careful control of eating patterns (no frequent repetitions of any food, avoiding the common allergenic foods, and introduction of foods in a controlled manner, i.e. introduction of one food at a time and carefully watching for a reaction) will reduce and prevent the development of food allergies.

The allergic reaction causes blockage of the Eustachian tube by two mechanisms: inflammatory swelling of the mucous membranes lining the tube and inflammatory swelling of the nose, causing the Toynbee phenomenon (swallowing when both mouth and nose are closed, forcing air and secretions into the middle ear). In chronic earaches, an allergic cause should always be considered, and the offending allergens determined and avoided.

One illustrative study of 153 children with earaches demonstrated that 93.3% of the children (using the RAST test for diagnosis – see [Chs 15](#) and [61](#) for further discussion) were allergic to foods, inhalants, or both. The 12 month success rate for 119 of the children, when treated with serial dilution titration therapy for inhalant sensitivities and an elimination diet for food allergens, showed that 92% improved. This compares favorably with the surgically treated control group (ear tubes and, as indicated, removal of the tonsils and adenoids), which showed only a 52% response.^[12]

In another study, a total of 104 children with recurrent otitis media ranging in age from 1.5 to 9 years were evaluated for food allergy by means of skin-prick testing, specific IgE tests, and food challenge.^[17] Results indicated a statistically significant association between food allergy and recurrent otitis media in 81/104 patients (78%). The elimination diet led to a significant amelioration of chronic otitis media in 70/81 (86%) patients as assessed by detailed clinical evaluation. The challenge diet with the suspected offending food(s) provoked a recurrence of serous otitis media in 66/70 patients (94%).

The frequency distribution of allergies to individual foods is listed in [Table 178.1](#), while the frequency distribution according to number of food allergens is listed in [Table 178.2](#).

Thymus gland extract

The thymus gland secretes a family of hormones which act on white cells to ensure their proper development

TABLE 178-1 -- Food allergy in children with chronic otitis media

| Food | No. of patients | Percentage of patients |
|------------|-----------------|------------------------|
| Cow's milk | 31 | 38 |
| Wheat | 27 | 33 |
| Egg white | 20 | 25 |
| Peanut | 16 | 20 |
| Soy | 14 | 17 |
| Corn | 12 | 15 |
| Tomato | 4 | 5 |
| Chicken | 4 | 5 |
| Apple | 3 | 4 |

1466

TABLE 178-2 -- The frequency distribution according to number of food allergens

| No. of food allergens | No. of allergic patients/total | Percentage |
|-----------------------|--------------------------------|------------|
| 1 | 11/81 | 13.6 |
| 2-4 | 66/81 | 81.5 |
| 5-7 | 3/81 | 3.7 |
| 8-10 | 1/81 | 1.3 |

and function. Studies with calf thymus extracts given orally have demonstrated impressive clinical results in a variety of clinical conditions in children.^{[18] [19] [20]} Specifically, thymus extracts have been shown to improve immune function, decrease children's food allergies, and improve a child's resistance to chronic respiratory infections. Thymus extracts may be of particular benefit in chronic otitis media. For more information, see [Chapter 53](#).

Humidifiers

Humidifiers are popular treatments for otitis media and upper respiratory tract infections

in children. This may be justified according to a 1994 study which evaluated the role of low humidity in this disorder.^[21] The study examined the effect of low humidity on the middle ear using a rat model. Twenty-three rats were housed for 5 days in a low-humidity environment (10–12% relative humidity) and 23 control rats were housed at 50–55% relative humidity. Microscopic ear examinations were graded for otitis media before testing and on test days 3 and 5. The lining of the middle ears and Eustachian tubes were examined by biopsy. Significantly more effusions (fluid in the Eustachian tubes) were observed in the low-humidity group on both days 3 and 5, but biopsy results were similar in both groups.

This study indicated that low humidity may be a contributing factor in otitis media. Possible explanations are that low humidity may induce nasal swelling and reduced ventilation of the Eustachian tube, or that it may dry the Eustachian tube lining which could lead to an inability to clear fluid as well as to increased secretions. The mast cells that reside in the lining of the Eustachian tubes may also come into play by releasing histamine and producing swelling.

Although preliminary, this research indicates that increasing humidity with the help of a humidifier may be an important goal in the treatment of otitis media with effusion.

THERAPEUTIC APPROACH

The key factor in the natural approach to chronic otitis media in children appears to be the recognition and elimination of allergies, particularly food allergies, and support for the immune system.

Diet

Since it is usually not possible to determine the exact allergen during an acute attack, the most common allergic foods should be eliminated from the diet, i.e.:

- milk and dairy products
- eggs
- wheat
- corn
- oranges
- peanut butter.

The diet should also eliminate concentrated simple carbohydrates – sugar, honey, dried fruit, concentrated fruit juice, etc. – since they inhibit the immune system. These simple dietary recommendations will bring relief to most children in a matter of days.

Nutritional supplements

- Children's multiple vitamin and mineral formula
- Vitamin A: 50,000 IU/day for up to 2 days in children under 6 years of age, and 4 days in children over 6 years of age

- Beta-carotene (natural mixed carotenoids): age in years × 20,000 IU/day (up to 200,000 IU/day)
- Vitamin C: age in years × 50 mg every 2 hours
- Bioflavonoids: age in years × 50 mg every 2 hours
- Zinc: age in years × 2.5 mg daily (up to 30 mg)
- Thymus extract: the equivalent of 120 mg pure polypeptides with molecular weights less than 10,000 or roughly 500 mg of the crude polypeptide fraction daily.

Botanical medicines

- *Echinacea* sp.: one-half the adult dosage is appropriate for children under the age of 6, and the full adult dosage (given below) is appropriate for children over the age of 6 (*Echinacea* is very safe for children). All dosages below can be given up to three times daily
 - dried root (or as tea): 0.5–1 g
 - freeze-dried plant: 325–650 mg
 - juice of aerial portion of *E. purpurea* stabilized in 22% ethanol: 2–3 ml
 - tincture (1:5): 2–4 ml
 - fluid extract (1:1): 2–4 ml
 - solid (dry powdered) extract (6.5:1 or 3.5% echinacoside): 150–300 mg

Physical medicine

Local application of heat is often very helpful in reducing discomfort. It can be applied as a hot pack, with warm

oil (especially mullein oil), or by blowing hot air into the ear with the aid of a straw and a hair dryer. These treatments help to reduce the pressure in the middle ear and promote fluid drainage.

Chapter 179 - Pelvic inflammatory disease

Nancy Roberts ND

DIAGNOSTIC SUMMARY

- Dyspareunia, leukorrhea
- Severe cramp-like, non-radiating lower abdominal pain; adnexal tenderness
- Chills with moderately high, intermittent fever typical, but not invariably present
- Cervical motion tenderness
- WBC 20,000/ul, with marked leukocytosis and/or elevated sedimentation rate
- *Neisseria gonorrhoea* and *Chlamydia trachomatis* most common, followed by *Ureaplasma urealyticum*, *Mycoplasma hominis*, *Streptococcus* sp., *E. coli*, *H. influenzae*, *Peptostreptococcus*, and *Peptococcus*.

GENERAL CONSIDERATIONS

Pelvic inflammatory disease (PID) is a categorical name for a range of pelvic infections and inflammations. Although salpingitis is the particular condition under the general label of PID (the adnexa are by definition always involved), non-infectious states such as pelvic adhesions and chronic salpingitis are also included.

PID causes women to make an estimated 2.5 million outpatient visits to health care providers each year. One-fourth of these women will suffer serious long-term sequelae and all are at risk for recurrence.^[1]

The social and physical costs of PID are also significant: the risk of ectopic pregnancy increases sixfold after a single episode of PID, and there is an estimated 13% risk of infertility after one infection – 70% after three.^[2] Although many of us have been numbed to increases in the costs of health care in the past two decades, such statistics about sequelae are unsettling. For this reason, prevention and aggressive full-spectrum care of the acute phase cannot be undervalued.

History

Inflammatory processes of the adnexal structures were

1470

not recognized until the 19th century. Prior to this time the uterus was thought to be the primary site for inflammation, although tubal and ovarian pathology were noted at autopsy. In 1843, Simpson wrote about pelvic cellulitis; 19 years later, Virchow described perimetritis.^[3] *Neisseria gonorrhoea* (GC) was regularly listed as the bacterial cause of the inflammatory effect, but until about the 1960s, the causal agent named most frequently was unknown. Even laboratory identification of GC was not very reliable at that time.

Etiology

It is now recognized that several organisms (listed in [Table 179.1](#)) are implicated in the etiology of PID. Because of the complexities of and inconsistencies in sampling and laboratory verification, it is difficult to make definitive statements about the causal agents in PID. Asymptomatic chlamydial infections are a big cause of PID. A higher proportion of PID has been ascribed to *Chlamydia trachomatis* than to *Neisseria gonorrhoea*.^[4]

***Neisseria gonorrhoea* (GC)**

The incidence of GC in the United States increased by a factor of 2.7 from 1960 to 1980.^[6] In 1975, there were approximately 1 million cases of GC reported in the US. The infection has reached pandemic proportions in the US, where it is estimated that for each reported case, four go unreported.^[3] Gonococci have been recovered from the urethra of 2.2% of sexually active servicemen who had minimal or no symptoms and from 40% of asymptomatic males who had contact with symptomatic women.^[7] In addition, an estimated 80% of the men and women exposed to *Gonococcus* will develop infections.^[6,2]

For a seemingly delicate and fastidious species, *Neisseria* has impressive infective abilities, preferring human columnar and transitional epithelia. In less than 1 hour after intercourse, *Gonococcus* can establish itself on the urethral mucosa where it successfully resists the flow of urine.^[8] Favored sites in the lower female genital tract are the Bartholin's and Skene's glands, the urethra, and the endocervical canal.^[3] Direct spreading can occur from the endocervix across the endometrial surface to the tubal mucosa, or there can be migration through subendothelial vascular and lymphatic channels.^[2] Perhaps the most common method of spreading, however, is

TABLE 179-1 -- Microorganisms involved in PID^[5]

| Organism | Incidence (%) |
|-------------------------------|---------------|
| <i>Neisseria gonorrhoea</i> | 40–60 |
| <i>Chlamydia trachomatis</i> | 30 |
| <i>Mycoplasma hominis</i> | 8 |
| <i>Ureaplasma urealyticum</i> | 4 |

by vector: GC attached to spermatozoa are physically carried to the fallopian tubes.^[3] Primary pathogens can also enter the upper tract from retrograde menstruation or uterine contractions during intercourse.^[9]

In the acute state, the gonococci and polymorphonucleocytes accumulate in the subepithelial connective tissue, resulting in patchy destruction of the overlying mucosa.^[8] ^[10] The consequent thinning of the mucosal lining is thought to facilitate GC penetration into deeper tissue.^[8] It is probably for this reason that gonococci are reported to survive only a short time in the fallopian tubes.^[11] However, they may not only be surviving, but thriving. The descent of the microbe beyond the surfaces being examined makes it difficult to detect.^[11]

Concomitant infections are known to occur with GC.^[12] Some researchers have even proposed that GC's primary role appears to be paving the way for secondary invaders from normal vaginal flora, allowing access to the upper tract.^[13] The associated infection will frequently be *Chlamydia trachomatis* (CT), but a superinfection can also be present, in which case one will find that anaerobic bacteria have colonized as well.^[12]

Chlamydia trachomatis (CT)

In the United States it is estimated that 20–30% of PID cases are caused by CT.^[5] ^[14] Further, one study found that acute chlamydial PID may be subclinical or silent in 66–75% of the cases.^[15] Laboratory diagnosis of chlamydial infection is difficult, which, combined with CT's asymptomaticity, renders thorough assessment of the scope of these infections nearly impossible.

A 5 year study conducted in urban Sweden showed that, despite a decrease in the numbers of gonococcal PID, the total cases of acute PID were unchanged or even increased in the last year of the study.^[16] Another European study, conducted in 1977, found that 62% of women with acute salpingitis had elevated (titer 1:64 or higher) chlamydial IgG antibodies.^[17] However, most of the other studies completed to date show much lower percentages. These numbers will no doubt change as diagnostic technology improves and the clinical presentation of *Chlamydia* is more widely understood.

Anaerobic infections

Anaerobes are the organisms most commonly isolated from the fallopian tubes or cul-de-sacs of patients with PID.^[18] Anaerobic bacteria are probably not the chief

causative agents, but rather are opportunists, establishing themselves in unsuccessfully defended tissues.

Anaerobic infections are commonly found in immunocompromised hosts and are generally of endogenous origin.^[19] The cervix and vagina of normal healthy women contain both anaerobic and aerobic bacteria.^[20] Anaerobic

1471

infections establish themselves more often in older patients and in women with a history of prior PID.^[6]

Other organisms

Facultative aerobic organisms found in tuboperitoneal fluids from women with salpingitis have included coliforms, *Haemophilus influenzae*, streptococci, and *Mycoplasma hominis*.^[21]

Mycoplasma hominis has not been demonstrated as a sole etiologic agent, but rather seems to be a common contributor to the polymicrobial milieu that is often discovered in PID. One study found *Mycoplasma hominis* in cervical cultures from 81% of women patients with GC, and 64% of those without GC.^[22]

Ramifications

There are serious physical consequences for women who have had PID. It has been estimated that, in the post-infection state, one of four women will suffer from one or more sequelae, such as abdominal pain, infertility, or ectopic pregnancy.^[6] Dyspareunia is a symptom which is often not investigated, but which, when relevant questions are asked, is frequently found in the post-PID sufferer.

Death from salpingitis is rare, and is generally due to rupture of the tubo-ovarian abscess with subsequent peritonitis. A mortality rate of 5.2–5.9% has been calculated for tubo-ovarian abscesses, and prior to 1950, mortality was 80–100%.^{[23] [24]} Better diagnostic understanding of this complication, treatment with antibiotics, and prompt surgical intervention have phenomenally improved both morbidity and mortality statistics.

The Fitz-Hugh–Curtis syndrome is a perihepatitis complicating the primary condition of PID. There are characteristic violin-string adhesions attaching the liver to the abdominal wall.^{[19] [25]} These adhesions are due to local peritonitis involving the anterior liver surface and the adjacent abdominal wall.^[26] Historically, GC was thought to be the main contributor to this syndrome, but CT is now found more frequently.^{[19] [20]}

Infertility is a serious concern. Once a woman has had PID, she is at risk for additional

attacks. This is in part because, after the fallopian tubes have been damaged by the infectious process, normal defense mechanisms are impaired. Reinfection has been found to be the most important cause of infertility after PID.^[27] One study comparing the rate of non-surgical infertility in 1973 with that of 1976 noted a 45% increase. This translates to 122,000 infertile couples per year.^[28] This increased incidence is consistent with the concurrent epidemic of STD-associated PID.

An alarming statistical analysis has shown that for each 1,000 girls born in 1950, 138 had one or more bouts of PID by age 30; 26 are infertile because of the PID; and nine have had surgery for ectopic pregnancy.^[6] Further, it has been postulated that by the year 2000 there will be one episode of salpingitis for each two women reaching reproductive age in 1970.^[20]

Ectopic pregnancy is a severe sequel and any woman with a history of PID faces a seven- to 10-fold increased risk.^[6] Ectopic pregnancies tripled in the United States from 1967 to 1977. In 1977, ruptured ectopic pregnancies accounted for 12% of maternal deaths and were the leading cause of maternal death in non-white women.^[28] In another study, which followed women with PID for 9.5 years, 12.8% were infertile after one infection, 35.5% after two, and 75% after three infections. The same study showed that one in 24 women will have an ectopic pregnancy.^[29]

Risk factors

Besides the obvious factor of sexual contact, the main risk factors are age, use or history of use of an IUD, and previous history of PID. An earlier "sexual debut" puts a young woman in a very high-risk group for PID, especially when there are multiple sexual partners. The risk in sexually active 15-year-olds is one in eight, while in the average 24-year-old it is one in 80.^[6] One interesting hypothesis for these data is that the cervical mucus in the younger woman may be estrogen-dominated, creating an environment which is more accessible to pathogens.^[21] Women with multiple partners have 4.6 times greater risk than women in monogamous relationships.^[20]

A woman bears a substantial risk of PID if she uses an IUD. Oral contraceptive (OC) users are somewhat less likely to have GC but, on the other hand, are at increased risk for chlamydial invasion. Birth control remains a potent issue, with barrier methods being techniques of choice because of their decreased PID risk. It should also be noted that one author included his own clinical observation that women in his practice who had vasectomized men as partners were only seldom in his office with PID.^[30]

The last risk factor to be considered is iatrogenic. This occurs when invasive procedures have introduced pathogens, or in some other way disturbed the tract flora, and induced PID. Among these procedures are:

- cervical dilation
- abortion
- curettage
- tubal insufflation
- hysterosalpingography

- insertion of an IUD.

A hospital in Lund, Sweden, reported that 15% of its PID cases were iatrogenic. This indicates that PID may not be strictly an STD.^[19]

1472

Pathogen access to the upper female tract

The route by which the pathogens gain access to the upper female tract has only recently been explored. Menstruation, sperm, and trichomonads have all been shown to be important in the transportation of pathogens into the salpinx.

Often, the onset of menses corresponds with the onset of an episode of PID. Infections occurring around the menses tend to be GC rather than CT, a clinical curiosity which may ultimately illuminate more about the etiology. One hypothesis is that menstrual regurgitation facilitates the inflammatory response by carrying sloughed endometrial epithelium which may have attached GC or intracellular CT. These organisms are then able to proliferate in the tubal epithelium or on peritoneal surfaces.^{[9] [31]}

Human sperm has proved an interesting and multifaceted variable in the precipitation of PID. Some of the research targets bacteriospermia as a cause of infertility in men, findings which are clearly relevant to PID. Increasingly, STD research is noting the incidence of asymptomatic male carriers.^{[3] [7] [30] [32] [33] [34] [35]} A very large population study discovered that 66–75% of the men who tested positive for GC were asymptomatic.^[7]

Designed to travel during intercourse, sperm also serve as effective vectors. Researchers took a very interesting look at this most basic interaction between man and woman by means of a laboratory experiment. They introduced organisms into capillary tubes containing cervical mucus, either alone or with added spermatozoa, and observed microbial motility. Cervical mucus had already been considered an effective mechanical and immunologic barrier between the abundant flora of the vagina and the upper tract, and the test results confirmed this idea. However, they also demonstrated that organisms attached to sperm could easily traverse the length of the mucus column. This may be particularly important during menses since sperm migration has been observed through menstrual plasma, but not during the luteal phase or through the cervical mucus of pregnancy.

Electron microscopy has produced amazing photographic evidence of organisms attached to sperm.^{[3] [36]} The mechanism observed with piliated GC is that pili twist together with the tails of the spermatozoa in a rope-in-a-spider-web arrangement around the bacteria. Sperm have also been found intimately associated with cytomegalovirus, *Toxoplasma*, *Ureoplasma urealyticum*,^[31] and *Chlamydia*.^[37]

Motile trichomonads serve as another transporter of PID. They are capable of

ascending from the vagina to the fallopian tubes, carrying additional invaders. In fact, it has been observed that trichomonads are never isolated from humans when heavy bacterial contamination is absent.^[31]

DIAGNOSIS

Pelvic or lower abdominal pain is the most dependable symptom of PID but, unfortunately, is not specific. Rebound tenderness is not reliably reported; cervical motion tenderness and adnexal tenderness are much more common. The clinical picture of the various types of PID can easily mislead: in a large study the clinical diagnosis of PID was confirmed at laparoscopy in only 65% of the patients. Appendicitis, hemorrhagic corpus luteum, pelvic endometriosis, ectopic pregnancy, mesenteric adenitis, and ovarian tumors accounted for 12%, while 23% were found to be normal.^[38] Many PID patients have atypical signs and symptoms and some have no signs and symptoms at all.^[6] [Table 179.2](#) lists those most commonly found.

The woman with GC may appear more toxic and febrile and manifest leukocytosis, while CT-caused PID may give her an elevated sedimentation rate (ESR). Most episodes of gonococcal PID occur at or shortly after menses.^[39] Gonococcal PID has a generally more severe clinical picture, but as discussed in [Chapter 143](#), tissue damage and long-term sequelae can be more severe in CT. This attempt to differentiate clinical pictures becomes meaningless, of course, in the presence of mixed infections.

Any putrid discharge should yield oxygen-sensitive organisms since offensive odor is considered diagnostic of anaerobic infection. Any woman who has such a discharge probably has well-developed PID, with opportunistic anaerobes following the primary invaders.^[27] The differential diagnosis of PID is shown in [Table 179.3](#).

TABLE 179-2 -- Common signs and symptoms in acute PID^[5]

| Symptom | Incidence (%) |
|---------------------------------|---------------|
| Lower abdominal pain | 90 |
| Adnexal tenderness on palpation | 90 |
| Pain on movement of the cervix | 90 |
| Vaginal discharge | 55 |
| Adnexal mass or swelling | 50 |
| Fever or chills | 40 |
| Irregular vaginal bleeding | 35 |
| Anorexia, nausea, and vomiting | 25 |

TABLE 179-3 -- Differential diagnosis of PID

 - Septic abortion
-

1473

In light of the Fitz-Hugh–Curtis syndrome, symptoms from the upper right quadrant in a sexually active woman may be an indirect sign of genital infection. The pain usually has a sudden onset and can overshadow the signs and symptoms of the underlying PID.^[26]

In the event of rupture of a tubulo-ovarian abscess, a sudden severe exacerbation of the pain can be observed. The pain is referred to the side of the rupture and is typically followed by generalized peritonitis and collapse. Shoulder pain may be present. The pulse will likely be elevated out of proportion to the fever and is frequently as high as 170.^[24] Surgery must be performed within 12 hours or mortality becomes probable.

A careful history is, as always, invaluable. STDs, birth control methods used, sexual activity, recent medical procedures, and the nature and onset of symptoms are key factors to consider.

Laboratory diagnosis

Laboratory findings during active PID are inconsistent in the research literature. Such confusion may be inevitable since we lack knowledge of the normal flora of the female upper genital tract.

Historically, this tract had been considered a sterile environment, but researchers have now begun to question this.^[1] In the large number and variety of laboratory and surgical examinations performed by physicians over the last 20 years, there has been a consistent lack of correlation between the organisms found in the different sectors of the female anatomy.^{[11] [13] [20] [40]} Pathogens cultured from the cervix are frequently not retrieved from the adnexa, and gonococci from the peritoneum are not found in the

upper tract. Some researchers report the adnexa as being free from an organism because they cannot isolate it from the exudate, but since *Chlamydia* is intracellular and gonococci are thought to be below the submucosa by the second day, these findings are unreliable.^[11]

It is difficult to determine the most appropriate diagnostic approach. As has been eloquently stated,^[18] PID results from infection of the endometrium and fallopian tubes by a wide array of bacterial pathogens, often in synergistic combination, and the inaccessible site of infection makes microbiologic confirmation difficult. Perhaps the best guideline to recommend is a conservative search. Invasive sampling of exudate and tissue should only be employed as a last resort.

Diagnostic laparoscopies have a death rate of 5.2/ 100,000 and major complications in 4.6/1,000 procedures.^[41] The most recent and least invasive technique is an upper tract culture via cervical entrance utilizing a double-lumen, catheter-protected brush.^{[42] [44]} Perhaps with more studies this procedure can be improved or elaborated; however, currently it is poorly correlated and frequently compromised by lower tract contamination.

A CBC and ESR are absolutely essential. The sedimentation rate in pregnancy is elevated from the increased plasma fibrinogen and globulin levels^[44] and will also be increased in anemia due to the higher plasma-to-erythrocyte ratio. An infection should be suspected with a sedimentation rate above 35 in the absence of pregnancy and anemia.

The C-reactive protein (CRP) has been investigated as a diagnostic tool in pelvic infections.^{[45] [46] [47]} The evaluation is based on the local inflammatory reaction that follows cell death in internal organs. This reaction induces an increased synthesis of a series of plasma proteins. The C-reactive protein is one of these acute-phase reactants and its levels increase 1–2 days after any tissue injury that affects more than the epithelial layer. The increase of CRP is quantitatively matched with the degree of tissue injury. This non-specific test does not stand alone, however, and should be evaluated with the WBC and the ESR.

Other diagnostic procedures to consider are:

- endocervical smears and cultures (a good approach but can be misleading for reasons previously discussed)
- urinalysis (to help with the differential diagnosis)
- serum human chorionic gonadotropin (to help rule out pregnancy)
- abdominal ultrasound (useful where displaced pregnancy is a possibility).

Liver enzymes will not be elevated with a chlamydial perihepatitis as the parenchyma is not involved.^[26]

Finally, however a case of PID is being worked up, the physician should always consider the possibility that the infection is polymicrobial. Mixed infections are very common; isolation of a particular microbe from the cervix does not absolutely establish it

as the sole etiologic agent of the PID, nor does isolation rule out other organisms.

THERAPEUTIC CONSIDERATIONS

Hospitalization is recommended for patients who are pregnant, are suspected of having a pelvic abscess, have adnexal masses, or show signs of peritoneal involvement. Referral is necessary if the diagnosis is uncertain or a surgical emergency threatens. Should the physician decide not to hospitalize, a regimen of antibiotic therapy, combined with the supportive therapies discussed below, can be tried if the patient's clinical and laboratory status can be reassessed in 48–72 hours. Laboratory values and objective patient criteria should direct all acute-phase treatment.

Antibiotics

As is well known, antibiotic therapy is not itself curative. Yet the literature is awash with big gun antibiotic

1474

TABLE 179-4 -- Antibiotic treatment of mild to moderate acute PID^[5]

• Cefoxitin (2 g i.m.) plus probenecid (1 g PO) in a single dose, or ceftriaxone (250 mg i.m.) plus doxycycline (100 mg PO b.i.d.) for 14 days

or

• Ofloxacin (400 mg PB b.i.d.) for 14 days plus either clindamycin (450 mg PO q.i.d.) or metronidazole (500 mg PO b.i.d.) for 14 days

protocols. Additional antibiotics are suggested for the anaerobic contingency; and such use quickly becomes complex, expensive, potentially dangerous, and often contradictory. For example, drugs which deter *Gonococcus* do not affect *Chlamydia*. Some protocols suggest switching drugs every 2 days until the desired therapeutic result is achieved, while others suggest simultaneous use of several antibiotics (see [Table 179.4](#)).

Mid-century literature predicted an end to GC with the fine-tuning of available chemotherapy:^[48]

Unless one succeeds in producing more virulent and resistant bacterial strains by present methods of treatment, it is possible to predict almost complete therapeutic success by means of both bacteriostatic and bactericidal agents.

We are no longer so optimistic. Antibiotic resistance has been increasing at a rapid rate. Research now shows that 2–3% of all GC in Holland produces beta-lactamase, as do

30–40% of all strains in Singapore, Malaysia, and Thailand.^[49] The 1985 United States STD treatment guidelines note that there is:^[50]

... increasing incidence of infections due to both penicillinase producing *N. gonorrhoeae* (PPNG) and chromosomal-mediated resistant *N. gonorrhoeae* (CMRNG), and there are published reports of the emergence of tetracycline-resistant gonococci in some geographic areas.

Fifteen per cent of women with PID fail to respond to primary antimicrobial treatment, 20% have at least one recurrence, and 15% are rendered infertile.^[18]

Given the polymicrobial nature of PID, the complexities of isolation, antibiotic-resistant strains of microorganisms, and the realities of recurrence rate with antibiotic use, a more fundamental approach combining immune system enhancement and non-toxic therapies is more sound. Antibiotics, whether herbal or pharmaceutical, can help with the first phase of treatment, but do not offer sufficient intervention for the devastation that regularly occurs in the wake of the primary infection.

Physical medicine

Diathermy

Pulsed high-frequency diathermy is very beneficial in the treatment of women with PID.^{[51] [52] [53]} Pulsing electric energy for a short duration (65 μ s every 1600 μ s) at high intensity achieves the desired therapeutic result without the hyperpyrexia typically associated with diathermy. Local recovery is enhanced, the reticuloendothelial system is stimulated, and gamma-globulin fractions are increased.^[20]

Sitz baths

Traditionally, sitz baths have been an important component of the naturopathic treatment of PID. The contrast sitz bath is primarily used to increase pelvic circulation and drainage (for further discussion, see [Ch. 42](#)).

Nutritional supplements

Chlorophyll

Chlorophyll derivatives are cell-stimulating agents which aid in the regeneration of tissues^{[54] [55]} and enhance production of hemoglobin and erythrocytes. They have the added benefit of being non-toxic. It has been suggested that:^[56]

... the action of chlorophyll consists for the most part of increasing the resistance of cells in some physiochemical manner so that enzymatic digestion of the cell membrane by invading bacteria or their toxin is checked.

Chlorophyll is theorized to break down carbon dioxide, resulting in the liberation of oxygen which inhibits anaerobic bacteria.^[57] Careful vaginal douching with chlorophyll is recommended in every case of PID to forestall or diminish the inevitable anaerobic population and to encourage cervical and possibly upper tract healing. These tissues must be healed to reduce the risk of infertility or ectopic pregnancy. One researcher reported that the discharge from several leukorrhea cases was cleared up in almost every instance, with comparatively few applications of chlorophyll.^[56]

Vitamin C

Vitamin C is very useful in the treatment of women with PID, for the following reasons:

- Its anti-inflammatory effects help to decrease tissue destruction.
- Its support of collagen tissue repair helps to prevent the spread of infection (especially important in GC infections which can spread through the subepithelial connective tissue, resulting in disorganization of the collagen matrix^[62]).
- Its fibrinolytic activity helps to prevent pelvic scarring.

Beta-carotene

The normal ovary has a high concentration of beta-carotene. As these structures are bombarded by inflammation and the unwelcome company of aggressive

1475

microbes, it is essential to maintain optimal levels of carotene to allow for an optimal defense. Beta-carotene potentiates the beneficial effects of interferon and enhances numerous other immune functions such as antibody levels and white blood cell activity.^[58] ^[59] It is also important as an antioxidant, helping to limit the cell damage induced by the inflammatory process (see [Ch. 67](#) for a full discussion of this nutrient).

Bromelain

Bromelain is an important component of the treatment regimen. Adnexal exudate in PID frequently suppurates to form abscesses. If during the acute stage, tissue irritation is relieved or ameliorated, much of the exudate can be absorbed and fewer adhesions formed.^[51] Adhesions will form as the exudate lingers, the structures being over-whelmed by the inflammation. Also, upon resolution, agglutination of the villous fold in the lumen of the tube may occur, resulting in scarring and tubal occlusion.^[3]

Bromelain activates fibrinolysis which can greatly diminish the enduring sequelae of the inevitable exudate. Bromelain also demonstrates antimicrobial properties, and an Italian study has shown that it penetrates the salpinx^[60] (see [Ch. 69](#) for further discussion).

Botanical medicines

Vaginal depletion packs

The use of the vaginal depletion pack is recommended as an integral part of PID treatment, as it promotes the drainage of exudate from the involved tissues. (The vaginal depletion pack is discussed in more detail in Appendix 12.)

Hydrastis canadensis

The immune-potentiating, specific anti-chlamydial properties and the general antibacterial nature of goldenseal make it indispensable in the care of PID. Since *Hydrastis canadensis* is also a trophorestorative to mucous membranes, the herb should be used throughout the rehabilitation period. (*Hydrastis* is discussed in more detail in [Ch. 91.](#))

Symphytum officinale

Comfrey is a soothing demulcent that is best used in the second phase of treatment. Its allantoin content encourages cell regeneration which is crucial for un-complicated recovery from PID.^[61]

Prevention

STD prevention is an extremely important issue for all heterosexually and bisexually active women. The woman with no history of PID still should be concerned about the significant population of asymptomatic male carriers of STDs. The choice of birth control is pivotal.

Oral contraceptives

A surprising number of articles laud the use of oral contraceptives (OC) for their apparent inhibition of gonococci.^[20] Burnham^[18] suggests OC use after a first episode of PID to prevent recurrence. Apparently, estrogens create a thicker cervical plug, which offers protection against gonococci.^[9]^[62] OCs also decrease the length and volume of menstrual blood flow, thus decreasing the exposure of the GC to this handy culture medium.

On the other hand, users of OCs have a higher risk of chlamydial infections.^[39]^[63]^[62]^[31] Progesterone induces hyperplasia and hypersecretion which can then produce cervical eversion, exposing the endocervical columnar epithelium – the target tissue of *Chlamydia*.^[39] Estradiol has been implicated in suppressing endocervical antibodies necessary for resolution of the CT.^[39] Animal experimentation finds that estrogen-treated individuals have a higher number of infected cervical cells and a longer duration of infection.^[64] Since women are probably not selectively exposed to GC versus CT, OCs

are not recommended.

Intrauterine devices

The IUD is an STD disaster.^{[6] [15] [18] [21] [26] [65] [66]} The reasons are straightforward – an IUD allows the colonization of bacteria on its surface while simultaneously reducing local immunologic capacity.^[67] Senanayake & Kramer^[68] suggest that if a woman is not concerned about child-bearing or possibly would “welcome the subfertility”, the IUD may be a good choice. The IUD is not recommended.

Barrier methods

Barrier methods of contraception are excellent choices for the prevention of PID. The condom is preferred to cervical protectors, as with this method the sperm more rarely reach the vaginal vault.

Douching

Haphazard douching is to be avoided since it disturbs the vaginal flora. However, if a woman believes that she has had intercourse with an infected partner, douching with a water-soluble chlorophyll solution may be a good supportive measure.

However, douching must be used with caution. One study compared 100 consecutive patients hospitalized for pelvic inflammatory disease with 762 controls and 119 women suspected of having PID.^[69] Current douching

1476

(defined as any douching during the previous 2 months) was more common among those with PID than among those in both control groups. Among current douchers, PID was related to the frequency of douching. Those who douched three or more times per month were 3.6 times more likely to get PID than those who douched less than once per month.

A much larger study surveyed 6,984 women over the age of 18 and found that 32% said they had douched within the past week, and 13% reported regular douching more than once a week.^[70]

Intercourse during menses

Intercourse during menses is not recommended unless a condom is used. GC risk is increased by the loss of the protective cervical mucus plug and by the prevalence of blood, a medium of choice for *Gonococcus*. The endometrium is also thought to offer local protection against bacterial invasion, and it is this layer which is being sloughed off

during menses.

Smoking

When 197 women hospitalized for their first pelvic inflammatory disease infection were compared with 667 controls with non-gynecologic conditions, it was found that cigarette smokers, compared with women who had never smoked, had an elevated risk of PID of 1.7 and former cigarette smokers had an elevated risk of 2.3. There was not a dose–response relationship.^[71]

A more rigorous study found similar results. This was a case-controlled, population-based study of 131 women between 18 and 40 years of age who were treated for their first episode of PID compared with 294 randomly selected patients from the same HMO. Current smokers, compared with those who had never smoked, had an increased risk of PID. Women who smoked 10 or more cigarettes a day had a higher risk than those who smoked less.^[72]

Education

A physician should review the signs and symptoms of PID with all sexually active women, and should encourage any woman to seek counsel if she appears to fit the clinical picture for PID. The diagnosis is easier to make and the recovery more rapid when treatment is instituted early.

THERAPEUTIC APPROACH

There are two phases to the treatment, both of which are important. The first therapeutic goal is to eliminate all pathogens and normalize the microflora of the adnexa. The second is to rehabilitate the damaged tissues.

Women should avoid intercourse until all signs and symptoms are resolved and their male partners have been examined and treated. In addition, all partners from up to 2 months prior to the illness should be examined.^[18] Increased bed rest must also accompany all forms of treatment.

Note. Referral for aggressive antibiotic treatment or hospitalization is necessary if the patient does not quickly respond to therapy.

Diet

All dietary inhibitors of immune function (sugar, alcohol, and processed and allergic foods) should be limited during the both phases of treatment.

Supplements

- Beta-carotene: 100,000 IU/day for 2+ months

- Vitamin E: 400 IU/day for 3 months
- Vitamin C: 500 mg four times/day for the first week of treatment and then decrease over 3 days to 250 mg three times/day
- Chlorophyll: 10 mg of fat/oil soluble four/day for 1 month
- Bromelain: 250 mg (1,800 mcu) four times/day for the first week and three times/day for 6 weeks.

Botanical medicines

- *Symphytum officinale* (after the acute phase)
 - 500 mg of freeze dried herb three times/day
 - 1:1 fluid extract, 30 drops two times/day
- *Hydrastis canadensis*: 400 mg of the solid extract three times/day during the acute phase; 200 mg three times/day during recovery
- Chlorophyll: douches alternating with vag packs
- Vag packs: daily during the acute phase until there is adequate clinical and laboratory response. After the acute phase, vag packs need to be used three times/week, alternating with chlorophyll douches, for 3 weeks.

Physical medicine

- Diathermy: pulsed, high-intensity diathermy for 10 minutes over the suprapubic area, 10 minutes over the liver, and 10 minutes in the area of the left adrenal (the right being presumably stimulated with the liver)
 - Sitz baths: one to two times/day throughout the acute phase. Contrast sitz baths are given in groups of three alterations of hot to cold. Two separate tubs are necessary to facilitate this process. The hot is at 105–115°F, the cold at 55–85°F, with the temperatures
-

1477

dependent on the strength of the patient. Standard treatment is 3 minutes hot and 30 seconds cold. The water level in the hot tub is set 1 inch higher than in the cold. Adequate draping is necessary to prevent chilling. As with all hydrotherapy treatments, one always finishes with the cold.

Chapter 180 - Peptic ulcer – duodenal and gastric

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

DIAGNOSTIC SUMMARY

- Epigastric distress 45–60 minutes after meals, or nocturnal pain. Both relieved by food, antacids, or vomiting
- Epigastric tenderness and guarding
- Symptoms chronic and periodic
- Gastric analysis shows acid in all cases, with hypersecretion in about half the patients with duodenal ulcers
- Ulcer crater or deformity usually occurring at the duodenal bulb (duodenal ulcer) or pylorus (gastric ulcer) on X-ray or fiber-optic examination
- Positive test for occult blood in stool.

GENERAL CONSIDERATIONS

Peptic ulcer formation occurs in the stomach (gastric ulcer) and the first portion of the small intestine (duodenal ulcer). Duodenal ulcers are more common, with an estimated prevalence of 6–12% in the United States. Approximately 10% of the US population has clinical evidence of duodenal ulcer at some time in their lifetime. It is four times more common in men than in women and four to five times more common than clinically evident benign gastric ulcer.

Although symptoms of a peptic ulcer may be absent or quite vague, most peptic ulcers are associated with abdominal discomfort noted 45–60 minutes after meals or during the night. In the typical case, the pain is described as gnawing, burning, cramp-like, or aching, or as “heartburn”. Eating or using antacids usually results in great relief.

Even though duodenal and gastric ulcers occur at different locations, they appear to be the result of similar mechanisms. Specifically, the development of a duodenal or gastric ulcer is a result of some factor damaging the protective factors which line the stomach

and duodenum.

In the past, the focus has primarily been on the acidic secretions of the stomach as the primary cause of both

1480

gastric and duodenal ulcers. However, more recently the focus has been on the bacteria *Helicobacter pylori* and non-steroidal anti-inflammatory drugs.

Gastric acid is extremely corrosive with a pH of 1–3. To protect against ulcers, the lining of the stomach and small intestine is protected by a layer of mucin. In addition, the constant renewing of intestinal cells and the secretion of factors which neutralize the acid when it comes in contact with the stomach and intestinal linings also protect against ulcer formation.

Excessive gastric acid output is rarely a factor in gastric ulcers as in these patients gastric acid output is usually normal or reduced. In contrast, almost half of patients with duodenal ulcers have increased gastric acid output. This increase may be due to an increased number of parietal cells. As a group, patients with duodenal ulcers have twice as many parietal cells as normal controls.

Even with an increase in gastric acid output, under normal circumstances there are enough protective factors to prevent the ulcer formation. However, when the integrity of these protective factors is impaired, an ulcer can form. A loss of integrity can be a result of *H. pylori*, NSAIDs, alcohol, nutrient deficiency, stress, and many other factors. Of these factors, *H. pylori* and NSAIDs are by far the most significant.

Helicobacter pylori

The role of *H. pylori* in peptic ulcer disease has been extensively investigated. It has been shown that 90–100% of patients with duodenal ulcers, 70% with gastric ulcers, and about 50% of people over the age of 50 test positive for *H. pylori*.^[1] The presence of *H. pylori* is determined by determining the level of antibodies to *H. pylori* in the blood or saliva, or by culturing material collected during an endoscopy as well as measuring the breath for urea.

Low gastric output as well as low antioxidant content in the gastrointestinal mucosa is thought to predispose to *H. pylori* colonization. *H. pylori* colonization increases gastric pH, thereby setting up a positive feedback scenario and increasing the likelihood for the colonization of the stomach and duodenum with other organisms.^[2]

Aspirin and other NSAIDs

Aspirin and other non-steroidal anti-inflammatory drugs are associated with a significant

risk of peptic ulcer. While most studies documenting the relative frequency of peptic ulcers as a consequence of aspirin and NSAIDs have focused on their use in the treatment of arthritis and headaches, recently the risk of gastrointestinal bleeding due to peptic ulcers was evaluated for aspirin at daily dosages of 300, 150, and 75 mg – dosages commonly recommended to prevent heart attacks and strokes.^[3]

One study, conducted at five test hospitals in England, found an increased risk of gastrointestinal bleeding due to peptic ulcer at all dosage levels. However, the dosage of 75 mg/day was associated with 40% less bleeding than 300 mg/day, and 30% less bleeding than 150 mg/day. The researchers concluded: “No conventionally used prophylactic aspirin regimen seems free of the risk of peptic ulcer complications.”

The combination of NSAID use and smoking is particularly harmful to the ulcer patient.^[4]

THERAPEUTIC CONSIDERATIONS

Individuals experiencing any symptoms of a peptic ulcer need competent medical care. Peptic ulcer complications such as hemorrhage, perforation, and obstruction represent medical emergencies that require immediate hospitalization.

Obviously, the best treatment of a peptic ulcer involves identification of the causative factor and its appropriate elimination.

Lifestyle factors

Stress and emotions

Stress is universally believed to be an important factor in the pathogenesis of peptic ulcers. However, this belief is based on uncontrolled observations. The medical literature is controversial, and every substantial attempt to examine this assumption has been fraught with methodological errors.^[5]

This problem is further complicated by the observation that men and women with peptic ulcers appear to have distinctly different psychological profiles. In addition, several studies have shown that the number of stressful life events is not significantly different in peptic ulcer patients as compared with carefully selected, ulcer-free controls. These data suggest that it is not simply the amount of stress, but rather the patient’s response to it that is the significant factor. A very large prospective study of 4,000 persons who had no history of peptic ulcer disease revealed that those who perceived stress in their lives are at increased risk of developing peptic ulcers^[6] (see [Ch. 60](#) for a more complete discussion).

It is probable that psychological factors are important in some patients with peptic ulcer disease, but not in others. As a group, ulcer patients have been characterized as tending to repress emotions. At the very least, patients should be encouraged to

discover enjoyable outlets of self-expression and emotions.

Smoking

Increased frequency, decreased response to peptic ulcer therapy, and an increased mortality due to peptic ulcers

1481

are all related to smoking. Three postulated mechanisms for this association are:^[6]

- decreased pancreatic bicarbonate secretion (an important neutralizer of gastric acid)
- increased reflux of bile salts into the stomach
- acceleration of gastric emptying into the duodenum.

Bile salts are extremely irritating to the stomach and initial portions of the duodenum. Bile salt reflux induced by smoking appears to be the most likely factor responsible for the increased peptic ulcer rate in smokers. However, the psychological aspects of smoking are also important, since the chronic anxiety and psychological stress associated with smoking appear to worsen ulcer activity.

Nutritional factors

Food allergy

Clinical and experimental evidence points to food allergy as a prime etiological factor.^[7]^[8]^[9]^[10] The lesions of peptic ulcers and the Arthus Reaction show the same microanatomical changes.^[1] In one study, 98% of patients with radiographic evidence of peptic ulcer had coexisting lower and upper respiratory tract allergic disease.^[9] In another study, 25 of 43 allergic children had X-ray-diagnosed peptic ulcers.^[10] Clinically, an elimination diet has been used with great success in treating and preventing recurrent ulcers.^[8]^[9] Food allergy is also consistent with the high recurrent rate of peptic ulcers.

It is ironic that many people with peptic ulcers soothe themselves by consuming milk, a highly allergic food. Milk should be avoided on this basis alone. However, there is additional evidence suggesting that milk should be avoided in patients with peptic ulcers; for example, population studies show that the higher the milk consumption, the greater the likelihood of ulcer, and milk significantly increases stomach acid production.^[11]

Fiber

A diet rich in fiber is associated with a reduced rate of duodenal ulcers as compared

with a low-fiber diet. The therapeutic use of a high-fiber diet in patients with recently healed duodenal ulcers reduces the recurrence rate by half.^[12] This is probably a result of fiber's ability to delay gastric emptying of the liquid phase, counteracting the rapid movement of this phase into the duodenum normally seen in ulcer patients. Although several fibers often used to supplement the diet (e.g. pectin, guar gum, psyllium, etc.) have been shown to produce beneficial effects, a diet rich in plant foods is best.^{[13] [14]}

Cabbage

Raw cabbage juice has been well documented as having remarkable success in treating peptic ulcers.^{[15] [16] [17]} One liter per day of the fresh juice, taken in divided doses, resulted in total ulcer healing in an average of only 10 days. Further research has shown that the high glutamine content of the juice is probably responsible for the efficacy of cabbage in treating these ulcers. In a double-blind clinical study of 57 patients, 24 using 1.6 g/day of glutamine and the rest using conventional therapy (antacids, antispasmodics, diet, milk, and bland diet), glutamine proved to be the more effective treatment. Half of the glutamine patients showed complete healing (according to radiographic analysis) within 2 weeks, and 22 of the 24 showed complete relief and healing within 4 weeks.^[19] Although the mechanism for these results is not known, it is postulated by the authors to be due to the role of glutamine in the biosynthesis of the hexosamine moiety in certain mucoproteins. This could stimulate mucin synthesis which would benefit peptic ulcer patients.

Bismuth subcitrate

Bismuth is a naturally occurring mineral that can act as an antacid as well as exerting activity against *H. pylori*. The best known and most widely used bismuth preparation is bismuth subsalicylate (Pepto-Bismol). However, bismuth subcitrate has produced the best results against *H. pylori* and in the treatment of peptic ulcers.^{[18] [19]} In the United States, bismuth subcitrate preparations are available through compounding pharmacies (to find a compounding pharmacist in your area, call the International Academy of Compounding Pharmacists 1-800-927-4227).

One of the key advantages of bismuth preparations over standard antibiotic approaches to eradicating *H. pylori* is that while the bacteria may develop resistance to various antibiotics it is very unlikely to develop resistance to bismuth.

The usual dosage for bismuth subcitrate is 240 mg twice daily before meals. For bismuth subsalicylate, the dosage is 500 mg four times daily. Bismuth preparations are extremely safe when taken at prescribed dosages. Bismuth subcitrate may cause a temporary and harmless darkening of the tongue and/or stool. Bismuth subsalicylate should not be taken in children recovering from the flu, chicken pox, or other viral infection as it may mask the nausea and vomiting associated with Reye's syndrome, a rare but serious illness.

Flavonoids

Flavonoids are known to counteract both the production and secretion of histamine, an important factor in ulcer formation. They are generally regarded as anti-allergy compounds. The use of these compounds seems particularly indicated, due to the probable allergic etiology of peptic ulcers.

1482

Catechin, via its ability to inhibit histidine decarboxylase, offers anti-ulcer activity. Experimental studies in guinea pigs and rats have demonstrated that catechin has significant anti-ulcer activity in various models.^[20] ^[21] In a human clinical study, oral administration (1,000 mg five times/day) resulted in reduced histamine levels in the gastric tissue (determined by biopsy) of normal patients and those with gastric and duodenal ulcers and acute gastritis.^[21] It was also demonstrated that the histamine levels, which significantly increase in patients with urticaria and food allergy after the local application of the antigen to the gastric mucosa, could be decreased by the prior administration of catechin.

In a recent study, several flavonoids were shown to inhibit *H. pylori* in a clear-cut concentration-dependent manner.^[22] In addition, unlike antibiotics the flavonoids were also shown to augment natural defense factors which prevent ulcer formation. The activity of flavone, the most potent flavonoid in the study, was shown to be similar to that of bismuth subcitrate.

