Preface

This new edition, titled *Applied Cerebral Angiography*, maintains the same structure of the previous work. There is a part with chapters describing the embryology and normal vascular anatomy, including the orbital and the extracranial sector. This is essential for the correct interpretation of the vascular pathology presented in the second part. This work is completely new: the text has been revised and greatly expanded, trying as far as possible to update the literature. Several new figures and drawings have been added. More attention has been given to the endovascular treatment, considering the increasingly important role played by this type of therapy in the various vascular pathologies. A greater space has been dedicated to ischemic stroke in describing its pathogenesis, the anatomo-pathological and angiographic findings influencing the endovascular treatment, which has become today an essential step in the therapy of this pathology. The new possibilities, positive results, and also the limits of this approach have been largely described and discussed.

We hope that also this new edition will be of practical use for all physicians interested in this field.

Turin, Italy

G.B. Bradac
E. Boccardi

Acknowledgements

The book reflects the work done and the experience gained in the neuroradiological units at the Molinette Hospital of the Turin University, at the Niguarda Hospital in Milan, and at the Santa Croce Hospital in Cuneo. It would not have been possible without the involvement in the daily work of many colleagues working for short or long time in these units. To all these doctors, among them we like especially to mention Prof. Mauro Bergui, Dr. Guido Stura (Turin), Dr. Luca Valvassori (Milan), and Dr. Luigi Gozzoli (Cuneo), as well as to the technicians, nurses, and secretaries we express our sincere thanks. We are also grateful for the collaboration among the members of the anesthesiological, neurosurgical, maxillary surgery, otolaryngology, and stroke units.

We are especially grateful to Mario Coriasco, B.Sc. (clinical radiographer and MR technologist), for his help in the technical aspects concerning the manuscript and for the image processing to improve the quality of the figures and to Mr. Günther Hippmann for his effort to correctly represent the schematic drawings.

Finally we would like to express our gratefulness for her support to Dr. Ute Heilmann of Springer Verlag and all the editorial team: Mr. Rakesh Kumar Jotheeswaran, Ms. Lizzy Raj, Mr. Claus-Dieter Bachem, Ms. Anna-Lena Buchholz.

Contents

1 Aortic Arch and Origin of the Brachiocephalic and Cerebral Arteries 1
1.1 Embryogenesis 1
1.2 Variants 5

2 Common (CCA) and Internal (ICA) Carotid Artery 11
2.1 Cervical Segment 11
2.2 Intracranial Segments of ICA 13
2.2.1 Petrous Segment of ICA 13
2.2.2 Cavernous Segment of ICA 15
2.2.3 Supraclinoid Segment of ICA 15
2.3 Congenital Anomalies of the CCA and ICA 25

3 External Carotid Artery 35
3.1 Superior Thyroid Artery (TH) 35
3.2 Lingual Artery (LA) 36
3.3 Facial Artery (FA) 37
3.4 Ascending Pharyngeal Artery (AphA) 38
3.5 Occipital Artery (O) 40
3.6 Posterior Auricular Artery 41
3.7 Internal Maxillary Artery (IMA) 41
3.7.1 Proximal Branches 41
3.7.2 Masticator Space 43
3.7.3 Distal IMA 44
3.7.4 The Terminal Branch 46
3.8 Superficial Temporal Artery 46
3.9 Cervical Arteries 47
3.10 Summary 48
3.10.1 Vascular Malformations 48
3.10.2 Hemangiomas 49
3.10.3 Juvenile Angiofibromas 54
3.10.4 Paragangliomas 54
3.10.5 Meningiomas 56
3.10.6 Other Tumors in the Head and Neck Area 62
3.10.7 General Considerations in Endovascular Treatment in the ECA Area 63

4 Anterior Cerebral Artery 67
4.1 Precommunicating Segment 67
4.2 Distal Segments 70
4.2.1 Infracallosal Segment. 70
4.2.2 Precallosal Segment 70
4.2.3 Supracallosal Segment 71
4.2.4 Distal Cortical Branches 71
4.3 Anatomical Variations 72
4.4 Vascular Territories 77
4.5 Angiogram 80

5 Middle Cerebral Artery 81
5.1 M1 Segment 81
5.2 M2, M3, and M4 Segments 82
5.3 Anatomical Variations 89
5.4 Vascular Territories 91
5.5 Angiogram 92

6 Extra- and Intracranial Vertebrobasilar Sector 95
6.1 Extracranial Sector. 95
6.1.1 Branches. 95
6.2 Intracranial Sector 98
6.2.1 Intracranial Branches of the VA. 98
6.2.2 Branches of the Basilar Artery. 100
6.2.3 Distal Branches of PICA, AICA, and SCA 108
6.2.4 Variants of Vertebral and Basilar Arteries 108

7 Posterior Cerebral Artery 115
7.1 P1 Segment 115
7.2 P2 Segment 117
7.3 P3 Segment 117
7.4 P4 Segment 118
7.5 Anatomical Variations 118
7.6 Vascular Territories 118
7.7 Angiogram 120

8 Vascular Territories 125

9 Cerebral Veins 129
9.1 Supratentorial Cerebral Veins 130
9.1.1 The Superficial System 131
9.1.2 The Deep System. 133
9.2 Infratentorial Cerebral Veins
(Veins of the Posterior Fossa) 143
9.2.1 Superior Group. 143
9.2.2 Anterior Petrosal Group. 148
9.2.3 Posterior Tentorial Group. 148
9.3 Dural Sinuses 148
9.3.1 Superior Sagittal Sinus (SSS) 149
9.3.2 Inferior Sagittal Sinus (ISS). 151

9.3.3 Straight Sinus (SS) and Falcine Sinus (FC) 151
9.3.4 Occipital Sinus (OS) and Marginal Sinus (MS) 152
9.3.5 Transverse Sinus (TS) 152
9.3.6 Sigmoid Sinus (SiS), and Jugular Vein 153
9.3.7 Superior Petrosal Sinus (SPS) 153
9.3.8 Inferior Petrosal Sinus (IPS) 153
9.3.9 Sphenoparietal Sinus (SpS) 157
9.3.10 Cavernous Sinus (CS) 157
9.3.11 Superior Ophthalmic Vein (SOV) 158
9.3.12 Inferior Ophthalmic Vein (IOV) 160
9.3.13 Considerations About Vein Variations 160

10 Extracranial Venous Drainage 163
10.1 Orbital Veins 163
10.2 Facial Veins 163
10.3 Retromandibular Vein 164
10.4 Posterior Auricular and Occipital Vein 164
10.5 Deep Cervical Vein 164
10.6 Venous Plexus of the Vertebral Artery 164
10.7 Emissary Veins 164
10.8 Diploic and Meningeal Veins 165
10.9 Internal Jugular Vein 165

11 Aneurysms 167
11.1 Incidence 167
11.2 Type and Location 167
11.3 Anatomopathological Aspects 167
11.4 Pathogenesis 168
11.5 Clinical Presentation 169
11.6 Aneurysm Location 169

Short Historical Aspects

In July 1927, Prof. Egas Moniz, director of the neurological clinic in Lisboa, presented at the congress of the Neurological French Society in Paris his experiences concerning a method to study the cerebral vessels that he called "*L'encephalographie arterielle*." The interest for this new method, called later "Cerebral Angiography," was great. Among the several neurological authorities present in the congress, we report the comment of Prof. Babinsky:

Le radiographies qui vient de presenter E.Moniz sont remarquables. Si les observations ulterieures établissent definitivement que les injections auxquelles il a recours sont inoffensives,tous les neurologistes seront reconnaissants a notre eminent collégue de leur avoir procuré un nouveau moyen pouvant permetre *de localizer des tumeurs intracraniennes dont le siege est souvent si difficile a determiner.*

Moniz, in the monograph *Die cerebrale Arteriographie und Phlebographie,* published in 1940, reported his further results confirming the diagnostic value of this technique not only in the tumor pathology but also in other pathological processes especially vascular malformations. In the chapter titled "Hirnarteriosclerose" Moniz reported a few cases of occlusion of the carotid artery and of its intracranial branches making the consideration that this pathology is "*selten ,aber doch haufiger als man annehmen moechte … eine sichere Diagnose dieser Affection war vor der Anwendung der Hirnangiographie nicht moeglich*."

Since then, great progresses have been made, starting with the introduction of the catheter technique (Seldinger 1953), the subtraction (Ziedses des Plantes 1963), followed by the development of more and more suitable catheters, guide wires, and less toxic contrast media. All these aspects along with the improved technological equipment have characterized the evolution of the cerebral angiography, which has become a very important neuroradiological diagnostic method opening the way for selective and superselective studies and further for the endovascular therapy.

Certainly, the evolution of new methods such as the angio-CT, angio-MR, and ultrasound allows to replace cerebral angiography in many cases today. However, every time the diagnosis is not sufficiently clear or finer details are

required to understand the clinical symptoms or to plan the therapy, especially when an endovascular approach is considered, angiography remains today the method of choice.

Aortic Arch and Origin of the Brachiocephalic and Cerebral Arteries

1

1.1 Embryogenesis

An important aspect in the embryological development of the cerebrovascular system, as pointed out by Streeter (1918), is that it is not an independent process but it is linked to the progressive development and differentiation of the tissues including the brain parenchyma, its membranes, and the soft tissues of neck and head to which the vascular structure continuously adapts.

The vascular structures develop from primitive vascular arches (Streeter 1918; Congdon 1922; Padget 1948; Barry 1951; Lazorthes 1961; Haughton and Rosenbaum 1974). These are longitudinal vessels developing on each side from a common trunk arising from the heart (truncus arteriosus) which ends in a dilatation (aortic sac) from which arise *the aortic arches*. These have an ascending course forming the primitive ventral (ascending) paired aorta. The vessels then bend dorsally continuing caudally in the paired primitive descending aorta. Both vessels distally fuse together. From these arches arise the brachiocephalic arteries. *In the embryogenesis, six arches in different phases develop and progressively disappear completely or partially*. The first appearing are the arches number one and two which rapidly regress. The third and fourth arches follow. These are the vascular structures which play the most important role in the developing of the brachiocephalic vessels and their future intracranial branches. The fifth arch is not constant. It is frequently incompletely formed, and regresses rapidly after its appearance. From the sixth aortic arch develops the pulmonary artery. In the embryogenesis a vessel (ductus arteriosus) connects each pulmonary artery with the thoracic aorta. This connection closes short after the birth.

The different phases of the development of the extracranial and intracranial cerebral arteries in the embryo have been thoroughly investigated by many authors (Streeter 1918; Congdon 1922; Padget 1944, 1948; Barry 1951; Lazorthes 1961; Arey 1965; Kier 1974; Haughton and Rosenbaum 1974; Lazorthes et al. 1976). A description of this very complex development is summarized, pointing at the more striking aspects considering separately for simplicity, the extra- and intracranial sectors.

At the 4–5 mm stage embryo, approximately 24–29 days of age (Fig. 1.1a), the first and second arches are already completely regressed. The third and fourth arches are developed. From the proximal part of the third arch arises on either side vessels from which develops the future ECA. From its distal part arises the future ICA. The more distal segment of the third arch (ductus caroticus) fuses with the fourth aortic arch continuing on both sides in the dorsal aorta. As described below, connections between ICA and bilateral longitudinal channels (BLA, future vertebro-basilar sector) are present. From the dorsal aorta arise on both sides segmental arteries which contribute later to the formation of the vertebral arteries. In the following stages many changes occur.

G.B. Bradac, *Applied Cerebral Angiography*, DOI 10.1007/978-3-319-57228-4_1

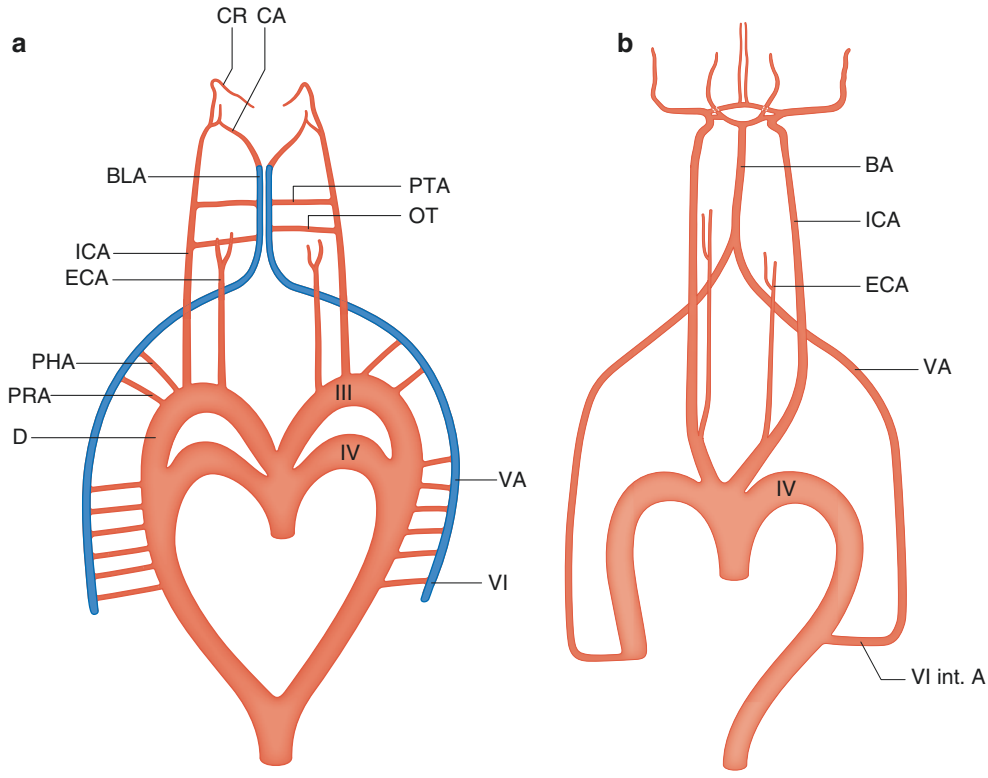

Fig. 1.1 (**a**) Drawing showing the evolution in the early stages (see also text). The first and second arches have already completely disappeared. The ECA arises from the proximal part while the ICA from the distal part of the third aortic arch. Connections between the bilateral longitudinal channels (BLA) and ICA through the trigeminal (PTA) and otic (OT) arteries and between BLA and *ductus caroticus* (D) through the hypoglossal (PHA) and proatlantal (PRA) arteries are present. The *ductus caroticus* connects the third and fourth arches. Intersegmental arteries are connected with a plexiform network from which develop the future vertebral arteries (VA). At this stage, the cranial (CR) and the caudal divisions (CA) of ICA appear. From the caudal division develops the PcomA, which is connected with the distal part of the bilateral longitudinal neural arteries from which develops later the basilar artery. MCA is not developed yet. (**b**) Drawing in advanced evolution (see also text). At this stage, the *ductus caroticus, the hypoglossal, and the proatlantal arteries*, as well *as the trigeminal and otic arteries*, disappear. The right dorsal part of the aorta is regressed. The superior (cervical) intersegmental arteries disappear with exception of the sixth from which arise the vertebral and subclavian arteries. The vertebral arteries (VA) are now developed and connected with the completely formed median basilar artery (BA). The distal branches of the ICA are almost completely formed as well as the circle of Willis. (**c**) Drawing showing the aortic arch and the extra-intracranial cerebral arteries at the end of the embryogenesis. *SA* subclavian artery, *TCT* thyrocervical trunk, *CCA* common carotid artery, *VA* vertebral artery, *ICA* internal carotid artery, *ECA* external carotid artery, *BA* basilar artery. Circle of Willis

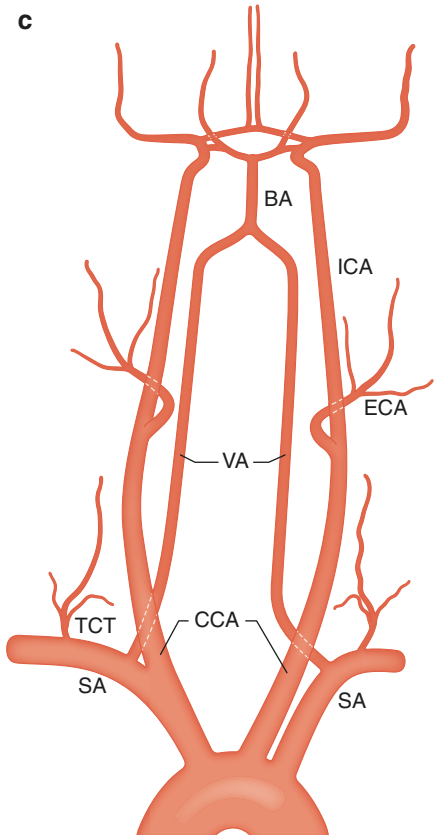

Fig. 1.1 (continued)

At the 20–24 mm stage embryo, approximately 42 days of age (Fig. 1.1b), the anastomoses of the ICA, and ductus caroticus with the BL, disappear (see below). The ECA and ICA arise now as a common trunk, the future common carotid artery (CCA). On the left, the CCA arises from the left fourth aortic arch. From the proximal part of the right fourth aortic arch arises the innominate artery continuing in the right CCA and in the future subclavian artery. The distal part of the right dorsal aorta regresses. On both sides the superior (cervical) intersegmental arteries regress, with exception of the sixth from which develop on either side the subclavian and vertebral arteries (see also Sect. 6.2.4). The more caudally located intersegmental branches become the intercostal arteries.

At this stage the caudal shifting of the heart becomes progressively more prominent leading to further changes of the brachiocephalic vessels. The common carotid artery and the subclavian artery become elongated and progressively located more cranially reaching the adult position. Furthermore the head which is bended ventrally in the first phases of the embryogenesis shifts progressively away from the chest acquiring the typical vertical position.

The final normal aortic arch (Fig. 1.1c) is characterized by the persistence of the left fourth primitive ventral arch from which arise (right to left) the brachiocephalic trunk (innominate artery), the left common carotid artery, and the left subclavian artery. From the brachiocephalic trunk arise the right common carotid artery and the subclavian artery giving off the right vertebral artery. The left vertebral artery arises from the left subclavian artery. Each common carotid artery divides in the external carotid artery (ECA), which supplies the extracranial and meningeal territories and the internal carotid artery (ICA) from which arise the intracranial branches for the cerebral hemisphere and the intraorbital arteries. The vertebral arteries join intracranially the basilar artery. They supply brainstem and cerebellum.

As far as it concerns the development of the intracranial cerebral arteries the most striking aspects are as follows:

1. *At the 4–5 mm stage* (24–29 days of age) (Fig. 1.1a)
   - *Bilateral longitudinal neural arteries* (*BLA*) *in the form of plexiform structures develop on the surface of the future brainstem*. The BLA are connected with arteries arising cranially from the ICA (trigeminal and otic arteries) and caudally from branches arising from the ductus caroticus (hypoglossal and proatlantal arteries). The vertebral arteries are in formation. They appear as a plexiform structure arising from intersegmental arteries developing from the dorsal aorta.
   - *There is appearing of the cranial* (*anterior*) *and caudal* (*posterior*) *division of the ICA*. From the cranial division arises *the anterior choroidal artery* which in this phase of the embryogenesis is well developed

supplying the large choroidal plexus. Opposite to it appear the branches of the primitive ophthalmic artery. More distally develops *the olfactory artery* from which arises a secondary branch, the *anterior cerebral artery*, replacing progressively the regressing olfactory artery. The third branch developing from the cranial division appearing at the 11–12 mm stage (35 days of age) is *the middle* cerebral *artery*. It appears first as a few twigs located between the anterior choroidal artery (AchA) proximally and the developing anterior cerebral artery (ACA) distally. Some of these twigs arise directly from the ACA. From the fusion of these twigs develop the middle cerebral artery.

- From the caudal division arises *the posterior communicating artery* (*PcomA*) *from which emerge* at its distal end a diencephalic branch which includes the medial posterior choroidal and a mesencephalic branch from which arises the lateral posterior choroidal artery. In the further evolution, the PcomA continues in *the posterior cerebral artery* (*PCA*) which progressively extends supplying the posterior part of the cerebral hemispheres. The PcomA (*pars carotica* of PCA) is connected with the cranial part of the bilateral longitudinal neural arteries from which develop the primitive duplicated basilar artery (BA), *which later fuse in the median BA, about the 9 mm stage* (*32 days of age*). The cranial part of these longitudinal channels will become the P1 segment (*pars basilaris* of the PCA). This will becomes progressively the predominant flow to the PCA while the PcomA, in the majority of the cases, partially or completely regresses.
- *The formation of the vertebral arteries progresses and is complete at the 12–14 mm stage embryo (35–38 days of age). They join intracranially the formed basilar artery. The connections of the ICA (primitive trigeminal, otic, hypoglossal, and proatlantal arteries) disappear. The flow towards the posterior circulation which was from cranial to caudal, following the regression of these connections, is now inverted directed from caudal to cranial.*

2. *At the 20–24 mm stage* (Fig. 1.1b) *of the embryonic evolution* (*40–42 days of age*) *the typical cerebral vessels can be identified*. All branches of the ICA are present and clearly recognizable. The development is not complete, since it continues adapting to that of the brain parenchyma.

The growth of the cerebral hemispheres and appearance of convolutions and sulci lead to further distal extent of the arteries and to the changes of the primitive rectilineal course in one more tortuous. The cerebellum develops later. It is supplied by the cerebellar branches arising from the BA and VAs. The development of the vertebral arteries is completed. The VAs are proximally connected with the subclavian arteries and converge cranially to the proximal part of the basilar artery which is now completely formed. From the vertebral and basilar arteries arise the vessels supplying the brainstem and cerebellum. The cerebellar arteries are the latest to develop. *One remarkable development is the formation at the base of the cerebrum of the circle of Willis about the age of 44–52 days of age* (De Vriese 1905; Padget 1944, 1948). This is an anastomotic circle described by Willis in the 1684, and since then called "*circle of Willis*," in which both anterior cerebral arteries are linked by the anterior communicating artery, and each carotid artery is connected through the posterior communicating artery with the respective PCA arising from the basilar artery (Fig. 1.2).

This is a natural well-constructed security system. Its functional value, however, is somewhat unpredictable owing to the many variants present. According to several authors (De Vriese 1905; Padget 1944–1948; Lazorthes 1961; Lazorthes et al. 1976) *the variants of the circle of Willis occur in the postnatal period and through the life due to various hemodynamic changes, among them the compression of the carotid and vertebral arteries by movements of the head and neck.*

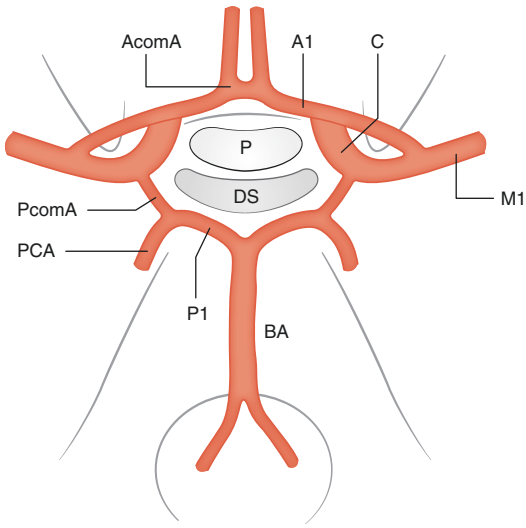

Fig. 1.2 Drawing of the circle of Willis. Internal carotid artery (C), first segment of the anterior cerebral artery (A1), first segment of the middle cerebral artery (M1). *BA* basilar artery, *P1* first segment of the posterior cerebral artery, *PCA* posterior cerebral artery, *AcomA* anterior communicating artery, *PcomA* posterior communicating artery, *P* pituitary gland, *DS* dorsum sellae

1.2 Variants

Some variations of the aortic arch and its branches have already been described in the eighteenth and nineteenth centuries by a few anatomists (Bayford 1789; Tiedermann 1822; Quain 1844; Gray 1859). Angiography, CT angiography, and MR angiography have made possible to demonstrate "in vivo" the great variety of these anomalies, their frequency, and their possible clinical relevance. The progressively better knowledge of the embryogenesis has, furthermore, allowed, at least in some cases, to connect these anomalies with a failure of the normal evolution occurring in specific time of it and involving specific parts of the developing arteries.

Owing to the complexity of the embryonic process, minor variants are the rule. However, these are not recorded in the literature as variants or anomalies. This definition is reserved to more or less complex changes (Adachi 1928; Edwards 1948; Apley 1949; Barry 1951; Lie 1968; Klinkhamer 1969; Haughton and Rosenbaum 1974; Beigelman et al. 1995; Morris 1997; Osborn 1999). In a recent study performed on 2033 patients examined with CT (Mueller et al. 2011), these have been described with a frequency of 13.3% of the cases.

In this chapter are described the variants concerning the aortic arch and the brachiocephalic arteries. Detailed anomalies of the intracranial arteries will be discussed in the specific chapters.

Among the most frequent and more simple anomalies, there are those characterized by the common origin of the left common carotid artery (LC) and the brachiocephalic trunk, and the origin of the LC from the brachiocephalic trunk, instead of arising from the aortic arch. Other variants are the anomalous origin of the left vertebral artery, occurring in about 6% of the cases (Adachi 1928; Uchino et al. 2013b; Mueller et al. 2011) arising from the aortic arch between the left common carotid artery and the left subclavian artery, or more rarely distal to the left subclavian artery. Less frequently, this anomaly involves the right VA, arising from the more proximal segments of the aortic arch or also distal to the left subclavian artery (*vertebral arteria lusoria*). More about the variants of the VAs are described in Sect. 6.2.4.

Among other more complex conditions, there is the right aberrant subclavian artery, arising distal to the left subclavian artery or close to it (*subclavian arteria lusoria*). It is considered to be due to partial persistence of the right dorsal aorta, while its proximal part between the right CCA and the right subclavian artery regresses. It can also be associated at its origin with a small aneurysmal dilatation (Kommerell's diverticulum), perhaps a rudimentary segment of the distal right dorsal aorta. On the aortic arch angiogram the artery appears as the last branch crosses the mediastinum from left to right. Since the first report by Kommerell in 1936 other authors have described this anomaly (Apley

1949; Bosniak 1964; Lie 1968; Klinkhamer 1969; Akers et al. 1991; Freed and Low 1997; Wong et al. 2007; Karcaaltincaba et al. 2009; Uchino et al. 2013b). Another anomaly of the right subclavian artery is that in which the artery arises from the aortic arch separately, proximal to the right CCA. The anomalous subclavian artery can be isolated or associated with other anomalies of the brachiocephalic branches. A frequent association is the common origin of both common carotid arteries and the separate origin of the right CCA proximal to the right subclavian artery. As far as other anomalies concerning the CCA and ICA and VAs see Sects. 2.3 and 6.2.4, respectively.

Extremely rare are other more complex anomalies such as the right aortic arch and the double-aortic arch. In the first case, due to interruption of the left aortic arch at the level of the descending aorta, the brachiocephalic arteries arise from the right aortic arch with a pattern described as a *mirror imaging*. In this condition, from the aortic arch arises (left to right) the left brachiocephalic trunk, which divides distally in the left common carotid and left subclavian arteries, the right common carotid and right subclavian arteries. The left subclavian artery can also arise isolated, distally from the right subclavian artery, appearing on the angiogram as the last branch crossing the mediastinum from right to left. In the double-aortic arch, due to persistence of both arches, commonly each arch gives off a common carotid and a subclavian artery.

Angiographic studies of normal and anomalous aortic arch are presented in Figs. 1.3, 1.4, 1.5, 1.6, 1.7, 1.8, 1.9, and 1.10.

In the majority of the cases these anomalies are asymptomatic, being discovered during a diagnostic study (angio CT-MR or angiography) performed for a cerebral pathology. However, the possibility of such anomalies should be taken into account by the angiographer. Infrequently, respiratory distress and dysphagia can be present, especially in cases of aberrant right subclavian artery and right VA, due to the course of the vessels, crossing the midline in the retro-esophageal space. Congenital heart malformations can be associated especially with a right aortic arch and double-aortic arch. Furthermore, the knowledge of these variants is important in patients in whom aortic arch, esophageal, or anterior neck surgery is planned.

Some more aspects concerning the embryological development and its abnormalities involving the specific arteries are described later (see Sects. 2.2.3.1, 2.2.3.2, 2.2.3.3, 2.3, 4.3, 5.3, 6.2.4, and 7.5 and Chap. 3).

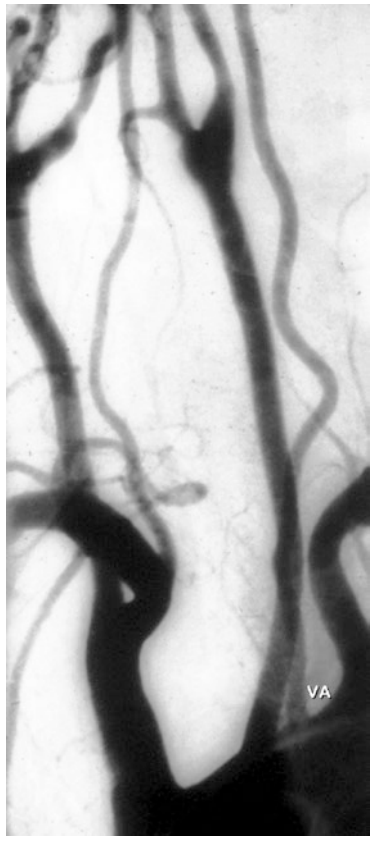

Fig. 1.6 Aortic arch angiogram. Owing to arteriosclerotic elongation of the aortic arch, there is a shifting of the origin of the left common carotid and brachiocephalic trunk towards the heart. Anomalous origin of the left VA (VA) from the aortic arch

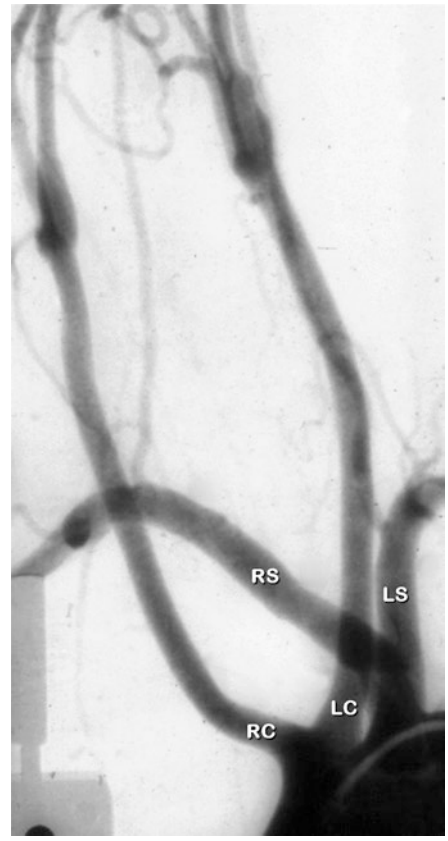

Fig. 1.7 Aortic arch angiogram anomaly. The left and right common carotid arteries (LC, RC) arise as a common trunk. The right subclavian artery (RS) arises distally with a separated or common origin with the left subclavian artery (LS)

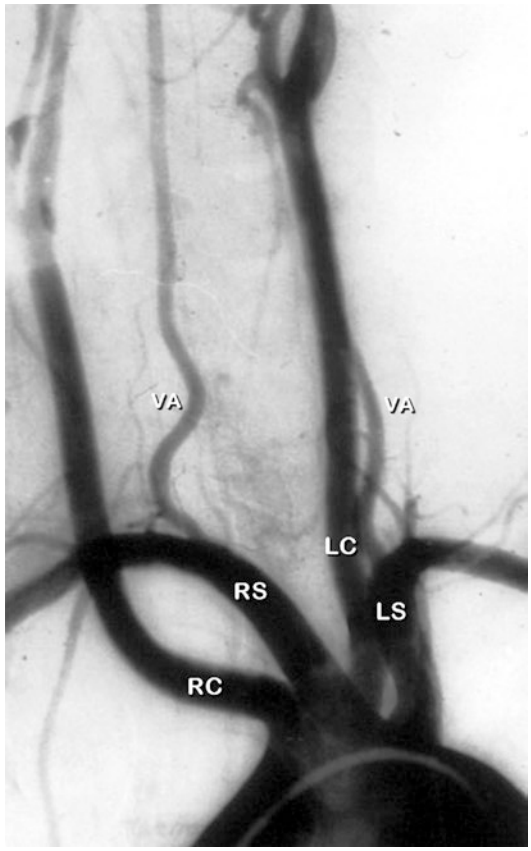

Fig. 1.8 Aortic arch angiogram. The typical brachiocephalic trunk is not formed. The right common carotid artery (RC) is displaced more proximally. It arises from the aortic arch separately from the subclavian artery (RS). This latter arises distally separately or together with the left subclavian artery. Left common carotid artery (LC)

Fig. 1.9 Aortic arch angiogram. The right common carotid artery (RC) arises more proximally. Its origin is separated from that of the right subclavian artery (RS). The typical brachiocephalic trunk is not formed. Left common carotid artery (LC), left subclavian artery (LS)

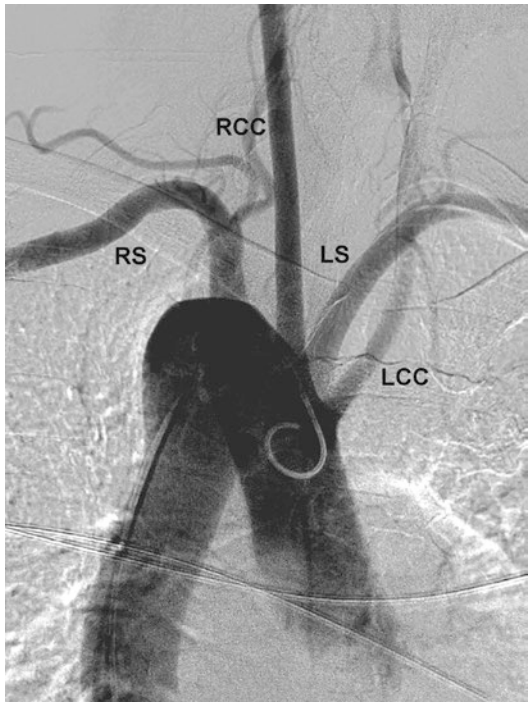

Fig. 1.10 Aortic arch angiogram showing the presence of a right aortic arch. From the ascending aorta arise separately or with a common trunk the left subclavian (LS) and the left common carotid artery (LC). Right common carotid (RC) and right subclavian artery (RS). Pattern which is a "mirror imaging" of the left aortic arch (see also text)

Common (CCA) and Internal (ICA) Carotid Artery

2

2.1 Cervical Segment

Early in the embryogenesis, both primitive proximal external carotid artery (ECA) and internal carotid artery (ICA) arise separately from the third aortic arch: the ECA from its proximal ventral part, and the ICA from the more distal part. The involution of the third aortic arch involving its segment distal to the origin of the ICA (*ductus caroticus*) on both left and right sides results in the formation of a common trunk from which develops on each side the common carotid artery (CCA) continuing cranially in the ICA and ECA. In the further evolution, the left CCA is annexed by the developed left fourth aortic arch, and the right CCA becomes a branch of the brachiocephalic trunk (innominate artery) proximal remnant of the distally regressed right fourth aortic arch (Haughton and Rosenbaum 1974).

The definitive common carotid arteries run cranially in the carotid space, surrounded by the three layers of the deep cervical fascia, called the carotid sheet. Approximately at the level of the hyoid bone, usually between the C4 and the C6 vertebral bodies, each CCA divides into the ICA and ECA.

Cases of a higher bifurcation, up to the first cervical vertebra (Lie 1968), or lower, in the thoracic area (Vitek and Reaves 1973), have been reported. The carotid sheet is a well-defined structure below the carotid bifurcation, though it is incomplete or absent at the level of the oral-nasal pharynx (Harnsberger 1995). The infrahyoid segment of the carotid space contains the common carotid artery and depending on the level of the bifurcation the proximal part of the ICA; the proximal part of the ECA; furthermore the internal jugular vein (IJV); portions of the cranial nerves IX, X, XI, and XII; the sympathetic plexus; and lymph nodes. In the infrahyoid segment, the vessels run in the so-called carotid triangle (Som et al. 2003a) (Fig. 2.1) defined by

(**b**) Common carotid angiogram, AP view, showing the course of the external carotid artery (ECA) (*arrows*) first medial and more distally lateral to the internal carotid artery (ICA). The *dotted line* corresponds to the axial plane presented in the following drawing. (**c**) Carotid space (CS), surrounded by the parotid space (PS), the parapharyngeal space (PPS), the retropharyngeal space (RPS), and the perivertebral space (PVS). Masticator space (MS). In the carotid space are indicated the ICA (anteriorly), the internal jugular vein (posteriorly), and the cranial nerves IX, X, XI, and XII. In the anterior part of the parotid space are indicated the ECA and anteriorly to it the retromandibular vein

the sternocleidomastoid muscle laterally and posteriorly, and by the superior belly of the omohyoid and the posterior belly of the digastric muscle inferiorly and superiorly, respectively. In the suprahyoid segment, the ICA is accompanied by the IJV located posterolaterally; the cranial nerves IX, X, XI, and XII; the sympathetic plexus; and the lymph nodes. The ECA runs more laterally.

Near the skull base, the borders of the carotid space (Harnsberger 1995) also called by others (Som and Curtin 2003; Mukherji 2003) the retrostyloid para-pharyngeal space are so outlined: laterally, the parotid space; anteriorly and medially, the para-pharyngeal and retropharyngeal spaces, respectively; and posteriorly, the perivertebral space (Fig. 2.2c).

The first segment of the ICA (carotid bulb) is slightly enlarged, becoming smaller and narrower 1–2 cm distally. The bulb can be enlarged, particularly in older, atherosclerotic patients in whom also tortuosity can develop in the form of

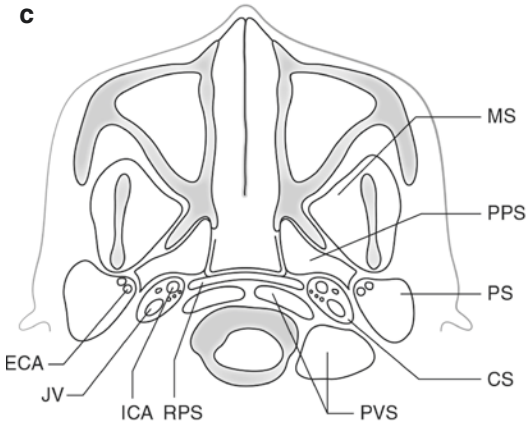

Fig. 2.2 (continued)

coiling or kinking. Tortuosity is also frequently present as expression of dysplasia. In children tortuosity of ICA is frequent; this commonly disappears later.

At its origin, the ICA lies commonly posteriorly and laterally to the ECA. More distally, it runs medially to the ECA (Fig. 2.2a, b). See also Chap. 3.

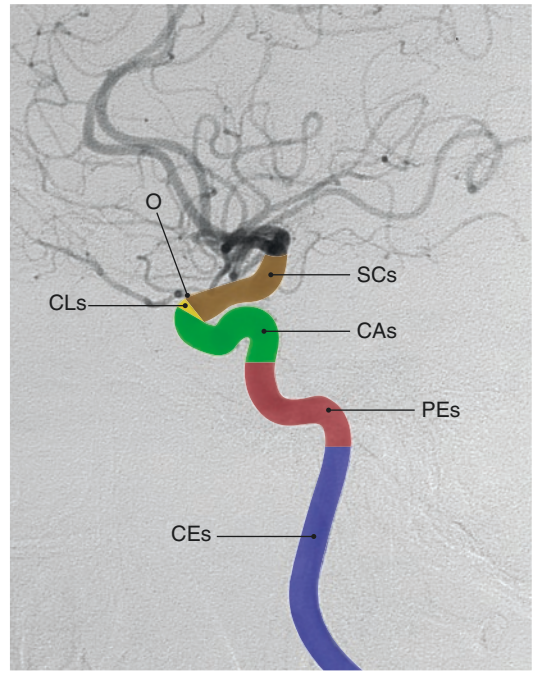

Fig. 2.3 Lateral angiogram on which are approximately indicated the segments of the internal carotid artery. *CEs* cervical segment, *PEs* petrous segment, *CAs* cavernous segment, *CLs* clinoid segment, *SCs* supraclinoid segment, *O* ophthalmic artery

2.2 Intracranial Segments of ICA

The intracranial segments of the ICA begin where the artery enters the cranial cavity at the level of the carotid foramen and end at the base of the brain at the anterior perforated substance. It can be subdivided into the petrous, cavernous, and supraclinoid segments (Fig. 2.3).

2.2.1 Petrous Segment of ICA

The ICA enters the base of the skull at the carotid foramen, anteriorly to the jugular fossa and jugular vein. It runs first entirely in the petrous bone, first with a vertical course for about 1 cm, and then horizontally medially directed for about 2 cm. It emerges at the petrous apex, running above the foramen lacerum, continuing in a short vertical segment toward the cavernous sinus. The ICA is surrounded by a fibrous-cartilaginous tissue, inferiorly covering the foramen lacerum and superiorly in continuation with the periosteum of the petrous canal. This segment, which has been called *lacerum segment*, terminates at the level of the petrolingual ligament (Bouthillier et al. 1996; Zyial et al. 1998) which runs between the lingula of the sphenoid bone anteriorly and the petrous apex posteriorly. It cannot be precisely defined neither on angiography nor on CT and MR studies. On the AP view the petrous ridge can be considered the reference point where approximately the ICA enters the cavernous sinus (Shapiro et al. 2014); see Figs. 2.3 and 2.4. Along its petrous course the ICA is surrounded by the sympathetic fibers and by a venous plexus. In its horizontal part it lies anteriorly, medially, and below the tympanic cavity and cochlea and runs below the Gasserian ganglion (Paulus et al. 1977; Bouthillier et al. 1996). It gives off two branches: the *caroticotympanic and the mandibular arteries.*

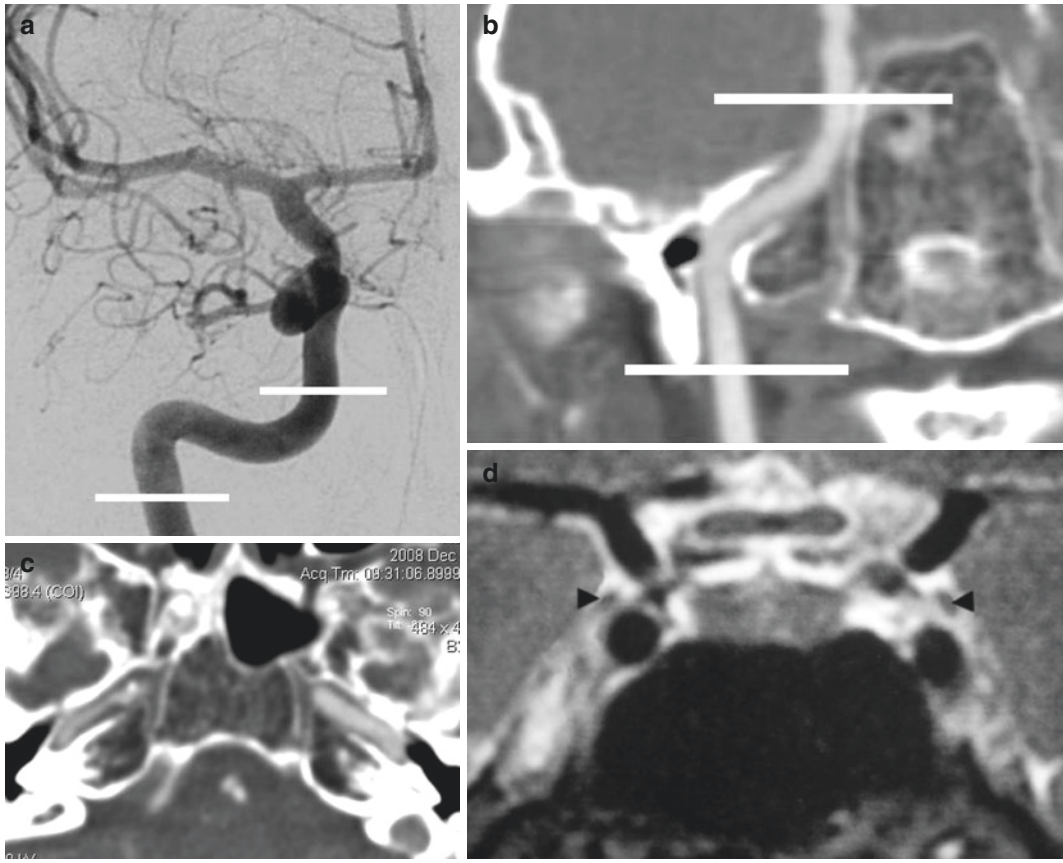

Fig. 2.4 (**a**) Carotid angiogram, AP view. The *lines* define approximately the course of the petrous segment of the ICA continuing into the cavernous segment. (**b**) CT—angiography, coronal reconstruction, showing the course of the petrous segment. (**c**) CT—angiography, showing the horizontal part of the petrous segment of the ICA running above the foramen lacerum. (**d**) MRI, coronal view, sellar, and parasellar area demonstrating the course of the ICA in the cavernous sinus. Cranial nerve III (*arrowheads*)

The caroticotympanic artery is an embryonic remnant of the hyoid stapedial artery (Sect. 2.2.3.1) that supplies the middle ear cavity. When present it arises at the genu between the vertical and horizontal segments running posteriorly. There is a possible anastomosis with the tympanic branch of the ascending pharyngeal artery (see also Sect. 3.4). The caroticotympanic artery can be involved in tumors of the skull base, particularly in tympanojugular paragangliomas. In cases of agenesis of the petrous segment of ICA it is considered to be involved together with the tympanic branch of the AphA in the formation of a kind of collateral circulation toward the distal ICA (see also Sect. 2.3 and Fig. 2.15).

The mandibular artery is a remnant of an embryonic branch arising slightly more cranial than the caroticotympanic artery. It divides into two branches directed anteriorly anastomosing with branches of the IMA: one runs in the pterygoid canal, anastomosing with the vidian artery; the other is more caudally located, anastomosing with the pterigovaginal artery (see also Sect. 3.7.3). The artery is sometimes visible on normal ICA angiogram (Fig. 11.9b) and can be especially involved in the vascularization of angiofibromas (Fig. 3.23).

Apart from the above-described pathological situations the caroticotympanic and the mandibular arteries are commonly not visible on the angiogram.

2.2.2 Cavernous Segment of ICA

In the cavernous segment the ICA runs in the space formed by the separation of a fold of the dura into two layers: the lateral one is the medial wall of the middle cranial fossa; the other is medial, in close contact in its inferior part with the periosteum of the sphenoid bone (periosteal layer). This space, in which run the ICA, venous channels, and nerves, has been called by Taptas (1982) "*the space of the cavernous sinus*." This definition, which distinguishes the space from its contents, is more appropriate than the commonly used "*cavernous sinus*" (see also Sect. 9.3.10). In this space, the ICA is directed first forward and upward, and then curves anteriorly with a horizontal course, making a second curve directed posteriorly and slightly medially to the anterior clinoid process. In its course, laterally to the sella turcica and pituitary gland which is separated by the medial layer of the dura, the artery is surrounded by a venous plexus, and the sympathetic fibers, and has a close relationship with cranial nerves III, IV, and VI and the first and second branch of the trigeminal nerves. The nerves run close to the lateral wall, attached to it by dural sheaths. These latter can fuse together, forming a thin, irregular inner layer adjacent to the external layer of the lateral wall (Umansky and Nathan 1982). Unlike the other nerves, cranial nerve VI runs inside the cavernous sinus.

Due to its "S-shaped" course, the cavernous segment is also called the siphon. It continues in the supraclinoid segment (Figs. 2.3 and 2.4). Before becoming supraclinoid, however, the ICA passes through a kind of dural collar formed by a proximal and a distal dural ring. This is a very short wedge-shaped segment called the *clinoid segment* (Bouthillier et al. 1996).

There are two branches of the cavernous segment: one is *the meningohypophyseal trunk (MHT)*, and the other is *the inferolateral trunk* (*ILT*).

The MHT arises from the medial surface of the first part of the cavernous segment. It gives off a branch supplying the neurohypophysis (inferior hypophyseal artery), which is recognizable on the angiogram as a slight blush. It also gives off dural branches for the clivus and tentorium (clival and tentorial branches). The tentorial branch has been called the artery of Bernasconi and Cassinari, who first reported its angiographic visualization in the 1982. These dural branches anastomose with meningeal branches of the contralateral ICA and inferiorly with clival branches of the AphA. There are also possible anastomoses with branches of the middle meningeal artery.

The ILT arises from the lateral surface of the segment running laterally to the sella turcica. It supplies cranial nerves III, IV, and VI and partially the *ganglion Gasseri*. It gives off dural branches for the dura of the cavernous sinus and adjacent area. In the supply of this area, there is a balance between the ICA system, represented by the ILT, and branches of ECA, represented by the middle meningeal artery, accessory meningeal artery, artery of the foramen rotundum, and recurrent meningeal artery branch of the ophthalmic artery. One system can be dominant over the other. Anastomoses are frequently present.

The MHT and ILT are very fine arteries (Fig. 2.5), not always recognizable on the lateral angiogram. They can be dilated and well visible when involved in the supply of pathological processes, especially meningioma and dural arteriovenous fistulas (Figs. 3.28b, 13.10, 13.13, and 13.14).

2.2.3 Supraclinoid Segment of ICA

The supraclinod segment (average length 2 cm) begins where the artery having passed the clinoid segment goes through the dura and enters the subarachnoid space, running posteriorly, superiorly between the anterior clinoid process laterally and the optic nerve located medially and superiorly to the ICA, reaching the lateral side of the optic chiasm. The dural ring surrounding the ICA, where the artery enters the subarachnoid space, is closely adherent to the artery laterally, but it is frequently less adherent medially, forming a thin cavity (carotid cave). Aneurysms arising below the dural ring (intracavernous

There is also a possible contribution from the anterior deep temporal artery (*arrow*). Middle deep temporal artery (*arrow with dot*). Superficial temporal artery (STA). In the later phase, the ocular complex (*arrowhead*) and the blush of the choroid plexus (*white arrow*) are recognizable. (**d**) Angiographic study in a different patient showing the origin of the MMA from the ophthalmic artery. Lateral view: ophthalmic artery (O). Lacrimal artery (*arrow head*), from which arise the frontoparietal and temporal branches (*arrow*) of the MMA. AP view: ophthalmic artery (O). Branches of the MMA (*bidirectional arrow*). Patient with a small aneurysm of the PcomA

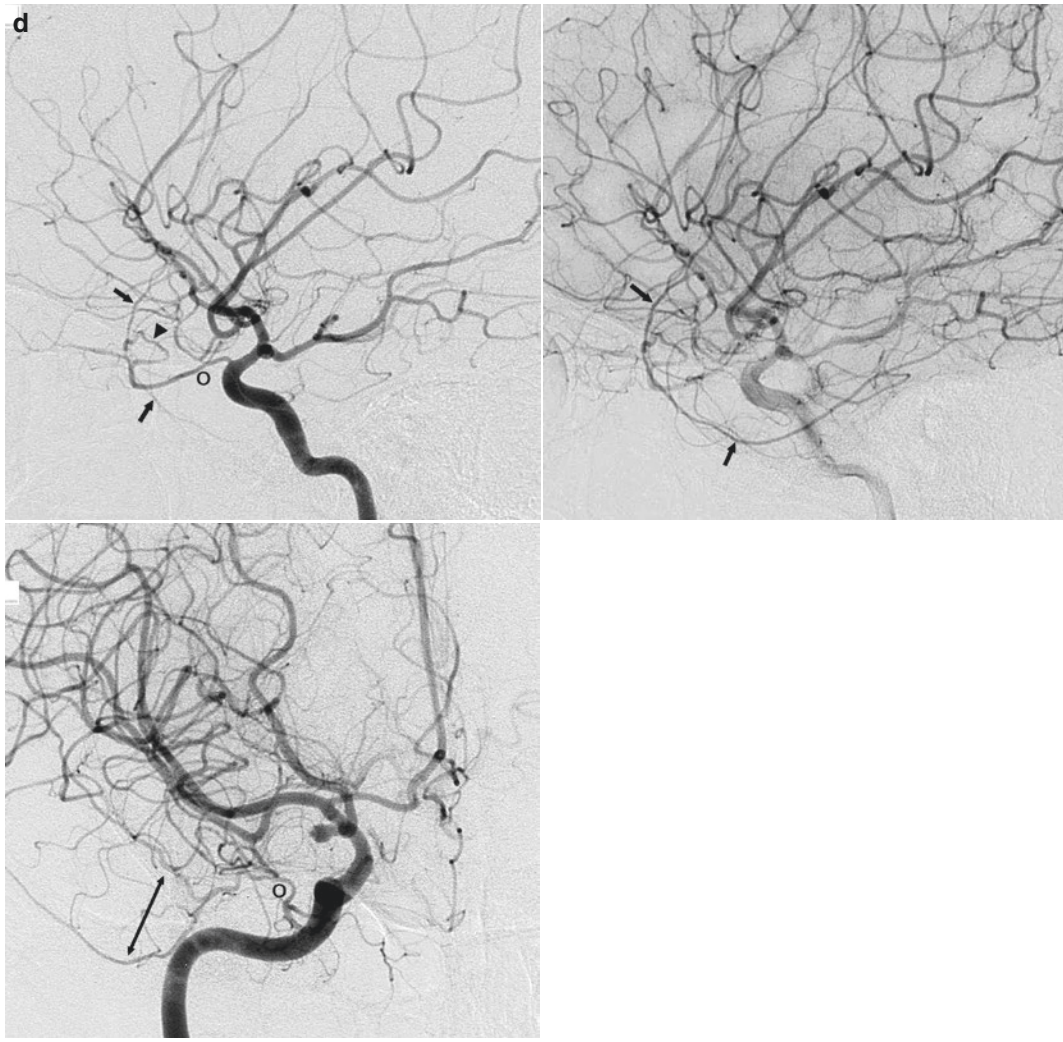

Fig. 2.5 (continued)

aneurysms) can, however, extend superiorly into the subarachnoid space. They are called "*cave aneurysms*" (Kobayashi et al. 1995; Rhoton 2002).

It is not possible for angiographic studies to establish with certainty where the supraclinoid segment begins. This, however, can be approximately located close to the origin of the ophthalmic artery, proximally to it, considering that the artery has commonly an intradural origin (Fig. 2.3). Gibo et al. (1981a) have subdivided the supraclinoid segment in three parts:

- *The ophthalmic segment*, from the origin of the ophthalmic artery to the origin of the posterior communicating artery (PcomA)
- *The communicating segment*, from the origin of the PcomA to the origin of the choroidal artery
- *The choroidal segment*, from the origin of the anterior choroidal artery to the terminal bifurcation of the ICA

At the level of the anterior perforated space (APS), the artery divides into the anterior and middle cerebral arteries.

2.2.3.1 The Ophthalmic Segment

In the ophthalmic segment arise the ophthalmic artery, superior hypophyseal arteries, and other small branches directed toward chiasma and floor of the third ventricle.

The Ophthalmic Artery

The ophthalmic artery (OA) arises from the superior-medial surface of the ICA, commonly very close to the point where the ICA had perforated the dura. It runs below the optic nerve (Hayreh and Dass 1962a, b; Hayreh 1962), pierces again the dura, and enters the orbita, together with the nerve, through the optic canal. Initially the artery runs inferolaterally to the optic nerve (first segment), then crosses the nerve forming a bend under or over the nerve (second segment), and runs further medially and parallel to it (third segment). It gives off three types of branches*: ocular, orbital*, *and extraorbital*. There is a great variability concerning the origin and course of these branches. Some typical pattern, however, can be recognized (Hayreh 1962).

- The ocular branches include the central retinal artery, the ciliar arteries, and the branches going to the optic nerve. Considering the origin of the optic nerve arteries, they can be classified (Hayreh 1962) into intracanalicular branches arising from the ophthalmic artery close to its origin or in its intracanalicular course, and in intraorbital branches. These latter arise more distally, commonly at the bend where the artery crosses under or over the optic nerve. The central retinal artery and the medial and lateral posterior ciliar arteries, both associated in the supply of the eyeball, arise commonly in the area where the ophthalmic artery crosses under or over the optic nerve.
- The orbital branches include the lacrimal artery, which supplies the lacrimal gland and conjunctiva. An important branch of the lacrimal artery, frequently present, is the recurrent meningeal artery, which runs backwards and passes through the superior orbital fissure, anastomosing with branches of the middle meningeal artery (MMA). There is frequently a balance between these arteries; one can predominate. It can be involved in many pathological processes typically basal meningiomas (Fig. 3.28a), and dural arteriovenous fistulas (Fig. 13.13), and in the supply of angiofibromas and chemodectomas extending toward the orbita and parasellar region (Fig. 3.23). Anastomosis of the lacrimal artery with the anterior deep temporal artery can be an important collateral circulation via the OA in occlusion of the ICA (Fig. 3.12). Other orbital branches are the muscular arteries, which supply the muscle and orbital periosteum.
- The extra orbital branches are numerous. They include the posterior and anterior ethmoidal arteries. The posterior arises from the first segment, and the anterior from the third. These branches have an ascending course and pass through the lamina cribrosa, supplying the dura of the basal anterior cranial fossa. From the anterior ethmoidal artery arises the anterior falx artery, which supplies the falx and anastomoses with the falx branches of the MMA. From the ethmoidal arteries arise branches with a descending course anastomosing with the ascending branches of the sphenopalatine arteries, branches of the internal maxillary artery (IMA). These arteries (Fig. 3.28a) are typically involved in the vascularization of meningiomas of the anterior cranial fossa (Bradac et al. 1990), and in dural arteriovenous fistulas of the region (Fig. 13.19). Involvement in the supply of angiofibroma extending toward the orbita can also occur (Fig. 3.23).

Other arteries of this group are the supraorbital (frequently prominent), the dorsonasal, the medial palpebral, and the supratroclear. These branches anastomose with branches of the ECA, in particular with the facial artery, infraorbital branch of the IMA, and frontal branches of the superficial temporal artery. Such anastomoses may be a collateral way via the OA toward the ICA when the latter is occluded (Figs. 3.12 and 3.13). Furthermore, these branches can be involved in vascular malformations of the craniofacial area (Fig. 3.19).

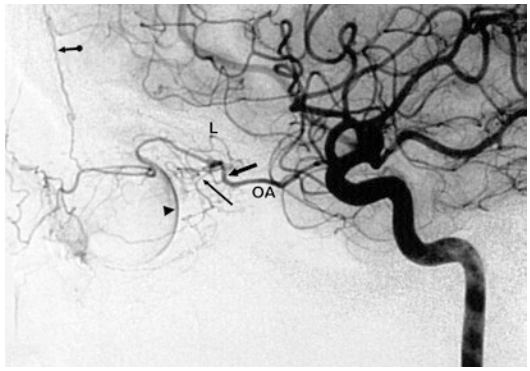

Fig. 2.6 Lateral ICA angiogram. Ophthalmic artery (OA). Bend of the artery around the optic nerve (*large arrow*). From this segment arises the ocular complex comprising the retina and ciliar arteries (*small arrow*). Choroid plexus (*arrow head*), lacrimal artery (L), anterior falx artery (*arrow with dot*)

On the angiogram of the ICA (Vignaud et al. 1972; Huber 1979; Morris 1997; Osborn 1999), the OA is always visible with the exception of the cases in which the artery arises from the MMA. The artery is better defined on the lateral view. From its origin, it runs superiorly for 1–2 mm, and then anteriorly, forming a slight curve with an inferior convexity. About 2 cm from its origin, the OA curves abruptly crossing the optic nerve. The central retinal artery, the ciliar arteries, and the distal branches for the optic nerve arise at the level of the above-described curve (Fig. 2.6). Thus, in embolization procedures involving the OA, the microcatheter should be advanced distally to the above-described curve. The blush corresponding to the plexus of the ocular choroid is always visible as a crescent-shaped structure. The ethmoidal arteries are occasionally evident especially in the lateral view. The anterior falx artery is also easily identifiable, when present, on the lateral angiogram. The other branches are difficult to recognize under normal conditions.

To explain some variations of the OA, it is useful to recall the most important aspects of its embryogenesis (Padget 1948; Hayreh and Dass 1962a, b; HaYreh 1962; Lasjaunias et al. 2001). The definitive OA develops from three sources: *the primitive dorsal OA*, arising from the cavernous portion of the ICA and entering the orbita through the superior orbital fissure; *the primitive ventral OA,* arising from the anterior cerebral artery and entering the orbita through the optic canal; and *the stapedial artery (StA)*, which gives off an orbital branch entering the orbita through the superior orbital fissure.

Inside the orbita and around the optic nerve, an arterial anastomotic circle is formed involving these three arteries. In the further evolution the proximal segment of the primitive ventral OA disappears, arising now from the supracavernous portion of the ICA. This artery will become the definitive OA. The primitive dorsal OA regresses, and the intraorbital branches of the StA are annexed by the definitive OA. In this process, the important changes involving the StA deserve an extra short description.

The StA is the main branch of the hyoid artery, embryonic vessel arising from a segment of ICA which in this stage of evolution is very small and incompletely developed. Later, this segment will become the petrous ICA (see also Sect. 1.1 and Chap. 3). *The StA enters the middle cranial fossa, passing through the tympanic cavity, and divides into intracranial and extracranial branches* (Moret et al. 1977; Lasjaunias et al. 2001). *The intracranial branch (supraorbital artery) is anteriorly directed and supplies the dura of the middle cranial fossa, and extends into the orbita, with a medial and lateral (lacrimal) branch. Both branches enter the orbita through the superior orbital fissure. In some cases, the lacrimal artery penetrates as an isolated branch through the foramen of Hyrtl, located in the greater wing of the sphenoid bone. The second branch of the StA (maxillomandibular artery) is directed extracranially, passing through the foramen spinosum. In the further evolution this branch anastomoses with the primitive ventral pharyngeal artery embryonic vessel representing the proximal external carotid artery. From this connection develops the final internal maxillary artery (IMA) and the middle meningeal artery (MMA). The blood flow is now reversed, being intracranially directed. The intracranial branch of the StA is annexed by the developed MMA, and its intraorbital segment is annexed by the definitive OA.*

As many authors have described (McLennan et al. 1974; Moret et al. 1977; Rodesch et al. 1991b; Morris 1997; Lasjaunias et al. 2001; Perrini et al. 2007), abnormal changes can occur in the embryological evolution of StA and the primitive ventral and dorsal ophthalmic arteries, leading to a series of conditions characterized by different angiographic patterns:

- The proximal part of the primitive ventral OA does not regress and so the OA arises from the anterior cerebral artery (Hassler et al. 1989). This evolution could also explain the origin of the OA from the distal ICA bifurcation as reported by some authors (Parlato et al. 2011).
- The primitive ventral OA disappears instead of the primitive dorsal OA, leading to the cavernous origin of the OA (Figs. 2.5a, 2.7c and 4.11c).
- The proximal segment of the primitive ventral OA does not develop, while the intraorbital part of the StA remains and is connected at the level of the superior orbital fissure with the MMA. In such a condition, the OA is only visible on the ECA, not on the ICA angiogram (Fig. 2.5b, c).
- The lacrimal branch can persist as an isolated branch of the MMA (meningolacrimal artery) entering the orbita through the foramen of Hyrtl and supplying partially the intraorbital structures, while the ocular and neuronal branches arise from the OA. In such cases, the orbital vascularization is partially visible on the ECA and partially on the ICA angiograms. There are commonly no anastomoses between these two systems. In other cases, the MMA gives off a branch, which enters the orbita through the superior orbital fissure and anastomoses with the lacrimal branch normally arising from the OA.
- Another condition is characterized by the origin of the MMA from the OA and so it is only recognizable on the ICA angiogram. This occurs when the intracranial part of the MMA does not develop; the proximal part of the intraorbital-transsphenoidal segment of the StA does not regress and anastomoses with the lacrimal branch of the OA (Fig. 2.5d).
- The MMA originates in the petrous segment of the ICA. This occurs when the first and intracranial segments of the StA do not regress and the extracranial part of the MMA (part of the maxillomandibular) does not develop. On the skull CT, the foramen spinosum is not present and the MMA is only visible on the ICA angiogram. In other cases the persistence of the first segment of the StA can appear as a small branch arising from the petrous segment of the ICA (caroticotympanic artery). See also Sect. 2.2.1.
- Finally, cases of origin of the ophthalmic artery from the basilar artery have been described (Schumacher and Wakhloo 1994; Sade et al. 2004). It is difficult to explain this very rare anomaly considering the classical description of the embryogenesis of the OA. Similarly difficult to explain is the embryological mechanism responsible for the origin of the MMA from the basilar artery as reported by some authors (Seeger and Hemmer 1976; Shah and Hurst 2007; Kumar and Mishra 2012).

Superior Hypophyseal Arteries

The superior hypophyseal arteries (SHA) are formed by a group of small branches arising commonly from the posteromedial surface of the ophthalmic segment of the ICA. The SHA supplies the infundibulum and the anterior lobe of the pituitary gland. Other small branches are involved in the supply of the optic nerve, chiasma, optic tract, and anterior part of the floor of the third ventricle. All these arteries are very small and not recognizable on a normal angiogram.

Supply of the Pituitary Gland

The adenohypophysis is supplied by the superior hypophyseal arteries. These run toward the pituitary stalk, where they connect forming a network of capillaries continuing in venules forming the so-called venous portal system,

through which flow the releasing and released-inhibiting hormones from the hypothalamus to the adenohypophysis. The neurohypophysis is supplied by the inferior hypophyseal artery which is a branch of the MHT. There are anastomoses between the branches of the superior hypophyseal and inferior hypophyseal arteries and those of the contralateral arteries.

Each half of the pituitary gland drains into the corresponding cavernous sinus. The further drainage occurs through the inferior petrosal sinuses.

2.2.3.2 The Communicating Segment

From this segment arises the posterior communicating artery (PcomA). The PcomA arises from the posterior surface of the ICA. It runs posteriorly and medially to join the posterior cerebral artery (PCA), in a close relationship with cranial nerve III, which is commonly laterally but some time medially located (Gibo et al. 1981a).

Commonly, the PcomA is slightly smaller than the PCA. It may be, however, very large, continuing directly into the PCA. This variant present in about 30% of the cases is termed the "fetal" origin of the PCA. Indeed, in the embryonic phase, the PCA develops as a posterior extension of the PcomA, caudal division of the ICA. The connection of the PCA with the basilar artery through the P1 segment develops later. In the further evolution, the PcomA (*pars carotica* of the PCA) becomes hypoplastic or regresses entirely, while the P1 segment (*pars basilaris* of the PCA) becomes well developed. This latter evolution occurs in about 70% of the cases (Zeal and Rhoton 1978; Huber 1979; Pedroza et al. 1987). See also Chaps. 1 and 7.

A slight widening of the PcomA at its origin (infundibulum) is not rare. It has been described in 6.5% of normal angiograms (Hassler and Salzmann 1967), and it has been interpreted as an early stage of aneurysm formation. Other studies (Epstein et al. 1970a) made on autopsy specimen have demonstrated neither an aneurysmal nor a preaneurysmal aspect.

The infundibulum appears as a homogeneous conical dilatation of 2–3 mm at the origin of the PcomA. Commonly, it is not considered as a pathological finding. Sometimes, however, the differential diagnosis with a real aneurysm can be difficult and be suspected when the infundibulum has not the typical conical form especially in patients with SAH in whom no other aneurysm can be detected. In these cases, it is also important to exclude, with a short-time angiographic control, the presence of an aneurysm responsible of the SAH not visualized in the first study. This will be discussed in Sect. 11.11. Some authors have reported the very rare evolution of the infundibulum into a saccular aneurysm (Marshman et al. 1998; Cowan et al. 2004; Radulovic et al. 2006; Fischer et al. 2011). In patients with infundibulum and unclear SAH or familiarity of aneurysms, a follow-up in yearly intervals has been proposed (Fischer et al. 2011).

From the PcomA arise many perforating branches. Since the first description by Duret (1874), many anatomical studies have been performed (Foix and Hillemand 1925a, b; Lazorthes and Salamon 1971; Percheron 1976b; Saeki and Rhoton 1977; Zeal and Rhoton 1978; Gibo et al. 1981a; Ono et al. 1984; Pedroza et al. 1987, Tatu et al. 2001). These arteries have been variously termed: tuberothalamic, premammillary, and anterior thalamoperforating arteries. The latter definition seems to us to be the most appropriate and it is the one we will adopt. Many branches are present, also in cases of a smaller PcomA. Among them, there is sometimes a large branch arising in front of or besides the mammillary body (Gibo et al. 1981a; Pedroza et al. 1987). These perforators supply the posterior part of the chiasma, the optic tract, and the mammillary body. They enter the posterior perforated substance, supplying the hypothalamus, subthalamus, and anterior thalamus. Some authors (Gibo et al. 1981a) have found that they can supply also the posterior limb of the internal capsule.

Variations. Anomalous origin of the PcomA is very rare. Its origin from the OA has been reported (Bisaria 1984). Cases of PcomA arising distally to the AchA have also been described (Moyer and Flamm 1992). As far as it concerns its relationship with the anterior choroidal

artery, see below in this chapter. The presence of a well-developed or hypo-aplastic PcomA has already been discussed. As it will be better described in the chapters treating the stroke this variation can play an important role as a way of a possible collateral circulation. Indeed the fetal PCA can be involved in occlusions involving the anterior circulation, but can represent a way of collateral circulation when the artery arises from the basilar artery. A different situation occurs in case of occlusion of the basilar artery, in which the fetal PCA can act as an important collateral way.

Depending on its development, the PcomA can be injected only on the ICA angiogram, on the vertebrobasilar angiogram or on both (Figs. 2.7 and 7.5). In the angio-MR, the PcomA, P1, and PCA complex can be well identified (Figs. 7.2 and 7.5d). The perforating branches can be only well examined on the lateral and AP vertebral and sometimes on the lateral carotid angiograms (Figs. 2.7c, 7.8, and 7.9). They

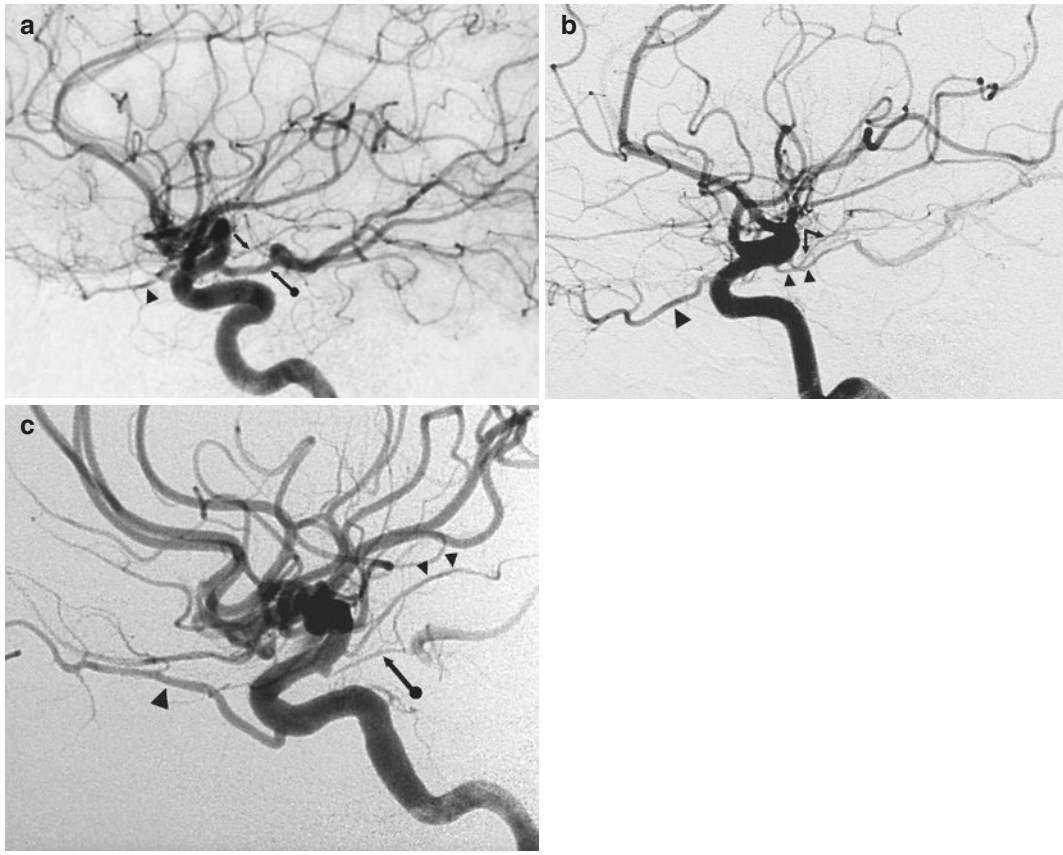

Fig. 2.7 Carotid angiogram. Lateral view in three different cases. (**a**) Large PcomA (*arrow with dot*) continuing in the PCA. Remark the very proximal origin of the temporal and parieto-occipital branches of the PCA. Anterior choroidal artery (*arrow*). Ophthalmic artery (*arrowhead*). (**b**) Small PcomA (*arrowheads*) continuing in the PCA. Anterior choroidal artery (*arrow with angle*). Ophthalmic artery (*arrowhead*). Owing to overlap, the anterior choroidal artery erroneously seems to arise proximally to the PcomA. This extremely rare condition can occur and should be identified by complementary projections. (**c**) Small PcomA (*arrow with dot*) continuing in the PCA. Note the ascending course of a perforating branch. There is a small infundibulum at the origin of the PcomA. Anterior choroidal artery (*arrowheads*). Anomalous origin of the ophthalmic artery from the cavernous portion of ICA (*arrowhead*)

appear as small branches running upwards and slightly backwards.

2.2.3.3 The Choroidal Segment

In the choroidal segment arise the anterior choroidal artery and perforators directly from the ICA.

The Anterior Choroidal Artery

In all cases studied by Rhoton et al. (1979) and Fujii et al. (1980), the anterior choroidal artery (AchA) arose from the posterior surface of the ICA, more laterally to the site of origin of the PcomA, and 2–4 mm distal to it. The AchA can be divided into a cisternal segment, from its origin to the choroid fissure, and a distal segment (Goldberg 1974; Rhoton et al. 1979). The cisternal segment, from which arise the main arteries supplying the parenchyma, has an average length of 25 mm (Otomo 1965; Rhoton et al. 1979). From its origin the AchA runs first medially, below the optic tract crossing it from lateral to medial. The artery runs then laterally around the midbrain in the circumpeduncular cistern. The basal vein lies superiorly and the PCA inferiorly. At the level of the lateral geniculate body, the artery curves sharply crossing the optic tract from medial to lateral, entering the temporal horn through the choroid fissure joining the choroid plexus. The artery extends posteriorly reaching the atrium, where it can anastomose with branches of the posterolateral choroidal artery. Rarely it extends anteriorly toward the foramen of Monro, supplying the plexus and anastomosing with the posteromedial choroidal artery.

From the cisternal segment arise many branches which can be divided into superior, lateral, and medial (Abbie 1933; Carpenter et al. 1954; Rhoton et al. 1979; Duvernoy 1999; Tatu et al. 2001). It can occur that the branches of the superior group do not arise from the main trunk of the AchA, but can have a separate origin directly from ICA. They supply the optic tract and enter the APS posteriorly to the perforators of the distal ICA and A1 segment of the ACA, and medially to those of the MCA. They supply the medial part of the globus pallidus, the tail of the nucleus caudatus, and sometimes the genu of the internal capsule (Goldberg 1974; Rhoton et al. 1979). The most posterior branches arise at the level of the lateral geniculate body, and penetrate the brain to supply the inferior part of the posterior limb of the internal capsule, its retrolenticular segment, and the optic radiations (Rhoton et al. 1979). According to some authors (Hupperts et al. 1994), they can be involved also in the vascularization of the parietal periventricular area. The lateral group supplies the uncus, amygdala, and hippocampus; the medial group the anterolateral midbrain; and the lateral geniculate body (Rhoton et al. 1979).

There is a marked interchangeability in the vascular territory described among the AchA, ICA, PcomA, PCA, and MCA (Rhoton et al. 1979). *Moreover, there are rich anastomoses between the Acha, PcomA, and PCA through branches on the surface of the temporal lobe near the uncus and of the lateral geniculate body. Other anastomoses occur with the choroidal arteries. All these aspects make it difficult to predict the effect of occlusion of the AchA* (Theron and Newton 1976; Rhoton et al. 1979; Friedman et al. 2001).

The artery is commonly well recognizable on the anteroposterior (AP) and lateral angiograms. On the lateral angiogram, the artery runs backward, forming an upward convex curve (cisternal segment). It runs further posteriorly entering the choroid fissure (plexal segment). The plexal segment in the temporal horn and atrium shows a typical blush in the later arterial-capillary phase. On the AP angiogram, the AchA runs first medially and then laterally, surrounding the cerebral peduncle, mixing with perforators of the middle cerebral artery (Figs. 2.7, 2.8, and 2.9).

Variations. Many anomalies concerning the origin and development of the AchA have been described. A few cases of origin from PcomA or middle cerebral artery (Carpenter et al. 1954; Morello and Cooper 1955; Sjoegren 1956; Otomo 1965; Herman et al. 1966; Theron and Newton 1976; Lasjaunias and Berenstein 1990) or from the ICA proximal to the PcomA (Moyer and Flamm 1992; Nishio et al. 2009), as well as a

(**b**) Lateral carotid angiogram in patient examined for a ruptured aneurysm of ICA. There is a well-developed AchA. Cisternal (C) and plexal (P) segments. Uncal branch (*arrow*). (**c**) Lateral carotid angiogram. Large PcomA continuing in the PCA (fetal type) (*arrow*). Above there is a well-developed artery, corresponding to a hyperplastic AchA (*arrow with dot*), which takes over partially the vascular territory of the PCA. Above the AchA there is a small branch (*arrowhead*) corresponding probably to a perforating branch arising from the AchA or directly from the ICA. (**d**) Carotid angiogram (oblique view). Large PcomA (*arrow*) continuing in the PCA. Above it there is a well-developed, hyperplastic AchA (*arrowhead*), which takes over the parietal vascular territory of the PCA

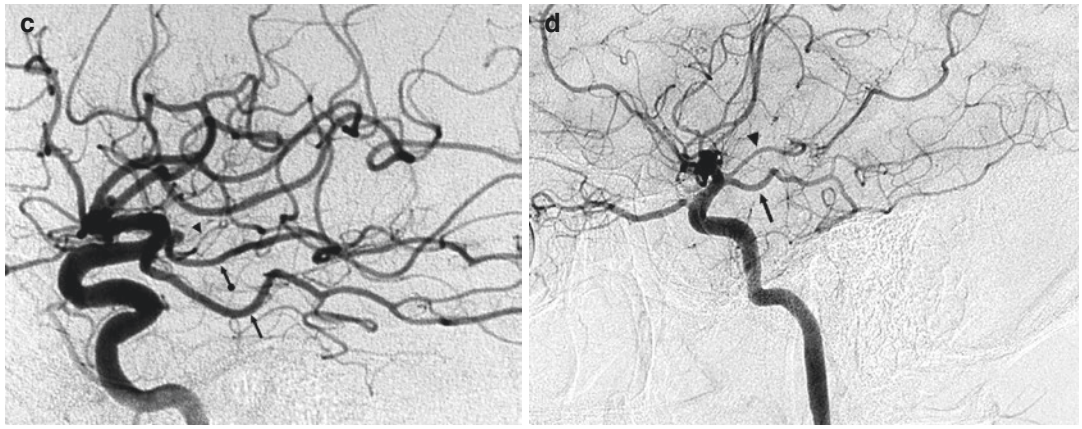

Fig. 2.9 (continued)

case of aplasia (Carpenter et al. 1954), have been reported. Other authors (Saeki and Rhoton 1977) found a few cases of duplicated AchA with two branches arising separately from ICA.

Another anomaly concerns development of the AchA, which can take, in accordance with the studies of some authors (Blackburn 1907; Bergquist 1975; Takahashi et al. 1980, 1990), a hyperplastic or a hypoplastic form. In the hyperplastic form the AchA is well developed taking over partially or almost completely the vascular territory of the PCA. On the angiogram the AchA appears as a large vessel running superiorly to the inferiorly located PcomA continuing in the PCA. The vascular territory normally supplied by the PCA is partially or almost completely taken over by branches of the hyperplastic AchA. This pattern has been interpreted in the past as expression of a duplicated PcomA or PCA. This anomaly probably occurs. However, in the majority of these cases, this pattern is due to a hyperplastic AchA due to an anomalous development and persistence of the anastomoses between AchA and PCA and PcomA normally present in the embryogenesis. The angiographic pattern can change depending on the site of the persistent anastomoses. If these are proximal the PcomA and PCA are hypoplastic and their vascular territory is largely replaced by a well-developed AchA. If the anastomoses are more distal the vascular territories are taken over partially by the AchA and partially by the PCA. In the hypoplastic form of the AchA, only its cisternal segment is developed. Examples are presented in Figs. 2.9a–d and 2.12.

The Perforators of ICA

The perforators of ICA arise from the choroidal segment of the ICA, typically from its posterior wall, distal to the origin of the AchA (Rosner et al. 1984; Mercier et al. 1993). They enter the APS in its posteromedial part overlapping with perforators arising from AchA and supply the genu of the capsula interna, its posterior limb, and the adjacent part of the pallidum. They can replace perforators of the AchA and pars of perforators of the MCA and vice versa. The perforators are rarely evident on the angiogram.

2.3 Congenital Anomalies of the CCA and ICA

- Extremely rare cases of *absence of the CCA* on the right or left have been reported. It has been suggested (Haughton and Rosenbaum 1974) that in these cases, the dorsal part of the third aortic arch (*ductus caroticus*) does not

regress. Consequently, there is no formation of the CCA and the ICA and ECA arise separately from the third aortic arch. An anomalous origin of the CCA can also occur (see also Sect. 1.2).

- *Aplasia and hypoplasia of ICA* are other rare anomalies. Tode is reported to be the first to have described an aplasia of the ICA in 1787 on an autoptic examination. Verbiest (1954) described this anomaly on an angiographic study. Later many authors have described this anomaly which in the majority of the cases is discovered incidentally in patients studied for other reasons. It can be uni- or bilateral (Lie 1968; Lee et al. 2003; Mahadevan et al. 2004). Association with a hypoplastic common carotid artery as well as with cerebral aneurysms and with other severe pathologies such as PHACES, and neurofibromatosis can occur (Lee et al. 2003; Mahadevan et al. 2004). Today congenital forms of hypo-aplasia can already be suspected in CT or MR showing, respectively, a small or absent carotid canal and reduction or absence of blood flow. In angiographic studies various types of collateral circulation may be demonstrated, which correspond probably to the phase of the embryological evolution in which the anomaly develops (Cali et al. 1993; Lee et al. 2003). Among the most frequent reported in the literature, there are *that occurring through the circle of Willis involving AcomA and PcomA, and that through the presence of a persistent primitive trigeminal artery* (Lie 1968; Given et al. 2001; Lee et al. 2003).

A particular form of collateral circulation is characterized by *the persistence of the primitive maxillary artery*, an embryonic vessel which arises at the cavernous portion of the ICA, and runs on the floor of the sella, forming an intrasellar anastomosis connecting both ICAs. Cases in which the anastomosis runs posterior to the dorsum sellae have also been reported. Many authors have been described this rare anomaly (Kishore et al. 1979; Staples 1979; Elefante et al. 1983; Alexander et al. 1984; Tracy 1987; Cali et al. 1993; Midkiff et al. 1995; Chen et al. 1998; Gozzoli et al. 1998; Lajaunias et al. 2001; Given et al. 2001), which should be taken into consideration in particular in patients in whom a transsphenoidal surgery for intrasellar adenoma is planned. Cases associated with hypopituitarism have been reported (Mellado et al. 2001; Moon et al. 2002).

According to De La Torre and Netzky (1960), the primitive maxillary artery is an embryonic vessel arising from the cavernous portion of ICA, giving off branches extending to the anteromedial and lateral adjacent areas anastomosing with branches of the middle meningeal artery. The artery normally regresses and becomes partially incorporated on both sides in the inferior hypophyseal artery branch of the MHT (Padget 1948). Parkinson (1964), in a large autopsy study, has shown the presence of anastomoses connecting both cavernous carotid arteries through the inferior hypophyseal artery running on the floor of the sella and through the clival arteries, both branches of the MHT. In cases of aplasia of ICA, either the inferior hypophyseal or the clival arteries can enlarge, becoming an important collateral circulation toward the absent ICA. An example is shown in Fig. 2.10.

Another very rare collateral is represented by the so-called *rete mirabile.* This is a well-known arterial network occurring in other vertebrates to compensate a rudimentary or absent ICA, but is a rarity in the humans. It is formed mainly by branches of the ECA, especially by those arising from the internal maxillary and ascending pharyngeal arteries. The appearance of the network also on the angiogram of the ICA suggests the involvement of persistent embryological vessels such as the stapedial artery, or neovascularization through the *vasa vasorum*. The *rete mirabile* occurs typically in cases of segmental aplasia of the ICA involving its petrous segment allowing the reconstitution of the distal ICA (Minagi and Newton 1966; Danziger et al. 1972; Mahadevan et al. 2004; Lin et al. 2013). Cases of associated aplasia of the transdural vertebral artery with a distal filling of the basilar artery through a rete mirabile involving PICA and spinal arteries have also been reported (Hyogo et al. 1996;

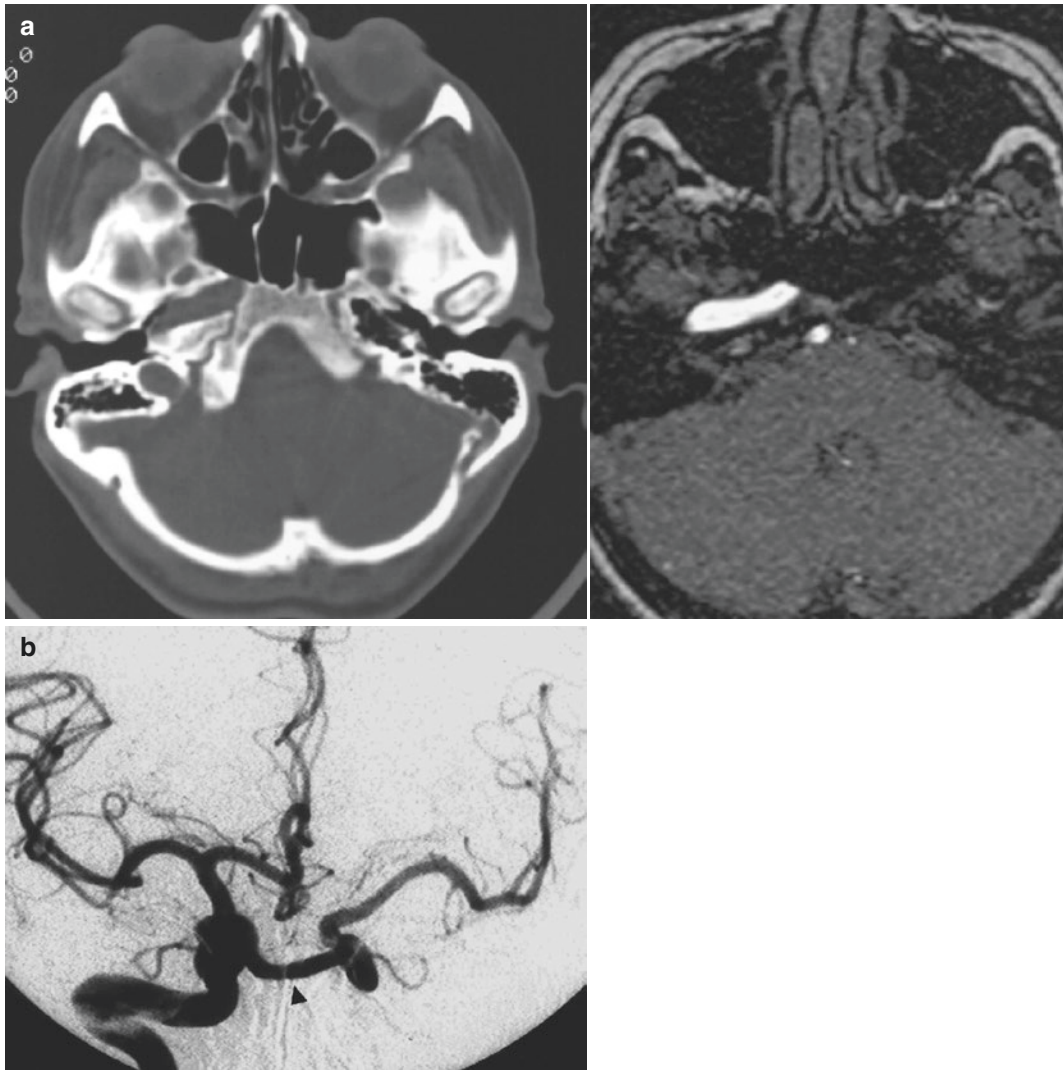

Fig. 2.10 Aplasia of ICA. (**a**) CT and MRI showing, respectively, that the canal of the horizontal portion of the petrous segment of ICA on the left is absent and there is no typical flow signal on the left on MRI. (**b**) Right carotid angiogram. AP view. There is filling of the cavernous portion of the left ICA through intrasellar anastomosis (*arrowhead*) corresponding to the primary maxillary artery (see also Sect. 2.5). Further filling of the middle cerebral artery. Aplastic A1 segment

Mahadevan et al. 2004; Hong et al. 2010a). Association with cerebral aneurysm as well as with other anomalies especially involving the origin of the carotid and vertebral arteries from the aortic arch can occur (Lee et al. 2003). Association with pseudoxhantoma elasticum has been reported (Del Zotto et al. 2012). An example is presented in Fig. 2.11.

- The pathogenesis of the hypo-aplasia of the ICA is not completely clear. It is thinkable that this anomaly occurs in the phase of the embryogenesis when the ICA first appears from the distal segment of the third aortic arch (see also Sect. 2.1).
- *Another very rare form of aplasia is that involving the distal intracranial internal carotid artery.* We observed this anomaly in a child examined for epileptic seizures due to severe cortical dysplasia. The vascular territory of the absent ICA was revascularized mainly through

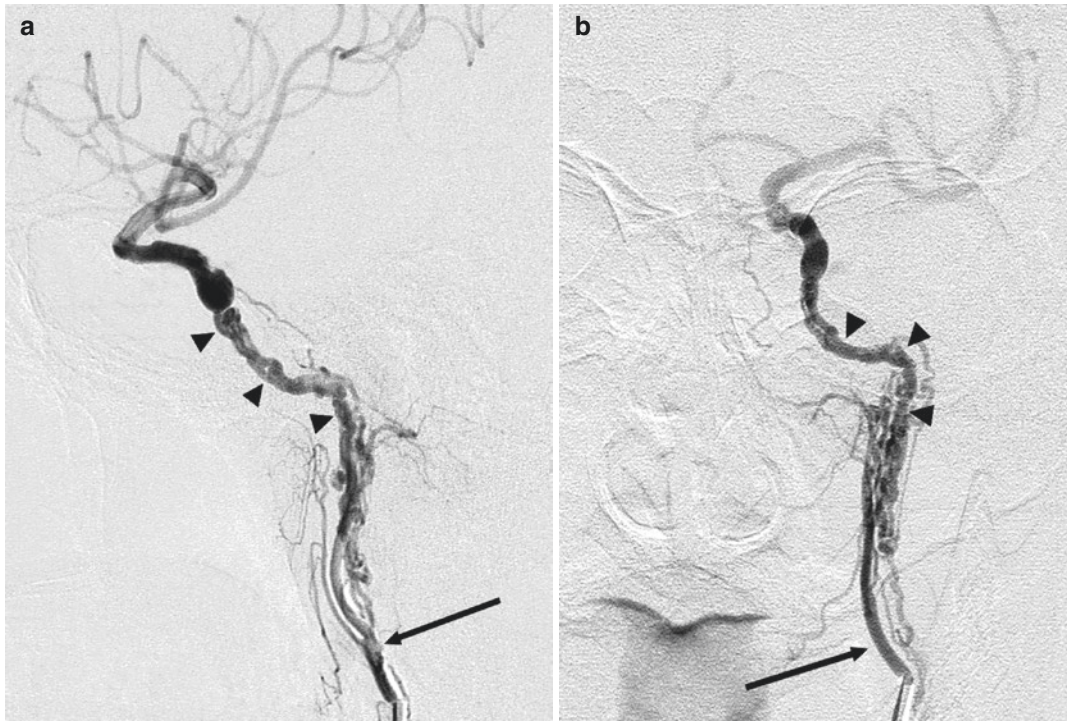

Fig. 2.11 Example of a collateral circulation through *a rete mirabile* incidentally discovered in an old patient. The angiogram of the left common carotid artery showed absence, probably congenital aplasia, of the ICA. A rich network of arteries arising from IMA and especially from the ascending pharyngeal artery (AphA) lead to a reconstruction of the intracranial ICA at its petrous segment. Selective angiogram of the AphA, lateral (**a**) and AP (**b**) views. AphA (*arrow*). Network (*arrowheads*) connecting the AphA with the petrous segment of ICA. A primitive trigeminal artery was present on the right ICA angiogram

anastomoses between the middle meningeal artery and the middle cerebral artery (Fig. 2.12). This kind of aplasia could be due to an anomalous embryogenetic evolution at the level of the distal division of the ICA in cranial and caudal segments (see also Sect. 1.1.).

- *Other anomalies are the embryogenic persistence of the connection between the carotid and* the *vertebrobasilar circulation* (Drawing 2.13c). Considering these in the cranio-caudal direction, the first is represented by the *PcomA* whose different evolution has already been described in Chaps. 1, 2, and 7. The other connections further caudal are *the primitive trigeminal artery (PTA), the otic artery (OT), the hypoglossal (PHA), and the proatlantal (PRA) arteries*. These arteries which regularly develop in the early phase of the embryogenesis (Chap. 1) are transitory vessels which last normally only few days (Padget 1948; Lie 1968) and disappear as their function is replaced by the PcomA and the formed vertebrobasilar system. In some rare cases, however, they do not regress. The most frequent persistent artery, with an incidence of 0.1–0.2% (Lie 1968; Huber 1979; Uchino et al. 2000; Meckel et al. 2013a), is the PTA. It takes its origin from the cavernous portion of the ICA, near the origin of the MTH, sometimes giving off branches for vascular territories normally supplied by the MTH (Parkinson and Shields 1974; Ohshiro et al. 1993; Salas et al. 1998; Suttner et al. 2000). It runs posteriorly passing through or over the dorsum sellae, sometimes having a more medial intrasellar course. This latter condition should be correctly diagnosed especially in the patients in whom a transsphenoidal surgery for pituitary

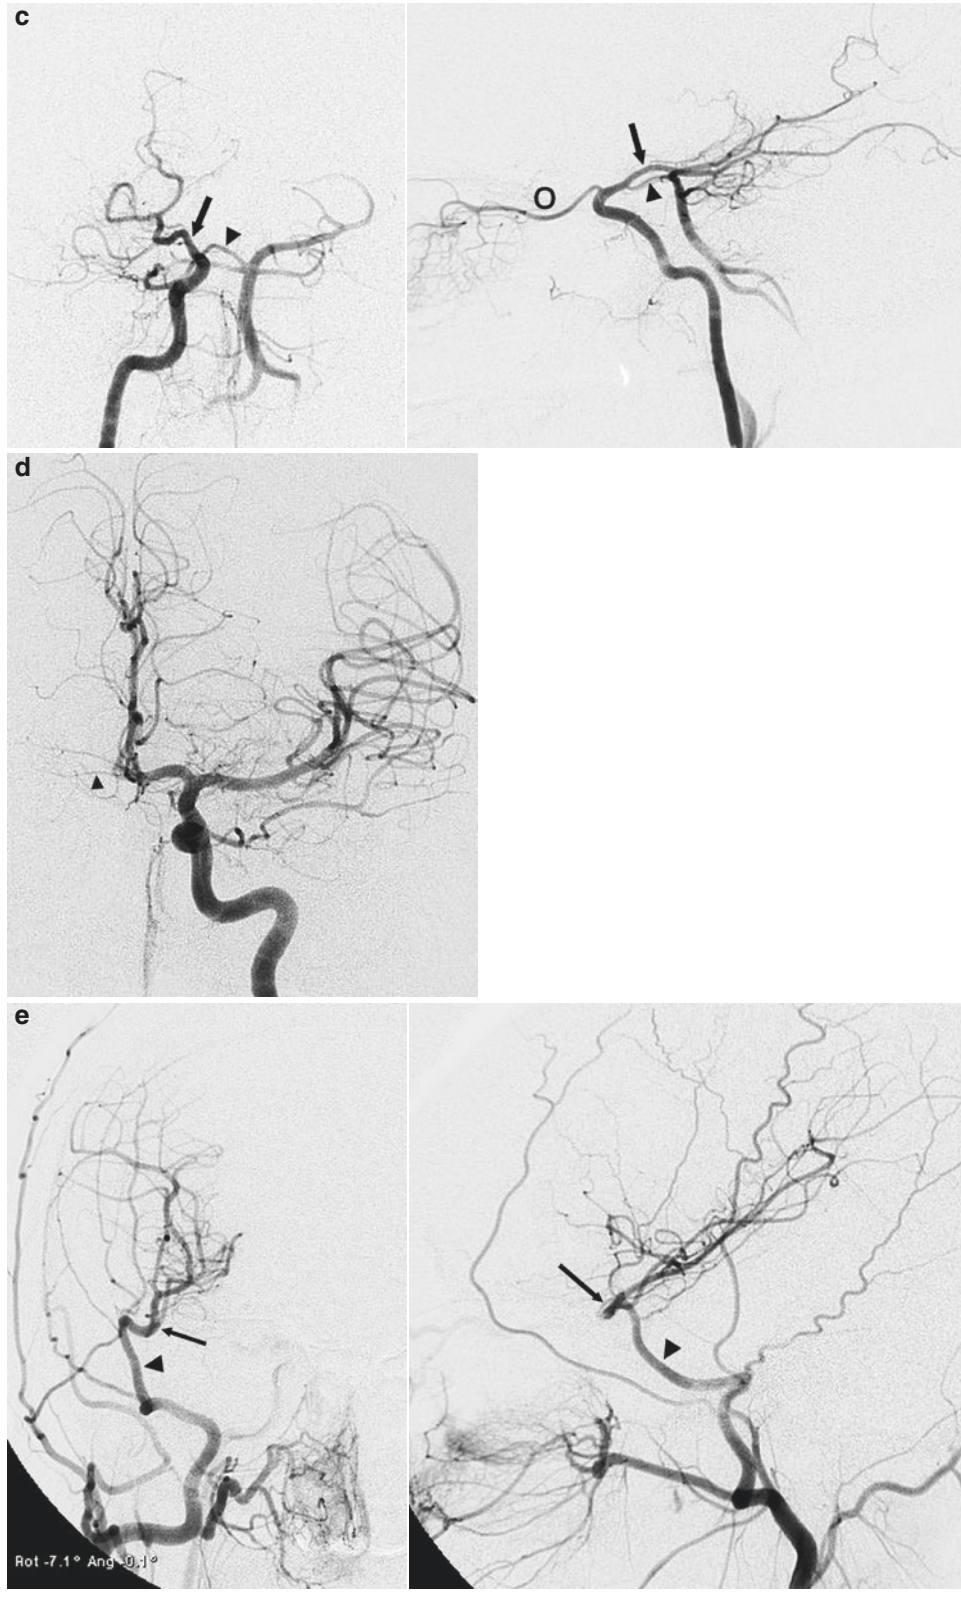

Fig. 2.12 (continued)

adenoma is planned (Lee and Kelly 1989; Richardson et al. 1989; Piotin et al. 1996; Dimmick and Faulderf 2009). Furthermore, as reported by some authors (Ohshiro et al. 1993; Salas et al. 1998; Suttner et al. 2000) PTA can also have a more lateral origin and course giving off, in these cases, branches supplying pons and trigeminal ganglion.

Close to the trigeminal nerve where this leaves the pons, the PTA is connected with the distal basilar artery (BA). Sutton (1950) was the first to report a persistent PTA on an angiographic study. Later two types of PTA have been described in anatomic and angiographic studies by Saltzman (1959) and Wollschlaeger and Wollschlaeger (1964). In one variant the PcomA is absent or hypoplastic and the PTA fills the BA from which arise the posterior cerebral and the superior cerebellar arteries (Fig. 2.13a). In another variant, the PcomA is well developed and continues in the posterior cerebral artery. The PTA supplies only the superior cerebellar artery. There is no connection with the PCA. Commonly the VAs which join the proximal BA and supply the PICA are normal developed. Sometimes they can be hypoplastic.

Association with hypo-aplasia of the BA involving its segment below the entry of the PTA can occur (see for this variant also Sect. 6.2.4).

The PTA can be the site of aneurysm (Ahmad et al. 1994) and cavernous fistula. This latter can be due to the rupture of the aneurysm or have a traumatic cause (Enomoto et al. 1977; Flandroy et al. 1987; Oka et al. 2000; Tokunaga et al. 2004; Geibprasert et al. 2008; Asai et al. 2010; Kobayashi et al. 2011; Meckel et al. 2013). Furthermore, it should be considered that the PTA can be an important collateral circulation from the BA toward the ICA in cases of agenesis or occlusion of the artery. It can, however, be responsible for symptoms due to a vascular steal phenomenon from the basilar artery to the ICA vascular territory, and it can be a way of emboli arising in the vertebra-basilar sector toward the carotid territory or vice versa.

- Other less frequent carotid-vertebrobasilar anastomoses are *the persistent otic, hypoglossal, and proatlantal arteries*. The otic artery connects the petrous ICA with the BA. There are only a few angiographic reports about this anomaly (Reynolds et al. 1980).
- The persistent hypoglossal artery (PHA) arises from the cervical ICA, at the level of C1–C2, and runs dorsally, entering the hypoglossal canal, which is enlarged (recognizable on the CT skull base), joining the vertebral artery, which is commonly hypoplastic or absent in its proximal segment (Kanai et al. 1992; Uchino et al. 2012b; 2013a) (Fig. 2.13b). Cases of PHA arising from the external carotid have also been described (Uchino et al. 2013b). The association with aneurysm has been reported (Brismar 1976; Kanai et al. 1992; De Blasi et al. 2009; Uchino et al. 2013a).
- Another very rare connection is represented by the *persistent proatlantal artery (PRA).* This is a vessel which arises from the cervical ICA or more rarely from ECA, runs dorsally, reaches the atlas, and runs further above it, connecting with the extradural suboccipital part of the vertebral artery. Padget (1954) and Bloch and Danziger (1974) in their study about the embryonic intersegmental arteries called the vessel running between the occipital bone and atlas, which normally disappears and partially contributes to the development of the extradural transverse segment of the vertebral artery (VA) *suboccipital or proatlantal intersegmental artery* (see also Sect. 6.2.4). In case of persistence of the PRA, some authors (Moffat 1959; Haughton and Rosenbaum 1974) have suggested that this is due to failure of the superior, dorsal part of the third aortic arch, from which the PRA arises, to regress. This embryonic vascular structure known as "*ductus caroticus*" remained connected with the proximal part of the third aortic arch from which develop the ICA and ECA (see also Sect. 1.1). In the further evolution a connection between ICA or ECA and VA through the persistent PRA and in some cases also of the PHA as described by some authors (Suzuki et al.

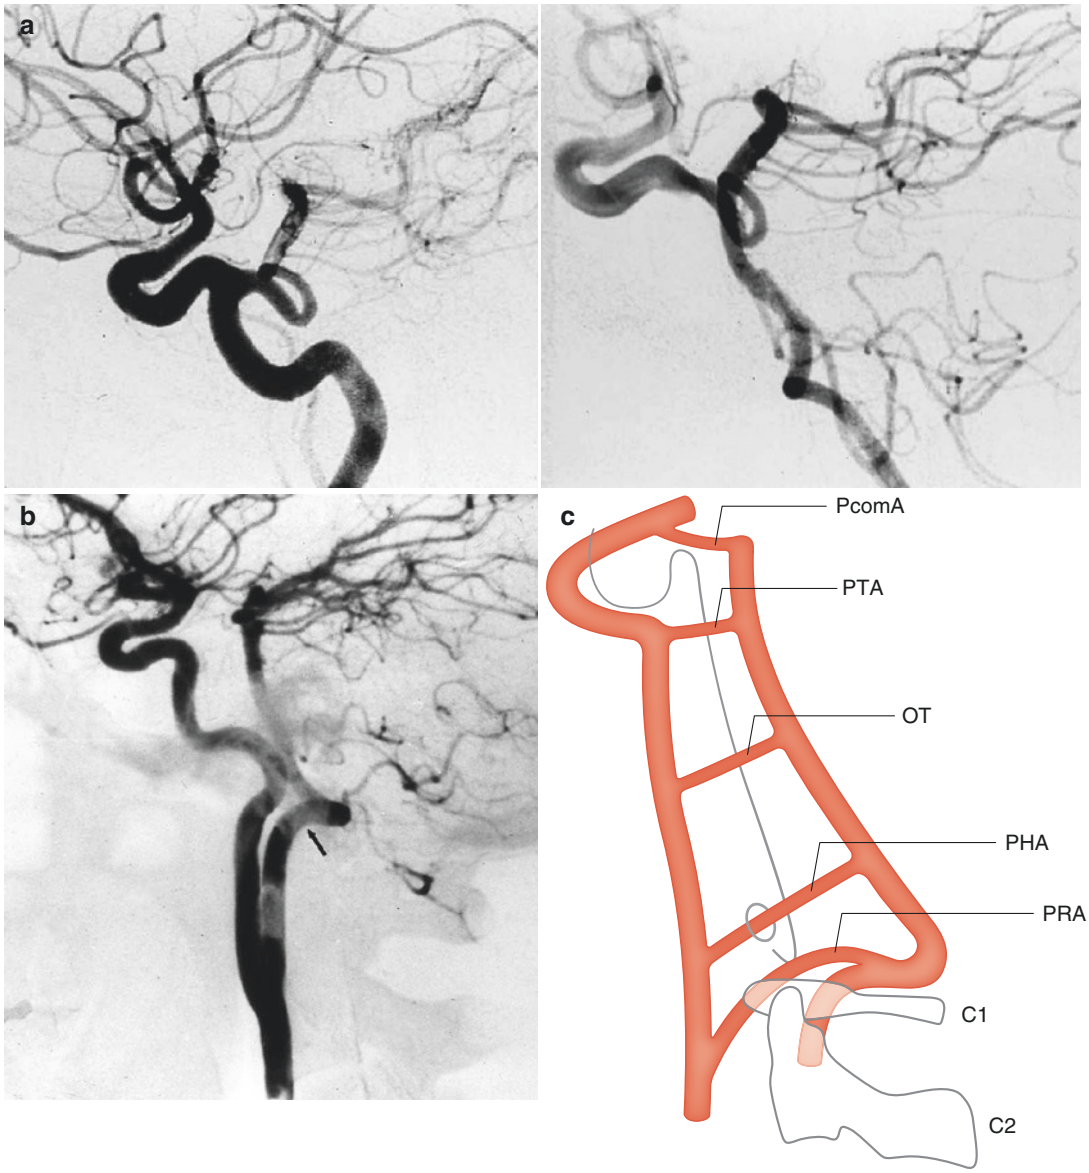

Fig. 2.13 Connections between the ICA and the vertebrobasilar sector. (**a**) Persistent primitive trigeminal artery connecting the cavernous portion of the ICA with the basilar artery. The connection is visible on the carotid and vertebral angiograms. (**b**) Persistent hypoglossal artery arising from ICA, entering the hypoglossal canal (*arrow*), and anastomosing with the vertebral artery. (**c**) Drawing showing the connections between ICA and BA and VA. *PcomA* posterior communicating artery, *PTA* primitive trigeminal artery, *OT* otic artery, *PHA* hypoglossal artery, *PRA* proatlantal artery

1979) can develop. Later other authors (Lasjaunias et al. 1978b; Suzuki et al. 1979) considering that the PRA after its connections with the VA frequently continues in a branch having the aspect and course of that of the occipital artery, and the occipital artery can have an anomalous origin from ICA, have suggested that in both conditions we are dealing with the same vessel, i.e., the proatlantal artery, which could correspond to the proatlantal artery as described by Padget. This can lose its connection with the VA, appearing as an anomalous or a normal occipital artery. Vice versa, the anomalous

occipital artery arising from the ICA can connect with the VA appearing as the proatlantal artery. In all cases, in which a PRA is present, the proximal VA is commonly hypoplastic or absent.

- A few other anomalies can occur. *The one is the origin of the superior cerebellar, anterior inferior cerebellar, and posterior inferior cerebellar arteries from the cavernous portion of the ICA* (Scotti 1975; Haughton et al. 1978; Siqueira et al. 1993; Morris 1997; Uchino et al. 2000; Shin et al. 2005; Meckel et al. 2013). This has been interpreted as a partial primitive trigeminal artery persistence (Lasjaunias and Berenstein 1990; Meckel et al. 2013).
- *Another very rare variant involves the PICA*, which arises from the extracranial ICA, enters the posterior fossa through the hypoglossal canal, and supplies the corresponding cerebellar vascular territory without having connections with the vertebral artery. This variant has been interpreted as a partial persistence of the embryonic hypoglossal artery (Andoh et al. 2001; Uchino et al. 2013a). Also cases of origin of PICA from the external carotid artery have been described, and interpreted as anastomosis between the hypoglossal branch of the ascending pharyngeal artery and the PICA and put in the group of variants of the PHA (Lasjaunias et al. 1981; Kim et al. 2009; Uchino et al. 2013a).
- *The internal carotid artery can have an aberrant course*. Among these anomalies there is the *retropharyngeal position* in which the artery runs very close to the pharynx or sometimes appears as a submucosal mass. It is frequently asymptomatic, but in some cases can be responsible of an oropharyngeal pulsatile or foreign body sensation, dysphagia, hoarseness, and respiratory distress. As reported by some authors (Marcucci et al. 2009; Munoz et al. 2010; Gupta et al. 2013) it can be uni- or bilateral. It is important to be aware of the anomaly for the anesthesiologist performing intubation and in cases of oropharyngeal surgery (Fig. 2.14).

Fig. 2.14 MR angiography with contrast medium. Incidental discovery of retropharyngeal course of both ICA (*arrow with angle*)

Another type of aberrant course is that in which the artery enters the temporal bone through an enlarged inferior tympanic canaliculus, and thus is located more posteriorly than in normal cases laterally to the jugular bulb and adjacent to the stylomastoid foramen. The distal vertical segment of the petrous ICA protrudes in the middle ear cavity to continue further in the horizontal petrous segment. This anomaly has been interpreted as an agenesis of the terminal part of the cervical ICA, with the formation of a collateral circulation between the enlarged tympanic branch of the ascending pharyngeal artery and the caroticotympanic branch of ICA remnant of the stapedial artery (Lo et al. 1985; Osborn 1999; Sauvaget et al. 2006; Saini et al. 2008). CT of the skull discloses the presence of a soft-tissue mass protruding in the tympanic cavity. The angiographic study shows the anomalous course of the artery, which appears smaller, often narrowed and irregular, clarifying the diagnosis especially differentiating the

anomalous ICA from a suspected small tympanic paraganglioma. An example is presented in Fig. 2.15.

- *A fenestration or duplication of the supraclinoid ICA* has been reported (Yock 1984; Banach and Flam 1993; Rennert et al. 2013). This is a very rare anomaly occurring probably in the embryogenic phase when the ICA divides in its anterior and posterior division (Chap. 1). Failure in this process may explain the presence of this anomaly.

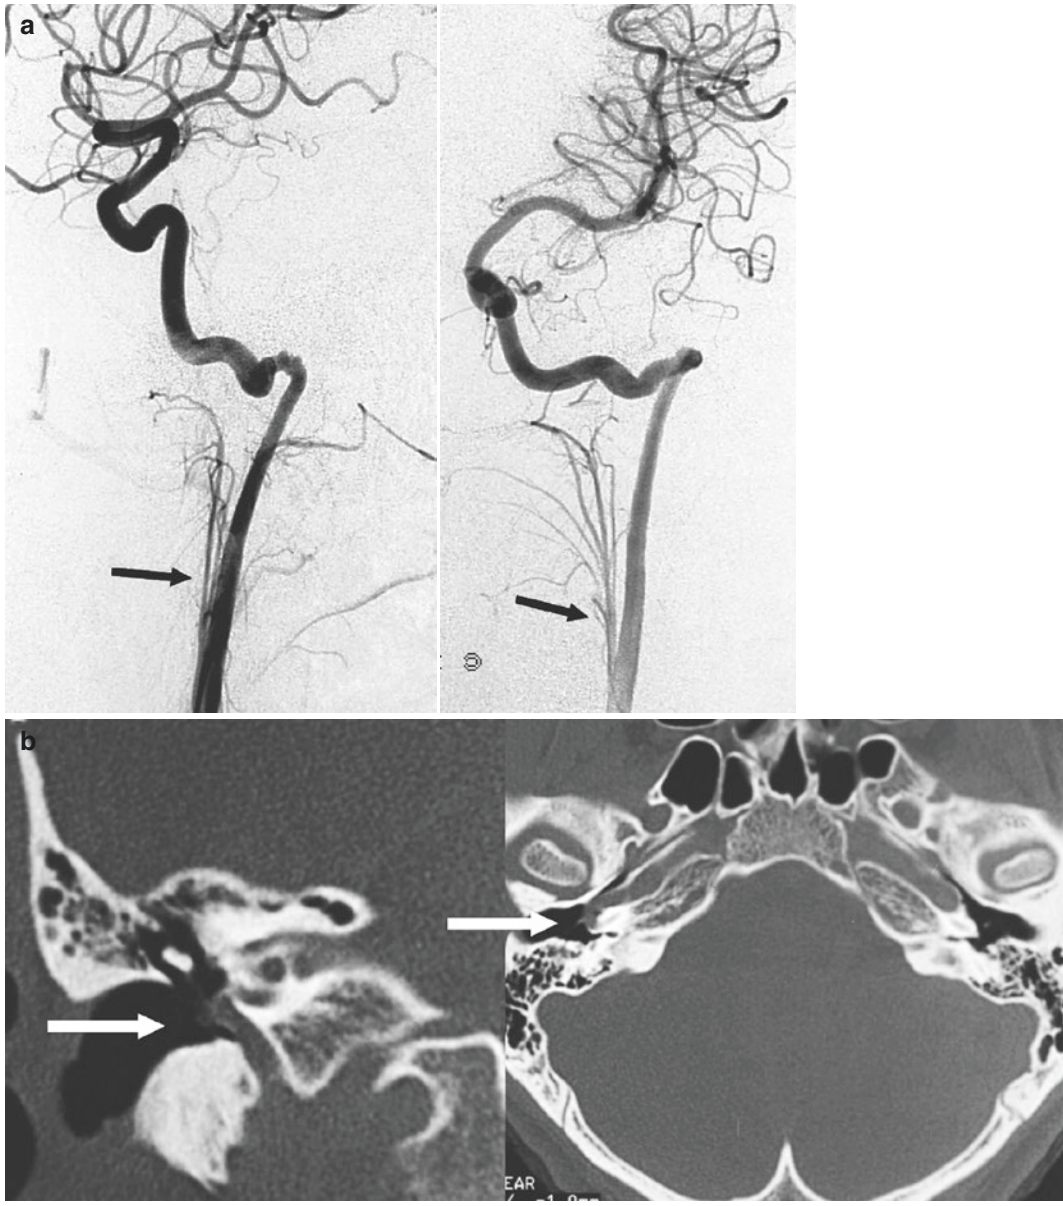

Fig. 2.15 Aberrant course of the ICA. (**a**) Lateral and AP ICA carotid angiogram. Origin of the AphA (*arrow*) from the ICA. The ICA runs more posteriorly and more laterally, respectively, on the lateral and AP angiograms. (**b**) CT, coronal and axial views. The ICA enters the middle ear cavity and is recognizable as a small, rounded, soft-tissue structure (*arrow*)

External Carotid Artery

3

The embryogenesis of the ECA is characterized first by the formation of small network of vessels arising from the first and second arches. These vascular structures rapidly disappear and the definitive ECA develops from the fusion of two vascular structures (Padget 1948; Salamon et al. 1974). One is the ventral pharyngeal artery embryonal vessel developing from the proximal part of the third aortic arch, and the other is the hyoidostapedial trunk which arises from the primitive internal carotid artery developing from the more distal part of the third aortic arch (see also Sects. 2.1 and 2.2.3.1).

The definitive ECA arises from the common carotid bifurcation at the C4 vertebral level. A more proximal or distal origin can occur. The ECA lies in the carotid triangle, initially medial and anterior to the ICA, seldom lateral to it. More cranially, it runs anterolateral to the ICA. The internal jugular vein is located posteriorly to the proximal ECA. More distally, near the skull base, the ECA is located laterally to the jugular vein. (Figs. 2.1 and 2.2). During its course, the ECA gives off several branches and divides near the mandibular condyle within the parotid gland into its terminal branches represented by the internal maxillary artery (IMA) and the superficial temporal artery (STA) (Fig. 3.8).

Among the relatively rare variants of the ECA, there is an isolated origin from the aortic arch (see also Sect. 2.3). Another particular anomaly is that occurring in the so-called nonbifurcating cervical carotid artery (Morimoto et al. 1990; Uchino et al. 2011; Nakai et al. 2012). In this case, the typical carotid bifurcation is not recognizable with its typical trunk of ECA and ICA. The common carotid artery seems to continue directly in the trunk of ECA from which arise its branches. The ICA appears to be a continuation of the ECA. The interpretation of this anomaly is not completely clear. According to some authors (Morimoto et al. 1990; Uchino et al. 2011; Nakai et al. 2012), we are dealing with a segmental agenesia of proximal ICA. The common carotid artery continues into the ECA.

3.1 Superior Thyroid Artery (TH)

The superior thyroid artery arises from the anterior wall of the ECA. It runs inferiorly and somewhat medially toward the thyroid gland. The artery gives off branches for the superior part of the thyroid gland and larynx. It anastomoses with the inferior thyroid artery, a branch of the thyrocervical trunk, arising from the subclavian artery (Figs. 2.2 and 3.1).

G.B. Bradac, *Applied Cerebral Angiography*, DOI 10.1007/978-3-319-57228-4_3

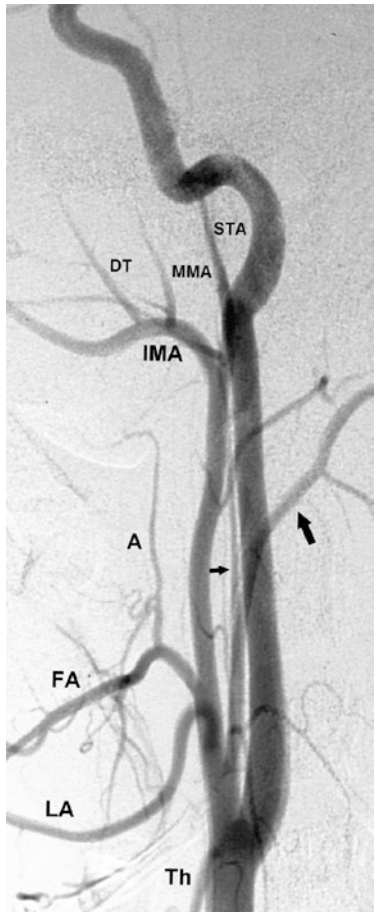

Fig. 3.1 Common carotid angiogram. Lateral view, showing the course of the ECA running anteriorly to the ICA. Some of the main branches are recognizable. Superior thyroid artery (Th), lingual artery (LA), facial artery (FA) from which arises the ascending palatine artery (A), occipital artery (*large arrow*), ascending pharyngeal artery (*small arrow*), internal maxillary artery (IMA) from which arise the middle meningeal artery (MMA) and the middle deep temporal artery (DT), superficial temporal artery (STA)

Fig. 3.2 ECA angiogram. Lateral view showing the common trunk of origin (*large arrow*) of the lingual (*small arrow*) and facial (*arrows with dot*) arteries

Fig. 3.3 Selective angiographic study of the lingual artery. Branches for the tongue (*arrows*) arising from the main trunk and partially from the dorsal lingual artery (DL). Sublingual branches (*arrow with angle*)

3.2 Lingual Artery (LA)

The LA is the second branch of the ECA arising from its anterior wall. It is not exceptional for the LA to have a common trunk with the facial artery. It runs anteromedially to the pharyngeal muscles toward the tongue. In its course, it gives branches for the sublingual and submandibular glands, and for the mucosa of the pharynx. Its terminal branch is the deep lingual artery which supplies the muscles and lingual mucosa. On the lateral angiogram, the lingual artery has a typical course, first upward, then downward, and finally upward again, forming a gentle superiorly concave curve. The deep lingual artery with its ascending fine branches, the dorsal lingual artery, and the sublingual artery are easy to recognize. The sublingual artery anastomoses through its submental branch with the corresponding branch of the facial artery. Examples of FA are presented in Figs. 3.1, 3.2, and 3.3.

3.3 Facial Artery (FA)

The FA is the third branch arising from the anterior wall of the ECA, frequently as a unique trunk with the lingual artery. It runs forward with an undulating course above the submandibular gland. It curves then around the lower edge of the mandible, continuing anteriorly and superiorly crossing the cheek, ending in the medial angle of the orbit as the angular artery. The latter anastomoses with branches of the ophthalmic artery, establishing a collateral circulation when the ICA is occluded. The FA gives off branches for the submandibular gland, the masseter artery for the masseter muscle anastomosing with masseter branches of the IMA and transverse facial artery, and an ascending palatine artery anastomosing with the descending palatine artery of the IMA and with pharyngeal branches of the AphA. It gives further branches for the mandible, skin, and muscle of the submental area, and cheek, nose, and lip.

The facial artery can be hypoplastic and represented only by the submental artery. In such cases, parts of its vascular territories become replaced by other branches of ECA, especially the lingual, transverse facial, and infraorbital arteries (Djindjian and Merland 1978).

The initially descending and then the obliquely ascending course of the facial artery is easily discerned on the lateral angiogram. Among its branches, the ascending palatine, the masseter, the submandibular, and the submental arteries are the most frequent identifiable. Examples are presented in Figs. 3.1, 3.2, 3.4, and 3.15.

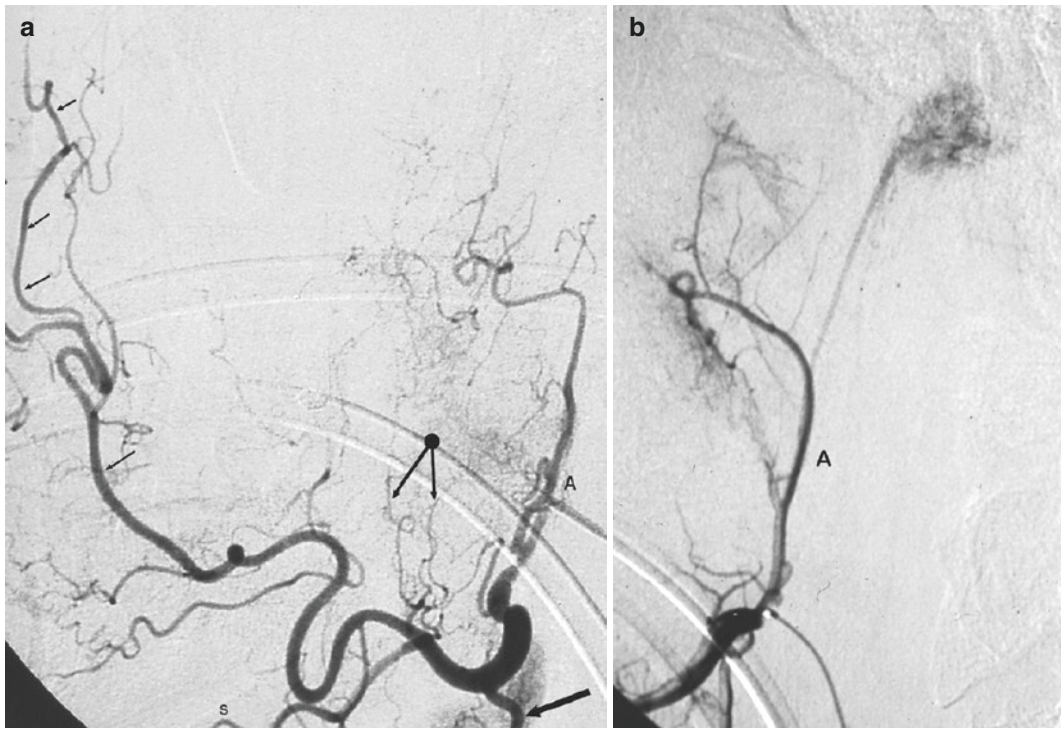

Fig. 3.4 (**a**) Selective angiographic study of the facial artery. Ascending palatine artery (A), branches for the submandibular gland (*arrow*) and masseter muscle (*arrow with dot*). Submental artery (S). Distal branches (*small arrows*) ending in the angular artery. (**b**) Selective study in a different patient. Ascending palatine artery (A), from which arises a branch supplying a large vagal paraganglioma

3.4 Ascending Pharyngeal Artery (AphA)

The AphA is a small vessel that arises from the posterior wall of the ECA, sometimes from the carotid bifurcation or from the proximal segment of the ICA. The AphA can also arise sharing a common trunk with the occipital artery. It runs upward parallel and adjacent to the ICA, posteriorly and medially to it (Figs. 3.5 and 3.6).

The AphA gives off pharyngeal branches for the paramedian mucosa of the naso-oropharynx, which are divided into superior, middle, and inferior branches. The superior branch can anastomose with pharyngeal branches coming from the accessory meningeal and pterygovaginal arteries, both branches of the IMA. The middle branches

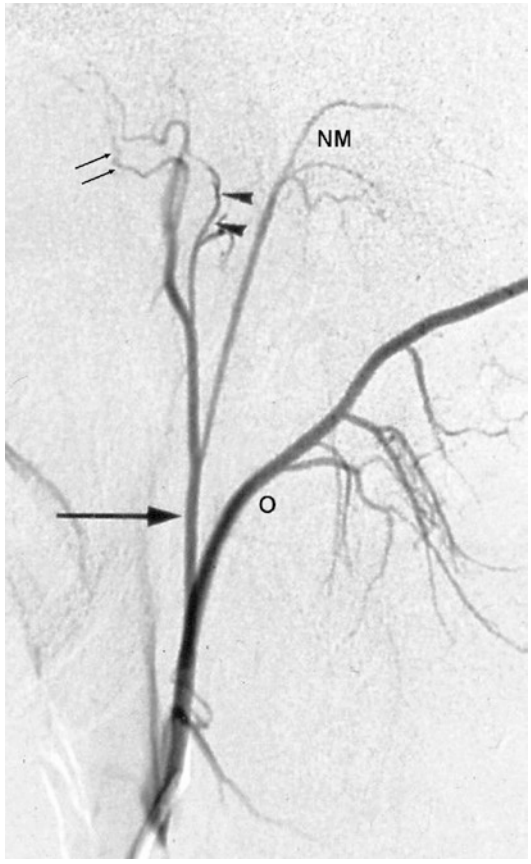

Fig. 3.5 Selective angiographic study, lateral view, of the common trunk of the ascending pharyngeal and occipital arteries. Occipital artery (O), ascending pharyngeal artery (*arrow*) with its tympanic (*arrowheads*), superior pharyngeal (*small arrows*) branches and neuromeningeal trunk (NM)

Fig. 3.6 Common carotid angiogram, showing the close relationship of the ascending pharyngeal artery (*arrows*) to the internal carotid artery

anastomose with the ascending palatine artery arising from the facial artery and, when present, with the mandibular artery, embryological remnant arising from the ICA.

Other branches are the cutaneomusculospinal arteries which can have anastomoses with the ascending cervical artery and vertebral arteries commonly at the C2–C4 levels.

Near the base of the skull, the AphA divides into its terminal branches, described below:

- Superior pharyngeal branches
- The inferior tympanic artery (Fig. 3.5) which vascularizes the tympanic cavity and can anastomose with the other tympanic branches arising from the stylomastoid artery branch of the occipital artery and tympanic branches arising from IMA
- The neuromeningeal trunk (Fig. 3.5) which can be subdivided into the hypoglossal and

jugular branches (Djindjian and Merland 1978; Lasjaunias and Doyon 1978)

The *hypoglossal branch* enters the hypoglossal canal, running together with the cranial nerve XII supplying it, and with the anterior condylar vein. It gives off branches for the meninges of the adjacent posterior fossa and a descending branch that anastomoses with the ascending radiculomeningeal branch of the vertebral artery, contributing to form the so-called odontoid arch (see also Sect. 6.1.1) (Figs. 3.7c, 3.33, 3.34, 6.2b, c, 13.3a, b, 15.30, and 15.33). The artery also gives off meningeal branches, which extend upward along the clivus (clival branches),

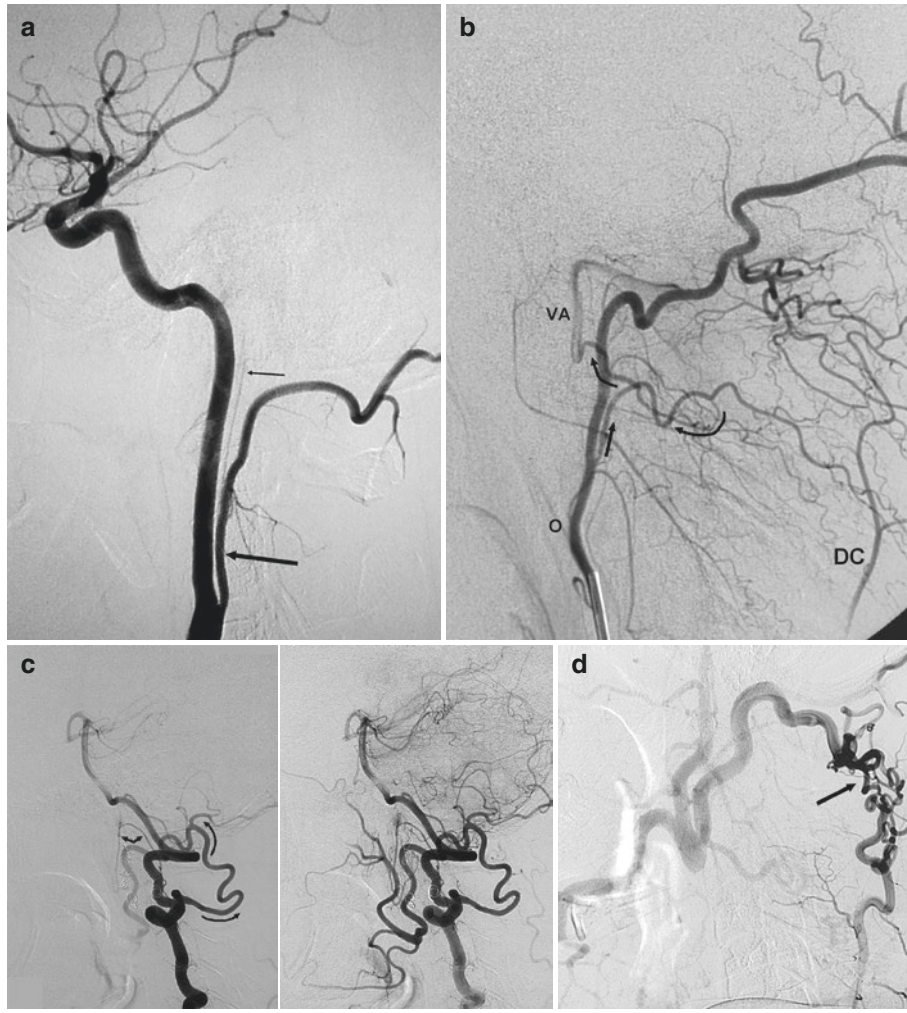

Fig. 3.7 Angiograms in four different patients. (**a**) ICA angiogram, lateral view. The occipital artery (*arrow*) and the AphA (*small arrow*) arise as a common trunk from the ICA. (**b**) Selective angiogram of the occipital artery (O) in another patient. There is a clear anastomosis (*arrows*) between the cutaneous-muscular branch of the ascending segment of the occipital artery with the VA. There are other anastomoses between the horizontal segment of the occipital artery and the deep cervical artery (DC). This latter is retrograde injected and partially also connected to the VA. (**c**) Lateral vertebral angiogram in a different patient (earlier and later phases). The patient had had a surgical ligature of the ECA. Through anastomoses involving cutaneous-muscular branches of the VA and the occipital artery at the C2 level (*arrows*) there is a progressively complete recanalization of the ECA. Odontoid arch (*arrow with angle*) leading to a retrograde filling of the AphA. (**d**) Another example of revascularization of ECA after proximal surgical ligature of the artery. The retrograde injection of the ECA occurs through anastomoses between the deep cervical artery and the occipital artery

anastomosing with the corresponding medial clival branches arising from the MHT (Fig. 3.32). Because of this anastomosis, the neurohypophysis can sometimes be visible on the lateral angiogram of the AphA (Djindjian and Merland 1978).

The *jugular branch* enters the posterior fossa through the jugular foramen, where it supplies cranial nerves IX, X, and XI. It supplies the adjacent dura, anastomosing with the more lateral, descending clival branches of the MHT. It then turns posteriorly to vascularize the dura of the cerebellar fossa and cerebellopontine angle.

The supply of the cranial nerves IX, X, XI, and XII is a very important aspect that should be taken into consideration in the endovascular treatment of lesions involving the AphA. Furthermore, the close relationship of the AphA with the ICA could explain the palsy of the last fourth nerves in many cases of dissection of the ICA (*Bradac et al.* 1990*,* 2000).

The branches of the AphA may be involved in many pathological processes. Examples are presented in Figs. 3.22, 3.24, 3.25, 3.26, 3.27, 13.3a, b, 13.6, 13.14, 13.15, 13.21, 13.22, and 13.23.

3.5 Occipital Artery (O)

The occipital artery takes its origin from the posterior wall of the ECA, frequently as a common trunk with the APhA (Figs. 3.5, 3.7a, and 3.20). Sometimes it can arise from the ICA (Newton and Young 1968; Teal et al. 1973) or from the vertebral artery through anastomosis at the C1 and C2 level (Lasjaunias et al. 1978b) (Figs. 3.7a, c, 3.20, 6.2b, 6.8a, 6.9a, and 15.33). The artery runs posteriorly and slightly superiorly with an undulating course, in which three segments may be identified. The first ascending, the second horizontal, and the third ascending again. It gives off the stylomastoid artery, several musculocutaneous branches for the neck and posterior part of the head, and meningeal branches.

- The stylomastoid artery arises from the first segment and runs up to the stylomastoid foramen, accompanying the facial nerve and supplying it. It anastomoses superiorly with the superior tympanic artery arising from the petrosquamosal artery, branch of the middle meningeal artery. The stylomastoid artery gives off branches also for the tympanic cavity and adjacent area (posterior tympanic arteries), where they anastomose with the tympanic branches arising from the AphA and IMA. The stylomastoid artery can arise from the posterior auricular artery or directly from the trunk of the ECA. It is a fine branch, not always evident on the lateral ECA angiogram. It can be dilated and is well recognizable when involved in the supply of pathological processes (Figs 3.25, 3.27c, and 13.1).
- Among the musculocutaneous branches, two frequently arise in the ascending segment. A third branch (the splenial artery) arises from the horizontal segment, has a descending course, and supplies the splenius muscle. The muscular branches can anastomose with the corresponding branches of the vertebral artery at the C1 and C2 level (Figs. 3.7b, c, 6.2b, 6.8a, 6.9a, and 15.33), and with the deep cervical artery.
- The mastoid branch (Fig. 3.8) arises from the second segment, approximately near the origin of the splenial artery. It has an ascending

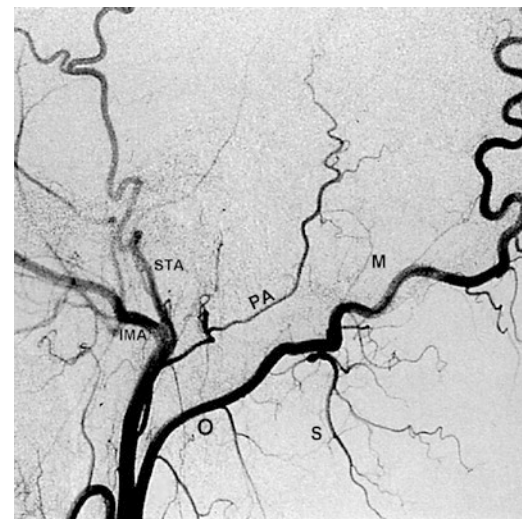

Fig. 3.8 Angiogram of the ECA. Lateral view. Occipital artery (O), with its muscular branches arising from its ascending and horizontal segments. *S* splenial artery, *M* mastoid branch, *PA* posterior auricular artery, *STA* superficial temporal artery, *IMA* internal maxillary artery

course, enters the cranial cavity through the foramen of the mastoid emissary vein, and supplies the meninges of the cerebellopontine angle and cerebellar fossa. These branches are in hemodynamic balance with those arising from the neuro-meningeal trunk of the AphA, with the petrosquamous branch of the middle meningeal artery (MMA), and with the meningeal branches of the vertebral artery (Lasjaunias et al. 1978b). One of the arteries can dominate and completely supply these territories.

- The occipital artery can be involved in several pathological processes (Figs. 3.25, 3.27, 13.4, 13.5, 13.13, 13.14, 13.16, 13.18, and 13.22).

3.6 Posterior Auricular Artery

This is a small branch arising near the terminal ECA (Figs. 3.8 and 3.15), sometimes as a common trunk with the occipital artery. It supplies the pinna of the ear, which on the angiogram appears as an evident blush in the capillary phase of the ECA angiogram.

3.7 Internal Maxillary Artery (IMA)

The internal maxillary artery is the larger of the terminal branches of the ECA. It originates behind the neck of the mandible, within the parotid gland. It runs obliquely forwards and medially in the masticator space, along the border of the lateral pterygoid muscle, and ends in the pterygopalatine fossa, where it divides into its terminal branches. It is always well recognizable on the lateral and AP angiograms (Figs. 3.9, 3.10 and 3.11).

3.7.1 Proximal Branches

Near its origin, the IMA gives off a few thin proximal branches for the mandibular joint, external auditory canal, and tympanic cavity (anterior tympanic artery). The latter can be involved in the vascularization of tympanic chemodectomas

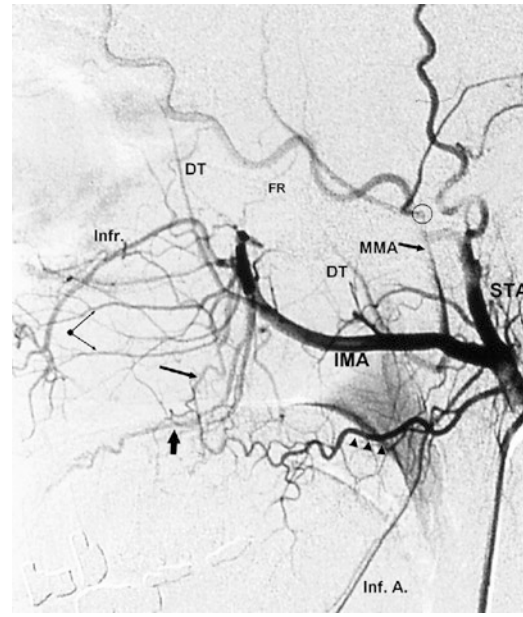

Fig. 3.9 Angiogram of the distal ECA, lateral view. Transverse facial artery (*arrowheads*). Superficial temporal artery (STA), internal maxillary artery (IMA), middle meningeal artery (MMA). The *circle* shows where the MMA passes through the *foramen spinosum*. Middle and anterior deep temporal arteries (DT), inferior alveolar artery (Inf.A.), infraorbital artery (Infr.). Fig. 3.11 (**a**) Angiogram of the distal ECA, performed to study a capillary-venous malformation of the mandible. Dilated inferior alveolar artery (IAL) supplying the malformation. Transverse facial artery (TR), buccal artery (*arrow*), deep temporal branches (DT), descending palatine artery (*arrowhead*), posterior superior alveolar artery (*arrow with dot*). Infraorbital artery (IO). The distal branches of the sphenopalatine artery are visible running between the infraorbital and posterior superior alveolar arteries. (**b**) Selective catheterization of the IAL, preceding embolization with PVA

(Fig. 3.25). Other more larger branches arising from the proximal segment are the middle meningeal artery (MMA), the accessory meningeal artery, and the inferior alveolar artery.

3.7.1.1 Middle Meningeal Artery

The MMA runs superiorly towards the base of the skull and passes through the foramen spinosum, becoming intracranial, running along the greater sphenoid wing, forming a large convex curve anteriorly and laterally well recognizable on the lateral and AP angiograms, respectively (Figs. 3.9 and 3.15). It is the important artery responsible for the vascularization of the dura, giving off the following branches:

- Branches for the dura of the frontoparietal and temporo-occipital convexity.
- Branches for the frontobasal area, anastomosing with the ethmoidal arteries arising from the ophthalmic artery.
- A meningeal branch can enter the orbita through the superior orbital fissure or through the foramen of Hyrtl and anastomose with the lacrimal artery, branch of the ophthalmic artery.
- Branches for the middle cranial fossa, where they anastomose near the cavernous sinus with the meningeal branches arising from the inferolateral trunk (ILT) meningohypophyseal trunk (MHT), foramen rotundum, and accessory meningeal arteries.
- Close to the foramen spinosum arises the petrosquamous branch, which supplies the dura covering the petrous bone, the tentorium, and extends largely in the posterior fossa where it anastomoses with the meningeal branches arising from the AphA, occipital, and vertebral arteries. The petrosquamous branch gives off a tympanic branch (superior tympanic artery), which runs in the petrous facial canal where it anastomoses with the stylomastoid artery (branch of the occipital or posterior auricular arteries). These arteries can both supply the facial nerve, but there is commonly a predominance of the petrosquamous branch (Lasjaunias

et al. 2001). Furthermore, the petrosquamous branch gives off branches for the tympanic cavity, where they anastomose with the anterior, posterior, and inferior tympanic arteries.

- In the paramedian area of the convexity, the branches anastomose with those of the contralateral side. These branches form an arcade from anterior to posterior, situated at the insertion of the lateral wall of the superior sagittal sinus with the meninges of the vault. This arcade anastomoses anteriorly with the artery of the anterior falx, a branch of the anterior ethmoidal artery, and posteriorly with the falx cerebelli artery. The arteries of the falx itself arise from the arcade as descending branches.

Branches of the MMA are involved in the supply of extra-intracranial tumors (Figs. 3.27 and 3.29), intracranial AVMs, and especially in DAVFs (Figs. 13.1, 13.5, 13.6, 13.9, 13.10, 13.11, 13.12, 13.13, 13.14, 13.15, 13.24, and 13.25).

3.7.1.2 Accessory Meningeal Artery

The artery is frequently small. It can have a common origin with the MMA. The accessory meningeal artery (AMA) gives off branches for the nasopharynx and palate and then it enters the cranial cavity through the foramen ovale, supplying the adjacent dura including part of the cavernous sinus. For the relationship to the ILT see Chap. 2. It is also partially involved in the supply of the trigeminal nerve. The small branch can be recognized on the lateral ECA angiogram (Fig. 3.15). It is involved in many DAVFs (Figs. 13.10, 13.13, 13.14, and 13.15).

3.7.1.3 Inferior Alveolar Artery

This branch of IMA is always visible on the lateral ECA angiogram despite its small caliber. It runs down toward the mandibular foramen supplying then the teeth and adjacent bone. An example of a normal inferior alveolar artery is presented in Figs. 3.9 and 3.15. In Fig. 3.11 there is a dilated artery supplying a vascular malformation.

3.7.2 Masticator Space

In the masticator space the IMA gives off the deep temporal branches (middle and anterior branches) which have an ascending course, forming a mild convex curve. They contribute in the supply of the temporal muscle. The anterior of these arteries gives off branches that run toward the *orbita*, perforate the malar bone, or pass through the inferior orbital fissure. These branches anastomose with the lacrimal artery, branch of the ophthalmic artery. This connection can become an important collateral in occlusion of the ICA (Djindjian and Merland 1978) (Figs. 3.12, 3.13, 3.14, and 11.5).

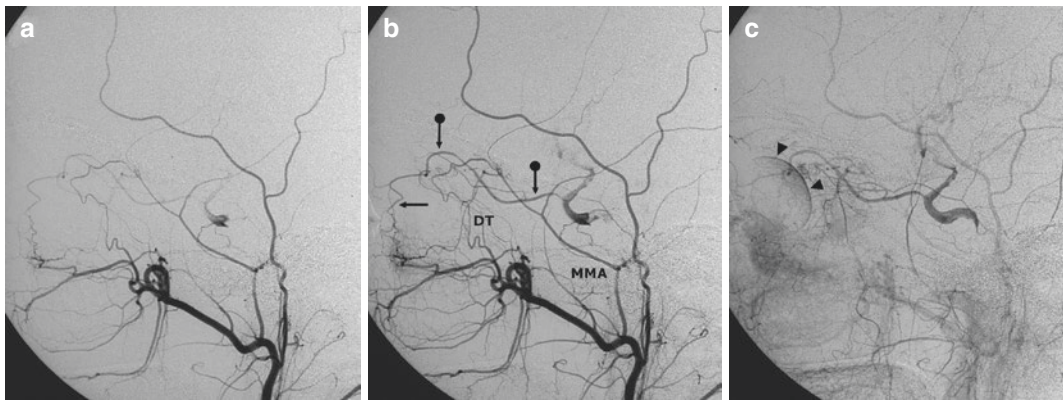

Fig. 3.12 (**a**, **b**) ECA angiogram, lateral view in a pat. with ICA occlusion. Filling of the ophthalmic artery (*arrow with dot*), and further of the ICA through anastomoses with the middle meningeal artery (MMA), anterior deep temporal artery (DT), infraorbital artery (*arrow*). (**c**) In a later phase, injection of the choroid (*arrowhead*)

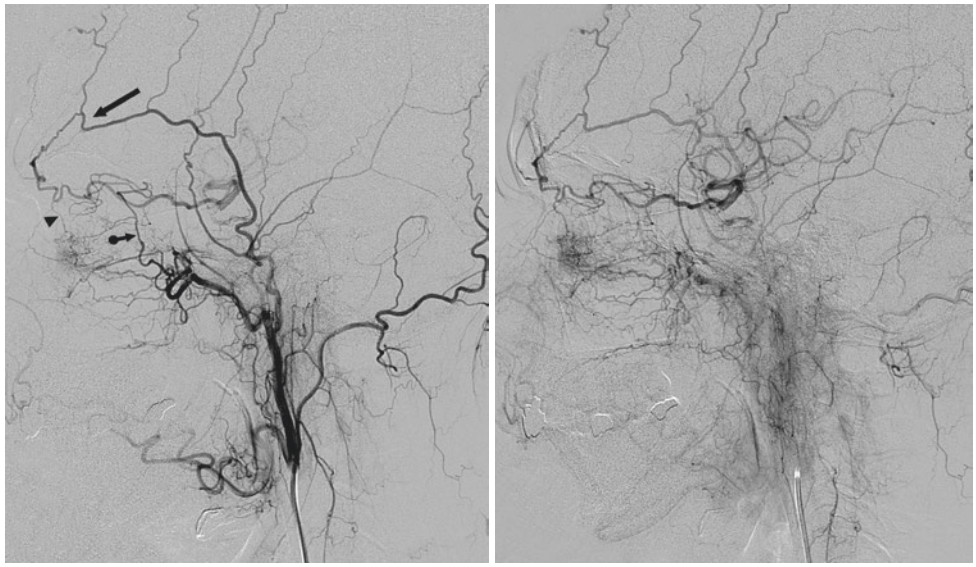

Fig. 3.13 ECA angiogram, lateral view (early and late phases) in a patient with almost complete occlusion of ICA (same case presented in Fig. 17.5). Through the STA (*arrow*), anterior deep temporal artery (*arrow with dot*), as well as fine branches arising from the infraorbital artery (*arrowhead*) retrograde injection of the ophthalmic and intracranial arteries

Other branches in the masticator space are the pterygoid, masseter, and buccal arteries. These arteries are not always recognizable on the angiogram. The masseter artery can be one or made by more than one branches appearing on the lateral angiogram as a fine branch or branches running downwards with and oblique course directed to the corresponding muscle. The buccal artery which supplies the buccinator muscle is more frequently recognizable running downwards with a vertical course anteriorly to the masseter artery (Figs. 3.11 and 3.15). The masseter and buccal arteries anastomose with the facial and transverse facial arteries. The pterygoid arteries are fine branches which cannot be identified with certainty on the angiogram.

3.7.3 Distal IMA

The distal IMA reaches the pterygopalatine fossa, a space bordered anteriorly by the posterior wall of the maxillary sinus and posteriorly by the pterygoid plate, where the artery forms a loop, entering finally the sphenopalatine foramen. Before entering the foramen, the IMA gives off several branches: the posterior superior alveolar artery, the descending palatine artery (great palatine artery), and the infraorbital artery.

The posterior superior alveolar (PSA) artery runs first on the posterior and then on the anterolateral wall of the maxillary sinus. It perforates the maxillary tuberosity running further forwards toward the incisive foramen. It gives off branches for the sinus (antral artery) and teeth. It anastomoses distally with the descending palatine and infraorbital arteries. The posterior superior alveolar artery is a small vessel, sometimes recognizable on the lateral angiogram, with its typical course, first downwards, then forming a curve anteriorly and superiorly (Figs. 3.9, 3.10, and 3.11).

The descending palatine artery (DPA) runs initially downwards along the wall of the maxillary sinus, enters the oral cavity at the greater palatine foramen, and then it forms a typical angle, coursing horizontally and anteriorly through the hard and soft palate supplying it. Anteriorly it ends at the incisive canal, anastomosing with PSA, the nasal branches of the sphenopalatine artery, and the infraorbital artery. The DPA is recognizable on the lateral angiogram owing to the undulating course in its horizontal segment (Figs. 3.9, 3.10, and 3.11).

The infraorbital artery (IFO) enters the *orbita* at the inferior orbital fissure, runs anteriorly, and penetrates the infraorbital canal, where it runs together with the infraorbital nerve. It is involved in the vascularization of the bone structure of the floor of the *orbita* and adjacent muscles and fatty tissue. More distally, it leaves the canal and gives off branches for the cheek, lower lid, upper lip, and nose. The IFO anastomoses with branches of the ophthalmic, facial, transverse facial buccal arteries and PSA and DPA. It can be an important collateral through the ophthalmic artery in cases of occlusion of the ICA (Figs. 3.12 and 3.13). On the lateral angiogram it is always well recognizable with its typical mild superiorly convex curve (Figs. 3.9, 3.10, and 3.11).

Other branches of the distal IMA are the *foramen rotundum artery* (FRA), the *pterygoid* (*vidian*) *artery* (VA), and the *pterygovaginal artery* (PVA) (Osborn 1980; Morris 1997; Lasjaunias et al. 2001) (Fig. 3.14a–d). The FRA runs with an oblique supero-posterior course, passes through the foramen rotundum together with the cranial nerve V2, and anastomoses with the ILT. The VA runs posteriorly with a more horizontal course. It passes through the vidian canal, together with the vidian nerve formed by the greater superficial petrosal and the deep petrosal nerves. It anastomoses with the horizontal branch of the mandibular artery, embryonic remnant arising from the petrous segment of the ICA (see also Sect. 2.2). On the lateral ECA angiogram, it is located below the FRA.

The PVA forms a curve directed posteriorly and inferiorly. It gives off branches for then superior nasopharyngeal mucosa anastomosing with

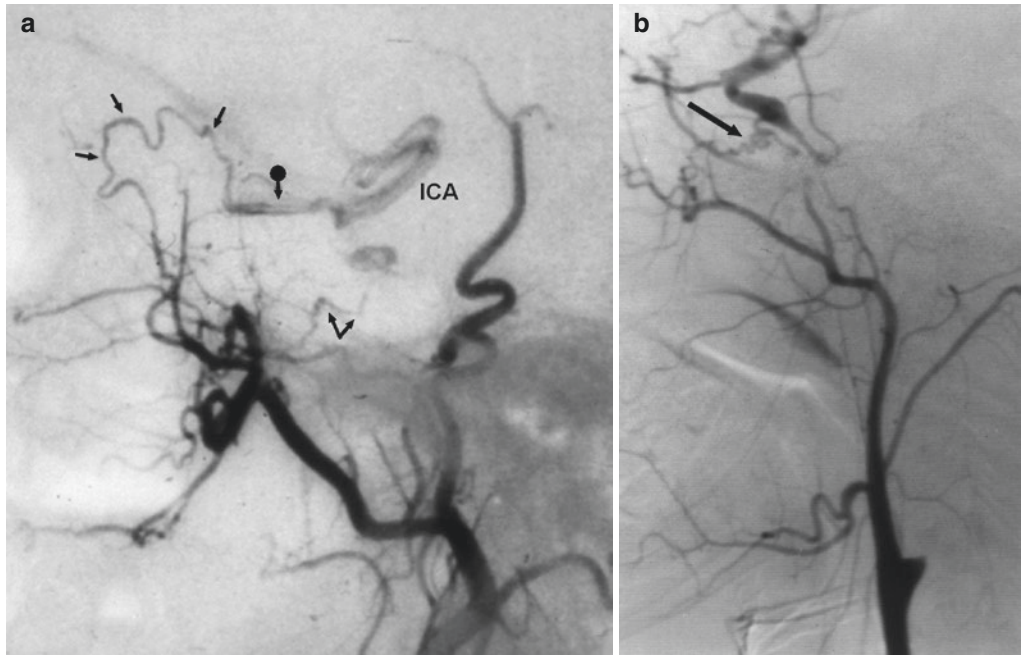

Fig. 3.14 Angiograms in four different patients. (**a**) ECA angiogram, lateral view, in a patient with occlusion of the ICA. Through anastomosis (*arrows*) between the deep anterior temporal artery and the lacrimal branch of the ophthalmic artery, there is injection of the ophthalmic artery (*arrow with dot*) and further of the ICA. Partial injection of the cavernous portion of the ICA, through the foramen rotundum artery (*arrow with angle*). (**b**) Angiogram in a pat. with occlusion of the ICA. (**c**) Angiogram of ICA in patient with surgical ligature of ECA. Through the mandibular artery there is filling of the vidian artery (*arrow*), and of the pterigovaginal artery with its typical superior convex curve (*arrow with dot*) and further of the IMA (see Sects. 2.2 and 3.7.3). (**d**) Angiogram of ICA in another patient with surgical ligature of ECA. Through the ILT (*arrow*) filling of the foramen rotundum artery and further of the IMA and indirectly of the pterigovaginal artery (*arrowhead*)

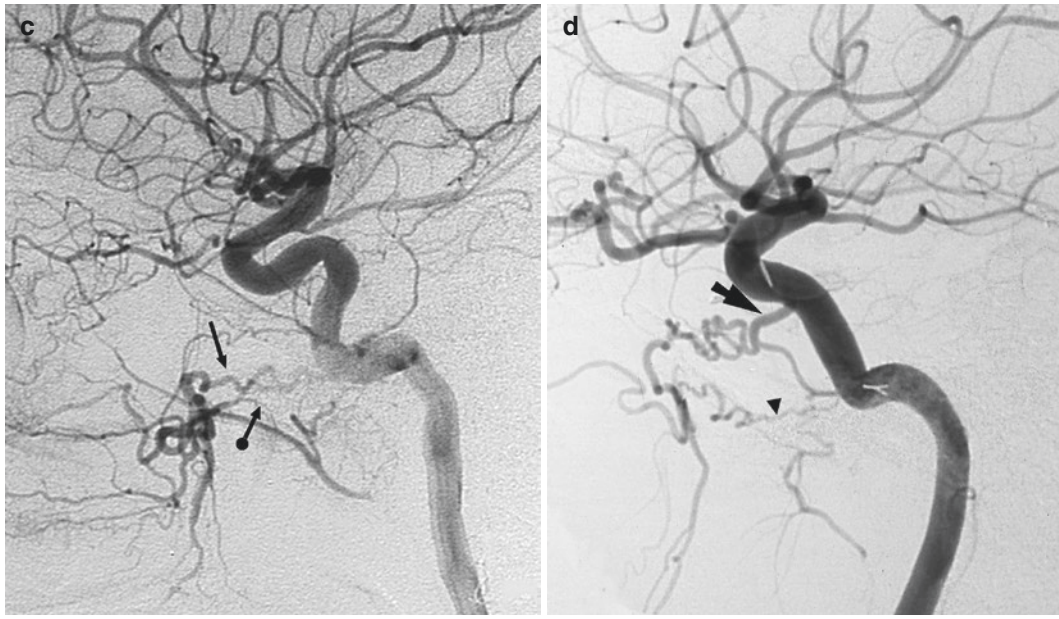

Fig. 3.14 (continued)

branches of the accessory meningeal and AphA. The artery anastomoses posteriorly with the inferior branch of the mandibular artery passing through the cartilage covering the foramen lacerum. It is rarely visible on the ECA lateral angiogram. See also Sect. 2.2.

The FRA, the VA, and PVA can be variously involved in the supply of extra- and intracranial tumors and DAVFs (Figs. 13.6, 13.10, and 13.15). They can play a role in the collateral circulation between ICA and ECA, in cases of occlusion of one of arteries (Fig. 3.14a–d).

3.7.4 The Terminal Branch

The terminal branch is the sphenopalatine artery. This enters the nasal cavity through the sphenopalatine foramen and gives off branches for the medial and lateral nasal mucosa. Anteriorly these branches are connected with branches of the facial, infraorbital, and descending palatine arteries. They anastomose further with the ethmoidal branches of the ophthalmic artery. These branches appear on the lateral angiogram as thin vessels running anteriorly below the infraorbital artery (Figs. 3.9, 3.10, and 3.11). Through their anastomoses with the ethmoidal arteries, they can be involved in the supply of frontobasal meningiomas (Fig. 3.28) and frontobasal DAVFs (Fig. 13.19).

3.8 Superficial Temporal Artery

The superficial temporal artery (STA) is the smaller of the terminal branches of the ECA. It runs upwards and often forms a sharp curve shortly after its origin when it turns over the zygomatic arch. The STA gives off the posterior deep temporal branch supplying the temporal muscle and several branches that run with an undulating course on the scalp, which they supply. This feature is characteristic, and it allows the differentiation of these cutaneous branches from the more rectilinear course of the MMA (Figs. 3.9, 3.15, and 3.29). Other branches are the transosseous which can be well developed when involved in the supply of vascular malformations. Through its anastomosis with the supraorbital branch of the ophthalmic artery, the STA can be involved in the collateral circulation toward the ICA, when this is occluded (Fig. 3.13).

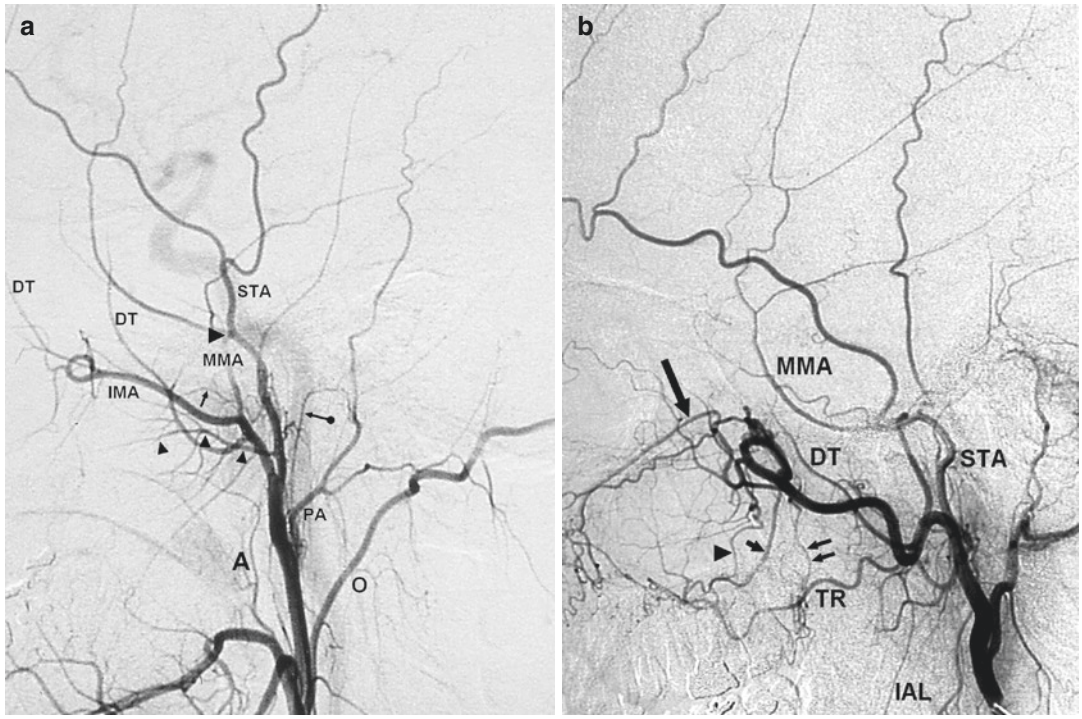

Fig. 3.15 (**a**) External carotid angiogram, lateral view, showing the undulating course of the cutaneous branches of the occipital (O), posterior auricular (PA), and superficial temporal (STA) arteries. The course of the middle meningeal artery (MMA) and middle and anterior deep temporal arteries (DT) appears straighter. The *arrowhead* shows where the MMA enters the cranial cavity through the foramen spinosum. Internal maxillary artery (IMA), accessory meningeal artery (*small arrow*), ascending pharyngeal artery (*arrow with dot*). Ascending palatine artery (A). Infraorbital artery (*large arrow*), posterior superior alveolar artery (*arrowhead*), descending palatine artery (*small arrow*), buccal artery (*two small arrows*), inferior alveolar artery (IAL). Well-developed transverse facial artery (TR)

Another important branch of the STA is the transverse facial artery, which arises from the first segment of the STA (Figs. 3.9, 3.11, 3.15, and 3.30). The artery courses horizontally along the zygoma and supplies partially the parotid gland and the skin of the cheek. It can give off a branch directly inferior to the deep surface of the masseter which it supplies, anastomosing with the masseter branches of the IMA (Salmon 1936). It anastomoses with the facial artery and can occasionally be well developed, especially when the facial artery is hypoplastic.

3.9 Cervical Arteries

In the examination of the upper neck and skull basis, the cervical arteries, represented by the ascending cervical (AC) and deep cervical (DC) arteries, should also be considered. The AC arises commonly from the thyrocervical trunk and the DC from the costocervical trunk both arising from the subclavian artery. The cervical arteries run upwards toward the skull basis, giving off branches supplying the soft tissues and the bone structures of the cervical spinal column. The AC runs more anteriorly, while the DC is more posteriorly located. This is well recognizable on the lateral angiogram. It can occur that one of the cervical arteries, either the AC or the DC, is less developed or absent especially in its distal part, and so its vascular territory is taken over by the other artery. There are many anastomoses, differently developed, between the cervical arteries, external carotid, and vertebral arteries (Lasjaunias 1981; Morris 1997). The most frequently visible are those at the C1–C2 level involving the deep

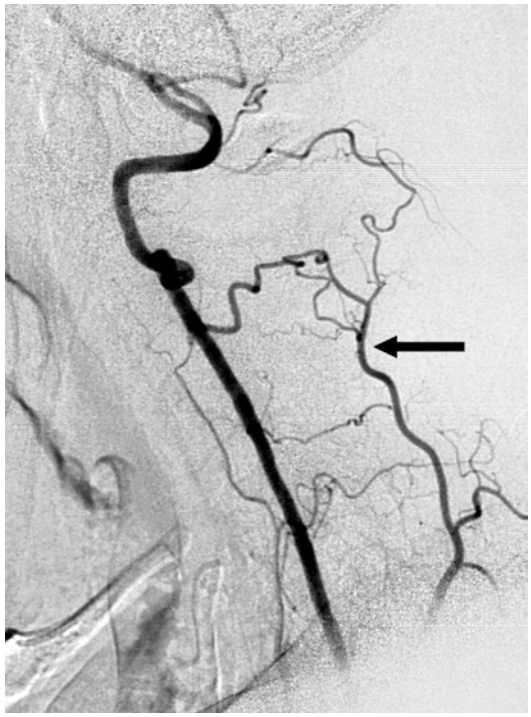

Fig. 3.16 Angiogram of the left subclavian artery in a patient with small vertebral artery. Well-developed deep cervical artery (*arrow*) supplying also the territory of the hypoplastic ascending cervical artery. There are anastomoses between both cervical arteries and with the vertebral artery

cervical, occipital, and vertebral arteries and that on the C2–C4 level between the ascending cervical, ascending pharyngeal, and vertebral arteries (Figs. 3.7b, d, and 3.16).

These anastomoses can play an important role as collateral circulation toward the ECA, ICA, and vertebrobasilar system in case of occlusive diseases (Figs. 3.7c and 15.29) and can be involved in DAVs (Fig. 13.5) and vascular malformations of the head and neck. In the cases in which they are used for an endovascular treatment the presence of their connections especially with the VA should be taken into consideration. Finally it should be remembered that the radiculomedullary arteries continuing in the anterior spinal artery can arise from the ascending cervical artery, instead of taking their origin from the vertebral artery.

3.10 Summary

- ECA supplies the soft tissues and bone of the craniofacial area.
- It represents the main meningeal supply for the intracranial dura mater. Its branches are in balance with the meningeal branches arising from the ophthalmic artery, ICA, and VA.
- It supplies a *few cranial nerves*.
- It can be an *important collateral way* to the intracranial circulation, in cases of an occluded ICA and VA.
- ECA is involved in the vascularization of vascular malformations of the extracranial area and in many richly vascularized tumors in the extra-intracranial area. Endovascular treatment of these lesions is an important part of the therapy. Indication and examples of treatment of extracranial lesions are presented in the following sections. The role of the ECA in the diagnosis and treatment of DAVFs and its contribution in brain AVMs will be discussed in the corresponding chapters.

3.10.1 Vascular Malformations

Vascular malformations represent a congenital pathology that may be already present in pediatric patients or clinically appear later owing to the slow growth. They can be classified into high- and slow-flow malformations. The first are arteriovenous (AV) angiomas in which commonly numerous dilated arteries converge to a vascular network (nidus) where there is a direct shunt with the dilated and early filled veins. The shunts can be sometimes very large, forming huge fistulas. The slow-flow malformations are capillary-venous angiomas, in which the supplying arteries are commonly normal, without an early venous drainage. In these later cases, the angiogram is frequently normal. Pathological blush or sometimes a pathological network can be demonstrated on superselective angiographic studies. Both high- and slow-flow components can be associated in the same malformation.

Lymphangiomas are another more rare vascular malformation involving the lymphatic vessels

which can be very dilated appearing as a large cystic space. They are more frequent in childhood and infancy. Lymphangiomas are thought to be due to a failure of the lymphatic sacs to drain into the veins or due to an abnormal sequestration of lymphatic tissue no longer connected with the normal lymphatic channels (Som et al. 2003b). Commonly, they cannot be demonstrated by angiography, unless we are dealing with hemolymphangiomas. These are mixed lesions where lymphatic tissues are associated with another type of angioma.

