Coenzyme Q₁₀

Coenzyme Q₁₀ (CoQ₁₀) is a fat-soluble quinone occurring in the mitochondria of every cell (see [Ch. 76](#) for a full discussion). The primary biochemical action of CoQ₁₀ is as a cofactor in the electron transport chain, the biochemical pathway that generates adenosine triphosphate (ATP). Since most cellular functions are dependent on an adequate supply of ATP, CoQ₁₀ is essential for the health of virtually all human tissues and organs. CoQ₁₀ also functions as an antioxidant, assisting in the recycling of vitamin E. [\[26\]](#) [\[27\]](#)

Biosynthesis of CoQ₁₀ begins with the amino acid tyrosine. Pantothenic acid, P5P and vitamin C are all required for the initial steps in its synthesis. An isoprenyl side chain from farnesyl diphosphate, an intermediate in cholesterol synthesis between 3-hydroxy-3-methylglutaryl-CoA (HMG-CoA) and squalene, is then added. An inadequate supply of this intermediate, which can be caused by HMG-CoA reductase inhibitors (cholesterol-lowering drugs of the statin family) results in decreased levels of CoQ₁₀. [\[28\]](#)

In two of the final steps in the synthesis of CoQ₁₀, methyl groups are provided by SAM (see [Fig. 52.8](#)). Adequate dietary methionine and a sufficient supply of the nutrients required for the re-methylation of homocysteine to methionine (5-methylTHF, methylcobalamin, and betaine) are required to generate sufficient SAM. Suboptimal amounts of SAM may negatively impact on the ability of the body to synthesize sufficient CoQ₁₀. This relationship between SAM and CoQ₁₀ has been suggested in various animal studies. [\[29\]](#) [\[30\]](#)

Creatine

In humans, over 95% of the total creatine content is located in skeletal muscle, of which approximately one-third is in its free form as creatine, also known as methyl-guanidinoacetic acid, while the remainder is present in a phosphorylated form as creatine phosphate (also called phosphocreatine). Creatine phosphate is utilized within skeletal muscle as a means for storing high-energy phosphate bonds.

Creatine is formed in the liver, kidney and pancreas, beginning with the combination of arginine and glycine to produce guanidinoacetate. A methyl group from SAM is then transferred, resulting in the formation of creatine. The by-product of this reaction, S-adenosylhomocysteine, is subsequently hydrolyzed into homocysteine and adenosine. In order to optimize endogenous production of creatine, the amino acids arginine, glycine, and methionine must be available as substrates. Additionally, cofactors needed to optimize re-methylation of homocysteine to form methionine are required to recycle the homocysteine to methionine for reuse as SAM (see [Fig. 52.9](#)).

Serum creatine levels have been positively correlated with plasma homocysteine levels, i.e. as creatine levels rise, so do homocysteine levels.^[31]

Epinephrine and melatonin

Derivatives of the aromatic amino acids, L-tyrosine and L-tryptophan, require methylation for the biosynthesis of their down-line metabolites.

The biosynthesis of catecholamines begins with the amino acid L-tyrosine and proceeds through dopa and dopamine, resulting in the formation of norepinephrine, the neurotransmitter substance found in the majority of sympathetic nerve terminals, as well as in some synapses of the central nervous system. In the chromaffin cells of the adrenal medulla, a methyl group is provided by SAM, resulting in the formation of epinephrine from norepinephrine. A number of metabolites are formed from the degradation of both norepinephrine and epinephrine.

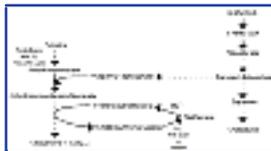

Figure 52-8 Synthesis of coenzyme Q₁₀ .

469

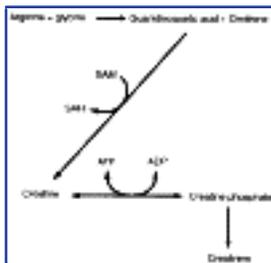

Figure 52-9 Synthesis of creatine, creatine phosphate and creatinine.

Catecholamine degradation proceeds independently, in addition to conjunction with monoamine oxidase, by catechol-O-methyltransferase. This enzyme catalyzes the transfer of a methyl group donated by SAM and, depending on the substrate, results in the formation of homovanillic acid, normetanephrine, and metanephrine.

The formation of melatonin from L-tryptophan proceeds through 5-hydroxytryptophan, serotonin, and N-acetylserotonin. Melatonin is then formed in the pineal gland by the donation of a methyl group. 5-Methoxytryptamine, an alternate metabolite of serotonin, also requires the addition of a methyl group.

Since elevated homocysteine results in suboptimal synthesis of SAM, some impact on

aromatic amino acid derivatives will occur. The exact nature of the impact on catecholamine metabolites is still unclear due to SAM's role in both synthesis and degradation. It appears likely that the biochemical stagnation associated with elevated levels of homocysteine would negatively impact the synthesis of melatonin.

Phosphatidylcholine

Phosphatidylcholine (PC) is a primary component of lecithin. It is the most frequently encountered phospholipid in animals and is structurally related to phosphatidylserine and phosphatidylethanolamine. PC consists of a glycerol backbone that is esterified with fatty acids on carbon atoms 1 and 2, and with a phosphoric acid/choline complex in position 3. Although phosphatidylcholine is usually referred to as if it were a single compound, it is actually a group of related compounds which vary depending upon the fatty acid composition at position C-1 and C-2.

Dietary choline is derived primarily from PC, which after absorption by the intestinal mucosa is metabolized to choline in the liver by the enzyme phospholipase D. Most choline is re-phosphorylated to PC; however, a small amount is carried to the brain via the bloodstream, where it is converted to the neurotransmitter acetylcholine. If PC or choline are lacking in the diet, they can be synthesized from phosphatidylserine and phosphatidylethanolamine (see [Fig. 52.4](#)). Synthesis of PC is dependent on the availability of SAM as a methyl donor, since synthesis involves the transfer of methyl groups from three SAM molecules to phosphatidylethanolamine in order to generate one molecule of PC.

The metabolic pathways of phosphatidylcholine, methionine, methylcobalamin and 5-methylTHF are interrelated, intersecting at the regeneration of methionine from homocysteine by betaine (see [Fig. 52.1](#)). The use of choline molecules as methyl donors in this process is probably the main factor that determines how rapidly a diet deficient in choline will induce pathological changes.^[18]

Taurine

Taurine is a unique amino acid because it carries a sulfonic acid group ($-\text{SO}_3\text{H}$) instead of a carboxyl group ($-\text{CO}_2\text{H}$). Taurine is biosynthesized from methionine or from cysteine via the trans-sulfuration pathway (see [Fig. 52.5](#)). As discussed previously, homocysteine can be re-methylated to form methionine; however, it can also be degraded to form cysteine. Once cysteine is generated, it can be directed into several different pathways including synthesis of glutathione, acetyl-CoA, 3'-phosphate 5'-phosphosulfate (PAPS), and taurine. Degradation involves a two-step process resulting in the formation of cystathionine and its subsequent cleavage to cysteine. Both of the enzymes involved require P5P as a cofactor, and the committed first step in the degradation of homocysteine, cystathionine synthase, also requires serine. In humans, defects in both of these enzymatic reactions occur. Homocysteinuria, resulting from an absence of cystathionine synthase, can lead to mental retardation. Low levels of this enzyme can also lead to abnormally high levels of homocysteine, especially when

remethylation cofactors are also deficient.

CLINICAL APPLICATIONS

Phase II detoxification

Because homocysteine is a critical intermediate in both methyl and sulfur group metabolism, elevated levels could indicate nutrient deficiencies which might compromise function in virtually all of the hepatic phase II detoxification reactions (see [Ch. 50](#)).

470

Amino acid conjugation reactions require either glycine, glutamine, or taurine. Glycine functions in the conjugation of aromatic acids (e.g. benzoic acid to hippuric acid). Elevated levels of homocysteine might indicate reduced nutritional levels of betaine and subsequently its down-line metabolite glycine. Taurine functions in acylations (e.g. bile conjugation). As discussed, optimal taurine synthesis requires proper movement of homocysteine into its degradation pathway. There are no known interactions between glutamine and homocysteine.

Sulfur conjugation requires *N*-acetylcysteine (NAC), glutathione (GSH), PAPS, or methionine/cysteine. NAC is used for mercapturic acid synthesis and is involved in detoxification of a wide variety of compounds including aromatic hydrocarbons, some phenols, halides, esters, epoxides, and caffeine. GSH is involved in dismutation reactions of organic nitrates (e.g. nitroglycerin). PAPS is utilized in sulfate ester synthesis, mostly with phenols, and some aliphatic alcohols (e.g. ethanol) and aromatic amines. Methionine and cysteine are used in cyanide-thiocyanate detoxification. A portion of the inorganic sulfur needed for the formation of all of these compounds passes through the homocysteine cycle.

Alkylation reactions require SAM, methylcobalamin, or 5-methylTHF. These compounds provide methyl groups to detoxify compounds containing OH, SH, or NH₂ groups. Examples of these reactions include norepinephrine to epinephrine, epinephrine to metanephrine, guanidoacetic acid to creatine, and *N*-acetylserotonin to melatonin.

Other phase II detoxification reactions which might be impacted by elevated homocysteine as a biological marker of reduced nutrient formation include acetylation by acetylcoenzyme A, which requires cysteine as a source of its cysteamine component; and the use of carnitine for the conversion of valproic acid to valproylcarnitine.

Heart disease

A significant component in the pathogenesis, prevention, and treatment of heart disease

involves the amino acid homocysteine. Increased blood levels of homocysteine are correlated with significantly increased risk of coronary artery disease (CAD),^{[32] [33] [34] [35]} myocardial infarction,^{[36] [37]} peripheral occlusive disease,^{[38] [39] [40] [41]} cerebral occlusive disease,^{[38] [41]} and retinal vascular occlusion.^[42]

It has been known for over 25 years that inborn errors of homocysteine metabolism result in high levels of homocysteine in the blood and severe atherosclerotic disease. We now know that, even within the range which is considered normal (4–16 $\mu\text{mol/L}$), there is a graded increase in risk for CAD. In a study of 304 patients with CAD vs. controls, the odds ratio for CAD increased as plasma homocysteine increased, even within the normal range. A 5 $\mu\text{mol/L}$ increase in plasma homocysteine was correlated with an increase in the odds ratio of 2.4 ($P < 0.001$), with no “threshold effect”.^[35]

A review of a number of studies found that mild hyperhomocysteinemia after a methionine load test occurs in 21%, 24%, and 32% of patients with CAD, cerebro-vascular disease, and peripheral vascular disease, respectively.^[43] Another group of researchers found the incidence of hyperhomocysteinemia ($>14 \mu\text{mol/L}$ by their definition) in a group of 1,160 elderly (ages 67–96) individuals, in the Framingham Heart Study, to be 29.3%. The study also indicated that plasma homocysteine levels increase with age.^[38]

Homocysteine facilitates the generation of hydrogen peroxide.^[44] By creating oxidative damage to LDL cholesterol and endothelial cell membranes, hydrogen peroxide can then catalyze injury to vascular endothelium.^{[44] [46]}

Nitric oxide and other oxides of nitrogen released by endothelial cells (also known as endothelium-derived relaxing factor, or EDRF) protect endothelial cells from damage by reacting with homocysteine, forming S-nitrosomethionine, which inhibits hydrogen peroxide formation. However, as homocysteine levels increase, this protective mechanism can become overloaded, allowing damage to endothelial cells to occur.^{[45] [46]} Because of the role of sulfate compounds in the formation of amino sugars needed to form the basement membrane of blood vessels, high levels of homocysteine are likely to contribute to the formation of blood vessels which are more susceptible to oxidative stress.^[47] The end result of the combination of oxidative damage and endothelial collagen instability can be the formation of atherosclerotic plaques.

Decreased plasma folate levels are correlated with increased levels of homocysteine, and a subsequent increased incidence of CAD. In a 15 year Canadian study of CAD mortality in 5,056 men and women aged 35–79 years, lower serum folate levels were correlated with a significantly increased risk of fatal CAD.^[48] In a cohort from the Framingham Heart Study, concentrations of folate and P5P were inversely correlated with homocysteine levels and the risk of extracranial carotid-artery stenosis.^[38] Low P5P and low vitamin B₁₂ have also been linked with hyperhomocysteinemia and a significantly increased risk of CAD.^[35]

Re-methylation of homocysteine and the subsequent formation of SAM is critical for biosynthesis of L-carnitine, CoQ₁₀, and creatine. Similarly, the trans-sulfuration pathway must be functioning properly for optimal biosynthesis of cysteine, GSH, pantethine, and

taurine. All of these nutrients are used clinically to reduce oxidative stress, improve risk factor markers, or treat heart disease.

Peripheral vascular disease

Elevated homocysteine levels have been established as an independent risk factor for intermittent claudication

471

(IC) and deep vein thrombosis. Elevated homocysteine levels corresponded with an increased incidence of intermittent claudication and decreased serum folate levels in a study of 78 patients with IC.^[49] A fourfold increase in risk of peripheral vascular disease was noted in individuals with hyperhomocysteinemia compared with those with normal homocysteine levels.^[50] A group of researchers in the Netherlands found high homocysteine levels to be a significant risk factor for deep-vein thrombosis, with a stronger relationship among women than men.^[51]

An increased risk of peripheral vascular occlusion has been noted in women taking oral contraceptives, which might be linked to the significantly increased homocysteine levels in women so affected. It is already known that oral contraceptives can cause declines or deficiencies in vitamins B₆, B₁₂, and folate, nutrients integral to the processing of homocysteine. Laboratory assessment of plasma homocysteine levels may be helpful to detect women who may be predisposed to peripheral vascular occlusion while on oral contraceptives.^[52]

Stroke

Stroke patients have significantly elevated homocysteine levels compared with age-matched controls,^[53] with a linear relationship between risk of stroke and homocysteine levels,^[54] and a significant decrease in blood folate concentrations in those with elevated homocysteine.^[55]

Pregnancy

Biochemical enzyme defects and nutritional deficiencies are receiving increasing attention for their role in causing neural tube defects (NTD) as well as other negative pregnancy outcomes, including spontaneous abortion, placental abruption (infarct), pre-term delivery, and low infant birth weight. Recent evidence has suggested that derangement of methionine-homocysteine metabolism could be the underlying mechanism of pathogenesis of neural tube defects and might be the mechanism of prevention observed with supplementation of folic acid.^[56] ^[57] It has been firmly established that a low dietary intake of folic acid increases the risk for delivery of a child with a NTD, and that periconceptional folic acid supplementation reduces the occurrence of NTD.^[58] ^[59] ^[60] ^[61] ^[62] ^[63] ^[64] Research also indicates that supplemental folic

acid intake results in increased infant birth weight and improved Apgar scores, along with a concomitant decreased incidence of fetal growth retardation and maternal infections.^{[65] [66] [67] [68]} A derangement in methionine-homocysteine metabolism has also been correlated with recurrent miscarriage and placental infarcts (abruption).^[69]

The amino acid homocysteine, when elevated, might be a teratogenic agent contributing to congenital defects of the heart and neural tube. Evidence from experimental animals lends support to this belief. When avian embryos were fed homocysteine to raise serum homocysteine to over 150 nmol/ml, dysmorphogenesis of the heart and neural tube, as well as of the ventral wall, was observed.^[70]

Because homocysteine metabolism, through the re-methylation and trans-sulfuration pathways, affects several biochemical pathways involving the production of nutrients which are essential to the optimal functioning of the cardiovascular, skeletal, and nervous systems, it is not surprising that these other nutrients have been linked to complications of pregnancy in animal models and humans. Low plasma vitamin B₁₂ levels have been shown to be an independent risk factor for NTD.^{[71] [72]} Methionine has been shown to reduce the incidence of NTD by 41% in an animal model when administered on days 8 and 9 of pregnancy.^{[73] [74]} This evidence indicates that a disturbance in the remethylation pathway with a subsequent decrease in SAM may be a contributing factor to these complications of pregnancy.

Phosphatidylcholine, due to its role as a precursor to acetylcholine and choline, is acknowledged as a critical nutrient for brain and nerve development and function.^{[75] [76] [77]} Since the metabolic pathways of choline (via betaine), methionine, methylcobalamin and 5-methylTHF are interrelated, intersecting at the regeneration of methionine from homocysteine, a disturbance in the metabolism of either of these two methyl-donor pathways, due to limited availability of key nutrients or decreased enzyme activity, will have a direct impact on the body's ability to optimize levels of SAM.

Evidence suggests that women with a history of NTD-affected pregnancies have altered folic acid metabolism.^{[78] [79] [80] [81]} Patients with a severe congenital deficiency of the enzyme MTHFR, which is needed for the formation of 5-methylTHF, have reduced levels of both methionine and adenosylmethionine in the cerebrospinal fluid and show demyelination in the brain and degeneration of the spinal cord.^{[2] [82]} Because of its direct impact in the activation of folic acid to its methyl derivative, a milder version of this enzyme defect is also strongly suspected to increase the incidence of NTD.^[83]

It is established that high vitamin A intake during the first 2 months of pregnancy is associated with a several-fold higher incidence of birth defects.^{[84] [85]} Although the mechanism of action remains to be elicited, in an animal model the activity of hepatic MTHFR is suppressed with high vitamin A levels, suggesting that its teratogenic effect during early pregnancy may be associated with a subsequent derangement in the remethylation of homocysteine.^[86]

Since a more significant correlation has been found between high homocysteine levels in women experiencing placental abruption, infarction, and spontaneous abortion than in control women, and since homocysteine and CoQ₁₀ synthesis are both dependent upon

the

methionine-SAM-homocysteine pathway, it is possible that low CoQ₁₀ and elevated homocysteine independently found in complicated pregnancy may also in fact be found to be related conditions.^{[87] [88]}

Nutritional intervention with the cofactors required for optimal metabolism of the methionine-homocysteine pathways offers a new integrated possibility for primary prevention of NTD and several other complications of pregnancy. Supplementation with betaine, and the active forms of cobalamin and folic acid, such as methylcobalamin and folinic acid, along with riboflavin-5'-phosphate (because of its role as a cofactor for the MTHFR enzyme), may play a significant role in reducing or preventing these emotionally devastating outcomes.

Neurological and mental disorders

In addition to the known impact of homocysteine on the cardiovascular system and micronutrient biochemical pathways, numerous diseases of the nervous system are correlated with high homocysteine levels and alterations in B₁₂, folate, or B₆ metabolism, including depression, schizophrenia, multiple sclerosis, Parkinson's disease, Alzheimer's disease, and cognitive decline in the elderly.

Methylation reactions via SAM, including methylation of DNA and myelin, are vitally important in the CNS. The neurologic complications of vitamin B₁₂ deficiency are thought to be due to a reduction of activity of the B₁₂-dependent enzyme methionine synthase, and the subsequent reduction of SAM production. The CNS lacks the alternate betaine pathway of homocysteine remethylation; therefore, if methionine synthase is inactivated, the CNS has a greatly reduced methylation capacity.^[89] Other causes of reduced methionine synthase activity include folic acid deficiency and nitrous oxide anesthesia exposure.^[90]

Homocysteine has also been found to be a neurotoxin, especially in conditions in which glycine levels are elevated, including head trauma, stroke, and B₁₂ deficiency.^[91] Homocysteine interacts with the *N*-methyl-D-aspartate receptor, causing excessive calcium influx and free radical production, resulting in neurotoxicity.^[91] The neurotoxic effects of homocysteine and/or reduced methylation reactions in the CNS contribute to the mental symptomatology seen in B₁₂ and folate deficiency. Increased homocysteine levels can also be seen in schizophrenics.^[92]

Significant deficiencies in B₁₂ and folate are common in the elderly population, and can contribute to a decline in cognitive function.^{[93] [94] [95]} An investigation of cognitive ability in older men (aged 54–81) found poorer spatial copying skills in those individuals with

higher homocysteine levels. Better memory performance was correlated with higher vitamin B₆ levels.^[96]

B₁₂ deficiency and increasing severity of cognitive impairment have been seen in Alzheimer's disease (AD) patients compared with controls and patients with other dementias.^[97] In a study of 52 AD patients, 50 hospitalized non-demented controls, and 49 elderly subjects living at home, patients with AD were found to have the highest homocysteine levels and the highest methylmalonic acid (an indicator of B₁₂ deficiency) levels.^[98] In a study of 741 psychogeriatric patients, high plasma homocysteine levels were found in demented and non-demented patients; however, only demented patients also had lower blood folate concentrations compared with controls. Patients with concomitant vascular disease had significantly higher plasma homocysteine than those without diagnosed vascular disease. Significantly higher homocysteine levels, compared with controls, have also been found in Parkinson's patients.^[99]

Homocysteine's effects on neurotransmitter metabolism, along with its potential reduction of methylation reactions, could be a contributing factor to the etiology of depression. Folate and B₁₂ deficiency can cause neuropsychiatric symptoms including dementia and depression. Although no studies have been performed to date investigating depression, folate and B₁₂ deficiency and homocysteine levels, with what is known about these deficiencies and methionine synthase inhibition, it is suggestive that this connection will be revealed in the future. We do know that SAM is used therapeutically as an antidepressant in Europe and is the third most popular antidepressant treatment in Italy in 1995.^[100] ^[101] As yet, SAM is not available as a supplement in the US.

Methylation of myelin basic protein is vital to the maintenance of the myelin sheath. The worst-case scenario of folate and B₁₂ deficiency includes demyelination of the posterior and lateral columns of the spinal cord, a disease process called subacute combined degeneration of the spinal cord (SCD).^[89] SCD can also be precipitated by nitrous oxide anesthesia, which causes an irreversible oxidation of the cobalt moiety of the B₁₂ molecule and the subsequent inhibition of methionine synthase activity, a decrease in homocysteine remethylation, and decreased SAM production.^[90] This has been treated using supplemental methionine, which further supports the theory of a nitrous oxide-induced biochemical block at methionine synthase.^[102] Particularly at risk for this condition are B₁₂-deficient individuals who then visit their dentist and receive nitrous oxide.^[90] ^[103]

Abnormal methylcobalamin metabolism is one of the proposed mechanisms for the pathophysiology of the demyelinating disease multiple sclerosis. Deficiency of vitamin B₁₂ has been linked to some cases of multiple sclerosis, and it is suggested that dietary deficiency, or more likely, a defect in R-protein-mediated absorption or methylation of B₁₂, might be a significant contributor to the pathogenesis of MS.^[104]

Diabetes mellitus

Homocysteine levels appear to be lower in individuals with type 1 diabetes mellitus. Forty-one type 1 diabetic subjects (age 34.8 ± 12 years, duration of illness: 10.7 ± 11.1 years) were compared with 40 age-matched control subjects (age 34.2 ± 9.1 years). Following an overnight fast, homocysteine was significantly ($P = 0.0001$) lower in the diabetic group (6.8 ± 2.2) than in the controls (9.5 ± 2.9). This difference was apparent in male and female subgroups.^[105] However, increased levels of homocysteine have been reported in type 1 diabetics with proliferative retinopathy^[106] and nephropathy.^[107]

Evidence to date suggests that metabolism of homocysteine is impaired in patients with non-insulin-dependent diabetes mellitus (NIDDM). Following a methionine load, hyperhomocysteinemia occurred with significantly greater frequency in patients with NIDDM (39%) as compared with age-matched controls (7%). The area under the curve over 24 hours, reflecting the total period of exposure to increased homocysteine, was also elevated with greater frequency in patients with NIDDM and macrovascular disease (33%) as compared with controls (0%). The authors concluded that hyperhomocysteinemia is associated with macrovascular disease in a significant proportion of patients with NIDDM.^[108] Other researchers have reported a correlation between increased homocysteine levels and the occurrence of macroangiopathy in patients with NIDDM. Intramuscular injection of 1,000 μg methylcobalamin daily for 3 weeks reduced the elevated plasma levels of homocysteine in these individuals.^[109]

Elevated homocysteine levels appear to be a risk factor for diabetic retinopathy in individuals with NIDDM. This might be due to a point mutation on the gene for the enzyme MTHFR.^[110] ^[111] A significantly higher percentage of diabetics with retinopathy exhibit this mutation.^[112] Elevated homocysteine levels cause cell injury to the small vessels, which may contribute to the development of retinopathy as well as macroangiopathy in the cardiovascular system.^[110]

Rheumatoid arthritis

Elevated total homocysteine levels have been reported in patients with rheumatoid arthritis. Twenty-eight patients with rheumatoid arthritis and 20 healthy age-matched control subjects were assessed for homocysteine levels, while fasting and in response to a methionine challenge. Fasting levels were 33% higher in rheumatoid arthritis patients than in controls. Four hours following the methionine challenge, the increase in plasma homocysteine concentration was also higher in patients with rheumatoid arthritis.^[112] Another study found statistically significant increases in homocysteine in RA patients ($P = 0.003$), with 20% of the patients having homocysteine levels above the reference range.^[113] A mechanism for this increased homocysteine in RA patients has not been elucidated. Penicillamine, a common sulfhydryl-containing arthritis treatment, has been found to lower elevated homocysteine levels in vivo.^[114] Further investigation

into both the prevalence of hyperhomocysteinemia and the mechanism of action impacting rheumatoid arthritis is needed.

Kidney failure

Because homocysteine is cleared by the kidneys, chronic renal failure, as well as absolute or relative deficiencies of 5-methylTHF, methylcobalamin, P5P, or betaine, results in increased homocysteine levels. In 176 patients with end-stage renal disease on peritoneal or hemodialysis, homocysteine concentrations averaged $26.6 \pm 1.5 \mu\text{mol/L}$ in patients with renal failure as compared with $10.1 \pm 1.7 \mu\text{mol/L}$ in normals. Abnormal values exceeded the 95th percentile for normal controls in 149 of the patients with renal failure.^[115] Data also indicate that plasma homocysteine values represent an independent risk factor for vascular events in patients on peritoneal and hemodialysis. Patients with a homocysteine concentration in the upper two quintiles ($> 27.8 \mu\text{mol/L}$) had an independent odds ratio of 2.9 (CI, 1.4–5.8; $P = .007$) of vascular complications. Vitamin B levels were also lower in patients with vascular complications than in those without.^[116]

Alcoholism and ethanol ingestion

Chronic alcoholism is known to interfere with one-carbon metabolism. Because of this, it is not surprising to find that mean serum homocysteine levels are two times higher in chronic alcoholics than in non-drinkers ($P < 0.001$). Beer consumers have lower concentrations of homocysteine compared with drinkers of wine or spirits ($P = 0.05$). In chronic alcoholics, serum P5P and red blood cell folate concentrations have been shown to be significantly lower than in control subjects.^[110] Plasma homocysteine is significantly higher, compared with controls, in 42 active alcoholics hospitalized for detoxication. In another group of 16 alcoholics, abstaining from ethanol ingestion, plasma homocysteine did not deviate from that of controls.^[111]

Feeding ethanol to rats produces prompt inhibition of methionine synthase as well as a subsequent increase in activity of betaine homocysteine methyltransferase. Despite the inhibition of methionine synthase, the enhanced betaine homocysteine methyltransferase pathway utilizes hepatic betaine pools to maintain levels of SAM.^[117] Results indicate that ethanol feeding produces a significant loss in SAM in the first week, with a return to normal SAM levels in the second week. Betaine

feeding enhances hepatic betaine pools in control as well as ethanol-fed animals; attenuates the early loss of SAM in ethanol-fed animals; produces an early increase in betaine homocysteine methyltransferase activity; and generates increased levels of SAM in both control and ethanol-fed groups.^[118] It has been shown that minimal supplemental dietary betaine at the 0.5% level increases SAM twofold in control animals and fivefold in ethanol-fed rats. Concomitant with the betaine-generated SAM, ethanol-induced hepatic fatty infiltration was ameliorated.^[117] Betaine supplementation

also reduces the accumulation of hepatic triglyceride produced after ethanol ingestion.^[118]

Gout

Although homocysteine levels have been positively correlated with increased uric acid levels,^{[2] [119] [120]} no studies exist to date which have investigated homocysteine levels in gout patients. It is possible the increased uric acid levels in gout are due to decreased SAM production because of the reduction in homocysteine recycling. The excess adenosine, which would have reacted with methionine to form SAM, is degraded to form uric acid as its end product.

Niacin is contraindicated in gout, as it competes with uric acid for excretion.^[121] Animal studies have shown that increased levels of S-adenosylhomocysteine (SAH), and thus homocysteine, cause significant reductions in SAM-dependent methylation reactions.^[12] Therefore, since degradation of the niacin-containing coenzyme nicotinamide adenine dinucleotide (NAD) is dependent on methylation by SAM, and SAM activity is severely reduced in hyperhomocysteinemia, niacin levels might be higher in these people, resulting in less uric acid excretion, higher uric acid levels and increased gout symptoms in susceptible individuals. This possibility and its mechanism need further investigation.

Osteoporosis

Homocystinuria due to cystathionine synthase deficiency is an autosomal recessive error of sulfur amino acid metabolism characterized clinically by lens dislocation, mental retardation, skeletal abnormalities and thromboembolic phenomena.^[122] Individuals with this enzyme deficiency have decreased concentrations of cysteine and its disulfide form, cystine. In children with homocystinuria, osteoporosis is a common presenting symptom.^[123] Because of the role of sulfur compounds in the formation of sulfated amino sugars, disturbed cross-linking of collagen has been proposed as a possible mechanism of action. One group of researchers studying 10 patients with homocystinuria found normal synthesis of collagen, but a significant reduction of cross-links.^[124]

Because of the correlation between homocystinuria and osteoporosis in children with this amino acidopathy, and because of the increase in homocysteine concentrations in postmenopausal women, several authors have implied that elevated homocysteine levels contribute to postmenopausal osteoporosis. To date, no evidence is available which demonstrates that homocysteine levels are higher in postmenopausal women with osteoporosis than in age-matched controls.

DIAGNOSTIC CONSIDERATIONS

Many of the studies cited herein have used a reference range, with 12–16 $\mu\text{mol/L}$ being the upper limit of the normal range. We will probably see this level drop, as we did with cholesterol testing, as researchers have found a highly significant increase in relative risk of atherosclerotic cardiovascular disease and other disease processes as homocysteine levels increase, even within the “normal” range. A number of clinical

laboratories currently perform plasma homocysteine determinations, by itself or within a cardiovascular panel.

THERAPEUTIC CONSIDERATIONS

If a dietary deficiency or an increased demand, resulting from genetic biochemical individuality exists for 5-methylTHF, methylcobalamin, P5P, or betaine, treatment with these micro-nutrients should reduce homocysteine levels. Several studies utilizing folic acid, B₆, B₁₂, and betaine, either alone or in combination, have demonstrated the ability of these nutrients to normalize homocysteine levels.^{[21] [39] [41] [125] [126]} In a recent placebo-controlled clinical study of 100 men with hyperhomocysteinemia, oral therapy with 650 mcg folic acid, 400 mcg vitamin B₁₂, 10 mg vitamin B₆, or a combination of the three nutrients was given daily for 6 weeks. Plasma homocysteine was reduced 41.7% ($P < 0.001$) during folate therapy and 14.8% ($P < 0.01$) during B₁₂ therapy, while 10 mg B₆ did not reduce plasma homocysteine significantly. The combination worked synergistically to reduce homocysteine levels by 49.8%.^[127] In 68 patients with recent myocardial infarction, 18% had increased plasma homocysteine. Oral folate therapy (2.5 mg) reduced this hyperhomocysteinemia in 94% of treated patients (mean decrease 27%).^[36]

In a group of 48 patients with peripheral atherosclerotic vascular disease, 50% had abnormally high fasting plasma homocysteine levels, while 100% had abnormal plasma homocysteine after a methionine load. Treatment with 5 mg folic acid and 250 mg pyridoxine for 12 weeks normalized 95% of the fasting levels and 100% of post-load homocysteine levels.^[39] Other studies confirm that oral folate supplementation will almost always lower high homocysteine, while B₆ and B₁₂ will

lower homocysteine only in those with a genetic metabolic defect and/or dietary deficiency in those nutrients.^{[125] [128]}

A deficiency of the P5P dependent enzyme cystathione synthase is the most common genetic abnormality affecting the trans-sulfuration pathway of homocysteine breakdown. Fortunately, B₆ supplementation stimulates this enzyme and, in combination with betaine, corrects the hyperhomocysteinemia in these individuals.^{[21] [125]}

Therapeutic approach

Supplements

- Folinic acid: 800 mcg t.i.d.
- Methylcobalamin: 800 mcg t.i.d.
- Pyridoxal 5'-phosphate: 20 mg t.i.d.

- Betaine (trimethylglycine): 1,200 mg t.i.d.
- N-acetylcysteine: 500 mg t.i.d.

Chapter 53 - Immune support

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

INTRODUCTION

The immune system is a complex integration of synergistic segments that are continuously barraged by stimuli. Immunology is a rapidly developing field with concepts being continually devised and revised. For the physician interested in assessing and maintaining a patient's health, the development of a thorough understanding of the immune system and the many factors which enhance and/or inhibit normal function is essential. The immune system is truly "wholistic", as evidenced by the close association of psychological, neurological, nutritional, environmental, and endocrinologic factors with immune function.

Supporting the immune system is critical to good health. Conversely, good health is critical to supporting the immune system. The best approach to supporting immune function is a comprehensive plan involving lifestyle, stress management, exercise, diet, nutritional supplementation, glandular therapy, and the use of plant-based medicines.

PSYCHONEUROIMMUNOLOGY

Psychoneuroimmunology is a term used to describe the interactions between the emotional state, nervous system function, and the immune system. The growing body of knowledge documenting the mind's profound influence on physiology in health and disease necessitates a fundamental change in the way physicians perceive their patients. An important step is the study of nervous system response to environmental or intra-psychic perceptions that activate endocrine processes which, in turn, influence the immune system.

A complete and detailed account of the many facets of psychoneuroimmunology (PNI), or behavioral immunology, is beyond the scope of this chapter. Instead, we will

concentrate on the effects of stress and neurotransmitters on the immune response.

Stress

The term stress-induced illness is certainly not a misnomer, since many clinical and experimental studies have clearly demonstrated that stress, personality, attitude, and emotion are etiologic or contributory in many diseases.^[4] Reaction to stressful stimuli is entirely individual, reinforcing the fact that people differ significantly in their perceptions and responses to various life events. The variations in response help to account for the wide diversity of stress-induced illnesses. Stress-induced increases in corticosteroids and catecholamines lead to an immunosuppressed state, leaving the host susceptible to infectious and carcinogenic illnesses. This immunosuppression is proportional to the level of stress and, although the effects are numerous, they appear to involve a common mechanism: an increase in intracellular cyclic AMP. Other mechanisms are also significant, with thymic involution and suppressed lymphopoiesis being perhaps the most important.

Cyclic nucleotides and immune function

In many systems of the body, cholinergic and beta-adrenergic stimulation mediate diametrically opposed actions. On the cellular level, this antagonism is mediated via cyclic AMP and cyclic GMP. Beta-adrenergic stimulation of responsive target tissues causes a rise in intracellular cAMP, whereas acetylcholine acting on muscarine receptors leads to increased levels of cGMP. The immune system is also affected by this yin–yang balance, although it appears to be much more complex than in other systems.

Cyclic AMP and GMP have shown antagonistic effects in all immune functions studied to date. The immune effects of cGMP include: ^[2] ^[3] ^[4] ^[5] ^[6] ^[7]

- enhanced lymphocyte mediated cytotoxicity
- stimulation of T-cell rosette formation (a measure of thymus-derived lymphocyte activity) with inhibition of B-cell rosette formation
- enhanced lymphoid cell and lymphocyte proliferation
- increased lymphocyte lysosomal enzyme release
- increased leukocyte chemotaxis.

From this information, it is apparent that cGMP usually serves to enhance immune function during infection and carcinogenesis. In contrast, cAMP appears to inhibit white cell proliferation and functional response, thus possibly serving to modulate the immune system.

While there are many conditions where enhancing cGMP activity and inhibiting cAMP activity is contraindicated (e.g. autoimmune disease, atopy, gout, and psoriasis), in

acute or chronic infection the cGMP:cAMP ratio should be enhanced. Although many exogenous

TABLE 53-1 -- Lifestyle practices associated with higher natural killer cell activity

-
- Not smoking
-
- Increased intake of green vegetables
-
- Regular meals
-
- Proper body weight
-
- More than 7 hours of sleep
-
- Regular exercise
-
- A vegetarian diet

compounds alter the cGMP:cAMP ratio, paramount in any treatment plan is adequate rest and elimination of stressful activity. This promotes an increase in cholinergic activity while concurrently lowering beta-adrenergic activity. In addition, other cAMP promoting factors should be eliminated (e.g. caffeine and its analogs) while increasing cGMP stimulators (e.g. ascorbic acid).^[6] ^[7]

LIFESTYLE

A healthy lifestyle goes a long way in establishing a healthy immune system. This benefit is perhaps most obvious when looking at the effects of lifestyle on natural killer cell activity.^[8] ^[9] [Table 53.1](#) lists the lifestyle practices which are associated with higher natural killer cell activity.

NUTRITIONAL FACTORS

The health of the immune system gland is greatly impacted by a person's nutritional status. Dietary factors which depress immune function include nutrient deficiency, excess consumption of sugar, consumption of allergic foods and high cholesterol levels in the blood. Dietary factors which enhance immune function include all essential nutrients, antioxidants, carotenes, and flavonoids.

Consistent with good health, optimal immune function requires a healthy diet that:

- is rich in whole, natural foods, such as fruits, vegetables, grains, beans, seeds, and nuts
- is low in fats and refined sugars
- contains adequate, but not excessive, amounts of protein.

On top of this, individuals are encouraged to drink five or six 8-ounce glasses of water per day (preferably pure). These dietary recommendations along with a positive mental attitude, a good high potency multivitamin-mineral supplement, a regular exercise

program, daily deep breathing and relaxation exercises (meditation, prayer, etc.), and at least 7 hours of sleep daily will go a long way in helping the immune system function at an optimum level.

Nutrient deficiency

Nutrient deficiency is the most frequent cause of a depressed immune system. Although, historically, research relating nutritional status to immune function has concerned itself with severe malnutrition states (i.e. kwashiorkor and marasma), attention is now shifting towards marginal deficiencies of single or multiple nutrients and the effects of overnutrition. The plethora of clinical and experimental data has made inevitable the conclusion that a single nutrient deficiency can profoundly impair the immune system.

Given the widespread problem of subclinical nutrient deficiency in Americans, it can be concluded that many are suffering from impaired immunity amenable to nutritional supplementation. This statement is particularly true in the elderly. Numerous studies have shown that most elderly Americans are deficient in at least one nutrient. Likewise, there are numerous studies which show that taking a multiple vitamin and mineral supplement enhances immune function in elderly subjects (whether they suffer from overt nutritional deficiency or not).

General factors

Protein

The importance of adequate protein intake to proper immune function has been extensively studied.^[10] The most severe effects of protein-calorie malnutrition (PCM) are on cell-mediated immunity, although all facets of immune function are ultimately affected. PCM is not, however, usually a single nutrient deficiency. It is normally associated with multiple nutrient deficiencies, and some immune dysfunctions attributed to PCM are most likely due to these other factors. Partial deficiencies of dietary vitamins produce a comparatively greater depression in the natural and inducible levels of cytotoxic activities than do partial protein deficiencies. Nonetheless, adequate protein is essential for optimal immune function.

Sugar

The oral administration of 100 g portions of carbohydrate as glucose, fructose, sucrose, honey, and orange juice all significantly reduces neutrophil phagocytosis, while starch has no effect. As can be seen in [Figure 53.1](#), effects start within less than 30 minutes, last for over 5 hours, and typically show a 50% reduction in phagocytic activity at the peak of inhibition (usually 2 hours after ingestion).^{[11] [12]} Since PMNs constitute 60–70%

of the total WBC and are a major portion of the defense mechanism, impairment of phagocytic activity leads to an immune-compromised state. Oral administration of increasing

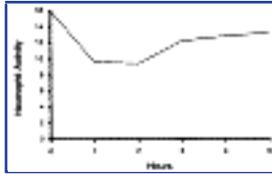

Figure 53-1 The effects of sugar on white cell phagocytic activity.

amounts of glucose progressively lowers neutrophil phagocytosis, with maximal inhibition corresponding to maximal blood glucose levels.

Oral ingestion of 75 g of glucose has also been shown to depress lymphocyte response to mitogens, apparently due to the elevation of insulin levels.^[13] Other parameters of immune function are also undoubtedly affected by sugar consumption.

It has been hypothesized that the ill effects of high glucose levels are a result of elevation of insulin levels and competition with vitamin C for membrane transport sites.^[14] ^[15] This is based on evidence that vitamin C and glucose appear to have opposite effects on immunological function and the fact that both require insulin for membrane transport into many tissues.

Considering that the average American consumes 125 g of sucrose, plus 50 g of other refined simple sugars, each day, the inescapable conclusion is that most Americans have chronically depressed immune systems. It is clear, particularly during an infection, that the consumption of simple sugars, even in the form of fruit juice, is deleterious to the host's immune status.

Short-term fasting could be encouraged, particularly during the first 24–48 hours of an acute infectious illness, since this results in a significant (up to 50%) increase in phagocytic index.^[11] The fast should not be continued for an excessive period, since eventually the leukocyte's energy sources will become depleted.

Obesity

Obesity is associated with decreased immune status, as evidenced by the decreased bactericidal activity of leukocytes, and increased morbidity and mortality from infections.^[16] Cholesterol and lipid levels are usually elevated in obese individuals, which may explain their impaired immune function (see below).

Lipids

Increased levels of cholesterol, free fatty acids, triglycerides,

and bile acids inhibit various immune functions, including: [\[17\]](#) [\[18\]](#) [\[19\]](#) [\[20\]](#)

- lymphoproliferation
- response to mitogens
- antibody response
- PMN chemotaxis
- phagocytosis.

Optimal immune function is therefore dependent on control of these serum components. Interestingly, L-carnitine, even at minimal concentrations, has been shown to neutralize lipid-induced immunosuppression.[\[20\]](#) This is probably due to carnitine's role as a rate-limiting factor in the removal of fat emulsion from the blood.[\[21\]](#)

Alcohol

Alcohol increases the susceptibility to experimental infections in animals; and alcoholics are known to be more susceptible to pneumonia. Studies of human polymorphonuclear leukocytes show a profound depression in the rate of mobilization into the traumatized skin of nutritionally normal people. Alcohol does not, however, alter phagocytosis or cytotoxic activity.[\[22\]](#)

Vitamins

Vitamin A

Vitamin A plays an essential role in maintaining the integrity of the epithelial and mucosal surfaces and their secretions. These systems constitute a primary non-specific host defense mechanism. Vitamin A has been shown to stimulate and/or enhance numerous immune processes, including: [\[23\]](#) [\[24\]](#) [\[25\]](#) [\[26\]](#)

- induction of cell-mediated cytotoxicity against tumors
- natural killer cell activity
- lymphocyte blastogenesis
- mononuclear phagocytosis
- antibody response.

These effects are not due simply to reversal of vitamin A deficiency, since many of them are further enhanced by the administration of (supposedly) excessive levels of vitamin A.[\[26\]](#) In addition, vitamin A prevents and reverses stress-induced thymic involution, while added vitamin A can actually promote thymus growth.[\[27\]](#) Retinol also demonstrates potent viricidal activity.[\[28\]](#)

Carotenes

Carotenes have demonstrated a number of immune-enhancing effects.^[29] In addition to being converted into vitamin A, carotenes function as antioxidants. Since the thymus gland is so susceptible to free radical damage, beta-carotene may be more advantageous in enhancing the immune system than retinol. For more information, see [Chapter 121](#).

Vitamin C

Vitamin C (ascorbic acid) plays an important role in the natural approach to immune enhancement. Although vitamin C has been shown to be antiviral and antibacterial, its main effect is via improvement in host resistance. Many different immunostimulatory effects have been demonstrated, including enhancing lymphoproliferative response to mitogens and lymphotropic activity and increasing interferon levels, antibody responses, immunoglobulin levels, secretion of thymic hormones, and integrity of ground substance.^{[23] [24] [25] [26] [27] [28] [29] [30]} Vitamin C also has direct biochemical effects similar to interferon.^[31]

Numerous clinical studies support the use of vitamin C in the treatment of infectious conditions. In addition to its well-known effects in reducing the frequency, duration, and severity of the common cold, vitamin C has also been shown to be useful in other infectious conditions.^{[30] [32] [33] [34] [35] [36]} Vitamin C levels are quickly depleted during the stress of an infection.^[37]

It is useful to supplement vitamin C concurrently with flavonoids since these compounds raise the concentration of vitamin C in some tissues and potentiate its effects, as well as exerting their own effects.^[38]

Vitamin E

Vitamin E enhances both humoral and cell-mediated immunity. A vitamin E deficiency results in lymphoid atrophy and decreased lymphoproliferative response to mitogens, splenic plaque-forming colonies, antibody response, and monocyte function.^{[23] [24]} Vitamin E supplementation (30–150 IU) has been shown to:^[39]

- increase lymphoproliferative response to mitogens
- prevent free radical-induced thymus atrophy
- enhance helper T-cell activity
- increase splenic plaque-forming colonies, serum immunoglobulins, antibody response, PMN phagocytosis, and reticuloendothelial system activity.

Elderly subjects may benefit from even higher dosages of vitamin E. A recent study sought to determine the effect of vitamin E supplementation at different dosages on immune function in 88 patients over the age of 65 years.^[40] To determine the effect of vitamin E on immune function, the researchers measured T-cell function by assessing

delayed-type hypersensitivity (DTH) skin response; antibody response to hepatitis B, tetanus, and diphtheria, and pneumococcal vaccines; and autoantibodies to DNA and thyroglobulin.

Vitamin E was given at either 60, 200, or 800 IU for

483

235 days. While the placebo group only experienced an 8% increase in DTH, the 60 IU group had a 20% increase in DTH; the 200 IU group had a 58% increase in DTH; and the 800 IU group had a 65% increase in DTH. With regard to antibody production, the best results were observed in the patients receiving 200 IU daily. No effect was noticed on autoimmune antibodies. No adverse effects were observed at any of the three dosage schedules of vitamin E.

Pyridoxine

A pyridoxine deficiency results in depressed cellular and humoral immunity, lymphoid tissue atrophy, leukopenia, reduction in quantity and quality of antibody production, depressed lymphoproliferative response to mitogens, and decreased thymic hormone activity.^{[23] [24]} Factors predisposing to deficiency are low dietary intake, excess protein intake, consumption of hydralazine (yellow) dyes, and alcohol and oral contraception use.

Folic acid and vitamin B₁₂

The megaloblastic state induced by a deficiency of vitamin B₁₂ and/or folate results in improper WBC production and abnormal lymphocyte responses. Folic acid deficiency (the most common vitamin deficiency in the US) has been shown to result in lymphoid atrophy and decreased lymphoproliferative response to mitogens, splenic plaque-forming colonies, and antibody production. A B₁₂ deficiency, besides producing a deficiency in folate conversion to its active tetrahydrofolate form, leads to impaired PMN phagocytosis and bactericidal action.^{[23] [24]}

Other B vitamins

Thiamin, riboflavin, and pantothenic acid deficiencies lead to reduced antibody response, decreased splenic plaque-forming colonies, and lymphoid atrophy.^[25]

Minerals

Iron

Iron deficiency is a commonly encountered isolated nutritional deficiency which causes

immune dysfunction in large numbers of patients. Marginal iron deficiency, even at levels that do not lower hemoglobin values, can influence the immune system. Lymphoid tissue atrophy, decreased lymphoproliferative response to mitogens, defective macrophage and neutrophil function, and decreased proportion of T-cell to B-cell ratios are common experimental and clinical findings.^[23] ^[24]

Iron is an important nutrient to bacteria as well as humans. During infection, one of the body's non-specific defense mechanisms to limit bacterial growth is to reduce plasma iron, and in vitro studies have shown that the bacteriostatic and some of the bactericidal effects of serum are eliminated by the addition of iron to the serum.^[41] As temperature rises, plasma iron levels drop, and when temperature is raised to fever levels, the growth of bacteria is inhibited, but not at high iron concentrations.

These observations lead us to the conclusion that iron supplementation is probably contraindicated during acute infection, especially in patients with low transferrin levels. However, in patients with impaired immune function, chronic infections, and subnormal iron levels, adequate supplementation is essential.

Trace minerals

Trace minerals primarily function as activators of enzyme-metal-substrate complexes in which they are loosely bound cofactors. The role of these elements in these metalloenzymes is either structural, in which they influence the reactivity of the protein by stabilizing strained configurations of binding ligands about the metal atom, or catalytic, in which they act as centers of positive charge.

Zinc

The hereditary zinc deficiency disease, acrodermatitis enteropathica (AE), offers an excellent model for understanding the role of zinc in immunity. In AE, the number of T-cells is reduced, lymphoproliferative response to mitogens is reduced, thymic hormone levels are lower, delayed cutaneous hypersensitivity is decreased, and PMN phagocytosis, chemotaxis, and cytotoxic activities are impaired. All of these effects are reversible upon adequate zinc administration and absorption.^[42]

Zinc serves a vital role in many immune system reactions, e.g. it promotes the binding of complement (C1q) to immune complex, acts as a protectant against iron-catalyzed free radical damage, acts synergistically with vitamin A, is required for lymphocyte transformation, acts independently on lymphocytes as a mitogen, and is a necessary cofactor in activating serum thymic factor.^[43] ^[44] Zinc inhibits, in vitro, the growth of several viruses including rhino, picorna and toga viruses, and herpes simplex and vaccinia virus.^[45]

Adequate zinc nutriture is particularly important in the elderly, and zinc supplementation in elderly subjects results in increased numbers of T-cells and enhanced cell-mediated immune responses.^[46]

Throat lozenges containing zinc became popular in the treatment of the common cold as a result of a double-blind clinical trial in 1984 which demonstrated that zinc-containing lozenges significantly reduced the average duration of common colds by 7 days.^[47] The lozenges used in this study contained 23 mg of elemental zinc, which

484

the patients were instructed to dissolve in their mouths every 2 waking hours after an initial double dose. After 7 days, 86% of the 37 zinc-treated subjects were symptom-free, compared with 46% of the 28 placebo-treated subjects. Additional studies have confirmed these results.^[48] Because high doses of zinc can actually impair immune function, a daily intake of greater than 150 mg of zinc for longer than 1 week cannot be recommended.

Selenium

Selenium in its vital role in glutathione peroxidase affects all components of the immune system including the development and expression of all white blood cells. Selenium deficiency results in depressed immune function, whereas selenium supplementation results in augmentation and/or restoration of immune functions. Selenium deficiency has been shown to inhibit resistance to infection as a result of impaired white blood cell and thymus function, while selenium supplementation (200 mcg/day) has been shown to stimulate white blood cell and thymus function.^{[49] [50] [51]}

The ability of selenium supplementation to enhance immune function goes well beyond simply restoring selenium levels in selenium-deficient individuals. For example, in one study selenium supplementation (200 mcg/day) to individuals with normal selenium concentrations in their blood resulted in a 118% increase in the ability of lymphocytes to kill tumor cells and an 82.3% increase in the activity of natural killer cells.^[50] These effects were apparently related to the ability of selenium to enhance the expression of the immune-enhancing compound interleukin-2 and, consequently, the rate of white blood cell proliferation and differentiation into forms capable of killing tumor cells and microorganisms. The supplementation regimen did not produce significant changes in the blood selenium levels of the participants. The results indicated that the immune-enhancing effects of selenium in humans require supplementation above the normal dietary intake.

ENHANCING THYMUS FUNCTION

Perhaps the most effective method in re-establishing a healthy immune system is employing measures to improve thymus function. Promoting optimal thymus gland activity involves:

- prevention of thymic involution or shrinkage by ensuring adequate dietary intake of

antioxidant nutrients

- use of nutrients that are required in the manufacture or action of thymic hormones
- using botanical medicines or glandular products containing concentrates of calf thymus tissue to enhance thymus activity.

Antioxidants

The thymus gland shows maximum development immediately after birth. During the aging process, the thymus gland undergoes a process of shrinkage or involution. The reason for this involution is that the thymus gland is extremely susceptible to free radical and oxidative damage caused by stress, radiation, infection, and chronic illness.

Many patients with impaired immune function as well as conditions associated with impaired immunity (e.g. chronic fatigue syndrome, cancer, AIDS, etc.) suffer from a state of oxidative imbalance characterized by a greater number of pro-oxidants in their system than antioxidants. This situation is quite detrimental to thymus function. One of the primary ways in which antioxidants impact the immune system, particularly cell-mediated immunity, may be via protecting the thymus gland from damage. The antioxidant nutrients most important for protecting the thymus include the carotenes, vitamin C, vitamin E, zinc, and selenium.

Nutrients

Many nutrients function as important cofactors in the manufacture, secretion and function of thymic hormones. A deficiency of any one of these nutrients results in decreased thymic hormone action and impaired immune function. Zinc, vitamin B₆, and vitamin C are perhaps the most critical. Supplementation with these nutrients has been shown to increase thymic hormone function and cell-mediated immunity.

Zinc is perhaps the critical mineral involved in thymus gland function and thymus hormone action. Zinc is involved in virtually every aspect of immunity. When zinc levels are low, the number of T-cells is reduced; thymic hormone levels are lower, and many white blood functions critical to the immune response are severely lacking. All of these effects are reversible upon adequate zinc administration and adsorption.^[52] ^[53]

Thymus extracts

A substantial amount of clinical data now supports the effectiveness of orally administered calf thymus extracts in restoring and enhancing immune function.^[54] ^[55] The effectiveness of thymus extracts is reflective of broad-spectrum immune system enhancement presumably mediated by improved thymus gland activity. This effect fits in nicely with one of the basic concepts of glandular therapy, i.e. that the oral ingestion of glandular material of a certain animal gland will strengthen the corresponding human gland. The result is a broad general effect indicative of improved glandular function.

Thymus extracts may provide the answer to chronic viral infections and low immune

function. The ability

of thymus extracts to treat and then reduce the number of recurrent infections was studied in groups of children with a history of recurrent respiratory tract infections. Double-blind studies revealed not only that orally administered thymus extracts were able to effectively eliminate infection, but also that treatment over the course of a year significantly reduced the number of respiratory infections and significantly improved numerous immune parameters.^[56]

Thymus extract has been shown to normalize the ratio of T-helper cells to suppressor cells whether the ratio is low or high.^{[54] [55]}

BOTANICALS

Many herbs have been shown to have antibacterial, antiviral, and immunostimulatory effects, and a complete discussion is outside the scope of this chapter (several immune-enhancing botanicals are discussed in depth in Section 5). This chapter focuses on two of the most popular immune-enhancing botanicals – *Echinacea* and *Astragalus*. These two herbs were selected based on their ability to exert broad-spectrum effects on immune functions. They stimulate the body's natural defense mechanisms via slightly different mechanisms and are in many ways the prototypes of the hundreds of plants with known antimicrobial and immunological activity.

Echinacea sp.

Perhaps the most widely used Western herb for enhancement of the immune system is echinacea. The two most widely used species are *Echinacea angustifolia* and *Echinacea purpurea*. Both have been shown to exert profound immune-enhancing effects. Several classes of constituents contribute to this action.^[57]

One of the most important immune-stimulating components of *Echinacea* are large polysaccharides, such as inulin, that activate the alternative complement pathway (one of the immune system's non-specific defense mechanisms) and increase the production of immune chemicals that activate macrophages. The result is increased activity of many key immune parameters: production of T-cells, macrophage phagocytosis, antibody binding, natural killer cell activity, and levels of circulating neutrophils.^[57]

Echinacea strengthens the immune system even in healthy people. For example, oral administration of an *E. purpurea* root extract (a dose of 30 drops three times daily) to healthy males for 5 days resulted in a remarkable 120% increase in leukocyte phagocytosis.^[58] In another study of healthy volunteers aged 25–40 years, the fresh-pressed juice of *E. purpurea* extract was found to increase the phagocytosis of *Candida albicans* by 30–40%; it also increased the migration of white cells to the scene

of battle by 30–40%.^[59]

Besides immune support, *Echinacea* also exerts direct antiviral activity and helps prevent the spread of bacteria by inhibiting a bacterial enzyme called hyaluronidase. This enzyme is secreted by bacteria in order to break through the body's first line of defense, the protective membranes such as the skin or mucous membranes, so that the organism can enter the body.

Echinacea is discussed fully in [Chapter 82](#) .

Astragalus membranaceus

The root of *Astragalus* is a traditional Chinese medicine used for viral infections. Clinical studies in China have shown it to be effective when used prophylactically against the common cold.^[60] It has also been shown to reduce the duration and severity of symptoms in acute treatment of the common cold as well as to raise white blood cell counts in chronic leukopenia.

Research in animals has shown that *Astragalus* apparently works by stimulating several factors of the immune system, including enhancing phagocytic activity of monocytes and macrophages, increasing interferon production and natural killer cell activity, enhancing T-cell activity, and potentiating other antiviral mechanisms.^{[60] [61]} *Astragalus* appears particularly useful in cases where the immune system has been damaged by chemicals or radiation. In immunodepressed mice, astragalus has been found to reverse the T-cell abnormalities caused by cyclophosphamide, radiation, and aging.^[62] Like *Echinacea*, the polysaccharides contained in the root of *Astragalus membranaceus* contribute to the immune-enhancing effects.

THERAPEUTIC APPROACH

A major challenge to the discerning clinician is to determine which of the above factors is the key to reactivating or supporting a patient's immune system. The regimen listed below is meant as a general approach and must be tailored to the patient's specific needs in order to maximize the desired effects and limit unnecessary treatment.

General measures

- Rest (bed rest better)
- Drink large amount of fluids (preferably diluted vegetable juices, soups, and herb teas)
- Limit simple sugar consumption (including fruit sugars) to less than 50 g a day.

Supplements

- High potency multiple vitamin and mineral formula
- Vitamin C – 500 mg every 2 hours

- Bioflavonoids – 1,000 mg/day
-

486

- Vitamin A – 5,000 IU/day; or beta-carotene – 25,000 IU/day
- Zinc – 30 mg/day
- Thymus extract – the equivalent to 120 mg pure polypeptides with molecular weights less than 10,000 or roughly 500 mg of the crude polypeptide fraction.

Botanicals

All dosages to be three times/day.

Echinacea sp.

- Dried root (or as tea): 0.5–1 g
- Freeze-dried plant: 325–650 mg
- Juice of aerial portion of *E. purpurea* stabilized in 22% ethanol: 2–3 ml
- Tincture (1:5): 2–4 ml
- Fluid extract (1:1): 2–4 ml
- Solid (dry powdered) extract (6.5:1 or 3.5% echinacoside): 150–300 mg.

Astragalus membranaceus

- Dried root (or as decoction): 1–2 g
- Tincture (1:5): 2–4 ml
- Fluid extract (1:1): 2–4 ml
- Solid (dry powdered) extract (0.5% 4-hydroxy-3-methoxy isoflavone): 100–150 mg.

Chapter 54 - Intestinal dysbiosis and dysfunction

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

INTRODUCTION

Overgrowth of inappropriate bacteria in the various segments of the intestines is becoming recognized as a significant, but rarely recognized, cause of chronic disorders not only of the intestines but also of other systems of the body. Although widespread, it is frequently unsuspected because its symptoms often mimic other disorders. Environmental exposure, widespread antibiotic use and a low-fiber diet, as well as digestive disorders, have resulted in increasing incidence of intestinal dysbiosis and dysfunction with age.

Further discussion of the substantive role of the digestive tract in health and disease can be found in [Chapters 7](#) , [9](#) , [19](#) , [21](#) , [23](#) , [31](#) , [57](#) , [131](#) , [163](#) and [165](#) . The length of the list in itself indicates the wide-ranging effects of intestinal dysbiosis. This chapter provides some overview and fills in the gaps between the above listed chapters.

SMALL INTESTINE

Bacterial overgrowth

The upper portion of the human small intestine is normally relatively free of bacteria. Overgrowth of organisms in this area results in carbohydrate fermentation which produces excessive gas, bloating, and abdominal distention, and protein putrefaction which produces vasoactive amines.^[1] For example, bacteria and yeast contain decarboxylases which can convert the amino acids histidine to histamine and tyrosine to tyramine, ornithine to putrescine and lysine to cadaverine. All of these compounds cause constriction and relaxation of blood vessels by acting on their smooth muscle. In the intestinal tract, excessive vasoactive amine synthesis can lead to increased gut permeability (i.e. the “leaky gut” syndrome), abdominal pain, altered gut motility, and

pain (see [Ch. 21](#)).

Diagnosis of small intestinal overgrowth involves comprehensive digestive and stool analysis (see [Ch. 9](#)) and breath tests which measure the hydrogen and methane

after the administration of lactulose and glucose (see [Ch. 7](#)).

Symptoms of small intestinal bacterial overgrowth are similar to those generally attributed to achlorhydria and pancreatic insufficiency – indigestion and sense of fullness (bloating) – but may also include symptoms generally associated with *Candida* overgrowth (discussed below), nausea, diarrhea, and arthritis. This latter association is quite important as many patients with rheumatoid arthritis exhibit small intestinal bacterial overgrowth, the degree of which correlates with the severity of symptoms and disease activity.^[2]

Several protective measures prevent bacterial overgrowth in the small intestine: digestive enzymes, liver secretions, peristalsis and immunological factors.^{[3] [4] [5] [6] [7]} Hydrochloric acid, bile and pancreatic enzymes play a critical role in preventing significant numbers of bacteria from transiting through the stomach or migrating up the small intestine.^{[4] [5]} Decreased motility of the small intestine due to a motility disorder (e.g. systemic sclerosis) or a meal high in refined sugar can also contribute to small intestinal bacterial overgrowth.^{[6] [7]} The mechanism by which a high sugar meal decreased mobility is simple: when blood sugar levels rise too rapidly, the feedback system inhibits gastrointestinal peristalsis. Since glucose is primarily absorbed in the duodenum and jejunum, inhibition of this portion of the gastrointestinal tract is the strongest. Low immune function, food allergies, stress, and other factors which reduce the level of secretory IgA can also contribute to bacterial overgrowth in the small intestine ([Table 54.1](#)). Finally, a weak ileocecal can lead to overpopulation of the small intestinal tract with bacteria from the colon. A weak ileocecal valve is most often the consequence of long-term constipation or straining excessively at defecation. In both of these cases, a low-fiber diet is most often responsible.

An overgrowth in the gastrointestinal tract of the usually benign yeast *Candida albicans* is now becoming recognized as a complex medical syndrome known as the yeast syndrome or chronic candidiasis (see [Ch. 48](#)).

TABLE 54-1 -- Factors associated with small intestinal bacterial overgrowth

- Decreased digestive secretions

- achlorhydria

- hypochlorhydria

- drugs which inhibit hydrochloric acid

—pancreatic insufficiency

—decreased bile output due to liver or gall bladder disease

- Decreased motility

—scleroderma (progressive systemic sclerosis)

—systemic lupus erythematosus

—intestinal adhesions

—sugar-induced hypomotility

—radiation damage

- Low secretory IgA

- Weak ileocecal valve

The overgrowth of *Candida* is believed to cause a wide variety of symptoms in virtually every system of the body, with the gastrointestinal, genitourinary, endocrine, nervous, and immune systems being the most susceptible. Eventually this syndrome will be replaced by a more comprehensive term to include small intestinal bacterial overgrowth and the leaky gut syndrome.

Treatment

Obviously, addressing the cause of the small intestinal bacterial overgrowth is the first step. The subject of decreased digestive secretions is discussed in [Chapter 55](#) . The decreased motility is usually addressed by decreasing sugar consumption while increasing dietary fiber (see [Ch. 57](#) for more in-depth discussion).^[7]

Restoring secretory IgA to normal levels involves eliminating food allergies (see [Ch. 51](#)) and enhancing immune function (see [Ch. 53](#)). Stress is particularly detrimental to secretory IgA. This effect offers an additional explanation as to why stressful events tend to worsen gastrointestinal function and food allergies.

Pancreatic enzymes and botanical medicines containing berberine can be used to inhibit the bacteria growing in the small intestinal overgrowth. In addition to exerting broad-spectrum antibiotic activity (including activity against *Candida albicans*), berberine has been shown to inhibit the bacterial decarboxylase enzyme which converts amino acids into vasoactive amines.^[8] Pancreatic enzymes, in addition to enhancing protein digestion, are largely responsible for keeping the small intestine free from bacteria as well as parasites (pathogenic bacteria, yeast, protozoa, and helminths).^[9] A lack of proteases or other digestive secretions greatly increases an individual's risk of having an intestinal infection including chronic *Candida* infections of the gastrointestinal tract.

COLON

The large intestine is not significantly involved in digestion but does play a role in the

absorption of water and electrolytes and provides temporary storage for waste products and the formation of stool. The health of the colon is largely determined by amount of dietary fiber and the proper elimination of waste products. (Irritable bowel syndrome is discussed in [Ch. 165](#) , and Crohn’s disease and ulcerative colitis are fully covered in [Ch. 163.](#))

Constipation

An old-time naturopathic belief was that “disease begins in the colon”. There appears to be great wisdom in that statement: improper elimination of waste products has

TABLE 54-2 -- Causes of constipation

| | |
|--------------------------|--|
| Dietary | Highly refined and low-fiber foods, inadequate fluid intake |
| Physical inactivity | Inadequate exercise, prolonged bed rest |
| Pregnancy | |
| Advanced age | |
| Drugs | Anesthetics, antacids (aluminum and calcium salts), anticholinergics (bethanechol, carbachol, pilocarpine, physostigmine, ambenonium), anticonvulsants, antidepressants (tricyclics, monoamine oxidase inhibitors), antihypertensives, anti-Parkinsonism drugs, antipsychotics (phenothiazines), beta-adrenergic blocking agents (propranolol), bismuth salts, diuretics, iron salts, laxatives and cathartics (chronic use), muscle relaxants, opiates, toxic metals (arsenic, lead, mercury) |
| Metabolic abnormalities | Low potassium stores, diabetes, kidney disease |
| Endocrine abnormalities | Low thyroid function, elevated calcium levels, pituitary disorders |
| Structural abnormalities | Abnormalities in the structure or anatomy of the bowel |
| Bowel diseases | Diverticulosis, irritable bowel syndrome (alternating diarrhea and constipation), tumor |
| Neurogenic abnormalities | Nerve disorders of the bowel (aganglionosis, autonomic neuropathy), spinal cord disorders (trauma, multiple sclerosis, tabes dorsalis), disorders of the splanchnic nerves (tumors, trauma), cerebral disorders (strokes, Parkinsonism, neoplasm) |
| Enemas (chronic use) | |

serious health repercussions. Constipation regularly affects over 4 million people in the United States.^[40] This high incidence translates to over \$500 million in annual sales of laxatives. There are a number of possible causes of constipation, but the most common cause is a low-fiber diet ([Table 54.2](#)).

Treatment

While constipation will usually respond to a high-fiber diet, plentiful fluid consumption, and exercise, many sufferers of chronic constipation do not avail themselves of these healthful approaches and use laxatives instead.

It is well accepted that increasing dietary fiber is an effective treatment of chronic constipation. High levels of dietary fiber increase both the frequency and quantity of bowel movements, decrease the transit time of stools, decrease the absorption of toxins from the stool, and appear to be a preventive factor in several diseases. Particularly effective in relieving constipation are bran and prunes. The typical recommendation for bran (oat preferable to wheat) is half a cup of bran cereal, increasing to 1.5 cups over several weeks. Whole prunes as well as prune juice possess good laxative effects. Eight ounces is usually an effective dose. Be sure that patients are consuming enough liquids. Prescribe the drinking of at least six to eight glasses per day. In addition, recommend the consumption of 25–35 g of fiber.

When patients need additional support, consider using fiber formulas. These formulas act as bulking agents. They can be composed of natural plant fibers derived from psyllium seed, kelp, agar, pectin, and plant gums like karaya and guar. They can also be made from purified semi-synthetic polysaccharides like methyl-cellulose and carboxymethyl cellulose sodium. Psyllium-containing laxatives are the most popular and usually the most effective.

If patients have been using stimulant laxatives, even natural ones like *Cascara sagrada* (*Rhamnus purshiana*) or senna (*Cassia senna*), they will need to “retrain” their bowels. [Table 54.3](#) lists the recommended rules for re-establishing bowel regularity. The recommended procedure will take 4–6 weeks.

Diverticular disease

Most often the presence of diverticula is without symptoms; however, if the diverticula becomes inflamed, perforated, or impacted, symptomatic diverticulitis results. Only about 20% of people with diverticulosis develop diverticulitis. Symptoms of diverticulitis include episodes of lower abdominal pain and cramping, changes in bowel habits (constipation or diarrhea), and

TABLE 54-3 -- Rules for bowel retraining

-
- Find and eliminate known causes of constipation
-
- Never repress an urge to defecate
-

- Eat a high-fiber diet, particularly fruits and vegetables

 - Drink six to eight glasses of fluid per day

 - Sit on the toilet at the same time every day (even when the urge to defecate is not present), preferably immediately after breakfast or exercise

 - Exercise for at least 20 minutes, three times per week

 - Stop using laxatives (except as discussed below to re-establish bowel activity) and enemas

 - Week 1: Every night before bed take a stimulant laxative containing either cascara or senna. Take the lowest amount necessary to reliably ensure a bowel movement every morning

 - Weekly: Each week decrease dosage by 50%. If constipation recurs, go back to the previous week's dosage. Decrease dosage if diarrhea occurs
-

a sense of fullness in the abdomen. In more severe cases, fever may be present along with tenderness and rigidity of the abdomen over the area of the intestine involved.

Treatment

Treatment of diverticular disease involves the recommendation of a high-fiber diet. In severe cases of diverticulitis, an antibiotic may be warranted.

Dysbiosis

The microecology of the human gastrointestinal tract is an incredibly complex ecosystem as there are at least 500 different species of microflora that are part of the “normal” intestinal flora.^[11] There are nine times as many bacteria in the gastrointestinal tract as there are cells in the human body. The type and number of gut bacteria play an important role in determining health and disease. A state of altered bacterial flora in the gut has become popularly known as “dysbiosis”. The term was first used by noted Russian scientist Elie Metchnikoff to reflect a state of living with intestinal flora that has harmful effects. He theorized that toxic compounds produced by the bacterial breakdown of food were the cause of degenerative disease.^[12] There is a growing body of evidence that is supporting and refining Metchnikoff's theory. The major causes of dysbiosis are listed in [Table 54.4](#) .

Obviously, treatment begins with addressing these major causes. In addition, it is important to re-seed the gastrointestinal tract with probiotics. The most important healthful bacteria are *Lactobacillus acidophilus* and *Bifidobacterium bifidum* (see [Ch. 105](#) for a full discussion).

The symbiosis or pathogenicity of the 500 normal microbial inhabitants of the human digestive tract is largely determined by the environment in which they live and the balance between the various types. *Candida albicans* is an example of an organism that, under normal circumstances, lives in harmony with the host, but if *Candida* overgrows and is out of balance with other gut microbes it can result in problems. In general, parasites

TABLE 54-4 -- Causes of intestinal dysbiosis

| |
|--------------------------------|
| • Dietary disturbances |
| —high protein |
| —high sugar |
| —high fat |
| —low fiber |
| —food allergies |
| • Lack of digestive secretions |
| • Stress |
| • Antibiotic/drug therapy |
| • Decreased immune function |
| • Malabsorption |
| • Intestinal infection |
| • Altered pH |

cause most of their problems by interfering with digestion and/or damaging the intestinal lining, either of which can lead to increased mucous secretion and/or diarrhea.

One of the most intriguing hypotheses explaining the balance and growth of the various organisms is the type of level of digestion of carbohydrates in the diet. The research in this area and clinical applications of modification of dietary carbohydrates are covered in a very interesting book, *Breaking the Vicious Cycle*, by nutritionist Elaine Gottschall.^[13] The presence of undigested and unabsorbed carbohydrates within the small intestine and/or colon result in increased fermentation and overgrowth of certain, toxic species of bacteria. Not only is the production of gas increased, but so also is the production of short-chain organic acids, such as lactic acid, which are damaging to the intestinal mucosa. The damage to the intestinal mucosa aggravates the problem by decreasing the level of disaccharides (lactase, sucrase, isomaltase and, less often, maltase) in the lining cells, thus further increasing the levels of undigested disaccharides. As the gastrointestinal tissues become more damaged, mucous secretion increases, further separating complex carbohydrates from their digestive sites.

Treatment involves the “specific carbohydrate diet”, which breaks the vicious cycle by

only allowing carbohydrates that are either predigested or easily digested and virtually totally absorbed in the duodenum, making them unavailable to more distal bacteria. Basically, all disaccharides (e.g. lactose, sucrose), all grain starches (e.g. wheat, rice, corn syrup), and starchy vegetables (e.g. potatoes) are eliminated, as are most legume starches. Simple sugars such as glucose and fructose (found in honey, fruits, and some vegetables) and lactose-hydrolyzed milk products are allowed.

Interestingly, although not acknowledged (all historic references are to conventional medical practitioners), several of these concepts were first promulgated by

TABLE 54-5 -- Common protozoa and helminths

“Professor” Arnold Erhardt at the turn of the century in his book *The Mucousless Diet*.

Parasites

Diarrheal diseases caused by parasites still constitute the greatest single worldwide cause of illness and death. The problem is more severe in underdeveloped countries with poor sanitation, but even in the United States diarrheal diseases are the third major cause of sickness and death. Furthermore, the ease and frequency of worldwide travel and increased migration to the United States is resulting in growing numbers of parasitic infections. In addition to normal inhabitants of the gastrointestinal system acting as parasites, there are also significant diarrheal diseases associated with protozoa and helminths ([Table 54.5](#)). (One parasite, *Ascaris lumbricoides* is discussed in more detail in [Ch. 131.](#))

The apparent incidence of the various parasites are listed in [Table 54.6](#) . These data come from state diagnostic laboratories which evaluated over 200,000 stool specimens in 1987. Parasites were found in 20.1% of the stool samples.

While the most commonly reported symptoms of parasitic infection are diarrhea and abdominal pain, these symptoms do not occur in every case ([Table 54.7](#)). In fact, there appears to be a growing number of individuals experiencing milder than usual gastrointestinal symptoms due to parasitic infections and/or symptoms not traditionally considered to be linked to parasitic infections. For example, in many cases of the irritable bowel syndrome, indigestion, and poor digestion, parasites may be causing the symptoms. In addition, parasitic infections are often an unsuspected cause of chronic illness and fatigue.

TABLE 54-7 -- Signs and symptoms of parasitic infections

-
- Abdominal pain and cramps

 - Constipation

 - Depressed secretory IgA

 - Diarrhea

 - Fatigue

 - Fever

 - Flatulence

 - Food allergy

 - Foul-smelling stools

 - Gastritis

 - Headaches

 - Hives

 - Increased intestinal permeability

 - Indigestion

 - Irregular bowel movements

 - Irritable bowel syndrome

 - Loss of appetite

 - Low back pain

 - Malabsorption

 - Weight loss

Treatment

A number of natural compounds can be useful in helping the body rid itself of parasites. However, before selecting a natural alternative to an antibiotic in parasitic infections, the underlying factors which may have been responsible for setting up the internal terrain

for a parasitic infection, e.g. achlorhydria, decreased pancreatic enzyme output, etc., must be controlled. Proper treatment with either an antibiotic or a natural alternative requires monitoring by repeating multiple stool samples 2 weeks after therapy (see [Ch. 131](#) for a more detailed therapy).

The treatment of parasitic infections typically utilizes high dosages of pancreatic enzymes (10 × USP 750–1,000 mg, 10–20 minutes before meals) and berberine-containing

plants such as *Hydrastis canadensis*, *Berberis vulgaris*, *Berberis aquifolium*, and *Coptis chinensis*. When using these plants, the dosage should be based on berberine content. As there is a wide range of quality, standardized extracts are preferred. Three times a day dosages are as follows:

- dried root or as infusion (tea): 2–4 g
- tincture (1:5): 6–12 ml (1.5–3 tsp)
- fluid extract (1:1): 2–4 ml (0.5–1 tsp)
- solid (powdered dry) extract (4:1 or 8–12% alkaloid content): 250–500 mg.

These dosage recommendations result in a berberine dosage of 25–50 mg three times daily or a daily dosage of up to 150 mg. This dosage is consistent with the dosage range in the positive clinical studies in various parasitic infections (see [Ch. 91](#)). For children a dosage based on body weight is appropriate. The daily dosage would be the equivalent to 5–10 mg of berberine/kg body weight.

Chapter 55 - Maldigestion

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

INTRODUCTION

Proper digestion, absorption, and elimination are necessary in order to gain the nutritional benefits from foods. Any disruption of these processes causes substantial, and usually progressive, health problems throughout the body. As discussed in several chapters in this textbook (e.g. [Chs 7](#) , [21](#) , [31](#) , [57](#) , [131](#) , [163](#) , and [165](#)), intestinal dysfunction is a common, yet inadequately recognized, problem.

This chapter provides some overview of digestive dysfunction and ways to improve digestion. Intestinal dysfunction, independent of digestive dysfunction, is discussed in [Chapter 54](#) . A full discussion of the various laboratory procedures for evaluation of digestive function can be found in [Chapters 9](#) , [19](#) , and [23](#) .

THERAPEUTIC CONSIDERATIONS

Indigestion

The term indigestion is often used by patients to describe a feeling of gaseousness or fullness in the abdomen. It can also be used to describe “heartburn”. Indigestion can be attributed to a great many causes, including not only increased secretion of acid but also decreased secretion of acid and other digestive factors and enzymes.

Indigestion is commonly treated with antacids and histamine (H_2)-receptor antagonists either self-prescribed by patients or prescribed by medical practitioners. The use of these agents will typically raise the gastric pH above 3.5, effectively inhibiting the action of pepsin, the enzyme involved in protein digestion that can be irritating to the stomach. Although raising the pH can reduce symptoms, it also substantially impairs protein digestion and mineral disassociation. In addition, the change in pH can adversely effect gut microbial flora including the promotion of an overgrowth of *Helicobacter pylori*.

Finally, most nutrition-oriented physicians believe that lack of acid, not excess, is the true culprit for most patients.

According to surveys, most people use antacids to relieve symptoms of reflux esophagitis.^[1] However, reflux esophagitis is most often caused by *overeating*, not excessive acid production. Other common causes include:

- obesity
- cigarette smoking
- chocolate
- fried foods
- carbonated beverages
- alcohol
- coffee.

These factors either increase intra-abdominal pressure or they decrease the tone of the esophageal sphincter.

Chronic heartburn may also be a sign of a hiatal hernia. However, while 50% of people over the age of 50 have hiatal hernias, only 5% of patients with hiatal hernias actually experience reflux esophagitis.

Perhaps the most effective treatment of chronic reflux esophagitis and symptomatic hiatal hernias is to utilize gravity. The standard recommendation is to simply place 4-inch blocks under the bedposts at the head of the bed. This elevation of the head is very effective in many cases. Another recommendation to heal the esophagus, is using deglycyrrhizinated licorice (DGL).

Hypochlorhydria

In the patient with chronic indigestion, rather than focus on blocking the digestive process with antacids, the natural approach to indigestion focuses on aiding digestion. Although much is said about hyperacidity conditions, a more common cause of indigestion is a lack of gastric acid secretion. There are many symptoms and signs that suggest impaired gastric acid secretion, and a number of specific diseases have been found to be associated with insufficient gastric acid output.^{[2] [3] [4] [5] [6] [7] [8] [9] [10] [11] [12]} These are listed in [Tables 55.1](#) and [55.2](#) .

Several studies have shown that the ability to secrete gastric acid decreases with age.^{[13] [15] [16]} Some studies found low stomach acidity in over half of those over the age

TABLE 55-1 -- Common signs and symptoms of low gastric acidity

- Bloating, belching, burning, and flatulence immediately after meals
-

- A sense of “fullness” after eating
- Indigestion, diarrhea, or constipation
- Multiple food allergies
- Nausea after taking supplements
- Itching around the rectum
- Weak, peeling, and cracked fingernails
- Dilated blood vessels in the cheeks and nose
- Acne
- Iron deficiency
- Chronic intestinal parasites or abnormal flora
- Undigested food in stool
- Chronic candida infections
- Upper digestive tract gassiness

TABLE 55-2 -- Diseases associated with low gastric acidity

- Addison’s disease
- Asthma
- Celiac disease
- Dermatitis herpetiformis
- Diabetes mellitus
- Eczema
- Gall bladder disease
- Graves’ disease
- Chronic autoimmune disorders
- Hepatitis
- Chronic hives
- Lupus erythematosus
- Myasthenia gravis
- Osteoporosis
- Pernicious anemia
- Psoriasis
- Rheumatoid arthritis

- Rosacea

- Sjögren's syndrome

- Thyrotoxicosis

- Hyper- and hypothyroidism

- Vitiligo

of 60. The best method of diagnosing a lack of gastric acid is the Heidelberg gastric analysis ([Ch. 19](#)).^[17] It has been suggested by Wright^[18] that the response to a bicarbonate challenge during Heidelberg gastric analysis, not simply resting pH, is the true test of the functional ability of the stomach to secrete acid.

Since the Heidelberg gastric acid analysis is not widely available, a clinical trial of HCl supplements can be used as described in [Appendix 7](#).

Etiology

Like peptic ulcer disease, achlorhydria and hypochlorhydria have been linked to the overgrowth of the bacteria *Helicobacter pylori*. Approximately 90–100% of patients with duodenal ulcers, 70% with gastric ulcers, and about 50% of people over the age of 50 test positive for *H. pylori*.^[19] The presence of *H. pylori* is determined by measuring the level of antibodies to *H. pylori* in the blood or saliva, or by culturing material collected during an endoscopy as well as measuring the breath for urea. More recently, a breath test has become available for assessment of current *H. pylori* activity.

Low gastric output is thought to predispose to *H. pylori* colonization and *H. pylori* colonization increases gastric pH, thereby setting up a positive feedback scenario and increasing the likelihood for the colonization of the stomach and duodenum with other organisms.^[20] Interestingly, there has been only scant research into the effects of antacids and H₂-receptor antagonists on promoting *H. pylori* overgrowth.^[21]

Although the typical conventional medicine approach is to focus only on the infective agent, as usual host defense factors are equally or more important. Unfortunately,

the research has focused on eradicating the organism and there is little information on protective factors against infectivity. Proposed protective factors against *H. pylori*-induced intestinal damage are maintaining a low pH and ensuring adequate antioxidant defense mechanisms.^{[22] [23] [24]} Low levels of vitamin C and vitamin E and other antioxidant factors in the gastric juice not only appear to lead to the progression of *H. pylori* colonization, but also contribute to the ulcer formation since the mechanism by which *H. pylori* damages the stomach and intestinal mucosa is via oxidative damage.^[25] Furthermore, antioxidant status and gastric acid output appear to explain the

observation that most people infected with *H. pylori* do not develop peptic ulcer disease or gastric cancer.

Deglycyrrhizinated licorice

Deglycyrrhizinated licorice (DGL) may prove useful for both eradicating the organism and stimulating increased host defense factors. DGL has shown good results in healing both duodenal ulcers and gastric ulcers (discussed more fully in [Ch. 180](#)). Rather than inhibit the release of acid, DGL stimulates the normal defense mechanisms that prevent ulcer formation. Specifically, DGL:^[26] ^[27]

- improves both the quality and quantity of the protective substances which line the intestinal tract
- increases the life span of the intestinal cell
- improves blood supply to the intestinal lining.

The active components of DGL are believed to be flavonoid derivatives. These compounds have demonstrated impressive protection against chemically induced ulcer formation in animal studies. Several similar flavonoids have also been shown to inhibit *H. pylori* in a concentration-dependent manner.^[28] In addition, unlike antibiotics, the flavonoids were also shown to augment natural defense factors which prevent ulcer formation. The activity of flavone, the most potent flavonoid in the study, was shown to be similar to that of bismuth subcitrate.

Bismuth

Bismuth is a naturally occurring mineral that can act as an antacid as well as exert activity against *H. pylori*.^[29] The best known and most widely used bismuth preparation is bismuth subsalicylate (e.g. Pepto-Bismol). However, bismuth subcitrate has produced the best results against *H. pylori* and in the treatment of nonulcer-related indigestion as well as peptic ulcers.^[30] ^[31] In the United States, bismuth subcitrate preparations are available through compounding pharmacies (contact the International Academy of Compounding Pharmacists: 1-800-927-4227).

One of the key advantages of bismuth preparations over standard antibiotic approaches to eradicating *H. pylori* is that while the bacteria may develop resistance to various antibiotics it is very unlikely to develop resistance to bismuth.

The usual dosage for bismuth subcitrate is 240 mg twice daily before meals. For bismuth subsalicylate the dosage is 500 mg four times daily.

Bismuth preparations are safe when taken at prescribed dosages. Bismuth subcitrate may cause a temporary and harmless darkening of the tongue and/or stool. Bismuth subsalicylate should not be given to children recovering from the flu, chickenpox, or any other viral infection as it may mask the nausea and vomiting associated with Reye's syndrome, a rare but serious illness.

Pancreatic insufficiency

Both physical symptoms and laboratory tests can be used to assess pancreatic function. Common symptoms of pancreatic insufficiency include abdominal bloating and discomfort, gas, indigestion, and the passing of undigested food in the stool. For laboratory diagnosis, the comprehensive stool and digestive analysis (discussed in [Ch. 9](#)) is quite useful.

The most severe level of pancreatic insufficiency is seen in cystic fibrosis. Although cystic fibrosis is quite rare, mild pancreatic insufficiency is thought to be a relatively common condition, especially in the elderly.

Pancreatic enzyme supplements

Pancreatic enzyme products are an effective treatment for pancreatic insufficiency and are widely used. Most commercial preparations are prepared from fresh hog pancreas (i.e. pancreatin) (see [Ch. 101](#) for a full discussion).

The dosage of pancreatic enzymes is based on the level of enzyme activity of the particular product as defined by the *United States Pharmacopoeia* (USP). A 1× pancreatic enzyme (pancreatin) product has in each milligram not less than 25 USP units of amylase activity, not less than 2.0 USP units of lipase activity, and not less than 25 USP units of protease activity. Pancreatin of higher potency is given a whole number multiple indicating its strength. For example, a full-strength undiluted pancreatic extract that is 10 times stronger than the USP standard would be referred to as 10× USP. Full-strength products are preferred to lower potency pancreatin products because lower potency products are often diluted with salt, lactose, or galactose to achieve desired strength (e.g. 4× or 1×). The dosage recommendation for a 10× USP pancreatic enzyme product is typically 350–1,000 mg three times/day immediately

before meals when used as a digestive aid and 10–20 minutes before meals or on an empty stomach when anti-inflammatory effects are desired.

Enzyme products are often enteric-coated. However, numerous studies have shown that non-enteric-coated enzyme preparations actually outperform enteric-coated products if they are given prior to a meal (for digestive purposes) or on an empty stomach (for anti-inflammatory effects).

For vegetarians, bromelain, papain and enzymes extracted from *Aspergillus oryzae* can substitute for pancreatic enzymes.

Chapter 56 - Non-pharmacological control of pain

Richard Kitaeff MA ND DAC

INTRODUCTION

Pain in its myriad forms is one of the most common symptoms for which patients seek relief. Acute pain is an unpleasant experience primarily associated with tissue injury, and the protective response patients have to pain provides the clinician with valuable diagnostic information.

The reaction to pain is highly subjective and, as a function of higher centers, is extremely variable. It is influenced by many factors depending on the individual patient and his or her situation. When pain becomes chronic, the multifactorial influences (e.g. anxiety; depression; social, cultural, and economic factors; and secondary gain) play an even larger role.

When treating a patient for pain, it is essential first to determine the primary cause, the pathogenesis, and secondary or contributing factors. The relief of pain may then be achieved by removal of the primary cause (e.g. cure of an infection), neutralization of the effect of the stimulus (e.g. emollients for an ulcer), relief of discomfort (e.g. biofeedback), suppression of the disease process (e.g. anti-inflammatory agents), and dulling or obliterating the sense of pain (e.g. analgesics or acupuncture).^[1]

Although the medical profession has chosen to emphasize the pharmacological methods of pain control, many non-pharmacological options are available. Their applicability and efficacy are documented below. (Although this chapter liberally utilizes childbirth pain control, the examples and concepts are generalizable to any situation involving acute and/or chronic pain.)

THE EXPERIENCE OF PAIN

A psychological model

Pain is generally acknowledged to be a complex physiological/psychological phenomenon. It involves motivational and emotional components and conceptual interpretation, which may or may not have their basis in actual nociception. Verbal reports of pain and associated

behavioral responses are controlled, at least in part, by psychological, cultural, and situational factors.

For acute pain, such as that of childbirth, in which the painful experience can be directly related to nociceptive input, a multiprocess feedback model can be considered. However, one must keep in mind the complexity of the psychological processes intervening between sensory event and observable response, ranging from the physiological to the social aspects of personality. These include:

- elements of information processing
- performance ability
- attention
- memory
- expectancy
- attitudes and beliefs
- secondary gain
- self-concept
- designated sick roles.

In the psychological model, the brain infers information from bodily signs and integrates this with existing personal and situational variables to direct behavior. When consideration must also be given to the interactions with interested observers, such as physicians, family members and birth attendants, who influence the interpretation with their own experiences and attitudes about pain, the complexity becomes even greater.

According to this model, which does not differ in essence from a general model of stress, a primary appraisal of the personal danger or threat posed by the painful stressor is followed by a secondary appraisal of one's ability to cope, based on emotional feedback, and contributions of situational and sociocultural response factors. On this basis, a woman in labor could choose to consider pain as "positive", "functional", or "creative"; "pain with a purpose"; or, alternatively, "part of a process involving injury".^[2] This conceptualization of painful stress suggests that intervention could be successful at several levels: cognitive patterning, physiological arousal associated with emotional stress, and control of environmental stimuli. Examples of appropriate strategies could be: cognitive coping skills such as restructuring and utilization of preparatory information and attention shifts; muscular relaxation, physical or electrical stimulation, and biofeedback techniques; and structuring of the environment in a way conducive to

effective coping (such as by making it non-threatening and comfortable).^[3]

Neuropsychological mechanisms of pain

According to research on the mechanisms of pain, pain can be treated not only by anesthetic blocks, surgical intervention and the like, but also by influencing the motivational-affective and cognitive factors as well.^[4] The traditional specificity theory of pain, first enunciated by Descartes in the 17th century, holds that pain messages are conducted from specific pain receptors at the periphery through discrete pathways to pain centers in the brain. However, there are individual differences in pain responses, pain is not consistently stopped by cutting or blocking the “pain pathway”, and it is now known that non-painful types of stimulation will activate the A-delta and C fibers that are associated with pain. Therefore, later modifications of pain theory took into account patterning of nerve impulses over time to reflect differences in degree and intensity of stimuli and summation of signals from an extended area.^[5]

The currently accepted view of pain is the gate control theory of Melzack & Wall ^[6] , which they formulated in 1965. Based on neurological data and a categorization of the words used to describe pain, this theory conceptualizes the pain experience as having sensory-discriminative, motivational-affective, and cognitive-evaluative components or modalities, corresponding to different patterns of nervous impulses. Neurologically, a specialized cluster of nerve cells in the substantia gelatinosa of the spinal column is thought to operate like a valve or gate, controlling nerve signals before they evoke the perception of, and response to, pain. Besides this monitoring of sensory data in the central nervous system, gating is also influenced by the relative amount of activity in large-diameter (A-beta) and small-diameter (A-delta and C) nerve fibers. The large fibers tend to inhibit transmission, or close the gate, preventing pain, and the small fibers tend to facilitate transmission, or open the gate, resulting in pain. The fact that large fibers are activated by pressure, touch, massage, and vibration suggests a mechanism for such pain control techniques as acupressure, acupuncture, and transcutaneous electrical nerve stimulation (TENS). Such stimulation apparently closes the spinal gate via the large-fiber system. Melzack & Casey^[4] expanded this theory by proposing the possibility of a higher level gate, in the reticular or limbic structures of the brain, that probably mediates the drive to escape from unpleasant stimuli.

At central nervous system levels, the biochemical mechanisms of gate control may involve the endorphins, natural morphine-like substances that have been implicated in the pain-controlling effects produced by acupuncture.^[7]

Pain in childbirth

A psychological/social learning approach to pain emphasizes control of motivation, expectation, focus of attention, stress, and feelings of anxiety, depression and helplessness. Factors specifically operative in labor pain include these as well as social support and the physiological factors of hunger, rest, and muscular tension.^[8]

All of these can contribute to the interpretation of pain being placed on the nociceptive message provided by uterine contractions. The influence of motivation on labor pain was effectively demonstrated in a prospective study of maternal attitudes toward pregnancy in 8,000 American women. One of the factors found to be strongly related to maternal attitude toward having a baby was the need for analgesics in labor.^[9]

Cultural conditioning may also be fundamental to the labeling of childbirth as painful. Throughout most of the world, analgesics are not required for labor; in fact, a Japanese anesthesiologist suggests that the idea of “painless delivery” is a strange one to his culture.^[10] American women, on the other hand, “live through a largely self-fulfilling prophecy of birth as a painful, terrifying ordeal, and/or as a medical, drugged process over which they have no control”.^[9] This relates to body fantasies of injury, brought about in a hospital environment where distress is an expected response to the expulsive reflex.^[2]

PAIN CONTROL

Moderating variables and psychological techniques

Psychological strategies

The psychological strategies recommended for control of labor pain, many of them part of prepared childbirth programs, generally aim to provide control, communication, relaxation, attention focus, and support, as well as physical counter-stimuli. There is considerable psychological research supporting the use of these in the development of pain tolerance.

The significance of various characteristics of an individual’s psychological profile has been studied by evaluating the effects on pain perception of such parameters as:

- introversion-extroversion ^[11] ^[12] ^[13]
- augmenters-reducers ^[14]
- field dependence^[15] ^[16]
- repression-sensitization. ^[17] ^[18] ^[19]

For example, on the repression-sensitization axis, repressors may be characterized as those who avoid having to cope with pain, while sensitizers have an obsessive need to cope. They like to be informed in advance about the situation and to have control over it. The superior initial tolerance exhibited by repressors in response to heat and pressure stimuli disappears in repeated trials, showing that the sensitizers’ predilection for challenge enables them to endure long-term pain better.

The importance of individual difference variables is also illustrated by the observation

that one-third of patients undergoing surgical operations do not request pain-killing medication.^[20] This common ability to suppress pain indicates that not all surgical patients consider themselves passive victims. In fact, during the postoperative period, pain persists longer for those who accept medication.

Cognitive strategies

The impetus for devising cognitive strategies to promote tolerance of pain has been particularly supported by investigations showing that pain tolerance increases with greater predictability and perception of control.^{[21] [22] [23] [24] [25]} Similarly, preparatory communications and information received prior to the onset of experimental or surgical pain consistently decreases the subjects' perception of pain.^{[26] [27] [28] [29]} Animal studies have demonstrated higher rates of instrumental responses when painful shocks are signaled than when they are unsignaled.^[30] Kanfer & Seidner^[31] found that subjects who could advance slides of travel pictures at their own rate tolerated ice-water immersion of the hand longer than yoked subjects whose slides were changed by the experimenter.

When surgery patients are given a sense of control by providing them with preparatory information concerning postsurgery discomforts and operative care, in combination with training in rehearsal of realistic, positive aspects of the surgical experience, they showed a significant reduction in postsurgical anxiety (as indicated by nurses' observations), requests for sedatives, and length of hospital stay.^[32] Furthermore, preparation for repeated periodontal surgery by auditory and visual messages classified as "control enhancement" was associated with reduction of pain after a second surgery.^[33] Subjects who could cognitively redefine a threat of electric shocks as interesting new physiological sensations also reduced stress to a greater extent than subjects not provided with this coping strategy.^[34]

Meichenbaum and Turk developed a procedure utilizing "stress inoculation".^[35] It begins with an educational phase (in which subjects are given a conceptual framework for understanding the nature of their stressful reactions), followed by rehearsal of behavioral and cognitive coping skills, based on a set of coping self-statements generated by the client in collaboration with the therapist. Such cognitive-behavioral techniques, sometimes in combination with EMG biofeedback control, have been found successful in treatment of chronic low back pain.^{[36] [37] [38]} Also, cognitive-behavioral strategies have been effective in alleviating the pain of irritable bowel syndrome,^[39] temporomandibular joint syndrome,^[40] cancer,^[41] migraine headaches,^[42] and rheumatic conditions.^[43] This emphasis on conceptualization, preparatory information, and cognitive transformation seems to have been incorporated into the Read method of natural childbirth, which replaces fear with knowledge about birth.^[8] Sheila

Kitzinger,^[2] in her method of prepared childbirth, similarly emphasizes the necessity of "acquiring knowledge and understanding of what labor involves, the terminology used by obstetricians and midwives, and information about what happens in hospitals".

A study by Stevens & Heide^[35] conducted at the University of Wisconsin used ice-water to test perception and endurance of pain in subjects who had been taught methods used in childbirth education classes. The controls for this training and an additional control group offered only distraction during the tests. Those who had been taught the techniques reported only about half the pain of the controls and endured it 2.5 times longer. The prepared childbirth strategies improved with practice, were effective for pain lasting longer than most contractions in labor, and were more effective than distraction techniques.^[44] However, this later finding introduces some confusion, since some prepared childbirth methods include either distraction techniques or some other deliberate disposition of one's attention.

Attention-focusing

Distraction of focused attention, mostly utilizing the rhythms of the breath, is essential to the Lamaze method, the most popular prepared childbirth program in America, and important in the Bradley and other methods. Sheila Kitzinger describes the controlled attention focusing as:^[2]

... concentration on what is happening, one's response to it as a task, and visualization of what is being achieved by the work of the uterus during contractions. The focus may be on the fantasy of the contractions as a shape provided by actual objects (furniture, architectural details, flowers, a painting) in the room, or a combination of these factors.

Stevens & Heide^[44] found that attention-focusing functions effectively as an analgesia for labor pain. Such strategies are strongly supported by much psychological research. The focus may be on a competing response, as in the Kanfer & Goldfoot^[45] study showing that when attention was directed to self-presented external slides, individuals were able to increase their tolerance of the pain of cold water. Focus on a competing response is also shown in the use of hypnosis as an analgesic and in the meditative states of Raj yogis, who pinpoint attention on the tip of their nose or a point on the back of their skull, and then do not react physiologically to cold water, bright lights, or sudden sounds.^[46] ^[47] Other adepts in unusual feats of pain tolerance, such as having spikes stuck through their skin, either maintain an unfocused attitude, without evaluation, or pinpoint attention totally on the pain, but without evaluation.^[48] In such cases, the attitude of detachment from the pain can be reflected by an undisturbed EEG pattern of alpha or beta waves throughout performance of the feat.

Relaxation training

Relaxation training is another essential element of pain control, and is found in all childbirth training programs. A considerable body of literature supports its importance in pain control, since a state of lowered autonomic arousal is incompatible with anxiety. While progressive muscular relaxation, systematic desensitization, and autogenic training are all well-established physiological approaches to muscular relaxation, meditation traditions provide quicker methods to achieve what Benson^[49] has called, the "relaxation response". One of the simplest meditation practices – maintaining a focal

awareness of the flow of the breath – is taught by Rahima Baldwin in *Special Delivery* and is identical to the ancient Buddhist practice of *vipassana* or insight meditation.

Hypnosis

Hypnosis or auto-hypnosis is another method utilized to induce deep relaxation for pain control. It incorporates many of the therapeutic elements already referred to – focused attention, positive expectation, and a supportive or permissive attitude – in making suggestions that alleviate anxiety. Thus, its success in pain management may be viewed from a cognitive-behavioral perspective.^[50] In one technique, “glove anesthesia” is induced in one hand and the “numb, heavy wooden feeling” so produced is transferred to the other hand, the face, and eventually to the abdomen in order to “relieve the discomfort” of uterine contractions (the word “pain” is never used, as this would be countersuggestive).^[51]

Control of environmental stress

Kitzinger^[2] cites animal research to show how environmental stress can interfere with the physiological processes of labor and delivery. Education for childbirth therefore promotes verbal and non-verbal support from husband, obstetrician, midwife or anyone else who is part of the birthing environment. Touch relaxation and coaching techniques combine the essential elements of relaxation, massage counter-stimulus, and the direct supportive communication of a partner.^[8]

Several studies agree that comfort in labor is also enhanced by a more vertical position such as the squatting posture that is adopted in many other cultures.^{[52] [53] [54]}

Counter-stimulus methods: massage, acupuncture, TENS

The hand reflexology method of grasping combs during labor to activate points on the fingertips and balls of the hand that relate to uterine functioning is one example of counter-stimulus strategy.^[8] Foot reflexology, acupressure,

acupuncture and transcutaneous electrical nerve stimulation (TENS) might also share a common autonomic nervous mode of operation.

Transcutaneous electrical nerve stimulation (TENS)

The use of TENS to control pain during delivery has been evaluated by several studies. The method used in a Swedish study, which was subsequently replicated in Germany and Britain, was originally developed in the US by Shealy for the control of acute and chronic pain.^{[55] [56]} Generally, the electrodes are placed over the painful area in order to stimulate the cutaneous nerves in that area. For use in labor, four electrodes are placed

on either side of the midline of the spine to stimulate the posterior primary rami of the spinal segments (T11–L1 and S2–S4) receiving the painful stimuli during labor (it is interesting to note that these are the loci of acupuncture points (BL-20, BL-27, and BL-28) which are traditionally thought to reflect female reproductive function).

The selection of this area for stimulation is based on Bonica's account of the neurological mechanism of delivery pain.^[57] During the first stage, pain receptors are assumed to be activated by contractions of the uterus and dilation of the cervix. The evoked impulses are mediated in afferents which run in the hypogastric nerves and reach the spinal cord via the dorsal roots T10–L1. The pain is referred to large areas of the abdomen and back. During the second stage, pain is also caused by distension and stretching of the delivery canal, the pelvic floor, the vulva, and the perineum. The pain is localized, and the impulses reach the spinal cord mainly via the pudendal nerves and the dorsal roots S2–S4. The pain during the first stage is characterized as an ache considered to be mediated in small-diameter C fibers. During the second stage, the pain has the more localized intensive nature usually identified with the delta-afferent fibers.^[57]
^[58]

In the typical application of this technique for control of pain during labor, low-intensity stimulation is given continuously and a high-intensity stimulation could be initiated by the parturient herself whenever pain increased. Stimulation via the thoracic electrodes is maintained throughout the delivery at an amplitude that is maximal for a pleasant sensation, whereas sacral stimulation is added from the later part of the first stage. [Table 56.1](#) summarizes the uniformly good results which have been reported.

It has been especially appreciated by those patients who complained of backache. An Austrian study compared the analgesic effects of TENS, pethidine and placebos on labor pain in 30 parturient women during the first stage of labor. No significant difference was found between the placebo, unspecific TENS, and control groups in the increase in pain during the test period.

TABLE 56-1 -- The results of the use of TENS for pain control in labor

| Study | <i>n</i> | Good(%) | Moderate(%) | None(%) |
|------------------------------------|----------|---------|-------------|---------|
| Augustinsson et al ^[55] | 147 | 44 | 44 | 12 |
| Andersson et al ^[59] | 27 | 48 | 37 | 15 |
| Kanfer & Goldfoot ^[45] | 35 | 20 | 62 | 18 |
| Stewart ^[60] | 67 | 31 | 56 | 13 |
| Kubista et al ^[61] | 102 | 55 | 24 | 21 |
| Bundsen et al ^[62] | 347 | 47 | 42 | 11 |

Patients who had received pethidine and those who had been given TENS experienced considerable relief of pain.^[63] It is curious that apart from a passing reference by Shealy to its use in labor, no research on its obstetric application appeared for many years in any of the US literature. A 1996 review of 30 studies on TENS stimulation of acupuncture points in labor substantiated the conclusions of earlier research.^[64]

In view of the relatively good results and lack of complications, the consensus of all the above studies is that the TENS method is recommended as a primary pain-relieving measure, to which conventional methods can be added as needed. Robson^[65] comments that TENS is non-invasive and is believed to be safe for both mother and baby. It is easy to apply and can be operated throughout labor by doctor, midwife, father, or mother. Augustinsson et al^[55] were most impressed by the lack of complications, since the conventional methods, including analgesic and sedative drugs, N₂ O inhalation, epidural anesthesia and local blockades, all possess a varying degree of potential risks.^[55] Another advantage is that TENS, since it does not give complete analgesia, does not eliminate pain as a diagnostic tool; it can be interrupted whenever needed for clinical evaluation. More importantly, perhaps, from the point of view of the woman in labor is the fact that her consciousness is not altered to the point of excluding her own active participation in, and experience of, the delivery.

Both Stewart^[60] and Augustinsson et al^[55] reported the method to be inadequate alone for analgesia in the second stage of labor. Augustinsson et al see this difference as possible support for the assumption that C fiber-mediated pain is more amenable to blocking by electrical stimulation than is A fiber-mediated pain. Stewart mentions simply that many patients did not wish to use the stimulator at that time as it proved a distraction from their efforts to bear down. In this connection, it is interesting to note that “those who were well prepared and keen on natural childbirth were not always the most enthusiastic and, in fact, two of the early failures were patients who had been to relaxation classes.”^[60] Robson^[65] explains that TENS could distract some patients from their breathing or other focus of attention learned in courses.

A related issue in the TENS literature is introduced by the comment of Andersson et al^[59] that there was a correlation between the degree of hypnotisability and pain relief in their subjects. Such a correlation may, of course, imply only a susceptibility to any type of therapeutic effect. Neumark et al^[63] tested this effect by including a placebo group that was given no current through the electrodes, and found that the result for the placebo group was not different from TENS applied non-specifically (i.e. incorrectly), but was significantly different from the effect of TENS placed over the relevant nerve distribution and from that of pethidine. Robson,^[65] while making no attempt to assess a patient's degree of susceptibility to hypnosis, switched off the machine for at least two contractions. All patients asked for it to be switched on again, indicating that the technique was providing pain relief. Augustinsson et al^[55] consider the suggestive effect, if it occurs, to be of minor significance, since several investigators have found the pain-reducing effect of TENS to be achieved through demonstrable neurophysiological mechanisms. Stewart^[60] points out that the increased personal contact between patient and attendant essential to the use of this method may introduce an element of suggestibility or distraction affecting the pain experience.

Acupuncture

Hundreds of studies have investigated the efficacy and mechanisms of acupuncture analgesia for acute and chronic pain, in surgical operations, and in childbirth. In a review article of 24 studies, Lewith & Machin^[66] found that the typical clinical trial showed a 70% efficacy when compared with placebo treatment. Reichmanis & Becker^[67] found similar results in a review of 17 studies of acupuncture analgesia in experimentally induced pain. At the same time, somatosensory EEG-evoked potential studies have provided objective evidence of the analgesic effect of acupuncture.^{[68] [69] [70]}

Hyodo & Gega^[10] of the Osaka Medical College have reviewed the literature (summarized in [Table 56.2](#)) on acupuncture anesthesia and analgesia in normal delivery and found mixed results. For example, Wallis et al^[72] reported that while 19 of the 21 volunteer parturients

TABLE 56-2 -- Results of acupuncture analgesia in the control of labor pain

| Study | n | Good(%) | Poor or none(%) |
|----------------------------------|----|---------|-----------------|
| Hyodo & Gega ^[10] | | | |
| Primipara | 16 | 62.5 | 37.5 |
| Multipara | 16 | 93.7 | 7.3 |
| Ito ^[71] | 80 | 85 | 15 |
| Wallis et al ^[72] | | 9–33 | 67–91 |
| Abouleish & Depp ^[73] | | 80.5 | 19.5 |

considered acupuncture unsuccessful in providing analgesia for labor, one-third of them indicated that they would choose acupuncture analgesia in labor again. Some authors criticize the technique as being inconsistent, unpredictable, incomplete, time-consuming, and interfering with movement and electronic monitoring.

In their own study, Hyodo & Gega^[10] tested 32 patients, equally divided between primiparas and multiparas. Low-frequency electrical current was introduced through needles at LI-4, ST-36, and SP-6, a standard therapeutic repertory for sedation of the reproductive organs. The result, as assessed by relief noted by the patient as well as by the obstetrician's observation, was 62.5% finding good or excellent effect on the subjective scale, and 62.6% good or excellent on the objective scale among the primipara; and 93.8% subjective relief, and 93.7% objective relief among the multipara. Overall, 90% of the cases experienced relief of pain within 20 minutes of initiation of acupuncture anesthesia. They noted the considerable disparity in reports of effectiveness of acupuncture from Japan and America, and explained it as a novelty effect:

It is natural that in Japan, where no analgesic methods are normally used, the scoring in favor of acupuncture will be high compared with that in

America.

They concluded that it is useful for delivery, especially because of its safety, despite more erratic and less potent results than conventional anesthetic techniques.^[10]

A considerable amount of research has focused on determining a mechanism for acupuncture analgesia. A 1995 review of studies on acupuncture effects in pain and disease pointed out that, like exercise, acupuncture produces rhythmic discharges in nerve fibers and causes the release of endogenous opioids and oxytocin. Furthermore, “experimental and clinical evidence suggests that acupuncture may affect the sympathetic system via mechanisms of the hypothalamic and brain-stem levels”.^[74] Animal studies continue to demonstrate that acupuncture analgesia is mediated in the central and peripheral nervous systems by opioid peptides.^{[75] [76] [77]} The cortex and hippocampus appear to participate in the modulation of chronic pain, and the analgesic action of electroacupuncture seems to operate along this pathway.^[76] A study carried out on dogs seems to verify the traditional theory of points of tonification and sedation, by differential production of sympathomimetic and parasympathomimetic effects on the cardiovascular system upon stimulation of different points.

In a study of labor induction and inhibition by electroacupuncture, Tsuei et al^[78] utilized SP-6 and SP-4 points, located in the territory of the L-4 dermatome. The spleen meridian, to which these loci belong, runs across the dermatomes of L-4, L-5, L-2, and L-1, and then upward from T-12 to T-5. Since the sympathetic nerve controlling the uterus through the pelvic plexus receives

preganglionic fibers from T-5 to L-4, Tsuei et al concluded that it is highly possible that stimulation of the electropermeable loci within this area may alter the physiologic function of the uterus.^[78] The LI-4 points of the upper extremities, often added to the spleen meridian points in the acupunctural control of labor pain, perhaps represent the central approach to the autonomic nervous system, since these loci control pain to the head and neck. It should be noted, however, that Motoyama^[79] has attempted to verify the traditional subtle anatomy of meridian pathways through tests of electrocutaneous resistance at meridian points, and claims that these effects cannot be adequately explained in terms of the conventional sympathetic dermatomes, but imply an alternative bioelectric transmission system.

The discovery of the Head McKenzie sensory zones has shown the possible mediation of the invisible meridians and points of traditional Eastern medicine between internal organs and corresponding skin areas. Nakatani^[80] was able to detect the electropermeable line as an apparent viscerocutaneous autonomic nerve reflex when organic diseases are involved. Hyodo^[81] has explained acupuncture stimulation as the transmission of impulses centrally from the reactive electropermeable loci, via a sympathetic afferent fiber, and the autonomic nerve in the viscera is stimulated to

response by the reverse of the McKenzie theory.

CONCLUSION

This chapter has presented many of the current non-pharmacological strategies for control of pain. Since the mechanism of pain perception has been shown to involve both physiological and psychological components, the optimal treatment might combine psychological factors of preparatory information, attention focus, relaxation, and supportive communication, in conjunction with the physical stimuli of transcutaneous electrical nerve stimulation or acupuncture. In fact, such a multidisciplinary approach to patients with chronic back pain was evaluated following a 4 week program which included back schooling, psychological intervention, and treatment by acupuncture, chiropractic, the Alexander technique and a pain specialist. Significant improvement was maintained for a period of 6 months.^[82] The selection, balance, and application of these treatment components should be based on consideration of an individual's coping styles. Such a treatment program could be developed to provide a more consistently effective analgesia than the individual components can provide separately. Relieving the pain of childbirth, for example, without diminishing or distorting the full consciousness of the experience for the mother, would be consistent with the goals of the contemporary physician of natural medicine.

Chapter 57 - Role of dietary fiber in health and disease

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

INTRODUCTION

The appreciation of the role of diet in determining the level of health continues to grow. A substantial body of research has now well established that certain dietary practices cause, as well as prevent, a wide range of diseases. In addition, the research is now showing that certain diets and foods can provide immediate therapeutic benefit.

This chapter discusses the major diseases of Western society and how they relate to one key component of the diet: dietary fiber. The dietary fiber hypothesis has two basic components:

- a diet rich in foods which contain plant cell walls(i.e. whole grains, legumes, fruits, and vegetables) is protective against a wide variety of diseases, in particular those that are prevalent in Western society
- a diet providing a low intake of plant cell walls is a causative factor in the etiology of these diseases and provides conditions under which other etiological factors are more active.

The term “Western diet” is used throughout this chapter, as well as in many other parts of the textbook. It refers to the typical diet of Western peoples, also referred to as “foods of commerce”. It consists of a high intake of refined carbohydrates, saturated fats, processed foods, salt and cholesterol, and an extremely low intake of dietary fiber.

The primitive diet

Detailed anatomical and historical evidence suggests that humans evolved as “hunter-gatherers” i.e. humans appear to be omnivores capable of surviving on both gathered (plant) and hunted (animal) foods.^[4] However, while the human gastrointestinal tract is capable of digesting both animal and plant foods, there are indications that it

functions better with plant foods.^[2] There is a tremendous amount of evidence showing that

deviating from a predominantly plant-based diet is a major factor in the development of heart disease, cancer, strokes, arthritis, and many other chronic degenerative diseases. It is now the recommendation of many health and medical organizations that the human diet should focus primarily on plant-based foods – vegetables, fruits, grains, legumes, nuts, seeds, etc. Such a diet is thought to offer significant protection against the development of chronic degenerative disease.^{[3] [4] [5]}

DIETARY FIBER AND CHRONIC DEGENERATIVE DISEASE

The belief in the beneficial effects of fiber in the diet goes back to at least 1585. However, the link between dietary fiber and chronic disease in the medical literature originated to a great extent from the work of two medical pioneers, Denis Burkitt MD and Hugh Trowell MD, authors of *Western diseases: their emergence and prevention*, which was first published in 1981.^[3] Based on extensive studies examining the rate of diseases in various populations (epidemiological data) and his own observations of primitive cultures, Burkitt formulated the following sequence of events:

- *First stage.* The primal diet of plant eaters contains large amounts of unprocessed starch staples; there are few examples of chronic degenerative diseases like osteoarthritis, heart disease, diabetes, and cancer.
- *Second stage.* Commencing Westernization of diet, obesity and diabetes commonly appear in privileged groups.
- *Third stage.* With moderate Westernization of the diet, constipation, hemorrhoids, varicose veins, and appendicitis become common complaints.
- *Fourth stage.* Finally, with full Westernization of the diet, chronic degenerative diseases like osteoarthritis, rheumatoid arthritis, gout, heart disease, cancer, etc. are extremely common.

Although now extremely well-recognized, the work of Burkitt and Trowell is actually a continuation of the landmark work of Weston A. Price, a dentist and author of *Nutrition and physical degeneration*.^[6] In the early 1900s, Dr Price traveled the world observing changes in teeth and palate (orthodontic) structure as various cultures discarded traditional dietary practices in favor of a more “civilized” diet. Price was able to follow individuals as well as cultures over periods of 20–40 years, and carefully documented the onset of degenerative diseases as their diets became more Westernized.

It is now well documented that diet is the major factor responsible for many chronic degenerative diseases. In 1984, the National Research Council’s Food and Nutrition Board established the Committee on Diet and Health and undertook a comprehensive analysis on diet and

TABLE 57-1 -- Diseases highly associated with a low-fiber diet

major chronic diseases. [5] It is the Food and Nutrition Board which develops the Recommended Dietary Allowance (RDA) guidelines on the desirable amounts of essential nutrients in the diet. Their findings, as well as those of the US Surgeon General and other research groups, have brought to the forefront the need for Americans to change their eating habits to reduce their risk for chronic disease. [Table 57.1](#) lists diseases with convincing links to a diet low in dietary fiber and plant foods. Many of these now common diseases were extremely rare before the 20th century.

Trends in US food consumption

During this century, food consumption patterns have changed dramatically: total dietary fat intake has increased from 32% of the calories in 1909 to 43% in 1985; overall carbohydrate intake dropped from 57 to 46%; and protein intake has remained fairly stable at about 11%. [5] Compounding these detrimental changes are the individual food choices accounting for the changes. There has been a rise in the consumption of meat, fats and oils, and sugars and sweeteners, in conjunction with the decreased consumption of non-citrus fruits, vegetables, potatoes, and grain products. These changes have resulted in the percentage of calories from starches or complex carbohydrates, as found naturally occurring in grains and vegetables, to drop from 68% in 1909 to 47% in 1980. Currently, more than half of the carbohydrates being consumed are in the form of sugars (sucrose, corn syrup, etc.) being added to foods as sweetening agents. High consumption of refined sugars is linked to many chronic diseases, including obesity, diabetes, heart disease, and cancer.

DEFINITION AND COMPOSITION OF DIETARY FIBER

Generally, the term “dietary fiber” refers to the components of plant cell wall and non-nutritive residues. Originally, the definition was restricted to substances that are not digestible by the endogenous secretions of the human digestive tract. This latter definition is specious, since it depends on an exact understanding of what exactly is not digestible.

TABLE 57-2 -- Dietary fiber constituents of the food groups

| Food group | Main dietary fibers |
|------------------------------------|---|
| Fruits and vegetables | Cellulose, hemicellulose, lignin, pectic substances, cutin, waxes |
| Grains | Cellulose, hemicellulose, lignin, phenolic esters |
| Seeds (other than grains) | Cellulose, hemicellulose, pectic substances, guar endosperm |
| Seed husk of <i>Plantago ovata</i> | Arabinogalacturonosyl-phamno-xylan (mucilage) |
| Food additives | Gum arabic, alginate, carrageenan, carboxymethylcellulose |

TABLE 57-3 -- Classification of dietary fiber

| Fiber class | Chemical structure | Plant part | Food sources | Physiological effect |
|-----------------------------------|---|--------------------------------|--------------------------------|--|
| I. Cellulose | Unbranched 1-4-beta-D-glucose polymer | Principal plant wall component | Wheat bran | Increases fecal weight and size |
| II. Non-cellulose polysaccharides | | | | |
| A. Hemicelluloses | Mixture of pentose and hexose molecules in branching chains | Plant cell walls | Oat bran | Increases fecal weight and size, binds bile acids |
| B. Gums | Branched chain uronic acid containing polymers | | Karaya, gum arabic | Laxative |
| C. Mucilages | Similar to hemicelluloses | Endosperm of plant seeds | Guar, legumes, psyllium | Hydrocolloids that bind steroids and delay gastric emptying, heavy metal chelation |
| D. Pectins | Mixture of methyl esterified galacturan, galactan, and arabinose in varying proportions | | Citrus rind, apple, onion skin | As above |
| E. Algal polysaccharides | Polymerized D-mannuronic acid and L-glucuronic acid | | Algin, agar, carrageenan | As above |

| | | | | |
|--------------|--|---------------------|---|---------------------------------|
| III. Lignins | Non-carbohydrate polymeric phenylpropene | Woody part of plant | Wood (40–50%), wheat (25%), apple (25%), cabbage (6%) | Antioxidants, anti-carcinogenic |
|--------------|--|---------------------|---|---------------------------------|

The composition of the plant cell wall varies according to the species of plant. Typically, the dry cell wall contains 35% cellulose, 45% non-cellulose polysaccharides, 17% lignins, 3% protein, and 2% ash.^{[7] [8] [9]} It is important to recognize that dietary fiber is a complex of these constituents, and supplementation of a single component does not substitute for a diet rich in high-fiber foods. However, in some clinical conditions the use of specific components is a useful adjunct to a healthy diet. [Tables 57.2](#) and [57.3](#) summarize the classifications of dietary fibers.

Cellulose

The best known dietary fiber component is cellulose. This unbranched 1–4-beta-D-glucose polymer ranges in size from 3,000 to 100,000 glucose units. It is a relatively insoluble, hydrophilic material. This ability to bind water accounts for its effect of increasing fecal size and weight. Although undigestible by humans, it is partially degraded by the microflora of the gut. This anaerobic process (fermentation) occurs in the colon, results in the degradation of about 50% of the cellulose, and is an important source of short-chain fatty acids (SCFAs).^{[7] [8]} SCFAs have very important properties in the colon, as discussed below.

Non-cellulose polysaccharides

The majority of polysaccharides in the plant cell wall are a non-cellulose type, i.e. they are water-soluble and possess diverse properties. Included in this class are hemicelluloses, gums, mucilages, algal polysaccharides, and pectin substances.^{[7] [8] [9]}

Hemicelluloses

These compounds contain a mixture of pentose and hexose molecules in branched-chain configurations of much smaller size than cellulose. Their ability to increase fecal weight is dependent on the pentose fraction. The hemicelluloses are also an important source of SCFAs via bacterial degradation.^{[7] [8] [9]}

Pectin and pectin-like substances

Pectins are found in all plant cell walls as well as in the outer skin and rind of fruits and vegetables. For example,

the rind of an orange contains 30% pectin; an apple peel 15%; and onion skins 12%. The gel-forming properties of pectin are well known to anyone who has made a jelly or jam. These same gel-forming qualities are responsible for the cholesterol-lowering effects of pectins. Pectins lower cholesterol by binding the cholesterol and bile acids in the gut and promoting their excretion.^{[7] [8] [9]}

Gums

Plant gums are a complex group of water-soluble, branched-chain, uronic acid-containing polymers. They are produced by the plant in response to injury, and are commercially produced by incising a plant or tree and collecting the fluid extract. Gums are used as emulsifiers, thickeners, and stabilizers by the food industry and as laxatives in pharmaceuticals.^{[7] [8] [9]}

Mucilages

Structurally, mucilages resemble the hemicelluloses, but they are not classed as such due to their unique location in the seed portion of the plant. They are generally mixed with the endosperm of the plant seeds, where they retain water, preventing seed desiccation.

Guar gum, found in leguminous plants, is the most widely studied mucilage. It is isolated from the endosperm of *Cyamopsis tetragonolobus*, a plant cultivated in India for livestock feed. It is used commercially as a protective colloid, stabilizer, thickening and film-forming agent for paper sizing, cheese, salad dressings, ice cream, soups, toothpaste, pharmaceutical jelly, lotion, skin cream, and tablets. It is also used as a laxative. Guar gum and other mucilages are perhaps the most potent cholesterol-lowering agents of the gel-forming hydrocolloids, including pectin and glucomannan. Guar gum has been shown to reduce fasting and postprandial glucose and insulin levels in both healthy and diabetic subjects; and it has decreased body weight and hunger ratings when taken with meals by obese subjects. Psyllium seed husk (*Plantago ovata*) is another example of a mucilage which is widely used as a bulking and laxative agent.^{[7] [8]}

Algal polysaccharides

Included in this category are alginic acid, agar, and carrageenan. Marine-derived polysaccharides are used extensively by the food industry. Alginate has been shown to inhibit heavy metal uptake in the gut, as do other gel-forming fibers. Agar is used as a thickening agent and as a gel for holding microbiological media. It has laxative and fecal bulk-increasing activity.^{[7] [8]}

Carrageenan is used in milk and chocolate products due to its ability to react with milk proteins. However, unlike other plant polysaccharides, it adversely affects the intestinal

mucosa.^[7] ^[8] It has been shown in rats to induce ulcer formation in the cecum, due to the promotion of mucosal macrophage release of lysosomal enzymes. Other rat studies have shown carrageenan to enhance carcinogen induction of neoplasia, colorectal carcinoma, birth defects, and hepatomegaly.^[10]

Lignins and lignans

Lignins are composed of aromatic polymers of coniferyl, para-coumaryl, and sinapyl alcohols in varying ratios. Vanillin (artificial vanilla) and other aromatic chemicals are synthesized from lignins. Lignans are fiber compounds related to lignins that are typically composed of cinnamic acid, cinnamyl alcohol, propenylbenzene, and allylbenzene precursor units. Many plant lignans show important properties, such as anticancer, antibacterial, antifungal, and antiviral activity. Plant lignins are metabolized by the gut flora into the animal lignins enterolactone and enterodiol, both of which possess anti-estrogenic activity and are believed to be protective against cancer.^[11]

Phytic acid

In the plant, phytic acid (inositol hexaphosphoric acid) is responsible for storing minerals such as calcium, phosphorus, magnesium, and potassium. There is some concern that phytates can adversely affect the uptake and utilization of many minerals, including calcium, iron, and zinc. The major sources of phytate in the diet are cereal grains and legumes (see [Table 57.4](#)). Phytate is destroyed by heat and by the enzyme phytase during the leavening of bread.^[7] ^[8]

Phytic acid exerts impressive antioxidant and antitumor effects.^[12] ^[13] ^[14] When administered in drinking water or injected, phytic acid has demonstrated a consistent antitumor effect in animals against colon cancer and fibrosarcomas. Clinical trials in humans are in preparation.

TABLE 57-4 -- Occurrence of phytic acid in plant tissues

| Plant phytic acid | Percentage dry weight |
|--------------------------|------------------------------|
| Soybeans | 1.4 |
| Wheat | 0.9 |
| Corn | 1.1 |
| Rice | 0.9 |
| Peanuts | 1.9 |
| Sesame seeds | 5.4 |
| Lima beans | 2.5 |
| Barley | 1.0 |
| Oats | 0.8 |

TABLE 57-5 -- Beneficial effects of dietary fiber

| |
|--|
| • Decreased intestinal transit time |
| • Delayed gastric emptying resulting in reduced postprandial hyperglycemia |
| • Increased satiety |
| • Increased pancreatic secretion |
| • Increased stool weight |
| • More advantageous intestinal microflora |
| • Increased production of short-chain fatty acids |
| • Decreased serum lipids |
| • More soluble bile |

PHYSIOLOGICAL EFFECTS OF DIETARY FIBER

It is beyond the scope of this chapter to detail all known effects of dietary fiber on humans. Instead, we will cover effects of greatest clinical significance (stool weight, transit time, digestion, colon function, short-chain fatty acids, and colon flora). Beneficial effects of dietary fiber are given in [Table 57.5](#).

Stool weight and transit time

Fiber has long been used in the treatment of constipation. Dietary fiber, particularly the water-insoluble, hydrophilic fibers such as cellulose (e.g. bran), increases stool weight as a result of their water-holding properties.^{[7] [8] [9]} Transit time, the time taken for passage of material from the mouth to the anus, is greatly reduced on a high-fiber diet. Cultures consuming a high-fiber diet (100–170 g/day) usually have a transit time of 30 hours and a fecal weight of 500 g. In contrast, Europeans and Americans who eat a typical, low-fiber diet (20 g/day) have a transit time of greater than 48 hours and a fecal weight of only 100 g.^{[3] [15]} Interestingly, when fiber is added to the diet of subjects with abnormally rapid transit times (less than 24 hours) it causes slowing of the transit time.^{[7] [8]}

Dietary fiber's effect on transit time is apparently directly related to its effect on stool weight and size. A larger, bulkier stool passes through the colon more easily, requires less intraluminal pressure, and subsequently less straining.^{[1] [2] [3] [4]} It has been hypothesized that the decreased intraluminal pressure (due to the greater leverage the colon mucosa has on a larger stool) results in less hydrostatic stress on the colon wall

and therefore avoids the ballooning effect, which results in diverticuli.

The increased intestinal transit time associated with the Western diet allows prolonged exposure of various compounds, both natural and man-made, to the intestinal flora, resulting in increased conversion to potential carcinogens.^{[3] [4] [7] [8]}

Digestion

Although dietary fiber increases the rate of transit through the GI tract, it slows gastric emptying, thus reducing postprandial hyperglycemia in both normal and diabetic subjects.^{[7] [8]} Pancreatic enzyme secretion and activity also increase in response to fiber, although excessive levels of fiber (greater than 10% of the meal by weight) have a converse effect.^[16] A number of research studies have examined the effects of fiber on mineral absorption. Although the results have been somewhat contradictory, it now appears that large amounts of dietary fiber may result in impaired absorption and/or negative balance of some minerals. While fiber as a dietary component does not appear to interfere with the minerals in other foods, supplemental fiber, especially hemicelluloses, may result in a negative mineral balance.^{[2] [3] [4]}

Short-chain fatty acids (SCFAs)

The fermentation of dietary fiber by the intestinal flora produces three main end products:

- short-chain fatty acids
- various gases
- energy.

The SCFAs, acetic, propionic, and butyric acids, are the main anions in the large intestine and have many important physiological functions. For every 20 g of fiber consumed each day, approximately 200 mmol of SCFAs will be produced, of which 62 will be acetate, 25 propionate, and 16 butyrate.^[8]

Propionate and acetate are transported directly to the liver and utilized for energy production, while butyrate provides an important energy source for the colonic mucosa. In fact, butyrate is the preferred substrate for energy metabolism in the distal colon.^{[7] [8]} Butyrate production may also be responsible for the anti-cancer properties of dietary fiber.^{[7] [8] [17]} Even at extremely low concentrations, butyrate has been shown, in vitro, to profoundly affect gene expression and other nucleic processes, such as DNA synthesis, resulting in suppressed cell proliferation in both normal and malignant cells. Butyrate causes trophic effects on normal colonocytes, stops the growth of neoplastic colonocytes, inhibits the pre-neoplastic hyperproliferation induced by certain tumor promoters in vitro, inhibits the expression of certain protooncogenes and causes differentiation of colon cancer cell lines.^[18] Some of these effects are due to the acetylation of histones and the stabilization of the chromatin structure. Short-chain fatty acids are exhibiting impressive anti-cancer results in both animal and human experiments.^[17] Butyrate is also being used in enemas in the treatment of ulcerative

colitis.

Certain fibers appear to be more effective than others in increasing the levels of SCFAs in the colon. Pectins (both apple and citrus, guar gum and other legume fibers) and vegetable fiber isolates produce more SCFAs than wheat fiber, corn fiber or oat bran.^[7]^[8]

Intestinal bacterial flora

Dietary fiber appears to improve all aspects of colon function. Of central importance is the role it plays in maintaining a “suitable” colonic bacterial flora. A low-fiber intake is associated with both an overgrowth of Enterobacteriaceae and other endotoxin-producing bacteria and a lower percentage of *Lactobacillus* and other acidophilic bacteria.^[7]^[8] A diet high in dietary fiber promotes acidophilic bacteria through the increased synthesis of colonic SCFAs, which reduces the colon pH, a condition conducive to the growth of beneficial bacteria.

DISEASES ASSOCIATED WITH A LOW-FIBER DIET

Because of the important physiological effects of dietary fiber, a diet low in dietary fiber will obviously lead to altered physiology or disease. The diseases with the strongest correlation with a lack of dietary fiber are diseases of the colon and gastrointestinal tract, heart disease and gallstones, obesity, and diabetes. Each of these will be briefly discussed below.

Diseases of the colon and gastrointestinal disorders

The epidemiological and experimental data documenting the protective effect of dietary fiber on colon cancer are overwhelming. There is evidence for similar strong links with other common diseases of the colon – diverticulitis, diverticulosis, irritable bowel syndrome, ulcerative colitis, and appendicitis as well as hemorrhoids, peptic ulcers, and hiatal hernia.^[3]^[4]^[7]^[8] Furthermore, these very same diseases will often respond to a high fiber diet.

Heart disease and gallstones

Dietary fiber has been shown to be quite protective against heart disease and gallstones. A diet high in dietary fiber is known to reduce total cholesterol and triglyceride levels while increasing HDL-cholesterol levels and the production and storage of less saturated bile acids.^[3]^[4]^[7]^[8]

The binding of bile acids and micellar components to various grains, food fibers, and isolated fiber compounds results in the reduction of the enterohepatic circulation of bile

salts and cholesterol. Loss of cholesterol and bile salts through the feces is the major pathway for elimination of these compounds from the body. Dietary fiber also decreases cholesterol biosynthesis and increases the conversion of cholesterol to the bile acids via activation of the vitamin C-dependent enzyme 7-alpha-hydroxylase, the rate-limiting step in bile acid synthesis.^{[7] [8]} This enhancement of bile acid synthesis and excretion is the result of dietary fiber's preferential binding of deoxycholic acid, resulting in a compensatory increase in circulating levels of chenodeoxycholic acid. Chenodeoxycholic acid has been shown to inhibit cholesterol absorption and synthesis at its rate-limiting enzyme HMG-CoA reductase.^[8] Binding of chenodeoxycholic acid by dietary fiber results in an increase in the taurocholate to glycocholate ratio. The ultimate result of these alterations in bile salt concentrations and ratios is a less saturated bile which solubilizes cholesterol more effectively and is resistant to stone formation.

Obesity

A dietary fiber-deficient diet is an important etiological factor in the development of obesity.^{[3] [4] [7] [8]} Dietary fiber plays a role in preventing obesity by:

- increasing the amount of necessary chewing, thus slowing the eating process
- increasing fecal caloric loss
- altering digestive hormone secretion
- improving glucose tolerance
- inducing satiety by increased gastric filling, stimulation of cholecystokinin release, and intestinal bulking action.

Other effects of dietary fiber on obesity are discussed below under diabetes mellitus – 60–90% of type II diabetics are obese.

Diabetes mellitus

Epidemiological and experimental data show diabetes mellitus to be one of the diseases most clearly related to inadequate dietary fiber intake.^{[3] [4] [7] [8]} Clinical trials that have demonstrated the beneficial therapeutic effect of dietary fiber on diabetes have further substantiated this association (discussed below). Dietary fiber's prevention and modulation of diabetes is due to its effects on glucose and, subsequently, insulin levels. A high-complex carbohydrate, high-fiber diet reduces postprandial hyperglycemia (largely by delaying of gastric emptying and thereby reducing insulin secretion) and increases tissue sensitivity to insulin (how, or if, this relates to chromium uptake and metabolism has not been determined).^{[7] [8]} Fermentation products of fiber, chiefly SCFAs, enhance hepatic glucose metabolism and may further contribute to the ameliorating effects of dietary fiber on diabetes.

CLINICAL USE OF DIETARY FIBER

The best and most cost-effective way of using dietary fiber in a clinical setting is via encouraging a diet rich in plant foods (see [Table 57.6](#) for the dietary fiber content of

selected foods). A good goal for dietary fiber intake

TABLE 57-6 -- Dietary fiber content of selected foods

| Food | Serving | Calories | Grams of fiber |
|----------------------------|----------------|-----------------|-----------------------|
| <i>Fruits</i> | | | |
| Apple (with skin) | 1 medium | 81 | 3.5 |
| Banana | 1 medium | 105 | 2.4 |
| Cantaloupe | ¼ melon | 30 | 1.0 |
| Cherries (sweet) | 10 | 49 | 1.2 |
| Grapefruit | ½ medium | 38 | 1.6 |
| Orange | 1 medium | 62 | 2.6 |
| Peach (with skin) | 1 | 37 | 1.9 |
| Pear (with skin) | ½ large | 61 | 3.1 |
| Prunes | 3 | 60 | 3.0 |
| Raisins | ¼ cup | 106 | 3.1 |
| Raspberries | ½ cup | 35 | 3.1 |
| Strawberries | 1 cup | 45 | 3.0 |
| <i>Vegetables (raw)</i> | | | |
| Bean sprouts | ½ cup | 13 | 1.5 |
| Celery (diced) | ½ cup | 10 | 1.1 |
| Cucumber | ½ cup | 8 | 0.4 |
| Lettuce | 1 cup | 10 | 0.9 |
| Mushrooms | ½ cup | 10 | 1.5 |
| Pepper (green) | ½ cup | 9 | 0.5 |
| Spinach | 1 cup | 8 | 1.2 |
| Tomato | 1 medium | 20 | 1.5 |
| <i>Vegetables (cooked)</i> | | | |
| Asparagus (cut) | 1 cup | 30 | 2.0 |
| Beans (green) | 1 cup | 32 | 3.2 |
| Broccoli | 1 cup | 40 | 4.4 |

| | | | |
|-----------------------|----------|-----|-----|
| Brussels sprouts | 1 cup | 56 | 4.6 |
| Cabbage (red) | 1 cup | 30 | 2.8 |
| Carrots | 1 cup | 48 | 4.6 |
| Cauliflower | 1 cup | 28 | 2.2 |
| Corn | ½ cup | 87 | 2.9 |
| Kale | 1 cup | 44 | 2.8 |
| Parsnip | 1 cup | 102 | 5.4 |
| Potato (with skin) | 1 medium | 106 | 2.5 |
| Potato (without skin) | 1 medium | 97 | 1.4 |
| Spinach | 1 cup | 42 | 4.2 |
| Sweet potatoes | 1 medium | 160 | 3.4 |
| Zucchini | 1 cup | 22 | 3.6 |

Legumes

| | | | |
|-----------------------|-------|-----|-----|
| Baked beans | ½ cup | 155 | 8.8 |
| Dried peas (cooked) | ½ cup | 115 | 4.7 |
| Kidney beans (cooked) | ½ cup | 110 | 7.3 |
| Lima beans (cooked) | ½ cup | 64 | 4.5 |
| Lentils (cooked) | ½ cup | 97 | 3.7 |
| Navy beans (cooked) | ½ cup | 112 | 6.0 |

Rice, breads, pastas, and flour

| | | | |
|---------------------------------|------------|-----|-----|
| Bran muffins | 1 muffin | 104 | 2.5 |
| Bread (white) | 1 slice | 78 | 0.4 |
| Bread (whole wheat) | 1 slice | 61 | 1.4 |
| Crisp bread, rye | 2 crackers | 50 | 2.0 |
| Rice, brown (cooked) | ½ cup | 97 | 1.0 |
| Rice, white (cooked) | ½ cup | 82 | 0.2 |
| Spaghetti (reg. cooked) | ½ cup | 155 | 1.1 |
| Spaghetti (whole wheat, cooked) | ½ cup | 155 | 3.9 |

Breakfast cereals

| | | | |
|-----------|-------|----|-----|
| All-Bran | ½ cup | 71 | 8.5 |
| Bran Chex | ? cup | 91 | 4.6 |
| Corn Bran | ? cup | 98 | 5.4 |

| | | | |
|------------------|---------|-----|-----|
| Cornflakes | 1¼ cup | 110 | 0.3 |
| Grape Nuts | ¼ cup | 101 | 1.4 |
| Oatmeal | ¾ cup | 108 | 1.6 |
| Raisin Bran-type | ? cup | 115 | 4.0 |
| Shredded Wheat | ? cup | 102 | 2.6 |
| <i>Nuts</i> | | | |
| Almonds | 10 nuts | 79 | 1.1 |
| Filberts | 10 nuts | 54 | 0.8 |
| Peanuts | 10 nuts | 105 | 1.4 |

is 25–35 g daily. This can easily be achieved if the dietary focus is on whole, unprocessed, plant foods.

In addition to the well-known use of dietary fiber as a laxative, the principle use of supplemental dietary fiber is in the treatment of irritable bowel syndrome and other functional disturbances of the colon, elevated cholesterol levels, and obesity.

The best fiber sources for non-laxative effects are psyllium, guar gum, glucomannan, gum karaya, and pectin, because they are rich in water-soluble fibers. While there are many fiber supplements to choose from, the most clinically effective are those that are rich in water-soluble fiber and low in added sugar or other sweeteners.

Irritable bowel syndrome

The treatment of irritable bowel syndrome (IBS) by increasing the intake of dietary fiber has a long, although irregular, history. In general, consuming a diet rich in complex carbohydrates and dietary fiber while avoiding sugar and refined foods is effective in many cases. The most effective fiber supplements are the water-soluble forms. However, the type of fiber often used in both research and clinical practice is wheat bran.^[4] As wheat is among the most commonly implicated foods in malabsorptive and allergic conditions, the use of wheat bran is usually not indicated in individuals with symptoms of IBS since food allergy is a significant causative factor in this condition. In addition, while patients with constipation are likely to respond to wheat bran, those with diarrhea may actually worsen their symptoms.

Elevated cholesterol levels

A recent review article concluded that soluble-fiber supplementation was very effective in lowering cholesterol levels.^[19] Specifically, a significant reduction in the level of serum total cholesterol was found in 68 of the 77 (88%) studies reviewed. The effect of soluble fiber supplementation was clearly dose-dependent. In other words, the higher the intake of soluble fiber, the greater the reduction in serum cholesterol. The average doses and

reductions noted in clinical trials are shown in [Table 57.7](#) .

Many of the studies utilized oat bran or oatmeal as

TABLE 57-7 -- Cholesterol-lowering effects of various fibers

| Fiber | Dosage (g) | Typical reduction in total cholesterol |
|-----------------|-------------------|---|
| Oat bran (dry) | 50–100 | 20% |
| Guar gum | 9–15 | 10% |
| Pectin | 6–10 | 5% |
| Psyllium | 10–20 | 10–20% |
| Vegetable fiber | 27 | 10% |

the source of fiber. The overwhelming majority of these studies demonstrated that individuals with high cholesterol levels will experience significant reductions with frequent oatmeal or oat bran consumption. In contrast, individuals with normal or low cholesterol levels will experience little change. In individuals with high cholesterol levels (above 220 mg/dl) the consumption of the equivalent of 3 g of soluble oat fiber lowers total cholesterol by 8–23%. This is highly significant as with each 1% drop in serum cholesterol level there is a 2% decrease in the risk of developing heart disease. Three grams of fiber would be provided by approximately one bowl of ready-to-eat oat bran cereal or oat meal. Although oatmeal's fiber content (7%) is less than that of oat bran (15–26%), it has been determined that the polyunsaturated fatty acids contribute as much to the cholesterol-lowering effects of oats as the fiber content. Although oat bran has a higher fiber content, oatmeal is higher in polyunsaturated fatty acids. In practical terms, the dosage level for dry oat bran would be ?–1 cup; for dry oatmeal 1–1? cups.^[19]
^[20]

Obesity

When taken with water before meals, water-soluble fiber sources bind to the water in the stomach to form a gelatinous mass that makes an individual feel full. As a result, they will be less likely to overeat. However, the benefits of fiber go well beyond this mechanical effect. Fiber supplements have been shown to enhance blood sugar control and insulin effects, as well as actually reduce the number of calories absorbed by the intestines.^[7] In some of the clinical studies demonstrating weight loss, fiber supplements were shown to reduce the number of calories absorbed by 30–180 calories/day. Over the course of a year, this could result in a reduction of 3–18 pounds.

The most impressive results in weight loss studies have been achieved with guar gum, a water-soluble fiber obtained from the Indian cluster bean (*Cyamopsis tetragonoloba*). In one study, nine women weighing between 160 and 242 pounds were given 10 g of

guar gum immediately before lunch and dinner. They were told not to consciously alter their eating habits. After 2 months, the women reported an average weight loss of 9.4 pounds – over 1 pound/week. Reductions were also noted for cholesterol and triglyceride levels.^[21] It is estimated that a person will lose 50–100% more weight by supplementing their diet with fiber than by simply restricting calories alone (see [Table 57.8](#) for information on clinical studies of the treatment of obesity with dietary fiber supplements).

Cancer prevention

The body of research documenting the cancer-preventing effects of a high-fiber diet has continued to accumulate. In addition to the epidemiological associations, researchers have now also performed prospective and supplementation studies. Virtually every study has shown a significant protective effect of dietary fiber for a wide range of cancers.

Several recent studies have shown benefit for prevention of breast cancer. One representative study evaluated the association between breast cancer and dietary intake in two Chinese populations (Shanghai and Tianjin) who are at low risk for breast cancer. These populations have one-fifth the rate of breast cancer of US white women. There were two case-controlled studies. In the 834 women studied, the intake of crude fiber, carotene and vitamin C showed a strong significant inverse association with breast cancer risk. The effect was closely associated with the intake of green vegetables. The women in the lowest tertile intake of crude fiber intake and the highest tertile intake of fat intake had a 2.9-fold increased risk for breast cancer relative to those in the highest tertile of crude fiber intake and the lowest tertile of fat intake.^[33]

The same protective effect has also been found in

TABLE 57-8 -- Clinical studies of the treatment of obesity with dietary fiber supplements

| Fiber | Number of subjects | Length of study | Dosage (g/day) | Calorie Restriction | Average weight loss (fiber) (lbs) | Average weight loss (placebo) | Reference |
|-------|--------------------|-----------------|----------------|---------------------|-----------------------------------|-------------------------------|--------------------|
| Guar | 9 | 2 months | 20 | None | 9.4 | No placebo group | 21 |
| Guar | 7 | 1 year | 20 | None | 61.9 | No placebo group | 22 |
| Guar | 21 | 2.5 months | 20 | None | 15.6 | No placebo group | 23 |

| | | | | | | | |
|---------------|----|------------|------|------|------|------------------------|--------------------|
| Guar | 33 | 2.5 months | 15 | None | 5.5 | 0.9 lbs | 24 |
| Glucomannan | 20 | 2 months | 3 | None | 5.5 | Weight gain of 1.5 lbs | 25 |
| Glucomannan | 20 | 2 months | 3 | None | 8.14 | 0.44 lbs | 26 |
| Citrus Pectin | 14 | 4 weeks | 5.56 | Yes | 12.8 | No placebo group | 27 |
| Mixture A | 60 | 12 weeks | 5 | Yes | 18.7 | 14.7 lbs | 28 |
| Mixture A | 89 | 11 weeks | 10 | Yes | 13.9 | 9.2 lbs | 29 |
| Mixture B | 45 | 3 months | 7 | Yes | 13.6 | 9 lbs | 30 |
| Mixture B | 97 | 3 months | 7 | Yes | 10.8 | 7.3 lbs | 31 |
| Mixture B | 52 | 6 months | 7 | Yes | 12.1 | 6.1 lbs | 32 |

Mixture A, 80% fiber from grains/20% fiber from citrus; mixture B, 90% insoluble/10% soluble fiber from beet, barley, and citrus fibers.

fibrocystic disease of the breast. In a study of the diet of 354 women with benign proliferative epithelial disorders of the breast who were compared with 354 matched controls and 189 unmatched controls, an inverse association between dietary fiber and the risk of benign, proliferative, epithelial disorders of the breasts was observed.^[34]

The protective effects of supplemental dietary fiber have now been demonstrated, even in those with previous colon cancer. A total of 411 patients with colorectal adenomas were placed on a 25% fat content diet, supplemented with 25 g of wheat bran daily, and a capsule of 20 mg of beta-carotene daily. Patients with the combination of a low-fat diet and added wheat bran had zero large adenomas at both 2 and 4 years, a statistically significant effect compared to the control group.^[35]

DOSAGE RECOMMENDATIONS

When using dietary fiber supplements, encourage patients to start out with a small dosage and increase gradually. Since water-soluble fibers are fermented by intestinal

bacteria, a great deal of gas can be produced. If the patient is not accustomed to a high-fiber diet, an increase in dietary fiber can lead to increased flatulence and abdominal discomfort. Start out with a dosage between 1 and 2 g before meals and at bedtime and gradually increase the dosage to 5 g.

POSSIBLE ADVERSE EFFECTS

Mineral malabsorption

A number of research studies have examined the effects of fiber on mineral absorption. Although the results have been somewhat contradictory, it now appears that large amounts of dietary fiber may result in impaired absorption and/or negative balance of some minerals. Fiber as a dietary component does not appear to interfere with the minerals in other foods. However, supplemental fiber, especially wheat bran, may result in a mineral deficiencies. Fiber supplements may also inhibit the absorption of certain drugs. A good recommendation would be for the patient to take the fiber supplement away from medications.

Safety

If a patient has a disorder of the esophagus, fiber supplements in a pill form are contraindicated as they may expand in the esophagus and lead to obstruction.^[36] Fiber supplements in capsules appear to be slightly better tolerated than tablets, but should still be used with caution. The difference is in how the tablets and capsules interact with water. One study showed that fiber (glucomannan) tablets swelled to seven times their original size within 1 minute of coming into contact with water.^[37] In contrast, fiber-filled gelatin capsules took 6 minutes to begin to swell. One very important recommendation is to consume amounts of water with the fiber supplement.

SUMMARY

A diet high in plant foods is associated with a decreased incidence of most of the degenerative diseases of Western society. While this is largely due to increased levels of dietary fiber, such a diet is also high in other important nutrients, most of which are also deficient in the Western diet. It is clear from the literature that the best source of dietary fiber is from whole foods, although fiber supplements do have a place in the treatment phase of specific diseases.

It must be stressed that even with a diet high in dietary fiber, when as little as 18% of the total calories are in the form of refined carbohydrates, many of the beneficial effects of dietary fiber are greatly reduced. There is no substitute for a healthy diet, i.e. a diet composed of foods as close to their original form as possible.

Chapter 58 - Rotation diet: a diagnostic and therapeutic tool

Sally J. Rockwell PhD CNN

INTRODUCTION

Food allergy/intolerance is a common component of many chronic diseases (see [Ch. 51](#)). However, it is often not recognized as problematic because conventional laboratory diagnosis is not very sensitive for food allergies and most allergists dismiss the concept of delayed hypersensitivity reactions to foods (see [Chs 10](#) and [15](#)). A time-honored effective approach to both diagnosis and treatment of food sensitivities is an elimination/rotation diet. This approach has the advantage of being low-cost, but the techniques must be followed assiduously to ensure clinical efficacy. [Table 58.1](#) lists the typical indications for an elimination diet.

THE ELIMINATION DIET

The first step in the elimination diet is to remove from the diet all of the most common allergenic foods – i.e. wheat and other glutinous grains, dairy products, eggs, corn, soy and tofu, peanuts, citrus fruits, yeast and refined sugars – and other often problematic substances such as highly processed foods, chemicals, additives, preservatives, artificial colorings, flavorings, caffeine (coffee, tea, cola drinks, chocolate), and alcohol.

The object is to avoid all suspect foods and substances for at least 5 days, or long enough to clear all traces of those foods from the digestive tract. The omitted foods are then reintroduced into the diet one at a time. By keeping an accurate food and symptom diary, the offending foods can be identified and eliminated; then,

TABLE 58-1 -- Indications for the use of the elimination diet

- Documented or suspected food allergies/intolerances
 - Chronic complaints that have not subsided with treatment
-

- Symptomatic patients whose tests results are all “normal”
 - Patients suspected of mental health problems due to lack of significant progress
 - Children and teens who are labeled ADD, hyperactive, or autistic, or who have behavior problems
-

depending upon the severity of the initial test response, the foods can be retested and added back into the diet within 3–6 months.

While some recommend eliminating only one food at a time, clinicians in this area have found that multiple allergies are the rule, not the exception. Eliminating only one allergen may not improve symptoms enough to allow the improvement to be recognized. The advantages of eliminating all major allergens in the beginning include rapid clearing, minimal adverse reactions, and accurate test results. When symptoms clear rapidly, the patient is inspired and eager to continue with the testing.

As Dr Doris Rapp explains:

If there are several tacks in the bottom of a shoe, the whole foot hurts; removing only one tack will make little or no difference. But remove all the tacks, let the foot heal, then add back one tack at a time and the source of pain is isolated and easily identified. If only one tack (or food) is removed, no significant difference will be noted.

Variations of the elimination diet range from the most stringent plan – i.e. elimination of all the major allergens, refined foods and toxic substances – to a more lenient approach – elimination of only wheat, dairy and refined sugars. Consideration of the patient’s lifestyle, age, weight, general health, food preferences, attitude and family system will determine the approach. For children and pregnant or lactating women, the amount of calories or carbohydrates should not be restricted; simply omit the major allergens.

Variations of the elimination diet

As can be seen in [Table 58.2](#) , all elmination/challenge diets are simply variations on the same theme:

1. Eliminate suspect foods for at least 5 days
2. Introduce/test by challenge ingestion
3. Carefully record reactions
4. Rotate foods, avoiding those shown to cause disagreeable reactions.

TABLE 58-2 -- Elimination diet variants

| Type | Protocol |
|---------------------------------|---|
| Water fast | Water-only fast for 5 days, reintroduce foods |
| Dilute juice fast | Dilute fruit juice fast for 5 days, reintroduce omitted foods |
| Fruit, melon and vegetable plan | Only fruits, melons and vegetables for 5 days, reintroduce omitted foods |
| Cave man (person) plan | Proteins, nuts, seeds, legumes, fruits and vegetables for 5 days – reintroduce omitted foods. Eat only natural, unprocessed foods |

Water fast

Water fast should only be done under the close guidance of a health professional experienced in supervising fasts. A lifetime of accumulated toxins can be released in a short period of time, creating unwarranted discomfort and complications which overwhelm the patient and interfere with testing (see [Ch. 47](#) for a complete description of fasting methodologies).

The dilute juice fast

Less severe than water fasting, and more acceptable to patients, is the dilute juice fast. The diluted juices provide a modest amount of calories, stabilize blood sugar levels and decrease the adverse detoxification–withdrawal reactions which may occur while eliminating all common allergens. The basic procedure is to use three parts distilled or mineral water to one part of fresh, sugar-free juice. The dilute juices are sipped throughout the day. Ideally, a different juice is used each day: celery, carrot, papaya, cranberry, berry, apple, pineapple, and other fruits or vegetables that have not been consumed on a daily basis. Citrus fruits should be avoided. Low-allergen protein supplements, e.g. Ultra Clear, Medi Pro Protein Powder, pure free-form amino acids, N Foods, or Vivonex, may be added after the third day. In addition, liberal amounts of pure water should be consumed throughout the day in order to dilute and flush out toxic substances.

Note. This works for most *Candida* patients as the juice is so dilute that it rarely creates a problem. However, commercially prepared juices (especially tomato and citrus juice) often contain molds which can be problematic.

Fruit and/or vegetable plan

The patient consumes unlimited amounts of clean fresh fruit and melons and raw, steamed, or baked vegetables throughout the day. If *Candida* overgrowth is severe, or if weight loss is desired, vegetables should be emphasized over fruits.

The cave man (person) plan

When the major allergenic foods are eliminated, what's left are the basic foods that the cave man consumed: vegetables, fruits, berries, honey, nuts, seeds, beans, peas, sprouts, roots, gourds, poultry, fish, seafood, and wild game.

Procedure

Beginning the elimination diet

An ideal elimination diet begins with:

1. 2 days of the dilute juice, then
 2. Fruits and vegetables for the next 2 days, then
-

519

3. 2 days of the cave person diet, or until symptoms clear.

Any one, or combination of, the above elimination plans will clear the patient of allergenic substances. If after 5 days the patient's symptoms have not diminished (or disappeared), continue for another 5 days. If not clear in 10 days, begin to rotate, as they may be reacting to a food or substance they are consuming every day. (Unsuspected environmental allergens may be contributing to the symptoms also – see "Helpful hints and suggestions", p. 52.)

Testing by challenge ingestion

Introduce one suspect food every other day. The object is to provide the patient with sufficient calories, build a reliable list of safe foods, and delay unpleasant reactions for as long as possible. Begin with rarely ingested foods as they are least likely to cause adverse reactions. Do not test foods which are known to cause severe reactions.

Suggested testing sequence

Reintroduce back into the diet in the following order whenever possible: vegetables, fruits, melons, beans, nuts and seeds, yeasts, dairy products and finally grains. When adding dairy, test goat products first: plain yogurt, cheeses, and then milk. Repeat the same process with cow's milk. Test grains in the following order: quinoa, amaranth, buckwheat, wild rice, brown rice, millet, *barley*, *spelt*, *kamut*, *teff*, *oats*, *rye*, corn and *wheat* last (gluten-containing grains are in *italics*). Also test dietary supplements one at a time.

Food and symptom diary

Have the patient record chronologically in a notebook all foods, liquids, supplements,

moods, symptoms and reactions. The foods eaten throughout the day should be noted in pencil, or blue or black ink. Highlight or circle symptoms using colored ink so that those adverse reactions will stand out clearly. In 2–3 weeks a repetitive pattern of symptoms will be clearly visible, which allows for identification and elimination of the problematic foods or food combinations causing symptoms.

In the beginning, a patient may not be able to describe in exact words how he or she feels, and so a numbering system may be useful to note general moods throughout the day. Number from 1 (poor) to 10 (excellent). Feeling sort of medium, neither poor nor excellent, would be recorded as a 5. In general, depending on the patient's health and motivation, foods causing a mild reaction should be avoided for 3 months, and those causing a severe reaction are best avoided for at least 6 months before being reintroduced.

Testing children

Play a game with children – make testing fun. Have them draw a picture of how they feel or write their name before and after testing a substance. Note the differences.

THE DIVERSIFIED ROTATION DIET

The basic concept of the diversified rotation diet is to:

- eliminate all major allergenic substances
- eat the remaining foods once every 4 days
- allow 2 or 4 days between food families.

Rotation can be simplified by using a template – the “master chart” – with foods correctly arranged according to their botanical family classifications. The spacing of the foods, and food families, are pre-organized into four columns, one for each day, so the patient simply chooses foods from the appropriate column each day. A color-coding system further simplifies the process of choosing the correct foods.

The master chart, plan I (see [Appendix 10](#)) is the most liberal of the two plans. It provides 4 days between specific foods and only 2 days between food families.

The master chart, plan II is used for severely sensitive individuals (see [Appendix 10](#)). It incorporates 4 days between specific foods and 4 days between food families. If necessary, it can be easily adapted to a 7 day rotation.

Using the master charts

Use a pencil to cross out the major allergens, plus any known or suspected problem foods, in each of the four columns. The patient may eat the remaining foods from the appropriate column throughout the day. The foods which are not crossed out are what

they are allowed to eat.

The arrows on the chart (?) indicate a food which is essentially the only food of a family and which is not cross-reactive with other foods. Therefore, it is not restricted to any one particular day, and can be moved to another column if additional food choices are needed.

Those who will be rotating for any length of time will welcome the benefits of using the color-coding system. A color is assigned to each day. Each column represents a day – day 1: green, column one; day 2: yellow, column two; day 3: blue, column three; and day 4: red, column four. After day 4, rotate back to day 1 and repeat the process. Food containers are labeled and color-coded to coordinate with the color of the day. The color-coding system enables the entire family to see at a glance which foods are permitted on each of the days.

Example. The first column of the master chart is day 1, green day; place green labels, green twist-ties or green rubber bands on all appropriate food containers for day 1, and so on.

Modifications for vegans

The master charts can be used for vegans by simply crossing out all foods of animal origin. After the initial elimination phase, proceed with the food challenges. Legumes (beans and peas) are generally an important part of the vegan diet; so test each legume, one at a time, beginning with the least allergenic, rarely eaten beans, then soy and tofu, and test peanuts last. Depending upon the allergic response to legumes, the patient may be able to tolerate legumes daily, as long as a different legume is eaten each day. In other words, while the *four days between foods* rule continues to be honored, the *one day between food families* rule may be safely ignored for some patients.

Food preparation

For testing purposes, use fresh, organic foods whenever possible. Otherwise frozen or dehydrated foods are a better choice than canned goods. Most vegetables are best raw, steamed, or baked. Fish, poultry, and meat are best poached, steamed, sautéed, baked or simmered in a crock pot. Soups and stews are fine. Use only sea salt for seasoning; all spices and flavorings need to be avoided until they are individually tested.

Stabilize blood sugar levels by advising the patient to eat small, frequent meals throughout the day. Using hypoallergenic foods, prepare four mixtures of “trail mix” – nuts and dried fruits – for each day. Refer to the master chart for specific food choices.