Miscellaneous

Vitamins A and E have been shown to inhibit the development of stress ulcers in rats and are important factors in maintaining the integrity of the mucosal barrier.^[23] ^[24] Zinc increases mucin production in vitro, and has been shown to have a protective effect on peptic ulcers in animals^[25] and a curative effect in humans.^[26]

Botanical medicines

Glycyrrhiza glabra. Licorice has historically been regarded as an excellent medicine for peptic ulcer. However, due to the known aldosterone-like side-effects of glycyrrhizic acid (GA), a procedure was developed to remove GA from licorice and form deglycyrrhizinated liquorice (DGL). The result is a very successful anti-ulcer agent without any known side-effects (see [Ch. 90](#)).^[2] ^[27] ^[28] ^[29] ^[30] ^[31]

The proposed mechanism of DGL is that it stimulates and/or accelerates the differentiation to glandular cells, as well as mucus formation and secretion.^[27] Clinical studies have demonstrated no significant differences in recurrence rates between cimetidine and DGL drug regimens, and rat and human studies have shown its efficacy in preventing aspirin-induced ulceration and gastric bleeding.^[29] ^[30] ^[31]

An obvious question related to DGL is: “Does DGL have any effect on *Helicobacter pylori*?”. The answer appears to be “yes” as DGL is composed of several flavonoids which have been shown to inhibit *H. pylori*.^[22]

It appears that in order to be effective in healing peptic ulcers, DGL must mix with saliva. DGL may promote the release of salivary compounds which stimulate the growth and regeneration of stomach and intestinal cells. DGL in capsule form has not been shown to be effective.

The standard dosage for DGL is two to four 380 mg chewable tablets between or 20 minutes before meals. Taking DGL after meals is associated with poor results. DGL therapy should be continued for at least 8–16 weeks after there is a full therapeutic response.

Rhubarb. In cases of active intestinal bleeding, rhubarb (*Rheum* sp.) preparations can be extremely effective. In one double-blind study, three kinds of alcohol-extracted rhubarb tablets were studied (*Rheum officinale* Baill; *Rheum palmatum* L.; *Rheum tanguticum* Maxim ex Balf).^[32] Their efficacies in a group of 312 cases of bleeding gastric and duodenal ulcers were 90.7, 93.7, and 92.8%, respectively. The time taken for the stool occult blood to change from positive to negative was 57.1, 53.4, and 56 hours, respectively. The beneficial actions are due to the presence of astringent anthraquinones and flavonoids.

Plantain banana. In rats, the dried extract of the unripe plantain banana has been found to have anti-ulcerogenic activity against a variety of experimentally induced ulcers.^{[33] [34]} This effect appears to be similar to that of DGL, i.e. stimulation of mucosal cell growth rather than inhibition of gastric acid secretion.

THERAPEUTIC APPROACH

Peptic ulcer disease should be recognized as a heterogeneous group of disorders with a common final pathway leading to an ulcerative lesion in either the gastric or duodenal mucosa. Patients must be carefully evaluated to determine which of the above factors is most relevant to their health problem. This is, however, difficult; a more general approach may be necessary.

The first step is to identify and eliminate or reduce all factors implicated in the etiology of peptic ulcers: food allergy, cigarette smoking, stress, and drugs – especially aspirin and other non-steroidal analgesics. Once the causative factors have been controlled, attention should be directed at healing the ulcers, inhibiting exacerbating factors (e.g. reducing excess acid secretion if present), and promoting tissue resistance. Finally, the proper diet and lifestyle should be developed to prevent further recurrence.

Peptic ulcer complications – hemorrhage, perforation, and obstruction – represent medical emergencies that require immediate hospitalization.

Psychological

Assist the patient in developing an effective stress reduction program – eliminating or controlling of stressors, and designing a regular relaxation plan.

1483

Diet

Eliminate allergic food, promote foods high in dietary fiber, and utilize various members of the cabbage family.

Supplements

- Vitamin A: 20,000 IU three times/day
- Vitamin C: 500 mg three times/day
- Vitamin E: 100 IU three times/day
- Flavonoids: 500 mg three times/day
- Zinc: 20 mg/day
- Glutamine: 500 mg three times/day
- Bismuth subcitrate: 240 mg twice daily before meals.

Botanical medicine

- Deglycyrrhizinated licorice root (DGL): 380–760 mg 20 minutes before meals three times/day.

Chapter 181 - Periodontal disease

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

DIAGNOSTIC SUMMARY

- Gingivitis – inflammation of the gingiva characterized by erythema, contour changes and bleeding
- Periodontitis – localized pain, loose teeth, demonstration of dental pockets, erythema, swelling and/or suppuration. X-ray may reveal alveolar bone destruction.

GENERAL CONSIDERATIONS

Periodontal disease is an inclusive term used to describe an inflammatory condition of the gingiva (gingivitis) and/or periodontium (periodontitis). Periodontal disease usually refers to a disease process that typically progresses from gingivitis to periodontitis.^{[1] [2]} Periodontal disease may be a manifestation of a more systemic condition, such as diabetes mellitus, collagen diseases, leukemia or other disorders of leukocyte function, anemia, or vitamin deficiency states.^[1] An association with atherosclerosis has also been reported.

Since alveolar bone loss may be non-inflammatory, our definition of periodontal disease excludes the processes causing only tooth loss (the majority of which are due to osteoporosis or endocrine imbalances).^[1] These conditions reflect systemic disease, with local factors playing only a minor role; therefore, the focus should be on treating the underlying condition rather than the “periodontal disease”. In this context, non-inflammatory alveolar bone loss should be viewed as a separate entity, as it involves a different etiology (see [Ch. 177](#)).

The focus of this chapter is the use of nutrition and lifestyle improvement as an adjunctive therapy to aid in the control and prevention of the causes of inflammatory periodontal disease. This is a good example of a condition that is probably best treated with combined expertise, i.e. a dentist or periodontist and a nutritionally minded

physician. Although oral hygiene is of great importance in treating and preventing periodontal disease,

1486

it is not sufficient in many cases. The host defense must be normalized if development and progression of the disease are to be controlled.^[1]^[3] To a large extent, the nutritional status of the individual determines the status of host defense factors.

Prevalence and epidemiology

The prevalence of periodontal disease increases directly with age. The rate of periodontal disease is approximately 15% at age 10, 38% at age 20, 46% at age 35, and 54% at age 50. As a group, men have a higher prevalence and severity of periodontal disease than women. Periodontal disease is inversely related to increasing levels of education and income. Rural inhabitants have a higher level of severity and prevalence than their urban counterparts.^[1]

Pathophysiology

Understanding the underlying pathophysiology of any disease process leads to a more effective treatment plan. In periodontal disease this involves understanding the normal host protective factors in the periodontium. It has been concluded that: "Clearly bacteria are essential agents, but their presence is in itself insufficient; host factors must be involved if the disease is to develop and progress."^[3]

Factors involved in host resistance include:

- the environment of the gingival sulcus
- bacterial factors
- leukocyte function
- complement activation
- IgE and mast cell function
- amalgam restoration
- miscellaneous local factors
- the structure and integrity of the collagen matrix of the periodontium and gingiva.

Gingival sulcus

The gingival sulcus is the V-shaped crevice that surrounds each tooth, being bounded by the surface of the tooth on one side and the epithelium lining the free margin of the gingiva on the other. The anatomy of the gingival sulcus is ideal for growth of bacteria as it is resistant to the washing and cleaning action of saliva. Furthermore, the gingival fluid (sulcular fluid) provides a rich nutrient source for microorganisms. The clinical determination of the depth of the gingival sulcus is an important diagnostic parameter.

Patients with periodontal disease should be monitored; biannual visits to the dentist should be sufficient in most cases.

Bacterial factors

Bacterial plaque has long been considered the etiological agent in most forms of periodontal disease.^[1] However, an appreciation of host defense factors has now developed.^[1] ^[3] Bacteria are known to produce and secrete numerous compounds that are quite detrimental to the status of the host's defense mechanisms. These compounds include:^[1]

- endotoxins and exotoxins
- free radicals and collagen-destroying enzymes
- leukotoxins
- bacterial antigens, waste products, and toxic compounds.

Polymorphonuclear leukocytes

Neutrophils (PMNs) constitute a first line of defense against microbial overgrowth. Defects in PMN functions are “catastrophic” to the periodontium.^[1] ^[3] PMN functions are depressed in the geriatric population as a whole, and in patients with diabetes, Crohn's disease, Chediak–Higashi syndrome, Down's syndrome, and juvenile periodontitis.^[1] ^[3] These patients are at extremely high risk for developing rapidly progressing periodontal disease, as are people with transient neutropenia. Transient defects in PMN function may be responsible for the periods of quiescence and exacerbation noted in periodontal disease. As well as serving a vital role in protecting against periodontal disease, PMNs also play a major role in tissue destruction. PMNs release numerous free radicals, collagenases, hyaluronidases, inflammatory mediators, and an osteoclast stimulator.^[1] ^[3]

Macrophages and monocytes

These leukocytes are found in increased numbers in periodontal disease. As well as serving to phagocytize bacteria and debris, these cells are the primary source of prostaglandins in the diseased gingiva and release large quantities of enzymes believed to play a major role in collagen destruction.^[1] ^[3]

Lymphocytes

The major role lymphocytes play in periodontal disease is via lymphokine production. Their role in periodontal disease is overshadowed by the roles of the other immune system components discussed, but lymphokines are involved in promoting PMN and monocyte chemotaxis, fibroblast destruction, and osteoclast activation.^[1] ^[3]

Complement

The complement system is composed of at least 22 proteins and accounts for more

than 10% of the total serum

1487

globulin. Upon activation, complement components act in a cascade fashion. Complement can be activated via the classical or alternative pathway. The complement system plays a critical role in immunological and non-specific resistance to infection and in the pathogenesis of tissue injury. The products of complement activation regulate a number of events, including the release of mediators from mast cells; promotion of smooth muscle contraction; chemotaxis of PMNs, monocytes, and eosinophils; and phagocytosis by immune adherence.^[4] The net effect is an increase in gingival permeability, resulting in increased penetration of bacteria and bacterial by-products and, in essence, the initiation of a positive feedback cycle.^{[1] [3]}

Other effects of complement activation include solubilization of immune complexes, cell membrane lysis, neutralization of viruses, and the killing of bacteria.^[4] In periodontal disease, activation of complement via the alternative pathway within the periodontal pocket is possibly the major factor in tissue destruction.

Mast cells and IgE

Mast cell degranulation is also a major factor in periodontal disease. Degranulation results in the release of inflammatory mediators, i.e. histamine, prostaglandins, leukotrienes, kinins, serotonin, heparin, and serine proteases.^[1] Mast cell degranulation can be initiated by IgE complexes, complement components, mechanical trauma, endotoxins, and free radicals. The finding of increased IgE concentrations in the gingiva of patients with periodontal disease suggests that allergic reactions may be a factor in the progression of the disease in some patients.^[5]

Amalgam restorations

Faulty dental restorations and prostheses are common causes of gingival inflammation and periodontal destruction.^[1] Overhanging margins provide an ideal location for the accumulation of plaque and the multiplication of bacteria. If the restoration is a silver amalgam filling there may be even more involvement, due to decreased activities of antioxidant enzymes. Mercury accumulation results in a depletion of the free radical-scavenging enzymes, glutathione peroxidase, superoxide dismutase, and catalase.^[6] The proteoglycans and glycosaminoglycans of the collagen matrix are particularly sensitive to free radical damage.^[7]

Miscellaneous local factors

Numerous local factors favor the progression of periodontal disease. These include:

- food impaction

- unreplaced missing teeth
- malocclusion
- tongue thrusting
- bruxism
- toothbrush trauma
- mouth breathing
- tobacco (discussed below).

Tobacco

Tobacco smoking is associated with increased susceptibility to severe periodontal disease and tooth loss.^{[1] [8] [9]} (Tobacco smoking is associated with increased susceptibility to virtually every major chronic disease.) Many of the harmful effects of tobacco smoking are a result of free radical damage, particularly to epithelial cells. Furthermore, smoking greatly reduces ascorbic acid levels, thereby potentiating its damaging effects.^[10] Carotenes and flavonoids have been shown to greatly reduce some of the toxic effects of smoking.^{[11] [12]}

Structure and integrity of collagen matrix

The collagen matrix of the periodontal membrane serves as periosteum to the alveolar bone and allows the dissipation of the tremendous amount of pressure exerted during mastication.^[13] The status of the collagen matrix of the periodontium, specifically the extracellular proteoglycans of the gingival epithelium, determines the rate of diffusion and the permeability of inflammatory mediators, bacteria and their by-products, and destructive enzymes from the oral cavity.^{[14] [15]} Due to the high rate of protein turnover in periodontal collagen, the integrity of the collagen matrix in this area is extremely vulnerable to atrophy when the necessary cofactors for collagen synthesis (e.g. protein, vitamin C, B₆ and A, zinc, copper, etc.) are absent or deficient.^[13]

The collagen of the periodontium is particularly rich in glycosaminoglycans.^{[13] [14] [15] [16]} Heparin sulfate, dermatan sulfate, and chondroitin 4-sulfate are the major glycosaminoglycans present. Stabilization of collagen is the major treatment goal outlined below.

THERAPEUTIC CONSIDERATIONS

Therapeutic goals in treating periodontal disease from a nutritional perspective are:

- decrease wound healing time (the time span for wound healing is longer in patients who are more susceptible to periodontal disease^[17])
 - improve membrane and collagen integrity
 - decrease inflammation and free radical damage (inflammation can induce a vicious cycle and promote periodontal disease)
 - enhance immune status (defects in the immune
-

system, particularly PMNs, are catastrophic to the periodontium).

Individual nutrients will be discussed below in the context of their role in achieving these therapeutic goals.

Vitamin C

Vitamin C (ascorbic acid) plays a major role in preventing periodontal disease, as is evident from many experimental studies.^{[1] [18] [19] [20] [21] [22]} The classical symptom of gingivitis seen in scurvy illustrates the vital function vitamin C plays in maintaining the membrane and collagen integrity and immunocompetence. Deficiency of vitamin C is associated with defective formation and maintenance of collagen, ground substance, and intercellular cement substance in mesenchymal tissue.^[1] The deficiency effects on bone include retardation or cessation of osteoid formation, impaired osteoblastic activity, and osteoporosis. Subclinical vitamin C deficiency plays a significant role in periodontal disease via these effects and its role in delaying wound healing.^{[1] [18] [19] [20] [21] [22]}

Decreased vitamin C levels are also associated with increased permeability of the oral mucosa to endotoxin and bacterial by-products, as well as impaired leukocyte functions (particularly PMNs). The role vitamin C plays in increasing chemotaxis and phagocytosis by PMNs is best exemplified by its effect on Chediak–Higashi syndrome. This autosomal recessive trait is associated with compromised PMN and monocyte chemotaxis and phagocytosis, all of which are responsive to vitamin C supplementation.^[23] This syndrome is also associated with an extremely rapidly progressing periodontitis.^{[1] [3]}

Vitamin C's other effects on immune status include enhancing lymphoproliferative response to mitogens and increasing interferon levels, antibody response, immunoglobulin levels, and secretion of thymic hormones. Vitamin C also possesses significant antioxidant and anti-inflammatory properties and decreases wound healing time.^[24]

Sucrose

Sugar is known to significantly increase plaque accumulation while simultaneously decreasing PMN chemotaxis and phagocytosis.^{[1] [25]} This inhibition of PMN function is due to osmotic effects and competition with vitamin C.

Vitamin C and glucose are known to compete for intracellular transport sites, with this intracellular transport being largely insulin-dependent (see [Ch. 53](#) for further information on nutrient factors and immune function).

Considering the fact that the average American consumes in excess of 175 g/day of sucrose and other refined carbohydrates, it is safe to say that most Americans have a

chronically depressed immune status which puts them at increased risk for periodontal disease.^[26]

Vitamin A

A vitamin A deficiency predisposes to periodontal disease. Deficiency of vitamin A is associated with:^[1]

- keratinizing metaplasia of the gingival epithelium
- early karyolysis of gingival epithelial cells
- inflammatory infiltration and degeneration
- periodontal pocket formation
- gingival calculus formation
- increased susceptibility to infection
- abnormal alveolar bone formation.

Vitamin A is necessary for collagen synthesis and wound healing, maintaining the integrity of epithelial and mucosal surfaces and their secretions, and enhancing numerous immune functions.^[24] Beta-carotene may be a more advantageous supplement due to its affinity for epithelial tissue and potent antioxidant activity.^[12]

Zinc and copper

Zinc functions synergistically with vitamin A in many metabolic processes.^[27] The severity of periodontal disease is positively associated with increased serum copper levels while zinc levels are significantly decreased, i.e. an increased copper to zinc ratio.^[28] This is consistent with other causes of chronic inflammation and signifies activation of metallothionein, which increases ceruloplasmin formation while increasing zinc sequestration in response to inflammation.^[27]

Zinc's importance in treating periodontal disease cannot be overstated. In the United States, marginal zinc deficiency is widespread, particularly in the elderly.^{[28] [29]} This may be a factor in the increasing prevalence of periodontal disease with age, although the geriatric population as a whole is at higher risk for development of numerous nutrient deficiencies. Zinc functions in the gingiva and periodontium include:^{[24] [27] [29] [30] [31]}

- stabilization of membranes
- inhibition of calcium influxes
- antioxidant activity
- metallo-component in at least 40 enzymes including enzymes for DNA, RNA, and collagen synthesis
- inhibition of plaque growth
- inhibition of mast cell degranulation
- numerous immune activities, including increased PMN chemotaxis and phagocytosis.

Zinc is also known to significantly reduce wound healing time.^{[24] [27]}

Zinc's positive effects in established periodontal disease are also due to its action on calcium- and calmodulin-mediated

1489

processes such as mast cell degranulation, tissue damage induced by endotoxin, and increased vascular permeability.^[27] These calcium-mediated events are responsible for much of the tissue destruction seen in periodontal disease.^[32]

Regular (twice daily) use of a mouthwash that contains a 5% zinc solution inhibits plaque growth.^[30] However, lower concentrations or less frequent mouth washing are not particularly successful.

Vitamin E and selenium

These two nutrients function synergistically in antioxidant mechanisms and seem to potentiate each other's effect. Vitamin E alone has been demonstrated to be of considerable value in patients with severe periodontal disease.^[4] ^[33] This can largely be attributed to the decreased wound healing time associated with vitamin E.^[34] The antioxidant effects of vitamin E are particularly needed if silver amalgam is present. Mercury depletes the tissues of the antioxidant enzymes superoxide dismutase, glutathione peroxidase, and catalase. In animal studies, this toxic effect of mercury is prevented by supplementation with vitamin E.^[6] Selenium and vitamin E's antioxidant activities also deter periodontal disease, as the effects of free radicals are extremely damaging to gingival proteo- and glycosaminoglycans.^[7]

Coenzyme Q

Ubiquinone, an essential coenzyme involved in mitochondrial oxidative phosphorylation, is also an effective antioxidant.^[35] ^[36] Coenzyme Q is widely used in Japan for many conditions, including periodontal disease. A review of seven studies using coenzyme Q found that 70% of the 332 patients involved responded favorably to supplementation.^[35] A double-blind study comprising 56 subjects found the supplemented group to respond significantly, while the placebo group displayed very little change in periodontal pocket depth and tooth mobility.^[36]

Flavonoids

As a group, these compounds are perhaps the most important components of an anti-periodontal disease program. Flavonoids are extremely effective in reducing inflammation and stabilizing collagen structures. Flavonoids affect collagen structure by:^[37] ^[38] ^[39] ^[40] ^[41] ^[42]

- decreasing membrane permeability, thereby decreasing the load of inflammatory

mediators and bacterial products

- preventing free radical damage with their potent antioxidant properties
- inhibiting enzymatic cleavage by hyaluronidases and collagenases
- inhibiting mast cell degranulation
- cross-linking with collagen fibers directly.

The more biologically active flavonoids, i.e. quercetin, catechin, anthocyanidins, and proanthocyanidins, should be supplemented, as rutin has very little collagenstabilizing effect.

Remarkable effects have been displayed by 3-O-methyl-(+)-catechin in the treatment of hamsters with experimentally induced periodontitis. Large doses of this flavonoid derivative significantly retarded plaque growth and alveolar bone resorption.^[43]

Folic acid

The use of folate, either topically or systemically, in double-blind studies produced significant reductions of gingival inflammation as determined by reduction in color changes, bleeding tendency, gingival exudate flow, and plaque scores.^{[44] [45] [46] [47] [48]} The folate mouthwash, 0.1% folic acid, is significantly more effective than the oral supplementation of either 2 or 5 mg/day, suggesting a local mechanism of action.^{[46] [47]} Folate has been demonstrated to bind plaque-derived endotoxin.^{[46] [47] [48]} The use of folate mouthwash is particularly indicated for pregnant women and oral contraceptive users, and for other conditions associated with an exaggerated gingival inflammatory response or folate anti-metabolites (e.g. phenytoin, methotrexate).^{[46] [47]}

Epithelial cells of the cervix and the oral cavity appear to suffer from a similar “end-organ” deficiency of folic acid under the hormonal influences of pregnancy and oral contraceptive use.^{[47] [49] [50]} The cervical dysplasia associated with oral contraceptive use also responds to pharmacological doses of folic acid, i.e. 8–30 mg/day.^{[49] [50]} (Whitehead’s work^[49] was the inspiration for the use of folic acid by Pack & Thomson^{[46] [47]} in the treatment of gingivitis of pregnancy.) The sera and leukocytes of pregnant women and oral contraceptive users contain a macromolecule that binds folate, which, more than malabsorption or decreased intake, appears to be the major factor for the “end-organ” folate deficiency.^[51] (It should be noted, however, that folic acid deficiency is the most common deficiency in the world.^[24])

Double-blind studies have shown that the beneficial effects of folic acid are not limited to women,^{[44] [45] [48]} and the positive effects are not limited to just gingivitis, since periodontitis improves as well.^[48]

Botanical medicines

A number of botanical compounds have shown an ability to inhibit plaque formation, including green

tea polyphenols and glycyrrhetic acid from licorice, but the most extensively studied compound is an alcoholic extract of *Sanguinaria canadensis*.

Sanguinaria canadensis

Bloodroot contains a mixture of benzophenanthridine alkaloids, but chiefly sanguinarine is available in commercial toothpastes and mouth rinses. Sanguinarine demonstrates properties useful in preventing dental plaque formation. It has broad antimicrobial activity as well as anti-inflammatory properties. In vitro studies indicate that the anti-plaque action of sanguinaria is due to its ability to inhibit bacterial adherence. Electron microscopic studies of bacteria exposed to sanguinarine demonstrate that bacteria aggregate and become morphologically irregular.^[52]

Sanguinarine appears to be less effective than chlorhexidine mouthwash, but it is effective in many cases and does have the advantage of being a natural compound versus a synthetic.^{[52] [53]}

Centella asiatica

An extract containing the triterpenoids of *Centella asiatica* (gotu kola) has demonstrated impressive wound healing properties (see [Ch. 74](#)). These properties can be put to good use in severe periodontal disease or if there is a requirement for surgery. One study demonstrated that centella extract was quite helpful in speeding up recovery after laser surgery for severe periodontal disease.^[54]

THERAPEUTIC APPROACH

As discussed above, many factors are involved in the initiation and promotion of periodontal disease. Effective therapy requires that all relevant factors be controlled. Since there are as yet no clear guidelines for determining which factors are most important for a given patient, a general approach is recommended here. All smoking patients should be assisted in stopping as continued smoking greatly decreases the success of any therapy for periodontal disease.

Hygiene

Periodic visits to a dentist, as needed, to eliminate plaque and calculus accumulation. Brushing after meals and daily flossing are necessary.

Diet

A diet high in dietary fiber may have a protective effect via increased salivary

secretion.^[18] Avoidance of sucrose and all refined carbohydrates is extremely important.

Supplements

- Vitamin C: 3–5 g/day in divided doses
- Vitamin E: 400–800 IU/day
- Beta-carotenes: 250,000 IU/day (higher doses if indicated) for up to 6 months (although not clinically tested in this condition, beta-carotenes are recommended instead of vitamin A due to their similar effects and greater safety)
- Selenium: 400 mcg/day
- Zinc: 30 mg/day of Zn picolinate (60 mg/day if another form); wash mouth with 15 ml of a 5% solution two times/day
- Folic acid: 2 mg/day; wash mouth with 15 ml of a 0.1% solution two times/day
- Quercetin: 500 mg three times/day.

Botanical medicines

High-flavonoid-containing extracts, such as those from bilberry (*Vaccinium myrtillus*), hawthorn (*Crataegus* sp.), grape seed (*Vitis vinifera*), or green tea (*Camellia sinensis*), can be used according to the dosages in the corresponding chapter. Of these extracts, green tea extract or the liberal consumption of green tea as a beverage may be the most cost-effective. For a green tea extract with a 50% polyphenol content, the dosage would be 200–300 mg twice daily.

- *Sanguinaria canadensis*: use toothpaste containing extract
- *Centella asiatica* triterpenoids: 30 mg twice daily of pure triterpenoids.

Chapter 182 - Pneumonia: bacterial, mycoplasmal, and viral

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

GENERAL CONSIDERATIONS

Acute pneumonia is still the fifth leading cause of death in the United States. It is particularly dangerous in the elderly. Although pneumonia may appear in healthy individuals, it is usually seen in immune-compromised individuals, particularly in drug and alcohol abusers. The growing population of those with chronic lung diseases and other debilitating illnesses and the use of respiratory therapy, immunosuppressive drugs, and other such technologies have contributed to further increase of nosocomial and opportunistic pneumonias, which have very high mortality rates.

In healthy individuals, pneumonia most often follows an insult to the host defense mechanisms: viral infection (especially influenza), cigarette smoke and other noxious fumes, impairment of consciousness (which depresses the gag reflex, allowing aspiration), neoplasms, and hospitalization (see [Table 182.1](#)).

The airway distal to the larynx is normally sterile due to several protective mechanisms, both mechanical and humoral. The mucus-covered ciliated epithelium which lines the lower respiratory tract propels sputum to the larger bronchi and trachea, evoking the cough reflex. The respiratory secretions contain substances which exert non-specific antimicrobial actions: alpha- 1-antitrypsin, lysozyme, and lactoferrin. At the level of the alveoli, potent defense mechanisms are present, including alveolar macrophages, a rich vasculature

TABLE 182-1 -- Etiologies of common pneumonias^[1]

| Type | Percentage |
|-------|------------|
| Viral | 20 |

| | |
|--------------------------------------|-------|
| (influenza) | (3) |
| Mycoplasmal | 10–20 |
| Bacterial | 12 |
| Bacterial superimposed on viral | 6 |
| Chlamydia | 10 |
| Unknown cause (legionnaires', toxic) | 38 |

1494

capable of rapidly delivering lymphocytes and granulocytes, and an efficient lymphatic drainage network.

Immunoglobulin respiratory system defenses

IgA

IgA is present in high concentrations in the secretions of the upper respiratory tract, and protects against viral infection. In the lower tract, IgA aids in:

- agglutinating bacteria
- neutralizing microbial toxins
- reducing bacterial attachment to mucosal surfaces
- activating the alternative complement pathway when complexed with an antigen.

IgG

IgG is present in the lower respiratory tract. It:

- serum agglutinates and opsonizes bacteria
- activates complement
- promotes chemotaxis of granulocytes and macrophages
- neutralizes bacterial toxins and viruses
- lyses Gram-negative bacteria.

THERAPEUTIC CONSIDERATIONS FOR ALL TYPES OF PNEUMONIA

Expectorants

Botanical expectorants have a long history of use in pneumonia. They act to increase the quantity, decrease the viscosity, and promote expulsion of the secretions of the respiratory mucous membranes. Many also have antibacterial and antiviral activity.

Some expectorants are also antitussives; however, *Lobelia inflata*, a commonly used expectorant, actually helps promote the cough reflex.^[2] Therefore, lobelia is much more effective at clearing the lungs than an expectorant like *Glycyrrhiza glabra* (licorice) which also exerts some antitussive effect. If the cough is productive, use lobelia. If it is non-productive use licorice. Other useful expectorants include balsam of Peru, senega root, grindelia, wild cherry bark, and horehound. In addition, bromelain (the proteolytic enzyme complex from pineapple) can be used as a mucolytic (discussed under “Pneumococcal pneumonia”).

Vitamin C

In the early part of this century, before the advent of effective antibiotics, many controlled and uncontrolled studies demonstrated the efficacy of large doses of vitamin C, but only when started on the first or second day of infection.^[3] If administered later, vitamin C tended only to lessen the severity of the disease. Researchers also demonstrated that in pneumonia white cells take up large amounts of vitamin C.^[3]

The value of vitamin C supplementation in elderly patients with pneumonia was demonstrated quite clearly in a recent double-blind study of 57 elderly patients hospitalized for severe acute bronchitis and pneumonia.^[4] The patients were given either 200 mg/day of vitamin C or a placebo. Patients were assessed by clinical and laboratory methods (vitamin C levels in the plasma, white blood cells, and platelets; sedimentation rates; and white blood cell counts and differential). Patients receiving the modest dosage of vitamin C demonstrated substantially increased vitamin C levels in all tissues even in the presence of an acute respiratory infection. Using a clinical scoring system based on major symptoms of respiratory infections, results indicated that the patients receiving the vitamin C fared significantly better than those on placebo. The benefit of vitamin C was most obvious in patients with the most severe illness, many of whom had low plasma and white blood cell vitamin C levels on admission.

Vitamin A

Vitamin A supplementation appears to be of value in pneumonia, especially in children with measles. This may be due to the increased rate of excretion of vitamin A found during severe infections such as pneumonia. An interesting study evaluated 29 patients with pneumonia and sepsis and found their mean excretion rate of vitamin A was 0.78 µmol/day. Subjects with fever excreted significantly more retinol than did those without fever. A remarkable 34% of the patients excreted more than 1.75 µmol/day of retinol, which is equivalent to 50% of the US RDA.^[5]

This may be particularly important for children. A randomized double-blind trial of 189 children with measles (average age 10 months) in South Africa evaluated the efficacy of vitamin A in reducing complications. Providing 400,000 IU (120 mg retinyl palmitate), half on admission and half a day later, reduced the death rate by more than 50%, and the duration of pneumonia, diarrhea and hospital stay by 33%.^[6]

However, another study did not show any benefit from vitamin A supplementation. The difference may be due to the lower dosage (100,000 IU) or to the fact that it was not

limited to children with pneumonia as a complication of measles, a condition known to also decrease vitamin A levels.^[7]

Vitamin E

Patients with influenza complicated by pneumonia experience a sharp rise in lipid peroxidation (LPO) products,

1495

especially those who are seriously ill. Administration of alpha-tocopherol promotes a significant decrease in LPO levels and more apparent clinical response.^[8]

Bromelain

Bromelain is a useful adjunct therapy for pneumonia due to its fibrinolytic, anti-inflammatory, and mucolytic actions and enhancement of antibiotic absorption.^[9] Bromelain's mucolytic activity is responsible for its particular effectiveness in respiratory tract diseases including pneumonia, bronchitis, and sinusitis.^[10]

THERAPEUTIC APPROACH FOR ALL TYPES OF PNEUMONIA

The general approach to all pneumonias includes enhancement of the immune system and support of respiratory tract drainage (for a full discussion of immune system stimulation, see [Ch. 53](#)). Drainage is supported by the use of local heat, massage, and expectorants.

For more discussion on cause-specific therapies for the various pneumonias, see the subsections below.

Supplements

- Vitamin A: 50,000 IU/day for 1 week; or beta-carotene: 200,000 IU/day (Note: do not use vitamin A in menstruating women, due to teratogenic effect)
- Vitamin C: 500 mg every 2 hours
- Vitamin E: 200 IU/day
- Bioflavonoids: 1,000 mg/day
- Zinc: 30 mg/day
- Thymus extract: the equivalent to 120 mg pure polypeptides with molecular weights less than 10,000 or roughly 500 mg of the crude polypeptide fraction.

Botanicals

- *Lobelia inflata*

—dried herb: 0.2–0.6 grams three times/day

—tincture: 15–30 drops three times/day

—fluid extract: 8–10 drops three times/day

- *Echinacea* sp.

- dried root (or as tea): 0.5–1 g

- freeze-dried plant: 325–650 mg

- juice of aerial portion of *Echinacea purpurea* stabilized in 22% ethanol: 2–3 ml

- tincture (1:5): 2–4 ml

- fluid extract (1:1): 2–4 ml

- solid (dry powdered) extract (6.5:1 or 3.5% echinacoside): 150–300 mg

Physical therapy

- Diathermy to chest and back: 30 min/day
- Mustard poultice: once/day
- Lymphatic massage: three times/day
- Postural drainage: three times/day.

For best results, use diathermy, then lymphatic massage, and finally postural drainage.

MYCOPLASMAL PNEUMONIA

DIAGNOSTIC SUMMARY

- Most commonly occurs in children or young adults
- Insidious onset over several days
- Non-productive cough, minimal physical findings, temperature generally less than 102°F
- Headache and malaise are common early symptoms
- WBC is normal or slightly elevated
- X-ray pattern patchy or inhomogeneous.

THERAPEUTIC CONSIDERATIONS

Mycoplasma are bacteria that lack cell walls. *Mycoplasma pneumoniae* is the most frequent cause of community-acquired, non-pyogenic pneumonia. Trachobronchitis is more common than pneumonia, often with pharyngitis (especially in children). Slow

recovery is the general rule, but the course is quite variable.

As there are no specific natural medicine recommendations for mycoplasmal infections available at this time, an antibiotic, typically an erythromycin, is indicated. Enhancement of general immune function is recommended.

ADDITIONAL THERAPIES

Antibiotic

- Erythromycin: 250–500 mg four times/day.

PNEUMOCOCCAL (STREPTOCOCCAL) PNEUMONIA

DIAGNOSTIC SUMMARY

- Pneumonia usually preceded by upper respiratory tract infection
 - Sudden onset of shaking, chills, fever, and chest pain
 - Sputum is pinkish or blood-specked at first, then becoming rusty at the height of the infection, and finally yellow and mucopurulent during resolution
 - Gram-positive diplococci are present in the sputum smear
 - Initially chest excursion is diminished on the
-

1496

- involved side, breath sounds suppressed, and fine inspiratory rales are heard
- Later classic signs of consolidation appear (bronchial breathing, crepitant rales, dullness)
 - Leukocytosis
 - X-ray shows lobar or segmental consolidation.

THERAPEUTIC CONSIDERATIONS

Pneumococcal pneumonia (*Streptococcus pneumoniae*) is the most common bacterial pneumonia and the most common cause of pneumonia requiring hospitalization. Careful clinical judgment is necessary in determining the severity of the disease and the status of the patient's immune system, since it is often necessary to administer antibiotics or to refer for hospitalization. A blood culture is a more accurate method of diagnosis than sputum culture, since 15–25% of all cultures are positive early in the disease, regardless of whether the patient has a bacterial pneumonia or not. This is not surprising, since the nasopharynx is the natural habitat of the pneumococcus (humans are the only known hosts).

Bovine spleen extracts

The most specific natural medicine for pneumococcal pneumonia appears to be bovine spleen extracts (see [Ch. 41](#)). The importance of spleen function in preventing pneumococcal pneumonia is demonstrated by examining post-splenectomy syndrome. One of the hallmark features of this syndrome is an increased risk of pneumococcal pneumonia. About 2.5% of patients having their spleen removed will die from pneumococcal pneumonia within 5 years of splenectomy. It is often recommended that a child that has undergone a splenectomy receive a pneumococcal vaccine and receive long-term antibiotic treatment. Use of spleen extracts, especially those rich in tuftsin, may be an effective natural alternative.

As far back as the 1930s, orally administered bovine spleen extracts were shown to possess some physiological action in increasing white blood cell counts in patients with extreme deficiencies of white blood cells, as well as being of some benefit in patients with malaria and typhoid fever.^{[11] [12] [13]}

Hydrastis canadensis

Hydrastis canadensis and probably other berberine-containing botanicals are very important in treating this difficult infection. Berberine has well documented antibiotic activity against pathogenic streptococci.^[14] In addition, its sparing effect on the normal gastrointestinal microbial flora is an advantage as compared with conventional antibiotics.

Antibiotics

Bacterial pneumonia is one of the conditions in which the conventional antibiotic approach, typically penicillin G or V, is clearly of great value for the patient. In general, an appropriately prescribed course of antibiotics will lead to substantial clinical improvement within a few days.

ADDITIONAL THERAPIES

Supplements

- Bovine spleen extracts: hydrolyzed (predigested) products concentrated for tuftsin and splenopentin content are preferable to crude preparations – 50 mg/day tuftsin and splenopentin or roughly 1.5 g/day of total spleen peptides
- Bromelain (1,200 to 1,800 mcu): 500–750 mg three times/day between meals.

Botanical medicines

Hydrastis canadensis. The dosage should be based on berberine content. As there is a wide range of quality in goldenseal preparations, standardized extracts are recommended. Three times a day dosages as follows:

- dried root or as infusion (tea): 2–4 g
- tincture (1:5): 6–12 ml (1.5–3 tsp)
- fluid extract (1:1): 2–4 ml (0.5–1 tsp)
- solid (powdered dry) extract (4:1 or 8–12% alkaloid content): 250–500 mg.

Antibiotic

- Penicillin V: 500 mg four times/day (for uncomplicated cases).

VIRAL PNEUMONIA

DIAGNOSTIC SUMMARY

- Onset typical of influenza: fever, myalgia, and headache
- Other symptoms, signs, and X-ray findings are similar to mycoplasmal pneumonia.

THERAPEUTIC CONSIDERATIONS

In addition to the treatment recommendations given under the general discussion of pneumonia, *Glycyrrhiza glabra* (licorice) is useful for its antiviral properties, immune-enhancing effects, and expectorant effects (see [Ch. 90](#)). Note, however, that glycyrrhiza does have some antitussive effect. In the case of viral pneumonia, this action is usually warranted. However, if the cough is productive, use lobelia.

1497

ADDITIONAL THERAPY

- *Glycyrrhiza glabra* (licorice)
 - powdered root: 1–2 g
 - fluid extract (1:1): 2–4 ml
 - solid (dry powdered) extract (4:1): 250 to 500 mg.

Chapter 183 - Premenstrual syndrome

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

DIAGNOSTIC SUMMARY

- Recurrent signs and symptoms that develop during the 7–14 days prior to menstruation
- Typical symptoms include: decreased energy, tension, irritability, depression, headache, altered sex drive, breast pain, backache, abdominal bloating, and edema of the fingers and ankles.

GENERAL CONSIDERATIONS

Premenstrual syndrome (PMS) is a recurrent condition of women characterized by troublesome symptoms 7–14 days before menstruation.^[4] Typical symptoms include (see also [Table 183.1](#)):

- decreased energy
- tension
- irritability
- depression
- headache
- altered sex drive
- breast pain
- backache
- abdominal bloating
- edema of the fingers and ankles.

TABLE 183-1 -- Signs and symptoms of the premenstrual syndrome

Behavioral

- Nervousness, anxiety, and irritability
- Mood swings and mild to severe personality change
- Fatigue, lethargy, and depression

Gastrointestinal

- Abdominal bloating
- Diarrhea and/or constipation
- Change in appetite (usually craving of sugar)

Female

- Tender and enlarged breasts
- Uterine cramping
- Altered libido

General

- Headache
 - Backache
 - Acne
 - Edema of fingers and ankles
-

1500

PMS is estimated to affect between 30 and 40% of menstruating women, with peak occurrences among women in their 30s and 40s. In most cases symptoms are relatively mild; however, in about 10% of women symptoms can be quite severe. Severe PMS with depression, irritability, and severe mood swings is referred to as premenstrual dysphoric disorder.^[2]

Although PMS has been a well-defined clinical entity for over 60 years, many physicians argue that it really does not exist.^[3] As a result many women suffering from PMS do not receive proper treatment. Instead they are told that it is “all in your head”. This view is gaining even more momentum as large pharmaceutical companies have recognized the huge market potential and began to sponsor clinical trials using psychotropic drugs (e.g. antidepressant drugs like Prozac and Zoloft; anti-anxiety drugs related to Valium; and gonadotropin-releasing hormone) to treat PMS symptoms despite the fact that risks due to side-effects appear to far outweigh the benefit.^[4]

A more rational approach to the problem of PMS is identification of the causative factors and appropriate treatment using dietary therapy, nutritional supplementation, and exercise.

Hormonal patterns in women with PMS

Although there is a wide spectrum of symptoms, there are common hormonal patterns in PMS patients when compared with women who have no symptoms of PMS. The primary finding is that estrogen levels are elevated and plasma progesterone levels are reduced 5–10 days before the menses, or the ratio of estrogen to progesterone is increased. In addition to this hormonal abnormality, hypothyroidism and/or elevated prolactin levels are common; FSH levels are typically elevated 6–9 days prior to the onset of menses and aldosterone levels are marginally elevated 2–8 days prior to the onset of menses.^{[1] [5] [6]}

Corpus luteum insufficiency and PMS

PMS symptoms occur during the luteal phase of the menstrual cycle. During this phase, the corpus luteum plays an important role in the production of progesterone primarily, but also of estrogen. It is theorized by many researchers and clinicians that PMS reflects “corpus luteum insufficiency”. Corpus luteum insufficiency is usually diagnosed by measuring the level of progesterone in the blood 3 weeks after onset of menstruation. If the level in the blood is below 10–12 ng/ml, corpus luteal insufficiency is a strong possibility.

In addition to PMS, corpus luteal insufficiency has also been linked to abnormal menstruation (excessive blood loss, absent, persistent, and more frequent menstruation), elevations in prolactin, and low thyroid function.^[7]

DIAGNOSIS AND CLASSIFICATIONS

Diagnosis of PMS is usually made by the association of the symptoms attributed to PMS and their occurrence during the luteal phase of the menstrual cycle. To aid in the diagnosis, symptom questionnaires are often used. Since recalled information is less accurate, in addition to a symptom questionnaire, it is a good idea to have the patient keep a menstrual symptom diary. The diary will help in documenting improvement as well as further clarifying the symptom pattern. Both a questionnaire and diary are provided in [Appendix 9](#) .

PMS classifications

In an attempt to bring some order to the clinically and metabolically confusing picture of PMS, several experts have created classification systems that identify PMS sufferers into subgroups.^[8] The system recommended here is the one developed by Dr Guy Abraham which divides PMS into four distinct subgroups.^[9] Each subgroup is linked to specific symptoms, hormonal patterns, and metabolic abnormalities. Following is a brief discussion of the individual subgroups. Please note that rarely do women experience a particular subgroup in a pure form; usually there are aspects of two or more subgroups that a woman with PMS experiences. A PMS questionnaire based on Dr Abraham’s

classifications can be found in [Appendix 9](#) .

PMS-A

PMS-A (A = anxiety) is the most common symptom category and is found to be strongly associated with excessive estrogen and deficient progesterone during the premenstrual phase. Common symptoms in patients in this category are anxiety, irritability, and emotional instability.

PMS-C

PMS-C (C = carbohydrate craving) is associated with increased appetite, craving for sweets, headache, fatigue, fainting spells, and heart palpitations. Glucose tolerance tests (GTT) performed on PMS-C patients during the 5–10 days before their menses show a flattening of the early part of the curve (which usually implies excessive secretion of insulin in response to sugar consumption), whereas during other parts of the menstrual cycle their GTT is normal.^[2] Currently, there is no clear explanation

1501

for this phenomenon, although an increased cellular capacity to bind insulin has been postulated. This increased binding capacity for insulin appears to be hormonally regulated, but other factors may also be involved, such as a high salt intake or decreased magnesium or prostaglandin levels.

PMS-D

PMS-D (D = depression) is the least common and is relatively rare in its pure form. Its key symptom is depression which is usually associated with low levels of neurotransmitters in the central nervous system. In PMS-D patients this is most likely due to increased breakdown of the neurotransmitters as a result of decreased levels of estrogen (in contrast to PMS-A which shows just the opposite results). The decreased ovarian estrogen output has been attributed to a stress-induced increase in adrenal androgen and/or progesterone secretion.

PMS-H

PMS-H (H = hyperhydration) is characterized by weight gain (greater than 1.5 kg), abdominal bloating and discomfort, breast tenderness and congestion, and occasional swelling of the face, hands and ankles. These symptoms are due to an increased fluid volume secondary to an excess of the hormone aldosterone which causes increased fluid retention. Aldosterone excess during the premenstrual phase of PMS-H patients may arise due to stress, estrogen excess, magnesium deficiency, or excess salt intake.

An alternative classification system and diagnostic hierarchy

Abraham's system is very useful in quickly identifying possible causes in a given case of PMS based on symptoms. However, an alternative is to classify patients according to cause. Of course, in order to classify the patient the causative factor(s) must be identified. The most common causative factors are discussed under "Therapeutic considerations".

The detection of these causative factors involves a diagnostic hierarchy based upon the clinical picture and history. Following the steps listed below should lead to the proper identification of the causative factor (if necessary). As a result, a more effective treatment plan can be tailored for the specific needs and as a result better relief achieved:

1. Begin following the recommendations summarized in "Therapeutic approach" ([p. 1510](#)).
2. Rule out hypothyroidism. Have the patient determine their basal body temperature (discussed in [Ch. 160](#)). If the basal body temperature is below 97.8°F, or if other symptoms associated with hypothyroidism are present, perform blood measurement of TSH and T₄.
3. Rule out depression.
4. If the patient has followed the recommendations in step 1, ruled out or addressed hypothyroidism or depression, and has not improved after 2–3 cycles, perform a complete blood count and chemistry panel (including serum ferritin, thyroid panel, and estrogen, progesterone, and prolactin levels) on day 21 of her cycle. The test should include:
 - a. complete blood count (CBC)
 - b. chemistry panel
 - c. thyroid panel
 - (i) T₃ uptake
 - (ii) thyroxine
 - (iii) free thyroxine index
 - d. ferritin
 - e. progesterone
 - f. estrogen
 - g. prolactin.
5. If there are no apparent abnormalities in the CBC and chemistry panel, additional recommended tests include: liver detoxification profile (see [Ch. 16](#)), adrenal stress index and food allergy detection (see [Ch. 15](#)).

THERAPEUTIC CONSIDERATIONS

PMS represents a “heterogenous” or “multifactorial” condition as there is no single cause that explains PMS in every case. Many factors appear to play a role, with some factors being more important in one case than another. However, there is tremendous overlap. [Table 183.2](#) lists the most common factors causing or contributing to PMS.

Estrogen and progesterone

One of the most common findings in women with PMS is an elevated estrogen to progesterone ratio.^{[1] [10] [11] [12] [13] [14]} Most commonly this derangement is caused by a combined mild estrogen excess and mild progesterone deficiency. The physiological effects of such an imbalance are listed in [Table 183.3](#).

TABLE 183-2 -- The primary causes of PMS

| |

Estrogen excess and liver function

In the early 1940s, Dr Morton Biskind observed an apparent relationship between B vitamin deficiency and PMS.^{[15] [16]} He postulated that PMS, as well as excessive menstruation and fibrocystic breast disease, was due to an excess in estrogen levels caused by decreased detoxification and elimination in the liver due to B vitamin deficiency. The liver utilizes various B vitamins to detoxify estrogen and excrete it in the bile.

There appears to be support for Dr Biskind's theory. Estrogen excess is known to produce cholestasis, a term which signifies diminished bile flow or stasis of bile. Naturopathic physicians often refer to this condition as a "sluggish liver". It reflects minimal impairment of liver function because normal indicators of liver status (such as liver enzymes: alkaline phosphatase, SGOT, SGPT, and GGTP) are not elevated. These enzymes, the conventional means of assessing liver status, are not very useful as they really only indicate liver damage, as they are only elevated when the liver is damaged. They have little correlation with liver function. Because of the liver's important role in numerous metabolic processes, even minor impairment of liver function can have profound effects.

Cholestasis can be caused by a large number of factors besides estrogen excess (see [Table 183.4](#)). The presence of cholestasis may be a predisposing factor to PMS, as with cholestasis there is reduced estrogen detoxification and clearance. Hence, a positive feedback scenario is produced. The high incidence of gallstones is a clear indication that many American women suffer from cholestasis.

Effects of estrogen on neurotransmitters

Another possible result of the increase in the estrogen to progesterone ratio is impairment of neurotransmitter

TABLE 183-4 -- Causes of cholestasis

synthesis and endorphin activity. This is one reason antidepressant drug therapy of PMS is gaining increased popularity, even though it does not address the underlying cause of the neurotransmitter dysfunction. It is interesting to note that the majority of the over 12 million patients on Prozac are women between the ages of 25 and 50 – the same population that has a high frequency of PMS.

Estrogen excess and endorphin levels

Estrogen excess during the luteal phase also negatively affects endorphin levels. One study found a direct correlation between an increased estrogen to progesterone ratio and endorphin activity in the brain.^[11] In essence, when the estrogen to progesterone ratio was increased there was a decline in endorphin levels. This reduction is significant considering the known ability of endorphins to normalize or improve mood. Other studies have shown that low endorphin levels during the luteal phase are common in women with PMS.^[17] Endorphins are lowered by stress and raised by exercise. The role of endorphins are further discussed below.

Estrogen impairs vitamin B₆

The way in which estrogen excess during the luteal phase negatively affects neurotransmitter and endorphin levels may be secondary to impairment of vitamin B₆ action. It is well known that estrogens negatively affect vitamin B₆ function. Vitamin B₆ levels are typically quite low in depressed patients, especially women taking estrogens (birth control pills or Premarin).^{[18] [19]} Vitamin B₆ supplementation has been shown to exert positive effects on all PMS symptoms (particularly depression) in many women (discussed in greater below). The improvement is achieved via a combined reduction in mid-luteal estrogen levels and an increase in mid-luteal progesterone levels.