There is a possible association of all these extracranial vascular malformations with intracranial malformations (aneurysms or angiomas) and with some neurocutaneous pathologies (see Chap. 12).

Location. They can involve the skin of the head and face as well as the mucosa of the oral and nasal cavities. The masticatory muscles more frequently the masseter muscle and bone structures (mandibular and maxillary bone) are more seldom affected; they may be secondarily involved as extensions of the malformation or be the primary location.

Clinical relevance. This varies from esthetic problems to more important clinical symptoms, involving respiration and deglutition up to severe hemorrhage and cardiac failure. Mandibular and maxillary AVM can present as incidental discovery of an osteolytic lesion or with acute life-threatening hemorrhage following dental loosening, dental extraction, or cheek trauma (Benndorf et al. 2001b; Noreau et al. 2001; Fan et al. 2002; Seehra et al. 2006; Siniscalchi et al. 2009; Liu et al. 2009; Churojana et al. 2012; Bergeron et al. 2013; Amat et al. 2015).

Diagnosis and treatment. The diagnosis can sometimes be obtained only by clinical observation. Extensive lesions require CT and MRI. Depending on the site and extension of the malformation, angiography may be necessary to identify the type of lesion and the vessels involved. With regard to the location, the supplying arteries can frequently be suspected. However, other vessels may be indirectly involved, and so a complete study of both ECAs and in some cases also of the cervical arteries is frequently necessary. To exclude intracranial malformations examination of the ICA and VA should also be performed. All these information are necessary to plan the therapy for which in all cases a multidisciplinary approach is mandatory.

Small asymptomatic lesions do not need necessarily a treatment which should be considered in symptomatic or large malformations. The endovascular treatment is in the majority of the cases the first choice of therapy used depending on the site of the malformation PVA, glue, or onyx which can lead to a complete cure in cases of small lesions. In other cases the endovascular treatment precedes the surgical excision or can be a palliative therapy aimed to reduce the volume of the AVM for cosmetic reasons or to reduce pain or the risk of hemorrhage (Thiex et al. 2011; Dmytriw et al. 2014). The endovascular treatment can be associated with injection of a sclerosing agent through direct puncture of the devascularized AVM or injection of glue especially in malformations involving bone structures. Positive results have been obtained in some cases through direct injection of bleomycin, an antiangiogenic drug (Dmytriw et al. 2014). The combination of these techniques depends on the site, extension of the lesion, and experience and attitude of the team involved. Examples are presented in Figs. 3.17; 3.18; 3.19, 3.20, and 3.21. Endovascular therapy commonly performed with injection of PVA can also be performed in patients presenting with dramatic epistaxis not linked to vascular malformations but due to disturbances of the coagulations or linked to a fragility of the microvasculature more frequent in old patients. This therapeutic approach allows in these cases a rapid and complete control of the bleeding.

3.10.2 Hemangiomas

Hemangiomas are real tumors (Mulliken and Glowacki 1982) consisting prevalently of masses of endothelial cells with or without vascular lumens. They can be present at birth, with a strong prevalence among females, or they can appear in the first months of life. Hemangiomas are characterized by a phase of rapid growth, followed by a period of progressive involution which can be

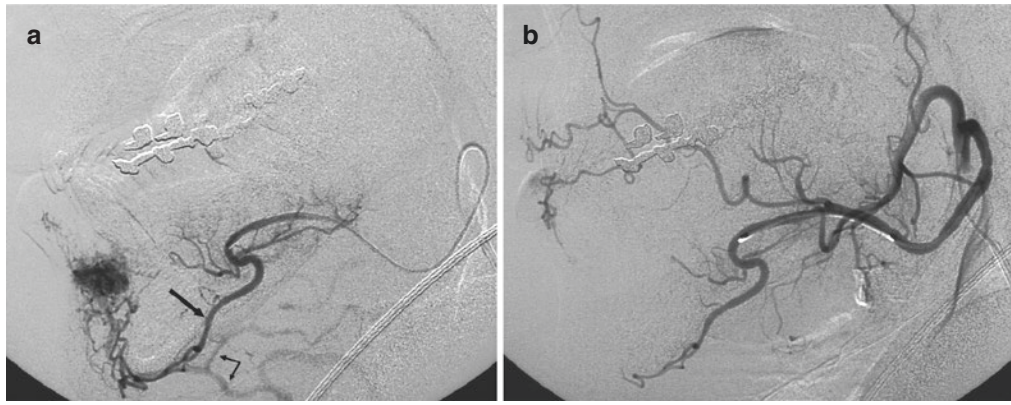

Fig. 3.17 Small arteriovenous angioma of the mental area supplied by the facial artery. (**a**) Lateral angiogram of the selective submental artery (*arrow*) showing the angioma and the early drainage in the submental veins (*arrow with angle*). (**b**) Control angiogram after occlusion of the malformation with polyvinyl alcohol (PVA) particles

Dilated facial artery (FA) supplying the malformation. Note the normalization of the lumen distally to the malformation (*arrow*). Early drainage in the facial vein (FV). (**b**) AP view of the FA. (**c**) Lateral angiogram after preoperative devascularization of the lesion

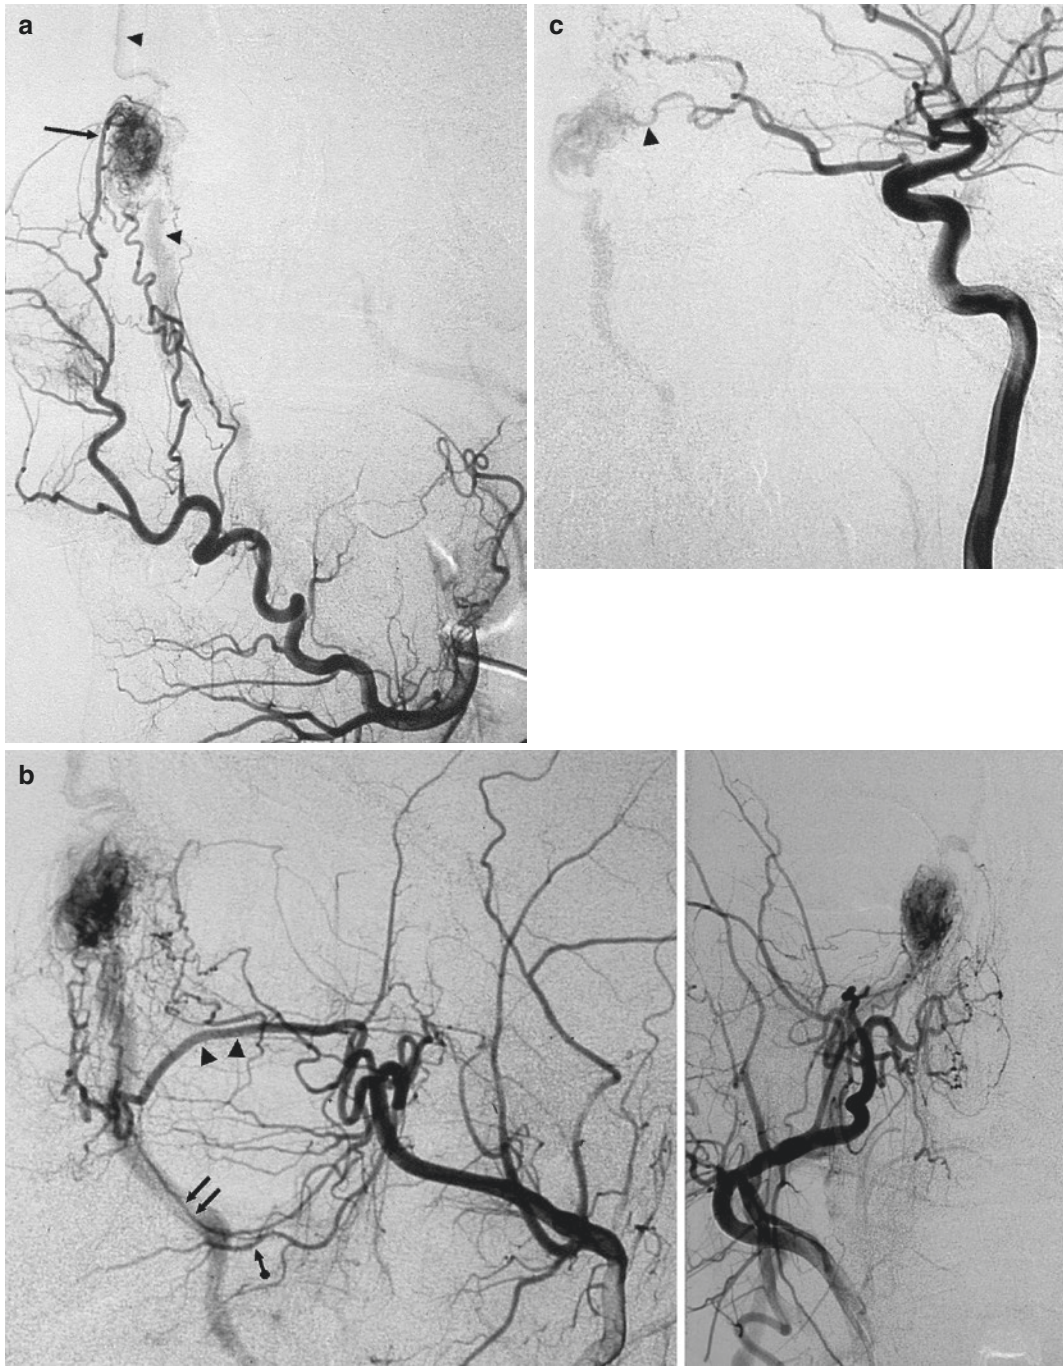

Fig. 3.19 Arteriovenous angioma of the right ala of the nose supplied by branches of the facial artery, internal maxillary artery, and ophthalmic artery. (**a**) Lateral angiogram of the facial artery. The arteriovenous angioma is supplied by the angular artery (*arrow*) and other small branches of the distal facial artery. Early drainage in the facial and frontal veins (*arrowhead*). (**b**) Lateral and AP angiograms of the internal maxillary artery. Clear involvement of the infraorbital artery (*arrowheads*) in the supply of the angioma. There is also a minimal involvement of the posterior superior alveolar artery (*arrows*). Normal descending palatine artery (*arrow with dot*). (**c**) Lateral internal carotid angiogram, showing the partial supplying through the nasal branch of the ophthalmic artery (*arrowhead*). The AVM was devascularized with polyvinyl alcohol (PVA), injected in the ECA branches, followed by surgical excision

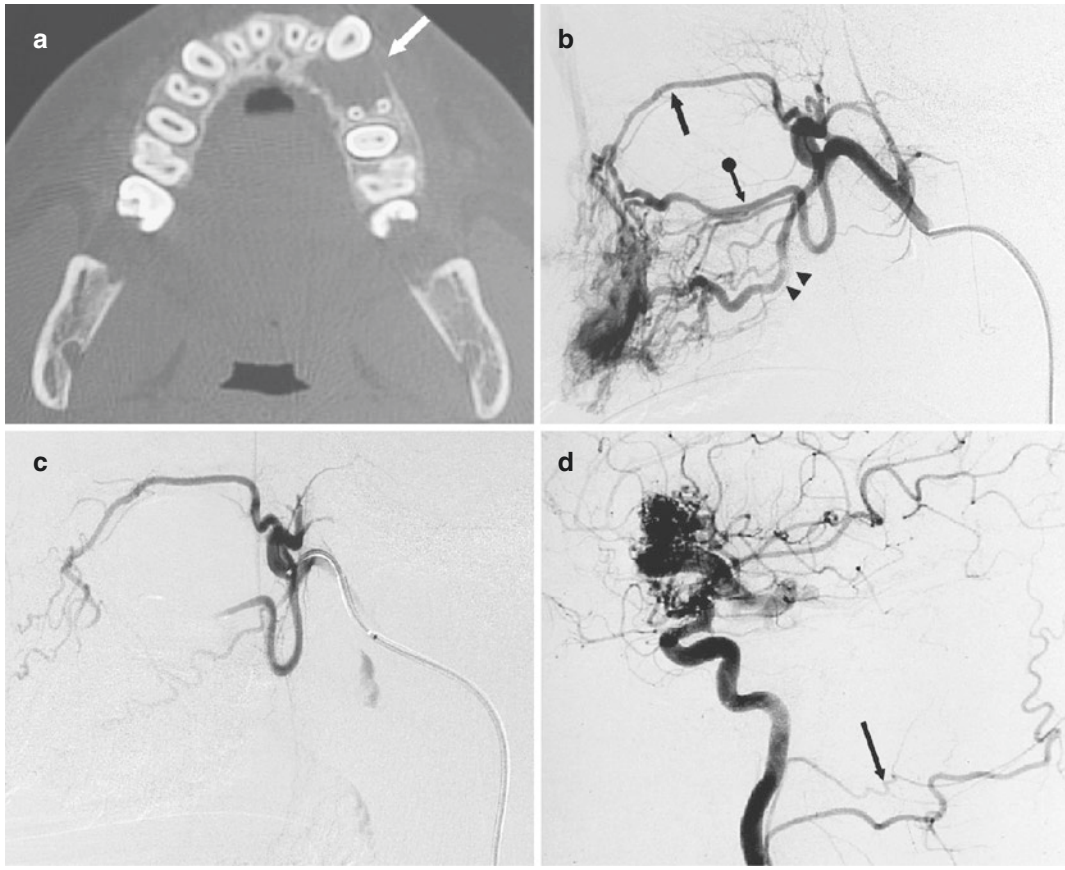

Fig. 3.20 Alveolar maxillary arteriovenous angioma presenting with hemorrhage. (**a**) CT shows the bone changes with displacement of the tooth (*arrow*). (**b**) Lateral angiogram of the internal maxillary artery. The angioma is supplied by branches of the infraorbital artery (*arrow*). Branches of the superior posterior alveolar artery (*arrow with dot*) and descending palatine artery (*arrowhead*) are also involved. (**c**) Acute endovascular treatment with devascularization using polyvinyl alcohol (PVA), followed by surgical curettage. Good outcome also in the long-term controls. (**d**) Internal carotid artery in the same patient showing an asymptomatic arteriovenous malformation. There is a common trunk of the occipital and ascending pharyngeal arteries arising from the internal carotid artery. Well-developed neuromeningeal trunk (*arrow*)

complete at the age of 6–7 years (Pitanguy et al. 1984) in about 95% of the cases. They are located in the head and neck involving prevalently the soft tissues. Involvement of the bone is rare. This occurs typically in the mandible. The clinical relevance varies from an asymptomatic small lesion on the skin to large disfiguring hemangiomas of the face and of the oral cavity leading to disturbances of the vision, deglutition, and respiration, and severe hemorrhages and cardiac failure.

Depending on the clinical condition MRI study and angiography can be indicated. The latter will show the frequently rich vascularized tumor which volume can be reduced by embolization using PVA particles.

Hemangiomas can be isolated or associated with other pathological conditions. Thrombocytopenia (Kasabach-Merritt syndrome) and association with several other abnormalities in the so-called PHACE syndrome can occur. Pascual-Castroviejo (1978) was the first to describe the association of extracranial capillary hemangiomas with vascular and nonvascular intracranial malformation. The definition of "PHACE" (posterior fossa malformation including intracranial hemangiomas, cervicofacial hemangiomas, eye

Multiple capillary angiomas presenting with a rich vascularization involving the skin (*arrowhead*) and the nasal mucosa. There is also a possible microaneurysmal dilatation along the descending palatine artery. Several branches are involved. Infraorbital artery (*arrow with dot*), nasal branches of the sphenopalatine artery (*arrow with angle*), superior posterior alveolar artery (*small arrow*). Descending palatine artery (*arrow*). (**b**) Lateral angiogram posttreatment with PVA. (**c**, **d**) Another patient in whom the small angioma was supplied only by pharyngeal branches of the AphA. (**c**) Angiogram of the AphA showing the small angioma (*arrow*). (**d**) Angiogram posttreatment

abnormalities, arterial anomalies, cardiac defects, and aortic coarctation) was coined by Frieden et al (1996). Later, other authors described similar complex syndromes in various combinations. In addition to the cutaneous hemangioma, similar lesions can be present also in the buccal, parapharyngeal, and subglottis areas. In the posterior fossa, Dandy-Walker malformation, hypoplasia of cerebellum, and hemangiomas in the cerebellopontine angle have been frequently reported as well as intraorbital hemangiomas. Cases of sternal defects have been described (Tortori-Donati et al. 1999; Metry et al. 2001; Poetke et al. 2002; Bhattacharaya et al. 2004; Church and Lowe

2006; Judd et al. 2007; Alsuwaidan 2012). Considering especially the arterial anomalies, these include hypoplasia of the internal carotid artery, its progressive occlusion associated with pattern mimicking the Moyamoya disease, and the persistence of fetal arteries. The etiopathogenesis of PHACE is unknown. Female predominance is present. Steroid therapy leads commonly to reduction or complete involution of the hemangiomas. In the cases in which the vascular tumor is responsible of a severe clinical involvement, angiography can be indicated, followed by devascularization of the tumor with PV.

3.10.3 Juvenile Angiofibromas

These are tumors that develop typically in young males before puberty, indicating an influence of male hormones. Rare cases of angiofibromas in older patients and also females have been described (Osborn 1959).

Juvenile angiofibromas are benign tumors formed by a fibrovascular stroma. The vascular component is very rich and consists of true arterial-capillary vessels and simple endothelial cavities.

Location. The tumor arises at the level of the sphenopalatine foramen, from which it can extend toward the nasal cavity and involve further the ethmoidal cells, the sinus sphenoidalis, and the maxillary sinus. The tumor can grow laterally into the pterygopalatine and further into the infratemporal fossa or superiorly, invading the *orbita* through the inferior orbital fissure. Through the foramina of the base of the skull, it can extend into the middle cranial fossa, with possible involvement of the cavernous sinus. Commonly, juvenile angiofibromas do not primarily destroy the bone structures, which are initially displaced and thinned and only later eroded.

Clinical relevance. The symptoms depend on the growth direction and extension. The most frequent presenting clinical signs are epistaxis and nasal obstruction.

Diagnosis and treatment. Initial examinations are CT and MR, followed by angiography. Pharyngeal branches of the AphA and distal branches of the IMA are the vessels commonly involved. Supply from the petrous and cavernous segments of the ICA through the mandibular artery and the ILT, respectively, and supply from branches of the ophthalmic arteries depending on the extension of the tumor can occur (Figs. 3.22 and 3.23). Preoperative endovascular treatment with devascularization of the tumor is an important part of the therapy (Valavanis and Chistoforidis 2000; Roche et al. 2007). Direct percutaneous embolization with *onyx* has been proposed (Gemmette et al. 2012; Lv et al. 2013; Gao et al. 2013). When the latter technique is used, it is important to perform, during the procedure, angiographic controls especially to identify the filling of dangerous anastomosis (see also Sect. 3.10.7).

3.10.4 Paragangliomas

Paragangliomas belong to a group of tumors in which three types can be distinguished (Lantos et al. 1997): the pheochromocytomas originating in the adrenal medulla, the sympathetic paragangliomas arising from neuroendocrine cells associated with the sympathetic chain, and the parasympathetic paragangliomas (chemodectomas) arising from cells which have chemoreceptor activity associated with paraganglionic structures. These latter will be described here. Women in the fourth and fifth decades of life are predominantly affected. In up to 10% of patients paragangliomas are multiple. Cases in the same family have been reported. A malignant potential evolution with metastasis especially in the lung and vertebral column is very rare, but possible, and is more frequent in younger patients (Zak and Lawson 1982; Ma et al. 2010; Obholzer et al. 2011). Differently from pheochromocytomas, paragangliomas are rarely active.

The tumor can present as a very small nodule or as a large mass reaching the diameter of 10–15 cm. Histologically is appears as an encapsulated mass consisting of epithelial cells with a high vascular stroma.

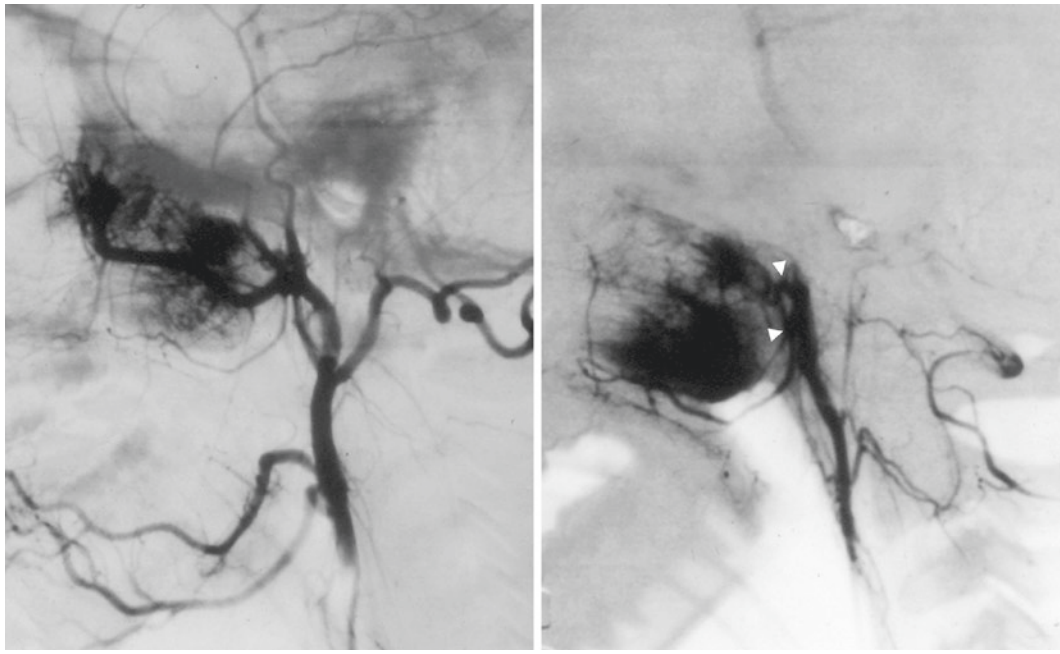

Fig. 3.22 Large juvenile nasopharyngeal angiofibroma, lateral angiogram of the external carotid artery (*left*) and of the ascending pharyngeal artery (*right*), showing the richly vascularized tumors, supplied by distal branches of the IMA and superior and middle pharyngeal branches of the AphA (*white arrows*). On both angiograms there is a partial filling of the vertebral artery through anastomoses with the occipital (*right*) and AphA (*right*). Note also the retrograde filling of the deep cervical artery (*right*). The lesion was preoperatively devascularized with PVA after advancing the catheter distally to the anastomoses

Fig. 3.23 Left ICA angiogram in a large juvenile angiofibroma with an intraorbital extension. On this angiogram, the partial involvement of the mandibular artery (*arrows*) and of branches of the ophthalmic artery (*arrow*) are recognizable. On the *right* another example of a juvenile angiofibroma extending intracranially in the parasellar region. This portion of the tumor is richly vascularized by branches of the cavernous portion of ICA, by the recurrent meningeal artery of the ophthalmic artery (*arrow*) and probably also from the mandibular artery

Location. Most frequently, paragangliomas are located in the temporo-basal area arising from paraganglionic structures in association with the tympanic branch of the glossopharyngeal nerve (tympanic paraganglioma) or from cells located in the adventitia of the bulb of internal jugular vein (jugular paraganglioma). The second location in frequency is the carotid body and vagal paragangliomas arising, respectively, from paraganglionic cells located at the carotid bifurcation or from cells associated with the vagal nerve or ganglion nodosum. Less common are lesions in the larynx, pharynx, lung, orbit, and nose. A curious location is that in the cauda equina where no paraganglionic structures are present. Interesting to note is that this site occurs more frequently in men (Sonneland et al. 1986; Singh et al. 2005; Taschner et al. 2012).

Clinical relevance. The mass effect is the dominant feature in carotid body paragangliomas. Various degrees of involvement of the last four cranial nerves are present in vagal and tympano-jugular lesions. In the latter case, otological symptoms, characterized by hearing loss, tinnitus, and palsy of cranial nerve VII, can occur.

Diagnosis and treatment. Initial examination is by CT and MRI which show the location and extension of the tumor. Angiography including study of the bilateral ICA, ECA, and vertebral artery is an essential diagnostic step. The supplying arteries can vary, depending on the location and extension of the tumor. Some basic features can be summarized as follows.

In paragangliomas of the ICA bifurcation and vagal paragangliomas, the pharyngeal branches of the AphA and branches of the occipital artery are always involved. The ascending palatine branch of the facial artery can also occasionally supply the tumor. In tumors of the ICA bifurcation, infiltration of the adventitia of the ICA can occur. In tympano-jugular paragangliomas the tympanic branches (anterior from IMA, posterior from the stylomastoid, superior from the petrosquamous branch of MMA, and inferior from the AphA) can be involved in various combinations, depending on the extension of the tumor. The vertebral artery may be involved through its extracranial and also intracranial branches in the rare cases of extension of the tumor in the posterior fossa. The ICA can supply the tumor through its caroticotympanic branch; furthermore through extension of the tumor into the carotid canal, there is a possible encasement of this segment of ICA.

The venous drainage almost always occurs in the internal jugular vein, which may also be directly infiltrated and occluded by the tumor. In these cases a retrograde injection of the sigmoid sinus and IPS can occur. These aspects of the venous circulation should always be carefully examined as well as in case of occlusion of the internal jugular vein the presence of a drainage through the contralateral jugular vein and through the venous plexus surrounding the vertebral artery should be demonstrated. Examples of paragangliomas are presented in Figs. 3.24, 3.25, 3.26, and 3.27.

Preoperative endovascular treatment aimed to lead to a devascularization of the tumor is mandatory (Valavanis and Christoforidis 2000). It should be noted that paragangliomas can consist of a single compartment to which converge all supplying arteries, or of multiple compartments each supplied by a specific artery. Compartment can be completely separated or be connected to each other (Moret et al. 1980). This should be taken into consideration in the treatment. The devascularization can be associated, in selective cases, with endovascular occlusion with balloon or coils of the ICA or VA. In some cases, especially in old patients, the endovascular devascularization, reducing the volume of the tumor and improving the clinical symptoms, can be considered as a useful palliative therapy.

3.10.5 Meningiomas

Meningiomas are a relatively common pathology, having a frequency of about 18% of all intracranial tumors. They typically predominate in women of middle to old age and are not rarely multiple. Meningiomas originate from

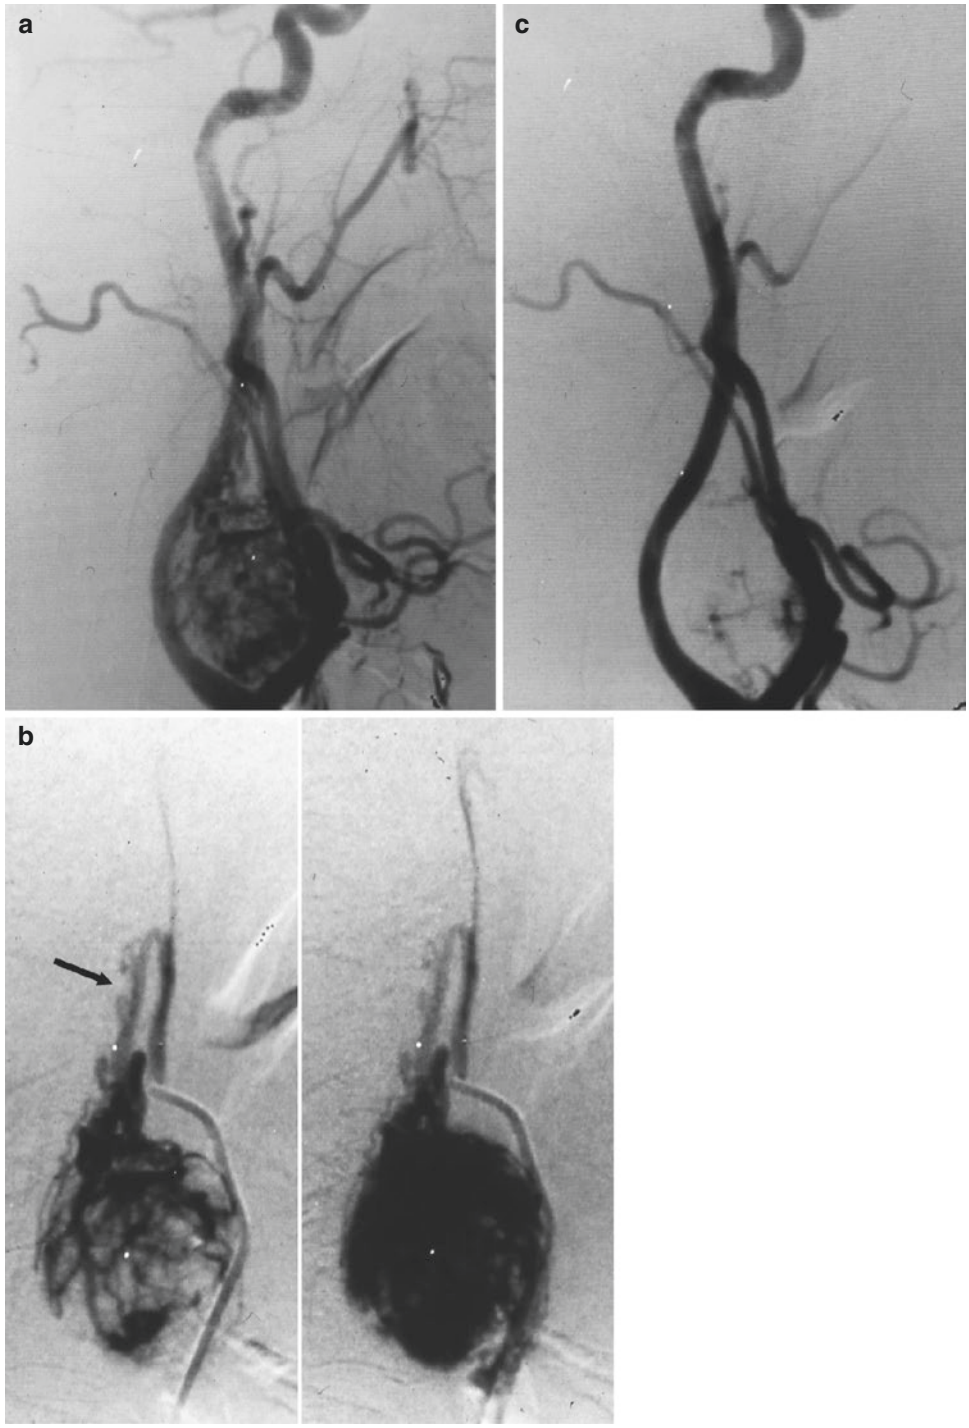

Fig. 3.24 Paraganglioma of the carotid bifurcation. (**a**) Common carotid angiogram, lateral view, showing the typical location of the richly vascularized tumor. (**b**) Selective study of the ascending pharyngeal artery which is the main supplying artery through its inferior pharyngeal branches (*arrow*). (**c**) Control angiogram after devascularization of the tumor with PVA

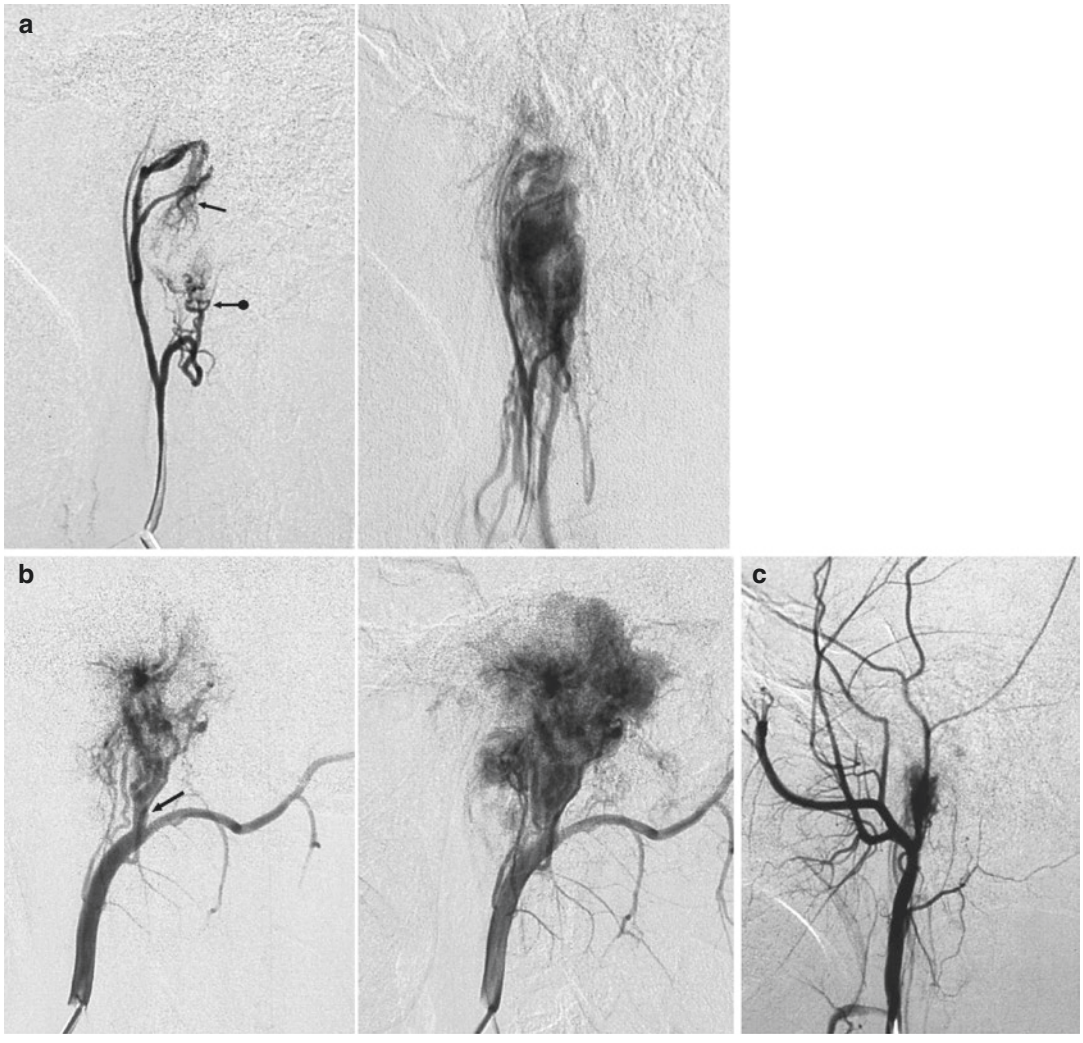

Fig. 3.25 Tympano-jugular paraganglioma supplied by branches of the occipital and ascending pharyngeal artery. A small component came from the anterior tympanic artery branch of the IMA. (**a**) Angiogram of the ascending pharyngeal artery. Lateral view. The pharyngeal (*arrow with dot*) and tympanic branches (*arrow*) supply the tumor. In the later phase, the anterior compartment of the tumor is well defined. (**b**) Angiogram of the occipital artery. Lateral view. A large stylomastoid artery (*arrow*) is involved in the supply of the posterior compartment of the tumor, well defined in the later phase. (**c**) Small supply from the anterior tympanic branch

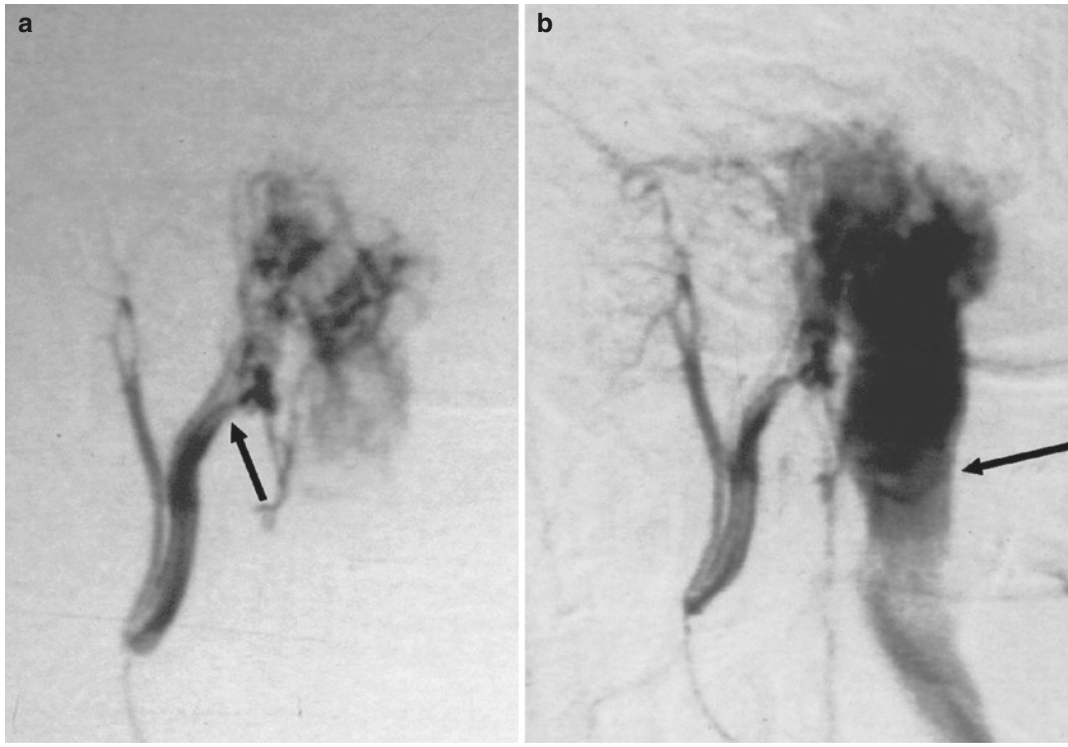

Fig. 3.26 Large tympano-jugular paraganglioma supplied mainly by tympanic branches of the ascending pharyngeal artery. (**a**) Angiogram (oblique view) of the selective catheterization of an enormous dilated ascending pharyngeal artery. Tympanic branches (*arrow*) supplying the tumor. (**b**) Drainage in the jugular vein (*arrow*) infiltrated by the paraganglioma

meningothelial cells (arachnoidal) of the meninges. These cells are thought to be a mixed cell type having mesenchymal and neural crest elements, which explains probably the variety of the histological aspects of the meningiomas (meningothelial, fibrous, transitional, psammomatous, and angiomatous) (Bradac et al. 1990; Schiffer 1993; Lantos et al. 1997). They are commonly benign tumors. Malignant degeneration, however, even if rare, can occur, and this is more frequent in males.

The vascularization can vary. It is particularly rich in the angiomatous type. Essentially there are two groups of supplying arteries (Bradac et al. 1990). The first consists of meningeal branches entering the tumor at the site of the dural attachment supplying the central part of it; the second consists of pial branches of the

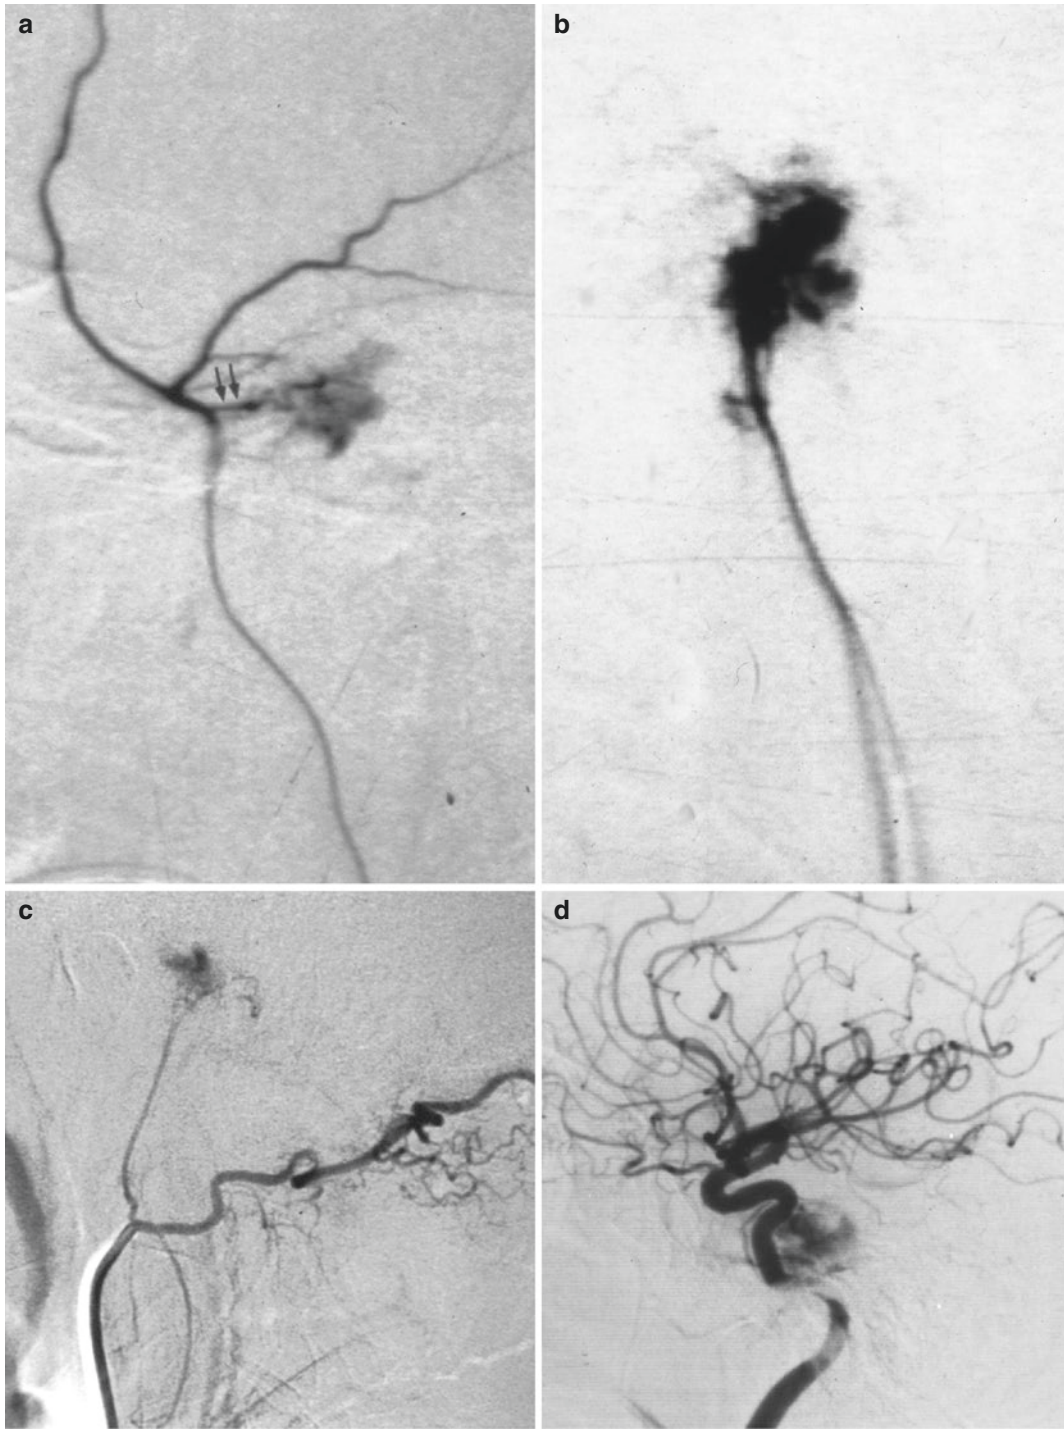

Fig. 3.27 Selective studies of a tympanic paraganglioma supplied by superior tympanic branches (**a**) of the petrosquamous branch (*arrows*) of the middle meningeal artery (*arrows*). There is a second supply arising from the inferior tympanic branch of the ascending pharyngeal artery. (**b**) Small paraganglioma (**c**) in another patient supplied only by the tympanic branch of the stylomastoid artery. Another example (**d**) of a large tympano-jugular paraganglioma with involvement of cavernous and petrous branches of the internal carotid artery

ICA and/or vertebral artery, which vascularize the more peripheral part of the tumor. One vascular sector can exert evident predominance over the other. The origin of the meningeal vascularization depends largely on the site of the primary dural attachment of the meningioma. In addition, the tumor can extend and secondarily involve further dural areas, leading to a recruitment of other meningeal feeders. Preoperative devascularization may be useful in selective cases. Examples are presented in Figs. 3.28 and 3.29.

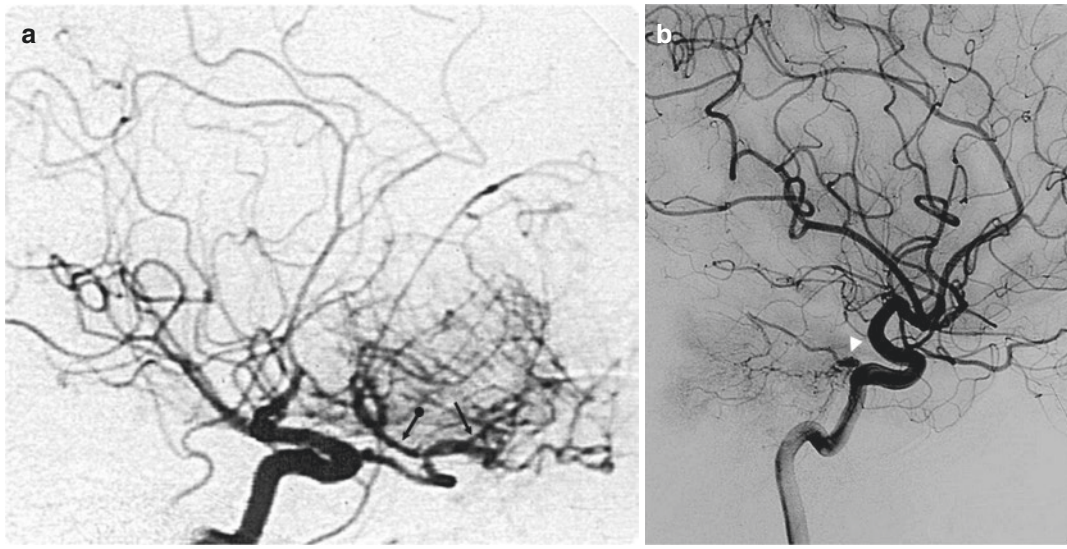

Fig. 3.28 (**a**) Frontobasal meningioma, carotid angiogram, lateral view. The tumor is richly vascularized by branches of the ophthalmic artery represented by the recurrent meningeal artery (*arrow with dot*) and posterior ethmoidal arteries (*arrow*). (**b**) Petroclival meningioma, carotid angiogram, lateral view. The tumor is vascularized by the enlarged branches of the MHT (*arrowhead*)

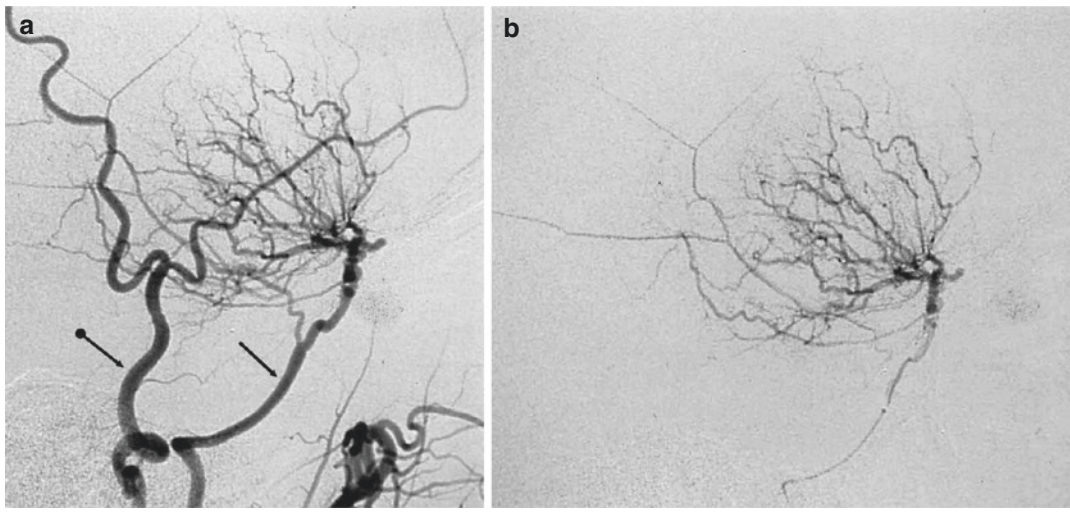

Fig. 3.29 Temporo-basal meningioma, richly vascularized by distal branches of the middle meningeal artery. (**a**) External carotid artery angiogram, lateral view. Middle meningeal artery (*arrow*) supplying the tumor. Superficial temporal artery (*arrow with dot*). (**b**) Selective study of the middle meningeal artery followed by devascularization of the lesion with polyvinyl alcohol. (**c**) Control angiogram posttreatment

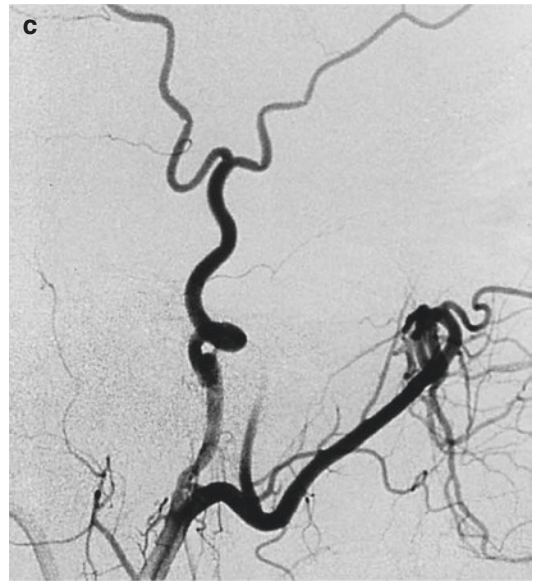
Fig. 3.29 (continued)



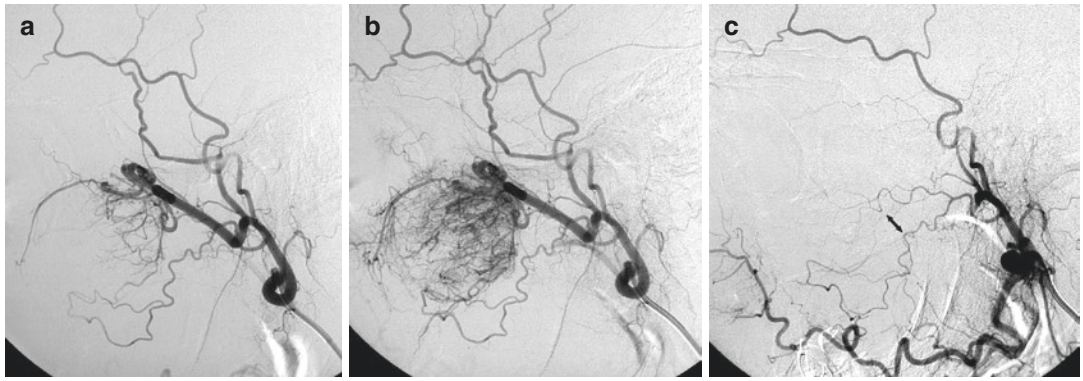


Fig. 3.30 Metastasis of melanoma involving the maxillary sinus with already minimal infiltration of the adjacent areas (soft tissue of the cheek and nasal cavity). The angiogram (**a**, **b**) shows an extremely richly vascularized tumor involving the distal branches of the IMA. There is possible involvement also of the inferior branches of the transverse facial artery. Preoperative devascularization with PVA with occlusion of distal branches and trunk of IMA was performed. (**c**) Control angiogram. Horizontal and inferior branches of the transverse facial artery (*bidirectional arrow*) are now better visible

3.10.6 Other Tumors in the Head and Neck Area

Angiographic study of these lesions is rare. Indications are commonly very large tumors leading to displacement or encasement of ICA or VA or tumors in which a very rich vascularization is suspected. In these latter cases angiography followed by devascularization facilitating further treatment can be very useful (Fig. 3.30).

3.10.7 General Considerations in Endovascular Treatment in the ECA Area

- Abundant anastomoses are present among all the branches of the ECA. In the endovascular treatment of the different pathologies of this sector, especially in cases of vascular malformations, proximal occlusion of the supplying arteries should be avoided, since this would rapidly lead to the formation of a collateral circulation, reinjecting the lesion. *The embolic material should be directly injected into the nidus or close to it. The possible involvement of the ascending and deep cervical arteries should be taken into account.*
- Many anastomoses (dangerous connections) can link the ECA with the ICA and VA (Table 3.1 and drawings 3.31, 3.32, and 3.33 and Fig. 3.34). Anastomoses are also present between the cervical arteries and ECA and VA. These connections are listed in Table 3.1 and should be always taken into consideration when endovascular treatment is planned. The anastomoses can be minimal or large (Morris 1997; Lasjaunias et al. 2001; Geibprasert et al. 2009). They can already be recognizable at the beginning of the treatment or may enlarge and appear during it, following superselective injection or opening of collateral paths as a consequence of occlusion of other arteries. *Frequent angiographic control is mandatory*.
- Another important aspect is the supply of a few cranial nerves from branches of the ECA (Table 3.2). This should be considered whenever a vascular treatment involves these branches. *It is important to take particular caution in the occlusion of these vessels and in the choice of embolic material in these cases*.

Table 3.1 List of most remarkable connections involving ECA

Anastomosis between ECA and ICA	
Foramen rotundum A. (IMA)	ILT (ICA)
Vidian A. (IMA)	Mandibular A. (ICA)

XII cranial nerve	Hypoglossal branch of the neuromeningeal trunk of the ascending pharyngeal artery

Anterior Cerebral Artery

4

The anterior cerebral artery (ACA) develops as a branch of the primitive olfactory artery which originates from the anterior cranial division of the ICA (see also Chap. 1). The primitive olfactory artery regresses and is replaced by the ACA (De Vriese 1905; Abbie 1934; Padget 1948; Liu and Kricheff 1974).

The final ACA can be divided into several segments (Huber 1979) (Fig. 4.1):

- A1 precommunicating segment: from its origin from the ICA to the anterior communicating artery (AcomA)
- Distally to the AcomA, the ACA continues as the pericallosal artery
- A2 (infracallosal segment)
- A3 (precallosal segment)
- A4 (supracallosal segment)

4.1 Precommunicating Segment

The first part of the ACA is called the A1 or the *precommunicating* segment. It arises at the terminal ICA and it runs medially above the chiasma and optic nerve with a horizontal, sometimes slightly descending, ascending or tortuous course joining the contralateral A1 by the way of the anterior communicating artery (AcomA). The length of the A1 is on average 12.7 mm (Perlmutter and Rhoton 1976) and that of the AcomA is on average 2–3 mm (Marinković et al. 1990; Tao et al. 2006) (Figs. 4.1 and 4.2). Many small arteries arise from the A1 segment and from the AcomA.

Perforating branches are found along the whole A1, but they are more numerous in its proximal part (Perlmutter and Rhoton 1976; Dunker and Harris 1976). Among the more distal branches a few arise also from the AcomA (Stephen and Stilwell 1969; Krayenbühl et al. 1972; Dunker and Harris 1976; Perlmutter and Rhoton 1976; Rosner et al. 1984; Lang et al. 1987; Marinković et al. 1990; Tao et al. 2006).

As far as it concerns the branches of A1, some of these arise from its inferior surface supplying the optic nerve and chiasma. From the superior surface of A1 arise branches supplying the suprachiasmatic anterior portion of the hypothalamus and anterior commissure while other branches enter the medial part of the anterior perforated substance (APS).

The branches of the AcomA are represented by small short perforating arteries in number of 4–5 supplying the lamina terminalis and the preoptic hypothalamic region. In addition to these branches there is a single longer branch, which runs in front of the lamina terminalis towards the rostrum and genu of the corpus callosum where commonly ends divide in two short terminal branches. Rarely it can extend more distally. It is involved in the supply of the lamina terminalis, anterior commissure, preoptic part of hypothalamus, anterior pillars of fornix, septum pellucidum, and part of the corpus callosum. This artery which has been reported to be present in about 90% of the cases (Marinković et al. 1990;

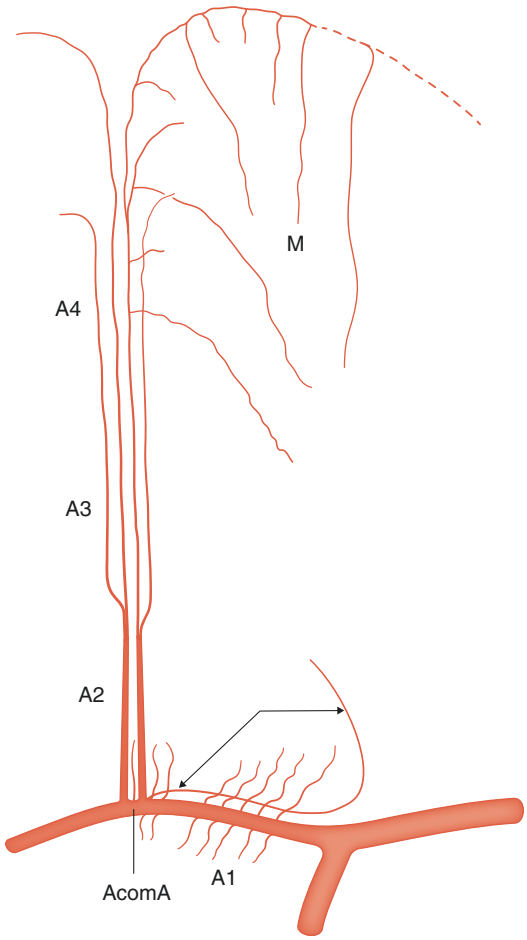

Fig. 4.1 Drawing showing the segments of the anterior cerebral artery. A1, A2, A3, and A4. Artery of Heubner (*arrow with angle*) arising in the angle A1–A2. Other perforators arise from the superior and inferior surface of A1. Anterior communicating artery (AcomA) from which arises the subcallosal artery. Medullary arteries (M, short and long branches) arising from cortical branches. Dashed line indicating leptomeningeal anastomoses with the MCA

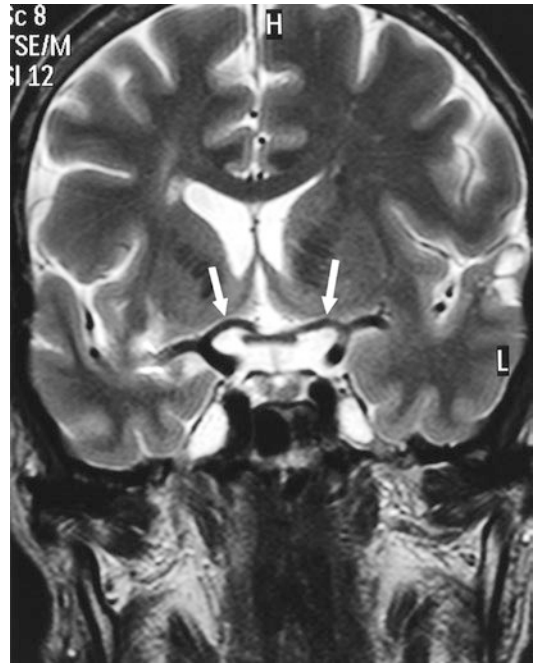

Fig. 4.2 Coronal MRI T2-weighted image showing the relationship of the A1 (*arrow*) to the chiasma

Tao et al. 2006) has been called *subcallosal artery*, which corresponds to the "artère cerebrale antérieure mediane courte" of Lazorthes (1961). Sometimes the artery can be well developed. It can extend between both pericallosal arteries along the corpus callosum supplying it and also the adjacent parts of the cerebral hemispheres. The artery has been called (*median artery of the corpus callosum, median callosal artery, arteria pericallosa triplex*) (De Almeida 1931; Lazorthes 1961; Baptista 1963; Stephen and Stilwell 1969; Perlmutter and Rhoton 1978; Huber 1979, Kakou et al. 2000; Marinković et al. 1990; Tao et al. 2006; Kornieieva et al 2017).

Another important branch is the *recurrent artery of Heubner*. It has been described by this author in 1872, and considered by Padget (1948) as an embryological remnant of the primitive olfactory artery. It is the largest and longest perforating branch. It commonly takes its origin from the distal A1 or proximal A2 segments, rarely from the AcomA. In a few cases, it can have a common origin with the frontopolar artery (Critchley 1930; Westberg 1963; Lazorthes 1961; Lazorthes et al. 1976; Perlmutter and Rhoton 1976; Rosner et al. 1984; Gomes et al. 1984; Tao et al. 2006). In its course, the artery of Heubner runs back parallel to the A1 and M1 segments to enter the APS mainly in its anterior part. It can be a single branch or sometimes be made by multiple branches, supplying the inferior part of the head of the nucleus caudatus, and the adjacent parts of the anterior limb of the internal capsule, and of putamen and pallidum (Perlmutter and Rhoton 1976; Rosner et al. 1984) (Drawing 4.1 and Figs. 4.3, 4.4, 4.5, 4.10, 4.11a–d, 4.13a–d, 5.15 and 11.12a).

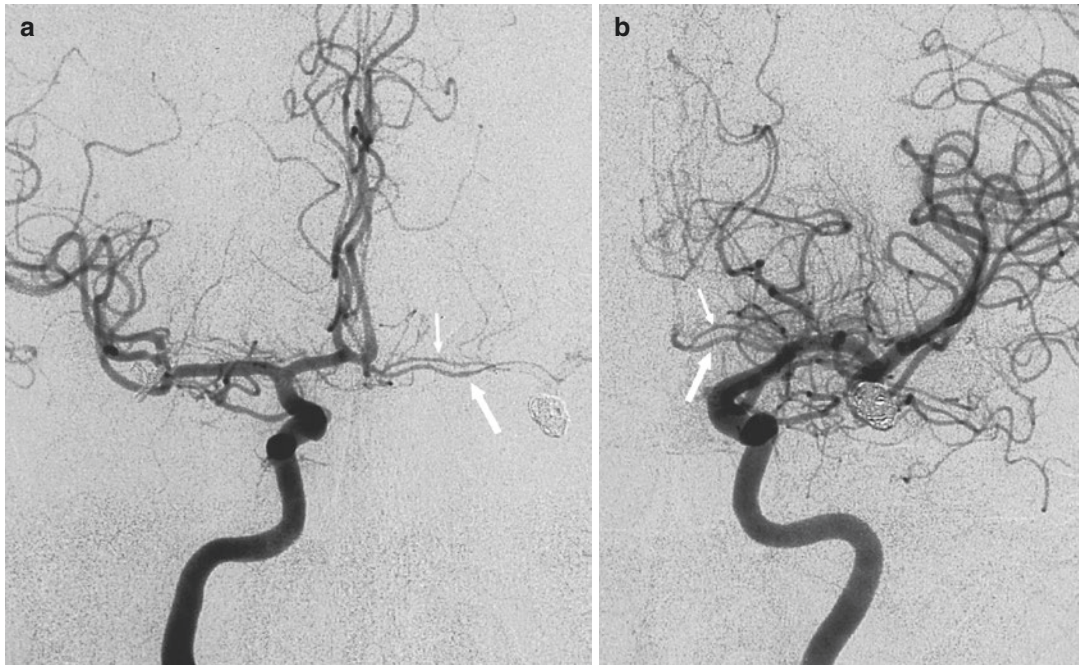

Fig. 4.3 Right (**a**) and left (**b**) AP carotid angiogram in a patient treated with coils for a ruptured left MCA aneurysm. Well-developed A1 on the right. Hypoplastic left A1 (*large white arrow*). Artery of Heubner (*small white arrow*) running parallel to the A1 segment

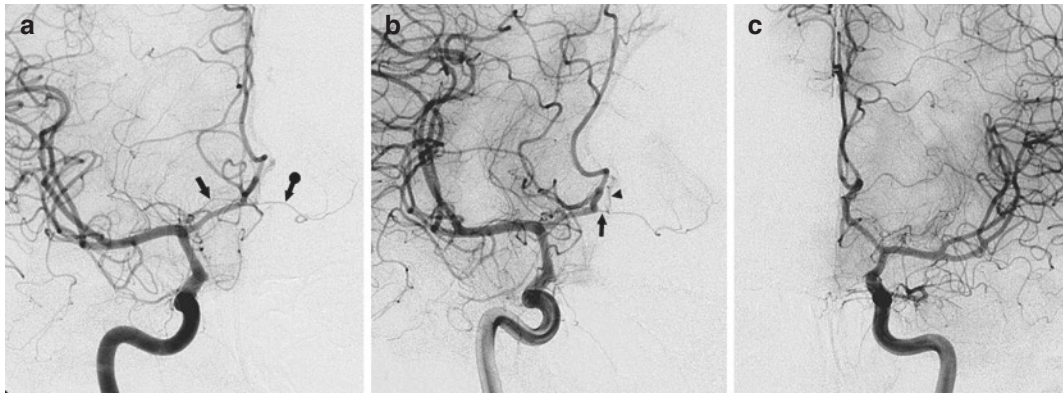

Fig. 4.5 Patient with meningioma of the *planum sphenoidale*. Bilateral carotid angiogram. AP view. Typical shifting of both A1. (**a**) On the right carotid angiogram, the right (*arrow*) and the left (*arrow with dot*) arteries of Heubner are clearly recognizable. (**b**) On the oblique view the origin of the left Heubner artery from the proximal left A2 can be demonstrated. Faint injection of the left A2 (*white arrowhead*). AcomA (*arrow*). (**c**) On the left ICA angiogram the Heubner artery is more difficult to identify

4.2 Distal Segments

Distal to the junction with the AcomA begins the *postcommunicating segment* called the *pericallosal artery*, which can be subdivided, according to its relationship to the corpus callosum, into three further segments (Liu and Kricheff 1974; Huber 1979) (Drawing 4.7 and Figs. 4.6 and 4.8).

4.2.1 Infracallosal Segment

This is also called the A2. It runs into the interhemispheric fissure upwards in front of the lamina terminalis towards the genu of the corpus callosum. It gives off *the orbitofrontal* (infraorbital) and the *frontopola*r arteries which can arise as a single or sometimes as a common trunk. The orbitofrontal artery runs forward and towards the floor of the anterior cranial fossa. The frontopolar artery runs anteriorly on the medial surface of the hemisphere towards the frontal pole.

4.2.2 Precallosal Segment

This, called the A3, is a short segment, which curves around the genu of the corpus callosum (Drawing 4.6 and Fig. 4.7). It gives off the *callo-*

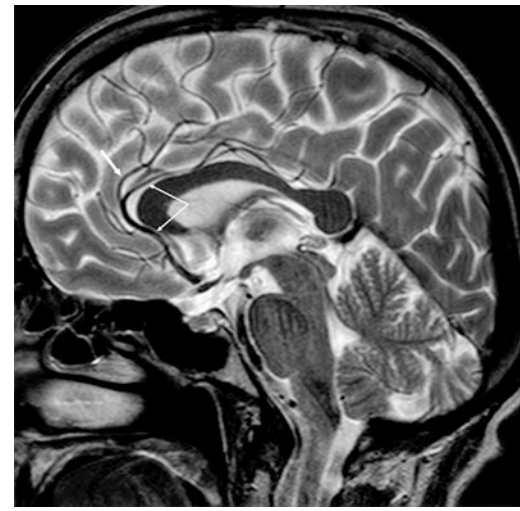

Fig. 4.6 MRI sagittal T2-weighted image. Infra-, pre-, supracallosal segments of the pericallosal artery (*white arrow with angle*). The supracallosal segment runs with an undulating course above the corpus callosum, partially in the pericallosal cistern and partially superior to it. From the precallosal segment arises the callosomarginal artery (*white arrow*)

somarginal artery, which runs from the frontal to the parietal region above the gyrus cinguli in the cingulate sulcus, giving off frontal branches and ending in the paracentral artery. In other cases it can be well developed only in the frontal area or be not recognizable as a trunk but only represented by small isolated branches. In some cases it can be completely absent. In the cases of hypo-aplasia of

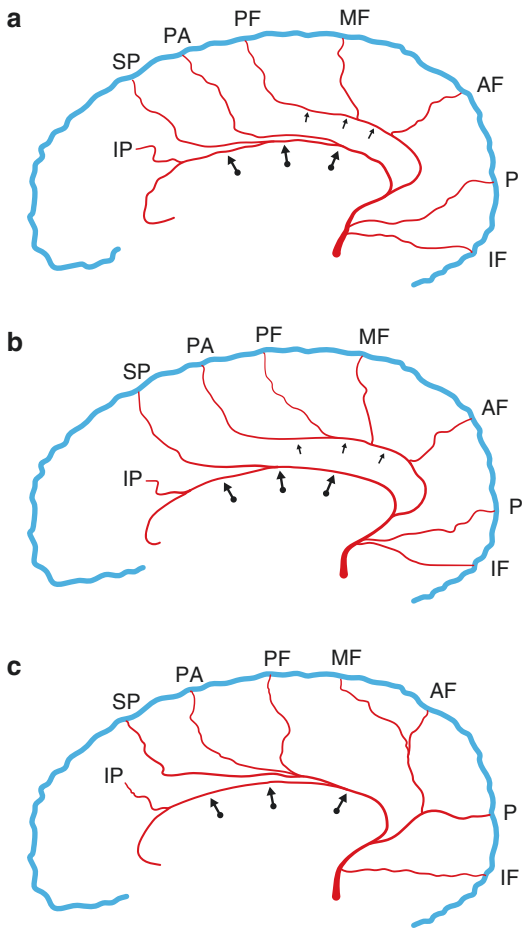

Fig. 4.7 (**a**–**c**) Drawing showing some variants concerning the distal segments of the ACA. Pericallosal artery (*arrows with dot*). Callosomarginal artery (*arrows*). Infraorbital artery (*IF*). Frontopolar artery (*P*). Anterior (*AF*), middle frontal (*MF*), posterior frontal (*PF*) arteries. Paracentral artery (*PA*). Superior parietal (*SP*), inferior parietal artery (*IP*)

the artery its cortical branches are replaced by arteries arising from the presupracallosal segments of the pericallosal artery. Vice versa it can occur such that all the cortical branches arise from the callosomarginal artery in the very rare case of aplasia of the pericallosal artery. The well-developed callosomarginal artery appears on the lateral carotid angiogram running superiorly to the pericallosal artery and on the AP view slightly displaced from the pericallosal artery which runs on the midline.

4.2.3 Supracallosal Segment

This segment is called the A4 (Figure 4.6 and drawing 4.7). It is the more distal segment of the pericallosal artery. It runs posteriorly in the pericallosal cistern, above the surface of the corpus callosum towards the splenium. This segment has been called posterior pericallosal artery and its extent depends on the size of the artery of the splenium, branch of the posterior cerebral artery. Occasionally, it can extend below the corpus callosum towards the foramen of Monro (Stephen and Stilwell 1969; Kier 1974; Perlmutter and Rhoton 1978, Kakou et al. 2000), as in the embryological life and anastomoses with the posterior medial choroidal artery (see also Sect. 12.8). The supracallosal artery can have an undulating course and sometimes shows an upward distension in its midportion. It is commonly well developed, but it can be sometimes hypoplastic especially in its distal segment, or rarely uni- or *bilaterally absent.*

A meningeal branch can arise from the precallosal segment supplying the inferior part of the falx (De Almeida 1931; Moniz 1940; Lasjaunias and Berenstein 1990). It anastomoses with branches of the middle meningeal artery descending along the falx. It can also be connected with the meningeal branch arising from the posterior cerebral artery (see Sect. 7.1).

4.2.4 Distal Cortical Branches

Several arteries arise from the supracallosal segment of the pericallosal artery, and/or callosomarginal artery, and run on the medial surface of the hemisphere (Ring and Waddington 1968; Moscow et al. 1974; Perlmutter and Rhoton 1978). These arteries can have a variable origin; their distal course, however, and their vascular territories are relatively constant. From anterior to posterior, the cortical branches are represented by the group of the *frontal arteries, paracentral branch, and parietal arteries*. The frontal arteries, which can be subdivided into the anterior, middle, and posterior branches, run in the frontal area. The posterior frontal artery

terminates in the superior limit of the precentral sulcus. The paracentral artery which frequently arises from the pericallosal artery, more rarely from the callosomarginal artery, or as a common trunk with the posterior frontal and superior parietal artery, runs towards the paracentral lobule and extends to the central sulcus with branches for the precentral and postcentral gyri. The more distal branches are the inferior and the superior parietal arteries. The inferior parietal runs on the inferior surface of the precuneus supplying it. It can occur that the pericallosal artery ends in the inferior parietal artery and it does not continue around the splenium. The other branch is the superior parietal artery, which is commonly larger. It takes its origin commonly from the pericallosal artery, sometimes as a common trunk with the posterior frontal and paracentral arteries. It runs towards the marginal segment of the cingulate sulcus and marks the boundary between the paracentral lobule and precuneus with branches supplying both the paracentral lobule and the superior part of the precuneus.

Examples of the pericallosal and callosomarginal arteries and origin and course of their branches are presented in Drawing 4.7 and in Fig. 4.8.

4.3 Anatomical Variations

One A1 segment is hypoplastic (diameter of 1 mm or less) in 10% of the cases and severely hypoplastic (diameter of less than 0.5 mm) or absent in 1% of the cases (Perlmutter and Rhoton 1976; Huber 1979; Yasargil 1984a, b). In a more recent anatomic study, the artery was absent in 2.2% of the cases examined (Tao et al. 2006) (examples of A1 variants are presented in Figs. 4.3, 4.9, 4.10, and 7.2). This variation is frequently associated with aneurysm of AcomA (Perlmutter and Rhoton 1976; Huber 1979; Yasargil 1984a, b). In case of occlusion of one carotid sector, the A1 segment can be an important collateral way, which can be impaired when this segment is hypo-aplastic.

Two or three AcomAs may be present in up to 40% of the cases (De Almeida 1931; Perlmutter and Rhoton 1976; Marinković et al. 1990) (Fig. 4.11a–d). The different patterns of the AcomA are probably due to the different embryological evolution of the primary plexiform network (De Vriese 1905; Padget 1944) which can develop into a single large or small vessel or into a complex network. Rarely the AcomA is absent. In these cases, the pericallosal arteries of both sides fuse proximally together (Marinković et al. 1990; Tao et al. 2005).

Fig. 4.8 Different patients in whom the various courses of the distal segments of the ACA are shown. (**a**) Well-developed pericallosal artery (P). Callosomarginal artery (CM), giving off frontal branches (*arrows*). The paracentral artery (*arrow with dot*) arises from the pericallosal artery. (**b**) Lateral carotid angiogram. Well-developed pericallosal artery (*arrowhead*), dividing distally in the superior (*arrow with angle*) and inferior (*arrows*) parietal arteries. Callosomarginal artery (*arrowheads*) giving off frontal branches and the paracentral artery. There is a common trunk arising from callosomarginal artery for the posterior frontal (PF) and the paracentral artery (PA). (**c**) Lateral carotid angiogram. Well-developed pericallosal artery. However, its distal segment is hypoplastic (*arrowheads*). From the pericallosal artery arise frontal branches (*double arrow*) and as a common trunk the paracentral artery (PA) and the parietal branches (*arrow with angle*). There is a common trunk for the infraorbital (IF) and the frontopolar (P) arteries arising from the infracallosal segment of the pericallosal artery. (**d**) Well-developed pericallosal artery which with an undulating course terminates in the parietal area (*arrowhead*). The callosomarginal artery as a trunk is not recognizable. From the infracallosal segment of the pericallosal artery arises a well-developed branch (*arrow*) supplying the anterior and middle frontal area. From the supracallosal segment arises another long branch (*arrow with dot*) supplying the posterior frontal and paracentral area. (**e**) Left ICA lateral angiogram. Well-developed callosomarginal artery from which arise all distal branches, while the pericallosal artery is on this side hypoplastic. (**f**) Pericallosal artery (*arrow*). Well-developed subcallosal artery (*arrow with dot*). (**g**) Well-developed callosomarginal artery (*large arrow*) supplying small convexity angioma. Another branch (*double arrow*), probably a dilated paracentral artery, arises from the dilated pericallosal artery

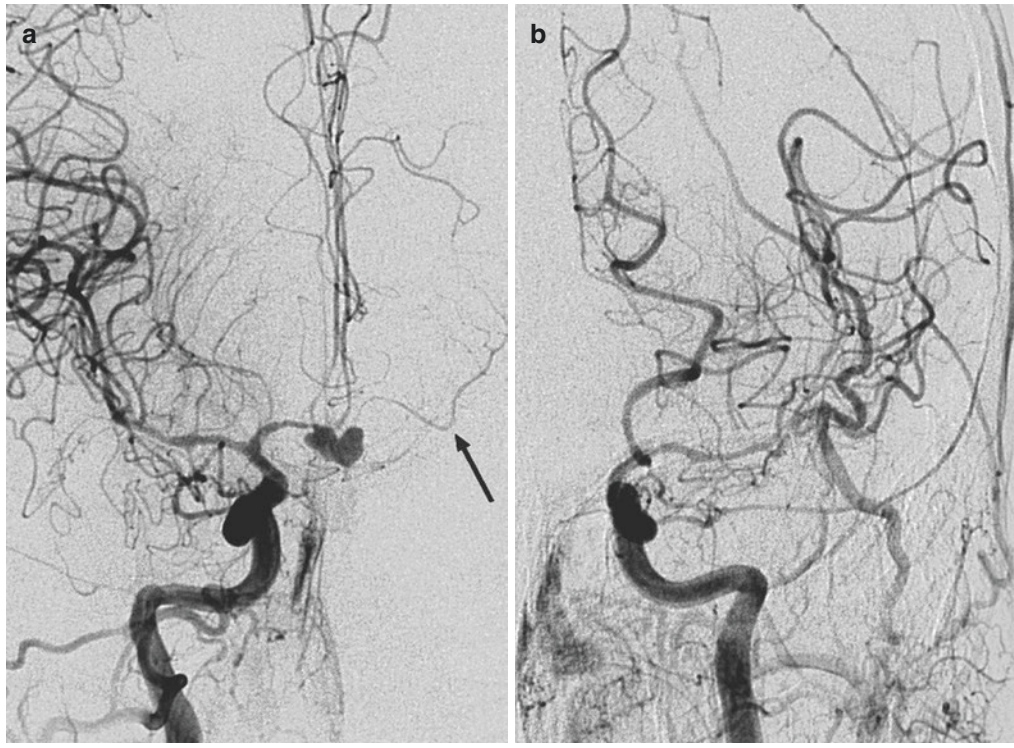

Fig. 4.10 Middle-aged woman presenting with SAH due to rupture of AcomA aneurysm. Right (**a**) and left (**b**) carotid angiograms. There is an irregular-shaped aneurysm with the neck in the angle between A1 and A2 of the right ACA. Owing to the aplasia of the left A1 there is no overlapping and so the left Heubner artery arising from the left proximal A2 is clearly recognizable (*arrow*). The aneurysm was occluded with coils and the already present spasm was treated with medical therapy with a final good result

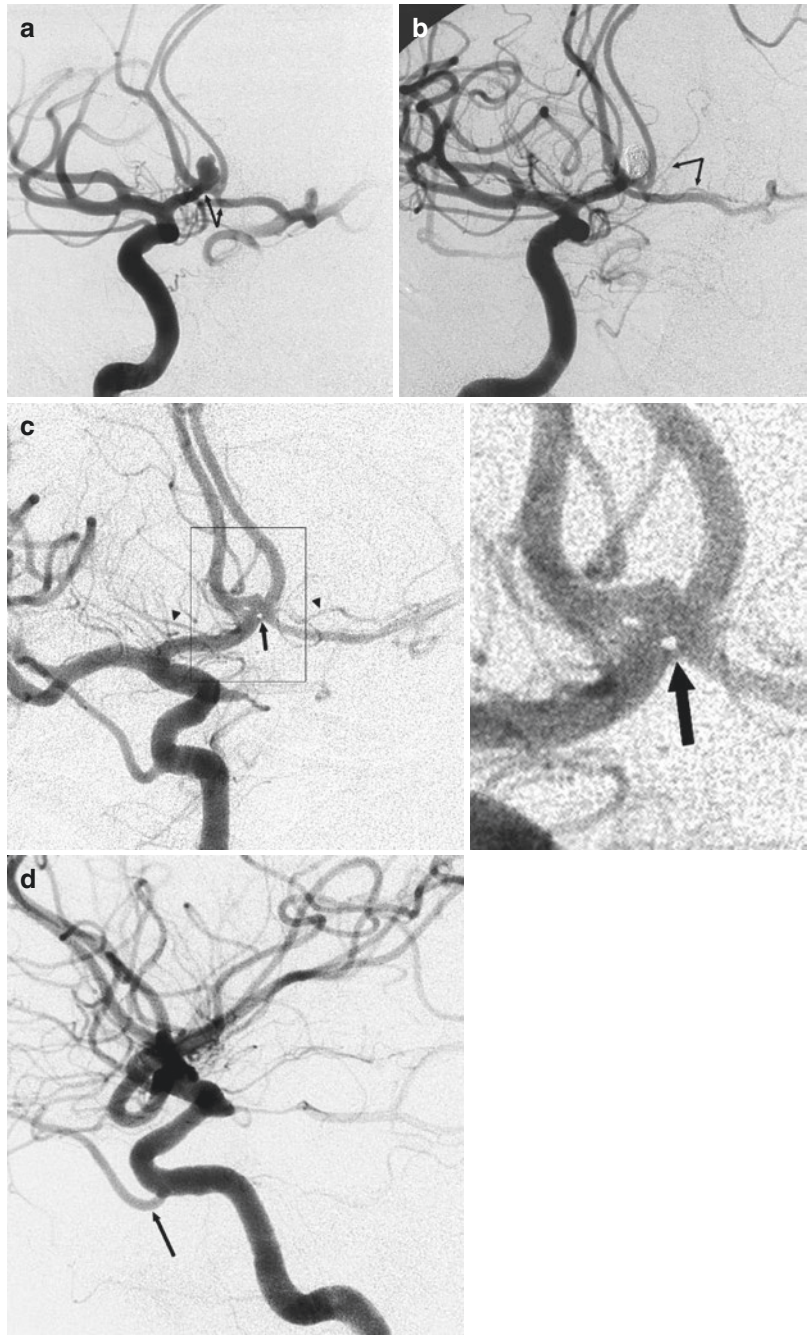

Fig. 4.11 Studies in two different patients. (**a**) Right internal carotid angiogram (oblique view) in a patient with a ruptured AcomA aneurysm. There is a duplication of the anterior communicating artery (*small arrow with angle*). In such cases, many projections are frequently necessary to identify the aneurysm neck. (**b**) Angiogram postcoiling. The left artery of Heubner arising as a common trunk with the frontopolar artery (*arrow with angle*) is well recognizable running parallel to the left A1. (**c**) Carotid angiogram (oblique view) in another patient with plexiform aspect (*arrow*) of AcomA. Detail of the area. The artery of Heubner is well visualized on both sides (*arrowheads*). Origin of the ophthalmic artery from the cavernous portion of the ICA. (**d**) Lateral carotid angiogram in the same patient showing better the anomalous origin of the ophthalmic artery (*arrow*)

Fig. 4.12 (**a**) Right carotid angiogram, AP view. Incidental discovery of aneurysm in a patient with duplication of A1. One A1 segment arises normally from the distal ICA bifurcation (*arrow*), and the other one arises from the ICA close to the origin of the ophthalmic artery. Where the two branches distally join together, an aneurysm is present. (**b**) Carotid angiogram in another patient with incidental discovery of a duplication of A1. In this case the A1 arises as a normal trunk, but along its course duplicated in two vessels

The artery of Heubner can exceptionally be absent on one side (Westberg 1963; Perlmutter and Rhoton 1976; Tao et al. 2006). In cases of hypoaplasia of the A1, the artery of Heubner can be very large and should not be confused with the A1.

Another very rare variant is the so-called *carotid-anterior cerebral artery anastomosis* in which an anomalous vessel arises from the ICA, close to the origin of the ophthalmic artery. It has an ascending course and passes inferiorly to the optic nerve to reach the A1–A2 junction. It can replace the normal A1, but both the anomalous branch and the normal A1 can be present so we could in this case also speak of a duplicated origin of the ACA. There are no clear embryological explanations for this anomaly. Since the first description of Robinson (1959), many authors have described this variant (Turnbull 1962; Nutik and Dilenge 1976; Bernini et al. 1982; Rosenorn et al. 1985; Milenkovic 1985; Friedlander and Ogilvy 1996; Morris 1997; Kilic et al. 2005; Chakraborty et al. 2006; Wong et al. 2008; Uchino et al. 2012a). The association of aneurysm of the AcomA is frequent. An example is presented in Fig. 4.12a.

The A1 segment may have a normal origin, but along its course it features duplication (two different vessels) or fenestration (one vessel with two lumens) (Wollschlaeger and Wollschlaeger 1974; Perlmutter and Rhoton 1976) (Figs. 4.12b, 5.3b and 5.11a).

The several variations involving the pericallosal, the callosomarginal, and their branches have already been described in Sects. 4.2.2 and 4.2.3. We present here other more rare variations involving these branches. One pericallosal artery can give off a few or sometimes the majority of the branches also for the contralateral hemisphere. As described in Sect. 4.1, together with both pericallosal arteries, there is frequently a third branch arising from the AcomA. It can be small and short ending in the proximal part of the corpus callosum (*subcallosal artery*) (Fig. 4.8f), or be well developed and take over partially the vascular territories of the pericallosal arteries (*median artery of the corpus callosum, arteria pericallosa triplex*—Fig. 4.15). In other cases, the pericallosal artery can be unique (*azygos pericallosal artery*—Figs. 4.13 and 4.14).

Another variant is the presence of an anastomotic connections between the pericallosal arteries more frequently at the level of the genu of the corpus callosum (Yasargyl and Carter 1974; Perlmutter and Rhoton 1976). In all these cases,

there is an increased tendency to develop aneurysms at the AcomA or distally.

An extremely rare anomaly is the persistence of the primitive olfactory artery from which the ACA develops. In the case reported by Tsuji et al. (1995), the anomalous artery ran anteriorly in the frontobasal area, forming then a curve posteriorly to reach the corpus callosum. An associate aneurysm was present.

4.4 Vascular Territories

The vascular territories supplied by the perforating branches arising from A1 and AcomA have already been described. These branches are *end arteries*, without anastomoses to each other. Occlusion of these branches, which can occur in case of stroke or in treatment of aneurysms of this area, can lead to various clinical symptoms such dysarthria, contralateral limb clumsiness, abulia alternating to agitation due to involvement of the Heubner artery, and consequent infarct of the head of the nucleus caudatus and adjacent areas (Mendez et al. 1989; Caplan et al. 1990). Memory loss, agitation, and confabulatory state can develop in involvement of the perforators arising from AcomA, especially the subcallosal artery due to ischemia involving fornix and genu of corpus callosum (Gade 1982; Parkin et al. 1988; Mosimann et al. 2012, Rizek et al. 2013; Meila et al. 2015).

As far as it concerns the cortical branches, the orbitofrontal artery supplies the gyrus rectus, olfactory bulb and tract, and medial part of the orbital gyri. The frontopolar artery supplies the medial and partially lateral surface of the frontal lobe. The frontal, paracentral, and parietal arteries supply the medial surface of the hemisphere in the frontoparietal area. These arteries extend also to the cortex of the convexity for about 1.3 cm connecting with the distal branches of the MCA and sometimes with the PCA. Among these branches, the paracentral and partially the superior parietal and posterior frontal arteries are involved in the supply of the medial and superior part of the *primary motor and sensory cortex and of the supplementary area*. The parietal branches supply the area corresponding to the precuneus where they connect with the parieto-occipital branches of the PCA. Along its course the pericallosal artery gives off perforators for the fornix, septum pellucidum, and corpus callosum and branches also for the gyrus cinguli. The branches supplying the corpus callosum can directly penetrate this structure or after their origin from the pericallosal artery can have a course parallel to it before entering the corpus callosum (Perlmutter and Rhoton 1978; Kakou et al. 2000).

From the distal branches, running on the surface of the cortex, arise small arteries that supply the brain parenchyma. These arteries enter the parenchyma with a perpendicular course and can be subdivided into cortical, medullary, and corticomedullary arteries (De Reuck 1972). The first of these supply the cortex and end with horizontal branches in the various cellular layers. The medullary arteries supply the superficial (short medullary branches) and deep white matter (long medullary branches). The latter run towards the ventricular wall. The cortico-medullary arteries have aspects of both. These arteries are *end arteries* that means that there are no connections between these branches nor are there anastomoses with the perforating branches arising from A1 or AcomA (Lazorthes 1961; De Reuck 1972).

In their course, the medullary arteries are surrounded by a thin space (perimedullary spaces, Virchow-Robin spaces). It had been supposed that the perivascular space was continuous with the subarachnoid space. This, however, was not confirmed by electron microscopy performed by Hutchings and Weller (1986). These authors showed that the pia matter represents a clear barrier, separating the subarachnoid space from the subpial space and perivascular space. Neither the subarachnoid space nor the pia matter extends into the brain, accompanying the blood vessels as they run into the perivascular space.

Differently of that occurring in the vascular territory of the perforators, potential leptomeningeal (pial) anastomoses are present at the surface of the hemisphere between distal branches of the ACA, MCA, and PCA. Connections with the MCA can develop in the frontoparietal convexity and in the frontobasal region and with the PCA

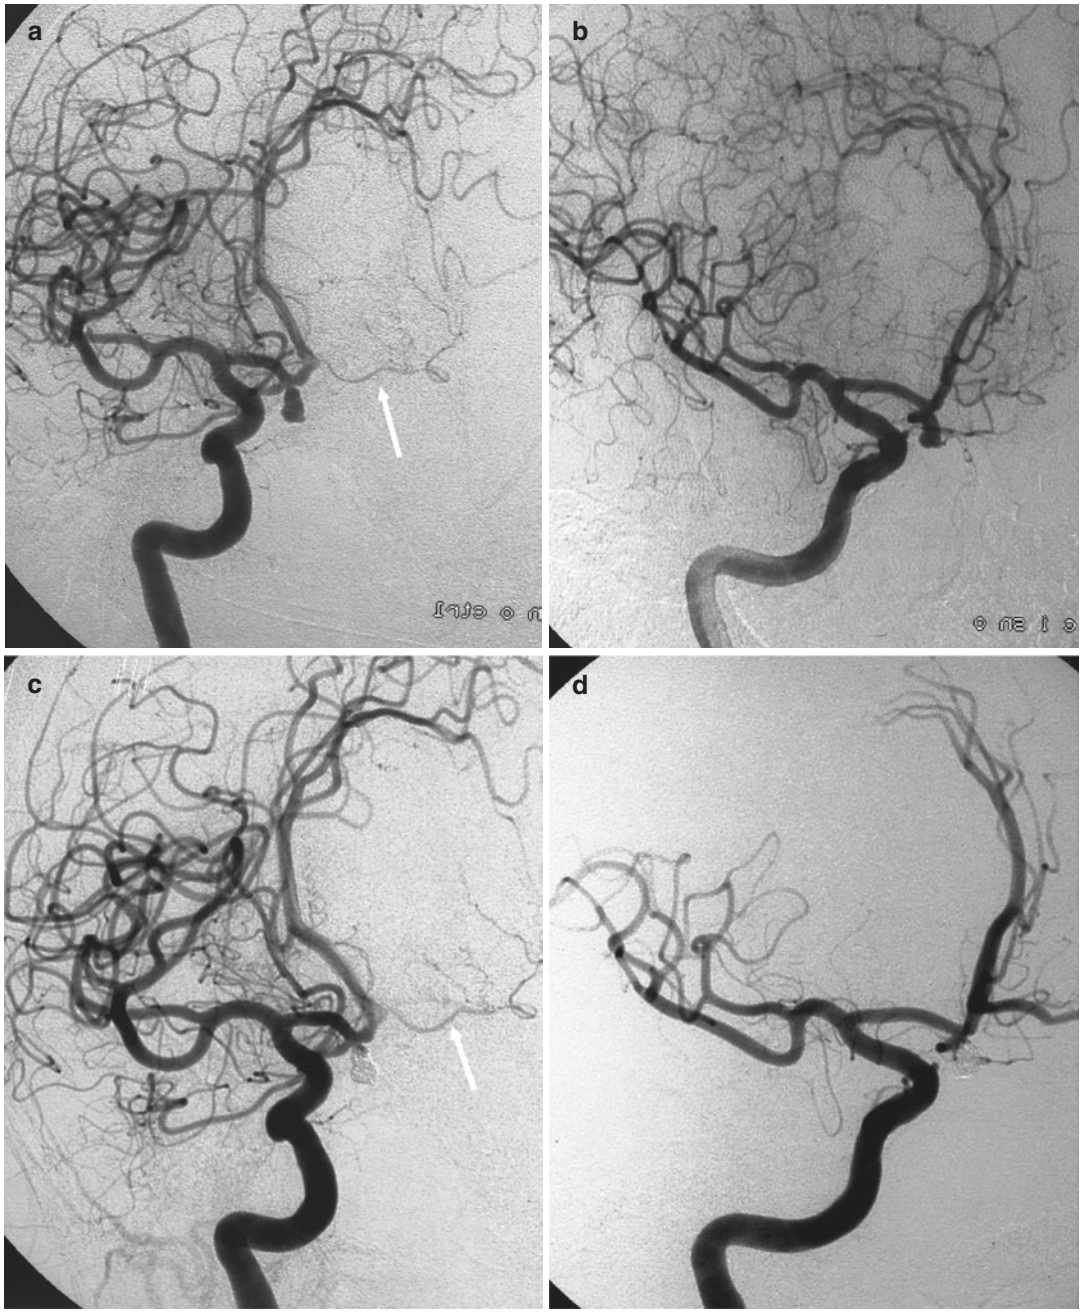

Fig. 4.13 Carotid angiogram with two oblique views (**a**, **b**) in a patient with ruptured aneurysm in the angle A1–A2 of the right anterior cerebral artery. The pericallosal artery is unique (azygos pericallosal artery). Left artery of Heubner (*white arrow*). (**c**, **d**) Control angiogram after occlusion of the aneurysm with coils. Note the Heubner artery (*white arrow*). Both A1 and Heubner artery are recognizable on the angiogram in (**d**)

on the medial surface and convexity of the occipital region. These anastomoses develop in the border regions of the vascular territory of each of the three major arteries. The location of these areas can change in relation to the variable extent of the vascular territory of the arteries (Van der Eecken 1954; Lazorthes 1961).

Anastomoses are also present between the posterior pericallosal artery of the ACA and splenial artery of the PCA.

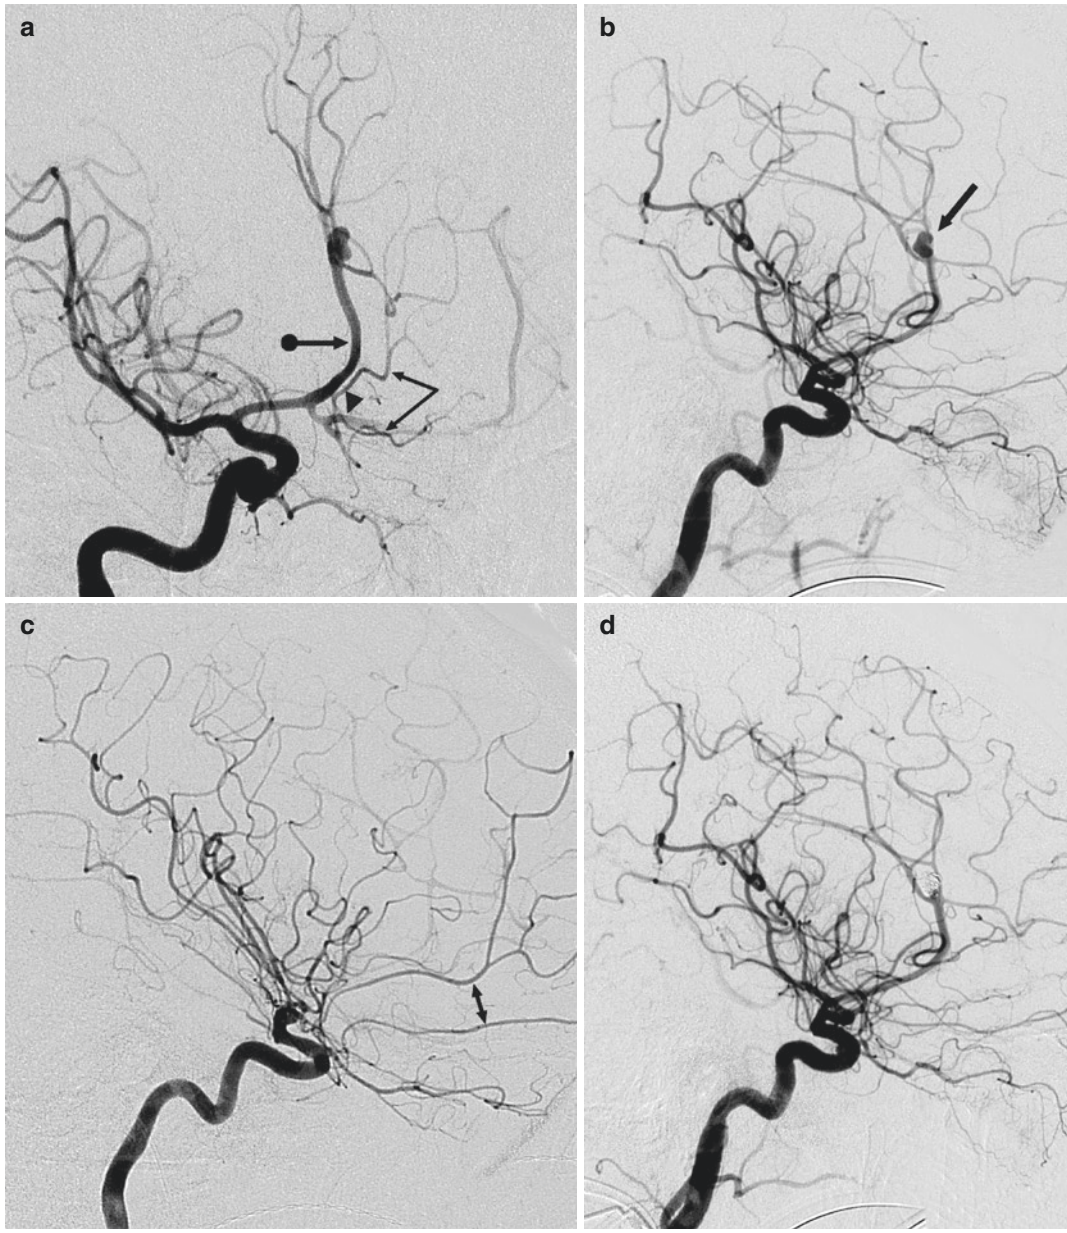

Fig. 4.14 Right carotid angiogram in patient with SAH. (**a**) Oblique view showing the aneurysm at the junction of the pericallosal–calloso-marginal arteries. The pericallosal artery (*arrow with dot*) is unique (azygos artery). It divides distally in branches for both hemispheres. Large right A1. Occlusion of the aneurysm. On the left angiogram (**c**) only the infraorbital and frontopolar branches (*bidirectional arrow*) are well injected

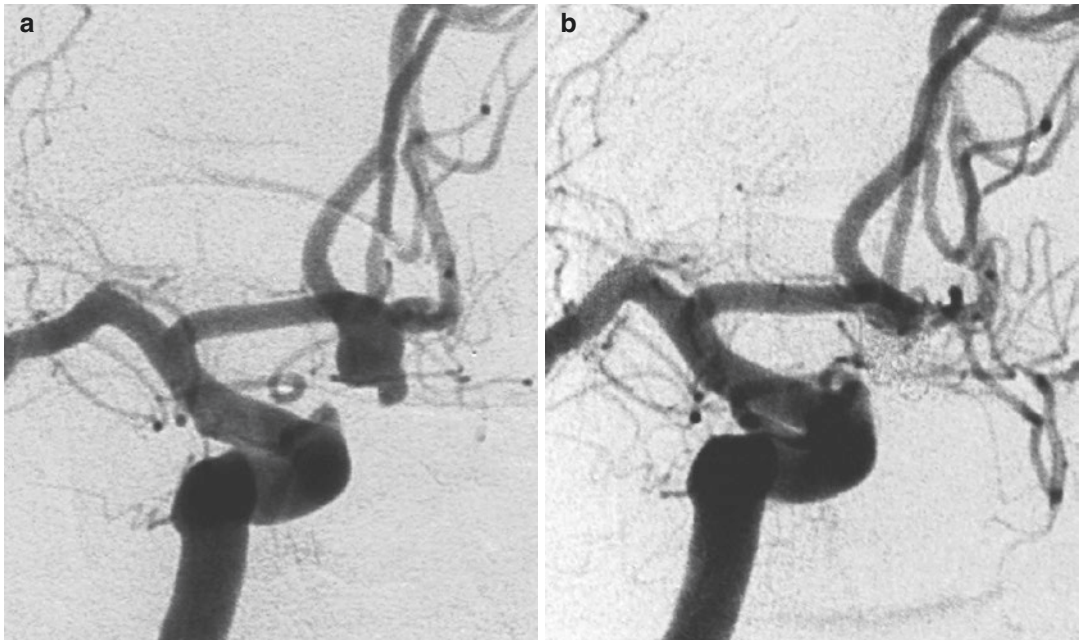

Fig. 4.15 Carotid angiogram (**a**) showing three pericallosal arteries in a patient with ruptured AcomA aneurysm treated with coils (**b**)

4.5 Angiogram

On the angiogram the A1 segment is well recognizable in the AP and oblique views (Figs. 4.3, 4.4, 4.5, 4.9, 4.10, 4.11, 4.13, and 4.15). The AcomA is not always precisely recognizable, even if its presence can be assumed when on the performed angiogram both ACAs are injected. It can be well identified in some cases (Figs. 4.3 and 4.5). In other cases, it can be more difficult to make a precise identification of the AcomA when anomalies are present (Fig. 4.11a–d). Among the perforators only the artery of Heubner can be clearly and frequently identified as a small branch running back to the A1 and proximal M1 with a straight or undulating course visible on the AP or oblique view (Figs. 4.3, 4.4, 4.5, 4.10, 4.11, 4.14, and 11.12). The demonstration of the artery on the angiogram, preceding the endovascular or surgical treatment of aneurysm of the AcomA as well as in surgery for other frontobasal pathologies, can be useful. The precise demonstration of other perforators is commonly more difficult. Sometimes a well-developed subcallosal artery can be recognizable on the lateral angiogram (Fig. 4.8f).

The pericallosal and the callosomarginal arteries can be discerned in the AP view. The course of these arteries as well as of their cortical branches, especially in the frontal area, may be more precisely demonstrated on the lateral angiogram. The variations in origin and course of these branches are great (Drawing 4.7 and Fig. 4.8). What is constant is the close relation of each branch with the vascular territory it supplies. Taking this into consideration we can try to identify the single branches starting from their distal end, which corresponds to its vascular territory, and follow their course retrogradely to their origin.

The angio-MR and angio-CT are other diagnostic possibilities, though the angiogram offers better specific information. Some relationship to the cerebral parenchyma (chiasma, diencephalon, and corpus callosum) can be readily identified with MR (Figs. 4.2 and 4.6).

Middle Cerebral Artery

5

The middle cerebral artery (MCA) arises in the embryogenesis as the latest branch from the cranial division of the ICA and develops to the largest artery supplying a large part of the cerebral hemispheres and basal ganglia. The development of the MCA correlates with the great extension of the cortical mantle in the mammal (Kier 1974). As visible in Drawings 5.1 and 5.2 the artery can be divided into four segments:

- M1 segment, running horizontally in the Sylvian fissure
- M2 segment, running vertically on the surface of the insula
- M3 segment, running laterally and exiting the insular cistern
- M4 segment, which comprises the distal cortical branches

5.1 M1 Segment

The first segment arises at the ICA distal bifurcation and runs horizontally and laterally in the Sylvian fissure below the anterior perforated substance (APS) towards the insula. Also called sphenoidal segment, because it runs parallel 1 cm posterior to the sphenoid ridge, the M1 ends at the anterior border of the *insula*, where it sharply turns superiorly and posteriorly to form the M2 segment. The M1 divides distally into two or three branches (bi-trifurcation). Its length varies, being on average of 16 mm in length (Umansky et al. 1985). It can be very short, and so the bi-trifurcation may be located near the bifurcation of the ICA. M1 gives off two types of important branches (Drawing in Fig. 5.2).

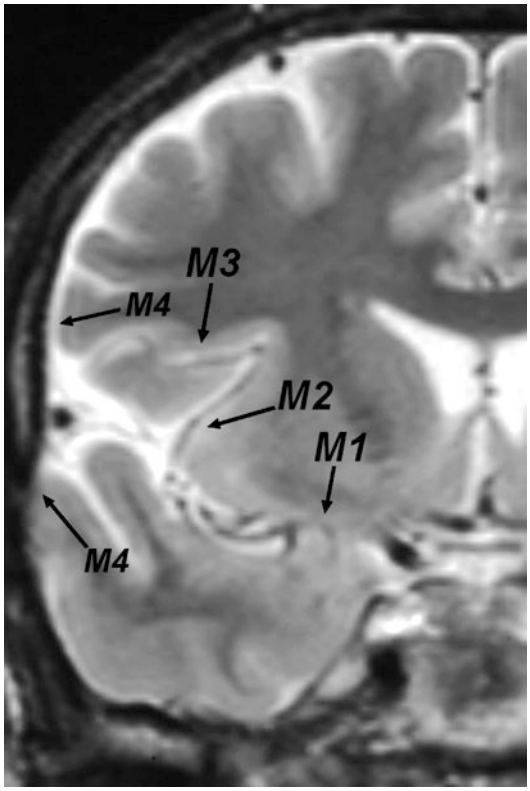

Fig. 5.1 Coronal MRI T2 weighted. The MCA runs first horizontally in the Sylvian cistern (M1), then on the surface of the insula (M2), further laterally (M3) exiting the insular cistern, and reaching the convexity (M4)

G.B. Bradac, *Applied Cerebral Angiography*, DOI 10.1007/978-3-319-57228-4_5

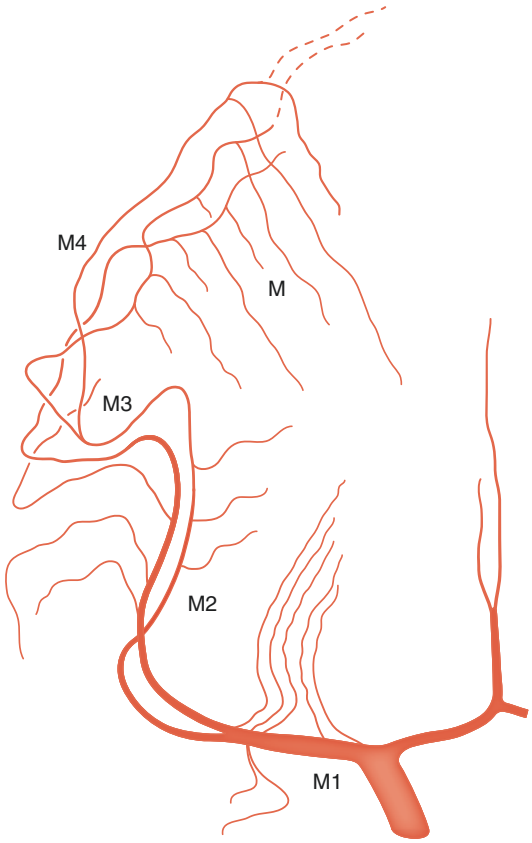

Fig. 5.2 Drawing showing the segments of the MCA on the AP view. M1, M2, M3, and M4. Deep perforators arising from M1. Medullary arteries (M, short and long branches) arising from the cortical branches. *Dashed lines* indicating anastomoses with ACA

Perforators. Since the first anatomical description of these perforating branches by Duret (1874), many detailed studies about these arteries have been performed. Also called the lenticulostriate arteries, these branches arise along the length of the M1 commonly from its superior surface. When the M1 is short, dividing early in its distal branches, the perforators commonly arise from the superior branch and sometimes from a branch of the M2 segment (Kaplan 1965; Westberg 1966; Lazorthes et al. 1976; Rosner et al. 1984; Umansky et al. 1985). The branches can be subdivided into medial, intermediate, and lateral groups. The medial is the group least constant and can be replaced by perforators arising from A1 (Rosner et al. 1984). In the microanatomical study of Umansky et al. (1985), the medial perforators of the MCA were replaced by perforators arising from the A1 segment or by the artery of Heubner in 26% of the cases. In the study of the same authors, perforators originate as a common trunk in about 50% of the cases.

The medial branches have a straight course, the intermediate a slightly tortuous course, and the lateral display the typical S-shaped aspect (Drawing 5.2 and Fig. 5.3). Perforators commonly enter the lateral part of the APS (Rosner et al. 1984; Rhoton 2002) and supply the superior part of the head of the nucleus caudatus and its body. They entirely supply the superior part of the internal capsule as well as the globus pallidus and putamen.

The different aspects concerning the M1 and the perforators should be carefully considered in the surgical or endovascular treatment of aneurysm located in the M1 segment, as well as in the endovascular treatment of occlusion-stenosis of this segment. Examples are presented in Figs. 5.3, 5.4, and 5.5.

Cortical branches: From the M1 segment arises frequently a branch for the pole of the temporal lobe and sometimes also an orbitofrontal branch for the pars orbitalis of the inferior frontal gyrus. In exceptional cases a temporal branch can arise from the ICA.

5.2 M2, M3, and M4 Segments

The M2 segment, also called the insular segment, is formed by the branches arising from the bitrifurcation of M1 which run on the surface of the insula. They curve then laterally forming the M3 segment directed towards the sylvian-insular cistern, extending finally to the surface of the cortex of the hemisphere forming the M4 segment. Considering their course and the area they supply, the cortical branches can be divided into *the*

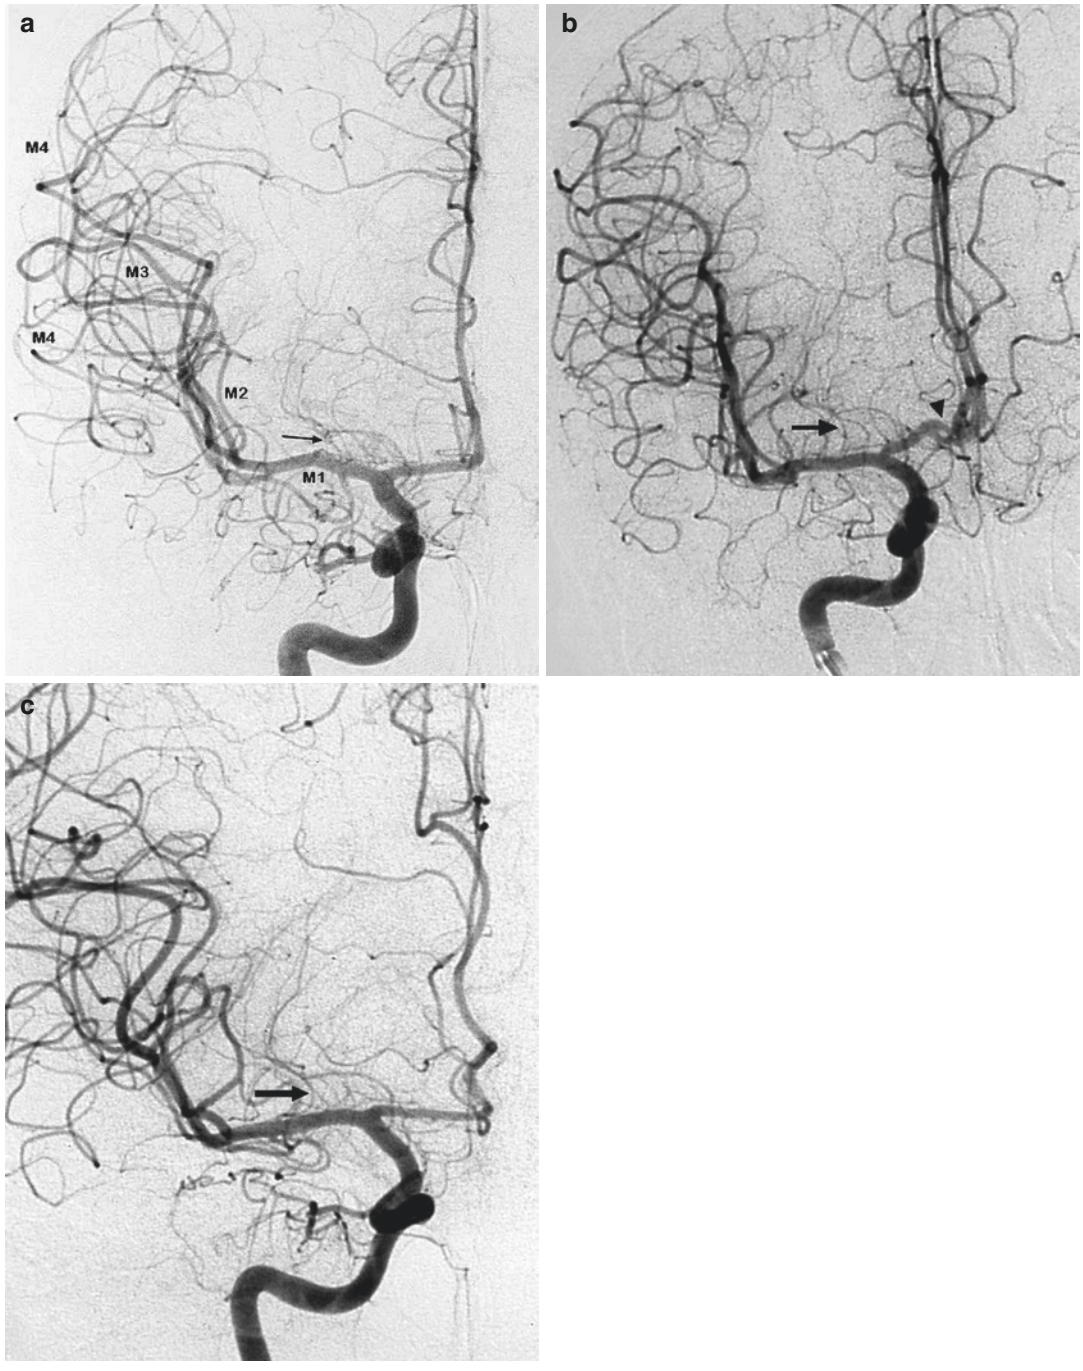

Fig. 5.3 AP carotid angiograms, in three different cases. In (**a**) the different segments (M1, M2, M3, M4) are indicated. In all three cases (**a**–**c**) the M1 segment is long. The deep perforators are well recognizable. The more distal perforators show the typical S shape (*arrow*). In (**a**) a temporal branch arising from the M1 is also recognizable. In (**b**) there is a fenestration of distal A1 (*arrowhead*)

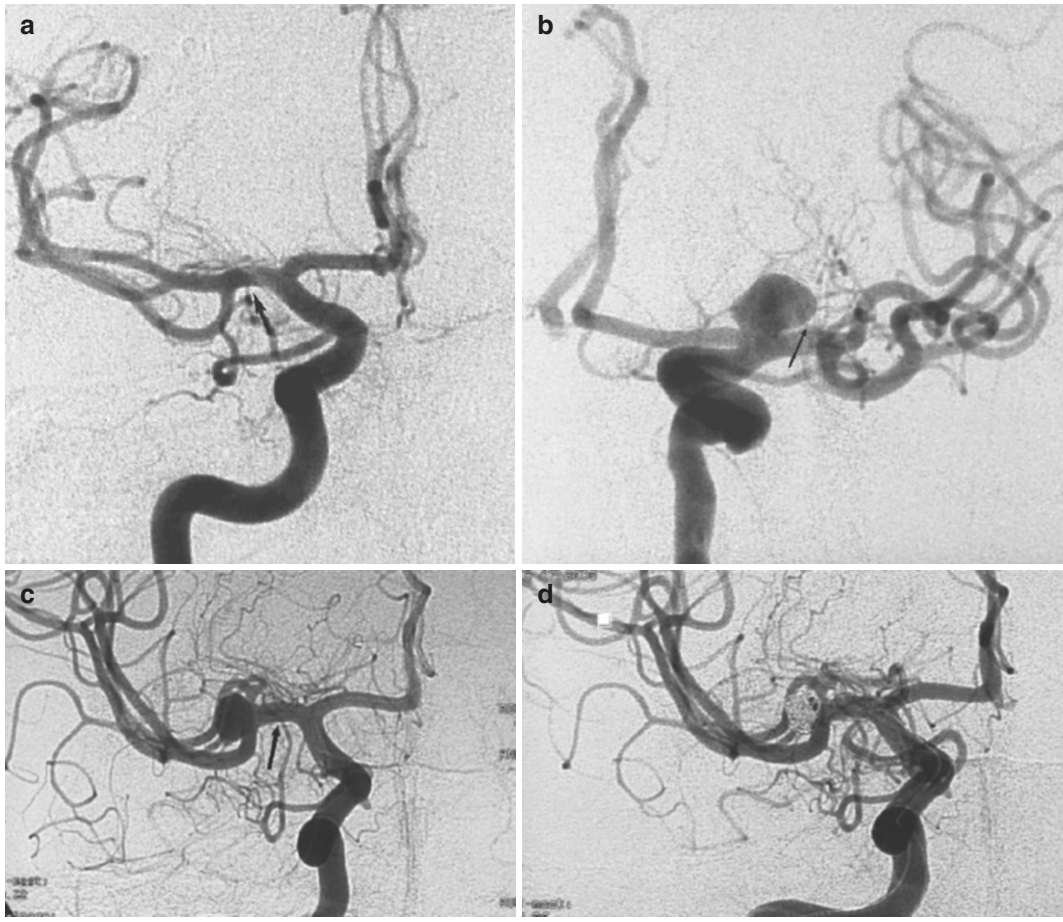

Fig. 5.4 AP carotid angiograms in three different cases. (**a**) Apparently very short M1 (*arrow*) owing to the early origin of a large temporal branch. The main trunk from which arise the perforators runs superiorly and bifurcates more distally. (**b**) Aneurysm with large neck at the carotid bifurcation. Owing to the short M1 the perforators (*arrow*) are close to the aneurysm. (**c**, **d**) The short M1 (*arrow*) gives off perforators that are close to the trifurcation from which arises an aneurysm presenting with SAH. Control angiogram after treatment with coils

orbitofrontal artery, ascending frontal arteries (operculo-frontal and central arteries), ascending parietal arteries (anterior and posterior), descending arteries (temporal branches), and terminal group (gyrus angularis artery) (Ring and Waddington 1967; Ring 1974; Huber 1979; Gibo et al. 1981b). Overlapping variations in course and origin make it difficult in a given case to identify precisely the arteries on the angiogram. On the basis of anatomical and angiographic studies, Michotey et al. (1974) and Salamon and Huang (1976) have *described two basic patterns that can be of some help in identifying the single artery* (Drawing 5.6a, b).

In cases of *bifurcation* of the M1 which is the most frequent pattern, two trunks are present: one anterosuperior and the other posteroinferior. The orbitofrontal, operculofrontal, and central arteries arise from the anterosuperior trunk. The remaining branches take their origin from the posteroinferior trunk. In cases of *trifurcation*, the orbitofrontal and operculofrontal arise from the anterosuperior trunk; the central, parietal, and gyrus angular arteries arise from a middle trunk, and the temporal branches arise from the posteroinferior trunk. Other variants characterized by a division of M1 in multiple trunks can also occur, but they are more rare

(Salamon and Huang 1976; Gibo et al. 1981b, Umansky et al. 1985).

The orbitofrontal artery is the first branch to leave the Sylvian-insular cistern. It is not constant and sometimes can originate directly from the M1 segment. It is directed anteriorly, with a slightly horizontal course, running frequently first in the sulcus separating the pars triangularis from the pars orbitalis of the inferior frontal gyrus and further extending towards its pars orbitalis. It is in balance with the infraorbital branch of the ACA.

The operculofrontal branch leaves the insular cistern and is directed first to the pars triangularis of the inferior frontal gyrus; in its ascending course, it divides further into three or more branches, which resemble a candelabrum. They supply the *Broca area* and the other frontal regions (prefrontal and premotor).

The central arteries. These, which are the most posterior ascending frontal branches, are formed commonly by two branches arising separately or as a common trunk, which run towards

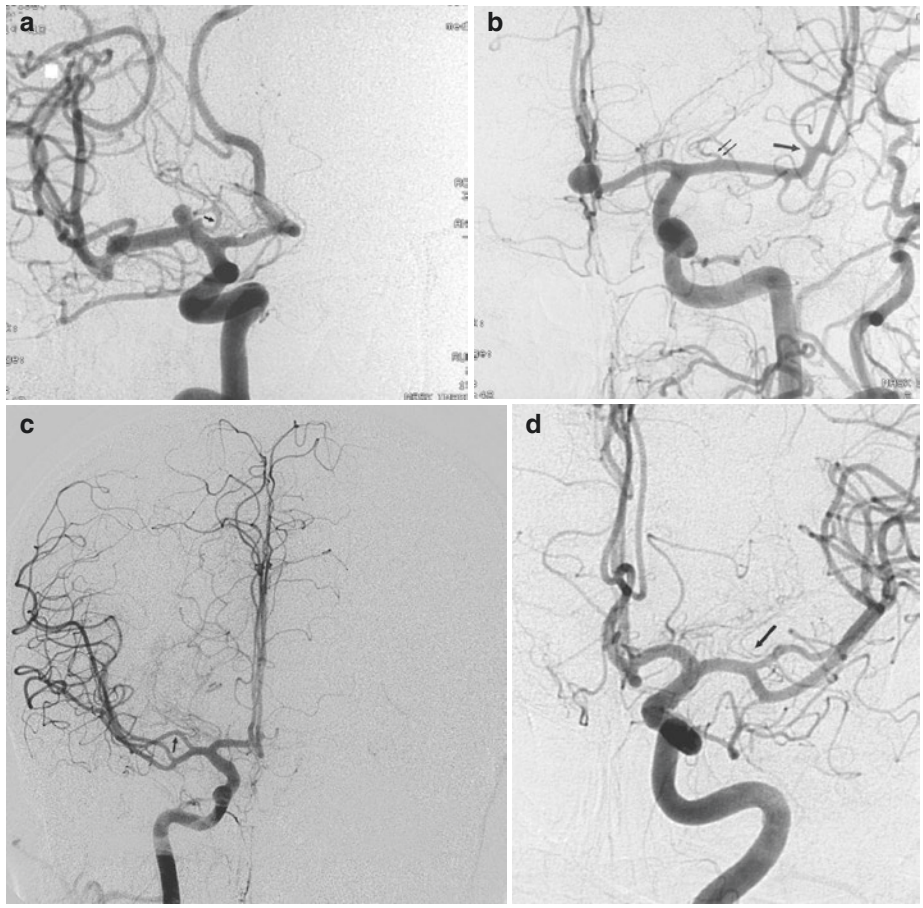

Fig. 5.5 Carotid angiograms in different cases. (**a**) Oblique view in a patient examined for an unruptured aneurysm with a neck on the M1 segment at the junction with a large perforator (*arrow*). This seems to be a large trunk from which all perforators arise. (**b**) AP view, in a patient examined for a ruptured aneurysm of the AcomA. There is a long M1 which trifurcates distally in the insular cistern (*arrow*). Some perforators arise from the proximal part of the long M1 and from the proximal part of A1. Other perforators seem to originate from the temporo-insular branch (*arrows*). (**c**) Example of a very short M1, which divides into a superior branch (*arrow*) from which arise the perforators, and into an inferior branch dividing further distally. (**d**) In this case the short M1 divides into superior and inferior branches. The perforators arise partially from M1 and partially from its superior branch (*arrow*). (**e**) Another patient with an incidental discovery of a middle cerebral aneurysm. Angiogram and detail magnification. The aneurysm is located at the bifurcation of a very short M1. The perforators arise from the superior branch of M1 (*white arrowhead*). At least one perforator seems to arise from the A1. Heubner artery (*black arrowheads*). AchA (*small black point*), hypoplastic PcomA (*two small black points*)

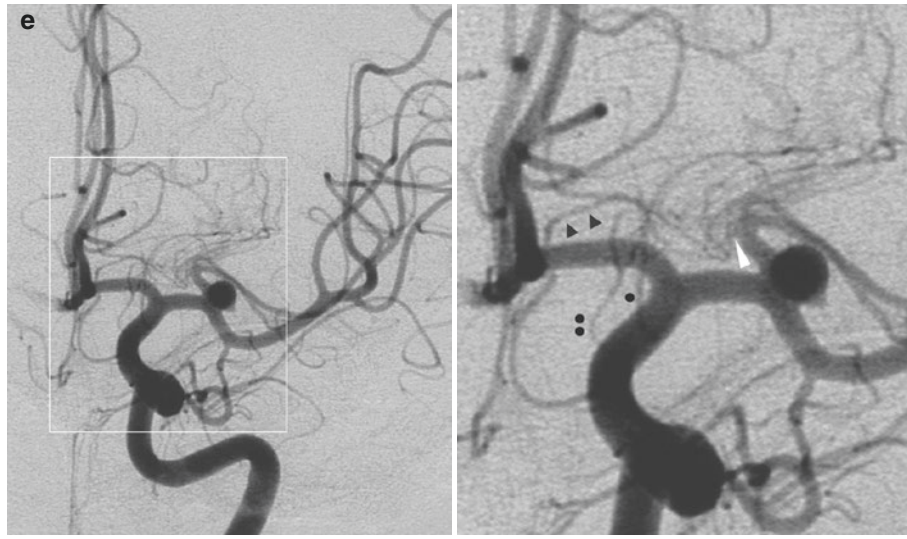

Fig. 5.5 (continued)

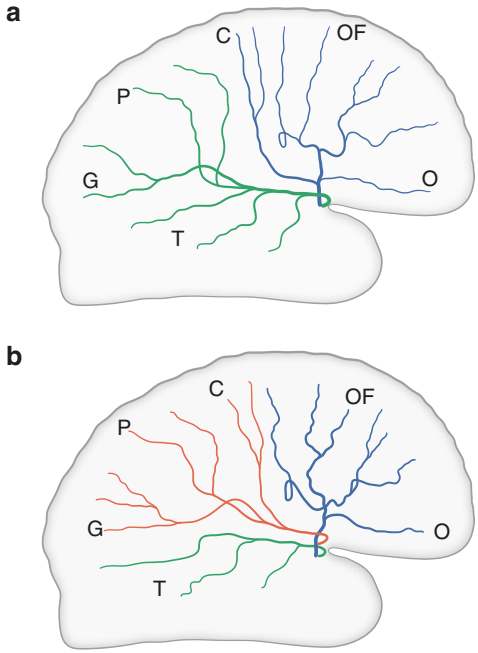

Fig. 5.6 Drawing showing the most frequent pattern of the distal branches of the MCA on a lateral projection (modified from Michotey; Salamon, and Huang). (**a**) In the bifurcation pattern, the orbitofrontal (O), operculofrontal (OF), and central arteries (C) arise from the anterosuperior trunk. The anterior and posterior parietal (P), gyrus angularis (G), and temporal (T) arteries arise from the inferoposterior trunk. (b) In the trifurcation pattern, the orbitofrontal (O) and operculofrontal (OF) arteries arise from the anterosuperior trunk. The central (C), anterior and posterior parietal (P), and gyrus angularis (G) arteries arise from the middle trunk and the temporal (T) branches from the inferoposterior trunk

the central fissure. They supply the precentral gyrus (*primary motor cortex*) and the postcentral gyrus (*primary sensory cortex*). These branches are frequently very fine and their identification on the angiogram can be difficult.

The parietal group consists of two arteries: the anterior parietal and posterior parietal arteries which frequently arise in the posterior part of the Sylvian fissure. The anterior branch is commonly very small, and difficult to be identified on the angiogram. It runs towards the postcentral sulcus and extends further to the parietal lobe. The posterior branch is commonly larger. Differently from the other ascending branches that run in the sulci, it has a superficial course towards the parietal lobe (Salamon and Houang 1976). It marks the borders between the parietal lobe and the posterior located supramarginal lobe. The posterior parietal branch has a less upward and more posteriorly directed course, in comparison to the other ascending branches. This pattern can help in identifying the artery on the lateral angiogram. This can also be useful, considering that the *central arteries* run in the adjacent area located anteriorly. In this context we report also the study of Christoforidis et al. (2002). These authors have suggested that the *central arteries* can be identified on the lateral carotid angiogram in an area projecting between the superior parietal and posterior frontal arteries, branches of the anterior cerebral artery (see Sect. 4.2.4).

The temporal group consists of several branches that emerge from the Sylvian fissure and take a descending course directed inferoposteriorly, supplying the temporal lobe. From their origin, they are termed *anterior*, *middle*, and *posterior*. The latter extends also to the lateral surface of the occipital lobe (temporo-occipital artery).

The angular artery, which is considered the terminal branch of the M4, is commonly that with the larger diameter according to the microsurgical anatomy study of some authors (Gibo et al. 1981). It emerges from the distal part of the Sylvian fissure and runs posteriorly towards the supramarginal and angular gyri. It plays an important role in the supply *of the Wernicke's area*. It is frequently identified on the lateral angiogram, since it forms an upward convex curve, as it turns around the Heschl's gyrus (Ring 1974; Huber 1979). It is not uncommon for the artery to extend with a few branches to the parietal and temporo-occipital areas, thereby replacing the corresponding arteries.

Examples of course of the cortical branches are presented in Figs. 5.6, 5.7, 5.8, 5.9, and 5.10.

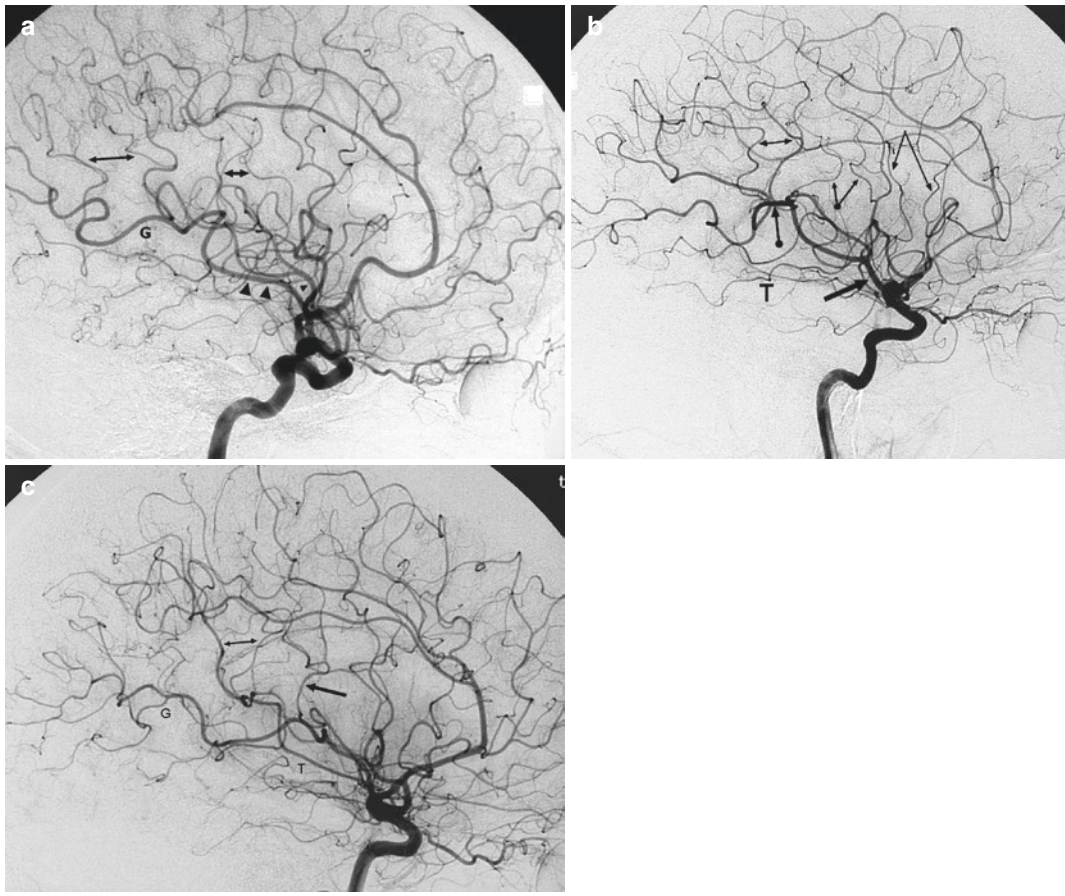

Fig. 5.7 (**a**) Lateral carotid angiogram. From a superior located trunk (*arrowhead*) arise the operculofrontal arteries and two small branches (*big bidirectional arrow*) which run towards the central area. From a large posterior trunk (*arrowheads*) arise a well-developed gyrus angularis artery (G) and two small parietal branches (*smaller bidirectional arrow*). (**b**) Lateral carotid angiogram. Operculofrontal arteries (*arrows with angle*). Common posterior trunk (*large black arrow*) for gyrus angularis, parietal, and temporal arteries. Small parietal branches (*bidirectional arrow*). Anteriorly to these, there are very fine arteries (*arrow with angle and dot*) running towards the central area. Typical curve of gyrus angularis artery (*arrow with dot*). The well-developed gyrus angularis artery gives off a large branch for the parietal area. Small temporal branches (T). (**c**) The parietal (*bidirectional arrow*), the gyrus angular (G), and the temporal (T) arteries seem to arise from a common trunk. It seems that arising also from the same common trunk, running anteriorly to the parietal arteries, there are small branches (*arrow*) directed towards the central area

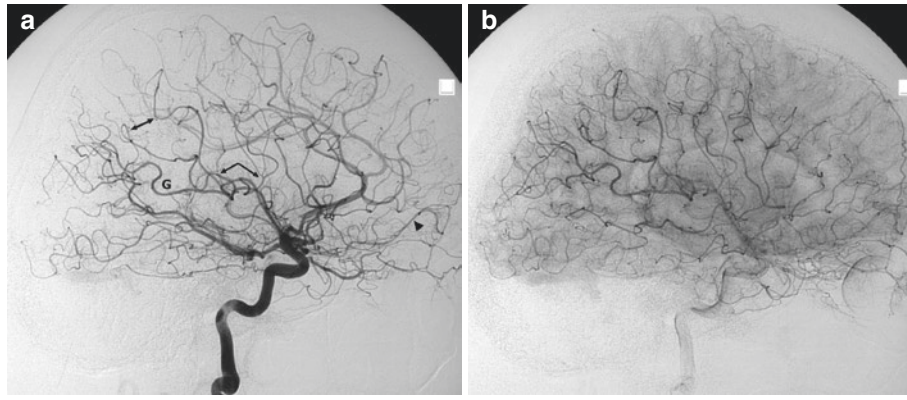

Fig. 5.8 Early and late phases of a lateral carotid angiogram. From a posterior trunk arise the gyrus angularis (G), the parietal branches (*bidirectional arrow*), and the small temporal branches. The anterior parietal branch is particularly well developed. Anteriorly to the parietal arteries there are small branches (*arrow with angle*), running towards the central area. Well-developed orbitofrontal artery (*arrowhead*). There is a fetal posterior cerebral artery

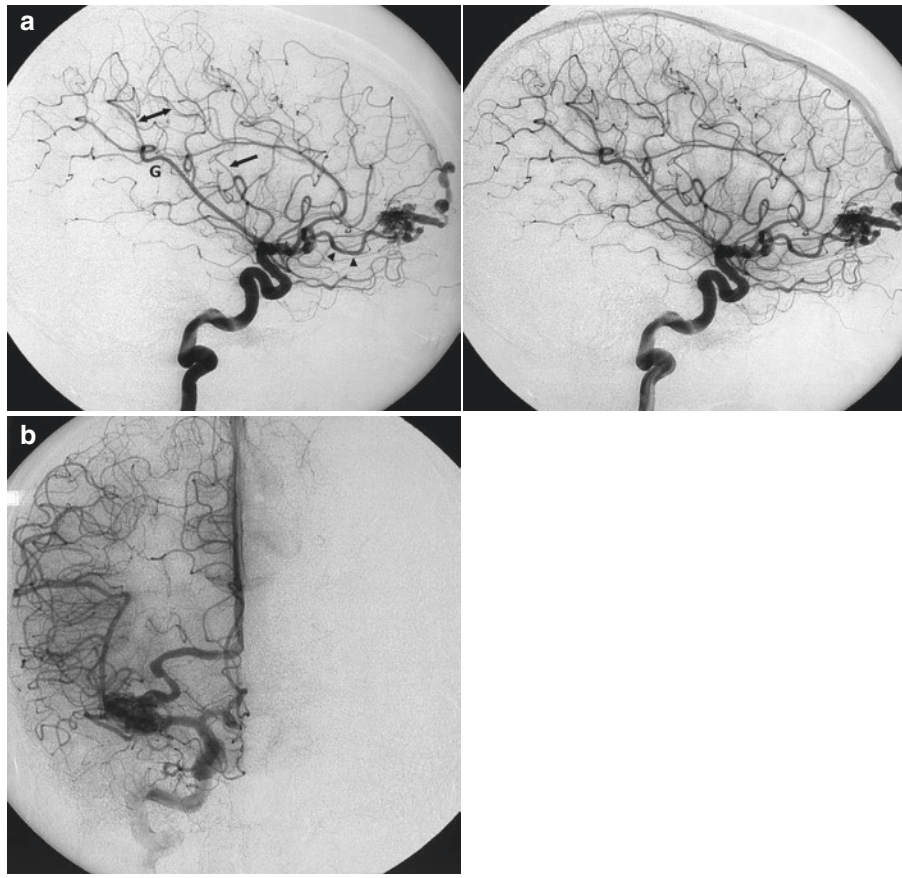

Fig. 5.9 (**a**) Early and later phases of lateral carotid angiogram in a patient with frontobasal AVM supplied by a dilated orbitofrontal artery (*two arrowheads*), draining in the SSS through a single fronto-orbital vein. There is a large posterior trunk continuing in the gyrus angularis artery (G), which gives off also parietal branches (*bidirectional arrow*). Anteriorly from the large trunk arises an artery (*arrow*) which divides distally into two branches directed to the central area. (**b**) Same case, AP view, showing better the supply of the AVM from the branch of the MCA and the unique venous drainage towards the SSS

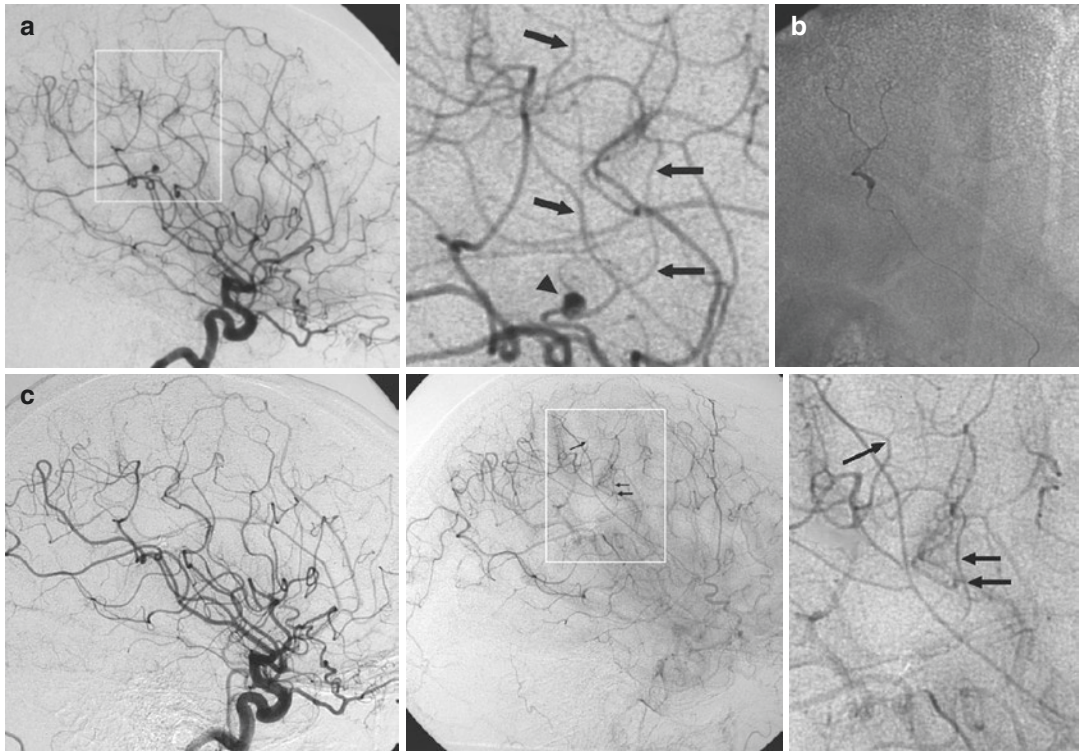

Fig. 5.10 Carotid angiogram in a patient presenting with SAH. (**a**) Lateral ICA angiogram (normal and magnification images), showing a very small probably dissecting aneurysm (*arrowhead*). The aneurysm involves a branch of the MCA which divides distally into two branches (*arrows*), corresponding probably to the central arteries. (**b**) The decision was taken to occlude the aneurysm and the parent artery. Selective study preceding the injection of glue. (**c**) Angiogram posttreatment with magnification showing the retrograde injection of the occluded branches (*arrows*) through opening of leptomeningeal anastomoses with ACA. There is the overlapping of the middle meningeal artery arising from the ophthalmic artery. The patient recovered well without any neurological deficit

5.3 Anatomical Variations

Some variants concerning the M1 segment and perforators have already been described.

Other rare variants are the isolated origin of the temporal branch from the ICA and *fenestration* and *duplication* of the M1 segment. In case of fenestration the vessel is unique, but it is divided into two lumens (Fig. 5.11). The duplication is characterized by the presence of two arteries arising from the distal ICA (Fig. 5.12). This should be differentiated from the condition called *accessory MCA* (*AMCA*), term coined by Crompton (1962). Also in these cases two arteries are present but one arises from the ICA and the other from the ACA. Considering that the MCA arises from several twigs originating from the distal cranial division of ICA and partially from the primitive ACA, the persistence of one twig arising from the ACA could explain this anomaly. Some authors (Handa et al. 1970a, b) proposed that the AMCA represents a large recurrent artery of Heubner. But this is no longer accepted by the majority of the authors (Huber 1979; Gibo et al. 1981b; Umansky et al. 1988; Takahashi et al. 1989; Müller et al. 1991; Tacconi

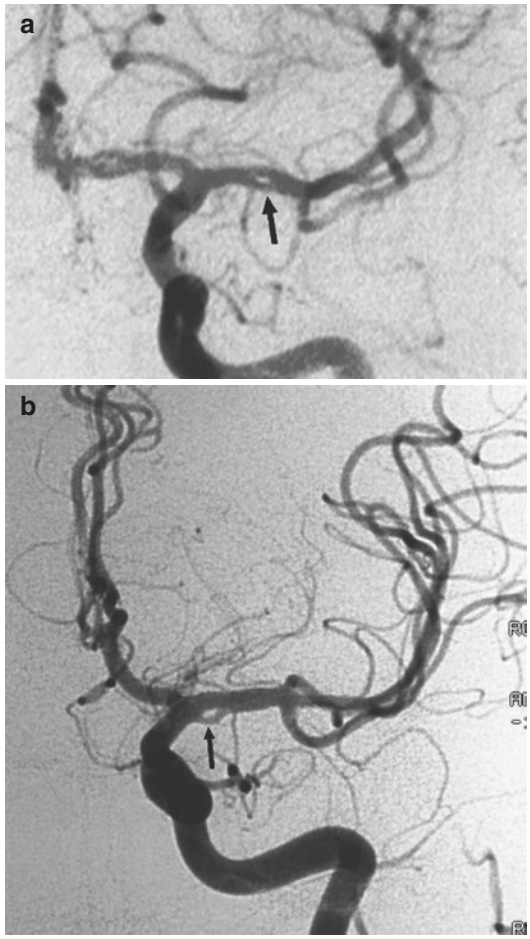

Fig. 5.11 Two examples of fenestration (**a**, **b**) of the M1 (*arrow*). On the angiogram in (**a**) there is also a fenestration of the A1

et al. 1995) since in all the cases studied the AMCA gave off perforators and cortical branches, while the recurrent artery of Heubner ends as a perforator branch. It should be mentioned that in one of the cases reported by Umansky et al. (1988) the Heubner artery originated from the AMCA. The AMCA diagnosed in our angiographic material could arise from the distal or more proximal A1. Examples are demonstrated in Figs. 5.13 and 5.14.

Cases of aplasia of the middle cerebral artery have been reported. This is a very rare condition frequently associated with aneurysm of the ACA (Nakazawa et al. 1985; Han et al. 1993; Amagasaki et al. 1998).

Fig. 5.12 There are two equally well-developed branches of the MCA arising from the internal carotid artery (duplication of the MCA). The perforators arise from the superior branch. Small aneurysm of the AcomA

Fig. 5.13 Incidental discovery of an accessory middle cerebral artery in a patient with aneurysm of the MCA. Parallel to the large M1, there is another smaller branch (*arrowheads*) arising from the proximal anterior cerebral artery, running above the main trunk of M1. The majority of the perforators arise from the main trunk close to the trifurcation. At least one perforator seems to originate from the accessory middle cerebral artery (*arrow*)

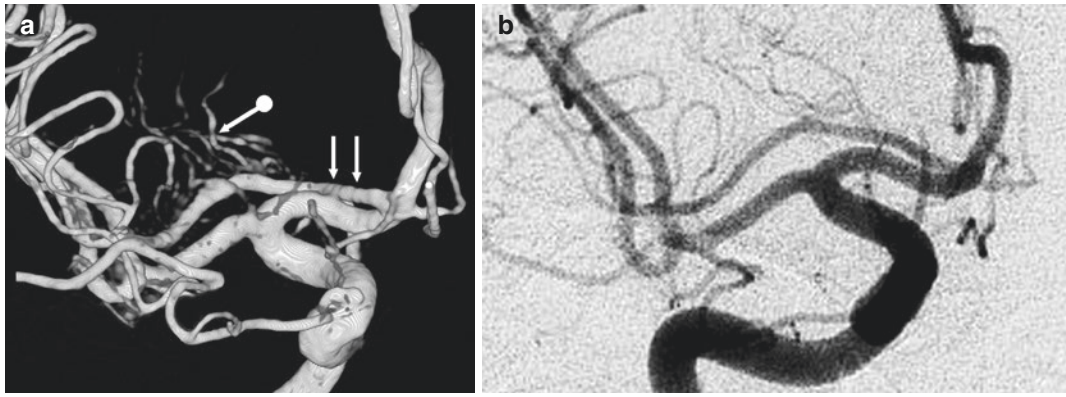

Fig. 5.14 Another example of an accessory middle cerebral artery arising in the distal segment of the A1. (**a**) On the 3D CT angiography the accessory branch (*arrow*) is well recognizable. It gives off the perforators (*arrow with dot*). (**b**) More detailed study on the ICA angiogram

5.4 Vascular Territories

The MCA supplies largely the lateral portion of the frontoparietal and occipital lobes. The distal cortical branches of MCA, however, do not reach the superior margin of the hemispheres. Therefore, there is an area in the paramedian convexity to a variable extent which is not supplied by the MCA but by branches of the ACA and PCA. Further, the MCA supplies the temporal pole, the latero-basal and lateral part of the temporal lobe, and the latero-basal part of the frontal lobe.

The vascular territories of the deep perforators have already been described. These arteries are *end-arteries*; that is, there is no anastomosis between the single branches and no connections with the medullary arteries. This is probably true in the majority of the cases. In a few cases, however, anastomotic connections between perforators of the MCA and the artery of Heubner have been demonstrated (Umansky et al. 1985). We could identify on the angiogram a possible anastomosis occurring between the artery of Heubner and a perforator of the M1 (Fig. 5.15). In another angiographic study a clear connection between the perforators of M1 was recognizable (Fig. 17.7). Other authors (Kodama and Suzuki 1974) have shown in microangiographic studies the existence of a few anastomoses between deep perforators and the medullary arteries.

From the branches running on the surface of the cortex arise branches entering the brain parenchyma having the same angio-architecture already described in Sect. 4.4. Short branches (cortical) supply the cortex, and others supply the white matter (medullary arteries). These latter run in the perimedullary space, some arresting in the superficial part of the white matter (short branches), and others extending to the deep part (long branches) converging towards the periventricular area and basal ganglia. All these branches are *end arteries.*

From the insular branches also arise medullary arteries which supply the subinsular area without, however, anastomosing with the deep perforators supplying the basal ganglia.

Conversely there is a potential collateral leptomeningeal circulation between the superficial distal branches of the MCA and ACA at the convexity in the frontoparietal and the PCA at the occipital convexity. Connections can develop on the temporo-occipital convexity between the MCA and PCA and between MCA and ACA in the frontobasal area. As already described in Sect. 4.4, considering that the vascular territory of the arteries can have a variable extent, the area of the connection (border area) can have a different location.

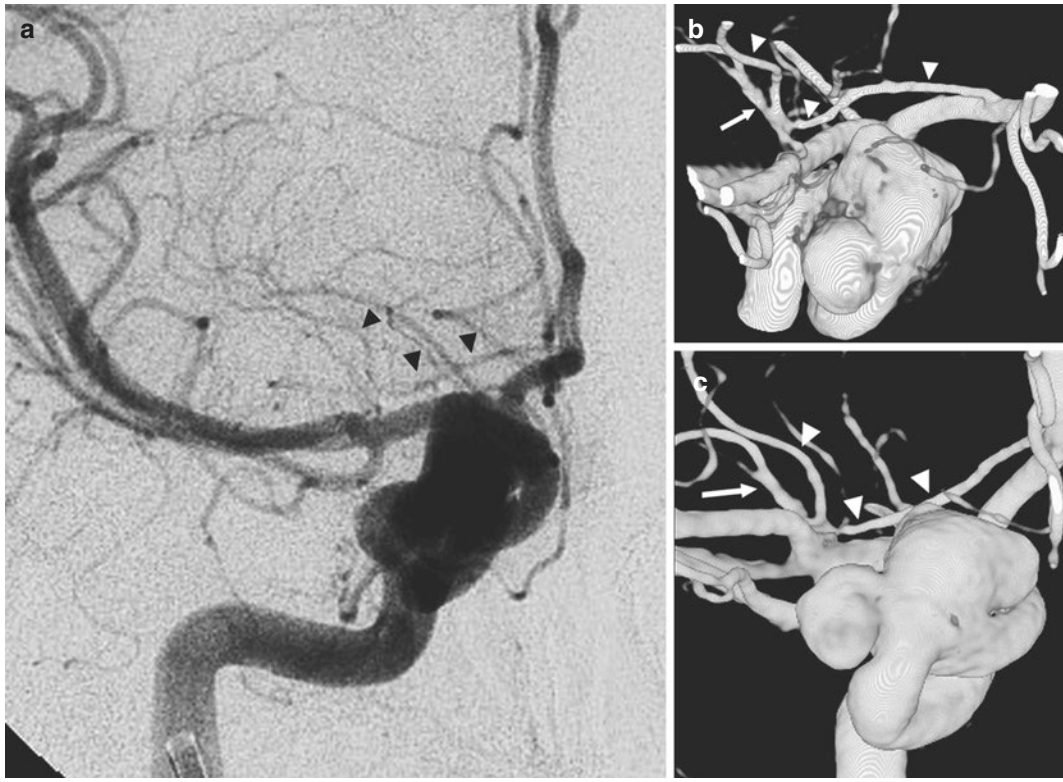

Fig. 5.15 (**a**) AP angiogram in a patient studied for a large aneurysm of the distal ICA. The Heubner artery (*arrowheads*) is well defined. (**b**) 3D angiographic study. The Heubner artery (*arrowhead*) seems to have a connection with a perforator of the M1 (*arrow*). (**c**) In another projection, the connection seems to be confirmed. Heubner artery (*arrowhead*). Perforator of M1 (*arrow*)

5.5 Angiogram

The M1 segment and the perforators are always well recognizable on the AP view. The length of the segment can vary, as already described, and this influences the origin of the perforators (Figs. 5.3, 5.4, and 5.5). On the AP view the M1 segment commonly has a horizontal course; in children it is more frequently directed upward (Harwood-Nash 1974); in older patients it can be very tortuous.

Some typical features of the M2 and M3 segments are recognizable on the AP and lateral angiograms. On the AP view the M2 branches have an ascending course directed towards the top of the insula where they form a loop. The highest and most medial loop corresponds commonly to the most distal branches (parietal and angular arteries). This is also called the *Sylvian point* (Chase and Taveras 1963; Huber 1979; Osborn 1999). The arteries run further laterally (M3 segments), and leave the insular cistern, reaching the convexity of the hemisphere. On the lateral angiogram the loops can sometimes be well recognizable. They are located on an ideal horizontal line marking the superior border of the insula. The most posteriorly located loop corresponds to the Sylvian point.

The arteries of the M4 segment are better demonstrated on the lateral angiogram (Drawing 5.6 and Figs. 5.7, 5.8, 5.9, and 5.10). Due to their great variations of origin and course and overlapping, a certain identification of the single artery can often be very difficult. Some morphologic features have already been described in Sect. 5.2: these can be helpful in identifying the arteries. Furthermore, as has been described for the distal branches of the ACA (Sect. 4.5), there is a great constancy for each artery or group of arteries, independently of the origin, to take, in their distal segment, a course towards the territory they supply. Taking this into consideration, from the practical point of view it is helpful for identifying the artery and their branches to define first, on the lateral angiogram, even if approximately, the vascular territory inside of which run the supplying vessels. The course of the identified artery can be retrogradely followed to the origin examining the early and late phases of the angiogram.

Extra- and Intracranial Vertebrobasilar Sector

6

6.1 Extracranial Sector

The vertebral artery (VA) originates bilaterally from the subclavian artery. It runs posterosuperiorly behind the anterior scalene muscle commonly reaching the foramen of the transverse process of the sixth cervical vertebra. This first segment of the VA has been called V1. The VA runs, further, vertically (V2 segment) through the foramina of the transverse processes from C6 to C2, surrounded by the venous plexus. The spinal nerves lie behind. Between the foramina of C2 and C1, the artery curves laterally and somewhat anteriorly. Exiting from C1 begins the V3 segment, which curves backward, running in the sulcus of the posterior arch of C1. The artery forms then a second upward and forward curve and reaches the foramen magnum, where it penetrates the dura forming the last segment (V4). It is conceivable that these curves protect the VA, allowing it to accommodate more easily movements in the atlanto-occipital region (Fig. 6.1).

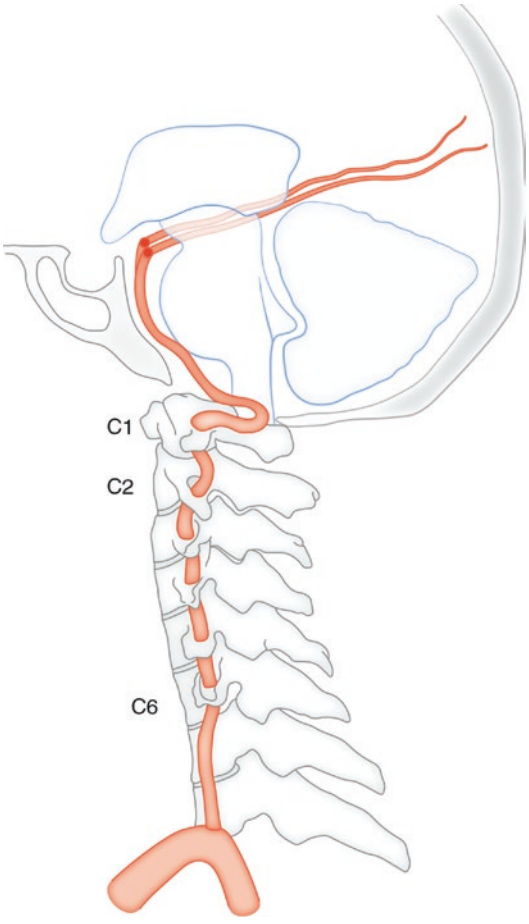

Fig. 6.1 Drawing showing the course of the vertebral artery arising from the subclavian artery and entering the intracranial cavity at the foramen magnum

6.1.1 Branches

In its extracranial course the VA gives off several branches.

- *Cutaneous-muscular branches*. These branches have potential anastomoses with branches of ECA and cervical arteries. The most frequent

G.B. Bradac, *Applied Cerebral Angiography*, DOI 10.1007/978-3-319-57228-4_6

well developed and recognizable on the angiogram are the anastomosis at the C1 and C2 levels with branches arising from the ascending and horizontal segment of the occipital artery and with the deep cervical artery. Other possible anastomoses are that with the AphA and the ascending cervical arteries at the C3–C4 levels. They can be recognized in normal angiograms (see also Sects. 3.4, 3.5 and 3.9) or in cases of occlusions of the VA or ECA, where they act as a collateral circulation towards the occluded sector or will be involved in several pathologies, in particular in DAVF and vascular malformations of the head and neck. Examples are shown in Figs. 3.7b–d, 3.16, 6.2b, 6.8a, 6.9a, 15.29, and 15.33.

- *Spinal branches* include those for the dura and bone structures, and radicular branches supplying the nerves. After supplying the nerves, a few radicular branches (radiculomedullary arteries) reach the spinal cord, continuing in the anterior spinal artery (ASA) and posterior spinal artery (PSA). It is not the aim of this book to treat the vascularization of the spinal cord, for which we refer to a specific work (Thron 1988). We recall only some basic aspects. Three longitudinal axes are involved: the one *is the anterior spinal artery* which runs on the median anterior sulcus of the spinal cord, from which arise the sulcal arteries giving off the perforators supplying a great part of the grey matter (anterior horns and part of the posterior horns) and the anterior part of the white matter. *The other two are the posterior spinal arteries* running on the posterolateral surface of the spinal cord. These are more irregular, sometimes discontinuous, mainly involved in the formation of a superficial reticular pial network from which arise perforators for the dorsal part of the posterior horns and for the dorsal and lateral white matter. The dorsal network is interconnected with its anterior part arising from the anterior axis. The ASA is well recognizable on the angiogram of the VAs and sometimes of the ascending cervical arteries arising from a radiculomedullary artery commonly at the C4–C6 levels. Its ascending and descending segments, anastomosing, respectively, cranially with the descending ASA arising from the intracranial VA and caudally with the ascending segment arising from the radiculomedullary artery of the intercostal artery are well shown (Figs. 6.2a and 16.9). The PSA is commonly not recognizable on angiogram in normal conditions.
- *Meningeal branches* of the distal extracranial VA: Two types of arteries can be present and be recognizable on the angiogram. The one is the meningeal artery running in the anterior part of the spinal canal, and the other runs posteriorly in the posterior fossa. The artery present in the spinal canal has been first described by Greitz and Lauren (1968) and called *anterior meningeal artery*. Further study (Lasjaunias et al. 1978a) has demonstrated that this artery is a radiculomeningeal branch arising from the VA at the level of the third vertebral body that runs cranially in the anterolateral part of the spinal canal and anastomoses with the contralateral branch at the level of the dorsal surface of the odontoid process. The anterior meningeal artery is connected further with the hypoglossal artery, which is a branch of the ascending pharyngeal artery, which enters the spinal canal through the hypoglossal foramen. These connections form the so-called odontoid arch. On the vertebral angiogram the artery is visible as a fine branch located anterior and lateral to the ASA (Drawing 3.33, Figs. 3.7c, 6.2b, c, 15.33, and 15.37; see also Sect. 3.4). The posterior group is represented by the falx cerebelli and posterior meningeal arteries, which originate from the extracranial VA, sometimes from its intracranial segment. They may also take their origin from the posterior inferior cerebellar, from the occipital or AphA arteries. There is a balance among these arteries, and so one can predominate in supplying the dura of the posterior fossa. *The falx cerebelli artery* (*FCA*) runs close to the falx and continues in the meningeal branch along the

Fig. 6.2 (**a**) AP right vertebral angiogram. Radiculomedullary artery (*arrowhead*) continuing in the ascending and descending segments (*arrows*) of the anterior spinal artery. Radiculomeningeal branch of the VA (*arrowhead*) anastomosing with the hypoglossal branch of the AphA (*arrow with dot*). Posteriorly runs the anterior spinal artery (*double small arrows*). Musculocutaneous branches at the C1–C2 levels, presenting possible anastomoses with the occipital and cervical arteries. (**c**) VA angiogram. Another example of a connection between the hypoglossal branch of the AphA (*arrow with dot*) and radiculomeningeal branch of the VA (*arrows*)

straight sinus. It anastomoses superiorly with the paramedian branches of the middle meningeal artery (see Sect. 3.7.1.1). On the lateral angiogram, the FCA runs slightly away from the inner table of the skull, and it is near the midline on the AP view (Figs. 6.3, 13.12, 13.16, and 15.37). *The posterior meningeal artery* runs on the dura covering the cerebellar hemispheres, so it has a more lateral course on the AP; it runs close to the inner table of the skull on the lateral angiogram (Figs. 13.1 and 15.35).

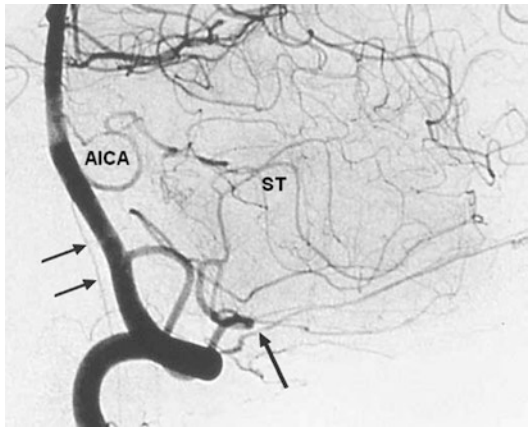

Fig. 6.3 Vertebral angiogram. Lateral view. Falx cerebellar artery (*arrow*). ASA (*double arrow*). Very tortuous segment of the first segments of PICA. Typical pattern of its supratonsillar segment (ST). AICA

6.2 Intracranial Sector

At the level of the foramen magnum, the VA penetrates the dura, where it is sometimes identifiable on the angiogram owing to a small change in its caliber. The artery runs in the subarachnoid space ventrolateral to the medulla oblongata and joins the contralateral artery at the bulbopontine junction to form the basilar artery (BA). The BA runs on the ventral surface of the pons in the median-paramedian position; it sometimes adopts a tortuous course displaying a lateral extension towards the cerebellopontine angle (Fig. 6.4). In the interpeduncular fossa under the floor of the third ventricle, the BA divides into the two posterior cerebral arteries (PCAs). The point of the division can be more caudally located, causing a cranial course of the proximal segments of the PCAs (Fig. 7.8c). The basilar artery may be elongated, especially in hypertensive and atherosclerotic patients, bulging in the floor of the third ventricle. In such cases, the PCAs have first a caudally directed course before they encircle the midbrain. Many arteries arise from the intracranial sector of the vertebrobasilar system (Drawing 6.5a–c). In this chapter the branches of the medulla and pons are described . The branches supplying midbrain, thalamus, and the temporo-occipital area are treated in Chap. 7.

Fig. 6.4 Tortuous basilar artery, probably due to atherosclerosis extending into the cerebellopontine angle, causing facial spasm

6.2.1 Intracranial Branches of the VA

6.2.1.1 Perforators of the VA

Small arteries arise from the posterior surface of the VA (Duvernoy 1999), running on the anterior surface of the medulla (anterior branches), especially in its superior part. Other branches of the VA extend to the lateral surface of the medulla (lateral branches) especially to its inferior and middle portion. Anastomoses, irregular in number, are present between these superficial vessels and branches of the PICA and BA typically on the surface of the olive (see also Sects. 6.2.1.2 and 6.2.2.2). From the superficial arteries arise perforators, which penetrate the medulla supplying it. These branches are not recognizable on the angiogram.

The perforating branches are basically "end arteries" without possibility of a collateral circulation. This is a common feature for all perforators supplying the brainstem which are progressively described in the next chapters.

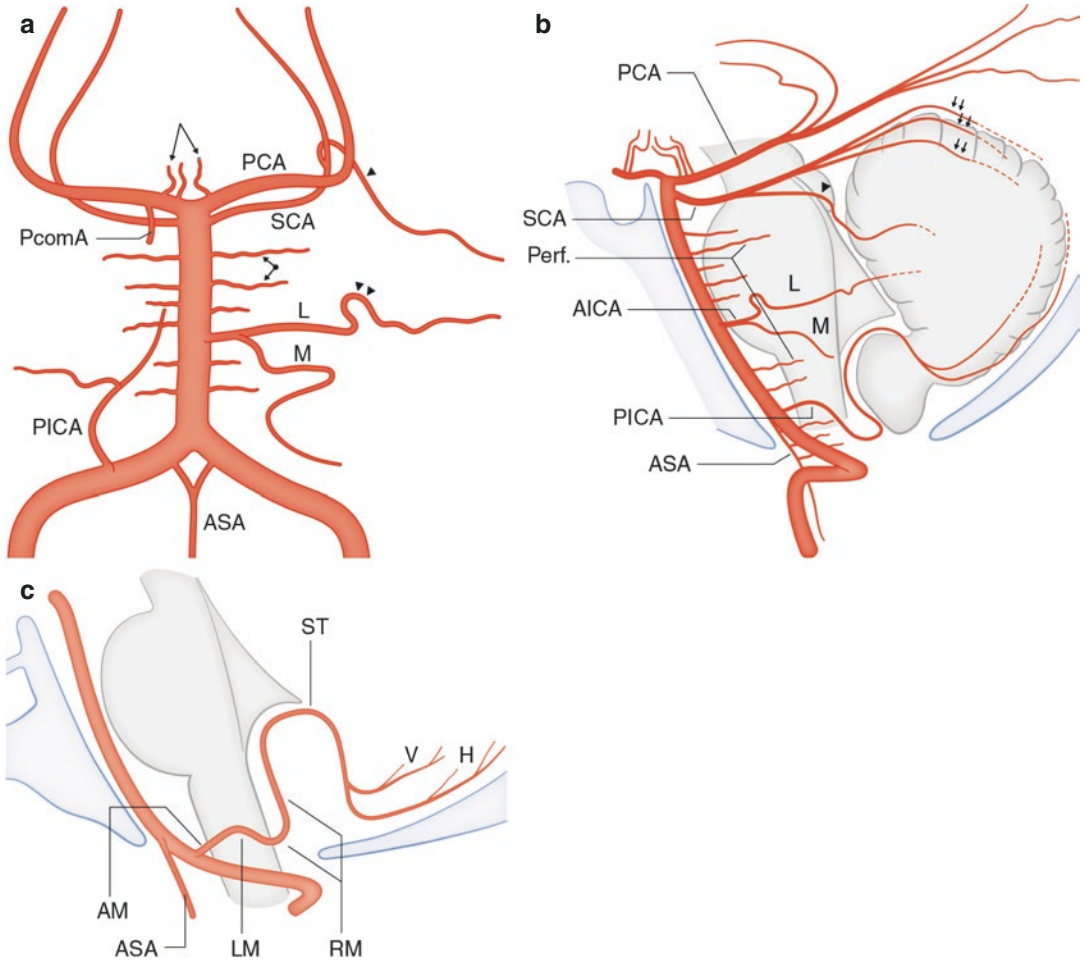

Fig. 6.5 (**a**) Drawing showing the intracranial vertebrobasilar sector in the AP projection. The two vertebral arteries unite in the basilar artery. Anterior spinal artery (ASA). Posterior inferior cerebellar artery (PICA) replacing on the right the absent AICA. Lateral branch (L) and medial branch (M) of the AICA replacing on the left the absent PICA. Loop of the lateral branch in front of the meatus acusticus (*arrowshead*). Superior cerebellar artery (SCA). Marginal branch (*arrowhead*). Lateropontine arteries (*arrows with angle and dot*). Posterior cerebral artery (PCA), posterior communicating artery (PcomA). Posterior thalamoperforating branches (*arrows with angle*). (**b**) Lateral view. Perforators for brainstem (*arrow dividing into two branches*). SCA with its vermian and hemispheric branches (*arrows*). Marginal branch (*arrowhead*). Pial anastomoses between PICA, AICA, and SCA (*dashed line*). Other indications as in (**a**). (**c**) Course of the PICA as seen on the lateral angiogram. Anterior medullary segment (AM), lateral medullary segment (LM), retromedullary segment (RM), supratonsillar segment (ST), vermian (V), hemispheric branches (H), and anterior spinal artery (ASA)

6.2.1.2 Posterior Inferior Cerebellar Artery

The posterior inferior cerebellar artery (PICA) arises bilaterally normally from the first intracranial, intradural segment of the VA. It can have, however, an extracranial origin below the foramen magnum at the C1 level (Margolis and Newton 1974; Fine et al. 1999). It can also rarely arise more proximally at the C1–C2 levels either from a normal VA or from a VA with an anomalous course (see Sect. 6.2.4). It runs anterolaterally to the *medulla*, reaching its posterior border after a variable course, which can be very tortuous, sometimes with a loop which can extend inferiorly to the foramen magnum. In this first part of its course (anterior AM and lateral LM

medullary segments) the PICA has a close relationship with cranial nerves IX, X, XI, and XII. Further, it takes an upward course (retromedullary segment RM) between the posterior surface of the *medulla* and the anterior surface of the *tonsilla*, which it surrounds superiorly, forming a typical loop (supratonsillar segment ST) commonly recognizable on the lateral angiogram. This pattern can be less evident when the PICA does not reach the superior pole of the *tonsilla*, having a more inferior course along the lateral surface of the *tonsilla*. Small branches for the choroid plexus of the IV ventricle arise at this level. The PICA runs then downwards on the posterior surface of the *tonsilla*, dividing into the vermian and hemispheric branches (Drawing 6.5a–c).