Maintain a supply of healthy snacks everywhere: home, school, office and automobile.

Helpful hints and suggestions

Control of withdrawal symptoms and allergenic reactions. Ascorbates buffered with calcium, potassium and/or magnesium are suggested as a daily source of vitamin C for allergenic individuals. They help to balance an acidic body pH, and are valuable for neutralizing unpleasant allergic reactions. Stabilizing pH eases the symptoms of withdrawal from allergenic foods, and the cravings which occur when breaking an addiction – whether it's sugar, wheat, coffee, cigarettes, alcohol or a drug.

For *daily use*, determine an individual's requirement for vitamin C. Begin with ? tsp of buffered ascorbate in ½ glass of water 3 times a day (between meals and at bedtime). Gradually increase by an additional ? tsp per dose every 2 days until they reach bowel tolerance: loose stool, gas or diarrhea. Reduce dosage. As the patient improves, their vitamin C requirement will likely decrease and the dosage may need to be decreased again.

Note. Buffered C should not be taken with meals as it will neutralize stomach acid, which is often deficient in patients with food allergy/intolerance (see [Ch. 19](#)).

For *temporary* relief of symptoms or to neutralize an adverse reaction, mix and drink a ½ teaspoon of buffered vitamin C in ½ glass of water or dilute juice. Available commercial products include Klaire Labs Bi-carbs, Cardiovascular's Tri-salts and Alka Seltzer Gold label (not the blue label). If all of the above are unavailable, ½ teaspoon of baking soda in ½ glass of water can be useful.

Environmental allergies. If the patient doesn't respond in a timely fashion, and all other possibilities have been ruled out, suspect environmental and/or chemical sensitivities. Step one is to eliminate all scented toiletries, room sprays and cleaning solutions in the home and work place.⚡

Ensure adequate protein intake. As the most allergenic foods also tend to be those highest in protein, care must be taken to ensure the patient is consuming enough protein. Patients with large numbers of food allergies should be referred to a competent nutritionist to help them develop an adequately balanced diet.

Be patient. Be especially patient and supportive of those who have experienced long-term conventional treatment only. You may be the first physician to remind them that symptoms are the body's way of communicating and that learning to pay attention to what they eat and drink, and the possible adverse symptoms, is a vital part of getting well again.

Allergy-free cook books. Recipes, plus dozens of helpful hints and suggestions can be found in specialty cook books. The author has published several self-help books and tapes, including *The rotation game*, complete with instructions, colored visual aids,

recipes, etc.

Utilization of the rotation diet can be greatly assisted through the use of a commercial product developed by the author: *The rotation game* (see address in footnote, below; a free copy of *Allergy Alert* newsletter is available on request).

Chapter 59 - Sports nutrition

Gregory S. Kelly ND*

INTRODUCTION

The increased focus on fitness and subsequent research in the exercise field have expanded the role of nutrition in sports performance. Because there is widespread belief among athletes that special nutritional practices will enhance their achievements in competition, the use of supplements has become common. This chapter reviews the efficacy of some of supplements currently promoted to athletes. The topic has been divided into two broad categories: sports nutrition for strength athletes; and sports nutrition for endurance athletes. This division is to a degree arbitrary, so some of the supplements discussed might be applicable for athletes in both of these categories.

SPORTS NUTRITION FOR STRENGTH ATHLETES

Creatine monohydrate

Creatine monohydrate has become one of the most popular supplements in the history of body-building. It is used primarily to increase strength and lean body mass and has shown consistent results in promoting these effects in experimental subjects.

In humans, over 95% of the total creatine content is located in skeletal muscle. Approximately one-third is in its free form as creatine, also known as methylguanidinoacetic acid, while the remainder is present in a phosphorylated form as creatine phosphate (also called phosphocreatine). Creatine phosphate is utilized within skeletal muscle storing high energy phosphate bonds.

Creatine is formed in the liver, kidney, and pancreas. Initially, arginine and glycine combine to produce guanidinoacetate. A methyl group from S-adenosylmethionine (SAM) is then transferred, resulting in the formation of creatine. The by-product of this reaction, S-adenosylhomocysteine, is subsequently hydrolyzed into homocysteine

and adenosine. In order to optimize endogenous production of creatine, the amino acids arginine, glycine, and methionine must be available as substrates. Additionally, magnesium is required as a cofactor to form SAM from methionine, and B₁₂, folic acid and betaine are required to recycle the homocysteine to methionine for reuse as SAM.

While creatine can be synthesized endogenously as described above, it is also found in a variety of foods in varying concentrations. The richest source is considered to be wild game, but in domesticated animals, beef (lean red meat) is the richest source; 1.1 kg of fresh uncooked steak contains about 5 g of creatine.^[1] Fish is also a good source, especially herring, salmon, and tuna. However, it is believed that creatine in foods may be destroyed or reduced significantly by cooking.

Creatine is transported to muscle tissue where it exists in equilibrium with creatine phosphate. Creatine phosphate spontaneously converts to creatinine (estimated to be at a rate of about 2 g/day for a 150 pound male) and is then excreted in the urine.^[2] While part of this turnover can be replaced through dietary sources of creatine, especially meat and fish, the remainder must be supplied by endogenous synthesis. Because of this, there is a constant drain on arginine, glycine, methionine, and nutritional cofactors to maintain a supply of creatine and creatine phosphate. In vegetarians, daily needs must be met exclusively by endogenous synthesis. When dietary creatine is high, the synthetic pathway is correspondingly regulated downward.^[3]

In addition to its use in skeletal muscle, some creatine is used by cardiac muscle. Chronic heart failure patients might have decreased stores of creatine and have been shown to have improved exercise capacity following administration of creatine.^[4] One week of creatine (20 g/day) supplementation to patients with chronic heart failure increased skeletal muscle energy-rich phosphagens and performance for both strength and endurance.^[4]

Creatine phosphate produces energy in the form of ATP in muscle cells for about 10 seconds of activity. After it is depleted, the muscle shifts to anaerobic glycolysis for fuel. It is thought skeletal muscles are capable of storing significantly more creatine than is generally supplied by the diet and by endogenous synthesis. Because of this, increased serum creatine, following an oral dose of creatine monohydrate, will be available for storage in muscle tissue. Over time, this increased dietary consumption can allow the muscle to become saturated with creatine. When the muscle has this extra creatine, it should theoretically be able to delay fatigue and refuel itself more quickly during high-intensity, short-duration exercise, and so should be capable of greater work.

When muscle absorbs creatine, it is hypothesized that it also brings water intracellularly with it, so the muscle becomes more “hydrated”. It is estimated that muscles are about 70% water, so this results in a larger, fuller muscle. Evidence suggests when a cell is well hydrated it might accelerate its synthesis of new proteins and might also minimize

protein degradation.^[5]

One gram of creatine monohydrate or less in water produces only a modest rise in plasma creatine concentration; however, a 5 g oral dose has been shown to significantly increase plasma creatine concentration. Repeated dosing with 5 g of creatine monohydrate every 2 hours sustains the plasma concentration at around 1,000 mmol/L.^[1]

Recent studies have shown that feeding large amounts of creatine (typically 20–30 g/day for 5 days) increases muscle total creatine (and phosphocreatine) content.^{[1] [6]} The extent of the increase normally observed is inversely related to the pre-supplementation level.^{[1] [6]} Vegetarians, because they have a very low dietary creatine intake and low to normal total creatine content, would be expected to show large increases.^[1] Muscle creatine uptake appears to be augmented substantially in individuals adhering to a program of repeated high-intensity exercise during the period of supplementation.^[1] Resynthesis of phosphocreatine following 1 minute of recovery from intense muscular contraction is accelerated in individuals consuming creatine.^[6] Adequate vitamin E status might also be needed to optimize creatine uptake.^[7]

In one study of eight subjects, biopsy samples were taken after 5 days of ingestion of 20 g creatine/day. In five of the eight subjects, there was substantially increased muscle total creatine concentration and creatine phosphate resynthesis during recovery. In the remaining subjects, creatine supplementation slightly increased total creatine concentration but did not increase creatine phosphate resynthesis.^[6] In three subjects measured, uptake into muscle was greatest during the first 2 days of supplementation, accounting for 32% of the total 30 g of creatine monohydrate given orally per day. In these subjects, renal excretion was 40, 61 and 68% of the creatine dose over the first 3 days, respectively. Approximately 20% or more of the creatine taken up was measured as phosphocreatine, while no changes were observed in the muscle ATP content.^[1]

Oral creatine monohydrate supplementation has also been shown, in a patient with extrapyramidal movement disorder and extremely low creatinine concentrations in serum and urine, to significantly increase brain creatine levels. Phosphorus magnetic resonance spectroscopy of the brain revealed no detectable creatine phosphate before oral substitution of creatine and a significant increase afterward. Partial restoration of cerebral creatine concentrations was accompanied by improvement of the patient's neurologic symptoms. Oral substitution of arginine, a substrate for creatine synthesis, was unable to elevate cerebral creatine levels.^[8]

Creatine supplementation has been shown to improve performance in situations where the availability of creatine phosphate is important, such as very high-intensity

exercise, especially where repeated bursts of energy are required with short recovery periods.^{[9] [10] [11] [12] [13]} Several studies have documented creatine monohydrate's effect

on muscle size and strength. Typically, after a 5–7 day loading dose, there is an increase in the amount of work done in repeated bouts of maximal exercise and a gain in body mass of between 0.5 and 1.0 kg.^[10] ^[12] One group of researchers reported 28 days of supplementation (20 g/ day) producing a fat-free mass increased by 1.7 kg.^[9]

While creatine supplementation increased performance in sprint-trained cyclists, it does not appear to improve endurance performance.^[14] One study actually reported a worsening in performance during prolonged continuous exercise following creatine supplementation. This finding remains unexplained, although the authors believe the increase in body mass due to supplementation might be a contributing factor.^[15] Research shows that creatine supplementation has no measurable effect on respiratory gas exchange and blood lactate concentrations during either incremental submaximal exercise or recovery, suggesting that creatine phosphate produces energy in the form of ATP in muscle cells for about 10 seconds of activity. After it is depleted, the muscle must shift to anaerobic glycolysis for fuel. Creatine supplementation does not influence substrate utilization during and after this type of exercise.^[16]

Results from an unpublished human trial indicate that insulin might be a potent upregulator of a muscle's ability to take in creatine. This has resulted in many users supplementing creatine monohydrate with a simple carbohydrate (such as glucose, dextrose, or maltose) which simultaneously causes a release in insulin. In a 4 week trial, a large increase in speed, anaerobic power, and lean body mass, along with a decrease in body fat, was reported in individuals receiving doses of 20 g/day of creatine for the first 5 days, followed by 10 g/day for the remainder of the 4 weeks. An even greater response in these parameters was reported in the athletes using a creatine/carbohydrate mix, which contained creatine monohydrate, dextrose, taurine, disodium phosphate, magnesium phosphate, and potassium phosphate.

Dosage

Typically, dosing of creatine monohydrate follows a loading and a maintenance cycle. During the loading period, larger doses of creatine monohydrate are ingested for 5–7 days. A typical dose for individuals weighing less than 225 pounds is 5 g q.i.d, while heavier individuals might take up to six doses per day. The maintenance dose would be 0.03 g/kg body weight.^[17] ^[18] Larger doses are probably not of any greater benefit since the capability of muscle to take in and store creatine is finite.^[1] In fact, this dosing schedule might exceed the ability of most individuals to incorporate creatine into muscle tissue, as evidenced by the renal excretion rate of creatine (40–68% of the supplemented dose) reported in individuals given 30 g/day.^[1] A recent study supports the possible use of lower oral doses. One study reported that 3 g/day for 28 days increased muscle creatine and creatine phosphate stores to a level comparable to a loading phase.^[17]

Most of the gains in size and strength occur within the first month, after which muscles are generally saturated with creatine. Evidence indicates that these gains will remain while supplementation continues, but will gradually disappear over time when the supplement is discontinued. Typically, levels of creatine drop back to pre-supplementation levels about 1 month after discontinuing supplementation. The size

and strength increase resulting from improved muscle cell hydration also disappear over this same time interval. However, actual gains in muscle mass due to increased work capacity while on creatine will remain.

Anecdotal reports suggest that 20–30% of individuals who take creatine do not respond with increased muscle mass or strength. Presently, this finding is unexplained; however, individuals with lower initial tissue levels are most likely to benefit.^[4] Because of the success of creatine monohydrate, several other forms have become available, including creatine phosphate and creatine citrate. These are claimed to produce similar results; however, creatine monohydrate is the only form shown, to date, to increase strength, lean body mass, and tissue creatine phosphate levels.

Toxicity

Reported side-effects from creatine supplementation include gastric disturbance, headaches, clenched teeth, and the sound of blood rushing in the ear. Creatine supplementation might cause serum creatinine levels to increase. This is due to the increase in muscle creatine phosphate and its subsequent spontaneous conversion to creatinine. Since most of the studies have only supplemented creatine for short periods of time, and in the single study reporting long-term supplementation only 1 g/day was utilized,^[19] it is not currently known whether long-term, high-dose supplementation has adverse side-effects.

Some concern exists that caffeine use (0.5 mg/kg per day) can have a negative impact on the effectiveness of creatine. However, in at least one study, participants were instructed to dissolve the creatine monohydrate in tea or coffee before ingestion. Body weight increase was still observed in seven of eight subjects and all subjects had increased muscle total creatine and phosphocreatine resynthesis.^[6] Although these results suggest caffeine does not negate the effects of creatine supplementation, until more is known it might be best to minimize caffeinated substances, or drink them several hours away from supplementation, if seeking optimal results.

Creatine supplementation is widely practiced by athletes in many sports and does not contravene current doping regulations.^[3] Since creatine supplementation does not enhance performance in endurance athletes and evidence suggests an actual decline in performance, endurance athletes should avoid creatine supplementation. In athletes concerned with improving strength, body composition, or short-duration repetitive high-intensity exercise, I recommend creatine monohydrate be incorporated into any supplementation protocol. Although quicker results will be seen following a loading dose, the cost-effectiveness of the 3 g/day dose might be a more appealing option for many athletes.

HMB

HMB (beta-hydroxy beta-methylbutyrate) is a new product which has only been available in limited supply since the end of 1995. The nutritional use of HMB for nitrogen retention has been patented by the Iowa State University Research Foundation and is licensed to Metabolic Technologies.

HMB is a leucine metabolite. It has not yet been established how HMB is synthesized from leucine in humans; however, in animals evidence suggests that the majority of circulating HMB is formed following the transamination of leucine to alpha-ketoisocaproate with its subsequent oxidation to HMB.^[20] It has not been determined either to what extent HMB is normally produced in vivo or which specific cofactors might influence its production.

While the mechanism of action of HMB is still equivocal, it is hypothesized that HMB decreases muscle protein turnover and might work primarily by minimizing protein degradation. Suggestive evidence of HMB's blocking of catabolism is based on its ability to decrease urinary 3-methylhistidine (a marker of muscle breakdown), and to decrease plasma levels of creatine phosphokinase and lactic dehydrogenase.^[21] Anecdotal reports indicate that individuals who work out more often and most intensely get the best results with HMB. This is important since typically the more an individual works out, the more muscle catabolism also occurs; so at a certain point, the anabolic gains achieved by stimulating the muscles through training are offset by the catabolic effects of frequent, high-intensity workouts. HMB's anti-catabolic effects might move this balance point further in the direction of anabolic growth, allowing an individual to train more often and still receive positive results in strength and mass gains.

In a human study conducted over a 3 week period, 3 g/day of oral HMB supplementation was shown to decrease body fat, increase lean mass and strength, and reduce muscle damage in individuals beginning resistance-training exercises. In this trial, participants also consumed either 117 or 175 g/day of protein. While protein intake did not seem to impact strength, participants with higher protein intakes, independent of HMB supplementation, appeared to have greater increases in lean body mass.^[21] Because these results came from individuals who had not previously engaged in weight training, doubt existed as to whether they would be reproducible in body-builders or other athletes who had already engaged in long-term resistance training. However, in a subsequent study, not yet published as a full paper, researchers have indicated that HMB feeding resulted in equal increases in strength, body composition, and decreased fat in both trained and untrained individuals.^[22]

Dosage

The recommended dosage for HMB is 3 g/day. Since relatively high protein intake was reported in the study demonstrating HMB's efficacy, and because it is unknown whether the same results will occur while on a low-protein diet, a similar protein intake of between 120 and 175 g/day for athletes supplementing with HMB might produce best results.

Toxicity

At this point, the primary concern regarding HMB is anecdotal evidence which indicates that many individuals have not experienced expected results with this supplement. Since HMB is thought to function primarily as an anti-catabolic substance, it is possible these individuals did not train with enough intensity to optimize its effect. The other possibility is that, similar to creatine monohydrate, HMB might be ineffective in some individuals. Since this is such a new supplement, no information is available on its long-term safety.

Whey protein

Whey protein, often referred to as lactalbumin, is currently the supplemental protein source of choice for many body-builders and strength athletes. Whey proteins represent the major proteins in human breast milk, as opposed to bovine milk which is comprised primarily of casein with lesser amounts of whey. Whey is comprised of alpha-lactoglobulin, beta-lactoglobulin, bovine serum albumin (BSA), and immunoglobulins (IgG1, IgG2, secretory IgA, and IgM). Other components of the lactalbumin fraction include: enzymes, iron binding proteins, calcium, potassium, sodium, phosphorous, and vitamins A, C, B₁, B₂, B₃, B₅, B₁₂, folic acid, and biotin. Whey is a balanced source of essential amino acids and peptides with a high protein efficiency ratio. It is considered to be an excellent source of sulfur amino acids (methionine and cysteine), as well as the branched-chain amino acids (leucine,

isoleucine and valine), and glutamine (see sections on branched-chain amino acids and glutamine for information on their potential benefits).

Whey transits the stomach quickly and is rapidly absorbed from the human intestine. The beta-lactoglobulin component remains soluble in the stomach and empties rapidly as an intact protein needing further hydrolysis by pancreatic enzymes. Casein, on the other hand, transits the stomach slowly.^[23]

No studies exist comparing the impact on nitrogen balance, body composition, or performance of different protein sources in trained athletes. However, whey has been shown to promote growth and enhance nitrogen balance in experimental animals, low-birth-weight infants, and burn victims.^{[24] [25] [26]}

Whey protein is rich in substrates for glutathione synthesis,^[27] and contains substantially more cysteine, which is considered to be a rate-limiting step in glutathione synthesis, than does casein. Whey also contains high amounts of glutamine and glycine.

Glutathione is a powerful antioxidant and is involved in metabolic detoxification

pathways. The role free radicals play in the development of exercise-induced tissue damage, or the protective role antioxidants might play, remains to be completely elucidated. Research has indicated that free radical production and subsequent lipid peroxidation are normal sequelae to the rise in oxygen consumption with exercise.^[28] However, physical training has been shown to result in an augmented antioxidant system and a reduction in lipid peroxidation. Supplementation with antioxidants appears to further reduce lipid peroxidation but has not been shown to enhance exercise performance.^[29]

Glutathione levels have been shown to decrease with exercise.^[30] Additionally, running a marathon causes a large increase in the tissue content of oxidized glutathione (189%) at the expense of reduced glutathione.^[31] While no information is available on the effects of resistance exercise and glutathione levels, it is hypothesized that an increased intake of antioxidants might protect against minor muscle injuries.^[32]

Whey protein is more efficient at inducing supernormal glutathione levels than a cysteine-enriched casein diet.^[33] A whey-rich diet has been shown to increase heart and liver tissue glutathione content in rats. The whey protein diet appeared also to increase longevity when fed at the onset of senescence.^[33] Whey-based formula enhances cysteine retention and results in greater taurine excretion, thought to be a reflection of greater taurine stores.^[34] Whey protein fed to three HIV-seropositive individuals over a period of 3 months, at doses increasing progressively from 8.4 to 39.2 g/day, resulted in progressive weight gain and increased glutathione levels in all three.^[35]

Experimental studies suggest that the whey protein component of milk might exert an inhibitory effect on the development of several types of tumor. It is thought that the rich supply of substrates for glutathione synthesis contributes to this inhibitory effect.^[36] In experimental animals, a diet consisting of 20 g of whey/100 g diet has been shown to be more protective than similar diets utilizing casein, soybean, or red meat against dimethylhydrazine-induced intestinal cancers.^[37] Peptides from whey protein have also been shown to have antithrombotic^[38] and immunoenhancing activities.^{[38] [39]}

Dosage

The routine use of a post-workout shake might be the most important nutritional supplementation habit for enhancing body composition. It is probably in this manner that whey can be best utilized by athletes concerned with maximizing lean body mass and strength.

Amino acid availability following a workout regulates protein synthesis and degradation. Because of the anabolic effects of insulin on protein synthesis and protein degradation, a rapid synergistic response occurs when both amino acids and insulin increase after a protein-containing meal.^[40] It is thought that the body is highly insulin-sensitive after exercise and preferentially shuttles carbohydrates and protein into muscle cells rather than fat cells. Experts think this sensitivity gradually declines post-workout for about 2 hours until it again reaches normal sensitivity.

A carbohydrate-whey protein supplement has been shown to be more effective in

generating a plasma insulin response than either a carbohydrate or a protein supplement alone during recovery from prolonged exhaustive exercise. The rate of muscle glycogen storage was also significantly faster during the carbohydrate-protein treatment. The participants in this study ingested 112.0 g of carbohydrate and 40.7 g of protein immediately after each exercise bout.^[41]

Whey is an excellent choice as a protein source for the post-workout shake because of its rapid transit into the small intestine and because of its high levels of branched-chain amino acids and glutamine. Glucose polymers or maltodextrins are considered to be the best form of carbohydrates to use because of their ability to stimulate an insulin response. Fat should not be added because it might slow transit and decrease the insulin response.

Toxicity

The primary concerns about supplementing whey protein are the possibility of food allergies, its lactose content, and proposed links to insulin-dependent diabetes mellitus (IDDM). While the possibility of food allergies from whey has to be considered, it is probable it is no more, and possibly less, antigenic than soy, casein, or egg-based protein supplements. A significant concern might

be the method of processing of the whey protein, since high temperatures during heating or drying can generate browning reaction products by covalent interaction of proteins and lactose. Browned proteins have lowered digestibility and are thought to result in greater uptake of intact protein through intestinal mucosa. All whey protein available contains some degree of lactose, although many have very low amounts.

The BSA component of whey has been implicated as a possible trigger for IDDM in children. A similarity exists between the amino acid sequence of the beta-cell protein, found on the insulin-secreting beta cells of the pancreas, and BSA. Because elevated levels of anti-BSA antibodies have been found in sera from children developing IDDM, it has been proposed that absorption of BSA, or partially digested fragments of BSA, stimulate the immune system which then incorrectly destroys beta cells.^[42] One study reported the prevalence of anti-BSA antibodies as 52% in children with less than 1 year of IDDM, 47% in children with greater than 1 year of IDDM, and 28% in the control group. The researchers concluded that the prevalence of anti-BSA antibodies is higher in IDDM subjects than in control subjects; however, because of the large overlap of antibody titers observed in patients and control subjects, anti-BSA antibodies were neither sensitive nor specific markers of IDDM.^[43] Others have found that IgG antibodies to BSA were not significantly increased at the onset of IDDM.^[44] Currently, the exact nature of the relationship between BSA and IDDM remains unclear.

Phosphatidylserine

Phosphatidylserine is becoming widely used by individuals engaged in resistance training, primarily due to its presumed ability to prevent muscle tissue degradation. Phosphatidylserine has been shown to have an effect on the body's production of glucocorticoids. While the mechanism of action of phosphatidylserine is still unknown, it has been proposed that it exerts an effect on the hypothalamic–pituitary–adrenal axis.^[45]

Phosphatidylserine is formed by adding a serine to a phosphatidyl group. This requires pyridoxal 5'-phosphate (active B₆), and occurs in the same biochemical loop involved with phosphatidylcholine, choline, betaine, and dimethylglycine metabolism.

Physical exercise induces a significant increase in plasma epinephrine, norepinephrine, adrenocorticotrophic hormone (ACTH), cortisol, growth hormone (GH), and prolactin (PRL). It is theorized that preventing the increase in cortisol subsequent to intense exercise would prevent the excess muscle tissue breakdown. Pretreatment of eight healthy men with both 50 and 75 mg of intravenous brain cortex-derived phosphatidylserine within 10 minutes of the start of exercise blunted the ACTH and cortisol responses to physical stress.^[46] Oral administration of phosphatidylserine derived from brain cortex, 800 mg/ day for 10 days, significantly blunted the ACTH and cortisol responses to physical exercise ($P = 0.003$ and $P = 0.03$, respectively), without affecting the rise in plasma GH and PRL. Although participants also experienced reductions in plasma cortisol concentrations at a dose of 400 mg/day of phosphatidylserine, the area under the curve of plasma cortisol was significantly lower after the higher dose of 800 mg/day.^[45]

While the results of this preliminary work appear promising, to date no trials have reported an increase in strength or an improvement in body composition after phosphatidylserine supplementation. Until these results are determined, claims of phosphatidylserine's ability to decrease muscle tissue catabolism should be considered unsubstantiated.

Arginine

Arginine is an amino acid which is used occasionally by body-builders to stimulate growth hormone secretion. It was very popular in the mid-1980s; however, interest in it has since waned. Several studies have shown its ability to stimulate growth hormone and insulin-like growth factor I secretion and improve nitrogen balance after i.v. administration; however, equivocal results have been obtained following oral supplementation.

Oral arginine/lysine (3 g/day of each) is apparently not a practical means of chronically enhancing GH secretion in older men.^[47] Additionally, it is debatable whether increasing growth hormone levels in people not already deficient has an anabolic effect.

Arginine is required for creatine synthesis and some believe it will enhance synthesis if supplemented. In rats, arginine and glycine supplementation increased muscle

creatine.^[48]

One study reported that individuals receiving arginine and ornithine, 5 days a week for 5 weeks, had higher gains in strength and enhancement of lean body mass when compared with controls. Dosages amounted to 2 or 1 g each of L-arginine and L-ornithine taken orally, and 600 mg of calcium and 1 g of vitamin C as placebos. Subjects taking the arginine and ornithine also had significantly lower urinary hydroxyproline, a marker of tissue breakdown, than subjects receiving placebo. The authors concluded that arginine and ornithine, in conjunction with a high-intensity strength training program, can increase strength and lean body mass, and minimize tissue breakdown.^[49]

Dosage

The typical dosage is 2 g/day. Based upon the results of Elam et al,^[49] it appears that a combination of arginine and ornithine might exert a positive impact on body composition and strength; however, no additional research has substantiated these findings.

Branched-chain amino acids

Leucine, isoleucine, and valine are considered as branched-chain amino acids (BCAAs) because of their similar chemical structures and interlocking methyl groups. Exercise results in marked alterations in amino acid metabolism within the body. The branched-chain amino acids, especially leucine, are particularly important since they contribute as energy substrates and as nitrogen donors in the formation of alanine, glutamine and aspartate. Calculations indicate that the recommended dietary intake of leucine is inadequate, since it is lower than the measured whole-body rates of leucine oxidation. This inadequacy is exacerbated in individuals who are physically active.^[50]

An increased supply of BCAAs appears to have a sparing effect on muscle glycogen degradation during exercise.^[51] Short-term (3–4 hours) infusion of branched-chain amino acids has been shown to suppress muscle protein breakdown.^[52] In humans nourished parenterally, provision of balanced amino acid solutions or of only the three BCAAs cause similar improvements in nitrogen balance for several days.^[40]

Administration of BCAAs can greatly increase their concentration in plasma and subsequently their uptake by muscle during exercise.^[51] Long-term exercise following BCAA administration results in significantly greater muscle NH_3 , alanine and glutamine production, as well as lower lactate production, than is observed during exercise without BCAA supplementation.^[53]

While evidence indicates that BCAAs might be significant in enhancing protein synthesis or minimizing protein degradation, supplementation with these amino acids has not

produced significant changes in body composition. If whey or another top-quality protein formula is being used, adequate amounts of BCAAs are provided.

Glutamine

Glutamine is the most abundant amino acid in the blood and in the free amino acid pool of skeletal muscle. Glutamine stimulates the synthesis and inhibits the degradation of proteins, is an important vehicle for the transport of nitrogen and carbon within the tissues, stimulates the synthesis of hepatic glycogen, and is an energy source for cell division.^[54] Because glutamine deficiency can occur during periods of metabolic stress, it has led to the reclassification of glutamine as a conditionally essential amino acid.^[55] Glutamine is also a precursor for the synthesis of amino acids, proteins, nucleotides, glutathione, and other biologically important molecules.

Glutamine is considered to have an anabolic effect on skeletal muscle. It stimulates the synthesis and inhibits the degradation of proteins. Experiments with various animal models have demonstrated that glutamine supplementation can result in better nitrogen homeostasis, with conservation of skeletal muscle.^[55] The mechanism by which glutamine affects skeletal muscle protein turnover, and thus muscle protein balance, is unknown. However, glutamine has an anabolic effect of promoting protein synthesis and also might reduce protein breakdown.^[56]

Glutamine was shown to increase cell volume, while insulin and glutamine together seem to work synergistically to enhance cellular hydration. The effects of glutamine in skeletal muscle include the stimulation of protein synthesis, which occurs in the absence or presence of insulin, the response being greater with insulin.^[57]

During various catabolic states, such as infection, surgery, burns, and trauma, glutamine homeostasis is placed under stress, and glutamine reserves, particularly in the skeletal muscle, are depleted. In these conditions, the body requirements of glutamine appear to exceed the individual's muscle deposits, resulting in a loss of muscle mass.^[58] In critically ill patients, parenteral glutamine reduces nitrogen loss and causes a reduction in mortality.^[54]

With regard to glutamine metabolism, exercise stress can be viewed in a similar light to other catabolic stresses. Plasma glutamine concentrations increase during prolonged, high-intensity exercise. However, during the post-exercise recovery period, plasma concentrations decrease significantly. Several hours of recovery are required before plasma levels are restored to pre-exercise levels. If recovery between exercise bouts is inadequate, the acute effects of exercise on plasma glutamine concentrations can be cumulative. It has been observed that overtrained athletes appear to maintain low plasma glutamine levels for months or years.^[59] Some experts believe that reduced concentration of plasma glutamine can provide a good indication of severe exercise stress.^[60] Research suggests that, after exercise, increased availability of glutamine promotes muscle glycogen accumulation by mechanisms possibly including diversion of glutamine carbon to glycogen.^[61]

Following trauma there is a loss of nitrogen, with a concomitant reduction of skeletal

muscle protein synthesis. This is accompanied by a decrease in the stores of muscle free glutamine. Nutritional support with either glutamine or its carbon skeleton, alpha-ketoglutarate, has been shown to counteract the postoperative fall of muscle free glutamine and of muscle protein synthesis.^[62]

Evidence suggests that oral glutamine supplementation results in an increased release of growth hormone. An oral glutamine load (2 g) was administered to nine healthy subjects to determine the effect on plasma glutamine, bicarbonate, and circulating growth hormone concentrations. Eight of nine subjects responded with an increase in plasma glutamine at 30 and 60 minutes before returning to the control value at 90 minutes. Ninety minutes after the glutamine administration load, both

plasma bicarbonate concentration and circulating plasma growth hormone concentration were elevated.^[63]

Dosage

Although some advocates recommend as much as 30 g, it is likely that only marginal benefits are found at supplementary levels higher than 2–3 g/day.

Ornithine alpha-ketoglutarate (OKG)

Ornithine alpha-ketoglutarate (OKG) is a salt formed of two molecules of ornithine and one molecule of alpha-ketoglutarate. OKG has been successfully used by the enteral and parenteral route in burn, traumatized, and surgical patients, and in chronically malnourished subjects. According to the metabolic situation, OKG treatment decreases muscle protein catabolism and/or increases synthesis. In addition, OKG promotes wound healing. The mechanism of action of OKG is not fully understood, but the secretion of anabolic hormones (insulin, human growth hormone), and the synthesis of metabolites (glutamine, polyamines, arginine, ketoacids) might be involved.^[64]

This supplement has been available for several years. It has been used successfully in hospitalized burn victims to slow protein loss. Only one study appears to have evaluated its effect on performance. In this study, OKG (10 g/day with 75 g of carbohydrates) was given for 6 weeks. The OKG group experienced a significant increase in bench-press strength and biceps circumference. Body weight and percentage fat were not different between groups. No differences in growth hormone levels were seen between groups. Body composition changes were seen among several individuals in the OKG group, but no significance was found either within or between experimental groups.^[64]

Anecdotal reports from some individuals supplementing with OKG indicate increased appetite and better disposition to train. Some anecdotal reports claim great results while

others experience no results.

Dosage

The recommended dosage of OKG is 10 g along with a 75 g carbohydrate drink.

Vitamin C

There have been several investigations during the past four decades of the potential effect of high-dose vitamin C supplementation on physical performance. However, the results have been equivocal. Most studies could not demonstrate an effect. On the other hand, a suboptimal vitamin C status results in an impaired working capacity which can be normalized by restoring vitamin C body pools.^[65]

A potent antioxidant required for collagen synthesis, ascorbic acid might help protect muscles from excessive damage due to training or trauma. Data suggests prior vitamin C supplementation might exert a protective effect against exercise-induced muscle damage.^[66]

Ascorbic acid might decrease cortisol production.^[67] It has also been suggested that ascorbic acid might have a role in facilitating an adequate response to stress.^[68]

Dosage

Because of ascorbic acid's potential for minimizing muscle damage and cortisol-induced muscle catabolism, 1–3 grams should be supplemented daily.

Boron

Recently, a proliferation of athletic supplements has been marketed touting boron as an ergogenic aid capable of increasing testosterone. While this might be true in some populations under specific conditions, boron's impact on testosterone is still equivocal.

Boron appears to increase testosterone levels in rats in a time- and dose-dependent manner.^[69] In postmenopausal women, increasing dietary intake of boron from 0.25 to 3.25 mg/day has been reported to more than double plasma testosterone.^[70] In a subsequent study of healthy men, boron supplementation resulted in an increase in the concentrations of both plasma estrogen and testosterone.^[71] However, one study reported that changing boron intake had no impact on testosterone levels in postmenopausal women.^[72]

The effect of boron supplementation was investigated in 19 male body-builders aged 20–27 years. Ten were given a 2.5 mg boron supplement, while nine were given a placebo every day for 7 weeks. Both groups demonstrated significant increases in total testosterone, lean body mass, and one-repetition maximum squat and bench-press. However, analysis of variance indicated no significant effect of boron supplementation

on any of the dependent variables. The authors concluded that the gains were a result of 7 weeks of body-building, not of boron supplementation.^[73]

Dosage

It is prudent to supplement the diet with 3 mg/day of boron to ensure against deficiency; however, an expectation of increased strength and improved body composition is unrealistic.

Chromium

Chromium is highly promoted in body-building circles as a fat-burning supplement and as an aid in increasing

lean mass. Available research does not support either of these claims.

Changes in body weight, a sum of three body circumferences, a sum of three skinfolds, and the one-repetition maximum for the squat and bench-press were examined in 59 college-age students over a 12 week weight-lifting program. Half of the students were given 200 mcg/day elemental chromium as chromium picolinate, while the other half received a placebo. No treatment effects were seen for the strength measurements. The only significant treatment effect found was an increase in body weight observed in the females supplementing with chromium.^[74]

The effects of 9 weeks of daily chromium supplementation (200 mcg chromium as picolinate) were investigated in a double-blind design in football players during sprint training. Chromium picolinate supplementation was ineffective in bringing about changes in body composition or strength.^[75]

The same results were shown in another study of 200 mcg of chromium supplemented to untrained males (23 ± 4 years), in conjunction with a progressive, resistive exercise training program. Chromium supplementation was not found to promote a significant increase in strength or lean body mass, or a significant decrease in percentage body fat.^[76]

Increasing dosage and length of supplementation also did not help. A double-blind, placebo-controlled protocol for 16 weeks provided 400 mcg of chromium as picolinate or a placebo. At the end of 16 weeks, the chromium group failed to show a significantly greater reduction in either percentage body fat or body weight, or a greater increase in lean body mass, than did the placebo group. It was concluded that chromium picolinate was ineffective in enhancing body fat reduction in this group.^[77]

In yet another study, this one involving 8 weeks of daily chromium supplementation in

36 men in a double-blind design, it was found that strength, mesomorphy, fat-free mass, and muscle mass increased with resistance training independently of chromium supplementation ($P < 0.0001$). These findings suggest that routine chromium supplementation has no beneficial effects on body composition or strength gain in men, although it must be noted that the placebo group received a trace level of chromium.^[78]

Evidence strongly indicates that supplementation of chromium will not enhance strength or body composition. Similar to boron, chromium-rich foods or a supplement containing chromium should be included in the diet to avoid deficiency; however, it is unrealistic to expect gains in strength or improvement in body composition.

Selenium

Selenium is a trace mineral which is utilized as a cofactor in several enzymes. It is commonly found in antioxidant formulas because of its role as a cofactor in the enzyme glutathione peroxidase. Evidence suggests that the administration of organic selenium partially compensates for and decreases the intensity of oxidative stress in athletes.^[79] While optimal antioxidant status is critical to athletes, selenium might have an additional role in the determination of body composition. Selenium deficiency can affect the metabolism of thyroid hormones. Iodothyronine 5'-deiodinase, which is mainly responsible for peripheral T_3 production, has been demonstrated to be a selenium-containing enzyme.^[80] In rats fed a selenium-deficient diet, hepatic iodothyronine 5'-deiodinase is decreased by 47%. Lower concentrations of T_3 and T_4 have also been demonstrated in selenium-deficient animals.^[81] Reduced peripheral conversion of T_4 to T_3 secondary to a selenium deficiency might create a functional hypothyroidism which would be expected to adversely impact body composition.

Toxicity

There is data suggesting that ingesting more than 750–1,000 $\mu\text{g}/\text{day}$ of selenium over an extended period of time may be harmful.

Vanadium (vanadyl sulfate)

Vanadium as vanadyl sulfate is widely utilized by athletes seeking to improve body composition. It is generally promoted as having an anabolic effect which enhances the transport of amino acids into cells. Several studies have indicated its ability to reduce fasting glucose and improve hepatic and peripheral insulin sensitivity in non-insulin-dependent diabetic humans.^[82] ^[83] ^[84] However, vanadyl sulfate does not appear to alter insulin sensitivity in non-diabetic subjects.^[84] A single study reported the effect of oral vanadyl sulfate (0.5 mg/kg per day) on anthropometry, body composition, and performance in a 12 week, double-blind, placebo-controlled trial involving 31 weight-training volunteers. No significant treatment effects for anthropometric parameters and body composition were observed. Both groups had similar improvements in performance in most exercises; however, a significant improvement in one repetition-maximum leg extension was found in the treatment group. The authors concluded that although vanadyl sulfate was ineffective in changing body composition in

weight-training athletes, its performance-enhancing effect required further investigation.^[85]

Toxicity

Anecdotal reports indicate that body-builders often supplement 15 mg t.i.d.; however, this practice is ill-advised due to both the lack of demonstrated efficacy and the lack of information regarding long-term toxicity of

high doses of vanadium. Dietary concentrations of 25 mg of vanadium per kg cause mild diarrhea and growth suppression in rats and up to 50 mg/kg severely depressed growth and caused increased diarrhea and mortality. When 12 humans were fed 13.5 mg/day of vanadium for 2 weeks and then 22.5 mg/day for 5 months, five patients developed cramps and diarrhea at the high dosage.^[86]

Zinc

Dietary deficiency of zinc is prevalent. Because of this, zinc supplements have been widely advocated for athletes. While it might not be wise to indiscriminately administer zinc, suggestive evidence indicates that zinc might impact body composition due to its interaction with a variety of hormones.

It is thought that intense exercise can result in changes in zinc metabolism. Zinc has been demonstrated to be lowered in trained adolescent gymnasts and even lower in females in the general population. This reduction might play a role in abnormalities of puberty, growth, or muscular performance.^[87]

Some investigators have concluded zinc might play an important role in modulating serum testosterone levels in normal men. Dietary zinc restriction in normal young men is associated with a significant decrease in serum testosterone concentrations, while zinc supplementation of marginally zinc-deficient normal elderly men resulted in an increase in serum testosterone from 8.3 ± 6.3 to 16.0 ± 4.4 nmol/L ($P = 0.02$).^[88] However, although zinc deficiency might inhibit testosterone production, zinc supplementation to an individual with adequate levels has not been shown to produce excess testosterone.

Zinc deficiency might result in reduced production of growth hormone (GH) and/or insulin-like growth factor I (IGF-I).^[89] Oral zinc replacement has normalized growth hormone levels and increased growth rate in teenagers found to be GH-deficient.^[90] Zinc supplementation causes a significant increase in liver synthesis of IGF-I (somatomedin C). In chronic zinc deficiency, reduced liver production of IGF-I is responsible for reduced physical growth; moreover, in this situation, receptor resistance to IGF-I (in addition to GH) has been demonstrated. Receptor sensitivity is re-established after supplementation with zinc. Zinc might also play a role in increasing the number of

receptors.^[91]

Zinc deficiency might affect the metabolism of thyroid hormones. The structure of nuclear thyroid hormone receptors contains zinc ions, crucial for the functional properties of the protein.^[80] In experimental animals, zinc deficiency decreases concentrations of triiodothyronine (T_3) and free thyroxine (fT_4) in serum by approximately 30% when compared with zinc-adequate controls. The concentration of thyroxine (T_4) in serum was not affected by zinc deficiency. In these animals, zinc deficiency also decreased the activity of hepatic iodothyronine 5'-deiodinase by 67%.^[81]

Toxicity

Zinc supplementation is generally safe if maintained at levels within two to eight times the RDA. Symptoms of zinc toxicity include gastrointestinal irritation, vomiting, adverse changes in HDL/LDL cholesterol ratios, and impaired immunity. The latter develops when levels above 180 mg/day are consumed for more than several weeks. Excess intake of zinc may either lower copper levels or aggravate an existing marginal copper deficiency.

Because of the multiple interactions of zinc with hormones critical to strength and body composition, it is recommended that athletes get a determination of zinc nutriture and supplement if required.

Summary

Based upon available information, strength athletes are likely to obtain improved results by following a supplementation routine which includes:

- creatine monohydrate (at least 3 g/day)
- a post-workout protein shake (40 g of protein)
- vitamin C (1–3 g/day)
- a multivitamin/mineral formulation containing approximately
 - 3 mg of boron
 - 200 mcg of chromium
 - 200 mcg of selenium
 - 100 mcg of vanadium
 - 15 mg of zinc.

The published results to date on HMB are impressive. For athletes utilizing HMB, the recommended dosage is 3 g/day. While a theoretical argument can be made for the inclusion of phosphatidylserine in a supplement routine, the high cost and the lack of information on bottom-line results of improved strength or body composition make it

difficult to justify its use. Although compelling evidence could be used to make an argument for many of the isolated amino acids, a high-quality protein supplement, such as whey, provides adequate levels of all of the amino acids for the majority of athletes. Because of the correlation of low glutamine levels and overtraining, supplementing 2 g/day of glutamine in addition to a protein supplement, in individuals whose training regimen places them at risk for overtraining, seems prudent.

SPORTS NUTRITION FOR ENDURANCE ATHLETES

Panax ginseng

Panax ginseng, also known as *Panax schinseng*, is a member

531

of the family Araliaceae. In Mandarin Chinese it is called *Ren Shen* but is commonly referred to as Korean or Chinese ginseng. Several closely related species are also often sold as ginseng. These include *Panax quinquefolium* (American ginseng); *Panax notoginseng*, also known as *Panax pseudoginseng* (Himalayan ginseng), and *Panax japonicum* (Japanese ginseng). Ginseng was used traditionally as a tonic for a broad range of medical conditions. It was believed to be a revitalizing agent capable of enhancing health and promoting longevity (for a more detailed discussion, see [Ch. 100](#)).

Soviet scholars, beginning in the early 1950s, were the first to establish the fact that many Araliaceae family plants, especially *Panax ginseng*, are adaptogens.^[92] Adaptogens, among their many properties, are thought to promote regeneration of the body after stress or fatigue and to rebuild strength. Because of its reputation as an adaptogen, *Panax ginseng* is among the most popular botanical supplements used by athletes.

Many animal studies with *Panax ginseng*, or its active components, have demonstrated an enhanced response to physical or chemical stress.^{[93] [94] [95] [96] [97]} In rats, the aqueous suspensions of roots of *Panax ginseng* were tested for anti-stress activity by the “mice swimming endurance test” and anabolic activity by noting gain in body weights and muscle. A significant increase in mice swimming time was shown by ginseng-fed rats as compared with the control group.^[98]

In animal models, administration of ginseng has been shown to impact several hormones which might impact performance. High doses of ginseng have been reported to increase blood testosterone level.^[99] Experiments indicate that the binding of corticosteroid to certain brain regions is increased in adrenalectomized rats given ginseng saponin.^[100] Ginseng saponin has also been reported to act on the hypothalamus and/or hypophysis, stimulating ACTH secretion which results in increased

synthesis of corticosterone in the adrenal cortex.^[101]

While studies with animals have been compelling, ginseng's value as an ergogenic aid in humans is still equivocal.^[102] Extracts of *Panax ginseng* are reported to increase plasma total and free testosterone, dihydrotestosterone, and FSH and LH levels in infertile males.^[103] The addition of ginseng root extract to a multivitamin base is reported to have improved subjective parameters in a population exposed to the stress of high physical and mental activity.^[104] In a double-blind, randomized, cross-over study, 50 healthy males received two capsules of a preparation containing ginseng extract, dimethylamino-ethanol bitartrate, vitamins, minerals, and trace elements, or two capsules of placebo every day for 6 weeks. The total workload and maximal oxygen consumption during exercise were significantly greater after the ginseng preparation than after placebo. The authors also noted decreased plasma lactate levels, carbon dioxide production, and heart rate during exercise in participants receiving the ginseng preparation.^[105] Others evaluated the impact on performance of a ginseng saponin extract (8 or 16 mg/ kg body weight) ingested daily for 7 days. Although time to exhaustion was significantly less during the pre-supplementation control trial than during the placebo and ginseng trials, no significant difference was found between the placebo and the ginseng trials.^[106] It should be noted that the duration of the supplementation period was only 1 week in this trial. Since, historically, ginseng, as a tonic, is used for prolonged time periods and since positive results have been reported following 6 weeks of supplementation, a longer trial might have demonstrated an ergogenic effect.

Research in support of the use of *Panax ginseng* as an ergogenic aid, although equivocal, is promising. Because of the anecdotal reputation and allure this plant holds, it is likely to continue to be utilized by many athletes.

Dosage

The quality of available ginseng preparations can vary greatly, so it is imperative to use *Panax ginseng* with documented potency. A typical dose for general tonic effect would contain at least 25 mg of the saponin ginsenoside.^[107] *Panax ginseng* contains 2–3% ginsenosides, so a dose of 8–12 g of crude herb, assuming it is of high quality, will provide adequate saponin content. Because of the variability in quality of *Panax ginseng* available, utilizing a preparation standardized for ginsenoside content may be preferable. The dosage for a product standardized to 5% ginsenosides would be 500 mg/day, and to 14% ginsenosides would be about 180 mg.^[107] If utilizing ginseng for a prolonged period of time, some authors have recommended discontinuing supplementation periodically for 2 week intervals.

Toxicity

The problem of quality control makes toxicology difficult to address. Studies have been performed on standardized extracts of ginseng which demonstrate the absence of side-effects and mutagenic or teratogenic effects. However, toxicity has been reported with products of uncertified constituents.

Eleutherococcus senticosus

Eleutherococcus senticosus, also known botanically as *Acanthopanax senticosus*, is a member of the Araliaceae family which also contains *Panax ginseng*. In China, the plant is called *Ci Wu Jia*; however, it is most commonly referred to as Siberian ginseng. Because of its wide availability and lower cost, the dried root and rhizome is commonly used as a ginseng substitute; however,

532

ginsenosides, characteristic of *Panax* sp., are not found in the roots of *Eleutherococcus senticosus*.^[107] (For a more detailed discussion, see [Ch. 83.](#))^[9]

Eleutherococcus senticosus is classified as an adaptogen and is believed to promote recovery and improve endurance. It has a long history of use in Chinese herbal medicine where it was used to enhance general health, longevity, appetite and memory. Soviet scientists, beginning in the late 1950s, because of the rarity of *Panax ginseng*, shifted the focus of their research to other members of the Araliaceae family in order to find suitable substitutes. Four adaptogenic plants were identified, studied and finally introduced into therapeutic practice, between 1955 and 1964. *Eleutherococcus senticosus* was considered to be the most important of these substitutes.^[108] Reports indicate that *Eleutherococcus* was used routinely by both Soviet Olympic athletes and military officers.

Extracts of *Eleutherococcus* prolong the exercise time to exhaustion in swimming rats,^[109] and modulate changes of the hypophyseo-adrenal system in rats under extreme conditions.^[110] Farnsworth et al^[111] reviewed the results of clinical trials of *Eleutherococcus* in humans. The data they gathered indicated that ingestion of extracts from the plant increased the ability to accommodate to adverse physical conditions, improved mental performance, and enhanced the quality of work under stressful conditions such as during athletic performance.^[111]

Others, however, have concluded that supplementation of *Eleutherococcus senticosus* had no ergogenic effect on the measured parameters associated with submaximal and maximal aerobic exercise tasks. The effect on performance during submaximal and maximal aerobic exercise was measured in 20 highly trained distance runners randomly assigned to matched pairs. Participants consumed either 3.4 ml of extract or placebo daily for 6 weeks. During the 8 week double-blind study, subjects completed five trials of 10 minute runs on a treadmill at their 10 km race pace and a maximal treadmill test. No significant differences were observed between *Eleutherococcus*- and placebo-supplemented groups for heart rate, oxygen consumption, respiratory exchange ratio, and rating of perceived exertion during the 10 km and maximal treadmill tests.^[112]

Recently, *Eleutherococcus senticosus* has received attention in the popular press under

the name of *Ci Wu Jia*. Trials of its effect on performance have been sponsored by PacificHealth Laboratories, Inc., which is the manufacturer of a standardized extract and the holder of a patent for the use of *Ci Wu Jia* to enhance stamina and physical performance during, and enhance recovery following cessation of, exercise. All reports on *Ci Wu Jia*'s impact on performance have been based on information provided by this manufacturer.

Ci Wu Jia reportedly has a carbohydrate-sparing action, shifting metabolism to a higher utilization of fat for energy. The carbohydrate shift is also reported to delay the lactic acid build-up associated with muscle fatigue. Reports indicate that *Ci Wu Jia* might slightly reduce heart rate during exercise and recovery. Participants have usually consumed 800 mg/day of the standardized extract for 2 weeks.

Overall, the evidence for an ergogenic affect from *Eleutherococcus senticosus* is fair. The reported benefits Russian athletes received from supplementation remain the most compelling evidence to date on the ergogenic potential of this plant.

Dosage

Recommended doses vary depending on the form of *Eleutherococcus* utilized. The dose of a 1:1 fluid extract (33% ethanol) is usually between 2.0 and 4.0 ml one to three times per day; however, doses up to 16.0 ml have been used. A standardized 20:1 solid concentrate, is also available. In this form, a minimum recommended dosage would be 300 mg/day, equivalent to 6 g of powdered root. Better results might be experienced at higher doses. In order to avoid accommodation, *Eleutherococcus* should be used for no longer than 60 consecutive days, followed by a period of 2–3 weeks of abstinence before again beginning supplementation.^[111]

Toxicity

Toxicity studies in animals have demonstrated that *Eleutherococcus* extracts are virtually non-toxic. In human clinical studies it was demonstrated that in the recommended dosage range, they (33% ethanol) are well tolerated and side-effects are infrequent. A few studies found mild side-effects at higher dosages (4.5–6.0 ml three times/day) when used for long periods (60 days). The symptoms included insomnia, irritability, melancholy, and anxiety.

Carnitine

Carnitine is promoted as a supplement needed to improve the body's ability to use stored fat as fuel. Supplementation purportedly enhances lipid oxidation, increases $\dot{V}O_{2max}$, and decreases plasma lactate accumulation during exercise.

Carnitine is a tri-methylated amino acid, roughly similar in structure to choline. The synthesis of carnitine begins with the methylation of lysine by S-adenosylmethionine. Cofactors required for optimal synthesis include:

- magnesium
 - iron
 - ascorbic acid
 - folic acid
-

533

- methylcobalamin
- betaine
- pyridoxal 5' phosphate
- niacin.

Carnitine is located in the mitochondrial membrane and is a cofactor needed for the transformation of free long-chain fatty acids (LCFAs) into acyl-carnitines for subsequent transport into the mitochondrial matrix. Inside the mitochondria, LCFAs are metabolized into energy by the process of beta-oxidation.

Several investigators have suggested that L-carnitine supplementation might benefit athletes. One study investigated the effect of giving 2 g/day of L-carnitine for 6 weeks to seven male marathon athletes. Improved running speed of 5.68% and decreased average oxygen consumption and heart rate in the treadmill test followed supplementation. The authors suggest that for carnitine to be effective as an ergogenic aid, several preconditions must be met: having an adequate supply of lipids available as fuel, shifting metabolism towards the utilization of fats as an energy source, and having a relative shortage of available endogenous carnitine. Because the average free and total plasma carnitine levels were below the normal ranges prior to supplementation, the L-carnitine might have helped to overcome a relative endogenous deficiency for the participants involved in this study.^[113]

In a double-blind cross-over study of 10 moderately trained male subjects, either 2 g of L-carnitine or placebo are provided orally 1 hour prior to exercise. Supplementation with L-carnitine induced a significant post-exercise decrease of plasma lactate and pyruvate and a concurrent increase of acetylcarnitine.^[114] Another study gave 2 g of L-carnitine or a placebo to subjects 1 h before they began exercise. At the maximal exercise intensity, treatment with L-carnitine increased both maximal oxygen uptake and power output. The authors also reported that, at similar exercise intensities, oxygen uptake, carbon dioxide production, pulmonary ventilation and plasma lactate were reduced in participants receiving L-carnitine.^[115]

While some of the results with L-carnitine supplementation have been promising, not all research is in agreement. One review of carnitine and physical exercise came to the following, among other, conclusions regarding carnitine supplementation:^[116]

- its impact on performance in athletes is equivocal
- it does not enhance fatty acid oxidation, spare glycogen or postpones fatigue during exercise

- it does not stimulate pyruvate dehydrogenase activity
- it does not reduce body fat or help with weight loss.

One research group found chronic carnitine supplementation, 6 g/day, resulted in no differences in $\dot{V}O_2$, respiratory exchange ratio, heart rate, or carbohydrate and fat utilization. They also reported that muscle carnitine concentration at rest was unaffected by supplementation.^[117] Similar results were reported with carnitine supplementation at 4 g/day for 14 days, which, while effective at increasing plasma total acid-soluble and free carnitine concentrations, had no significant effect on muscle carnitine concentrations.^[118]

Another group found that loading of athletes with L-carnitine for the 10 days prior to a marathon, while abolishing the exercise-induced fall in plasma-free carnitine and increasing the production of acetylcarnitine, resulted in no detectable improvement in performance.^[119]

Still another study investigated the effects of L-carnitine supplementation on metabolism and performance of endurance-trained athletes during and after a marathon run. In a double-blind cross-over field study, seven male subjects received 2 g of L-carnitine 2 hours before the start of a marathon run and again after 20 km of running. Although the administration of L-carnitine was associated with a significant increase in the plasma concentration of all analyzed carnitine fractions, significant changes in running time, plasma concentrations of carbohydrate metabolites (glucose, lactate, and pyruvate), of fat metabolites (free fatty acids, glycerol, and beta-hydroxybutyrate), of hormones (insulin, glucagon, and cortisol); and of enzyme activities (creatine kinase and lactate dehydrogenase) were not observed.^[120]

Although available data on L-carnitine as an ergogenic aid is not compelling, under some experimental conditions pretreatment has favored aerobic processes. It is possible that L-carnitine might only exert a beneficial effect when there are actual deficiencies. Availability of fat as a substrate for fuel might also impact on the ability of carnitine to act as an ergogenic aid.

Dosage

Supplementation of 2 g 1 hour prior to intensive exercise might provide some benefits; however, based on the mixed results and the cost of the supplement, chronic administration of L-carnitine is difficult to justify.

Toxicity

See above.

Choline

Choline supplements have been advocated as a means of preventing the decline in choline reported to occur during exercise. Choline in the diet primarily consists of phosphatidylcholine, which after absorption by the intestinal mucosa, is metabolized to choline in the liver. Most choline is re-phosphorylated to phosphatidylcholine; however,

a small amount of choline is carried to

the brain via the bloodstream, where it is converted to acetylcholine, a chemical messenger required for adequate nerve impulses and memory storage and retrieval.

Running a 26 km marathon reduced plasma choline by approximately 40% according to one study.^[121] The decline has been proposed to reduce acetylcholine levels, resulting in a reduction in the transmission of contraction-generating impulses across skeletal muscle.^[122] It has been proposed that this reduction might negatively affect endurance performance.^[121] ^[122]

One study investigated the effect of lecithin on the plasma choline concentrations during continuous strain in 10 top level triathletes (four women and six men). The participants received either a placebo or 0.2 g lecithin/kg body mass 1 hour before each exercise. Bicycle exercise without lecithin supply decreased plasma choline concentrations in all the triathletes, on average by 16.9%. When lecithin was given before exercise, average plasma choline concentrations remained at the same level as the initial values. In trial II, with 13 adolescent runners (three girls and 10 boys), mean plasma choline concentrations remained stable when running without supplementation of lecithin.^[123]

However, another research group found that trained cyclists do not deplete choline during supramaximal brief or prolonged submaximal exercise, nor do they benefit from choline supplementation, as choline bitartrate (2.43 g), to delay fatigue under these conditions.^[124]

No evidence to date provides compelling justification for the supplementation of choline as an ergogenic aid. Its potential efficacy for improving physical performance remains largely theoretical.

Coenzyme Q₁₀ (ubiquinone)

Coenzyme Q₁₀ (CoQ₁₀), because of its role in mitochondrial energy production, is reputed to enhance performance; however, no studies have demonstrated a significant improvement in any aspect of athletic performance.

Biopsy of muscle found that CoQ₁₀ levels were positively correlated to exercise capacity and marathon performance.^[125] Providing 150 mg/day of CoQ₁₀ orally for 2 months to a group of middle-aged men resulted in increased circulating blood levels of CoQ₁₀ and improved perceived level of vigor; no improvement in aerobic capacity was found.^[126] Supplementing cyclists with 100 mg/ day of CoQ₁₀ for 8 weeks produced no measurable effect on performance, $\dot{V}O_{2\max}$, submaximal physiological parameters, or lipid peroxidation.^[127] Others have found that oral ubiquinone was ineffective as an ergogenic

aid in both young and older trained men.^[128]

Based upon available research, CoQ₁₀ appears to have no value as an ergogenic aid.

Pyridoxal-alpha-ketoglutarate (PAK)

Pyridoxal-alpha-ketoglutarate (PAK) consists of pyridoxine (about 54%) and alpha-ketoglutarate (about 46%). It is thought to improve the generation of high-energy phosphate bonds, such as ATP or GTP. In addition, an increased level of alpha-ketoglutarate, along with pyridoxal 5'-phosphate, in the mitochondria might enhance the transamination of pyruvate to alanine, which may prevent or reduce lactic acid formation.^[129]

Administration of PAK has been shown to decrease the plasma concentration of lactate in response to isometric exercise in a group of insulin-independent non-ketotic diabetic patients.^[130] The administration of 30 mg/kg of PAK for 30 days has been reported to increase $\dot{V}O_{2\text{ max}}$ (a measurement of maximal aerobic power) and to decrease lactic acid accumulation during short supramaximal workloads. The administration of alpha-ketoglutarate or pyridoxine separately did not alter $\dot{V}O_{2\text{ max}}$ significantly.^[129]

Individually and in combination, the use of PAK and sodium bicarbonate on short-term maximal exercise capacity was studied in eight cyclists. Oral tablets of sodium bicarbonate and PAK were given in doses of 200 and 50 mg/kg, respectively. The investigators found no significant differences between treatments in the ability to sustain maximum power during the exercise trial; however, the best results obtained were from individuals utilizing both PAK and bicarbonate. PAK supplemented by itself did not improve participants' ability to sustain maximum power.^[131]

Dosage

The typical dose is 1800–3000 mg/day, depending upon body weight. While PAK might be complementary to athletic training, particularly in conjunction with sodium bicarbonate, available information is limited. PAK supplementation appears to positively influence some physiological parameters associated with enhanced aerobic performance; however, to date this supplement has not been shown to produce a “bottom line” result of improving actual performance.

Pyruvate

Supplementation of pyruvate is becoming popular with athletes due to reports of its endurance and weight loss-enhancing effects. Pyruvate is a stable salt form of pyruvic acid, the naturally occurring end-product of the metabolism of carbohydrates. It is stabilized by the addition of either sodium, potassium, calcium, or magnesium to pyruvic acid. Pyruvic acid occurs naturally in the diet, with fruits and vegetables being good sources. Red apples are possibly the best source with an estimated 450 mg of pyruvic

acid per apple.

Pyruvate is a three-carbon compound containing a carboxylic acid and a ketone group. During the process of glycolysis, glucose is converted to pyruvate. Pyruvate is then either converted to acetylCoA, for entry into the citric acid cycle under aerobic conditions, or to lactate under anaerobic conditions. Pyruvate's mechanism of action for weight loss and for enhancing endurance is unknown.

In published research, pyruvate has usually been given in conjunction with dihydroxyacetone. This combination has been reported to be useful in weight loss routines, where it is partially, isocalorically substituted for glucose in obese women. Participants were placed on severely restrictive hypocaloric diets for 21 days while housed in a metabolic ward. In one study, participants fed dihydroxyacetone and pyruvate (DHAP) showed greater weight loss (6.5 ± 0.3 kg, vs. 5.6 ± 0.2 kg for the placebo) and fat loss (4.3 ± 0.2 kg, vs. 3.5 ± 0.1 kg for placebo).^[132] In another trial, pyruvate and dihydroxyacetone, given as approximately 20% of energy intake, reduced the reaccumulation of body weight (1.8 ± 0.2 vs. 2.9 ± 0.1 kg) and fat (0.8 ± 0.2 vs. 1.8 ± 0.2 kg) associated with refeeding after a calorie restricted diet.^[133]

Pyruvate alone has been reported to be an effective addition to a weight loss program. In one study, participants were obese women housed in a metabolic ward consuming a 4.25 MJ/day liquid diet for 21 days with or without pyruvate partially, isoenergetically substituted for glucose. Participants fed pyruvate showed greater weight loss (5.9 ± 0.7 kg, vs. 4.3 ± 0.3 kg for placebo) and fat loss (4.0 ± 0.5 kg, vs. 2.7 ± 0.2 kg for placebo).^[40] The reports indicate that pyruvate had no impact on enhancing nitrogen balance, serum protein concentrations or lean body mass in these subjects.^{[132] [133] [134]}

Since the published studies were conducted on obese women consuming restricted calorie diets of either 500 or 1,000 calories/day, these weight losses should not be extrapolated to athletes or other populations on normal or high-calorie diets. Additionally, in the published trials pyruvate has been substituted for glucose, a substance which impacts fat metabolism in overweight individuals because of its role in insulin secretion. It is possible, under similar circumstances, that partially, isocalorically substituting protein or fat for glucose might have produced similar, if not better, results.

Pyruvate has been reported to increase the time required to reach exhaustion and to decrease perceived exertion. In the published studies, pyruvate was again given in relatively high amounts in conjunction with dihydroxyacetone. In both studies, untrained males received either 100 g of pyruvate and dihydroxyacetone or 100 g of a glucose polymer derived from the hydrolysis of corn starch as a placebo for 7 days. Arm endurance was 133 ± 20 minutes after placebo and 160 ± 22 minutes after DHAP.^[135] Leg endurance was 66 ± 4 minutes after placebo and 79 ± 2 minutes after DHAP.^[136] Muscle glycogen, determined by biopsy, at rest and exhaustion did not differ between placebo and DHAP subjects.^[136] Plasma free fatty acids, glycerol, and

beta-hydroxybutyrate were similar during rest and exercise for placebo and DHAP subjects in both studies.^[135]^[136] Supplementation of a DHAP mixture has also been reported to decrease the perceived level of exertion.^[137]

Feeding DHAP for 7 days appears to increase submaximal endurance in untrained athletes; however, it is unresolved whether similar results would be obtained with trained athletes. In the published studies 25 g/day of pyruvate were given along with 75 g/day of dihydroxy-acetone; however, in the lay press Stanko has been quoted as saying: “We see a linear response between 2 and 5 g a day and then the response plateaus. In other words, the response with 10 or 15 g or more is the same as with 5 g.” Supporting documentation for this assertion has apparently not been published in scientific literature to date, nor has any research been published on the endurance effects of the supplementation of pyruvate without dihydroxyacetone.

Dosage

Dosage recommendations are 2–5 g/day, taken with food. Better results might be obtained by spreading the 5 g into two or three divided doses.

Since the reported results on endurance were obtained in trials comparing DHAP against a glucose polymer, the only justifiable conclusion is that subjects consuming 100 g of DHAP rather than 100 g of hydrolyzed corn starch, a substance with no nutritional value, experienced better endurance. Research evaluating the performance effects of adding 2–5 g of pyruvate to the diet of trained athletes still needs to be published. The available evidence suggesting that pyruvate acts as an ergogenic aid in high dosages in combination with dihydroxyacetone is questionable. No evidence exists in support of claims of ergogenic action for pyruvate supplementation at the recommended dose of between 2 and 5 g.

Performance drinks

Performance drinks are commonly consumed as an ergogenic aid during endurance sports activities. These drinks are designed to maintain normal hydration, electrolyte balance and blood glucose levels during exercise. Current evidence indicates that ingestion of performance drinks during exercise enhances athletic performance and normalizes markers of thermoregulation. A variety of beverages formulated to provide fluid, carbohydrates, and electrolytes during and following exercise are commercially available. These beverages commonly contain 4–8%

carbohydrate (as glucose, fructose, sucrose or maltodextrins) and small amounts of electrolytes (most often sodium, potassium, and chloride). Contrary to popular belief, rates of sweating and urine flow are not influenced by fluid ingestion during exercise.^[138]

Studies have shown that 5–10% solutions of glucose, glucose polymers (maltodextrins)

and other simple sugars all have suitable gastric-emptying characteristics for the delivery of fluid and moderate amounts of carbohydrate substrate. The optimal concentration of electrolytes, particularly sodium, remains unknown. Most currently available sports drinks provide a low level of sodium (10–25 mmol/L) in recognition of the fact that sodium intake can promote intestinal absorption of fluid as well as assist in rehydration.^[139]

Exercise and dehydration result in increases in core temperature, body fluid osmolality, and heart rate; losses of plasma and other body fluid volumes; and depletion of glycogen. All of these homeostatic disturbances can be ameliorated by fluid consumption during exercise.^[140]

During exercise, water and electrolytes are lost from the body in sweat. Sweat rate is determined primarily by the metabolic rate and the environmental temperature and humidity. Under some conditions, the sweat rate can exceed the maximum rate of gastric emptying of ingested fluids. If this occurs, some degree of dehydration is observed. Excessive replacement of sweat losses with plain water or fluids with a low sodium content following prolonged exercise has resulted in hyponatraemia, so sodium replacement is considered essential for post-exercise rehydration.^[141]

For moderate-intensity exercise, water ingestion 30–60 minutes prior to exercise seems to minimize homeostatic disturbances; however, at higher intensities of athletic performance, it probably has little effect.^[140] During exercise, ingestion of both water and carbohydrate beverages has been shown to minimize homeostatic disturbances. Subjects allowed to drink a carbohydrate-electrolyte beverage (4.85% polyose, 2.65% fructose) or distilled water ad libitum during 3 hours of continuous exercise in the heat (31.5°C) showed no significant differences between drinks for rectal temperature, heart rate, or sweat rate during exercise.^[142] No differences in thermoregulatory responses in individuals consuming either carbohydrate beverages or water have been observed.^[143]

The efficacy of a given drink is limited by the rate of absorption of fluid from the intestines, which is in turn limited by gastric emptying. Several factors influence gastric emptying, including exercise intensity and the carbohydrate composition of the solution.^[144] The gastric-emptying rate might also be influenced by the caloric content, volume, osmolality, temperature, and pH of the ingested fluid; metabolic state and biochemical individuality of the athlete; and the ambient temperature.^[145]

The caloric content of the ingested fluid might be the most important variable governing gastric-emptying rate. At rest and during running, water has a faster gastric-emptying time than all other drinks. Gastric emptying is progressively slowed as the caloric content of the fluid increases.^[144] During moderate exercise, gastric emptying occurs at a rate similar to that during rest; however, more intense exercise appears to inhibit gastric emptying. Evidence indicates that beverages containing below 10% carbohydrate have gastric-emptying rates closest to that of water.^[146] Drinks containing less than or equal to 8–10% carbohydrate are absorbed into the body at similar rates and should behave similarly in replenishing body fluids lost in sweat during exercise.^[147]

Several other factors have been shown to impact gastric emptying. Isotonic drinks

appear to empty quickly throughout exercise, whereas the gastric-emptying rate of hypertonic drinks has been shown to decrease over time.^[148] Fat is believed to delay gastric emptying; however, medium-chain triglycerides (MCTs) might not inhibit gastric emptying as most fat does. Research indicates that MCT-containing drinks have faster gastric-emptying times than drinks containing 100% maltodextrins.^[149]

It has been suggested that maltose might be a superior source of carbohydrate for endurance athletes. Some researchers have suggested that ingestion of an 8% solution of maltodextrin or sucrose every 15 minutes during exercise might provide optimal fluid and carbohydrate replacement.^[150] The rates of gastric emptying and the peak rates of exogenous carbohydrate oxidation are not significantly different between maltose and glucose.^[151]

While ingestion of 13 g carbohydrate per hour did not improve performance during prolonged moderate intensity cycling in one study,^[152] most studies report that ingestion of carbohydrate beverages has a beneficial effect on performance. Carbohydrate ingested during exercise appears to be readily available as a fuel for the working muscles, at least when the exercise intensity does not exceed 70–75% of maximum oxygen uptake.^[153] Rating of perceived exertion is reported to be higher in athletes consuming water than in athletes consuming carbohydrate drinks.^[154] For exercise leading to exhaustion in less than 30 minutes, carbohydrate ingestion is not effective in minimizing homeostatic perturbations or improving exercise performance;^[140] however, for exercise of longer duration, ingestion of performance beverages appears to enhance performance. Research has shown that 275 ml of a 6% carbohydrate-electrolyte beverage consumed every 20 minutes maintained blood glucose and enhanced performance better than water during endurance cycling.^[155] One study compared the effects of orange flavored drinks containing 0, 6.4, and 10% carbohydrate. The solutions, 3 ml/kg body weight, were given double-blind and counter-balanced at time 0 and every 20 minutes during exercise. Blood glucose and lactate, and temperature were similar for all solutions; however,

performance improved with consumption of a carbohydrate drink during exercise. The best results were obtained with ingestion of a 10% carbohydrate drink.^[156]

Eight well-trained men cycled for up to 255 minutes at a power output corresponding to $\dot{V}O_2$ at lactate threshold (approximately 68% $\dot{V}O_{2\max}$) on three occasions separated by at least 1 week. Subjects drank 5 ml/kg body weight of either a water placebo or a liquid beverage containing a moderate (6% carbohydrate) or high (12% carbohydrate) concentration of carbohydrate, beginning at minute 14 of exercise and every 30 minutes thereafter. Exercise time to fatigue was shorter in subjects receiving placebo (190 minutes) as compared with 6% carbohydrate (235 minutes) and 12% carbohydrate (234 minutes) beverages.^[157]

In another study, 12 subjects were exercised to exhaustion on a cycle ergometer at a

workload corresponding to 70% of maximum oxygen uptake. In one trial, no drinks were given, and in the other trials subjects drank 100 ml every 10 minutes. Median exercise time was greatest (110.3 minutes) for individuals receiving a hypotonic glucose-electrolyte solution (90 mmol/L glucose; 60 mmol/L Na⁺ ; 240 mosmol/kg), followed by individuals receiving an isotonic glucose-electrolyte solution (I: 200 mmol/L glucose; 35 mmol/L Na⁺ ; 310 mosmol/kg) (107.3 min), water (93.1) and no drink (80.7). Significant treatment effects were also observed for heart rate, rectal temperature and serum osmolality.^[158]

Twelve highly trained male runners ran 15 km at self-selected pace on a treadmill in warm conditions to demonstrate differences in physiological responses, fluid preferences, and performance when ingesting sports drinks or plain water before and during exercise. One hour prior to the start of running, an equal volume (1,000 ml) of either water or a 6 or 8% carbohydrate-electrolyte drink was ingested. Blood glucose was significantly higher 30 minutes following ingestion of the 6 and 8% carbohydrate-electrolyte beverages compared with water, significantly lower at 60 minutes post-ingestion with both sports drinks than with water, but similar after 7.5 km of the run for all beverages. During the first 13.4 km, oxygen uptake and run times were not different between trials; however, the final 1.6 km performance run was faster with both carbohydrate-electrolyte drinks than with water.^[159]

Research indicates that a sugar drink immediately prior to exercise can impair performance. Carbohydrates will invoke an insulin response which increases the likelihood of hypoglycemia occurring during exercise. A fall in blood glucose will result from the ingestion of glucose solutions fed 15–45 minutes before prolonged exercise; however, the consumption of 18–50% solutions of glucose or glucose polymers 5 minutes before prolonged exercise has potential for improving endurance performance.^[140]

Many experts recommend consuming a beverage high in carbohydrates within 1 hour after exercise. Exercise-induced depletion of muscle glycogen levels can be rapidly restored by glucose ingestion. Provided adequate carbohydrate is consumed, it appears that the frequency of intake, the form (liquid vs. solid) and the presence of other macronutrients does not affect the rate of glycogen storage.^[160] During the post-exercise recovery period, ingesting a carbohydrate-electrolyte beverage is effective in minimizing physiological disturbances. Subjects drink more; plasma volume increases to a higher level; plasma osmolality, glucose, and potassium are greater; and body weight increases more with the ingestion of carbohydrate beverages than with pure water.^[161]

Dosage

The optimum frequency, volume and composition of drinks will vary widely depending on the intensity and duration of the exercise, the environmental conditions and the physiology of the individual. However, in general, isotonic beverages, with either glucose, glucose polymers, or maltodextrins as the carbohydrate source, produce the best results. Prior to exercise, only water should be consumed. Drinking carbohydrate solutions 15–60 minutes prior to exercise should be avoided since it can impair performance; however, ingestion immediately prior to beginning exercise might be

beneficial. This is because once endurance exercise is started, insulin is generally not increased, so the carbohydrates will likely be available as energy substrates. The staggered ingestion of performance drinks will be beneficial when exercise duration exceeds 30 minutes; however, during shorter duration exercise and especially weight-lifting, there appears to be no additional benefit in ingesting anything other than water.

SUMMARY

Based upon available information, evidence remains mixed but promising on the supplementation of *Panax ginseng* and *Eleutherococcus senticosus*. L-Carnitine's role as an ergogenic aid remains something of a mystery. The mixed results reported in the literature and the high cost of the supplement make it difficult to justify chronic administration of 2 g/day. No evidence to date supports the supplementation of choline as an ergogenic aid. CoQ₁₀'s failure in several studies to demonstrate any performance-enhancing effect should end any debate or recommendations concerning routine administration of this nutrient as an ergogenic aid. Although PAK supplementation has been shown to enhance certain parameters associated with aerobic exercise, it has not yet demonstrated improved performance. Although evidence suggests that pyruvate acts as an ergogenic aid in high dosages in combination with dihydroxyacetone, available

evidence does not support claims of an ergogenic action for pyruvate supplementation at a dose of between 2 and 5 g. The staggered ingestion of isotonic, 6–10% carbohydrate performance drinks should be a routine practice in endurance exercise activities of greater than 30 minutes' duration.

Chapter 60 - Stress management

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

INTRODUCTION

Stress is defined as any disturbance – heat or cold, chemical toxin, microorganisms, physical trauma, strong emotional reaction, etc. – that can trigger the “stress response”. How an individual handles stress plays a major role in determining their level of health. Comprehensive stress management involves a truly wholistic approach designed to counteract the everyday stresses of life. Most often the stress response is so mild it goes entirely unnoticed. However, if stress is extreme, unusual, or long-lasting, the stress response can be overwhelming and quite harmful to virtually any body system.

Before discussing methods on how to help patients deal effectively with stress, it is important to understand the stress response. Ultimately, the success of any stress management program is dependent on its ability to improve an individual’s immediate and long-term response to stress.

THE GENERAL ADAPTATION SYNDROME

The stress response is actually part of a larger response known as the “general adaptation syndrome”, a term coined by the pioneering stress researcher Hans Selye. To fully understand how to combat stress, it is important to understand the general adaptation syndrome. The general adaptation syndrome is composed of three phases: alarm, resistance, and exhaustion.^[4] These phases are largely controlled and regulated by the adrenal glands.

The initial response to stress is the alarm reaction which is often referred to as the “fight or flight response”. The fight or flight response is triggered by reactions in the brain which ultimately cause the pituitary gland to release adrenocorticotrophic hormone (ACTH), which causes the adrenals to secrete adrenaline and other stress-related

hormones.

The fight or flight response is designed to counteract danger by mobilizing the body's resources for immediate

544

physical activity. As a result, the heart rate and force of contraction of the heart increases to provide blood to areas necessary for response to the stressful situation. Blood is shunted away from the skin and internal organs, except the heart and lung, while at the same time the amount of blood supplying required oxygen and glucose to the muscles and brain is increased. The rate of breathing increases to supply necessary oxygen to the heart, brain, and exercising muscle. Sweat production increases to eliminate toxic compounds produced by the body and to lower body temperature. Production of digestive secretions is severely reduced since digestive activity is not critical for counteracting stress. Blood sugar levels increase dramatically as the liver converts stored glycogen into glucose for release into the bloodstream.

While the alarm phase is usually short-lived, the next phase – the resistance reaction – allows the body to continue fighting a stressor long after the effects of the fight or flight response have worn off. Other hormones, such as cortisol and other corticosteroids secreted by the adrenal cortex, are largely responsible for the resistance reaction. For example, these hormones stimulate the conversion of protein to energy, so that the body has a large supply of energy long after glucose stores are depleted, and promote the retention of sodium to keep blood pressure elevated.

As well as providing the necessary energy and circulatory changes required to deal effectively with stress, the resistance reaction provides the changes required for meeting emotional crisis, performing strenuous tasks and fighting infection. However, while the effects of adrenal cortex hormones are quite necessary when the body is faced with danger, prolongation of the resistance reaction or continued stress increases the risk of significant disease (including diabetes, high blood pressure, and cancer) and results in the final stage of the general adaptation syndrome, i.e. exhaustion.

Exhaustion may manifest as a partial or total collapse of a body function or specific organ. Two of the major causes of exhaustion are loss of potassium ions and depletion of adrenal glucocorticoid hormones like cortisone. Loss of potassium results in cellular dysfunction and, if severe, cell death. Adrenal glucocorticoid store depletion decreases glucose control, resulting in hypoglycemia.

Another cause of exhaustion is weakening of the organs. Prolonged stress places a tremendous load on many organ systems, especially the heart, blood vessels, adrenals, and immune system and is associated with many common diseases, as listed in [Table 60.1](#).

STRESS: A HEALTHY VIEW

The father of modern stress research was Hans Selye MD. Having spent many years studying stress, Dr Selye

TABLE 60-1 -- Diseases strongly linked to stress^[1]

-
- Angina

 - Asthma

 - Autoimmune disease

 - Cancer

 - Cardiovascular disease

 - Common cold

 - Diabetes (adult onset – type II)

 - Depression

 - Headaches

 - Hypertension

 - Immune suppression

 - Irritable bowel syndrome

 - Menstrual irregularities

 - Premenstrual tension syndrome

 - Rheumatoid arthritis

 - Ulcers

 - Ulcerative colitis

developed valuable insights into the role of stress in disease. According to Dr Selye, stress in itself should not be viewed in a negative context. It is not the stressor that determines the response; instead it is the individual's internal reaction which then triggers the response. This internal reaction is highly individualized. What one person may experience as stress, the next person may view entirely differently. Selye perhaps summarized his view best in a passage in his book *The Stress of Life*:^[2]

No one can live without experiencing some degree of stress all the time. You may think that only serious disease or intensive physical or mental injury can cause stress. This is false. Crossing a busy intersection, exposure to a draft, or even sheer joy are enough to activate the body's stress mechanisms to some extent. Stress is not even necessarily bad for you; it is also the spice of life, for any emotion, any activity causes stress. But, of course, your system must be prepared to take it. The same stress which makes one

person sick can be an invigorating experience for another.

The key statement Selye made may be “your system must be prepared to take it”. A significant body of knowledge has now accumulated delineating methodologies for assisting patients in developing healthful, rather than disease-facilitating, responses to both short-term and long-term stress.

DIAGNOSTIC CONSIDERATIONS

Many people who are “stressed out” may not be able to identify exactly what is causing them to feel stressed. Typical presenting symptoms include insomnia, depression, fatigue, headache, upset stomach, digestive disturbances, and irritability.

To determine the role that stress may play, the “social readjustment rating scale” developed by Holmes & Rahe^[3] may be utilized (see [Table 60.2](#)). The scale was originally designed to predict the risk of a serious disease due to stress. Various life-changing events are numerically

TABLE 60-2 -- The social readjustment rating scale

| Rank | Life event | Mean value |
|------|-----------------------------------|------------|
| 1 | Death of spouse | 100 |
| 2 | Divorce | 73 |
| 3 | Marital separation | 65 |
| 4 | Jail term | 63 |
| 5 | Death of a close family member | 63 |
| 6 | Person injury or illness | 53 |
| 7 | Marriage | 50 |
| 8 | Fired at work | 47 |
| 9 | Marital reconciliation | 45 |
| 10 | Retirement | 45 |
| 11 | Change in health of family member | 44 |
| 12 | Pregnancy | 40 |
| 13 | Sex difficulties | 39 |
| 14 | Gain of a new family member | 39 |

| | | |
|----|---|----|
| 15 | Business adjustment | 39 |
| 16 | Change in financial state | 38 |
| 17 | Death of a close friend | 37 |
| 18 | Change to different line of work | 36 |
| 19 | Change in number of arguments with spouse | 35 |
| 20 | Large mortgage | 31 |
| 21 | Foreclosure of mortgage or loan | 30 |
| 22 | Change in responsibilities at work | 29 |
| 23 | Son or daughter leaving home | 29 |
| 24 | Trouble with in-laws | 29 |
| 25 | Outstanding personal achievement | 28 |
| 26 | Wife begins or stops work | 26 |
| 27 | Beginning or end of school | 26 |
| 28 | Change in living conditions | 25 |
| 29 | Revision of personal habits | 24 |
| 30 | Trouble with boss | 23 |
| 31 | Change in work hours or conditions | 20 |
| 32 | Change in residence | 20 |
| 33 | Change in schools | 20 |
| 34 | Change in recreation | 19 |
| 35 | Change in church activities | 19 |
| 36 | Change in social activities | 18 |
| 37 | Small mortgage | 17 |
| 38 | Change in sleeping habits | 16 |
| 39 | Change in number of family get-togethers | 15 |
| 40 | Change in eating habits | 15 |
| 41 | Vacation | 13 |
| 42 | Christmas | 12 |
| 43 | Minor violations of the law | 11 |

rated according to their potential for causing disease. Notice that even events commonly viewed as positive, such as an outstanding personal achievement, carry with them stress.

If a person is under a great deal of immediate stress or has endured a fair amount of stress over a few months time or longer, it is appropriate to more accurately assess adrenal dysfunction by utilizing laboratory methods.

Interpretation

The standard interpretation of the social readjustment rating scale is that a total of 200 or more units in 1 year is considered to be predictive of a high likelihood of experiencing a serious disease. However, rather than using the scale solely to predict the likelihood of serious disease, the scale can be used to evaluate a person's level of stressor exposure, as everyone reacts differently to stressful events.

THERAPEUTIC APPROACH

Whether the patient is currently aware of it or not, they have developed a pattern for coping with stress. Unfortunately, most people have found patterns and methods that ultimately do not support good health. Negative coping patterns must be identified and replaced with positive ways of coping. Try to identify any negative or destructive coping patterns listed in [Table 60.3](#) that the patient may have developed and replace the pattern with more positive measures for dealing with stress.

Stress management can be substantially improved by assisting the patient in five equally important areas:

- techniques to calm the mind and promote a positive mental attitude
- lifestyle factors
- exercise
- a healthful diet designed to nourish the body and support physiological processes
- dietary and botanical supplements designed to support the body as a whole, but especially the adrenal glands.

Calming the mind and body

Learning to calm the mind and body is extremely important in relieving stress. Among the easiest methods for the patient to learn are relaxation exercises. The goal of relaxation techniques is to produce a physiological response known as a “relaxation response” – a response that is exactly opposite to the stress response. Although an individual may relax by simply sleeping, watching television, or reading a book, relaxation techniques are designed specifically to produce the “relaxation response”.

The relaxation response was a term coined by Harvard professor and cardiologist Herbert Benson MD in the early 1970s to describe a physiological response that is just the opposite of the stress response.^[1] With the stress response (see [Table 60.4](#)), the sympathetic nervous

TABLE 60-3 -- Negative coping patterns

-
- Dependence on chemicals

 - drugs, legal and illicit

 - alcohol

 - smoking

 - Overeating

 - Too much television

 - Emotional outbursts

 - Feelings of helplessness

 - Overspending

 - Excessive behavior
-

546

TABLE 60-4 -- The stress response

-
- The heart rate and force of contraction of the heart increase to provide blood to areas necessary for response to the stressful situation

 - Blood is shunted away from the skin and internal organs, except the heart and lung, while at the same time the amount of blood supplying required oxygen and glucose to the muscles and brain is increased

 - The rate of breathing increases to supply necessary oxygen to the heart, brain, and exercising muscle

 - Sweat production increases to eliminate toxic compounds produced by the body and to lower body temperature

 - Production of digestive secretions is severely reduced since digestive activity is not critical for counteracting stress

 - Blood sugar levels are increased dramatically as the liver dumps stored glucose into the bloodstream

system dominates. With the relaxation response (see [Table 60.5](#)), the parasympathetic nervous system dominates. The parasympathetic nervous system controls bodily functions such as digestion, breathing, and heart rate during periods of rest, relaxation, visualization, meditation, and sleep. While the sympathetic nervous system is designed to protect against immediate danger, the parasympathetic system is designed for repair, maintenance, and restoration of the body.

The relaxation response can be achieved through a variety of techniques. The

methodology should be determined by patient interest, as all produce the same physiological effect – a state of deep relaxation. The most popular techniques are meditation, prayer, progressive relaxation, self-hypnosis, and biofeedback. To produce the desired long-term health benefits, the relaxation technique should be utilized at least 5–10 minutes each day.

Breathing

Producing deep relaxation with any technique requires learning how to breathe. One of the most powerful methods of producing less stress and more energy in the body is by breathing with the diaphragm. Diaphragm breathing activates the relaxation centers in the brain. [Table 60.6](#) lists a 10 step technique for teaching diaphragmatic breathing.

TABLE 60-5 -- The relaxation response

-
- The heart rate is reduced and the heart beats more effectively. Blood pressure is reduced
-
- Blood is shunted towards internal organs, especially those organs involved in digestion
-
- The rate of breathing decreases as oxygen demand is reduced during periods of rest
-
- Sweat production decreases, as a person who is calm and relaxed does not experience nervous perspiration
-
- Production of digestive secretions is increased, greatly improving digestion
-
- Blood sugar levels are maintained in the normal physiological range

TABLE 60-6 -- Instructions to assist patients in learning diaphragmatic breathing

-
1. Find a comfortable and quiet place to lie down or sit
-
2. Place your feet slightly apart. Place one hand on your abdomen near your navel. Place the other hand on your chest
-
3. You will be inhaling through your nose and exhaling through your mouth
-
4. Concentrate on your breathing. Note which hand is rising and falling with each breath
-
5. Gently exhale most of the air in your lungs
-
6. Inhale while slowly counting to 4. As you inhale, slightly extend your abdomen, causing it to rise about 1 inch. Make sure that you are not moving your chest or shoulders
-
7. As you breathe in, imagine the warmed air flowing in. Imagine this warmth flowing to all parts of your body
-
8. Pause for 1 second, then slowly exhale to a count of 4. As you exhale, your abdomen should move inward
-

9. As the air flows out, imagine all your tension and stress leaving your body

10. Repeat the process until a sense of deep relaxation is achieved

Progressive relaxation

One of the most popular techniques for producing the relaxation response is progressive relaxation. The technique is based on a very simple procedure of comparing tension with relaxation. Many people are not aware of the sensation of relaxation. In progressive relaxation an individual is taught what it feels like to relax by comparing relaxation with muscle tension.

The basic technique is to have the patient contract a muscle forcefully for a period of 1–2 seconds and then give way to a feeling of relaxation. The procedure systematically goes through all the muscles of the body, progressively producing a deep state of relaxation. The procedure begins with contracting the muscles of the face and neck, then the upper arms and chest, followed by the lower arms and hands. The process is repeated progressively down the body, i.e. the abdomen, the buttocks, the thighs, the calves, and the feet. This whole practice is repeated two or three times. This technique is often used in the treatment of anxiety and insomnia.

Progressive relaxation, deep breathing exercises, or some other stress reduction technique form an important component of a comprehensive stress management program.

Lifestyle factors

A patient's lifestyle is a major determinant in their stress levels. The two primary areas of concern (other than addressing negative coping patterns) are time management and relationship issues.

One of the biggest stressors for most people is time. They simply do not feel they have enough of it. [Table 60.7](#) provides tips on time management for patients.

Another major cause of stress for many people is interpersonal relationships. Interpersonal relationships

TABLE 60-7 -- Patient tips for improved time management

- Set priorities. Realize that you can only accomplish so much in a day. Decide what is important, and limit your efforts to that goal
-

- Organize your day. There are always interruptions and unplanned demands on your time, but create a definite plan for the day based on your priorities. Avoid the pitfall of always letting the “immediate demands” control your life
-
- Delegate authority. Delegate as much authority and work as you can. You can’t do everything yourself. Learn to train and depend on others
-
- Tackle tough jobs first. Handle the most important tasks first, while your energy levels are high. Leave the busy work or running around for later in the day
-
- Minimize meeting time. Schedule meetings to bump up against the lunch hour or quitting time; that way they can’t last forever
-
- Avoid putting things off. Work done under pressure of an unreasonable deadline often has to be redone. That creates more stress than if it had been done right the first time. Plan ahead
-
- Don’t be a perfectionist. You can never really achieve perfection anyway. Do your best in a reasonable amount of time, then move on to other important tasks. If you find time, you can always come back later and polish the task some more

can be divided into three major categories: marital, family, and job-related. The quality of any relationship ultimately comes down to the quality of the communication. Learning to communicate effectively goes a very long way in reducing the stress and occasional (or frequent) conflicts of interpersonal relationships. [Table 60.8](#) lists seven tips for effective communication, regardless of the type of interpersonal relationship.

Exercise

The immediate effect of exercise is stress on the body. However, with a regular exercise program, the body adapts and exercise becomes an effective stress reduction technique. With regular exercise, the body becomes stronger, functions more efficiently, and has greater endurance. Exercise is a vital component of a comprehensive stress management program and overall good health.

People who exercise regularly are much less likely to suffer from fatigue and depression. Tension, depression, feelings of inadequacy, and worries diminish greatly with regular exercise.

Exercise alone has been demonstrated to have a tremendous impact on improving mood and the ability to handle stressful life situations. This effect is seen in adolescents, as well as adults. For example, 2,223 boys and 2,838 girls (mean age, 16.3 years) from 10 teams and 25 different individual sports were studied for the relationship between emotional and psychological well-being. The sport and vigorous recreational activity index was positively associated with emotional well-being independently of other variables.^[4]

Dietary guidelines

Individuals suffering from stress or anxiety need to support the biochemistry of the body

by following some important dietary guidelines. Specifically, they must:

- eliminate or restrict the intake of caffeine
- eliminate or restrict the intake of alcohol
- eliminate refined carbohydrates from the diet
- eat a diverse range of whole foods
- increase the potassium to sodium ratio
- eat regular planned meals in a relaxed environment
- control food allergies.

According to Selye, the difference between stress being harmful or not is based upon the strength of the system. From a purely physiological perspective, it can

TABLE 60-8 -- Keys to assist patients in improving communication

-
- The first key to successful communication is the most important. Learn to be a good listener. Allow the person you are communicating with to really share their feelings and thoughts uninterrupted. Empathize with them, put yourself in their shoes. If you first seek to understand, you will find yourself being better understood
-
- Be an active listener. This means that you must be truly interested in what the other person is communicating. Listen to what they are saying instead of thinking about your response. Ask questions to gain more information or clarify what they are telling you. Good questions open lines of communication
-
- Be a reflective listener. Re-state or reflect back to the other person your interpretation of what they are telling you. This simple technique shows the other person that you are both listening and understanding what they are saying. Re-stating what you think is being said may cause some short-term conflict in some situations, but it is certainly worth the risk
-
- Wait to speak until the person or people you want to communicate with are listening. If they are not ready to listen, no matter how well you communicate your message will not be heard
-
- Don't try to talk over somebody. If you find yourself being interrupted, relax, don't try and out-talk the other person. If you are courteous and allow them to speak, eventually (unless they are extremely rude) they will respond likewise. If they don't, point out to them that they are interrupting the communication process. You can only do this if you have been a good listener. Double-standards in relationships seldom work
-
- Help the other person become an active listener. This can be done by asking them if they understood what you were communicating. Ask them to tell you what is was that they heard. If they don't seem to be understanding what it is you are saying, keep trying until they do
-
- Don't be afraid of long silences. Human communication involves much more than human words. A great deal can be communicated during silences; unfortunately in many situations silence can make us feel uncomfortable. Relax. Some people need silence to collect their thoughts and feel safe in communicating. The important thing to remember during silences is that you must remain an active listener

be strongly argued that delivery of high-quality nutrition to the cells of the body is the critical factor in determining the strength of the system.

When the eating habits of Americans are examined as a whole, it is little wonder that so many people are suffering from stress, anxiety, and fatigue. Most Americans are not providing their body with the high quality nutrition it deserves. Instead of eating foods rich in vital nutrients, most Americans focus on refined foods high in calories, sugar, fat, and cholesterol.

Caffeine

The average American consumes 150–225 mg of caffeine daily, or roughly the amount of caffeine in two cups of coffee. Although most people can handle this amount, some people are more sensitive to the effects of caffeine than other people, due to decreased activity of phase I detoxification (see [Ch. 16](#)). Even small amounts of caffeine can affect sensitive people, while those with normal sensitivity will respond to large amounts. Excessive caffeine consumption can produce “caffeinism characterized by symptoms of depression, nervousness, irritability, recurrent headache, heart palpitations, and insomnia”. People prone to feeling stress and anxiety tend to be especially sensitive to caffeine.^[5] ^[6]

Alcohol

Alcohol produces chemical stress on the body. It also increases adrenal hormone output, interferes with normal brain chemistry, and interferes with normal sleep cycles. While many people believe that alcohol has a calming effect, a study of 90 healthy male volunteers given either a placebo or alcohol demonstrated significant increases in anxiety scores after drinking the alcohol.^[6]

Refined carbohydrates

Refined carbohydrates (e.g. sugar and white flour) are known to contribute to problems in blood sugar control, especially hypoglycemia. The association between hypoglycemia and impaired mental function is well-known. Unfortunately, most patients experiencing depression, anxiety, or other psychological condition are rarely tested for hypoglycemia, nor are they prescribed a diet which restricts refined carbohydrates.

Numerous studies have shown a high percentage of hypoglycemia in depressed patients.^[7] ^[8] As depression is one of the most frequent causes of anxiety, this provides a link between hypoglycemia and feelings of stress. Simply eliminating refined carbohydrate from the diet is occasionally all that is needed for effective therapy in patients that have depression or anxiety due to hypoglycemia.

Potassium to sodium ratio

One of the key dietary recommendations to support the adrenal glands is to ensure adequate potassium levels within the body. This can best be done by consuming foods rich in potassium and avoiding foods high in sodium. Most Americans have a dietary potassium-to-sodium (K:Na) ratio of less than 1:2. In contrast, most researchers recommend a dietary potassium-to-sodium ratio of greater than 5:1 for health. However, even this may not be optimal. A natural diet rich in fruits and vegetables can produce a K:Na ratio greater than 50:1, as most fruits and vegetables have a K:Na ratio of over 100:1.

Meal planning

Mealtimes should be spent in a relaxed environment. As noted above, digestion is a process largely controlled by the parasympathetic nervous system. Eating in a rushed manner, in a noisy or hurried environment is not conducive to good digestion or good health.

Food allergies

People with symptoms of anxiety or chronic fatigue need to be concerned about food allergies. As far back as 1930, pioneering allergist Albert Rowe began noticing that anxiety and fatigue were key features of food allergies.^[9] Originally, Rowe described a syndrome known as “allergic toxemia” to describe a syndrome that included the symptoms of anxiety, fatigue, muscle and joint aches, drowsiness, difficulty in concentration, and depression. Around the 1950s, this syndrome began to be referred to as the “allergic tension-fatigue syndrome”. With the popularity of the new chronic fatigue syndrome, many physicians and other people are forgetting that food allergies can lead to anxiety as well as chronic fatigue.

Nutritional and botanical support

Nutritional and botanical support for the individual experiencing signs and symptoms of stress largely involves supporting the adrenal glands. Long-term stress and corticosteroids cause the adrenal glands to shrink and become dysfunctional, aggravating the stress symptoms of anxiety, depression, or chronic fatigue.

An abnormal adrenal response, either deficient or excessive hormone release, significantly alters an individual’s response to stress. Often the adrenals become “exhausted” as a result of constant demands placed upon it. An individual with adrenal exhaustion will usually suffer from chronic fatigue and may complain of feeling “stressed out” or chronically anxious. They will typically have a reduced resistance to allergies and infection.

Nutritional supplements

The nutrients especially important for supporting adrenal function include vitamin C, vitamin B₆, zinc, magnesium, and pantothenic acid. All of these nutrients play a critical role in the health of the adrenal gland as well as the manufacture of adrenal hormones. During stress, the levels of these nutrients in the adrenals decrease substantially.

For example, during chemical, emotional, psychological, or physiological stress, the urinary excretion of vitamin C is increased. Examples of chemical stressors include cigarette smoke, pollutants, and allergens. Extra vitamin C in the form of supplementation and an increased intake of vitamin C-rich foods is often recommended to keep the immune system working properly during times of stress.

Equally important during high periods of stress or in individuals needing adrenal support is pantothenic acid (B vitamin). Pantothenic acid deficiency results in adrenal atrophy characterized by fatigue, headache, sleep disturbances, nausea, and abdominal discomfort. Pantothenic acid is found in whole-grains, legumes, cauliflower, broccoli, salmon, liver, sweet potatoes, and tomatoes. In patients suffering from chronic stress or a history of corticosteroid (prednisone) use, the typical level of supplementation is 100–500 mg daily.

The appropriate daily doses of vitamin B₆ is 50–100 mg; of zinc is 20–30 mg; and of magnesium should be 250–500 mg.

Botanical medicines

Several botanical medicines support adrenal function. Most notable are the ginsengs. Both Chinese ginseng (*Panax ginseng*) and Siberian ginseng (*Eleutherococcus senticosus*) exert beneficial effects on adrenal function and enhance resistance to stress. These ginsengs are often referred to as “general tonics” or “adaptogens”.

The term “general tonic” implies that an herb will increase the overall tone of the whole body. The ginsengs are also often referred to as “adrenal tonics” in that they increase the tone and function of the adrenal glands. Chinese and Siberian ginseng can be used to:

- restore vitality in debilitated and feeble individuals
- increase feelings of energy
- increase mental and physical performance
- prevent the negative effects of stress and enhance the body’s response to stress
- offset some of the negative effects of cortisone
- enhance liver function

- protect against radiation damage.

All of these applications are backed up by good clinical research.^{[10] [11] [12]}

The modern term “adaptogen” is a more descriptive term used to describe the general tonic effects of Siberian and Chinese ginseng. An adaptogen is defined as a substance that:

- must be innocuous and cause minimal disorders in the physiological functions of an organism
- must have a non-specific action (i.e. it should increase resistance to adverse influences by a wide range of physical, chemical, and biochemical factors
- usually has a normalizing action irrespective of the direction of the pathologic state.

According to tradition and scientific evidence, both Siberian and Chinese ginsengs possess this kind of equilibrating, tonic, anti-stress action, and so the term adaptogen is quite appropriate in describing its general effects.

The ginsengs have been shown to enhance the ability to cope with various stressors, both physical and mental.^{[10] [11] [12]} Presumably this anti-stress action is mediated by mechanisms which control the adrenal glands. Ginseng delays the onset and reduces the severity of the alarm phase response of the general adaptation syndrome.

People taking either of the ginsengs typically report an increased sense of well-being. Clinical studies have confirmed that both Siberian and Chinese ginsengs significantly reduce feelings of stress and anxiety. For example, in one double-blind clinical study, nurses who had switched from day to night duty rated themselves for competence, mood, and general well-being, and were given a test for mental and physical performance along with blood cell counts and blood chemistry evaluation.^[13] The group administered *Panax ginseng* demonstrated higher scores in competence, mood parameters, and mental and physical performance when compared with those receiving placebos. The nurses taking the ginseng felt more alert, yet more tranquil, and were able to perform better than the nurses not taking the ginseng.

In addition to these human studies, several animal studies have shown the ginsengs to exert significant anti-anxiety effects. In several of these studies, the stress-relieving effects were comparable to diazepam (Valium); however, while diazepam causes behavior changes, sedative effects, and impaired motor activity, ginseng produces none of these negative effects.^[14]

Based on the clinical and animal studies, it appears that ginseng offers significant benefit to people suffering from stress and anxiety. *Panax ginseng* is generally regarded as being more potent than *Eleutherococcus senticosus*. *Panax ginseng* is probably better for the patient who has experienced a great deal of stress, is recovering from a long-standing illness, or has taken corticosteroids like prednisone for a long period of time. For the patient under mild to moderate stress and experiencing less obvious

impaired adrenal function, *Eleutherococcus senticosus* may be the best choice.

Chapter 61 - Alkylglycerols

Peter T. Pugliese MD

INTRODUCTION

Sharks have existed, virtually unchanged, for some 450 million years. Some scientists attribute this long staying power to the well developed immune system in the shark, an immune system which is quite similar to our own. Sharks have both a humoral and a cellular component to their immune system, and therefore have both B-cells and T-cells. Sharks also have a spleen and a thymus gland just as we do, although they possess large quantities of alkylglycerols found mainly in the liver. In this chapter we shall explore the use of alkylglycerols from the shark both as immune stimulants and as powerful agents in the treatment of neoplastic disorders.

HISTORY

Alkylglycerols are ether-linked biological compounds that have a long and fascinating history. Much of the early history is found in the literature of histochemistry and is related to methods of staining specific cellular components. One of the greatest histologists of all time was Robert Feulgen (1884–1955), a German physiological chemist to whom we owe the Feulgen reaction. (The Feulgen reaction, or test, is a method to detect animal nucleic acids. It involves an acid hydrolysis with HCL followed by a 1% solution of decolorized rosaniline, which yields a red color in the presence of nucleic acids.) Robert Feulgen and K. Voit discovered plasmalogens in 1924.^[1] At the time they thought they had discovered an aldehyde, which they called *plasma*. The origin of plasmal was believed to be an unknown substance, which they called *plasmalogen*. They were able to demonstrate the presence of this compound in many

tissues, from protozoa to humans.

Plasmalogens, it was learned later, were ether lipid compounds that are formed in the metabolic pathway of phosphoglycerides. They differ from phosphoglycerides in that they contain an ether linkage on the C-1 of the glycerol molecule. Intensive work on the structure

and formation of the plasmalogens continued over the next 35 years. It was many years, however, before a formula for plasmalogens was finally agreed upon, yet the biological function of plasmalogens remained unknown until after 1960 when their role in organisms was finally discovered.

As in many discoveries there are always unsung heroes: scientists who work quietly in some obscure laboratory, publish a paper and are seen no more. Such was the case with research on the alkylglycerols. The work of Kossel & Edbacher^[2] on the starfish *Astropecten aurantiacus* was unknown until 1943 when Bergmann & Stansbury^[3] compared their preparation of batyl alcohol, a natural alkylglycerol obtained from the starfish, to the original work of Kossel & Edbacher^[2] and found similar physical and chemical properties of both compounds. From 1915 the story jumps to the 1920s, after the First World War, and to Japan where Tsujimoto & Toyama^[4] were working on unsaponifiable compounds from liver extracts. (Unsaponifiable fractions are those fatty compounds that do not form soaps when shaken with strong bases such as potassium or sodium hydroxide. Steroids are an example of this class of compounds.) It was the work of these two investigators that identified two major alkylglycerols in shark and ray liver oil. They called the first compound *selachyl alcohol* from the family name for sharks, Selachioidei, and *batyl alcohol* from the ray family Batoidei. They were uncertain of the exact chemical structure at the time, due to questions about the role of an oxygen atom in the molecules.

In 1924, Toyama^[5] isolated a third compound from the liver oils of the rattfish, *Chimera monstrosa*, which he called *chimyl alcohol*. Four years later Heilbron & Owens^[6] described the crucial role of the oxygen atom as an ether linkage. They refluxed batyl alcohol with hydroiodic acid and obtained octodecyl iodide, which was conclusive evidence of a glyceryl ether structure.

At about this time, a great deal of work was being conducted on shark liver oil in an attempt to isolate the fat-soluble vitamins A and D. Ether lipids consisting mainly of batyl, chimyl and selachyl alcohols were purified from shark liver oil as a side product of this isolation. This material provided a ready source for further investigation of the ether lipids. This was fortuitous because the first therapeutic use of ether lipids was in 1930 when Giffin & Watkins^[7] employed yellow bone marrow to treat a patient with leukopenia. At the time they did not know that the active principle in the marrow was batyl alcohol. Eight years later Marberg & Wiles^[8] isolated batyl alcohol from the

unsaponifiable fraction of yellow marrow.

The biological function of the ether lipids was not fully elucidated until after 1960, although many investigators ascribed certain biological functions to these compounds, e.g. the antileukopenic effect described above, a central depressant action described by Berger^[9] in 1948, an erythropoietic effect reported by Sandler^[10] in 1949, a tuberculostatic effect reported by Emmerie et al^[11] in 1952, a wound healing action reported by Bodman & Maisin^[12] in 1958 and a radioprotective effect reported by Brohult^[13] in 1960. The alkyl glycerol ethers were found to be widespread in nature, in fact almost universal, although no clear physiological role was defined for them. Current research has opened many investigative channels for these compounds and new information is now available that is beginning to shed light on the molecular action of the ether lipids. A review of the chemistry of the alkyl glyceryl ethers will help to prepare the reader to understand the physiological action and the potential therapeutic applications.

BASIC CHEMISTRY OF THE ALKYL GLYCERYL ETHERS FROM SHARK LIVER OIL

Some definitions

Lipid chemistry is often viewed as an impenetrable complexity by the student. The terminology is indeed not easy to master at first, but with time and repetition it becomes easier. Part of this problem rests with the lipid chemists who have some difficulty in agreeing on nomenclature. In the case of the ether lipids, we shall limit this discussion to only a few naturally occurring compounds, specifically those occurring in shark liver oil. *Lipids may be broadly defined as a class of organic compounds that are water-insoluble.* They can then be further divided into simple lipids and complex lipids. For example, simple lipids are esters of fatty acids and an alcohol, such as palmitic acid and glycerol to form a monoglyceride. Another example of a simple lipid is a cholesterol ester.

Complex lipids are esters which contain phosphorus and/or nitrogen bases and/or sugars as well as fatty acids and an alcohol. Lecithin, which is phosphatidyl choline, is an important complex lipid. The plasmalogens, which we shall discuss later, are lipid compounds that contain an ether linkage along with both a phosphorus and a nitrogen group, so they are classified as complex lipids.

We also speak of neutral lipids which are not ionically charged, and ionic lipids, or charged lipids. Fats such as common triglycerides found in lard, are neutral lipids, while phospholipids are charged lipids. There are a few other terms that must be defined so that we are all talking the same language. The term *alkoxy* refers to an organic group RO, which is part of an ether group ROR. Recently the term has been shortened to alkyl, so we denote ether lipid as alkylglycerides. Note that there is no other oxygen atom associated with the R components. The term *acyl* refers to a R – C = O. The term *carbonyl* refers to a C = O group, and the term *carboxyl* refers to a –COOH

group, where one oxygen has a double bond to the carbon atom.

The ether bond is the key to understanding the unique functioning of the alkylglycerol. This bond, C–O–C, is found throughout nature in many important biological compounds, the most familiar of which is thyroxin from the thyroid gland. In the plant world, guaicol is another familiar ether-linked substance. Glycerol ethers are quite widespread, having been isolated from many life forms and in many different molecular arrangements. The basic structure of these compounds consists of a glycerol molecule with one or more of the hydroxyl groups being replaced by long-chain fatty acids. The bonding of three fatty acid molecules to the glycerol molecule with an ester linkage is known as a triglyceride, or common fat. The ester linkage is characterized by the –COO group where one oxygen is linked in a double bond to a carbon atom. A typical triglyceride and alkylglycerol are shown in [Figures 61.1](#) and [61.2](#).

While the chemistry of the alkylglycerols in many animals and plants has been studied quite extensively, we shall limit our discussion to the main ether lipids found in shark liver oil. A note, however, on the composition of shark liver oil is in order. Shark liver oil contains high levels of vitamins A and D along with other constituents besides the ether lipids. In commercial preparations of the alkylglycerols extracted from shark liver oil, all of these components are removed in the extraction process.

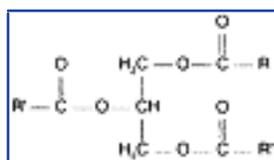

Figure 61-1 Triglyceride.

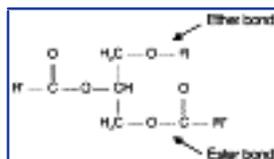

Figure 61-2 Alkylglycerol.

In this article, therefore, when we speak of shark liver-derived alkylglycerols we are referring to a highly refined end product containing only the alkylglycerols.

One of the major sources of natural alkylglycerols is obtained from the Greenland shark, *Somniosus microcephalus*, which contains up to 50% of alkylglycerols. Other sources include the elasmobranch fish such as the small shark, *Chimaera monstrosa*, and the dogfish, *Squalus acanthias*. Cod liver oil and certain mollusks are additional sources of alkylglycerols.^[14] These compounds are found in various organs of the animals studied, including bone marrow fat, spleen liver, plasma and erythrocytes, and in milk.^{[15] [16]} These compounds are found in the unsaponifiable fraction of the oils obtained from the

animals. Tsujimoto & Toyama^[4] were the first investigators to report the presence of ether lipids in shark liver oil. Three major natural alkylglycerols obtained from the Greenland shark are batyl alcohol, chimyl alcohol and selachyl alcohol. The chemical structure of these compounds is given in [Fig. 61.3](#) . Note that while chimyl and batyl alcohol are saturated chains, selachyl alcohol contains one unsaturated bond. Note also that all the ether bonds are on the number 3 carbon of glycerol. In the natural state these compounds are usually present as ester compounds, with carbons 1 and 2 esterified with C₁₆ or C₁₈ saturated fatty acids. A fourth natural compound is a

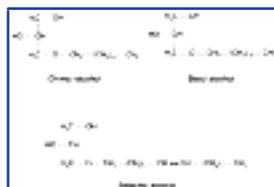

Figure 61-3 Batyl alcohol, chimyl alcohol and selachyl alcohol.

558

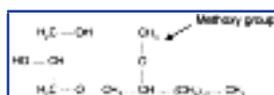

Figure 61-4 Methoxy-substituted alkylglycerol.

methoxy-substituted alkylglycerol, shown in [Fig. 61.4](#) , which is quite an active compound, but comprises only a small percentage of natural shark liver oil-derived alkylglycerols, about 3%.

The biological synthesis of the lipid ethers has been well worked out. Most cells in the human body contain lipid ethers but only in small quantities. The following synthesis scheme has been published and is summarized by Mangold & Paltauf^[17] as follows:

- *Step 1.* Coenzyme A derivatives of long-chain fatty acids are reduced to alkyl and alkenyl chains via their alcohols, through an aldehyde.
- *Step 2.* The ether bond is formed by reaction of these alcohols with acyldihydroxyacetone phosphates, resulting in the formation of alkylacyldihydroxyacetone phosphates.
- *Step 3.* Reduction of the alkylacyldihydroxyacetone phosphates leads to the formation of alkylglycerophosphates.

This may be further summarized as:

fatty acid \rightarrow aldehyde \rightarrow alcohol \rightarrow alkyl ether \rightarrow 1-alkenyl ether

It is unlikely that ether lipids exist in nature as free forms; rather, they are esterified. Being ether compounds, they react as aliphatic ethers, i.e. they are stable to most oxidizing and reducing substances, but undergo only one general, non-enzymatic

reaction, which is acid hydrolysis.

It is not the purpose of this chapter to discuss the isolation and identification of the alkylglycerols. The scheme for this work is well developed and may be found in references by Mangold & Weber.^[18] We shall devote our coverage in this chapter instead to the naturally occurring alkylglycerols from shark liver oil and relate the structure and fate of these compounds to their physiological effects and potential therapeutic use.

Absorption, fate and excretion

After oral ingestion of ether lipids, absorption occurs from the intestine. About 95% of radioactive (C₁₄ -labeled) chimyl alcohol is absorbed in the intestine, with 5% being excreted in the feces in one study.^[19] In the gastrointestinal tract a large proportion of the ingested ether lipid in the form of 1-O-alkylglycerols are cleaved at the ether bond with the alkyl moieties giving rise to fatty acids. The remainder is incorporated into 1-O-alkyl 2,3-diacyl-*sn*-glycerols and 1-O-alkyl-2-acyl-*sn*-glycerol and 1-O-alkyl-2-acyl-*sn*-glycerol-3-phosphoethanolamines.^[20] Ether lipids are only minor components of human diet, so that the major portion of ether lipids in the body is synthesized in the body.^[20] Absorption of the intact ether lipid is the rule since ether lipids are not subject to the action of lipase, which is specific for the ester bond. This means that the "fat" is absorbed rather than the fatty acids. After feeding chimyl alcohol to rats, analysis of the lymph fluid shows that 2–4% of the ether lipids is found as fatty acids combined in phospholipids, about 50% is found in the triglyceride fraction, while another 40% is found as the free chimyl alcohol, or as an esterified alcohol. In the triglyceride fraction, most of the original compound is found as palmitic acid, which indicates that the ether bond in the chimyl alcohol was split during the absorption process. The cetyl alcohol (a C 15 fatty alcohol) moiety of chimyl alcohol is oxidized to palmitic acid (a C 16 fatty acid) during its passage through the intestinal mucosa.

TOXICOLOGY OF THE ALKYLGLYCEROLS

Toxicity in animals

Oral toxicity studies with alkylglycerols have been conducted on rats, mice and dogs. Alexander et al^[21] reported that mice given a diet containing 18% alkyldiacylglycerols showed no ill effects after 2 years. Work by Brohult,^[22] Peifer et al,^[23] Carlson,^[24] Berger^[9] and Bandi^[25] on oral feeding of alkylglycerols to rats has shown that they are relatively non-toxic. Carlson^[24] tested dogs with chimyl batyl and selachyl alcohols by feeding levels of 2.4 g/kg of body weight and found no ill effects.

Subcutaneous injections of batyl alcohol in mice by Berger^[9] found that a dose of 3 g/kg was needed to obtain a subcutaneous LD₅₀. Peritoneal injections of batyl alcohol in rats at levels of 5–10 mg/kg of body weight had no effect on the thymus gland or on the production of adenosine triphosphate.

Toxicity in humans

Brohult^[22] observed that a healthy human being consumes about 10–100 mg/day of alkylglycerols in an average diet. Sandler^[10] gave healthy adult males 45 mg/day of batyl alcohol for 10 days with no ill effects. This was a relatively low dose compared with that consumed by people who eat shark meat and shark by-products. Only the consumption of shark liver has been reported to produce ill effects, mainly diarrhea, due to the high squalene content. Alkylglycerols from the Greenland shark have been used for over 30 years without undesirable side-effects.

559

BIOLOGICAL EFFECTS

Bacteriostatic effects

As early as 1952 the bacteriostatic effects of alkylglycerols on tubercle bacillus (*Mycobacterium tuberculosis*) in vitro were reported.^[11] This material was isolated from cod liver oil and consisted of the unsaponifiable fraction. There is very little published data on the antimicrobial effects of the alkylglycerols from natural sources, but a more recent report using a synthetic product, racemic *sn*-1(3)-dodecylglycerol, showed some activity against *Streptococcus mutans* BHT.^[26] These investigators found that substantial decreases in the viability of this organism were associated with an accumulation of phosphatidic acid. Current research shows that antibiotic resistance in bacteria is associated with the lipid content of the bacteria in both Gram-positive and Gram-negative organisms.^[27] The action of the alkylglycerol was to inhibit the synthesis of lipids in the microbial cell.

Hemopoietic effects

Bone marrow was found to be a useful therapy in treating secondary anemia over 60 years ago. Later it was found that the unsaponifiable fraction of the marrow lipids was responsible for this action, i.e. the stimulation of erythrocyte production. Sandler^[10] found that batyl alcohol had a beneficial effect on erythrocyte production in rats. Further studies with subcutaneous injections in humans showed an increase in reticulocyte levels in the blood. The erythropoietic, thrombopoietic and granulopoietic stimulatory activities of 1-octadecylglycerol ethers was confirmed by several investigators.^{[28] [29] [30]} It is interesting that chimyl alcohol is able to stimulate hemopoiesis, but selachyl alcohol is not.^[31]

Protection against radiation damage

The effects of 1-alkylglycerols in the treatment of radiation-induced leukopenia have been studied extensively. Some investigators have confirmed these beneficial effects,^[32]

[33] while others have not.[34] [35] Work by Lorenz et al[36] found that lethal irradiation in mice and guinea pigs was counteracted by post-irradiation injection of bone marrow. It was thought by Sandler^[19] that batyl alcohol might be the active factor in bone marrow that prevented irradiation leukopenia. His observations, however, noted an increase mainly in erythropoiesis. Additional studies by Arturson & Linback^[37] using intraperitoneal injections of batyl alcohol in mice showed an increase in the production of both erythrocytes and reticulocytes.

Other studies have confirmed the positive effect of the alkoxyglycerols on post-irradiation damage. The work of Brohult & Homberg^[28] showed that lethal irradiation is counteracted by post-irradiation injections of batyl alcohol. In 1963 Brohult published a thesis on the use of alkylglycerols in radiation treatment. A summary of the major findings in this paper is as follows:

- The post-irradiation decrease in thrombocytes and white cell is notably less in patients treated with alkylglycerols than in those not given alkylglycerols.
- Patients with low thrombocyte counts due to radiation treatment or chemotherapy had increased counts after treatment with alkylglycerols.
- In irradiated rats pretreated with alkylglycerols there was less of a decrease in megacaryocytes and nucleated cells in the bone marrow compared with untreated irradiated controls.
- Selachyl alcohol was more effective than batyl alcohol in preventing megacaryocyte decrease.
- There was a dose-related response with a maximum response at a certain level and then a decreased response when that level was exceeded.
- The alkylglycerols increase the growth rate of rats after treatment and irradiation compared with untreated irradiated rats.
- Batyl alcohol has a greater effect than selachyl alcohol on increasing growth rate in rats.
- In a series of 350 patients with cervical cancer treated with alkylglycerol and given radiation therapy, there was a greater survival rate for 1 year and 5 years than in untreated irradiated controls (we shall discuss this topic in more detail when we discuss the clinical uses of the alkylglycerols).

IMMUNOLOGICAL ASPECTS OF AKYLGLYCEROLS

An overview of the immune system

Early in the investigation and study of ether lipids it was evident that there was an augmentation of the immune system seen in animals that ingested these compounds. It was also apparent that the macrophage was the key cell in this reaction. A brief introduction to the immune system will acquaint the reader with the relationship of the macrophage to other immune active cells and to the immune system in general. The immune system comprises a set of physiological responses used by the body to destroy or neutralize foreign matter, either living or non-living. Included in this system is a process of maintaining an immune surveillance of the body's own cells to detect and destroy malignant cells.

The essential role of the immune system, therefore, is one of recognition of the components of “the self” and protection from “non-self entities”. Our own cellular constituents make up a vast array of complex molecules to identify and classify. Adding additional complex biochemicals from bacteria, viruses and parasites of all kinds increases the complexity of the system manifold.

There are two basic responses of the immune system: a *non-specific response* that protects non-selectively against foreign matter, or cells, without the need for recognition of specific identities – examples of this response include the barrier provided by the skin, the inflammatory response to injury, and the complement system; and a *specific response* which depends on recognition of a specific substance prior to an attack by the immune system. The specific response involves highly specialized cells and the formation of specific chemical substances employed in the attack. One of these substances, known collectively as *antibodies*, are *adapter molecules* that identify foreign organisms and interact with the other components of the immune system. Each of these components has three main regions, two of which communicate with complement and the phagocytic cells, known as the biological part, and the other serving to recognize and bind to microorganisms, known as the external recognition function. The body makes millions of these antibodies. The most common antibodies are the immunoglobulins known as IgG, IgA, IgM, IgE and IgD. Chemically, the antibody molecule consists of two active regions, known as the Fc, or constant, part, and the Fab, or variable antigen-specific, part. There are two heavy chains and two light chains in each antibody molecule. The Fc part consists only of heavy chains while the Fab part consist of light and heavy chains.

Complement

A family of proteins known as complement provides a direct means of killing microbes without the need for phagocytosis; however, it plays an important role in phagocytosis as will become apparent in our discussion of alkylglycerols and macrophage activation. A brief review of the major steps in the complement reaction is outlined. Complement is so named because it complements and amplifies the action of the antibodies. Some of the components of the complement system circulate constantly in the bloodstream in an inactive form and are activated in the presence of infection or tissue damage. A cascade reaction results in which some 20 proteins are involved in generating the active moieties. However, we need not discuss all of these, only the major components. Five of the active proteins resulting from the cascade form a complex known as the *membrane attack group complex* or *MAC*. This MAC invades the microbial plasma membrane and disrupts it by creating a leaky channel. Other cascade-generated proteins cause vasodilatation and increased vascular permeability.

The major action of the complement proteolytic cascade is to cleave a component known as C_3 into two active units C_{3a} and C_{3b} . Complement C_{3b} is an *opsonin*, a material

that helps to attach phagocytes to the microbe. Antibodies are required to activate complement in the classic system, but our concern here is with another complement activation pathway that does not require antibodies, the so-called *alternate complement pathway*. This system is triggered by certain carbohydrates on the bacterial surface which initiate the cascade at a point about halfway through the classic system to generate C_{3b} . The interaction of complement with macrophages is a key step in many immune reactions, as complement enhances the ability of macrophages to bind, ingest, and destroy microorganisms.^[38]

The macrophage

The macrophage is an extremely versatile and highly regulated cellular system. Besides their microbicidal activity, macrophages are equipped to recognize and destroy both intracellular and extracellular replicating invaders, whether or not these invaders are prokaryotic or eukaryotic types. They are important scavengers for effector cells and molecules of host origin, as well as for exogenous compounds which they can take up, degrade and detoxify or contain. They are known to regulate a large number of body functions including iron and lipid metabolism. The large number of secretory products generated by the macrophage helps to regulate other cells, including the fibroblasts and cells involved in the formation of myeloid component in the bone marrow.

Obviously such powerful cells need to be tightly controlled, and so they are. The resident macrophages in the tissues are usually downregulated to a high degree. The process of *activation*, which we shall discuss in detail, comes from a variety of extracellular stimuli. We have learned over the years that the macrophage is a multipotential cell with the capacity to develop in many ways, depending on the specific signal it receives. This system is far from being fully understood, but the control of this delicate balance of activities is essential to life, so it has become a prime area of intensive investigation.

The macrophages originate from precursor cells in the bone marrow and pass into the circulation as *monocytes*. They remain in the bloodstream for several hours and then migrate to various tissues where they are transformed into macrophages. The macrophage is an activated monocyte, and is easily distinguished from the smaller neutrophil by its size and characteristic nucleus. While both cells are phagocytic, the macrophage has a far greater potential for killing bacteria. A greater cytoplasmic volume and more cytoplasmic organelles are present in the macrophage, including more lysosomes, microtubules, microfilaments and Golgi membranes. After leaving the bloodstream, the macrophage will enter the peritoneal cavity, other serous cavities, and the red pulp of the spleen and the lymph nodes.

Macrophages possess receptors for the Fc pieces of the immunoglobulins and for the C_{3b} complement fraction

discussed above. The adherence of a particle to the macrophage is mediated by complement or by complement plus antibody. Either IgM or IgG is required for this reaction to take place along with C_3 . If IgG is bound to the particle it can be ingested without the addition of complement C_3 .

The concept of immune activation is quite comprehensive in that it embodies many intercellular and molecular events.^[39] The lymphocytes play a key role in activating the macrophage, particularly the T-helper lymphocytes. Macrophages are usually downregulated with respect to their surface active receptors when they are resident in most tissues (resident macrophages are usually not activated). They may be fully activated in several stages, e.g. an inflammatory response in tissues will evoke a reaction that changes the C_3 complement on the surface of the macrophage to fully empower the cell to engulf and destroy bacteria or red cells. They are then further activated to a high killer state by secretions from T-lymphocytes, one of which includes gamma interleukin.

Macrophage activation by alkylglycerols

Inflamed cancerous tissue releases alkyl-lysophospholipids and other alkylglycerols which are degradation products of alkyl phospholipids and alkyl neutral lipids. These compounds are found in cancerous tissue in high concentration, but are in a very low concentration in normal tissues. One of these products, dodecylglycerol (DDG), is one of the most potent macrophage activators known.^{[40] [41] [42] [43]} The use of the natural *sn*-3-octylglycerol, or batyl alcohol, found in shark liver oil produced the same effect as DDG.^[44] The mechanism of macrophage activation by the natural alkylglycerols is most likely identical to the action of lysophospholipids. Keeping in mind that activated macrophages exhibit increased phagocytosis, one method of assaying substances for activation potency is to measure the ingestion of various particles. Erythrocytes coated with IgG are common target particles used in this assay.

Lysophosphatidylcholine has been shown to be effective in increasing macrophage ingestion of IgG-coated erythrocytes.^{[40] [41]} Mice were treated with intraperitoneal injections of batyl alcohol in saline and the macrophages were harvested 4–5 days later. Sheep erythrocyte coated with IgG showed a greatly increased ingestion of erythrocytes. There was no increased ingestion when the cells were coated with IgM or complement, which suggests that batyl alcohol activates the macrophages for Fc-mediated ingestion only. It was interesting that batyl alcohol was more effective at a lower dose than the synthetic compound.^[42]

There is evidence that oral intake of natural alkylglycerols results in higher levels of plasmalogens in the erythrocytes in human subjects. (Plasmalogens are ether compounds that are formed in the metabolic pathway of phosphoglycerides. They differ from phosphoglycerides in that they contain an ether linkage on the C-1 of the glycerol molecule.) It is known that plasmalogens protect animal cell membranes against

oxidative stress. In rat studies, batyl alcohol is incorporated into all tissues except brain tissue and this action is a stereospecific incorporation.^[45] It has been shown that alkylglycerols are present in human and cow's milk,^[44] ^[46] along with other immunological factors.^[47] Since the neonate has not developed a mature immune system,^[48] the prospect of transmitting immune functional components in the milk is a practical way to provide some protection for the newborn.^[49] In one study, lactating rats were fed alkylglycerols dissolved in corn oil; the composition of the alkylglycerols was similar to that found in shark liver oil, in that batyl alcohol, chimyl alcohol and selachyl alcohol were the major constituents.^[49] The findings from this study showed that while peripheral blood granulocytes were elevated there was no elevation of peripheral lymphocytes. Plasma levels of immunoglobulins were elevated in those pups whose dams were fed alkylglycerols, but not in the controls. Both IgG and IgM were elevated to a significant degree.

CLINICAL USES OF AKYLGLYCEROLS

Akylglycerols have been used primarily to treat various types of cancer, usually as adjunct therapy combined with radiation. We shall present in detail the work of Brohult et al^[50] on cervical cancer tumor regression and on the decrease of complications resulting from irradiation therapy. Finally we shall discuss a new akylglycerol, a methoxy-substituted alkylglycerol that occurs naturally at only 3% in shark liver oil, but may be available as a synthetic compound.

Tumor regression with alkylglycerol treatment

Patient selection was determined by stages with the stages being defined as follows:

- Stage I – carcinoma strictly confined to the cervix (early stage)
 - Stage IA – cases of early stromal invasion
 - Stage IB – all other cases of stage I
 - Stage IIA – the carcinoma extends beyond the cervix but has not extended onto the pelvic wall; the carcinoma involves the vagina, but not the lower third; no parametrial involvement
 - Stage IIB – the carcinoma extends beyond the cervix but has not extended onto the pelvic wall; the carcinoma involves the vagina, but not the lower third; parametrial involvement is noted
 - Stage III – the carcinoma has extended onto the
-

562

pelvic wall; on rectal examination there is no cancer-free space between the tumour and the pelvic wall; the tumour involves the lower third of the vagina

- Stage IV – the carcinoma has extended beyond the true pelvis or has involved the mucosa of the bladder or rectum.

(These definitions are from the International Federation of Gynecology and Obstetrics.)

Treatment

Patients were treated with shark liver oil-derived alkylglycerol continuing 100 mg of alkylglycerol, given as two capsules three times a day for a total dose of 600 mg/day. The treated group received 600 mg/day for 7 days prior to irradiation and for 1–3 months after radiation therapy. The study covered three time periods: period 1, from 1 September 1964 to 15 February 1964, comprising 458 patients; period 2, from 1970 to 1973, comprising 137 patients in a double-blind study; period 3, from late 1973 to 1975, comprising 245 patients who were treated with alkylglycerols on an “every second patient”.

The control group consisted of all patients who received radiation therapy for cervical cancer but did not receive alkylglycerols.

Findings

The control group in this study consisted of 4,404 patients treated during the same periods, while the total treated group was 841 patients. The mortality after 5 years was 31.0% for the group treated with alkylglycerols and 39.6% for the control group. The difference is statistically significant ($P < 0.001$).^[50]

Protection against radiation injuries

Studies of patients treated in 1963–1966 and in 1970–1972 by Brohult et al^[51] were aimed at evaluating further the protective effects of ether lipids against irradiation injuries in patients with cancer of the cervix of the uterus. Alkylglycerols derived from Greenland shark liver oil were administered to one group of patients at a level of 600 mg/day during the radiation treatment and 300 mg/day for 1–3 months after treatment. Another group of patients was treated the same way during and after radiation, but was also treated prophylactically 8 days before radiation with 600 mg/day of alkylglycerols. The patients receiving alkylglycerols during and after radiation treatment are referred to as the non-prophylactic group, and the patients also given alkylglycerols before the radiation as the prophylactic group. The system proposed by Kottmeier & Gray^[52] was used for evaluation of the radiation injuries that had occurred in the bladder, rectum, uterus, and intestine. Radiation injuries of grade I, with minimal objective changes in the mucosa, were excluded. Patients with radiation injuries of grades II–IV were treated as a single group: “patients with radiation injuries”. Grade II was characterized by moderate to severe changes, such as necroses, ulcerations, moderate stenoses, and/or reactions with lengthy bleeding. Radiation complications of grade III included injuries to the bladder, radiation fistulas from the ureters, and rectal and intestinal stenoses of such severity that colostomy or resection was needed. Grade IV was characterized by rectal and intestinal fistulas. Complications included patients with clinical features of radiation injury in whom the symptoms were found to be caused by tumor growth or a combination of tumor growth and radiation injury. These complications were termed “complex injuries” and represented a very serious situation. All patients with complex

injuries were dead after 5 years.

The incidence of radiation injuries varies with the spread of the cancer and the radiation technique. The incidence is higher in the more advanced tumor stages than in the less advanced ones. It is also higher after ^{60}Co three-beam treatment of combined high-voltage and X-ray treatment than after conventional X-rays or radium alone. When comparing the groups statistically, standardized proportions have been used in order to cancel out differences with regard to stage distribution and radiation technique.

The total incidence of injuries was lower in the groups that had received alkylglycerols (18.1% in the prophylactic group and 24.4% in the non-prophylactic group) than in the controls (37.1%). The prophylactic group had a considerably lower incidence of complex injuries and multiple injuries than both the controls and the non-prophylactic groups. The differences were highly significant ($P < 0.001$). Analysis of the patients divided into groups according to tumor stage or radiation technique showed that the incidence of complex injuries was lower in all subgroups of prophylactically treated patients than in the corresponding control groups. A double-blind study in 1970–1972 showed a pronounced protective effect of prophylactic treatment against injuries after radiation therapy.^[51] The use of increased doses of radium in intracavitary irradiation was followed by a high incidence of radiation injuries, which was considerably reduced by treatment with alkylglycerols, especially when these compounds were administered prophylactically.^[53]

The alkylglycerols in other medical conditions

While there are few studies to support the use of natural alkylglycerols in disease states other than cancer it seems appropriate to consider this agent in any condition that would benefit from stimulation of an immune component. Currently the alkylglycerols are viewed as

adjunct therapy rather than primary therapeutic agents, except for the methoxy-substituted alkylglycerols. Newer forms of the alkylglycerols have been synthesized and are being tested successfully with a wide range of tumor types. Conditions that are characterized by a hyperproliferative state may benefit from treatment with alkylglycerol.

Considering that one possible effect of the alkylglycerols is competitive inhibition of diacylglycerol, it is plausible that protein kinase C would also be inhibited by this same action since diacylglycerol is a stimulator of protein kinase C. Protein kinase C is essential to the oxidative burst in neutrophils, and agents that inhibit protein kinase C will inhibit this action.^[54] The work by Yamamoto et al^[42] supports the role of ether analogues as activators of macrophages and as primary cytotoxic agents. This dual role would suggest a wider application of alkylglycerol as adjunct therapy. It has been observed by Oth & Jadhav^[55] that alkylglycerols given to lactating mice will increase the

peripheral granulocyte count as well as the serum immunoglobulins in the pups. This action suggests the possible use of alkylglycerols in most infectious disorders.

Experimental antitumor activity with methoxy-substituted alkylglycerol

About 3% of the alkylglycerols in the Greenland shark liver oil consists of methoxy-substituted alkylglycerols. The methoxy-substituted alkylglycerols have been found to inhibit tumor growth in cultured cells. Two cell lines were used, a methylchol-anthrene-induced murine sarcoma (MCG1-SS) and a juvenile osteogenic sarcoma (2T). Marked growth inhibition was noted for the mixture of 2-methoxyalkylglycerols from Greenland shark liver oil, different single components derived from this oil (2-methoxyhexadecylglycerol, 2-methoxyhexadecenylglycerol, and 2-methoxyoctadecenylglycerol), and various synthetic compounds including, for example, 2-ethoxyhexadecylglycerol, 2-methoxyhexadecenylglycerol, and 3-methoxyhexadecylglycerol. ^[56]

In several tumor–host systems, including solid tumors, leukemias, and lymphomas, the methoxy-substituted alkylglycerols were incorporated into the feed in different concentrations (0.1–2%, w/w). Growth inhibition was noted for melanoma B16, for a methylcholanthrene-induced sarcoma (MCG101) and Lewis lung tumor (LLT) in C57BL/6J mice, for lymphoma LAA in A/Sn mice with synthetic 2-methoxyhexadecylglycerol, and for a spontaneous mammary carcinoma in C3H mice with methoxy-substituted alkylglycerols from Greenland shark liver oil. The survival time of DBA/2J mice transplanted with lymphatic leukemia P1534 was increased by synthetic 2-methoxyhexadecylglycerol. ^[56] ^[57] Metastases induced by the injection of MCG1-SS cells into a tail vein or into the portal vein were inhibited in the liver by methoxy-substituted alkylglycerols from Greenland shark liver oil. ^[57] Spontaneous metastasis formation from a methylcholanthrene-induced sarcoma (MCG1-SS) in lymph nodes and lungs of CBA mice was inhibited by methoxy-substituted alkylglycerols derived from Greenland shark liver oil as well as by synthetic 2-methoxyhexadecylglycerol. ^[56] Spontaneous metastasis formation from melanoma B16 was inhibited by synthetic 2-methoxyhexadecylglycerol. ^[57]

It is notable that the same substance can both stimulate the immune system and inhibit tumors. This has also been shown to be true for alkyllysophospholipids synthesized with a methoxy group in the 2-position of the glycerol part of the molecule. These substances have been studied at the Max-Planck Institute for Immunobiology at Freiburg and at the Department of Haematology and Oncology of the University of Munich.

The German research groups have shown that even alkyllysophospholipids without the 2-methoxy group in the glycerol part can activate macrophages in the bone marrow. This shows that ordinary glycerol ethers, after incorporation into phospholipids, can activate the body's immune defense system. These investigators think that the macrophage-stimulating effects of alkyllysophospholipids explain the effects of these substances on tumors and tumor spread. Tumor cells have only a low activity of enzymes which can break down ethers. This means that alkyl ethers are incorporated into the cell membrane's phospholipids which are then recognized and attacked by

macrophages which have a high activity of ether catabolic enzymes.

In experiments performed at the University of Stockholm,^[58] it has been shown that both types of methoxy-substituted alkylglycerols (methoxy group in the 1-position and methoxy group in the 2-position of the glycerol part of the molecule) inhibit growth of two tumour cell lines (neuroblastoma from mice and glioma cells from rats), while alkylglycerols without methoxy groups did not have any growth-inhibiting effects on the tumor cell line studied.

Interactions between different types of alkylglycerols and human neutrophil granulocytes have been studied by Palmblad et al.^[59] Platelet-activating factor (PAF) was the most potent with regard to the ability to produce an oxidative response, followed by the methoxy-substituted alkylglycerols. The study shows that there is a dissociation between the ability of an alkylglycerol to initiate oxidative and calcium responses, indicating strict structure–activity relationships for the different alkylglycerols studied.

INDICATIONS AND DOSAGE

At present, there are no medical conditions for which shark liver oil-derived alkylglycerols are used as specific therapy; however, they may be used as ancillary,

auxiliary or augmentative agents in many disorders. In cancer chemotherapy or irradiation therapy, they are not only protective but also additive in the overall therapeutic effect. Any disorder that has a proliferative component, and that would include most inflammatory disorders, will respond to alkylglycerols. Immune disorders in particular, can be treated effectively with alkylglycerols. In the prevention of infection or neoplastic diseases, 50 mg of alkylglycerol three times a day is suggested. For aggressively treated disorders, 300 mg/day or more may be needed. The use of the methoxy-derived alkylglycerols must await further research and availability of this powerful alkylglycerol.

CONCLUSIONS

Ether lipids are well known as a new class of tumoricidal compounds, producing strong biological signals. While many new compounds have been synthesized, natural compounds have been known for a long time, beginning with the work of Hanahan on platelet-activating factor, a 1-O-alkyl glycerol. This class of compound, known as plasmalogens, is known to inhibit phosphorylation reactions, particularly those catalyzed by protein kinase C. The dual action of alkylglycerols on both the physical structure of the cell, such as the cell membrane, and the complex biochemical pathways makes them extremely interesting as modulators of cell functions.

The biological action of the alkylglycerols suggests they may have both prophylactic and

inhibitory properties against tumors. This action is highly selective and appears to be related mainly to the chemical structure of the alkylglycerol. Most clinical trials with alkylglycerols have been with very advanced cases, but these results are encouraging. The mechanisms involved in antitumor activity are many and include macrophage activation, immune cytotoxicity, NK cell activation, enzyme inhibition and activation, and cell membrane disturbances. Other actions include the anti-infective properties as well as the radiation protective properties of these agents.

Two areas which hold promise with the use of alkylglycerols are the suppression of autoimmune disorders and the selective destruction of leukemic cells. Much of this work is covered in a report of the First International Symposium on Ether Lipids in Oncology published by The American Oil Chemist Society in 1987.^[60] The outlook for the use of alkylglycerols in medical treatment and in the maintenance of health is very optimistic.

Chapter 62 - *Allium cepa* (onion)

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

Allium cepa (family: Amarylladaceae or Liliaceae)
Common name: onion

GENERAL DESCRIPTION

There are numerous forms and varieties of onion as this perennial or biennial herb is cultivated worldwide. The part used is the fleshy bulb. Common varieties are white globe, yellow globe and red globe.

CHEMICAL COMPOSITION

Onion, like garlic, contains a variety of organic sulfur compounds, including:

- S-methylcysteine sulfoxide
- trans-S-(1-propenyl)cysteine sulfoxide
- S-propylcysteine sulfoxide
- dipropyl disulfide.

Onion also has the enzyme alliinase, which is released when the onion is cut or crushed, causing conversion of trans-S-(1-propenyl)cysteine sulfoxide to the so-called lacrimatory factor (propanethial S-oxide). Other constituents include:^[1] ^[2]

- flavonoids (primarily quercetin)
- phenolic acids (e.g. caffeic, sinapic, and p-coumaric)
- sterols
- saponins
- pectin

- volatile oils.

HISTORY AND FOLK USE

Although not as valued a medicinal agent as garlic, onion has been used almost as widely. Like garlic (*Allium sativum*), onion has been used as an antispasmodic, carminative, diuretic, expectorant, stomachic, anthelmintic, and anti-infective agent. Externally it has been used as a rubefacient and poultice, giving relief in skin diseases and insect bites.^{[1] [2] [3]}

568

PHARMACOLOGY

Onion and garlic, due to their similar constituents, have many of the same pharmacological effects. There are, however, some significant differences that make one more advantageous than the other in certain conditions.

Antimicrobial activity

Although onion does exhibit some antibacterial, antifungal, and anthelmintic activity, it is not nearly as potent as garlic. Although this suggests that garlic may be better indicated in cases of infection,^{[2] [3] [4]} onion can usually be consumed in larger quantities than garlic, which may increase the concentration of antimicrobial constituents in vivo to approximate those of garlic.

Cardiovascular effects

Like garlic, onions and onion extracts have been shown to decrease blood lipid levels, increase fibrinolysis, decrease platelet aggregation, and lower blood pressure in several clinical studies.^{[5] [6] [7]} Onion oil, compared with garlic oil, is a stronger inhibitor of the enzymes cyclo-oxygenase and lipoxygenase, which mediate eicosanoid metabolism (prostaglandins, thromboxanes and leukotrienes).^[8] This suggests that onions would also have a greater effect on inhibition of platelet aggregation and other events mediated by eicosanoids. Garlic and onion consumption is associated with lower levels of cholesterol and triglycerides, and an increase in fibrinolytic activity^[9] (see [Ch. 63](#) for details). As the quantity of onion consumed in the study cited was so much larger than that of garlic (600 g of onion/week compared with 50 g of garlic), an argument could be made that onion consumption was the major determinant.

Diabetes

Onions have been shown to have significant oral hypoglycemic action, comparable to that of the prescription oral hypoglycemic agents tolbutamide and phenformin.^{[10] [11]} The active hypoglycemic principle in onions is believed to be allyl propyl disulphide (APDS),

although other constituents, such as quercetin and anthocyanidins, may play a significant role as well. Experimental and clinical evidence suggests that APDS lowers glucose by competing with insulin (also a disulfide) for degradation sites, thereby increasing the half-life of insulin. Other mechanisms, such as increased hepatic metabolism of glucose or increased insulin secretion, have been proposed.

Anti-asthmatic action

Onion has historically been used as an anti-asthmatic agent.^{[2] [3]} Its action in asthma, as well as in other conditions associated with increased lipoxygenase derivatives (leukotrienes), such as psoriasis and atopic dermatitis, appears to be greater than that of garlic. (As mentioned previously, onion oil is a much greater inhibitor of cyclo-oxygenase and lipoxygenase.)^[8] The net effect is similar to that of cortisol, which inhibits all eicosanoid metabolism via inhibition of phospholipase. Inhibition of leukotriene formation and onion's quercetin and isothiocyanates content are probably the primary factors responsible for onion's anti-asthmatic effects. These effects have been confirmed in experimental studies.^{[12] [13]}

Antitumor effects

An onion extract was found to be cytotoxic to tumor cells in vitro and to arrest tumor growth when tumor cells were implanted in rats.^[14] The onion extract was shown to be unusually non-toxic, since a dose as high as 40 times that of the cytotoxic dose for the tumor cells had no adverse effect on the host. Another species of allium, *Allium ascalonicum* (shallots), has been shown to exhibit significant antileukemic activity in mice.^[15]

One human study evaluated onion consumption and stomach cancer in over 120,000 men and women between 55 and 69 years of age. After a 3.3 year follow-up, 139 stomach cancers were diagnosed. The researchers found a strong inverse association between onion consumption and stomach cancer incidence, but no association with the use of leeks or garlic.^[16]

DOSAGE

Onion can be eaten liberally as part of a nutritious diet. Therapeutic dosages in the various forms are typically 50–150 g/day.

TOXICOLOGY

There have been virtually no reports of toxicity. However, those with heartburn may note an aggravation of symptoms. One study evaluated symptoms of acid reflux in 16 normal subjects and 16 heartburn patients. Subjects were studied with an esophageal pH probe for 2 hours after eating a plain hamburger and a glass of ice water, then on another day an identical meal with a slice of raw onion. In the normal patients, ingestion of onions did not increase any of the variables measured (number of reflux episodes, pH < 4, time of pH < 4, heartburn episodes and belches). In contrast, heartburn subjects experienced

a significant increase in all. While the authors of the study conclude that onions can be a potent and long-lasting reflexogenic agent in heartburn patients,^[17] an alternative explanation may be that onion simply improved digestive acid secretion, making the symptoms of reflux more noticeable.

SUMMARY

The above discussion on the onion highlights its medicinal value, particularly in cardiovascular disease, diabetes mellitus, and inflammatory conditions. As onion is chiefly regarded as a food or seasoning, this chapter, and the other chapters in this section about common foods and seasonings (e.g. [Chs 63](#) , [80](#) and [124](#)) raise questions about the medicinal effects of other common vegetables and/or seasonings. They also may have significant pharmacological effects that have not been investigated. A diet rich in such foods, spices or seasonings may offer protection and possibly treatment for a wide variety of diseases. Once again, the importance of a relatively natural, unprocessed diet to long-term health is supported. The liberal use of the *Allium* species appears particularly indicated considering the major disease processes of the 20th century.

Chapter 63 - *Allium sativum* (garlic)

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

Allium sativum (family: Amaryllidaceae or Liliaceae)
Common names: garlic, allium

GENERAL DESCRIPTION

Garlic, a member of the lily family, is a perennial plant that is cultivated worldwide. The garlic bulb is composed of individual cloves enclosed in a white skin. It is the bulb, either fresh or dehydrated, that is used as a spice or medicinal herb.

CHEMICAL COMPOSITION

Garlic contains 0.1–0.36% of a volatile oil composed of sulfur-containing compounds:

- allicin
- diallyl disulfide
- diallyl trisulfide
- others.

The garlic oil is obtained by steamed distillation of the crushed fresh bulbs.^[1] These volatile compounds are generally considered to be responsible for most of the pharmacological properties of garlic. Other constituents of garlic include:^[1] ^[2]

- alliin (S-allyl-L-cysteine sulfoxide)
- S-methyl-L-cysteine sulfoxide
- protein (16.8%, dry weight basis)
- high concentrations of trace minerals (particularly selenium)
- vitamins
- glucosinolates

- enzymes (alliinase, peroxidase, and myrosinase).

Alliin is mainly responsible for garlic's pungent odor. It is formed by the action of the enzyme alliinase on the compound alliin. The essential oil of garlic yields approximately 60% of its weight in allicin after exposure to alliinase. The enzyme is inactivated by heat, which accounts for the fact that cooked garlic produces neither

572

as strong an odor as raw garlic nor nearly as powerful physiological effects.^[1]

HISTORY AND FOLK USE

Garlic has been used throughout history for the treatment of a wide variety of conditions. Its usage predates written history. Sanskrit records document the use of garlic remedies approximately 5,000 years ago, while the Chinese have been using it for at least 3,000 years. The *Codex Ebers*, an Egyptian medical papyrus dating to about 1550 BC, mentions garlic as an effective remedy for a variety of ailments, including hypertension, headache, bites, worms, and tumors. Hippocrates, Aristotle and Pliny cited numerous therapeutic uses for garlic. In general, garlic has been used throughout the world to treat coughs, toothache, earache, dandruff, hypertension, atherosclerosis, hysteria, diarrhea, dysentery, diphtheria, vaginitis, and many other conditions.^{[1] [2] [3]}

Stories, verse and folklore (such as its alleged ability to ward off vampires) give historical documentation to garlic's power. Sir John Harrington in *The Englishman's doctor*, written in 1609, summarized garlic's virtues and faults:^[3]

```
Garlic then have power to save from death  
Bear with it though it maketh unsavory breath,  
And scorn not garlic like some that think  
It only maketh men wink and drink and stink.
```

In 1721, during a widespread plague in Marseilles, four condemned criminals were recruited to bury the dead. The gravediggers proved to be immune to the disease. Their secret was a concoction they drank consisting of macerated garlic in wine. This became known as *vinaigre des quatre voleurs* (four thieves' vinegar), and it is still available in France today.

Garlic's antibiotic activity was noted by Pasteur in 1858. Garlic was used by Albert Schwietzer in Africa for the treatment of amebic dysentery, and as an antiseptic in the prevention of gangrene during the two World Wars.

PHARMACOLOGY

Although garlic has a wide range of well-documented effects, its most important clinical

uses are in the areas of infection, cancer prevention, and cardiovascular disease.

Antimicrobial activity

Garlic has been shown to have broad-spectrum antimicrobial activity against many genera of bacteria, viruses, worms, and fungi, as summarized in several works.^{[4] [5] [6]} These findings support the historical use of garlic in the treatment of a variety of infectious conditions.

Antibacterial activity

As far back as 1944, studies have demonstrated that both garlic juice and allicin inhibited the growth of *Staphylococcus*, *Streptococcus*, *Bacillus*, *Brucella*, and *Vibrio* species at low concentrations.^{[7] [8]} In more recent studies using serial dilution and filter paper disk techniques, fresh and vacuum-dried powdered garlic preparations were found to be effective antibiotic agents against many bacteria, as listed in [Table 63.1](#). In these studies, the antimicrobial effects of garlic were compared with commonly used antibiotics, including penicillin, streptomycin, chloramphenicol, erythromycin, and tetracyclines. Besides confirming garlic's well-known antibacterial effects, the studies demonstrated its efficacy in inhibiting the growth of some bacteria which had become resistant to one or more of the antibiotics.

Garlic administration has also been shown to significantly reduce the number of coliforms and anaerobes in the feces.^[11]

Antifungal activity

Garlic has demonstrated significant antifungal activity in many in vitro and in vivo studies.^{[4] [12] [13] [14] [15] [16] [17]} From a clinical perspective, inhibition of *Candida albicans* has the most significance, as both animal and in vitro studies have shown garlic to be more potent than nystatin, gentian violet, and six other reputed antifungal agents.^{[4] [13] [14] [15]} Aqueous garlic extracts have been shown in vivo to be very effective, even at a dilution of 1:100, against the very common tinea corporis, capitis and cruris fungal skin infections.^[13]

In one study at a major Chinese hospital, garlic therapy alone was used effectively in the treatment of cryptococcal meningitis, one of the most serious fungal infections imaginable.^[16]

TABLE 63-1 -- Microbes inhibited by garlic^{[4] [5] [6] [9] [10]}

| |
|---|
| • Bacteria |
| —alpha- and beta-hemolytic <i>Streptococcus</i> |
| — <i>Citrobacter</i> sp. |
| — <i>Escherichia coli</i> |

| |
|---------------------------------------|
| — <i>Klebsiella pneumoniae</i> |
| — <i>Mycobacteria</i> |
| — <i>Proteus vulgaris</i> |
| — <i>Salmonella enteritidis</i> |
| — <i>Staphylococcus aureus</i> |

| — <i>Human rhinovirus</i> type 2 |
| — <i>Parainfluenza virus</i> type 3 |
| — <i>Vaccinia virus</i> |
| — <i>Vesicular stomatitis virus</i> |

Anthelmintic effects

Garlic extracts have been shown to have anthelmintic activity against common intestinal parasites, including *Ascaris lumbricoides* (roundworm) and hookworms.^{[11] [18]}

Antiviral effects

Garlic's antiviral effects have been demonstrated by its protection of mice from infection with intranasally inoculated influenza virus, and by its enhancement of neutralizing antibody production when given with influenza vaccine.^[19]

The in vitro virus-killing effects of fresh garlic, allicin, and other sulfur components of garlic were determined against *Herpes simplex* types 1 and 2, *Parainfluenza virus* type 3, *Vaccinia virus*, *Vesicular stomatitis virus*, and *Human rhinovirus* type 2. The order for virucidal activity was:

ajoene > allicin > allyl methyl thiosulfinate > methyl allyl thiosulfinate

Ajoene was found in oil-macerates of garlic but not in fresh garlic extracts. No antiviral activity was found for alliin, deoxyalliin, diallyl disulfide, or diallyl trisulfide. Fresh garlic extract was virucidal against all viruses tested. Virucidal activity of commercial products was dependent upon their preparation processes. Those products producing the highest level of allicin and other thiosulfinates had the best virucidal activity.^[20]

Immune-enhancing effects

A large amount of research has shown that garlic has many immune-potentiating properties, most of which are thought to be due to volatile factors composed of sulfur-containing compounds: allicin, diallyl disulfide, diallyl trisulfide and others. Fresh garlic, commercial products containing allicin, and aged garlic preparations have all shown these properties. Garlic has been shown to enhance the pathogen-attacking activity of T-cells, neutrophils and macrophages, to increase the secretion of interleukin, and to increase natural killer cell activity.^{[21] [22] [23] [24]} The increase in killer cell activity was a remarkable 140% in those eating the equivalent of two bulbs a day and 156% in those consuming 1,800 mg of odorless aged garlic.

Anti-cancer effects

The famous Greek physician Hippocrates prescribed eating garlic as a treatment for cancer. Animal research and some human studies suggest this advice may have been well-founded. Several garlic components have displayed significant anti-cancer effects.^{[25] [26] [27]}

Human studies showing garlic's anti-cancer effects are largely based on epidemiological studies.^{[25] [26] [27] [28]} These studies show an inverse relationship between cancer rates and garlic consumption. In China, a study comparing populations in different regions found that death from gastric cancers in regions where garlic consumption was high was significantly less than in regions with lower garlic consumption.^[28]

Garlic extracts and allicin have displayed potent antitumor effects in animal studies.^{[29] [30] [31] [32] [33] [34] [35] [36] [37] [38]} Human studies have shown that garlic inhibits the formation of nitrosamines (powerful cancer-causing compounds formed during digestion).^{[39] [40]}

Cardiovascular effects

Garlic appears to be an important protective factor against heart disease and strokes via its ability to impact the process of atherosclerosis at many steps. As there is substantial clinical information on garlic's beneficial effects on the cardiovascular system, the pharmacology is discussed in the section on "clinical applications" below.

Other effects

Anti-inflammatory effects

Garlic extract has demonstrated significant antiinflammatory activity in experimental models of inflammation.^{[2] [11]} This activity is probably a result of garlic's inhibition of the formation of inflammatory compounds.

Hypoglycemic action

Garlic (and onions) has often been used in the treatment of diabetes. Allicin has been shown to have significant hypoglycemic action. This effect is thought to be due to increased hepatic metabolism, increased release of insulin and/or insulin-sparing effect.^[41] The latter mechanism appears to be the major factor, as allicin and other sulfhydryl compounds in garlic and onions compete with insulin (also a disulfide protein) for insulin-inactivating compounds, which results in an increase in free insulin.

Miscellaneous effects

Garlic possesses diuretic, diaphoretic, emmenagogue, and expectorant action.^{[1] [9]} It is also a carminative, anti-spasmodic and digestant, making it useful in cases of flatulence, nausea, vomiting, colic, and indigestion.^{[11] [42]}

CLINICAL APPLICATIONS

Although garlic has long been used in infectious conditions, a use supported by its antimicrobial and immune-enhancing properties, the primary clinical use of garlic

has focused on its role in cardiovascular disease. Specifically, garlic is recommended primarily for its ability to lower cholesterol and blood pressure in the attempt to reduce the risk of dying prematurely from a heart attack or stroke.

Cardiovascular disease

The majority of studies showing a positive effect of garlic and garlic preparations in reducing the risk of cardiovascular mortality are those which use products that deliver a sufficient dosage of allicin. Since allicin is the component in garlic that is responsible for its easily identifiable odor, several manufacturers have developed highly sophisticated methods in an effort to provide the full benefits of garlic without odor. These "odorless" garlic products concentrate for alliin because alliin is relatively "odorless" until it is converted to allicin in the body. Products concentrated for alliin and other sulfur

components and stabilized in enteric-coated tablets provide all the benefits of fresh garlic but are more “socially acceptable”.

In addition to the use of garlic preparations, garlic consumption as a food should be encouraged, despite its odor, in patients with high cholesterol levels and high blood pressure.

Garlic and garlic preparations should also be encouraged in patients with diabetes, candidiasis, asthma, infections (particularly respiratory tract infections), and gastrointestinal complaints.

Cholesterol-lowering activity

Foremost in garlic's ability to offer significant protection against heart disease and strokes is its ability to lower blood cholesterol levels, even in apparently healthy individuals.^{[43] [44] [45] [46] [47]} According to the results from numerous double-blind, placebo-controlled studies in patients with initial cholesterol levels greater than 200, supplementation with commercial preparations providing a daily dose of at least 10 mg alliin or a total allicin potential of 4,000 mcg can lower total serum cholesterol levels by about 10–12%; LDL cholesterol will decrease by about 15%; HDL cholesterol levels will usually increase by about 10%; and triglyceride levels will typically drop by 15%.^{[47] [48] [49] [50] [51]}

Although the effects of supplemental garlic preparations on cholesterol levels are modest, the combination of lowering LDL and raising HDL can greatly improve the HDL to LDL ratio, a significant goal in the prevention of heart disease and strokes. Garlic preparations standardized for alliin content exert several other beneficial effects in preventing heart disease and strokes (discussed below).

In addition to taking a garlic supplement, individuals

TABLE 63-2 -- Effects of garlic and onion consumption on serum lipids under carefully matched diets

| Garlic/onion | Cholesterol | Triglyceride |
|---------------|-------------|--------------|
| None | 208 mg/dl | 109 mg/dl |
| 10–200 g/week | 172 mg/dl | 75 mg/dl |
| 50–600 g/week | 159 mg/dl | 52 mg/dl |

with high cholesterol levels should eat more garlic and onions, as increased dietary intake of garlic and onion can also lower cholesterol levels.^{[43] [44] [45] [46] [52]} In a 1979 population study, researchers studied three populations of vegetarians in the Jain community in India who consumed differing amounts of garlic and onions.^[53] Numerous favorable effects on blood lipids, as shown in [Table 63.2](#), were observed in the group that consumed the largest amount. Blood fibrinogen (discussed below) levels were highest in the group eating no onions or garlic. The study is quite significant because

the subjects had nearly identical diets, except in garlic and onion ingestion.