Estrogen effects on aldosterone

In many cases of PMS, aldosterone levels are marginally elevated 2–8 days prior to the onset of menses. This elevation may be a result of estrogen excess increasing the secretion of aldosterone.

Estrogen and prolactin secretion

Excessive levels of prolactin are implicated in many cases of PMS, especially in women experiencing breast pain or fibrocystic breast disease (discussed in [Ch. 151](#)).^{[20] [21]} Estrogens, both internally produced and ingested as birth control pills or Premarin, are known to increase prolactin secretion by the pituitary gland. Following the

recommendations given below for lowering the luteal phase estrogen to progesterone

ratio may be all that is necessary to lower prolactin levels. In particular, the herb *Vitex agnus-castus* (chaste berry) may prove to be very useful in cases of high prolactin levels due to corpus luteum insufficiency (discussed below). Vitamin B₆ and zinc supplementation also lower prolactin levels and are discussed below. Prolactin levels also tend to be elevated in low thyroid function.

Reducing the estrogen to progesterone ratio

Central to effective treatment in most cases of PMS is lowering of the luteal phase estrogen to progesterone ratio. An elevation in this ratio may be the underlying factor in the hormonal, neurotransmitter, endorphin, and other physiological disturbances in most cases of PMS. Effective treatment usually involves six components.

Diet

A number of dietary factors are known to reduce circulating estrogens or block the attachment of estrogen to receptor sites. Chief among these dietary recommendations are the following:

- increase the consumption of plant foods (vegetables, fruits, legumes, whole grains, nuts, and seeds)
- limit consumption of meat and dairy products
- reduce fat and sugar intake
- increase consumption of soy foods.

In addition, it is important to reduce the load of environmental estrogens by avoiding foods sprayed with pesticides and herbicides.

Gastrointestinal flora

One of the key ways in which the liver detoxifies cancer-causing chemicals as well as the body's hormones such as estrogen is via attaching glucuronic acid to the toxin and excreting it in the bile. Beta-glucuronidase is a bacterial enzyme which uncouples (breaks) the bond between excreted toxins and glucuronic acid. Not surprisingly, it has been found that excess beta-glucuronidase activity is associated with an increased cancer risk, particularly estrogen-dependent breast cancer, and presumably PMS. The activity of this enzyme can be reduced by establishing a proper bacterial flora.^[22] The dietary guidelines go a long way toward this goal. In addition, supplementation with probiotics helps to establish a normal intestinal flora. Probiotics, literally translated, means "for life", and is a term used to signify the health-promoting effects of "friendly bacteria". The most important friendly bacteria are *Lactobacillus acidophilus* and *Bifidobacterium bifidum*.

The dosage of a commercial probiotic supplement is based upon the number of live organisms. The ingestion of 1–10 billion viable *L. acidophilus* or *B. bifidum* cells daily is a sufficient dosage for most people. Amounts exceeding this may induce mild gastrointestinal disturbances, while smaller amounts may not be able to colonize the

gastrointestinal tract. Probiotics are extremely safe and are not associated with any side-effects.

Nutritional supplements

Estrogen excess is known to stress nutritional needs for B vitamins, magnesium, and possibly other nutrients. In addition, B vitamins and magnesium are also necessary for the proper detoxification of estrogens.

Liver detoxification

Supporting liver function focuses on protecting the liver by following the dietary guidelines above and the nutritional supplement recommendations below. In addition, most naturopathic physicians often use formulas containing “lipotropic factors”. Lipotropic factors are, by definition, substances that hasten the removal or decrease the deposition of fat and bile in the liver through their interaction with fat metabolism. In essence, they produce a “decongesting” effect on the liver and promote improved liver function and fat metabolism. Compounds commonly employed as lipotropic agents include choline, methionine, betaine, folic acid, and vitamin B₁₂, along with herbal cholagogues and choloretics. Most major manufacturers of nutritional supplements offer lipotropic formulas. The typical daily doses are 1,000 mg of choline and 500 mg of methionine and/or cysteine.

Botanical medicines

Chaste berry (*Vitex agnus-castus*) and phytoestrogen-containing herbs like dong quai, black cohosh, and licorice are popular herbal recommendation for PMS. Their appropriate use is described below.

Progesterone therapy

Although progesterone administration is a popular recommendation made by many physicians (MDs and NDs alike), we have some reservations. First of all, although progesterone administration has been the most common prescription for PMS by the medical community, controlled clinical trials have failed to consistently demonstrate the superiority of progesterone therapy over a placebo (there is a significant placebo response in PMS).^[23] ^[24] ^[25] ^[26] ^[27] ^[28] The studies that are positive have used

dosages which far exceed the normal levels for progesterone (200–400 mg twice daily as a vaginal or rectal suppository from 14 days before the expected onset of menstruation until the onset of vaginal bleeding).^[27] ^[28] Side-effects, although generally mild, are common. In one of the more recent double-blind studies that did show a positive effect with progesterone therapy (400 mg twice a day by vaginal or rectal

administration), adverse events were reported by 51% of patients in the progesterone treatment group (compared with 43% in the placebo group).^[28] Irregularity of menstruation, vaginal itching, and headache were reported more frequently by the women taking the progesterone. Secondly, philosophically we would rather help the body to naturally improve the estrogen and progesterone ratio by addressing the underlying causative factors such as reduced detoxification or clearance of estrogen along with reduced corpus luteum function rather than artificially and drastically tipping the ratio in favor of progesterone. We do not recommend progesterone creams as the first step for treating PMS, but rather as a possible last choice after other natural measures have failed.

Thyroid function

Low thyroid function (hypothyroidism) has been shown to affect a large percentage of women with PMS.^[29] ^[30] For example, in one study, 51 of 54 PMS subjects demonstrated low thyroid status compared with 0 of 12 for the control group.^[29] In another study, seven of 10 in the PMS group were low compared with 0 of 9 for the control group.^[30] Other studies have also shown hypothyroidism to be only slightly more common in women with PMS compared with controls.^[31] ^[32] Many women with PMS and confirmed hypothyroidism given thyroid hormone experience complete relief of symptoms.^[29] For more information see [Chapter 162](#) .

Stress, endorphins, and exercise

Like many common conditions associated with “modern” living, stress definitely plays a role in PMS. When stress is extreme, unusual, or long-lasting, it triggers biological changes in the brain largely as a result of altered adrenal gland function and endorphin secretion or action. These changes produce a domino effect as they lead to alterations in normal physiology. Effective treatment of PMS must include stress management (see [Ch. 60](#)).

Exercise

Several studies have shown that women engaged in a regular exercise program do not suffer from PMS nearly as often as sedentary women.^[33] ^[34] ^[35] In one of the more thorough studies, mood and physical symptoms during the menstrual cycle were assessed in 97 women who exercised regularly and in a second group of 159 female non-exercisers.^[33] Mood scores and physical symptoms assessed throughout the menstrual cycle revealed significant effects for exercise on negative mood states and physical symptoms. The regular exercisers obtained significantly lower scores on impaired concentration, negative mood, behavior change, and pain.

In another study, 143 women were monitored for 5 days in each of the three phases of the cycle (mid-cycle, premenstrual and menstrual).^[34] The women were 35 competitive athletes, two groups of exercisers (33 high exercisers and 36 low exercisers) and 39 sedentary women. The high exercisers experienced the greater positive mood scores and sedentary women the least. The high exercisers also reported the least depression and anxiety. The differences were most apparent during the premenstrual and

menstrual phases. These results are consistent with the belief that women who frequently exercise (but not competitive athletes) are protected from PMS symptoms. In particular, regular exercise protects against the deterioration of mood before and during menstruation.

These studies provide evidence that women with PMS need to exercise. One of the ways exercise may be positively impacting PMS is through elevations in endorphin levels and lowering of cortisol levels.

Coping style

Many women with PMS tend to employ “negative” coping styles.^[36] Examples of negative coping mechanisms are listed in [Table 183.5](#).

It is important to identify the manner in which the patient deals with stress and to counsel them on more positive ways of coping.

Psychotherapy

Various psychotherapy methods have been successful in improving the psychological aspects of PMS. In particular, psychotherapy in the form of biofeedback or short-term individual counseling (especially cognitive therapy) has documented clinical efficacy.^[37]^[38] One of the advantages that cognitive therapy in the treatment

TABLE 183-5 -- Negative coping styles in women with PMS

| |
|----------------------------|
| • Feelings of helplessness |
| • Overeating |
| • Too much television |
| • Emotional outbursts |
| • Overspending |
| • Excessive behavior |
| • Dependence on chemicals |
| —drugs, legal and illicit |
| —alcohol |
| —smoking |

of PMS has over antidepressant drug therapy is that learning techniques such as cognitive-behavioral coping skills can produce excellent results that will be maintained

over time.

Depression and low serotonin

There are some important relationships between PMS and depression. Depression is a common feature in many cases of PMS, and PMS symptoms are typically more severe in depressed women.^[1] The reason appears to be a decrease in the brain level of various neurotransmitters, with serotonin and gamma-aminobutyric acid (GABA) being the most significant.^{[39] [40]} Use of antidepressant drugs like Prozac is quickly becoming the dominant medical treatment for PMS.^[1] Approximately 80% of the 12 million Americans on Prozac are women between the ages of 25 and 50. Not surprisingly, this also represents the highest frequency of PMS.

Dietary considerations

Women suffering from PMS typically eat a diet which is even worse than the standard American diet. Guy Abraham MD reports that, compared with symptom-free women, PMS patients consume:^[9]

- 62% more refined carbohydrates
- 275% more refined sugar
- 79% more dairy products
- 78% more sodium
- 53% less iron
- 77% less manganese
- 52% less zinc.

In addition to providing benefits against PMS symptoms, the dietary recommendations given below also provide significant protection against the development of breast cancer, other cancers, heart disease, strokes, osteoporosis, diabetes, and virtually every other chronic degenerative disease.

The seven most important dietary recommendations for PMS are listed in [Table 183.6](#) .

Vegetarian diet and estrogen metabolism

Vegetarian women have been shown to excrete two to

TABLE 183-6 -- Dietary recommendations for women suffering from PMS

-
- Vegetarian or predominantly vegetarian diet
-
- Reduce the intake of fat
-
- Eliminate sugar
-
- Reduce exposure to environmental estrogens
-
- Increase the intake of soy foods
-

- Eliminate caffeine
 - Keep salt intake low
-

three times more estrogen in their feces and have 50% lower levels of free estrogen in their blood compared with omnivores.^[41] ^[42] These differences are thought to be a result of the lower fat and higher fiber intake of the vegetarian women. These dietary differences may also explain the lower incidence of breast cancer, heart disease, and menopausal symptoms in vegetarian women.

At the very least, recommend a diet lower in saturated fat and cholesterol (achieved by reducing or eliminating the amounts of animal products) and higher in fiberrich plant foods (fruits, vegetables, grains, and legumes). Limit the intake of animal protein sources to no more than 110–170 mg/day and recommend fish, skinless poultry, and lean cuts rather than fat-laden choices.

It appears that many of the effects that a vegetarian diet has on lowering circulating estrogen levels are related to a higher intake of dietary fiber. The fiber promotes the excretion of estrogens directly and indirectly by promoting a more favorable bacterial flora with lower levels of beta-glucuronidase activity.

Fat intake and estrogen metabolism

Decreasing the percentage of calories as fat, in particular saturated fat, has dramatic effects on reducing circulating estrogen.^[43] ^[44] In one study, when 17 women switched from the SAD, composed of 40% of calories as fat and only 12 g as fiber, to a low-fat, high-fiber diet consisting of 25% of the calories as fat and 40 g as fiber daily, there was a 36% reduction in blood estrogen levels, with 16 out of the 17 women demonstrating significant reductions in only 8–10 weeks.^[45] A low-fat diet has also been shown to improve PMS symptoms.^[45]

Besides possibly improving PMS symptoms, another good reason to reduce the intake of fat is that there is a great deal of research linking a diet high in saturated fat and cholesterol to numerous cancers, heart disease, and strokes. Both the American Cancer Society and the American Heart Association have recommended a diet containing less than 30% of calories as fat.

The easiest way for most people to achieve this goal is to eat less animal products and more plant foods. With the exception of nuts and seeds, most plant foods are very low in fat. With regard to nuts and seeds, while they do contain high levels of fat calories, the calories are derived largely from polyunsaturated essential fatty acids. It is also very important to eliminate the intake of margarine and foods containing *trans*-fatty acids and partially hydrogenated oils.

Sugar

Sugar has several detrimental actions in PMS. Eating foods high in simple sugars

increases insulin secretion and can be harmful to blood sugar control, especially if

1506

the patient is hypoglycemic or diabetic. Sugar, especially when combined with caffeine, also has a detrimental effect on PMS and mood (discussed below). The most significant symptom-producing food in PMS appears to be chocolate.^[46] A high intake of sugar also impairs estrogen metabolism. The evidence is based on the higher frequency of PMS symptoms in women consuming a high-sugar diet and the fact that a high sugar intake is also associated with higher estrogen levels.^[47]

Encourage patients to read food labels carefully for clues about sugar content. If the words sucrose, glucose, maltose, lactose, fructose, corn syrup, or white grape juice concentrate appear on the label, extra sugar has been added.

Environmental estrogens

Widespread environmental contamination has occurred with a group of compounds known as “halogenated hydrocarbons”. Included in this group are the toxic pesticides DDT, DDE, PCB, PCP, dieldrin, and chlordane. These molecules are hard to break down and are stored in fat cells. These chemicals mimic estrogen in the body and are thought to be a major factor in the growing epidemics of estrogen-related health problems such as PMS, breast cancer, and low sperm counts.^[48] ^[49]

Soy foods

Soy and soy foods contain compounds referred to as “phytoestrogens” because they are capable of binding to estrogen receptors. Phytoestrogens are also often referred to as “anti-estrogens” because their estrogenic effect is only 2% as strong as estrogen at the very most. However, because of this low activity, phytoestrogens have a balancing action on estrogen effects. If estrogen levels are low (as in menopause), since phytoestrogens have some estrogenic activity, they will cause an increase in estrogen effect. If estrogen levels are high (as in PMS), since phytoestrogens bind to estrogen receptor binding sites, thereby competing with estrogen, there will be a decrease in estrogen effects.

Caffeine

Caffeine must be avoided by patients with PMS, especially if anxiety or depression, or breast tenderness and fibrocystic breast disease are major symptoms.^[50] ^[51] There is considerable evidence demonstrating that caffeine consumption is strongly related to the presence and severity of PMS. The effect of caffeine is particularly significant in the psychological symptoms associated with PMS such as anxiety, irritability, insomnia, and depression. The effect of caffeine on fibrocystic breast disease is discussed in [Chapter](#)

Salt

Excessive salt (sodium chloride) consumption, coupled with diminished dietary potassium, greatly stresses the kidney's ability to maintain proper fluid volume. As a result some people are "salt-sensitive", in that high salt intake increases blood pressure and/or water retention. Patients who experience more water retention during the mid-luteal phase may be especially sensitive to salt intake. However, it is simply not a matter of reducing salt intake, as potassium intake must be simultaneously increased. This is easily done by increasing the intake of high-potassium foods (i.e. fruits and vegetables) and decreasing high-sodium foods (most processed foods). Total daily sodium intake should be below 1,800 mg.

Micronutrients

Although all essential nutrients are critical to good health and in dealing with PMS symptomatology, our discussion focuses on the six key nutrients followed by some practical recommendations.

Vitamin B₆

The first use of vitamin B₆ in the management of cyclical conditions in women was in the successful treatment of depression caused by birth control pills as noted in several studies in the early 1970s. These results led researchers to try and determine the effectiveness of vitamin B₆ in relieving PMS symptoms. Since 1975 there have been at least a dozen double-blind clinical trials.^{[52] [53]} The majority of these studies have demonstrated a positive effect. For example, in one double-blind cross-over trial, 84% of the subjects had a lower symptomatology score during the B₆ treatment period.^[54] Although PMS has multiple causes, B₆ supplementation alone appears to benefit most patients.

It is important to note, however, that not all double-blind studies of vitamin B₆ have been positive.^{[52] [53]} These negative results may have been caused by many factors, such as the inability of some women to convert B₆ to its active form due to a deficiency in another nutrient (e.g. vitamin B₂ or magnesium) which was not supplemented. These results suggest that supplementing pyridoxine by itself may not result in adequate clinical results for all women suffering from this disorder and that some women may have difficulty converting vitamin B₆ into its active form, pyridoxal-5-phosphate. To overcome this conversion difficulty, it may be necessary to use a broader-spectrum nutritional supplement or to use injectable pyridoxal-5-phosphate.

For most indications, the therapeutic dosage of vitamin B₆ is 50–100 mg daily. This dosage level is generally regarded as being safe, even for long-term use. When using

dosages greater than 50 mg, it may be important to divide it into 50 mg dosages throughout the day. A single dosage of 100 mg of pyridoxine did not lead to a significant increase in pyridoxal-5-phosphate levels in the blood, indicating that a 50 mg oral dosage of pyridoxine is about all the liver can handle at once.^[55]

Vitamin B₆ is one of the few water-soluble vitamins that is associated with some toxicity when taken in large doses or moderate dosages for long periods of time. One-time doses greater than 2,000 mg/day can produce symptoms of nerve toxicity (tingling sensations in the feet, loss of muscle coordination, and degeneration of nerve tissue) in some individuals. Chronic intake of dosages greater than 500 mg daily can be toxic if taken daily for many months or years.^[56] There are also a few rare reports of toxicity occurring at chronic long-term dosages as low as 150 mg/day.^{[56] [57] [58]} The toxicity is thought to be a result of supplemental pyridoxine overwhelming the liver's ability to add a phosphate group to produce the active form of vitamin B₆ (pyridoxal-5-phosphate). As a result it is speculated that either pyridoxine is toxic to the nerve cells or it actually acts as an anti-metabolite by binding to pyridoxal-5-phosphate receptors, thereby creating a relative deficiency of vitamin B₆. Another possibility is that minute amounts of contaminants or vitamin B₆ analogs may have been introduced during synthesis. While at normal dosages these are not a problem, at larger dosages they may block B₆ activation sites. Again, it appears to make sense to limit dosages to 50 mg at a time. If more than 50 mg/day is desired, then the dosages should be spread out throughout the day.

There are extensive interactions between vitamin B₆ and magnesium as they work together in many enzyme systems. In fact, one of the ways in which vitamin B₆ may improve the symptoms of PMS is by increasing the accumulation of magnesium within the cells of the body.^[59] In fact, without vitamin B₆, magnesium will not get inside the cell.

Magnesium

Magnesium deficiency is strongly implicated as a causative factor in premenstrual syndrome.^[60] Red blood cell magnesium levels in PMS patients have been shown to be significantly lower than in normal subjects.^{[9] [61]} As magnesium plays such an integral part in normal cell function, magnesium deficiency may account for the wide range of symptoms attributed to PMS. Furthermore, magnesium deficiency and PMS share many common features, and magnesium supplementation has been shown to be an effective treatment of PMS.^[62]

A recent study designed to better understand the association between magnesium and the menstrual cycle measured plasma, red blood cell (RBC), and mononuclear blood cell (MBC) magnesium in 26 women with confirmed PMS and in a control group of 19

women during the follicular, ovulatory, early luteal, and late luteal phases of the menstrual cycle.^[63]

The principal findings of the study were as follows:

- There were no significant differences in plasma magnesium levels in PMS patients compared with controls, nor was there a menstrual cycle effect on plasma magnesium in either group.
- PMS patients had significantly lower RBC and MBC magnesium concentrations compared with controls.
- These lower RBC and MBC magnesium concentrations were consistent across the menstrual cycle.
- Magnesium measures did not correlate with the severity of mood symptoms.

The observation of low RBC magnesium concentrations in PMS patients has now been confirmed by four independent studies. In general, it is thought that women with PMS have a “vulnerability to luteal phase mood state destabilization” and that chronic, and enduring intracellular magnesium depletion serves as a major predisposing factor towards destabilization.

In addition to emotional instability, magnesium deficiency in PMS is characterized by excessive nervous sensitivity with generalized aches and pains, and a lower premenstrual pain threshold. One clinical trial of magnesium in PMS showed a reduction of nervousness in 89%, breast tenderness in 96%, and weight gain in 95%.^[9] In another double-blind study, high-dosage magnesium supplementation (360 mg three times daily) was shown to dramatically relieve PMS-related mood changes.^[62]

While magnesium has been shown to be effective on its own, even better results may be achieved by combining it with vitamin B₆ and other nutrients. Several studies have shown that when PMS patients are given a multivitamin and mineral supplement containing high doses of magnesium and pyridoxine they experience a substantial reduction in PMS symptoms.^{[64] [65]}

The optimum intake for magnesium should be based on body weight, 6 mg/kg. For a 50 kg woman, the recommendation would be 300 mg, 420 mg for a 154 pound woman, and 540 mg for a 90 kg woman. As this is difficult to achieve by diet alone, supplementation is recommended. In the treatment of PMS, a dosage of twice this amount, 12 mg/kg, may be needed.

Magnesium bound to aspartate or one of the Krebs cycle intermediates (malate, succinate, fumarate, or citrate) is preferred to magnesium oxide, gluconate, sulfate, and chloride due to better absorption and fewer side-effects (laxative effects).^{[66] [67]}

Calcium

Calcium appears to be a bit of a double-edged sword in PMS. High calcium intake due

is linked as a possible causative factor perhaps by the combination of calcium, vitamin D, and phosphorus of milk reducing the absorption of magnesium.^[9] At the same time, there are studies showing positive improvements in PMS symptomatology with calcium supplementation (1,000–1,336 mg).^[68] ^[69] In one of the more recent studies, calcium and manganese supplementation (1,336 and 5.6 mg, respectively) improved mood, concentration, and behavior. In another study, 1,000 mg/day improved mood and water retention.^[68] It is theorized, based primarily on animal research, that calcium improves the altered hormonal patterns, neurotransmitter levels, and smooth muscle responsiveness noted in PMS.

Further support for the importance of calcium supplementation in PMS was the finding that women with PMS have reduced bone mineral density (based on dual-photon absorptiometry).^[70]

Zinc

Zinc levels have been shown to be low in women with PMS.^[71] Zinc is required for proper action of many body hormones, including the sex hormones, as well as in the control of the synthesis and secretion of hormones. In particular, zinc serves as one of the control factors for prolactin secretion.^[72] When zinc levels are low, prolactin release increases, while high zinc levels inhibit this release. Hence, in high prolactin states, zinc supplementation is very useful. An effective dosage range for zinc supplementation for elevated prolactin levels in women is 30–45 mg in the picolenate form.

Vitamin E

Although vitamin E research concerning PMS has focused primarily on breast tenderness, significant reduction of other PMS symptomatology has also been demonstrated in double-blind studies.^[9] ^[73] Nervous tension, headache, fatigue, depression, and insomnia were all significantly reduced. In one double-blind study, patients receiving vitamin E (400 IU/day) demonstrated a 33% reduction in physical symptoms (such as weight gain and breast tenderness), a 38% reduction in anxiety, and a 27% reduction in depression after 3 months of use. In contrast, the placebo group only reported a 14% reduction in physical symptoms. The group taking vitamin E also noted higher energy levels, fewer headaches, and less cravings for sweets.

Essential fatty acids

Women with PMS have been shown to exhibit essential fatty acid and prostaglandin abnormalities, with the chief abnormality most often reported being a decrease in gamma-linolenic acid (GLA).^[74] Gamma-linolenic acid is derived from linoleic acid. This

conversion requires adequate vitamin B₆, magnesium, and zinc levels as these nutrients function in the key enzyme responsible for this conversion, delta-6-desaturase. Given the fact that deficiency of one or more of these nutrients is common in PMS, decreased GLA levels could almost be expected.

Evening primrose, blackcurrant, and borage oil contain GLA, with typical levels being 9, 12, and 22%, respectively. Although these essential fatty acid sources are quite popular, the research on GLA supplements is controversial in the treatment of PMS. Specifically, the double-blind studies with GLA supplements like evening primrose oil in PMS are largely negative in that they showed no greater benefit over a placebo. A meta-analysis of the clinical trials of evening primrose oil for the treatment of PMS concluded that evening primrose is of little value in the management of PMS.^[75] The three most well-controlled studies failed to show any beneficial effects for evening primrose.^{[76] [77] [78]}

A better approach to the essential fatty acid and prostaglandin abnormalities of PMS may be to provide the necessary nutrients required for proper essential fatty acid metabolism along with providing adequate levels of the essential fatty acids and GLA. In other words, it may be more appropriate to provide a broader range of support than simply trying to increase GLA levels.

Multiple vitamin and mineral supplements

A high-quality multiple vitamin and mineral supplement providing all of the known vitamins and minerals serves as a foundation upon which to build. For women with PMS there are two very sound reasons for taking a high potency multiple:

- Nutritional deficiency is relatively common among women with PMS
- High potency multiple vitamin and mineral formulations have been shown to produce significant benefits in PMS.

When compared with normal women, the frequency of nutritional supplementation and the calculated intake of selected nutrients by PMS patients have been shown to be much lower. Although women with PMS have been shown to consume vitamins in their food at levels that are close to the recommended daily allowance, compared with women who did not have PMS their intake levels were only 2.2% as much for thiamin, 2.2% for riboflavin, 16.7% for niacin, 8.7% for pantothenic acid, and 2.7% for pyridoxine.^[9]

Several double-blind studies have shown that PMS patients given a multivitamin and mineral supplement containing high doses of magnesium and pyridoxine experience reductions (typically at least a 70% reduction) in both pre- and postmenstrual symptoms.^{[64] [65]}

Botanical medicines

Although a wide variety of herbs have been used in folk medicine for the many disorders of menstruation, and many have been evaluated for their “phytoestrogen” effects, few have been specifically evaluated for their efficacy in relieving premenstrual symptoms. The herbs which are most likely to be useful are probably those which exhibit a tonic effect on the female glandular system. This tonic effect is thought to be a result of phytoestrogens in the plants or other compounds which help to improve the hormonal balance of the female system, as well as the plant’s ability to improve blood flow to the female organs.

Although phytoestrogens are capable of exerting estrogenic effects, the activity is only 2% as strong as estrogen. However, because of this low activity, phytoestrogens have a balancing action on estrogen effects. If estrogen levels are low, since phytoestrogens have some estrogenic activity, they will cause an increase in estrogen effect. If estrogen levels are high, since phytoestrogens bind to estrogen receptor binding sites, thereby competing with estrogen, there will be a decrease in estrogen effects.

Because of the balancing action of phytoestrogens on estrogen effects, it is common to find the same plant recommended for conditions of estrogen excess (like PMS) and conditions of estrogen deficiency (like menopause, menstrual abnormalities). Many of these herbs have been termed “uterine tonics” because they work to nourish and tone the female glandular and organ system rather than exerting a drug-like effect. This non-specific mode of action makes many herbs useful in a broad range of female conditions including PMS.

The four most useful herbs in the treatment of PMS and related symptoms (as well as menopause) are *Angelica sinensis* (angelica or dong quai), *Glycyrrhiza glabra* (licorice root), *Cimicifuga racemosa* (black cohosh), and *Vitex agnus-castus* (chaste berry). These herbs have been used historically to lessen a variety of female complaints including hot flashes.

Angelica sinensis

In Asia, angelica’s reputation is perhaps second only to ginseng. Predominantly regarded as a “female” remedy, angelica has been used in menopausal symptoms (especially hot flashes), as well as in such conditions as dysmenorrhea (painful menstruation), amenorrhea (absence of menstruation), metrorrhagia (abnormal menstruation), and to assure a healthy pregnancy and easy delivery.

Angelica has demonstrated good uterine tonic activity, causing an initial increase in uterine contraction followed by relaxation.^[79] In addition, administration of angelica to mice resulted in an increase of uterine weight and an increase of glucose utilization by the liver and uterus.^[80] These effects reflect phytoestrogenic activities. Angelica is particularly helpful when, in addition to PMS, a woman experiences painful menstruation

(dysmenorrhea).

The typical dosage schedule is to start angelica on day 14 and continue until menstruation begins, unless the woman typically experiences dysmenorrhea, in which case it should be continued until menstruation has stopped.

Glycyrrhiza glabra

The medicinal use of licorice in both Western and Eastern cultures dates back several thousand years. In addition to being used for a variety of female disorders, it was used primarily as an expectorant and antitussive in respiratory tract infections and asthma. Other traditional uses include treating peptic ulcers, malaria, abdominal pain, insomnia, and infections. Many of these uses have been substantiated by modern research.

Licorice is particularly useful in premenstrual syndrome as it is believed to lower estrogen while simultaneously raising progesterone levels.^[81] ^[82] It raises progesterone levels by inhibiting the enzyme responsible for breaking it down. Licorice is also useful in reducing water retention by blocking the hormone aldosterone.

Licorice works to block the effects of aldosterone much in the same way that it impacts estrogen.^[83] ^[84] Its chief component, glycyrrhetic acid, binds to aldosterone receptors, but its activity is only about 25% as strong as the body's own aldosterone. This lower level of activity means that in cases of high aldosterone (such as often occurs in PMS), licorice may actually reduce the aldosterone effect by competing with aldosterone for binding sites. If aldosterone levels are normal, the chronic ingestion of licorice in large doses may cause symptoms of aldosterone excess, namely high blood pressure due to sodium and water retention. Prevention of the side-effects of glycyrrhizin may be possible by following a high-potassium, low-sodium diet. Although no formal trial has been performed, patients who normally consume high-potassium foods and restrict sodium intake, even those with high blood pressure and angina, have been reported to be free from the aldosterone-like side-effects of glycyrrhizin.^[85] Licorice should probably not be used in patients with a history of hypertension, renal failure, or current use of digitalis preparations.

The typical dosage schedule is to begin licorice on day 14 of the cycle and continue till menstruation.

Cimicifuga racemosa

Black cohosh was widely used by the American Indians and later by American colonists for the relief of menstrual cramps and menopause. Recent scientific

investigation into Remifemin, an extract of black cohosh standardized to contain 1 mg of

triterpenes calculated as 27-deoxyacteine per tablet which has been used in Germany for over 40 years, has shown that it is a safe and effective natural alternative to hormone replacement therapy in the treatment of menopause and may offer some benefits in PMS as well. In one study of 135 women, Remifemin was judged to have “performed very well” in PMS in that it reduced feelings of depression, anxiety, tension, and mood swings.^[86]

Vitex agnus-castus

The chaste tree is native to the Mediterranean, where its berries have long been used for female complaints. As its name signifies, chaste berries were used in suppressing the libido.

While black cohosh is the more popular herbal approach to menopausal symptoms in Germany, chaste berry extract is probably the most popular herbal approach to PMS. In two surveys of gynecological practices in Germany, physicians graded chaste berry extract as good or very good in the treatment of PMS. More than 1,500 women participated in the studies.^[87] ^[88] One-third of the women experienced complete resolution of their symptoms while another 57% reported significant improvement.

Chaste berry extract appears to be particularly useful in cases of corpus luteum insufficiency or prolactin excess.^[89] It appears that its beneficial effects in PMS and these other conditions are related to altering gonadotropin-releasing hormone (GnRH) and follicle-stimulating hormone-releasing hormone (FSH-RH). In other words, it appears that chaste berry extract has profound effects on the hypothalamus and pituitary function. As a result it is able to normalize the secretion of other hormones, e.g. reducing the secretion of prolactin and reducing the estrogen to progesterone ratio.

Chaste berry extract may also be useful in certain cases of amenorrhea (absence of menstruation) due to prolactin excess, one of the most frequent causes of amenorrhea. This application, however, requires patience as 3 months of use is necessary to lower prolactin levels.^[89]

THERAPEUTIC APPROACH

The approach to the woman with PMS first involves evaluation of symptoms and identifying possible causes and hormonal disturbances. In an effort to clarify the treatment approach, here are seven key steps to consider:

1. Evaluate PMS symptoms by having the patient complete the questionnaire in [Appendix 9](#).
2. Rule out hypothyroidism and/or depression.
3. Begin following the dietary recommendations for PMS:
 - a. follow a vegetarian or predominantly-vegetarian diet
 - b. reduce the intake of fat
 - c. eliminate sugar
 - d. reduce exposure to environmental estrogens

- e. increase the intake of soy foods
- f. eliminate caffeine
- g. keep salt intake low
4. Follow the guidelines for nutritional supplementation given above.
5. Select the appropriate herbal support:
 - a. if the patient has PMS-associated breast pain, infrequent periods, or a history of ovarian cysts, utilize *Vitex agnus-castus*
 - b. if the patient typically experiences menstrual cramps, utilize *Angelica sinensis*
 - c. if the patient is bothered by PMS water retention, utilize *Glycyrrhiza glabra*
 - d. if the patient suffers from uterine fibroids, utilize *Cimicifuga racemosa*.
6. Establish a program for stress reduction and recommend regular exercise.
7. If after at least three complete periods the patient is not experiencing a significant improvement or complete resolution of symptoms, work to identify additional causative factors as detailed above.

Nutritional supplements

- Multivitamin and mineral
- Vitamin B₆: 100 mg/day
- Magnesium: 500 mg/day
- Vitamin E: 400 IU/day.

Botanical medicines

- *Angelica sinensis*
 - three times a day
 - powdered root or as tea: 1–2 g
 - tincture (1:5): 4 ml (1 tsp)
 - fluid extract: 1 ml (¼ tsp)
- *Glycyrrhiza glabra*
 - three times a day
 - powdered root or as tea: 1–2 g
 - fluid extract (1:1): 4 ml (1 tsp)
 - solid (dry powdered) extract (4:1): 250–500 mg
- *Cimicifuga racemosa*
 - twice a day
 - standardized extract (4 mg 27-deoxyacteine): 1 tablet (2 for menopausal women)

- *Vitex agnus-castus*
 - daily dosage
 - standardized extract (0.5% agnuside): 175–225 mg daily
 - liquid extract: 2 ml.
-

Joseph E. Pizzorno Jr ND

DIAGNOSTIC SUMMARY

- Sharply bordered reddened rash or plaques covered with overlapping silvery scales
- Characteristically involves the scalp, the extensor surfaces (backside of the wrists, elbows, knees, buttocks, and ankles), and sites of repeated trauma
- Family history in 50% of cases
- Nail involvement results in characteristic “oil drop” stippling
- Possible arthritis.

GENERAL CONSIDERATIONS

Psoriasis is an extremely common skin disorder. Its rate of occurrence in the United States is between 2 and 4% of the population. Psoriasis affects few blacks in tropical zones but is more common among blacks in temperate zones. It appears commonly among Japanese but is rare in American Indians. Psoriasis affects men and women equally, and the mean onset is 27.8 years of age, although 2% show onset by 2 years of age.

Psoriasis is the classic example of a hyperproliferative skin disorder. The rate of cellular division rate in psoriatic lesions is very high (1,000 times greater than in normal skin), exceeding the rate in squamous cell carcinoma. Even in uninvolved skin, the number of proliferating cells is up to two and one-half times greater than in non-psoriatics.

The basic defect lies within the skin cells themselves. The incidence of psoriasis is increased in HLA-B₁₃, HLA-B₁₆, and HLA-B₁₇, reflecting a possible genetic error in mitotic control which is confirmed by the observation that 36% of patients have one or more family members with psoriasis.^[4] The rate at which cells divide is controlled by a delicate balance between two internal control compounds – cyclic AMP and cyclic GMP. Increased levels of cyclic GMP (cGMP) are associated with increased cell proliferation;

conversely, increased levels of cyclic AMP (cAMP) are associated with enhanced cell

1514

maturation and decreased cell proliferation. Both decreased cAMP and increased cGMP have been measured in the skin of individuals with psoriasis.^{[2] [3]} The result is excessive cell proliferation.

THERAPEUTIC CONSIDERATIONS

Although psoriasis may have a significant genetic component, rebalancing the cyclic AMP:GMP ratio can be substantially achieved through natural medicine intervention. A number of controllable factors appear to cause or contribute to psoriasis, including:

- incomplete protein digestion
- bowel toxemia
- impaired liver function
- alcohol consumption
- excessive consumption of animal fats
- nutritional deficiencies
- stress.

These are briefly discussed below.

Incomplete protein digestion

Incomplete protein digestion or poor intestinal absorption of protein breakdown products can result in elevated levels of amino acids and polypeptides in the bowel. These are metabolized by bowel bacteria into several toxic compounds. The toxic metabolites of the amino acids arginine and ornithine are known as polyamines (e.g. putrescine, spermidine, and cadaverine) and have been shown to be increased in individuals with psoriasis. Polyamines inhibit the formation of cyclic AMP and therefore contribute to the excessive rate of cell proliferation ([Fig. 184.1](#)).^{[4] [5] [6]} Lowered skin and urinary levels of polyamines are associated with clinical improvement in psoriasis.^[4]

There are a number of natural compounds which can inhibit the formation of polyamines that may be of benefit in the treatment of psoriasis. For example, vitamin A and the alkaloids of *Hydrastis canadensis* (goldenseal) such as berberine inhibit bacterial decarboxylase, the enzyme which converts the amino acids into polyamines.^{[7] [8]} However, the best way to prevent the excessive formation of polyamines is to evaluate digestive function with the aid of Heidelberg Gastric Analysis and/or a Comprehensive Digestive Stool Analysis and then take the action necessary (e.g. hydrochloric acid supplementation) to ensure complete protein digestion and absorption (chapters on these assessment methods are available in Section 2).

Bowel toxemia

A number of gut-derived toxins are implicated in the development of psoriasis, including endotoxins (cell wall components of Gram-negative bacteria), streptococcal products, *Candida albicans*, yeast compounds, and IgE and IgA immune complexes.^{[9] [10] [11]} These compounds lead to increases in cyclic GMP levels within skin cells, thereby increasing the rate of proliferation dramatically. *Candida albicans* overgrowth in the intestines (chronic candidiasis) may play a major role in many cases.

A diet low in dietary fiber is associated with increased levels of gut-derived toxins.^[9] Dietary fiber is of critical importance in maintaining a healthy colon. Many fiber components bind bowel toxins and promote their excretion in the feces. It is therefore essential that the diet of an individual with psoriasis be rich in beans, fruits, and vegetables. Natural compounds which bind endotoxins and promote their excretion may also be used. For example, an aqueous extract of the herb *Smilax sarsaparilla* was found in a 1942 study to be effective in psoriasis, particularly the more chronic, large plaque-forming variety.^[12] In this controlled study of 92 patients, sarsaparilla greatly improved the psoriasis in 62% of the patients and resulted in complete clearance in another 18% (i.e. 80% of the subjects experienced significant benefits). This benefit is apparently due to sarsaparilla components binding to and promoting the excretion of bacterial endotoxins.

Since clinical severity as well as therapeutic response have been shown to correlate well with the level of circulating endotoxins, control of gut-derived toxins is

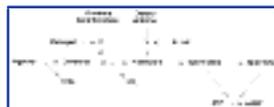

Figure 184-1 Amino acids, polyamines, and inhibition of adenylate cyclase.

critical in the treatment of psoriasis. Every effort should be made to promote proper binding and elimination of these compounds through supporting the excretion in the feces as well as proper handling of absorbed endotoxins by the liver.

Liver function

Correcting abnormal liver function is of great benefit in the treatment of psoriasis.^[13] The connection between the liver and psoriasis relates to one of the liver's basic tasks – filtering and detoxifying the blood returning through the portal circulation from the bowels. As mentioned above, psoriasis has been linked to the presence of several microbial by-products in the blood. If the liver is overwhelmed by excessive levels of these toxins from the bowel, or if there is a decrease in the liver's detoxification ability,

the systemic toxin level will increase and the psoriasis will get worse.

Alcohol consumption is known to significantly worsen psoriasis.^[14] Alcohol has this effect since it both increases the absorption of toxins from the gut (by damaging the gut mucosa) and impairs liver function. Alcohol intake must be eliminated in individuals with psoriasis.

Silymarin, the flavonoid component of *Silybum marianum*, has been reported to be of value in the treatment of psoriasis.^[13] Presumably this is a result of its ability to improve liver function, inhibit inflammation, and reduce excessive cellular proliferation.^{[15] [16]}

Nutrition

Omega-3 fatty acids

The manipulation of dietary oils is extremely important in the management of psoriasis since serum free fatty acid levels are typically abnormal in these patients.^[17] Of particular benefit are the omega-3 fatty acids. Most of the clinical research has utilized fish oils rich in eicosapentaenoic acid (EPA) and docosohexanoic acid (DHA). Several double-blind clinical studies have demonstrated that supplementing the diet with 10–12 g of fish oils (providing 1.8 g EPA and 1.2 g DHA) results in significant improvement.^{[18] [19] [20]} This amount of EPA and DHA would be equivalent to the amount of EPA in about 150 g of salmon, mackerel, or herring. Consumption of cold-water fish and the daily supplementation with one tablespoon of flaxseed oil may be more advantageous than fish oil supplementation, given the problem with lipid peroxides in many commercially available fish oil supplements.

The improvement in psoriasis from EPA is largely due to the competition of EPA for arachidonic acid binding sites, which results in the inhibition of the production of inflammatory compounds. In the skin of individuals with psoriasis, the production of inflammatory leukotrienes from arachidonic acid is many times greater than normal.^[21] Leukotrienes are potent inflammatory agents and promoters of guanylate cyclase activity.

In the involved epidermis, the cellular contents of free arachidonic acid and 12-HETE (a product of lipoxygenase metabolism of arachidonic acid) are 250 and 810 times greater, respectively, than in uninvolved epidermal tissue.^[21] These elevations appear to be due to the presence in the plaques of a yet-to-be-defined inhibitor of cyclooxygenase, which normally metabolizes arachidonic acid to less inflammatory compounds.

Trauma also induces the release of free arachidonic acid and may account for the common clinical observation of plaques at the sites of repeated trauma. These observations are significant, since the increase in 12-HETE stimulates the 5-lipoxygenase pathway, promoting leukotriene formation. This pathway is inhibited by EPA and glutathione peroxidase, suggesting that a selenium deficiency may be a contributory factor (see below under nutritional considerations).

As might be expected, cyclooxygenase inhibitors (e.g. aspirin and most other non-steroidal anti-inflammatory agents) may exacerbate psoriasis, while lipoxygenase inhibitors (e.g. benoxaprofen) may cause improvement.^[22] Naturally occurring substances, such as quercetin (the ubiquitous plant flavonoid), vitamin E, onion, and garlic, are known to inhibit lipoxygenase and therefore may be of benefit.

Since arachidonic acid is found only in animal tissues, it is necessary to limit the intake of animal products, particularly animal fats and dairy products.

Diet, fasting, and food allergy control

The evaluation of 316 psoriasis patients with 366 controls, both groups being in the age range 16–65 years, found that psoriasis was positively associated with body mass index and inversely related to intake of carrots, tomatoes, fresh fruits, and the index of beta-carotene intake.^[23] Research at a Swedish hospital studying the effects of fasting and vegetarian regimens on chronic inflammatory disease found that such diets helped psoriatic patients.^[24] The improvement was probably due to decreased levels of gut-derived toxins and polyamines. Patients have also benefited from gluten-free and elimination diets.^{[25] [26]}

Individual nutrients

Decreased levels of vitamin A and zinc are common in patients with psoriasis.^{[27] [28] [29]} Given vitamin A and zinc's critical role in the health of skin, supplementation might be warranted even without this association.

Chromium supplementation may be indicated to increase insulin receptor sensitivity as psoriatics typically have increased serum levels of both insulin and glucose.^[30]

Glutathione peroxidase (GP) levels are low in psoriatic patients, possibly due to such factors as alcohol abuse, malnutrition, and the excessive skin loss of the hyperproliferative disease. The depressed levels of GP normalize with oral selenium and vitamin E therapy.^[31] Another study compared 113 patients with moderate to severe psoriasis with 104 healthy controls and found that male psoriatic patients between 20 and 49 years of age and women with the disease of longer than 20 years had particularly low serum concentrations in whole blood selenium. The lowest whole blood selenium values were found in the subgroup of male patients with widespread disease of long duration who also required treatment with methotrexate and retinoids.^[32]

There is a growing body of evidence that indicates that the active form of vitamin D (1,25-dihydroxycholecalciferol) has a role in controlling cellular proliferation and differentiation. This recognition has led to clinical trials of both oral and topical forms of

vitamin D in the treatment of psoriasis. One controlled study found that 2–5 weeks of topical 1,25-dihydroxycholecalciferol resulted in definite to total improvement in all five patients treated.^[33] Another study by the same researchers, this one uncontrolled, found that four of seven patients had complete remission (after 1–3 months) with daily oral doses of 1.0 µg of 1alpha(OH)D₃.^[34] Patients with severe psoriasis have also been found to have significantly low serum levels of 1,25-dihydroxycholecalciferol which normalized after treatment with oral 1alpha(OH)D₃.^[35]

Fumaric acid

Over the past three decades, fumaric acid therapy has become increasingly popular in western Europe for psoriasis. Therapy consists of the oral intake of dimethylfumaric acid (240 mg daily) or monoethylfumaric acid (720 mg daily) and the topical application of 1–3% of monoethylfumaric acid. Clinical studies have shown that it is useful in many patients with psoriasis, but side-effects such as flushing of the skin, nausea, diarrhea, general malaise, gastric pain, and mild liver and kidney disturbances can occur.^[36] We recommend using fumaric acid therapy only after other natural therapies have proven ineffective.

Psychological aspects

A large number (39%) of patients with psoriasis report a specific stressful event occurring within 1 month prior to their initial episode. Such patients have a better prognosis.^[37] A few case histories have been reported which document the successful treatment of psoriasis with hypnosis and biofeedback alone.^[38]

Physical therapeutics

Sunlight (ultraviolet light) is extremely beneficial for individuals with psoriasis. The standard medical treatment of psoriasis typically involves the use of the drug psoralen and ultraviolet A (PUVA therapy). However, ultraviolet B (UVB) exposure alone leads to inhibition of cell proliferation and has been shown to be as effective as PUVA therapy with fewer side-effects.^{[1] [39] [40] [41]} Ultraviolet exposure may also benefit through its induction of vitamin D synthesis in the skin.

The induction of localized elevation of temperature (42–45°C) to the affected area by ultrasound and heating pads has been shown to be an effective treatment of psoriasis.^{[42] [43]}

Topical treatments

A number of natural proprietary formulas as well as over-the-counter preparations can be used to provide symptomatic relief. Three botanical agents are worth discussing as alternatives to hydrocortisone: glycyrrhetic acid from licorice (*Glycyrrhiza glabra*), chamomile (*Matricaria chamomilla*), and capsaicin from cayenne pepper (*Capsicum*

frutescens).

Glycyrrhiza glabra (licorice root)

The licorice component glycyrrhetic acid exerts an effect similar to that of topical hydrocortisone in the treatment of psoriasis and eczema. In fact, in several studies, glycyrrhetic acid was shown to be superior to topical cortisone, especially in chronic cases. For example, in one study in patients with eczema, 93% of the patients applying glycyrrhetic acid demonstrated improvement compared with 83% using cortisone.^[44] Glycyrrhetic acid can also be used to potentiate the effects of topically applied hydrocortisone by inhibiting the 11-beta-hydroxy-steroid dehydrogenase which catalyzes the conversion of hydrocortisone to an inactive form.^[45]

Matricaria chamomilla (chamomile)

Chamomile preparations are widely used in Europe for the treatment of a variety of common skin complaints including psoriasis, eczema, and dry, flaky, irritated skin. The flavonoid and essential oil components of chamomile possess significant anti-inflammatory and anti-allergy activity.^[46]

Capsicum frutescens (cayenne pepper)

Capsaicin is the active component of cayenne pepper (*Capsicum frutescens*). When topically applied, capsaicin is known to stimulate and then block small-diameter pain fibers by depleting them of the neurotransmitter substance P. Substance P is thought to be the principal chemomediator of pain impulses from the periphery.

In addition, substance P, which is elevated in the skin of psoriatics, has been shown to activate inflammatory mediators in psoriasis. Several clinical studies have found that the topical application of 0.025 or 0.075% capsaicin is effective in improving psoriasis.^[47] ^[48]

In one double-blind study, 44 patients with symmetrically distributed psoriasis lesions applied topical capsaicin to one side of their body and a placebo to the other side.^[28] After 3–6 weeks, significantly greater reductions in scaling and redness were observed on the capsaicin side. Burning, stinging, itching, and skin redness were noted by nearly half of the patients initially, but this diminished or vanished upon continued application.^[48] In a more recent study, patients applied capsaicin 0.025% cream ($n = 98$) or vehicle alone ($n = 99$) four times a day for 6 weeks.^[47] Efficacy was based on a physician's global evaluation and a combined psoriasis severity score including scaling, thickness, erythema, and pruritus. Capsaicin-treated patients demonstrated significantly greater improvement in global evaluation and in pruritus relief, as well as a significantly greater reduction in combined psoriasis severity scores.