Vascular Territories. The PICA gives off perforators arising from its LM segment for the *lateral medulla*. There is a balance between these branches and those of the VA which commonly predominate (Duvernoy 1999). Furthermore the PICA supplies *the posterior medulla* together with the PSA, through perforators arising from its RM segment. The distal branches supply the *tonsilla*, inferior vermis, and inferior surface of the cerebellar hemisphere.

Variants. The anomalous origin of the PICA has already been described. The PICA can be well developed and also partially supply the contralateral hemisphere. It can be hypoplastic or absent and replaced partially or completely by a large anterior inferior cerebellar artery. Among other very rare anomalies there are cases of fenestration of PICA as described by some authors (Theodopoulos and Lawton 2000; Lesley 2008; Kumar et al. 2012). As far as it concerns its anomalous origin from ICA/ECA see Sect. 2.3.

On the angiogram, the PICA and its segments can be better studied on the lateral view. The first segments (anterior medullary and lateral medullary) can be characterized by a tortuous course. Commonly easier to identify are the retromedullary and supratonsillar segments, which surround the *tonsilla* and the distal vermian and hemispheric branches. On the AP view, the different segments cannot easily be separately distinguished. Examples are presented in Figs. 6.2b, 6.3, 6.6, 6.7, 6.8a, 6.9, 6.10, 6.11, and 6.12.

6.2.1.3 Anterior Spinal Artery

The ASA is formed by two small branches that arise from each VA distal to the PICA (Drawing 6.5a–c). In about 10% of the cases, the ASA has a unilateral origin. The artery gives off branches which run on the anterior median-paramedian surface of the *inferior medulla*, from which arise perforators supplying it. The anterior median and paramedian *superior part of the medulla* is supplied by the VA (Duvernoy 1999). The ASA is frequently recognizable on the angiogram (Figs. 6.2a, b, 6.3, 6.8a, b, 6.9, 6.10, 6.11, 15.33, 16.9, 16.11, and 16.14).

6.2.1.4 Posterior Spinal Artery

The PSA arises on both sides from the PICA or distal VA. They are very small arteries from which arise perforators supplying the posterior medulla together with the PICA. They are not recognizable on the angiogram, unless they are involved in pathological processes (Fig. 6.8b).

6.2.2 Branches of the Basilar Artery

6.2.2.1 Median-Paramedian Perforators

The median-paramedian perforators are small branches which arise from the posterior surface of the basilar artery (Drawing 6.5b). The majority enter the pons at the level of the basilar sulcus. Others adopt first a transverse path before entering the pons. Some of these arteries' perforating branches are long reaching the floor of the fourth ventricle; others are more lateral and shorter. They supply the median, paramedian, and partially the lateral part of the pons (Kaplan and Ford 1966; Tatu et al. 2001; Duvernoy 1999). These very fine branches are not recognizable on the angiogram.

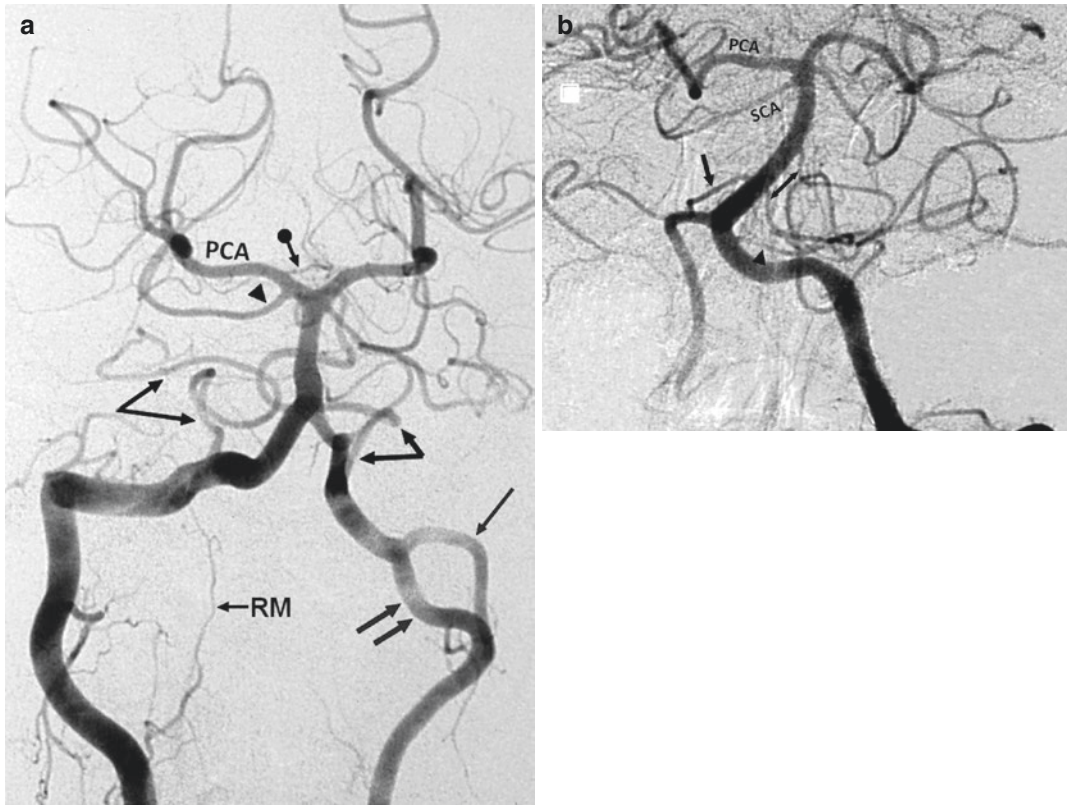

Fig. 6.6 (**a**) Right vertebral angiogram with retrograde filling of the left vertebral artery. The latter is duplicated. The true artery is smaller (*arrow*) than the anomalous branch (*double arrow*). The two branches fuse together continuing in the basilar artery. On the right and on the left there is a well-developed PICA (*arrow with angle*) supplying also the territory of the hypoplastic AICA. From the P1 of the right PCA arises a large posterior thalamoperforating branch (*arrow with dot*) dividing distally into small branches. The right SCA arises from the right P1 (*arrowhead*). Presence on the right of a radiculomeningeal branch (*white arrow*). (**b**) Left VA angiogram with retrograde filling of the hypoplastic right VA. On the left, the PICA (*arrowhead*) and two AICAs (*bidirectional arrow*) are present. On the right there is a well-developed AICA (*arrow*) supplying the territory of the absent PICA. Superior cerebellar (SCA) and posterior cerebral (PCA) arteries

6.2.2.2 Lateral Pontine Branches

The lateral pontine branches arise from the basilar artery and run laterally towards the middle cerebellar peduncle (MCP). They give off perforators that supply the lateral pons and MCP (Drawing 6.5a, b). A few lateral pontine branches arising from the more proximal segment of the BA extend also to the lateral superior part of the medulla anastomosing with the corresponding branches of VA and PICA especially on the surface of the olive (Akar et al. 1995; Duvernoy 1999). The lateral pontine branches are frequently well visible on the AP angiogram. Example are presented in Figs. 6.9b, 6.11a, 12.13, and 12.14.

6.2.2.3 Anterior Inferior Cerebellar Artery

The anterior inferior cerebellar artery (AICA) arises from the basilar artery, commonly from its first or second segment (Scialfa et al. 1976; Naidich et al. 1976). It runs laterally with a straight course towards the lateral inferior part of

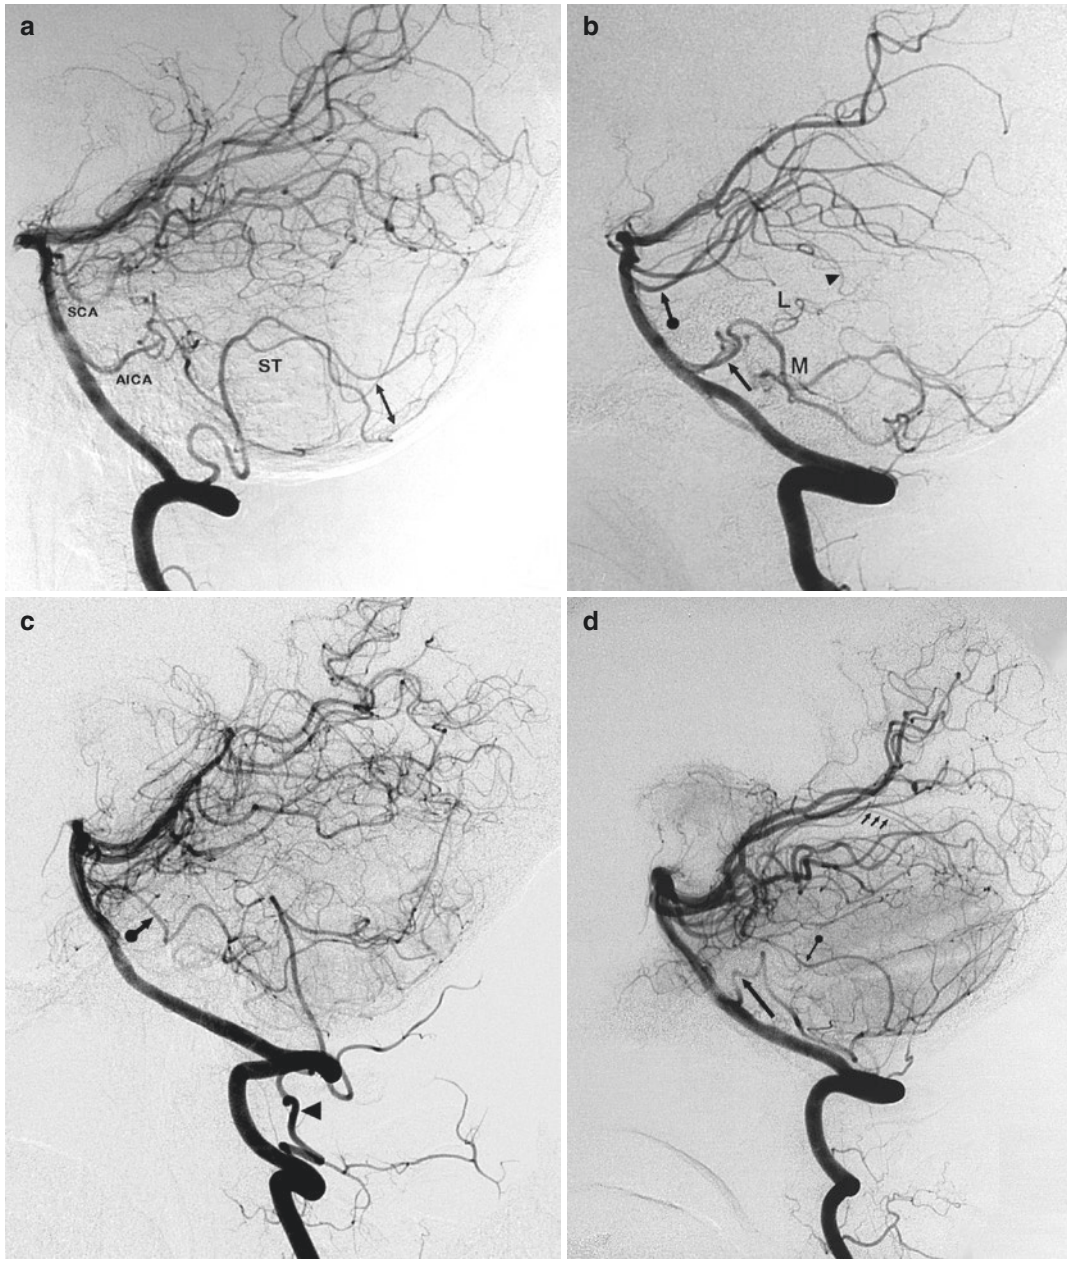

Fig. 6.7 (**a**) Lateral vertebral angiogram. Tortuous first segment of the PICA. Typical supratonsillar loop (ST). Vermian and hemispheric branches (*bidirectional arrow*). AICA. SCA. (**b**) The PICA is absent bilaterally. It is replaced by two well-developed AICAs (*arrow*). The lateral branch (L) is small, while the medial (M) is well developed. SCA (*arrow with dot*). Marginal branch (*arrowhead*) of the SCA. (**c**) Origin of the PICA from C2 (*arrowhead*). The vascular territory of the PICA is partially supplied by the medial branch of the AICA (*arrow with dot*). Well-developed musculocutaneous branches at the C1 and C2 levels, which seem in this case to arise from the anomalous PICA. (**d**) The PICA is absent. Its vascular territory is replaced by a well-developed AICA (*arrow*). Cerebellar branches of the SCA (*arrows*), forming the typical convex curve. Well-developed marginal branch (*arrow with dot*)

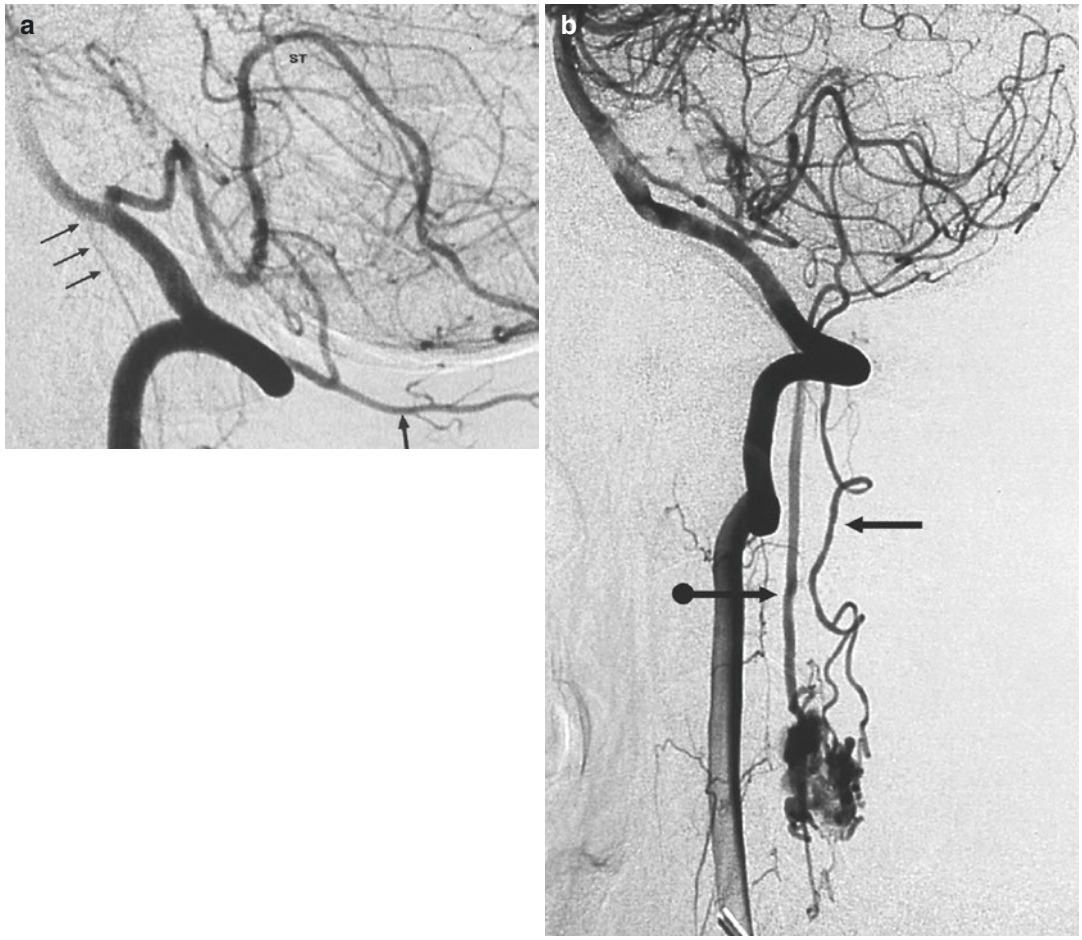

Fig. 6.8 (**a**) Lateral vertebral angiogram (detail). PICA with its typical supratonsillar loop (ST). ASA (*arrows*). Muscular branch at the level of C1, which can potentially anastomose with the corresponding branch of the occipital artery (*arrow*). (**b**) Patient with arteriovenous malformation involving the cervical spinal cord. Lateral vertebral angiogram showing the supply by a very dilated ASA (*arrow with dot*) and PSA (*arrow*)

the pons and the MCP. In its course, the artery crosses the VI cranial nerve; shortly after, it divides into two major branches: the rostrolateral (RL) and the caudomedial (CM) branches (Naidich et al. 1976) (Drawing 6.5a, b). Anterior to the flocculus, the lateral branch reaches the VII and VIII cranial nerves. Here, it describes a rather complex loop, which can partially extend into the meatus acusticus. In this part of its course, the lateral branch gives off the labyrinthine artery. The latter can rarely arise directly from the basilar artery (Naidich et al. 1976; Brunsteins and Ferreri 1990). The lateral branch runs further towards the horizontal fissure of the cerebellum, where it anastomoses with the marginal branch of the superior cerebellar artery. One of these branches can predominate and replace completely the other. The CM branch is frequently smaller. It is directed to the anterior medial surface of the cerebellum. Sometimes, it can arise as a separate trunk from the BA and it can be well developed, supplying partially or completely the vascular territory of the PICA when this is hypo-aplastic.

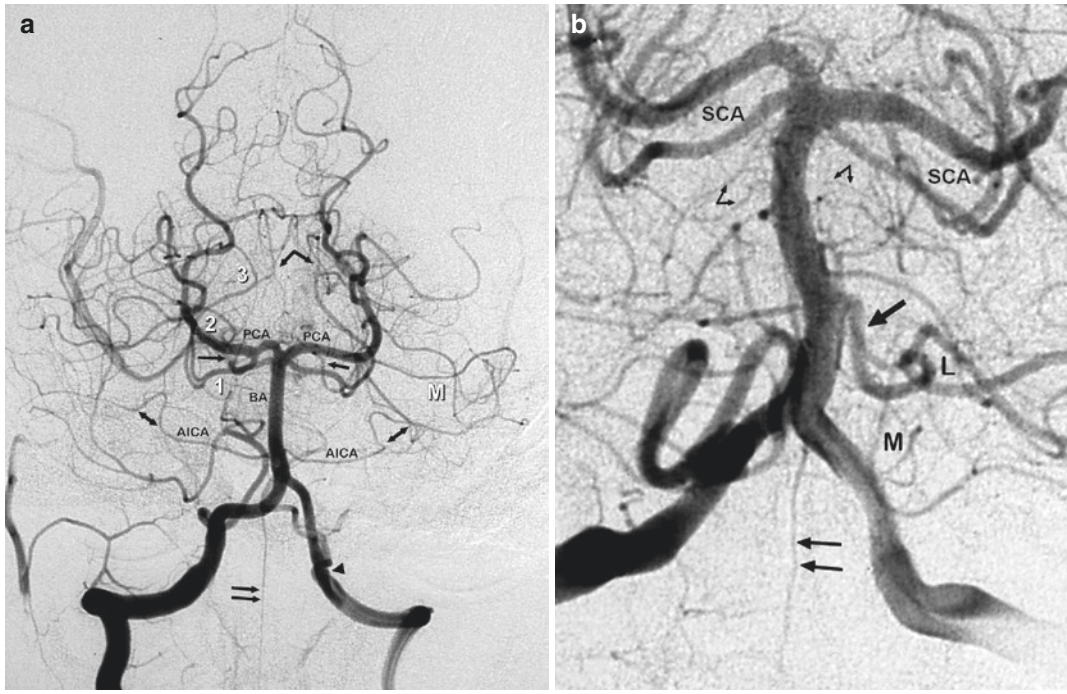

Fig. 6.9 Vertebral angiograms in two different patients. AP view. (**a**) Asymmetric vertebral artery. Basilar artery (BA). Both PICAs are well developed. That on the left probably has an extracranial origin (*arrowhead*). Unilateral origin of ASA (*double arrow*). Bilateral AICA. Note the loop in front of the internal meatus acusticus (*bidirectional arrows*). The numbers *1*, *2*, and *3* indicate, respectively, the pontine, midbrain, and quadrigeminal segments of the SCA. The latter converge to each other (*arrow with angle*) continuing in the terminal vermian branches. Large marginal branch of the SCA (M). From both PCA retrograde injection of the PcomA (*arrow*) which is well developed on the right. This allows a precise identification of the P1. On the right there is a C1 anastomosis with the occipital artery. (**b**) Bilateral voluminous VA. A well-developed AICA bilaterally replaces the absent PICA. The *arrow* indicates the left AICA with its lateral branch (L) and medial branch (M) extending to the territory of the PICA. Superior cerebellar artery (SCA). The lateral pontine arteries of the BA (*arrow with angle*). Unilateral ASA (*double arrow*) arising from the left VA

Vascular Territories. The AICA gives off perforators that supply the lateral part of the pons, the MCP, and sometimes can also contribute to supply the lateral superior part of the medulla in balance with the lateral pontine branches of the BA (Akar et al. 1995; Duvernoy 1999) (see also Sect. 6.2.2.2). The distal branches supply the flocculus and the adjacent anterior parts of the cerebellum. The labyrinthine artery supplies the VII and VIII cranial nerves.

Variants. The sizes of the AICA and PICA are closely correlated. When one is well developed the other can be small or absent. In an angiographic study (Takahashi et al. 1968), in 48% of the cases both the AICA and PICA were well developed. In 40% of cases, one or both AICAs were dominant, replacing partially or completely the PICA. In 10% of cases, the AICA was hypoplastic or absent, and its vascular territory was replaced by a well-developed PICA. In addition to the main trunk of the AICA, an accessory AICA with a separate origin from the BA may be present (Naidich et al. 1976).

Angiogram. The artery is easily recognizable on the lateral and particularly on the AP vertebral angiogram. In this latter view, the lateral branch runs towards the internal meatus acusticus, where it forms a loop which can frequently be clearly identified. At this level arises the labyrinthine

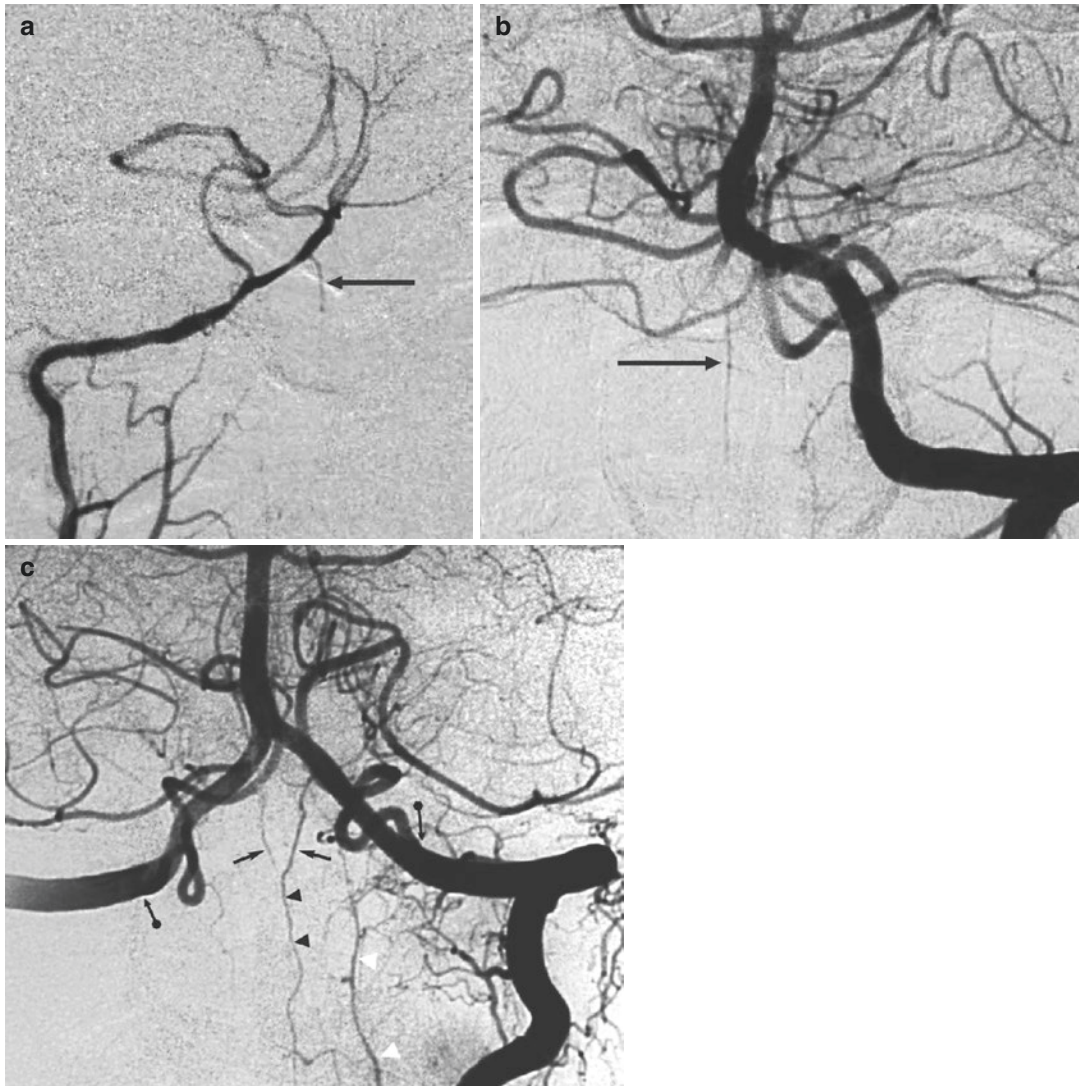

Fig. 6.10 Left and right (**a**, **b**) vertebral angiograms in the same patient. (**a**) Right hypoplastic VA, from which arises the ASA (*arrow*). (**b**) On the angiogram of the voluminous left VA, there is a partial retrograde injection of the right VA with filling of the ASA (*arrow*). (**c**) Left VA angiogram with retrograde injection of the right VA. ASA (*arrowheads*) with its bilateral contributions (*arrows*) from both VAs. Radiculomeningeal artery (*white arrowheads*)

artery, which however cannot commonly be identified. More distal branches extend to the anterior surface of the cerebellar hemisphere. Angiographic examples are presented in Figs. 6.3, 6.6, 6.7, 6.9, 6.11, 6.12, 6.13, 6.14a, b, 7.8a, 12.14, 12.15, and 12.16. The medial branch is particularly well visible when it replaces the hypo-aplastic PICA (Figs. 6.7, 6.9b, 6.12, 6.14, 15.42, 16.11, and 16.13).

6.2.2.4 Superior Cerebellar Artery

The SCA is the most constant among the cerebellar arteries and is almost always present. It arises as a unique trunk, which divides into superior and inferior branches. It can be double or rarely triple (Mani et al. 1968; Hardy and Rhoton 1978). An origin from the P1 may also occur. From its origin, the SCA runs laterally on the surface of the superior part of the pons (*pontine segment*) and

Fig. 6.11 VA angiogram, AP view. Dominant left VA, which gives off a large PICA. There are two well-developed AICAs. That on the right replaces the vascular territory of the right PICA. Bilateral origin of ASA (*bidirectional arrow*). The lateral pontine branches arising from the basilar artery are well visible (*arrow with angle*). Note on the right the early division of the SCA

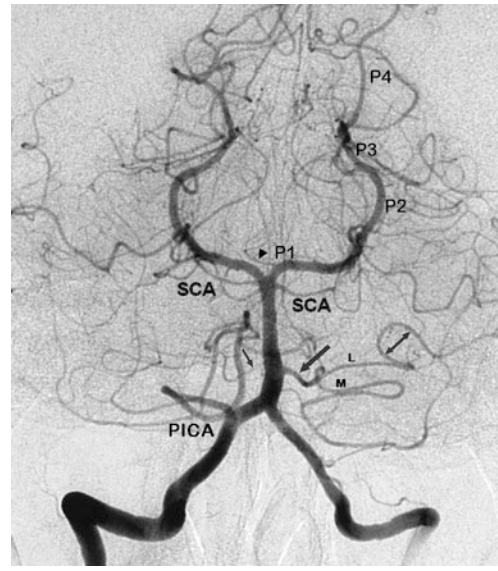

Fig. 6.12 Vertebral angiogram. AP view. Right VA angiogram with reflux in the smaller left VA. On the right, a well-developed PICA replaces mainly the vascular territory of the small AICA (*small arrow*). On the left, there is a well-developed AICA (*arrow*) supplying the vascular territory of the absent PICA. Lateral (L) and medial (M) branches of the left AICA. Note the typical loop of the lateral branch in front of the meatus acusticus (*bidirectional arrow*). The SCA is double on the right. The four segments of the PCA (P1–P4) show their typical course. A large posterior thalamo-perforating branch arising from the left P1 is recognizable (*arrowhead*)

lies inferiorly to the third cranial nerve. It turns then posteriorly and courses around the midbrain (*midbrain segment*) inferiorly to the posterior cerebral artery. The trunk or one of its branches can make a loop caudally coming in contact with the trigeminal nerve (Hardy and Rhoton 1978). It reaches further the quadrigeminal plate (*quadrigeminal segment*), where both the right and left SCA approach to each other and continue each in the vermis branch which is considered the terminal branch (Drawing 6.5a, b).

Branches. In its course around the midbrain, the SCA gives off small branches which supply the superior-posterior part of the pons and midbrain and branches for the cerebellar hemisphere. The first among these latter is the marginal artery, which runs laterally towards the horizontal fissure and supplies the corresponding cerebellar area, in balance with the lateral branch of the AICA. One of these arteries can predominate. In its course around the

Fig. 6.13 Fenestration (*arrow*) of the basilar artery near the origin of the AICA

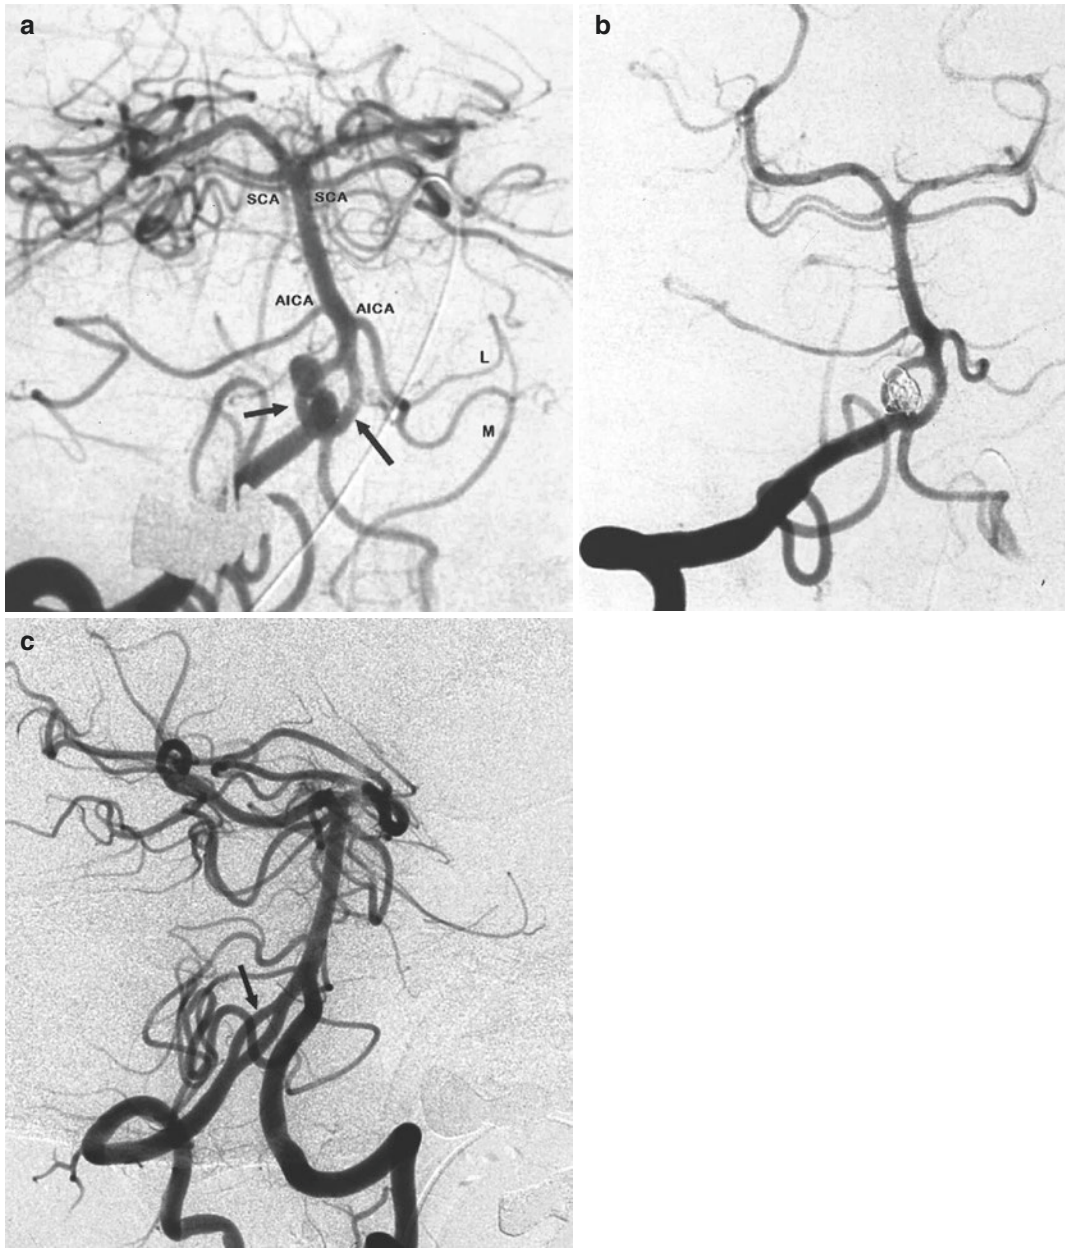

Fig. 6.14 (**a**) Angiogram in a duplicated proximal basilar artery (*arrows*) associated with ruptured aneurysm treated acutely with coils (**b**). There is asymmetry of the vertebral arteries: that of the left is hypoplastic. Bilateral well-developed AICA. That on the left replaces the absent PICA. Lateral branch (L), medial branch (M), and superior cerebellar arteries (SCA) duplicated on the right. One arises from the basilar artery and the other has a common origin with the P1. Duplication (**c**) of the vertebral artery (*arrow*) in another patient. Left vertebral angiogram with reflux in the right duplicated vertebral artery

midbrain, the SCA lies inferiorly to the superior surface of the cerebellum; so to reach it, the branches run first upward, towards the convexity, and then downward on the surface of the cerebellum. The terminal branch is the artery for the superior vermis. The vermis branches of both side approach to each other, running almost parallel.

From the midbrain segment arises a *meningeal artery*, sending small branches to the posterior part of the tentorium (Wollschlaeger and Wollschlaeger 1974).

Vascular Territories. Each artery supplies the posterosuperior part of pons and midbrain. It can also contribute to the supply of the posterolateral midbrain in balance with perforators arising directly from the posterior cerebral artery (PCA), the collicular artery, and the posteromedial choroidal artery (Duvernoy 1999). The distal branches supply the superior vermis and superior cerebellar hemisphere.

Variants. The SCA can arise uni- or bilaterally from the P1 segment of the posterior cerebral artery (Figs. 6.6a and 15.44b). When the SCA is duplicated, one branch can arise from the BA and the other from the P1 (Fig. 6.14b).

On the angiogram. The pontine, midbrain, and quadrigeminal segments are easily recognizable on the AP view (Figs. 6.9, 6.11, 6.12, 6.14, and 12.13). The midbrain segment is identified on the lateral view running inferiorly to the posterior cerebral artery (Figs. 6.7 and 7.9). Because of the overlapping, there can be some difficulties to distinguish the cerebellar branches from those of the PCA. The cerebellar arteries form a superior convex curve with a stepladder appearance. The vermis branches are the superior ones (Figs. 6.7 and 7.9. The marginal branch, when well developed, is easy to identify due to its course downwards to the cerebellar horizontal fissure (Fig. 6.7). On the AP view the cerebellar branches, due to their location below the tentorium, run inferiorly to the temporal branches of the PCA (Figs. 6.9 and 7.5).

6.2.3 Distal Branches of PICA, AICA, and SCA

The angioarchitecture of the distal branches of the cerebellar arteries is similar to that already described at the level of the arteries of the cerebral hemispheres (De Reuck 1972). These arteries run on the surface of the cerebellar cortex connected to each other distally in the so-called border zone through leptomeningeal anastomoses. From the superficial arteries arise with a perpendicular course perforating branches supplying the cortex and branches (medullary arteries) extending towards the white matter and deep nuclei. The penetrating branches are *end arteries* without the possibility of a collateral circulation.

6.2.4 Variants of Vertebral and Basilar Arteries

There is a frequent asymmetry of the size of the VAs. The left VA is dominant in the majority of cases; less frequently the right VA is larger. One VA may be hypoplastic, ending intracranially in the PICA. In cases of unilateral ASA, the presence of a hypoplastic VA does not exclude that the ASA takes its origin from this artery (Fig. 6.10a, b).

Other rare conditions are *duplication and fenestration*. These can be found also in the anterior circulation (Sects. 2.3, 4.3, 5.3, and 7.5) but are reported to be more frequent in the vertebrobasilar sector (Uchino et al. 2012b), involving the extra- and intracranial segments of the vertebral and the basilar artery. The definition of fenestration or duplication as reported in the literature is not always homogeneous. This is due partially to the different terminology used by the authors for the same finding and to the difficulty in some cases to make a differential diagnosis between these two conditions. To simplify matter, from a practical point of view, we define *duplication* as occurring when two clearly separated vessels are present. In the case of *fenestration* the vessel is unique but on one part of its course there is a double lumen.

In this context it is useful to recall some aspects of the embryological development of the vertebrobasilar system (Schmeidel 1932; Padget 1948, 1954) (see also Chap. 1). Each VA is formed by metameric cervical intersegmental arteries arising from the upper part of the primitive dorsal aorta connected with a longitudinal plexiform structure. Later the metameric arteries regress with the exception of that from which arises the vertebral artery, commonly the sixth (Padget 1954). The longitudinal plexiform structure evolves bilaterally forming the final vertebral artery connected proximally through the sixth metameric artery with the subclavian artery and distally with the basilar artery.

As far as it concerns the numbering of the intersegmental arteries, we follow that proposed by Padget (1954). According to this author, the intersegmental artery accompanying the first cervical nerve should not be numbered in the cervical series, since it does not run between two cervical segments. Instead it runs between the occipital bone and the first cervical segment, which is the atlas. It should be called suboccipital intersegmental or proatlantal intersegmental artery, which normally regresses and partially becomes the transverse suboccipital part of the VA (see also Chap. 2, Sect. 2.3). The first cervical intersegmental artery is that running between the first and second cervical segments. *Therefore the intersegmental artery from which develops the stem of the vertebral artery and the subclavian artery is the sixth running between the sixth and seventh vertebral bodies.*

The persistence together with the normal VA of another intersegmental metameric artery explains probably the duplication of the extracranial vertebral artery. The most frequent duplication is at the C1–C2 levels due to persistence of the first intersegmental artery (Fig. 6.6a). The anomalous artery enters the spinal canal joining intracranially the normal VA. It can also occur that only the anomalous vessel persists, while the normal VA does not develop. Another frequent pattern, commonly on the left, is the presence of the normal VA, arising from the subclavian artery and entering the transverse foramen at the C6 level with, in addition, a second VA with an abnormal origin and course (Fig. 6.15). The latter

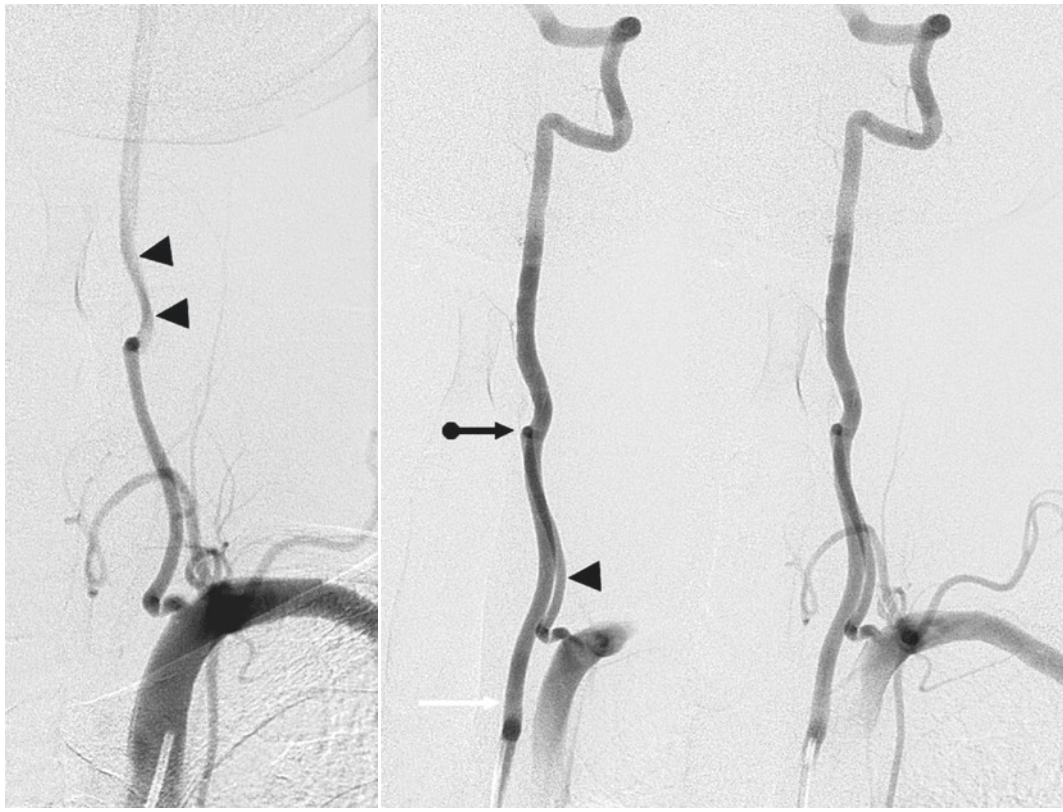

Fig. 6.15 Incidental discovery of a duplicated left VA. (**a**) Left subclavian angiogram showing the normal origin of the left VA. More distally, the contrast medium is more diluted (*arrowheads*). This is due to the presence of a second more voluminous VA having an abnormal origin from the aortic arch. (**b**) Selective angiogram of this second VA (*arrow*), which joins distally (*arrow with dot*) the VA with a normal course and origin (*arrowhead*) which is retrograde filled as well as the subclavian artery. Courtesy of Dr. Gozzoli and Dr. Boghi, Neuroradiology of Cuneo Hospital

is thought to be due to the persistence of the fifth intersegmental artery (Goddard et al. 2001). The abnormal VA arises from the aortic arch proximal to the subclavian artery (SA) and enters the fourth or fifth transverse foramen (TF). Both the normal and abnormal VAs fuse distally together. The abnormal VA can also develop from the seventh intersegmental artery, arising in this case from the aortic arch, distal to the SA and entering the seventh TF. Duplication can occur less frequently also on the right. A bilateral duplication has also been reported (Ionete and Omojola 2006).

Other anomalies of the VA are the single anomalous origin from the aortic arch, commonly on the left occurring in about 6% of the cases. The origin can be proximal or distal to the left subclavian artery, as described above, with entering the fifth–fourth or seventh transverse foramen, respectively (Figs. 1.6 and 15.28). Anomalous origin of the right VA is more rare. This can occur from the aortic arch more proximal between the right subclavian and right common carotid arteries, or more distally between the left common carotid and left subclavian arteries or distal to the left subclavian artery (*vertebral arteria lusoria*). The entering of the TF is commonly the fifth–fourth in the cases of more proximal origin and seventh in the cases of vertebral arteria lusoria. The latter occurs typically in association with anomalous origin of the right subclavian (*subclavian arteria lusoria*) close or distal to the left subclavian artery. Origin of the VAs from the common carotid artery more frequently on the right has also been reported.

A very rare anomaly is the thoracic origin of the VA, arising as a common trunk with the upper thoracic intercostal arteries. It has been interpreted as due to persistence in the upper thoracic region of a connection between the intersegmental arteries supplying the spinal canal and the embryological longitudinal plexus from which develops the VA (Chiras et al. 1982; Stoesslein et al. 1982).

Another anomalous pattern is the fenestration of the extracranial VA, probably due to the partial persistence of the longitudinal plexiform structure (Fig. 6.16).

There is a rich literature dedicated to duplication, fenestration, or anomalous origin and course of the VAs, either in the distal segment of the VA, commonly at the C1–C2 levels (Rieger and Huber 1983; Tokuda et al. 1985; Hashimoto et al. 1987; Takahashi et al. 2003; Uchino et al. 2013b), or at the origin of the VA (Kemmetmueller 1911; Adachi 1928; Suzuki et al. 1978; Eisenberg et al. 1986; Takasato et al. 1992; Lemke et al. 1999; Lasjaunias et al. 2001; Goddard et al. 2001; Ionete and Omojola 2006; Satti et al. 2007; Karcaaltincaba et al. 2009; Dabus and Walker 2010; Meila et al. 2012; Uchino et al. 2013b).

Anomalies of the VAs should always be taken into account especially in patients in whom surgery involving the aortic arch, anterior neck, or craniovertebral junction is planned (*Tokuda* et al. 1985*; Matula* et al. 1997*; Lemke* et al. 1999*; Albayram* et al. 2002*; Takahashi* et al. 2003*; Uchino* et al. 2013b). *In particular, the demonstration of an anomalous right subclavian and anomalous right VA arising distally to the left subclavian artery is important in mediastinal and esophageal surgery* (*Lacout* et al. 2012). *A duplication of the VA at the C1–C2 levels should also be taken into consideration in patients, in whom a puncture of the subarachnoid space is planned. Anomalous cervical course has been considered to be a risk factor favoring dissection of the artery* (*Jackson* et al. 2000). *Also in patients having suffered a stroke in the vertebrobasilar sector, in which one or both VAs cannot be demonstrated in their typical site of origin on the routine angiographic examination, the possibility of an anomalous origin should be considered.*

Fenestration and duplication can be found also in the intracranial VA and BA (Takahashi et al. 1973; Wollschlaeger and Wollschlaeger 1974; Lasjaunias et al. 2001; Tanaka et al. 2006). In MR angiographic study of 3327 patients (Uchino et al. 2012c) this anomaly was diagnosed in 2.77% of the cases involving the intradural segment of the VA, the vertebrobasilar junction, and more frequently the basilar artery in its proximal and middle segments. The anomaly is probably due to failure of the bilateral

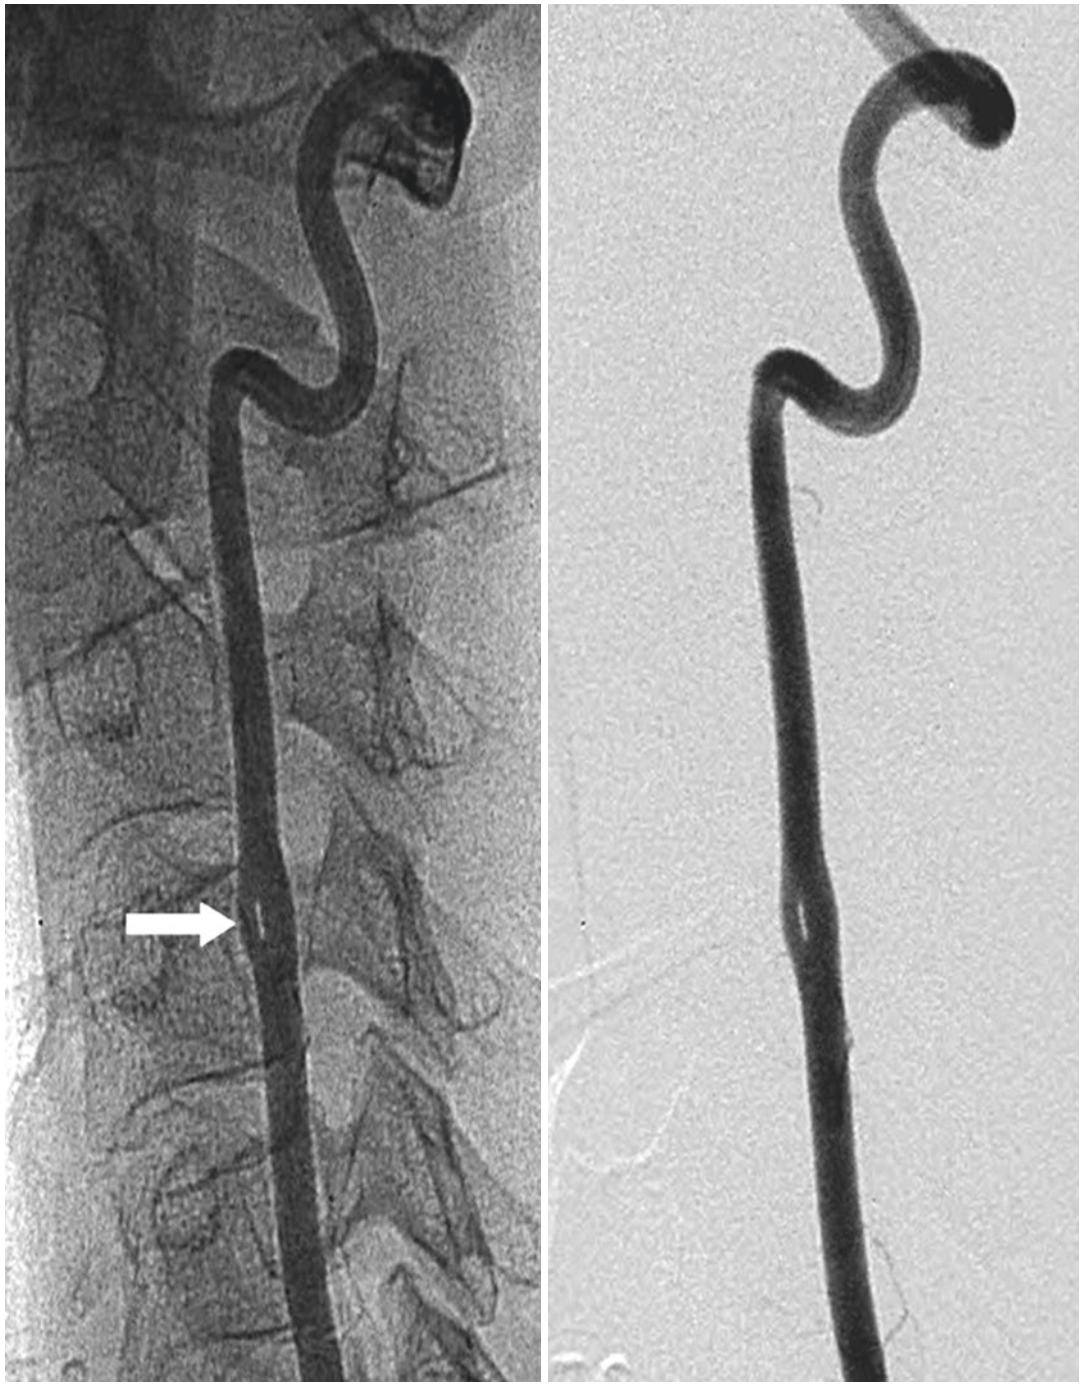

Fig. 6.16 Incidental discovery of fenestration of the vertebral artery (*arrow*) in its extracranial course

plexiform longitudinal channel to develop into a single vessel (Figs. 6.13 and 6.14) (see also embryogenesis, Chap. 1). Aneurysms at the site of the anomaly but also elsewhere are frequent (Campos et al. 1987; Picard et al. 1993; Tasker and Byrne 1997; Uchino et al. 2012b; Krings et al. 2007b; Stark et al. 2013; Trivelato et al. 2016) (Fig. 6.14a, b).

Other anomalies are that characterized by failure of fusion of the two primitive longitudinal channels presenting in the form of two BA due to the persistence of the two primitive longitudinal channels (Goldstein et al. 1999; Ho et al. 2004). In the cases of partial fusion the pattern is that of an apparently short BA. In the caudal failure of fusion the angiographic pattern is that of a higher vertebrobasilar junction. In the cranial failure the pattern is of an apparently lower origin of the PCA. From the distal unfused segments of the BA the SCAs are recognizable.

A segmental aplasia of the BA (Lasjaunias et al. 1979; Ricolfi et al. 1996; Hoh et al. 2004; Burger et al. 2007; Caranci et al. 2012; Bradac 2014) has also been described. In this last condition the VAs join together continuing in the proximal segment of the BA, which is not connected with its distal segment. The latter can be fed like in the first phases of the embryogenesis by the well-developed PcomA. In other cases the BA has no connections neither with the PcomA nor with the VAs. It appears as an isolated trunk supplied by the primitive trigeminal artery. The persistence of the trigeminal artery associated probably to impairment in the development of the VAs at the level of the intersegmental arteries leads to a reduction of the flow from the VAs towards the BA leading to a progressive interruption between these arteries.

A case of segmental aplasia is presented in Fig. 6.17.

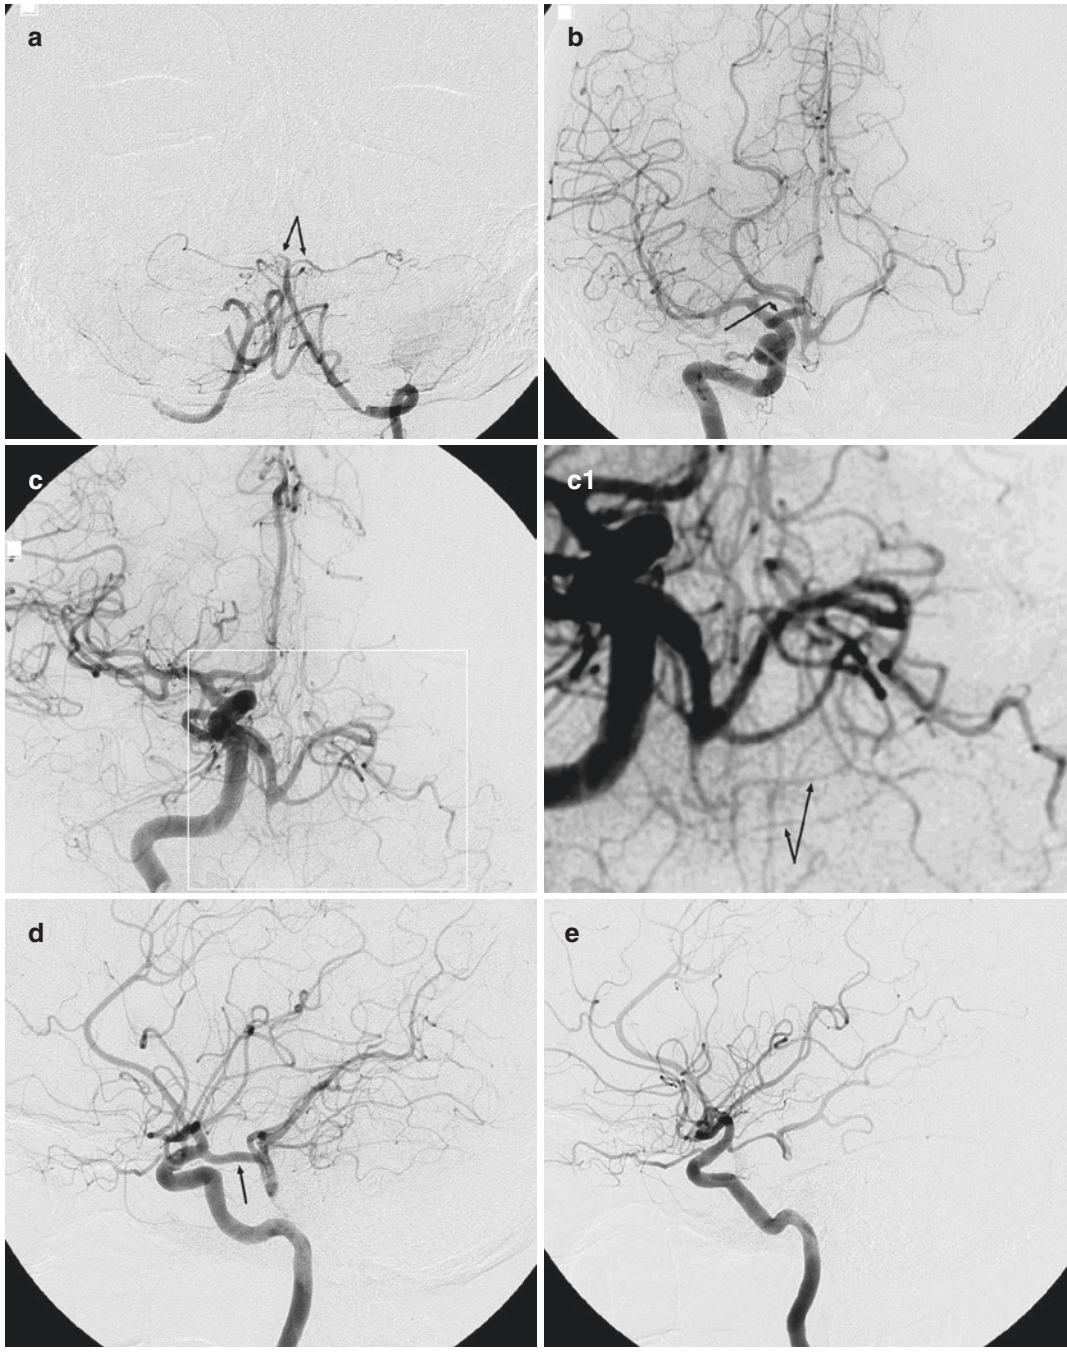

Fig. 6.17 Incidental discovery of a segmental aplasia of the basilar artery in a middle-aged hypertensive patient. The routine MR examination was normal apart from a few micro-ischemic lesions in the white matter of the cerebral hemispheres. An unexpected interruption of the flow in the middle basilar artery was visible on MR angiography that led to conventional angiography. (**a**) Left vertebral angiogram with retrograde filling of the right VA. Both VAs were small. They gave off two well-developed PICAs. The BA was small, ending in the AICAs (*arrow with angle*). (**b**) Right ICA angiogram. AP view. A well-developed PcomA (*arrow*) is connected with the P1. Through this connection, there is a filling of the distal, short BA from which arise with an ascending course both PCAs and SCAs. (**c**) Right ICA angiogram, modified AP view, better showing the filling of the distal BA and of its distal branches. (C1), magnified detail showing the filling of the lateral pontine branches (*arrow with angle*). (**d**, **e**) Right and left ICA angiograms. Lateral view, showing the PcomA connected with the BA and PCAs

Posterior Cerebral Artery

7

From the caudal division of ICA arises the PcomA from which posteriorly develops progressively the PCA, and anteriorly and caudally a connection with BA. Later in evolution in the majority of the cases the connection of the PcomA with the PCA (also called pars carotica) regresses or becomes hypoplastic, while in the connection of the BA with the PCA (also called pars basilaris) the future P1 becomes predominant (see also Chap. 1 and Sect. 2.2.3.2). The posterior shift of the vascular territories of the PCA (posterior temporal and occipital areas) leads to increased distance between the origin of the PCA and its distal vascular territories. The decrease of this distance by shifting the origin of the PCA from ICA to the BA could be interpreted as a natural evolution to compensate this process (Kier 1974).

- The course of the PCA arising from the BA can be divided into four segments (Huber 1979) (Drawings 7.1 and 7.4)
- P1 (precommunicating segment): from its origin from the BA to the junction with the PcomA
- P2 (ambient segment): around the midbrain towards the quadrigeminal plate
- P3 (quadrigeminal segment): on the surface of the quadrigeminal plate
- P4 (distal segments)

7.1 P1 Segment

This is the first segment, extending from its origin at the basilar artery to its junction with the PcomA (Drawings 7.1 and 7.4 and Figs. 7.2 and 7.6). The P1 segment (pars basilaris of the PCA) is a short segment, with an average length of 7.1 mm (Zeal and Rhoton 1978). It runs in the interpeduncular fossa, where it has a close relationship with the commonly inferiorly located cranial nerve III. The P1 can have a horizontal or a slightly ascending or descending course.

The P1 segment gives off perforating branches called *thalamoperforating pedicles* (Foix and Hillemand 1925a, b) or *paramedian thalamic arteries* (Percheron 1976a, b). It seems to be more simple to call these arteries *posterior thalamoperforating branches*, while the *anterior thalamoperforating branches* arise from PcomA. They enter the posterior perforated substance (PPS), supplying the medial part of the mesencephalon, the medial part of the thalamus, and the posterior part of the hypothalamus (Lazorthes and Salamon 1971; Saeki and Rhoton 1977; Zeal and Rhoton 1978; Duvernoy 1999; Tatu et al. 2001).

They can also take over the supply of the anterior part of the thalamus, normally supplied by the PcomA, when this is absent (Percheron 1976a, b). On the contrary when P1 is absent, its

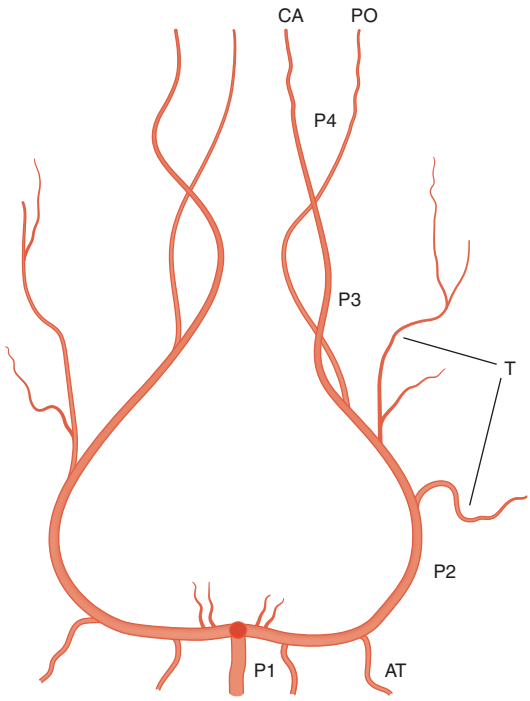

Fig. 7.1 Drawing. Course of the P1, P2, P3, and P4 segments of the posterior cerebral artery (PCA) in the AP view. Anterior temporal artery (AT), middle temporal and temporo-occipital branches (T), calcarine artery (CA), and parieto-occipital artery (PA)

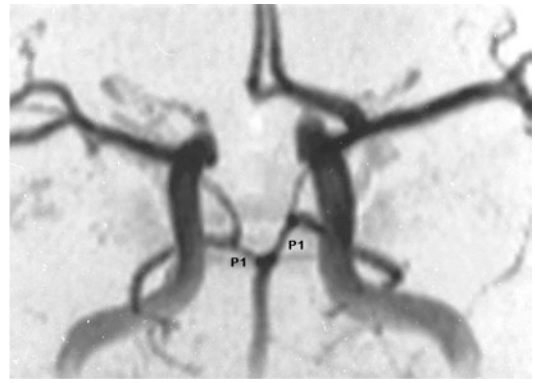

Fig. 7.2 Angio-MRI. The P1 segments are well defined owing to the presence of the posterior communicating artery (PcomA) bilaterally

vascular territory can be taken over by the PcomA or by branches arising from the contralateral P1.

The posterior thalamoperforating arteries commonly consist of several small branches, although not rarely a larger trunk, further dividing into small branches, may predominate. They can arise entirely only from one P1, as previously described (Westberg 1966; Percheron 1976a, b; Saeki and Rhoton 1977; Zeal and Rhoton 1978; Castaigne et al. 1981) and also documented more recently (Brassier et al. 1988; Lazzaro et al. 2010). Furthermore, even in cases of hypoplasia of the P1, perforators may arise from it (Zeal and Rhoton 1978). All these variants probably explain the different patterns of midbrain and thalamic infarction in cases of proximal occlusion of the P1. Examples are presented in Figs. 7.8a–c, 6.6, and 6.12.

Another branch which arises from the P1 and sometimes from the P2 is the *collicular* (*quadrigeminal*) *artery*, which runs around the midbrain contributing to the supply of its lateral and posterior part. There is frequently a second smaller artery, running close and parallel to the collicular artery, called the accessory collicular artery (Zeal and Rhoton 1978; Duvernoy 1999; Tatu et al. 2001).

From the P1 and sometimes from the P2 or the parieto-occipital branch arises the posterior medial choroidal artery, which, after reaching the quadrigeminal plate and giving off branches for the posterior thalamus, courses forward in the roof of the third ventricle running together with the internal cerebral vein towards the foramen of Monro. It supplies the choroid plexus of the third ventricle (Galloway and Greitz 1960; Wackenheim and Braun 1970; Margolis et al. 1974; Fujii et al. 1980) (Figs. 7.3 and 7.4).

Near the origin of the P1 arises *a meningeal branch*, which has been described by Wollschlaeger and Wollschlaeger (1965), who termed it the *artery of Davidoff and Schechter*, in honor of their former teachers. It runs first parallel and inferiorly to the PCA, and then dips under the notch of the tentorium running further medially and posteriorly towards the region where the tentorium and falx join together, vascularizing these dural structures. This meningeal branch is not rare but it is very fine and so not recognizable on the normal angiogram (Wollschlaeger and Wollschlaeger 1965). It can be involved in pathological processes of the region, especially in meningiomas and dural arteriovenous fistula (Weinstein et al. 1974) (Figs. 13.16, 13.17, and 13.18).

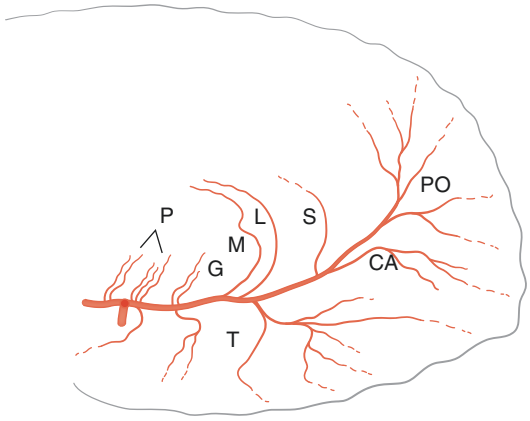

Fig. 7.3 Drawing. Course of the PCA and its branches in the lateral view. Anterior from PcomA and posterior from P1 thalamoperforating arteries (p), thalamogeniculate artery (G), posterior choroidal arteries, medial (M), lateral (L), splenial artery (S), parieto-occipital arteries (PO), calcarine artery (CA), temporal arteries (T), anastomoses indicated by *dashed lines* with the anterior cerebral artery (ACA) and middle cerebral artery (MCA)

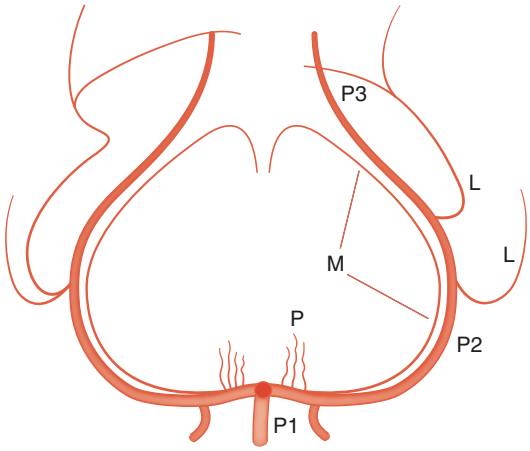

Fig. 7.4 Course of the P1, P2, and P3 segments of the PCA in the AP view. Posterior thalamoperforating branches (P), medial (M), and lateral (L) posterior choroidal arteries

7.2 P2 Segment

Also called the circumpeduncular segment, the P2 segment runs around the midbrain (Drawings 7.1 and 7.4), commonly separated from it by several millimeters, and terminates on the surface of the quadrigeminal plate. The P2 segment lies inferior to the optic tract and basal vein, and superior to the superior cerebellar artery. The parahippocampal gyrus lies laterally, with the free margin of the tentorium above. The P2 segment gives off the thalamogeniculate artery, which can be a single branch or present with two or three vessels supplying the lateral thalamus (Duvernoy 1999; Tatu et al. 2001). The artery can arise in the proximal or more distal P2 segment (Zeal and Rhoton 1978).

Other branches are the peduncular perforators for the lateral midbrain and the posterior lateral choroidal artery. The latter, which can sometimes arise from the parieto-occipital artery, consists of a single or several branches (Zeal and Rhoton 1978). Basically, there is an anterior branch which runs in the circumpeduncular cistern, enters the choroid fissure, and extends forwards to supply the plexus of the temporal horn anastomosing with the anterior choroidal artery (AchA). A posterior branch reaches the pulvinar, gives branches to it, and terminates in the choroid plexus of the lateral ventricle at the level of the atrium, anastomosing with branches of the AchA (Galloway and Greitz 1960; Wackenheim and Braun 1970; Margolis et al. 1974; Fujii et al. 1980; Duvernoy 1999) (Figs. 7.3 and 7.4).

From the P2 arise cortical branches for the temporal lobe. They are also called the inferior temporal arteries and supply entirely the inferior medial surface of the temporal lobe, including the hippocampus and the inferior medial surface of the occipital lobe. These cortical branches are named in relation to the site of origin and vascular territories involved: anterior, middle, and posterior (Zeal and Rhoton 1978). From the posterior temporal artery can arise a few branches supplying the primary visual cortex (Margolis et al. 1974) (Figs. 7.6 and 7.7).

7.3 P3 Segment

The short P3 segment runs in the quadrigeminal cistern on the surface of the quadrigeminal plate, approaching that of the other side at a variable distance, averaging 16 mm (Margolis et al. 1974) (Drawings 7.1 and 7.4).

7.4 P4 Segment

The P4 segment consists of the terminal branches represented by the parieto-occipital, calcarine, and splenial arteries (Drawings 7.1 and 7.3). The parieto-occipital arises either together with the calcarine artery, at the level of the calcarine fissure, or sometimes as a single trunk, more proximally from the P2 segment. The parieto-occipital artery runs posterosuperiorly on the medial surface of the hemisphere and gives off branches for the precuneus, cuneus, and, as reported by some authors (Margolis et al. 1974), also for the primary visual cortex in about 35% of the cases. The calcarine artery arises at the calcarine fissure, usually located laterally to the parieto-occipital artery. Further, it runs medially and inferiorly along the calcarine fissure, supplying the primary visual cortex.

The splenial artery, also called the posterior pericallosal artery, has a variable origin, frequently from the P3 segment or from the parieto-occipital artery. It runs around the splenium and anastomoses anteriorly with the posterior pericallosal artery branch of the pericallosal artery (Drawing 7.3).

7.5 Anatomical Variations

The P1 segment can be hypoplastic or absent. When the P1 is absent, the PCA takes its origin directly from the ICA via a large PcomA. This aspect, corresponding to the initial embryological pattern, is called the fetal origin of the PCA (Fig. 7.5a, c). It can occur uni- or bilaterally; its frequency is reported as being between 30 and 40% of cases (Zeal and Rhoton 1978; Pedroza et al. 1987). Conversely, when the P1 is well developed, the PcomA is commonly small or can be completely absent (Fig. 7.5d). Among the variants concerning the proximal segment of the PCA, duplication with two separated branches arising from the ICA or one from the ICA and the other from the basilar artery has been reported (Hoyt et al. 1974; Wollschlaeger and Wollschlaeger 1974; Bulsara et al. 2007; Uchino et al. 2016). Other studies have shown that in the majority of these cases, the duplication represents a variant of the AchA, which can be hyperplastic and take over partially or completely the vascular territory of the PCA (see Sect. 2.2.3.3 and Figs. 2.9 and 2.12). Cases of fenestration of P1 have been reported (Wollschlaeger and Wollschlaeger 1974; Uchino et al. 2016). Variants involving the posterior thalamoperforating arteries have already been described.

7.6 Vascular Territories

- The posterior thalamoperforating arteries (P1) supply the medial and anterior parts of the midbrain and medial thalamus. Frequently, a common large trunk supplies both midbrain and thalamus. In other cases several smaller branches supply selectively the midbrain and the thalamus.
- The collicular artery (P1), middle posterior choroidal artery, and small perforators arising directly from the P1–P2 segment supply the lateral and posterior parts of the midbrain.
- The thalamogeniculate artery (P2) supplies the lateral thalamus, optic tract, and posterior limb of the internal capsule. The posterior choroidal arteries (P1–P2) supply the posterior thalamus.
- There are many variants concerning the origin and extension of the vascular territories of all these branches. Furthermore, they form a rich anastomotic network on the surface of the midbrain and posterior thalamus that involves also the superior cerebellar artery and the AchA. This probably explains the absence or the different extension of ischemic lesions in occlusion of the proximal PCA distal to the P1.
- The cortical branches comprise the temporal arteries (P2) supplying the medial inferior surface of the temporal and occipital lobes, the parieto-occipital (P3) supplying the medial

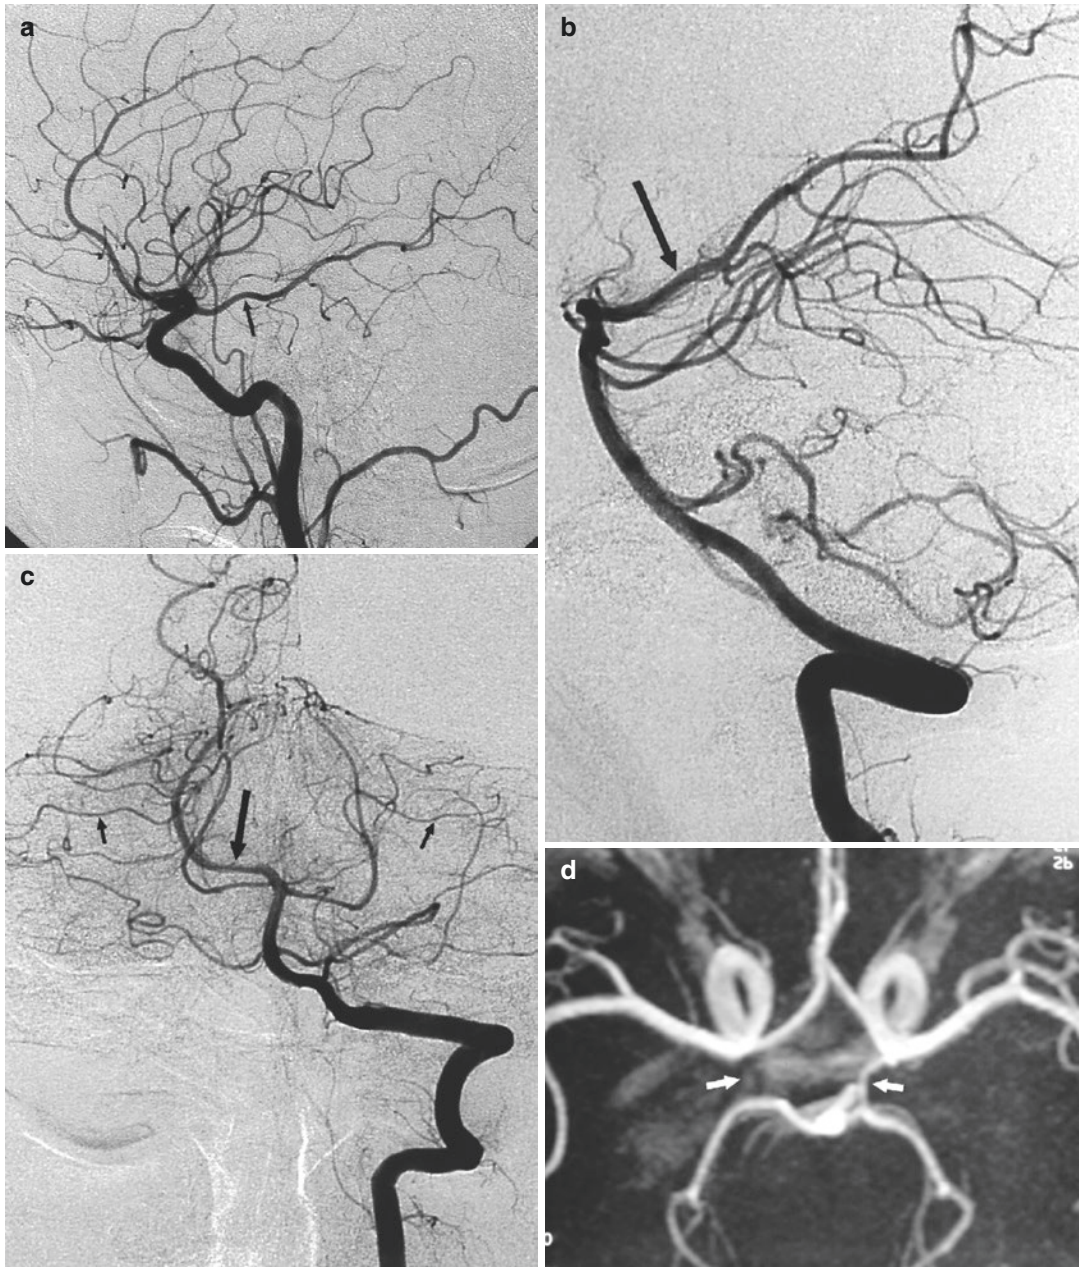

Fig. 7.5 (**a**, **b**, **c**) Angiographic study in the same patient. (**a**) Left PCA arising directly from the ICA (fetal pattern; *arrow*), (**b**) lateral vertebral angiogram showing the right PCA (*arrow*), and (**c**) vertebral angiogram, AP view. Right PCA (*arrow*) arising from the basilar artery. Hypoplastic or absent left P1. The marginal artery of the left superior cerebellar artery (*small arrow*) is easily identifiable. Owing to the minimal overlap, the right marginal artery is also well recognizable (*small arrow*). There are two well-developed AICA. (**d**) MR angiography in another patient. Left PcomA (*arrow*). On the right, absence of the PcomA (*arrow*)

surface of the hemisphere in the precuneus and cuneus areas and partially also the convexity of the posterior parietal and occipital regions, and the calcarine artery (P3) supplying *the primary visual cortex* and adjacent areas. Contributors in the supply of the primary visual cortex arise also from the parieto-occipital and temporo-posterior arteries.

- The splenial artery (P3) supplies the splenium. It can anastomose with the posterior pericallosal artery, branch of the ACA.
- Between the branches of the PCA surrounding the midbrain and running towards the thalamic area, there are many superficial anastomoses. However, the perforating branches which arise from them and penetrate the parenchyma are basically *end arteries* (Duvernoy 1999).
- Between the superficial distal branches of the PCA and those of the ACA and MCA there are potential leptomeningeal anastomoses at the temporo-occipital and parietal convexity. Leptomeningeal connections can develop also in the anterior part of temporo-medial convexity between the temporal branches of the MCA and PCA. From the superficial branches arise small arteries entering the brain parenchyma supplying cortex (cortical branches) and white matter (medullary branches), having the same angio-architecture already described in the vascular territories of ACA and MCA (Sects. 4.4 and 5.4). These arteries are *end arteries* without any possibility of collateral circulation.

7.7 Angiogram

The P1 segment is well demonstrated on the CT or MR angiography and on the AP view of the vertebral angiogram (Figs. 7.2 and 7.6). The perforators appear as small branches directed upward and somewhat posteriorly, respectively,

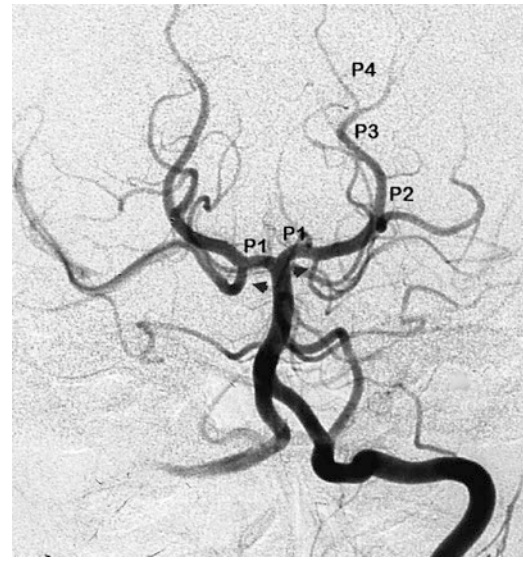

Fig. 7.6 Vertebral angiogram, AP view. The retrograde injection of the PcomA bilaterally (*arrow*) allows the precise definition of the P1 segment of the posterior cerebral artery (PCA). The P2, P3, and P4 are also shown

in the AP (Figs. 6.6, 6.12, and 7.8) and lateral view (Fig. 7.9). The P2 segment is better visualized in the AP view in its course surrounding the midbrain. In the lateral view, the segments of both sides are superimposed. Among the branches arising from the P2, the thalamogeniculate and both medial and lateral choroidal arteries are distinct on the lateral angiogram (Fig. 7.9). The thalamogeniculate arteries consist of one or more small branches running upwards and slightly posteriorly between the posterior thalamo-perforators and the choroidal arteries. The medial choroidal frequently forms a double curve with a posterior convexity, and the lateral choroidal arteries form a simple curve with a posterior convexity located posterior to the medial choroidal arteries (Wackenheim and Braun 1970) (Fig. 7.9). In Figs. 12.5, 12.7, 12.9, 12.26, and 12.27 are presented examples of involvement of the artery in arteriovenous malformation.

The lateral branch of the posterior choroidal artery can lead to a blush in the capillary phase visible in the AP and lateral views corresponding to the plexus of the lateral ventricle.

As far as it concerns the branches supplying the hemispheres, the anterior temporal branches, which arise from P2, are well recognized on the AP and lateral views. On the latter projection they have a course that is anterior to the basilar artery (Fig. 7.9). The more distal branches arising from the P2 and P3 segments can be easily recognized on the AP and lateral views (Figs. 7.6, 7.7, 7.8, and 7.9). A more precise identification, however, is possible on the lateral angiogram, where in particular the calcarine artery can be easily identified owing to its particular course and location between the parieto-occipital superiorly and the temporo-occipital arteries inferiorly (Fig. 7.9). On the AP view, superimposition of these branches makes their precise identification more difficult. Basically, the calcarine artery runs in the paramedian area, medially to the parieto-occipital artery. The splenial artery is easily identified on the lateral angiogram located posteriorly to the choroidal arteries (Fig. 7.9).

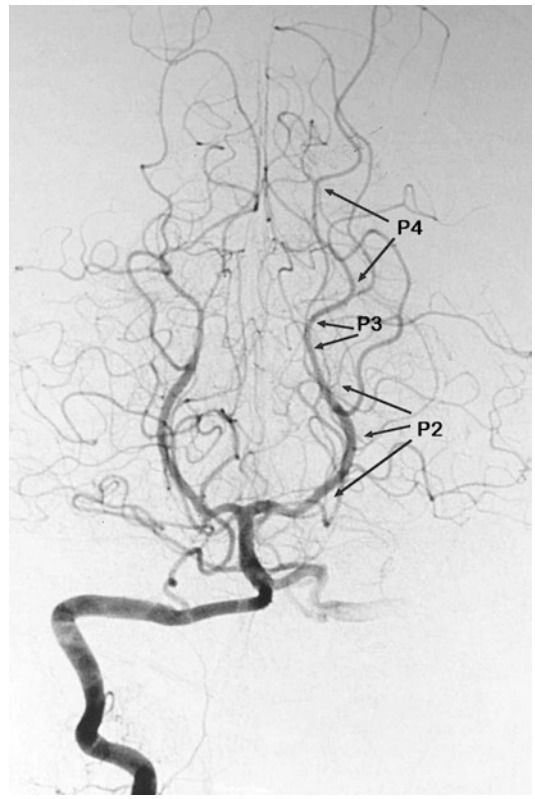

Fig. 7.7 Vertebral angiogram, AP view, showing the typical course of the PCA with its typical P2, P3, and P4 segments

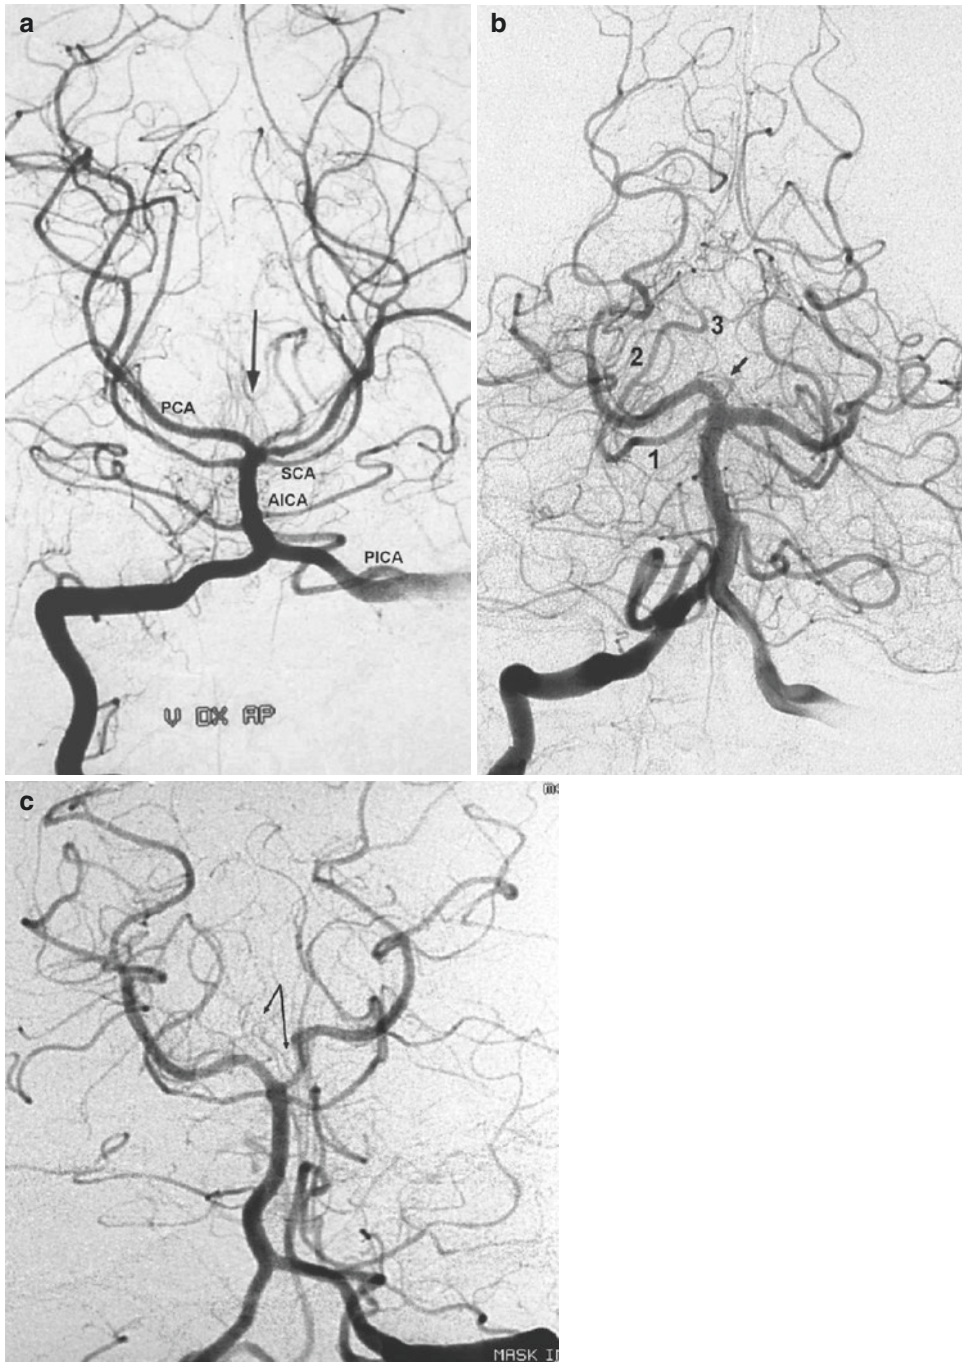

Fig. 7.8 (**a**) Vertebral angiogram, AP view. The posterior thalamoperforating branches (*arrow*) are well visible. They arise prevalently from the right P1. There is a partial overlap with distal branches of the left posterior inferior cerebellar artery (PICA). Anterior inferior cerebellar artery (AICA), superior cerebellar artery (SCA), and posterior cerebral artery (PCA). The PCA and SCA both run around the midbrain. In the AP view, the SCA is medially located. (**b**) Vertebral angiogram, AP view. A faint network of vessels corresponding to the posterior thalamoperforating artery is recognizable, in which a larger branch arising from the right P1 (*arrow*) predominates. The numbers 1, 2, and 3 correspond, respectively, to the pontine, midbrain, and quadrigeminal segments of the SCA. (**c**) Vertebral angiogram, AP view. Ascending course of the P1 owing to a short basilar artery. At least three well-developed posterior thalamoperforating arteries are recognizable: two on the left and one on the right (*double arrow*)

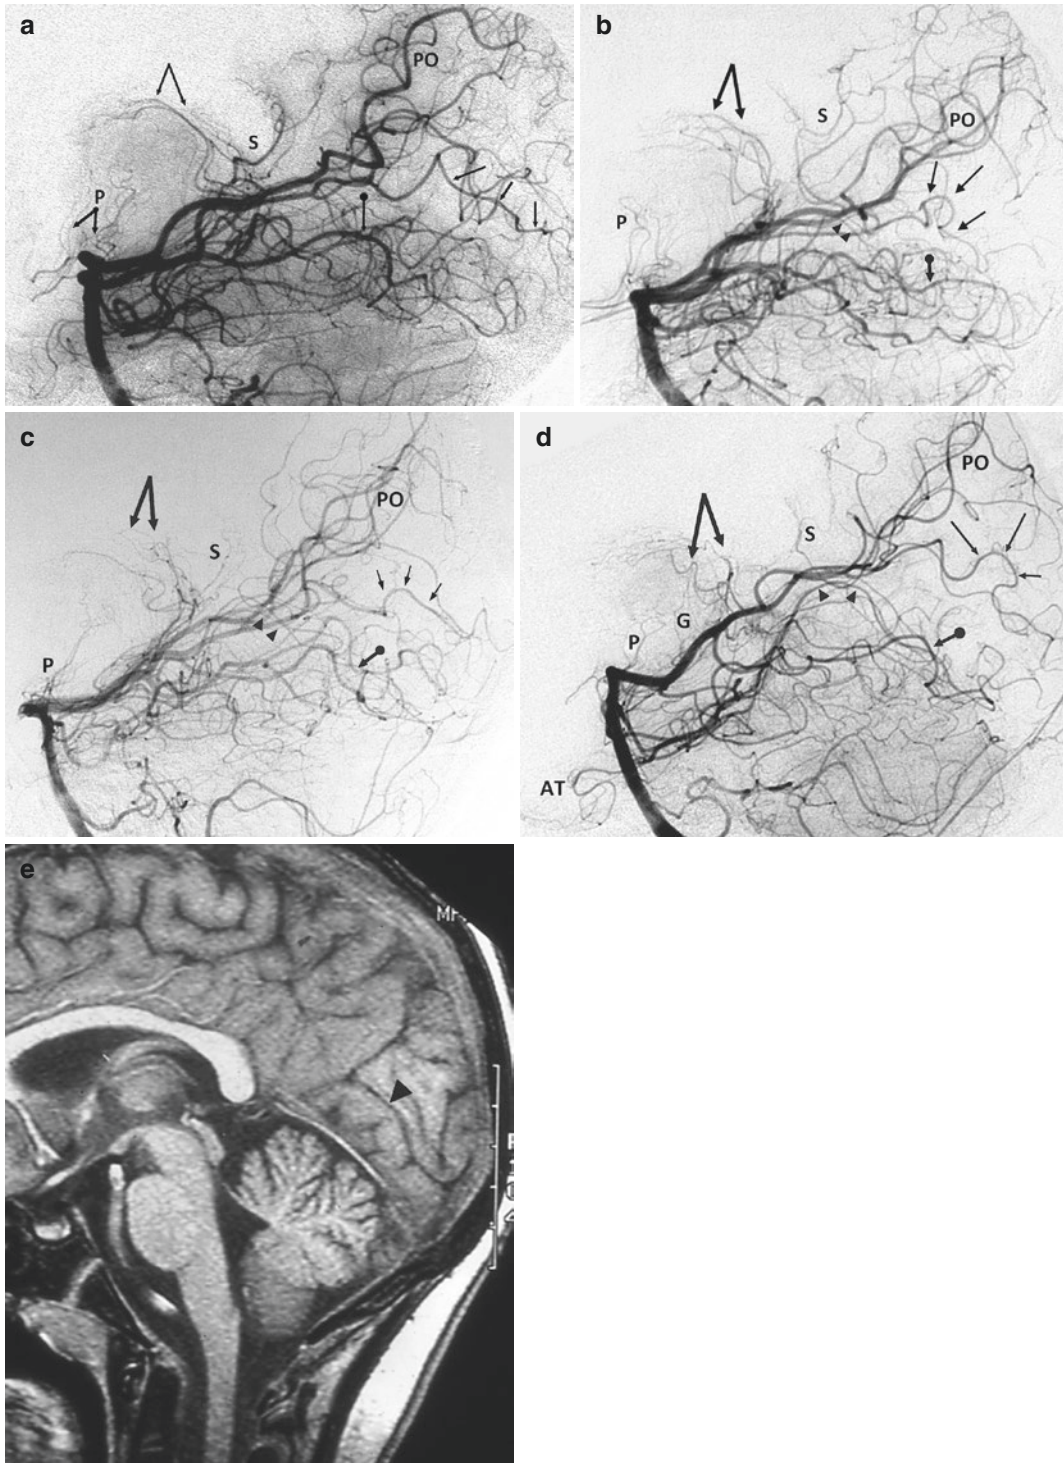

Fig. 7.9 Vertebral angiograms (**a**–**d**), lateral views in four different patients. Thalamoperforating artery arising from P1 and PcomA (P). Medial and lateral posterior choroidal arteries (*arrow with dot*). Splenial artery (S). Thalamogeniculate artery (G) recognizable in (**d**). Parietooccipital artery (PO), calcarine artery (*arrows*), posterior temporal artery (*arrow with dot*). Anterior temporal branch recognizable in (**d**). There is overlap of the temporal branches of the PCA and the cerebellar branches of the SCA. The latter can be identified owing to their typical superiorly convex curve (*arrowheads*). (**e**) T1-weighted MR showing the typical calcarine fissure (*arrowhead*)

Vascular Territories

8

In this chapter, the vascular territories of the brain as viewed in the axial planes on CT or MRI are presented (Figs. 8.1 and 8.2). The cerebral hemispheres are vascularized by the anterior cerebral (ACA), middle cerebral (MCA), posterior cerebral (PCA), and anterior choroidal (AchA) arteries. From the proximal segments of these arteries (A1, M1, P1) and cisternal segment of the choroidal artery arise small branches (deep perforators) that enter the brain parenchyma at the level of the anterior and posterior perforated substance supplying basal ganglia, thalamus, and internal capsule. Other perforators arise from the anterior communicating (AComA) and posterior communicating (PComA) arteries, which belong to the circle of Willis, and from the distal segment of the internal carotid artery.

The perforators are *end arteries* with no possible collateral circulation. From the more distal branches of ACA, MCA, PCA, and AchA running on the surface of the cerebral hemispheres arise perforating branches supplying cortex (cortical branches) and white matter (medullary branches). Like the deep perforators, these perforators are *end arteries*.

Instead there are potential pial (leptomeningeal) anastomoses between the distal superficial branches of all the cerebral arteries at the border (*border zone*) between their vascular territories (De Reuck 1972). There is a certain degree of variability of the extent of the vascular territory of each artery leading to changes in the location of the border zone. See also Chaps. 4, 5, and 7.

In the posterior fossa, medulla and pons are vascularized by perforators arising from the vertebral basilar, and anterior and posterior spinal arteries. The midbrain is vascularized by perforators of PCA and AchA. Furthermore, perforating branches for medulla, pons, and midbrain arise from the first segments of the three cerebellar arteries (PICA, AICA, and SCA). All these perforating branches are *end arteries*.

Cerebellum is supplied by the distal branches of the three cerebellar arteries running on the surface of the cerebellar parenchyma. From the superficial branches arise perforators supplying the cortex (cortical branches) and the white matter and deep grey nuclei (medullary branches). The perforators are *end arteries*, while potential leptomeningeal anastomoses are present among the distal superficial branches of the three cerebellar arteries (De Reuck 1972). See also Chap. 6.

Cerebral Veins

9

The very complex embryological evolution of the venous system of the brain has been largely studied by many authors (Evans 1912; Sabin 1917; Streeter 1918; Markowski 1922; Hochstetter 1938; Padget 1956, 1957; Kaplan and Ford 1966; Okudera et al. 1984). We summarize the essential points.

In the early stages, the venous drainage is characterized by *a superficial capillary network draining through three dural plexuses called the anterior, middle, and posterior dural stems in the paired primary head sinus* (*PHS*), *also called vena capitis lateralis, continuing posteriorly in the anterior cardinal veins* (*future internal jugular veins*). The further evolution is characterized by a progressive dwindling and disappearing of the PHS and changes in the three dural stems. From the anterior dural stem arises the *primitive marginal sinus* which extends medially connecting with that of the other side through plexiform anastomoses evolving in the formation of the *superior sagittal sinus* (*SSS*). Through the growth of the brain the SSS extends posteriorly continuing in the *torcular herophili* formed by the distal part of the SSS and the proximal *transverse sinus* derived from the proximal middle dural stem. From the distal middle dural and the posterior dural stems derive the *distal TS and the sigmoid sinus*, respectively, continuing in the internal jugular vein. Frequently, the SSS drains, as occurs in the adult, into the right transverse sinus. This asymmetric drainage has been explained by the more direct vertical drainage of the right cardinal vein (internal jugular vein) towards the heart, while that of the left has a more long course to reach the superior cava vein.

To the transverse sinus converge now two new temporary dural channels (Okudera et al. 1994; Padget 1957). The one is the so-called *pro-otic sinus* directed anteromedially. Its anterior remnant contributes to the formation of the cavernous sinus and for some authors also to the superior petrosal sinus. To the formed cavernous sinus converge anteriorly the developed supraorbital and maxillary veins (see Sect. 10.1) and it is connected posteriorly with the developed superior and inferior petrosal sinuses. The other one is the *primitive tentorial sinus more laterally located* and to which converge the lateral and medial telencephalic veins, precursors of the superficial and deep middle cerebral veins (SMCV, DMCV), respectively. Other tributaries are the diencephalic and mesencephalic veins. Following the growth of the temporal lobe the sinus is displaced medially favoring the connection of the SMCV in the developed CS. The sinus disappears, but in some cases it does not regress or its regression is only partial explaining the various forms of drainage of the SMCV, DMCV, and basal vein (see Sects. 9.1.1.2, 9.1.2.6 and 9.3.10).

To the dural sinuses converges progressively the superficial venous system, including the veins of the white matter (medullary veins) and the cortical veins.

The deep venous system appears later between the 6th and 11th weeks of age. It is

G.B. Bradac, *Applied Cerebral Angiography*, DOI 10.1007/978-3-319-57228-4_9

characterized by several veins draining mainly the blood of the well-developed choroid plexus of both hemispheres. These are the bilateral telencephalic, diencephalic, and mesencephalic veins entering the primitive marginal sinus, and the single median vein known *as the median prosencephalic vein* (*PV*) *described by Markowski* (1922) *or as primitive internal cerebral vein* (*Padget* 1956, 1957) *entering the primitive marginal sinus on the right through the primitive straight sinus. Later both marginal sinuses fuse together forming the SSS. The dorsal shift of the SSS leads to a posterior displacement also of the straight sinus.*

The development of the basal ganglia and thalamus and the growth of the brain result in the formation *of the new paired internal cerebral veins* (*ICV*) receiving tributaries of these structures characterized by the medullary, subependymal, and thalamic veins. The drainage of these veins is centripetally directed, differently from the superficial medullary veins which have a centrifugal flow towards the superficial system. The appearance of the ICV leads progressively to a regression of the PV, with exception of its more distal part which together with the distal segments of both ICVs forms *the Galen vein draining into the straight sinus*. In addition to the straight sinus, another primitive dural channel can be present, called the *falcine sinus* running within the falx and connecting the Galen vein with the superior sagittal sinus. It normally disappears. It can persist and be incidentally discovered during normal examinations (see Sect. 9.3.3). It is frequently the main venous drainage often associated with hypo-aplasia of the straight sinus in the Galen vein malformation which is linked to the persistence of the PV (see also Sect. 12.8).

In the meantime important changes involve the telencephalic, diencephalic, and mesencephalic veins which following the growth of the brain and the development of the primitive tentorial sinus are connected with this new structure and no longer enter the marginal sinus. Following the regression of the primitive tentorial sinus all its tributaries anastomose contributing to the formation of the basal vein. Variations in this process explain the great variations of the drainage of the basal vein and as above already mentioned of the SMCV and DMCV (Sects. 9.1.1.2, 9.1.2.6 and 9.3.10).

As far as it concerns the embryogenesis of *the veins of the posterior fossa*, the early-appearing veins are the primitive anterior vein draining the anterior part of the brainstem and the primitive posterior vein draining the cerebellar structure. In the early phases, the anterior is the most voluminous and will be involved also in the formation of the petrosal vein, its tributaries, and the superior petrosal sinus. The posterior vein is first smaller, since in this phase the cerebellum is not yet completely developed. Later, in connection with the growth of the cerebellum, a group of veins develops, draining in the transverse or straight sinuses. A partial part of the drainage of the posterior fossa will be enclosed in the Galen vein.

The pattern of the cerebral veins at the end of the embryological development is not so constant in comparison to that of the arteries. It is characterized by many variations, involving the morphology, flow direction, type of drainage, as well as presence of many connections. In spite of the great variations some typical aspects can always be recognized. The veins are basically grouped in the veins of the cerebral hemispheres (supratentorial) and those of the brainstem and cerebellum (infratentorial or veins of the posterior fossa). The drainage occurs through the sinuses and further extracranially in the jugular veins and vertebral plexuses.

9.1 Supratentorial Cerebral Veins

The supratentorial can be subdivided into the superficial and deep systems (Kaplan and Ford 1966; Salamon and Houang 1976). The first drains the blood towards the superior sagittal, transverse, sigmoid, and cavernous sinuses and the second into the internal cerebral and basal veins continuing in the Galen vein and straight sinus.

9.1.1 The Superficial System

This comprises the superficial medullary veins, which drain the superficial white matter. They run in a centrifugal direction towards the cortex, where they join the pial veins continuing in the cortical veins receiving the blood of the cortex. The latter run within the subarachnoid space along the superficial sulci, frequently crossing the gyri. Close to the sinuses, they perforate the arachnoid, and run in the subdural space (bridging veins) with a less or more long course before entering the sinuses.

9.1.1.1 Superior Group

The veins of this group have an ascending course entering the superior sagittal sinus (SSS). The group includes the veins of the lateral surface of the fronto-parieto-occipital lobes, part of the veins of the medial surface of the hemispheres (see Sect. 9.1.1.4), and those of the anterior part of the frontobasal region. The posterior part of the frontobasal area drains in the system of the basal vein (see Sect. 9.1.2.6). Sometimes, a large vein called the *vein of Trolard* (Fig. 9.1) is present anastomosing the SSS with the veins normally draining into *the superficial*

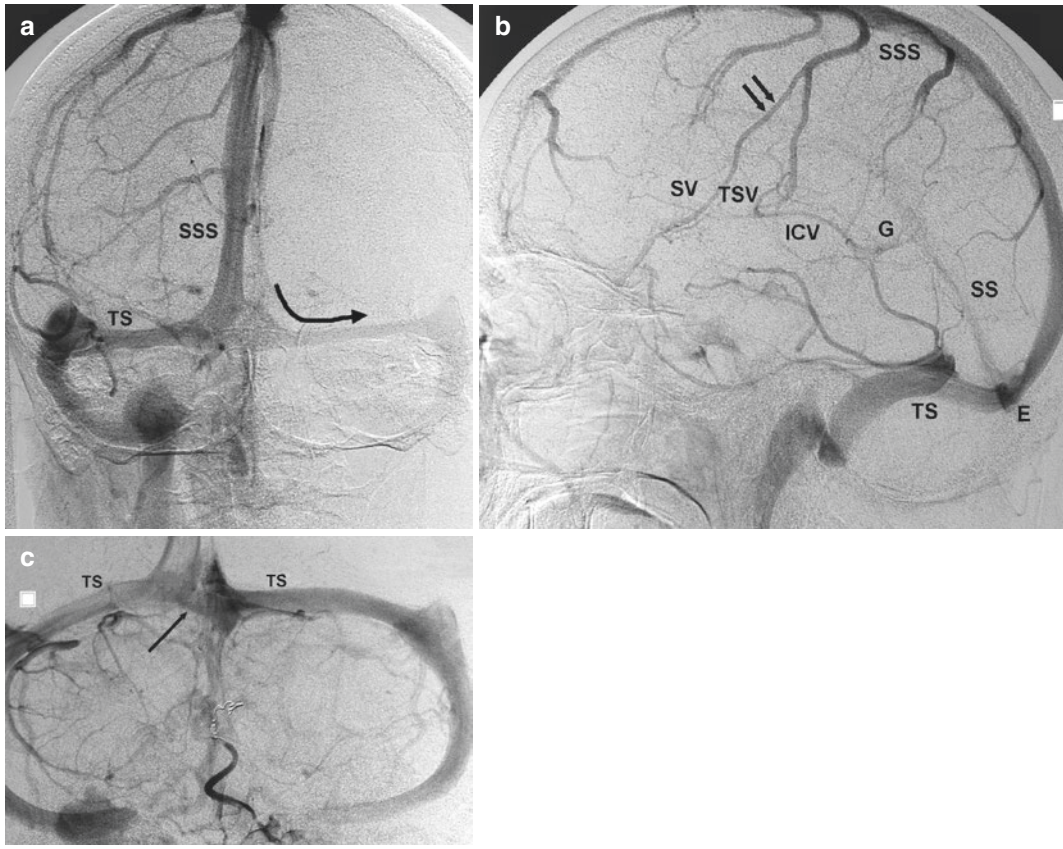

Fig. 9.1 Carotid angiogram, AP (**a**) and lateral (**b**) view, venous phase. The SSS drains predominantly in *the right TS*. The left TS is only poorly filled, since it receives blood predominantly from the SS. The SS continuing in the TS (*curved arrow*) is only faintly filled since to it drain only the right deep veins. Among the cortical veins entering the SSS, there is a large Trolard vein (*double arrow*). The drainage of the temporal region occurs into the TS. Thalamostriate vein (TSV), septal vein (SV), internal cerebral vein (ICV), Galen vein (G), straight sinus (SS), torcular herophili (E). (**c**) Vertebral angiogram in the same patient. On this angiogram is documented the presence of the *left TS*, in which drains predominantly the SS. At the torcular herophili, a complementary dural channel (*arrow*) connects the right and the left TSs (patient treated for distal PICA aneurysm, with occlusion also of the distal PICA with coils)

middle cerebral vein forming a connection between the superior and anterior-inferior group. The flow can predominate towards the SSS and so the superficial middle cerebral vein is small or also absent or the drainage occurs predominantly towards a large superficial middle cerebral vein. In the frontal area the veins enter the SSS at a right angle. The more posterior veins join the sinus, forming a progressively more oblique angle in the direction against the flow of blood into the SSS (Figs. 9.1 and 9.5). This aspect has been interpreted as due to the progressively posterior extension of the brain (Padget 1956, 1957). The veins are well recognizable on the AP and especially on the lateral carotid angiogram.

9.1.1.2 Anterior-Inferior Group

The main vein in this group is the *superficial middle cerebral vein* (*SMCV*) which collects several branches of the lateral inferior surface of the frontal and parietal area and from the lateral superior surface of the temporal lobe. It can be single or represented by a group of veins.

The SMCV runs along the surface of the Sylvian fissure, continuing into the sphenoparietal sinus (see also Sect. 9.3.9). The latter enters the sinuses *of the parasellar region* (*cavernous and lateral cavernous sinuses*) or runs towards the base of the skull, where it divides into small channels that pass through the foramina of the base, reaching the pterygoid plexus. *This variant is called paracavernous drainage* (Wolf and Huang 1963) (see also Sects. 9.3.9 and 9.3.10, Figs. 9.20 and 9.21). It can occur that the sphenoparietal sinus is absent or poorly developed and so then SMCV drains directly into the cavernous, lateral, or paracavernous sinuses (San Millan Ruiz et al. 2004; Tubbs et al. 2007b). In another type of drainage, the SMCV runs *on the floor of the middle cranial fossa reaching the superior petrous sinus or continuing within a tentorial sinus* towards the *transverse sinus*. This is due to the persistence of the primitive tentorial sinus (see also embryogenesis).

The anastomosis of the SMCV with a frontoparietal vein forming *the Trolard vein* has already been described. The SMCV can also anastomose with a temporal vein forming a large channel called *the vein of Labbé*, which runs on the surface of the temporal lobe entering posteriorly the transverse sinus (Hacker 1968, 1974). The vein of Labbé can be the dominant venous drainage of the temporal area when the SMCV is small or absent. It can also occur that the SMCV divides early into two branches, the one continuing in the vein of Labbé and the other in a frontal vein entering the superior sagittal sinus.

Examples of SMCV on AP and lateral angiograms are presented in Figs. 9.4a, b, 9.5, 9.9, and 9.10 and Drawings 9.20, 9.21, and 9.22.

As far as it concerns the *deep middle cerebral vein* and veins of the insula, see Sect. 9.1.2.6.

9.1.1.3 Posterior-Inferior Group

The veins of this group, also called the tentorial group, drain the lower lateral and lateral basal surface of the temporal and occipital lobes. These veins converge to the lateral tentorial sinus which is an intratentorial channel entering the transverse sinus. More rarely the veins drain directly in the transverse sinus or converge in a large vein of Labbé (Figs. 9.4, 9.7, 9.8, and 9.10). The veins of the medial basal surface of the temporal lobe drain into the basal vein, those of the basal occipital area into a lateral tentorial channel entering the transverse sinus.

9.1.1.4 Veins of the Medial Surface of the Hemispheres

The veins of the medial frontoparietal surface run upward, and curve over the superior margin of the hemisphere where they connect with the veins of the lateral surface, and together enter the SSS. The lower part of the medial surface involving the region of the cingulate gyrus and corpus callosum drains into the *anterior pericallosal vein* in the frontal region and into *the posterior pericallosal vein* (*splenial vein*) in the parietal area (Oka et al. 1985). The drainage can occur also partially into the inferior sagittal sinus (ISS).

As far as it concerns the medial surface of the occipital lobe, the venous drainage occurs through the anterior calcarine vein (also called internal occipital vein) which has a course anteriorly directed entering the posterior pericallosal vein, sometimes the basal vein, and through the posterior calcarine vein directed posteriorly draining into the SSS (Oka et al. 1985).

The anterior pericallosal vein is a paired vein which courses around the genu of the corpus callosum and further in the cisterna of the lamina terminalis reaching *the anterior cerebral vein* tributary of the basal vein (Drawing in Fig. 9.2). Sometimes, the anterior pericallosal vein runs upward entering the

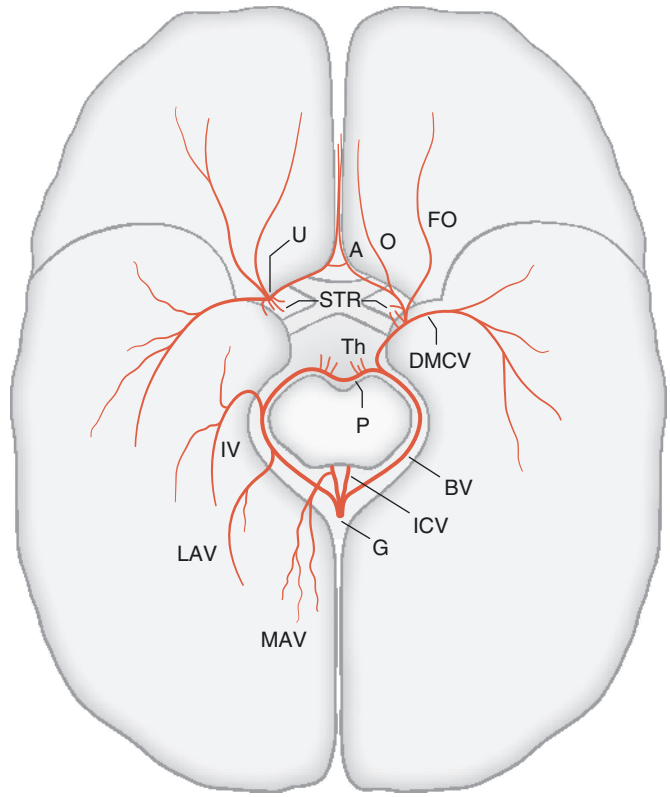

Fig. 9.2 Drawing. The basal vein and its tributaries seen from below

BV	Basal vein
ICV	Internal cerebral vein
G	Galen vein
MAV	Medial atrial vein
LAV	Lateral atrial vein
IV	Inferior ventricular vein
P	Peduncolar vein (both peduncolar vein can be connected by small posterior communicating vein)
Th	Thalamo striate veins (draining in the peduncular veins)
DMCV	Deep middle cerebral vein (draining in the BV on the right and in the uncal vein on the left)
U	Uncal vein
STR	Striate vein (draining in the DMCV)
O	Olfactory vein
Fo	Fronto orbital vein
A	Anterior cerebral vein (both anterior cerebral vein can be connected by a small anterior communicating vein)

ISS. The posterior pericallosal vein is commonly a paired, sometimes a single vein which runs in the pericallosal cistern around the splenium entering the Galen vein, sometimes the basal or internal cerebral veins (Ben-Amor and Billewicz 1970; Duvernoy 1975; Salamon and Huang 1976).

On the angiogram the veins of the medial surface are superimposed with the veins of the lateral surface and so they cannot be commonly identified. Among these veins the splenial vein can sometimes be easily recognized on the lateral carotid and vertebral angiograms (Figs. 9.6, 9.9a, and 9.10).

9.1.2 The Deep System

The deep system drains the blood of the deep structures of the cerebral hemispheres (deep white matter and deep gray nuclei with adjacent structures). The venous drainage occurs through

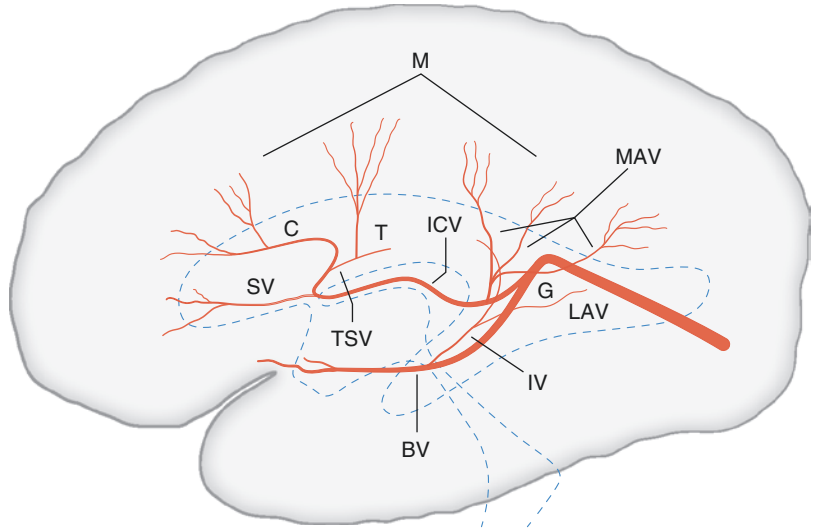

Fig. 9.3 Drawing. Lateral view of the deep cerebral veins

ICV Internal cerebral vein
TSV Thalamo-striate vein

IV Inferior ventricular vein
M Deep medullary veins
BV Basal vein
G Galen vein
T Terminal vein

several channels (medullary, subependymal, striate, thalamic, and choroidal veins). The flow is centripetally directed towards main collectors: *the internal cerebral vein and the basal vein both draining into the Galen vein. However, while the internal cerebral vein is a regular tributary of the Galen vein, the drainage of the basal vein and its tributaries in the Galen vein is not constant, since due to several variants, they can take a different way of drainage* (*see Sect. 9.1.2.6*).

9.1.2.1 Medullary Veins

These veins originate in the deep white matter and run towards the lateral ventricles, where they enter the subependymal veins (Huang and Wolf 1964; Wolf and Huang 1964). The deep medullary veins can anastomose with the superficial one, forming a continuous venous channel that extends from the cortex to the subependymal veins (Schlesinger 1939; Kaplan 1959). On the AP, better on the lateral carotid angiogram, the medullary veins especially those in the frontal and parietal regions are frequently well visible as very fine vessels directed centrally with an oblique or a perpendicular course, joining the subependymal veins. The medullary veins of the occipital and temporal areas are commonly not recognizable on the normal angiograms (Drawings 9.3 and Figs. 9.6 and 9.11).

9.1.2.2 Subependymal Veins

The subependymal veins derive their blood from the medullary veins and from the striate veins (Wolf and Huang 1964; Stein and Rosenbaum 1974; Salamon and Huang 1976). Their main function is to relay the blood to the internal cerebral and basal veins. Some of these veins (septal vein, thalamostriate, and caudate veins) in spite of possible variants are relatively constant and easily recognizable on the angiogram. The presence of others is more variable.

The *septal vein* (SV), also called the vein of the septum pellucidum, is a paired vein arising each from several tributaries characterized by deep medullary veins in the frontal region, converging to the anterior lateral corner of the frontal

horn. The SV runs further to the medial corner and then turns backward, continuing into the two sleeves of the septum pellucidum, joining the internal cerebral vein at the foramen of Monro where it joins the thalamostriate vein. It can easily be recognizable on the lateral angiogram due to its horizontal course in the frontal region towards the thalamostriate vein. Sometimes it can be duplicated with superior and inferior trunks fusing together in a unique vessel entering the internal cerebral vein. It can have an anomalous course, running in the superior part of the septum pellucidum, turning then downward, reaching the internal cerebral vein behind the foramen of Monro. It can contribute in the formation of the *direct lateral vein* together with caudate vein or be connected posteriorly with the *medial atrial vein*. (Drawing 9.3 and Figs. 9.1, 9.6, 9.11, and 12.23). It can occur in cases of DVA of the frontal region that the majority of the medullary veins or all of these drain into an anomalous common collector and not in the septal vein which in these cases can be minimally filled or completely absent (Fig. 12.25a, c). In other cases the dilated SV can be the main collector of the medullary veins in the frontal region (Fig. 9.25).

The *thalamostriate vein* (TSV) is usually prominent among the subependymal veins. It is formed by the junction of the *terminal vein*, which runs beneath *the stria terminalis* between the thalamus and the body of the nucleus caudatus, and the *caudate veins* (*CV*). The TSV is easily recognizable especially on the lateral ICA angiogram, where it is directed anteriorly and slightly caudally to join the septal vein. The pattern of the CV is more variable. Frequently (long longitudinal caudate vein) it runs on the lateral wall of the frontal horn, curving then medially with a course on the head of the nucleus caudatus joining the TSV. It is well recognizable on the lateral angiogram as a channel running above the septal vein with a course parallel to it forming then a curve towards the TSV. Sometimes the CV extends more posteriorly draining directly in the internal cerebral vein after having made a short course on the floor of the lateral ventricle. This anomalous pattern has been called by some authors *the direct lateral vein* which can receive some tributaries also from the anomalous SV. To the TSV and CV converge the medullary veins of the posterior frontal and anterior parietal regions and the superior striate veins. Despite its name, the TSV does not drain the thalamus (Giudicelli et al. 1970; Salamon and Houang 1976). Examples of TSV and its tributaries are presented in Drawing 9.3 and Figs. 9.1, 9.5, 9.6, 9.7b, 9.11, and 9.25.

Other subependymal veins are the *medial atrial* (MAV) and the *lateral atrial* (LAV) veins and the *inferior ventricular* (*IVV*) *and the hippocampal veins*. The MAV and LAV run on the medial and lateral wall of the atrium and occipital horn, respectively. They receive the medullary veins of the posterior parietal, occipital, and posterior temporal regions. The MAV is frequently well recognizable especially on the lateral angiogram as a stem formed by several tributaries entering the internal cerebral vein near the Galen vein. The LAV is a fine vessel difficult to identify on the angiogram. It can reach the MAV forming a common trunk or runs more laterally entering the IVV or the basal vein.

The *inferior ventricular vein* (*IVV*) *is the most prominent subependymal vein of the temporal region* to which converge many of the medullary veins of this area. It begins in the body of the lateral ventricle, accompanies the body and tail of the nucleus caudatus, and runs anteriorly in the roof of the temporal horn, forming an anterior concave curve. Short before the uncus it turns medially, and exits at the choroid fissure, entering the basal vein. *The hippocampal veins* are transverse channels running on the surface of the hippocampus, on the floor of the temporal horn. They exit the temporal horn connecting into a longitudinal vein running on the surface of the parahippocampal gyrus entering the IVV or basal vein. The hippocampal veins are very fine vessel, not recognizable on the angiogram. Examples of MAV, LAV, and IVV are presented in Drawings 9.2 and 9.3 and in Figs. 9.6, 9.11, 9.25, and 12.6.

9.1.2.3 Striate Veins

Striate veins drain the blood of the basal ganglia, internal capsule, and claustrum. The superior group runs towards the subependymal veins of the posterior frontal and parietal regions entering mainly the

TSV and the CV. The inferior group drains into the inferior striate veins, which run downward, and pass through the anterior perforated space reaching in the deep portion of the Sylvian fissure, the stem of the deep middle cerebral vein, which is one of the tributaries of the basal vein (Wolf and Huang 1963; Salamon and Houang 1976). These veins are rarely recognizable on the angiogram (Figs. 9.7 and 9.10) (see also Drawing 9.20b–d).

9.1.2.4 Thalamic Veins

These veins can be subdivided *into a superior group draining into the ICV and an inferior group entering the basal vein*. Among the superior group, a few drain the anterior part of the thalamus entering the ICV near the foramen of Monro. The posterior superior part of the thalamus is drained by larger veins which run first parallel to the ICV, entering this near the Galen vein.

A few of the veins of the inferior group emerge at the posterior perforated substance, reaching the peduncular veins, tributaries of the proximal basal vein, or posterior mesencephalic vein. Other drains the posterior part of the thalamus entering the distal basal vein or posterior mesencephalic vein (Giudicelli et al. 1970; Salamon and Huang 1976). They can be sometimes recognizable on the lateral vertebral angiogram (Fig. 9.16b and Drawing 9.13).

9.1.2.5 Choroidal Veins

The choroidal plexus is drained by the superior and inferior choroidal veins which enter, respectively, the ICV and BV (Ben Amor et al. 1971; Salamon and Huang 1976). The choroidal veins belong to the group of the subependymal veins. They receive blood only from the choroidal plexus and are recognizable on the carotid and vertebral angiograms as a faint blush in the capillary phase.

9.1.2.6 Collectors of the Deep System

- *The internal cerebral vein.*

  It is a paired venous channel arising at the level of the foramen of Monro or near to it. It is located near the midline, where it runs in the *tela choroidea* on the roof of the third ventricle. Each vein arises at a junction of the SV with the TSV and receives during its course several subependymal veins. Each ICV ends in the cistern of the quadrigeminal plate, below the splenium, where both veins unite and together with both BV enter the Galen vein. The ICV is always recognizable on the lateral carotid angiogram owing to its typical S-shaped form and on the AP view due to its paramedian position.

  The ICV and some of its tributaries (*SV, TSV, and CV*) *are a constant venous finding. They are better demonstrated on the later lateral angiogram when the cortical veins slowly disappear* (*Drawing 9.3 and Figs. 9.1, 9.4, 9.5, 9.6, 9.7, 9.10, and 9.11*). *Differently from the ICV and TSV, the SV appears later on the angiogram. On the AP view commonly only the ICV and the TSV are well recognizable. As far as it concerns the other deep veins, overlapping or variations and different filling make their certain identification in every case impossible. Their identification can be easier when they are enlarged, when involved in the drainage of vascular malformations* (*see Chap. 12*).

- *Basal Vein* (*BV*)

  First described by Rosenthal in the 1824, the BV is an important, frequently large vein collecting blood from the supratentorial and infratentorial veins. It is formed on the undersurface of the anterior perforated substance (APS) by the union of several veins (Drawings 9.2, 9.20b, and 9.21a). In many cases, the *deep middle cerebral vein* (DMCV) is the most important tributary of the BV, which in these cases can be considered its direct continuation (Duvernoy 1975). The DMCV is formed by several veins running on the surface of the insula (insular veins), directed inferiorly and anteriorly towards the pole of the insula (Wolf and Huang 1963). They can be recognized on the lateral angiogram as small channels directed downward with an oblique course (Figs. 9.8, 9.9b, 9.10, and 9.26c). Among them the most prominent and more frequently recognizable is the posterior insular vein running in the posterior limiting sulcus of the insula. The central insular vein with its course in the central sulcus of the insula and the most anterior insula vein which runs in the anterior limiting sulcus of the insula are more rarely identified with certainty. The DMCV runs

further medially in the deep portion of the Sylvian fissure, where it is joined by *the inferior striate veins* running through the APS. These are very fine vessels, sometimes recognizable on the AP view of the angiogram (Figs. 9.7b and 9.10). At the level of the APS, the DMCV is joined by other veins coming from *the frontobasal area* (*olfactory and frontobasal veins*) *and by the anterior cerebral vein*. This latter receives blood from the genu and rostrum of the corpus callosum by the way of the anterior *pericallosal vein* (Sect. 9.1.1.4). This latter continues in the vein of *the lamina terminalis entering the anterior cerebral vein*. The right and left anterior cerebral veins are linked by the anterior communicating vein, running above the optic chiasma (Duvernoy 1975; Ono et al. 1984). The frontobasal veins and the anterior cerebral veins are rarely recognizable on the angiogram (see Figure 9.4b).

By the union of all these venous channels at the level of the APS is formed the BV, which from its point of origin runs first medially towards the anterior surface of the cerebral peduncle continuing then around it directed posteriorly and medially towards the Galen vein. In its course the BV lies laterally to the upper part of the cerebral peduncle and medially and above the uncus. The posterior cerebral artery lies inferiorly, while the anterior choroidal artery crosses the BV superiorly from medial to lateral. In its more distal segment the BV runs slightly upward along the posterior part of the thalamus to join the vein of Galen or the ICV (Drawings in Figs. 9.2, 9.3, 9.20, and 9.21).

The BV receives along its course many tributaries. Near its origin there are *the peduncular veins* located in the interpeduncular fossa, draining the inferior thalamic veins. The peduncular veins of both sides are connected to each other by a small communicating vein. Other tributaries are *the inferior ventricular, the hippocampal, and the lateral atrial veins*, which have already been described (see Sect. 9.1.2.2), and cortical veins of *the inferomedial temporal lobe and of the medial anterior part of the occipital lobe, and sometimes the posterior pericallosal vein, also called splenial vein* (see also Sect. 9.1.1.4). Another vein that can be connected with the BV is the *lateral mesencephalic vein*, which runs in the lateral mesencephalic sulcus and can be connected with the petrosal vein, forming an anastomosis between the supratentorial and infratentorial venous sectors (Wolf et al. 1963; Bradac 1970; Wackenheim and Braun 1970; Salamon and Houang 1976).

Many variants have been described (Johanson 1954; Padget 1956, 1957; Wolf et al. 1963; Bekov 1965; Babin 1971; Duvernoy 1975; Salamon and Huang 1976): one is represented by the *posterior mesencephalic vein* (*PM*). This is a venous channel which can take its origin in the interpeduncular fossa having a long course similar to that of the BV or be present only in its more distal segment as a continuation of the lateral mesencephalic vein. The PM enters the Galen vein. It can replace the BV or be present in addition to it. In this latter case it has been proposed (Duvernoy 1975) to call this vessel the "accessory basal vein."

Not rarely the anterior tributaries mainly the DMCV which normally converge forming the BV do not connect with the BV. Instead they join together forming a common trunk called *uncal vein* due to its relationship with the uncus. This vein, which can be very prominent, drain either in the sinuses of the paraseller area (CS and LCS) or through the paracavernous sinus in the pterygoid sinus (Drawings 9.20 and 9.21 and Figs 9.4a, b, 9.5a–c, 9.7a, 9.8, and 9.10). It can also occur that the uncal vein enters the SMCV short before the latter reaches the sinuses. In these cases the BV can appear on the angiogram as very small due to the partial filling when minimal connections with the anterior tributaries are still present, or its proximal segment is not present and the distal part is replaced by the posterior mesencephalic vein. It can also occur that the distal part of the BV drains through the lateral mesencephalic vein in the petrosal vein. Sometimes the anterior tributaries of the BV do not join together but have each a separate drainage partially in the uncal vein continuing in its ways of drainage as described above and partially into the pontomesencephalic veins (Fig. 9.9a, b).

Connections between these two type of drainage can be present. Rarely the BV can drain posteriorly into the straight or transverse sinuses after a short course within tentorium due to persistence of the primitive tentorial sinus (see also embryogenesis).

On the angiogram, the BV is well recognizable in the lateral view as a venous channel, forming a slight upwardly concave curve in its course towards the Galen vein. In the AP view, the main trunk forms a small curve corresponding to the peduncular vein before showing a straight, medially directed course towards the Galen vein. The presence and recognition of its tributaries are irregular. This typical pattern can change when anatomical variations are present.

In conclusion, to the BV can converge the venous blood of many veins coming from different regions involving basal ganglia, corpus callosum, insular and frontobasal areas, as well as part of the brainstem. The drainage in the BV of these venous channels, however, is not constant, since as described above they can take a different way of drainage leading to changes in the morphological and angiographic pattern of the BV.

As far as it concerns the BV and the posterior mesencephalic vein, considering that one vessel can replace the other, and that both can be present and the numerous variants, it is not possible in the given case to establish which vessel we are dealing with. In the routine daily work, from the practical point of view, it is acceptable to define the vein visible on the carotid angiogram as the BV, since it drains blood from the supratentorial area, while the vessel visible on the vertebral angiogram draining blood predominantly from the infratentorial area can be defined as the posterior mesencephalic vein.

Aspects of the basal vein and its tributaries are presented in Drawings 9.2, 9.3, 9.20, and 9.21 and Figs. 9.4a, 9.5, 9.6, 9.7, 9.8, 9.9, 9.10, 9.25, 9.26, 12.5, and 12.6.

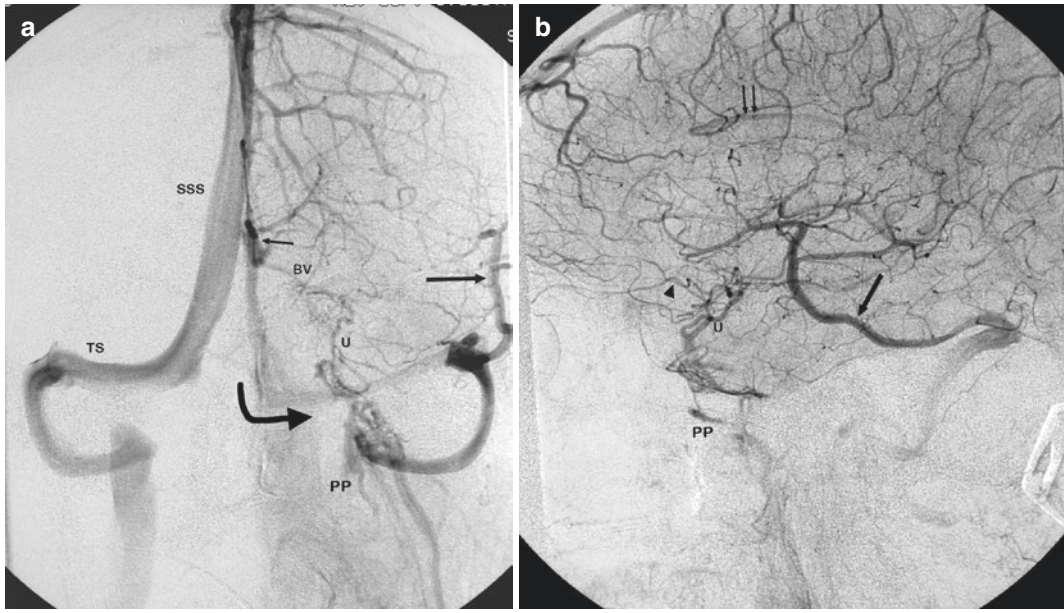

Fig. 9.4 Left carotid and left vertebral angiograms in the same patient. (**a**, **b**) Left carotid angiogram. AP and lateral views of the venous phases. The SSS drains selectively into the right TS. The distal part of the left TS is filled through a large vein of Labbé (*arrow*). Its proximal part is poor filled receiving blood only from the SS (*curved arrow*). Olfactory vein (*arrowhead*). Large uncal vein (U) receiving the anterior tributaries of the basal vein (BV), which is only partially filled. The uncal vein drains into the paracavernous sinus continuing in the pterygoid plexus (PP). Inferior sagittal sinus (*arrows*). (**c**, **d**) Vertebral angiogram. The SS is better filled receiving blood from the thalamic and pontomesencephalic veins. It enters the left TS which is therefore better filled. There is also a small connection (*arrow with dot*) with the right TS. Occipital sinus (OS). Cavernous sinus (CS) continuing in the IPS. This latter enters, on the left, the internal jugular vein more caudally than commonly

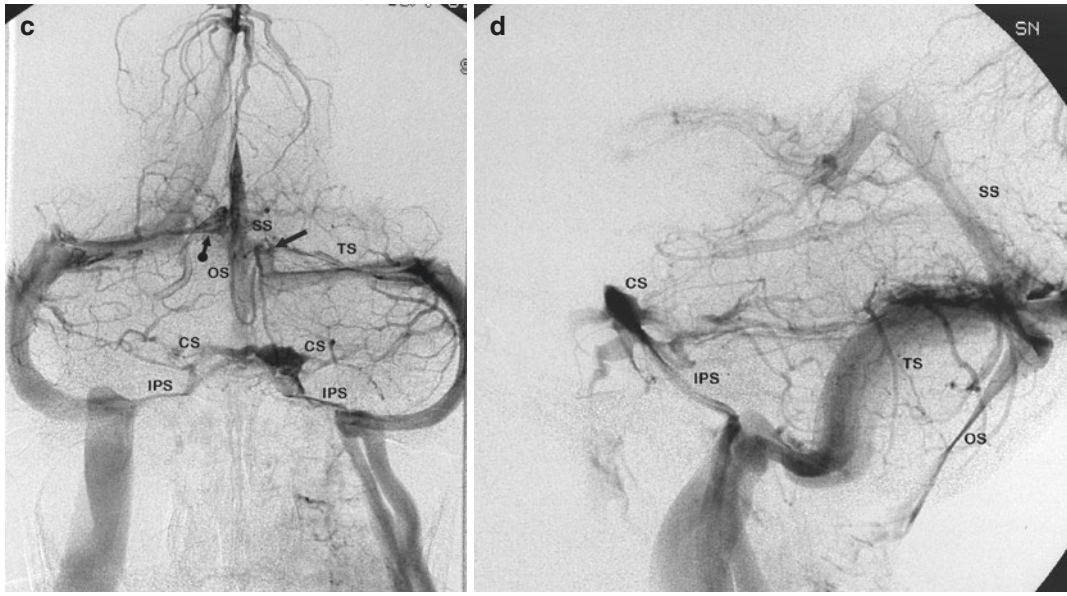

Fig. 9.4 (continued)

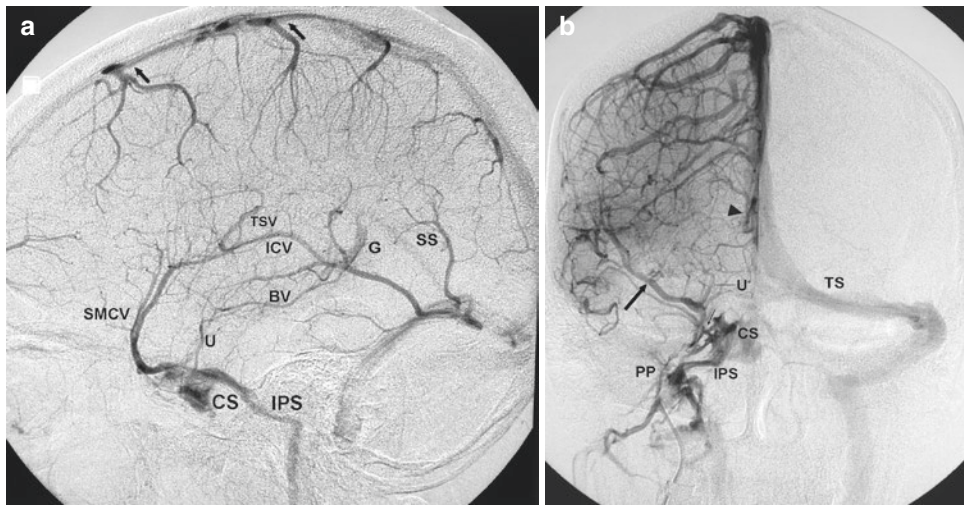

Fig. 9.5 (**a**) Carotid angiogram, venous phase, lateral view. There is a large superficial middle cerebral vein (SMCV) draining into the cavernous sinus (CS), connected with the inferior petrosal sinus (IPS). Small uncal vein (U) receiving partially the anterior tributaries of the basal vein (BV) which is consequently only partially filled. Thalamostriate vein (TSV), internal cerebral vein (ICV), Galen vein (G). Straight sinus (SS). Typical course of the cortical veins (*arrows*) draining into the SSS with frontal to occipital in a progressively reverse direction to the flow of the sinus. (**b**) AP view, right carotid angiogram, venous phase in a different patient. Preferential drainage of the SSS in the left TS. Internal cerebral vein (*arrowhead*) draining in the Galen vein and further in the SS which is, however, not recognizable due to the faint amount of contrast medium. The duplicated SMCV (*large arrow*) drains mainly into a venous channel located laterally to the cavernous sinus (CS), corresponding probably to a lateral cavernous sinus. Anastomoses (*small arrow*) between the sinuses are recognizable. The further drainage occurs into the inferior petrosal sinus (IPS) and into the pterygoid plexus (PP). Uncal vein (U) draining into the SMCV. ICV (*arrowhead*). (**c**, **d**) AP and lateral views, venous phase in another patient. The SSS drains into the right TS. The left TS is poorly injected in its proximal part since it receives blood only from the SS (*curved arrow*). The distal part of the left TS is better filled through posterior temporal veins (*bidirectional arrow*). There is a SMCV composed by several branches (*arrow*) draining into the cavernous sinus and further into of the IPS. Partial drainage also in the pterygoid plexus. On the lateral view the uncal vein (U) draining into the cavernous sinus is well recognizable. Poor injection of the basal vein (BV). Internal cerebral vein (ICV). Galen vein (G)

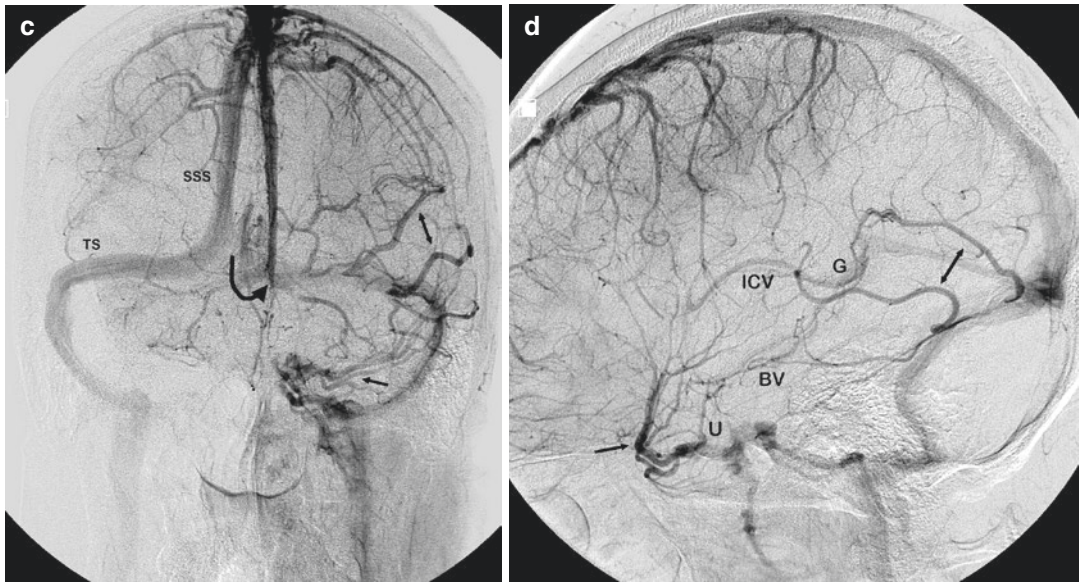

Fig. 9.5 (continued)

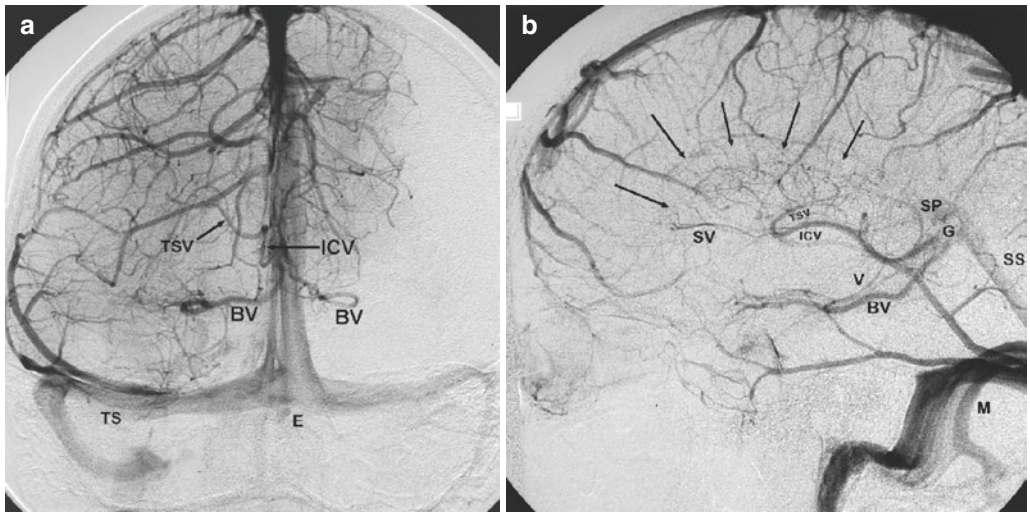

Fig. 9.6 AP (**a**) and lateral (**b**) right carotid angiogram with partial injection also of the left ICA. Venous phase. (**a**) The SSS ends in the torcular herophili (E) from which arise both TSs. The deep system drains into the SS which drains mainly into the right TS. This probably explains the better filling of the right TS. A small connection with the torcular herophili is also present. The tributaries of the deep system (TSV, ICV, and both BVs) are well recognizable. Bilateral filling of the cortical veins in the frontoparietal area draining into the SSS. The drainage of the temporal area occurs through large temporal veins which enter the TS after a short intratentorial course. (**b**) On the lateral angiogram the veins of the deep system are better demonstrated. Faint network corresponding to the medullary veins (*arrows*). Septal vein (SV), internal cerebral vein (ICV), thalamostriate vein (TSV), basal vein (BV), inferior ventricular vein (V), septal vein (SP), Galen vein (G). Straight sinus (SS). There is a large emissary mastoid vein (M)

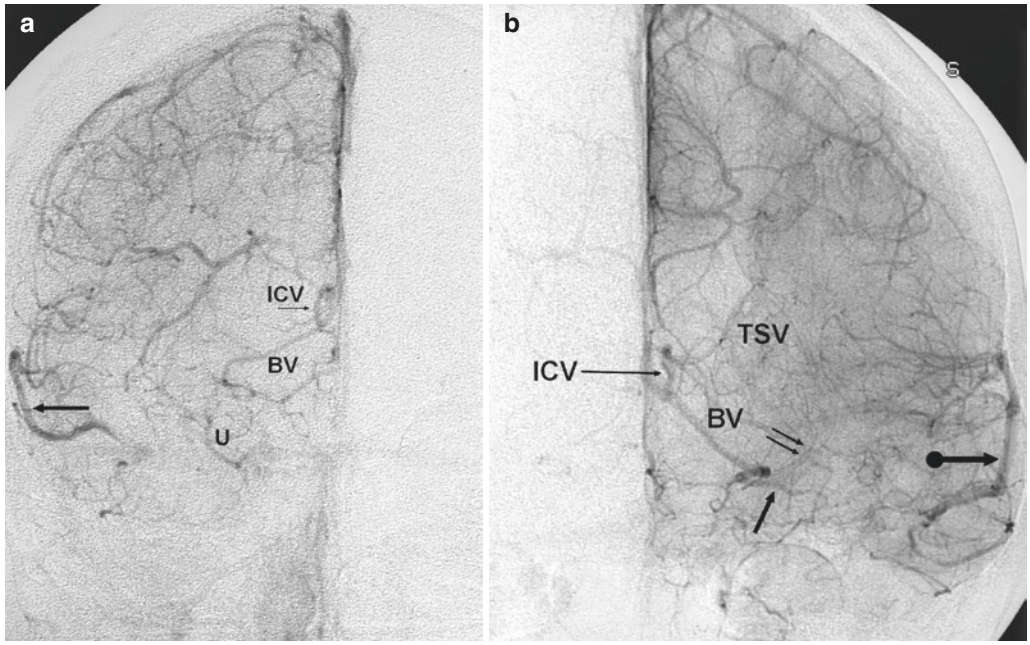

Fig. 9.7 Carotid angiogram AP view in two different patients. (**a**) Large uncal vein (U) draining into the cavernous sinus. Basal vein (BV), internal cerebral vein (ICV). The drainage of the temporal region is directly prevalently into a vein of Labbé (*arrow*). (**b**) To the basal vein (BV) converges the deep middle cerebral vein (*arrow*) collecting the inferior striate veins (*double small arrows*). Internal cerebral vein (ICV) to which converges the thalamostriate vein (TSV). Vein of Labbé (*arrow with dot*)

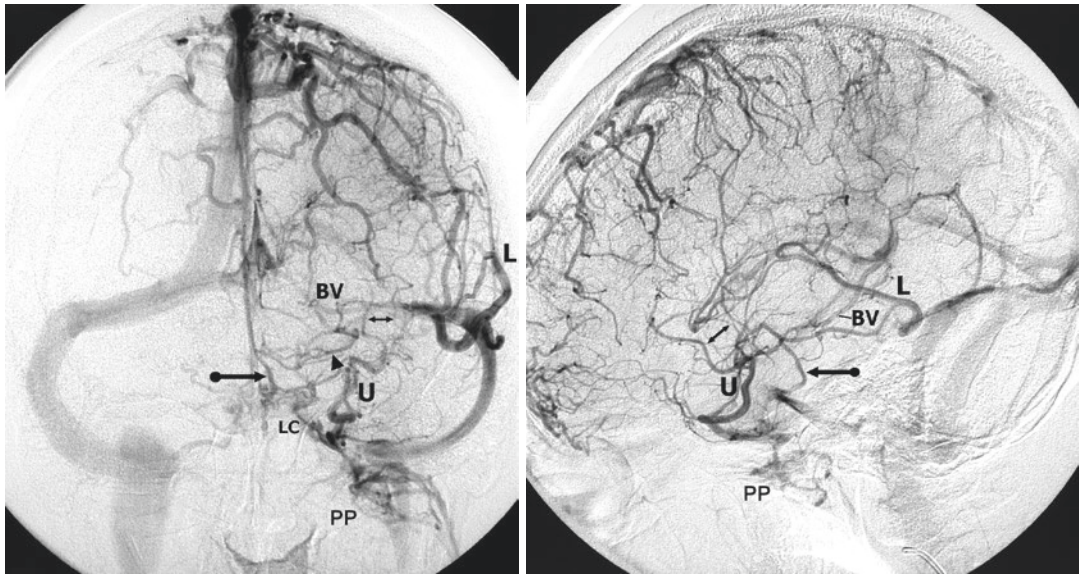

Fig. 9.8 Carotid angiogram. Venous phase AP and lateral views in the same patient (same indications). There is no SMCV; the drainage of the temporal area occurs mainly through a large vein of Labbé (L) draining into the TS. A few tributaries of the BV, among them the insular veins (*bidirectional arrow*), are well recognizable; they converge through the deep middle cerebral vein only partially to the BV. Instead they join together converging into a large uncal vein (U) draining into the paracavernous sinus continuing in the pterygoid plexus. A small component enters the lateral cavernous sinus (LC) draining further into the pterygoid plexus (PP). Another part of the drainage (*arrowhead*) is connected with the peduncular vein continuing in the pontomesencephalic vein (*arrow with dot*) which has a more lateral course than normally. Only the distal part of the BV can be recognized. It could also be the posterior mesencephalic vein

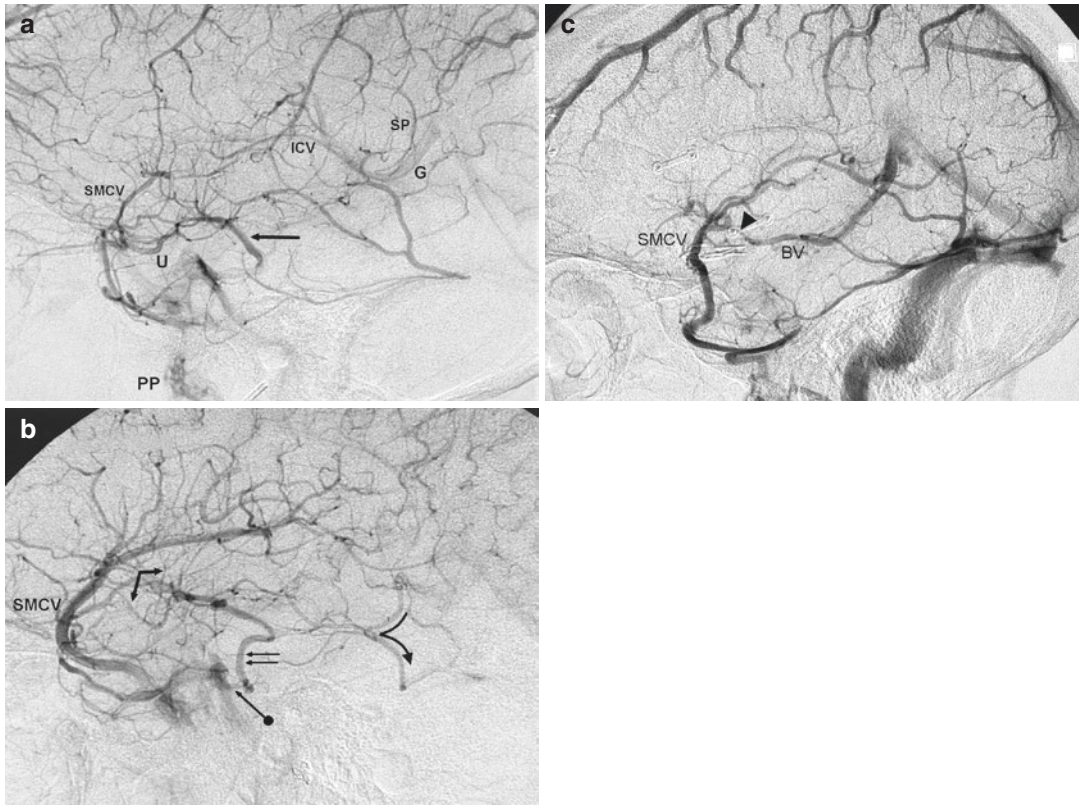

Fig. 9.9 Lateral carotid angiogram, venous phase, in three different patients. (**a**) The anterior tributaries of the basal vein do not join the vein. Instead, they converge partially into the uncal vein (U) and partially into a large lateral pontomesencephalic vein (*arrow*) which have a more lateral course than normally. The uncal vein enters the SMCV which drains in the paracavernous sinus continuing in the pterygoid plexus. BV is not recognizable. Internal cerebral vein (ICV). Galenic vein (G). Splenial vein (SP). (**b**) Large superficial middle cerebral vein (SMCV) entering the cavernous sinus. The anterior tributaries (insular veins, *arrow with angle*), which normally through the deep medial cerebral vein reach the basal vein, converge to a large antero-pontomesencephalic vein (*double arrow*). Bridging veins with the cavernous sinus (*arrow with dot*). Partial filling of the distal BV which drains into a lateral mesencephalic vein (*arrow*). (**c**) The anterior tributaries of the BV unite forming the vein on the undersurface of the anterior perforate substance (*arrowhead*). Large SMCV running through the middle cranial fossa draining partially in the pterygoid plexus continuing further into a tentorial vein draining into the TS

9.1.2.7 Vein of Galen

The vein of Galen is a unique large trunk lying in the cistern called "cistern of Galen vein." It forms a typical curve, running very close to the splenium or at various distances to it (Johanson 1954) entering the straight sinus. It is always well recognizable on the carotid and vertebral angiograms especially on the lateral view. To the Galen vein converges blood deriving from the deep structures of the cerebral hemispheres and partially from the infratentorial area.

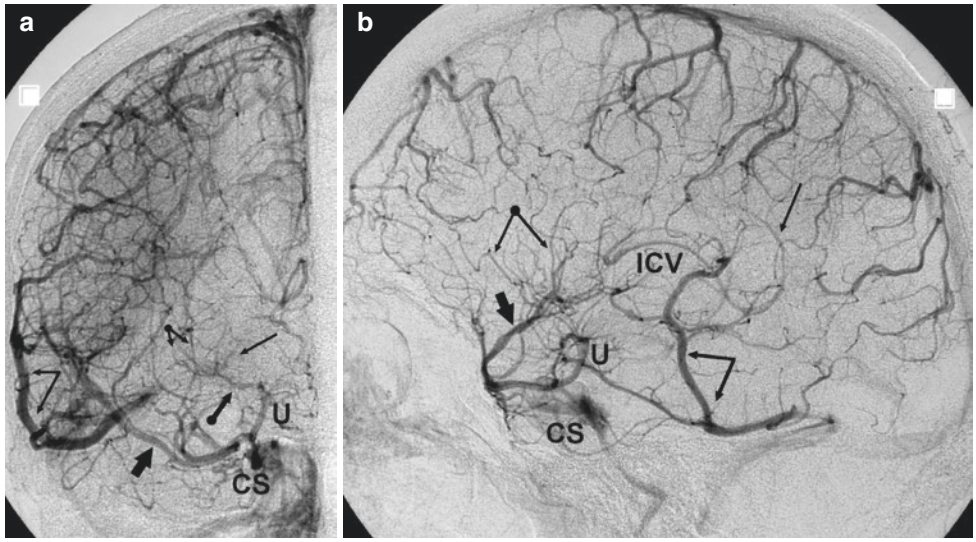

Fig. 9.10 Right carotid angiogram, venous phase AP and lateral views. (**a**) AP view. Insular veins (*arrow angle*), inferior striate veins (*small arrow*) converge to the deep middle cerebral vein (*arrow with dot*) which continues into a large uncal vein (U) which enters the SMCV (*large arrow*) draining into the CS continuing in the IPS. (**b**) Lateral view. SMCV (*large arrow*). Uncal vein (U). Cavernous sinus (CS) continuing in the IPS. The venous drainage of the temporal region occurs also through large superficial temporal veins (*arrow with angle*) which enter the TS after a short course within the tentorium. The typical BV is not recognizable. Internal cerebral vein (ICV). Splenial vein (*small arrow*)

9.2 Infratentorial Cerebral Veins (Veins of the Posterior Fossa)

Owing to the irregularity in the development and course of the veins of the posterior fossa and the frequent overlapping, it is difficult or impossible to identify all these venous channels in a given case. Some patterns, however, permit recognition on a venous angiogram of many of these veins. Three major venous drainage groups can be considered: *the superior or Galen group, draining mainly in the vein of Galen; the anterior or petrosal group, draining into the petrosal vein; and the posterior-tentorial group, draining into the transverse and straight sinuses directly or indirectly after a short course within the tentorium* (Huang and Wolf 1965; Huang et al. 1968, 1969; Bradac et al. 1967, 1971; Bradac 1970; Rosa and Viale 1970; Duvernoy 1975; Salamon and Houang 1976; Wackenheim and Braun 1978; Matsushima et al. 1983) (Drawings 9.12 and 9.13 and Figs. 9.14, 9.15, and 9.16).

9.2.1 Superior Group

This group includes many venous channels draining mainly in the Galen vein. To this group belong *the pontomesencephalic, lateral mesencephalic, medullary, precentral, superior vermian, and brachial veins.*

The anterior pontomesencephalic vein (APM) is a longitudinal venous channel running on the anterior surface of the pons in or adjacent to the midline. On the lateral vertebral and sometimes carotid angiograms the APM defines well the anterior profile of the pons. It can occur, however, that the APM is more laterally located, and so a precise morphological definition of the pons cannot be achieved. Superiorly the APM is often connected through the peduncular vein with the BV or the PM and inferiorly with the anterior medullary (AM) vein, which runs on the midline of the anterior surface of the medulla continuing caudally into the anterior spinal vein. Transverse pontine veins some-

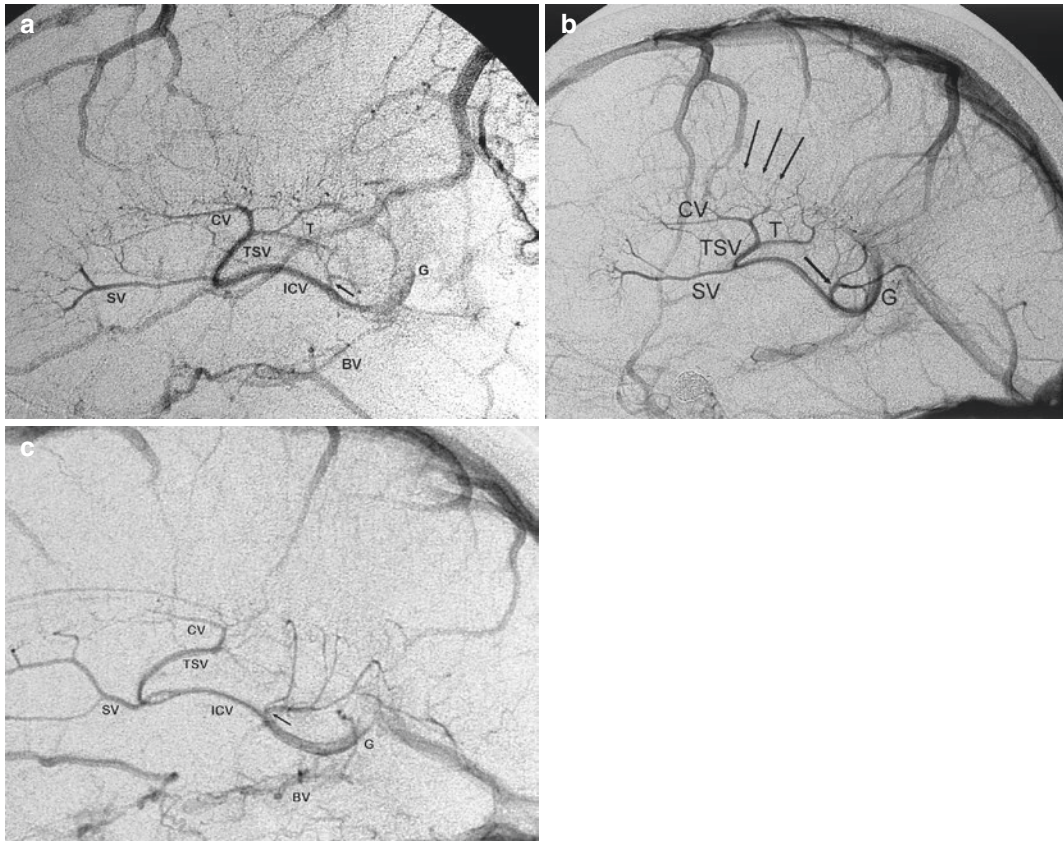

Fig. 9.11 Lateral carotid angiogram in three different patients. Late venous phase, showing detailed deep drainage. (**a**) The diffuse network corresponding to the medullary veins draining in the subependymal veins is well recognizable. Septal vein (SV), thalamostriate vein (TSV), formed by the junction of the terminal vein (T) and caudate vein (CV). Medial atrial vein (*arrow*) to which converge many tributaries. Internal cerebral vein (ICV) entering the Galen vein (G). Small basal vein (BV). (**b**) Subependymal veins. Septal vein (SV), terminal vein (T), caudate vein (CV), thalamostriate vein (TSV), medial atrial vein (*arrow*). Galen vein (G). Small ISS (*arrows*). (**c**) There is an anomaly of the septal vein (SV). Two vessels are present, one superiorly, and the other inferiorly located. Both converge to a unique trunk which enter the ICV behind the foramen of Monro. Caudate vein (CV). Thalamostriate vein (TSV). Medial atrial vein (*arrow*), Galen vein (G). Small basal vein (BV)

times relatively large running on the surface of the pons connect the APM with the petrosal vein. As described also in Sect. 9.3.10, bridging veins connect the APM with the cavernous sinus.

In addition to the anteromedial channel, there is bilaterally another longitudinally running vein or group of small veins laterally located (Tournade 1972; Duvernoy 1975). This venous channel runs on the posterolateral surface of the pons (lateral pontine veins) continuing caudally in the lateral medullary vein which runs on the posterolateral surface of the medulla. This latter leaves then the lateral position, running medially along the floor of the fourth ventricle. This segment, also called marginal vein or vein of the restiform body, fuses then on the midline with the vein of the other side forming the posterior median medullary vein continuing into the posterior spinal vein. On the surface of the medulla there are transverse channels connecting antero-median and lateral medullary veins.

The trunk formed by the lateral medullary and lateral pontine veins joins the anterior cerebellar vein (vein of the horizontal cerebellar fissure), entering the petrosal vein.

SS	Straight sinus

Fig. 9.13 Lateral view of the posterior fossa veins

The lateral mesencephalic vein (LM) runs in the lateral mesencephalic sulcus, draining superiorly into the BV or posterior mesencephalic vein (PM) or inferiorly into the petrosal vein through the brachial veins. Both connections can be present, and so the LM becomes an anastomotic channel, connecting supra- and infratentorial sectors. It can be a large or frequently a very fine vessel, well recognizable on the lateral angiogram, in particular the segment running in the mesencephalic sulcus. On the AP view, it forms a convex curve medially to the PM running downward towards the petrosal vein.

The precentral vein (PC) is commonly a single midline vessel entering the Galen vein. It originates in the precentral cerebellar fissure between the lingual and central lobule by the junction coming bilaterally of two or three branches called the brachial veins, since they cross the brachium pontis and brachium conjunctivum. Through the brachial veins the PC is connected with the petrosal vein. The brachial veins can be recognized as a channel directed downward and laterally reaching the petrosal vein.

The superior vermian vein (SV) can be a single large trunk or be formed by several small branches, which run median or paramedian over the culmen with a superior convex curve around this structure. They join the precentral vein or the vein of Galen. The precentral vein and the SV define on the lateral angiogram the superior border of the superior vermis.