Hypertension

Garlic has demonstrated hypotensive action in both experimental animal models and humans with hypertension.^{[43] [44] [45] [46] [54] [55] [56]} A meta-analysis of published and unpublished randomized controlled trials of garlic preparations was conducted to determine the effect of garlic on blood pressure relative to placebo.^[54] Eight trials (seven double-blind, one single-blind) were identified as meeting analytical criteria. A total of 415 subjects were included in the analysis.

All trials used a dried garlic powder standardized to contain 1.3% alliin at a dosage of 600 to 900 mg daily (corresponding to 7.8 and 11.7 mg of alliin or the equivalent of approximately 1.8–2.7 g of fresh garlic daily).

The meta-analysis concluded that garlic preparations designed to yield allicin can lower systolic and diastolic blood pressures over a 1–3 month period. The typical drop from pooled data was 11 mmHg in the systolic and 5.0 mmHg in the diastolic. This degree of blood pressure reduction in hypertensives can be quite significant. It is estimated that if the blood pressure-lowering effects of garlic can be maintained, the risk of stroke may be reduced by 30–40% and the risk of heart attack by 20–25%.

Platelet aggregation inhibition

Excessive platelet aggregation is strongly linked to atherosclerosis, heart disease, and strokes. Garlic preparations standardized for alliin content as well as garlic oil have demonstrated significant inhibition of platelet aggregation.^{[43] [44] [45] [46] [57]} In one study, 120 patients with increased

platelet aggregation were given either 900 mg/day of a dried garlic preparation containing 1.3% alliin or a placebo for 4 weeks.^[57] In the garlic group, spontaneous platelet aggregation disappeared, the microcirculation of the skin increased by 47.6%, plasma viscosity decreased by 3.2%, diastolic blood pressure dropped from an average of 74 to 67 mmHg, and fasting blood glucose concentration dropped from an average of 90 to 79 mg/dl.

Fibrinolytic activity

Epidemiological studies have suggested that excessive fibrinogen formation is a major primary risk factor for cardiovascular disease.^[58] Fibrinogen is an “acute phase” protein involved in the clotting system. However, it plays many other roles, including several which promote atherosclerosis, such as acting as a cofactor for platelet aggregation, determining the viscosity of blood, and stimulating the migration and proliferation of

smooth muscle cells in the intima of the artery walls.

Early clinical studies stimulated detailed population studies on the possible link between fibrinogen levels and cardiovascular disease. The first such study was the Northwick Park Heart Study in the UK. This large study involved 1,510 men aged 40–64 years who were randomly recruited and tested for a range of clotting factors, including fibrinogen. At 4 years follow-up, a stronger association was found between cardiovascular deaths and fibrinogen levels than for cholesterol. This association has been confirmed in five other prospective epidemiological studies.^[58]

The clinical significance of these findings can be summarized as follows:

1. Fibrinogen levels should be determined and monitored in patients with, or at high risk for, coronary heart disease or stroke.
2. Garlic and other natural therapies which promote fibrinolysis (e.g. omega-3 oils, bromelain, capsicum, etc.) may offer significant benefit in the prevention of heart attacks, strokes, and other thromboembolic events.

Garlic preparations standardized for alliin content as well as garlic oil, and both fried and raw garlic have been shown to significantly increase serum fibrinolytic activity in humans.^[59] ^[60] This increase occurs within the first 6 hours after ingestion and continues for up to 12 hours.

Prevention of LDL oxidation

There is growing evidence that lipoprotein (LDL) oxidation plays a significant role in the development of atherosclerosis. Accordingly, substances which prevent oxidation of LDL slow down atherosclerosis. Antioxidants vitamin E, vitamin C, and beta-carotene have all been shown to offer protection against LDL oxidation and heart disease.

Garlic is known to exert antioxidant activity, but until recently, there were no studies examining its effects on LDL oxidation. Healthy human volunteers given 600 mg/day of a garlic preparation providing 7.8 mg alliin for 2 weeks had a 34% lower susceptibility to lipoprotein oxidation compared with controls.^[61] These results are quite significant given the short amount of time they took to produce coupled with the importance of reducing lipoprotein oxidation.

In another study, a placebo-controlled double-blind trial of 23 subjects with coronary artery disease who had one to three major coronary arteries that were 75% blocked or higher, 300 mg of garlic powder, 2 and 4 hours after a single dose, showed the atherogenicity of the patients' sera to be markedly decreased. There was less cholesterol accumulation and lower levels of oxidized LDL in human aortic smooth muscle cells cultured with patients sera after treatment compared with those cultured with sera obtained prior to the administration of the garlic. After 3 weeks of therapy at 300 mg, three times daily, blood serum atherogenicity was decreased twofold compared with initial levels.^[62]

DOSAGE

The modern use of garlic features the use of commercial preparations designed to offer the benefits of garlic without the odor. The marketplace is swamped with garlic products with each manufacturer claiming their product is the best.

Preparations standardized for alliin content provide the greatest assurance of quality. However, American consumers must be aware of the subtle techniques manufacturers of garlic products use to disguise the quality of their products.

Based on a great deal of clinical research, the dosage of a commercial garlic product should provide a daily dose equal to at least 4,000 mg of fresh garlic. This dosage translates to at least 10 mg alliin or a total allicin potential of 4,000 mcg.

Figure 63-1 Conversion of alliin to allicin.

576

TOXICITY

For the vast majority of individuals, garlic is non-toxic at the dosages commonly used. For some, however, it can cause irritation to the digestive tract, while others are apparently unable to effectively detoxify allicin and other sulfur-containing components. Prolonged feeding of very large amounts of raw garlic to rats results in anemia, weight loss and failure to grow.^[63] Although the exact toxicity of garlic has yet to be definitively determined, side-effects are rare at the dosage recommended above.

Chapter 64 - *Aloe vera* (Cape aloe)

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

Aloe vera (family: Lilaceae)
Common name: Cape aloe

GENERAL DESCRIPTION

There are more than 300 species of aloe plants, but the most popular medicinal variety is currently *Aloe vera*. The nomenclature of *Aloe vera* has been somewhat confused as the plant has been known by a variety of names, most notably *Aloe barbadensis* and *Aloe vulgari*. The geographical origination of the plant is unclear. Historical records indicate that it may have originated from Egypt or the Middle East. Aloe has been introduced and naturalized throughout most of the tropics and warmer regions of the world, including the Caribbean, the southern US, Mexico, Latin America, the Middle East, India and other parts of Asia.^[1]

Aloe vera is a perennial plant with yellow flowers and tough fleshy triangular or spear-like leaves arising in a rosette configuration. The leaves are up to 20 inches long and 5 inches across at the base, tapering to a point. There may be as many as 30 leaves per plant. The margins of the leaf are characterized by saw-like teeth. Inside, the meaty leaf is filled with gel that arises from a clear central mucilaginous pulp. Mature aloe measures 1.5–4 feet long and has a base of 3 inches or greater in diameter.

The leaf is composed of three distinct layers: an outer layer of tough tissue; a corrugated lining just beneath the outer layer; and the major portion of the leaf, the inner layer consisting of parenchymal cells containing large vacuoles of a semi-solid, gelatinous transparent gel. The bitter latex of the corrugated layer protects the plants from predators. Should an animal bite the leaf, the sap causes irritation. The dried latex (juice) derived from the corrugated layer is the source of the laxative properties of aloe.

The parenchymal tissue or gel is the portion of the aloe used in other applications.^[2]

Aloe vera terminology

- *Aloe vera gel* – naturally occurring, undiluted parenchymal tissue obtained from the decorticated leaves of *Aloe vera*
- *Aloe vera concentrate* – *Aloe vera gel* from which the water has been removed
- *Aloe vera juice* – an ingestible product containing a minimum of 50% *Aloe vera gel*
- *Aloe vera latex* – the bitter yellow liquid derived from the pericyclic tubules of the rind of *Aloe vera*, the primary constituent of which is aloin.

CHEMICAL COMPOSITION

Aloe vera contains numerous compounds possessing biological activity. While many botanical medicines suffer from substantial geographical variation in content, commercial aloe is quite consistent. One study found that the composition of the major compounds is remarkably invariable, with aloeresin A, aloesin, and aloin (both epimers A and B) contributing between 70 and 97% of total dry weight, in a ratio of approximately 4:3:2, respectively. Minor compounds were less evenly distributed, with aloinoside A and aloinoside B being found in higher concentrations in Western Countries. The aloin content of the exudate did vary but there were no distinct geographical discontinuities.^[3]

Anthraquinones

In 1851, it was discovered that the cathartic action of aloe was due to aloin, a lemon yellow powder formed from drying of the bitter latex. From this material several anthracenes have been isolated, the major anthraquinone being barbaloin. Barbaloin and aloin are often referred to synonymously. Although aloe contains other anthraquinone derivatives, including the anthracene known as aloe-emodin, barbaloin is considered the most potent cathartic. As a whole, the anthraquinone compounds are water-soluble glycosides easily separated from the water-insoluble resinous material.^[1]
^[2] ^[3] ^[4] ^[5]

Saccharides

Recent research on *Aloe vera* has focused on the glycoprotein, mucopolysaccharide, and polysaccharide constituents. Aloe contains polysaccharides galactose, xylose, arabinose, and acetylated mannose. This latter polysaccharide, which is similar to guar and locust bean, has received considerable clinical research attention as an antiviral and immunopotentiating agent, especially in the treatment of AIDS. Acemannan, a water-soluble, long-chain polydispersed beta-(1,4)-linked mannan polymer interspersed

with O-acetyl groups, is discussed below.

Prostanoids

Several prostanoid compounds have been discovered in *Aloe vera* extracts.^[6] The conversion of essential fatty acids to prostanoids by the enzyme cyclooxygenase in a plant such as *Aloe vera* is quite rare. The major unsaturated fatty acid in the plant is gamma-linolenic acid (C18:3) which can be converted to eicosatrienoic acid, the precursor to prostaglandins of the 1 series. The 1 series prostaglandins are known to exert more favorable effects on inflammation, allergy, platelet aggregation, and wound healing. The presence of gamma-linoleic acid and/or prostaglandins in a stable medium, along with inhibitors of thromboxane synthesis, may be another of the important chemical characteristics of aloe responsible for its wound healing effects.

Superoxide dismutase

Extracts from the parenchymatous leaf gel and the rind of aloe (*Aloe barbadensis* Miller) have been shown to contain seven electrophoretically identifiable superoxide dismutases (SODs). Two of these seven are manganese-SODs, while the other five activities are cupro-zinc SODs.^[7]

Other constituents

Other biological active compounds found in *Aloe vera* include:

- a serine carboxypeptidase
- salicylates
- minerals
- vitamins
- sterols
- amino acids.

[Table 64.1](#) provides a partial listing of the remarkably diverse range of compounds isolated from *Aloe vera*.^{[2] [3] [4] [5]}

HISTORY AND FOLK USE

Aloe vera has a storied history of use. Mesopotamian clay tablets dated 1750 BC indicate that *Aloe vera* was being used for medicinal purposes. Egyptian records from 550 BC also mentioned aloe for infections of the skin. The ancient Greeks were also aware of aloe's medicinal effects as both Pliny (23–79 AD) and Dioscorides (first century AD) wrote of aloe's ability to treat wounds and heal infections of the skin. *Aloe vera* is still widely used in many traditional systems of medicine. In India, for example, in addition to external applications, aloe (whole leaves, the exudate, and the fresh gel) is used as a cathartic, stomachic, and anthelmintic. *Aloe vera* has been adopted into the materia medicas by many cultures of the world.^[1]

TABLE 64-1 -- Chemical composition of *Aloe vera*^[5]

| | |
|----------------|---|
| Anthraquinones | Aloin, barbaloin, isobarbaloin, anthranol, aloetic acid, anthracene, ester of cinnamic acid, aloe-emodin, emodin, chrysophanoic acid, ethereal oil, resistannol |
| Saccharides | Cellulose, glucose, mannose, L-rhamnose, aldopentose |
| Prostanoids | Gamma-linolenic acid |
| Enzymes | Oxidase, amylase, catalase, lipase, alkaline phosphatase |
| Amino acids | Lysine, threonine, valine, methionine, leucine, isoleucine, phenylalanine |
| Vitamins | Vitamins B ₁ , B ₂ , B ₆ , C, and E, folic acid, choline, β-carotene |
| Minerals | Calcium, sodium, manganese, magnesium, zinc, copper, chromium |
| Miscellaneous | Cholesterol, triglycerides, steroids, uric acid, lignins, β-sitosterol, gibberellin, salicylic acid |

In the United States, the history of aloe can be traced as far back as the *United States Pharmacopoeia* of 1820, where a number of aloe preparations were described. Most of these preparations were designed to take advantage of aloe's laxative effects. By the early 1900s, more than 27 different aloe preparations were in popular use. In 1920, aloe began being cultivated for pharmaceutical use.^[4]

A major development in the modern use of aloe occurred in 1935 when a group of physicians successfully used the fresh juice to treat a patient suffering from facial burns due to X-rays.^[6] The relief offered by aloe in the topical treatment of burns, minor irritations, skin ulcers, and other skin disorders is a major reason why companies supplying dermatologic and cosmetic products have incorporated aloe in many of their formulations.

Although more and more of aloe's medicinal effects are being confirmed, aloe is still predominantly administered without direct medical supervision. Therefore, the history and folk use of aloe are continuing to evolve.

PHARMACOLOGY

Gastrointestinal effects

The pharmacology of aloe is surprisingly diverse – laxative, immune potentiation, antimicrobial and wound-healing activities help explain its wide ranging folk and clinical

applications.

Laxative effects

Although physicians have prescribed the whole aloe leaf as a cathartic for more than 2,000 years, it was not until 1851 that the active principle aloin was discovered.^[1] In small doses, aloin acts as a tonic to the digestive system, giving tone to the intestinal muscle. At higher dosages, it becomes a strong purgative. Its actions are most obvious on the large intestine where it increases colonic secretions and peristaltic contractions. In combination with strychnine and belladonna, aloin became one of the most popular laxatives for chronic constipation for many years. Since aloin often causes painful contraction, other anthraquinone laxatives like cascara and senna are now much more popular.^{[9] [10]}

A substantial amount of research activity continues in an effort to understand the laxative effects of aloe. Research using the rat large intestine shows that the increase in water content of the large intestine induced by barbaloin precedes the stimulation of peristalsis, attended by diarrhea. Therefore, it is suggested that the increase in water content is a more important factor than the stimulation of peristalsis in the diarrhea induced by barbaloin.^[11] Further studies by the same researchers suggests that aloe-emodin-9-anthrone (AE-anthrone), produced from barbaloin in the rat large intestine may be the actual chemical mediator of this effect. AE-anthrone not only caused an increase in the intestinal water content, but also stimulated mucus secretion.^[12]

Bowel detoxification

In 1985, Bland^[13] reported the effect of orally consumed *Aloe vera* juice on urinary indican, gastrointestinal pH, stool culture, and stool specific gravity in a semi-controlled study of 10 (five men and five women) healthy human subjects.^[13] Urinary indican (see [Ch. 31](#)) is used as an indicator of the degree to which either dietary protein is malabsorbed or intestinal bacteria are engaged in putrefactive processes. After one full week of drinking 6 ounces of *Aloe vera* juice three times daily, urinary indican levels decreased one full unit. This suggests that regular *Aloe vera* juice consumption can lead to improved protein digestion and assimilation and/or reduced bacterial putrefaction.

Inhibition of gastric acid secretion

With Heidelberg gastric analysis, the *Aloe vera* juice was shown to increase gastric pH by an average of 1.88 units. This supports the findings of other researchers that *Aloe vera* gel can inhibit the secretion of hydrochloric acid. The Heidelberg test also demonstrated that *Aloe vera* juice can slow down gastric emptying, possibly leading to improved digestion.

Six of the 10 subjects showed marked alterations in stool cultures after the week long study. This implies that *Aloe vera* juice may exert some bacteriostatic or fungistatic activity. In the four subjects with positive cultures for yeast, there was a reduction in the

number of yeast colonies.

Stool specific gravity was reduced after the week of *Aloe vera* juice. This implies improved water retention, yet none of the subjects complained of diarrhea or loose stools while taking the *Aloe vera* juice.

Immune-enhancing and antimicrobial activity

Antibacterial and antifungal activity

Aloe has demonstrated activity against many common bacteria and fungi in several studies. In the most detailed of these studies, Robson et al^[14] assayed the antimicrobial properties of an *Aloe vera* extract and reviewed the work of others.^{[15] [16] [17]} Both mean inhibitory and mean lethal concentrations were determined and compared with silver sulfadiazine, a potent antiseptic used in the treatment of extensive burns. As shown in [Table 64.2](#), the antimicrobial effects of *Aloe vera* compare quite favorably with those of silver sulfadiazine. A 60% *Aloe vera* extract was found to be bactericidal against *Pseudomonas aeruginosa*, *Klebsiella pneumoniae*, *Serratia marcescens*, *Citrobacter* sp., *Enterobacter cloacae*, *Streptococcus pyogenes*, and *Strep. agalacticae*. Seventy per cent concentrations of aloe were bactericidal for *Staphylococcus aureus*, 80% for *E. coli*, and 90% for *Streptococcus faecalis* and *Candida albicans*. Organisms inhibited in other studies include *Mycobacterium tuberculosis*, *Trichophyton* sp., and *Bacillus subtilis*.^{[2] [4] [5]} The antimicrobial activity against common skin pathogens of *Aloe vera* gel in a cream base was shown to be slightly better than silver sulfadiazine in agar well diffusion studies.^[14]

Antiviral effects

Acemannan (acetylated mannose) in injectable form has been approved for veterinary use in fibrosarcomas and feline leukemia. Its action in feline leukemia is quite impressive. Feline leukemia, like AIDS, is caused by a retrovirus (feline leukemia virus or FeLV). The virus is

TABLE 64-2 -- Antimicrobial effects of *Aloe vera* extract in cream base compared with silver sulfadiazine in agar well (6 mm) diffusion^[14]

| Organism | <i>Aloe vera</i> | AgSD |

| <i>S. faecalis</i> | 6 | 11 |
| <i>B. subtilis</i> | 19 | 14 |

Inhibition zones measured in mm.

so lethal that once cats develop clinical symptoms they are usually euthanized. Typically over 70% of cats will die within 8 weeks of the onset of clinical signs. In a study of 44 cats with clinically confirmed feline leukemia, acemannan was injected (2 mg/kg) weekly for 6 weeks and re-examined 6 weeks after termination of treatment.^[18] At the end of the 12 week study, 71% of the cats were alive and in good health.

Acemannan has demonstrated significant antiviral activity against several viruses, including the feline AIDS, human immunodeficiency virus type 1 (HIV-1), influenza virus and measles virus.^{[19] [20] [21]}

Immune enhancement

Acemannan is a potent immunostimulant.^{[18] [22] [23] [25]} Among the effects noted for acemannan include the enhancement of macrophage release of interleukin-1-alpha, cytokines, tumor necrosis factor, nitric oxide release, as well as phagocytosis and non-specific cytotoxicity. Acemannan also enhances T-cell function and interferon production, although these actions may also be due to enhanced macrophage function. Macrophage production of cytokines IL-6 and TNF-alpha were dependent on the dose of acemannan provided. These effects can be quite substantial. For example, in one study, acemannan has been shown to enhance the macrophage respiratory burst (twofold increase above the media controls), phagocytosis (45% compared with 25% in controls), and killing of *Candida albicans* (38% killing of *Candida albicans* compared with 0–5% killing in controls).^[26]

Hematopoietic effects

Several complex carbohydrates have been found to significantly stimulate hematopoiesis. CARN 750, a polydispersed beta-(1,4)-linked acetylated mannan isolated from the *Aloe vera* plant, has been shown to have hemato-augmenting properties. Subcutaneous injections of 1 mg/mouse of CARN 750 optimally increased hematopoietic progenitors, measured as interleukin-3-supported colony forming units-culture (CFU-C) and high proliferative potential colony-forming cells (HPP-CFC) assays in the spleen. Providing 2 mg/animal of CARN 750 optimally increased bone marrow cellularity, frequency and absolute number of HPP-CFCs and CFU-Cs. The hematopoietic activity of CARN 750 increased with the frequency of administration. The

greatest increase in activity in mice myelosuppressed with radiation.^[27]

Anti-inflammatory activity

Aloe vera has been shown to exert a number of anti-inflammatory actions, including blocking of the generation of inflammatory mediators like thromboxanes

583

and bradykinin, reducing neutrophil infiltration during inflammation, and reducing edema.^{[2] [4] [5] [14] [28] [29] [30] [31]} There are several compounds in aloe responsible for these actions. The most important are glycoproteins, which inhibit and actually break down bradykinin, a major mediator of pain and inflammation; various anthraquinones; and salicylates. These anti-inflammatory substances may be of significance in both topical (discussed below) and oral applications.

One comprehensive study evaluated the effects of aqueous, chloroform, and ethanol extracts of *Aloe vera* gel on carrageenan-induced edema in the rat paw, and neutrophil migration into the peritoneal cavity stimulated by carrageenan. Also evaluated was the capacity of the aqueous extract to inhibit cyclooxygenase activity. The aqueous and chloroform extracts decreased the edema induced in the hind paw and the number of neutrophils migrating into the peritoneal cavity, whereas the ethanol extract only decreased the number of neutrophils. The aqueous extract was also found to inhibit prostaglandin E₂ production from arachidonic acid, demonstrating an inhibitory action on cyclooxygenase. The aqueous extract contained anthraglycosides, reductor sugars and cardiotonic glycosides, while the ethanol extract contained saponins, carbohydrates, naftoquinones, sterols, triterpenoids and anthraquinones, and the chloroform extract contained sterols and anthraquinones.^[32]

Another useful aspect of aloe is its ability to inhibit lipid peroxidation and scavenge free radicals. One study measured the activity of seven anthraquinones and four anthrones against non-enzymatic and enzymatic lipid peroxidation in vitro and their ability to scavenge free radicals. Using rat hepatocytes exposed to strong oxidizing agents, dithranol and anthrone provided the strongest inhibition of non-enzymatic peroxidation. Rhein anthrone and aloe-emodin showed the highest inhibitory activity against peroxidation of linoleic acid catalyzed by lipoxygenase. Anthrone, dithranol and rhein anthrone were the most effective free radical scavengers.^[33]

Other effects

Wound healing

The topical effects of *Aloe vera* appear to be due to a combination of enhancement of wound healing along with anti-inflammatory, moisturizing, emollient, and antimicrobial actions.^{[2] [4] [5] [14] [34] [35] [35A] [36] [37] [38] [39]} *Aloe vera* contains a number of compounds

necessary for wound healing, including vitamin C, vitamin E and zinc. Unlike many other anti-inflammatory substances, *Aloe vera* has been shown to stimulate fibroblast and connective tissue formation, thereby promoting wound repair. Finally, aloe appears to stimulate the epidermal growth and repair process, presumably due to its polysaccharides. Mannose-6-phosphate, the major sugar in the *Aloe vera* gel, may its most active growth substance.^[40]

Another interesting effect of aloe in wound healing is its ability to counteract the wound healing suppression effects of cortisone. In one study, *Aloe vera* at doses of 100 and 300 mg/kg daily for 4 days blocked the wound healing suppression of hydrocortisone acetate up to 100% using the wound tensile strength assay. The authors suggested this response was because of the growth factors present in *A. vera* masking the wound healing inhibitors.^[41]

Alcohol detoxification

Oral administration of aloin (300 mg/kg) given 12 hours prior to the administration of alcohol (3.0 g/kg) significantly decreases the blood alcohol area under the curve by a remarkable 40%. This suggests an increase in the rate of blood alcohol elimination from the body of 45–50%. Analysis of hepatic triglyceride (TG) levels revealed that both ethanol and the aloin given alone significantly increased the TG levels in a comparable manner. However, the level obtained by the combined treatment of aloin and ethanol was not statistically different from that produced by either treatment alone. The levels of serum L-aspartate:2-oxoglutarate aminotransferase (AST) and L-alanine:2-oxoglutarate aminotransferase (ALT) activities were not increased by acute alcohol intoxication, aloin alone, or the combined treatment of alcohol and aloin.^[42]

CLINICAL APPLICATIONS

Burns, frost bite, and other tissue damage

Despite growing consumer awareness of *Aloe vera*'s soothing effects on burns and wound healing during the past 40 years, few human studies have been carried out. Most of the studies on *Aloe vera* have utilized different animals in various models of inflammation and wound healing. Virtually all of the studies support the topical use of *Aloe vera* gel, especially in minor burns or skin inflammation. Some recent research is now supporting its use even for more severe tissue damage.

While limited, the human research has been promising. For example, one study found *Aloe vera* gel quite successful in three patients with chronic leg ulcers of 5, 7, and 15 years' duration.^[43] The gel was applied to the ulcers on gauze bandages. Rapid reduction in ulcer size was noted in all three subjects and complete resolution occurred in two. Encouraging results were also reported for acne and seborrhea.

In a study of 27 patients with a partial-thickness burn wound, treatment with *Aloe vera* gel was compared with vaseline gauze. The average time of healing in the

aloe gel area was a statistically significant and dramatic 1 week shorter: 11.9 days compared with 18.2 days for the vaseline gauze treated wound. Histological evaluation showed early epithelialization in the *Aloe vera* gel treated area.^[44]

Another study compared the therapeutic effects of systemic pentoxifylline with topical *Aloe vera* cream in the treatment of frostbite. The frostbitten ears of 10 New Zealand white rabbits were assigned to one of four treatment groups: untreated controls, those treated with *Aloe vera* cream, those treated with pentoxifylline, and those treated with *Aloe vera* cream and pentoxifylline. The control group had a 6% tissue survival. Tissue survival was notably improved with pentoxifylline (20%), better with *Aloe vera* cream (24%), and the best with the combination therapy (30%).^[45]

Aloe appears to be effective even in particularly severe tissue injuries, such as those seen in necrotizing fasciitis. Necrotizing fasciitis usually manifests as a low grade cellulitis that quickly deteriorates to a limb and life-threatening soft tissue infection. Immediate surgical debridement is essential followed by aggressive wound management. An interesting report describes excellent results in two cases. Case #1 was a 72-year-old female who, upon presenting to the ER with a “sore bottom”, was diagnosed with five problems:

- anal-rectal abscess
- Fournier’s gangrene
- ulcerative enterocolitis
- chronic blood loss/anemia
- protein caloric malnutrition.

After debridement, her anal-rectal wound extended from the labia to the left buttock. Care was multidisciplinary and included applying a water-based aloe gel and saline-soaked gauze twice a day. After 45 days, the wound exhibited a pink base with granulation tissue and contraction of the wound edges.

Case #2 was a 48-year-old male with seroma of the left leg secondary to a crush injury. Within 3 days he developed deep vein thrombosis in that leg as well as two large seroma cavities on either side of the thigh. Care included packing with aloe gel and saline soaked sponges. Two weeks after admission, the anterior wound was covered with a split thickness skin graft, while partial closure of the lateral cavity was attempted unsuccessfully with retention sutures. After 5 weeks, healing was complete for the anterior wound and 95% complete for the posterior wound.^[46]

Radiation burns

Research into the topical applications of *Aloe vera* gel began in the 1930s in the treatment of radiation burns. During the 1930s, X-rays were used therapeutically for cancer, eczema and other skin complaints, and as a depilatory agent. In 1935, Collins &

Collins^[8] reported the success of *Aloe vera* gel in one single case, a woman with a patch of severe X-ray dermatitis on her forehead. The woman had tried various medical treatments for 8 months, only to have her condition worsen. The Collins were going to perform a skin graft, but as a temporary measure applied a preparation of fresh whole *Aloe vera* leaves to reduce the itching. The result was that “Twenty-four hours later she reported that the sensation of itching and burning had entirely subsided”, and by 5 weeks “there was complete regeneration of the skin of the forehead and scalp, new hair growth, complete restoration of sensation, and absence of scar”. Five months after treatment was started there was complete healing. Other case reports followed which, although not as positive as this initial study, clearly indicated that *Aloe vera* was effective in some cases.

Up until the 1940s most of the studies on aloe were reported case histories.^[4] In order to substantiate these case studies, animal studies began to appear in the literature. Rowe and colleagues performed several studies in rats with radiation-induced ulcers and determined that fresh aloe pulp was effective while dried aloe powder was not effective.^{[4] [37] [38]}

In 1953, Lushbaugh & Hale,^[39] working for the US Atomic Energy Commission, produced one of the most convincing studies of the efficacy of *Aloe vera* gel. Twenty albino rats were exposed to beta-radiation and different treatments were used on quadrants of the affected area of each animal. The treatments used were fresh *Aloe vera* leaf, a commercial *Aloe vera* ointment, application of a dry gauze bandage, and an untreated control. Both fresh *Aloe vera* and the *Aloe vera* ointment produced clear improvements. At the end of 2 months the *Aloe vera*-treated areas were completely healed while the other two areas had still not healed at the end of 4 months.

However, a recent, large, placebo-controlled, double-blind study has cast doubt on the efficacy of aloe for severe radiation burns. Two phase III randomized trials were reported in this study. The first one was double-blind, utilized a placebo gel, and involved 194 women receiving breast or chest wall irradiation. The second trial randomized 108 such patients to *Aloe vera* gel vs. no treatment. Skin dermatitis was scored weekly during both trials both by patients and by health care providers. Skin dermatitis scores were virtually identical on both treatment arms during both of the trials.^[47]

This surprising result might be explained by a another recent study which compared the efficacy of commercially available gels with an acemannan-rich extract from aloe leaves in the treatment of irradiated mice. Male C3H mice received graded single doses of gamma radiation ranging from 30 to 47.5 Gy to the right leg. In most experiments, the gel was applied daily, beginning

immediately after irradiation. To determine the timing of application for best effect, gel was applied beginning on days -7, 0, or +7 relative to the day of irradiation (day 0) and

continuing for 1, 2, 3, 4, or 5 weeks. The right inner thigh of each mouse was scored on a scale of 0 to 3.5 for severity of radiation reaction from the seventh to the 35th day after irradiation. Dose–response curves were obtained by plotting the percentage of mice that reached or exceeded a given peak skin reaction as a function of dose. The researchers found that while the acemannan-rich extract gel was highly effective, the commercially available gel showed no improvement over the control. They also found that the aloe gel had to be applied immediately after irradiation and continued for at least 2 weeks. There was no effect if the aloe gel was applied only before irradiation or beginning 1 week after irradiation. Clearly, the quality and concentration of aloe constituents are crucial if clinical results are to be obtained.^[48]

Psoriasis

A recent double-blind, placebo-controlled study evaluated the clinical efficacy and tolerability of topical *Aloe vera* extract 0.5% in a hydrophilic cream and obtained very impressive results. Sixty patients (36 male/24 female) aged 18–50 years (mean 25.6) with slight to moderate chronic plaque-type psoriasis and PASI (psoriasis area and severity index) scores between 4.8 and 16.7 (mean 9.3) were enrolled and randomized to two groups. The mean duration of the disease prior to enrollment was 8.5 years (range 1–21). Patients self-administered trial medication topically at home three times daily for 5 consecutive days/week (maximum 4 weeks active treatment). Patients were examined on a weekly basis and those showing a progressive reduction of lesions, desquamation followed by decreased erythema, infiltration and lowered PASI score were considered healed. The study was scheduled for 16 weeks with 12 months of follow-up on a monthly basis. The treatment was well tolerated by all the patients, with no adverse drug-related symptoms and no drop-outs. By the end of the study, the *Aloe vera* extract cream had cured 25/30 patients (83.3%) compared with the placebo cure rate of only 2/30 (6.6%), resulting in significant clearing of the psoriatic plaques (328/396 (82.8%) vs. placebo 28/366 (7.7%)), and a decreased PASI score to a mean of 2.2.^[49]

Gastric ulcers

The use of *Aloe vera* gel internally to treat peptic ulcers was studied in 1963.^[50] Twelve patients with X-ray-confirmed duodenal ulcers were given 1 tablespoon of an emulsion of *Aloe vera* gel in mineral oil once daily. At the end of 1 year, all patients demonstrated complete recovery and no recurrence. Based on experimental evidence, the following factors were thought to be responsible for the effectiveness:

- *Aloe vera* gel inactivates pepsin in a reversible fashion. When the stomach is devoid of food, pepsin is inhibited by *Aloe vera* gel; however, in the presence of food, pepsin is released and allowed to digest the food.
- The gel inhibits the release of hydrochloric acid via interference with histamine binding to the parietal cells.
- *Aloe vera* gel is an extremely good demulcent which heals and prevents aggravating irritants from reaching the sensitive ulcer.

AIDS

Although acemannan has demonstrated some direct antiviral activity against HIV-1 by inhibiting glycosylation of viral glycoproteins, its main promise in treating AIDS and HIV may be to enhance the action of azidothymidine (AZT), the antiviral drug used in AIDS. In vitro studies have shown that acemannan combined with suboptimal non-cytotoxic concentrations of AZT or acyclovir acts synergistically to inhibit the replication of HIV and herpes simplex type 1 (HSV-1).^[21] Based on these studies, as well as preliminary human studies, researchers believe that the use of acemannan may reduce the amount of AZT required by as much as 90%.^[51] This is quite significant. In addition to AZT being extremely expensive, AZT's use is often associated with severe side-effects, including anemia and granulocytopenia due to bone marrow suppression.

Preliminary clinical studies are suggesting that acemannan and *Aloe vera* may be beneficial when administered orally in HIV-positive individuals.^[52] ^[53] In one study, 14 HIV patients prescribed oral acemannan (800 mg/day) demonstrated significant increases in circulating monocytes/macrophages. In particular, there were significant increases in the number of large circulating monocytes, indicating improvement in phagocytizing, processing, and presenting cells in the blood.^[53] In another study of 15 AIDS patients receiving an oral dose of acemannan (800 mg/day), the average scores of Modified Walter Reed Clinical (MWR) scoring, absolute T-4, absolute T-8, and p24 core antigen levels all improved in those surviving (see [Table 64.3](#)) at the end of 900 days. Two patients died of AIDS, and another committed suicide. From this study, as well as others, it

TABLE 64-3 -- Acemannan in the treatment of AIDS^[52]

| Test | Pretreatment | After 900 days |
|-------------------------------------|---------------------|---------------------|
| Modified Walter Reed Clinical (MWR) | 65 | 2.0 |
| Absolute T-4 | 322/mm ³ | 324/mm ³ |
| Absolute T-8 | 469/mm ³ | 660/mm ³ |
| p24 core antigen | 5 of 15 | 4 of 12 |

has been suggested that prognostic criteria to determine the most responsive patients are those with an absolute T-4 count greater than 150/mm³ and p24 levels less than 300.^[52]

In another study, *Aloe vera* juice (0.6 L/day) was used in conjunction with essential fatty acids and a multiple vitamin, mineral and amino acid supplement to treat 30 patients. The 15 AIDS, 12 ARC and two HIV-seropositive patients continued with regular medication, including AZT. After 180 days, all patients showed clinical improvement

according to modified Karnofsky Quality Of Life Assessment scores and the Modified Walter Reed Clinical Evaluation; 25% of those positive for the p24 core antigen converted to non-reactive; anemia induced by AZT showed improvement in all patients; and the patients gained an average of 7%.

Unfortunately, a more recent study does not reproduce these early promising results. A comprehensive study assessed the safety and efficacy of acemannan as an adjunctive to antiretroviral therapy among 63 male patients (mean age, 39 years) with advanced HIV disease receiving zidovudine (ZDV) or didanosine (ddl).^[54] The randomized, double-blind, placebo-controlled trial provided a large dose of acemannan (400 mg orally four times daily). Eligible patients had CD4 counts of 50–300/ μ l twice within 1 month of study entry and had received 26 months of antiretroviral treatment (ZDV or ddl) at a stable dose for the month before entry. CD4 counts were made every 4 weeks for 48 weeks. p24 antigen was measured at entry and every 12 weeks thereafter. Sequential quantitative lymphocyte cultures for HIV and ZDV pharmacokinetics were performed in a subset of patients.

The mean baseline CD4 counts were 165 and 147/ μ l in the placebo and acemannan groups, respectively; 90% of the patients were receiving ZDV at entry. Six patients in the acemannan group and five in the placebo group developed AIDS-defining illnesses. There was no statistically significant difference between the groups at 48 weeks with regard to the absolute change or rate of decline at CD4 count. Among ZDV-treated patients, the median rates of CD4 change (ACD4) in the initial 16 weeks were -121 and -120 cells/year in the placebo and acemannan groups, respectively; ACD4 decline from week 16 to 48 was 0 and -61 cells/year in the acemannan and placebo groups ($P = 0.11$), respectively. There was no statistical difference between groups with regard to adverse events, p24 antigen, quantitative virology, or pharmacokinetics. Twenty-four patients, 11 receiving placebo and 13 receiving acemannan, discontinued study therapy prematurely, none due to serious adverse reactions. The decreased, but not statistically significant, rate of loss of CD4 cells in the acemannan group from weeks 16 to 48, provides a possible ray of hope that long-term use, such as reported above, may be of value and should be investigated.

Asthma

Oral administration of an extract of *Aloe vera* for 6 months was shown to produce good results in the treatment of asthma in some individuals of various ages.^[55] The exception to this was the fact that the *Aloe vera* extract was not effective at all in patients dependent upon corticosteroids. The mechanism of action is thought to be via restoration of protective mechanisms followed by augmentation of the immune system.

The extract used in the study was produced from the supernatant of fresh leaves stored in the dark for 7 days at 4°C. The dosage was 5 ml of a 20% solution of the aloe extract in saline twice daily for 24 weeks. Eleven of 27 patients (40%) without corticosteroid dependence reported significant improvement at the study's conclusion.

Studies indicate that subjecting the leaves to dark and cold results in an increase in the polysaccharide fraction. One gram of the crude extract obtained from leaves stored in

the cold and dark produced 400 mg of neutral polysaccharide, as compared with only 30 mg produced from leaves not subjected to cold or dark.

Diabetes

Aloe vera also exhibits a hypoglycemic effect in both normal and alloxan-induced diabetic mice.^[56] A small human study shows benefit in diabetics. Five patients with non-insulin dependent diabetes ingested half a teaspoonful of aloe 4 times daily for 14 weeks. Fasting blood sugar in every patient fell from a mean of 273 to 151 mg/dl with no change in body weight. The authors concluded that aloe lowers blood glucose levels by an unknown mechanism.^[57] A more recent and larger study (49 men and 23 women) now provides more support for the efficacy of aloe in combination with glibenclamide in diabetes. While there was no response to glibenclamide alone, the combination was very effective.^[58] The patients were provided with 1 tablespoon of aloe gel and 5 mg of glibenclamide twice a day, with 5 mg twice a day of glibenclamide serving as the control. After 2 weeks, fasting blood sugar decreased significantly in the treated group, and by day 42 had decreased from an average of 289 mg% to a remarkable 148 mg%. While the drop in serum cholesterol was not significant, serum triglycerides decreased from 223 mg% to (again remarkable) 128 mg% by day 42. No adverse effects were noted using standard blood chemistries.

Contraception

An interesting new application of aloe is as a spermicide. Twenty samples of fresh ejaculate from healthy human volunteers between 20 and 30 years of age were treated in vitro with a 1% concentration of zinc acetate combined

with lyophilized *Aloe barbadensis* (at concentrations of 7.5–10%). The combination of zinc acetate with lyophilized *Aloe barbadensis* was shown to possess powerful spermicidal and antiviral effects which were thought to be due to their concentration of minerals (boron, barium, calcium, chromium, copper, iron, potassium, magnesium, manganese, phosphorus, and zinc), which were toxic to the sperm tail, causing instant immobilization. Studies with rabbit vaginal epithelium showed no irritation. This is important because nonoxynol-9, the active spermicidal ingredient used in vaginal contraception for over 30 years, appears to cause cell membrane damage in vaginal and cervical epithelium and may possibly have teratogenic effects.^[59]

Cancer prevention

The antigenotoxic and chemopreventive effect of *Aloe barbadensis* on benzo[a]pyrene (B[a]P)–DNA adducts was investigated in vitro and in vivo in an animal model. Aloe showed a time-course and dose-dependent inhibition of [3H]B[a]P–DNA adduct formation in primary rat hepatocytes, inhibited cellular uptake of [3H]B[a]P in a dose-dependent manner, and significantly inhibited adduct formation in various organs

(liver, kidney, forestomach and lung). When mice were pretreated with aloe for 16 days before B[a]P treatment, inhibition of BPDE-I–DNA adduct formation and persistence was enhanced. Phase II glutathione-S-transferase activity was slightly increased in the liver, but phase I cytochrome P450 activity was not affected.^[60]

This translates into animal cancer studies as protection from Norman murine sarcoma in mice^[61] and efficacy in treatment of spontaneous neoplasms in dogs and cats.^[62]

TOXICOLOGY

Although rare, hypersensitivity reactions manifesting as generalized nummular eczematous and papular dermatitis as a result of topically applied *Aloe vera* preparations have been reported. It should be noted that *Aloe vera* gel has been shown to delay wound healing in cases of surgical wounds such as those produced during laparotomy or cesarean delivery.^[63] Topical aloe preparations are not therefore useful for treating deep vertical wounds.

DOSAGE

Aloe vera gel can be applied liberally for topical applications. A wide range of products are available on the market; however, simple pure *Aloe vera* gel is sufficient.

Aloe vera juice can be consumed orally as a beverage or tonic. As detailed information is currently lacking as to the optimal dose for these types of products, it is recommended that no more than 1 quart be consumed in any one day.

The dose of acemannan being used in HIV/AIDS patients is 800–1,600 mg/day. This would correspond to a dose of approximately 0.5–1 L/day for most *Aloe vera* juice products. However, it appears that there may be great variation in the amount of acemannan in various products.

Chapter 65 - *Angelica* species

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

Angelica sinensis or *polymorpha* (family: Umbelliferae or Apiaceae)
Common names: Chinese angelica, tang-kuei (dong-quai)

Angelica acutiloba (family: Umbelliferae or Apiaceae)
Common name: Japanese angelica

Angelica archangelica (family: Umbelliferae or Apiaceae)
Common name: European angelica

Angelica atropurpurea (family: Umbelliferae or Apiaceae)
Common name: American angelica

Angelica sylvestris (family: Umbelliferae or Apiaceae)
Common name: wild angelica

GENERAL DESCRIPTION

Angelica spp. are biennial or perennial plants with hollow fluted stems that rise to a height of 3–7 feet. The umbel of greenish-white flowers bloom from May to August. The plants are found in damp mountain ravines and meadows, on river banks, and in coastal areas; angelica is also a widely cultivated species. In Asia, it is grown primarily for its medicinal action, while in the US and Europe, it is cultivated for use as a flavoring agent in most major categories of food products, including alcoholic (e.g. bitters, liqueurs, and vermouths) and non-alcoholic beverages, ice cream, candy, gelatins, and puddings. With all species, the roots and rhizomes are the most extensively used portions of the plant.

Angelica sinensis **and** *A. acutiloba*

In Asia, the authentic and original medicinal angelica is *Angelica sinensis* (dong-quai), native to China. While at least nine other angelica species are used in China, dong-quai is by far the most highly regarded. For several thousand years, dong-quai has been cultivated for medicinal use in the treatment of a wide variety of disorders, in particular, “female” disorders. Several hundred years ago, when the supply of Chinese angelica was scarce, the

590

Japanese began to cultivate *A. acutiloba*, an angelica species indigenous to Japan, as a substitute.^[1] The two species appear to have very similar therapeutic effects, although it is interesting to note that in China, the Japanese angelica is thought to have no therapeutic value, while in Japan, Chinese angelica is thought of as being without effect. Experimentally, both species exhibit very similar therapeutic effects, so each country’s claim to produce a superior dong-quai appears to be based more on emotion than scientific investigation.

Angelica archangelica **and** *A. atropurpurea*

Historical usage suggests that European angelica (*A. archangelica*) and American angelica (*A. atropurpurea*) have properties different from the Asian species. This difference has not, however, been evaluated by chemical analysis.

CHEMICAL COMPOSITION

Angelica sinensis **and** *A. acutiloba*

No comprehensive data could be found listing the concentration of the chemical constituents. It is assumed that Chinese and Japanese angelica are similarly composed of various coumarins and flavonoids which are responsible for their medicinal actions. The essential oil of oriental angelica contains:^[2]

- *n*-butylphthalide
- cadinene
- carvacrol
- *n*-dodecanal
- isosafrole
- linoleic acid
- palmitic acid
- safrole
- sesquiterpene
- *n*-tetradecanol.

Angelica archangelica

Also very rich in coumarins, this species of angelica is particularly phototoxic. Coumarins, including osthole, angelicin, osthenol, umbelliferone, archangelicine, bergapten, and ostruthol, are found in significant concentrations, with osthole composing nearly 0.2% of the root. The root is also a good source of flavonoids, including archangelenone and caffeic acids. The root contains 0.3–1.0% volatile oil that is composed mainly of beta-phyllandrene, alpha-pinene, borneol, limonene, and four macrocyclic lactones.^[2] ^[3]

HISTORY AND FOLK USE

Angelica sinensis and *A. acutiloba*

In Asia, angelica's reputation is perhaps second only to ginseng. Predominantly regarded as a "female" remedy, angelica has been used in such conditions as dysmenorrhea, amenorrhea, metrorrhagia, menopausal symptoms, and to assure a healthy pregnancy and easy delivery. Angelica is also used in the treatment of abdominal pain, anemia, injuries, arthritis, migraine headache, and many other conditions.^[2] ^[4]

Angelica archangelica

One of the most highly praised herbs in old herbal texts, archangelica was used by all north European countries as:

... a protection against contagion, for purifying the blood, and for curing every conceivable malady: it was held a sovereign remedy for poisons, agues and all infectious maladies.

According to one legend, archangelica was revealed in a dream as a cure for the plague. One explanation for the name is related to its blooming near May 8, the feast day of Michael the Archangel. It was therefore seen as a "protector against evil spirits and witchcraft".^[5]

Archangelica has been used for a wide variety of conditions, including flatulent dyspepsia, pleurisy, respiratory catarrh, and bronchitis. The plant was believed to possess carminative, spasmolytic, diaphoretic, expectorant, and diuretic activity.^[5]

Angelica atropurpurea

American angelica's therapeutic use mirrors that of European angelica. Its most common use is for heartburn and flatulent colic.^[6]

PHARMACOLOGY

The pharmacology of *Angelica* spp. relates to their high coumarin content. However, unlike other scientific investigations of botanical medicines, much of the research done on *Angelica* spp. has been done on plant extracts, rather than isolated constituents. The overwhelming majority of the studies have been done on the Asian species. Some of the pharmacological activities demonstrated include:

- phytoestrogen activity
- analgesic activity
- cardiovascular effects
- smooth muscle-relaxing effects
- anti-allergy and immunomodulating activity
- antimicrobial activity.

Phytoestrogen effects

Plant estrogenic substances or phytoestrogens are components of many medicinal herbs with an historic use

591

in conditions which are now treated by synthetic estrogens. Chinese and Japanese angelica contain highly active phytoestrogens, although these compounds are much lower in activity than animal estrogens (1:400 as active). This helps to explain why angelica was used in both excessive and deficient estrogen conditions. Phytoestrogens demonstrate an alterative effect by competing with estrogen for binding sites. When estrogen levels are low they are able to exert some estrogenic activity; when estrogen levels are high they reduce overall estrogenic activity by occupying estrogen receptor sites. This alterative action of angelica's phytoestrogens is probably the basis of much of the plant's use in amenorrhea and menopause.

Japanese angelica has demonstrated uterine tonic activity, causing an initial increase in uterine contraction followed by relaxation.^{[7] [8]} In addition, administration of Japanese angelica to mice resulted in an increase of uterine weight, increase of the DNA content of the uterus and liver, and increase of glucose utilization by the liver and uterus.^{[1] [7]} Because of these and other effects, angelica has been referred to as a uterine tonic.

Cardiovascular effects

Although not used historically for these purposes, angelica does possess significant hypotensive action.^{[1] [7]} This is largely due to its vasodilator activity. Dihydropyranocoumarins and dihydro-furanocoumarins from Umbelliferous plants have been shown to possess significant coronary vasodilatory, spasmolytic, and

cyclic-AMP-phosphodiesterase inhibitory properties.^[9] The mechanism of action appears to be largely a result of calcium channel antagonism. Agents that interact with calcium channels (calcium channel blockers) are quickly coming into prominence in the treatment of a wide variety of conditions, including hypertension and angina. Umbelliferous plants such as angelica may offer similar effects.

Other cardiovascular effects noted for angelica are negative inotropic and anti-arrhythmic action.^[1]

Smooth muscle-relaxing activity

Calcium channel blocking compounds are also capable of relaxing the smooth muscles of visceral organs. Angelica (essential oil) has demonstrated relaxing action on the smooth muscles of the intestines and uterus, while the water extract produces an initial contraction and then prolonged relaxation.^{[1] [7] [8]} This confirms its historical use in the treatment of intestinal spasm and uterine cramps. Its action on other smooth muscles could explain its hypotensive action (vascular smooth muscle) and historical use in asthma (bronchial smooth muscle).

Analgesic activity

Both Chinese and Japanese angelica have demonstrated pain-relieving and mild tranquilizing effects in experimental studies in animals.^{[1] [7] [10] [11]} Angelica's analgesic action was 1.7 times that of aspirin in one study.^[11] Its analgesic activity, combined with its smooth muscle-relaxing activity, supports its historical use in such conditions as uterine cramps, trauma, headaches, and arthritis.

Anti-allergy and immunomodulating activity

Angelica has a long history of use by Chinese and Japanese herbalists in the prevention and treatment of allergic symptoms in individuals who are sensitive to a variety of substances (pollen, dust, animal dander, food, etc.).^{[1] [12]} Its action is related to its ability to inhibit the production of IgE in a selective manner. Since IgE levels in patients with atopic conditions are typically 3–10 times greater than the upper limit of normal, angelica may offer some benefit by reducing these elevated antibodies.

Coumarin compounds have demonstrated immune-enhancing activity in both healthy and cancer patients.^{[13] [14]} Coumarins have been shown to stimulate macrophages and increase phagocytosis.^[13] Such activity is thought to offer significant protection against metastasis and growth of tumor cells. Upon coumarin administration, macrophages are said to be "activated" and thus capable of entering the tumor, where a specific destruction of the tumor cells may occur.^{[13] [14]}

Coumarin compounds of angelica and the polysaccharides of the water extract of Japanese angelica have immune-modulating activity. They have been shown to possess mitogenic activity to B-lymphocytes, interferon-producing activity, antitumor activity, and complement-activating (both the classical and alternative pathway)

activity.^{[15] [16] [17] [18]} Chinese angelica has been shown to increase murine IL-2 production, stimulate the reticuloendothelial system, and increase tumor necrosis factor production.^{[19] [20]} These effects on the immune system by coumarins, polysaccharides, and extracts of *Angelica* sp. would seem to support their historical anti-cancer effects and their use as adjuncts to current cancer therapy.

Antibacterial activity

Extracts of Chinese angelica have been shown to possess antibacterial activity against both Gram-negative and Gram-positive bacteria, while extracts of Japanese angelica exhibited no antibacterial action.^[7] The inconsistency could be due to different essential oil concentrations of the extracts used in the studies. The oil of *A. archangelica* has also exhibited significant antifungal and anthelmintic properties but virtually no antibacterial

activity.^{[3] [21] [22]} As other herbs have much greater antimicrobial activity, *Angelica* sp. would be considered a less than optimum agent if this effect is desired.

CLINICAL APPLICATION

Angelica spp. have been used throughout the world in the treatment of a wide variety of conditions. At this time, it appears that *A. archangelica* and *A. atropurpurea* are most indicated as expectorants, antispasmodics, and carminatives in the treatment of such conditions as respiratory ailments, gas, and abdominal spasm. Chinese angelica (*A. sinensis* or *polymorpha*) and Japanese angelica (*A. acutiloba*) appear most useful in the treatment of disorders of menstruation, menopause (especially hot flashes), atopic conditions, smooth muscle spasm (e.g. uterine cramps, migraines, abdominal spasm, etc.), and possibly as an immunostimulatory adjunct in cancer therapy. Further human research is needed to document the degree clinical of efficacy of *Angelica* spp.

DOSAGE

- Dried root or rhizome: 1–2 g orally, or by infusion, three times/day
- Tincture (1:5): 3–5 ml, three times/day
- Fluid extract (1:1): 0.5–2 ml, three times/day.

TOXICOLOGY

Angelica is generally considered to be of very low toxicity. However, it does contain many photoreactive substances which may induce photosensitivity. This should be kept in mind when using any Umbelliferous plant. This activity can be used therapeutically in the treatment of vitiligo and psoriasis.

Chapter 66 - *Aspergillus oryzae* enzyme therapy

Corey Resnick ND

INTRODUCTION

Enzymes derived from *Aspergillus oryzae* and other fungal species are effective in the treatment of a broad range of human diseases. In certain cases, fungal enzymes are significantly more effective than animal-derived enzymes or other available therapies. Some fungal enzyme preparations are particularly well suited for human use because of their ability to hydrolyze physiologically and/or pathologically important substrates over a wide pH range.

Although new to many clinicians in the US, fungal enzymes have been used in ethnic food production for many centuries, and in clinical practice and research for about 50 years. In Japan, *Aspergillus oryzae* has been used in the fermentation of soybeans to produce soy sauce, tamari and miso. (It is interesting to note that the traditional method of adding hot water to miso, rather than boiling the miso, preserves some of the activity of *Aspergillus* enzymes, which are remarkably heat stable.)

Clinically, enzyme preparations have typically been used in oral administration at mealtimes to assist digestion by hydrolyzing dietary substrates such as gluten, casein or lactose. Of possibly greater interest, however, is the use of fungal enzymes administered orally between meals. Based on the theory that some portion of the enzyme is absorbed intact into the bloodstream, enzymes can hydrolyze substrates of therapeutic importance (e.g. fibrin). Indirect evidence in support of this theory is presented later in this chapter.

Beginning around the 1950s, published research in Europe and Scandinavia reported on the therapeutic use of purified, concentrated preparations of enzymes from *A. oryzae* and other fungal species. Bergkvist was among the first to report on the isolation and purification of individual enzymes produced by *A. oryzae*. Wolf and Ransberger studied the effects of enzymes from *Aspergillus* and other species (e.g. *Lens esculenta* and *Pisum sativum*) along with animal enzymes (e.g. trypsin, chymotrypsin) in the treatment

and others studied the effectiveness of intravenously administered proteolytic enzymes from *A. oryzae* in the treatment of vascular disease in humans and animals.

Recent research has studied increasingly diverse types and sources of fungal enzymes, including various protease, lipase, carbohydrase, and cellulase preparations. Controlled in vivo studies using enteral and parenteral routes and in vitro studies have examined the effectiveness of these enzymes in a wide range of conditions including:

- maldigestion
- malabsorption
- pancreatic insufficiency
- steatorrhea
- celiac disease
- lactose intolerance
- arterial obstruction
- thrombotic disease.

Anecdotal reports indicate that plant enzymes are being used in an even broader spectrum of clinical conditions.

This chapter reviews published clinical and experimental research in the emerging field of fungal enzyme therapy. Theoretical discussions are presented regarding the oral administration of fungal enzymes for therapeutic purposes, with suggested areas for further research.

PHARMACOLOGY

Intact protein absorption

Contrary to long held theories that the healthy intestinal mucosa is an essentially impermeable barrier to proteins and large polypeptides, there is now irrefutable evidence that macromolecules can and do pass intact from the human gut into the bloodstream under normal conditions.^{[1] [2] [3] [4] [5] [6] [7]} This may help to explain the apparent effectiveness of enzyme therapy in the nutritional management of a number of conditions, including vascular disease, maldigestion/malabsorption, food allergies, inflammatory bowel disease, immune dysfunction and certain inflammatory disorders.^{[1] [2] [8] [9] [10] [11] [12] [13] [14] [15] [16] [17]}

Evidence for intestinal absorption of intact proteins

Numerous whole proteins, including plant and animal enzymes, have been shown in

human and animal studies to be absorbed intact into the bloodstream following oral administration. These include human albumin and lactalbumin, bovine albumin, ovalbumin, lactoglobulin, ferritin (MW, 500,000), chymotrypsinogen, elastase, and other large molecules, such as botulism toxin (MW, 1,000,000).^{[1] [2] [3] [18] [19] [20] [21]} Even inert particles, such as carbon particles from India ink^[1] and whole viruses,^[22] can cross the healthy intestine.

Immunoglobulins have been detected in peripheral tissues following oral administration. In a study done in rats, 5% of an oral dose of bovine IgG was found substantially intact in peripheral tissues.^[6] Studies have demonstrated the intact absorption of plant enzymes, such as bromelain derived from pineapple and peroxidase (MW, 40,000) from horseradish. An in vivo study in fish showed that 0.7% of a dose of horseradish peroxidase was detected intact in examined peripheral tissues following oral administration.^[23]

Proteins and polypeptides absorbed intact from the gut can exert pharmacological effects in target tissues. Several peptide hormones are known to be biologically active when administered orally, including luteinizing hormone-releasing factor and thyrotropin-releasing hormone.^{[24] [25]} Even insulin can cross the intestinal mucosa intact and produce significant hypoglycemia under limited circumstances (e.g. in the presence of protease inhibitors or hypertonic solutions in the intestinal lumen).^{[26] [27]}

It now appears probable that enzymes such as acid-stable protease from *Aspergillus oryzae* (molecular weight ~ 35,000) are absorbed intact following oral administration. To the extent that such absorption does occur, *Aspergillus*-derived proteases may exhibit properties in the bloodstream which they are known to possess in other applications. This may include the ability to hydrolyze dietary proteins and polypeptides which have leaked into the bloodstream as food antigens. Protease from *Aspergillus* is also known to possess thrombolytic, fibrinolytic and anti-inflammatory properties,^{[28] [29] [30] [31] [32] [33] [34]} and has been shown to be effective when administered intravenously in re-establishing circulation through chronically obstructed arteries in humans (see below).^{[35] [36]}

Mechanism for intestinal absorption of macromolecules

Two general types of mechanisms have been suggested to account for the intact absorption of macromolecules and particles.^{[1] [2]} In the “transcellular route” macromolecules are believed to penetrate the brush-border membrane of intestinal mucosal cells by:

- diffusion through aqueous “pores” or through lipid regions in the membrane
- pinocytosis (endocytosis) or phagocytosis
- carrier-mediated transport systems
- some combination of these routes.

A “paracellular” or intercellular route also appears likely, in which molecules pass between mucosal cells. This route includes passage through so-called “extrusion zones” which occur as old cells are displaced by new ones in the rapidly proliferating mucosal tissue.

A specialized cell type has recently been identified overlying Peyer's patches (subepithelial lymphoid tissue) throughout the small intestine. These so-called "M" cells permit subepithelial tissue lymphocytes to come extremely close to the intestinal lumen, apparently facilitating lymphocyte "sampling" of luminal antigens and thereby stimulating an immune response.

A number of studies have shown rapid passage through M cells (by pinocytosis) of macromolecules such as horseradish peroxidase and solid particles such as viruses.^{[1] [2] [37] [38] [39]}

Pancreatic recycling of enzymes

There is strong evidence that the body seeks to conserve its digestive enzymes by absorbing intact endogenous and exogenous enzymes. Several human studies have shown that exogenous pancreatic enzymes, trypsin and chymotrypsin, are absorbed intact into the bloodstream in an enzymatically active form following oral administration.^{[40] [41] [42] [43] [44]}

Even more dramatic is the finding that both endogenous and exogenous pancreatic enzymes are not only absorbed intact from the gut, but also transported through the bloodstream, taken up intact by pancreatic secretory cells, and re-secreted into the intestinal lumen by the pancreas, co-mixed with newly synthesized pancreatic enzymes.^[45] The existence of this enteropancreatic circulation of proteolytic enzymes is closely analogous to the recycling of bile salts by the liver.

Of further interest is the possibility that oral supplementation with enzymes may have a sparing effect on the body's own digestive enzymes, perhaps aiding organ regeneration, by hydrolyzing substrates (foods) for which endogenous enzyme would otherwise be required. Support for this hypothesis may also be found in the phenomenon of adaptive secretion by which the pancreas, stomach and possibly other organs secrete specific digestive enzymes in direct response to the type and amount of food substrate present.^{[46] [47]}

COMPARISON OF FUNGAL LIPASE AND PANCREATIN

pH range

Many of the enzymes derived from *A. oryzae* and related fungal species possess unusually high stability and activity under a broad range of pH conditions. These properties distinguish them from animal enzymes such as pepsin, pancreatin, trypsin, chymotrypsin, pancrelipase and pancreatic amylase which require pH conditions often lacking in those with impaired health. For example, pepsin is active only below a pH of about 4.5, while pancreatin has digestive activity only in an alkaline medium. In contrast,

some preparations of *A. oryzae* enzymes are stable and active at pH values of 2–12.

Enzyme replacement therapy

Human and animal studies have compared the effectiveness of acid-stable lipase from various fungal species with that of pancreatin in the treatment of malabsorption and steatorrhea due to pancreatic insufficiency. Administered orally at mealtime, fungal lipase has been found to be effective in these conditions and to offer certain advantages over both conventional and enteric-coated pancreatic enzyme replacement therapy.

Treatment of steatorrhea using pancreatic enzyme replacement therapy is often unsatisfactory due to several factors. Gastric acid destroys up to 90% of the lipase content of exposed pancreatic enzymes (i.e. conventional pancreatin administered in powder, capsule or tablet form).^[48] ^[49] ^[50] This necessitates large dosages for efficacy and contributes to increased expense, number of tablets or capsules required, and poor patient compliance.^[51] ^[52] Furthermore, pancreatin can cause hyperuricosuria and renal damage in large doses due to its high purine content.^[53] Although H₂ receptor antagonists such as cimetidine are often used along with pancreatin to lessen intragastric inactivation,^[54] ^[55] this is unsuccessful at increasing lipid digestion in many patients^[56] and carries the risk of possible adverse side-effects.

Various forms of enteric-coated pancreatin (i.e. enteric-coated capsules, tablets, granules and microspheres) are formulated to dissolve above pH 5.5–6.0 and are intended to protect exogenous pancreatin against gastric acidity.^[54] ^[57] These are seldom completely effective, however, as, while the capsules or tablets usually remain intact in the stomach, they often fail to dissolve in the duodenum due to hyperacidity; most patients with pancreatic insufficiency also have decreased bicarbonate secretion. Similarly, jejunal acidification can occur, preventing activation of enteric-coated enzyme preparations designed to release in the jejunum.^[58] In addition, chemical excipients required for enteric coating can be problematical in sensitive individuals.

By contrast, a lipase preparation from *Aspergillus oryzae* is resistant to inactivation by gastric acidity and is enzymatically active from pH 2 to 10. It digests dietary fat, beginning in the stomach and continuing in the small intestine.^[51] ^[59] It is water-soluble, heat-stable, non-toxic and free from some of the potential drawbacks of pancreatin replacement therapy.^[51]

CLINICAL APPLICATIONS

Malabsorption and steatorrhea

Chronic pancreatitis and cystic fibrosis are the most common causes of pancreatic exocrine insufficiency.

Pancreatogenic steatorrhea results from failure of fat digestion, leading to lipid malabsorption, impaired nutrition, weight loss, and considerable social embarrassment.^[48]^[60] Lipase preparations from *Aspergillus oryzae* have been shown to be highly effective in treating malabsorption and steatorrhea under a wide variety of conditions.

A 1985 cross-over study in Germany compared the effectiveness of 10 teaspoons of a conventional pancreatic enzyme preparation (360,000 lipase units) with that of 10 capsules of enteric-coated pancreatin (100,000 lipase units) and 10 capsules of acid-stable fungal enzymes from *Rhizopus arrhizus* (75,000 lipase units) in human patients with chronic pancreatitis, severe pancreatic exocrine insufficiency and steatorrhea.^[59] Seventeen patients in the study were divided into two treatment groups based on surgical status.

Nine patients had received Whipple's procedure (bowel resection with partial duodenopancreatectomy) 3–8 months prior to the study (group A). This group had shown a pre-operative reduction in stimulated pancreatic enzyme secretion to less than 10% of normal. In the remaining eight, non-surgical patients (group B), stimulated secretion was reduced to between 4 and 28% of normal.

All patients were placed on a diet containing 100 g fat/day and stools were collected for 72 hours, 5 days after discontinuing all medications (pancreatic enzymes, antacids, and H₂ receptor antagonists). Thereafter, each group was placed on identical 2 week periods of treatment using enteric-coated pancreatin first, then conventional pancreatin and, finally, acid-stable fungal enzymes.

Stools were collected for the last 3 days of each treatment period and analyzed for stool weight, fat concentration, and total fecal fat excretion. Prior to treatment, all fecal parameters were pathologically elevated in all 17 patients, diarrhea and characteristic abdominal symptoms were present, and the patients had a tendency to lose weight.

All three treatment protocols led to a significant reduction in total daily stool weight and total daily fecal fat excretion as compared with controls in both groups. Perhaps more importantly, all patients in both groups became virtually symptom-free on each of the three treatment protocols. [Table 66.1](#) shows fecal fat excretion and stool weight for controls and under each treatment protocol in group A and group B. Individual patient results in each group have been averaged together.

A 1988 placebo-controlled, randomized, cross-over study in England compared the effectiveness of 400 mg (4800 lipase units) of acid-stable lipase from *A. oryzae* with that of 10,000 mg (60,000 lipase units) of pancreatin in the treatment of chronic pancreatic exocrine insufficiency in dogs.^[51]

Eleven dogs (weighing 15–21 kg) used in the study

TABLE 66-1 -- Stool weight and fecal fat in patients with steatorrhea

| Treatment protocol | Fecal fat (g/day) | | Stool weight (g/day) | |
|---------------------------|-------------------|---------|----------------------|---------|
| | Group A | Group B | Group A | Group B |
| Placebo | 180 | 82 | 906 | 675 |
| Enteric-coated pancreatin | 75 | 39 | 494 | 324 |
| Pancreatin | 55 | 48 | 437 | 345 |
| Fungal lipase | 87 | 48 | 519 | 316 |

The upper limit of the normal range for fecal fat excretion is 7 g/day and for stool weight is 250 g/day

underwent total pancreatectomy to produce pancreatic exocrine insufficiency. All animals received intrasplenic autografts of islet of Langerhans tissue to preserve pancreatic endocrine function. Animals served as their own controls by the use of pre-surgical data.

The dogs were maintained on fixed diets containing 46 g/day fat. Each treatment protocol lasted 3 weeks, beginning and ending with weighing of animals and 3 day specimen collections for determination of fecal fat excretion and stool volume.

Dogs in the untreated placebo group experienced significant weight loss ($P < 0.01$) due to malabsorption averaging 0.9 kg over a 3 week period. Dogs receiving either 400 mg/day of *A. oryzae* lipase or 10,000 mg/day of pancreatin did not show significant weight loss.

Similarly, both fecal fat excretion and stool volume were pathologically elevated in the placebo group. Significant reductions occurred in both fecal fat and stool volume, with no significant difference between fungal lipase and pancreatin treated animals.

The most significant finding of the English study was the fact that a small dose of acid-stable lipase from *A. oryzae* (400 mg) was as effective as a dosage of conventional pancreatin 25 times larger (10,000 mg) in the treatment of malabsorption, malnutrition and steatorrhea due to pancreatic exocrine insufficiency in dogs. In the German study, an acid-stable fungal lipase from *R. arrhizus* produced largely the same effect as 1.3 times greater lipase activity from enteric-coated pancreatin and 4.8 times greater lipase activity from conventional pancreatin in the treatment of severe pancreatogenic steatorrhea in humans.^[59]

Unlike pancreatin, *A. oryzae* lipase delivers enzyme activity in the broad range from pH 2 to 10. It safely digests dietary fat, beginning in the stomach and continuing in the small intestine, and is more effective than pancreatin in the abnormal acidic conditions

commonly found in the duodenum and jejunum of pancreatic insufficiency patients.

Lactose intolerance

Lactose intolerance produces symptoms such as abdominal pain, bloating, cramping, flatulence, belching and

597

diarrhea.^[61] Maldigestion of lactose is a common problem in children and adults, occurring in 76% of apparently healthy children in one study, and 56% in another single-blind, controlled trial.^[62] Lactose maldigestion can result from genetic non-persistence of intestinal lactase activity at some time after weaning as well as from secondary lactase deficiencies. It may or may not produce symptoms of lactose intolerance.^[61]

A lactase enzyme derived from *Aspergillus oryzae* is effective in the treatment of lactose maldigestion and lactose intolerance when taken orally at the time of milk ingestion.^[62]^[63]^[64]^[65]^[66]^[67] Moreover, this enzyme aids in the in vivo digestion of milk sugar even in healthy individuals classified as normal lactose digesters. Furthermore, the *A. oryzae*-derived lactase is more effective in the digestion of lactose than a similar enzyme derived from the yeast, *Kluyveromyces lactis*.^[62]

It is known that milk pre-hydrolyzed in vitro by incubating it under refrigeration with lactase is effective in the prevention of lactose intolerance in susceptible individuals. A 1986 single-blind, controlled study was designed to determine whether ingestion of lactase at mealtime was equally as effective in the treatment of lactose intolerance as pre-hydrolyzed milk, since the latter requires refrigeration which is difficult to obtain in “underdeveloped” parts of the world. The hydrogen breath test was used as an accurate and sensitive measurement of lactose digestion in vivo (see [Ch. 23](#)).

The study included 48 healthy Guatemalan pre-school children. The ability of participants to digest lactose from ingested whole cow's milk was tested against four treatment protocols as follows (each protocol included 240 ml of whole cow's milk containing 12 g. of lactose):

1. whole, intact cow's milk
2. milk pre-hydrolyzed in vitro with lactase enzyme
3. varying amounts of lactase from *K. lactis* administered orally with milk
4. varying amounts of lactase from *A. oryzae* administered orally with milk.

Twenty-seven of the children (56%) proved to be maldigesters of lactose from the ingestion of intact milk. Twenty-five of these lactose maldigesters (93%) were found to show no lactose maldigestion (i.e. successfully treated) after the ingestion of milk pre-hydrolyzed with lactase in vitro for 24 hours. Pre-hydrolyzed milk was used as the standard for successful treatment in comparing the effectiveness of lactase enzymes

derived from *A. oryzae* and *K. lactis*.^[62]

All experimental dosages of in vivo lactase from both *A. oryzae* and *K. lactis* significantly reduced the volume of post-challenge hydrogen excretion as compared with intact milk ($P < 0.05$). However, lactase from *A. oryzae* was found to be equally as effective as pre-hydrolyzed milk, while *K. lactis* lactase was only 82% as effective.

This research supports the addition of microbial beta-galactosidase (lactase) to milk at mealtimes as effective in the prevention of signs and symptoms of lactose maldigestion. Ingestion of lactase with milk at mealtime avoids the inconvenience of refrigerated 24 hour incubation as well as the sweeter flavor produced when milk is pre-hydrolyzed.

In a somewhat surprising result, *A. oryzae* lactase was also found to increase the degree of lactose digestion in the 21 children classified as normal, complete digesters. This demonstrates that the capacity for lactose digestion is actually a continuum, even in lactase-persistent subjects, rather than an all-or-none phenomenon.

The efficacy of these enzymes in lactose-intolerant children and adults has now been replicated in several studies.^{[61] [68]}

Vascular disease

Numerous cross-over, single-blind and placebo-controlled studies have confirmed the effectiveness of a proteolytic enzyme derived from *Aspergillus oryzae* in treating chronically obstructed arteries in humans.^{[28] [29] [30] [31] [32] [35] [36] [69] [70] [71] [72] [73]}

In fact, intravenous therapy with fungal protease from *A. oryzae* is dramatically more effective than anticoagulant therapy (e.g. heparin, warfarin) at recanalizing obstructed arteries and improving blood flow through stenosed arterial segments.^{[35] [36] [73]}

A 1978 controlled, single-blind cross-over study evaluated the effectiveness of protease from *A. oryzae* versus anticoagulant therapy and placebo in 18 patients (ages 63–75) with stable intermittent claudication of at least 6 months' duration.^[35] Patients were divided into two groups, and a full assessment of each patient was carried out prior to testing. Translumbal aortogram, Doppler ultrasound scanning and peripheral systolic blood pressure were used to assess the patency of eight different arterial segments in each patient (a total of 72 segments in each group). Anticoagulation therapy with warfarin was introduced following assessment and continued throughout an observation period of 3 months and subsequent trial periods. Assessment of peripheral circulation was repeated after the 3 month observation period on anticoagulant therapy. Thereafter, a series of six intravenous infusions of fungal protease and normal saline was given to experimental and control groups, respectively, at regular intervals over the next 2 weeks. Assessment of peripheral circulation was repeated at the end of the protease infusion treatment. No other form of therapy was given, except warfarin for anticoagulation. On admission to the study, the first group of patients receiving fungal protease therapy showed 27 obstructed segments (completely obstructed), 34 stenosed segments (partially obstructed) and only 11 patent arterial segments. The nine patients

receiving

TABLE 66-2 -- Changes in patency of 72 arterial segments after placebo or fungal enzyme treatment

| Arterial status | Placebo | | Treated | |
|-----------------|---------|-------|---------|-------|
| | Initial | Final | Initial | Final |
| No. patent | 21 | 21 | 11 | 27 |
| No. stenosed | 26 | 23 | 34 | 35 |
| No. obstructed | 25 | 28 | 27 | 10 |

saline (placebo) showed 25 obstructed, 26 stenosed and 21 patent arterial segments prior to treatment (see [Table 66.2](#)).

At the end of the 3 month observation period (anticoagulation therapy only), no changes in Doppler ultrasound scanning or ankle/arm blood pressure ratios were found in either group.

At the end of the 2 week trial period, the saline group showed that three of the 72 arterial segments had progressed to increased obstruction (i.e. 4% worse). In contrast, treatment with the fungal protease infusion resulted improved patency of 33 of 72 arterial segments (i.e. a 46% improvement). These changes were significant at the 0.1% level ($P < 0.001$).

The saline group was offered the opportunity to receive a further course of treatment without disclosing a change in regimen from saline to fungal protease infusion. Five placebo patients declined further treatment, while four patients with 32 arterial segments subsequently received the cross-over fungal protease infusion protocol. After treatment, five completely obstructed segments became recanalized.

This research demonstrated that 3 months of anticoagulant therapy produced no improvement whatsoever in peripheral circulation;^[35] and neither did subsequent infusions of saline (placebo) during a 2 week period. Six intravenous infusions of a fungal protease derived from *A. oryzae* given within 2 weeks significantly improved peripheral circulation in over half of the chronically obstructed arterial segments in these patients.

Furthermore, detailed analysis of study results suggested that an increase in the number and/or dosage of protease infusions might have resulted in even greater improvement in obstructed and stenosed arterial segments.

Other studies have shown fungal protease to be effective in the treatment of arterial obstruction in patients with more advanced conditions, such as gangrene and other severe ischemic disease.^{[36] [70] [72]}

Celiac disease

It has been known since the 1950s that the gluten found in wheat, rye and other grains is the cause of intestinal damage in celiac disease, with the gliadin fraction of gluten being the source of its toxicity.^{[74] [75]} By the 1970s, fractionation studies had succeeded at identifying the components of gliadin involved in the toxic mechanism. The carbohydrate moiety, consisting mainly of glucose, galactose, xylose and arabinose, is the source of gluten's gastrointestinal toxicity in the celiac patient, rather than the protein fraction as had been previously suspected.^{[76] [77] [78]}

Amylolytic enzymes from *Aspergillus* species are effective in vitro in the treatment of celiac disease, as they enzymatically cleave the toxic carbohydrate portion of gliadin. Fungal carbohydrase preparations render grains like wheat and rye virtually harmless to individuals with gluten enteropathy.^{[76] [77]}

A 1977 study attempting to identify the source of gliadin toxicity used a preparation of amylolytic enzymes from *Aspergillus niger* to remove the carbohydrate portion of gliadin in vitro.^[76]

To be certain of the variables being tested, native gliadin was chromatographed showing that carbohydrate was associated with four main protein bands. When the carbohydrase-treated gliadin was chromatographed, no alteration was detected in the protein pattern, but carbohydrate was completely absent.

To further establish that the protein make-up remained unchanged as compared with native gliadin, peptide mapping of the treated gliadin was carried out using electrophoresis followed by chromatography. Peptide maps showed no difference between the treated and untreated gliadin, confirming that no alteration had occurred in the primary structure of the protein.

Gliadin treated in this manner was baked into loaves of bread made with gluten-free flour. The study compared the effect of bread with treated versus untreated gliadin on four patients with previously diagnosed celiac disease. All four patients had been on gluten-free diets for at least 3 months prior to the study and were virtually symptom-free. Previously, their clinical and physical signs and symptoms had included the diarrhea, malabsorption, decreased body weight and height, anemia, tetany, impaired D-xylose absorption, decreased intestinal mucosal enzyme secretion, flattened mucosal brush-border and subepithelial tissue lymphocytosis typical of celiac disease.

During the test period, patients 1, 2 and 3 received a total of 50 g of treated gliadin baked into loaves of bread (10 g gliadin/450 g loaf). Xylose absorption tests and

intestinal biopsies from jejunal villi were performed before and after each test period.

The celiac patient receiving untreated gliadin (patient no. 4) experienced a return of signs and symptoms of celiac disease – diarrhea, abdominal pain, low values on xylose absorption studies, decreased mucosal enzyme secretion (alkaline phosphatase, lactase, sucrase) and characteristic histological damage (mucosal lymphocytosis and loss of enterocyte height). The patients who received the treated gliadin remained symptom-free during the test period and showed no abnormalities in

histological parameters (i.e. general morphology, epithelial cell height, tissue lymphocytes were normal in these patients).

This study demonstrated that carbohydrate-digesting enzymes from *Aspergillus* sp. can be used in vitro to remove the toxicity of gluten to celiac patients and supports the hypothesis that carbohydrate components of gliadin are responsible for its toxicity, rather than protein components as had been widely suspected. It appears that no controlled studies have been done to evaluate the effectiveness of amylytic fungal enzymes at reducing gluten toxicity to celiac patients in vivo by administering these enzymes with gluten-containing foods at mealtime.

It should be noted that although celiac patients show intolerance to the carbohydrate portion of gliadin, this is likely not the only source of gluten-induced pathology. A number of studies suggest that protein components of gluten produce systemic allergic manifestations in some patients.^{[1] [2] [8] [9] [13] [79] [80]} It appears that both gastrointestinal intolerance and immunological hypersensitivity are capable, either individually or in concert, of producing disease symptoms in susceptible individuals. Future studies may also show that both pathological mechanisms are amenable to treatment by hydrolysis of the offending portions of gluten with the appropriate orally administered fungal enzymes. This, however, remains to be proven.

Food allergies

Antigen sampling by subepithelial immune tissue in the gut helps under normal conditions to program the body's defenses and protect against exposure to "foreign" dietary proteins and polypeptides. Under pathological conditions, food allergies can be caused by several factors, including the increased supply of dietary antigens which leak into the bloodstream as a result of inadequate protein digestion.^{[1] [2] [4] [8] [9] [10] [11] [21]}

By digesting dietary protein, fungal enzymes administered orally at mealtime work to decrease the supply of antigenic macromolecules available to leak into the bloodstream. In addition, orally administered fungal enzymes which have themselves been absorbed intact may help to "digest" antigenic dietary proteins which they encounter in the bloodstream. Further research is needed to evaluate the role of fungal enzymes in the

treatment of food allergies.

SUMMARY

Although the intact absorption of orally administered protein, including enzymes, can no longer be reasonably denied, the quantitative significance of this process will require additional study. While it appears unlikely that this route of absorption is significant from the standpoint of overall nutritional status, considerable evidence exists supporting the biological and therapeutic importance of intact protein absorption and the role of fungal enzyme therapy.

The emerging field of fungal enzyme therapy holds promise as an effective therapy or adjunct in a wide range of conditions, including maldigestion, malabsorption, pancreatic insufficiency, steatorrhea, celiac disease, lactose intolerance, arterial obstruction, and thrombotic disease.

Chapter 67 - Beta-carotene and other carotenoids

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

INTRODUCTION

The carotenoids represent the most widespread group of naturally occurring pigments in nature. They are a highly colored (red and yellow) group of fat-soluble compounds, composed of hydrocarbons (carotenes) and their oxygenated derivatives (oxycarotenoids or xanthophylls). The basic carotenoid structure consists of eight isoprenoid units with a series of conjugated double bonds. All photosynthetic organisms, whether bacteria or plants, contain carotenoid pigments. These compounds not only function as auxiliary pigments in photosynthesis, but also play a crucial role in protecting the organism or plant against photosensitization by its own chlorophyll.

Over 600 carotenoids have been characterized, but only about 30–50 are believed to have vitamin A activity. Biological activity of a carotenoid has historically been considered synonymous with its corresponding vitamin A activity. However, recent research suggests that this function of carotenoids has been overemphasized, as carotenoids have been found to exhibit many other very important physiological activities. For a carotenoid to have vitamin A activity, it must have an unaltered beta-ionone ring with an attached polyene side chain containing 11 carbon atoms. Beta-carotene has been termed the most active of the carotenoids, due to its higher provitamin A activity (see [Fig. 67.1](#)).

Apocarotenoids are compounds that have been shortened by the removal of at least one end of the molecule beyond a designated location (e.g. beta-Apo-8'-carotenal has been cleaved at the 8' carbon). Apocarotenes and xanthophylls have reduced or no vitamin A activity.^{[1] [2]}

Figure 67-1 Beta-carotene.

DIETARY SOURCES

The carotenoids present in green plants are found in the chloroplasts with chlorophyll, usually in complexes with a protein or lipid. Beta-carotene is the predominant form in most green leaves and, in general, the greater the intensity of the green color, the greater the concentration of beta-carotene. Orange-colored fruits and vegetables, e.g. carrots, apricots, mangoes, yams, squash, etc., typically have higher concentrations of provitamin A carotenoids, the provitamin A content again paralleling the intensity of the color. Yellow vegetables have higher concentrations of xanthophylls, and hence a lowered provitamin A activity. In the orange and yellow fruits and vegetables, beta-carotene concentrations are high, but other provitamin A carotenoids typically predominate. The red and purple vegetables and fruits, such as tomatoes, red cabbage, berries, and plums, contain a large portion of non-vitamin A-active pigments, including flavonoids. Legumes, grains, and seeds are also significant sources of carotenoids. Carotenoids are also found in various animal foods, such as salmon and other fish, egg yolks, shellfish, milk, and poultry. Carotenoids are frequently added to foods as colorants. [Table 67.1](#) lists carotenoids with provitamin A activity found in common food sources, while [Table 67.2](#) lists some important carotenoids that have no vitamin A activity. ^{[1] [2]} The structures of two of these, lycopene and zeaxanthin, are illustrated in [Figures 67.2](#) and [67.3](#).

METABOLISM

Absorption

A variety of factors are known to influence the absorption efficacy of vitamin A and carotenoids. Although retinol does not require bile acids to facilitate absorption, carotenoids do. Other factors that affect vitamin A and carotenoid absorption include:

- the presence of fat, protein, and antioxidants in the food
- the presence of bile and a normal complement of pancreatic enzymes in the intestinal lumen
- and the integrity of the mucosal cells.

The absorption efficiency of dietary vitamin A is usually quite high (80–90%), with only a slight reduction in efficiency at high doses. In contrast, beta-carotene's absorption efficiency is much lower (40–60%), and it decreases rapidly with increasing dosage.^{[1] [3]} Carotene supplements are better absorbed than the carotenes from foods.^[4]

TABLE 67-1 -- Provitamin A carotenoids and food sources

| Carotenoid | Activity (%) | Food sources |
|------------|--------------|--------------|
|------------|--------------|--------------|

| | | |
|------------------------|-------|---|
| Beta-carotene | 100% | Green plants, carrots, sweet potatoes, squash, spinach, apricots, green peppers |
| Alpha-carotene | 50–54 | Green plants, carrots, squash, corn, watermelons, green peppers, potatoes, apples, peaches |
| Gamma-carotene | 42–50 | Carrots, sweet potatoes, corn, tomatoes, watermelons, apricots |
| Beta-zeacarotene | 20–40 | Corn, tomatoes, yeast, cherries |
| Cryptoxanthin | 50–60 | Corn, green peppers, persimmons, papayas, lemons, oranges, prunes, apples, apricots, paprika, poultry |
| Beta-apo-8'-carotenal | 72 | Citrus fruit, green plants |
| Beta-apo-12'-carotenal | 120 | Alfalfa meal |

TABLE 67-2 -- Non-provitamin A carotenoids and food sources

| Carotenoid | Food source |
|-------------------|--|
| Lycopene | Tomatoes, carrots, green peppers, apricots, pink grapefruit |
| Zeaxanthin | Spinach, paprika, corn, fruits |
| Lutein | Green plants, corn, potatoes, spinach, carrots, tomatoes, fruits |
| Canthaxanthin | Mushrooms, trout, crustaceans |
| Crocetin | Saffron |
| Capsanthin | Red peppers, paprika |

Transformation in the intestinal mucosa

As stated above, of the more than 600 carotenoids that have been reasonably well characterized, only about 30–50 are believed to have provitamin A activity. Yet carotenoids provide the majority of dietary vitamin A. Provitamin A carotene conversion to vitamin A is dependent on diverse factors:^[5]

- protein status
- thyroid hormones

- zinc
- vitamin C.

The conversion diminishes as carotene intake increases and when serum retinol levels are adequate.^[6] Beta-carotene and other provitamin A carotenes were originally believed to be cleaved by carotene dioxygenase at the 15,15' double bond, which would yield two molecules of all-*trans* retinal. It is currently believed, however, that the dioxygenase enzyme non-specifically attacks any one of the double bonds of the beta-carotene, resulting in the formation of a corresponding apo-beta-carotenal or retinal.^[7] The apocarotenal formed can either be degraded to retinal or absorbed. The retinal formed is then converted to retinol by retinaldehyde reductase.

Uncleaved provitamin A carotenoids, apocarotenoids, and non-provitamin A carotenoids, like retinol, are transported in the chylomicra.

Transport, storage, and excretion

No specific carrier protein exists in the plasma for carotenoids. These compounds are typically transported in human plasma in association with the plasma lipoproteins, particularly by LDL. As a consequence, patients with high serum cholesterol or LDL levels tend to have high serum carotene levels. The concentrations found in the plasma usually reflect the dietary concentration, with beta-carotene typically comprising only 20–25% of the total serum carotene level.^[8]

Carotenes may be stored in adipose tissue, the liver, other organs (the adrenals, testes, and ovaries have the highest concentrations), and the skin (see [Table 67.3](#)). Deposition in the skin results in carotenoderma. This is a benign (and probably beneficial) state. Carotenoderma not directly attributable to dietary intake or supplementation, however, may be indicative of a deficiency in a necessary conversion factor, i.e. zinc, thyroid hormone, vitamin C, or protein.^{[1] [2]}

PHYSIOLOGICAL ROLES

Reproduction

Beta-carotene has also been reported to have a specific effect in fertility distinct from its role as a precursor to vitamin A.^{[9] [10] [11]} In bovine nutritional studies, cows fed

TABLE 67-3 -- Distribution of carotenoids in some human tissues (mcg/kg)

| Tissue | Carotenoids | Beta-carotene |
|---------|-------------|---------------|
| Adrenal | 20.1 ± 11.9 | 10.8 ± 5.5 |

| | | |
|----------|------------|-----------|
| Liver | 8.3 ± 21.3 | |
| Testis | 5.0 ± 7.7 | 4.7 ± 2.0 |
| Fat | 3.9 ± 6.0 | 1.3 ± 1.1 |
| Pancreas | 2.3 ± 1.2 | 1.1 ± 1.0 |
| Spleen | 1.6 ± 2.2 | 1.2 ± 0.5 |
| Lung | 0.6 ± 1.0 | |
| Thyroid | 0.6 ± 0.4 | |

beta-carotene-deficient diets exhibited delayed ovulation and an increase in the number of follicular and luteal cysts.^[9] ^[10] The corpus luteum has the highest concentration of beta-carotene of any organ measured.^[11] The carotene cleavage activity changes with the ovulation cycle, with the highest activity occurring during the midovulation stage. It has been speculated that a proper ratio of carotene to retinol must be maintained to ensure proper corpus luteum function.

As the corpus luteum produces progesterone, inadequate corpus luteum function could have significant deleterious effects. Inadequate corpus luteum secretory function is one of the characteristic features of infertile and/or irregular menstrual cycles.^[12] Furthermore, an increased estrogen to progesterone ratio has been implicated in a variety of clinical conditions, including ovarian cysts, premenstrual tension syndrome, fibrocystic breast disease, and breast cancer.^[13] Since supplemental beta-carotene given to cows significantly reduced the incidence of ovarian cysts (42% in control group vs. 3% in the beta-carotene group), it may have a similar effect in humans.^[10] ^[11] Another bovine condition that benefited from increased dietary beta-carotene levels is cystic mastitis.^[12] It appears that farmers have a greater appreciation of beta-carotene than do many nutritionists. Of course, there are significant financial reasons as the annual monetary loss from bovine mastitis in the US has been estimated to be at least \$1.5–2.0 billion and ovarian cysts represent the major cause of infertility in cattle.

Immune system

Some of these effects are probably related to vitamin A's ability to prevent stress-induced thymic involution as well as promote thymus growth. As carotenes are better antioxidants, they may turn out to be even better at protecting the thymus gland than vitamin A, since the thymus gland is particularly susceptible to free radical and oxidative damage. The clinical use of vitamin A and beta-carotene in infectious diseases is discussed below.

Beta-carotene's primary effects appear to enhance thymus gland function (discussed below) and increase interferon's stimulatory action on the immune system.^[14] Interferon is a powerful immune-enhancing compound that plays a central role in protection against viral infections.

Antioxidant activity

In general, carotenes exert significant antioxidant activity, while the antioxidant activity of vitamin A is relatively minor in comparison.^[15] The antioxidant activity of carotenes are thought to be the factor responsible for their anti-cancer effects noted in population studies (discussed below). Since aging is associated with free radical

606

damage, a hypothesis developed that carotenes may also protect against aging as well. There is evidence that seems to support this hypothesis. It appears that tissue carotenoid content is the most significant factor in determining maximal life span potential (MLSP) of mammalian species ($r = 0.835$ for 12 mammalian species, and for primates alone, $r = 0.939!$).^[16] For example, human MLSP of approximately 90 years correlates with a serum carotene level of 50–300 mcg/dl, while other primates, such as the rhesus monkey, have a MLSP of approximately 34 years, correlating with a serum carotene level of 6–12 mcg/dl.

While beta-carotene has received most of the attention, many carotenes which have either low or no vitamin A activity exert much greater protection compared with beta-carotene. For example, while beta-carotene generates vitamin A much more efficiently than alpha-carotene, alpha-carotene is approximately 38% stronger as an antioxidant and 10 times more effective in suppressing liver, skin, and lung cancer in animals compared with beta-carotene.^[17] Even more powerful is lycopene.^[18] Studies have shown lycopene to exhibit the highest overall singlet oxygen quenching of the carotenoids thus far studied. Its activity is roughly double that of beta-carotene. Furthermore, lycopene may exert even more impressive anti-cancer effects.

To evaluate the role of lycopene as a protective factor in digestive tract cancers, a case–control study was conducted in northern Italy, where tomato intake is high, but also heterogenous, in that some people eat a lot of tomatoes while others eat very few if any. Tomatoes are a perfect food to study as they are quite high in lycopene, but very low in carotene.

The data were obtained from a series of hospital-based studies on various cancers of the digestive tract between 1985 and 1991.^[19] Frequency of consumption of raw tomatoes was divided into four levels: less than two; three to four; four; five to six; and greater than seven servings per week. Results showed a consistent pattern of protection by high intake of raw tomatoes in all examined cancer sites of the digestive tract. The degree of protection was similar to, but somewhat more marked than, those afforded by green vegetables and fruit studies carried on in the same areas. The results support the findings of other researchers who found, for example, a 40% reduction in the risk of esophageal cancer by simply consuming one serving of raw tomatoes per week and a 50% reduced rate for cancers of all sites among elderly Americans reporting a high tomato intake. These results suggest that increasing dietary lycopene levels may

be a significant protector against cancer.

According to a detailed analysis of the levels of carotenoids in 120 fruits and vegetables, lycopene is found in very few.^[20] [Table 67.4](#) provides a list of the foods which contained lycopene.

TABLE 67-4 -- Lycopene content of common foods

| Food | Lycopene (mg/100 g) |
|---------------------------|----------------------------|
| Apricot, canned | 0.06 |
| Apricot, dried | 0.8 |
| Grapefruit (pink and raw) | 3.4 |
| Guava juice | 3.3 |
| Tomato, raw | 3.1 |
| Tomato juice, canned | 8.6 |
| Tomato paste, canned | 6.5 |
| Tomato sauce, canned | 6.3 |
| Watermelon, raw | 4.1 |

These values indicate that lycopene levels are retained in food processing.

CLINICAL APPLICATIONS

There are three primary sources of carotenes on the market:

- synthetic all-*trans* beta-carotene
- beta- and alpha-carotene from the algae *Dunaliella*
- mixed carotenes from palm oil.

Of these three, palm oil carotenes seem to be the best form (see [Table 67.5](#)).

Palm oil carotenes appear to give much better antioxidant protection. The carotene complex of palm oil closely mirrors the pattern in high carotene foods. In particular, unlike the synthetic version which only provides the *trans* configuration of beta-carotene, natural carotene sources provide beta-carotene in both a *trans* and *cis* configuration:

- 60% beta-carotene (both *trans* and *cis* isomers)
- 34% alpha-carotene
- 3% gamma-carotene
- 3% lycopene.

Palm oil carotenes have been shown to be about 4–10 times better absorbed than synthetic all-*trans* beta-carotene. ^[21] ^[22] ^[23] Carotenes from *Dunaliella* have also been shown to be well absorbed. ^[24]

The widespread health concerns concerning the use of “tropical oils” like palm and coconut do not apply to carotene products extracted from palm oil as the fat content is minimal. In addition, the real problem with palm oil occurs when it is processed, i.e. partially hydrogenated.

Prevention of cancer

Epidemiological studies have clearly demonstrated a strong inverse correlation between dietary carotene intake and a variety of cancers involving epithelial tissues (lung, skin, uterine cervix, gastrointestinal tract, etc). ^[25] ^[26] The epidemiological association is much stronger for

TABLE 67-5 -- Antioxidant potential of different carotene products (per 25,000 IU of vitamin A activity)

| Source | Carotenoid | Quenching rate | % in source | mg/25,000 IU | Antioxidant potential |
|-----------|----------------|----------------|-------------|--------------|-----------------------|
| Palm oil | Alpha-carotene | 1.9 | 33 | 7.36 | 2.60 |
| | Beta-carotene | 1.4 | 63 | 14.04 | 3.66 |
| | Gamma-carotene | 2.5 | 2.5 | 0.56 | 0.26 |
| | Lycopene | 3.1 | 0.1 | 0.02 | 0.01 |
| | Total | | | | 6.54 |
| Algal | Alpha-carotene | 1.9 | 4.0 | 0.61 | 0.22 |
| | Beta-carotene | 1.4 | 96.0 | 14.69 | 3.83 |
| | Total | | | | 4.05 |
| Synthetic | Beta-carotene | 1.4 | 100 | 14.97 | 3.90 |
| | Total | | | | 3.90 |

carotene than for vitamin A. This may reflect carotene’s superior antioxidant, immune potentiating activity, and anticarcinogenic activity. ^[27]

While there is no argument that a diet high in carotenes is protective against cancer, the big question is: “Can beta-carotene supplementation reduce the risk of cancer?” The

answer appears to be that synthetic beta-carotene supplementation does not. Three highly publicized reports on cancer prevention trials featuring synthetic all-*trans* beta-carotene in high-risk groups have produced negative results. It is important to take a close look at each of these studies to help put things into perspective.

The Alpha-tocopherol, Beta-carotene Cancer Prevention Study Group

This study's population was 29,000 men in Finland who smoked and drank alcohol.^[28] The men were given beta-carotene (20 mg daily) and/or vitamin E. The results of this study indicated an 18% increase in lung cancer in the beta-carotene group. This result was not totally unexpected as studies in primates demonstrated that when animals were fed alcohol and beta-carotene, they experienced an increase in liver damage as a result of oxidative damage.^[29] Other researchers have pointed out that beta-carotene is very susceptible to oxidative damage.^[30] The protection against oxidative damage of beta-carotene is the presence of other antioxidant nutrients.^[31] Absence of these protective nutrients could result in the formation of cancer-causing compounds, stressing the importance of relying on foods and broader-spectrum nutritional antioxidant support. Adding support to this statement is the fact that the group that received both beta-carotene and vitamin E did not show an increase in cancer, and in the group not receiving beta-carotene supplements there was a strong protective effect of high dietary beta-carotene and blood carotene levels against lung cancer. All together, this data strongly suggests that the protection offered by beta-carotene is only apparent when other important antioxidant nutrients are provided and may not be provided by the synthetic forms.

The CARET study

The second trial reporting on the role of beta-carotene in a high-risk group is the Carotene and Retinol Efficacy Trial (CARET).^[32] This study was composed of over 18,000 US men and women smokers and asbestos workers. This study was halted 21 months prematurely on 13 January 1996 after 4 years of intervention indicated that beta-carotene supplementation (30 mg daily) increased lung cancer by 28% and overall deaths by 17%. While this appears dramatic, a closer look at the numbers and percentages puts them in their proper perspective. Among active smokers, the risk of lung cancer during the CARET study was 5 out of every 1,000. The 28% increase found with beta-carotene supplementation increased this number to roughly 6 out of 1,000.^[32]

Interestingly, once again, in the group not taking beta-carotene, the lowest rate of cancer was found among individuals with the highest blood beta-carotene levels; and in former smokers, beta-carotene supplementation actually reduced cancer risk by 20%.

The Physician's Health Study

The Physician's Health Study is composed of 22,071 US male physicians taking either 50 mg of beta-carotene or a placebo every other day for 12 years. Results demonstrated no significant effect – positive or negative – on cancer or cardiovascular

disease, even in the group (11%) who smoked.^[33]

General comments on the “negative” studies

The results of these three studies indicate that synthetic beta-carotene supplementation may have adverse effects in high-risk groups for cancer and cardiovascular disease. These studies do not invalidate the hundreds of studies showing the preventive effect of a diet rich in carotenes and nutritional antioxidants against cancer and cardiovascular disease. These results seem to indicate the need for a diet high in carotenes and, if carotene supplementation is desired, people should not smoke, natural

608

forms should be used, and the beta-carotene needs to be protected against the formation of toxic derivatives by taking extra vitamin C and E, and selenium.

Other prospective studies

In addition to these three highly publicized studies, there have been several prospective and double-blind studies showing promising results. In particular, beta-carotene supplementation has been shown to be especially effective in the treatment of early cancerous lesions of the oral cavity and esophagus.^[34] ^[35] Although beta-carotene has been shown to exert these benefits on its own (in dosages ranging from 15 to 180 mg/day), one of the most positive studies showing a reduction in cancer risk with supplemental beta-carotene to date is one that featured a broader supplement program. The Linxian Cancer Chemoprevention Study is a prospective study of 30,000 rural Chinese adults. In one of the substudies, subjects received one of four supplement programs:

- retinol and zinc
- riboflavin and niacin
- vitamin C and molybdenum
- beta-carotene, vitamin E, and selenium (dosages 1–3 times greater than the US RDA).

The latter group demonstrated 13% fewer cancer deaths and a reduction of 9% in overall deaths.^[36] ^[37] These results again support the notion that a combination of antioxidants is superior to high levels of any single antioxidant.

Prevention of cardiovascular disease

As in cancer, a high dietary carotene intake is also associated with lowering the risk of cardiovascular disease.^[38] Like other antioxidants, beta-carotene may inhibit damage to cholesterol and the lining of the arteries.^[39] However, it appears that beta-carotene is less effective in protecting against cardiovascular disease than vitamin E, probably

because vitamin E protects against oxidative damage to cholesterol better than beta-carotene.^[40]

Immune enhancement

Carotenes have demonstrated a number of immune-enhancing effects in recent studies.^[14] However, the immune-enhancing effects were demonstrated as far back as 1931 when it was found that a diet rich in carotenes, as determined by blood carotene levels, was inversely related to the number of school days missed by children.^[41] Originally it was thought that the immune-enhancing properties of carotenes were due to their conversion to vitamin A. We now know that carotenes exert many immune system-enhancing effects independent of any vitamin A activity.^[14]

One of the most impressive studies was conducted on normal human volunteers.^[42] Results demonstrated that oral beta-carotene (180 mg/day, approximately 300,000 IU) significantly increased the frequency of OKT4+ (helper/inducer T-cells) by approximately 30% after 7 days, and of OKT3+ (all T-cells) after 14 days.^[32] As T4+ lymphocytes play a critical role in determining host immune status, this study indicates that oral beta-carotene may be effective in increasing the immunological competence of the host in conditions that are characterized by a selective diminution of the T4 subset of T-cells, such as the acquired immunodeficiency syndrome (AIDS) and cancer.

However, rather than supplementing the diet with synthetic beta-carotene, it may be more advantageous to use natural carotene sources or to increase the intake of carotene-rich foods. In another study, 126 healthy college students were randomly assigned to one of the following groups:

- group A, the control group
- group B, a group that used a 15 mg (25,000 IU) beta-carotene supplement daily
- group C, a group that consumed approximately 15 mg beta-carotene per day from carrots.

Better results, i.e. increase in white blood cell number and function, were achieved in the group eating the carrots.^[43]

As the absorption studies have shown supplemental beta-carotene to be much better absorbed than the carotenes from carrots and other vegetables, the differences are likely the result of form, i.e. natural is better than synthetic.^[4]

Vaginal candidiasis

It is a well-established fact that women are more susceptible to vaginal candidiasis when the immune system is depressed, a depression which may be due to low carotene levels. Beta-carotene levels were determined in exfoliated vaginal cells in 22 women with vaginal candidiasis and compared to vaginal cells from 20 controls. The beta-carotene level/1 million cells in the women with vaginal candidiasis was 1.46 ng

compared with 8.99 ng in the control group, i.e. one-sixth that of normal.^[44]

These results, coupled with beta-carotene's known effects on enhancing the immune system, suggest that a low tissue level of beta-carotene is associated with vaginal candidiasis, and a high dietary or supplemental intake of beta-carotene may be protective against vaginal candidiasis.

Photosensitivity disorders

Beta-carotene has become the treatment of choice for photosensitivity disorders. It is most effective in the treatment

609

of erythropoietic protoporphyria (EPP), while its effectiveness in other photosensitivity disorders, such as polymorphous light eruption, solar urticaria, and discoid lupus erythematosus is significant, but not as great.^{[45] [46] [47] [48] [49] [50] [51] [52] [53]} Beta-carotene also has a small but significant effect in increasing the exposure at which manifestations of sunburn begin, thus allowing some subjects the opportunity to stay in the sun long enough to get a "tan" for the first time.^[53]

Patients with EPP are characterized by elevated levels of porphyrins in blood, feces, and skin and by sensitivity to visible light. This sensitivity manifests itself after exposure to sunlight by a burning sensation followed by swelling and redness. Topical sunscreens are of no value. The photosensitivity is due to excitation of the porphyrin molecule by ultraviolet radiation, resulting in the production of free radicals that are very deleterious to the skin. Direct cell damage results in the release of chemical mediators which in turn damage other cells, resulting in the manifestations of itching, burning, redness, and swelling.

In EPP, it appears that carotene levels must be maintained in the blood at 600–800 mcg/dl for optimum effects and that the protective effect is not usually observed until after 4–6 weeks of therapy. The actions of beta-carotene and other carotenes in human tissue are similar to their action in plant cells, i.e. they function as a cellular screen against sunlight-induced free radical damage.

DOSAGES

For carotenes, a daily dosage of 25,000 IU (15 mg of beta-carotene) appears to be reasonable for general health. For the treatment of pre-cancerous lesions and immune enhancement, the dosage range is 25,000–300,000 IU. In the treatment of EPP, the dosage is based on maintaining blood carotene levels between 600 and 800 mcg/dl. For the best clinical impact, it appears the natural mixed forms of carotene should be used in conjunction with a broad range of other natural antioxidants (see [Ch. 99](#)).

TOXICITY

Supplementing the diet with beta-carotene has not been shown to possess any significant toxicity despite its use in very high doses in the treatment of numerous photosensitive disorders (see above). Occasionally patients will complain of loose stools, which usually clears spontaneously and does not necessitate stopping treatment. Elevated carotene levels in the blood do not lead to vitamin A toxicity, nor do they lead to any other significant disturbance besides a yellowing of the skin (carotenoderma). The ingestion of large amounts of carrots or carrot juice (0.45–1.0 kg/day of fresh carrots for several years) has, however, been shown to cause neutropenia as well as menstrual disorders.^[54] ^[55] Although the blood carotene levels of these patients did reach levels (221– 1,007 mcg/dl) similar to those of patients taking high doses of beta-carotene (typically 800 mcg/dl), the disturbances are due to some other factor in carrots, as neither of these effects nor any others have been observed in subjects consuming very high doses of pure beta-carotene, e.g. 300,000–600,000 IU/day (180–360 mg beta-carotene, which is equivalent to 4–8 pounds of raw carrots) over long periods of time.^[56] ^[57] ^[58] ^[59] ^[60] Doses up to 1,000 mg/kg have been given to rats and rabbits for long periods of time with no signs of embryotoxicity, toxicity, tumorigenicity, or interference in reproductive functions.^[61]

Chapter 68 - Boron

Gregory S. Kelly ND*

INTRODUCTION

Boron is an ubiquitous constituent of man's external environment. It typically occurs in nature as borates hydrated with varying amounts of water. Boric acid and borax are important boron-containing compounds.^[1]

In trace amounts, boron is essential for the growth of many plants, and is found in animal and human tissues at low concentrations.^[1] Although it has yet to be recognized as an essential nutrient for humans, recent data from animal and human studies suggest that boron may be important for mineral metabolism, brain function and performance, and prevention of both osteoporosis and osteoarthritis.

SOURCES

Because boron in plants is dependent on the availability of boron in the soil, the same food crop can vary greatly in boron content depending on where and how it is grown. In general, soils exposed to high degrees of precipitation have decreased levels of boron.^[2] Food processing results in additional loss of boron.^[3] Foods of plant origin, such as leafy vegetables, non-citrus fruits, nuts, legumes, and sea vegetables are considered to be the best sources of boron.^{[1] [4]} Wine has also been shown to contribute appreciable amounts of boron to the diet.^[5] A diet containing an abundance of these items would provide 2–6 mg/day of boron.^{[4] [6]}

Daily intake of boron is dependent upon several variables. Concentration of boron in water varies considerably according to geographic source. In some areas, boron in drinking water and water-based beverages may account for most of the total dietary boron intake. Individual food preference greatly influences daily intake of boron. Fruits, vegetables, tubers, and legumes have higher concentrations of boron than do cereal grains or animal tissues. Boron has also been determined to be a notable contaminant

or major ingredient of many

612

personal care products and it is occasionally used (boric acid) as a food preservative.^[7]

In a recently published study, 32 subjects from Sydney, Australia, aged 20–53, were assessed over a 7 day period for their dietary intake of boron. The average boron intake in male and female subjects was found to be 2.28 ± 1.3 and 2.16 ± 1.1 mg/day respectively.^[5] The boron content of selected Australian foods has been found to correlate with values in Finnish and US Food and Drug Administration tables and is presented in [Table 68.1](#).^[5]

METABOLISM

Chemical properties

Elemental boron was first isolated in 1808. It is the first member (atomic number 5) of the metalloid or semiconductor family of elements, which include silicon and germanium, and is the only non-metal of the group IIIA elements. Like carbon, boron has a tendency to form double bonds and macromolecules.^[8] Boron, as boric acid, acts as a Lewis acid, accepting hydroxyl (OH⁻) ions and leaving an excess of protons.^[9] Because boron complexes with organic compounds containing hydroxyl groups, it interacts with sugars and polysaccharides, adenosine-5-phosphate, pyridoxine, riboflavin, dehydroascorbic acid, and pyridine nucleotides.^[10] Borate cross-links with polysaccharides, most likely as borate di-esters, to form

TABLE 68-1 -- Concentration of boron in selected Australian foods

| Food | Boron (mg/100 g) |
|--------------------|------------------|
| Almond | 2.82 |
| Apple (red) | 0.32 |
| Apricots (dried) | 2.11 |
| Avocado | 2.06 |
| Banana | 0.16 |
| Beans (red kidney) | 1.40 |
| Bran (wheat) | 0.32 |
| Brazil nuts | 1.72 |
| Broccoli | 0.31 |

| | |
|------------------------|------|
| Carrot | 0.30 |
| Cashew nuts (raw) | 1.15 |
| Celery | 0.50 |
| Chick peas | 0.71 |
| Dates | 1.08 |
| Grapes (red) | 0.50 |
| Hazel nuts | 2.77 |
| Honey | 0.50 |
| Lentils | 0.74 |
| Olive | 0.35 |
| Onion | 0.20 |
| Orange | 0.25 |
| Peach | 0.52 |
| Peanut butter | 1.92 |
| Pear | 0.32 |
| Potato | 0.18 |
| Prunes | 1.18 |
| Raisins | 4.51 |
| Walnut | 1.63 |
| Wine (Shiraz Cabernet) | 0.86 |

gels with unique properties. These gels are very plastic in nature and quickly reassemble in response to externally applied stress.^[9] Five naturally occurring boron ester compounds have been identified as antibiotics.^[11]

Biochemistry

Boron in food, sodium borate and boric acid are well absorbed from the digestive tract.^[12] These compounds are also absorbed through damaged skin and mucous membranes; however, they do not readily penetrate intact skin.^[13]

No accumulation of boron has been observed in soft tissues of animals fed chronic low doses of boron; however, in acute poisoning incidents, the amount of boric acid in brain and liver tissue has been reported to be as high as 2,000 ppm. Within a few days of consumption of large amounts of boron, levels in blood and most soft tissues quickly reach a plateau.^[14] Tissue homeostasis is maintained by the rapid elimination of excess boron primarily in the urine; with bile, sweat, and breath also contributing as routes of elimination.^[10] In humans, urinary boron excretion increases over time in all

boron-supplemented subjects who have been studied.^[15]

Evidence suggests that supplemental boron does accumulate in bone; however, cessation of exposure to dietary boron results in a rapid drop in bone boron levels. The half-life of boric acid in animals is estimated to be about 1 day.^[14]

Biological functions

Boron contributes to living systems by acting indirectly as a proton donor and by exerting an influence on cell membrane structure and function.^[16] Although the absolute essentiality of boron for plants is well documented, studies to date have not shown it to be unequivocally essential for either animals or humans. However, boron supplementation has been shown to affect certain aspects of animal physiological function. Experimental animals supplemented with boron demonstrate a high degree of variability in their response. In general, supplemental dietary boron has most marked effects when the diet is deficient in known nutrients.^[17]

Evidence suggests that boron might have a slight effect on decreasing fasting serum glucose concentrations in postmenopausal women.^[11]

Life span

Boron in an animal model has been shown to have an effect upon life span, although the process is undefined. Extremes in dietary boron, both a deficiency and an excess, decreased the median life span of *Drosophila* by 69%, while supplementing the diet with low levels of boron increased life span by 9.5%.^[18]

Brain function

Brain electrophysiology and cognitive performance were assessed in response to dietary manipulation of boron (approximately 0.25 vs. approximately 3.25 mg boron/2,000 kcal per day) in three studies with healthy older men and women. A low boron intake was shown to result in a decrease in the proportion of power in the alpha band and an increase in the proportion of power in the delta band. Other changes in left–right symmetry and brain wave coherence were noted in various sites, indicating an influence on brain function. When contrasted with the high boron intake, low dietary boron resulted in significantly poorer performance ($P < 0.05$) on tasks emphasizing manual dexterity, eye–hand coordination, attention, perception, encoding and short- and long-term memory. Collectively, the data from these studies indicate that boron may play a role in human brain function, alertness and cognitive performance.^[19]

Hematological

Boron supplementation to human subjects, who had previously followed a dietary regimen deficient in boron, increased blood hemoglobin concentrations, mean corpuscular hemoglobin, and mean corpuscular hemoglobin concentration; and lowered hematocrit, red cell count, and platelet count.^[20]

Mineral metabolism

Boron also impacts mineral metabolism and has been shown to impact levels of certain hormones in human subjects. In the first nutritional study with humans involving boron,^[13] postmenopausal women first were fed a diet that provided 0.25 mg boron/2,000 kcal for 119 days, and then were fed the same diet with a boron supplement of 3 mg boron/day for 48 days. The boron supplementation reduced the total plasma concentration of calcium and the urinary excretions of calcium and magnesium, and elevated the serum concentrations of 17 beta-estradiol and testosterone.^[4]

In a study designed to determine the effects of boron supplementation on blood and urinary minerals in athletic subjects on Western diets, findings suggested that boron supplementation modestly affected mineral status.^[15]

DEFICIENCY SIGNS AND SYMPTOMS

Information on boron deficiency is very limited, especially in humans. It is thought that insufficient intake of boron becomes obvious only when the body is stressed in a manner that enhances the need for it. When the diets of animals and humans are manipulated to cause functional deficiencies in nutrients such as calcium, magnesium, vitamin D, and methionine, a large number of responses to dietary boron occur.^[21] There is evidence to suggest that more than 21 days on a boron-deficient diet are required to demonstrate detectable effects in humans.^[22] The variables that are changed, due to a boron-deficient diet, abruptly improve about 8 days after boron supplementation is introduced.^[4] Evidence indicates that hemodialysis results in an excessive decrease in serum boron as compared with controls.^[23] While by no means being pathognomonic for a boron deficiency, blood urea nitrogen has been found to be slightly elevated during boron depletion.^[24]

NUTRIENT INTERACTIONS

Vitamin D

There is considerable evidence that dietary boron alleviates perturbations in mineral metabolism that are characteristic of vitamin D₃ deficiency.^[25] After 26 days, chicks fed on a diet inadequate in vitamin D exhibited decreased food consumption and plasma calcium concentrations and increased plasma concentrations of glucose, beta-hydroxybutyrate, triglycerides, triiodothyronine, cholesterol, and alkaline phosphatase activity. Supplemental boron returned plasma glucose and triglycerides to

concentrations exhibited by chicks fed on a diet adequate in vitamin D.^[26]

In rachitic chicks, boron elevated the numbers of osteoclasts and alleviated distortion of the marrow sprouts of the proximal tibial epiphysial plate, a distortion characteristic of vitamin D₃ deficiency.^{[25] [27]} Higher apparent-balance values of calcium, magnesium, and phosphorus have been observed for rats fed on a vitamin D-deprived diet if the diet is supplemented with boron.^[17]

After supplementation with 3.25 mg boron daily, plasma levels of D₂ increased in men over 45 and postmenopausal women on low magnesium and copper diets.^[28]

Calcium

Boron supplementation may have a favorable impact on calcium metabolism. A boron supplement of 3 mg/day affected several indices of mineral metabolism of seven women consuming a low-magnesium diet and five women consuming a diet adequate in magnesium; the women had consumed a conventional diet supplying about 0.25 mg boron/day for 119 days. Boron supplementation modestly reduced the urinary excretion of calcium when dietary magnesium was low.^[4]

In men over 45 and postmenopausal women, changes caused by boron supplementation include increased concentration of plasma ionized and total calcium as well

as reduced serum calcitonin concentration and urinary excretion of calcium.^[28] A 1993 study demonstrated that a low boron diet elevated urinary calcium excretion. The high level of calcium excretion was maintained throughout the 6 week study; however, it remained elevated even after boron supplementation began.^[29]

Copper

Supplemental boron acts to increase serum levels of both copper and copper-dependent enzymes in humans. Boron supplementation (3 mg/day), to five men over the age of 45, four postmenopausal women, and five post-menopausal women on estrogen therapy who had been fed a low boron diet (0.23 mg/2,000 kcal) for 63 days, resulted in higher erythrocyte superoxide dismutase, serum enzymatic ceruloplasmin, and plasma copper.^[28] In a subsequent study, these same variables were again found to be higher during boron repletion than while subjects were fed on a diet low in boron.^[30]

Magnesium

When magnesium deprivation is severe enough to cause typical signs of deficiency, a significant interaction between boron and magnesium is found.^[8] A combined deficiency

of boron and magnesium causes detrimental changes in the bones of animals. Supplemental boron elevates plasma Mg concentrations and enhances growth.^[27]

Boron supplementation has resulted in increased serum magnesium concentrations in human female subjects studied.^[14] Boron supplementation increases red blood cell magnesium concentrations.^[31] It has been shown that serum magnesium concentrations are greater in sedentary females whose diets are supplemented with boron than in exercising female athletes who are supplemented with boron.^[32] This finding, while unexplained to date, may indicate an increased loss of boron through urine and perspiration during exercise.

Phosphorous

Supplemental boron seems to lower serum phosphorus concentrations in female subjects ages 20–27.^[32] However, exercise training diminishes these changes,^[14] again possibly indicating increased losses or an increased need for boron as a result of exercise. A low magnesium status along with supplementation of boron may depress the urinary excretion of phosphorus. This does not occur in women with an adequate magnesium intake.^[4]

Methionine and arginine

In experimental animals, a beneficial impact is consistently observed after boron supplementation when the diet contains marginal methionine and excessive arginine. Among the signs exhibited by rats fed on a diet marginal in methionine and magnesium are depressed growth and bone magnesium concentration, and elevated spleen weight/body weight and kidney weight/body weight ratios. Findings indicate that the severity of these symptoms is alleviated with boron supplementation.^[33]

HORMONE INTERACTIONS

In rats, supplemental dietary boron substantially depressed plasma insulin, plasma pyruvate concentrations, and creatine kinase activity and increased plasma thyroxine (T4) concentrations. Boron supplementation also decreased plasma aspartate transaminase activity.^[34] In animal experiments, boron supplementation offsets the elevation in plasma alkaline phosphatase caused by vitamin D deficiency.^[24]

One researcher has hypothesized that boron might be required for the synthesis of steroid hormones as well as vitamin D. Since the biosynthesis of steroids such as vitamin D, testosterone, and 17 beta-estradiol involves one or more hydroxylation steps, and because of boron's ability as a Lewis acid to complex with hydroxyl groups, boron may facilitate the addition of hydroxyl groups to the steroid structures.^[4] It has also been suggested that boron may act in an unspecified manner to protect hormones from rapid inactivation.^[4]

An increase in dietary intake of boron from 0.25 to 3.25 mg/day has been reported to increase plasma 17 beta-estradiol by more than 50% and to more than double plasma

testosterone levels in postmenopausal women. The elevation seemed more marked when dietary magnesium was low.^[4] In a subsequent study of healthy men, boron supplementation resulted in an increase in the concentrations of both plasma estrogen and testosterone; however, not all published trials support these observations.^[5]

Ten male bodybuilders, aged 20–26, were given a 2.5 mg boron supplement, while nine male bodybuilders, aged 21–27, were given a placebo for 7 weeks. Because both groups demonstrated significant increases in total testosterone ($P < 0.01$), lean body mass ($P < 0.01$), one repetition maximum squat ($P < 0.001$) and bench press ($P < 0.01$), the authors concluded that the gains were a result of 7 weeks of bodybuilding, not of boron supplementation.^[35]

[Table 68.2](#) lists boron’s impact on selected hormones in either animals or humans. Some of these interactions have only been demonstrated in animal models (*) while others have not been demonstrated unequivocally to date in all age and gender segments of a human population (**).

TABLE 68-2 -- Boron’s observed impact on selected hormones

| Hormone | Increases | Decreases |
|-------------------------|-----------|-----------|
| Alkaline phosphatase | | + |
| Aspartate transaminase* | | + |
| Calcitonin | | + |
| Cholecalciferol | | + |
| Creatine kinase* | + | |
| 17 beta-estradiol** | + | |
| Insulin* | | + |
| Super oxide dismutase | | + |
| Testosterone** | | + |
| Thyroxine* | | + |

CLINICAL APPLICATIONS

Osteoporosis

A considerable body of evidence has shown that both compositional and functional properties of bone are affected by boron status.^[36] In experimental animals, histologic

findings suggest that supplemental boron enhances maturation of the growth plate.^[24] Boron is also found at the highest concentrations in growing and calcifying areas of long bones.^[4] In two human studies, boron deprivation caused changes in indices associated with calcium metabolism in a manner that could be construed as being detrimental to bone formation and maintenance; these changes were enhanced by a diet low in magnesium.^[4] ^[24] The author concluded that boron and magnesium are apparently needed for optimal calcium metabolism and are thus needed to prevent the excessive bone loss which often occurs in postmenopausal women and older men.^[24]

Osteoarthritis and rheumatoid arthritis

A dietary boron deficiency may be a contributing factor in some cases of arthritis.^[37] In areas of the world where boron intake routinely is 1.0 mg/day or less, the estimated incidence of arthritis ranges from 20 to 70%, whereas in areas of the world where boron intake ranges from 3–10 mg/day, the estimated incidence of arthritis ranges from 0 to 10%.^[37]

Analytical evidence indicates that persons with arthritis have lower boron concentrations in femur heads, bones, and synovial fluid when compared with persons without this disorder. There have also been observations that bones of patients using boron supplements are much harder to cut than those of patients not supplementing with boron.^[3]

In 1961, the first anecdotal evidence suggesting that boron may be beneficial for osteoarthritis was presented when one patient had reduction of swelling and stiffness and remained symptom free for 1 year following supplementation with 3 mg of elemental boron twice daily for 3 weeks. A human study also offers evidence that boron supplementation may be beneficial in the treatment of this condition. In a double-blind placebo-controlled trial of 20 subjects with osteoarthritis, 50% of subjects receiving a daily supplement containing 6 mg of boron noted a subjective improvement in their condition. Only 10% of those receiving the placebo improved during the same time interval. There was greater improvement in the condition of all joints ($P < 0.01$) as well as less pain on movement ($P < 0.001$) in subjects receiving the boron supplementation.^[38]

Clinical observations indicate that children with juvenile arthritis (Still's disease) improve with boron supplementation (6–9 mg/day) in 2–3 weeks, while adults with osteoarthritis may require 2–4 months of supplementation before benefits are detected. Persons with rheumatoid arthritis may experience an aggravation of symptoms (Herxheimer response) for 1–3 weeks, but generally notice improvement within 4 weeks of beginning boron supplementation.^[3]

DOSAGE

The optimal dose of boron for prevention of osteoporosis and proper physiological function appears to be 3–6 mg/day. While it is best to obtain boron by means of a diet with an abundance of fruits, vegetables, legumes, and nuts, persons whose diet is

limited in these items may need a supplement containing 3 mg of elemental boron. In patients with arthritis, a trial period of 2–4 months with a dose of 3 mg of boron t.i.d. seems to be indicated.

TOXICOLOGY

Although boron is potentially toxic to all organisms, and, as boric acid and borax, has been used as a pesticide and food preservative, higher animals usually do not accumulate boron because of their ability to rapidly excrete it.^[9] Authenticated cases of poisoning in humans have been few and have primarily been the result of accidental ingestion of insecticides and household products containing borates, or use of large amounts of boric acid in the treatment of burns.^[39]

The improper use of boric acid-containing antiseptics is still one of the most common causes of toxic accidents in newborns and infants. Since boric acid is readily absorbed through damaged skin, it should not be applied topically to extensive wounds.^[12]

In animals, chronic low-level boron exposure has been shown to cause reduced growth, cutaneous disorders, and suppression of male reproductive system function.^[40] Studies indicate that male rodents suffer testicular atrophy with dietary exposure to boric acid above 4,500 ppm and have decreased sperm motility at all exposure levels above 1,000 ppm.^[41]

Goats orally dosed with toxic but sublethal amounts of

boron show significant increases in packed cell volume, hemoglobin, inorganic phosphate, creatine phosphokinase, conjugated bilirubin, sodium, glucose, cholesterol, and aspartate transaminase. Several serum components were significantly decreased after boron dosing, including alkaline phosphatase, magnesium, glutamyltransferase and potassium. There was also an elevation of cerebrospinal fluid monoamine metabolites.^[42]

Humans given 100 mg of boron intravenously or 270 mg of boric acid orally reported no discomfort and showed no obvious signs of toxicity.^[43] ^[44] Airborne exposures to boron oxide and its hydration product, boric acid, have been reported to cause respiratory and eye irritation.^[45] A fatal outcome has been reported following ingestion of 1 g of boric acid by a child; however, adults have survived acute intakes of nearly 300 g.^[46]

Common signs and symptoms of acute boron toxicity include nausea, as well as vomiting and diarrhea which are blue-green in color.^[46] Other symptoms seen with acute exposure are abdominal pain, an erythematous rash involving both the skin and mucous membranes, stimulation or depression of the central nervous system, convulsions, hyperpyrexia, renal tubular damage, abnormal liver function, and jaundice.^[12] Increased urinary riboflavin excretion has also been reported subsequent to acute boric acid

ingestion.^[47] Symptoms of chronic intoxication include anorexia, gastrointestinal disturbances, debility, confusion, dermatitis, menstrual disorders, anemia, convulsions, and alopecia.^[12]

Because of its ability to increase the excretion of boron, in cases of toxicity, *N*-acetylcysteine is the preferred intervention. ^[48]

SUMMARY

Although the skeletal response to boron is modified by other nutritional variables such as calcium, magnesium, vitamin D, methionine, and arginine, there is considerable evidence that both compositional and functional properties of bone are affected by boron status.

Findings suggest that boron is an important nutrient not only for mineral metabolism but also for varied aspects of optimal health in humans. While all published trials are not in agreement on the impact of boron supplementation on levels of 17 beta-estradiol and testosterone, evidence strongly suggests that boron deficiency results in decreased levels in postmenopausal women, while supplementation tends to normalize levels in these same women. Boron's impact on sex hormones in other segments of the population is still equivocal. No evidence exists to suggest boron supplementation will act pharmaceutically to increase levels of either 17 beta-estradiol or testosterone above normal physiological levels.

Based on available information, boron appears to offer benefits in the prevention of osteoporosis and arthritis. It is also a safe and potentially effective mineral to consider in any treatment regimen for rheumatoid and osteoarthritis.

Chapter 69 - Bromelain

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

Proteolytic enzyme of *Ananas comosus* (family: Bromeliaceae)
Synonyms: bromelin, plant protease concentrate

GENERAL DESCRIPTION

Bromelains are sulfhydryl proteolytic enzymes obtained from the pineapple plant. Commercial bromelain is usually derived from the stem, which differs from the bromelain derived from the fruit. Commercial bromelain is a mixture of several proteases (including carboxypeptidase) and small amounts of several non-proteolytic enzymes (acid phosphatase, peroxidase and cellulase), polypeptide protease inhibitors, and organically bound calcium. Japan, Taiwan, and Hawaii are the major suppliers of commercial bromelain.^[1]

CHEMICAL COMPOSITION

Stem bromelain (in its purified form) is a basic glycoprotein with one oligosaccharide moiety and one reactive sulfhydryl group per molecule. It has a molecular weight of 28,000, and its isoelectric point is pH 9.55. It exhibits activity over the pH range of 3–10, with optimal activity being between 5 and 8, depending on the substrate.^[1]

Fruit bromelain is an acidic protease (isoelectric point pH 4.6). Its status as a glycoprotein is still in dispute and its molecular weight has been reported as 18,000 by one group of investigators and 31,000 by another.^[1]

HISTORY

Bromelain was introduced as a therapeutic agent in 1957, and since that time over 200

scientific papers on its therapeutic applications have appeared in the medical literature.^[2]^[3] Many of the early studies were with Ananase (Rorer), an enteric-coated bromelain tablet. Later studies implied that the failure of bromelain in some of these early studies was due to the enteric coating and inadequate dosages.

620

PHARMACOLOGY

Commercial bromelain has been reported to exert a wide variety of pharmacological effects:^[1]^[2]^[3]

- digestion assistance
- anti-inflammatory activity
- burn debridement
- prevention of induced pulmonary edema
- smooth muscle relaxation
- inhibition of blood platelet aggregation
- enhancement of antibiotic absorption
- cancer prevention and remission
- ulcer prevention
- sinusitis relief
- appetite inhibition
- shortening of labor
- enhanced wound healing.

Most of these are discussed below.

Activating and deactivating factors

Being sulfhydryl proteases, like papain and ficin, both stem and fruit bromelains are inhibited by oxidizing agents, such as hydrogen peroxide, methyl bromide, and iodoacetate, and by certain metallic ions, such as lead, mercury, cadmium, copper, and iron. Bromelain is also inhibited by human serum both in vivo and in vitro. Magnesium and cysteine are activators of commercial bromelain.^[1]

Activity

The activity of bromelain is expressed in a variety of enzyme units. The use of milk clotting units (mcu) is the officially recognized method in the Food Chemistry Codex (FCC). Different grades of bromelain are available based on mcu.

Absorption

Bromelain has been shown to be absorbed via a number of routes, and has been

effectively administered orally, parenterally, and through intravenous infusion.^{[4] [5] [6]} Experiments with dogs have shown oral administration to result in peak levels at 10 hours, while detectable levels are still apparent at 48 hours. Intravenous infusion peaks in 50 minutes and remains detectable for 5 hours.^[5] There is definite evidence that, in both animals and humans, up to 40% of the absorbed orally administered bromelain can be absorbed intact.^{[4] [5] [6]}

Digestive activity

Bromelain is quite effective as a substitute for trypsin or pepsin in cases of pancreatic insufficiency and post-pancreatectomy.^[2] Because of bromelain's wide pH activity, it can act on substrates in the low pH of the stomach as well as in the high pH of the small intestine. The combination of bromelain with pancreatin and ox bile has been demonstrated via double-blind studies to be highly effective in the treatment of patients with pancreatic insufficiency.^[7]

Anti-inflammatory activity

Several mechanisms may account for bromelain's anti-inflammatory effects:

- activation of proteolytic activity at sites of inflammation (although bromelain's proteolytic actions are inhibited by serum factors)
- fibrinolysis activity via the plasminogen-plasmin system
- depletion of kininogen
- inhibition of biosynthesis of pro-inflammatory prostaglandins and induction of prostaglandin E₁ accumulation (which tends to inhibit the release of PMN lysosomal enzymes).^{[3] [8] [9]}

The first hypothesis has not been substantiated, while the latter three may be part of the same mechanism of action. After tissue injury the kinin, complement, fibrinolytic, and clotting systems are activated. These systems are closely interrelated via activation of the Hageman factor (XII) and feedback mechanisms.

Fibrin's role in promotion of the inflammatory response is to form a matrix that walls off the area of inflammation, resulting in blockage of blood vessels and inadequate tissue drainage and edema; while the kinin system cascade causes the production of kinins (e.g. bradykinin and kallidin), which increase vascular permeability, causing edema as well as evoking pain. Bromelain activates fibrinolysis by stimulating plasmin production (see [Fig. 69.1](#)), resulting in depolymerization of fibrin and thereby preventing fibrin-clogged venous stasis and localized edema.^{[8] [9] [10] [11]} Plasmin has been shown to block the mobilization of endogenous arachidonic acid by phospholipases, thereby reducing platelet aggregation and possibly other prostaglandin-mediated phenomena.^[12] Bromelain has also been shown to reduce plasma kininogen, resulting in inhibition in the production of kinins.^[13] The depletion of kininogen has been demonstrated to significantly reduce edema.

These actions, the activation of plasmin and the reduction of kinin levels, are probably

the main pharmacological effects of bromelain. Bromelain's ability to reduce inflammation has been documented in a variety of experimental models and clinical studies.

Inhibition of platelet aggregation

Bromelain has been demonstrated to be a potent inhibitor of platelet aggregation, both in vitro and in vivo.^[14]

Figure 69-1 Bromelain's effects on the fibrin and kinin pathways.

Again, this is probably due to its plasmin-increasing effects. Plasmin is known to inhibit platelet aggregation by blocking the mobilization of arachidonic acid from membrane-bound phospholipid pools.^[12] Platelet aggregation is a major factor in atherogenesis (see [Ch.133](#)). Bromelain supplementation (in conjunction with potassium and magnesium) has been reported to be quite effective in treating angina (see also [Table 69.1](#)).^[15]

Antibiotic, mucolytic, and permeability-modifying activities

Bromelain has been shown in clinical studies to increase serum levels of a variety of antibiotics (e.g. amoxycillin, tetracycline, and penicillin) in many different tissues and body fluids (e.g. cerebral spinal fluid, sputum,

TABLE 69-1 -- Diseases and conditions in which bromelain has documented clinical efficacy^{[1] [2] [3] [4] [5] [6] [7] [8] [9] [10] [11] [12] [13] [14] [15] [16] [17] [18] [19] [20] [21] [22] [23] [24] [25] [26] [27] [28] [29] [30] [31] [32] [33] [34]}

- Angina

- Sinusitis

- Dysmenorrhea

- Staphylococcal infection

- Ecchymosis

- Surgical trauma

- Edema

- Thrombophlebitis

mucus, blood, urine, uterus, salpinx, ovary, gall bladder, appendix, and epithelial tissue).^[16] ^[17] ^[18] In these studies the researchers concluded that bromelain itself possesses significant effects. Bromelain was as effective as antibiotics in treating a variety of infectious processes, i.e. pneumonia, perirectal abscess, cutaneous staphylococcus infection, pyelonephritis, and bronchitis.^[16]

CLINICAL APPLICATIONS

As is evident, bromelain has wide-ranging clinical utility. Bromelain is particularly effective in virtually all inflammatory conditions, regardless of etiology, including those resulting from physical trauma, infectious agents, surgical procedures, immunological reactions, and prostaglandin metabolism.

Respiratory tract diseases

It appears that bromelain's mucolytic activity is responsible for its particular effectiveness in respiratory tract diseases.^[19] In the treatment of chronic bronchitis, bromelain was shown to have an antitussive effect and to reduce the viscosity of sputum. Spirometric examination of patients before and after treatment indicated increased vital capacity and FEV₁, while the residual volume was reduced. These favorable effects were believed to be the results of enhanced resolution of respiratory congestion, due to bromelain's ability to fluidify and decrease bronchial secretions.

Acute sinusitis has also responded to bromelain therapy. Good-to-excellent results were obtained in 87% of bromelain-treated patients, compared with 68% of the placebo group.^[20]

Thrombophlebitis

Numerous investigators have demonstrated that orally administered bromelain has a potent favorable effect on acute thrombophlebitis, deep vein thrombosis, cellulitis, ecchymosis, and edema.^{[15] [21] [22] [23]} In a double-blind study involving 73 patients with acute thrombophlebitis, bromelain, as an adjunct to analgesics, was shown to reduce all the symptoms of inflammation: pain, edema, redness, tenderness, elevated skin temperature, and disability.^[21] In this study and others, the common daily dose of bromelain was 60–160 mg of 1,200 mcu bromelain. According to some researchers, doses of 400–800 mg are needed to achieve consistent results in patients with thrombophlebitis; this probably holds true for most other conditions.^[15]

Surgical procedures and athletic injuries

The effect of orally administered bromelain on the reduction of edema, bruising, healing time, and pain following various surgical procedures has been demonstrated in several clinical studies.^{[24] [25] [26] [27]} Tassman's studies of patients undergoing oral surgery concluded that, while post-surgical medication alone is effective, a regimen of pre- and post-surgical medication is recommended.^{[24] [25]} In a double-blind study of patients undergoing oral surgery, bromelain was found to be significantly superior to placebo: swelling decreased in 3.8 days with bromelain, compared with 7 days for the placebo; and the duration of pain was reduced to 5.1 days in the bromelain group, compared with 8.1 in the placebo.^[25] Similar observations were made in studies of episiotomy cases. Bromelain reduced edema, inflammation, and pain, and pre-operative administration potentiated the effects.^[26]

Bromelain has been used in a variety of sports-related injuries. A 1960 study involving boxers highlights its effects.^[27] Among the 74 boxers receiving bromelain, in 58 all signs of bruising cleared completely within 4 days. In the remainder, complete clearance took 8–10 days. Among the 72 controls, at the end of 4 days only 10 showed bruises completely cleared, the remainder taking 7–14 days. It is important to recognize that, while bromelain has been shown to effectively reduce pain, this probably is the result of a reduction in tissue inflammation and edema, rather than a direct analgesic effect.

In a recent open clinical trial, 59 patients with blunt injuries to the musculoskeletal system (e.g. contusions, muscle strains, ligament tears) were given 500 mg of bromelain three times daily, 30 minutes before meals. Swelling, pain at rest and during motion, signs of inflammation, and tenderness to palpation all rapidly improved.^[28]

Dysmenorrhea

Bromelain and papain have been used successfully in the treatment of dysmenorrhea.^[29] Bromelain is believed to be a smooth muscle relaxant, since it decreases the spasms of the contracted cervix in these patients. Failure of the

bromelain protease, when used alone (purified by adsorption), to produce this effect was the first indication that the pharmacologically important factor is not the main protease. The muscle-relaxing effects of bromelain on the uterus are believed to be a result of decreasing prostaglandins of the 2-series, e.g. PGF_{2a} and PGE₂, while increasing levels of PGE₁-like compounds.^[3]

DOSAGE

Unless bromelain is being used as a digestive aid, administration should be on an empty stomach (between meals). The dosage depends largely on the potency of the bromelain preparation. Most currently available bromelain is in the 1,800–2,000 mcu range, with the typical dosage being 125–450 mg t.i.d. between meals.

TOXICITY

Very large doses of bromelain (nearly 2.0 g) have been given with no side-effects.^[30] It is virtually non-toxic, as no LD₅₀ exists up to 10 g/kg. Chronic use appears to be well tolerated. Although no significant side-effects have been noted, as with most therapeutic agents, allergic reactions may occur in sensitive individuals or with prolonged occupational exposure.^{[31] [32]}

Bromelain can induce IgE-mediated respiratory and gastrointestinal allergic reactions, as well as cross-react with papain, wheat flour, rye flour, grass pollen, and birch pollen.^{[31] [32]} While side-effects are seldom observed, sensitivity manifested by urticaria or skin rash has occurred. There are no reported cases of anaphylactoid reactions. Other possible, but unconfirmed, reactions include nausea, vomiting, diarrhea, metrorrhagia, and menorrhagia.^[33]

Chapter 70 - *Camellia sinensis* (green tea)

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

Camellia sinensis (family: Theaceae)
Common names: green tea

GENERAL DESCRIPTION

Both green tea and black tea are derived from the same plant, the tea plant (*Camellia sinensis*). The tea plant originated in China, but is now grown and consumed worldwide. The tea plant is an evergreen shrub or tree that can grow up to a height of 30 feet, but is usually maintained at a height of 2–3 feet by regular pruning. The shrub is heavily branched with young hairy leaves. Parts used are the leaf bud and the two adjacent young leaves together with the stem, broken between the second and third leaves. Older leaves are considered of inferior quality.

Green tea vs. black tea

Green tea is produced by lightly steaming the freshly cut leaf, while black tea is produced by allowing the leaves to oxidize. During oxidation, enzymes present in the tea convert many polyphenolic therapeutic substances to compounds with much less activity. With green tea, oxidation is not allowed to take place because the steaming process inactivates these enzymes. Green tea is very high in polyphenols with potent antioxidant and anti-cancer properties. Oolong tea is a partially oxidized tea.

Of the nearly 2.5 million tons of dried tea that are produced each year, only 20% are green tea. India and Sri Lanka are the major producers of black tea. Green tea is produced and consumed primarily in China, Japan, and a few countries in North Africa and the Middle East.

CHEMICAL COMPOSITION

The chemical composition of green tea varies with climate, season, horticultural practices, and age of the leaf (position of the leaf on the harvested shoot). The

626

major components of interest are the polyphenols.^[1] ^[2] The major polyphenols in green tea are flavonoids, e.g.:

- catechin
- epicatechin
- epicatechin gallate
- epigallocatechin gallate
- proanthocyanidins.

Epigallocatechin gallate is viewed as the most significant active component. The leaf bud and the first leaves are richest in epigallocatechin gallate. The usual concentration of total polyphenols in dried green tea leaf is around 8–12%.

Other compounds of interest in dried green tea leaf include:

- caffeine (3.5%)
- an unusual amino acid known as theanine (one-half of the total amino acid content which is usually 4%)
- lignin (6.5%)
- organic acids (1.5%)
- protein (15%)
- chlorophyll (0.5%).

One cup of green tea usually contains about 300–400 mg of polyphenols and between 50 and 100 mg of caffeine.

Commercial preparations are available that have been decaffeinated and concentrated for polyphenols to between 60 and 80% total polyphenols.

PHARMACOLOGY

Most of the epidemiological and experimental studies on tea have focused on the cancer-causing and cancer-protective aspects. Green tea polyphenols are potent antioxidant compounds which have demonstrated greater antioxidant protection than vitamin C and E in experimental studies.^[3]

In addition to exerting antioxidant activity on its own, green tea may increase the activity

of antioxidant enzymes. In mice, oral feeding of a polyphenolic fraction isolated from green tea in drinking water for 30 days resulted in significantly increased activities of antioxidant and detoxifying enzymes (glutathione peroxidase, glutathione reductase, glutathione-S-transferase, catalase, and quinone reductase) in the small intestine, liver, and lungs, and in small bowel and liver.^[4]

With regard to cancer, a number of in vitro and experimental models of cancer have shown that green tea polyphenols may offer significant protection.^{[5] [6] [7] [8]} Specifically, green tea polyphenols inhibit cancer by blocking the formation of cancer-causing compounds like nitrosamines, suppressing the activation of carcinogens, and increasing detoxification or trapping of cancer-causing agents. Numerous studies have shown that green tea (including green tea polyphenols and extracts) exert significant inhibitory effects on the formation of nitrosamines in various animal and human models. For example, when human volunteers ingest green tea along with 300 mg sodium nitrate and 300 mg proline, nitrosoproline formation is strongly inhibited.^[9]

CLINICAL APPLICATION

The primary clinical application for green tea is in the prevention of cancer. Epidemiological studies have demonstrated that green tea consumption may be one of the major reasons why the rate of cancer is so low in Japan. In contrast, however, black tea consumption appears associated with a substantial increase in the risk of several forms of cancer. Green tea also appears to be of value in several chronic diseases, especially those of the heart and liver.

Cancer

Green tea

The forms of cancer which appear to be best prevented by green tea are those of the gastrointestinal tract, including cancers of the stomach, small intestine, pancreas, and colon; the lung; and estrogen-related cancers, including most breast cancers.^[10]

A study in Shanghai, China, found a strong inverse association between green tea consumption and various cancers.^[11] For men, compared with non-regular green tea drinkers, the group with the highest green tea consumption had an 18% reduced risk for colon cancer; 28% for rectal cancer; and 37% for pancreatic cancer. In women, the highest group of green tea consumers had a reduced risk of 33% for colon, 43% for rectal, and 47% for pancreatic cancer.

In preventing breast cancer, in vitro studies have shown that green tea extracts have inhibitory effects on the growth of mammary cancer cell lines.^[8] The main anti-cancer action is inhibiting the interaction of estrogen with its receptors. Polyphenol compounds in green tea extracts block the interaction of tumor promoters, hormones and growth factors with their receptors – a kind of sealing-off effect. The sealing-off effect would account for the reversible growth arrest noted in the in vitro studies.

In animal studies, green tea has been shown to very effectively inhibit the lung carcinogenesis induced by injections of asbestos and benzo(a)pyrene. Rats consuming water with 2% green tea experienced a cancer rate of only 16% compared with 46% for those consuming water without green tea extract.^[12]

Black tea

In contrast to green tea's protective effects, population studies seem to indicate that black tea consumption

627

may increase risk for certain cancers (e.g. cancer of the rectum, gall bladder, and endometrium).^{[12] [13]}

For example, in one study, the relationship between black tea consumption and cancer risk was analyzed using data from an integrated series of case-control studies conducted in northern Italy between 1983 and 1990.^[11] The data set included 119 biopsy-confirmed cancers of the oral cavity and throat, 294 of the esophagus, 564 of the stomach, 673 of the colon, 406 of the rectum, 258 of the liver, 41 of the gall bladder, 303 of the pancreas, 149 of the larynx, 2,860 of the breast, 567 of the endometrium, 742 of the ovary, 107 of the prostate, 365 of the bladder, 147 of the kidney, 120 of the thyroid, and a total of 6,147 controls admitted to hospital for acute non-cancerous conditions. The risk of developing cancer due to tea consumption was derived after allowance for age, sex, area of residence, education, smoking, and coffee consumption. Results indicated an increased risk with tea consumption for cancers of the rectum, gall bladder, and endometrium. There was no association with cancers of the oral cavity, esophagus, stomach, bladder, kidney, prostate, or any other site considered.

In another study, men of Japanese ancestry were clinically examined, beginning during the period 1965–1968.^[12] For 7,833 of these men, data on black tea consumption habits were recorded. Since 1965, newly diagnosed cancer incidence cases have been identified: 152 colon, 151 lung, 149 prostate, 136 stomach, 76 rectum, 57 bladder, 30 pancreas, 25 liver, 12 kidney and 163 at other (miscellaneous) sites. Compared with “almost-never” drinkers, men who habitually drink black tea more than once a day had a four times greater chance of developing rectal cancer.^[14]

Cardiovascular and liver disease

A prospective epidemiological study begun in 1986 by researchers in Japan evaluated the relationship between diet and chronic disease in Japanese men aged 40 and older.^[15] As daily green tea intake increased from less than three, to four to nine, to greater than 10 cups/day, significant increases in serum HDL and decreases in LDL lipoproteins were found. In addition, green tea consumption was found to significantly improve liver profiles, with aspartate aminotransferase and alanine aminotransferase

levels decreasing significantly with increasing green tea consumption.

DOSAGE

The normal amount of green tea consumed by Japanese and other green tea drinking cultures is about three cups daily or about 3 g of soluble components providing roughly 240–320 mg of polyphenols. For a green tea extract standardized for 80% total polyphenol and 55% epigallocatechin gallate content, this would mean a daily dose of 300–400 mg.

Note. When selecting commercial products, it is important to look for the level of epigallocatechin gallate, as well as total polyphenol content.

TOXICITY

Green tea is not associated with any significant side-effects or toxicity. As with any caffeine-containing beverage, overconsumption may produce a stimulant effect (nervousness, anxiety, insomnia, irritability, etc.).

TABLE 70-1 -- World tea production by type

| Type | Dry weight (×1000 tons) |
|--------|-------------------------|
| Black | 1,940 |
| Green | 515 |
| Oolong | 60 |
| Total | 2,515 |

Chapter 71 - *Capsicum frutescens* (cayenne pepper)

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

Capsicum frutescens (family: Solanacea)
Common names: cayenne pepper, capsicum, chili pepper, red pepper, American pepper

GENERAL DESCRIPTION

Cayenne pepper (also known as chili or red hot pepper) is the fruit of *Capsicum annuum*, a shrubby, tropical plant which can grow to a height of up to 3 feet. The fruit is technically a berry. Paprika is a milder and sweeter tasting fruit produced from a different variety of *Capsicum*. Although cayenne pepper is native to tropical America, it is now cultivated in tropical locations throughout the world and has found its way into the cuisine of many parts of the world, particularly south-east Asia, China, southern Italy, and Mexico.

CHEMICAL COMPOSITION

The most important constituents of cayenne pepper are the pungent compounds, with capsaicin being the most prominent (see [Fig. 71.1](#)). Typically, cayenne pepper contains about 1.5% capsaicin and related principles. Other active constituents present include carotenoids, vitamins A and C, and volatile oils.

HISTORY AND FOLK USE

The folk use of cayenne pepper is quite extensive. It has been used for:

- asthma
 - fever
-

- sore throats and other respiratory tract infections
- digestive disturbances
- poultices
- cancers.

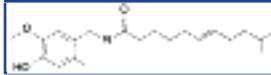

Figure 71-1 Capsaicin.

It was also used as a counter-irritant in the topical treatment of arthritis and neuralgia.

PHARMACOLOGY

The pharmacology of cayenne pepper centers around its capsaicin content. When topically applied to the skin or mucous membranes, capsaicin is known to stimulate and then block small-diameter pain fibers by depleting them of the neurotransmitter substance P. Substance P is thought to be the principal chemomediator of pain impulses from the periphery. In addition, substance P has been shown to activate inflammatory mediators into joint tissues in osteoarthritis and rheumatoid arthritis.^[1]

When taken internally, cayenne pepper exerts a number of beneficial effects on the cardiovascular system. In addition to possessing several antioxidant compounds, studies have shown that cayenne pepper reduces the likelihood of developing atherosclerosis by reducing blood cholesterol and triglyceride levels, and platelet aggregation as well as increasing fibrinolytic activity^{[2] [3] [4]} (for the significance of these effects see [Ch. 133](#)). Cultures consuming large amounts of cayenne pepper have a much lower rate of cardiovascular diseases.

CLINICAL APPLICATIONS

Cayenne pepper should be recommended as a food for its beneficial antioxidant and cardiovascular effects. Although people with active peptic ulcer may be bothered by “spicy” foods containing cayenne pepper, spicy foods in normal individuals do not cause ulcers. In fact, cayenne pepper exerts several beneficial effects on gastrointestinal function, including acting as a digestant and carminative.^[5]

Interestingly, capsaicin, although hot to the taste, has actually been shown to lower body temperature by stimulating the cooling center of the hypothalamus.^[6] The ingestion of cayenne peppers by cultures native to the tropics appears to offer a way for these people to deal with high temperatures.

The modern clinical use of cayenne pepper has focused on the use of topical capsaicin-containing preparations. Commercial ointments containing 0.025 or 0.075%

capsaicin are available over the counter. These preparations may offer significant benefit in a number of conditions, including the pain associated with pain disorders, diabetic neuropathy, cluster headache, osteoarthritis, and rheumatoid arthritis. In addition, topically applied capsaicin may be useful in psoriasis.

Post-herpetic neuralgia

The first studies and approved use for topically applied capsaicin was in relieving post-herpetic neuralgia. Numerous studies now document this FDA approved application. For example, in one study 39 patients with chronic post-herpetic neuralgia (average duration 24 months) were treated with 0.025% capsaicin cream for 8 weeks. During therapy, the patients rated their pain. Nineteen patients (48.7%) substantially improved after the 8 week trial; five (12.8%) discontinued therapy due to side-effects such as intolerable capsaicin-induced burning sensations (four) or mastitis (one); and 15 (38.5%) reported no benefit. The decrease in pain ratings was significant after 2 weeks of continuous application. Of the responders, 72.2% were still improved 10–12 months after the study; with most continuing to apply the cream regularly.

In general, the results of this study are consistent with other studies, i.e. about 50% of people with post-herpetic neuralgia respond to topically applied capsaicin (0.025%).^{[7] [8] [9] [10] [11]} Although this may not be a great response, it is better than the 10% response noted in the placebo group. Higher concentration (0.075 vs. 0.025%) may produce better results (as high as 75% response).^[12]

Trigeminal neuralgia

Topically applied capsaicin may be effective in reducing the pain of trigeminal neuralgia.^[13] In one study, 12 patients were followed up for 1 year after the topical application over the painful area of capsaicin three times a day for several days. Six patients had complete and four patients had partial relief of pain; the remaining two patients had no relief of pain. Of the 10 patients who were responsive to therapy, four had relapses of pain within 95–149 days. There were no relapses following the second therapy for the remainder of the year. These results are quite promising for a condition that usually does not respond to any therapy short of surgery.

Post-mastectomy pain

Topically applied capsaicin may help in the relief of pain after breast reconstruction or mastectomy. In one double-blind study, 23 patients with post-mastectomy pain syndrome (PMPS) applied either capsaicin (0.075%) or vehicle-only cream four times daily for 4–6 weeks.^[14] There was a significant difference in jabbing pain, in category pain severity scales, and in overall pain relief scales in favor of capsaicin. Five of 13 patients on capsaicin were categorized as good-to-excellent responses, with eight (62%) having 50% or greater improvement. Only one of 10 cases had a good response to vehicle, with three rated as 50% or better.

In another study, 14 patients with post-mastectomy pain had significant pain relief following application of 0.025% capsaicin cream four times daily for 4–6 weeks.^[15] Unpleasant or painful sensations to light touch or pressure in the painful area (hyperaesthesia, allodynia) were also improved.

Mouth pain due to chemotherapy or radiation

In a study conducted at the Yale Pain Management Center, capsaicin was shown to dramatically reduce the pain from mouth sores as a result of chemotherapy or radiation treatment.^[16] The interesting feature in this study was the vehicle used to deliver the capsaicin – taffy. The researchers chose taffy because it could be held in the mouth long enough to desensitize the neurons, its sugar decreased the initial burning sensation, and its soft edges would not aggravate sore mouths like a hard candy. All 11 patients in the Yale study said their pain decreased – in two cases stopping entirely – after eating the capsaicin-laced candy.

Diabetic neuropathy

Topically applied capsaicin has been shown to be of considerable benefit in relieving the pain of diabetic neuropathy in numerous double-blind studies.^{[17] [18] [19] [20] [21] [22]} In one large double-blind 8 week study, investigators at 12 sites enrolled 277 men and women with painful diabetic neuropathy of the hands and feet; 69.5% of the group applying the capsaicin cream (0.075%) showed improvement compared with 53.4% in those applying only the vehicle cream.

In another study, 40 patients applied either 0.075% capsaicin cream or placebo to their affected extremities daily. After 4 weeks, 76% of treated patients had some pain relief, compared with 50% of placebo patients. In addition, those responding to capsaicin said their pain was cut in half, while those on placebo averaged between 15 and 20% relief.

Cluster headaches

Several studies have found that intranasal application of capsaicin ointment by a physician may relieve cluster headaches. In one double-blind study, patients in acute cluster were randomized to receive either capsaicin or placebo in the nostril for 7 days.^[23] Patients recorded the severity of each headache for 15 days. Headaches on days 8–15 of the study were significantly less severe in the capsaicin group versus the placebo group. There was also a significant decrease in headache severity in the capsaicin group on days 8–15 compared with days 1–7, but not in the placebo group. Episodic patients appeared to benefit more than chronic patients.

Arthritis

Topically applied capsaicin may be effective in relieving the pain of osteoarthritis and rheumatoid arthritis. While one study showed it to be more effective in osteoarthritis, another study showed just the opposite.

In the double-blind study showing more effect in osteoarthritis, seven patients with rheumatoid arthritis and 14 patients with osteoarthritis who had painful involvement of the hands applied either capsaicin 0.075% or vehicle-only cream to the hands four times daily. Capsaicin reduced tenderness and pain associated with osteoarthritis, but not rheumatoid arthritis.^[24]

In the study showing greater benefit for rheumatoid arthritis, 70 patients with osteoarthritis and 31 with rheumatoid arthritis received capsaicin or placebo for 4 weeks.^[25] The patients were instructed to apply 0.025% capsaicin cream or its vehicle (placebo) to painful knees four times daily. Significantly more relief of pain was reported by the capsaicin-treated patients than the placebo patients throughout the study; after 4 weeks of capsaicin treatment, rheumatoid and osteoarthritis patients demonstrated mean reductions in pain of 57 and 33%, respectively. These reductions in pain were statistically significant compared with those reported with placebo. According to overall evaluations, 80% of the capsaicin-treated patients experienced a reduction in pain after 2 weeks of treatment.

Psoriasis

Excessive substance P levels in the skin have been linked to psoriasis. This finding prompted researchers to study the effects of topically applied capsaicin. In one double-blind study, 44 patients with symmetrically distributed psoriasis lesions applied topical capsaicin to one side of their body and a placebo to the other side.^[26] After 3–6 weeks, significantly greater reductions in scaling and redness were observed on the capsaicin side. Burning, stinging, itching, and skin redness were noted by nearly half of the patients initially, but these diminished or vanished upon continued application.

In a more recent study, 197 patients applied capsaicin 0.025% cream or placebo cream four times a day for 6 weeks.^[27] Efficacy was based on a physician's evaluation and a combined psoriasis severity score including scaling, thickness, erythema, and pruritus. Capsaicin-treated patients demonstrated significantly greater improvement in physician's evaluation and in pruritus relief, as well as a significantly greater reduction in combined psoriasis severity.

DOSAGE

Cayenne pepper can be used liberally in the diet. Creams containing 0.025 or 0.075% capsaicin can be applied to affected areas up to four times daily.

TOXICITY

Cayenne pepper is generally recognized as safe (GRAS) in the US. Topically applied capsaicin may produce a local burning sensation; however, this effect will go away with time and rarely is severe enough to mean that use of the cream cannot be continued. This was the only adverse effect noted.

Chapter 72 - Carnitine

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

INTRODUCTION

Carnitine is an essential nutrient for the transport of long-chain fatty acids into the mitochondrial matrix. Carnitine (beta-hydroxy/gamma-butyrobetaine) was originally isolated from meat extracts in 1905 and its exact chemical structure was determined in 1932 (see [Fig. 72.1](#)). However, despite extensive physiological and pharmacological studies in the 1930s, no physiological role for carnitine could be determined.^{[1] [2] [3]} Carnitine's role in human physiology remained a mystery until nearly 50 years after its discovery.

The compound was virtually forgotten until Carter et al^[4] created new interest in carnitine in 1952 when they established it as a growth factor for the meal worm *Tenebrio molitor* (hence carnitine's other name vitamin BT). When other species of organisms were also shown to be dependent on carnitine, researchers began to re-examine its role in humans.

Researchers soon found that carnitine was essential in the oxidation of lipids.^{[1] [2] [3]} When the first carnitine-deficient human subjects were described in 1973, it stimulated greater investigation.^[5] It had always been assumed that an individual could synthesize adequate amounts of carnitine, ingest adequate amounts of dietary carnitine, or meet needs by a combination of both. The discovery that some individuals required supplemental carnitine to maintain normal energy metabolism has resulted in the need to consider carnitine as a vitamin or essential.^[6]

Since carnitine can be synthesized (as described below)

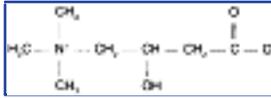

Figure 72-1 L-Carnitine.

634

from the essential amino acid lysine, many nutritionists and researchers have argued that it should not be considered a vitamin. Others argue that if niacin, which can be synthesized from the essential amino acid tryptophan, can be labelled a vitamin then so should carnitine.

BIOSYNTHESIS

Carnitine is synthesized in humans from lysine with the aid of another essential amino acid, methionine. In non-mammalians, carnitine synthesis begins with stepwise methylation of free lysine by S-adenosyl-methionine to produce trimethyllysine. In mammals, however, protein bound trimethyllysine, rather than free lysine, appears to be the major precursor for carnitine synthesis.^{[1] [2] [3]}

Trimethyllysine is then converted through a series of enzymatic reactions to butyrobetaine. This can occur in the liver, kidney, brain, heart, and skeletal muscle. However, the conversion of butyrobetaine to carnitine can only occur in the liver, kidney, and brain, as the enzyme required, butyrobetaine hydroxylase, is only present in these tissues.^{[1] [2] [3]}

The synthesis of carnitine is largely controlled by the activity of butyrobetaine hydroxylase. This enzyme appears to be age-dependent. In infancy, the activity of butyrobetaine hydroxylase has been shown to be only 12% of the normal adult mean. By 2.5 years, the activity is 30% of the adult mean, and by 15 years the level is within the standard deviation of the adult mean.^{[1] [2] [3]} This data would seem to indicate the importance of preformed-carnitine in breast milk.