Aloe vera

A recent, very exciting, double-blind, placebo-controlled study found that topical application of an *Aloe vera* extract in a hydrophilic cream was highly effective in psoriasis vulgaris. Sixty patients with slight to moderate chronic plaque-type psoriasis, PASI (psoriasis area and severity index) scores of between 4.8 and 16.7 (mean 9.3), and mean duration of the disease of 8.5 years (range 1–21) applied either the aloe or a placebo gel three times a day. The treatment was well tolerated by all the patients, with no adverse drug-related symptoms and no drop-outs. By the end of the study (4–12 months of treatment), the *Aloe vera* extract cream had cured 25/30 patients (83.3%) compared with the placebo cure rate of only 2/30 (6.6%), resulting in significant clearing of the psoriatic plaques (328/396 (82.8%) vs. placebo 28/366 (7.7%), and a decreased PASI score to a mean of 2.2.^[49]

THERAPEUTIC APPROACH

Despite the complexity of this disease, the therapeutic approach is fairly straightforward: decrease bowel toxemia, rebalance fatty acid levels and inflammatory processes in the skin, and utilize the listed therapeutic regimen to further balance the abnormal cell proliferation.

Diet

- Limit sugar, meat, animal fats, and alcohol
- Increase intake of dietary fiber and cold water fish and, if necessary, bring weight to normal levels
- Eliminate sources of gluten
- Identify and address any food allergies.

Supplements

- High potency multiple vitamin and mineral formula
- Flaxseed oil: 1 tbsp/day
- Vitamin A: 50,000 IU/day (do not use in pregnant or women at risk for pregnancy)
- Vitamin E: 400 IU/day
- Chromium: 400 mcg/day
- Selenium: 200 mcg/day
- Zinc: 30 mg/day
- Water-soluble fiber (psyllium, pectin, guar gum, etc.): 5 g at bedtime.

Botanical medicines

- *Hydrastis canadensis* (goldenseal)
—the dosage should be based on berberine content; as there is a wide range of quality in goldenseal preparations, standardized extracts are preferred three times/day

—dried root or as infusion (tea): 2–4 g three times/day

—fluid extract (1:1): 2–4 ml (0.5–1 tsp) three times/day

—solid (powdered dry) extract (4:1 or 8–12% alkaloid content): 250–500 mg three times/day

- *Smilax sarsaparilla*

—dried root or by decoction: 1–4 g three times/day

—liquid extract (1:1): 8–16 ml (2–4 tsp) three times/day

—solid extract (4:1): 250–500 mg three times/day

- *Silybum marianum* (milk thistle)

—silymarin: 70–210 mg three times/day.

Psychological

Evaluate stress levels and utilize stress reduction techniques as appropriate.

Physical medicines

- Ultrasound: 42–45°C, 20 minutes, three times/week
- UVB: 295–305 nm, 2 mW/cm², 3 minutes, three times/week.

Topical treatment

Preparations containing one or more of the ingredients described above. Apply to affected areas of the skin two to three times/day.

Chapter 185 - Rheumatoid arthritis

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

DIAGNOSTIC SUMMARY

- Fatigue, low-grade fever, weakness, weight loss, joint stiffness, and vague joint pain may precede the appearance of painful, swollen joints by several weeks
- Severe joint pain with considerable inflammation that begins insidiously in the small joints and progresses to affect all joints
- X-ray findings usually show soft tissue swelling, erosion of cartilage, and joint space narrowing
- Rheumatoid factor usually present in serum
- Extra-articular manifestations are common, including vasculitis, muscle atrophy, subcutaneous and systemic granulomas, pleurisy, pericarditis, pulmonary fibrosis, lymphadenopathy, splenomegaly, anemia, and leukopenia.

GENERAL CONSIDERATIONS

Rheumatoid arthritis (RA) is a chronic inflammatory condition that affects the entire body but especially the synovial membranes of the joints. The joints typically involved are the hands, feet, wrists, ankles, and knees. Between 1 and 3% of the population is affected; female patients outnumber males almost 3:1; and the usual age of onset is 20–40 years, although rheumatoid arthritis may begin at any age.^{[1] [2]}

The onset of RA is usually gradual, but occasionally it is quite abrupt. Fatigue, low-grade fever, weakness, joint stiffness, and vague joint pain may precede the appearance of painful, swollen joints by several weeks. Several joints are usually involved at the onset, typically in a symmetrical fashion, i.e. both hands, wrists, or ankles. In about one-third of persons with RA, initial involvement is confined to one or a few joints.^{[1] [2]}

Involved joints will characteristically be quite warm, tender, and swollen. The skin over

the joint will take on a ruddy purplish hue. As the disease progresses, deformities develop in the joint of the hands and feet.

1520

Colloquial terms used to describe these deformities include swan neck, boutonnière, and cock-up toes.^{[1] [2]}

Pathogenesis

There is abundant evidence that RA is an autoimmune reaction, where antibodies develop against components of joint tissues. Yet what triggers this autoimmune reaction remains largely unknown. Speculation and investigation have centered around genetic susceptibility, abnormal bowel permeability, lifestyle and nutritional factors, food allergies, and microorganisms. RA is a classic example of a multifactorial disease where an assortment of genetic and environmental factors contribute to the disease process.

Genetic factors

The histocompatibility antigen HLA-DR₄ is found in 70% of patients with RA compared with 28% of controls. This strongly implies that susceptibility to RA is influenced by genetic factors which govern immune response. Severe RA is also found at four times the expected rate in first-degree relatives of probands with seropositive disease. As strong as these genetic associations are, environmental factors are necessary for the development of the disease. This is evident from the discordance demonstrated in monozygotic twin studies.^[1]

Abnormal bowel permeability

An interesting association between rheumatoid arthritis and abnormal bowel function may provide a unified theory as to the cause of RA. Individuals with RA have increased intestinal permeability to dietary and bacterial antigens as well as alterations in bacterial flora.^{[3] [4] [5]} Food allergies may contribute greatly to the increased permeability of the gut in RA. Non-steroidal anti-inflammatory drugs have also been implicated. This altered permeability to gut-derived antigens contributes greatly to the increased levels of circulating endotoxins (lipopolysaccharide components of the cell walls of Gram-negative bacteria) and immune complexes characteristic of RA.

The increased gut permeability and inappropriate bacterial flora could also result in the absorption of antigens that are very similar to antigens in joint tissues. Antibodies formed to microbial antigens are hypothesized to cross-react with the antigens in the joint tissues. Increasing evidence appears to support this concept. For example, antibodies to *Campylobacter*, *Salmonella*, and *Shigella* have been shown to cross-react with collagen, while antibodies to *Klebsiella pneumoniae*, *Proteus vulgaris* and *Yersinia*

enterocolitica have been shown to cross-react with other joint tissues. ^[6] ^[7]

Dysbiosis and small intestinal bacterial overgrowth

Perhaps more important than specific causative organisms is the fact that many patients with rheumatoid arthritis exhibit altered microbial flora and small intestinal bacterial overgrowth (SIBO). In fact, the degree of SIBO has been shown to be associated with the severity of symptoms and disease activity.^[8] For more information on SIBO, see [Chapter 7](#).

The presence of abnormal antibodies and immune complexes

The serum and joint fluid of nearly all individuals with RA contain the rheumatoid factor (RF). The RF is the number of antibodies against the Fc fragment of IgG. RF antibodies belong to the IgM, IgG, and IgA classes, but only IgM RF is readily measured by currently available methods, which include latex agglutination, bentonite flocculation, and sensitized sheep or human red blood cell test.

Most of the RF is formed locally in the affected joints by the inflammatory infiltration of activated B-cells and plasma cells. The serum titer of RF usually correlates well with the severity of arthritis symptoms.

The presence of circulating immune complexes is one of the major factors thought to contribute to the pathogenesis of RA. The cell-mediated, humoral, and non-specific immune responses to the immune complexes lead to much of the proliferative inflammation seen in RA.

These abnormalities are quite similar to the Arthus reaction and serum sickness, immune complex-induced reactions dependent upon neutrophils, and complement activation. Although the amount of circulating immune complexes has not correlated well with disease activity, there is little doubt that the formation of immune complexes and abnormal antibodies and the sequelae of events that follow are major factors in the progression of RA.

Microbial hypotheses

As interesting as the various microbial hypotheses are, they are not in themselves comprehensive enough to explain all of the events observed in RA. A variety of microorganisms (e.g. Epstein–Barr virus, rubella virus, amebic organisms, and *Mycoplasma*) have been suggested to be causative factors in the pathogenesis of RA, despite the fact that no microbial agent has been consistently isolated in RA patients.^[9]

The fact that studies have focused on attempting to isolate whole organisms from synovial fluids and on the presence of antibodies to viable and whole organisms, coupled with the failure to isolate any offending organisms, has prompted many researchers committed

to the “germ theory” to suggest that some atypical viral-like agent(s) may be responsible in RA.^[9]

Microbial factors, particularly their role in increasing the level of circulating immune complexes, definitely contribute to the pathogenesis of RA, but at this time it appears highly unlikely that there is a single causative microbe in RA. Nonetheless, researchers continue to search for a causative agent.

One popular microbial hypothesis, which was later disproved, involved the Epstein–Barr virus (EBV).^[10] The link between EBV and RA was initially based on three basic immunopathologic observations:

- EBV is a polyclonal activator of B-cells, which induce autoantibody and rheumatoid factor production both in vitro and in vivo.
- Lymphocytes from patients with RA show evidence of impaired regulation of EBV infection in vitro.
- Antibodies to EBV-determined antigens such as rheumatoid arthritis nuclear antigen (RANA), EBV nuclear antigen, and viral capsid antigen are elevated in sera from patients with RA.

Researchers have subsequently concluded that EBV is an unlikely etiological agent, based on the prevalence of EBV antibodies in healthy controls.^[10]

Mycoplasmas have also received some attention as possible etiologic factors in RA.^[11] Mycoplasmas can infect joints and induce arthritis. Mycoplasmal antigens have been detected in the synovial fluid of RA patients, implying that frequent and persistent colonization of mycoplasmas may lead to host sensitization and IC formation. However, these effects are not specific to mycoplasmas alone.

Another popular microbial hypothesis is based on the work of Dr Roger Wyburn-Mason.^[12] During the 1960s, Dr Wyburn-Mason routinely identified an amebic organism in the synovial fluid of patients with arthritic conditions. The potent antibiotic metronidazole (Flagyl) was shown to be active against the organism and is part of the protocol recommended by the Rheumatoid Disease Foundation (Route 4, Box 137, Franklin, TN 37064; tel: 615-646-1030), an organization which promotes additional research in this area.

In summary, it appears that the presence of high levels of circulating immune complexes containing microbial antigens in general, as well as the increased microbial antigenic load observed in RA patients, are of greater significance than antibodies to one particular organism or group of organisms.

Decreased DHEA levels

Defective androgen synthesis has been proposed as a potential predisposing factor for rheumatoid arthritis. For example, in one large study dehydroepiandrosterone sulfate (DHEAS) levels were measured in 185 postmenopausal women (aged 45–65 years) with rheumatoid arthritis.^[13] Compared with 518 postmenopausal women in the control group, DHEAS levels were below normal in the 120 patients with RA who had never taken corticosteroids, and levels were even lower in the 39 patients who were currently taking corticosteroids.

Supplemental DHEA has shown therapeutic benefits in patients with systemic lupus erythematosus (SLE) in studies conducted at Stanford Medical Center.^{[14] [15]} In the double-blind study, 28 female patients with mild to moderate SLE were given DHEA (200 mg/day) or placebo for 3 months.^[15] Outcomes were assessed using the SLE Disease Activity Index (SLEDAI) score, patient's and physician's overall assessments of disease activity, and concurrent corticosteroid usage. In the patients receiving DHEA, the SLEDAI decreased by nearly two points, while the placebo group's average score increased by almost a full point. Patient and physician assessments also showed improvements in the SLE group and exacerbation in the placebo group. The average dosage of corticosteroids decreased by 30% in the SLE group and increased by 40% in the control group. The number of lupus flare-ups was three in the SLE group, compared with eight in the placebo group. Mild acne was a frequent side-effect of DHEA.

Given DHEA's positive effects in SLE,^{[14] [15]} even in the absence of double-blind clinical studies in rheumatoid arthritis, DHEA supplementation appears warranted. For conservative practitioners it should be used at least to correct the physiological deficit, which can be determined with a 24 hour urinary measure. For more aggressive practitioners, it can be used to try to significantly impact disease activity. In the later goal, the dosage required will likely be above 50 mg. The major side-effect at this dosage and above is mild to severe acne and possibly increased androgenization in women.

DIAGNOSIS

RA is easily recognized in its most advanced and characteristic form. However, diagnosis of early RA is often much more difficult. The American Rheumatism Association has established criteria for the diagnosis of "classic", "definite", "probable", and "possible" RA, which are listed in [Table 185.1](#).^[16]

Laboratory and X-ray findings

Rheumatoid factor

A variety of non-rheumatoid diseases will show elevated levels of RF. These diseases usually share the common feature of chronic inflammation with persistent antigenic

challenge and include other connective tissue diseases

1522

TABLE 185-1 -- Criteria for the classification of RA

Classic RA

The diagnosis of RA requires seven of the following criteria to be observed by a physician. In criteria 1–5 the joint signs or symptoms must be continuous for at least 6 weeks. Any one of the features listed under exclusions will exclude a patient from this and other categories.

1. Morning stiffness

2. Pain on motion or tenderness in at least one joint

3. Swelling (soft tissue thickening or fluid, not bony overgrowth alone) in at least one joint

4. Swelling of at least one other joint with any interval free of joint symptoms between the joint involvement may not be more than 3 months

5. Symmetric joint swelling with simultaneous involvement of the same joint on both sides of the body (bilateral involvement of proximal interphalangeal, metacarpophalangeal, or metatarsophalangeal joints is acceptable without absolute symmetry). Terminal phalangeal joint involvement will not fulfill this criteria

6. Subcutaneous nodules over bony prominences, on extensor surfaces, or in juxta-articular regions

7. X-ray changes typical of RA, which must include bony decalcification localized to or most marked adjacent to the involved joints and not just degenerative changes. Degenerative changes do not exclude patients from any group classified as having RA

8. Positive agglutination test – demonstration of the “rheumatoid factor” by an acceptable method

9. Poor mucin precipitate from synovial fluid or an inflammatory synovial effusion with 2,000 or more white cells/mm³ and without crystals

10. Characteristic histologic changes in synovium with three or more of the following: marked villous hypertrophy; proliferation of superficial synovial cells often with palisading; marked infiltration of chronic inflammatory cells with tendency to form lymphoid nodules; deposition of compact fibrin either on the surface or interstitially; foci of necrosis

11. Characteristic histologic changes in nodules showing granulomatous foci with central zones of cell necrosis, surrounded by a palisade of proliferated mononuclear and peripheral fibrosis and chronic inflammatory cell infiltration

Definite RA

This diagnosis requires five of the above criteria. In criteria 1–5, the joint signs must be continuous for at least 6 weeks

Probable RA

This diagnosis requires three of the above criteria. In at least one of the criteria 1–5, the joint signs or symptoms must be continuous for at least 6 weeks

Possible RA

This diagnosis requires two of the following criteria and total duration of joint symptoms must be at least 3 months:

1. Morning stiffness
 2. Tenderness or pain on motion with history of recurrence or persistence of 3 weeks
 3. History or observation of joint swelling
 4. Elevated sedimentation rate or C-reactive protein
 5. Iritis
-

(e.g. systemic lupus erythematosus, Sjögren's syndrome, polymyositis, and scleroderma), as well as infectious diseases (e.g. tuberculosis, leprosy, syphilis, viral hepatitis, bacterial infections, infectious mononucleosis, and influenza). Positive results are also found in patients with idiopathic pulmonary fibrosis, sarcoidosis, chronic active hepatitis and cirrhosis, lymphomas, cryoglobulinemia, and repeated blood transfusions.^[1]

RF may also be transiently elevated after immunizations and other assaults to the immune system. Studies of apparently healthy individuals demonstrate that the overall prevalence is about 4%, but in persons over the age of 60 some surveys have demonstrated a prevalence rate of over 40%. However, titers of RF in the elderly and apparently healthy individuals are typically quite low, less than 1:80.^[1]

Antinuclear antibodies

Antinuclear antibodies (ANA) are found in 20–60% of RA patients. Titers specific for native DNA are typically normal, while titers to single-stranded or denatured DNA are usually elevated. ANA titers are typically lower in RA than systemic lupus erythematosus.^[1]

EBV antibodies

Antibodies to an Epstein–Barr virus antigen can be identified by immunodiffusion or by immunofluorescence in the serum of most patients with RA. These antibodies are referred to as anti-rheumatoid arthritis precipitin (anti-RAP) and anti-rheumatoid arthritis nuclear antigen (anti-RANA). The significance of these antibodies remains to be determined.

Other laboratory abnormalities

Anemia is quite common, usually normocytic and normochromic or hypochromic. Decreased erythropoiesis is common in chronic inflammatory conditions like RA. Although the serum iron level and total iron binding capacity are usually low, supplemental iron is of no value

1523

and may actually promote further free radical damage.^{[1] [17]} Therefore, iron supplementation is not indicated unless the anemia is due specifically to blood loss. Serum ferritin levels may be useful in determining the appropriateness of iron therapy; however, it must be kept in mind that ferritin is elevated during acute inflammation and correlates well with other indicators of disease activity such as the erythrocyte sedimentation rate and C-reactive protein.

The erythrocyte sedimentation test (ESR) is commonly elevated and may be used as a rough estimator of disease activity in patient monitoring with the caveat that occasionally the ESR does not accurately reflect disease activity.

Synovial fluid

Synovial fluid findings usually reflect the degree of inflammation. The high content of fibrinogen may lead to spontaneous clotting of the fluid, but this should not be confused with the mucin clot. Adding 1% acetic acid will dissolve the fibrin. In RA the mucin clot is poor because of smaller-than-normal polymers of hyaluronic acid.

Neutrophils are the primary cells found in the fluid and may range from 10,000 to 50,000/mm³. Complement levels are generally low and the neutrophils typically contain cytoplasmic inclusion bodies with ingested immune complexes.

X-rays

X-ray findings usually show soft tissue swelling, erosion of cartilage, and subtle joint space narrowing early in the disease process. As the disease progresses, the erosion of joint spaces is more pronounced, as is the evidence of diffuse osteoporosis.

Standard medical therapy

Standard medical therapy is of limited value in most cases of RA as it fails to address the complex underlying causes of this disease. Standard medical treatment of RA involves, in addition to drugs, such physical therapy modalities as exercise, heat, cold,

massage, diathermy, lasers, and paraffin baths.^[1] ^[2]

Non-steroidal anti-inflammatory drugs

The first drug generally employed is aspirin. It is often quite effective in relieving both the pain and inflammation and is also relatively inexpensive. Since the therapeutic dose required is relatively high, toxicity often occurs. Tinnitus and gastric irritation are early manifestations of toxicity.^[1] ^[2]

Other non-steroidal anti-inflammatory drugs (NSAIDs) are often used as well, especially when aspirin is ineffective or is not well tolerated. Typical representatives of this class of drugs include:

- ibuprofen (Motrin, Advil, Nuprin, piroxicam (Feldene))
- diclofenac (Voltarin)
- fenoprofen (Nalfon)
- indomethacin (Indocin)
- naproxen (Naprosyn)
- tolmetin (Tolectin)
- sulindac (Clinoril).

While more expensive, none of these drugs have demonstrated superior efficacy over aspirin. Like the use of these drugs in osteoarthritis, use of these drugs in the treatment of rheumatoid arthritis is a classic example of suppression of symptoms, while accelerating the factors which promote the disease process. In the case of rheumatoid arthritis, NSAIDs have been shown to greatly increase the already hyperpermeable gastrointestinal tract of rheumatoid arthritis sufferers.^[18] The use of NSAIDs in rheumatoid arthritis is also a significant cause of serious gastrointestinal tract reactions, including ulcers, hemorrhage, and perforation. Approximately 20,000 hospitalizations and 2,600 deaths occur as a result of NSAIDs each year in individuals with rheumatoid arthritis.^[19]

If NSAIDs are not effective, corticosteroids may be used. However, most experts and medical textbooks clearly state that long-term use of corticosteroids in rheumatoid arthritis is not advised due to the side-effects. Nonetheless, long-term corticosteroid use is quite common in patients with rheumatoid arthritis.

If NSAID and cortisone therapy does not offer benefit, more aggressive and potentially more toxic treatments are used along with continued use of NSAIDs and corticosteroids. Hydroxychloroquine, gold therapy, penicillamine, azathioprine, methotrexate, and cyclophosphamide are examples of drugs currently in use. Unfortunately, in most cases, the benefit produced by these drugs is greatly outweighed by the significant toxicity they possess. The use of these drugs often requires the use of additional drugs to deal with side-effects. It is not uncommon for individuals with rheumatoid arthritis to be on 12 or more prescription drugs at one time. And finally, joint surgery and replacement are reserved for the most severe cases.

Corticosteroids

Prednisone is by far the most frequently prescribed oral corticosteroid. Other drugs in this category include prednisolone, methyl-prednisolone, dexamethasone, and betamethasone. Prednisone blocks many key steps in

1524

the allergic and inflammatory response including the production and secretion of the inflammatory mediators such as histamine, prostaglandins, and leukotrienes by white blood cells. This disruption of the normal defense functions of the white blood cells is effective in stopping the inflammatory response, but essentially cripples the immune system.

Although prednisone is often of great benefit in the short-term management of many chronic inflammatory diseases, long-term use generally causes more problems than benefits. As long-term corticosteroid use has many significant side-effects, most physicians try to reserve the use of prednisone for acute worsening of the rheumatoid arthritis. Because long-term treatment with corticosteroids suppresses the natural production of the corticosteroids produced by the adrenal gland, sudden withdrawal of the drugs may lead to collapse, coma, and death.

The side-effects of oral corticosteroids are a function of dosage levels and length of time on the medication. Most of the problems of side-effects are not due to taking too much of the drug for a short period of time, but rather reflect long-term use. At lower doses (less than 10 mg/day), the most notable side-effects are usually increased appetite, weight gain, retention of salt and water, and increased susceptibility to infection.

Common side-effects of long-term corticosteroid use at higher dosage levels include:

- depression and other mental/emotional disturbances (up to 57% of patients being treated with high doses of prednisone for long periods of time develop these symptoms)
- high blood pressure
- diabetes
- peptic ulcers
- acne
- excessive facial hair in women
- insomnia
- muscle cramps and weakness
- thinning and weakening of the skin
- osteoporosis
- susceptibility to the formation of blood clots.

The other drugs used in rheumatoid arthritis are often referred to as “disease-modifying

drugs". These drugs include hydroxychloroquine, gold therapy, penicillamine, azathioprine, methotrexate, and cyclophosphamide.

Hydroxychloroquine (Plaquinil)

Hydroxychloroquine was originally used in the treatment of malaria. In the treatment of rheumatoid arthritis, hydroxychloroquine is thought to work via inhibiting the immune system. Hydroxychloroquine must be used for at least 6 months to determine if it is going to be of value in rheumatoid arthritis. Since hydroxychloroquine is associated with a high rate of side-effects, use is often discontinued before this time period. Mild adverse effects include skin rashes, loss of hair, headache, blurring of vision, ringing in the ears, loss of appetite, nausea, vomiting, stomach cramps, and diarrhea. More severe side-effects include emotional or psychotic mental changes, seizures, excessive muscle weakness, damage to the eyes with significant impairment of vision, anemia, decreased white blood cell counts, and frequent infections.

Gold therapy

Gold salt injection aids about 50% of patients, but severe side-effects occur in nearly one-third of patients. Oral gold salts are slightly less toxic, but still cause skin rashes, painful mouth ulcers, bone marrow suppression, and, in some cases, even more serious side-effects such as kidney damage. Like hydroxychloroquine, a trial of 6 months is required to determine the likely benefit of gold therapy.

Penicillamine

Penicillamine was originally used in the treatment of copper, mercury, and lead poisoning. It works by binding to these metals and promoting their excretion. Penicillamine has been used in the treatment of rheumatoid arthritis since the early 1960s. Its use has fallen out of favor in the 1990s because of a growing concern for its safety as well as questionable effectiveness. Penicillamine can cause kidney damage, blood and bone marrow toxicity, and severe muscular weakness. Like other disease-modifying drugs, it must be used for at least 6 months to determine if it is effective.

Azathioprine

Azathioprine is a drug which suppresses the immune system. It is often used to severely impair the immune system after organ transplantation in an attempt to prevent tissue rejection. Azathioprine is more powerful than the previously discussed disease-modifying drugs and provides more immediate benefits. With this increased potency comes significant toxicity. Side-effects include skin rash, loss of appetite, nausea, vomiting, diarrhea, sore on lips and mouth, bone marrow suppression, weakness, and fatigue. Azathioprine is also associated with increasing the risk of certain cancers.

Methotrexate

Methotrexate is used primarily in the treatment of cancer and a severe disabling form of psoriasis. It works by inhibiting the utilization of folic acid which is required for cell reproduction. Without the ability to utilize folic

1525

acid, cells are unable to divide and multiply. The goal in the case of rheumatoid arthritis is to inhibit the replication of white blood cells and thus the immune system.

Methotrexate is the next step in potency and toxicity. Side-effects include gastrointestinal ulceration and bleeding; loss of hair; mouth and throat ulcers; severe bone marrow suppression; damage to the lungs, liver, and kidneys; increased rate of infections; and increased risk for developing cancer.

Cyclophosphamide

Cyclophosphamide is used primarily in the treatment of various forms of cancer. It is more powerful than all the previously described disease-modifying drugs. Toxicity is a major problem with side-effects being comparable to methotrexate, but more severe.

THERAPEUTIC CONSIDERATIONS

There is little argument that rheumatoid arthritis is an aggressive disease which calls for aggressive measures. There is also little argument that current medical treatment of rheumatoid arthritis is aggressive. The big question is: Is aggressive chemotherapy for rheumatoid arthritis actually providing benefit? And at what cost to the patient?

Research is only beginning to determine the effects of treatment on the long-term outcome of rheumatoid arthritis because in order to fully answer the questions raised in the previous paragraph patients must be followed for at least 20 years. Many of the disease-modifying drugs have only been used for the last two or three decades.

A revealing study evaluated the long-term outcome of therapy in 112 patients with rheumatoid arthritis treated with conventional drug therapy.^[20] After 20 years, despite aggressive therapy with standard drug regimens, only 18% of all patients were able to lead a normal life. Most patients (54%) were either dead (35%) or severely disabled (19%). Most mortalities were directly related to rheumatoid arthritis. The results of this study clearly indicate that, although current drug therapy may be effective in providing short-term benefit, this approach is not providing long-term benefits to patients with rheumatoid arthritis.

Rheumatoid arthritis as a multifactorial condition requires a comprehensive therapeutic approach which focuses on reducing those factors known to be involved in the disease

process (gut permeability, circulating immune complexes, free radicals, immune dysfunction, etc.), controlling inflammation and promoting joint regeneration. The natural approach involves improving poor digestion, food allergies, increased gut permeability, increased circulating immune complexes, and excessive inflammatory processes. Foremost in the natural approach is the use of diet to control inflammation.

Diet

Diet has been strongly implicated in rheumatoid arthritis for many years, in terms of both cause and cure. Population studies have demonstrated that rheumatoid arthritis is not found in societies that eat a more “primitive” diet and is found at a relatively high rate in societies consuming the so-called “Western” diet.^[21] Therefore, a diet rich in whole foods, vegetables, and fiber, and low in sugar, meat, refined carbohydrate, and saturated fat appears to offer some protection against developing rheumatoid arthritis. In addition, dietary therapy is showing tremendous promise in the treatment of rheumatoid arthritis.^{[22] [23] [24]} The major focus in dietary therapy is:

- eliminating food allergies
- following a vegetarian diet
- modifying the intake of dietary fats and oils
- increasing the intake of antioxidant nutrients.

Food allergy

Elimination of allergic foods has been shown to offer significant benefit to some individuals with rheumatoid arthritis.^{[25] [26] [27] [28]} Virtually any food can result in aggravating rheumatoid arthritis, but the most common offending foods are wheat, corn, milk and other dairy products, beef, and nightshade family foods (tomato, potato, eggplants, peppers, and tobacco) as well as food additives.

A well-designed study highlights the effectiveness of eliminating food allergens as part of a healthy diet and lifestyle program in the treatment of rheumatoid arthritis.^[29] In a 13 month study, two groups of patients suffering from rheumatoid arthritis were studied to determine the effect of diet on their condition. One group followed a therapeutic diet, the other group continued to eat as they wished. Both groups started the study by visiting a spa for 4 weeks.

The treatment group began their therapeutic diet by fasting for 7–10 days. Dietary intake during the fast consisted of herbal teas, garlic, vegetable broth, decoction of potatoes and parsley, and the following juices: carrots, beets, and celery. No fruit juices were allowed. Patients with rheumatoid arthritis have historically benefited from fasting; however, strict water fasting should only be done under direct medical supervision. Fasting decreases the absorption of allergic food components as well as reducing the levels of inflammatory mediators. A juice fast or a fast similar to the one used in this study is probably safer than a water fast and may actually yield better results. Short-term fasts of 3–5 days’ duration are recommended during acute worsening of

rheumatoid arthritis (see [Ch. 47](#) for a full discussion of therapeutic fasting.)

1526

After the fast, the patients reintroduced a “new” food item every second day. If they noticed an increase in pain, stiffness, or joint swelling within 2–48 hours, this item was omitted from the diet for at least 7 days before being reintroduced a second time. If the food caused worsening of symptoms after the second time, it was omitted permanently from the diet.

The results of the study further supported the positive results noted in other studies showing that shortterm fasting followed by a vegetarian diet results in “a substantial reduction in disease activity” in many patients.^[30]^[31]^[32] The results indicated a therapeutic benefit beyond elimination of food allergies alone. The authors suggested that the additional improvements were due to changes in dietary fatty acids (discussed below). In addition, other studies have shown that improvements with a vegetarian diet are associated with improvements in fecal flora (also discussed below).

In a 1 year follow-up to this important study, all the patients who responded to the diet still followed the diet.^[33] Significant benefits were noted in the patients who responded to the diet compared with those subjects who did not respond and with the control group on an omnivorous diet. These long-term results support recommending a vegetarian diet in the treatment of rheumatoid arthritis.

Fecal flora

Altered gastrointestinal tract flora has been linked to rheumatoid arthritis and other autoimmune diseases (see above). Two recent randomized, clinical studies demonstrate that significant changes in microbial flora are associated with clinical improvements.^[34]^[35] In the first study, researchers sought to determine the effect of vegetarian diet-induced improvement of RA on fecal flora in 53 patients.^[34] Rather than the traditional method of isolating, identifying, and enumerating different bacterial species in fecal samples, the researchers examined bacterial fatty acid profiles. Human fecal flora is a very complex ecosystem with over 400 different species, making it very difficult to isolate and identify the species. Because of the lack of reproducibility and the fact that many bacteria do not grow well on selective culture media and many prevent the growth of other species, classic bacteriological techniques are generally regarded as being unsuitable for the study of the microecology of the human gut.

Instead of focusing on specific species, the researchers used another approach to detect overall changes in bacterial flora of stool cultures collected at baseline, 4 weeks, and thereafter every 3 months for 1 year. The technique used was computerized comparison of bacterial fatty acid profiles produced by gas–liquid chromatography of stool samples. The fatty acids extracted are structural components of bacterial cell membranes. Each bacterial species has its own characteristic composition. In a stool sample, the profile of fatty acids represents all the bacteria present in the sample. This

technique has proven to be more sensitive than classical quantitative culture in detecting microecological changes in stool samples.

In the first study, the 53 patients, based on repeated clinical assessments, were assigned to either a high-improvement index (HI) or a low-improvement index (LI). Significant alteration in the intestinal flora was observed when the patients changed from the omnivorous to the vegetarian diet. These results further document a direct association between intestinal flora and disease activity in rheumatoid arthritis.

The second study, of 43 patients, provided additional support for the positive effects of a vegetarian diet producing clinical improvements in RA.^[35] Forty-three RA patients were divided into a treatment group or a control group. The treatment group followed a vegetarian diet for 1 month, the control group consumed their normal diet. At the end of only 30 days, positive changes in fecal flora correlated with improvements in RA.

These findings are not surprising. Fecal flora undoubtedly play a major role in health. The total surface area of the gastrointestinal system is approximately 300–400 m². Only a single epithelial layer separates the host from enormous amounts of dietary and microbial antigens. Fortunately, the gut-associated lymphoid tissue, the largest lymphoid organ, helps to protect the individual from antigens that pass through this epithelial layer. Alterations in intestinal flora change the antigenic challenge. In an autoimmune condition like rheumatoid arthritis, this change may significantly impact disease activity.

Gas–liquid chromatography of stool samples may prove to be a relatively quick and easy method of forecasting clinical improvement in rheumatoid arthritis.

Digestion

Proper digestion is a requirement for optimum health, and incomplete or disordered digestion can be a major contributor to the development of many diseases including rheumatoid arthritis. The problem is not only that ingestion of foods and nutritional substances is of little benefit when breakdown and assimilation are inadequate, but also that incompletely digested food molecules can be inappropriately absorbed. Since many individuals with rheumatoid arthritis are deficient in digestive factors, including hydrochloric acid and pancreatic enzymes, incomplete digestion may be a major factor in rheumatoid arthritis.^{[36] [37]}

Supplementation with appropriate digestive aids appears warranted. Beyond its physiological role in digestion, pancreatic enzymes may offer additional

benefits. Specifically, the proteases in pancreatin have been shown to reduce circulating levels of immune complexes in autoimmune diseases such as:^{[38] [39]}

- rheumatoid arthritis
- lupus erythematosus
- periarteritis nodosa
- scleroderma
- ulcerative colitis
- Crohn's disease
- multiple sclerosis
- AIDS.

Since clinical improvements usually correspond with decreases in immune complex levels (the erythrocyte sedimentation rate can be used as a rough indicator), pancreatic or bromelain (discussed below) supplementation is often warranted.

Dietary fats

Fatty acids are important mediators of allergy and inflammation through their role as precursors of inflammatory prostaglandins, thromboxanes, and leukotrienes. Altering dietary oil intake can significantly increase or decrease inflammation depending on the type of balance of fatty acids. The basic goal is twofold:

- reduce the level of arachidonic acid
- increase the level of DHGLA and EPA.

Vegetarian diets are often beneficial in the treatment of many chronic allergic and inflammatory conditions, including rheumatoid arthritis, presumably as a result of decreasing the availability of arachidonic acid for conversion to inflammatory prostaglandins and leukotrienes, while simultaneously supplying linoleic and linolenic acids.

An important nutritional approach to decreasing the inflammatory response is the consumption of cold-water fish such as mackerel, herring, sardines, and salmon. These fish are rich sources of eicosapentaenoic acid (EPA) which competes with arachidonic acid for prostaglandin and leukotriene production. The net effect of consumption of these fish is a significantly reduced inflammatory/ allergic response.

To test the hypothesis that omega-3 fatty acids may protect against the development of RA, a population-based case-control study in women living in the Seattle area compared fish consumption in 324 cases of RA with 1,245 controls.^[40] Consumption of broiled or baked fish was associated with a decreased risk of rheumatoid arthritis. An apparent dose-dependent response was noted in that consuming more than two servings per week offered greater protection compared with one serving per week.

Based on this study and the one described previously on the benefits of a vegetarian diet, it appears that the best diet for the prevention of rheumatoid arthritis is a vegetarian diet with the exception of cold-water fish. Flaxseed oil supplementation (discussed

below) may also be useful.

Nutritional supplements

GLA

Evening primrose, blackcurrant, and borage oil contain gamma-linolenic acid, an omega-6 fatty acid that eventually acts as a precursor to the anti-inflammatory prostaglandins of the 1 series. Although quite popular, the research on GLA supplements in rheumatoid arthritis is controversial and not as strong as the research on omega-3 oils. Studies have actually shown that over the long term GLA supplementation will increase tissue arachidonic acid levels while decreasing tissue levels of EPA.^[41] Obviously, this effect is contrary to the treatment goal of trying to reduce inflammation by reducing tissue levels of arachidonic acid and raising levels of EPA.

Some studies in rheumatoid arthritis have shown benefit with GLA supplementation, while others have not.^{[42] [43] [44]} The key factor appears to be whether or not subjects are allowed to take their anti-inflammatory drugs. These drugs inhibit the formation of inflammatory prostaglandins and would mask the negative effects of the altered tissue fatty acid profile produced by GLA supplements.

Although positive results have been reported with GLA supplementation, closer examination is required. For example, in one double-blind study, 37 patients with rheumatoid arthritis were given either GLA (1.4 g/day) or placebo for 24 weeks. GLA supplementation reduced the number of tender joints by 36%, the tender joint score by 45%, swollen joint count by 28%, and the swollen joint score by 41%.^[44] In contrast, no patients in the placebo group showed significant improvement in any measure. The superficial results of this study indicate that borage oil may be useful in reducing the inflammatory process of rheumatoid arthritis. However, in this study the subjects continued to take their anti-inflammatory drugs and probably masked the detrimental effects on tissue arachidonic acid and EPA levels.

The recommended daily dosage for GLA in the treatment of rheumatoid arthritis is 1.4 g. Since evening primrose oil is 9% GLA, this means that approximately 31 500 mg capsules of evening primrose oil would have to be consumed each day. This dosage would typically cost a person nearly \$100 per month to attain. Taking less than the recommended dosage is not likely to produce benefit. For several reasons, including cost, omega-3 oils appear to be a better choice.

Also, another controversial aspect is the fact that because GLA can be formed from linoleic acid, it is difficult to determine to what extent the effects are due to GLA vs. linoleic acid. Most sources of GLA are much richer in linoleic acid than GLA. For

example, evening primrose contains only 9% GLA, but contains 72% linoleic acid.

Omega-3 fatty acids

The studies of fish oil supplementation in the treatment of rheumatoid arthritis have demonstrated far better and more consistent responses than the studies with GLA supplementation. The first double-blind, placebo-controlled study of rheumatoid arthritis patients using 1.8 g/day of EPA showed less morning stiffness and tender joints.^[45] These results led to considerable scientific interest as well as numerous popular press accounts of the possible benefits of fish oil for allergic and inflammatory conditions.

Over a dozen follow-up studies have consistently demonstrated positive benefits.^{[46] [47] [48] [49] [50] [51] [52] [53]} As well as improvements in symptoms (morning stiffness and joint tenderness), fish oil supplementation has produced favorable changes in suppressing the production of inflammatory compounds secreted by white blood cells. Unfortunately, since it has been shown that commercially available fish oils contain very high levels of lipid peroxides and greatly stress antioxidant defense mechanisms, at this time it makes the most sense to rely on cold-water fish and flaxseed oil for the omega-3 oils rather than fish oil capsules.^{[54] [55] [56]}

Although several studies have shown that flaxseed oil is not as effective in increasing tissue concentrations of EPA and lowering tissue concentrations of arachidonic acid as fish oils, these studies failed to address an important factor.^{[57] [58]} The studies were all performed on subjects continuing to consume a diet rich in omega-6 fatty acids. Although the desaturation and elongation enzymes prefer alpha-linolenic acid to the omega-6 oils, in these studies only relatively small amounts of alpha-linolenic acid were converted to EPA because of the much higher concentrations of omega-6 oils. A more recent study was undertaken to determine the potential for dietary flaxseed oil to increase tissue EPA concentration in healthy human subjects.^[59]

Unlike the previous studies, this study incorporated a diet low in omega-6 oils by restricting the use of other vegetable oils while supplementing the diet with 13 g (approximately 1 tbsp) of flaxseed oil daily. The results of the study indicated that flaxseed oil supplementation, along with restriction of linoleic acid, will raise tissue EPA levels comparable to fish oil supplementation. Furthermore, several human and animal studies have demonstrated that flaxseed oil supplementation can inhibit the autoimmune reaction as well as EPA.^[60]

Unfortunately, a small, 22 patient double-blind study over a 2 month period did not show any benefit with flaxseed oil (30 g/day) versus the same amount of safflower oil.^[61] However, upon examination of the data, a possible explanation presents itself. In order to provide clinical benefit, flaxseed oil would have to reduce the tissue concentration of arachidonic acid while simultaneously increasing the tissue concentration of EPA and DHA. Tissue analysis in patients involved in this study who were taking flaxseed oil did not demonstrate significant changes in tissue levels of either arachidonic acid or EPA and DHA. Previous studies have shown that it is possible to raise tissue levels of EPA and DHA and lower levels of arachidonic acid with flaxseed oils if the intake of omega-6 oils is restricted. The failure to improve tissue lipid concentrations in this study led to the

ineffectiveness of flaxseed oil.

The reason behind the failure to improve lipid concentrations is either failure to restrict the use of other vegetable oils while supplementing the diet with flaxseed oil or failure to correct an underlying zinc deficiency. Evidence to support a failure to restrict the intake of omega-6 oils is offered by the fact that there was no significant change in the alpha-linolenic acid to linoleic acid ratio in test subjects. Evidence to support failure to correct an underlying zinc deficiency comes from serum zinc analysis on test subjects. Zinc functions in delta-6-desaturase, the enzyme involved in the conversion of alpha-linolenic acid to EPA and DHA. Zinc deficiency is common in rheumatoid arthritis. In fact, several studies have shown zinc supplementation to improve rheumatoid arthritis. The fact that tissue levels of alpha-linolenic acid increased while on the flaxseed oil and that EPA and DHA levels did not suggests zinc deficiency. This led researchers to measure serum zinc in the patients in the study.

The researchers concluded:

Low conversion of alpha-linolenic acid to EPA and DHA [due to a zinc deficiency], together with a low alpha-linolenic acid to linoleic acid ratio, might explain why a short term alpha-linolenic acid supplementation did not alter the RA disease activity.

At this time, our recommendation is to follow the dietary recommendations of a vegetarian diet with the exception of cold-water fish, restrict omega-6 fatty acids, and supplement the diet with one tablespoon of flaxseed oil daily.

Dietary antioxidants

The importance of consuming a diet rich in fresh fruits and vegetables cannot be overstated in the dietary treatment of rheumatoid arthritis. These foods are the best sources of dietary antioxidants. While the benefits of vitamin C, beta-carotene, vitamin E, selenium, and zinc

as antioxidant nutrients are becoming well-recognized and well-accepted, there are still other plant compounds which promote healthy joints. Of particular benefit in rheumatoid arthritis are flavonoids, due to their neutralization of inflammation and support of collagen structures.^[62] In short, the antioxidant benefits of fresh fruits and vegetables go well beyond the antioxidant effects of vitamins and minerals.

Several studies have shown that the risk of RA is highest in people with the lowest levels of nutrient antioxidants (e.g. serum concentrations of alpha-tocopherol, beta-carotene, and vitamin C). For example, in one study, persons with rheumatoid arthritis and systemic lupus erythematosus that developed 2–15 years after donating blood for a serum bank in 1974 were designated as cases.^[63] For each case, four

controls were selected from the serum bank donors, matched for race, sex, and age. Stored serum samples from cases and controls were assayed for alpha-tocopherol, beta-carotene, and retinol. Cases of both diseases had lower serum concentrations of alpha-tocopherol, beta-carotene, and retinol in 1974 than their matched controls.

Selenium and vitamin E

Selenium levels are low in patients with rheumatoid arthritis.^[64] ^[65] Low selenium levels may be a significant nutritional factor as selenium plays an important role as an antioxidant and serves as the mineral cofactor in the free radical scavenging enzyme glutathione peroxidase. This enzyme is especially important in reducing the production of inflammatory prostaglandins and leukotrienes. As free radicals, oxidants, prostaglandins, and leukotrienes cause much of the damage to tissues seen in rheumatoid arthritis, a deficiency of selenium would result in even more significant damage.

Clinical studies have not yet clearly demonstrated that selenium supplementation alone improves the signs and symptoms of rheumatoid arthritis. However, one clinical study indicated that selenium combined with vitamin E had a positive effect.^[66]

The best food sources are Brazil nuts, fish, and grains. However, the amount of selenium in grains and other plant foods is directly related to the amount of selenium available in the soil.

Zinc

Zinc has antioxidant effects and is a cofactor to the antioxidant enzyme superoxide dismutase (copper–zinc SOD). Zinc levels are typically reduced in patients with rheumatoid arthritis and several studies have used zinc in the treatment of rheumatoid arthritis, with some of the studies demonstrating a slight therapeutic effect.^[67] ^[68] ^[69] Most of the studies utilized zinc in the form of sulfate. Better results may be produced by using a form of zinc with a higher absorption rate such as zinc picolinate, zinc monomethionine, or zinc citrate. Foods rich in zinc include oysters, whole grains, nuts, and seeds.

Manganese and superoxide dismutase

Manganese functions in a different form of the antioxidant enzyme superoxide dismutase (manganese SOD). Manganese-containing SOD is deficient in patients with rheumatoid arthritis.^[70] The injectable form of this enzyme (available in Europe) has been shown to be effective in the treatment of rheumatoid arthritis.^[71] However, it is not clear if any orally administered SOD can escape digestion in the intestinal tract and exert a therapeutic effect. In one study, oral SOD was shown not to affect tissue SOD levels.^[72]

Perhaps a better and more economical method of raising SOD is to supplement the diet with additional manganese. Manganese supplementation has been shown to increase

SOD activity.^[73] Although no clinical studies have been conducted to determine the effectiveness of manganese supplementation in rheumatoid arthritis, it appears to be indicated based on the low levels seen in patients with rheumatoid arthritis as well as its biochemical functions. Good dietary sources include nuts, whole grains, dried fruits, and green leafy vegetables. Meats, dairy products, poultry, and seafood are considered poor sources of manganese.

Vitamin C

Vitamin C functions as an important antioxidant. The white blood cell and plasma concentrations of vitamin C are significantly decreased in rheumatoid arthritis patients.^[74] Supplementation with vitamin C increases SOD activity, decreases histamine levels, and provides some anti-inflammatory action.^[75] ^[76] Foods rich in vitamin C include broccoli, Brussels sprouts, cabbage, citrus fruits, tomatoes, and berries.

Pantothenic acid

Whole blood pantothenic acid levels have been reported to be lower in rheumatoid arthritis patients compared with normal controls.^[77] In addition, disease activity was inversely correlated with pantothenic acid levels. Correction of low pantothenic acid levels to normal brings about some alleviation of symptoms.

In one double-blind study, subjective improvement was noted in patients receiving 2 g/day of calcium pantothenate.^[78] Patients noted improvements in duration of morning stiffness, degree of disability, and severity of pain. Good dietary sources of pantothenic acid are whole grains and legumes.

Copper

Copper aspirinate (salicylate) is a form of aspirin that yields better results in reducing pain and inflammation than standard aspirin preparations. These copper-containing substances may be indicated in RA patients requiring aspirin.^[79] ^[80]

The wearing of copper bracelets has been a long-time folk remedy which appears to have some scientific support, as found in a double-blind study performed in Australia. Presumably, copper is absorbed through the skin and is chelated to another compound which is able to exert anti-inflammatory action.^[81]

Copper is a component, along with zinc, in one type of superoxide dismutase (copper–zinc SOD). Deficiency may result in significant susceptibility to free radical damage as a result of decreased SOD levels. However, an excess intake of copper may be detrimental due to its ability to combine with peroxides and damage joint tissues.^[80]

[82]

Sulfur

The sulfur (cysteine) content in fingernails of arthritis sufferers is lower than that of healthy controls.^[83] Normalizing the sulfur content of the nails by administering intravenous or intragluteal colloidal sulfur was reported to alleviate pain and swelling according to clinical data from the 1930s.^[84] ^[85] Presumably, increasing the sulfur content of the body through increased consumption of sulfur-rich foods like legumes, garlic, onions, Brussels sprouts, and cabbage or through supplementation may be of equal benefit.

Niacinamide

Dr William Kaufman and Dr Abram Hoffer have reported very good clinical results in the treatment of hundreds of patients with rheumatoid arthritis and osteoarthritis using high-dose niacinamide (i.e. 900–4,000 mg in divided doses daily).^[86] ^[87] While these promising results have been confirmed in osteoarthritis (see [Ch. 176](#)), they have never been fully evaluated in detailed clinical studies of rheumatoid arthritis patients. Niacinamide has been shown to impact the autoimmune process involved in insulin-dependent diabetes mellitus (see [Ch. 147](#)).

Botanical medicines

Many botanicals possess significant anti-inflammatory action and are useful in the treatment of rheumatoid arthritis. The suggestions below represent some of the more popular and better researched of these botanical medicines. Several herbs are also discussed in relation to their ability to enhance the function or secretion of endogenous corticosteroids as well as their ability to prevent or reverse some of the negative effects of orally administered cortisone.

Curcuma longa

Curcumin, the yellow pigment of *Curcuma longa* (turmeric), exerts excellent anti-inflammatory and antioxidant effects.^[88] ^[89] ^[90] ^[91] ^[92] ^[93] Curcumin is as effective as cortisone or the potent anti-inflammatory drug phenylbutazone in models of acute inflammation. However, while phenyl-butazone and cortisone are associated with significant toxicity, curcumin is without side-effects.

Curcumin exhibits many direct anti-inflammatory effects including inhibiting the formation of leukotrienes and other mediators of inflammation. However, curcumin also appears to exert some indirect effects. In models of chronic inflammation, curcumin is much less active in animals that have had their adrenal glands removed. This observation suggests that curcumin works to enhance the body's own anti-inflammatory mechanisms. Possible mechanisms of action include:

- stimulation of the release of adrenal corticosteroids

- “sensitizing” or priming cortisone receptor sites, thereby potentiating cortisone action
- preventing the breakdown of cortisone.