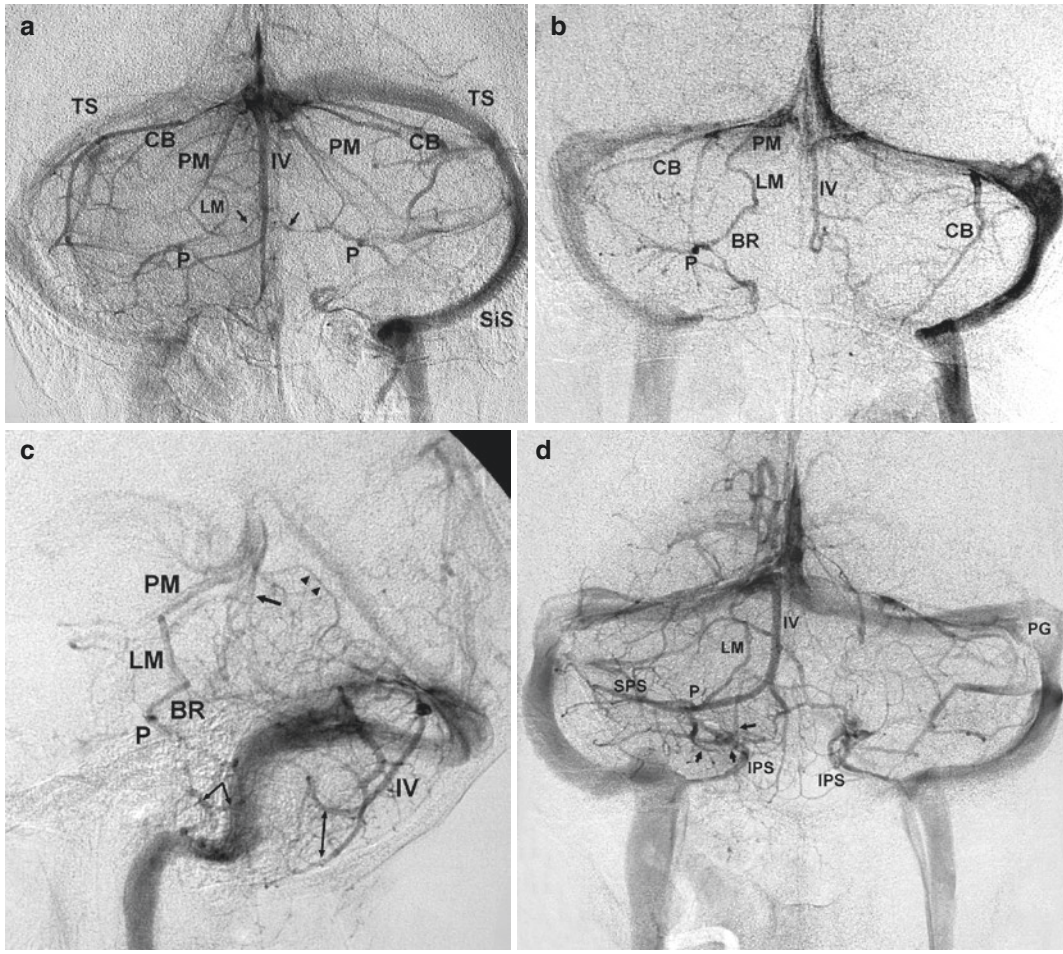

Fig. 9.14 (**a**) Vertebral angiogram, AP view, venous phase. Left and right peduncular veins (*arrow*) continuing in the posterior mesencephalic veins (PM). On the right there is a lateral mesencephalic vein (LM) connected superiorly with the PM and inferiorly through the brachial vein, with the petrosal vein (P). Inferior vermian vein (IV) with its tonsillary tributaries, hemispheric cerebellar veins (CB) draining into the TS after a short transtentorial course. The right TS is less filled since it receives blood predominantly from the SSS leading to a less concentration of contrast medium. The left TS receives blood predominantly from the straight sinus. Sigmoid sinus (SiS) continuing in the internal jugular vein. (**b**, **c**) AP and lateral venous phases in another patient. (**b**) Right lateral mesencephalic vein (LM) connecting PM with the petrosal vein (P) through the brachial vein (BR). Inferior vermian vein (IV). Hemispheric cerebellar veins (CB). (**c**) On the lateral angiogram the courses of PM, LM, BR, and petrosal vein (P) are well recognizable. There is a faint injection of the APM. Precentral vein (*arrow*). Superior vermian vein (*arrowhead*). Inferior vermian vein (IV) with its tonsillar tributaries (*bidirectional arrow*). Vein of the lateral recess of the IV ventricle (*arrow with angle*). Asymmetric filling of the TSs sinuses. (**d**) Vertebral angiogram, AP view, in another patient. The straight sinus enters the torcular herophili leading to symmetric filling of both TSs. Large Pacchionian granulations especially on the left (PG). Large inferior vermian vein (IV). Vein of the lateral recess of the fourth ventricle (*arrows*). Lateral mesencephalic vein (LM) connected caudally with the petrosal vein (P) and distally with the posterior mesencephalic vein. Superior petrosal sinus (SPS) and inferior petrosal sinus (IPS)

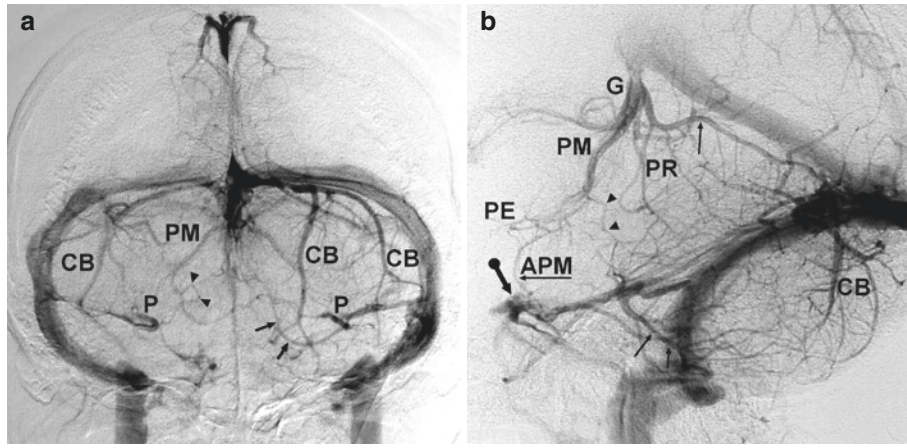

Fig. 9.15 (**a**, **b**) AP and lateral views, venous phases of the vertebral angiogram in the same patient. (**a**) AP view. The left TS is better filled, since in it drains the SS. The right TS receives predominantly the blood from the SSS. A latero-mesencephalic vein (LM) is recognizable. It is connected with the posterior mesencephalic vein (PM) and with the petrosal vein (P) draining in the superior petrosal sinus. Hemispheric cerebellar veins draining in the TS. Vein of the lateral recess of the IV ventricle (*arrows*) converging to the petrosal vein. A typical inferior vermian vein is not recognizable. It is replaced by large hemispheric vein (CB) and by the vein of the lateral recess. (**b**) On the lateral angiogram, the small LM (*arrowheads*) and the large PM are well visible. The LM is connected inferiorly with the petrosal vein to which converges also a large vein of the IV ventricle (*arrows*). Faint injection of the anterior pontomesencephalic veins (APM) connected through the peduncular veins (PE) with the PM. Cerebellar hemispheric veins (CB). Precentral vein (PR). Superior vermian vein (*arrow*). Galen vein (G) draining into the straight sinus. Bridging veins (*arrow with dot*) connecting APM with the cavernous sinus

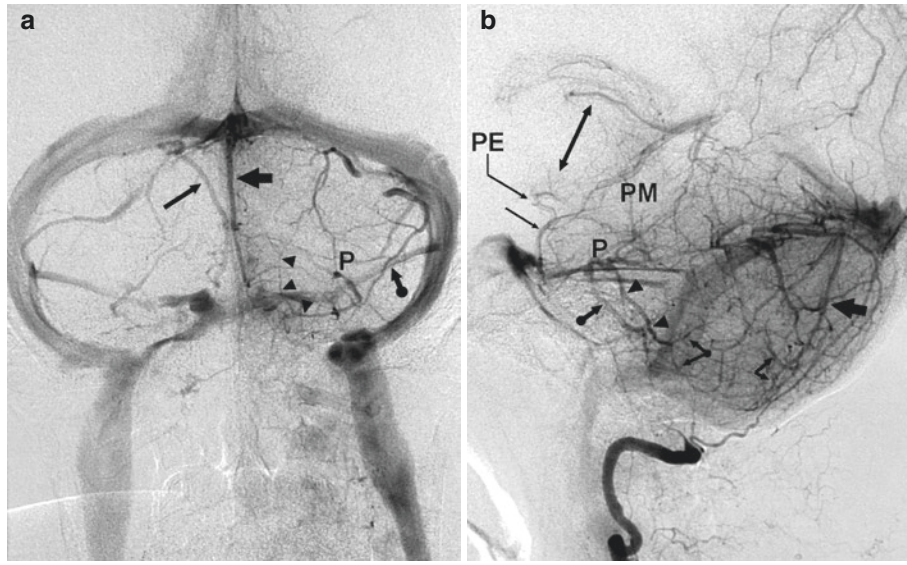

Fig. 9.16 Left vertebral angiogram. AP and lateral views. Venous phase. (**a**) AP view. Well-filled left inferior vermian vein (*large arrow*). The right inferior vermian vein (*small arrow*) is also partially injected. It drains more laterally into the TS. Vein of the lateral recess of the IV ventricle (*arrowhead*) entering the petrosal vein (P). Superior petrosal sinus (*arrow with dot*). Asymmetric filling of both TSs. That of the left is better injected probably because in it drains predominantly the SS. The right TS receives predominantly blood from the SSS. A large venous channel connects both TSs. (**b**) Lateral view. Left inferior vermian vein (*large arrow*), with its retrotonsillary tributaries (*arrow with angle*). Vein of the lateral recess of the IV ventricle (*arrowheads*) with its anterior tonsillar tributaries (*arrow with angle with dot*). Petrosal vein (P). Anterior pontomesencephalic vein (*small arrow*) connected through bridging veins with the cavernous sinus. Peduncular vein (PE). Lateral pontine vein (*arrow with dot*) continuing in the lateral medullary vein. Posterior mesencephalic vein (PM). Thalamic veins (*bidirectional arrow*)

9.2.2 Anterior Petrosal Group

This group consists of several tributaries converging to a single trunk represented by *the petrosal vein* (P), which enters the superior petrosal sinus commonly above the internal auditory meatus (Huang et al. 1968; Bull and Kozlowski 1970; Duvernoy 1975; Naidich et al. 1976; Salamon and Houang 1976). The petrosal vein is a large, but very short venous channel (a few millimeters), located in the cerebellopontine angle, running in close relationship with the trigeminal nerve. It is frequently well recognizable especially on the AP view. Tributaries of the P are the APM via the transverse pontine veins and the lateral mesencephalic and precentral veins through the brachial veins (see also Sect. 9.2.1). Other tributaries of the petrosal vein are those running on the anterior surface of the cerebellum including the superior and inferior branches entering mainly the vein of the great horizontal fissure (anterior cerebellar vein). The last tributary of the petrosal vein to be considered is the vein of the lateral recess of the IV ventricle. To it converge many branches arising especially from the inferior vermis and *tonsilla*. The vein runs first inferiorly and anteriorly, and then turns superiorly to reach the petrosal vein. It is sometimes recognizable on the AP and lateral angiograms owing to its typical course.

9.2.3 Posterior Tentorial Group

The most important vein is the inferior vermian vein. It is formed by the union of the superior and inferior retrotonsillary tributaries. It is a paired vein running posterosuperiorly in the inferior paramedian vermis sulcus, entering the straight or transverse sinuses, sometimes after a short course within the tentorium. A course more lateral is not uncommon. On the lateral angiogram, when the vein has its typical location, it is well recognizable at a variable distance from the occipital bone. On the AP view, it has a median paramedian location. The other veins of this group are the hemispheric cerebellar veins which run on the surface of the hemispheres entering the transverse sinus frequently after a short intratentorial course. The hemispheric veins can replace the inferior vermian vein when this is hypo-aplastic.

9.3 Dural Sinuses

The cranial sinuses are venous channels lying in the dura, enclosed between its external (periosteal) and internal (meningeal) layers. The wall has endothelial lining and no musculature. There is no valve inside, but frequently there are fibrous trabeculae crossing the sinus (Browder et al. 1972). Particular structures extending within the sinuses are *the arachnoid villi* (*arachnoid granulations: AG*) also called Pacchionian granulations or Pacchionian bodies from Antonio Pacchioni who first described this in the 1705. They play an important role in the returning of the cerebrospinal fluid (CSF) towards the vascular system. The AG develop from the arachnoid membrane, and grow under the influence of the pulsation of the cerebrospinal fluid invading the sinuses (Trolard 1892; Le Gros 1920; Cooper 1958). They are commonly found where to the sinus afferent cortical veins join the sinus. Indeed, as it has been demonstrated by ultrastructure microscopic studies (Krisch 1988) and described on CT-MR and angiographic examinations (Leach et al. 1996; Gailloud et al. 2001), the AG are formed by the protrusion into the sinus of the arachnoid layer and arachnoid space surrounding the vein entering the sinus. All sinuses can be involved, but the AG are found mainly in the transverse sinus (Leach et al. 1996; Gailloud et al. 2001). Other more rare locations are in the superior sagittal sinus (SSS), lacunae lateral to the SSS, and occipital and straight sinuses. They can also develop and invade the dura mater far from the sinuses extending towards the calvarium producing bone defects as large as 1 cm in diameter more typically in the frontoparietal region (Grossman and Potts 1974; Tural et al. 2012). They are commonly absent in the early childhood, appearing progressively in the adult age (Le Gros 1920; Leach et al. 1996; Gailloud et al. 2001). Commonly they can be easily differentiated from sinus thrombosis, since they never

appear as hyperdensity on CT or hyperintensity on T1-weighted images. Furthermore they are not associated with abnormal flow signs as visible on CT-MR angiography or conventional angiography (Leach et al. 1996).

Another formation which can involve the sinuses *are herniations of brain parenchyma* developing inside of the AG. They have been first described by Wolbach in the 1908 in an autoptic study. Since then, sporadic cases have been reported on angiographic and MR studies by many authors (Kollar et al. 1998; Liang et al. 2002; Chan et al. 2011; Coban et al. 2013; Kocyigit et al. 2015; Asadi et al. 2015). A large number of cases have been reported more recently by Battal et al. (2014, 2015), and by Malekzadehlashkariani et al. (2016). According to these last authors brain herniations occur more frequently in the transverse sinus, straight sinus, and calvarium of the occipital bone. In the majority of the cases, cerebellar or temporal lobe parenchyma is involved. Multiplicity is frequent. The typical density or signal of brain parenchyma on CT or MR, respectively, is identified inside of the AGs (Malekzadehlashkariani et al. 2016). They have been reported as incidental findings or in patients with various pathologies. Their possible clinical relevance has been discussed.

The dural sinuses collect blood from the superficial and deep cerebral veins and from the meninges through the meningeal veins, which accompany the respective meningeal arteries. A connection with the diploic veins and with the extracranial venous system through emissary veins is also present (see Sects. 10.7 and 10.8). The main drainage occurs bilaterally in the internal jugular vein.

9.3.1 Superior Sagittal Sinus (SSS)

The SSS arises anteriorly at the junction of the falx cerebri with the dura lining the inner table of the calvarium. At this level, the SSS communicates with the veins of the nasal cavity and then with the facial vein. It extends on the midline posteriorly, following the calvarium, forming a typical upward convex curve, ending in the torcular herophili where it continues in both transverse sinuses. The SSS is very small, sometimes absent anteriorly, while it increases progressively in caliber in its medial-posterior portion. When the SSS is aplastic in the frontal region the cortical veins, sometime represented by large bilateral paramedian cortical channels, run posteriorly to reach the SSS.

Many variants can occur (Hacker 1974). One of the most frequent is the drainage directed predominantly or entirely in one TS commonly that of the right. In these cases a large part of the blood of the superficial venous system of both hemispheres flows into the involved TS. It can also occur that in the same TS drains predominantly also the straight sinus (SS). In this condition the involved TS receives blood from the superficial and deep venous system of both hemispheres and partially also from the veins of the posterior fossa. *More frequently, however, in the cases of a predominant drainage of the SSS on one TS, the SS drains predominantly in the other TS.*

The SSS can divide into separate segments proximal to the torcular herophili, draining each segment into the corresponding TS or one segment exceptionally into the occipital sinus (Fig. 9.17d). The two segments of the SSS can be connected to each other by a small or large horizontal venous channel. In other cases the distal SSS and the torcular herophili form a complex network of small channels continuing in the TSs.

All these features are well recognizable especially on the AP view of the angiogram (Figs. 9.1, 9.4, 9.5, 9.6, and 9.17a–d).

The SSS is poorly formed in children, characterized by several irregular channels rather than a single sinus. It acquires its final aspect later in the childhood (Harwood-Nash 1974).

There are some other anatomic aspects of the SSS which should be considered, but commonly not recognizable on the angiogram. The sinus can be connected with the ISS through a venous channel running within the falx, which is commonly small, but can occasionally be very large (Oka et al. 1985). Close to the SSS there are enlarged venous pouches called "*lacunae*" connected with sinus. These are venous spaces contained in the dura most frequently in the posterior

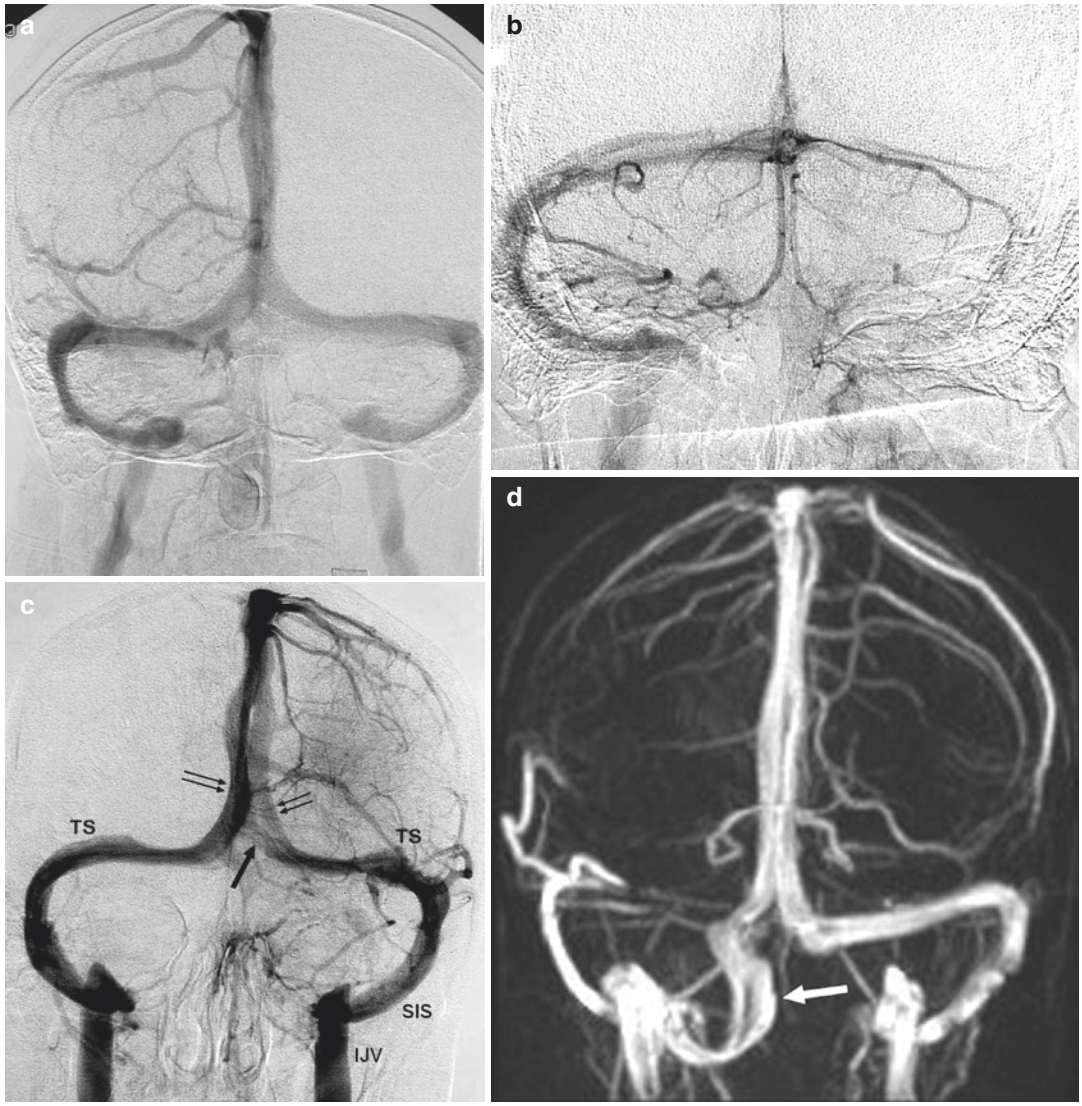

Fig. 9.17 Bilateral carotid (**a**) and vertebral (**b**) angiograms. Venous phases. (**a**) On both carotid angiograms, there is a similar venous pattern with the SSS ending in the torcular herophili. The drainage continues in both TSs, which are equally filled. The superficial venous system is equally distributed in both TSs. Into the torcular herophili drains also the SS receiving the deep venous drainage. (**b**) Vertebral angiogram. The right TS is better filled, probably due to the predominant drainage in it of the SS. This cannot be recognizable on the carotid angiogram owing to the inferior amount of blood of the SS in comparisons to that of the SSS. (**c**) Carotid angiogram. Venous phase. The SSS (*double arrows*) divides at the torcular herophili in two channels, each draining into the corresponding TS. A venous channel (*arrow*) connects both TSs. (**d**) MR angiography. Study of the venous phase. Anomalous drainage of the SSS. One distal segment drains in the left TS, and that on the right into a well-developed occipital sinus (*arrow*). The proximal part of the right TS is aplastic. It is filled by a Labbè vein. (**e**) MR T1-weighted image and angio-MR in a young patient. Incidental discovery of a large falcine sinus in which more than one channel is recognizable (*arrows*). There is a small straight sinus (*arrowhead*) (courtesy of Drs. Gozzoli G. and Boghi A. Neuroradiology. Cuneo)

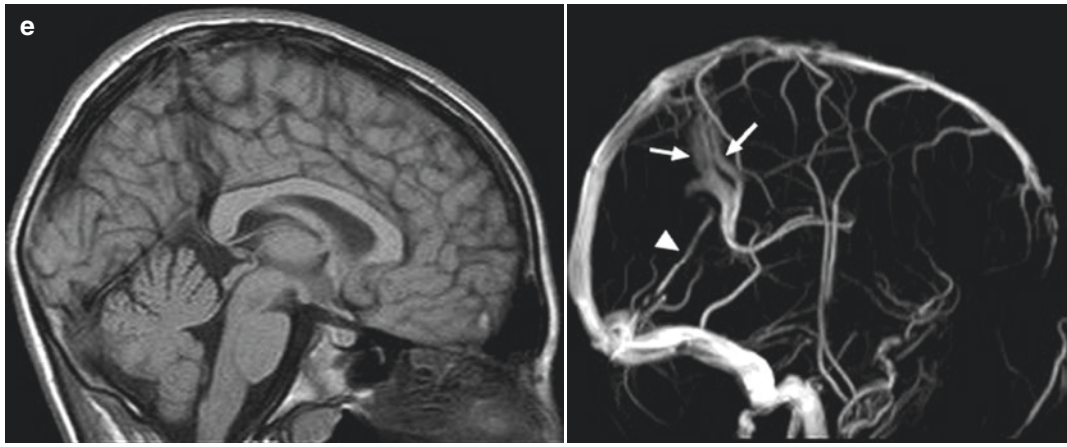

Fig. 9.17 (continued)

frontal and parietal regions. The lacunae drain the blood of the meningeal veins, and there is commonly no connections with the cortical veins which reach the SSS passing beneath the lacunae opening into the sinus separately from the lacunae. In a few cases, however, the cortical vein can empty in the lacunae (Oka et al. 1985).

Finally it should be remembered that the flow in the SSS is laminar, and so on one carotid angiogram, it can appear smaller, since the other part depends on the other carotid sector.

9.3.2 Inferior Sagittal Sinus (ISS)

The inferior sagittal sinus is commonly a small channel running within the inferior free margin of the falx, commonly a few millimeters above the edge of the falx cerebri. It begins in the anterior middle part of the falx above the anterior part of the body of the corpus callosum. It becomes larger in its course posteriorly. It ends in the falco-tentorial apex, joining the vein of Galen. Part of the venous drainage of the corpus callosum and gyrus cingula can occur in the ISS (see Sect. 9.1.1.4). It is not always visible in the angiogram since it can be very small or absent (Hacker 1974; Oka et al. 1985) (Figs. 9.4b and 9.11b). It can occasionally be very large (Figs. 9.26 and 20.5) and dilated when involved as drainage of vascular malformation (Fig. 12.11).

9.3.3 Straight Sinus (SS) and Falcine Sinus (FC)

The SS originates at the confluence of the vein of Galen with the ISS. The SS lies on the midline, at the junction of the falx cerebri with the tentorium. It is commonly one channel but sometimes can be double or triple, running downwards and backwards with an oblique course reaching the torcular herophili. In this case the blood of the SS flows equally in each TS. It can, however, occur that the SS enter selectively one transverse sinus commonly that of the left. In these cases the drainage of the deep venous system of both hemispheres as well as part of the veins of the posterior fossa occurs in one TS.

Since it drains blood from the cerebral hemispheres and also from the posterior fossa, it can be only partially filled and may give a false image of a small sinus when only a carotid or vertebral angiogram is performed (Figs. 9.1, 9.4, 9.6, 9.14, 9.15, and 9.16) (Drawings 9.3 and 9.13).

The straight sinus can rarely be associated in the normal population with *a falcine sinus* (*FC*), an embryonic vessel which runs within the falx connecting the Galen vein or the SS with the SSS. It can also be connected with the ISS. The FC normally disappears, but in some cases can persist together with the SS or replace it (Cai et al. 2009; Ryu 2010). It can be a single vessel or made up by more than one venous channels (Fig. 9.17e)

and sometimes can be characterized by an extensive network of veins not necessarily communicating with the SSS (Tubbs et al. 2007a). The FC can be present in cases of acquired occlusion of the straight sinus and typically in the Galen vein malformation (see Sect. 12.8).

9.3.4 Occipital Sinus (OS) and Marginal Sinus (MS)

This is a small channel, exceptionally very large, running on the midline from the torcular herophili, with which it is connected at its posterosuperior end. It extends anteriorly to the posterior margin of the foramen magnum and further towards the sigmoid sinus or jugular vein, draining into these venous channels. It has been reported to be larger and more frequent in neonates and younger children becoming smaller and more rare in older children and adults (Lang 1991; Widjaja and Griffiths 2004). This evolution of the OS can be explained by the upright position progressively taken by the child learning to walk considering that in this position the venous drainage occurs preferentially in the venous vertebral plexuses reducing the flow in the jugular vein and indirectly in the OS (Widjaja and Griffiths 2004).

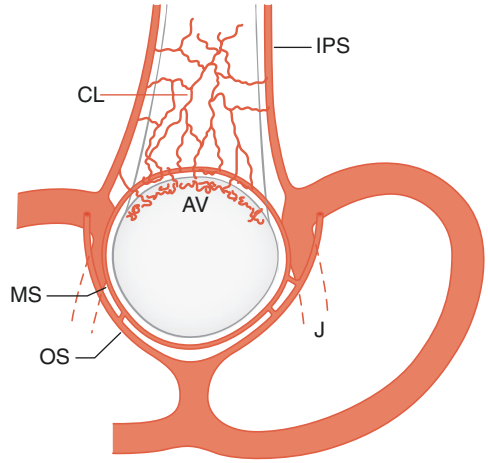
The OS is frequently well developed in the vein of Galen malformation (Sect. 12.8).

Medially the OS communicates with the marginal sinus (MS), which is a small venous channel that bilaterally surrounds the foramen magnum. The MS is connected anteriorly with the clival plexus and the jugular bulb, and anteroinferiorly with the anterior internal vertebral plexus (McDougall et al. 1997). Examples of OS and MS are presented in Drawing 9.18 and in Figs 9.4 and 9.17d.

9.3.5 Transverse Sinus (TS)

Also called lateral sinus, the TS is contained within two layers of the tentorium where it is connected with the dura of the calvarium. It begins at the torcular herophili and runs laterally and slightly anteriorly along the groove of the squamous portion of the occipital bone. It then turns downward and medially, leaving the tentorium and becoming the sigmoid sinus where the transverse and the superior petrosal sinuses meet.

The two TSs are frequently asymmetric: that of the right is frequently larger. In these cases the larger TS receives the majority of the venous drainage from the SSS which drains the superficial venous system of the hemispheres. The smaller TS, commonly that of the left, receives blood predominantly from the SS to which converge the veins draining the deep structures and those of the posterior fossa. The proximal part of the TS can be hypoplastic-aplastic while its distal part is injected by a large vein of Labbé (Kaplan et al. 1973; Hacker 1974). In some cases, the aplasia of the proximal part of the TS visible on



MS	Marginal sinus, with its connections with CL, AV and OS
OS	Occipital sinus, draining in the jugular bulb
IPS	Inferior petrosal sinus
J	Internal jugular vein
CL	Venous plexus of the clivus
AV	Anterior epidural vertebral venous plexus

Fig. 9.18 Drawing showing the marginal and occipital sinuses and tributaries. The marginal sinus (MS) circling the foramen magnum connected anterosuperiorly with the venous plexus of the clivus (CL), anteroinferiorly with the anterior epidural vertebral venous plexus (AV), and posteriorly with the occipital sinus (OS). The latter drains anteriorly into the jugular bulb or sigmoid sinus. The inferior petrosal sinus (IPS) is connected with the clival venous plexus with the anterior epidural vertebral plexus (AV) and jugular vein (J)

the carotid angiogram is only apparent, since it will be filled on the vertebral angiogram through its tributaries represented by the cerebellar veins.

Similarly to that occurring in the SSS and SS, a precise morphological image of the sinus can be obtained in many cases only if both carotid and vertebral angiograms are performed.

Examples are presented in Drawings 9.12, 9.13, 9.18, 9.21, and 9.22 and Figs. 9.1, 9.4, 9.5, 9.6, 9.14, 9.15, 9.16, and 9.17a–d.

9.3.6 Sigmoid Sinus (SiS), and Jugular Vein

The SiS is the direct continuation of the TS. It curves inferiorly and medially behind the inferior part of the petrous bone, reaching the jugular foramen where it ends in the internal jugular vein. The first segment of the jugular vein (jugular bulb) bulges upward in a rounded fossa of the temporal bone, below the internal auditory canal. The bulb is frequently larger on the right since the TS and the SiS are larger on this side (Hacker 1974; Katsuta et al. 1997) (Drawings 9.18, 9.19, 9.21, and 9.22 and Figs. 9.14, 9.15, 9.16, and 9.17a–d).

9.3.7 Superior Petrosal Sinus (SPS)

The superior petrosal sinus is a small channel lying within the attachment of the tentorium to the superior border of the petrous bone. It extends laterally, connecting with the TS. Medially it is connected with the posterior part of the cavernous sinus. The most important tributary of the SPS is the petrosal vein (Drawings 9.12, 9.13, 9.20, 9.21, and 9.22 and Figs. 9.14, 9.15, and 9.16).

9.3.8 Inferior Petrosal Sinus (IPS)

The inferior petrosal sinus lies in the groove between the petrous temporal bone and the clivus. It begins in the posterior part of the cavernous sinus and runs inferiorly and slightly laterally to join the internal jugular vein. Many reports have been devoted to the anatomy around the jugular foramen, considering especially the relationship of the drainage of the IPS into the jugular vein (Shiu et al. 1968; Miller et al. 1993; Gailloud et al. 1997; Benndorf and Campi 2002; Calzolari 2002; Mitsuhashi et al. 2007). These

Inferior striate veins (SR)

studies have shown that the IPS is commonly formed by a unique channel, but occasionally it consists of a plexus of veins. It usually enters the jugular bulb, but it can also extend extracranially, joining the jugular vein 3–4 or more centimeters below the base of the skull. It can occasionally drain into the anterior condylar vein, thereby having no connection with the jugular vein or, as we have observed in one of our cases, be connected with the posterior condylar vein. In extremely rare cases, the IPS can be completely absent.

The IPS can be identified on the carotid or vertebral angiograms or by selective catheterization (Figs. 9.4, 9.5, 9.10, 9.23, and 9.24). Drawings are presented in Figs. 9.18, 9.19, 9.20, 9.21, and 9.22.

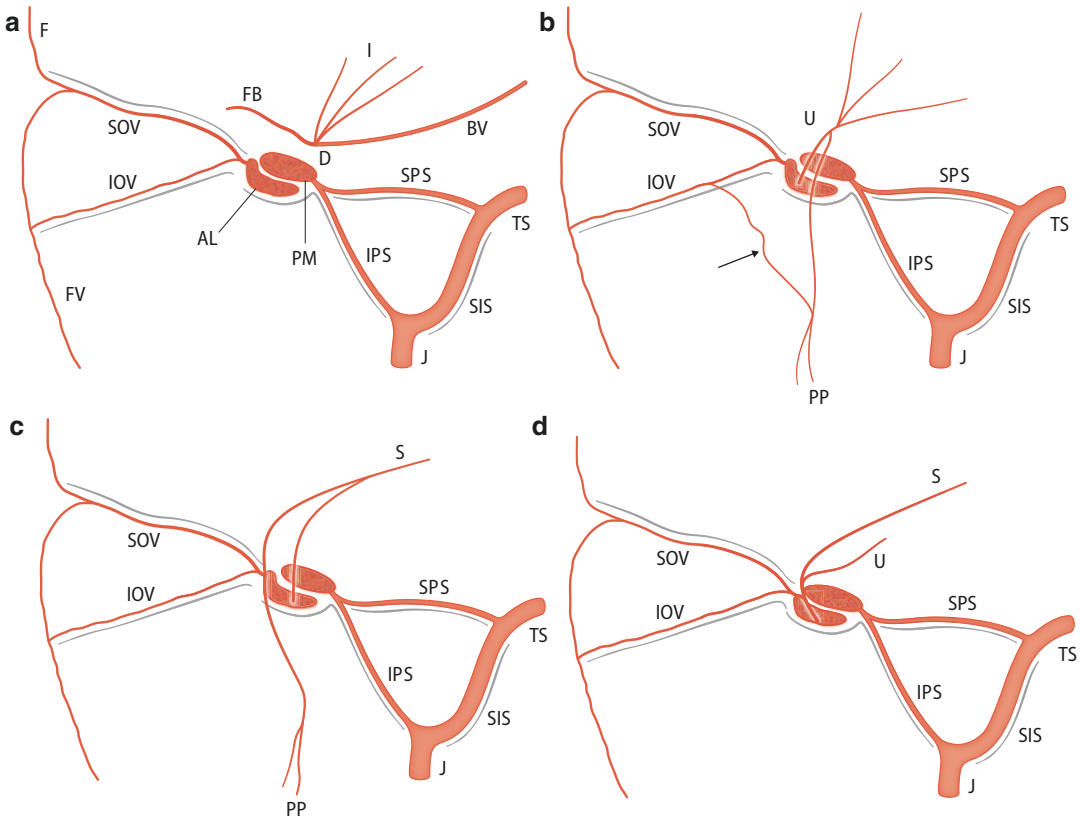

Fig. 9.21 (**a**–**d**) Lateral view. Drawings showing the most frequent ways of drainage *of the deep middle* (*D*) and *superficial middle* (*S*) *cerebral veins*. *Connections* of *the cavernous sinus with the ophthalmic veins* (*SOV-IOV*) *and petrous sinuses* (*SPS-IPS*) *are also presented. The anterolateral and posteromedial segments of the cavernous sinus between them run the ICA are indicated. The lateral cavernous sinus is not presented in these lateral views.* (**a**) The deep middle cerebral vein with its tributaries (insular and frontobasal veins) drain in the basal vein (BV). The ophthalmic veins drain into the anterolateral part of the cavernous sinus, while the petrous sinuses are connected with its posteromedial part. (**b**) The deep middle cerebral vein receiving the insular veins drains into the uncal vein which can enter the cavernous sinus or alternatively the pterygoid plexus through the paracavernous sinus. (**c**) Superficial middle cerebral vein draining into the cavernous sinus, or alternatively in the pterygoid plexus through the paracavernous sinus. (**d**) The superficial middle cerebral vein drains into the cavernous sinus. Drainage of the uncal vein into the superficial middle cerebral vein. Explication of the legend. Anterolateral (AL) and posteromedial (PM) segments of the cavernous sinus. Deep middle cerebral vein (D) with a few of its tributaries, insular veins (I), and frontobasal veins (FB). Uncal vein (U). Superficial middle cerebral vein (S). Pterygoid plexus (PP). Superior (SOV) and inferior (IOV) ophthalmic veins. Frontal (F) and facial (FV) veins. Superior (SPS) and inferior (IPS) petrous sinuses. Transverse (TS), and sigmoid (SIS) sinuses. Jugular vein (J)

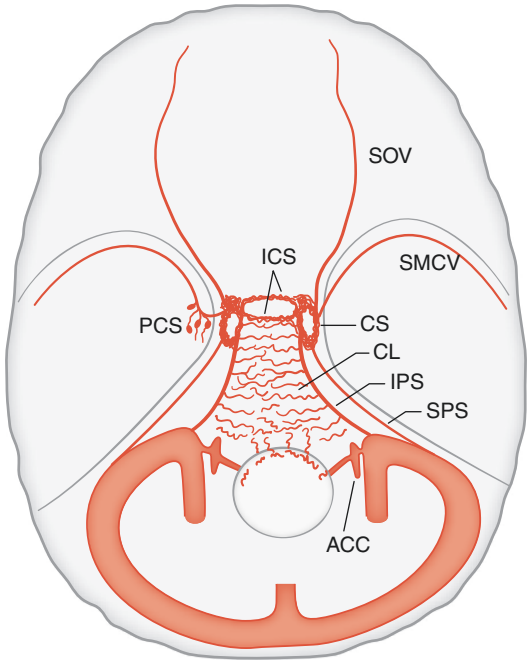
In examining the venous drainage of the craniocervical region, it should be taken into consideration that this area is a crossing point of several venous channels as described in details by some authors on the basis of anatomical, surgical, and magnetic resonance imaging studies (Katsuta et al. 1997; Arnautovic et al. 1997; San Millan Ruiz et al. 2002). These authors describe the almost constant presence of a venous pouch called the anterior condylar confluence (*ACC*), which has been described already in 1868 by Trolard. It is located extracranially, medially to the jugular vein, in front of the hypoglossal canal, slightly caudal to the junction of the IPS with the jugular bulb. *The ACC is formed by the confluence of several venous channels: the anterior, lateral, and posterior condylar veins and*



ICS	Intercavernous anastomosis
CS	Cavernous sinus
PCS	Paracavernous sinus
SPS	Superior petrosal sinus
IPS	Inferior petrosal sinus
CL	Clival venous plexus
SMCV	Superficial middle cerebral vein draining in the CS on the right and in the PCS on the left
SOV	Superior ophthalmic vein
ACC	Anterior condylar confluence

Fig. 9.22 Cavernous sinus and its tributaries seen from above. The lateral sinus is not indicated in this drawing

other small anastomoses with the IPS and the jugular bulb. Other connections are the prevertebral venous plexus, the venous plexus surrounding the petrous segment of ICA (Rektorzik plexus) and the inferior occipito-petrosal vein or inferior petro-occipital vein (IOPV). (Drawing 9.19).

The anterior condylar vein passes through the hypoglossal canal, reaching *the anterior internal vertebral plexus* (*AV*). This is an epidural venous network connected cranially with the clival venous plexus and marginal sinus, and laterally with *the venous plexus* (*VA*) *surrounding the vertebral artery in its horizontal course on the atlas*. This plexus, which has been called by Arnautovic the suboccipital cavernous sinus, has also a connection posterolaterally with the deep cervical vein. It continues downwards in the cervical region with the venous plexus surrounding the vertebral artery in its course through the foramina.

The lateral condylar vein connects the ACC with the VA and further with the AV. *The posterior condylar vein* passes through the posterior condylar foramen, located behind the occipital condyle. It connects the jugular bulb with the VA medially and with the deep cervical vein posteriorly. The posterior condylar vein can also give small connections with the ACC.

The IOPV, named in the literature also inferior petro-occipital sinus or inferior petro-clival vein, is a venous channel running extracranially along the petro occipital suture, connecting the Rektorzik plexus to the ACC or Jugular Bulb. It can, however, connect directly the CS to these structures (Benndorf, 2009; Kurata et al, 2012; Tubbs et al, 2014).

All these venous channels connected with the ACC are not always equally developed or present and so not regularly visible on the carotid or vertebral angiograms. Some connections can only be visualized on selective venograms. However, it is important to be aware of the presence of this venous circuit, since its knowledge is useful in many examinations involving this area. Indeed the IPS is an important way in the cavernous sinus sampling for the diagnosis of pituitary adenoma and can also be used in the endovascular treatment of cavernous sinus fistulae. In this context, it should be mentioned that in the catheterization of the IPS, a frequent occurrence is the entering of the catheter erroneously in one of the condylar veins especially the ACC. Further, the knowledge of the various channels present in the area is essential in the diagnosis and endovascular treatment of dural fistula in the cervico-cranial region (see Sect. 13.7) and of direct fistulae involving the vertebral artery in its course in the area (see Chap. 14).

Finally, as reported in several studies (Epstein et al. 1970; Eckenhoff 1970; Braun and Tournade 1977; Arnautovic et al. 1997; Valdueza et al. 2000; San Millan Ruiz et al. 2002) it should be emphasized that through these connections, the venous drainage of the brain can change with a flow directed prevalently in the internal jugular vein in the supine position of the body or directed

in the AV and VA in the upright position, and they can be an important collateral way in case of impaired flow in the internal jugular vein.

9.3.9 Sphenoparietal Sinus (SpS)

The SPS is also known as sinus of Breschet, since it has been described by this author in 1829. It runs within the dura as a continuation of the meningeal veins of the frontoparietal and sometimes also temporal region, accompanied by the anterior branch of the middle meningeal artery (Oka et al. 1985; Tubbs et al. 2007b). Reaching the base of the skull, it separates from the artery and runs in the dura along the undersurface of the lesser wing of the sphenoid bone draining into the cavernous sinus. Alternatively it can turn towards the floor of the middle cranial fossa draining in the paracavernous sinus and further in the pterygoid plexus. More rarely it can run along the middle cranial fossa reaching the superior petrosal or the transverse sinuses. This latter pattern, also called sphenopetrosal sinus, is considered a remnant of the tentorial sinus through which, in the embryonic age, the SMCV drains into the TS (Padget 1956). To the sinus converges commonly the SMCV (see also Sect. 9.1.1.2).

9.3.10 Cavernous Sinus (CS)

The commonly so-called cavernous sinus (*CS*) is a paired structure lying adjacent to either side of the body of the sphenoid bone (Drawings 9.19, 9.20, 9.21, and 9.22). It originates from a fold of the dura which diverges in two layers: one medial (periosteal), adherent to the periosteum of the sphenoid, and one lateral forming the medial wall of the middle cranial fossa. The lateral layer also forms the roof of the sinus, continuing medially into the diaphragma sellae. The CS extends from the superior orbital fissure anteriorly to the petrous apex posteriorly. Actually, as also described in Sect. 2.2.2, it is not a typical venous sinus, but a space containing vascular (ICA, and veins) and nervous elements called by Taptas (1982) *space of the cavernous sinus.*

As far as it concerns the venous component, according to the anatomical studies of Parkinson (1973, 1982), Parkinson and West (1982), and Taptas (1982), it is considered to be a venous plexus formed by a network of several small veins. The plexus of each side communicates via the anterior and posterior small channels running within the dura of the diaphragma sellae forming the so-called coronary sinus which surrounds the pituitary gland. The presence of the ICA leads to the formation in the cavernous space of two venous compartments: one anterolateral and the other posteromedial, which have varying connections to each other and connections with several afferent and efferent veins.

Anteriorly, the venous plexus receives the superior and inferior ophthalmic veins passing through the superior orbital fissure. *Laterally*, it is joined by the SMCV directly or through the SpS and by the uncal vein (see also Sect. 9.1.2.7). The SMCV and the uncal vein can instead drain in the *paracavernous sinus* (*P*) continuing in the *pterygoid plexus* or in the so-called *lateral cavernous sinus* (*LCS*). This latter is a small venous space, described by San Millan Ruiz et al. (1999) and Gailloud et al. (2000), located within the lateral wall of the CS. Many connections can be present between cavernous, lateral cavernous, and paracavernous sinuses in extremely various combinations which can be recognized on the angiogram as has been well demonstrated in the study of Ide et al. (2014). Furthermore the SMCV can drain into the transverse sinus through the persistent primary tentorial sinus.

The posteromedial compartment is connected with the SPS, IPS, and a network of dural veins extending on the clivus down to the foramen magnum (Hanafee et al. 1965; Doyon et al. 1974). The clival plexus is connected caudally with the anterior internal vertebral venous plexus and lateroposteriorly with the marginal sinus.

Bridging veins connect the posteromedial compartment with the pontine veins (Matsushima et al. 1983; Kiyosue et al. 2008) (see also Sect. 9.2.1, Drawing 9.13, and Figs. 9.15 and 9.16).

Aspects of the CS, LCS, and paracavernous sinuses as well as their tributaries are presented in Drawings 9.20, 9.21, and 9.22. Angiographic studies are shown in Figs. 9.4, 9.5, 9.7a, 9.8, 9.9, 9.10, 9.23, and 9.24.

9.3.11 Superior Ophthalmic Vein (SOV)

The superior ophthalmic vein arises near the roof of the nose in the superomedial angle of the orbita, by the junction of the superior tributaries' continuation of the frontotemporal veins and inferior tributaries' continuation of the angular vein, terminal branch of the facial vein (Drawings 9.20, 9.21, and 9.22). It runs backward and laterally, first outside the muscle cone, and then it enters the cone, running further laterally along the undersurface of the superior rectus muscle. In its course the vein crosses superiorly the ophthalmic artery and the optic nerve. The vein takes finally a medial and downward course, leaving again the muscle cone, passing the superior orbital fissure, and entering the anterolateral compartment of the venous plexus of the cavernous sinus (Hanafee et al. 1965, 1968; Lombardi and Passerini 1967; Doyon et al. 1974). *It can occur that the drainage is not in the CS but in the paracavernous sinus. This variant explains probably the filling of the SOV in some type of fistula without involvement of the cavernous sinus as it has been described by some authors* (Theron et al. 1975; Bradac et al. 1981b) (see also Sect. 13.7 and Fig. 13.9). *The same anomaly explains the uncommon venous pattern we have observed in a case of intraorbital angioma* (Chap. 23, Fig. 23.5).

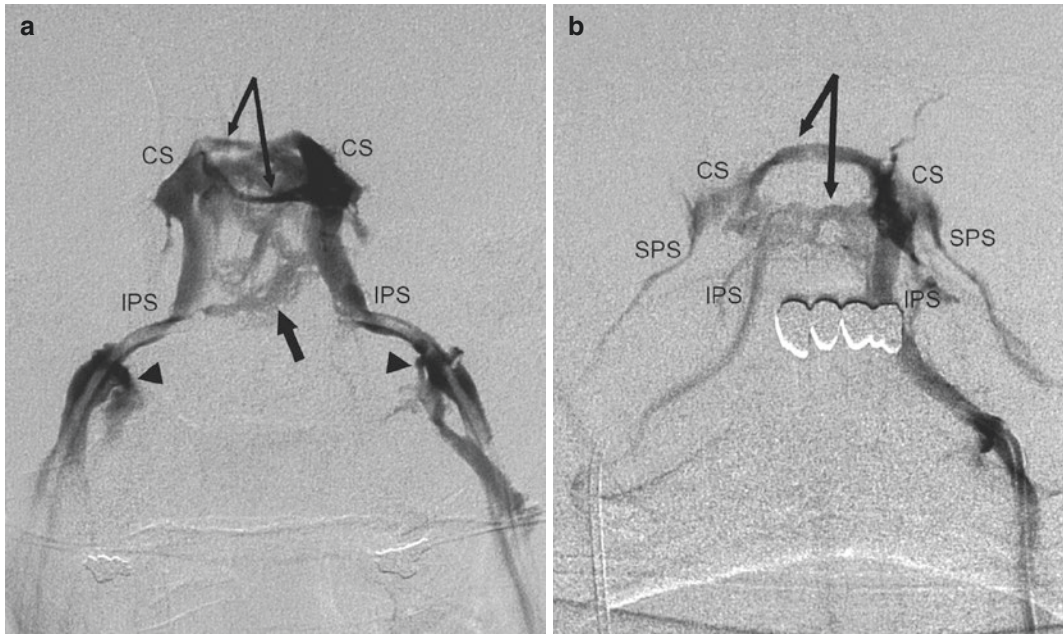


Fig. 9.23 Selective catheterization of the inferior petrosal sinus. (**a**) Catheter in both IPS. Cavernous sinus (CS). Connection between both cavernous sinuses (coronary sinus, *arrow with angle*). Clival venous plexus (*arrow*). Anterior condylar confluence (*arrowhead*). Filling also of the lateral condylar vein, better visible on the left. (**b**) Injection in the left IPS with retrograde injection also of the right IPS. Cavernous sinus (CS), superior petrosal sinus (SPS). Connections between the cavernous sinuses (*arrow with angle*). (**c**) The injection in the jugular bulb shows that the IPS consists of a network of veins. Partial retrograde injection in the contralateral IPS. Anterior condylar confluence (ACC). (**d**) Bilateral selective catheterization of the IPS. The catheters are placed at the distal end of both IPS. Injection of contrast medium through the left catheter. Retrograde filling of the left lateral condylar vein (LCV). Through the ACC there is the injection of the AV connected with the clival venous plexus (*arrow with angle*). Intercavernous sinus connections (*arrows*). Retrograde filling of the right IPS, the right lateral condylar vein (RCV) continuing distally with the vertebral artery venous plexus

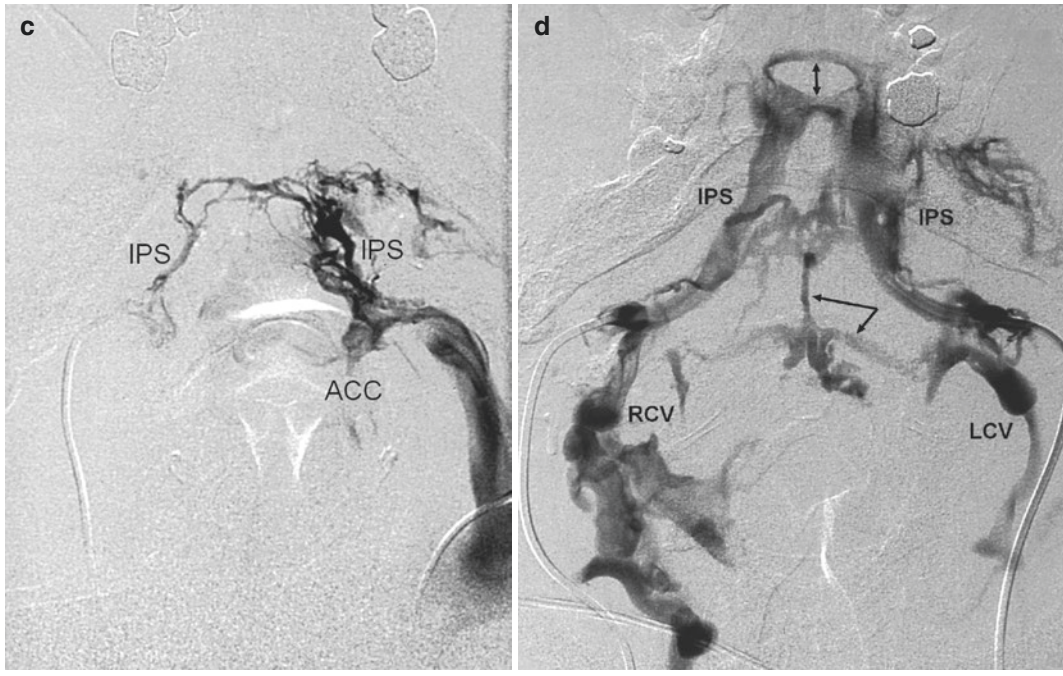

Fig. 9.23 (continued)

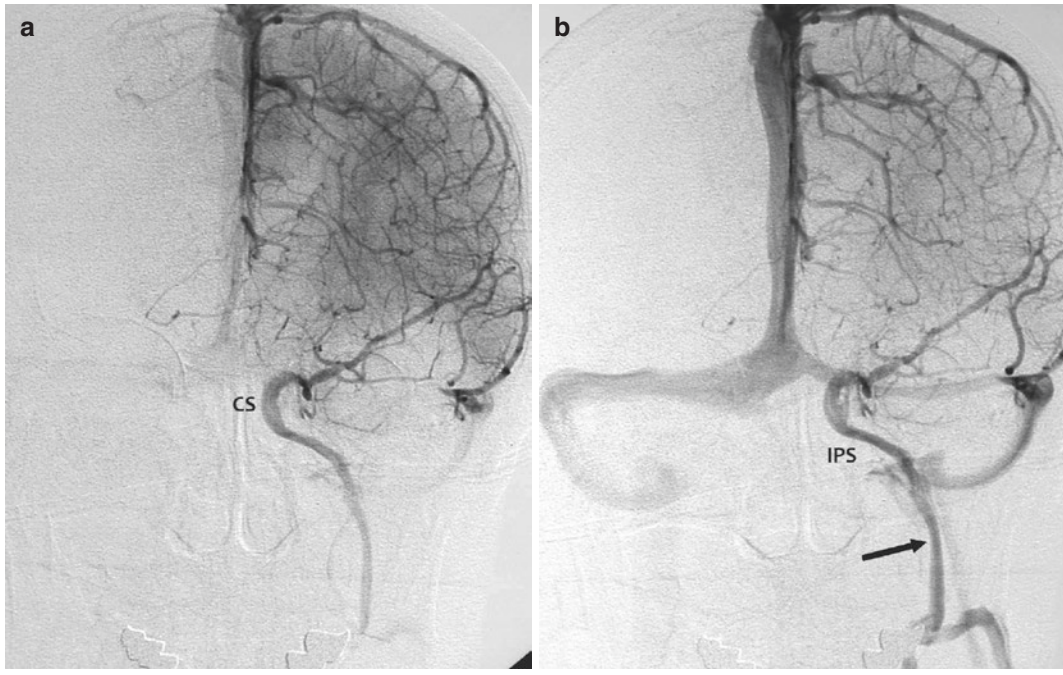

Fig. 9.24 Carotid angiogram: venous phase AP. (**a**, **b**) The cavernous sinus (CS) drains into the inferior petrosal sinus (IPS). This latter seems to have a small connection with the jugular bulb as visible in the late phase (**c**). However, the flow is directed mainly towards a venous channel (*arrow*) not connected with the IJV. Considering its course it seems to be a condylar vein, probably the lateral draining caudally in the vertebral artery venous plexus (VA) which is further connected with the distal portion of the deep cervical vein. (**d**) Lateral view, same indications

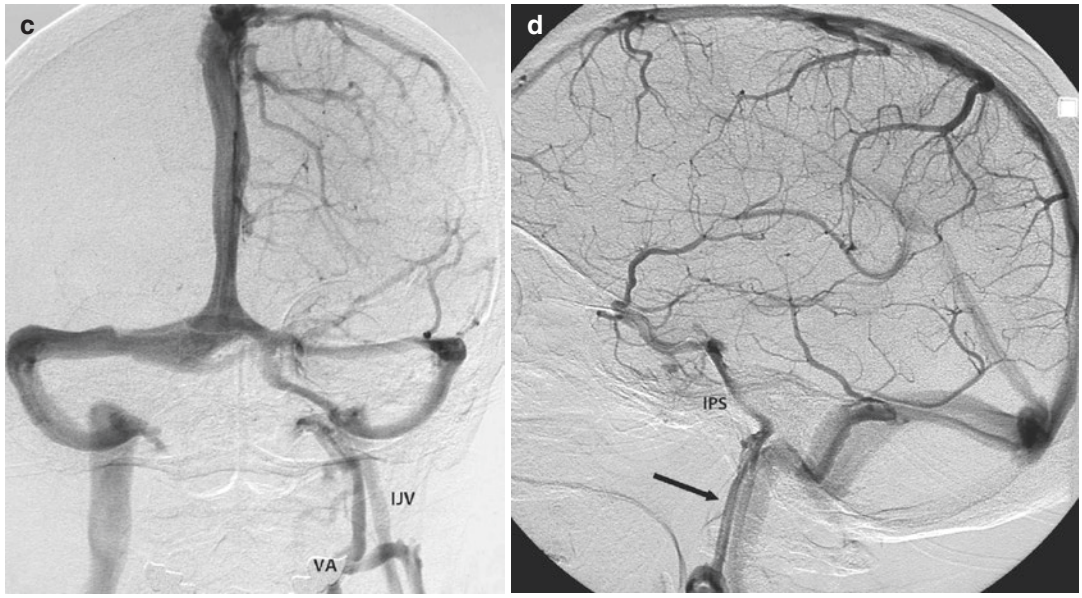

Fig. 9.24 (continued)

9.3.12 Inferior Ophthalmic Vein (IOV)

The inferior ophthalmic is a small vein, sometimes replaced by a network of fine venous channels. It lies within the muscle cone above the inferior rectus muscle. Anteriorly, it communicates with the facial vein and posteriorly it has some connections with the pterygoid plexus through fine anastomoses passing the inferior orbital fissure. The IOV drains into the CS directly or after entering the SOV (Drawings 9.20 and 9.21).

The SOV and IOV drain blood from the intraorbital (globe, muscles, fat, and lacrimal gland) and craniofacial structures through the connections with the facial and frontotemporal veins and pterygoid plexus. This explains also the fact that the ophthalmic veins, especially the SOV, are frequently recognizable in the venous phase of the external carotid angiogram (Tornow and Piscol 1971; Hacker and Porrero 1969; Bradac et al. 1974).

The SOV is an important route in the treatment of fistulae involving the cavernous sinus. This is particularly true when the venous drainage is directed predominantly in the SOV or in the cases in which the SOV is the unique possible route, since the IPS (*thrombotic occlusion, aplasia, or anomalous drainage*) or the IOPV *cannot be catheterized* (Agid et al. 2004; Kirsch et al. 2006; Kato et al. 2007; Kurata et al, 2012).

9.3.13 Considerations About Vein Variations

- As described in the previous sections, variations in the venous drainage involving the veins of the brain parenchyma and sinuses are frequent and numerous. They appear, however, with a frequent repetitive pattern allowing to consider them as *normal* anomalies.
- In some cases the anomalies can be conspicuous, as it occurs, for example in the DVAs (Chap. 12, Sect. 12.6), which have been interpreted in the past as pathological venous malformations (venous angiomas). Actually they are considered only variations without pathological significance, even if, in rare cases, thrombosis can occur.
- In other very rare cases, the variations are very complex involving a great part of the venous system, including the superficial, deep veins,

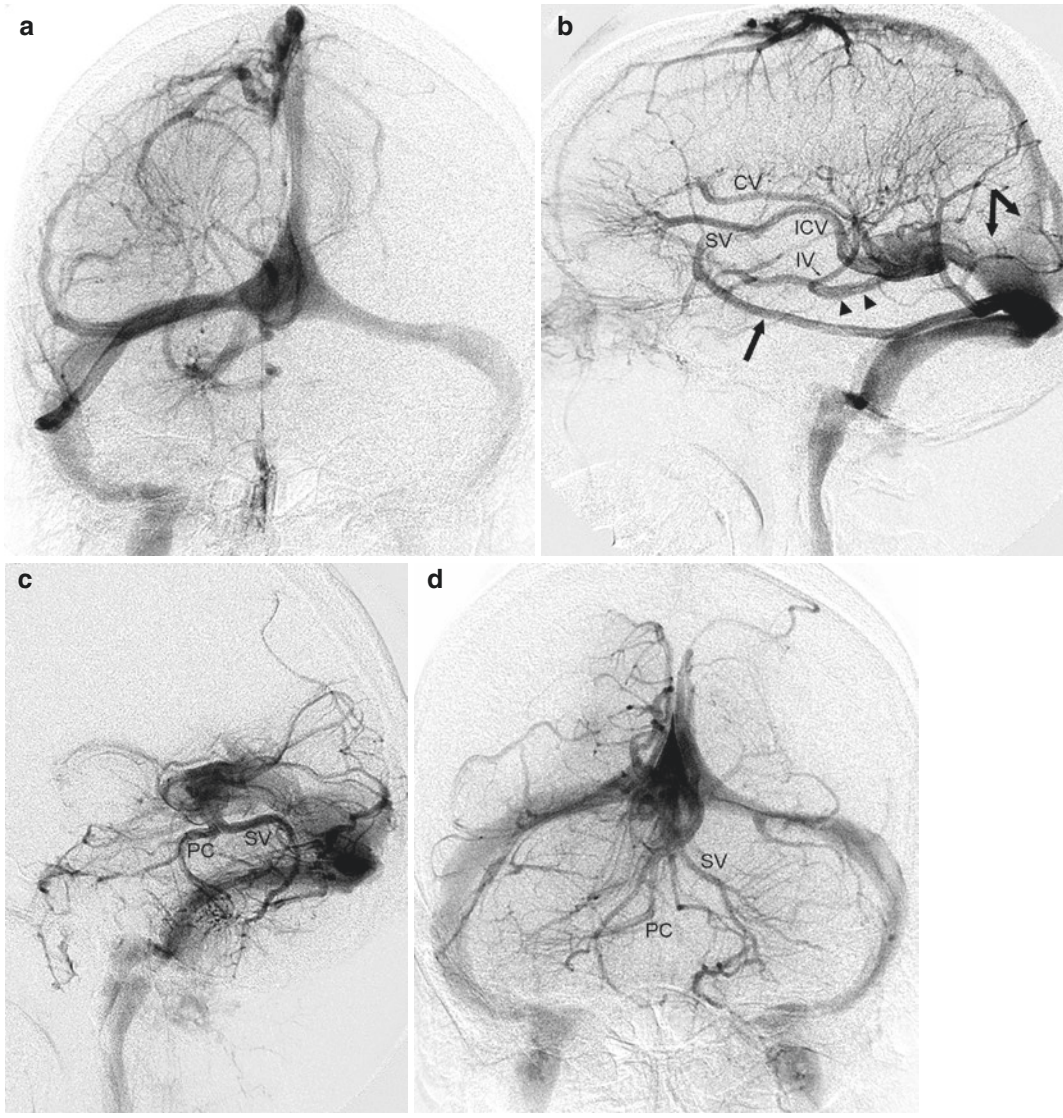

Fig. 9.25 Incidental discovery of grossly anomalies of the venous drainage. (**a**, **b**) On the AP and lateral views of the venous phase of the right carotid angiogram there are a diffuse dilatation of the medullary veins draining into the deep system. The drainage in the superficial system is poor with exception of a large superficial middle cerebral vein which drains posteriorly in the TS after a course in the tentorium (*arrow*). In the frontal and parietal regions the dilated medullary veins converge to dilated collectors represented by the septal vein (SV) continuing in the ICV and the caudate vein (CV) which has an anomalous course entering the ICV. It is possible that also the inferior ventricular vein (IV) and the basal vein (*arrowheads*) act as collectors. This pattern is not much different from that of DVA. There is also a dilatation of the Galen vein and of the distal straight sinus receiving a duplicated SSS (*arrow with angle*). (**c**, **d**) On the AP and lateral views of the venous phase of the vertebral angiogram, dilated medullary veins are also visible. The collectors seem to be a dilated precentral vein (PC) and a superior vermis vein (SV)

and sinuses. They can be an incidental discovery or diagnosed in association with venous thrombosis or other vascular intracranial or intraorbital pathologies (Figs. 9.25, 9.26, 20.5, and 23.4).

- Variations can involve the sinuses in association with other venous anomalies or to be the primary pathology in pediatric dural arteriovenous fistulas (Chap. 13, Sect. 13.8).

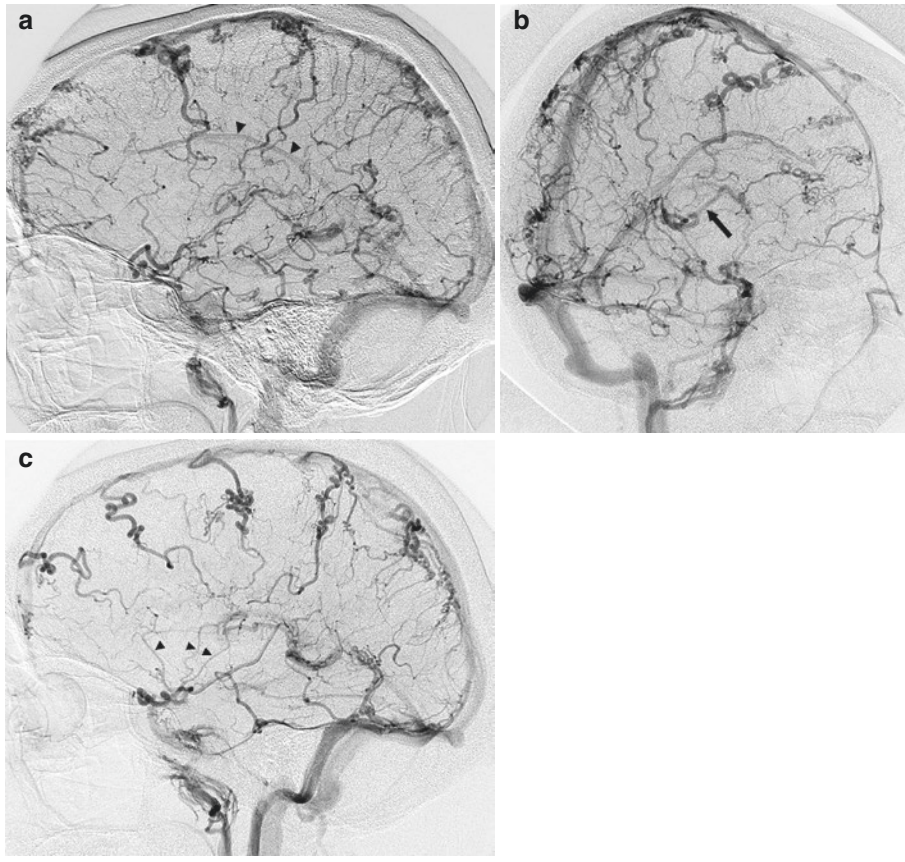

Fig. 9.26 Incidental discovery of grossly venous anomalies involving predominantly the superficial venous system bilaterally. The arterial phases were normal. (**a**) Right ICA lateral angiogram, venous phase. The course of the cortical veins is tortuous forming coiling, sometimes very tight and small network. Minimal tortuosity also of the ICV. Dilated inferior sagittal sinus (*arrowhead*). (**b**) Oblique view showing better the small tortuosity also of the ICV (*arrow*). (**c**) Left ICA lateral angiogram. Venous phase. Similar pattern as on the right. Note the dilated insular veins (*arrowheads*) continuing in a tortuous and dilated venous channel which could be a dilated uncal vein entering the cavernous sinus

Extracranial Venous Drainage 10

10.1 Orbital Veins

The orbital veins develop from the primitive maxillary and supraorbital veins, tributaries of the cavernous sinus developed from the pro-otic sinus (see also embryology, Chap. 9). The final result of the embryological evolution of these venous channels is the superior and inferior ophthalmic veins, draining posteriorly in the cavernous sinus. They are connected anteriorly with the facial and frontal veins. Other connections are those with the pterygoid plexus (see also Sects. "Superior and Inferior Ophthalmic Veins" 9.3.11 and 9.3.12) (Drawing in Fig. 10.1).

10.2 Facial Veins

The anterior facial vein begins in the naso-orbital angle, with the angular vein, which anastomoses with the ophthalmic veins. From its origin, the vein runs inferiorly and posteriorly with an oblique course along the face; it crosses over the mandible, and shortly after it is joined by the retromandibular vein; together they form the common facial vein, which enters the internal jugular vein at the level of the hyoid bone.

The anterior facial vein receives tributaries from the orbit, lips, facial skin, and muscles and from the menton-submental region. Occasionally, the lingual and superior thyroid veins also join the anterior facial vein instead to drain separately into the internal jugular vein. The anterior facial

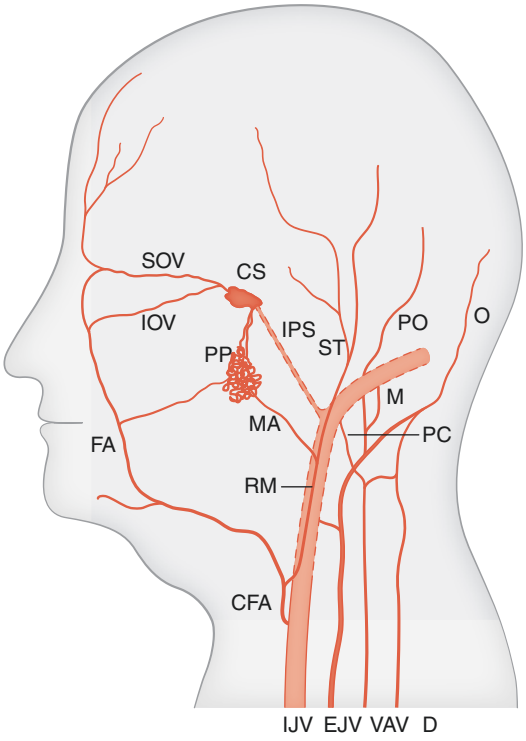

Fig. 10.1 Internal jugular vein (IJV), retromandibular vein (RM), to which converge the superficial temporal vein (ST) and the maxillary vein (MA). Pterygoid plexus (PP), facial vein (FA), common facial vein (CFA), formed by the confluence of the RM and FA entering the IJV. Posterior auricular vein (PO), superficial temporal vein (ST), occipital vein (O), external jugular vein (EJV), to which converge PO and O. Mastoid vein (M), posterior condylar vein (PC), deep cervical vein (D), to which drain partially the occipital vein and venous plexus of the vertebral artery (VAV), with some of its connections. Superior–inferior ophthalmic veins (SOV–IOV), connected anteriorly with the facial and frontal veins and posteriorly with the cavernous sinus (CS). Inferior petrosal sinus (IPS)

G.B. Bradac, *Applied Cerebral Angiography*, DOI 10.1007/978-3-319-57228-4_10

vein is connected posteriorly with the pterygoid plexus through the deep facial vein (Fig. 10.1).

10.3 Retromandibular Vein

Also known as the posterior facial vein, the retromandibular vein arises, below the neck of the mandible at the *junction of the maxillary and the superficial temporal veins*. The superficial temporal vein drains the temporal region and the maxillary vein drains the pterygoid venous plexus. The latter is a venous network lying between the pterygoid muscles to which converge many tributaries coming mainly from the deep facial vein, inferior ophthalmic vein, and veins running through the paracavernous sinus (Fig. 10.1).

The retromandibular vein runs through the parotid gland together with the external carotid artery, which is posteromedially located, and the facial nerve lying laterally (Fig. 2.2).

The vein joins the anterior facial vein forming together *the common facial vein* tributary of the internal jugular vein.

10.4 Posterior Auricular and Occipital Vein

The posterior auricular vein runs posterior to the pinna; it connects with the occipital vein and together joins the external jugular vein (EJV). The two veins drain the pinna and the scalp and muscles of the occipital region, and fuse together entering the EJV. *The EJV, which receives also an anastomotic branch from the retromandibular vein, runs superficially between the platysma and superficial fascia ending in the brachiocephalic vein, near and lateral to the internal jugular vein* (*IJV*) (Fig. 10.1).

10.5 Deep Cervical Vein

This vein drains the deep muscles of the neck, between which it runs. The deep cervical vein, which can be very large, drains the occipital vein, and is connected with the posterior condylar vein and the venous plexus of the vertebral artery (San Millan Ruiz et al. 2002) (Fig. 9.19). *Distally, it enters the brachiocephalic vein, either as an isolated channel or after joining the venous plexus of the vertebral artery.*

10.6 Venous Plexus of the Vertebral Artery

This is formed by a venous network surrounding the vertebral artery within its course through the transverse foramina. At the level of the horizontal segment of the vertebral artery (see Sect. 9.3.8), the venous plexus is connected medially with the anterior epidural vertebral plexus and posterolaterally with the deep cervical vein. Other connections are with the posterior and lateral condylar veins and indirectly with the ACC, IJV, and SIS (see also Sect. 9.3.8). Distally, it ends together with the deep cervical vein in the brachiocephalic vein (Drawing in Fig. 9.19). *It is together with the IJV, an important extracranial venous drainage of the brain.*

10.7 Emissary Veins

These veins pass through the cranial vault and link the intracranial dural venous sinuses with the extracranial veins. Their presence is not constant. They can be classified with regard to the dural sinus involved:

1. Those related to the superior sagittal sinus (SSS): an emissary vein can connect the SSS with the vein of the nasal cavity passing through the foramen cecum. Another emissary vein can connect the SSS with the scalp vein in the parietal region.
2. Those related to the torcular herophili and/or transverse sinus (TS) and sigmoid sinus (SiS): the most frequent are the mastoid vein, which connects the TS with the posterior auricular or occipital veins and passes through the mastoid foramen, and the posterior condylar vein, which arises from the SiS or jugular bulb and

is connected with the venous plexus surrounding the vertebral artery. In this group, we would include also the anterior condylar vein, which passes through the condylar foramen and connects the ACC with the epidural anterior vertebral plexus (Fig. 9.18). A rare connection can be present between the TS–torcular herophili and occipital vein.

3. Those related with the cavernous sinus (CS): a small anastomosis connects the CS and pterygoid plexus via the paracavernous sinus. An infrequent connection is presented by the petro-occipital sinus, linking the CS with the ACC.

10.8 Diploic and Meningeal Veins

The diploic veins run within the diploe which are connected with the scalp veins, dural sinuses, and meningeal veins. *The meningeal veins* run in the dura accompanying the meningeal arteries. They drain superiorly into the SSS directly or through the venous lacunae, posteriorly in the TS, and inferiorly in the sinuses along the cranial base. The largest meningeal vein is that associated with the anterior branch of the middle meningeal artery continuing in the sphenoparietal sinus (see Sect. 9.3.9).

10.9 Internal Jugular Vein

The IJV is the inferior continuation of the SiS, and it begins in the posterior segment of the jugular foramen, forming at its origin a small dilatation called the jugular bulb, which reaches its final diameter of about 10 mm within the first year of age (Okudera et al. 1994). Extracranially, the IJV runs in the carotid space (Fig. 2.1), lateral to the internal carotid artery, and terminates in the brachiocephalic vein. The latter is very short on the right side. The IJVs are frequently asymmetric, one being larger than the other. The IJV is the main venous extracranial drainage of the brain parenchyma. Among the extracranial tributaries, the most important is the common facial vein. For the connections of the IJV with the inferior petrosal sinus and condylar veins, see Sect. 9.3.8.

The course and the tributaries of the brachiocephalic veins are well known from anatomic and angiographic studies. On the AP view commonly used in the catheterization of the IJV, this arises from the brachiocephalic trunk laterally to the sometimes very large inferior thyroidal veins and medially to the vertebral vein and EJV. More cranially the vertebral vein after receiving frequently as tributary the distal deep cervical vein joins the vertebral artery forming around it, the vertebral venous plexus, and it is then located medially to the IJV.

Aneurysms

11

11.1 Incidence

The precise incidence of cerebral aneurysms is unknown. From autopsy studies, it is estimated at 5% (Stehbens 1972, 1990).

11.2 Type and Location

Cerebral aneurysms are commonly of a saccular type (berry aneurysms) located at the bifurcation of the arteries of the circle of Willis. The most frequent sites are the internal carotid artery (30–35%). Among them, those in the area of the junction of the posterior communicating artery (PcomA) account for more than the half. Also very frequently are aneurysms involving the area of the anterior cerebral artery (ACA: 33–34%) and those of the middle cerebral artery (MCA: 20%).

Aneurysms in the posterior circulation are less common (10%). Of these, half are basilar artery aneurysms (Locksley 1966a, b; Weir 1987; Nakstad et al. 1988).

Multiple aneurysms occur with an incidence that varies from 20 to 40% (Locksley 1966a; Nakstad et al. 1988; Rinne et al. 1994). They are more often in women.

It is thinkable that in those patients in whom there is a tendency to develop multiple aneurysms, these do not appear always simultaneously but in different periods of life. This could explain the appearance, sometimes even years (Wermer et al. 2005) after the diagnosis of the first aneurysm, of the so-called *de novo* aneurysm. The presence of multiple aneurysms suggests that at least in these cases we are dealing not with a focal but with a diffuse progressing vascular disease of the cerebral vessels which needs to be monitored (Bruneau et al. 2011) (Fig. 11.16c–f).

11.3 Anatomopathological Aspects

Unlike aneurysms affecting the aorta and other extracranial arteries, which are commonly fusiform, cerebral aneurysms are in the majority of the cases saccular (berry aneurysm) (Stehbens 1990; Powell 1991). They are characterized by a dilated sac attached to the parent artery by a neck which can be narrow or large, sometimes so large as the base of the sac. The sac can have a regular spherical aspect or appear more elongated or lobulated with two or more lobular components. Commonly the site of rupture is on the top of the sac (dome), where sometimes small extroflexions (blebs) can be recognized, indicating the point of rupture. Rarely the rupture occurs at the neck. They vary in size. The majority have a diameter of 5–7 mm, though smaller and larger aneurysms also occur; those larger than 25 mm are termed *giant aneurysm*.

G.B. Bradac, *Applied Cerebral Angiography*, DOI 10.1007/978-3-319-57228-4_11

Histopathological studies show structural changes in the wall, where there is no internal elastic lamina and the tunica media is absent or very thin. Its smooth muscle cells are replaced by connective tissue.

11.4 Pathogenesis

Some considerations about the cerebral arteries should first be made. They are composed of four layers, represented by the adventitia, media, internal elastic lamina, and intima. *There is no external elastic lamina. The arteries have a thin wall and are located in the subarachnoid space, where they have relatively little external support.*

As far as the pathogenesis of the aneurysms is concerned, this remains a little unclear and controversial. The first hypothesis has been that they were congenital. Indeed in the early 1930s, Forbus showed in histological studies a congenital gap defect of the media in the wall of the cerebral arteries, which was interpreted as a locus *minoris resistentiae*, where aneurysm could develop. Other authors (Carmichael 1950; Crompton 1966a, b; Crawford 1959) explained the formation of aneurysms as due to the association of the inborn defect with an acquired degenerative process linked to hypertension and atherosclerosis. Later, however, it has been demonstrated that these gaps are very frequent in normal individuals without the presence of aneurysms, and it has progressively become accepted that *cerebral aneurysm is an acquired lesion* (Glynn 1940; Stehbens 1959, 1972, 1989, 1990), linked to a degenerative process involving the internal elastic lamina and media weakening the wall. Indeed these changes linked to atherosclerosis can appear already in a young age as demonstrated with microscopical studies by Stehbens (1975). These associated with hemodynamic factors such as hypertension, variations of circle of Willis, sometimes arteriovenous malformations, and perhaps also undetected metabolic disorders would favor the formation of the aneurysms. Other authors (Pope et al. 1984; Pope 1989; Ostergaard and Oxlund 1987; Chyatte et al. 1990; Van den Berg et al. 1999) have demonstrated a reduction of reticular fibers owing to a decrease in type III collagen in patients with aneurysm. In a few of these patients, genetic disorders could also be demonstrated (Chyatte and Mjerzejewski 1991).

There are other more uncommon pathological conditions in which cerebral aneurysm can occur. Among them, there are a few systemic diseases of the connective tissue, such as fibromuscular dysplasia, Ehlers-Danlos syndrome, Marfan syndrome, neurofibromatosis, polycystic kidney, and aortic coarctation. In some of these patients, hypertension is also present as an adjuvant factor (Schwartz and Baronofsky 1960; Handa et al. 1970a; Stehbens 1989; Butler 1996; Osborn 1999; Benyounes et al. 2011).

Aneurysms can occur in different types of arteritis and in cases of cardiac myxoma. Other factors reported to promote aneurysm formation are smoking, consumption of alcohol, and oral contraceptives (Hillbom and Kaste 1982; Lindergärd et al. 1987; Juvela et al. 1993). The incidence of aneurysms is reported to be high in some families (Edelsohn et al. 1972; Hashimoto 1977; Crompton 1979; Norrgard et al. 1987).

Finally intracranial aneurysms can occur following a traumatic lesion of the arterial wall leading to dissection and to formation of a pseudoaneurysm (Birley and Trotter 1928; Benoit and Wortzman 1973; Jacobson et al. 1984; Bozzetto-Ambrosi et al. 2006; De Andrade et al. 2008; Nakstad et al. 2008). In the past, angiography was the method of choice to examine patients with craniocerebral trauma. Aneurysm could be easily detected. Today the diagnosis is performed commonly with CT. With this method, in spite of the improved quality, small aneurysms can escape to the routine CT diagnosis. As reported by others, (Gjertsen et al. 2007; Jussen et al. 2012) we think that in patients with severe trauma especially in whom CT has shown an intracranial hemorrhage a study of the vessels with CT angiography or conventional angiography is mandatory to exclude a vascular lesion especially an aneurysm of the cerebral or meningeal arteries.

As far as aneurysms due to dissection, or developing in AVMs or occurring in other rare angiopathies or cardiac diseases, are concerned see Chaps. 12, 16, 17, and 18.

11.5 Clinical Presentation

Aneurysms are typical in patients of adult age with a predominance among women. Aneurysms in pediatric patients are rare; they are more frequent in boys. In 90% of the cases, the aneurysm presents with subarachnoid hemorrhage (SAH) (10 cases of SAH/year/100.000 people). On CT bleeding in the subarachnoid space and in the ventricular system is commonly easily recognizable. The hemorrhage can involve the adjacent parenchyma especially in aneurysm of the middle and anterior cerebral arteries. Extension to the subdural space can occur in aneurysm near the skull basis.

Morgagni was the first to describe an autopsy case of cerebral aneurysm in the 1761. This pathology, however, has been considered for a long time, as a rarity with little clinical relevance. An exception to this general medical thinking has been Gull, who described in 1858 in an autopsy study a series of aneurysms making the consideration that "*this apparent rarity is doubtful … probably due to careless inquiry*." He also suggested that aneurysm could be the cause of SAH. It has been the merit of Symonds only later in the years 1923 and 1924 to have identified some typical symptoms of the SAH and have correlated these with a rupture of a cerebral aneurysm.

Today this clinical condition with its typical sudden onset of headache, stiff neck vomiting, and frequently disturbances of consciousness (drowsiness, confusion, and coma) is commonly easily recognized and correctly diagnosed. The grade of hemorrhage as well as the involvement of the ventricular system, brain parenchyma, and presence of hydrocephalus can be demonstrated on CT. In some cases, due to the very high increase of the intracranial pressure, death can ensue within minutes and hours. In other patients, the bleeding can be minimal (warning leak), the mild clinical symptoms can be misinterpreted, and the diagnosis of SAH can be eluded. Particular clinical aspects, which occur especially in severe SAH, are pulmonary complications and myocardial dysfunction including arrhythmias, troponin elevation, myocardial infarction, and the syndrome called "neurogenic stunned myocardium" (Kono et al. 1994; Urbaniak et al. 2007; Frontera et al. 2008). All these cardiac complications can lead to cerebral infarct (Mayer et al. 1999; Gaita et al. 2002; Jain et al. 2004; Lee et al. 2006c).

In other cases, the patient presents with neuropathy, particularly oculomotor palsy in PcomA and basilar artery aneurysms. Trigeminal neuralgia can also occur in large aneurysms in this location. Visual symptoms, due to compression of chiasma and/or optic nerve, and sometimes hydrocephalus due to compression of the third ventricle can be present in large aneurysms of the anterior communicating artery and carotid ophthalmic lesions. Symptoms as a result of brain compression can occur in large basilar artery and middle cerebral artery aneurysms. The typical cavernous sinus syndrome occurs in intracavernous aneurysms. In exceptional cases, aneurysms present with ischemia. This occurs especially in non-ruptured, partially thrombosed aneurysms (Antunes and Correll 1976; Stewart et al. 1980). Ischemia can be due to distal embolization or involvement of perforators adjacent to the aneurysm.

In addition to aneurysms in patients presenting with related symptoms, an increasing number of asymptomatic aneurysms are today diagnosed with CT and MRI in patients who underwent the examination for other reasons. The clinical problems and therapeutic considerations with such aneurysms are discussed in Sect. 11.10.

11.6 Aneurysm Location

11.6.1 Extracranial ICA Aneurysms

Aneurysms in this location are uncommon. Trauma is a possible etiology. Atherosclerosis

can be another cause in the elderly. In younger patients, aneurysms may be associated with collagenopathies such as FMD, Ehlers-Danlos, and Marfan syndromes in which dissecting aneurysms are frequent (see Chap. 16).

11.6.2 Intracranial ICA Aneurysms

These aneurysms have been differently subdivided considering their origin and location. This has been and still is useful for the surgical approach. Today these aneurysms are basically endovascular treated and so this classification is less important, as also emphasized by other authors (Shapiro et al. 2014). For a general nomenclature, however, a subdivision remains of utility.

11.6.2.1 Aneurysms of the ICA Petrous Segment

These are very rare. Spontaneous in some cases traumatic dissection can be assumed to be the most frequent etiological mechanism (Fig. 11.1).

11.6.2.2 Cavernous Aneurysms

These are located within the cavernous sinus and are thus extradural. They are frequently large or giant. Pathogenesis is not completely clear. Spontaneous dissection or degenerative changes due to atherosclerosis are probably the etiology in many cases (see also Sect. 11.8). Association with collagene tissue disease is present in some cases. Traumatic and infectious diseases are other possible causes. They can be asymptomatic and incidentally discovered or especially when large, present with the typical cavernous sinus syndrome,

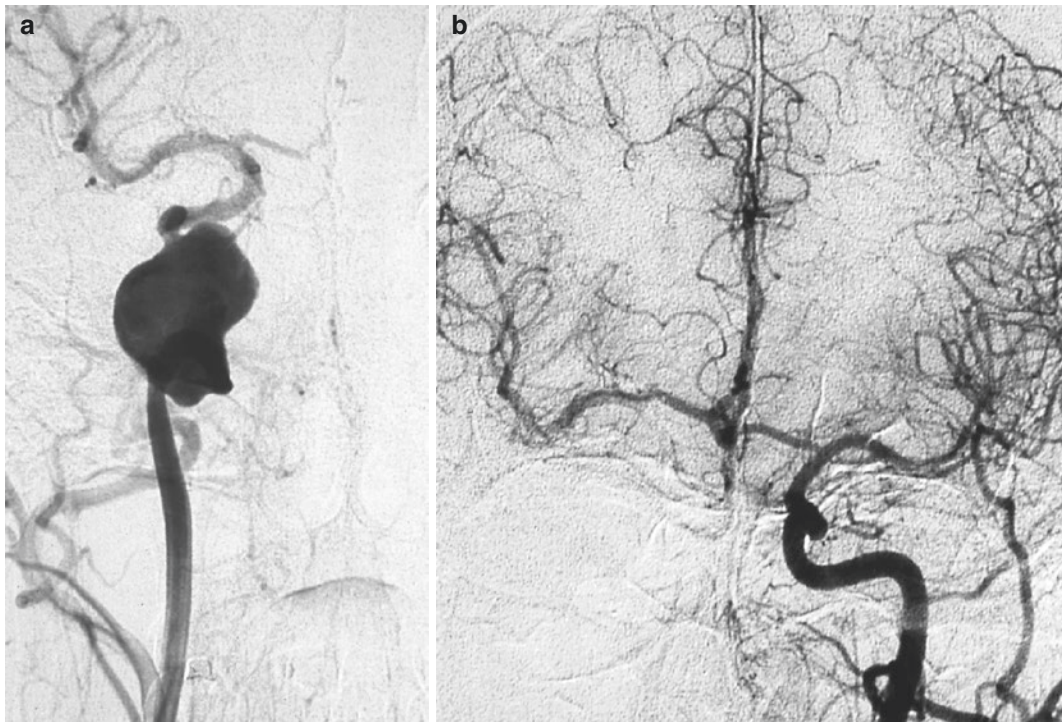

Fig. 11.1 Giant aneurysm of the petrous segment of the right ICA, presenting with palsy of cranial nerve VI. (**a**) ICA angiogram showing the aneurysm which was treated with occlusion of the ICA. (**b**) Left control angiogram, showing the good collateral circulation through the AcomA and exclusion of the aneurysm. The occlusion was preceded by a test as described in Sect. 11.9

first described by Jefferson (1938) and characterized by involvement in various combinations of cranial nerves III, IV, VI, and partially V. Commonly there is no risk of SAH, and in general the clinical prognosis is good, and so in the decision for the treatment of these aneurysms, their size, the symptoms, and the age of the patient should be considered. These aneurysms can rupture in the sphenoid sinus and nasal cavity, leading to a dramatic epistaxis. This is, however, an extremely rare evolution (Linskey et al. 1990).

Occlusion of the aneurysm and ICA or selective occlusion of the aneurysm with stent plus coils and flow-diverter stent are today possible methods (Fig. 11.2a–d).

In some cases, intracavernous aneurysms, even small, can extend upwards, reach the subarachnoid space, and rupture causing SAH. This can occur since the dural ring surrounding the ICA, through which the artery passes to become intradural, is medially not adherent to the artery; a small cavity (cave) is thereby formed. Aneurysms developing here, in spite of their

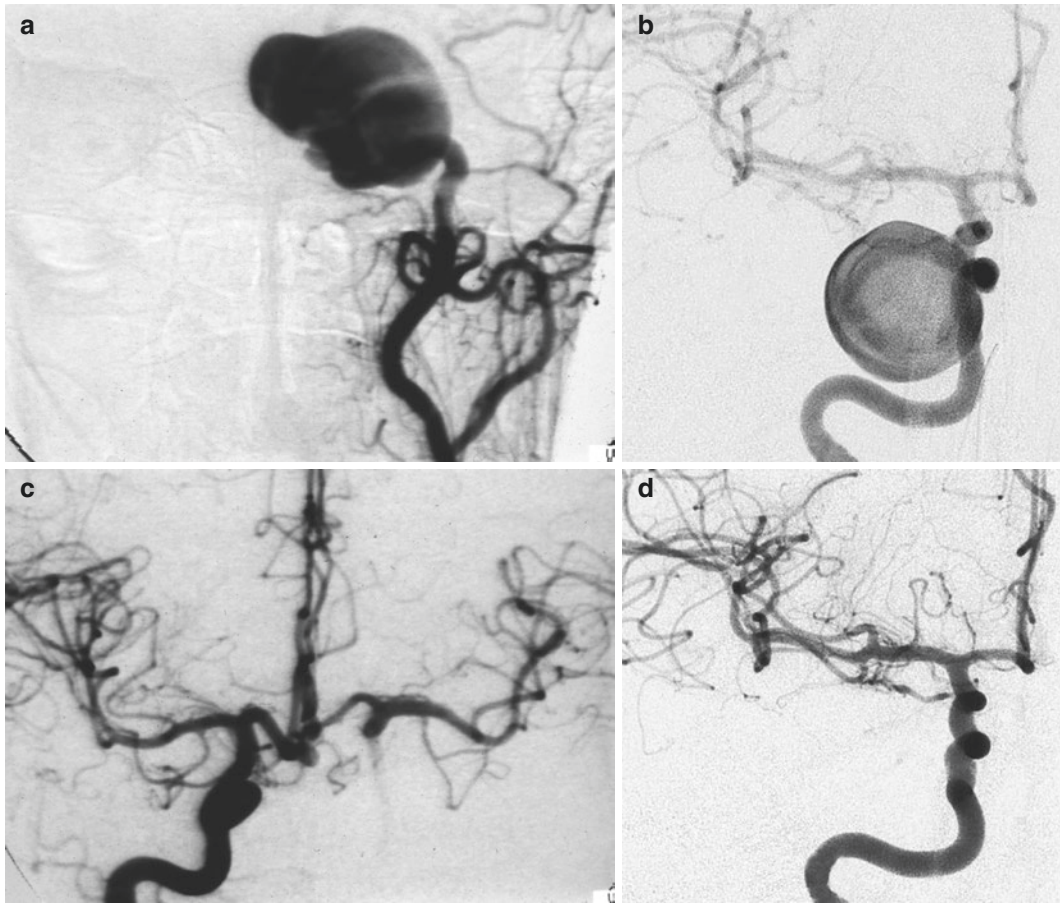

Fig. 11.2 Two examples of giant aneurysms of the cavernous portion of ICA with typical cavernous sinus syndrome treated differently. (**a**) Left ICA angiogram showing the aneurysm. There is no filling of the intracranial branches. (**c**) Right ICA angiogram showing the exclusion of the aneurysm and a good collateral circulation towards the occluded left ICA performed after the test occlusion. Another patient with the same clinical symptoms due to a giant cavernous aneurysm. Right ICA angiogram pretreatment (**b**) and posttreatment (**d**). Occlusion of the aneurysm with flow diverter (silk)

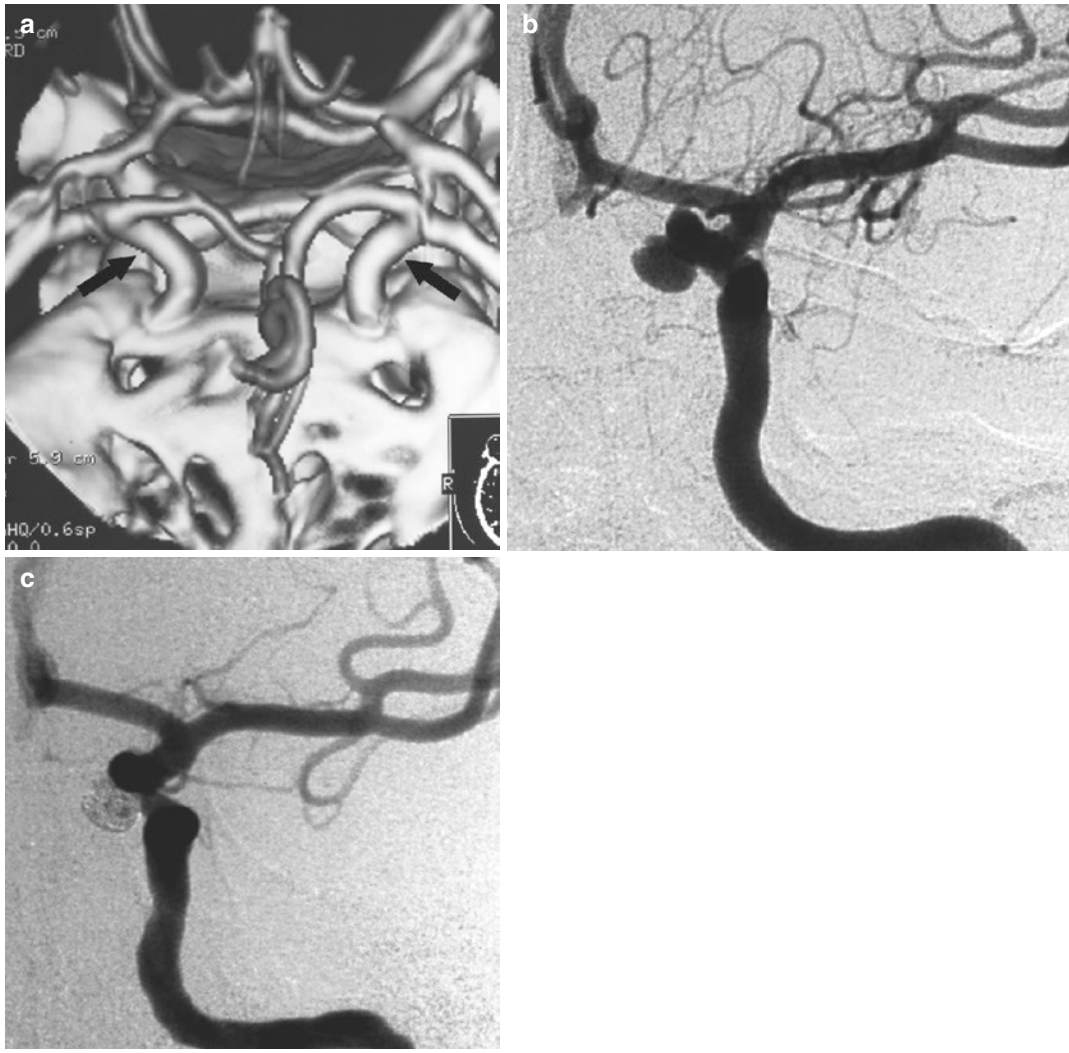

Fig. 11.3 Small left cave aneurysm presenting with SAH. (**a**) On the CT angiography, the aneurysm was not recognizable. The *arrows* show the normal aspect of both ICAs. (**b**) The left angiogram showed the aneurysm which was occluded with coils (**c**)

intracavernous location, can expand intradurally and become responsible of a SHA. These aneurysms are also called *cave aneurysm* (Fig. 11.3).

11.6.2.3 Paraclinoid: Paraophthalmic Aneurysms

In this group, the aneurysms arising in the ophthalmic segment of ICA are described, which are those developing between the origin of the ophthalmic artery and the origin of the PcomA. These comprehend the *carotid-ophthalmic aneurysms*, those *arising from the posterior wall of ICA* among them the superior hypophyseal aneurysms and *those from the superior wall of ICA*.

The carotid-ophthalmic originate at the junction with the ophthalmic artery or close to it. They are directed upward and are frequently large (Figs. 11.4, 11.5, and 11.6).

The aneurysm of the posterior wall arises at the junction of small branches represented by the superior hypophyseal arteries and by other arteries directed to the optic chiasm, optic nerve, and floor of the third ventricle. These aneurysms are very rare; they are directed downward and medially

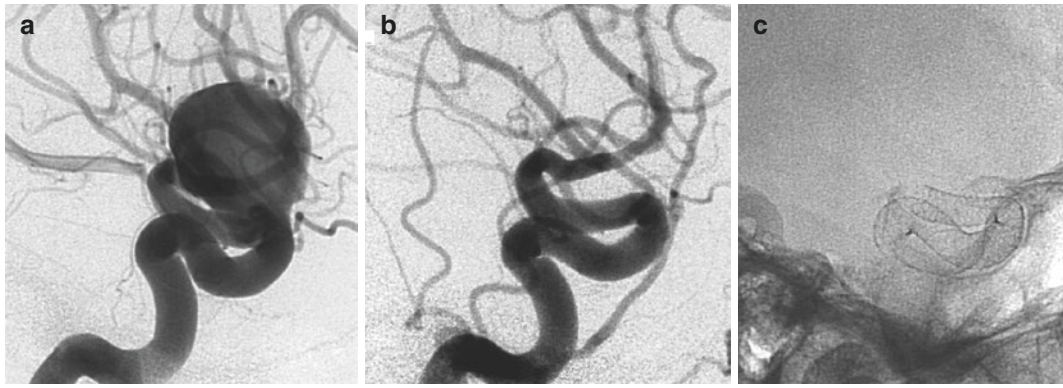

Fig. 11.4 Large carotid ophthalmic aneurysm presenting with progressive worsening of the visual acuity. (**a**) ICA lateral angiogram showing the giant aneurysm. (**b**) ICA angiogram after occlusion of the aneurysm with a flow-diverter stent (pipeline). (**c**) Rx image showing the stent

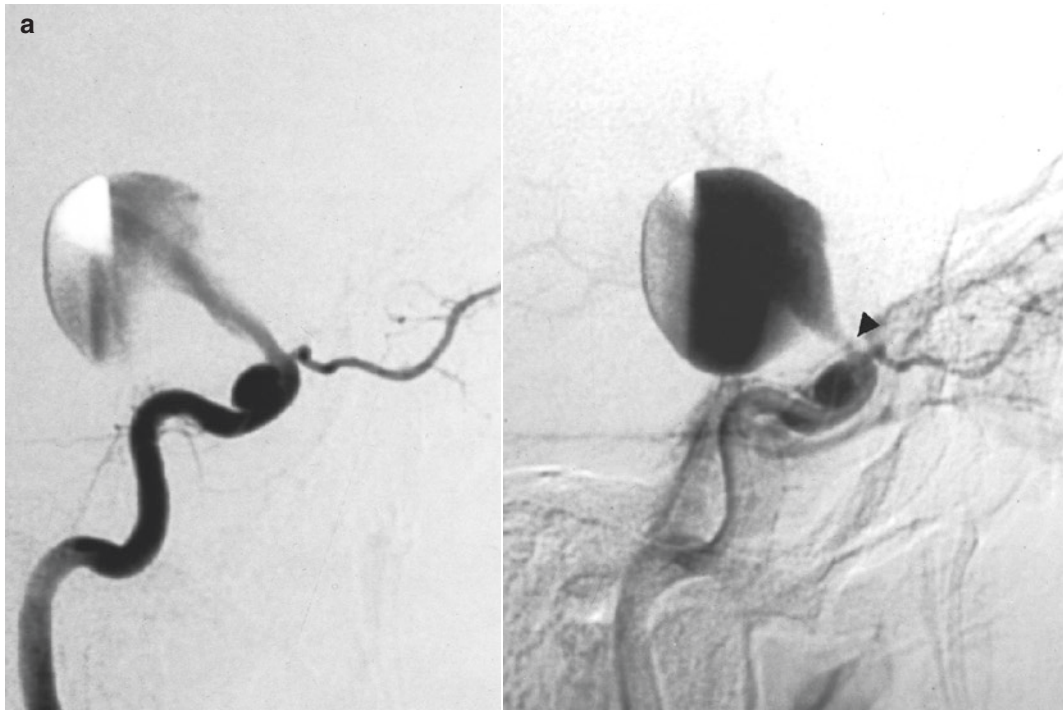

Fig. 11.5 Giant carotid ophthalmic aneurysm presenting acutely with severe disturbances of visual acuity. (**a**) Right lateral carotid angiogram, early and late phases, showing the progressive injection of the aneurysm through a relatively small neck, close to the origin of the ophthalmic artery (*arrowhead*). A second small intracavernous aneurysm is present. (**b**) Left carotid angiogram, upward displacement (*arrowheads*) of both A1 segments and partial filling of the right middle cerebral artery (MCA) through leptomeningeal anastomoses (*arrows*) with the right anterior cerebral artery (ACA). (**c**) Right vertebral angiogram, showing the leptomeningeal collateral circulation towards the right MCA from the posterior cerebral artery (PCA; *arrows*). (**d**) The ICA was occluded with a balloon positioned in the intracavernous segment. The patient recovered completely and a left control angiogram 2 months later showed the normal course of both the A1 and filling of the right MCA. (**e**) Right common carotid angiogram showing the retrograde injection of the distal ICA and MCA through the ophthalmic artery via a collateral circulation involving an anastomosis between the anterior deep temporal artery and the lacrimal branch of the ophthalmic artery (*angled arrow*). The aneurysm is completely excluded

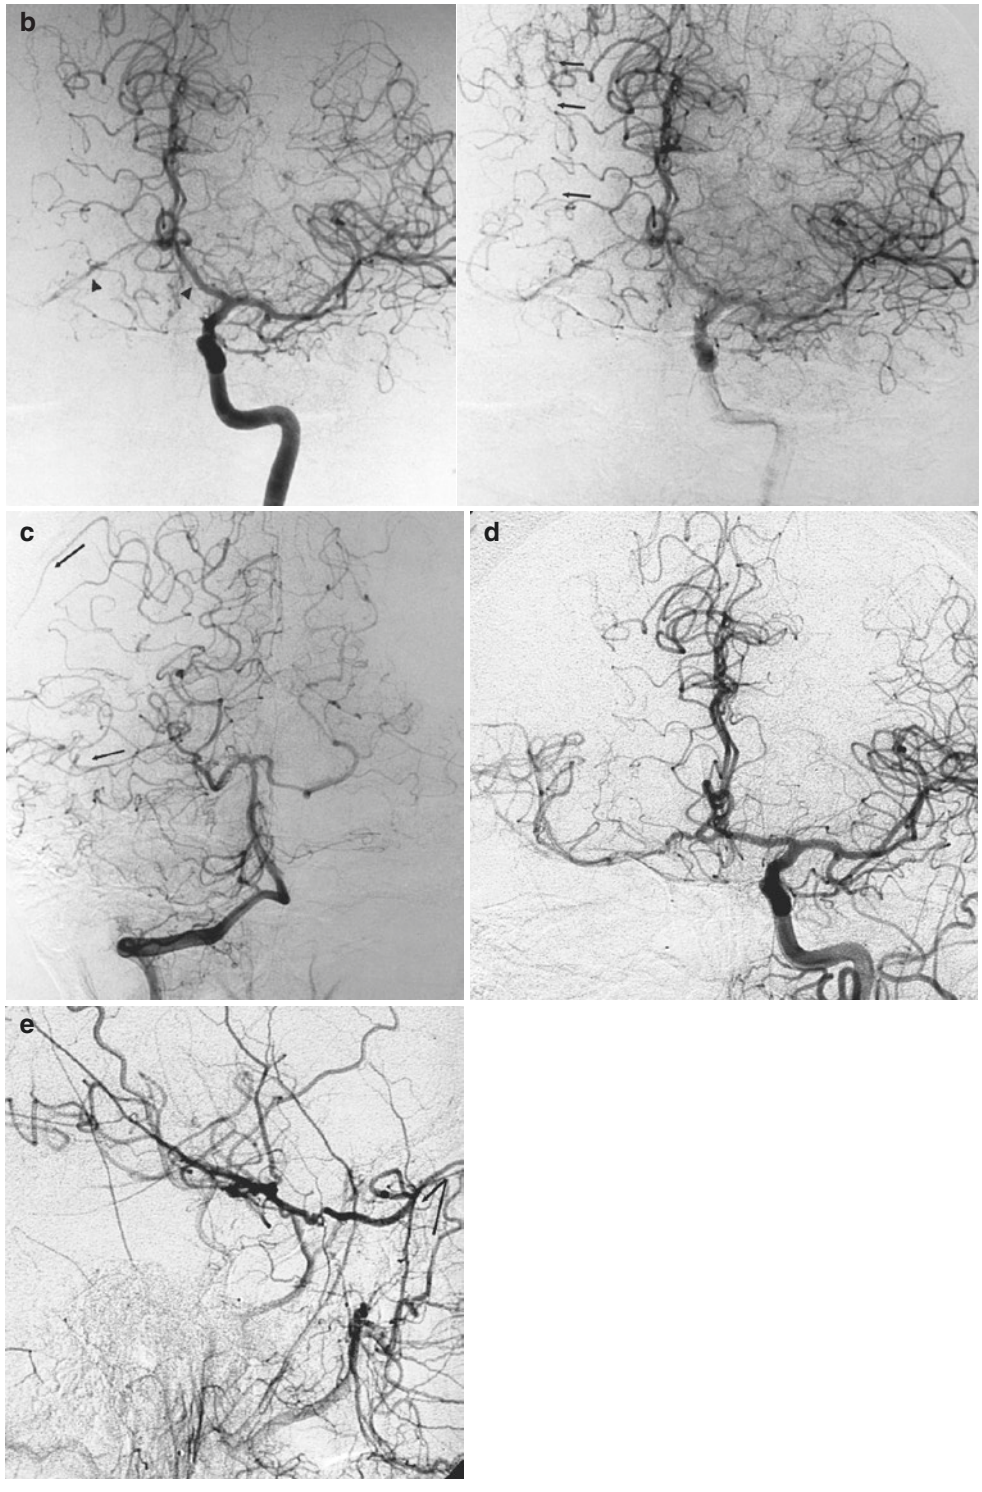

Fig. 11.5 (continued)

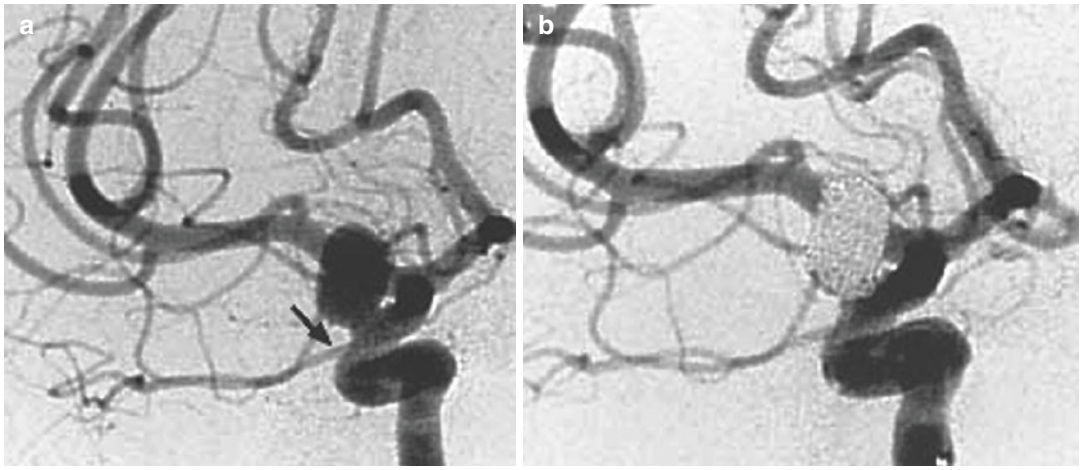

Fig. 11.6 Carotid ophthalmic aneurysm presenting with hemorrhage. (**a**) Carotid angiogram, oblique view showing the aneurysm. Origin of the ophthalmic artery (*arrow*). (**b**) Carotid angiogram showing the occluded aneurysm with coils

toward the chiasma and sella turcica, becoming intrasellar when large (Fig. 11.7).

The aneurysms developing on the anterior wall distally to the carotid-ophthalmic aneurysms are also very rare. They have been called by some authors *nonbranching aneurysms* (Ogawa et al. 2000). These are probably dissecting aneurysms. An example is presented in Fig. 11.8a–b, e–h. In the group of *nonbranching*, a particular form are the *blister-like aneurysms* (Fig. 11.8c, d). These are described more in detail in Chap. 16.

11.6.2.4 Aneurysms of the Communicating and Choroidal Segments

These consist of aneurysms of *the posterior communicating artery* (*PcomA*) *and anterior choroidal artery* (*AchA*). PcomA aneurysms are *located at the junction of this artery with the ICA*; they are posteriorly directed and can compress cranial nerve III. They can be very large, elongated, and with an irregular wall (Fig. 11.9a, b). More rarely the aneurysm *can arise selectively from the trunk of the PcomA* (true PcomA aneurysm) (Fig. 11.9c). In some of these later cases, the etiopathogenesis is probably a dissection (Mizutani et al. 1998; Nakao et al. 2004; Duncan and Terblanche 2005; He et al. 2011; Kocak et al. 2013). Involvement of the anterior thalamoperforating branches is frequent.

AchA aneurysms arise at the origin of the artery; it can also occur that the aneurysm arises directly from the first segment of the AchA or at the level of perforators of ICA immediately distal to the AchA. They are directed posteriorly and laterally. They are frequently small but large aneurysm can also occur (Figs. 11.10 and 15.25). A variable number of perforators arise from the choroidal segment of the ICA, and can be stretched around the neck of the aneurysm. In endovascular treatment, it is sometimes difficult to identify precisely the neck of the aneurysm despite several projections.

11.6.2.5 Aneurysm of the Carotid Bifurcation

These are typical T-bifurcation aneurysms similar to those located at the basilar-tip (Gibo et al. 1981a; Ingebrigtsen et al. 2004; Van Rooij et al. 2008). They are relatively rare and easily recognizable on the angiogram. These aneurysms can, sometimes, be very large with a large neck which can involve the adjacent A1 and M1 segments. Perforating branches arising from the choroidal segment of ICA and from A1 and M1 are stretched

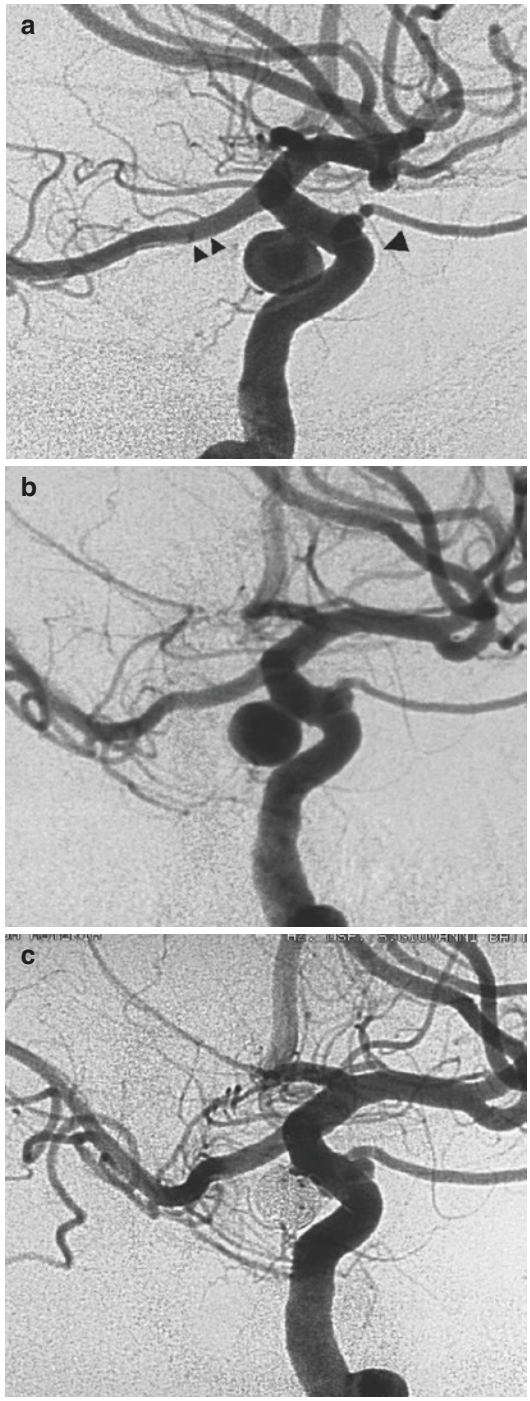

Fig. 11.7 Superior hypophyseal aneurysm presenting with hemorrhage. Two different oblique (**a**, **b**) views of the carotid angiogram to better identify the aneurysm and its neck. PCA (*arrowheads*), ophthalmic artery (*arrowhead*). Control angiogram (**c**) after occlusion of the aneurysm with coils

around the neck and the posterior wall of the aneurysm or in cases of a large neck can be directly involved. Examples are presented in Figs. 11.11 and 5.4b.

11.6.3 Anterior Cerebral Artery Aneurysms

These are very frequent aneurysms arising mainly *in the A1–A2 angle of the ACA*. The neck of the aneurysm can be large and partially involve the adjacent A1–A2 segments or the AcomA. As it has been described in the anatomy, these aneurysms are frequently associated with anomalies of the anterior part of the circle of Willis; furthermore, many perforators arise from the A1 and AcomA. This should be taken into account in the surgical or endovascular treatment of these lesions (Figs. 4.4, 4.9, 4.10, 4.11a, b, 4.13, 4.15, and 11.12a).

The *aneurysm can be found sometimes along the A1 segment*. This is a very rare location (less than 1%). It has been reported that in these cases, the aneurysm takes its origin at the junction with a perforating branch (Handa et al. 1984; Wakabayashi et al. 1985; Suzuki et al. 1992; Wanibuchi et al. 2001). This is certainly true for many of these aneurysms. In other cases, however, a relationship with a perforator could not be demonstrated (Lubicz et al. 2006–2009; Cho et al. 2014; Liu et al. 2016) suggesting a dissection as a possible pathogenesis. They are located more frequently in the proximal part of A1 and can have a saccular or a fusiform shape. Not rarely they are small with a feature similar to the blister-like aneurysm described above. For these aneurysms, surgery has been the therapy of choice (Dashti et al. 2007; Park et al. 2013). With advances in endovascular techniques this treatment has become progressively a good alternative. Flow-diverter stents would be the best treatment Clarençon et al. (2017); however their use in the acute phase is controversial. Depending on the morphological aspect, coils alone or assisted with balloon or stents as well as occlusion of the aneurysm as well as the involved segment of A1 have been used (Lubicz

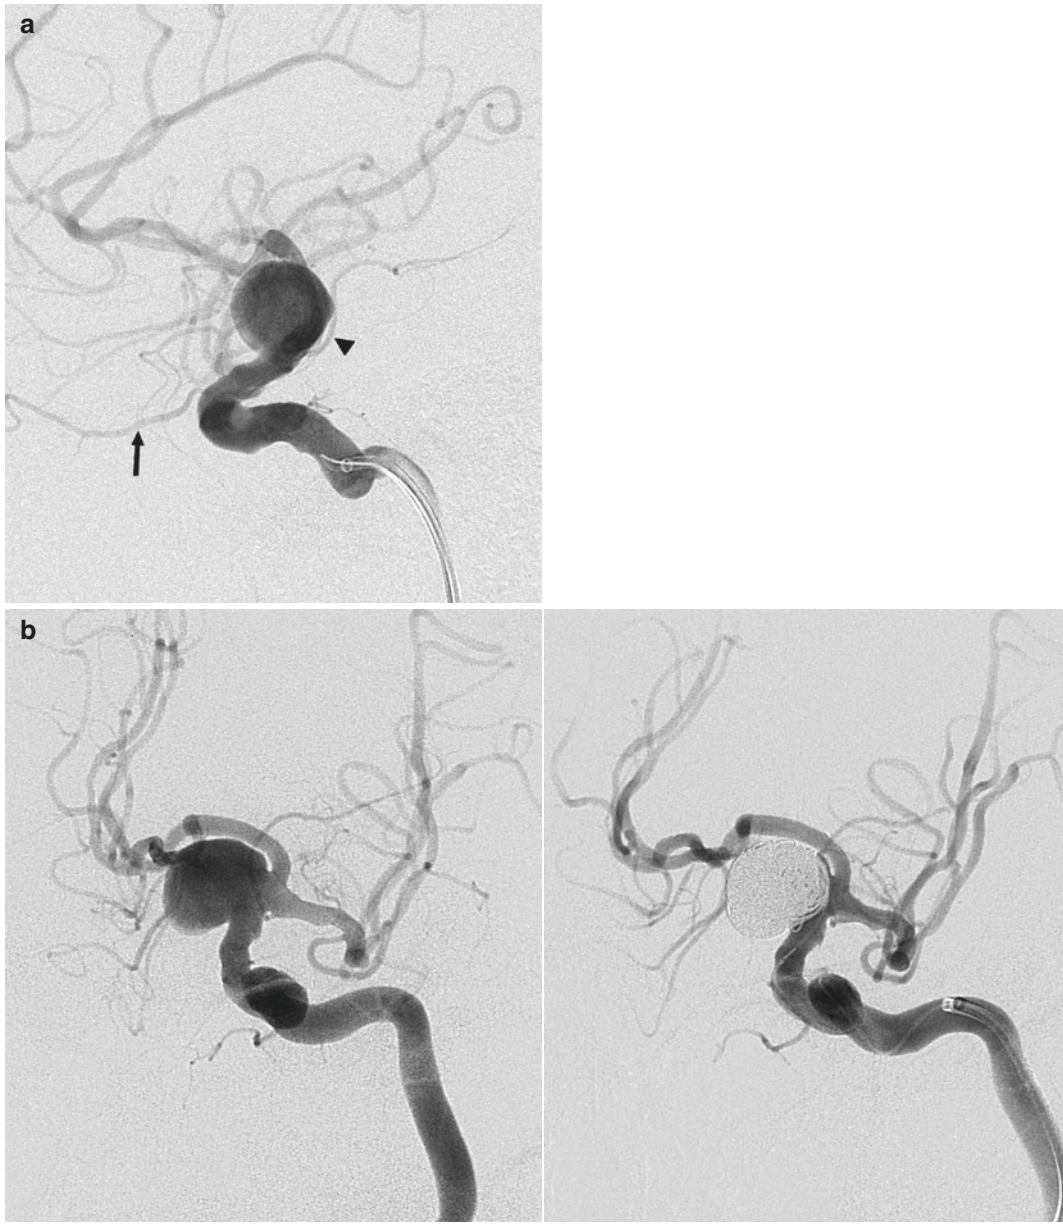

Fig. 11.8 Three different patients with aneurysm arising on the superior wall of ICA. (**a**, **b**) Large aneurysm presenting acutely with disturbances of the visual acuity in a hypertensive 60-year-old man. (**a**) Lateral view. The aneurysm is located on the anterior wall of the ICA near its distal bifurcation. Ophthalmic artery (*arrow*), AchA (*arrowhead*). The image has been performed at the beginning of the treatment. (**b**) Oblique view showing the aneurysm and its large neck. Pretreatment and posttreatment angiograms. Occlusion of the aneurysm with stent (enterprise) and coils. (**c**, **d**) Fifty-year-old woman presenting with SAH. (**c**) Angio-CT, showing a minimal bulge on the superomedial wall of ICA (*arrow*, image above). A week later the bulge is more evident (*arrow*, image below). (**d**) ICA angiogram showing the small bulge (*arrow*, image above), which a week later has become a clear saccular aneurysm (*arrow*, image below) (Courtesy of dott. Venturi F., Neuroradiology of Turin). During the surgical exploration, the aneurysm ruptured. The patient died. (**e**–**h**) Sixty-year-old woman presenting with SAH on the ICA angiogram (oblique view) (**e**), a nonbranching probably dissecting aneurysm was shown on the superior-medial surface of the ICA, which was also a little irregularly fusiform dilated. The aneurysm was acutely treated with coils and stent (enterprise) (**f**). The patient recovered, but a week later she suffered a second severe SAH. The control angiogram (**g**) showed a minimal (*arrow*) recanalization of the aneurysm and irregularity of the ICA wall. A severe spasm was also present. A flow-diverter stent (**h**) was inserted in the already present enterprise. The patient recovered slowly

(**b**) Oblique view better showing the irregular and elongated part (*arrow*) of the aneurysm. (**c**) Lateral carotid angiogram, posttreatment, showing the occluded aneurysm with coils

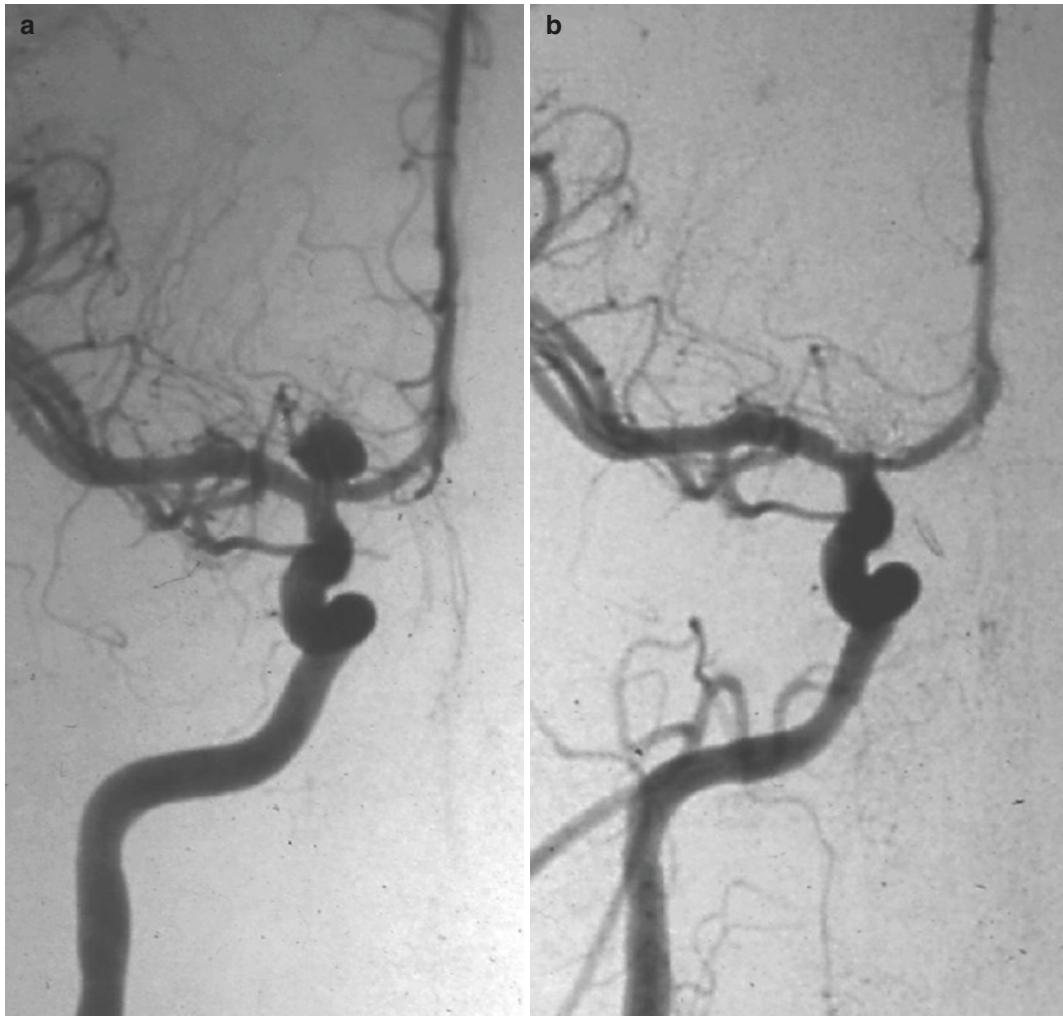

Fig. 11.11 Aneurysm of the distal carotid bifurcation, presenting with hemorrhage. (**a**) Carotid angiogram, AP view, showing the aneurysm. (**b**) Control angiogram showing the occluded aneurysm with coils

et al. 2009; Tollard et al. 2011; Chang et al. 2011; Park et al. 2013; Cho et al. 2014; Kim et al. 2014; Liu et al. 2016). An example is presented in Fig. 11.12b. An unsolved problem is the involvement of the perforators especially in the cases in whom also part of A1 is occluded in the treatment. In this context, it is useful to remember that the perforating branches of M1 can partially arise from A1 and/or from the Heubner artery (see Sect. 5.1). In one of our cases treated with occlusion of the proximal segment of A1, the CT performed routinely a few days later in completely asymptomatic patient showed ischemia in the putamen and pallidum probably due to involvement of the perforators arising in this case from the A1.

Another typical location, though less common, *is the pericallosal-calloso-marginal junction*. Depending on the site of the junction the aneurysm can be located anterior to the genu of the corpus callosum, distal to it or proximal beneath the genu. Examples are presented in Figs. 4.14 and 11.13.

Rarely, other aneurysms involving commonly the distal segment of the ACA, such as dissecting, mycotic, flow dependent, or developing in various arteriopathies as well as following trauma, can occur (Nakstad et al. 1986;

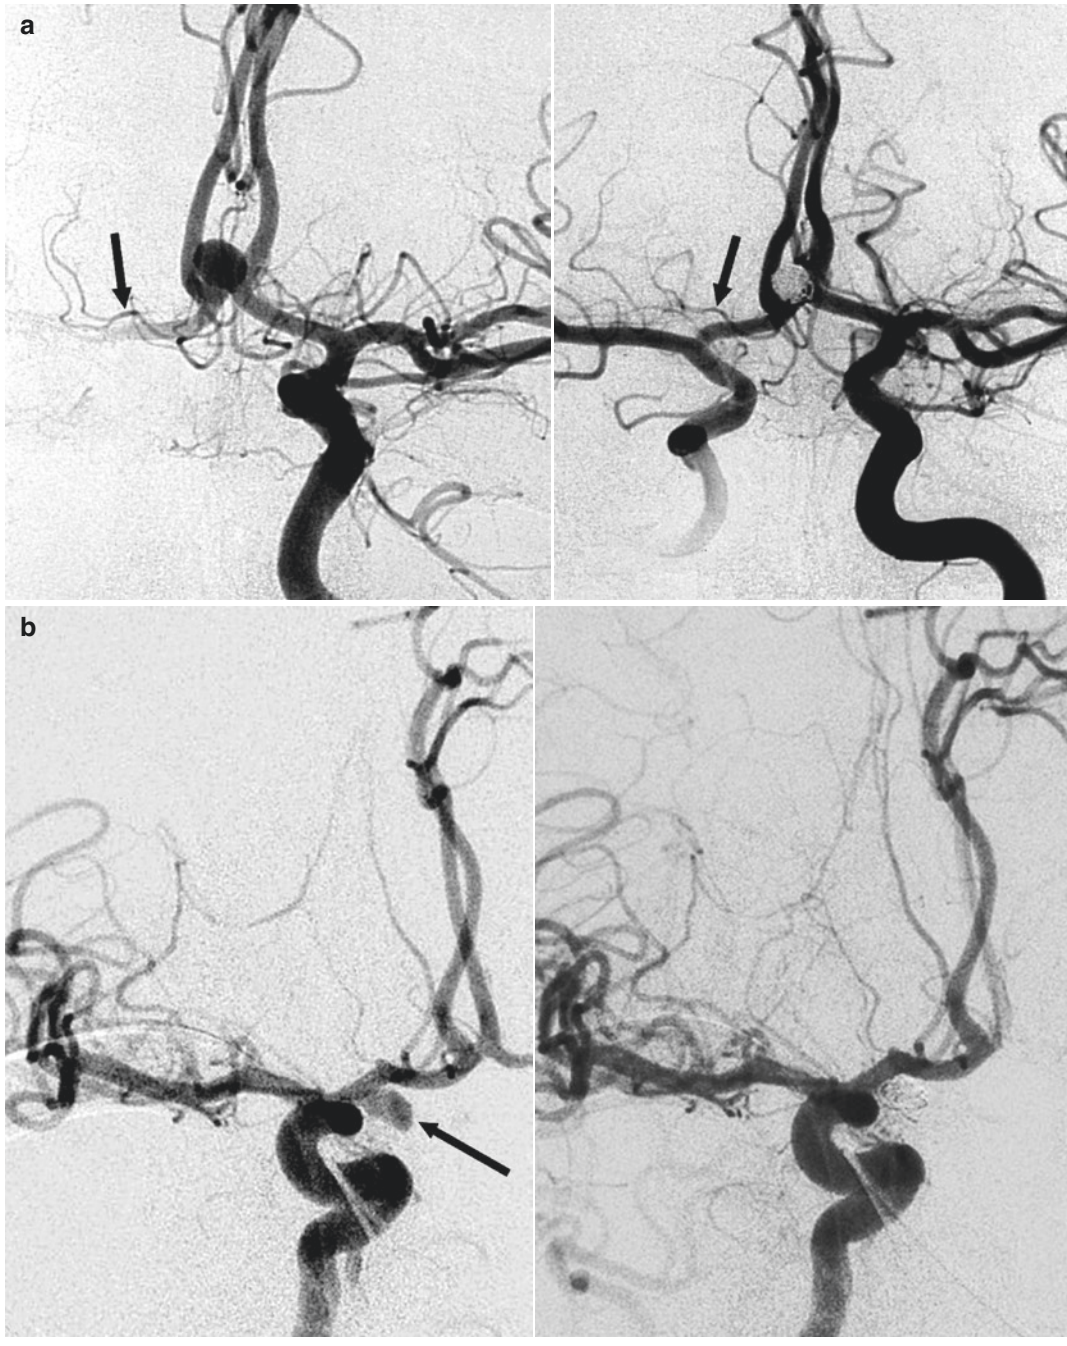

Fig. 11.12 (**a**) ICA angiogram. AP view. Pre- and post-treatment with coils of a ruptured AcomA aneurysm. On the right the artery of Heubner dividing distally into two branches is easily recognizable (*arrow*). On the left, it cannot be identified with certainty due to overlapping with other branches. (**b**) ICA angiogram. AP view in another patient. Angiogram pre- and posttreatment. Aneurysm in the proximal part of A1 directed anteriorly and slightly inferiorly (*arrow*) presenting with SAH. Occlusion with coils

(**a**) CT demonstrating the small hemorrhage with surrounding edema (*arrow*). (**b**) The angiography showed a small pericallosal probably "flow-dependent" aneurysm (*arrow*). (**c**) Selective catheterization of the aneurysm which was occluded with coils. (**d**) Final control angiogram showing the occluded aneurysm

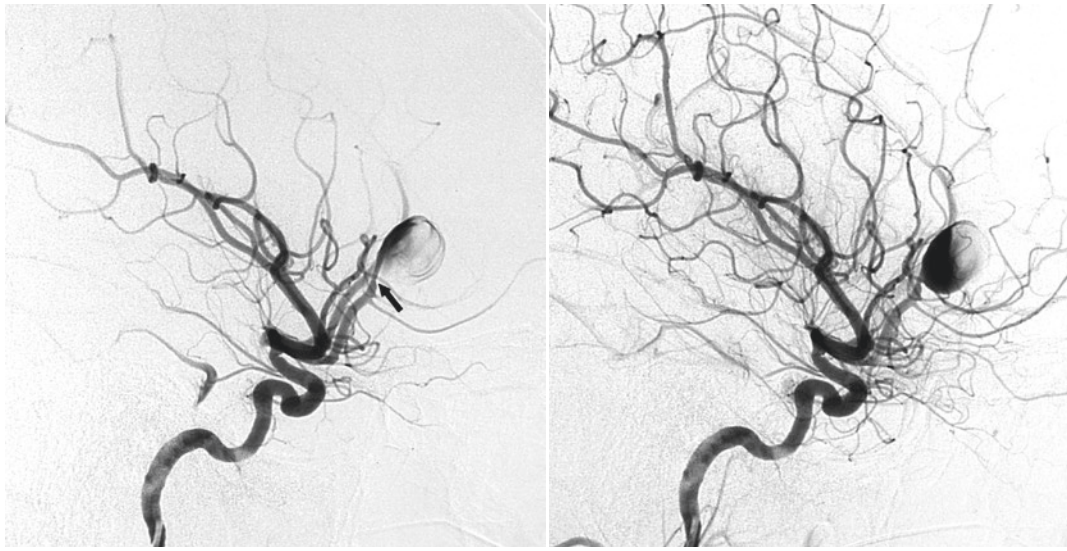

Fig. 11.15 Young patient presenting with severe SAH with a parenchymatous component owing to rupture of an aneurysm of the proximal pericallosal artery. Narrowing of the artery (*arrow*) proximally to the aneurysm suggesting probably dissection. In the later phase progressive filling of the aneurysm and of the distal pericallosal artery. The aneurysm was treated with clipping, but a week later SAH occurred again. The angiography revealed the recanalization of the aneurysm which was now enormously increased. Occlusion of the aneurysm and parent artery with coils was performed

Ohkuma et al. 2003; Cohen et al. 2005; Pandey et al. 2007; Fukuma et al. 2015; Hensler et al. 2016). An example of dissecting aneurysm of the pericallosal artery is presented in Fig. 11.15. A flow-dependent aneurysm is demonstrated in Fig. 11.14 (see also Chaps. 16, 17, and 18).

11.6.4 MCA Aneurysms

Most of these aneurysms arise at the bi-trifurcation of the M1 (Fig. 11.16a–f). It is not always easy to separate the MCA branches from the neck of the aneurysm. Furthermore in cases of early division of the M1 (short M1), the perforators can arise very close to the aneurysm (Figs. 5.4c, d and 5.5a, e). Considering all these morphologic aspects, despite improvement in the endovascular techniques, surgery can be the method of choice in some cases.

Other more rare aneurysms such as dissecting, mycotic, flow dependent, or associated to various arteriopathies and cardiopathies can occur (see Chaps. 16, 17, and 18). Examples are presented in Figs. 5.10, 11.17, 16.17, 17.1, 17.7, 18.1, and 18.2.

11.6.5 Aneurysms of the Posterior Circulation

Basilar aneurysms are the most frequent in the vertebrobasilar sector. They are typically located at the top of the artery. The perforators are commonly shifted laterally and stretched along the sac,

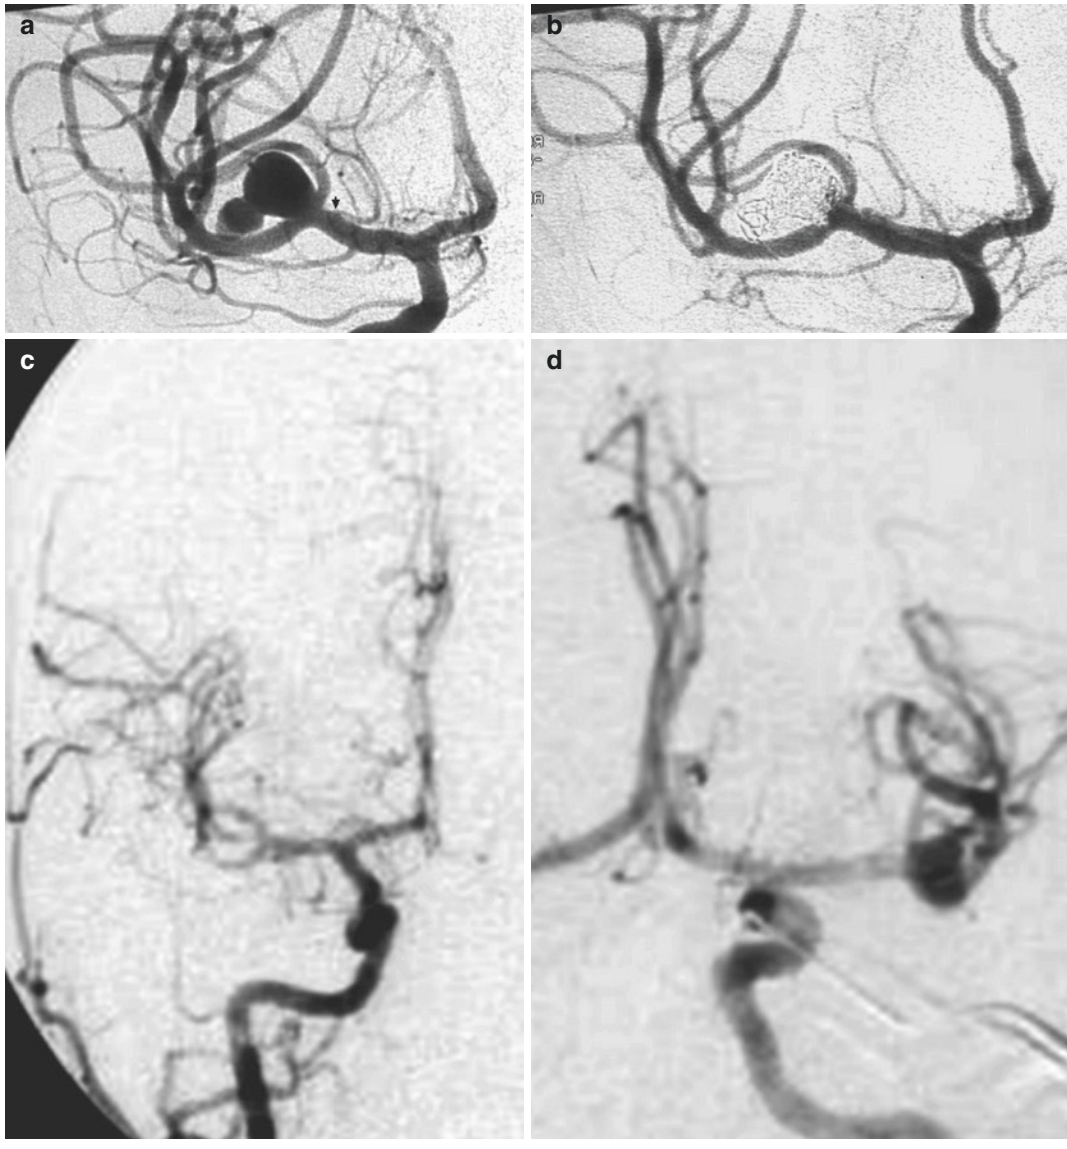

Fig. 11.16 (**a**, **b**) Bilobated large saccular aneurysm at the MCA bifurcation, presenting with hemorrhage. Origin of the distal perforator close to the aneurysm (*arrow*). Pretreatment angiogram (**a**), posttreatment with coils (**b**). Another example of MCA aneurysm in a young patient (**c**–**f**) presenting with SAH. (**c**) Normal right ICA angiogram. (**d**) Left ICA angiogram showing a middle cerebral aneurysm which was treated by surgery. About 8 years later the patient suffered a new SAH. (**e**) A new aneurysm was now recognizable on the right ICA angiogram. (**f**) Left ICA angiogram showing that the treated aneurysm was occluded

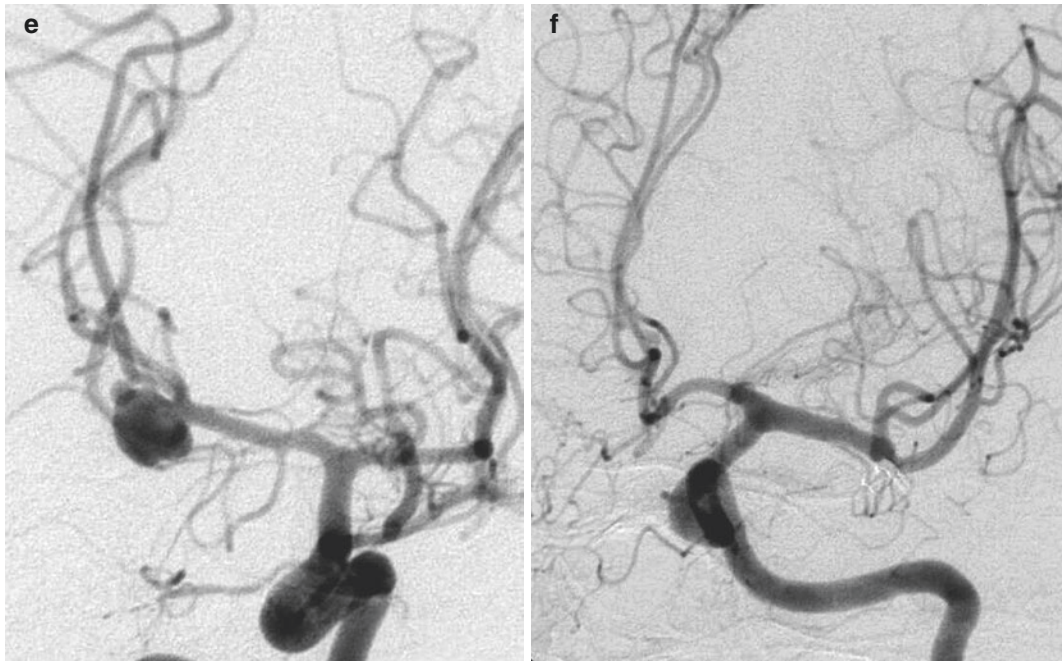

Fig. 11.16 (continued)

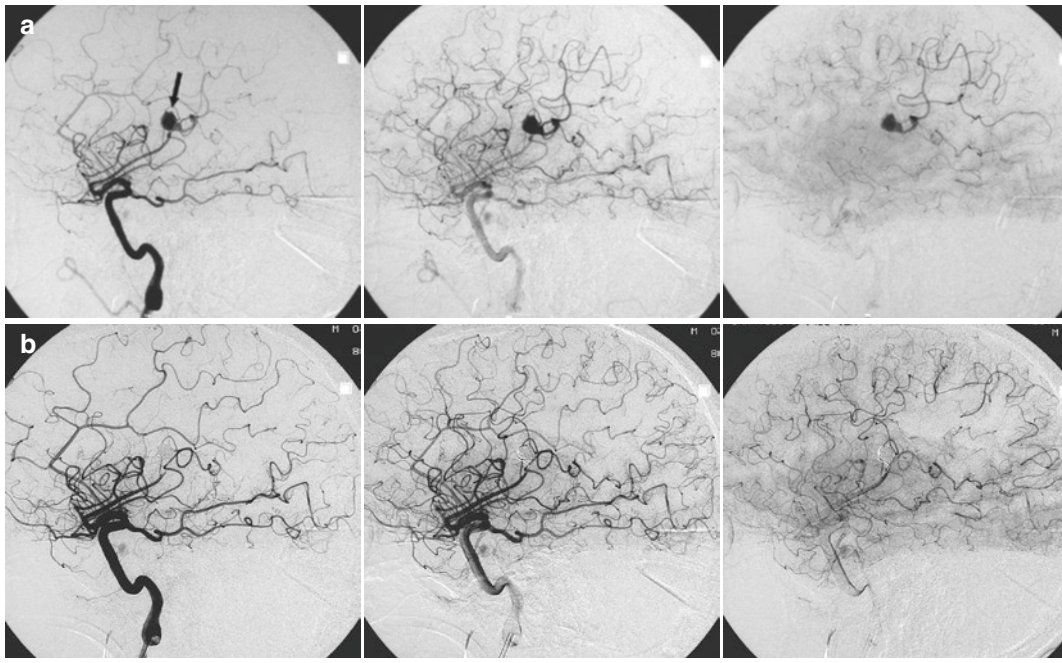

Fig. 11.17 Right carotid angiogram in young patient with transient ischemic episodes. (**a**) Slightly oblique view (early and later phases). There is a large irregular aneurysm (*arrow*) on a distal branch of the MCA. A second small aneurysm is visible more distally. No infection or collagenopathies were present. The aneurysms were thought to be a spontaneous dissection. A decision was taken to occlude the aneurysm and the parent artery which appeared to be a parietal branch. (**b**) Posttreatment angiogram postcoiling. There is a beginning of a retrograde filling of the occluded branch, through leptomeningeal anastomoses. A minimal ischemic lesion developed in the parietal area responsible for a mild motor deficit. Complete recovery in a few weeks

but they are not directly involved since they arise from the P1; this can, however, occur when the neck enlarges involving the proximal part of the P1. Examples are presented in Figs. 11.18, 11.19, and 11.20. Other locations are the distal lateral basilar artery between the origin of the PCA and SCA (Fig. 11.21). Also typical, even if more rare, are the aneurysms of the trunk of basilar artery, more frequently located distally to or close to the origin of the anterior inferior cerebellar artery. These aneurysms are frequently large with a fusiform aspect, often due to a dissection (Figs. 11.29, 11.30, and 16.14). Exceedingly rare (Ding et al. 2013) are aneurysms involving the latero-pontine branches of BA developing at they origin from BA or along their course at the junction with one perforating branch. They are sometimes very small, on the first angiogram, becoming larger on the control. Spontaneous thrombosis is frequent. Flow-related aneurysm associated with AVM can also occur. (Forbrig et al. 2016) Fig. 12.13.

- *Vertebral-PICA Aneurysms.* The vertebral-PICA junction is another typical site of aneurysms. These, however, are sometimes located not exactly at the junction but close to it, in the proximal part of the PICA (medullary segment) (Mukonoweshuro et al. 2003; Bradac and Bergui 2004; Mericle et al. 2006; Cellerini et al. 2008) (Figs. 11.22 and 11.23).
- *Vertebral Artery Aneurysms.* These involve selectively the VA. The pathogenesis is frequently a dissection. They are presented in Chap. 16.
- *Distal Aneurysms of the Cerebellar Arteries.* These are very rare aneurysms, occurring in fewer than 1% of all aneurysms (Lubicz et al. 2003a; Mitsos et al. 2008). The great majority is located in the PICA (Bradac and Bergui 2004; Mitsos et al. 2008), followed by the SCA and AICA aneurysms (Gacs et al. 1983; Chaloupka et al. 1996; Kurosu et al. 2000; Leonardi et al. 2001; Zager et al. 2002; Menovsky et al. 2002; Gonzales et al. 2004; Peluso et al. 2007; Mitsos et al. 2008; Tokimura et al. 2012).
- Unlike the majority of the intracranial aneurysms, which arise at an arterial branching point, distal cerebellar aneurysms arise frequently directly from the artery where it forms a curve, which can be very sharp, especially in the course of the PICA. It has been suggested that this could be the cause of a *hemodynamic stress on the wall* of the artery contributing to the formation of the aneurysm (Lewis et al. 2002; Horiuchi et al. 2003; Mitsos et al. 2008). *Dissection* is another possible pathogenesis, which has been increasingly reported (Lefkowitz et al. 1996; Yamamura et al. 1999; Dinichert et al. 2000; Tawk et al. 2003; Bradac and Bergui 2004; Maimon et al. 2006; Mitsos et al. 2008; Cellerini et al. 2008; Fukushima et al. 2009). *Flow-dependent aneurysms* of the cerebellar arteries related to a more distal AVM, DAVF, and cerebellar hemangioblastoma are relatively frequent in our experience as well as in the reports of several authors (Hudgins et al. 1983; Kaech et al. 1987; Guzman and Grady 1999; Kaptain et al. 1999; Menovsky et al. 2002; Lewis et al. 2002; Peluso et al. 2007). Examples of distal aneurysms of the cerebellar arteries are presented in Figs. 11.24, 11.25, 12.14, 12.15, 12.16, and 16.12. Aneurysms of the distal branches of the cerebellar arteries can rarely also develop in *a great variety of vasculopathies and cardiac diseases* as described in Chaps. 17 and 18.
- In aneurysms involving the distal segment of the cerebellar arteries, the occlusion also of the parent artery can commonly be performed, without or with minimal clinical problems, since the perforators for the medulla arise in the proximal segments (see anatomy). Furthermore, the distal cortical branches are revascularized through a frequently rich collateral circulation via leptomeningeal anastomoses involving the distal branches of the cerebellar arteries.
- *Aneurysms of the Posterior Cerebral Arteries.* These are rare aneurysms with a relatively typical location at the P1–P2 passage. More rare are those located along the course of the P2 and P3. Such aneurysms are frequently large without a well-defined neck, sometimes with a fusiform aspect. Their etiology is thought to be frequently a dissection (Lazinski et al. 2000; Ciceri et al. 2001; Li et al. 2007a;

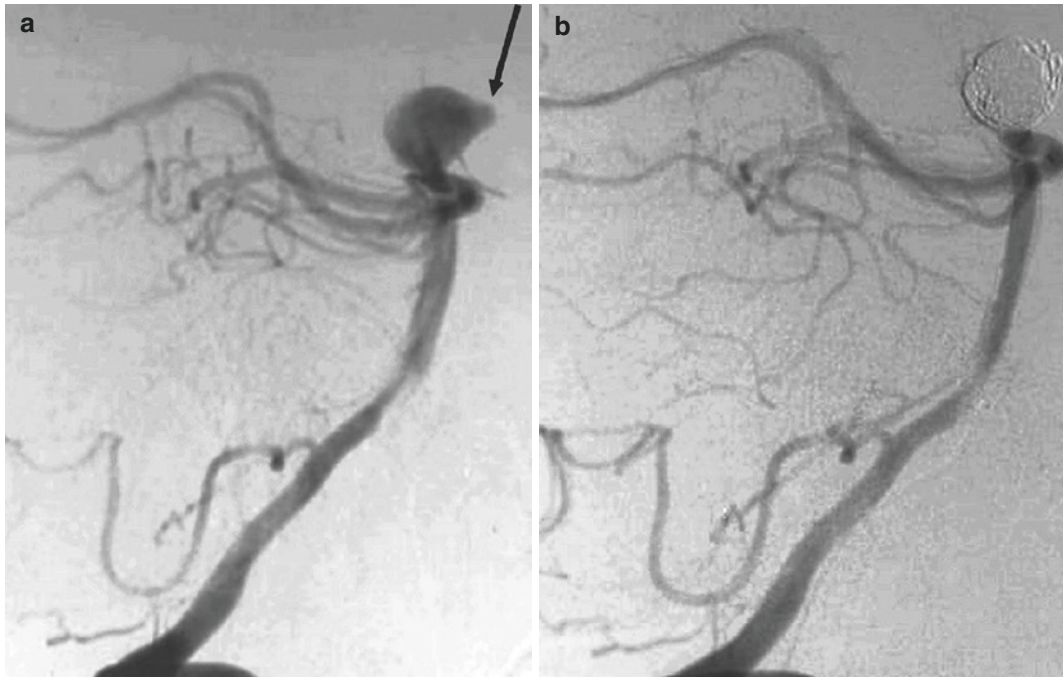

Fig. 11.18 (**a**) Vertebral angiogram in patient presenting with SAH, showing a basilar-tip aneurysm where a bleb (*arrow*) probably indicating the site of rupture is visible. (**b**) Posttreatment angiogram showing the occlusion of the aneurysm with coils

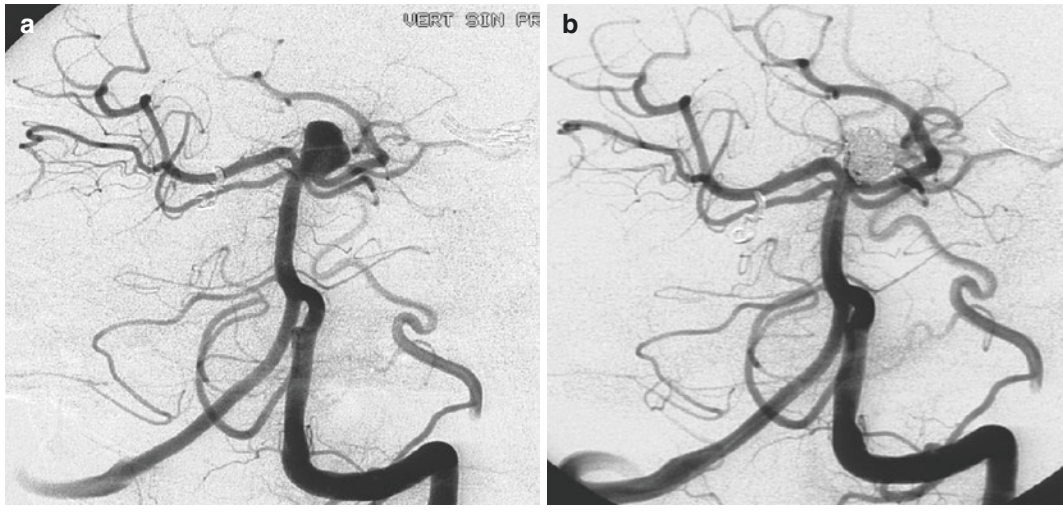

Fig. 11.19 Nonruptured basilar-tip aneurysm with a neck involving partially the left P1. The patient had already been treated for a ruptured aneurysm of the AcomA. (**a**) Angiographic study pretreatment. (**b**) Control angiogram posttreatment. Occlusion of the aneurysm with coils assisted with positioning of a stent (enterprise) in the distal BA and left P1

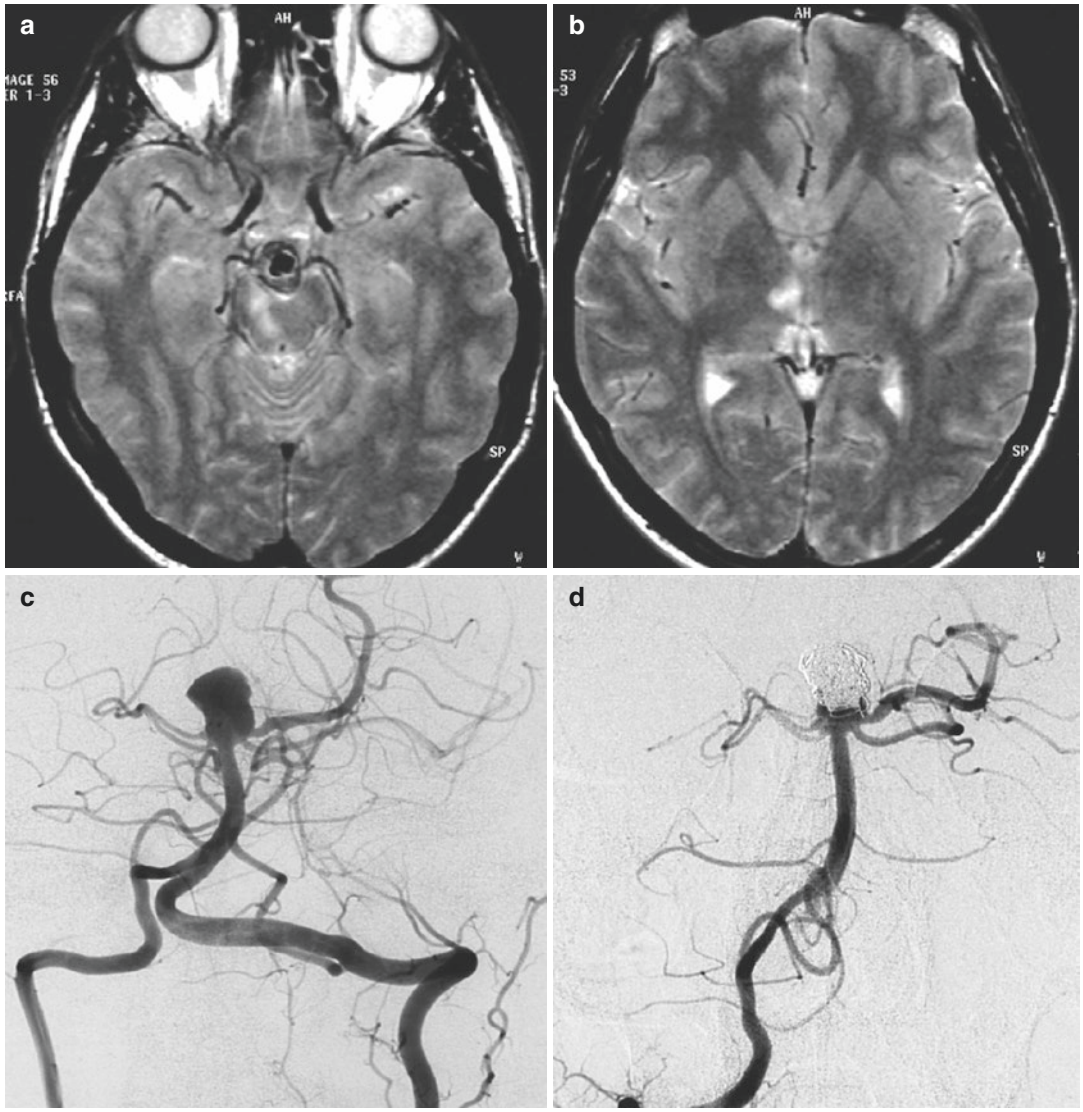

Fig. 11.20 A 40-year-old man presenting with acute midbrain-thalamic syndrome. (**a**, **b**) On MRI small ischemic lesions were recognizable in the right medial part of midbrain and thalamus, corresponding to the vascular territory of perforators arising from P1. A large basilar-tip aneurysm, probably responsible for the thromboembolic occlusion of the right P1, was demonstrated. (**c**) The patient recovered, and the aneurysm was occluded with coils a week later

Roh et al. 2008; Zhao et al. 2013). This is especially true for such aneurysms in pediatric patients (Laughlin et al. 1997; Lasjaunias et al. 2005; Vilela and Goulão 2006; Bradac et al. 2008a).

In many cases, occlusion of the aneurysm and parent artery cannot be avoided by endovascular as well as surgical treatment. The risk of a temporo-occipital infarction is relatively low owing to the rich leptomeningeal collateral circulation. Greater risk is present in more proximal occlusions as a result of involvement of perforators supplying the midbrain and thalamus arising from P1–P2 (Pia and Fontana 1977; Sakata et al. 1993; Ciceri et al. 2001; Arat et al. 2002; Hallacq et al. 2002; Li et al. 2007a; Roh et al. 2008)

(see also Chap. 7). Owing to the anatomical variations of the branches from which arise the perforators for midbrain and thalamus, the developing of an ischemic lesion is a little unpredictable. Fortunately, when ischemia occurs, the clinical impairment is commonly mild and resolves over ensuing weeks. Examples of aneurysms of the PCA are presented in Figs. 11.26 and 11.27.