As is apparent from [Figure 72.2](#), two essential amino acids (lysine and methionine), three vitamins (ascorbate, niacin, and vitamin B₆), and a metal ion (reduced iron) are required for the synthesis of carnitine. Obviously, a deficiency of any one of these nutrients would result in significantly impaired carnitine synthesis.^{[1] [2] [3]}

METABOLISM

Transportation into tissues

The heart and skeletal muscles, as well as many other tissues, depend primarily on fatty acid oxidation as a source of energy. Since they cannot synthesize carnitine, its transport into these tissues is of critical importance.

Specific carnitine binding transport proteins have been identified for several tissues, e.g. cardiac muscle, skeletal muscle, epididymis, liver, and kidney.^{[1] [3]} The transport proteins facilitate the transfer of carnitine from the serum into the cells via carrier-mediated transport mechanisms. This active transport mechanism allows the tissues to concentrate carnitine at levels 10 times greater than those found in the plasma.

Figure 72-2 Biosynthesis of carnitine.

Excretion and degradation

Urinary excretion of unchanged carnitine is the major route of elimination of carnitine. As the tubular reabsorption of carnitine by the kidneys is extremely efficient, the daily turnover of carnitine is estimated to be only 4–6% of the total body pool of the healthy individual.^{[1] [2] [3]} Factors which increase carnitine excretion and degradation are discussed below under causes of carnitine deficiency.

PHYSIOLOGICAL FUNCTIONS

Carnitine's basic function is in the transport of longchain fatty acids into the mitochondrial matrix and the facilitation of beta-oxidation.^{[1] [2] [3]} As acyl-CoA formed in the endoplasmic reticulum or outer mitochondrial membrane cannot penetrate the inner mitochondrial membrane to the site of fatty acid beta-oxidation, the acyl group must be transferred from CoA to carnitine. The acyl-carnitine molecule then transports the fatty acid molecule to the mitochondrial surface of the inner mitochondrial membrane and releases the fatty acid into the matrix where beta-oxidation occurs. This process is summarized in [Figure 72.3](#).

Carnitine has several other physiological functions, including oxidation of the ketoacid analogues of the branched chain amino acids valine, leucine, and isoleucine.^{[1] [2] [3]} This function is extremely important during fasting, starvation, and exercise.

Figure 72-3 Role of carnitine in the transport of long-chain fatty acids through the inner mitochondrial membrane.

Carnitine concentrations are extremely high in the epididymis and spermatozoa, suggesting a role for carnitine in male reproductive function.^{[1] [2] [3]} The epididymis derives the majority of its energy requirements from lipids, as do the spermatozoa, during transport through the epididymis. After ejaculation, spermatocytes depend on glycolysis of glucose and fructose and on oxidation of lactate and pyruvate. Carnitine (in the form of acetylcarnitine which is derived from pyruvate) serves as a readily available substrate. The motility of ejaculated sperm correlates positively with acetylcarnitine content.^{[1] [3]}

DEFICIENCY

Carnitine deficiency may arise from several causes, as listed in [Table 72.1](#) .

Carnitine deficiency states have been classified into two major groups:

- systemic carnitine deficiency
- myopathic deficiency.

Diagnosis of systemic carnitine deficiency can be made using serum or 24 hour urine samples. Total, free, and esterified carnitine levels should be determined. In myopathic carnitine deficiency, diagnosis requires skeletal muscle biopsy.^[7]

To date, no patients with primary systemic carnitine deficiency have been identified. The systemic deficiency has always been secondary to some other factor rather than a defect in carnitine synthesis.^{[1] [2] [3] [7] [8]}

The consequences of systemic carnitine deficiency are impaired lipid metabolism and lipid accumulation in the skeletal muscles, myocardium, and liver. Progressive muscle weakness with lipid storage myopathy is found in all patients.^{[1] [2] [3] [7]} In adults, auxiliary non-mitochondrial oxidation mechanisms are apparently stimulated, resulting in some degree of adaptation. This adaptation occurs in starvation, diabetes, high fat diets, and other causes of secondary carnitine deficiency. Systemic carnitine deficiencies usually respond dramatically to orally administered supplemental L-carnitine. ^{[7] [8]}

Children are apparently unable to adapt to low carnitine levels as well as adults.^[7] Several cases of carnitine deficiency in children, presenting a clinical picture resembling Reye's syndrome (acute encephalopathy associated with altered liver function due to

lipid accumulation), have been reported.^{[8] [9] [10]}

The clinical presentation of secondary carnitine deficiency in children includes hypotonia, failure to thrive, recurrent infections, encephalopathy, nonketotic hypoglycemia, and cardiomyopathy.^[7] Several fatal cases of systemic carnitine deficiency have been reported.^{[8] [11]}

In primary myopathic carnitine deficiency, there is an inborn error of carnitine metabolism that is limited to skeletal muscle.^{[7] [8]} The defect appears to be in the transport of carnitine into the skeletal muscle as serum carnitine, and the carnitine levels in other tissues are normal. Severe lipid-storage myopathy is the result.

Supplemental carnitine is generally of no value in myopathic carnitine deficiency. Rather, improvements have been noted using diets high in medium-chain triglycerides and low in long-chain triglycerides.^[7]

CARNITINE AS A NUTRIENT

Carnitine in the infant diet

It is well known that oxidation of long-chain fatty acids, which requires carnitine, is critical to the survival and

TABLE 72-1 -- Causes of carnitine deficiency

-
- Dietary deficiency of the precursor amino acids lysine and methionine

 - Deficiency of any cofactor (such as iron, ascorbic acid, pyridoxine and niacin) required by the enzymes of the lysine to carnitine pathway

 - Genetic defect of carnitine biosynthesis

 - Defective intestinal absorption of carnitine

 - Liver or kidney dysfunction which impairs carnitine synthesis

 - Increased metabolic losses of carnitine due to catabolism, impaired tubular resorption, or genetic defect

 - Defective transport of carnitine from tissues of synthesis to tissues where it is maximally utilized

 - Increased carnitine requirement due to a high fat diet, drugs (e.g. valproic acid), metabolic stress, or disease
-

normal development of the newborn.^[3] Carnitine concentrations in fetal and umbilical cord blood are higher than in maternal blood, suggesting the placenta may actively

transport carnitine to the fetus since carnitine synthesis is not fully developed.^[3] The initial carnitine concentration in the newborn is dependent upon maternal carnitine concentration.

Supplementation of carnitine during pregnancy may be needed to ensure adequate tissue concentrations in the fetus as well as the mother. Serum carnitine levels are typically lower in pregnant women than non-pregnant women, presumably due to increased excretion.^{[12] [13]}

The newborn infant is almost entirely dependent on external sources of carnitine.^[3] Breast-fed infants have the best chance of achieving optimal carnitine concentrations. The bioavailability of carnitine from breast milk is significantly greater than that in cow's milk-based formulas,^[14] and soy-based infant formulas contain no detectable carnitine.^[3] Formula feeding may necessitate supplemental carnitine to achieve normal carnitine concentrations in these infants.

Carnitine administration to preterm infants has potentiated weight gain and growth.^[15] In preterm infants, serum values of carnitine decrease dramatically due to limited storage capacity coupled with a decreased ability to synthesize carnitine. Administration of L-carnitine to preterm infants is thought to be very important.

Dietary carnitine content

Analysis of several hundred foods for carnitine content indicates that meat and dairy products are the major dietary sources of carnitine.^[3] In general, the redder the meat, the higher the carnitine content. Cereals, fruits, and vegetables contain little or no carnitine. Preliminary studies indicate that the daily diet contains 5–100 mg of carnitine.^[3]

CLINICAL APPLICATIONS

Many disease states, in addition to classical as well as secondary carnitine deficiency, may benefit from carnitine administration. There is good evidence to support the assertion that supplemental carnitine may benefit the conditions listed in [Table 72.2](#) and discussed below.

Carnitine is available in several different forms. Always be sure that the form being used is L-carnitine alone or bound to either acetic or propionic acid. Never use the D form of carnitine (discussed below under safety issues). As to which form is best, it really depends upon the objective. For Alzheimer's disease and brain effects, it appears that L-acetylcarnitine (LAC) may provide the greatest benefit. For angina, L-propionylcarnitine (LPC) may be the best choice because the myocardium appears to prefer it to L-acetylcarnitine followed by L-carnitine

TABLE 72-2 -- Conditions which may benefit from carnitine supplementation

- Cardiovascular diseases
-

- Angina pectoris
- Acute myocardial infarction
- Myocardial necrosis
- Arrhythmias and cardiotoxicity induced by drugs
- Familial endocardial fibroelastosis
- Cardiac myopathy
- Idiopathic mitral valve prolapse
- Elevated cholesterol levels
- Elevated triglyceride levels
- Enhancing physical performance
- Alzheimer's disease, senile depression, and age-related memory defects
- Kidney disease and hemodialysis
- Diabetes
- Liver diseases
- Alcohol-induced fatty liver disease
- Liver cirrhosis
- Muscular dystrophies
- Low sperm counts and decreased sperm motility
- Chronic obstructive pulmonary disease
- AIDS
- Inborn errors of amino acid metabolism
- Organic acidurias
- Glutaric aciduria
- Isovaleric acidemia
- Propionicacidemia
- Methylmalonic aciduria
- Toxicity from various drugs

(LC).^[16] ^[17] L-Carnitine is, however, the most widely available, least expensive, and best studied form of carnitine.

Cardiovascular disease

Normal heart function is critically dependent on adequate concentrations of carnitine. A

deficiency of carnitine in the heart would be similar to trying to run an automobile without a fuel pump. There may be plenty of fuel, but there is no way to get it to the engine. While the normal heart stores more carnitine than it needs, if the heart does not have a good supply of oxygen, carnitine levels quickly decrease. This lack of oxygen leads to decreased energy production in the heart and increased risk for angina and heart disease.

Carnitine is useful in angina due to its ability to improve oxygen utilization and energy metabolism by the myocardium. As a result of improving fatty acid utilization and energy production, carnitine also prevents the production of toxic fatty acid metabolites.^[18] These compounds are extremely damaging as they disrupt cellular membranes. Changes in the properties of cell membranes throughout the heart are thought to contribute to impaired contraction of the heart muscle and increased susceptibility to irregular beats, and eventual death of heart tissue. Supplementing the diet with carnitine increases heart carnitine levels and has been shown to prevent the production of fatty acid metabolites which can damage the heart. In addition to angina, all of these

637

effects make carnitine beneficial in recovery from a heart attack, arrhythmias, and congestive heart failure.^[19]

Carnitine also exerts a beneficial effect on blood lipids by lowering triglycerides and total cholesterol levels while raising HDL-cholesterol. After 4 months of therapy with L-carnitine in patients with elevated blood lipids, typical changes observed are a 20% reduction for total cholesterol, a 28% decrease in triglycerides, and a 12% increase in HDL levels.^{[20] [21]} Due to the higher cost of carnitine compared with other natural agents (e.g. inositol hexaniacinate, garlic, and gugulipid), its use should be reserved for those cases unresponsive to these more cost-effective measures.

Carnitine has also been shown to be of benefit in the treatment of intermittent claudication, which is a condition like angina but instead of the pain occurring in the heart it occurs usually in the calf muscle. Like angina, the pain is described as a cramp or tightness. The cause of the pain is reduced oxygen delivery along with an increase in the production of toxic metabolites and cellular free radicals. Its benefits in peripheral vascular disease are the result of improved energy production during ischemia rather than any effect on blood flow. Nonetheless, good results have been obtained in intermittent claudication and other peripheral vascular diseases (discussed below).

Angina

Numerous clinical trials have demonstrated that carnitine improves angina and heart disease (note that all three commercial forms have been used).^{[19] [22] [23] [24] [25] [26] [27] [28]} Supplementation with carnitine normalizes heart carnitine levels and allows the heart muscle to utilize its limited oxygen supply more efficiently. This translates to an improvement in cases of angina. Improvements have been noted in exercise tolerance

and heart function. The results indicate that carnitine is an effective alternative to drugs in cases of angina.

L-Propionylcarnitine (LPC) may offer the greatest benefit in angina, as well as in other cardiovascular conditions. LPC is taken up by myocardial cells much more rapidly than other forms of carnitine.^[16] In one study, LPC (15 mg/kg intravenously) significantly diminished myocardial ischemia as demonstrated by a significant 12 and 50% reduction in ST-segment depression and left ventricular end-diastolic pressure, respectively, during the atrial pacing test.^[29] Left ventricular ejection fraction increased by 18%. Recovery of heart function after exercise occurred much quicker in the LPC group compared with the placebo group.

L-Carnitine and LAC have also shown very good results. In one of the larger studies, 200 patients with exercise-induced stable angina received either standard therapy alone (e.g. nitroglycerine, calcium channel blockers, beta-blockers, antihypertensives, diuretics, digitalis, antiarrhythmics, anticoagulants, and hypolipidemics) or in combination with 2,000 mg a day of L-carnitine over a 6 month period.^[30] Compared with the control group, the patients on L-carnitine exhibited a significant reduction in premature ventricular contractions at rest, as well as an increased tolerance to exercise as demonstrated by an increased maximal cardiac frequency, increased maximal systolic blood pressure, cardiac output, and reduced ST-segment depression (70% reduction in the L-carnitine group vs. no change in the control group). Reductions in LDL-cholesterol (8%) and triglycerides (12%) were also noted. These results are highly significant and provide a strong rationale for the inclusion of carnitine in patients using standard medical therapy.

Recovery from myocardial infarction

In addition to benefiting angina patients, carnitine has also been shown to be useful in helping individuals recover more quickly from a heart attack.^[19] In one double-blind study of 160 patients who had been released from a hospital after a heart attack, the group receiving 4 g of L-carnitine daily showed significant improvements in heart rate, blood pressure, angina attacks, rhythm disturbances, and clinical signs of impaired heart function compared to the control group.^[31]

In Italy, a larger study involving 472 patients showed additional benefits.^[32] The study was performed to evaluate the effects of L-carnitine administration on long-term left ventricular dilation in patients with acute anterior myocardial infarction. Placebo or L-carnitine was given at a dose of 9 g/day intravenously for the first 5 days and then 6 g/day orally for the next 12 months. Left ventricular volumes and ejection fraction were evaluated on admission, at discharge from hospital and at 3, 6 and 12 months after acute myocardial infarction. A significant attenuation of left ventricular dilation in the first year after acute myocardial infarction was observed in patients treated with L-carnitine compared with those receiving placebo. The percent increase in both end-diastolic and end-systolic volumes from admission to 3, 6 and 12 month evaluation was significantly reduced in the L-carnitine group.

Arrhythmias

In double-blind trials, reductions in the use of conventional antiarrhythmic drugs have occurred in patients with angina who have received carnitine.^[19]

Congestive heart failure

Several double-blind clinical studies have shown that carnitine (again, LPC appears to be more effective than LC or LAC) improves cardiac function in patients with

638

congestive heart failure.^[19] In one double-blind study of LPC versus placebo in a group of 60 patients with mild to moderate (II and III NYHA class) congestive heart failure LPC produced demonstrable benefit.^[33] The group was made up of men and women aged between 48 and 73 years in chronic treatment with digitalis and diuretics for at least 3 months and who still displayed symptoms. Thirty of these patients were chosen randomly and for 180 days received 500 mg of LPC three times a day in addition to their usual treatment. At basal conditions and after 30, 90 and 180 days, the maximum exercise time was evaluated using an exercise tolerance test performed on an ergometer bicycle and the left ventricular ejection fraction was tested by means of echocardiography. After 1 month of treatment, the patients treated with LPC, compared with the control group, showed significant increases in the values of both tests, increases which became even more evident after 90 and 180 days. At the stated times, the increases in the maximum exercise time were 16.4, 22.9, and 25.9%, respectively. The ventricular ejection fraction increased by 8.4, 11.6 and 13.6%, respectively.

In another double-blind study in similar patients, at the end of 6 months of treatment, maximum exercise time on the treadmill increased 16.4% and the ejection fraction increased by 12.1% after 180 days in the group treated with PLC at a dosage of 1 g twice daily.^[34]

Peripheral vascular disease

All three forms of carnitine (2–4 g daily) have been shown to improve the walking distance without pain in patients with intermittent claudication. Presumably this improvement is the result of improved energy metabolism within the muscle, as carnitine was not shown to improve blood flow to the calf. LPC appears to offer better effects than either L-carnitine or LAC.^[35] ^[36] However, in one double-blind study, L-carnitine at a dosage of 2 g twice daily demonstrated a 75% increase in walking distance after only 3 weeks of therapy.^[37]

Enhancing physical performance

The ability to enhance exercise tolerance and physical performance with carnitine may not be limited to patients with cardiovascular disease, as carnitine supplementation has also been shown to be of benefit in healthy subjects and athletes. Efficient utilization of fatty acids by skeletal muscle, like the myocardium, is also dependent upon adequate supply of carnitine.

Carnitine supplementation (usually 2 g two to three times daily) has resulted in significant improvements in cardiovascular function in response to exercise in several double-blind studies in both athletes and normal subjects.^[38] ^[39] ^[40] Compared to control groups, the subjects on carnitine have shown not only improvements in exercise intensity or time, but also evidence of improved energy metabolism within the muscle (lowered blood lactic acid and free fatty acid levels). Obviously, the improved production of energy by the exercising muscle as well as improved heart function could be responsible for carnitine's ability to enhance physical performance.

Although at least three studies showed the benefits of carnitine on exercise performance to be no more of value than a placebo, carnitine supplementation should still be viewed as beneficial, especially in endurance-related events.^[41] ^[42] ^[43] The reason behind this statement is the fact that studies have demonstrated that carnitine improves energy producing enzymes levels in long distance runners.^[44] These athletes received either a placebo or 2 g of L-carnitine twice daily for 4 weeks. Runners receiving the L-carnitine showed a significant increase in enzymes involved in energy production (cytochrome c reductase and cytochrome oxidase). In contrast, there were no changes in the placebo group.

It is interesting to note that normal subjects taking carnitine have improved cardiovascular function and a more rapid return of heart rate to the resting rate after exercise.^[45] The significance of these improvements is that it appears that carnitine is able to mimic the benefits in heart and vascular function produced by regular exercise training without working up a sweat.

Alzheimer's disease, senile depression, and age-related memory defect

A great deal of research has been conducted over the last decade with L-acetylcarnitine (LAC) in the treatment of Alzheimer's disease, senile depression, and age-related memory defects. As described above, LAC is a molecule composed of acetic acid and L-carnitine bound together. This reaction occurs naturally in the human brain, and therefore it is not exactly known how much greater an effect is noted with LAC vs. L-carnitine or PAC. However, LAC is thought to be substantially more active than these other forms of carnitine in conditions involving the brain.^[46] ^[47]

LAC is structurally related to acetylcholine, a major neurotransmitter responsible for memory and proper brain function. In Alzheimer's disease, and to a lesser extent the normal aging human brain, there is a defect in the utilization of acetylcholine. The close structural similarity between LAC and acetylcholine led researchers to begin testing LAC

in Alzheimer's disease. The results have been encouraging.

Researchers have now shown that LAC does indeed mimic acetylcholine and is of benefit not only in patients with early-stage Alzheimer's disease, but also in elderly patients who are depressed or who have impaired memory.^[47] It has also been shown to act as a powerful

639

antioxidant within the brain cell, to stabilize cell membranes, to improve energy production within the brain cell as well as enhancing or mimicking the function of acetylcholine.^[48]

The results in delaying the progression of Alzheimer's disease have been outstanding. The studies have been well controlled and extremely thorough.^[46] ^[49] ^[50] ^[51] For example, in one study, LAC (2 g twice daily) or placebo was given to 130 patients with Alzheimer's disease over the course of 1 year.^[51] The patients were evaluated by 14 different outcome measures such as assessment scales, cognitive function tests, memory tests, and physician evaluations. The group receiving the LAC had better outcome scores in all cases.

The memory impairment need not be as severe as in Alzheimer's disease in order for LAC to demonstrate benefit.^[52] ^[53] ^[54] In one double-blind study of 236 elderly subjects with mild mental deterioration, as evident by detailed clinical assessment, the group receiving 1,500 mg of LAC daily demonstrated significant improvement in mental function, particularly in memory and constructional thinking.^[54]

Many of the elderly suffer from depression not only as a result of experiencing a great deal of loss in their lives, but also because of the biochemical changes in the brain associated with aging. LAC has been shown to improve depression in elderly subjects in double-blind studies using assessment scales standard to scientific research of antidepressant drugs (e.g. Hamilton Depression Scale, Clinical Global Impression, Sandoz Clinical Assessment, etc.). The usual dosage has been 500 mg three times daily. Those elderly subjects with the highest depression scores are usually the ones who benefit the most from acetyl-L-carnitine.^[55] ^[56]

Down syndrome

Given that both Down syndrome and Alzheimer's disease are characterized by a deficit in cholinergic transmission, a study was conducted to assess the effect of a 90 day treatment with L-acetylcarnitine (LAC) in individuals with Down syndrome.^[57] Findings were evaluated statistically and compared to three further groups of subjects: untreated Down syndrome, mental deficiency due to other cases treated and not treated with LAC. Treated Down syndrome patients showed statistically significant improvements of visual memory and attention both in absolute terms and in comparison with the other groups. No improvement was found in mentally deficient non-Down subjects, so that the

favorable effect of LAC appears to be specific for Down patients. An effective dosage is 20 mg of LAC for every 2 pounds of body weight. It is suggested that the action of LAC in these pathologies is related to its direct and indirect cholinomimetic effect.

Kidney disease and hemodialysis

Carnitine supplementation is very much indicated in kidney diseases because the kidney is a major site of carnitine synthesis. Damage to the kidney or reduced kidney function has a profound effect on carnitine metabolism. It is well established that patients undergoing hemodialysis suffer from carnitine deficiency due to the loss of considerable quantities of carnitine during dialysis as well as decreased synthesis. Serum carnitine levels drop nearly 80% during hemodialysis.^{[1] [2] [3]}

Carnitine supplementation has been extensively studied in patients undergoing hemodialysis due to chronic renal failure. These studies indicated that L-carnitine supplementation is effective in reducing triglyceride levels while raising HDL-cholesterol levels and thus helps to decrease the risk of heart disease in dialysis patients.^{[58] [59] [60]}
^[61] Carnitine-treated dialyzed patients have also shown additional benefits, including: ^[62]
^{[63] [64]}

- disappearance of angina pectoris and arrhythmias occurring during dialysis
- reduction of muscle symptoms including muscle cramps
- increased muscle mass
- significant improvement of the chronic anemiaseen in these patients as demonstrated by an increased hematocrit, hemoglobin, and red bloodcell count.

In the last decade, a major advancement in the treatment of the anemia associated with hemodialysis is recombinant human erythropoietin (EPO) therapy. However, this therapy is expensive and is not without side-effects. In a recent study, L-carnitine (1 g intravenously after every dialysis session) administered for 6 months led to a significant reduction in dosage as well as improvements in membrane fragility and endogenous EPO secretion.^[65] Given the high cost of EPO, if doctors are unwilling to follow this procedure, insurance companies should get involved and force dialysis units to employ L-carnitine.

Diabetes

Patients with diabetes have been reported to have reduced serum carnitine concentrations but normal skeletal muscle carnitine levels. Due to the increased risk of atherosclerotic cardiovascular disease and reduced kidney and liver function found in diabetic patients, supplementation with L-carnitine appears warranted.

Carnitine (especially LPC) has also been shown to greatly improve peripheral vascular function, as well as nerve function, in patients with diabetes.^[66] The improvement in nerve conduction is largely due to significantly increased conduction velocity.^[67]

Liver disease

Carnitine plays an extremely important role in the utilization and metabolism of fatty acids in the liver. There is some evidence that carnitine deficiency within the liver promotes fatty infiltration (also known as steatosis or liver congestion).^[68]

Alcohol ingestion is a common cause of fatty infiltration of the liver. It has been suggested that chronic alcohol consumption results in a functional deficiency of carnitine. A functional deficiency means that there is plenty of carnitine around, but its function is inhibited just as if there was a deficiency. Many commonly used agents for fatty infiltration, such as choline, niacin, and cysteine, appear to have little value in relieving alcohol-induced fatty liver. However, carnitine significantly inhibits, and reverses, alcohol-induced fatty liver disease.^[69]

Since carnitine normally facilitates fatty acid transport and oxidation in the mitochondria, a high liver carnitine level may be needed to handle the increased fatty acid load produced by alcohol consumption or other liver injury.^[70] Supplemental carnitine has been shown to reduce free fatty acid levels in patients with liver cirrhosis, and to reduce serum triglycerides and liver enzyme levels while elevating HDL-cholesterol in alcohol-induced fatty liver disease.^{[68] [69] [70]}

Carnitine's use in liver disorders associated with fatty infiltration appears warranted, especially when these changes are due to the ingestion of alcohol or exposure to xenobiotics (man-made chemicals toxic to biological processes such as pesticides and herbicides).

Muscular dystrophies

Patients with various muscular dystrophies have reduced levels of carnitine in their skeletal muscles.^{[71] [72] [73]} Although levels were not as low as those observed in patients with classical myopathic carnitine deficiency, the low carnitine levels are thought to contribute to the muscular weakness experienced by these patients. Unfortunately, for some reason it has not been determined if supplemental carnitine would be of any value in patients with muscular dystrophy.

Low sperm counts and decreased sperm motility

In the human sperm, high carnitine concentrations are critical to sperm energy metabolism. Several studies have shown that the level of free carnitine in the seminal fluid is inversely correlated with sperm count and motility.^{[74] [75]} The lower the carnitine content, the more likely it is that a man is infertile.

Given the known physiological role of carnitine in sperm function and its link to male infertility, a recent study was designed to assess the therapeutic effect of carnitine in

men with low sperm counts and depressed sperm motility.^[76] One hundred men selected from infertility clinics participated in the “Italian Study Group on carnitine and male infertility”. Each subject was given 3,000 mg of L-carnitine daily for 4 months.

The results of the study indicated that L-carnitine was able to increase sperm counts and sperm motility, in both a qualitative and a quantitative manner:

- the number of ejaculated sperm increased from 142 to 163 billion
- the percentage of motile sperm increased from 26.9 to 37.7%
- the percentage of sperm with rapid linear progression increased from 10.8 to 18%
- the mean sperm velocity increased from 28.4% to 32.5%.

The results are even more impressive if only the patients with the poorest sperm motility are studied. This subgroup saw even more significant gains on all parameters. For example, the percentage of motile sperm increased from 19.3 to 40.9% and the percentage of sperm with rapid linear progression increased from 3.1 to 20.3%.

Chronic obstructive pulmonary disease

Patients with chronic respiratory insufficiency are often severely affected by even the simplest physical activity. Treatment with L-carnitine (2 g three times/day) resulted in significant improvements in exercise capability.^[77]

AIDS

Several reports indicate that systemic carnitine deficiency may be a problem in patients with AIDS. Reduced levels of serum carnitine are most often found in AIDS patients. However, more important is the carnitine depletion in peripheral blood mononuclear cells (PBMC). In fact, even AIDS patients with normal serum carnitine levels demonstrate low levels of carnitine in white blood cells.^[78] Increasing the carnitine content of the PWBC strongly improved lymphocyte function and highlights the importance of carnitine to immune function.

L-Carnitine has been shown to prevent the toxicity of the drug AZT on the mitochondria of the muscle cells.^[79] AZT poisons the mitochondria of the muscle, leading to abnormal energy production within the muscle which manifests clinically as muscle fatigue and pain. If L-carnitine is able to prevent this negative effect of AZT in human patients with AIDS, it would be a major improvement in the clinical management of AIDS.

Preliminary studies indicate that L-carnitine supplementation can improve immune function and reduce the level of HIV-induced immune suppression. When AIDS patients being treated with AZT were given 6 g

of L-carnitine/day, it led to significant increased PBMC proliferation and reduced blood levels of triglycerides and circulating tumor necrosis factor.^[80] Given the suspected systemic carnitine deficiency along with the tremendous safety of use, carnitine supplementation appears to be warranted in AIDS.

Inborn errors of amino acid metabolism

The use of carnitine in the treatment of inborn errors of metabolism involving the urea acid cycle appears to be well justified. Preliminary studies have shown impressive therapeutic response to L-carnitine supplementation in cases of glutaric aciduria, isovaleric acidemia, propionic acidemia, and methylmalonic aciduria.^{[81] [82] [83] [84]}

Protection against drug toxicity

Carnitine has been shown to protect against the damaging effects on the heart produced by the chemotherapy drug adriamycin.^[85] Carnitine has also been shown to improve the symptoms attributed to anticonvulsant medications such as valproic acid (trade names: Depa, Depakene, Depakote, and Deproic) and carbamazepine (trade names: Epitol and Tegretol).^{[86] [87]} However, the most recent study has challenged the need to administer carnitine prophylactically since no significant differences were noted in well-being scores between the carnitine group and the placebo group.^[88]

DOSAGE

The daily dosage of L-carnitine in all of its forms has typically been between 1,500 and 4,000 mg in divided doses. Given the safety of carnitine, it appears to be better to err on the side of taking too much rather than too little. The exception is in patients undergoing hemodialysis. A paradoxical effect on triglyceride levels and platelet aggregation in patients on hemodialysis has been reported.^[89] Slightly higher doses were used (3 g/day) compared with other studies of supplementation in chronic renal failure (typical dose 20 mg/kg body weight or 2 g/day). In addition, the study size was extremely small, and the results are in conflict with other studies using similar doses. However, it appears wise to reduce the risk of this effect by using lower doses and carefully monitoring patients with impaired renal function.

TOXICOLOGY

L-Carnitine is extremely safe, with no significant side-effects ever being reported in any of the human clinical studies. Again, it is important to mention that only L-carnitine should be used. The D form, the mirror image of the L form, has produced side-effects indicating that it interferes with the natural L form of carnitine. Patients undergoing hemodialysis given a mixture containing D,L-carnitine for 45 days experienced muscle pain and loss of muscle function presumably due to lack of energy.^[90] The symptoms disappeared upon cessation of D,L-carnitine supplementation. Subsequent studies showed that D-carnitine produces an L-carnitine deficiency in cardiac and skeletal muscle.^[91] While L-carnitine results in significant improvement in exercise tolerance in angina patients, D,L-carnitine actually dangerously reduces exercise tolerance in these

patients.^[92]

Interactions

There are no known adverse interactions between carnitine and any drug or nutrient. Carnitine and coenzyme Q₁₀ appear to work synergistically when combined.^[93] The same is true for pantethine.^[94]

Perhaps the most important interaction is the one with choline. In young adult women, daily choline supplementation (20 mg/kg body weight) resulted in a 75% lower urinary carnitine excretion than in controls, without significantly altering plasma carnitine concentrations. Studies in guinea pigs demonstrated that choline supplementation resulted in a significantly lower urinary excretion and higher skeletal muscle carnitine concentrations. These studies indicate that choline supplementation results in a conservation of carnitine and may increase intracellular carnitine levels.^[95]

Chapter 73 - Catechin [(+)-cyanidanol-3]

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

INTRODUCTION

This naturally occurring flavonoid has been widely used in Europe in the treatment of hepatic disease and other conditions. It is found in high concentrations in *Acacia catechu* (black catechu, black cutch) and *Uncaria gambier* (pale catechu, gambier). ^[1]

PHARMACOKINETIC STUDIES IN HUMANS

Studies of radiolabeled catechin demonstrate that 55% of the oral dose administered to human volunteers is excreted in the urine. ^[2] Of this excreted catechin, 70% was excreted within 12 hours and 90% within 24 hours. Urinary excretion of unchanged catechin was quite low (0.1–1.4% of oral dose). The major urinary metabolites (composing three-quarters of the total urinary excretion) are glucuronides of catechin, and 3'-O-methyl-catechin and its sulphate. The majority of metabolites retained the flavanol ring structure. Ring scission is a minor metabolic pathway and results in the excretion of benzoic, hippuric, and phenylpropionic acids.

Unchanged catechin is detected in the plasma between 30 minutes and 12 hours after ingestion, while metabolites persist for at least 120 hours. Researchers have concluded that the rapid rate of absorption, coupled with relatively low plasma levels of the unchanged catechin molecule, suggests that hepatic extraction and localization are extremely efficient, a desirable trait considering catechin's hepatoprotective properties. ^[1]

^[2]

PHARMACOLOGY

Antiviral and immunostimulatory effects

Many flavonoids have been shown to possess antiviral activity, with quercetin being

perhaps the most effective. Catechin has, however, been shown to inhibit infectivity by human viruses (e.g. polio virus, parainfluenza virus type 3, respiratory syncytial virus, and herpes simplex

type 1).^[3] This appears to be due to a direct flavonoid virus interaction.

Perhaps more important, however, are its immune stimulation properties.^[4] Catechin and 3'-O-methylcatechin, its major derivative, have been shown to significantly increase spontaneous, pokeweed mitogen- and *Staphylococcus aureus*-induced lymphocyte transformation, and immunoglobulin synthesis. Catechin has also been shown to increase T-cell rosette formation;^[5] stimulate cell-mediated immune response (as measured by the leukocyte migration inhibition test); and promote antigen-induced proliferative response in patients with HBsAg-positive chronic active hepatitis.^[6]

Many of the immunostimulatory effects of flavonoids may be due to their ability to inhibit the catabolism of cGMP in leukocytes,^[7] an action known to augment many immune responses (see [Ch. 53](#) for further discussion concerning cyclic nucleotides' effects on immune functions).

Antioxidant

Catechin has been shown, in vitro and in vivo, to be a powerful free radical scavenger and antioxidant, preventing both environmental chemical- and normal metabolism-induced oxidative damage.^[8] Catechin has a sparing effect on glutathione metabolism as well.

Anti-endotoxin effects

The role of endotoxins (lipopolysaccharide cell wall components of Gram-negative bacteria) in the pathogenesis of liver diseases (particularly all types of hepatitis, and alcohol-induced cirrhosis) and associated systemic disorders has been demonstrated by many investigators (see [Ch. 54](#) for a complete discussion).

Under normal conditions, endotoxins, produced by intestinal Gram-negative bacteria, are absorbed into the portal venous circulation and detoxified by Kupffer cells. Impairment of the reticuloendothelial system (RES), phagocytic function, or the portal-sinusoidal blood flow – i.e. interference of normal endotoxin clearance mechanisms – amplifies the biologic activities of endotoxins (e.g. activation of the alternative complement pathway, lipid peroxidation, and promotion of such calcium-mediated phenomena as smooth muscle contraction and mast cell degranulation).

Catechin's anti-endotoxin effects are both direct – degradation of endotoxin and

prevention of free radical-induced damage by the lipid portion of the endotoxin molecule – and indirect – stabilization of biomembranes and interference with the liver adenylate cyclase system (this latter is significant since exotoxins, such as cholera toxin from *Vibrio cholerae*, cause their symptoms by excessive activation of adenylate cyclase which disturbs the cyclic AMP/ATP balance in the cells).^[9]

Collagen effects

Catechin affects collagen metabolism in various ways. These include:

- an increase in cross-linkage formation in normal^[10] and lathyrtic^[11] collagen (covalent binding of seven catechin residues per collagen alpha-chain)
- a reduction in prolyl and lysyl hydroxylase activities^[12]
- an accelerated conversion of soluble to insoluble collagen in lathyrtic,^[13] diabetic,^[14] and genetically abnormal^[15] collagen.

Collagen synthesized in the presence of catechin has been shown to be resistant to the action of collagenase^[10] and pepsin. ^[16] Collagen biosynthesis has variously been reported to be decreased,^[12] unaffected,^[17] and, in the case of adjuvant arthritis,^[18] increased in the presence of catechin. The significance of these effects is discussed below.

Histidine decarboxylase

This enzyme is responsible for converting histidine to histamine. Catechin and other flavonoids have been shown to be potent inhibitors of histidine decarboxylase in vitro^[19] and in vivo.^[20] This action has wide clinical application, e.g. allergic conditions, peptic ulcers, inflammatory processes, and other conditions where histamine is involved.

CLINICAL AND EXPERIMENTAL STUDIES

Hepatitis

An international workshop in 1981 on the use of catechin in diseases of the liver concluded that the flavonoid has much promise for the treatment of many types of hepatic disease, particularly both acute and chronic viral hepatitis.^[1] Catechin has been shown, in numerous double-blind clinical studies, to decrease serum bilirubin levels in patients with all types of acute viral hepatitis (i.e. types A, B, and non-A, non-B).^{[1] [21] [22] [23] [24] [25] [26] [27]} Furthermore, there is a more rapid relief of clinical symptoms (i.e. anorexia, nausea, asthenia, pruritus, and abdominal discomfort), a more accelerated clearance of HBsAg from the blood, and a greater reduction of SGPT and SGOT levels than in control groups. The hepatoprotective effect of catechin is related to its free radical and antioxidant properties, its anti-endotoxin effects, and its ability to stabilize membranes.

The most recent double-blind study utilizing catechin involved 338 patients with chronic hepatitis B as confirmed by the presence of hepatitis B e antigen (HBeAg).^[27] Patients

were given either catechin at a daily dose of 1.5 g for 2 weeks, followed by 2.25 g for a further 14 weeks, or a placebo. The HBeAg titer decreased by

647

at least 50% in 44 of 144 cases treated with catechin compared with 21 of 140 cases treated with placebo. The HBeAg disappeared in 16 of the catechin cases and four of the placebo, and a seroconversion was observed in six catechin patients and three placebo patients. The mean HBeAg titer in the catechin group was significantly lower than that in the placebo group at the end of the 16 weeks of therapy. The patients whose HBeAg titers were lowered were largely those with chronic active hepatitis, and they had higher initial values of SGPT, SGOT, and gamma-globulin than the patients whose HBeAg titers remained unchanged. The mean values for these liver function tests also fell significantly in the former subgroup. Catechin was well tolerated, the only notable side-effect being a transient febrile reaction in 13 patients.

Alcohol-induced liver disease

Elevated hepatic NADH:NAD ratios and decreased ATP concentrations are found during ethanol intoxication. These metabolic disturbances, along with the increased production of acetate (as a result of ethanol detoxification), produce cholestasis and induce hepatic lipid accumulation by decreasing fatty acid oxidation and favoring incorporation of fatty acids into triglycerides.^[28]

In animal studies, catechin has been shown to correct these aberrations.^{[28] [29] [30]} However, clinical studies in humans have failed to show convincing evidence that catechin is of benefit in alcohol-related liver disease.^{[31] [32]} This could be a result of insufficient dosage. In the animal studies, the dose is usually 200 mg/kg, compared with 20–40 mg/kg in human studies. Furthermore, the high rate of patient drop-out in long-term studies has prevented adequate evaluation. A recent long-term clinical trial (6 months) demonstrated that 2 g of catechin gave some protection against ethanol-induced hepatic damage, as evidenced by lowering of hepatic enzymes (SGOT, SGPT, and gamma GT).^[32]

Peptic ulcer

Catechin, via its ability to inhibit histidine decarboxylase, offers anti-ulcer activity. Experimental studies in guinea pigs and rats have demonstrated that catechin has significant anti-ulcer activity in various models.^{[19] [20] [33]} In a human clinical study, oral administration (1,000 mg five times a day) resulted in reduced histamine levels in the gastric tissue (determined by biopsy) of normal patients and those with gastric and duodenal ulcers and acute gastritis.^[20] It was also demonstrated that the histamine levels, which significantly increase in patients with urticaria and food allergy after the local application of the antigen to the gastric mucosa, could be decreased by the prior administration of catechin.

Postoperative complications

The formation of adhesions is a common and severe problem in surgery, particularly in abdominal surgery. Lower abdominal surgery, particularly appendectomies and gynecological procedures, are often followed by adhesions which may result in pain and obstruction. The incidence of postoperative peritoneal adhesions varies from 67 to 92%.^[34] It has been assumed that surgery leads to the stimulation of connective tissue formation, resulting in an overproduction of procollagen and collagen and increased deposition around the damaged or ischemic area.

In rats, catechin, when administered within the first 5 days following the procedure, substantially inhibits adhesion formation following experimental adhesion induction.^[35] Catechin, via its inhibition of procollagen and collagen biosynthesis, should also reduce adhesion formation in humans. Intraperitoneal administration was significantly more effective than the oral administration in the experimental study. However, in humans, oral administration may result in sufficient tissue concentrations. Catechin has also been shown, in a double-blind study, to significantly reduce postoperative edema.^[35]

Osteogenesis imperfecta (OI)

This heterogenous autosomal dominant bone disease is characterized by defective synthesis of collagen, resulting in impaired connective tissue and bone matrix formation. Prior to the use of catechin for this disorder, treatment was based solely upon orthopedic measures, as no effective medical treatment was available.^[36] The main clinical problems in OI are multiple fractures of the long bones in children and progressive collapse of the vertebral bodies in adulthood. Catechin has been shown to reduce fractures. There is also histological, electron microscopic, and biochemical evidence of improvement after treatment.^[36] ^[37] Catechin's role in improving collagen defects in OI probably centers around its ability to:

- reduce, by its reduction of lysyl hydroxylase activity, the increased level of hydroxylysine reported in the collagen of many patients with type I OI
- increase the number of cross-links in the collagen matrix (which may be deficient or exhibit delayed maturation in OI)
- improve the supramolecular organization and stability of the collagen fibers
- possibly increase the reduced collagen production occurring in OI.

Rheumatoid arthritis and scleroderma

The effects that catechin has on collagen suggest that the flavonoid would have therapeutic benefit in rheumatoid

arthritis and scleroderma, as well as in other collagen diseases. Inflammation and collagen are linked in several ways. Pre-existing collagen is destroyed during the initial stages of inflammation, whereas its biosynthesis is increased in the later stages. Catechin appears to be an ideal agent due to its ability to inhibit the breakdown of collagen caused by either free radicals or enzymes (hyaluronidase, collagenase, and pepsin), coupled with its ability to cross-link with collagen fibers and inhibit pro-collagen biosynthesis.^[12]

Catechin was included in a long-term treatment program of 115 patients with generalized scleroderma that brought about arrest of progression in 89% of the patients, and a subtotal or total recovery in more than 40%.^[38] Although a number of combinations of collagen inhibitors were used in the study, the combination of catechin with D-penicillamine and L-glutamine was the most effective. Unfortunately, catechin was not used alone.

Cancer

Several epidemiological studies have now shown an inverse correlation between tea consumption and the incidence of several cancers. For example, people in Japan smoke more cigarettes than those in Western countries, yet their incidence of lung cancer is lower. Other studies show a lower incidence of colonic polyps in humans drinking green tea. This protection has been attributed in part to their high tea consumption. This is consistent with laboratory research showing a preventive effect of tea in animal models of lung cancer. In mice models, drinking green tea resulted in lung tumor induction being inhibited by 50%. Green and black tea reduced the incidence of cancer of the lung, forestomach, esophagus, and liver in rats and mice when these were induced by carcinogens. These anti-cancer effects appear to be due to catechin's potent antioxidant activity of tea, lowering the modification of DNA in the tissues by hydroxyl radicals and similar active oxygen compounds.^[39]

DOSAGE

Typically, the dosages used have been:

- 1 g three times a day for hepatic disease
- 1 g five times a day for peptic ulcers
- 500 mg three times a day for osteogenesis imperfecta.

TOXICOLOGY

Catechin was initially regarded as being remarkably free from side-effects. However, soon after its introduction in France, rare but serious side-effects began to be linked with catechin. Chief among the serious side-effects were autoimmune hemolysis, febrile reactions, and urticaria. Catechin must be used with extreme caution.

Two different series of case reports highlight the seriousness of side-effects. In the first, six patients who developed hemolysis while receiving catechin were studied.^[40] The

disorder was episodic in all patients and resolved after discontinuation. The causative antibodies could be demonstrated in all six cases, even when the hemolytic episode had preceded analysis by more than 1 year. It seems that the stable association of catechin with RBC generates antigenic sites against which a heterogeneous immune response is elicited, giving rise to long-lasting drug-dependent antibodies as well as autoantibodies.

In the other series of patients, five patients who received catechin for 4–36 months were presented.^[41] Three developed both hemolytic anemia and thrombocytopenia, while two had only thrombocytopenia. After suspending the catechin, the hematological values returned to normal in all of the patients. Catechin-dependent platelet antibodies were detected in four of the five patients, and catechin-dependent red blood cell antibodies were present in three.

Chapter 74 - *Centella asiatica* (gotu kola)

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

Centella asiatica (family: Umbelliferae or Apiaceae)
Synonym: *Hydrocotyle asiatica* L.
Common names: gotu kola, Indian pennywort, South African pennywort, mandukaparni

GENERAL DESCRIPTION

Centella asiatica is an herbaceous perennial plant native to India, China, Indonesia, Australia, the South Pacific, Madagascar, and southern and middle Africa. This slender, creeping plant flourishes in and around water. Although it grows best in damp, swampy areas, centella is often observed growing along stone walls or other rocky, sunny areas at elevations of approximately 2,000 feet in India and Ceylon.^[1]

Depending on the environment, the form and shape of centella can change dramatically. In shallow water, centella will form floating leaves, while in dry locations, the leaves are small and thin, and numerous roots are formed.^[1]

Typically, the constantly growing roots give rise to reddish stolons. The round-to-reniform, smooth-surfaced leaves, found on furrowed petioles, can reach a width of 1 inch and a length of 6 inches. The leaf margin may be smooth, crenate, or slightly lobed. Usually three to six red flowers arise in a sessile manner or on very short pedicels in axillary umbels at the end of 0.08–0.3 inches long peduncles. The fruit, formed throughout the growing season, is approximately 0.2 inches long with seven to nine ribs and a curved, strongly thickened pericarp.^[1]

Historically, the entire plant is used medicinally, with harvesting occurring at any time during the year.^[1]

CHEMICAL COMPOSITION

Although the primary pharmacologically active constituents of *Centella asiatica* are known to be triterpenoid compounds,^[2] the exact chemical profile of centella is difficult to determine due to duplicate names and contradictory findings. In addition, centella samples from

652

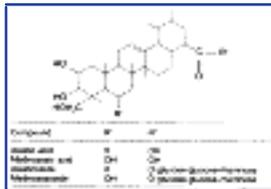

Figure 74-1 The triterpene compounds of *Centella asiatica*.

India, Sri Lanka, and Madagascar apparently do not contain the same constituents.^[3]^[4] In India, three (and possibly more) chemically different subspecies of *Centella asiatica* have been found.^[5]

The concentration of triterpenes in centella can vary between 1.1 and 8%, with most samples yielding a concentration between 2.2 and 3.4%.^[5]

[Figure 74.1](#) below illustrates the major triterpenoid components of *Centella asiatica*:

- asiatica acid
- madecassic acid
- asiaticoside
- madecassoside.

The Madagascar variety is most commonly used to produce standardized extracts and yields triterpene concentrations of asiatic acid (29–30%), madecassic acid (29–30%), asiaticoside (40%), and madecassoside (1–2%).^[2]

Centella also contains a green, volatile oil which is composed of an unidentified terpene acetate (which accounts for 36% of the total oil), camphor, cineole, and other essential oils. Centella oil also contains glycerides of fatty acids, various plant sterols such as campesterol, stigmasterol, and sitosterol, and various polyacetylene compounds.^[1]^[2]

Other notable compounds isolated from centella include the flavonoids keampferol, quercetin, and their glycosides, myoinositol, sugars, a bitter substance (vellarin), amino acids, and resins.^[1]^[2]

HISTORY AND FOLK USE

Centella has been utilized as a medicine in India since prehistoric times and is thought to be identical to the plant mandukaparni, listed in the *Susruta Samhita*. Centella was also used extensively as a medicine, both internally and externally, by the people of Java and other islands of Indonesia. The medicinal use of centella in India and Indonesia centered around its ability to heal wounds and relieve leprosy.^[1]

In the 19th century, centella and its extracts were incorporated into the Indian pharmacopeia, where in addition to being recommended for wound healing, it was recommended in the treatment of skin conditions such as leprosy, lupus, varicose ulcers, eczema, and psoriasis. It was also used to treat diarrhea, fever, amenorrhea, and diseases of the female genitourinary tract.^[1]

In China, the leaves are prescribed for turbid leukorrhea and toxic fevers, while the shoots are used for boils and fevers. The plant is also used in the treatment of fractures, contusions, strains, and snakebites.^[1] Centella was also used in China to delay senescence. One of the reported “miracle elixirs of life”, centella’s reputation as a promoter of longevity stems from the report of Chinese herbalist, LiChing Yun, who reportedly lived 256 years. LiChing Yun’s longevity was supposedly a result of his regular use of an herbal mixture chiefly composed of centella.^{[6] [7]}

Centella asiatica was first accepted as a drug in France in the 1880s. Since then, extracts of centella have been used in the treatment of many of the same conditions listed above along with those described in “Clinical applications” ([p. 653](#)).

Centella, or gotu kola, has aroused much curiosity in American consumers. Many confuse gotu kola with kolanuts and assume gotu kola’s rejuvenating activity is nothing more than the stimulant effect of caffeine. However, gotu kola is not related to the kolanut (*Cola nitida* or *Cola acuminata*), nor does it contain any caffeine.

PHARMACOLOGY

Centella asiatica, specifically the triterpenes, exerts remarkable wound-healing activity. Although the exact mechanism of action has not yet been fully determined, a number of interesting observations have been made.

In one of the early pharmacological investigations of centella, Boiteau & Ratsimamanga ^[8] demonstrated that asiaticoside substantially hastened the healing of experimentally induced wounds. These authors concluded that asiaticoside works selectively in stimulating the rapid and healthy activity of the reticuloendothelial system.

Additional studies on the mechanisms of action of centella’s enhancing wound-healing have shown that asiaticoside given orally, by intramuscular injection, or by implantation to rats, mice, guinea pigs, and rabbits produces a wide range of effects, as shown in

[Table 74.1](#) .

The efficacy of centella in stimulating collagen synthesis has now been demonstrated in human tissue cultures.^[13] Interestingly, this research also demonstrated an added benefit when vitamin C was added to the experimental cultures.

The outcome of centella's complex actions is a balanced

TABLE 74-1 -- Physiological effects of *Centella asiatica*

- Stimulates hair and nail growth^{[1] [8] [9] [10]}

- Increases vascularization of connective tissue^{[1] [8] [9] [10]}

- Increases the formation of mucin and structural glycosaminoglycans like hyaluronic acid and chondroitin sulfate^{[1] [8] [9] [10] [12]}

- Increases the tensile integrity of the dermis^{[1] [8] [9] [10]}

- Increases keratinization of epidermis through stimulation of the stratum germinativum^{[1] [10] [12] [13] [14]}

- Possesses a eutrophic or balancing effect on connective tissue^{[1] [10]}

multiphasic effect on cells and tissues participating in the process of healing, particularly connective tissues. Enhanced development of normal connective tissue matrix is perhaps the prime therapeutic action of *Centella asiatica*.

CLINICAL APPLICATIONS

Obviously, from the brief description of centella's pharma-cological activity given above, it is a valuable agent for the healing of wounds. [Table 74.2](#) provides an abridged list of documented clinical applications of *Centella asiatica*. The more popular uses of this valuable plant are discussed below.

Burns

The standardized extract from *Centella asiatica* has been effectively used in the treatment of patients with second- and third-degree burns caused by boiling water, electrical current, or gas explosion. Daily local application and/or intramuscular injections of the extract resulted in excellent results when the treatment was begun immediately after the accident. The extract prevented or limited the shrinking and swelling of the skin

TABLE 74-2 -- Clinical applications of *Centella asiatica*

| Conditions | References |
|---------------------|--|
| Anal fissure | 15 |
| Bladder ulcers | 16 , 17 |
| Burns | 18 , 19 |
| Cellulite | 20 , 21 , 22 , 23 , 24 , 25 |
| Cirrhosis | 26 , 27 , 28 |
| Dermatitis | 20 , 29 |

| Peptic ulcer | 39 , 40 |
| Perineal lesions | 41 |
| Periodontal disease | 42 |
| Retinal detachment | 43 |
| Scleroderma | 44 , 45 , 46 , 47 |
| Skin ulcers | 48 , 49 , 50 , 51 , 52 , 53 , 54 , 55 |
| Surgical wounds | 8 , 43 , 49 , 56 , 57 , 58 , 59 , 60 , 61 |
| Tuberculosis | 8 , 62 |
| Venous disorders | 63 , 64 , 65 , 66 , 67 , 68 , 69 , 70 , 71 , 72 , 73 , 74 , 75 |
| Wound healing | 8 , 43 , 49 , 56 , 57 , 58 , 59 , 60 , 61 |

caused by skin infection, and it inhibited scar formation, increased healing, and decreased fibrosis.^{[18] [19]}

Cellulite

Standardized extracts of *Centella asiatica* have demonstrated good results in the treatment of cellulite in a number of clinical studies.^{[10] [20] [21] [22] [23] [24] [25]} Bourguignon ^[20] observed the action of the extract on several types of cellulite in 65 patients who had undergone other therapies without success. Over a period of 3 months, very good results were produced in 58% of the patients and satisfactory results in 20%. Other

investigations have shown a similar success rate (~80%).^[21] ^[22] ^[23] ^[24]

The effect of centella in the treatment of cellulite appears to be related to its ability to enhance connective tissue structure and reduce sclerosis by acting directly on fibroblasts (see [Ch. 141](#) for further discussion.)

Cirrhosis of the liver

Darnis et al^[26] reported on the therapeutic use of an extract of *Centella asiatica* in alcohol-induced cirrhosis (six patients), cirrhosis of unknown etiology (two patients), and chronic hepatitis. In the cirrhosis patients, improvement in the histological findings and regression of inflammatory infiltration were observed. No effect was observed in the patients with chronic hepatitis. Other reports have supported the use of centella in fibrotic conditions of the liver.^[27] ^[28]

Keloids

The standardized extract of *Centella asiatica* has demonstrated impressive clinical results in the treatment of keloids and hypertrophic scars.^[32] ^[33] ^[34] Its mechanism of action appears to be multifaceted, but is basically due to reducing the inflammatory phase of scar formation while simultaneously enhancing the maturation phase of scar formation.

Keloids and hypertrophic scars are characterized by a prolonged inflammatory phase which may go on for months or even years without progressing to the maturation phase. The inflammatory phase is characterized histologically by large numbers of immature, swollen collagen bundles intermingled with inflammatory debris, while the maturation phase is characterized by mature fibrocytes, normal collagen fibers, and few inflammatory cell elements.

In one study, a total of 227 patients with keloids or hypertrophic scars were treated by oral administration with a standardized centella extract (effective dosage 60–90 mg). The centella extract was used alone in 139 patients (the curative group) and 88 used the extract along with surgical scar revision (preventive group).^[32]

In the curative group, 116 patients (82%) were found

after 2–18 months to have benefited from the extract, either by relief of their symptoms or by disappearance of the inflammatory phase. In a double-blind substudy of 46 of the 139 patients, 22 out of 27 receiving the extract improved, while only nine of 19 given a placebo improved.

In the preventive group, the centella extract also demonstrated significant positive

effect. The therapeutic course in these patients was started a few weeks prior to surgery. If a positive response was observed, the patient was brought to surgery and kept on the centella extract for 3 months. (This method of preselection allowed the researchers to offer other forms of therapy to unresponsive patients.) Clinical improvement was observed in 72 of the 88 patients (79%).

Leprosy

Several investigators have reported impressive clinical results using *Centella asiatica* and its extracts (oral, intramuscular, and/or topical) in the treatment of leprosy in both uncontrolled and controlled studies.^{[11] [19] [35] [36]} The therapeutic response is comparable to that of dapsone, the standard allopathic drug used in the treatment of leprosy.

In addition to its wound-healing activity, it appears that oxyasiaticoside, an oxidized form of asiaticoside, inhibits the growth of the tubercle bacillus in vitro and in vivo by dissolving the waxy coating of *Mycobacterium leprae*.^[8]

Improving mental function

Appa Rao et al^[38] reported a significant increase in the mental abilities of 30 developmentally disabled children treated with *Centella asiatica*. After a 12 week period, the children were more attentive and better able to concentrate on assigned tasks.

Centella's triterpenes have demonstrated mild tranquilizing, anti-stress, and anti-anxiety action via enhancement of cholinergic mechanisms.^[76] Presumably this mechanism is responsible for the enhancement of mental function as well.

Scleroderma

The standardized extract of *Centella asiatica* has been tested in several trials in the treatment of scleroderma (including systemic sclerosis).^{[44] [45] [46] [47]} In addition to decreasing skin induration, patients have noticed a lessening of arthralgia and improved finger motility. Presumably the positive therapeutic response is a result of centella's eutrophic effect on connective tissue, thereby preventing the excessive collagen synthesis observed in scleroderma.

Venous disorders

Numerous studies have demonstrated that standardized extracts of *Centella asiatica* are effective in the treatment of venous insufficiency. This appears to be due to centella's ability to enhance the connective tissue structure of the perivascular sheath, reduce sclerosis, and improve blood flow through the affected limbs.^{[1] [10] [63] [64] [65] [66] [67] [68] [69] [70] [71] [72] [73] [74] [75]}

Significant improvement in symptomatology (such as feelings of heaviness in the lower legs, paresthesias, nocturnal cramps, etc.), physical findings (edema, telangiectasias, trophic ulcers, vein distensibility, etc.), and functional capacity (improved venous flow)

was observed in approximately 80% of patients in the clinical trials^{[1] [10] [63] [64] [65] [66] [67] [68] [69] [70] [71] [72] [73] [74] [75]} (for further discussion, see [Ch. 193](#)).

Wound healing

Standardized extracts of *Centella asiatica* have been shown, in a large number of clinical studies, to greatly aid wound repair.^{[1] [8] [10] [43] [48] [49] [50] [51] [52] [53] [54] [55] [56] [57] [58] [59] [60] [61]} The types of wounds healed include:

- surgical wounds such as episiotomies and ENT surgeries
- skin ulcers due to arterial or venous insufficiency
- traumatic injuries to the skin
- gangrene
- skin grafts
- schistosomiasis lesions
- perineal lesions produced during childbirth.

DOSAGE

The majority of clinical studies on *Centella asiatica* utilized proprietary formulas available in Europe (e.g. Madecassol, TECA, and Centelase). These standardized extracts contain asiaticoside (40%), asiatic acid (29–30%), madecassic acid (29–30%), and madecassoside (1–2%).

Since the concentration of triterpenes in centella can vary between 1.1 and 8%, it is difficult to calculate an appropriate dosage when simply using the crude plant material. However, since most samples yield a concentration between 2.2 and 3.4%, approximately 2–4 g/day of crude plant material would contain an appropriate quantity of triterpenes, although it is not known if this correlates with the clinical efficacy of the standardized extracts.

Daily dosages of the various forms of centella are as follows:

- Standardized extract (40% asiaticoside, 29–30% asiatic acid, 29–30% madecassic acid, and 1–2% madecassoside): 60–120 mg/day
- Crude dried plant leaves: 2–4 g/day
- Tincture (1:5): 10–20 ml/day
- Fluid extract (1:1): 2.0–4.0 ml/day.

TOXICOLOGY

Centella asiatica and its extracts are very well-tolerated,

especially orally.^[1] However, the topical application of a salve containing centella has been reported to cause contact dermatitis, although quite infrequently.^[1]

While the oral administration of asiaticoside at a dose of 1 g/kg body weight has not proved toxic in toxicology studies, the toxic dose of asiaticoside by intramuscular application to mice and rabbits is reported as 40–50 mg/kg body weight.^[1]

Asiaticoside has been implicated as a possible skin carcinogen where repeated applications are used in an experimental animal model.^[77] Teratological studies using the extract in rabbits have proved negative.^[32]

Chapter 75 - *Cimicifuga racemosa* (black cohosh)

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

Cimicifuga racemosa (family: Ranunculaceae)
Common names: black cohosh, macrotys, rattleweed, black snake root

GENERAL DESCRIPTION

Cimicifuga racemosa is a perennial herb native to North America that grows on hillsides and in woods at higher elevations from Maine and Ontario to Wisconsin, Georgia, and Missouri. The large, creeping rhizome produces stems up to 9 feet high. The ovate or oblong leaflets are 1–6 inches long and 4 inches wide, while the smaller leaflets are ternate, then pinnate, and sometimes even further divided. Small, white, fetid flowers grow in long racemes from May to August. The rhizome is the portion of the plant used for medicinal purposes.

CHEMICAL COMPOSITION

The components of *cimicifuga* which have garnered the most attention are the triterpene glycosides:

- actein
- cimicifugoside (aglycone cimegenol)
- 27-deoxyactein.

Other compounds of interest include flavonoids (formononetin) and caffeic acid derivatives (isoferulic acid) (see [Figs 75.1](#) and [75.2](#)).

HISTORY AND FOLK USE

The generic name *Cimicifuga* comes from the Latin *cimex*,

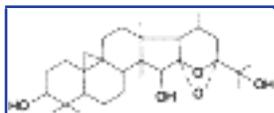

Figure 75-1 Cimigenol.

658

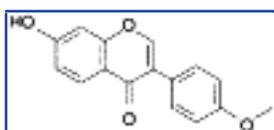

Figure 75-2 Formononetin.

a bug, and *fugo*, to drive away, alluding to its use as a vermifuge. Native Americans used *cimicifuga* rhizomes for the relief of pain during menses and childbirth as well as snakebite. The rhizome of *Cimicifuga racemosa* was listed in the National Formulary from 1936 to 1950, and in the United States Pharmacopeia from 1820 to 1936. Eclectic physicians in the early part of the 20th century used *cimicifuga* in gynecological disorders as well as rheumatoid and myalgic pain.

While use in the US declined dramatically from 1950 to 1995, *cimicifuga* preparations have been used extensively in Europe during this same period primarily as a natural alternative to hormone replacement therapy during menopause. This popularity is based upon substantial empirical and clinical evidence.

PHARMACOLOGY

The primary pharmacological effects of *cimicifuga* appear to revolve around its ability to impact endocrine regulatory mechanisms.^{[1] [2] [3] [4]} Much of this activity may be related to various phytoestrogenic components of *cimicifuga*, with formononetin perhaps being the most significant.^[5] However, the activity of phytoestrogens is substantially less than endogenous estrogens, indicating they exert more of an anti-estrogen than pro-estrogen effect. The estrogenic action of *cimicifuga* goes well beyond its phytoestrogen content. For example, the isoflavonoid formononetin has been identified as being the chief phytoestrogen of *cimicifuga*; however, it is much less active than many other phytoestrogens (e.g. genestein), as its relative binding affinity for estrogen receptors is only one-hundredth as strong as 17-beta-estradiol.^[5]

In addition, *cimicifuga*'s action appears to be more closely related to estriol than to estradiol. While estradiol is associated with an increased risk for breast, ovarian, and endometrial cancers, estriol is actually associated with offering some protection against these cancers.^{[6] [7]} The reason may be that estriol is much weaker in action and has a

shorter dwelling time on receptors on the surface of the cells compared with the more potent estradiol. Estrogen-dependent tumors are not stimulated by the weak-acting estriol, as it is acting as a partial antagonist to estradiol. Physiologically, estriol exerts its effects primarily on the vaginal lining, while estradiol exerts its effects primarily on the uterine lining. This action appears to mirror the effects with extracts of cimicifuga noted in clinical studies in menopausal women concerning its effect on the vaginal epithelium.

Cimicifuga's primary effect on endocrine regulatory mechanisms appears to be the result of complex synergistic actions of its key ingredients – the triterpenes and flavone derivatives. Evidence suggests that these compounds act on both the hypothalamus and vasomotor centers to produce significant clinical benefits in menopause. For example, one study involved in determining the endocrinological actions of cimicifuga extract involved treating 110 women with either cimicifuga extract (supplying a total daily dosage of 8 mg of 27-deoxyactein) or placebo.^[4] After 2 months of treatment, LH decreased by 20% in the cimicifuga group compared with the placebo group. Unlike estrogens, cimicifuga does not affect the release of prolactin and follicle-stimulating hormone (FSH). Researchers then divided the extract into three distinct types of active compounds based upon their ability to reduce LH secretion in ovariectomized rats and to compete in vitro with 17-beta-estradiol for estrogen receptor binding sites, as follows:

- constituents that did not bind to estrogen receptors, but that did suppress LH secretion
- constituents able to bind to estrogen receptor sites and to inhibit LH secretion
- compounds able to bind to estrogen receptors, but which did not inhibit LH secretion.

The authors concluded that: “the LH suppressive effect of *Cimicifuga racemosa* extracts observed in menopausal women and ovariectomized rats is caused by at least three different synergistically acting compounds.”

In summary, one of cimicifuga's key pharmacological effects is inhibition of the secretion of luteinizing hormone (LH) by the pituitary. This effect is accomplished equally by components which do and do not bind to estrogen receptors. If cimicifuga was simply mimicking the effects of estrogen, it would certainly alter the secretion of other pituitary hormones just like estrogen, but it does not.

CLINICAL APPLICATIONS

A special extract of *Cimicifuga racemosa* standardized to contain 1 mg of triterpenes calculated as 27-deoxyactein per tablet (trade name = Remifemin) is the most widely used and thoroughly studied natural alternative to hormone replacement therapy in menopause. In 1996, nearly 10 million monthly units of this extract were sold in Germany, the US, and Australia. Clinical studies have shown this cimicifuga extract to relieve not only hot flashes, but also depression and vaginal atrophy.^{[4] [8] [9] [10] [11]}

While there is also some evidence that cimicifuga may provide benefit in other

gynecological complaints such as premenstrual syndrome, amenorrhea (both primary

TABLE 75-1 -- Cimicifuga in the treatment of menopause

| Symptom | Percentage no longer present (%) | Percentage improved % | Total percentage improved (%) |
|--------------------------|----------------------------------|-----------------------|-------------------------------|
| Hot flashes | 43.3 | 43.3 | 86.6 |
| Profuse perspiration | 49.9 | 38.6 | 88.5 |
| Headache | 45.7 | 36.2 | 81.9 |
| Vertigo | 51.6 | 35.2 | 86.8 |
| Heart palpitation | 54.6 | 35.2 | 90.4 |
| Ringing in the ears | 54.8 | 38.1 | 92.9 |
| Nervousness/irritability | 42.4 | 43.2 | 85.6 |
| Sleep disturbances | 46.1 | 30.7 | 76.8 |
| Depressive moods | 46.0 | 36.5 | 82.5 |

and secondary), dysmenorrhea, polymenorrhea, uterine fibroids, and fibrocystic breast disease, its primary clinical application is menopause.^{[12] [13] [14]}

Menopause

In a large open study involving 131 doctors and 629 female patients, cimicifuga extract (two tablets twice daily providing a daily dosage of 4 mg 27-deoxyactein) produced clear improvement of menopausal symptoms in over 80% of patients within 6–8 weeks.^[9] As shown in [Table 75.1](#) , both physical and psychological symptoms improved.

Most patients reported noticeable benefits within 4 weeks after the onset of cimicifuga therapy. After 6–8 weeks, complete resolution of symptoms were achieved in a large percentage of patients. Cimicifuga was very well tolerated as there was no discontinuation of therapy and only 7% of patients reported mild transitory stomach complaints.

In a double-blind study, 60 patients were given cimicifuga extract (two tablets twice daily providing a daily dosage of 4 mg 27-deoxyactein), conjugated estrogens (0.625 mg daily), or diazepam (2 mg daily) for 12 weeks.^[9] Results from standard indexes of menopausal symptoms indicated a clear advantage of cimicifuga extract over both drugs. Cimicifuga's effect on relieving the depressive mood and anxiety associated with menopause was far superior to either diazepam or conjugated estrogens, as shown in

[Table 75.2](#) .

One of the most utilized assessments in clinical studies in menopause is the Kupperman Menopausal Index. This quantitative assessment of menopausal symptoms is achieved by grading in severity: severe = 3, moderate = 2, mild = 1, not present = 0. The symptoms assessed are:

TABLE 75-2 -- Effect on Kupperman Menopausal Index of cimicifuga compared with conjugated estrogens and diazepam

| Treatment group | Beginning | At 12 weeks |
|----------------------|-----------|-------------|
| Cimicifuga | 35 | 14 |
| Conjugated estrogens | 35 | 16 |
| Diazepam | 35 | 20 |

- hot flashes
- depressive moods
- profuse perspiration
- feelings of vertigo
- sleep disturbances
- loss of concentration
- headache
- joint pain
- nervousness/irritability
- heart palpitation.

The results on the Kupperman Menopausal Index from this trial clearly demonstrate cimicifuga extract's superiority over conjugated estrogens and diazepam, especially when safety and side-effects are taken into consideration.

In another double-blind study, 80 patients were given cimicifuga extract (two tablets twice daily providing a daily dosage of 4 mg 27-deoxyactein), conjugated estrogens (0.625 mg daily), or placebo for 12 weeks.^[10] Cimicifuga produced better results in the Kupperman Menopausal Index, the Hamilton anxiety test, and the vaginal lining than estrogens or placebo. The number of hot flashes experienced each day dropped from an average of five to less than one in the cimicifuga group. In comparison, the estrogen group only dropped from five to 3.5. Even more impressive was the effect of cimicifuga on the vaginal lining. While both conjugated estrogens and the placebo produced little effect, a dramatic increase in the number of superficial cells was noted in cimicifuga group.

In a double-blind study of 110 women, cimicifuga extract (two tablets twice daily providing a daily dosage of 4 mg 27-deoxyactein) was shown to exert significant improvements in menopausal symptoms.^[4] In addition to providing relief of hot flashes, cimicifuga once again demonstrated impressive results on the vaginal lining as

confirmed by vaginal smear.

In a study of 60 women under the age of 40 who had hysterectomies leaving at least one intact ovary, the women were given either cimicifuga extract (two tablets twice daily providing a daily dosage of 4 mg 27-deoxyactein), estriol (1 mg daily), conjugated estrogens (1.25 mg daily), or estrogen-progestin combination (Trisequens,

one tablet daily).^[11] Although the hormone therapies produced better results as determined by a modified Kupperman's Menopausal Index, cimicifuga still displayed significant effects in relieving the symptoms of "surgical menopause". These results indicate that cimicifuga can be a suitable alternative to estrogens in women having partial, and possibly even complete, hysterectomies.

Effects on bone resorption

One of the most publicized effects of estrogen is its role in maintaining bone health and preventing osteoporosis. While there is experimental and epidemiological evidence that phytoestrogens prevent osteoporosis and reduce bone resorption, there are currently no long-term studies demonstrating cimicifuga can prevent or improve osteoporosis. However, based on cimicifuga's mechanism of action and long-term clinical experience, many experts believe it will be shown to positively influence bone resorption. In patients at high risk for osteoporosis or those with confirmed low bone density, physicians should monitor therapy with cimicifuga by using the Osteomark-NTX or other suitable indicator of bone resorption.

DOSAGE

The dosage of cimicifuga is based on its content of 27-deoxyactein, which serves as an important biochemical marker to indicate therapeutic effect. The dosage of the cimicifuga extract used in the majority of clinical studies has been 2 mg of 27-deoxyactein twice daily. Here are the approximate dosage recommendations using other forms (non-standardized) of *Cimicifuga racemosa*:

- 27-deoxyactein: 2 mg b.i.d.
- powdered rhizome: 1–2 g
- tincture (1:5): 4–6 ml
- fluid extract (1:1): 3–4 ml (1 tsp)
- solid (dry powdered) extract (4:1): 250–500 mg.

The German Commission E has recommended that treatment with cimicifuga be limited to 6 months (which is also the standard recommendation for hormone replacement therapy); however, this recommendation was made prior to the detailed toxicology studies discussed below. Based on currently available data, cimicifuga is appropriate for

long-term continued use.

TOXICOLOGY

The standardized extract of *Cimicifuga racemosa* providing 1 mg of 27-deoxyactein per approximately 40 mg of extract per tablet known as Remifemin has been used in Germany since 1956 and has a remarkable safety record. No serious side-effects have ever been reported. The BGA, the German equivalent to the FDA in the US, includes no contraindications or limitations of use for cimicifuga. Therefore, cimicifuga offers a suitable natural alternative to hormone replacement therapy for menopause, especially where hormone replacement therapy is contraindicated, e.g. in women with a history of cancer, unexplained uterine bleeding, liver and gall bladder disease, pancreatitis, endometriosis, uterine fibroids or fibrocystic breast disease.

Since cimicifuga extract shows some, albeit weak, estrogenic activity, researchers have sought to determine Remifemin's effect on established breast tumor cell line whose growth in vitro depends on the presence of estrogens. The results from these experiments show no stimulatory effects, but rather inhibitory effects.^[15] Furthermore, combining Remifemin with tamoxifen was shown to potentiate the inhibitory effects of tamoxifen.

Detailed toxicology studies have also been performed on Remifemin. No teratogenic, mutagenic, or carcinogenic side-effects have been noted. The no-effect dosage in studies in a 6 month chronic toxicity study in rats was at 1,800 mg/kg body weight – or roughly 90 times the therapeutic dose.^[16] A 6 month toxicological study in rats is comparable to an unlimited treatment time in humans.

Chapter 76 - Coenzyme Q₁₀

Alan R. Gaby MD

INTRODUCTION

Coenzyme Q₁₀ (CoQ₁₀) is a compound found naturally in the human body. Because of its ubiquitous presence in nature and its quinone structure (similar to that of vitamin K), CoQ₁₀ is also known as ubiquinone ([Fig. 76.1](#)). The primary biochemical action of CoQ₁₀ is as a cofactor in the electron-transport chain, the series of redox reactions that are involved in the synthesis of ATP. Since most cellular functions are dependent on an adequate supply of ATP, CoQ₁₀ is essential for the health of virtually all human tissues and organs.

Although CoQ₁₀ can be synthesized in vivo, situations may arise in which the body's synthetic capacity is insufficient to meet CoQ₁₀ requirements. Susceptibility to CoQ₁₀ deficiency appears to be greatest in cells that are the most metabolically active (such as those in the heart, immune system, gingiva, and gastric mucosa), since these cells presumably have the highest requirements for CoQ₁₀. Tissue deficiencies or subnormal serum levels of CoQ₁₀ have been reported to occur in a wide range of medical conditions, including cardiovascular disease, hypertension, periodontal disease, and acquired immuno-deficiency syndrome (AIDS). In addition, CoQ₁₀ levels decline with advancing age, and this decline might contribute in part to some of the manifestations of aging.

A need for supplemental CoQ₁₀ could theoretically result from:

- impaired CoQ₁₀ synthesis due to nutritional deficiencies
 - a genetic or acquired defect in CoQ₁₀ synthesis or utilization
-

- increased tissue needs resulting from a particular illness
- the requirement to prevent the side-effects of a medical intervention.

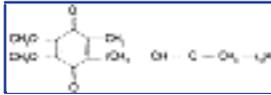

Figure 76-1 Coenzyme Q₁₀ .

Since oral administration of CoQ₁₀ can increase tissue levels of the nutrient, it is possible to correct CoQ₁₀ deficiency and its associated metabolic consequences by supplementation. ^[1]

Detection of CoQ₁₀ deficiency

CoQ₁₀ participates in the citric acid cycle (Krebs cycle) enzyme known as succinate dehydrogenase-CoQ₁₀ reductase. An assay of the activity of this enzyme has been used to detect deficiencies of CoQ₁₀. ^[2] If the enzyme is fully saturated with CoQ₁₀ in vivo, then addition of exogenous CoQ will not increase enzyme activity. On the other hand, exogenous CoQ will increase activity appreciably when tissue levels of CoQ₁₀ are low. More recently, measurements of serum CoQ₁₀ levels have been used to detect deficiencies.

CLINICAL APPLICATIONS

Immune function

Cells and tissues that play a role in immune function are highly energy-dependent and therefore require an adequate supply of CoQ₁₀ for optimal function. Several studies have demonstrated immune-enhancing effects of CoQ₁₀ or its analogues. ^[3] ^[4] ^[5] These effects included increased phagocytic activity of macrophages, increased proliferation of granulocytes in response to experimental infections, and prolonged survival in mice infected with *Pseudomonas aeruginosa*, *Staphylococcus aureus*, *Escherichia coli*, *Klebsiella pneumoniae*, or *Candida albicans*. Inoculation of animals with Friend leukemia virus reduced CoQ₁₀ levels in the blood and spleen, ^[6] whereas treatment of infected animals with CoQ₁₀ increased the survival rate and decreased the severity of hepatomegaly and splenomegaly. ^[7]

Immune function tends to decline with advancing age. In a study of elderly mice, suppression of the immune response was associated with a marked decline of CoQ₁₀ levels in thymic tissue. ^[8] This immune suppression was partly reversed by treatment

with CoQ₁₀.^[9] In a study of eight chronically ill patients, administration of 60 mg/day of CoQ₁₀ was associated with significant increases in serum levels of immunoglobulin G (IgG) after 27–98 days of treatment.^[10] These studies suggest that CoQ₁₀ may help to prevent or reverse the immunosuppression that is associated with aging or chronic disease.

Acquired immunodeficiency syndrome (AIDS)

AIDS is a complex disease that is associated with a wide range of nutritional deficiencies and immunological disorders. While correction of nutritional deficiencies will not cure AIDS, appropriate nutritional interventions may help to prevent weight loss and enhance overall immune function. In addition, since oxidative stress is believed to be involved in the pathogenesis of AIDS-related diseases, the antioxidant activity of CoQ₁₀ may be of value for individuals with AIDS.^[11]

In one study, blood levels of CoQ₁₀ were significantly lower in patients with AIDS-related complex (ARC) than in a control group and were significantly lower in patients with AIDS than in those with ARC.^[12] Six patients with AIDS or ARC were treated with 200 mg/day of CoQ₁₀. T-cell helper/suppressor ratios increased in three patients, becoming normal in one case. Five patients reported symptomatic improvement, which was dramatic in some cases. Furthermore, none of the patients developed opportunistic infections during a 4–7 month follow-up period. This study demonstrates that CoQ₁₀ deficiency is common in patients with HIV infection, and that supplementation with CoQ₁₀ may improve immune function and reduce the incidence of opportunistic infections.

Cancer

Because of its role in enhancing immune function, CoQ₁₀ has been considered as a possible anti-cancer agent. Administration of CoQ₁₀ reduced tumor size and increased survival in mice exposed to a chemical carcinogen.^[13] Preliminary studies in humans, though uncontrolled, are promising. In one study, 32 women with breast cancer who were classified as “high risk” because of tumor spread to the axillary lymph nodes received 90 mg/day of CoQ₁₀, along with vitamin C, vitamin E, beta-carotene, and essential fatty acids. In six of these women, the tumor became smaller. During the 18 month treatment period, none of the patients died (the expected number of deaths was four) and none showed signs of further distant metastases. Six patients had an apparent partial remission. In addition, patients receiving CoQ₁₀ required fewer pain killers.^[14]

In another report, two women with metastatic breast cancer received 390 mg/day of CoQ₁₀. One was a 44-year-old woman with numerous liver metastases. After treatment with CoQ₁₀ for 11 months, all of the liver metastases had disappeared and the patient was reported to be in excellent health. The other patient was a 49-year-old woman with breast cancer that had metastasized to the pleural cavity. After 6 months of CoQ₁₀ therapy, the pleural fluid had completely resolved and the patient was reported to be in

excellent health.^[15]

Although these reports are anecdotal, the results are far better than would normally be expected. Considering that CoQ₁₀ is virtually free of side-effects, empirical treatment of breast cancer with CoQ₁₀ seems justified.

Periodontal disease

Periodontal disease affects about 60% of young adults and 90% of individuals over the age of 65. Although proper oral hygiene is helpful, many people suffer from intractable gingivitis, often requiring surgery and resulting in eventual loss of teeth. Because periodontal disease is so common, the costs of periodontal surgery and other treatments contribute a significant amount to the overall cost of health care in the United States.

Healing and repair of periodontal tissues require efficient energy production, which depends on an adequate supply of CoQ₁₀. However, gingival biopsies revealed subnormal tissue levels of CoQ₁₀ in 60–96% of patients with periodontal disease and low levels of CoQ₁₀ in leukocytes in 86% of cases.^{[16] [17] [18] [19]} These findings indicate that periodontal disease is frequently associated with CoQ₁₀ deficiency.

Eighteen patients with periodontal disease received either 50 mg/day of CoQ₁₀ or a placebo in a 3 week double-blind trial.^{[20] [21]} Results were assessed according to a “periodontal score”, which included gingival-pocket depth, swelling, bleeding, redness, pain, exudate, and looseness of teeth. All eight patients receiving CoQ₁₀ improved, compared with only three of 10 receiving the placebo ($P < 0.01$). The treating dentists, who were unaware that a study was being conducted, consistently remarked about the “very impressive” rate of healing in patients treated with CoQ₁₀. One prosthodontist commented that the amount of healing that took place in 3 weeks in patients receiving CoQ₁₀ would normally require about 6 months.

In an open trial, administration of CoQ₁₀ produced “extraordinary post-surgical healing” (two to three times as fast as usual) in seven patients with advanced periodontal disease.^[22] The beneficial effect of CoQ₁₀ has also been confirmed in dogs, where it reduced the severity of experimentally induced periodontal disease.^[23]

Gastric ulcer

Susceptibility to gastric ulceration is related to the balance between ulcer-promoting factors (such as excessive gastric acidity and infection with *Helicobacter pylori*) and resistance factors (such as tissue integrity, production of protective mucus, and repair

mechanisms). Free radical damage is believed to be one of the primary mechanisms by which external factors induce gastric injury and peptic ulceration.^{[24] [25]} Since CoQ₁₀ possesses antioxidant activity, it may be capable of preventing ulceration by reducing the amount of free radical damage. In addition, the production of protective mucus and the rapid cell turnover of gastric mucosa are highly energy-dependent processes, which require the presence of adequate amounts of CoQ₁₀.

The efficiency of these protective and reparative processes may be compromised in some patients with gastric ulcers. With advancing age, the fundic mucosa and its rich blood supply are gradually replaced by pyloric tissue, which has poor vascularity. This change in cell type may result in hypoxia in certain portions of the stomach. The hypoxic state of gastric tissue could explain why gastric ulcers frequently become intractable in elderly patients or in those with chronic heart or lung disease.

The importance of CoQ₁₀ for healing of gastric ulcers has been demonstrated in animals.^[26] Gastric ulcers were induced in mice by the application of acetic acid. The mice were then maintained either in room air (20% oxygen) or under mild hypoxic conditions (17% oxygen). Ulcers healed normally in mice exposed to room air, but increased in size under hypoxic conditions. However, in hypoxic mice treated with CoQ₁₀ (50 mg/kg per day) the ulcers healed normally.

This study demonstrates that hypoxia has an adverse effect on the healing of gastric ulcers in animals, and that the effect of hypoxia can be prevented by administration of CoQ₁₀. Although human studies have not been done, empirical use of CoQ₁₀ seems to be a reasonable option for elderly patients with intractable gastric ulcers, particularly those who also have diseases likely to produce hypoxia.

Obesity

The tendency to become overweight is associated in some cases with impaired energy production. This abnormality may be in part genetically determined. Individuals with a family history of obesity have a 50% reduction in their thermogenic response to meals, suggesting the presence of an hereditary defect in energy output. Since CoQ₁₀ is an essential cofactor for energy production, it is possible that CoQ₁₀ deficiency is a contributing factor in some cases of obesity.

Serum levels of CoQ₁₀ were found to be low in 14 (52%) of 27 morbidly obese patients.^[27] Nine of these 27 individuals (five with low CoQ₁₀ levels) received 100 mg/day of CoQ₁₀ along with a 650 kcal/day diet. After 8–9 weeks, the mean weight loss in the CoQ₁₀-deficient group was 13.5 kg, compared with 5.8 kg in those with normal levels of CoQ₁₀.

One possible interpretation of this study is that about 50% of obese individuals are deficient in CoQ₁₀ and that replacement therapy accelerates weight loss during calorie

restriction. However, it is also possible that CoQ₁₀ treatment had nothing to do with the accelerated weight loss. Obese individuals with low CoQ₁₀ levels may have other metabolic abnormalities which are more directly related to their obesity. A low CoQ₁₀ level might therefore have been an effect, rather than a cause, of the abnormalities that caused obesity. Until a controlled study

is done to evaluate the effectiveness of this therapy, the potential value of CoQ₁₀ as a treatment for obesity remains speculative.

Physical performance

Because CoQ₁₀ is involved in energy production and its concentration in muscle is correlated with performance, it is possible that supplementation could enhance aerobic capacity and muscle performance. In one study, six healthy sedentary men (mean age, 21.5 years) performed a bicycle ergometer test before and after taking CoQ₁₀ (60 mg/day) for 4–8 weeks.^[28] CoQ₁₀ treatment improved certain performance parameters, including work capacity at submaximal heart rate, maximal work load, maximal oxygen consumption, and oxygen transport. These improvements ranged from 3 to 12% and were evident after about 4 weeks of supplementation. This study suggests that administration of CoQ₁₀ improves physical performance in sedentary individuals. The effect of CoQ₁₀ on the performance of trained athletes has not shown benefit (see [Ch. 59](#) for a more complete discussion).

Muscular dystrophy

Biochemical evidence of CoQ₁₀ deficiency was found in cardiac and skeletal muscle of animals with hereditary muscular dystrophy.^[29] In addition, treatment with CoQ₁₀ or its analogues increased survival and improved the performance of dystrophic mice, rabbits, and monkeys, as determined by a reduction of creatinuria, regaining of righting reflex, and weight gain.^{[30] [31] [32] [33]}

Deficiency of CoQ₁₀ has been found in muscle mitochondria of humans with muscular dystrophy.^[34] This deficiency could conceivably be involved in the pathogenesis of cardiac disease, which occurs in virtually every form of muscular dystrophy and myopathy. In a double-blind study, 100 mg of CoQ₁₀ was given daily for 3 months to 12 patients with progressive muscular dystrophy. CoQ₁₀ treatment resulted in significant improvements in cardiac output and stroke volume, as well as increased physical well-being in four of eight patients.^[35] Subjective improvements included increased exercise tolerance, reduced leg pain, better control of leg function, and less fatigue. The mechanism of action of CoQ₁₀ is probably related to improved energy production in

muscle cells.

Allergy

When passively sensitized guinea pig lung tissue was preincubated with CoQ₁₀, release of both histamine and slow-reacting substance of anaphylaxis induced by antigen challenge was markedly inhibited.^[36] This study raises the possibility that CoQ₁₀ may be of value in the treatment of various allergy-related disorders. However, no clinical trials have been performed in this area.

Cardiovascular disease – general considerations

Enhancing myocardial function is an important, though frequently overlooked, component of the overall prevention and treatment of cardiovascular disease. CoQ₁₀ plays a key role in energy production, and is therefore essential for all energy-dependent processes, including heart muscle contraction. CoQ₁₀ deficiency has been documented in patients with various types of cardiovascular disease. It is not clear whether a decline in CoQ₁₀ levels is a primary cause or a consequence of heart disease. However, given the fundamental involvement of CoQ₁₀ in myocardial function, it is not unlikely that CoQ₁₀ deficiency would exacerbate heart disease and that correction of such a deficiency would have therapeutic value.

In addition, CoQ₁₀ has been shown to be a potent antioxidant. In fact, ubiquinol-10, the reduced form of CoQ₁₀, protected human low-density lipoproteins (LDL) more efficiently against lipid peroxidation than did vitamin E.^[37] Since oxidation of LDL is believed to be an initiating factor in the development of atherosclerosis, CoQ₁₀ would appear to be a preventive factor.

Cardiac disease

Circulating levels of CoQ₁₀ are significantly lower in patients with ischemic heart disease and in those with dilated cardiomyopathy (mostly New York Heart Association [NYHA] functional class III or IV) than in healthy controls.^{[38] [39]} In another study, CoQ₁₀ levels in myocardial tissue (estimated by enzymatic methods) were low in approximately 75% of patients undergoing cardiac surgery. Concentrations of CoQ₁₀ declined progressively in both blood and myocardial tissue with increasing severity of heart disease.^[40] Myocardial deficiencies of CoQ₁₀ were also found in the majority of patients with aortic stenosis or insufficiency, mitral stenosis or insufficiency, diabetic cardiomyopathy, tetralogy of Fallot, atrial septal defects and ventricular septal defects.^[41] In patients with cardiomyopathy and myocardial deficiency of CoQ₁₀, oral administration of 100 mg/day of CoQ₁₀ for 2–8 months resulted in an increase in myocardial CoQ₁₀ levels, ranging from 20 to 85%.^[42] These findings suggest that CoQ₁₀ deficiency is common in patients with various types of cardiovascular disease, and that oral administration of CoQ₁₀ can

increase tissue levels of this nutrient.

Cardiomyopathy

In one study, 126 patients with dilated cardiomyopathy (98% of whom were in NYHA functional class III or IV)

667

received 100 mg/day of CoQ₁₀ for periods of up to 66 months. After 6 months of treatment, the mean ejection fraction increased from 41% to 59% ($P < 0.001$), and remained stable thereafter with continued treatment. After 2 years 84% of the patients were still alive, and at 5.5 years 52% were alive.^[43] These survival rates are considerably better than the published survival statistics of patients given conventional therapy (i.e. 2-year survival rate of 50% for symptomatic cardiomyopathy, and 1-year survival rate of 50% for decompensated cardiomyopathy).

In another study, 88 patients with cardiomyopathy received 100 mg/day of CoQ₁₀ for periods of 1–24 months. Significant improvements in at least two of three cardiac parameters (ejection fraction, cardiac output, and NYHA class) were seen in 75–85% of the patients. Approximately 80% of the patients improved to a lower (i.e. more favorable) NYHA functional class.^[44]

In a double-blind, cross-over trial, 19 patients with cardiomyopathy (NYHA classes III and IV) received 100 mg/day of CoQ₁₀ or a placebo, each for 12 weeks. Compared with placebo, CoQ₁₀ treatment significantly increased cardiac stroke volume and ejection fraction. Eighteen patients reported improvement in activity while taking CoQ₁₀.^[45]

Congestive heart failure

The potential of CoQ₁₀ as a treatment for congestive heart failure (CHF) was suggested as early as 1967 by Japanese researchers.^[46] In 1976, these same investigators administered 30 mg/day of CoQ₁₀ to 17 patients with CHF. All of the patients improved, and nine (53%) became asymptomatic after 4 weeks of treatment.^[47]

In an open trial of 34 patients with refractory NYHA class IV CHF, administration of 100 mg/day of CoQ₁₀ resulted in sustained improvement in cardiac function in 28 cases (82%). The survival rate after 2 years was 62%, compared with an expected 2-year survival rate of less than 25% for similar patients.^[48]

In another study, 12 patients with advanced CHF who had failed to respond adequately to digitalis and diuretics received 100 mg/day of coenzyme Q₁₀ for 7 months. Two-thirds of the patients showed definite clinical improvement after a mean treatment period of 30

days. In these patients, dyspnea at rest disappeared and energy level and tolerance for activity increased. Objective improvements included decreased hepatic congestion, reductions in heart rate and heart volume, and a decline in systolic time intervals (suggesting improved myocardial performance). Withdrawal of coenzyme Q₁₀ was followed by severe clinical relapse, with subsequent improvement upon resumption of treatment.^[49]

In a large multicenter trial, 1,113 CHF patients received 50–150 mg/day of CoQ₁₀ for 3 months (78% of the patients received 100 mg/day). The proportion of patients with improvements in clinical signs and symptoms were as follows:^[50]

- cyanosis, 81%
- edema, 76.9%
- pulmonary rales, 78.4%
- enlargement of the liver area, 49.3%
- jugular reflux, 81.5%
- dyspnea, 54.2%
- palpitations, 75.7%
- sweating, 82.4%
- arrhythmia, 62%
- insomnia, 60.2%
- vertigo, 73%
- nocturia, 50.7%.

The results of these uncontrolled studies were confirmed more recently in a double-blind trial. Some 641 patients with CHF (NYHA classes III or IV) were randomly assigned to receive placebo or CoQ₁₀ (2 mg/kg per day) for 1 year. Conventional therapy was continued in both groups. The number of patients requiring hospitalization during the study for worsening heart failure was 38% less in the CoQ₁₀ group than in the placebo group ($P < 0.001$). Episodes of pulmonary edema were reduced by about 60% in the CoQ₁₀ group, compared with the placebo group ($P < 0.001$).^[51]

Angina

Twelve patients with stable angina pectoris were randomly assigned to receive 150 mg/day of CoQ₁₀ or a placebo in a 4 week double-blind cross-over trial. CoQ₁₀ treatment significantly increased exercise tolerance on a treadmill (time before onset of chest pain), and significantly increased the time until ST-segment depression occurred. Compared with placebo, there was a 53% reduction in the frequency of anginal episodes and a 54% reduction in the number of nitroglycerin tablets needed during CoQ₁₀ treatment; however, these differences were not statistically significant.^[52]

These results suggest that CoQ₁₀ is a safe and effective treatment for angina pectoris. Although the amelioration of anginal attacks was not statistically significant, the magnitude of the effect was large. It would therefore be worthwhile to perform a similar

study with a larger number of patients.

Arrhythmias

Twenty-seven patients with ventricular premature beats (VPBs) and no evidence of organic heart disease received a placebo for 3–4 weeks, followed by 60 mg/day of CoQ₁₀ for 4–5 weeks. The reduction in VPBs was significantly greater after CoQ₁₀ than after placebo. The beneficial

668

effect of CoQ₁₀ was seen primarily in diabetics, in whom the mean reduction in VPB frequency was 85.7%. A significant reduction in VPBs also occurred in one (11%) of nine otherwise healthy patients and in four (36%) of 11 patients with hypertension.^[53]

Prevention of adriamycin toxicity

The clinical value of adriamycin as an anti-cancer agent is limited by its toxicity, which includes cardiomyopathy and irreversible heart failure. Adriamycin-induced cardiotoxicity is believed to be caused, at least in part, by a reduction in CoQ₁₀ levels and by inhibition of CoQ₁₀-dependent enzymes. In rats treated with adriamycin, administration of CoQ₁₀ restored the levels of this nutrient to normal and prevented adriamycin-induced morphologic changes in the heart.^[54] Treatment with CoQ₁₀ also prevented adriamycin-induced cardiotoxicity in rabbits.^[55]

Cancer patients receiving adriamycin had lower myocardial levels of CoQ₁₀ than did controls. The magnitude of CoQ₁₀ depletion was directly related to the severity of cardiac impairment.^[56] To determine the effect of CoQ₁₀ supplementation on adriamycin cardiotoxicity, seven patients receiving adriamycin were also given 100 mg/day of CoQ₁₀, beginning 3–5 days before adriamycin was started. Another seven patients (control group) received adriamycin without CoQ₁₀. Cardiac function deteriorated significantly in the control group, whereas patients given CoQ₁₀ had little or no cardiotoxicity, even though the cumulative dose of adriamycin in the CoQ₁₀ group was 50% greater than that in the control group.^[57] Despite the small number of patients in this study, the results are highly encouraging. Since administration of CoQ₁₀ does not appear to affect the antitumor activity of adriamycin, CoQ₁₀ prophylaxis seems appropriate for all patients receiving adriamycin.^[58]

Protection during cardiac surgery

Postoperative low cardiac output is a major cause of early death following cardiac surgery. Fifty patients undergoing cardiac surgery for acquired valvular lesions were

randomly assigned to receive 30–60 mg/day of CoQ₁₀ for 6 days prior to surgery or to a control group that did not receive CoQ₁₀. Postoperatively, a state of severe low cardiac output developed in 48% of the patients in the control group, compared with only 12% of those in the CoQ₁₀ group. These results suggest that pre-operative administration of CoQ₁₀ increases the tolerance of the heart to ischemia during aortic cross-clamping.^[59]

Mitral valve prolapse

Cardiac performance was evaluated using an isometric hand-grip test in 194 children with symptomatic mitral valve prolapse. Prior to treatment, all patients had an abnormal hand-grip test. Sixteen children received 2 mg/kg per day of CoQ₁₀ or a placebo for 6 weeks, in a single-blind trial. Hand-grip strength became normal in seven of the patients receiving CoQ₁₀ and in none of the placebo-treated patients.^[60]

However, the relevance of this study to the treatment of mitral valve prolapse in adults is doubtful. Aside from the study's inadequate blinding, isometric hand-grip may not be a reliable test of cardiac function. Furthermore, impaired cardiac function is not typical of mitral valve prolapse in adults, and the symptoms associated with this condition do not appear to be caused by diminished cardiac function. While the symptoms associated with mitral valve prolapse may respond to magnesium supplementation,^[61] the role of CoQ₁₀ in the treatment of this disorder is unclear.

Hypertension

Enzymatic assays revealed a deficiency of CoQ₁₀ in 39% of 59 patients with essential hypertension, compared with only 6% of healthy controls. In animal models of hypertension, including spontaneously hypertensive rats, uninephrectomized rats treated with saline and deoxycorticosterone, and experimentally hypertensive dogs, orally administered CoQ₁₀ significantly lowered blood pressure.^{[62] [63] [64] [65]}

Twenty-six patients with essential hypertension received 50 mg of CoQ₁₀ twice a day. After 10 weeks of treatment, mean systolic blood pressure decreased from 164.5 to 146.7 mmHg and mean diastolic blood pressure decreased from 98.1 to 86.1 mmHg ($P < 0.001$). The fall in blood pressure was associated with a significant reduction in peripheral resistance, but there were no changes in plasma renin activity, serum and urinary sodium and potassium, and urinary aldosterone. These results suggest that treatment with CoQ₁₀ decreases blood pressure in patients with essential hypertension, possibly because of a reduction in peripheral resistance.^[66]

In another study, 109 patients with essential hypertension received CoQ₁₀ (average dose, 225 mg/day) in addition to their usual antihypertensive regimen. The dosage of CoQ₁₀ was adjusted according to clinical response and blood CoQ₁₀ levels (the aim was to attain blood levels greater than 2.0 mcg/ml). The need for antihypertensive medication declined gradually, and after a mean treatment period of 4.4 months, about half of the patients were able to discontinue between one and three drugs.^[67] Similar

results have been reported by others.^[68]

It should be noted that the effect of CoQ₁₀ on blood pressure was usually not seen until after 4–12 weeks of therapy. That observation is consistent with the delayed

increase in enzyme activity that results from administration of CoQ₁₀. Thus, CoQ₁₀ is not a typical antihypertensive drug; rather, it seems to correct some metabolic abnormality that is involved in the pathogenesis of hypertension.

Diabetes mellitus

Diabetes mellitus is a multifactorial disease that is associated with a number of different metabolic abnormalities. The electron transport chain, of which CoQ₁₀ is a component, plays a major role in carbohydrate metabolism. A deficiency of CoQ₁₀ might therefore have an adverse effect on glucose tolerance.

Decreased levels of CoQ₁₀ (measured as total CoQ) were found in rats with experimentally induced diabetes. Administration of CoQ₇ (an analog of CoQ₁₀) partially corrected abnormal glucose metabolism in alloxan-diabetic rats. (Before CoQ₁₀ became commercially available, some therapeutic trials were done with CoQ₇. These two compounds are considered to be nutritionally equivalent.)

Thirty-nine diabetics received 120 mg/day of CoQ₇ for 2–18 weeks. Fasting blood sugar levels fell by at least 30% in 31% of the patients and the concentration of ketone bodies declined by at least 30% in 59% of the patients. One patient who was poorly controlled on 60 units/day of insulin showed a marked fall in fasting blood sugar and ketone bodies after receiving CoQ₇.^[69]

Infertility

Because sperm production and function are highly energy-dependent processes, CoQ₁₀ deficiency could presumably be a contributing factor to infertility in men. In one study, administration of 10 mg/day of CoQ₇ resulted in a considerable increase in sperm count and motility in a group of infertile men.^[70] Additional research is needed to determine whether CoQ₁₀ therapy has a role in the treatment of infertility.

Drug interactions

Cholesterol-lowering drugs such as lovastatin and pravastatin inhibit the enzyme 3-hydroxy-3-methylglutaryl(HMG)-CoA reductase, which is required for biosynthesis of

both cholesterol and CoQ₁₀. Thus, administration of these drugs might compromise CoQ₁₀ status by decreasing its synthesis. Supplementation of the diet of rats with lovastatin (400 mg/kg of diet) for 4 weeks reduced the concentration of CoQ₁₀ in the heart, liver, and blood.^[71] In another study, administration of lovastatin to five patients receiving CoQ₁₀ for heart failure was followed by a reduction in blood levels of CoQ₁₀ and a significant deterioration of clinical status. Some of these patients improved after the dosage of CoQ₁₀ was increased or the lovastatin was discontinued.^[72]

These results suggest that people who have low CoQ₁₀ levels and suboptimal cardiac function might develop clinically significant CoQ₁₀ depletion after taking an HMG-CoA reductase inhibitor. Although individuals with high CoQ₁₀ levels and good cardiac function can probably tolerate these drugs better, a case can be made that all patients being treated with HMG-CoA reductase inhibitors should also receive CoQ₁₀ prophylactically.

The beta-blockers propranolol and metoprolol have been shown to inhibit CoQ₁₀-dependent enzymes.^[73] The antihypertensive effect of these drugs might therefore be compromised in the long run by the development of CoQ₁₀ deficiency. In one study, administration of 60 mg/day of CoQ₁₀ reduced the incidence of drug-induced malaise in patients receiving propranolol.^[74]

A number of phenothiazines and tricyclic antidepressants have also been shown to inhibit CoQ₁₀-dependent enzymes. It is therefore possible that CoQ₁₀ deficiency may be a contributing factor to the cardiac side-effects that are frequently seen with these drugs. In two clinical studies, supplementation with CoQ₁₀ improved electrocardiographic changes in patients on psychotropic drugs.^[75]

DOSAGE

The optimal dose of CoQ₁₀ is not known and probably varies according to the severity of the condition being treated. For example, 30 mg/day of CoQ₁₀ was reportedly effective in the treatment of mild congestive heart failure, 90 mg/day resulted in improvements in some cases of cancer, and 390 mg/day was associated with complete regression of liver metastases in a patient with breast cancer.

The usual dosage of CoQ₁₀ is 30 mg/day, with a range of 20–100 mg/day. Although higher doses were used in some studies, it is not clear that these larger amounts are necessary for most clinical situations. The dosage of CoQ₁₀ should be adjusted according to the response of the patient. Larger doses (up to 100 mg/day) may be needed in cases of severe cardiac disease. Because of the serious nature of the cardiotoxicity induced by adriamycin, CoQ₁₀ prophylaxis should follow the reportedly effective dosage schedule (100 mg/day, beginning 3–5 days prior to the start of adriamycin therapy). Some cases of muscular dystrophy may require large doses of

CoQ₁₀ ; the dosage in these cases should be assessed according to clinical response.

Since the synthesis of new CoQ₁₀ -dependent enzymes is a slow process, a clinical response might not occur until 8 or more weeks after therapy is begun.^[76]

TOXICOLOGY

Coenzyme Q₁₀ is generally well tolerated, and no serious adverse effects have been reported with long-term use. Because safety during pregnancy and lactation has not been proven, CoQ₁₀ should not be used during these times unless the potential clinical benefit outweighs the risks. CoQ₁₀ is contraindicated in cases of known hypersensitivity. In a series of 5,143 patients treated with 30 mg/day of CoQ₁₀ , the following incidence of side-effects was reported:^[59]

- epigastric discomfort, 0.39%
- loss of appetite, 0.23%
- nausea, 0.16%
- diarrhea, 0.12%.

Chapter 77 - *Coleus forskohlii*

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

Coleus forskohlii (family: Labiatae)
Synonyms: *Coleus barbatus*, *Plectranthus barbatus*, *P. forskohlii*
Common name: coleus

GENERAL DESCRIPTION

Coleus forskohlii is a small member of the mint (Labiatae) family. It grows as a perennial on the sun-exposed, dry hill slopes between an altitude of 1,000 to 6,000 feet on the mountains in the subtropical, temperate climactic zone of India, Nepal, Sri Lanka, and Thailand. Its Latin name comes from the word *coleos*, which means “sheath” and refers to the fused filaments that form a sheath around the stylus of the flower. The epithet, *forskohlii*, was given to commemorate the Finnish botanist Forskal, who traveled extensively in Egypt and Arabia in the 18th century.

The radially spread rootstock is the portion of the plant that has been used for medicinal purposes. The rootstock is also the source of a compound of unique biological importance, forskolin. No other species of *Coleus* contains forskolin.

CHEMICAL COMPOSITION

The primary chemical of clinical interest contained in *C. forskohlii* is the diterpine forskolin ([Fig. 77.1](#)). In 1974, forskolin was discovered during a large-scale screening of medicinal plants by the Indian Central Drug Research Institute. The screening revealed the presence of a hypotensive

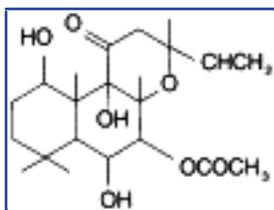

Figure 77-1 Forskolin.

674

and spasmolytic component which was initially named coleanol.^[1] Additional investigation determined the exact chemical structure and the name was changed to forskolin. Between 1981 and 1994, forskolin was investigated in over 5,000 in vitro research studies designed to understand better the cellular processes governed by cAMP (discussed below). While most of these studies have used this isolated constituent, there is evidence that other components within the plant extract enhance the absorption and biological activity of forskolin. However, no detailed analysis of the chemical composition of *C. forskohlii* could be found.

HISTORY AND FOLK USE

Coleus forskohlii has a long history of use in Ayurvedic, Siddha, and Unani systems of medicine. Studies of the pharmacological activity of forskolin substantiate the traditional uses of *C. forskohlii* in such conditions as:^[1]

- cardiovascular disease
- eczema
- abdominal colic
- respiratory disorders
- painful urination
- insomnia
- convulsions.

PHARMACOLOGY

The basic mechanism of action of forskolin is the activation of adenylate cyclase, which increases cyclic adenosine monophosphate (cAMP) in cells.^[2] Cyclic AMP is perhaps the most important cell-regulating compound. Once formed, it activates many other enzymes involved in diverse cellular functions.

Under normal situations, cAMP is formed when an activating hormone (e.g. epinephrine) binds to a receptor site on the cell membrane and stimulates the activation of adenylate cyclase. This enzyme is found in all cellular membranes and only the specificity of the receptor site determines which hormone will activate it in a particular cell. In contrast, forskolin appears to directly activate adenylate cyclase, bypassing

hormonal transmembrane activation of adenylate cyclase.

The physiological and biochemical effects of a raised intracellular cAMP level include:

- inhibition of platelet activation and degranulation
- inhibition of mast cell degranulation and histamine release
- increased force of contraction of heart muscle
- relaxation of the arteries and other smooth muscles
- increased insulin secretion
- increased thyroid function
- lipolysis.

Recent studies have found forskolin to possess additional mechanisms of action independent of its ability to directly stimulate adenylate cyclase and cAMP-dependent physiological responses.^[3] Specifically, forskolin has been shown to inhibit a number of membrane transport proteins and channel proteins through a mechanism that does not involve the production of cAMP. The result is again a transmembrane signaling that results in activation of other cellular enzymes. Research is underway to determine the exact receptors to which forskolin is binding.

Another action of forskolin is the inhibition of platelet-activating factor (PAF) by interfering with PAF binding to receptor sites.^[4] PAF plays a central role in many inflammatory and allergic processes, including neutrophil activation, increasing vascular permeability, smooth muscle contraction including bronchoconstriction, and reduction in coronary blood flow. Treatment of platelets with forskolin prior to PAF exposure results in a 30–40% decrease in PAF binding. This decrease in PAF binding caused by forskolin was concomitant with a decrease in the physiological responses of platelets induced by PAF. However, this forskolin-induced decrease in PAF binding was not a consequence of cAMP formation, as the addition of a cAMP antagonist did not inhibit the action of forskolin. In addition, the inactive analog of forskolin, dideoxyforskolin, which does not activate adenylyl cyclase, also reduced PAF binding to its receptor. Researchers speculate that the action of forskolin on PAF binding is due to a direct effect of this molecule and its analog on the PAF receptor itself or to components of the post-receptor signaling for PAF.

CLINICAL APPLICATIONS

The therapeutic ramifications of *C. forskohlii* based on the pharmacology of forskolin are immense. There are many conditions where a decreased intracellular cAMP level is thought to be a major factor in the development of the disease process. At present, *C. forskohlii* appears to be especially well indicated in these types of conditions which include:

- atopic dermatitis
- asthma
- psoriasis
- angina

- hypertension.

Although *C. forskohlii* can be used alone, it may prove to be most useful when combined with other botanicals and/or other measures in the treatment of these disorders.

Inflammatory conditions

Allergic conditions such as asthma and eczema are characterized by a relative decrease in cAMP in both

675

the bronchial smooth muscle and the skin. As a result, mast cells degranulate and smooth muscle cells contract more readily. In addition, these allergic conditions are also characterized by excessive levels of PAF.

Asthma and eczema

Current drug therapy for allergic conditions like asthma and eczema is largely designed to increase cAMP levels by using substances which either bind to receptors to stimulate adenylate cyclase (e.g. corticosteroids) or inhibit the enzyme phosphodiesterase which breaks down cAMP once it is formed (e.g. methylxanthines). These actions are different than forskolin's ability to increase the production of cAMP via transmembrane activation of adenylate cyclase. The cAMP-elevating action of forskolin supports the use of *C. forskohlii* extracts alone or in combination with standard drug therapy in the treatment of virtually all allergic conditions.

Coleus forskohlii extracts may be particularly useful in asthma, as increasing intracellular levels of cAMP results in relaxation of bronchial muscles and relief of respiratory symptoms. Forskolin has been shown to have remarkable effects in relaxing constricted bronchial muscles in asthmatics.^{[5] [6] [7]} This type of smooth muscle is also found in the gastrointestinal tract, uterus, bladder, and arteries. Forskolin has been shown to have tremendous antispasmodic action on these various smooth muscles. This antispasmodic action of forskolin supports the folk medicine use of *C. forskohlii* in the treatment of not only asthma, but also intestinal colic, uterine cramps (menstrual cramps), painful urination, angina, and hypertension. In addition to forskolin's ability to relax smooth muscle, its other anti-allergic activities, such as inhibiting the release of histamine and synthesis of allergic compounds, are also of benefit in the treatment of asthma.^[8]

One double-blind clinical study sought to compare the anti-asthmatic effects of forskolin with the drug fenoterol. Sixteen patients with asthma were studied using three different preparations:

- single inhalation doses of fenoterol
- dry powder capsules of fenoterol (0.4 mg)
- metered doses of fenoterol (0.4 mg), and forskolin dry powder capsules (10.0 mg).

All three caused a significant improvement in respiratory function and bronchodilation. However, while the fenoterol preparations caused tremors and decreased blood potassium levels, no such negative effects were seen with forskolin.

In another study, the bronchodilating effect (after 5 minutes) of forskolin was as good as that produced by fenoterol in 12 healthy volunteers (non-smokers), as determined by whole body plethysmography.^[9] Both substances were administered by metered dose inhalers. At the beginning (after 3 and 5 minutes), the protective effect of forskolin against inhaled acetylcholine was as good as that produced by fenoterol, while later on (after 15 and 30 minutes), fenoterol provided stronger protection.

Whether orally administered forskolin in the form of *C. forskohlii* extract would produce similar bronchodilatory effects is yet to be determined. However, based on the plant's historical use and additional mechanisms of action, it appears likely.

Psoriasis

Psoriasis is a common skin disorder that seems to be caused by a relative decrease in cAMP as compared with cyclic guanine monophosphate (cGMP). The result is a tremendous increase in cell division. In fact, cells divide in psoriasis at a rate 1,000 times greater than the normal. Preliminary studies have indicated that forskolin may be of great benefit to individuals with psoriasis via its ability to re-establish the normal balance between cAMP and cGMP.^[4]

Cardiovascular effects

Perhaps the most useful clinical applications of *C. forskohlii* extracts will turn out to be for cardiovascular diseases such as hypertension, congestive heart failure, and angina. The cardiovascular effects of *C. forskohlii* and its components have been studied in great detail.^{[1] [10] [11]} Its basic cardiovascular actions involve lowering of blood pressure along with improving contractility of the heart. Again, this is related to increasing cAMP levels throughout the cardiovascular system which results in relaxation of the arteries and increased force of contraction. The net effect is significant improvement of cardiovascular function.

Hypertension and cardiac failure

Several clinical and animal studies have supported the use of forskolin in hypertension and cardiac failure.^{[10] [11] [12] [13]} In one human study involving seven patients with dilated cardiomyopathy, forskolin was shown to improve left ventricular function primarily via reduction of preload and without raising metabolic costs.^[12] This study confirmed earlier

animal studies showing forskolin increases the contractile force of heart muscle.^[11]

In another human study, the hemodynamic effects of intravenous (3 mcg/kg per minute) forskolin given to patients with dilated cardiomyopathy was evaluated.^[13] Although systemic vascular resistance and diastolic pressure fell, forskolin had no effect on cardiac index, ejection fraction, or myocardial oxygen consumption at this very

676

low dosage. However, when a small dosage of dobutamine was given along with the forskolin, an increase of all four parameters was observed. At a higher dosage (4 mcg/kg per minute), forskolin increased heart function by 19% and produced a 16% rise in heart rate. However, these changes were associated with symptomatic flush syndromes. These results indicate that forskolin may best be used in congestive heart failure in combination with other botanicals such as *Crataegus* (see [Ch. 79](#)).

Forskolin has also been shown to be a direct cerebral vasodilator, indicating that it may prove to be useful in cerebral vascular insufficiency and post-stroke recovery.^[14]

An additional mechanism of action particularly beneficial in a wide range of cardiovascular conditions is inhibition of platelet aggregation. In this area, the evidence indicates that the standardized *C. forskohlii* extract is superior to pure forskolin.^[15] In an animal model for evaluating in vivo inhibition of platelet aggregation, rats were divided into four groups: group 1 received *C. forskohlii* extract (480 mg/kg supplying 20 mg/kg of forskolin); group 2 received forskolin (20 mg/kg); group 3 received dipyridamole; and group 4 served as the control. All treatments were given orally once daily. ADP-induced platelet aggregation was measured on odd days 1 through 15. All three treatments produced significant inhibition of platelet aggregation. On day 15, the inhibitions were approximately 42% for group 1, 37% for group 2, and 52% for group 3. Hence, the extract of *C. forskohlii* produced greater inhibition than the pure forskolin.

OTHER CLINICAL APPLICATIONS

Coleus forskohlii extracts concentrated and standardized for forskolin content may prove to be useful in a number of other clinical applications, including:

- weight-loss programs
- hypothyroidism
- malabsorption and digestive disorders
- depression
- prevention of cancer metastases
- immune system enhancement.

Glaucoma

In clinical studies, forskolin has been shown to greatly reduce intraocular pressure (IOP) when it is applied directly to the eyes.^{[16] [17] [18] [19]} This effect indicates that topical forskolin preparations may turn out to be of benefit in the treatment of glaucoma. Unlike current drug therapy, forskolin actually increases intraocular blood flow, has no side-effects, and does not induce miosis.

Weight-loss programs

Lipolysis, the breakdown of stored fat, is regulated by cAMP. Forskolin has been shown to stimulate lipolysis as well as inhibit the synthesis of fat in adipocytes.^{[20] [21] [22] [23]} Forskolin has also been shown to counteract the age-related decreased response of fat cells to lipolytic hormones like epinephrine.^[24]

Hypothyroidism

Forskolin has been shown to increase thyroid hormone production as well as stimulate thyroid hormone release.^[25]

Malabsorption and digestive disorders

Forskolin stimulates digestive secretions including the release of hydrochloric acid, pepsin, amylase, and pancreatic enzymes.^{[26] [27]} Forskolin has been shown to promote nutrient absorption in the small intestine.^[28] *C. forskohlii* extracts may prove to be quite useful in treating dry mouth, as forskolin increases salivation.^[29]

Depression

Forskolin has been shown to exert antidepressant activity in animal studies.^[30]

Cancer metastases

Forskolin has been shown to be a potent inhibitor of cancer metastasis in mice injected with malignant cells.^[31] As little as 82 mcg administered to mice inhibited metastasis by over 70%.

Immune system enhancement

Forskolin exhibits potent immune system enhancement (primarily through activation of macrophages and lymphocytes) in several models.^{[32] [33] [34]}

DOSAGE

The recommended dosage should be based upon the level of forskolin. As the forskolin content of *Coleus* root is typically only 0.2–0.3%, crude *Coleus* products may not be

sufficient to produce a pharmacological effect and the safety of the whole root at high dosages is not as well studied. It is best to use standardized extracts which have known forskolin content.

Daily dosages are as follows:

- forskolin: 5–10 mg two to three times daily
- standardized extract (18% forskolin): 50 mg two to three times daily
- dried root: 2–5 g two to three times daily.

TOXICOLOGY

The animal studies on forskolin indicate low toxicity. The pharmacology of forskolin suggests it would be wise to restrict the use *C. forskohlii* preparations in patients with low blood pressure and peptic ulcers. *C. forskohlii* preparations should be used with caution in patients on prescription medications, especially anti-asthmatics and antihypertensives, due to its ability to potentiate these and other drugs' effects.

Chapter 78 - *Commiphora mukul* (mukul myrrh tree)

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

Commiphora mukul (family: Burseraceae)
Common name: mukul myrrh tree

GENERAL DESCRIPTION

Commiphora mukul is a small thorny tree 4–6 feet tall that is native to Arabia and India. In its natural setting, the tree remains essentially free of foliage for most of the year. Its bark is ash-colored and comes off in rough flakes, exposing the under-bark that also peels off. Upon injury, the tree exudes a yellowish gum resin that has a balsamic odor. This oleoresin is referred to as “gum guggul” or “guggulu”. It is this resin which is used for medicinal purposes. When tapped during the winter, the average tree yields 1.5–2 lb of resin.^[1]

CHEMICAL COMPOSITION

Guggulu contains a mixture of diverse chemical constituents which can be separated into several fractions.^[1] The first step in the fractionation process involves mixing guggulu with ethyl acetate, yielding a soluble and an insoluble fraction (see [Fig. 78.1](#)). The insoluble fraction, containing the carbohydrate constituents, is regarded as toxic and is the major reason why extracts of the soluble portion are preferred to crude gum guggul for medical use. The insoluble portion has no demonstrable pharmacological activity other than toxicity.^[1]

In contrast, the soluble portion possesses significant cholesterol-lowering and anti-inflammatory activity. The soluble portion can be further separated into base, acid, and neutral fractions. The neutral portion possesses almost all of the cholesterol lowering activity while the acid portion possesses the anti-inflammatory components.^[1]

Upon further purification of the neutral portion, it was determined that the ketone fraction contains the most potent cholesterol-lowering components. The ketone fraction is composed of C₂₁ or C₂₇ steroids, with the major components being Z- and E-guggulsterone (see [Fig. 78.2](#)).

680

Figure 78-1 Chemical segregation of gum guggulu.

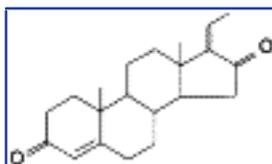

Figure 78-2 E-Guggulsterone.

These compounds are considered the major active components of gum guggul and its extracts.^[1]

For medicinal purposes, a standardized extract known as gugulipid, which is standardized to contain a minimum of 50 mg of guggulsterones/g, is regarded as the most beneficial in terms of safety and effectiveness.^[1] ^[2] In addition to guggulsterones, gugulipid contains various diterpenes, sterols, esters, and fatty alcohols. These accessory components appear to exert a synergistic effect.^[1] ^[2]

HISTORY AND FOLK USE

Guggulu is a highly valued botanical medicine in the Indian system of medicine, Ayurveda. It is included in formulas for a variety of health conditions including rheumatoid arthritis and lipid disorders. The classic Ayurvedic medical text, the *Sushrutasamhita*, describes in detail the usefulness of guggul in the treatment of obesity and other disorders of fat metabolism, including “coating and obstruction of channels”.^[1] ^[2]

Inspired by this description, researchers began studying, in well-designed scientific studies, the clinical effectiveness of gum guggul and its extracts in disorders of lipid metabolism – specifically, its ability to lower cholesterol and triglyceride levels and promote weight loss. This research resulted in the development of a natural cholesterol-lowering substance that is safer and more effective than many cholesterol-lowering drugs, including niacin. Gugulipid was granted approval in India for

marketing as a lipid-lowering drug in 1986.^{[1] [2]}

PHARMACOLOGY

Lipid disorders

Numerous studies in humans and animals have shown that gum guggul (both crude and purified alcohol extract),^{[3] [4] [5] [6] [7]} its petroleum ether extract (referred to as fraction A),^{[8] [9] [10] [11]} and gugulipid (standardized ethyl acetate extract)^{[12] [13]} all exert effective lipid-lowering activity. All lower both elevated cholesterol and triglyceride levels. The effect on cholesterol is particularly beneficial as guggul lowers VLDL and LDL cholesterol while simultaneously elevating HDL-cholesterol, thus offering protection against heart disease due to atherosclerosis.

Guggul preparations appear most indicated in type IIb (increased LDL, VLDL, and triglycerides) and type IV (increased VLDL and triglycerides) hyperlipidemias. In the human clinical trials using gugulipid, cholesterol levels typically dropped 14–27% in a 4–12 week period while triglyceride levels dropped from 22 to 30%.^{[12] [13] [14]}

As seen in [Table 78.1](#) , the effect of gugulipid on serum

TABLE 78- -- Serum lipid effects of gugulipid compared with standard drugs

| Agent | Total cholesterol | HDL cholesterol | Triglycerides |
|----------------|-------------------|-----------------|---------------|
| Gugulipid | -24% | +16% | -23% |
| Cholestyramine | -14% | +8% | +10% |
| Clofibrate | -10% | +11% | -22% |
| Lovastatin | -34% | +8% | -25% |

cholesterol and triglycerides is comparable to that of conventional lipid lowering drugs. Clofibrate, niacin, and cholestyramine lower cholesterol levels 6–12%, 10–17% and 20–27%, respectively, but are associated with some degree of toxicity. In contrast, appropriate extracts of gugulipid are without reported side-effects. In addition to the excellent safety demonstrated in the human studies, safety studies in animals have demonstrated gugulipid to be non-toxic (see “Toxicology” below).

The primary mechanism of action for gum guggul and gugulipid's cholesterol-lowering action is stimulation of liver metabolism of LDL cholesterol, i.e. guggulsterones increase the uptake of LDL cholesterol from the blood by the liver.^{[14] [15]} However, another action of guggulsterone which also affects lipid levels is its ability to stimulate thyroid function.^[16] This thyroid-stimulating effect may be responsible for some of gugulipid's

weight loss activity.

In addition to lowering lipid levels, gum guggul and its extracts, including gugulipid, have been shown to prevent the formation of atherosclerosis and aid in the regression of pre-existing atherosclerotic plaques in animals. This implies that it may have a similar effect in humans.

Gum guggul and gugulipid have also been shown to prevent the heart from being damaged by free radicals and to improve the metabolism of the heart.^[9] ^[14] Gum guggul and its extracts have a mild effect in inhibiting platelet aggregation and promoting fibrinolysis, implying that it may also prevent the development of a stroke or embolism.^[2] ^[14]

This research indicates that gugulipid offers considerable benefit for preventing and treating atherosclerotic vascular disease, the leading cause of death in the US.

Anti-inflammatory effects

The guggulsterone fraction of gum guggul has been shown to exhibit significant anti-inflammatory action in experimental models of inflammation (e.g. raw paw edema and adjuvant arthritis method).^[17] ^[18] ^[19] Its activity in models of acute inflammation is comparable to approximately one-fifth that of hydrocortisone, and equal to phenylbutazone and ibuprofen.^[17] In models of chronic inflammation, it was shown to be more effective than hydrocortisone, phenylbutazone, and ibuprofen in reducing the severity of secondary lesions. The antiinflammatory action is thought to be due to inhibition of delayed hypersensitivity reactions.^[18] ^[19]

DOSAGE

While the crude oleoresin (gum guggul), alcohol extract, and petroleum ether extract all exert lipid-lowering and anti-inflammatory action, they are associated with side-effects (skin rashes, diarrhea, etc.) at the doses required to produce a clinical effect. It is interesting to note that in classic Ayurvedic texts, the purification of crude guggul in Triphala kashaya is recommended to eliminate these side-effects.^[2]

Gugulipid, the standardized ethyl acetate extract of the gum guggul, has demonstrated not only greater clinical efficacy, but also much greater patient tolerance than crude or purified gum guggul. The dosage of gugulipid is based on its guggulsterone content. Clinical studies have demonstrated that 25 mg of guggulsterone three times per day is an effective treatment for elevated cholesterol levels, elevated triglyceride levels, or both. For a 5% guggulsterone content extract, this translates to an effective dose of 500 mg three times per day.

For comparison, the daily dosage of the other forms would be:

- crude gum guggul – 10 g
- alcoholic extract – 4.5 g

- petroleum ether extract – 1.5 g.

TOXICOLOGY

The side-effects of crude gum guggul, alcoholic and petroleum ether extracts are discussed above. In clinical studies, gugulipid has not displayed any untoward side-effects, nor has it adversely affected liver function, blood sugar control, kidney function, or hematological parameters.^[11] ^[12] ^[13]

Safety studies in rats, rabbits, and monkeys have demonstrated gugulipid to be non-toxic.^[14] It does not possess any embryotoxic, fetotoxic effects and is therefore considered safe to use in pregnancy. In mice, the oral and intraperitoneal LD₅₀ values are 1,600 mg/kg.^[1]

Chapter 79 - *Crataegus oxyacantha* (hawthorn)

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

- *Crataegus oxyacantha* (family: Rosacea)
Common names: hawthorn, may bush, whitethorn, haw

GENERAL DESCRIPTION

Crataegus oxyacantha is a spiny tree or shrub that is native to Europe. It may reach a height of 30 feet, but is often grown as a hedge plant. Its common name, hawthorn, is actually a corruption of “hedgethorn”, as it was used in Germany to divide plots of land. Its botanical name, *Crataegus oxyacantha*, is from the Greek *kratos*, meaning hardness (of the wood), *oxus* meaning sharp, and *akantha* meaning a thorn. The fruit and blossoms are used medicinally.^[1]

Other species of crataegus, e.g. *C. monogyna* and *C. pentagyna*, have similar pharmacological actions to *C. oxyacantha* and may be suitable alternatives.^{[2] [3]}

CHEMICAL COMPOSITION

Hawthorn leaves, berries, and blossoms contain many biologically active flavonoid compounds, particularly anthocyanidins and proanthocyanidins (polymers of anthocyanidins, also known as biflavans or procyanidins) (see [Fig. 79.1](#)).^{[4] [5]} These flavonoids are responsible for

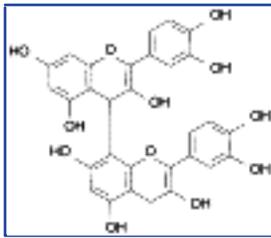

Figure 79-1 Proanthocyanidin B₂ .

684

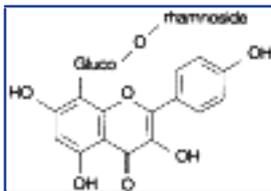

Figure 79-2 Vitexin-4'-rhamnoside.

the red to blue colors not only of hawthorn berries, but also of blackberries, cherries, blueberries, grapes, and many flowers as well. These compounds are highly concentrated in hawthorn berry and flower extracts.

High-performance liquid chromatography and thin layer chromatography (of crataegus extracts) have demonstrated that extracts of the flowers are particularly rich in flavonoids (quercetin, quercetin-3-galactoside, vitexin, vitexin-4'-rhamnoside, etc.) and proanthocyanidins (see [Fig. 79.2](#)). ^[5] ^[6]

In addition to flavonoids, crataegus extracts also contain:^[7]

- cardiotonic amines (e.g. phenylethylamine, o-methoxyphenylethylamine, tyramine, isobutylamine)
- choline and acetylcholine
- purine derivatives (e.g. adenosine, adenine, guanine, and caffeic acid)
- amygdalin
- pectins
- triterpene acids (ursolic, oleonic, and crategolic acids).

HISTORY AND FOLK USE

Crataegus flowers and berries have been utilized primarily as cardiac tonics and mild diuretics in organic and functional heart disorders. They were also utilized for their astringent qualities for relief of the discomfort of sore throats.^[1]

PHARMACOLOGY

The pharmacology of crataegus centers on its flavonoid components. The proanthocyanidins in crataegus are largely responsible for its cardiovascular activities.

Synergism with vitamin C

As stated above, crataegus is particularly rich in anthocyanidins and proanthocyanidins. These flavonoids have very strong “vitamin P” activity. Included in their effects are an ability to increase intracellular vitamin C levels, stabilize vitamin C (by protecting it from oxidation), and decrease capillary permeability and fragility.^{[4] [8] [9]}

Collagen-stabilizing action

Crataegus' flavonoid components possess significant collagen-stabilizing action. Collagen is the most abundant protein of the body and is responsible for maintaining the integrity of ground substance, tendons, ligaments, and cartilage. Collagen is destroyed during inflammatory processes that occur in rheumatoid arthritis, periodontal disease, and other inflammatory conditions involving bones, joints, cartilage, and other connective tissue. Anthocyanidins, proanthocyanidins and other flavonoids are remarkable in their ability to prevent collagen destruction. They affect collagen metabolism in many ways, including:

- the unique ability to actually cross-link collagen fibers, resulting in reinforcement of the natural cross-linking of collagen that forms the collagen matrix of connective tissue (ground substance, cartilage, tendon, etc.)^{[4] [8] [9]}
- the prevention of free radical damage, due to potent antioxidant and free radical scavenging action^{[4] [8] [9] [10]}
- the inhibition of enzymatic cleavage by enzymes secreted by leukocytes during inflammation^{[4] [8] [9]}
- the prevention of the release and synthesis of compounds that promote inflammation, such as histamine, serine proteases, prostaglandins, and leukotrienes.^{[9] [10] [11] [12]}

These effects on collagen and their potent antioxidant activity make hawthorn extracts extremely useful in the treatment of a wide variety of inflammatory conditions. Hawthorn berries, like cherries,^[13] are particularly effective in the treatment of gout, as their flavonoid components are able to reduce uric acid levels as well as reduce tissue destruction.

Cardiovascular effects

Crataegus extracts are effective in reducing blood pressure, angina attacks, and serum cholesterol levels, preventing the deposition of cholesterol in arterial walls and improving cardiac function.^{[2] [14] [15]} Hawthorn extracts are widely used in Europe for their antihypertensive and cardiotonic activity. The beneficial pharmacological effects of crataegus in the treatment of these conditions appear to be a result of the following

actions:

- improvement of the blood supply to the heart by dilating the coronary vessels^{[2] [14] [16] [17] [18] [19]}
 - improvement of the metabolic processes in the heart which results in an increase in the force of
-

685

contraction of the heart muscle and elimination of some types of rhythm disturbances^{[2] [14] [20] [21] [22]}

- inhibition of angiotensin-converting enzyme (ACE).^[23]

Crataegus' ability to dilate coronary blood vessels has been repeatedly demonstrated in experimental studies.^{[2] [14] [16] [17] [18] [19]} This effect appears to be due to relaxation of vascular smooth muscle. Various flavonoid components in crataegus have been shown to inhibit vasoconstriction by a variety of substances, including hypophysin, histamine, and acetylcholine.^{[2] [8] [9]} In addition, procyanidins have been shown to inhibit angiotensin converting enzyme (discussed below).^[23]

Improvement in cardiac metabolism has been demonstrated in humans and animals to whom crataegus extracts have been administered.^{[2] [14] [20] [21]} The improvement is not only a result of increased blood and oxygen supply to the myocardium, but also a result of flavonoid–enzyme interactions. In particular, crataegus extracts and various flavonoid components in crataegus have been shown to inhibit cyclic AMP phosphodiesterase (cAMP-PDE).^[22] This results in increased levels of cAMP within the myocardium, leading to a positive inotropic effect, i.e. an increase in the force of contraction. This is particularly beneficial in cases of congestive heart failure (discussed below).

Recently, several proanthocyanidins have demonstrated a specific inhibition of angiotensin-converting enzyme similar to that of captopril.^[23] Captopril (D-2-methyl-3-mercapto-propanoyl-L-proline, SQ 14,225) is a synthetic ACE inhibitor widely used in the treatment of essential and renal hypertension. The proanthocyanidins that appear to have the highest activity are proanthocyanidins B-5 3,3'-di-O-gallate and C-1 3,3',3?-tri-O-gallate. It is not surprising that these proanthocyanidins are found in relatively high concentrations in hawthorn berries, flowers, and their extracts.^{[4] [5]}

CLINICAL APPLICATIONS

The clinical use of crataegus revolves around its cardiovascular effects. Its use in atherosclerosis, hypertension, congestive heart failure, and arrhythmias is discussed below:

Atherosclerosis

Crataegus preparations, although in a supplement form, should be thought of as a

necessary food in the prevention and treatment of atherosclerosis. Increasing the intake of flavonoid compounds by taking crataegus extracts has numerous health-promoting effects, including reducing cholesterol levels and decreasing the size of existing atherosclerotic plaques.^[15] This again is probably a result of collagen stabilization.

A decrease in the integrity of the collagen matrix of the artery results in cholesterol deposition. Many researchers feel that if the collagen matrix of the artery remains strong, the atherosclerotic plaque will never develop. Crataegus flavonoids, by increasing the integrity of collagen structures, may offer significant protection against atherosclerosis. In addition, feeding proanthocyanidin extracts to animals has resulted in reversal of atherosclerotic lesions, as well as decreases in serum cholesterol levels.^[15]

Flavonoids contained in hawthorn extracts appear to offer significant prevention, as well as potential reversing effects, in the treatment of atherosclerotic processes, which are still the major causes of death in the US.

Hypertension

Crataegus exerts a mild antihypertensive effect, which has been demonstrated in many experimental and clinical studies. Its action in lowering blood pressure is quite unique, in that it does so through a number of diverse pharmacological effects. Specifically, it dilates the coronary vessels, inhibits ACE, acts as an inotropic agent, and possesses mild diuretic activity.

Crataegus' effects generally require prolonged administration, and in many instances it may take up to 2 weeks before adequate tissue concentrations are achieved.

It should be kept in mind that as beta-blockers (e.g. Inderal) lower blood pressure by reducing cardiac output, crataegus administration to patients on these drugs may produce a mild hypertensive response.

Congestive heart failure

Crataegus has a long history of use in the treatment of congestive heart failure, particularly in combination with digitalis or other herbs containing cardiac glycosides (e.g. *Cereus grandifloris*, also known as *Cactus grandifloris*, and *Convallaria majalis*). It potentiates the action of the cardiac glycosides, presumably via its ability to inhibit cAMP-PDE and to interact with calcium channels.

Because of this enhancing effect, lower doses of cardiac glycosides can be used. In addition, magnesium has also been shown to augment digitalis action. For mild to moderate cases of CHF, crataegus extract used alone may be sufficient, but for moderate to severe CHF, it should be used in combination with other cardiac glycosides.

In early or mild stages of CHF, the effectiveness of crataegus has been repeatedly demonstrated in double-blind studies.^{[24] [25] [26] [27]} In one of the most recent studies, 30

patients with congestive heart failure (NYHA stage II) were assessed in a randomized double-blind study.^[26] Treatment consisted of a crataegus extract standardized to contain 15 mg procyanidin oligomers per 80 mg

686

capsule. Treatment duration was 8 weeks, and the substance was administered at a dose of one capsule taken twice a day. The group receiving the crataegus extract showed a statistically significant advantage over placebo in terms of changes in heart function as determined by standard testing procedures. Systolic and diastolic blood pressures were also mildly reduced. Like all other studies with crataegus extracts, no adverse reactions occurred.

In another study, 78 patients with CHF (NYHA stage II) were given either 600 mg of standardized crataegus extract or placebo daily.^[27] The parameter used to measure effectiveness was the patient's working capacity on a bicycle ergometer. After 56 days of treatment, the crataegus group had a mean increase of 25 W compared with the placebo group's increase of only 5 W. In addition, the crataegus group also experienced a mild, but significant, reduction in systolic blood pressure (from 171 to 164 mmHg) and heart rate (from 115 to 110 beats/minute). There was no change in blood pressure or heart rate in the placebo group.

DOSAGE

The dosage depends on the type of preparation and source material. Standardized extracts, similar to those used in Europe and Asia as prescription medications, are available commercially. The doses listed for the various crataegus formulas are for use three times a day:

- berries or flowers (dried): 3–5 g or as infusion
- tincture (1:5): 4–5 ml (alcohol may elicit pressor response in some individuals)
- fluid extract (1:1): 1–2 ml
- freeze dried berries: 1–1.5 g
- flower extract (standardized to contain 1.8 vitexin-4'-rhamnoside): 100–250 mg.

TOXICOLOGY

Crataegus has been shown to have low toxicity. In rats, the typical acute LD₅₀ of the tincture is about 25 ml/kg for oral administration; toxicity for chronic administration is found at about 5 ml/kg.^[14] Similar results, adjusted for concentration, are found with other forms of crataegus.

Although some studies have shown that proanthocyanidins may be carcinogenic, more careful evaluation has indicated that the carcinogenicity was probably due to nitrosamines found in the extracts used.^[28] Purified proanthocyanidins have been found

to be non-mutagenic, according to the *Salmonella* mutagenicity assay system.^[24]

Chapter 80 - *Curcuma longa* (turmeric)

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

Curcuma longa (family: Zingiberaceae)
Common names: turmeric, curcuma, Indian saffron

GENERAL DESCRIPTION

Curcuma longa, a perennial herb of the ginger family, is extensively cultivated in India, China, Indonesia, and other tropical countries. It has a thick rhizome from which arise large, oblong, and long-petioled leaves. The rhizome is the part used; it is usually cured (boiled, cleaned, and sun-dried) and polished.^[1]

CHEMICAL COMPOSITION

Turmeric contains:^[1] ^[2]

- 4–14% of an orange-yellow volatile oil that is composed mainly of turmerone, atlantone, and zingiberone
- 0.3–5.4% curcumin
- sugars (28% glucose, 12% fructose, 1% arabinose)
- resins
- protein
- vitamins
- minerals.

Its chemical structure is shown in [Figure 80.1](#) .

HISTORY AND FOLK USE

Turmeric is the major ingredient of curry powder and is also used in prepared mustard. It is extensively used in foods for both its color and flavor. In addition, turmeric is used in both the Chinese and Indian (Ayurvedic)

Figure 80-1 Curcumin.

690

systems of medicine as an anti-inflammatory agent and in the treatment of numerous conditions, including flatulence, jaundice, menstrual difficulties, bloody urine, hemorrhage, toothache, bruises, chest pain, and colic.^[1] Turmeric poultices are often applied locally to relieve inflammation and pain.

PHARMACOLOGY

Turmeric and its derivatives have a great deal of pharmacological activity.^[2] Although a number of components have demonstrated activity, the volatile oil components and curcumin are believed to be the most active components. Turmeric has been found to be:

- an effective antioxidant
- anticarcinogenic
- anti-inflammatory
- cardiovascular
- hepatic
- gastrointestinal
- an antimicrobial agent.

Antioxidant effects

Turmeric extracts exert significant antioxidant activity. Although both water- and fat-soluble extracts have been shown to be effective antioxidants in various in vitro and in vivo models, curcumin is the most potent component.^{[3] [4] [5] [6]} The antioxidant activity of curcumin is comparable to standard antioxidants like vitamins C and E, and butylated hydroxyanisole (BHA) and butylated hydroxytoluene (BHT).^{[3] [7]} Because of its bright yellow color and antioxidant properties against lipid peroxidation, curcumin is used in butter, margarine, cheese, and other food products.

For active oxygen species, curcumin is slightly weaker than vitamin C, but stronger than vitamin E and superoxide dismutase. Against hydroxyl radicals, curcumin offers greater effectiveness than these vitamins.^{[3] [4] [7]} Not all of the antioxidant properties of turmeric are due to curcumin alone, as the aqueous extract of turmeric is more effective against superoxide than curcumin and is much stronger in inhibiting oxidative damage to DNA.^[5]

[6]

Anticarcinogenic effects

The anti-neoplastic effects of turmeric and curcumin have been demonstrated at all steps of carcinogenesis: initiation, promotion, and progression. In addition to inhibiting the development of cancer, several studies suggest that curcumin can also promote cancer regression.

Turmeric and curcumin are non-mutagenic and have been shown to suppress the mutagenicity of several common mutagens (cigarette smoke condensates, benzopyrene, DMBA, etc.), as do chili and capsaicin.^{[8] [9] [10]} Turmeric and curcumin have also demonstrated impressive anti-cancer effects against a number of chemical carcinogens on a wide range of cell types in both in vitro and in vivo studies.^{[11] [12] [13] [14] [15] [16] [17] [18]} Curcumin has demonstrated an impressive ability to reduce the levels of urinary mutagens.^{[19] [20]}

The protective effects of turmeric and its derivatives are only partially explained by its direct antioxidant and free radical scavenging effects. It also inhibits nitrosamine formation, enhances the body's natural antioxidant system, increases the levels of glutathione and other non-protein sulfhydryls, and acts directly on several enzymes and gene loci.

Anti-inflammatory effects

The volatile oil fraction of *Curcuma longa* has been demonstrated to possess anti-inflammatory activity in a variety of experimental models, e.g. Freund's adjuvant-induced arthritis, formaldehyde- and carrageenan-induced paw edema, and cotton pellet and granuloma pouch tests.^{[21] [22]} Its effects in these studies were comparable to cortisone and phenylbutazone.

Even more potent in acute inflammation is curcumin.^{[23] [24] [25]} Curcumin is as effective as cortisone or phenylbutazone in models of acute inflammation, but only half as effective in chronic models. However, while phenylbutazone and cortisone are associated with significant toxicity, curcumin displays virtually no toxicity (see "Toxicology", p. 692).

The rank in order of potency of curcumin analogues, cortisone, and phenylbutazone in carrageenan-induced paw edema is:^{[24] [25]}

sodium curcuminat > tetrahydrocurcumin >
curcumin > cortisone > phenylbutazone >
triethylcurcumin

Sodium curcuminat can be produced by mixing turmeric with slaked lime. This mixture, applied as a poultice, is an ancient household remedy for sprains, muscular pain, and

inflamed joints.^[25]

Curcumin's counter-irritant effect may also be a major factor in its topical anti-inflammatory action.^[24] Capsaicin, a similar pungent principle from *Capsicum frutescens* (cayenne pepper), has been shown to be quite effective as a topical pain reliever in cases of post-herpetic neuralgia and arthritis. Both capsaicin and curcumin deplete nerve endings of the neurotransmitter of pain, substance P.^[26]

Used orally, curcumin exhibits many direct anti-inflammatory effects including:^{[2] [23] [24] [27] [28] [29]}

- inhibition of leukotriene formation
- inhibition of platelet aggregation
- promotion of fibrinolysis
- inhibition of neutrophil response to various stimuli involved in the inflammatory process
- stabilization of lysosomal membranes.

691

In addition to its direct anti-inflammatory effects, curcumin also appears to exert some indirect effects. In models of chronic inflammation, curcumin is much less active in adrenalectomized animals. Possible mechanisms of action include:

- stimulation of the release of adrenal corticosteroids
- "sensitizing" or priming cortisol receptor sites, thereby potentiating cortisol action
- increasing the half-life of endogenous cortisol through alteration of hepatic degradation.

Cardiovascular effects

The effects of turmeric and curcumin on the cardiovascular system include the lowering of cholesterol levels^{[30] [31]} and the inhibition of platelet aggregation.^{[32] [33]} This is of great significance in preventing atherosclerosis and its complications.

Adding as little as 0.1% curcumin to a high cholesterol rat diet decreases cholesterol levels to one-half of those found in rats fed cholesterol but no curcumin.^[30] This indicates that even at small doses, curcumin may be effective.

Curcumin's cholesterol-lowering actions include interfering with intestinal cholesterol uptake; increasing the conversion of cholesterol into bile acids by increasing the activity of hepatic cholesterol-7-alpha-hydroxylase, the rate-limiting enzyme of bile acid synthesis; and increasing the excretion of bile acids via its choleric effects.^{[30] [31] [34]}

Turmeric and curcumin's action on inhibiting platelet aggregation appears mediated by

inhibiting the formation of thromboxanes (a promoter of aggregation) while simultaneously increasing prostacyclin (an inhibitor of aggregation).^[32] ^[33]

Hepatic effects

Curcumin has exhibited hepatoprotection similar to that of glycyrrhizin and silymarin (see [Chs 90](#) and [111](#) for further discussion) against carbon tetrachloride and galactosamine-induced liver injury.^[2] ^[35] This protection is largely a result of its potent antioxidant activity. Similar results are seen with Javanese turmeric (*Curcuma xanthorrhiza*). Mice given intraperitoneal injections of the hepatotoxic drugs carbon tetrachloride (32 mg/kg) and acetaminophen (600 mg/kg) experienced significantly decreased liver damage, as measured by SGOT and SGPT when treated with 100 mg/kg of turmeric.^[36]

The antioxidant and hepatoprotective effects alone would support turmeric's historical use in liver disorders; however, turmeric and curcumin also exert anti-inflammatory and choleric effects. The increases of SGOT and SGPT commonly seen in experimental models of inflammation have been prevented by curcumin.^[23]

Curcumin is an active choleric, increasing bile acid output by over 100%.^[2] In addition to increasing biliary excretion of bile salts, cholesterol, and bilirubin, curcumin also increases the solubility of the bile.^[34] This suggests a benefit in the prevention and treatment of cholelithiasis.

Gastrointestinal effects

Turmeric and its components exert a number of beneficial effects on the gastrointestinal system. Turmeric's long use as a carminative has significant research support.^[2] Specifically, curcumin has been shown to inhibit gas formation by *Clostridium perfringens* and in rats given diets rich in flatulence-producing foods. In addition, sodium curcuminates has been shown to inhibit intestinal spasm, and another compound from turmeric, *p*-tolymethylcarbinol, has been shown to increase the secretion of secretin, gastrin, bicarbonate, and pancreatic enzymes.^[2]

As a component of curries and spicy foods, there is some concern that turmeric may be irritating to the stomach. However, several studies have shown turmeric to be beneficial to gastric integrity. Turmeric and curcumin have been shown to increase the mucin content of the stomach and exert gastroprotective effects against ulcer formation induced by stress, alcohol, indomethacin, pyloric ligation, and reserpine.^[2] ^[37] However, at high doses, curcumin or turmeric may be ulcerogenic (see "Toxicology", [p. 692](#)).

Antimicrobial effects

Alcohol extracts and the essential oil of *Curcuma longa* have been shown in one study to inhibit the growth of most organisms occurring in cholecystitis, i.e. *Sarcina*, *Gaffkya*, *Corynebacterium*, and *Clostridium*.^[2] Other microorganisms which are inhibited include *Staphylococcus*, *Streptococcus*, *Bacillus*, *Entamoeba histolytica*, and several

pathogenic fungi.^{[2] [38]} The concentrations used in these studies were relatively high: 0.5–5.0 mg/ml of the alcohol extract and essential oil, and 5–100 ug/ml of curcumin.

CLINICAL APPLICATIONS

Turmeric and curcumin have several clinical applications. Most notable are:

- cancer prevention and treatment adjunct
 - inflammation
 - atherosclerosis
 - liver disorders
 - cholelithiasis
 - irritable bowel syndrome.
-

692

Cancer prevention and treatment adjunct

As discussed above, turmeric and curcumin have demonstrated significant protective effect against cancer development in experimental studies in animals. There is also some human research showing similar results.

In one human study, 16 chronic smokers were given 1.5 g of turmeric daily while a control group of six non-smokers served as a control group.^[19] At the end of the 30 day trial, the smokers receiving the turmeric demonstrated significant reduction in the level of mutagens excreted in the urine. These results are quite significant as the level of urinary mutagens is thought to correlate with the systemic load of carcinogens and the efficacy of detoxification mechanisms. Due to widespread exposure to smoke, aromatic hydrocarbons, and other environmental carcinogens, the frequent use of turmeric as a spice appears warranted.

Turmeric extracts and curcumin have demonstrated direct antitumor results in a number of experimental models of skin, epithelial, stomach and liver cancers.^{[15] [39] [40]} This effect has also been substantiated in a human study.^[41] Sixty-two patients with either ulcerating oral or cutaneous squamous cell carcinomas who had failed to respond to the standard treatments of surgery, radiation, and chemotherapy were given either an ethanol extract of turmeric (for oral cancers) or an ointment containing 0.5% curcumin in Vaseline. The ointment or extract was applied topically three times daily. At the end of the 18 month study, the treatment was found to have been effective in reducing the smell of the lesion (90%), itching, exudate (70%), pain (50%), and size of the lesion (10%). Although these are not spectacular results, it must be pointed out that this patient population had failed to respond to standard medical treatment.

While more human studies are needed on the use of turmeric and curcumin in cancer, there is ample evidence to support their use in cancer prevention and as an adjunct in

an overall cancer treatment plan.

Inflammation

Curcuma longa has been used in Ayurvedic medicine, both locally and internally, in the treatment of sprains and inflammation. This use seems to be substantiated not only by the experimental studies described above, but also by clinical investigations.^[42] ^[43]

In one double-blind crossover clinical trial in patients with rheumatoid arthritis, curcumin (1,200 mg/day) was compared to phenylbutazone (300 mg/day). The improvements in the duration of morning stiffness, walking time, and joint swelling were comparable in both groups.^[42] However, while phenylbutazone is associated with significant adverse effects, curcumin has not been shown to produce any side-effects at the recommended dosage level.

In another study which used a new human model for evaluating NSAIDs, the postoperative inflammation model, curcumin was again shown to exert comparable anti-inflammatory action to phenylbutazone.^[43] While curcumin has an anti-inflammatory effect similar to phenylbutazone and various NSAIDs, it does not possess direct analgesic action.

The results of these studies indicate that turmeric or curcumin may provide benefit in the treatment of inflammation. Furthermore, the safety and excellent tolerability of curcumin compared with standard drug treatment is a major advantage.

TOXICOLOGY

Toxicity has not been reported at standard dosage levels. The oral LD₅₀ levels for turmeric, its alcohol extracts, and curcumin have not been determined, as 2.5 g/kg fed to mice, rats, guinea pigs, and monkeys, and 3.0 g/kg sodium curcumin fed to rats resulted in neither mortality nor chromosomal aberrations in teratology tests.^[2] ^[44] ^[45] ^[46] At very high doses, curcumin or turmeric may damage the gastrointestinal system, as curcumin, with doses of 100 mg/kg body weight, is ulcerogenic in rats.^[2]

DOSAGE

Based on the evidence presented above, turmeric should be consumed liberally in the diet. When specific medicinal effects are desired, higher doses of turmeric can be given or extracts of *Curcuma longa* or curcumin can be used.

The recommended dosage for curcumin as an anti-inflammatory is 200–400 mg three times a day. To achieve a similar amount of curcumin using turmeric would require a dosage of 4,000–40,000 mg.

Because the absorption of orally administered curcumin may be limited (pharmacokinetic studies in animals show that 40–85% of an oral dose of curcumin

passes through the gastrointestinal tract unchanged^[44] ^[45]), curcumin is often formulated in conjunction with bromelain to possibly enhance absorption. In addition, bromelain also has anti-inflammatory effects (see [Ch. 69](#)).

A curcumin–bromelain combination is best taken on an empty stomach 20 minutes before meals or between meals.

Providing curcumin in a lipid base such as lecithin, fish oils, or essential fatty acids may also increase absorption. This combination is probably best absorbed when taken with meals.

Chapter 81 - Dehydroepiandrosterone

Alan R. Gaby MD*

INTRODUCTION

Dehydroepiandrosterone (DHEA) is a steroid hormone secreted by the adrenal glands and to a lesser extent by the testes and ovaries. First identified in 1934, DHEA was subsequently shown to be produced in greater quantity than any other adrenal steroid. However, although circulating levels of DHEA and its ester DHEA-sulfate (DHEA-S) are 20 times higher than those of any other adrenal steroid, the function of DHEA in the body was, until recently, unknown. Since DHEA can be converted into other hormones, including estrogen and testosterone, scientists assumed that DHEA is merely a “buffer hormone”, a reservoir upon which the body can draw to produce the other hormones. However, the recent identification of DHEA receptors in the liver, kidney and testis of rats strongly suggests that DHEA has specific physiologic actions of its own.^[1]

During the past several years, there has been a great deal of interest in DHEA as a possible anti-aging hormone and as a potential treatment for a wide array of medical conditions. This interest has been sparked by two different lines of evidence. First, circulating levels of DHEA decline progressively with age – the levels in 70-year-old individuals are only about 20% as high as those in young adults. This age-related decline does not occur with any of the other adrenal steroids. Furthermore, epidemiologic evidence suggests that higher DHEA levels are associated with increased longevity and prevention of heart disease and cancer. It has therefore been suggested that some of the manifestations of aging may be caused by DHEA deficiency.

Second, numerous animal studies have shown that administration of DHEA prevents obesity, diabetes, cancer, and heart disease; enhances the functioning of the immune system; and prolongs life.^[2] Since most of these studies were carried out on rodents, which have little circulating DHEA, it is not clear whether the results

* Reprinted with permission from *Alternative Medicine Review* 1996; 1(2): 60–69

have relevance to human health. However, a growing body of human research, combined with the intriguing observations of innovative clinicians, suggests that DHEA may indeed have value in the treatment of various medical conditions. If this hormone can be convincingly shown to retard the aging process and to fight certain diseases, then DHEA therapy will be recognized as a major breakthrough in clinical medicine.

CLINICAL APPLICATIONS

Aging

Preliminary results in mice suggest that DHEA may retard the aging process. Animals treated with this hormone look younger and have glossier coats and less gray hair than control animals.^[3]

In a recent study, 30 individuals between the ages of 40 and 70 years received 50 mg/day of DHEA or a placebo, each for 3 months, in double-blind cross-over fashion. During DHEA treatment, a remarkable increase in physical and psychological well-being was reported by 67% of the men and 84% of the women. There was no change in libido and no side-effects were seen.^[4]

In this author's experience, elderly individuals who suffer from weakness, muscle wasting, tremulousness, fatigue, depression, declining memory and other signs of aging frequently have serum DHEA-S levels near or below the lower limit of normal. Treatment with DHEA (usually 5–10 mg/day for women and 10–20 mg/day for men) often results in improved mood, energy, memory, appetite, and skin color, sometimes after as little as 2 weeks. With continued treatment, the benefits may become even more pronounced and muscle wasting may be partially reversed.

Cancer prevention

Administration of DHEA inhibited tumor formation in a strain of mice that develops spontaneous breast cancer.^[5] DHEA has also been shown to prevent chemically induced colon^[6] and liver^[7] cancer, as well as skin papillomas in mice.^[8]

Premenopausal women with breast cancer had significantly lower plasma levels of DHEA than age-matched controls without breast cancer, whereas postmenopausal women had significantly higher DHEA levels than age-matched controls.^[9] In another study, women with DHEA levels in the highest tertile were 60% less likely to develop breast cancer than were women in the lowest tertile.^[10] In a prospective case-control study, serum DHEA and DHEA-S levels were significantly lower in individuals who subsequently developed bladder cancer than in those who did not.^[11]

These findings suggest that DHEA has anti-cancer activity and that low DHEA levels

may be a risk factor for cancer. However, further research is required before guidelines can be developed regarding DHEA therapy and cancer. The observation that some postmenopausal women with breast cancer have elevated DHEA levels, and the fact that DHEA is converted in part to estrogen and testosterone should be cause for concern. It is not known whether the anti-cancer effects of DHEA are stronger than the prostate cancer-promoting effects of additional testosterone or the breast cancer-promoting effects of additional estrogen. Until those questions can be answered, DHEA therapy should be approached with caution in patients who are at risk for developing hormone-dependent cancers.

Effects on immune function

DHEA exerts a number of different effects on the immune system. Some of these effects appear to result from the anti-glucocorticoid actions of DHEA. For example, DHEA antagonized the suppressive effects of dexamethasone on lymphocyte proliferation in mice^[12] and prevented glucocorticoid-induced thymic involution.^[13] Administration of DHEA has also been shown to preserve immune competence in burned mice,^[14] an effect that extends beyond its anti-glucocorticoid action.^[15] Administration of DHEA also protected against acute lethal infections with Coxsackie virus B4 and herpes simplex type 2 encephalitis in mice. DHEA appeared to act by preventing the suppression of immune competence caused by the viral infections.^[16]

DHEA has also been shown to influence immune function in humans. In a double-blind study, administration of 50 mg/day of DHEA to postmenopausal women (mean age, 56.1 years) produced a twofold increase in natural killer cell activity and a 6% decrease in the proportion of helper T-cells.^[17] While the increase in natural killer cell activity might be expected to enhance immune surveillance against cancer and viral infections, the decline in helper T-cells could have adverse consequences. On the other hand, since DHEA is known to mediate T-cell responses,^[18] the decline in helper T-cells could merely be a reflection of enhanced T-cell function. Although the implications of these changes in immune function are not entirely clear, it should be noted that 50 mg/day of DHEA has been shown to produce supraphysiologic serum levels in postmenopausal women.^[19] Lower doses may therefore be more appropriate and might result in more clear-cut improvements in immune function.

Autoimmune diseases

The potential value of DHEA as a treatment for autoimmune disease was suggested by the observation that DHEA reduced the severity of renal damage in the NZB x NZW mouse, an animal model of spontaneous lupus.

A clinical trial was therefore performed with 10 women suffering from mild or moderate systemic lupus erythematosus (SLE).^[20] Each patient received 200 mg/day of DHEA for 3–6 months. Eight of the 10 patients reported improvements in overall well-being,

fatigue, energy, and/or other symptoms. For the group as a whole, there was a significant improvement in the physician's overall assessment of disease activity. After 3 months, the average prednisone requirement had decreased from 14.5 to 9.4 mg/day. Of three patients with significant proteinuria, two showed marked reductions and one a modest reduction in protein excretion. There was no significant correlation between changes in serum DHEA or DHEA-S levels and clinical response. In addition, pre-treatment levels of these hormones did not predict clinical response. Side-effects were limited to mild or moderate acneiform dermatitis and mild hirsutism.

Administration of relatively large doses of DHEA has also been reported to increase stamina and improve the sense of well-being in patients with multiple sclerosis.^[21]

During the past 5 years, a number of practitioners have been prescribing DHEA for patients with autoimmune disease. Pre-treatment plasma levels of DHEA or DHEA-S are usually below normal in patients receiving prednisone or related drugs, because these medications cause adrenal suppression. However, in my experience, DHEA-S levels are also frequently low in patients with autoimmune disease who are not receiving corticosteroids.

I have seen a 76-year-old woman with rheumatoid arthritis who was maintained on 5 mg/day of prednisone. After taking 10 mg/day of DHEA for several weeks, her joint symptoms improved and she was able to wean off the prednisone. Another woman with poorly controlled dermatomyositis had marked clinical improvement and was able to reduce her prednisone by 50% after receiving 10 mg of DHEA twice a day. A woman with a 3 year history of persistent bleeding due to inflammatory bowel disease reported no further bleeding after taking 15 mg/ day of DHEA. Two other women with SLE had clinical improvements with DHEA. However, low doses were not effective in these cases; results became apparent only after the dose was increased to around 100 mg/day or more.