Curcumin has demonstrated some beneficial effects in human studies comparable to standard drugs. In one double-blind clinical trial in patients with rheumatoid arthritis, curcumin (1,200 mg/day) was compared with phenylbutazone (300 mg/day).^[94] The improvements in the duration of morning stiffness, walking time, and joint swelling were comparable in both groups. However, it must be pointed out that while phenylbutazone is associated with significant adverse effects, curcumin has not been shown to produce any side-effects at the recommended dosage level.

In another study which used a new human model for evaluating NSAIDs, the postoperative inflammation model, curcumin was again shown to exert comparable anti-inflammatory action to phenylbutazone.^[95]

It must be pointed out that while curcumin has an anti-inflammatory effect similar to phenylbutazone and various NSAIDs, it does not possess direct analgesic action.

The results of these studies indicate that turmeric or curcumin may provide benefit in the treatment of acute exacerbations of inflammation in rheumatoid arthritis. Furthermore, the safety and excellent tolerability of curcumin compared with standard drug treatment is a major advantage. Toxicity reactions to curcumin have not been reported. Animals fed very high levels of curcumin (3 g/kg body weight) have not exhibited any significant adverse effects.^[96]

The recommended dosage for curcumin as an anti-inflammatory

1531

is 400–600 mg three times a day. To achieve a similar amount of curcumin using turmeric would require a dosage of 8,000–60,000 mg. Because there remains a question on the absorption of orally administered curcumin, curcumin is often formulated in conjunction with bromelain to possibly enhance absorption. In addition, bromelain also has anti-inflammatory effects (see below). If a curcumin–bromelain combination is used, it is important to take it on an empty stomach 20 minutes before meals or between meals. Providing curcumin in a lipid base such as lecithin, fish oils, or essential fatty acids may also increase absorption.

Bromelain

Bromelain refers to a mixture of enzymes found in pineapple. Bromelain was introduced as a medicinal agent in 1957, and since that time over 200 scientific papers on its therapeutic applications have appeared in research literature.^[97] Bromelain has been reported to exert a wide variety of beneficial effects, including reducing inflammation in

rheumatoid arthritis.^[98]

Several mechanisms may account for bromelain's anti-inflammatory effects, including the inhibition of proinflammatory compounds. Much of bromelain's anti-swelling effects are due to activating compounds which break down fibrin. Fibrin's role in the promotion of the inflammatory response is to form a matrix that walls off the area of inflammation, resulting in blockage of blood vessels and inadequate tissue drainage and edema. Bromelain also blocks the production of kinins, compounds produced during inflammation which increase swelling as well as cause pain.

Zingiber officinalis

Ginger possesses numerous pharmacological properties, the most relevant in rheumatoid arthritis being its antioxidant effects; its inhibition of prostaglandin, thromboxane, and leukotriene synthesis; and its antiinflammatory effects. Fresh ginger may be more effective in the treatment of rheumatoid arthritis over dried preparations as it contains a protease that may have similar action to bromelain on inflammation.^[99]

Ginger's ability to inhibit the formation of inflammatory mediators along with its strong antioxidant activities and protease component suggest a possible benefit in inflammatory conditions.^[100] To test this hypothesis, a preliminary clinical study was conducted on seven patients with rheumatoid arthritis, in whom conventional drugs had provided only temporary or partial relief.^[101] All patients were treated with ginger. One patient took 50 g/day of lightly cooked ginger while the remaining six took either 5 g/day of fresh ginger or 0.1–1 g/day of powdered ginger. Despite the difference in dosage, all patients reported a substantial improvement, including pain relief, joint mobility, and a decrease in swelling and morning stiffness.

In the follow-up to this study, 28 patients with rheumatoid arthritis, 18 with osteoarthritis, and 10 with muscular discomfort who had been taking powdered ginger for periods ranging from 3 months to 2.5 years were evaluated.^[102] Based on clinical observations, it was reported that 75% of the arthritis patients and 100% of the patients with muscular discomfort experienced relief in pain or swelling. The recommended dosage was 500–1,000 mg/day, but many patients took three to four times this amount. Patients taking the higher dosages also reported quicker and better relief.

There remain many questions concerning the best form of ginger and the proper dosage. Most studies have utilized 1 g of dry powdered ginger root. This amount is a relatively small dose of ginger compared with the average daily dietary dose of 8–10 g consumed in India.

Although most scientific studies have used powdered ginger root, fresh (or possibly freeze-dried) ginger root at an equivalent dosage may yield better results because it contains higher levels of gingerol as well as the active protease.

In an effort to provide some practical application of the information presented here on ginger, it can be recommended that a daily dosage of 2–4 g of dry powdered ginger may

be effective. This amount would be equivalent to approximately 20 g or two-thirds of an ounce of fresh ginger root, roughly a 0.5 inch slice. These amounts of ginger can easily be incorporated into the diet in fresh fruit and vegetable juices. There do not appear to be any side-effects with ginger at these levels.

Bupleuri falcatum

Chinese thoroughwax root is an important component in various Chinese traditional medicine prescriptions, particularly in remedies for inflammatory conditions. Recently these formulas have also been used in combination with corticosteroid drugs like prednisone.^[103] Chinese thoroughwax has been shown to enhance the activity of cortisone.

The active constituent components of Chinese thoroughwax are steroid-like compounds known as saikosaponins. These compounds have diverse pharmacological activity including significant anti-inflammatory action.^[104] The saikosaponins apparently both increase the release of cortisone and other hormones by the adrenal gland and potentiate their effects. Saikosaponins have also been shown to prevent the adrenal gland atrophy caused by corticosteroids.^[105] It has been recommended that patients on corticosteroid drugs should take herbal formulas containing Chinese thoroughwax to help protect the adrenal gland.^[106]

Glycyrrhiza glabra and *Panax ginseng* appear to enhance the action of Chinese thoroughwax and the three are almost always used together in traditional Chinese herbal formulas. Both licorice root and ginseng have components with anti-inflammatory activity.^[106] In addition, these herbs have also been shown to improve the activity of the adrenal glands. Perhaps licorice's major effect is its ability to inhibit the breakdown of adrenal hormones by the liver. When used in combination with Chinese thoroughwax, the net effect is increased corticosteroids in the circulation, as a result of Chinese thoroughwax promoting secretion of these hormones by the adrenal glands combined with licorice root's ability to inhibit the liver breakdown.

Preparations containing Chinese thoroughwax, licorice, and *Panax ginseng* may help to restore adrenal function in patients with a history of long-term or high-dosage corticosteroid use.

Physical medicine

Physical therapy has a major role in the management of patients with rheumatoid arthritis. While not curative, proper physical management can improve patient comfort and preserve joint and muscle function. Heat is typically used to help relieve stiffness and pain, relax muscles, and increase range of motion. Moist heat (e.g. moist packs, hot baths) is more effective than dry heat (e.g. heating pad), and paraffin baths are used if skin irritation from regular water immersion develops. Cold packs are of value during

acute flare-ups.

Strengthening and range-of-motion exercises are important for improving and maintaining joint function, as well as general health. Patients with well-developed disease and significant inflammation should begin with progressive, passive range-of-motion and isometric exercises. As inflammation is ameliorated, active range-of-motion and isotonic exercises are more appropriate.

Balneotherapy

Balneotherapy, the therapeutic use of mineral baths and mud packs, is a form of physical therapy often recommended in cases of rheumatoid arthritis in Europe. A study conducted in Israel provides some evidence of benefit.^[107] The study was along the western shore of the Dead Sea at the Ein Gedi Spa. This area along the Dead Sea is renowned for its many hot, thermomineral springs and a large natural concentration of mud useful for therapeutic purposes. The area is also popular to persons with rheumatoid arthritis because of its unique climatic conditions — high barometric pressures, low humidity, high temperatures, paucity of rainfall, and absence of air pollution.

Standard spa therapy for rheumatoid arthritis in this region consists of mud packs, sulfur baths, and bathing in the waters of the Dead Sea. In a previous study, it was shown that sulfur and mud pack therapy, alone or in combination, are effective in reducing inflammation and pain in active rheumatoid arthritis. A recent study was conducted to determine whether there was any treatment advantage to sulfur baths or bathing in the Dead Sea, alone or in combination, in the treatment of active rheumatoid arthritis.

Thirty-six patients with active rheumatoid arthritis were treated for 12 days at the spa. The patients were divided randomly into four study groups: group 1 was treated with daily baths in the Dead Sea; group 2 was treated with daily sulfur baths; group 3 was treated with a combination of daily Dead Sea bathing and sulfur baths; and group 4 served as a control group. All patients were assessed by a rheumatologist who was blinded to the treatment modalities and group allocation. Clinical parameters assessed included: duration of morning stiffness, 15 m walk time, grip strength, activities of daily living assessment, patient's assessment of disease activity, number of active joints, and the Ritchie articular index.

The study found a statistically significant improvement lasting up to 3 months in only the three treatment groups. In morning stiffness, 15 m walk time, grip strength, activities of daily living assessment, and patient's assessment of disease activity, there was an advantage shown for Dead Sea baths, either alone or in combination with sulfur baths. The number of active joints and the Ritchie index improved to a similar degree in all three treatment groups. [Table 185.2](#) lists the results on the Ritchie index by treatment group.

Several research studies have attempted to determine why the Dead Sea baths were so effective. The Dead Sea is extremely saline – 10 times greater than the Mediterranean Sea. However, this is not the most likely explanation, since a double-blind study in

rheumatoid arthritis that compared Dead Sea bath salts with regular table salt dissolved in the patient's home bath heated to 35°C for 20 minutes a day for 2 weeks showed statistically significant improvements in most of the clinical variables in the group using the Dead Sea bath salts compared with the group using table salt. Although muscle tone, joint mobility, and pain intensity are somewhat influenced by hydromechanical and thermal stimuli, the improvement noted with Dead Sea bathing is generally superior to regular hot baths. A possible

TABLE 185-2 -- Results of spa therapy for rheumatoid arthritis

| | Baseline | End of treatment | 1 month | 3 months |
|---------|-----------------|-------------------------|----------------|-----------------|
| Group 1 | 27.3 | 13.1 | 12.6 | 15.9 |
| Group 2 | 23.2 | 10.1 | 14.8 | 11.2 |
| Group 3 | 21.4 | 7.8 | 12.7 | 19.3 |
| Group 4 | 25.4 | 28 | 28.5 | 27.1 |

1533

explanation may be in the trace mineral content of the Dead Sea. It is possible that trace elements such as zinc and copper – key components in the antioxidant enzyme superoxide dismutase – as well as boron, selenium, rubidium, and other minerals may be absorbed through the skin. Below normal levels of several trace minerals have been reported in patients with rheumatoid arthritis.

The results of the present study are quite impressive in that most patients had severe active rheumatoid arthritis, yet no patient in the treatment group experienced any side-effect or aggravation of the disease. Compare this result with standard drug therapy for rheumatoid arthritis. Hopefully, there will be further studies to help understand the beneficial effects of Dead Sea baths.

THERAPEUTIC APPROACH

RA is a disease known to have many contributing factors. Effective treatment using natural therapies requires controlling as many of these factors as possible. Foremost is the use of dietary measures to reduce the causes and ameliorate the symptoms of RA. Symptom relief can also be attained through the use of standard physical therapy techniques (i.e. exercise, heat, cold, massage, diathermy, lasers, and paraffin baths), anti-inflammatory botanicals and nutrients and, in appropriate patients, bowel detoxification.

Rheumatoid arthritis is often an aggressive disease that needs aggressive treatment. In mild to moderate rheumatoid arthritis, the measures listed above are extremely effective on their own. In severe cases, NSAIDs and other drugs may be necessary, at least in the acute phase. However, encourage patients not to abandon the natural measures as

they will actually enhance the effectiveness of the drugs, resulting in lower dosages. When the drugs are necessary, prescribe deglycyrrhizinated licorice (DGL) to protect against developing peptic ulcers.

Diet

The first step is a therapeutic fast or an elimination diet followed by careful reintroduction of foods to detect those which determine symptoms. Virtually any food can result in aggravating RA, but the most common offenders are:

- wheat
- corn
- milk and other dairy products
- beef
- nightshade (*Solanum*) family foods – tomato, potato, eggplants, peppers, and tobacco.

After isolating and eliminating all allergens, a general healthy diet rich in whole foods, vegetables, and fiber, and low in sugar, meat, refined carbohydrates, and animal fats is indicated. Foods particularly beneficial for the RA patient include cold-water fish (mackerel, herring, sardines, and salmon) and flavonoid-rich berries (cherries, hawthorn berries, blueberries, blackberries, etc.) and their extracts.

Supplements

- DHEA: 50–200 mg/day
- EPA: 1.8 g/day; or flaxseed oil: 1 tbsp/day
- Niacinamide: 500 mg four times/day (monitor liver enzymes)
- Pantothenic acid: 500 mg four times/day
- Quercetin: 250 mg between meals three times/day
- Tryptophan: 400 mg three times/day
- Vitamin C: 1–3 g/day in divided doses
- Vitamin E: 400 IU/day
- Copper: 1 mg/day
- Manganese: 15 mg/day
- Selenium: 200 mcg/day
- Zinc: 45 mg/day
- Betaine HCl: 5–70 grains with meals (see [Appendix 7](#))
- Pancreatin (10 × USP): 350 mg–750 mg between meals three times/day; or bromelain: 250–750 mg (1,800–2,000 mcu) between meals three times/day.

Botanical medicines

The following botanicals may be used alone or in combination with others. Severe inflammation and joint destruction require more aggressive therapy.

Patients with a history of corticosteroid use (e.g. prednisone) and those being weaned

off corticosteroids need the botanicals *Bupleuri falcatum*, *Glycyrrhiza glabra*, and *Panax ginseng*, which prevent and/or reverse the adrenal gland atrophy induced by these drugs.

Dosages are as follows:

- Curcumin: 400 mg three times/day; or ginger: incorporate 8–10 g of fresh ginger into the diet each day or recommend ginger extracts standardized to contain 20% gingerol and shogaol at a dosage of 100–200 mg three times/day
- *Bupleuri falcatum*
 - dried root: 2–4 g

 - tincture (1:5): 5–10 ml

 - fluid extract (1:1): 2–4 ml

 - solid extract (4:1): 200–400 mg
- *Panax ginseng*
 - crude herb: 4.5–6 g/day

 - standardized extract (5% ginsenosides): 100 mg one to three times/day
- *Glycyrrhiza glabra*
 - dried root: 2–4 g

1534

- tincture (1:5): 10–20 ml

- fluid extract (1:1): 4–6 ml

- solid extract (4:1): 250–500 mg.

Physical medicine

- Heat (moist packs, hot baths, etc.): 20–30 minutes one to three times/day
- Cold packs for acute flare-ups
- Paraffin baths (if skin irritation is caused by hot water)
- Active (or in severe cases passive) range-of-motion exercises: 3–10 repetitions one to two times/day
- Progressive isometric (and isotonic as the joints improve) exercise: 3–10 repetitions several times per day with generous periods of rest

Massage: one to three times/week.

Chapter 186 - Rosacea

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

DIAGNOSTIC SUMMARY

- Chronic acneiform eruption on the face of middle-aged and older adults associated with facial flushing and telangiectasia
- The acneiform component is characterized by papules, pustules, and seborrhea; the vascular component by erythema and telangiectasia; and the glandular component by hyperplasia of the soft tissue of the nose (rhinophyma)
- The primary involvement occurs over the flush areas of the cheeks and nose

More common in women (3:1), but more severe in men.

GENERAL CONSIDERATIONS

Rosacea is a chronic skin disorder in which the nose and cheeks are abnormally red and may be covered with pimples similar to those seen in acne (see [Ch. 125](#)). Rosacea is a relatively common skin disorder in adults between the ages of 30 and 50, with women being affected about three times as often as men.

Many factors have been suspected of causing acne rosacea:

- alcoholism
- menopausal flushing
- vasomotor neurosis
- seborrheic diathesis
- local infection
- B-vitamin deficiencies
- gastrointestinal disorders.

Most cases are associated with moderate to severe seborrhea, although sebum

production is not increased in many. Vasomotor lability is prevalent, and migraine headaches are three times more common than in age- and sex-matched controls.

1538

THERAPEUTIC CONSIDERATIONS

Hypochlorhydria

Gastric analysis of rosacea patients has led to the postulate that it is the result of hypochlorhydria.^[1] Psychological factors, i.e. worry, depression, stress, etc., often reduce gastric acidity.^[2] Hydrochloric acid supplementation results in marked improvement in those rosacea patients who have achlorhydria or hypochlorhydria.^[1] ^[2] Rosacea patients have also been shown to have decreased secretion of lipase (although bicarbonate and chymotrypsin secretion were normal) and to benefit from pancreatic supplementation.^[3]

Helicobacter pylori

Given the high incidence of hypochlorhydria, it is perhaps not surprising that a high incidence of *Helicobacter pylori* infection in the stomach has also been found in rosacea patients.^[4] In a pilot study, *H. pylori* was found in the serum of 46 of 94 rosacea patients, 38 of 88 patients with other inflammatory diseases and five of 14 patients without an inflammatory disease. These researchers believe that the flushing reaction in rosacea is caused by gastrin or vasoactive intestinal peptides. They also quote an Irish study which found that 19 of 20 patients with acne rosacea were positive for *H. pylori*.

Another study which evaluated histological sections of the stomach mucosa found that 84% of 31 patients were *H. pylori*-positive.^[5] Interestingly, 20% of these histologically positive patients were serologically negative. The consistency between clinical success in the treatment of rosacea with metronidazole and the abatement of *H. pylori* isolates and serology after treatment provides additional evidence suggesting an etiologic relationship between rosacea and *H. pylori* infection.

Food allergy

The statistically significant incidence of migraine headaches accompanying rosacea points to food intolerance, as does the reflex flushing caused by vasodilator substances.

B vitamins

The administration of large doses of B vitamins has been shown to be quite effective,^[6] with riboflavin appearing to be the key factor.^[7] The mite *Demodex folliculorum* has been considered a causative factor, but it is a normal inhabitant of follicles. Although it may account for the more granulomatous response of some patients, it is interesting to note

that researchers were able to infect the skin of riboflavin-deficient rats with *Demodex*, but not the skin of normal rats.^[7]

While B vitamins are important for rosacea patients, some care must be exercised as some patients' rosacea may be aggravated by large dosages of these common nutrients. There is a case report of a 53-year-old female who presented to a dermatology clinic with a 9 month history of a facial eruption which resembled acne rosacea. Treatment with oral hydroxychloroquine, ibuprofen, terfenadine, prednisone, erythromycin and tetracycline had been tried during the 9 months without success. Topical desoximethasone, hydrocortisone, and cosmetic elimination also yielded no benefit. Patch test revealed a positive reaction to nickel. The eruption began at the time of a personal stress when she went through a marital separation. To help with her stress, she began taking 100 mg/day of pyridoxine and 100 mcg/day of B₁₂. Discontinuation of the vitamins resulted in dramatic improvement and with rechallenge her condition reappeared. The authors noted that inflammation and exacerbations of acne related to vitamins B₂, B₆, and B₁₂ have been reported in the European literature.^[8]

THERAPEUTIC APPROACH

Although the cause(s) has not yet been determined, sufficient information is available to adequately treat most patients. The control of hypochlorhydria and food intolerance forms the basis of therapy. This is supported with B-complex supplementation and the avoidance of vasodilating foods.

General recommendations

See [Chapter 125](#) for general recommendations.

Diet

Avoid coffee, alcohol, hot beverages, spicy foods, and any other food or drink that causes a flush. Eliminate from the diet all refined and/or concentrated sugars, foods containing *trans*-fatty acids such as milk, milk products, margarine, shortening and other synthetically hydrogenated vegetable oils as well as fried foods. Avoid milk and foods high in iodized salt.

Supplements

- B-complex: 100 mg/day (avoid niacin)
 - Pancreas extract (8–10 x USP): 350–500 mg before meals
 - Hydrochloric acid: provided in [Appendix 6](#).

Chapter 187 - Seborrheic dermatitis

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

DIAGNOSTIC SUMMARY

- Superficial erythematous papules and scaly eruptions occurring on the scalp, cheeks, and intertrigo of the axilla, groin, and neck
- Usually non-pruritic
- Seasonal, worse in winter.

GENERAL CONSIDERATIONS

Seborrheic dermatitis is a common papulosquamous condition with an appearance similar to eczema. Clinically it may be associated with excessive oiliness (seborrhea) and dandruff. The scale may be yellowish and either dry or greasy. The erythematous, follicular, scaly papules may coalesce to form large plaques or circinate patches. Flexural involvement is often complicated with *Candida* infection. The condition occurs either in infancy (usually between 2 and 12 weeks of age) or in the middle-aged or elderly and has a prognosis of lifelong recurrence.

The cause of seborrheic dermatitis is unknown. Genetic predisposition, emotional stress, diet, hormones, and infection with yeast-like organisms have all been implicated. Seborrheic dermatitis is now recognized as one of the most common manifestations of AIDS, affecting as many as 83%. This recent observation has given increased credence to the infection theory of seborrheic dermatitis.

THERAPEUTIC CONSIDERATIONS

Food allergy

Seborrheic dermatitis usually begins as “cradle cap” and, although not primarily an allergic disease, has been associated with food allergy (67% develop some form of

allergy by 10 years of age).^[1]

Biotin

The underlying factor in infants appears to be a biotin deficiency.^[2] A syndrome clinically similar to seborrheic

1542

dermatitis has been produced by feeding rats a diet high in raw egg white (high in avidin, a glycoprotein that binds biotin, making it unavailable for absorption). Since a large portion of the human biotin supply is provided by intestinal bacteria, it has been postulated that the absence of normal intestinal flora may be responsible for biotin deficiency in infants.^[2] A number of articles have demonstrated successful treatment of seborrheic dermatitis with biotin in both the nursing mother and the infant.^{[2] [3]}

In adults, treatment with biotin alone is usually of no value. It has been postulated that long-chain fatty acid synthesis is impaired in seborrheic lesions. B vitamins (biotin, pyridoxine, pantothenic acid, niacin, and thiamin and the lipotropics) are vital for fatty acid metabolism.

Pyridoxine

Both the administration of desopyridoxine, which induces pyridoxine deficiency in humans, and the placing of rats on a pyridoxine-deficient diet cause dermatological lesions indistinguishable from seborrheic dermatitis.^[4] Despite these results, oral and parenteral applications of pyridoxine have shown little success. However, in the sicca form of the disorder (involvement of the scalp – dandruff – brow, nasolabial folds, and bearded area with varying degrees of greasy adherent scales on an erythematous base), all patients cleared completely within 10 days with local application of a water-soluble ointment containing 50 mg/g of pyridoxine. Other types of seborrheic dermatitis, particularly flexural and infected, did not respond to this mode of therapy.

In patients with elevated levels of urinary xanthurenic acid, oral, parenteral, and local applications of pyridoxine all returned excretion levels to normal, implying transcutaneous absorption of pyridoxine.^{[4] [8]} These results are clouded, however, by the results of another study which indicate that the improvement from topical application may be due more to reduction in sebaceous secretion rate from the ointment itself, the added pyridoxine having no effect.^[9]

The patient should be checked for exposure to pyridoxine antimetabolites. Examples include the hydrazine dyes (FD&C yellow #5) and drugs (INH and hydralazine), dopamine, penicillamine, oral contraceptives, and excessive protein intake.^[10]

Folic acid

Oral treatment with folic acid has been only moderately successful (the use of the tetrahydro form showed dramatic results for one patient who became unresponsive to folic acid after childbirth). Patients with the sicca form were unresponsive.^[5] Parenteral injections of vitamin B₁₂, both synthetic and liver-extracted, have been shown to be very effective in many cases.^[6] This may be due to vitamin B₁₂'s role as a cofactor (with choline) in 5-methyl-tetrahydro folate methyltransferase, which regenerates tetrahydrofolate. It has been hypothesized that folate becomes trapped as 5-methyltetrahydrofolate by a lack of B₁₂ and/or choline.

Miscellaneous factors

Other B vitamins have also been shown to be involved in seborrheic dermatitis; experimentally induced ariboflavinosis produces the sicca form of the disorder.^[7]

THERAPEUTIC APPROACH

Although the optimal approach to treating all patients with seborrheic dermatitis is not clear at this time, effective therapy is available for most patients. In infants, alleviation of the biotin deficiency and control of the food allergies are the keys. For adults, correcting the impaired long-chain fatty acid synthesis by supplementing with large doses of vitamin B complex is the primary therapy. To maximize therapeutic results, we recommend a broad-spectrum approach. (Note that the following dosages are for adults; children's doses should be modified according to weight.)

Diet

Detect and treat food allergens. In nursing infants, the food allergies of the mother should be considered.

Supplements

- Biotin: 3 mg two times/day
- B complex: 50 mg two times/day
- Zinc: 25 mg/day (picolinate)
- Flaxseed oil: 1 tbsp/day.

Topical treatment

- Pyridoxine ointment: 50 mg/g (in water soluble base).

Chapter 188 - Senile cataracts

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

DIAGNOSTIC SUMMARY

- Clouding or opacity in the crystalline lens of the eye
- Absence or altered red reflex (small cataracts stand out as dark defects)
- Gradual loss of vision.

GENERAL CONSIDERATIONS

Cataracts are the leading cause of impaired vision and blindness in the United States. Approximately 4 million people have some degree of vision-impairing cataract, and at least 40,000 people in the US are blind due to cataracts. Cataracts are a source of a tremendous financial burden on our society; cataract surgery is the most common major surgical procedure done in the United States each year (600,000 per annum) for persons on Medicare.

Cataracts may be classified by location and appearance of the lens opacities, by cause or significant contributing factor, and by age of onset. Many factors may cause or contribute to the progression of lens opacity, including ocular disease, injury, or surgery, systemic diseases (e.g. diabetes mellitus, galactosemia), toxin, ultraviolet and near-ultraviolet light, or radiation exposure, and hereditary disease.

Aging-related (or senile) cataracts are discussed in this chapter and diabetic- and galactose-induced cataracts (sugar cataracts) are discussed in [Chapter 147](#) .

The crystalline lens is, obviously, a vital component of the optical system due to its ability to focus light (via changes in shape) while maintaining optical transparency. Unfortunately, this transparency decreases with age. The majority of the geriatric population display some degree of cataract formation. In the normal aging eye there is a

progressive increase in size, weight, and density of the lens throughout life.

Cataract formation is characterized histopathologically by:

- fibrous metaplasia of the epithelium
 - liquefaction of fibers resulting in Morgagnian globule
-

1546

formation (drops of fluid beneath the capsule and between the lens fibers)

- sclerosis (melding of fibers)
- posterior migration and swelling of the epithelium.

By a topoanatomic classification these basic alterations result in five types of cataracts:

- anterior subcapsular cataract – fibrous metaplasia of lens epithelium (usually follows iritis and adherence of the iris to the lens – posterior synechia)
- anterior cortical cataract – liquefaction of lens fibers occurs and Morgagnian globules form in the cortex anteriorly
- nuclear cataract – an exaggeration of the normal, aging-related, melding of fibers in the nucleus
- posterior cortical cataract – liquefaction and globular degeneration of the posterior lens cortex
- posterior subcapsular cataract – epithelial cells migrate posteriorly under the capsule and form large irregular nucleated cells.

About 75% of senile cataracts are cortical and the rest are nuclear. Clinically, cortical cataracts take three forms:

- spoke wheel, beginning in the periphery and coursing anteriorly and posteriorly to the nucleus
- perinuclear punctate opacities
- granular opacities under the posterior capsule (subcapsular cataracts).

THERAPEUTIC CONSIDERATIONS

The etiology of cataract formation is ultimately related to an inability to maintain normal homeostatic concentrations of Na^+ , K^+ , and Ca^{2+} within the lens. These abnormalities are apparently the result of decreased Na^+ , K^+ -ATPase activity,^{[1] [2] [3] [4] [5] [6]} a defect usually due to free radical damage to some of the sulfhydryl proteins in the lens, including Na^+ , K^+ -ATPase which contains a sulfhydryl component.

In cataract formation, the normal protective mechanisms are unable to prevent free radical damage. The lens, like many other tissues of the body, is dependent on adequate levels and activities of superoxide dismutase (SOD), catalase, and glutathione (GSH), and adequate levels of the accessory antioxidants vitamins E and C and

selenium, to aid in preventing free radical damage. Individuals with higher dietary intakes of vitamin C and E, selenium, and carotenes have a much lower risk for developing cataracts.^[7] These compounds are discussed individually below.

Antioxidants

Vitamin C

In addition to preventing cataracts, antioxidant nutrients like vitamin C may offer some therapeutic effects as well. Several clinical studies have demonstrated that vitamin C supplementation can halt cataract progression and, in some cases, significantly improve vision. For example, in one study conducted in 1939, 450 patients with cataracts were placed on a nutritional program that included 1 g/day of vitamin C, resulting in a significant reduction in cataract development.^[1] Though similar patients had previously required surgery within 4 years, in the vitamin C-treated patients only a small handful of patients required surgery and in most patients there was no evidence that the cataract progressed over the 11 year period of the study.

It appears the dosage of vitamin C necessary to increase the vitamin C content of the lens is 1,000 mg.^[2] The lens of the eye and active tissue of the body require higher concentrations of vitamin C. The level of vitamin C in the blood is about 0.5 mg/dl, whereas in the adrenal and pituitary glands, the level is 100 times this concentration. In the liver, spleen, and lens of the eye, it is concentrated by at least a factor of 20. In order for these concentrations to be maintained in these tissues, the body has to generate enormous amounts of energy to pull vitamin C out of blood against this tremendous gradient. By keeping blood vitamin C levels elevated, you are helping the body to concentrate vitamin C into active tissue by reducing the gradient. That is probably why dosages of at least 1,000 mg are required to increase the vitamin C content of the lens.

In another study, 450 patients with incipient cataract were placed on a nutritional program that included 1 g/day of vitamin C, resulting in a significant reduction in cataract development.^[3]

Glutathione

This tripeptide composed of glycine, glutamic acid, and cysteine is found at very high concentrations in the lens. GSH plays a vital role in maintaining a healthy lens and has been postulated as a key protective factor against toxins of both intra- and extralenticular origin. It functions as an antioxidant, maintains reduced sulfhydryl bonds within the lens proteins, acts as a coenzyme of various enzyme systems, participates in amino acid transport with gamma-glutamyl transpeptidase, and is involved in cation transport.^[4] GSH levels are diminished in virtually all forms of cataracts.

Ascorbic acid and glutathione interactions

These two antioxidants work in close conjunction and are the most important of all the

host protective factors against the induction of cataracts. The reactions are as follows:

1547

Light may also cause oxidation of AA, leading to hydrogen peroxide formation:

An interesting cycle is then set into motion. The dehydroascorbate and hydrogen peroxide produced are reduced by selenium-containing glutathione peroxidase:

The oxidized glutathione (GSSG) serves as an inducer of the hexose monophosphate shunt, which provides the NADPH necessary for reducing GSSG via riboflavin-dependent glutathione reductase:

The NADP is reduced by hexose monophosphate dehydrogenase as follows:

This combination of enzymatic and non-enzymatic scavenging of free radicals is a key mechanism for the protection of the lens from damage due to photochemical and other forms of oxidative damage.

Selenium and vitamin E

These antioxidants are known to function synergistically and are therefore discussed together. Maintaining proper selenium levels appears to be especially important as human lens glutathione peroxidase is selenium-dependent. Low selenium levels would greatly promote cataract formation. Previous studies have shown the selenium content

in human lens with a cataract is only 15% of normal levels.^[5] A more recent study was conducted to better examine the role of selenium in cataract formation.^[6]

Selenium levels in the serum, lens, and aqueous humor were determined in 48 patients with cataracts and compared with matched controls. The selenium levels of the serum and aqueous humor were found to be significantly lower in the patients with cataracts (serum, 0.28 vs. 0.32 mcg/ml; aqueous humor, 0.19 vs. 0.31 mcg/ml). However, the selenium levels in the lens itself did not significantly differ in patients with cataracts and normal controls.

The most important finding of the study was the decreased level of selenium in the aqueous humor in patients with cataracts. Excess hydrogen peroxide levels, up to 25 times the normal levels, are found in the aqueous humor in patients with cataracts. An excess of hydrogen peroxide is associated with increased lipid peroxidation and altered lens permeability as a result of damage to the sodium–potassium pump. These changes ultimately leave the lens unprotected against free radical and sun damage. As a result, a cataract is formed. Since selenium-dependent glutathione peroxidase is responsible for the breaking down of hydrogen peroxide, it is quite obvious that low selenium levels appear to be a major factor in the development of a cataract.

Superoxide dismutase

The activity of SOD in the human lens is lower than it is in other tissues as a result of the increased ascorbate and glutathione levels. A progressive decrease in SOD is encountered in cataract progression. Oral supplementation is probably of little value, as it has been demonstrated that it does not affect tissue SOD activity.^[8] Of greater value is supplementation with the trace mineral cofactors of SOD, as the levels of these cofactors are greatly reduced in the cataractous lens (copper, over 90%; manganese, 50%; and zinc, over 90%).^[9]

Catalase

Catalase is concentrated in the epithelial portion of the lens (anterior surface), with very low levels found in the rest of the lens. Its primary function is to reduce (to water and oxygen) the hydrogen peroxide formed from the oxidation of ascorbate.

Tetrahydrobiopterin

Pteridine compounds are believed to play a protective role against cataract formation via prevention of oxidation and damage by ultraviolet light. This prevents the formation of high molecular weight proteins in the lens. Tetrahydrobiopterin functions as an essential coenzyme in the hydroxylation of monoamines such as phenylalanine hydroxylase, tyrosine hydroxylase, and tryptophan hydroxylase. Studies of human senile cataracts have demonstrated decreased levels of pteridine-synthesizing enzymes and tetrahydrobiopterin.^[10] Supplemental folic acid may help to compensate for this deficiency.

Other nutritional factors

Riboflavin

Lenticular GSH requires flavin adenine dinucleotide (FAD) as a coenzyme for glutathione reductase.^{[11] [12]} Deficiency of riboflavin, the precursor of FAD, is believed to enhance cataract formation due to depressed glutathione reductase activity. While riboflavin deficiency is fairly common in the geriatric population (33%), original studies demonstrating an association between riboflavin deficiency and cataract formation were followed by

1548

studies demonstrating no association. The patient's riboflavin status can be determined by measuring RBC glutathione reductase activity before and after flavin adenine dinucleotide (FAD) stimulation.^[12]

Although correction of the deficiency is warranted, no more than 10 mg/day of riboflavin should be prescribed for cataract patients, since it is a photosensitizing substance, i.e. superoxide radicals are generated by the interaction of light, ambient oxygen, and riboflavin/ FAD. Riboflavin and light (at physiological levels) have been used experimentally to induce cataracts. The evidence appears to suggest that excess riboflavin does more harm than good in the cataract patient.

Amino acids

Methionine is a component of the lenticular antioxidant enzyme methionine sulfoxide reductase and a precursor of cysteine, a component of GSH. Cysteine, along with the other amino acid precursors of GSH, has been shown to be of some aid in cataract treatment.^[13]

Zinc, vitamin A and beta-carotenes

These nutrients are known antioxidants and are vital for normal epithelial integrity. Adequate status of these nutrients is important for the epithelial portion of the lens. In particular, beta-carotene may act as a filter, protecting against light-induced damage to the fiber portion of the lens. Beta-carotene is the most significant of the singlet oxygen free radical scavengers and is used in treating photosensitive disorders.^[14]

Melatonin

Melatonin is a very efficient free radical scavenger and antioxidant which can neutralize hydroxyl and peroxy radicals as well as enhancing endogenous and exogenous antioxidant efficiency. In animal models, melatonin has been an effective inhibitor of

DNA damage, lipid peroxidation and cataract formation. Melatonin is present at significant levels in the cell nucleus, the aqueous cytosol, and lipid-rich cellular membranes.^[15]

Diet

Evaluation of 207 patients with cataracts compared with 706 controls found a protective action from some vegetables, fruit, calcium, folic acid, and vitamin E. The study also found an increased incidence with elevated salt and fat intake.^[16]

Dairy products

Cataracts often develop in infants with a homozygous deficiency of either galactokinase or galactose-1-phosphate uridyl transferase and in laboratory animals fed a high galactose diet. Abnormalities of galactose metabolism can be identified by measurements of the activity of these enzymes in red blood cells. It has been suggested that this is an important mechanism in approximately 30% of cataract patients.^[12] However, this mechanism of cataract formation appears only to be significant in diabetic cataract formation and is probably not relevant to senile cataract formation (for further discussion, see [Ch. 147](#)).

Heavy metals

A number of heavy metals have been shown to have increased concentrations in both the aging lens and the cataractous lens. Although the levels are higher in the latter, the significance of this is unknown.^[9]

Cadmium

The cadmium concentration in the cataractous lens is two to three times higher than in age-matched controls. Since cadmium displaces zinc from binding in enzymatic proteins by binding to the sulfhydryl groups, it may contribute to deactivation of free radical quenching and other protective/repair mechanisms.

Other elevated elements of unknown significance include bromine, cobalt, iridium, and nickel.^[9]

Botanical medicines

There are a number of excellent choices from the botanical world to help with antioxidant mechanisms.

Flavonoid-rich extracts

Among the best may be flavonoid-rich extracts from *Vaccinium myrtillus* (bilberry), *Vitis vinifera* (grape seed), and *Pinus maritima* (pine bark) as well as curcumin from *Curcuma*

longa. The occurrence of cataracts in rats can be retarded by changing their diet from a commercial laboratory chow to a “well-defined diet”.^[17] Preliminary research suggests that flavonoid components in the well-defined diets may be responsible for the protective effects.^[18]

Of the flavonoid-rich extracts, bilberry anthocyanosides may offer the greatest protection. In one human study, bilberry extract plus vitamin E stopped progression of cataract formation in 97% of 50 patients with senile cortical cataracts.^[19]

Hachimijiogan

An ancient Chinese formula, Hachimijiogan, has been shown to increase the antioxidant level of the lens of

1549

the eye.^[20] This activity may explain its use in treating cataracts for hundreds of years. According to clinical research, its therapeutic effect is quite impressive in the early stages of cataract formation. In one study, 60% of the subjects on Hachimijiogan noted significant improvement, 20% of the group showed no progression and only the remaining 20% of the group displayed progression of the cataract. Hachimijiogan contains the following eight herbs (per 24 g):

- *Rehmania glutinosa* – 6,000 mg
- *Poria cocos sclerotium* – 3,000 mg
- *Dioscorea opposita* – 3,000 mg
- *Cormus officinalis* – 3,000 mg
- *Epimedium grandiflorum* – 3,000 mg
- *Alisma plantago* – 3,000 mg
- *Astragalus membranaceus* – 2,000 mg
- *Cinnamomum cassia* – 1,000 mg.

THERAPEUTIC APPROACH

In cases of marked vision impairment, cataract removal and lens implant may be the only alternative. As with most diseases, prevention or treatment at an early stage is most effective. Since free radical damage appears to be the primary factor in the induction of senile cataracts, avoidance of oxidizing agents and promotion of free radical scavenging are critically important to successful treatment. The patient should avoid direct ultraviolet light, bright light, and photosensitizing substances; wear protective lenses when outdoors; and greatly increase intake of antioxidant nutrients. Progression of the pathological process can be stopped and early lesions can be reversed. However, significant reversal of well-developed cataracts does not appear possible at this time.

Since the geriatric population is especially susceptible to nutrient deficiencies, every

effort should be made to ensure that the patient is ingesting and assimilating adequate macro- and micronutrients.

Diet

Avoid rancid foods and other sources of free radicals. Increase consumption of legumes (high in sulfur-containing amino acids), yellow vegetables (carotenes), and vitamin E and C rich foods.

Supplements

- Vitamin C: 1 g three times/day
- Vitamin E: 600 to 800 IU/day
- Selenium: 400 mcg/day
- Beta-carotene: 200,000 IU/day
- L-Cysteine: 400 mg/day
- L-Glutamine: 200 mg/day
- L-Glycine: 200 mg/day.

Botanical medicines

- Bilberry extract (25% anthocyanidin content): 80 mg three times/day
- Hachimijiogan formula: 150 mg three times/day.

Chapter 189 - Streptococcal pharyngitis

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

DIAGNOSTIC SUMMARY

- Abrupt onset of sore throat, fever, malaise, nausea, and headache
- Throat red and edematous, with or without exudation
- Tender cervical lymph nodes
- Positive rapid detection of streptococcal antigen
- Group A streptococci on throat culture.

GENERAL CONSIDERATIONS

Throat cultures yield group A beta-hemolytic streptococci in 10% of patients presenting clinically with a sore throat. Signs and symptoms of “strep throat” resemble viral pharyngitis, requiring a culture for definitive diagnosis. However, 10–25% of the general, asymptomatic population are carriers for group A streptococci.

Rapid strep screens which detect the presence of group A streptococcal antigens are a major clinical advancement. Since definitive diagnosis with a positive culture usually takes 2 days, antibiotic therapy during this time period for presumed group A strep throat leads to unnecessary exposure to antibiotics and an increased likelihood of developing antibiotic-resistant organisms. “Second-generation” rapid strep screens, such as the Strep A OIA test, are showing excellent sensitivity and specificity.^[1]

The hope is that the use of these rapid strep screens will likely eliminate the unnecessary use of antibiotics. Even in positive cases, antibiotics may not be necessary.^[2] Strep throat is usually a self-limiting disease. Although standard medical textbooks strongly assert that antibiotics are highly effective in preventing the sequelae of strep infections, recent research has shown that clinical recovery is similar in both cases where antibiotics are prescribed and those where they are not.^{[3] [4]} The primary concern with not using antibiotics is the development of the “non-suppurative

post-streptococcal syndromes” (rheumatic fever, post-streptococcal glomerulonephritis,

1552

etc.). However, antibiotic administration does not significantly reduce the incidence of these sequelae. Most cases of rheumatic fever and glomerulonephritis due to group A beta-hemolytic strep throat are the result of the afflicted not consulting a physician.^[3]

At this time, it appears that the use of antibiotics should be reserved for those patients who are suffering from severe infection, or who are unresponsive to therapy (i.e. no response after 1 week of immune supportive therapy), and those with a prior history of rheumatic fever or glomerulonephritis. Even then, antibiotics like penicillin fail to eradicate the streptococci in over 20% of patients. The primary reason is the presence of beta-lactase-positive organisms (*Staphylococcus aureus* and *Bacteroides* sp.) which shield streptococci by deactivating the penicillin.^[5]

Antibiotics are often praised for their role in effectively eliminating rheumatic fever as a serious concern. However, the dramatic decrease in the incidence of rheumatic fever began before the advent of effective antibiotics.^[6] Improved socioeconomic, hygienic, and nutritional factors were, as in most infectious diseases, more important than the liberal use of penicillin. The present attack rates after a streptococcal infection are 0.4–2.8% for rheumatic fever and 0.2–20% for glomerulonephritis. Obviously, such a wide range of reported sequelae makes accurate evaluation of the risk difficult.

THERAPEUTIC CONSIDERATIONS

The primary therapeutic consideration is the status of the patient's immune system. If the patient's immune system is in good function, the illness will be short-lived. Enhancing general immune function as described in [Chapter 53](#) may shorten the course. In cases of poor immune function, every effort should be made to strengthen the immune system by following the recommendations given in [Chapter 53](#).

Vitamin C

During the 1930s there was considerable interest in the relationship between malnutrition and the development of the sequelae of streptococcal pharyngitis. Both experimental animal work and epidemiological surveys demonstrated a correlation between vitamin C deficiency and the development of sequelae. Rheumatic fever is virtually non-existent in the tropics where vitamin C intake is higher, and 18% of children in high-risk groups have subnormal serum vitamin C levels.

Vitamin C supplementation of streptococcal-infected, vitamin C-deficient, rheumatic fever-susceptible, guinea pigs totally prevents their development of rheumatic fever.^{[7] [8]} Uncontrolled clinical studies demonstrated very positive results when children were given orange juice supplementation. Unfortunately, this promising line of research

appears to have been dropped, probably due to the advent of, supposedly effective, antibiotics.

Hydrastis canadensis and Echinacea augustifolia

The guidelines for enhancing the immune system, as presented in [Chapter 53](#) , are particularly well indicated for streptococcal pharyngitis, particularly the botanicals *Hydrastis canadensis* and *Echinacea augustifolia*. The berberine alkaloid of hydrastis exerts antibiotic activity against streptococci and, perhaps more importantly, has been shown to inhibit the attachment of group A streptococci to pharyngeal epithelial cells. To promote the spread of colonies, streptococci secrete large amounts of hyaluronidase. This enzyme is inhibited by echinacea and bioflavonoids. *Echinacea* also promotes increased phagocytosis, natural killer cell activity, and properdin levels (see [Chs 82](#) and [91](#) for more discussion of these botanical effects).

Bacteriotherapy

Colonizing the throat with group A non-beta-hemolytic streptococci may prove to be an effective treatment for recurrent group A beta-hemolytic streptococci pharyngitis. In a double-blind study, 130 patients with recurrence of group A beta-hemolytic streptococci pharyngotonsillitis received antibiotic treatment for 10 days, followed by 10 days of group A non-beta-hemolytic streptococci alpha-streptococci.^[9] The clinical recurrences (bacteriologically verified) in the alpha- and placebo-treated patient groups were 2 and 23%, respectively, in patients given spray for at least 5 days. No side-effects were reported.

THERAPEUTIC APPROACH

For further information, consult [Chapter 53](#) . If antibiotics are used, follow the recommendations for *Lactobacillus acidophilus* supplementation given in [Chapter 105](#) .

Supplements

- Vitamin A: 50,000 IU/day for 1 week; or beta-carotene: 200,000 IU/day (*Note: do not use vitamin A in menstruating women due to its teratogenic effect*)
- Vitamin C: 500 mg every 2 hours
- Bioflavonoids: 1,000 mg/day
- Zinc: 30 mg/day
- Thymus extract: the equivalent of 120 mg pure polypeptides with molecular weights less than 10,000 or roughly 500 mg of the crude polypeptide fraction.

- *Echinacea* sp.
 - dried root (or as tea): 0.5–1 g
 - freeze-dried plant: 325–650 mg
 - juice of aerial portion of *E. purpurea* stabilized in 22% ethanol: 2–3 ml
 - tincture (1:5): 2–4 ml
 - fluid extract (1:1): 2–4 ml
 - solid (dry powdered) extract (6.5:1 or 3.5% echinacoside): 150–300 mg
- *Hydrastis canadensis* – the dosage should be based on berberine content. As there is a wide range of quality in goldenseal preparations, standardized extracts are recommended. Three times a day dosages are as follows:
 - dried root or as infusion (tea): 2–4 g
 - tincture (1:5): 6–12 ml (1.5–3 tsp)
 - fluid extract (1:1): 2–4 ml (0.5–1 tsp)
 - solid (powdered dry) extract (4:1 or 8–12% alkaloid content): 250–500 mg.

Local treatment

Gargle with salt water twice daily: 1 tbsp salt/240 ml of warm water.

Chapter 190 - Trichomoniasis

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

DIAGNOSTIC SUMMARY

- Profuse, malodorous, white to green colored discharge from vagina
- Discharge usually has a pH greater than 4.5, a weak amine odor, and large numbers of WBCs and trichomonads on wet mount
- Vulvovaginal pruritus, burning, and/or irritation
- Vulva and introitus usually show erythema
- Cervix may or may not have a mottled erythema “strawberry cervix” (less than 5%)
- Dysuria and/or dyspareunia may be present
- R/O trichomoniasis in males exhibiting signs of prostatitis, urethritis, or epididymitis.

GENERAL CONSIDERATIONS

Trichomoniasis is a remarkably common disease:^{[1] [2] [3]}

- one in five women in the United States will have trichomoniasis at some time in her life
- approximately 2.5 million women acquire this infection annually
- trichomonas is present in 3–15% of asymptomatic women attending gynecological clinics and 20–50% of women attending clinics for sexually transmitted diseases.

In addition, gonorrhea and trichomoniasis are common coexisting infections, with up to 40% of women with trichomonas having gonorrhea and vice versa.^[4]

Aside from these alarming statistics, there are other reasons for taking trichomonal infections seriously:^[2]

- Trichomoniasis is a frequent cause (90%) of cervical erosion and therefore may be a factor in malignant transformation.

- Trichomoniasis may complicate interpretation of Pap smears, increasing the number of false-positive tests.
 - Trichomoniasis increases the rate of sterility among males and females, the latter due to salpingitis and the
-

1556

former because of toxic products decreasing motility of spermatozoa.

- There is increased postpartum fever and discharge in women who contract *Trichomonas vaginalis* at delivery.
- Neonates infected via the birth canal may manifest serious illness (rare).
- Prostatitis and epididymitis are common in infected males.
- Infection may confuse and/or complicate other urinary or genital tract problems.
- Metronidazole (Flagyl), the most commonly used anti-trichomonal agent, has been found to be carcinogenic and teratogenic in rodents.