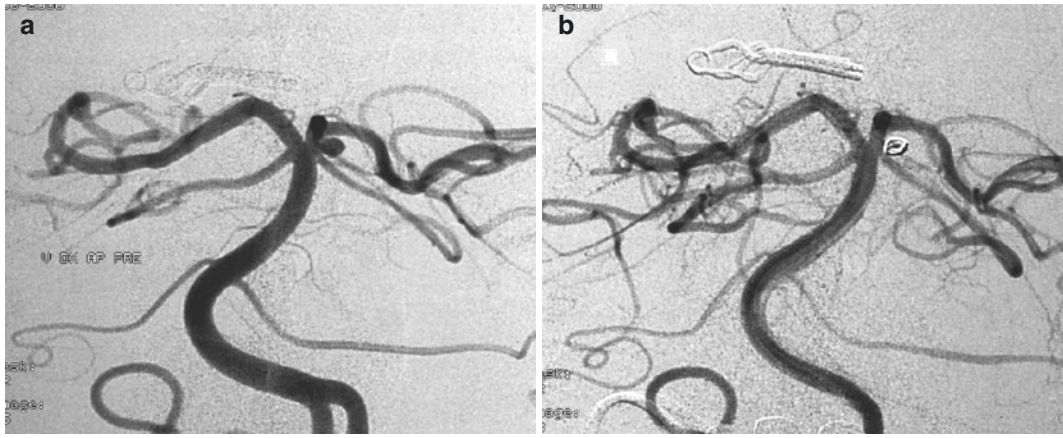

Fig. 11.21 Patient already operated on for an AcomA aneurysm. A second aneurysm was present at the junction of the left PCA and SCA. (**a**) Vertebral angiogram. (**b**) Control angiogram posttreatment showing the occlusion of the aneurysm with coils

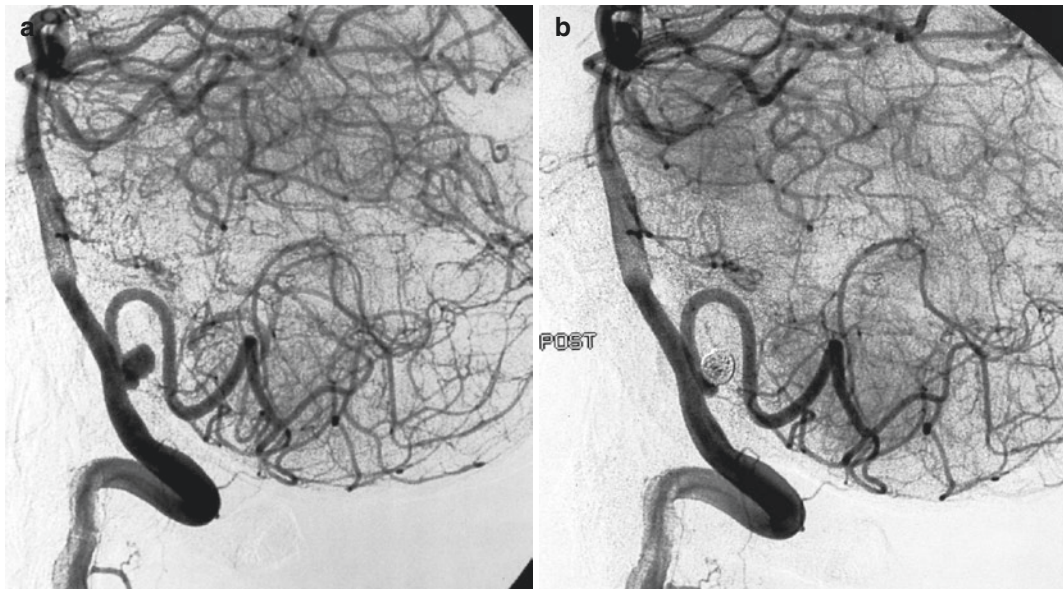

Fig. 11.22 Patient presenting with SAH due to rupture of a typical VA-PICA aneurysm. Pre- and posttreatment vertebral angiogram, with occlusion of the aneurysm with coils

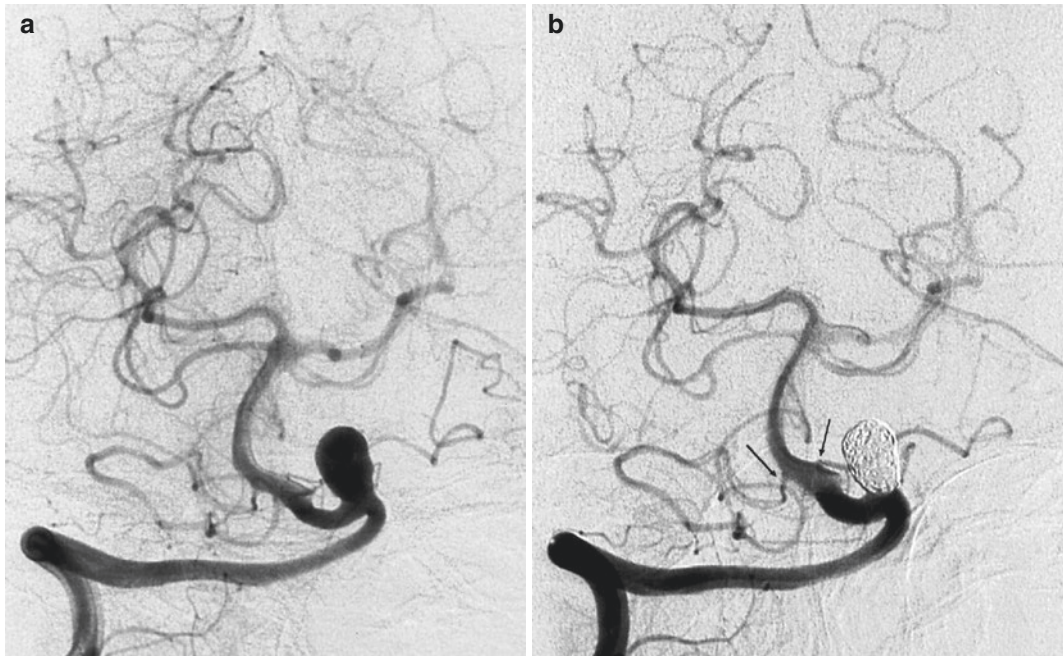

Fig. 11.23 Large unruptured aneurysm in a young patient. There was a well-developed right vertebral artery and a hypoplastic left vertebral artery. The aneurysm was located at the junction of the vertebral artery with a hypoplastic left PICA. There was a bilateral well-developed anterior inferior cerebellar artery (AICA; *arrows*), supplying the vascular territory of both PICAs. Right vertebral angiogram pre- and posttreatment with coils

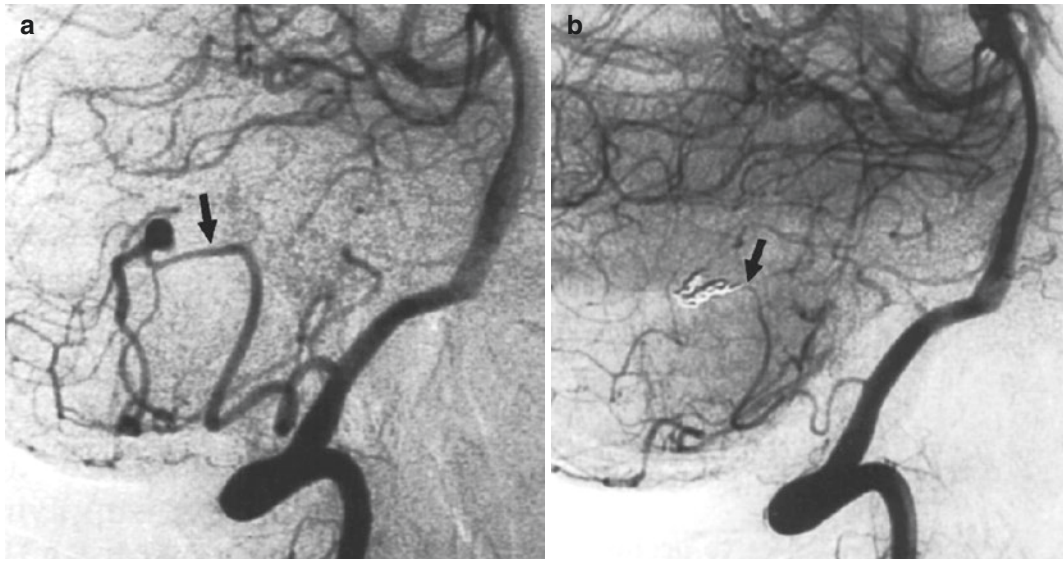

Fig. 11.24 Aneurysm of the supratonsillar segment of the PICA presenting with hemorrhage. (**a**) Vertebral angiogram showing the aneurysm. Supratonsillar segment (*arrow*). There is also a dilatation of the retrotonsillar segment of the PICA

Fig. 11.25 Aneurysm of the retromedullary segment of the PICA presenting with hemorrhage. Pretreatment vertebral angiogram (**a**) presenting the aneurysm and posttreatment angiogram (**b**) showing its occlusion with coils (*arrow*). Two months later, the patient was admitted again owing to a new hemorrhage. The angiogram (**c**) showed regrowth of the aneurysm (*arrow*), which probably was originally a dissecting aneurysm. Occlusion of the aneurysm and of the parent artery was performed (**d**). The patient recovered completely

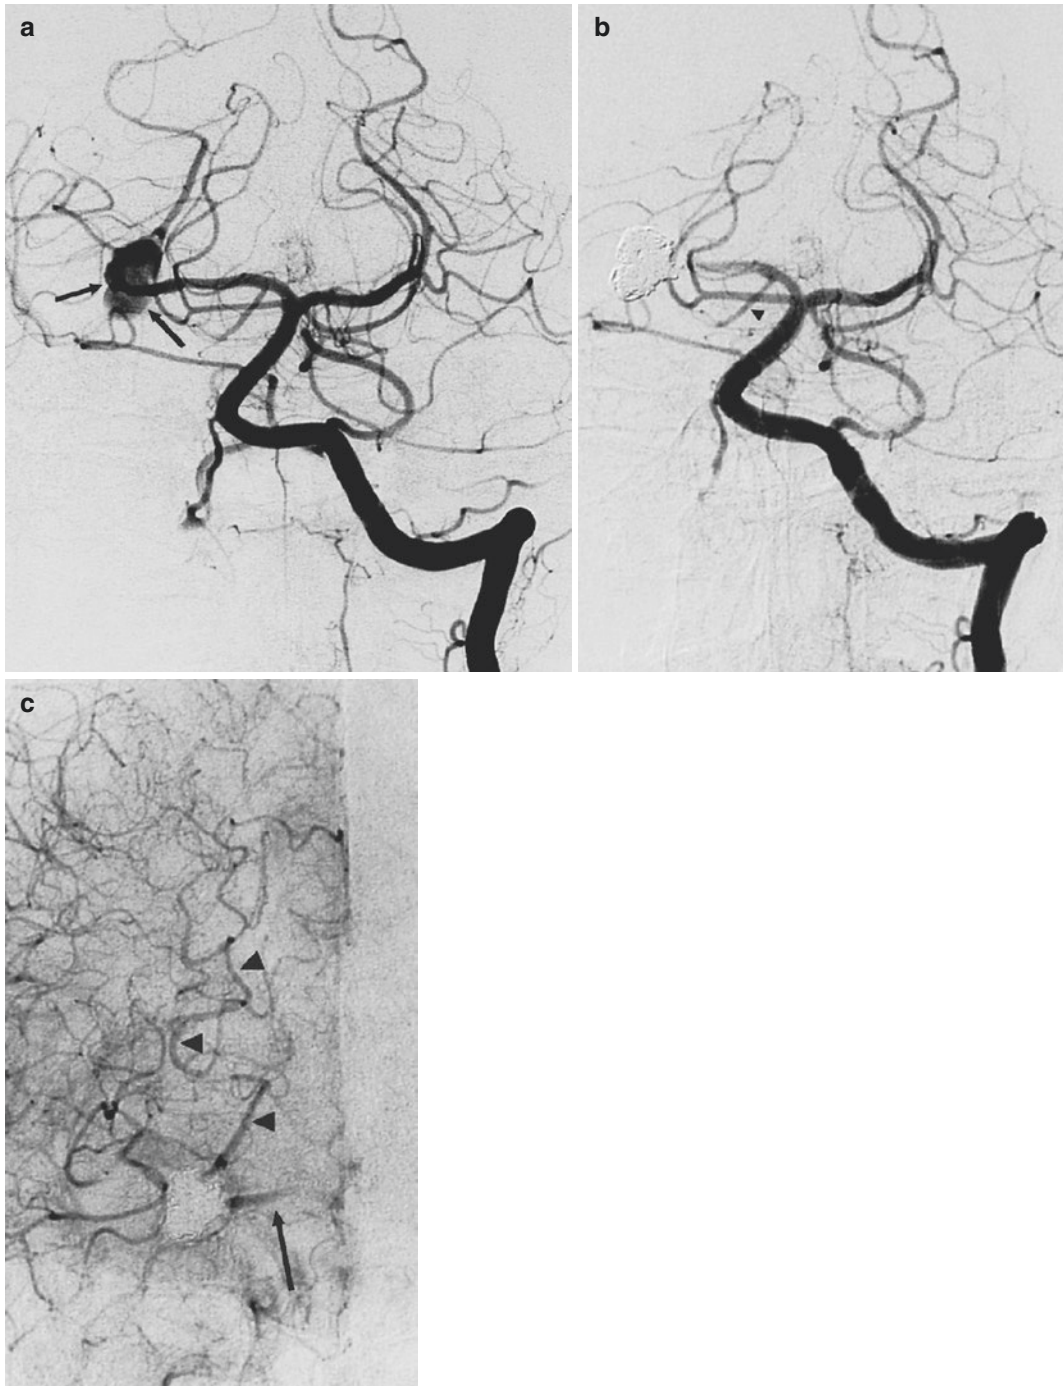

Fig. 11.26 Unruptured irregularly, probably dissecting aneurysm involving the P2 segment of the right PCA in a patient presenting with a transient episode of hemianesthesia. Left vertebral angiogram (**a**) showing the aneurysm (*arrows*). Posttreatment angiogram (**b**) with occlusion of the aneurysm and the P2 segment of the PCA. Note the posterior communicating artery (*arrowhead*). Carotid angiogram (**c**) with retrograde injection of the posterior cerebral artery up to the aneurysm (*arrowheads*), through leptomeningeal anastomosis between the MCA and PCA. There is also injection of the proximal P2 (*arrow*) through the posterior communicating artery. The patient tolerated the treatment well despite a small ischemic lesion in the lateral thalamus owing to involvement of the thalamogeniculate artery, as demonstrated by MRI

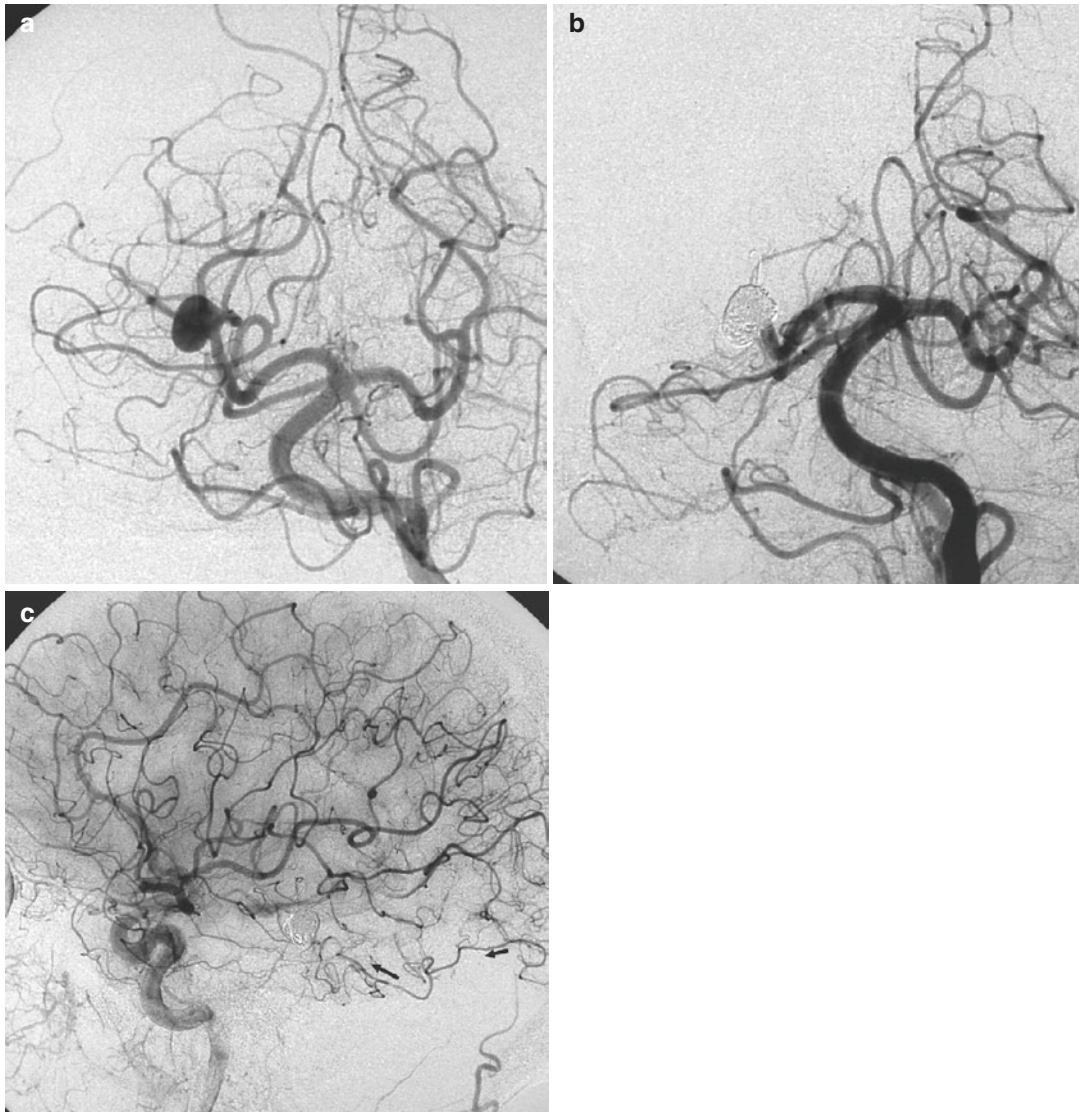

Fig. 11.27 Unruptured aneurysm without a defined neck in a young patient. (**a**) Left vertebral angiogram, showing the aneurysm at the P2 segment of the right PCA. (**b**) Control angiogram after occlusion of the aneurysm and the parent artery. (**c**) Carotid angiogram. Retrograde injection of distal branches of the PCA (*arrows*) through opening of a leptomeningeal anastomosis with branches of the MCA

11.7 Dissecting Aneurysms

They are found most frequent in the posterior circulation, where they typically affect the basilar and vertebral arteries. Aneurysm of distal branches of the cerebellar and posterior cerebral arteries can also be due to dissection. Dissecting aneurysms in the anterior circulation are less common. The distal ICA, proximal MCA and ACA, and PcomA are the most usual locations. Distal branches can occasionally be involved. All aspects of these particular aneurysms are discussed extensively in Chap. 16.

11.8 Large and Giant Aneurysms

Large and giant aneurysms are relatively rare, representing, respectively, about 15 and 5% of all cerebral aneurysms. They can be saccular or fusiform.

Fusiform aneurysms are located predominantly in the vertebrobasilar sector where the most frequent location is the basilar artery followed by the vertebral and the P1–P2 segments of the PCA. Fusiform aneurysm in the anterior circulation is more rare. The most frequent involved artery is the MCA followed by the ICA and ACA (Drake and Peerless 1997). Unlike saccular aneurysm, in which a neck is recognizable, in fusiform a large part or the entire vessel expands. The pathogenesis of these aneurysms cannot be always determined. Considering however their clinical evolution the fusiform aneurysms can be subdivided basically into two groups (Shokunbi et al. 1988; Nakatomi et al. 2000; Leibowitz et al. 2003).

In some cases, the fusiform aneurysm grows gradually. Its pathogenesis is thought to be due to a primary lesion of the internal elastic lamina characterized by its disruption and fragmentation occurring in a particular form of atherosclerosis. Intima hyperplasia, infiltration and fibrosis of the media, and neovascularization causing intramural bleeding follow. All this leads to a progressive dilatation and tortuosity of the artery, promoted also by the frequent presence of hypertension. The increased luminal diameter leads to a slowing down of the circulation and formation of thrombi on the wall which promotes further the pathologic process with progressive rigidity of the wall and dilatation (Hegedus 1985; Echiverri et al. 1989). The prognosis of these patients is commonly very poor. The progressive dilatation leads to compression of the brain parenchyma. Ischemia, due to involving of the perforating branches or due to embolization, occurs. Hemorrhage is uncommon (Little et al. 1981; Nishizaki et al. 1986; Echiverri et al. 1989; Pessin et al. 1989; Leibowitz et al. 2003), even though in some studies it has been reported as being not so rare (Flemming et al. 2004) (Fig. 11.28).

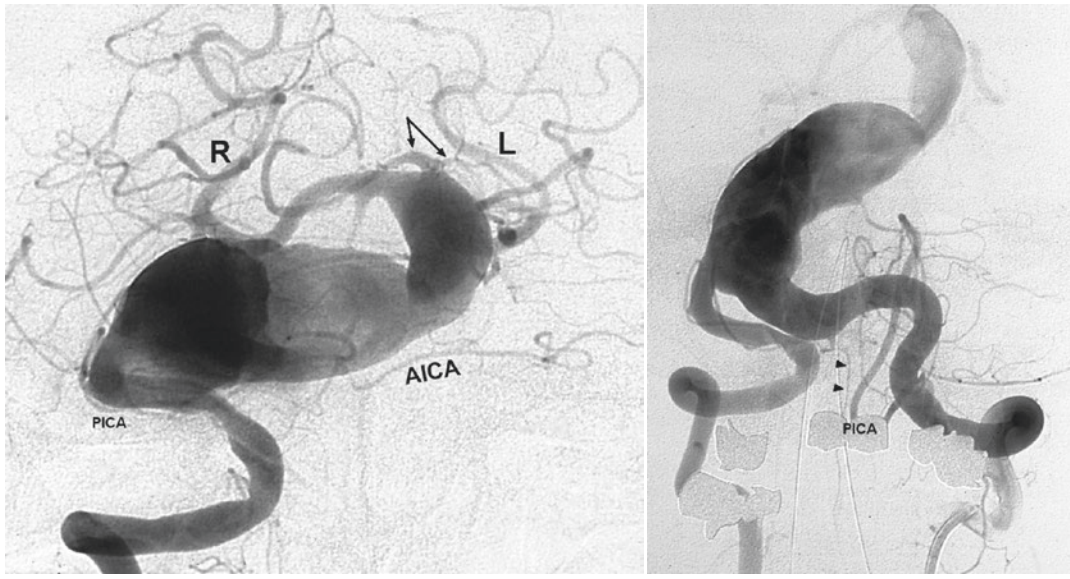

Fig. 11.28 Patient presenting with progressive tetraplegia due to giant fusiform aneurysm of the basilar artery compressing the brainstem. Left and right vertebral angiogram. The left and right PCAs are well recognizable (L and R) as is the right superior cerebellar artery (*arrow with angle*). That on the left is very small. AICA is on the left. Well-developed PICA is on the left and small PICA on the right. Anterior spinal artery (*arrowheads*). Occlusion of the left vertebral artery with a balloon, proximal to the PICA, was performed to reduce the flow in the aneurysm. There was a partial clinical improvement, followed by a severe fatal subarachnoid hemorrhage 1 month later

In other cases, the pathogenesis is probably a dissection due to pathological changes involving the internal elastic lamina and the media occurring in various pathological conditions which are described in detail in Chap. 16. These patients are commonly younger in whom the aneurysm presents frequently with acute symptoms due to compression of brain, ischemia, and frequently with hemorrhage.

Saccular aneurysms can be found in the anterior circulation (cavernous, supraclinoid portion of the ICA proximal ACA and MCA) and in the posterior circulation (VA, BA, and PCA) (Figs. 11.1, 11.2, 11.4, 11.5, 11.29, and 11.30). It is thinkable that they evolve from smaller saccular aneurysm due to the same causes which had led to the formation of the aneurysm, that is, degenerative changes of the internal elastic lamina and media favored by hemodynamic factors (see Sect. 11.4). However, the reason why this occurs in a few aneurysms and while not in the other is not clear. In other cases the pathogenesis is probably dissection. They can present with hemorrhage but frequently the symptoms are due to mass effect. *A particular subgroup of these aneurysms* are those in which the growth appears in spite that the aneurysm is partially or completely thrombosed (Schubiger et al. 1987). It has been suggested that a proliferation of new capillaries within the thrombotic part of the aneurysm occurs. Their rupture causes hemorrhage especially at the periphery of the intra-aneurysmal thrombus leading to a progressive dissection and growth (Katayama et al. 1991; Nagahiro et al. 1995; Yasui et al. 1998; Kaneko et al. 2001). Other authors (Atlas et al. 1987; Zhao et al. 2004; Krings et al. 2007a) have also discussed the possibility that in association of the angiogenesis an

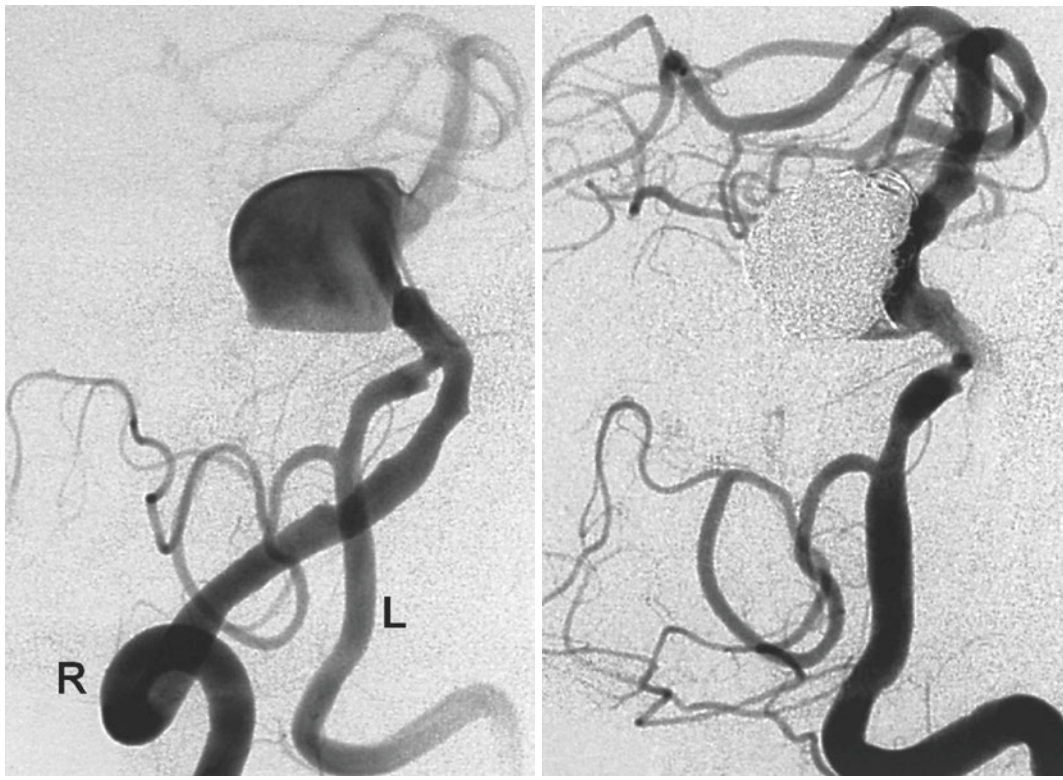

Fig. 11.29 Giant aneurysm of the middle basilar artery presenting with brainstem syndrome in an older patient. A clear neck cannot be recognizable. Atheromatous changes along the course of the VAs and BA are visible. Left (L) and right (R) vertebral arteries. The aneurysm was occluded with coils supported by balloon (remodeling technique). On the right the angiogram posttreatment. There was a clinical improvement of the symptoms

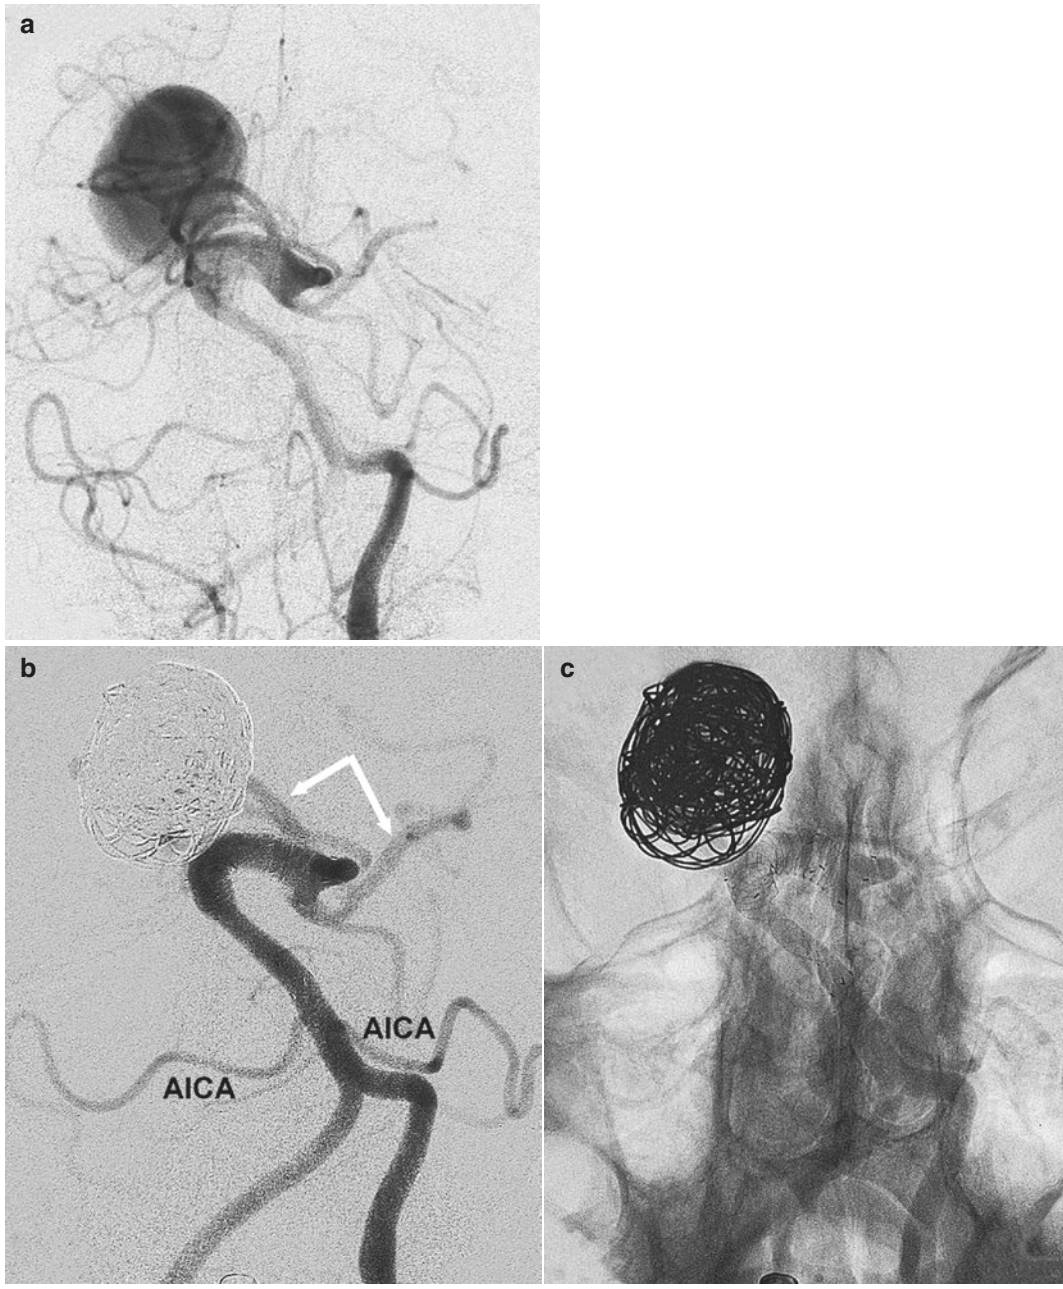

Fig. 11.30 Giant aneurysm of the basilar artery (BA) in middle-aged hypertensive patient presenting with acute cranio-cervical pain. (**a**) Vertebral angiogram showing a giant aneurysm in the middle-superior part of a tortuous and dilated BA. (**b**) Vertebral angiogram posttreatment showing the occlusion of the aneurysm with coils and flow diverter. The latter better visible on the nonsubtracted images. Anterior inferior cerebellar arteries (AICA), PCAs (*arrow with angle*). Due to overlapping SCAs are not clearly identified. Progressive improvement of the clinical condition. Compare this case with that in Fig. 11.29, presenting a similar situation treated years before indicating the evolution in the possibility of treatment

inflammation process develops which stimulates additional proliferation of capillaries with further hemorrhage. The inflammatory aspect seems to be confirmed by the presence on MR investigation of a rim enhancement of the wall of the aneurysm associated frequently by an edema of the surrounding parenchyma (Krings et al. 2007a). Taking into consideration these possible evolutions, the ideal treatment should be the complete surgical excision. This is, however, not always possible and linked with high risks.

11.9 Diagnosis and Treatment

In patients with SAH, CT angiography can be a very useful diagnostic method instead of conventional angiography. However, negative results, especially with small aneurysms near the skull base, do not exclude with certainty the presence of an aneurysm. MR angiography can be employed as a screening method to detect aneurysms in selective group of persons, such as those with polycystic kidney or in family with a rich incidence of aneurysm. MR angiography is not commonly used in the acute phase of SAH. Conventional vessel angiography remains the gold standard that is to be performed every time there is an unclear diagnosis or if an endovascular treatment has been considered.

Cushing (1926), was the first to approach surgically a cerebral aneurysm. Dott (1933), Toennis (1936), and Dandy (1938) were the first to treat a cerebral aneurysms diagnosed with the cerebral angiography introduced by Moniz (1927). Since then many improvements in the surgical technique have been made leading to a progressive morphological and clinical good results.

The endovascular technique especially through the development of the detachable coils (Guglielmi et al. 1991a, b) has opened a new, certainly revolutionary approach for the treatment of cerebral aneurysms. Since then, the increasing quality of coils and microcatheters, the application in selected cases of new techniques (Balloon-coil Moret et al. 1997), and the later introduction of stents in association with coils have progressively expanded the indications for endovascular treatment (Moret et al. 1997; Boccardi et al. 1998; Molineux et al. 2002; Murayama et al. 2003a; Henkes et al. 2004; Bradac et al. 2005, 2007; Gallas et al. 2005; Park et al. 2005; Kurre and Berkefeld 2008; Wanke and Forsting 2008; Loumiotis et al. 2012; Pierot et al. 2012; Fargen et al. 2012; Lubicz et al. 2006, 2017). Further progress has been obtained with the development of flow-diverter stents which allow to treat more difficult aneurysm such as fusiform, those with more complex morphology, or aneurysms presenting with recanalization, as progressively reported (Berge et al. 2012; Martinez et al. 2015; Yavuz et al. 2014; Saleme et al. 2014; Caroff et al. 2015; Clarençon et al. 2017; Gawlitza et al. 2015; Chalouhi et al. 2015; Puri et al. 2016). There is, however, one limitation, which should be considered in the use of flow-diverter stent. Indeed, the need to associate this device to an antiplatelet therapy makes its use commonly not indicated in the acute phase of SAH.

Today the endovascular treatment is the first choice of therapy in the majority of the aneurysms with good morphological and clinical results. Complications mainly characterized by ischemia due to distal embolization, occlusion of perforators or parent artery occurring during or in the next hours after the treatment, as well as hemorrhage due to rupture of the aneurysm have become with increasing experience progressively more rare. An extremely seldom complication has been reported by some authors (Fealey et al. 2008; Ulus et al. 2012; Cruz et al. 2014; Lobotesis et al. 2015). This is characterized by distal parenchymal lesions which present on MR-CT with ischemic-like areas or small enhancing lesions surrounded by edema, appearing weeks or months after an uneventful treatment and commonly reacting positively to corticosteroid therapy. The cause of this strange phenomenon is not clear. Inadvertent foreign body embolization occurring during the treatment has been considered (Shotar et al. 2016). In a few cases where a biopsy has been performed a granulomatous angiitis related to the foreign material has been identified (Fealey et al. 2008; Shapiro et al. 2015; Shotar et al. 2016).

More problematic remains the treatment of giant and fusiform aneurysm. For these, different endovascular strategies can be applied. The most old technique is the occlusion of the parent artery with coils or balloon. This technique has been frequently used in paraclinoid ICA aneurysm. For this treatment the patient has to pass a test of occlusion of the ICA commonly performed with balloon. Once the balloon is inflated, heparin is injected, the clinical condition of the conscious patient is continuously monitored, and an angiographic study of the contralateral carotid and of the vertebral arteries is performed. After 25–30 min if no neurological deficit develops and the angiographic study reveals a good collateral circulation of the circle of Willis including the examination of the venous phase in the hemisphere of the occluded ICA, this can be occluded. The accepted delay of the appearance of the veins in the involved hemisphere indicating tolerance has been differently reported varying from a simultaneous appearance (Lubicz et al. 2003b; Van Rooji et al. 2005) to 1.5–2 s (Abud et al. 2005; Clarençon et al. 2011; Kim et al. 2014; Whisenant et al. 2015). In a recent study (Matouk et al. 2012) 3 s has been accepted. We performed the test of occlusion in a *conscious* patient which allows a precise clinical monitoring. If the clinical condition remains unchanged, the collateral circulation is efficient, and the venous delay is between 1.5 and 2 s, the ICA is occluded definitely. The treatment is characterized, in the great majority of the cases by an excellent result (Van der Schaaf et al. 2002; Abud et al. 2005; Li et al. 2007; Van Rooji et al. 2005; Clarençon et al. 2011; Matouk et al. 2012; Whisenant et al. 2015). Ischemic lesions, however, even if very rare, due to a hemodynamic or embolic mechanism cannot be completely excluded.

The same technique can be useful in the occlusion of one VA in cases of giant or fusiform aneurysms where the posterior circulation is guaranteed by the contralateral VA. Also occlusion of the basilar artery in cases of fusiform or giant aneurysm has been used, provided that the distal part of the BA is revascularized through an efficient circle of Wills (Henkes et al. 2006). Distal aneurysms can be treated with a sacrifice of the parent artery, when a good leptomeningeal collateral circulation is present. If this is insufficient the parent vessel occlusion can be preceded by bypass-surgery (Van Roij and Sluzewski 2009).

The introduction of stent in association with coils and flow-diverter stents has opened new ways in the treatment of large and fusiform aneurysms and progressively those with complex morphology as reported by several authors (Yang et al. 2007; Lubicz et al. 2008; Liebig and Henkes 2008; Gall et al. 2009; Chapot et al. 2009; Fiorella et al. 2009b; Szikora et al. 2010; Leonardi et al. 2011; Briganti et al. (2012); Kalmes et al. (2015); Deutschman et al. 2012) (see also Sect. 16.6).

As far as it concerns the flow-diverter stent, there is no doubt about its utility in the treatment of morphologic complex aneurysms. However, some problems linked with this device remain unsolved at this time. In particular, as demonstrated in the studies of Bing et al. (2013) and Roszelle et al. (2013), improvement should be directed in the attempt to guarantee an adequate porosity which should on the one hand exclude the flow into the aneurysm and on the other hand allow a flow into a small adjacent perforator. Furthermore, this device can be associated with complications responsible for morbidity and mortality with a rate reported to be 3.9% and 6.6%, respectively, in the study of Velioglu et al. (2012), and 3% and 3% in the report of Piano et al. (2013). In the extensive meta-analysis of Brinjikji et al. (2013) morbidity and mortality were, respectively, 5% and 4% and these results remained grossly unchanged in a more recent study of Kalmes et al. (2015) in which the morbidity and mortality were 7.4% and 3.8%, respectively. Complications are due basically to ischemia or hemorrhage.

Ischemia results from thrombus at the site of the stent leading to occlusion of the parent vessel or to distal embolization. Another cause of ischemia is occlusion of the perforating branches, which occurs more frequently in the posterior circulation (Kulcsar et al. 2010; Siddiqui et al. 2012; Meckel et al. 2013b; Brinjikji et al. 2013; Kalmes et al. 2015; Wang et al. 2016a).

As far as it concerns *the hemorrhage*, it can be due to rupture of the aneurysm (Kulksar et al.

2011, 2012; Chow et al. 2012; Kalmes et al. 2015), or occurring as delayed hemorrhage distal to the aneurysm, mainly but not always in the vascular territory of the flow diverter (Velat et al. 2012; Cruz et al. 2012; Leung et al. 2012; Brinjikji et al. 2013). Hemorrhages *occurred predominantly in giant and posterior circulation aneurysms* (Rouchaud et al. 2016; Wang et al. 2016a). The cause of hemorrhage is not completely clear. In cases of *hemorrhage due to aneurysm rupture*, some authors (Cebral et al. 2011) have suggested that the stent leads to flow modifications responsible indirectly for an increased intra-aneurysmal pressure and consequently rupture of the aneurysm. For other authors (Tulamo et al. 2010; Kulksar et al. 2011), the intraluminal thrombus could be the source of proteases with proteolytic activity which could favor the rupture of the wall. The same mechanism could be responsible for the rupture of aneurysms completely occluded with coils and excluded from the circulation.

In cases of distal hemorrhage, this could be due to hemorrhagic transformation of distal ischemic lesions occurring more frequently in giant aneurysms requiring the use of more than one stent and a more longer treatment (Velat et al. 2012; Chiu et al. 2013; Rouchaud et al. 2016). Interesting to note is that the same can occur in the treatment of aneurysm treated with coils in association with stents (flow diverter or not flow diverter), indicating that in some cases, at least, the hemorrhagic transformation of microembolic ischemic lesions favored by the antiplatelet therapy could be the cause of the hemorrhage (Kayan et al. 2016). Other authors (Cruz et al. 2012) examining the distal hemorrhage in aneurysm treated in the anterior circulation (large aneurysms of the distal ICA or proximal MCA) have suggested that the flow diverter could reduce the arterial compliance of these vessels leading to changes of the blood pressure in the form of a higher systolic and lower diastolic values transmitted distally which could favor the formation of the hemorrhage. Also a sudden hyperperfusion distal to the aneurysm as suggested by others (Chiu et al. 2013) could be taken into consideration. Similar mechanism has been reported also in giant aneurysm treated by surgery (Murakami et al. 2002). Another possible complication is a distal SAH which can be severe, but sometimes be minimal, and it is discovered on the routine CT 24 h after the treatment. These patients can have only a mild headache which rapidly disappears or will be completely asymptomatic. All these signs disappear rapidly. As also reported by others (Piano et al. 2013; Gawlitza et al. 2015), we observed this event in two patients. The SAH can be due to minimal damage with partial dissection through the guide wire, or be the result of hyperperfusion in association with a toxicity of the contrast medium due to the frequent angiographic controls damaging the wall of the distal small arteries causing the bleeding.

Another interesting aspect which has become progressively known in patients treated with stents is the narrowing of the lumen of the artery due to *intimal hyperplasia*. In a large study presented by Kim et al. (2016) it has been demonstrated that this is a reversible phenomenon. It was more evident within 8 months after the treatment followed by a progressive regression with almost normalization of the lumen within 24 months. It has been suggested that weeks to months after the treatment, smooth muscle cells migrate from the tunica media into the intima leading to thickening of it. Later this infiltration regresses and the intima returns to its primary structure. In later controls, especially in treated fusiform aneurysm, the stent can be incorporated in the new restructured intima.

In conclusion, *the introduction of the endovascular treatment and its positive evolution due to the extremely rapid development of new devices and progressive higher experience have certainly improved the treatment and prognosis of many patients. However, we are far from an ideal endovascular treatment and one should be cautious in the indication of treatment and in the choice of the device, in the attempt to determine the best treatment in the given patient* (Van Rooij 2012; Kalmes et al. 2015). *The aneurysm remains an insidious pathology and its treatment is still burdened by a certain degree of morbidity and mortality. This is especially true for large, giant, fusiform dissecting aneurysms and those with a*

complex morphology which still can have a little unpredictable, sometimes very bad evolution in spite of the apparently technically successful treatment.

11.10 Unruptured Aneurysms

Modern diagnostic methods have revealed an increase in the number of unruptured aneurysms, raising the question of whether they should be treated or not. The rupture of an aneurysm can have catastrophic clinical consequences for the patient. Technical improvements in surgery and endovascular treatment mean today that unruptured aneurysms can be treated and good results obtained, with a low rate of complications, though they are not completely excluded (Roy et al. 2001; Henkes et al. 2004; Bradac et al. 2007; Naggara et al. 2010).

Some factors that can influence the decision have been reported in an international study (Wiebers et al. 2003) of unruptured aneurysms that appeared in Lancet (2003). According to this study, the risk of hemorrhage is low in aneurysms with a diameter of less than 7 mm, but it increases progressively with greater diameters. This consideration seems to be in contradiction with the experience that the majority of the aneurysms diagnosed in patients with SAH are relatively small. However, it is today commonly accepted that the risk of hemorrhage is particularly high in the acute phase when the aneurysm develops and, at this time, it is commonly relatively small (Wiebers et al. 1987). If the aneurysm does not rupture in this phase, the wall fortifies and the risk of hemorrhage decreases. Later, some of these unruptured aneurysms can grow and this associated with changes in their wall increases progressively the risk of hemorrhage.

Independent of the diameter, the risk of rupture is reported to be greater in aneurysms of the posterior circulation and in patients who have already undergone treatment for another ruptured aneurysm.

In the attempt to clarify this matter, further studies have been performed related to the morphology of the aneurysm (irregular shape, multilobar, presence of blebs, as well as perianeurysmal environment). The latter involves constraints on the shape of the aneurysm that could favor its rupture (Rüfenacht 2005). Another factor, which has been considered, is the transmission of pressure and flow rates within the aneurysm, which has been reported to be higher in bifurcation aneurysms (Sorteberg and Farhoudi 2006). Postprocessing analysis of 3D visualization of the angiogram has shown the possible influence of the flow within the aneurysm being dependent on its location (Cebral et al. 2005) and also on its geometry, particularly when the aneurysm has a main axis parallel to the parent artery (Szikora et al. 2008).

In spite of the Lancet report (2003) and the above-reported interesting studies, which have enhanced some aspects of the aneurysm which can influence the decision to treatment, there is today, in many incidentally discovered aneurysms, no certain criteria to define the risk of rupture and no general consensus for or against the preventive treatment of an unruptured aneurysm (Raymond et al. 2008; Raymond 2009; Nagara et al. 2010). The decision still depends on many factor, among them the experience and attitude of the medical team involved, the situation of the patient, especially the age and his emotional reactions to the informations about the pathology.

11.11 Negative Angiograms in Patients with SAH

In about 15–20% of patients with SAH, the aneurysm is not detected on the angiogram. In some patients, particularly in cases with a perimesencephalic pattern of bleeding, the SAH is thought frequently not due to an aneurysm (Rinkel et al. 1991). In other cases, the aneurysm can be definitely thrombosed at the time of the bleeding and thus no longer recognizable, even in later controls. Vasospasm and large hematoma can, however, temporarily hide the presence of an aneurysm that can be demonstrated later.

In rare cases, no spasm or hematoma is present, but the aneurysm is not visualized on the

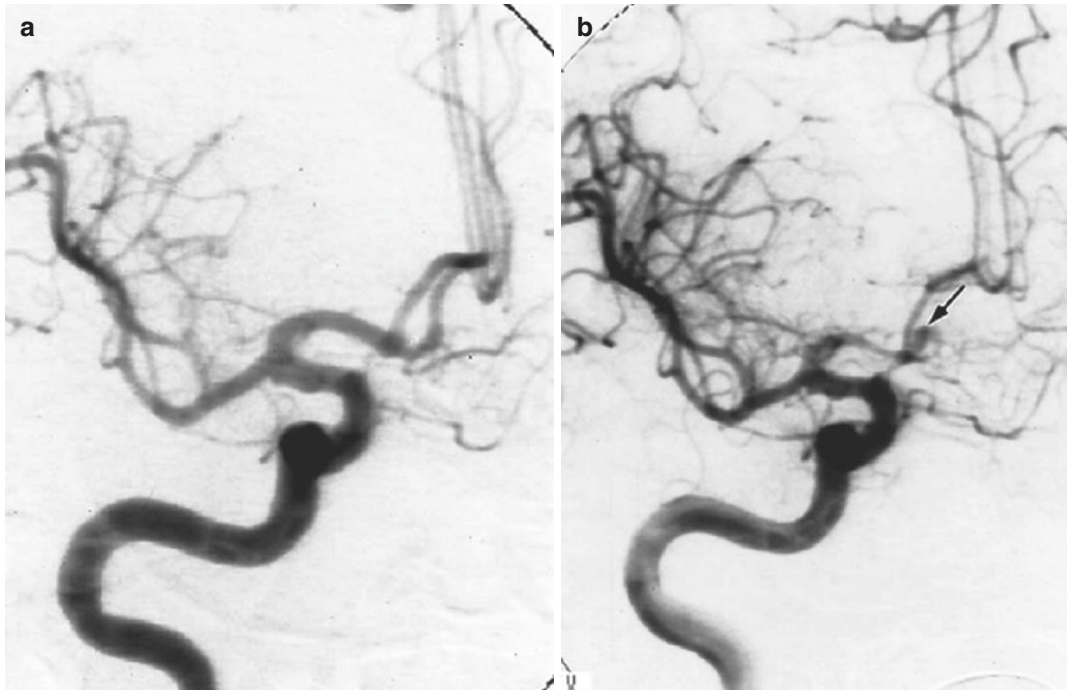

Fig. 11.31 Middle-aged woman with SAH, in whom a complete angiographic study with several projections did not reveal a vascular malformation. A SAH occurred again 2 weeks later. The angiographic study revealed now the aneurysm of the AcomA. (**a**) First right carotid angiogram judged normal. (**b**) The second angiogram showing the aneurysm. Minimal spasm is also present

angiogram performed in the acute phase. It can however be detected 1 or 2 weeks later. This has been reported in about 10–19% of the cases in which the first angiogram was negative (Bradac et al. 1997; Urbach et al. 1998; Alves et al. 2005) (Fig. 11.31). The cause of this phenomenon is not completely known. A temporary thrombosis of the aneurysm can occur. In other cases, the bleeding could be due to a dissection involving the wall of the artery not recognizable in the acute phase. Later this could lead to the formation of the aneurysm. This mechanism probably occurs in the so-called *blister-like aneurysms* (see Sect. 16.5). The extremely rare possibility of SAH due to spinal AVM should also be considered in these cases with a normal angiogram.

11.12 Vasospasm

Vasospasm as a complication of SAH has already been recognized and described in the early 1950s (Ecker and Riemenschneider 1951). Today it is reported to occur in about 70% of the cases. Among them, symptomatic ischemia occurs in about 35% (Wintermark et al. 2006; Komotar et al. 2007; Hanggi et al. 2008). Spasm can occur after every SAH, but younger patients and those with severe hemorrhage, as recognizable on CT, are more at risk of developing vasospasm.

Diagnosis. All patients with SAH should be closely monitored for vasospasm in the days after the acute episode. This can be done using daily transcranial Doppler (TCD), followed on the third or fourth day by CT-perfusion, whenever the TCD shows an increased velocity (more than 120–130 cm/s), especially when this occurs over a short period of time. Independently of and/or in association with these technical controls, every clinical worsening of the patient that is not due to rebleeding or hydrocephalus, excluded by CT examination, can be an indirect sign of spasm. In these cases, angiography should be performed when spasm is confirmed, by endovascular therapy.

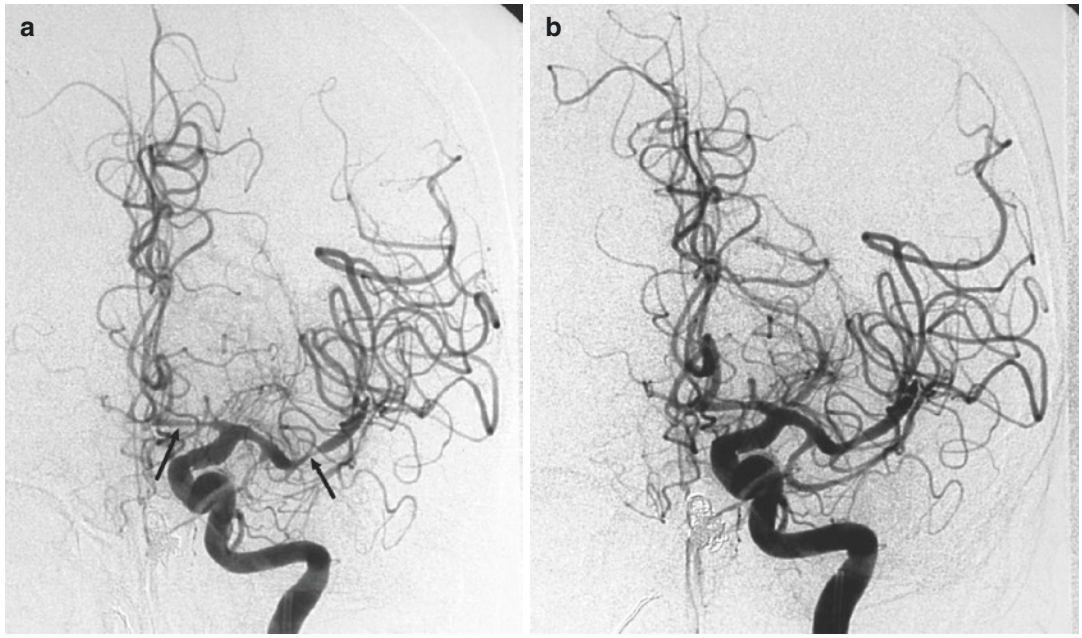

Fig. 11.32 Middle-aged patient with severe SAH due to rupture of a PICA aneurysm that was occluded with coils. The asymptomatic patient deteriorated a few days later owing to severe spasm involving, in particular, the anterior circulation. Left carotid angiogram (**a**) showing the severe spasm involving the A1 and M2 segments (*arrows*). Also, there is minimal spasm of the M1 segment. A similar pattern was seen on the right. The patient was treated with an injection of nimodipine in the ICA, with excellent angiographic results, demonstrated on the left angiogram (**b**). Similar result on the right

Therapy. Medical therapy consists of prophylactic nimodipine, oral or intravenous, depending on the grade of risk for a given patient. Nimodipine is a calcium antagonist which is supposed to act by blocking the effects of many vasoconstrictors of cerebral smooth muscle (Pickard et al. 1987). In many centers, this is associated with monitored hypertensive, hypervolemic, and hemodilution (*triple—H*) therapy. By confirmed spasm on angiography, the most used therapy today is the injection of nimodipine into the ICA uni- or bilaterally at the dose of 1–2 mg per vascular territory (Fig. 11.32). Selective injection in the A1–M1 segments can be useful in certain cases as well as the injection into the vertebrobasilar sector. A partial or complete resolution is obtained in 60–70% of cases (Boker et al. 1985; Bracard et al. 1999; Biondi et al. 2004; Bandeira et al. 2007; Hänggi et al. 2008). The resolution of the spasm may be only temporary, and so a second or more administrations can be necessary in the following days (Biondi et al. 2004). In selected cases of severe spasm not responsive to nimodipine, balloon angioplasty of the distal segment of ICA A1–M1 segments can be performed (Murayama et al. 2003b; Abruzzo et al. 2012). The progressive improvement of the endovascular material makes it possible today to perform this treatment with a low risk.

11.13 Aneurysms in Children

Intracranial aneurysms in children are rare, representing less than 5% of all cerebral aneurysms. They differ from those of the adults in the location, etiology, and clinical presentation. As reported by several authors (Ostergaard and Voldby 1983; Laughlin et al. 1997; Allison et al. 1998; Proust et al. 2001; Lasjaunias et al. 2005; Huang et al. 2005), they are more frequent in boys, whereas in the adults there is a predominance among women. This seems to indicate a gender influence.

The most frequent location of the aneurysms is reported to be the anterior circulation. Among them, ICA (ICA bifurcation, more rarely cavernous) and MCA aneurysms are predominant (Ostergaard and Voldby 1983; Heiskanen 1989; Laughlin et al. 1997; Allison et al. 1998; Proust et al. 2001; Huang et al. 2005; Aryan et al. 2006; Vaid et al. 2008) in the posterior circulation are more rare. These later, however, are more frequent in comparison to the adults. These can involve the BA and VA and their branches. Among these a frequent location is reported in the PCA (Meyer et al. 1989; Laughlin et al. 1997; Huang et al. 2005; Aryan et al. 2006; Vilela and Goulão 2006; Bradac et al. 2008a). The aneurysm can present as in the adult with a SAH (Heiskanen 1989; Proust et al. 2001; Vaid et al. 2008), but differently from aneurysms in the adulthood, in about 50% of the cases the symptoms in children are due to the mass effect as reported by several other authors (Lasjaunias et al. 1997; Massimi et al. 2003; Huang et al. 2005; Aryan et al. 2006; Lv et al. 2009; Gandolfo 2012). This is due to the fact that at the time of diagnosis the aneurysms are frequently large, sometimes giant. Giant aneurysms can be found in the anterior and in the posterior circulation. This later location seems to be more frequent in children.

Unlike in adults, a frequent cause of aneurysm in children is trauma, even minor (Ventureyra and Higgins 1994; Yazbak et al. 1995). Other etiologies are infectious, collagen diseases (FMD, Ehlers–Danlos syndrome, Marfan syndrome, polycystic kidney, pseudoxanthoma elasticum, neurofibromatosis), coarctation of the aorta hemoglobinopathies, as well as a family history of aneurysms (Ostergaard and Voldby 1983; Pasqualin et al. 1986; Roche et al. 1988; Meyer et al. 1989; Allison et al. 1998; Huang et al. 2005). Spontaneous dissection has been increasingly also recognized as a cause of aneurysm in children (Laughlin et al. 1997; Massimi et al. 2003; Lasjaunias et al. 2005; Vilela and Goulão 2006; Bradac et al. 2008a). In some cases, the etiology remains uncertain. Examples of aneurysm in the pediatric age are presented in Figs. 16.16 and 16.17.

Vascular Malformations of the Central Nervous System

12

12.1 Introduction

Rokitansky (1846) is reported to be the first to have described this kind of pathology which he called "vascular brain tumor in pial tissue." It was Virchow (1862–1863) who first clearly differentiated tumors from brain angiomas, which were identified as vascular malformations of congenital derivation. The concept that brain arteriovenous malformations (BAVM) is an anomaly caused by errors during vascular development in the embryo has been suggested by Cushing and Bailey (1928) and Dandy (1928). However, some difficulties in the differential diagnosis between BAVM and tumors remained, as noted by Zülch (1957) and Russell et al. (1959). An accurate description of this pathology as a definite congenital malformation was proposed by McCormick (1966, 1976). The same author made a classification, which, with a few modifications (Challa et al. 1995; Yaşargil 1987, 1999; Chaloupka and Huddle 1998; Valavanis et al. 2004), is still valid today.

12.2 Classification

- Arteriovenous malformation (AVM)
- Vein of Galen malformations
- Cavernous malformations (cavernomas)
- Capillary malformations (telangiectasias)
- Developmental venous anomaly (DVA)
- Transition forms
- Vascular malformations as part of well-defined congenital-hereditary syndromes
- Rendu-Osler syndrome
- Sturge-Weber syndrome
- Wyburn-Mason syndrome
- Klippel-Trenaunay-Weber syndrome

12.3 AVM

12.3.1 Pathogenesis and Pathology

The pathogenesis of AVMs is not completely clear. In this context some aspects of the development of the cerebral vessels should be shortly reconsidered. This occurs in two phases: vasculogenesis and angiogenesis. In the vasculogenesis, angioblasts differentiate into endothelial cells to form the primary vascular plexus. Later, angiogenesis follows, in which the primary plexus undergoes remodeling and organization, leading to the formation of the final cerebral vessels with the typical pattern of arteries, capillaries, and veins (Streeter 1918; Risau and Flamme 1995; Risau 1997). The causes of an aberrant vasculo-angiogenesis leading to AVM are unknown. Many factors are probably involved; among them, some endothelial growth factors (VEGFR1-VEGFR2) and their binding receptors (FLt-1; FLK-1) and a group of cytokines the angiopoietin-1 (Ang1) and angiopoietin-2 (Ang2) and their receptors have been identified as important for the normal development of the cerebral

G.B. Bradac, *Applied Cerebral Angiography*, DOI 10.1007/978-3-319-57228-4_12

vessels (Risau and Flamme 1995; Shalaby et al. 1995; Fong et al. 1995; Sonstein et al. 1996; Davis et al. 1996; Zhang et al. 1996; Maisonpierre et al. 1997; Uranishi et al. 2001; Hashimoto et al. 2001, 2005). Highest levels of these factors, as well as their altered balance, possibly due to gene mutations could lead to aberrant development and formation of AVMs. In this context, it is interesting to note that AVMs can develop in some cases of hereditary hemorrhagic telangiectasia in which a known gene mutation has been identified (Zhang et al. 1996; Matsubara et al. 2000; Letteboer et al. 2006; Saba et al. 2007).

Also not clear is when the AVMs develop. Some authors (Mullan et al. 1996a, b) *have suggested that this occurs in the gestational period*. In some cases the AVMs may be relatively small at birth and grow later. In this context, however, a few consideration should be made. Indeed in spite of the routine use of ultrasound diagnosis during gestation, AVMs are commonly not identified, while the extremely more rare vein of Galen malformation can be easily diagnosed. Furthermore there are reports, describing the appearance of cerebral AVMs later in life in patients, in whom previously performed magnetic resonance imaging (MRI) showed no malformations. In some of these patients, cerebral AVMs develop in the pathologically altered brain as a result of different causes such Moyamoya disease (Schmit et al. 1996), hemangiomatosis (Song et al. 2007), heterotopia (Stevens et al. 2009), and after radiosurgery (Rodriguez-Arias et al. 2000); in others, the brain parenchyma was completely normal (Gonzalez et al. 2005; Bulsara et al. 2002). These observations *raise doubts about the congenital nature* of cerebral AVMs, which, at least in some cases, seem to be acquired lesions caused by different nonspecific insults on the brain, perhaps in patients in whom an altered genetic background preexists (Kim et al. 2011).

The main angioarchitectural characteristic of an AVM is an area called the "*nidus*," in which there is a direct shunting between arteries and veins without interposed capillaries. The elevated intravascular flow leads to changes of the vessels. Histology shows the nidus to be composed basically of dilated arteries and veins. In some vessels, the wall structure is still recognizable, characterized by the presence of a media with smooth muscle cells and an elastic lamina in the arteries and an absence of muscle cells in the veins. In other arteries, prominent changes, characterized by areas of wall thickening caused by the proliferation of fibroblasts, muscle cells, and an increase in connective tissue, are present. Segments with thinning of the wall also occur, which potentially can lead to aneurysm formation. Severe changes take place in the venous sector, forming the so-called arterialized veins, in which a wall thickening is recognizable due to fibroblast proliferation without smooth muscle cells. The interposed parenchyma shows gliosis, hemosiderin pigmentation, and calcification, resulting from ischemia or previous hemorrhages. The surrounding parenchyma may appear normal or show similar changes (Challa et al. 1995; Kalimo et al. 1997; Brocheriou and Capron 2004).

12.3.2 Incidence

The incidence of AVM is reported in studies involving general autopsy to be 0.15–0.8% (McCormick 1984; Jellinger 1986), with an annual detection of about 1–2 AVM per 100,000 persons. Multifocal lesions can occur with a frequency of 1–10% (Perret and Nischioka 1966; Rodesch et al. 1988; Willinski et al. 1990). These latter are reported to be more frequent in *children* in whom multiplicity appears to be twice as common as in adults (Rodesch et al. 1988; Lasjaunais 1997; Berenstein et al. 2010).

12.3.3 Clinical Relevance

Most AVMs are diagnosed in young or middle-aged patients. In about 20% they are discovered in *children*. As far as it concerns the clinical presentation, 5–10% remain asymptomatic and are diagnosed incidentally by CT or MR investigations performed for other reasons. Some 40–50% present with intracranial hemorrhage, 30% with seizures, 10–15% with headaches, and 5–10% with neurological deficits (Perini et al. 1995; Stapf et al.

2002; Hofmeister et al. 2000; Valavanis et al. 2004). The incidence of symptomatic AVM in the adult population is reported to be one-tenth the frequency of intracranial aneurysms (Berenstein and Lasjaunias 1992; Valavanis et al. 2004). The highest risk in AVM is hemorrhage (Graf et al. 1983; Brown et al. 1985; Crawford et al. 1986; Ondra et al. 1990; Mast et al. 1997) which has been calculated to be between 1.7 and 4.1% per year in AVMs presenting without history of hemorrhage. In the reports of the same authors the mortality and morbidity following the first hemorrhage was between 10 and 30% and 10 and 20%, respectively. The risk of a repeated hemorrhage after an initial episode is reported to increase in the first year, later rapidly decreasing (Mast et al. 1997), reaching for some authors (Graf et al. 1983) the level of the initial risk. Hemorrhage is the most frequent initial symptom in *children* (Berenstein and Lasjaunias 1992; Rodesch et al. 1995; Lasjaunais 1997; Di Rocco et al. 2000; Klimo et al. 2007; Berenstein et al. 2010; Soltanolkotabi et al. 2013).

Cases of spontaneous thrombosis of AVMs (Sukoff et al. 1972; Levine et al. 1973; Mabe and Furuse 1977; Pascual-Castroviejo et al. 1977; Sartor 1978; Nehls and Pittman 1982; Omojola et al. 1982; Wakai et al. 1983; Pasqualin et al. 1985; Barker and Anslow 1990; Ezura and Kagawa 1992; Hamada and Yonekawa 1994; Abdulrauf et al. 1999) as well as its possible recanalization occurring even a few years later (Mizutani et al. 1995) have been reported. Also the reappearance of the malformation after its proven complete obliteration after gamma knife radiosurgery can occur (Lindquist et al. 2000). A long follow-up of these patients is mandatory. *All this seems to indicate that AVM, at least in some cases, is a dynamic pathology with an evolution, which is probably influenced by many not precisely known factors.*

12.3.4 Location

The majority of AVMs (85%) are located in the supratentorial area. They can be located in a sulcus (sulcal) in a gyrus (gyral), or involve both (sulcogyral) (Valavanis et al. 2004). They can remain superficial or extend deeply toward the ventricles, basal ganglia and thalamus. AVMs involving primary deep structures are rare (Saatci et al. 2011). These later are more frequent *in pediatric patients* (Berenstein and Lasjaunias 1992).

The infratentorial AVMs are rare with a frequency reported between 5 and 15% (Perret and Nischioka 1966; Yasargil 1999; Batjer and Samson 1986; Valavanis et al. 2004; Saatci et al. 2011). The most frequent are those involving the cerebellum (hemisphere, vermis), located on the superior-inferior convexity or on its anterior surface. The AVM can remain superficial or extend toward the deep structures with extension toward the brainstem. Primary AVM of the brainstem are very rare. Their frequency is in the range of 2–3% of all AVMs (Garcia-Monaco et al. 1990; Liu et al. 2003).

12.3.5 Diagnosis

MRI, including functional studies, provides information about the site and extension of the malformation and its relationship with the adjacent areas. Furthermore, it shows which functional changes have occurred in the affected and unaffected hemisphere (Alkadhi et al. 2000; Bradac et al. 2014). Angiography is essential in defining the angioarchitecture of the malformation. This comprises angiography of the internal and external carotid arteries and vertebral artery, followed, when necessary, by selective examinations aimed to better characterize the supplying arteries, venous drainage, and aspects of the nidus.

12.3.5.1 Supplying Arteries (Feeders)

These are variously dilated and tortuous, unique or multiple, and arise from one or more vascular territories. Cortical branches are involved in superficial AVMs (Figs. 12.1, 12.2, 12.3, 12.4, 12.5, and 12.6). Perforators (deep and medullary branches) and choroidal arteries can be recruited every time deep structures and ventricles are primary or secondary involved by large cortical AVM extending to the depth (Figs. 12.5, 12.7a–d, 12.8a, 12.9, 12.10, 12.11 and 12.20).

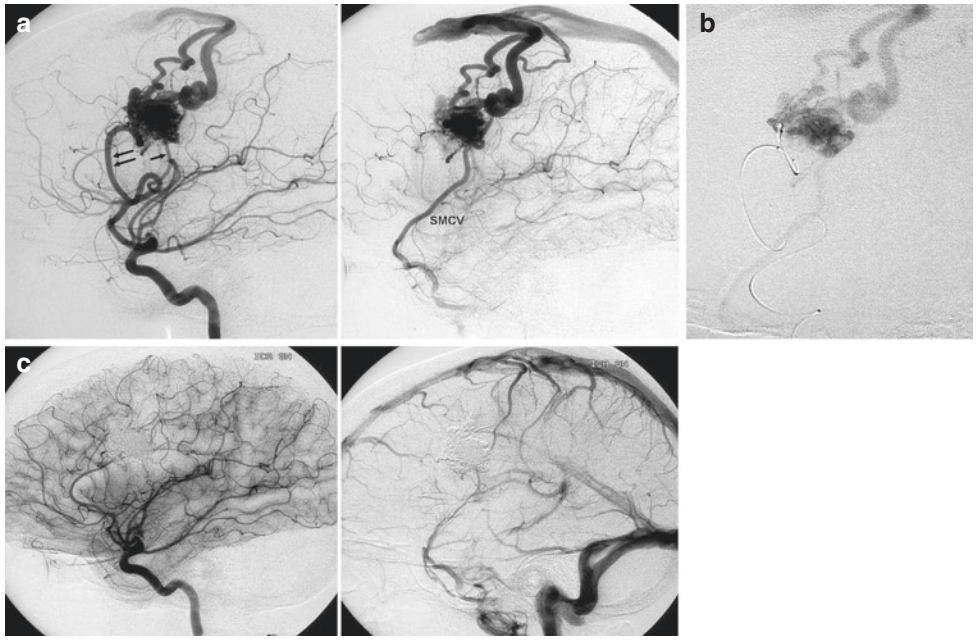

Fig. 12.1 Well-defined nidus of a lateral frontal AVM presenting with epilepsy in a young patient. (**a**) Lateral carotid angiogram, early and late phases. The AVM is supplied by a dilated insular branch (*double arrow*). A second, smaller feeder appears posteriorly (*arrow*). Cortical drainage in the SSS, where a partial retrograde injection of its anterior segment is visible. A second drainage occurs in the SMCV. (**b**) Selective catheterization of the anterior feeder preceding embolization with onix. (**c**) Lateral carotid angiogram, arterial and venous phases performed 2 months later confirming the complete occlusion of the AVM and normalization of the arteries and veins. Clinically: intact patient

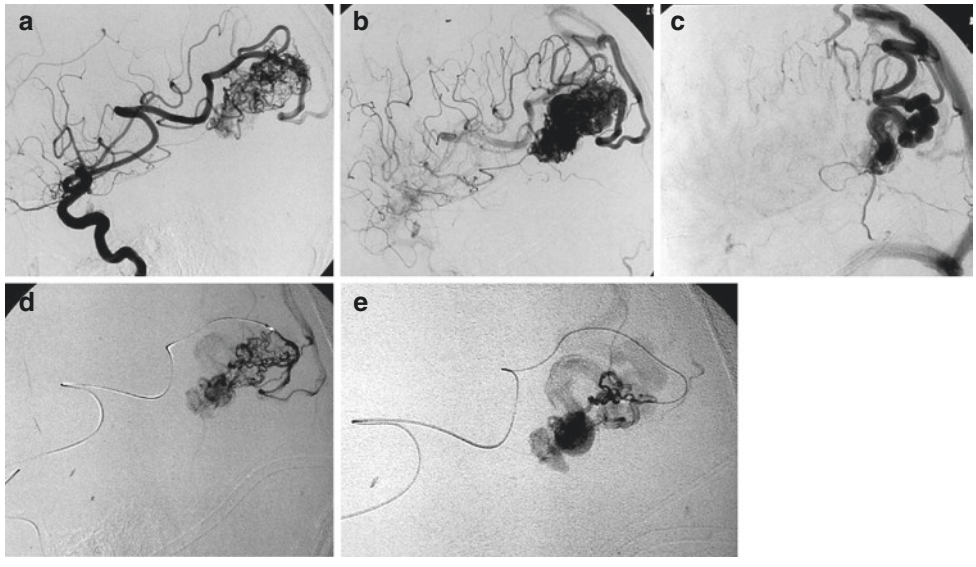

Fig. 12.2 Latero-temporo-occipital AVM, presenting with hemorrhage. Carotid lateral angiogram. (**a**) arterial phase showing the supply through the distal branches of the dilated gyrus angularis artery. (**b**), (**c**) Venous phases, showing the different venous drainage related to the corresponding compartments. These are well demonstrated on super-selective studies (**d**), (**e**). At the periphery of the nidus, an isolated arteriovenous shunt is recognizable (**d**)

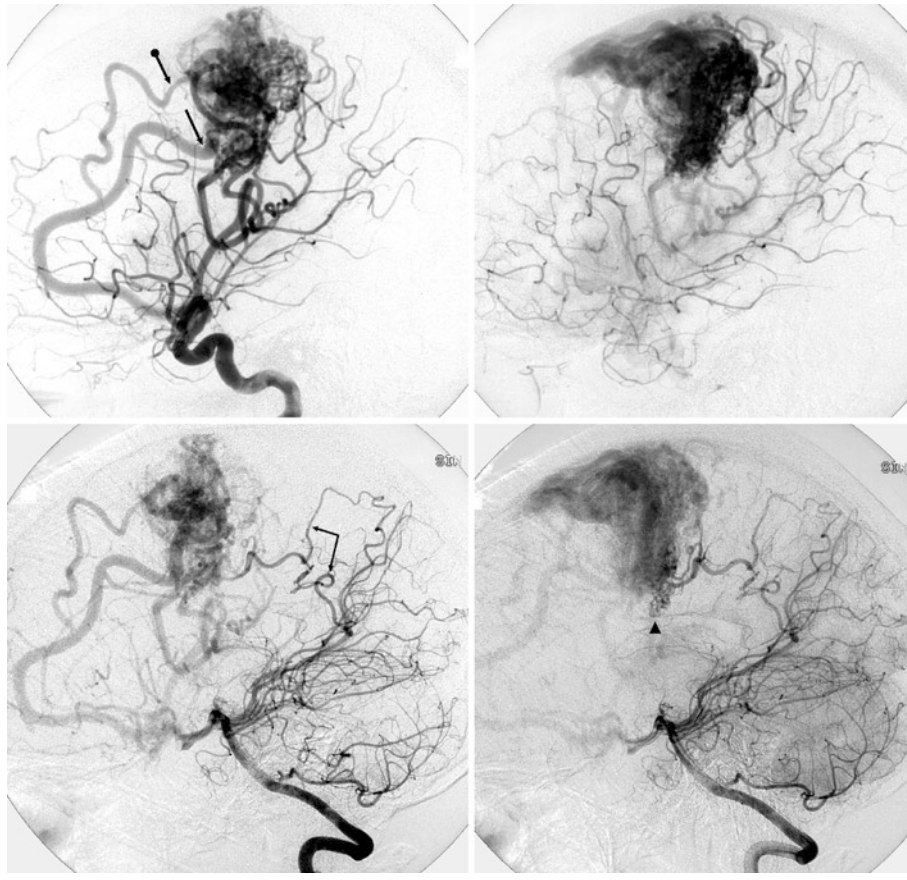

Fig. 12.3 Incidental discovery of a large parietal AVM in patient with headache. (same case as in Fig. 12.8b). Carotid angiogram (*above*) showing the involvement of the enlarged pericallosal artery from which arise the dilated posterior frontal artery (*arrow with dot*) and a large trunk probably the paracentral artery (*arrow*). There is also involvement of branches of the MCA probably the central arteries. On the vertebral angiograms (*below*) an indirect involvement of the PCA is visible. This occurs through opening of leptomeningeal anastomoses between PCA and ACA (*arrow with angle*), with retrograde filling of the distal segment of the pericallosal. In the later phase is recognizable a minimal part (*arrow with dot*) of the AVM, not present on the carotid angiogram

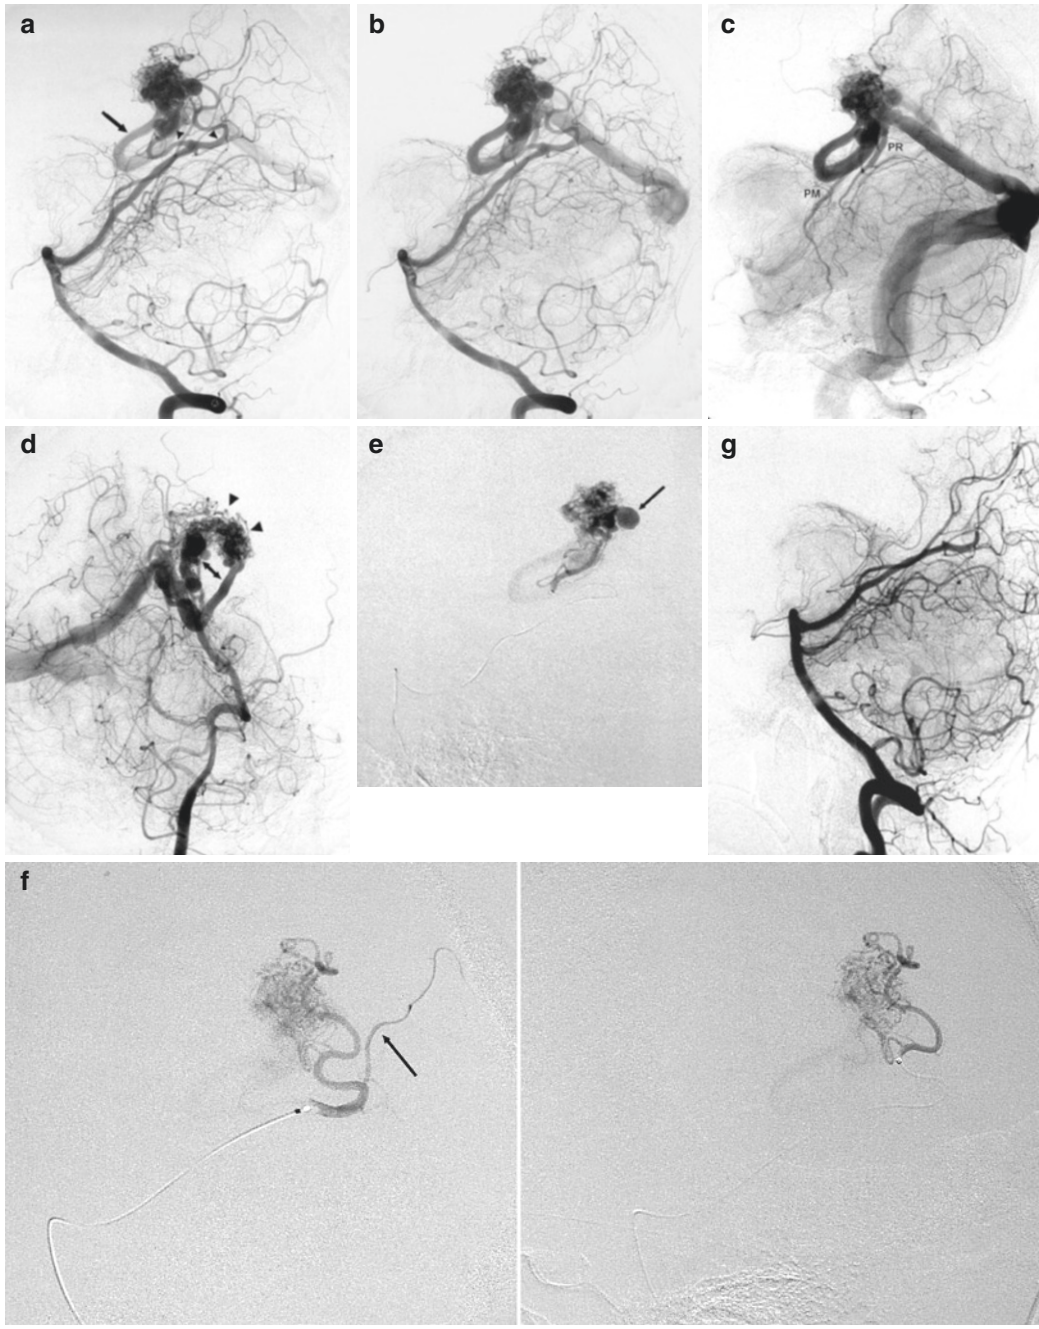

Fig. 12.4 Large hematoma located in the left deep medial occipital retrosplenial area in a young patient, removed in the acute phase. Angiographic study a few days later. (**a**), (**b**) The vertebral angiogram showed an AVM supplied by two feeders (*arrowheads*) arising from the P4 segment of the left PCA. The main drainage occurred into a large venous channel probably a medial atrial vein (*arrow*) continuing in the Galen vein and straight sinus. (**c**) In the later venous phase, a retrograde filling of the precentral vein (PR) and posterior mesencephalic vein (PM is visible). (**d**) Oblique view. Better demonstration of the nidus (*arrowheads*) and of the venous drainage (*arrow*). (**e**) Catheterization of the feeder supplying the compartment with an intranidal aneurysm (*arrow*) occluded with glue. (**f**) Catheterization of the second feeder with a progressive advance of the microcatheter distal to a normal parenchymal branch (*arrow*) before the injection of glue. (**g**) Posttreatment angiogram showing the occlusion of the AVM. The remaining minimal component supplied by the pericallosal artery was treated later by radiosurgery with final good outcome

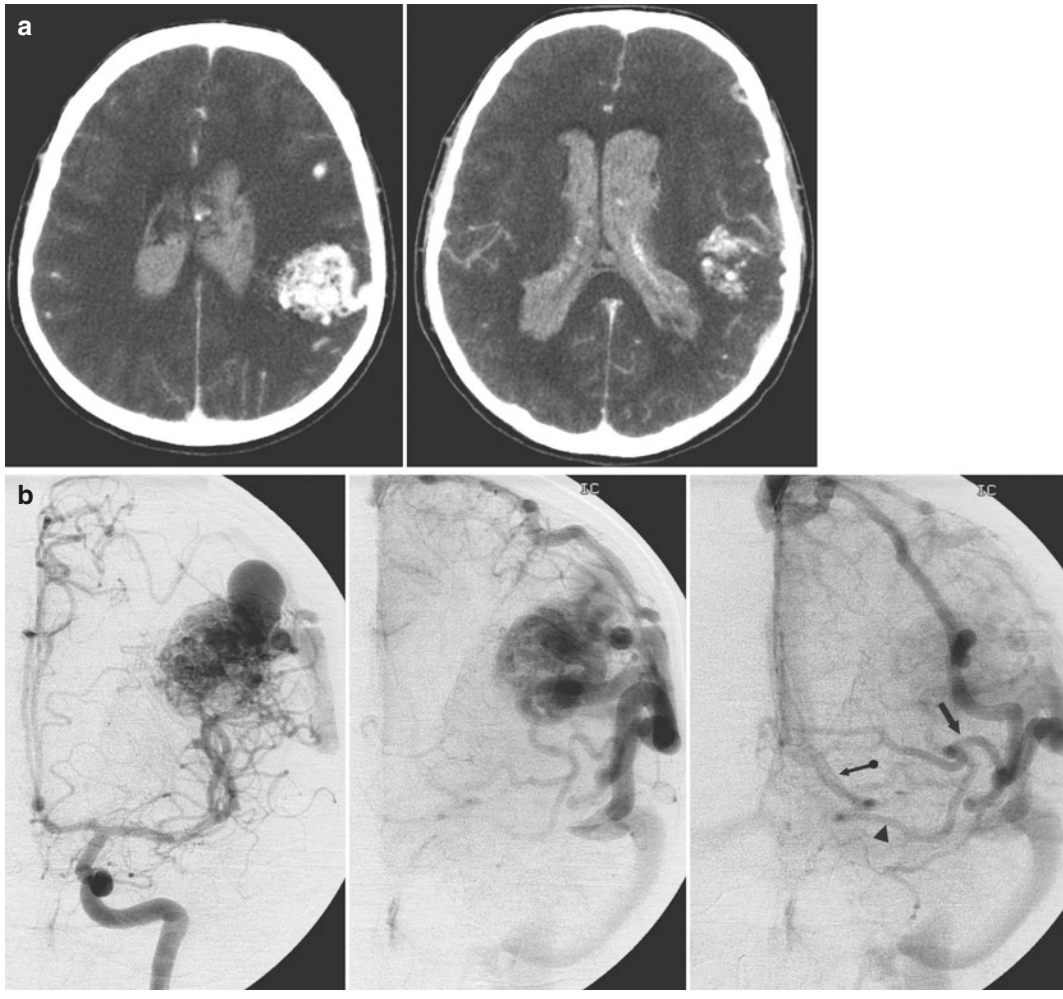

Fig. 12.5 Young patient presenting with severe intraventricular hemorrhage leading to deep coma. (**a**) CT showed a severe intraventricular hemorrhage and a left parietal AVM. (**b**) Left ICA angiogram, AP view. Earlier ad late phases. Parietal AVM supplied by branches of the MCA. On the periphery of the malformation there is a large aneurysm. On the later phases the superficial cortical venous drainage directed toward the SSS and in the SMCV is recognizable. Through connections between SMCV and insular veins (*arrow*) later filling also of the DMCV (*arrow head*) and BV (*arrow with dot*). (**c**) Oblique view, showing better the aneurysm (*arrow*). (**d**) On the vertebral angiogram a small aneurysm (*arrow*) on the course of the left lateral posterior choroidal artery close to the nidus, could be clearly recognized. Thinking that the aneurysm was responsible of the intraventricular hemorrhage, the decision was taken to treat it. Selective angiogram preceding the occlusion with glue. Angiogram posttreatment. (**e**) A few days later ICA angiogram was performed aimed to treat the aneurysm which was spontaneously almost completely thrombosed. This was confirmed on a second angiogram 1 month later in which the aneurysm was no longer visible. The patient did not recover from its primary severe hemorrhage and remained in a vegetative state. No other treatment was performed

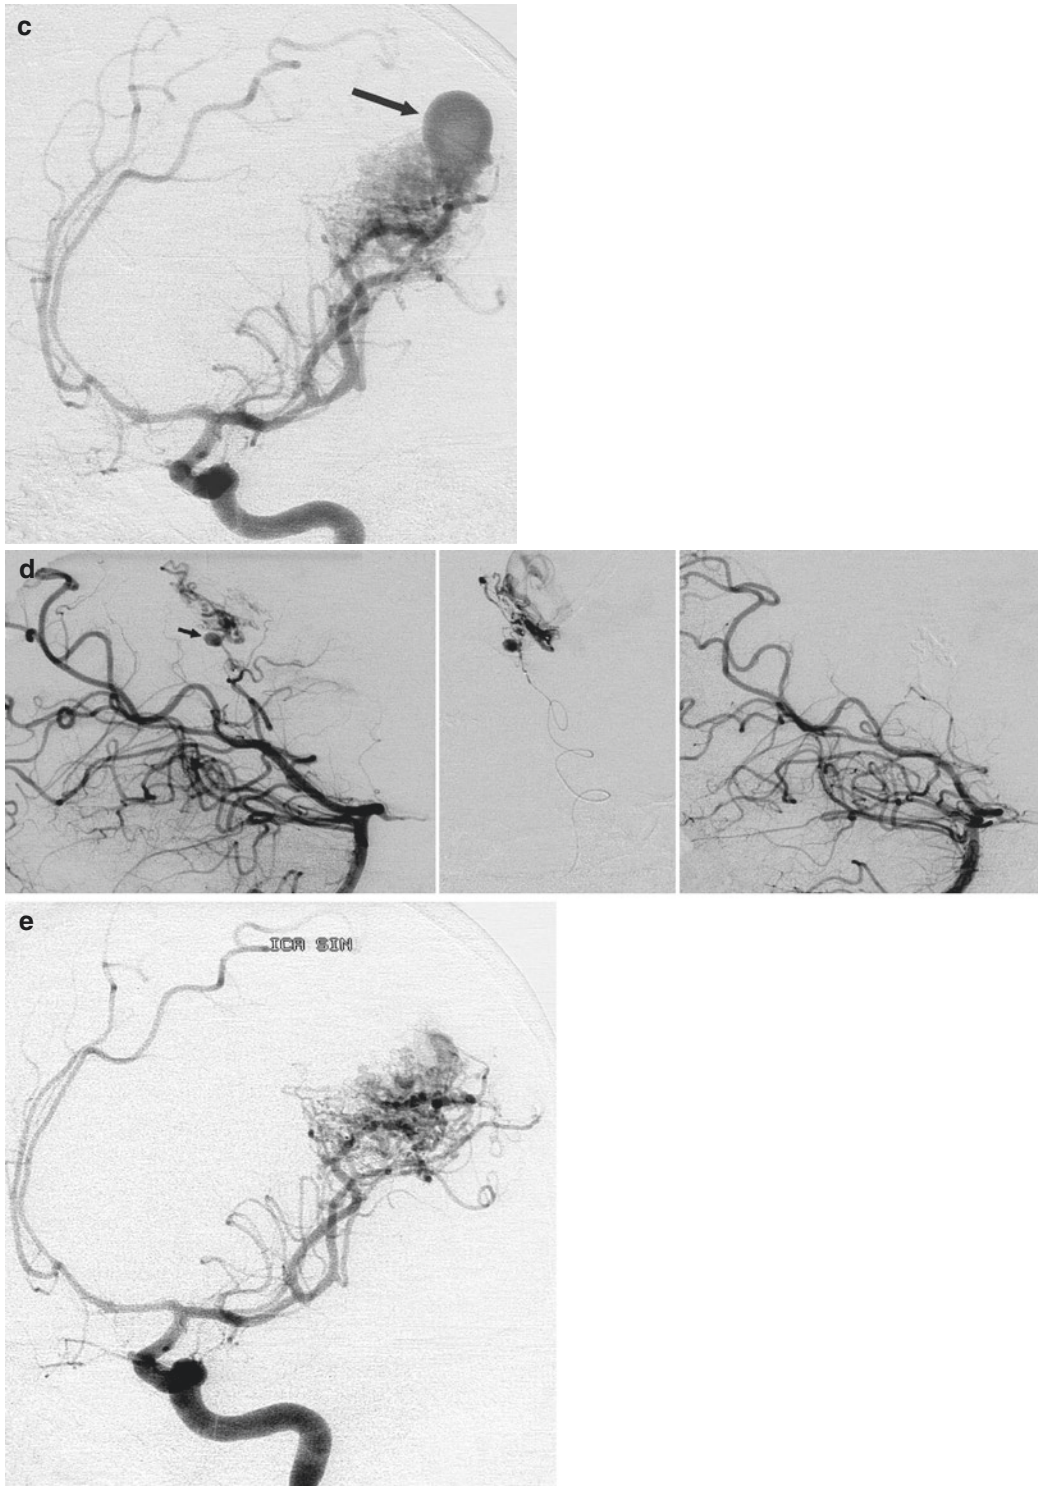

Fig. 12.5 (continued)

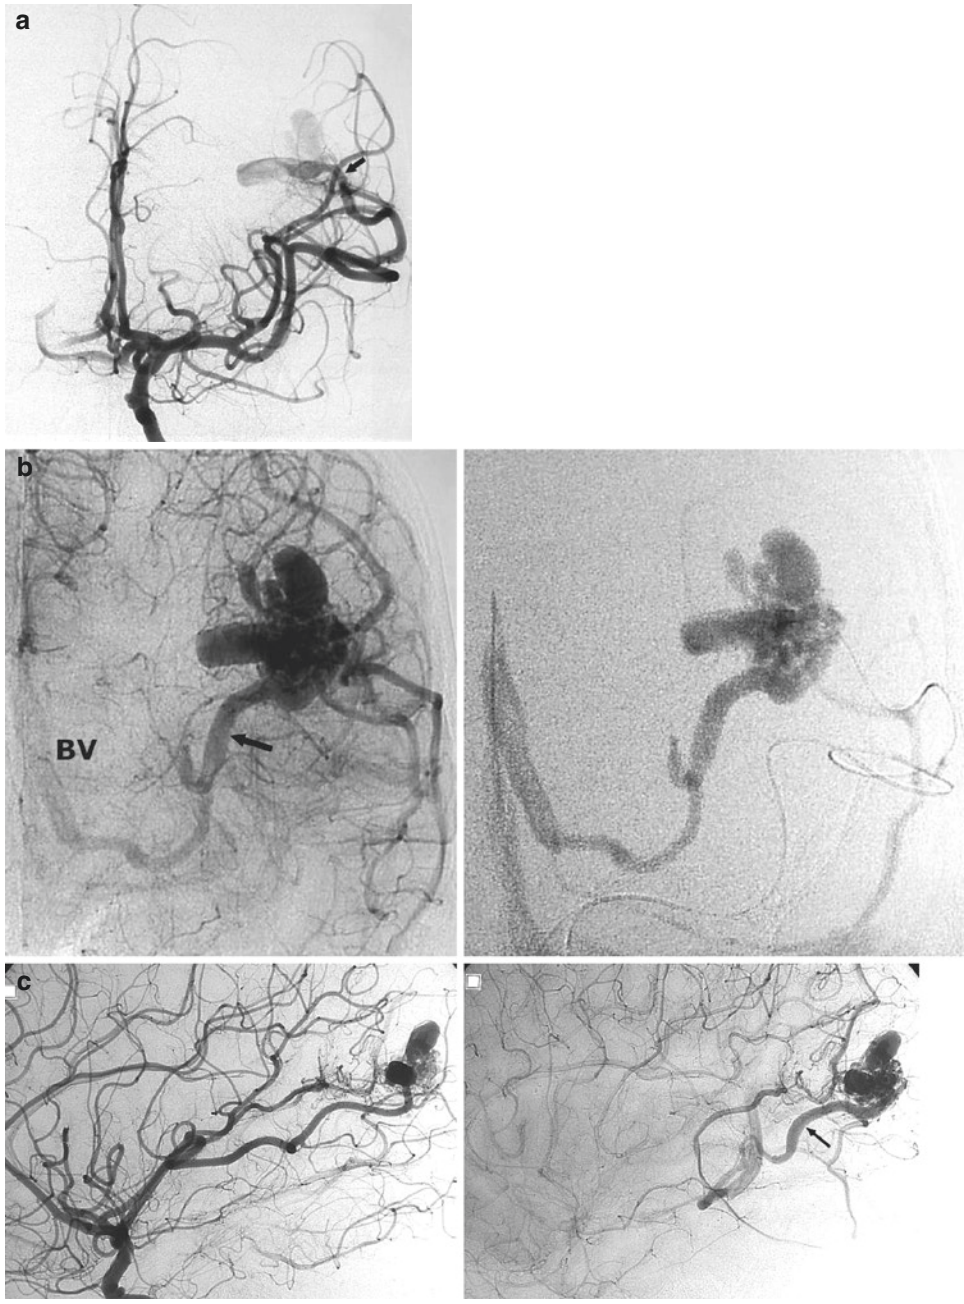

Fig. 12.6 Laterotemporal occipital AVM in a child presenting with epileptic seizures. (**a**) Carotid angiogram AP view. The AVM consists mainly of a direct fistula (*arrow*) between the gyrus angularis artery and the venous sector, which is characterized by a large complex venous pouch. (**b**) Late phase, showing the further cortical and deep drainage. This latter occurs through a dilated medullary branch of the lateral atrial vein (*arrow*) continuing into the distal segment of the basal vein (BV). On the selective study (*on the right*) the deep venous drainage is better demonstrated. (**c**) Lateral ICA angiogram, early and late phases, showing the feeding branches and the venous drainage involving the lateral atrial vein (*arrow*). (**d**) Lateral carotid angiogram, after occlusion of the fistula with glue. A minimal network corresponding to the persistent nidus is still recognizable. This was treated with radiotherapy with a final good clinical outcome

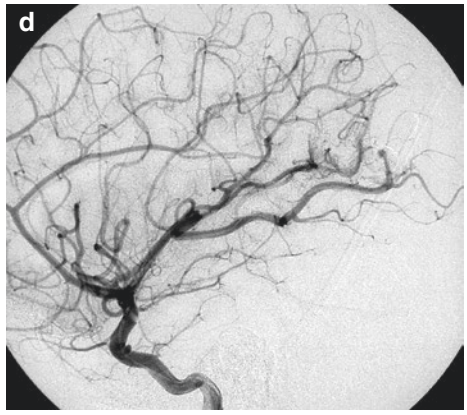

Fig. 12.6 (continued)

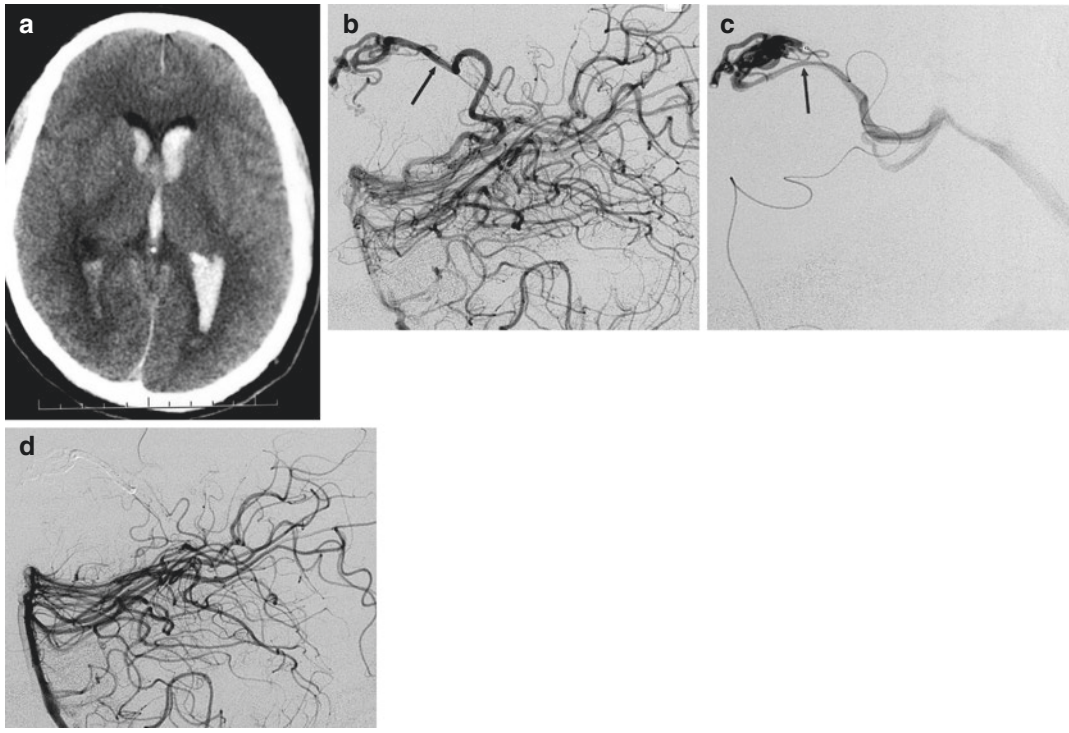

Fig. 12.7 AVM in a young patient presenting with hemorrhage involving the third and lateral ventricles. (**a**) CT showing the hemorrhage. (**b**) Lateral vertebral angiogram shows a dilated posterior medial choroidal artery supplying the small AVM on the roof of the third ventricle. (**c**) On the selective study the nidus and the venous drainage in the internal cerebral vein (*arrow*) continuing in the Galen vein is well visible. (**d**) Control angiogram after occlusion of the AVM with acrylic glue

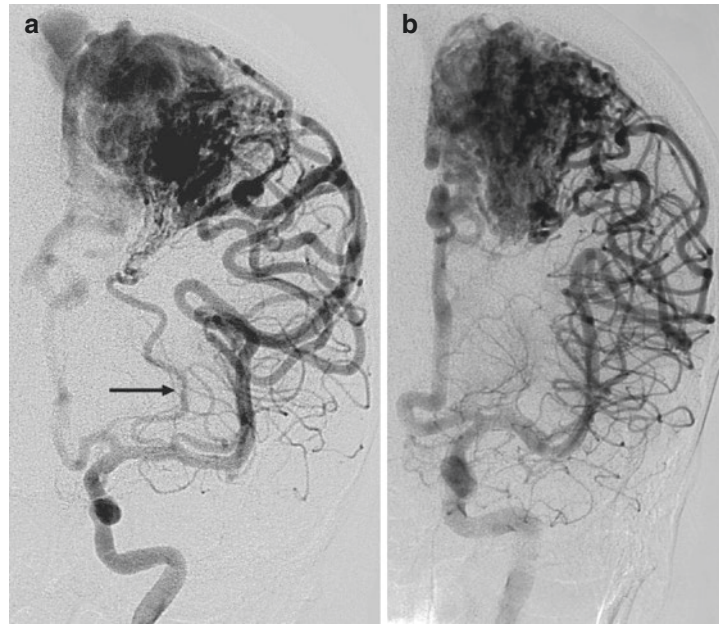

Fig. 12.8 Large superficial AVM extending into the deep white matter in two different patients. (**a**) in addition to the cortical feeders there is the involvement of a large perforator (*arrow*). (**b**) a similar AVM in which, however, the perforators are not involved

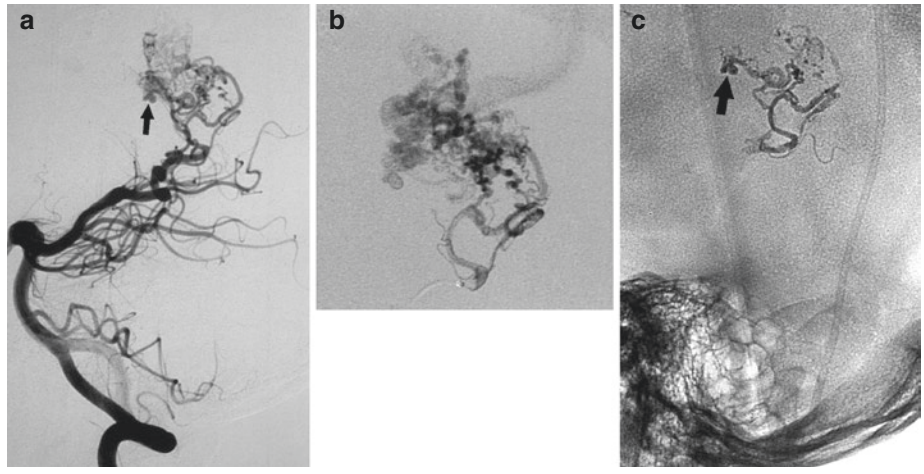

Fig. 12.9 Example of an intranidal aneurysm, probably responsible of repetitive small intraventricular hemorrhage in a young patient with a large right parietal AVM extending deeply toward the lateral ventricle. (**a**) Lateral vertebral angiogram showing the deep part of the AVM where a small aneurysm is visible (*arrow*) supplied by the medial posterior choroidal artery. (**b**) Selective study preceding the injection of acrylic glue. (**c**) Cast of the glue involving part of the nidus and the aneurysm (*arrow*). Despite the only partial treatment, the hemorrhagic episodes arrested completely over a period of many years

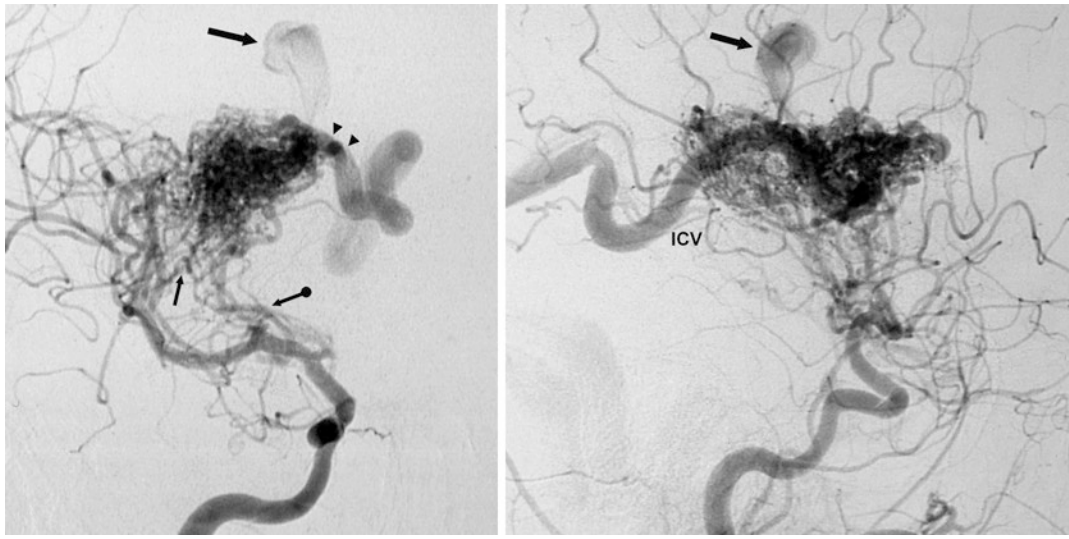

Fig. 12.10 AVM in a child involving the basal ganglia and the adjacent white matter presenting with hemorrhage. Carotid angiogram, AP and lateral views. The AVM is supplied mainly by dilated perforators arising from M1 (*arrow with dot*) and by branches of the M2 segment (*arrow*). The drainage occurs in the thalamostriate vein (*arrowhead*) continuing into the internal cerebral vein (ICV). On the periphery of the AVM, there is a partial injected venous pouch (*large arrow*), which corresponds probably to a venous pseudoaneurysm. Surgery was performed

Fig. 12.11 Young girl presenting with sudden headache followed by coma due to rupture of AVM in the right nucleus caudatus. (**a**) CT showing the hemorrhage in the superior part of right head of the nucleus caudatus and in the ventricular system. (**b**) Right and left AP, ICA angiograms showing the AVM supplied by small branches of the right pericallosal artery and by a dilated perforating branch artery (arrow) arising from the proximal part of the right A1 supplying also a small aneurysm (*arrowhead*). The supplying perforator could be the Heubner artery. Considering, however, that the AVM is located in the superior part of the nucleus caudatus (commonly vascular territory of the MCA), and that the perforators of the MCA can partially arise from the ACA (see also Sect. 5.1), it is thinkable that this perforating branch is not the Heubner artery. (**c**) Right ICA lateral angiogram showing the drainage of the AVM in the SSS and ISS (*bidirectional arrows*) and partially also in the deep system through the by the hemorrhage deformed caudate vein (*arrowheads*). (**d**) Acute treatment aimed to occlude the aneurysm thought responsible of the hemorrhage. AP view showing the origin of the perforator from the proximal A1 (*arrow*). Detail demonstrating the microcatheter (*arrowheads*) which was advanced first in the left A1, then through the AcomA in the right A1 and in the right perforating artery and further close to the aneurysm where glue was injected. (**e**) Control angiogram showing the occlusion of the distal segment of the artery (*arrow*) with exclusion of the aneurysm. The patient recovered slowly and the small remaining part of the AVM was later treated with surgery

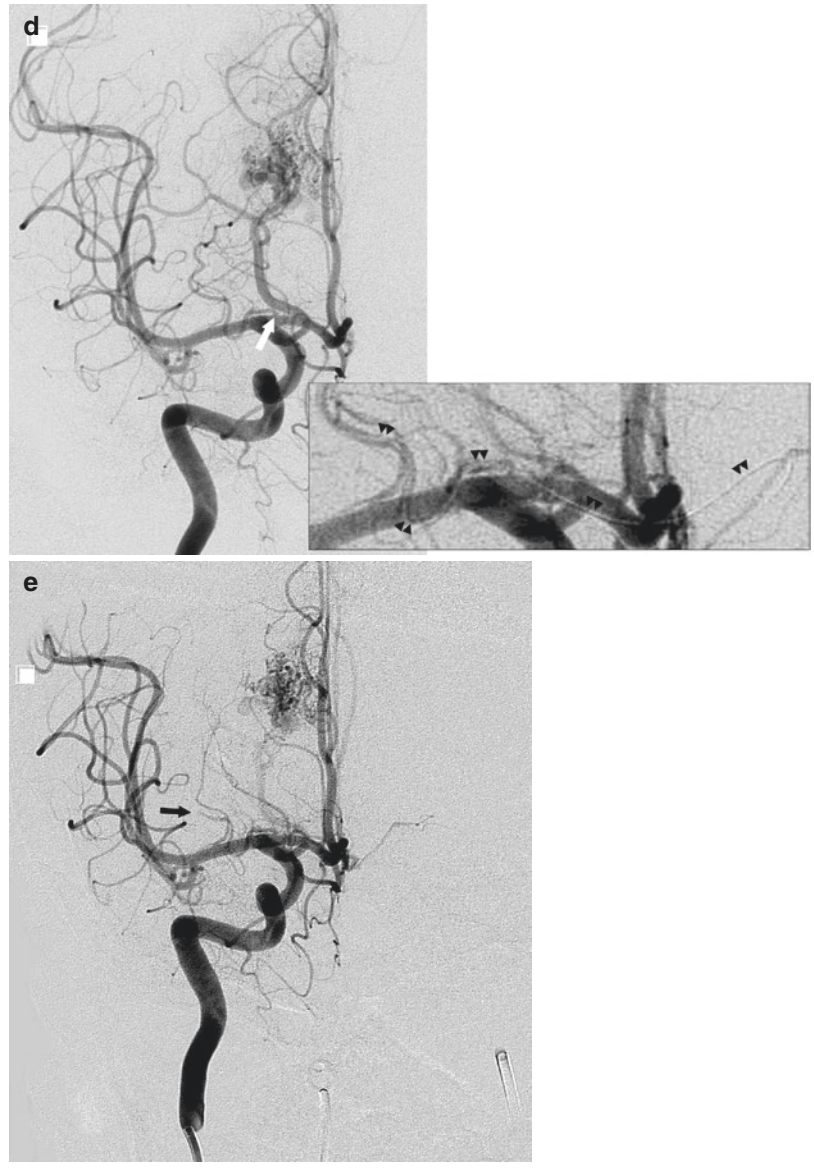
Fig. 12.11 (continued)



Each feeder can end in the nidus, connected through one or more small branches with one or more venous channels, in various combinations (Houdart et al. 1993), forming what is termed the plexiform aspect of the nidus (Figs. 12.1 and 12.2). Otherwise, after giving branches to the AVM, the feeders continue distally to supply the normal parenchyma (Fig. 12.4). It can occur that on the angiogram, they appear to end in the nidus, though they do in fact run further distally. The distal part, however, is not recognizable, owing to the steal phenomenon present in the nidus. In other cases, a large artery "*en passage feeder*," running adjacent to the nidus, can give some

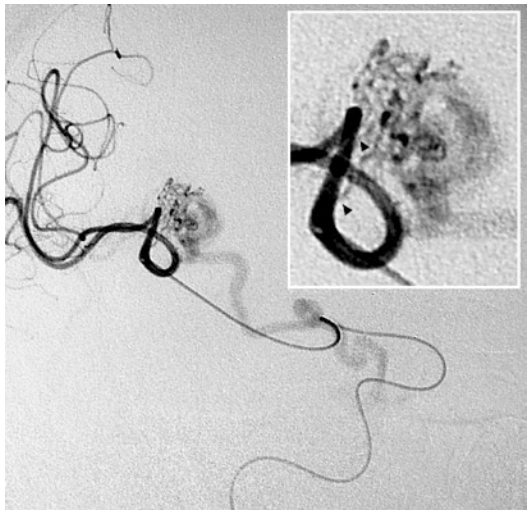


Fig. 12.12 *(Fig. 12.17a of the Cerebral Angiography 2nd Edition). Example of "en passage feeder." From the proximal part of a branch of MCA which distally supplies the normal parenchyma arise small branches (*arrowhead*) supplying a temporo-insular AVM

small branches to the nidus, coursing further to the normal parenchyma (Fig. 12.12). All these aspects should be carefully studied with selective injections since embolization of these feeders carries the risk of ischemia of the normal parenchyma (Berenstein and Lasjaunias 1992; Valavanis 1996; Chaloupka and Huddle 1998; Pierot et al. 2004; Valavanis et al. 2004).

Sometimes, indirect feeders can reach the nidus through the opening of leptomeningeal (pial) anastomoses (Fig. 12.3). This occurs when an important branch supplying the AVM ends completely in the nidus and no branches reach the distal normal parenchyma, which is supplied indirectly by the developed collateral circulation. The latter can extend to the AVM and supply indirectly its distal part (Berenstein and Lasjaunias 1992; Chaloupka and Huddle 1998; Valavanis et al. 2004).

Involvement of meningeal branches is reported in about 30% of the cases (Newton and Cronquist 1969; Rodesch and Terbrugge 1993). This occurs through anastomoses between the meningeal arteries and the pial branches involved in the vascularization of the AVM. In this context, it should be remembered that dilated dural branches can be a cause of headache. In selected cases, these branches can be catheterized and used to reach the nidus of the AVM where embolic material can be injected.

Finally an interesting aspect, occurring in the cerebral arteries as well as in the branches of ECA, when involved, and in the draining veins, is that their dilatation due to the increased in-out flow disappears with return to normalization, when the vascular malformation is eliminated. This is due to the specific characteristic of the cerebral vessels to adapt to the different vascular conditions (Fig. 12.1).

12.3.5.2 Aneurysms

Many type of aneurysms can be identified in the examination of AVMs. There are aneurysms which are located far from the nidus on one or more supplying arteries. They are thought to be due to the increased flow (*flow-related or "stress" aneurysm*) and frequently, though not always, disappear when the AVM is excluded (Berenstein and Lasjaunias 1992; Valavanis and Yasargil 1998). They can be an incidental discovery in the study of an AVM, but can be also the cause of a subarachnoid or parenchymatous hemorrhage (Stapf et al. 2006). The frequency of these aneurysms is reported to increase with the age of the AVM. This probably means that the development of these aneurysms is due to the high flow associated with the AVM and especially to the long-lasting AV shunt (Valavanis 1996). In our experience the majority of these aneurysms occur in old patients especially in the vertebrobasilar sector. Examples are presented in Figs. 11.14, 12.13, 12.14, and 12.16. Similar aneurysms can develop in other conditions. (Fig. 12.15) (See Sect. 11.6.5).

Other small aneurysms are located close or within the nidus (*intranidal aneurysm)*. These can be better identified by selective studies. They are very frequent and are thought to be responsible for the hemorrhage of the AVM in many cases (Willinsky et al. 1988; Marks et al. 1992; Turjman

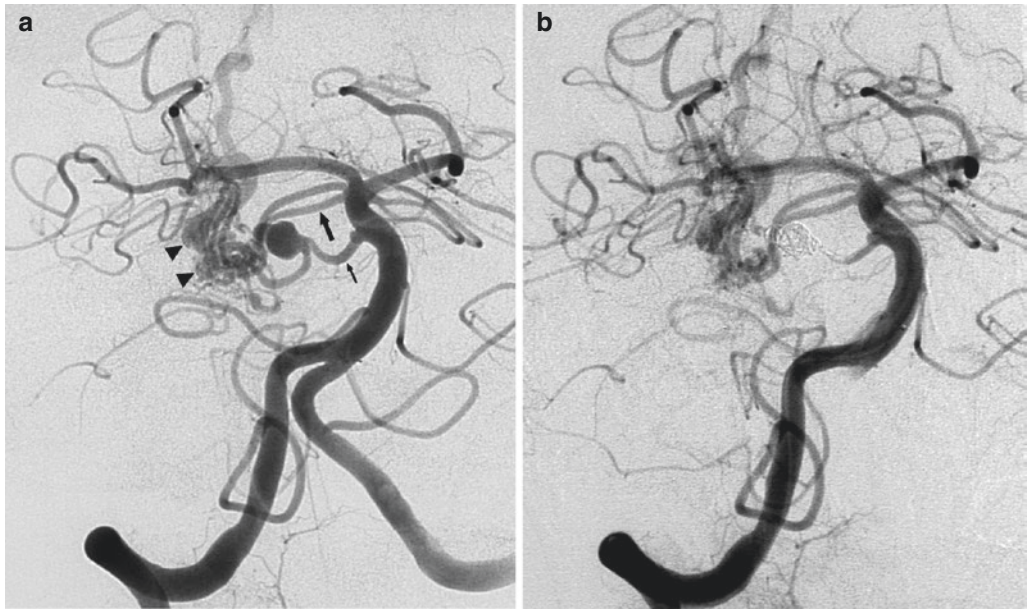

Fig. 12.13 Old patient presenting with severe SAH involving predominantly the right cerebellopontine angle. (**a**) Vertebral angiogram showing a small AVM in the cerebellopontine angle (*arrowheads*) supplied by a double superior cerebellar artery (*large arrow*). A dilated lateropontine artery (*small artery*). On the course of this latter a flow-dependent aneurysm is recognizable. This was thought to be responsible for the SAH and acutely occluded with coils together with the parent artery. (**b**) Posttreatment angiogram. The comatose patient recovered also from his small pontine infarct. The AVM was treated by surgery

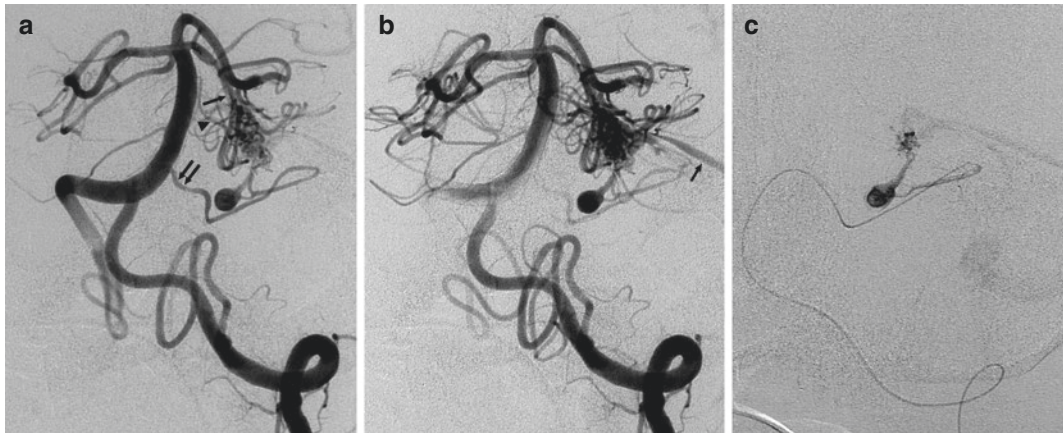

Fig. 12.14 Old patient presenting with severe SAH involving predominantly the left cerebellopontine angle. (**a**) Vertebral angiogram (*partial oblique view*), showing the AVM supplied by branches of the superior cerebellar artery (*arrow*). A dilated lateral pontine artery (*arrow head*) is also involved. There is also an important supply from the AICA (*two arrows*). On its course a large flow-dependent aneurysm is recognizable. (**b**) In the later phase the drainage in the superior petrosal sinus (*arrow*) is visible. (**c**) Selective study of AICA, preceding the occlusion of the aneurysm and of the distal AICA with coils. The patient recovered, and the AVM was treated later with surgery

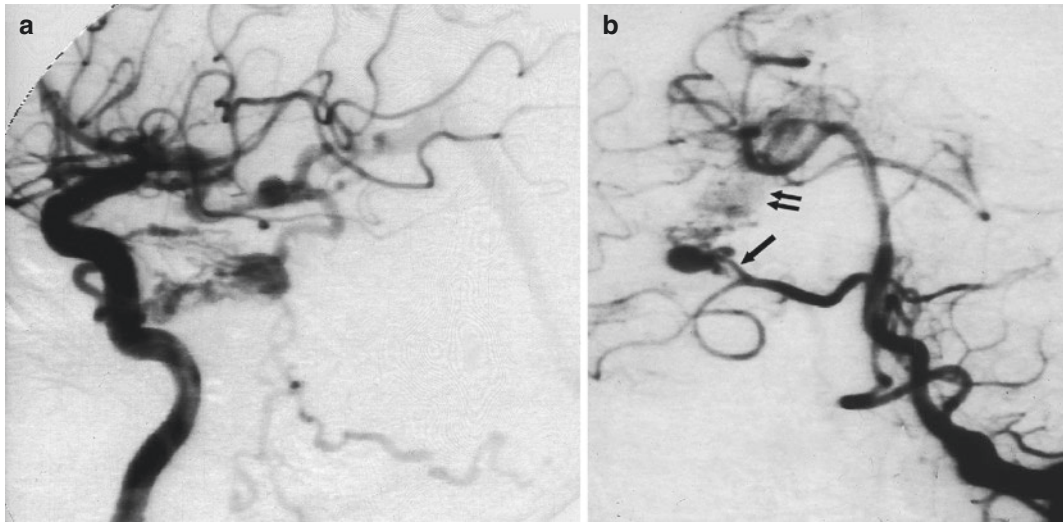

Fig. 12.15 Old patient presenting with SAH involving predominantly the posterior fossa. An angiographic study showed the pattern of a typical petro-tentorial DAVF (see Chap. 13, Sect. 13.7). (**a**) Lateral ICA angiogram showing the fistula at the level of the superior petrous sinus and the drainage in the lateral mesencephalic vein. (**b**) Vertebral angiogram, AP view, showing the supplying of the fistula (*arrows*) through the dilated AICA. On its rostro-lateral branch a flow-dependent aneurysm (*arrow*) is recognizable

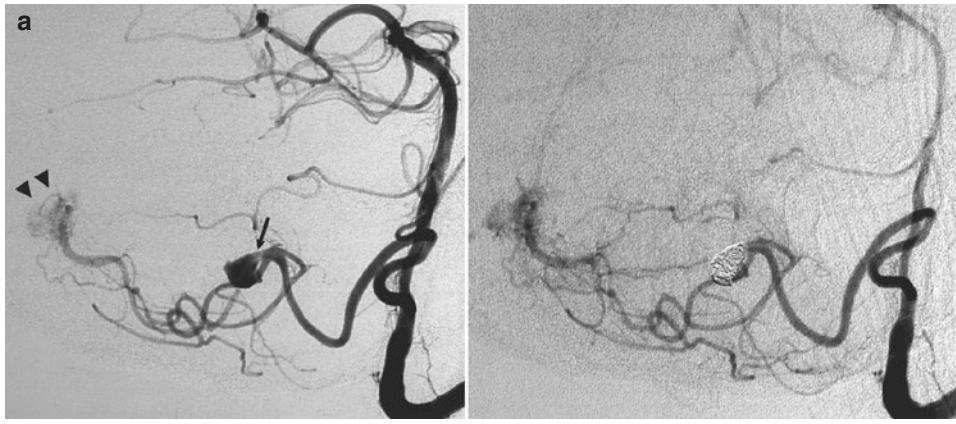

Fig. 12.16 Examples of flow-dependent aneurysms in two different patients. (**a**) Severe SAH in an old patient predominantly in the posterior fossa with involvement of the fourth ventricle. On the vertebral angiogram a small AVM (*arrowheads*) supplied by distal branches of the PICA was demonstrated. A flow-dependent aneurysm (*arrow*) is recognizable on the supratonsillar segment of the PICA. This was occluded with coils. No further hemorrhage occurred, but the patient did not recovered from the SAH. He remained comatose and died 3 months later. (**b**)–(**d**) Another old patient presenting with SAH, less severe than the above described case. The angiographic study revealed a small AVM involving the inferior cerebellar vermis and partially the right cerebellar hemisphere. (**b**) Right VA angiogram. The PICA is replaced by a well-developed AICA supplying the AVM. On its distal cerebellar branch a flow-dependent aneurysm (*arrow head*), better visible on the selective study is recognizable. (**c**) Control angiogram after occlusion of the aneurysm with onyx. (**d**), left VA angiogram. Flow-dependent aneurysms are visible on the supratonsillar segment (*arrow head*) and on the vermis branch (*arrows*) with dot of the PICA. Note the normal posterior meningeal artery (*arrow*). Selective angiogram, preceding the distal occlusion of the PICA and aneurysms with Onix. The patient recovered. The AVM was treated by surgery

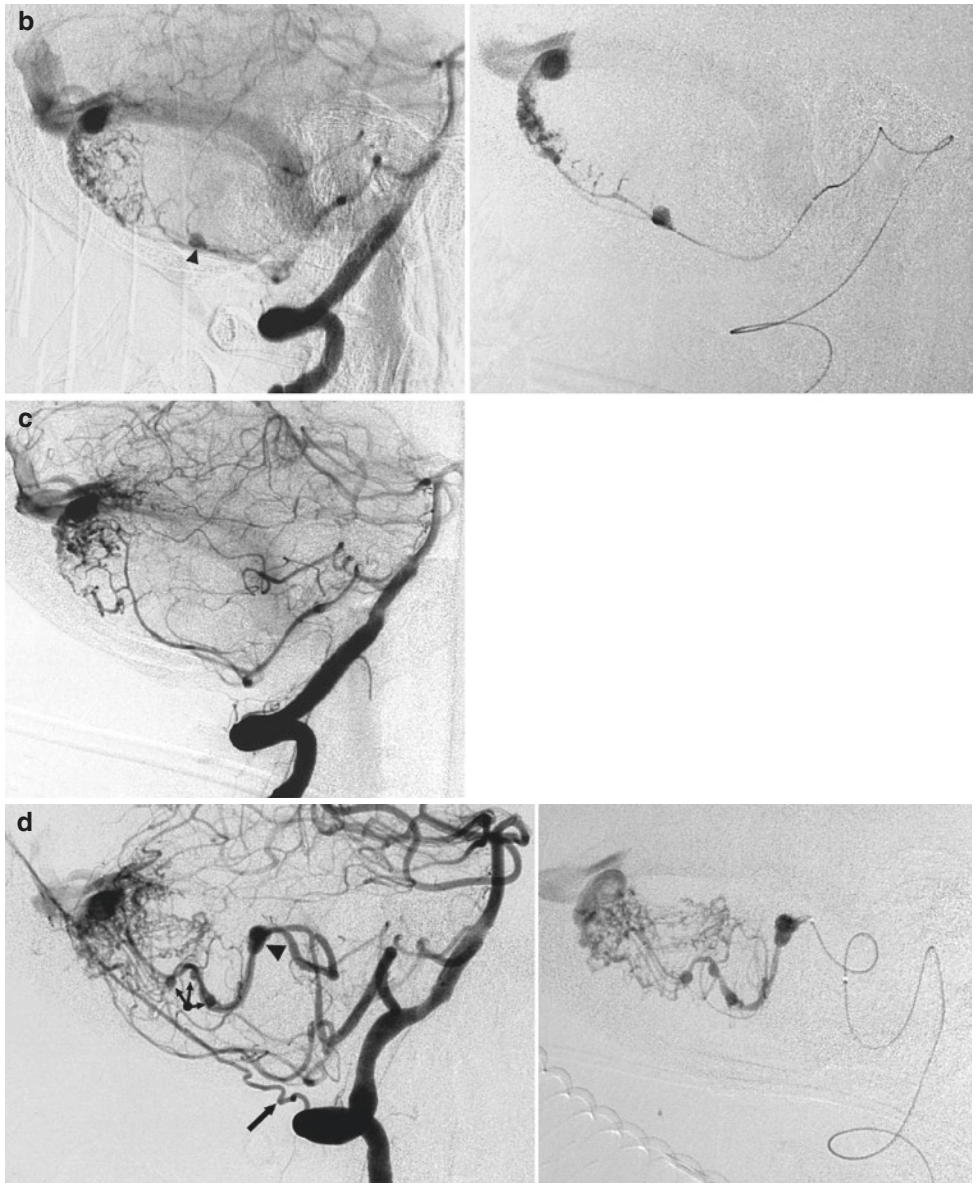

Fig. 12.16 (continued)

et al. 1994; Pollock et al. 1996; Redekop et al. 1998; Bradac et al. 2001; Pierot et al. 2004; Valavanis et al. 2004, Signorelli et al. 2014), (Figs. 12.4, 12.5, 12.9, 12.11, 12.17, and 12.18).

Rarely aneurysms can be found on an arterial branch independent of the AVM. The pathogenesis of these is probably the same of other aneurysms, as described in Sect. 11.4.

One notable type is the *pseudoaneurysm*, which develops at the site of rupture of the AVM. This type is detected in patients presenting clinically with a recent AVM rupture. Pseudoaneurysms lack a true vessel wall and consist of a pouch arising from a partially reabsorbed hematoma which still communicates with the lumen of the ruptured vessel. They can be

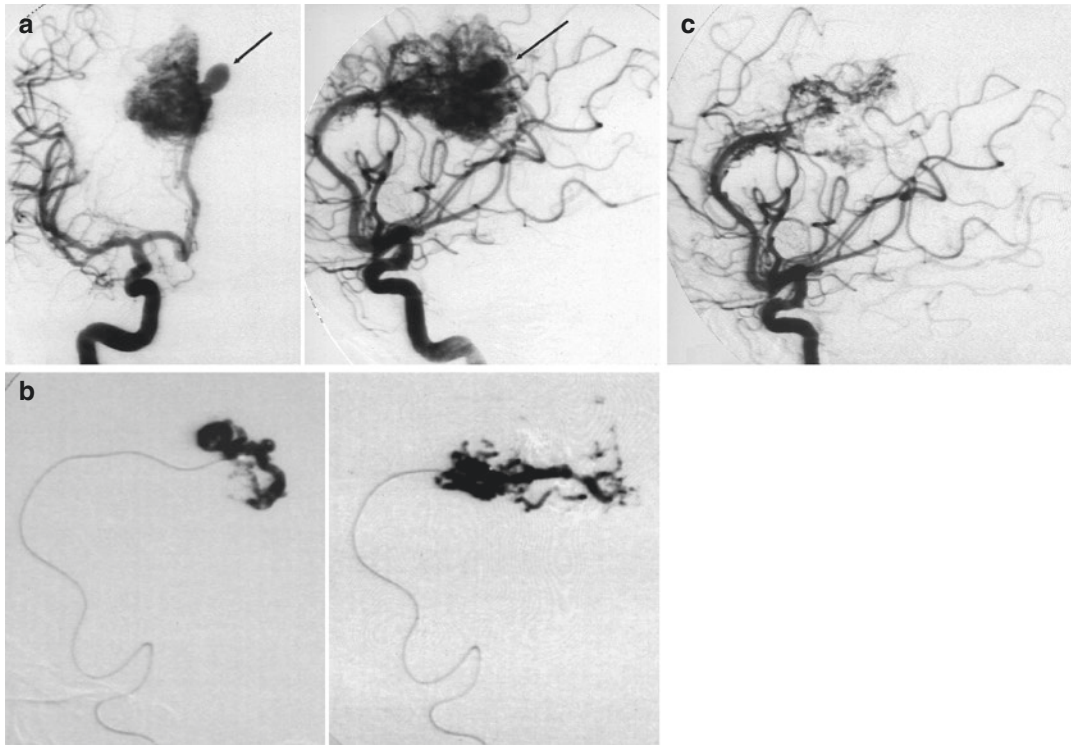

Fig. 12.17 AVM involving the corpus callosum and adjacent gyrus cingula in a young patient presenting with hemorrhage. (**a**) Right carotid angiogram, AP and Lateral views. A dilated pericallosal artery supplies the well-defined nidus. In its posterior part a large aneurysmal dilatation is visible. (**b**) Two selective studies of distal branches of the pericallosal artery preceding the injection of acrylic glue aimed to occlude partially the nidus and especially the aneurysm. (**c**) Control angiogram, post-treatment, well tolerated by the patient, who was operated 1 month later with a final clinical good result

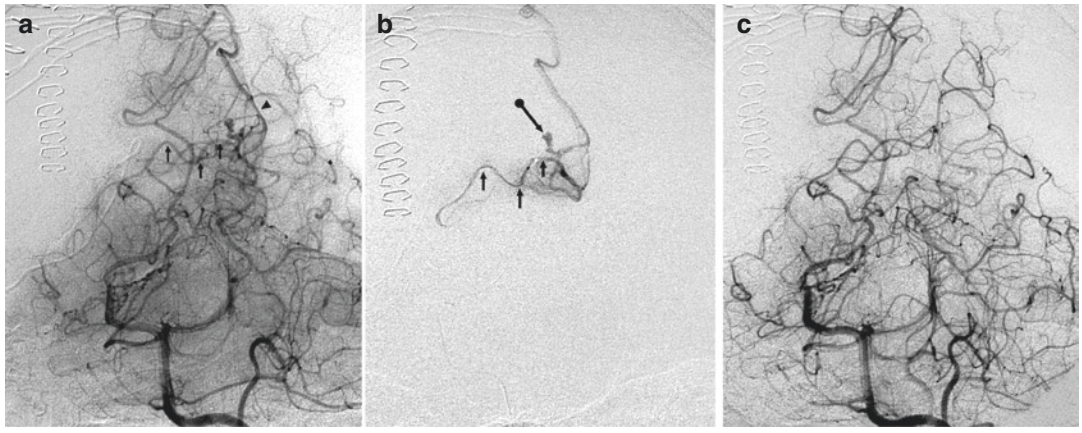

Fig. 12.18 Very small medial occipital AVM presenting with a large hemorrhage in a young man. The parenchymatous hematoma was acutely operated on. Two days later the vertebral angiography showed the AVM. (**a**) Oblique view. A small supplying branch (*arrow*) arising from the P4 segment of the PCA is recognizable. This seems to continue directly in the venous drainage (*arrowhead*). (**b**) On the selective study the fistulous pattern is better identified. Feeding artery (*arrows*), continuing in the single draining vein. A small aneurysmatic dilatation (*arrow with dot*) along the course of the feeding artery is also visible. The AVM was occluded with glue. (**c**) VA angiogram posttreatment

angiographically identified by their irregular shape and location at the margin of the recent hematoma diagnosed with CT or MR (Berenstein and Lasjaunias 1992; Garcia-Monaco et al. 1993; Valavanis 1996, 2004) (Fig. 12.10).

12.3.5.3 Other Changes of the Arteries

Among other changes of the arteries there are stenosis (Willinsky et al. 1998) due to thickening of the wall (see also Sect. 12.3.1) (Fig. 12.19). Moyamoya pattern has also been reported, probably being the result of hemodynamic stress (Mawad et al. 1984; Berenstein and Lasjaunias 1992).

12.3.5.4 Venous Drainage

The type of drainage depends on the location of the AVM and thus predictable. It can, however, be aberrant due to preexistent variants or the formation of a collateral venous drainage following occlusion or stenosis in the venous sector or it may be a venous adaptation in the attempt to reduce the high intranidal pressure. The venous drainage can be superficial, deep, or both, and can consist of one single draining vein or several venous channels. It can also occur that a unique large drainage vein can divide early giving the erroneous appearance of a multiple venous drainage. Examples are presented in Figs. 12.1, 12.2, 12.4, 12.5, 12.6, 12.7a–d, 12.10, 12.11, 12.18, and 12.20.

The veins draining the AVM are always dilated. The dilatation is sometimes enormous, forming large pouches (Fig. 12.6) which can be due to the presence of *a large fistula which occur more frequently in children* (Rodesch et al. 1995; Lasjaunais 1997). In these latter cases, according to some authors (Krings et al. 2005), the presence of a hereditary hemorrhagic telangiectasia should be suspected. Another cause of venous dilatation is a distal stenosis or thrombotic occlusion. The cause of stenosis may differ. It can be due to hyperplasia of the wall components as a reaction to the increased flow and pressure. Otherwise, the stenosis occurs when the vein enters the dura or may the result of a kinking or bone compression.

Some aspects of the venous drainage (unique vein, deep venous drainage, stenosis, large pouches) are considered potential risks of hemorrhage (Vinuela et al. 1985, 1987; Berenstein and

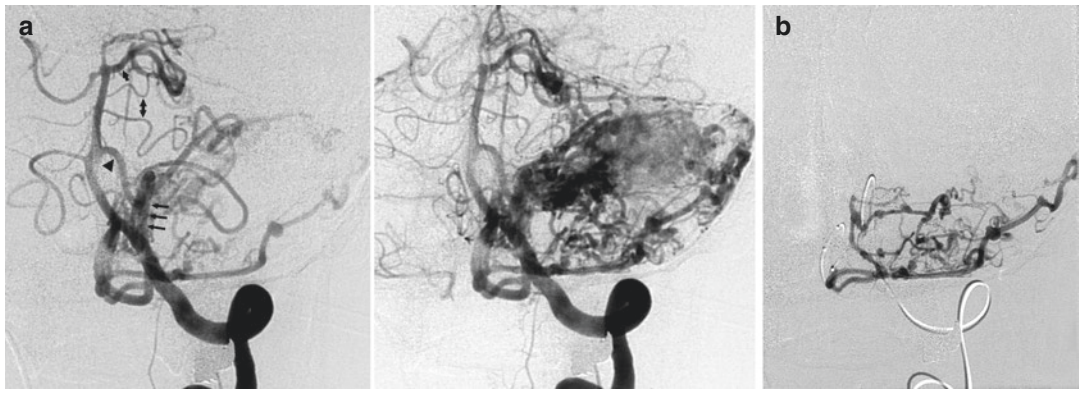

Fig. 12.19 AVM with a diffuse character, involving largely the left cerebellar hemisphere, presenting with SHA in a young woman. (**a**) Left AP vertebral angiogram (*early and later phase*), showing the AVM supplied by branches of the PICA (*three arrows*), AICA (*arrowhead*) and SCA (*arrow*). The dilated lateral pontine arteries (*bidirectional arrow*) are also involved. Wall irregularities and several aneurysms are recognizable along the course of the branches of the PICA supplying the AVM. These are better visible on the selective study (**b**) preceding the treatment with glue, followed by complete surgical eradication of the AVM

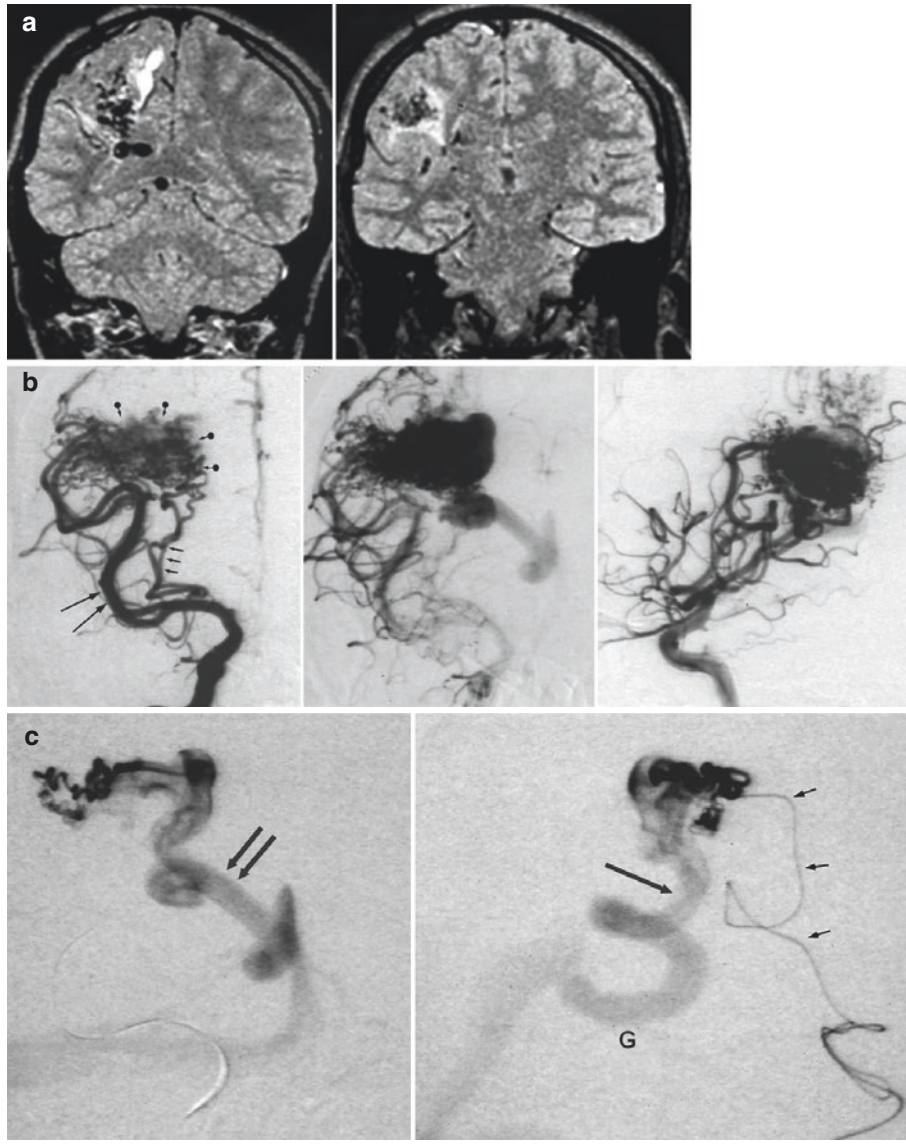

Fig. 12.20 Parietal AVM with a history of a previous bleeding in a young patient. (**a**) Coronal MRI, T2-weighted image showing the extension of the AVM toward the ventricle and an area of gliosis due to the previous hemorrhage. (**b**) Carotid angiogram, AP view, early and late phases, and lateral angiogram showing the nidus (*arrows with dot*) and the supplying branches of the MCA (*cortical*, *large arrows* and *perforators*, *small arrows*). There is a predominant large deep venous drainage (**c**) AP and Lateral views showing part of the selective study. Microcatheter (*small arrows*). Portion of the nidus draining into the dilated medial atrial vein (*arrow*) entering the Galen vein (G). Surgery was performed after partial embolization with glue

Lasjaunias 1992; Turjman et al. 1995; Mueller-Forell and Valavanis 1996; Pierot et al. 2004; Valavanis et al. 2004).

12.3.5.5 Nidus

The extension of the nidus varies from very large to very small. Small AVMs have a greater tendency to rupture (Graf et al. 1983; Pierot et al. 2004) (Fig. 12.18). The same is true for deeply located and posterior fossa AVMs (Figs. 12.5, 12.9, and 12.11). Some authors (Garcia-Monaco et al. 1990; Berenstein and Lasjaunias 1992) reported a higher tendency to hemorrhage also in temporo-insular and callosal AVMs (Fig. 12.17).

On the angiographic studies the nidus appears as formed by one or more compartments. AVMs with only one compartment are those in which the same unique vein of drainage appears after injection of all feeders involved. Those with multiple compartments are characterized by a specific and separate venous drainage linked to a corresponding feeder. When multiple compartment are present, one can be larger and predominant to the other (Yasargil 1987; Berenstein and Lasjaunias 1992; Valavanis et al. 2004). Small connections between the compartments are frequently present as recognizable in the endovascular treatment. Indeed, the very slow injection of embolic material can pass from one compartment to the adjacent one.

There are other aspects of the nidus which should be considered. One are the intranidal aneurysms which have already been described in Sect. 12.3.5.2. The other is the presence of very large arteriovenous shunts, leading to the formation of large fistulas. The fistula can be the unique feature of the AVM or be associated to the plexiform component (Fig. 12.6).

The nidus of the AVM is commonly characterized by well-defined borders, but in some cases its boundaries cannot be precisely recognizable. In these cases, many feeders can be present which are, however, not particularly dilated and can present with dysplastic aspects characterized by narrowings and small aneurysms. The venous drainage is slower than that of the typical AVMs (Fig. 12.19). In some rare cases this aspect is prominent with some clinical and structural features very different from the typical AVM. Some authors (Lasjaunias et al. 2008) have proposed to call this kind of malformation "*cerebral proliferative angiopathy*." Histopathological studies have demonstrated that it consists of a diffuse network of capillaries and venous ectasias in which areas of normal brain parenchyma are present. The malformation is usually very large, involving frequently more than one lobe sometimes the whole hemisphere. Children and young female are predominantly involved. The clinical presentation is commonly characterized by epileptic seizure, headache and stroke-like symptoms. Hemorrhages are rare. On MR, the typical aspect of the AVM with a nidus with dilated supplying arteries and draining veins is not recognizable. Instead, a diffuse network of vascular structures intermingled by areas of normal parenchyma and frequently a diffuse irregular enhancement on T1-weighted images indicating probably alterations of the blood-brain barrier is recognizable. Furthermore on perfusion studies (Lasjaunias et al. 2008) an increase of the blood volume and a longer mean transit time differently from AVM, can be demonstrated, probably due to the richness of capillaries and to the absence of the typical AV shunts. On the angiogram there is a diffuse vascular network supplied by arteries which are not particularly dilated. Some of the draining vein can be dilated, but their appearance is not so rapid as in AVMs. A large transdural supply is frequently present. Treatment (surgery, radiotherapy, and endovascular) considering the extent of the malformation, the absence of certain supplying arteries, and as demonstrated in histopathological studies the presence within the abnormal vascular network of normal brain tissue is commonly not indicated. In cases of hemorrhage, the endovascular treatment can be considered and directed to possible source of the bleeding represented by intranidal aneurysms. An example is presented in Fig. 12.21.

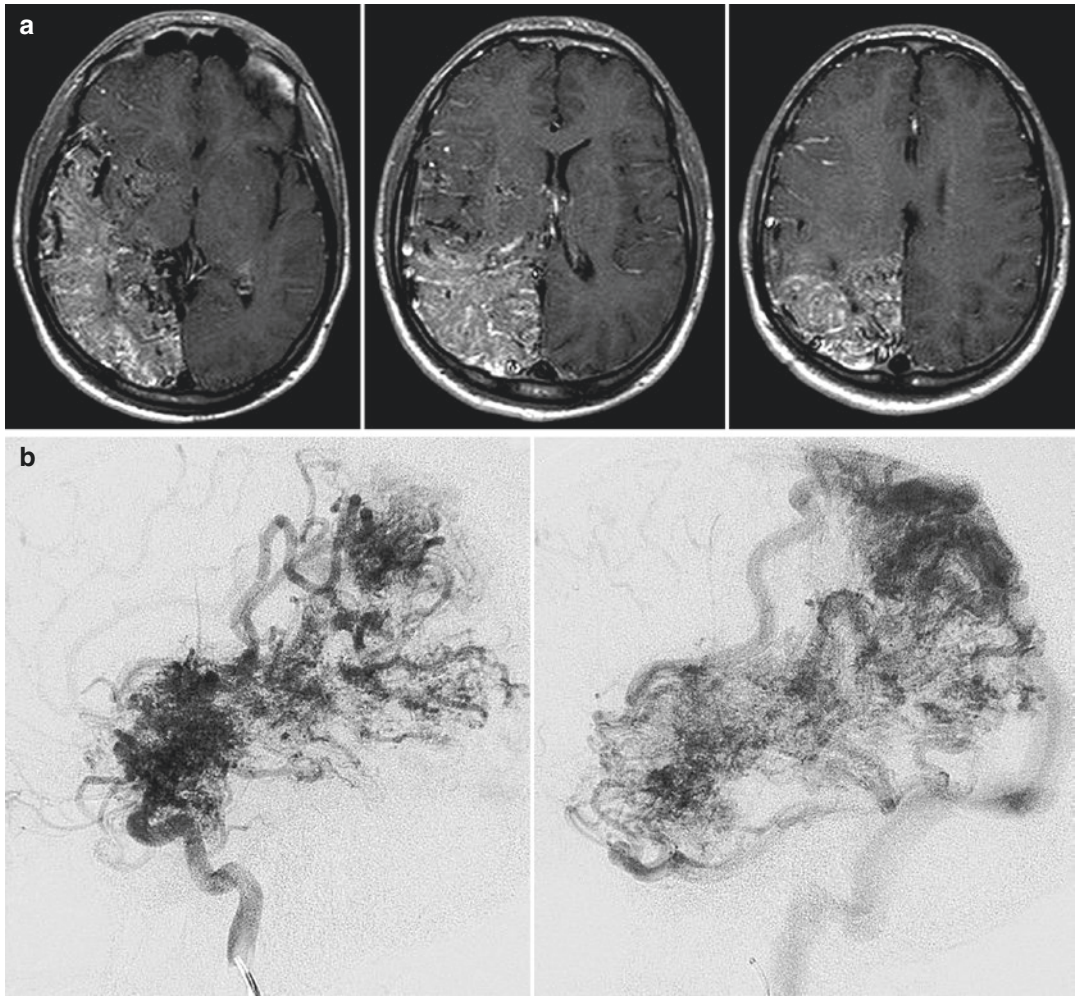

Fig. 12.21 (**a**–**e**) Cerebral proliferative angiopathy in young woman presenting with epileptic seizures. (**a**) T1-weighted images with contrast medium. There is a rich, diffuse enhancement in the temporo-occipito-parietal areas, in which several vascular structures, a few dilated, are recognizable. (**b**) Right ICA lateral angiogram. Early and later phases. Vascular malformation characterized by a diffuse network in which areas of probably normal parenchyma are recognizable. There are some dilated arteries as well as some dilated veins appearing in the late phase. (**c**) AP view of the right and left carotid angiograms showing the extension of the malformation. Mild dilated right ACA (*arrow*). (**d**) Vertebral angiogram. AP and Lateral views showing the basal and posterior part of the malformation. Minimal dilatation of the right PCA (*arrow*). (**e**) Right ECA angiogram showing also the involvement of meningeal branches

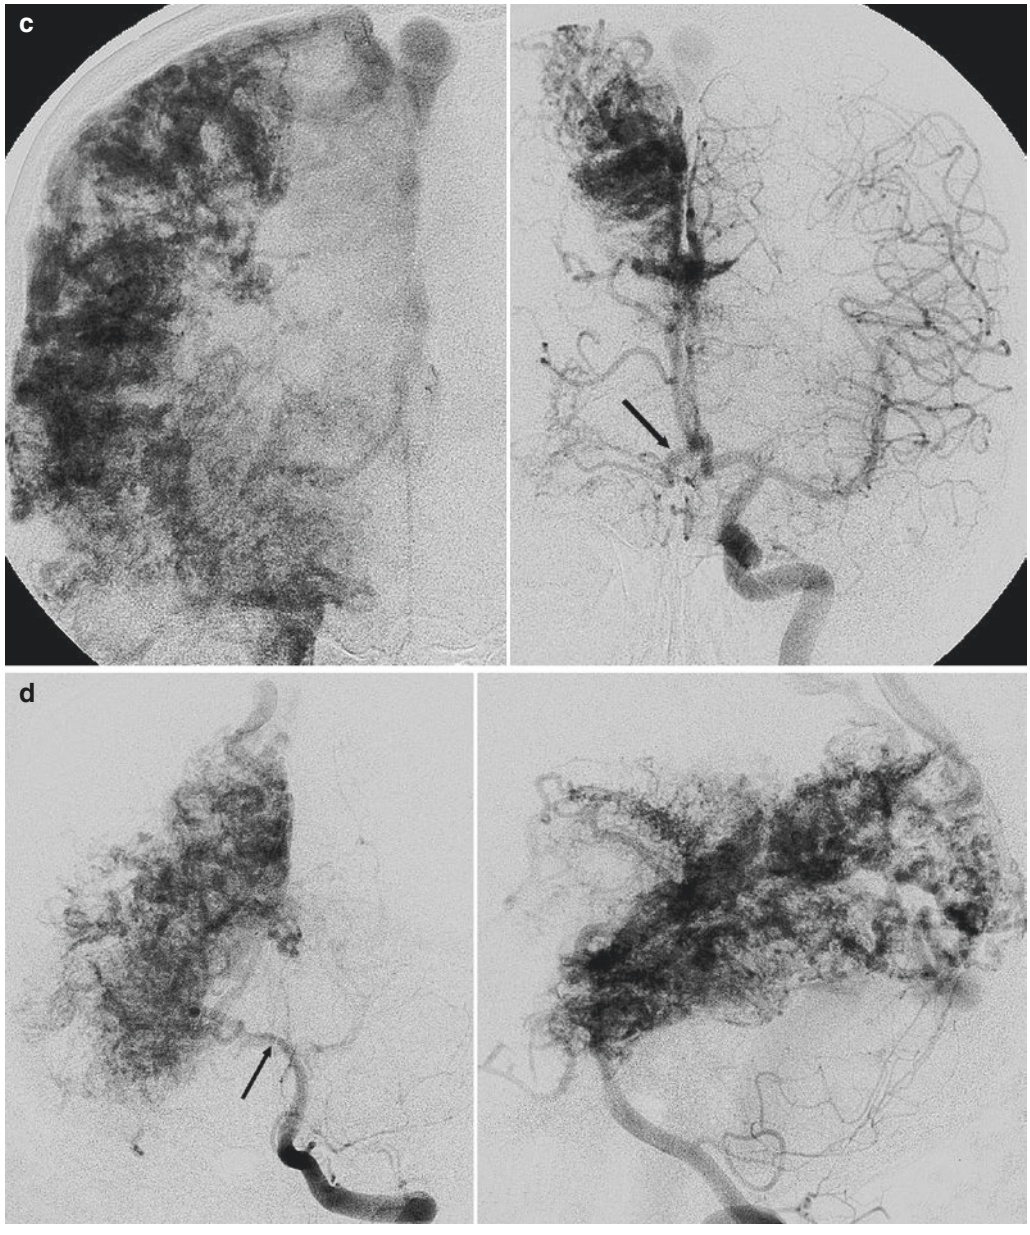

Fig. 12.21 (continued)

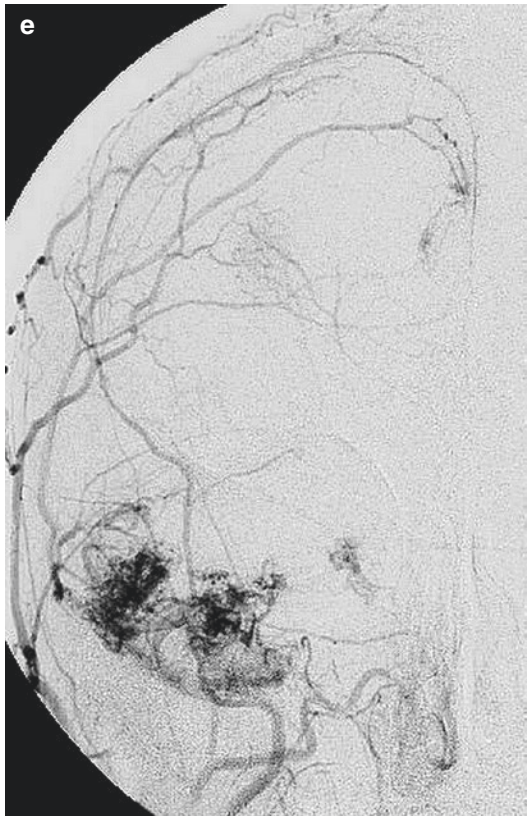

Fig. 12.21 (continued)

12.3.5.6 Perinidal Changes

In a number of cases, one can observe around the nidus the presence of a rich vascular network, consisting of tiny vessels; this is usually due to dilatation of collateral following the demand of blood flow from the AVM. Some authors have described the development of new vessels as expression of angiogenesis, in response to chronic ischemia of the perinidal parenchyma (Berenstein and Lasjaunias 1992; Valavanis et al. 2004).

12.3.6 Treatment

In spite of the introduction of cerebral angiography which made the diagnosis of AVMs easier, this pathology was considered for many years beyond of any useful surgical therapy. This attitude changed in the 1950s following the experiences published by some authors (Olivecrona and Riives 1948; Olivecrona 1950; Toennis and Lange-Cosack 1953) who showed that a complete surgical extirpation was possible with an acceptable risk of morbidity and mortality. Since then, better definition of the site, size, morphology, and hemodynamic aspects of the AVM, combined with an improved knowledge of its pathophysiology and the technical improvement in surgical and endovascular treatments as well as in radiosurgery, applied in various combinations has progressively improved the treatment allowing to achieve in many patients a complete cure with relatively low rates of morbidity and mortality as reported by many authors (Spetzler and Martin 1986; Berenstein and Lasjaunias 1992; Colombo et al. 1994; Valavanis 1996; Debrun et al. 1997; Valavanis and Yasargil 1998; Valavanis et al. 2004; Beltramello et al. 2005; Picard et al. 2005; Vinuela et al. 2005; Raymond et al. 2005; Nagaraja et al. 2006; Mounayer et al. 2007; Panagiotopoulos et al. 2009).

Considering especially the endovascular treatment, the rate of morbidity (0-8%) and mortality (0-4%) reported in the literature varies greatly. (Katsaridis et al. 2008; Berenstein et al. 2010; Saatci et al. 2011; Pierot et al. 2009, 2013; Van Rooji et al. 2012a, b; Soltanolkotabi et al. 2013; Baharvahdat et al. 2014; Crowley et al. 2015; de Castro-Alfonso et al. 2016). These different results can be explained by the different complexity and localization of the treated AVM, the different strategy of treatment aimed to try to occlude completely the AVM or only partial of it, and the experience of the operators. The most feared complication is the hemorrhage which can be due to mechanical lesion of a feeding artery or to premature occlusion of a principal draining vein. Also an extensive but not complete occlusion of the AVM can lead to flow slowing and thrombosis of the draining veins responsible of impairment of the drainage of the remaining part of the AVM responsible for hemorrhage.

As far as it concerns the endovascular treatment, considering that *in the nidus no active brain parenchyma* is present, the injection of the embolic material, strictly confined into the nidus,

avoids the damage of normal parenchyma and so reduces the risk of complications. This approach should be considered especially in the treatment of AVM in so-called *eloquent areas*. In this context, however, it should be taken into account that all regions of the brain are eloquent, even if the clinical symptoms due to damage of the brain parenchyma are in some areas more evident than in other.

Among the factors playing a role in the positive results are the technical improvements characterized by the introduction of more suitable microcatheters and guide wire and the use of better liquid agents such the acrylic glue (Glubran) and more recently the onyx. This latter permits a slower injection with a larger penetration of the embolic agent in the nidus. In cases of small- or medium-sized AVMs, the endovascular treatment could be performed trying to occlude completely the malformation. In cases of large or deeply located AVMs, the embolization can be directed to eliminate those components of the AVMs which are considered a risk of hemorrhage such aneurysms (flow related, intranidal, or pseudoaneurysm), or to reduce partially the volume of the malformation to facilitate surgery or radiosurgery.

It is still open to question whether an invasive therapy or a noninvasive management should be chosen in cases of asymptomatic AVM or those with minimal symptoms. The age of the patient, location and extension of the AVM, and anticipated difficulty of treatment will play a role in the decision. Also, aspects of the angioarchitecture thought to increase the risk of hemorrhage should be considered. In this context studies have been made trying to identify gene factors which could favour hemorrhage in AVMs. Some authors (Pawlikowska et al. 2004; Chen et al. 2008) have found polymorphism in the inflammatory cytokine IL6 gene (IL6-174 GG) in AVMs presenting with hemorrhage. Furthermore association of genotypes of tumor necrosis factor-alpha. 238 G > A and apolipoprotein E2 polymorphisms with hemorrhage in AVMs has been demonstrated (Achrol et al. 2006, 2007).

More information is certainly needed about the evolution of this very complicated pathology. Such data could emerge from a multicenter, randomized trial still ongoing (Fiehler and Stapf 2008; Mohr et al. 2014), assessing possible invasive treatment and noninvasive management of patients with AVM. The first results of this study shows a superiority of the medical management concerning death and stroke in comparison to the interventional therapy (Mohr et al. 2014). The study is continuing and enlarged to additional 5 years to see if these preliminary results will be confirmed.

12.4 Cavernous Malformations (Cavernomas)

12.4.1 Pathology

These appear as well-circumscribed masses formed by dilated vascular channels without intervening brain parenchyma. The wall of the channels is lined by a single layer of vascular endothelium, surrounded by fibrous tissue. Some of these channels show thrombosis. Evidence of hemosiderin due to previous hemorrhage is present within and around the malformation. There may be calcification. Cavernous malformations can grow following hemorrhage or because of their intrinsic activity.

12.4.2 Incidence

Based on MRI and anatomo-pathologic studies, the incidence is reported to be 0.4–0.9% of the general population (McCormick 1984; Otten et al. 1989; Robinson et al. 1991; Maraire and Awad 1995). Cavernous malformations can be single or, frequently multiple. Familial cases have been increasingly recognized, especially in patients of Hispanic-American origin (Rigamonti and Brown 1994; Zambranski et al. 1994; Gunnel et al. 1996). In this group of patients an autosomal dominant pattern of inheritance linked to a gene mutation known CCM1 in the chromosome 7 has been identified (Gunnel et al. 1996). Other more rare mutations are the CCM2 in chromosome 7 and CCM3 in chromosome 3. In other families these

mutations have not been found, suggesting that probably other not known mutations occur. Cavernomas have been considered to be congenital. However, "de novo" lesions appearing during life can develop in families in whom the cavernomas are known, but also as sporadic cases (Pozzati et al. 1996; Tekkök and Ventureyra 1996; Porter et al. 1997; Brunereau et al. 2000; Massa-Micon et al. 2000). Furthermore, the possibility that, at least in some cases, venous hemodynamic changes induce the development of cavernoma have been considered. This could explain the frequent association of cavernoma with DVA (Dillon 1995; Hong et al. 2010b). Cases of "de novo" cavernoma have been described in pathological conditions leading to changes of the venous circulation. Some authors (Desal et al. 2005) reported a case of cavernoma probably induced by many triggers factors acting in different phases including the presence of a DVA, a "de novo" formation of a DAV fistula and a thrombophlebitis. Other authors (Janz et al. 1998; Ha et al. 2013) have described the appearance of cavernomas in patients with DAVF especially in those cases associated with venous reflux. In conclusion, it is thinkable that the formation of cavernomas is linked to a genetically predisposition, to which different factors can act favoring their development.

12.4.3 Location

Cavernomas can be found throughout the brain and spinal cord. They are more frequent in the subcortical white matter and pons. Extraparenchymal lesions can occur (Meyer et al. 1990; Sepehrnia et al. 1990) and are particularly frequent in the cavernous sinus, especially in women.

12.4.4 Diagnosis and Clinical Relevance

In CT, cavernomas appear as rounded, hyperdense masses, sometimes with calcifications. In MR, they are hypointense on T1- and hyperintense on T2-weighted images. Not rarely the signal is inhomogeneous. In large cavernomas, the pattern is frequently characterized by a mass made of several rounded cavities. Very useful for the diagnosis are the T2*-weighted gradient echo and the susceptibility-weighted images (SWI) (Haacke et al. 2009 Bradac et al. 2014). With this technique the cavernoma appears as a lesion characterized by a signal loss due to the deoxyhemoglobin in the venous channels and hemosiderin linked to previous hemorrhages. Enhancement in CT and MR is typical (Rigamonti et al. 1987). Frequently the presence of an associated DVA can be demonstrated. Examples are presented in Figs. 12.22 and 12.24. Angiograms are commonly negative. In cases of cavernoma within the cavernous sinus, the differential diagnosis with cavernous sinus meningioma can be very difficult (Bradac et al. 1987).

Cavernomas are frequently asymptomatic and discovered incidentally on CT or MR. They can present clinically with seizures, hemorrhage, or impairment of brain parenchyma due to its compression. With regard to the association with DVA, see also Sect. 12.6. The alternative management between microsurgical resection or conservative therapy remains controversial: the clinical presentation, location, aspect of the lesion, and experience of the team involved are the essential factors influencing the decision (Mouchtouris et al. 2015).

12.5 Capillary Malformations (Telangiectasias)

The telangiectasias are similar to the cavernous angiomas. They are formed by a collection of dilated capillary, between those, however, unlike cavernomas there is brain parenchyma. The incidence on autopsy is reported to be 0.1–0.15% (McCormick 1984; Jellinger 1986). They are frequently associated with cavernomas, and some authors have suggested that these lesions represent the phenotypic spectrum within a single pathological entity (Rigamonti et al. 1991; Chaloupka and Huddle 1998).

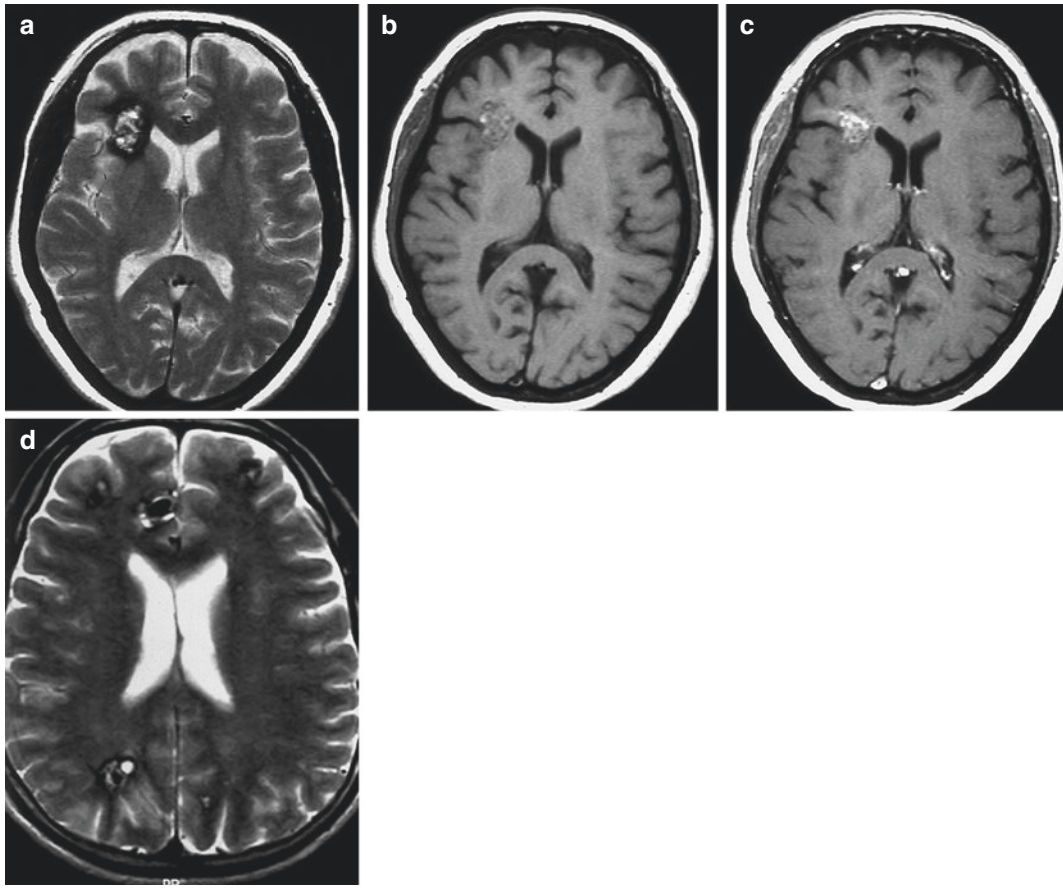

Fig. 12.22 Incidental discovery of cavernoma in two different patients. (**a**)–(**c**) MRI study of the lesion located in the frontal region. T2-weighted image (**a**) showing the irregular foci of hyperintensity surrounded by hypointense rim of hemosiderin. T1-weighted images without (**b**) and with (**c**) contrast medium showing the rich enhancement of the cavernoma. (**d**) Another patient in whom multiple cavernomas have been diagnosed. T2-weighted image showing the inhomogeneous pattern of the lesions

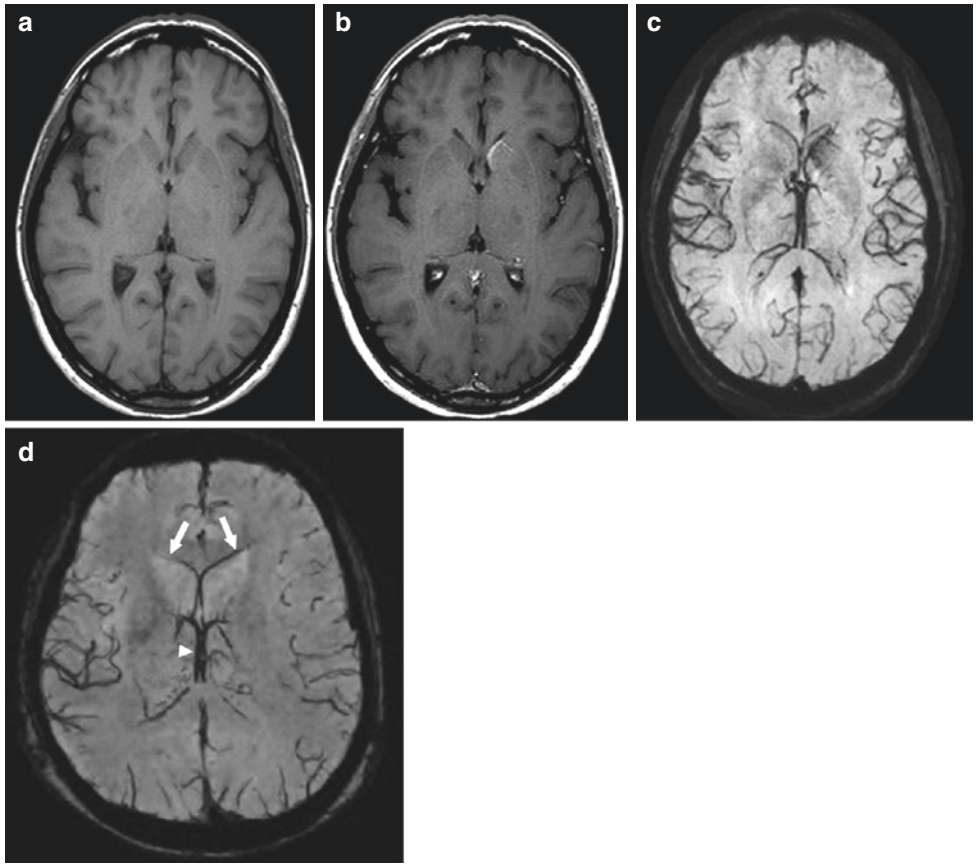

Fig. 12.23 Suspected telangiectasia studied with T1-weighted images without (**a**) and with (**b**) contrast medium. There is a small enhancement in the region of the caudate nucleus. On the SWI (**c**), vascular structures (*small arrow*) are recognizable connected with the septal vein. (**d**) Study of the normal anatomy. Same section as in (**c**) showing the course of both septal veins (*arrows*) running from the lateral to the medial corner of the frontal horn. The veins turn back along the septum pellucidum joining the ICV (*arrowhead*)

Telangiectasias can be found everywhere in the brain parenchyma and spinal cord, with a predominance in the pons and basal ganglia. The neuroradiological diagnosis is similar to that for cavernous angiomas. Also in these cases the use of SWI can be very useful in detecting small lesions not recognizable on T1- and T2-weighted images (El-Koussy et al. 2012) (Fig. 12.23).

12.6 Developmental Venous Anomaly (DVA)

12.6.1 Pathology

Also called venous angioma, DVA is prevalently located in the white matter of the cerebral hemisphere, whereby several medullary veins converge to a unique collector draining further superficially

in one of the sinuses or in one of the subependymal vein continuing in the ICV or BV. Another typical location is the white matter of the cerebellar hemisphere, where medullary veins converge commonly to the vein of Galen through the precentral vein or into the petrosal vein. DVA is considered to be the result of a focal abnormal development of the medullary veins (Saito and Kobayashi 1981).

12.6.2 Incidence

DVA has been reported as being the most common vascular malformation detected on autopsy (Sarwar and McCormick 1978; McCormick 1984) with an incidence of 2.6%. Today, it is not considered a pathological malformation (Saito and Kobayashi 1981; Lasjaunias et al. 1986a).

12.6.3 Diagnosis and Clinical Relevance

DVAs appear as enhanced venous channels after contrast medium on T1-weighted images and as hypointense channels on T2* gradient echo and SWI images (Fig. 12.24). On the angiogram, DVAs are typically recognizable in the capillary-venous phases, characterized by several medullary veins converging on a large collector (Figs. 20.5, 12.25 and 9.25).

Most DVAs are asymptomatic. When hemorrhages occur, these are considered commonly due to the associated cavernous angiomas (Ostertun and Solymosi 1993; Forsting and Wanke 2006). Rarely thrombosis of the main collector can lead to hemorrhagic ischemia (Ostertun and Solymosi 1993; Field and Russell 1995).

A few DVAs do not completely fit the typical features described above. These lesions probably represent a transition-form between DVA and AVM (Awad 1993; Mullan et al. 1996a, b; Bergui and Bradac 1997; Komiyama et al. 1999; Im et al. 2008; Oran et al. 2009). On the angiogram, several not dilated arterial feeders are connected with veins that have the feature of DVA, but unlike these appear on an early phase (Fig. 12.25f).

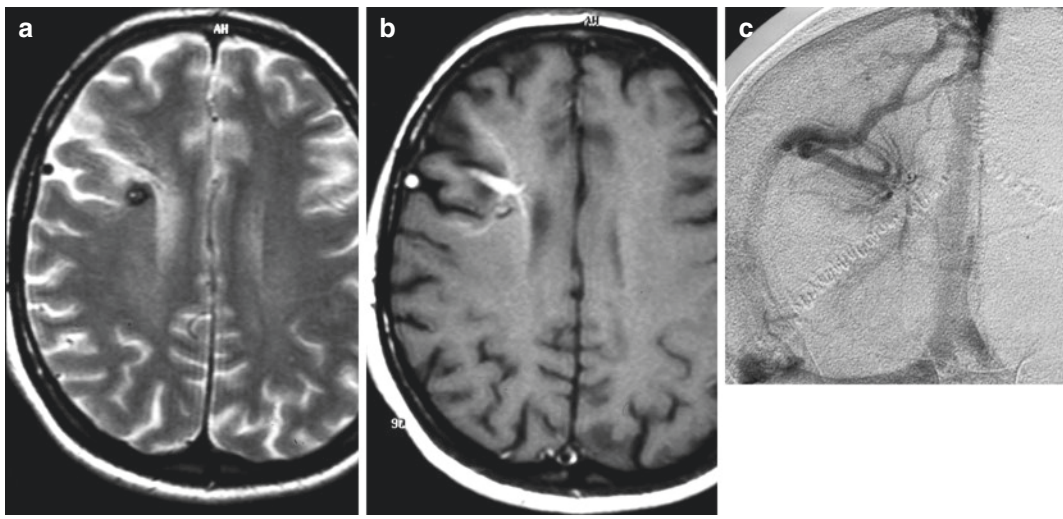

Fig. 12.24 Incidental discovery of a cavernoma associated to a DVA. (**a**) T2* gradient echo MR image showing a small cavernoma surrounded by a nonspecific area of hyperintensity corresponding to a gliosis or edema. (**b**) T1-weighted MR images after contrast medium. Partial enhancement of the cavernoma and structures having the feature of vessels. (**c**) Venous phase of the carotid angiogram confirming the presence of a large DVA

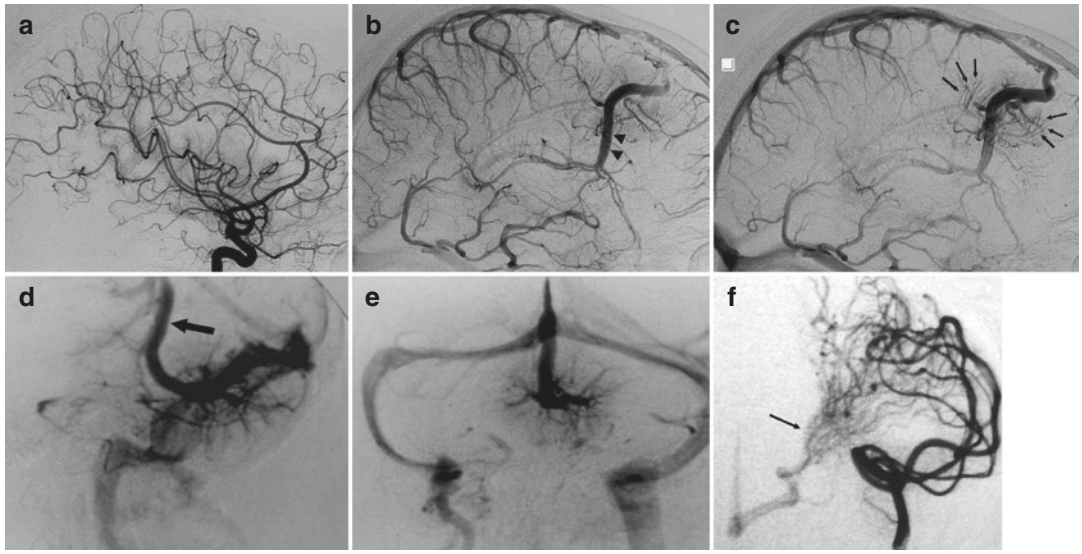

Fig. 12.25 (**a**–**e**) Two example of DVAs. Carotid angiogram, (**a**) normal arterial phase; (**b**), (**c**) in the late venous phase a large frontal cortical vein, draining also partially the temporal region is recognizable (*arrowheads*). To this converge all the medullary veins of the area (*arrows*). The septal vein is not recognizable, probably absent. Further drainage occurs in the superior sagittal sinus. (**d**), (**e**) Venous phase of a vertebral angiogram in another patient. Lateral (**d**) and (**e**) AP view. There is an enlarged precentral vein (*arrow*) to which converge the majority of the medullary veins of both cerebellar hemispheres. (**f**) Example of a mixed angioma. Carotid angiogram. AP view. Selective study of the middle cerebral artery. There is a pathological network (*arrow*), consisting of a medullary veins injected early through connections with medullary branches of the middle cerebral artery. All the veins converge on a dilated atrial vein continuing into the Galen vein

12.7 Central Nervous System Vascular Malformation (Part of Well-Defined Congenital or Hereditary Syndrome)

12.7.1 Rendu-Osler Syndrome (Hereditary Hemorrhagic Telangiectasias)

Rendu-Osler is an autosomal dominant neurocutaneous disease caused by mutations of two genes, the endoglin gene (ENG) and the active like kinase gene (ALK). It is characterized by telangiectasias of the skin and mucosa of the oral-nasal cavities and gastrointestinal tract which can be responsible of severe hemorrhages (Fig. 3.21). Arteriovenous angiomas and fistulae are also frequently present in the lung and liver. In addition, different types of vascular malformations can involve the central nervous system. The most frequent are AVMs, which are often relatively small and multiple (Putman et al. 1996; Chaloupka and Huddle 1998; Berenstein and Lasjaunias 1992; Garcia-Monaco et al. 1995). According to some authors (Krings et al. 2005), the presence of AVMs characterized mainly by a large fistula occurring in children should arise the suspicion of an underlying hereditary hemorrhagic telangiectasia. See also Sect. 12.3.5.4.