Dr Davis Lamson (personal communication) has given DHEA to six patients with ulcerative colitis who had failed to respond to a combination of conventional therapy and nutritional treatments. In all six cases, the bleeding, diarrhea, and overall condition improved.

Some patients with chronic fatigue syndrome (CFS) have also improved clinically with DHEA therapy. However, since cortisol deficiency appears to be the primary problem in some patients with CFS, and since DHEA can antagonize the effects of cortisol, DHEA therapy may actually make some patients with CFS worse. It is important, therefore, to measure both DHEA and cortisol levels before treating patients with CFS.

Acquired immunodeficiency syndrome

Preliminary evidence suggests that DHEA may play a role in acquired immunodeficiency syndrome (AIDS). In one study, DHEA inhibited the replication of HIV, the virus believed to cause AIDS.^[22] In addition, DHEA has been shown to enhance the immune response to viral infections. Furthermore, DHEA levels are low in people infected with HIV and these levels decline even more as the disease progresses to

full-blown AIDS.^[23] In a study of 108 HIV-infected men with marginally low helper T-cell counts (between 200 and 499), those with serum DHEA levels below normal were 2.34 times more likely to progress to AIDS than were men with normal DHEA levels.^[24] These studies suggest that DHEA deficiency may be one of the factors contributing to immune system failure in HIV-infected patients.

To date, only one clinical trial has tested the effect of giving DHEA to HIV-infected patients. Although DHEA did not improve CD4 counts or serum p24 antigen levels, the dosage used (750–2,250 mg/day) seems excessively large, possibly beyond the “therapeutic window” in which DHEA exerts its beneficial effects.^[25] The concept of a therapeutic window has been clearly demonstrated for cortisol. For example, cortisol is known to enhance immune function at physiologic levels. However, both a deficiency and an excess of cortisol result in impaired immune function. Future trials of DHEA in HIV-infected patients should therefore use lower doses, perhaps 50–200 mg/day.

Allergic disorders

Eight patients with severe attacks of hereditary angioedema were treated with 37 or 74 mg/day of DHEA-S (equivalent to 25 or 50 mg, respectively, of DHEA) every 1–3 days, for 3–29 months. DHEA-S treatment resulted in a dramatic clinical improvement in all eight patients.^[26]

Practitioners who use DHEA have observed that treatment sometimes reduces the severity of food or chemical allergies. I have seen several patients with multiple chemical sensitivities who responded to physiologic doses of DHEA (5–15 mg/day for women, 10–30 mg/day for men). However, it is difficult to predict which patients will improve.

Subnormal serum levels of DHEA-S are common in asthmatics. DHEA deficiency may result in part from corticosteroid-induced adrenal suppression. However, low levels of DHEA-S were also found in 21% of asthmatics who were not taking steroids.^[27] DHEA deficiency may also result from long-term administration of inhaled corticosteroids. In a study of 36 postmenopausal asthmatic

women, those who were receiving at least 1 mg/day of beclomethasone dipropionate had nearly a 50% reduction in serum DHEA levels, compared with women who were not receiving the drug. Apparently, inhaled corticosteroids are absorbed in amounts sufficient to cause some degree of adrenal suppression.^[28]

I have seen two female patients with long-standing asthma who had clinical improvement after receiving 10 mg/day of DHEA. In one of these patients, chronic nasal polyps also disappeared, much to the surprise of her otolaryngologist.

Obesity

Administration of DHEA prevented the development of obesity in genetically obese mice.^[29] However, studies in humans have so far failed to demonstrate a role for DHEA in the treatment of obesity.

Cardiovascular disease

Administration of DHEA reduced the severity of atherosclerosis in cholesterol-fed rabbits.^[30] DHEA-S has also been shown to have digitalis-like activity, accounting for 62–100% of the total plasma digitalis-like factors in 11 healthy adults.^[31]

Mean plasma DHEA-S levels were significantly lower in men with a history of heart disease than in men without such a history. In men with no history of heart disease at baseline, a low plasma DHEA-S level (less than 140 mcg/dl) was associated with a more than threefold increase in the age-adjusted risk of death from cardiovascular disease.^[32] Similar findings were reported by others,^[33] although another epidemiologic investigation found only a modest protective effect of DHEA.^[34]

In women, no inverse association was found between DHEA-S levels and cardiovascular disease. In fact, cardiovascular death rates were highest in women in the highest tertile of DHEA-S levels and lowest in women in the middle tertile (a U-shaped distribution).^[35]

Osteoporosis

At the time of menopause, the amount of DHEA manufactured by the ovaries declines. And, even though the ovaries are not the major source of DHEA, serum DHEA levels decline by more than 60% after menopause.^[36]

The possible relationship between DHEA deficiency and osteoporosis was suggested by a study of women with Addison's disease. In these patients, the onset of menopause was followed by an unusually rapid rate of bone loss. This accelerated bone loss was associated with marked reductions in plasma concentrations of DHEA and testosterone (94 and 63% lower, respectively, than those of healthy postmenopausal women).^[37] These findings suggest that DHEA and/or testosterone is essential for the maintenance of bone mass in postmenopausal women.

In another study, bone mineral density was measured at the lumbar spine, hip, and radius in 105 women aged 45–69 years. Fifty women had normal measurements, whereas 55 had low bone density. The average serum DHEA-S level was 60% lower in the women with low bone density than in those with normal bones. Women with low DHEA values were 40 times more likely to have osteoporosis than were women with normal DHEA levels. In contrast, there was no relationship between estrogen levels and bone density.^[38] In a group of 29 postmenopausal women, there was a significant positive correlation between bone mineral content of the distal radius and ulna and

age-adjusted serum DHEA levels.^[39]

There are several mechanisms by which DHEA might prevent osteoporosis. First, one of the breakdown products of DHEA, 5-androstene-3 β , 17 β -diol, is known to bind strongly to estrogen receptors.^[40] Therefore, DHEA, like estrogen, might exert an inhibitory effect on bone resorption. Second, there is evidence that androgens (a class of hormones that includes DHEA and testosterone) stimulate bone formation and calcium absorption.^[41] Third, the partial conversion of DHEA to estrogen and testosterone would be expected to provide additional protection against bone loss.

I often recommend low doses of DHEA (usually 5–10 mg/day) for postmenopausal women whose serum DHEA-S levels are near or below the lower limit of normal. In some cases, DHEA relieves symptoms such as hot flashes that are usually attributed to estrogen deficiency. A combination of DHEA and identical-to-natural progesterone (usually given as a topical cream) may be more effective against hot flashes than either treatment alone.

Dementia

In one study, intracerebroventricular administration of DHEA or DHEA-S improved the results of certain memory tests in mice.^[42] Some investigators have found low levels of DHEA in patients with Alzheimer's disease.^[43] However, others have failed to confirm those observations.^[44] In a small, uncontrolled trial, administration of DHEA appeared to produce modest improvements in cognition and behavior in a group of male patients with Alzheimer's disease.^[45]

Diabetes

Administration of 0.4% DHEA in the diet reversed hyperglycemia, preserved beta-cell function, and increased insulin sensitivity in genetically diabetic mice.^[46] Although DHEA has been reported to ameliorate insulin

resistance in one patient with diabetes,^[47] very large doses of DHEA (1,600 mg/day for 28 days) caused mild abnormalities of glucose metabolism.^[48] The role of DHEA in the overall management of diabetes is therefore still unclear.

TOXICITY

For a steroid hormone, DHEA also appears to be relatively safe. Administration of 1,600 mg/day for 28 days to healthy volunteers resulted in some degree of insulin resistance, but no other significant side-effects occurred. In the SLE studies, 200 mg/day given for a number of months was well tolerated, with the exception of mild to moderate acne and

occasional mild hirsutism.

Addition of 0.6% DHEA to the diet of rats reduced body weight and enhanced the development of chemically induced pre-neoplastic pancreatic lesions.^[49] Although that dose of DHEA is extremely large (the equivalent human dose would be approximately 2,000 mg/day), this report indicates that DHEA is by no means innocuous and should therefore be treated with respect.

DOSAGE

As this review suggests, DHEA shows promise for preventing age-related decline and as a treatment for certain diseases. Innovative practitioners have therefore begun prescribing DHEA for their patients and the public is becoming increasingly interested in this purported “anti-aging pill”.

Although DHEA appears to be safe, its long-term effects are unknown. It is possible that adverse consequences will become evident with chronic use. It is therefore important that we treat this hormone with respect and err on the side of caution. Although some practitioners are routinely prescribing 50 mg/day for healthy women and 100 mg/day for healthy men, those doses may be supraphysiologic and I am concerned about their long-term safety.

Unlike hydrocortisone (cortisol), for which the physiologic replacement dose is known, it is not clear what the physiologic dose of DHEA is. However, it may be lower than many doctors believe. I have treated one patient with severe adrenal insufficiency who had a clear response to 15 mg/day of DHEA. She experienced marked clinical improvement at that dose and her serum level of DHEA-S increased from barely detectable to well above the lower limit of normal. Another woman with a history of bilateral adrenalectomy reported marked symptom relief with DHEA doses as low as 5–10 mg/day.

In my practice, I usually prescribe 5–15 mg/day for women and 10–30 mg/day for men. Many patients have obvious improvements with these doses. Some patients who did not improve have tried larger doses, but in most cases, the larger doses were not helpful either. The one exception has been patients with lupus or other autoimmune diseases, who sometimes needed as much as 100 mg/day or more to obtain benefit. I have typically prescribed DHEA in capsule form, in a base of hydroxymethylcellulose, which is said to produce sustained release of the hormone and supposedly better results. With large doses, I recommend twice-a-day dosing, usually morning and evening.

Although serum measurements of DHEA and DHEA-S are available through most laboratories, it is not clear how closely one should rely on these measurements; nor is it clear whether DHEA or DHEA-S is the more reliable test. The normal range for DHEA-S as listed by my local laboratory is 350–4,300 ng/ml for women and 800–5,600 ng/ml for men. Many older individuals have values near or below the lower limit of normal. However, I prefer not to use an age-adjusted reference range (as published by some laboratories), since it seems that the age-related decline in serum DHEA-S is

undesirable.

When DHEA therapy appears to be clinically indicated, I will consider treating women whose DHEA-S levels are below 600 ng/ml and men whose levels are below 1,200 ng/ml. There are as yet no data on what constitutes an optimum serum level. Consequently, I continue to err on the side of caution by using low doses of DHEA.

There are also no data available concerning long-term administration of DHEA. While lifetime replacement therapy seems appropriate for patients with age-related DHEA deficiency, other patients should be assessed on a case-by-case basis.

I have found that about 10% of patients who are taking thyroid hormone develop symptoms of thyrotoxicosis after starting DHEA therapy. That observation is consistent with a report that DHEA potentiates the action of thyroid hormones.^[50] Symptoms of thyroid overtreatment responded to a reduction in the thyroid-hormone dosage, and patients reported that they felt better on DHEA plus lower-dose thyroid hormone than they did on thyroid hormone alone.

SUMMARY

In conclusion, DHEA appears to be one of the major therapeutic advances of the past 20 years. However, we must treat this powerful hormone with caution and respect, in order to maximize its benefits and minimize its risks.

Chapter 82 - *Echinacea* species (narrow-leafed purple coneflower)

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

Echinacea sp. (family: Asteraceae)

Echinacea angustifolia

Common names: narrow-leafed purple coneflower, black sampson, snakeroot

Echinacea purpurea

Common name: purple coneflower

Echinacea pallida

Common name: pale purple coneflower

GENERAL DESCRIPTION

Echinacea sp. are perennial herbs native to midwestern North America, from Saskatchewan to Texas. The genus derives its name from the Greek *echinos* (meaning sea urchin). This refers to the prickly scales of the dried seed head portion of the flower. There are nine species of *Echinacea* which have been taxonomically classified by McGregor based on comparative anatomy and morphology (see [Table 82.1](#)). ^[1]

Of the nine species, *E. angustifolia*, *E. purpurea*, and *E. pallida* are the most commonly used clinically. *E. angustifolia*, with a typical height of up to 2 feet, is shorter than *E. purpurea* (1.5–5 feet) and *E. pallida* (1–3 feet). Another

TABLE 82-1 -- Taxonomic formation of the genus *Echinacea*^[3]

| Species | Synonyms |
|-------------------------------|-------------------------------|
| <i>Echinacea angustifolia</i> | <i>Brauneria angustifolia</i> |

| | |
|--------------------------------|--------------------------------|
| <i>Echinacea atrorubens</i> | <i>Rudbeckia atrorubens</i> |
| <i>Echinacea laevigata</i> | <i>Brauneria laevigata</i> |
| <i>Echinacea pallida</i> | <i>Rudbeckia pallida</i> |
| <i>Brauneria pallida</i> | |
| <i>Echinacea paradoxa</i> | <i>Brauneria paradoxa</i> |
| <i>Echinacea purpurea</i> | <i>Rudbeckia purpurea</i> |
| <i>Rudbeckia hispida</i> | |
| <i>Rudbeckia serotina</i> | |
| <i>Echinacea speciosa</i> | |
| <i>Echinacea intermedia</i> | |
| <i>Echinacea simulata</i> | <i>Echinacea speciosa</i> |
| <i>Echinacea sanguinea</i> | |
| <i>Echinacea tennesseensis</i> | <i>Brauneria tennesseensis</i> |

key to species identification is that *E. angustifolia* and *E. purpurea* have yellow pollen, while *E. pallida* is noticeably paler and has white pollen. The portions of the plant used for medicinal purposes includes the aerial portion, the whole plant including the root, and the root itself. The tap root of *E. angustifolia* can reach a length of 3–4 feet. ^[2] ^[3]

E. angustifolia has thick, hairy, 1–3 inches long leaves found at the base of a purple seed head shaped like a cone. The only exception to the family of “purple” coneflower is *E. paradoxa* which has a yellow flower.

CHEMICAL COMPOSITION

Analysis of *Echinacea* sp. has yielded a wide assortment of chemical constituents with pharmacological activities. The broad chemical composition of this medicinal plant suggests possible synergistic effects among its constituents. For example, in some experimental models, while the water-soluble polysaccharides have shown greater stimulatory effects on the cellular immune system, the lipophilic components have demonstrated more potent effects on enhancing macrophage phagocytosis. ^[3] ^[4]

The important constituents, from a pharmacological perspective, of *Echinacea* sp. can be divided into seven categories:

- polysaccharides
- flavonoids

- caffeic acid derivatives
- essential oils
- polyacetylenes
- alkylamides
- miscellaneous chemicals.

Polysaccharides

A number of immunostimulatory and mild antiinflammatory polysaccharides have been isolated from *Echinacea* sp.^{[2] [3] [5] [6] [7] [8] [9]} Most notable are inulin, which is found in a high concentration (5.9%) in *E. angustifolia* root, and the high molecular weight (25,000–50,000) polysaccharides found in the aerial part of *E. purpurea*, as these components possess significant immune-enhancing properties. Typically the most potent immune-enhancing polysaccharides are the water-soluble, acidic, branched-chain heteroglycans composed of many types of sugars rather than the polyfructose content of inulin.

Flavonoids

The leaves and stems of *E. angustifolia* and *E. purpurea* have been shown to contain numerous flavonoids, with rutoside being the most abundant.^{[3] [9]} The total flavonoid content (calculated as quercetin) for *E. angustifolia* and *E. purpurea* was 0.48 and 0.38% respectively.^{[2] [3] [9] [10]}

Caffeic acid derivatives

Caffeic acid serves as the backbone for a number of important medicinal plant compounds in other plants as well as *Echinacea* sp. (see [Fig. 82.1](#)). The first compound believed to be unique to *Echinacea* was echinacoside, a compound eventually shown to be composed of caffeic acid, a caffeic acid derivative (similar to catechol), glucose, and rhamnose, all attached to a central glucose molecule (see [Figs 82.2](#) and [82.3](#)).^[11] Echinacoside accumulates in the roots, but is also found in smaller concentrations in the flowers. The roots of *E. angustifolia* contain 0.3–1.3%, while the roots of *E. pallida* contain a similar concentration of 0.4–1.7%.^[12] It is assumed that *E. purpurea* has similar echinacoside levels as well.

Other caffeic acid derivatives important in the pharmacology of *Echinacea* include cichoric acid, chlorogenic

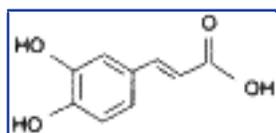

Figure 82-1 Caffeic acid.

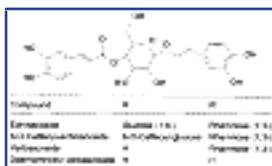

Figure 82-2 Echinacoside and similar compounds.

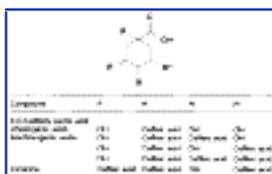

Figure 82-3 Other caffeic acid derivatives.

acid, and cynarin.^[3] Cichoric acid was originally isolated from *E. purpurea* and is found in much higher concentrations in this species compared with *E. angustifolia* and *E. pallida*.^{[2] [3] [9]} However, *E. angustifolia* and *E. pallida* have higher amounts of other types of caffeic acid derivatives.^{[2] [3] [13]} These differences are not thought to have much clinical significance; rather they may prove to be valuable in quick chemical differentiation of species.

Essential oils

The essential oil content varies among the three common species:^[14]

- *E. angustifolia* root and leaves contain less than 0.1%
- *E. purpurea* root 0.2% and flowers and leaves contain 0.6%
- *E. pallida* root contains up to 2% and the leaves contain less than 1%.

Interestingly, in one study the essential oil content of *E. pallida* root was found to rise to 3.5–4% in April and May, but fall to 1–1.5% for the rest of the year.^[15] The major essential oil components are sesquiterpene derivatives, borneol, alpha-pinene, and related aromatic compounds.^{[2] [3]}

Polyacetylenes

A number of polyacetylenes have been identified from the roots of all three commercial species.^[16] The difference in the type of polyacetylene and susceptibility to breakdown may help to differentiate which species is best for commercial use. Since the polyacetylenes of *E. pallida* are quite susceptible to auto-oxidation, *E. angustifolia* may be better for commercial products.^[17] Research has shown that long-term storage greatly decreases the content of polyacetylenes to only trace levels at best. However, the polyacetylene derivatives of auto-oxidation of *E. pallida* are quite characteristic and

useful in differentiating *E. pallida* from *E. angustifolia*.

Alkylamides

Alkylamides typically exert a tingling sensation on the tongue. This is representative of their mild anesthetic effect. These compounds are found in highest concentrations in the roots. The roots of *E. angustifolia* contain higher concentrations (0.004–0.039%) than *E. purpurea* (0.009–0.151%) and *E. pallida* (.001%).^[9] ^[18]

Miscellaneous

There are undoubtedly other constituents which contribute to the pharmacology of *Echinacea*. The occurrence of a “colorless alkaloid” was first reported by the great John Uri Lloyd in 1897 and substantiated recently by the isolation of the alkaloids tussilagine and isotussilagine.^[19] Other compounds isolated from *Echinacea* sp. include: ^[2] ^[3]

- resins
- glycoproteins
- sterols
- minerals
- fatty acids.

HISTORY AND FOLK USE

Echinacea was used extensively by the native Americans living in areas where it grew. In fact, *Echinacea* was used by the American Indians against more illnesses than any other plant. The root was used externally for the healing of wounds, burns, abscesses, and insect bites; internally for infections, toothache and joint pains; and as an antidote for snake (rattlesnake) bites.^[20]

A commercial product containing *Echinacea* was introduced to Americans around 1870 by H. C. F. Meyer, a German lay healer, who recommended it as a wonder cure called “Meyer’s blood purifier”.^[2] ^[3] Meyer recommended it for almost every conceivable malady and there were numerous case reports of successful treatments for snake bites, typhus, diphtheria, and other infections.

Echinacea angustifolia became a favorite with Eclectic physicians as it was thought to be greater in activity than other species. Eclectics used it externally as a local antiseptic, stimulant, deodorant, and anesthetic; and internally for “bad blood”, i.e. to correct “fluid depravation with tendency to sepsis and malignancy”.^[21]

Although many physicians began to investigate and use *Echinacea* as a serious medicine, in 1909 the Council on Pharmacy and Chemistry of the American Medical Association refused to recognize *Echinacea* as an active drug stating: “In view of the lack of any scientific scrutiny of the claims made for it, *Echinacea* is deemed unworthy of further consideration until more reliable evidence is presented in its favor.” Despite this opposition, *Echinacea* was included in the National Formulary of the US and

remained there until 1950.^[2] ^[3]

With the demise of the Eclectic movement, the popularity of *Echinacea* in the US waned except amongst naturopathic physicians until around 1980 when *Echinacea* was rediscovered due to the increased consumer interest in immune system disorders such as candidiasis, chronic fatigue syndrome, AIDS, and cancer.^[22] Although interest in *Echinacea* decreased in America between the 1930s and 1980s, European physicians continued research. Much of this research was initiated by a 1932 study by Gerhard Madaus. Madaus demonstrated immune-enhancing effects of a preparation from the fresh juice of the aerial portion of *E. purpurea*. This was followed by development of a commercial product and a great deal of scientific study. Thus, *E. purpurea* began to be as respected as *E. angustifolia* among herbal practitioners in Europe.^[2] ^[3]

PHARMACOLOGY

The chemistry, pharmacology and clinical applications of *Echinacea* have been the subject of over 200 scientific studies.^[2] ^[3] The overwhelming majority of the clinical studies have utilized an injectable form of a commercial product, Echinacin, containing an extract of the juice of the aerial portion *E. purpurea* along with 22% ethanol (for preservation). Other studies have utilized an oral Echinacin and another commercial product, Esberitox, which contains not only *E. purpurea* root extract, but also extracts of *E. pallida*, *Thuja occidentalis*, and *Baptisia tinctoria*. A recent review of published studies on the immunomodulating effects of *Echinacea* identified 26 controlled clinical studies, 16 of which featured Esberitox.^[23]

This section summarizes some of the pharmacological information on *Echinacea* with attention to the species used, part of the plant used, solvent used for extraction, and other relevant features. When no species delineation is made, the activity described is similar in all species.

Tissue regeneration and anti-inflammatory properties

Echinacin, as well as polysaccharide components of *Echinacea*, have been shown to promote tissue regeneration and reduce inflammation in experimental studies.^[8] ^[24] ^[25] ^[26] ^[27] This is apparently largely due to inhibition of the enzyme hyaluronidase via formation of a polysaccharide complex with hyaluronic acid, thereby maintaining the structure and integrity of the collagen matrix in connective tissue and ground substance. In addition to increased hyaluronic acid stabilization, *Echinacea* also stimulates fibroblast growth and manufacture of glycosaminoglycans, a critical goal in wound healing.^[27]

Echinacea both exerts a mild direct cortisone-like effect and enhances the secretion of adrenal cortex hormones.^[2] ^[3] ^[25] The polysaccharide portion appears to be responsible for the direct anti-inflammatory effects, although the alkylamide fraction has also

demonstrated some activity.^[28]

Immunostimulatory properties

Echinacea possesses a broad spectrum of effects on the immune system as a result of its content of a diverse range of active components affecting different aspects of immune function.^{[2] [3]} For example, inulin, the major component in the root of *E. angustifolia*, activates the alternative complement pathway and thus promotes chemotaxis of neutrophils, monocytes, and eosinophils; solubilization of immune complexes; neutralization of viruses; and bacteriolysis. *Echinacea* also increases the levels of properdin, the normal serum globulin that stimulates the alternative complement pathway.^{[2] [3] [29]} Another non-specific immune enhancement is *Echinacea's* enhancement of serum leukocyte and granulocyte counts.^{[2] [3] [30] [31] [32] [33]}

The high-molecular-weight heteroglycan polysaccharide components of *Echinacea* have profound immunostimulatory effects.^{[2] [3] [5] [6] [7]} The majority of these effects appear to be mediated by the binding of active *Echinacea* polysaccharides to carbohydrate receptors on the cell surface of macrophages and T-lymphocytes. It should be noted, however, that some of the T-cell activation in early studies is now thought to be due to a contaminant protein. Later studies using a purer polysaccharide fraction have not shown significant results.^[3]

Echinacea promotes non-specific T-cell activation, i.e. transformation, production of interferon, and secretion of lymphokines. The resultant effect is enhanced T-cell mitogenesis, macrophage phagocytosis, antibody binding, natural killer cell activity; and increased numbers of circulating PMNs.^{[2] [3] [5]}

Echinacea polysaccharides have also been shown to enhance macrophage phagocytosis and stimulate macrophages to produce increased amounts of tumor necrosis factor (TNF), interferon, interleukin 1, to destroy tumor cells in tissue culture, and to inhibit *Candida albicans* infection in rats infected intravenously with a lethal dose (3×10^5 cells) of *C. albicans*.^{[2] [3] [6] [7] [34]} The interactions with macrophages are most likely responsible for much of the immune system enhancement of *Echinacea* polysaccharides.

In addition to the polysaccharides, lipophilic alkylamides and caffeic acid derivatives like cichoric acid are thought to contribute to the immunostimulatory aspects of *Echinacea*, especially alcoholic extracts.^{[3] [4] [35]} While most research has been devoted to the water-soluble components such as polysaccharides, the lipophilic fraction yields the most potent enhancement of macrophage phagocytosis.^{[3] [4]}

The carbon clearance test is often used to measure systemic macrophage activation. The method involves measuring the rate of disappearance of carbon granules from the blood at varying intervals following administration of the test substance. Root extracts of *Echinacea* administered orally tend to yield greater effects on phagocytic activity than the aerial portion with *E. purpurea* > *E. angustifolia* > *E. pallida*.^{[3] [4]}

Although many of the studies have utilized injectable preparations, oral preparations are generally thought to yield similar or even better results, although direct comparisons are apparently not available. For example, intramuscular Echinacin administered to healthy males on four successive days was shown to increase granulocytic phagocytosis by nearly 50%, while the oral administration of an *E. purpurea* root extract at a dose of 30 drops three times daily to healthy males for five consecutive days resulted in an increase of 120%.^[29] This difference may, however, be due to the differing constituents of the forms used. The expressed juice of the aerial portion *E. purpurea*, as found in Echinacin, has lower

707

concentrations of several of the phagocytosis-stimulating compounds characteristic to *Echinacea*, including polysaccharides, alkylamides and caffeic acid derivatives like cichoric acid compared with alcoholic extract.^[3]

In general, *Echinacea* appears to offer benefit for all infectious conditions. An exception to this statement may be acquired immunodeficiency syndrome (AIDS). It is unclear at this time if *Echinacea* should be recommended for AIDS. Although this condition is associated with widespread depression of the immune system, presumably due to the human immunodeficiency virus (HIV), stimulation of T-cell replication may also stimulate replication of the virus as well. In addition, Echinacin has been shown to lower T-helper cells and decrease T-helper:suppressor cell ratios.^[2] ^[3] While there are some anecdotal reports of *Echinacea*'s efficacy in HIV-infected individuals, more research is necessary to determine *Echinacea*'s effects in HIV.

Antiviral properties

The juice of the aerial portion of *E. purpurea* along with alcoholic and aqueous extracts of the roots have been shown to possess antiviral activity. Some of the viruses inhibited in cell cultures include influenza, herpes and vesicular stomatitis viruses.^[3] ^[36]

Although certain *Echinacea* components (e.g. echinacoside, other caffeic acid derivatives, polysaccharides, etc.) may block virus receptors on the cell surface, the antiviral effects may also be due to inhibition of hyaluronidases. The viral-inhibiting action of *Echinacea* is significantly diminished when hyaluronidase is added to the cell cultures.^[3] ^[24] ^[37] Many organisms secrete hyaluronidase, which increases connective tissue permeability and allows the organism to become more invasive.^[38]

Clinically, the inhibition of hyaluronidase coupled with general immunostimulation of *Echinacea* are probably more important than direct antiviral activity. The non-specific antiviral action of *Echinacea* enhances cytotoxic killing of virus-infected cells and the release of interferon. Interferons bind to cell surfaces, where they stimulate synthesis of intracellular proteins that block the transcription of viral RNA.

Antibacterial properties

The direct antibacterial activity of *Echinacea* is quite mild. This is somewhat surprising as *Echinacea* has a long history of effective use in both internal and external bacterial infections. It is possible that it possesses some anti-infective properties which prevent bacterial adherence, though this has yet to be determined. Clearly its clinical efficacy is due to its strong immune-potentiating actions.

Echinacea does possess some mild antibacterial action due largely to echinacoside, the complex caffeic acid derivative, found in highest concentrations in the root of *E. angustifolia*. Echinacoside and caffeic acid have been shown to have antibacterial action against *Staphylococcus aureus*, *Corynebacterium diphtheria*, and *Proteus vulgaris*. Approximately 6.3 mg. of echinacoside is equivalent to 10 Oxford units of penicillin.^[2] ^[3]
^[11]

Anti-neoplastic activity

Obviously, *Echinacea* possesses indirect anti-neoplastic activity via its general immuno-enhancing effects. Specifically important is its stimulation of macrophages to greater cytotoxic activity against tumor cells. (Z)-1,8-pentadecadiene, a lipid-soluble component found in the root of *E. angustifolia* and *E. pallida*, has been shown, in vivo, to possess significant direct anti-neoplastic activity.^[39]

CLINICAL APPLICATIONS

Echinacea has long been used clinically for conditions where its pharmacological actions have proven efficacy, especially in infections. Clinical studies have demonstrated effectiveness in a number of infectious conditions using all three routes of administration: injectable, oral, and topical. Again, the majority of clinical studies have utilized Echinacin, containing an extract of the juice of the aerial portion *E. purpurea* along with 22% ethanol (for preservation) and Esberitox. A recent review of published studies on the immunomodulating effects of *Echinacea* identified 26 controlled clinical studies, 16 of which featured Esberitox.^[23]

Infections

Numerous clinical studies have confirmed *Echinacea*'s immune-enhancing actions. Various *Echinacea* extracts or products have shown results in:

- general infectious conditions
- influenza
- colds
- upper respiratory tract infections
- urogenital infections

- other infectious conditions.

The common cold

One of the most popular uses of *Echinacea* is in the treatment of the common cold. Two recent studies offer considerable support for this clinical application. In one study, 180 patients with influenza were given either an extract of *E. purpurea* root at a daily dose of 450 mg or 900 mg, or a placebo. The 450 mg dose was found to be no more effective than a placebo; however the group taking the 900 mg dose showed significant reduction of cold symptoms.^[40]

708

In the other study, 108 patients with colds received either an extract of the fresh-pressed juice of *E. purpurea* (4 ml twice daily) or placebo for 8 weeks.^[41] The number of patients remaining healthy was as follows: *Echinacea*, 35.2%; placebo, 25.9%. The length of time between infections was: *Echinacea*, 40 days; placebo, 25 days. When infections did occur in patients receiving *Echinacea*, they were less severe and resolved quicker. Patients showing evidence of a weakened immune system (CD4/CD8 ratio <1.5) benefited the most from *Echinacea*.

Candidiasis

The effect of *Echinacea* against *C. albicans* noted in animal studies has been confirmed in several clinical studies.^{[2] [3]} A study featured in [Table 82.2](#) demonstrated that Echinacin greatly accentuates the efficacy of a topical antimycotic agent (econazol nitrate), decreasing reoccurrence from 60.5% to 5–16.7%. The researchers used standardized skin tests to show that this enhancement was due to *Echinacea*'s boosting of cell-mediated immunity.^[42] Also of interest is the similarity in the efficacies of the oral and injectable forms.

Other applications

Snake bites

Echinacea has quite a reputation among naturopathic physicians and native American healers for the treatment of snake bites. No studies of this use were carried out, but *Echinacea*'s inhibition of hyaluronidase might account for much of its reputed efficacy since most snake venoms permeate the system as a result of hyaluronidase in the venom breaking down connective tissue of the ground substance.^[24]

Wound healing

Several uncontrolled clinical studies have been reported to substantiate *Echinacea*'s wound healing activities.^{[3] [43] [44] [45]} The largest (4,598 patients) demonstrated that a

salve of the juice of the aerial portion of *E. purpurea* had an 85% overall success rate in the treatment of inflammatory skin conditions such as abscesses, folliculitis, wounds of all

TABLE 82-2 -- Treatment of recurrent candidiasis with echinacin – rate of reoccurrence at 6 months^[42]

| Therapeutic scheme | No. of patients | Reoccurrence rate |
|---|-----------------|-------------------|
| Topical antimycotic alone | 43 | 60.5% |
| Topical antimycotic + subcutaneous Echinacin | 20 | 15.0 |
| Topical antimycotic + intramuscular Echinacin | 60 | 5.0 |
| Topical antimycotic + intravenous Echinacin | 20 | 15.0 |
| Topical antimycotic + oral Echinacin | 60 | 16.7 |

kinds, eczema, burns, herpes, and varicose ulcers of the leg.^[3]

Arthritis

Echinacea's anti-inflammatory activity has been shown in uncontrolled studies to be useful in rheumatoid arthritis.^[46] In one study, 15 drops of Echinacin three times daily resulted in a 21.8% decrease in inflammation. Although this improvement was less than cortisone (42%) and prednisone (49.2%), no side-effects were noted with Echinacin while the drugs have well known side-effects.

Cancer

Echinacea extracts have been shown to inhibit the growth of Walker carcinosarcoma and lymphocytic leukemia in experimental studies.^[39]

Several studies have noted a stimulatory effect of *Echinacea* on leukocyte counts in patients receiving radiation for cancer therapy.^{[32] [33]} A study using Esberitox demonstrated that 85% of 55 patients showed a stabilization of leukocyte counts compared with the control group, which showed a steady decline in levels (starting at 6,000 and decreasing to 2,500 after 45 days).^[32] This strongly supports the recommendation of *Echinacea* to patients undergoing orthodox cancer treatments.

COMMERCIAL PREPARATIONS

As evident from the above information, determining which *Echinacea* preparation is best is difficult to determine. It is not only difficult to determine which species is most effective – the portion of the plant used and how it is prepared are also serious issues. Dosage recommendations for all currently available forms are given below along with a few observations regarding the “preparations controversy”.

Another problem needing to be addressed is quality control. Since as early as 1904,

many commercial sources of *Echinacea* have contained adulterants and no *Echinacea*. For example, it has been estimated that due to supplier errors in collection, greater than 50% (and possibly as high as 90% at times) of the *Echinacea* sold in the US from 1908 to 1991 has actually been *Parthenium integrifolium*, Missouri snakeroot.^[2] ^[47] Some suggest that this adulteration is due to confusion of the common names. Others point out that while the *Parthenium integrifolium* plant looks quite different "... once the root is cut and sifted it has an uncanny resemblance to *E. angustifolia* or *E. Pallida* roots, though it possesses its own characteristic flavor and fragrance".^[47] From a practical as well as a clinical viewpoint, physicians should require from suppliers adequate documentation that they are in fact supplying *Echinacea* as well as its species.

Species

Although studies have shown various *Echinacea* species, or components found in higher concentrations in one species, to be more effective than others, each commercial species has its advantages and disadvantages. No "best" species can at this time be recommended, as differing experimental models have at times yielded inconsistent results. Rather, the clinician must recognize the unique value of each species. Although *E. angustifolia* has long been considered the best species and to possess the greatest activity, some studies dispute this. For example, in one study *E. purpurea* demonstrated greater enhancement of phagocytosis.^[4] In fact, in a recent study, an aqueous extract of *E. angustifolia* did not demonstrate any impact on phagocytic function in rats, whether it was administered orally, intraperitoneally, or intravenously.^[48] As *E. purpurea* is the easiest to grow commercially, it may become the most utilized in the US, as it is Europe.

Part of the plant to use

Most laboratory studies report that the root possesses the greatest immune-enhancing properties. However, most of the actual clinical data are based on using Echinacin, a product containing the juice of the aerial portion, or Esberitox, a product that also contains baptisia and thuja. Therefore, this question can not be answered until more clinical research is done with monopreparations obtained from the root.

Preparations

Echinacea products are available in many different forms:

- crude plant in either ground or powdered form
- freeze-dried
- alcohol-based tinctures and liquid extracts
- aqueous tinctures and liquid extracts
- dry powdered alcoholic or aqueous.

It is thought by some that dried powdered extracts offer the greatest shelf life and are

therefore considered to be the “best”. In addition, dry powdered extracts offer the greatest concentration of active compounds and a greater degree of product standardization. Others prefer using the fresh freeze-dried root, in the belief that it will provide the full range of active compounds in a active yet stable form.

In Europe, it is popular to standardize hydro/alcoholic extracts for echinacoside (for *E. angustifolia*) or cichoric acid (for *E. purpurea*). While these extracts are thought by their proponents to be the most potent, it must be noted that even 4–10× homeopathic preparations have been shown to produce activity, while the majority of clinical studies have utilized Echinacin and Esberitox.^[31] While Esberitox (containing *E. purpurea* root) has the highest quality of clinical research, it is hard to evaluate the role of *Echinacea* in this product as it also contains standardized extracts of *Thuja occidentalis* and *Baptisia tinctoria*, both of which exert significant effects on immune system cells.

Solvents

Again, this is extremely difficult to answer as both hydrophilic and lipophilic components have been shown to possess immune-enhancing activities. Even a small amount of ethanol results in precipitation or breakdown of the immuno-active polysaccharides, suggesting that aqueous extracts may be best. However, an aqueous extract would leave behind valuable lipophilic immune-enhancing alkylamides and caffeic acid derivatives. To optimize an extract’s immune-enhancing effects, many manufacturers use low ethanol (10–20%) hydro/alcoholic mixtures. These extracts typically contain both polar and lipophilic compounds.

DOSAGE

As a general immune stimulant during infection, dosages are (three times/day):

- dried root (or as tea): 0.5–1 g
- freeze-dried plant: 325–650 mg
- juice of aerial portion of *E. purpurea* stabilized in 22% ethanol: 2–3 ml (0.5–0.75 tsp)
- tincture (1:5): 2–4 ml (1–2 tsp)
- fluid extract (1:1): 2–4 ml (1–2 tsp)
- solid (dry powdered) extract (6.5:1 or 3.5% echinacoside): 150–300 mg.

The question of whether *Echinacea* should be used on a long-term or continual basis really depends on the need. In a healthy individual with no apparent depression of the immune system, continual administration is certainly not indicated. However, as recent studies have shown, patients with impaired immune function experience long-term benefit.^[40] The usual recommendation with long-term use is 8 weeks on followed by 1 week off.

TOXICOLOGY

When used at the recommended doses, there is no danger of toxicity, as no studies

have reported acute or chronic toxicity reactions due to *Echinacea* extracts. Echinacin, given intravenously, has resulted in the production of fever (0.5–1°C elevation in body temperature) on occasion. This is presumably a result of secretion of interferon-alpha and interleukin 1 by activated macrophages.^{[2] [3]}

The LD₅₀ of intravenous Echinacin has been determined to be 50 ml/kg body weight in mice and rats.

The polysaccharides in *E. purpurea* (aerial portion) were shown to have an LD₅₀ of 1,000–2,500 mg/kg when given peritoneally to mice. Chronic administration of Echinacin to rats at doses many times the human therapeutic doses gave no evidence of any toxic effects.^[49] Mutagenic tests with Echinacin demonstrated no mutagenic activity.^{[2] [3]}

A recent review of the safety and efficacy of *Echinacea* sp. found no toxicity in both adults and children in cases of both acute and long-term administration.^[50] Extremely high dosages (1,000 times greater than those typically used) were found to be immunosuppressive.

SUMMARY

Echinacea is one of the most widely used botanical medicines. Its primary clinical applications have been in cases of infection or when immune system enhancement is desired. Clinical and experimental investigations have confirmed these applications. Although some of the clinical data are based on injectable formulations, oral administration is thought to yield similar results over time. In fact, there are some evidence indicating that oral administration may have a more profound effect on macrophage activity.

Chapter 83 - *Eleutherococcus senticosus* (Siberian ginseng)

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

Eleutherococcus or *Acanthopanax senticosus* (family: Araliaceae)
Common names: Siberian ginseng, touch-me-not, devil's shrub, eleuthero ginseng

GENERAL DESCRIPTION

Eleutherococcus senticosus, or Siberian ginseng, is a shrub that stands 5–8.5 feet high. Its erect, spiny shoots, 1.5–2.5 inches in diameter, are covered with a light grey or brownish bark. The leaves are long-petioled in a compound, palmate configuration. The leaflets (five) are elliptic, and finely serrated at the margins on both sides, with scattered, minute spinules along the veins.^[1]^[2]

Eleuthero grows abundantly in parts of the Soviet Far East, Korea, China, and Japan, north of latitude 38. Its distribution is much greater than that of *Panax ginseng* (see [Ch. 100](#)).^[1]

The root is the most widely used component, with the highest concentration of biologically active substances occurring in the fall, just before defoliation. The leaves are also used medicinally, with their highest concentration of biologically active substances occurring in July, just before flowering.

CHEMICAL COMPOSITION

The initial phytochemical report on eleuthero was published in 1965 by members of the Institute of Biologically Active Substances, in Vladivostok, Russia.^[1] Seven compounds, termed eleutherosides A–G, were isolated from a physiologically active fraction of the methanol extract of eleuthero. The total eleutheroside content of the root is in the range

0.6–0.9%, and of the stems is in the range 0.6–1.5%. The ratio of the eleutherosides A–G obtained is approximately 8:30:10:12:4:2:1 respectively. Their structure is shown in [Fig. 83.1](#) . [Table 83.1](#) , modified from Farnsworth et al's^[1] excellent review of eleuthero, summarizes what is currently known about the components of *Eleutherococcus senticosus*. It is important to recognize

714

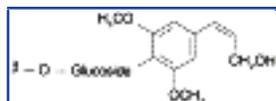

Figure 83-1 Eleutheroside B.

that thin-layer chromatographic analysis has shown that the ginsenosides characteristic of *Panax* sp. (American, Chinese, Korean, Japanese ginsengs) are not present in the roots of *Eleutherococcus senticosus*.

HISTORY

The ginseng plants, i.e. members of the family Araliaceae, including *Eleutherococcus senticosus*, are among the most ancient and esteemed of all medicinal herbs. Their use in Chinese herbal medicine dates back more than 4,000 years.^{[1] [2] [3]} References in ancient documents to members of the Araliacea family were imprecise, giving rise to some confusion in modern interpretation. However, the value of eleuthero as a medicinal agent was certainly known to the Chinese, as evidenced by the following ode [*Ode to Wujia (Eleutherococcus senticosus)* by Ye Zhishen (Qing Dynasty)]:^[3]

From earth and heavens the quintessence originates,
Five folioles clustering your leaves,
And pretty little thorns wrapped whole your shoots;
Oh what a jackal's gaunt leg looks much alike.
How wonderful is Winzhang-grass, the Eleutheroginseng
Dispensing in liquor for drinking,
And decocting with burnet for daily using, It will keep your virgin face
And prolong your life for ever and ever; Even if a cartload of gold and
That cannot estimate your price of nature.

The Chinese have long believed that the regular use of eleuthero would increase longevity, improve general health and appetite, and restore memory.

The Russians have a separate history of eleuthero and even go as far as saying, despite a long history of use by Chinese herbalists (references date back to 2,000 BC), that "Eleutherococcus was not known in Oriental folk medicine".^[1] The Russian history of eleuthero begins in 1855 when a pair of Russian scientists, C. I. Maximovich and L. I. Shrenk, traveled from St Petersburg to the Ussuri region of Russia on the Amur river. It

was in this area that Maximovich observed a vast thicket of unusual

TABLE 83-1 -- Compounds found in *Eleutherococcus senticosus*^[1]

| Compound | Type | Location |
|---|-----------------|--------------|
| Eleutheroside A (daucosterol) | Sterol | Roots, stems |
| Eleutheroside B(syringin) | Phenylpropanoid | Roots, stems |
| Eleutheroside B ₁ (isofraxidin-7-0-alpha-L-glucoside; also known as beta-calycanthoside) | Coumarin | Roots |
| Eleutheroside B ₂ | Unknown | Roots |
| Eleutheroside B ₃ | Unknown | Roots |
| Eleutheroside B ₄ ((-)-sesamin) | Lignan | Roots |
| Eleutheroside C (methyl-alpha-D-galactoside) | Sugar | Roots, stems |
| Eleutheroside D ((-)-Syringarsinol di-0-beta-D-glucoside) | Lignan | Roots, stems |
| Eleutheroside E (different crystalline form of D; also known as acanthoside D) | Lignan | Roots, stems |
| Eleutheroside F | Unknown | Roots |
| Eleutheroside G | Unknown | Roots |
| Eleutheroside I (= mussenin B) | Triterpene | Leaves |
| Eleutheroside K | Triterpene | Leaves |
| Eleutheroside L | Triterpene | Leaves |
| Eleutheroside M (= hederasaponin B) | Triterpene | Leaves |
| Senticosides A–D (may be identical to eleutherosides I, K, L and M) | Triterpene | Leaves |
| Vitamin E | Benzofuran | Roots |
| Beta-carotene | Carotenoid | Roots |
| Isofraxidin | Coumarin | Roots |
| Coumarin X | Coumarin | Roots |
| Complex mixture | Essential oil | Roots |
| Copper | Mineral | Roots |
| (-)-Syringaresinol | Lignan | Roots |
| Caffeic acid | Phenylpropanoid | Roots |

| | | |
|--------------------------|-----------------|--------------|
| Caffeic acid ethyl ester | Phenylpropanoid | Roots |
| Coniferyl aldehyde | Phenylpropanoid | Roots |
| Synapyl alcohol | Phenylpropanoid | Roots |
| Beta-sitosterol | Sterol | Roots |
| Polysaccharides | Sugar | Roots, fruit |
| Galactose | Sugar | Roots |
| Glucose (alpha and beta) | Sugar | Roots |
| Maltose (alpha and beta) | Sugar | Roots |
| Sucrose | Sugar | Roots |
| Oleanolic acid | Triterpene | Roots |

715

plants, with leaves resembling horse chestnut and young shoots resembling ginseng. Unable to identify the plant, the two scientists brought back samples to St Petersburg for classification. The plant was given the genus name of *Eleuthero*, or “free-berried shrub”, and the species name of *senticosus*, which means “thorny” in Latin.

However, it wasn’t until the middle of the 20th century that eleuthero was again “discovered”, when Russian scientists began investigating substances which produce a “state of non-specific resistance” in the body. Substances with this effect were termed adaptogens. As defined by Brekhman in 1958, an adaptogen is a substance that:^{[1] [4]}

- must be innocuous and cause minimal disorders in the physiological functions of an organism
- must have a non-specific action (i.e. it should increase the resistance to adverse influences by a wide range of physical, chemical, and biochemical factors)
- usually has a normalizing action irrespective of the direction of the pathologic state (alterative action).

Brekhman’s research with adaptogens began with *Panax ginseng*, since this was the best known natural adaptogen. After confirming the adaptogenic action of panax in human studies, Brekhman began searching for an alternative to this plant because of the difficulty and expense in obtaining panax. Initially, all six species of Araliaceae native to Russia were investigated, and eleuthero was found to be the most promising. Numerous studies (in vivo, in vitro, and human studies) have been conducted since the late 1950s, nearly all in the Soviet Union. These are not referenced here as they are not translated and not widely available. Instead, review articles and original articles in English are cited.^{[1] [2] [3] [4] [5] [6] [7] [8]}

PHARMACOLOGY

As mentioned above, a number of experimental and clinical studies have demonstrated that eleuthero does possess adaptogenic properties, i.e. the ability to increase non-specific body resistance to stress, fatigue, and disease. Additional experimental and clinical research supports other therapeutic applications of *Eleutherococcus senticosus*.

Experimental studies

Adaptogenic activity

An important characteristic of an adaptogen is its ability to “normalize”, irrespective of the direction of pathology. *Eleutherococcus senticosus* has been found in experimental models to:

- impede the adrenal hypertrophy induced by ACTH and the adrenal atrophy induced by cortisone
- impede the thyroid hypertrophy induced by thyroidin and thyroid gland atrophy induced by 6-methylthiouracil
- reduce blood glucose levels in alimentary and adrenal hyperglycemia, and increase glucose levels in insulin-induced hypoglycemia
- reduce leukocytosis induced by the parenteral administration of milk, as well as leukopenia induced by endotoxins
- reduce erythrocytosis induced by cobaltous nitrate and erythropenia induced by phenylhydrazine.

These are summarized in [Table 83.2](#) . Similar results have been obtained with *Panax ginseng* (see [Ch. 100](#)).

Stress control

Another important action of adaptogens is the inhibition of the alarm phase of the stress reaction. Eleuthero has shown similar action to *Panax ginseng* in experiments designed to demonstrate an anti-alarm action. Specifically, eleuthero has been shown to increase the swimming time of rats, reduce activation of the adrenal cortex in response to stress (alarm phase reaction), and prevent stress-induced thymic and lymphatic involution.^{[1] [2] [3] [4] [5] [6] [7]}

Radiation protection

In addition to its confirmed adaptogenic activity, eleuthero has also demonstrated both protective and therapeutic

TABLE 83-2 -- Abnormalities normalized by *Eleutherococcus senticosus*

| Function | Normalization action of <i>Eleutherococcus</i> |
|-----------------|--|
| Adrenal | Impedes hypertrophy induced by ACTH |
| | Impedes atrophy induced by cortisone |
| Thyroid | Impedes hypertrophy induced by thyroidin |
| | Impedes atrophy induced by 6-methylthiouracil |
| Kidney | Increases renal capacity in pyelonephritis |
| Blood pressure | Decreases high blood pressure through improvement of atherosclerosis |
| | Increases pressure in hypotension |
| Blood glucose | Reduces alimentary and adrenal hyperglycemia |
| | Increases blood sugar in insulin-induced hypoglycemia |
| Leukocyte | Reduces leukocytosis induced by the administration of milk |
| | Reduces leukopenia induced by endotoxins |
| Erythrocyte | Reduces erythrocytosis induced by cobaltous nitrate |
| | Reduces erythropenia induced by phenylhydrazine |
| Stress | Reduces activation of the adrenal cortex in response to stress |
| | Prevents stress-induced thymic and lymphatic involution |
| Radiation | Protects against radiation exposure |
| Cancer | Inhibits carcinogenesis from urethane, 6-methylthiouracil, indole |
| Cholesterol | Reduces hepatic biosynthesis |
| DNA | Stimulates synthesis |

actions in animals exposed to both single and prolonged X-ray radiation. In one study, both *Eleutherococcus senticosus* and *Panax ginseng* were found to double the life span of rats exposed to prolonged radiation (total doses of 1620–7,000 rads). When eleuthero was combined with antibiotics, the lifetime of irradiated rats (total dose of 3,000 rads over 60 days) increased threefold.^[8]

These results suggest that eleuthero may be of benefit in protecting against harmful radiation and as an adjunctive aid in radiation therapy in oncology. The latter suggestion is further supported by studies of eleuthero that have demonstrated an inhibition of carcinogenesis.

Carcinogenesis inhibition

Eleutherococcus preparations have been shown in experimental studies in animals to inhibit:^{[1] [4]}

- urethane-induced lung adenomas
- 6-methylthiouracil-induced tumors of the thyroid
- myeloid leukemia induced by indole
- the formation of spontaneous mammary gland tumors and leukemia
- transplantation of a variety of tumors.

As is evident from the discussion of eleuthero's adaptogenic activities, eleuthero shares many features with *Panax ginseng*. In addition to adaptogenic activities, eleuthero, like panax, has been shown to:^[1]

- increase resistance to infection in animals
- reduce hepatic cholesterol biosynthesis
- increase reproductive capacity and sperm counts in bulls
- possess significant antioxidant activity
- stimulate DNA synthesis and cellular repair enzymes.

Part of eleuthero's anticancer effects may be due to its immuno-stimulating effects. In vitro, it increases phagocytosis of *Candida albicans* by granulocytes and monocytes from healthy donors by 30–45%.^{[9] [10]}

CLINICAL STUDIES

Adaptogenic activity in healthy individuals

Farnsworth et al^[4] reviewed the results of clinical trials designed to evaluate the "adaptogenic" effects of eleuthero. In these studies, the fluid extract of *Eleuthero senticosus* root was administered to more than 2,100 healthy human subjects. The data indicated that eleuthero:

- increased the ability of humans to withstand many adverse physical conditions (i.e. heat, noise, motion, work load increase, exercise, and decompression)
- increased mental alertness and work output
- improved the quality of work under stressful conditions and athletic performance.

The male and female subjects ranged in age from 19 to 72 years. Dosages of the fluid extract (33% ethanol) ranged from 2.0 to 16.0 ml, one to three times a day, for periods of up to 60 consecutive days.

Adaptogenic activity in disease states

Farnsworth et al^[1] also reviewed the results of clinical trials which evaluated the adaptogenic effects of eleuthero in patients with various diseases. A fluid extract (33% ethanol) of *Eleuthero senticosus* root was administered to more than 2,200 human subjects with a variety of illnesses, including angina, hypertension, hypotension, acute pyelonephritis, various types of neuroses, acute craniocerebral trauma, rheumatic heart disease, chronic bronchitis, and cancer.

Eleuthero appears to be effective in atherosclerotic conditions, as evidenced by its ability to lower elevated serum cholesterol and prothrombin levels, reduce blood pressure, and eliminate anginal symptoms in human subjects. Its action on blood pressure is truly adaptogenic, as eleuthero has also been shown to increase blood pressure in subjects with hypotension.^[1]

Its effect in regulating blood pressure may be indicative of improved renal function; it has been demonstrated that patients with acute pyelonephritis given eleuthero extract demonstrate increased renal capacity, as measured by an increased secretion of phenol red.^[1]

Eleuthero appears to have some psychotropic action, as it has been proven effective in the treatment of a variety of psychological disturbances. Eleuthero has consistently demonstrated an ability to increase the sense of well-being, regardless of the psychological complaint (insomnia, hypochondriasis, various neuroses, etc.). A possible explanation of this effect is improved balance of the biogenic amines (serotonin, dopamine, norepinephrine, epinephrine, etc.), as eleuthero extract administered to rats has been shown to increase biogenic amine content in the brain, adrenals, and urine.^[1]

There is not yet sufficient data to fully evaluate eleuthero's action in other disease states. However, it must be kept in mind that an adaptogen is non-specific in its action and possesses a normalizing action irrespective of the direction of the changes from physiological norms.

TOXICOLOGY

Toxicity studies in animals have demonstrated that eleuthero extracts are virtually non-toxic. The LD₅₀ of the 33% ethanol extract of eleuthero is 14.5 ml/kg in mice and greater than 20.0 ml/kg in rats. No long-term toxicity was observed when a daily dose of 5.0 ml/kg of the fluid extract was administered to rats. Teratogenicity has been studied in three species (rats, rabbits, and minks), with no adverse effects observed.^[1]

In human clinical studies, it was demonstrated that eleuthero extracts (33% ethanol) in the recommended dosage range are well tolerated and side-effects are infrequent. A few studies found mild side-effects at higher dosages (4.5–6.0 ml three times daily)

when used for long periods (60 days). The symptoms included insomnia, irritability, melancholy, and anxiety. In individuals with rheumatic heart disease, pericardial pain, headaches, palpitations, and elevations in blood pressure have been reported.^[4] These symptoms are probably due to the mild stimulating effects of eleuthero and, while not serious, would indicate the need to decrease the dosage and/or allow a washout period.

DOSAGE

The standard dosage of the fluid extract (33% ethanol) of *Eleutherococcus senticosus* roots used in the majority of studies ranged from 2.0 to 4.0 ml (up to 16.0 ml), one to three times a day, for periods of up to 60 consecutive days. In multiple dosing regimens, there is usually a 2–3 week interval between courses.^[4] ^[4]

Dosages are as follows:

- dried root: 2–4 g
- tincture (1:5): 10–20 ml
- fluid extract (1:1): 2.0–4.0 ml
- solid (dry powdered) extract (20:1): 100–200 mg.

SUMMARY

Eleutherococcus senticosus, or Siberian ginseng, possesses significant adaptogenic action. Currently, it can be recommended as a general tonic and in the clinical situations mentioned above (angina, hypertension, hypotension, acute pyelonephritis, various types of neuroses, acute craniocerebral trauma, rheumatic heart disease, chronic bronchitis, and cancer), although it must be pointed out that its clinical application may turn out to be much broader, given its non-specific mechanisms of action.

Chapter 84 - *Ephedra* species

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

Ephedra sinica (family: Ephedraceae)
Common names: Chinese ephedra, Ma Huang, Chinese joint fir

Related species:

E. distacha (European ephedra)

E. trifurca or *E. viridis* (desert tea)

E. nevadensis (Mormon tea, cay note, canutillo, whorehouse tea, tapopote, teamster's tea)

E. americana (American ephedra)

E. gerardiana (Pakistani ephedra)

GENERAL DESCRIPTION

Ephedra spp. are erect, branching shrubs found in desert or arid regions throughout the world. The 1.5–4 foot shrubs typically grow on dry, rocky, or sandy slopes. The many slender, yellow-green branches of ephedra have two very small leaf scales at each node. The mature, double-seeded cones are visible in the fall.

CHEMICAL COMPOSITION

The chemical analysis of the stems and branches of *Ephedra* sp. has focused on their alkaloid content. In *Ephedra sinica*, the total alkaloid content can be up to 3.3%, with 40–90% of this being ephedrine. The remaining alkaloids are primarily pseudoephedrine

and nor-pseudo-ephedrine.^[1] ^[2] In *Ephedra gerardiana*, the alkaloid content usually varies from 0.8 to 1.4%, about half ephedrine and half other alkaloids (pseudoephedrine, *N*-methylephedrine, norephedrine, etc.).^[2] Mormon tea or *Ephedra nevadensis* is reported to contain little or no ephedrine.^[2]

HISTORY AND FOLK USE

Ephedra sinica's medicinal use in China dates from approximately 2800 BC. Ma Huang (the stem and branch) was used primarily in the treatment of the common cold, asthma, hay fever, bronchitis, edema, arthritis, fever, hypotension, and urticaria.^[1]

720

The Chinese believed the effect of the root and rhizome (Ma Huanggen) to be the opposite of the stem and branches, and limited its use to the treatment of profuse night sweating.^[1] Two hypotensive principles (ephedradine A and B) have since been isolated from ephedra root, along with a hypertensive compound (1-tyrosine betaine or maokine).^[1]

Western medicine's interest in ephedra began in 1923 with the demonstration that the isolated alkaloid ephedrine possessed a number of pharmacological effects. Ephedrine was synthesized in 1927 and has since been used extensively for clinical conditions in which sympathomimetic effects are desired.^[3]

PHARMACOLOGY

The pharmacology of ephedra centers around its ephedrine content. Ephedrine and pseudoephedrine have been extensively investigated and are widely used in both prescription and over-the-counter medications for asthma, hay fever, and rhinitis. In 1973, over 20 million prescriptions contained one of these alkaloids.

Ephedrine

Ephedrine's basic pharmacological action is that of a sympathomimetic. Ephedrine stimulates both alpha- and beta-adrenergic receptors as well as the release of nor-epinephrine. Ephedrine shares many pharmacological actions with epinephrine, although ephedrine is much less active. Ephedrine also differs from epinephrine in its ability to be absorbed orally, its longer duration of action, and its more pronounced effect upon the central nervous system. The CNS effects of ephedrine are similar to those of amphetamine but, again, much less potent.^[1] ^[2] ^[3] ^[4] Its chemical structure is shown in [Figure 84.1](#).

The cardiovascular effects of ephedrine are also similar to those of epinephrine. It increases both diastolic and systolic blood pressure, cardiac output, and heart rate, but for a longer (about 10 times) period. Like epinephrine, ephedrine will also increase

coronary, cerebral, and muscle blood flow at the expense of renal and splanchnic blood flow.^{[1] [2] [3] [4] [5]}

The bronchial muscle relaxation induced by ephedrine is much less than epinephrine, but, again, the duration of action is much longer. Other smooth muscles, with

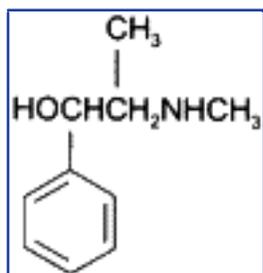

Figure 84-1 Ephedrine.

the exception of the human uterus, are generally affected by ephedrine in the same manner (mild relaxation) as epinephrine. Ephedrine relaxes the human uterus where the effects of epinephrine are more complex.^{[1] [2] [3] [4]}

Extracts of ephedra have been shown to inhibit complement in vitro, and a Chinese herbal medicinal prescription, Makyokanseki-to, was found to inhibit cyclic AMP activity.^{[6] [7]}

The principle adverse effects of ephedrine are CNS stimulation, nausea, tremors, tachycardia, and urinary retention.^{[1] [2] [3] [4]}

The major route of elimination of ephedrine is as the unchanged drug in the urine. The average half-life is 6 hours, although acidifying the urine will decrease the half-life considerably. Alkalinization will increase the half-life.^{[8] [9]}

Pseudoephedrine

Pseudoephedrine exhibits bronchodilating activity similar to ephedrine, but has weaker pressor, cardiac, and central nervous system effects. Pseudoephedrine is often recommended over ephedrine in the treatment of chronic asthma as it has fewer side-effects.^{[3] [4]}

Pseudoephedrine has also demonstrated significant anti-inflammatory effects in various experimental models.^{[8] [9] [10]} Other ephedra alkaloids, including ephedrine, also exhibited anti-inflammatory activity, but at much lower potency. As the anti-inflammatory effect of pseudoephedrine is essentially identical in normal and adrenalectomized mice, the anti-inflammatory activity is not exerted via the adrenal glands. Instead, it appears that the anti-inflammatory activity of pseudoephedrine and other ephedra alkaloids is due to inhibition of prostaglandin E₂ synthesis.

CLINICAL APPLICATIONS

Asthma and hay fever

Ephedra and its alkaloids have proven effective as bronchodilators for the treatment of mild to moderate asthma and hay fever.^{[3] [4]} The peak bronchodilation effect occurs in 1 hour and lasts about 5 hours after administration.

The therapeutic effect of ephedra will diminish if used over a long period of time due to the weakening of the adrenal gland caused by ephedrine. Therefore it is often necessary to use ephedra in combination with herbs, such as *Glycyrrhiza glabra* and *Panax ginseng*; and nutrients, such as vitamin C, magnesium, zinc, vitamin B₆, and pantothenic acid, which all support the adrenal glands.

The folklore herbal treatment of asthma involved the use of ephedra in combination with herbal expectorants. (Expectorants are herbs that modify the quality and

721

quantity of secretions of the respiratory tract, resulting in the expulsion of the secretions and an improvement in respiratory tract function.) Commonly used expectorants include:

- *Glycyrrhiza glabra* (licorice)
- *Grindelia camporum* (grindelia)
- *Euphorbia hirta* (euphorbia)
- *Drosera rotundifolia* (sundew)
- *Polygala senega* (senega).

Common cold

Ephedrine and pseudoephedrine are components of many OTC products for the self-treatment of the common cold.^[4] In China, ephedra, in combination with various other herbs, has been found to be clinically effective in the treatment of cold symptoms as well as those of influenza, pneumonia, whooping cough, and bronchitis.^[1]

Weight loss aid

In both human and animal studies, ephedrine has been shown to promote weight loss.^{[11] [12] [13] [14] [15] [16] [17] [18]} Although ephedrine has demonstrated an anorectic effect,^[11] its main mechanism for promoting weight loss appears to be increasing the metabolic rate of adipose tissue.^{[11] [12] [13] [14] [15] [16]} Therefore, ephedra's weight-reducing effects are most significant in those individuals with a low basal metabolic rate.^[13] These effects can be greatly enhanced when used in combination with methylxanthines caffeine and theophylline, as well as aspirin,^{[13] [14] [15] [16] [17] [18]} which potentiates the action of

ephedrine and other ephedra compounds.

In one animal study, when ephedrine was used alone, it resulted in a 14% decrease in body weight and a 42% decrease in body fat. However, when used in combination with caffeine or theophylline, the decreases were 25 and 75%, respectively.^[14] However, when either caffeine or theophylline were used alone, there was no significant loss in body weight. The reason for the greater decrease in body weight is the increased metabolic rate and fat cell breakdown promoted by ephedrine and enhanced by caffeine and theophylline.

It is recommended that, for methylxanthines, *Camellia sinensis* (green tea) or extracts of *Cola* sp. be used rather than coffee or black tea.

DOSAGE

The optimum dosage of ephedra depends on the alkaloid content in the form used. The average total alkaloid content of *Ephedra sinica* is 1–3%. When used in the treatment of asthma or as a weight loss aid, the ephedra dose should have an ephedrine content of 12.5–25.0 mg and be taken two to three times daily. For the crude herb, an equal dose would be approximately 500–1,000 mg three times per day. Standardized preparations are often preferred as they have more dependable therapeutic activity.

TOXICOLOGY

Ephedra can produce the same side-effects as ephedrine, i.e. increased blood pressure and heart rate, insomnia, and anxiety. A highly potent CNS stimulant, ephedrine may even induce toxic psychosis at high dosages.^[19] But, according to the American Pharmaceutical Association: “There is far more discussion of ephedrine tachyphylaxis or tolerance than is evidenced as a significant problem in the scientific literature.” A 1977 study of ephedrine therapy in asthmatic children concluded: “Ephedrine is a potent bronchodilator that, in appropriate doses, can be administered safely along with therapeutic doses of theophylline without the fear of progressive tolerance or toxicity.”

The FDA advisory review panel on non-prescription drugs recommended that ephedrine not be taken by patients with heart disease, high blood pressure, thyroid disease, diabetes, or difficulty in urination due to enlargement of the prostate gland. Nor should ephedrine be used in patients on antihypertensive or antidepressant drugs.

Pregnant women should also avoid the use of ephedra and ephedrine. Ephedrine administered to chick embryos has resulted in cardiovascular teratogenicity and embryotoxicity at doses as low as 1 $\mu\text{mol/egg}$.^[20] The teratogenic effect of ephedrine is potentiated by caffeine.^[21] Presumably, this activity of ephedrine is the result of the production of nitrosamines.^[22] Simultaneous vitamin C administration might reduce the formation of nitrosamines from ephedra alkaloids.^{[23] [24]}

Chapter 85 - Fatty acid metabolism

Richard S. Lord PhD
J. Alexander Bralley PhD

INTRODUCTION

Fatty acids are common denominators for all life forms. The same oleic acid that is found in the cell membranes of olive trees is also critical for the cellular structure and functions of bacteria, fungi, and humans. Thin layers of fatty acids provide the separation of the inside from the outside of living cells. Plants fill their seeds with fatty acids because they are the most efficient storage form of energy.

Although a growing body of research is now documenting the critical importance of fatty acids for maintaining health, common food choices in modern society do not lead to appropriate levels or balances of these nutrients. Years of negative associations of dietary fat with calories, cholesterol and cancer have resulted in a general public attitude that foods containing fats are simply to be avoided. Many food manufacturers have taken advantage of this attitude by modifying fat content and labeling, wherever possible, to tout “low fat” foods. Advertisements for such foods further instill the notion that dietary fat is bad. Amid the clamor over the largely mistaken problems associated with dietary fats, many very real problems have been created by the large-scale use of modified fats by food suppliers. Individuals do not feel the effects of abusing dietary fats on the short term because of the presence of many protective mechanisms that make health threats from fat abuse a very insidious process.

Modern diets of fast foods and packaged dinners tend to be rich in saturated fats and hydrogenated oils and are frequently lacking in essential fatty acids. We now know that not only the amount, but also the type of dietary fat plays a major role in maintaining health. Some saturated fatty acids stimulate cholesterol formation but most do not.

The old concept of three essential fatty acids has been replaced by recognition of critical roles for multiple polyunsaturated fatty acids. Dietary fats simultaneously provide the major cellular energy source, control the

passage of compounds into and out of cells, determine the integrity of nerve tissue, and serve to form powerful hormones.

The essential hormone function is mediated by some special fatty acids that affect energy flow, cell division, immune responses and many other body controls. These critical fatty acids are used to make powerful tissue-specific compounds called eicosanoids. The various roles of fatty acids are illustrated in [Figure 85.1](#). More about these functions will be discussed after some basic fatty acid relationships are explained.

FATTY ACID STRUCTURE AND METABOLISM

There are about 30 structural isomers and homologs of fatty acids that occur in human tissues. They are named in various ways, including those with Latin prefixes (*penta-*, *hexa-*, ...) for the number of carbon atoms. These are the chemical names approved by the International Union of Pure and Applied Chemists (IUPAC). Many also have common names and, because the common name is in widest use among clinicians, they are used here. A lexicon of fatty acid terms is provided in [Table 85.1](#).

Figure 85-1 Metabolic roles of fatty acids.

Saturated fatty acids

Fatty acids containing the maximum number of carbon–hydrogen bonds are called saturated. They have higher energy or caloric yield than corresponding unsaturated fatty acids. They are present as major components of most foods and are very high in manufactured foods such as candy bars. The most abundant members in human tissues are those that are 12 (myristic), 14 (palmitic), or 18 (stearic) carbons long. The elongation process can be repeated to yield members that are 20, 22, and 24 carbons long. Although such very long-chain fatty acids are minor components of the lipid membranes of the body, they undoubtedly perform valuable functions, apparently helping to stabilize membranes, especially those in peripheral nerve cells.

Unsaturated fatty acids

Three major families of unsaturated fatty acids (UFA) are found in human tissues: the

ω9, the ω6, and the ω3 UFAs (or n-9, n-6 and n-3). The ω6 and ω3 polyunsaturated fatty acids (PUFAs) are defined by the position of the double bond closest to the terminal methyl group of the fatty acid molecule. In the ω6 family, the first double bond occurs between the sixth and seventh carbons from the methyl group end of the molecule, whereas in the ω3 family the first double bond occurs between the third and fourth carbons.

The older delta (Δ) naming scheme gives the positions of all double bonds, counting from the carboxyl or number 1 carbon. The omega (ω) scheme takes advantage of the fact that the double bonds are always separated by three carbons and simply gives the total length and number of double bonds separated by a colon. The number following the ω symbol gives the position of the first double bond counting from the omega carbon (see [Fig. 85.2](#) for naming conventions).

Fatty acids can be synthesized from acetyl-CoA derived from carbohydrate, protein, and other non-lipid sources. This pathway produces saturated fatty acids, predominantly palmitic acid (16:0). Palmitic acid can be desaturated, forming the ω7 class of unsaturated fatty acids. Palmitic acid can also be lengthened to stearic acid (18:0) and desaturated to form oleic of the ω9 class. Under ordinary metabolic conditions, these two classes are not further lengthened or desaturated to any appreciable extent. The ω6 and ω3 classes of unsaturated fatty acids are derived from dietary polyunsaturated fats. These classes can be further lengthened and desaturated. None of the four ω classes of unsaturated fatty acids, however, is interconvertible. These reactions can be repeated in various combinations, giving an array of saturated and unsaturated fatty acids for use in the essential functions of tissue maintenance.

TABLE 85-1 -- Lexicon of fatty acid terms

| Term or abbreviation | Definition or explanation |
|-----------------------------|--|
| AA | See arachidonic acid |
| ALA | see alpha linolenic acid |
| Alpha linolenic acid | ω9,12,15 octadecatrienoic acid; 18:3 ω3 |
| Arachidonic acid | ω5,8,11,14 eicosatetraenoic acid; 20:4 ω6 |
| Carnitine | The molecule to which fatty acids are attached in the process of their enzyme-mediated entry into the mitochondrial matrix. This enzyme is inhibited by malonyl-CoA formed during fatty acid synthesis from carbohydrate |
| Cerebronic acid | The 2-hydroxy derivative of lignoceric acid (24:0); found in glycosphingolipids in brain |
| Cervonic acid | Another name for DHA |

| | |
|---------------------------|---|
| <i>cis</i> | Geometrical isomer in which two substituents are on the same side of a double bond |
| Clupanodonic acid | Another name for 7,10,13,16,19-docosapentaenoic acid (DPA3), an ω3 series very long-chain, highly unsaturated fatty acid; found in fish oils and the phospholipids in brain |
| delta (?) | Used to describe the position of double bonds relative to the carboxyl end of a fatty acid |
| Desaturase | Tightly bound to the endoplasmic reticulum membrane, this enzyme, in association with cytochrome b5 and cytochrome b5 reductase utilizes NADH and O ₂ to introduce double bonds into fatty acids. There are at least four separate desaturases, named according to the position in the fatty acid that they desaturate Delta-9-desaturase, delta-6-desaturase, and delta-5(4) desaturase act on fatty acyl-CoA thioesters, always inserting double bonds between the thioester bond (carboxylate group) and the double bond closest to it, leaving a three-carbon gap. Activities of these enzymes fluctuate according to dietary fat intake to maintain optimal fluidity state of the membrane lipids. Their concentrations decrease in starvation and increase greatly on re-feeding carbohydrate. They are suppressed when dietary unsaturated fatty acid intake (including <i>trans</i> isomers) is high |
| DGLA | See dihomogammalinolenic acid |
| Dihomogammalinolenic acid | 8,11, 4 eicosatrienoic acid; 20:3 ω6 |
| DHA | 4,7,10,13,16,19 Docosahexaenoic acid; 22:6 ω3; an ω3 series very long-chain, highly unsaturated fatty acid; found in fish oils and the phospholipids in the brain (also known as cervonic acid) |
| Dienoic | Containing two double bonds |
| EFA | Essential fatty acid |
| Eicosanoid | A product of the specific, enzyme-directed oxidation of polyunsaturated fatty acids containing 20 (eicosa) carbons. This term encompasses the prostaglandins, thromboxanes, and leukotrienes |
| Eicosapentaenoic acid | 5,8,11,14,17 eicosapentaenoic acid; 20:5 ω3; one of the most abundant fatty acids in fish oils |
| Elongase | An enzyme that adds 2-carbon units (acetate) to the carboxyl end of an existing saturated or unsaturated fatty acid. Mitochondrial form utilizes acetyl-CoA while endoplasmic form has malonyl-CoA as substrate |
| EPA | See eicosapentaenoic acid |

| | |
|------------------------------|--|
| Gamma linolenic acid | ?6,9,12 octadecatrienoic acid; 18:3 ?6 |
| GLA | See gamma linolenic acid |
| HUFA | Highly unsaturated fatty acid; generally having five or six double bonds |
| LA | See linoleic acid |
| Lauric acid | Tetradecanoic acid; C12:O; first isolated and identified from the laurel plant |
| LCP | Long-chain polyunsaturated fatty acid |
| Linoleic acid | ?9,12 octadecadienoic acid; 18:2 ?6 |
| Meads acid | ?5,8,11 eicosatrienoic acid; 20:3?9. This compound is not normally produced in appreciable amounts due to the saturation of the desaturase enzymes with the more strongly binding essential fatty acids and their metabolic products. It accumulates, however, in essential fatty acid deficiency, making it a marker for this condition |
| Monoenoic | Containing one double bond |
| MUFA | Monounsaturated fatty acid |
| Omega (?) | Used to describe the position of double bonds relative to the methyl end of a fatty acid |
| P+M/S ratio | Polyunsaturated + monounsaturated to saturated fatty acid ratio |
| P/S ratio | Polyunsaturated to saturated fatty acid ratio |
| Phospholipase A ₂ | An enzyme that catalyzes the hydrolysis of the fatty acid ester from position 2 of phosphoglycerides. Dependent on calcium, this enzyme is responsive to intracellular calcium, calmodulin, etc. It releases primarily polyenoic fatty acids (arachidonic acid, etc.) within membranes for eicosanoid synthesis |
| PUFA | Polyunsaturated fatty acid |
| Phosphatide | Diacylglycerol phosphate to which various groups may be attached through phosphoester linkage; the principal components of cell membranes |
| Polyenoic | Containing more than two double bonds |
| Saturated fatty acid | A fatty acid in which all of the carbon atoms except for the carboxyl carbon are fully hydrogenated as -CH ₂ -(and -CH ₃) |
| Beta (β)-oxidation | The mitochondrial metabolic pathway whereby fatty acids are converted into acetyl-CoA which enters the citric acid cycle to ultimately yield ATP. The carbon atoms of the fatty acid are oxidized to CO ₂ |

| | |
|------------------------|---|
| Stearidonic acid | ?6,9,12,15 octadecatetrienoic acid; 18:3?3; a product of elongation of ALA and a precursor to EPA. A good source is black currant seed oil |
| Timnodonic acid | Another name for eicosapentaenoic acid (EPA) or 20:4?6 |
| <i>trans</i> | Geometrical isomer in which two substituents are on opposite sides of a double bond |
| Unsaturated fatty acid | A fatty acid in which two or more adjacent pairs of carbon atoms are lacking hydrogen atoms, having instead an additional carbon-carbon bond or double bond |
| ? | The Greek letter, delta (see delta above) |
| ? | The Greek letter, omega (see omega above) |

726

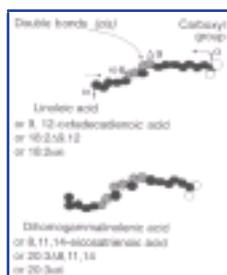

Figure 85-2 Naming conventions for unsaturated fatty acids.

The desaturase enzymes function to place double bonds at positions up to nine carbons from the carboxyl end of the molecules. When you count from the other end, the position varies, depending on the length of the fatty acid. Thus, for stearic acid with 18 carbons, a desaturase can form a double bond nine carbons from the carboxyl end which is also nine carbons from the methyl end ($18 - 9 = 9$). These differences become important because the type of eicosanoid hormones that can be formed later depend on the position of the first double bond from the methyl end.

The geometry of the desaturase will not allow insertion farther than nine carbons (9) from the carboxyl group. This is the reason that linoleic acid (9, 12) cannot be synthesized in humans. Fatty acids of various chain lengths can act as substrates as well as those that already possess double bonds at other positions. [Figure 85.3](#) shows the products of the 9 desaturase acting on three saturated fatty acids.

The activity of the desaturase enzymes is critical for maintaining the ratio of saturated and unsaturated components in cell membranes. Tumor tissue and virus-transformed cells have a higher content of unsaturated fatty acids, especially oleic acid which increases relative to the amount of stearic acid. Such shifts increase the metabolic rates

of many lipid-dependent enzymes and

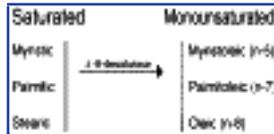

Figure 85-3 Formation of monounsaturated fatty acids.

are associated with a higher capacity for cell division.^[1] Individuals with recurrent tumors may already have too much oleic acid relative to stearic acid, and encouraging a diet high in olive oil or other highly unsaturated fatty acids is contraindicated.

Trans fatty acids

In the tissues of plants and higher animals, the insertion of double bonds always results in the *cis* geometry. The message “partially hydrogenated vegetable oil” on food labels indicates that a natural oil has been chemically modified in a process that converts some of the *cis* unsaturated fatty acids to the *trans* form. Oleic acid is transformed into its *trans* isomer, elaidic acid, which is the most abundant *trans* fatty acid in most hydrogenated oils. In human tissues, *trans* unsaturated fat behaves as if it were saturated, meaning more risk of heart disease, etc. Adverse impact on HDL or LDL cholesterol of *trans* fatty acids is well documented in the medical research literature.^{[2] [3]} ^[4] Interference with eicosanoid production is also suspected and research in the area of health risks of *trans* fatty acids is accelerating. *Trans* fatty acid levels in cell membranes are determined by dietary intake of hydrogenated oils.^[5] A person eating a doughnut for breakfast (3.19 g of *trans* fatty acids), a small order of French fries with lunch (3.43 g), two teaspoons of margarine on bread with dinner (1.24 g), and two cookies for a snack (1.72 g) would ingest a total of 9.58 g of *trans* fatty acids, enough to negate the serum cholesterol-lowering effects of a decrease in saturated fat of 10% of total energy intake.^[6]

Elaidic acid is generally the most abundant of the *trans* fatty acids because it is produced by the hydrogenation of the most common oils used in the food industry, including corn, soybean, and safflower. These oils contain relatively high amounts of oleic and linoleic acids, both of which may convert to elaidic acid during the hydrogenation process. Hard margarine may contain as much as 60% of the total unsaturated fatty acids as elaidic acid. Palmitelaidic acid is a *trans* fat that can be formed from hydrogenation of natural fatty acids containing palmitoleic acid, or partial saturation of PUFAs with isomerization. The plasma level reflects body burden of *trans* fatty acids and is useful in monitoring intake of hydrogenated oils.

Polyunsaturated fatty acids (PUFAs)

Dietary PUFAs are largely composed of two classes of fatty acids, the ω 6 family (e.g. LA), which is abundant in vegetable seed oils, and the ω 3 family (e.g. ALA), which is high in vegetable leaves and modest in soybean oil.^[7] When the diet supplies adequate linoleic and alpha linolenic acids, they may be used to form the eicosanoid precursors

as shown in [Table 85.2](#) .

TABLE 85-2 -- Polyunsaturated fatty acid families

| Family | Configuration | Name |
|--------|---------------|-----------------------------|
| ?6 | 18:2 | Linoleic (LA) |
| | 18:3 | Gamma linolenic (GLA) |
| | 20:3 | Dihomogammalinolenic (DGLA) |
| | 20:4 | Arachidonic (AA) |
| ?3 | 18:3 | Alpha linolenic (ALA) |
| | 20:5 | Eicosapentaenoic (EPA) |
| | 22:5 | Docosapentaenoic (DPA-3) |
| | 22:6 | Docosahexaenoic (DHA) |

The ?6 desaturase enzyme acts as a gateway for the flow of fatty acids through the desaturation and elongation pathway. Although it can act on any long-chain fatty acid, the substrate binding affinity increases greatly with the number of double bonds already present ([Fig. 85.4](#)). Thus 18:3 binds stronger than 18:2, which binds stronger than 18:1. The result is that ALA is quickly converted to EPA while oleic acid is slowly converted into 20:3?9 in the presence of appreciable amounts of either LA or ALA. When the two essential fatty acids are absent, however, 20:3?9 accumulates because the desaturase is free to act on oleic acid. Elevated 20:3?9 (eicosatrienoic acid) is a marker of essential fatty acid deficiency that could be used

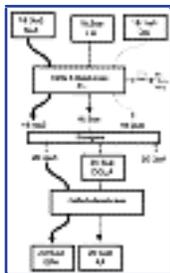

Figure 85-4 Formation of longer and more saturated fatty acids.

in addition to the actual concentrations of the essential fatty acids in plasma and erythrocyte membranes.

The ?6 desaturase enzyme requires the zinc ion for activity. For this reason,

supplementing a patient with sources of LA and ALA will do little good if zinc deficiency is present. The changes in body growth, organ weights and lipid concentrations of plasma and liver produced by zinc deficiency are reversed by the addition of primrose oil, but not safflower oil, showing the role of zinc in the $\Delta 6$ desaturase enzyme.^[8] The enzyme is also inhibited by high concentrations of saturated fatty acids, monounsaturated and *trans* fatty acids, all of which compete for the enzyme binding site and yield products that are of less significance to the cell.

The primary function of the pathway described above is to supply the parent compounds for the 1-, 2-, and 3- series prostanoid and leukotriene pathways (see below). The PUFAs have great impact on health due to their conversion to these compounds collectively called eicosanoids. They possess extremely potent biological activities, and their homeostatic functions in regulating blood vessel leaking, lipid accumulation, inflammation and immune cell behavior are relevant to the initiation and progress of heart and blood vessel disease.^[9] These compounds in turn are used to amplify and balance signals to the organs, the blood clotting system, and the immune system.

Production of eicosanoid hormones is shown in [Figure 85.5](#). The parent compounds are the polyunsaturated fatty acids, DGLA, AA, and EPA, and the pathway utilizes the same enzyme for all three series of products. The concentrations of the three fatty acids present in the phospholipid of the cell membranes where the hormones are produced determine which product will predominate. There is direct substrate competition for the active site on the enzyme as depicted in [Figure 85.5](#). In a similar manner, the lipoxygenase enzyme initiates the sequence of reactions leading to leukotriene formation. The 2-series that is derived from AA is by far the most pro-inflammatory. The effects of GLA and DGLA on rheumatoid arthritis and many other inflammatory diseases are mediated via this mechanism. Since dietary intake is a

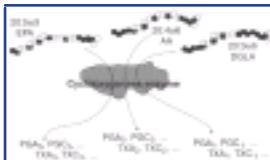

Figure 85-5 Fatty acid relationships to eicosanoid formation.

primary determinant of the fatty acids that go into this pathway, there is a direct link between the balance of specific fats in the diet and inflammatory responses and other local control processes. Long-term health maintenance is highly dependent on proper balance of dietary fatty acids.

Many people do not eat the fresh nuts, seeds, whole grain breads and seafood products that are the rich sources of essential fatty acids. The same individuals are likely to have high intakes of saturated and *trans* fatty acids. The recognition of vast health effects has led to the recent surge of interest in fatty acids. It is no longer adequate (or even correct) simply to recommend the replacement of fats high in saturated fatty acids with

those that are high in unsaturated fatty acids. Balanced intake of the unsaturated fatty acids, not just a high PUFA/saturated ratio, is required for optimal control of almost every tissue in the body.^[10]

While the actions needed to correct fatty acid abnormalities are quite straightforward, the subject of clinical applications of fatty acid profiling is complex. Those who seek to understand the underlying biochemical and physiological concepts are generally in need of good reference sources. Some that we have found helpful are listed in the “Further reading” section.

CONTROL OF FATTY ACID SUPPLY AND DISTRIBUTION

Fatty acids are present in the diet in the form of triglycerides in solid fats or liquid oils and as phosphatides in cell membranes of whole foods ([Table 85.3](#)). They are rarely present in nature as free fatty acids.

Digestion and assimilation

Fats are first digested by the action of bile acids and then pass into intestinal epithelial cells along with cholesterol where they are associated with proteins, becoming particles called chylomicrons. These are passed into the lymphatic system to flow directly through the heart into systemic circulation. Enzymes in capillary cell walls

TABLE 85-3 -- Dietary sources of even-numbered medium- and long-chain saturated fatty acids

| Cs | Name | Source |
|----|---------------------|---|
| 10 | Capric acid (C10:O) | Most plants and butter in small amounts |
| 12 | Lauric (C12:O) | Palm kernel, coconut, laurels |
| 14 | Myristic (C14:O) | Nutmeg, palm kernel, coconut, myrtle |
| 16 | Palmitic (C16:O) | Common in all animal and plant fats |
| 18 | Stearic (C18:O) | Common in all animal and plant fats |
| 20 | Arachidic (C20:O) | Peanut (arachis) oil |
| 22 | Behenic (C22:O) | Seeds |
| 24 | Lignoceric (C24:O) | Cerebrosides, peanut oil |

cause the transfer of fatty acids from the chylomicrons, which become greatly reduced in size and return for uptake by the liver as chylomicron remnants. By this process, the fatty acids in foods become directly incorporated into the membranes of all tissues.

Synthesis and distribution

Because of the critical life-supporting functions in forming cell membranes and

supplying energy sources and hormone controls, there are several mechanisms for assuring that the supply of fatty acids will be continuous, even during short intervals between meals (see [Fig. 85.6](#)). In the fasting state, fatty acids are either produced from carbohydrate or protein or mobilized from adipose stores. The liver handles the role of supply depot by forming another class of lipid-protein particles called very low density lipoproteins (VLDL). These particles deliver fatty acids and cholesterol to the tissues by mechanisms similar to that for chylomicrons, except that the remnant LDL particles are taken up in total by binding to receptor sites on cell surfaces. By ensuring a constant supply of fatty acids, the body controls one of the most critical materials for carrying out the various life-sustaining functions of growth and repair.

Effect of low-fat diets

An individual on a low-fat, high-carbohydrate diet utilizes the fatty acid synthetic pathway extensively. As shown in [Figure 85.7](#) , this pathway requires citrate to leave the mitochondria to generate malonyl-CoA. The resultant high concentrations of malonyl-CoA inhibits the activity of the enzyme that is the gateway to fatty acid

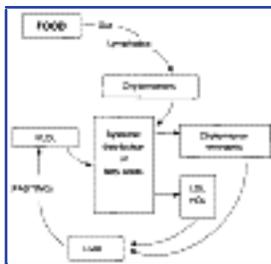

Figure 85-6 Mechanisms for continuous supply of fatty acids to all tissues.

729

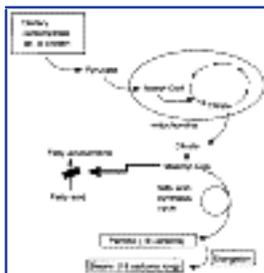

Figure 85-7 Carbohydrate conversion to fat; inhibition of fatty acid oxidation.

oxidation. It is for this reason that very low fat diets do not result in weight loss nearly as fast as one might expect. The burning of excess fat is actually inhibited by the high carbohydrate intake. In individuals with low body fat and good lean mass, high carbohydrate intake spares the use of fatty acids, and the medium-chain fatty acids that are otherwise so quickly used for energy may accumulate above normal in membranes.

Dramatically increased fatty acid oxidation occurs in starvation and diabetes mellitus with production of large amounts of ketone bodies that accumulate to give the ketoacidotic condition. Carnitine deficiency results in impairment of fatty acid oxidation and failure of gluconeogenesis, leading to hypoglycemia.

FATTY ACIDS AND HUMAN DISEASES

Quantification of the approximately 30 fatty acids that are present in human tissues is now routinely available. Both deficiencies and excesses of individual fatty acids lead to metabolic problems. Some specific clinical associations are discussed below (see [Ch. 13](#) for additional discussion of specific fatty acid imbalances.) [Table 85.4](#) lists typical signs and symptoms of fatty acid abnormalities while [Table 85.5](#) lists the better documented clinical applications of supplemental fatty acids.

Developmental disorders

Children with attention-deficit hyperactivity disorder have lower concentrations of key fatty acids in plasma and in red blood cells.^[11] Pre-term infants deprived of essential fatty acids during late pregnancy are likely to have failures of normal development, especially the visual system, unless 3 fatty acids are supplemented.^[12]

TABLE 85-4 -- Signs and symptoms associated with fatty acid abnormalities

| Signs and symptoms | Fatty acid association | Action |
|---|---|---|
| Emaciation, weakness, disorientation | Caloric deprivation | Add balanced of fat, protein, and CHO |
| Reduced growth, renal dysplasia, reproductive deficiency, scaly skin | Classic essential fatty acid deficiency | Add good quality fats and oils |
| Eczema-like skin eruptions, loss of hair, liver degeneration, behavioral disturbances, kidney degeneration, increased thirst, frequent infections, poor wound healing, sterility (m) or miscarriage (f), arthralgia, cardiovascular disease, growth retardation | Linoleic acid insufficiency | Add corn or safflower oils |
| Growth retardation, weakness, impairment of vision, learning disability, poor coordination, tingling in arms/legs, behavioral changes, mental disturbances, low metabolic rate, high blood pressure, immune dysfunction | Alpha or gamma linolenic acid insufficiency | Add flax, primrose, borage, or black currant oils |

| | | |
|---|--|---------------------------------------|
| Depression, anxiety, learning behavioral and visual development | Long-chain PUFA-dependent neuromembrane function | Add fish oils |
| | | Avoid hydrogenated oils |
| Cardiovascular disease risk | Prostanoid balance | Add ?3 PUFAs |
| Cancer | Low stearic to oleic ratio | Use ?6 PUFAs with caution |
| | Prostanoid imbalance | |
| Rheumatoid arthritis | Low GLA and DGLA | Add primrose oil |
| Deficiency of vitamin B ₁₂ and/or carnitine | Increased odd numbered FAs | Add B ₁₂ and/or carnitine |
| Myelinated nerve degeneration | Increased very long-chain FAs | Add high-erucate rape or mustard oils |
| Fatty liver | Saturated and ?9 accumulation in liver | Restrict alcohol |
| | | Add lecithin |
| | | Increase Methionine |
| Accelerated aging | High PUFA intake without increased antioxidants | Add vitamins E and C, Se, Mn, and Zn |

TABLE 85-5 -- Clinical utilization of GLA and ALA (x, moderate; xx, strong clinical response)

| Application | GLA | ALA |
|---|------------|------------|
| Lower blood pressure, lower blood cholesterol, and lower risk of stroke and heart attack | x | xx |
| Normalize fat metabolism in diabetes and decrease the amount of insulin required by diabetics | x | x |
| Prevent liver damage due to alcoholism and decrease withdrawal symptoms after discontinuing the habitual use of alcohol | x | x |
| Provide adjunctive treatment for schizophrenics | x | xx |

| | | |
|--|----|----|
| Cause weight loss by increasing metabolic rate and fat burn-off | x | xx |
| Relieve premenstrual breast pain (mastalgia) and premenstrual syndrome of bloating, irritability, depression and aggressive behavior | xx | x |
| Prevent drying and atrophy of tear and salivary glands (Sjögren's syndrome) | x | |
| Prevent arthritis in animals | x | x |
| Improve the condition of hair, nails, and skin | x | xx |
| Improve certain kinds of eczema | x | x |
| Slow down or stop deterioration in multiple sclerosis | x | x |
| Help treat diabetic neuropathy in type II diabetes | x | x |
| Kill cancer cells in tissue culture without harming normal cells | x | xx |

Heart disease

Higher palmitic and lower ω 3 fatty acids in serum are correlated with higher incidence of coronary heart disease in middle-aged men at high risk for cardiovascular disease.^[13] Improvements in plasma fatty acids and vitamins E and C were the only factors found to be related to improvements in life expectancy and 70% lowering of heart disease in a study population.^[14]

Cancer

Tumor tissue and virus-transformed cells have a higher content of unsaturated fatty acids, especially oleic acid which increases relative to the amount of stearic acid. Such shifts increase the metabolic rates of many lipid-dependent enzymes and are associated with a higher capacity for cell division.^[15] Changes in dietary fatty acid intake cause alterations in immune response, including antitumor activity.^[16]

Neurological disorders

Adrenal leukodystrophy and related conditions are associated with the accumulation in nerve sheath membranes of fatty acids more than 20 carbons long. This situation may be made worse by the lack of sufficient long-chain polyunsaturated fatty acids. The indicator for this situation is the sum of the 22–26 carbon length even-numbered fatty acids.

SUMMARY

Many health problems are related to inappropriate fat intake and suboptimal fatty acid

composition of the body. The therapeutic value of oils rich in specific fatty acids is being reported in the research literature with increasing frequency for a wide range of diseases. The availability of laboratory methodologies for accurate evaluation of fatty acid status now allows for sophisticated clinical manipulation of these important nutrients.

Chapter 86 - Fish oils

Alexander G. Schauss PhD

INTRODUCTION

A significant body of evidence now shows that consumption of fish oil may be beneficial to health.^{[1] [2] [3] [4] [5]} Numerous studies have reported an inverse association between fish oil consumption, risk of cardiovascular disease, and various forms of cancer. Fish oil supplements have also been reported to ameliorate the signs and symptoms of other diseases, such as psoriasis and rheumatoid arthritis, and to play a role in the management of diabetes.

The unique health benefits of fish oil were first investigated in Greenland Eskimos who paradoxically consumed a very rich diet that was high in saturated animal fat from seals, whales, and fish, yet had very low rates of coronary heart disease. Later studies discovered that the Greenland Eskimos' diet contained large quantities of omega-3 fatty acids.

DESCRIPTION

Marine life is generally rich in the omega-3 fatty acids (also referred to as n-3 fatty acids) eicosapentaenoic acid (EPA) and docosahexanoic acid (DHA). These very long-chained and highly polyunsaturated fatty acids (PUFA) contain, respectively, 20 and 22 carbons and 5 and 6 double bonds, and are also referred to as 20:5n-3 PUFA and 22:6n-3 PUFA. The 20:5n-3 PUFAs and 22:6n-3 PUFAs are abundant in shellfish, sea mammals, and fish. EPA and DHA are very low or absent in domesticated land animals.

The source of EPA and DHA found in most marine foodstuffs are phytoplankton. The phytoplankton, naturally rich in EPA and DHA, serve as food for a variety of sea creatures. Fish oil from herring, cod liver, salmon, mackerel, and sardines is rich in omega-3 fatty acids, while containing varying levels of EPA and DHA. [Table 86.1](#) lists

the relative concentration of fatty acids in some common fish species.

The habitat in which fish grow has a major impact on their fatty acid composition.^[7] In the wild, fish consume

TABLE 86-1 -- Relative concentration of fatty acids in fish oils^[6]

| Oil | Cholesterol (mg/100 g) | Unsaturated | | n-3 PUFAs | | |
|-----------|------------------------|-------------|-----------|-----------|----------|----------|
| | | Mono- (%) | Poly- (%) | 18:3 (%) | 20:5 (%) | 22:6 (%) |
| Cod liver | 570 | 18 | 51 | 0.7 | 9.0 | 9.5 |
| Herring | 760 | 19 | 60 | 0.6 | 7.1 | 4.3 |
| Menhaden | 600 | 34 | 32 | 1.0 | 12.7 | 8.0 |
| Salmon | 485 | 24 | 40 | 1.0 | 8.0 | 11.0 |
| Pilchard | – | 25 | 29 | Trace | 17.0 | 9.0 |
| Mackerel | – | 21 | 43 | Trace | 11.0 | 11.0 |
| Anchovy | – | 28 | 29 | Trace | 17.0 | 9.0 |
| Sardine | – | 24 | 34 | Trace | 15.0 | 10.0 |

food sources which contain higher levels of alpha-linolenic acid (18:3n-3). This is an important point given the increasing harvesting of fish reared in fish pens. In the natural ocean environment, phytoplankton, which are high in EPA and DHA, form the basis of the food chain. In contrast, commercial fish foods contain less DHA and EPA and hence result in lower concentrations of omega-3 fatty acids. Studies have shown that wild fish (hunted fish) have higher concentrations of omega-3 fatty acids than pond-reared/cultured fish fed commercial feedstuffs devoid in EPA/DHA.^[8]

Another dietary omega 3 fatty acid is alpha-linolenic acid (LNA), an 18-carbon-chain fatty acid with three double bonds (18:3n-3 PUFA). Foods such as tofu, canola oil, black currant oil, flaxseed oil (the best non-fish source), nuts, and soybeans are important sources of LNA for those not eating seafood. However, soy-derived oils and foods and most nuts also contain large amounts of omega-6 fatty acids which will neutralize many of the therapeutic benefits of the omega-3 fatty acids.

Dietary requirement

The first suspected case of omega-3 fatty acid deficiency in humans was reported in 1988.^[9] The patient was a 7-year-old girl with retarded growth who had been fed solely by gastric tube since 3 years of age. She began to experience normal growth after

taking cod liver oil and linseed oil supplements.

Omega-3 fatty acid requirements in humans remain controversial. Some investigators contend that as little as one meal of fish a week is sufficient, while others suggest that a much higher intake level is necessary for individuals to fully profit from its multitudinous benefits.

Since the concentration of EPA and DHA in fish can vary depending on its growth environment, fish oil supplements offer a viable and reliable source of fish oil.

Fish oil supplements can supply high concentrations of eicosapentaenoic acid and docosahexanoic acid. The most popular combination of EPA- and DHA-rich fish oil is the brand "MaxEPA". MaxEPA (18% EPA and 12% DHA) and other fish oil supplements (e.g. blue-fin tuna oil which contains 7% EPA and 25% DHA) are derived from cold-water ocean fish. However, this does not imply that the beneficial fish are always pelagic (i.e. from deep ocean waters) since some freshwater fish contain higher levels of EPA and DHA than some salt-water species.

Most fish oil capsules contain between 300 and 500 mg of omega-3 fish oil per 1 g capsule. Patients using fish oil at the therapeutic levels discussed in this chapter may require between 15 and 30 capsules to derive the described benefits. At 9 calories/g of oil, this can represent a significant increase in caloric intake.

EPA/DHA-rich fish oil capsules should be kept in capsules (such as soft gelatin) capable of providing an oxygen barrier, otherwise toxic lipid peroxides (e.g. malondialdehyde) may form. Encapsulated liquid sources generally do not have this protection unless they contain antioxidants. Emulsified fish oils are preferred as they are better absorbed in humans.

Encapsulated products typically contain fish oil, not fish liver oil. This distinction is important since fish liver oil contains the fat-soluble vitamins A and D, which if taken in excessive amounts have the potential to cause toxicity. The lowest consistently reported daily intakes associated with chronic toxicity in adults are 50,000 IU for vitamin A and 10,000 IU for vitamin D (see [Ch. 108](#)). However, there is mounting evidence that vitamin D from sunlight and fish oil may reduce the incidence of certain cancers, such as breast cancer. Hence, some vitamin D residuals in the fish oil may actually increase its protective value against cancer as well as CHD.

Explaining inconsistent results of fish oil supplementation trials

There are many papers in the fish oil literature whose results are equivocal or contradictory. Much of these differences in outcomes can be explained by the use of olive oil as a placebo or the lack of control for saturated or omega-6 PUFA dietary intake.

Olive oil cannot be considered an inert placebo in trials that investigate effects on platelet function or CHD risk. Several studies have shown that olive oil supplementation

has similar inhibitory effects on various aspects of platelet function, including decreased platelet aggregation and thromboxane TXA_2 release, increased platelet membrane oleic acid content, and decreased platelet membrane arachidonic acid content.^[11] ^[12] Further, an excess of oleic acid impairs incorporation of arachidonic acid into platelet phospholipids.

Another possible complicating factor is the squalene found in olive oil and some deep-water fishes, but not in other vegetable oils.^[13] Other problems include the differing ratios of fatty acids, the position of the fatty

acids on the glycerol backbone, and the susceptibility to peroxidation of the various fish oil preparations.^[14]

PHARMACOLOGY

In general, the effects of supplemental and dietary unsaturated fatty acids appear to be mediated through changes in serum lipids, altered ratios of prostaglandins, decreased platelet aggregation, and modification of cell membrane activity.^[14]

Fish oils appear to reduce undesirable circulating fats and decrease the production of the prothrombotic substance thromboxane (TXA_2) by occupying TXA_2 receptors and enhancing the production of the platelet antiaggregatory substance prostacyclin. These actions play an important role in inflammation, atherogenesis, thrombosis, and CHD.

Through the vasodilatory effects of prostacyclin PGI_3 , fish oils may improve peripheral circulation, thereby facilitating VLDL cholesterol removal. This may be accomplished by altering membrane fluidity in a specific manner, thus affecting the activity of membrane-bound enzymes and resulting in changes in receptor activity, specificity, and signal transduction.

Evidence also suggests that fish oils decrease hepatic synthesis of fatty acids and triglycerides, and reduce secretion of VLDL cholesterol, while displacing arachidonic acid from tissue phospholipids. This results in omega-3 EFA levels that inhibit thromboxane synthesis.

Researchers have noted that fish oil effects are selective. EPA and DHA not only displace arachidonic acid from phospholipid pools and inhibit cyclooxygenase, but EPA also becomes a preferred substrate for cyclooxygenase when peroxide tone is high. This results in decreased production of the vasoactive and aggregatory prostacyclin PGI_2 and increased production of PGI_3 which has more potent anti-aggregatory effects. According to some researchers, increased bleeding time is due to either less thromboxane (TXA_2) or higher prostacyclin I_3 levels,^[15] although there are those who

contend that EPA conversion to PGI₃ is the primary cause.^[16] Many researchers believe this change is one of the primary factors that decrease the risk of atherosclerosis and thrombosis.^{[17] [18] [19] [20] [21] [22] [23]} These findings may explain some of the epidemiological evidence of decreased coronary artery disease and prolonged bleeding time seen in some Eskimos and in those Japanese found eating a diet rich in fish.^[24]

Fish oils rich in EPA and DHA have also been found to suppress production of inflammatory mediators found in patients with rheumatoid arthritis and psoriasis. The anti-inflammatory effect of the omega-3 fatty acids is probably due to reduced production of leukotrienes, interleukin-2, and tumor necrosis factor, all principal mediators of inflammation.

In relation to CAD, ingestion of fish oil and its effect on platelets, erythrocytes, neutrophils, monocytes, and liver cells are considered to be important in explaining its benefits. The increased concentrations of EPA and DHA from the ingestion of fish oil has been shown to:

- decrease production of prostaglandin E₂ (PGE₂) metabolites
- decrease production of thromboxane A₂ (an active vasoconstrictor and platelet aggregator)
- increase prostacyclin PGI₃ (an active vasodilator and inhibitor of platelet aggregation)
- increase production of leukotriene B₅ (a weak inducer of inflammation; weak chemotactic agent)
- decrease production of leukotriene B₄ (a weak inducer of inflammation; inducer of leukocyte adherence and chemotaxis).

CLINICAL APPLICATIONS

Cardiovascular disease

The EPA and DHA in fish oil inhibit the development of atherosclerosis which can increase the risk of primary cardiac arrest.^[25] Evidence from large animal studies indicates that fish oil prevents atherosclerosis by mechanisms other than simply lowering cholesterol, including:

- stimulation of endothelial production of nitric acid
- decrease of cytokine and interleukin 1 production
- inhibition of monocyte migration into the plaque.

These three events can, when uncontrolled, contribute to the characteristic yellowish plaques (atheromas) that contain the combination of cholesterol, lipophages, and lipid material seen in the intima and inner media of large and medium-sized arteries found in atherosclerosis. Hence, the demonstrated ability of fish oil to control all three, combined with its ability to lower VLDL and elevated triacylglycerols, can be a useful approach in

the prevention of ventricular fibrillation and sudden death.

That fish oil can perform this favorable reduction in risk of sudden death, not shown to be possible by the consumption of linolenic acid or linoleic acid from vegetable oils, has been shown in several double-blind, placebo-controlled, randomized trials conducted in human subjects, especially when compared with vegetable oils.^[22]

In addition, diets rich in omega-3 fatty acids from fish oil lower triglyceride levels, especially in those with severe hypertriglyceridemia, for whom attempts to correct the cause through exercise, the drug gemfibrozil or other dietary modifications have proven inadequate. This benefit is not seen with plant source oils containing land-based alpha-linolenic fatty acid-rich polyunsaturated fat sources or the reduction of saturated animal fatty acids.^[23]

The therapeutic use of fish oil supplements is also essential in patients with type V hyperlipidemia. At a 1994 scientific meeting on the role of fish oil in cardiovascular

health, the following favorable mechanisms of action of omega-3 fatty acids in humans were reported:^[21]

- inhibition of very-low-density lipoprotein (VLDL) triglyceride synthesis
- decreased apoprotein B synthesis
- enhancement of VLDL turnover with an increased fractional catabolic rate of VLDL
- depression of LDL synthesis
- reduction of postprandial lipidemia.

The incidence of diabetes is also low in Greenland Eskimos. Studies have shown that the type of fat consumed by humans may have a profound effect on insulin action in tissues. Patients with insulin-dependent diabetes mellitus (IDDM) are prone to disorders of lipoprotein and lipid metabolism, especially hyperlipidemias. The combination of low-density lipoprotein (LDL) cholesterol and elevated plasma cholesterol (hypertriacylglyceridemia) is associated with an increased risk of coronary heart disease. This combination is a major contributor to the morbidity and mortality associated with non-insulin-dependent diabetic (NIDDM) patients.^[26] In individuals with NIDDM, fish oil ingestion has been demonstrated to favorably alter arterial wall compliance without adversely affecting cholesterol levels, blood pressure, or fasting blood sugar levels, thereby contributing to a reduced risk of vascular complications seen in IDDM and NIDDM patients.^[27]

All of the above benefits of fish oil may not be conferred by only eating fish. Favorable therapeutic and preventive effects may require between 5 and 20 g/day of LNA and fish oil, which is unlikely in contemporary diets in industrialized societies – hence, the use of fish oil supplements.

The prevention of thrombosis by fish oil consumption is suggested by a number of studies, particularly in patients receiving coronary bypass surgery. In a randomized controlled trial of bypass patients who received warfarin or aspirin as anticoagulants, those subjects who also received fish oil had significantly less vein graft occlusions.^[28]

Despite all of these findings as they relate to coronary heart disease (CHD), a 1997 American Heart Association (AHA) science advisory report on fish oil consumption states: “There is no convincing role for fish oil supplements in the prevention of CHD.”^[29]

The AHA report does accept mounting evidence that sudden cardiac deaths may be prevented, although “further studies are needed to explore the potential of fish oil in the prevention of sudden cardiac death”. Apparently, the American Heart Association’s scientists require “compelling evidence” before they would recommend general usage of fish oil supplements to reduce CHD or sudden death. This, despite the conclusion of one of the studies they cite which finds that fish oils reduce myriad potential atherogenic processes associated with atherosclerosis, CHD, and sudden cardiac-related deaths.^[30]

Researchers have focused more on fish oil supplements than on fish consumption as dietary surveys have found that less than half of the Australian, American, and Canadian populations regularly eat fish. In addition, some popular species of fish that are consumed by humans contain low levels of the omega-3 essential fatty acids.

Elevated serum lipids

The most consistent effect of fish oils on serum lipids is a reduction in total triglycerides and VLDL cholesterol, especially in patients with severe hypertriglyceridemia. In general, dietary fish oils appear to both reduce undesirable serum circulating fats and decrease the production of the prothrombotic thromboxanes. In most studies, fish oil supplementation causes a significant reduction of VLDL cholesterol, plasma triglycerides, plasma cholesterol, and LDL cholesterol. In hypertriglyceridemic patients, fish oil supplementation typically results in a significant decline in VLDL cholesterol levels, because large decreases in triglyceride levels lead to a decrease in VLDLs.^{[5] [22] [31] [32] [33]}

There are some studies that do not find decreases of total cholesterol or LDL cholesterol following fish oil supplementation.^{[34] [35] [36] [37]} However, these equivocal studies used olive oil as a placebo, which, as discussed above, is not appropriate.

For patients with elevated serum cholesterol (7.75 mmol/L) or triglycerides (5.64 mmol/L), there is sufficient evidence to consider fish oil supplementation in the range of 5–10 g/day.^[38] In one study of 365 patients, supplementation with 10 ml/day (9.2 g) of MaxEPA resulted in significant reductions in triglyceride levels which were maintained over a period of 4 years.^[39] Continuing reductions were observed in persons remaining in the study more than 4 years. The authors concluded: “For triglycerides to remain depressed it seemed necessary to maintain a daily intake of 9.2 g MaxEPA.”

In a Canadian study, triglyceride levels decreased 31% in 9 days following fish oil

supplementation.^[40] However, total and HDL cholesterol levels did not change. Nine days after supplementation ceased, triglyceride levels showed a trend of returning to baseline.

As total cholesterol and LDL cholesterol levels are predictors of death from cardiovascular and coronary heart disease, their control is crucial. Almost all epidemiologic studies show that populations eating fish have a reduced death rate from CHD.

By 1990, 22 primary and secondary prevention trials demonstrated that lowering serum total cholesterol and LDL cholesterol through either diet or drugs reduced the incidence of coronary heart disease among survivors of myocardial infarction. A 10 year prospective study of male mortality rates due to cardiovascular disease

found that LDL cholesterol, HDL cholesterol, and total cholesterol levels are the most predictive indices of subsequent mortality from cardiovascular disease among men with and without pre-existing cardiovascular disease.^[41]

Support for fish oil intake in the reduction of CHD comes primarily from epidemiological studies^{[1] [2] [3]} and clinical and experimental studies in animals and humans.^{[5] [22] [42] [43] [44] [45] [46] [47] [48]} A 20 year prospective study conducted in the Netherlands found that consuming as little as 35 g/day of fish (0.5 pounds/week) might be of benefit in preventing, and reducing mortality from, coronary heart disease.^[49] In contrast, two epidemiological studies found no relationship between fish consumption and cardiovascular mortality.^{[50] [51]}

The effect of fish oil consumption on lowering serum lipids may account for the lower mortality rate due to cardiovascular disease found in coastal Alaskan natives, who, compared with mainland Americans, eat a diet rich in fish and other sea creatures. Autopsies on 339 Alaskan natives found that only 10.3% died of cardiovascular causes, compared with 50% of all deaths among those subjects who lived on the American mainland.^[52]

The possibility of fewer fatal arrhythmias due to high fish consumption has also been proposed to explain the lower death rate of native Alaskans.^[53] Two studies involving rats have shown that ingestion of either as much as 30% or as low as 0.4% of energy in the form of omega-3 fatty acids from fish decreased the incidence of ventricular fibrillation.^{[54] [55]} The anti-arrhythmic aspects of PUFAs are supported by a number of clinical and experimental studies in animals and humans.^{[42] [43] [44] [45] [46]} Some investigators conclude that fish oil is more effective at reducing ventricular arrhythmias than pharmacologic agents in the prevention and management of cardiovascular disease.^[47]

Recent evidence also suggests fish oil may prevent cardiovascular in Rhesus monkeys

and hyperlipidemic pigs despite lack of improvement in serum cholesterol levels.^[56] ^[57] This retardation in the initiation and progression of atherogenesis may be due to fish oil's depression of inflammatory eicosanoid metabolism in platelets, macrophages, and monocytes.

The therapeutic dosage of fish oil for the treatment of cardiovascular disease should be 5 g/day or more.^[23] One researcher has suggested that for both prophylactic and therapeutic applications, the most efficacious use of fish oil would be to concomitantly lower total fat intake to no more than 30% of calories and saturated fatty acids to no more than 30% of total fat, while limiting omega-6 fatty acids (vegetable oils) to a maximum of 10% of total fat intake.^[23]

Hypertension

There is some evidence from placebo-controlled studies that fish oil reduces blood pressure in a dose–response fashion, especially in patients with hypercholesterolemia and hypertension, but not in subjects with normal blood pressure.^[58]

Fish oil seems to have hypotensive effects, ranging from limited (at dosages of 5 g/day or less) to substantial (at larger dosages),^[48] ^[59] ^[60] ^[61] ^[62] ^[63] ^[64] ^[65] ^[66] ^[67] although there is some conflicting evidence.^[68] It has been proposed that fish oil depresses vascular response to the hormones involved in hypertension.^[38] Another suggestion is that fish oil acts by increasing vasodilatory prostaglandins PGI₁ and PGI₃, and that this increase accounts for observed reductions in blood pressure.^[38]

To test this hypothesis, one study examined the effect of fish oil on blood pressure in men with mild, essential hypertension.^[69] One group received 10 ml of fish oil (3 g of omega-3 fatty acids), a second group received 50 ml (9 g of EPA and 6 g of DHA), a third group received 50 ml of safflower oil (39 g of omega-6 fatty acids), and a fourth group received 50 ml of a mixture of coconut, olive, and safflower oils. The latter group represented the approximate amount and ratio of fatty acids consumed in the average American diet (39% saturated fat, 46% monounsaturated fat, and 15% polyunsaturated fat). The group receiving the highest dose of fish oil (50 ml) had an average reduction of 6.5 mmHg in systolic pressure and 4.4 mmHg in diastolic pressure. None of the other groups, including the low fish oil-supplemented group, demonstrated blood pressure reductions in the aggregate. The study did not find the expected association between increased production of PGI₁ and PGI₃ and sustained reduction in blood pressure. This suggests that vasodilatory prostaglandins are probably not the primary mediators of blood pressure reduction by fish oil consumption, although they may play a role.

Another proposed mechanism is that fish oils may facilitate excretion of sodium and fluid by the kidneys. This is supported by a reported but not published double-blind cross-over study in which researchers placed healthy, non-hypertensive men and women on a diet supplemented with approximately 1 g/day of PUFAs for 28 days.^[70] Each participant received capsules with either fish oil or safflower oil. The fish oil dose was similar to the amount consumed in a single daily serving of tuna, lake trout, or salmon. After 2 weeks, the subjects crossed over to the other supplement. The study

found an average 2–3 mmHg drop in both diastolic and systolic blood pressure in those who received fish oil supplements. The researchers also found that fish oil increased urine output by approximately 10%, performing much like a low-sodium diet. This resulted in a reduction in fluid volume. Unlike diuretics, the fish oil supplementation did not increase potassium excretion.

Angina pectoris

Significant rheological improvements in patients with

738

stable angina pectoris may occur following daily fish oil supplementation with 2.8 g of EPA and 1.8 g of DHA (15 capsules of MaxEPA).^[71] In a double-blind, placebo-controlled study, fish oil supplementation resulted in increased red cell deformability, reduced whole blood viscosity, and prolonged bleeding time compared with olive oil supplementation. The frequency of angina attacks decreased in both groups. However, neither type of oil affected exercise capacity or hemodynamic response to exercise.

Myocardial infarction

Several studies of rodents have shown that dietary fats modulate the electrical stability of the myocardium. The appropriate fatty acids can reduce the vulnerability to arrhythmia during myocardial ischemia.^{[54] [55] [72]} Raising the omega-3 fatty acids to higher levels in the myocardium may also prevent post-infarction ventricular fibrillation.^{[45] [73] [74]}

One study evaluated the effect of dietary intervention in 2,033 men recovering from myocardial infarction.^[75] Patients were randomly allocated to receive one of four types of dietary advice:

- lowered intake of dietary fat
- consumption of at least two portions of fatty fish (200–400 g) a day
- supplementation with three capsules (1.5 g) of MaxEPA a day
- increased dietary fiber intake.

At the end of 2 years, the group given fish were found to have increased their EPA intake to four times that of other subjects. This group also experienced significantly lower mortality. The fat advice and fiber advice produced no differences in mortality. Although the rate of recurrence of heart attack was similar in all groups, the fish and fish oil group had a 29% reduction in risk of death compared with the other groups. These findings are in direct conflict with an earlier study showing no such benefits.^[76] However, it may be significant that the earlier study was conducted over the short period of 6

weeks.

Even in patients with no apparent clinical evidence of arterial disease, fish consumption has been shown to improve arterial wall function. One study found that, in both healthy and NIDDM patients, those who ate fish showed significantly better compliance of their left subclavian artery and femoral arteries.^[77]

Immune function

Research in both animals and humans has not yet determined whether fish oil supplementation suppresses or enhances immune function. For example, recent laboratory animal experiments show that supplementation with GLA or fish oil results in marked changes in the structure and function of leukocyte membranes consistent with improved immune response.^[78] In addition, animal studies have shown enhancement of the metabolic processes associated with resistance to infection and such diseases as cancer.^[79] However, long-term supplementation with EPA results in pronounced inhibition of the oxidative processes necessary for the immune response.

In humans, an omega-3 enriched, low-fat, lowcholesterol diet suppresses immune function, possibly increasing susceptibility to infection. For example, increasing the typical American diet content of omega-3 fatty acid intake from 1 to 2.5% over a 6 week period results in decreased PGE₂ levels, helper cell activity, and other indices of immune function.^[78] More research is needed to clarify the differences in animal and human responses to fish oils.

Pregnancy and lactation

During pregnancy, growth of new tissue raises the requirement for EFAs, as mobilization moves polyunsaturated fatty acids from maternal tissue stores to the fetus. A study of 19 normal pregnant women found an increased requirement for omega-3 EFA intake during pregnancy, lactation, and infancy.^[80] The authors stated that because omega-3 EFA decreases in the maternal circulation during pregnancy and remains low for at least 6 weeks after pregnancy, "it may be reasonable to increase the omega-3 PUFA in the diet before, during, and after pregnancy". The authors further suggest that "dietary supplementation may be indicated", since maternal levels of eicosapentaenoic acid were 42% of normal value. The study concludes:

It seems reasonable to suggest that 18:3 omega-3 intake be increased during pregnancy, lactation, and infancy, when requirements for omega-3 PUFA are highest, during the development of the nervous system, which is rich in lipids containing high proportions of omega-3 PUFA. The mental apparatus of the coming generation is developed in utero, and the time to begin supplementation is before conception. A normal brain cannot be made without an adequate supply of omega-3 PUFA, and there may be no later opportunity to repair the effects of an omega-3 fatty acid deficiency once the nervous system is formed.

Supplementation with either ALA or EPA would restore EFA levels in such individuals.

Nephrotic syndrome

Both hypertriglyceridemia and hypercholesterolemia are common in patients with nephrotic syndrome. This association results in an increased risk of coronary heart disease. Fish oils have been found to lower serum triglycerides in patients with nephrotic syndrome and may therefore be of clinical benefit.^[40]

Autoimmune diseases

Fish oils may play a role in the treatment of autoimmune disease (e.g. lupus erythematosus, dermatomyositis, autoimmune nephritis, and multiple sclerosis)^{[81] [82] [83]} and inflammatory disorders (e.g. rheumatoid arthritis,^[84] psoriasis,^[85] and atopic dermatitis^[1]). At this time, no controlled studies have been completed using fish oil in the treatment of autoimmune diseases in humans. The evidence of fish oil's possible benefits is derived from animal studies using inbred mice strains.^[38] Anecdotal reports by lupus patients suggest some benefit.

Rheumatoid arthritis

Rheumatoid arthritis is uncommon among Eskimos. There is mounting evidence that omega-3 fatty acids found in fish oil may beneficially influence the course of treatment in patients with rheumatoid arthritis due to their inhibition of inflammation upon incorporation into cell membranes.^[86]

A population-based, case-controlled study in women found a decreased risk of rheumatoid arthritis in those who consumed the most fish.^[84] A double-blind, placebo-controlled, study of rheumatoid arthritis patients given 1.8 g/day of fish oil showed less morning stiffness and tender joints. This particular study led to media coverage of the possible benefits of fish oil for this condition. However, analysis of the study showed that the possible benefits of the fish oil could have been due to the unusually rapid deterioration of the control group (placebo) rather than from any improvement by the fish oil group.^[53]

Another double-blind, placebo-controlled, study of patients with rheumatoid arthritis found significant improvements in several clinical indices during the 12 weeks of fish oil supplementation.^[87] Another study of patients with either rheumatoid arthritis or psoriasis also demonstrated improvement.^[25] Patients taking 18 g of fish oil (containing 153 mg EPA and 103 mg DHA) for 6 weeks reported significant improvement in symptoms. Samples of peripheral blood mononuclear cells from these patients showed suppressed synthesis of two principal mediators of inflammation, interleukin-1, and tumor necrosis

factor, as compared with patients receiving placebo. Of particular interest was the finding that the anti-inflammatory effect of the fish oils continued for up to 4 weeks after cessation of supplementation.

In another randomized double-blind placebo-controlled study conducted over a 24 week period, 49 patients with rheumatoid arthritis experienced significant clinical benefit, particularly in tender joints, from supplementation of either a low dose of 27 mg/kg EPA and 18 mg/kg DHA, or a high dose of 54 mg/kg EPA and 36 mg/kg DHA. Interleukin-1 levels decreased 54.7% in the high-dose group and 40.6% in the low-dose group.^[66]

Psoriasis

Patients with psoriasis (vulgaris) have been successfully treated with a low-fat diet supplemented with fish oil.^[88] An impressive 77% (23% did not respond) of the patients reported either excellent, moderate, or mild improvement. It was interesting to note that a number of patients did not show improvement until at least 4 months of supplementation. This may indicate the importance of allowing adequate time for clinical improvement after initiating fish oil therapy.

Fish oils presumably improve the condition by decreasing the levels of inflammatory leukotriene compounds, especially leukotriene B₄, a lipoxygenation product of arachidonic acid. The EPA in fish oil replaces the arachidonic acid in phospholipids, leading to the formation of leukotriene B₅ rather than B₄, resulting in a much weaker (at least 30 times less) inflammatory response.^[89] This effect has been demonstrated in neutrophils isolated from the peripheral blood of patients given fish oil to treat their psoriasis.^[88] Patients who showed evidence of clinical response to fish oil therapy for their psoriasis were shown to have higher levels of leukotriene B₅ than those failing to improve.

Cancer

Numerous animal studies have demonstrated anticancer activity by fish oil.^[90] Experimental studies in rats have demonstrated that while corn oil-fed rats show an increased risk for colon cancer, fish oil-fed rats show both decreased risk and slowed progression of this cancer.^[91] Fish oil appears to exert this anticancer effect by altering carcinogen metabolism and modifying prostaglandin synthesis.

In Japan, which enjoys the lowest breast cancer rate of the industrialized countries, fish consumption is highest. Conversely, in those countries where the risk of breast cancer is highest, the proportion of calories in the diet from fish is relatively low. A large epidemiological study of 23 dietary factors in countries with high and low risks of cancer found a strong association between the percentage of calories from fat and the risk of breast cancer.^[92] Fish consumption was found to have the next most significant association, a negative correlation.

However, it remains premature to recommend fish oil as an anticancer substance until studies of its therapeutic efficacy are completed, especially in humans. Further, there is

some conflicting evidence on the role of fish oil in oncogenic processes.^[7]

Migraine headache

There are anecdotal reports that patients suffering from migraine headaches given 1 g/day of MaxEPA, particularly

males, have significantly less frequent and/or less intense episodes. These results might be due to changes in prostaglandin synthesis and/or reduction in platelet serotonin release, with resultant reduction in cerebral vasospasm.

Malaria

Malaria afflicts more than 500 million people worldwide, with about 5% of victims dying each year. Unpublished studies at the US Department of Agricultural Research Service center in Beltsville, Maryland, have found evidence that the omega-3 fatty acids in fish oil may be beneficial in the treatment of malaria.^[93] In their research, mice were fed dietary fish oils for 4 weeks and then inoculated with parasites, either *Plasmodium yoelii* or *Plasmodium berghei*. As the mice continued to eat the high-fish-oil diet, the parasites multiplied as usual. However, after 3–4 weeks, the mice were free of the parasites. The researchers suspected that the cause of the parasite's death was rupture of the parasites' cell membranes or red blood cell hosts. The researchers theorized that infected cells are more susceptible to rupture because the parasites foster a number of destructive oxidative reactions to which a diet high in fish oils makes them more vulnerable.

This finding is particularly promising since *P. berghei* is a chloroquine-resistant strain of malaria. Studies are underway by the World Health Organization to examine the benefits of treating malaria with dietary fish oil and qinghaosu, a Chinese botanical.

TOXICITY

A review of fish oil supplementation and CHD found that 10 MaxEPA capsules or 25 ml/day of cod liver oil (providing 1.8 g of EPA) is "safe over a long term".^[94] Long-term studies of potentially adverse effects of fish oil supplementation in humans have not been published. However, this is also true of all other oils, such as vegetable oils and most currently prescribed hypolipidemic drugs.^[38]

Care must also be taken to use fish oil, not fish liver oil, as the later can be excessively high in vitamins A and D, and cause toxicity.

Finally, large dosages of fish oil supplements may result in a significant increase in the

total caloric intake.

Bleeding time

There have been concerns expressed about prolonged bleeding time in populations having a relatively high intake of fish. Several studies have shown that this effect appears to be dose-dependent, although collagen-induced platelet aggregation was not shown to be inhibited.^[95] Many studies have shown that fish oil supplements prolong bleeding time, inhibit platelet aggregation, and decrease thromboxane A₂ production.^[17]

[\[59\]](#) [\[96\]](#) [\[97\]](#) [\[98\]](#) [\[99\]](#) [\[100\]](#) [\[101\]](#) [\[102\]](#) [\[103\]](#) [\[104\]](#) [\[105\]](#) [\[106\]](#) [\[107\]](#) [\[108\]](#) [\[109\]](#)

Recent research suggests that, while the effect of fish oil supplementation on bleeding time is largely determined by the dosage, duration, and composition of the supplement, the typical treatment regimes are safe. In one double-blind placebo-controlled trial, daily supplementation with 30 ml of a Scandinavian fish oil formulation (ESKIMO-3: 35% n-3 fatty acids, 18% EPA, and 12% DHA) given for both short (4 weeks) and long (6 months) durations resulted in no changes in bleeding time.^[20] Another controlled study used 1.5, 3, or 6 g of fish oils (SuperEPA) as a supplement for 3 months and found no effect on bleeding time in 45 healthy male volunteers with normal triglycerides.^[110]

Caution should be taken when recommending fish oil supplementation to pregnant women (studies to date on bleeding time have all been carried out on males), individuals known or suspected of any bleeding disorder, or those prescribed therapeutic levels of aspirin or warfarin, who should consult with their physician.

There is conflicting evidence as to the degree to which fish oil may affect fibrinolysis. Plasma PAI-1 is an inhibitor of fibrinolysis. Increased PAI-1 activity has been linked to the development of myocardial infarction and thrombosis by several investigators. In at least one double-blind, randomized study conducted on an untreated essential hypertensive population, a modest increase in fibrinogen levels was observed after fish oil and corn oil intake was increased by 4 g of omega-3 PUFAs.^[111] However, no change in PAI-1 activity or tissue plasminogen activator (tPA) activity was found.

Toxin contamination

While increased bleeding may not be a problem, there may be other risks from increased consumption of fish.^[112] For example, some fish may be contaminated from industrial effluents and toxins. Many of these toxicants, such as PCB, are known to increase the risk of cancer. In animal experiments it has been demonstrated that eating such contaminated fish as infrequently as once a week may increase the risk of developing cancer and create a significant risk to pregnant women and infants.^[113] ^[114] With the growth of aqua-businesses, or fish farms, it remains unknown whether such exposure is being reduced. Some new fish varieties grow so quickly that the opportunity for toxic build-up in organs and fat is significantly decreased. However, as noted earlier, the EPA and DHA concentration and fatty acid balance of these fish oils may be adversely affected by the commercial feed they receive.

Oxidation

There is a possibility that a diet rich in fish oil taken for many months may induce a deficiency of vitamin E,

741

which could contribute to cardiac necrosis.^{[115] [116]} For this reason, concurrent vitamin E supplementation appears warranted. However, there is no evidence that the incidence of cardiac necrosis is higher in Eskimos.

The omega-3 fatty acids found in fish oil are susceptible to oxidative breakdown. For this reason they must be protected from oxidation by proper extraction and storage, encapsulation or stabilization with an antioxidant, such as vitamin E. Inappropriately stored fish oils (i.e. exposure to oxygen) may result in the formation of toxic lipid peroxides.

DOSAGE

The dosages reported to be most effective range between 5 and 15 g/day of fish oil. Clinical results may require 4–6 months to manifest.

CONCLUSION

A substantial body of evidence now documents the beneficial effects of fish and fish oil consumption. The omega-3 fatty acids eicosapentaenoic acid and docosahexaenoic acid are the components of fish oil responsible for its preventive and therapeutic effects. These include:

- lowering of blood pressure
- improved plasma lipid profiles
- antithrombotic activity
- decreased risk of ventricular arrhythmias and atherosclerosis.

However, determining which source of fish oil, i.e. eating fish or supplementing with fish oil, and which fish species are most desirable is difficult, as the various species and sources have different levels and ratios of eicosanoid metabolites.

In an effort to resolve this question, one study compared the effects of fish oil (4.5 g EPA/DHA) from fish with fish oil supplements in 25 mildly hyperlipidemic men over a 5 week period. Both fish and fish oil supplements lowered serum triglycerides and raised HDL cholesterol. There was no difference between the two treatments in their effects on total cholesterol, apolipoprotein B, LDL cholesterol, or blood pressure. However, dietary fish did lower fibrinogen (15.6%) and thromboxane (10.5%) and increase bleeding time

(10.8%), as compared with both controls and those receiving fish oil supplements.^[117] These findings suggest that while both fish consumption and fish oil supplementation produce desirable effects on lipids and lipoproteins, fish consumption is more effective in improving several of the hemostatic factors involved in cardiovascular disease.

Which fish or fish oil products produce the most desirable combination of therapeutic effects remains unknown. Further research is needed. In the interim, it seems evident that humans could benefit from a diet containing fresh or fresh/frozen fish consumed at least three or four times a week, with additional fish oil supplementation when warranted. To ensure that fish is safe for consumption, either continued vigilance by regulatory agencies or effectively enforced industry standards are required to prevent contaminated fish containing toxicants from reaching the market place. Fish oil supplement manufacturers must provide sufficient information about the source of the fish oil. Information on the fish oil's source, EPA and DHA concentration and ratio, toxic residual levels (if any), and risk of oxidative activity should be provided.

Chapter 87 - Flavonoids – quercetin, citrus flavonoids, and HERs (hydroxyethylrutosides)

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

INTRODUCTION

The flavonoids are a group of plant pigments that are largely responsible for the colors of many fruits and flowers. Recent research suggests that flavonoids may be useful in the treatment and prevention of many health conditions. In fact, many of the medicinal actions of foods, juices, herbs, and bee pollen are now known to be directly related to their flavonoid content. Over 4,000 flavonoid compounds have been characterized and classified according to chemical structure. A few representatives of this class of useful clinical agents (quercetin, citrus bioflavonoids, and hydroxyethylrutosides) are discussed in this chapter.

One of the most beneficial group of plant flavonoids are the proanthocyanidins (also referred to as procyanidins). The most potent proanthocyanidins are those bound to other proanthocyanidins. Collectively, mixtures of proanthocyanidin dimers, trimers, tetramers, and larger molecules are referred to as procyanidolic oligomers or PCOs for short. The PCOs are discussed in [Ch. 106](#).

HISTORICAL PERSPECTIVE

Flavonoids, as well as vitamin C, were discovered by Albert Szent-Gyorgyi (1893–1986), one of the most respected and honored biochemists of the 20th century. Szent-Gyorgyi received the Nobel Prize in 1937 for his discovery of some of the properties of these molecules.

It was during the process of isolating vitamin C that Szent-Gyorgyi discovered the flavonoids. A friend with bleeding gums had stopped the bleeding by taking a crude vitamin C preparation isolated from lemon. When the problem reappeared later on, Szent-Gyorgyi gave his friend a purer form of vitamin C. He expected to observe an

even more impressive result, but the purer form of vitamin C did not work. Szent-Gyorgyi then isolated the flavonoid fraction from the original crude vitamin C preparation, gave it to his friend and observed complete healing.

746

Szent-Gyorgyi termed his discovery “vitamin P” due to its ability reduce vascular permeability, one of the hallmark features of scurvy. He went on to show that the clinical symptoms of scurvy are the result of a combined deficiency of vitamin C and flavonoids. However, because flavonoids could not fulfill all the requirements of a vitamin, the designation as vitamin P was abandoned. Although flavonoids are often referred to as “semi-essential” nutrients, their importance in human nutrition appears to be as important to good health as the essential vitamins and minerals.

Good dietary sources of flavonoids include citrus fruits, berries, onions, parsley, legumes, green tea, and red wine. The average daily intake in the United States for flavonoids is estimated to be between 150 and 200 mg.

CHEMICAL DESCRIPTIONS

Quercetin ([Fig. 87.1](#))

Quercetin is a flavonoid that serves as the aglycone for many other flavonoids, including the citrus flavonoids rutin, quercitrin, and hesperidin. These derivatives differ from quercetin in that they have sugar molecules attached to the quercetin backbone. Quercetin is consistently the most active of the flavonoids in experimental studies and many medicinal plants owe much of their activity to their high quercetin content.

Citrus bioflavonoids

Citrus bioflavonoid preparations can include rutin, hesperidin, quercitrin, and naringin. Most of the clinical research on rutin and crude bioflavonoid complexes occurred before 1970. Since then, most of the clinical research has utilized a standardized mixture of rutinoides known as hydroxyethylrutoides (HERs). Impressive clinical results have been obtained in the treatment of capillary permeability, excessive bruisability, hemorrhoids, and varicose veins with HERs (discussed below). Citrus bioflavonoids can be viewed as providing similar effects to, but probably not as potent as, HERs or quercetin.

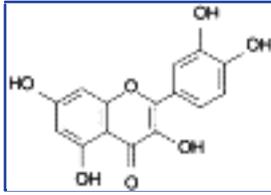

Figure 87-1 Quercetin.

PHARMACOLOGY

As a class of compounds, flavonoids have been referred to as “nature’s biological response modifiers” because of their ability to modify the body’s reaction to other compounds such as allergens, viruses, and carcinogens, as evidenced by their anti-inflammatory, anti-allergic, antiviral, and anticarcinogenic properties. In addition, flavonoids act as powerful antioxidants, providing remarkable protection against oxidative and free radical damage. The practical aspect of this antioxidant activity is highlighted by the results of a study in 805 men designed to determine the effect of dietary flavonoids on protecting against heart disease. The study demonstrated an inverse correlation between flavonoid intake and death from a heart attack.^[1] This effect is probably a result of the potent antioxidant effects of the flavonoids preventing, similar to vitamins C and E, the formation of oxidized cholesterol. However, the antioxidant activity of flavonoids is generally more potent and effective against a broader range of oxidants than traditional antioxidant nutrients like vitamins C and E, selenium, and zinc.^{[2] [3]}

Because different flavonoids tend to provide different benefits, additional and more specific beneficial effects are discussed under the three selected categories. There is significant overlap among these flavonoids, however.

Quercetin

Quercetin consistently demonstrates the greatest activity among the flavonoids studied in experimental models, particularly in vitro studies. The primary actions that will be briefly reviewed here are its anti-inflammatory effects, inhibition of aldose reductase, antiviral activity, and anti-cancer properties.

Anti-inflammatory effects

Quercetin has demonstrated significant anti-inflammatory activity due to direct inhibition of several of the initial processes of inflammation via interaction with calcium channels and/or calmodulin (the intracellular calcium-binding protein) as well as through other mechanisms such as by inhibiting mast cell and basophil degranulation, neutrophil and monocyte lysosomal secretion, prostaglandin (most notably, leukotriene) formation, lipid peroxidation, and the resultant cascade of effects that are often a result of these processes. For example, it inhibits both the manufacture and release of histamine and other allergic/inflammatory mediators. In addition it exerts potent antioxidant activity and vitamin C-sparing action.^{[2] [3] [4] [5] [6] [7] [8] [9] [10]}

Effect on histamine release

The release of histamine and other inflammatory mediators from mast cells and basophils is involved in the

747

pathogenesis of acute allergic and inflammatory responses. Mast cells are widely distributed throughout the human body, but are found in higher concentrations in the blood vessels of the subepithelial connective tissue of the respiratory tract, conjunctiva, gastrointestinal tract, and skin. Mast cell and basophil degranulation is an active process that requires calcium influx. Quercetin and many other flavonoids have been shown to be potent inhibitors of mast cell, neutrophil and basophil degranulation.^{[6] [7] [8] [9]}

A generally accepted hypothesis for this action is that quercetin inhibits receptor-mediated calcium influx, thereby inhibiting the primary signal for degranulation. However, quercetin is also active under conditions in which the calcium channel mechanism is not operative, indicating that other mechanisms are responsible as well.

Membrane stabilization, antioxidant activity, and hyaluronidase inhibition

Quercetin has been shown to inhibit many of the inflammatory processes attributed to activated neutrophils.^[9] This is probably due to its membrane stabilizing action, potent antioxidant effect (which prevents the production of free radicals and inflammatory leukotrienes), and inhibition of the enzyme hyaluronidase (thus preventing the breakdown of the collagen matrix of connective tissue and ground substance). Quercetin's membrane stabilizing effect could also account for its action in preventing mast cell and basophil degranulation. This effect also inhibits inflammation by decreasing neutrophil lysosomal enzyme secretion.^[9] Neutrophils and monocytes contain lysosomes that, upon secretion of their contents, contribute greatly to the inflammatory process.

Effects on eicosanoid metabolism

Excessive leukotriene formation has been linked to asthma, psoriasis, atopic dermatitis, gout, ulcerative colitis, and possibly cancer.^{[11] [12]} Quercetin has been shown to inhibit many steps in eicosanoid metabolism. Probably of most significance is its inhibition of phospholipase A2 and lipoxygenase enzymes (see [Ch. 132](#) for diagram).^{[2] [3] [10]} The net result is a significant reduction in the formation of leukotrienes. The leukotrienes C4, D4, and E4 (composing the slow-reacting substances of anaphylaxis (SRS-A)) are derived from arachidonic acid and are 1,000 times as potent as histamine in promoting inflammation. Leukotrienes promote inflammation by causing vasoconstriction (thereby increasing vascular permeability) and bronchoconstriction (thus inducing asthma), and by promoting WBC chemotaxis and aggregation. The reduction of leukotriene formation has significant anti-inflammatory effects.

Inhibition of aldose reductase

Quercetin is a strong inhibitor of aldose reductase, the enzyme responsible for the conversion of blood glucose to sorbitol. This compound is strongly implicated in the development of diabetic complications, i.e. diabetic cataracts, neuropathy, and retinopathy.^[13] The mechanism by which sorbitol is involved in the development of diabetic complications is best understood by considering its involvement in cataract formation. Although the lens does not have any blood vessels, it is an actively metabolizing tissue that continuously grows throughout life. Elevated blood sugar levels result in shunting of glucose to the sorbitol pathway. Since the lens membranes are virtually impermeable to sorbitol and lack the enzyme required to break down sorbitol (polyol dehydrogenase), sorbitol accumulates to high concentrations. These high concentrations persist even if glucose levels return to normal. This accumulation creates an osmotic gradient that results in water being drawn into the cells to maintain osmotic balance. As the water is pulled in, the cell must release small molecules like amino acids, inositol, glutathione, niacin, vitamin C, magnesium and potassium in order to maintain osmotic balance. Since these latter compounds function to protect the lens from damage, their loss results in an increased susceptibility to damage. As a result, the delicate protein fibers within the lens become opaque and a cataract forms.

Quercetrin, which is hydrolyzed by gut bacteria to yield quercetin and a sugar moiety, was shown to significantly decrease the accumulation of sorbitol in the lens of diabetic animals, effectively delaying the onset of cataracts.^[14] In addition to its effect on aldose reductase, quercetin is also of value in diabetes for its ability to enhance insulin secretion and protect the pancreatic beta-cells from the damaging effects of free radicals, and for its inhibition of platelet aggregation.^{[2] [3]}

Antiviral activity

Flavonoids as a group possess significant antiviral activity, with quercetin having the greatest antiviral activity against herpes virus type I, para-influenzae 3, polio virus type I, and respiratory syncytial virus.^{[15] [16] [17]} Quercetin has been shown, in vitro, to inhibit both viral replication and infectivity. In vivo studies in animals have also shown quercetin to inhibit viral infection.^{[17] [18]} This would suggest that quercetin may be of some benefit in viral infections, including the common cold.

Anti-cancer properties

Many flavonoids have also been shown to inhibit tumor formation, but again quercetin has consistently been shown to be the most effective. In experimental models, quercetin has demonstrated significant antitumor activity

against a wide range of cancers, including squamous cell carcinoma, leukemia, and

cancers of the breast, ovaries, colon, rectum, and brain. Unfortunately, there are no human studies to support the impressive results noted in animal and in vitro studies.^[19]
^[20] ^[21] ^[22]

Citrus flavonoids

In addition to possessing antioxidant activity and an ability to increase intracellular levels of vitamin C, rutin, hesperidin, and HER exert many beneficial effects on capillary permeability and blood flow, primarily via strengthening endothelial cells and supporting collagen structures. Collagen, the most abundant protein of the body, is responsible for maintaining the integrity of “ground substance” as well as the integrity of tendons, ligaments, and cartilage. Collagen is also the support structure of the skin and blood vessels. Citrus flavonoids affect collagen metabolism in several ways. They reinforce the natural cross-linking of collagen that forms the so-called collagen matrix of connective tissue and protect against free radical damage with their potent antioxidant and free radical scavenging action and inhibit enzymatic cleavage of collagen by enzymes secreted by leukocytes during inflammation, and microbes during infection. Like quercetin, citrus flavonoids also prevent the release and synthesis of compounds that promote inflammation and allergies, such as histamine, serine proteases, prostaglandins, and leukotrienes.^[4]

CLINICAL APPLICATIONS

There is much overlap between the clinical uses of flavonoid preparations. Most of the clinical research has focused on HER products.

Allergic and inflammatory conditions

Based largely on in vitro studies, quercetin appears to be indicated in virtually all inflammatory and allergic conditions, including asthma, hayfever, rheumatoid arthritis, and lupus, as well as in diabetes, and cancer. However, the main shortcoming is the limited number of clinical studies and poor absorption. Earlier pharmacokinetic studies in animals and humans indicated that very little quercetin is absorbed intact, with the majority of the oral dose (53%) being excreted in the feces.^[23] ^[24] One of the main problems in studying the absorption of quercetin and other flavonoids is their degradation by microorganisms in the colon. To side-step this issue, a recent study examined the absorption of quercetin in healthy ileostomy patients with complete small intestines.^[25]

The study examined the absorption of quercetin from fried onions (a rich source of quercetin glycosides), rutin, or 100 mg of pure quercetin. Absorption was defined as oral intake minus ileostomy excretion and corrected for degradation within the ileostomy bag. Absorption results were as follows: 52% from onions, 17% from quercetin rutinoid, and 24% for pure quercetin. These results indicate that humans do absorb appreciable amounts of quercetin and that absorption (but not necessarily pharmacological activity) may be enhanced when quercetin is bound to glucose. In other words, citrus bioflavonoid preparations and/or HERs may prove to be more

effective clinically.

Capillary fragility, excessive bruisability and hemorrhoids

Early studies demonstrated rutin to be effective in reducing capillary fragility, easy bruising, swelling and bruising after sports injuries, and nose bleeds.^{[26] [27] [28] [29]} More recent and much more extensive studies have been performed with HERs. Positive double-blind clinical studies exist in the treatment of venous insufficiency including varicose veins, hemorrhoids, diabetic vascular disease, and diabetic retinopathy.^[30]

In double-blind studies in patients with chronic venous insufficiency, HER improves microvascular blood flow and clinical symptoms (pain, tired legs, night cramps, and restless legs) in 73–100% of patients.^{[31] [32] [33] [34] [35] [36]} Several of the studies were performed in pregnant women where HER was shown to be of great benefit in improving venous function as well as in helping to relieve hemorrhoidal signs and symptoms. In one study, 90% of the women given HER (1,000 mg daily for 4 weeks) had improved symptoms compared with only 12% in the placebo group.^[37] Similar results in hemorrhoids not associated with pregnancy have been reported.^{[30] [38]}

Diabetes

Flavonoids appear to be quite important in the long-term care of diabetes. One of the hallmark features of diabetes is a significant disturbance of blood flow through small blood vessels. HERs appear to improve blood flow in diabetics significantly and can be useful in the treatment of diabetic microvascular disease and retinopathy. However, PCO or bilberry extracts may be better than quercetin, citrus flavonoids and HER in diabetics.^{[38] [39] [40]}

COMMERCIALLY AVAILABLE FORMS

Quercetin

Quercetin is available alone in powder and capsule form. However, if the quercetin is being used for its antiinflammatory properties, products which provide a combination of the pineapple enzyme bromelain may provide additional benefit. Bromelain exerts anti-allergy and anti-inflammatory activity on its own and it may also

enhance the absorption of quercetin. Combination preparations of protein-digesting enzymes, like bromelain, and flavonoids have been shown to potentiate each other's anti-inflammatory activity.^[41]

Citrus bioflavonoids

Mixed preparations of citrus bioflavonoids are the most widely used and least expensive flavonoid sources. However, mixed citrus flavonoids are the least active and generally the least quantified source of flavonoids, as most commercially available sources of mixed citrus flavonoids only contain 50% flavonoids. Preparations containing pure rutin and hesperidin or those which clearly state the levels of rutin and hesperidin are better than products which do not quantify the amount of the individual flavonoid components. HERs are probably the better choice when opting for the benefits in this class of flavonoids.

DOSAGES

The recommended dosage range for quercetin is 200– 400 mg 20 minutes before meals (three times per day). If the quercetin is being used for its anti-inflammatory properties and bromelain is also indicated, administration with bromelain may enhance absorption. Combination preparations of proteolytic enzymes and flavonoids have been shown to have significant anti-inflammatory activity in experimental studies.^[41] If used with bromelain, the amount of bromelain (1,800 mcu activity) should be equal to the amount of quercetin.

The dosage used for HERs in the double-blind clinical studies in the treatment of venous insufficiency and hemorrhoids has ranged from 1,000 to 3,000 mg daily. This translates to a dosage of citrus bioflavonoids, rutin, and hesperidin of 3,000–6,000 mg daily.

TOXICITY

Quercetin appears to be well tolerated in humans. Carcinogenic and teratogenic studies in rats and rabbits have shown that quercetin is without apparent side-effect, even when consumed in very large quantities (2,000 mg/kg body weight and 5–10% of total diet) for long periods of time (up to 2 years).^{[41] [42] [43] [44] [45] [46]} In addition, quercetin administration (up to 2,000 mg/kg body weight) to pregnant rats had no teratogenic effects.^[47] As is true of any other compound, allergic reactions may occur. Although uncommon, if they occur, discontinue use.

Citrus bioflavonoids, rutin, hesperidin, and HER appear to be extremely safe and without side-effect even during pregnancy.^[30]

INTERACTIONS

Quercetin, rutin, hesperidin, HER, and green tea polyphenols do not appear to interact with any drug. Citrus bioflavonoid preparations, if they contain naringin, may interact with drugs. This flavonoid is found in grapefruit juice, but not in orange juice. Studies in humans have shown grapefruit juice (i.e. naringin) to increase the oral bioavailability of drugs like nifedipine, felodipine, verapamil, and terfenadine, as well as inhibiting the breakdown of various drugs, particularly caffeine, coumarin, and estrogens.^[48] Avoidance of grapefruit juice and flavonoid preparations containing naringin is

recommended when taking any of these drugs.

Chapter 88 - *Ginkgo biloba* (ginkgo tree)

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

Ginkgo biloba (family: Ginkgoaceae)
Common names: ginkgo tree, maidenhair tree

GENERAL DESCRIPTION

Ginkgo biloba is a deciduous tree which, living as long as 1,000 years, may grow to a height of 100–122 feet and a diameter of 3–4 feet. The ginkgo has short horizontal branches with short shoots bearing fan-shaped leaves that measure 2–4 inches across. Because the leaf resembles a maidenhair fern, the ginkgo has been called “maidenhair tree”. Ginkgo bears an inedible foul-smelling fruit and an edible ivory-colored inner seed that is sold in marketplaces in the Orient. Extracts from the leaves of the ginkgo tree are used medicinally.

CHEMICAL COMPOSITION

The active components of ginkgo leaves are the ginkgo-flavone glycosides or ginkgo heterosides (flavonoid molecules with sugars attached which are unique to the ginkgo), several terpene molecules unique to ginkgo (ginkgolides and bilobalide), and organic acids.^[1]

The *Ginkgo biloba* extract (GBE), marketed in Europe under the trade names Tanakan, Rokan, Ginkgobil, Kaveri, and Tebonin, is a very well-defined and complex product prepared from the green leaves. Extracts identical to these preparations are available in the United States as food supplements. The culturing, harvesting, and extracting techniques have been thoroughly standardized and require careful control.

GBE is standardized to contain 24% flavonoid glycosides, as these molecules represent a convenient analytical reference group. Although they play a major role in the

pharmacological activity of GBE, other components are also important. The three major backbone flavonoids of the *Ginkgo biloba* flavonols are quercetin, kaempferol, and isorhamnetin (see [Fig. 88.1](#)). The sugar (glucoside) components are glucose and rhamnose, which are present

752

Figure 88-1 The major backbone flavonoids of GBE.

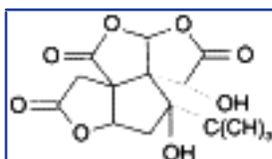

Figure 88-2 Bilobalide.

as single sugars or disaccharides (two sugar molecules attached to each other).

Other significant flavonoid components of the extract include proanthocyanidins, largely composed of dimers and oligomers of delphinidine and cyanidine. The major terpene molecules of GBE, which account for 6% of the extract, are the ginkgolides and bilobalide (see [Fig. 88.2](#)). These substances are unique to ginkgo and are not found in any other plants. Other constituents of GBE include a number of organic acids. These compounds contribute valuable properties to the extract by making the usually water-insoluble flavonoid and terpene molecules of ginkgo water-soluble.

HISTORY AND FOLK USE

Ginkgo biloba is the world's oldest living tree species. The sole surviving species of the family Ginkgoaceae, ginkgo tree can be traced back more than 200 million years to the fossils of the Permian period, and for this reason it is often referred to as "the living fossil".

Once common in North America and Europe, the ginkgo was almost destroyed during the Ice Age in all regions of the world except China, where it has long been cultivated as a sacred tree.

In the late 17th century, Engelbert Kaempfer, a German physician and botanist, became the first European to discover and catalog the ginkgo tree. The flavonoid kaempferol is

named after Kaempfer. In 1771, Linnaeus named the tree *Ginkgo biloba*.

The ginkgo tree was brought to America in 1784 to the garden of William Hamilton near Philadelphia. The ginkgo is now planted throughout much of the US as an ornamental tree. The ginkgo, which is the tree most resistant to insects, disease, and pollution, is frequently planted along streets in cities.^[1]

Ginkgo biloba's medicinal use can be traced back to the oldest Chinese materia medica (2800 BC). The ginkgo leaves have been used in Traditional Chinese Medicine for their ability to "benefit the brain", relieve the symptoms of asthma and coughs, and help the body eliminate filaria.

Ginkgo leaf extracts are now among the leading prescription medicines in both Germany and France, where they account for 1 and 1.5%, respectively, of total prescription sales. In 1989 alone, over 100,000 physicians worldwide wrote over 10,000,000 prescriptions for GBE. The popularity of GBE has increased since.

PHARMACOLOGY

The standardized concentrated extract of the leaves of *Ginkgo biloba* (24% ginkgo heteroside content) has demonstrated remarkable pharmacological effects. Interestingly, the total extract is more active than single isolated components.^{[1] [2]} This suggests synergism between the various components of GBE, an explanation which is well supported in more than 400 clinical and experimental studies utilizing the extract.^{[1] [2] [3] [4]}

Tissue effects

GBE exerts profound, widespread tissue effects, including membrane-stabilizing, antioxidant, and free radical-scavenging effects. GBE also enhances the utilization of oxygen and glucose.^{[1] [2] [3]}

Cellular membranes provide the first line of defense in maintaining the integrity of the cell. Largely composed of fatty acids (phospholipids), cellular membranes also serve as fluid barriers, exchange sites, and electrical capacitors. These membranes are fragile and vulnerable to damage, especially the lipid peroxidation induced by oxygenated free radicals. GBE is an extremely effective inhibitor of lipid peroxidation of cellular membranes.^{[1] [2]}

Red blood cells provide excellent models for evaluating the effects of substances on membrane functions. Red blood cell studies utilizing GBE have demonstrated that, in addition to directly stabilizing membrane structures and scavenging free radicals, GBE also enhances membrane transport of potassium into the cell and sodium out by activating the sodium pump. In essence, GBE leads to better membrane polarization. This effect is particularly important in excitable tissues, such as nerve cells.^{[1] [2]}

Nerve cell effects

GBE's membrane-stabilizing and free radical-scavenging effects are perhaps most evident in the brain and nerve

753

cells. Brain cells contain the highest percentage of unsaturated fatty acids in their membranes of any cells in the body, making them highly susceptible to free radical damage.

The brain cell is also highly susceptible to hypoxia. Unlike most other tissues, the brain has very little energy reserves. Its functions require large amounts of energy which must be supplied by a constant supply of glucose and oxygen. Diminished circulation to the brain sets off a chain of reactions which disrupt membrane function and energy production and ultimately lead to cellular death.

GBE is remarkable in its ability to prevent metabolic and neuronal disturbances in experimental models of cerebral ischemia.^{[1] [2] [5] [6] [7] [8]} It accomplishes this by enhancing oxygen utilization and increasing cellular uptake of glucose, thus restoring energy production.

All of the above-mentioned metabolic effects are in addition to GBE's ability to re-establish effective tissue perfusion. Particularly interesting is GBE's ability to normalize the circulation in the areas most affected by microembolization, namely the hippocampus and striatum.^{[1] [2]}

Discussion of additional nervous tissues actions of GBE are incorporated into the clinical indications section below. Briefly, GBE promotes increased nerve transmission rate, improves synthesis and turnover of brain neuro-transmitters, and normalizes acetylcholine receptors in the hippocampus (the area of the brain most affected by Alzheimer's disease).^{[1] [2]}

Vascular effects

The mechanisms of GBE's vascular effects have been investigated utilizing a number of in vivo and in vitro techniques ([Table 88.1](#)).^{[1] [2]} Isolated vessel techniques allow for separation of GBE's effects on different parts of the vascular system – e.g. arterial, arteriolar, microcirculatory, venular, and venous components – while in vivo studies provide information on the total circulatory phenomena, i.e. GBE's ability to increase the perfusion rate to various regions.

In general, GBE exerts its vascular effects primarily through its effects on the lining of the blood vessels (vascular endothelium) and the system which regulates blood vessel

tone. Its vasodilating action is explained by direct stimulation of the release of endothelium-derived relaxing factor (EDRF) and prostacyclin (a beneficial prostaglandin). In addition, GBE inhibits an enzyme which results in relaxation of the blood vessel.^{[1] [2]}

On the venous system, GBE stimulates greater tone, thus aiding the dynamic clearing of toxic metabolites which accumulate during ischemia (times of insufficient oxygen supply)^{[1] [2]} (see [Fig. 88.3](#)).

GBE normalizes circulation by producing tonic effects. These effects are much more apparent in an ischemic vascular area than on a normally perfused area.^[9]

TABLE 88-1 -- The cellular and membrane mechanisms of the vasoregulatory effects of GBE

| Site of action | Upstream flow (arteriole) | | Exchange area (capillary) | | | |
|--|--|--|--|---|---|--|
| | Tissue pathological condition | Arterial spasm | Arterial thrombosis | Vascular atony | Hypoxic vasoparalysis | Capillary hyperpermeability and plasma |
| Effects found with Ginkgo biloba extract | Vasorelaxation | Diminished platelet hyperaggregability | Restitution of arterial tone | Diminished accumulation of toxic wastes: K ⁺ , CO ₂ , and lactate | Amelioration of capillary hyperpermeability | |
| Cellular and membrane mechanisms explaining <i>Ginkgo biloba</i> 's effect | Release of EDRF from endothelium | Release of PGI ₂ | Direct effect | Consequence of venous tonic effect | Direct membrane effect | |
| | Inhibition of PDE | Direct membrane effect | Potentialiation of a-adrenergic effects* | Mitochondrial metabolic restart | | |
| | Potentialiation of a-adrenergic effects* | | | | | |

* Partly through COMT inhibition.

Figure 88-3 GBE's impact on ischemia.

However, despite intense investigation, many of GBE's tonic effects on vascular components are still largely unexplained. It is truly remarkable that a substance can simultaneously combat the phenomena resulting from vascular spasm and, with the same efficiency, restore circulation to areas subject to vasomotor paralysis.

The importance of this dual action is becoming more apparent in cerebral insufficiency, as single direction drugs, i.e. vasodilators, can often aggravate the condition by preferentially dilating the healthy areas, thereby deflecting blood and oxygen away from the ischemic area.

Platelet effects

GBE and isolated ginkgolides have profound effects on platelet function, including inhibition of platelet aggregation, adhesion, and degranulation.^[3] These effects appear to be due to direct membrane and antioxidant effects, increased synthesis of prostacyclin and an antagonism of a substance known as platelet activating factor (PAF).

BE and the ginkgolides have been shown to be potent inhibitors of PAF.^{[3] [10] [11] [12]} PAF is a potent stimulator of platelet degranulation and is involved in many inflammatory and allergic processes, including neutrophil activation, increasing vascular permeability, smooth muscle contraction including bronchoconstriction, and reduction in coronary blood flow. GBE and ginkgolides compete with PAF for binding sites and inhibit the various events induced by PAF.^{[1] [2] [13] [14]} These actions may be responsible for many of the clinical effects of GBE. Interestingly, despite these effects on PAF, GBE exerts no inhibition of platelet aggregation in humans.