DIAGNOSIS

Trichomonas vaginalis is a flagellate 15–18 microns in length. It is shaped like a turnip, with three to four anterior and one posterior flagella mounted in an undulating membrane.^[5] Transmission is via sexual intercourse. Although women have in the past been thought to be the reservoir for *Trichomonas* and men merely the vector, current information suggests that men may also be reservoirs.^{[6] [7] [8]}

Diagnosis is made by clinical signs and symptoms (see “Diagnostic summary”), saline wet mount, and culture. Trichomonal cultures (using the Feinberg *Trichomonas* medium) have recently been advocated to increase diagnostic sensitivity. Errors^[9] reported in 1972 that only 50% of women with *Trichomonas*, as defined by a positive culture, have the organism identified by microscopic wet mount. Among patients with trichomonal vaginitis, the organism can be cultured from the vagina and para-urethral glands in 98%, from the urethra in 82%, and from the endocervix in 13%. In 65%, *T. vaginalis* can be seen on a Pap smear.^[10]

Trichomonal vaginitis

In women, *T. vaginalis* usually infests the vagina and urethra. However, infection may involve the endocervix, Bartholin’s glands, Skenes glands, or bladder. The vagina appears to be a good reservoir for the organism. Under stimulation of estrogen, the vaginal walls are well glycogenated – essential for *T. vaginalis* to thrive. Prepubescent and postmenopausal women seldom have symptomatic trichomonal infections.^[6]

In addition to estrogen, an elevated pH increases susceptibility to *Trichomonas*. The normal adult vagina maintains a pH of 3.5–4.5 due to the metabolism of free glucose into lactic acid by vaginal *Lactobacillus acidophilus*. A decrease in the number of lactobacilli will increase pH. *Trichomonas* organisms grow optimally at a vaginal pH of

5.5–5.8.^[11] Other conditions also increase vaginal pH:^[6]

- progesterone, which increases in the latter half of the menstrual cycle and during pregnancy
- excess intravaginal secretions (i.e. cervical mucus)
- overgrowth of certain bacteria such as *Streptococcus* and *Proteus*.

***Trichomonas* in the male**

Although the incidence is lower in men, it is estimated that 5–15% of non-gonococcal urethritis is caused by trichomonal infections.^[2] ^[6] Men suffering from *T. vaginalis* are most often asymptomatic, yet mild cases of urethritis, prostatitis, and epididymitis have been reported.^[8] Trichomonads have been identified in semen, urethral discharge, urine, and prostatic fluid and have been found in the prostatic secretions and semen of up to 23% of men with chronic non-gonococcal prostatitis.^[12] ^[13]

Although men are thought to be only vectors for *Trichomonas*, the parasite is now known to persist in the male reproductive tract. The reinfection of treated females who are sexually active is well-documented.^[8] ^[14] Therefore, treatment of both sexual partners is necessary.

THERAPEUTIC CONSIDERATIONS

Diet

Dietary factors affect the body's ability to defend itself against foreign bodies and substances both directly and indirectly. As with any infection, it is not the pathogenicity of the organism but rather the "fertility of the soil" that allows the organism to grow and flourish. A well-balanced diet high in natural fiber (vegetable, fruits) and low in fat, sugar, and refined carbohydrates aids immune function (see [Ch. 53](#) for more discussion).

Lifestyle

Depression and anxiety have been associated with exacerbations of trichomonal infections.^[6] Therefore, reducing stress is definitely indicated. This may be achieved by a variety of means, including exercise and meditation.

The practice of safe sex or abstinence (while infected) will also lower incidence of infection and reinfection. Greater than 66% of prostitutes who do not practice safe sex have trichomonal infections.^[14]

Nutritional supplements

For years, it has been the view of many alternative health care providers that the supplementation of vitamins and minerals is beneficial in the prevention and treatment of disease. Although considerable research has supported this view, it is only recently

that such groups as the American Medical Association (AMA) have considered

1557

the importance of single nutrients in disease. An interesting report sponsored by the AMA summarizes how nutrients such as iron, zinc, B-complex, and vitamins A and C, as well as calcium and magnesium, increase immune function.^[15]

B-complex

Pyridoxine, pantothenic acid, vitamin B₁₂, and folate aid the phagocytic and bactericidal effects of neutrophils and B- and T-cell activity.^[16]

Ascorbic acid

Vitamin C aids in phagocytic cell migration and killing functions.^[17] In addition, vitamin C preserves cell integrity by inactivating free radicals and oxidants produced during phagocytosis.^[18]

Vitamin A

Secretory IgA production appears to be impaired in vitamin A-deficient humans. Many studies indicate that modest increases in vitamin A enhance resistance to infection.^[19] ^[20] ^[21] Vitamin A maintains the composition of external cell membranes and surface glycoproteins, decreasing susceptibility to infectious organisms.^[15] Excess vitamin A is a known teratogen and can be toxic in high dosages. Therefore, particular caution must be taken in treating pregnant women, children, and the elderly (see [Ch. 121](#) for a full discussion).

Vitamin E

Vitamin E in doses two- to 10-fold greater than the minimum requirements have been found to enhance antibody responses and accelerate the clearance of particulate matter by the reticuloendothelial system (RES), as well as enhancing host resistance.^[22] Conversely, one study found that megadoses of vitamin E in healthy volunteers will inhibit multiple immune functions.^[23]

Calcium and magnesium

Many minerals, especially divalent cations, have regulatory influences on the external membrane functions of all body cells. Calcium and magnesium ions also participate in the activation of the complement pathway.^[15] This may be important for the prevention and treatment of *T. vaginalis*. *Trichomonas* activates the alternate complement pathway which can lead to parasite lysis.^[24] Unlike the classical complement pathway, which

requires both calcium and magnesium, the alternate pathway requires only magnesium.

Zinc

Zinc supplementation is important in the treatment of trichomonal infections of both men and women. The antimicrobial spectrum of zinc is broad and includes many potential genitourinary pathogens: Gram-positive and -negative bacteria, *T. vaginalis*, *Candida albicans*, and *Chlamydia trachomatis*, as well as many viruses.^{[25] [26]} Of particular significance is the fact that trichomonads are readily killed by zinc at a concentration of 0.042% (6.4 mmol/L),^[8] a concentration which can occur in the prostatic fluid of men. The zinc concentration of prostatic fluid ranges from 0.015 to 0.10% (2.3–15.3 mmol/L).^{[27] [28]} This suggests that persistent trichomonal infections in men may be due to a low-level zinc deficiency. Zinc sulphate (220 mg two times/day for 3 weeks) has been recommended as a possible treatment for trichomonal infections refractory to metronidazole.^[29]

For women with drug-resistant trichomoniasis, zinc douches in combination with metronidazole may provide welcome relief. In a small study, the women suffering from recalcitrant trichomoniasis (4 months to 4 years culture-positive despite conventional treatment), all became culture-negative through the use of a combination of 1% zinc sulfate douching (for 3 days after each menstrual period) and 1.6–2.2 g/day of metronidazole (suppositories plus oral).^[30]

Iron

Iron deficiency, often too small to lower hemoglobin values, causes immune dysfunctions.^[31] Iron-deficient humans demonstrate defective macrophage and neutrophil functions.^[15] Too much iron can, however, increase availability to microorganisms, leading to increased growth of the pathogen.^[32]

Botanical medicines

Trichomonas, as mentioned earlier, activates the alternate complement pathway.^[24] Complement has the ability to lyse *T. vaginalis* in vitro and in vivo.^{[33] [34]} There are several botanical medicines which activate the alternate complement pathway. Of these, *Angelica* sp. and *Echinacea purpurea* are the most widely used. *Angelica* spp. contain coumarin compounds which have been shown to activate both classical and alternate pathways (see [Ch. 65](#)).

Inulin, an active constituent of *Echinacea*, also activates complement and promotes chemotaxis of neutrophils, monocytes, and eosinophils (see [Ch. 82](#)).

Topical trichomonocides

Betadine (povidone-iodine)

Iodine has long been recognized as being a highly potent

1558

trichomonacide. Povidone-iodine (PVP) has a broad therapeutic effect in killing a large number of different microorganisms causing vaginitis, including *Trichomonas vaginalis*.^[35] ^[36] Povidone-iodine (iodine which is absorbed into polyvinyl pyrrolidone) has several advantages over iodine in that it has little sensitizing potential, does not sting, is water-soluble, and washes out of clothing.

A success rate of 98.1% has been reported in patients with intractable trichomonal, monial, non-specific, and mixed vaginitis with a 2 week treatment regimen using Betadine preparations.^[37] ^[38] Other studies suggest a 28 day course of Betadine pessaries, particularly if the patient is using oral contraceptives.^[39]

Propolis

An ethanol extract of propolis (150 µg/ml) has been shown to have a 100% lethal effect in vitro on the protozoans *Trichomonas vaginalis* and *Toxoplasma gondii* after 24 hours of contact.^[40] This extract has also been shown to decrease the inflammation associated with trichomonal vaginitis.

Essential oils

The diverse antimicrobial action of essential oils has been well demonstrated. Many possess strong antitrichomonal properties. In a study of 40 essential oils tested for their ability to kill *Trichomonas*, *Mentha piperita* (peppermint) and *Lavandula angustifolia* (lavender) had the fastest killing effects (20 and 15 minutes, respectively).^[41]

Melaleuca alternifolia

Melaleuca alternifolia (tea tree) oil is a powerful cidal agent (see [Ch. 96](#)). Commonly used as a germicidal agent in Great Britain and Australia, a 40% solution of tea tree oil has been found to be a highly effective treatment.^[42] The 40% solution of the oil produced no irritation, burning, or other side-effects. Daily vaginal douches with a 0.4% solution of melaleuca oil in 1 litre of water was also found to be an effective treatment.^[43]

Berberine-containing botanicals

The plant alkaloid, berberine sulphate, has been shown in vitro to inhibit the growth of several protozoa, including *Entamoeba histolytica*, *Giardia lamblia* and *Trichomonas vaginalis*.^[44] ^[45] No clinical trials have been reported in trichomonas vaginalis (see [Ch. 91](#) for further discussion).

THERAPEUTIC APPROACH

Discussion with the patient of such factors as diet, sexual habits, and lifestyle is a must. Inform the patient that *Trichomonas* is a sexually transmitted disease (STD) and that treatment of the sexual partner(s) is necessary to prevent reinfection. During the treatment, sexual intercourse should be avoided. If intercourse does occur, use of a condom is necessary.

Diet

Decrease refined carbohydrates, alcohol, and fats and increase fiber.

Nutritional supplements

- Vitamin A: 25,000 IU/day; or beta carotene:200,000 IU/day
- Vitamin C: 500–1,000 mg every 4 hours
- B-complex: 20–50 mg/day
- Zinc (picolinate): 10–15 mg/day
- Vitamin E: 200 IU/day
- *Lactobacillus acidophilus*: 2 caps two times/day.

If effective, *L. acidophilus* treatment will change the quantity and quality of the stool. If this change does not occur, check the quality of the *L. acidophilus* product being used (see [Ch. 105](#) for further discussion).

Botanical medicines

The following are three times/day doses:

- *Hydrastis canadensis*
 - dried root: 0.5–1.0 g
 - tincture (1:10): 6–12 ml
 - fluid extract (1:1): 1–2 ml
 - solid extract (4:1): 250 mg
- *Echinacea angustifolia*
 - dried root: 1–2 g
 - tincture (1:10): 8–12 ml
 - fluid extract: 1.5–3.0 ml
 - solid extract (6.5:1): 250 mg

- *Angelica* sp.
 - dried root or rhizome: 1–2 g
 - tincture (1:5): 3–5 ml
 - fluid extract (1:1): 0.5–2 ml

Topical treatment

- Betadine douche, pessary, or saturated tampon: two times/day for 14 days
- *Melaleuca alternifolia* oil (40% solution): swab on affected area two times/day, or
 - douche: 1 litre of a 0.4% solution two times/day
 - suppository: one at night
- Zinc sulphate douche: 1% solution two times/day
- *Lactobacillus* culture yogurt douches daily, preferably in the morning.

Chapter 191 - Urticaria

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

DIAGNOSTIC SUMMARY

- Urticaria (hives): well-circumscribed erythematous wheals with raised serpiginous borders and blanched centers which may coalesce to become giant wheals. Limited to the superficial portion of the dermis
- Angioedema: similar eruptions to urticaria, but with larger well-demarcated edematous areas that involve subcutaneous structures as well as the dermis
- Chronic versus acute: recurrent episodes of urticaria and/or angioedema of less than 6 weeks' duration are considered acute, while attacks persisting beyond this period are designated chronic
- Special forms: special forms have characteristic features – dermatographism, cholinergic urticaria, solar urticaria, cold urticaria.

INTRODUCTION

Urticaria is localized pruritic edema of the skin characterized by white or pink papules or plaques with surrounding axon flare. The lesions are consistent with lesions of histamine-induced wheals. The lesions may develop variable erythema and coalesce to form plaques. About 50% of patients with urticaria develop angioedema – a deeper, less-defined edema of the subcutaneous and soft tissues.

Urticaria and angioedema are relatively common conditions: it is estimated that 15–20% of the general population has had hives at some time. Although persons in any age group may experience acute or chronic urticaria and/or angioedema, young adults (post-adolescence through the third decade of life) are the most often affected.^{[1] [2]}

The basic pathophysiology involves the release of inflammatory mediators from mast cells or basophilic leukocytes. Although classically this occurs as a result of IgE–antigen complexes interacting with these cells, other mechanisms are probably more important

in the majority of patients. The true incidence of IgE-mediated

1562

urticaria is probably quite low when compared with non-immunologic urticaria.^{[1] [3]}

PATHOPHYSIOLOGY

The signs and symptoms of acute and chronic urticaria show consistent patterns despite the many diverse etiologic and initiating factors (see below) that have been found, yet the pathogenesis of urticaria cannot be entirely ascribed to any one mechanism. However, at the present time, it appears that mast cells and mast cell-dependent mediators play the most prominent role in the pathogenesis of urticaria.^[3]

Mast cells are widely distributed throughout the body and are found primarily near small blood vessels, particularly in the skin. The granule-containing mast cell is a secretory cell capable of releasing both preformed and newly synthesized molecules, termed mediators. These mediators (listed in [Table 191.1](#)) play key roles in the pathogenesis of both immunologic and non-immunologic inflammatory reactions. There are three distinct sources of mediators:

- preformed mediators, which are contained in the granules and are released immediately
- secondarily formed mediators, which are generated immediately or within minutes by the interaction of the primary mediators and nearby cells and tissues
- granule matrix-derived mediators, which are preformed but slowly dissociate from the granule after discharge and remain in the tissues for hours.

TABLE 191-1 -- Mast cell-derived mediators^[3]

| |
|---|
| <i>Preformed, rapidly released</i> |
| • Histamine |
| • Eosinophil chemotactic factors of anaphylaxis (ECF-A) |
| • Eosinophil chemotactic oligopeptides |
| • Neutrophil chemotactic factor |
| • Superoxide anions |
| • Exoglycosidases (beta-hexosaminidase, beta-delta-galactosidase,* beta-glucuronidase) |
| • Serotonin* |
| • Arylsulfatase A |
| <i>Secondary or newly generated</i> |

- Slow-reacting substances (SRS-A): LTC, LTD, LTE

- Prostaglandins

- Monohydroxyeicosatetraenoic acids (HETEs)

- Hydroperoxyeicosatetraenoic acids (HPETEs)

- Thromboxanes

- Platelet-activating factor (PAF)^{*}

- Prostaglandin generating factor of anaphylaxis (PGF-A)

Preformed, granule-associated

- Heparin

- Proteases (chymotrypsin/trypsin)

- Peroxidase[‡]

- Superoxide dismutase^{*}

- Arylsulfatase B

- Inflammatory factors of anaphylaxis (IFA)^{*}

* Found in mast cells of species other than human.

The most common immunological mechanism is mediated by IgE.

The early vascular changes appear to be the result of mast cell-dependent vasoactive mediators, particularly histamine and some secondarily generated end-products of arachidonic acid metabolism. The wheal and flare reactions occur within minutes of initiation and last 30–60 minutes.

The more prolonged, and delayed, reactions reflect leukocytic infiltration in response to the release of mast cell granule-derived chemotactic factors. These late-phase reactions develop over time and are characterized by erythema, edema, and induration beginning within 2 hours and lasting 12–24 hours. Leukocyte infiltration may contribute to the urticarial tissue response by inducing a second wave of mast-cell activation, or by releasing toxic lysosomal enzymes and mediators characteristic of the type of infiltrating cell.

The actual events initiated by the mediators also depend on the tissues into which they are released. For example, the release of histamine into the skin primarily produces pruritus and vascular permeability, while histamine release into the lung may induce bronchospasm.

CAUSES OF URTICARIA

Fundamental to the treatment of urticaria is the recognition and control of causative factors.

Physical

Urticaria can be produced as a result of reactions to various physical stimuli. The most common forms of physical urticarias are dermographic, cholinergic, and cold urticarias (Table 191.2). These are briefly described below. Less common types of physical urticarias or angioedema are:^[1]

- contact
- solar
- pressure
- heat contact
- aquagenic
- vibratory
- exercise-induced.

Dermographism

Dermographism or dermographic urticaria is a readily elicited whealing of the skin which evolves rapidly when moderate amounts of pressure are applied. This may occur as a result of simple contact with furniture, garters, bracelets, watch bands, towels, or bedding.

The incidence of dermographic urticaria has been estimated at 1.5–5% in the general population. It is the

1563

TABLE 191-2 -- Clinical aspects of physical urticarias^[1]

| Type | Eliciting stimulus | Time of onset | Duration of lesion | Diagnostic test | Associated symptoms |
|--------------------------------|--|-------------------|--------------------|-----------------------|---------------------|
| Dermographic urticaria (tarda) | Stroking, scratching (rubbing for red dermographism) | 2–5 min (0.5–5 h) | 1–5 h (48 h) | Firm stroking of skin | Headache, malaise |

| | | | | | |
|------------------------------|---|-----------|-----------|------------------------------------|--|
| Cholinergic urticaria | Physical exercise + overheating - mental stress | 2–20 min | 30–60 min | Bicycling, running, sauna | Headache, gastrointestinal upset, wheezing, salivation, lacrimation, syncope |
| Cold urticaria | Cold contact | 2–5 min | 1–2 h | Ice cube, cold arm bath, cold air | Wheezing, syncope |
| Solar urticaria | Light of varying wavelengths | 2–15 min | 0.25–3 h | Phototest | Wheezing, dizziness, syncope |
| Pressure urticaria | Pressure | 3–8 h | 8–24 h | Locally applied weights | Flu-like syndrome, fever, leukocytosis, arthralgias |
| Heat contact urticaria | Contact with heat | 2–15 min | 30–60 min | Hot arm bath | Gastrointestinal upset, dizziness, fatigue, wheezing, dyspnea |
| Aquagenic urticaria | Contact with water | 2–30 min | 30–60 min | Bath, compresses | |
| Vibratory angioedema | Vibration | 0.5–4 min | 1 h | Vibrating motor | Faintness, headache |
| Exercise-induced anaphylaxis | Exercise after a heavy meal | 2–5 min | 10–30 min | Exercise | Flushing, headache, disorientation, glottis edema, dyspnea, collapse |
| Familial cold urticaria | Cold wind, change from cold to warm air | 0.5–3 h | 48 h | Cold wind and subsequent rewarming | Tremor, headache, arthralgias, fever |

most frequent type of physical urticaria and is found twice as frequently in women as in men, with the average age of onset in the third decade. The incidence is much greater among the obese, especially those who wear tight clothing.

Dermographic lesions usually start within 1–2 minutes of contact as an erythema, which is replaced within 3–5 minutes by edema and surrounding reflex urticaria. Maximal

edema is usually produced within 10–15 minutes. While the erythema generally regresses within an hour, the edema can persist up to 3 hours.

Dermographism may be associated with other diseases, including:^[1]

- parasitosis
- insect bites
- neuropsychiatric disorders
- hormonal changes
- thyroid disorders
- pregnancy
- menopause
- diabetes
- immunological alterations
- other urticarias
- during or following drug therapy
- *Candida albicans*
- angioedema
- hypereosinophilia.

Cholinergic urticaria

Cholinergic, or heat reflex, urticaria is the second most frequent physical urticaria. These lesions, which depend upon the stimulation of the sweat gland via cholinergic afferent fibers, consist of pinpoint wheals surrounded by reflex erythema. The wheals arise at or between follicles and develop preferentially on the upper trunk and arms.

The three basic types of stimuli that may produce cholinergic urticaria include passive overheating, physical exercise, and emotional stress. Typical eliciting activities, besides physical exercise, may include taking a warm bath or sauna, eating hot spices, or drinking alcoholic beverages. The lesions usually arise within 2–10 minutes after provocation and last for 30–50 minutes.

A variety of systemic symptoms may also occur, suggesting a more generalized mast cell release of the mediators than in the skin. Headache, periorbital edema, lacrimation, and burning of the eyes are common symptoms. Less frequent symptoms include nausea, vomiting, abdominal cramps, diarrhea, dizziness, hypotension, and asthmatic attacks.^[1]

Cold urticaria

Cold urticaria is an urticarial and/or angioedematous reaction of the skin when it comes into contact with cold objects, water, or air. Lesions are usually restricted

to the area of exposure, and develop within a few seconds to minutes after the removal of the cold object and rewarming of the skin. The lower the object's or element's temperature, the faster the reaction.

Widespread local exposure and generalized urticaria can be accompanied by:

- flushing
- headaches
- chills
- dizziness
- tachycardia
- abdominal pain
- nausea
- vomiting
- muscle pain
- shortness of breath
- wheezing
- unconsciousness.

Cold urticaria has been observed to accompany a variety of clinical conditions including:^[1]

- viral infections
- parasitic infestations
- syphilis
- multiple insect bites
- penicillin injections
- dietary changes
- stress.

The association of cold urticaria with infectious mononucleosis is well-established. Other conditions associated with cold urticaria include cryoglobulinemia and myeloma where cold urticaria may precede the diagnosis by several years.^[1]

Drugs

Drugs are the leading cause of urticarial reactions in adults. In children, they are usually due to foods, food additives, or infections.^[1]

Most drugs are composed of small molecules incapable of inducing antigenic/allergenic activity on their own. Typically, they act as haptens which bind to endogenous macromolecules, ultimately causing the production of hapten-specific antibodies. Alternately, drugs can interact directly with mast cells to induce degranulation. Many drugs have been shown to produce urticaria. [Table 191.3](#) provides a condensed list.

The two most common urticaria-inducing drugs, penicillin and aspirin, are briefly discussed below.

Penicillin

Antibiotics, including penicillin and related compounds, are the most common cause of drug-induced urticaria.

The allergenicity of penicillin in the general population is thought to be at least 10%. Nearly 25% of these individuals will display urticaria, angioedema, or anaphylaxis upon ingestion of penicillin.^[1] ^[5]

An important characteristic of penicillin is that it cannot be destroyed by boiling or steam distillation. This is a problem since penicillin and related contaminants can exist undetected in foods. It is not known to what degree penicillin in the food supply contributes to urticarial reactions. However, urticaria and anaphylactic symptoms have been traced to penicillin in milk,^[6] soft drinks,^[7] and frozen dinners.^[8] In one study of 245 patients with chronic urticaria, 24% had positive skin tests and 12% had positive RAST tests for penicillin sensitivity.^[9] Of those 42 patients sensitive to penicillin, 22 improved clinically on a dairy product-free diet while only two out of 40 patients with negative skin tests improved on the same diet. This study would seem to provide indirect evidence of the importance of penicillin in the food supply in urticaria.

In an attempt to provide direct evidence, penicillin-contaminated pork was given to penicillin-allergic volunteers. No significant reactions were noted other than transient pruritus in two volunteers.^[10] Penicillin in milk appears to be more allergenic than penicillin in

1565

meat.^[6] Presumably this is due to the fact that penicillin can be degraded into more allergenic compounds in the presence of carbohydrate and metals, suggesting that penicillin in milk may be more allergenic than artificially contaminated meat.^[9]

Aspirin

Urticaria is a more common indicator of aspirin sensitivity than is asthma (see [Ch. 132](#)). The incidence of aspirin sensitivity in patients with chronic urticaria is at least 20 times greater than in normal controls.^[11] ^[12] ^[13] ^[14] ^[15] Studies (summarized in [Table 191.4](#))

have demonstrated that 2–67% of patients with chronic urticaria are sensitive to aspirin.

Aspirin inhibition of cyclooxygenase apparently shunts eicosanoid metabolism towards leukotriene synthesis, thereby increasing smooth muscle contraction and vascular permeability. In addition, aspirin and other NSAIDs have been shown to dramatically increase gut permeability and may alter the normal handling of antigens.^{[38] [43]}

The daily administration of 650 mg of aspirin for 3 weeks has been shown to desensitize patients with urticaria and aspirin sensitivity. While taking the aspirin, patients also became non-responsive to foods to which they usually reacted, e.g. pineapple, milk, egg, cheese, fish, chocolate, pork, strawberries, and plums.^[44] Others have noted this effect in patients with asthma, but they have also found that the effect disappears within 9 days after stopping the treatment, suggesting the loss of effect or a possible placebo response.^[45]

Food allergy

IgE-mediated urticaria can occur upon the ingestion of a specific reaginic antigen. Although any food can be the agent, the most common offenders are milk, fish, meat, eggs, beans, and nuts.^{[1] [5] [46] [47] [48] [49] [50]} Individuals with atopy are most likely to experience urticaria as a result of IgE-related mechanisms.

A basic requirement for the development of a food allergy is the absorption of the allergen through the intestinal barrier. Several factors are known to significantly increase gut permeability, including vasoactive amines ingested in foods or produced by bacterial action on essential amino acids, alcohol, NSAIDs, and possibly many food additives (see [Ch. 21](#) for a full discussion).

In addition, several investigators have reported alterations in gastric acidity, intestinal motility, and the function of the small intestine and biliary tract in up to 85% of patients with chronic urticaria.^{[51] [52] [53] [54] [55]} Selective IgA deficiency, gastroenteritis, hypochlorhydria or achlorhydria, and other disruptive factors reported in patients with chronic urticaria, may temporarily or

permanently alter the barrier and immune function of the gut wall and predispose an individual to allergic sensitization.

In one study of 77 patients with chronic urticaria, 24 (31%) were diagnosed as achlorhydric and 41 (53%) were shown to be hypochlorhydric.^[53] Treatment with HCl and a vitamin B-complex gave impressive clinical results, highlighting the importance of correcting any underlying factor in the treatment of chronic urticaria (see [Ch. 19](#) for further discussion).

Although IgE-mediated reactions are thought to predominate in immunologic urticaria, it has been suggested that IgG-mediated reactions are probably responsible for the majority of adverse reactions to foods seen in general practice (see [Ch. 51](#)). IgG antigen–antibody complexes are capable of promoting complement activation and subsequent generation of anaphylatoxins which promote mast cell degranulation. This could be a significant factor in some cases of urticaria.

[Figure 191.1](#) summarizes the basic aspects of a hypothetical model of immune defense in the normal and urticarial gut.

Food colorants

Food additives are a major factor in many cases of chronic urticaria in children. Colorants (azo dyes), flavorings (salicylates, aspartame), preservatives (benzoates, nitrites, sorbic acid), antioxidants (hydroxytoluene, sulfite, gallate), and emulsifiers/stabilizers (polysorbates, vegetable gums) have all been shown to produce urticarial reactions in sensitive individuals.^{[1] [5] [16] [17] [18] [19] [20] [21] [22] [23] [24] [25] [26] [27] [28] [29] [30] [31] [32] [33] [34] [35] [36] [37] [39] [40] [41] [42] [50] [56] [57] [58] [59] [60] [61]}

The importance of the control of food additives is well demonstrated in a recent study of 64 patients with common urticaria. Within 2 weeks on an additive-free diet, 73% of the patients had a significant reduction in their symptoms. The diet strictly forbade preservatives, dyes, or antioxidants. No fruits were allowed except honey. Rice, potatoes, and unprocessed cereals were allowed as well as fresh milk.^[62]

Tartrazine

In 1959, the azo dye tartrazine (FD&C yellow #5) was the first food dye reported to induce urticaria.^[63] Tartrazine

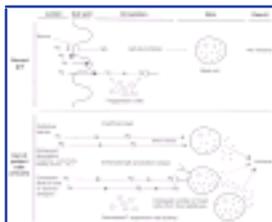

Figure 191-1 Hypothetical model of immune defense in the normal and urticarial

gut.

is one of the most widely used colorants. It is added to almost every packaged food as well as many drugs, including some antihistamines, antibiotics, steroids, and sedatives.^[64] Reactions to this food additive are so common that its use has been banned in Sweden.^[65]

In the United States, the average daily per capita consumption of certified dyes is 15 mg, of which 85% is tartrazine. Among children, consumption is usually much higher. Tartrazine sensitivity has been calculated as occurring in 0.1% of the population.^[64]

Tartrazine sensitivity is extremely common (20–50%) in individuals sensitive to aspirin.^[5]^[64] Like aspirin, tartrazine is also a cyclooxygenase inhibitor and known inducer of asthma, urticaria, and other allergic conditions, particularly in children.^[64] Inhibition of cyclooxygenase by tartrazine or aspirin apparently shunts eicosanoid metabolism towards leukotriene synthesis, thereby increasing smooth muscle contraction and vascular permeability.

In addition, tartrazine, as well as benzoate and aspirin, increases the production of the lymphokine leukocyte inhibitory factor.^[66] This results in an increase in perivascular mast cells and mononuclear cells. Histological examination of patients with urticaria shows that greater than 95% have an increase in perivascular mast cells and mononuclear cells.^[67]

[Table 191.4](#) summarizes the findings in studies using provocation tests to determine sensitivity to tartrazine and other food additives in patients with urticaria. Results have varied from 5 to 46%. Diets eliminating tartrazine as well as other azo dyes and food additives in sensitive individuals have in many cases been shown to be of great benefit. These studies are summarized in [Table 191.5](#). [Table 191.6](#) shows a recommended test battery.^[61]

Food flavorings

Salicylates

A broad range of salicylic acid esters are used to flavor foods such as cake mixes, puddings, ice cream, chewing gum, and soft drinks. The mechanism of action of these agents is thought to be similar to that of aspirin.^[5]

Salicylates are also found naturally in many foodstuffs. It is estimated that daily salicylate intake from foods is in the range of 10–200 mg/day.^[68] As this is very close to the level of salicylate used in clinical testing (usually 300 mg), dietary salicylate may be a significant factor in aspirin-sensitive individuals.

Most fruit, especially berries and dried fruits, contain salicylates. Raisins and prunes have the highest amounts. Salicylates are also found in appreciable amounts in candies made of licorice and peppermint. Moderate levels of salicylate are found in nuts and seeds. Vegetables, legumes, grains, meat, poultry, fish, eggs, and dairy products typically contain insignificant levels of salicylates. Salicylate levels are especially high in some herbs and condiments, including curry powder, paprika, thyme, dill, oregano, and turmeric. Although the intake of these herbs and spices is relatively small, they can make a significant contribution to dietary salicylate.^[68]

Other flavoring agents

Other flavoring agents such as cinnamon, vanilla, menthol, and other volatile compounds may produce urticaria in some individuals.^[5] Recently the artificial sweetener aspartame has been shown to induce urticaria.^[69]

Food preservatives

Benzoates

Benzoic acid and benzoates are the most commonly used food preservatives. Although for the general population the incidence of adverse reactions to these compounds is thought to be less than 1%, the frequency of positive challenges in patients with chronic

urticaria varies from 4 to 44%, as illustrated in [Table 191.4](#).

Fish and shrimp frequently contain extremely high quantities of benzoates. This may be one reason why adverse reactions to these foods are so common in patients with urticaria.

BHT and BHA

Butylated hydroxytoluene (BHT) and butylated hydroxyanisole (BHA) are the primary antioxidants used in prepared and packaged foods. Typically, 15% of patients with chronic urticaria test positive to oral challenge with BHT.^{[18] [31] [37] [41]} The use of chewing gum containing BHT was enough to induce urticaria in one patient.^[70]

Sulfites

Sulfites, like tartrazine, have been shown to induce asthma, urticaria, and angioedema in sensitive individuals.^[71] The source may be varied, as these compounds are ubiquitous in foods and drugs. They are typically added to processed foods to prevent microbial spoilage and to keep them from browning or changing color. The earliest known use of sulfites was in the treatment of wines with sulfur dioxide by the Romans. Sulfites are sprayed on fresh foods such as shrimp, fruits, and vegetables. They are also used as antioxidants and preservatives in many pharmaceuticals. Sulfites have caused such a wide range of health problems, such as asthma and urticaria, that their use on fruits and vegetables has been banned in the US.^[65]

The average person consumes an average of 2–3 mg/ day of sulfites. Wine and beer drinkers typically consume up to 10 mg/day and individuals who rely on restaurants for meals may ingest up to 150 mg/day.^[71]

Normally, the enzyme sulfite oxidase metabolizes sulfites to safer sulfates which are excreted in the urine. Those with a poorly functioning sulfoxidation system, however, have an increased ratio of sulfite to sulfate in their urine. Sulfite oxidase is dependent on the trace mineral molybdenum. Although most nutrition textbooks list molybdenum as an uncommon deficiency, an Austrian study of 1,750 patients found that 41.5% were molybdenum-deficient.^[72]

Food emulsifiers and stabilizers

A variety of compounds is used to emulsify and stabilize many commercial foods to ensure that the solids, oils, and liquids do not separate out. Most of the foods containing these compounds are heterogeneous, as they usually contain antioxidants, preservatives, and dyes. Polysorbate in ice cream has been reported to induce urticaria, and vegetable gums such as acacia, gum arabic, tragacanth, quince, and carrageenin may also induce urticaria in susceptible individuals.^[5]

Infections

Infections are a major cause of urticaria in children.^[1] Apparently in adults immunological tolerance occurs to many microorganisms due to repeated massive antigen exposure. The role of bacteria, viruses, and yeast (*Candida albicans*) in urticaria is briefly reviewed below. Chronic *Trichomonas* infections have also been found to cause urticaria.

Bacteria

Bacterial infections contribute to urticaria in two major settings: in acute streptococcal tonsillitis in children, and in chronic dental infections in adults. In the first setting acute urticaria predominates, while in the second, chronic urticaria predominates.^[1]

Viruses

Hepatitis B is the most frequent cause of viral-induced urticaria. One study found that 15.3% of patients with chronic urticaria had anti-hepatitis B surface antibodies.^[73] Urticaria has also been strongly linked to infectious mononucleosis and may develop several weeks before clinical manifestation. The incidence of urticaria during infectious mononucleosis is 5%.^[1]

Candida albicans

The association between *Candida albicans* and chronic urticaria has been suggested in several clinical studies. The number of patients with chronic urticaria who react positively to an immediate skin test with *Candida* antigens is 19–81% compared with 10–15% of normals.^{[20] [74] [75] [76] [77] [78] [79] [80]} It appears that sensitivity to *Candida albicans* is an important factor in at least 25% of patients with chronic urticaria.^[77] Approximately 70% of patients with a positive skin reaction also react to oral provocation tests using foods prepared with yeasts.

Treatment with nystatin has proven that elimination of the organism can achieve a cure in a number of individuals with positive skin tests, although a placebo response cannot be ruled out. More patients responded to a “yeast-free” diet than to simple elimination of the organism. The yeast-free diet employed excluded bread,

buns, sausage, wine, beer, cider, grapes, sultanas, marmite, bovril, vinegar, tomato, ketchup, pickles, and prepared foods containing food yeasts.

In a study of 49 patients with positive sensitivity to *Candida*, nine responded to a 3 week course of nystatin, while 18 became symptom-free only after adopting the yeast-free diet.^[75] This would seem to support the importance of diet along with eliminating the

yeast.

Further support for the importance of diet can be found in a study of 36 patients with a positive skin-prick test to *Candida*. Only three patients became asymptomatic from nystatin alone, compared with 23 on diet therapy following the nystatin therapy.

Desensitizing patients to *Candida albicans* with the use of a *Candida* cell wall extract has also demonstrated encouraging results in some patients, although the treatment of these individuals also included increasing gastrointestinal fermentation and acidity, as well as elimination of yeast.^{[79] [80]}

OTHER CONSIDERATIONS

Psychological aspects

In one retrospective study involving 236 cases of chronic urticaria, psychological factors, i.e. stress, were reported to be the most frequent primary cause.^[81] Stress appears to play an important role by decreasing intestinal secretory IgA levels.

In one study of 15 patients with chronic urticaria, relaxation therapy and hypnosis was shown to provide significant benefit.^[82] Patients were given an audio tape and asked to use the relaxation techniques described on the tape at home. At a follow-up examination 5–14 months after the initial session, six patients were free of hives and an additional seven reported improvement.

Ultraviolet light therapy

Ultraviolet light has been shown to be of some benefit to patients with chronic urticaria.^{[83] [84]} Both ultraviolet A (UVA) and ultraviolet B (UVB) have been used. Patients with cold, cholinergic, and dermographic urticaria display the greatest therapeutic response.

Thyroid

One study reported that thyroid hormone replacement therapy dramatically improved chronic urticaria in patients who had normal thyroid function but had evidence of thyroid autoimmunity. In seven patients with chronic urticaria, five were begun on thyroid hormone and two had their dosages increased. Their urticaria resolved within 2–4 weeks, at which time the thyroid therapy was discontinued. In five patients, their symptoms returned within 4 weeks, then resolved within 4 weeks of restarting the hormone therapy. Antithyroid antibodies did not correlate with clinical response.^[85]

Supplements

Vitamin B₁₂

Vitamin B₁₂ has been anecdotally reported to be of value in the treatment of acute and chronic urticaria.^[86] ^[87] Although serum B₁₂ levels are normal in most patients, additional B₁₂ appears to be of value. However, since injectable B₁₂ was used, the placebo effect (see [Ch. 4](#)) cannot be ruled out.

Quercetin

Considering the importance of mast cell degranulation in the pathogenesis of urticaria, quercetin's significant in vitro activity as a mast cell stabilizer (and inhibitor of many of the pathways of inflammation; see [Ch. 87](#)) suggests that it may be very useful in treating urticaria. This possibility is strengthened by the observation that sodium cromoglycate (at 200–400 mg four times/day), a compound similar to quercetin, confers excellent protection against the development of urticaria and angioedema in response to ingested food allergens.^[88]

THERAPEUTIC APPROACH

The basic therapeutic approach is identification and control of all factors which promote the patient's urticarial response. Obtaining a careful and thorough history is paramount to this process. Acute urticaria is usually a self-limiting disease, especially once the eliciting agent has been removed or reduced. Chronic urticaria also responds to the removal of the eliciting agent(s). In severe anaphylaxis, appropriate emergency care procedures should be followed.

Diet

An elimination or oligoantigenic diet is of utmost importance in the treatment of chronic urticaria (see [Chs 15](#) and [51](#)). The diet should not only eliminate suspected allergens, but also all food additives.

The strictest elimination diets allow only water, lamb, rice, pears, and vegetables. Those foods most commonly associated with inducing urticaria (i.e. milk, eggs, chicken, fruits, nuts, and additives) should definitely be avoided.^[50] Foods containing vasoactive amines should be eliminated even if no direct allergy to them is noted. The primary foods to eliminate are cured meat, alcoholic beverages, cheese, chocolate, citrus fruits, and shellfish.

The importance of eliminating food additives cannot be overstated. If food additives do in fact increase the

number of perivascular mast cells in the skin, they may also do the same in the small

intestine, thereby greatly increasing the risk of developing a “leaky” gut.

Also of value is control of arachidonic acid-dependent prostaglandins through the use of a low animal fat diet.

Supplements

- Vitamin C: 1 g three times/day
- Vitamin B₁₂ : 1,000 mcg/i.m. per week
- Quercetin: 250 mg 20 minutes before meals.

Psychological

Perform relaxation techniques daily. Listening to audio-taped relaxation programs may be an appropriate way to induce the desired state.

Physical medicine

Daily sunbathing for 15–20 minutes or the use of a UVA solarium, especially in chronic physical urticaria, is recommended.

Chapter 192 - Vaginitis and vulvovaginitis

Paul Reilly ND

DIAGNOSTIC SUMMARY

- Increased volume of vaginal secretions
- Abnormal color, consistency, or odor of vaginal secretions
- Vulvovaginal itching, burning, or irritation
- Introitus may show patchy erythema, and vaginal mucosa may exhibit congestion, or petechiae
- Dysuria or dyspareunia may be present.

GENERAL CONSIDERATIONS

Vaginitis is one of the most common reasons for women to seek medical attention, accounting for approximately 7% of all visits to gynecologists.^[1] A recent study reported that 72% of young sexually active females had one or more forms of vulvovaginitis.^[2] Another study of 821 women found vaginal infections to be six times more common than urinary tract infections.^[3] In fact, patients with dysuria are more likely to have vaginitis than a urinary tract infection (rUTI). Furthermore, when questioned carefully, most women can distinguish between “internal” dysuria of a UTI and the “external” dysuria felt when urine passes over inflamed labial tissues.^[3] Thus, it seems appropriate to question patients with dysuria more specifically about symptoms of vaginal discharge or irritation.

In addition to causing physical discomfort and embarrassment, vaginitis is medically important for several reasons. It may be a symptom of a more serious underlying problem, such as chronic cervicitis or a sexually transmitted disease. If infectious in nature, the agent may cause an ascending infection of the genital tract, leading to endometritis, salpingitis, and pelvic inflammatory disease. These may in turn lead to tubal scarring, infertility or ectopic pregnancies. Chronic asymptomatic vaginal infections have been implicated in recurrent urinary tract infections by their action as a reservoir of the infectious agent.^[4] ^[5] Some types of vaginal infections during pregnancy increase the

risk of miscarriage, and,

1574

if present at delivery, increase the incidence of neonatal infections, with potentially serious or fatal consequences. Finally, evidence is accumulating which links some forms of vaginitis to cervical cellular abnormalities and increased risk of cervical dysplasia.

TYPES OF VAGINITIS

There are three general types of vaginitis: hormonal, irritant, and infectious. Each is further divided into several specific subgroups based on etiology.

Hormonal vaginitis

Atrophic vaginitis

This is primarily a problem of postmenopausal women and those whose ovaries have been surgically removed. The vaginal epithelium becomes thin and atrophic due to the lack of estrogenic stimulation, which may result in formation of adhesions, dyspareunia, and increased susceptibility to infection. The most commonly reported symptoms are itching or burning and a thin watery discharge that may occasionally be blood-tinged. (Note that any vaginal bleeding in a postmenopausal woman requires a complete work-up to rule out the presence of carcinoma.) For a more extensive discussion, see [Chapter 170](#).

Increased vaginal discharge

When increased quantities of normal secretions exist in the absence of other symptomatology, the diagnosis of “physiological vaginitis” is often applied. This is inappropriate, since no inflammation actually exists. The increased discharge frequently reflects increased hormonal stimulation, such as occurs during pregnancy or at some stages of the menstrual cycle. It is primarily a diagnosis of exclusion after ruling out other causes. In most cases, no further treatment is required other than reassurance that the discharge is normal. Overly zealous douching or washing will briefly alleviate symptoms, but may ultimately aggravate the situation by causing an irritant vaginitis.

Irritant vaginitis

Irritant vaginitis is caused by physical or chemical agents which damage the delicate membranes of the vagina. In most cases, the cause is easily identified by careful history and examination.

Chemical vaginitis

This type is due to the use of medications or hygiene products which directly irritate the vaginal mucosa. A variant of this subgroup is allergic vaginitis where the damage is elicited by an immunologic reaction to a product rather than direct toxic reaction.

Traumatic vaginitis

Injury caused by physical agents or sexual activity can cause vaginitis.

Foreign body vaginitis

A foul-smelling discharge may signal the presence of a foreign body in the vagina – the most common being a forgotten tampon. Contraceptive devices, pessaries, and a wide variety of other items may also be found upon examination.

Infectious vaginitis

Infectious vaginitis may be sexually transmitted or may arise from a disturbance to the delicate ecology of the healthy vagina. Vaginal “infections” frequently involve common organisms found in the cervix and vagina of many healthy, asymptomatic women.^[6]

The unifying factor in the pathogenesis of pelvic infections is not so much which organisms are present in the patient’s genital tract but rather what happens to the patient to make her susceptible to infection.

Factors influencing the vaginal environment include the pH, glycogen content, glucose level, the presence of other organisms (particularly lactobacilli), the natural flushing action of vaginal secretions, the presence of blood, and the presence of antibodies and other compounds in the vaginal secretions. Many of these factors are, in turn, affected by the woman’s internal milieu and general health.

Immune dysfunction will predispose a woman to increased infections, including vaginal infections. Depressed immunity may occur as a result of nutritional deficiencies, medications (e.g. steroids), pregnancy, or serious illness. Other factors may predispose to infectious agents: diabetes mellitus, the wearing of synthetic pantihose (which tend to retain moisture), and a suspected but still unproven link between birth control pills and *Candida* infections.^[7]

Risk factors for sexually transmitted infections include increased numbers of sexual partners, unusual sexual practices, and the type of birth control (barrier methods reduce risk of infection).

Approximately 90% of vulvovaginitis will be associated with one of three organisms, *Trichomonas vaginalis*, *Gardnerella vaginalis*, or *Candida albicans*.^[8] The relative

frequency of each form varies with the population studied, as well as with sexual activity levels. Less frequent causes of vaginitis include *Neisseria gonorrhoea*, herpes simplex,

TABLE 192-1 -- Diagnostic differentiation of common causes of infectious vaginitis

| | <i>Candida</i> | NSV | <i>Trichomonas</i> | Gonorrhea | Herpes |
|-------------------------|--|------------------------|---|---|---|
| Keynote symptoms | Itching | Odor | Odor and itching | Asymptomatic or cervicitis | Vesicles or ulcers |
| Discharge | | | | | |
| pH | <4.5 | >4.5 | >5.0 | <4.5 | <4.5 |
| Odor | None | Fishy/amines | May be fishy | None | None |
| Appearance | Curdy, adherent, scant to thick | Gray, homogeneous | Greenish-yellow, frothy | Mucopurulent cervicitis | None |
| Pelvic examination | Adherent white patches with an erythematous border | Unremarkable | May show petechial lesion on cervix or vagina mucosa, a "strawberry cervix" | Cervical discharge, may have adenexal tenderness | Small, multiple vesicles or ulcers on cervix or vulva |
| Microscopic examination | Mycelia (10% KOH) | "Clue cells", few WBCs | Motile, flagellated organisms, few WBCs | Many WBCs with Gram-negative intracellular diplococci | Unremarkable |
| Culture media | Sauerbaud's | CNAF | Diamond's | Thayer–Martin | Live cell |

and *Chlamydia*. Each is described more fully below. [Table 192.1](#) summarizes the diagnostic differentiation of the most common causes of infectious vaginitis.

Trichomonas vaginalis

Trichomonas is a flagellated protozoan slightly larger than a leukocyte. It may be found in the lower urogenital tract of both men and women. Humans appear to be its only host, and sexual transmission appears to be its primary mode of dissemination. *Trichomonas* does not invade tissues and rarely causes serious complications. The most frequent symptom is leukorrhea associated with itching and burning. The discharge is frequently malodorous, greenish yellow, and frothy. The so-called "strawberry cervix" with punctate hemorrhages is found in only a small percentage of *Trichomonas* cases. Trichomonads

grow optimally at a pH of 5.5–5.8.^[9] Thus, conditions which elevate the pH, such as increased progesterone, will favor overgrowth of *Trichomonas*. Conversely, a vaginal pH of 4.5 in a woman with vaginitis is suggestive of an agent other than *Trichomonas*. A saline wet mount of fresh vaginal fluid will demonstrate the presence of small motile organisms to confirm the diagnosis in 80–90% of symptomatic carriers.^{[9] [10] [11]}

Candida albicans

Both the relative frequency and the total incidence of candidal vaginitis have increased dramatically, 2.5-fold, in the past 20 years. This increase parallels a declining incidence of gonorrhea and *Trichomonas*.^[7] Several factors have contributed to this increased incidence, chief among them being the increased use of antibiotics. The alterations antibiotics cause in both intestinal and vaginal ecology favor the growth of *Candida*. Recently Miles et al^[11] found a 100% correlation between genital and gastrointestinal *Candida* cultures, leading to the suggestion that significant intestinal colonization with *Candida* may be the single most significant predisposing factor in vulvovaginal candidiasis.^{[7] [11]} Steroids, oral contraceptives, and the continuing increase in diabetes mellitus all contribute to the problem. *Candida* is 10–20 times more frequent during pregnancy, due to the elevated vaginal pH, increased vaginal epithelial glycogen, elevated blood glucose, and intermittent glycosuria. Yeast infections are three times more prevalent in women wearing pantihose than those wearing cotton underwear, because the pantihose prevents drying of the area.^[12]

Most cases of recurrent candidal vaginitis are due either to autoinoculation from the GI tract or failure to recognize and treat the presence of one or more predisposing factors (see [Table 192.2](#)). In extremely persistent cases, sexual partners should be examined for evidence of candidal balanitis in order to rule out reinfection from that source. Allergies have been reported to cause recurrent candidiasis, which resolves when the allergies are treated.^[13]

The primary symptom of candidal vaginitis is vulvar itching, which can be quite severe. This is associated

TABLE 192-2 -- Predisposing factors to candidal vaginitis

 - Steroids

with the presence of a thick, curdy or “cottage cheese” discharge, which may reveal pinpoint bleeding when removed. The presence of such a discharge is strong evidence of a yeast infection, but its absence does not rule out *Candida*.^[2] Fewer than 20% of symptomatic *Candida* patients will actually display classical thrush patches. Other clues to a candidal etiology are the presence of brightly erythematous satellite patches, a vaginal pH close to 4.5, and the absence of a foul odor. Neither the character of the discharge nor the symptomatology is sufficient alone to make a diagnosis of *Candida*. A wet mount in saline or 10% KOH should always be performed and the presence of mycelia confirmed. Budding forms of yeast may be found in both normal and symptomatic vaginas, but the mycelial stage is only found in symptomatic women.^[1]

Non-specific vaginitis (NSV)

This is defined as vaginitis not due to *Trichomonas*, gonorrhea, or *Candida*. Whereas itching is the predominant symptom of candidal vaginitis, the presence of a discharge and odor are the keynotes to NSV. The odor is variously described as fishy, foul, or rotten, and reflects the production of the amines putrescine and cadaverine by anaerobic bacteria. The discharge is non-irritating, grey and homogeneous, and may occasionally be frothy, or even thick and pasty. The pH will be elevated to 5.0–5.5 in most cases, and there appears to be a correlation between elevated pH and the presence of odor.^[14] Microscopic examination of saline wet mounts will reveal the presence of typical “clue cells” (epithelial cells covered with bacteria which obliterate the edges). Application of 10% KOH to another slide or to the speculum will accentuate the characteristic amine odor.