12.7.2 Sturge-Weber Syndrome (Encephalotrigeminal Angiomatosis)

Sturge-Weber syndrome is a familial neurocutaneous disease, characterized by a facial vascular nevus, in the trigeminal distribution, mainly in the first branch, a retinal angioma, and leptomeningeal angiomatosis.

12.7.3 Pathology and Diagnosis

The pathology consists of a rich network of thin-walled capillaries and venules, lying between the pial and subarachnoid membrane. There is also typically a paucity of cortical veins which is probably responsible for the stasis and progressive hypoxia of the cortex, which becomes atrophic and partially calcified.

It is assumed today that the primary cause of the syndrome is a maldevelopment of the venous drainage, involving the cortical veins and the distal part of the superficial medullary veins. The drainage is redirected through a collateral circulation, particularly involving the deep medullary veins toward the subependymal veins and choroid plexus.

The dystrophic, calcified cortex can be well studied with CT and MRI. The contrast medium shows the enhancement of the angiomatous plexus and the redirected venous drainage (Smirniotopoulos and Murphy 1992; Chaloupka and Huddle 1998). On the angiogram the absence or paucity of the cortical veins as well as the redirected venous drainage toward the deep venous system can be demonstrated (Berenstein and Lasjaunias 1992).

12.7.4 Wyburn-Mason Syndrome

Wyburn-Mason syndrome is an exceptionally rare neurocutaneous disease, characterized by a cutaneous facial nevi in the distribution of the trigeminal nerve and an extensive AVM typically involving the visual pathways, including the retina, the optic nerve, optic tract and sometimes the diencephalon an the occipital lobe (Patel and Gupta 1990; Chaloupka and Huddle 1998). Some authors have proposed for this syndrome the term unilateral retinocephalic vascular malformation (Theron et al. 1974). Unusual variants, include bilateral intracranial vascular anomalies (Patel and Gupta 1990). Other variants of this disease have been described characterized by involvement of hypothalamus, corpus callosum, hypophysis or in other cases of pons, cerebellum associated with facial bone malformations. Considering the multiple aspects of the disease and the probable metameric development, the term "*cerebrofacial AV metameric syndrome*" (*CAMS*) has been proposed by some authors (Krings et al. 2007c). CT and MRI are useful diagnostic tools, but angiography is the essential diagnostic step to decide if there is a possibility of partial endovascular treatment.

12.7.5 Klippel-Trenaunay-Weber Syndrome

This is a very rare syndrome characterized by unilateral soft tissue or osseous limb hypertrophy, cutaneous telangiectasia, and venous malformations and/or occasional high-flow AVM of the affected limb. Commonly the lower limb is affected but involvement of the upper limb can also occur (Chaloupka and Huddle 1998). The typical syndrome can be associated by many other pathologies. Vascular malformation and hemangiomas can be present in other organs including head, neck, abdominal, pelvic organ, and thorax (Samuel and Spitz 1995). Intracranial hemorrhage due to aneurysms and AVMs have been described (Makiyama et al. 1994). Cases of cerebral infarct due to carotid dissection and spinal cord ischemia due to occlusion of the anterior spinal artery (Brunaud et al. 1994) as well as the association with Kasabach-Merritt syndrome (Samuel and Spitz 1995) and with Sturge-Weber syndrome have been reported (Kanterman et al. 1996). CT and MRI are useful in detecting all these different lesions; angiography is essential in the evaluation of the vascular pathology especially when endovascular treatment has been taken into consideration.

12.8 Arteriovenous Shunts Involving the Vein of Galen

The real incidence of this pathology is unknown. It can be estimated to be less than 1 per 1,000,000. The first description of "aneurysms of the vein of

Galen" was made in 1937 by Jaeger et al. Today we know that these malformations constitute a group of lesions that have been more precisely classified only in the recent years.

- **Vein of Galen aneurysmal malformations**. Nowadays, there is a common agreement that the pathogenesis of this malformation, which can be termed "true vein of Galen malformation," is a malfunction in the embryogenesis, involving the median prosencephalic vein (Raybaud et al. 1989; Mickle and Quisling 1994; Burrows et al. 1996; Brunelle 1997; Lasjaunais 1997; Chaloupka and Huddle 1998; Rao and Mathuryia 2011). As it has already been described in Chap. 9, *the prosencephalic vein (PV)* is an embryological vessel which receives the venous drainage of the deep cerebral structures and choroid plexus, continuing into the falcine sinus. The vein disappears in a period between the sixth and eleventh weeks, and it is replaced by the vein of Galen, arising from the unification of the caudal remnant of the Prosencephalic vein with the in the meantime developed internal cerebral veins. In the malformation of the Galen vein, the PV does not regresses and appears as a dilated vein draining in the straight sinus. Frequently, however the drainage occurs in the persistent falcine sinus, while the straight sinus is hypo or aplastic (Raybaud et al. 1989; Mickle and Quisling 1994; Burrows et al. 1996). The pathogenesis of the arteriovenous shunt remains unknown. Raybaud et al. (1989) suggested that it may be linked to an embryogenetic error involving the choroidal arteries, which, in the same embryonic period when the PV is prominent, are the most active arterial vessels; thus they are the most vulnerable to maldevelopment.

12.8.1 Diagnosis and Treatment

CT and MR allow easy identification of this kind of malformation. Selective and superselective angiograms are essential for a precise study. Angiography in patients with this pathology present a series of technical problems, since in the majority of the cases they are neonatal or infants aged 1 to 2 years. The femoral approach is more difficult and there is the necessity to limit the quantity of contrast medium; thus, it is prudent and rational to postpone the angiography until the patient is at least 5–6 months old. The angiographic study and the endovascular treatment should be performed earlier if rapid clinical deterioration, particularly as a result of heart failure, occurs, which can rapidly improve after embolization with complete occlusion or only partial reduction of the shunt (Lylyk et al. 1993; Lasjaunais 1997; Bhattacharaya and Thammaroj 2003; McSweeney et al. 2010; Khullar et al. 2010; Boccardi et al. 2013). In this context, it should, however, be taken into consideration, as reported by some authors (Brevis-Nunez et al. 2013), that the normalization of the heart activity in the days postembolization can be followed by a severe myocardial dysfunction similar to that occurring in patients with SAH (see Sect. 11.5). The cause of this condition is not completely clear; temporary increase of the hydrocephalus observed in some of these cases after the embolization has been suggested (Brevis-Nunez et al. 2013).

On the angiogram, two type of shunts can be recognized (Lasjaunais 1997): *the choroidal type*, characterized by the presence of many feeders shunting with the PV, commonly on its anterior surface, and the *mural type*, in which one or two feeders are connected with the inferolateral part of the PV. The feeders can be uni- or bilateral. The most common vessels involved are the posterior choroidal and the distal segment of the pericallosal arteries. In the embryo, the distal segment of the pericallosal artery runs around the splenium and extends anteriorly into the *tela choroidea*, anastomosing with the posterior medial choroidal artery. This connection normally disappears, but it can persist forming in the vein of Galen malformation the so-called limbic arch (Raybaud et al. 1989). The collicular and posterior thalamic branches, the anterior choroidal as well as the superior cerebellar arteries can also be involved; sometimes, secondary feeders can arise from peripheral branches of the middle cerebral

artery and its perforators and from meningeal branches.

The venous drainage occurs into a dilated PV, which appears as a rounded or elongated channel, with the greatest dimension along the sagittal axis. In at least 50% of the cases the further drainage occurs into the Falcine sinus (Raybaud et al. 1989) which replaces the hypo-aplastic straight sinus. In other cases, this latter can be the main drainage appearing frequently dilated, and sometimes duplicated. Other anomalies of the dural sinuses are frequently present. Among them there is a large occipital sinus and the presence of two segments of falcine sinus, one directed toward the SSS and the other back to the distal straight sinus forming a kind of loop (Raybaud et al. 1989). Aplasia and thrombosis of the transverse and sigmoid sinuses uni- or bilaterally as well as aplasia of the internal jugular vein can occur leading in these cases to a rerouting of the venous drainage anteriorly toward the cavernous sinus and ophthalmic vein and the pontomesencephalic veins.

Endovascular treatment is today the therapy of choice and has certainly improved the prognosis of these patients. The transarterial route alone or combined with the venous approach allows today a complete or partial occlusion of the malformation. The venous approach occurs through catheterization of the jugular vein via the femoral vein and a further catheterization of the transverse sinus and straight or falcine sinus followed by positioning of coils in the dilated prosencephalic vein . In cases of occlusion of the TS sinus the route through the occipital sinus can be used. In some cases a direct approach of the straight or falcine sinus after craniectomy is necessary. Depending on the morphological aspect of the shunt, and on the difficulty of the treatment, this can be performed in one or more sessions. Anatomical and clinical cure can be obtained in about 50–70% of the cases (Lylyk et al. 1993; Lasjaunais 1997; McSweeney et al. 2010; Khullar et al. 2010; Boccardi et al. 2013). In other cases, in spite of the technical good result, a progression of the disease occurs. In this context, in some cases, occlusion of the dural sinuses with progressively thrombosis of the cortical and medullary veins occurs in spite of the occlusion of the shunt. In general the worst results occur in neonatal patients in comparison with infants aged 1–2 years or with older children who have a clearly better outcome (Lylyk et al. 1993; Lajaunais 1997; Khullar et al. 2010; McSweeney et al. 2010; Boccardi et al. 2013). Examples are presented in Figs. 12.26 and 12.27.

- **Vein of Galen dilatation.** In this group of lesions, which occur in older patients, the ectatic vein is the normal developed great vein of Galen, into which drains an AVM. The dilatation can be associated with an obstruction of the venous drainage, involving the straight sinus or torcular herophili leading to a rerouting of the drainage in the superficial and deep veins. The filling of these latter does not occur in the true vein of Galen malformation, since they are not developed replaced by the prosencephalic vein (Lasjaunais 1997).

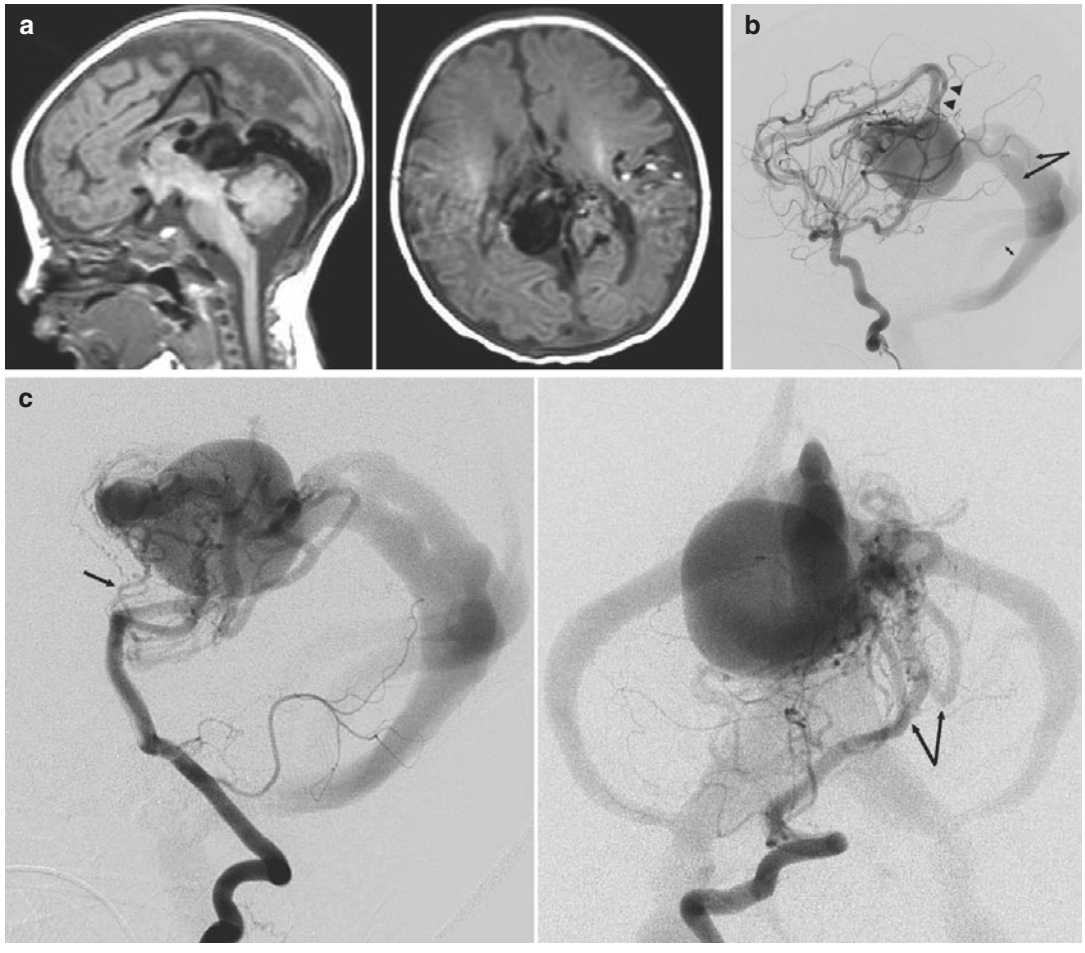

Fig. 12.26 Vein of Galen malformation in a 3-month-old child. Treatment owing to heart failure. (**a**) MRI T1-weighted images showing the malformation. (**b**) Right ICA angiogram, lateral view, showing the dilated prosencephalic vein draining into the dilated and fenestrated (*arrow with angle*) straight sinus. The malformation is supplied by the distal pericallosal artery (*arrowheads*) and by the posterior choroidal arteries of the PCA. Anterior and posterior systems converge forming the so-called limbic arch. The bidirectional arrow shows the further drainage into the transverse sinus and dilated occipital sinus. (**c**) Right VA angiograms, AP and Lateral views, showing the supplying arteries arising from the left PCA. Posterior thalamoperforating branches (*arrow*). Medial and Lateral choroidal arteries (*arrow with angle*). Following selective catheterization, coils were placed in the choroidal arteries, leading to a great decrease of the flow with significant clinical improvement. (**d**) Two years later, a control vertebral angiogram showed the partial persistence shunt. (**e**), after selective catheterization of the remaining branches, the shunt was completely occluded with glue. On the non-subtracted image the cast of the coils and glue is demonstrated. (**f**) Final control of the left ICA and Left VA. Normal clinical development of the child

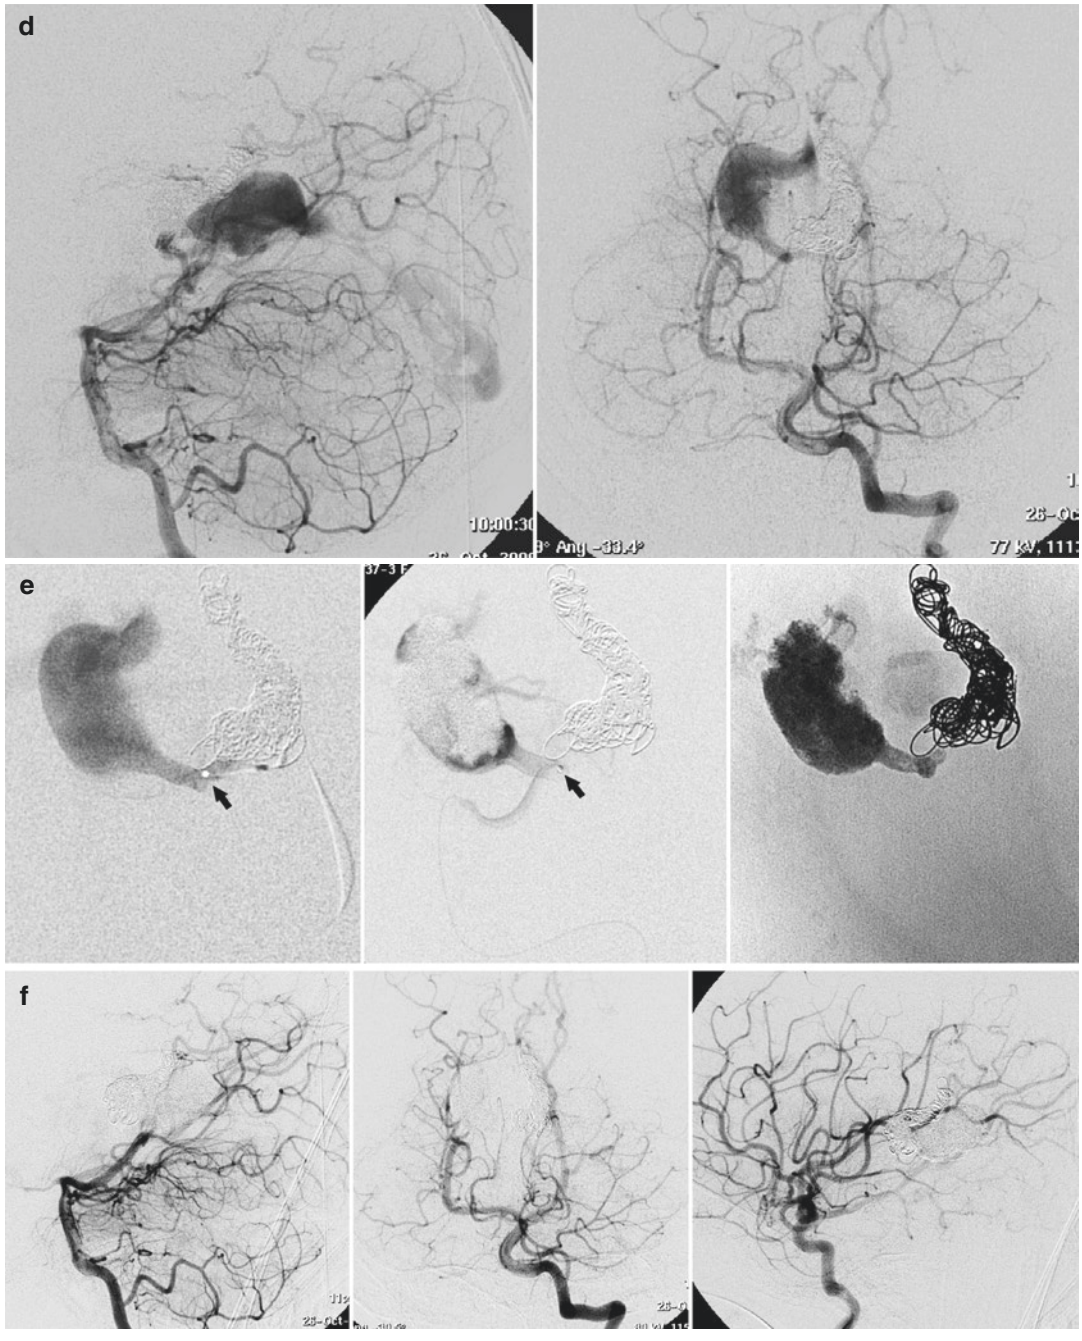

Fig. 12.26 (continued)

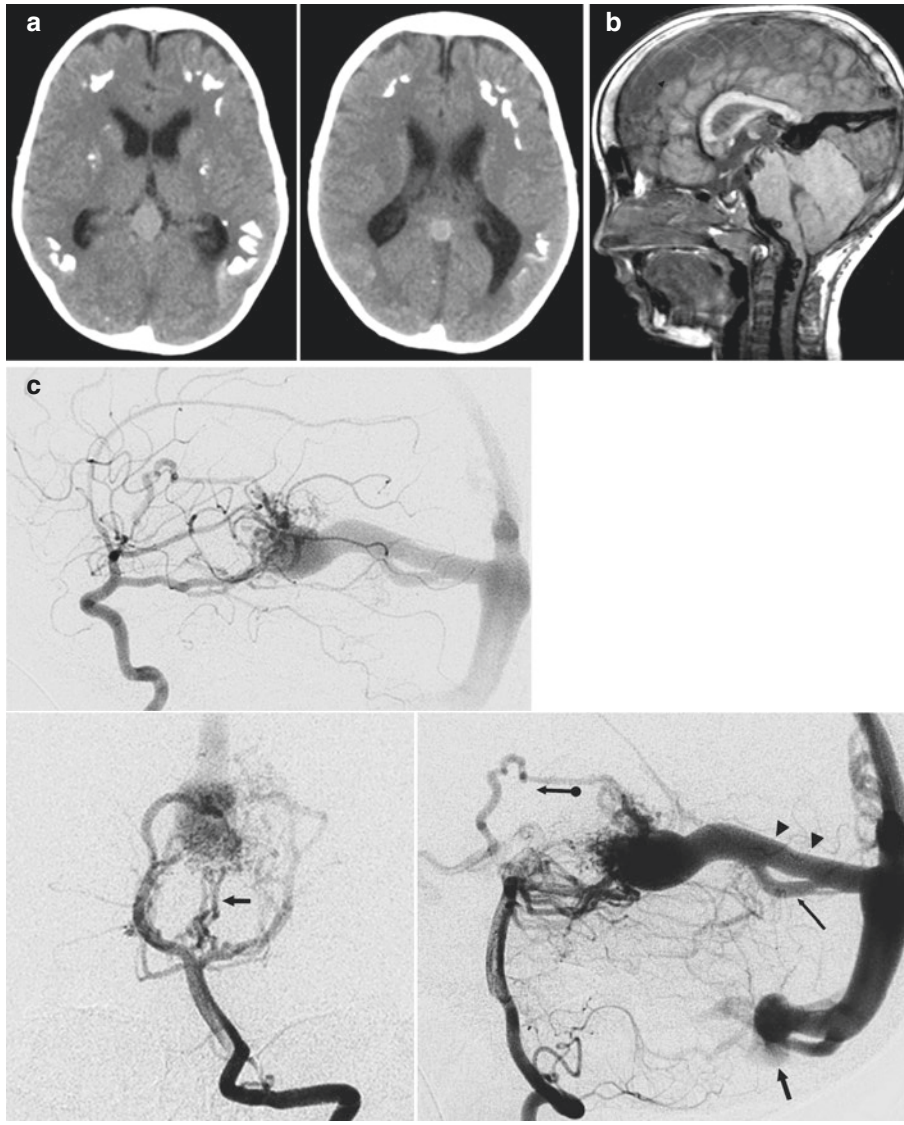

Fig. 12.27 Vein of Galen malformation in a 5-year-old child discovered incidentally after examination for craniocerebral trauma. On the clinical examination the child was normal. (**a**) On CT a large rounded probably vascular structure in the cistern of the Galen vein was recognizable. In addition there were several small calcifications involving the subcortical white matter and basal ganglia. These are thought to be due to a chronic ischemia linked to the venous flow impairment involving the medullary and subependymal veins. There was no hydrocephalus. (**b**) MRI T1-weighted image showing the dilated prosencephalic vein draining into the falcine sinus. There is a partial anterior rerouting of the venous drainage in the dilated pontomesencephalic veins. (**c**) Left lateral ICA angiogram, and vertebral angiogram (*lateral and AP view*). Supply of the malformation through the posterior choroidal arteries and posterior thalamoperforating branches (*arrow*) better demonstrated on the AP view. The prosencephalic vein and the falcine sinus (*arrow head*) as well as a duplication of the sinus (*arrow*) are clearly visible. Bilateral thrombosis of transverse sinuses. Anteriorly rerouting of the venous drainage (*arrow with dot*). The left ICA angiogram showed no involvement of the pericallosal artery. Similar pattern on the right ICA angiogram. (**d**) VA angiogram, showing the partial occlusion of the malformation after injection of glue in the selectively catheterized posterior choroidal arteries. (**e**) One year later, a control angiogram showed no changes of the partial treated malformation and unchanged normal clinical condition. A decision was taken to complete the treatment using the venous route. A catheterization of the falcine sinus (*arrowhead*) was performed after a surgical craniectomy. Coils were positioned in the prosencephalic vein (*arrow*) with complete occlusion of the malformation. (**f**) Final normal ICA and VA angiograms

Dural Arteriovenous Fistulas 13

Isolated cases of dural arteriovenous fistula (DAVF) have been reported by some authors in the 1950s (Verbiest 1951; Obrador and Urquiza 1952). Progressive identification and precise description of this pathology came at the end of the 1960s, especially through selective and superselective angiographic studies, allowing to differentiate it as a special pathological entity (Hayes 1963; Laine et al. 1963; Newton et al. 1968; Newton and Hoyt 1970; Djindjian et al. 1968, 1973).

13.1 Incidence

DAVFs account for 10–15% of all intracranial vascular malformations. Both sexes are affected, but a sexual predominance occurs in some type of DAVF. The fistulas are more frequent in middle-aged and older patients, though younger patients and children can be affected.

13.2 Pathology and Pathogenesis

DAVFs consist of a shunt between dural (meningeal) arteries and sinuses, either directly or mediated by pial veins. DAVF is considered to be an acquired pathology (Houser et al. 1979; Chaudary et al. 1982). The specific pathogenetic process, however, leading to a formation of the fistula is still debated. Some authors believe (Houser et al. 1979; Mironov 1995), DAVFs are preceded by thrombosis of a sinus. When the lumen recanalizes, microscopic AV shunts, normally present within the wall of the sinus (Kerber and Newton 1973) may enlarge and open into the sinus. Considering, however, that sinus thrombosis is not necessarily associated with DAVF and that DAVFs are not always associated with sinus thrombosis, other authors (Chaloupka and Huddle 1998; Chaloupka et al. 1999) have suggested that the primary cause is angiogenesis within the sinus wall. This leads to the formation of abnormal arteriovenous connections and finally to DAVF. Indeed, abnormal artery-vein connections have been demonstrated in histological studies of resected specimens of sinuses of patients with DAVF (Nishijima et al. 1992; Hamada et al. 1997). The cause of these microfistulas in the sinus wall is not clear. Some authors have shown with studies in animal models that venous hypertension can lead to DAVF formation more frequently in animals with induced hypertension than in those without (Terada et al. 1994; Lawton et al. 1997). In this context, flow changes in the venous sector due to partial venous thrombosis and venous hypertension has been suggested to be at least one of the cause of the "de novo" developing of dural arteriovenous fistula occurring after endovascular occlusion of brain AVM (Paramasivan et al. 2013). Other studies (Uranishi et al. 1999; Shin et al. 2007a) have demonstrated in resected dural specimens of DAVF of patients and in rat models the presence of an angiogenetic growth factor that can participate in the fistula formation. Other authors

G.B. Bradac, *Applied Cerebral Angiography*, DOI 10.1007/978-3-319-57228-4_13

(Klisch et al. 2005) examined, in blood of patients with DAVFs, the concentration of the endothelial growth factor (VEGF) and the angiopoietic receptor (TIE-2). These factors were increased in the pretreatment phase and decreased after the endovascular treatment.

Another difficulty is that to explain the developing of DAVFs located in the dura close to the sinus, but not draining directly into it. The outflow is characterized by pial veins, which, after a course more or less long, enter a near or distant sinus. In these cases a nonspecific thrombophlebitic process involving the pial veins has been suggested (Djindjian and Merland 1978).

13.3 Clinical Relevance

Many DAVFs remain asymptomatic or have a benign course. In other cases, DAVFs can have a more aggressive course, characterized by cranial nerve palsy, ischemia, hemorrhage, and cognitive disorders. In this context, it has become increasingly clear that the main factor responsible for the symptoms and evolution of DAVFs is the pattern of venous drainage (Lasjaunias et al. 1986b; Halbach et al. 1987, 1988c, 1989, 1990; Awad et al. 1990; Awad 1993; Barnwell et al. 1991; Lasjaunias and Rodesch 1993; Cognard et al. 1995; Davies et al. 1996).

13.4 Location

DAVfs can occur everywhere. The most frequent are those involving the transverse-sigmoid sinuses followed by the cavernous sinus. Less common are DAVFs of the superior sagittal sinus, those in the tentorial area, and in the anterior cranial fossa. Very rare are DAVFs located in the region of the foramen magnum.

13.5 Diagnosis

DAVVs involve the preexisting vascular structures (meningeal branches, dural sinuses cortical/pial veins) of the area in which they develop, and so a typical repetitive pattern can be expected, corresponding to the site and type of fistula. However, it should be noted that *the pathogenetic mechanism leading to the fistula can vary and there are many variants concerning the arteries supplying the dura and the venous drainage of the area involved. Furthermore the pattern of the fistula can be altered by thrombosis involving the sinuses, and so it is not surprising that fistulas at the same site can have some different angiographic patterns.*

A complete angiographic study with examination of the ECAs, ICAs, VAs, and in particular cases also cervical arteries is essential for the diagnosis. This provides information about all the meningeal sometimes leptomeningeal branches involved and the venous drainage. The site, the extension of the DAVF, and in particular the type of the venous drainage explain the symptoms and offer information about the risk and prognosis of the fistula. Furthermore, a decision can be made about whether the fistula should be treated and, if so, whether surgical or endovascular therapy should be used; in the case of endovascular treatment which route—arterial or venous—is the most appropriate.

13.6 Classification

Castaigne et al. (1976) were the first to distinguish DAVFs draining directly into the sinus from those in which the drainage into the sinus was mediated by cortical/pial veins. Taking into consideration mainly the type of venous drainage, Djindjian and Merland (1978) made the first classification. This was revised by Cognard et al. (1995) and Borden et al. (1995). Five types of DAVFs can be identified:

1. Drainage into a main sinus with an anterograde flow.
2. (a) Drainage into a main sinus with possible retrograde reflux within the sinus, but not into the pial veins; the latter drain normally into the affected sinus.
   (b) Drainage into the sinus with reflux into the pial veins with or without association of sinus reflux.
3. Drainage into the sinus is mediated by pial veins.

4. Drainage into the sinus is mediated by pial veins, which present large ectasia.
5. Drainage involves the spinal perimedullary veins.

The type 1 has commonly a benign course. In types 2 and 3, the impaired normal drainage can lead progressively to venous congestion, ischemia, and intracranial hypertension. In types 3 and 4, hemorrhage is frequent owing to rupture of the pial veins draining the shunt. Cranial nerve palsy can occur, particularly in DAVFs of the cavernous and DAVFs located close to the brainstem. Drainage involving the veins of the spinal cord can lead to a myelopathy.

The fistulae are not static lesions, but they can change passing from one type to another with morphological and clinical improvement or worsening. In the study of some authors (Kim et al. 2010), this occurred in 16% of the cases, more frequent in the DAVS of the transverse-sigmoid sinuses and in those involving the cavernous sinus. All these aspects should be considered in the management of this pathology.

13.7 Detailed Considerations in the Most Frequent Fistulas

- *DAVFs involving the transverse sinus (TS) and the sigmoid sinus (SiS)* are the most frequent, occurring in about 63% of all fistulas (Halbach et al. 1987; Awad 1993). In many cases, these belong to the type 1 and so can be characterized by a benign course. The only symptom is bruit, since the fistula is close to the petrous bone, containing the auditory apparatus. In some cases, the bruit can become very loud and intolerable for the patient, necessitating treatment. Some of these fistulas can change (Piton et al. 1984) and become of the type 2, with a large reflux in the SSS and in the veins of the brain parenchyma especially in the temporal veins, leading to a progressively venous congestion. This occurs, especially, when a distal or proximal thrombosis of the sinus occurs, or in the very rare cases in which the sinus is thrombosed proximally and distally (*isolated sinus*). The symptoms in such patients can be very severe, characterized by cognitive disorders, epileptic seizures, or other neurological deficit (Naito et al. 2001; Bradac et al. 2002, Kiura et al. 2007). Examples are presented in Figs. 13.1, 13.2, and 13.3.

In some cases, the fistula can be localized in the proximal part of the TS *near the torcular herophili or in the torcular itself* (Figs. 13.4 and 13.5).

Several arteries can be involved in the supply of these fistulas. These are commonly branches of the ECA (occipital, ascending pharyngeal, middle meningeal arteries). Meningeal branches of the cavernous portion of the ICA and meningeal branches of the VA are also frequently involved. A supply from pial branches of the cerebellar and posterior cerebral arteries, especially in fistula of the torcular herophili can also occur.

In fistulas of the torcular herophili thrombosis of the proximal TS uni- or bilaterally, and of the distal SSS is not rare. This leads to a rerouting of the venous drainage in the straight sinus and then in the basal and deep cerebral veins. The impaired venous drainage can lead to congestion in the cerebral and cerebellar hemispheres (Fig. 13.4). In other cases the venous drainage occurs in one TS (Fig. 13.5). The other TS is not involved, due to duplication of the distal SSS, each segment entering separately one TS. It can occur in these cases that the SS enters the not involved TS avoiding impairment of the depp venous drainage. This latter, however, can be severely impaired in cases of thrombosis extending towards the SS and Galen vein.

A particular aspect, especially recognizable in some cases of fistula of the TS or SiS, is the changes of the sinuses, which *appear divided in two or more compartments* (Figs. 13.2 and 13.3). Why this occur is not known. It has been suggested that this could be related to a partial thrombosis of the sinus followed by its recanalization and formation of two or more separated venous channels (Piske et al. 2005). An accessory dural sinus separated but communicating with the main sinus can also develop and become the main venous drainage.

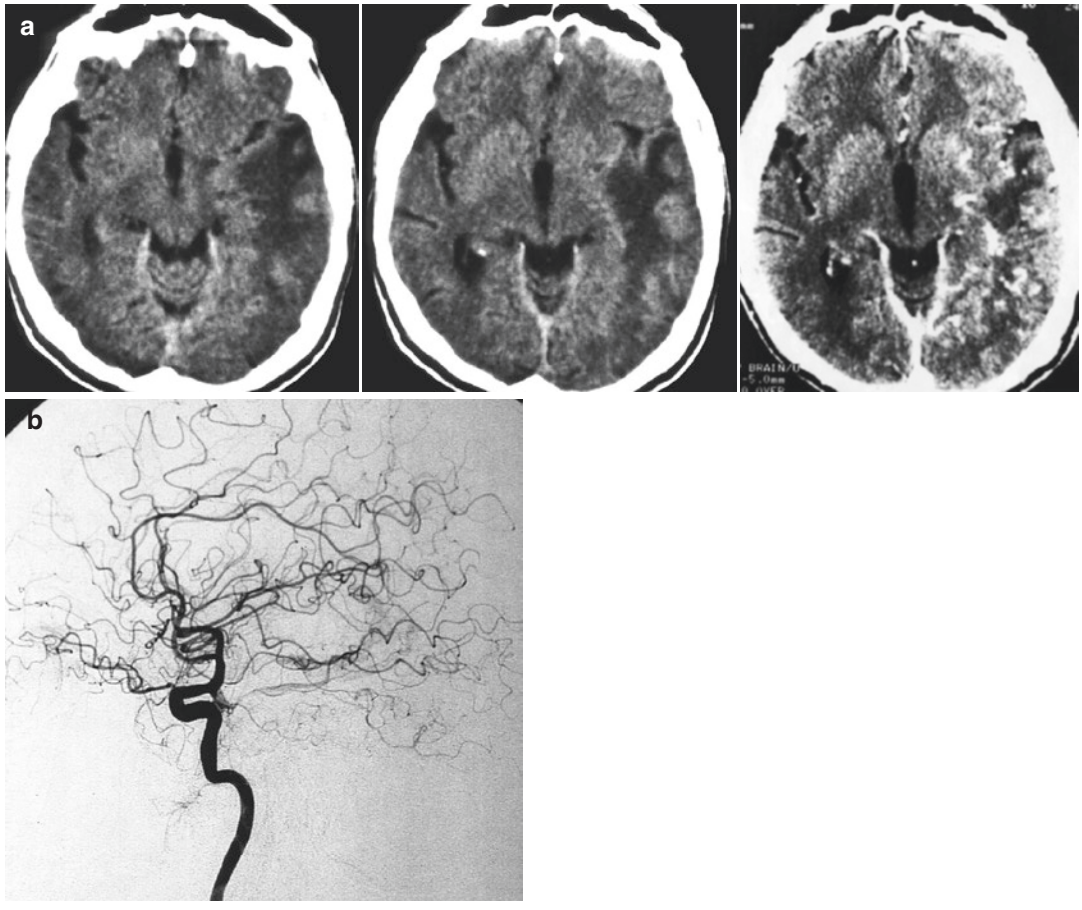

Fig. 13.1 Patient with mild aphasia and cognitive disorders. (**a**) CT showed changes involving predominantly the white matter in the left temporo-insular area with rich contrast enhancement suggesting vascular malformation. (**b**) Normal ICA angiogram. (**c**) On the ECA angiogram a DAVF involving the distal transverse sinus was demonstrated. The sinus was proximally and distally occluded. The main supplying artery was the occipital artery with its stylomastoid (S) and mastoid (M) branches. (**d**) A partial supply came from the middle meningeal artery (MMA). (**e**) On the VA angiogram the involvement of the posterior meningeal artery (*arrow*) and small C1 branches (*small arrows*) was shown. (**f**) selective catheterization of the stylomastoid and MMA arteries preceding the injection of glue. The Branches arising from the VA were occluded with polyvinyl alcohol (PVA). (**g**) The occlusion of the fistula was confirmed on a control angiogram of the ECA and VA 3 months later. (**h**) Normalization of the CT. Complete recovery of the patient

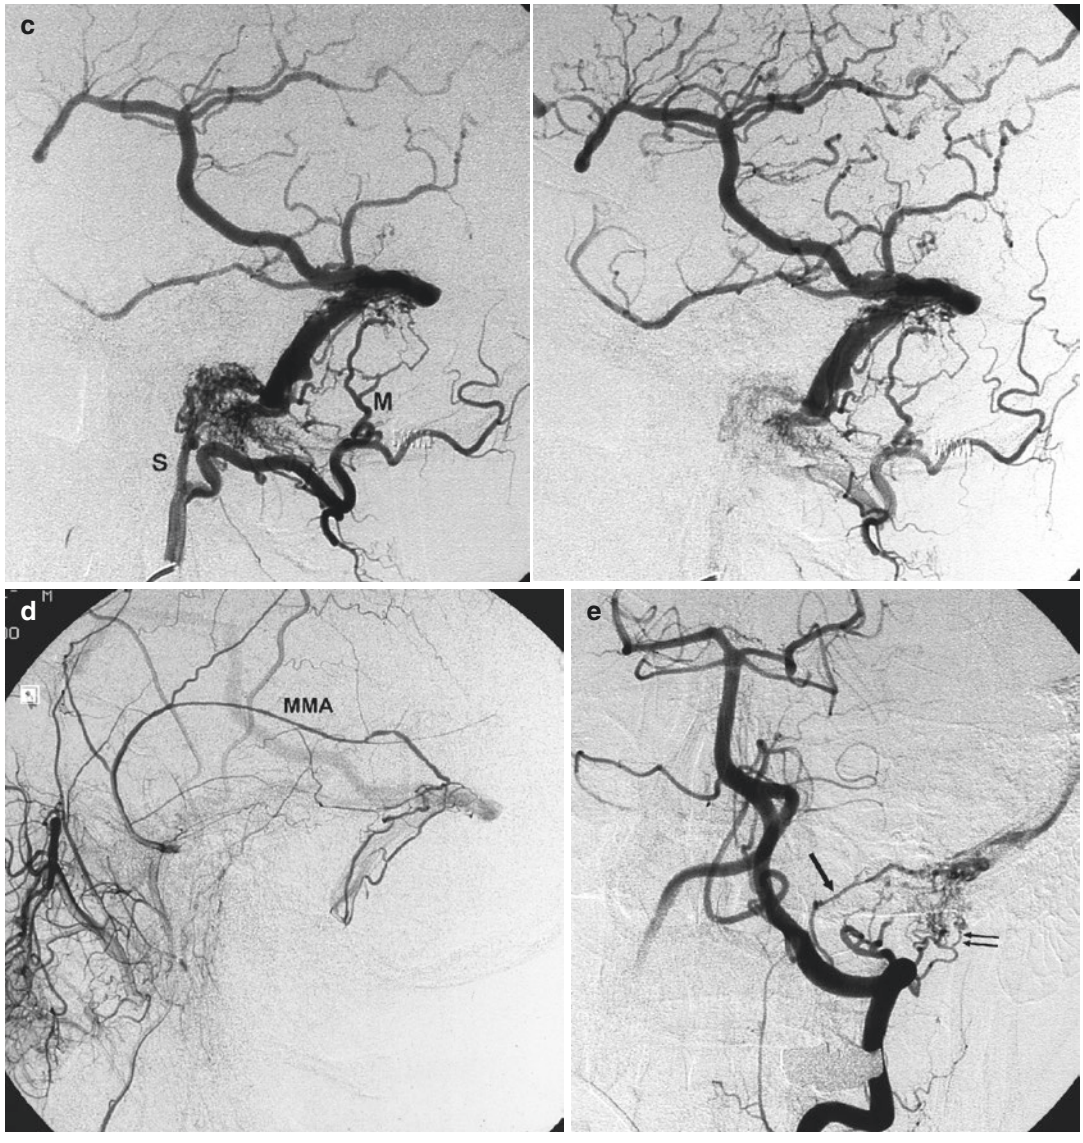

Fig. 13.1 (continued)

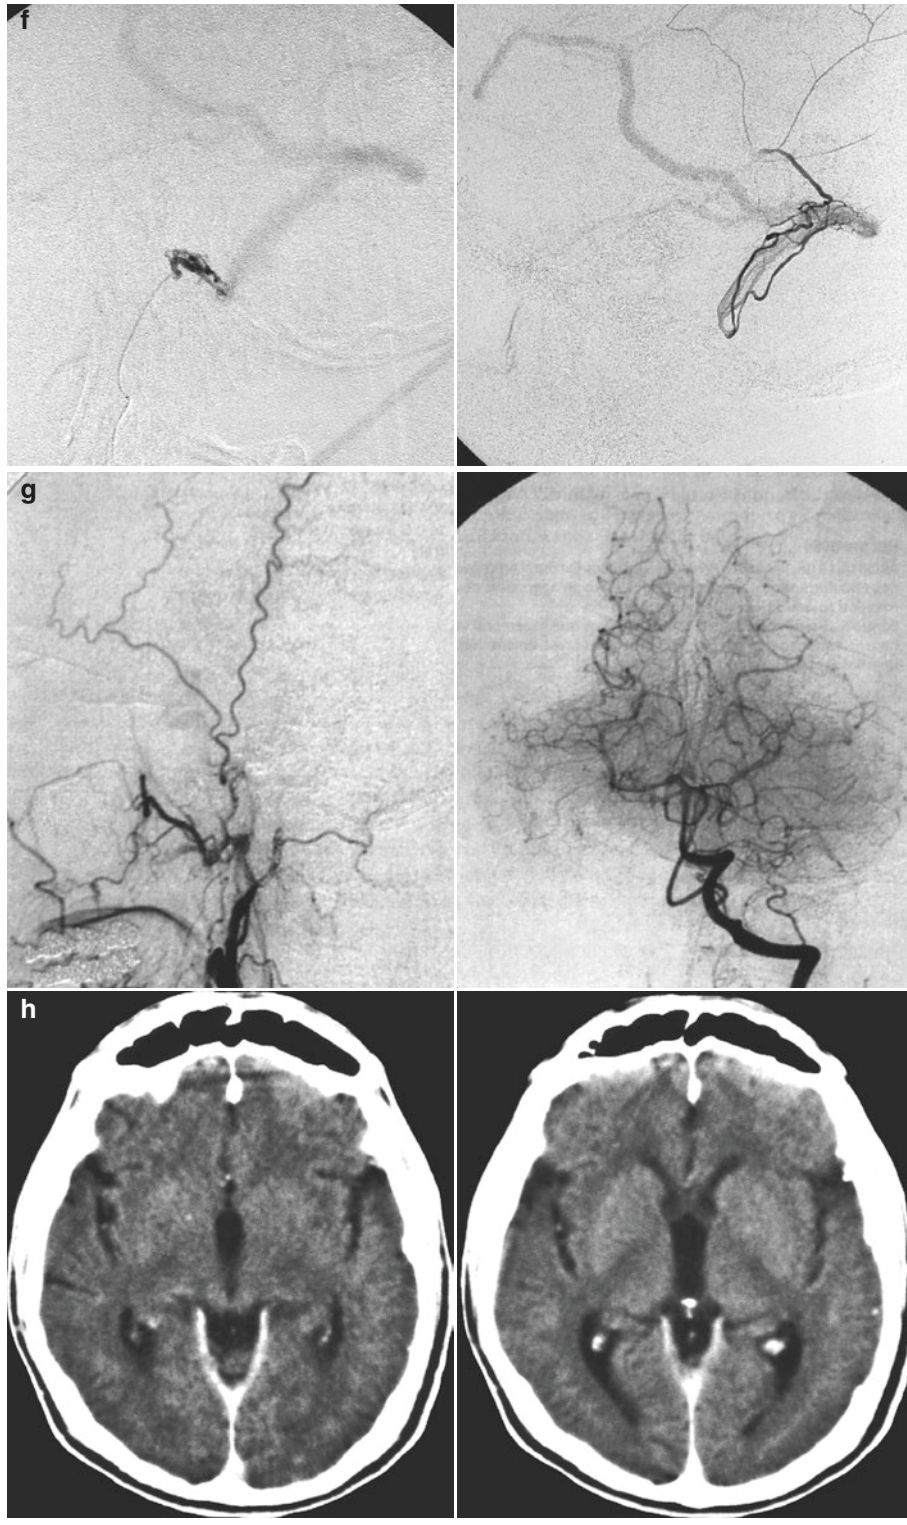

Fig. 13.1 (continued)

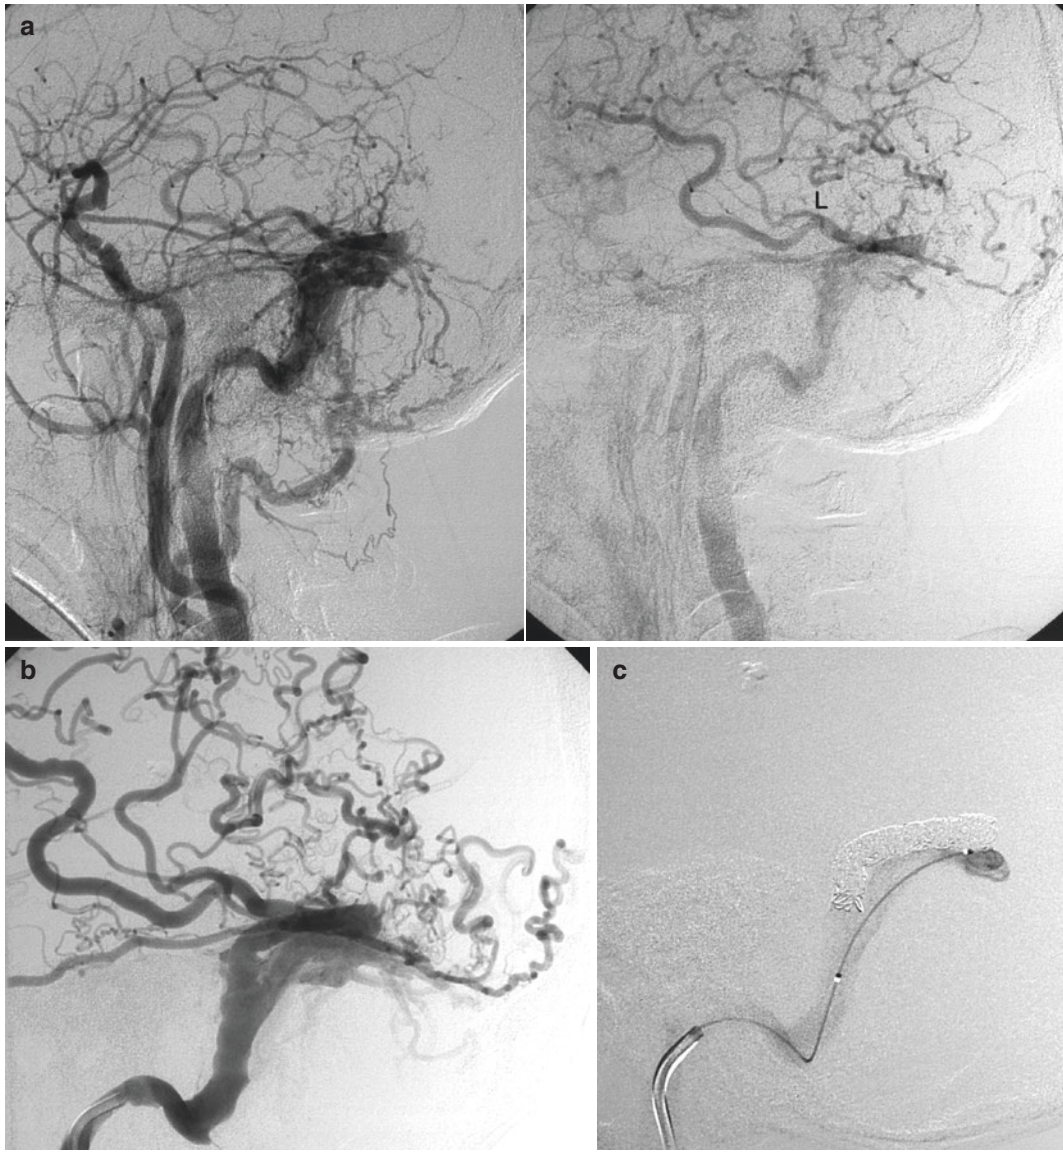

Fig. 13.2 Old patient with known DAVF involving the transverse sinus already treated with occlusion of several branches of ECA with PVA. The patient returned 6 months later suffering from the same symptoms, characterized by high bruit and headache. (**a**) The angiogram of the common carotid artery showed a complete recanalization of the fistula. The transverse sinus was proximally occluded. In the later phase a retrograde injection of the temporal veins including a large vein of Labbé (L) was visible. (**b**) Venous angiogram after catheterization of the sigmoid and further of the proximal transverse sinus. The retrograde filling of the cortical veins is better visible as well as the duplication of transverse sinus. (**c**), (**d**) A microcatheter was advanced first in the superior segment of the duplicated sinus were coils were placed (**c**) followed by catheterization and occlusion of the inferior segment with coils (**d**). (**e**) Control angiogram showing complete occlusion of the fistula

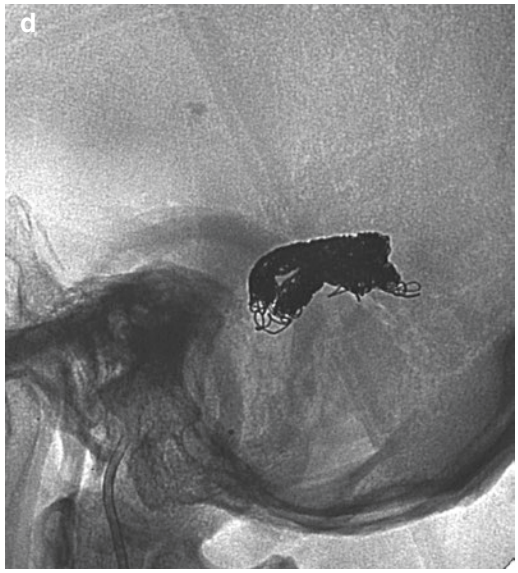

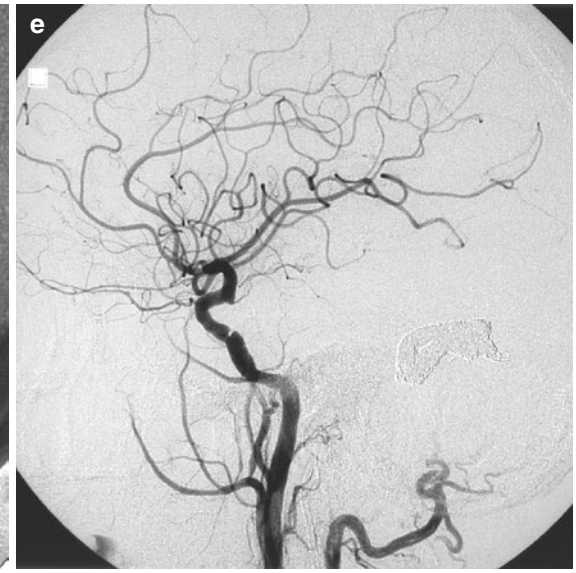

Fig. 13.2 (continued)

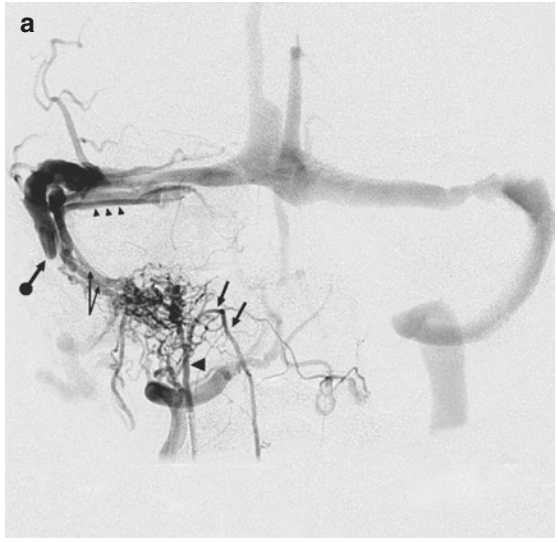

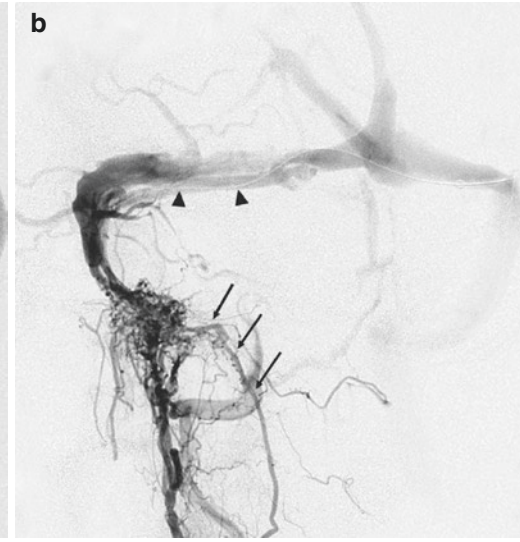

Fig. 13.3 Fistula at the level of the right SiS. (**a**) Selective study of the AphA. AP view. The enlarged AphA (*arrowhead*) supplies the fistula. Through its hypoglossal branch (*arrows*) there is a large connection with the radiculomeningeal branch of the VA. The venous drainage occurs through two separated dural venous channels (*arrow with angle*) converging to a dural sinus (accessory sinus, arrow heads) running parallel to the main transverse sinus (TS). There is a connection between the accessory sinus and the main sinus. This latter is distally completely occluded (*arrow with dot*). There is a retrograde injection of the left TS, the SS and SSS. (**b**) Injection of the AphA, oblique view. The connection with the VA is better recognizable. Through the left TS, a microcatheter has been advanced in the accessory right dural sinus (*arrowheads*) and further in the two distal dural channels were coils were placed occluding the fistula

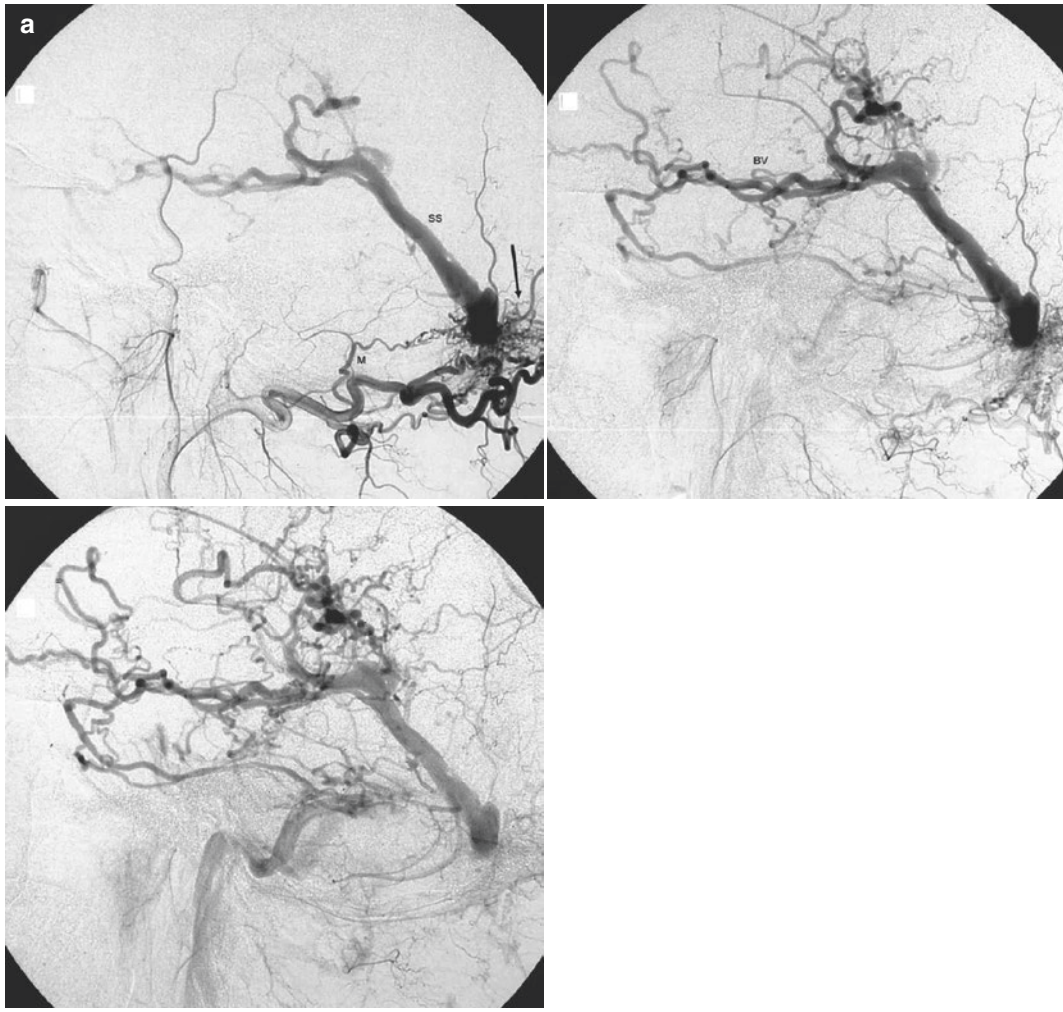

Fig. 13.4 DAVF of the torcular herophili in a patient with signs of intracranial hypertension (headache, cognitive disorder, impairment of visual acuity). Bilateral angiographic study of the ICA and ECA and of both vertebral arteries showed a DAVF at the level of the torcular herophili supplied by the occipital artery and MMA bilaterally. Neither ICA was involved. A minimal supply arose from pial branches of the cerebellar arteries, visible on the left vertebral angiogram. Occlusion of the fistula was obtained by selective injection of acrylic glue in both occipital arteries and the MMA. Complete recovery of the patient. (**a**) Lateral left occipital angiogram, showing a rich network of branches arising from the mastoid (M) and distal transosseous (*arrow*) branches of the occipital artery, converging on the torcular herophili, probably thrombosed. There is retrograde injection of the straight sinus (SS) and both basilar veins (BV), continuing to the anterior tributary and then to the temporal vein. There is also retrograde injection of the internal cerebral vein, dilated medial atrial vein, and inferior sagittal sinus. (**b**) Right occipital angiogram (AP views) showing the shunt and retrograde injection of the SS. The TS on the right is proximally thrombosed and filled distally (*arrows*) through anastomosis involving retrograde injection of the subependymal veins, then the medullary vein, and further the cortical vein. The TS on the left is also thrombosed and filled distally through anastomosis involving the BV and temporal vein. (**c**) Left lateral vertebral angiogram, showing a minimal supply from the pial branches of the cerebellar arteries (*arrow*). (**d**) Left carotid angiogram (venous phase). There is a diffuse venous congestion owing to impairment of the deep venous drainage and partial thrombosis also of the distal superior sagittal sinus (SSS). (**e**) Left vertebral angiogram, AP view, venous phase. There is diffuse congestion involving the drainage of the cerebellar vein as a result of thrombosis of the proximal transverse sinus bilaterally. Normal filling of the distal transverse sinus (TS). (**f**) Left common carotid angiogram, lateral view, arterial and venous phases, showing occlusion of the fistula and normalization of the venous drainage after treatment. Similar results on the right common carotid angiogram, not shown. (**g**) Vertebral angiogram, presenting occlusion of the fistula after treatment

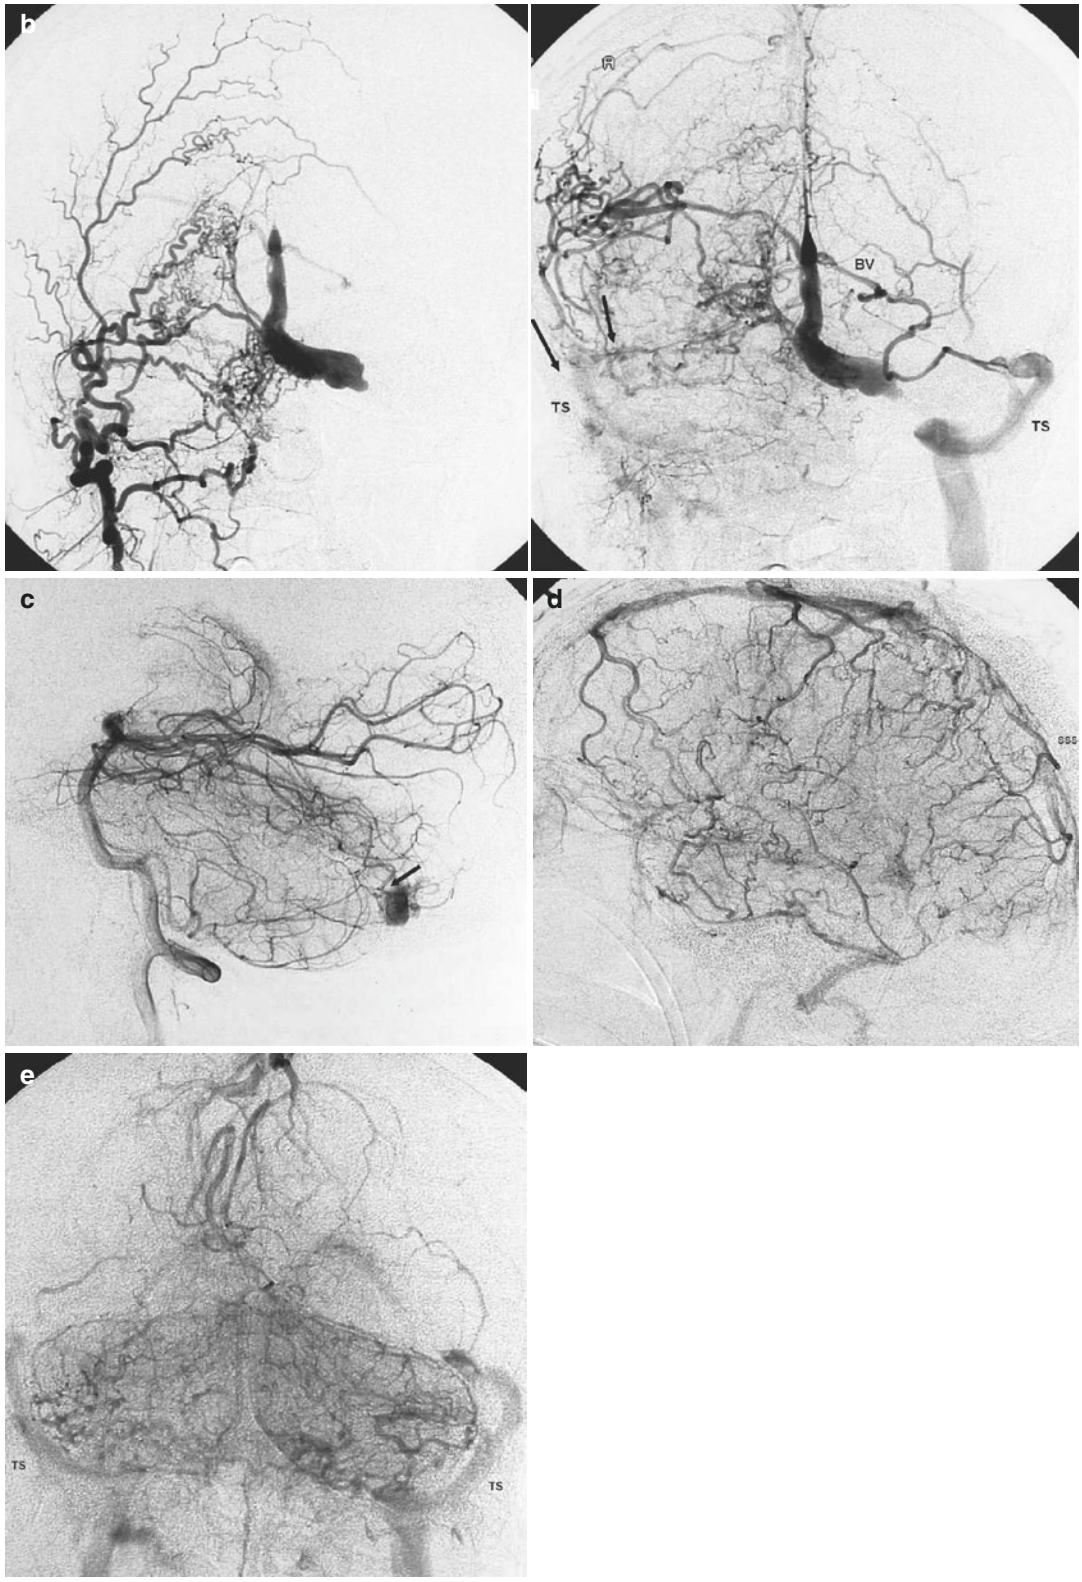

Fig. 13.4 (continued)

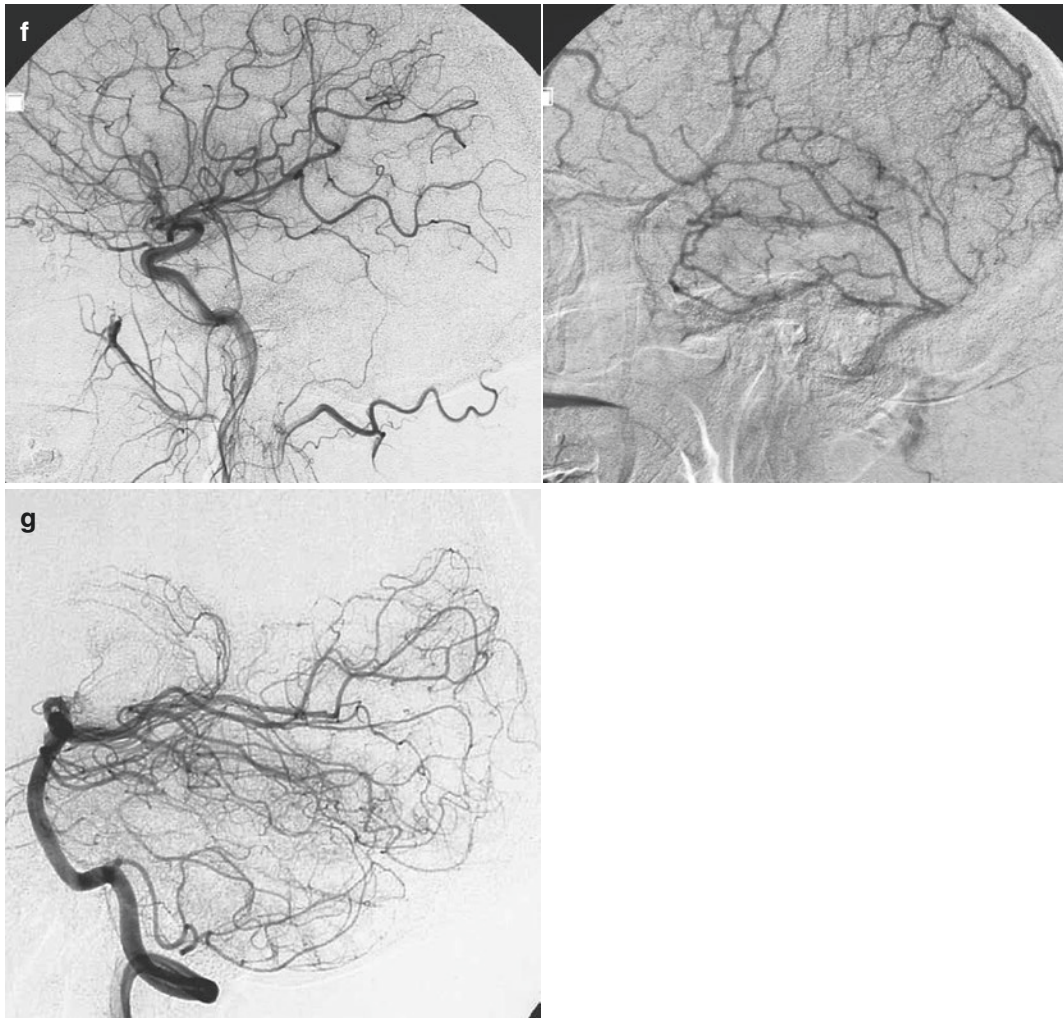

Fig. 13.4 (continued)

These possible patterns should be taken into account since are important in the endovascular treatment of these fistulae.

Occlusion of these fistulae can be today achieved by endovascular treatment either through selective catheterization of the feeders, followed by injection of acrylic glue, onyx, or similar embolic material or by a venous approach through the sinuses following by the placing of coils (Kirsch et al. 2009; Macdonald et al. 2010). Surgery can be reserved for those cases in which the endovascular treatment has failed in leading to a complete occlusion or in those cases in which it appears not appropriate due to an unfavorable anatomical/morphological condition.

- *DAVFs involving the cavernous sinus* (CS) are the second-most frequent fistulas, with a frequency reported being 12% of all fistulae (Awad 1993; Cognard et al. 1995). Women are predominantly affected. The fistula can be uni- or bilateral. Clinical symptoms, can vary, being minimal or severe due to involvement of

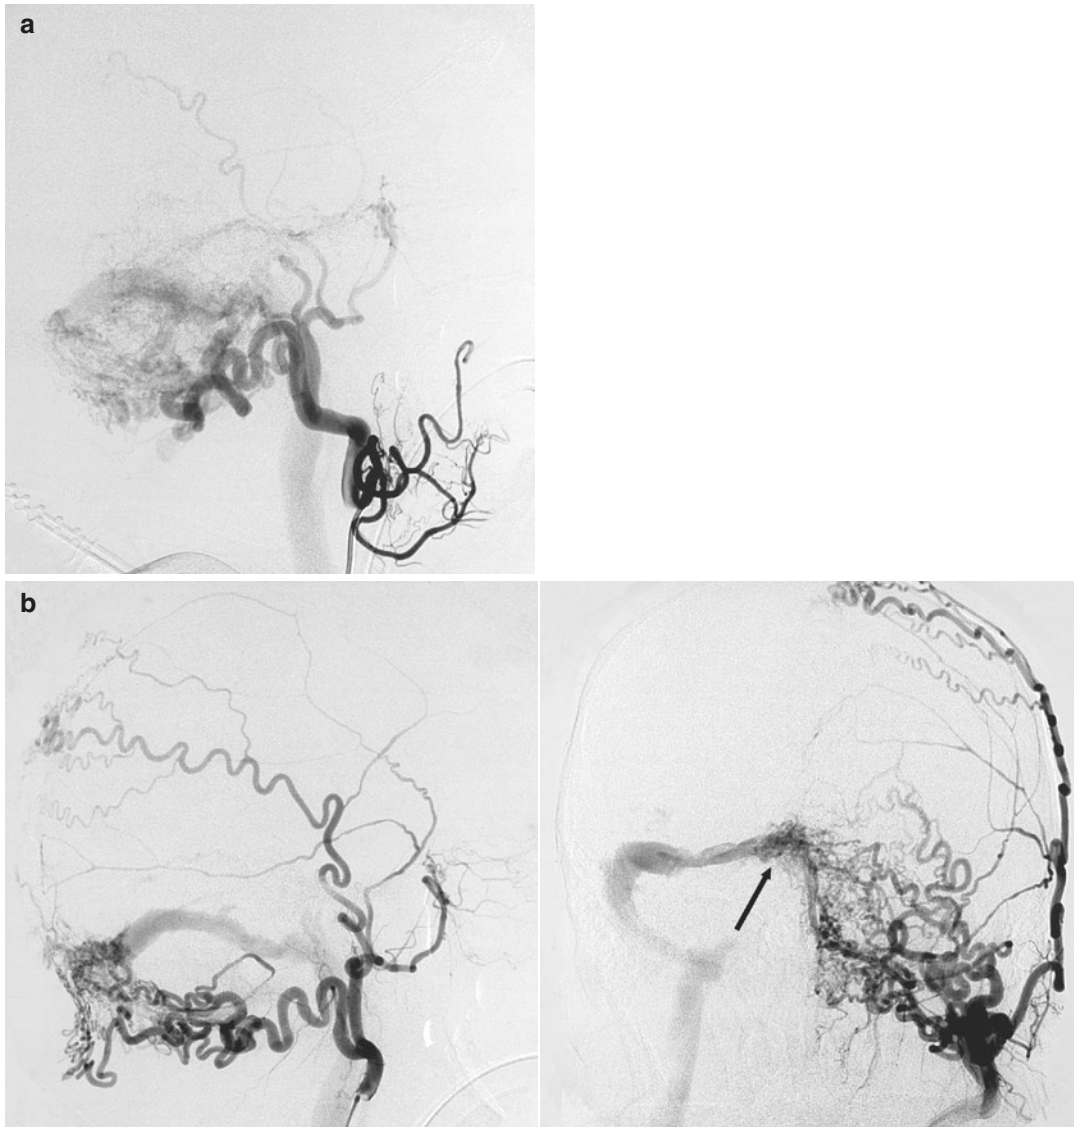

Fig. 13.5 DAVF involving the torcular herophili. Many feeders arising from ECA, ICA, and VA bilaterally were present; not all are shown in the figures. The main supplying branches were the right and left occipital arteries. There was also involvement of the deep cervical artery. (**a**) Lateral angiogram of the large right occipital artery with many branches converging to the torcular. Filling of the MMA which was also involved. (**b**) Similar pattern visible on the lateral and AP angiograms of the left occipital artery. The site of the fistula (*arrow*) is well visible on the AP angiogram. (**c**) Angiogram of the deep left cervical artery with branches converging to the torcular. In all studies the drainage occur in the right TS continuing in the SiS. (**d**) AP of the venous phase of the right and left ICA angiograms showing that the main venous drainage of both hemispheres occur through the SSS continuing in the left TS (*arrow*). It is thinkable that there were two separate distal segments of then SSS draining each in the corresponding TS. (**e**) Right ICA angiogram. Venous phase. There is a normal drainage of the deep venous system in the SS draining to the left TS. There were no connections with the involved right TS. (**f**) Vertebral angiogram. Venous phase. The main venous drainage converge to the left TS. After partial devascularization with PVA injected in the distal occipital arteries. Complete occlusion was obtained with coils put in the distal right TS

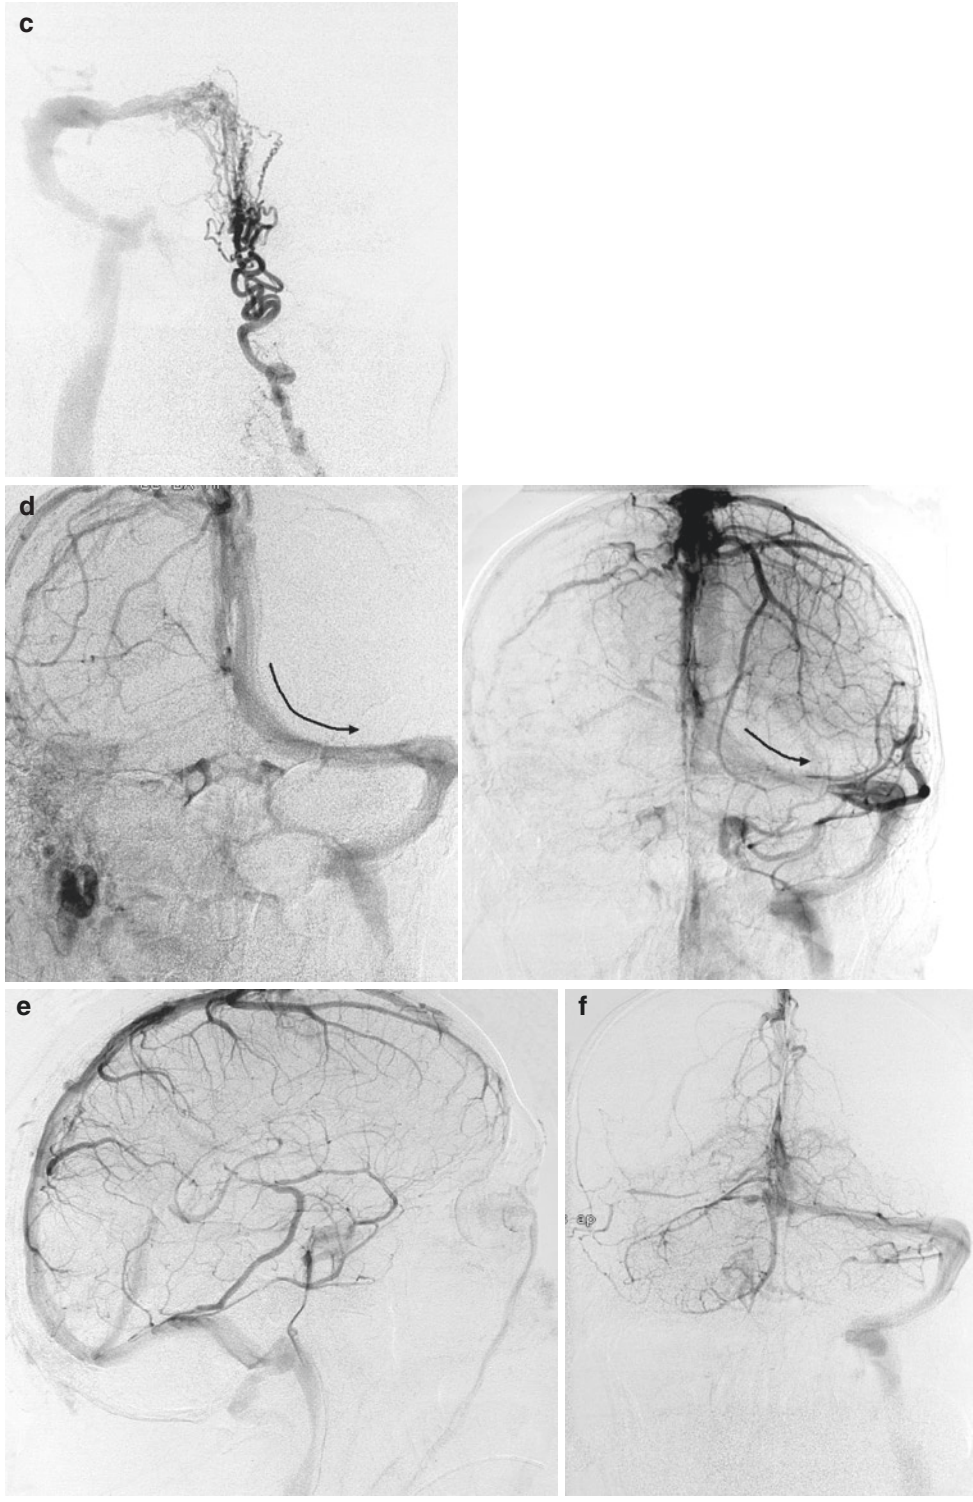

Fig. 13.5 (continued)

the intraorbital or brain parenchymal structures. Spontaneous occlusion of the fistula can occur.

Many arterial feeders in various combinations can be involved, arising from the distal internal maxillary artery, MMA, AphA, and cavernous portion of the ICA uni- or bilaterally, converging to the cavernous sinus (Figs. 13.6, 13.7, and 13.8). The venous drainage can show different patterns, considering that the network of veins running in the *space of the cavernous sinus* has vary connections (see Sect. 9.3.10).

Since the anterior part is connected with the superior ophthalmic vein (SOV) and inferior ophthalmic vein (IOV), a fistula in this sector will lead to a retrograde filling of these vessels. It should be noted that the IOV connects with the pterygoid plexus which can be indirectly involved. *A fistula posteriorly located* will be characterized by a drainage into the inferior petrosal (IPS), superior petrosal (SPS) sinuses and sometimes into the inferior petro-occipital vein (IOPV), since this posterior location communicates with these venous channels (Cheng et al. 1999; Agid

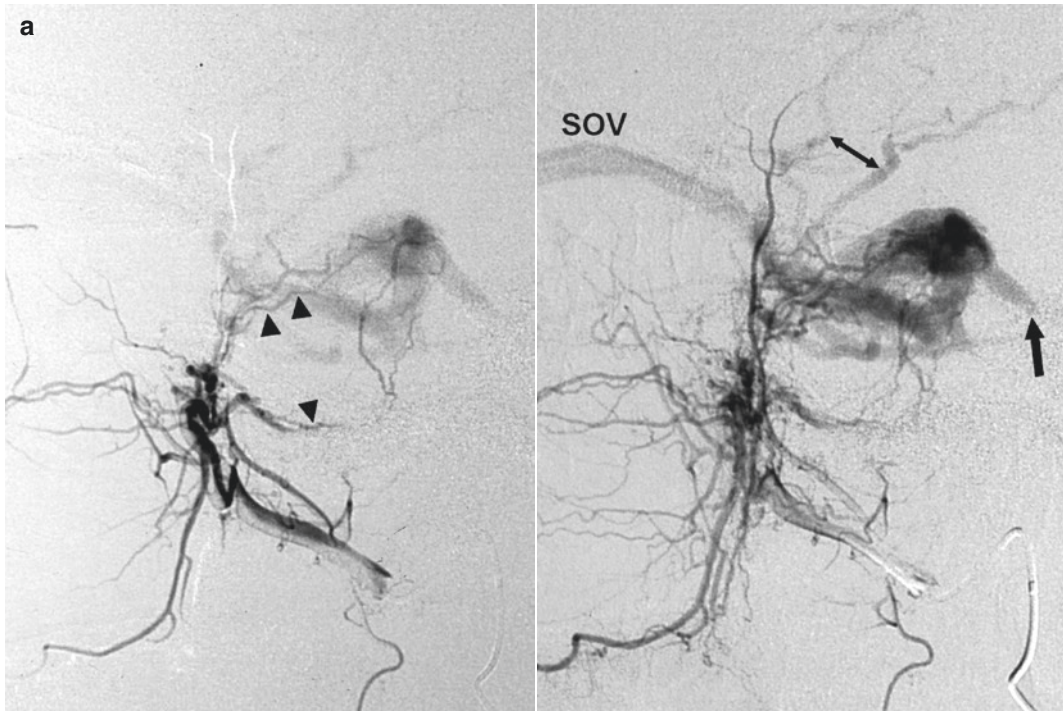

Fig. 13.6 Old woman presenting with bilateral exophthalmos, chemosis, and diplopia. The angiographic study of the bilateral ICA, ECA and vertebral artery revealed DAVF at the level of the left cavernous sinus (CS) supplied by branches of the distal internal maxillary artery (IMA) and ascending pharyngeal artery. (**a**) Lateral angiogram of the distal left IMA showing the involvement of the foramen rotundum (*arrowheads*) and vidian arteries (*arrowhead*). In the later phase, partial injection of the inferior petrosal sinus, which appears to be thrombosed (*arrow*). There is also a partial retrograde injection of the superficial middle cerebral vein an uncal vein (*bidirectional arrow*). (**b**) Lateral angiogram of the ascending pharyngeal artery (APhA), showing the supply through its clival branches (*arrows*). (**c**) Lateral angiogram of the MMA involved with several branches (*arrows*). (**d**) Left ECA angiogram, AP view, showing involvement of the left cavernous sinus. Through intercavernous anastomoses (*arrowhead*), injection of the right cavernous sinus (CS) of the right superior ophthalmic vein (SOV) and further of the facial vein (F). The left ophthalmic vein was not injected, probably thrombosed. Occlusion with PVA of the supplying arteries was performed, followed by treatment with low doses of heparin. Clinical improvement

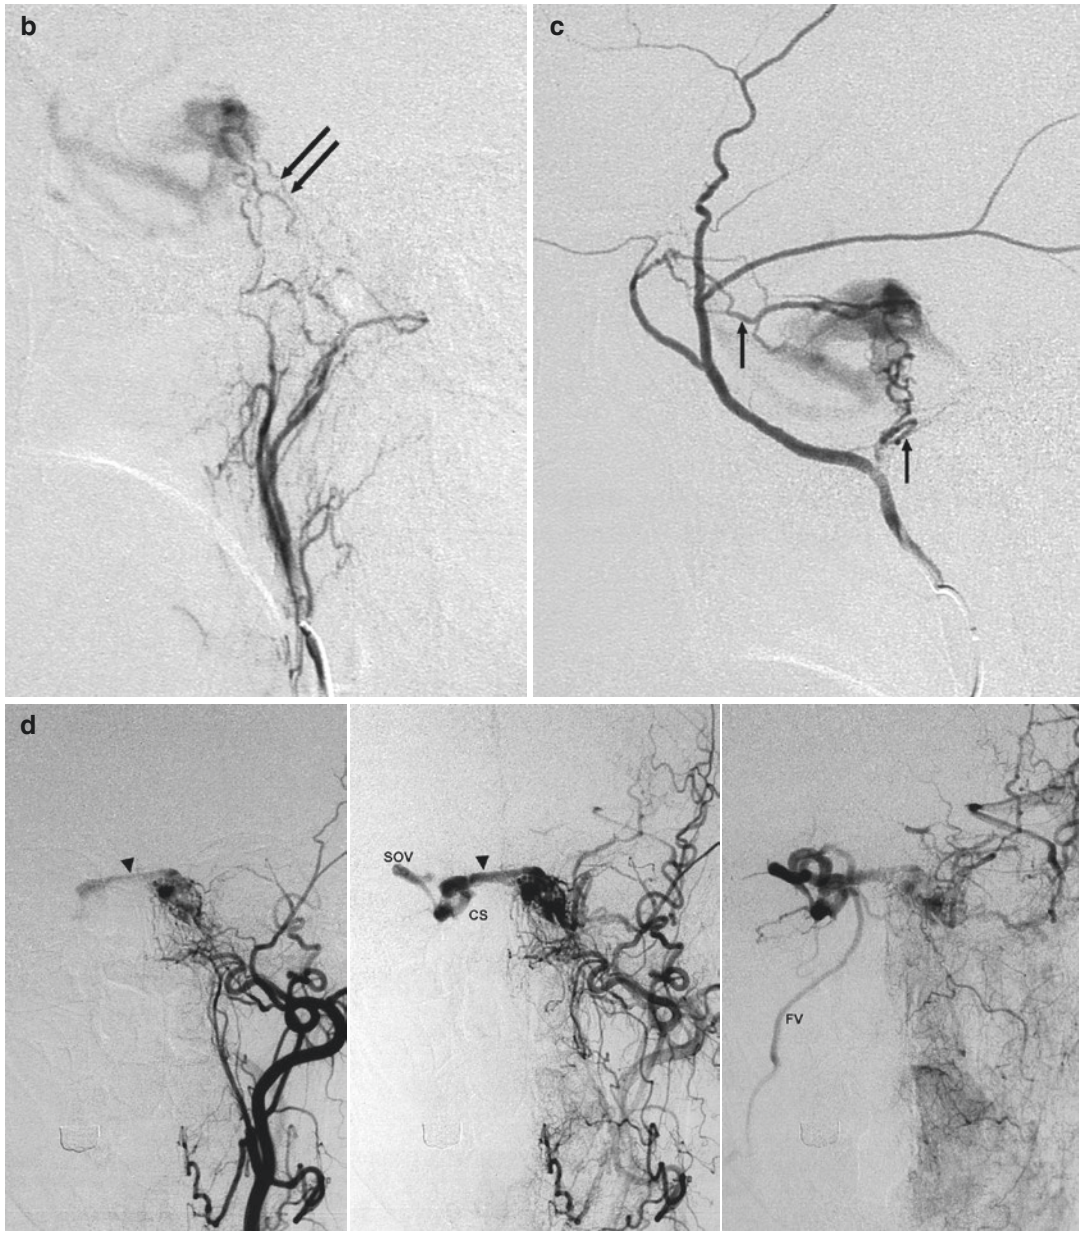

Fig. 13.6 (continued)

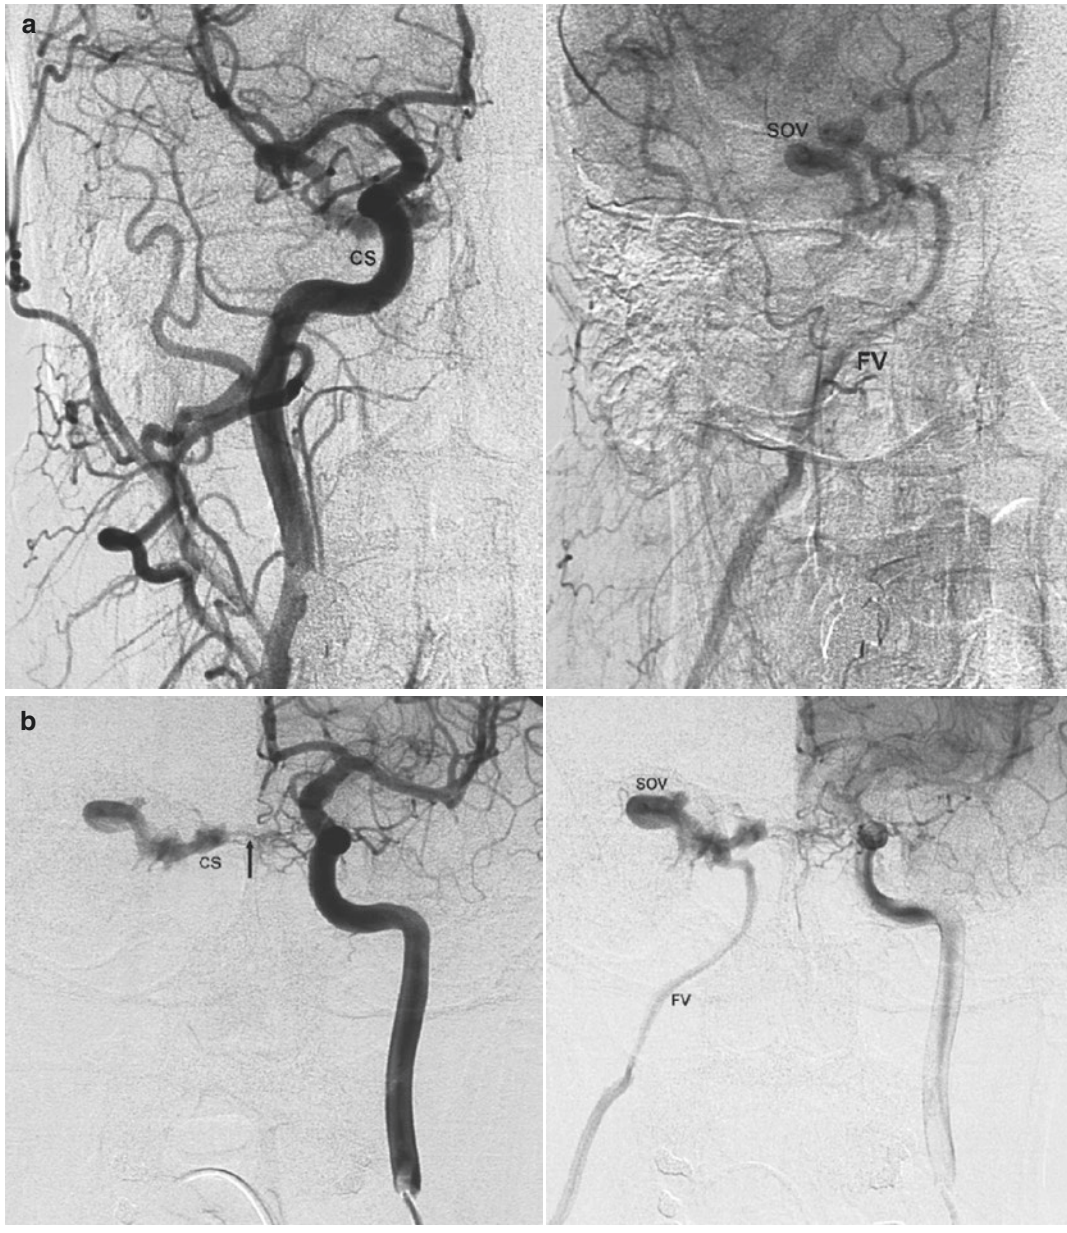

Fig. 13.7 Middle-aged man with sudden onset of exophthalmos and diplopia due to a cavernous fistula located in the right sinus, supplied mainly by cavernous branches of both ICAs. There was a minimal involvement of the ECA. The drainage occurred anteriorly in the superior ophthalmic vein and further in the facial vein. This venous route was used to occlude the fistula with coils. (**a**) Right carotid angiogram, AP view. Cavernous sinus (CS), superior ophthalmic vein (SOV), facial vein (FV). (**b**) Left carotid angiogram, AP view. Left cavernous branches of the ICA supplying the fistula (*arrow*). Right cavernous sinus (CS), right superior ophthalmic vein (SOV), facial vein (FV). (**c**) Injection of contrast medium into the ophthalmic vein, near the cavernous sinus, during selective catheterization with microcatheter (*arrows*). The small arrow shows the distal microcatheter during its progress. (**d**) Right and left carotid angiogram posttreatment

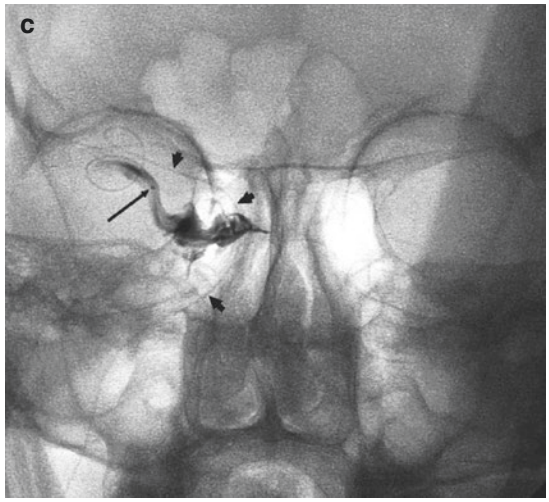

Fig. 13.7 (continued)

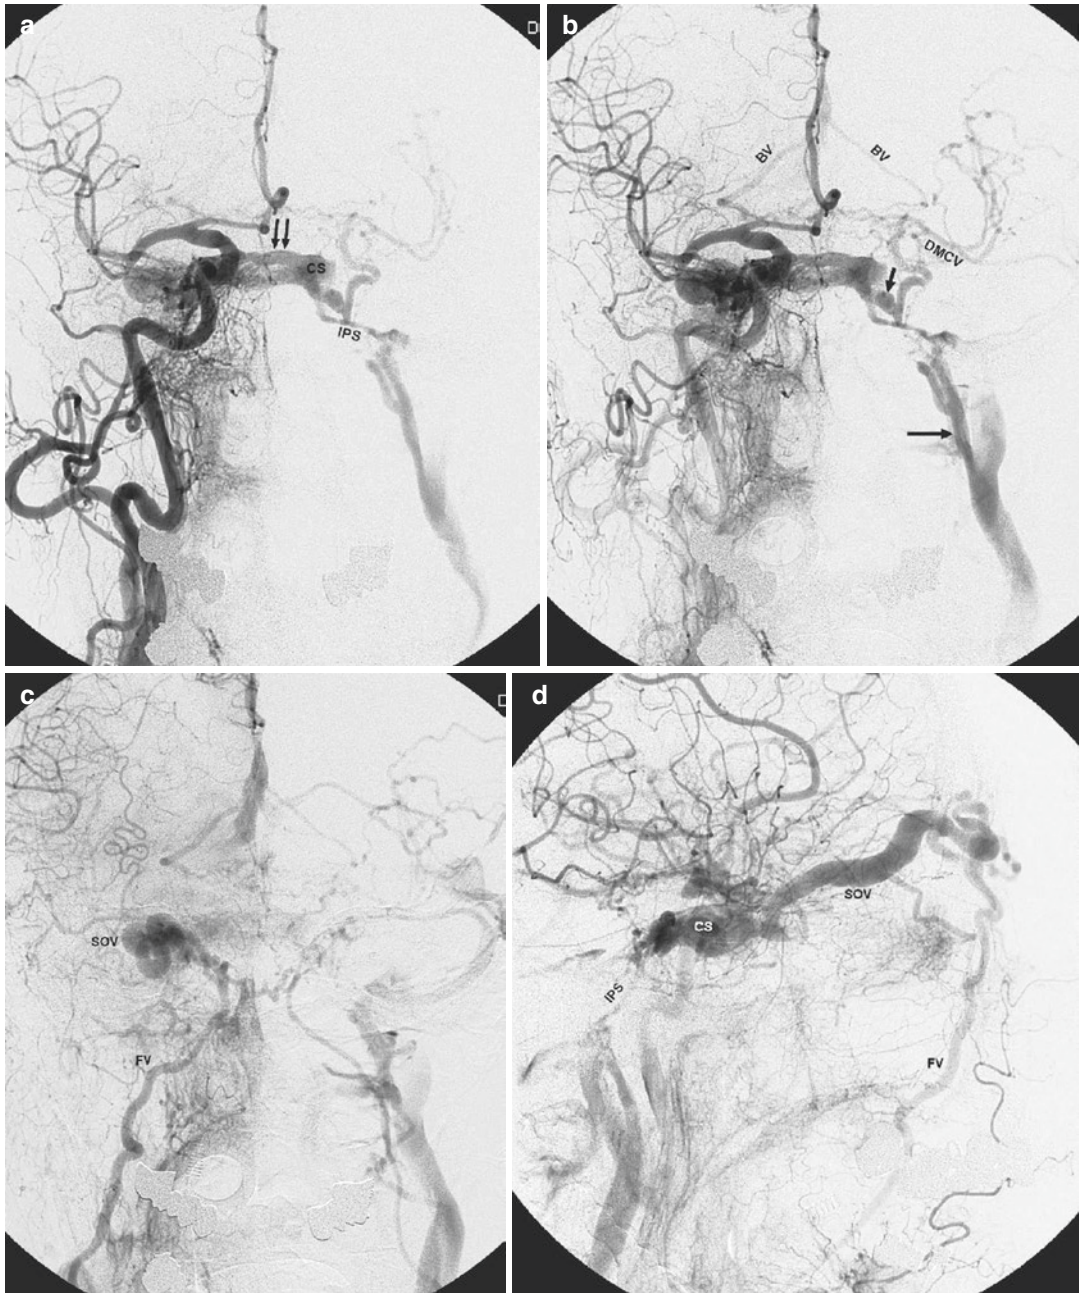

Fig. 13.8 Large DAVF involving the right CS in an old woman presenting with bilateral exophthalmos and diplopia. Several branches of IMA, AphA, and intracavernous branches of ICA bilaterally are involved. The patient has already been treated with occlusion of ECA branches with PVA. Reappearance of symptoms after a short period of clinical improvement. (**a**), (**b**), (**c**) Right ICA angiogram, AP view. There is immediate filling of the right CS and of the superior ophthalmic vein. Through intercavernous anastomoses (*double arrows*), there is a rapid filling of the left CS, then of the inferior petrosal sinus (IPS). This latter does not enter the jugular bulb but reaches the IJV more distally (*arrow*). Through a large connections between the left CS and the paracavernous sinus (*arrow*) there is a retrograde filling of the dilated uncal vein and further of the deep middle cerebral vein (DMCV) with its insular tributaries and of the basal vein (BV) bilaterally. On the right through the retrograde filling of the superior ophthalmic vein (SOV), filling of the facial vein (FV). (**d**) Right ICA angiogram. Lateral view, showing the drainage of the CS in the right ophthalmic vein (SOV) and facial vein (FV) and in the left IPS. (**e**) Selective catheterization of the right CS, advancing the microcatheter first in the right IJV, then in the facial vein and finally in the SOW. Occlusion of the fistula by placing coils in the right CS

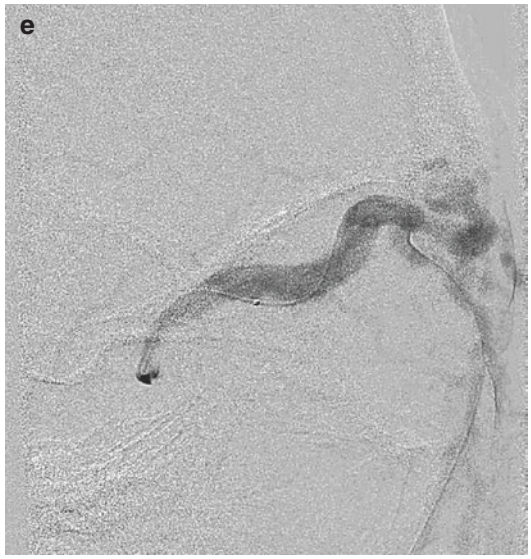

Fig. 13.8 (continued)

et al. 2004; Kurata et al. 2012). Such a situation occurs when the two compartments do not communicate to each other or the links are minimal. A dominant drainage can also occur when one of the routes (ophthalmic veins or IPS, Fig. 13.6) is occluded by thrombosis, which leads to a rerouting of the drainage. In other cases the two compartments, probably, are largely in communication and so both draining patterns are present.

Since the CSs are connected by a large intercavernous anastomotic channel, the contralateral sinus is also frequently involved.

Furthermore, as it has already been described in Sect. 9.3.10, the CS is connected with several veins of the brain parenchyma which can be indirectly involved in the cases of CS fistula (Figs. 13.6 and 13.8). As described below, various patterns can develop.

The superficial and deep middle cerebral as well as the uncal veins can have different types of drainage, but frequently drain into the CS, and so they can be retrograde filled in the case of CS fistula.

Involvement of the deep middle cerebral vein, which is the most important tributary of the basal vein (BV), can lead to a retrograde injection of the basal vein.

The BV can also be involved, considering that the CS is linked through bridging veins with the pontomesencephalic veins connected with the peduncular veins tributaries of the BV.

The drainage in the SPS can lead to a retrograde injection of the petrosal vein, which is connected with the lateral mesencephalic vein and further with posterior mesencephalic or BV.

To the petrosal vein converge also many cerebellar veins which can be indirectly involved.

All these possible pathological venous drainages explain the various clinical symptoms, which are commonly proptosis, chemosis, nerve palsy, and pain (Vinuela et al. 1984; Cheng et al. 1999). Glaucoma and involvement of visual acuity can also occur probably due to impairment of the venous drainage of the central retinal vein. Involvement of the veins of the brain parenchyma can lead to a venous congestion with ischemia or hemorrhage in the temporal area, basal ganglia, brainstem, and cerebellum (Takahashi et al. 2001; Suh et al. 2005; Kim et al. 2006; Kiyosue et al. 2008; Miyamoto et al. 2009). It should furthermore be mentioned that all these clinical symptoms can be present in all DAVfs involving the CS, primarily or secondarily.

There is a rich literature dedicated to the endovascular treatment of these fistulae, in which the arterial or venous route can be chosen (Halbach et al. 1989; Quinones et al. 1997; Cheng et al. 1999; Benndorf et al. 1999, 2001a; Agid et al. 2004; Satomi et al. 2005; Kirsch et al. 2006; Kato et al. 2007; Yung et al. 2011; Yu et al. 2011). Examples of endovascular treatment are presented in Figs. 13.6, 13.7, and 13.8. The treatment is indicated in patients with severe clinical presentation and in cases with involvement of veins of cerebral parenchyma. In the cases in which the symptoms are mild and there is not a large shunt, a conservative therapy can be chosen, considering also that a possible spontaneous occlusion and/or improvement of the symptoms can occur (Satomi et al. 2005; Bujak et al. 2010; Kim et al. 2010; Choi et al. 2015). However, also a clinical worsening and changes in the venous drainage especially with involvement of brain parenchyma veins can occur (Choi et al. 2015). A close control for these untreated patients is mandatory.

- *DAVFs in the middle cranial fossa*. This is a very rare location of fistula, involving typically the venous channels forming the paracavernous sinus (PCS) to which can converge the SMCV (directly or through the SpS), the DMCV, the uncal vein, and occasionally also

the ophthalmic veins (see Sects. 9.1.1.2, 9.3.9, 9.3.10, and 9.3.11). Therefore it is not surprising that the venous drainage can present with various patterns. The fistula is supplied in various combinations by branches arising from ECA (AphA, MMA, AMA, foramen rotundum artery) and from ICA (MHT, ILT). They present frequently with hemorrhage.

Examples are presented in Figs. 13.9 and 13.10. In the case presented in Fig. 13.9, the involvement of the paracavernous sinus led to a retrograde injection of the SpS and of the SOV, with clinical symptoms mimicking a cavernous sinus fistula. It is thinkable that this type of fistula is due to the preexistent anomalous drainage of the SOV in the paracavernous sinus, instead of draining in the cavernous sinus. A few cases of this kind of fistula frequently traumatic are reported in the literature (Pakarinen 1965; Theron et al. 1975; Bradac et al. 1981b; Freckmann et al. 1981; Unterhofer et al. 2009; Shi et al. 2013).

Another example of fistula in the middle cranial fossa presenting with hemorrhage is shown in Fig. 13.10. the fistula involved the SpS in its course on the floor of the middle cranial fossa towards the TS. The SpS was partially thrombosed with reflux in the SMCV.

- *DAVFs of the SSS* occur with a frequency of about 7% of all DAVFs (Awad 1993). They can be of type 1, but it is not seldom to be of types 2 and 3. In the type 2, the venous reflux can be extensive and involve a large part of the cortical veins of the hemisphere, leading to an extensive venous congestion. In type 3 the drainage in the sinus is mediated by dilated cortical veins, which enter the sinus after a fairly long, tortuous course. Branches of the ECA, mainly the MMA, are commonly involved, frequently bilaterally. Transosseous branches of the superficial temporal and occipital arteries can be present. The anterior meningeal artery, arising from the ophthalmic artery, and the meningeal branches of the VA may sometimes be involved. Epileptic seizures,

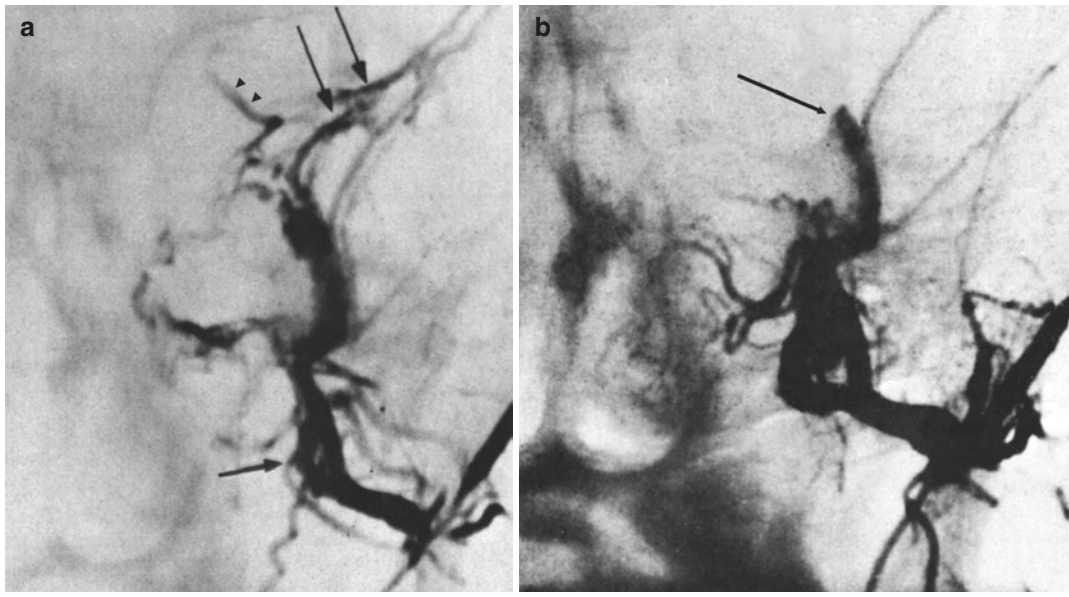

Fig. 13.9 Fistula in the middle cranial fossa developing a few days after a blunt head trauma, presenting clinically with symptoms suggesting a cavernous sinus fistula. ICA angiogram was normal. (**a**) The selective angiogram of the middle meningeal artery showed a fistula involving a network of veins (*arrow*) in the middle cranial fossa, corresponding to dilated veins of the paracavernous sinus. The drainage continued in the sphenoparietal sinus (*arrows*) and in the superior ophthalmic vein (*arrowheads*). The CS was not involved. (**b**) Control angiogram after occlusion (*arrow*) of the fistula with PVA

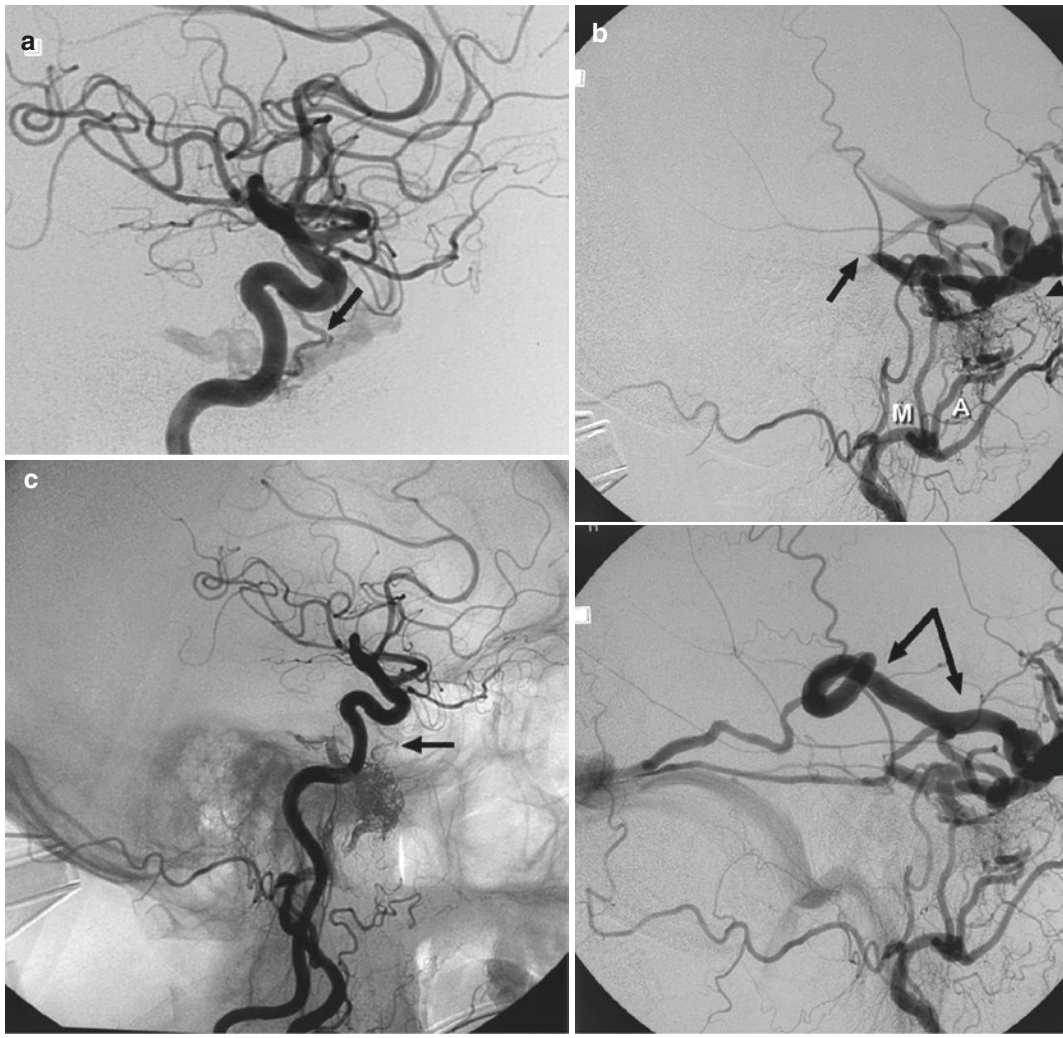

Fig. 13.10 Fistula in the middle cranial fossa presenting with hemorrhage. (**a**) Lateral ICA angiogram showing the dilated ILT (*arrow*). (**b**) ECA angiogram, early and later phases. The middle meningeal (M), the accessory meningeal (A), and the forum rotundum (*arrowhead*) arteries supply the fistula. The shunt seems to involve predominantly the SpS in its course on the floor of the middle cranial fossa draining in this case in the TS through tentorial channels. One of these is thrombosed (*arrow*). There is a retrograde filling of the SMCA (*arrow with angle*). A treatment with onyx injected in the middle meningeal artery was performed. *Considering the risk of a retrograde injection of the embolic material in the ILT and in the ICA, several angiographic controls of the ICA were performed during the treatment.* (**c**) Common carotid angiogram post treatment showing the occlusion of the fistula. Note the small ILT (*arrow*)

hemorrhage, and/or clinical signs of intracranial hypertension, such as headache and cognitive disorders, are present (Halbach et al. 1988c; Riva et al. 1991). Surgical disconnection of the shunt or selective embolization with acrylic glue or onyx may be effective treatments (Collice et al. 2000; Van Dijk et al. 2004; Rodesch et al. 2009). Examples are presented in Figs. 13.11 and 13.12.

- *Tentorial DAVFs* occur with a frequency of about 8%. They are commonly of type 3, characterized by an high hemorrhagic risk (Picard et al. 1990; Awad et al. 1990; Awad 1993; King and Martin 1992; Cognard et al. 1995; Deasy et al. 1999; Tomak et al. 2003; Seong et al. 2006; Jiang et al. 2009). Tentorial DAVFs can be schematically divided into an anterior and posterior group. Those of the *anterior*

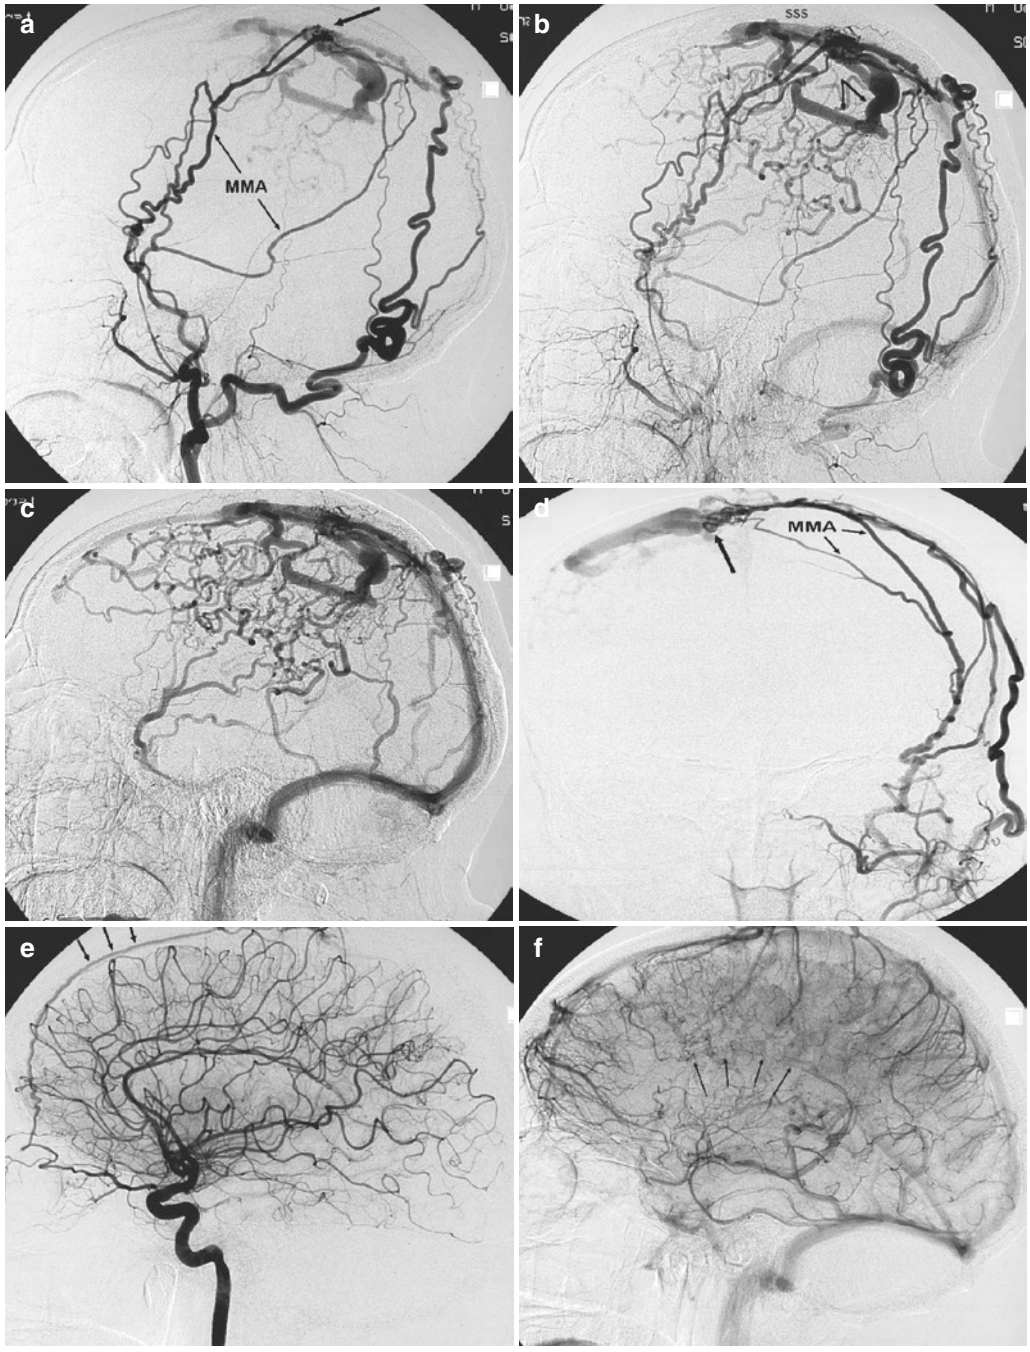

Fig. 13.11 Middle-aged patient presenting with increased headache and suspected epileptic seizures. The angiographic study shows DAVF located in the right parietal area, close to the SSS. (**a**), (**b**), (**c**) Right ECA angiogram showing the DAVF supplied by branches of both middle meningeal artery (MMA) and by transosseous branches of the occipital artery. Site of the shunt (*arrow*). The drainage occurs in the enlarged cortical veins (*arrow with angle*), which after a tortuous course enter the superior sagittal sinus (SSS). There is an extensive retrograde injection of the cortical veins of the right hemisphere. (**d**) Left ECA angiogram, oblique view. Involvement of the MMA (*arrows*). Site of the shunt (*arrow*). (**e**) On the ICA angiogram, a minimal contribute through the anterior meningeal artery (*arrows*) is visible. (**f**) In the venous phase the venous congestion demonstrated in (**a**), (**b**), (**c**) explains the poor filling of the frontoparietal veins (*arrows*). The patient underwent surgical treatment

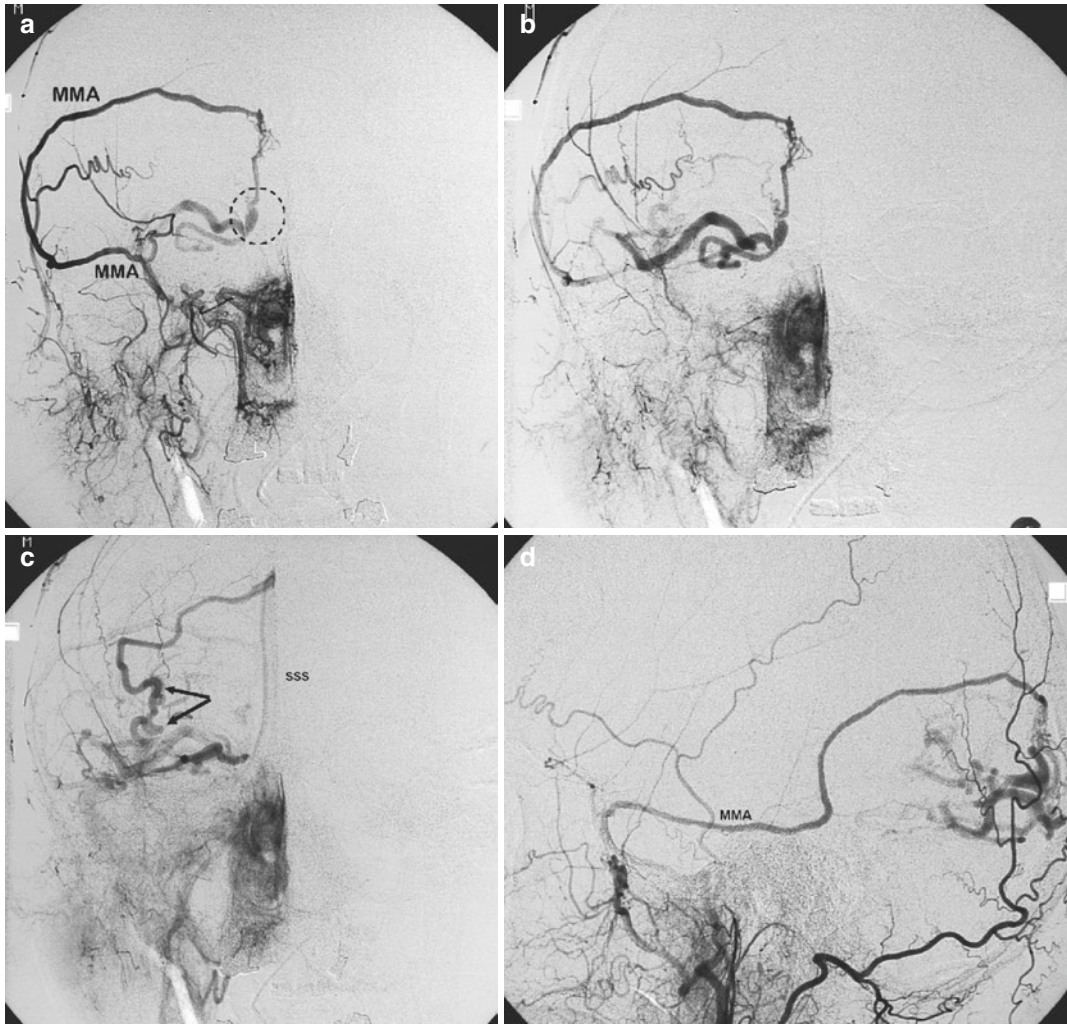

Fig. 13.12 Old patient suffering from acute headache. CT showed a suspected vascular malformation in the right occipital area. ICA angiogram was normal. (**a**), (**b**), (**c**) Angiogram of right ECA. AP view. There is a large middle meningeal artery (MMA) supplying the fistula in the paramedian right occipital region. Site of the shunt (*circle*). The venous drainage occur through cortical veins (*arrow with angle*) which, after a long, tortuous course enter the superior sagittal sinus (SSS). (**d**), (**e**) ECA angiogram, followed by selective MMA study. Site of the shunt (*arrows*) and venous drainage. (**f**) Vertebral angiogram showing the involvement of the falx cerebellar artery (FCA). Endovascular treatment with injection of onyx in the MMA allowed complete occlusion of the fistula. Carotid (**g**) and vertebral (**h**) angiograms posttreatment

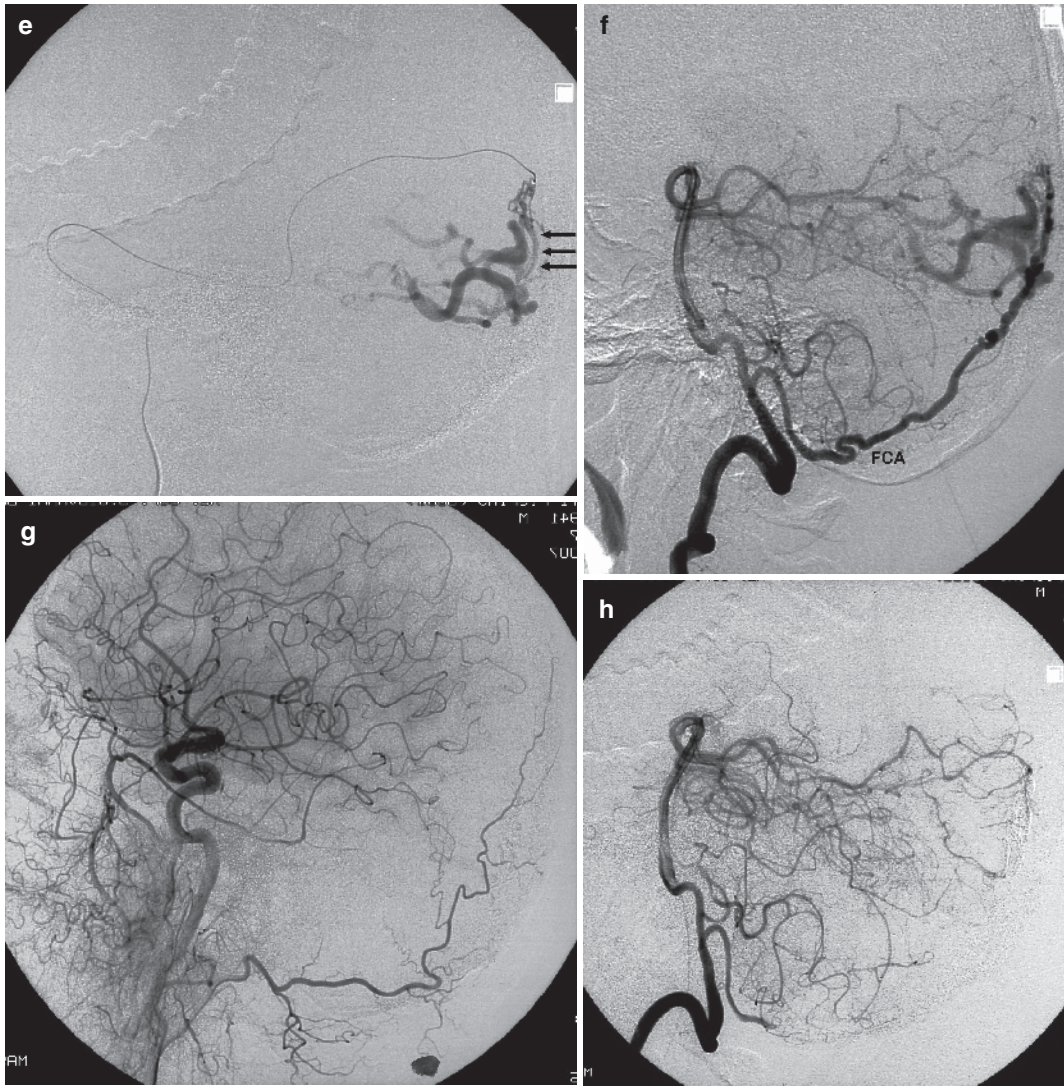

Fig. 13.12 (continued)

group, also called petrotentorial fistulas, are commonly located in the area corresponding to the attachment of the tentorium to the superior ridge of the petrous bone, involving the SPS which is commonly partially or completely thrombosed. The pattern of these fistulas is frequently (Figs. 13.13 and 13.14) characterized by many arterial tributaries represented in various combinations, by branches of ECA (petrosquamosal branch of the MMA, the AMA, the artery of the foramen rotundum, and branches of the occipital artery and AphA), cavernous branches of the ICA, leptomeningeal branches of the PCA, and cerebellar arteries. A rich network of vessels can be recognizable at the level of the superior ridge of the petrous bone converging to the thrombosed SPS and so the venous drainage occurs in the petrosal vein and continues retrogradely through the brachial veins to the dilated lateral mesencephalic vein, then to the basal vein or posterior mesencephalic vein, and further to the Galen vein and straight sinus. In some cases, the venous drainage can be directed more medially towards the pontomesencephalic veins and further through the peduncular vein in the basal vein (Fig. 13.15).

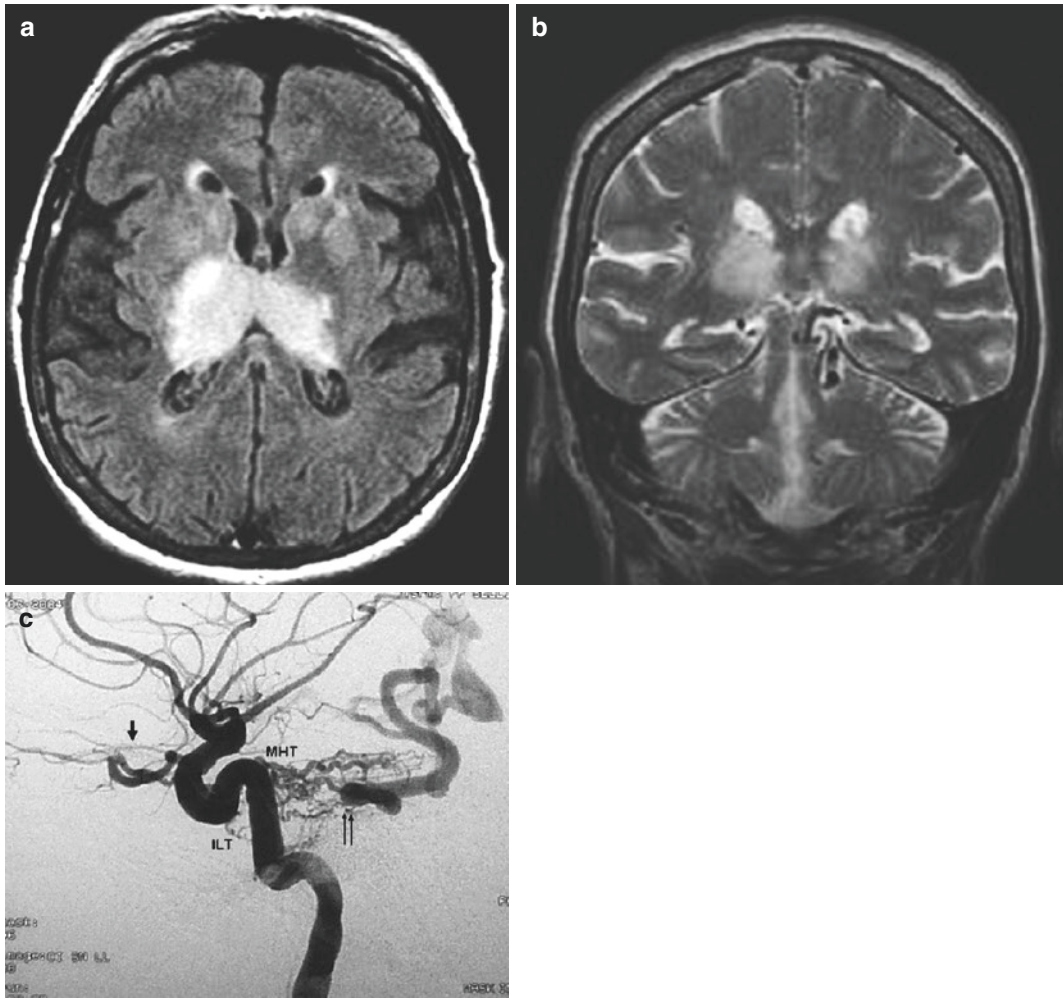

Fig. 13.13 Petrotentorial DAVF in a patient with slowly progressive cognitive disorders. (**a**), (**b**) Axial MR Flair image and coronal T2-weighted image showed nonspecific hyperintensity involving both thalami and partially both basal ganglia. On the coronal image anomalous vascular structures lateral to the midbrain suggesting vascular malformation are recognizable. (**c**) Angiogram of ICA showing a DAVF with a shunt (*arrows*) in the area where the tentorium attaches to the superior ridge of the petrous bone, supplied by dilated branches of the MHT and ILT. A recurrent branch of the ophthalmic artery is also involved (*large arrow*). The venous drainage occurs through the petrosal vein in the lateral mesencephalic vein. (**d**) ECA angiogram. Lateral and AP views. The petrosquamous branch of the MMA (*arrowhead*), the accessory middle meningeal artery (*arrow*) and the mastoid branch of the occipital artery supply the DAVF. Projecting on the superior petrous sinus which is probably completely or partially thrombosed (*arrows*) there is a large petrosal vein continuing in the lateral mesencephalic vein (LMV) and further into the posterior mesencephalic vein entering the Galen vein. The straight sinus (SS) is thrombosed and so the venous drainage is rerouted anteriorly in the contralateral basal vein (BV) and further in the deep (*arrow with dot*) and in the superficial (*arrows with dot*) middle cerebral vein. (**e**) Selective study (AP and lateral views) of the MMA better showing the shunt (*arrow*). The fistula was occluded with acrylic glue. (**f**) MRI Flair image performed a few weeks later showing the progressive reduction of the hyperintensity of the thalami. Gradually, clinical improvement of the patient

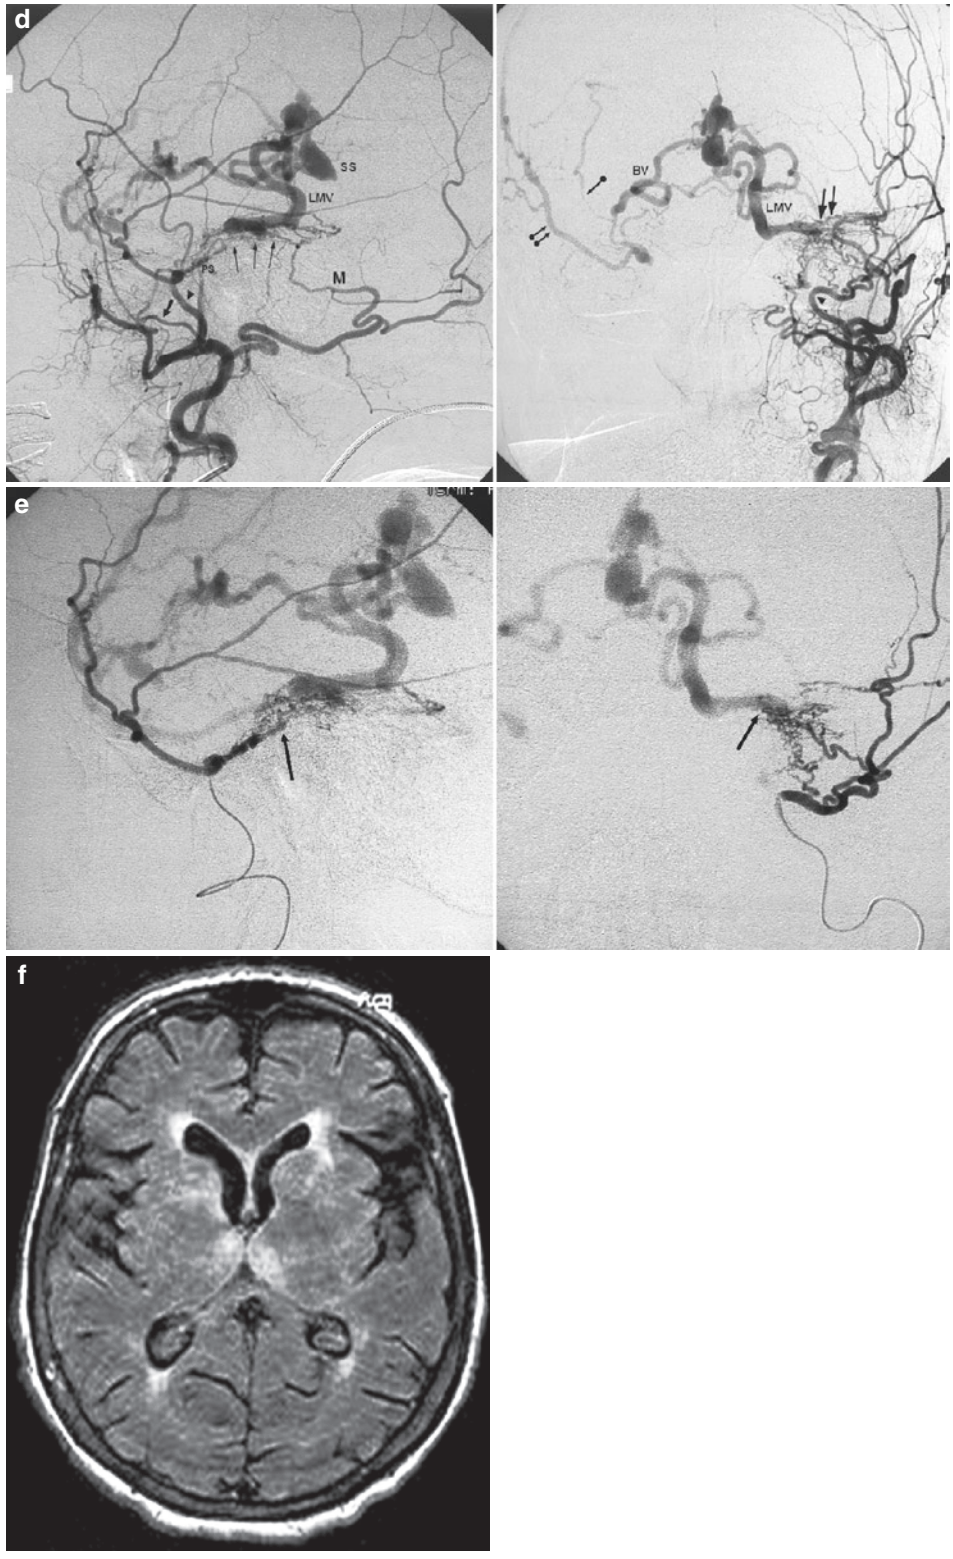

Fig. 13.13 (continued)

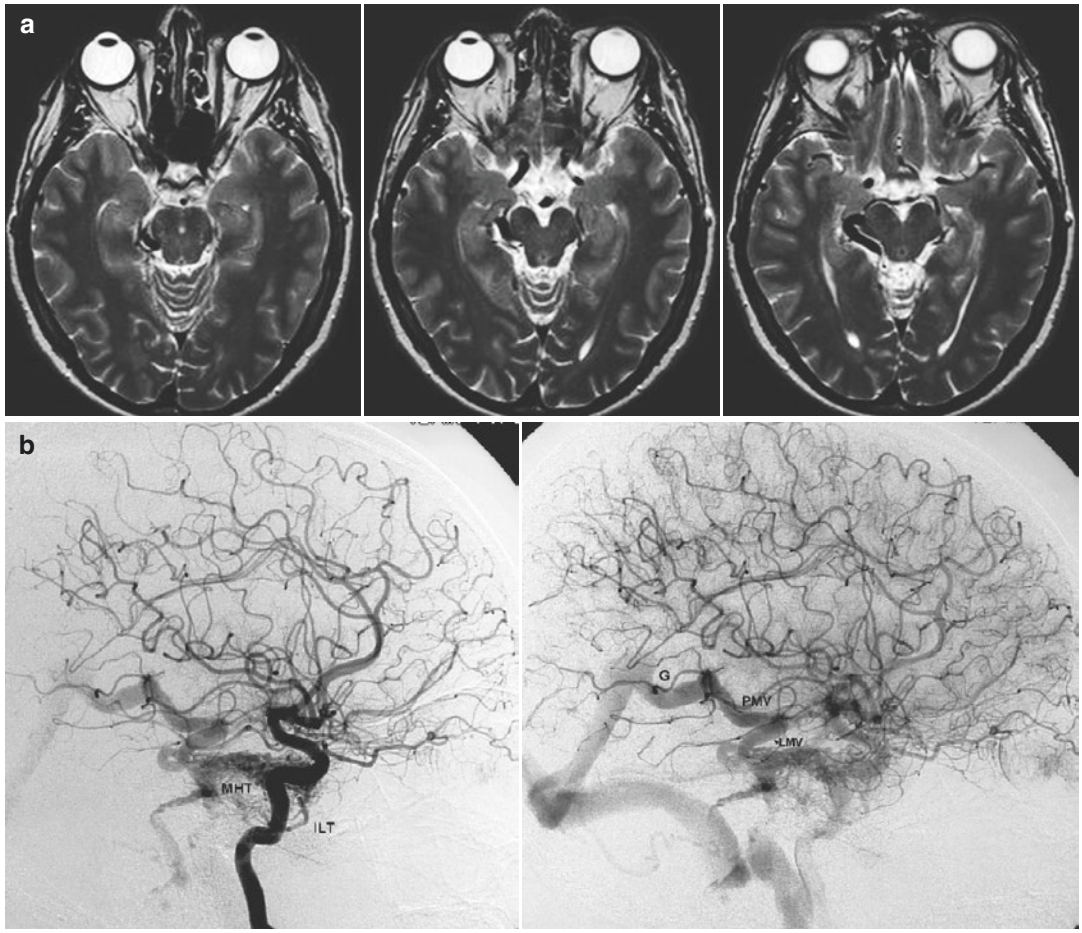

Fig. 13.14 Petrotentorial DAVF in a young patient with sudden onset of cranial nerve IV palsy. MRI (**a**) showed an abnormal vessel running laterally to the midbrain. On the ICA angiogram (**b**), there are several branches arising from the MHT and ILT converging on the petrotentorial area. The superior petrosal sinus is not evident, probably thrombosed. The drainage involves the petrosal vein continuing to the large lateral mesencephalic vein (LMV) and posterior mesencephalic vein (PMV), then to the vein of Galen (G) and straight sinus. A minimal drainage is directed towards the transverse sinus. Other feeders are (**c**), (**d**), and (**e**), the mastoid branch (M) of the occipital artery, the clival branches (*arrow*) of the neuromeningeal trunk (NM), and the tympanic branch of the APhA. Branches of the middle meningeal artery (*small arrows*), especially the petrosquamous branch (PS) and branches of the accessory meningeal artery (*large arrow*), are also involved. There is perhaps a minimal component from the foramen rotundum artery. On the image (**f**) The route of the microcatheter advanced through the TS and SS into the Galenic and mesencephalic veins to the site of the shunt is shown. Injection of contrast medium during treatment characterized by placement of coils. Angiogram of the ICA and ECA posttreatment (**g**) showing occlusion of the fistula

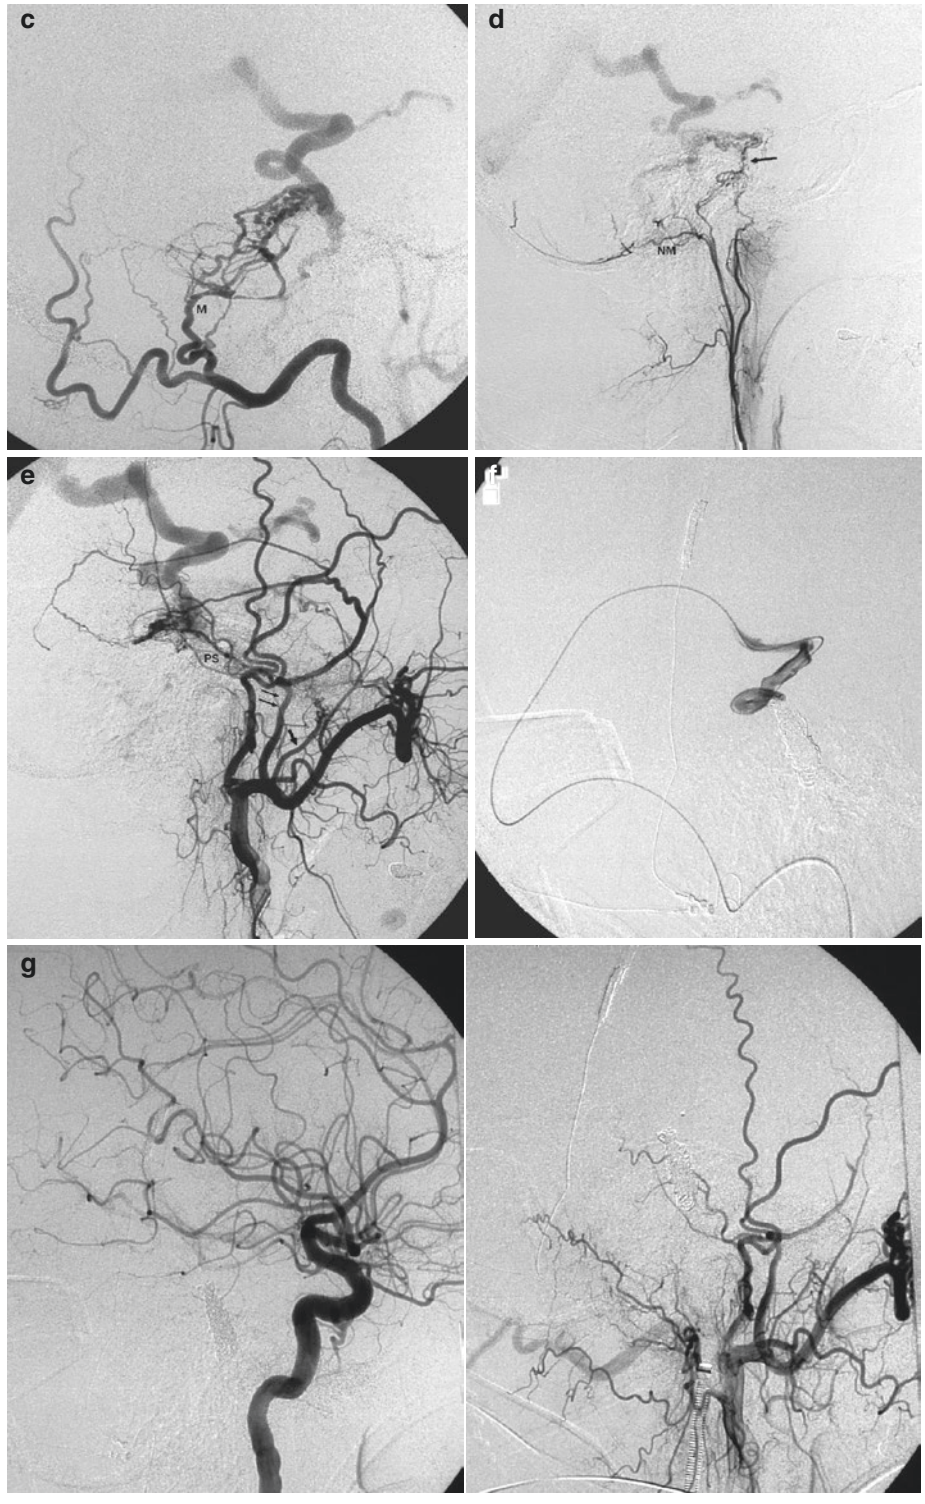

Fig. 13.14 (continued)

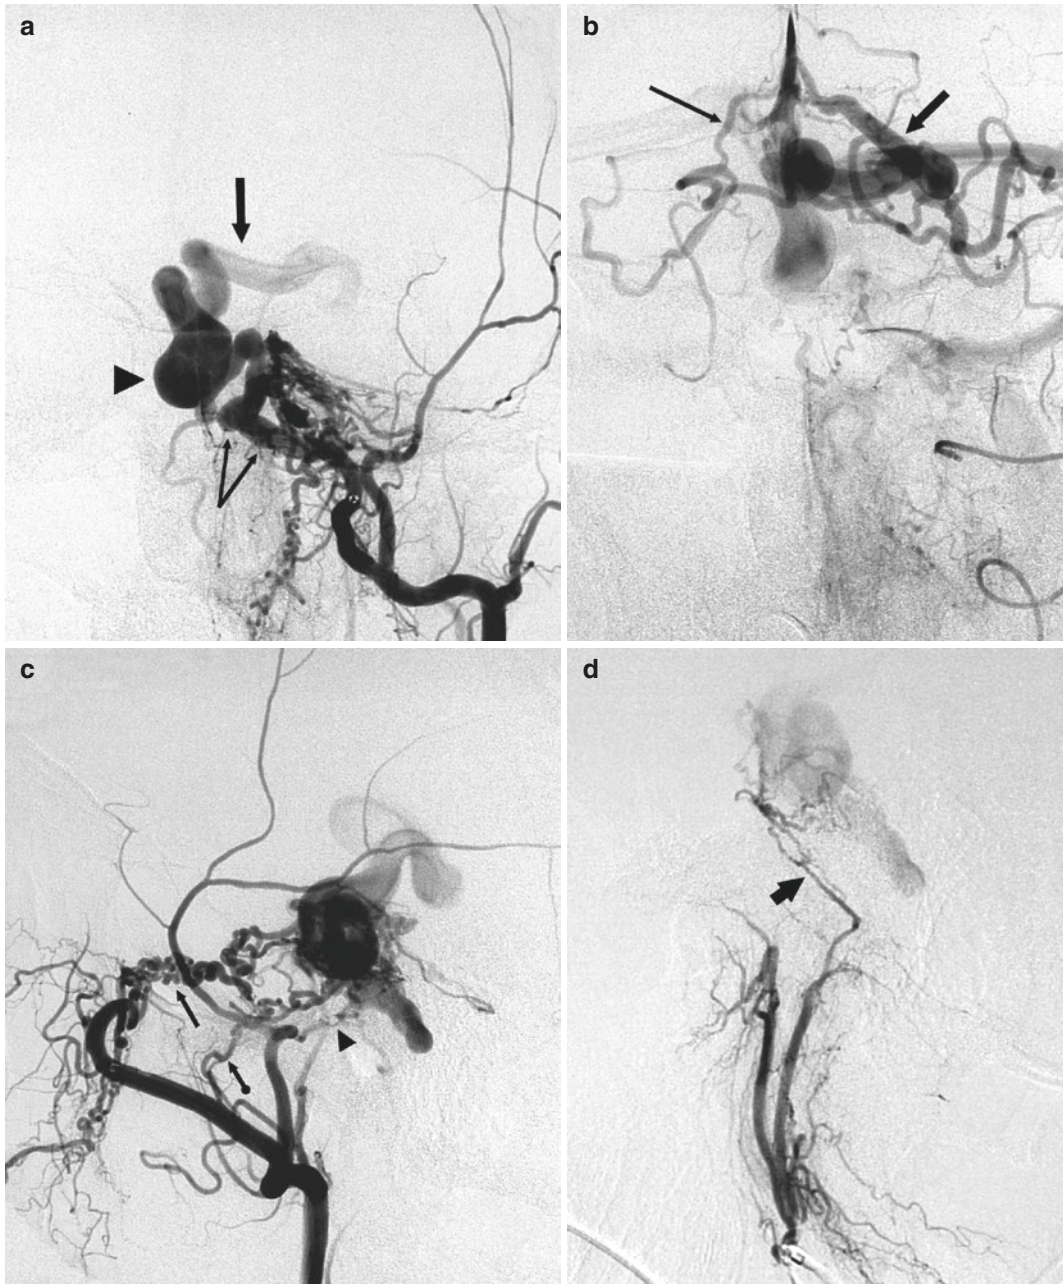

Fig. 13.15 Another example of petrotentorial fistula presenting with trigeminal neuralgia. (**a**), (**b**) Angiogram of the IMA. Earlier and later phases. AP view. Several dilated distal branches of IMA supply a pathological network projecting in the area of the medial petrous ridge draining in a dilated venous channel (*arrow with angle*) directed medially continuing in enormously dilated and tortuous probably pontomesencephalic veins (*arrowhead*). The drainage continues in the left peduncular vein (*arrow*). In the later phase the drainage in both basal veins, left (*arrow*) and right (*small arrow*) and further in the SS and left TS is recognizable. (**c**) IMA angiogram. Lateral view showing better the supplying branches: foramen rotundum artery (*arrow*), accessory meningeal artery (*arrow with dot*), and petrosquamous branch of the MMA (*arrowhead*). (**d**) Angiogram of the AphA which contributes with its clival branches (*arrow*). (**e**) ICA angiogram showing the involvement of the cavernous and petrous branches of ICA and also of the recurrent meningeal branch of the ophthalmic artery. Endovascular devascularization with PVAs followed occlusion of the fistula with coils after reaching the shunt through the venous route as shown in Fig. 13.14

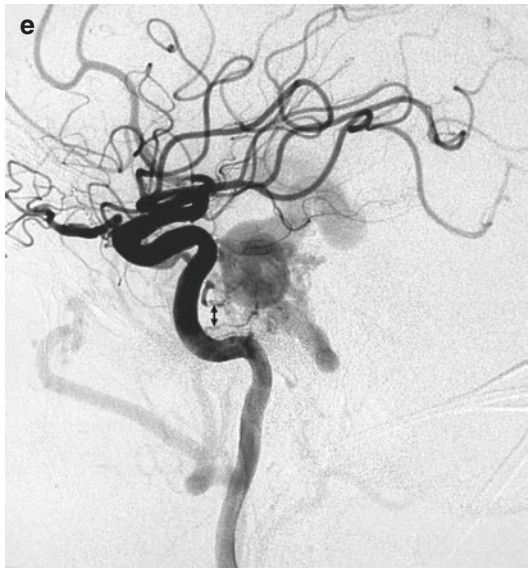

Fig. 13.15 (continued)

Tentorial DAVFs can be located more posteriorly along the tentorial incisura or in the area of the Galen vein. The supplying arteries are similar to those already described, but there is a greater involvement of the meningeal branches of the VA and more frequently of pial branches of the superior cerebellar and posterior cerebral arteries. Furthermore there is a frequent involvement of *a meningeal branch* arising from the posterior cerebral artery (see also Sect. 7.1). The precise point of the shunt is not always possible to be identified. The fistula can involve the Galen vein with further drainage in the SS. This channels, however, can be thrombosed and so the venous drainage is rerouted anteriorly with retrograde injection of the deep venous system ICVs and BVs. In other cases the shunt involves selectively the distal segment of the basal vein which is retrograde injected, while the Galen vein and the SS are patent.

Examples are presented in Figs. 13.16, 13.17, and 13.18.

Both surgical and endovascular treatment are difficult. With endovascular treatment good results can be obtained by injecting acrylic glue in the shunt reached through the feeding arteries. The venous route when possible can be an excellent alternative. The association of both technique can be useful in some cases.

- DAVFs of the *anterior fossa*, also called ethmoidal amount to around 6% of all DAVFs (Picard et al. 1987; Kobayashi et al. 1988; Cognard et al. 1995; Awad 1993): They are reported more frequently in males (Martin et al. 1990; Van Dijk et al. 2004). They are of types 3 and 4 and present commonly with hemorrhage (Ito et al. 1983; Martin et al. 1990; Awad 1993). The supplying arteries are the posterior and anterior ethmoidal arteries, branches of the ophthalmic artery. Among the anterior ethmoidal arteries, the anterior meningeal branch is often largely involved. This artery supplies normally the dura of the falx and adjacent dura of the frontal convexity. Since it anastomoses with the corresponding falx branch of the MMA, this latter may also be involved. The ethmoidal arteries anastomose with the ethmoidal arteries arising from the sphenopalatine branches of the IMA, which consequently become involved. Drainage is via the pial veins of the frontal convexity, which are frequently dilated, forming large venous pouches and entering then SSS. More rarely the drainage is directed posteriorly towards the cavernous sinus (Martin et al. 1990). The involvement of the ophthalmic artery and the drainage in the cavernous sinus, explain the impairment of the visual acuity and the ocular motility dysfunction. An example of this type of fistula is presented in Fig. 13.19.

Surgical excision has been the therapy of choice. Due to the improvement of the endovascular technique with selective catheterization of the ophthalmic artery, followed by injection of glue or Onyx™, this approach has become a possible good alternative treatment as reported also by some authors (Lv et al. 2008; Agid et al. 2009).