Absorption and distribution of GBE

The pharmacokinetics (absorption, distribution, and elimination) of GBE have been studied in rats using radiolabeled extracts.^{[1] [2] [3]} Following oral administration, at least 60% of the radiolabeled extract was absorbed. Since blood levels peaked after 1.5 hours, upper gastrointestinal tract absorption was suspected.

The flavonoids appear to have an affinity for organs rich in connective tissues, such as the aorta, eyes, skin, and lungs. Levels of radioactivity in these tissues are two to three times higher than those in blood and decrease little over the course of time. Retained specific activity in the heart is twice that found in the skeletal muscles. Of the glands, the adrenals retained the greatest level of radioactivity.

At 72 hours, the hippocampus and the striated bodies show radioactivity five times greater than that of the blood. This deposition pattern, which parallels the circulation improvement observed after ischemia due to blood clot in rats, is alleviated by GBE extracts. Other areas of the brain such as the cerebral cortex, brain stem, and cerebellum do not show such high levels of radioactivity.

CLINICAL APPLICATIONS

Ginkgo biloba extract's primary clinical application has been in the treatment of vascular insufficiency. In over 50 double-blind clinical trials, both patients with chronic cerebral (brain) arterial insufficiency and peripheral arterial insufficiency have responded favorably to GBE. As described above, GBE exerts an extraordinary array of

755

pharmacological activities which imply a broad spectrum of possible clinical applications, an implication borne out by the new applications of GBE which are constantly being discovered.

Cerebral vascular insufficiency and impaired mental performance

Cerebral vascular insufficiency is an extremely common condition in the elderly of developed countries, due to the high prevalence of atherosclerosis (hardening of the arteries). In well-designed studies, GBE has displayed a statistically significant regression of the major symptoms of cerebral vascular insufficiency and impaired mental performance. These symptoms included: [\[1\]](#) [\[2\]](#) [\[3\]](#) [\[4\]](#) [\[11\]](#) [\[12\]](#) [\[13\]](#) [\[14\]](#) [\[15\]](#) [\[16\]](#) [\[17\]](#) [\[18\]](#)

- short-term memory loss
- vertigo
- headache
- ringing in the ears
- lack of vigilance
- depression.

The significant regression of these symptoms by GBE suggests that vascular insufficiency may be the major causative factor accounting for these so-called "age-related cerebral disorders" versus a true degenerative process.

In a comprehensive review, an analysis was made on the quality of research on over 40 clinical studies with GBE in the treatment of cerebral insufficiency. The results of the analysis indicate that GBE is effective in reducing all symptoms of cerebral insufficiency, including impaired mental function (senility), and the quality of research was comparable to Hydergine (dihydroergotamine), an FDA-approved drug used in the treatment of cerebral vascular insufficiency and Alzheimer's disease. Eight studies stood out as

being extremely well-designed and are summarized in [Table 88.2](#).^{[11] [12] [13] [14] [15] [16] [17] [18]}

It appears that by increasing cerebral blood flow, and therefore oxygen and glucose utilization, *Ginkgo biloba* extract offers relief of these presumed “side-effects” of aging and may offer significant protection against their development. Furthermore, *Ginkgo biloba*’s anti-aggregatory effect on platelets offers additional protection against a stroke. This has been supported in a clinical study of post-stroke patients which demonstrated that GBE improved blood flow and blood viscosity.^[19]

As well as improving blood supply to the brain, experimental and clinical studies show that GBE increases the rate at which information is transmitted at the nerve cell level.^{[20] [21] [22]} The memory-enhancing effects of GBE are not limited to the elderly. In one double-blind study, the reaction time in healthy young women performing a memory test was improved significantly after the administration of GBE.^[22]

Alzheimer’s disease

GBE is showing great benefit in many cases of senility

including Alzheimer's disease.^{[1] [2] [3] [4] [20] [23]} In addition to GBE's ability to increase the functional capacity of the brain via the mechanisms described above, it also has been shown to normalize the acetylcholine receptor in the hippocampus of aged animals, increase cholinergic transmission, and to address many of the other major elements of Alzheimer's disease.^{[1] [2]}

Although preliminary studies in established Alzheimer's patients are quite promising, at this time it appears that GBE only helps to reverse or merely delay mental deterioration in the early stages of Alzheimer's disease. This may help to enable the patient to

maintain a normal life for a while and stay away from being put in a nursing home.

The benefits of GBE in early-stage Alzheimer's is quite evident when looking at the results from a recent double-blind study.^[23] In the study, 40 patients with a preliminary diagnosis of senile dementia of the Alzheimer's type received either 80 mg of *Ginkgo biloba* extract or placebo three times daily for 3 months. Patients were assessed by standard tests including the SKT, Sandoz Clinical Assessment Geriatric Scale, and EEG at baseline and at 1, 2, and 3 months. Results indicated that *Ginkgo biloba* extract improved all parameters, usually in the first month, compared with the placebo. Consistent with other studies involving *Ginkgo biloba* extract, the longer *Ginkgo biloba* extract is used, the more obvious the benefits become. *Ginkgo biloba* extract was well tolerated and no side-effects were noted in the trial.

In addition, to offering benefit in early-stage Alzheimer's disease, if the mental deficit is due to vascular insufficiency or depression and not Alzheimer's disease, GBE will usually be effective in reversing the deficit.^{[1] [2] [3] [4]}

Tinnitus

Permanent severe tinnitus is an extremely difficult condition to treat. Previous studies have shown contradictory results of GBE in the treatment of tinnitus. For example, in Meyer's study, GBE improved the condition in all patients regardless of prognostic factor.^[24] However, in Coles' study, 21 patients with tinnitus took GBE for 12 weeks: 11 reported no change, four reported slight to very slight improvement, and five reported that their tinnitus was worse.^[25] The explanation for these different results is that in Meyer's study the patients had recent onset tinnitus, while in Coles' study 18 patients had the tinnitus for at least 3 years.

The most recent study of GBE in tinnitus utilized a two part design: the first part was an open part, without a placebo control; the second part was a double-blind placebo-controlled cross-over study.^[26] The 80 patients in the open study had been referred to the department of audiology, Sahlgren's Hospital, Goteborg, Sweden, due to permanent severe tinnitus. Twenty patients reporting a positive effect to *Ginkgo biloba* extract (14.6 mg twice daily) after 2 weeks were recruited for the double-blind study. Patients were given either the GBE or placebo for 2 weeks and were then crossed over into the other group. Evaluation indicated that six patients preferred GBE, seven preferred placebo, and seven had no preference.

On the surface, this study would seem to indicate that GBE is not effective for permanent severe tinnitus. However, the study was really designed for the GBE to fail. First of all the dosage used (14.6 mg twice daily or 29.2 mg daily) is far less the standard dosage of 40 mg three times daily (or roughly four times the daily dosage used in the study). Secondly, in studies in patients with cerebral vascular insufficiency it is well-established that GBE often takes at least 2 weeks before benefit becomes apparent. The longer that GBE is used, the more obvious the benefit. In a condition like permanent severe tinnitus, 2-4 weeks is simply not enough time. However, given the small insufficient dosage, it probably would not have mattered if the subjects had been

studied for a longer period of time.

The degree to which GBE is of benefit in permanent severe tinnitus remains to be determined, but given GBE's excellent safety profile it is certainly worth a try.

Cochlear deafness

Ischemia is usually the underlying factor in acute cochlear deafness. GBE has been shown to improve recovery in cases of acute cochlear deafness due to unknown factors or due to sound trauma or pressure (barotrauma).^[27]

Senile macular degeneration and diabetic retinopathy

GBE appears to address the multifactorial pathophysiology of senile macular degeneration, the most common cause of blindness in adults, quite effectively. In double-blind studies, GBE demonstrated a statistically significant improvement in long-distance visual acuity in both macular degeneration and diabetic retinopathy.^{[1] [2] [28]}

GBE has demonstrated impressive protective effects against free radical damage to the retina in experimental studies. Furthermore, GBE has been shown to prevent diabetic retinopathy in diabetic rats, suggesting it may have a protective effect in human diabetics as well.^{[1] [2]}

Peripheral arterial insufficiency

Peripheral arterial disease has as its primary lesion the same cholesterol-containing plaque which is responsible for other conditions associated with atherosclerosis, e.g. coronary artery disease and cerebral vascular insufficiency.

The arterial obstruction or narrowing causes a reduction in blood flow during exercise or at rest. Clinical symptoms are caused by the consequent ischemia. The

most common symptom of peripheral arterial disease is a pain upon exertion – intermittent claudication. The pain usually occurs in the calf and is described as a cramp or tightness or severe fatigue. The pain is usually bilateral. The cause of the pain is not only reduced oxygen delivery, but also an increase in the production of toxic metabolites and cellular free radicals. These free radicals accumulate and react with the lipid constituents of the cell membrane.

Pain at rest indicates serious reduction in resting blood flow. It is obviously a sign of severe disease. The pain may be localized to one or more toes, or it may have a stocking-type distribution. The character of the pain is usually described as burning or gnawing and is generally worse at night. Cyanosis or pallor of the extremity is usually

apparent. In moderate to severe narrowing of the artery, there are trophic changes, including a dry, scaly, and shiny epidermis. The hair may disappear, and the toenails may become brittle, ridged, and deformed.

The standard medical approach to peripheral vascular disease and intermittent claudication includes avoidance of tobacco (which causes vasoconstriction), a regular exercise program consisting of walking, and/or a prescription for pentoxifylline (Trental). Surgery is also an option, though most patients with intermittent claudication need not take this risk.^[29]

Trental has emerged as the “drug of choice” in the standard medical treatment of intermittent claudication.^[30] A total of 17 placebo-controlled trials have shown that Trental will prolong the total and pain-free walking distance in patients with intermittent claudication. However, the level of improvement (approximately 65% for pain-free walking distance) is less than that achieved with exercise or with *Ginkgo biloba* extract.

In nine double-blind randomized clinical trials of GBE versus placebo in two matched groups of patients with peripheral arterial insufficiency of the leg, GBE was shown to be quite active and superior to placebo (eight studies) and equal to pentoxifylline (one study).^{[1] [2] [3] [31] [32] [33] [34] [35] [36]} Not only were measurements of pain-free walking distance (75–110%) and maximum walking distance (52.6–119%) dramatically increased, but plethysmographic and Doppler ultrasound measurements also demonstrated increased blood flow through the affected limb, and blood lactate levels also dropped.^{[6] [7] [8] [9] [10] [11] [12] [13] [14] [15]}

The demonstration that *Ginkgo biloba* extract improves limb blood flow as well as improved walking tolerance (in studies following strict methodology and with sufficient patients for reliable evaluation) indicates that GBE is far superior to pentoxifylline and standard medical therapy in peripheral arterial insufficiency. This includes other peripheral vascular disorders such as diabetic peripheral vascular disease, Raynaud’s syndrome, acrocyanosis, and post-phlebitis syndrome.

The longer the period over which GBE is used, the

TABLE 88-3 -- Effect of GBE on cardiovascular performance measures

| Parameter | Time of measurement | |
|---|---------------------|----------|
| | Week 0 | Week 104 |
| Pain-free walking distance (m) | 62.9 | 172.4 |
| Total walking distance (m) | 113.8 | 384.0 |
| Rest flow (ml/100ml per min) | 1.6 | 2.7 |
| Peak flow (ml/100ml per min) | 3.7 | 6.9 |
| Doppler measurement after strain (mmHg) | 46.5 | 72.6 |

greater is the benefit. [Table 88.3](#) below summarizes a 2 year trial of GBE (160 mg/day) in the treatment of peripheral arterial disease (Fontaine's stage IIb). Pain-free walking distance increased by 300%.^[4]

The usual daily dosage of GBE is 120 mg (40 mg three times a day); however, some of the studies employed a dosage of 160 mg/day, including the study summarized in [Table 88.3](#).

Impotence

Most cases of impotence (erectile dysfunction) are due to impaired blood flow to erectile tissue. Recent evidence indicates that *Ginkgo biloba* extract may be extremely beneficial in the treatment of erectile dysfunction due to lack of blood flow.^[37] Sixty patients with proven erectile dysfunction who had not reacted to papaverine injections up to 50 mg were treated with *Ginkgo biloba* extract in a dose of 60 mg/day for 12–18 months. The penile blood flow was re-evaluated by duplex sonography every 4 weeks.

The first signs of improved blood supply were seen after 6–8 weeks. After 6 months' therapy, 50% of the patients had regained potency and in 20% a new trial of papaverine injection was then successful; 25% of the patients showed an improved blood flow, but papaverine was still not successful. The remaining 5% were unchanged.

According to the results in this preliminary study, *Ginkgo biloba* extract appears to be very effective in the treatment of erectile dysfunction due to lack of blood flow. The improvement of the arterial inflow to erectile tissue is assumed to be due to the known effect of *Ginkgo biloba* extract on enhancing blood flow through both arteries and veins without any change in systemic blood pressure.

It should be noted that ginkgo's effects are more apparent with long-term therapy and better results may have been obtained with a 120 mg/day dose in order to take full advantage of ginkgo's effect on improving blood flow.

Premenstrual syndrome and idiopathic cyclic edema

Premenstrual syndrome (PMS) is often characterized by fluid retention, vascular congestion, increased capillary

permeability, and breast tenderness. A recent double-blind placebo controlled study sought to determine the effectiveness of GBE on these symptoms.^[38] The population studied was a group of 165 women between the ages of 18 and 45 years who had suffered from these congestive symptoms for at least three cycles. The patients were then assigned to receive either the ginkgo extract (80 mg twice daily) or placebo from

the 16th day of the period to day 5 of the next. Based on extensive symptom evaluation by the patients and physicians, it was concluded that the ginkgo extract was effective against the congestive symptoms of PMS, particularly breast pain or tenderness. Patients taking the ginkgo extract also noted improvements in neuropsychological assessments. These results indicate that *Ginkgo biloba* extract may hold some promise in the treatment of PMS.

Antidepressant effects

The ability of GBE to improve general mood in patients suffering from cerebral vascular insufficiency in double-blind studies has led researchers to begin investigating the antidepressive effects of GBE. In a recent double-blind study, 40 elderly patients (age range, 51–78 years) with depression who had not benefitted fully from standard antidepressant drugs were given either 80 mg of GBE three times daily or a placebo.^[39] By the end of the eighth week study, the total score of the Hamilton Rating Scale for Depression in the *Ginkgo biloba* extract group had dropped from 14 to 4.5. In comparison, the placebo group dropped from 14 to only 13. This study indicated two things:

- Ginkgo biloba extract can be used with standard antidepressants
- it may enhance their effectiveness, particularly in patients over 50 years of age.

In addition, it is important to point out that the dosage used in the study (80 mg three times daily) is higher than the standard dosage of 40 mg three times daily.

Allergies

Mixtures of ginkgolides as well as the *Ginkgo biloba* extract standardized to contain 24% ginkgo flavonglycosides have shown clinical effects in allergic conditions due to their inhibition of platelet activating factor (PAF) – a key chemical mediator in asthma, inflammation, and allergies.^{[13] [14]}

In one double-blind placebo study, the ability of a mixture of ginkgolides to block the effects of PAF when PAF was injected into the skin was investigated.^[13] Normally, when PAF is injected it causes an immediate formation of a hive (classic wheal and flare reaction). However, if the ginkgolide mixture (120 mg) was given prior to PAF injection, it effectively counteracted the wheal and flare reaction. Specifically, the ginkgolide reduced the flare (reddened) area by a mean of 62.4% and the wheal (hive) volume by a mean of 60%.

Mixtures of ginkgolides, as well as purified ginkgolides, are under investigation in several European countries. The hope is that they will be shown to be clinically effective in asthma, eczema, and other allergies, as well as in many other conditions in which PAF plays a central role.^{[13] [14]}

Future applications of GBE

Experimental studies as well as some preliminary clinical evidence indicate that GBE may be of benefit in cases of angina, congestive heart failure, and acute respiratory distress syndrome. Its action on PAF may also make it useful for a great number of other applications in addition to allergies including various types of shock, thrombosis, graft protection during organ transplantation, multiple sclerosis, and burns.^{[1] [2]}

DOSAGE

Most of the clinical research on *Ginkgo biloba* has utilized a standardized extract, containing 24% ginkgo heterosides (flavoglycosides), at a dose of 40 mg three times a day. However, some studies have used the higher dosage of 80 mg two to three times daily.

It is difficult to devise a dosage schedule using other forms of ginkgo due to extreme variation in the content of active compounds in dried leaf and crude extracts. Whatever form of ginkgo is used, it appears to be essential that it is standardized for content and activity. For example, a standard 1:5 tincture obtained from the highest possible flavonoid content crude ginkgo leaf would require 1 ounce of the tincture/day to provide the equivalent dosage level of the standardized extract.

Clinical research clearly shows that GBE should be taken consistently for at least 12 weeks in order to determine effectiveness. Although most people report benefits within 2–3 weeks, some may take longer to respond.

TOXICITY

GBE is extremely safe and side-effects are uncommon. In 44 double-blind studies involving 9,772 patients taking GBE, the number of side-effects reported was extremely small. The most common side-effect, gastrointestinal discomfort occurred in only 21 cases, followed by headache (seven cases) and dizziness (six cases).^{[2] [3] [4]}

In contrast to the tolerance of the leaf extract, contact with or ingestion of the fruit pulp has produced severe

allergic reactions.^[40] Contact with the fruit pulp causes erythema and edema, with the rapid formation of vesicles accompanied by severe itching. This is similar to an allergic reaction to the poison ivy-oak-sumac group, suggesting cross-reactivity between *Ginkgo biloba* fruit and this family. Ingestion of as little as two pieces of fruit pulp has been reported to cause severe gastrointestinal irritation from the mouth to the anus.

Chapter 89 - Glucosamine

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

INTRODUCTION

Glucosamine is a simple molecule, manufactured in the body from glucose and an amine. One of the primary physiological roles of glucosamine is in the joints where it stimulates the manufacture of glycosaminoglycans, key structural components of cartilage. Glucosamine also promotes the incorporation of sulfur into cartilage. Because of this effect, glucosamine sulfate is thought to be the best source of glucosamine.

As some people age, they apparently lose the ability to manufacture sufficient levels of glucosamine. The result is that synthesis of glycosaminoglycans does not keep up with degradation. The inability to manufacture glucosamine at an adequate rate has been suggested to be the major factor leading to osteoarthritis.

Food sources

There are no food sources of glucosamine. Commercially available sources of glucosamine are derived from chitin – the exoskeleton of shrimp, lobsters, and crabs.

Deficiency signs and symptoms

As stated above, it is thought that a deficiency of glucosamine is a major factor in the development of osteoarthritis. The weight-bearing joints, like the knees and hips, and joints of the hands are the tissues most often affected with osteoarthritis. In affected joints, there is substantial cartilage destruction followed by hardening and the formation of large bone spurs in the joint margins. Pain, deformity, and limited joint motion result. The

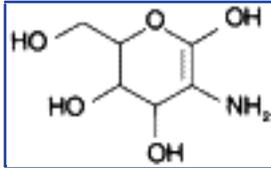

Figure 89-1 Glucosamine.

762

onset of osteoarthritis can be very subtle; morning joint stiffness is often the first symptom. As the disease progresses, there is pain on motion of the involved joint that is made worse by prolonged activity and relieved by rest.

Available forms

Glucosamine is commercially available as glucosamine sulfate, glucosamine hydrochloride, and *N*-acetyl-glucosamine. Glucosamine sulfate, the only form of glucosamine that has been the subject of over 300 scientific investigations and over 20 double-blind studies, is the preferred form. Glucosamine sulfate has also been used by millions of people worldwide and is registered as an aid in osteoarthritis in over 70 countries.

When authors or manufacturers discuss glucosamine hydrochloride or *N*-acetyl-glucosamine (NAG), if references are provided all clinical studies have used glucosamine sulfate and no other form. Only glucosamine sulfate provides proven clinical effectiveness.

Glucosamine sulfate vs. NAG

NAG differs from glucosamine sulfate in that instead of a sulfur molecule, NAG has a portion of an acetic acid molecule attached to it. Glucosamine sulfate and NAG are entirely different molecules and appear to be handled by the body differently. Companies marketing *N*-acetyl-glucosamine (NAG) claim that this form is better absorbed, more stable, and is better utilized than glucosamine sulfate. These contentions are without support in the scientific literature. Detailed human studies on the absorption, distribution, and elimination of orally administered glucosamine sulfate have shown an absorption rate of as high as 98% and that once absorbed it is then distributed primarily to joint tissues where it is incorporated into the connective tissue matrix of cartilage, ligaments, and tendons.^{[1] [2]} In addition, there are impressive clinical studies on thousands of patients. In contrast, there has never been a double-blind study using NAG for any application. Nor have there ever been any detailed absorption studies on NAG in humans.

Further evidence of the superiority of glucosamine sulfate to NAG is offered by studies in laboratory animals. Several studies have demonstrated that glucosamine absorption and utilization is at least twice that of NAG.^{[3] [4] [5] [6] [7] [8] [9] [10] [11] [12] [13] [14]} The researchers

have concluded that:^[5]

glucosamine is a more efficient precursor of macromolecular hexosamine [glycosaminoglycans] than N-acetylglucosamine. It is possible that N-acetylglucosamine does not penetrate the cell membranes and, as a result, is not available for incorporation into glycoproteins and mucopolysaccharides.

The body preferentially utilizes glucosamine sulfate rather than NAG. This preference appears largely due to the active processes which enhance absorption of glucosamine sulfate in the intestines.^[15]

The absorption of NAG by humans is poor for several reasons:

- NAG is quickly digested by intestinal bacteria
- NAG binds with dietary lectins in the gut, resulting in a lectin-NAG complex which is excreted in the feces
- a large percentage of NAG is metabolized by intestinal cells.

In addition to the question of absorption, several studies have shown that the articular tissue is not able to utilize NAG as well as it does glucosamine.^{[4] [5]} These absorption and utilization problems suggest NAG is highly unlikely to possess the same kind of anti-arthritic and anti-inflammatory properties that glucosamine sulfate has been shown to possess.

Glucosamine sulfate vs. glucosamine HCl

Research has shown that sulfur is an extremely important component in the therapeutic effect of glucosamine sulfate, its substitution is likely to decrease the efficacy of supplemental glucosamine.^[16] Sulfur is an essential nutrient for joint tissue where it functions in the stabilization of the connective tissue matrix of cartilage, tendons, and ligaments. Even healthy humans have low serum sulfate (0.3–0.4 mM) and synovial sulfur levels, but in osteoarthritis these concentrations are even lower. As far back as the 1930s, researchers demonstrated that individuals with arthritis are commonly deficient in this essential nutrient.^{[17] [18]} Restoring sulfur levels brought about significant benefit to these patients.^[18] In addition to sulfur playing a critical role in the manufacture of glycosaminoglycans (GAGs) like chondroitin sulfate and keratan sulfate, sulfur has been shown to inhibit the various enzymes which lead to cartilage destruction in osteoarthritis (e.g. collagenase, elastases, and hyaluronidase).^{[16] [19]}

Because one of the primary effects of glucosamine sulfate is to promote the manufacture of GAGs, a lack of the sulfur moiety may mean less GAG synthesis when glucosamine HCl is used. Therefore, it is unlikely that glucosamine HCl will show the same excellent clinical results achieved with glucosamine sulfate, because it lacks this critical element.

In fact, preliminary results indicate that glucosamine hydrochloride may be no more

effective than a placebo in relieving osteoarthritis. The results of the first clinical trial featuring glucosamine hydrochloride were announced at the 12th Panamerican Conference of Rheumatology by Joseph Houpt, Chief of Rheumatology, Mount Sinai Hospital in Toronto, Ontario, July 1998. The double-blind, placebo-controlled 10-week study examined the effects of glucosamine hydrochloride in patients with osteoarthritis

of the knee. Patients received either 500 mg of glucosamine hydrochloride or a placebo three times daily. Forty-five patients received glucosamine hydrochloride, while 53 received the placebo. The results indicated that 49% of patients receiving glucosamine hydrochloride felt they had improved compared to 45% of the placebo group who said they felt improved. However, the difference between the two groups was not statistically significant. What these results call into question is the viability of glucosamine hydrochloride as an effective form of glucosamine.

The more than 20 published clinical trials with glucosamine sulfate have demonstrated a success rate of 72% to 95% in various forms of osteoarthritis. In osteoarthritis of the knee the success rate is over 80%. Clearly, the success rate noted by glucosamine hydrochloride in this preliminary study is much less than the rate reported with glucosamine sulfate.

CLINICAL APPLICATIONS

The primary use for glucosamine sulfate is in the treatment of osteoarthritis. Glucosamine is a safe and effective natural alternative to aspirin and other non-steroidal anti-inflammatory drugs (NSAIDs) in the treatment of osteoarthritis. Clinical and experimental research is indicating that current drugs being used in osteoarthritis may be producing short-term benefit, but actually accelerating the progression of the joint destruction. NSAIDs tend to inhibit cartilage repair by inhibiting glycosaminoglycan synthesis and the incorporation of sulfur into cartilage.^{[20] [21]} Since osteoarthritis is caused by a degeneration of cartilage, it appears that while NSAIDs are fairly effective in suppressing the symptoms, they possibly worsen the condition by inhibiting cartilage formation and accelerating cartilage destruction (see [Ch. 176](#) for further discussion).^[22]
^{[23] [24] [25]}

Osteoarthritis

Numerous double-blind studies have shown glucosamine sulfate to produce much better results compared with NSAIDs and placebos in relieving the pain and inflammation of osteoarthritis. In one of the more recent studies comparing glucosamine sulfate with a placebo, 252 patients with osteoarthritis of the knee were given either a placebo or 500 mg of glucosamine sulfate three times daily for 4 weeks.^[26] Results indicated that glucosamine sulfate was significantly more effective than the placebo in improving pain and movement after 4 weeks. Previous studies have shown that the longer glucosamine sulfate is used, the greater the therapeutic benefit. The rate and

severity of side-effects with glucosamine did not differ from the placebo. These results are consistent with other double-blind studies versus a placebo.^{[27] [28] [29] [30]}

Head-to-head double-blind studies have shown glucosamine sulfate to produce much better results compared with NSAIDs in relieving the pain and inflammation of osteoarthritis, despite the fact that glucosamine sulfate exhibits very little direct anti-inflammatory effect and no direct analgesic or pain relieving effects.^{[31] [32] [33] [34]} While NSAIDs offer purely symptomatic relief and may actually promote the disease process, glucosamine sulfate appears to address the cause of osteoarthritis. By promoting cartilage synthesis, thus treating the root of the problem, glucosamine sulfate not only relieves the symptoms, but also helps the body to repair damaged joints. The clinical effect is impressive, especially when glucosamine's safety and lack of side-effects are considered.

In one of the earlier comparative studies in which glucosamine sulfate (1,500 mg/day) was compared with ibuprofen (1,200 mg/day), pain scores decreased faster in the first 2 weeks in the ibuprofen group. However, by week 4 the group receiving the glucosamine sulfate experienced a significantly better improvement than the ibuprofen group.^[31] Physicians rated the overall response as good in 44% of the glucosamine sulfate-treated patients as compared with only 15% of the ibuprofen group.

Three more recent studies designed to further evaluate the comparative effectiveness of glucosamine sulfate to NSAIDs provide even better evidence. The first study consisted of 200 subjects with osteoarthritis of the knee given either glucosamine sulfate (500 three times daily) or ibuprofen (400 mg three times daily) for four weeks.^[32] Consistent with previous studies, the ibuprofen group experienced quicker pain relief. However, by the end of the second week the group taking glucosamine sulfate experienced as good results as the ibuprofen group with one major exception – while the rate of side-effects with glucosamine were mild and only affected 6% of the group, ibuprofen produced more significant side-effects much more frequently, with 35% of the group experiencing them.

In the second study, 329 patients were given 1,500 mg glucosamine sulfate, 20 mg piroxicam, both compounds,

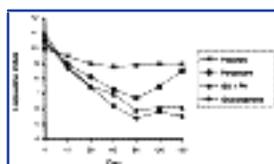

Figure 89-2 Symptom relief (Lequesne index) from glucosamine compared with piroxicam and placebo.

TABLE 89-1 -- Side-effects and drop-outs from glucosamine compared with piroxicam and placebo

| | Placebo | GS | Piroxicam | GS + piroxicam |
|---------------------------|----------------|-----------|------------------|-----------------------|
| Incidence of side-effects | 24.4% | 14.8% | 40.9% | 5.9% |
| Drop-outs | 3 | 0 | 20 | 3 |

GS, glucosamine sulfate.

or a placebo for 90 days.^[33] The main efficacy variable was represented by the Lequesne index, a standard method of assessing disease activity. As can be seen in [Figure 89.1](#) , the results of the study were strikingly in favor of glucosamine sulfate alone.

These impressive results with glucosamine sulfate were achieved without side-effects. In fact, patients on glucosamine sulfate had fewer side-effects than the placebo and no drop-outs (the side-effect and drop-out values among the four groups are shown in [Table 89.1](#)).

In the third study, 178 patients suffering from osteoarthritis of the knee were randomized into two groups.^[34] One group received 1,500 mg of glucosamine sulfate per day, the other received 1,200 mg of ibuprofen. Treatment lasted for 4 weeks. Outcome measurements included knee pain at rest, at movement, and at pressure; knee swelling; overall improvement rated by the investigators, and adverse effects.

Knee pain (average score)

| Time | Glucosamine sulfate | Ibuprofen |
|-------------------------|---------------------|-----------|
| Before treatment | 8.42 | 8.46 |
| Week 2 | 5.54 | 5.63 |
| Week 4 | 3.60 | 4.18 |
| 2 weeks after treatment | 3.26 | 3.84 |

Knee swelling (average score)

| Time | Glucosamine sulfate | Ibuprofen |
|-------------------------|---------------------|-----------|
| Before treatment | 1.43 | 1.48 |
| Week 2 | 0.77 | 0.89 |
| Week 4 | 0.47 | 0.48 |
| 2 weeks after treatment | 0.36 | 0.54 |

Clinical improvement

| Effectiveness | Glucosamine sulfate | | Ibuprofen | |
|---------------|---------------------|---------------|---------------|---------------|
| | After 4 weeks | After 6 weeks | After 4 weeks | After 6 weeks |
| Symptom-free | 45% | 55% | 32% | 36% |
| Improved | 39% | 32% | 45% | 41% |
| Unchanged | 11% | 7% | 15% | 14% |
| Worsened | 5% | 6% | 8% | 9% |
| Side-effects | | | | |
| | Glucosamine sulfate | | Ibuprofen | |
| Side-effects | 6% | | 16% | |
| Drop-outs | 0% | | 10% | |

Clearly these results confirm previous studies showing glucosamine sulfate is more effective and safer than conventional therapy for osteoarthritis.

In addition to showing benefit in double-blind studies, oral glucosamine sulfate was shown to offer significant benefit in an open trial involving 252 doctors and 1,506 patients in Portugal.^[35] This large study provides valuable clinical information on the appropriate use of glucosamine sulfate. The patients received 500 mg of glucosamine sulfate three times daily over a mean period of 50 days. Symptoms of pain at rest, on standing, and on exercise and limited active and passive movements all improved steadily throughout the treatment period. Objective therapeutic efficacy was rated by doctors as “good” in 59% of patients, and “sufficient” in a further 36%. Although not a controlled study, a 95% response rate is very impressive. The results with glucosamine sulfate were rated by both doctors and patients as being significantly better than those obtained with previous treatment, including NSAIDs, vitamin therapy, and cartilage extracts. Glucosamine sulfate produced good benefit in a significant portion of patients who had not responded to any other medical treatment.

In the study, obesity was associated with a significant shift from good to fair. This finding may indicate that higher dosages may be required for obese individuals or that oral glucosamine is not enough to counteract the added stress of obesity on the joints. Patients with peptic ulcers and individuals taking diuretics were also associated with a shift from good to sufficient in efficacy, as well as tolerance. Individuals with current peptic ulcers should try and take glucosamine sulfate with foods. Individuals taking diuretics may need to increase the dosage to compensate for the reduced effectiveness. The improvement with glucosamine lasted for 6–12 weeks after the end of treatment.

DOSAGE

The standard dosage for glucosamine sulfate is 500 mg three times per day. Obese

individuals may need higher dosages based on body weight (e.g. 20 mg/kg body weight daily). Also, individuals taking diuretics may also need to take higher dosages.

TOXICITY

Glucosamine sulfate has an excellent safety record in animal and human studies. Based on these studies, many experts have recommended that glucosamine sulfate “be considered as a drug of choice for prolonged oral treatment of rheumatic disorders”. Side-effects, when they do appear, are generally limited to light to moderate gastrointestinal symptoms, including stomach upset, heartburn,

765

diarrhea, nausea, and indigestion. If these symptoms occur, the glucosamine sulfate should be taken with meals.

In regards to people who are “sulfur-sensitive”, an important distinction needs to be made. When patients report they are allergic to sulfur, what they usually mean is that they are allergic to the so-called sulfa drugs or sulfite-containing food additives. It is impossible to be allergic to sulfur as sulfur is an essential mineral. The sulfate form of sulfur is present in human blood. In short, glucosamine sulfate is extremely well-tolerated and no allergic reactions have been reported.

Chapter 90 - *Glycyrrhiza glabra* (licorice)

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

Glycyrrhiza glabra (family: Leguminosae)
Common names: licorice, glycyrrhiza

GENERAL DESCRIPTION

Glycyrrhiza is a perennial, temperate zone herb or subshrub, 3–7 feet high, with a long, cylindrical, branched, flexible, and burrowing rootstock with runners. The parts used are the dried runners and roots, which are collected in the fall.

CHEMICAL COMPOSITION

The major active component of licorice root is the triterpenoid saponin glycyrrhizin (also known as glycyrrhizic acid or glycyrrhizinic acid) (Fig. 90.1), which is usually found in concentrations ranging from 6 to 10%. The intestinal flora is believed to hydrolyze glycyrrhizin, yielding the aglycone molecule (glycyrrhetic acid) and a sugar moiety, resulting in absorption of both.^[1]

A processed licorice extract, deglycyrrhizinated licorice (DGL), which is used in the treatment of peptic and aphthous ulcers, is made by removing the glycyrrhizin molecule. The active components of DGL are flavonoids. These compounds have demonstrated impressive protection against chemically induced ulcer formation in animal studies.^[2]

Other active constituents of licorice include isoflavonoids (isoflavonol, kumatakenin, licoricone, glabrol,

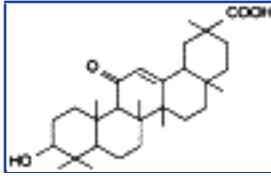

Figure 90-1 Glycyrrhizinic acid.

768

etc.), chalcones, coumarins (umbelliferone, herniarin, etc.), triterpenoids and sterols, lignins, amino acids, amines, gums and volatile oils.^[3]

HISTORY AND FOLK USE

The medicinal use of licorice in both Western and Eastern cultures dates back several thousand years. It was used primarily as a demulcent, expectorant, antitussive, and mild laxative. Licorice is one of the most popular components of Chinese medicines. Its traditional uses include treating peptic ulcers, asthma, pharyngitis, malaria, abdominal pain, insomnia, and infections.^[3]

PHARMACOLOGY

Licorice is known to exhibit many pharmacological actions, including the following:^[3]

- estrogenic
- aldosterone-like action
- anti-inflammatory (cortisol-like action)
- anti-allergic
- antibacterial, antiviral, and antitrichomonas
- antihepatotoxic
- anticonvulsive
- choleric
- anti-cancer
- expectorant
- antitussive activities.

The majority of these actions are discussed individually below.

Although much of the pharmacology focuses on glycyrrhizin and glycyrrhetic acid, it should be kept in mind that licorice has many other components, such as flavonoids, that may have significant pharmacological effects.

Estrogenic activity

Glycyrrhizin exhibits alterative action upon estrogen metabolism – i.e. when estrogen levels are too high, it will inhibit estrogen action, and when estrogens are too low, it will

potentiate estrogen action when used in greater amounts.^[4] Glycyrrhetic acid has been shown to antagonize many of the effects of estrogens, particularly exogenous estrogens.^[5] The estrogenic action of glycyrrhiza is due to its isoflavone content, as many isoflavone structures (e.g. daidzein and genistein from soy) are known to possess estrogenic effect. This effect has been demonstrated in experimental animal studies using the crude extract, suggesting that the estrogenic activity of the isoflavones are more significant than the estrogen antagonism of glycyrrhetic acid.

Pseudoaldosterone activity

The chronic ingestion of glycyrrhiza in large doses leads to a well-documented pseudoaldosteronism syndrome, i.e. hypertension, hypokalemia, sodium and water retention, low plasma renin activity, and suppressed urine and serum aldosterone levels.^{[6] [7] [8] [9] [10] [11]} In normal subjects, the amount of glycyrrhizin needed to produce these side-effects is between 0.7 and 1.4 g, which corresponds to approximately 10–14 g of the crude herb.^[7] Although glycyrrhiza possesses mineralocorticoid activity (about four orders of magnitude lower than aldosterone) and binds to aldosterone receptors, it is largely without effect in adrenalectomized animals or in patients with severe adrenocorticoid insufficiency. Therefore, it can be concluded that its primary effects are largely as a result of glycyrrhetic acid inhibiting the breakdown of aldosterone in the liver.^[12] Glycyrrhizin and glycyrrhetic acid have been shown to suppress 5-beta-reductase, the main enzyme in humans responsible for inactivating cortisol, aldosterone, and progesterone. These effects can be put to good use in the treatment of Addison's disease, a severe disease of adrenal insufficiency.^[11]

Anti-inflammatory and anti-allergic activity

Glycyrrhiza has significant anti-inflammatory and anti-allergic activity.^{[13] [14]} Although both glycyrrhizin and glycyrrhetic acid bind to glucocorticoid receptors, and much of glycyrrhiza's anti-inflammatory activity has been explained by its "cortisol-like effects", many of the effects of glycyrrhiza actually antagonize or counteract cortisol.^[15] Included are antagonism to such actions of cortisol as activation of tryptophan oxygenase, accumulation of hepatic glycogen, stimulation of hepatic cholesterol synthesis, inhibition of thymus atrophy, and inhibition of ACTH synthesis and secretion. Glycyrrhizin does, however, reinforce cortisol's inhibition of antibody formation, stress reaction, and inflammation. Like its mineralocorticoid effect, glycyrrhiza's major influence on glucocorticoid metabolism is probably related to its suppression of 5-beta-reductase activity, thus increasing the half-life of cortisol.

Glycyrrhiza's major cortisol-like effect relates to its ability to inhibit phospholipase-A2.^[16] This enzyme is responsible for cleaving lipids from biomembranes for eicosanoid metabolism. In addition to this effect, glycyrrhizin has also been shown to inhibit cAMP-phosphodiesterase, thereby raising cAMP levels and prostaglandin formation by activated peritoneal macrophages from rats.^{[17] [18]} Glycyrrhizin has been shown to inhibit experimentally induced allergenic reactions, such as the Arthus' phenomenon, the Schwartzman's phenomenon, and Forssman's anaphylaxis, and to be an antidote against many toxins, including diphtheria, tetanus, and tetrodotoxin.^{[18] [19]}

Immunostimulatory and antiviral effects

Glycyrrhizin and glycyrrhetic acid have been shown to induce interferon.^[20] The induction of interferon leads to significant antiviral activity, as interferons bind to cell surfaces where they stimulate synthesis of intracellular proteins that block the transcription of viral DNA. The induction of interferon is also followed by activation of macrophages and augmentation of natural killer cell activity.

Glycyrrhizin has been shown to directly inhibit the growth of several DNA and RNA viruses in cell cultures (vaccinia, herpes simplex, Newcastle disease, and vesicular stomatitis viruses) and to inactivate herpes simplex 1 virus irreversibly.^[21] Glycyrrhizin, as stated above, also inhibits the thymolytic and immunosuppressive action of cortisone.

Antibacterial activity

Alcohol extracts of glycyrrhiza have displayed antimicrobial activity in vitro against *Staphylococcus aureus*, *Streptococcus mutans*, *Mycobacterium smegmatis*, and *Candida albicans*.^[22] The majority of the antimicrobial effects are due to isoflavonoid components, with the saponins having a lesser antibacterial effect.

Antihepatotoxic activity

Glycyrrhetic acid inhibits carbon tetrachloride and galactosamine-induced liver damage. The mechanism of action is prevention of non-enzymatic lipid peroxidation and inhibition of the production of free radicals by the enzymatic action of NADPH-cytochrome P450 reductase on CCl₄.^[23]

CLINICAL APPLICATIONS

The clinical applications of licorice can be divided into three main categories:

- use of oral licorice preparations containing glycyrrhetic acid
- use of deglycyrrhizinated licorice (DGL)
- use of topical preparations containing glycyrrhetic acid.

Key uses of oral licorice include:

- viral infections (e.g. the common cold, HIV and AIDS, viral hepatitis)
- premenstrual syndrome (PMS)
- acute intermittent porphyria
- Addison's disease, inflammation

- as a sweetening agent.

The key use of DGL is in ulcerative conditions of the gastrointestinal tract (e.g. peptic ulcers, canker sores, and inflammatory bowel disease). Topical preparations containing glycyrrhetic acid can be used in eczema, psoriasis, and herpes.

Preparations containing glycyrrhetic acid

The common cold

Licorice has long been used in treating the symptoms of the common cold. This historical use is justified by its immune-enhancing and antiviral effects.

HIV and AIDS

Glycyrrhizin-containing preparations are showing promise in the treatment of human immunodeficiency virus (HIV) related diseases including AIDS. Although much of the research has featured intravenous administration, this route of administration may not be necessary, as glycyrrhizin and glycyrrhetic acid are easily absorbed orally and are well-tolerated. This is most evident in a recent double-blind study on the clinical effectiveness of glycyrrhizin by long-term oral administration to 16 hemophiliac patients with evidence of HIV infection.^[24] Patients received daily doses of 150–225 mg of glycyrrhizin for 3–7 years. Helper and total T-lymphocyte numbers, other immune system parameters, and glycyrrhizin and glycyrrhetic acid levels in the blood were monitored. The results indicated that orally administered glycyrrhizin was converted into glycyrrhetic acid which was detected in sera, without manifesting any side-effect. None of the patients given the glycyrrhizin had progression of immunologic abnormalities or development to AIDS. In contrast, the group not receiving glycyrrhetic acid showed decreases in helper and total T-cell counts and antibody levels. Two of the 16 patients in the control group developed AIDS.

In another study, 10 HIV positive patients without AIDS took 150–225 mg glycyrrhizin daily.^[25] After 1–2 years, none developed symptoms associated with AIDS or AIDS-related complex (ARC), while one of 10 patients of a matched control group developed ARC and two progressed to AIDS and subsequently died.

The result of glycyrrhizin in HIV-positive and AIDS patients is almost immediate improvement in immune function. In one study, nine symptom-free HIV-positive patients received 200–800 mg glycyrrhizin in vitro daily. After 8 weeks., the groups had increased helper T-cells, improved helper/suppressor ratios and improved liver function.^[26]

In another study, six AIDS patients received 400– 1,600 mg glycyrrhizin in vitro daily.^[27] After 30 days, five of the six showed a reduction or disappearance of the P24 antigen which indicates active disease.

The results of these studies and others in HIV-positive and AIDS patients are

encouraging.

Hepatitis

Some of the studies in HIV patients used an intravenous glycyrrhizin-containing product, Stronger Neominophagen C (SNMC), consisting of 0.2% glycyrrhizin, 0.1% cysteine and 2.0% glycine in physiological saline solution. This product is used in Japan primarily for the treatment of hepatitis. The other components, glycine and cysteine, appear to modulate glycyrrhizin's actions. Glycine has been shown to prevent the aldosterone effects of glycyrrhizin, while cysteine aids in the liver in detoxification reactions.

In addition to AIDS, SNMC has demonstrated impressive results in treating chronic hepatitis B, one of the most difficult infections for the body to clear.^{[19] [28] [29]} SNMC has been shown to improve liver function and lower levels of liver enzymes. Approximately 40% of patients will have complete resolution.

Premenstrual syndrome

The symptoms of the premenstrual syndrome (depression, craving for sweets, weight gain due to water retention, breast tenderness, etc.) have been largely attributed to an increase in the estrogen to progesterone ratio. As licorice is considered to have alterative action on estrogen metabolism, and both glycyrrhizin and glycyrrhetic acid possess anti-estrogenic effect and suppress the breakdown of progesterone, administration of licorice 2 weeks prior to the onset of menstruation (the mid-luteal phase) may help to reduce PMS symptomatology.

Acute intermittent porphyria (AIP)

This disorder of heme biosynthesis is characterized by recurrent attacks of neurological and psychiatric dysfunction. The symptoms include:

- abdominal complaints of nausea, vomiting and colicky pain, occasionally severe enough to present as an acute abdomen without fever or leukocytosis
- variable neurological signs and symptoms, e.g. paresthesia, hypesthesia, neuritic pain, wrist or foot drop, loss of deep tendon reflexes, etc.
- variable mental and emotional disturbances, typically restlessness, disorientation, and visual hallucinations (which are seen in one-third of the patients).

As estrogens are known to exacerbate or induce AIP, it is quite possible that some of the so-called PMS symptoms are exacerbations of AIP due to the midcycle estrogen surge.

A partial (50%) deficiency of uroporphyrinogen I synthase results in increased inducibility

of aminolevulinic acid (ALA) synthase by drugs and foreign chemicals and by 5-beta-reductase steroid metabolites (very potent inducers of ALA synthase). AIP is also associated with a marked deficiency in the activity of 5-alpha-reductase, resulting in increased 5-beta-reductase activity.^[30] Glycyrrhetic acid and glycyrrhizin have been shown to significantly reduce 5-beta-reductase while increasing 5-alpha-reductase.^[31] (Note that lead also increases 5-beta-reductase activity, resulting in a presenting picture similar to AIP.^[31] Chronic or acute lead toxicity must be ruled out in these patients.)

Addison's disease

As described above, licorice exerts an "aldosterone-like effect" useful in treating Addison's disease.

Inflammation

Virtually any inflammatory or allergic condition may be reduced by licorice by the mechanisms discussed above in the "Pharmacology" section ([p. 768](#)). Historically, licorice has been successfully used for treating asthma and other atopic conditions.^[3] ^[13]

Licorice has been shown to enhance the action of corticosteroids like prednisone and prednisolone, as well as the levels of the body's own corticosteroids.^[32] ^[33] In one study, six subjects received an i.v. dose of prednisolone with or without 200 mg glycyrrhizin. Glycyrrhizin was found to increase significantly the concentration of total and free prednisolone by inhibiting its breakdown. Furthermore, the effects of prednisolone appeared to be potentiated by glycyrrhizin.^[33]

Sweetening agent

As glycyrrhizin is 50–100 times sweeter than sucrose, licorice can be used as a sweetening or flavoring agent to mask the bitter taste of other medications.^[3]

Preparations without glycyrrhetic acid

Peptic ulcer

By far, the most popular medicinal use of licorice in the United States is in the treatment of peptic ulcers. Original research focused on glycyrrhetic acid. In fact, glycyrrhetic acid was the first drug proven to promote healing of gastric and duodenal ulcers.^[34] Most researchers and most physicians using licorice in the treatment of peptic ulcers now use deglycyrrhizinated licorice (DGL). DGL was actually shown to be more effective than glycyrrhetic acid, without side-effects.^[35]

DGL's mode of action is different than the current drugs, such as antacids and H₂-receptor antagonists, which focus on reducing gastric acidity. Though effective,

these treatments can be expensive, carry some risk of toxicity, disrupt normal digestive processes, and alter the structure and function of the cells that line the digestive tract. The latter factor is just one of the reasons why peptic ulcers will develop again if antacids, cimetidine, ranitidine, and similar drugs are used.

Rather than inhibit the release of acid, DGL stimulates the normal defense mechanisms that prevent ulcer formation and stimulate healing of the damaged mucous membranes. Specifically, DGL:^[36] ^[37]

- increases the blood supply to the damaged mucosa
- increases the number of cells producing the mucous that protects the mucous membranes
- increases the amount of mucous the cells produce, and increases the life span of the intestinal cell.

Numerous clinical studies over the years have found DGL to be an effective anti-ulcer compound. DGL has been shown to be extremely effective in the treatment of gastric ulcers.^[38] ^[39] ^[40] ^[41] ^[42] In one study, 33 gastric ulcer patients were treated with either DGL (760 mg, three times a day) or a placebo for 1 month.^[41] There was a significantly greater reduction in ulcer size in the DGL group (78%), than in the placebo group (34%). Complete healing occurred in 44% of those receiving DGL, but only in 6% of the placebo group.

Comparison to conventional anti-ulcer drugs

In several head to head comparison studies, DGL has been shown to be more effective than cimetidine (Tagemet), ranitidine (Zantac), or antacids in both short-term treatment and maintenance therapy of peptic ulcers.^[38] ^[39] ^[43] However, while these drugs are associated with significant side-effects (see above), DGL is extremely safe and is only a fraction of the cost.

Subsequent studies have shown DGL to be as effective as Tagemet and Zantac for both short-term treatment and maintenance therapy of gastric ulcer.^[38] ^[39] ^[40] For example, in a head to head comparison with Tagemet, 100 patients received either DGL (760 mg, three times a day between meals) or Tagemet (200 mg, three times a day and 400 mg at bedtime).^[39] The percentage of ulcers healed after 6 and 12 weeks were similar in both groups. Yet, while Tagemet is associated with some toxicity, DGL is extremely safe to use.

Gastric ulcers are often a result of the use of alcohol, aspirin or other non-steroidal anti-inflammatory drugs, caffeine, and other factors that decrease the integrity of the gastric lining. As DGL has been shown in human studies to reduce the gastric bleeding caused by aspirin, DGL is strongly indicated for the prevention of gastric ulcers in patients requiring long-term treatment with ulcerogenic drugs, such as aspirin,

non-steroidal anti-inflammatory agents, and corticosteroids.^[42]

Duodenal ulcers

DGL is also effective in duodenal ulcers. This is perhaps best illustrated by one study in patients with severe duodenal ulcers. In the study, 40 patients with chronic duodenal ulcers of 4–12 years' duration and more than six relapses during the previous year were treated with DGL.^[44] All of the patients had been referred for surgery because of relentless pain, sometimes with frequent vomiting, despite treatment with bed rest, antacids, and anticholinergic drugs. Half of the patients received 3 g of DGL daily for 8 weeks; the other half received 4.5 g/day for 16 weeks. All 40 patients showed substantial improvement, usually within 5–7 days, and none required surgery during the 1 year follow-up. Although both dosages were effective, the higher dose was significantly more effective than the lower dose.

In another more recent study, the therapeutic effect of DGL was compared with that of antacids or cimetidine in 874 patients with confirmed chronic duodenal ulcers.^[43] Ninety-one percent of all ulcers healed within 12 weeks; there was no significant difference in healing rate in the groups. However, there were fewer relapses in the DGL group (8.2%) than in those receiving cimetidine (12.9%), or antacids (16.4%). These results, coupled with DGL protective effects, suggest that DGL is a superior treatment of duodenal ulcers.

Apthous ulcers

Recurrent aphthous stomatitis (canker sores) is a common problem. DGL may be effective in promoting healing. In one study, 20 patients were instructed to use a solution of DGL as a mouthwash (200 mg powdered DGL dissolved in 200 ml warm water) four times daily.^[45] Fifteen of the 20 (75%) experienced 50–75% improvement within 1 day, followed by complete healing of the ulcers by the third day. DGL in tablet form may produce even better results.

Topical application

Eczema and psoriasis

Glycyrrhetic acid exerts an effect similar to that of topical hydrocortisone in the treatment of eczema, contact and allergic dermatitis, and psoriasis. In fact, in several studies, glycyrrhetic acid was shown to be superior to topical cortisone, especially in chronic cases. For example, in one study in patients with eczema, 93% of the patients applying glycyrrhetic acid demonstrated improvement compared with 83% using cortisone.^[46]

Glycyrrhetic acid can also be used to potentiate the effects of topically applied hydrocortisone by inhibiting the 11-beta-hydroxysteroid dehydrogenase which catalyses the conversion of hydrocortisone to an inactive form.^[47]

Herpes simplex

Topical glycyrrhetic acid and derivatives have been shown, in clinical studies, to be quite helpful in reducing the healing time and pain associated with cold sores and genital herpes.^[48] ^[49] As mentioned earlier, glycyrrhizin inactivates herpes simplex 1 virus irreversibly and stimulates the synthesis and release of interferon.^[21]

DOSAGE

The dosage of licorice for most clinical applications is based upon the content of glycyrrhetic acid. The exception is in the treatment of peptic ulcer. In this application, deglycyrrhized licorice (DGL) is preferred as it produces equally effective results compared with glycyrrhetic acid, but is free from any side-effects.

For most purposes, the goal is to achieve a high level of glycyrrhetic acid in the blood without producing side-effects (discussed below). In general, the following three times a day dosages are safe and effective in raising glycyrrhetic acid levels:

- powdered root: 1–2 g
- fluid extract (1:1): 2–4 ml
- solid (dry powdered) extract (4:1): 250–500 mg.

In the treatment of AIDS, pure glycyrrhetic acid products or extracts standardized for glycyrrhetic acid are recommended. Toxicity can become a problem for patients taking licorice for any period longer than 1 month (see below).

Dosage instructions for DGL

In order to be effective in healing peptic ulcers, it appears that DGL must mix with saliva. DGL may promote the release of salivary compounds which stimulate the growth and regeneration of stomach and intestinal cells. DGL in capsule form has not been shown to be effective.^[50] ^[51]

The standard dosage for DGL is two to four 380 mg chewable tablets between or 20 minutes before meals. Taking DGL after meals is associated with poor results.^[52] DGL should be continued for 8–16 weeks, depending on the response.

TOXICITY

The main hazards of licorice administration are due to the aldosterone-like effects of glycyrrhetic acid. If ingested regularly, licorice root (greater than 3 g/day for more than 6 weeks) or glycyrrhizin (>100 mg/day) may cause sodium and water retention,

hypertension, hypokalemia, and suppression of the renin–aldosterone system. Monitoring of blood pressure and electrolytes and increasing dietary potassium intake is suggested.^[6] ^[7]

There is a great individual variation in the susceptibility to the symptom-producing effects of glycyrrhizin. Adverse effects are rarely observed at levels below 100 mg/day, while they are quite common at levels above 400 mg/day.^[7]

Prevention of the side-effects of glycyrrhizin may be possible by following a high-potassium, low-sodium diet. Although no formal trial has been performed, patients who normally consume high-potassium foods and restrict sodium intake, even those with high blood pressure and angina, have been reported to be free from the aldosterone-like side effects of glycyrrhizin.^[53]

Licorice should probably not be used in patients with a history of hypertension or renal failure, or those who are currently using of digitalis preparations.

Chapter 91 - *Hydrastis canadensis* (goldenseal) and other berberine-containing botanicals

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

Hydrastis canadensis (family: Ranunculaceae)

Common names: goldenseal, yellow root, Indian turmeric, eye root, jaundice root

Berberis vulgaris (family: Berberidaceae)

Common name: barberry

Berberis aquifolium (family: Berberidaceae)

Common names: Oregon grape, trailing mahonia

Coptis chinensis

Common name: goldthread

INTRODUCTION

The plants goldenseal (*Hydrastis canadensis*), barberry (*Berberis vulgaris*), Oregon grape (*Berberis aquifolium*), and goldthread (*Coptis chinensis*) share similar indications and effects due to their high content of berberis alkaloids. The chief berberis alkaloid, berberine, has been extensively studied in both experimental and clinical settings. Its pharmacological effects are reviewed below. The general description, history and folk use, chemical composition, and specific clinical indications for each plant are presented here. The pharmacology of these plants is primarily discussed in terms of the activity of berberine.

GENERAL DESCRIPTION

Hydrastis canadensis

Goldenseal is native to eastern North America and is cultivated in Oregon and Washington. It is a perennial herb with a knotty yellow rhizome from which arises a single leaf and an erect hairy stem. In early spring, it bears two five- to nine-lobed rounded leaves near the top, which are terminated by a single greenish-white flower. The parts used are the dried rhizome and roots.^[1] ^[2]

Berberis vulgaris

The common barberry is a deciduous spiny shrub that

776

may reach 16 feet in height. Native to Europe, it has been naturalized in eastern North America. Parts used are the barks of the stem and root.^[1] ^[2]

Berberis aquifolium

The Oregon grape is an evergreen spineless ornamental shrub, 3–7 feet in height, native to the Rocky Mountains from British Columbia to California. Parts used are the rhizome and roots.^[1] ^[2]

Coptis chinensis

Goldthread is a perennial herb native to China. The parts used are the rhizomes and root.^[3]

CHEMICAL COMPOSITION

Hydrastis canadensis

Alkaloids isolated from hydrastis include:

- hydrastine (1.5–4.0%)
- berberine (0.5–6.0%)
- berberastine (2.0–3.0%)
- canadine
- candaline
- hydrastinine
- other related alkaloids.

Other constituents include meconin, chlorogenic acid, phytosterins, and resins.^[1] ^[2]

Berberis vulgaris

Barberry contains several alkaloids in its roots:

- jatrorrhizine
- berberine
- berberubine
- berbamine
- bervulcine
- palmatine
- columbamine
- oxyacanthine.

It also contains chelidonic, citric, malic, and tartaric acids.^[1] ^[2]

Berberis aquifolium

Oregon grape contains the alkaloids berbamine, berberine, canadine, corypalmine, hydrastine, isocorydine, mahonine, and oxyacanthine. Resins and tannins have also been reported.^[1] ^[2]

Coptis chinensis

Goldthread root contains berberine (5–8%) and other alkaloids similar to those found in goldenseal.^[3]

HISTORY AND FOLK USE

Hydrastis canadensis

Native to North America, hydrastis was used extensively by the American Indian as an herbal medication and clothing dye. Its medicinal use centered around its ability to soothe the mucous membranes of the respiratory, digestive, and genitourinary tracts in inflammatory conditions induced by allergy or infection. The Cherokee and other Indian tribes used hydrastis in disorders of the eye and skin.^[1] ^[2]

Berberis vulgaris

This plant is native to most of Europe, and very similar species are found in North Africa and Asia. Barberry's historical use is as an antidiarrheal agent, bitter tonic, antipyretic, and antihemorrhagic.^[1] ^[2]

Berberis aquifolium

Oregon grape's historical and folk use is similar to that of hydrastis. In addition, Oregon grape was used in the treatment of chronic skin conditions such as acne, psoriasis, and eczema.^[1] ^[2]

Coptis chinensis

In China, goldthread was used in the traditional medicine system to “drain fire”. It was used primarily in infectious conditions similar to the historical use of goldenseal. Some specific uses included fever, dysentery, gastrointestinal infection, furuncles, boils, and eye infections.^[3]

PHARMACOLOGY

The medicinal value of hydrastis, barberry, Oregon grape root, and goldthread is thought to be due to their high content of isoquinoline alkaloids, of which berberine has been the most widely studied. Berberine has demonstrated antibiotic, immunostimulatory, anticonvulsant, sedative, hypotensive, uterotonic, cholorectic, and carminative activity. Berberine's pharmacological activities support the historical use of the berberine-containing herbs.

Antibiotic activity

Perhaps the most celebrated of berberine's effects has been its antibiotic activity. Although not as potent as many prescription antibiotics, berberine exhibits a broad spectrum of antibiotic activity. Berberine has shown antimicrobial activity against bacteria, protozoa, and fungi, including:^[1] ^[2] ^[3] ^[4] ^[5] ^[6] ^[7] ^[8] ^[9] ^[10]

- *Staphylococcus* sp.
 - *Streptococcus* sp.
-

- *Chlamydia* sp.
- *Corynebacterium diphtheria*
- *E. coli*
- *Salmonella typhi*
- *Vibrio cholerae*
- *Diplococcus pneumonia*
- *Pseudomonas* sp.
- *Shigella dysenteriae*
- *Entamoeba histolytica*
- *Trichomonas vaginalis*
- *Neisseria gonorrhoeae*
- *N. meningitidis*
- *Treponema pallidum*

- *Giardia lamblia*
- *Leishmania donovani*
- *Candida albicans*.

Its action against some of these pathogens is actually stronger than that of prescription antibiotics commonly used for these pathogens. Berberine's action in inhibiting *Candida*, as well as other pathogenic bacteria, prevents the overgrowth of yeast that is a common side-effect of antibiotic use. [Table 91.1](#) lists the in vitro sensitivity of various organisms to berberine sulphate.

The antimicrobial activity of berberine increases with pH in all organisms studied.^[5] At pH of 8.0, its antimicrobial activity in vitro is typically two to four times greater than it is at pH 7.0, which in turn is one to four times greater than at pH 6.0. This suggests that alkalization will improve its clinical efficacy, particularly in the treatment of urinary tract infections.

Anti-infective activity

Researchers investigated berberine's ability to inhibit the adherence of group A streptococci to host cells based on the fact that the therapeutic effect of berberine appeared to be greater than its direct antibiotic effects.^[11] Recent studies have shown that certain antimicrobial agents can block the adherence of microorganisms to host cells at doses much lower than those needed to kill cells or to inhibit cell growth.

Berberine's ability to inhibit the adhesion of streptococci to host cells has several modes of action. First, berberine causes streptococci to lose lipoteichoic acid (LTA). LTA is the major substance responsible for the adhesion of the bacteria to host tissues. Another important action of berberine is preventing the adhesion of fibronectin to the streptococci as well as eluting already bound fibronectin.

The significance of the results of this study are quite profound. It raises many questions and forces researchers as well as practitioners to look at the treatment of bacterial infections in a new light. Is it better to utilize a substance with bactericidal or bacteriostatic actions over

TABLE 91-1 -- In vitro sensitivity of microorganisms to berberine sulphate^{[5] [6] [9]}

| Organism | Inhibitory concentration (µg/ml)* |
|-----------------------------------|-----------------------------------|
| Bacteria | |

~Tested in a solid medium, which typically requires a four to 10 times greater concentration for the same level of inhibition.

* Minimum concentration that totally inhibits growth in a liquid medium at pH 8.0. Maximum concentration tested was 100 µg/ml, unless otherwise noted.

a substance which prevents the adherence of bacteria to host cells? Is the true value of botanicals with “anti-infective” actions a multifactorial effect on all aspects of infections

from immune stimulation to antimicrobial and anti-adherence actions?

The results of the study indicate that berberine interferes with infections due to group A streptococci not only by inhibiting streptococcal growth, but also by blocking these organisms to host cells. The study implies berberine-containing plants may be ideal in the treatment of “strep throat”, a condition historically treated with goldenseal by American naturopathic physicians. Berberine’s action in inhibiting *Candida albicans* prevents the overgrowth of yeast that is a common side-effect of antibiotic use.

Immunostimulatory activity

Berberine has been shown to increase the blood supply to the spleen.^[12] This improved blood supply may promote optimal activity of the spleen by increasing the

release of compounds, such as tuftsin, that potentiate immune function. Berberine has also been shown to activate macrophages, via both enhanced priming and triggering.^[13]

Anti-cancer effects

Berberine exhibits potent anti-cancer activity both directly by killing tumor cells and indirectly by stimulating white blood cells.^{[13] [14] [15]} The most impressive effect was noted in a study demonstrating antitumor activity against human and rat malignant brain tumors.^[15] Several experimental approaches were used in the study. In vitro studies were performed on a series of six human malignant brain tumor cell lines and rat 9L brain tumor cells. Berberine used alone at a dose of 150 mcg/ml showed an average cancer cell kill of 91%. This kill rate was over twice that of 1,3-bis(2-chloro-ethyl)-1-nitrosourea (BCNU), the standard chemotherapeutic agent for brain tumors, which had a cell kill rate of 43%. Studies in rats harboring solid 9L brain tumors also showed that berberine has antitumor effects. Rats treated with berberine, 10 mg/kg, had a 81% cell kill. However, the combination treatment, berberine and BCNU, exhibited additive effects on killing cancer cells. These results indicate that berberine may prove to be more effective than BCNU or, at the very least, a valuable therapeutic addition in the treatment of difficult brain cancers.

Antipyretic activity

Historically, berberine-containing plants have been used as febrifuges. Berberine produces an antipyretic effect three times as potent as aspirin in a pyretic model in rats.^[16] However, while aspirin suppresses fever through its action on prostaglandins, berberine appears to lower fever by increasing the immune system’s handling of fever-producing compounds from microorganisms.

CLINICAL APPLICATIONS

The broad antimicrobial effects of berberine combined with its anti-infective and immune-stimulating actions supports the historical use of berberine-containing plants in infections of the mucous membranes. Berberine-containing plants may also be useful as an adjunct to standard cancer therapy.

Infectious diarrhea

Berberine has shown significant success in the treatment of acute diarrhea in several clinical studies. It has been found effective against diarrheas caused by *E. coli* (traveler's diarrhea), *Shigella dysenteriae* (shigellosis), *Salmonella paratyphi* (food poisoning), *Klebsiella* sp., *Giardia lamblia* (giardiasis), and *Vibrio cholerae* (cholera).^[17]
^[18] ^[19] ^[20] ^[21] ^[22] ^[23] ^[24] ^[25] ^[26] ^[27] Studies in hamsters and rats have shown that berberine also has significant activity against *Entamoeba histolytica*, the causative organism of amebiasis.^[7] ^[8]

It appears that berberine is effective in treating the majority of common gastrointestinal infections. The clinical studies have produced results with berberine comparable to standard antibiotics in most cases. In fact, in several studies results were better.

For example, in a study of 65 children below 5 years of age with acute diarrhea caused by *E. coli*, *Shigella*, *Salmonella*, *Klebsiella* or *Faecalis aerogenes*, those given berberine tannate (25 mg/every 6 hours) responded better than those treated with standard antibiotic therapy.^[22]

In another study, 40 children aged 1–10 years infected with the parasite giardia received either berberine (5 mg/kg body weight each day), the drug metronidazole (10 mg/kg body weight each day), or a placebo of vitamin B syrup in three divided doses.^[23] After 6 days, 48% of patients treated with berberine were symptom-free and, on stool analysis, 68% were *Giardia*-free. In the metronidazole (Flagyl) group, 33% of patients were without symptoms and, on stool analysis, all were *Giardia*-free. In comparison, 15% of patients on placebo were asymptomatic and, on stool analysis, 25% were *Giardia*-free. These results indicate that berberine was actually more effective than metronidazole in relieving symptoms at half the dose, but was less effective than the drug in clearing the organism from the intestines.

And finally, in a study of 200 adult patients with acute diarrhea, the subjects were given standard antibiotic treatment with or without berberine hydrochloride (150 mg/day). The patients receiving berberine recovered more quickly.^[24] An additional 30 cases of acute diarrhea were treated with berberine alone. Berberine arrested diarrhea in all of these cases with no mortality or toxicity.

Despite these results, due to the serious consequences of an ineffectively treated infectious diarrhea due to highly pathogenic organisms, the best approach may be to

use berberine-containing plants as an adjunct to standard antibiotic therapy.

Much of berberine's effectiveness is undoubtedly due to a combination of its direct antimicrobial activity, inhibition of microbial attachment to mucous membranes and blocking of the action of toxins produced by several pathogenic bacteria.^{[28] [29] [30]} The toxin-blocking effect is most evident in diarrheas caused by enterotoxins (e.g., *Vibrio cholerae* and *E. coli*), cholera and traveler's diarrhea respectively.^{[25] [26] [27] [28]}

While cholera is a serious disorder that needs standard antibiotic therapy, traveler's diarrhea is usually self-limiting. Good results with berberine in the treatment of traveler's diarrhea have been obtained. In one study, patients with traveler's diarrhea randomly received

berberine sulfate 400 mg in a single dose or served as controls.^[27] In treated patients, the mean stool volumes were significantly less than those of controls during three consecutive 8 hour periods after treatment. At 24 hours after treatment, significantly more treated patients stopped having diarrhea as compared with controls (42% vs. 20%).

For those patients planning to travel to an underdeveloped country or an area of poor water quality or sanitation, the prophylactic use of berberine-containing herbs during, and 1 week prior to and after visiting may be useful.

Trachoma

Water extracts of berberine-containing plants have been employed in a variety of eye complaints, including infectious processes, by cultures throughout the world. Recently, berberine has shown remarkable effect in the treatment of trachoma.^{[31] [32]} Trachoma, an infectious eye disease due to the organism *Chlamydia trachomatis*, is a major cause of blindness and impaired vision in underdeveloped countries. It affects approximately 500 million people worldwide, and results in blindness in 2 million.

The drug sulphacetamide is currently the most widely used anti-trachoma drug. In clinical trials comparing berberine (0.2%) and sulphacetamide (20.0% solution), sulphacetamide showed the best improvement (decrease in conjunctival discharge, edema, and papillary reactions), but the conjunctival scrapings of all patients receiving sulphacetamide were still positive for *Chlamydia trachomatis*. These patients had a high rate of recurrence of the symptoms. In contrast, patients treated with the berberine solution showed very mild ocular symptoms, which disappeared more gradually, but their conjunctival scrapings were always negative for *Chlamydia trachomatis*. These patients did not suffer relapse even 1 year after treatment, which suggests that berberine is probably curative for trachoma.^{[31] [32]}

Berberine's efficacy is believed to be due to stimulation of some host defense

mechanism, rather than simply a direct action on the organism. As the berberine concentration used in these studies was 100 times less than the concentration of sulphacetamide, and berberine is much cheaper, it may be more cost-effective than other treatments for trachoma. Berberine (0.2% solution) is an appropriate therapy for many types of conjunctivitis.

Cholecystitis and cirrhosis of the liver

Berberine has been shown in several clinical studies to stimulate the secretion of bile (cholorectic effect) and bilirubin.^[33] ^[34] ^[35] In one study of 225 patients with chronic cholecystitis, oral berberine doses of 5–20 mg three times a day before meals caused, over a period of 24–48 hours, disappearance of clinical symptoms, decrease in bilirubin level, and an increase in the bile volume of the gall bladder.

Berberine has been shown to correct the hypertyraminemia of patients with liver cirrhosis. It prevents the elevation of serum tyramine following oral tyrosine load by inhibiting the enzyme tyrosine decarboxylase found in bacteria in the large intestine.^[35] Berberine inhibits tyrosine decarboxylase and tryptophanase activities of *Streptococcus faecalis* and *E. coli*, but not those of animal enzymes. Tyramine is believed to be responsible for some of the cardiovascular and neurological complications of liver disease, such as hepatic encephalopathy. The accumulation of tyramine and its derivatives may cause lowering of peripheral resistance, with resultant high cardiac output, reduction in renal function, and cerebral dysfunction. Berberine, by lowering plasma tyramine levels, helps prevent the complications of cirrhosis. This tyramine-lowering effect of berberine may have significance in other conditions as well.

Cancer

Berberine and another alkaloid found in berberine-containing plants, berbamine, have been shown to exert beneficial effects as adjuncts in cancer therapy. In fact, berbamine has been used in China since 1972 in the treatment of depressed white blood cell (WBC) counts due to chemotherapy and/or radiation.

In one study, 405 patients with WBC counts < 4,000 were given 150 mg of berbamine daily (50 mg orally three times daily) for 1–4 weeks. Berbamine was viewed as “significantly effective” if WBC increased to > 4,000 after 1 week or increased to > 1,000 after 2 weeks; “effective” if WBC increased to > 4,000 after 2 weeks or increased > 1,000 after 4 weeks; and “ineffective” if there was no change in WBC after 4 weeks of treatment. The overall results for the 405 patients are as follows:

- significantly effective in 163 cases (40.2%)
- effective in 125 cases (38.8%)
- ineffective in 117 cases (29%).

The total effective rate was 71%. However, WBC before therapy was related to overall effectiveness. The effective rate was only 54.8% in 31 cases where WBC was < 1,000

and 82.7% in cases where WBC count was between 3,100 and 3,800.^[36]

DOSAGES

As no detailed clinical studies have differentiated which berberine-containing herb to use for specific conditions, the following is offered only as a guideline based on experimental studies and historical use. However, the plants can be viewed as interchangeable.

780

Hydrastis canadensis. This is used in the treatment of:

- infective, congestive and inflammatory states of the mucous membranes
- digestive disorders
- gastritis
- peptic ulcers
- colitis
- anorexia
- painful menstruation.

Berberis vulgaris. This is used in the treatment of gall bladder disease, including gallstones, and as a less expensive form of berberine in the treatment of the conditions listed above for hydrastis.

Berberis aquifolium. This is used in the treatment of chronic skin diseases and in the conditions listed above for hydrastis.

Coptis chinensis. This is used in the treatment of infective, congestive and inflammatory states of the mucous membranes, fever, and infectious disorders of the skin.

The dosage should be based on berberine content. As there is a wide range of quality in goldenseal preparations, standardized extracts are recommended. Three times a day dosages as follows:

- dried root or as infusion (tea): 2–4 g
- tincture (1:5): 6–12 ml (1.5–3 tsp)
- fluid extract (1:1): 2–4 ml (0.5–1 tsp)
- solid (powdered dry) extract (4:1 or 8–12% alkaloid content): 250–500 mg.

TOXICITY

Berberine and berberine-containing plants are generally non-toxic at the recommended

dosages. However, berberine-containing plants are not recommended for use during pregnancy and higher dosages may interfere with B vitamin metabolism.

The oral LD₅₀ in rats for berberine is greater than 1,000 mg/kg body weight, indicating that the toxicity is extremely low.^[37]

Chapter 92 - 5-Hydroxytryptophan

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

INTRODUCTION

5-Hydroxytryptophan (5-HTP) is the intermediate between tryptophan and serotonin. Although 5-HTP may be relatively new to most clinicians, it has been available through pharmacies for several years and has been intensely researched for the past three decades. It has been used clinically since the 1970s.

TRYPTOPHAN AND 5-HTP METABOLISM

Once tryptophan is absorbed from the intestines, it is carried by the blood to the liver along with the other amino acids consumed during the meal. Ingested tryptophan can pass into the general circulation, it can be metabolized into blood proteins, or it can be converted to kynurenine (which then goes on to form nicotinic acid, picolinate and other important metabolites) in the liver. After conversion to kynurenine, it cannot be converted to serotonin. The same is likely true if the tryptophan is incorporated into blood proteins. Unchanged tryptophan can be converted to 5-HTP and then to serotonin. However, if this conversion occurs outside the brain, brain chemistry will not be influenced, and even under the best-case scenario only 3% of a dosage of L-tryptophan in supplemental or dietary form is likely to be converted to serotonin in the brain.^[1]

The manufacture of serotonin from tryptophan within the brain is highly dependent upon the level of tryptophan or 5-HTP which crosses the blood-brain barrier. While 5-HTP easily crosses the blood-brain barrier, the delivery of tryptophan into the brain is dependent upon several factors. The first factor of importance is the level of free tryptophan in the blood. There are a number of situations where the liver's conversion of tryptophan to kynurenine takes place at an elevated rate, i.e. stress, elevated cortisol levels, low B-vitamin status, and high dosages of L-tryptophan (i.e. greater than 2,000 mg). All of these situations lead to increased activity of the enzymes (tryptophan

oxidase and kynurenine formamidase) that

784

convert tryptophan to kynurenine. Elevated levels of kynurenine block the entry of tryptophan into the brain and lower brain serotonin levels. Increasing tryptophan intake makes matters worse when tryptophan oxidase activity is increased.

Unlike 5-HTP, which easily enters the brain, the transport of tryptophan across the blood–brain barrier involves the binding of tryptophan to a transport molecule. As tryptophan shares this transport vehicle with several other amino acids, when the ratio of tryptophan to these other amino acids is low (i.e. when the level of tryptophan is low and the level of the other amino acids is high), very little tryptophan is transported into the brain. The protein in almost all foods contains relatively small amounts of tryptophan and larger proportions of other amino acids. This low ratio of tryptophan to the other amino acids generally leads to low serotonin levels with a high-protein intake. Just the opposite occurs with a high-carbohydrate meal.

PHARMACOLOGY

Several pharmacokinetic studies have shown that about 70% of a dosage of 5-HTP taken orally is delivered to the bloodstream.^{[2] [3]} The remaining 30% is metabolized by intestinal cells.

Once absorbed, there is ample evidence from these pharmacokinetic studies as well as the clinical studies that 5-HTP is delivered to the brain, resulting in increased formation of not only serotonin, but also other brain chemicals such as other monoamines like melatonin, endorphins, dopamine, and norepinephrine. By raising brain serotonin levels (as well as by other effects), 5-HTP has shown positive effects in the various conditions associated with low serotonin levels.

Besides raising serotonin and melatonin levels, 5-HTP has been shown to raise beta-endorphin levels. Much of the pain-relieving and mood-elevating benefits of 5-HTP may be related more to its ability to enhance endorphin levels than to its ability to increase serotonin levels. This endorphin-increasing action is useful for both migraine and tension headache, fibromyalgia, as well other painful situations. In addition, raising endorphin levels produces significant effects on mood and behavior.

By raising serotonin (and melatonin) and beta-endorphin levels, 5-HTP produces a significant impact on helping to regulate and improve brain chemistry. But it goes well beyond affecting these systems, as 5-HTP has been shown also to raise the levels of other important neurotransmitters such as dopamine and norepinephrine.^[4] The ability of 5-HTP to increase both serotonin (and other indoleamines) and catecholamines is quite significant and unique to 5-HTP. It is an effect that 5-HTP does not share with L-tryptophan. The effective treatment of depression requires more than simply raising serotonin levels; catecholamine levels must also be increased. 5-HTP provides the brain

with both sets of tools.

In a head-to-head comparison study of 5-HTP and L-tryptophan in the treatment of depression, 5-HTP proved superior.^[5] The proposed reason is the fact that 5-HTP easily crosses the blood–brain barrier and is not affected by competing amino acids and 5-HTP affects brain chemistry in a broader and more positive fashion. L-Tryptophan is often effective in cases of low serotonin, especially insomnia, but 5-HTP is more broadly effective.

5-HTP vs.L-tryptophan

Nutrition-oriented physicians have long used precursor therapy for affecting brain chemistry. Unfortunately, L-tryptophan has produced inconsistent results. These inconsistent results are likely due to its inconsistent elevation of brain serotonin level.

There are many advantages of 5-HTP over L-tryptophan. Chief among them are that 5-HTP easily crosses the blood–brain barrier and is one step further on the path to serotonin synthesis. The conversion of tryptophan to 5-HTP by tryptophan hydrolase is the most important step in the manufacture of serotonin. This enzyme is inhibited by a number of factors, including:

- stress
- vitamin B₆ insufficiency
- low magnesium levels
- insensitivity to insulin
- various hormones
- genetic factors.

In addition, as noted above, these same factors and others are known to increase the activity of tryptophan oxygenase, increasing the conversion of L-tryptophan to kynurenine.

Perhaps the biggest advantage of 5-HTP over L-tryptophan is that it is safer. Although L-tryptophan is safe if properly prepared and free of the contaminants linked to eosinophilia myalgia syndrome (EMS), 5-HTP is inherently safer. The reasons are that taking L-tryptophan to produce positive effects in the treatment of depression, insomnia, and other low serotonin conditions requires a relatively high dosage (e.g. a minimum of 2,000 mg in insomnia and 6,000 mg in depression). At high dosages such as these, L-tryptophan is potentially problematic, as more L-tryptophan will be shunted towards the kynurenine pathway and L-tryptophan promotes oxidative damage. Excessive levels of dietary tryptophan or high dosages of L-tryptophan result in tryptophan actually acting as a free radical.^[6] By contrast, 5-HTP is an antioxidant.^[7] This antioxidant difference is due to the additional molecule of oxygen and hydrogen in 5-HTP. This simple change in molecular structure allows the phenolic ring structure to effectively accept or quench the unpaired electron of a free radical.

CLINICAL APPLICATIONS

There is a massive amount of evidence that suggests that low serotonin levels are a common consequence of modern living. The lifestyle and dietary practices of many people living in this stress-filled era result in lowered levels of serotonin within the brain. As a result, many people are overweight, crave sugar and other carbohydrates, experience bouts of depression, get frequent headaches, and have vague muscle aches and pain. All of these maladies are correctable by raising brain serotonin levels. The primary therapeutic applications for 5-HTP are low serotonin states, as listed in [Table 92.1](#).

Depression

Some of the first clinical studies on 5-HTP for the treatment of depression began in the early 1970s in Japan. The first study involved 107 patients with either unipolar depression or manic bipolar depression.^[9] These patients received 5-HTP at dosages ranging from 50 to 300 mg/day. The researchers observed a very quick response (within 2 weeks) in more than half of the patients. Seventy-four of

- Chronic pain disorders

the patients either experienced complete relief or were significantly improved, and none experienced significant side-effects. These promising results were repeated in several other Japanese studies. One of the interesting aspects in two of these studies was the fact that 5-HTP was shown to be effective in some patients (50% in one study, 35% in another) who had not responded positively to any other antidepressant agent.^{[9] [10]}

The most detailed of the Japanese studies was conducted in 1978.^[11] The study enrolled 59 patients with depression: 30 were male and 29 were female. The groups were mixed, in that both unipolar and bipolar depressions were included along with a number of other subcategories of depression. The severity of the depression in most cases was moderate to severe. Patients received 5-HTP in dosages of 50 or 100 mg three times daily for at least 3 weeks.

The antidepressant activity and clinical effectiveness of 5-HTP was determined by using a rating scale developed by the Clinical Psychopharmacology Research Group in Japan. The improvements among the various patients are detailed in [Table 92.2](#). These results indicate that 5-HTP was helpful in 14 out of 17 patients with unipolar depression and 12 out of 21 patients with bipolar depression. The degree of improvement in most cases ranged from excellent to very good.

The results achieved in this open study are quite good, given how rapidly they were achieved. Thirty-two of the 40 patients who responded to 5-HTP did so within the first 2 weeks of therapy. Typically, in most studies with antidepressant drugs the benefits are not apparent until after 2 weeks to 1 month of use. For this reason, the length of study when assessing antidepressant drugs should be at least 6 weeks, because it may take that long to significantly affect brain chemistry in a positive manner. In contrast, many of the studies with 5-HTP were shorter than 6 weeks because statistically significant results were achieved so soon ([Table 92.3](#)). However, the longer 5-HTP is used, the better are the results. Some people

TABLE 92-2 -- Improvement in various subtypes of depression

| Subtype | Improvement ^a | | | | | | |
|--------------------------------|--------------------------|---|---|---|---------|---|--------------------------|
| | 1 | 2 | 3 | 4 | 5, 6, 7 | 8 | 1+2+3/total ^b |

| Total | 1 | 6 | 17 | 8 | 7 | 1 |

may need to be on 5-HTP for at least 2 months before they experience the benefits.

The only major side-effect noted in this study was mild nausea. The occurrence of nausea due to 5-HTP is actually less frequent than that experienced with other antidepressant drugs (roughly 10% of subjects taking 5-HTP at a daily dosage equal to or less than 300 mg experience nausea compared with about 23% taking Prozac) and about the same as that which occurs with a placebo. In double-blind studies, about 10% or so of people taking the placebo typically complain of nausea. Nonetheless, very mild nausea may be a natural consequence of elevated serotonin levels with 5-HTP. About 30% of the 5-HTP taken orally is converted to serotonin in the intestinal tract. This can lead to a mild case of nausea. Fortunately, this effect wears off after a few of weeks of use.

A 5-HTP dosage of 300 mg is sufficient in most cases, but in some cases a higher dosage may be necessary. For example, in one study it was shown that 13 out of 18 subjects with depression given 5-HTP at a level of 150 or 300 mg/day experienced good to excellent results.^[12] This percentage of responders is quite good, but if we look at the level of serotonin in the blood as a rough indicator of brain serotonin levels, some interesting conclusions can be made (see [Table 92.4](#)).

The measurements in [Table 92.4](#) suggest that serotonin levels in depressed individuals are considerably lower than those found in normal subjects and that individuals who

respond to 5-HTP show a rise in serotonin to levels consistent with normal subjects. The level of serotonin in those who do not respond to 5-HTP remained quite low. These results imply that non-responders may require higher dosages to raise serotonin levels or that additional support may be necessary. When prescribing higher dosages, it is important that the 5-HTP be taken in divided dosages not only to reduce the problem with nausea, but also because rate of brain cell uptake of 5-HTP is limited.

TABLE 92-4 -- Level of serotonin in blood (ng/ml): controls, responders, and non-responders

| | Before | After 1 week (150 or 300 mg/day 5-HTP) |
|-----------------|--------|--|
| Normal subjects | 150 | |
| Responders | 78 | 148 |
| Non-responders | 56 | 77 |

The first studies of 5-HTP in a double-blind format (the Japanese studies) were open trials.^[13] The antidepressive effects of 5-HTP were also compared with L-tryptophan in the early 1970s.^[5] In one study, 45 subjects with depression were given L-tryptophan (5 g/day), 5-HTP (200 mg/day), or a placebo. The patients were matched in clinical features (age, sex, etc.) and severity of depression. The main outcome measure was the Hamilton Rating Scale for Depression (HDS), the most widely used assessment tool in clinical research in depression.

The HDS score is determined by having the test subject complete a series of questions where they rate the severity of their symptoms on a numerical basis, as follows:

- 0 – not present
- 1 – present but mild
- 2 – moderate
- 3 – severe
- 4 – very severe.

Symptoms assessed by the HDS include depression, feelings of guilt, insomnia, gastrointestinal symptoms and other bodily symptoms of depression (e.g. headaches, muscle aches, heart palpitations, etc.), and anxiety. The HDS is popular in research because it provides a good assessment of the overall symptoms of depression. [Table 92.5](#) shows the results of the study.

A review of head-to-head comparison studies showed that 5-HTP, at a dosage of 200 mg/day, produced therapeutic success on a par with tricyclic antidepressant drugs.^[14] Research has also shown that combining 5-HTP with clomipramine and other types of antidepressant drugs produces better results than any of the compound given alone.^[15] ^[16] ^[17] ^[18] ^[19] ^[20] For example, in one study, 5-HTP combined with a monoamine oxidase (MAO) inhibitor demonstrated significant advantages compared with the MAO inhibitor

alone (see [Table 92.6](#)).^[19]

This line of research suggests that 5-HTP might also be used in conjunction with St John's wort extract or *Ginkgo biloba* extract, two herbal medicines with proven antidepressant activity.

| After 15 days | 11.77 | 6.03 |

Because 5-HTP was very expensive back in 1972, researchers developed a test to determine who was most likely to respond to it, so that it would not be wasted on people who were unlikely to respond.^{[13] [21] [22] [23]} The test involved the patients first having a spinal tap to measure the level of 5-HIAA (the breakdown product of serotonin) in the cerebrospinal fluid (CSF). The drug probenecid, which prevents the transport of 5-HIAA from the CSF to the bloodstream, was given for the next 3 days. As a result of this blocking action the amount of serotonin produced over a 4 day period could be calculated by a repeat spinal tap on day 4. Since the 5-HIAA could not leave the CSF, it accumulated and provided a measure of serotonin manufacture.

The researchers discovered that the average level of 5-HIAA after 3 days of probenecid was significantly lower in depressed individuals than in controls matched for age, sex, and weight. This low level of serotonin reflected a decreased rate of manufacture within the brain. 5-HTP was most effective in patients with a low 5-HIAA response to 3 days of probenecid.^{[21] [22] [23]} In other words, 5-HTP is most effective as an antidepressant when the amount of serotonin manufactured in the brain is reduced.

As stated above, 5-HTP will often produce very good results in patients who are unresponsive to antidepressant drugs. One of the more impressive studies involved 99 patients described as suffering from "therapy-resistant" depression.^[24] These patients had not responded to any previous therapy including all available antidepressant drugs

and electroconvulsive therapy. These therapy-resistant patients received 5-HTP at dosages averaging 200 mg/day but ranging from 50 to 600 mg/day. Complete recovery was seen in 43 of the 99 patients and significant improvement was noted in eight more. Such significant improvement in patients suffering from long-standing, unresponsive depression is quite impressive, prompting the author of another study to state:^[25]

L-5-HTP merits a place in the front of the ranks of the antidepressants instead of being used as a last resort. I have never in 20 years used an agent which: (1) was effective so quickly; (2) restored the patients so completely to the persons they had been and their partners had known; [and] (3) was so entirely without side-effects.

A 1987 review article on 5-HTP in depression highlighted the need for well-designed double blind, head-to-head studies of 5-HTP versus standard antidepressant drugs.^[26] Although 5-HTP was viewed as an antidepressant agent with few side-effects, the authors of this review felt that the big question to answer was how 5-HTP compared with the new breed of antidepressant drugs, the selective serotonin reuptake inhibitors like Prozac, Paxil, and Zoloft. In 1991, a double-blind study comparing 5-HTP with a selective serotonin reuptake inhibitor (SSRI) was conducted in Switzerland.^[27] 5-HTP was compared in the study with the SSRI fluvoxamine (Luvox). Fluvoxamine is used primarily in the United States as a treatment for obsessive compulsive disorder (OCD), an anxiety disorder characterized by obsessions and compulsions affecting an estimated 5 million Americans. Fluvoxamine exerts antidepressant activity comparable to (if not better than) other SSRIs like Prozac, Zoloft, and Paxil.

In the study, subjects received either 5-HTP (100 mg) or fluvoxamine (50 mg) three times daily for 6 weeks. The assessment methods used to judge effectiveness included the Hamilton Rating Scale for Depression (HSD), self-assessment depression scale (SADS), and physician's assessment (Clinical Global Impression). As can be seen in [Table 92.7](#), the percentage decrease in depression was slightly better in the 5-HTP group (60.7% vs. 56.1%). 5-HTP was quicker acting than the fluvoxamine and a

TABLE 92-7 -- 5-HTP vs. fluvoxamine in percentage changes in the HDS

| | Decrease in HDS | 5-HTP (n = 34) | Fluvoxamine (n= 29) |
|---------------|------------------------|-----------------------|----------------------------|
| After 2 weeks | Mean decrease (%) | 23 | 18.9 |
| | Less than 35% decrease | 20 | 19 |
| | 35–50% decrease | 10 | 8 |
| | 50–75% decrease | 4 | 2 |
| After 4 weeks | Mean decrease (%) | 46.2 | 46.1 |
| | Less than 35% decrease | 2 | 8 |
| | 35–50% decrease | 7 | 3 |
| | 50–75% decrease | 12 | 13 |
| | More than 75% decrease | 3 | 5 |

| | | | |
|---------------|------------------------|------|------|
| After 6 weeks | Mean decrease (%) | 60.7 | 56.1 |
| | Less than 35% decrease | 4 | 5 |
| | 35–50% decrease | 8 | 3 |
| | 50–75% decrease | 12 | 8 |
| | More than 75% decrease | 10 | 13 |

higher percentage of patients responded to 5-HTP than to fluvoxamine.

The advantages of 5-HTP over fluvoxamine are evident when looking at the subcategories of the HDS: depressed mood, anxiety, physical symptoms, and insomnia. For depressed mood, 5-HTP produced a 65.7% reduction in severity compared with 61.8% for fluvoxamine; for anxiety, 5-HTP produced a 58.2% reduction in severity compared with 48.3% for fluvoxamine; for physical symptoms, 5-HTP produced a 47.6% decrease in severity compared with 37.8% for fluvoxamine; and, for insomnia 5-HTP produced a 61.7% decrease in severity compared with a 55.9% decrease for fluvoxamine. However, perhaps more important than simply relieving insomnia is 5-HTP's ability to improve the quality of sleep. By contrast, antidepressant drugs greatly disrupt sleep processes. On the self-assessment depression scale (SADS), 5-HTP produced a 53.3% drop in SADS values compared with a drop of 47.6% for the fluvoxamine group. Anything over a 50% drop is an excellent result. In fact, a 50% drop is the best SSRIs generally produce.

5-HTP is equal to or better than standard antidepressant drugs and the side-effects are much less severe (see [Table 92.8](#)). In the study comparing 5-HTP with fluvoxamine, this is how the physicians described the differences among the two groups:

Whereas the two treatment groups did not differ significantly in the number of patients sustaining adverse events, the interaction between the degree of severity and the type of medication was highly significant: fluvoxamine predominantly produced moderate to severe, oxitriptan [5-HTP] primarily mild forms of adverse effects.

Fourteen (38.9%) of the patients receiving 5-HTP reported side-effects compared with 18 patients (54.5%) in the fluvoxamine group. The most common side-effects with 5-HTP were nausea, heartburn, and gastrointestinal problems (flatulence, feelings of fullness, and rumbling sensations). These side-effects were rated as being very mild to mild. In contrast, most of the side-effects experienced

TABLE 92-8 -- 5-HTP vs. antidepressant drugs: comparison of side-effects

| Side-effect | Percentage of patients experiencing side-effects | | |
|----------------|--|------------|-------|
| | 5-HTP | Tricyclics | SSRIs |
| Nausea | 9 | 15 | 23 |
| Headache | 5 | 16 | 20 |
| Nervousness | 2.5 | 11 | 16 |
| Insomnia | 2.5 | 7 | 17 |
| Anxiety | 2.5 | 9 | 14 |
| Drowsiness | 7 | 23 | 11 |
| Diarrhea | 2.5 | 4 | 12 |
| Tremor | 0 | 18 | 11 |
| Dry mouth | 7 | 64.5 | 12 |
| Sweating | 2.5 | 15 | 9 |
| Dizziness | 5 | 25.5 | 7 |
| Constipation | 5 | 25 | 5.5 |
| Vision changes | 0 | 14.5 | 4 |

in the fluvoxamine group were of moderate to severe intensity. The only subject to drop out of the 5-HTP group did so after 35 days (5 weeks), while four subjects in the fluvoxamine group dropped out after only 2 weeks. Based on the studies in weight loss, the longer that 5-HTP is used (e.g. after 4–6 weeks of use), the less of a problem there is with any mild nausea.

5-HTP has been shown to have “equipotency” with SSRIs and tricyclic antidepressants in terms of effectiveness, but offers several advantages in that it is better tolerated and is associated with fewer and much milder side-effects; and because many people prefer to use a naturally occurring, natural substance like 5-HTP over synthetic drugs.

L-Tyrosine: an adjunct to 5-HTP

In the early 1970s, researchers discovered that, in about 20% of patients who responded well to 5-HTP, the results tended to decrease after 1 month of treatment. The antidepressant effects of 5-HTP in these subjects began to wear off gradually after the first month despite the fact that the level of 5-HTP in the blood, and presumably the level of serotonin in the brain, remained at the same level as when they were experiencing benefit.^[6]

The researchers discovered that while serotonin levels appeared to stay at the same levels after 1 month of treatment, the levels of the other important monoamine neurotransmitters, dopamine and norepinephrine, declined.^[28] As discussed above, when depressed patients are treated with 5-HTP they experience a rise not only in

serotonin, but also in catecholamines like dopamine and norepinephrine. In about 20% of subjects, the catecholamine-enhancing effects of 5-HTP tended to wear off. Providing these patients with L-tyrosine, the amino acid precursor to the catecholamines, helped to re-establish the efficacy of 5-HTP.^[6] ^[28] The dosage was 200 mg/day for 5-HTP and 100 mg/kg body weight for L-tyrosine. This dosage for L-tyrosine is quite high and would require substantial clinical supervision.

Weight loss

A considerable body of scientific evidence documents the major role serotonin in the brain plays in influencing eating behavior. One of the key findings is that when animals and humans are fed tryptophan-free diets, appetite is significantly increased, resulting in binge eating – carbohydrates would be preferable, but in fact the animals will binge on whatever is available.^[1] ^[2] A diet low in tryptophan leads to low brain serotonin levels; as a result the brain senses it is starving and so stimulates the appetite control centers in a powerful way. This stimulation results in a preference for carbohydrates. Researchers discovered that when animals or humans are

789

fed a carbohydrate meal, more tryptophan is delivered to the brain, resulting in more serotonin being manufactured. This scenario has led to the idea that low serotonin levels leads to “carbohydrate craving” and plays a major role in the development of obesity as well as bulimia.^[29]

Cravings for carbohydrate can be mild or quite severe. They may range in severity from the desire to nibble one piece of bread or cookie to uncontrollable binging. At the upper end of the spectrum of carbohydrate addiction is bulimia, a potentially serious eating disorder characterized by binge eating and purging of the food through forced vomiting or the use of laxatives. The serotonin theory of bulimia is that low serotonin levels trigger the binge eating which leads to a rush of serotonin being produced and released in the brain.^[30] ^[31] This increased serotonin effect produces a brief reduction in feelings of stress and tension. This serotonin “fix” is short-lived and is followed by feelings of guilt and low self-esteem. The current medical treatment for bulimia is the use of drugs which enhance the effects of serotonin. Although there are no reports in the medical literature of 5-HTP being used in the treatment of bulimia, given its effects on serotonin levels it merits consideration.

5-HTP may help to prevent the decline in serotonin levels associated with a reduced calorie intake. Concentrations of tryptophan in the bloodstream and subsequent brain serotonin levels plummet with dieting.^[32] In response to severe drops in serotonin levels, the brain puts out a strong message to eat. This situation sets up the scenario to explain why most diets do not work.

As far back as 1975, researchers demonstrated that giving 5-HTP to rats who were genetically bred to overeat and be obese resulted in significant reduction in food

intake.^[33] It turns out that these rats bred to be fat have decreased activity of the enzyme which converts tryptophan to 5-HTP and subsequently to serotonin.

There is circumstantial evidence that many humans are genetically predisposed to obesity. This predisposition may involve the same mechanism as rats genetically predisposed to obesity. By providing preformed 5-HTP, this genetic defect is bypassed and more serotonin is manufactured.

The early animal studies with 5-HTP as a weight loss aid have been followed by a series of three human clinical studies. The first study involved 19 significantly overweight female subjects with a body mass index ranging between 30 and 40.^[34] Analysis of the pretreatment dietary intake concluded that these women tended to overeat carbohydrates. Food intake and eating behavior were assessed using a 3 day diet diary at the beginning and end of the two treatment periods. All food was carefully weighed before meals and re-weighed if there were any leftovers. Participants also filled out a self-evaluation of appetite and satiety twice weekly, and mood was evaluated using standard psychological tests.

TABLE 92-9 -- The effect of 5HTP on food intake

| | Food intake (calories/day) | Protein intake (g/day) | Carbohydrate intake (g/day) |
|--------------|---------------------------------------|-----------------------------------|--|
| Pretreatment | 2,903 | 101 | 274 |
| Placebo | 2,327 | 85 | 223 |
| 5-HTP | 1,819 | 79 | 176 |

The daily dosage of 5-HTP used in the study was 8 mg/kg body weight. Patients were given either the 5-HTP or a placebo 20 minutes before meals for 5 weeks, and after a 1 week interval were switched to receive the other treatment. No dietary restrictions were prescribed because the researchers wanted to answer the question, “Does 5-HTP reduce appetite and promote weight loss without any conscious effort?” To make sure that the women actually took the 5-HTP, researchers measured the level of the serotonin breakdown product, 5-hydroxy-3-indole acetic acid (5-HIAA), in the urine. The results of the study are listed in [Table 92.9](#).

These results with 5-HTP were achieved without the women making any conscious effort to reduce food consumption. The average amount of weight loss during the 5 week period of 5-HTP supplementation was a little more than 3 pounds, compared with less than 1 pound of total weight loss during the placebo period.

Interestingly, evaluation of the various self-tests indicated that appetite or degree of initial hunger did not differ between the two groups. What differed was satiety. In other words, the 5-HTP did not reduce the appetite before a meal, but after consuming an adequate amount of food the satiety centers in the brain were stimulated and the

women did not feel hungry. As a result their caloric intake was dramatically reduced.

The level of 5-HIAA, the breakdown product of serotonin, in the group receiving the 5-HTP increased by over 50-fold over the control group. This increase provided two things: (1) it assured researchers that subjects actually took the 5-HTP, and (2) it clearly indicated that 5-HTP increased serotonin manufacture.

The next study sought to determine if 5-HTP helped overweight individuals to adhere to dietary recommendations.^[35] Fourteen overweight female subjects with a body mass index ranging between 30 and 40 were enrolled in the double-blind study.^[8] Again, analysis of the pretreatment dietary intake concluded that these women tended to overeat. The women were randomly assigned to receive either 5-HTP (300 mg) or placebo 30 minutes before meals. The 12 week study was divided into two 6 week periods. For the first 6 weeks there were no dietary recommendations, and for the second 6 weeks the women were placed on a 1,200 calorie diet.

The women were seen every 2 weeks to evaluate body weight, diet diaries, self-evaluations of appetite and

TABLE 92-10 -- Impact of 5-HTP on weight loss

| | Placebo | 5-HTP group |
|----------------------------|---------|-------------|
| Weight (pounds) | | |
| Baseline | 207.68 | 229.46 |
| After 6 weeks | 206.58 | 225.94 |
| After 12 weeks | 205.4 | 219.12 |
| Total weight loss (pounds) | | |
| After 6 weeks | 1.1 | 3.52 |
| After 12 weeks | 2.28 | 10.34 |

satiety. The women were also asked if they experienced the presence of meat aversion, taste or smell alterations, early satiety, and nausea and/or vomiting. To verify patient compliance, urinary measurement of 5-HIAA was again determined. As shown in [Table 92.10](#) , the women taking the placebo lost 2.28 pounds while the women taking the 5-HTP lost 10.34 pounds.

Like the previous study, 5-HTP appeared to promote weight loss by promoting satiety. While some of the women reported some aversion to meat or altered taste and smell, every women (100%) reported early satiety (see [Table 92.11](#)). Most of the women receiving 5-HTP also experienced very mild nausea during the first 6 weeks of the trial,

but during the last 6 weeks none complained of nausea. The fact that weight loss is accelerated during the second 6 week period makes it highly unlikely that 5-HTP promotes weight loss as a result of producing nausea.

The latest study with 5-HTP enrolled overweight women with a body mass index ranging between 30 and 40 and an overactive appetite.^[36] The 28 subjects of the study were given either 5-HTP (300 mg three times daily before meals) or a placebo. For the first 6 weeks there were no dietary restrictions, and for the second 6 weeks the women were placed on a diet of 1,200 calories/day. Carbohydrates contributed to 53% of the calories, fats comprised 29%, and proteins provided 18%. No carbohydrate-rich foods were permitted between meals. Subjects were examined every 2 weeks to evaluate food intake and body weight. Routine blood measurements were also performed at the beginning, at 6 weeks, and at the end of the study. To verify patient compliance, urinary measurement of 5-HIAA was determined.

The results from this study were even more impressive

TABLE 92-11 -- Impact of 5-HTP on appetite and satiety

| | 5-HTP | | Placebo | |
|------------------|-----------|------------|-----------|------------|
| | Weeks 1–6 | Weeks 7–12 | Weeks 1–6 | Weeks 7–12 |
| Taste alteration | 2/7 | 1/7 | 0/7 | 0/7 |
| Smell alteration | 2/7 | 1/7 | 0/7 | 0/7 |
| Meat aversion | 3/7 | 1/7 | 0/7 | 0/7 |
| Early satiety | 7/7 | 6/7 | 2/7 | 2/7 |
| Nausea | 5/7 | 0/7 | 1/7 | 2/7 |

than the previous studies for several reasons. The group receiving the 5-HTP lost an average of 4.39 pounds after the first 6 weeks and an average of 11.63 pounds after 12 weeks. In comparison, the placebo group lost an average of only 0.62 pounds after the first 6 weeks and 1.87 pounds after 12 weeks. The lack of weight loss during the second 6 week period in the placebo group obviously reflects the fact that the women had difficulty adhering to the diet.

Early satiety was reported by 100% of the subjects during the first 6 week period. During the second 6 week period, even with severe caloric restriction, 90% of the women taking 5-HTP reported early satiety. Once again, many of the women receiving the 5-HTP reported mild nausea during the first 6 weeks of therapy. However, the symptom was never severe enough for any of the women to drop out of the study. No other side-effects were reported.

Based upon the urinary measurements of 5-HIAA, the women took their 300 mg of 5-HTP with meals and as a result were able to achieve weight loss. The amount of weight loss was amplified by a better capability to adhere to a 1,200 calorie diet. The structure of the dietary changes reflected primarily a reduction in pasta, bread, and

other carbohydrate-rich foods (the study was conducted in Rome).

Insomnia

Several clinical studies have shown 5-HTP to produce good results in promoting and maintaining sleep in normal subjects as well as in those experiencing insomnia.^[36] ^[37] ^[38] ^[39] ^[40] ^[42] ^[43] One of the key benefits with 5-HTP in the treatment of insomnia is its ability to increase sleep quality. This effect is evident by its ability to increase REM sleep (typically by about 25%) while simultaneously increasing deep sleep stages 3 and 4 without increasing total sleep time.^[36] ^[38] The sleep stages that are reduced by 5-HTP to compensate for the increases are non-REM stages 1 and 2, the least important stages of sleep. In one of the studies, the subjects receiving 200 mg of 5-HTP increased the amount of REM sleep by 15.5 minutes during the 5 night study.^[36] Those subjects taking 600 mg of 5-HTP increased REM sleep time by an average of 20 minutes for the 5 night study. These results indicate that 5-HTP increases the amount of dream time by about 3–4 minutes a night.

Although there was a clear dose-related effect, the lower dosage is sufficient in most cases. In addition, taking too much 5-HTP may increase REM sleep to an abnormal level, lead to an increased risk for disturbing dreams (i.e. nightmares), and cause mild nausea.

Migraine and tension headache

The relationship of serotonin and headaches is fully described

in [Chapter 172](#) . Because migraine sufferers have low levels of serotonin in their tissues, some researchers refer to migraine as a “low serotonin syndrome”.^[43] Although the primary benefits of 5-HTP in the prevention of both migraine and tension headache is related to its ability to normalize underlying imbalances in the serotonin system, it also influences the endorphin system in a positive way.

There have been several clinical studies with 5-HTP in headaches, both vascular and non-vascular, that have showed excellent results. In particular, the use of 5-HTP in the prevention of migraine headache offers considerable advantages over drug therapy. Although a number of drugs have been shown to be useful in the prevention of migraine headaches, all of them carry significant side-effects.

The problem with drug therapy in the prevention of migraine headaches is perhaps best exemplified by one of the most commonly used drugs, methysergide (Sansert). Methysergide therapy for the prevention of migraine attacks is effective in about 60–80% of cases. However, this effectiveness is not without a high price as side-effects are quite common and can be quite severe. Retroperitoneal fibrosis, pleuropulmonary fibrosis and fibrotic thickening of cardiac valves may occur in patients receiving

long-term methysergide maleate therapy. Therefore, this preparation must be reserved for prophylaxis in patients whose vascular headaches are frequent and/or severe and uncontrollable and for those who are under close medical supervision.

There have been several studies which have compared 5-HTP with methysergide in the prevention of migraine headaches. In one of the largest double-blind studies, 124 patients received either 5-HTP (600 mg daily) or methysergide (3 mg daily) in identically looking pills for 6 months.^[44] Treatment was determined to be successful if there was a reduction higher than 50% in the frequency of attacks or in the number of severe attacks. Although 75% (30 of the remaining 40 patients) taking methysergide demonstrated significant improvement compared with 71% (32 of the 45 patients), this difference was not viewed as being statistically significant (see [Table 92.12](#)). The advantage of 5-HTP over methysergide was demonstrated when researchers looked at side-effects. Side-effects were more frequent in the group receiving methysergide than in the 5-HTP group. In fact, five patients in the methysergide

TABLE 92-12 -- 5-HTP vs. methysergide: clinical effects of treatment in 124 patients

| | Methysergide | 5-HTP |
|--------------------------------|---------------------|--------------|
| No attacks (100% reduction) | 35% | 25% |
| Improvement (>50% reduction) | 40% | 46% |
| No improvement | 12.5% | 29% |
| Withdrawal due to side-effects | 12.5% | 0 |

group had to withdraw during the trial because of side-effects.

Two other studies comparing 5-HTP with drugs used in the prevention of migraine headaches (pizotifen and propranolol) demonstrated that 5-HTP compared quite favorably in terms of effectiveness.^{[45] [46]} While these drugs have significant side-effects, 5-HTP is extremely well tolerated even at dosages as high as 600 mg/day. One of the other key differences noted in these studies between 5-HTP and the drugs was 5-HTP's ability to improve mood and relieve feelings of depression.

Juvenile headache

One of the best uses of 5-HTP is in chronic headaches in children. These headaches are a big problem because of the tremendous risk for side-effects of the current drugs used to treat as well as prevent these headaches in children. Fortunately, there have been several studies of 5-HTP in the treatment of chronic headaches in children and adolescents that have shown excellent results.^{[47] [48] [49]} Given the risks of current drugs used in chronic childhood headaches, a trial of 5-HTP for 2 months certainly seems reasonable. If the headaches are also accompanied by sleep disorders, 5-HTP appears to be especially well-suited.

In one study, 48 elementary and junior high students suffering from recurrent headaches (at least one headache every 2 weeks) and sleep disorders, including

difficulty it getting to sleep, frequent awakenings, sleep walking, nightmares, and bedwetting, were divided into two groups.^[47] Group A was given 5-HTP for 2 months followed by a placebo for 2 months, while group B received just the opposite. It was necessary to divide group A into a nine patient subgroup, Group C. These nine patients did so well on the 5-HTP they did not want to switch over to the other medication even though they had no idea whether they were in fact taking 5-HTP or were on a placebo. The dosage of 5-HTP was based on the child's weight: 4.5 mg/kg per day.

The headache index was reduced by about 70% when the kids were taking 5-HTP compared with an 11.5% drop when they were taking the placebo. In the nine patients in group C, there was an 81.8% decrease in the headache index after the second month. Interestingly, these same patients only exhibited an 18.2% reduction after the first month. These results indicate that evaluation of the benefits of 5-HTP in the treatment of headaches requires at least a 2 month trial. The failure to show benefit with 5-HTP in some studies in headaches may be due to the fact that they lasted less than 2 months. The 25 patients experienced a modest reduction in frequent awakenings, nightmares, sleep walking, and talking while asleep and no change in difficulty falling asleep or in bedwetting.

Overall this study demonstrated very good effects in

792

these children. Perhaps the most impressive aspect to consider, however, was the fact that these benefits were achieved without side-effect. Not a single child reported a side-effect while taking 5-HTP. Interestingly, for some reason children rarely experience even mild nausea from 5-HTP.

The possible benefits of 5-HTP in children with recurrent headache and/or sleep disorders is far-reaching. Evaluation of the 48 children in the trial demonstrated inadequate school progress compared with their classmates. The children were shown to be of normal intellectual capacity, but demonstrated inattentiveness similar to that observed in depression. Many of the children may have been suffering from depression. The unwillingness of the nine subjects in Group C to switch to the other unknown medication (which was in fact the placebo) is a strong indicator that these children and their parents noted some rather dramatic improvements beyond simply a reduction in headaches or improved sleep.

The manner in which 5-HTP may be of benefit in migraine headaches may not simply be the overcoming of some defect in serotonin synthesis. As noted previously, part of the clinical benefit of 5-HTP may be via an ability to increase the levels of beta-endorphin. A decrease in beta-endorphin level in migraine as well as tension headache sufferers has been demonstrated by several investigators.^{[50] [51]}

A clinical trial measured the effects of 5-HTP on serotonin and beta-endorphin levels in 20 juvenile patients suffering from migraine or tension-type headaches.^[52] Patients were

monitored and evaluated for frequency and intensity of headache attacks for 3 months prior to 5-HTP treatment and 3 months of therapy. The researchers reported a statistically significant reduction in the headache score with 5-HTP treatment in both migraine and tension-type sufferers. These improvements were likely due to increased beta-endorphin levels as noted in [Table 92.13](#). However, the level of beta-endorphin achieved with 5-HTP, especially as measured in the white blood cell, was still far less than that observed in control patients not suffering from recurrent headache. These results imply that longer periods of 5-HTP supplementation may be required before there is a normalization of beta-endorphin levels in children prone to headaches.

These results may indicate that 5-HTP alone is not able to raise beta-endorphin levels sufficiently to reduce or eliminate headaches, suggesting that other therapies designed to increase beta-endorphin levels should be used along with 5-HTP. Examples of other therapies which have been shown to raise beta-endorphin levels are exercise, acupuncture, and biofeedback.

Fibromyalgia

The history of the development of 5-HTP as an effective treatment for fibromyalgia began with studies on the drug fenclonine.^[53] This drug blocks the enzyme which inhibits the conversion of tryptophan to 5-HTP and, as a result, blocks serotonin production. During the late 1960s and early 1970s, it was thought that increased serotonin formation may promote migraine headaches (the opposite of what was later proved, i.e. increasing serotonin levels reduce migraine headache occurrence). The researchers discovered that providing headache sufferers with fenclonine resulted in very severe muscle pain. This effect was the exact opposite of what was expected, but led to some important advances in the understanding of fibromyalgia – a way to induce its severe symptoms of (as well as symptoms nearly identical to) EMS, the condition caused by contaminated L-tryptophan. The researchers also discovered that migraine sufferers had a greater reaction to the drug than non-headache sufferers. In fact, in most normal subjects fenclonine produced no fibromyalgia. These occurrences highlight just how sensitive migraine sufferers are to low serotonin levels.

Migraine headaches and fibromyalgia share a common feature: both are low serotonin syndromes.^[54] After over 25 years of research, one of the lead researchers has stated: “In our experience, as well as in that of other pain specialists, 5-HTP can largely improve the painful picture of primary fibromyalgia.”^[55]

A double-blind study in 50 patients with fibromyalgia found that 100 mg of 5-HTP three times per day significantly improved their symptoms.^[56] As shown in [Table 92.14](#),

TABLE 92-13 -- Serotonin and beta-endorphin levels in juvenile patients with headaches before and after administration of 5-HTP

| | Serotonin (serum, mcg/L) | Beta-endorphin (plasma, pmol/L) | Beta-endorphin (white blood cells, pmol/106 GB/L) |
|------------------------|-------------------------------------|--|--|
| Migraine (13 subjects) | | | |

| | | | |
|---------------------------|-------|------|-------|
| Before | 104.6 | 16.2 | 110.5 |
| After | 115.7 | 19.4 | 120.3 |
| Tension-type (7 subjects) | | | |
| Before | 90.7 | 14.5 | 142.3 |
| After | 97.2 | 17.6 | 152.4 |
| Total (20 subjects) | | | |
| Before | 100.5 | 15.7 | 129.3 |
| After | 108.3 | 18.4 | 140.4 |
| Controls (17 subjects) | 96 | 21.3 | 359.3 |

TABLE 92-14 -- Patients' and physicians' opinion on the effectiveness of 5-HTP vs. placebo in fibromyalgia

| Response | 5-HTP | Placebo |
|----------|-------|---------|
| Good | 11 | 1 |
| Fair | 8 | 5 |
| Poor | 4 | 8 |
| None | 0 | 9 |

5-HTP was rated substantially better than placebo by subjects and evaluating physicians. Improvements were noted in all symptom categories: number of painful areas, morning stiffness, sleep patterns, anxiety, and fatigue. In another study, 100 mg of 5-HTP taken three times daily demonstrated maximum results by day 30 of the 90 day trial.^[57]

One of the primary benefits with 5-HTP in fibromyalgia may be its ability to improve sleep quality. A key finding in patients with fibromyalgia is a reduced REM sleep and an increase in non-REM sleep.^[58] In addition, the deeper levels (stages III and IV) are not achieved for long enough periods. As a result, people with fibromyalgia wake up feeling fatigued and in pain. The severity of the pain of fibromyalgia correlates with the rating of sleep quality. For example, a study of 50 women with fibromyalgia syndrome recorded their sleep quality, pain intensity, and attention to pain for 30 days, using palm-top computers programmed as electronic interviewers.^[59] They described their previous night's sleep quality within 30 minutes of awakening each day, and at randomly selected times in the morning, afternoon, and evening rated their present pain. The researchers found that a night of poor sleep was followed by a significantly more painful day, and a more painful day was followed by a night of even poorer sleep. 5-HTP may help to

break the cycle by addressing the low serotonin level as well as by promoting a restful sleep.

Parkinson’s disease

The use of 5-HTP in Parkinson’s disease provides some benefit, but only if used in combination with the drug Sinemet (the combination of L-dopa with the decarboxylase inhibitor, carbidopa). Although brain levels of serotonin are decreased in Parkinson’s disease, the reduction in dopamine receptors is more severe. Increasing serotonin levels with 5-HTP in patients not taking Sinemet are associated with worsening of symptoms, especially rigidity.^[60]

One of the key benefits of taking 5-HTP in Parkinson’s disease is that it can help to counteract the negative effects that the L-dopa in the Sinemet has on sleep and mood.^[61]
^[62] ^[63] In addition, 5-HTP has also been shown to improve the physical symptoms of Parkinson’s disease.

About nine out of 10 people with Parkinson’s disease

TABLE 92-15 -- The effect of HTP on depression in Parkinson’s disease

| Patient no. | L-dopa (mg/day) | Carbidopa (mg/day) | 5-HTP (mg/day) | HDS | |
|-------------|-----------------|--------------------|----------------|--------|-------|
| | | | | Before | After |
| 1 | 1,000 | 175 | 125 | 22 | 11 |
| 2 | 300 | 75 | 75 | 14 | 3 |
| 3 | 400 | 150 | 100 | 21 | 13 |
| 4 | 1,000 | 100 | 100 | 12 | 6 |
| 5 | 500 | 125 | 500 | 18 | 22 |
| 6 | 1,125 | 112.5 | 300 | 18 | 7 |
| 7 | 500 | 50 | 100 | 17 | 13 |

suffer from depression. The degree of depression in Parkinson’s disease is a reflection of their serotonin levels. The lower the level of serotonin, the more severe is their depression. One study examined the effect of 5-HTP in seven Parkinson’s disease patients, all of whom were on Sinemet.^[61] The initial dosage of 5-HTP was 75 mg, which was increased by 25 mg every 3 days until the patients reported a relief of their depression, or up to a maximum of 500 mg/day for 4 months. The impressive results obtained in these patients are shown in [Table 92.15](#).

Six out of seven patients responded to 5-HTP. Note that the dosages of 5-HTP in these five out of the six patients who responded ranged from only 75 to 125 mg. The only patient who did not respond took 500 mg of 5-HTP.

Seizure disorders

Most of the recent research on 5-HTP has focused on its use in the treatment of several seizure disorders.^{[64] [65] [66] [67] [68]} 5-HTP has shown good results in most (but not all) studies in patients suffering from diseases characterized by myoclonus, with the exception of epilepsy which is not helped by 5-HTP.

The best response to 5-HTP for myoclonus occurs in people who have intention myoclonus, which is most often produced as a result of ischemic damage to the brain.^[32]

Intention myoclonus can be a problem after a stroke or heart attack, overdose of a drug like heroin, a severe asthma attack, or an adverse reaction to anesthesia or other chemical. Improvements in intention myoclonus with 5-HTP have been demonstrated in patients. 5-HTP has also produced good results in patients with progressive myoclonus epilepsy, essential myoclonus, palatal myoclonus, and Friedreich's ataxia.^[69]

In a 1983 article, one researcher of 5-HTP stated: "Some helpless bedridden patients dramatically improved to the extent that they could walk again and resume independent living."^[70] Because of the phenomenal results, 5-HTP was the first compound to be evaluated as an orphan drug by the Pharmaceutical Manufacturing Associations Commission on Drugs for Rare Diseases.

TOXICOLOGY

The major concern with 5-HTP is a possible link to L-tryptophan and the eosinophilia-myalgia syndrome (EMS). However, an important distinction must be made in the manufacturing process. While L-tryptophan is produced via bacterial fermentation and filtration, 5-HTP is commercially available through an extraction process from the seed of *Griffonia simplicifolia*, an African plant. 5-HTP extracted from this natural source avoids the contamination problem associated with past manufacturing of L-tryptophan.

Detailed analyses of all the evidence by the Centers for Disease Control (CDC) and other experts have led to the conclusion that the cause of the EMS epidemic could be traced to a single Japanese manufacturer, Showa Denko.^{[71] [72]} Of the six Japanese companies which supplied L-tryptophan to the United States, Showa Denko was the largest (50–60% of all the L-tryptophan). The L-tryptophan was used not only as a nutritional supplement, but also in infant formulas and nutrient mixtures for intravenous feeding.

There was a single case report linking 5-HTP to a condition similar to EMS in 1980.^[73] However, this case involved the use of very high dosages of 5-HTP (1,400 mg) over a 20 month period. Further examination of the patient indicated a defect in tryptophan metabolism that resulted in elevations in kynurenine. Such defects in tryptophan

metabolism are common in patients with scleroderma, which shares many common features with EMS. It appeared that either the 5-HTP may have contained a contaminant to which this man was sensitive, or taking such high dosages of 5-HTP over a prolonged period of time aggravated his abnormal handling of L-tryptophan.

There has also been a report of a 28-year-old woman, her husband, and her two sons, 33 and 13 months old, developing an EMS-like illness in response to contaminated 5-HTP.^[74] The young boys had inherited the inability to convert tryptophan to 5-HTP. As a result, they required daily administration of 5-HTP (5–7 mg/kg). Both boys had been receiving the 5-HTP almost from birth.

The mother was not taking 5-HTP, but she was preparing it for the young boys by opening the capsules, mixing the powder in juice or water, and giving it to them orally with a syringe. She never took the 5-HTP, she only touched it with her hands as she emptied the capsules.

When the second boy was about 9 months old, the mother began experiencing symptoms of EMS. Upon consulting a physician in July of 1991 it was noted that her eosinophil count was well over 30%. She continued to worsen and was hospitalized in August of 1991 with a tentative diagnosis of EMS. At this time she was referred to the National Institutes of Health (NIH) for further evaluation.

Because of the possible link between the mother's symptoms and the 5-HTP, the boys and the father were also evaluated. The older boy had an eosinophil count of 9% (normal is 1–4%) and the younger boy had a count of 6%. The father had no abnormalities.

The 5-HTP that the boys were using was analyzed by HPLC and found to contain an impurity not found in the 5-HTP that the NIH was using in their studies for ataxia and myoclonus. Switching the boys to the contaminant-free 5-HTP brought about normalization of eosinophil counts. The mother's case is interesting because she was the most severely affected and she was only coming into contact with the contaminated 5-HTP through her skin.

Evidence that uncontaminated 5-HTP does not cause EMS is also provided by researchers who have been using 5-HTP for over 25 years. They state that: "EMS has never appeared in the patients of ours who received only uncontaminated L-tryptophan or 5-hydroxytryptophan (5-HTP)."^[75] Furthermore, researchers at the NIH studying the effects of uncontaminated 5-HTP on various metabolic conditions have not observed a single case of EMS nor has a case of elevated eosinophils been attributed to 5-HTP in these studies.^[74] In short, there has never been a report of uncontaminated 5-HTP causing EMS.

Although there has never been a single person developing EMS from 5-HTP products proven to be free from the contaminants, and it is extremely unlikely that anyone would, nonetheless, to be on the safe side we recommend that long-term continual use of 5-HTP be monitored by regular (every 6 months) eosinophil determination. For any person suffering from scleroderma due to the problem with tryptophan metabolism

noted in these patients, we recommend an eosinophil determination after the first month of 5-HTP use, especially if dosages are greater than 500 mg/day.

DOSAGE

The dosage should be started at 50 mg three times per day. If the response is inadequate after 2 weeks, increase the dosage to 100 mg three times per day. This recommendation will greatly reduce the mild symptoms of nausea often experienced during the first few weeks of 5-HTP therapy. Because 5-HTP does not rely on the same transport vehicle as L-tryptophan, it can also be taken with food.

For insomnia, prescribe 100–300 mg 30–45 minutes before retiring. Start with the lower dose for at least 3 days before increasing dosage.

Chapter 93 - *Hypericum perforatum* (St John's wort)

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

Hypericum perforatum (family: Hypericaceae)
Common names: St John's wort, Klamath weed, hypericum

GENERAL DESCRIPTION

St John's wort (*Hypericum perforatum*) is a shrubby perennial plant with numerous bright yellow flowers. It is commonly found in dry, gravelly soils, fields, and sunny places. St John's wort is native to many parts of the world including Europe, Asia, and the United States. It grows especially well in northern California and southern Oregon.^[1]

The plant is glabrous throughout, green or sometimes glaucescent; the stems are erect, branched at the top and 30–100 cm long; the leaves are oval or elliptic or oblong-ovate, or rather narrow, oblong-linear, subotuse, flat or more or less revolute-margined with numerous pellucid and a few black granular dots. The yellow flowers are numerous, forming a broadly paniculate, almost corymbose inflorescence, 7–11 cm long and 5–11 cm broad. The lanceolate bracts are 0.5 cm long and acute. The calyx is deeply parted, 5 mm long and about two to three times shorter than corolla. The sepals are lanceolate or narrow lanceolate 4–5 mm long, 1 mm broad, as long as ovary, acute or acuminate, sparingly furnished with black oval dots, with a smooth or sparsely toothed margin. The petals are oblong to oblong-elliptic, 1.2–1.5 cm long and 0.5–0.6 cm broad, with or without numerous black granular dots and lines on the margin in the upper part, while the surface is full of yellow glandular dots, thin lines, and stripes. The three-bundled stamens are numerous; the ovary is ovoid, 3–5 mm long. The seed is 1 mm long, cylindrical, brown, and minutely pitted longitudinally.^[1]

The whole plant is used medicinally. Harvesting time is generally July through August. The plant must be dried immediately to prevent degradation of active principles.^[1]

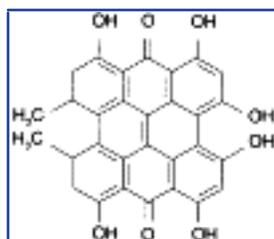

Figure 93-1 Hypericin.

CHEMICAL COMPOSITION

The major compounds of interest have been hypericin (see [Fig. 93.1](#)) and pseudohypericin. These compounds are typically found in very low concentrations, ranging from 0.0095 to 0.466% in the leaves and as much as 0.24% in the flowers.^[1]

More recently, researchers have been interested in the other chemical constituents (especially the various flavonoid and xanthenes). The interest in these other components stems largely from pharmacological studies with commercially available extracts demonstrating effects and benefits beyond hypericin and pseudohypericin. The other active components include:^{[1] [2]}

- flavonoids (flowers 16%, leaves 12%, and whole herb 9%)
- xanthenes
- phenolic carboxylic acids (caffeic, chlorogenic, ferulic, and gentisic acids)
- essential oils (whole herb content 0.13%)
- carotenoids
- alkanes
- phloroglucinol derivatives
- phytosterols
- medium-chain fatty acid alcohols.

HISTORY AND FOLK USE

St John's wort has a long history of folk use. Dioscorides, the foremost physician of ancient Greece, as well as Pliny and Hippocrates, utilized St John's wort in the treatment of many illnesses. Its Latin name, *Hypericum perforatum*, is derived from Greek and means "over an apparition", a reference to the belief that the herb was so obnoxious to evil spirits that a whiff of it would cause them to depart.

The naming of St John's wort has its origins in folk traditions. One claims that red spots, symbolic of the blood of St John, appeared on the leaves of the plant on the anniversary of the saint's beheading. Another comes from a common medieval belief that if one slept with a piece of the plant under his pillow on St John's Eve, "the Saint would appear

in a dream, give his blessing, and prevent one from dying during the following year”.

Many people from the time of the ancient Greeks through the Middle Ages believed St John’s wort to have magical powers. Recent research on St John’s wort appears to offer some explanation of this “magical” power. Based on a long history of use as a mood-elevating substance and preliminary in vitro experiments and clinical studies, in 1984 the German Commission E permitted the medicinal use of St John’s wort for depression, anxiety, or nervous excitement.

The Commission E evaluates efficacy of herbal medicines based on a doctrine of reasonable certainty versus the United States FDA’s doctrine of absolute proof. Herbal products can be marketed with drug claims if they have been proven to be safe and effective. Whether the herbal product is available by prescription or OTC is based upon its application and safety of use. Herbal products sold in German pharmacies are reimbursed by insurance if they are prescribed by a physician.

Because the German system allowed companies to market their products according to the guidelines of the Commission E, many companies achieved success with their products allowing them to fund the necessary research to gain greater acceptance within mainstream conventional medicine. The case of St John’s wort extract in the treatment of depression is a perfect case in point to illustrate how the Commission E monographs have fueled the science of botanical medicine. For example, originally it was thought that hypericin acted as an inhibitor of the enzyme monoamine oxidase (MAO) – thereby resulting in the increase of CNS monoamines such as serotonin and dopamine. However, newer information indicates that St John’s wort possesses no in vivo inhibition of MAO (discussed below). It appears that the antidepressant activities are related more to modulating the relationship between the immune system and mood, as well as by inhibiting serotonin reuptake (discussed below). In addition, it appears that while hypericin is an important marker, there are other compounds such as flavonoids which are thought to play a major role in the pharmacology of St John’s wort.

Over 25 double-blind randomized trials involving a total of 1,757 outpatients with mild to moderately severe depression have shown St John’s wort extracts standardized for hypericin to yield excellent results in the treatment in depression with virtually no side-effects.^{[1] [3]} In 1994 a total of 66 million daily doses of St John’s wort preparations were prescribed by German physicians.^[4]

PHARMACOLOGY

St John’s wort extracts (primarily of the flowering tops) have shown a wide variety of effects in experimental

and clinical studies. Some of the activities demonstrated include:^{[1] [2]}

- antidepressant effects
- antiviral effects
- antibiotic effects
- increased healing of wounds and burns.

Antidepressant activity

Among the different biological hypotheses for depression, the biogenic amine hypothesis is the most widely accepted. This hypothesis suggests that depression is the result of a deficiency in function of the biogenic amines, e.g. serotonin, catecholamines, dopamine, etc. These neurotransmitters are stored in granules within neurons. After stimulation of the neurons, these neurotransmitters are released into the synaptic cleft via exocytosis. After binding to postsynaptic receptors, the neurotransmitters are either taken up again and re-stored in the vesicles or they are catabolized by the enzymes monoamine oxidase (MAO) or catechol-O-methyltransferase (COMT). Most antidepressant drugs increase the availability of these amines, particularly serotonin, by either inhibiting the re-uptake or blocking MAO.

As stated above, initial studies indicated that St John's wort extract's antidepressant action was based on the ability of crude hypericin preparations to inhibit both types A and B MAO.^{[5] [6]} As a result of this inhibition, there is an increase in the level of neurotransmitters within the brain that maintain normal mood and emotional stability including serotonin, catecholamines, and dopamine. These preliminary results identified hypericin as the supposed active constituent. However, later chemical analysis of these crude hypericin preparations identified a content of as much as 20% of other St John's wort constituents, with the flavonoids being the most important.^[1] In other words, it is not known to what extent hypericin or the flavonoids individually contribute to any MAO inhibition.

To better understand the influence of hypericin, hypericum total extract, and hypericum fractions on the activity of MAO and COMT, a study was conducted.^[7] An inhibition of MAO could be shown in the following concentrations:

- hypericin to 10^{-3} mol/L
- hypericum total extract to 10^{-4} mol/L
- one extract fraction up to 10^{-5} mol/L.

A COMT inhibition could not be shown for hypericin, with hypericum extract to 10^{-4} mol/L and with two extract fractions also up to 10^{-4} mol/L. The MAO inhibiting fraction contained hypericins as well as flavonols, the COMT-inhibition fraction being mainly flavonols and xanthenes. The key result from this study, as well as in another in vitro/ex vivo study, is the demonstration that the concentrations of inhibition shown, particularly with regard to the inhibition of MAO activity, are likely not sufficient to explain the clinically proven antidepressive effect of St John's wort extract.^{[7] [8]} Therefore, additional mechanisms are likely responsible for these clinical benefits.

At least two other mechanisms have been proposed: modulation of interleukin-6 activity and inhibition of the re-uptake of serotonin. The modulating effect of St John's wort extract on interleukin-6 (IL-6) is the most interesting as it proposes a mechanism by which St John's wort interacts with the link between the immune system and mood. The immune system and the nervous system share many common biochemical features and regulatory interactions. In regards to IL-6, this cytokine is heavily involved in the communication between cells within and outside the immune system. With regard to the nervous system, IL-6 is known to modulate hypothalamic-pituitary-end organ axes, especially the hypothalamic-pituitary-adrenal (HPA) axis. The hypothesis is that an elevation in IL-6 results in activation of the HPA axis leading to elevations in CRH and other adrenal regulatory hormones – hallmark features in depression. St John's wort extract has shown an ability to reduce IL-6 levels, and hence this action may explain the clinical effectiveness of St John's wort extract.^[9]

The study demonstrating reduction of IL-6 levels involved taking blood samples from five healthy volunteers and four depressive patients.^[9] The release of interleukin-6 (IL-6), interleukin-1 beta (IL-1 beta) and tumor necrosis factor-alpha (TNF-alpha) was measured quantitatively after an incubation time of 24 hours on microtiter plates. A massive suppression of the interleukin-6 release was found for PHA-stimulated St John's wort extract. If these effects can be duplicated in vivo, it would provide a mechanism by which St John's wort extract modulates CRH release and, subsequently, mood.

St John's wort extract has also been shown to inhibit the re-uptake of serotonin similar in fashion to drugs like fluoxetine (Prozac), paroxetine (Paxil), and sertraline (Zoloft). The study demonstrating a 50% serotonin re-uptake inhibition utilized the 0.3% hypericin content standardized extract at a concentration of 6.2 mcg/ml and did not attempt to identify the active inhibitors.^[10] The authors of the study concluded that "the antidepressant activity of Hypericum extract is due to inhibition of serotonin uptake by postsynaptic receptors". However, an important point must be made – until pharmacokinetic studies demonstrate that St John's wort components pass across the blood-brain barrier, a primary site of action outside the central nervous system cannot be ruled out.

Extracts of St John's wort have been tested in various animal models designed to study its antidepressant

effects. In these studies, St John's wort extract was found to enhance the exploratory activity of mice in a foreign environment, extend the narcotic sleeping time in a dose-dependent fashion, antagonize the effects of reserpine, and decrease aggressive behavior in socially isolated male mice.^{[1] [11]} These activities are consistent with the expected effects of antidepressant compounds and appear to be the result of increased monoamine activity.

Anti-viral activity

In vitro studies have shown that hypericin and pseudohypericin exhibit strong antiviral activity against herpes simplex virus I and II as well as influenza types A and B, and vesicular stomatitis virus.^[12] These compounds have also demonstrated remarkable antiviral activity against Epstein–Barr virus.^[13]

A tremendous amount of excitement was generated when researchers from New York University Medical Center and the Weizmann Institute of Science in Israel demonstrated the anti-retroviral activity of hypericin and pseudohypericin.^[14] This preliminary study examined the effect of these compounds on two animal retroviruses, Friend leukemia virus and radiation leukemia virus, both in vitro and in vivo (in mice). The researchers found the effective dose of hypericin in mice to be 1.5– 2.0 mcg/ml. The researchers concluded:

Hypericin and pseudohypericin display an extremely effective antiviral activity when administered to mice after retroviral infection. ... The antiviral activity is remarkable both in its mechanism of action ... and in the potency of one administration of a relatively small dose of the compounds. Availability ... and the relatively convenient and inexpensive procedure for the extraction and purification of hypericin and pseudohypericin further enhance the potential of these compounds.

Later, two possible mechanisms were described to explain the antiviral activity of both hypericin and pseudohypericin.^[15] First, inhibition of assembly or processing of intact virions from infected cells – released virions contain no detectable activity of reverse transcriptase. Second, these compounds also directly inactivate mature and properly assembled retroviruses.

The antiviral activity of hypericin against HIV appears to require the interaction with light to activate the hypericin.^[16] ^[17] Another requirement is sufficient concentrations, as entry of hypericin into infected cells is dependent upon the concentration of hypericin in the blood. At sufficient concentrations, hypericin incubated with HIV-infected whole blood decreases culturable HIV, indicating significant antiviral activity.^[18]

Antibacterial activity

St John's wort extracts have broad-spectrum antimicrobial activity against both Gram-negative and Gram-positive bacteria.^[19] The organisms they studied included *Staphylococcus aureus*, *Streptococcus mutans*, *Proteus vulgaris*, *Escherichia coli*, and *Pseudomonas aeruginosa*.

Pharmacokinetic studies

Recent pharmacokinetic studies have been published using the 0.3% hypericin content standardized extract.^[1] ^[20] The major drawbacks of these studies is the focus on

hypericin and pseudohypericin. Nonetheless, these studies effectively demonstrated that hypericin and pseudohypericin are absorbed. In one of the studies, it was shown that after 4 days of taking the standard dosage of the extract (300 mg t.i.d.), a steady state is reached with mean maximal plasma levels during the steady-state period of 8.5 ng/ml for hypericin and 5.8 ng/ml for pseudohypericin.^[20] Interestingly, even though pseudohypericin is found in higher concentrations in the extract than hypericin, higher blood levels are achieved with hypericin, indicating that hypericin is more bioavailable than pseudohypericin.

CLINICAL APPLICATIONS

The primary use of St John's wort is in the treatment of depression. It may also be of benefit in the treatment of chronic viral infections and, topically, in various skin products.

Depression

Extracts of St John's wort standardized for hypericin content (most studies used the 0.3% hypericin content extract) has significant support in the treatment of mild to moderate antidepressant.^{[1] [3] [21]} The official German Commission E monograph for St John's wort lists psychovegetative disturbances, depressive states, fear, and nervous disturbances as clinical indications for St John's wort.

The clinical evaluation of St John's wort extract began with an initial clinical study of six depressed women, aged 55–65, which measured the change in urinary metabolites of noradrenaline and dopamine following administration of a standardized extract of St John's wort extract (0.14% hypericin content).^[22] Researchers found a significant increase in the catecholamine metabolite 3-methoxy-4-hydroxyphenylglycol, a marker commonly used to evaluate the efficacy of antidepressant therapy. A follow-up study by the same researchers followed 15 women with depression taking the same standardized extract.^[22] The results demonstrated a significant improvement in symptoms of anxiety, apathy, hypersomnia and insomnia, anorexia, psychomotor retardation, depression, and feelings of worthlessness. No side-effects were observed.

Since this initial study, a total of 1,592 patients have been studied in 25 double-blind controlled studies (15 compared with placebo, 10 compared with antidepressant drugs including five studies comparing St John's wort to tricyclics: two vs. imipramine; two vs. amitriptyline; and one vs. desipramine).^{[1] [3] [21] [23]}

In these studies, St John's wort extract was shown to produce improvements in many psychological symptoms, including:

- depression
- anxiety

- apathy
- sleep disturbances
- insomnia
- anorexia
- feelings of worthlessness.

Even more impressive is that St John's wort extract was able to achieve these benefits without producing significant side-effects.

The scientific investigation of St John's wort is not complete. From a clinical perspective, the major shortcomings of the existing clinical trials is their relatively short term (8 weeks) and the lack of studies in severely depressed patients.^[23] Given the growing popularity of hypericum, studies which address these shortcoming are needed. The currently available information clearly supports the short-term use of St John's wort extract as an alternative to standard antidepressant drugs in cases of mild to moderate depression. Whether it will be shown to be suitable in the treatment of serious depressions (i.e. depressions associated with psychotic symptoms and/or depressions with serious risk of suicide) remains to be answered.

As stated above, there have been over 25 double-blind studies with St John's wort extract in the treatment of depression. The methodological quality of this research, particularly the studies since 1989, has been judged as being acceptable by strict criteria.^{[3] [21] [23]} The overall results have also been judged as providing good documentation of antidepressant activity.^{[3] [21] [23]} The double-blind studies with the highest methodological quality rating are listed in [Table 93.1](#) . Several of the better studies are discussed below.

In the study with the highest methodological rating, 135 depressed patients were treated in 20 centers.^[35] Patients were given either St John's wort extract (0.3% hypericin content, 300 mg t.i.d.) or imipramine (25 mg t.i.d.) for a period of 6 weeks. Inclusion diagnoses were typical depressions with single episode, several episodes, depressive neurosis, and adjustment disorder with depressed mood in accordance with DSM-III-R. Main assessment criteria were the Hamilton Depression Scale (HAMD), the Depression Scale according to von Zerssen (D-S) and the Clinical Global Impressions (CGI). In both treatment groups, there were significant decreases in the HAMD from 20.2 to 8.8 in the St John's wort group, and from 19.4 to 10.7 in the imipramine group. The D-S point value also dropped from 39.6 to 27.2 in the St John's wort group, and 39.0 to 29.2 in the imipramine group (see [Table 93.2](#)). The analysis of CGI revealed comparable results in both treatment groups. The main advantage, however, was not so much a difference in therapeutic outcome, but rather a significant advantage in terms of lack of side-effects and excellent patient tolerance in the St John's wort group.

Another high quality randomized, double-blind study examining the effectiveness and tolerance of the 0.3% hypericin content standardized St John's wort extract compared with maprotiline was performed in a group

TABLE 93-1 -- Summary of clinical trials with St John's wort extract in depression

TABLE 93-2 -- Hypericum compared with imipramine

| | St John's wort | Imipramine |
|--------------------------------|----------------|------------|
| Hamilton Depression Scale | | |
| Initial measurement | 20.2 | 19.4 |
| Week 6 | 8.8 | 10.7 |
| Depression Scale (von Zerssen) | | |
| Initial measurement | 39.6 | 39 |
| Week 6 | 27.2 | 29.2 |

of 102 patients with depression.^[34] Patients were given either St John's wort extract (300 mg t.i.d.) or maprotiline (25 mg t.i.d.) for a period of 4 weeks. Effectiveness was determined using the HAMD, D-S, and CGI scales. The total score of the HAMD scale dropped during the 4 weeks of therapy in both treatment groups by about 50%. The mean values of the D-S and the CGI scales showed similar results, and after 4 weeks of therapy, no significant differences in either treatment group were noticed. The onset of the effects occurred up to the second week of treatment, but were observed earlier with maprotiline than with the St John's wort extract. However, maprotiline treatment resulted in the typical side-effects with tricyclics, e.g. tiredness, mouth dryness, and heart complaints, while St John's wort caused no significant side-effects.

In a multicenter double-blind study, 72 depressive patients with a HAMD greater than 16 were given either St John's wort extract (0.3% hypericin content, 300 mg) or placebo three times daily for 4 weeks.^[25] At the end of the trial period, there was a significant advantage for the St John's wort group as 27 out of 34 (81%) patients in this group responded based on a HAMD score less than 10, compared with nine out of 38 (26%) in the placebo group. Another way of looking at the results in this study is to examine the drop in the average HAMD in both groups. In the treatment group, the HAMD dropped from an average of 20.8 at the beginning of the trial to 9.2 after 4 weeks, while in the placebo group the drop was from 20.4 to 14.7. At the end of the 4 week trial, the placebo group and treatment group were subsequently treated for an additional 2 weeks with St John's wort extract in both groups, with the average HAMD in the treatment group dropping below 6 and the original placebo group dropping to below the responder rate of 10.

In another double-blind study, 105 patients with different types of mild to moderate depressions were given either 300 mg of the St John's wort extract standardized to contain 0.3% hypericin or an identically looking placebo three times daily for 4 weeks.^[32] The effectiveness of treatment was judged after 2 and 4 weeks according to the HAMD scale, the standard measure to assess an antidepressant's effectiveness. The results are shown in [Table 93.3](#).

Using the criteria of a decrease in the HAMD of greater

TABLE 93-3 -- Hypericum compared with placebo

| | St John's wort | Placebo |
|----------|-----------------------|----------------|
| Baseline | 15.81 | 15.83 |
| Week 2 | 9.64 | 12.28 |
| Week 4 | 7.17 | 11.30 |

than 50% or achieving a value less than 10 as identification of responders, 28 out of 42 patients (67%) in the St John's wort group responded, compared with 13 of 47 patients (27.7%) in the placebo group. The results of this study are consistent with other well-designed studies comparing St John's wort with placebo.

Seasonal affective disorder

Seasonal affective disorder (SAD) represents a subgroup of major depression with a regular occurrence of symptoms in autumn/winter and full remission in spring/summer. Light therapy has become the standard treatment of this type of depression. Apart from this, pharmacotherapy with antidepressants also seems to provide an improvement of SAD symptoms. The aim of a controlled, single-blind study was to evaluate if St John's wort could be beneficial in treating SAD patients and whether the combination with light therapy would be additionally advantageous.^[36] Patients who fulfilled DSM-III-R criteria for major depression with seasonal pattern were randomized in a 4 week treatment study with 900 mg of St John's wort extract/day (0.3% hypericin content) combined with either bright (3000 lux, $n = 10$) or dim light (<300 lux therapy). The significant reduction in the Hamilton Depression scale in both groups (72 and 60%, respectively) indicates that St John's wort extract may offer support to patients with SAD as a sole therapeutic agent as well as in combination with light therapy.

Insomnia

St John's wort has been shown to improve sleep quality and well-being in healthy elderly subjects.^[37] With antidepressant drugs, particularly tricyclic antidepressants and MAO inhibitors, REM (rapid eye movement) sleep is reduced. St John's wort did not interfere with REM sleep like other antidepressants and was shown to increase the intensity of deep sleep during the total sleeping period as demonstrated by brain wave studies. While St John's wort improved sleep quality it did not act as a sedative (i.e. it did not reduce sleep onset) nor did it change total sleep duration.

Mental function

One of the most interesting comparative studies was a double-blind study where St John's wort extract (0.3%

hypericin content) was compared with maprotyline in 24 healthy volunteers by measuring resting brain wave (EEG) tracings and mental activity (visual and acoustic evoked potentials).^[38] Interpretation of the differences in reactions indicated that, unlike maprotyline, which interferes with mental function, St John's wort actually improves memory and other mental activities.

AIDS and other viral infections

The research suggests that St John's wort may be a useful adjunctive treatment for herpes simplex, mononucleosis, and influenza, although further human studies are needed to establish the optimal dosage of the standardized extract. Combined with its antidepressant activity, St John's wort also appears to be a promising treatment for chronic fatigue syndrome.

The greatest promise of St John's wort, however, may be in the treatment of AIDS. In response to the *in vitro* and animal studies, many AIDS patients began self-administering St John's wort. Although most patients reported feeling better with a more positive outlook, more energy, and less fatigue, it was not known to what degree this was due to a placebo effect.^[39] ^[40] To better determine the benefits, a number of trials evaluated the efficacy of standardized extracts of St John's wort in the treatment of HIV-infected individuals.

In one study, St John's wort extracts providing approximately 1 mg of hypericin/day were studied in 31 patients.^[41] Baseline and 4-monthly measurements, including physical exam, T-cell subsets, and other laboratory parameters, were performed. Concomitant use of AZT and other treatments was permitted. The results of the study were encouraging. In the subgroup of 10 patients who took no AZT either before or during the study ("AZT virgins"; none had AIDS), the mean helper T-cell count increased 13% from baseline after 1 month on St John's wort and maintained this increase for 4 months. Although these increases were not statistically significant, in contrast, helper T-cell counts of the 10 patients using AZT throughout the study fell significantly after an initial mild rise. Side-effects were limited to reversible liver enzyme elevations in five patients with all levels returned to baseline after 1 month without St John's wort extract.

In another open pilot study, 18 HIV patients (three with the CDC II, eight with CDC III, four with CDC IV B and three with CDC IV C1 classification) were treated solely with standardized St John's wort extract (weekly intravenous injection and daily oral intake), providing a daily intake of 2 mg of hypericin.^[42] The 16/18 patients with good compliance showed stable or even increasing counts of absolute helper T-cells over the 40 months of observation. Also the helper to suppressor T-cell ratio showed an improvement in the majority of these patients. Clinically, it was noteworthy that only two of these 16 patients encountered an opportunistic infection during the 40 months of observation. The other 14/16 patients remained clinically stable and active in work and life. This steady-state situation of the HIV infection also correlated with stable values of hemoglobin,

leukocytes and platelets. Furthermore, none of the otherwise known viral complications due to CMV, herpes or EBV was encountered in these 16 patients.

Despite these good preliminary results, the trials proved disappointing as significant blood levels of hypericin could not be achieved using the extract either orally or intravenously. Use of the standardized extract for the treatment of HIV infection has since been replaced by the use of intravenously administered synthetic hypericin. Preliminary studies are again producing some encouraging results with good safety, although photosensitivity may occur (see “Toxicity”, p. 804) and long-term controlled evaluation is needed.^[43] ^[44] (for further discussion, see [Ch. 141](#)).

Topical application

St John’s wort has a historical use as an aid in wound healing. Research has demonstrated antibacterial and wound healing activity.^[2] St John’s wort preparations have also been used in burns, as a sunscreen, and in the treatment of muscular pain.^[2] Oil-based preparations are preferred for topical applications.

DOSAGE

The dosages of St John’s wort preparations are based upon their hypericin content. The overwhelming majority of the studies in depression have used St John’s wort extract standardized to contain 0.3% hypericin. This extract is produced via an extraction with 80% methanol (which is subsequently removed). Although hypericin is a key component, this extract is composed of a wide range of compounds constituting the remaining 99.7% of the extract. Manufacturers of these standardized extracts employ HPLC techniques to identify not only the hypericin and pseudohypericin, but also related compounds, flavonoid components, xanthenes, cinnamic acid, and several other key components. The point is that although the dosage is based upon hypericin levels, assuring appropriate levels of these other constituents is also vitally important.

To achieve the benefits noted in the clinical trials, it is difficult to recommend any other forms beyond standardized extracts. Nonetheless, here are dosage recommendations for various forms of St John’s wort:

- dried flowers: 2–4 g three times/day
 - tincture (1:5): 3–6 ml three times/day
 - fluid extract (1:1): 1–2 ml three times/day
-

- standardized fluid extract (0.14% hypericin–1.0 mg hypericin/3 cc): 0.5–0.9 ml three times/day
- standardized solid (dry-powdered) extract (0.14% hypericin): 600 mg three times/day
- standardized solid (dry-powdered) extract (0.3% hypericin): 300 mg three

times/day.

TOXICITY

There is considerable evidence that St John's wort can cause severe photosensitivity in animals grazing extensively on the plant. The term "hypericism" has been used to describe a skin disease found in animals who graze on large quantities of St John's wort.^[45] However, reports of photosensitivity in humans have been rare and have been limited to those taking excessive quantities for HIV infection. St John's wort is unlikely to be toxic to humans when used at recommended medicinal doses. However, individuals with AIDS taking large amounts of St John's wort extracts (or hypericin) have developed photosensitivity.^[44]

Because of the possibility of photosensitivity, avoidance of exposure to strong sunlight and other sources of ultraviolet light when using St John's wort is often recommended to individuals, especially those with fair skin. However, while this recommendation may be appropriate, it must be pointed out that the therapeutic dosage of 2.7 mg/day of hypericin is about 30–50 times below the level required to produce phototoxicity.^[46]

Historically, those taking St John's wort have been advised to avoid foods and medications that are known to negatively interact with MAO-inhibiting drugs such as tyramine-containing foods (cheeses, beer, wine, pickled herring, yeast, etc.) and drugs such as L-dopa and 5-hydroxytryptophan should be avoided. However, given the recent research demonstrating the lack of any in vivo MAO inhibition, this recommendation is no longer justified.

No significant side-effects have been reported in the numerous double-blind studies, but perhaps the best demonstration of the excellent safety record of St John's wort extract is a large-scale study involving 3,250 patients conducted in Germany.^[47] Results were analyzed by means of a patient questionnaire. Pooled data indicated that symptoms of depression were reduced in frequency and intensity by approximately 50%. The frequency of undesired side-effects was reported in 79 patients (2.43%) and 48 (1.45%) discontinued therapy. The most frequently noted side-effects were gastrointestinal irritation (0.55%), allergic reactions (0.52%), fatigue (0.4%), and restlessness (0.26%).

The frequency and severity of side-effects with St John's wort extract are clinically insignificant, especially when compared with the well-known side-effects of tricyclics and other antidepressants. There have been no deaths due to St John's wort toxicity, a stark contrast to the 31 deaths per 1 million prescriptions produced by synthetic antidepressants.^[48]

Chapter 94 - Introduction to the clinical use of Chinese prepared medicines

M. Harrison Nolting ND LAc
Qiang Cao MD(China) ND LAc

INTRODUCTION

In traditional Chinese medicine, herbal medicines, which are considered synonymous with drugs, have been in use for more than 2,000 years.^[1] Secret family (or company) recipes called “patent” medicines were first produced in the Song Dynasty (960–1234 AD) and were dispensed by government agencies such as the “Imperial Benevolence Pharmacy”.^[2] The long history and development of these prepared medicines, as well as their current widespread popularity, attest to the ancient adage that such preparations are convenient, effective, and economical.^[3] ^[4] In recent years, most of these “patent” medicine recipes have become part of the public domain, making it more appropriate to refer to this group as prepared medicines. But since the term “patent” has virtually become synonymous with all Asian produced medicines in pill, capsule, or liquid form, the term will certainly persist.^[5]

History of use in the West

Yeung’s Handbook of Chinese herbs and formulas^[6] and Bensky & Gamble’s Chinese herbal medicine^[7] are major English works which provide basic Chinese herbal information. The introduction of Chinese prepared medicines and the books describing them have increased Western interest in Chinese herbs. The authors hope this growing interest in the prepared medicines will lead the serious student to closely study the history and development of the entire traditional Chinese materia medica. Mastering the art of herbal medicine practice requires lengthy study of the strategies as well as the formulas of Chinese herbal medicine.^[6] ^[7] ^[8] ^[9] ^[10]

Although Chinese medicine and pharmacy began to spread outside of China’s borders nearly 2,000 years ago, it is only in the last 20 years that interest has grown in North America. Much of this is due to former President Nixon’s trip to the People’s Republic of

China in the early 1970s and subsequent reporters' visits and articles, especially those of James Reston of the *New York Times*.

The growth of acupuncture and oriental medical practices such as herbal medicine in the United States has been steady since that time.^[11] In 1997, the number of practitioners of acupuncture and Oriental medicine, including those who utilize prepared medicines in their practice, had risen to over 20,000.

The traditional loose herb recipes used in Chinese herbal medicine are cooked and made into medicinal soups which are often quite bitter and difficult for the American palate. The Chinese solution to this dilemma is to increase the use of raw licorice in the formula and to offer sugar wafers to the patient to help offset the bitter taste, although most Chinese welcome a bitter taste as a normal part of Asian cuisine. The prepared medicines offer an alternative to the traditional preparations. A number of companies, particularly in Taiwan and California, have begun to popularize the manufacture and sale of powder and tincture formulas in single herb form to help “bridge” the traditional form and the prepared, more palatable, forms of medicine. This allows the practitioner to still utilize the traditional approach, that of mixing and adjusting the formulas tailored to the patient’s individual diagnosis. Prepared formulas are fixed, of course, and do not allow any adjustments in the ingredients.

Prior to the mid-1970s, the FDA restricted the import and sale of traditional medicines by ethnic groups. New legislation and court rulings since then have lifted these restrictions, which, coupled with the explosion of acupuncture on the American health scene, has opened the door to the spread of prepared medicines.^[12]

Now, due to this rapid growth in the sale and use of prepared medicines, problems with adulterants and false labeling are increasing, especially in California, where a multi-agency herbal medicine task force involving numerous California and federal government agencies was formed in response. In fact, it is stated in California Department of Health Services documents that “most imported Asian patent medicines do not fully comply with California laws”.^[13] While some of these violations are indeed potentially dangerous and may involve toxic ingredients and the inclusion of endangered species, many involve labeling issues and can often be sorted out by revising the labeling at the company of origin.

Market

The market for Chinese prepared medicines is huge. China will become the largest pharmaceutical market in the world within a few years. In herbal medicine, the Chinese sales alone were \$2.3 billion in 1995. It is estimated that there are over 5,000 “licensed patent medicines” in China.^[14] Outside of the enormous “inside China market”, the growing interest and use of natural medicine worldwide are driving the consumption of prepared medicines rapidly upward. As mentioned already, this growth has sparked

abuse and problems with product labeling and safety that the entire profession is working to counteract.

FORMULATIONS AND PREPARATIONS

Chinese patent medicines are prepared in a number of different forms. As far back as 200 BC, Chinese pharmaceuticals had developed a surprising level of sophistication. Pills were bound together using a wide variety of animal and human substances. [Table 94.1](#) shows the 15 major dosage forms of Chinese prepared medicines.

In China, the prepared medicines are produced at factories located throughout the country. Reputation and awards are very important to these mainland Chinese operations. Factories such as the Chongqing Tong Jun Ge Medicine Works in Sichuan province, built in 1908, are quite proud of their products. This factory produces more than 200 medicines in 14 therapeutic categories.^[16]

The most famous factory is at the Tong Ren Tang Pharmacy in Beijing. The Tong Ren Tang Pharmacy has been operated by the same family for 317 years. Prepared medicines produced in the factory hold the highest reputation in China, where the factory has supplied medicines to Chinese royalty over several centuries. The drug control acts implemented by the Chinese government in the 1970s and 1980s have helped to further guarantee quality control of prepared medicines in China.

Adulterants, endangered species

Many prepared medicines made outside mainland China lack the same quality controls as the factories within China. In 1975, an herbal-based preparation called Toukuwan was manufactured in Hong Kong by the Nan-Lien Pharmaceutical Company and widely promoted in the United States as a treatment for rheumatism and

arthritis. The FDA banned the import of Toukuwan after it discovered four drugs including valium in the Chuifong preparation. Various prescription drugs have also been discovered in other prepared medicines. The *Journal of the American Medical Association* also reported four cases of agranulocytosis caused by prepared medicines in 1975 prior to the FDA ban.

The Chuifong product has continued to appear under various names such as “miracle herbs” since 1975.^[17] ^[18] Caution must be used when purchasing and prescribing prepared herbal medicines, and the authors recommend using only well-known and reputable manufacturers. If there is any doubt, utilize products produced at companies in America which are typically under far more quality control standards than those parts of Asia.

In May 1994, TRAFFIC USA and the World Wildlife Fund published *Prescription for Extinction: Endangered Species and Patented Oriental Medicines in Trade*.^[19] This report gave insight into the vast number of endangered species being used in natural medicine. Bastyr University’s Department of Acupuncture and Oriental Medicine has been conducting an in-depth study of the endangered species used in the practice of Chinese herbal medicine. The work at Bastyr has forged strong relationships with conservation groups, federal agencies, consumers, students, and others at institutions involved in the field of traditional Chinese medicine. The Bastyr project, called the Endangered Species Project (ESP), is creating a database listing all common Chinese herbal formulations, with their respective ingredients, sold in the United States. The database indicates which products and traditional formulas contain endangered or threatened species according to Appendices I, II, and III of the Convention on International Trade in Endangered Species Of Wild Fauna and Flora (CITES).^[20]

DISPENSARY GUIDE

The 10 Chinese prepared medicines described in [Table 94.2](#) represent a small sample of the most common and therapeutically effective formulations. Several common varieties of preparations such as pills, tablets, oral liquid, tincture and plaster are included. An attempt has been made to introduce preparations focusing on major human systems such as cardiovascular, respiratory, CNS, urinary, female, and dermatology. This systems approach is a common method of teaching prepared

medicines.

Ingredients are listed with their Chinese (Pinyin) name, botanical name and percentage in formula. Actions are listed in terms of Traditional Chinese Medicine with Western activities when pertinent. Indications are given according to major Chinese sources. Administration and dosage information is provided with specific directions for adult as well as pediatric use. Packing information is also provided to help ensure proper recognition and dosage. A special notes section is included to highlight unique uses, cautions and contraindications of the preparations.