The organism most frequently cited as responsible for NSV is *Gardnerella vaginalis* (formerly *Haemophilus vaginalis*). This association was first reported by Gardner & Dukes in 1955 and has been repeatedly noted in studies of NSV since then. Recently, debate has arisen concerning the causative role of *Gardnerella* in NSV. Although it is recovered from 95% of women with NSV, *Gardnerella* may also be recovered from 40% of asymptomatic women.^[1] When purified cultures of *Gardnerella* were placed in the vaginas of 13 volunteers, 10 showed no symptoms of vaginitis or positive cultures. Two women showed positive cultures for 2–3 months but developed no symptoms, and the 13th volunteer developed signs of vaginitis.^[15] Evidence continues to mount indicating that *Gardnerella* is a saprophyte which prospers in the conditions of NSV, but that the responsible organism may be the anaerobic microorganisms found in the condition, or the combination of *Gardnerella* and the vaginal anaerobes. This argument is furthered by the fact that *Gardnerella* lacks the enzymes to produce the amines characteristic of NSV, whereas the anaerobes do possess them. Additionally, the antibiotic most effective in treating NSV appears to be more active against anaerobes than *Gardnerella*, again lending credence to the newer theories downplaying the causative role of this organism.^{[15] [16] [17]}

Gonorrhea

Neisseria gonorrhoea is an uncommon cause of vaginitis, responsible for less than 4% of cases.^[3] Gonococcal vaginitis is more common in young girls because the vaginal epithelium is thinner prepubertally. During reproductive years, mucopurulent cervicitis is the primary symptom. Spread of the infection frequently causes other symptoms, such as urethritis, Bartholinitis or salpingitis, which finally prompt the seeking of medical treatment. Gonorrhea, either alone or in combination with other organisms, is cultured in 40–60% of cases of pelvic inflammatory disease (PID), a major cause of infertility. Because of the potential for serious sequelae, and the fact that up to 80% of gonorrheal infections in women are asymptomatic, all work-ups for vaginitis should include routine GC cultures on Thayer–Martin medium. In addition, any purulent discharge from the cervical os should be cultured and examined microscopically. The presence of three or more PMNs with Gram-negative intracellular diplococci per HPF is highly suggestive of GC, with less than 2% false-positives.^[3]

Herpes simplex

Herpes simplex infection is the most common cause of genital ulcers in the US. Other causes to be ruled out include syphilis, chancroid, lymphogranuloma venereum, and granuloma inguinale. For a more thorough discussion see [Chapter 157](#).

Chlamydia trachomatis

Chlamydia trachomatis is an obligate intracellular parasite which rarely causes vaginitis but is frequently found in association with other common etiologic agents. With the recent availability of better culture techniques and antibody tests, *Chlamydia* is now recognized as a major health problem in the US and in most Western societies. *Chlamydia* infects 5–10% of women and is usually asymptomatic until the development of complications, such as cervicitis, salpingitis, or urethritis. Certain populations have infection rates as high as 25%.^[18] *Chlamydia* is the organism most frequently recovered in cultures of women with PID,^[19] and tubal scarring appears to be more frequent after chlamydial infection than after GC. Thus, *Chlamydia* may be far more important in causing infertility and ectopic pregnancy than has been previously recognized.

Chlamydial infection during pregnancy increases the risk of prematurity and neonatal death. If a healthy baby is born to an infected woman, there is a 50% chance it will develop chlamydial conjunctivitis and a 10% chance of pneumonia.^[18] Because of the considerable risks of untreated *Chlamydia*, consider testing for this agent in all women with vaginitis, particularly those who are also pregnant.

THERAPEUTIC CONSIDERATIONS

Dietary considerations

The internal milieu of the vagina is a reflection of the condition of the entire body. Vaginal secretions are continuously released which affect, and are affected by, the microbial flora. These secretions contain water, nutrients, electrolytes, and proteins, such as secretory IgA. The quantity and character of these components are altered by hormonal and dietary factors. A general healthful diet is recommended in all cases to assure availability of all nutrients in sufficient quantity to optimize the body's ability to respond to changing conditions. A well-balanced diet low in fats, sugars, and refined foods is particularly important in cases due to infectious organisms, particularly *Candida*. Patients with depressed immunity are susceptible to increased rates of infection, particularly those due to *Candida*, *Trichomonas*, and herpes (see [Ch. 53](#) for further discussion of the effects of diet on immune function).

Nutrients particularly important for proper immune function include zinc, vitamin A, vitamin C, vitamin E, manganese, and B complex.

A diet high in lysine-containing foods and low in arginine-containing foods will reduce the number and severity of herpetic outbreaks. However, many of the foods high in lysine are animal products which are also high in fats. A low-arginine diet combined with lysine supplements will ensure adequate levels of lysine without excessive intake of fats.

Nutritional supplements

For general maintenance of health and immune competence, a high quality multivitamin and multimineral supplement will provide low-cost compensation for most dietary inadequacies. In addition, the following nutrients may be useful in one or more types of vaginitis.

Vitamin A and beta-carotene

Both of these nutrients are necessary for normal growth and integrity of epithelial tissues, such as vaginal mucosa. Vitamin A is essential for adequate immune response and resistance to infection. Secretory IgA, a major factor in resistance to infection, is lower in vitamin A-deficient subjects.^[20] Beta-carotene is a source of non-toxic vitamin A precursors. In addition, it has been shown to enhance T-cell numbers and to favorably alter their ratios.^[21] Excessive vitamin A can be toxic and teratogenic. This is of particular concern in females of reproductive age. Limit total vitamin A intake to 5,000 IU/day. If large doses of vitamin A are used, patients should be cautioned to be particularly careful about contraception. Use mixed carotenoids rather than synthetic beta-carotene.

B vitamins

One or more of the B vitamins is used in virtually every metabolic activity of the body. B vitamins are needed for carbohydrate metabolism, protein catabolism and synthesis, cell replication, and immune function. B₂ and B₆ have been shown to have estrogen-like effects and to act synergistically with estradiol. B₁ and pantothenic acid enhance the action of estradiol, although they have no estrogenic activity themselves.^[22] This suggests that B vitamins may be of use in estrogen deficiency conditions such as atrophic vaginitis, especially if combined with phytoestrogens.

Vitamin C and bioflavonoids

These nutrients are essential in any process related to immune function. Deficiency of vitamin C reduces the phagocytic activity of leukocytes. Both vitamin C and bioflavonoids improve connective tissue integrity, thus reducing spread of infection. Both nutrients are also useful in reducing the frequency and severity of herpetic outbreaks.^[23]
^[24] ^[25] ^[26] ^[49]

Vitamin E

Lack of vitamin E depresses immune response and host resistance. This may be corrected by high doses of supplemental vitamin E. Several experiments have shown increased resistance to chlamydial infection when subjects were supplemented with vitamin E. Vitamin E also regulates retinol in humans, and an inadequacy of vitamin E hinders the utilization of vitamin A, despite adequate retinol intake.^[27] The use of vitamin E for treatment of atrophic vaginitis has been reported since the 1930s. Vitamin E has beneficial effects upon many of the symptoms of menopause without the risks of estrogen therapy. Symptoms reported to be improved in various studies included:

- hot flashes
- vaginal atrophy
- chills
- headaches
- vaginal infection rates
- diabetic vulvovaginitis.

Vitamin E is thought to exert its effects in many of these hormonally related problems because it reduces the oxidative breakdown of progesterone, favoring its transformation into pregnanediol.^[28] ^[29] ^[30] ^[31] ^[32] ^[33] ^[34] ^[35] Topical applications combined with oral doses appear to offer the best results.

Excessive vitamin E intake, however, may be immunosuppressive (above 1200 IU/day)

and may transiently elevate blood pressure. It is reported to improve glycogen storage and the tone of heart muscle. Thus, extra caution should be exercised in patients with diabetes, hypoglycemia, hypertension, or heart disease. For these high-risk patients, begin with a daily dose of 100 IU and, while monitoring blood sugar or blood pressure, increase the dosage slowly over time (e.g. 50 IU/day).

Zinc

All DNA and RNA polymerases and repair and replication enzymes require zinc. Zinc enhances PGE₁ synthesis, normalizes lymphocyte activity, and enhances epithelial growth. Low levels of zinc are associated with depressed immunity and thymic atrophy, both of which are correctable when zinc is replenished. Zinc is also essential for proper utilization of vitamin A. Many otherwise well nourished adults receive less than 50% of the RDA of zinc from their diets and have one or more measurable signs of deficiency.^{[36] [37] [38]}

Treatment with topical and oral zinc has been shown to reduce the duration and severity of herpes outbreaks. This effect may be due either to the effect of the zinc on production of prostaglandins, or to the direct antiviral activity of the zinc ion. High levels of zinc are also toxic to *Chlamydia* and *Trichomonas* and have been used successfully in cases which did not respond to antibiotic therapy.^{[39] [40] [41] [42] [43]}

Lysine

Oral supplementation with lysine has been shown to decrease the frequency and severity of herpes outbreaks but not necessarily to shorten healing time. The postulated mechanism of action is that the lysine becomes incorporated into the virus capsule in place of arginine, resulting in an inactive virus. Lysine should be taken at low doses prophylactically and at higher doses at the first sign of prodromal symptoms, which correspond to the time of greatest viral replication. Effectiveness is dose-related, and best results are obtained if combined with the low-arginine diet.^{[44] [45]}

Lithium

One of the latest treatments for herpes is the use of lithium ointments. Lithium interferes with replication of DNA type viruses, such as herpes virus, without affecting host cells. Lithium succinate (8% solution) may be combined with zinc in a topical ointment, or it may be used alone.^{[46] [47]}

Botanical medicines

Glycyrrhiza glabra

Licorice has antiviral activity against RNA and DNA viruses and has been used successfully in the treatment of herpes. The number and severity of recurrences may be reduced by the repeated applications of the gel to active lesions.^[60] The isoflavonoid

compounds in licorice are reported to be effective against *Candida*.^[60] (For further discussion see [Ch. 90.](#))

Chlorophyll

Chlorophyll has a bacteriostatic and a soothing action. Water-soluble chlorophyll may be added to douching solutions for symptomatic relief.^{[61] [62] [63]}

Allium sativum

Garlic is antibacterial, antiviral, and antifungal, and has even been shown to be effective against some antibiotic-resistant organisms. Garlic may be added to douching solutions or may be wrapped in gauze and placed as a tampon/suppository for most forms of infectious vaginitis.^{[64] [65] [66] [67] [68]}

Hydrastis canadensis and Berberis vulgaris

Goldenseal and Oregon grape contain berberine, which has a significant effect against many bacteria. Berberine enhances immune function when taken internally as a tea and offers symptomatic local relief when used in douching solutions, as it is soothing to inflamed mucous membranes^{[69] [70] [71] [72]} (for further discussion, see [Ch. 91](#)).

Estrogenic plants

Atrophic vaginitis due to lack of estrogen may be treated by use of phytoestrogens. These compounds have a molecular structure similar to that of estrogen and have an effect similar to, but weaker than, that of estrogen. Phytoestrogenic plants include:

- soy
- black cohosh
- fennel
- anise
- ginseng
- dong quai
- alfalfa
- red clover
- licorice.

These plants may be used as teas, in salads, or in capsules.^{[73] [74] [75] [76] [77]} The simultaneous advantage and disadvantage of phytoestrogens is that they lack the potency of synthetic estrogens. Thus their benefits will be slower to be noticed, but they are also less likely to produce undesirable side-effects. Extensive discussion of plants

with phytoestrogens can be found in [Chapters 75](#) , [123](#) , [170](#) , and [183](#) .

Melaleuca alternifolia

An alcoholic extract of tea tree oil diluted to 1% in water exerts a strong antibacterial and antifungal action. It has been shown to be effective in treatment of trichomoniasis, candidiasis, and cervicitis. Treatment consists of daily douching combined with saturated tampons used weekly. No adverse reactions were reported, and patients commented favorably on its soothing effect^[78] (for further discussion, see [Ch. 96](#)).

Melissa officinalis

Melissa is a member of the mint family with a long history of use as an antiviral agent. Studies done in Europe have shown that *Melissa* extracts are effective in controlling herpetic symptoms and reducing the frequency and severity of both oral and genital herpes. *Melissa* may be taken orally in the form of water extracts or applied topically in the form of creams.^[79]

Botanical mixture

Women with abnormal vaginal discharge who presented to a gynecological clinic in India were randomized to receive either a cream containing *Azadirachta indica* (neem) seed oil, *Sapindus mukerossi* (reetha) saponin extract and quinine or placebo. They applied the cream intravaginally at bedtime for 14 days. The results were quite impressive. Symptomatic and microbial assessment revealed that 10 of 12 women with *Chlamydia trachomatis* vaginitis recovered within 1 week, and 10 of 17 with bacterial vaginosis recovered within 2 weeks. There was no benefit found in women with candidal or trichomonal infections and none of the women using the placebo recovered from any of the infections.^[80]

Other agents

Lactobacillus acidophilus

These desirable bacteria are an integral component of the vaginal flora. Lactobacilli help to maintain a healthy vaginal ecology by preventing the overgrowth of less desirable species. They do this by the production of lactic acid, natural antibiotic substances, and peroxides. In addition, they compete with other bacteria by the utilization of glucose. Whenever there is a disturbance of the vaginal flora, re-establishment of these organisms is important. This may be accomplished by the insertion of live lactobacillus-culture yogurt (careful reading of labels is important, since most commercially available yogurts do not use lactobacilli), but a more efficient and less messy method is to insert one capsule of lactobacillus into the vagina twice daily for 1–2 weeks. Whenever antibiotics (particularly broad-spectrum) are taken for any reason, regular use of lactobacillus will reduce the risk of complications, such as *Candida* overgrowth^[1] ^[48] (see [Ch. 105](#) for further discussion).

Iodine

Iodine used topically as a douche is effective against a wide range of organisms, including *Trichomonas*, *Candida*, *Chlamydia*, and non-specific vaginitis. Povidone-iodine (Betadine) has all the advantages of iodine without the disadvantages of stinging and staining. A study published in 1969 found povidone-iodine to be effective in treating 100% of cases of candidal vaginitis, 80% of trichomonas, and 93% of combination infections. A douching solution diluted to one part iodine in 100 parts water (e.g. 1.5–3 teaspoons Betadine to 1 quart of water) used twice daily for 14 days is effective against most organisms.^{[50] [51] [52] [53] [54] [55] [56] [57]}

Boric acid

Capsules of boric acid have been used to treat candidiasis with success rates equal to or better than those of nystatin. This treatment offers an inexpensive, easily accessible therapy for vaginal yeast infections.^{[58] [59]}

Gentian violet

Swabbing the vagina with gentian violet has been called: “as close to a specific treatment for candida as exists.”^[7]

DIAGNOSTIC APPROACH

Some women are hesitant to mention symptoms of vaginitis to their doctors out of embarrassment, associating them with poor personal hygiene or “venereal disease”. Because of the relative frequency of occurrence, and the potential for serious consequences if untreated, all female patients should be questioned directly regarding the presence of pruritus, vaginal discharge, dysuria, or other symptoms of vaginitis. The following protocol outlines the basic approach to making the correct diagnosis. Table 125.1 summarizes the key diagnostic criteria:

1. Obtain a complete gynecological and sexual history, including details of the sexual activity and practices of the patient and her partner(s). Determine method
-

- of contraception, personal hygiene habits, and any self-medications. Rule out the presence of associated symptoms suggestive of PID or systemic infection. Inquire about previous occurrences and their diagnosis, treatment, and resolution.
2. Identification of the causative agent is essential for successful treatment and evaluation. To facilitate diagnosis, the patient should be instructed to avoid douching, intercourse, and vaginal medications for 1–2 days prior to the office visit.
 3. Determine by speculum exam whether the discharge emanates from the vagina or

the cervix. Note the condition of the vaginal mucosa and the character of any discharge. Specimens should be collected, and then placed on slides for saline and KOH examination.

4. Appropriate cultures should be taken if the diagnosis remains in question, or if screening for GC or *Chlamydia* is desired (highly recommended).
5. The best time to test for low-level persistent infection is just before the menstrual period. *Candida* and other yeasts are particularly likely to be demonstrated at that time.

THERAPEUTIC APPROACH

Since approximately 90% of all cases of vaginitis are due to *Candida*, *Trichomonas*, or *Gardnerella* infections, the following recommendations are primarily directed towards treatment of these organisms. Due to their infectious nature, immune support (through proper diet, nutritional supplementation and botanical medicines) is an important aspect of the therapy. For further recommendations on treating atrophic vaginitis, see [Chapter 170](#) ; for herpes simplex, see [Chapter 157](#) ; and for *Chlamydia*, see [Chapter 143](#) .

Diet

For all causes of vaginitis, a nutrient-dense diet is recommended. All refined foods and simple carbohydrates should be eliminated and *trans* and saturated fats kept to a minimum. If food allergies are suspected, they should be determined and eliminated.

Supplements

Vitamin A: 5,000 IU/day; or beta-carotene: 50,000 IU/day

Vitamin C: 500–1000 mg every 4 hours

B complex: a good balanced B complex averaging 20–50 mg of each of the major components

Zinc: 10–15 mg/day (picolinate is best; 30–50 mg if using other forms)

Vitamin E: 200 IU/day of D-alpha-tocopherol

Lactobacillus sp.: 0.5 tsp twice daily.

Botanical medicines

- *Hydrastis* + *Echinacea* + *Phytolacca* (2:2:1)
 - tincture: 20–60 drops every 2–4 hours
 - tea: 1 tsp/cup every 2–4 hours.

Topical treatment

Douches and saturated tampons. Douches and saturated tampons are effective methods of achieving high concentrations of therapeutic agents in the vagina. The following agents are useful in the treatment of the common forms of vaginitis. The list is by no means exhaustive. Only the agents which have been mentioned in several articles or texts are included. Many other agents are doubtlessly also effective. In treating a particular woman, choose one or more of the agents below – do not try to include all at once. The variety provides alternatives for use in resistant cases.

Betadine. Various gels, pessaries, and fluids are available. A 1:100 dilution in a retention douche kills most organisms within 30 seconds.

Boric acid caps. Six hundred milligrams placed in capsules (note that repeated use may cause irritation, and use for more than 7 days may result in problems from systemic absorption).

Allium sativum. Chopped garlic may be added to any douching solution or a clove can be peeled, wrapped in gauze, and then inserted as a suppository. If irritation results, remove immediately.

Gentian violet swab. Note that sensitivity reactions are common, and staining of clothes can occur if a pad is not used.

Hydrastis canadensis. Decoction of 2 tsp/cup of hot water for douching.

Lactobacillus sp. ½ tsp or ¼ cup of yogurt in a cup of warm water.

Glycyrrhiza glabra. Use a decoction in douches or apply the gel locally.

Lithium sulfate. Eight per cent solution.

Melaleuca alternifolia. Use a 1% dilution as a douche, combined with insertion of a saturated tampon for 24 hours once a week (note that repeated use may result in sensitivity in some women).

White vinegar. This traditional naturopathic formula for treatment of vaginitis consists of 1–2 tablespoons of white vinegar and 2 tablespoons of green clay added to a pint of water and used as a douche.

Zinc sulfate. One tablespoon of a 2% solution in 1 pint of water may be used as a douche or combined with galvanic therapy.

Other botanicals. Several herbs have been repeatedly mentioned by traditional texts

and modern practitioners as effective in treating vaginitis. They may be used alone or in combination with other agents in douching solutions:

1581

- *Abies canadensis* (hemlock)
- *Hydrastis canadensis* (goldenseal)
- Eucalyptus
- *Calendula officinalis* (marigold – use the succus form)
- chlorophyll.

General recommendations

1. In all cases of vaginitis, lactobacillus capsules or lactobacillus-culture yogurt should be used daily to reinoculate the vagina with these desirable organisms.
2. Treatment failures may be due to incorrect diagnosis, reinfection, failure to treat predisposing factors, or resistance to the treatment used.
3. Sexual activity should be avoided during treatment to avoid reinfection and to reduce trauma to inflamed tissues. If this is not possible, at least assure that condoms are used.
4. In recurrent cases, consider treating sexual partners.
5. Women, particularly those with candidal vaginitis, should be instructed to wear cotton underwear.
6. Early symptomatic relief of pruritus and burning is often possible with the use of warm sitz baths, either plain or with herbs or Epsom salts.
7. In severe cases, it is often helpful to thoroughly cleanse the vagina with a calendula succus-saturated cotton swab to remove the microbial-saturated discharge.
8. A constant uterine discharge will alkalinize the vagina, thus decreasing its natural resistance. Effective treatment requires identifying and treating the cause of such a discharge. The vaginal depletion pack can be very useful in this situation (see Appendix 12).

Specific recommendations

Candida. Due to the high correlation of vaginal *Candida* with intestinal overgrowth of the same organism, it is suggested that the internal condition be treated simultaneously to prevent recurrences. Treatment of *Candida* should continue for at least one full menstrual cycle. Some authors suggest therapy for another 3–4 months during the week preceding the menses. Treatment is as follows:

- Betadine: 2 times/day
- Boric acid caps: inserted daily for 14 days
- Gentian violet swab: use daily for 14 days or longer
- *Glycyrrhiza glabra*: daily.

Trichomonas:

- Betadine: two times/day
- Zinc sulfate: daily
- *Melaleuca alternifolia* oil: daily.

Chlamydia:

- Betadine: daily
- Zinc sulfate: daily.

Herpes:

- Avoid arginine-rich foods
- Lysine: 1,000–2,000 mg/day maintenance dose, double during outbreak
- Zinc sulfate: daily
- Lithium sulfate: add to the zinc sulfate douching solution
- *Melissa officinalis*: ointment or cream three times/day.

NSV:

- Betadine: daily
- *Hydrastis canadensis*: daily.

Atrophic vaginitis:

- B complex: 100 mg/day
- Vitamin E: 400 IU/day
- Topical application: vitamin E cream.

Chapter 193 - Varicose veins

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

DIAGNOSTIC SUMMARY

- Dilated, tortuous, superficial veins in the lower extremities
- May be asymptomatic or associated with fatigue, aching discomfort, feeling of heaviness, or pain
- Edema, pigmentation, and ulceration of the skin of the distal leg may develop
- Women are affected four times as frequently as men.

GENERAL DISCUSSION

Veins are fairly frail structures. Defects in the wall of a vein lead to dilation of the vein and damage to the valves.^[1] When the valves become damaged, the increased static pressure results in the bulging veins known as varicose veins.

Varicose veins affect nearly 50% of middle-aged adults. The subcutaneous veins of the legs are the veins most commonly affected, due to the gravitational pressure that standing exerts on the veins. When an individual stands for long periods of time, the pressure build-up in the vein can increase up to 10 times. Hence, individuals with occupations that require long periods of standing are at greatest risk for developing varicose veins.^[2]

Women are affected about four times as frequently as men; obese individuals have a much greater risk; and the risk increases with age due to loss of tissue tone, loss of muscle mass, and weakening of the walls of the veins. Pregnancy may also lead to the development of varicose veins, as pregnancy increases venous pressure in the legs.^[2]

In general, varicose veins pose little harm if the involved vein is near the surface. These types of varicose veins are, however, cosmetically unappealing. Although significant

symptoms are not common, the legs may feel heavy, tight, and tired.

A more serious form of varicose vein involves obstruction and valve defects of the deeper veins of the leg. This type of varicose vein can lead to problems such

1584

as thrombophlebitis, pulmonary embolism, myocardial infarction, and stroke. Phlebography and Doppler ultrasonography are the most accurate methods of diagnosis of deep vein involvement.

Cause of varicose veins

Several theories explain the cause of varicose veins:

- genetic weakness of the veins or venous valves
- excessive venous pressure due to a low-fiber-induced increase in straining during defecation
- long periods of standing, and/or heavy lifting
- damage to the veins or venous valves secondary to thrombophlebitis
- weakness of the vascular walls due to either abnormalities in the proteoglycans of the interendothelial cement substance or excessive release of lysosomal enzymes (beta-*N*-acetyl-glucosaminidase, beta-glucuronidase, and arylsulfatase) which break down the ground substance, resulting in increased capillary permeability and loss of integrity of the venous structure.

THERAPEUTIC CONSIDERATIONS

While several nutritional and botanical agents can assist in improving the structural integrity of the veins, long-term success is dependent on correcting the common problem of inadequate dietary fiber.

Dietary factors

Fiber

In contrast to the United States and England, varicose veins are rarely seen in parts of the world where high-fiber, unrefined diets are consumed.^{[3] [4]} A low-fiber diet, high in refined foods, contributes to the development of varicose veins.

Individuals consuming a low-fiber diet tend to strain more during bowel movements, since their smaller and harder stools are more difficult to pass. This straining increases the pressure in the abdomen, which obstructs the flow of blood up the legs. The increased pressure may, over a period of time, significantly weaken the vein wall, leading to the formation of varicose veins or hemorrhoids, or may weaken the wall of the

large intestine and produce diverticuli in the large intestine.^[5]

A high-fiber diet is the most important component in the treatment and prevention of varicose veins (and hemorrhoids). A diet rich in vegetables, fruits, legumes, and grains promotes peristalsis; and many fiber components attract water and form a gelatinous mass which keeps the feces soft, bulky, and easy to pass. The net effect of a high-fiber diet is significantly less straining during defecation.

Bulking agents

Natural bulking compounds can also be used. These substances, particularly psyllium seed, pectin, and guar gum, possess mild laxative action due to their ability to attract water and form a gelatinous mass. This, as mentioned above, keeps the feces soft and promotes peristalsis, significantly reducing straining during defecation. These types of fibers are generally less irritating than wheat bran and other cellulose fiber products.

Physical measures

Exercise and avoidance of standing for long periods of time will reduce the risk of development of varicose veins. Exercise, especially walking, riding a bike, or jogging, is particularly beneficial, as the contraction of leg muscles pushes pooled blood back into circulation.

Elastic compression stockings are occasionally beneficial. Surgical stripping of the vein can be performed in severe cases.

Botanical medicines

Centella asiatica

When given orally, an extract of centella containing 70% triterpenic acids (asiatic acid, madecassic acid, and asiatoside) has demonstrated impressive clinical results in the treatment of cellulite, venous insufficiency of the lower limbs, and varicose veins.^[6] ^[7] ^[8] ^[9] ^[10]

Several experimental studies have discovered that centella exerts a normalizing action on the metabolism of connective tissue. Specifically, it possesses an ability to enhance connective tissue integrity by stimulating glycosaminoglycan synthesis without promoting excessive collagen synthesis or cell growth.^[7] Glycosaminoglycans are the major components of the amorphous intercellular matrix (ground substance) in which collagen fibers are embedded. The net outcome of centella's effect on connective tissue is the development of normal tissue.

Its effect in venous insufficiency and varicose veins appears to be related to its ability to enhance connective tissue structure, reduce sclerosis, and improve the blood flow

through the affected limbs.^{[6] [7] [8] [9] [10]}

Escin

Escin is a compound isolated from the seeds of the *Aesculus hippocastanum* (horse chestnut), an herb which has a long folk history of use in the treatment of varicose veins and hemorrhoids.^[11] It has anti-edema and anti-inflammatory properties and decreases capillary permeability

1585

by reducing the number and size of the small pores of the capillary walls.^{[12] [13]} The reduction in capillary permeability and edema appears to be due to inhibition of the lysosomal enzymes (mentioned above) which break down the proteoglycans of the ground substance. Investigators have also demonstrated that escin has venotonic activity.^[14]

A venotonic is a substance which improves venous tone by increasing the contractile potential of the elastic fibers in the vein wall. As mentioned earlier, relaxation of the venous wall contributes greatly to the development of varicose veins. Escin's venotonic activity has been confirmed in clinical trials that demonstrate a positive effect in the treatment of varicose veins and thrombophlebitis.^{[12] [15]} In fact, extracts of horse-chestnut seed standardized for escin appear to be as effective as compression stockings without the nuisance. For example, in a well-designed study, the effectiveness of horse-chestnut-seed extract versus leg-compression stockings was examined in 240 patients with varicose veins.^[15] Patients received either horse-chestnut-seed extract (50 mg of escin per day), compression stockings, or a placebo. Patients were treated over a period of 12 weeks. Effectiveness was evaluated by a *phlethysmograph*— a machine that measures the volume of fluid in the leg. After the 12-week trial, lower-leg volume of the more severely affected leg decreased an average of 56.5 ml with compression therapy and 53.6 ml with horse-chestnut-seed extract, while it increased by 9.8 ml with the placebo.

In the treatment of varicose veins, escin can be given orally, or an escin/cholesterol complex can be applied topically. The topical formula is also of benefit in the treatment of bruises, due to escin's ability to decrease capillary fragility and swelling.

Ruscus aculeatus

Butcher's broom is a subshrub of the lily family that grows in the Mediterranean region. The rhizome has a long history of use in treating venous disorders such as hemorrhoids and varicose veins.^[16]

The active ingredients in butcher's broom are ruscogenins. These compounds have demonstrated a wide range of pharmacological actions, including anti-inflammatory and vasoconstrictor effects.^{[17] [18]} In Europe, butcher's broom extracts are used extensively,

both internally and externally, in the treatment of varicose veins and hemorrhoids.

Flavonoid-rich extracts

Since increasing the integrity of the wall of the vein may also reduce the risk of developing varicose veins, it appears that flavonoid-rich berries, such as hawthorn berries, cherries, blueberries, and blackberries are beneficial in the prevention and treatment of varicose veins. These berries are very rich sources of proanthocyanidins and anthocyanidins.^{[19] [20] [21]}

These bioflavonoids give the berries their blue-red color. Proanthocyanidins and anthocyanidins also improve the integrity of ground substance and the vascular system. Extracts of several of these berries are used widely in Europe for various circulatory conditions.^{[19] [20] [21]}

Another rich source of flavonoids is buckwheat, which is high in rutin. In a recent double-blind, placebo-controlled study, 77 patients with chronic venous insufficiency were given placebo tea or *Fagopyrum esculentum* (buckwheat) tea for 12 weeks. The tea was standardized to contain 5% total flavonoids, yielding a daily dosage of 270 mg of rutin. A statistically significant decrease in total leg volume was seen in the treated group along with statistically insignificant improvements in capillary permeability and symptoms. No adverse effects were noted.^[22]

These extracts' efficacy is related to their ability to:^{[19] [20] [21]}

- reduce capillary fragility
- increase the integrity of the venous wall
- inhibit the breakdown of the compounds composing the ground substance
- increase the muscular tone of the vein.

Consumption of these berries or of their extracts is indicated for individuals with varicose veins, as well as for those who wish to prevent them.

Bromelain and other fibrinolytic compounds

Individuals with varicose veins have a decreased ability to break down fibrin.^[23] This is extremely important as fibrin is deposited in the tissue near the varicose veins. The skin then becomes hard and "lumpy" due to the presence of the fibrin and fat. In addition, decreased fibrinolytic activity increases the risk of thrombus formation, which may result in thrombophlebitis, myocardial infarction, pulmonary embolism, or stroke.

Herbs that increase the fibrinolytic activity of the blood are therefore indicated. Capsicum (cayenne),^[24] garlic,^[25] onion,^[26] and ginger^[27] all increase fibrin breakdown. Liberal consumption of these spices in foods is recommended for individuals with varicose veins and other disorders of the cardiovascular system.

The proteolytic enzyme from pineapple, bromelain, also appears to be indicated in the

treatment of varicose veins. Vein walls are an important source of plasminogen activator, which promotes the breakdown of fibrin. Veins that have become varicosed have decreased levels of plasminogen activator. Bromelain acts in a similar manner to plasminogen activator to cause fibrin breakdown.^[28] Bromelain may help to prevent the development of the hard and lumpy skin ((lipodermatosclerosis) found around varicosed veins.

1586

THERAPEUTIC APPROACH

Varicose veins are extremely common in our society, largely due to dietary and lifestyle factors. The supplements and botanicals are recommended in order to strengthen the walls of the vein and increase fibrinolytic activity. To treat and reduce risk of varicose veins, it is important to:

- consume a diet high in fiber
- exercise regularly
- avoid standing in one place for long periods of time (use elastic support stocking if standing is necessary)
- avoid obesity
- employ measures which increase the integrity of the connective tissue and vein wall
- enhance fibrinolytic activity.

Diet

A high-complex carbohydrate diet rich in dietary fiber is indicated. The diet should contain liberal amounts of proanthocyanidin- and anthocyanidin-rich foods, such as blackberries, cherries, blueberries, etc. Garlic, onions, ginger, and cayenne should also be consumed liberally.

Supplements

- Vitamin A: 10,000 IU/day
- Vitamin B: complex – 10–100 mg/day
- Vitamin C: 500–3,000 mg/day
- Vitamin E: 200–600 IU/day
- Bioflavonoids: 100–1,000 mg/day
- Zinc: 15–30 mg/day.

Botanical medicines

- *Aesculus hippocastanum*
—bark of root: 500 mg three times/day

- Escin
 - 10 mg three times/day
 - an escin/cholesterol complex may be applied topically in a 1% concentration
- *Centella asiatica* extract (70% triterpenic acid content): 30 mg three times/day
- *Ruscus aculeatus* extract (9–11% ruscogenin content): 100 mg three times daily
- *Vaccinium myrtillus*
 - fresh berries: 55–110 g three times/day
 - extract containing 25% anthocyanoside: 80–160 mg three times/day
- Bromelain (minimum 1,500 MCU): 500–750 mg three times/day between meals.

Chapter 194 - Viral pharyngitis

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

DIAGNOSTIC SUMMARY

- Sore throat with pain on swallowing
- Throat infected, with edematous tonsils and fauces
- Throat culture negative for Group A beta-hemolytic streptococci
- Fever, malaise, cervical lymphadenopathy, and leukocytosis.

GENERAL CONSIDERATIONS

In adults, over 90% of “sore throats” are viral in origin. Nonetheless, ruling out “strep throat” (group A beta-hemolytic streptococci pharyngotonsillitis) is important as physical findings in viral pharyngitis and streptococcal pharyngitis are indistinguishable.

THERAPEUTIC CONSIDERATIONS

Although many plants and plant constituents have been shown to have antiviral activity, a more general, patient-oriented, approach is indicated. This includes examination of all the factors that determine the resistance status of the host:

- past infection
- fatigue
- stresses (physical, emotional, mental)
- environmental pollution
- nutritional status
- current medications.

Since this is a self-limiting condition, stimulating and aiding the body’s natural defense mechanisms will result in a shorter illness and less risk of morbidity. Generally, this

involves the application of the principles outlined in [Chapter 53](#) .

Antiviral botanicals

The herbs with the best documented antiviral activity include:

1588

- *Echinacea* sp.
- *Glycyrrhiza glabra* (licorice root)
- *Melissa officinalis* (lemon balm)
- *Aloe vera*
- *Astragalus membranaceus*
- *Allium sativum* (garlic).

Full discussion of these botanicals can be found in their respective chapters.

Another botanical of value is *Zingiber officinale* (ginger). While not a particularly strong antiviral, it does have analgesic properties and is useful for relieving the pharyngeal irritation.^[1]

Zinc lozenges

Several studies have now shown that zinc lozenges provide relief of pharyngitis and prevent progression when utilized at the first signs of the pharyngeal discomfort which presages the common cold. A recent double-blind, placebo-controlled study of 100 patients experiencing the early signs of the common cold were provided a lozenge which provided either 13.3 mg of zinc (from zinc gluconate) as long as they had symptoms, or placebo.

Subjective daily symptom scores were recorded for cough, headache, hoarseness, muscle ache, nasal drainage, nasal congestion, scratchy throat, sore throat, sneezing, and fever (assessed by oral temperature). The time to complete resolution of symptoms was significantly shorter in the zinc group than in the placebo group (median of 4.4 days compared with 7.6 days). The zinc group had significantly fewer days with coughing (median of 2.0 days compared with 4.5 days), headache (2.0 days vs. 3.0 days), hoarseness (2.0 days vs. 3.0 days), nasal congestion (4.0 days vs. 6.0 days), nasal drainage (4.0 days vs. 7.0 days), and sore throat (1.0 day vs. 3.0 days). More patients in the zinc group than in the placebo group had mild side-effects (90% vs. 62%), nausea (20% vs. 4%), and bad-taste reactions (80% vs. 30%).^[2]

However, a few other early studies did not show benefit from zinc lozenges. This inconsistency was probably due to inappropriate lozenge formulation. The explanation for this can be found in an interesting study which evaluated the actual amount of zinc released into the saliva by various formulations. This study showed that sucking on hard

candy lozenges containing zinc gluconate and citric acid delivered an insignificant amount of Zn^{2+} . It was found that saliva completely suppresses the ionization of zinc to free Zn^{2+} in the presence of citric acid or a 30-fold molar excess of mannitol plus sorbitol. In the presence of excess glycine under the same conditions, there was no interference with ionization to produce Zn^{2+} . In contrast, even the presence of large excesses of glycine was found to not interfere, with greater than 90% of zinc from zinc gluconate being found as free Zn^{2+} .^[3]

Echinacea

Two recent studies have provided substantial documentation for the efficacy of *Echinacea* in the treatment of the common cold. In one study, 120 patients who had suffered at least 3 URIs in the previous 6 months were treated with a randomized, double-blind protocol. The treatment group received juice of the *Echinacea purpurea* herb according to a specific protocol: 20 drops every 2 hours the first day symptoms were experienced, followed by 20 drops 3 times per day until cured. Compared to the placebo group, the treatment group experienced a 50% reduction in the number of colds and a 50% reduction in duration (4 days).^[6]

The second study involved 160 patients who began treatment after 1–3 days of symptoms (headache, fever, cough, pharyngitis). The randomized, double-blind study used 90 drops (= 900 mg) per day of an extract of *Echinacea pallida* root. Compared to the placebo group, the treatment group experienced a 30% decrease in duration and symptoms.^[7]

The message is clear, when used at the first sign of symptoms, *Echinacea* is significantly more effective than waiting until symptoms fully develop.

Other considerations

While poor immune function is appropriately suspected in patients suffering from chronic pharyngitis, other factors should also be considered. For example, some people experience repeated challenges to their pharynx from microbes residing in their toothbrush. Changing to a new toothbrush or washing the toothbrush in the dishwasher every 17–31 days helps many patients.^[4] Another significant cause of chronic pharyngeal problems is food allergy. Typical upper respiratory tract symptoms of chronic delayed food allergy include:^[5]

- chronic rhinitis
- sinusitis
- pharyngitis
- lateral and lingual tonsil hypertrophy
- chronic laryngitis
- glossitis
- face and neck rashes
- eczema.

THERAPEUTIC APPROACH

The old adage of drinking plenty of fluids, restricting food intake and getting plenty of rest should be instituted, along with the elimination of concentrated sugars (which are known to depress the immune system; see [Ch. 53](#)) and suspected allergens. As fever is a natural defense mechanism, it should be supported. Antipyretics should not be used unless the temperature approaches 104°F, at

1589

which point the body's ability to control its temperature becomes impaired. In addition to the immune support, traditional naturopathic therapy includes hydrotherapy, diaphoretics, and "drainage remedies" (see [Ch. 42](#)).

Diet

Eliminate all sources of concentrated simple sugars: sugar, honey, fruit juice, dried fruit, etc. Restrict food intake to less than 1,000 calories/day. Increase fluid intake to 8 oz/hour using water and the herbal teas listed below.

Supplements

- Vitamin A: 50,000 IU/day for 1 week; or beta-carotene: 200,000 IU/day (*Note*: do not use vitamin A in menstruating women due to teratogenic effect)
- Vitamin C: 500 mg every 2 hours
- Bioflavonoids: 1,000 mg/day
- Zinc: use lozenges supplying 15–25 mg of elemental zinc (gluconate form without citrate mannitol or sorbitol). Dissolve in the mouth every two waking hours after an initial double dose. Continue for up to 3 days
- Thymus extract: the equivalent of 120 mg pure polypeptides with molecular weights less than 10,000, or roughly 500 mg of the crude polypeptide fraction.

Botanicals

- *Echinacea* sp.
 - dried root (or as tea): 0.5–1 g
 - freeze-dried plant: 325–650 mg
 - juice of aerial portion of *E. purpurea* stabilized in 22% ethanol: 2–3 ml
 - tincture (1:5): 2–4 ml
 - fluid extract (1:1): 2–4 ml

—solid (dry powdered) extract (6.5:1 or 3.5% echinacoside): 150–300 mg

- *Glycyrrhiza glabra*

—powdered root: 1–2 g

—fluid extract (1:1): 2–4 ml

—solid (dry powdered) extract (4:1): 250 to 500 mg.

Local treatment

- Gargle with salt water twice daily: 1 tbsp salt/240 ml of warm water
- *Zingiber officinalis* (ginger): strong tea with fresh root or chew fresh root.

Physical therapy

- Carrot poultice around neck
- Hydrotherapy – see [Chapter 42](#) .

| 2. | Have you, at any time in your life, taken other “broad-spectrum” antibiotics for respiratory, urinary, or other infections for 2 months or longer, or in short courses four or more times in a 1 year period? | 20 |
| 3. | Have you ever taken a broad-spectrum antibiotic (even a single course)? | 6 |
| 4. | Have you, at any time in your life, been bothered by persistent prostatitis, vaginitis, or other problems affecting vaginitis, your reproductive organs? | 25 |
| 5. | Have you been pregnant? | |
| | One time | 3 |
| | Two or more times | 5 |
| 6. | Have you taken birth control pills? | |
| | For 6 months to 2 years | 8 |
| | For more than 2 years | 15 |
| 7. | Have you taken prednisone or other cortisone-type drugs? | |
| | For 2 weeks or less | 6 |
| | For more than 2 weeks | 15 |
| 8. | Does exposure to perfumes, insecticides, fabric shop odors, and other chemicals provoke: | |
| | —mild symptoms | 5 |
| | —moderate to severe symptoms? | 20 |
| 9. | Are your symptoms worse on damp, muggy days or in moldy places? | 20 |

| | | |
|-----|---|-----|
| 10. | Have you had athlete's foot, ringworm, "jock itch", or other chronic infections of the skin or nails? | |
| | Mild to moderate | 10 |
| | Severe or persistent | 20 |
| 11. | Do you crave sugar? | 10 |
| 12. | Do you crave breads? | 10 |
| 13. | Do you crave alcoholic beverages? | 10 |
| 14. | Does tobacco smoke <i>really</i> bother you? | 10 |
| | Total score of this section | ___ |

Major symptoms

For each of your symptoms, enter the appropriate figure in the "point score" column:

- If a symptom is occasional or mild, score 3 points
- If a symptom is frequent and/or moderately severe, score 6 points
- If a symptom is severe and/or disabling, score 9 points.

| | | Point score |
|-----|--------------------------------|-------------|
| 1. | Fatigue or lethargy | ___ |
| 2. | Feeling of being "drained" | ___ |
| 3. | Poor memory | ___ |
| 4. | Feeling "spacey" or "unreal" | ___ |
| 5. | Depression | ___ |
| 6. | Numbness, burning, or tingling | ___ |
| 7. | Muscle aches | ___ |
| 8. | Muscle weakness or paralysis | ___ |
| 9. | Pain and/or swelling in joints | ___ |
| 10. | Abdominal pain | ___ |
| 11. | Constipation | ___ |
| 12. | Diarrhea | ___ |
| 13. | Bloating | ___ |
| 14. | Persistent vaginal itch | ___ |

| | | |
|------------------------------------|--|-----|
| 15. | Persistent vaginal burning | ___ |
| 16. | Prostatitis | ___ |
| 17. | Impotence | ___ |
| 18. | Loss of sexual desire | ___ |
| 19. | Endometriosis | ___ |
| 20. | Cramps and/or other menstrual irregularities | ___ |
| 21. | Premenstrual tension | ___ |
| 22. | Spots in front of eyes | ___ |
| 23. | Erratic vision | ___ |
| Total score of this section | | ___ |

Other symptoms

For each of your symptoms, enter the appropriate figure in the “point score” column:

- If a symptom is occasional or mild, score 1 point
- If a symptom is frequent and/or moderately severe, score 2 points
- If a symptom is severe and/or disabling, score 3 points.

APPENDIX 3: Fasting – patient guidelines

Trevor K. Salloum ND

WHY FAST?

Fasting is one of the quickest ways to increase elimination of wastes and to enhance the reparative processes of the body. Fasting has been practiced throughout history and is universally employed in the animal kingdom.

Scientific inquiry into fasting began in the early 1900s. Research has found it to be useful in the treatment of:

- diabetes
- epilepsy
- obesity
- psychological illnesses
- arthritis
- heart disease
- skin disease
- toxic poisoning.

Loss of minerals or vitamins is usually not of concern during a short fast; humans have effective biochemical mechanisms for adapting to long periods without food.

The short fast (3–5 days) is a good chance for the body to acquire optimal rest, both mental and physical. This is an opportunity to build health, break old habits, and increase awareness of oneself. Although longer fasts are required in chronic disease, the short fast can be conducted at home, rather than at an in-patient facility.

The ideal time to begin a fast is when hunger disappears or at the first sign of an illness. Although a short fast can be implemented at any time, it is better to begin on a weekend or during a time period when you can be inactive. The more rest, the better the results: energy can be directed towards healing, instead of other body functions.

Before embarking on a fast, check with your physician. If you are on any medications

(including herbs and nutritional supplements) or have any chronic disease, slight alterations may be necessary. A physical examination is important before a fast to ensure there are no contraindications and to allow your physician to monitor your progress more effectively.

1598

A positive mental outlook is important. The benefits of fasting include:

- decreased weight
- clearer skin
- increased elimination
- tissue repair
- decreased pain and inflammation
- increased concentration
- relaxation and spare time
- savings in food costs.

Perhaps the greatest benefit is the satisfaction that you are taking a major role in improving your health.

FASTING DIRECTIONS

Starting your fast

Prepare for your fast on the day before you stop eating by making your last meal one of only fresh fruits and vegetables (some authorities recommend a full day of raw food to start a fast). In addition, finish all last-minute errands so that you can establish an environment as free of stress and responsibility as possible.

During the fast

Only water – distilled or spring water is best – should be taken by mouth while fasting. (Some authorities recommend fruit or vegetable juice, but this is actually an elimination diet rather than a fast.) The quantity of water should be dictated by thirst, but drink at least a few glasses every day.

Take no coffee, tea, juice, soft drinks, cigarettes, or anything else by mouth except water. If possible, avoid the smell and sight of food. If you have to prepare food for other family members, satisfy your senses with the aroma – no sampling!

Try to keep your mind away from food by reading a book (especially a book on fasting), listening to music, writing a letter, watching a movie, taking a leisurely walk in a park, driving to a pleasant destination, etc.

Exercise is not usually encouraged while fasting. You want to conserve fuel and allow maximal healing. Short walks or light stretching are useful, but heavy work-outs tax the system and inhibit repair and elimination.

Cleansing the skin with lukewarm water is encouraged, but extremes of temperature can be tiring. Try to avoid deodorants, soaps, sprays, detergents, synthetic shampoos, and exposure to other chemicals. These only hinder elimination and add to the body's detoxification and elimination burden.

Sunlight is essential for healthy cells, but excessive exposure will strain the body's protective systems. Try to obtain at least 10–20 minutes of direct sun exposure per day. Many fasting institutions have solariums in which guests sunbathe.

Rest is one of the most important aspects of the fast. Try to take a nap or two during the day. You will probably require less sleep at night, since your daily activity has

decreased.