- Another complex group of DAVFs is that *located at or close to the foramen magnum* (Barnwell et al. 1990, 1991; McDougall et al. 1997; Ernst et al. 1999; Miyachi et al. 2008; Abiko et al. 2008; Manabe et al. 2008; Choi et al. 2012). Pulse-synchronous tinnitus is a common clinical symptom. Palsy of the cranial nerves especially of the hypoglossal nerve can occur. Retrograde filling of the IPS

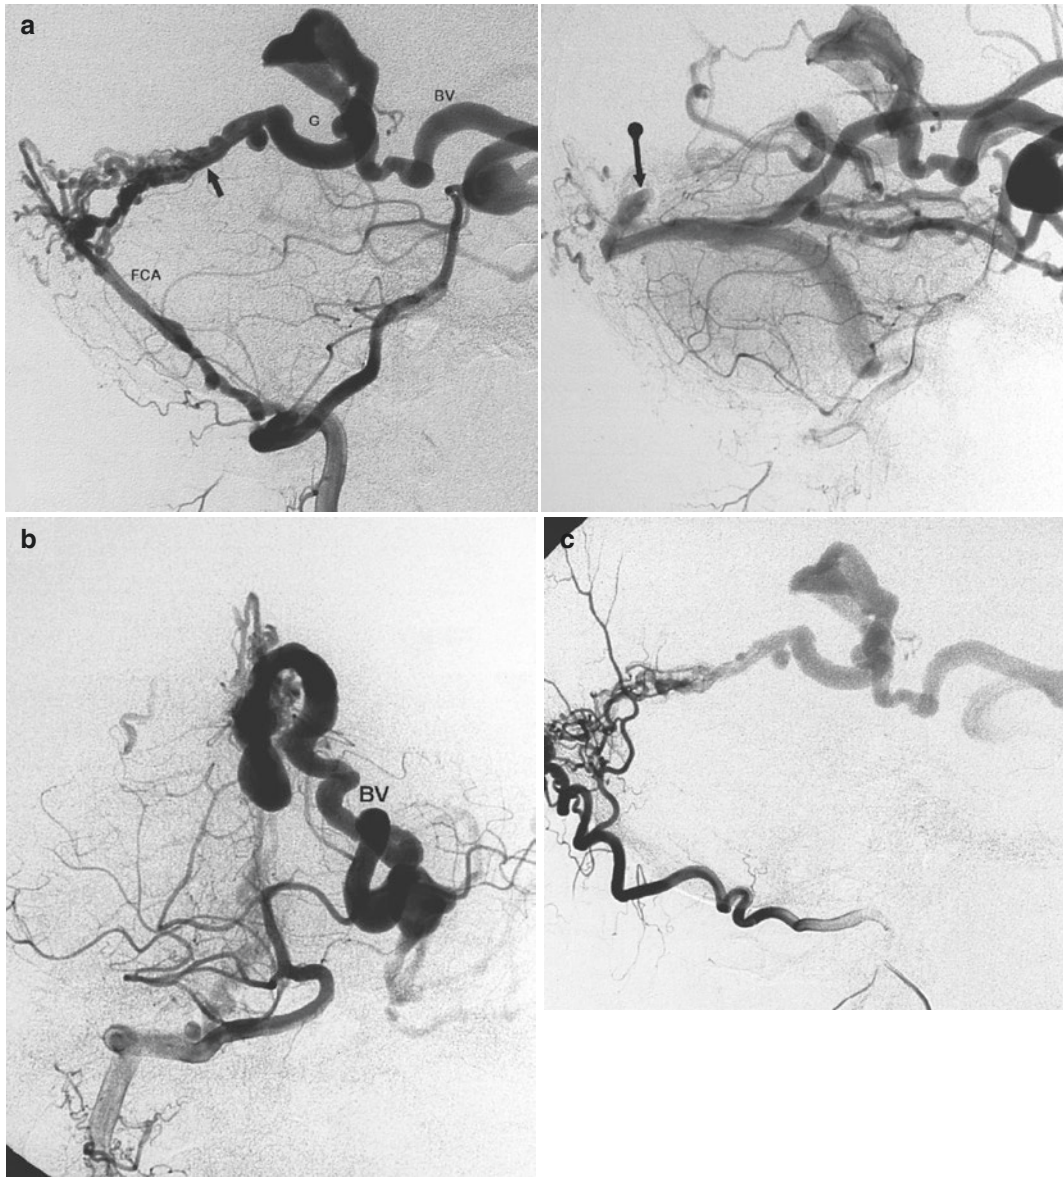

Fig. 13.16 Posterior tentorial DAVF in a patient suffering from headaches and cognitive disorder. The malformation was supplied mainly by the falx cerebelli artery (FCA) arising from the right VA. A small meningeal branch arose also from the left VA. Other feeders were the bilateral occipital and MMA arteries. The ICA was not involved. (**a**) Lateral right vertebral angiogram showing a dilated falx cerebelli artery (FCA), continuing into branches (*arrow*), running in the dura along the straight sinus, connected with the vein of Galen (G). Retrograde filling of the dilated tortuous basal vein (BV). This drains further into the temporal veins. In the later venous phase, the stump of the occluded straight sinus (*arrow with dot*) is recognizable. (**b**) Right vertebral angiogram (AP view) showing the drainage to the retrograde injected BV. (**c**) Left occipital artery and (**d**) selective left MMA supplying the DAVF. (**e**) ICA angiogram venous phase, showing the diffuse venous congestion due to impairment of the deep venous drainage. (**f**) Right vertebral angiogram after endovascular treatment. Acrylic glue was injected close to the shunt after selective catheterization of the right FCA and left MMA. The shunt is not completely occluded. The remaining supply (*arrow*) may be due to either pial branches of the SCA or a meningeal branch. A selective study was not performed. The patient improved and refused further treatment

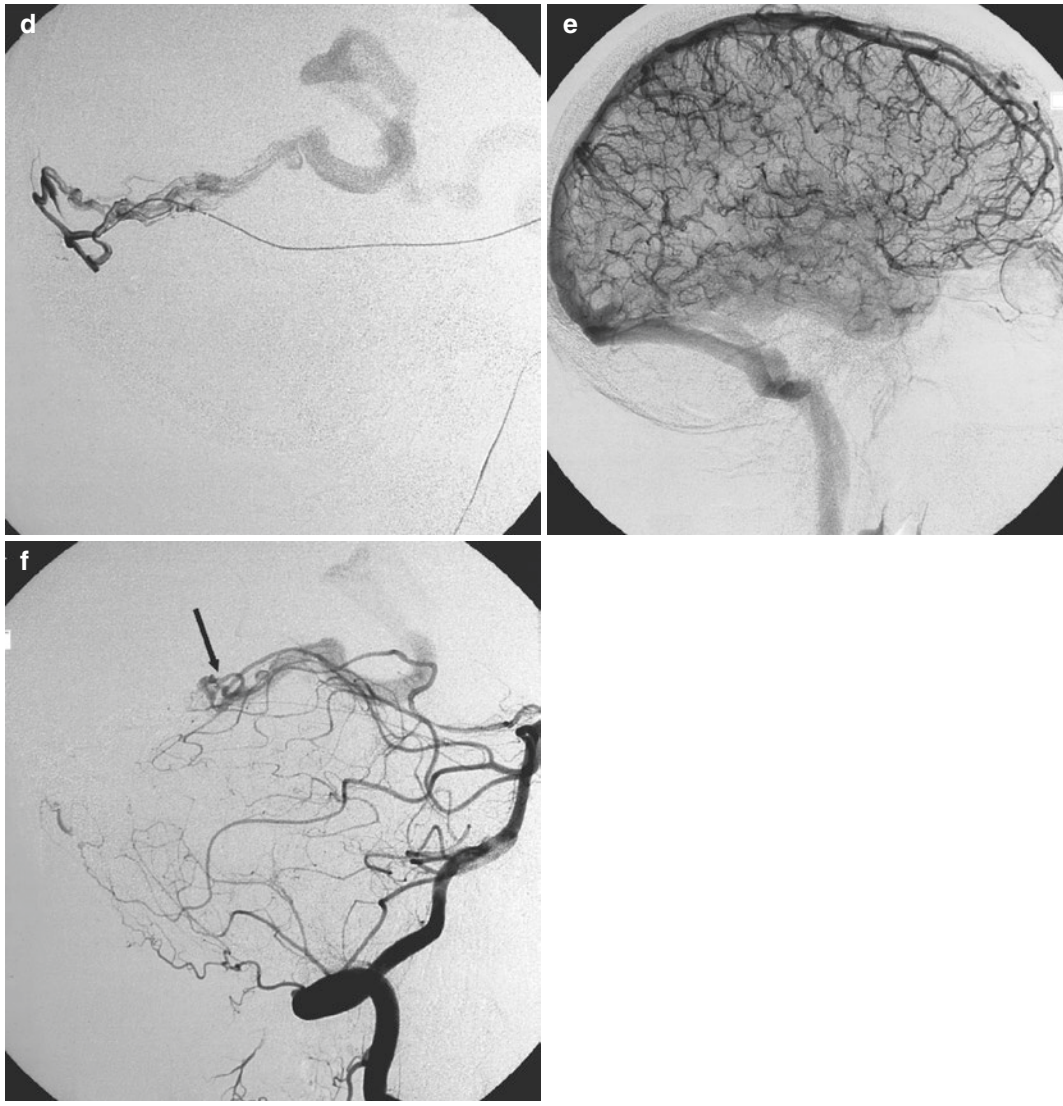

Fig. 13.16 (continued)

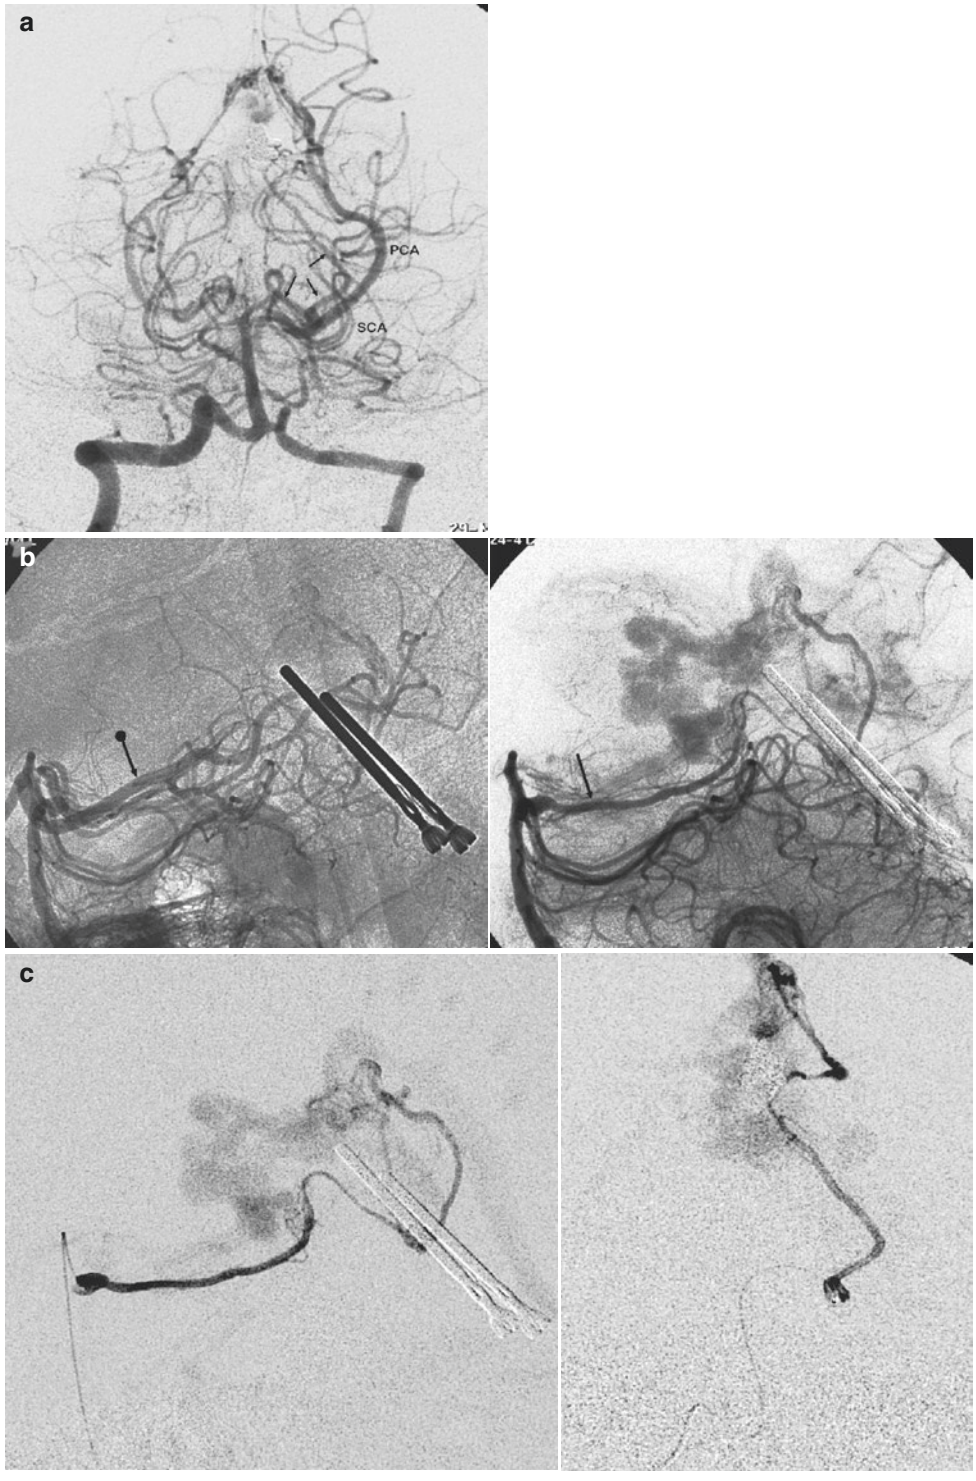

Fig. 13.17 Posterior tentorial DAVF. (**a**) Vertebral angiogram, AP view. Left posterior cerebral artery (PCA), superior cerebellar artery (SCA), meningeal branch (*arrows*) arising from the PCA close to its origin from the basilar artery. (**b**) Lateral vertebral angiogram. Owing to overlap with the PCA (*arrow with dot*), the meningeal branch (*arrow*) connected with the vein of Galen is better evident only later, when the contrast medium has left the PCA. Clips of previous surgery are present. (**c**) Selective catheterization of the meningeal branch, lateral and AP view, showing its supply of the DAVF. Injection of onyx followed. The patient recovered

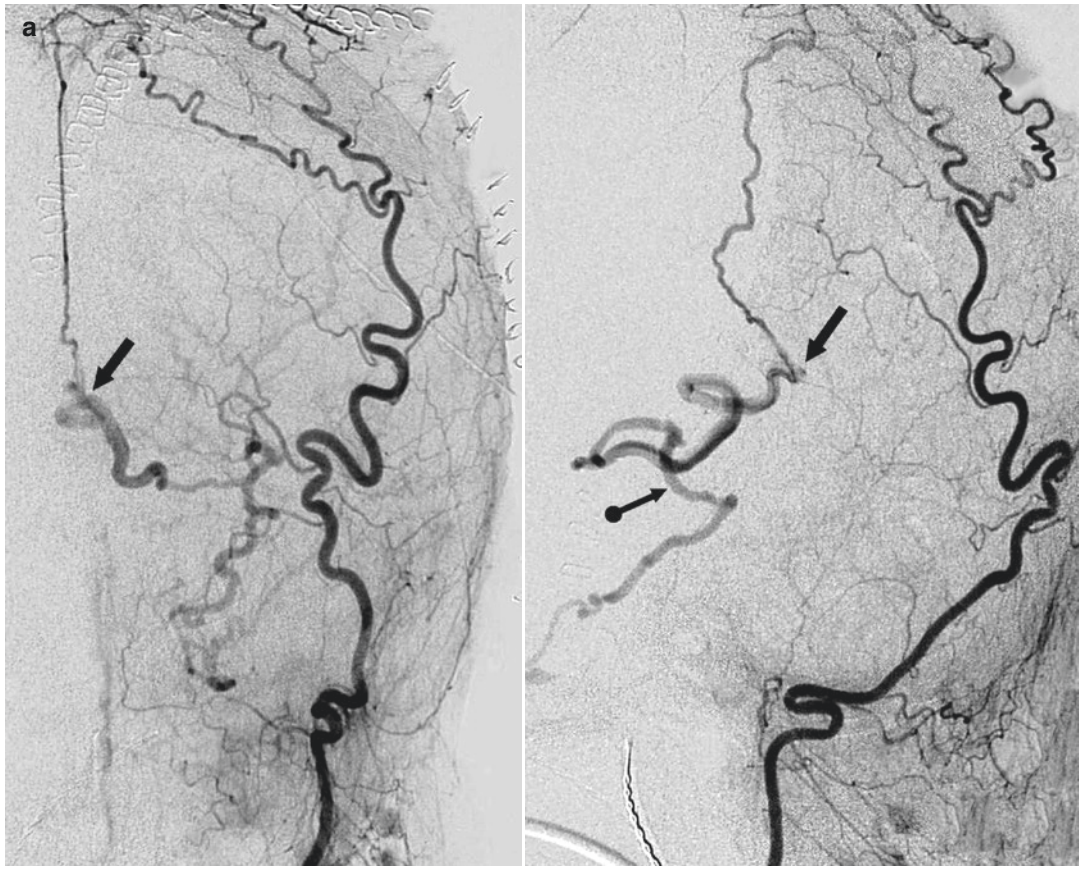

Fig. 13.18 Middle-aged man presenting with temporobadsal hemorrhage due to a posterior tentorial DAVF supplied by meningeal branches of the ECA and VA. There are no involvement of the ICA. (**a**) Angiogram of the left occipital artery (AP and Lateral view). Through transosseous branches, injection of a meningeal branch of the falx, connected (*arrow*) with the distal portion of the BV or posterior mesencephalic vein, which with a tortuous retrograde course continues into the lateral mesencephalic vein (*arrow with dot*). Galen vein is not involved. (**b**) Left VA angiogram. AP view (early and late phases). The fistula is supplied by a branch, probably a meningeal artery (*arrow with angle and dot*) arising from the left P1 near its origin from the basilar artery. There is a possible involvement of the FCA. Venous drainage along the midbrain (*arrow*). The petrosal vein and superior petrosal sinus are probably thrombosed and so the venous drainage (*arrow with angle*) is diverted towards the superficial middle cerebral vein (SMCV). (**c**) Left VA angiogram. AP view with a different projection (early and late phases) showing the diverted venous drainage (*arrow*) towards the SMCV. There is no filling of the left TS and SPS. There was a minimal filling of the left internal jugular vein (JV). The extracranial drainage occurred through the right internal jugular vein (JV) and the right vertebral artery venous plexus (*arrow with dot*). (**d**) Left VA angiogram, lateral view, showing the drainage involving BV and lateral mesencephalic vein (LM) and its diversion towards the SMCV (*arrowheads*). In a later phase normal filling of the Galen vein (G) and straight sinus (SS). (**e**) Selective study (*arrow*) of the meningeal branch arising from P1, preceding the injection of glue leading to a closure of the fistula, demonstrated on the control angiogram. Complete occlusion of the fistula confirmed also through study of the ECA and ICA. Complete recovery of the patient

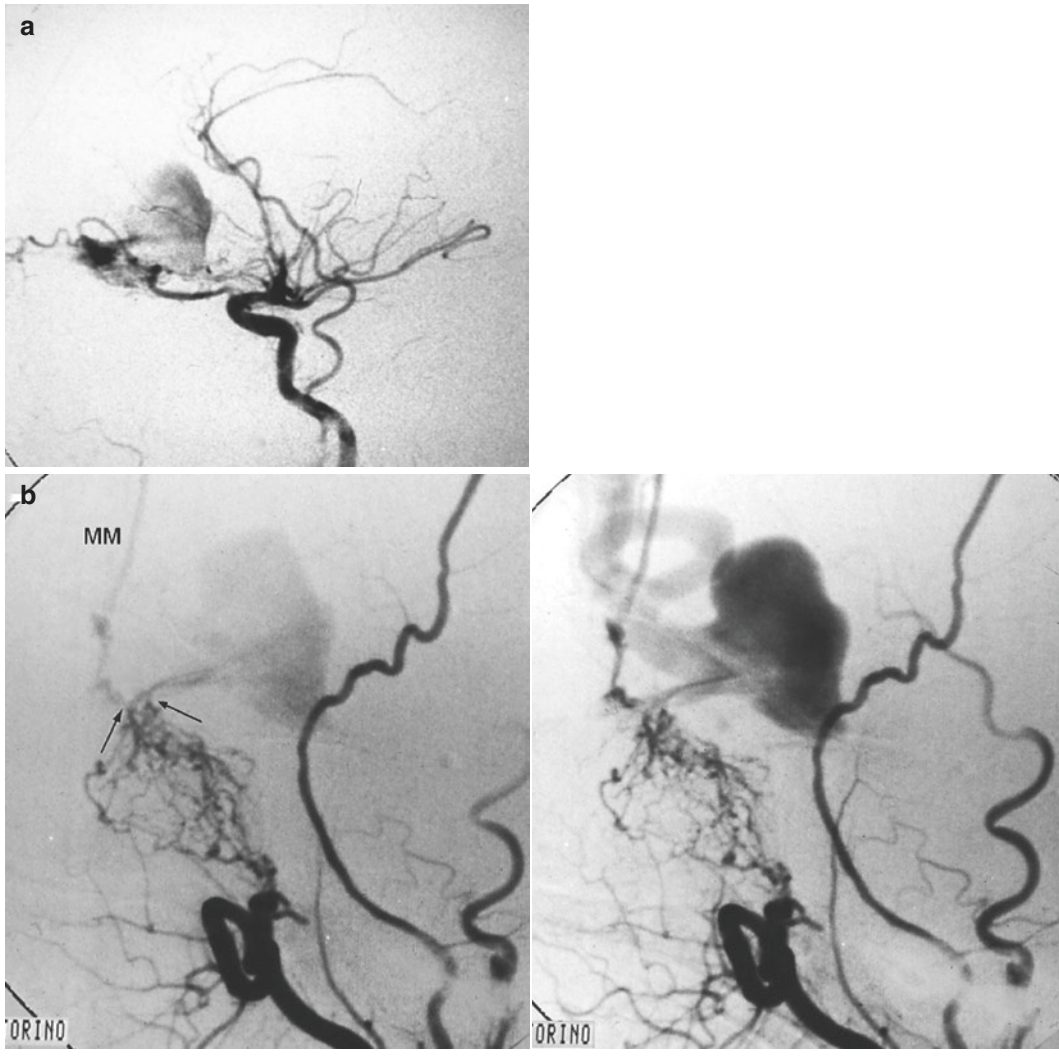

Fig. 13.19 DAVF of the anterior cranial fossa presenting with hemorrhage, supplied by anterior ethmoidal branches of the ophthalmic artery as visible on the lateral ICA angiogram. (**a**) On the lateral angiogram of the internal maxillary artery (**b**) branches of the sphenopalatine artery anastomosing with ethmoidal branches of the ophthalmic artery are also involved as well as the anterior falx branch of the middle meningeal artery. (MM). *Arrows* show the site of the shunt. The drainage occurred in the pial veins, forming a large pouch entering the SSS. Selective angiographic study (**c**) in the lateral and AP views of the MMA better showing its supply to the fistula. Treatment by surgery

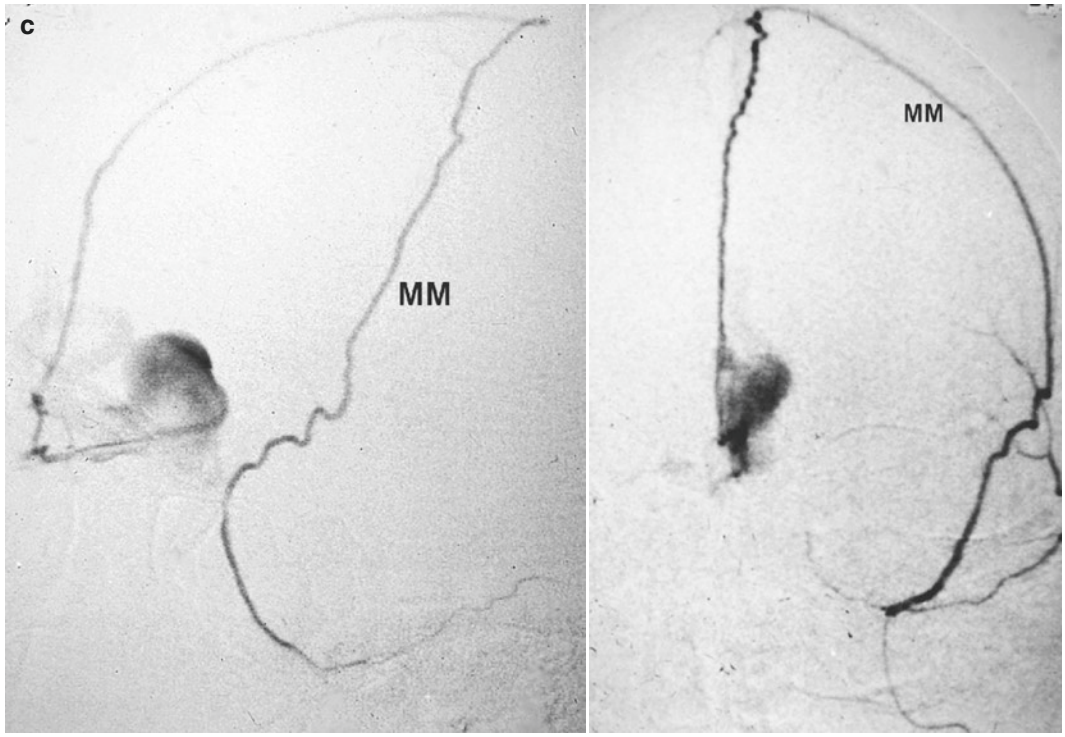

Fig. 13.19 (continued)

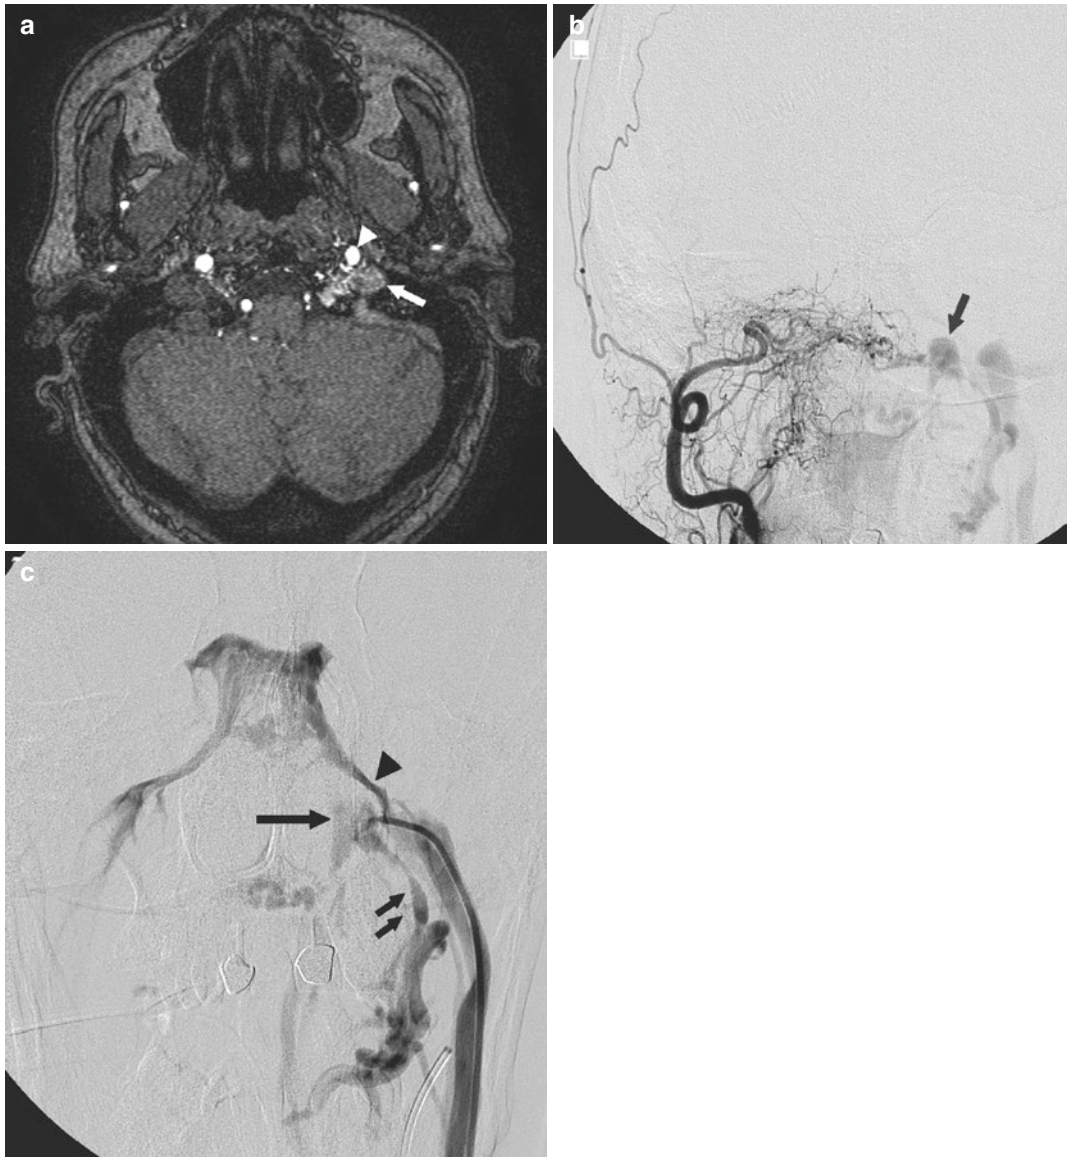

Fig. 13.20 Middle-aged woman presenting with headache and left pulse-synchronous tinnitus. (**a**) MR study (fast sequence with contrast) showed on the left a pathological early enhancement (*arrow*) involving the IJV, ACC, and hypoglossal foramen, suggesting DAVF. A retrograde injection of the sigmoid sinus is also present. ICA (*arrowhead*). On bilateral ICA, ECA, and vertebral angiograms (*not shown*), the fistula at the level of the ACC was demonstrated. There was a bilateral involvement of branches of the APhA, IMA, and of the radiculomeningeal branch of the left VA. Particularly useful to localize the shunt were the angiograms of the contralateral ECA with the selective studies of APhA. (**b**) Angiogram of the right distal ECA showing a rich network arising mainly from the AphA running along the inferior clivus and connected with the ACC (*arrow*). (**c**) Left venous angiogram. Catheterization of the IJV with the tip of the catheter in the ACC (*arrow*). Filling of the lateral condylar vein (arrows). Retrograde injection of the IPS (*arrowhead*). Coils were placed in the ACC leading to occlusion of the fistula. (**d**) Right AP common carotid and left lateral common carotid angiograms showing the occlusion of the fistula. Coils in the ACC (*arrow*) "Courtesy of dott. Gozzoli and dott. Boghi, Neuroradiology-Cuneo"

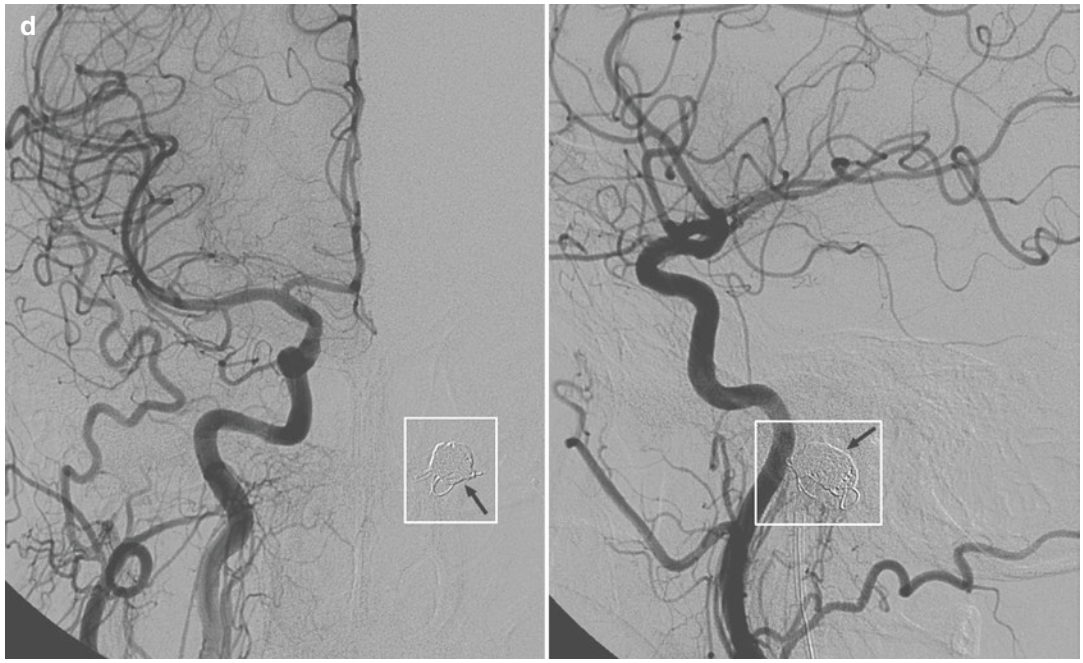

Fig. 13.20 (continued)

and CS can cause symptoms similar to that occurring in CS fistula. These DAVFs involve several uni-or bilateral feeders that arise from the AphA especially from its hypoglossal branch, occipital artery, VA and, more rarely, from IMA and ICA. The venous drainage can vary, since this area is a crossing point for several venous channels represented by the IPS, jugular vein, sigmoid sinus, anterior condylar confluence with its connections, and marginal sinus with its connections (for anatomical aspects of the venous channels see also Sect. 9.3.8). MR can be a useful complementary study in identifying the precise site of these fistulas. An example is shown in Fig. 13.20.

In some of these fistulas, as reported also by other authors (Rodesch et al. 1991b; Pierot et al. 1992) the shunt involves directly the pial veins surrounding the medulla, continuing further caudally in the perimedullary veins of the cervical spinal cord and cranially in the pontomesencephalic veins. Examples are presented in Figs. 13.21, 13.22, and 13.23.

Fig. 13.21 Middle-aged patient presenting with paraparesis. (**a**) MRI T2-weighted image, showing hyperintensity lesion in the cervical spinal cord. (**b**) Lateral external carotid angiogram. There is a fistula involving the hypoglossal branch (*arrow*) of the ascending pharyngeal artery (APhA) connected with dilated medullary veins continuing caudally in the perimedullary veins of the cervical cord (*arrowheads*). (**c**) Oblique view angiogram of the occipital and APhA (*arrow*) arising as a common trunk. The hypoglossal branch of the APhA supplies the fistula (*arrowhead*). (**d**) Selective study (lateral oblique view) preceding the injection of Onyx. Distal tip of the microcatheter in the hypoglossal branch at the site of the shunt (*arrow*). (**e**) MRI T2-weighted image showing the disappearance of the lesion with complete recovery of the patient

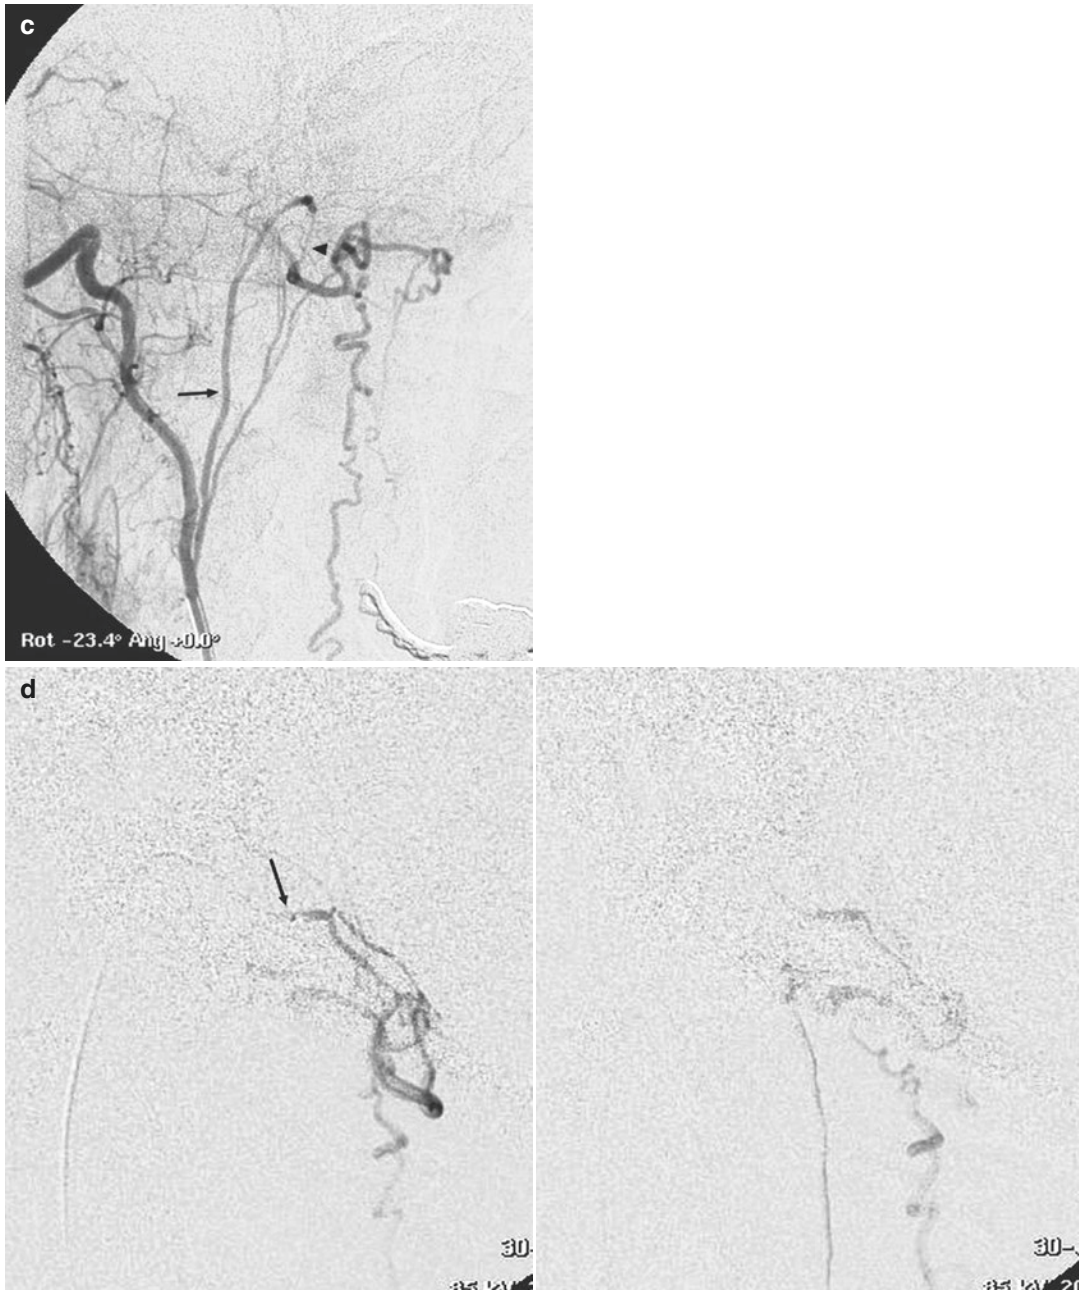

Fig. 13.21 (continued)

Fig. 13.21 (continued)

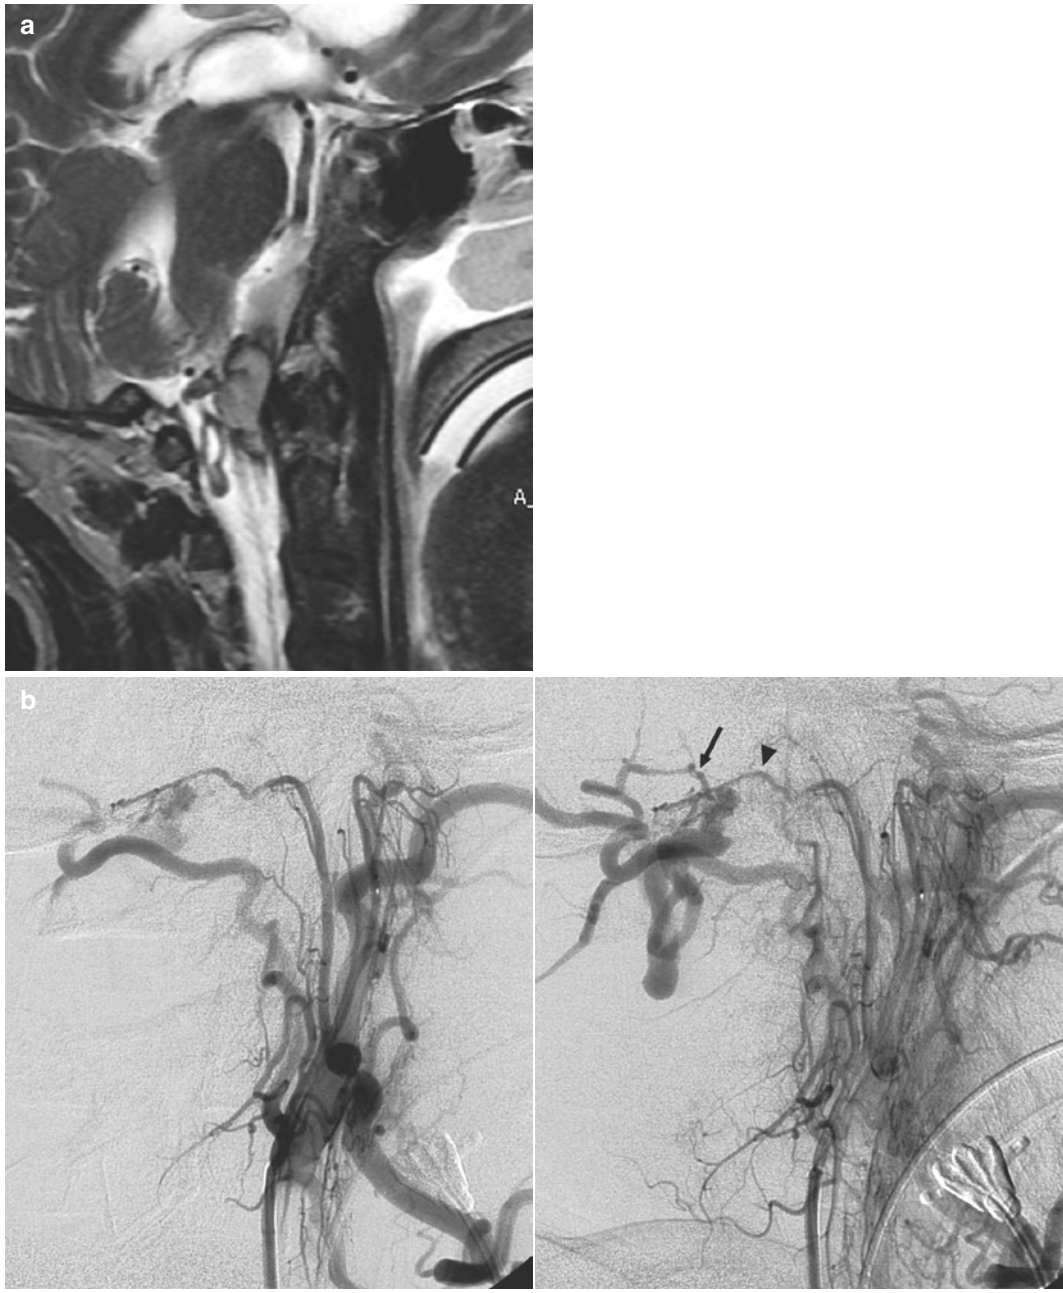

Fig. 13.22 DAVF of the foramen magnum presenting with SAH and subdural hematoma localized in front of the medulla in a young patient. (**a**) MRI T2-weighted sagittal image showing the hematoma and dilated perimedullary veins. (**b**) External carotid angiogram, lateral views, early and later phases, showing the fistula supplied by the hypoglossal branch of the APhA (*arrowhead*) and mastoid branch of the occipital artery (*arrow*). (**c**) Selective study of the APhA showing the site of the shunt (*circle*) and venous drainage involving dilated veins lateral to the medulla, continuing caudally to the perimedullary veins (*arrows*) of the spinal cord. The drainage is also directed intracranially, involving, among others, the pontine veins (*arrowheads*). (**d**) The same site of the shunt visible on the selective occipital artery angiogram. (**e**) Right vertebral angiogram showing a small meningeal component (*arrowhead*). In the later phases, the drainage (*inclined arrows*) in the enormous dilated pontine vein is visible. Endovascular treatment with almost complete occlusion of the fistula with acrylic glue followed by surgical evacuation of the hematoma was performed. The deeply comatose patient recovered

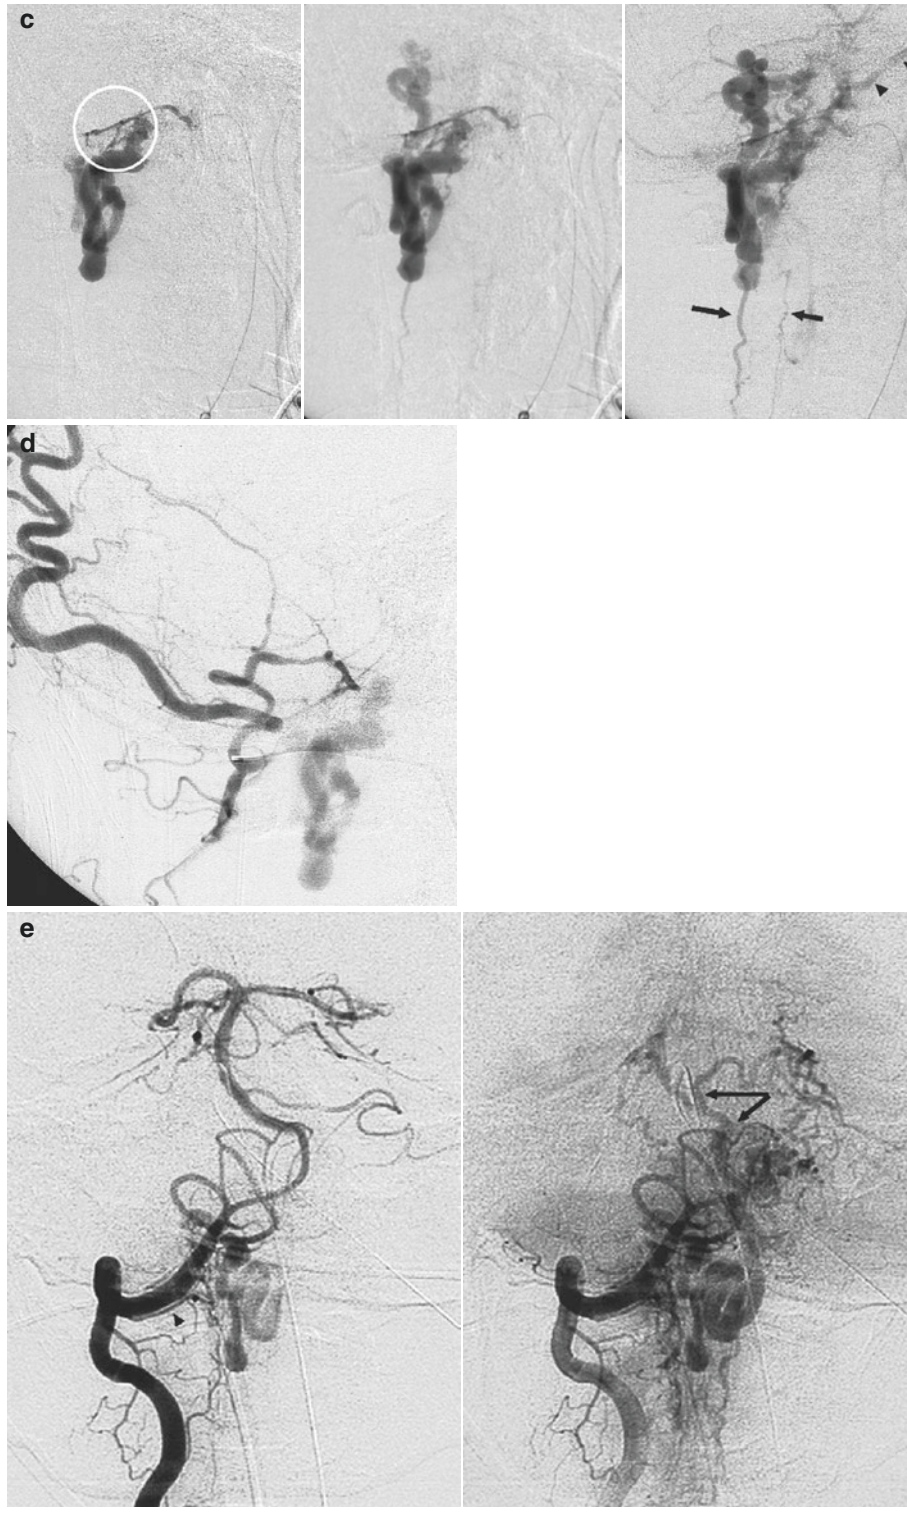

Fig. 13.22 (continued)

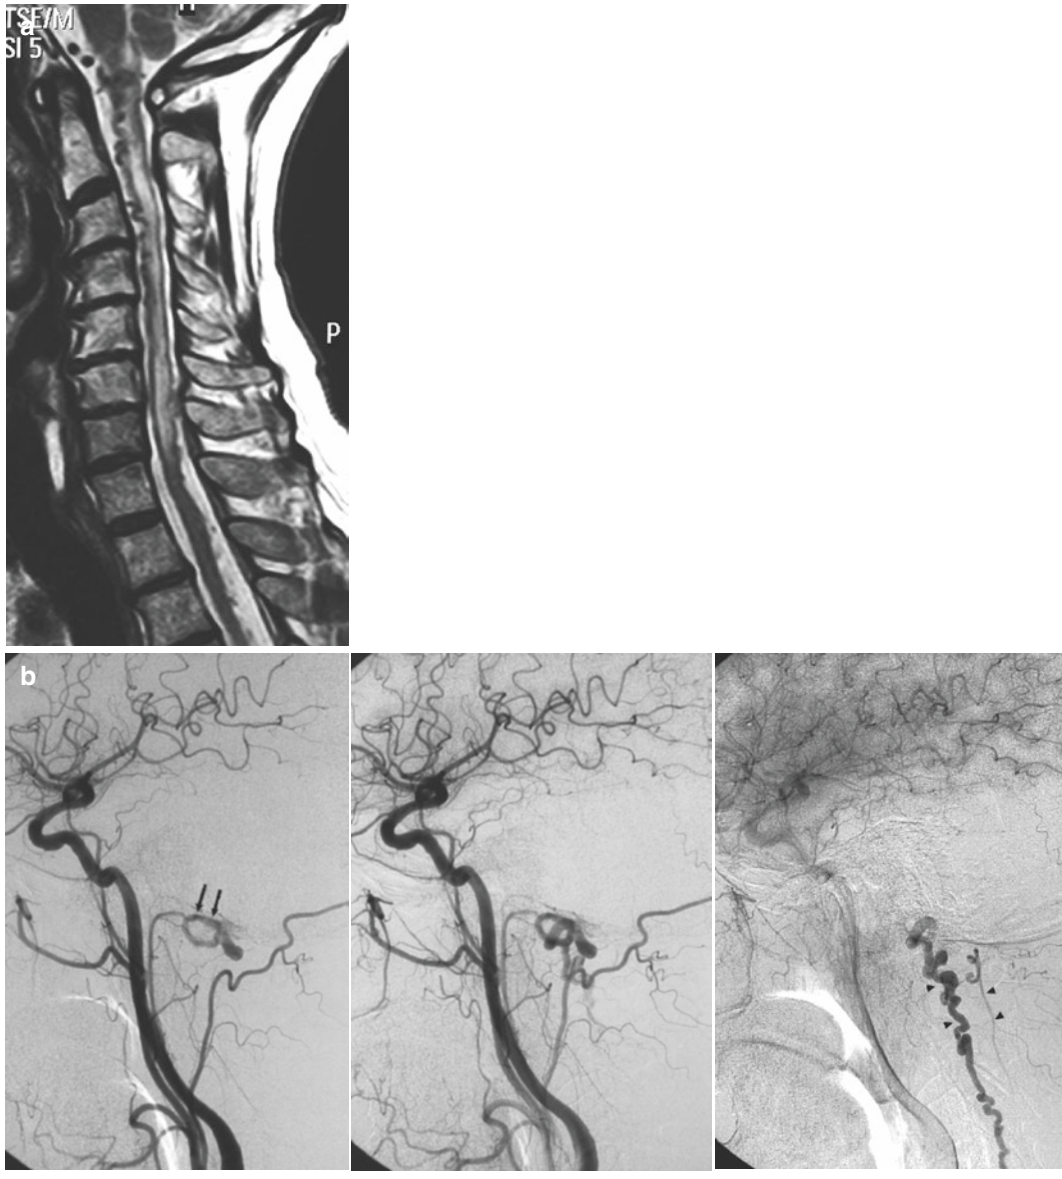

Fig. 13.23 Old woman presenting with rapid progressive tetraplegia. (**a**) MRI T2-weighted image. Extensive hyperintensity of the cervical spinal cord associated with dilated vascular structures is shown, suggesting vascular malformation. (**b**) Angiogram of the common carotid artery. Lateral view. A DAVF supplied by the hypoglossal branch of the AphA is identified. Site of the shunt (*arrows*). In the later phases the drainage in the dilated perimedullary veins is recognizable (*arrowheads*). (**c**) Vertebral angiogram. Lateral view. Supply from a small meningeal branch (*arrow*). Perimedullary drainage (*arrowheads*). Endovascular treatment with catheterization of the hypoglossal branch and injection of glue was soon performed. The patient, however, did not recover and died

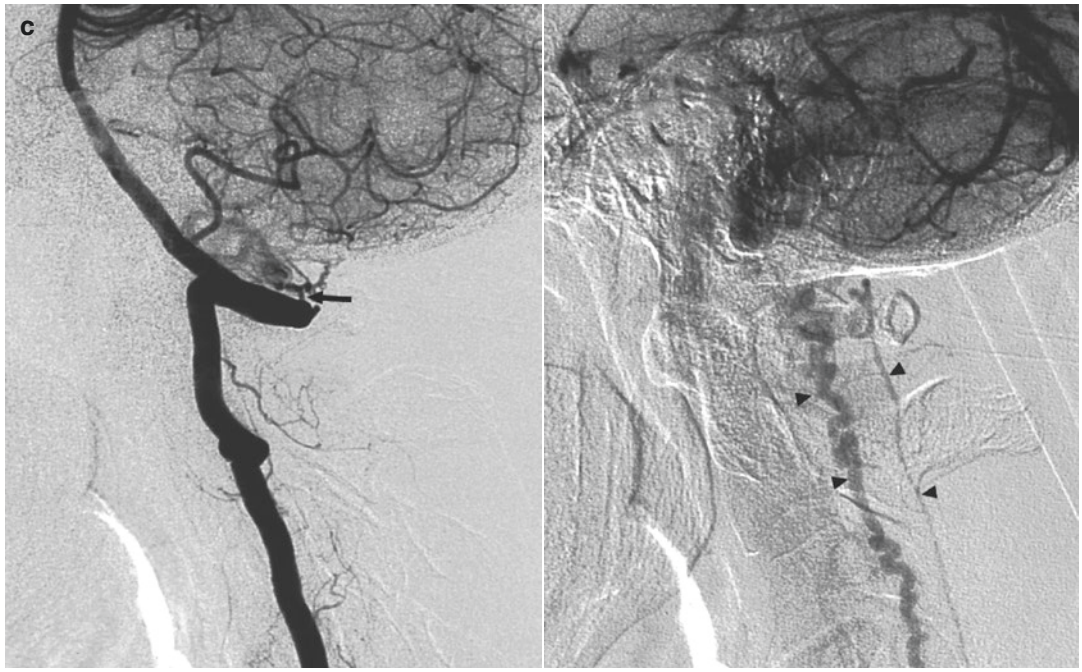

Fig. 13.23 (continued)

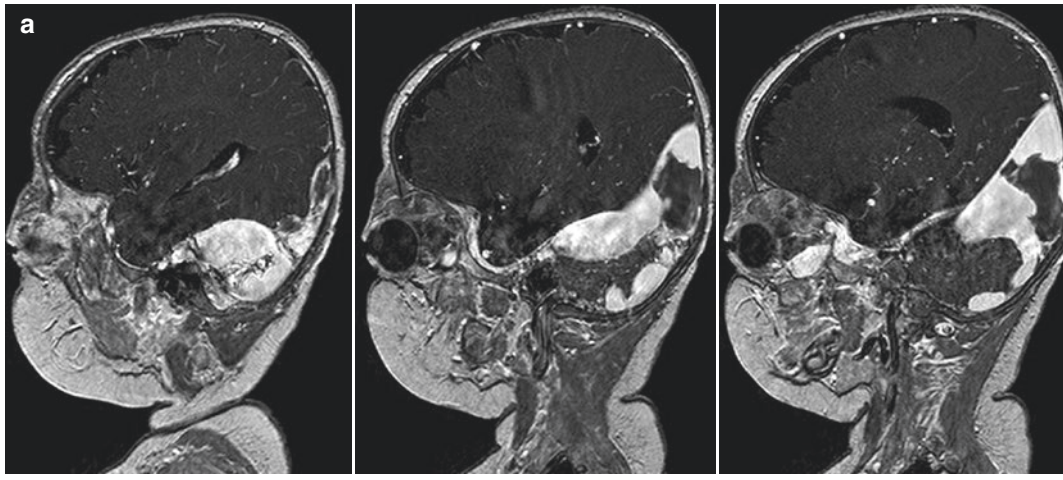
13.8 DAFVs in Pediatric Patients

These are rare malformations. According to Lasjaunais (1997), they can be divided into the following two groups:

- DAVFs in *neonates and younger children.* These very rare fistulas, and are characterized by huge dural lakes which are thought to be the primary pathology, commonly involving the SSS, TS, and SiS, associated with thrombotic occlusion or hypo-agenesis of the jugular vein. There is a slow-flow communication between the sinuses. Secondary to the sinus malformation, many shunts develop within the wall of the sinus. Pathogenesis is unclear. They are considered as congenital malformation developing in the prenatal period. An example is presented in Fig. 13.24.
- DAVFs *in older children.* They can share the same features as those in adults. In one third of the cases, however, some particular aspects are present (Garcia-Monaco et al. 1991; Lasjaunais 1997). The DAVFs are multifocal and show in addition the development of shunts involving the pial arteries. The sinuses to which the high-flow dural shunts converge can be dilated without, however, presenting the huge lakes of the previous group. Thrombosis of the sinuses is frequently present. This can be due to many factors; among them trauma and a systemic hypercoagulable state have been considered (Kraus et al. 2000; Walcott et al. 2013; Gross et al. 2013). Other authors (Morales et al. 2010) have reported a case of DAVF in a child developed subsequent to a sinus thrombosis. This raises the question if in children, similarly to the adults, theses fistulae at least in some cases are acquired lesions. An Example is shown in Fig. 13.25.

Progress has been made in the endovascular treatment of this complex pathology. This treatment alone or associated with surgery has improved the prognosis in many of these patients.



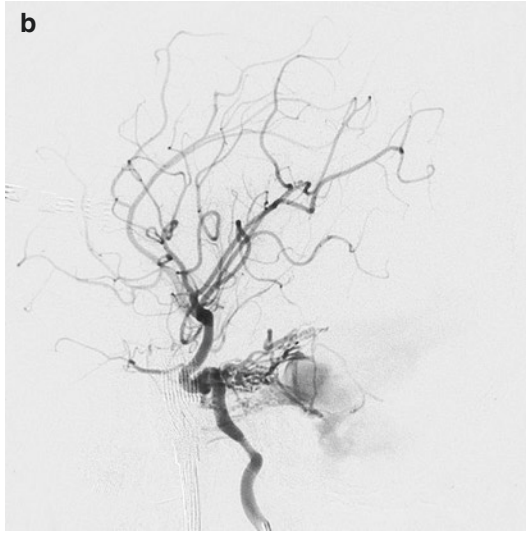


Fig. 13.24 One-year-old child presenting with epileptic seizures. (**a**) MR study T1-weighted images with contrast medium. Lateral view. A venous lake due to an huge dilatation of the TS and SiS extending anteriorly to the SPS and posteriorly to the torcular herophili and posterior part of the SSS is recognizable. An intraorbital pathology (lymphangioma) (*arrow*) was also present. (**b**) On the ICA angiogram there are several branches arising from the cavernous segment of the artery converging to the SPS and TS. The several components of the dilated sinuses fill slowly and only partially (**c**). On the later phases of the ICA angiogram, the normal antero-middle portion of the SSS is filled. The distal dilated segment communicates slowly (*arrow*) with the huge lake. There is a partial rerouting of the venous drainage towards the SMCV (*arrow with dot*) draining into the CS further continuing into the retrograde filled SOV. The jugular vein is not recognizable. (**d**) ECA angiogram showing a second rich supply from the petrosquamous branch of the MMA. Occlusion of the supplying vessels, followed by surgical eradication of the huge lake was performed

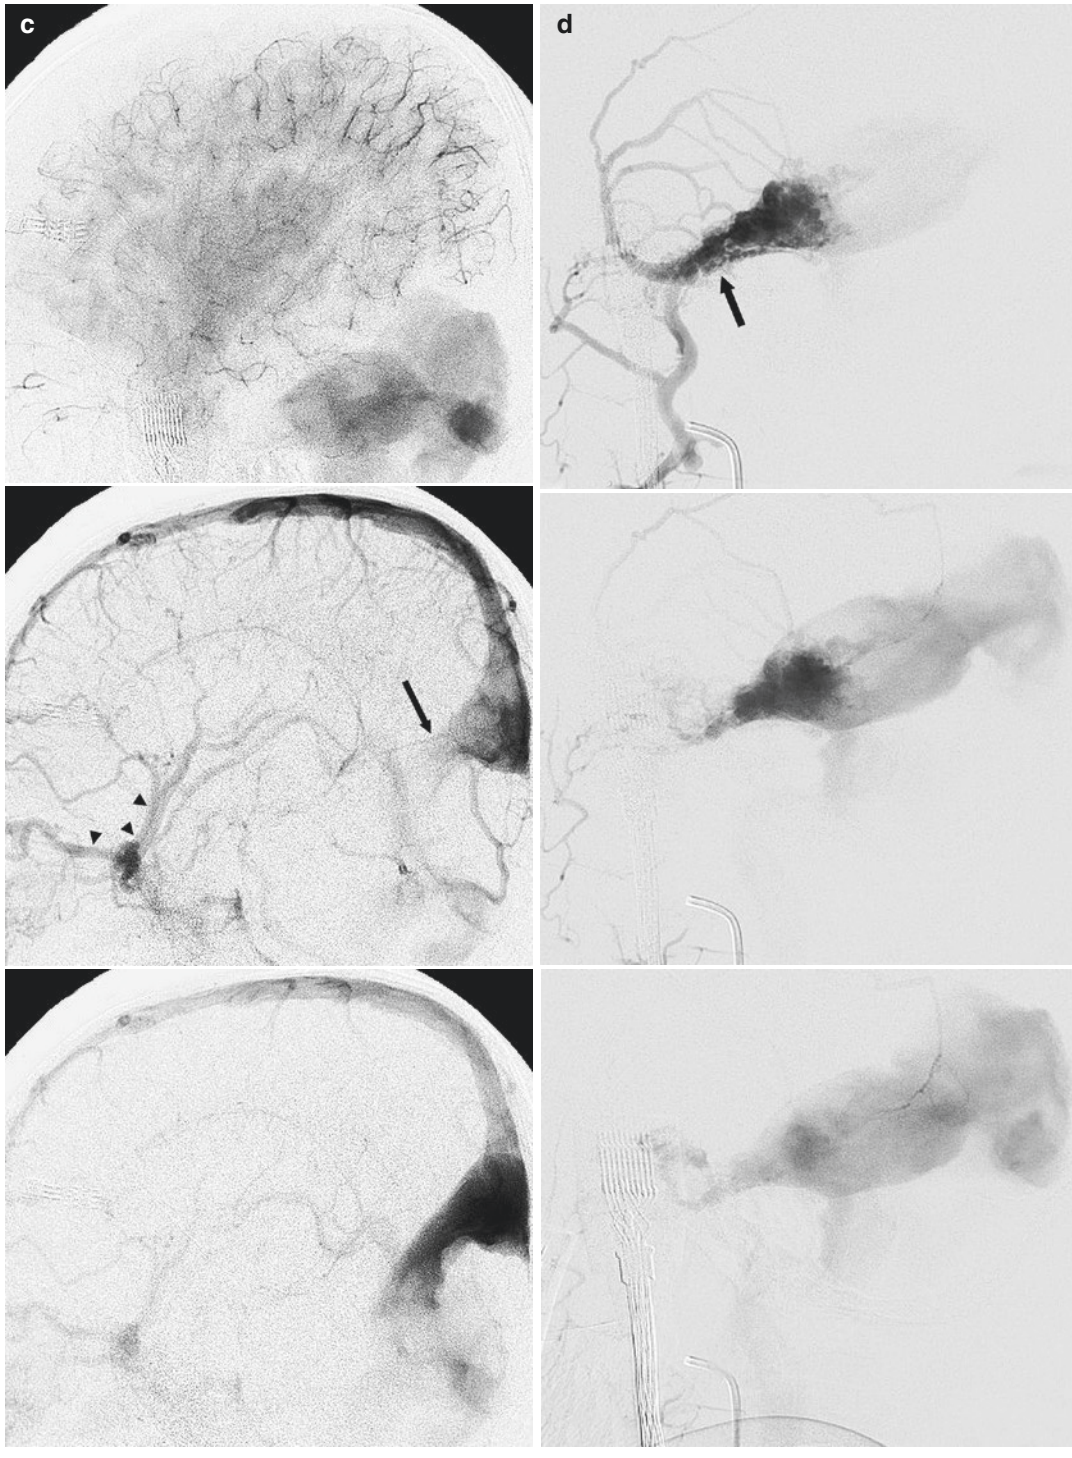

Fig. 13.24 (continued)

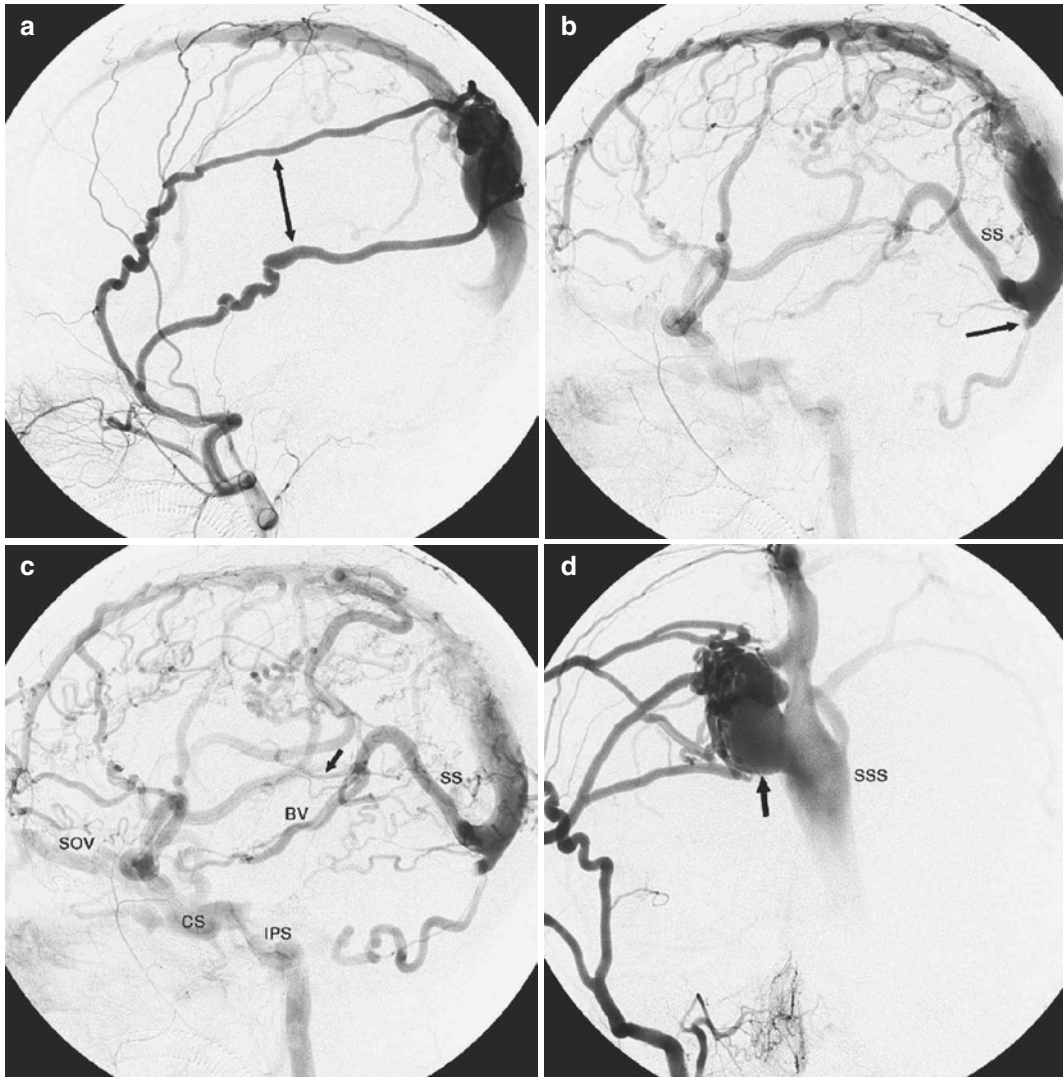

Fig. 13.25 Dural arteriovenous fistula at the level of the SSS in a child. Angiogram (**a**) of the right external carotid artery (lateral view). Dilated branches of the middle meningeal artery (MMA) (*arrow*), supplying the fistula in the middle portion of the enlarged SSS. A meningeal supply also came from the left MMA. Early (**b**) and late (**c**) venous phase. The SSS is distally occluded at the level of the torcular Herophili (*arrow*). There is a venous congestion, with rerouting of the venous drainage partially in the straight sinus (SS) and further in the internal cerebral vein (*arrow*), especially in the basal vein (BV) bilaterally, continuing to its anterior tributaries. The superficial venous system drains mainly into the cavernous sinus (CS) and further to the inferior petrosal sinus (IPS), jugular vein, and superior ophthalmic vein (SOV). There is also a retrograde injection of the dilated cerebellar vein. Right external carotid angiogram, AP view (**d**) showing that the connection to the SSS occurs through a large venous pouch (*arrow*), to which converge several branches of the MMA. In the late phase (**e**), the duplicated SSS, dilated on the left, is visible. Both TSs are proximally occluded (*arrows*). Retrograde injection of the basal veins (BV)

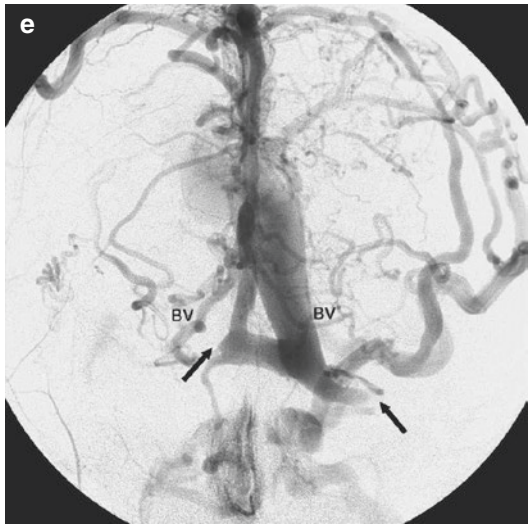

Fig. 13.25 (continued)

Arteriovenous Fistulas 14

Arteriovenous fistulas are direct abnormal communication between arteries and veins. They can occur in any locations where both vessels run very close to each other.

14.1 Carotid-Cavernous Fistulas

These are the most frequent type of arteriovenous fistulas, characterized by a direct shunt between the intracavernous segment of the internal carotid artery (ICA) and the surrounding venous plexus of the cavernous sinus. The pathogenesis is commonly a rupture of the artery and veins, after a penetrating or blunt trauma. Spontaneous fistulas can also occur: these are commonly due to rupture of an intracavernous aneurysm of ICA, frequently linked to an associated angiodysplasia such as FMD, Ehlers-Danlos syndrome and neurofibromatosis (Kanner et al. 2000). Fistulas resulting from spontaneous dissection of ICA have been described (Bradac et al. 1985), and cases developing from laceration of the artery during transsphenoidal surgery have also been reported.

14.1.1 Clinical Presentation

Carotid-cavernous fistulas are characterized by a typical cavernous sinus syndrome with ophthalmoplegia, visus involvement, pulsating exophthalmos, chemosis, and bruit. The symptoms can appear acutely or slowly, progressively days or weeks after the trauma, or have a spontaneous onset. Commonly adults, but sometimes also children can be involved. Like in cases of DAVFs involving the cavernous sinus also in direct carotid-cavernous fistulas, ischemic or hemorrhagic cerebral complications can develop as a result of the several connections of the cavernous sinus as described in Sects. 9.3.10 and 13.7.

14.1.2 Diagnosis and Treatment

The dilated cavernous sinus and superior ophthalmic vein can be easily recognized on CT or MRI. Angiography is essential for a precise diagnosis and in planning treatment. Carotid-cavernous fistulas are high-flow shunts with a rapid injection on the angiogram of the cavernous sinus. Depending on the location of the shunt and anatomical, further drainage can prevalently be directed as follows: anteriorly in the superior-inferior ophthalmic veins, in which the flow is reversed extracranially, draining into the facial vein system; posteriorly into the superior-inferior petrosal sinuses. Through intercavernous anastomoses, there can be involvement of the contralateral cavernous sinus. The pontomesencephalic, the basal, and the superficial and deep middle cerebral veins can also be involved (see also Sects. 9.3.10 and 13.7).

G.B. Bradac, *Applied Cerebral Angiography*, DOI 10.1007/978-3-319-57228-4_14

In cases of a large laceration of the ICA, the blood flow passes completely in the venous sector, and on the angiogram no cerebral arteries are recognizable. The angiographic study consists of a bilateral carotid examination to exclude a possible bilateral lesion and to check for a collateral circulation. The ECA should be also investigated since in some cases its branches, especially the internal maxillary and ascending pharyngeal arteries can be involved. To precisely identify the site of the shunt, a vertebral angiogram with compression of the involved ICA is very useful.

Endovascular treatment with a detachable balloon to occlude the shunt proposed and developed by Serbinenko (1974) and Debrun et al. (1975a, b) has progressively become the therapy of choice. The treatment is performed today with a balloon or coils with good clinical and anatomical results and limited morbidity and mortality (Berenstein and Kricheff 1979; Debrun et al. 1981; Scialfa et al. 1983; Kendall 1983; Lewis et al. 1995; Gupta et al. 2006). An alternative route, introduced by Mullan (1979), Manelfe and Berenstein (1980), and Halbach et al. (1988a) and increasingly used today, is the endovascular venous approach. With this technique coils are directed positioned in the cavernous sinus reached with a microcatheter pushed from the IJV in the facial and further in the superior ophthalmic veins. Another way is that through the inferior petrosal sinus.

Examples are presented in Figs. 14.1, 14.2, and 14.3.

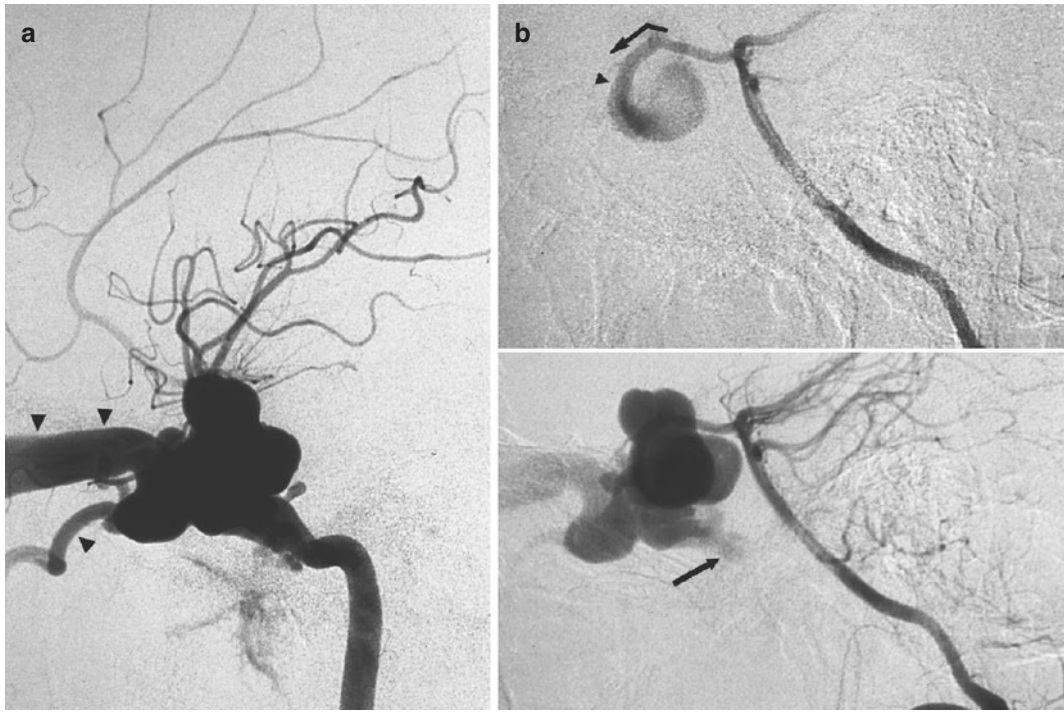

Fig. 14.1 Traumatic carotid-cavernous fistula. (**a**) Internal lateral carotid angiogram. There is an immediate injection of the dilated and deformed cavernous sinus and filling of the dilated superior (*arrowheads*) and inferior ophthalmic veins. (**b**) Lateral vertebral angiogram with compression of the involved internal carotid artery. Through the posterior communicating artery, there is injection of the internal carotid artery and fistula. Site of the shunt (*arrowhead*). In a later phase, there is a partial injection of the inferior petrosal sinus, which could be thrombosed (*arrow*)

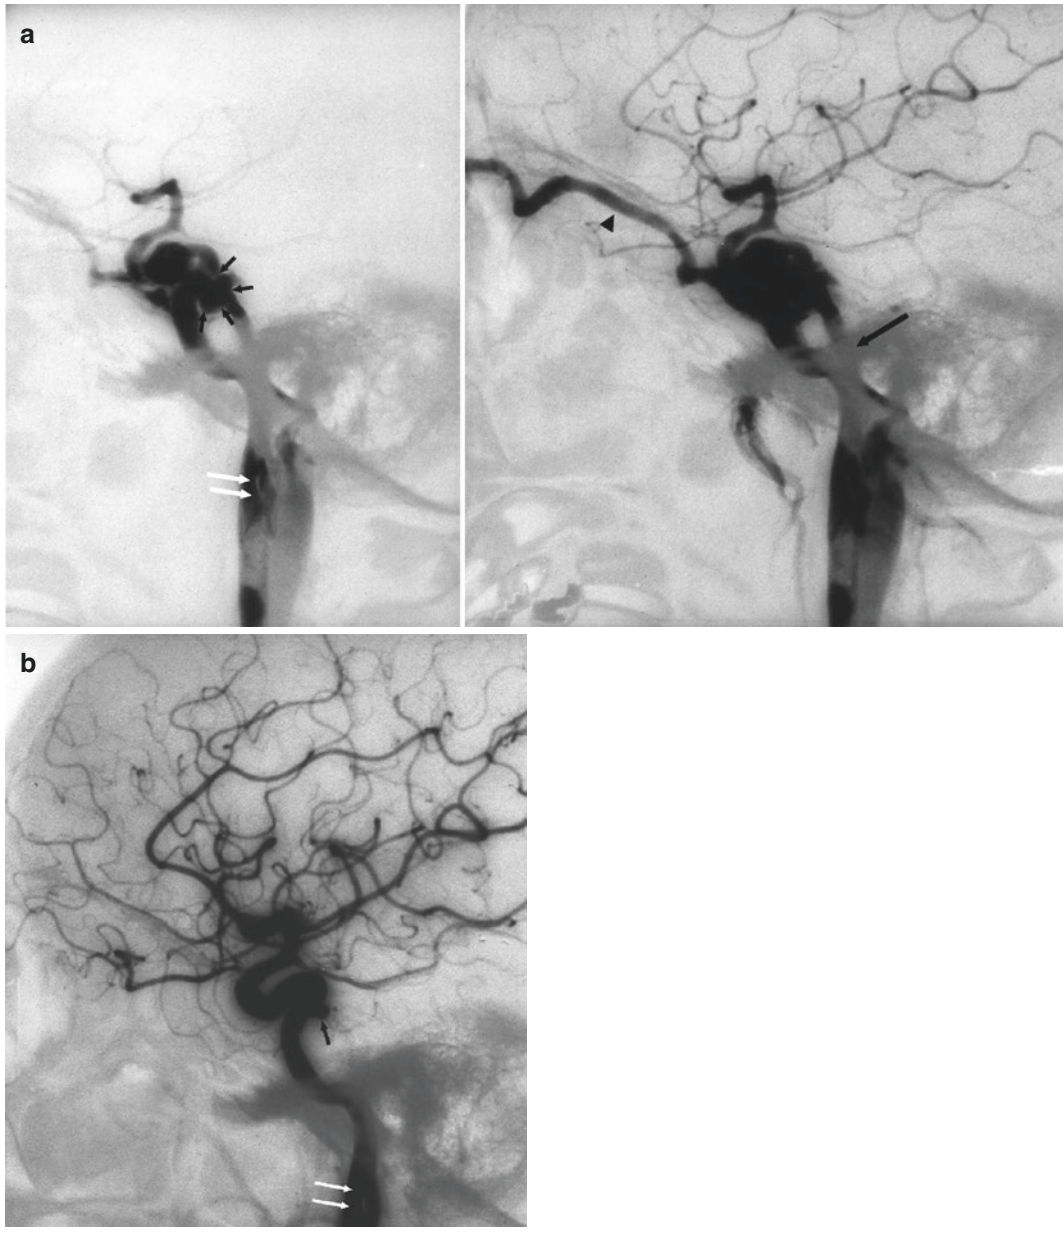

Fig. 14.2 Spontaneous carotid-cavernous fistula in a young patient, which appeared after heavy vomiting caused by alcohol intoxication. (**a**) Lateral carotid angiogram. The small arrows show the site of the shunt. There is drainage in the superior ophthalmic vein (*arrowhead*) and inferior petrosal sinus (*arrow*). There is also a minimal injection of the pterygoid plexus. The extracranial internal carotid artery is slightly enlarged, and there is an intraluminal defect (*white arrows*), suggesting dissection. It is possible that the dissection has extended intracranially, leading to formation of the fistula. The shunt was occluded with a balloon. (**b**) Control angiogram 2 months later. The balloon is now deflated. A small pseudoaneurysm (*arrow*) at the site of the fistula is recognizable. The dissection is unchanged (*white arrow*)

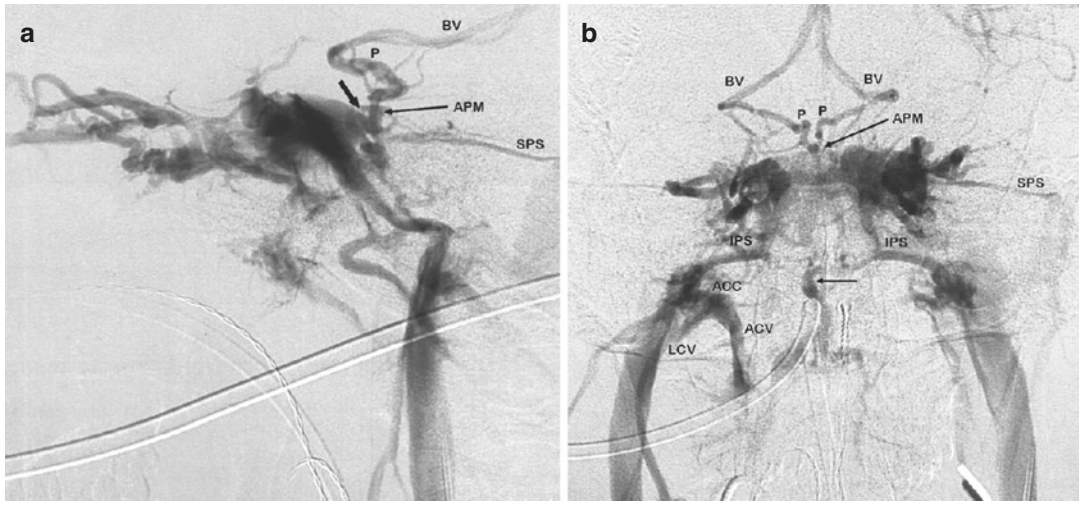

Fig. 14.3 Large traumatic carotid-cavernous fistula. Left carotid angiogram, lateral (**a**) and AP (**b**) 2 s after injection into the internal carotid artery. Extensive anterior (ophthalmic veins) and posterior (petrosal sinuses) drainage. There is also an injection of the contralateral sinus. Bridging veins visible in the lateral view (*arrow*) connect the cavernous sinus with the anterior pontomesencephalic veins (APM), which via the peduncular veins (P) continue into the basal vein (BV) bilaterally. Inferior petrosal sinus (IPS), superior petrosal sinus (SPS), and anterior condylar confluence (ACC) continuing into the anterior condylar vein (ACV) and lateral condylar vein (LCV). Through injection of the clival venous plexus, filling also of the anterior epidural vertebral plexus (*arrow*)

14.2 Vertebral Arteriovenous Fistulas

This is a very uncommon pathology, characterized by a shunt between the vertebral artery and the surrounding vertebral venous plexus. The pathogenesis is traumatic due to a penetrating or blunt cervico-vertebral trauma (Goodman et al. 1975; Halbach et al. 1988b), associated sometimes with bony fractures. Cases of spontaneous fistulas can occur (Halbach et al. 1988b), sometimes in patients with angio-dysplasia such as FMD, Ehlers-Danlos and Marfan syndrome (Bahar et al. 1984), and neurofibromatosis (Deans et al. 1982; Kahara et al. 2002). It can develop at any level of the vertebral artery, but C1, C2, and C3 are the most frequent locations.

14.2.1 Clinical Presentation

Progressive vertebrobasilar insufficiency leading to ischemia in the brainstem and/or spinal cord can occur. The dilated venous sector can compress the nerve root. Paraspinal bruit and cervical pain are present.

14.2.2 Diagnosis and Treatment

Angiography is essential to define the lesion precisely and to plan the treatment, which will be basically endovascular (Moret et al. 1979; Miller et al. 1984). Examples are presented in Figs. 14.4 and 14.5.

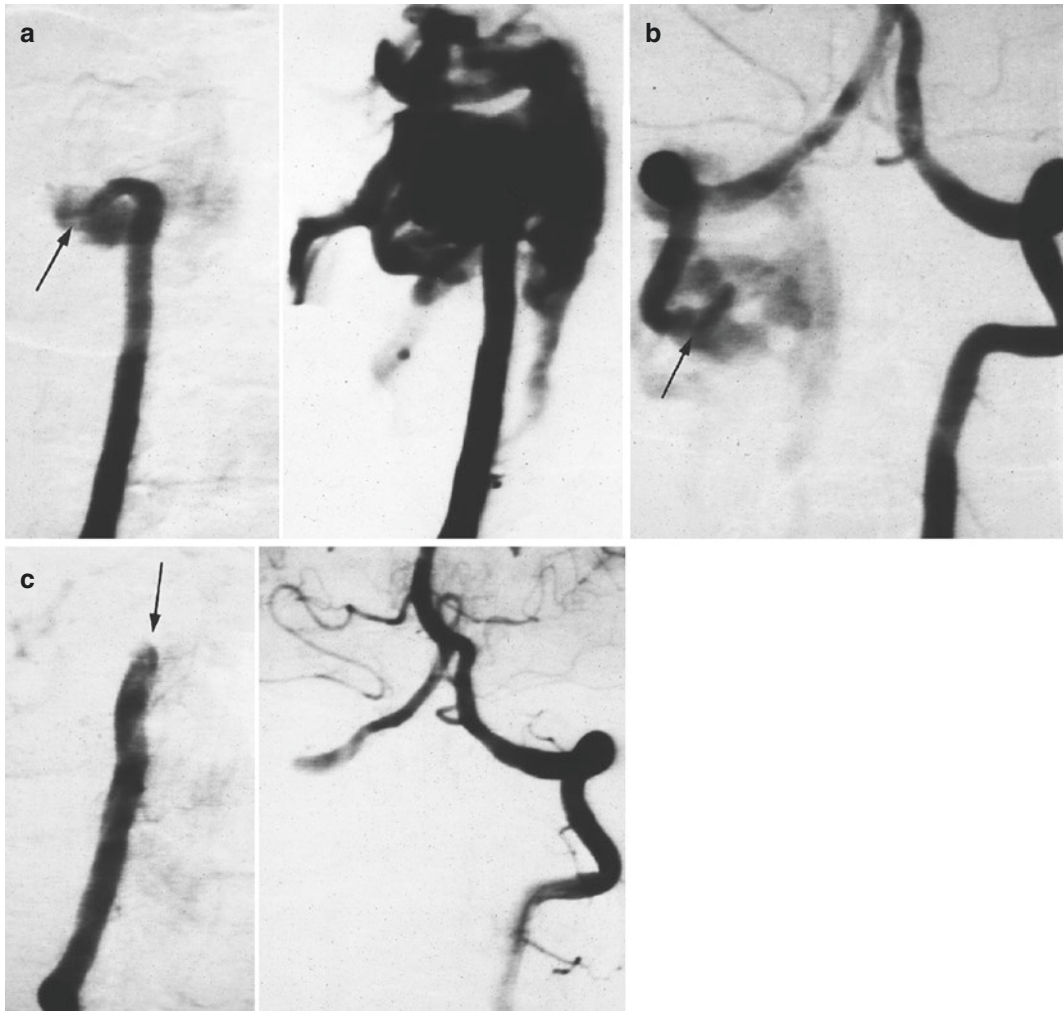

Fig. 14.4 Spontaneous vertebral arteriovenous fistula. (**a**) Right vertebral angiogram, showing the site of the shunt (*arrow*) at the C2 level. There is immediate extensive venous drainage. (**b**) Left vertebral angiogram with retrograde injection of the right vertebral artery better displaying the site of the shunt (*arrow*). Occlusion of the fistula and right vertebral artery with a balloon. (**c**) Control angiograms of the right occluded vertebral artery (*arrow*) and left vertebral artery showing the retrograde filling of the occluded right VA down to the site of occlusion

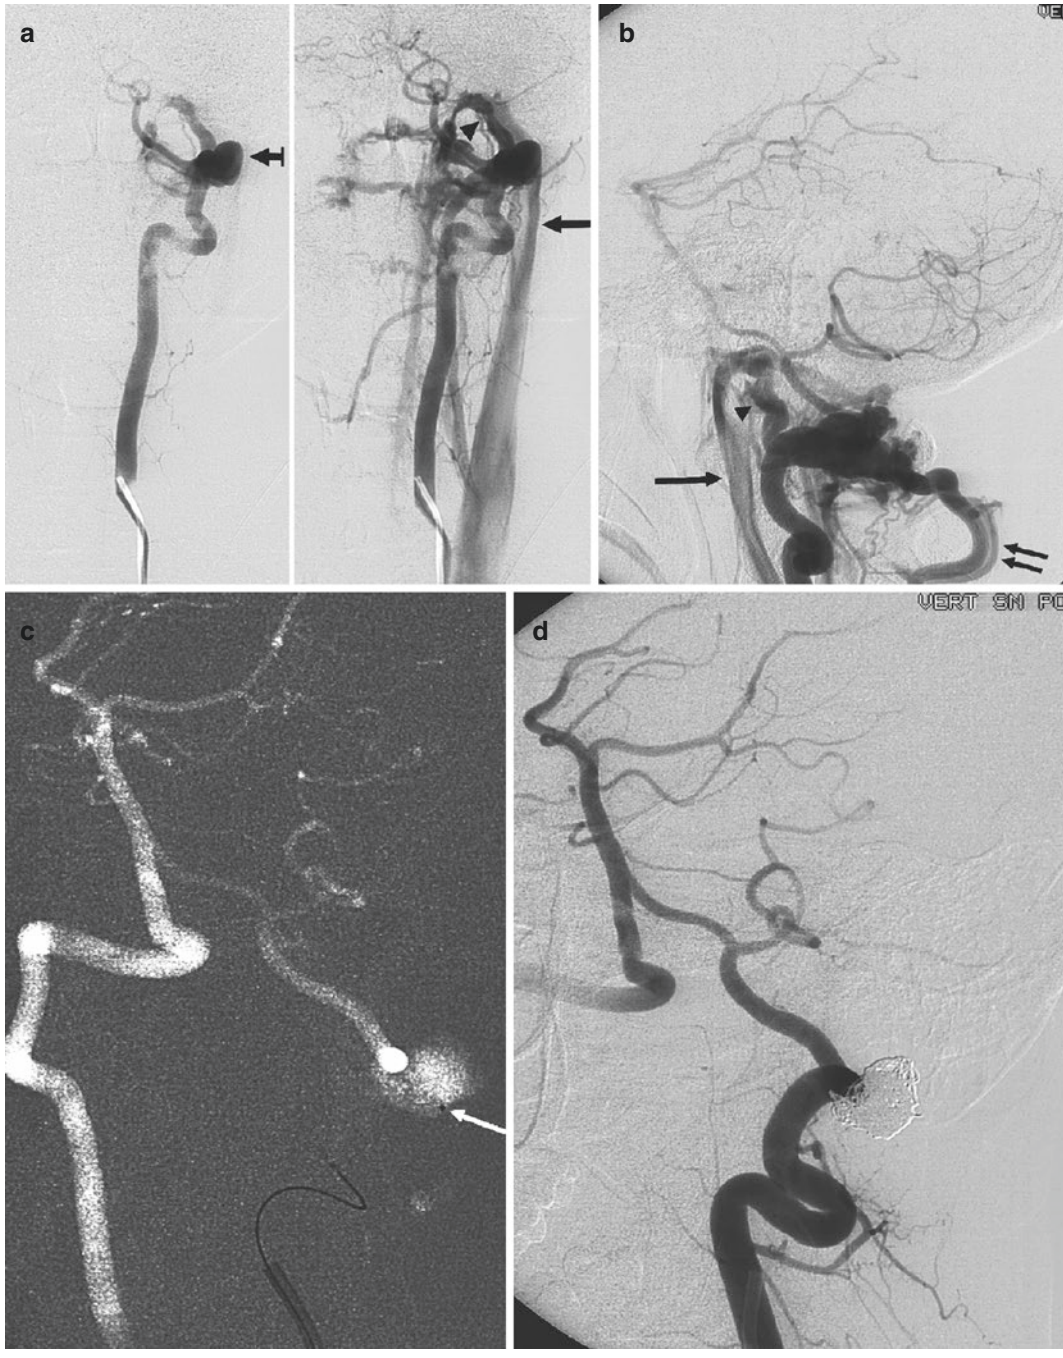

Fig. 14.5 Spontaneous fistula between the left vertebral artery and surrounding venous plexus at the level of C1. Left vertebral angiogram, AP view (**a**), lateral view (**b**). There is a shunt between the dilated vertebral artery and venous plexus, which is dilated and forming a large pouch (*arrow with line*). The venous drainage continues into the retrogradely injected and dilated lateral or posterior condylar vein (*arrowhead*) and further into the internal jugular vein (*large arrow*). There is also drainage into the deep cervical vein (*double arrows*). Right vertebral angiogram (**c**) prior to endovascular treatment. There is retrograde injection of the left vertebral artery and venous pouch site of the shunt. A microcatheter has been advanced into the left vertebral artery and placed in the venous pouch. The white arrow shows the distal marker of the microcatheter. Left vertebral angiogram (**d**) post treatment. Occlusion of the fistula with coils

Ischemic Stroke

15

Stroke is the third cause of death and disabling in the general population after heart disease and cancer. It can be basically divided into one group due to occlusion of the vessels (arteries or veins) leading to ischemia and another in which rupture occurs resulting in hemorrhage. The latter is discussed in Chaps. 11, 12, 13 16, 17, 21, and 22. In this chapter the ischemic stroke due to a pathology involving the arteries is described. Thrombosis in the venous sector is discussed in Chap. 20.

It is slightly more frequent in men than in women. It is more rare in young patients. Some racial differences occur. In general it is less frequent in Caucasian than in non-Caucasian and there is an higher incidence in blacks in comparison to the whites (Sacco et al. 1991; Sacco 1993). The main pathological process responsible for stroke is atherosclerosis affecting the extra-intracranial arteries. Less commonly, stroke is due to other pathologies, such as spontaneous dissection and other nonatherosclerotic arteriopathies as well as heart diseases. These latter will be described in Chaps. 16–18, and 19.

Atherosclerosis is a generalized condition involving predominantly certain vascular territories: the aorta, the iliac, the coronary, and the extra-intracranial arteries. It is a typical pathology of the adulthood, and the likelihood of occurrence increases with the age. There is a slight predominance among men.

15.1 Pathology

It is not the aim of this monography to treat the pathology of the atherosclerosis, for which we refer to specific works (Miller and Sobey 2011). We describe here only the basic point. The pathologic changes begin with a dysfunction of the endothelial cells, due to various stress factors such as hypertension, diabetes, elevated cholesterol level especially of the low-density lipoproteins, obesity, hyperhomocysteinemia, and cigarette smoking, which promote the passage and deposit of cholesterol in the subendothelial space. Further injury of the endothelial cells promotes the passage into the subendothelial space of monocytes, which progressively engulf lipid and become foam cells. Dysfunction and proliferation of smooth muscle cells, migration of lymphocytes, cell necrosis, and collagen production follows (Witznum and Steinberg 1991; Ohara et al. 1993; Libby and Clinton 1993; Garcia et al. 1998). All these processes lead to the formation of the atheromatous plaque covered by a well-formed fibrous cap, which can extend progressively into the lumen of the artery, resulting in stenosis. The evolution of the plaque can vary from a stable course to a slow or rapid growth leading to a progressive narrowing and occlusion. Hemodynamically, stenosis, leading to a major reduction of flow and thereby, increasing the risk of ischemia, has to be rather severe,

G.B. Bradac, *Applied Cerebral Angiography*, DOI 10.1007/978-3-319-57228-4_15

as previously described (Brice et al. 1964; Archie and Feldman 1981). It is important to note, however, that in a certain number of cases, the plaque can slowly progress up to complete occlusion of the vessel, but remains asymptomatic. *This occurs when the collateral circulation is efficient and there has been no distal embolization during the progression of the plaque.*

Erosion of the endothelial cells and breakdown of the fibrous plaque leads to exposure and delivery of the material inside the plaque, favoring the formation of thromboembolic material. Further reduction of the lumen up to occlusion can occur due to formation of an intraplaque hemorrhage. This latter can be due to the entry of blood into the plaque through erosion of the fibrous cap or disruption of the vasa vasorum which are abundant in advanced atherosclerotic lesions (Fisher and Ojeman 1986; Bo et al. 1989; Beach et al. 1993). The improvement of the diagnostic tools allows today to study the structure of the plaque, giving useful information about its possible evolution (see also Sect. 15.4.1).

15.2 Location

Atherosclerosis affects mainly the extracranial segments of the arteries. Especially involved are *the carotid* bifurcation and the adjacent segments of the internal and common carotid arteries, and *the proximal vertebral* and the subclavian arteries. Other less frequent sites, however, not so rare as previously thought are the *aortic arch and the proximal common carotid artery*. Multiple vessels are frequently involved. Atherosclerosis can also involve *the intracranial arteries*. According to some reports, the incidence of significant intracranial atherosclerosis in patients with transient ischemic attacks (TIAs) or stroke has been given as 4% (Thijs and Albers 2000). The incidence of these lesions is reported to be higher among Blacks and Asians (Caplan et al. 1986; Caplan 1989; Feldmann et al. 1990; Wong et al. 1998; Min et al. 2000; Thijs and Albers 2000). The most common site are the distal ICA and the basilar and intracranial vertebral arteries. Less frequent involved are the first segment of the middle and anterior cerebral arteries, the pericallosal artery around the genu of then corpus callosum and the first segments (P1–P2) of the posterior cerebral artery (Fisher et al. 1965; Fisher and Caplan 1971; Castaigne et al. 1973, 1981; Kavase et al. 1979; Hinton et al. 1979; Bradac and Oberson 1983; Caplan et al. 1986; Caplan 1989). Today, the intracranial lesions are the object of greater attention.

15.3 Pathogenesis of Ischemia and Basic Diagnostic and Therapeutic Approach

The mechanism leading to ischemia can be grouped into three categories:

- Thromboembolic occlusion or severe stenosis linked to atheromasic changes of the arteries or occlusion due to cardiac embolization leads to ischemia strictly related to the supplied territory. These infarcts are also called by some authors territorial infarcts (Ringelstein et al. 1983, 1985; Weiller et al. 1991).
- The occlusion or severe stenosis can involve the arteries in their proximal segments and the suffering territory is more distal and not in the vascular territory of a defined artery. Instead, the infarct is located at the borders of two different vascular territories (*border-zone infarcts*), where the collateral circulation due to the hypoperfusion is insufficient. This occurs typically in occlusion or severe stenosis of the ICA with cortical infarcts in the border zones between ACA, MCA and PCA. Similar infarcts can occur in the cerebellum in the distal border-zone areas between the PICA, AICA, and SCA in severe stenosis or occlusion of the vertebral arteries. Distal infarcts can occur also in the vascular territories of the deep and superficial perforators since these arteries are end arteries where no collateral circulation is present. The same type of infarct can also occur in hypoperfusion due to cardiac failure.

- A particular form of infarct is *the lacunar infarct* (from Latin, *Lacuna-ae*, small cavity). The term was first used by Dechambre in the 1838 and later by Durand-Fardel in the 1843 to express pathological findings due to small infarcts, hemorrhages or other causes. More precise reports were presented by Pierre Marie (1901) and Ferrand (1902), who used the term *lacunae* to describe small infarcts in the basal ganglia, capsula interna, and pons which presented some typical clinical aspects. However, the clinical relevance and the peculiar aspects of this pathology, termed *lacunar syndrome*, were emphasized and comprehensively discussed by Fisher (1965, 1968, 1979). CT and MRI have later played an important role in the diagnosis and identification of these lesions.
  Today lacunar infarcts are reported to account for about 25% of all cerebral infarcts (Bamford et al. 1987; Bougosslavsky et al. 1988b; Arboix et al. 1990; Boiten and Lodder 1991). Lacunar infarcts are due to involvement of the perforators (deep and superficial) due to various pathogenetic mechanisms. The vessels can be occluded directly by lipohyalinosis or indirectly through a microatheroma involving the parent artery from which they arise. Their vascular territory can also be involved due to hypoperfusion in cases of occlusion or severe stenosis located more proximal or in cases of cardiac failure. Microemboli from atheromasic plaques or in cardiac diseases can also lead to occlusion of the perforators.
- All these mechanisms can act in isolation or be variously associated with one another. Taking this into consideration, the neuroradiological diagnosis of these patients should include CT and MRI to examine the brain parenchyma, followed by a complete study of the cerebral vessels including the extra and intracranial sectors. The latter can be performed today with highly accurate CT and MR angiography and for the extracranial arteries also with ultrasound examinations. However, catheter angiography should be instituted every time the diagnosis is insufficiently clear or more information about the vessels are needed or in cases where endovascular treatment is considered. In addition to the study of the brain parenchyma and cerebral vessels, the aortic arch and a cardiac examination should be routinely performed.
  Considering, in particular the patients with an acute stroke, the type, site, size of the ischemia, and the identification of the artery and vascular territory involved can be today studied rapidly with CT. This should include CT-perfusion indicating which part of the parenchyma can be considered as lost and which can be savaged, and CT angiography. These give the information which are essential for the therapy especially in the cases of endovascular treatment.

15.4 Mechanism of Ischemia in the Anterior Circulation

The atheromasic process leading to ischemia can be various and complex due to the different location of the atheromasic plaque, which can involve typically the ICA bifurcation, but also, even if more rarely, all segments of the carotid from its origin from the aortic arch to its end. Plaques can develop in the aortic arch and in the intracranial branches of the ICA. The size and the evolution of the atheroma can be extremely various. Occlusion can also occur due to cardiac embolism or other vasculopathies (see Chaps. 16, 17, and 18). All these aspects can make sometimes difficult a precise diagnosis of the pathogenetic process responsible for the stroke in a given case. The angiographic studies can add some more information useful in the comprehension of the mechanism responsible for the ischemia and which are essential in planning the therapy.

15.4.1 Carotid Artery

15.4.1.1 Locations and Aspects of the Atheromasic Plaques

- *The most frequent and typical atheroma develops at the extracranial ICA bifurcation*, which can be responsible for narrowing of the lumen. Four degrees of stenosis have been

distinguished: *mild* when the lumen is reduced by less than 30%; *moderate* with 30–70% reduction of the lumen; *severe* if the reduction is greater than 70%; and *preocclusion state*, when the narrowing is more than 90%. In a few of these cases with a very severe stenosis, only a filiform column of contrast medium is visible in the late phase of the angiogram, demonstrating that the artery is patent but only minimally filled by contrast medium layering in the dorsal part of the lumen. This finding has been called in the past pseudo-occlusion (Sekhar et al. 1980; Bradac and Oberson 1983) (Fig. 15.4).

Today CT-MR angiography are valid diagnostic tools to study and measure the stenosis (Anzalone et al. 2005, Weber et al. 2015) being frequently a good alternative to the angiography. A few methods have been proposed: among them, the European Carotid Surgery Trial (ECST 1998) and North American Symptomatic Carotid Endarterectomy Trial (NASCET 1991) are the most used (Fig. 15.1) Differences in the applied criteria lead to differences in the results with this methods.

There is broad agreement that a stenosis of 70% with NASCET (corresponding to a stenosis of about 80% with ECST) is a clear indication for endarterectomy, thereby reducing significantly the risk of stroke. Alternatively, endovascular treatment has increasingly been

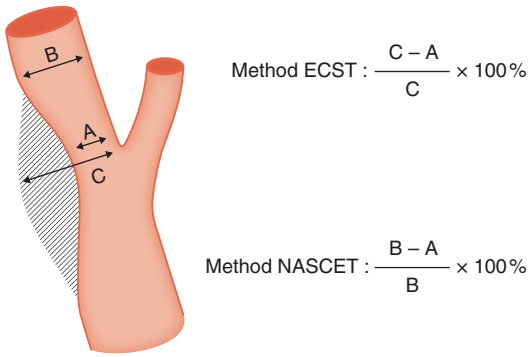

Fig. 15.1 Methods to measure ICA stenosis on the angiogram: European Carotid Surgery Trial (ECST) and North American Symptomatic Carotid Endarterectomy Trial (NASCET)

successfully performed (Wholey et al. 2000; Bonaldi 2002; Ringleb et al. 2006; Wittkugel et al. 2008; Stingele et al. 2008; Clark 2010) (Figs. 15.2 and 15.3).

Another important aspect, as it has already been described in Sect. 15.1, is the evolution of the plaque which can be extremely different (Arbeille et al. 1996). There are *stable plaques* which remain unchanged for years leading to a minimal narrowing of the lumen whose surface remain regular and smooth. When growth occurs, this is slow allowing a good collateral circulation to develop. Stable plaques can remain asymptomatic and discovered incidentally during vessels studies performed for other reasons. *That is true also for severe stenosis or occlusion provided that no embolization occurred and there is a good collateral circulation*. Other plaques are *unstable* characterized by a progressively sometimes even acute growth or ulcerations on which a superimposed thrombus develops. Distal embolization or acute hypoperfusion or both lead to ischemia presenting in various form of stroke (TIAs, mild, severe) (Figs. 15.2 and 15.4). An anterograde extension of the thrombus can also rarely develop (Fisher 1954; Castaigne et al. 1970). Furthermore it should be considered that changes of the plaque can occur which modify its aspect and so a stable plaque can become unstable or vice versa.

Taking this into account, attention has been progressively given to the components of the atheroma. These information can be obtained today using many methods (ultrasound, CT, and especially MR) in various combinations to each other. Progressively experience has shown that some components of the plaque such the fibrous cap, the amount of lipids, the presence of hemorrhage can be better studies with MRI (Ouhlous et al. 2005; Cappendijk et al. 2005; Cai et al. 2005; Wasserman et al. 2008; Gao et al. 2009; Watanabe and Nagayama 2010; Kurosaki et al. 2011; Liu et al. 2012; Yoon et al. 2012; Ture et al. 2012), while CT is more useful in demonstrating calcifications (Kwee 2010; Korn et al. 2015). The characterization of the plaque will give information

about its evolution, considering that the presence of calcifications is reported to be a sign of a more stable plaque (Kwee 2010; Korn et al. 2015), while thin or ruptured fibrous cap a rich lipid core and intraplaque hemorrhage occur more frequently in unstable plaques and so increasing the risk of stroke (Watanabe and Nakayama 2010; Kurosaki et al. 2011; Liu et al. 2012; Treiman et al. 2015). The morphologic aspect of the plaque, together with other aspects of the cerebral circulation especially the presence of absence of a collateral circulation as well the age, gender, and general clinical condition of the patient will influence the kind of therapy (medical or more aggressive approach), and also which kind of approach either the endovascular or the endarterectomy should be chosen. All these aspects should be considered in the attempt to offer the patient the more appropriate treatment (Rosencranz and Gerloff 2010).

- *Atheroma can also occur in the intracranial segments of the ICA*, typically in the distal petrous and cavernous segment. These changes have already been described in the past by some authors on autoptic studies (Yates and Hutchinson 1961; Castaigne et al. 1970). Recently, some authors have shown on autoptic (Mazighi et al. 2008) and on MR studies (Lee et al. 2015) that even subtle atheromasic changes without clear stenotic character are frequently present in the distal

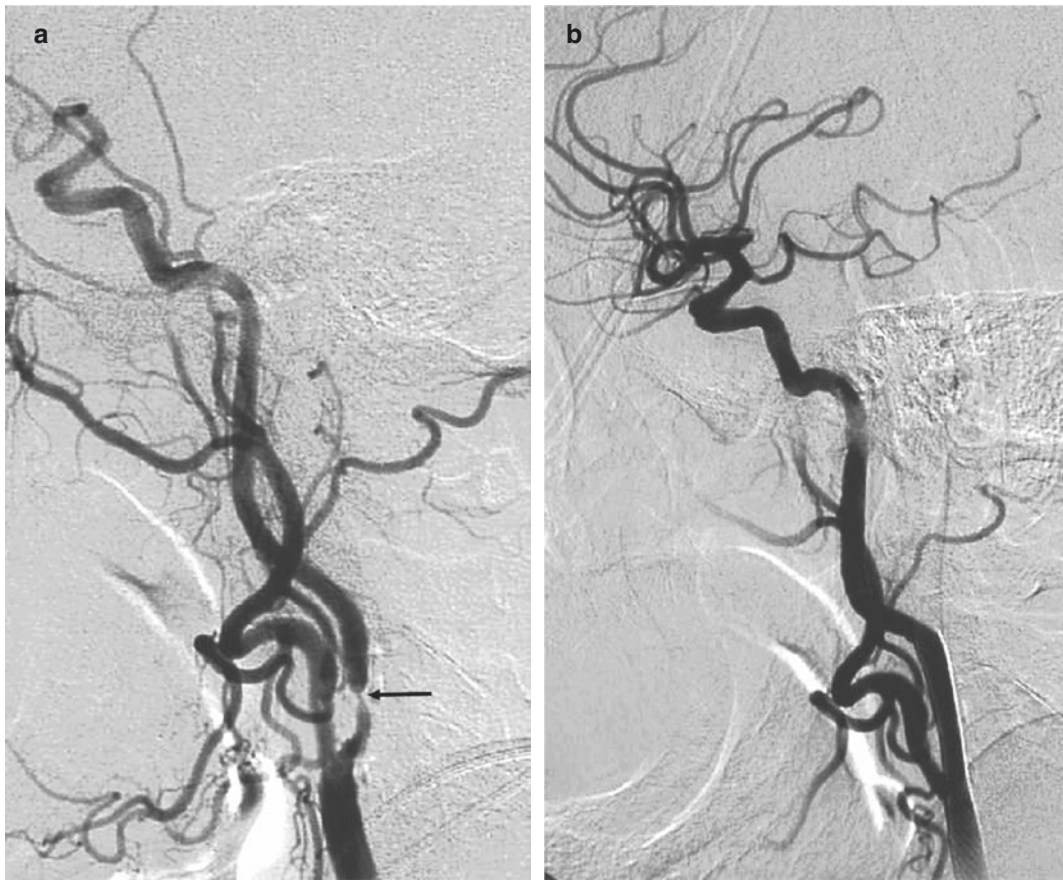

Fig. 15.2 Two examples of atherosclerotic plaque leading to severe stenosis of the ICA in patients with TIAs. (**a**) Carotid angiogram showing the stenosis (*arrow*) with slowing of the flow. (**b**) Angiogram after angioplasty and stent showing normalization of the lumen and flow. (**c**) Carotid angiogram showing the stenosis (*arrow*). (**d**) Angiogram after angioplasty and stent with normalization of the lumen and improvement in flow

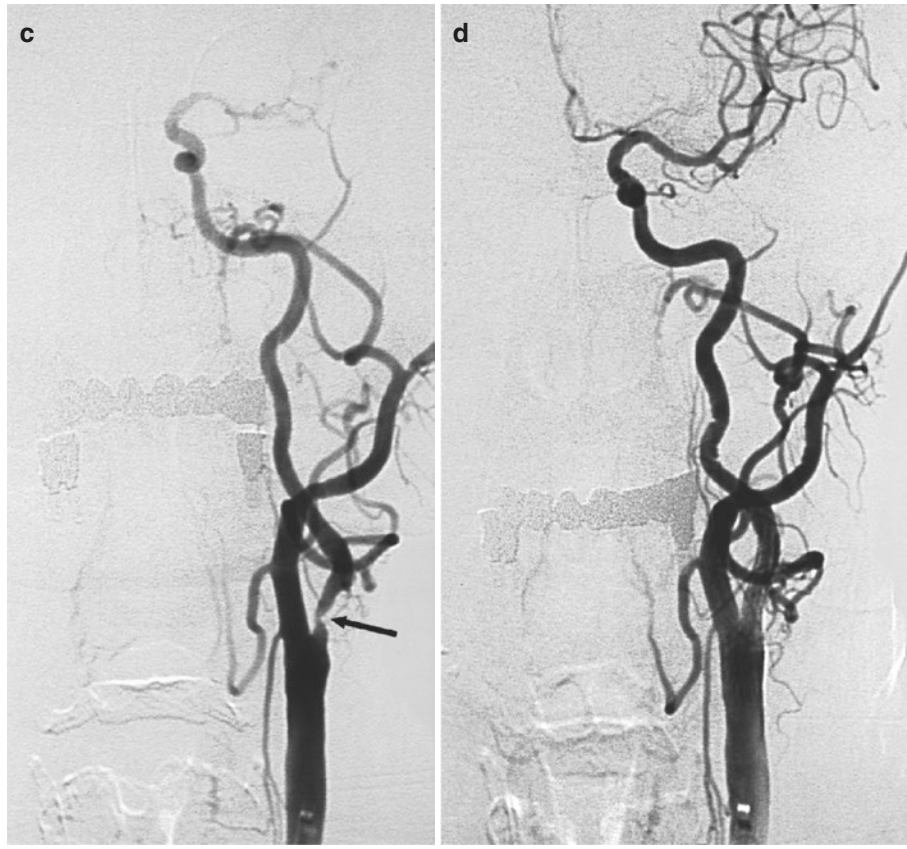

Fig. 15.2 (continued)

Fig. 15.3 Very old female patient with asymptomatic moderate to severe stenosis of the left ICA (**a**). The ICA was an important collateral way through the circle of Willis for the right carotid sector since the right ICA was occluded. A preventive endovascular treatment with stent and angioplasty (**b**) was performed without any clinical problems

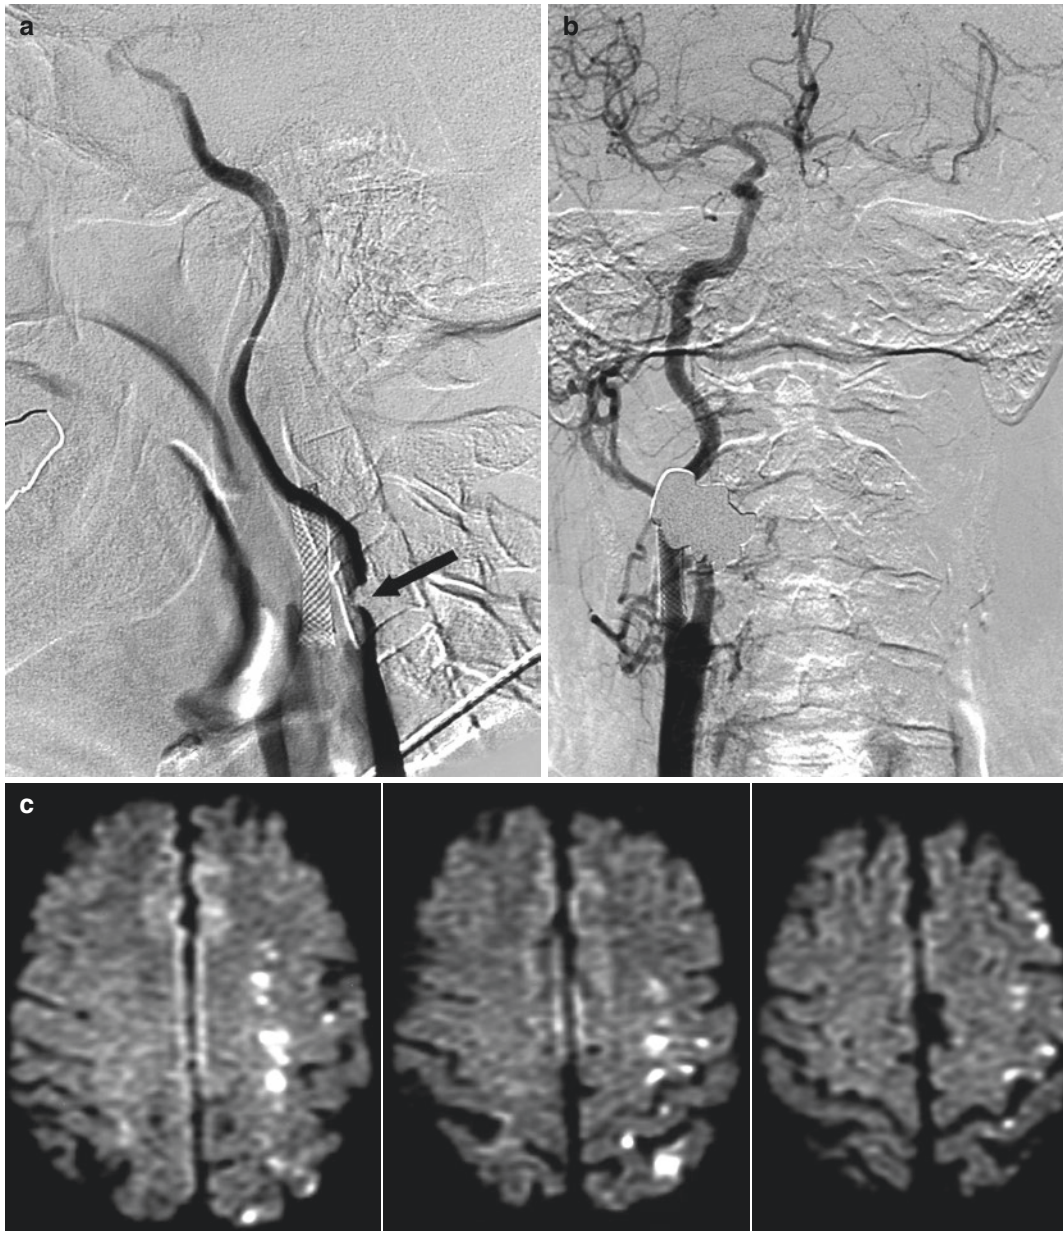

Fig. 15.4 Patient already treated with stent for stenosis of the right ICA. Acute mild neurological symptoms owing to impairment of the circulation in the left cerebral hemisphere. (**a**) left ICA angiogram showing subocclusion of the ICA due to a large atheroma (*arrow*) responsible for severe flow impairment. (**b**) Right ICA angiogram showing a good collateral circulation to the left vascular territory. (**c**) CT was normal. MRI, diffusion-weighted images showed several ischemic lesions in the vascular territory of the medullary arteries, probably due to hypoperfusion. The small cortical lesions are probably embolic. Surgical treatment of the stenosis was successfully performed a week later, with good clinical results

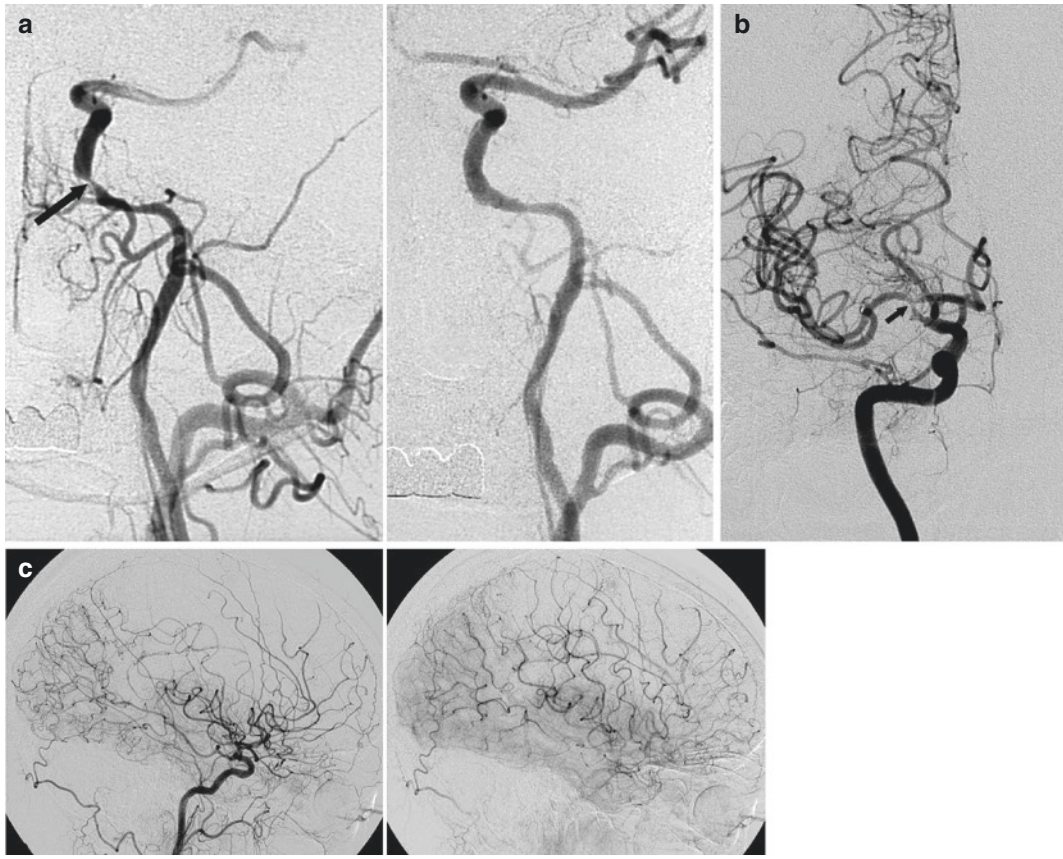

Fig. 15.5 (**a**) Middle-aged patient with TIAs not responsive to medical therapy. Carotid angiogram. AP view. On the left, angiogram showing severe stenosis of the proximal intracavernous portion of the ICA (*arrow*). There is impairment of the intracranial flow. On the right, angiogram postendovascular treatment with angioplasty and stent with restoration of the intracranial circulation. (**b**), (**c**) Middle-aged hypertensive black woman presenting with stroke characterized by left hemiplegia. (**b**) On the AP view of the right carotid angiogram a severe stenosis of the distal ICA (*arrow*) involving also partially the M1 segment is recognizable. (**c**) Lateral view. Early and late phases. There is a slowing down in the filling of distal branches of the MCA and ACA. Retrograde injection of some branches of the MCA (*arrows*) through opening of leptomeningeal anastomoses

ICA in patient who suffered an ischemic stroke. Other authors (Hong et al. 2011) showed a correlation with the degree of the carotid siphon calcification and the occurrence of lacunar infarct and concluded that this finding can be used to predict the risk of lacunar infarct.

The lesion can be associated with an extra cranial plaque *(tandem lesions).* This condition has been reported to occur with a frequency of about 10% (Craig et al. 1982; Kappelle et al. 1999). In a more recent study (Marquering et al. 2013) performed in patients with recent TIAs or stroke, examined with CT, the association of extra-intracranial stenosis was diagnosed in 38% of the cases. The intracranial stenosis was between 30 and 50% of the lumen. Its frequency and severity increased in patients with an extracranial stenosis of or more than 70%.

All these studies indicate that attention should be paid to the presence of atheromasic changes of intracranial ICA. The clinical relevance of these lesions is, however, not definitely clear. Certainly, in some cases, these can grow to severe stenosis responsible for stroke (Fig. 15.5a–c). Furthermore it is possible that even subtle changes can favor the distal occlusion of ICA through emboli arising from plaques of the extracranial segment or of cardiac origin.

- *Another site of atheromasic plaques which has progressively gained more attention and can be the source of emboli is the aortic arch.* These atheromas are more frequent in old patients and their frequency increases in patients older than 60 years of age (Amarenco et al. 1992, 1994a, b). Other studies have shown that the risk of stroke increases when the plaque is larger (thickness more than 4 mm) and is ulcerated or there is a superimposed thrombus (Uemo et al. 2007; Di Tullio et al. 2008). In the diagnosis of these lesions, the transesophageal echocardiography and MRI as a screening method and in the acute phase CT angiography are very accurate diagnostic tools.

15.4.1.2 Findings in Angiographic Studies in Patients with Stroke

- *The study can show stenosis of different degrees at the ICA bifurcation,* frequently not associated with pathological findings intracranially. These patients present frequently with mild stroke or transient ischemic attacks (TIAs). The cause of the transient ischemia can be acute hypoperfusion or a temporary occlusion of cerebral arteries followed by a spontaneous rapid thrombolysis. Distal embolization and hypoperfusion can occur together (Fig. 15.4). Among the involved branches, there is the ophthalmic artery. Its occlusion leads to "amaurosis," which frequently is transient (*fugax*) due to the spontaneous recanalization; unfortunately sometimes the lesion is irreversible.
- In the acute phase of the stroke a medical therapy is commonly the treatment of choice. In the following days or weeks with the clinical improvement, the type of therapy will change depending on the grade of stenosis, the morphology of the plaque, and the type and extension of the ischemia. Taking all these aspects into consideration in patients with moderate–severe stenosis and in those in whom the plaque appears unstable a more aggressive therapy (angioplasty with stent, or endarterectomy) will be considered. Whether an endovascular or a surgical approach is chosen varies in the different centers depending mainly on the experience and obtained results of the teams involved. Some criterions, however, are commonly accepted. Endarterectomy is favored in older patients and in those in whom diffuse atherosclerotic changes with great tortuously especially of the carotid artery will make difficult and more risky an endovascular approach. This latter is performed in patients with high carotid bifurcation as well as in those in whom the contralateral carotid is occluded or other severe comorbidities are present. The type of plaque will also influence the type of approach considering that as also reported by other authors (Mansur et al. 2011; Yoon et al. 2012) the risk of endovascular treatment can be higher in the cases of unstable plaques.
- Endovascular or surgical therapy can be indicated in asymptomatic patients with severe stenosis. This can be performed also in stenosis of lower grade in those patients in whom the involved carotid, considering also the circle of Willis, is the main perfusion way of the brain since the contralateral carotid is occluded. Examples of ICA stenosis and treatment are presented in Figs. 15.2, 15.3, and 15.4.

- *In other cases, a major stroke occurs. The angiographic pattern can vary. Frequently, there is occlusion of the extracranial ICA, due to a thrombus superimposed on an atherosclerotic plaque. More rarely, the occlusion is due to a big embolus originating from the heart or from aortic arch, arrested often at the level of a tortuosity of the ICA. In both cases, the thrombus can extends intracranially or, more often, be the source of a distal embolization (tandem lesions). In these cases, the MCA and its branches are commonly* the vessels involved (see Sect. 15.4.2). Not so rare, however, there is occlusion of the distal ICA (Moehlenbruch et al. 2012; Mpotsaris et al. 2013; Maurer et al. 2015; Cohen et al. 2015) (see below). Improvement of the endovascular technique allows today, in many of these cases, a rapid reopening of the extra cranial (stenting with or without angioplasty) and intracranial a mechanical thrombectomy) occlusion. The occlusion at the ICA bifurcation can frequently be easily overcome by the devices used today, indicating that the occlusion is due to a fresh thrombus, formed on a preexisting atheromasic plaque. An interesting aspect, as described also by other authors, (Malik et al. 2011; Maurer et al. 2015) is that in a certain number of these patients, the opening of the extracranial ICA leads to a spontaneous resolution also of the intracranial lesion, probably due to the re-stablished flow favouring the thrombolysis of the distal fresh embolus.
- More rarely *the primary site of the occlusion is located in the intracranial segment of ICA, or more frequently the occlusion involves the MCA (see Sect.* 15.4.2). *The pathogenesis is thought to be in the majority of the cases a cardiac embolization, since no pathological changes are recognizable at the ICA bifurcation or along its course, while a cardiac disease can be identified in many of these patients* (Zaidat et al. 2002; Flint et al. 2007; Mpotsaris et al. 2013). *The source of emboli from atheromasic plaque in the aortic arch should also be considered*. The different location of the occlusion, either in the ICA or in the MCA depends probably on the size of the embolus which is larger in ICA occlusion. As described above, the frequent presence in the distal ICA, of atheromasic changes not necessarily leading to stenosis can be a factor favoring the occlusion. It can also occur that a retrograde extension of the thrombus down to the ICA bifurcation develops, making it difficult, in these cases to establish where the primary occlusive process has started (Castaigne et al. 1970).

In the o*cclusions of the intracranial segment of ICA due to a primary occlusion or in tandem lesions, two different condition can basically be recognized*:

In one, the occlusion is located at the level of the ophthalmic artery commonly proximal to the origin of the artery. More rarely the occlusion is more distal involving the origin of the ophthalmic artery and the supraclinoid segment of ICA, but not its terminal branches (A1 and M 1) (Drawings 15.6a, c)*. In these cases, the collateral circulation can be guaranteed through the circle of Willis provided that no anomalies are present and also through anastomoses between ECA and ophthalmic artery when the occlusion is proximal to the ophthalmic artery*. In many cases the collateral circulation is very efficient to protect the brain parenchyma avoiding ischemia. In cases of stroke, this can be due to the acute hypoperfusion linked to an insufficient collateral flow or frequently due to occlusion of intracranial branches by emboli arising from the occluding thrombus. These are sometimes indirectly recognizable on the performed contralateral angiograms of the ICA, VA, or ECA. *In some of these cases, especially when the patient is clinically stable, it is probably better to perform a more conservative therapy, instead to try to reopen the ICA, with the risk of further embolization*. This

approach can be reconsidered when the collateral circulation is impaired due to anomalies of the circle of Willis or the presence of other lesions involving especially the other ICA, or there is a progressive clinical worsening.

In other cases the occlusion is more distally located, involving not only the supraclinoid segments of ICA (communicating and choroidal), but also the first segment of the MCA (M1) and the first segment of the ACA (A1) (Drawings 15.6b, d). *In some cases the occlusion does not extend to the more distal segments of the ACA which can be filled through the AcomA and so contribute to the collateral circulation through pial anastomoses with the MCA. This way of collateral circulation can be impaired when the occlusion extends also towards the A2*. The angiographic pattern in which both M1 and A1 are involved is called "*T occlusion.*" This is a rare condition, since in the majority of the cases the ICA occlusion extend only to the M1 forming a pattern called *"L occlusion"* or *partial "T occlusion"* (Liebeskind et al. 2015; Bradac et al. 2017). It is thinkable that in some of these cases a partial involvement of the proximal A1 is present, but this finding is difficult to be demonstrated.

The only possible collateral flow is through leptomeningeal anastomoses between ACA, PCA, and MCA. It can occur, in a few of these patients, that the collateral circulation is already rich, immediately after the occlusion explaining the mild clinical symptoms and the good outcome (Arnold et al. 2003; Flint et al. 2007; Bradac et al. 2017; Liebeskind et al. 2015) (Fig. 15.8). In the majority of the cases, however, the collateral circulation is poor and it is associated with a bad prognosis. The endovascular treatment leading to a reopening of the artery with complete or partial revascularization of the hemisphere had improved the prognosis in many of these patients (Castano et al. 2010; Moehlenbruch et al. 2012; Machi et al. 2012; Berkhemer et al. 2015; Bradac et al. 2017).

There are, however, some "unfavorable conditions" which can impair the final result. Among them there are anomalies of the circle of Willis: both ACAs arise from the occluded ICA and the A1 segment of the normal contralateral ICA is hypo-aplastic or the A1 segment is completely thrombosed up to the A1–A2 angle and so no collateral flow is possible from the normal A1 towards A2 of the affected side through the AcomA. The PCA (fetal origin) arises from the occluded ICA and the P1 is hypo-aplastic. The collateral flow through leptomeningeal anastomoses from PCA towards ACA and MCA is impaired. This latter condition can also be unfavorable for a collateral circulation towards the AchA since in this case this artery cannot be retrograde injected by the way of anastomosis with branches of PCA, especially through the posterior choroidal arteries.

Another possible condition influencing negatively the result is the involvement of the collateral circulation through a distal embolization leading to occlusion of the arteries involved in the leptomeningeal collaterals. Emboli can arise from the occluding thrombus or occurring during the endovascular treatment. This involvement of the collateral circulation leads to a suffering of the brain parenchyma and this can explain, in these cases, the failure of its recovery, in spite of the rapid proximal revascularization obtained with the endovascular treatment, as also reported by other authors (Bang et al. 2011).

Examples of distal ICA involvement in cases of tandem lesions or primary occlusion are presented in Figs. 15.7, 15.8, 15.9, 15.10, 15.11, 15.12, and 15.13. In a few of these cases, endovascular treatment makes it possible to reopen the distal ICA with restoration of the collateral circulation through the circle of Willis and ECA, while the proximal ICA remain occluded. In accordance with other authors (Jakubowska et al. 2008) we think that this can be an acceptable result, which can be sufficient to avoid a bad clinical course (Fig. 15.14a– d).

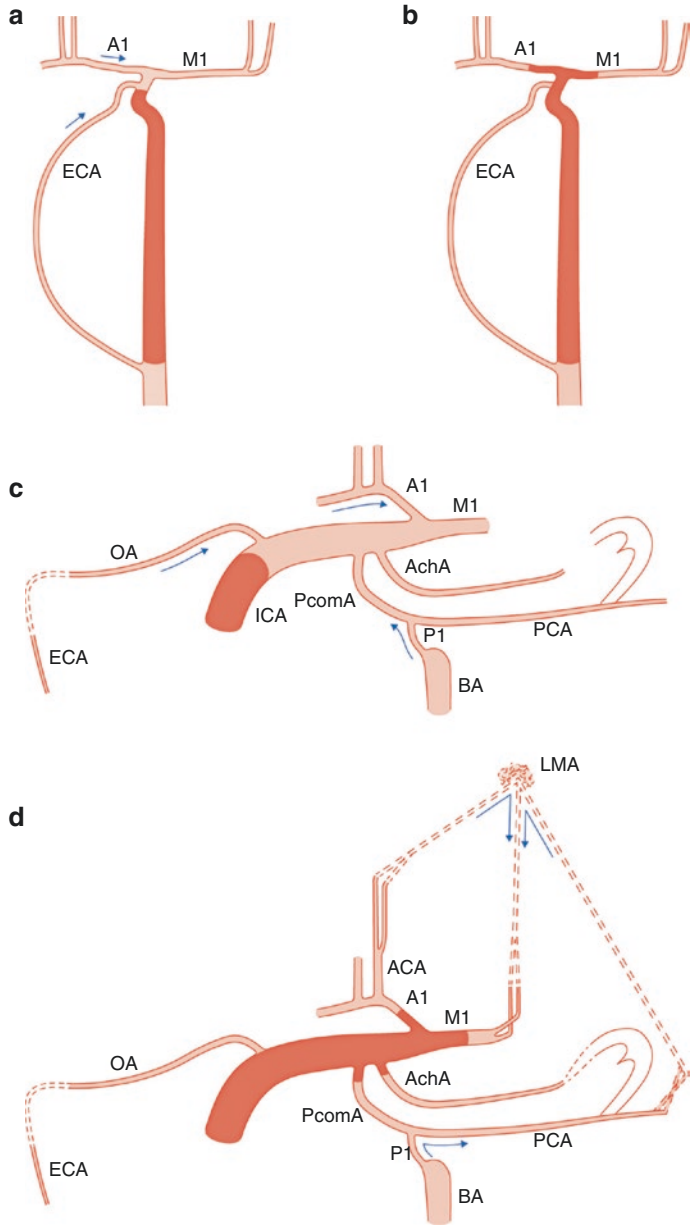

Fig. 15.6 Drawing, AP view. Different findings in occlusion of the ICA proximal to the ophthalmic artery (**a**) and distal to it with involvement of communicating, choroidal, A1 and M1 segments (T occlusion) (**b**). In (**a**) a collateral circulation occurs through the ECA-ophthalmic artery anastomosis and through the circle of Willis provided that this is not impaired by hypo/aplasia of the A1. In (**b**), the above-described collateral ways are involved in the thrombotic process. The only possible collateral circulation is leptomeningeal anastomoses between distal branches of anterior cerebral (ACA) and posterior cerebral arteries (PCA) with middle cerebral artery (MCA). (**c**) Lateral view. Occlusion of the internal carotid artery (ICA) proximal to the ophthalmic artery (OA). Possible collateral circulation through OA and circle of Willis. External carotid artery (ECA); first segment of anterior cerebral artery (A1); first segment of middle cerebral artery (M1); posterior cerebral artery (PCA); posterior communicating artery (PcomA); basilar artery (BA) and P1 segment; and anterior choroidal artery (AchA). (**d**) Distal occlusion of ICA involving the communicating, choroidal, M1, and A1 segments. Possible collateral circulation only through leptomeningeal anastomoses (LMA). Possible anastomoses between posterior and anterior choroidal arteries. For the role played by anomalies of Circle of Willis see text.

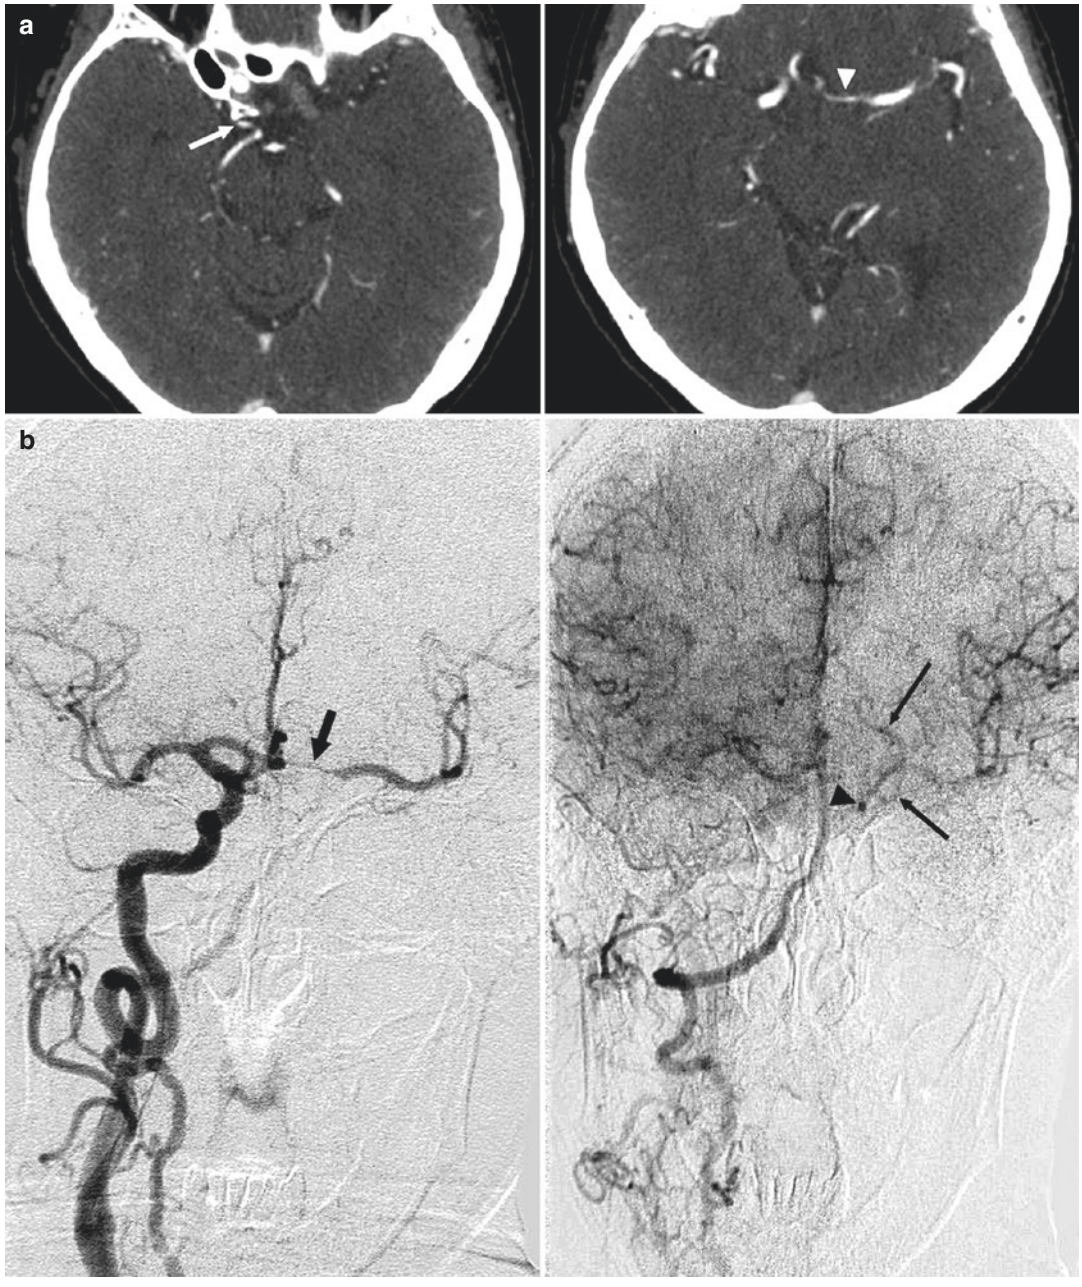

Fig. 15.7 Acute occlusion of the left extracranial ICA, probably embolic in a cardiopathic middle aged woman, at the level of tight coiling. Further distal embolization and occlusion of the distal intracranial ICA (tandem lesion). (**a**) Angio-CT. The right PCA (fetal type) is filled by a large PcomA (*arrow*). Distal left ICA occlusion. Good filling of the left MCA through A1 (*arrowhead*) in spite of its small size. The left PCA is of a fetal type, arising mainly from the occluded ICA. (**b**) Right carotid angiogram. Tight coiling of the ICA. Hypoplastic left A1 (*arrow*). There is, however, a good filling of the left MCA and a faint retrograde injection of the left PCA and PcomA (*arrows*) to the point of the occlusion of ICA (*arrowhead*). (**c**) Angiogram of the left ICA, showing the occlusion at the very tight coiling (*arrow*) associate with a distal occlusion (*arrow with dot*). Progressively proximal and distal reopening with aspiration device. (**d**) Left ICA angiogram posttreatment. Now the anomaly of the circle of Willis with the fetal origin of the PCA is better demonstrated. On the posttreatment CT, ischemic lesions were recognizable on the basal ganglia. The patient had a mild motor deficit which improved in the next months with a final good clinical outcome (Courtesy of Prof. Bergui M and Dr Ventilii G, Neuroradiology of Turin)

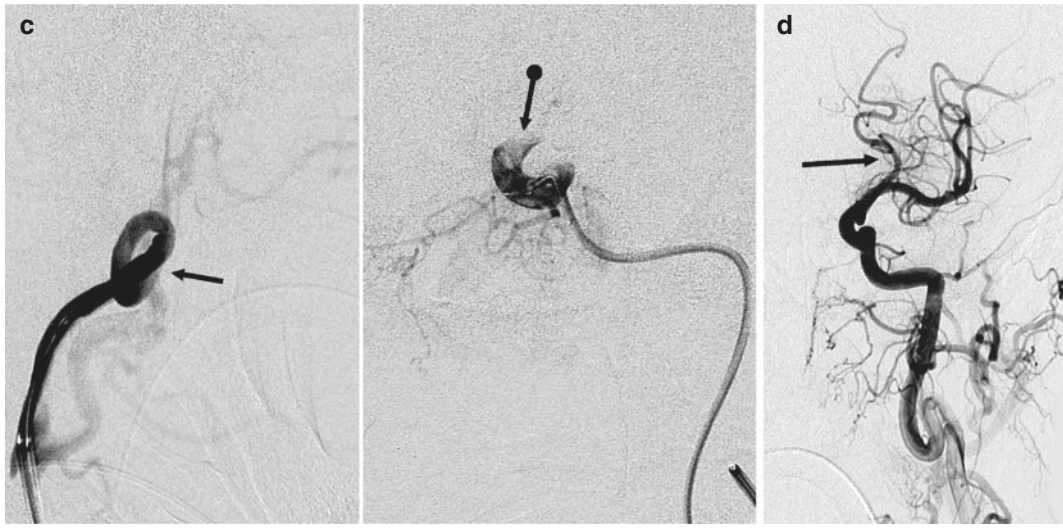

Fig. 15.7 (continued)

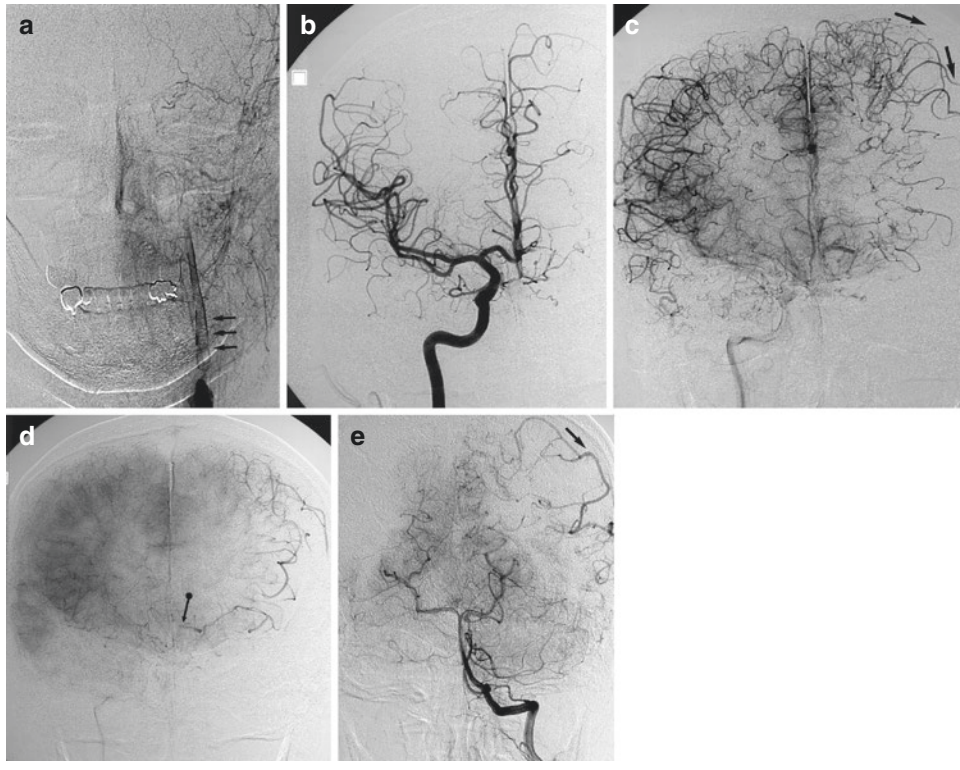

Fig. 15.8 Middle-aged patient with acute onset of right hemiplegia and minimal aphasic disturbances. (**a**) Severe stenosis of left ICA bifurcation with superimposed thrombus extending intracranially. (**b**)–(**d**) Right ICA angiogram (early and late phases). Through the AcomA partial filling of the left A1 (*arrow with dot*). There is a rich leptomeningeal collateral circulation (*arrow*) through distal branches of left A.C.A towards the left MCA. (**e**) On the vertebral angiogram the origin of the PCAs from the BA is demonstrated. A collateral circulation from the left PCA towards the MCA is recognizable (*arrow*). The patient presented with a stable mild clinical symptomatic. Medical therapy was chosen and the patient recovered with minimal neurological deficit

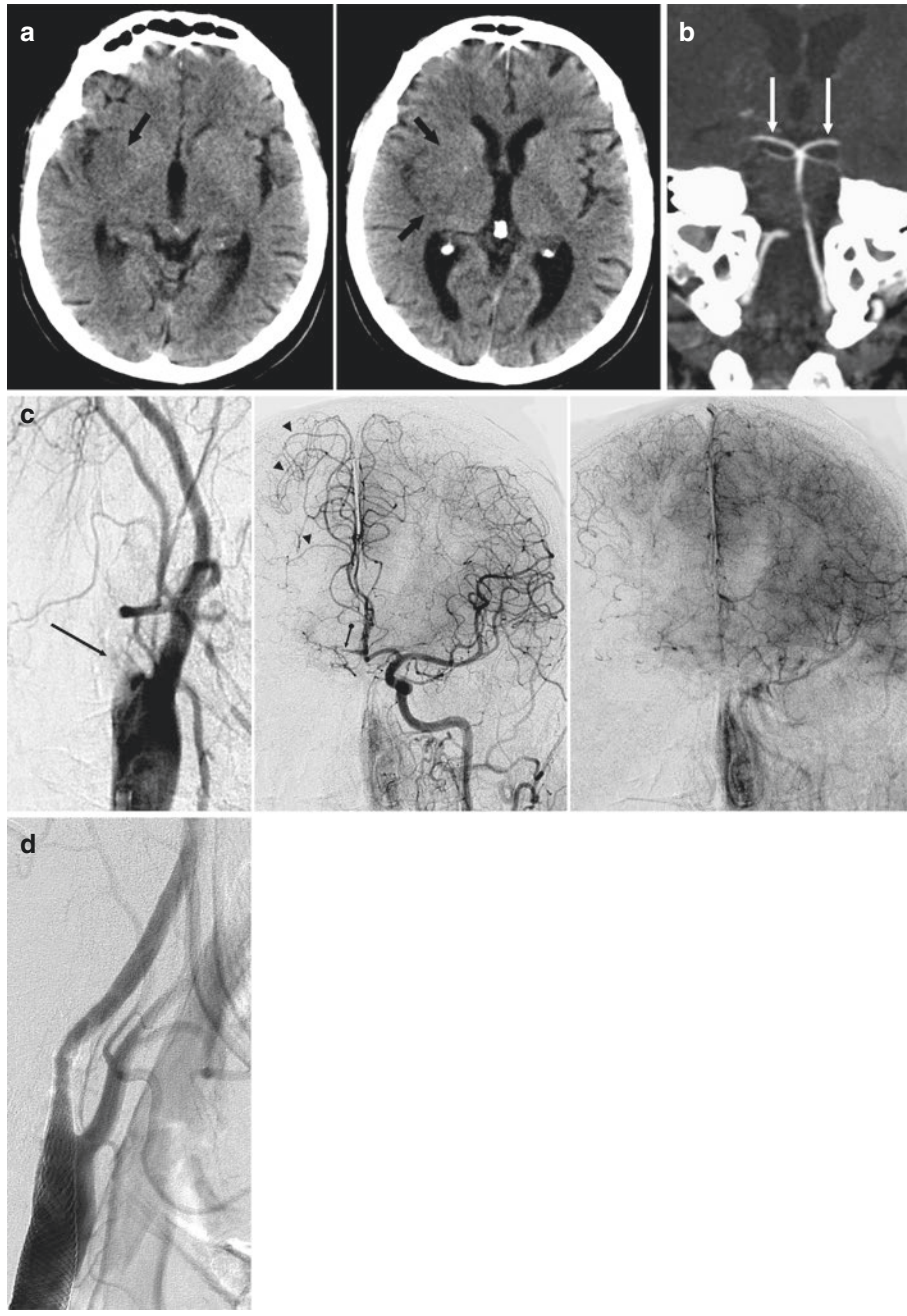

Fig. 15.9 70-year-old patient examined about 6 h after the stroke presenting with a mild agitation and left hemiplegia. (**a**) CT showing a probable ischemia involving the insula and right basal ganglia (*arrows*). (**b**) On the CT angiography, occlusion of the right ICA was visible. There was a partial collateral circulation through the anterior and posterior part of the circle of Willis. Both PCA arise from the BA (*arrow*). (**c**) Right and left carotid angiogram showed, occlusion of the proximal right ICA (*arrow*) and partial filling of the right A1 (*arrow with dot*) through the AcomA. Partial collateral leptomeningeal circulation (*arrowheads*) from distal right ACA towards the right MCA. (**d**) Reopening of the right ICA with angioplasty and stent. (**e**) Injection of the distal occluded ICA (*arrow*) and progressively reopening with a mechanical thrombectomy (solitaire) of the distal ICA and further of the MCA with complete recanalization. (**f**) Posttreatment CT showing presence of contrast in the infarcted areas (*above*) involving the basal ganglia and the insular and parietal areas. Progressively disappearing of the contrast in the following days (*below*). Slowly clinical improvement of the left hemiplegia in the following months

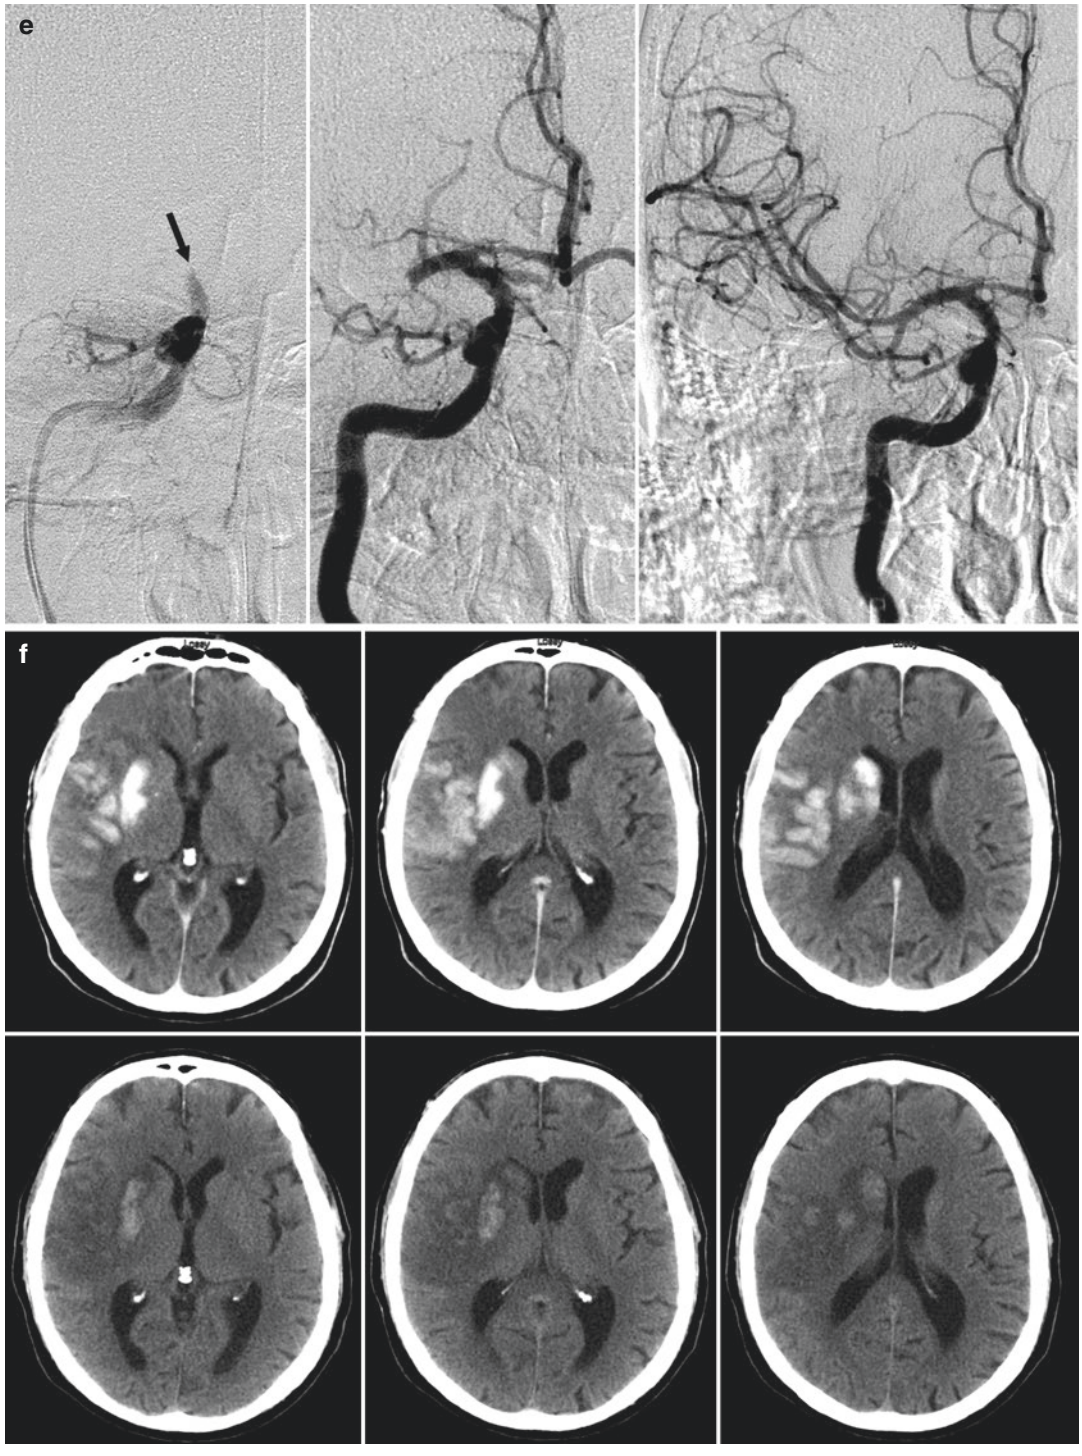

Fig. 15.9 (continued)

Furthermore, it should be remembered that in ICA "*distal occlusion*" the perforators of ACA, MCA, AchA, and distal ICA and depending on the preexisting anomalies of the circle of Willis, also of PcomA, are always involved. This explains the frequent presence of ischemic lesions in the basal ganglia, even in the most favorable cases with a rapid and complete recanalization.

- A particular rare condition is that occurring in patients, who have a known occluded ICA, in whom ischemia occurs months or years later. In such cases, the etiopathogenesis is frequently linked to emboli arisen from atheroma in the stump of the occluded ICA, in the distal common carotid artery or ECA, which can reach the intracranial vessels though anastomoses between the branches of ECA and ophthalmic artery (Barnett et al. 1978; Countee and Vijayanathan 1979; Countee et al. 1981; Bradac and Oberson 1983).

15.4.2 Middle Cerebral Artery

- The MCA is the most frequently vessel involved in stroke of the anterior circulation. Similarly to the distal ICA occlusion, also the occlusion of the MCA, in the majority of the cases, is embolic (Zaidat et al. 2002; Mpotsaris et al. 2013). The source of the emboli is thought to be most commonly cardiac occurring in patients with cardiac diseases. Another possible mechanism are emboli arising from thrombi formed at the ICA bifurcation typically in the cases of "tandem lesions." In a certain number of cases, however, the source of the emboli remains unclear, since neither a cardiac nor a carotid pathology can be identified. It could be that in these patients, the thromboembolic material has been formed on minimal atheromasic changes no longer visible on the angiogram or the source was more proximal, located in the aortic arch.

The occlusion involves the M1 segment (Figs. 15.15, 15.16, 15.17, 15.18, 15.19, 15.20, and 15.21) or more distal branches Figs. 18.2, 18.3, and 18.4.

In some cases, after successful reopening of the vessel, it appears clear that the embolus has been arrested at the level of a stenosis of M1 due to a microatheroma (Fig. 15.16a, b).
In occlusion of the M1, the perforators are always involved. The degree of involvement depends on many factors (location in the proximal or more distal M1 of the embolus, morphological aspects of M1, short or long and on the site of origin of the perforators (see Sect. 5.1). *Perforators are end arteries, and so their occlusion, even for a relatively short time, can lead to ischemia in their territories.* This is confirmed in those cases where despite a rapid reopening of the occluded M1 through the endovascular treatment, ischemic lesions in the basal ganglia are frequently demonstrated in CT or MR, which should always performed 24–48 h later (Bradac et al. 2008b) (Figs. 15.15, 15.18, 15.19, 15.20, and 15.21). Frequently, these patients remain asymptomatic or only with minimal neurological deficit. Certainly the lesions are sometimes very limited. However, the absence or the presence only of minimal clinical symptoms in these patients is a little surprising, since it is well known that the basal ganglia are involved in brain activity concerning movements, cognition and behavior. Indeed many connections between associations cortical areas and deep structures in form of cortico-striato-pallido-nigral-thalamic-cortico circuit are well known (Yeterian and Van Hoesen 1978; Alexander et al. 1986; DeLong 2000). Complementary functional MR study could be useful in the follow-up of these patients.