Due to the questionable standards of prepared medicines manufactured in Asia and generally outside of China, only mainland Chinese sources known to the authors are listed. The authors also urge practitioners to scrutinize the labels of products from unknown sources. With correct labeling, ingredients of prepared medicines should be obvious to anyone who can read Latin or Chinese herbal names.

In recent years, prepared medicine companies have become well established in the United States. Several high-quality manufacturers are now producing formulas in forms more suitable to Westerners. These tinctures, powders and capsules are usually based on the same classical formulas described in this chapter.

TABLE 94-2 -- Ten Chinese prepared medicines

| Formula name | Ingredients | Actions | Indications | Dosage |
|---------------------|--------------------|----------------|--------------------|---------------|
|---------------------|--------------------|----------------|--------------------|---------------|

| | | | | |
|---|--|---|--|--|
| <p>Yin Chiao Chieh Tu Pien (Lonicera and Forsythia dispel heat tablets)</p> | <p>Lonicera flower (Jin Yin Hua), 17.85% Forsythia fruit (Lian Qiao), 17.85% Arctium fruit (Niu Bang Zi), 10.72% Platycodon root (Jie Geng), 10.72% Mentha herb (Bo He), 10.72% Soja seed (Dan Dou Chi), 8.93% Licorice root (Gan Cao), 8.93% Lophaterum leaf (Zhu Ye), 7.14% Scizonepeta herb (Jing Jie), 7.14%</p> | <p>Antiphlogistic Disinfectant Carminative Refrigerant</p> | <p>Common cold and flu Fever and sensation of chill Pain and weariness of limbs Headache Cough Swelling sore throat Mumps Parotitis</p> | <p>Two to four tablets b.i.d. or t.i.d</p> |

Chapter 95 - *Lobelia inflata* (Indian tobacco)

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

Lobelia inflata (family: Campanulaceae)
Common name: Indian tobacco

GENERAL DESCRIPTION

Lobelia is an indigenous North American annual or biennial plant with an erect, angular, hairy stem that contains a milky sap and grows from 6 inches to 3 feet in height. Numerous small, two-lipped, blue flowers grow in spike-like racemes from July to November.

CHEMICAL COMPOSITION

Lobelia contains about 0.48% pyridine (piperidine) alkaloids composed mainly of lobeline (see [Fig. 95.1](#)) with lesser amounts of lobelanine, lobelanidine, and other alkaloids. Other constituents include resin, gum, lipids, and chelidonic acid.^{[1] [2] [3]}

HISTORY AND FOLK USE

Lobelia was used extensively by Thomsonians as an emetic, diaphoretic, expectorant, sedative, antispasmodic, and anti-asthmatic. Conditions for which it has been used include, among others:

- asthma
- whooping cough
- bruises
- sprains
- ringworm

- insect bites
- poison ivy symptoms.

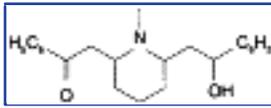

Figure 95-1 Lobeline.

816

Thomson stated: “there is no vegetable which the earth produces more harmless in its effect on the human system, and none more powerful in removing disease and promoting health than lobelia”.^[4] Lobelia has also been used as an aid in stopping smoking.

PHARMACOLOGY

Lobeline has many of the same pharmacological actions as nicotine, but is generally regarded as being less potent.^[5] ^[6] These actions include stimulation of the autonomic ganglia (nicotinic receptors) followed by depression.

Gastrointestinal effects

The emetic action of lobeline is mediated by its stimulation of the emetic chemoreceptor trigger zone in the area postrema of the medulla oblongata (this area is outside the blood–brain barrier) and activation of the vagal and spinal afferent nerves that form the sensory input of the reflex pathways involved in vomiting.^[7]

Respiratory effects

Indian tobacco is a very effective expectorant. Although it has a long history of use in asthma, it causes bronchoconstriction and is a respiratory stimulant in vitro,^[8] suggesting a cholinergic effect in the respiratory system. However, it also binds to the nicotine acetylcholine receptors in ganglions, thus promoting the release of epinephrine and norepinephrine.^[8] It is this action on adrenal hormone secretion that is responsible for lobelia’s therapeutic effects in asthma.^[9]

CLINICAL APPLICATIONS

Lobelia is primarily used as an expectorant in such conditions as pneumonia, asthma, and bronchitis. It appears that its major actions are mediated by the adrenal cortex.^[8] Experimentally induced lung edema in rats is responsive to lobeline in many models that are unresponsive to any other medication.^[8] Furthermore, although lobeline causes bronchoconstriction in dogs and rats, in guinea pigs and (presumably) humans the

opposite – bronchodilation – occurs.^[10] This is probably related to adrenal stimulation.

Although effective when used alone in the treatment of asthma, it has traditionally been used in combination with other botanical agents.^[9] Typically it is combined with *capsicum frutescens* and *symphlocarpus factida*.

Lobelia is also used to lessen nicotine withdrawal, as it has a similar action to nicotine.^[1]
^[2]

DOSAGE

- Dried herb: 0.2–0.6 g three times/day
- Tincture: 15–30 drops three times/day
- Fluid extract: 8–10 drops three times/day.

TOXICOLOGY

Ingestion of toxic levels of lobelia usually results in vomiting, thereby lessening the likelihood of a fatal outcome.^[4] Like nicotine poisoning, toxic symptoms include:

- nausea
- salivation
- diarrhea
- disturbed hearing and vision
- mental confusion
- marked weakness.

Faintness and prostration ensue; blood pressure falls; the pulse becomes weak, rapid, and irregular; breathing is difficult; and collapse occurs followed by convulsions. Death may result from respiratory failure.^[5] The antidote in acute poisoning is 2 mg of atropine, which is given subcutaneously.^[11]

Chapter 96 - *Melaleuca alternifolia* (tea tree)

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

Melaleuca alternifolia (family: Myrtaceae)
Common name: tea tree

GENERAL DESCRIPTION

Tea tree (*Melaleuca alternifolia*) is a small tree native to only one area of the world: the north-east coastal region of New South Wales, Australia. The leaves, the portion of the plant that is used medicinally, are the source of a valuable therapeutic oil. Although there are over 50 members of the *Melaleuca* family, the oil from the leaf of *Melaleuca alternifolia* has received the most research attention.

CHEMICAL COMPOSITION

Tea tree leaves contain about 1.8% of oil obtained via steam distillation.^[1] This oil contains over 48 compounds, but is chiefly composed of:^[2]

- 1-terpinen-4-ol
- 1,8-cineol
- gamma-terpinene (see [Fig. 96.1](#))
- *p*-cymene
- other terpenes.

The Australian standard (AS 2782-1985) for “Oil of *Melaleuca* (Terpinen-4-ol type)” sets a minimum content of terpinen-4-ol at 30% and a maximum 1,8-cineol content of 15%.^[1]

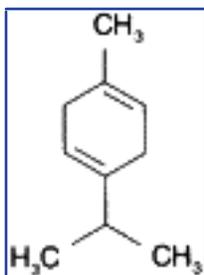

Figure 96-1 Gamma terpinene.

818

HISTORY AND FOLK USE

The medicinal properties of crushed tea tree leaves were known to the Bundjalung Aborigines of northern New South Wales, Australia. In fact, the waters of a lagoon where tea tree leaves had fallen and decayed for hundreds of years were viewed as having tremendous healing properties.^[1]

The popular name of tea tree was first reported in 1777 Captain Cook's account of his second voyage entitled, *A Voyage to the South Pole*:^[1]

... we at first made it [some beer] of a decoction of the spruce leaves; but finding that this alone made the beer too astringent, we afterwards mixed with it an equal quantity of the tea plant (a name it obtained in my former voyage from our using it as tea then, as we also did now), which partly destroyed the astringency of the other, and made the beer exceedingly palatable, and esteemed by everyone on board.

The leaves of *Melaleuca alternifolia* were also used by the early settlers of Australia to make tea, hence the further use of the popular name of "tea tree".^[1]

The first report of tea tree's medicinal use appeared in the *Medical Journal of Australia* in 1930.^[3] A surgeon in Sydney reported impressive results using a solution of tea tree oil to clean surgical wounds. According to the author:

The results obtained in a variety of conditions when it (tea tree oil) was first tried were most encouraging, a striking feature being that it dissolved pus and left the surface of infected wounds clean so that its germicidal action became more effective without any apparent damage to the tissues. This was something new, as most efficient germicides destroy tissue as well as bacteria....

During World War II, tea tree oil was issued to soldiers to use as a disinfectant. The Australian Army went so far as to commandeer supplies of the oil and exempt leaf cutters from national service in order to maintain production. The production of tea tree

oil during World War II was regarded as an “essential” industry.^[1]

After World War II, the tea tree oil industry stagnated for more than 30 years. There were a number of reasons for this, including the general trend away from natural medicines toward synthetic medical drugs. However, during the late 1970s and early 1980s, the Australian tea tree oil industry was reborn as successful plantations growing *Melaleuca alternifolia* were established.^[1]

Tea tree oil has been used in the treatment of:^[1]

- acne
- aphthous stomatitis
- tinea pedis (athlete’s foot)
- boils
- burns
- carbuncles
- corns
- gingivitis
- herpes
- impetigo
- infections of the nail bed
- insect bites
- lice
- mouth ulcers
- psoriasis
- root canal treatment
- ringworm
- sinus infections
- pharyngitis
- skin and vaginal infections
- thrush
- tonsillitis.

A variety of tea tree oil-based cosmetic products exist in the marketplace, including toothpastes, shampoos and conditioners, creams, hand and body lotions, soaps, gels, liniments, and nail polish removers.

PHARMACOLOGY

Tea tree oil possesses significant antiseptic properties and is regarded by many as the ideal skin disinfectant. This claim is supported by its efficacy against a wide range of organisms, its good penetration and lack of irritation to the skin.^[1] The therapeutic uses of tea tree oil are based largely on its antiseptic and antifungal properties. Organisms inhibited by tea tree oil are listed in [Table 96.1](#) .

CLINICAL APPLICATIONS

The historical uses of tea tree oil demonstrate its wide range of applications as an antiseptic. Three of the more popular and documented uses are in the treatment of skin infections, vaginal infections, and common foot complaints.

TABLE 96-1 -- Organisms inhibited by *Melaleuca alternifolia* oil^[1] ^[4] ^[5] ^[6]

| Organism | Mean inhibitory zone (mm) |
|------------------------------------|---------------------------|
| <i>Bacillus subtilis</i> | 24.1 |
| <i>Bacteroides fragilis</i> | 26.1 |
| <i>Branhamella catarrhalis</i> | 56.4 |
| <i>Candida albicans</i> | 20.3 |
| <i>Clostridium perfringens</i> | 27.9 |
| <i>Escherichia coli</i> | 33.9 |
| <i>Enterococcus faecalis</i> | 16.9 |
| <i>Lactobacillus acidophilus</i> | 27.1 |
| <i>Mycobacterium smegmatis</i> | 31.0 |
| <i>Propionibacterium acnes</i> | |
| <i>Pseudomonas aeruginosa</i> | 0 |
| <i>Serratia marcescens</i> | 24.8 |
| <i>Staphylococcus aureus</i> | 25.4 |
| <i>Streptococcus pyogenes</i> | |
| <i>Trichomonas vaginalis</i> | |
| <i>Trichophyton mentagrophytes</i> | |

Skin infections

Tea tree oil is useful in a broad range of dermal infections, not only because of its broad-spectrum antiseptic properties, but also because of its capacity to mix with sebaceous secretions and penetrate the epidermis.

A clinical trial in patients with furuncles demonstrated that tea tree oil encouraged more rapid healing without scarring, compared with matched controls.^[7] Presumably the positive clinical effects were due to the oil's germicidal activity against *Staphylococcus aureus*. The method of application included cleaning the site, followed by painting the

surface of the furuncle freely with tea tree oil two or three times a day.

For most skin infections, the most effective treatment appears to be direct application of full-strength, undiluted oil at the site of infection. If irritation occurs, diluted preparations may be tried.

Acne

Topical application of tea tree oil is a suitable alternative to benzoyl peroxide preparations. In one study, 124 patients with mild to moderate acne randomly received either a 5% gel of tea tree oil or 5% benzoyl peroxide lotion to be applied topically daily. After 3 months, both treatments produced a significant improvement in the mean number of both non-inflamed and inflamed lesions, although with non-inflamed lesions benzoyl peroxide was found to be more effective. An important finding was that there were fewer reports of side-effects (dryness, pruritis, stinging, burning, and skin redness) with tea tree oil (44% vs. 79%).^[8]

Common foot problems

Tea tree oil, in emollient form (8% tea tree oil) or in solution (40%), can be massaged into the feet daily for the treatment of tinea pedis, foot irritation, and bromhidrosis (severely foul-smelling feet).

One author concluded after 6 years of using different concentrations and preparations that tea tree oil eradicates or improves the symptoms of tinea pedis when used daily by the patient at home.^[4] He also reported that even undiluted forms had little effect on onychomycosis (discussed further below). Diluted tea tree oil in solution was found to reduce foot irritation and promote wound healing with surgical incision in cases of corns, calluses, bunions, and hammer toes, and was extremely effective in diminishing bromhidrosis.

In tinea pedis, a double-blind study found that 10% tea tree oil cream compared quite favorably with the antifungal tolnaftate in relieving symptoms but was less effective in eliminating the fungi from cultures.^[5] Specifically, both the tea tree group (24 out of 37) and the tolnaftate group (19 out of 33) showed significant improvement in the four clinical parameters of scaling, inflammation, itching, and burning, but only 30% of the subjects applying tea tree oil cream were culture negative, compared with 85% in the tolnaftate group.

Fungal nail infection

Fungal nail infections (onychomycosis) are the most frequent cause of nail disease, affecting approximately 2–13% of the population. Standard medical treatments include debridement, topical antifungals, and systemic antifungals. All current therapies have high recurrence rates. Oral therapy has the added disadvantages of high cost and potentially serious adverse effects. A recent study compared the efficacy and tolerability of topical application of 1% clotrimazole solution with that of 100% tea tree oil for the

treatment of toenail onychomycosis.^[9]

The 117 patients received twice daily applications of either 1% clotrimazole (CL) solution or 100% tea tree (TT) oil for 6 months. Debridement and clinical assessment were performed at 0, 1, 3, and 6 months. Cultures were obtained at 0 and 6 months. Each patient's subjective assessment was also obtained 3 months after the conclusion of therapy. After 6 months of therapy, the two treatment groups were comparable based on culture cure (CL = 11%, TT = 18%) and clinical assessment documenting partial or full resolution (CL = 61%, TT = 60%). Three months later, about one-half of each group reported continued improvement or resolution (CL = 55%, TT = 56%). These results indicate that topical therapy with tea tree oil, in conjunction with debridement, provides excellent improvement in nail appearance and symptomatology.

Vaginal infections

Tea tree oil demonstrates germicidal activity against a number of common vaginal pathogens and opportunistic organisms, including *Trichomonas vaginalis* and *Candida albicans*.^{[10] [11]}

A 40% solution of tea tree oil emulsified with isopropyl alcohol and water was found in a clinical study to be highly effective for the treatment of cervicitis, chronic endocervicitis, trichomonal vaginitis, and vaginal candidiasis.^[11] Weekly in-office treatment (usually four to six were necessary) involved thorough washing of the perineum, labia, and vagina with a suitable scrub (the commercial product pHisoHex was used in the study). After drying, the affected areas were washed with a 1% tea tree oil solution. This was followed by insertion of a tampon (three 4 × 4 inch sponges) saturated with the 40% tea tree oil solution. Patients were instructed to remove the tampon after 24 hours.

For infectious processes, i.e. trichomonas and candidiasis, daily vaginal douches containing 1 quart of water

with a 0.4% concentration of the oil were prescribed. No irritation, burning or other side-effects were reported or observed with either the office applications or the douches.

DOSAGE

A number of commercial products exist which contain tea tree oil. Tea tree oil can be used as a topical antiseptic for reducing microbial counts in wounds, surgical incisions, and skin and vaginal infections. In addition, tea tree leaves can be used to make teas which may be of benefit in cases of sore throat, tonsillitis, sinus infections, and colitis.

TOXICITY

Tea tree oil is extremely safe for use as a topical antiseptic. However, it may cause allergic contact dermatitis in some individuals. During a 3 year period, seven patients were seen in an outpatient dermatology clinic in Kona, Hawaii, for contact dermatitis due to the use of commercially available product containing 100% tea tree oil.^[12] The patients were treating pre-existing skin conditions, which included foot fungus, dog scratches, insect bites, and rashes. All patients presented with an eczematous dermatitis. Patch tests indicated that all patients were sensitive to a 1% solution of tea tree oil. It is recommended that individuals apply the oil to a small area of skin before using tea tree oil for the first time to avoid the bother of developing contact dermatitis over a larger area.

The oral ingestion of tea tree oil cannot be recommended, as this could lead to a toxic reaction. However, folk use suggests that oral ingestion of tea from the leaves is reasonably safe.

Chapter 97 - Melatonin

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

GENERAL DESCRIPTION

Melatonin (not to be confused with melanin, the compound responsible for skin pigment) is a hormone manufactured from serotonin and secreted by the pineal gland (see [Fig. 97.1](#)). The pineal gland, a small pea-sized gland at the base of the brain, has been a source of curiosity since antiquity. The ancient Greeks considered the pineal gland as the seat of the soul, a concept that was extended by the philosopher Descartes. In the 17th and 18th centuries, physicians associated “madness” with the pineal gland. Physicians in the early 1900s believed the pineal gland was somehow involved with the endocrine system. The identification of melatonin in 1958 provided the first solid scientific evidence of an essential role for the pineal gland. It is now thought that the sole function of the pineal gland is to manufacture and secrete melatonin.

The exact function of melatonin is still poorly understood, but it is critically involved in the synchronization of hormone secretion. The natural biorhythm of hormone secretion is referred to as the “circadian” rhythm. The human body is governed by an internal clock that signals the secretion of various hormones at different times to regulate body functions. Melatonin plays a key role as the biological time keeper of hormone secretion. Melatonin also helps to control sleep/wake cycles. Release of melatonin is stimulated by darkness and suppressed by light via a multisynaptic pathway which connects the pineal gland to the retina.

SYNTHESIS AND SECRETION

Melatonin secretion is largely related to the length of

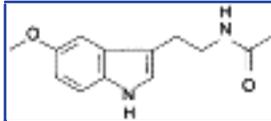

Figure 97-1 Melatonin.

822

Figure 97-2 Melatonin synthesis.

the night, since most of the melatonin synthesis occurs during the dark phase as a result of increased activity of the enzyme serotonin-*N*-acetyltransferase.^[1] Hence, there is a normal circadian pattern of melatonin synthesis and secretion (see [Fig. 97.2](#)). The longer the night, the longer the duration of synthesis and secretion. The most consistent observation in humans is that melatonin profiles show a phase change from winter to summer, with earlier secretion in summer than in winter. When humans are kept strictly in darkness for 14 hours/day for a period of 2 months, the melatonin secretion pattern expands to cover almost the entire dark period, and concomitantly, in extended periods of 14 hours of light, the rhythm contracts to less than 10 hours, with accompanying changes in body temperature and sleep.^[2]

Light of sufficient intensity at night rapidly reduces melatonin production.^[3] The most effective spectrum of light which produces melatonin-lowering effect is the green band (540 nm), corresponding to the rhodopsin absorption spectrum in the human eye.^[4] This observation is of considerable importance, in understanding not only the physiological effects of melatonin, but also its importance in the control of circadian rhythms and the treatment of seasonal affective disorder (discussed further in [Ch. 126](#)).^[5]

The antidepressant effect of light therapy in the treatment of seasonal affective disorder (SAD) is probably due to balancing of the altered circadian rhythm by restoring proper melatonin synthesis and secretion by the pineal gland. Disruption of pineal function is thought to be a major reason for seasonal affective disorder as well as jet-lag.^{[1] [6]}

Clinical evaluation of melatonin secretion

The circadian pattern of melatonin secretion and the response of body tissues to orally administered melatonin can be monitored by either salivary or serum levels, as saliva and serum melatonin concentrations correlate well.^[7] However, salivary melatonin is preferable because it eliminates the need for multiple blood draws and allows the patient the luxury of collecting the sample at home. Typically, patients will be asked to collect saliva according to the laboratories own technique (either soaking a swab or simply expectorating saliva into a small container) at four different times (including nocturnal determination). Monitoring circadian secretion of melatonin is clinically indicated in the conditions in [Table 97.1](#)

TABLE 97-1 -- Conditions where determining melatonin levels may be appropriate

-
- Insomnia related to disturbed circadian rhythm
-
- Seasonal affective disorder
-
- Delayed sleep phase syndrome
-
- Stress
-
- Cancer
-
- Multiple sclerosis
-
- Abnormal sexual development
-
- Administration and monitoring of melatonin therapy

and can assist the clinician in proper timing of melatonin dosage.

PHARMACOLOGY

In addition to its role in synchronizing hormone secretion, melatonin has been shown to possess antioxidant effects.^[8] This action may explain the studies in rats showing that melatonin supplementation led to longer lives (31 months vs. 25 months). However, the clinical significance of melatonin's antioxidant effects have not been fully determined. It is hard to imagine that its antioxidant effects would have greater significance than vitamin C, vitamin E, and a host of other antioxidants which can be delivered at much higher concentrations. Melatonin has also been shown to exert some sedative and anti-cancer effects (discussed below).

The pharmacokinetics of orally administered melatonin has recently been studied. Daytime serum melatonin levels in normal adults are in the range of 20 pg/ml rising to levels of about 150 pg/ml at night.^[9] Oral dosages of 0.1–0.3 mg produce serum concentrations that are equivalent to normal physiologic night-time melatonin levels.^[10] However, because melatonin demonstrates a large hepatic first-pass effect and a biphasic elimination pattern, therapeutic dosages are typically 1–3 mg.^{[2] [11] [12]}

CLINICAL APPLICATIONS

The primary clinical uses of melatonin are in the treatment of jet-lag, insomnia, and as an adjunct in cancer therapy. In addition, the role of melatonin in depression is discussed. There are other possible indications for melatonin based on very preliminary studies. For example, low melatonin levels have been found in multiple sclerosis, coronary artery disease, epilepsy, and postmenopausal osteoporosis. The studies in multiple sclerosis

and coronary artery disease are also briefly discussed below along with a discussion on

the relationship to vitamin B₁₂ and melatonin secretion.

Jet-lag

Several double-blind studies have shown melatonin to be very effective in relieving jet-lag.^{[13] [14] [15] [16]} Different dosage recommendations have been given. Some researchers have recommended that melatonin be taken at the beginning of the sleep period at the point of departure starting a few days before departure (especially when traveling eastward). Others have recommended taking melatonin just one time on the first evening upon arriving at the new destination. The later recommendation avoids the problem of extreme drowsiness sometimes produced by melatonin at an unwanted time.

A recent study was designed to answer the question of optimal timing of melatonin supplementation.^[17] In the study, 52 members of an airline cabin crew flying an international route were randomly assigned to three groups:

- early melatonin – 5 mg started 3 days prior to arrival until 5 days after return home
- late melatonin – placebo for 3 days then 5 mg melatonin for 5 days at new destination)
- placebo.

Daily ratings in jet-lag, mood, and sleepiness measures demonstrated that the best recovery was in the late melatonin group. The early melatonin group actually demonstrated a worse recovery compared with the placebo group. This study suggests that the best way to use melatonin for jet-lag is 5 mg in the evening at the new destination for 5 days.

Insomnia

Melatonin plays an important role in the induction of sleep. Low melatonin secretion at night can be a cause of insomnia. Several double-blind trials have shown melatonin supplementation to be very effective in promoting sleep.^{[18] [19] [20] [21] [22]} However, it appears that the sleep-promoting effects of melatonin are most apparent when melatonin levels are low.^[23] In other words, melatonin is not like taking a sleeping pill. It will only produce its effects when melatonin levels are low. When melatonin is given just before going to bed in normal subjects or in patients with insomnia who have normal melatonin levels, it produces no sedative effect. This is because, normally, just prior to going to bed there is a rise in melatonin secretion. Melatonin supplementation is only effective as a sedative when the pineal gland's own production of melatonin is very low. However, low melatonin levels are thought to be an extremely common cause of insomnia in the elderly.^[24]

In one of the most interesting studies, 26 elderly insomniacs with lower than normal melatonin levels were given 1–2 mg of melatonin 2 hours prior to the desired bedtime for 1 week. Rapid and slow release melatonin preparations were used. Both sleep latency and sleep quality were evaluated. While there was no discernible difference in sleep onset and sleep efficiency (percentage of time asleep of total time in bed)

between the two forms, the timed-release form yielded better results on sleep maintenance.^[25]

Cancer

Melatonin has been shown to inhibit several types of cancers, particularly hormone-related cancers like those of the breast and prostate.^[26] It has been shown to inhibit both the initiation and promotion of cancer. It has been theorized that the increased cancer incidence reported in individuals living and/or working in an environment in which they are exposed to higher than normal artificial electromagnetic fields may be caused by suppression of melatonin synthesis.^[27] The exposure of humans or animals to light (visible electromagnetic radiation) at night rapidly depresses pineal melatonin production and blood melatonin levels. Likewise, the exposure of animals to various pulsed static and extremely low-frequency magnetic fields also reduces melatonin levels. Reduction of melatonin by artificial electromagnetic field exposure may be a significant risk factor for cancer.

Melatonin has also been shown to exert anti-cancer effects in clinical trials in cancer patients. In these studies, melatonin has been given at moderate (e.g. 10 mg daily) to extremely high levels (i.e. greater than 40 mg daily). Melatonin has most often been used in combination with other anti-cancer agents, including interleukin 2 and interferon. The results are promising.

While interferon and interleukin 2 (IL-2) are often ineffective when used alone, in combination with melatonin very good results have been obtained. For example, in one study, 80 patients with advanced solid neoplasms were randomized to receive either IL-2 alone (3 million IU/day for 6 days a week for 4 weeks) or in combination with melatonin (40 mg/day orally at 8.00 p.m.).^[28] A complete response was obtained in 3/41 patients treated with IL-2 plus melatonin compared with none of the patients receiving IL-2 alone. A partial response was achieved in 8/41 patients treated with IL-2 and melatonin compared with only one in the IL-2 only group. The survival rate after one year was 19/41 in the IL-2 and melatonin compared with only 6/30 in the IL-2 group. In another study of 100 patients with metastatic solid tumors, for whom no standard therapy was available, the percentage of survival at 1 year was significantly higher in patients treated with IL-2 and melatonin than in those receiving the supportive care alone (21/52 versus 5/48).^[29]

Similar results have been shown with melatonin in combination with interferon, tumor necrosis factor, and tamoxifen, as well as when melatonin was used alone.^{[30] [31] [32] [33] [34] [35]} These preliminary results are quite encouraging, as improvements in survival time and quality of life assessments have been produced in approximately 30% of patients taking anywhere from 10–50 mg daily (at 8.00 p.m.). However, although melatonin has been shown to increase survival time in these studies, the results are good but not earth-shattering. For example, in one study of patients with solid tumors with brain

metastasis 15/24 patients (63%) died within 1 year in the melatonin group compared with 21/26 (88%) in the group receiving supportive care only. These studies, although randomized, are not double-blind, indicating that a placebo response may be partially responsible for some of the improvements noted.

Depression

Initial studies performed in the 1980s demonstrated that melatonin levels are typically below normal in patients with clinical depression.^[36] ^[37] ^[38] However, in all of these studies it turned out that antidepressant drugs or other factors were responsible for the depressed melatonin levels. More recent studies have not supported the association of low melatonin levels being common in patients with clinical depression.^[39] These studies measured melatonin levels in drug-free, depressed patients and were careful to match these subjects with a comparable control group. In addition, it has been demonstrated that normal subjects secreting *no* melatonin do not frequently suffer from depression.^[1]

Initially it was thought that melatonin may affect mood as a result of reducing cortisol levels by inhibiting the secretion by the pituitary hormone, ACTH, which then signals the adrenal glands to secrete cortisol. With melatonin deficiency, cortisol levels would be expected to be increased. This appears to be the case in many depressed patients, as both decreased melatonin and increased cortisol concentrations are frequently found.^[39] ^[40] ^[41] However, it is unlikely that melatonin supplementation can significantly reduce cortisol levels as research has shown that melatonin supplementation does not suppress either ACTH or cortisol secretion.^[42]

This research indicates that melatonin is unlikely to produce any significant positive effects in the treatment of depression in most patients. Clinical research seems to bear this out. In fact, one double-blind study conducted in 1973 demonstrated that melatonin supplementation actually dramatically worsened clinical depression in some cases.^[43] Obviously worsening of depression is quite serious as it increases the risk for suicide. A possible explanation for the worsening is the fact that the melatonin was given two to four times during the day – a time when melatonin levels are typically low. Another study in non-depressed subjects demonstrated that when melatonin was given during the day it tended to cause fatigue, confusion, and sleepiness.^[44]

Multiple sclerosis

Multiple sclerosis (MS) is the most common of the demyelinating diseases of the central nervous system. The clinical course and prognosis of the disease is extremely variable. The illness typically tends to progress in a series of relapses and remissions. The patient with MS seems, in most cases, to enter a phase of slow and steady deterioration of neurologic function. The pineal gland has been implicated recently in the pathogenesis and clinical course of MS. In a recent study, 32 MS patients randomly selected from consecutive hospital admissions to a neurology service due to exacerbation of symptoms had their nocturnal levels of melatonin monitored.^[45] The study revealed that the progressive decline in melatonin may be relevant to the pathophysiology, and specifically to the course, of the disease. The specific role of melatonin in remission of MS is unknown, but what is known is that when melatonin

levels decline it is associated with an exacerbation of symptoms. Patients with chronic progressive MS have been shown to have lower melatonin levels compared with those with a relapsing/remitting course. However, at this time it is not known whether melatonin therapy would have any benefit in MS.

Coronary artery disease

Melatonin levels are significantly lower in patients with coronary heart disease than in healthy controls. In a recent study, patients with coronary heart disease had nocturnal melatonin levels that were one-fifth that found in healthy controls. The absence of melatonin would cause increased night-time sympathetic activity which would increase the risk for coronary disease. Melatonin serves as a suppressor of sympathetic activity nocturnally. Lower levels of melatonin may lead to increased circulating epinephrine and norepinephrine, which has been implicated in damage to vessel walls. Atherogenic uptake of LDL cholesterol is accelerated by these amines at pathophysiological concentrations.^[46] In another study melatonin was found to inhibit platelet aggregation.^[47]

Interactions with vitamin B₁₂

Vitamin B₁₂ has been shown to influence melatonin secretion.^[48] The low levels of melatonin in the elderly may be a result of low vitamin B₁₂ status. Vitamin B₁₂ (1.5 mg/day of methylcobalamin) has been shown to produce good results in the treatment of sleep-wake rhythm

disorders presumably as a result of improving melatonin secretion.^[49]

DOSAGE

At this time, it appears that melatonin therapy is most appropriate for use when low melatonin levels are suspected, as occurs in some cases of insomnia and in jet-lag. Evaluation of salivary melatonin levels can provide valuable diagnostic insight as to the likely success or failure of melatonin in the treatment of insomnia. A dosage of 3 mg at bedtime is more than enough as dosages as low as 0.1 mg and 0.3 mg have been shown to produce a sedative effect when melatonin levels are low.^[10] Higher dosages may be required to produce the anti-cancer benefits noted above.

TOXICOLOGY

Although there appear to be no serious side-effects at recommended dosages, conceivably melatonin supplementation could disrupt the normal circadian rhythm. In one study, a daily dosage of 8 mg/day for only 4 days resulted in significant alteration to the circadian rhythm.^[42] It is not known what sort of effect would occur at commonly

recommended dosages (i.e. 3 mg). In addition, as noted above, some depressed patients got much worse when they were given melatonin during the day.

Chapter 98 - *Mentha piperita* (peppermint)

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

Mentha piperita (family: Labitae)
Common name: peppermint

GENERAL DESCRIPTION

Peppermint is a natural hybrid of garden spearmint (*M. spicata*) and water mint (*M. aquatica*). First described in England in 1696, peppermint now grows all over the world.^[1] The two most popular varieties are white peppermint (*M. piperita* var. *officinalis*) and black peppermint (*M. Piperita* var. *vulgaris*). Both are typical members of the mint family, i.e. herbs with square stems, horizontal rhizomes, and lanceolated leaves with a serrated edge. Black peppermint has deep red stems with purplish-tinged dark green leaves, while the white has green stems with lighter green leaves. Both varieties produce purple flowers during the summer months. For medicinal effects, the aerial portion of the plant is the most widely used.

CHEMICAL COMPOSITION

The major medicinal component of peppermint is its volatile oil, which can be found in concentrations of up to 1.5% in the herb, but is usually present in the 0.3–0.4% range. The principal components of the oil are menthol (29–28%) (see [Fig. 98.1](#)), menthone (20–31%) and menthyl acetate (3–10%), although gas chromatographic analysis of peppermint oil will typically show more than 40 different peaks. Most of the volatile oil components are terpenoids.^[1]

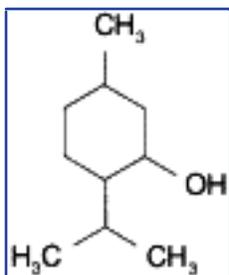

Figure 98-1 Menthol.

828

The composition of menthol and other volatile oil components is sensitive to climate and latitude, as well as to the maturity of the plant. Pharmaceutical-grade peppermint oil is produced by distilling the fresh aerial parts of the plant harvested at the very beginning of the flowering cycle. The oil is standardized to contain not less than 44% free menthol and a minimum of 5% esters calculated as menthyl acetate. The ketone component (calculated as menthone) usually ranges from 15 to 30% with the remainder of the oil being composed of various terpenoids.^[1] Menthol is also synthesized by hydrogenation of thymol.

Other components of peppermint herb which may contribute to its medicinal effects include polymerized polyphenols (19% of dry weight), flavonoids (12%), tocopherols, carotenes, betaine, and choline.^[2]

HISTORY AND FOLK USE

Although peppermint was not officially recognized until the 17th century, mints have been used for their medicinal effects for thousands of years. Records from the ancient Egyptian, Greek, and Roman eras show that other members of the mint family, particularly spearmint (*Mentha spicata*), were used.^[1]

The most popular uses of peppermint for medicinal purposes were in the treatment of indigestion and intestinal colic, colds, fever, and headache.

PHARMACOLOGY

The pharmacology of peppermint is attributed almost entirely to its menthol components. The major categories of actions for peppermint and menthol are:

- carminative
- antispasmodic
- choleric
- external analgesic
- nasal decongestant.

Carminative effects

Carminatives promote the elimination of intestinal gas. Peppermint and peppermint oil are well-accepted carminatives. Although the exact mechanism of action has not been determined, one proposed mechanism is relaxation of the esophageal sphincter leading to the released gas pressure in the stomach.^[3]

Antispasmodic effects

The mechanism behind peppermint oil's antispasmodic effects has been determined. Researchers have concluded that the ability of peppermint oil to inhibit contractions of isolated smooth muscles is via blockage of the influx of calcium into the muscle cells.^[4]^[5] The researchers hypothesized that the clinical effectiveness of peppermint oil in the treatment of the irritable bowel syndrome is a result of inhibition of the hypercontractility of intestinal smooth muscle, thereby returning the muscle to its proper tone.

Choleretic effects

Choleretics stimulate the flow of bile. Menthol and related terpenes have been shown to exert a choleretic effect as well as improve the solubility of the bile.^[6]^[7]^[8]^[9]^[10]

External analgesic effects

The external analgesic and counter-irritant effects of menthol are well accepted. When applied to the skin, peppermint oil or menthol stimulates the nerves which perceive cold, while simultaneously depressing those for pain. The initial cooling effect is followed by a period of warmth.

CLINICAL APPLICATIONS

Peppermint oil is the most extensively used of all the volatile oils. Pharmaceutical preparations often utilize peppermint oil or menthol for its therapeutic and flavoring properties. For example, it is used extensively in antacid products and irritant laxatives for both its flavor and its therapeutic effects. The same is true for its inclusion in mouthwash preparations and after-dinner mints.

The pharmacological effects of peppermint and peppermint oil are useful in a number of clinical situations. The most notable are:

- irritable bowel syndrome
- intestinal colic
- gallstones
- musculoskeletal pain
- the common cold.

Irritable bowel syndrome

Peppermint oil has been used in treating the irritable bowel syndrome (IBS) for many years. IBS can include a combination of any of the following symptoms:

- abdominal pain and distension
 - more frequent bowel movements with pain, or relief of pain with bowel movements
 - constipation or diarrhea
 - excessive production of mucus in the colon
 - symptoms of indigestion such as flatulence, nausea, or anorexia
 - varying degrees of anxiety or depression.
-

829

One of the central findings in IBS is a hypercontractility of intestinal smooth muscle. As described above, peppermint oil inhibits the hypercontractility of intestinal smooth muscle making it useful in cases of the irritable bowel syndrome as well as intestinal colic.

The preferred delivery of peppermint oil in the treatment of IBS is by enteric-coated preparations which prevent the oil from being released in the stomach. Without enteric coating, peppermint oil tends to produce heartburn. With the coating, the peppermint oil travels to the small and large intestine where it relaxes intestinal muscles. Several clinical studies have demonstrated that enteric-coated peppermint oil is quite effective in reducing the abdominal symptoms of the irritable bowel syndrome.^{[11] [12] [13]}

Although effective on its own, enteric-coated peppermint oil is best used within a comprehensive treatment protocol for IBS (see [Ch. 184](#)).

Cholelithiasis

A formula containing menthol and related terpenes (menthone, pinene, borneol, cineol, and camphene) has demonstrated efficacy in several studies in dissolving gallstones.^{[6] [7] [8] [9] [10]} This approach to gallstone removal offers an effective alternative to surgery and has been shown to be safe even when consumed for prolonged periods of time (up to 4 years). Terpenes, like menthol, help to dissolve gallstones by reducing bile cholesterol levels while increasing bile acid and lecithin levels in the gall bladder. As menthol was the major component of this formula, peppermint oil, especially if enteric-coated, may offer similar benefits.

External analgesic

Menthol and related substances can be used as counter-irritants in the treatment of arthritis, fibromyositis, tendonitis, and other inflammatory conditions involving the

musculoskeletal system.

The common cold

Menthol and peppermint oils are often employed in the treatment of the common cold as components of topical nasal decongestants, cough and throat lozenges, ointments, salves, and inhalants. Whether the use of these products is of benefit has not been proven in clinical studies. However, their popularity appears to represent their ability to help make breathing easier during the common cold. The best method for using menthol or peppermint oil is by applying commercial preparations to the upper chest during periods of rest so that the vapors can be inhaled continuously.

Peppermint tea may also be of benefit during the common cold. Peppermint, as well as other members of the mint family, has demonstrated significant anti-viral activity as well as a mild diaphoretic effect.^[14] The most active antiviral components, the polyphenols, are concentrated in the tea.^[2] Peppermint oil has shown antiviral activity against Newcastle disease, herpes simplex, and vaccinia.

Headache

A recent study demonstrated another valuable use for peppermint oil – the relief of tension headaches. In a double-blind, placebo-controlled, randomized cross-over trial, topical application to the forehead and temples resulted in a statistically significant decrease in muscle tension as reported subjectively and measured objectively by EMG activity of the temporal muscle. In addition, the oil application resulted in decreased pain sensitivity.^[15]

DOSAGE

Peppermint is most widely used as a tea (infusion), on its own or in combination with other botanicals. The infusion is usually prepared with 1 to 2 teaspoons of the dried leaves per 8 ounces of water.

The dosage of peppermint oil administered in an enteric-coated capsule for the treatment of the irritable bowel syndrome is one to two capsules (0.2 ml/capsule) three times daily between meals. This dosage is also appropriate for the treatment of gallstones.

The dosage of menthol as an external analgesic is 1.26–16% applied to the affected area no more than three or four times daily.

TOXICOLOGY

Peppermint herb is generally regarded as safe (GRAS) when used as a tea; however, hypersensitivity reactions have been reported. Adverse reactions to enteric-coated peppermint oil capsules are rare, but can include hypersensitivity reactions (skin rash),

heartburn, bradycardia, and muscle tremor.

When applied topically, peppermint oil or menthol can induce contact dermatitis and hypersensitivity reactions. The likelihood of developing such a reaction is enhanced when heating pads are used in conjunction with topically applied preparations containing menthol.^[16]

The LD₅₀ of menthol in rats is 3,280 mg/kg. The fatal oral dose in humans is 1 g/kg. Repeated high dose feeding of rats for 28 days with peppermint oil produced signs of dose-related brain lesions, but the dosage (40 mg/kg) far exceeds those used in humans.^{[1] [17] [18]}

Chapter 99 - Naturally occurring antioxidants

Robert A. Ronzio PhD

INTRODUCTION

We depend on our oxygen-rich world for survival. Mitochondria use oxygen to maximize the energy yield in converting fuel molecules to carbon dioxide. Paradoxically, oxygen is such a powerful reactant that it can disrupt cellular function and impair homeostatic mechanisms primarily through oxygen radicals. Recent research suggests that free radical attack and cumulative oxidative damage are associated with many degenerative conditions, including cancer,^{[1] [2]} atherosclerosis,^{[3] [4]} cataracts,^[5] inflammation and autoimmune disease,^{[6] [7]} lung disease,^[8] neurologic disorders,^{[9] [10]} aging,^{[11] [12]} and cell death.^[13] [Table 99.1](#) summarizes prominent examples of the more than 100 conditions that reflect oxidative damage. Free radicals may be a consequence of the disease process, or they may be a cause. The following discussion focuses on the formation and physiologic effects of free radicals and

oxygen-based reactants, and then addresses the body's antioxidant defenses.

FREE RADICALS AND REACTIVE OXYGEN SPECIES

Definitions

Free radicals

Free radicals are highly reactive molecules. Unlike most molecules, which contain pairs of electrons, free radicals possess at least one unpaired electron, an unstable condition. Consequently, free radicals will tear electrons from bystander molecules indiscriminately to make up for their own deficiency. Nitric oxide (NO•) and superoxide (O₂•⁻), are examples of physiologically important radicals: NO• functions as a vasodilator and as a defensive chemical. It may also play a role in memory. Superoxide is a defensive compound. Furthermore, hydrogen peroxide and superoxide can influence growth, and the suggestion has been made that these species function as messengers. They may also regulate cellular redox state and cellular antioxidant levels (glutathione), thereby indirectly altering signal transduction and ultimately growth responses.^[14] Hydroxyl radical (•OH) is one of the most reactive radicals occurring in the body. An initial event generates free radicals, and propagation steps repeated many times perpetuate their

formation. Thus, free radical reactions tend to “snowball” unless held in check by antioxidant defenses.^[15]

Reactive oxygen species

In addition to free radicals, the body generates an array of oxidizing agents, including hydrogen peroxide (H_2O_2), lipid peroxide (ROOH), and hypochlorite (OCl^-). Although $\text{O}_2^{\bullet-}$ and H_2O_2 are not very reactive chemically, they can yield hydroxyl radical in the presence of transition metal ions. Reduced iron catalyzes the conversion of superoxide to singlet oxygen, an activated oxygen molecule with unstable electron configuration. Furthermore, nitric oxide and superoxide, in excess, form peroxynitrite (ONOO^-), an extremely powerful oxidizing agent and radical generator. It is useful to consider these metabolites collectively as “reactive oxygen species” (ROS) to include the various forms of more or less reactive oxidizing agents, whether or not they are free radicals.^[14]

Likely targets of free radicals and ROS include polyunsaturated fatty acids in membrane lipids, serum lipoproteins, proteins and even DNA. ([Fig. 99.1](#)) The products may be lipid peroxides, protein carbonyls and altered purines such as 8-oxo-2-deoxyguanosine.^{[11] [16]} The consequences are often subtle: damage to membrane receptor proteins may alter cellular regulatory mechanisms such as signal transduction; inactivation of proteins required for ATP production, leading to an energy deficit; and inactivation of calcium ATPase, changing calcium homeostasis.^[17] There is strong circumstantial evidence that ROS and free radicals also play a role in cancer initiation and promotion. While ROS often damage DNA and induce malignant transformation, the development of cancer depends on many factors, including the rates of damage and repair, the status of defenses, and alternative pathways for initiation and promotion. Apoptosis – programmed cell death – is regulated by a complex pathway involving activation of transcription factors. Oxidative stress induced by ROS is one of the triggers of apoptosis in several model systems.^[18] Indeed, conditions ranging from diabetes mellitus and heart failure to HIV infection may entail apoptosis.^[19]

The formation of free radicals and ROS

Although not plentiful, free radicals are surprisingly common in the body. Free radicals and ROS arise through a variety of mechanisms. Some sources are spontaneous chemical accidents: free radicals are generated by air pollutants such as ozone and nitric oxides, and by cosmic rays and radiation. On the other hand, oxygen may react with heme proteins such as myoglobin, hemoglobin and cytochrome C, as well as iron (Fe^{2+}) to generate superoxide, which yields H_2O_2 . The extremely reactive hydroxyl radical can be formed from H_2O_2 in the presence of Fe^{2+} , or Cu^+ . Therefore, the release of these ions from storage sites during inflammation and injury may promote the spontaneous production of free radicals.

In addition, normal metabolism yields free radicals and ROS:

- Approximately 1–3% of oxygen molecules passing through mitochondria end up as

superoxide due to the leakage of electrons from the electron transport chain during damage, generating about 10 g/day of superoxide.^[20] The aging process may be related to mitochondrial deterioration.

- Cells contain peroxisomes, organelles that oxidize fatty acids while producing H_2O_2 . Drugs like clofibrate that cause peroxisome proliferation may act as promoters by stimulating the production of hydrogen peroxide.
- The oxidation of purines from DNA, RNA and ATP relies on the enzyme, xanthine oxidase, which produces superoxide. Various cytoplasmic oxidases generate ROS, including dopamine oxidase, beta hydroxylase, urate oxidase and others.
- The detoxication of metabolites and xenobiotics by microsomal mixed function oxidases (cytochrome P450) can generate ROS (1 mole of free radical is generated for each mole of toxin metabolized). Drugs such as penicillamine and phenylbutazone can be metabolized to free radicals. Also, several xenobiotics such as paraquat and alloxan catalyze the formation of superoxide through

833

cyclic reactions (“redox recycling”), promoting auto-oxidation. A number of pesticides and drugs are hepatotoxins for these reasons.^[21]

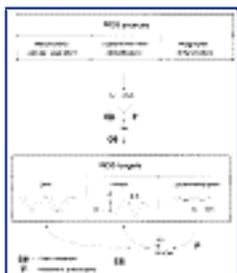

Figure 99-1 ROS sources, targets and sites of antioxidant neutralization.

In addition, ROS are made for useful purposes. Phagocytic cells, including macrophages, monocytes, neutrophils and eosinophils, create ROS as part of their defensive mechanism. The binding of immune complexes, bacterial endotoxins or other inflammatory agents to cell surface receptors triggers a “respiratory burst” in phagocytic cells. This localized production of highly reactive chemicals oxidizes viruses, bacteria and other foreign materials. Initially, plasma membrane NADPH oxidase releases superoxide, which dismutates to H_2O_2 . Myeloperoxidase in lysosomes then transforms H_2O_2 and chloride ion to hypochlorite, the same powerful oxidizer found in commercial bleach. Hypochlorite spontaneously reacts with amines and ammonia to produce very reactive chloramines. In addition, nitric oxide is produced, which reacts with molecular oxygen to yield nitrogen oxides, NO_2 and N_2O_3 – potent oxidizing agents. Note that the respiratory burst can activate xenobiotics.^[22]

Inflammation

Inflammation represents a major source of oxidants. Infection, toxic exposure, ischemia

and trauma activate phagocytic cells.^[6] Inappropriate activation of ROS production is potentially dangerous. Inflammation activates the arachidonic acid cascade, which converts polyunsaturated fatty acids to eicosanoids, lipid peroxides such as PGG₂ and PGH₂, leukotrienes and HETE via cyclooxygenase and lipoxygenase. Cyclooxygenase itself activates xenobiotics, creating an additional oxidant burden.^[23] The autooxidation of polyunsaturated fatty acids with three or more double bonds in membranes yields pro-inflammatory PGG₂-like isomers called F₂ isoprostanes. The more or less continuous production of ROS by activated phagocytes during chronic, possibly low-level, inflammation may eventually deplete antioxidant defenses, thus allowing ROS to attack cells.^[24] Ensuing tissue injury often impairs function in a downward spiral from health to disease. For example, free radicals and ROS are present at high levels in colons of patients with ulcerative colitis.^[25]

Oxidative stress

The term “oxidative stress” refers to a shift in the ratio of prooxidant/antioxidant balance.^[26] The imbalance can be due to excessive ROS production and/or to limited antioxidant defenses, which could be the result of inadequate dietary intake of antioxidant nutrients or chronic conditions such as malabsorption syndromes.

ANTIOXIDANTS

Antioxidants are substances that inhibit the oxidation of a target molecule, often by free radical attack.^[15] Antioxidants are both lipid-soluble and water-soluble. In addition, there is a “pecking order” among antioxidants; some are more readily oxidized than others and will be consumed rapidly unless replenished or recycled.^[27] [Table 99.2](#) lists the primary and secondary antioxidant defenses that protect against free radicals and ROS, including enzymes, nutrients and metabolites. Certain antioxidants are “preventive inhibitors”, which block the initiation of free radical attack ([Fig. 99.2](#)). Preventive inhibitors include defensive enzymes such as catalase, superoxide dismutase (SOD), peroxidases as well as the tripeptide glutathione. Beta-carotene, chelating agents such as organic acids, and

TABLE 99-2 -- Antioxidant defenses

| |

- Metallothionein (cysteine)

Vitamin antioxidants

- Beta-carotene (provitamin A)
- Vitamin C
- Vitamin E (tocopherols)

Plant antioxidants (non-vitamins)

- Carotenoids and xanthophylls
- Phenolic acids and polyphenols
- Diketones
- Tocotrienols

Metabolites

- Coenzyme Q₁₀
- Uric acid
- Cysteine
- Glutathione
- Polyfunctional organic acids (citric acid, malic acid)
- Bilirubin, biliverdin
- Lipoic acid
- Histidine
- Melatonin
- Peptides (carnosine, anserine)

Figure 99-2 Preventive antioxidants.

Figure 99-3 Chain-breaking antioxidants.

plant polyphenols also represent preventive antioxidants when they quench singlet oxygen or sequester metal catalysts. Other antioxidants function as “chain breakers”, which convert free radicals to stable products and thus block free radical chain reactions. Vitamin E and ascorbic acid are essential chain-breaking antioxidants ([Fig. 99.3](#)).

Enzyme antioxidants

Three types of enzymes detoxify ROS:

- superoxide dismutase (SOD)
- catalase
- glutathione peroxidase.

These enzymes occur throughout the body in cells, tissues and fluids. SOD very rapidly converts superoxide to H_2O_2 . Because H_2O_2 may yield dangerous hydroxyl radicals, if allowed to accumulate, SOD cooperates with catalase to break down H_2O_2 to water, and with glutathione peroxidases to inactivate both H_2O_2 and lipid peroxides.

SOD

By “dismuting” superoxide to H_2O_2 , SOD intervenes before ROS causes damage. The mitochondrial enzyme requires manganese, while the cytoplasmic form requires copper and zinc. These trace mineral nutrients are often classified as antioxidants, although it is their enzyme host that more accurately deserves this classification. Evidence for the role of SOD in preventing damage comes from a variety of sources. Aorta from copper-deficient rats contains less Cu-SOD activity and more lipid peroxidation than non-deficient animals^[28]. Mn SOD is induced during acute inflammation.^[29] Patients with a familial dominant form of amyotrophic lateral sclerosis possess a defective gene that decreases cytoplasmic SOD by 40%.^[30] The level of SOD in the cerebral cortex of Alzheimer’s

disease patients is 25–35% lower than in the brains of healthy people.^[31]

Liposomal SOD has been used therapeutically in patients with Crohn’s disease.^[32] Administering SOD bound to polyethylene glycol together with catalase reduced reperfusion injury in animals.^[33] The SOD gene has been cloned, and chimeric enzymes

with increased stability are being studied. Oral supplementation with coated plant or liver Cu/Zn SOD has anecdotally been noted to ameliorate symptoms in some patients with inflammatory conditions and sunburn. Others have reported no effect using ingested animal-derived, uncoated SOD.^[34]^[35] Studies with supplemental SOD have been confounded by the observation that less than 20% of commercially available SOD met label claims for SOD, catalase or peroxidase activities.^[36] Unlike mammalian enzymes, a coated, non-soy legume-derived SOD resists the action of pancreatic enzymes and a recent double-blind, placebo-controlled study suggested that oral ingestion of this material can increase the activity of erythrocyte SOD within 4 hours.^[37]

Catalase

This iron-dependent enzyme occurs widely in cells and is a component of peroxisomes which generate H_2O_2 through oxidative metabolism. Catalase seems specifically designed to prevent a build-up of H_2O_2 . Animal studies with catalase, usually in conjunction with SOD, suggest protection against ischemic injury to the retina,^[38] intestinal ROS damage,^[39] and radiation.^[40] The transcytosis of catalase and SOD across capillaries has also been observed.^[41]

Glutathione peroxidases

This family of enzymes work together with catalase. They require reduced glutathione to reduce peroxides cytoplasmic H_2O_2 as well as lipid peroxides. Unlike catalase and SOD, glutathione peroxidases use the trace mineral nutrient selenium in the form of selenocysteine. For this reason, selenium is sometimes referred to as an antioxidant nutrient. Glutathione peroxidases exist as several isoforms. A recently identified phospholipid hydroperoxide glutathione peroxidase can reduce membrane lipid peroxides to readily metabolized, non-toxic fatty acid alcohols.^[42]

Selenium plays a role in the induction of glutathione-requiring enzymes, including the peroxidases. It should be noted that selenoprotein P, a plasma protein, seems to function in protecting endothelial cells of the liver and glomerular capillaries from oxidative damage, independent of peroxidases.^[43] Defensive enzymes are often inducible. For example, in animal models, exhaustive exercise caused oxidative stress, leading to increased levels of SOD, glutathione peroxidase and glutathione transferase.^[44] On the other hand, prior supplementation with vitamin E and selenium reduced ROS production and lesser amounts of detoxification enzymes were induced.^[44]

Other defensive enzymes

Glutathione transferase adds glutathione to potentially toxic substances and is considered a component of phase II detoxification enzymes. Non-selenium-dependent glutathione peroxidase reduces aldehydes produced by radical-induced fragmentation of polyunsaturated fatty acids, epoxides produced during detoxification, in addition to peroxides. Like glutathione peroxidase, glutathione transferase requires a ready supply of reduced glutathione, produced by the action of glutathione reductase from oxidized glutathione. In turn, glutathione reductase requires NADPH, dependent on a robust

glucose metabolism. NADPH and glutathione serve other reductases that help to regenerate tocopherol and ascorbate, demonstrating that overall metabolic balance is a prerequisite for adequate antioxidant defense.

Nutrient antioxidants

Vitamin E (tocopherols)

Vitamin E refers to eight fat-soluble compounds, of which alpha-tocopherol is the most active in the usual biological test systems (although some human models, such as the RBC membrane stabilization test, suggest other forms may be more active). Vitamin E is acknowledged as the primary chain-breaking antioxidant of lipids, lipoproteins and membranes. Vitamin E contributes to membrane repair;^[45] it blocks the formation of nitrosoamines,^[46] helps protect LDL against oxidative damage,^[47] ^[48] reduces symptoms of tardive dyskinesia – perhaps by reducing nerve damage,^[49] and decreases platelet aggregation and blood clot formation.^[50]

According to the “oxidation hypothesis” of cardiovascular disease, the oxidation of LDL and other lipoproteins helps to initiate atherosclerosis, and an antioxidant role for vitamin E in preventing cardiovascular disease has been proposed.^[51] Each molecule of LDL possesses on average seven molecules of alpha-tocopherol, while there is less than one molecule of beta-carotene per LDL molecule. On the other hand, vitamin E accounts for only 30% of total antioxidants present in LDL in some people. The oxidation of polyunsaturated fatty acids and cholesterol in LDL does not begin until tocopherol, beta-carotene and antioxidants have been consumed. Supplementation with 800 IU of alpha-tocopherol daily for 3 months increased the tocopherol level in isolated LDL and decreased the rate of LDL lipid peroxidation by 40%.^[52] More recently, the Cambridge Heart Antioxidant Study demonstrated a large, significant reduction in non-fatal

myocardial infarction among patients with atherosclerosis who had been supplemented with vitamin E (400 or 800 IU) compared with a placebo for a median of 1.4 years.^[53] Alpha-tocopherol was administered at a daily level of 2,000 IU to patients with moderately severe Alzheimer’s disease.^[54] With vitamin E supplementation, there was a 230 day delay in the onset of severe dementia or death compared with controls, although there was no improvement in cognition with supplementation. These data lend support to the possible involvement of oxidative stress in neurodegenerative disease and a role of antioxidant supplementation in therapeutic programs. A protective role in cancer is less clear: the Nurses’ Health Study failed to confirm a reduced risk of breast cancer in patients with high intakes of vitamins E and C.^[55]

Whole foods provide mixtures of tocopherols, including alpha, beta and gamma isomers, and the typical US diet supplies twice as much gamma-tocopherol as the alpha form. Alpha-tocopherol predominates in the body, probably due to selection by

tocopherol binding protein of the liver. Gamma-tocopherol, not the alpha form, selectively blocks peroxynitrite and acts as a radical sink. Gamma-tocopherol seems to complement the actions of alpha-tocopherol in blocking “electron-loving” mutagens and acting as an antioxidant.^[56] Supplementing with alpha-tocopherol, a form common in supplements, may not be as effective as using natural mixed tocopherols.

Tocotrienols are a form of vitamin E having an unsaturated side chain. The antioxidant literature on these compounds is meager compared with vitamin E. They appear to complement tocopherols. Tissue distribution of tocotrienols, coenzyme Q₁₀ and vitamin E differ, suggesting that selective mechanisms maintain the lipid antioxidants in various tissues.^[57]

Tocopherol and other chain-breaker antioxidants become radicals as they deactivate potentially toxic substances. The tocopheryl radical (chromanoxyl radical) does not readily attack lipids and proteins and will decompose unless converted back to tocopherol by ascorbic acid, glutathione and coenzyme Q₁₀, illustrating the theme that antioxidant defenses complement each other.^{[58] [59]}

The current RDA (1997) for vitamin E of 15 IU (10 mg alpha-tocopherol equivalents, TE) for men and 12 IU (8 mg TE) for women was designed to prevent myopathy and neuropathy. However, the typical US diet provides less than the RDA of alpha-tocopherol. Healthy people consuming balanced diets supplying the RDA of vitamin E experienced decreased oxidative damage when supplemented with vitamin E at 10 times the RDA.^[60] The daily vitamin E requirement varies dramatically according to factors that increase oxidative stress, including an increased consumption of polyunsaturated fatty acids, even with as little as 2.5 g of fish oil daily.^[61] The best sources of vitamin E – such as unrefined vegetable oils, wheat germ, liver and eggs – represent high fat foods and it is difficult to provide high levels of vitamin E in the usual diet without supplementation. Synthetic alpha-tocopherol contains a mixture of α and β isomers; only the α form (actually RRR – alpha-tocopherol) is active in the body. Esterified alpha-tocopherol is considerably more stable than unesterified tocopherol, and supplemental forms incorporate acetate, succinate or palmitate, which are readily hydrolyzed and absorbed during digestion. Emulsified vitamin E is more readily assimilated than non-emulsified E. As with other fat-soluble vitamins, absorption of vitamin E depends on fat digestion and absorption. Therefore, conditions that impair fat digestion and assimilation will reduce tocopherol uptake.

Ascorbic acid (vitamin C)

This prominent, water-soluble antioxidant occurs in body fluids and the cytoplasm. Ascorbic acid is one of the most efficient chain-breaking antioxidants in human plasma,^[59] and can react with a wide range of ROS and free radicals, including superoxide, singlet oxygen, hypochlorite, and sulfur radicals. Ascorbic acid protects lipids and membrane from oxidative damage by scavenging peroxy and hydroxyl radicals. It is also reported to reduce the risk of cataracts and retinal damage,^[62] increase immune function and detoxication,^[63] and decrease heavy metal toxicity.^[64] Ingested ascorbic acid reduces the gastrointestinal production of nitrosoamines and fecal mutagens.^[65] These factors help to explain why increased ascorbic acid intake is

linked to a reduced risk of cancer of the cervix, stomach, colon and lung.^[66] Ascorbate supplementation can also reduce plasma LDL oxidation.^[67]

Plasma ascorbic acid is a biomarker of oxidative stress. As an example, cigarette smoking depletes the ascorbic acid pool and decreases the body's reduction capacity to maintain plasma ascorbic acid in the reduced (bioactive) form.^[68]

Ascorbic acid functions with glutathione and lipoic acid to regenerate alpha-tocopherol. Like the tocopheryl radical, the ascorbyl radical is relatively stable and has little tendency to attack cells. Dehydroascorbate can be reduced back to ascorbate by glutathione and NADPH by redox recycling. In animal models, high levels of ascorbate can compensate for low glutathione production, and vice versa. When exposed to catalytic levels of iron or copper ions, ascorbate promotes the formation of H₂O₂ and hydroxyl radicals.^[11] ^[68] In vivo, the effect requires high ascorbate and the depletion of tocopherol.^[69] Possibly during inflammation, released iron or copper and ascorbate play a pro-oxidant role. Excessive dietary iron or iron accumulation could also promote ascorbate-induced oxidation.

The current (1997) RDA for vitamin C of 60 mg has long been challenged as inadequate. Convincing evidence that the RDA for (healthy young) men should be at least

837

200 mg is based upon careful tissue saturation studies.^[70] Lifestyle choices such as cigarette smoking increase the need for vitamin C. Taking vitamin C with flavonoids can increase absorption and stabilize vitamin C.^[71]

Carotenoids

Carotenoids represent over 500 different (red, orange, yellow) plant pigments and are conveniently divided into carotenes and xanthophylls (oxygenated carotenes). The most well-known carotenoid is beta-carotene. Although it is the most abundant in nature, beta-carotene does not stand alone: in green leafy vegetables xanthophylls make up 90% of the carotenoids. Beta-carotene represents only one-quarter to one-third of the carotenoids in plasma.

Carotenoids exhibit tissue specificity. Thus, beta-carotene is the major carotenoid in liver, adrenal gland, kidney, ovary and adipose tissue, while lycopene, a red carotene from tomatoes, is prevalent in testes and human plasma.^[72] Lycopene effectively quenches free radicals, although it does not form vitamin A.^[73]

Lutein and zeaxanthin are xanthophylls that accumulate in the body: they are the only carotenoids found in the retina and macula of primates. Lutein and lycopene are plentiful in blood. Levels of these carotenoids in blood are not affected by vitamin A

status. Plasma alpha-carotene, beta-carotene and lutein are useful biomarkers of carotenoid-rich food consumption, while lutein may serve as an intake biomarker for the Cruciferae (cabbage) family.^[74] There is a preferential uptake of lutein and zeaxanthin from the intestine into chylomicron, a general carrier of lipid nutrients.^[75]

The beneficial effects of carotenoids in chemoprevention of cancer are thought to occur through protection against oxidative stress and immune enhancement.^[76] In general, carotenoids are versatile antioxidants; lycopene, lutein, zeaxanthin, and others complement the antioxidant activity of beta-carotene. Beta-carotene absorbs energy from singlet oxygen and releases it as heat. It is especially effective at low oxygen tension, as found in tissues, where it can scavenge peroxy radicals and alkoxy radicals.^[77] Carotenoids also enhance immune function, regardless of their provitamin activity. They quench ROS due to inflammation, help to maintain membrane receptors and they modulate the release of prostaglandins and leukotrienes.^[78]

Increased carotenoid levels have been associated with decreased LDL oxidation,^[79] and increased protection against coronary heart disease.^[80] The increased consumption of carotenoids, especially lutein and zeaxanthin, correlates with a decreased risk of advanced, age-related macular degeneration.^[81] Carotenoids and beta-carotene are linked to a decreased risk of some forms of cancer. Indeed, 29 of 31 lung cancer studies suggest that high dietary carotenoids offer significant protection.^[82] Supplementation of healthy male non-smokers with 15 mg of beta-carotene daily for 26 days increased the function of isolated blood monocytes, suggesting that increased beta-carotene consumption could enhance cell-mediated immune function.^[83] A study of Finnish men who had a decade long history of heavy cigarette smoking and alcohol use found an increased risk of lung cancer with beta-carotene supplementation, but not in those administered both vitamin E and beta-carotene.^[84] Subjects who had the highest level of serum beta-carotene at the beginning of the study – indicative of a greater intake of fruits and vegetables – had the lowest risk of developing lung cancer. Beta-carotene could act as a pro-oxidant, unless protected by other antioxidants such as vitamin E, when there is excessive oxidative stress (smoking, alcohol consumption) and when diets are inadequate. The failure to find a reduced risk of lung cancer with beta-carotene supplements is also consistent with the generally accepted view of the chemopreventive properties of antioxidants; they can block cancer initiation and early promotion, but are less effective during very late stages of carcinogenesis.

It should be mentioned that another intervention trial also suggested that beta-carotene increased the risk of cancer in high risk groups (smokers or those exposed to asbestos).^[85] In contrast, the Linxian China Study, which involved administering beta-carotene, vitamin E and selenium to marginally malnourished people, lowered the risk of cancer mortality.^[86] The Physician's Health Study did not detect any effect on the incidence of cancer or heart disease after 12 years of supplementation with beta-carotene.

The synthetic form of beta-carotene represents the all *trans* isomer, while fruits, vegetables and algae provide varying amounts of the 9-*cis* isomer together with minor carotenoids. The 9-*cis* isomer appears to be a somewhat more efficient antioxidant.^[87] Natural mixed carotenoids containing alpha and beta-carotenes, as well as

xanthophylls, were better absorbed, and functioned as more effective antioxidants in vivo than synthetic (all trans) beta-carotene.^[88] (For additional discussion of the broad impact of carotenoids on health, see [Ch. 67.](#))

Vitamin A can act as a free radical trap and lipid peroxy radical scavenger; it contributes to the antioxidant status of LDL, for example.^[89] Vitamin A analogs, such as 13-*cis* retinoic acid and *trans* retinoic acid, can also reduce lipid peroxidation in vitro. However, the major role of vitamin A and its derivative in most tissues remains the regulation of transcription and translation in differentiation.

Antioxidants produced by the body

Glutathione

This sulfhydryl reducing agent is a tripeptide containing cysteine. Glutathione occurs in high (millimolar)

838

concentrations in most cells and plays many roles. It serves as a detoxifying agent, assists amino acid transport, quenches free radicals, and helps regulate the internal redox environment of cells. As a substrate for glutathione peroxidases, glutathione plays a key role in antioxidant defenses. In addition, glutathione reacts directly with singlet oxygen, hydroxyl radicals and superoxide radicals to form oxidized glutathione (GSSG).^[90] Glutathione reductases regenerate reduced glutathione (GSH) and the ratio of GSH/GSSG is normally >100:1.^[90] Together with ascorbate, GSH participates in the regeneration of vitamin E, which emphasizes the cooperation of antioxidants. Oxidative stress decreases this ratio, activates transcription factors and increases production of interleukin 1 and tumor necrosis factor.^[91] Depletion of intracellular glutathione is associated with immunodeficiency.

AIDS patients appear to have low levels of reduced glutathione, which could activate transcription factor NF-kappaB to increase transcription of the HIV genome.^[92] A clinical study demonstrated that low GSH levels in CD4 T cells from HIV-infected subjects is associated with a decreased survival of 2–3 years.^[93]

N-Acetylcysteine is an effective precursor for glutathione and can raise intracellular GSH.^[94] Higher blood levels of glutathione correlate with higher degrees of health in elderly subjects.^[95] Whether glutathione concentrations predict aging and whether low glutathione is a cause of aging remain to be determined.

There is evidence that dietary glutathione is absorbed and can increase plasma glutathione concentrations in animals and humans.^[96] ^[97] Oral supplementation of glutathione for maintenance and antioxidant protection ranges from 5 to 15 mg/kg body weight for antioxidant support. Detoxification protocols call for somewhat higher intakes,

15–25 mg/kg.^[98]

Coenzyme Q₁₀ (ubiquinone)

Ubiquinones are a family of fat-soluble antioxidants containing 1–12 isoprene units. The predominant form in humans is ubiquinone 10 or coenzyme Q₁₀ (CoQ). Long recognized as a lipophilic electron carrier in mitochondrial ATP production, CoQ also functions as an important antioxidant, which can recycle tocopherol.^[99] CoQ can enhance the immune system,^[100] and has been used to improve status in patients with angina,^[101] various cardiomyopathies and heart disease.^[102] Ubiquinol, the reduced form of CoQ, protects LDL against lipid peroxidation.^[103] Folkers noted that cancer patients are often low in CoQ.^[104] CoQ deficiencies occur in the myocardium of older persons, especially those with heart disease.^[105]

CoQ synthesis requires vitamins B₂, B₆, B₁₂ and folate, and synthesis may not be optimal in people with a low intake of these important vitamins. The normal value for CoQ in plasma is approximately 0.4 μmol/L, mostly in the reduced form. Ubiquinol is readily oxidized, and dietary forms are ubiquinones, which are readily reduced after absorption. A decline in lipid peroxidation in plasma after supplementation with CoQ supports an antioxidative role for CoQ.^[106] Because CoQ is not well absorbed, increasing plasma CoQ levels can be difficult. Oral supplementation with 30 mg of emulsified CoQ (CoQ-zyme) was as effective as 100 mg of powdered CoQ.^[107]

Uric acid (urate)

Uric acid is a waste product of a purine metabolism, which occurs in high levels in plasma. Urate is a broad-spectrum antioxidant, capable of scavenging free radicals and of chelating transition metals.^[108] Uric acid is responsible for 21–34% of the total plasma antioxidant activity, where it appears to protect alpha-tocopherol from peroxy radicals.^[109]

Polyfunctional organic acids

Citrate, fumarate, succinate, malate and tartrate can bind (chelate) transition metal ions and block ROS production, thus acting as preventive antioxidants. These acids require the presence of chain-breaking antioxidants for maximum effectiveness. Not all chelates confer antioxidant properties; for example, iron-ascorbate and iron EDTA complexes catalyze oxidation.^[68]

Melatonin

In addition to helping to set the body biorhythms, this hormone quenches hydroxyl radicals very efficiently. The central nervous system consumes 20% of the oxygen used daily and thus is likely to generate ROS at a high rate. Melatonin production and sleep may play a pivotal part in preventing oxidative damage of nerves.^[110] Though melatonin

is sometimes sold as a food supplement, in reality it is a potent hormone.

Storage and transport proteins: ferritin, transferrin, ceruloplasmin

Free iron and copper ions catalyze the conversion of H_2O_2 to hydroxyl radicals; therefore proteins that bind these ions help to protect tissues against ROS. Under normal circumstances, it is questionable whether unbound iron is normally present in cells. However, with chronic inflammation, iron may be released from ferritin, and potentially this may pose a hazard. Iron storage disease is linked to oxidative damage. Transferrin (which has a high affinity for iron) and ceruloplasmin (which binds copper) can be considered part of the antioxidant defenses.^[111] Iron stored in ferritin does not participate in

839

free radical generation. Another intracellular sulfur-rich protein, metallothionein, binds many metals, including copper.

NON-NUTRITIVE ANTIOXIDANTS

Flavonoids

The typical diet provides a wide range of substances of plant origin that play important roles in maintaining health. Many act as antioxidants. One of the largest classes is the flavonoids, found mainly in fruits, leaves, stems and roots of vegetables, legumes and tea. Flavonoids potentiate the effects of vitamin C and protect other easily oxidizable substances. About 5,000 flavonoids have been reported; undoubtedly more remain to be discovered. Natural phenolics include: flavonoids (anthocyanidins, catechins, flavanones, flavones, flavonols and isoflavones); tannins (ellagic acid, gallic acid); phenyl isopropenoids (such as caffeic acid, coumaric acids, ferulic acid); lignans; and other substances, including catechol, resveratrol (grape skins), rosmarinic acid (rosemary) and others. Substantial amounts of ingested quercetin are absorbed by the GI tract in humans.^[112] Quercetin and kaempferol are among the most abundant flavonoids in the diet.

Various flavonoids inhibit peroxidation in vitro by scavenging ROS, superoxide, hydroxyl radical and singlet oxygen. For example, rutin, myricetin and quercetin scavenge superoxide,^[113] and block LDL oxidation.^[114] Flavonoids from bilberries and grapes were able to protect collagen from superoxide-induced damage.^[115] Flavonoids can also bind transition metals, limiting their ability to catalyze free radical formation.^[116] The increased consumption of flavonoids correlated with the decreased risk of some forms of cancer and cardiovascular disease.^[117] Quercetin inhibited melanoma cells, as a specific example.^[118] Ascorbic acid enhances the inhibition of cancer cells by fisetin and quercetin in vitro, suggesting that ascorbate potentiates the action of flavonoids as

chemoprotective agents.^[119]

Previous estimates of daily consumption of total flavonoids ranged from 200 mg to 1,000 mg daily. However, accurate food consumption data and refined analytical methods based on high-performance liquid chromatography indicate that for northern European elderly men, the mean daily intake of the anti-cancer flavonoids was only about 23 mg daily, with quercetin being the predominant flavonoid.^[120] Though quercetin consumption was low, this flavonoid level represents substantially more antioxidant activity than the typical daily consumption of vitamin E or beta-carotene. Furthermore, this level of flavonoid consumption correlated with a decreased risk of cardiovascular disease,^[120] but not cancer^[121] (see [Ch. 125](#) for further discussion).

Botanical extracts

Botanical extracts have been used for centuries by natural health care practitioners. Recent research has now demonstrated that much of their clinical efficacy is due to their flavonoid constituents, which are often organ-specific.

***Silybum marianum* and other hepatoprotective botanicals**

Milk thistle extracts containing silymarin,^[122] as well as extracts of Indian herbs such as *Picrorhiza kurroa*,^[123] *Eclipta alba*,^[124] and *Tinospora cordifolia*,^[125] or combinations (Livotrit Plus™), concentrate flavonoids in the liver where they exert hepatoprotective effects. Since liver detoxication promotes autoxidation due to ROS produced by cytochrome P450,^[126] the antioxidant properties of these botanical flavonoids largely explains the beneficial effects these plant extracts in normalizing liver function^[127] (see [Ch. 111](#) for a more in-depth discussion).

Proanthocyanidins

A variety of plant sources yield a family of flavonoids called proanthocyanidins. Often they are chained together (oligomers); hence the name oligomeric proanthocyanidins or OPCs. Pine bark and grape seeds are typical commercial sources. Animal experiments indicate that grape seed extracts can limit lipid peroxidation in the brain, suggesting that constituents or their colonic fermentation products, are absorbed and cross the blood brain barrier.^[128] Preparations of European pine bark (Pycnogenol™) have been used as supplements for capillary dysfunction associated in patients with diabetes and for other venous abnormalities.^[129] OPCs are also present in legume-derived polyphenols (Phytolens™), which inhibit peroxynitrite-induced apoptosis in human colonic cells, a model system for gut inflammation.^[130]

Frenchmen consume a high fat diet, yet appear to have a lower mortality due to heart disease. Several explanations have been proposed for the so-called “French paradox”. Of particular interest is the correlation of heart protection with wine consumption. The cholesterol-lowering effect of spirits is not unique to wine. However, red wine contains abundant tannins and other polyphenols, and drinking red wine increases the antioxidant capacity of serum.^[131] Such experiments suggest the absorption of

polyphenols. Red wine has a higher phenol antioxidant index measured against isolated LDL than white wine.^[132] In addition, grape skins and red wine contain resveratrol, a phenolic compound, and phytoalexin, a compound produced by plants in response to environmental stressors. Resveratrol apparently inhibits platelet aggregation and eicosanoid syntheses and blocks cellular events linked to tumor initiation, promotion and

progression.^[133] These effects seem to be independent of its antioxidant properties (see [Ch. 111](#) for further discussion).

Catechins

Tea is a rich source of polyphenols that are highly substituted with hydroxyl groups. Catechin and gallic acid derivatives – including epigallocatechin, epigallocatechin-3 gallate and epicatechin-3 gallate – which function as radical quenchers in vitro.^[134] ^[135] Tea consumption has been linked to a decreased risk of cancer, and antiproliferative effects seem to be a function of polyphenol content.^[136] Urokinase, a proteolytic enzyme overexpressed in many cancers, can be inhibited by green tea flavonoids. Thus, green tea polyphenols probably have multiple effects in the body, including quenching radicals. Green tea extracts free of caffeine are now commercially available (see [Chs 84](#) and [89](#)).

Other botanicals

Extracts of *Ginkgo biloba* have long been known to support vascular function and cerebral insufficiency. It seems probable that active constituents, ginkgolides and related flavonoids reduce oxidative stress.^[137] ^[138] Turmeric has a long history of use in Eastern traditions. Curcuminoids are the bright yellow pigments isolated from this source. These lipids limit the metabolism of environmental mutagens. Consumption of extracts equivalent to 20 mg of curcuminoids for 45 days decreased serum lipid peroxides.^[139] Animal studies suggest that consumption of curcumin can limit lipid peroxide induced cataracts and curcumin may suppress colon cancer.^[140] Curcuminoids are diketones, not flavonoids, which emphasizes the point that many other plant ingredients besides polyphenols may function as antioxidants and as anticarcinogens (see [Chs 97](#) and [105](#) for further discussion).

COMPARING ANTIOXIDANTS

There are several points to consider in comparing flavonoids. Studies of the quenching activity of antioxidants frequently employ single time points measured at a single concentration of antioxidant (end-point assay). This practice can lead to erroneous conclusions when comparing the effectiveness of antioxidants. A far more reliable approach evaluates the IC₅₀, the concentration of antioxidant yielding 50% inhibition of a given oxidant or radical. The smaller the IC₅₀, the more efficient the antioxidant. To

illustrate, [Table 99.3](#) compares IC₅₀ values for several standardized botanical extracts and reference compounds using DPPH (diphenyl picrylhydrazyl radical), one of the test systems used for measuring free radical quenching.^[141] Pine bark OPCs, grape seed OPCs, and polyphenols from non-soy legumes (Phytolens™) effectively quench organic free radicals.^[130] It is important to compare antioxidant activity in several systems, such as superoxide, lipid peroxidation in LDL or microsomes, chemiluminescence to detect the formation of reactive oxygen species, and so on. [Table 99.3](#) presents additional data for quenching superoxide. Accordingly, the order of decreasing effectiveness of these superoxide quenchers is: legume-derived polyphenols (Phytolens™) > ascorbic acid > grape seed OPCs > pine bark OPCs > catechin.^{[127] [130]}

After demonstrating in vitro effectiveness, the question arises: “Does a given antioxidant improve cellular function?”. Phytochemicals possess multiple effects, ranging from enzyme inhibition to enzyme induction via alteration of signal transduction. Flavonoids, in particular, often possess multiple effects, leading them to be considered as “biological response modifiers”. There is also a growing awareness of the necessity of understanding the impact of flavonoids on the oxidative stress that contributes to mutagenesis and programmed cell death (apoptosis). Consumption of green tea and red wine flavonoids, and of oligomeric proanthocyanidins can decrease various indices of oxidative stress, such as plasma malondialdehyde or F₂-isoprostanes (from fatty acid peroxidation), tissue inflammation or urinary output of oxidized DNA bases.

Effectiveness of an antioxidant in vivo relies upon adequate absorption and assimilation. Water solubility of polyphenols would likely favor intestinal uptake; however, quercetin is readily absorbed, despite minimal water solubility.^[112] The effects of bioactive ingredient or ingredients in botanical extracts are seldom completely

TABLE 99-3 -- Comparison of free radical quenching by plant antioxidants and reference compounds^{[127] [130]}

| Test substance | DPPH* IC ₅₀ (ppm) | Superoxide# IC ₅₀ (ppm) |
|---|------------------------------|------------------------------------|
| Pine bark oligomeric proanthocyanidins | 4.4 | 17.8 |
| Grape seed oligomeric proanthocyanidins | 2.8–12.2 | 10.1–43.9 |
| Phytolens™ legume polyphenols | 4.9 | 5.6 |
| Catechin | 3.7 | 40.0 |
| Ascorbic acid | 14.5 | 7.0 |

IC₅₀ is the concentration of antioxidant able to reduce 50% of a given radical; therefore, the smaller the IC₅₀, the more effective the antioxidant.

* , 1,1-diphenyl-2-picrylhydrazyl radical.

#, superoxide generated by phenazine methosulfate and NADH.

understood. An additional complication is the fact that intestinal bacteria degrade complex polyphenols to simple phenolic acids. These may be more bioactive than the starting material.

THE ADEQUACY OF ANTIOXIDANT DEFENSES

Protection by free radical scavenging enzymes is limited and free radical damage is not completely prevented even in healthy people. All cells lack an enzyme defense against hydroxyl radicals, the most damaging species. Therefore, when free radical production exceeds the scavenging systems, hydroxyl radicals can be released, causing severe cellular damage. The body's ability to respond to oxidative stress is a function of age, inheritance, medical history, degree of exposure to pollutants and other environmental stressors, and diet.

Age

Because repair mechanisms decline with age, the body gradually loses functional resiliency, especially to oxidative stress. According to the free radical theory of aging, aging represents progressive oxidative damage.^[142] Ames et al^[11] have estimated that the average human cell sustains 10,000 DNA "hits" per day. Although most of these are repaired, unrepaired damage accumulates with age. Subtle structural alterations occur first, leading to decreased repair of damaged membranes and DNA, ultimately limiting the function of the nervous system, the endocrine system and the immune system.^[11] A direct link between free radical scavenger enzymes and aging was suggested by the demonstration that transgenic fruit flies with extra copies of SOD and catalase genes produced elevated levels of these enzymes; they lived 30% longer than normal flies; and age-dependent oxidative damage also slowed down.^[143]

Inheritance

Due to heredity, the levels of protective enzymes can vary among individuals. People who possess low levels of these enzymes face greater risks of free radical-induced disease. This distinction is blurred somewhat because these enzymes are often inducible, and increased enzyme synthesis occurs in many organs, such as liver and lung, as they adapt to increased oxidative burden (upregulation of antioxidant defense enzymes).^[144]

Medical history and environmental exposure

Processes such as trauma, inflammation and infection generally increase ROS production. Oxidative stress sometimes accompanies drug treatment. Cigarette smoke, ozone, oxides of nitrogen, solvents and pesticides can cause toxicity when radicals are created during their detoxification. The gut epithelium does not appear to adapt to long-term oxidative stress and, because of low initial levels of defensive enzymes, may

be especially susceptible to oxidative damage with even moderate inflammation.^[145]

Strenuous physical exercise increases ROS production, and supplementing with antioxidant vitamins such as E, C and CoQ decreases associated oxidative damage, especially in older people,^[146] and increases LDL antioxidant capacity in endurance athletes.^[147] However, the paradox between exercise-induced oxidative stress and the obvious benefits of exercise has not been entirely resolved.

Nutritional status

Americans do not consume enough antioxidants, and the trend seems unlikely to change in the foreseeable future. Perhaps only 10–20% eat the minimum of five daily servings of fruits and vegetables recommended by federal agencies.^[148] ^[149] Median intakes of key antioxidants indicate that the consumption of vitamins C and E, beta-carotene, zinc, selenium, copper and manganese are low for specific segments of the population, and far below the RDAs for some. Furthermore, the RDAs do not address contributing factors concerning chronic diseases, lifestyle choices or medical history, nor do they address the issue of mutually supportive roles of antioxidants. The immune system, in particular, requires ample antioxidant nutrients.^[150] They protect immune cells against oxidative damage and limit the production of non-inflammatory eicosanoids. As an example, supplementing apparently healthy, elderly people (who were consuming an otherwise typical diet), with 60–800 mg vitamin E improved several aspects of cell-mediated immunity within 4 months.^[151] ^[152] The research also suggested that consumption of 200 mg/day may be more effective than 800 mg/day. Overall studies indicate that the RDAs for this nutrient and other antioxidants are inadequate for optimal immune function (see [Ch. 108](#) for an indepth discussion of optimum nutrient levels).

GUIDELINES FOR USE OF ANTIOXIDANTS

Antioxidants represent powerful additions to the healthcare practitioner's armamentarium. However, their application in treatment protocols requires an understanding of their strengths and limitations. No single supplement, nutrient or food can maintain the body's antioxidant defenses: there are simply too many oxidants to be neutralized, too many layers of antioxidant defenses to be sustained, and the range of reactivities of water- and lipid-soluble ROS is far too great. Multiple, complementary antioxidants are far more effective than large amounts of a single antioxidant. Often antioxidants work

synergistically. An additional consideration: antioxidant requirements should be balanced against oxidant burden. Thus, exposure to pollutants such as cigarette smoke, nitric oxides and ozone as well as chronic inflammation increases oxidative stress. High intake of fish oil and polyunsaturated fatty acids increases the need for vitamin E. The goal is to support the body's defense system, rather than quenching all free radicals in

the body, which would be counterproductive. Superoxide and nitric oxide play essential roles in maintaining the body's defenses and homeostatic mechanisms, for example.

Precautions in using antioxidant supplementation

1. The uptake, assimilation and disposal or potential toxicity of polyphenols generally are not well studied.^[153]
2. Flavonoids are metabolized and detoxified by liver enzymes, and pharmacologic doses may increase toxin burden. Some flavonoids can induce phase I detoxification enzymes, increasing the ability to transform toxins. The trade-off lies in the possible increased sensitivity to mutagens. In this context, quercetin at typical dietary levels appears to be a possible anticarcinogen.^[154]
3. Vitamin E can exacerbate hypertension in susceptible people. High levels may antagonize other fat-soluble vitamins, thus decreasing bone mineralization. It may be contraindicated for patients receiving anticoagulants or for those with a vitamin K deficiency.^[155]
4. Large amounts of vitamin C rarely increase oxalate production; the effects seems to be counterbalanced by increased vitamin B₆.^[156]
5. Excessive iron and iron overload may cause hydroxyl radical production in vivo.^[157]
6. Beta-carotene may increase the risk of lung cancer in high risk populations unless protected by antioxidants like vitamin E. In addition, beta-carotene may exacerbate liver abnormalities in patients with alcoholic liver disease. Fatal coronary heart disease increased in patients receiving 20 mg/day beta-carotene (with or without alpha-tocopherol).^[158] Possibly high levels of beta-carotene are contraindicated for those with smokers with myocardial infarctions.
7. An antioxidant in one system is not necessarily an antioxidant in all systems. For example, vitamin C, vitamin E and beta-carotene exhibit pro-oxidant activity in vitro under certain conditions. Pro-oxidant effects of carotenoids are poorly understood and consumption of large amounts themselves could be hazardous in susceptible individuals. Depending on the concentration of supporting antioxidants, even flavonoids can become prooxidants.^[159]
8. Vitamin A is a teratogen when the intake is 25,000 IU or more per day for several months. The general advice to women who are or who might become pregnant is to limit their daily intake of vitamin A from supplements to no more than 5,000 IU/day and to limit their consumption of liver and liver products.^[160]

HOW TO CHOOSE ANTIOXIDANTS

The traditional definition of an essential (e.g. mineral or vitamin) nutrient is too restrictive from the perspective of life-long protection against chronic disease. The presence of vast numbers of non-vitamin antioxidants – in addition to established nutrients in vegetables, legumes, fruits and grains – poses the question of whether those antioxidants are in fact essential in the diet for optimal health and disease prevention. Consequently, antioxidant supplementation cannot substitute for a prudent diet, cessation of smoking and regular exercise. Supplementation may be most effective for those individuals who have the lowest baseline antioxidant levels, whether due to genetic or environmental causes. Foods supply a rich assortment of substances that can function as antioxidants. As an example, the total oxygen radical capacity of certain

fruits has been determined.^[161] Strawberry, plum, orange, red grapes, kiwi fruit and grape fruit possess high quenching activity. Blackberry, blueberry, raspberry, strawberry, plums, red wine and red grapes contain large amounts of anthocyanidins with strong antioxidant properties.^[162] Further research will undoubtedly uncover many more phytochemical interactions.

Though the picture is far from complete, antioxidants apparently operate synergistically.^[163] Thus, animal studies indicate that an increased diversity of antioxidants provides more antioxidant protection than single supplements.^[164] Even members of the B complex, such as pantothenic acid, may indirectly stimulate antioxidant production.^[165] It should be emphasized that many ingredients in foods play important physiologic roles in addition to their properties as antioxidants. Furthermore, their effects may be indirect; antioxidants and response elements help the cell to adapt to ROS exposure and to correct ROS-induced damage.^[166] Exploration of the role of a major oxidant, peroxynitrite, and nitrogen oxides as NOS (“nitrogen reactive species”) in chronic degenerative diseases is still in its infancy.^[167] Consequently, the antioxidants that best defuse these reactive compounds have not yet been established.

[Table 99.4](#) provides a summary of a recommended intake of antioxidants for maintenance as compiled by the European Federation of Health Product Manufacturers.^[168] The levels often prescribed in treatment protocols may be considerably higher than those listed. Thus, the consumption of a broad spectrum of antioxidants in amounts geared to meet an individual’s oxidant burden and nutritional status appears to be essential in order to promote optimal health and to minimize the effects of genetic predisposition that compromise defenses against aging, degenerative disease and toxic chemical exposure.

TABLE 99-4 -- Recommended safe upper limits of daily intake of antioxidants for maintenance^[168]

| Nutrient | Safe upper limit | Comments |
|------------------|------------------|--|
| Alpha-tocopherol | 900 IU | No toxicity for alpha-tocopherol has been reported. Mild, reversible side-effects have been noted at intakes greater than 1000 mg/day |
| Beta-carotene | 25 mg | Generally no adverse side-effects have been noted other than hypercarotenemia at levels of about 30 mg/day. One study noted an apparent slight increased risk of cancer at 20 mg/day with a high alcohol consumption ^[60] |

| | | |
|-----------|----------|---|
| Vitamin C | 2,000 mg | There are generally no adverse effects with long-term consumption of up to several grams of vitamin C daily. High consumption may be contraindicated with renal insufficiency disease and iron overload |
| Vitamin A | 9,000 RE | Toxicity with chronic consumption of 12,000–23,000 retinol equivalents/day can occur rarely |
| Copper | 9 mg | Copper is interrelated with zinc. Contaminated water is often a source of toxic levels |
| Manganese | 20 mg | Supplementation may raise blood pressure and chronic toxicity may cause neurologic disorders |
| Selenium | 450 mcg | Excessive selenium can be toxic, though organic selenium seems safer. Selenite reportedly reacts with glutathione to produce ROS. Selenocysteine can enter amino acid pools directly, while selenomethionine may be funneled into protein with imbalanced dietary protein |
| Zinc | 30 mg | Rigorous homeostatic mechanisms regulate zinc balance Extremely high levels block copper assimilation and are immunosuppressive |

Chapter 100 - *Panax ginseng* (Korean ginseng)

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

Panax ginseng C.A. Meyer (family: Araliaceae)
Synonym: *Panax schinseng* Nees
Common names: Korean ginseng, Chinese ginseng, Asiatic ginseng, Oriental ginseng

GENERAL DESCRIPTION

Korean or Chinese ginseng is a small perennial plant which originally grew wild in the damp woodlands of northern China, Manchuria, and Korea. Wild ginseng is now extremely rare. However, ginseng is a widely cultivated plant, especially in Korea, but also in Russia, China, and Japan. In addition to *Panax ginseng* C.A. Meyer, four other closely related species are often used:

- *Panax quinquefolium* (American ginseng)
- *Panax japonicum* C.A. Meyer (Japanese ginseng)
- *Panax pseudoginseng* (Himalayan ginseng)
- *Panax trifolium*.

Panax ginseng C.A. Meyer is the most widely used and most extensively studied species. Its pharmacology is the major focus of this chapter.^{[1] [2]}

Fully mature, Korean ginseng is a herbaceous plant with a tap-root, five-lobed palmate leaves, and greenish-white flowers in an umbel. In the first year, ginseng bears only a single leaf with three leaflets. In the second year, it bears a single leaf with five leaflets, and in its third year it bears two leaves with five leaflets. It usually starts flowering in its fourth year, while bearing three leaves. The roots of the cultivated plant are 3–4 mm in diameter and 10 cm long, while the roots of wild plants may attain 10 cm in diameter

and a length of 50–60 cm.

Ginseng is often processed in two forms, white and red ginseng. White ginseng is the dried root whose peripheral skin is frequently peeled off. Red ginseng is the steamed root, which shows a caramel-like color.^[2]

There are many types and grades of ginseng and ginseng extracts depending on the source, age, and parts of the root used, and the methods of preparation. Old, wild, well-formed roots are the most valued, while rootlets

of cultivated plants are considered the lowest grade. For largely economic purposes, the majority of ginseng in the American marketplace is derived from the lowest grade root, diluted with excipients, blended with adulterants, or totally devoid of active constituents, i.e. ginsenosides.^[3]

High quality preparations are available, however. These preparations are extracts of the main root of plants between 4 and 6 years of age and have been standardized for ginsenoside content and ratio to ensure optimum pharmacological effect.

CHEMICAL COMPOSITION

Ginseng contains at least 13 different triterpenoid saponins, collectively known as ginsenosides, which are believed to be the most important active constituents. The usual concentration of ginsenosides is between 2 and 3%. The ginsenosides have been designated R_0 , R_{b1} , R_{b2} , R_{b3} , R_c , R_d , R_e , R_f , 20-gluco- R_f , R_{g1} , and R_{g2} . The ginsenosides originate from three fundamental aglycones:

- oleanolic acid (ginsenoside R_0)
- 20-S-protopanaxadiol (ginsenosides R_{b1} to R_d)
- 20-S-protopanaxatriol (ginsenosides R_e to R_{g2}).

As can be seen from [Table 100.1](#), the ginsenosides differ primarily in their sugar groups.

Ginsenosides R_{b1} , R_{b2} , R_c , R_e , and R_{g1} are present in significant concentrations in Korean ginseng. In contrast, American ginseng (*Panax quinquefolius*) contains primarily ginsenosides R_{b1} and R_e , and does not contain ginsenosides R_{b2} , R_f , or, in some instances, R_{g1} . This allows for

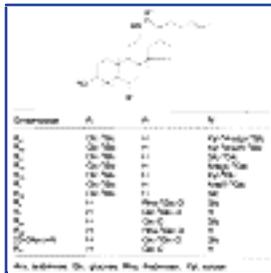

Figure 100-1 Ginsenosides of *Panax ginseng*.

easy detection of species using HPLC (high-pressure liquid chromatography).^{[1] [2] [4]}

Other components include:^{[1] [2] [4]}

- panacene, a volatile oil
- free and glucoside-bound sterols (e.g. beta-sitosterol and its beta-glucoside)
- polyacetylene derivatives B-elemene and panaxinol
- 8–32% starch
- low molecular weight polysaccharides
- pectin
- vitamins (e.g. thiamin, riboflavin, B₁₂, nicotinic acid, pantothenic acid, and biotin)
- 0.1–0.2% choline
- minerals
- simple sugars (glucose, fructose, sucrose, maltose, trisaccharides, etc.)
- various flavonoids.

Although it had been reported that ginseng contains large amounts of germanium (i.e. 300 ppm), a follow-up study using highly sensitive (detection limit of 1 ppb), flameless atomic absorption spectrometry combined with solvent extraction demonstrated that the highest concentration of germanium measured in samples of ginseng purchased in the Osaka market was only 6 ppb.^[5] More research is needed to accurately determine the germanium content of botanical medicines, as the reported concentrations vary widely. Such low levels suggest that a connection between the pharmacology of ginseng and its germanium content is unlikely.

HISTORY AND FOLK USE

Perhaps the most famous medicinal plant of China, ginseng has been generally used alone or in combination with other herbs to restore the “Yang” quality. It has also been used as a tonic for its revitalizing properties, especially after a long illness. Conditions for which ginseng is utilized in folk medicine are shown in [Table 100.1](#) It has been used as an alterative, anodyne, aperitif, aphrodisiac, cardiostimulant, carminative, emetic, estrogenic, expectorant, gonadotrophic, nervine, sedative, sialogogue, stimulant, stomachic, and tranquilizer.^{[1] [6]}

As can be seen from this list, ginseng has been used for most conditions, reflecting a broad range of nutritional and medicinal properties.

PHARMACOLOGY AND CLINICAL INDICATIONS

Since the 1950s, a great amount of research has been conducted worldwide to determine whether the therapeutic properties attributed to ginseng belong in the realm of legend or fact. Unfortunately, inconsistent results (due mostly to different procedures in the preparation of

extracts, use of non-official parts of the plant, use of adulterants, and lack of quality control in the ginseng used) have made determination of ginseng's true properties difficult. Nonetheless, enough good research does exist to indicate that ginseng possesses pharmacological activity consistent with its near-legendary status, especially when high quality extracts, standardized for active constituents, are used.

Over the years, ginseng has been reported to have numerous pharmacological effects in humans and laboratory animals, including:^{[1] [2] [4] [7]}

- general stimulatory effects during stress
- decrease in sensitivity to stress
- increase in mental and physical capacity for work
- improved endocrine system function
- ameliorating radiation sickness, experimental neurosis, and cancer
- enhanced protein synthesis and cell reproduction
- improved glucose control in humans and alloxan-induced diabetes in rats
- modulation of various immune system parameters
- lowering of serum cholesterol
- protection of the liver from hepatotoxins.

Some of these actions are discussed in greater detail below.

Adaptogenic activity

Ginseng was originally investigated for its “adaptogen” qualities. An “adaptogen” was defined in 1957 by the Russian pharmacologist I. I. Brekhman as a substance that:^[2]

- must be innocuous and cause minimal disorders in the physiological functions of an organism
- must have a non-specific action (i.e. it should increase resistance to adverse influences by a wide range of physical, chemical, and biochemical factors)
- usually has a normalizing action irrespective of the direction of the pathologic state.

According to tradition and scientific evidence, ginseng possesses this kind of equilibrating, tonic, anti-stress action, and so the term adaptogen is quite appropriate in describing its general effects.^{[2] [7] [8]}

From a clinical perspective, ginseng can be used as a general tonic, especially in debilitated and feeble individuals. Use in this manner is consistent with its historic application.

Anti-fatigue (mental and physical) activity

Some of the first studies of ginseng's adaptogenic activities were performed during the

late 1950s and early 1960s by Brekhman and Dardymov in the USSR, and by Petkov in Bulgaria.^{[7] [8] [9] [10] [11]}

In one of Brekhman's experiments, Soviet soldiers given an extract of ginseng ran faster in a 3 km race than those given a placebo. In another, radio operators tested after administration of ginseng extract transmitted text significantly faster and with fewer mistakes than those given placebo. These and similar results found by European researchers, who demonstrated improvement in human physical and mental performance after the administration of ginseng extracts, prompted researchers to confirm the results in experimental models using mice.^{[2] [7] [8] [9]}

In perhaps the best known of these experiments, mice were subjected to swimming in cold water or running up an apparently endless rope to determine if ginseng could increase the time to exhaustion. The results indicated that ginseng possessed significant antifatigue activity, as a clear dose-dependent increase in time to exhaustion was noted in mice receiving ginseng.^{[2] [8] [12] [13] [14] [15]} In one study, the time to exhaustion was increased up to 183% in the mice given ginseng 30 minutes prior to exercising, compared with controls.^[8]

Experimental animal studies indicated that much of the anti-fatigue action of ginseng was due to the stimulant effect of ginseng on the CNS. Stress coupled with ginseng ingestion induced alterations in energy metabolism during prolonged exercise.^{[10] [11] [12] [13] [14] [15]}

Ginseng has been shown to increase locomotor activity,^[16] modify EEG tracings,^[10] improve metabolic activity in the CNS,^[17] and affect the hypothalamo-pituitary-adrenal axis (discussed below), all of which could be largely responsible for ginseng's anti-fatigue activity on mental

and physical performance. The CNS activity of ginseng is essentially different from that of the usual stimulants. While stimulants are active under most situations, ginseng reveals its stimulatory action only under the challenge of stress.^[17]

On the physical level, ginseng's anti-fatigue properties appear to be closely related to its ability to spare glycogen utilization in exercising muscle.^[14] Exercise physiologists have clearly established that during prolonged exercise, the development of fatigue is closely related to the depletion of glycogen stores and the build-up of lactic acid, both in skeletal muscle and in the liver. If an adequate supply of oxygen is available to the working muscle, non-esterified fatty acids are the preferential energy substrate, thus sparing utilization of muscle glycogen, blood glucose, and, consequently, liver glycogen. The greater the ability to conserve body carbohydrate stores by mobilizing and oxidizing fatty acids, the greater the amount of time to exhaustion. Ginseng enhances fatty acid oxidation during prolonged exercise, thereby sparing muscle glycogen stores.^[14]

Mental and physical anti-fatigue activity effects have been demonstrated in both animal studies and double-blind, clinical trials in humans. In addition to several Russian studies using soldiers and athletes as subjects, other studies have been published.^{[18] [19]}

In one double-blind, clinical study, nurses who had switched from day to night duty rated themselves for competence, mood, and general well-being, and were given an objective test of psychophysical performance, blood counts, and blood chemistry. The group administered ginseng demonstrated higher scores in competence, mood parameters, and objective psychophysical performance when compared with those receiving a placebo.^[18]

In a double-blind, cross-over study on university students in Italy, ginseng extract was compared with placebo in various tests of psychomotor performance. A favourable effect of ginseng relative to baseline performance was observed in attention (cancellation test), mental arithmetic, logical deduction, integrated sensory-motor function (choice reaction time), and auditory reaction time. However, statistically significant superiority over the placebo group was noted only for mental arithmetic. It is interesting to note that in the course of the trial the students taking ginseng reported a greater sensation of well-being.^[19]

From a clinical standpoint, ginseng's anti-fatigue properties may be useful whenever fatigue or lack of vigilance is apparent. Athletes, in particular, may derive some benefit from ginseng use.

Standardized extracts of *Panax ginseng* in combination with *Ginkgo biloba* (a formula called Gincosan) improved the retention of learned behavior in experiments on young (3 months) and old (26 months) rats. Results suggest *Panax* and *Ginkgo* extracts possess properties similar to those of nootropic drugs.^[20]

Anti-stress activity

Ginseng has been shown to enhance the ability to cope with various stressors, both physical and mental. Presumably, as has been demonstrated in several animal studies, this is a result of delaying the alarm phase response in Selye's classic model of stress. These studies found that adrenal cholesterol levels are many times higher in animals given ginseng than in their matched controls, indicating increased tolerance to stress and delayed alarm phase response.^{[4] [14] [21] [22]}

Italian researchers have studied the effect of a standardized ginseng extract, whose ginsenosides composition was accurately determined, on the adrenal functions of rats exposed to cold.^{[4] [21]} The ginseng extract significantly counteracted body temperature decline without affecting blood glucose or cortisone levels. In a group of adrenalectomized rats, the ginseng extract had no significant effects. Administration of hydrocortisone to the adrenalectomized rats did, however, cause body temperature to be maintained when the rats were exposed to cold.

Histologically, it was noted that there was:

- evidence of hyperfunctioning in the supraoptic and paraventricular nuclei of the hypothalamus in rats fed the ginseng extract
- remarkable increase in corticotropic basophilic cells (ACTH-producing) in the pars distalis of the pituitary
- hyperplasia of the adrenal zona fasciculata, indicating that hyperfunctioning of the adrenal was promoted by the administration of the ginseng extract.

Other researchers have demonstrated that ginseng saponins significantly increase plasma ACTH and cortico-steroids (in a parallel kinetic pattern).^[23] ^[24] Since this effect could be blocked by dexamethasone (which acts on the hypothalamus and pituitary to prevent ACTH release), it was concluded that ginsenosides act predominantly on the hypothalamus or pituitary to promote secretion of ACTH. This has been further confirmed by indirect studies. ACTH first stimulates an increase in cAMP in the adrenal and then promotes corticosteroid synthesis. Ginseng administration has been shown to increase adrenal cAMP in normal rats, but not in hypophysectomized rats.

These investigations make quite clear that ginseng's anti-stress action is mediated by the hypothalamo-pituitary-adrenal axis, as:

- the anti-stress action of ginseng is greatly reduced by adrenalectomy
- ginseng continues to exert its anti-stress action after hypophysectomy only if ACTH is administered
- histological and chemical evidence demonstrates a strong link between ginseng and the hypothalamo-pituitary-adrenal axis
- dexamethasone blocks the effects of ginseng.

This release of ACTH and associated pituitary substances (e.g. beta-lipoprotein, endorphins, enkephalins, etc.), coupled with their end-organ effects, is probably responsible for many of the anti-fatigue and anti-stress actions of ginseng, as ACTH and corticosteroids have been shown to bind directly to brain tissue to increase mental activities during stress. From a clinical perspective, it is apparent that ginseng has a balancing effect or alterative action on the hypothalamic-pituitary-adrenal axis by adjusting metabolic and functional systems governing hormonal control of homeostasis. This assists the body's response to the challenge of stress and therefore is indicated when disruption of this axis is apparent.

Ginseng may prove especially effective in restoration of normal adrenal function and prevention of adrenal atrophy associated with corticosteroid administration. In rats, ginseng has been found to inhibit cortisone-induced adrenal and thymic atrophy.^[25] Ginseng could be combined with other botanicals with adrenal-enhancing activity (e.g. *Bupleuri falcatum*, *Glycyrrhiza glabra*, *Curcuma longa*, and *Eleutherococcus senticosus*)

in the treatment of adrenal atrophy (a.k.a. exhaustion) (also see [Chs 80](#) and [90](#)). ^[26] ^[27]

Diabetes

Ginseng, used either alone or in combination with other botanicals, has a long folk use in the treatment of diabetes. Ginseng has confirmed hypoglycemic activity. The constituents responsible for this effect include five types of substances: ^[28] ^[29] ^[30] ^[31] ^[32]

- five glycans (polysaccharides designated panaxans A to E)
- adenosine
- a carboxylic acid
- a peptide
- a fraction designated DPG-3-2.

The ginsenosides are devoid of hypoglycemic action. (This highlights the importance of using crude, standardized, extracts containing all active principles as opposed to using isolated ginsenosides or pure ginsenoside extracts.)

It is interesting to note that ginseng will increase serum cortisol levels in non-diabetic individuals, while in patients with diabetes, serum cortisol levels will be reduced. ^[33] As cortisol antagonizes insulin, this is presumably a beneficial effect. In addition, DPG-3-2 only exhibits hypoglycemic action or provokes insulin secretion in diabetic and glucose-loaded normal mice while having no effect on normal mice fed a standard diet. ^[28] This again demonstrates ginseng's non-specific balancing effect, baffling to researchers who are accustomed to investigating compounds with consistent pharmacological effects.

Ginseng is indicated as an adjunctive therapy in the treatment of diabetes, both for its hypoglycemic effect and for its ability to decrease the atherogenic index (see below).

Reproductive effects

Although it is claimed to be a "sexual rejuvenator", human studies supporting this belief are scanty. Ginseng has, however, been shown to: ^[34]

- promote the growth of the testes and increase spermatogenesis in rabbits
- accelerate the growth of the ovary and enhance ovulation in frogs
- stimulate egg-laying in hens
- facilitate lordotic response in female rats
- increase gonadal weight in both male and female rats
- increase testicular nucleic acid content in rats
- increase sexual activity and mating behavior in male rats.

These animal study results seem to support ginseng's use as a fertility and virility aid.

In other experimental animal studies, ginseng has been shown to increase testosterone levels while decreasing prostate weight. ^[35] This suggests that ginseng should have

favorable effects in the treatment of benign prostatic hyperplasia; however, no clinical trials have yet been reported.

Ginsenosides have also been shown to bind to human myometrial receptor proteins, and they apparently exert estrogen-like action on the vaginal epithelium. These are significant enough to prevent the atrophic vaginal changes associated with postmenopause and other menopausal symptoms.^[36]

Other clinical indications involving the reproductive system (based on historical use and experimental evidence) include decreased sperm counts, testicular atrophy or hypofunction, and other organic causes of male infertility, and ovarian atrophy or hypofunction, amenorrhea, and other organic causes of female infertility. It should be noted that several reports of mastalgia have been reported in women taking ginseng.^[37]
^[38]

Anti-cancer properties

Long-term oral administration of ginseng to newborn mice has been shown to reduce the incidence and also to inhibit the proliferation of tumors induced by various chemical carcinogens, including DMBA, urethane, and aflatoxin B1.^[39]

Its anti-cancer effects in other experimental models can be summarized as follows:^[39] ^[40]

- it is observed only in slow-growing tumors, such as Ehrlich and sarcoma 180 ascites tumor
- it is not observed in rapidly growing tumors, such as L1210 and P388, and Walker carcinoma
- there is no dose–response relationship or cumulative effect.

The lack of a dose–response relationship suggests that ginseng’s anti-cancer effects are indirect and subject to a threshold mechanism. Thus, ginseng once again appears to demonstrate non-specific effects.

Cell proliferating and anti-aging effects

Ginseng has a dual effect on cell growth: it stimulates cell division in an adequate nutritional environment, but it acts cytostatically under adverse conditions (as described above).^[41] Furthermore, ginseng has yielded impressive results in lengthening the life span of cells in culture.^[42]

This enhancement of cellular proliferation and function has been shown on a variety of cell types (epithelial, hepatic, lymphocyte, fibroblast, thymic, neural, etc.) and may be a

result of potentiation of nerve growth factor (NGF) by ginsenosides.^{[3] [43]}

Clinically, these results indicate a potential use of ginseng in healing damage to virtually all tissue types. Again this demonstrates ginseng's non-specific action.

Immunostimulating effects

That ginseng possesses immunostimulating activity is evidenced by its ability to enhance:^{[44] [45]}

- antibody plaque forming cell response
- circulatory antibody titer against sheep erythrocytes
- cell-mediated immunity
- natural killer cell activity
- the production of interferon
- lymphocyte mitogenesis
- reticuloendothelial system proliferative and phagocytic functions.

Extracts of *Panax ginseng* were found to stimulate NK-function in normal individuals and patients with either chronic fatigue syndrome or acquired immunodeficiency syndrome.^[46] Ginseng has been shown to prevent viral infections in experimental animals,^[47] presumably a result of the combination of effects listed above.

Perhaps the most important immune system-enhancing effect of ginseng is its ability to produce a marked hyperplasia of the Kupffer cells of the liver and of the folliculi in the spleen and lymph nodes.^{[4] [21]} The hyperplastic folliculi show an increase in the number and volume of light centers, thus demonstrating morphological evidence of increased host defense capacity against a wide variety of external assaults.

It should be noted that large dosages of ginseng may be contraindicated in acute infections. This is due to its *in vitro* inhibition of lymphocyte transformation (similar to cortisone) at high (i.e. greater than 1 mg/ml), but not low, concentrations.^{[44] [48] [49]} In fact, *in vitro*, ginseng at 1.6 mcg/ml has been shown to inhibit phytohaemagglutinin-induced transformation of peripheral blood lymphocytes to a greater degree than cortisone at 500 mcg/ml.^[48] The greatest degree of inhibition, however, was observed when ginseng was used in combination with cortisone. These results suggest that ginseng at high doses may be effective against T-cell-mediated inflammatory diseases without producing glucocorticoid-like side-effects. It also suggests that a lower dose of cortisone could be used if ginseng is given simultaneously.

When using ginseng, it is important to remember that ginseng's *in vitro* effect on lymphocyte proliferation is biphasic, i.e. a strong inhibition at high concentrations and a moderate stimulation at low concentrations, and that while ginseng has demonstrated significant inhibition of lymphocyte proliferation *in vitro*, this has not been the observed effect *in vivo*, where lymphocyte proliferation has been enhanced.^[44] These effects may be related to ginseng-induced elevation of interferon (which inhibits lymphocyte

proliferation) which is dose-dependent.

From a clinical perspective, the chronic ingestion of ginseng by individuals with mild immunodeficiency may reduce the risk of viral infection. Use in this manner is consistent with the historical use of ginseng by debilitated individuals.

Cardiovascular effects

Ginseng has paradoxical effects on blood pressure. It appears that at low doses it possesses a hypertensive effect, but when administered at larger doses a hypotensive effect is noted.^[50] Accordingly it has been reported useful in the treatment of essential hypertension in humans, but it has also been shown to have hypertensive effects as well.^[51] This pressor effect must be kept in mind when administering ginseng to both normotensive and hypertensive individuals.

Ginseng administered to human subjects with hyperlipidemia has been shown to reduce total serum cholesterol, triglyceride, and non-esterified fatty acid levels, while raising serum HDL cholesterol levels. Platelet adhesiveness was also decreased.^[52]

These results in humans confirmed earlier studies on rats fed high-cholesterol diets.^[53]^[54] The mechanism of action appears to be through accelerated degradation, conversion, and excretion of cholesterol and triglyceride, despite increased lipogenesis and cholesterologenesis.

Ginseng has also been shown to be effective in inhibiting experimental disseminated intravascular coagulation in rats. It also inhibited platelet aggregation by various aggregating agents and the conversion of fibrinogen to fibrin. Its mechanism of action appears to be via promotion of urokinase's fibrinolytic activity.^[55]

From a clinical perspective, it appears that ginseng may offer some protection against atherosclerotic disease, further supporting its use as a general tonic. It may also possess a blood pressure-regulating effect.

Hepatic effects

Obviously, any adaptogenic substance must impact the liver, due to the liver's central role in metabolic and detoxification reactions. Ginseng affects the liver in several ways. As was previously mentioned, ginseng promotes hyperplasia of Kupffer cells (hepatic macrophages).^[4]^[21] As these cells are responsible for filtering out much of the toxins and debris from the portal circulation, increasing their number and activity could have profound effect.

Ginseng has also been shown to increase nuclear RNA biosynthesis, indicating

increased protein synthesis.^{[3] [56]} In fact, ginseng has been shown to increase not only nuclear RNA synthesis, but also ribosomal and messenger RNA, the amount of rough endoplasmic reticulum, and the activity of RNA polymerase.^{[3] [56] [57] [58]} These results indicate that ginseng activates virtually every step in protein biosynthesis.

As protein synthesis is often reduced in the elderly, the significance of the above-described effects on enhancement of hepatic protein synthesis would be extremely high. However, these results have yet to be confirmed by clinical studies.

Ginseng has also been shown to reverse diet-induced fatty liver in animals and to possess significant antihepatotoxic action.^{[52] [59]}

The clinical indications of these hepatic actions of ginseng are quite broad and support its general tonic/ adaptogen properties.

Radiation-protecting effects

Ginseng has been shown to offer some protection against harmful radiation, both in vivo and in vitro, and to hasten recovery from radiation sickness.^{[60] [61]} In wake of ever-increasing environmental radiation contamination, ginseng may be an appropriate prophylactic against radiation exposure.

TOXICOLOGY

The problem of quality control makes toxicology difficult to address. This is exemplified by a 1979 *JAMA* article entitled "Ginseng abuse syndrome".^[62] In this article, a number of side-effects are reported, including:

- hypertension
- euphoria
- nervousness
- insomnia
- skin eruptions
- morning diarrhea.

Given the extreme variation in quality of ginseng in the American marketplace and the use of both non-official parts of the plant and adulterants, it is not surprising that side-effects were noted. None of the commercial preparations used in the trial had been subjected to controlled analysis. Furthermore, the species of ginseng used included *Panax ginseng*, *Panax quinquefolius*, *Eleutherococcus senticosus*, and *Rumex hymenosepalus* in a variety of different forms, i.e. roots, capsules, tablets, teas, extracts, cigarettes, chewing gum, and candies.

It is virtually impossible to derive any firm conclusions from the data presented in the *JAMA* article. The author's final words do, however, seem sensible and appropriate:

An important caveat is that these GAS [ginseng abuse syndrome] effects are

neither uniformly negative nor uniformly predictable. Nevertheless, long-term ingestion of large amounts of ginseng should be avoided, as even a panacea can cause problems if abused.

Studies have been performed on standardized extracts of ginseng which demonstrate the absence of side-effects and mutagenic or teratogenic effects.^[4] ^[13] ^[63] ^[64] These studies differ markedly from the trial reported in *JAMA* in that high quality extracts were used.

DOSAGE

The dosage is inversely proportional to the ginsenoside content, i.e. if an extract or ginseng preparation contains high concentrations of ginsenosides (and presumably other active components), a lower dose will suffice. The standard dose for ginseng is in the range of 4.5–6 g daily.

Currently, there is almost a total lack of quality control in ginseng products marketed in the United States. Independent research and published studies have clearly documented that there is a tremendous variation in the ginsenoside content of commercial preparations.^[3] ^[4] In fact, many products on the market contain only trace amounts of ginsenosides, and some formulations contain no ginseng at all. This has led to several problems, ranging from toxicity reactions^[62] (discussed below) to lack of medicinal effect. The widespread disregard for quality control in the health food industry has done much to tarnish the reputation of ginseng as well as other important botanicals.

The authors recommend the use of standardized ginseng preparations to ensure sufficient ginsenoside content, consistent therapeutic results, and reduced risk of toxicity. Products should be standardized in their ginsenoside content. The typical dose (taken one to three times daily) for general tonic effects should contain a saponin content of at least 5 mg of ginsenosides with a ratio of R_{b1} to R_{g1} of 2:1. For example, for a high quality ginseng root powder containing 5% ginsenosides, the dose would be 100 mg.

As each individual's response to ginseng is unique, the patient should be monitored for signs of possible ginseng toxicity (see below). It is best to begin at lower doses and increase gradually. The Russian approach for long-term administration is to use ginseng cyclically for a period of 15–20 days followed by a 2 week interval without any ginseng.

Chapter 101 - Pancreatic enzymes

Anthony J. Cichoke MA DC

HISTORY

Pancreatic enzymes have a long history of clinical use. In the early 20th century, John Beard (a Scottish embryologist) successfully treated cancer using a pancreatic extract, which he described in his book, *The Enzyme Treatment of Cancer and its Scientific Basis*.

In 1934, Ernst Freund (a Viennese physician) found a substance which dissolved cancer cells in the blood of people free from cancer. Cancer patients did not have this material, which Freund called “normal substance”.

It was Professor Doctor Max Wolf (considered by many to be the father of modern enzyme therapy) who identified “normal substance” as an enzyme which decomposes fatty materials and proteins. Wolf worked with Freund in Vienna in the early 1930s. This association and the work of John Beard sparked his interest in the possibilities of treating malignant diseases with enzymes. Dr Wolf founded the Biological Institute of New York City and, after studying various enzymes and enzyme combinations, developed what he considered an optimal preparation for the treatment of various acute and chronic conditions. His preparation was a combination of a fractionated hydrolysate of beef pancreas, calf thymus, *Pisum sativum* (common pea), *Lens esculenta* (edible lentil), mannitol, and papaya.

In the 1960s, Irving Innerfield conducted landmark research in the area of pancreatic enzymes, primarily relating to the clinical use of trypsin, chymotrypsin, and pancreatin, as well as streptokinase.

In 1971, Professor Heinrich Wrba, head of the Austrian Cancer Research Institute at the University of Vienna stated:

Our present knowledge allows us to include this [enzyme] therapy into the

small list of highly-effective causal anti-cancer compounds. It [enzyme therapy] will certainly play an important role in cancer treatment over the next few years.

However, it was Karl Ransberger who continued Wolf's research and refined it, bringing it to doctors, hospitals and patients throughout the world. Ransberger encouraged

858

and funded research projects in numerous hospitals and universities in Europe, the Americas, and elsewhere. His research, and that of others, has validated enzyme therapy's effectiveness in treating numerous conditions, including arthritis, cancer, multiple sclerosis, cardiovascular disease, HIV/AIDS, and other diseases.

PANCREATIC ENZYMES

Pancreatic enzymes aid in a surprising variety of bodily functions, including:

- digestion
- detoxification
- bolstering the immune system
- slowing the aging process
- improving blood clot lysing
- enhancing tissue repair
- facilitating the inflammatory response
- fighting viruses.

Genetic weakness, illness, injury, exercise, aging and toxins (both endogenous and exogenous) may result in inadequate production or excessive need for pancreatic enzymes. In these and other situations, additional enzymes from an external source may be necessary.

Many variables influence the proper choice of pancreatic enzymes, including:

- therapeutic goals
- patient's health status
- product
 - type of enzyme(s)
 - activity levels
 - quality control (including pH and temperature ranges)
 - variables which affect therapeutic application (e.g. enteric coating).

Pancreatic enzymes play an integral role in the digestion of proteins, fats, and carbohydrates. Pancreatic juice contains numerous enzymes, including amylase, lipase, ribonuclease, and deoxyribonuclease;^[1] and the proenzymes trypsinogen, chymotrypsinogen, and procarboxypeptidase, which are converted in the small intestine to their active forms, trypsin, chymotrypsin, and carboxypeptidase, respectively.

Protein leaves the stomach primarily in the form of proteases, peptones and large polypeptides.^[2] Upon reaching the small intestine, these are further digested by the proteolytic enzymes, trypsin, chymotrypsin, and carboxypolypeptidase. Protein digestion mainly occurs in the duodenum and jejunum. Carbohydrates are digested by α -amylase in the pancreatic juice, which breaks down starches (converting them into maltose and other small glucose polymers), while pancreatic lipase digests fats.^[2]

Pancreatic enzyme supplements

The pancreatic enzyme supplements most commonly used include chymotrypsin, trypsin, and pancreatin (which contains *proteolytic*, *amylolytic* and *lipolytic* properties), as well as pancrelipase (similar to pancreatin, but with a higher proportion of lipase). Primarily obtained from hog or ox pancreas, some of these enzymes (such as lipase) can also be obtained from microbial sources (e.g. *Aspergillus niger* and *Aspergillus oryzae*).

According to the *US Pharmacopoeia*, chymotrypsin and trypsin are crystallized from ox pancreas gland extract, and pancreatin from both hog and ox sources, while pancrelipase is derived from hog pancreas.^[3] Porcine pancreas is especially rich in amylase and lipase and is similar to human pancreas.^[1] Bovine pancreas contains considerable amounts of proteolytic enzymes but substantially lower amounts of lipase and amylase.^[1]

Other countries (such as Germany, Japan, England, and India) utilize their own pharmacopoeia, and foreign companies may use other sources to formulate their enzyme products.

Age, sex and species of pork or ox can affect enzyme concentration and activity levels. For example, sow glands (from pork) are high in lipase, while butcher hogs (young male hogs, up to 90 kg and 6 months) are high in protease. Beef cows and bulls have different enzyme levels than steers or heifers. Beef, though providing all three basic enzyme types, does not exhibit the activity levels of pork (which has an activity level ? to ½ higher). Further, hog physiology is more similar to humans than to that of any other animal.

Enzyme extraction processes

Because enzymes are particularly sensitive to environmental changes, it is especially important during extraction to control pH (usually with buffers), temperature (using

pre-cooled solutions and apparatus), substrate, and proteolysis (controlled through the use of inhibitors) in order to render a product that is enzymatically active.^[4] Several steps are typically involved in the production of pancreatic enzyme supplements:

- cell membrane rupture
- fractionation
- crystallization
- enzyme isolation.

Rupturing the cell membrane

Although a wide variety of methods are employed in enzyme extraction, most entail rupturing the cell membrane of the animal tissue. This can be achieved through mincing, homogenizing, shaking with fine glass beads (at high speed), grinding with sand, freezing (and subsequent

859

thawing), oscillations (ultrasonic or sonic), autolysis (either alone or with toluene, ethyl acetate or sodium sulfide), treatment with solvents (e.g. acetone), or lysis with added enzymes.^[5]

Extracting enzymes from animal tissues is easier than extracting from microorganisms, according to Dixon & Webb^[5]. They state that, in many cases, simple extraction with water may be sufficient.

All extraction processes, however, must control pH and temperature to protect the enzymes from deactivation.

Fractionation

Once the enzyme is brought into a solution, it must be separated from the other substances in the solution. Gel filtration or dialysis can be used to remove the small molecules, leaving large molecules (primarily proteins, with some polysaccharides).^[5] Various fractionation methods can be employed for purifying the enzymes, including changing the pH, heating, using organic solvents and/or salts, adsorption, column chromatography, and electrophoresis.^[5] Inhibitor affinity chromatography and substrate affinity chromatography are also used.^[6]

Crystallization

After an enzyme has been purified, it may be possible to crystallize it. Dixon & Webb^[5] view this as a final stage method of fractionation. Crystallization can be achieved with ammonium sulfate solutions (the typical method), or at a constant salt concentration by

gradually changing the temperature or the pH.^[5]

Enzyme isolation

Chymotrypsin

One method (used in Germany) for extracting chymotrypsin (in the form of its inactive precursor chymotrypsinogen) is by fractionated extraction, ultrafiltration and subsequent chromatographic purification of pancreatic juice. The chymotrypsinogen is converted to the active chymotrypsin by treatment with trypsin in an acid environment.

Trypsin

Trypsinogen can be isolated from the animal pancreas by fractionated precipitation and then activation to trypsin in a slightly alkaline environment.

Pancreatin

Pancreatin can be obtained by an extraction procedure where, after elimination of the insoluble tissue, organic solvents dissolve and precipitate the enzymes.^[1] However, because part of the lipase and other enzymes are inactivated during the manufacturing process, pancreatin, isolated in this way, is not very active.^[1]

According to Ruysen & Lauwers,^[1] more effective pancreatin can be produced through lyophilization, i.e. by drying under reduced pressure or with acetone. At this low temperature, the enzymes are more stable and less likely to be denatured.^[1]

After proper defatting, the pancreatin is stable, provided it contains not more than a small percentage of moisture.^[1] However, it may contain undesirable microorganisms (such as *Salmonella*) and must, therefore, be decontaminated.^[1] Under carefully controlled conditions, pancreatin can be decontaminated by a terminal heat treatment.^[1]

According to the *US Pharmacopeia*,^[3] each milligram of pancreatin should contain:

- not less than 25 USP units of amylase activity
- not less than 2.0 USP units of lipase activity
- not less than 25 USP units of protease activity.

The *US Pharmacopoeia* states that: "One USP unit [or 1x] of amylase activity is contained in the amount of pancreatin that decomposes starch at an initial rate such that one microequivalent of glucosidic linkage is hydrolyzed per minute" under the conditions listed in the USP to assay for amylase activity. "One USP unit [or 1x] of lipase activity is contained in the amount of pancreatin that liberates 1.0 μ Eq of acid per minute at a pH of 9.0 and 37°" under the conditions detailed in the USP to assay for lipase activity. "One USP unit [or 1x] of protease activity is contained in the amount of pancreatin that digests 1.0 mg of casein" under the conditions enumerated in the USP to assay for

protease activity.^[3] Therefore, a product labeled “4x” would be four times stronger than a product labeled “1x”.

Pancrelipase

Pancrelipase is similar to pancreatin and according to the USP should contain:

- not less than 100 USP units of amylase activity
- not less than 24 USP units of lipase activity
- not less than 100 USP units of protease activity.

Pharmacology

Chymotrypsin and trypsin are proteolytic enzymes which break down proteins into peptides. Chymotrypsin liberates the amino acids, L-tyrosine, L-tryptophan, and L-phenylalanine, as well as other molecules including several synthetic esters and amides.^[4] Trypsin hydrolyzes primarily lysyl and arginyl residues.^[4]

Pancreatin contains amylase, lipase, and protease.

Amylase breaks down starch; lipase breaks down fats; and protease breaks down proteins.

Absorption

In the past, the efficacy of enzyme therapy has been discounted, since the intestinal epithelial mucosa had been thought to be impermeable to large protein molecules.^{[7] [8] [9]} Research over the past two decades has shown that the intestinal epithelium can be crossed by macromolecules, including intact proteins such as proteolytic enzymes.^[10]

These macromolecules normally penetrate the mucosal surface via the transcellular route as, in the healthy mucosa, the tight junctions (zonula occludens) between the enterocytes prohibit paracellular passage.^{[11] [12] [13] [14]} Binding to the luminal membrane of the enterocyte is followed by phagocytosis.^[15] Some of the vacuole membrane vesicles formed fuse with lysosomes, and within the resulting phagolysome, the peptides and proteins may be hydrolyzed by lysosomal enzymes.^[13] Other macromolecules avoid intracellular digestion and are passed from the enterocytes through the basolateral membrane into the interstitial space.^[16] In the interstitial space, the macromolecules become available to macrophages and lymphoid cells.^[17] Those molecules not taken up by macrophages or lymphatic cells eventually pass from the interstitial space into the blood or lymph.^[18]

The transport of macromolecular material from the lumen to the interstitium has been

extensively studied in the epithelium covering the lymphatic structures, such as Peyer's patches or isolated follicles.^[15] In these regions, specialized enterocytes, the follicle-associated epithelium cells (FAE cells)^[12] or M-cells^[19] (called M-cells because of their occurrence in the microfolds of the luminal surface), transport macromolecular material in both directions.^[12] The gut-associated immune system is thus supplied with antigenic macromolecules from the intestinal lumen.^[20] ^[21] ^[22] The immunoglobulins produced by the plasma cells in the lamina propria (mainly IgA) are transported transcellularly to the luminal surface.

The exact degree of the intestinal absorption of intact molecules or large breakdown products of dietary proteins is not yet totally clear.^[23] ^[24] Although it is generally assumed that, apart from a very small proportion, all protein is hydrolyzed into amino acids or small molecular weight peptides before absorption by the mucosa, some research supports the hypothesis that a considerable proportion of dietary protein is taken up in the form of macromolecules and is only then hydrolyzed intercellularly in the peripheral tissue into amino acids ("distributed digestion").^[25] ^[26] ^[27]

Regardless of the nutritional significance, the transepithelial transfer of particulate matter is at least antigenically sufficient to elicit a response of the gut-associated immune system.^[12] The production and secretion of the immunoglobulins promote binding and proteolysis of the antigen material on the mucosal brush-border, thereby reducing its absorption (immunological barrier).^[28]

Absorption of enzymes

The intestinal transport of macromolecules is especially important for understanding the functions of enzymes.^[29] Hydrolases such as trypsin or elastase can be transported functionally intact into the blood from the lumen of the gut. These circulating proteinases are bound to anti-proteinases like alpha-2 macroglobulin or alpha-1 anti-proteinase^[20] and can be resorbed from the main stream by pancreatic cells (interpancreatic circulation as an enzyme conservation process).^[29] Thus, the intestinal absorption of intact enzymes appears to be important for the balance between hydrolases and anti-proteinases in the intracellular space^[30] and is an important factor for the establishment and maintenance of the internal stability in the body.

It should be kept in mind that, although there are a number of absorption mechanisms, the primary mechanism for enzymes and other macromolecular enteral absorption is pinocytotic transfer by the M-cells of the small intestinal epithelium. After connection to a receptor in the mucosa of the intestinal wall, the enzymes are then absorbed into the wall by pinocytosis, guided through the intestinal cells in vesicles, and finally released into the blood by exocytosis.^[31]

To clarify rate of absorption, Steffen, et al,^[32] investigated the absorption of an enzyme mixture "A" (EMA: pancreatin, 100 mg; papain, 60 mg; lipase, 10 mg; amylase, 10 mg; trypsin, 24 mg; chymotrypsin, 1 mg; bromelain, 45 mg; the bioflavonoid, rutin, 50 mg) in rabbits. Using electrophoresis, they found that entire enzyme molecules were absorbed. Although enzyme particles were also present, the ratio to the entire amount administered was not measured. EMA was found in both lungs and liver after 1–2 hours.

After 1–4 hours, approximately twice as much EMA was found in the liver as in the lungs. The absorption maximum in all animals occurred approximately 1 hour after administration. After 24 hours, EMA was no longer found in either the lungs or liver.

The absorption rate of individual and combined enzymes can be seen in [Table 101.1](#) . The absorption rate of orally ingested EMA is about 20% within 6 hours.^[21] (For additional discussion of the intestinal absorption of intact macromolecules, see [Chs 21](#) and [66](#) .)

Factors affecting enzyme activity

Factors affecting enzyme activity include:

- pH
- temperature
- substrate and substrate concentration
- cofactors
- metal ions
- inhibitors and coating.

TABLE 101-1 -- Absorption rate of individual and combined enzymes (within 6 hours)^[33]
[34]

| Enzyme | Absorption rate |
|--|-----------------|
| Amylase | 45% |
| Chymotrypsin | 14–16% |
| Pancreatin | 18–19% |
| Papain | 6% |
| Trypsin | 26–28% |
| Enzyme combination (bromelain, chymotrypsin, pancreatin, papain, and trypsin, with the bioflavonoid rutin) | 22% |

Optimal pH range

Each enzyme has an optimal pH range, depending upon such variables as temperature and substrate concentration, at which the enzymatic catalytic reaction occurs most rapidly.

Chymotrypsin is stable at a pH of 3 or 4, suffers reversible denaturation at a pH below 3.0, and becomes inactive at a pH of above 10.0.^[1] Trypsin, stable at a pH of 3.0 (and at low temperature), is irreversibly denatured at a pH of 8.0 or higher.^[1]

The effects of temperature

In general, an increase of 10°F (5.5°C) in the enzymatic environment will approximately double the rate of the chemical reaction.^[35] However, since enzymes are proteins, excessively high temperatures denature enzymes, thus destroying their activity. Optimal temperature for an enzyme is the temperature at which the catalyzed enzymatic reaction progresses most rapidly without damage to the enzyme.

The enzymes in the human body develop high levels of activity at about body temperature, increasing to maximum at about the temperature of a severe fever, i.e. 104°F (40°C).

Substrate concentration

The rate of any reaction is accelerated by increasing the substrate concentration until the enzyme is saturated by substrate. At this level, the rate of reaction becomes independent of substrate concentration and is no longer accelerated by the addition of more substrate.

Cofactors

Although all enzymes consist of protein, some are complex proteins, i.e. they have a protein component and a “cofactor”. If the cofactor is removed, the protein (no longer active enzymatically) is called the *apoenzyme*. A cofactor might be a metal (e.g. iron, magnesium, copper, or zinc), a prosthetic group (a moderately-sized organic molecule), or a coenzyme (small organic compounds). Prosthetic groups and metals can aid in the catalytic function of the enzyme, while coenzymes take part in the enzymatic reaction. Many vitamins, trace elements, and minerals essential to human bodily function are part of enzymatic cofactors.

Coenzymes are essential for the activity of many enzymes and serve as a type of substrate in certain reactions. In these reactions, the coenzyme is converted to a form no longer active in catalyzing the reaction. The reaction requires a mix which contains one molecule of cofactor for every molecule of substrate to be converted.

Metal ions

Specific metal ions are required for the activity of many enzymes. Certain metal ions increase activity while others decrease or inhibit activity. Calcium, cobalt, copper, iron, magnesium, manganese, molybdenum, potassium and zinc are the most frequent

enzyme activators in humans.

Certain heavy metal ions inhibit enzyme reactions. These heavy metals include barium, lead and mercury, and they combine with the sulfhydryl reactive group (-SH) which is part of the active site of many enzymes.

Inhibitors

Ions, atoms, or molecules which terminate or retard enzyme activity are called inhibitors. These inhibitors are classified as non-competitive or competitive. Non-competitive inhibitors combine with the enzyme at a location other than the active site. The non-competitive inhibitor retards the conversion of the substrate by the enzyme, although it does not affect the bonding of the substrate of the enzyme.

An inhibitor is classified as *competitive* when it combines with the active site of the enzyme, preventing the substrate from having access to the active site.

Supplement coating

The normal human stomach has a pH of approximately 1.5–3.0.^[36] This low pH inhibits bacterial growth and activates certain enzymes. This acidic nature, however, can destroy pH-sensitive supplemental enzymes. For this reason, many enzyme products are enterically coated. This coating allows the product to reach the small intestine before disintegrating.^[4] Other products are encapsulated in “microspheres”, which delays their disintegration.

In one study, cellulose acetate phthalate (CAP) and

maize starch were used as the coating materials for encapsulating pancreatic protease.^[37] Results indicate that the coating materials were stable for at least 3 hours (time to pass through each part of the GI tract) in simulated gastric conditions (pH 3.97), but disintegrated rapidly under simulated intestinal conditions (pH of 6.82 and temperature of 39.5°C).

Measuring enzyme activity

When considering enzymes and enzyme applications, it is extremely important to understand the variables affecting their performance. When selecting an enzyme for therapeutic purposes, more than whether a given product contains amylase, protease, lipase, or other enzymes must be considered. The activity levels of the enzymes are of critical importance.

Unfortunately, the labels on most enzyme products sold in this country do not indicate

the activity levels of the enzymes contained therein. In addition, when the activity is stated, the consumer has no way of knowing which enzyme assay the manufacturer used unless the label also indicates that the product conforms to the guidelines of the *USP*. This is particularly confusing because activity levels are greatly affected by the conditions under which the assay was performed (including temperature, pH and substrate).

Adding to the confusion, enzyme manufacturers utilize diverse assay methodologies. Therefore, directly comparing the enzymatic activity of competing products is difficult, if not impossible. The utilization of a single assay system (such as detailed in the *USP*) is probably necessary to directly compare competitive products. Several standardized assay systems are available for enzyme suppliers and are found in the *US Pharmacopoeia* (for a definitive assay), the *NFIA Laboratory Methods Compendium*, and the *Food Chemical Codex*.

Incomplete labeling and the inconsistent use of standardized assay methodologies make evaluation of competitive products extremely challenging. Price could be the first indication of inequities in assay procedures. For example, if company A is selling a product at 1,000 units/g for \$30.00 a bottle, and company B is selling a product at 5,000 units/g for \$10.00 a bottle, the units are most likely not the same.

For clinical reliability, utilize only appropriately labeled products or obtain the assay procedures from each of the manufacturers. If possible, compare competitor products by assays performed in an independent laboratory.

CLINICAL APPLICATIONS

Historically, enzyme therapy has been used in a wide variety of applications, ranging from the classic substitution of enzymes for intestinal deficiency to the centuries-old external application of enzymes to treat wound-healing disturbances (e.g. leg ulcers). Enzymes have been used individually or in complex enzyme mixtures. Clinical uses of individual enzymes can be seen in [Tables 101.2](#) , [101.3](#) , [101.4](#) , [101.5](#) , [101.6](#) .

TABLE 101-2 -- Clinical applications of chymotrypsin

-
- In debridement, treatment of abscesses and ulcerations, liquefaction of mucous secretions^[38]
-
- In ophthalmic cataract surgeries and therapy of eyeball hematomas and ophthalmorrhagias^{[38] [39]}
-
- Before and after tooth extraction as well as in operative dentistry^{[40] [41]}
-
- After episiotomy surgeries^[42]
-
- As an anthelmintic against enterozoic worms^[43]
-
- In early recognition of tumor cells ^[44]
-
- In histologic gastroenteric diagnostics ^[45]
-

- In inflammatory conditions (local and systemic) to promote the dispersion of blood extravasates and effusions from fractures^{[39] [46] [47] [48] [49] [50] [51] [52] [53]}
- Surgical trauma^{[42] [51]}
- Sporting injuries^{[46] [47] [48] [49] [50]}
- Accidental soft tissue trauma^{[46] [47] [48] [49] [50] [53]}
- Intervertebral disc lesions^[54]
- In uveitis vitreous hemorrhage, diabetic retinopathy and asthmatic symptoms^[55]

TABLE 101-3 -- Clinical applications of trypsin

- In debridement of necrotizing wounds, ulcerations, abscesses, empyemas, hematomas, fistulas, and decubitus^{[56] [57] [58] [59]}
- To accelerate healing in injuries, inflammations, phlogistic edemas and traumatic changes^{[46] [47] [48] [49] [50] [51] [52] [53]}
- As an auxiliary agent in meningitis therapy^[60]
- As an ointment or dressing (wet or dry) ^[1]
- As a liquid or an aerosol to liquefy sputum in bronchial disorders and in the preparation of sputum for cytological examination^[1]
- As an anti-inflammatory agent, oily suspensions are injected intramuscularly^[1]
- As an aid in the treatment of intraocular hemorrhage, thrombophlebitis, intestinal obstruction (due to cirrhosis or carcinoma)^[61]

TABLE 101-4 -- Clinical applications of amylase (needs calcium ions for enzymatic activity)

- Acts on starch, glycogen and related poly- and oligosaccharides^[5]
- In combination with other enzymes, as a digestant^{[38] [62] [63]}
- As an anti-inflammatory^[62]
- In treatment of deficiencies of exocrine pancreas, amyloseous dyspepsia and cystic fibrosis^[1]

TABLE 101-5 -- Clinical applications of lipase

- In pancreatin-containing remedies to increase pancreatic/lipolytic activities (replacement therapy)^{[64] [65] [66] [67]}

Inflammatory diseases

One of the basic concepts in systemic enzyme therapy is that all kinds of inflammatory processes (from sports injuries to arthritis to sinusitis to fibrocytis) respond to enzymes. The following is the postulated mechanism of action:

1. In the damaged area, various repair mechanisms are activated, resulting, among other effects, in fibrin surrounding the traumatized region.
2. After having been partly or completely sealed off by microthrombi, blood vessels become highly permeable, and the injured area is disconnected from the normal circulatory system. Stasis results, inhibiting the repair processes.
3. Supplemental enzymes, after absorption, are bound in complexes (e.g. alpha-2-macroglobulin-hydrolase) and circulate to the injured area from the bloodstream.
4. Hydrolytic enzymes directly attack the microclots breaking open the clogged vessels and re-establishing circulation.

By restoring normal blood flow, post-inflammatory pain and edema are reduced more rapidly and, equally important, the important physiological inflammatory repair process is not blocked or diminished (as with anti-inflammatory agents), but rather accelerated and reinforced.

Even inflammatory diseases, such as arthritis or herpes zoster, have been shown to respond to the systemic application of enzymes.^{[93] [94] [95]} Despite the supportive research, the administration of enzymes in traumatology and injuries is not widely used. All types of injuries, e.g. sprains, strains, hematomas, dislocations, and even postoperative conditions can be effectively treated with enzymes.

Individual enzymes and enzyme combinations (particularly ones including trypsin, chymotrypsin, pancreatin, amylase, lipase, papain, and bromelain, with rutin) are effective in treating inflammation because they help limit the injury, aid its rectification, and promote new, healthy tissue formation. They are inflammation activators, not inflammation inhibitors. Enzymes can accelerate the inflammatory process which is a necessary component of wound healing. This acceleration means, on the one hand, that the work of damage control, damage repair, and new tissue construction is carried out more actively, and thus completed more swiftly. On the other hand, it also means that there can be a temporary increase in the visual and sensory effects produced by the inflammation (i.e. more redness, swelling, heat, and pain).

Since the inflammatory reaction is so universal, it appears that enzymes and enzyme mixtures can be effectively used to treat a wide variety of chronic disorders.

Autoimmune and immune complex-mediated diseases

In autoimmune disease, tissue-bound immune complexes activate the complement system. Activation of the enzyme cascade results in an intense protein-destroying inflammatory response, leading to significant local tissue destruction. For instance, when immune complexes collect in the kidneys, complement activation causes inflammation, resulting in glomerulonephritis.

Research shows that some enzymes can inhibit immune complex-mediated diseases, such as glomerulonephritis, by interrupting the complement cascade. Other disorders with similar mechanisms also respond to supplemental enzymes. Some are conditions, such as Crohn's disease, pulmonary fibrosis, chronic rheumatism, and ankylosing spondylitis, which have not responded well to conventional medical treatments.

Cardiovascular disorders

Cardiovascular disease, the number one killer in the US, kills nearly one in every two Americans. In 1988, heart and blood vessel diseases killed nearly 1 million Americans, almost as many as cancer, accidents, pneumonia, influenza, and all other causes of death combined. But cardiovascular disease is not limited to the elderly; nearly 175,000 Americans under the age of 65 die from this disease every year.^[96]

In normal circulation, there is a constant dynamic balance between blood clotting and fibrinolysis.^[97] If fibrinolysis is impaired, abnormal clot formation occurs. If fibrinolysis increases, a tendency toward excessive bleeding results. Therefore, maintenance of proper equilibrium is extremely important for the circulatory system.

One study examined the effects of various enzyme combinations on fibrinolysis and fibrin formation. The researchers induced fibrin deposition with calcium ions or staphylocoagulase in the plasma of centrifuged, acellular citrated blood from humans or rabbits and treated the clot with various concentrations of enzyme suspensions. The

clots were degraded more rapidly the higher the enzyme content of the solution.^{[98] [99]}

Combination enzyme therapy

Because trypsin, chymotrypsin, lipase, and amylase are substrate-specific, combinations of enzymes are frequently employed for a broader spectrum of activity. In addition, when combined, some enzymes act synergistically with others – hence the use of pancreatin (from animal pancreas), as well as products which include both enzymes from different sources and activating substances. For example, one German product contains an enzyme extract consisting of proteinases, triacylglycerol lipase, and α -glycosidase (amylase), minor amounts of elastase, nuclease, and carboxypeptidase, and Ca^{2+} ions to increase activity.

Enzyme combinations should not be viewed as simply intensified forms of pancreatin. An enzyme combination has a number of therapeutic advantages as opposed to a preparation with only one or two components. Combining enzymes from diverse sources, i.e. animal, plant, and fungi, results in a wider range of optimal pH, synergism of the combined enzymes, increased percentage of absorption, increased level of effectiveness, and broader range of application.

Further, Streichhan states that enzyme combinations are better than single enzymes because:^[92]

- isoenzymatic activity differences of single biocatalysts are more readily balanced by combining uniformly acting hydrolases of varying origins
- giant molecular substrates are more quickly and more intensively fragmented by a multihydrolytic preparation because the differently acting hydrolases are able to simultaneously disintegrate the giant molecular substrates at many different locations
- certain enzymatic mixtures have a broader range of action than pancreatin, bromelain, or any other standardized monohydrolytic preparation – this is because certain enzyme mixtures characteristically possess differences in optimal pH and also differences in reactive properties of the proteo-, lipo-, and/or glycolytic acting hydrolases.

Enzyme therapy (hydrolytic enzymes from plants, animals, and fungi) combined with rutin is a proven method for treating a number of conditions, as seen in [Table 101.7](#).

DOSAGE

Enzymes may be administered rectally, topically, orally, or by injection, depending on the condition being treated. Rectally, a retention implant or suppository is given. Topically, ointment is spread over the involved area. Orally, lozenges (dissolved in the

mouth), oral tablets or enteric-coated tablets are used.

 - Fibrocystic breast disease^{[146] [175]}

 - Ulcerative colitis and Crohn's disease^{[120] [124] [176] [177]}

A wide range in daily dosage has historically been used because:

- there are individual differences in patient health
- the level of effective absorption in tablet strength can vary
- there are a wide variety of influencing ranges in pH
- enzyme activity levels vary between products.

For example, pancreatin dosage depends on the condition being treated, as well as the patient's diet and digestive requirements. Dosage can vary because of pancreatin's susceptibility to inactivation in the stomach and duodenum.^[182]

[Table 101.8](#) indicates the composition of three enzyme combinations ("A", "B", and "C"), while [Table 101.9](#) lists several conditions effectively treated with these products, the dose required, and the treatment period.

TABLE 101-8 -- Composition of enzyme combinations (mg)^[179]

| Enzyme | "A" | "B" | "C" |
|----------------|------------|------------|------------|
| Pancreatin | 100 | 100 | 0 |
| Papain | 60 | 60 | 100 |
| Bromelain | 45 | 45 | 0 |
| Lipase | 10 | 10 | 0 |
| Amylase | 10 | 10 | 0 |

TOXICOLOGY

Oral enzymes

In general, side-effects of orally administered enzymes are few and due primarily to excessive dosages or hypersensitivity reactions. According to Wolf & Ransberger, high dosages (70 tablets of 17.5 g each) of a proteolytic enzyme mixture have been given without long-term side effects.^[187] Studies and literature searches commissioned by regulatory authorities such as the FDA have apparently confirmed that enzyme preparations obtained from suitable sources (e.g. non-toxic, non-pathogenic sources) are safe to consume.¹⁸⁸

With normal use, stools can be pale or have a pungent odor. Transient intestinal upset, such as diarrhea and gas, may result from excessive dosage of pancreatin. Hyperuricosuria (excess uric acid in the urine) and hyperuricemia (excess uric acid in the blood) have been associated with extremely high doses of exogenous pancreatic enzymes.

If the pancreatin preparations are held in the mouth before swallowing, stomatitis can result, as well as ulcerations, and irritation of the mucosa, particularly in infants where pancreatin may also cause perianal soreness.^[1] ^[178]

It is not known whether pancreatin given to pregnant woman can harm the fetus since animal reproductive studies have not been conducted. Therefore, pancreatin should probably not be used during pregnancy.^[178] Also, since it is not known if pancreatin is distributed into mother's milk, caution should be exercised with nursing women.^[178]

Sneezing, lacrimation, rash and other hypersensitivity reactions have been reported in sensitive individuals. Pancrelipase (and any other enzyme derived from pork sources) is contraindicated in those who are hypersensitive or allergic to pork products.

Enzymes should not be used by hemophiliacs, nor immediately before or after operations with an increased risk of bleeding. Trypsin is especially contraindicated in those with blood-clotting mechanism disorders, in liver disease, and as an aerosol within a week of pulmonary hemorrhage.^[4]

Enzyme enemas

Enzyme enemas can sometimes cause the rectum or anus to itch or burn. However,

these are only minimal side-effects in relation to the positive benefits obtained.

Topical application

Enzymatic activity directed toward proteinaceous components of the epithelium can cause irritation. For

866

example, prolonged skin contact with proteolytic enzymes may cause irritation of the skin, mucous membranes of the throat, nose, and eyes.¹⁸⁸

Injectable enzymes

Injectable forms require more care. Chymotrypsin, when injected, can occasionally create anaphylactic reactions.^[1] When injected, trypsin's toxicity is greatly increased, and rapid infusion is far more toxic than slower infusion.^[1] In addition, trypsin must not be administered intravenously.^[1] Further, intradermal or scratch testing is advised before parenteral administration.^[1] Other contraindications to trypsin's use are pork allergy and pancreatitis.

It should be remembered that, at the beginning of therapy, an individual's symptoms may occasionally increase in severity. This is a sign that a therapeutic reaction is occurring and should be evaluated positively. The medication need not be discontinued, although a temporary reduction in dose might be advisable.

Chapter 102 - Phage therapy: bacteriophages as natural, self-limiting antibiotics*

Elizabeth Kutter PhD

INTRODUCTION

Phage therapy involves the use of specific viruses – viruses that can attack only bacteria – to kill pathogenic microorganisms. The art was first developed early in this century, but since the advent of chemical antibiotics in the 1940s, it has been little used in the West. Today, however, the growing incidence of bacteria which are resistant to most or all available antibiotics is leading to widespread renewed research interest in the possibilities of phage therapy.^{[1] [2] [3] [4]} Most of the recent articles appearing in the West reflect little knowledge of the extensive Eastern European research and clinical utilization of phage therapy. The good clinical results of Eastern European research provide a substantial basis for optimism and complement the limited recent animal work in the West. We need to draw as much as possible on the largely unknown body of knowledge that has accumulated in Poland and the former Soviet Union as we again explore phage therapy, and to give credit where it is due for the many years of hard, careful work in the field. This chapter has been written in order to put phage therapy into historical and ecological context and to explore some of the most interesting and extensive research in Eastern Europe.

* Special thanks to Drs Liana Gachechiladze, Zempira Alavidze, Amiran Meipariani, Taras Gabisonia, Mzia Kutateladze, Rezo Adamia, Teimuraz and Nino Chanishvili and their colleagues at the Bacteriophage Institute, Tbilisi, for their hospitality and efforts to help me understand the extensive therapeutic work carried out there. Others who have been particularly helpful with information and communication include Dr Marina Shublade, pediatrician in Tbilisi for 10 years, now residing in Seattle; Nino Mzavia, Nino Trapidze, Timur and Natasha Zurabishvili, who have worked in my laboratory; Bill Summers (Yale), Hans-Wolfgang Ackermann (Laval University), Eduard Kellenberger (Basel) and Bruce Levin (Emory); Kathy d'Acci, clinical laboratory director, St Peter's Hospital, Olympia; physicians Jess Spielholz MD, and Robin Moore ND; and, especially, the many colleagues and students involved in our laboratory in Olympia, particularly Barbara Anderson, Pia Lippincot, Mark Mueller, Stacy Smith, Elizabeth and Chelsea Thomas and Jim Neitzel.

HISTORIC CONTEXT

Discovery

A century ago, Hankin^[5] reported that the waters of the Ganges and Jumna rivers in India had a marked antibacterial action which could pass through a porcelain filter, an antibacterial activity destroyed by boiling. He particularly studied the water's effects on *Vibrio cholerae* and suggested that the substance responsible was what kept cholera epidemics from being spread by ingestion of the water of these rivers. However, he did not explore the phenomenon further. Edward Twort and Felix d'Herelle independently reported isolating filterable entities capable of lysing bacterial cultures and of producing small cleared areas on bacterial cultures, implying that discrete particles were involved.^[6] They are jointly given credit for the discovery of bacteriophages.

Early research

It was d'Herelle, a Canadian working at the Pasteur Institute in Paris, who gave these newly discovered organisms the name *bacteriophages*— using the suffix *phage* “not in its strict sense of *to eat*, but in that of *developing at the expense of*”.^[7] He carefully characterized them as viruses which multiply in bacteria and worked out the details of infection of different bacterial hosts by various phages under a variety of environmental conditions. The 90th Annual Meeting of the British Medical Association in Glasgow featured a very interesting discussion among d'Herelle, Twort and several other eminent scientists of the day on the nature and properties of bacteriophages. The main question was whether the observed bacteriolytic principle was an enzyme produced by bacterial activity or a form of tiny virus. Gradually, it became clear that it is indeed viral in nature, able to reproduce and direct the synthesis of its own enzymes.

D'Herelle summarized the early phage work in a 300 page book, *The Bacteriophage*.^[7] He wrote classic descriptions of plaque formation and composition, infective centers, the lysis process, host specificity of adsorption and multiplication, the dependence of phage production on the precise state of the host, isolation of phages from sources of infectious bacteria, and the factors controlling stability of the free phage. He quickly became fascinated with the apparent role of phages in the natural control of microbial infections. He noted, for example, the frequent specificities of the phages isolated from recuperating patients for disease organisms infecting them and the rather rapid variations over time of the phage populations. Throughout his life, he worked to develop the therapeutic potential of properly selected phages against the most devastating health problems of the day. However, he initially focused on simply understanding phage biology. Thus, the first known report of successful phage therapy came from Bruynoghe & Maisin,^[8] who used phage to treat staphylococcal skin infections.

After much travel, including the study of epidemics in Latin America and a year at the Pasteur branch in Saigon, d'Herelle left the Pasteur Institute in 1922. He worked in

Holland and then became employed as a health officer by the League of Nations, based in Alexandria, Egypt. Phage therapy and sanitation measures were the primary tools in his arsenal to deal with major outbreaks of infectious disease throughout the Middle East and India. In 1928, he was invited to Stanford to give the prestigious Lane lectures; his discussions were published as the monograph, *The Bacteriophage and its Clinical Applications*.^[9] He gave many lectures for medical schools and societies as he crossed the country. He accepted a regular faculty position at Yale, where he was supported by George Smith who had translated his first two books into English. He continued to spend summers in Paris working with the phage company he had established there and returned permanently to France in 1933.

George Eliava, director of the Georgian Institute of Microbiology, saw bacteriocidal action of the water of the Koura river in Tbilisi (Tiflis) which he could not explain until d'Herelle's bacteriophage work was published. Eliava then spent 1920–21 at the Pasteur Institute and was a very early collaborator of d'Herelle's; several phage papers of his are cited in d'Herelle.^[7] The two developed the dream of founding an Institute of Bacteriophage Research in Tbilisi – to be a world center of phage therapy for infectious disease, including scientific and industrial facilities and supplied with its own experimental clinics. The dream quickly became a reality due to the support of Sergo Orjonikidze, the People's Commissar of Heavy Industry, despite KGB opposition to this "foreign project". A large campus on the river Mtkvari was allotted for the project in 1926. D'Herelle sent supplies, equipment and library materials. In 1934 and 1935, he visited Tbilisi for a total of 6 months and wrote a book on *The Bacteriophage and the Phenomenon of Recovery*,^[10] which was translated into Russian by Eliava. D'Herelle intended to move to Georgia; in fact, a cottage built for his use still stands on the institute's grounds. However, in 1937, Eliava was arrested as a "people's enemy" by Beria, then head of the KGB in Georgia and soon to direct the Soviet KGB as Stalin's much-feared henchman. Eliava was soon executed, sharing the tragic fate of many Georgian and Russian progressive intellectuals of the time, and d'Herelle, disillusioned, never returned to Georgia. However, their institute survived and is still functioning at its original site on the Mtkvari (which it now shares with the more modern Institutes of Molecular Biology & Biophysics and of Animal Physiology).

In 1938, the Bacteriophage Institute was merged with the Institute of Microbiology & Epidemiology, under the direction of the People's Commissary of Health of

Georgia. In 1951, it was formally transferred to the All-Union Ministry of Health set of Institutes of Vaccine and Sera, taking on the leadership role in providing bacteriophages for therapy and bacterial typing throughout the former Soviet Union. Under orders from the Ministry of Health, hundreds of thousands of samples of pathogenic bacteria were sent to the institute from throughout the Soviet Union to isolate more effective phage strains and to better characterize their usefulness. In 1988, an official Scientific Industrial Union "Bacteriophage" was formed, centered in Tbilisi with branches in Ufa, Habarovsk and Ghorki.

Initial attempts at commercialization

From the beginning, a major commercial use of phages has been for bacterial identification through a process called *phage typing* – the use of patterns of sensitivity to a specific battery of phages to precisely identify microbial strains. This technique takes advantage of the fine specificity of many phages for their hosts and is still in common use around the world. However, the sophisticated ability of phages to destroy their bacterial hosts can also have a very negative commercial impact; phage contaminants occasionally spread havoc and financial disaster for the various fermentation industries that depend on bacteria, such as cheese production and fermentative synthesis of chemicals.^[11]

Phage therapy has been evaluated extensively, with many successes being reported for a variety of diseases, including dysentery, typhoid and paratyphoid fevers, pyogenic and urinary-tract infections and cholera. Phages have been given orally, through colon infusion, as aerosols, and poured directly in lesions. They have also been given as injections: intradermal, intravascular, intramuscular, intraduodenal, intraperitoneal, and even into the lung, carotid artery and pericardium. The early strong interest in phage therapy is reflected in some 800 papers published on the topic between 1917 and 1956. These have been reviewed in some detail by Ackermann & Dubow.^[12] The reported results were quite variable. Many of the physicians and entrepreneurs who initially became excited by the potential clinical implications jumped into applications with very little understanding of phages, microbiology or basic scientific process. Thus, many of the studies were anecdotal and/or poorly controlled; many of the failures were predictable, and some of the reported successes did not make much scientific sense. Often, uncharacterized phages, at unknown concentrations, were given to patients without specific bacteriological diagnosis, and there is no mention of follow-up, controls or placebos.