Enemas are not usually necessary, but this will depend on your individual health. If you are worried about constipation, a longer pre-fast period of fresh fruits and vegetables will assist elimination.

Body temperature usually drops during a fast, as does blood pressure, and pulse and respiratory rates – all measures of the slowing of the metabolic rate of the body. It is important, therefore, to stay warm. If needed, you may use a hot water bottle at night.

Breaking your fast

Breaking your fast is a good time for you to consider carefully what you are eating and why. While breaking your fast, as outlined in [Table A3.1](#) , and in the days that follow, it can be very helpful to you and your physician to carefully record what you eat and how you feel after eating. Many of today's health problems are due to food allergies and overeating. Take this time to choose which eating habits you truly want to establish. As you break your fast, eat slowly, chew thoroughly, limit quantities, eat foods at room temperature, and enjoy!

If you have problems

Most discomfort during fasting is usually brief as the body works quickly to restore homeostasis. You may experience headaches, dizziness, nausea, coated tongue, bad odor, mild palpitations, and mucous discharge. If your symptoms are intolerable and persist, notify your physician or break your fast with an orange and resume fasting when symptoms disappear.

TABLE 3-1 -- Breaking your fast

| Breakfast | Lunch | Dinner |
|----------------------------------|---|--|
| <i>Day one</i> | | |
| One of the following: | A different fruit from the breakfast list | 8 oz of any fruit |
| ½ melon | | |
| ½ nectarine | | |
| ¼ pineapple | | |
| <i>Day two</i> | | |
| 12 oz of one type of fresh fruit | 14 oz of whole pears, papaya, or citrus fruit | Raw vegetable salad with leafy greens, tomato, celery, and cucumber or two pears, two apples, and an avocado |
| <i>Day three</i> | | |

Resume healthy diet – raw fresh fruits, raw/steamed vegetables, whole grains, nuts, seeds, and legumes

1599

SUMMARY

It is important to realize that, although fasting is a very effective way to improve your health, it is only one part of a total health-building program, not a panacea. Fresh air, rest, exercise, sunshine, pure food and water, emotional poise, and wholesome foods eaten in appropriate quantities are equally important in building and maintaining health.

**APPENDIX 4: Gluten and gliadin content of selected foods****TABLE 4-1 -- ^a**

| Food | Total protein | Prolamines ^b (% of total protein) | Glutelins ^c (% of total protein) | Cross-reactivity with gliadin |
|-------------|----------------------|---|--|--------------------------------------|
| Wheat | 10–15 | 40–50 | 30–40 | ++++ |
| Rye | 9–14 | 30–50 | 30–50 | +++ |
| Oats | 8–14 | 10–15 | ~5 | ++ |

| Millet | 7–16 | 57 | 30 | |
| Buckwheat | | | High | - |

^a From Baker PG. Facts about gluten. Lancet 1975; ii: 1307.

^b Primarily gliadin.

^c Primarily gluten.

APPENDIX 5: Healthy exchange lists

EXCHANGE LIST 1: VEGETABLES

Vegetables provide the broadest range of nutrients of any food class. They are rich sources of vitamins, minerals, carbohydrates, and protein. The little fat they contain is in the form of essential fatty acids. Vegetables provide high quantities of other valuable health-promoting substances, especially fiber and carotenes. In Latin, the word vegetable means “to enliven or animate”. Vegetables give us life. More and more evidence is accumulating to show that vegetables can prevent as well as treat many diseases.

The best way to consume many vegetables is in their fresh, raw form. In their fresh form, many of the nutrients and health-promoting compounds of vegetables are provided in much higher concentrations. Drinking fresh vegetable juices is an effective way of achieving your daily quota of vegetables.

When cooking vegetables it is very important that they not be overcooked. Overcooking will not only result in loss of important nutrients, but will also alter the flavor of the vegetable. Light steaming, baking, and quick stir-frying are the best ways to cook vegetables. Do not boil vegetables unless you are making soup, as much of the nutrients will be left in the water. If fresh vegetables are not available, frozen vegetables are preferred to their canned counterparts.

Vegetables are excellent “diet” foods as they are very high in nutritional value but low in calories. In List 1 you will notice there is also a list of “free” vegetables. These vegetables are termed “free foods” and can be eaten in any desired amount because the calories they contain are offset by the number of calories your body burns in the process of digestion. If you are trying to lose weight, these foods are especially valuable, as they help to keep you feeling satisfied between meals.

List 1 shows the vegetables to use for 1 vegetable exchange. Please notice that starchy vegetables like potatoes and yams are included in List 3 (breads, cereals, and starchy vegetables).

List 1 Vegetables

One vegetable exchange = 1 cup cooked vegetables or fresh vegetable juice or 2 cups raw

Artichoke (1 medium)

Asparagus

Bean sprouts

Beets

Broccoli

Brussels sprouts

Carrots

Cauliflower

Eggplant

Greens

Beet

Chard

Collard

Dandelion

Kale

Mustard

Spinach

Turnip

Mushrooms

Okra

Onions

Rhubarb

Rutabaga

Sauerkraut

String beans, green or yellow

Summer squash

Tomatoes, tomato juice, vegetable juice cocktail

Zucchini

The following vegetables may be used as often as desired, especially in their raw form:

Alfalfa sprouts

Bell peppers

Bok choy

Cabbage

Chicory

Celery

Chinese cabbage

Cucumber

Endive

Escarole

Lettuce

Parsley

Radishes

Spinach

Turnips

Watercress

EXCHANGE LIST 2: FRUITS

Fruits are a rich source of many beneficial nutrients, and regular fruit consumption has been shown to offer significant protection against many chronic degenerative diseases, including cancer, heart disease, cataracts, and strokes. Fruits make excellent snacks as they contain fructose or fruit sugar. This sugar is absorbed slowly into the bloodstream, thereby allowing the body time to utilize it. Fruits are also excellent sources of vitamins and minerals as well as health-promoting fiber compounds. However, fruits are not as nutrient-dense as vegetables because they are typically higher in calories, which is

List 2 Fruits

Each of the following equals one exchange:

| | |
|---------------------------|----------------|
| Fresh juice | 1 cup (240 ml) |
| Pasteurized juice | ? cup |
| Apple | 1 large |
| Apple sauce (unsweetened) | 1 cup |
| Apricots, fresh | 4 medium |
| Apricots, dried | 8 halves |
| Banana | 1 medium |
| Berries | |
| Blackberries | 1 cup |
| Blueberries | 1 cup |
| Cranberries | 1 cup |
| Raspberries | 1 cup |
| Strawberries | 1½ cups |
| Cherries | 20 large |
| Dates | 4 |
| Figs, fresh | 2 |
| Figs, dried | 2 |
| Grapefruit | 1 |
| Grapes | 20 |

| | |
|---|----------|
| Mango | 1 small |
| Melons | |
| Cantaloupe | ½ small |
| Honeydew | ¼ medium |
| Watermelon | 2 cups |
| Nectarine | 2 small |
| Orange | 1 large |
| Papaya | 1½ cups |
| Peach | 2 medium |
| Persimmon, native | 2 medium |
| Pineapple | 1 cup |
| Plums | 4 medium |
| Prunes | 4 medium |
| Prune juice | ½ cup |
| Raisins | 4 tbsp |
| Tangerine | 2 medium |
| <i>Additional fruit exchanges (no more than one per day):</i> | |
| Honey | 1 tbsp |
| Jams, jellies, preserves | 1 tbsp |
| Sugar | 1 tbsp |

why vegetables are favored over fruits in weight loss plans and overall healthy diets.

EXCHANGE LIST 3: BREADS, CEREALS, AND STARCHY VEGETABLES

Breads, cereals, and starchy vegetables are classified as complex carbohydrates. Chemically complex carbohydrates are made up of long chains of simple carbohydrates or sugars. This means the body has to digest or break down the large sugar chains into simple sugars. Therefore, the sugar from complex carbohydrates enters the bloodstream slower. This means that blood sugar levels and appetite are better controlled.

Complex carbohydrate foods like breads, cereals, and starchy vegetables are higher in fiber and nutrients but lower in calories than foods high in simple sugars like cakes and candies. Choose whole grain products (e.g. whole grain breads, whole grain flour products, brown rice, etc.) in preference to their processed counterparts

1605

List 3 Breads, cereals, and starchy vegetables

One of the following equals one exchange:

| Breads | |
|-----------------------------------|---------|
| Bagel, small | ½ |
| Dinner roll | 1 |
| Dried breadcrumbs | 3 tbsp |
| English muffin, small | ½ |
| Tortilla (6 inch) | 1 |
| Whole wheat, rye, or pumpernickel | 1 slice |
| Cereals | |
| Bran flakes | ½ cup |
| Cornmeal, dry | 2 tbsp |
| Cereal, cooked | ½ cup |
| Flour | 2½ tbsp |

| | |
|--|---------|
| Grits, cooked | ½ cup |
| Pasta, cooked | ½ cup |
| Puffed cereal, unsweetened | 1 cup |
| Rice or barley, cooked | ½ cup |
| Wheat germ | ¼ cup |
| Other unsweetened cereal | ¾ cup |
| Crackers | |
| Arrowroot | 3 |
| Graham (2½" square) | 2 |
| Matzo (4" x 6") | ½ |
| Rye wafers (2" x 3½") | 3 |
| Saltines | 6 |
| Starchy vegetables | |
| Corn | ½ cup |
| Corn on cob | 1 small |
| Parsnips | ½ cup |
| Potato, mashed | ½ cup |
| Potato, white | small |
| Squash, winter, acorn, or butternut | ½ cup |
| Yam or sweet potato | ¼ cup |
| Prepared foods | |
| Biscuit, 2" diameter (omit 1 fat exchange) | 1 |
| Corn bread, 2" x 2" x 1" (omit 1 fat exchange) | 1 |
| French fries, 2–3" long (omit 1 fat exchange) | 8 |
| Muffin, small (omit 1 fat exchange) | 1 |
| Potato or corn chips (omit 2 fat exchange) | 15 |
| Pancake, 5" x ½" (omit 1 fat exchange) | 1 |
| Waffle, 5" x ½" (omit 1 fat exchange) | 1 |

(white bread, white flour products, white rice, etc.). Whole grains provide substantially more nutrients and health-promoting properties and their carbohydrates are absorbed more slowly. Whole grains are a major source of complex carbohydrates, dietary fiber, minerals, and B vitamins. The protein content and quality of whole grains is greater than that of refined grains. Diets rich in whole grains have been shown to be protective

against the development of chronic degenerative diseases, especially cancer, heart disease, diabetes, varicose veins, and diseases of the colon including colon cancer, inflammatory bowel disease, hemorrhoids, and diverticulitis. Whole grains can be used as breakfast cereals, side dishes, casseroles, or used as part of the main entrée.

EXCHANGE LIST 4: LEGUMES (BEANS)

Legumes (beans) are among the oldest cultivated plants – fossil records demonstrate that even prehistoric people domesticated and cultivated certain legumes for food.

List 4 Legumes (beans)

One half cup of the following cooked or sprouted beans equals one exchange:

Black-eyed peas

Chick peas

Garbanzo beans

Kidney beans

Lentils

Lima beans

Pinto beans

Soybeans, including tofu (omit one fat exchange)

Split peas

Other dried beans and peas

Today, the legumes are a mainstay in most diets of the world. Legumes are second only to grains in supplying calories and protein to the world's population. Compared with grains, they supply about the same number of total calories, but usually provide 2–4 times as much protein.

EXCHANGE LIST 5: FATS AND OILS

The human body requires the fatty acids linoleic and linolenic acid. These fatty acids function as components of nerve cells, cellular membranes, and hormone-like substances known as prostaglandins. While essential fatty

List 5 Fats and oils

Each of the following equals one exchange:

Polyunsaturated

Vegetable oils

| | |
|-----------------------|----------|
| Canola | 1 tsp |
| Corn | 1 tsp |
| Flax | 1 tsp |
| Safflower | 1 tsp |
| Soy | 1 tsp |
| Sunflower | 1 tsp |
| Avocado (4" diameter) | ? |
| Almonds | 10 whole |
| Pecans | 2 large |
| Peanuts | |
| Spanish | 20 whole |
| Virginia | 10 whole |
| Peanut butter | 1 tbsp |
| Seeds | |
| Flax | 1 tbsp |
| Pumpkin | 1 tbsp |
| Sesame | 1 tbsp |
| Sunflower | 1 tbsp |
| Walnuts | 6 small |

Mono-unsaturated

| | |
|-----------|---------|
| Olive oil | 1 tsp |
| Olives | 5 small |

Saturated (use sparingly)

| | |
|----------------------|---------|
| Butter | 1 tsp |
| Bacon | 1 slice |
| Cream, light or sour | 2 tbsp |
| Cream, heavy | 1 tbsp |
| Cream cheese | 1 tbsp |
| Salad dressings | 2 tsp |
| Mayonnaise | 1 tsp |

1606

acid fats are critical to human health, too much fat in the diet, especially saturated fat, is linked to numerous cancers, heart disease, and strokes. Most nutritional experts strongly recommend that the total fat intake be kept below 30% of the total calories. It is also recommended that at least twice the amount of unsaturated fats be consumed as saturated fats. This recommendation is easy to follow by simply reducing the amount of domesticated animal products in the diet, increasing the amount of nuts and seeds consumed, and using natural polyunsaturated oils like canola, safflower, soy, and flaxseed oils as salad dressings.

EXCHANGE LIST 6: MILK

The drinking of cow's milk is a relatively new dietary practice for humans. Many people are allergic to milk or lack the necessary enzymes to digest it. This may explain why many people have difficulty with milk. For those who tolerate it, milk consumption should be limited to no more than one or two servings per day.

EXCHANGE LIST 7: MEATS, FISH, CHEESE, AND EGGS

When choosing from this list, it is important to choose primarily from the low fat group and to remove the skin of poultry. This will keep the amount of saturated fat low. Although many people advocate vegetarianism, the exchange list below provides high concentrations of certain nutrients difficult to get in an entirely vegetarian diet such as the full range of amino acids, vitamin B₁₂, and iron. The most important recommendation may be to

List 6 Milk

One cup equals one exchange:

Non-fat milk or yogurt

Non-fat soy milk

2% milk (omit one fat exchange)

Cottage cheese, low fat (omit one fat exchange)

Low-fat yogurt (omit one fat exchange)

Whole milk (omit two fat exchanges)

Yogurt (omit two fat exchanges)

One ounce of cheese equals one milk exchange and one fat exchange

List 7 Meat, fish, cheese, and eggs

Each of the following equals one exchange:

Low fat (less than 15% fat content)

| | |
|---|------|
| Beef – baby beef, chipped beef, chuck, steak (flank, plate), tenderloin plate ribs, round (bottom, top), all cuts rump, spare ribs, tripe | 28 g |
|---|------|

| | |
|------|------|
| Fish | 28 g |
|------|------|

| | |
|---|------|
| Lamb – leg, rib, sirloin, loin (roast and chops), shank, shoulder | 28 g |
|---|------|

| | |
|--|------|
| Poultry – chicken or turkey without skin | 28 g |
|--|------|

| | |
|--|---------|
| Veal – leg, loin, rib, shank, shoulder, cutlet | 28 g |
| <i>Medium fat (for each omit ½ fat exchange)</i> | |
| Beef – ground (15% fat), canned corned beef, rib eye, round (ground commercial) | 28 g |
| Cheese – mozzarella, ricotta, farmer’s, Parmesan | 28 g |
| Eggs | 1 |
| Organ meats | 28 g |
| Pork – loin (all tenderloin), picnic and boiled ham, shoulder, Boston butt, Canadian bacon | 28 g |
| <i>High fat (for each exchange omit 1 fat exchange)</i> | |
| Beef – brisket, corned beef, ground beef (more than 20% fat), hamburger, roasts (rib), steaks (club and rib) | 28 g |
| Duck or goose | 28 g |
| Lamb – breast | 28 g |
| Pork – spareribs, loin, ground pork, country-style ham, deviled ham | 28 g |

use these foods in small amounts as “condiments” in the diets rather than as mainstays. Definitely stay away from cured meats like bacon, pastrami, etc. as these foods are rich in compounds which can lead to the formation of cancer-causing nitrosamines.

Possible exceptions to the recommendation of reducing the intake of animal foods are cold-water fish such as salmon, mackerel, and herring which provide the essential omega-3 fatty acids. These beneficial oils have been shown in hundreds of studies to lower cholesterol and triglyceride levels, thereby reducing the risk for heart disease and strokes. The omega-3 fatty acids are being recommended to treat or prevent not only high cholesterol levels, but also high blood pressure, other cardiovascular diseases, cancer, autoimmune diseases like multiple sclerosis and rheumatoid arthritis, allergies and inflammation, eczema, psoriasis, and many others. While many are recommending fish as substitutes for land animals, care must be taken to ensure the fish are wild caught rather than the much less healthy ones grown on farms.

APPENDIX 6: Hydrochloric acid supplementation – patient instructions

1. Begin by taking one hydrochloric acid (HCl) capsule (10 grains) at your next large meal. At every meal after that of the same size take one more capsule (one capsule at the next meal, two at the meal after that, then three at the next meal, and so on).
2. Continue to increase the dose until you reach seven capsules or you feel a warmth in your stomach, whichever occurs first. A feeling of warmth in the stomach means that you have taken too many capsules for that size of meal. Take one less. However, it is a good idea to try the larger dose again at another meal to make sure that it was the HCl that caused the warmth and not something else.
3. After you have determined the largest dose that you can take at your large meals without feeling any warmth, maintain that dose at all meals of similar size. Take fewer capsules with smaller meals.
4. When taking several capsules, it is best to take them throughout the meal, rather than all at once.
5. As your stomach begins to regain the ability to produce the amount of HCl needed to properly digest your food, you will notice the warm feeling again. This is the time to start decreasing the dose level.
6. Every 3 days, decrease by one capsule per meal. If the warmth continues, decrease more rapidly. If maldigestion symptoms return, add capsules back until digestion improves again.

APPENDIX 7: Patient instructions for measuring basal body temperature

INTRODUCTION

Your body temperature reflects your metabolic rate, which is largely determined by hormones secreted by the thyroid gland and by the ability of your cells to convert these hormones to their more active form. Your level of thyroid activity can be determined simply by measuring your basal body temperature. All that is needed is a high-quality thermometer.

PROCEDURE

1. Place the thermometer by your bed before going to sleep at night. If using a mercury thermometer, shake it down to below 95°F.
 2. On waking, place the thermometer in your armpit for a full 10 minutes. It is important to make as little movement as possible. Lying and resting with your eyes closed is best. Do not get up until the 10 minute test is completed.
 3. After 10 minutes, read and record the temperature and date. (A convenient form is printed at the end of this appendix: [Fig. A7.1.](#))
 4. Record the temperature for at least three mornings (preferably at the same time of day) and give the information to your physician. Menstruating women must perform the test on the second, third, and fourth days of menstruation. Men and postmenopausal women can perform the test at any time.
-

1610

The image shows a small, partially visible form with a grid structure. It appears to have columns for recording data over time, likely for temperature and date as mentioned in the text.

Figure 7-1 Form to record temperature and date when measuring basal body temperature.

INTERPRETATION

Your basal body temperature should be between 97.6° and 98.2°F. Low basal body temperatures are quite common and may reflect hypothyroidism. Common signs and symptoms of hypothyroidism are:

- depression
- difficulty in losing weight
- dry skin
- headaches
- lethargy or fatigue
- menstrual problems
- recurrent infections
- sensitivity to cold.

High basal body temperatures (above 98.6°F) are less common, but may be evidence of hyperthyroidism. Common signs and symptoms of hyperthyroidism include:

- bulging eyeballs
- fast pulse
- hyperactivity
- inability to gain weight
- insomnia
- irritability
- menstrual problems
- nervousness.

**APPENDIX 8: Premenstrual syndrome questionnaire****Grading of symptoms**

1. None
2. Mild – present but does not interfere with activities
3. Moderate – present and interferes with activities, but not disabling
4. Severe – disabling (unable to function).

Grade your symptoms for last menstrual cycle only.

| Subgroup | Symptoms | Week after period | Week before period |
|-----------------|-----------------------|--------------------------|---------------------------|
| PMS-A | Anxiety | _____ | _____ |
| | Irritability | _____ | _____ |
| | Mood swings | _____ | _____ |
| | Nervous tension | _____ | _____ |
| | Total | _____ | _____ |
| PMS-C | Increased appetite | _____ | _____ |
| | Headache | _____ | _____ |

APPENDIX 9: Rotation diet master chart, plans I and II

Sally Rockwell PhD CCN

1614

PLAN I

| Food family | Day 1 (green) | Day 2 (yellow) | Day 3 (blue) | Day 4 (red) |
|---------------------|---|-----------------------|--|----------------------|
| Proteins | | | | |
| Fin fish | <i>Fish may be eaten daily as long as a different fish is selected each day</i> | | | |
| Shellfish | Mussel, escargot, clam | Shrimp | Oysters, scallops, abalone | Crab, squid, octopus |
| Fowl flesh and eggs | Chicken, goose | Turkey ? | Cornish game hen, quail, pheasant | Duck |
| Red meat | Beef (veal, liver, etc.) | | Pork (ham, bacon, etc.), lamb | Rabbit |
| Dairy | Cow (milk, yogurt, cheeses) | | Goat (milk, yogurt, cheeses) | |
| Legumes | Kidney, soy, and lima beans | | Pinto, garbanzo and black beans; black-eyed and split peas | |

| | | | | |
|----------------------|---|--|--|--|
| Sprouts | Nut, seed, and legume | Nut and seed | Nut, seed, and legume | Nut and seed |
| Nuts, seeds and oils | Soy, walnuts | Almonds | Peanut, pecan, pumpkin | Cashew, pistachio, safflower, corn |
| | Filbert ? | Pine nuts ? | Chestnuts ? | Avocado ? |
| | Sesame ? | Brazil nuts ? | Macadamia ? | Olive ? |
| | | Sunflower, apricot | | |
| Grains and flours | Buckwheat, soy, quinoa, tofu, arrowroot, guar gum | Rice, millet, rye, potato, flaxseed, xanthan gum | Amaranth, garbanzo, kudzu root, chestnut | Barley, oats, wheat, corn, tapioca, agar ? |
| Sweeteners | Honey, raisins | Dates, molasses, rice, syrup | Figs, currants | Coconut, malt, sago palm, maple syrup |

Vegetables

| | | | | |
|-------------|--|--|---|---------------------------|
| Beet | Beets, Swiss chard | Carrots, parsley | Spinach | Avocado |
| Mustard | Cabbage, broccoli, white radish, kale, nappa | | Bok choy, red radish, Brussels sprouts, cauliflower | Parsnip, celery |
| Composite | | Leaf and bib lettuce, common artichoke | | Iceberg lettuce, romaine |
| Gourd | Cucumber, winter squash | | Summer squash, pumpkin, zucchini | |
| Lily | Onion, garlic | | Chives, leeks, shallots, asparagus | |
| Night shade | | White potato, peppers | Chestnuts | Tomato, eggplant, peppers |

| | | | | |
|---------------|-------------------------------------|------------------------|------------------------------------|-----------------------------|
| Miscellaneous | String beans | Yams ? | Peas | Bamboo shoots |
| | | Jicama ? | Okra ? | Jerusalem artichoke ? |
| | | Mushrooms ? | Olives ? | Sweet potato ? |
| Fruits | | | | |
| Plum | | Plum, prune, apricot | | Peach, cherry, nectarine |
| Apple | Apple | | Pear, quince | |
| Citrus | | Lemon, orange, kumquat | | Lime, grapefruit, tangerine |
| Berries | Boysenberry, blackberry, strawberry | Huckleberry, cranberry | Logan berry, raspberry, gooseberry | Blueberry |
| Gourd | Melons | | Cantaloupe, melons | Pomegranate ? |
| Miscellaneous | Rhubarb, grapes | Kiwi ? | Pineapple ? | Mango, banana ? |
| | Papaya ? | Guava ? | | |
| | Persimmon ? | | | |
| Bulk | Pectin | Flaxseed ? | Chia seed ? | Psyllium seed ? |

PLAN II

| | Day 1 (green) | Day 2 (yellow) | Day 3 (blue) | Day 4 (red) |
|----------------|--|---|--|---|
| Proteins | Fin fish | Red meat | Shellfish | Fowl (flesh and eggs) |
| | Anchovy, bass, butterfish, catfish, cod, flounder, herring, mackerel, halibut, perch, salmon, snapper, sole, trout, tuna, turbot, etc. | Beef (veal, liver, etc.), lamb, pork (ham, bacon, etc.), rabbit | Abalone, clam, crab, escargot, mussel, octopus, oysters, scallops, shrimp, squid | Chicken, Cornish game duck, goose, hen, pheasant, quail, turkey |
| | | | Frog legs ? | Rabbit ? |
| | Legumes (all beans and peas): | Dairy: | Grass family: | |
| | Black, garbanzo, kidney, lima, pinto, and soy beans; black-eyed and split peas; tofu | Cow (milk, yogurt, cheeses), goat (milk, yogurt, cheeses) | Bamboo shoots, barley, corn, millet, oats, rice, rye, wheat, kamut, spelt, teff | |
| | Sprouts | Sprouts | Sprouts | Sprouts |
| Nuts and seeds | Peanut, soy, pecans, walnut | Filbert ? | Almond | Cashew, pistachio, sunflower seeds |
| | Sesame ? | Pine nut ? | Brazil nut ? | |
| | | Pumpkin seeds | Chestnut ? | |
| | | | Macadamia ? | |

| | | | | |
|-------------------|---|---|---|---|
| Oils | Peanut, soy | Animal fat, butter | Almond, apricot, Coconut | Safflower, sunflower |
| | Sesame ? | Avocado ? | | Chicken, turkey and other poultry fats |
| | Walnut | Olive ? | Corn | |
| | | | Cotton seed | |
| Grains and flours | Arrowroot ? | Agar agar ? | Grass family flours | Buckwheat |
| | Garbanzo, peanut, soy | Amaranth, quinoa | Chestnut flour ? | Potato |
| | Kudzu root ? | Flaxseed meal ? | Xanthan gum ? | Quinoa ? |
| | | Gelatin | | Tapioca ? |
| Sweeteners | Honey ? | Molasses, rice syrup | Palm family | Malt syrup ? |
| | Fig ? | Whey, lactose | Coconut, date, sago | Currants ? |
| | Raisins ? | | Corn syrup | |
| Vegetables | Carrot family | Gourd family (all squash) | Mustard family | Composite family |
| | Carrot, celery, dill, parsley, parsnip | Cucumber, pumpkin, summer squash, winter squash, zucchini | Bok choy, broccoli, Brussels sprouts, cabbage, cauliflower, kale, nappa, radish | Common artichoke, dandelion greens, and bib, iceberg, leaf and romaine lettuces |
| | Lily family | Beet family | Bamboo shoots, corn | Nightshade |
| | Asparagus, chives, garlic, leeks, onion, shallots | Beets, spinach, Swiss chard | | Eggplant, white potato, peppers, pimento, and tomato |
| | Peas, string beans, fava beans | Avocado ? | Okra | Rhubarb |
| | | Olives ? | Chestnuts ? | Yam, yucca ? |
| | | Sweet potato ? | | Mushroom ? |
| | | | | |

|--------|---|-----------------------------------|--|---|
| Fruits | Apple family | Heather family | Prune family | Citrus family |
| | Apple, pear, quince | Blueberry, cranberry, huckleberry | Apricot, cherry, nectarine, peach, plum, prune | Grapefruit, kumquat, lemon, lime, orange, tangerine |
| | Rose family | All melons, cantaloupe | Guava ? | Gooseberry |
| | Boysenberry, blackberry, strawberry, Logan berry, raspberry | | | |
| | Papaya ? | Pomegranate ? | Persimmon ? | Currant ? |
| | Fig ? | Kiwi ? | Pineapple ? | Mango ? |
| | Grape, raisin ? | | | Banana ? |
| Bulk | Pectin | Flaxseed | Chia seed | Psyllium seed |

APPENDIX 10: Sit and reach test

Purpose

The sit and reach test is used to measure the extensibility of the muscles of the posterior thigh and back.

Equipment

- Yardstick measured in inches
- Tape for stick
- Data cards.

Procedure

1. The person sits on a mat with the legs fully extended and the feet about 4–6? apart.
2. The yardstick is placed between the legs with the 15? mark at the soles of the feet for males and the 14? mark at the soles of the feet for females.
3. All individuals should be given an opportunity to warm up by stretching prior to testing.
4. The person's legs are held down by a partner and he/she bends forward slowly and reaches as far as possible along the top of the stick with both hands extended.
5. The distance reached to the nearest half-inch in the best of three trials is the person's score.

Evaluation

Good score: 19–21 inches

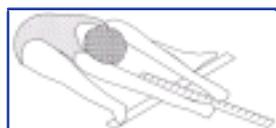

Figure 10-1 Sit and reach test.

APPENDIX 11: Vaginal depletion pack

INTRODUCTION

The vaginal depletion pack (“vag pack”) was originally developed by the eclectic physicians of the 19th century and later modified to its present form by John Bastyr ND. Over the last 50 years, it has been regularly used by most naturopathic physicians in the treatment of various vaginal disorders.

Although no controlled studies of the clinical efficacy of the vag pack have been published, it has a long, and apparently successful, history of use. Its primary application has been in the treatment of cervical erosions, cervical dysplasia, pelvic inflammatory disease, and pelvic congestion. The mode of action is apparently through its local antibacterial, anhydrous, alterative, and sclerotic activities. These are thought to inhibit local microbial growth, stimulate the body to slough off abnormal cervical cells, and promote lymphatic drainage. However, no research has been done to determine the actual mechanism.

PROCEDURE

Supplies

- Open-mouth 1 lb container with tight sealing lid
- Anhydrous magnesium sulfate (keep tightly closed)
- Glycerin
- *Hydrastis canadensis* tincture: 0.5 ounce
- *Thuja occidentalis* oil (not thuja in oil): 0.5 ounce
- *Melaleuca alternifolia* oil: 0.25 ounce
- Bitter orange oil: 0.25 ounce
- Vita Minerals 120 (iron sulfate solution): 1 ounce
- Cotton: 0.5 inches thick and 2 inches wide by 3 inches long
- Cotton string (surgical grade): 4 inches long (dental floss also works well).

The solution

The following steps must be carefully followed. Deviation results in either a runny, inconvenient liquid or a rock

1620

hard, unusable precipitate. Each step requires vigorous stirring before proceeding to the next!

1. Fill the container half full with anhydrous $MgSO_4$.
2. Add glycerin until soupy. Mix until the solution begins to cool.
3. Add oils.
4. Add *Hydrastis canadensis*.
5. Add VM120.
6. Stir occasionally over the next 2–3 hours until the solution cools. It should have a thick, tar-like consistency.
7. Store in a tightly sealed container in a cool, dry place. The solution will require stirring if not used regularly.

The tampon

The cotton is folded lengthwise and tied at one end to make a tampon 1 inch thick and 3

inches long, with approximately 3 inches of string hanging from the tied end.

Application

The best time for application is during normal times of uterine drainage, i.e. right before or after the menses and during ovulation. The procedure is as follows:

1. Fold 1 tablespoon of the formula into the untied end of the cotton tampon (some find it easier to put the solution into the cotton tampon before folding and tying it).
2. Expose the cervix with a vaginal speculum and open it wide enough to insert the tampon.
3. Slide the vag pack, formula end first, through the speculum until it fits tightly against the cervix. (A uterine forceps can be used to hold the pack and aid its insertion.)
4. Carefully remove the speculum while leaving the pack in place. Avoid touching the sides of the vagina as the fresh pack can cause some irritation. The uterine forceps is used to hold the pack in contact with the cervix as the speculum is removed. Ensure that the string is left exposed in the introitus.
5. Leave the pack in for 24 hours, at which time the woman can remove it by simply pulling on the string.
6. Have the woman douche after an additional 24 hours. A mild vinegar solution is recommended.
7. The procedure can be performed weekly until the desired results are obtained.

CLINICAL APPLICATIONS

Typically, the woman will notice an increase in drainage, both while the vag pack is in place and during the following 24–48 hours. If the woman experiences any burning or discomfort, the pack can be removed early, followed by douching.

Cervical dysplasia

When used in the treatment of abnormal cervical cells (see [Ch. 142](#)), inspection of the cervix within a few days of the application will reveal a red eroded appearance where the cells have sloughed off. This will typically heal within 7–10 days.

The number of applications needed varies with the woman and the condition: class II Paps typically clear after four to six applications and class III Paps after eight to 12 applications. The senior editor has successfully treated women with class IV Paps (with confirmed dysplasia), which required 1 year of biweekly vag packs in conjunction with the therapies listed in [Chapter 142](#). However, considering the high risk associated with class IV Paps and cervical dysplasia, the authors recommend conization in these cases.

During therapy, Paps should be repeated every 2 months to ensure adequate response (the cervix should be allowed to heal for at least 10 days after a vag pack to ensure an accurate Pap).

Pelvic inflammatory disease

When used as part of the therapy for pelvic inflammatory disease (PID), best results are obtained when used in conjunction with the alternating sitz bath (which also stimulates drainage; see [Ch. 42](#)) and immune stimulation (see [Ch. 53](#)). In this situation, women report much greater drainage, requiring the use of mini-pads. The therapy appears to help prevent the adhesions typical of PID.

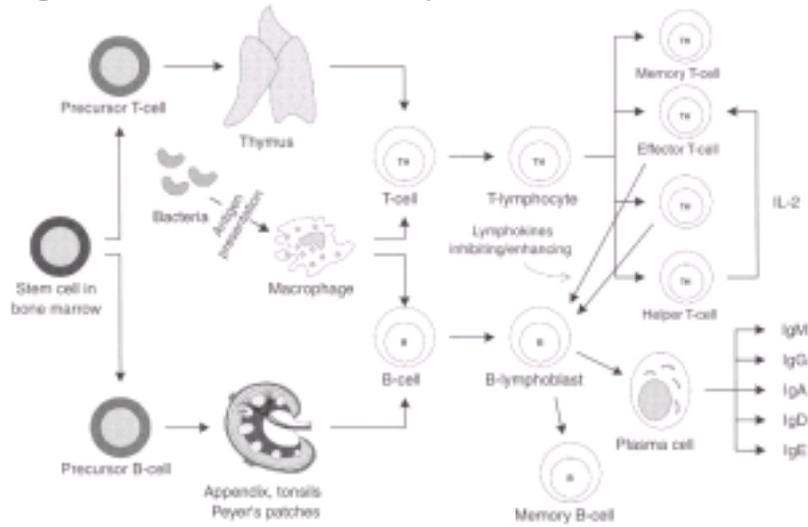

Figure 20-2 Lymphocyte gates set using LeucoGATE™. Lymphocyte gates for data acquisition were established using SimulSET™ software. Acquisition gates are defined by combining the fluorescence parameters from the LeucoGATE™ tube (A) with the forward- and right-angle light-scattering parameters (B). The light scatter gate (region 5, panel B) was set to include at least 95% of the lymphocytes. The cells of other lineages that also were included in this gate can be identified and enumerated by their characteristic immunofluorescence (C). Lymphocytes are confined to region 1, monocytes are found in region 2, while granulocyte and debris fall in regions 3 and 4, respectively. The analysis of subsequent tubes can be corrected by using the numbers of cells with each of the regions defined in (C), to obtain more precise values for enumeration of lymphocyte subsets.

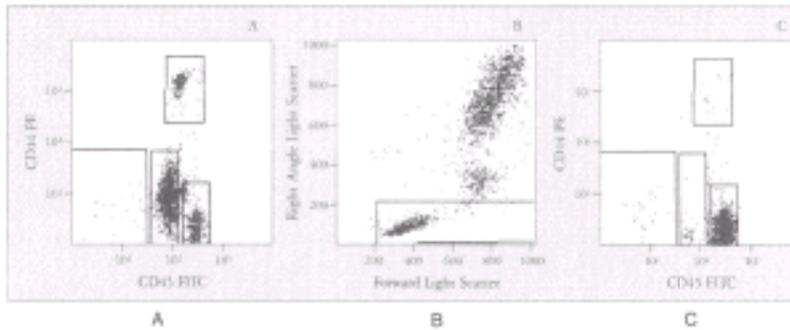

Figure 20-3 CD69 Expression vs. tritiated thymidine incorporation. Incorporation of ³H-thymidine was compared with CD69 expression as a measure of T-cell response to varying concentrations of a co-mitogenic pair of antibodies, CD2 and CD2R. Tritiated thymidine incorporation was measured after 3 days of stimulation of PBMCs in media plus autologous plasma; the percentage of CD69 expression was measured by flow cytometry after 4 hours of stimulation under identical conditions.

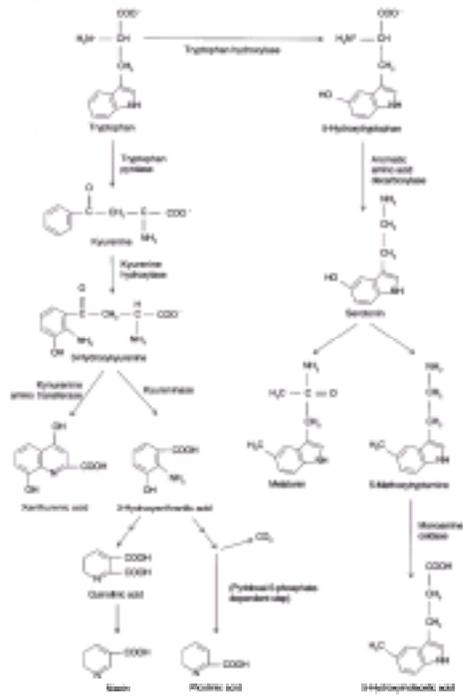

Figure 29-2 Methylmalonate is converted into succinic acid using a vitamin B₁₂-dependent enzyme, methylmalonyl CoA mutase.

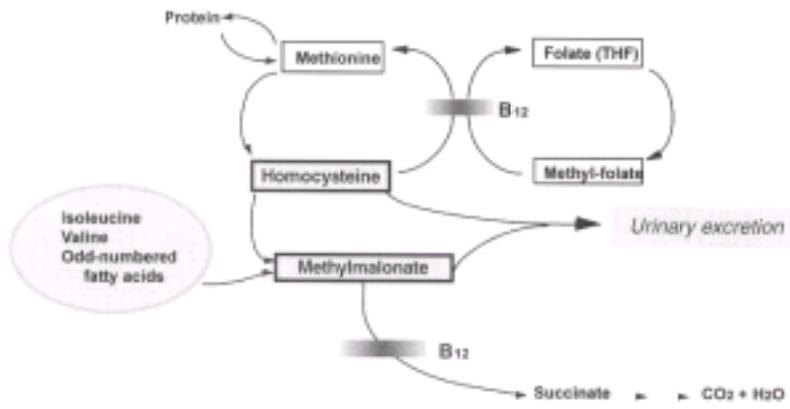

Figure 30-1 Toxic metal induction of porphyria and cell injury occurs as follows: (1) metals promote an increase in reactive prooxidants; (2) metals complex with glutathione compromising antioxidant and thiol status; (3) metals impair enzymes and other proteins via SH-complexation; (4) oxidant stress induced by metals causes cell injury and oxidation of porphyrinogens to porphyrins which are excreted in the urine (porphyria).^[7]

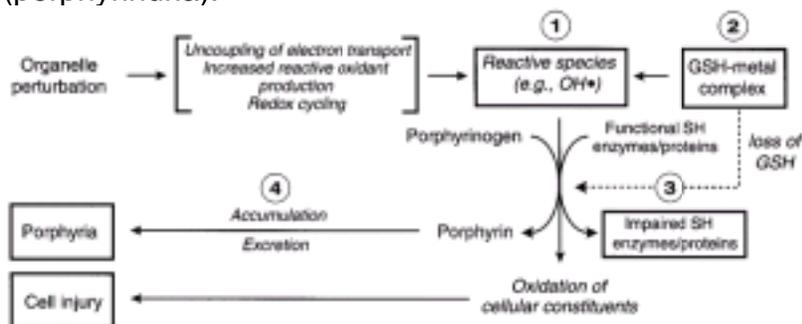

Figure 30-2 Biosynthesis of heme. The enzymes that drive the heme pathway are: (1) d-aminolevulinate (ALA) synthetase, (2) ALA dehydratase, (3) uroporphyrinogen I synthetase (PBG deaminase) and uroporphyrinogen III cosynthetase, two enzymes that work in concert, (4) uroporphyrinogen decarboxylase, (5) coproporphyrinogen oxidase, (6) protoporphyrinogen oxidase, and (7) ferrochelatase (heme synthetase). Spilled porphyrins derived from porphyrinogens with 8-, 7-, 6-, 5-, and 4-carboxyl groups are largely excreted in the urine, while the less polar 2-carboxyporphyrin (protoporphyrin) is excreted exclusively in the feces. The physiologically relevant pathway leading to heme is via uroporphyrinogen III in which the propionyl and acetyl groups are “reversed” compared with the type I pathway, which “dead ends” with coproporphyrinogen I. The physiological significance of the type I pathway remains unclear; however, coproporphyrin I is elevated in hepatobiliary diseases.

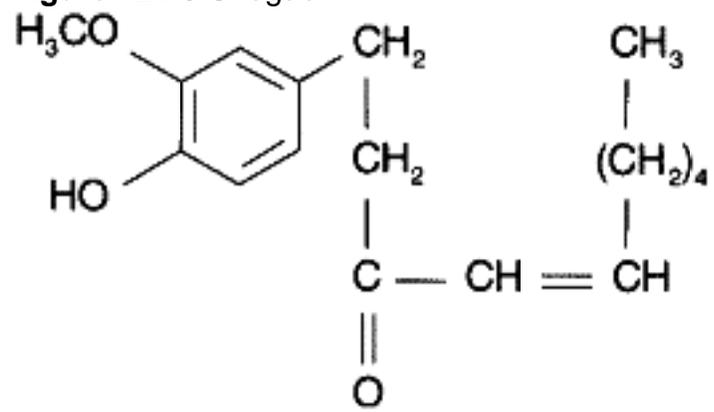

Figure 126-1 Relationship between folate cycle, SAM and transmethylation.

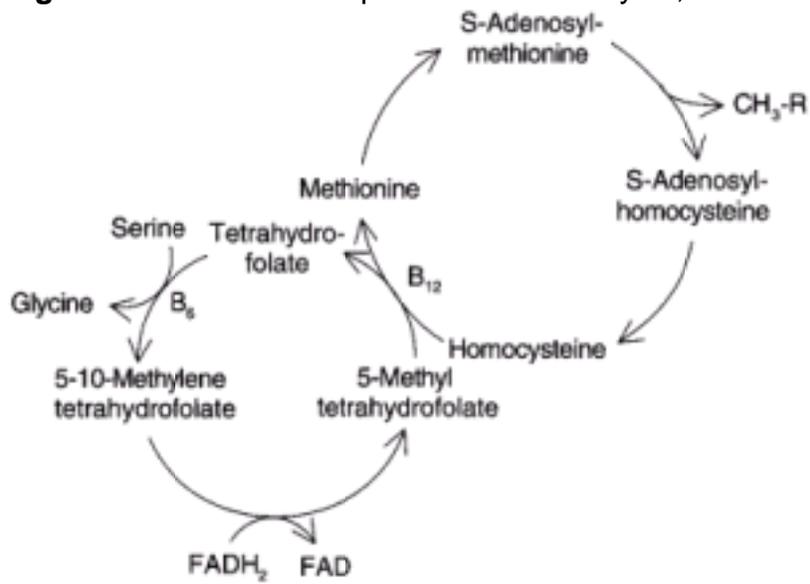

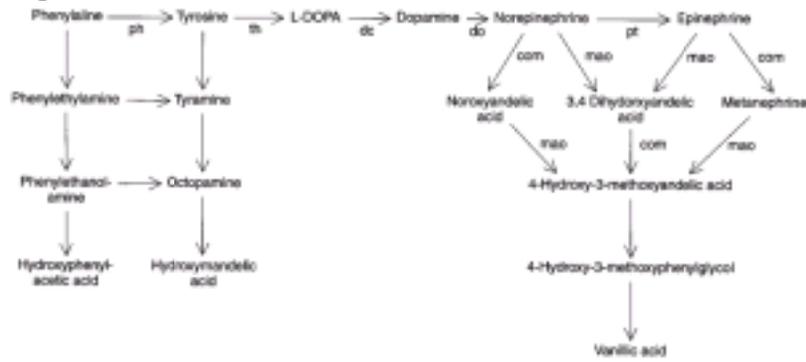

Figure 126-3 Catecholamine metabolism.

- com Catechol-O-methyl-transferase; SAM dependent
- dc Dopa decarboxylase (aaad); pyridoxal-5-phosphate dependent
- do Dopamine oxidase; O₂, ascorbate, copper and iron dependent; tryptamine and histamine inhibit
- mao Monoamine oxidase; many drugs and plant compounds are inhibitory
- ph Phenylalanine hydroxylase; O₂, dihydrobiopterin dependent
- pt Phenylethanol-amino N-methyltransferase; low activity in CNS; S-adenosyl-methionine (SAM) dependent; inhibited by tyramine, dopamine
- th Tryptophan hydroxylase; inhibited by tryptophan, phenylalanine, dopa and dopamine; tetrahydrobiopterin, O₂, Fe dependent, rate limiting enzyme for dopamine synthesis

Figure 132-1 Arachidonic acid metabolism.

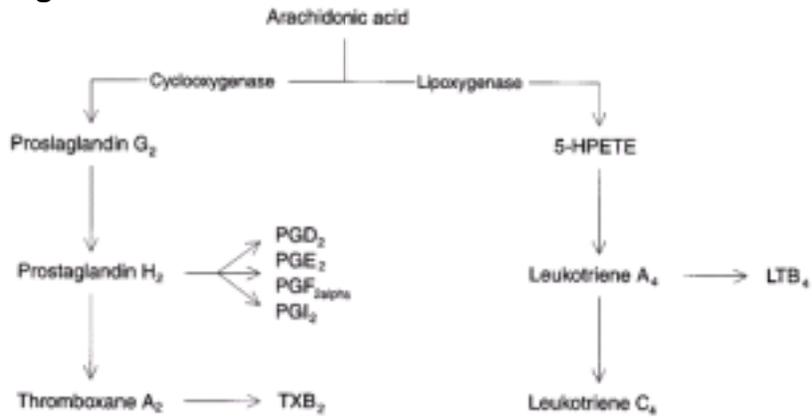

Figure 134-1 cGMP, cAMP, and histamine.

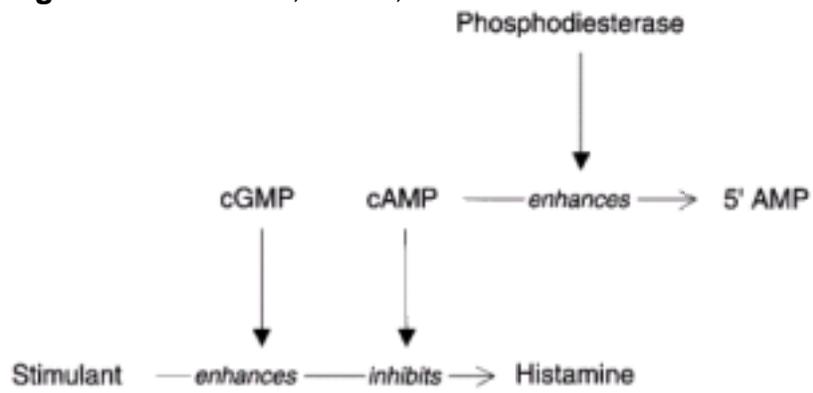

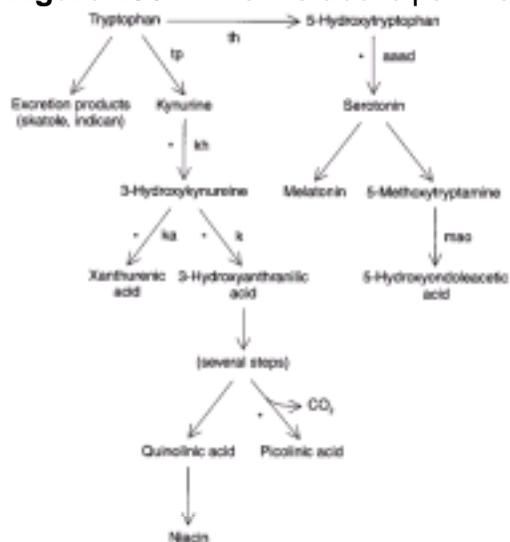

Figure 136-1 The metabolic pathways of tryptophan, serotonin, and their metabolites.

- * Pyridoxal-5-phosphate (PLP) dependent step
- aaad Aromatic amino acid decarboxylase, PLP dependent step; the rate for decarboxylation of 5-hydroxytryptophan is 16% of the rate of DOPA
- kh Kynurenine hydroxylase
- k Kynureninase, PLP dependent step
- ka Kynurenine aminotransferase, PLP dependent step
- mao Monoamine oxidase
- th Tryptophan hydroxylase, tetrahydrobiopterin dependent step
- tp Tryptophan pyrrolase (tryptase), inducible enzyme