Much of the understanding gained by d’Herelle was ignored in this early work, and inappropriate methods of preparation, “preservatives” and storage procedures were often used. On one occasion, d’Herelle reported testing 20 preparations from various companies and finding that not one of them contained active phages! On another occasion, a preparation was advertised as containing a number of different phages, but it turned out that the technician responsible had decided it was easier to grow them up in one large batch than in separate batches. Not surprisingly, checking the product showed that one phage had outcompeted all the others, and this was not, in fact, a polyvalent preparation. In general, there was no quality control except in a few research centers. Large clinical studies were rare, and the results of those that were carried out were largely inaccessible outside of Eastern Europe.

Specific problems of early phage therapy work

In the 1940s, the new “miracle” antibiotics such as penicillin became widely available, and phage therapy was largely abandoned in the Western world. Many believe (erroneously) that it was proven not to work; however, it simply was never adequately researched. It is thus important to carefully consider the reasons for the early problems

and the question of efficacy. These included:

- paucity of understanding of the heterogeneity and ecology of either the phages or the bacteria involved
- failure to select phages of high virulence against the target bacteria before using them in patients
- use of single phages in infections which involved mixtures of different bacterial species and strains
- emergence of resistant bacterial strains – this can occur by selection of resistant mutants (a frequent occurrence if only one phage strain is used against a particular bacterium) or by lysogenization (if temperate phages are used, as discussed below)
- failure to appropriately characterize or titer phage preparations, some of which were totally inactive
- failure to neutralize gastric pH prior to oral phage administration
- inactivation of phages by both specific and non-specific factors in bodily fluids
- liberation of endotoxins as a consequence of widespread lysis of bacteria within the body (the Herxheimer reaction) – this can lead to toxic shock (which can also be caused by antibiotics)
- lack of availability or reliability of bacterial laboratories for carefully identifying the pathogens involved (necessitated by the relative specificity of phage therapy).

BACTERIOPHAGE PHYSIOLOGY

Viruses are like spaceships that are able to carry genetic material between susceptible cells and then reproduce

874

Figure 102-1 Phage diagram (bacteriophage T4).

in those cells, just as HIV specifically infects human T-lymphocytes which carry the CD-4 surface protein. In the case of bacteriophages, the targets are specific kinds of bacterial cells – they cannot infect the cells of more complex organisms. Each virus consists of a piece of genetic information, determining all of the properties of the virus, which is carried around packaged in a protein coat ([Fig. 102.1](#)). Most phages have tails, the tips of which have the ability to bind to specific molecules on the surface of their target bacteria ([Fig. 102.2](#)). The viral DNA is then ejected through the tail into the host cell, where it directs the production of progeny phages – often over 100 are

produced in just half an hour. Each strain of bacteria has characteristic protein, carbohydrate and lipopolysaccharide molecules present in large quantities on its surface. These molecules are involved in forming pores, motility, and binding of the bacteria to particular surfaces. Each such molecule can act as a receptor for particular phages. Development of resistance to a particular

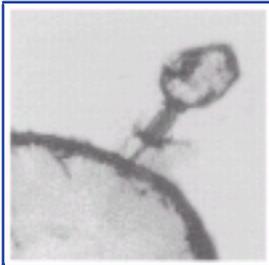

Figure 102-2 Electron micrograph of phage infecting a bacterium.

phage generally reflects mutational loss of its specific receptor; this loss often has negative effects on the bacterium and does not protect it against the many other phages which use different receptors.

Each kind of bacterium has its own phages, which can be isolated wherever that bacterium grows: from sewage, feces, soil, even ocean depths and hot springs. The process of isolation is easy. The sample is placed in an appropriate salt solution; the supernate is separated, and then passed through a filter with a pore size small enough to remove the bacteria. The solution is then mixed (at several different dilutions) with a culture of the bacteria in question. A few drops are spread on a block of appropriate nutrient-agar medium. The next day, a dense lawn of bacteria is seen, dotted with round cleared areas called “plaques”. Each plaque contains about a billion phages, all of them progeny of a single initial phage which multiplied at a high rate and destroyed the bacteria there in the process. An individual plaque is then transferred to a fresh culture of the bacteria in a liquid medium, allowing the culturing of a homogeneous stock of that particular phage, whose properties can then be studied.

Properties of phages

One major source of confusion in the early phage work was the perception that all phages were fundamentally similar, though subject to adaptive change depending on the recent conditions of growth. One consequence of this was that often new phages were isolated for each series of experiments, so there was little continuity or basis for comparison. Phages specific for virtually every known bacterial species have been isolated, but few have been well classified.

A second early source of confusion affecting therapeutic uses was the question of whether the lytic principle termed “bacteriophage” simply reflected an *inherent property* of the specific bacteria or required regular reinfection by an external agent. During the 1930s and 1940s, it became increasingly clear that in some senses both were true – that there were in fact two quite fundamentally different groups of bacteriophages. *Lytic* phages always have to infect from outside, reprogram the host cell and release a burst

of phage through breaking open, or lysing, the cell after a relatively fixed interval. *Lysogenic* phages, on the other hand, have another option. They can actually integrate their DNA into the host DNA, much as HIV can integrate the DNA copy of its RNA.

Key technical developments that helped to clarify the general nature and properties of bacteriophages included:

- the concentration and purification of some large phages by means of very high-speed centrifugation and the demonstration that they contained equal amounts of DNA and protein^[13]
-

875

- visualization of phages by means of the electron microscope (EM).^{[14] [15]}

Soon after, Ruska^[12] reported the first attempts to use the EM for phage systematics.^[16] This has since become a key tool of the field.^[12] Each phage was found to have its own specific shape and size, from the “lunar lander”-style complexity of T4 and its relatives to the globular heads with long or short tails of lambda and T7, to the small filamentous phages that looked much like bacterial pili (see [Fig. 102.3](#)).

Lytic phages

A much better understanding of the interactions between lytic phages and bacteria began with one-step growth curve experiments.^{[17] [18]} These demonstrated an eclipse period during which the DNA began replicating, and there were no free phages in the cell; a period of accumulation of intracellular phages; and a lysis process which released the phage to go in search of new hosts. This phage infection cycle is outlined in [Figure 102.4](#).

In 1943, an event happened which was to have a major impact on the orientation of phage research in the United States and much of western Europe, strongly shifting the emphasis from practical applications to basic science. Physicist-turned-phage biologist Max Delbrueck met with Alfred Hershey and Salvador Luria and formed the “Phage Group”, which eventually expanded largely through the influence of the summer “Phage Course” at Cold Spring Harbor, Long Island, in 1945. Their influence

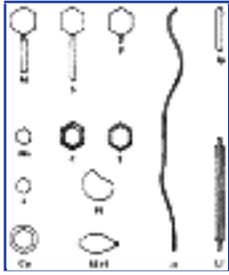

Figure 102-3 Various phages.

on the origins of molecular biology has been well documented.^{[19] [20]} A major element of the successes of phages as model systems for working out fundamental biological principles was that Delbrueck convinced most phage biologists in the United States to focus on one bacterial host (*E. coli* B) and seven of its lytic phages. These were arbitrarily chosen and named T(type)1–T7. As it turned out, T2, T4 and T6 were quite similar to each

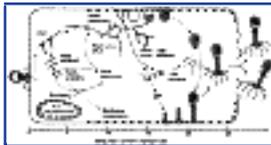

Figure 102-4 Bacteriophage intracellular growth cycle. Noteworthy features: nucleolytic action on host chromosome furnishes DNA precursors; replicating DNA is much longer than virion DNA; several phage-coded proteins become associated with the host membrane; maturation of phage head occurs at a membrane site.

other, defining a family now called the “T-even phages”. These phages were key in demonstrating that DNA is the genetic material, that viruses can encode enzymes, that gene expression is mediated through special copies in the form of “messenger RNA”, that the genetic code is triplet in nature, and many other fundamental concepts. The negative side of this strong focus on a few phages growing under rich laboratory conditions, however, was that there was very little study or awareness of the ranges, roles and properties of bacteriophages in the natural environment.

Lysogenic phages

The integration of lysogenic phage DNA into the host DNA leads to virtually permanent association as a *prophage* with a specific bacterium and all its progeny. The prophage directs the synthesis of a repressor, which blocks the reading of the rest of its own genes and also those of any closely related lysogenic phages – a major advantage for the bacterial cell, protecting it from infection by a significant class of phages and giving it a potential weapon against many competing bacteria. Occasionally, a prophage escapes from regulation by the repressor, cuts its DNA back out of the genome by a sort of site-specific recombination and goes ahead to make progeny phage and lyse open the cell. Sometimes the cutting-out process makes mistakes, and a few bacterial genes get carried along with the phage DNA to its new host; this process, called

transduction, plays a significant role in bacterial genetic exchange. Such lysogenic phages are bad candidates for phage therapy, due both to their mode of inducing resistance and to the fact that they can potentially lead to transfer of genes involved in bacterial pathogenicity; this is discussed in more detail below. However, their specificity often makes them very useful for phage typing in distinguishing between bacterial strains.

CLINICAL APPLICATION

Current research

The growing understanding of phage biology has the potential to facilitate more rational thinking about the therapeutic process and the selection of therapeutic phages. However, there was generally little interaction between those who were so effectively using phages as tools to understand molecular biology and those working on phage ecology and therapeutic applications. Many in the latter group were spurred on by a concern about the increasing incidence of nosocomial infections and of bacteria resistant against most or all known antibiotics. This is particularly true in Poland, France and the former Soviet Union where use of therapeutic phages never fully died out and where there has been some ongoing research and clinical experience. In France, Dr Jean-Francois Vieu led the therapeutic phage efforts until his retirement some 10 years ago. He worked in the *Service des Entiobactiries* of the Pasteur Institute in Paris and, for example, prepared *Pseudomonas* phages on a case-by-case basis for patients. The experience there is discussed in Vieu^[21] and Vieu et al.^[22] Phage therapy was used extensively in many parts of eastern Europe as a regular part of clinical practice, and there is now a company in Moscow making phage for this purpose. However, most of the research and much of the phage preparation came under the direction of key centers in Tbilisi, Georgia, and Wroclaw, Poland. These two groups are discussed below.

Institute of Immunology and Experimental Medicine, Polish Academy of Sciences

The most detailed publications documenting phage therapy have come from Stefan Slopek's group at the Institute of Immunology and Experimental Medicine, Polish Academy of Sciences, Wroclaw. They published a series of extensive papers describing work carried out from 1981 to 1986 with 550 patients.^[23] ^[24] ^[25] This set of studies involved 10 Polish medical centers, including the Wroclaw Medical Academy Institute of Surgery Cardiosurgery Clinic, Children's Surgery Clinic and Orthopedic Clinic, the Institute of Internal Diseases Nephrology Clinic, and Clinic of Pulmonary Diseases. The patients ranged in age from 1 week to 86 years. In 518 of the cases, phage use followed unsuccessful treatment with all available other antibiotics. The major categories of infections treated were:

- long-persisting suppurative fistulas
- septicemia
- abscesses
- respiratory tract suppurative infections and bronchopneumonia
- purulent peritonitis

- furunculosis.

In a final summary paper, the authors carefully analyzed the results with regard to such factors as nature and severity of the infection and monoinfection versus infection with multiple bacteria.^[25] Rates of success ranged from 75 to 100% (92% overall), as measured by marked improvement, wound healing, and disappearance of titratable bacteria; 84% demonstrated full elimination of the suppurative process and healing of local wounds. Infants and children did particularly well. Not surprisingly, the poorest results came with the elderly and those in the final stages of extended serious illnesses, two groups with weakened immune systems and generally poor resistance.

The bacteriophages all came from the extensive collection of the Bacteriophage Laboratory of the Institute of

Immunology and Experimental Therapy, Polish Academy of Sciences, Wroclaw. In the later studies, some of the specific phages were named. All were virulent, capable of completely lysing the bacteria being treated. In the first study alone, 259 different phages were tested (116 for *Staphylococcus*, 42 for *Klebsiella*, 11 for *Proteus*, 39 for *Escherichia*, 30 for *Shigella*, 20 for *Pseudomonas*, and one for *Salmonella*); 40% of them were selected to be used directly for therapy. All of the treatment was in a research mode, with the phage prepared at the institute by standard methods and tested for sterility. Treatment generally involved 10 ml of sterile phage lysate orally half an hour before each meal, with gastric juices neutralized by taking (basic) Vichy water, baking soda or gelatum. In addition, phage-soaked compresses were generally applied three times a day where dictated by localized infection. Treatment ran for 1.5–14 weeks, with an average of 5.3. For intestinal problems, short treatment sufficed, while long-term use was necessary for such problems as pneumonia with pleural fistula and pyogenic arthritis. Bacterial levels and phage sensitivity were continually monitored, and the phage(s) were changed if the bacteria lost their sensitivity. Therapy was generally continued for 2 weeks beyond the last positive test for the bacteria.

Few side-effects were observed; those that were seen seemed to be directly associated with the therapeutic process. On about days 3–5, pain in the liver area was often reported, lasting several hours. The authors suggested that this might be related to the extensive liberation of endotoxins as the phage is destroying the bacteria most effectively. In severe cases with sepsis, patients often ran a fever for 24 hours on about days 7–8.^[23]

Various methods of administration were successfully used, including oral, aerosols and infusion rectally or in surgical wounds. Intravenous administration was not recommended for fear of possible toxic shock from bacterial debris in the lysates.^[23] However, it was clear that the phages readily entered the body from the digestive tract and multiplied internally wherever appropriate bacteria were present, as measured by their presence in blood and urine as well as by therapeutic effects.^[26] This interesting

and rather unexpected finding has been replicated in many studies and systems.^[27] ^[28]
^[29] ^[30]

Detailed notes were kept throughout on each patient. The final evaluating therapist also filled out a special inquiry form that was sent to the Polish Academy of Science research team along with the notes. The Computer Center at Wroclaw Technical University carried out extensive analyses of the data. They used the categories established in the WHO (1977) International Classification of Diseases in assessing results. They also looked at the effects of age, severity of initial condition, type(s) of bacteria involved, length of treatment and other concomitant treatments. The papers included many specific details on individual patients which helped to give some insight into the ways phage therapy was used, as well as an in-depth analysis of difficult cases.

Bacteriophage Institute, Tbilisi

The most extensive and least widely known work on phage therapy was carried out under the auspices of the Bacteriophage Institute at Tbilisi, in the former Soviet republic of Georgia. According to various physicians there, phage therapy is part of the general standard of care, used especially extensively in pediatric, burn and surgical hospital settings. Phage preparation was carried out on an industrial scale, employing 700 people just before the break-up of the Soviet Union, and many tons of a variety of products were shipped throughout the former Soviet Union. They were available both over the counter and through physicians. The largest use was in hospitals, to treat both primary and nosocomial infections, alone or in conjunction with other antibiotics and particularly when antibiotic-resistant organisms were found. The military is still one of the strongest supporters of phage therapy research and development because they have proven so useful for wound and burn infections as well as for preventing debilitating gastrointestinal epidemics among the troops.

From the institute's inception, the industrial part was run on a self-supporting basis, while its scientific branch was government-supported. The latter included the electron microscope facility, permanent strain collection, laboratories studying phages of the enterobacteria, staphylococci and pseudomonads and formulating new phage cocktails, and groups involved in immunology, vaccine production, *Lactobacillus* work and other therapeutic approaches. It also carried out the very extensive studies needed for approval by the Ministry of Health in Moscow of each new strain, therapeutic cocktail and means of delivery. This careful study of the host range, lytic spectrum and cross-resistance properties of the phages being used was a major factor in the reported successes of the phage therapy work carried out through the institute. All of the phages used for therapy are lytic, avoiding the problems engendered by lysogeny. The problems of bacterial resistance were largely solved by the use of well-chosen mixtures of phages with different receptor specificities against each type of bacterium as well as of phages against the various bacteria likely to be causing the problem in multiple infections. The situation was further improved whenever the clinicians typed the pathogenic bacteria and monitored their phage sensitivity. Where necessary, new cocktails were then prepared to which the given bacteria were sensitive. Not infrequently, using a phage in conjunction with other antibiotics was shown to give better

results than either the phage or the antibiotic alone.

The depth and extent of the work involved are very

impressive. For example, in 1983–85 alone, the institute's Laboratory of Morphology and Biology of Bacteriophages carried out studies of growth, biochemical features and phage sensitivity on 2,038 strains of *Staphylococcus*, 1,128 of *Streptococcus*, 328 of *Proteus*, 373 of *P. aeruginosa*, and 622 of *Clostridium* received from clinics and hospitals in towns across the former Soviet Union. New broader-acting phage strains were isolated using these and other institute cultures and were included in a reformulation of their extensively used Piophage preparation; it now inhibited 71% of their *Staphylococcus* strains instead of 58%; 76% of *Pseudomonas* instead of 55%; 51% of *E. coli* instead of 11%; 30% of *Proteus* instead of 3%; 60% of *Streptococcus* instead of 38%; and 80% of *Enterococcus* instead of 3%.^[31] In the years since, the formulation has continued to be improved based on further studies, and phages against *Klebsiella* and *Acinetobacter* have been isolated and developed into therapeutic preparations. One of the latest developments is their *IntestiPhage* preparation, which includes 23 different phages active against a range of enteric bacteria.

A good deal of work has gone into developing and providing the documentation for Ministry of Health approval of specialized new delivery systems, such as a spray for use in respiratory tract infections, in treating the incision area before surgery, and in sanitation of hospital problem areas such as operating rooms. An enteric-coated pill was also developed, using phage strains that could survive the drying process, and accounted for the bulk of the shipments to other parts of the former Soviet Union.

Much of the focus in the last 12 years has been on combating nosocomial infections, where multi-drug-resistant organisms have become a particularly lethal problem and where it is also easier to carry out proper long-term research. Clinical studies of the effectiveness of the phage treatment and appropriate protocols were carried out in collaboration with a number of hospitals, but little has been published in accessible form. Zemphira Alavidze and her colleagues, who are currently doing most of the actual therapeutic development and clinical application, have manuscripts in preparation which describe their work in institutions such as the Leningrad (St Petersburg) Intensive Burn Therapy Center, the Academy of Military Medicine in Leningrad, the Karan Trauma Center, and the Kemerovo Maternity Hospital. Some of the most intensive studies were carried out in Tbilisi at the Pediatric Hospital, the Burn Center, the Center for Sepsis and the Institute for Surgery. Special mixtures were developed for dealing with strains causing nosocomial infections in various hospitals, and they were very effectively used in sanitizing operating rooms and equipment, water taps and other sources of spread of the infections (most of them involving predominantly *Staphylococcus*). The number of sites testing positive for the problem bacteria decreased by orders of magnitude over the several months of the trial at each site.

Recent work in the West

Levin & Bull,^[1] and Barrow & Soothill^[4] have provided good reviews of much of the animal research carried out in Britain and the United States since interest in the possibilities of phage therapy began to resurface in the early 1980s. The results, in general, are in very good agreement with the clinical work described above in terms of efficacy, safety and importance of appropriate attention to the biology of the host–phage interactions, reinforcing trust in the reported extensive eastern European results.

In Britain, Smith & Huggins^[27] ^[28] carried out a series of excellent, well-controlled studies on the use of phages in systemic *E. coli* infections in mice and then in diarrhetic disease in young calves and pigs. For example, they found that injecting 10^[6] colony-forming units of a particular pathogenic strain intramuscularly killed 10 out of 10 mice, but none died if they simultaneously injected 10^[4] plaque-forming units of a phage selected against the K1 capsule antigen of that bacterial strain. This phage treatment was more effective than using such antibiotics as tetracycline, streptomycin, ampicillin or trimethoprim/ sulfafurazole. Furthermore, the resistant bacteria that emerged had lost their capsule and were far less virulent. In calves, they found very high and specific levels of protection. They had to isolate different phages for each of their pathogenic bacterial strains, since they did not succeed in isolating phages specific for more general pathogenicity-related surface receptors such as the K88 or K99 adhesive fimbriae, which play key roles in attachment to the small intestine. Still, the phage was able to reduce the number of bacteria bound there by many orders of magnitude and to virtually stop the fluid loss. The results were particularly effective if the phage was present before or at the time of bacterial presentation, and if multiple phages with different attachment specificities were used. Furthermore, the phage could be transferred from animal to animal, supporting the possibility of prophylactic use in a herd. If the phage was given only after the development of diarrhea, the severity of the infection was still substantially reduced, and none of the animals died.^[30]

Levin & Bull^[1] carried out a detailed analysis of the population dynamics and tissue phage distribution of the 1982 Smith & Huggins^[27] study, which can be helpful in assessing the parameters involved in successful phage therapy and its apparent superiority to antibiotics. They have gone on to do interesting animal studies of their own and conclude that phage therapy is at least well worth further study.^[1]

Barrow & Soothill^[4] carried out a series of studies preparatory to using phages for infections of burns patients.

Using guinea pigs, they showed that skin graft rejection could be prevented by prior treatment with phages against *Pseudomonas aeruginosa*. They also saw excellent protection of mice against systemic infections with both *Pseudomonas* and *Acinetobacter* when appropriate phages were used.^[4] In the latter case, as few as 100

phages protected against infection with 10^{10} bacteria – several times the LD_{50} !

Merrill et al^[32] have carried out a series of experiments designed to better understand the interactions of phages with the human immune system, and have started a company called Exponential Therapeutics to explore the possibilities of phage therapy. Their published work has been with a lytic derivative of the lysogenic phage lambda – a poor choice for therapeutic use, as discussed above and below – but they have gathered some very interesting data about factors affecting interactions between phages and the immune system.

Bacterial pathogenicity

Most bacteria are not pathogenic; in fact, they play crucial roles in the ecological balance in the digestive system, mucous membranes and all body surfaces. They often actually help to protect against pathogens. This is one reason why broad-spectrum antibiotics have such a broad range of side-effects and why more narrowly targeted bacteriocidal agents would be highly advantageous. Interestingly, most of the serious pathogens are close relatives of non-pathogenic strains.

Studies clarifying the mechanisms of pathogenesis at the molecular level have progressed remarkably in recent years, crowned by the determination of the complete sequence of (non-pathogenic) *E. coli* K12 and several other bacterial species, and extensive cloning and sequencing of pathogenicity determinants. Generally, a number of genes are involved, and these are clustered in so-called “pathogenicity islands”, or Pais, which may be 50,000– 200,000 base pairs long. They generally have some unique properties indicating that the bacterium itself probably acquired them as a sort of “infectious disease” at some time in the past, and then kept them because they helped the bacterium to infect new ecological niches where there was less competition. Many of these Pais are carried on small extrachromosomal circles of DNA called *plasmids*, which can also be carriers of drug-resistance genes. Others reside in the chromosome where they are often found embedded in defective lysogenic prophages which have lost some key genes in the process and cannot be induced to form phage particles. However, they can sometimes recombine with related infecting phages. Therefore, it makes sense to avoid using lysogenic phages or their lytic derivatives for phage therapy to avoid any chance of picking up and moving such pathogenicity islands.

For bacteria in the human gut, pathogenicity involves two main factors:

- the production of toxin molecules, such as shiga toxin (from *Shigella* and some pathogenic *E. coli*) or cholera toxin; these toxins modify proteins in the target host cells and thereby cause the problem
- the acquisition of cell-surface adhesions which allow the bacterium to bind to specific receptor sites in the small intestine, rather than just moving on through to the colon.

They also all contain the components of so-called type III secretion machinery, related to those involved in the assembly of flagella (for motility) and of filamentous phages, and

instrumental in many plant pathogens. For all of the pathogenic enteric bacteria, the infection process triggers changes in the neighboring intestinal cells. These include degeneration of the microvilli, formation of individual “pedestals” cupping each bacterium above the cell surface, and, in the case of *Salmonella* and *Shigella*, induction of cell-signalling molecules that trigger engulfment of the bacterium and its subsequent growth inside the cell.

Recently, *E. coli* O157 has been the subject of much concern, with contamination of such products as hamburgers and unpasteurized fruit juices leading to serious problems. Particularly in young children and the elderly, deaths have occurred from hemorrhagic colitis (bloody diarrhea) and from hemolytic-uremic syndrome, where the kidneys are affected. Antibiotic therapy has shown no benefit.^[33] Our laboratory has found that the Jack-in-the-box version of O157, at least, is susceptible to several of our phages, and we plan to explore their potential use further, both as prophylactics and as therapeutic agents during outbreaks.^[34]

T-even phages

A substantial fraction of the phages in the therapeutic mixes are relatives of bacteriophage T4, which has played such a key role in the development of molecular biology. This family is generally called the T-even phages, an historical accident reflecting the fact that T2, T4 and T6 from the original collection of Delbrueck's Phage Group all turned out to be related. Large sets of T-even phages have been isolated for study from all over the world: Long Island sewage treatment plants, animals in the Denver zoo, and dysentery patients in eastern Europe (the latter using *Shigella* as host). Members of the family are found infecting all of the enteric bacteria and their relatives.^[35] Most of the T-even phages use 5-hydroxymethylcytosine instead of cytosine in their DNA, which protects them against most of the restriction enzymes that bacteria make to protect themselves against invaders and gives them a much more effective host range. T4's entire DNA sequence is known, and we know a great deal about its

infection process in standard laboratory conditions and about the methods it uses to target bacteria so effectively.^[36]^[37] We can potentially use this knowledge to develop more targeted approaches to phage therapy, particularly as more is learned about the similarities and differences in its extended family.^[38]^[39] We know that different members of the T-even family use different outer membrane proteins and oligosaccharides as their receptors, and we understand the tail-fiber structures involved well enough to potentially predict which phages will work on given bacteria and to engineer phages with new specificities.^[40]^[41]

The T-even bacteriophages share a unique ability which contributes significantly to their widespread occurrence in nature and to their competitive advantage. There have still been far too few studies of T4 ecology and its behavior under conditions more closely approaching the natural environment and the circumstances it will encounter in phage

therapy – often anaerobic and/or with frequent periods of starvation. The limited available information in that regard was summarized by Kutter et al.^[36] ^[37] A variety of studies are shedding light on the ability of these highly virulent phages to coexist in balance with their hosts in nature. For example, they can reproduce in the absence of oxygen as long as their bacterial host has been growing anaerobically for several generations. They are also able to control the timing of lysis in response to the relative availability of bacterial hosts in their environment. When *E. coli* are singly infected with T4, they lyse after 25–30 minutes at body temperature in rich media, releasing about 100–200 phages/cell. However, when additional T-even phages attack the cell more than 4 minutes after the initial infection, the cell does not lyse at the normal time. Instead, it continues to make phages for as long as 6 hours.^[42] ^[43] We have found that they can also survive for a period of time in a hibernation-like state inside starved cells, allowing their host to readapt when nutrients are again supplied, and produce a few additional phages. This is particularly interesting and important since bacteria undergo many drastic changes to survive periods of starvation which increase their resistance to a variety of environmental insults.^[44]

Thus, for many reasons, the T-even phages make excellent candidates for therapeutic use in enteric and other Gram-negative bacteria, and studies of their ecology and distribution are being carried out with these goals in mind both in Tbilisi and at Evergreen State College.

Advantages of phages

Phages have many potential advantages:

- They are self-replicating but also self-limiting because they will multiply only as long as sensitive bacteria are present.
- They can be targeted far more specifically than most antibiotics to the problem bacteria, causing much less damage to the normal microbial balance in the gut. The bacterial imbalance or “dysbiosis” caused by many antibiotic treatments can lead to serious secondary infections involving relatively resistant bacteria, often extending hospitalization time, expense and mortality (see [Chs 7](#) and [9](#)). Particular resultant problems include *Pseudomonads*, which are especially difficult to treat, and *Clostridium difficile*, the cause of serious diarrhea and membranous colitis.^[45]
- Phages can often be targeted to receptors on the bacterial surface which are involved in pathogenesis, so any resistant mutants are attenuated in virulence.
- Few side-effects have been reported for phage therapy.
- Phage therapy would be particularly useful for people with allergies to antibiotics.
- Appropriately selected phages can easily be used prophylactically to help prevent bacterial disease at times of exposure or to sanitize hospitals and to help protect against hospital-acquired (nosocomial) infections.
- Especially for external applications, phages can be prepared fairly inexpensively and locally, facilitating their potential applications to underserved populations.
- Phages can be used either independently or in conjunction with other antibiotics to help reduce the development of bacterial resistance.

CONCLUSION

Clearly the time has come to look more carefully at the potential of phage therapy, both by strongly supporting new research and by looking carefully at the research already available.^[46] As Barrow & Soothill^[4] conclude:

Phage therapy can be very effective in certain conditions and has some unique advantages over antibiotics. With the increasing incidence of antibiotic-resistant bacteria and a deficit in the development of new classes of antibiotics to counteract them, there is a need to investigate the use of phage in a range of infections.

Phages are quite specific as to the bacteria they attack, and the stipulations of Ackermann & DuBow^[12] are important here. The specificity of phages means that:

Phages have to be tested [against the bacteria] just as antibiotics, and the indications have to be right, but this holds everywhere in medicine. However, phage therapy requires the creation of phage banks and a close collaboration between the clinician and the laboratory. Phages have at least one advantage. ... While the concentration of antibiotics decreases from the moment of application, phage numbers should increase. Another advantage is that phages are able to spread and thus prevent disease. Nonetheless, much research remains to be done ... on the stability of therapeutic preparations; clearance of phages from blood and tissues; their multiplication in the human body; inactivation by antibodies, serum or pus; and the release of bacterial endotoxins by lysis. ... In addition, therapeutic phages should be characterized at least by electron microscopy.

While it seems premature to broadly introduce injectable phage preparations in the West without further extensive research, their carefully implemented use in gut and external applications and for a variety of agricultural purposes could potentially help to reduce the emergence of antibiotic-resistant strains. Furthermore, compassionate use of appropriate phages seems warranted in cases where bacteria resistant against all available antibiotics are causing life-threatening illness. They are especially useful in dealing with recalcitrant nosocomial infections, where large numbers of particularly vulnerable people are being exposed to the same strains of bacteria in a closed hospital setting. In this case, the environment as well as the patients can be effectively treated.

Chapter 103 - Phosphatidylserine

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

INTRODUCTION

Phosphatidylserine is the major phospholipid in the brain, where it plays a major role in determining the integrity and fluidity of cell membranes. Normally the brain can manufacture sufficient levels of phosphatidylserine, but if there is a deficiency of methyl donors like S-adenosylmethionine (SAM), folic acid, and vitamin B₁₂, or essential fatty acids, the brain may not be able to make sufficient phosphatidylserine. Low levels of phosphatidylserine in the brain are associated with impaired mental function and depression in the elderly.

PHYSIOLOGICAL FUNCTIONS

Phosphatidylserine is responsible for many functions essential to the structural matrix and function of cell membranes. With the help of phosphatidylserine and other phospholipid components, the cell membranes control:

- the cellular exchange of nutrients and waste products
- movement of electrolytes into and out of cells
- reception of molecular messages from outside the cell
- transformation of messages into enzymatic responses
- cell movement and shape
- cell-to-cell recognition and communication.

Although phosphatidylserine is found in every cell type in the body, it plays an especially vital role in nerve tissue. It is critical in membrane-to-membrane fusion – a key process in neurotransmitter release – as well as activating cell surface receptors and supporting the transmission of chemical signals.

PHARMACOLOGY

The pharmacology of phosphatidylserine appears to be a result of restoring proper levels of phosphatidylserine in cell membranes. As a result, cellular function improves.

884

This improvement is most notable in brain tissue. Phosphatidylserine supplementation in animal studies has been shown to significantly improve acetylcholine release, memory, and age-related brain changes.^{[1] [2] [3]} Presumably these effects are responsible for the positive effects noted in human clinical trials.

Absorption studies in animals indicate that phosphatidylserine is well absorbed orally. Absorption of phosphatidylserine is very similar to the absorption of phosphatidylcholine, the major component of soy lecithin. Like phosphatidylcholine, with absorption into the intestinal cell the lipid component at position 2 is cleaved from the glycerol backbone. This lysoform of phosphatidylserine is then re-esterified by the enterocyte and transported to various tissues where (presumably) it is reacylated with a specific fatty acid depending upon where it is being delivered. For example, in the brain most of the phosphatidylserine incorporates oleic acid (C18:1n9) or docosahexanoic acid (C22:6n3, DHA) while in the testes C:14:0 and arachidonic acid (C20:4n6) are the major forms.

Originally, phosphatidylserine was isolated from bovine brain, but with the concern for bovine spongiform encephalopathy (mad cow disease) an alternative preparation derived from soy was developed. Commercially available phosphatidylserine is now a semi-synthetic product manufactured from soy lecithin. In the United States phosphatidylserine is available in a complex containing the following:

- phosphatidylserine – 100 mg
- phosphatidylcholine – 45 mg
- phosphatidylethanolamine – 25 mg
- phosphatidylinositol – 5 mg.

The effectiveness of the soy-derived phosphatidylserine has yet to be proven as all of the published clinical studies to date have utilized bovine phosphatidylserine. The difference between the two is that the bovine source has predominantly DHA at the 2 position while the soy preparation has primarily linoleic acid (C18:2n6). Given DHA's critical role in brain metabolism, until soy phosphatidylserine is shown to produce results equal to that achieved with bovine phosphatidylserine, co-supplementation with DHA should be encouraged when using phosphatidylserine from soy sources.

CLINICAL APPLICATIONS

The primary use of phosphatidylserine is in the treatment of depression and/or impaired

mental function in the elderly including Alzheimer's disease. To date there have been 11 double-blind studies completed with phosphatidylserine in the treatment of age-related cognitive decline, Alzheimer's disease or depression. Good results have been obtained with these studies.^{[4] [5] [6] [7] [8] [9]} In the largest study, a total of 494 elderly patients (aged between 65 and 93 years) with moderate to severe senility were given either phosphatidylserine (100 mg three times daily) or a placebo for 6 months.^[4] The patients were assessed for mental performance, behavior, and mood at the beginning and the end of the study. Statistically significant ($P < 0.01$) improvements in mental function, mood, and behavior were noted in the phosphatidylserine-treated group.

Phosphatidylserine appears to positively affect mood in depressed elderly subjects.^{[10] [11] [12] [13] [14]} This effect could also explain some of phosphatidylserine's positive effects on memory and cognition. The link between depression and impaired mental function is well-established in the geriatric population. In one small double-blind study of 10 depressed elderly patients, phosphatidylserine was shown to improve depressive symptoms, memory and behavior.^[15] Unlike typical antidepressant drugs, phosphatidylserine promoted this improvement without influencing the levels of serotonin and other monoamine neurotransmitters, suggesting another mechanism of action. Improved brain cell membrane fluidity may be one explanation. Another is the fact that phosphatidylserine has been shown to reduce cortisol secretion in response to stress.^{[16] [17] [18]} Typically, cortisol levels will be elevated in depressed patients.

DOSAGE

The standard dosage recommendation for phosphatidylserine is 100 mg three times daily.

TOXICOLOGY

No side-effects or adverse interactions have been reported. Animal studies have shown that phosphatidylserine from bovine sources given orally is extremely well tolerated. Dogs tolerated up to 70 g/day for 1 year without any apparent side-effect. In over 35 clinical studies involving more than 800 subjects, phosphatidylserine has been shown to be without side-effect at standard dosage (100 mg three times daily). Rarely, stomach upset has been reported and a large dose (e.g. 600 mg) taken prior to retiring may produce sleeplessness.

Chapter 104 - *Piper myhisticum* (kava)

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

Piper methysticum (family: Piperaceae)
Common name: kava

GENERAL DESCRIPTION

Kava is a hardy, slow-growing perennial that generally resembles other members of the pepper family. It is an attractive shrub and can attain heights of more than 9 feet. The plant does not have many leaves, but those it does have are thin, single, heart-shaped, alternate, petiolate, 4–10 inches long, and sometimes wider than they are long. Although *Piper methysticum* does flower, it is incapable of self-reproduction; its propagation is vegetative and now solely due to human effort.^{[1] [2]}

For medicinal purposes, it is the rootstock that is used. The rootstock is knotty, thick, and sometimes tuberous with holes or cracks created by partial destruction of the parenchyma. In other words, the rootstock is often somewhat pithy. From the main rootstock, there are extensions of lateral roots up to 9 feet long.^{[1] [2]}

CHEMICAL COMPOSITION

Analysis of the composition of the dried kava rootstock indicates that it contains approximately 43% starch, 12% water, 3.2% simple sugars, 3.6% proteins, 3.2% minerals (primarily potassium), and 15% kavalactones (see [Table 104.1](#)).^{[1] [2]}

Based on detailed analysis of the active ingredients of kava, a laborious process over the past 110 years, many experts now believe that the pharmacological activities of kava are due mostly, if not entirely, to the presence of compounds known as kavalactones (also referred to as kava alpha-pyrone). These compounds are found in the fat-soluble resin of the root. Although the kavalactones are the primary active

components, other components appear to contribute to the sedative and anxiolytic activities of kava, as one study found the sedative activity of a crude preparation to be more effective than the

TABLE 104-1 -- Kavalactones

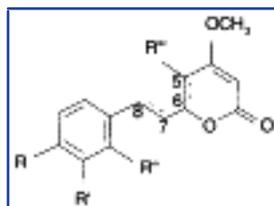

Figure 104-1 Kavalactones.

isolated kavalactones ([Fig. 104.1](#)).^[3] The kavalactone content of the root can vary between 3 and 20%.

HISTORY AND FOLK USE

Oceania, i.e. the Pacific island communities of Micronesia, Melanesia, and Polynesia, is one of the few geographic areas of the world that did not have alcoholic beverages before European contact in the 18th century. However, these islanders did possess a “magical” drink used in ceremonies and celebrations because of its calming effect and ability to promote sociability. The drink, also called kava, is still used today in this region of the world, where the people are often referred to as the happiest and friendliest in the world.

The origins of kava usage are not known as it predates written history in Oceania.^[1] ^[2] It was first described for the Western world by captain James Cook in the account of his voyage to the South Seas in 1768.

Many myths and legends surround the early use of kava. The plant itself probably originated in the New Guinea/Indonesia area and was spread from island to island by early Polynesian explorers in canoes, along with other plants. Each culture has its own story on the origins of kava. For example, in Samoa a story is told about the origins of kava and sugar cane. The story goes that a Samoan girl went to Fiji where she married a great chief. After some time, she returned to Samoa, but before doing so, she noticed two plants growing on a hill. She saw a rat chewing on one of the plants and noticed that the rat seemed to go to sleep. She concluded that the plant was a comforting food. She decided she would take this plant, sugar cane, back to Samoa, but then she noticed that the rat awoke and began to chew the root of another plant – kava. The animal which had been weak and shy became bold, strong, and more energetic. She decided that she would take both plants back with her to plant in Samoa. The plants grew very well in Samoa and soon a chief from a neighboring island exchanged two laying hens for roots of the two plants. Hence, the Samoans take credit for the spread of both the sugar cane and kava.

In Tonga, a legend is told about a great chief named Loau who lived on the island of Euaiki. He went to visit his servant Feva’ anga, who wanted to give a feast in honor of the chief, but it was a time of great famine. In desperation, he and his wife killed and cooked their only daughter to be served to the chief. However, Loau recognized the human flesh in the food when it was served and would not eat it. He instructed Feva’ anga to plant the food in the ground and to bring him the plant that would spring forth. On receiving the mature plant, Loau instructed that a drink be prepared from it and consumed with due ceremony.

The kava ceremony

Regardless of exactly how kava originated, it has been used in ceremonies by the Oceanic people for thousands of years. There are three basic kava ceremonies: the full ceremonial as enacted on every formal occasion; the one performed at the meeting of village elders, chiefs, and nobles and for visiting chiefs and dignitaries; and the less

formal kava circle common on social occasions.^[1] ^[2]

The first step of any kava ceremony was the preparation

889

of the beverage. A description of the classic process was written in 1777 by Georg Forster, a young naturalist on James Cook's second Pacific voyage:

[Kava] is made in the most disgusting manner that can be imagined, from the juice contained in the roots of a species of pepper-tree. This root is cut small, and the pieces chewed by several people, who spit the macerated mass into a bowl, where some water (milk) of coconuts is poured upon it. They then strain it through a quantity of fibres of coconuts, squeezing the chips, till all their juices mix with the coconut-milk; and the whole liquor is decanted into another bowl. They swallow this nauseous stuff as fast as possible; and some old toppers value themselves on being able to empty a great number of bowls.

As this traditional method of preparation became frowned upon or made illegal by colonial governments and missionaries, more "sanitary" methods of preparation, involving grinding or grating, took its place in many parts of Oceania.

The full kava ceremony, reserved for very highly honored guests, involves leading all of the guests to a platform. The ceremony begins with the arrival of a group of young men dressed in ceremonial attire and carrying a bowl of the kava drink and necessary utensils. The bowl is placed between the kava preparers and the visitors. The kava is placed in a cup by a specially selected individual who then turns and faces the visitor and delivers the beverage to the chief guest. The guest is instructed to hold the cup with both hands and drink from it. If the whole cup is drained without stopping, everyone says "a maca" (pronounced "a matha," meaning "it is empty") and claps three times with cupped hands. The cup bearer then returns to the kava bowl and proceeds to serve the person next in rank or importance.

Important people who visit Fiji and other islands of Oceania still participate in the kava ceremonies. For example, during a 1992 presidential campaign visit to Hawaii, Hillary Clinton participated in a kava ceremony conducted by the Samoan community on O'ahu.

The effects of drinking kava

Kava drinkers relate a pleasant sense of tranquillity and sociability upon consumption. Subjective reports given by scientists who have sampled kava themselves are relatively abundant. One of the first scientific studies of kava was performed by the noted

pharmacologist Louis Lewin in 1886. A later description written in 1927 is as follows:^[1]

When the mixture is not too strong, the subject attains a state of happy unconcern, well-being and contentment, free of physical or psychological excitement. At the beginning, conversation comes in a gentle, easy flow and hearing and sight are honed, becoming able to perceive subtle shades of sound and vision. Kava soothes temperaments. The drinker never becomes angry, unpleasant, quarrelsome or noisy, as happens with alcohol. Both natives and whites consider kava as a means of easing moral discomfort. The drinker remains master of his consciousness and his reason. When consumption is excessive, however, the limbs become tired, the muscles seem no longer to respond to the orders and control of the mind, walking becomes slow and unsteady and the drinker looks partially inebriated. He feels the need to lie down.... He is overcome by somnolence and finally drifts off to sleep.

A more recent description is provided by researcher R. J. Gregory, who writes from his own experience:

Kava seizes one's mind. This is not a literal seizure, but something does change in the processes by which information enters, is retrieved, or leads to actions as a result. Thinking is certainly affected by the kava experience, but not in the same ways as are found from caffeine, nicotine, alcohol, or marijuana. I would personally characterize the changes I experienced as going from linear processing of information to a greater sense of "being" and contentment with being. Memory seemed to be enhanced, whereas restriction of data inputs was strongly desired, especially with regard to disturbances of light, movements, noise and so on. Peace and quiet were very important to maintain the inner sense of serenity. My senses seemed to be unusually sharpened, so that even whispers seemed to be loud while loud noises were extremely unpleasant.

Drinking about half a coconut shell (100–150 mL) of certain varieties of kava is enough to put most people into a deep, dreamless sleep within 30 minutes. Unlike alcohol and other sedatives, kava does not produce any morning hangover. The kava drinker awakens having fully recovered normal physical and mental capacities.

PHARMACOLOGY

Many of the first comprehensive studies on the activities of kavalactones were conducted by a team of scientists from the Freiburg University Institute of Pharmacology in Germany, led by Hans J. Meyer, during the 1950s and 1960s.^[3] This research determined that kavalactones exhibit sedative, analgesic, anticonvulsant, and muscle-relaxant effects in laboratory animals. These studies seemed to confirm earlier empirical and subjective observations. More recent studies have utilized better-defined kava extracts.

Isolated kavalactones compared with crude extracts

Some evidence suggests that the whole complex of kavalactones and other compounds naturally found in kava produce greater pharmacological activity. In addition, studies have shown that kavalactones are more rapidly absorbed when given orally as an extract of the root rather than as the isolated kavalactones. The bioavailability of lactones, as measured by peak plasma concentrations, is up to three to five times higher from the extract than when given as isolated substances.^[3] Further evidence that kava root extracts are superior

890

to isolated kavalactones is offered by an animal study showing that while isolated kavalactones are well absorbed by brain, crude kava preparations produce brain concentrations of lactones two to 20 times higher.^[4] This evidence suggests that crude extracts standardized for kavalactone content may offer the greatest therapeutic benefit.

Several clinical trials have featured a kava extract standardized to contain 70% kavalactones. However, this high percentage of kavalactones may be sacrificing some of the other constituents that may contribute to the pharmacology of kava. More important than the actual percentage of kavalactones is the total dosage of the kavalactones and the assurance that the full range of kavalactones and other important constituents are present.

Standardized preparations of kava are now gaining greater popularity in Europe and the United States as mild sedatives and anxiolytics.

Sedative effects

Recent studies have confirmed and/or elaborated on the sedative effects of kava. Most notable are studies demonstrating that kavalactones exert many of their effects through non-traditional mechanisms. For example, most sedative drugs including the benzodiazepines (e.g. Valium, Halcion, Tranxene, etc.) work by binding to specific receptors (benzodiazepine or GABA receptors) in the brain which then leads to the neurochemical changes (potentiation of GABA effects) which promote sedation. Studies in animals have shown that the kavalactones do not bind to benzodiazepine or GABA receptors.^[5] Instead, the kavalactones are thought to somehow modify receptor domains rather than interacting specifically with receptor binding sites. In addition, other studies have indicated that the kavalactones appear to act primarily on the limbic system, the ancient part of the brain which affects all other brain activities and is the principle seat of the emotions.^[6] It is thought that kava may also promote sleep by altering the way in which the limbic system modulates emotional processes. It appears that many of the laboratory models of identifying how a substance works to promote a calming effect are simply not sophisticated enough to evaluate the physiological effects of kava.

Analgesic effects

In another example of the unusual pharmacological qualities of kava, a study designed to evaluate its pain-relieving effects could not demonstrate any binding to opiate receptors.^[7] The significance of this finding is that the study used experimental models where non-opiate analgesics like aspirin and other non-steroidal anti-inflammatory drugs are ineffective. In addition, it was determined that the sedative or muscle-relaxing effects were not responsible for the pain-relieving effects. These findings indicate that kava reduces pain in a manner unlike morphine, aspirin, or any other pain reliever.

Anxiolytic effects

An interesting effect of kava compared with other anxiolytics is that unlike the drugs, kava does not lose effectiveness with time. Kavalactones, even when administered in large dosages, demonstrated no loss of effectiveness in animal studies.^[8] Again, this is another example of the unusual qualities of kava.

Anti-ischemia effects

Another pharmacological activity of kava of importance is its ability to protect against brain damage due to ischemia.^[9] This effect has been demonstrated in two animal models of focal cerebral ischemia. The effectiveness of the kavalactones was due to its ability to limit the infarct area as well as provide a mild anticonvulsant effect. Kava extract may prove useful in the recovery from a stroke.

CLINICAL APPLICATIONS

Several European countries have approved kava preparations in the treatment of nervous anxiety, insomnia, and restlessness on the basis of detailed pharmacological data and favorable clinical studies.

Anxiety

Early clinical trials used D,L-kavain, a purified kavalactone, at a dose of 400 mg/day. For example, in one double-blind placebo-controlled study of 84 patients with anxiety symptoms, kavain was shown to improve vigilance, memory, and reaction time.^[10] In another double-blind study, kavain was compared to oxazepam (a drug similar to diazepam or Valium) in 38 patients.^[11] Both substances caused progressive improvements in two different anxiety scores (Anxiety Status Inventory and the Self-rating Anxiety Scale) over a 4 week period. However, while oxazepam and similar drugs are addictive and cause side-effects, kavain appeared to be free of these complications.

In perhaps the most significant study, a 70% kavalactone extract was shown to exhibit significant therapeutic benefit in patients suffering from anxiety.^[12] The study was

double-blind; 29 patients were assigned to receive 100 mg of the kava extract three times daily, while another 29 patients received a placebo. Therapeutic effectiveness was assessed using several standard

psychological assessments including the Hamilton Anxiety Scale. The result of this 4 week study indicated that individuals taking the kava extract had a statistically significant reduction in symptoms of anxiety including feelings of nervousness and somatic complaints such as heart palpitations, chest pains, headache, dizziness, and feelings of gastric irritation. No side-effects were reported with the kava extract.

In another double-blind study, two groups of 20 women with menopause-related symptoms were treated for a period of 8 weeks with the 70% kavalactone extract (100 mg three times daily) or placebo.^[13] The measured variable was once again the Hamilton Anxiety Scale. The group receiving the kava extract demonstrated significant improvement at the end of the very first week of treatment. Scores continued to improve over the course of the 8 week study. In addition to improvement in symptoms of stress and anxiety, a number of other symptoms also improved. Most notably there was an overall improvement in subjective well-being, mood, and general symptoms of menopause, including hot flashes. Again, no side-effects were noted.

Two additional studies have shown that unlike benzodiazepines, alcohol, and other drugs, kava extract is not associated with depressed mental function or impairment in driving or the operation of heavy equipment.^{[14] [15]} In one of these studies, 12 healthy volunteers were tested in a double-blind cross-over manner to assess the effects of oxazepam (placebo on days 1–3, 15 mg on the day before testing, 75 mg on the morning of the experiment), the extract of kava standardized at 70% kavalactones (200 mg three times daily for 5 days), and a placebo on behavior and event-related potentials (ERPs) in electroencephalograph (EEG) readings on a recognition memory task. The subjects' task was to identify within a list of visually presented words those that were shown for the first time and those that were being repeated. Consistent with other benzodiazepines, oxazepam inhibited the recognition of both new and old words as noted by ERP. In contrast, kava showed a slightly increased recognition rate and a larger ERP difference between old and new words. The results of this study once again demonstrate the unusual effects of kava. In this case, it improves anxiety, but unlike standard anxiolytics, kava actually improves mental function and, at the recommended levels, does not promote sedation.

DOSAGE

In clinical studies using pure kavalactones or kava extracts standardized for kavalactones, the dosage is based on the level of kavalactones. As the kavalactone content of the root varies between 3 and 20%, preparations standardized for kavalactone content are preferred to crude preparations. A standard bowl of traditionally prepared kava drink contains approximately 250 mg of kavalactones, and in Oceania,

several bowls may be consumed at one sitting. Dosages are as follows:

- anxiolytic dosage: 45–70 mg of kavalactones three times/day
- sedative dosage: 180–210 mg of kavalactones 1 hour before retiring.

TOXICOLOGY

Although no side-effects have been reported using standardized kava extracts at recommended levels in the clinical studies, several case reports have been presented indicating that kava may interfere with dopamine and worsen Parkinson's disease. Until this issue is resolved, kava extract should not be used in Parkinson's patients.^[16]

Side-effects may also develop at high dosages. High daily dosages of kava consumed over a prolonged period (a few months to a year) are associated with "kava dermatopathy" – a condition of the skin characterized by a peculiar generalized scaly eruption known as kani.^[16] The skin becomes dry and covered with scales, especially the palms of the hands, soles of the feet, forearms, the back, and shins. It was thought at one time that kava dermatopathy may be due to interference with niacin. However, in a double-blind, placebo-controlled study, niacinamide (100 mg/day) demonstrated no therapeutic effect.^[17] It appears that the only effective treatment for kava dermatopathy is reduction or cessation of kava consumption. No cases of kava dermatopathy have been reported in those taking standardized kava extracts at recommended levels.

Other reported adverse effects of extremely high doses of kava (e.g. greater than 310 g/week) for prolonged periods include:^[18]

- biochemical abnormalities (low levels of serum albumin, protein, urea, and bilirubin)
- presence of blood in the urine
- increased red blood cell volume
- decreased platelet and lymphocyte counts
- shortness of breath.

However, the validity of this report of adverse effects is questionable because the subjects were also heavy users of alcohol and cigarettes. Nonetheless, high doses of kava are unnecessary and should be avoided.

Chapter 105 - Probiotics

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

INTRODUCTION

Probiotics, translated “for life”, refer to bacteria in the intestine considered beneficial to health. At least 400 different species of microflora colonize the human gastrointestinal tract. The most important healthful bacteria are *Lactobacillus acidophilus* and *Bifidobacterium bifidum*. This chapter focuses on the principal uses of commercial probiotic supplements containing either or both *L. acidophilus* and *B. bifidum* as well as the fructo-oligosaccharides which facilitate their growth.

Foods fermented with lactobacilli have been, and still are, of great importance to the diets of most of the world’s people. Most cultures use some form of fermented food in their diet such as yogurt, cheese, miso, and tempeh. The symbiotic relationship between humankind and lactobacilli has a long history of important nutritional and therapeutic benefits for humans.

DESCRIPTION

At the turn of the century, Metchnikoff^[1] asserted that yogurt was the elixir of life. He theorized that putrefactive bacteria in the large intestine produce toxins which invite disease and shorten life. He believed that the eating of yogurt would cause the lactobacilli to become dominant in the colon and displace the putrefactive bacteria. For years, these claims of healthful effects from fermented foods were considered unscientific folklore. However, a substantial, and growing, body of scientific evidence has now demonstrated that lactobacilli and fermented foods play a significant role in human health.

Colonization of Gram-positive lactobacilli begins after birth, after which there is a dramatic increase in their concentration. *Bifidobacterium bifidum* is first introduced through breast-feeding to the sterile gut of the infant, and large numbers are soon

observed in the feces. Later, other bacteria (including such beneficial strains as *L. casea*, *L. fermentum*, *L. salivores*, *L. brevis*, etc.) become

TABLE 105-1 -- Lactobacilli found in the human intestine

established in the gut through contact with the world ([Table 105.1](#)). Unfortunately, other, potentially toxic, bacteria also eventually cultivate the colon.^[2]

Commercial forms

For clinical efficacy, products containing *L. acidophilus* and *B. bifidum* must provide live organisms in such a manner that they survive the commercial process (transportation, storage, etc.) and the hostile environment of the gastrointestinal tract. Several factors, such as species, strain, adherence, growth media, and diet, are involved in successful colonization.^{[3] [4]} Typically, a high-quality commercial preparation will produce greater colonization than simply eating yogurt. One of the key reasons that most currently available yogurts are not clinically very useful is that they are made with *L. bulgaricus* or *Streptococcus thermophilus*. While these two bacteria are friendly and possess some health benefits, they do not colonize the colon.

Proper manufacturing, packaging and storing of the product are necessary to ensure viability, the right amount of moisture, and freedom from contamination. Lactobacilli do not respond well to freeze-drying (lyophilization), spray drying, or conventional frozen storage. Excessive temperature during packaging or storage can dramatically reduce viability. Typically, unless the product has been shown to be stable, refrigeration is necessary. Some products do not have to be refrigerated until after the bottle has been opened.

While there are a number of excellent companies providing high-quality probiotic

products, it is difficult to sort through all of manufacturer's claims of superiority, and some products have been shown to contain no active *L. acidophilus*. In fact, one study concluded: "Most of the lactobacilli-containing products currently available [1990] either do not contain the *Lactobacillus* species advertised and/or contain other bacteria of questionable benefit."^[5] Another study evaluated 16 commercial lactobacillus products for actual microbial content. Four contained the *L. acidophilus* as stated on the label, while 11 were found to be contaminated with pathogens.^[6] Clearly, the clinician needs documentation of product quality and content before prescribing for their patients.

CLINICAL APPLICATIONS

The intestinal flora plays a major role in the health of the host.^{[2] [3] [4]} The intestinal flora is intimately involved in the host's nutritional status and affects immune system function, cholesterol metabolism, carcinogenesis, toxin load, and aging. Due to the importance of *L. acidophilus* and *B. bifidum* to human health, probiotic supplements can be used to promote overall good health. There are several specific uses for probiotics, however. The primary areas of use discussed here are:

- promotion of proper intestinal environment
- post-antibiotic therapy
- vaginal yeast infections
- urinary tract infections
- cancer prevention.

Promotion of proper intestinal environment

Lactobacilli have long been known to play an important role in the prevention of, and defense against, diseases, particularly those of the gastrointestinal tract and vagina. As part of the "normal flora", they inhibit the growth of other organisms through competition for nutrients, alteration of pH and oxygen tension to levels less favorable to pathogens (disease causing organisms), prevention of attachment of pathogens by physically covering attachment sites, and production of limiting factors such as antimicrobial factors.^{[2] [3] [4]}

Lactobacilli produce a variety of factors which inhibit or antagonize other bacteria. These include metabolic end-products such as organic acids (lactic and acetic acid), hydrogen peroxide, and compounds known as bacteriocins.^{[7] [8] [9] [10] [11] [12] [13] [14] [15] [16] [17] [18]} Although some researchers have isolated substances from lactobacilli which they labeled antibiotics, these are probably more accurately described as bacteriocins. Bacteriocins are defined as proteins which are produced by bacteria which exert a lethal effect on closely related bacteria ([Table 105.2](#)). In general, bacteriocins have a narrower range of activity than antibiotics, but are often more lethal.

Some of the antimicrobial activity of *L. acidophilus* has been shown to be due to their production of hydrogen peroxide.^{[17] [18]} However, this reaction requires folic acid and riboflavin, which if in short supply will reduce H₂ O₂ production. In addition to these direct effects, some researchers believe the antimicrobial activity is also due to immune

system stimulation.^{[19] [20] [21] [22] [23] [24]}

The earliest reported therapeutic uses of *L. acidophilus* in the 1920s suggested that their proliferation in the gut was associated with a concomitant decrease in potentially harmful coliform bacteria. This effect has since been confirmed.^{[25] [26] [27]} However, it is believed that many of the earlier commercial products were less reliable than those used in later published clinical trials because of

inappropriate strains and problems in production, storage, and distribution to consumers.^[28]

Post-antibiotic therapy

Acidophilus supplementation is particularly important for preventing and treating antibiotic-induced diarrhea, *Candida* overgrowth, and urinary tract infections. *L. acidophilus* has been shown to correct the increase of Gram-negative bacteria observed following the administration of broad-spectrum antibiotics as occurs with any acute or chronic diarrhea.^{[2] [3] [4] [29] [30] [31]} Similarly, a mixture of *B. bifidum* and *L. acidophilus* inhibited the lowering of fecal flora induced by ampicillin and maintained the equilibrium of the intestinal ecosystem.^[29]

Although it is commonly believed that acidophilus supplements are not effective if taken during antibiotic therapy, the research actually supports the use of *L. acidophilus* during antibiotic administration.^{[29] [30]} Reductions of friendly bacteria and/or superinfection with antibiotic-resistant flora may be prevented by administering *L. acidophilus* products during antibiotic therapy. A dosage of at least 15–20 billion organisms is required. Probiotic supplements should, however, be taken as far away from the antibiotic as possible.

Vaginal yeast infections

Lactobacillus acidophilus has been shown to retard the growth of *Candida albicans* – the major yeast involved in vaginal yeast infections.^[32] Clinical studies have suggested that the introduction of yogurt or lactobacilli to the vagina can assist in clearing up and preventing recurrent vaginal yeast infections as well as bacterial vaginosis.^[33]

Lactobacillus acidophilus is a normal constituent of the vaginal flora, where it contributes to the maintenance of the acid pH by fermenting vaginal glycogen to lactic acid.^{[34] [35] [36] [37]} It has been shown that suppression of *L. acidophilus* by broad-spectrum antibiotics leads to the overgrowth of yeast and other bacteria.^[38]

Reestablishment of normal vaginal lactobacilli can be accomplished by having the woman douche twice a day with an acidophilus solution containing 10⁸ live organisms/ml. However, the right strains must be used.

The appropriate lactobacilli produce hydrogen peroxide in the vaginal tract. It is present in 96% of normal vaginas but is absent in women suffering from chronic vaginosis. The production of hydrogen peroxide by lactobacilli is toxic to pathogens such as *Gardenerella vaginalis*.^[39] Not all women's vaginas are colonized by the right strains of lactobacilli. One study evaluated the lactobacilli in 275 women in the second trimester of

pregnancy by obtaining vaginal cultures to detect H₂ O₂ -production status as well as the presence of pathological organisms. Women colonized by H₂ O₂ -positive lactobacilli were less likely to have bacterial vaginosis, symptomatic candidiasis and vaginal colonization by *Gardnerella vaginalis*, *Bacteroides*, *Peptostreptococcus*, *Mycoplasma hominis*, *Ureaplasma urelurealyticum*, and *Viridans streptococci*.^[40] The women who did not have any vaginal lactobacilli were also more likely to have *Chlamydia trachomatis*. The researchers also reported that most commercially available products contain lactobacilli that do not produce H₂ O₂ or lactobacillus strains derived from dairy foods, which are unable to bind to vaginal epithelial cells.

While douching appears to be the preferred therapy for vaginal infections, even simple consumption of appropriate yogurt products appears beneficial. For example, one study of 33 patients with recurrent *Candida vaginitis*, found a threefold decrease in infections when they consumed 8 ounces/day of yogurt containing H₂ O₂ -producing *Lactobacillus acidophilus* for a period of 6 months. The mean number of infections per 6 months was 2.54 in the control group, and 0.38 in the yogurt-treated group. *Candida* colonization decreased from a mean of 3.23/6 months in the control group to 0.84/6 months in the yogurt group.^[41] As might be expected, the researchers found an association between the presence of *Lactobacillus* sp. in the rectum and the vagina.

Urinary tract infection

One of the problems with antibiotic therapy for urinary tract infections is that the disturbance in the bacterial flora which protects against urinary tract infections leads

to recurrent infections. The insertion of lactobacilli suppositories into the vagina of women after they had been treated with antibiotics has been shown to significantly reduce the recurrence rate.^[42] In one study, freeze-dried lactobacilli suppositories given intravaginally once weekly for 1 year to eight women with recurrent UTIs resulted in an impressive 78% reduction in the incidence of infection.^[6]

Cancer

A series of population studies has suggested that the consumption of high levels of cultured milk products may reduce the risk of colon cancer.^[43] *Lactobacillus bulgaricus*, the primary lactobacilli used for traditional yogurt, has demonstrated potent antitumor activity.^[44] Feeding milk and colostrum fermented with *L. acidophilus* DDS1 has been reported to result in a 16–41% reduction in tumor proliferation in animal studies.^[45] In human studies, ingestion of *L. acidophilus* resulted in reduced activity of the bacterial enzymes associated with the formation of cancer-causing compounds in the gut.^[46] The beneficial effects of lactobacilli against cancer appear to extend well beyond the colon. In a double-blind trial conducted in 138 patients surgically treated for bladder cancer, patients were stratified into three groups: (A) with primary multiple tumors, (B) with

recurrent single tumors, and (C) with recurrent multiple tumors.^[47] In each group, patients were randomly allocated to receive the oral *Lactobacillus casei* preparation (LCP) or placebo. LCP showed a better effect than placebo in preventing cancer recurrences in subgroups A and B. However, no significant effect was noted in group C.

Lactobacillus acidophilus preparations are also of value in cancer patients receiving chemotherapy drugs or radiation therapy involving the gastrointestinal tract. In one study, 24 patients scheduled for internal and external irradiation of the pelvic area for gynecological cancers were selected for a controlled study to test the prevention of intestinal side-effects by administration of *L. acidophilus*.^[48] The test group received 150 ml/day of a fermented milk product supplying them with live *L. acidophilus* bacteria in a 6.5% lactulose substrate, resulting in prevention of radiotherapy-associated diarrhea.

Traveler's diarrhea

Lactobacilli supplements are routinely recommended by nutritionally oriented doctors to their patients who travel to developing countries. However, one published report casts doubt on this practice. A randomized, double-blind, placebo-controlled trial was conducted on 282 British soldiers deployed to Belize. They received two capsules containing *L. fermentum*, *L. acidophilus* or a placebo daily for 3 weeks. There were 10^{11} colony-forming units of bacteria in each capsule of lactobacilli. No protection from traveler's diarrhea was provided by either species.^[49] Unfortunately, the H_2O_2 -producing status of the supplement was not reported.

Lactose intolerance

Lactose in yogurt with live bacteria is better tolerated in people who are lactose-intolerant than lactose in other dairy foods. This is primarily due to the activity of microbial B-galactosidase which breaks down lactose in vivo. Yogurt containing mixed strains of *Streptococcus salvarius* ssp. *thermophilus* and *L. delbrueckii* ssp. *bulgaricus*, and fermented milks containing *S. thermophilus*, *L. bulgaricus*, *L. acidophilus* or *B. bifidus* were evaluated. All the yogurt products dramatically improved lactose digestion regardless of their total or specific B-galactosidase activity. The fermented milks had marginal improvement with *B. bifidus* and almost complete lactose digestion with *L. bulgaricus*. These results suggest that B-galactosidase is not the only factor in promoting lactose digestion.^[50]

Comparable results are found in children. One study of 14 lactose-malabsorbing children, with a mean age of 9.5 years, found that consumption of live yogurt containing *L. bulgaricus* and *S. thermophilus* resulted in significantly fewer symptoms than after consuming regular milk and pasteurized yogurt. Breath hydrogen correlated with the degree of symptoms.^[51]

Crohn's disease

An interesting study found that four of five patients with disease went into remission for 22 months after having their bowel flora completely replaced with healthier bacteria. The

researchers hypothesized that antigens or epitopes on host coliforms in Crohn's patients may cross-react with, or mimic, antigens or epitopes on epithelial cells of the colon or ileum. The five patients were initially treated with broad-spectrum oral and intravenous antibiotics to sterilize the bowel. They were then reinoculated by oral and rectal administration of two strains of non-pathogenic *E. coli* and lactobacilli. The clinical improvement lasted 3–4 months.^[52]

DOSAGE

The dosage of a commercial probiotic supplement is based upon the number of live organisms. The ingestion of one to 10 billion viable *L. acidophilus* or *B. bifidum* cells daily is a sufficient dosage for most people. Amounts exceeding this may induce mild gastrointestinal disturbances, while smaller amounts may not be able to colonize the gastrointestinal tract.

897

PROMOTING GROWTH OF LACTOBACILLI

Fructo-oligosaccharides

Food components which may help to promote the growth of friendly bacteria include fructo-oligosaccharides (FOSs). These short-chain polysaccharides have only recently entered the US market. However, in Japan the number of consumer products containing purified FOSs reached 450 in 1991, and in 1990 the Japanese market for FOSs exceeded \$46 million.^[53]

FOS, which is not digested by humans, provides a preferred substrate for healthful bacteria. Human studies have shown FOS to increase bifidobacteria and lactobacilli while simultaneously reducing the colonies of detrimental bacteria. Other benefits noted with FOS supplementation include:^[53] ^[54]

- increased production of short-chain fatty acids like butyrate
- improved liver function
- reduction of serum cholesterol and blood pressure
- improved elimination of toxic compounds.

The dosage recommendation for pure FOS is 2,000– 3,000 mg daily. Natural food sources of FOS include bananas, Jerusalem artichoke, onions, asparagus, and garlic. However, the estimated average daily ingestion of FOS from food sources is estimated to be only 800 mg. Thus, the supplementation of FOS may often be of clinical benefit.^[54]

Spirulina

Another possible way to improve the conditions in the intestine is by the consumption of

spirulina. While no human studies appear to have been published, intriguing veterinary research has shown that providing horses with spirulina stimulates the growth of *Lactobacillus* in the cecum. The researchers suggest that this may be due to the mucopolysaccharides in spirulina.^[55]

TOXICITY

Probiotics are safe and are not associated with any side-effects other than a transient increase in gastrointestinal gas.

Interactions

Lactobacillus acidophilus and *B. bifidum* are negatively affected by alcohol and antibiotics.^[56] Although there is no evidence that the organism interferes with the activity of most antibiotics, the metabolism of sulfasalazine, chloramphenicol palmitate, and phthalylsulfathiazole is affected by *L. acidophilus*.^[57]

Chapter 106 - Procyanidolic oligomers

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

GENERAL DESCRIPTION

The proanthocyanidins (also referred to as procyanidins) are one of the most beneficial groups of plant flavonoids. The most active proanthocyanidins are those bound to other proanthocyanidins. Collectively, mixtures of proanthocyanidin dimers, trimers, tetramers, and larger molecules are referred to procyanidolic oligomers or PCOs for short.^{[1] [2]}

Although PCOs exist in many plants, as well as red wine, commercially available sources of PCOs include extracts from grape seed skin (*Vitex vinifera*) and the bark of the maritime (Landes) pine.^{[1] [2]} This chapter reviews the benefits of PCOs from grape seeds and pine bark.

CHEMICAL COMPOSITION

Grape seed and pine bark PCO extracts are well defined chemically. Grape seed extracts are available which contain 92–95% PCOs while the pine bark extracts vary from 80 to 85%. Proanthocyanidin B₂ is shown in [Figure 106.1](#).

HISTORY AND FOLK USE

In 1534, French explorer Jacques Cartier lead an expedition up the Saint Lawrence River. Trapped by ice,

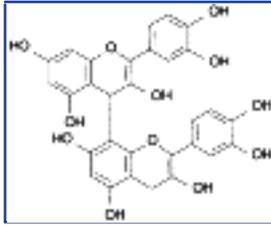

Figure 106-1 Proanthocyanidin B₂ .

900

Cartier and his crew were forced to survive on a ration of salted meat and biscuits. Cartier's crew began to exhibit signs and symptoms of scurvy, the cause of which was unknown at that time. Fortunately for Cartier and the surviving members of his crew, they met a Native American who advised them to make a tea from the bark and needles of pine trees. As a result, Cartier and his men survived.

More than 400 years later, Professor Jacques Masquelier of the University of Bordeaux, France, read the book Cartier wrote detailing his expedition. Intrigued by Cartier's story, Masquelier and others concluded that pine bark must contain some vitamin C as well as bioflavonoids which can exert vitamin C-like effects.

Masquelier termed the active components of the pine bark "pycnogenols".^[1] ^[3] This term was used to describe an entire complex of proanthocyanidin complexes found in a variety of plants including pine bark, grape seeds, lemon tree bark, peanuts, cranberries, and citrus peels. The term "pycnogenols" has been replaced in the scientific community by the terms proanthocyanidins, oligomeric proanthocyanidin complexes (OPCs), and/or procyanidolic oligomers (PCO). In the United States, Pycnogenol® is a registered trademark of Horphag Ltd of Guernsey, UK, and refers to the procyanidolic oligomer (PCO) extracted from the bark of the French maritime pine.

Masquelier patented the method of extracting PCOs from pine bark in France in 1951, and from grape seeds in 1970. The PCO extract from grape seed emerged as the preferred source based on research between 1951 and 1971, as well as intensive research from 1972 to 1978.^[1] The 1970s research was conducted with the goal of gaining approval for PCO as a medicinal agent by the French equivalent of the FDA. During this time, detailed analytical, toxicity, pharmacological, and clinical studies were performed on PCOs derived from grape seeds. PCOs from both grape seeds and pine bark have been marketed in France for decades where they have been promoted to improve retinopathies, venous insufficiency, and vascular fragility.

PHARMACOLOGY

Extracts of PCOs have demonstrated a wide range of activity as listed in [Table 106.1](#) .

Protection of collagen

Collagen, the most abundant protein of the body, is

TABLE 106-1 -- Pharmacological activity of proanthocyanidins^{[1] [2]}

-
- Increase intracellular vitamin C levels
-
- Decrease capillary permeability and fragility
-
- Scavenge oxidants and free radicals
-
- Inhibit destruction of collagen

responsible for maintaining the integrity of ground substance as well as the integrity of tendons, ligaments, and cartilage. Collagen is also the support structure of the dermis and blood vessels. PCOs are remarkable in their effect in supporting collagen structures and preventing collagen destruction. They affect collagen metabolism in several ways. They have the unique ability to cross-link collagen fibers, resulting in reinforcement of the natural cross-linking of collagen that forms the so-called collagen matrix of connective tissue.^{[4] [5]} They also protect against free radical damage with their potent antioxidant and free radical scavenging action; and inhibit enzymatic cleavage of collagen by enzymes secreted by leukocytes during inflammation and microbes during infection.^{[6] [7]} PCOs also prevent the release and synthesis of compounds that promote inflammation and allergies such as histamine, serine proteases, prostaglandins, and leukotrienes.^[4]

Antioxidant and free radical scavenging activity

Perhaps the most celebrated effects of PCOs in the United States are their potent antioxidant and free radical scavenging activity. Free radical damage has been linked to the aging process and virtually every chronic degenerative disease including heart disease, arthritis, and cancer. Fats and cholesterol are particularly susceptible to free radical damage. When damaged, fats and cholesterol form toxic derivatives known as lipid peroxides and cholesterol epoxides, respectively. The antioxidant and free radical scavenging effects of PCOs were discovered by Masquelier in 1986.^[4]

A recent study evaluated the free radical scavenging activity of PCOs and determined their inhibitory effects on xanthine oxidase (a primary generator of oxygen-derived free radicals) and the lysosomal enzyme system (which governs the release of enzymes which can damage the connective tissue framework that acts as a protective sheath surrounding capillary walls).^[7] This research, summarized in [Table 106.2](#), provides a detailed explanation of the vascular protective action of PCOs and a strong rationale for their use in vascular disease.

In experimental models, the antioxidant activity of

TABLE 106-2 -- Antioxidant and free radical scavenging activities of PCOs

-
- Trap hydroxyl free radicals
-

- Trap lipid peroxides and free radicals
 - Markedly delay the onset of lipid peroxidation
 - Chelate free iron molecules, thereby preventing iron-induced lipid peroxidation
 - Inhibit production of free radicals by non-competitively inhibiting xanthine oxidase
 - Inhibit the damaging effects of the enzymes (e.g. hyaluronidase, elastase, collagenase, etc.) which can degrade connective tissue structures
-

901

PCOs is much greater (approximately 50 times) than that of vitamin C and vitamin E. From a cellular perspective, one of the most advantageous features of PCOs' free radical scavenging activity is that, because of their chemical structure, they are incorporated into cell membranes. This physical characteristic, along with their ability to protect against both water- and fat-soluble free radicals, provides significant cellular protection against free radical damage.

The researchers concluded their discussion with the following comment: "These findings, together [with] those of other investigators, provide a strong rationale for using these compounds in the therapeutic management of microvascular disorders."

CLINICAL APPLICATIONS

Venous and capillary disorders

The primary clinical applications of PCOs are in the treatment of:

- venous and capillary disorders including venous insufficiency
- varicose veins
- capillary fragility
- disorders of the retina, including diabetic retinopathy and macular degeneration.

Good clinical studies have shown positive results in the treatment of these conditions.^[9]
[\[9\]](#) [\[10\]](#) [\[11\]](#) [\[12\]](#) [\[13\]](#) [\[14\]](#) [\[15\]](#)

Visual function

Increased intake of PCO is likely to benefit almost everyone. This suggestion is perhaps best illustrated by research evaluating the effects of grape seed PCOs extract on visual function in healthy subjects.^[14] ^[15] In the studies, 100 normal volunteers with no retinal disorder received 200 mg/day of PCOs or placebo for 5 or 6 weeks. The group receiving PCOs demonstrated significant improvement in visual performance in dark and after

glare tests compared with the placebo group.

Atherosclerosis

There are now numerous studies demonstrating that an individual's level of antioxidants may be a more significant factor in determining the risk of developing heart disease than cholesterol levels. Antioxidants prevent the oxidation of cholesterol and its carrier proteins as well as preventing the initial damage to the artery which ultimately leads to the process of atherosclerosis. Large-scale studies with vitamin E, vitamin C, and beta-carotene have shown that these antioxidants are capable of significantly reducing the risk of dying of a heart attack or a stroke. For example, in one study of 87,245 nurses, it was discovered that nurses who took 100 IU of vitamin E daily for more than 2 years had a 41% lower risk of heart disease compared with non-users of vitamin E supplements.^[16] Another study of 39,910 male health care professionals produced similar results: a 37% lower risk of heart disease with the intake of more than 30 IU of supplemental vitamin E daily.^[17]

Since PCOs have a greater antioxidant effect than vitamins C and E, it is only natural to speculate they could offer greater protective effects. Support exists for this contention. For example, several studies have shown the protective effects of red wine against heart disease and stroke by protecting against LDL oxidation.^[18] The active components in the wine are thought to be proanthocyanidins. Also, a recent study of 805 men beginning in 1985 demonstrated an inverse correlation between flavonoid intake and death due to heart attack.^[19]

In addition to preventing damage to cholesterol and the lining of the artery, PCO extracts have been shown to lower blood cholesterol levels and shrink the size of the cholesterol deposit in the artery in animal studies.^[1] ^[20] Additional mechanisms of PCOs useful in preventing atherosclerosis include inhibition of platelet aggregation and inhibition of angiotensin-I-converting enzyme.^[21] ^[22] Presumably, PCO extracts may exert similar benefits in humans. PCO extracts, although in a supplement form, should be thought of as a necessary food in the prevention and treatment of atherosclerosis.

DOSAGE

As antioxidant support, a daily dose of 50 mg of either the grape seed or pine bark extract is suitable. For comparison, it is now estimated that the average daily intake of total flavonoids in the United States is about 25 mg. An intake greater than 30 mg offers significantly reduced risk for cardiovascular mortality.^[19]

When being used for therapeutic purposes, the daily dosage should be increased to 150–300 mg.

TOXICITY

PCO extracts are without known side-effects.

Chapter 107 - *Pygeum africanum* (bitter almond)

Michael T. Murray ND
Joseph E. Pizzorno Jr ND

Pygeum africanum (family: Rosaceae)
Synonym: *Prunus africanum*
Common names: bitter almond, red stinkwood

GENERAL DESCRIPTION

Pygeum africanum is an evergreen tree native to Africa that can grow to a height of 120–150 feet. It has pendulous branches with thick, oblong-shaped, leather-like, mat-colored leaves and creamy white flowers. The fruit (drupe) resembles a cherry when ripe. The dark brown to gray bark of the trunk is the part used for medicinal purposes.

CHEMICAL COMPOSITION

The major active components of the bark are:

- lipid-soluble pentacyclic triterpenes
- sterolic triterpenes
- fatty acids
- esters of ferulic acid (see [Fig. 107.1](#)).

The pentacyclic triterpenic components include ursolic acid (see [Fig. 107.2](#)), oleanolic acid, crataegolic acid, and their derivatives. The sterolic fraction is composed mainly of beta-sitosterol and beta-sitosterone (see [Fig. 107.3](#)). The fatty acids range from C12 to C24 and the important ferulic acid esters are those bound to *n*-tetracosanol and *n*-docosanol. ^{[1] [2] [3] [4]}

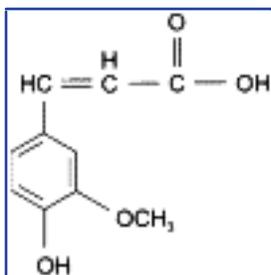

Figure 107-1 Ferulic acid.

904

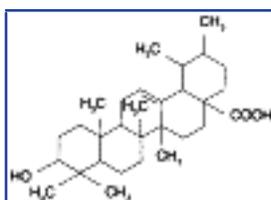

Figure 107-2 Ursolic acid.

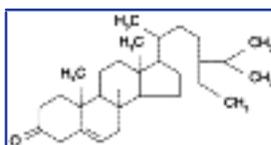

Figure 107-3 β -Sitosterone.

HISTORY AND FOLK USE

The powdered bark of *Pygeum africanum* was used by the natives of tropical Africa as a treatment for urinary disorders. It was often given with palm oil or milk.

PHARMACOLOGY

Pharmacological screening of various extracts prepared with solvents of differing degrees of polarity indicated that the highest activity was found in lipophilic extracts. This finding is interesting in light of pygeum's historical administration in lipophilic media (palm oil or milk). Virtually all of the pharmacological research has featured a pygeum extract standardized to contain 14% triterpenes including beta-sitosterol and 0.5% *n*-docosanol. This extract has been extensively studied in both experimental animal studies and clinical trials with humans.

The primary target organ for pygeum's effects in males is the prostate. The three major active components of pygeum appear to exert different, yet complementary, effects in benign prostatic hyperplasia (BPH). In addition, pygeum has been shown to enhance the secretions of the prostate and bulbourethral glands, in terms of both quantity and

quality.

Ferulic acid esters

The esters of ferulic acid act primarily on the endocrine system. Studies in animals have shown docosanol to reduce levels of leutinizing hormone and testosterone while raising adrenal steroid secretion of both adrenal androgens and corticosteroids.^{[5] [6]} Docosanol also significantly reduces serum prolactin levels. This reduction of prolactin is quite significant as prolactin increases the uptake of testosterone and increases the synthesis of dihydrotestosterone within the prostate. The accumulation of testosterone within the prostate and its subsequent conversion to the more potent dihydrotestosterone is thought to be the major contributing factor to the hyperplasia of the prostatic cells observed in BPH.^[7] Although traces of docosanol are present in pygeum, the esterification with ferulic acid results in greater bioavailability and activity.^{[2] [4] [8]}

Ferulic acid esters, as well as the sterol fraction of pygeum, exert cholesterol-lowering action systematically, as well as reducing the intraprostatic cholesterol content.^[8] Breakdown products of cholesterol have been shown to accumulate in the prostate tissue affected with either BPH or cancer.^[7] These metabolites of cholesterol initiate degeneration of prostatic cells which can promote prostatic enlargement. Drugs which lower cholesterol levels have been shown to have a favorable influence on BPH, preventing the accumulation of cholesterol in the prostatic cells and limiting subsequent formation of damaging cholesterol metabolites. The lowering of intraprostatic cholesterol content is an important aspect of the pharmacology of pygeum.

The sterolic fraction is also endowed with competitive action against testosterone accumulation within the prostate. In addition, the sterols of pygeum have also been shown to reduce inflammation by preventing the intraprostatic formation of inflammatory prostaglandins.^{[8] [9]}

Other components

Other components of pygeum are also important. For example, the pentacyclic triterpenes exhibit anti-inflammatory effects within the prostatic epithelium and may be responsible for stimulation of the secretory cells of the prostate, seminal vesicles, and bulbourethral glands.^{[8] [9] [10]} And finally, the fatty acids components are similar to those of *Serenoa repens* (see [Ch. 110](#)) and may exert similar effects as well as improve the oral bioavailability of other components of the lipophilic extract.

CLINICAL APPLICATIONS

Prostate disorders

The pharmacological actions of the standardized pygeum extract supports its use in prostate disorders, BPH in particular. Adding further support are the results from numerous clinical trials of over 600 patients.^{[11] [12] [13] [14] [15] [16] [17] [18] [19] [20] [21] [22] [23] [24] [25] [26] [27] [28] [29] [30] [31] [32] [33]} Consistently, these studies have demonstrated pygeum to

effectively reduce the symptoms and clinical signs of BPH, especially in early cases. However, it must be

pointed out that improvement is largely symptomatic, as the results on reducing the size of the prostate or the residual urine content of the bladder are modest. The results of the clinical trials on pygeum are given in [Table 107.1](#). Below, there is a discussion of some of the most important aspects of these studies.

One of the major findings in evaluating the effectiveness of pygeum in BPH has been the high rate of responders to placebo. This is well-demonstrated in one of the larger double-blind studies.^[29] Similar to the results in other double-blind studies, pygeum extract was shown to be statistically superior to a placebo in reducing the major symptoms of BPH (nocturnal frequency, difficulty in starting micturition, and incomplete emptying of the bladder). However, there was a high percentage of responders to the placebo (see [Table 107.2](#) below). It seems that simply taking a capsule provides relief to many sufferers.

Another study highlights the importance of double-blind

TABLE 107-2 -- Patients responding to placebo and pygeum

| Symptom | Placebo group | Pygeum group |
|--------------------|---------------|--------------|
| Nocturia | 26/52 = 50% | 44/56 = 78% |
| Daytime frequency | 16/50 = 33% | 27/54 = 50% |
| Incomplete voiding | 14/40 = 35% | 21/32 = 66% |
| Dribbling | 15/34 = 44% | 13/33 = 39% |
| Urine flow rate | 11/43 = 26% | 21/38 = 55% |

studies which feature both objective and subjective findings. In the study, both patients and physicians rated the placebo and pygeum extract to be effective in improving subjective symptoms of daytime frequency, nocturia, weak stream, after-dribbling,

hesitation, and interruption of flow.^[28] However, urodynamic variables (flow, frequency, and histogram) clearly demonstrated the superiority of pygeum over placebo.

One of the shortcomings of some of the clinical research on pygeum is the lack, in many of the studies, of objective measures such as urine flow rate (ml/s), residual urine content, and prostate size. Studies that have used objective measurements have shown some good results. For example, in one open trial, 30 patients with BPH given 100 mg/day of the pygeum extract for 75 days demonstrated significant improvements in objective parameters: maximum flow rate increased from 5.43 to 8.20 ml/s and the residual urine volume dropped from 76 to 33 ml.^[22]

Male infertility and impotence

Pygeum may be effective in improving fertility in cases where diminished prostatic secretion plays a significant role. Pygeum has been shown to increase prostatic secretions and improve the composition of the seminal fluid.^{[34] [35] [36]} Specifically, pygeum administration to men with decreased prostatic secretion has led to increased levels of total seminal fluid plus increases in alkaline

phosphatase and protein. Pygeum appears to be most effective in cases where the level of alkaline phosphatase activity is reduced (i.e. less than 400 IU/cm³) and where there is no evidence of inflammation or infection (i.e. absence of white blood cells or IgA). The lack of IgA in the semen is a good predictor of clinical success. In one study, the patients with no IgA in the semen demonstrated an alkaline phosphatase increase from 265 to 485 IU/cm³.^[34] In contrast, those subjects with IgA showed only a modest increase from 213 to 281 IU/cm³.

Pygeum extract has also shown an ability to improve the capacity to achieve an erection in patients with BPH or prostatitis as determined by nocturnal penile tumescence in a double-blind clinical trial.^[37] BPH and prostatitis are often associated with erectile dysfunction and other sexual disturbances. Presumably by improving the underlying condition, pygeum can improve sexual function.

Pygeum vs. serenoa

The standardized liposterolic extract of *Serenoa repens* is another popular botanical treatment for BPH (see [Ch. 110](#)). In a double-blind study which compared the pygeum extract with the extract of serenoa, the serenoa extract produced a greater reduction of symptoms and was better tolerated.^[38] In addition, the improvement of objective parameters, especially urine flow rate and residual urine content, is better in the clinical studies with serenoa. However, there may be circumstances where pygeum is more effective than serenoa. For example, serenoa has not been shown to produce the effects that pygeum has produced on prostate secretion. Although the two extracts have

somewhat overlapping mechanisms of actions, they can be used in combination.

DOSAGE

The dosage of the lipophilic extract of *Pygeum africanum* standardized to contain 14% triterpenes including beta-sitosterol and 0.5% *n*-docosanol is 100–200 mg/day in divided doses. The crude herb is not used.

TOXICOLOGY

Acute and chronic toxicity tests in the rat and mouse have shown that the standardized extract of *Pygeum africanum* bark is non-toxic. Increasing doses from 1 to 6 g/kg in the mouse and from 1 to 8 g/kg in the rat caused no deaths within 48 hours. In chronic toxicity studies, dosing the animals with from 60 to 600 mg/kg for 11 months did not produce any negative effects.

In the human clinical trials, the pygeum extract also demonstrated no significant toxicity. The most common side-effect is gastrointestinal irritation, resulting in symptoms ranging from nausea to severe stomach pains; however, rarely does the presence of these side-effects result in discontinuation of therapy.

Chapter 108 - Recommended optimum nutrient intakes (RONIs)

Alexander G. Schauss PhD

INTRODUCTION

In 1998, the Food and Nutrition Board of the US Institute of Medicine recommended that to reduce the likelihood of neural tube defects in children, “women should eat a varied diet *and take an extra 400 micrograms of folic acid* to be absolutely sure that they get enough of the nutrient”.

That the public should use a dietary supplement, not just food, to reassure themselves that they are getting the necessary levels of a nutrient to prevent a disease or condition is nothing less than a paradigm shift in official public health policy.

In recent years a convincing link between the intake of folic acid and neural tube defects has been established. As a result, the National Institutes of Health and US Department of Health and Human Services have given special attention to the need for folic acid in the diet in the prevention of such neural tube defects as spina bifida.

Folic acid is but one of the B vitamins that in recent years has been the subject of research into the role that nutrients play in the prevention, mitigation or treatment of cancers, cardiovascular diseases, mental disorders, and other diseases or conditions. For example, researchers are continuing to unravel the association between levels of folate, pyridoxine (vitamin B₆) and inositol, and the reduction of excessive levels of blood homocysteine, a marker associated with the risk of cardiovascular disease.

This chapter will discuss the recommended optimal daily intake of nutrients necessary to maintain health and reduce the risk of disease. The conclusion reached by the author for each nutrient is based on a review of thousands of epidemiological, clinical, and experimental papers, offering evidence for optimal versus minimal intake levels.

The RDAs

The weaknesses of the RDAs

Since the mid-1940s, the US recommended daily allowances (RDAs) have served as a nutritional guideline.

910

These guidelines were developed from minimalist criteria aimed solely at the prevention of nutritionally related clinical deficiencies. More recently, in the mid-1990s, these guidelines were superseded by Food and Drug Administration (FDA) nutritional guidelines known as the recommended daily intake levels (RDIs). Curiously, the RDIs show no more promise than did the RDAs in providing the public with useful information on the intake of nutrients in the prevention, mitigation and treatment of a wide range of conditions and diseases for which diet does, or may, play a role. Hence, it is worthwhile to understand the limits of the RDAs and RDIs to fully appreciate the need for recommended optimal nutrition intake (RONIs). Since our understanding of the optimal level of each nutrient in the prevention, mitigation, and treatment of disease remains a somewhat primitive science, the discussion will be framed around the concept of recommended optimal nutrition intake (RONI). As our understanding of the role of each nutrient in disease processes becomes more sophisticated, the values for the RONIs are certain to change. Yet they certainly provide us with better guidelines to maintain health than the minimalist basis from which the RDAs were constructed.

The history of the RDAs

In May 1941, a committee of the National Academy of Sciences suggested for the first time that a “recommended daily dietary allowance” of essential nutrients be established. These guidelines were developed with the goal of reducing the incidence of nutritional deficiency diseases in the general population, such as scurvy (deficiency of vitamin C), pellagra (deficiency of niacin), and beri-beri (deficiency of vitamin B₁). Since then, nutritionists, dietitians, and physicians have relied on the RDAs, including nine revisions, as guidelines for advising public health officials and the public on recommended nutrient intake levels.

According to the committee that established the RDAs, they were intended:

- as guidelines for the prevention of nutritional deficiencies
- to be related to the nutrient status of population groups, not individuals.

In essence, the RDAs provide no information on the role of nutrients in the prevention, amelioration, or treatment of conditions or diseases.

A common mistake made by many public health practitioners is to use the RDAs to evaluate the adequacy of an individual's diet. Even worse is the assumption that maintaining a diet that provides an RDA level of nutrients will somehow ensure wellness over one's lifetime. Only recently has it become apparent that "healthy normal people" are an ideal. Among Americans aged 60 and over, more than 80% suffer from at least one or more chronic diseases, such as cancer, atherosclerosis, osteoporosis, macular degeneration, or diabetes.

Since at least 1951, critics of the RDAs have asserted that they lack the ability to recommend levels of nutrients sufficient to maintain health for a person seeking a healthy life span that is associated with a morbidity-free existence.

Studies used to determine the level of a nutrient that is sufficient to prevent a nutritional deficiency are typically conducted for only 6–9 months, about 1% of the average person's life span. This suggests that these minimalist dietary standards are based on data incapable of suggesting levels of nutrients essential to prevent many conditions and diseases associated with morbidity.

Even more germane to this issue is the attention focused in recent years on the role of substances not generally recognized as nutrients that appear to be directly involved in the prevention or mitigation of a diverse host of diseases from colon cancer to coronary heart disease, cataracts, birth defects, and stroke.

Early editions of the RDAs that were published in the 1940s clearly stated that the RDAs "vary greatly in disease". Yet in spite of this realization, the RDAs continue to focus only on the prevention of nutritional deficiencies in population groups. However, this began to change in 1989 with the release of the 10th edition of the RDAs by the National Academy of Sciences.

The 10th edition acknowledged for the first time that levels of a nutrient, specifically the nutrient vitamin C, may need to be higher than the RDA for groups at risk of developing chronic diseases, particularly, smokers. This welcome recommendation by the National Academy of Sciences has opened the door to an entirely new paradigm, namely, the determination of optimal nutrient intake levels needed to minimize the risk of developing conditions and diseases affecting various population groups (i.e. women at risk of birth defects).

Unfortunately, the RDAs' noble attempt remains inadequate because of its minimalist foundation. While a higher level of vitamin C intake for smokers is indeed suggested in the 10th edition, studies of the blood levels of vitamins and minerals in smokers have shown that low levels of other nutrients such as beta-carotene, zinc, vitamin B₆, and vitamin E may also be needed at significantly higher levels than that recommended for vitamin C or prescribed by the RDAs. Mounting evidence suggests that all of these nutrients, not just vitamin C, and probably many other nutrients and non-nutritive substances, may need to be taken by smokers to compensate for the nutrient loss such

a habit produces.

The RDAs also fail to address excessive use of alcohol – yet another example of a common addiction that increases nutrient requirements. Individuals who chronically

consume alcohol have been found to have lower levels of folate, vitamin B₁, vitamin B₆, vitamin A, beta-carotene, zinc, and vitamin C.

The lifestyles of individuals are also neglected in the RDAs. Dieters, for example, are a population who have frequently been found to have low nutrient status. Studies have shown that it is extremely difficult, if not impossible, to meet all of the RDAs for nutrients, let alone maintain health, when chronically consuming less than 1,200 calories/day. An analyses of 11 major reducing diets shows that none can provide 100% of the RDA for vitamins alone. What about individuals with eating disorders (i.e. bulimia nervosa)? Or those working under chronic conditions of stress? Individuals who smoke cigarettes? Or heavy alcohol consumers?

We have come to realize that individuals may have habits or lifestyles that require nutrient levels that are well in excess of those recommended by the RDAs.

It is important to understand the limits of the RDAs and to appreciate the potential benefits of higher nutrient intake levels. [Table 108.1](#) outlines five limitations of the RDAs as dietary intake guidelines in the prevention of conditions and diseases that affect morbidity and mortality.

The need for a guideline to optimal intake levels of nutrients

A growing body of evidence indicates that intakes of certain vitamins and minerals at levels well above the RDAs may be necessary to protect against the development of certain conditions and diseases that affect our quality of life and/or life span. For example, antioxidants, such as vitamin C, beta-carotene, vitamin E, and selenium, may prevent free radical damage to vascular endothelial cells associated with the most common form of cardiovascular disease, atherosclerosis. These vitamins/minerals

TABLE 108-1 -- Limitations of the RDAs

- They are meant to serve as a guideline for the prevention of nutritional diseases, not the promotion of health
 - The recommendations are based on the nutrient status of large population groups numbering in the millions, not as a guideline to determine individual dietary nutrient requirements
-

- The estimates of the RDAs are based only on short-term research that represents less than 1% of the average person's lifespan, so they cannot provide nutrient recommendations that may be of benefit over a lifetime in the prevention or amelioration of diseases associated with aging or certain lifestyles

- They do not make adjustments for variations in nutrient needs associated with conditions or diseases that affect nutrient requirements

- They provide no data on compensatory levels of nutrient intake needed to compensate for nutrient-demanding lifestyle factors such as: chronic stress, chronic intense exercise, cigarette smoking, alcoholism, restrictive dieting routines, polluted environments, exposure to chemical carcinogens, etc.

may be required in much higher amounts than the RDA to prevent atherosclerosis than those levels suggested by the RDAs to prevent deficiency symptoms, unless, of course, the development of atherosclerosis is a deficiency symptom of these vitamins. The same might be said of many cancers, heart disease, birth defects, eye diseases (e.g. macular degeneration and cataracts), hearing loss, diabetes, and other conditions and diseases.

The development of recommended optimum nutrient intakes

As a result of numerous epidemiological, clinical and experimental studies, it is now possible to extrapolate a list of recommended optimum nutrient intakes, or RONIs, for all of the major vitamins and minerals essential to our health.

Nearly 20 years ago an attempt was made by Drs Cheraskin and Ringsdorf at the University of Alabama School of Medicine in Birmingham to establish RONIs. Their study of optimal intake levels of vitamins and minerals in humans spanned a period of 15 years. They examined the dietary intake and physiological levels of nutrients in over 13,500 male and female subjects living in six diverse regions of the United States. The results of their multimillion dollar study was compiled into over 49,000 pages found in 153 bound volumes.

A small but significant portion of their findings has been published, in a series of over 100 research papers, during a period of 20 years, ending in the early 1990s.

Cheraskin & Ringsdorf's research investigated the health status of its subjects through a relatively time-consuming evaluation of each person's health status. Each subject in the study completed the following test or procedure:

1. the 195 item Cornell Medical Index Health Questionnaire (CMI)
2. physical and anthropometric measurements
3. dental examination
4. eye examination
5. cardiac function tests, including an electroencephalo-gram (EKG)
6. a glucose tolerance test (GTT)
7. a panel of 50 blood chemistries

8. a comprehensive study of each subject's diet, including a study of food intake over a 7-day period.

Their study attempted to find evidence that there may exist an "ideal" diet consisting of micronutrients, carbohydrates, protein, and fat which could contribute to health and longevity. The hypothesis of the study concluded that relatively symptomless and disease-free individuals are healthier than those with clinical symptoms and signs and that this difference was due to the intake of nutrients from the diet and/or dietary supplementation.

Findings

Cheraskin & Ringsdorf's 15 year study of 13,500 subjects found that the healthiest individuals, meaning those with the least clinical symptoms and signs, were those who had consumed dietary supplements and eaten a diet nutritionally dense in nutrients relative to their caloric intake.

Nutritionally, density of the diet proved to be a key variable among the healthiest subjects. For example, Cheraskin & Ringsdorf discovered that the "healthiest" subjects had a mean vitamin C intake of 410 mg a day, a good portion of which was consumed from food. The finding of a vitamin C intake above 400 mg a day is particularly interesting in light of anthropological evidence of vitamin C intake in pre-agricultural diets. One study found that humans living prior to the dawn of agriculture (<10,000 BC) consumed approximately 392 mg of vitamin C a day, well above the 60 mg suggested by the RDAs.

This represents only a 4% difference in daily vitamin C intake between humans living many generations apart!

Equally intriguing is continuing evidence to suggest that the incidence of cancer and other chronic diseases of modern civilization is relatively rare in ancestral humans who lived prior to the advent of agriculture. Could the higher intake of vitamin C and other nutrients in primitive diets be related to the lower incidence of such chronic degenerative diseases? This is a question that may take years to be resolved, but it does warrant further inspection.

Epidemiologic evidence of a protective effect of vitamin C for non-hormone-dependent cancers is strong, according to a 1991 National Cancer Institute report. Of the 46 studies in which dietary vitamin C was calculated, 33 found statistically significant protection against cancer, with the highest vitamin C intake conferring the most protection. Of 29 additional studies that assessed fruit intake, 21 found significant protection. For cancers of the esophagus, larynx, oral cavity, and pancreas, evidence for a protective effect of vitamin C or some component in fruit (e.g. bioflavonoids and carotenoids) remains strong and consistent. For cancers of the stomach, rectum,

breast, and cervix there is also strong evidence of a protective effect against cancer. Several recent lung cancer studies have found significant protective effects of vitamin C. Therefore, the concept of an “ideal” or suggested recommended optimum nutrient intake (RONI) of 410 mg/day of vitamin C or more may not be out of line, even though it is more than four times higher than the RDA.

The evidence in support of vitamin C at higher intake levels, along that with many similar findings for other nutrients, such as selenium, suggests that the RDAs may represent the nutritional equivalent of the minimum wage. Clearly, there is a profound need for a new paradigm to replace the minimalistic and outmoded RDAs.

RONIs present estimates of vitamin and mineral intake levels that may reduce the risk of conditions and diseases that impair our ability to function or increase our risk of illness.

RONIs survey questionnaire

The following questions can serve as a guideline to determine if higher nutrient requirements than the RDAs are warranted for an individual.

If the patient answers yes to any of the 16 items listed below, the RONIs that follow in the next section for each vitamin and mineral may be of benefit in determining a reasonable and safe daily intake of the respective nutrient. The asterisk (*) following any question indicates that there currently exists reasonable scientific evidence to support a nutrient intake of certain vitamins and minerals well above the RDAs:

1. Are you under chronic emotional stress?*
2. Do you have frequent colds and flus (more than three/year)?*
3. Do you wish to reduce your risk of developing cardiovascular disease?*
4. Do you wish to reduce your risk of developing cancer?*
5. Do you wish to reduce your risk of developing osteoporosis?*
6. Do you wish to reduce your risk of developing macular degeneration of the eye?*
7. Do you have skin problems?*
8. Do you smoke cigarettes?*
9. Are you regularly exposed to side-stream smoke at home or work?*
10. Do you frequently drink alcohol?*
11. Do you take birth control pills?*
12. Are you pregnant?*
13. Are you over the age of 50?*
14. Are you postmenopausal?*
15. Do you exercise more than three times a week for 1 hour at a time?
16. Is the air you breathe polluted?*

THE RONIs

The following sections discuss each nutrient for which a RONI could be determined based on existing scientific evidence. The format for each nutrient is identical, allowing

you to contrast the RDA with the RONI for that nutrient. RONIs are divided by gender and age along the same parameters as the RDAs for easy comparison. The recommendations made are based on the median weight and height for each designated age group, as listed in [Table 108.2](#) . If the patient's height and weight are significantly higher or lower than the figures found for the age group, adjust accordingly.

TABLE 108-2 -- Median weight and height for US population of designated age

| Category | Age (years) | Weight (lb) | Height (in) |
|----------|-------------|-------------|-------------|
| Males | 15–18 | 145 | 69 |
| | 19–24 | 160 | 70 |
| | 25–50 | 174 | 70 |
| | 51+ | 170 | 68 |
| Females | 11–14 | 101 | 62 |
| | 15–18 | 120 | 64 |
| | 19–24 | 128 | 65 |
| | 25–50 | 138 | 64 |
| | 51+ | 143 | 63 |

The nutrients discussed in the following sections are divided into three nutrient classifications in alphabetical order ([Table 108.3](#)). A comprehensive list of references for each nutrient is found in the reference section under the nutrient of interest.

Fat-soluble vitamins

Vitamin A (see [Table 108.4](#))

Vitamin A is required for reproduction, embryonic development, the maintenance of epithelial tissue (i.e. skin, lung, vagina, uterus, gastrointestinal tract), cell differentiation, and vision. It may be important in cancer prevention and treatment of precancerous conditions. Illness, and particularly febrile conditions and lipid malabsorption, can markedly increase vitamin A requirements.

TABLE 108-3 -- Vitamin and mineral comparisons between RDAs and RONIs

Fat soluble vitamins

- Vitamin A/beta-carotene

• Vitamin D

• Vitamin E

• Vitamin K

Water-soluble vitamins

• Ascorbic acid (vitamin C)

• Cyanocobalamin (vitamin B₁₂)

• Folic acid

• Niacin/niacinamide (vitamin B₃)

• Pyridoxine (vitamin B₆)

• Riboflavin (vitamin B₂)

• Thiamin (vitamin B₁)

Minerals

• Boron

• Calcium

• Chromium

• Copper

• Iodine

• Iron

• Magnesium

• Manganese

• Phosphorous

• Potassium

• Selenium

• Sodium

• Zinc

TABLE 108-4 -- Vitamin A (µg RE)

| Category | Age | RDA | Optimal |
|----------|-----|-----|---------|
|----------|-----|-----|---------|

| | | | |
|---------|-------|-------|-------|
| Males | 11–14 | 1,000 | 1,000 |
| | 15–18 | 1,000 | 1,000 |
| | 19–24 | 1,000 | 2,000 |
| | 25–50 | 1,000 | 2,000 |
| | 51+ | 1,000 | 2,000 |
| Females | 11–14 | 800 | 800 |
| | 15–18 | 800 | 800 |
| | 19–24 | 800 | 2,000 |
| | 25–50 | 800 | 2,000 |
| | 51+ | 800 | 2,000 |

Excessive intake of vitamin A, but not of the provitamin A carotenoids, can cause toxicity, the most serious of which are birth defects. Hence, women of child-bearing age should show prudence in taking excessive amounts of vitamin A without the advice of a health practitioner. Pregnant women should preferentially ingest foods rich in carotenoids or consume a mixed carotene supplement to ensure adequate vitamin A supplies, given the role of vitamin A in cell differentiation.

Vitamin A toxicity in adults is uncommon at doses below 100,000 IU/day. If toxicity does develop, symptoms disappear within a short period of time after reduction of intake.

Beta-carotene (see [Table 108.5](#))

Beta-carotene is a source of vitamin A, since it is the most nutritionally active vitamin A precursor among carotenoids. Beta-carotene is also referred to as a “provitamin” since it converts to vitamin A in the body. Of the nearly 600 carotenoids which have been identified in natural sources, less than 50 are vitamin A precursors such as beta-carotene. Animal studies have shown that beta-carotene is not mutagenic, teratogenic, embryotoxic, or carcinogenic, nor does it cause hypervitaminosis A (vitamin A toxicity).

TABLE 108-5 -- Beta-carotene (mg)

| Category | Age | RDA | Optimal |
|----------|-------|-----|---------|

n/a, not available.

Retinol equivalents: 1 retinol equivalent = 1 µg retinol or 6 µg beta-carotene.

Beta-carotene and its related carotenoids protect against various cancers and can enhance cancer resistance directly as an antimutagen and anticarcinogen and indirectly as an antioxidant, reducing cell damage. In particular, increased beta-carotene levels seem to decrease the risk of developing lung cancer, important information for cigarette smokers or those regularly exposed to side-stream smoke. Individuals with low intakes of beta-carotene have a 30–220% higher risk of developing lung cancer than those with a high intake of this nutrient. A 12 year study of almost 3,000 men living in Switzerland found an association between low blood levels of vitamin A and beta-carotene and increased risk of lung cancer and death from all cancers. Men with low carotene levels had nearly twice the risk of developing lung cancer, as compared with men with normal levels, and nearly 3.5 times the risk of stomach cancer.

Beta-carotene also has non-vitamin A functions based on its ability to act as an antioxidant by scavenging free radicals. For example, carotenoids protect against the damage from excessive ultraviolet exposure that can lead to UV-related tissue damage and skin cancer.

Vitamin D (see [Table 108.6](#))

Vitamin D is a prohormone classified as a vitamin. It is important for bone maintenance and the metabolism and absorption of phosphorous and calcium, while also contributing to the functioning of the reproductive system, the digestive system, and the immune system.

Vegetarians, the elderly, and individuals receiving limited exposure to sunlight ultraviolet, may be at risk of inadequate vitamin D levels. The elderly may be at particular risk of poor vitamin D status due to:

- decreased exposure to sunlight
- decreased intake of vitamin D fortified foods
- decreased absorption of the nutrient in the gastrointestinal tract

- decreased caloric intake.

TABLE 108-6 -- Vitamin D*

| Category | Age | RDA | Optimal |
|-----------------|------------|------------|----------------|
| Males | 11–14 | 10 | 10 |
| | 15–18 | 10 | 10 |
| | 19–24 | 10 | 12 |
| | 25–50 | 5 | 20 |
| | 51+ | 5 | 24 |

| | 15–18 | 10 | 12 |
| | 19–24 | 10 | 12 |
| | 25–50 | 5 | 18 |
| | 51+ | 5 | 22 |

10 µg cholecalciferol = 400 IU of vitamin D.

* As cholecalciferol.

The skin of elderly individuals also produces approximately half the vitamin D after exposure to the sun as produced by a young person.

Good vitamin D status may be associated with reduced risk of hypertension while also playing a role in regulating blood pressure. There is epidemiological evidence, including one very large study of US Navy personnel, that adequate vitamin D levels may decrease the chance of developing certain lethal skin melanomas (skin cancers) in adults with occupations and lifestyles that prevent regular exposure to sunlight for up to 15 minutes a day.

There is also increasing evidence that vitamin D combined with calcium might reduce the number of colorectal tumors. This is an important finding given the increasing incidence of colon cancer. Although those studying this phenomena conclude that optimal intake of calcium and vitamin D reduces colon cancer risk, they are unable as yet to explain the mechanism for this protective effect.

Vitamin D can be toxic at prolonged (several months) high intakes. No adverse effects, however, have been reported in healthy adults who have consumed up to 62 times the RDA of this nutrient. Since vitamin D has been shown to be teratogenic in animals, a pregnant, or potentially pregnant woman, should take vitamin D supplements with

caution.

Sunlight ultraviolet exposure on the skin promotes vitamin D production. It is important to note that this process is self-limiting and will not cause vitamin D toxicity (hypervitaminosis D) in healthy people.

Vitamin E (tocopherols and tocotrienols) (see [Table 108.7](#))

Vitamin E is essential to all mammals. The term vitamin E applies to a family of eight related compounds, the tocopherols and the tocotrienols. The four major forms of vitamin E are designated alpha, beta, delta, and gamma. The tocotrienols are less widely distributed in nature than the tocopherols. Tocotrienols are less biologically active than the tocopherols.

TABLE 108-7 -- Vitamin E (mg tocopherol)

| Category | Age | RDA | Optimal |
|----------|-------|-----|---------|
| Males | 11–14 | 10 | 70 |
| | 15–18 | 10 | 100 |
| | 19–24 | 10 | 400 |
| | 25–50 | 10 | 400 |
| | 51+ | 10 | 800 |
| Females | 11–14 | 8 | 70 |
| | 15–18 | 8 | 90 |
| | 19–24 | 8 | 400 |
| | 25–50 | 8 | 400 |
| | 51+ | 8 | 800 |

Alpha-tocopherol equivalents: 1 mg D-alpha tocopherol = 1 IU alpha-tocopherol.

One of the most important functions of vitamin E is to protect living cell membranes from damage by oxygen free radicals, a process known as “oxidative damage”. By reacting with a free radical, the tocopherol molecule is converted into the tocopheroxyl radical, which can then be reduced back to harmless tocopherol by either vitamin C or glutathione. Any deficiency of this vitamin can affect the life span of red blood cells.

Vitamin E plays a role in preventing mutagenesis, in the repair of membranes and DNA, and in maintenance of immunocompetence, especially as it relates to normal

T-lymphocyte function.

Many studies have found that the incidence of various cancers is higher in individuals with low levels of vitamin E. Evidence to date is strong that a low intake of vitamin E is a risk factor for cancer in many, but not all, organs. The expression of its protective effect may depend on the primary causes, which vary. This is particularly important for smokers or those exposed to cigarette smoke, since vitamin E is a respiratory tract antioxidant. There is evidence that vitamin E inhibits platelet aggregation, thereby reducing the risk of developing blood clots that can potentially lead to myocardial infarcts or stroke.

Immunity and infection resistance have been shown to be enhanced by vitamin E supplementation in elderly people. Adequate vitamin E levels may also protect against cataract development. In one study, vitamin E supplementation reduced the risk of cataracts by more than 50% compared with those not supplemented. The benefit of vitamin E supplementation is unclear for both recreational exercisers and high-intensity athletes. However, vitamin E may play an important role in preventing exercise-induced muscle injury.

Although vitamin E is required throughout an individual's life span, its levels decline with aging, probably due to lowered caloric intake or poor food choices.

In general, high intake of vitamin E seems very safe. Very few side-effects have been reported in any scientifically controlled studies, with intakes as high as 3,200 mg (3,200 IU). Vitamin E supplementation is not, however, recommended for individuals receiving anticoagulant therapy who may also be vitamin K-deficient. The suggested optimal levels are for natural vitamin E (D-alpha tocopherol, D-alpha tocopheryl acetate or D-alpha tocopheryl succinate). All forms of natural vitamin E become active antioxidants (free radical scavengers) inside the body. The synthetic forms of vitamin E have the DL-designations in front of the form provided.

Vitamin K (phylloquinone) (see [Table 108.8](#))

Vitamin K is found in food and created by bacteria in normal intestines. Phylloquinone is the natural form of the vitamin and the primary dietary source of vitamin K.

TABLE 108-8 -- Vitamin K (mg)

| Category | Age | RDA | Optimal |
|----------|-------|-----|---------|
| Males | 11–14 | 45 | 45 |
| | 15–18 | 65 | 65 |
| | 19–24 | 70 | 70 |
| | 25–50 | 80 | 80 |
| | 51+ | 80 | 80 |

| | | | |
|---------|-------|----|----|
| Females | 11–14 | 45 | 45 |
| | 15–18 | 55 | 55 |
| | 19–24 | 60 | 60 |
| | 25–50 | 65 | 65 |
| | 51+ | 65 | 65 |

Vitamin K’s primary function is in the production of blood clots and skeletal health. There is also growing evidence that vitamin K plays a role in bone development, especially loss of bone mass in postmenopausal osteoporosis.

A normal mixed diet contains 300–500 µg/day of vitamin K, well in excess of the RDA. The RDA recommends a daily intake of 1 µg/kg body weight of phylloquinone for adults and children. There is no known toxicity association with the administration of high doses of phylloquinone.

There is insufficient evidence to support supplemental intake of vitamin K beyond that found in most diets, except possibly in postmenopausal women and in women suffering from menorrhagia.

Water-soluble vitamins

Ascorbic acid (vitamin C) (see [Table 108.9](#))

Adequate vitamin C (ascorbic acid) intake is necessary for immunity, maintenance of bones, formation of collagen, and a broad range of other biologic functions.

In a study which measured the vitamin C intake of

TABLE 108-9 -- Vitamin C (mg)

| Category | Age | RDA | Optimal |
|----------|-------|-----|---------|
| Males | 11–14 | 50 | 150 |
| | 15–18 | 60 | 200 |
| | 19–24 | 60 | 200 |
| | 25–50 | 60 | 400 |
| | 51+ | 60 | 800 |

| | | | |
|---------|-------|----|------|
| Females | 11–14 | 50 | 150 |
| | 15–18 | 60 | 200 |
| | 19–24 | 60 | 200 |
| | 25–50 | 60 | 400 |
| | 51+ | 60 | 1000 |

A new RDA for adults for vitamin C of 200 mg/day has been suggested, following US Department of Agriculture and National Cancer Institute recommendations for fruit and vegetable consumption that results in vitamin C intakes of greater than 210 mg/day.

1,038 doctors and their wives, those with the fewest signs and symptoms of illness or degenerative diseases consumed an average of 410 mg/day of vitamin C, about nine times the RDA. To achieve this level of intake usually requires supplementation. Cigarette smoking is associated with a significant decrease in vitamin C levels. For a typical smoker to attain the same vitamin C level as a non-smoker consumption of three to four times as much vitamin C is required. Alcoholics also have low vitamin C status, and may require considerably more vitamin C due to their condition. The elderly may especially benefit from vitamin C supplementation. Increased lipid (fat) peroxidation has been associated with accelerated aging and degeneration. One study demonstrated that supplementation over a 1 year period with vitamin C at levels much higher than the RDA significantly decreased lipid peroxide levels in elderly subjects.

Research suggests that vitamin C may decrease the risk of developing cataracts, cancers of the gastrointestinal tract, and cardiovascular disease. In a 12 year study of 3,000 men living in Switzerland, those with low blood levels of vitamin C had an increased risk of stomach and intestinal cancer. For people over 60, low vitamin C levels were associated with nearly a threefold increased risk of developing stomach cancer and twice the risk for intestinal cancer. The interest in vitamin C in the treatment of cancer is partially based on studies showing significantly reduced levels in patients with malignancies. Most evidence suggests that larger than RDA doses of vitamin C may be beneficial in reducing the risk of developing various cancers, rather than treating them. This may be due to the higher levels of vitamin C improving certain indices of immune competence and response that boost disease resistance.

High dietary intake of vitamin C has been reported to be associated with low death rates from cerebrovascular and cardiovascular diseases. A cohort study of 11,348 non-institutionalized US adults found that women and men with the highest vitamin C intake and regular vitamin C supplements had a 25 and 42% decrease in cardiovascular mortality, respectively. Vitamin C supplementation may reduce the risk of cardiovascular mortality by influencing cholesterol levels, platelets, and even blood pressure.

Since the levels of vitamin C decline with age after mid-life, there is evidence that suboptimal levels of vitamin C may increase the risk of cataracts. Those individuals who

consume the lowest levels of vitamin C seem to have the highest incidence of cataractous lenses. One study has shown that those subjects who supplemented with vitamin C significantly lowered their risk of developing cataracts.

Vitamin C markedly increases non-heme iron absorption. In some diets, only 3% of non-heme iron is absorbed compared with as much as 23% of the heme iron form. The addition of 50–100 mg of vitamin C with meals can double or triple non-heme iron absorption. Two grams (2,000 mg) of vitamin C taken throughout the day with meals increases the absorption of non-heme iron fivefold.

Bone density and vitamin C status decline after age 35. Vitamin C is an important nutrient in bone metabolism, especially in the synthesis of collagen which forms the structural framework of bones. A number of studies show that vitamin C supplementation results in improved maintenance of bone mineral density in postmenopausal women. Studies have also shown reductions in healing time of wounds with high-dose vitamin C supplementation.

Vitamin C taken at optimal ranges is virtually free of any known or observed side-effects. Doses of greater than 500 mg/day may increase urinary oxalate kidney stones in patients with a prior history of oxalate kidney stones, although this continues to be contested by conflicting evidence. Doses in excess of 1,000 mg at a time have been known to cause diarrhea (bowel tolerance), hyperuricosuria and hyperoxaluria in healthy individuals. There is also evidence that doses as high as 10,000 mg/day have no adverse side-effects.

Cyanocobalamin (vitamin B₁₂) (see [Table 108.10](#))

Vitamin B₁₂ is synthesized by bacteria and found in virtually all animals, but rarely in any plant foodstuffs. Vitamin B₁₂ is essential for the functioning of the central nervous system and a number of enzymes involved in amino acid, nucleic acid, and fatty acid metabolism. It is also necessary in the metabolism of folic acid (folate), which is essential for thymidine, and thus DNA, synthesis.

Vitamin B₁₂ deficiency is common among the elderly, due to lack of gastric intrinsic factor. This often results in neurological, cerebral, and psychiatric abnormalities. In such cases an injectable form of vitamin B₁₂ has proven superior to oral vitamin B₁₂ supplement. However, there is growing evidence that oral vitamin B₁₂ (cyanocobalamin) is a completely safe alternative to vitamin B₁₂ injections. One study has found that some individuals with gastric disease who poorly absorb vitamin B₁₂ from food can absorb crystalline supplement form. Some experts have

TABLE 108-10 -- Vitamin B₁₂ (Cyanacobalamin) (µg)

| Category | Age | RDA | Optimal |
|----------|-----|-----|---------|
|----------|-----|-----|---------|

| | | | |
|---------|-------|-----|-----|
| Males | 11–14 | 2.0 | 2.0 |
| | 15–18 | 2.0 | 2.0 |
| | 19–24 | 2.0 | 2.0 |
| | 25–50 | 2.0 | 2.0 |
| | 51+ | 2.0 | 3.0 |
| Females | 11–14 | 2.0 | 2.0 |
| | 15–18 | 2.0 | 2.0 |
| | 19–24 | 2.0 | 2.0 |
| | 25–50 | 2.0 | 2.0 |
| | 51+ | 2.0 | 3.0 |

argued that the only legitimate need for vitamin B₁₂ supplementation is in patients with a congenital defect of vitamin B₁₂ metabolism, such as vitamin B₁₂-responsive methylmalonic acidemia.

Vitamin B₁₂ deficiency is more likely in very strict vegetarians, since the best sources of vitamin B₁₂ are meat and meat products and, to a lesser extent, milk and milk products, some seafoods, and egg yolk.

There is increasing evidence that vitamin B₁₂ may play a role in the prevention of some types of cancers. Smokers, for example, have been found to have significantly decreased levels of precancerous bronchial squamous metaplasia when given vitamin B₁₂ (500 µg/day) and folic acid supplements as compared to those receiving placebo. Although there is increasing evidence that vitamin B₁₂ may reduce one risk factor for arteriosclerosis, the accumulation of homocysteine (homocysteinemia), the actual risk reduction has not been definitively determined.

There is insufficient evidence to advocate an intake of vitamin B₁₂ above the RDA in any population group, except in the elderly, or when there exists evidence of pernicious anemia. In the case of pernicious anemia, vitamin B₁₂ injections (parenteral cobalamin) or weekly oral doses of 1,000 µg is suggested. However, during such treatment, care should be given to not take large amounts of folic acid, since this may mask the nerve damage associated with vitamin B₁₂ deficiency.

Vitamin B₁₂ is not carcinogenic, teratogenic, or mutagenic. It is considered safe even at

1,000 times the RDA.

Folic acid (pteroylglutamic acid) (see [Table 108.11](#))

Recognition of the critical importance of folate for maintaining health is growing. It is essential not only in preventing the vitamin-related anemia, but in four dreaded conditions: heart disease, cancer, stroke, and neural tube defects.

Folic acid is required in the metabolism of some amino acids, for the synthesis of nucleic acids, and in a number of enzyme cofactors. Certain population groups are at particular risk of developing folate deficiency, especially pregnant women and adolescent females. Like newborn

TABLE 108-11 -- Folic acid (folate) (μg)

| Category | Age | RDA | Optimal |
|----------|-------|-----|---------|
| Males | 11–14 | 150 | 500 |
| | 15–18 | 200 | 750 |
| | 19–24 | 200 | 1,000 |
| | 25–50 | 200 | 2,000 |
| | 51+ | 200 | 2,000 |
| Females | 11–14 | 150 | 500 |
| | 15–18 | 180 | 750 |
| | 19–24 | 180 | 1,000 |
| | 25–50 | 180 | 1,000 |
| | 51+ | 180 | 2,000 |

infants, which are also at risk, these groups experience considerable growth, confirming the importance of folic acid in protein synthesis and the DNA and RNA replication required in cell growth. Inadequate folic acid is also seen in the elderly, where it is less well absorbed.

Since folic acid deficiency is a well-documented cause of birth defects in animals, numerous studies have looked at its role in such human congenital malformations as neural tube defects, cleft palate, and cleft lip. Folic acid and multivitamin supplementation have been demonstrated in numerous studies to decrease or eliminate the recurrence of neural tube defects or cleft palate/cleft lip in human offspring.

Folic acid may also reduce a risk factor associated with atherosclerosis. Folic acid is required for the conversion of homocysteine to methionine. A deficiency of folic acid is associated with elevated homocysteine (homocystinemia), which is a risk factor for atherosclerosis. Normal subjects given 5 mg/day of folic acid for 2 weeks had significant decreases in homocysteine levels, especially in those whose initial homocysteine levels

were high. There is also mounting evidence that smokers and heavy coffee drinkers require a higher intake of folic acid.

Folate is required for critical brain metabolic functions. Low folate levels have been implicated in poorer antidepressant response to selective serotonin reuptake inhibitors. Borderline to deficient serum or red blood cell folate levels have been detected in from 15 to 38% of adults diagnosed with depressive disorders.

Folic acid supplementation in healthy adults is safe even at high levels of intake, although such supplementation can mask clinical signs of pernicious anemia, which if left untreated can lead to permanent nerve damage. There is also some continuing controversy about whether folic acid supplementation of 400 µg or more reduces zinc absorption. To be on the safe side, until additional studies are completed, an optimal level of zinc intake is suggested.

Niacin (nicotinic acid) and (niacinamide) nicotinamide (see [Table 108.12](#))

Niacin is the generic descriptor for nicotinic acid (pyridine-3-carboxylic acid) and derivatives exhibiting biological activity of nicotinamide (nicotinic acid amide). Niacin is critical in many biochemical processes, particularly those involving energy metabolism and lipid metabolism. Niacin is a vitamin whose requirements in humans is met in part by conversion of the essential amino acid tryptophan to niacin. Several studies have calculated that 39–86 mg of tryptophan produce the same levels of niacin metabolites as does 1 mg of niacin. For this reason the convention is to consider 1 mg of niacin as equivalent to 60 mg of tryptophan. Because most proteins contain at least 1–2% tryptophan, it is possible to maintain adequate

TABLE 108-12 -- Niacin (mg)

| Category | Age | RDA | Optimal |
|----------|-------|-----|---------|
| Males | 11–14 | 17 | 25 |
| | 15–18 | 20 | 30 |
| | 19–24 | 19 | 30 |
| | 25–50 | 19 | 30 |
| | 51+ | 15 | 30 |

| | | | |
|---------|-------|----|----|
| Females | 11–14 | 15 | 25 |
| | 15–18 | 15 | 25 |
| | 19–24 | 15 | 25 |
| | 25–50 | 15 | 25 |
| | 51+ | 15 | 25 |

1 niacin equivalent = 1 mg niacin or 60 mg dietary tryptophan.

niacin status on a diet relatively devoid of niacin but containing at least 100 g/day of protein.

Its use as a drug-like agent that lowers low-density lipoprotein (LDL) and very low-density lipoprotein (VLDL) cholesterol and triglycerides, while increasing high-density lipoprotein (HDL) cholesterol has generated much interest. Nicotinic acid given in doses of 1.5–3.0 g/day has been shown to decrease total and LDL cholesterol and to increase HDL cholesterol concentrations. There is also interest in its notorious, but not harmful, vasodilatory or “flushing” effect in increasing blood flow to the extremities in certain circulatory disorders. This effect comes only from the nicotinic acid form, not from the amide. There is no evidence that levels above twice the RDA for niacin in healthy persons prevent disorders associated with high cholesterol (hypercholesterolemia) or other hyperlipidemias.

The only evidence for a significantly higher intake of niacin above the RDA in healthy asymptomatic individuals comes from the prospective study of Cheraskin & Ringsdorf discussed earlier in the introduction. In this study it was found that those individuals with the least number of signs and symptoms associated with physical illness or degeneration were consuming an average of 115 mg of niacin a day, or approximately six or seven times the RDA. A single study is inadequate, however, to suggest this amount is optimal; additional studies are needed.

Because nicotinic acid can increase blood sugar levels, nicotinic acid supplementation is contraindicated in diabetics. Also, large intakes of nicotinic acid (>1,000 mg) have been associated with stomach pain, diarrhea, cardiac arrhythmias, itching, and nausea. These side-effects have, however, have not been observed in humans supplementing with the esterified form of vitamin B₃ (inositol hexaniacinate).

Vitamin B₆ (pyridoxine, pyridoxal, pyridoxal 5' phosphate, pyridoxamine, and corresponding phosphorylated forms) (see [Table 108.13](#))

Vitamin B₆ is a group of nitrogen-containing compounds

TABLE 108-13 -- Pyridoxine (mg)

| Category | Age | RDA | Optimal |
|----------|-----|-----|---------|
|----------|-----|-----|---------|

| | | | |
|---------|-------|-----|------|
| Males | 11–14 | 1.7 | 2.0 |
| | 15–18 | 2.0 | 5.0 |
| | 19–24 | 2.0 | 10.0 |
| | 25–50 | 2.0 | 10.0 |
| | 51+ | 2.0 | 25.0 |
| Females | 11–14 | 1.4 | 2.0 |
| | 15–18 | 1.5 | 5.0 |
| | 19–24 | 1.6 | 10.0 |
| | 25–50 | 1.6 | 10.0 |
| | 51+ | 1.6 | 20.0 |

that occur naturally in three primary forms: pyridoxine, pyridoxal, and pyridoxamine.

Vitamin B₆ is required for growth and maintenance of almost every bodily function, amino acid metabolism, and production of neurotransmitters derived from amino acids. It also plays a role in glycogen breakdown, fatty acid metabolism, hormone metabolism, heme biosynthesis, and purine biosynthesis. Studies in humans indicate that the bioavailability of vitamin B₆ from natural sources is limited. In food, B vitamin levels vary. Vitamin B₆ levels in whole wheat bread and peanut butter are, respectively, 75 and 63% as available as that in tuna.

Supplementation of vitamin B₆ has been used in treating carpal tunnel syndrome, premenstrual syndrome (PMS), cardiovascular disorders, and diabetic neuropathy. Elderly people may have an increased requirement for vitamin B₆ to maintain health, particularly for their immune system. In one study, healthy elderly people were given either 50 mg/day of vitamin B₆ or placebo. Those supplemented had significant improvement in immunocompetence, especially lymphocytic activity.

There is preliminary evidence that inadequate vitamin B₆ status may contribute to the development of coronary heart disease by increasing plasma homocysteine. Homocysteine has been found to be highly atherogenic in animals and may contribute to atherosclerosis in humans. Added evidence that vitamin B₆ might be important in preventing cardiovascular diseases comes from experimental studies in animals. When these animals are given vitamin B₆-deficient diets, they develop atherosclerotic lesions similar to those found in human atherosclerosis.

While there is increasing evidence for a role in vitamin B₆ supplementation in preventing some kinds of cardiovascular diseases, and for enhancing immunity, optimal levels in healthy individuals need not exceed 12–15 times the RDA, even in the elderly.

Supplementation of vitamin B₆ up to 250 mg/day is safe for most individuals.

Very high doses of vitamin B₆ have been associated with sensory and motor impairment. Daily intakes up to 500 mg/day, which is 250 times the RDA, for up to 6 months appear to be safe. Supplements of pyridoxal 5' phosphate may be preferred over pyridoxine hydrochloric

acid supplements in individuals wishing to avoid any reversible side-effects from vitamin B₆ supplementation.

Riboflavin (vitamin B₂) (see [Table 108.14](#))

Riboflavin is a precursor of two coenzymes (riboflavin-5'-phosphate and flavin mononucleotide) needed for a wide variety of enzymes in intermediary metabolism. Riboflavin is also required as a precursor of several flavoenzymes that are needed by tissue proteins.

The need for riboflavin varies with energy requirements, explaining why riboflavin-deficient people tire easily and have a poor appetite. Riboflavin is especially important for tissue repair, vision, and blood.

There is growing evidence that riboflavin may be important in preventing the development of cataracts, commonly associated with aging. There is equivocal evidence that riboflavin supplementation may be required in those exercising regularly. This may be more of a consideration if the exerciser is on a calorie-restrictive diet.

Significantly higher than RNI or RDA levels of riboflavin have been employed in migraine prophylaxis with promising results. In one open pilot trial involving 25 patients with a history of migraine related to the syndrome of mitochondrial encephalomyopathy, lactic acidosis, or stroke-like episodes (MELAS), 400 mg/day of riboflavin was given as a prophylactic treatment for migraine. 68% of patients reported improvement on an index of severity. A second randomized, placebo-controlled trial involving 55 patients with similar migraines resulted in a reported 50% improvement among those receiving riboflavin versus a 15% response in the placebo group. It is theorized that riboflavin may in some migraine patients correct a mitochondrial dysfunction resulting from impaired oxygen metabolism. Therefore, the use of riboflavin at significantly higher than RNI levels may suggest that in this and other conditions, the RNI for riboflavin may be inadequate to meet metabolic needs essential in overcoming the pathogenic condition.

Evidence is building for a role for riboflavin as an antioxidant, due to its role as a precursor for glutathione

TABLE 108-14 -- Riboflavin (mg)

| Category | Age | RDA | Optimal |
|----------|-------|-----|---------|
| Males | 11–14 | 1.5 | 2.0 |
| | 15–18 | 1.8 | 2.2 |
| | 19–24 | 1.7 | 2.5 |
| | 25–50 | 1.7 | 2.5 |
| | 51+ | 1.4 | 2.5 |
| Females | 11–14 | 1.3 | 1.8 |
| | 15–18 | 1.3 | 1.8 |
| | 19–24 | 1.3 | 2.0 |
| | 25–50 | 1.3 | 2.0 |
| | 51+ | 1.2 | 2.0 |

reductase. A number of studies have demonstrated that certain vitamins, particularly riboflavin and retinol and their derivatives, have the ability to modify molecular reactivity and response to carcinogens. Dietary riboflavin has such an important role. The mechanism of action is through controlling the induction of repair enzymes (poly(ADP-ribose) polymerase, DNA polymerase beta and DNA ligase) responsive to carcinogens that cause damage to DNA. Studies have shown that DNA damage increases proportionate to a deficiency of riboflavin and that increased damage to DNA is reversed via riboflavin supplementation.

Riboflavin has no known toxicity, although its theoretical photosensitizing properties raise the possibility of potential risk. The basis for this concern is that riboflavin forms an adduct with tryptophan which increases its rate of photo-oxidation. There is insufficient evidence to support riboflavin supplementation in healthy adults above twice the RDA.

Thiamin (vitamin B₁) (see [Table 108.15](#))

Thiamin consists of one pyrimidine and one thiazole ring linked by a methylene bridge. This is important to know because many processed foods are rich in sulfites which split the thiamine molecule into the pyrimidine and thiazole moieties, thus destroying its biological activity.

In a study of 1,009 dentists and their wives evaluated for daily thiamin intake, those subjects having the least number of signs or symptoms associated with illness or degenerative diseases consumed an average of 9 mg/day of thiamin, approximately eight times the RDA for this nutrient.

There is insufficient evidence to suggest intakes of thiamin above eight times the RDA in healthy persons. However, individuals regularly consuming high intakes of refined carbohydrates (i.e. refined sugar-sucrose, wheat flour products made with unfortified 70% extraction flour) may require supplemental intake of thiamin in the range of 5–15

mg/day until such time as the diet improves.

Manifestations of thiamin deficiency (beri-beri) can be induced by chronic alcoholism.

TABLE 108-15 -- Thiamin (mg)

| Category | Age | RDA | Optimal |
|----------|-------|-----|---------|
| Males | 11–14 | 1.3 | 3.3 |
| | 15–18 | 1.5 | 3.5 |
| | 19–24 | 1.5 | 3.5 |
| | 25–50 | 1.5 | 7.5 |
| | 51+ | 1.2 | 9.2 |
| Females | 11–14 | 1.1 | 3.1 |
| | 15–18 | 1.1 | 3.1 |
| | 19–24 | 1.1 | 3.1 |
| | 25–50 | 1.1 | 7.1 |
| | 51+ | 1.0 | 9.0 |

To date, thiamin, when taken orally, has been reported as harmless in humans, although gastric upset can be experienced at high doses exceeding 100–200 times the RDA.

Minerals

This author has provided an extensive discussion of minerals and trace elements and their role in human health in *Minerals, Trace Elements and Human Health*. Readers interested in this topic are advised to consider this work as a source of information, especially as it relates to non-essential elements, such as aluminum, cadmium, lead, mercury and other potentially toxic elements.

Boron (see [Table 108.16](#))

Boron has only recently been established to be of nutritional significance to humans. An insufficiency manifests only when the body is stressed in some way that enhances the need for boron. Boron is particularly important for optimal calcium, and thus bone metabolism. Most persons eating Westernized diets consume between 0.1 and 0.5 mg/day of boron. Human studies indicate that consuming less than 0.25 mg/day of boron, or less than one-half the estimated average minimum requirement for humans, may require supplementation. Thus an intake of between 1 and 4 mg/day may be

appropriate to contribute to optimal health. There is no evidence to suggest that intakes above 10 mg are either beneficial or completely safe. Boron supplementation affects serum phosphorous and magnesium concentrations in young women and the effect is modified by exercise. Boron affects bone mineral density, along with calcium, phosphorous, and magnesium.

Supplementation of 3 mg/day of boron for postmenopausal women has resulted in improvement in both calcium and magnesium retention and elevation in circulating serum concentrations of testosterone and estrogen (17-beta-estradiol). This improvement is more marked in women who have been on low magnesium diets. Similar improvements might also be found if the women were

TABLE 108-16 -- Boron (mg)

| Category | Age | RDA | Optimal |
|-----------------|------------|------------|----------------|
| Males | 11–14 | n/a | 1.5 |
| | 15–18 | n/a | 2.0 |
| | 19–24 | n/a | 2.5 |
| | 25–50 | n/a | 2.5 |
| | 51+ | n/a | 2.5 |
| Females | 11–14 | n/a | 1.5 |
| | 15–18 | n/a | 2.0 |
| | 19–24 | n/a | 2.5 |
| | 25–50 | n/a | 3.0 |
| | 51+ | n/a | 3.0 |

vitamin D-deficient. There is preliminary evidence based on animal studies that boron has an effect in males on steroidogenesis (e.g. production of testosterone) and testicular function and development proportional to the boron concentration in the testes.

There is increasing interest in the role of boron on brain function. Results in animals and humans indicate that dietary boron influences brain electrical activity. Individuals in a low state of alertness consume less boron (<0.5 mg/day) than those found to be more alert (>3.0 mg/day).

Preliminary evidence in animals has demonstrated that boron may modulate immune function that might be of significance to humans. Adequate boron suppresses inflammatory processes.

There is some evidence that boron (as sodium tetraborate decahydrate) may prevent arthritis in sheep. In a randomized double-blind clinical trial of 20 patients with severe osteoarthritis given either 6 mg of boron or placebo, five improved and five did not, but

only one of the 10 patients on the placebo improved. Boron deficiency in chicks results in a syndrome that resembles human arthritis.

There is evidence from other human studies that optimal intakes of boron can enhance memory and cognitive function. There is also preliminary evidence of an association between sufficient boron intake and resistance to dental caries (tooth decay).

In all human studies to date, patients reported no side-effects when consuming less than 10 mg/day of boron.

Calcium (see [Table 108.17](#))

Calcium is primarily stored in bones (99%), where the ratio of calcium to phosphorous is nearly constant at slightly greater than 2:1. Calcium is involved in numerous vital functions throughout the body, including:

- protein and fat digestion
- energy production
- nerve transmission
- neuromuscular activity
- the absorption of other nutrients, such as vitamin B₁₂.

TABLE 108-17 -- Calcium (mg)

| Category | Age | RDA | Optimal |
|----------|-------|-------|---------|
| Males | 11–14 | 1,200 | 1,000 |
| | 15–18 | 1,200 | 1,000 |
| | 19–24 | 1,200 | 1,000 |
| | 25–50 | 800 | 700 |
| | 51+ | 800 | 700 |

| | 19–24 | 1,200 | 1,200 |
| | 25–50 | 800 | 800 |
| | 51+ | 800 | 800 |

Estimates of adult calcium requirements in humans vary from 300 to 400 mg/day to between 1200 and 1500 mg/day. The lowest requirements are usually seen in

populations with low protein intakes. In general, persons with very low protein intakes require less calcium per day. High levels of protein, which are usually also high in phosphorous, require higher calcium intakes. An increase in protein intake affects urinary calcium and calcium retention. It is recommended that calcium intake be increased during adolescence, pregnancy and lactation.

In recent years, calcium has received considerable attention in the mass media because of age-related osteoporosis, which is occurring in epidemic proportions in many developed countries and has been linked in to calcium intake. Articles and advertisements suggest that high intakes of calcium via supplementation or enrichment of foods/beverages is essential to the development and maintenance of strong, healthy bones. The attention this nutrient has received is most important to women. Women are more prone to osteoporosis than men because of smaller skeletal mass at maturity and because the most rapid period of bone loss occurs after menopause. However, numerous studies do not show a relationship between levels of dietary calcium intake and the incidence of osteoporosis. In the largest prospective scientific study of bone in premenopausal women aged 20–40 years, no relationship could be found between calcium intake and bone mineral density. This is consistent with studies reported since 1985.

When developing or maintaining bone mineral density is a goal, optimal intake of all nutrients essential to bone formation and homeostasis is required. Diet, hormones, age, and gender are just some of the factors that influence calcium requirements and metabolism. Because of these variables and the interrelationships among calcium, protein, phosphorous, magnesium, zinc, vitamin D and boron, etc., it remains difficult to select a single calcium requirement for any age group or gender. Some new supplements incorporating the nutrients required for bone, including hydroxyapatite, have appeared in the marketplace, and may be superior to calcium supplementation alone to ensure adequate nutrient needs of bone.

New studies show that even moderate consumption of calcium in foods or as supplements can reduce both heme and non-heme iron absorption. These reductions could have important nutritional implications, especially for premenstrual and pregnant women who are already at risk for iron deficiency. Therefore, it is advisable that calcium supplements in excess of 250 mg not be consumed with meals.

Chromium (see [Table 108.18](#))

Chromium is a trace element essential to the metabolism of lipids (e.g. cholesterol), glucose, and insulin regulation.

TABLE 108-18 -- Chromium (µg)

| Category | Age | RDA* | Optimal |

| | 51+ | 50–200 | 300 |

* Estimated safe and adequate daily dietary intake of mineral, National Research Council, 1989.

The long-term effects of a suboptimal intake of chromium has been related to:

- a decrease in tissue chromium associated with aging
- an increased incidence of diabetes and atherosclerosis, particularly in developed nations.

Illness, aging, stress (i.e. trauma, surgery, intense heat or cold), and strenuous exercise seem to increase chromium losses or needs.

Studies of humans with heart disease have demonstrated that chromium deficiency is associated with atherosclerosis, suggesting that optimal chromium levels may reduce the risk of heart disease. Tissues of humans who have died of heart disease have been found to have less chromium than tissues of humans who died of accidental causes. In those patients with atherosclerotic plaque who died of heart disease, no detectable chromium was found in these tissues. There is also evidence in humans that a diet sufficient in chromium along with selenium, copper, potassium, magnesium, and calcium reduces the risk of cardiovascular disease, by having a beneficial effect on serum cholesterol and triglyceride levels. Chromium taken with nicotinic acid (niacin) or the chromium supplement, chromium picolinate (200–400 µg/day), has been shown to lower cholesterol levels in individuals with elevated cholesterol.

Traces of chromium have been shown to be required for health as part of the glucose tolerance factor (GTF) involved in the regulation of blood glucose. The brain has high requirements for blood glucose as a fuel. The amount of chromium in foods decreases with processing. The widespread tendency toward increased consumption of highly processed foods, particularly refined sugar, which stimulates urinary losses of chromium, may result in a marginal intake of chromium and depletion of tissue

chromium stores.

The safety of chromium supplementation is well established. Even in pharmacological doses (50–1,000 mg/day for 1–3 months), it has no toxicity in cats, rats or mice.

Copper (see [Table 108.19](#))

Copper is an essential element in the human body. About 95% of copper is found in serum as part of ceruloplasmin. Copper is needed by all tissues, but is highest in the liver where it contributes to energy and detoxification mechanisms. The element is also required to absorb, utilize and synthesize hemoglobin, maintain the integrity of the outer covering of nerves (myelin), metabolize vitamin C, and oxidize fatty acids.

Both excess and deficiency of copper can result in problems such as:

- bone/joint and connective tissue disturbances
- cardiovascular degeneration
- abnormal electrocardiogram
- accelerated aging
- depigmentation and dermatitis
- anemia
- neurological impairments.

There is no evidence of a decline in copper status with age.

Proper balance of copper to zinc (and other trace elements) is necessary for good health. A low ratio of copper to zinc can result from dietary deficiency of copper or excessive zinc intake, and may result in hypercholesterolemia, myocardial and arterial damage, and increased mortality. High levels of serum copper found in humans living in areas with low selenium levels in their soil and high copper content in drinking water have been associated with a significantly elevated incidence of atherosclerosis. The zinc-to-copper ratio, should ideally be between 8:1 and 14:1.

Excess fructose consumption in the presence of inadequate copper intake has been shown in several mammalian species to lead to heart arrhythmias and even heart failure. The level of copper and amount of dietary fructose which results in such cardiovascular problems in humans remain unknown. However, it is known that dietary fructose exacerbates the signs associated with copper deficiency. These signs include anemia, hypercholesterolemia,

TABLE 108-19 -- Copper (mg)

| Category | Age | RDA* | Optimal |
|----------|-----|------|---------|
|----------|-----|------|---------|

| | | | |
|---------|-------|---------|-------|
| Males | 11–14 | 1.5–3.0 | 1.5–4 |
| | 15–18 | 1.5–3.0 | 1.5–4 |
| | 19–24 | 1.5–3.0 | 1.5–4 |
| | 25–50 | 1.5–3.0 | 1.5–4 |
| | 51+ | 1.5–3.0 | 1.5–4 |

| | 15–18 | 1.5–3.0 | 1.5–4 |
| | 19–24 | 1.5–3.0 | 1.5–4 |
| | 25–50 | 1.5–3.0 | 1.5–4 |
| | 51+ | 1.5–3.0 | 1.5–4 |

* Estimated safe and adequate daily dietary intake of mineral, National Research Council, 1989

impaired glucose tolerance, pancreatic atrophy, cardiomyopathy, and increased mortality. Fructose consumption during lactation also produces a significant reduction in copper concentrations in breast milk. Even the homeostasis of hormones is impaired by the consumption of fructose with a low-copper diet, which in animal studies has been shown to decrease levels of plasma thyroid hormones, insulin, epinephrine, norepinephrine, and an increase in the glucocorticoids.

Copper supplementation should be approached with caution since copper is amongst the most powerful producers of free radicals. However, in proper balance with zinc, the two elements act as antioxidants by removing damaging free radicals such as the superoxide radical. Excess copper supplementation suppresses immune function.

Iodine (see [Table 108.20](#))

Iodine accumulates in thyroid tissue and is incorporated into thyroxine and triiodothyronine, the hormones of the thyroid gland. Iodine deficiency is the most common cause of endemic goiter and cretinism. Milk and dairy products, as well as bread and bakery products, are the main source of iodine in human food. Iodine is concentrated in milk and eggs, which are only second to seafood as the richest sources of iodine. Marine (sea) salt is a poor source of iodine. In conjunction with two enzymes (myeloperoxidase and hydrogen peroxide), iodine is known to be bactericidal. This bactericidal activity is accomplished by an abundant cellular halide, the chloride anion.

The RDA for iodine is 2 µg/kg body weight in adults and somewhat more in children. This amount seems optimal to ensure the biosynthesis of the thyroid hormones. An additional 25 and 50 µg may be required during pregnancy and lactation, respectively. The most common supplementation of iodine is via iodized salt, 1 g of which supplies approximately 75 µg of iodine. In the event of a nuclear reactor accident, a single dose of 300 mg of potassium iodide helps to block the uptake of radioactive iodine-131 by the

thyroid.

Iodine in large amounts disturbs all thyroid functions.

TABLE 108-20 -- Iodine (mcg)

| | 25–50 | 150 | 150 |
| | 51+ | 150 | 150 |

Iron (see [Table 108.21](#))

Most iron in the body is found in the hemoglobin of red blood cells. Some iron is also found in the myoglobin present in skeletal muscles and the heart. The remaining iron is found in enzymes essential to energy production.

Iron deficiency is one of the most common deficiency diseases in the world. Even in the US, repeated dietary surveys have found inadequate iron intake to meet even the RDA. The most common cause of this is nutritional, including inadequate absorption of iron due to poor iron intake, reduced bioavailability, etc. Iron loss, resulting from pregnancy, internal bleeding, parasitic infections (e.g. hook worm), low stomach acid (e.g. hypochlorhydria, achlorhydria), and malabsorption, is also an important factor contributing to iron deficiency. There are some data that suggest that iron deficiency anemia may be a secondary outcome of vitamin A deficiency which contributes to defective iron transport. The risk of iron deficiency is relatively high in menstruating women eating a diet inadequate in iron. This is one reason the RDA for iron is higher for women than for men. However, many women are on reduced calorie diets which are unable to provide enough iron and require supplementation.

Non-heme iron is the main source of iron in the diet, although it is much more poorly absorbed than heme iron, which is only found in animal sources. Meat, fish, and vitamin

C enhance the absorption of non-heme iron, improving absorption. However, new studies are showing that even moderate consumption of calcium in foods or as supplements can reduce both heme and non-heme iron absorption. These reductions could have important nutritional implications, especially for those, such as premenstrual women and pregnant women, who may already be at high risk for iron deficiency. Symptoms of iron deficiency anemia include fatigue, irritability, paleness, intolerance to cold, and a general sense of lack of well-being. Brain function can also be impaired due to iron deficiency. Inadequate iron levels tend to affect the right hemisphere of the brain and have been linked to cognitive impairment, poor attention span, restlessness, and the inability of concentrate. Optimal levels of iron are also essential to immune function.

TABLE 108-21 -- Iron (mg)

| | 51+ | 280 | 550 |

Iron supplementation is not safe for individuals with any iron storage disorder such as hemosiderosis, idiopathic hemochromatosis, or thalassemias.

Magnesium (see [Table 108.22](#))

Magnesium, half of which is in the bone, is required for many metabolic functions. One of its most important is in maintaining the function of the nervous system and neuromuscular transmission and activity. Magnesium deficiency is associated with:

- tremors
- muscle spasms
- convulsions
- neuropsychiatric disturbances
- coronary artery disease
- angina pectoris
- cardiac arrhythmias
- hypertension.

Along with calcium, sodium and potassium, magnesium affects the muscle tone of blood vessels.

Blood levels of magnesium are low in patients with myocardial ischemia, coronary artery spasm, mitral valve prolapse, and cardiac tachyarrhythmias. Low tissue and blood levels have also been observed in patients prior to, during and after myocardial infarction. Recent studies have also implicated lack of sufficient magnesium as a cause of pre-eclampsia and hypertension in pregnant women. Magnesium insufficiency directly and indirectly affects cardiac function through its effect on potassium, sodium and calcium concentrations in cells and surrounding fluids. Given that coronary and heart disease contribute profoundly to morbidity and mortality in developed countries, an intake above the RDA level is advocated by researchers who have studied this essential nutrient.

Manganese (see [Table 108.23](#))

Manganese is involved in protein, fat and energy metabolism, and is required for bone growth and development,

TABLE 108-23 -- Manganese (mg)

| Category | Age | RDA* | Optimal |
|----------|-----|------|---------|
|----------|-----|------|---------|

| | | | |
|---------|-------|-----|----|
| Males | 11–14 | 2–5 | 5 |

* Estimated safe and adequate daily dietary intake of mineral, National Research Council, 1989.

and reproduction. Diets high in refined carbohydrates may provide inadequate intake of manganese. Addition of supplemental iron to the diet can depress manganese retention if iron nutriture is poor. Concentrations of manganese in tissues and organs remain relatively constant with age. Sources of dietary manganese are mainly plant foods since animal tissue contains very low amounts of this nutrient. One exceptionally rich dietary source for manganese is tea. However, tea can inhibit the uptake of iron.

Phosphorous (see [Table 108.24](#))

About 85% of the phosphorous found in the body is in bone as calcium phosphate and hydroxyapatite. Deficiencies of this nutrient are extremely rare as foodstuffs seem to provide an ample supply. Both animal and plant food are rich in phosphates. However, a vitamin D deficiency may reduce absorption of phosphorous. Most adults consume between 1,000 and 1,500 mg of phosphorous each day of which 50–60% is usually absorbed.

A phosphorous intake greatly in excess of calcium, especially if the calcium intake is minimal (400 mg/day or less), can reduce calcium availability and contribute to calcium deficiency. In general, the calcium to phosphorous ratio should be about 1:1 and definitely above 1:2.

TABLE 108-24 -- Phosphorous (mg)

| | 25–50 | 800 | 800 |
| | 51+ | 800 | 800 |

Potassium (see [Table 108.25](#))

Potassium is an essential element in maintaining fluid balance in the cells, transmission of nerve impulses, skeletal muscle contractility, and normal blood pressure. However, it must exist in balance with sodium. During nerve transmission and muscle contraction, potassium and sodium exchange places. Together with high sodium intake, decreased potassium intake may be implicated in hypertension and heart disease. Potassium is also a catalyst in protein and carbohydrate metabolism. Diuretic drugs can deplete potassium and so can be dangerous. When sodium is lost with water from the body, the ultimate damage comes when potassium moves out of the cells with cell water.

There is no RDA for potassium. However, some believe that the minimum requirement should be between 1,600 and 2,000 mg/day. Since an intake of about 1,600 mg/day is required just to maintain normal body stores and a normal concentration in plasma and fluid, a higher level would ensure optimal levels. According to some researchers, a diet rich in fruits and vegetables and low in sodium should ensure the maintenance of optimal potassium levels. However, it has been calculated that due to the poor absorbability of potassium in fruit without chloride, only 40% of the potassium, e.g. in a banana, is retained. Unfortunately this finding is often not calculated into food value tables which estimate total potassium intake from foods. This is one reason why, when potassium supplementation is suggested by a physician, potassium chloride is recommended. A low-sodium diet enhances potassium conservation, whereas a high-sodium diet promotes potassium excretion.

In a study of vegetarians compared with non-vegetarians, significantly lower blood pressure was found in every decade of age and only 2% of the vegetarians had hypertension (higher than 160/95) as compared with 26% hypertensives in the non-vegetarians. This study further confirms the important role that potassium plays in the regulation of blood pressure. In a study of 10,000 subjects in the United States, it was found that those with the highest levels of calcium, potassium, vitamin A and

TABLE 108-25 -- Potassium (g)

| | 51+ | 2 | 3 |

vitamin C had the lowest incidence of hypertension, suggesting that potassium is not the only essential nutrient in maintaining normotensive status in humans.

Selenium (see [Table 108.26](#))

Selenium is a trace element whose most important biologic function in maintaining health is as an antioxidant. Vitamin C intake of 600 mg/day has been shown to increase dietary selenium absorption by nearly 100%.

There is growing evidence that selenium may be protective against certain cancers (e.g. breast, colon, lung) and numerous tumors. Studies to date have given considerable credibility to the theory that decreased selenium status is associated with an increased risk of cancer. A landmark prospective study involving 1,312 subjects (75% of whom were male), reported in the December 1996 *Journal of the American Medical Association*, found that patients who took daily selenium supplementation at triple the RDA had 63% fewer cases of prostate cancer, 58% fewer colon or rectal cancers, and 47% fewer lung cancers than those who took the placebo. Overall in the selenium group there were 50% fewer cancer deaths than in the placebo group. It is believed that selenium may inhibit tumor growth and induce suicide in malignant cells.

There is evidence that in elderly people, several hundred micrograms of selenium and 400 mg of vitamin E improve their mental status, motivation, initiation, emotional stability, mental alertness, interest in the environment, and self-care, while decreasing anxiety, depression, poor appetite, and fatigue. This suggests that optimal selenium

nutrition is increasingly important in the latter decades of life.

Adequate levels of selenium taken with chromium, copper, potassium, magnesium, and calcium have been found to reduce the risk of cardiovascular disease.

There are data suggesting that ingesting more than 750–1000 ug/day of selenium over an extended period of time may be harmful. Therefore optimal levels need to be below this level until there are assurances that higher intakes are safe.

TABLE 108-26 -- Selenium (mcg)

| Category | Age | RDA | Optimal |
|-----------------|------------|------------|----------------|
| Males | 11–14 | 40 | 75 |
| | 15–18 | 50 | 150 |
| | 19–24 | 70 | 200 |
| | 25–50 | 70 | 200 |
| | 51+ | 70 | 250 |
| Females | 11–14 | 45 | 75 |

| | 51+ | 500 | 400 |

* Estimated minimum requirement, National Research Council, 1989.

Sodium/sodium chloride (see [Table 108.27](#))

Sodium chloride is the primary source of sodium (39% sodium by weight). The healthy adult can maintain sodium balance with an intake of approximately that required by an infant. Close regulation of the concentration and content of sodium within the body is crucial for health. Disorders of sodium regulation are a central feature of many human diseases. In general, the regulation of sodium in the body involves two processes: the control of sodium loss and the control of sodium intake. Sodium chloride occurs naturally in most foods. The problem is that sodium chloride is also added to most processed foods, often in amounts well in excess of that required physiologically or to maintain health. This added intake has been the subject of numerous studies. These studies have frequently found that the level of sodium chloride ingested by Americans is 10–20 times the level required to maintain health.

Many studies have found an association between excessive intake of salt and hypertension. The highest intakes (28 g/day) have been found in northern Japan where it is estimated that 38% of the population is hypertensive. In contrast, Alaska natives consume only 4 g/day and rarely develop hypertension. However, some studies do not show an association between salt and hypertension. These studies tend to be too small to discover the association and frequently fail to consider dietary potassium intake. Numerous studies have shown that potassium can limit some of the toxic effects of excessive sodium ingestion. For most individuals, the most prudent approach would be to limit salt intake by restricting salted processed foods. This alone should reduce daily salt intake by between 3 and 5 g, or about one-third the daily salt intake in the average American (10–14.5 g/day). Refraining from adding salt to food at the table would further reduce salt intake another one-third. This would leave only one-third remaining, or approximately that amount of salt per day found in populations with a very low incidence of hypertension. Potassium chloride may be an acceptable substitute to sodium chloride, especially

when other agents, such as citric acid or other acids, have been added to mask its unpleasant bitter taste. However, it is important to recognize that some individuals with hypotension (low blood pressure) may benefit from added salt. Nevertheless, there remains no known benefit from large sodium or sodium chloride intake. Maintaining a low salt intake throughout life may decrease the risk of developing hypertension in the portion of the population at risk.

Zinc (see [Table 108.28](#))

An adequate supply of zinc is essential for growth and physical development, and for

the metabolism of proteins, fats and carbohydrates. Most aspects of reproduction in both males and females require zinc. This mineral is also vitally important to the immune system. Virtually every enzyme reaction in the brain involves zinc, and its essentiality in the development and function of the central nervous system and brain is uncontested. Zinc is antagonistic to such toxic elements as cadmium, mercury and lead. The highest concentrations of zinc are in the ear and eye. Disorders associated with impairment of either organ may benefit from continuous optimal intakes of zinc over a lifetime.

The typical intake of zinc in Western diets is around 10 mg, two-thirds of the RDA. The elderly often consume

TABLE 108-28 -- Zinc (mg)

| Category | Age | RDA | Optimal |
|-----------------|------------|------------|----------------|
| Males | 11–14 | 15 | 15 |
| | 15–18 | 15 | 18 |
| | 19–24 | 15 | 20 |
| | 25–50 | 15 | 20 |
| | 51+ | 15 | 20 |
| Females | 11–14 | 12 | 12 |
| | 15–18 | 12 | 15 |
| | 19–24 | 12 | 17 |
| | 25–50 | 12 | 17 |
| | 51+ | 12 | 17 |

less than half the RDA for zinc. While some individuals seem to be poor absorbers, most cases of zinc deficiency, whether chronic or marginal, are self-inflicted. This may result from slimming diets, vegetarianism, or other life-style habits (e.g. alcoholism, excessive exercise). However, in some cases relative zinc deficiencies are induced by exposure to toxic metals, such as cadmium from cigarette smoke or excess copper from copper water pipes. There is increasing evidence that zinc levels decline following physical stress or injury. Zinc is one of the few minerals lost rapidly in the urine following acute or chronic psychological stress, which can lead to inadequate zinc status, despite RDA intake.

Impairments of taste, vision, smell, and appetite are often early signs of inadequate zinc status. There is a simple test for zinc status (Zinc Status, Ethical Nutrients, San Clemente, CA) which evaluates the ability to taste a pre-mixed solution of zinc. Individuals unable to taste this solution have been found to be zinc-deficient, in some cases despite being asymptomatic.

Insufficient zinc has multiple effects on the immune system, particularly T-lymphocytes,

decreased number and activity of killer cells, and impaired antibody production.

There is insufficient evidence to suggest that zinc intake should be twice the RDA for zinc. However, since repeated studies of Westernized diets indicate that most populations consume less than the RDA of this essential mineral, it seems prudent that some supplementation of zinc, or increase in zinc-rich foods, be considered a part of maintaining an optimal level of this nutrient over a lifetime.

Zinc supplementation is generally safe if maintained at levels within two to eight times the RDA. Symptoms of zinc toxicity include gastrointestinal irritation, vomiting, adverse changes in HDL/LDL cholesterol ratios, and impaired immunity. The latter develops when levels above 180 mg/day are consumed for more than several weeks. Excess intake of zinc may either lower copper levels or aggravate an existing marginal copper deficiency.