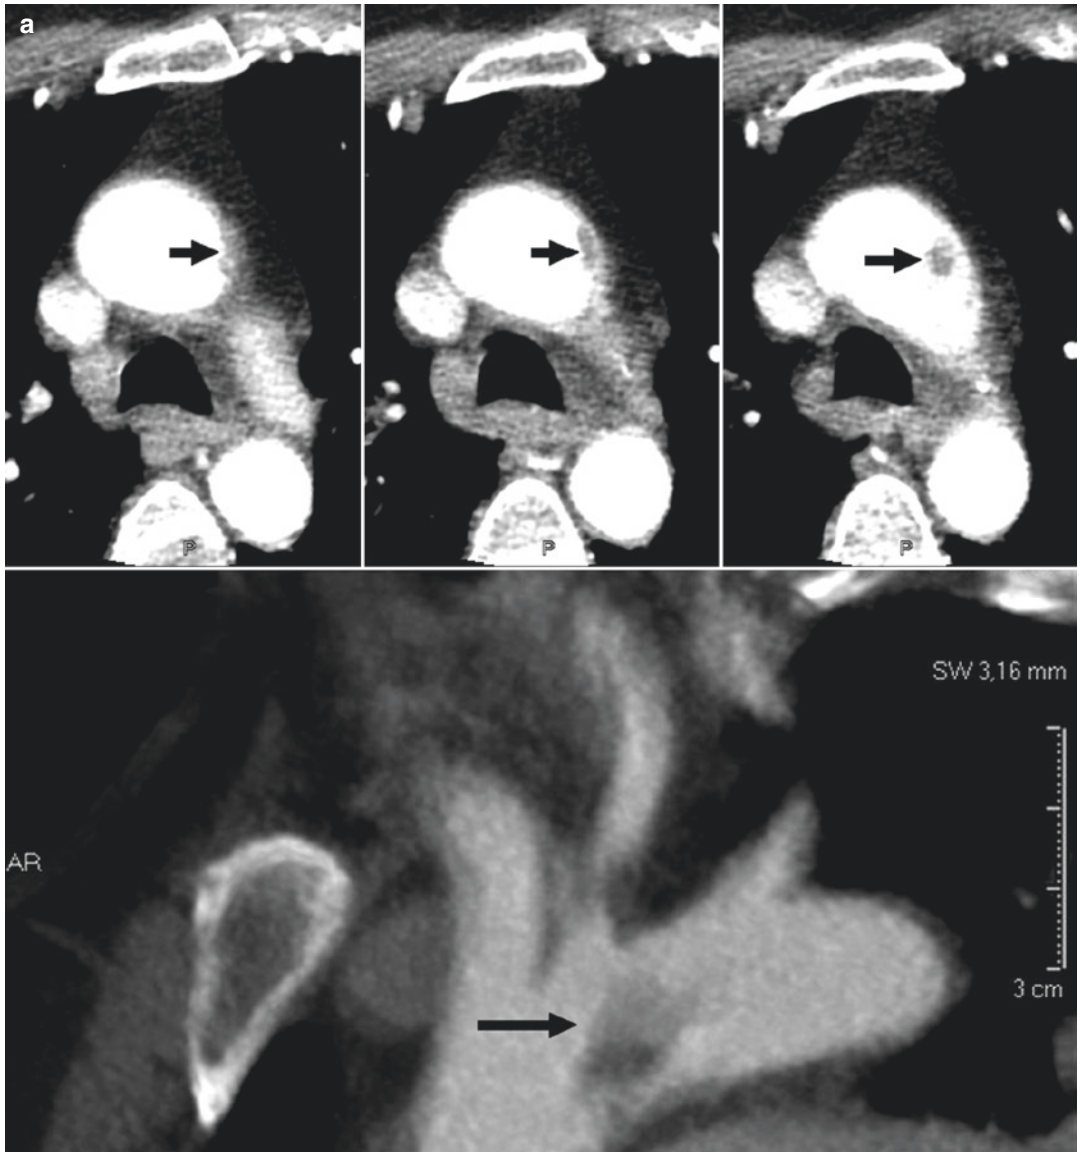

Fig. 15.10 50-year-old woman admitted in a comatose state with right hemiplegia about 3 h after the stroke. (**a**) On CT no certain ischemic lesions were visible. The CT angiography showed a large plaque with a superimposed thrombus (*arrows*) in the aortic arch. (**b**) The intracranial study (volume rendering) showed a distal occlusion probably embolic of the left ICA (*arrow*) (sides inverted). The occlusion was located distally to the origin of the small PcomA (*arrowhead*) connected with the PCA arising mainly from the BA. There was a good filling of the right ACA but no filling of the left A1 and M1. The leptomeningeal collateral circulation towards the occluded ACA and MCA probably only possible through the left PCA was very poor. (**c**) The right and left angiograms confirmed the "T Occlusion" of the left ICA (*arrow*). The occlusion was distal to the origin of the small PcomA (*arrowhead*) continuing in the PCA. Retrograde filling of the large P1 (*arrow with dot*). (**d**) Rapid reopening of the occlusion using a solitaire stent. Note also the filling of the perforators. The distal branches of ACA and MCA, however, remained occluded (*arrows*) in spite to a few attempts to reopen them, probably occluded by emboli arising from the proximal thrombus and/or due to severe impairment of the microvasculature (see Sect. 15.8). (**e**) CT performed 24 h later showed a large infarct involving the ACA, MCA, and AchA vascular territories, sparing the territory of the PCA. Minimal hemorrhagic component in the basal ganglia. The patient died

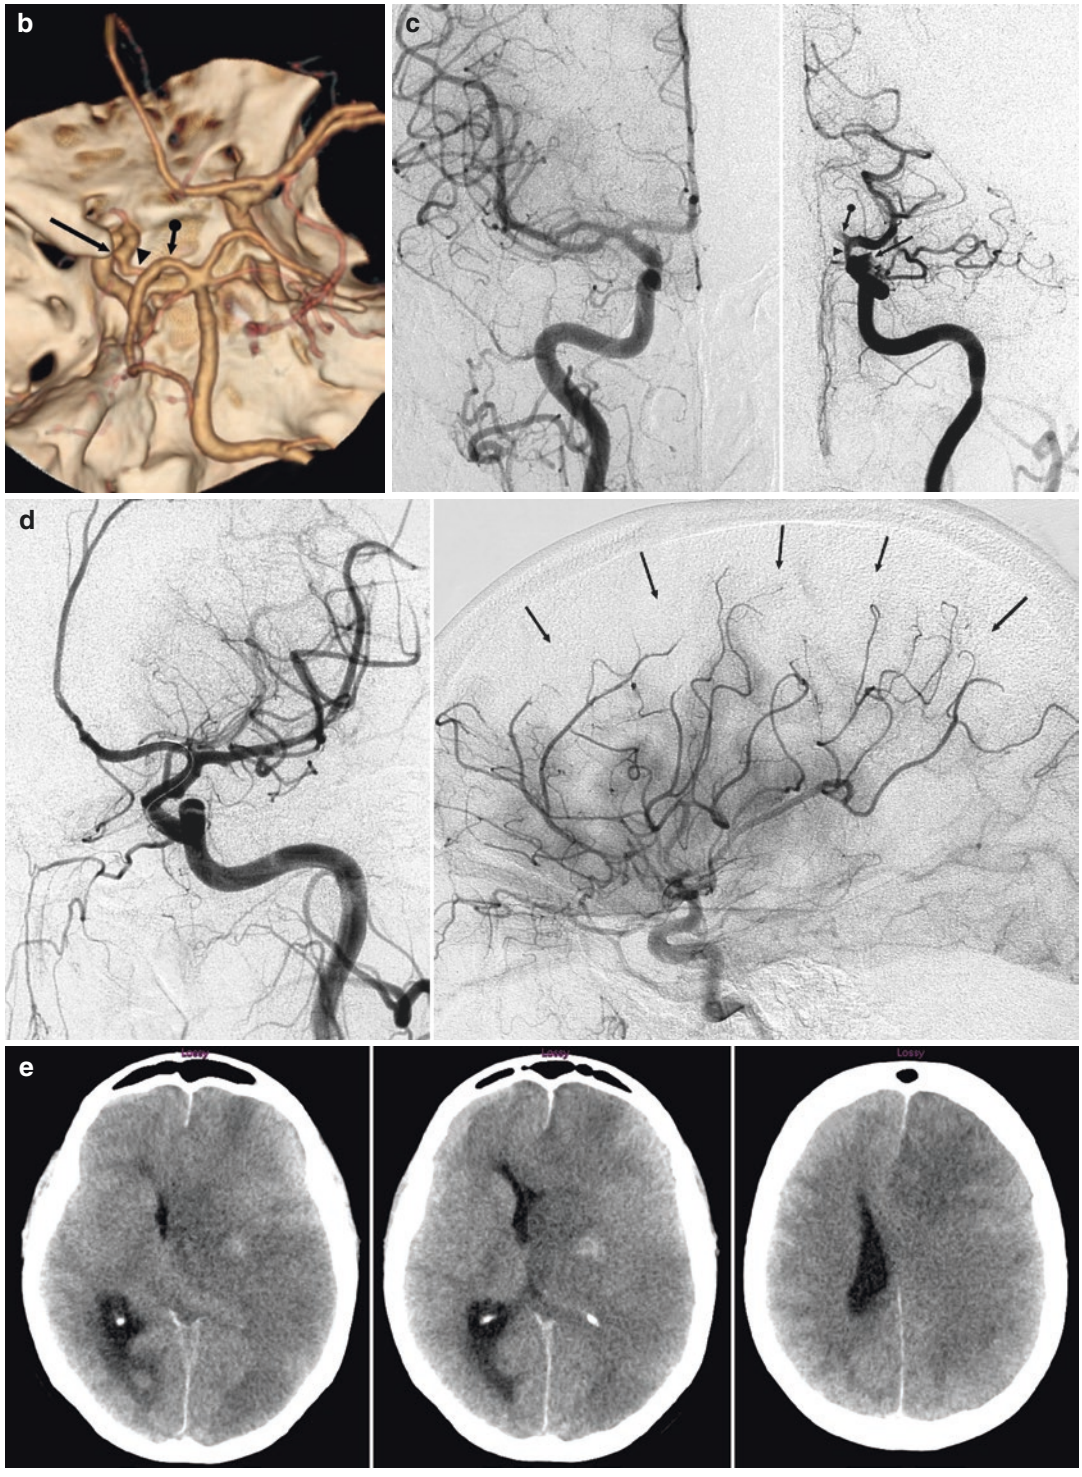

Fig. 15.10 (continued)

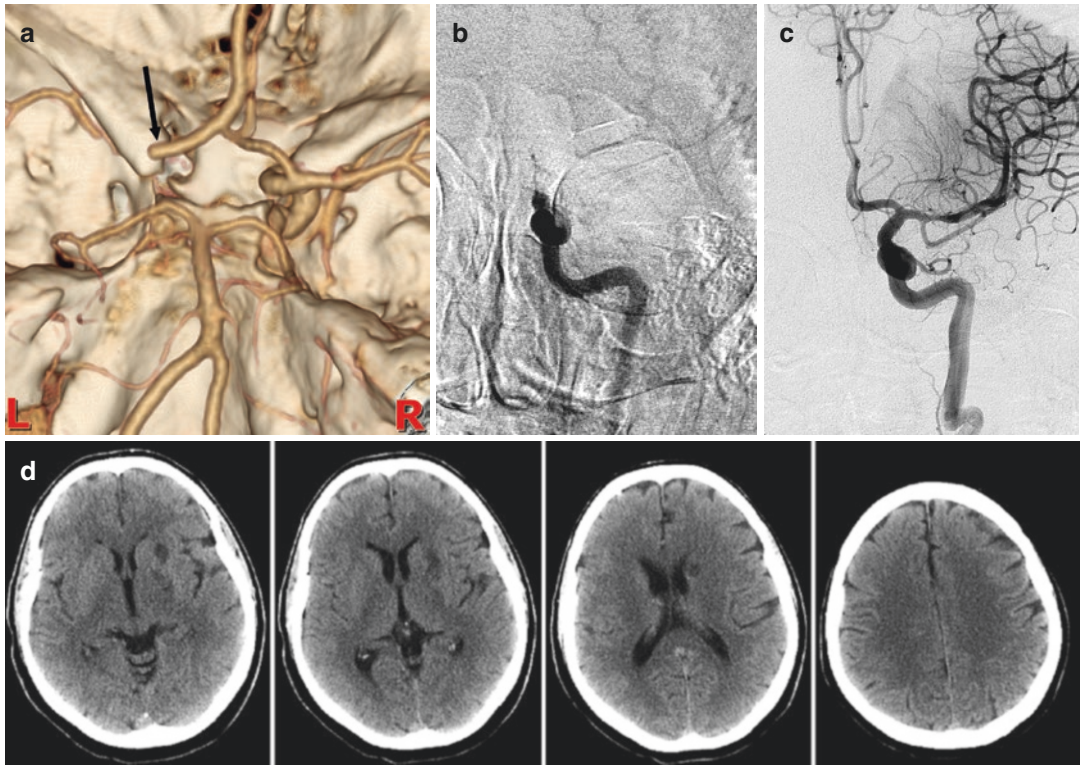

Fig. 15.11 Distal intracranial ICA occlusion in a 58-year-old woman. (**a**) Angio-CT represented by volume rendering technique (the sides are inverted). Occlusion of the left ICA. Through the AcomA filling of a well-developed left ACA and left A1 (*arrow*). There is a distal filling of M1, indicating the presence of a rich leptomeningeal collateral circulation towards the left MCA from the left ACA and probably also left PCA, considering that both PCAs arise from the basilar artery. (**b**) Left carotid angiogram showing the distal ICA occlusion. (**c**) Left posttreatment angiogram showing the complete revascularization obtained with a solitaire stent. Blush in the vascular territory of the perforators. (**d**) Posttreatment CT. Small ischemia at the level of the basal ganglia. Rapid clinical complete recovery

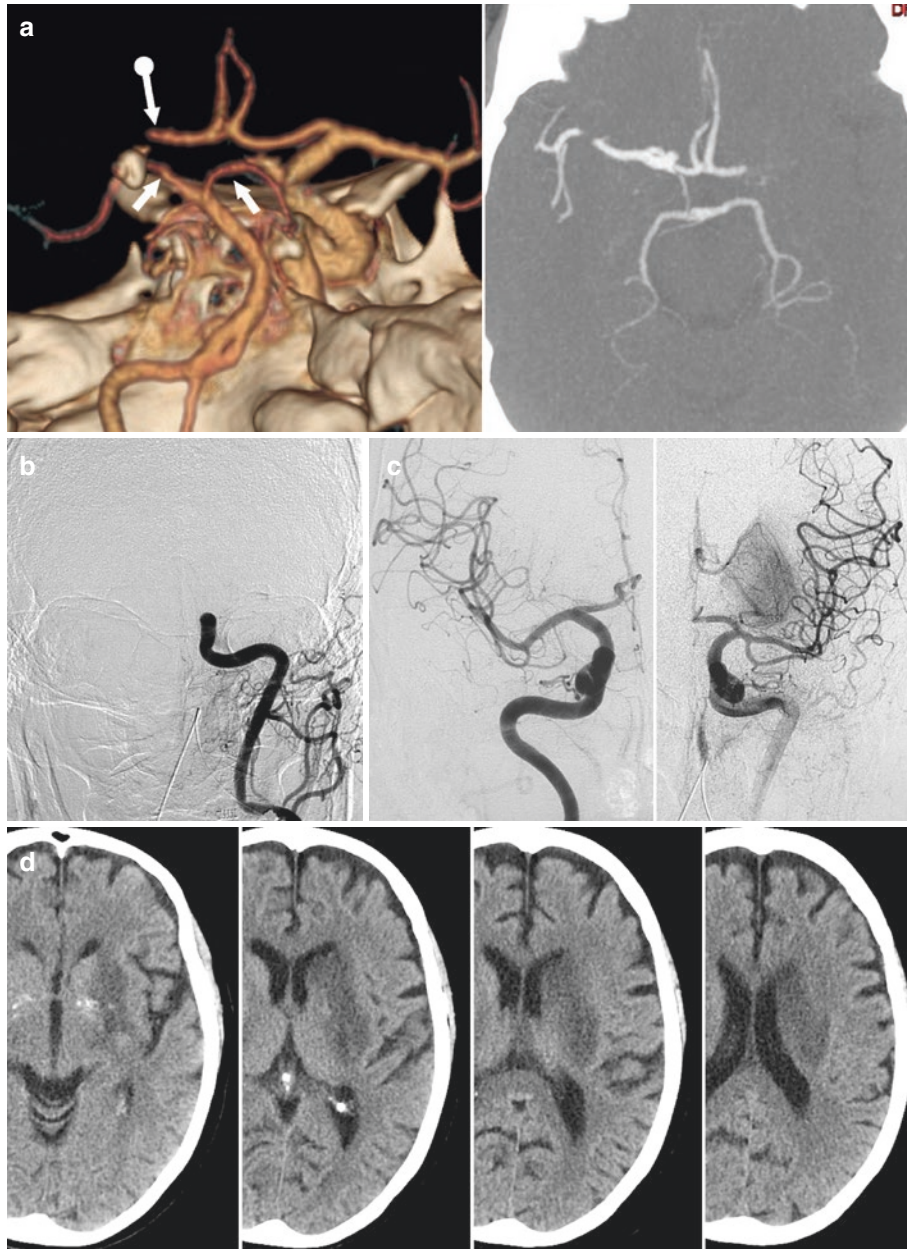

Fig. 15.12 Distal intracranial ICA occlusion in a 68-year-old woman. (**a**) Angio-CT represented by volume rendering (*left*) and multiplanar reconstruction (*right*). Occlusion of the left ICA. Through an efficient AcomA filling of the left ACA and left A1 (*arrow with dot*). Fenestration of the BA from which arise Both PCAs (*arrows*). There is also a right PcomA on the right. There was a collateral circulation towards the MCA. (**b**) Left carotid angiogram showing the ICA occlusion. (**c**) Post-treatment left ICA angiogram showing the complete revascularization after thrombectomy with solitaire stent. Note the rich blush in the vascular territory of the perforators and early filling of the inferior striate veins draining in the BV and superior striate veins draining in the thalamo-striate vein. Right ICA angiogram (*right on the figure*). (**d**) Posttreatment CT. Ischemia involving pallidum, putamen, and superior part of the head of the nucleus caudatus. Improvement of the motor deficit and mild aphasia with final good recovery 3 months later

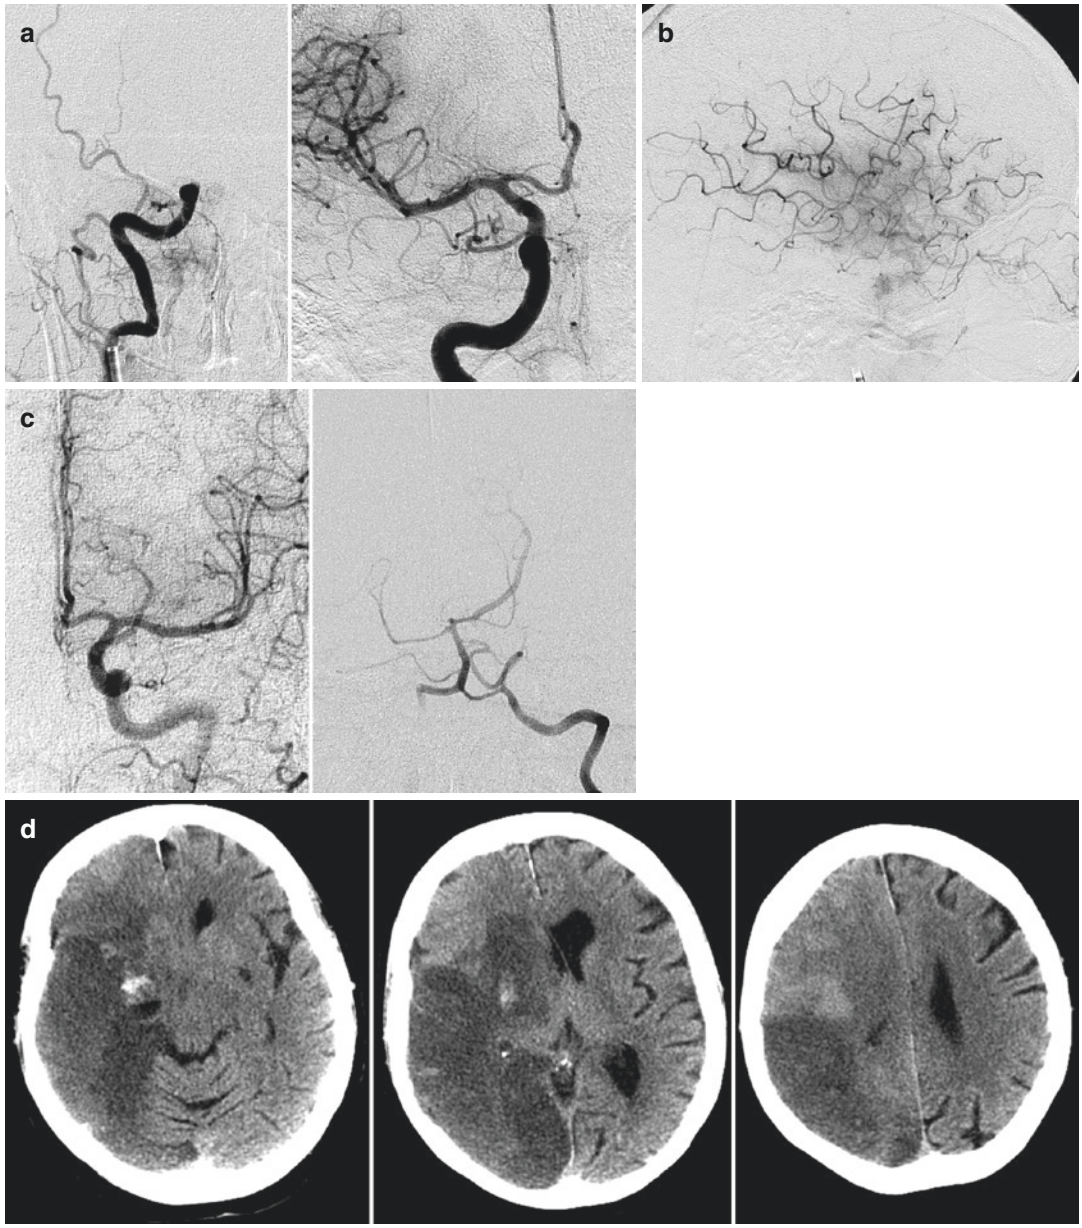

Fig. 15.13 Distal intracranial ICA occlusion in a 70-year-old woman. After exclusion of ischemia on CT, the patient was soon transferred in the angiographic room. (**a**) Right carotid angiogram showing the ICA occlusion (*on the left of the figure*). Carotid angiogram posttreatment (*on the right*), showing the revascularization achieved rapidly with a solitaire stent. (**b**) On the lateral right angiogram, however, occlusion of several distal branches of MCA was visible. (**c**) The posttreatment left carotid and vertebral angiograms showed the left PCA filled on both the ICA and VA angiograms. There was no right PCA on the vertebral angiogram, indicating that this artery arose from the right occluded ICA and remained occluded. (**d**) Posttreatment CT. There is a large ischemia in the vascular territories of MCA and PCA. Minimal hemorrhagic component in the basal ganglia. The patient survived with severe motor deficit. It is thinkable that in this case the impairment of the leptomeningeal collateral circulation due to diffuse occlusion of the distal leptomeningeal anastomoses was probably due to many factors acting together such distal embolization, the unfavorable condition in the circle of Willis and damage of the microvasculature due to the ischemia (see also Sect. 15.8)

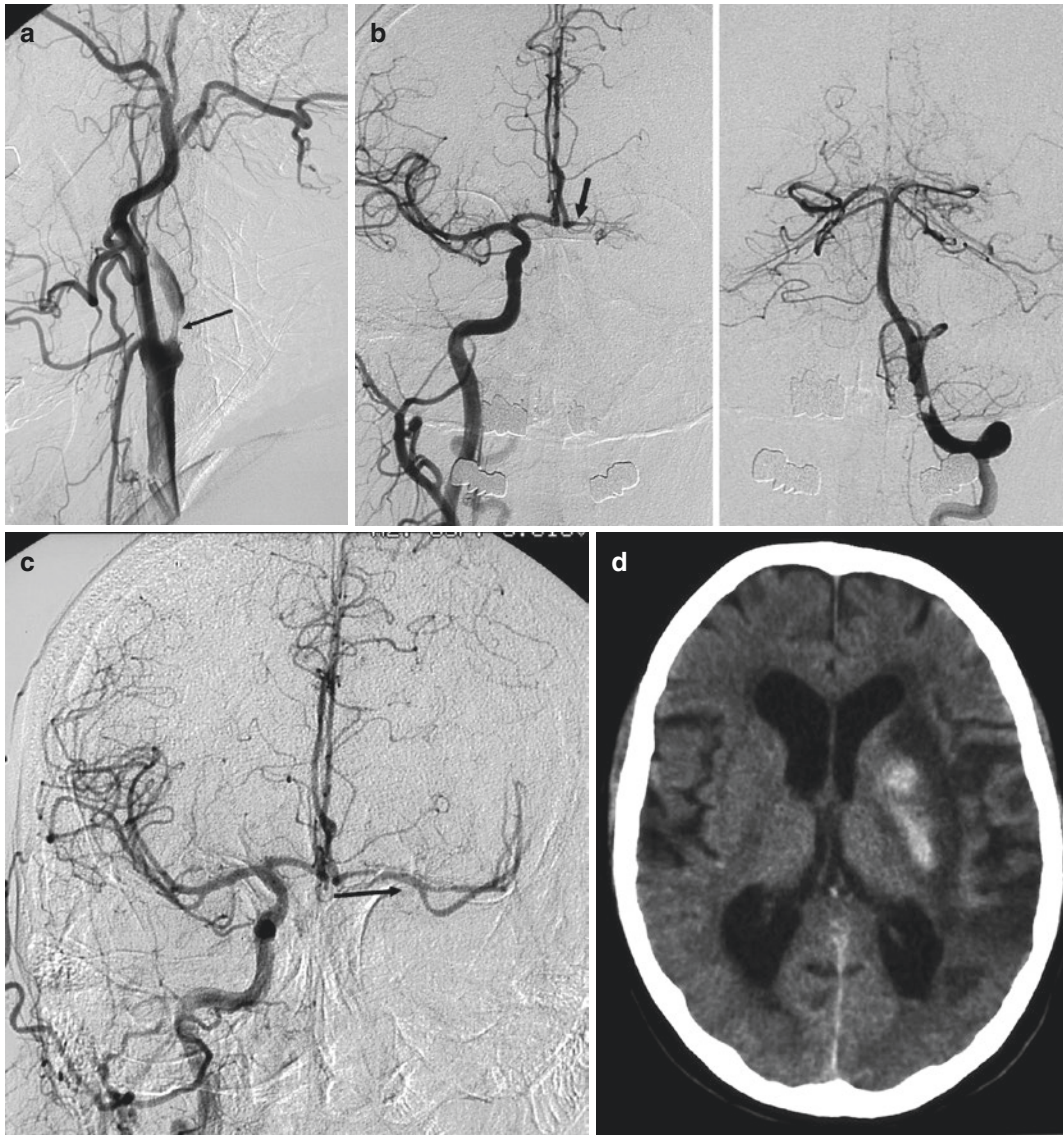

Fig. 15.14 75-year-old man presenting with aphasia right hemiplegia and progressive cognitive disturbances. Intravenous thrombolysis was first performed without positive response. (**a**) On the left carotid angiogram a severe stenosis of the ICA (*arrow*) was demonstrated. There was no filling of the distal ICA and no collateral circulation through the ECA. (**b**) Right carotid and left vertebral angiogram. Through the AcomA filling of the left ACA and filling of the distal part of a small left A1 (*arrow*). On the vertebral angiogram both PCAs arose from The basilar artery. There was a poor leptomeningeal collateral circulation. (**c**) After a stent application at the left ICA bifurcation a microcatheter was advanced in the distal ICA, followed by a mechanical thrombectomy. This led to a reopening of the distal ICA, A1, and MCA and improvement of the collateral circulation through the circle of Willis. There was a reocclusion of the ICA bifurcation. (**d**) Posttreatment CT showed an ischemic lesion with an hemorrhagic component in the basal ganglia. Ischemic foci in the insular an parietal areas. There was a partial slow recovery

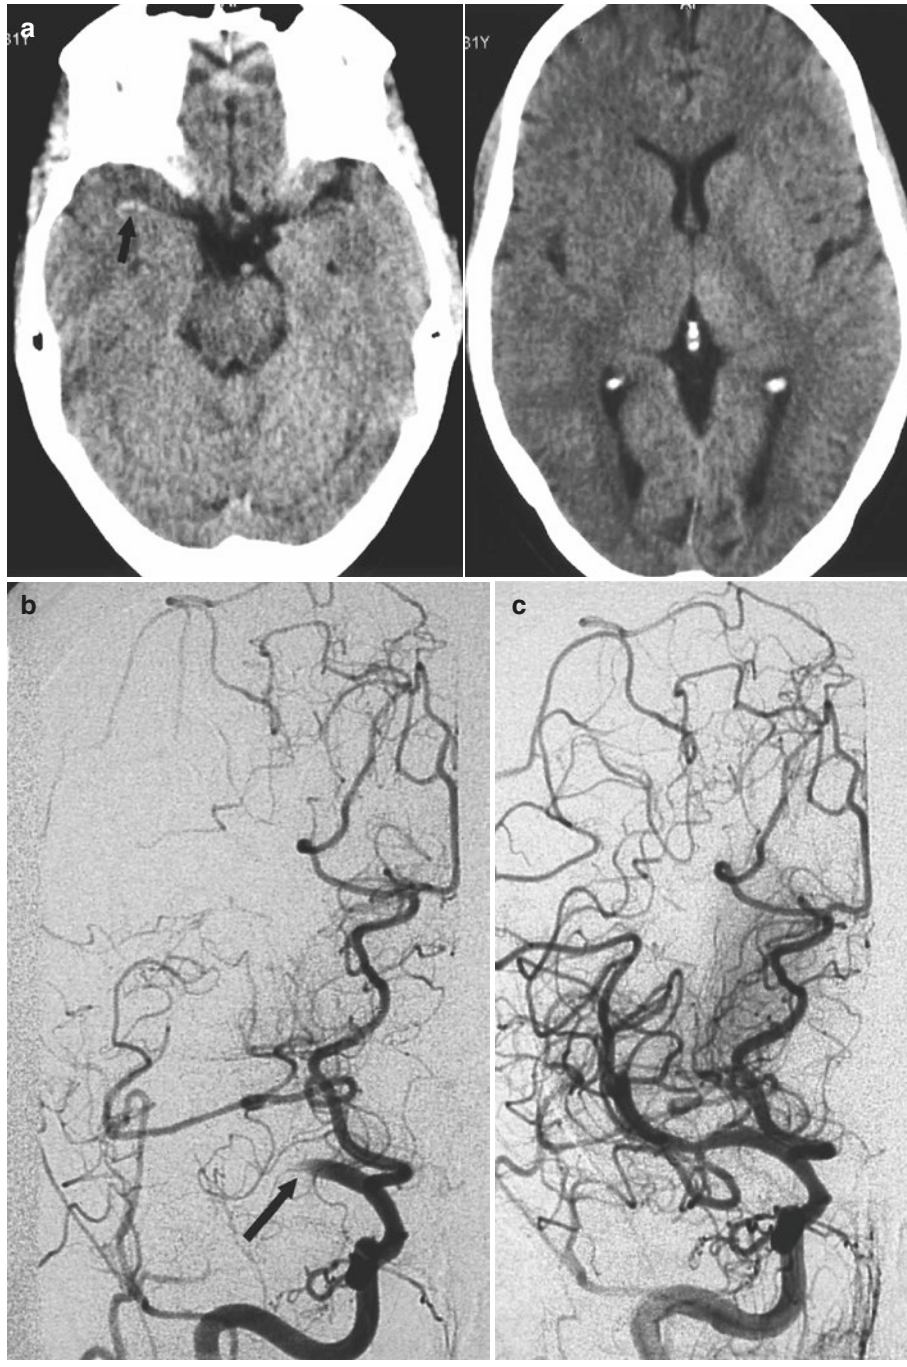

Fig. 15.15 Young cardiopathic patient with sudden onset of left hemiplegia. (**a**) On CT, hyperdensity of the MCA (*arrow*) and ill-defined borders of the right basal ganglia are recognizable. (**b**) On the right ICA angiogram, on occlusion of the proximal right M1 is visible (*arrow*). There is a fetal origin of the PCA, not involved in the occlusion. The left ACA arises from the left ICA. There is a rich leptomeningeal collateral circulation from the PCA towards the MCA. (**c**) Control angiogram after selective pharmacological thrombolysis showing the reopening of the occlusion where a minimal irregularity of the wall remains. (**d**) On CT performed 3 days later, there is a small ischemic lesion in the putamen. Rapid complete recovery of the patient

Fig. 15.15 (continued)

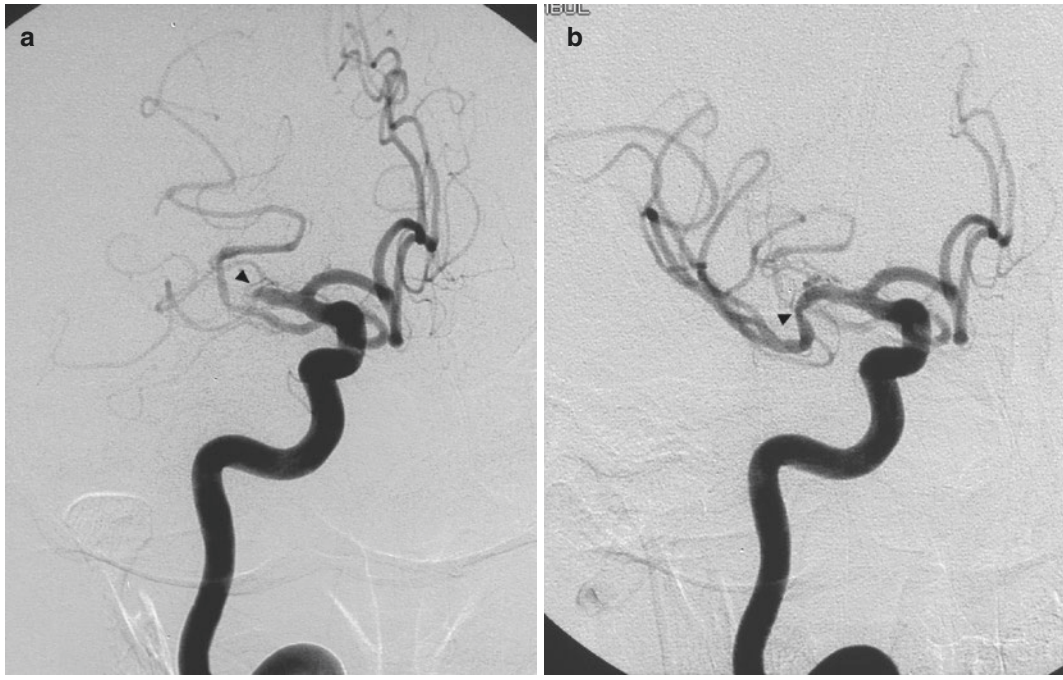

Fig. 15.16 Older woman with heart dysrhythmia presenting with sudden onset of hemiplegia and cognitive disorders. (**a**) The right ICA angiogram disclosed occlusion of the proximal M1 (*arrow head*). Note the presence of a fetal PCA not involved in the occlusion (compare this case with that in Fig. 18.3). Rapid reopening of the occlusion with a solitaire stent. (**b**) The posttreatment angiogram showed a microatheroma (*arrowhead*) associated with a tortuous distal M1, which probably favored the arrest of the embolus. A small infarct in the basal ganglia was visible on the posttreatment CT. The patient recovered rapidly

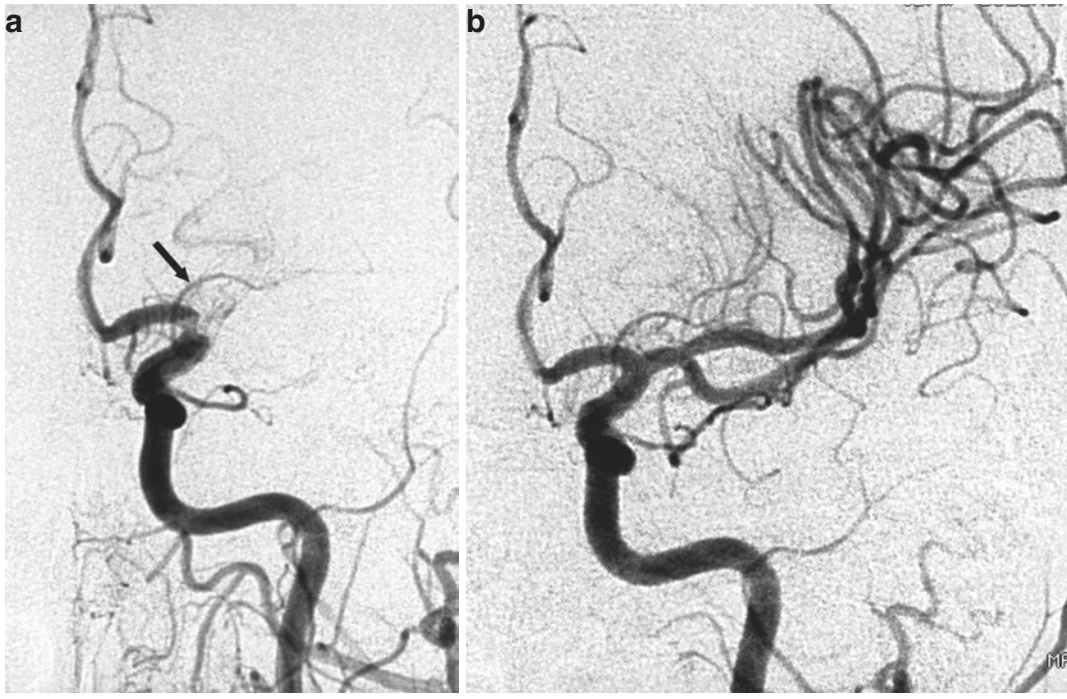

Fig. 15.17 Young patient with acute occlusion of proximal M1, due to a cardiac embolism occurring during a cardiac vascular intervention. (**a**) Left carotid angiogram showing the occlusion. Note the filling of the AchA (*arrow*). (**b**) Complete recanalization achieved with pharmacological selective thrombolysis. Note the early bifurcation due to the short M1, where the embolus was lodged. The perforators arise from the superior branch. On the posttreatment CT small ischemic lesions were visible in the basal ganglia. The patient recovered completely

In other cases, in CT performed after successful endovascular reopening of the M1, small hemorrhages are recognizable in the basal ganglia following the hemorrhagic transformation of the ischemic area. Contrast medium present in the infarcted area can have a similar pattern which, however, rapidly disappears in the CT controls.

In proximal occlusion of MCA the efficiency of the leptomeningeal collateral circulation between branches of ACA, PCA, and distal branches of MCA plays an important role to protect the distal vascular territories. These, however, can be impaired by embolization involving the distal branches, which can be due to emboli arising from the thrombus lodged in the proximal MCA. Distal embolization can also occur during endovascular treatment with disruption or asportation of the thrombus lodged in the proximal MCA. Furthermore distal branches can be selectively involved by small emboli, arising from ICA or heart and passing through the proximal ICA involving its distal branches (Figs. 18.3, 18.4, 18.5).

The therapeutic endovenous or selectively intra-arterial thrombolysis-thrombectomy has improved in many cases the prognosis of these patients.

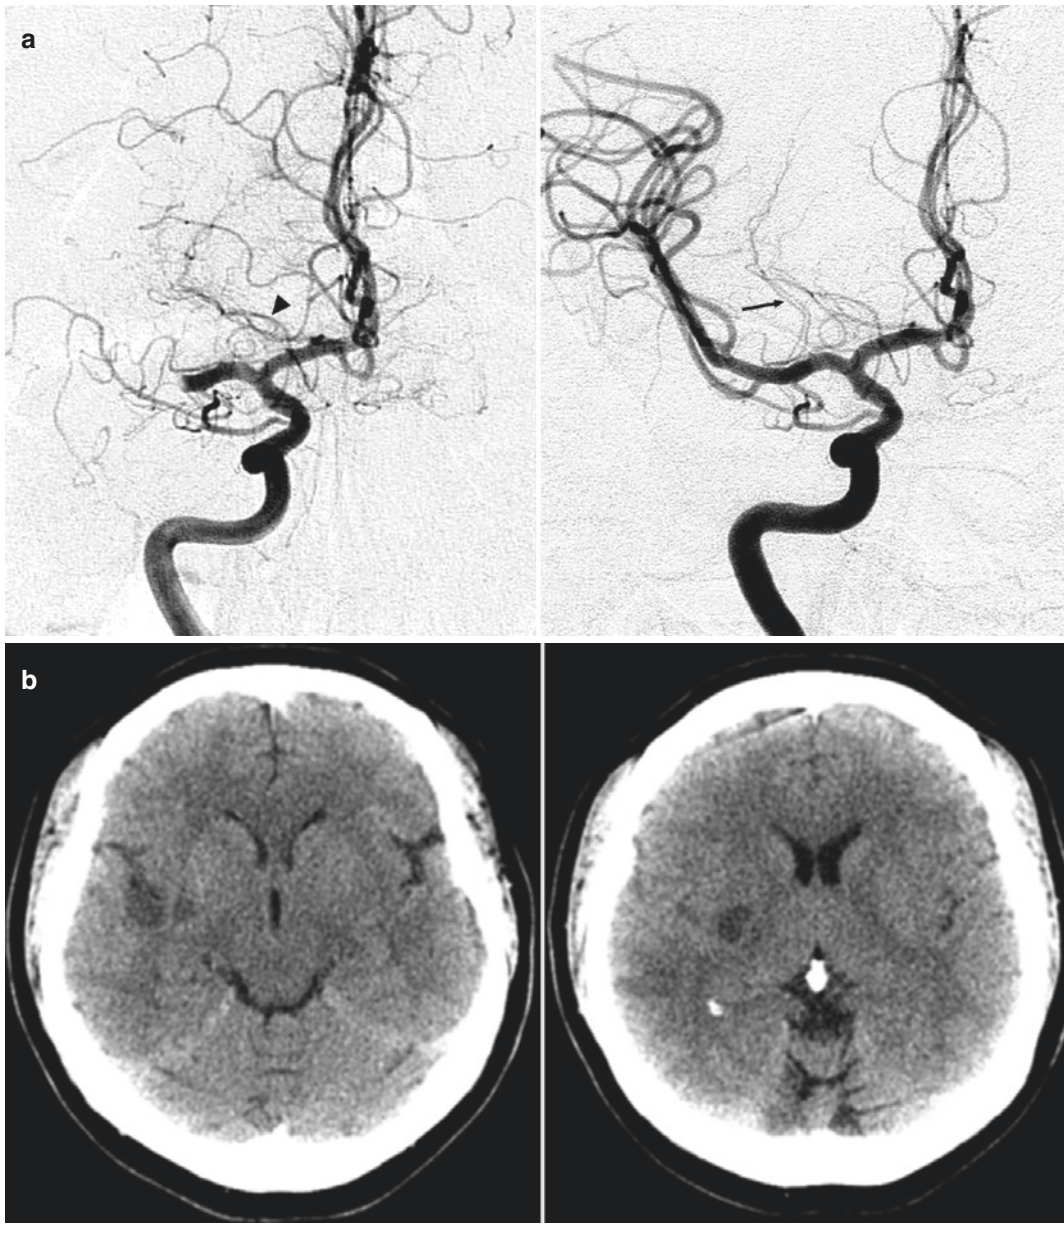

Fig. 15.18 (**a**) Probably embolic occlusion in middle-aged cardiopathic patient. Angiogram pretreatment (*on the left*). Occlusion of the proximal M1. A temporal branch and a small artery directed towards the insula are not involved. The AchA (*arrowhead*) as well as the perforators arising from the ACA are well recognizable. On the angiogram on the right is demonstrated the complete recanalization achieved rapidly with a solitaire stent. The perforators are now well filled (*arrow*). (**b**) The CT post-treatment showed small ischemic foci in the basal ganglia and in the insula region. The patient recovered completely

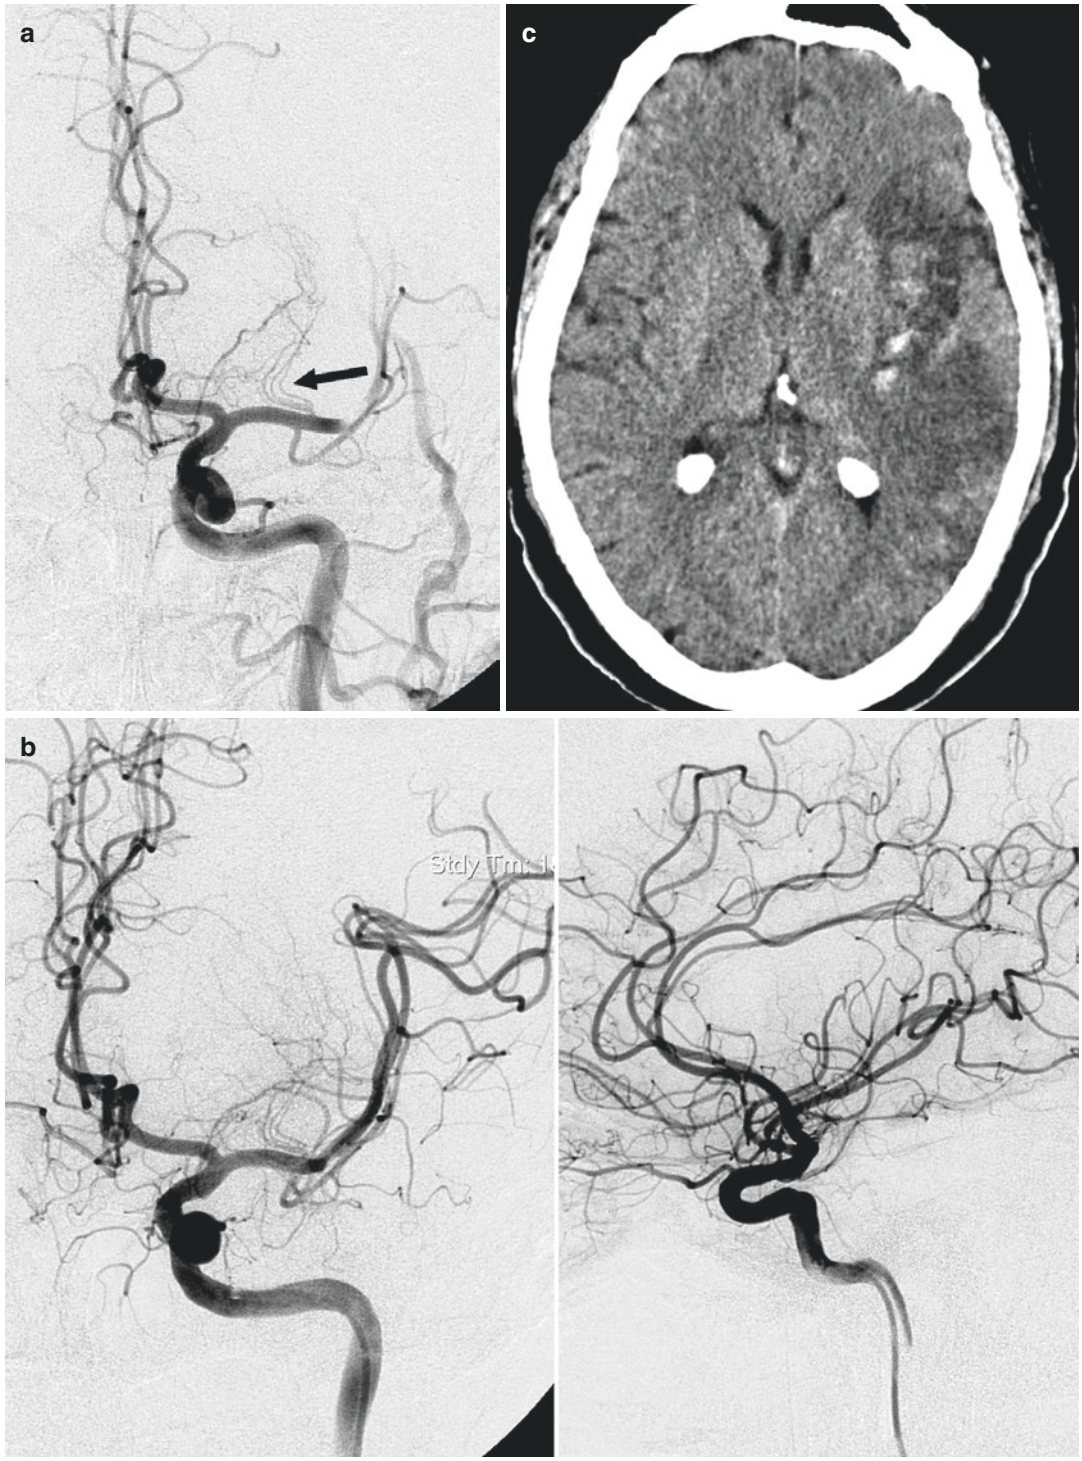

Fig. 15.19 Probably embolic occlusion (middle-aged diabetic and cardiopathic patient), presenting with aphasia and hemiplegia. Intravenous thrombolysis was performed without clinical improvement. The patient was transferred in the angiographic room for treatment. (**a**) The left carotid angiogram showed the occlusion of the MCA at the passage M1–M2. The perforators (*arrow*) were not involved. (**b**) AP and lateral views, after mechanical thrombolysis (solitaire stent) with reopening of the occlusion. As visible on the lateral angiogram, some distal branches remained occluded, probably due to embolization from thrombus in the M1 or following endovascular treatment. (**c**) Posttreatment CT showed an insular ischemia with partial involvement of the temporal and parietal areas. Minimal hemorrhagic component. The basal ganglia were not involved. Slowly, progressively recovery in the following months

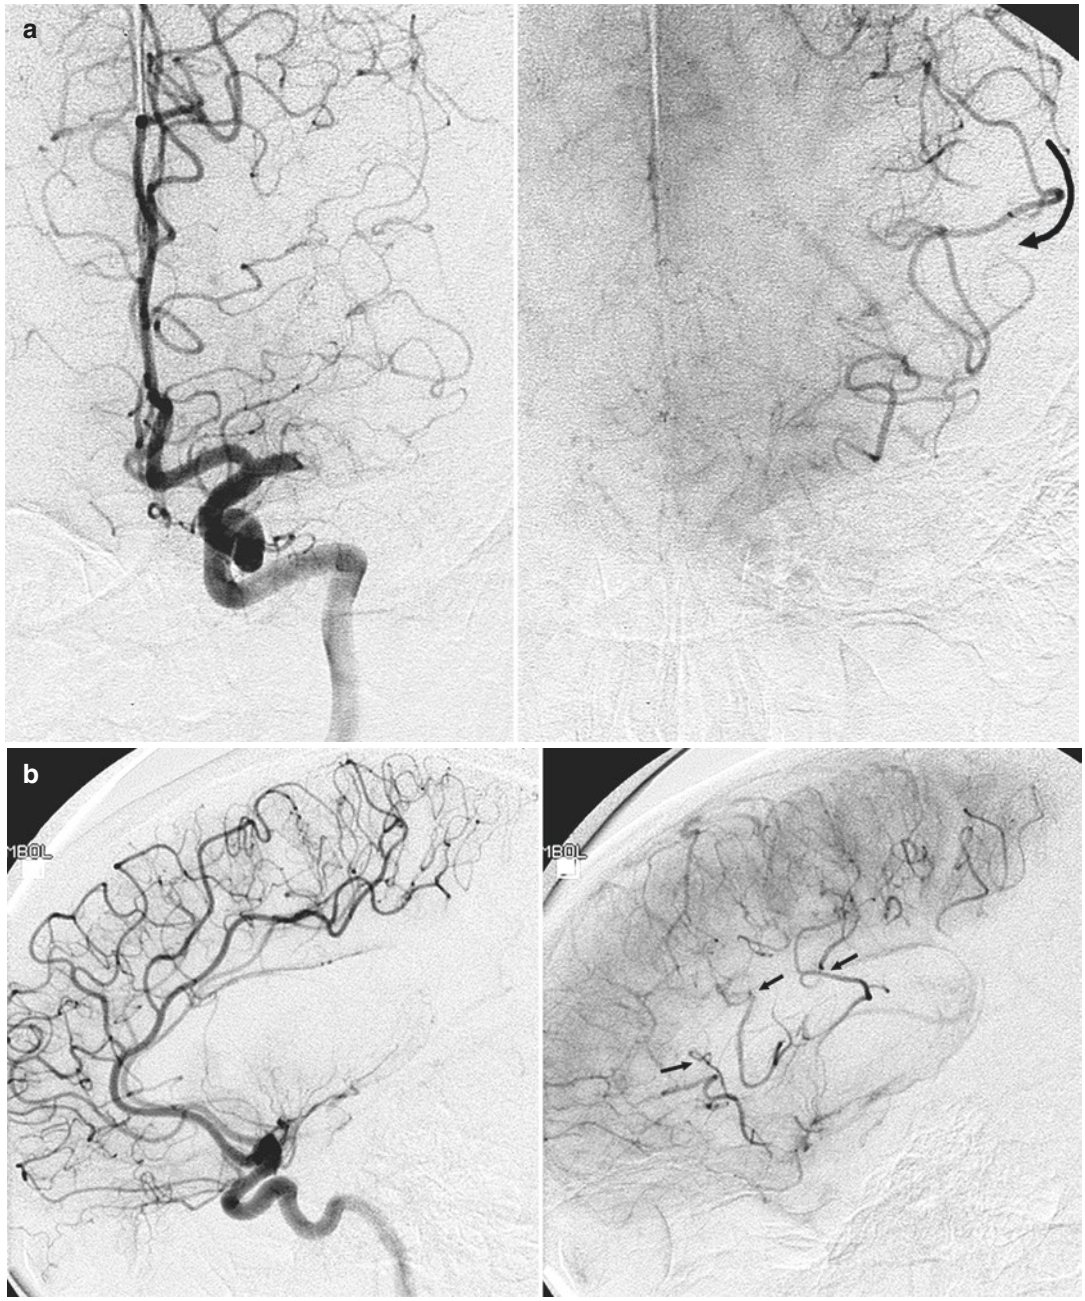

Fig. 15.20 Young woman presenting with right hemiplegia and aphasia. (**a**) Left carotid angiogram. Occlusion of the proximal M1. Rich collateral circulation (*arrow*). through opening of leptomeningeal anastomoses between ACA and MCA. (**b**) Lateral angiogram showing the collateral circulation (*arrows*). Faint filling of the deep venous system. (**c**) Reopening of the occluded M1 with aspiration device. There is a poor filling of the distal perforators (*arrowheads*). (**d**) CT performed 24 h later showed ischemia involving lateral putamen (*arrow*). Good and rapid recovery. Only a minimal motor deficit was present a month later

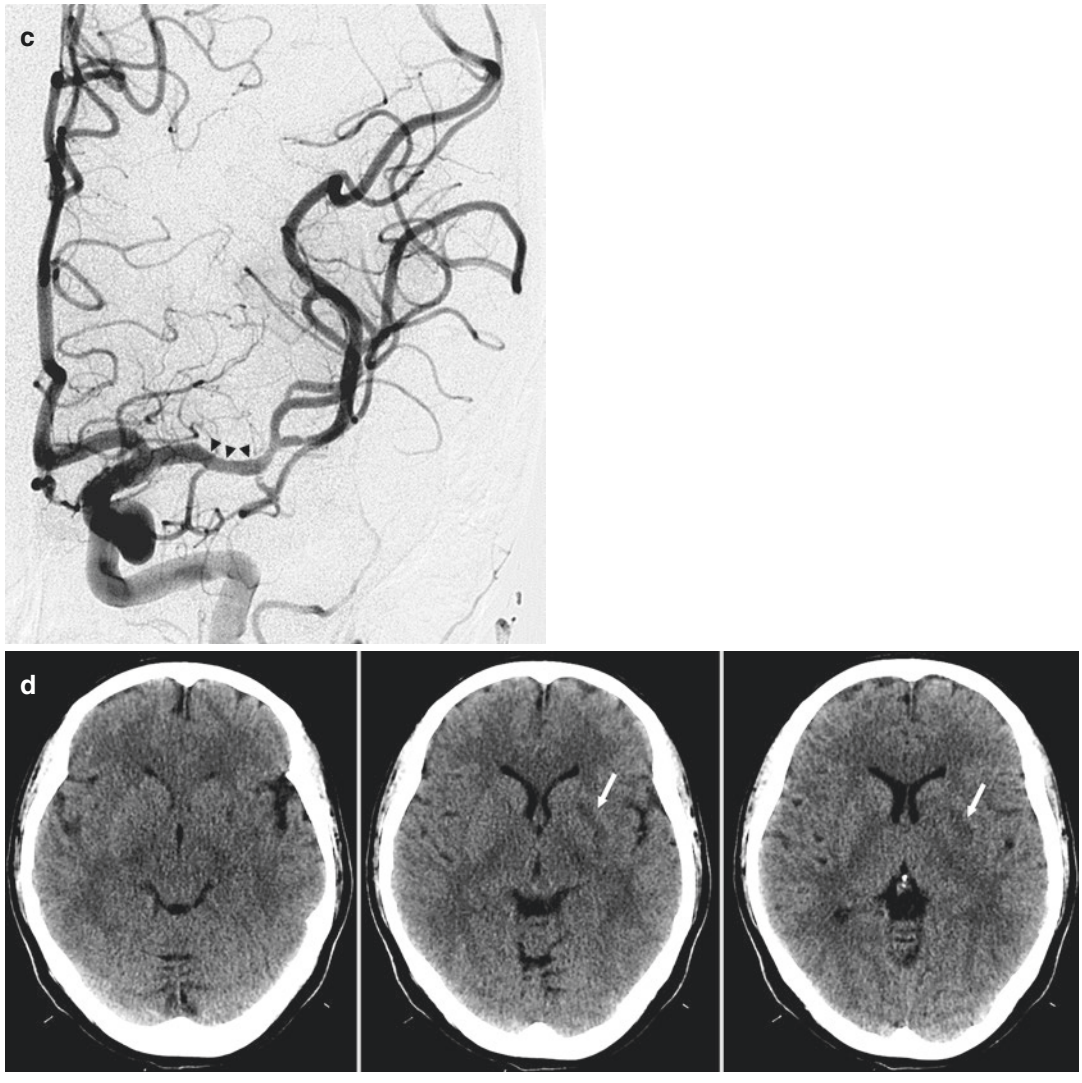

Fig. 15.20 (continued)

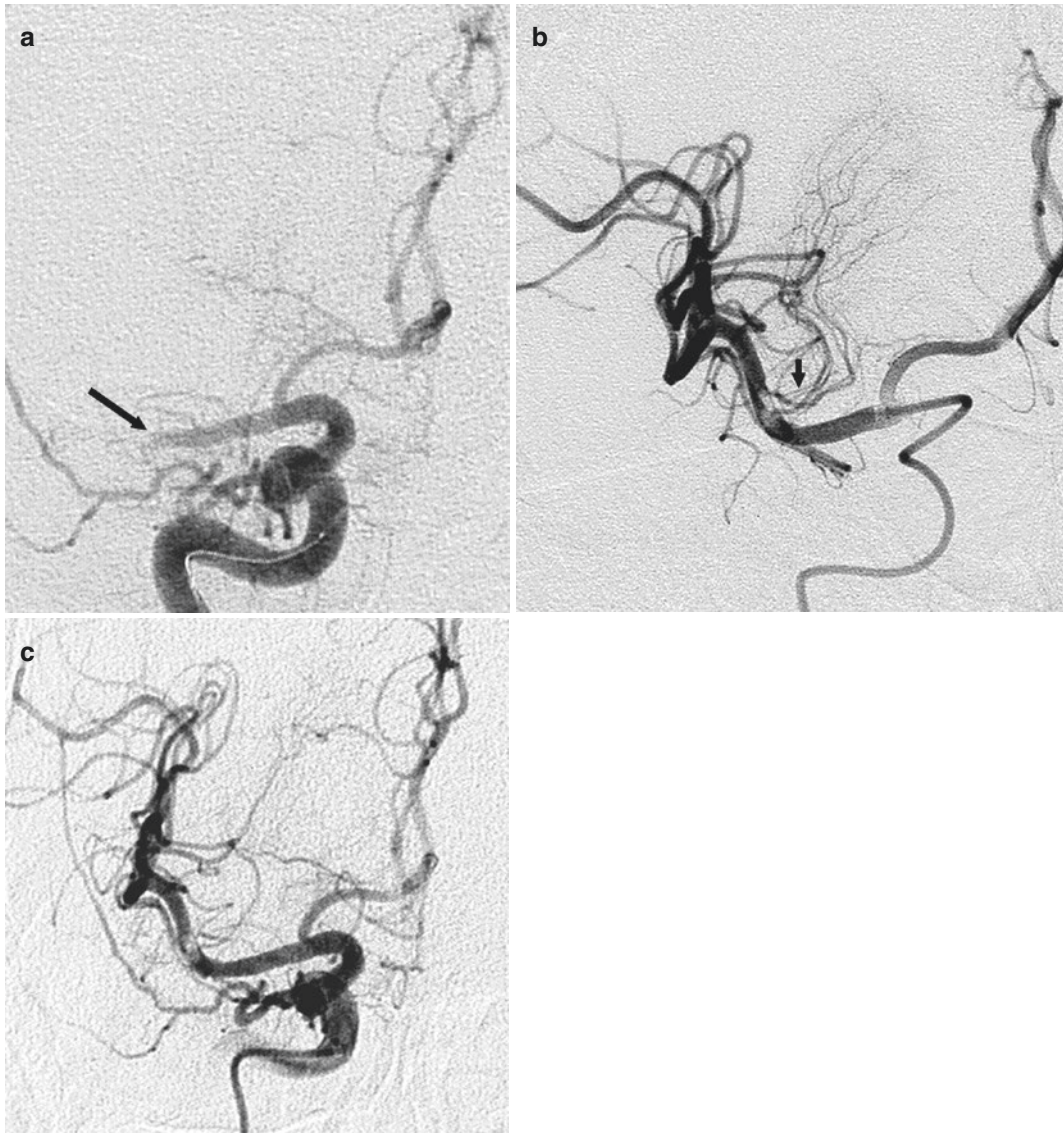

Fig. 15.21 Old cardiopathic woman presenting with hemiplegia due to a probably embolic occlusion of the right M1. (**a**) Right carotid angiogram showing the occlusion (*arrow*). (**b**) Angiogram after mechanical reopening (solitaire stent) of the M1. In the distal segment, a small thrombus is still recognizable. Note that at this level originate the perforators (*arrow*). (**c**) After a further passage with the solitaire, the thrombus is smaller and the distal flow is better. The perforators, however, are now only poorly injected. (**d**) CT performed 2 days later showed ischemia in the basal ganglia with a partially hemorrhagic transformation. Small edema is present. The ischemia involved also the upper part of the nucleus caudatus (MCA territory). Small ischemic foci in the parietal area. There is an old ischemia on the left. The patient recovered slowly. She presented with a mild left hemiplegia 4 months later

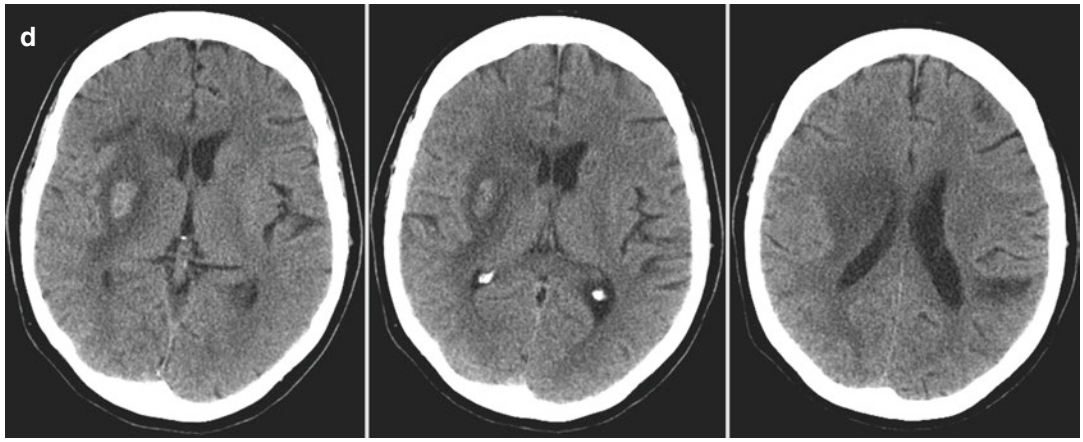

Fig. 15.21 (continued)

- *Microatheroma* of the M1 (Caplan 1989; Bougosslavski et al. 1991; Mazighi et al. 2008) is another less common cause of ischemia which directly involves the perforators. Distal cortical and white matter vascular territories can also be involved in these cases by either hypoperfusion or distal embolization. In selected cases, endovascular treatment (angioplasty, stent) has opened new ways of therapy (Figs. 15.22 and 15.23) with promising results.

15.4.3 Anterior Choroidal Artery

Infarcts in the territory of the anterior choroidal artery (AchA) are frequently associated with ischemia in adjacent vascular territories, especially in the MCA and PCA. The pathogenesis is carotid or cardiac embolism, or atheroma in the supraclinoid segment of ICA (Helgason et al. 1986; Boiten and Lodder 1991; Hupperts et al. 1994; Levy et al. 1995). Involvement of the AchA in *distal ICA occlusion* has already been described (Sect. 15.4.1). Ischemia due to an isolated embolization (Fig. 15.24) as well as that due to an inadvertent occlusion of the artery or its perforators (Friedman et al. 2001; Küker and Schulz 2014) in surgical or endovascular treatment of aneurysm of AchA or located in adjacent area can occur (Fig. 15.25).

The vascular territories of the perforators of the AchA can be partially replaced by other arteries. Furthermore there are many anastomoses connecting AchA and PCA. This explains the irregular presence of ischemic lesions in cases of occlusion of AchA (see Sects. 2.2.3.3, 15.7.1).

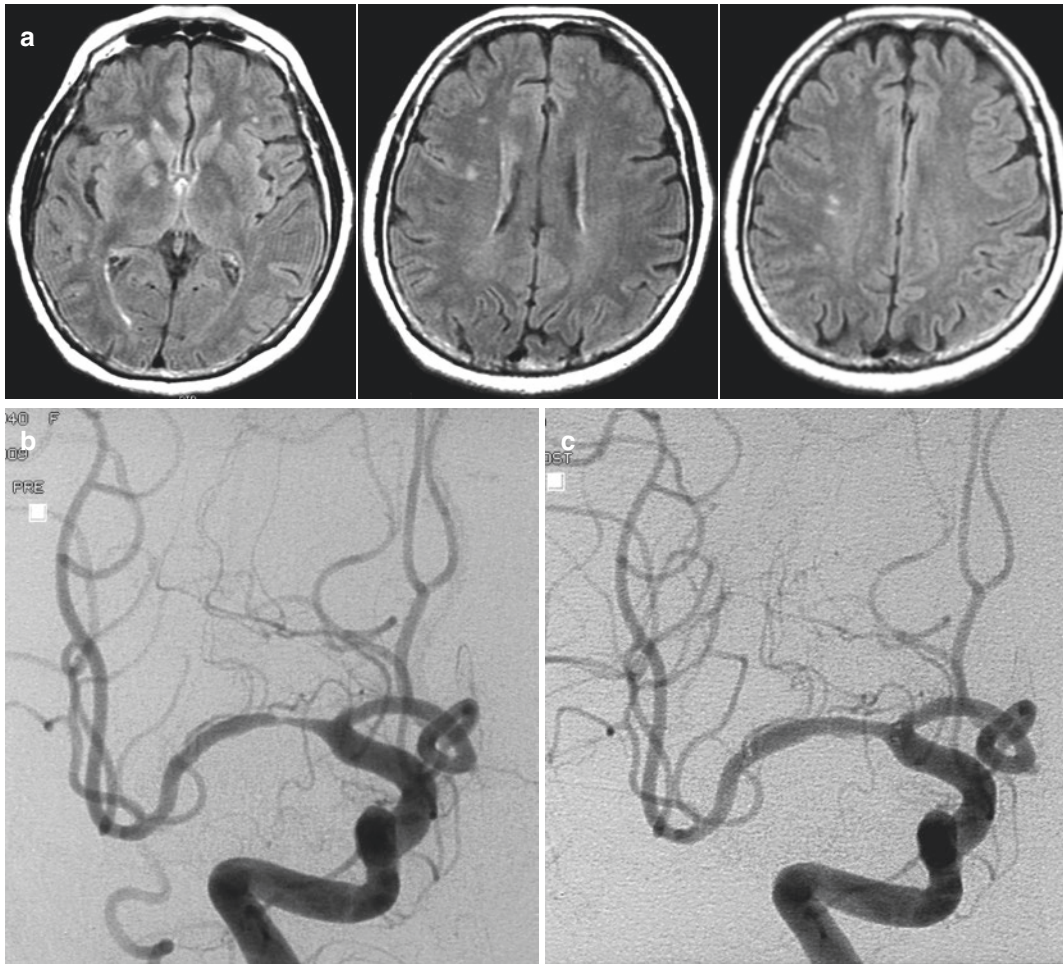

Fig. 15.22 Middle-aged woman presenting with mild neurological deficit, indicating impairment of the right ICA vascular territory. (**a**) MRI showed small ischemic lesions in the right basal ganglia and white matter. Minimal lesions also on the left. (**b**) On the right ICA angiogram severe stenosis of the proximal M1 was recognizable. There is a normal filling of the distal perforators. Endovascular treatment (angioplasty and stent) was performed a week later. (**c**) Angiogram posttreatment. It is conceivable that the ischemic lesions were due partially to involvement of the proximal perforators occluded by the microatheroma. Hypoperfusion in the distal perforators and medullary arteries was responsible of the more distal lesions

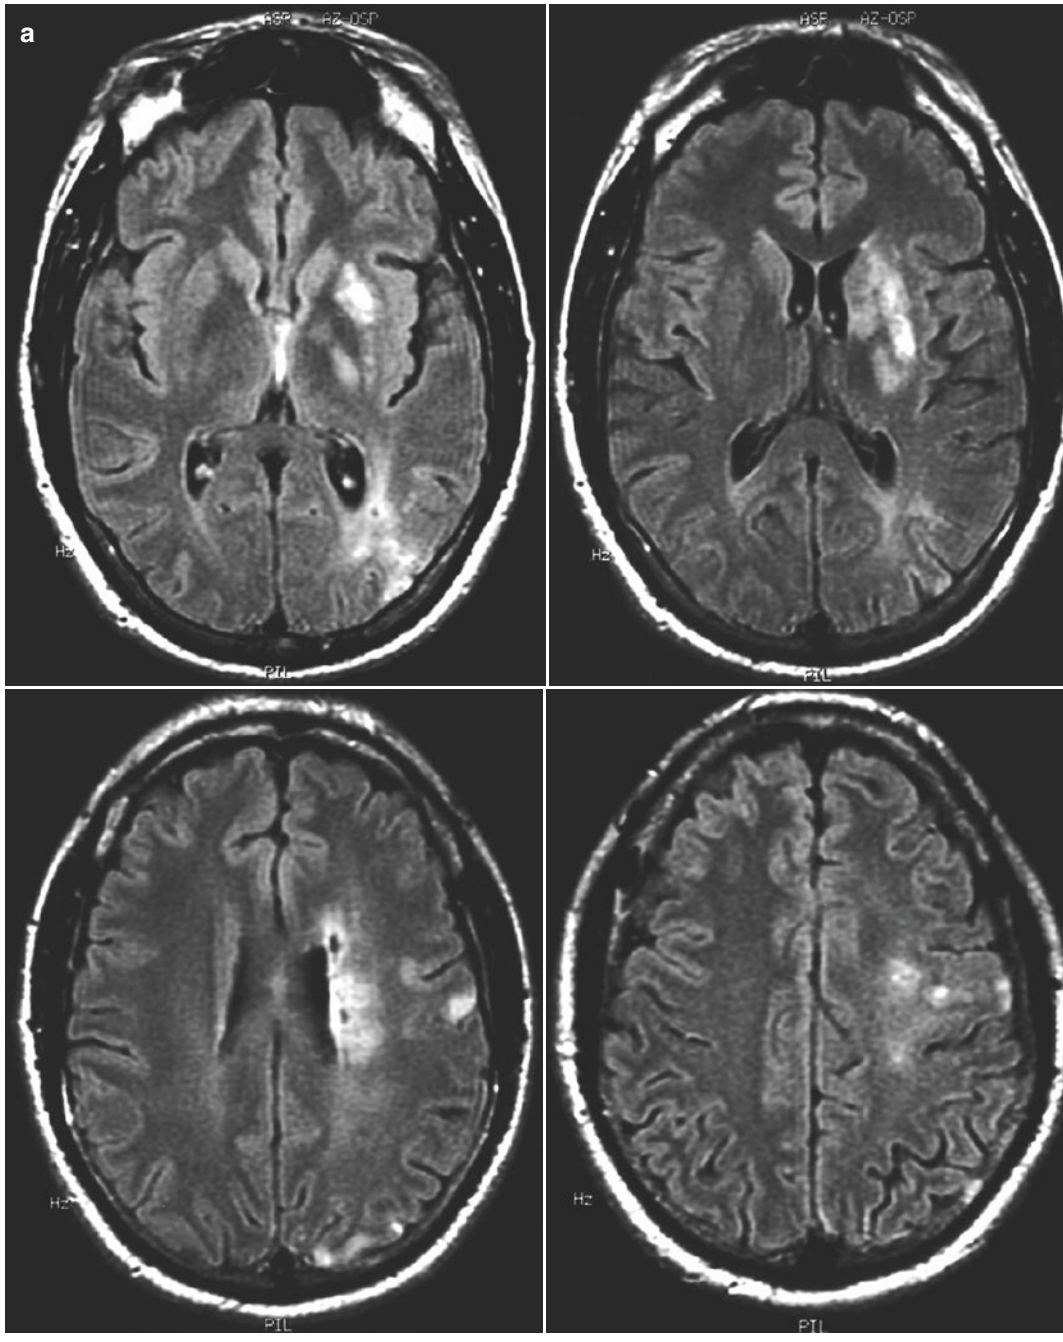

Fig. 15.23 Acute ischemia in a middle-aged woman involving the left basal ganglia, white matter, and partially the cortex. (**a**) MRI showing the ischemic lesions. (**b**) On the angiogram of the left ICA, a severe stenosis of the proximal M1 (*arrow*) was visible. The proximal perforators are probably occluded by the microatheroma. The more distal are well filled. Ischemia was probably due to direct occlusion of some perforators and hypoperfusion involving the distal perforators and medullary arteries. The cortical lesions could be embolic. Three weeks later endovascular treatment (angioplasty and stent) was performed. (**c**) Angiogram posttreatment. Recovery of the patient

Fig. 15.23 (continued)

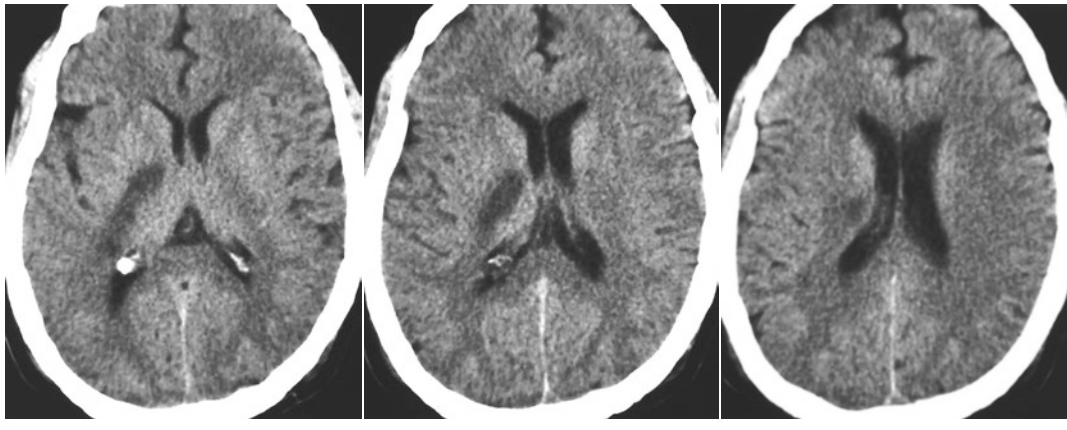

Fig. 15.24 Middle-aged woman with cardiac dysrhythmia presenting with stroke due to occlusion, probably embolic of the AchA. CT showing the ischemia in the corresponding vascular territory

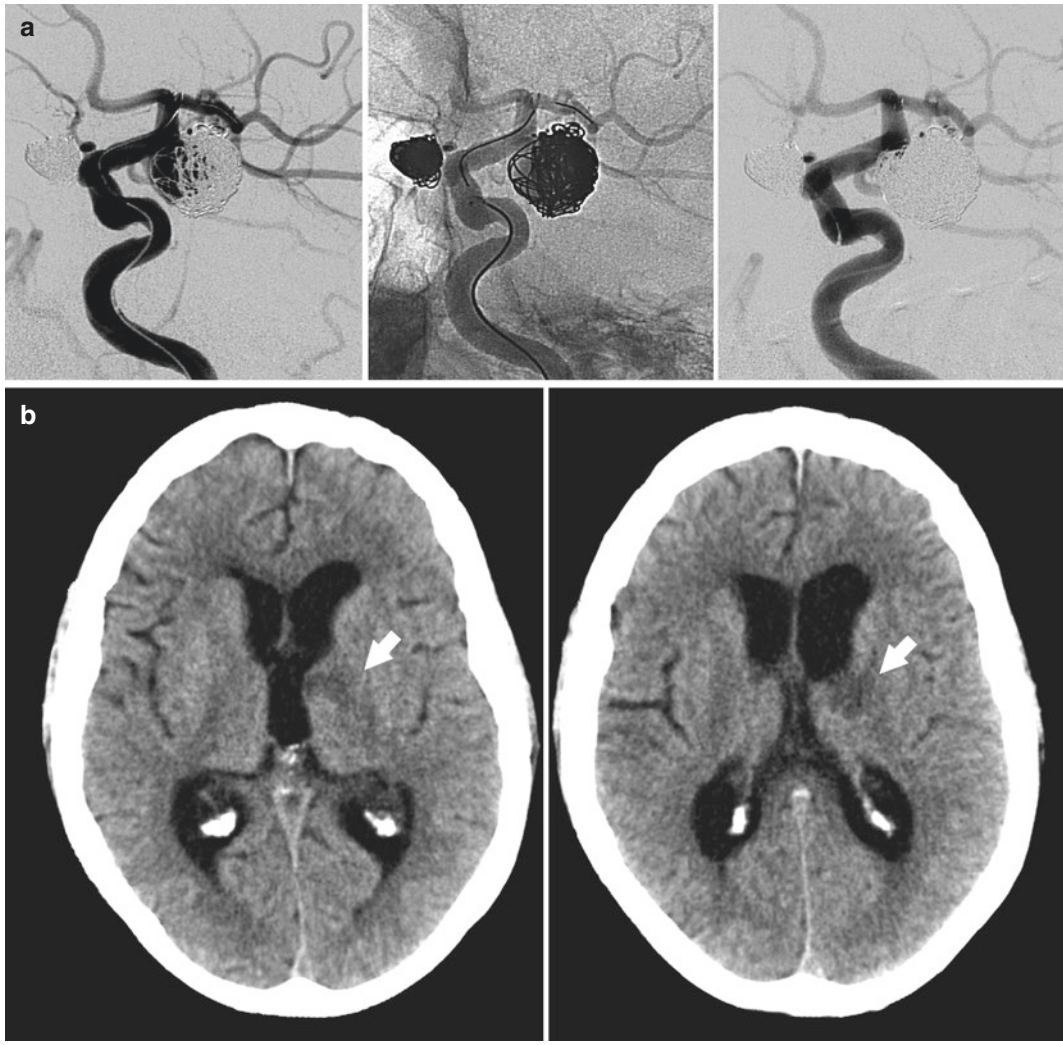

Fig. 15.25 Symptomatic ischemia in the vascular territory of the AchA after endovascular treatment of large aneurysm of the ICA involving probably also the AchA. (**a**) Carotid angiogram showing the large aneurysm already treated 1 year before in the acute phase due to an SAH. A retreatment was performed due to the partial recanalization. In spite of several projections the origin of the AchA was not clearly identified. Complete occlusion of the Aneurysm with coils (angiogram on the right). Coils are also visible in another carotid-ophthalmic aneurysm treated years before. (**b**) Ischemia in the vascular territory of the AchA demonstrated on CT performed 24 h after the treatment

15.4.4 Anterior Cerebral Artery

Infarcts in the territory of the ACA can be due to selectively occlusions of the artery (Fig. 15.26) but more frequently are associated with ischemia involving other vascular territories after carotid or cardiac embolism (Figs. 18.3, 18.4 and 18.5). Embolization is frequently associated with variants in the anterior portion of the circle of Willis, which favor the passage of emboli in the ACA (Kazui et al. 1993). Also variations of the distal branches can explain the type and extension of the infarct (Boccardi et al. 2002) (see also Sect. 4.3). The vascular territories of perforators and/or peripheral branches in varying combinations can be involved depending on the proximal or more distal location of the occlusion.

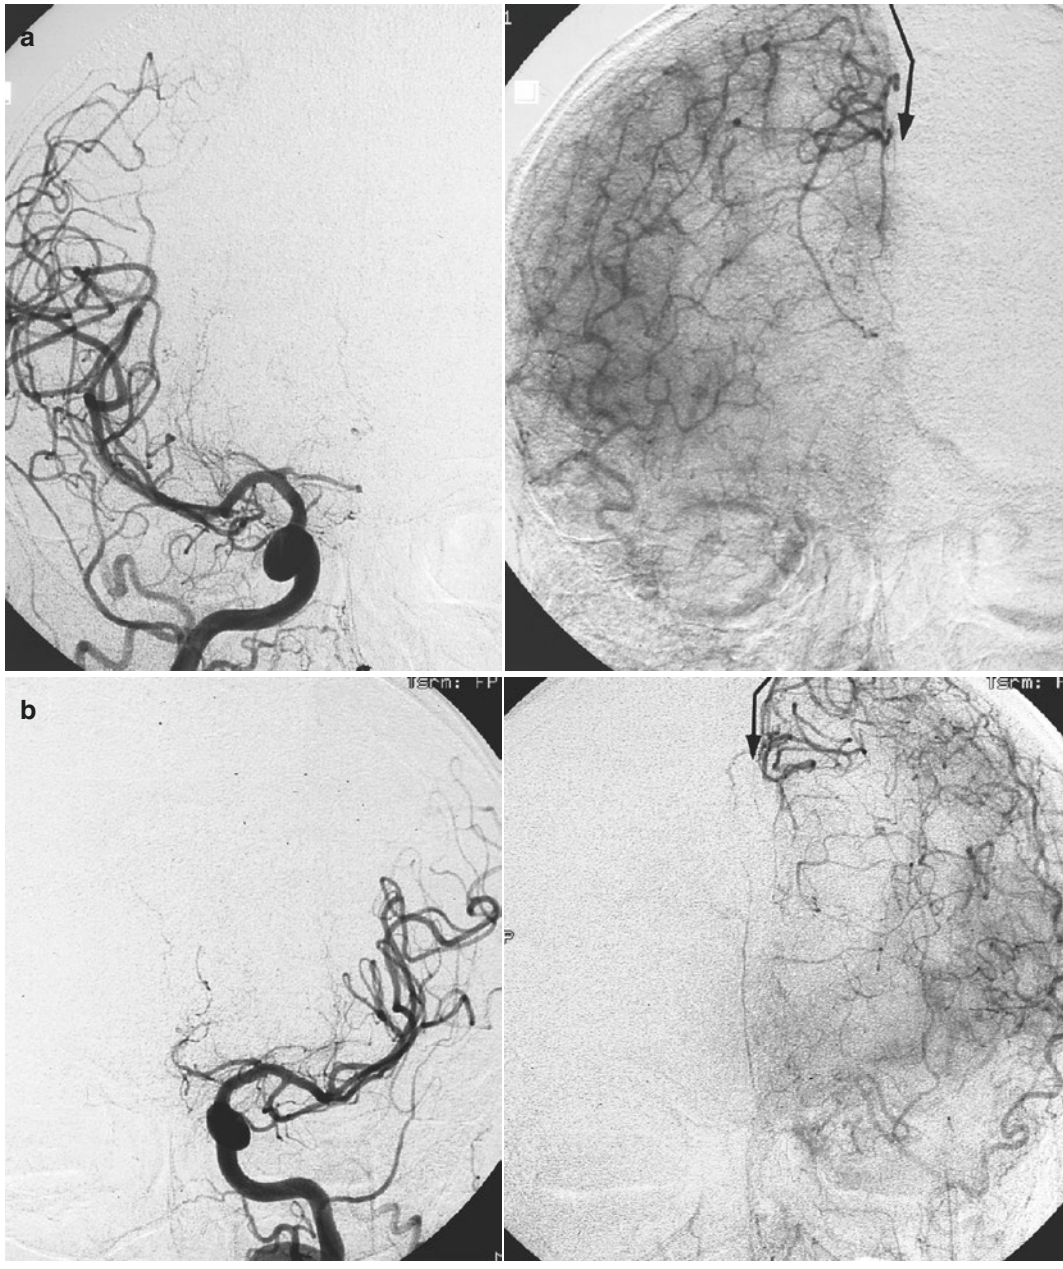

Fig. 15.26 Old female patient with stroke due to bilateral occlusion of the ACA. (**a**) right ICA angiogram showing the occlusion at the passage of the A1–A2 segments. In the late phase, beginning collateral circulation (*arrow*) through opening of anastomoses with distal branches of the MCA. (**b**) Left ICA angiogram showing a similar finding

Considering especially the artery of Heubner, its involvement also in proximal occlusion of the ACA can vary due to its possible different site of origin (see also Chap. 4). Also the inadvertent occlusion of the artery of Heubner as well as of the other perforating branches arising from A1 and/or AcomA especially the subcallosal artery in treatments of aneurysms of AcomA, can lead to ischemia involving, respectively, the head of the nucleus caudatus and adjacent areas and the lamina terminalis, preoptic part of the hypothalamus, anterior commissure, anterior pillars of fornix, and genu of corpus callosum (see Chap. 4, Sects. 4.1 and 4.4).

Microatheroma typically located in the pericallosal segment can be another rare cause of ischemia (Fig. 15.27).

15.4.5 Lacunar and Other Deep Infarcts in the Anterior Circulation

These infarcts are due to involvement of the deep perforators supplying the basal ganglia and capsula interna and perforators (medullary arteries) supplying the superficial and deep white matter. As already described, these arteries do not anastomose to each other, and neither there are connections between the deep perforators and medullary arteries (De Reuck 1972; Moody et al. 1988, 1990, 1991). Both vascular territories or only one can be involved. The typical lacunar infarct is due to the occlusion of a single perforator and it is small, reaching the maximal diameter of 15 mm. This pathological condition, also called "*small vessel disease*," presents with clinical symptoms which depend on the site and extension of the damaged parenchyma. Isolated lesions can be asymptomatic. Stroke can occur followed by improvement. Multiple lesions can develop presenting with or without stroke leading to a progressive decline of different neurological function with cognitive impairment and finally to dementia.

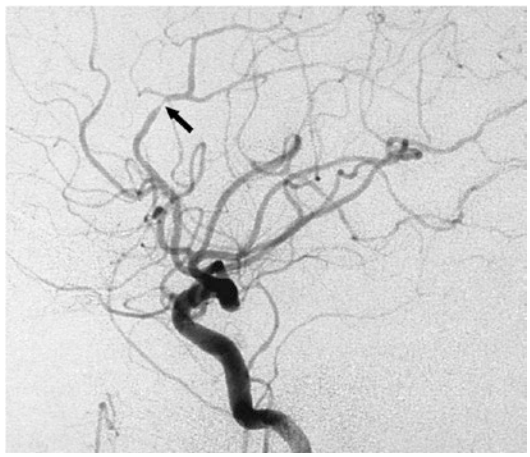

Fig. 15.27 Typical location of a microatheroma in the pericallosal artery in an asymptomatic patient

A frequent pathogenesis is a special type of atherosclerosis, occurring particularly in patients with hypertension and diabetes called by Fisher (1965, 1968) *lipohyalinosis*, which is characterized by a large presence in the wall of the vessels of hyaline material. In other cases the histological examination has shown a finding characterized by eosinophilic material representing accumulation of necrotic smooth muscles cells and extravasated plasma proteins, called fibrinoid necrosis. Both processes lead to stenosis and occlusion of the artery causing ischemia and sometimes rupture of the wall and hemorrhage. The lesions can be very numerous and disseminated in both hemispheres. MR demonstrates on T2-weighted images the hyperintense ischemic lesions not rarely associated with small hypointense foci due to old microhemorrhages well defined with T2*-weighted gradient-echo and SW-weighted images. Pathological examinations disclose infarcts commonly small (less than 15 mm in diameter) in the basal ganglia and white matter. In this latter, also areas of rarefaction due to destruction of fibers and area of gliosis have been demonstrated (Brun and Englund 1986; Pantoni et al. 1996). No pathological changes of the arteries can be detected on the angiogram in many of these patients.

Another pathogenesis of deep infarcts involving predominantly the white matter, and which are commonly larger than the typical lacunar infarct is thought to be occlusion or severe stenosis of the ICA leading to hypoperfusion or embolization or both, as reported by several authors (Levine et al. 1988; Waterston et al. 1990; Angeloni et al. 1990;

Weiller et al. 1990, 1991; Bougosslawski et al. 1991; Bougosslavsky and Regli 1992; Bladin and Chambers 1993; Horowitz and Turim 1997; Boiten et al. 1997; Read et al. 1998; Bradac et al. 2008b). Romero et al. 2009; Enzinger et al. 2010). In this context, the type of ICA plaque as source of emboli plays probably an important role (Altaf et al. 2006; Baradaran et al. 2017)(See also Sects. 15.4.1). Furthermore, as suggested by some authors (Patankar et al 2006), the presence of ICA atheromasic lesions could be an indirect sign of diffuse atherosclerosis involving not only the extracrtanial ICA but also its intracranial perforators branches. Cardiac emboli or emboli arising from aortich arch atheroma are also a possible pathogenesis.

Another type of ischemic lesion is that termed *striatocapsular infarct*, also called by Fisher (1965, 1979) "giant" or "super" lacunas. These differently from the small lacunas involve the vascular territory of more than one deep perforators arising from ICA, AchA, MCA, and ACA. (Ghika et al. 1989; Boiten and Lodder 1991; Nicolai et al. 1996; Horowitz and Turhim 1997; Bradac et al. 2008b). The pathogenesis of these lesions varies. They can be due to occlusion of the M1 segment of the MCA due to emboli arising from atheroma of the ICA or cardiac in origin. Another cause can be a severe stenosis due to microatheroma located at the ostium of the perforators arising from M1 or distal ICA. The striatocapsular infarct can be associated with lesions in the white matter for involvement of the medullary arteries due to hypoperfusion or distal embolization (Figs. 15.22 and 15.23).

Association of ischemic lesions and microhemorrhages can occur in patients with amyloid angiopathy and in other nonatherosclerotic vasculopathies (see also Chaps. 17, 18, 19 and 22).

In conclusion, the pathogenetic process leading to ischemia in the vascular territory of the deep or superficial perforators cannot always be assessed with certainty since several mechanisms can be involved and these can also occur together (Jackson and Sudlow 2005). *In this context, also morphological variants should be considered, as already described (see anatomy). In particular, it should be noted that the lenticulostriate arteries can arise as a common trunk* (Fisher 1979; Umansky et al. 1985) *responsible for the vascularization of a large territory. In case of its occlusion due to lipohyalinosis leading to a large lacunas, it will be difficult to make a differential diagnosis with a striatocapsular infarct in which more than one perforators are involved in which the pathogenesis is commonly different (see above). We mention here that lacunar infarcts in the anterior circulation are frequently associated with similar lesions in the posterior circulation* (*see Sects.* 15.5.3, 15.5.4, *and* 15.5.5). *Finally it should be taken into account that similar lesions can occur in other vascular pathologies not linked to arteriosclerosis and in other diseases.*

Two other particular conditions deserve a short description. The one is a very rare type of infarct located lateral to the basal ganglia involving the *white matter of the external capsule* in the border area between the deep perforators arising from M1 and the medullary arteries arising from the insular branches. These lesions have been termed subinsular infarcts by Pullicino et al. (1992). The other is the so-called *Binswanger's disease,* described by the author in 1894 on the basis of anatomo-pathologic studies, characterized mainly by diffuse ischemic lesion involving the white matter. Further histological and in vivo MR examinations have shown that the parenchymal lesions and the clinical symptoms are basically not different from those due to involvement of deep and superficial (medullary) perforators occurring in arteriosclerotic patients with small vessels disease. Binswanger's disease is today considered by many authors as an aspect of the disease and not as a specific entity.

15.5 Posterior Circulation

The most frequent sites of atherosclerotic plaques in the vertebrobasilar sector are at the origin of the VA from the subclavian artery and at the intracranial VA shortly after the artery perforates the dura (Castaigne et al. 1973; Caplan 1996). The third frequent location is the basilar artery, particularly in its middle segment (Castaigne et al. 1973; Pessin et al. 1987; Caplan 1996). Atheroma can be found also at the P1–P2 segment

of the PCA (Bradac and Oberson 1983; Fisher 1986; Pessin et al. 1987). The composition of the atheroma, basically, does not differ from that in the carotid sector (Fisher and Ojeman 1986; Amarenco et al. 1990). Commonly, the plaques are less ulcerated than that in the carotid sector, but ulceration is not rare in the plaques of the subclavian arteries near the origin of the VA (Amarenco et al. 1998).

15.5.1 Subclavian and Innominate Arteries

Atheroma of the subclavian and innominate arteries are frequently and commonly asymptomatic. The atheroma can grow, leading to severe stenosis or occlusion of the artery. When this occurs proximal to the origin of the VA, blood flow from the normal VA intracranially and then down into the contralateral VA, further filling the distal subclavian artery. This situation, described first by Reivich et al. (1961), is termed the subclavian steal syndrome. This can present with TIAs involving the brainstem or pain in the ischemic arm, but frequently it remains completely asymptomatic. Symptoms occur commonly in patients with diffuse atherosclerotic lesions that involve also the carotid sector (Hennerici et al. 1998). Since it has a benign course, this syndrome only rarely needs aggressive treatment. Examples are presented in Fig. 15.28.

15.5.2 Vertebral Artery

Severe stenosis or occlusion of one VA at its origin remains frequently asymptomatic provided that no embolization occurs and the other VA as well as the circle of Willis sufficiently supply the vertebrobasilar sector. In contrast to thrombus of the ICA bifurcation, which can extend intracranially, thrombus of the extracranial VA does not extend intracranially, probably because the rich collateral circulation that arises from the other VA, the deeply and ascending cervical arteries, and from ECA, maintains sufficient flow.

Flow impairment can occur when stenosis of one VA at its origin is associated with occlusion or hypoplasia of the other or due to bilateral severe stenosis and in cases in which the vertebrobasilar sector is an important collateral way towards the severe affected carotid sector. In these cases endovascular treatment (stenting with or without angioplasty) has progressively become an accepted therapeutic approach (Taylor et al. 2008; Karameshev et al. 2010; Stayman et al. 2011; Edgell et al. 2013). Examples are presented in Fig. 15.29.

The atherosclerotic plaque can also be the source of emboli which are not so rare as previously thought (Wityk et al. 1998). In this context see also Sect. 15.5.4.

Another very rare cause of stroke in the vertebrobasilar sector is the involvement of the extracranial VA due to degenerative processes (hyperplasia of the facets, lateral disc herniation, fibrous band) leading to stenosis or temporary occlusion during neck rotation (Mapstone and Spetzler 1982; Vilela et al. 2005; Andereggen et al. 2012). This condition can be the cause of stroke due distal embolism or hemodynamic impairment of flow. Surgical treatment is considered the most appropriate therapy.

Occlusion of the intracranial VA due to artery-to-artery or cardiac embolism or thrombus developed on a preexisting microatheroma is a more serious condition since it involves the perforators of the VA that supply the anterolateral medulla. Depending on the distal extension of the superimposed thrombus, the PICA, supplying prevalently the dorsal medulla and cerebellum, and the anterior spinal artery supplying the anterior medulla can be involved. However, probably owing to a rapid spontaneous lysis of the embolus or thrombus in the VA, the ischemia is frequently only temporary or limited only to the PICA territory, which has commonly a benign course.

The thrombus can extend to the basilar artery. This is a very critical condition which needs a rapid endovascular treatment leading to a reopening of the artery. Examples of occlusion involving primary the VA with different distal extension of the thrombus are presented in Figs. 15.30, 15.31, and 15.32).

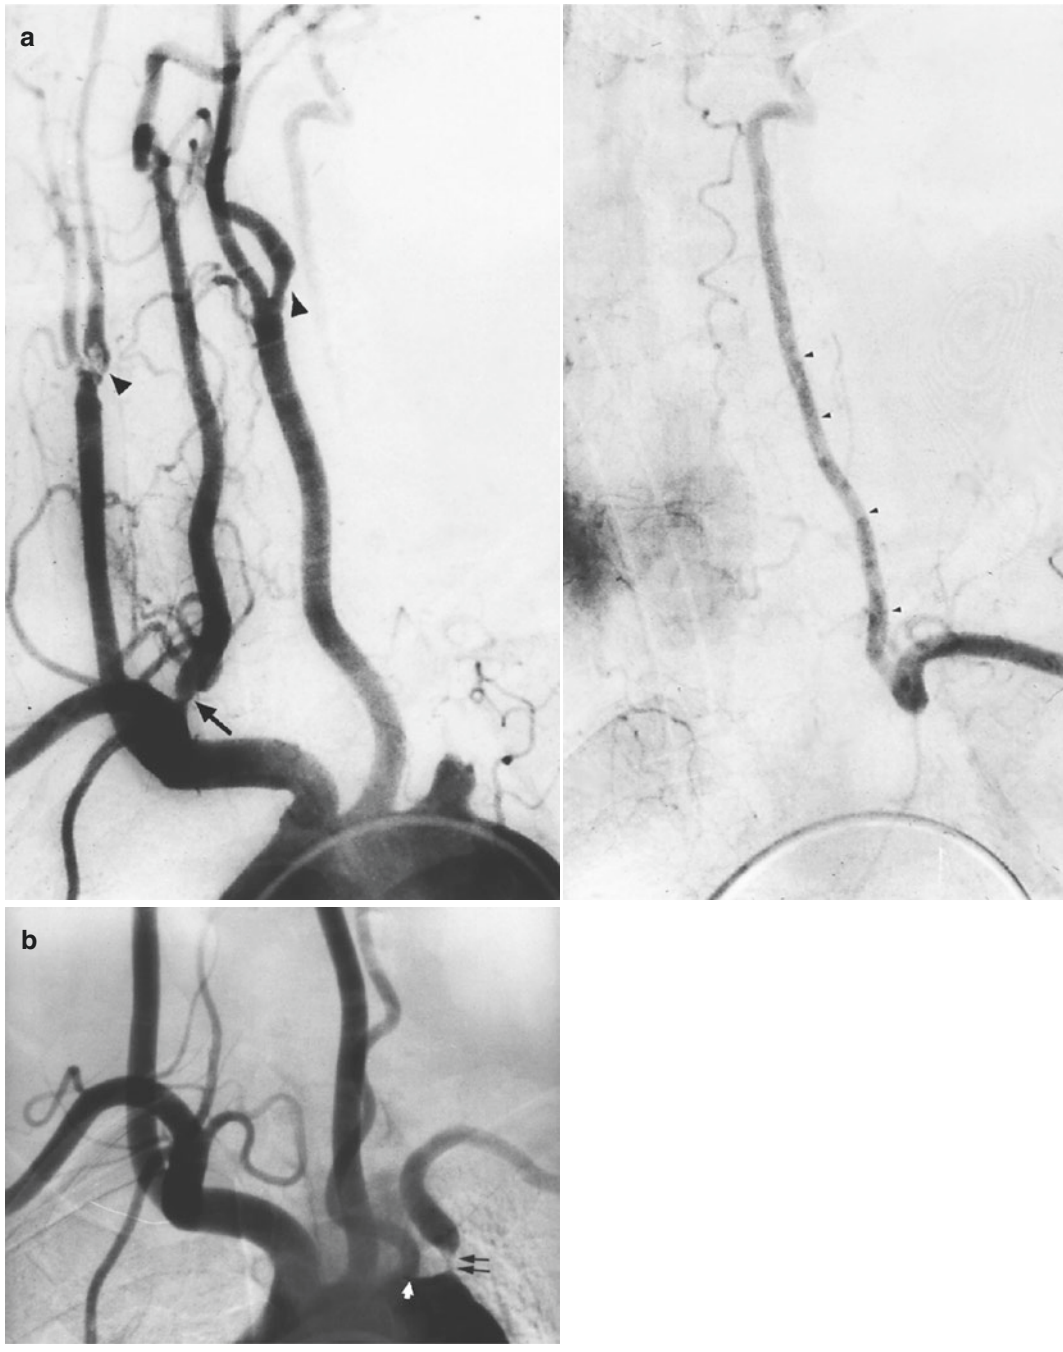

Fig. 15.28 (**a**) Subclavian steal syndrome, aortic arch angiogram. Occlusion of the proximal left subclavian artery. There is a well-developed right VA, stenotic at its origin (*arrow*). The blood flows in the right VA intracranially, and then down into the left VA (*small arrowheads*) and further into the distal left subclavian artery. Atheromasic changes at the carotid bifurcations bilaterally (*arrowheads*). (**b**) Aortic arch angiogram in a different patient. Severe stenosis of the proximal left subclavian artery (*arrows*). A subclavian steal syndrome is not present, since the left VA originates directly from the aortic arch

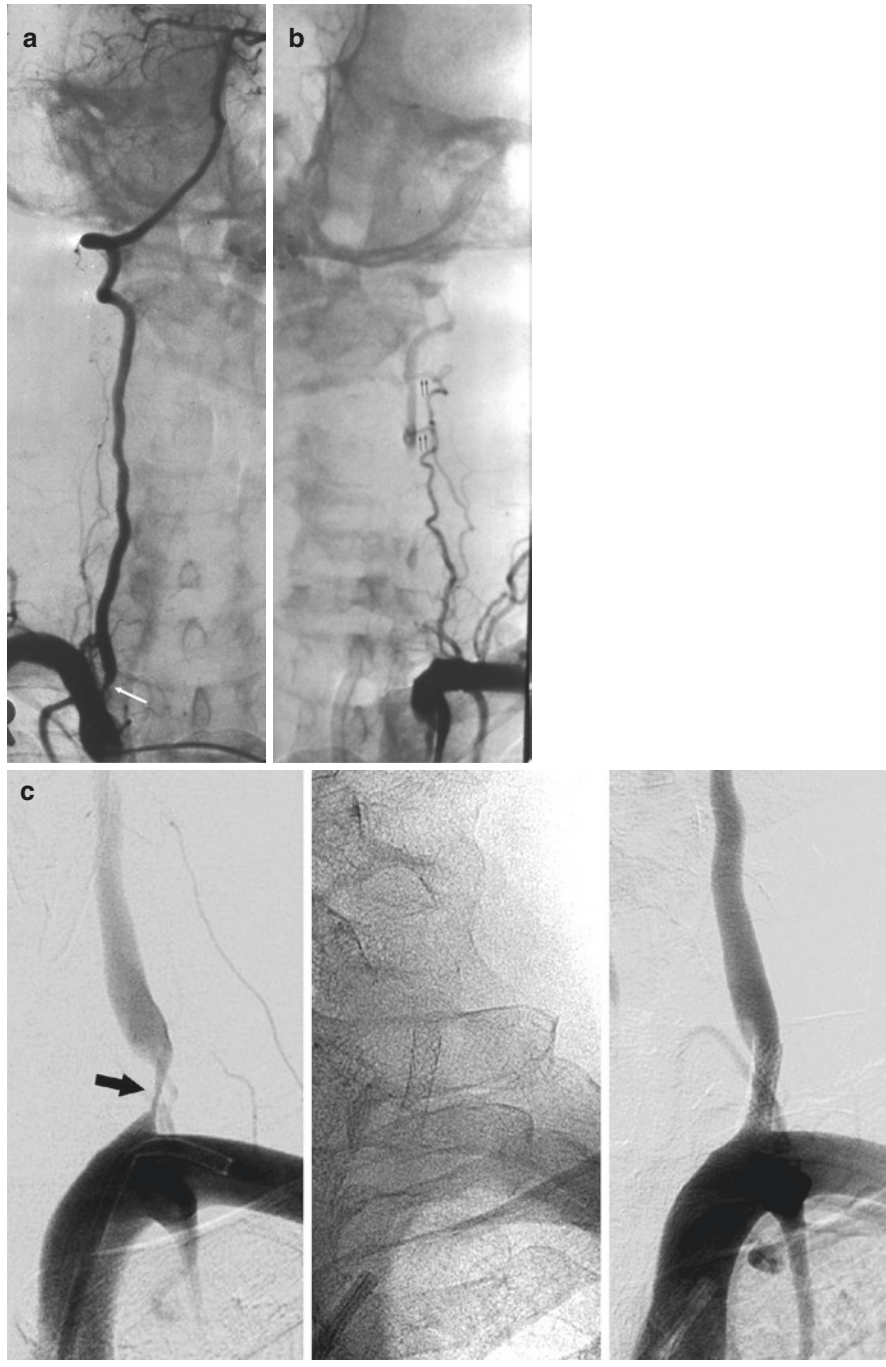

Fig. 15.29 (**a**), (**b**) Middle-aged patient presenting with vertigo, ataxia, and nystagmus. (**a**) On the right VA angiogram a moderate stenosis of the VA at its origin was visible (*arrow*). There was a normal flow in the intracranial vertebrobasilar sector. The PICA was not recognizable, but a well-developed AICA was present. This was visible on a more selective study. (**b**) The left VA was occluded. There was a partial distal revascularization through anastomosis with the ascending cervical artery. The patient recovered and the stenosis was later treated with angioplasty and stent. (**c**) Severe impairment of flow in the vertebrobasilar sector in another patient with severe stenosis of the dominant left VA (*arrow*) and hypoplastic right VA. Angiograms pre- and poststenting

Fig. 15.30 (**a**) Acute ischemia involving the anterior medulla, corresponding to the vascular territory of the anterior spinal artery, demonstrated on the MRI with diffusion-weighted image. (**b**) Angiography shows a normal left angiogram and an occlusion of the right VA distal to the PICA (**c**). On both angiograms the anterior spinal artery was not identified, probably occluded. Note the presence of the odontoid arch (*arrowhead*)

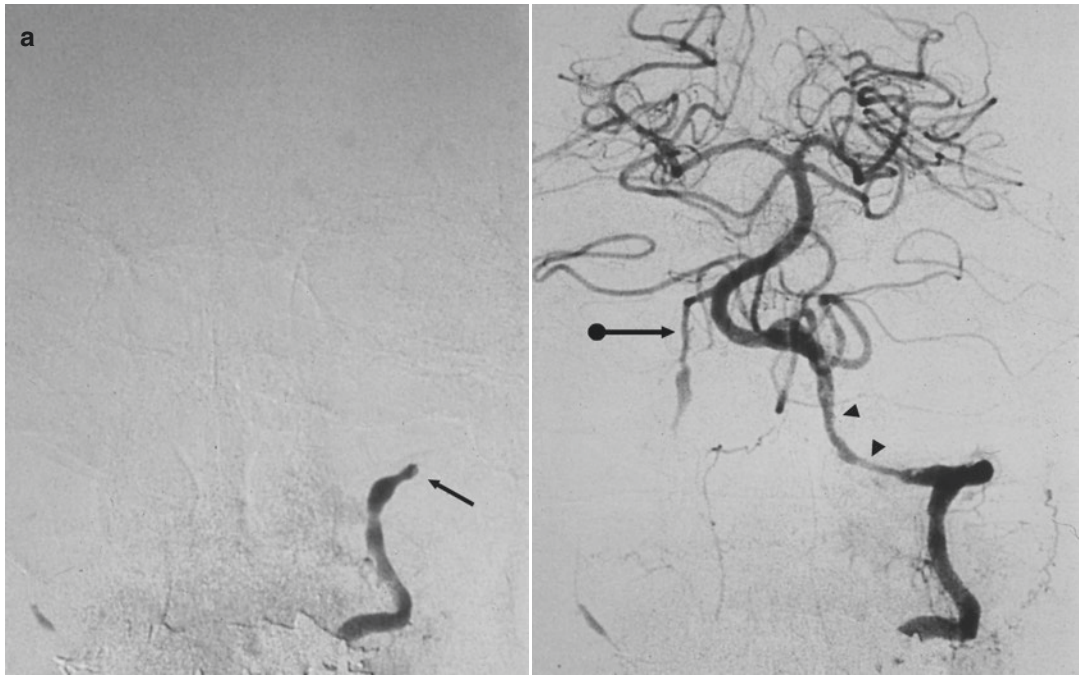

Fig. 15.31 Acute thromboembolic occlusion of the left VA at the extra-intracranial passage in an old patient with an old occlusion of the contralateral VA. Left vertebral angiogram showing the occlusion of the VA (*arrow*). Control angiogram (*right on the figure*) after selective pharmacological thrombolysis. Reopening of the artery with complete revascularization of the vertebrobasilar sector. Severe atheromatous changes of the VA (*arrowhead*) on which the thrombus developed are now recognizable. There is a partial retrograde filling in the occluded right VA (*arrow with dot*)

Endovascular treatment can also be considered in cases of symptomatic *intracranial microatheroma* of one VA especially if associated with lesions or hypoplasia of the contralateral VA, not responsive to medical therapy (Fig. 15.33).

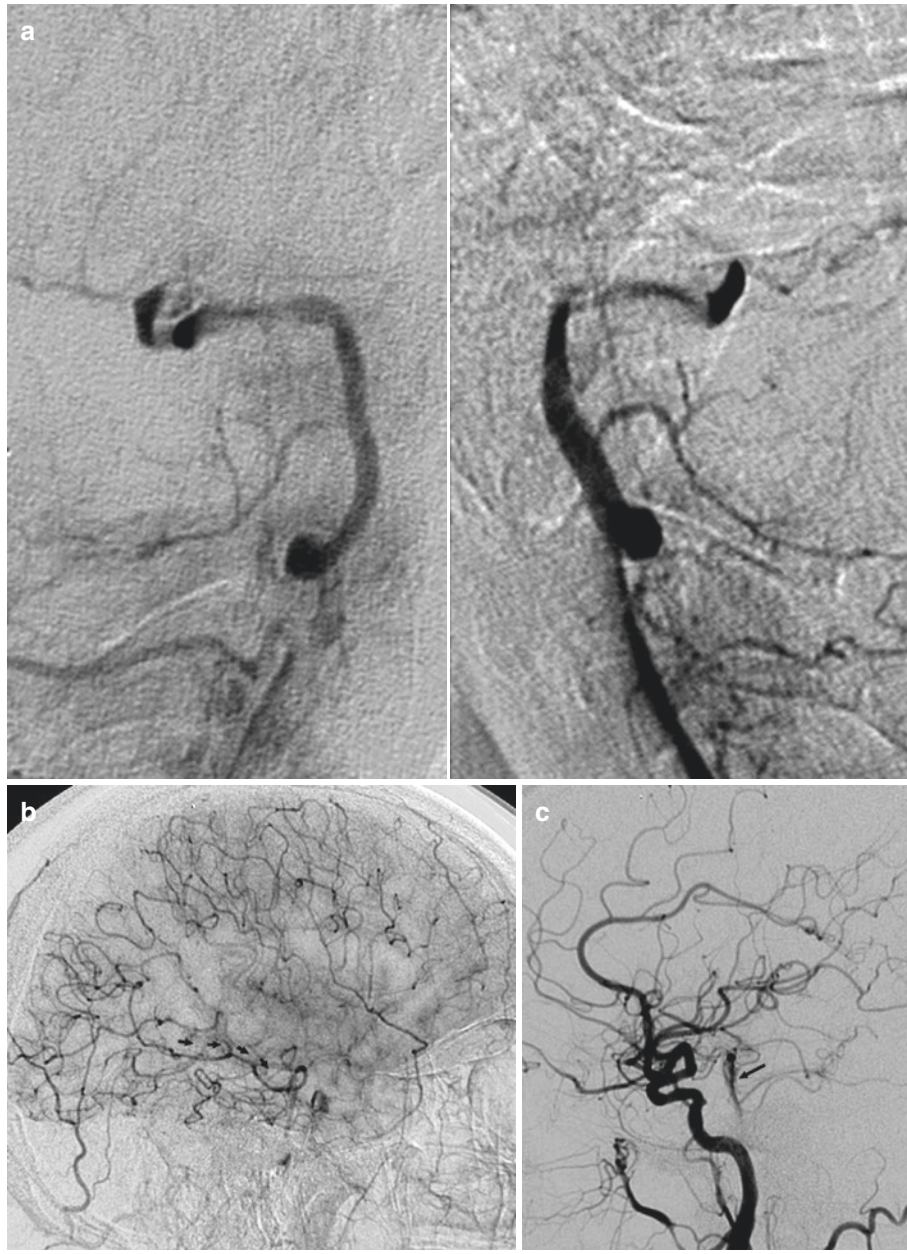

Fig. 15.32 60-year-old hypertensive, diabetic patient presenting with symptoms indicating involvement of posterior circulation, progressively worsening. Consciousness was not affected. CT and CT angiography showed small ischemic area in the cerebellum. Brainstem appeared normal. Basilar artery was not recognizable. (**a**) Left and right vertebral angiograms showed occlusion of both VAs at the extra-intracranial passage. (**b**) right carotid angiogram, late phase. Through leptomeningeal anastomoses (*arrow*) there is a retrograde filling of the right PCA and distal BA. (**c**) left carotid angiogram. Filling of the distal BA through a small PcomA (*arrow*). (**d**) Mechanical thrombectomy (aspiration device and solitaire stent) with reopening of the right VA and restoring of the intracranial circulation. Partial retrograde injection of the occluded left VA. (**e**) DWI-MRI performed 3 days later showed several ischemic lesions due to involvement of median, paramedian perforators of BA, as well as its lateropontine branches. Small infarcts are also recognizable in the cerebellum. Severe tetraparesis and partial involvement of the last cranial nerves in a conscious patient were present. Slowly improvement occurred in the following months

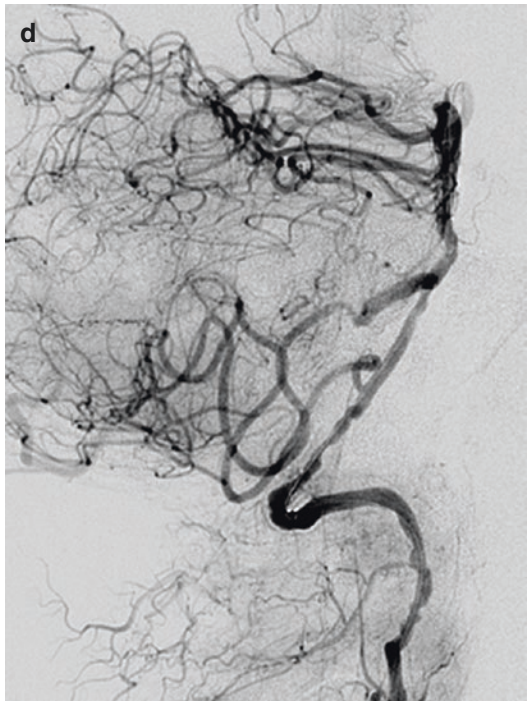

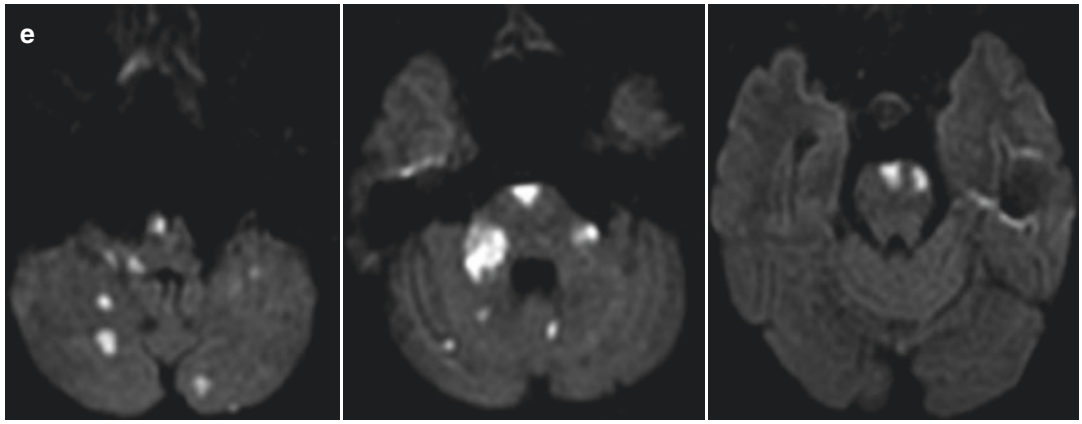

Fig. 15.32 (continued)

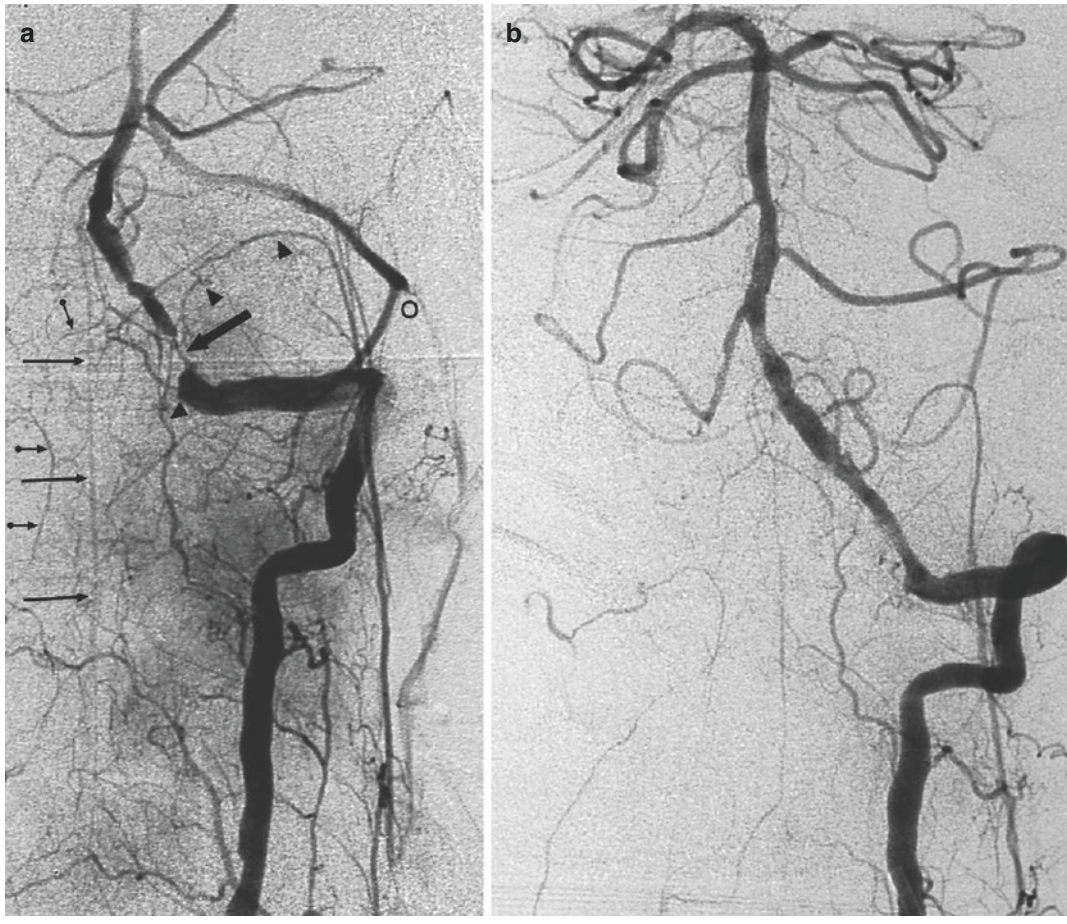

Fig. 15.33 TIAs in the vertebrobasilar sector in middle-aged hypertensive patient, in whom MRI disclosed an ischemia in the inferior pons. (**a**) Left vertebral angiogram showed a severe stenosis (*arrow*) of the VA at its entrance in the cranial cavity. The PICA is not recognizable, though the ASA is well injected (*small arrows*). There is a slowing down of the distal flow. The right VA was occluded. Probably due to the impairment of the flow in the VA, there is a good filling of the occipital artery (o) through opening of the C1 anastomosis. It seems that the proximal pharyngo-occipital trunk is retrograde injected. There is a clear connection (*arrowhead*) between the hypoglossal branch of the ascending pharyngeal artery and the radiculomeningeal branch of the VA. Connection of the left radiculomeningeal branch of the VA with the contralateral one (*arrow with dot*). (**b**) Endovascular treatment of the stenosis with angioplasty and stent with improvement of the flow in the vertebrobasilar sector

15.5.3 Basilar Artery

Involvement of the basilar artery (BA) is another very serious condition. It can occur as an extension of the thrombus in the case of occlusion of the intracranial VA (Castaigne et al. 1973). Another very frequent cause is embolism cardiac in origin or arising from plaques located in the extra or intra cranial segment of the VA. Emboli flow frequently into the distal part of the BA (Caplan 1980) provided that no stenotic plaque is located along the artery arresting their course, or the emboli are large occluding the middle portion of the BA. Some examples are presented in Figs. 15.34, 15.35, 15.36, 15.37, 15.38, 15.39, and 15.40.

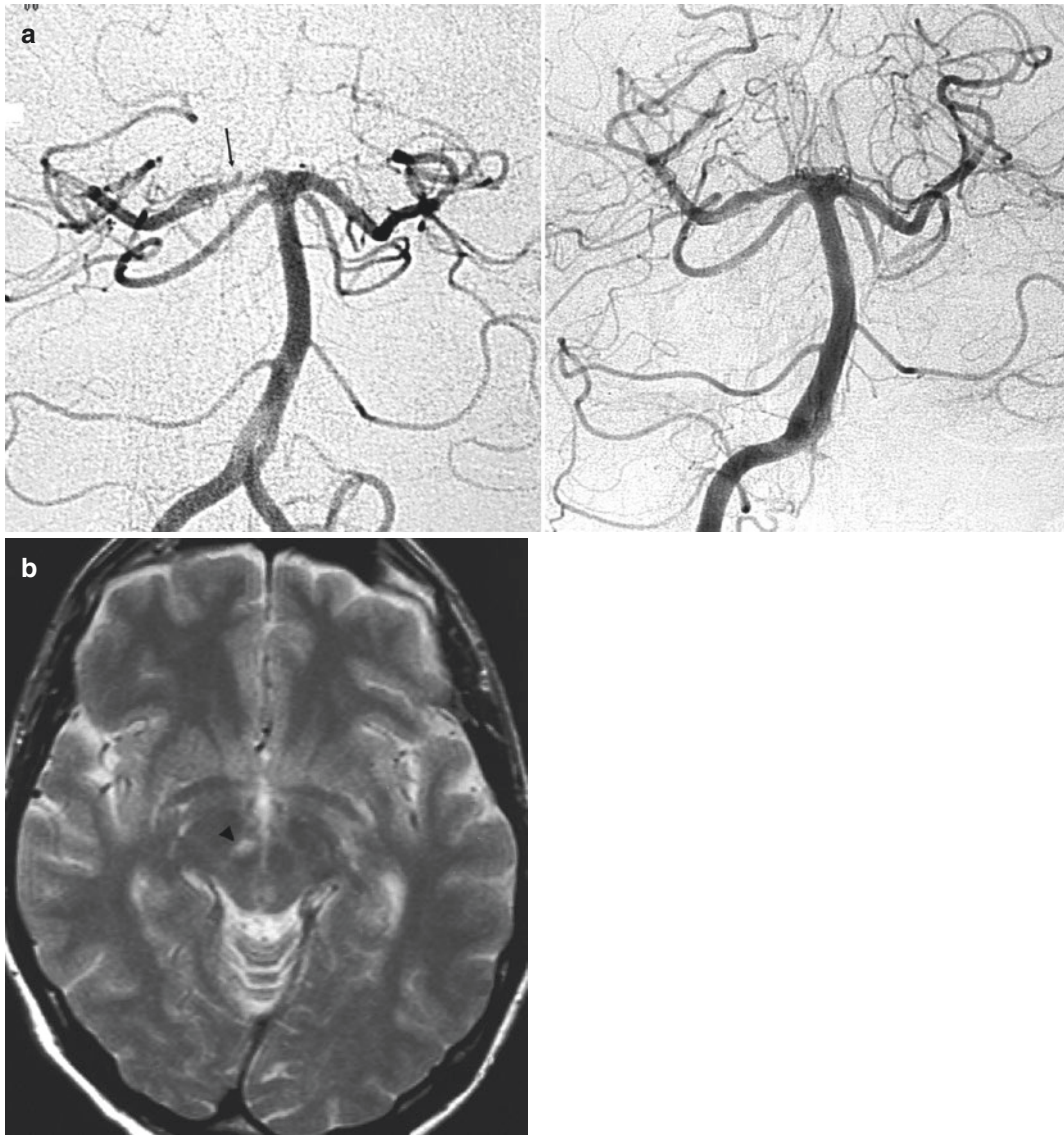

Fig. 15.34 Acute "top of the basilar" syndrome in a middle-aged patient. (**a**) On the right vertebral angiogram there is a normal filling of the basilar artery. Fenestration in its proximal segment. Small irregularities are visible on the right P1 segment (*arrow*), and there is no filling of the perforators. Selective pharmacological thrombolysis was performed with normalization of the P1 segment and reappearance of the perforators (*figure on the right*). The comatose patient recovered completely. (**b**) On the MRI performed 3 days later in an asymptomatic patient a small ischemic lesion was recognizable in the medial right midbrain (*arrowhead*)

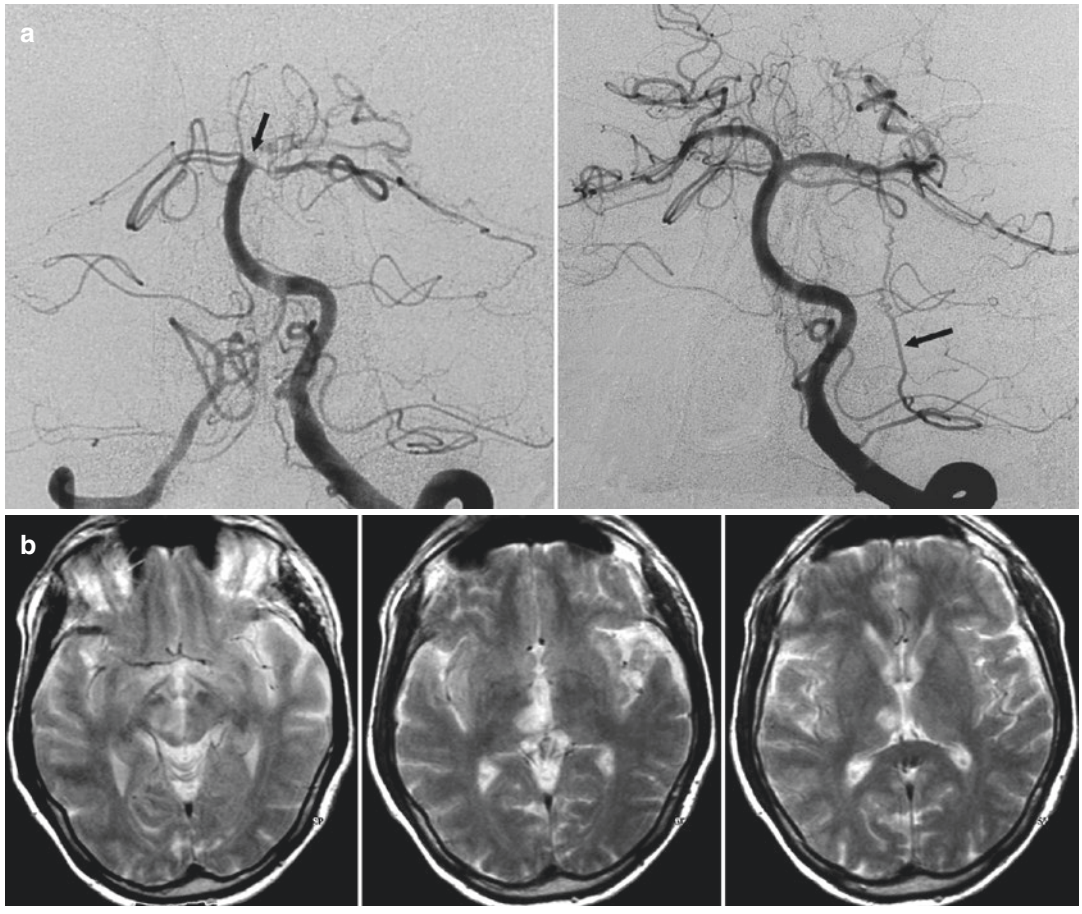

Fig. 15.35 Acute "top of the basilar" syndrome. (**a**) Angiogram of the left well-developed VA, with retrograde injection of the hypoplastic right VA. The distal basilar artery is occluded (*arrow*). There is no injection of either PCA. Normal right SCA, and partial occlusion of the left SCA. (**b**) After selective pharmacological thrombolysis, reopening of the distal basilar artery and its branches. Note the injection of the perforators arising from both P1. There is a good filling of the posterior meningeal artery (*arrow*). (**c**) On the MRI performed a few days later, ischemic lesions involving the right medial midbrain and medial thalamus were recognizable. The comatose patient recovered slowly with a favorable outcome in the following months

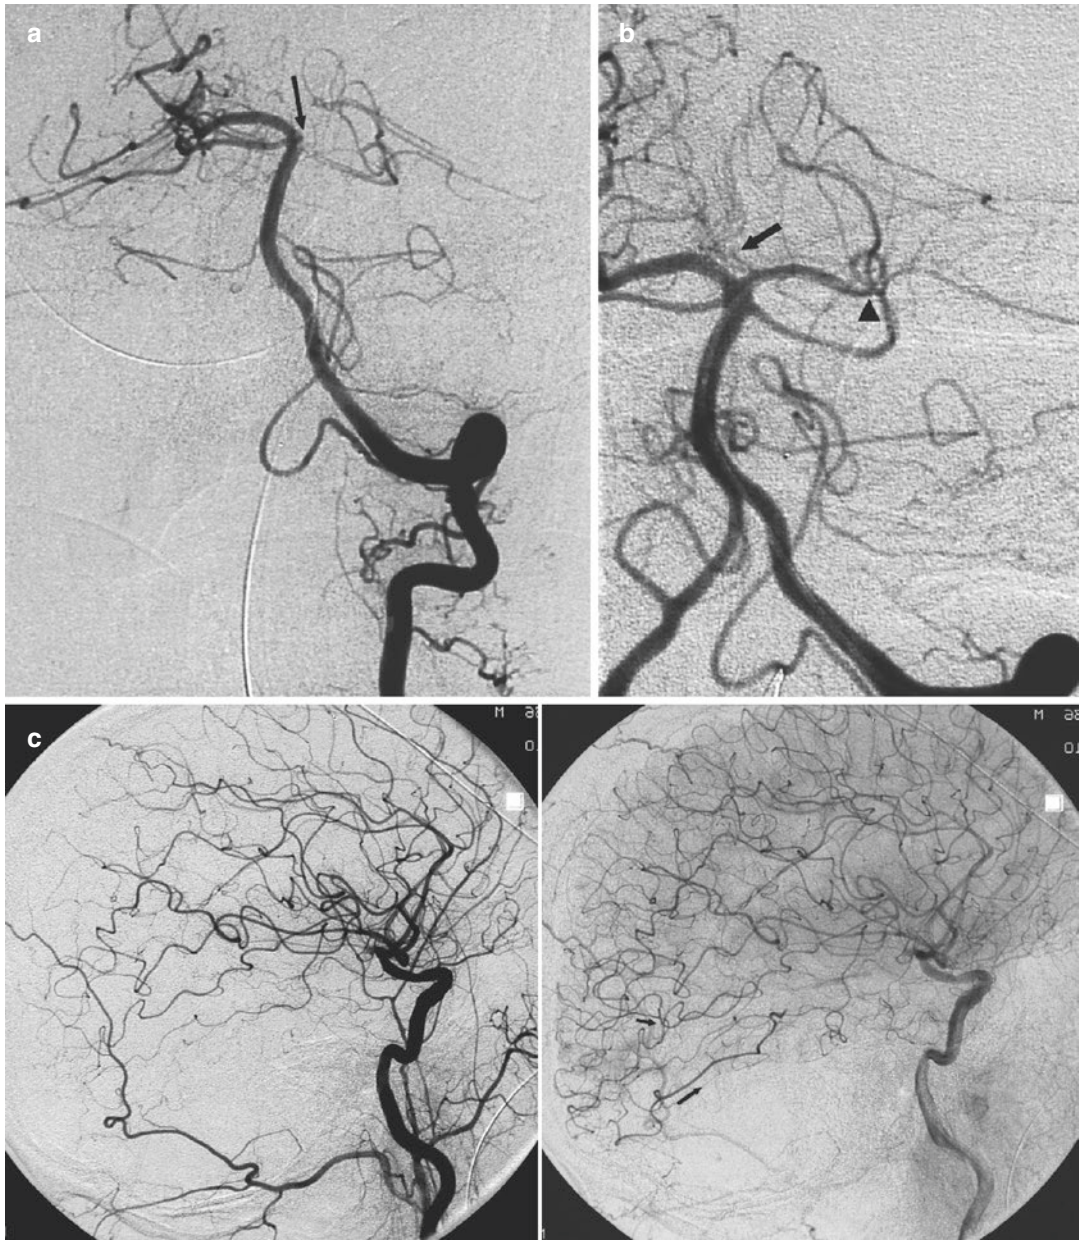

Fig. 15.36 Cardioembolic occlusion of the top of the basilar artery in an old patient presenting with acute symptoms indicating progressively vertebrobasilar insufficiency, followed by coma. (**a**) Occlusion of the BA (*arrow*) with involvement also of the left PCA and SCA was shown on the left VA angiogram. (**b**) VA angiogram post selective pharmacological fibrinolysis, showing the reopening of the BA and of the perforating branches (*arrow*) which seem to originate predominantly from the left P1. There is also revascularization of the left SCA and PCA. This latter, however, remains occluded at its P2 segment (*arrowhead*). (**c**) On the left carotid angiogram, a partial retrograde filling of the left PCA through leptomeningeal anastomoses with the MCA was recognizable (*arrows*). (**d**) MRI 24 h later showed some ischemic lesions bilaterally in the medial thalamus owing to the temporary occlusion of the posterior thalamoperforating arteries arising mainly from the occluded left PCA. Small ischemia also in the left posterior thalamus. Old right frontal ischemia. Progressively recovery of the patient

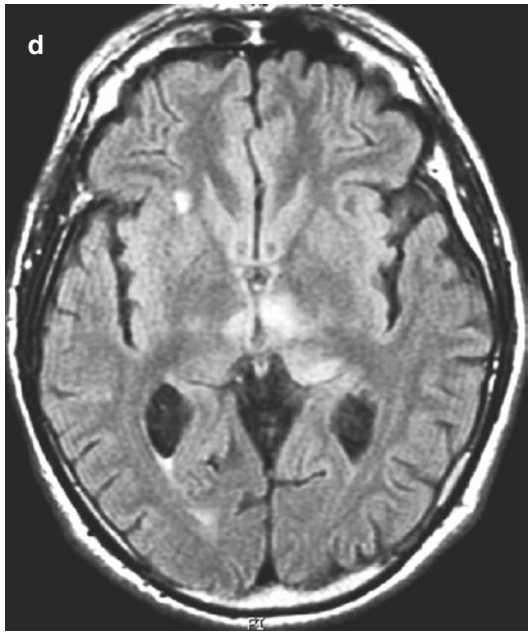

Fig. 15.36 (continued)

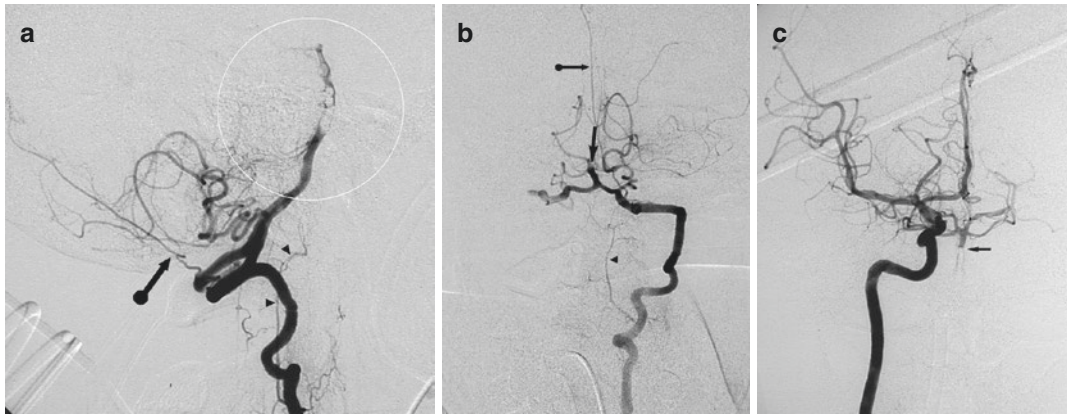

Fig. 15.37 Acute brainstem syndrome. (**a**), (**b**) Vertebral angiogram. AP and lateral views, showing the occlusion due to a large thrombus in the middle segment of the basilar artery (*arrow*) distal to the origin of the AICA. Radiculomeningeal branch (*arrowhead*), falx cerebelli meningeal artery (*arrow with dot*). (**c**) The right carotid angiogram showed through the PcomA a patent distal segment of the basilar artery (*arrow*) and also injection of the PCAs and SCAs. The thrombus in the BA is also well defined. (**d**) Detail obtained during selective study with a microcatheter, showing better the thromboembolic material in the BA. (**e**) Selective pharmacological thrombolysis allowed a complete recanalization of the BA. Small pontine ischemic lesions were visible on CT a few days later. There was a good recovery

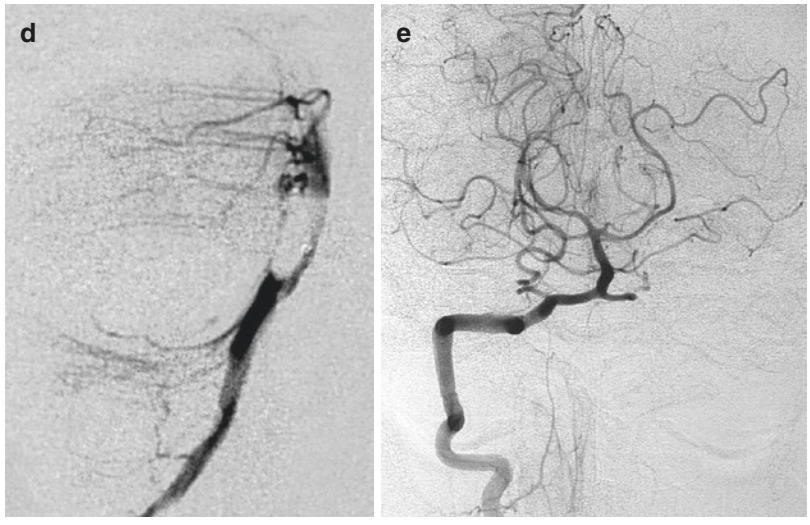

Fig. 15.37 (continued)

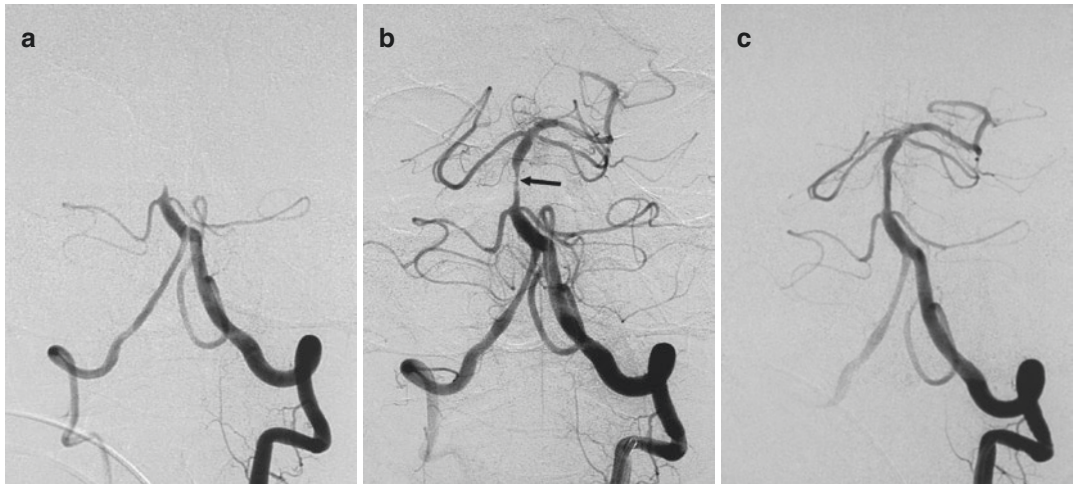

Fig. 15.38 Old patient with acute occlusion of the middle basilar artery owing to a thrombus superimposed on a long microatheroma. (**a**) Left VA angiogram. Occlusion of the BA distal to the origin of the AICAs. Retrograde injection of the hypoplastic right VA. (**b**) Reopening of the basilar artery with a selective pharmacological thrombolysis, showing the presence of the long stenosis (*arrow*), which was treated with angioplasty. (**c**) Angiogram after treatment

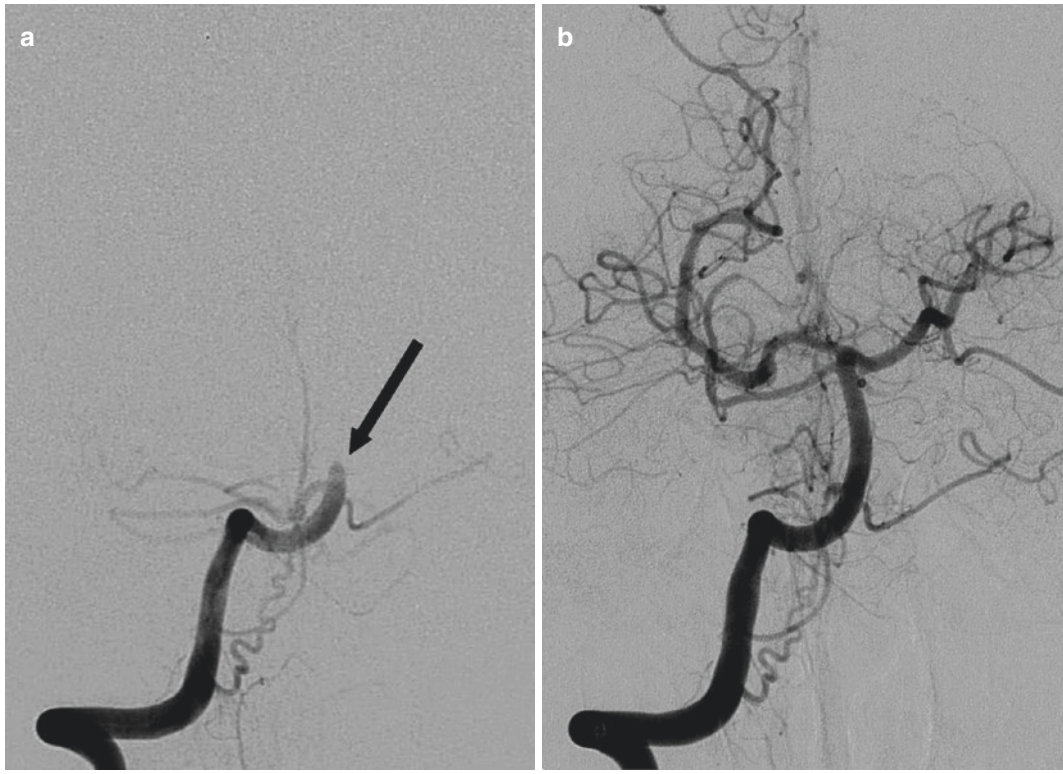

Fig. 15.39 Young woman admitted in a peripheral hospital with unclear symptoms suggesting, brainstem syndrome progressively leading to coma. On the admission in our department ca 7 h later, CT showed no certain ischemic lesions. (**a**) On the vertebral angiogram the occlusion of the BA distal to the origin of the AICAs was recognizable (*arrow*). Certainly the time passed from the start of the symptoms was relatively long. However, considering the young age of the patient and the experience that in occlusion of the BA positive results can be obtained also by relatively delayed treatment, endovascular treatment was decided. (**b**) Control angiogram performed after the rapid reopening of the BA with a solitaire stent. The left PCA was better filled on the left carotid angiogram. The left SCA remained partially occluded. Also the right AICA was suffering, probably occluded by embolus. The patient regained rapidly the consciousness, but was tetraplegic with palsy of cranial nerves with exception of eye movements. (**c**) MRI (DWI) performed 48 h later showed a large anterior and paramedian infarct in the pons. There was no lesion in the medulla, in the upper pons and mesencephalon sparing the reticular formation responsible of the consciousness. Several small cerebellar and a small left occipital lesions were also present. A few months later, after intensive physiotherapy, the patient was severely dysarthric and able to perform some minimal movements with the hands and finger. One year later however, she was independent, presenting with moderate right motor deficit and mild dysarthria

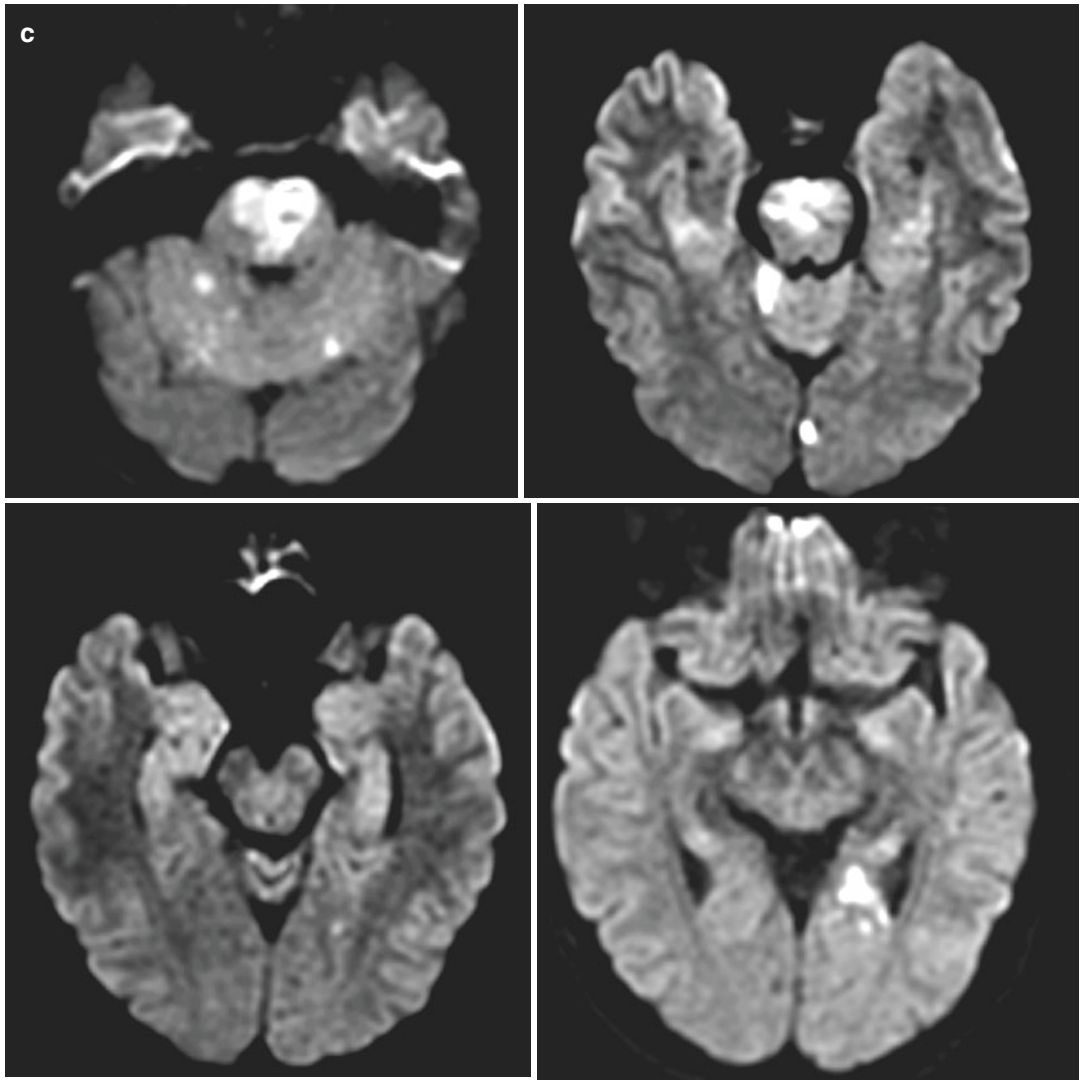

Fig. 15.39 (continued)

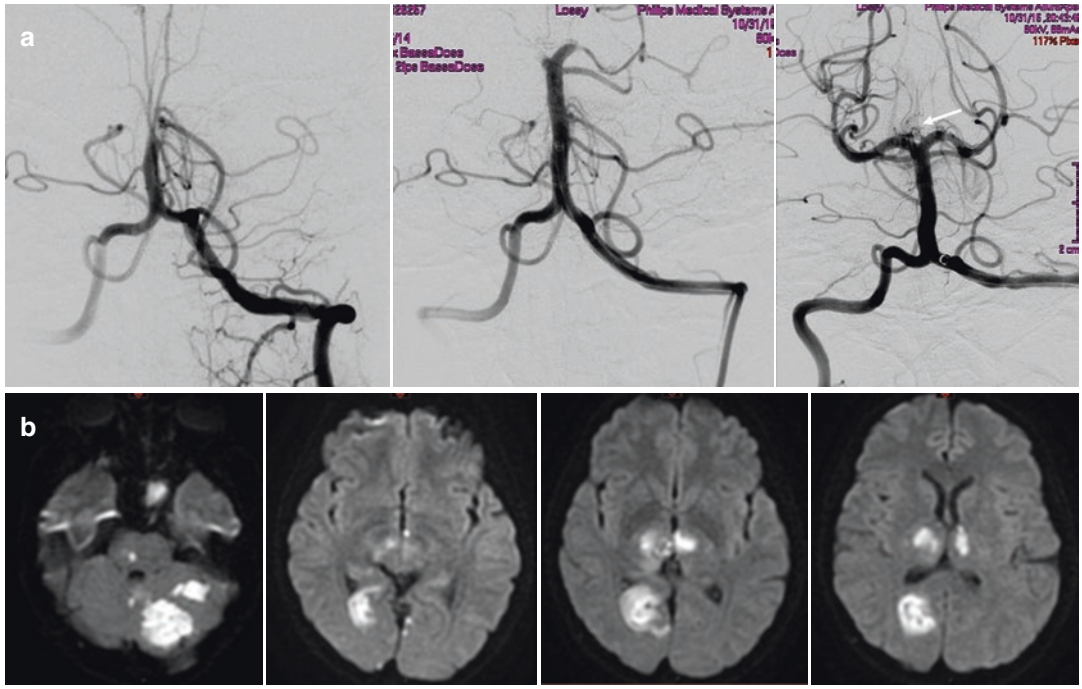

Fig. 15.40 Probably embolic occlusion of the BA in its middle segment due to embolization following a small dissection of the right VA occurring in a young woman. (**a**) Vertebral angiogram pre- and posttreatment with progressively reopening of the BA and PCAs with a solitaire stent. Note the reopening of the perforators (*arrow*). (**b**) Ischemic lesions were visible on CT and better on MRI (diffusion-weighted images) performed a few days later. These involved the cerebellum and the right occipital area. A small ischemia was recognizable in the pons. Severe lesions were recognizable on the medial hypothalamus and thalamus bilaterally. The patient regained very slowly the consciousness. Two months later, she was able to stand up and walk with minimal help. The striking symptoms were disturbances of the wake-sleep cycle, characterized by frequent episodes of sleep during the day probably a consequence of the bilateral thalamic lesions

The occlusion of the BA is always a very serious condition, since it involves, depending on the site and extension of the occlusion, the perforators for upper medulla and pons. The frequent involvement of the PCA leads to further ischemia in its vascular territory (see Sect. 15.5.5). Collateral circulation can occur only through leptomeningeal anastomoses between the cerebellar arteries. Another important collateral way can be represented by the PCA, if the artery (fetal type) arises from the ICA, and so it is not involved in the occlusion. In these cases a retrograde filling of the distal BA can develop through the PCA connected with the P1 provided that this is not absent (Figs. 15.32, 15.36, and 15.37). This is a relatively favorable condition. However, this can be impaired by distal embolization through emboli arising from the BA thrombus or during the endovascular treatment.

Zeumer et al. (1982) performed the first selective endovascular treatment of BA occlusion. Since then the advantages of this type of therapy has progressively become evident, and it is today the treatment of choice, improving in many cases the prognosis of the patients. Unfortunately, in some cases, in spite of the obtained reopening of the BA, severe clinical symptoms develop, due to impairment of the perforators. Nevertheless, in some of these patients a remarkable clinical improvement due to intensive care and rehabilitation can be achieved (Fig. 15.39 and 15.40).

Microatheroma of the BA can involve perforators at their origin and lead to pontine lacunar infarct (Fisher and Caplan 1971; Caplan 1989).

The occlusion usually involves the paramedian branches; less commonly it involves those that are more lateral. Microatheroma can be very thin and thus escape neuroradiological diagnosis. In other cases, it can be large enough to lead to stenosis of various degree of the BA, which is recognizable on MRI and CT angiography; in selected cases, microatheroma can be subjected to endovascular treatment (Figs. 15.41 and 15.42). The same risks we have described in the treatment of atheroma of M1 and distal ICA are present in similar lesions of the VA and BA. In particular, there is a risk of occlusion of the perforating branches. Also intrastent restenosis or thrombosis can occur; however, this seems to be rarer in comparison to that occurring in the anterior circulation (see also Sect. 15.8).

As in the white matter and basal ganglia also in brainstem especially in the pons lacunar infarcts can occur due to *lipohyalinosis*. The association of these lesions with similar microinfarcts in the anterior circulation is frequent. They often occur in hypertensive and diabetic patients (Fisher and Caplan 1971; Caplan 1996; Bradac et al. 2008b). The prognosis of these lacunar lesions are "quoad vitam" better than those due to occlusion of the branches by microatheroma. An example is presented in Fig. 15.43.

15.5.4 Cerebellar Arteries

There are many pathological conditions which can lead to impairment of the cerebellar arteries.

PICA, AICA, and SCA can be involved in acute thromboembolic occlusion of the intracranial VA and/or BA. The site and extent of the ischemia can vary considering that the cerebellar arteries supply the cerebellum but partially also the brainstem. The cerebellar parenchyma can be partially protected by the leptomeningeal collateral circulation between the distal branches of the cerebellar arteries. This can be insufficient if more than one cerebellar arteries is involved. This probably occur in the cases of very acute large cerebellar infarct with important swelling leading to compression of the fourth ventricle and hydrocephalus.

Microatheroma of intracranial VA or BA can occlude or narrow the ostium of the cerebellar arteries causing ischemia in their vascular territories due to hypoperfusion or distal embolization (Amarenco et al. 1990; Amarenco and Caplan 1993).

Stenosing or occluding atheromasic plaques of the extracranial VA especially when bilateral can cause hypoperfusion and infarct in the distal border zones of the cerebellar arteries (Savoiardo et al. 1987; Amarenco et al. 1994a, b, 1998). Emboli can arise from the plaques or from Heart, reaching the VA or BA and enter selectively the cerebellar arteries. Considering that the emboli can be very small and distal cerebellar parenchyma can be protected due the presence of leptomeningeal anastomoses between the PICA, AICA, and SCA, the infarcts are commonly small located in the border-zone areas, frequently asymptomatic and discovered incidentally. It is, however, important to recognize these microlesions, since, as emphasized by some authors (Park et al. 2009a; De Cocker et al. 2015, 2016), they are a sign of an already present atheromasia of the VAs or cardiac pathology.

Lacunar infarcts in the deep cerebellar structures (white matter and deep grey nuclei) can also occur even if they are more rare in comparisons to that in the cerebral hemispheres (Fisher 1965, 1968).Hypoperfusion and microembolization can be considered but as pathological studies have shown the lesion are frequently also due to intrinsic atherosclerotic changes (lipohyalinosis). Some authors (Park et al. 2009a; De Cocker et al. 2016) have described the frequent association of deep cerebellar with deep cerebral ischemic lesions. Lipohyalinosis is a well-known pathology involving the perforators of the cerebral hemispheres responsible for small ischemic lesions and for microhemorrhages (see also Sect. 15.4.5). The same findings can be found in cerebellum. It is therefore conceivable that we are dealing with the same basic pathology.

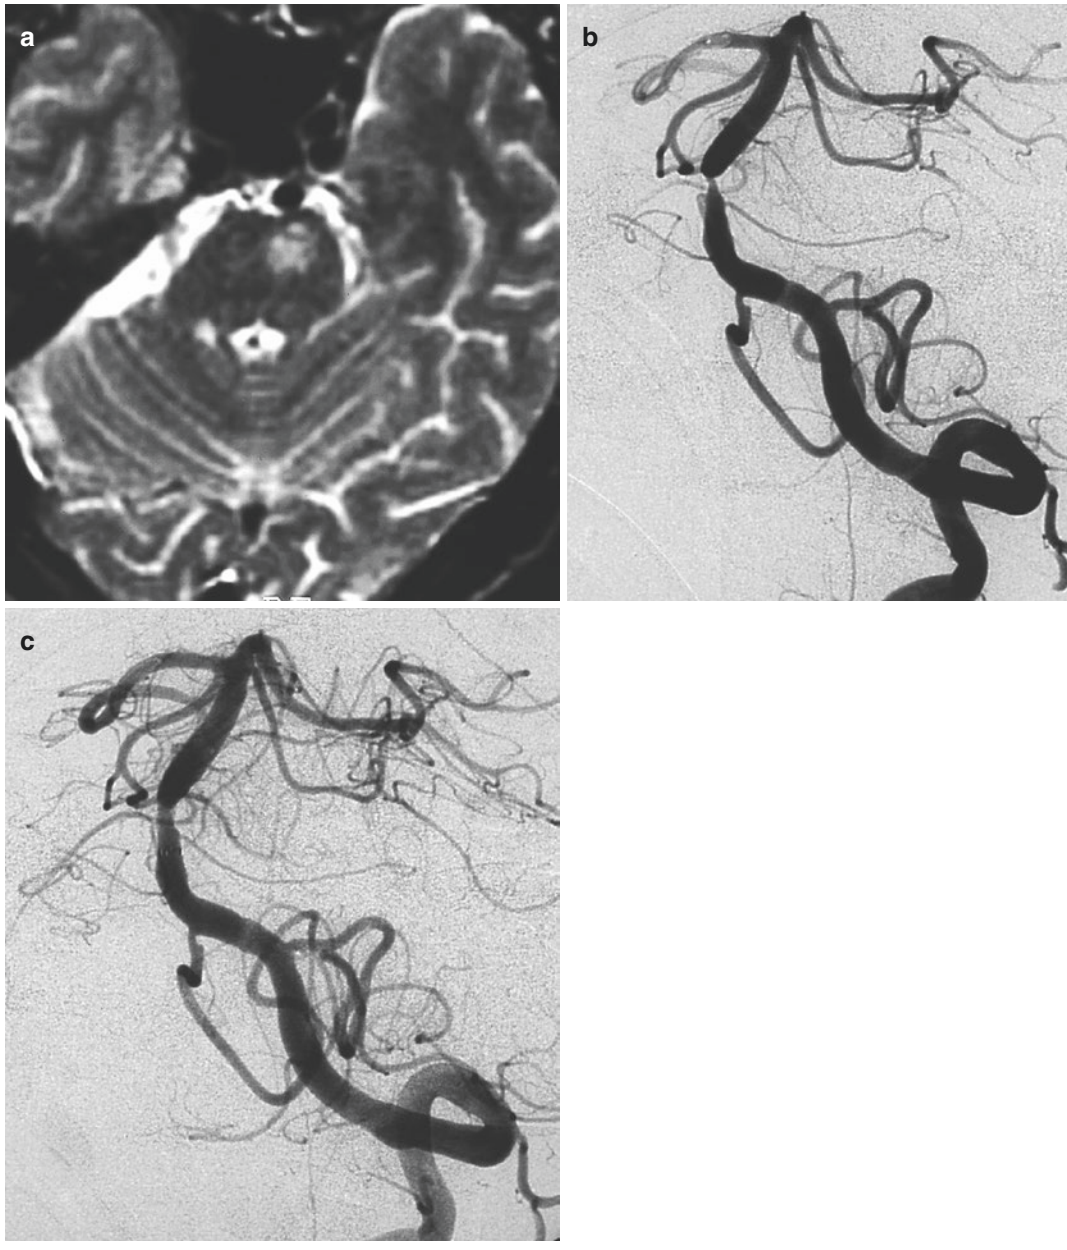

Fig. 15.41 Middle-aged patient with repeated mild stroke episodes involving the posterior circulation, not responsive to medical therapy. (**a**) MRI disclosed a small paramedian pontine infarct. (**b**) The vertebral angiogram showed a severe stenosis of the BA. (**c**) Posttreatment angiogram after angioplasty and application of a stent. The patient tolerated well the treatment

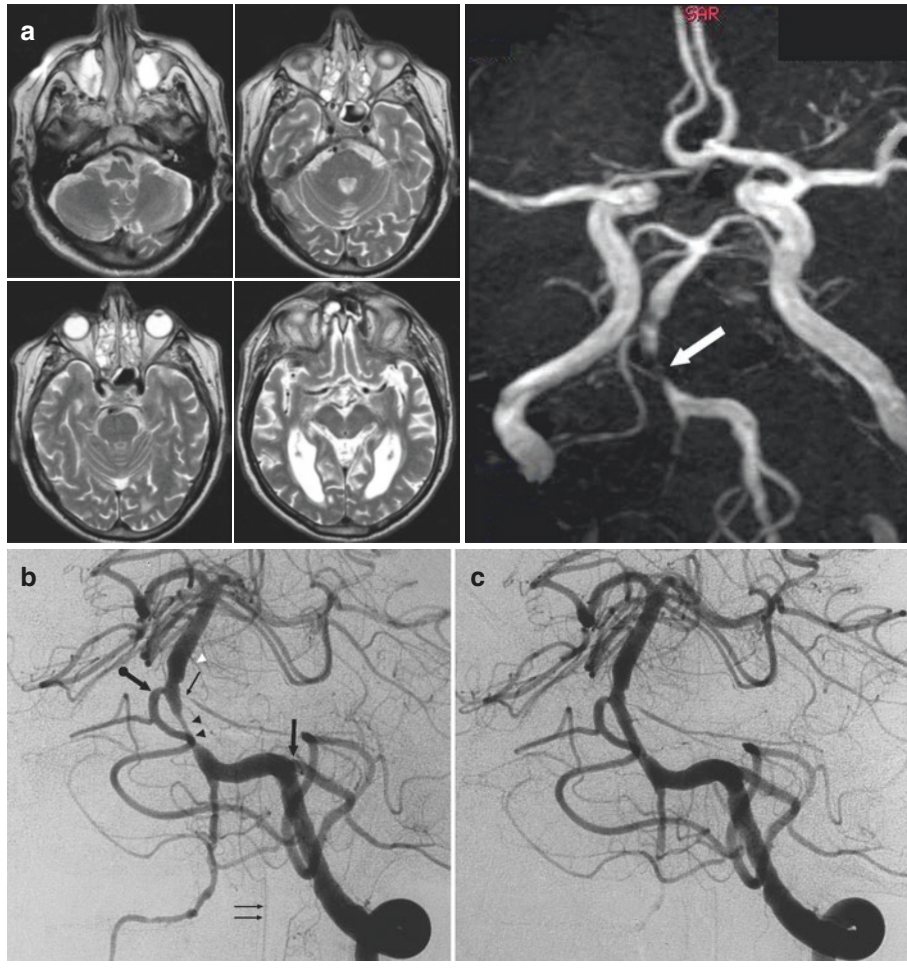

Fig. 15.42 Old hypertensive patient with repeated TIAs suggesting involvement of the posterior circulation. (**a**) MRI showed extensive micro-ischemic lesions in the white matter of both cerebral hemispheres. Brainstem and cerebellum were normal. On the MR angiography a severe stenosis of the BA was visible (*arrow*). Considering the risk of occlusion, the decision to perform endovascular treatment was taken. (**b**) Left VA angiogram with retrograde injection of an hypoplastic right VA. There is a severe stenosis of the BA (arrow heads) involving also partially the left AICA (*small arrow*). The distal BA is normal. Lateropontine branches (*white arrowhead*). Unilateral origin of the ASA (*small arrows*). Well-developed left PICA (*large arrow*). Well-developed right AICA (*arrow with dot*) supplying also the territory of the absent or occluded right PICA. (**c**) Angiogram post treatment (angioplasty and stent). The patient tolerated well the procedure

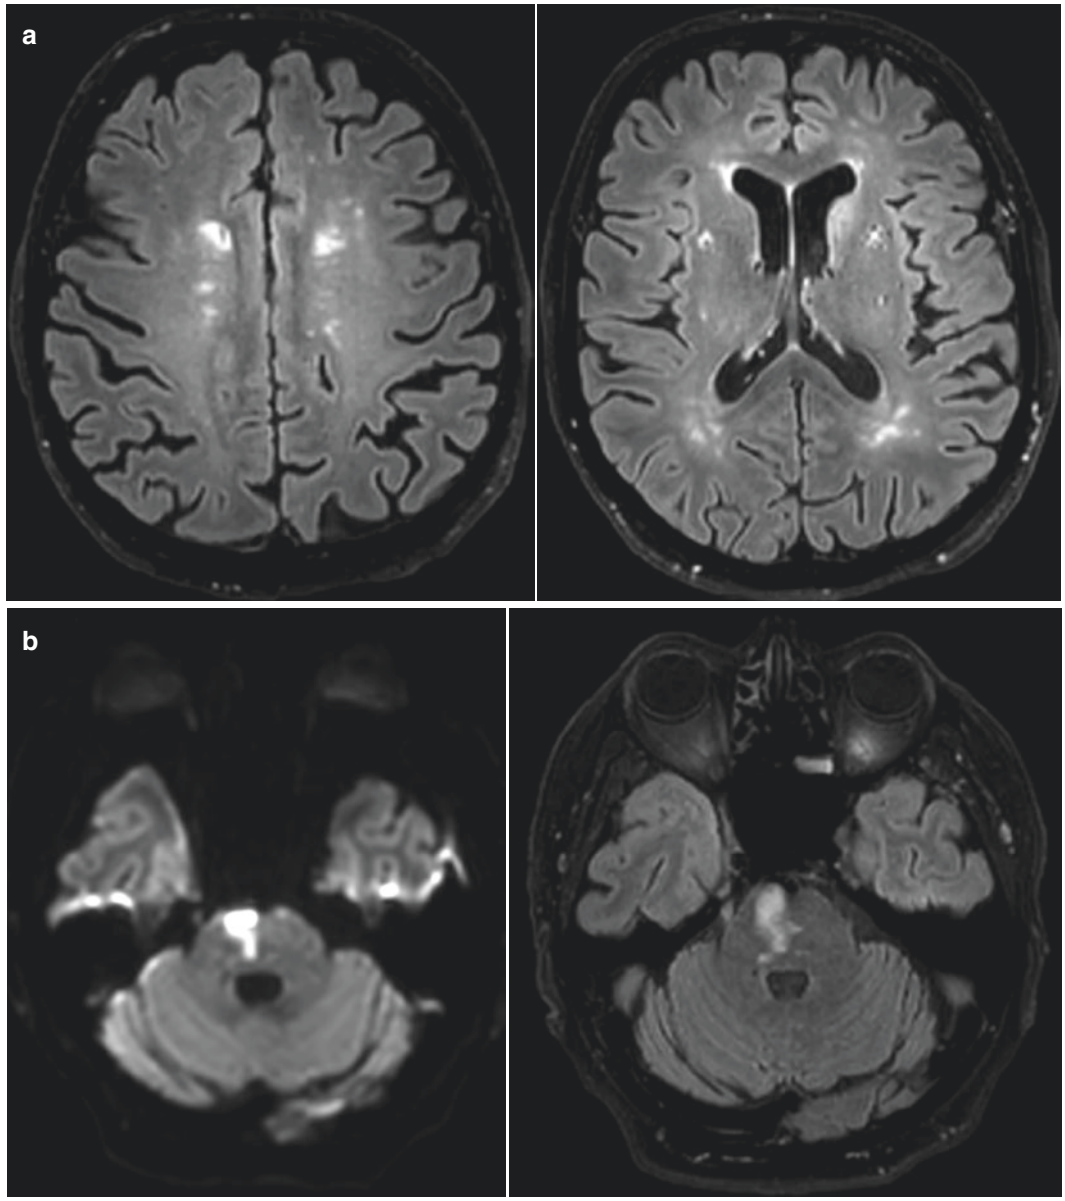

Fig. 15.43 80 year old hypertensive patient presenting with acute left hemiplegia. (**a**) MRI. T2 weighted images, showing several old ischemic lesions in the white matter and basal ganglia of both hemispheres. Small hypointensity lesions corresponding to old microhemorrhages are also present. (**b**) MRI T2-weighted and Diffusion Weighted images showing acute ischemia in the right pons. (**c**) MRI-Angiography showing no alterations of the vertebral and basilar arteries. The ischemia was probably due to occlusion of the right paramedian perforating branches in a patient with diffuse small vessels disease due to lipohyalinosis. The patient recovered slowly

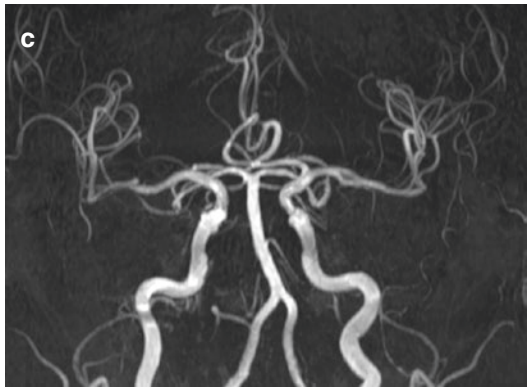

Fig. 15.43 (continued)

15.5.5 Posterior Cerebral Artery

Ischemia in the vascular territory of the PCA uni- or bilaterally occurs commonly in association with the occlusion of the BA and the extension of the thrombosis to the PCA through the P1. The most frequent cause of isolated occlusion of the PCA is embolism from plaques of the extra-or intracranial VA or it can be cardiac in origin (Castaigne et al. 1973, 1981; Milandre et al. 1994; Caplan 1996; Yamamoto et al. 1999; Brandt et al. 2000; Kumral et al. 2004). Embolism to the PCA can arise from the ICA in cases of fetal origin of the PCA and in cases of persistent embryonic carotid-basilar and carotid vertebral anastomoses.

Another cause of ischemia is a primary microatheroma that is commonly located at the P1–P2 (Bradac and Oberson 1983; Fisher 1986; Pessin et al. 1987; Caplan 1996), which can be complicated by a superimposed thrombosis. Ischemia can also occur in cases of aneurysm of the BA or VA due to direct involvement of perforators or to embolization.

The ischemic lesion can differ according to the site and extent of the stenosis/occlusion; it can involve the deep or cortical territories or both (Bougosslavsky et al. 1988a; Caplan et al. 1988b; Caplan 1996; Brandt et al. 2000). Involvement of the posterior thalamoperforating branches (P1) leads to ischemia of the medial midbrain and medial thalamus. The ischemia may be bilateral when both P1s are involved or when the perforators arise unilaterally just from the affected P1. Occlusion of the thalamogeniculate artery (P2) is responsible for ischemia in the lateral thalamus. Perforators arising from the P2 segment supplying the midbrain and the branches for the posterior thalamus (posterior choroidal arteries arising from P1–P2) can also be involved. These areas, however, may be more protected since they have a complementary supply from the AchA and SCA.

The distal territories have greater protection owing to the presence of leptomeningeal anastomoses between PCA, MCA, and ACA: however, ischemia can occur due to further embolism occluding the distal branches. Among the distal vascular territories, the primary visual cortex is frequently involved, with an incidence of up to around 90% of the cases (Kumral et al. 2004).

Lipohyalinosis involving perforators is another cause of ischemia which can be responsible for small lacunar infarcts in the midbrain and thalamus.

Examples of ischemia due to involvement of the PCA are presented in Figs. 15.34, 15.35, 15.36, 15.37, 15.40, 15.44, 15.45, and 11.20.

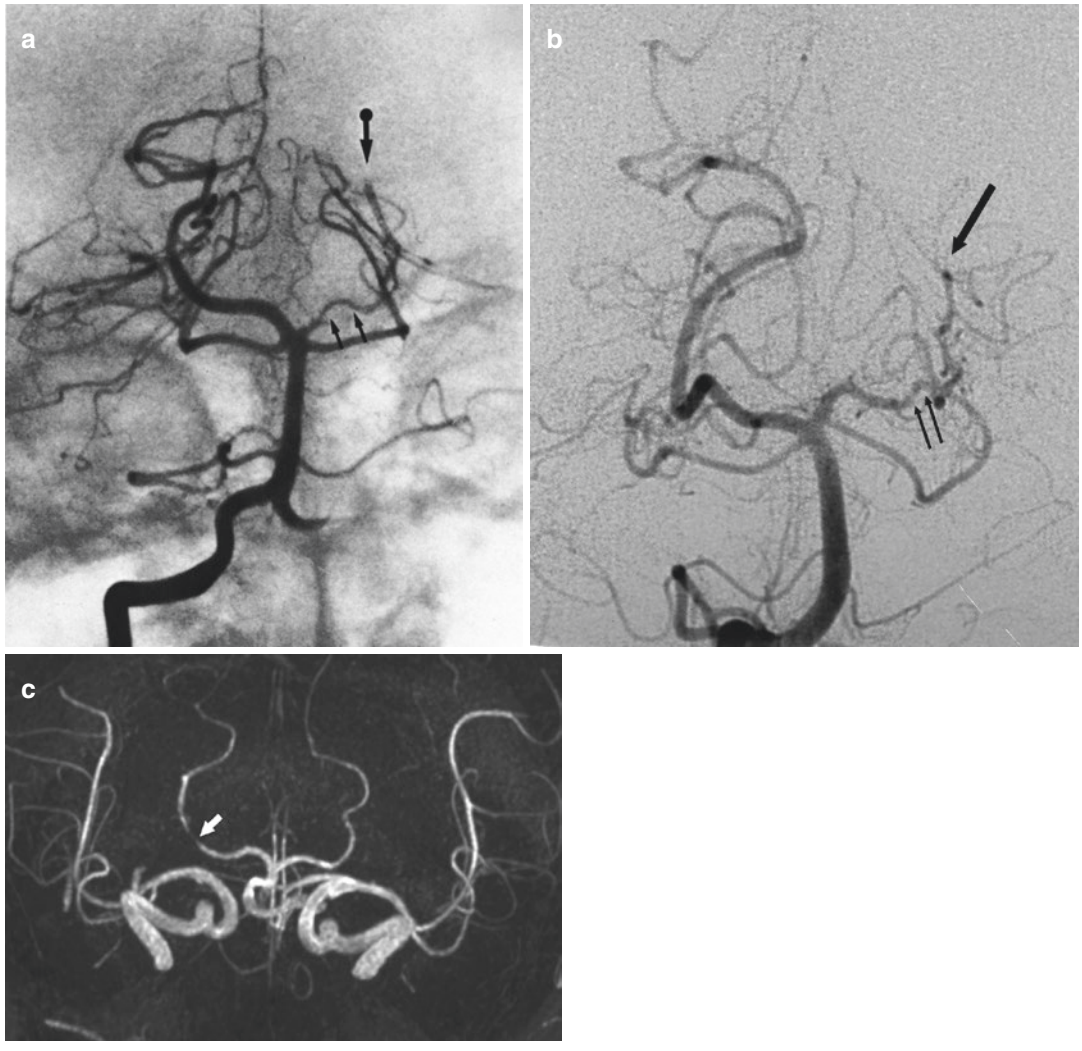

Fig. 15.44 Atheromatous changes involving the P1-P2 segments of the left PCA (*arrows*) demonstrated on the angiograms in (a and b). The distal PCA (*arrow*) is probably occluded by emboli. (**c**) Atheromasic plaque in the P2 segment in old patient demonstrated on MRI angiography

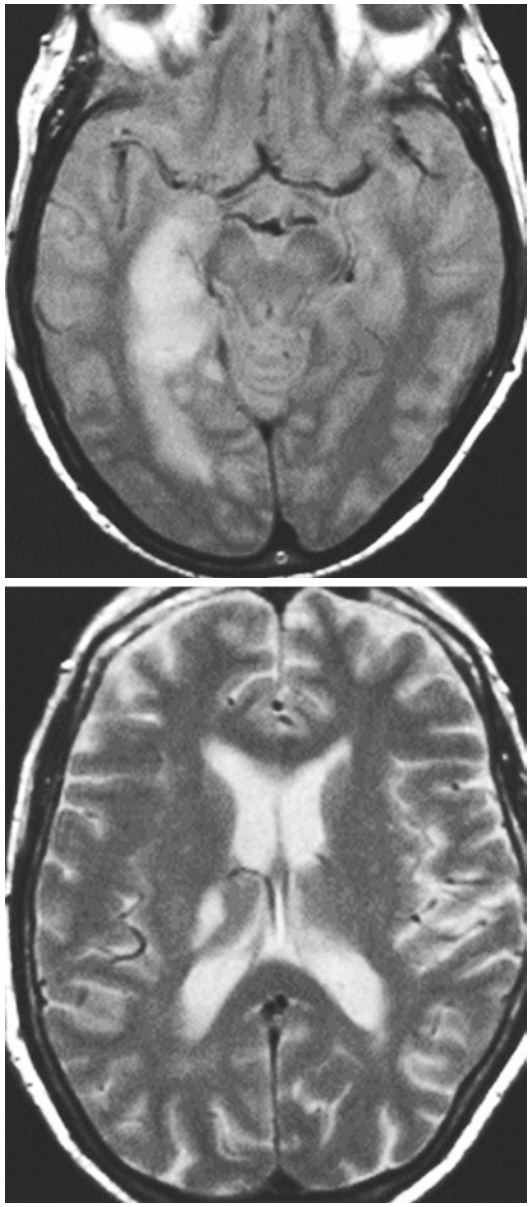

Fig. 15.45 Old cardiopathic patient with embolic occlusion of the right PCA in its P2 segment. MRI study showing ischemia in the medial temporal and occipital regions and in the lateral thalamus (thalamogeniculate artery). The medial midbrain and medial thalamus corresponding to the vascular territories of the perforators arising from P1 are spared

15.6 Changes in the Venous Sector

On the normal angiogram, the filled veins strictly correlated with the injected arterial sector appearing typically in the venous phase after the arterial and capillary phases. On the angiogram of patients with focal cerebral ischemia, *"early filling of veins"* in the ischemic and peri-ischemic areas associated with a capillary blush of the involved parenchyma are often recognizable in the acute and sometimes subacute phase of the ischemia; later this phenomenon disappears. This angiographic sign which has been correlated to a local increased perfusion called "*luxury perfusion syndrome*" (Lassen 1966) has been in the past the object of several and intensive studies, when the cerebral angiography was the main diagnostic method in the diagnosis of ischemia (Cronquist and Laroche 1967, 1969; Taveras et al. 1969; Bradac et al. 1975; Huber 1979; Bradac and Oberson 1983) and redescribed more recently (Dorn et al. 2012b). It has been interpreted as due to metabolic changes occurring in the ischemic area, characterized by lowered oxygen tension and acidosis, leading to vasodilatation and vasoparalysis of the small arteries, facilitating the rapid passage of contrast medium in the venous sector.

15.7 Collateral Circulation

One important factor which can avoid or reduce the ischemia in cases of occlusion of the extra-intracranial segments of the carotid and vertebral arteries, is the presence of an efficient collateral circulation. Many collateral ways can be involved.

15.7.1 Collateral Circulation Between Intracranial Arteries

- The most important in this group is the circle of Willis, involving A1, AcomA, P1, and PcomA (Fig. 1.2), connecting both carotid sectors and these with the vertebrobasilar system. However, as it has been described in

this and in previous chapters, variants are frequent which can impair, in the given case, partially or severely the collateral way.

- A second important collateral circulation are the leptomeningeal (pial) anastomoses between ACA, MCA, PCA, and AchA developing on the cortex of the cerebral hemispheres and between PICA, AICA and SCA on the cerebellar cortex.
- Perforators supplying the deep structures (grey nuclei and capsula interna) of the cerebral hemispheres, those responsible for the vascularization of the brainstem, and the medullary arteries supplying the white matter of the cerebral hemispheres and the white matter and grey nuclei of the cerebellum, are considered *end arteries* without any possibility of collateral circulation. Their involvement can occur in occlusion or stenosis of the parent artery from which they arise, or selectively due to emboli, atherosclerotic plaques at their origin or lipohyalinosis.

  In a few reports (Kodama and Suzuki 1974; Umansky et al. 1985), a few connections between single deep perforators and between these and medullary arteries have been identified. Occasionally, on the angiogram, connections between perforating branches can be demonstrated or at least suspected (Fig. 5.15). These anastomoses have been postulated to explain the network of vessels present in Moyamoya disease (see also Sect. 17.3.1). In a similar pathological condition, these connections could be clearly demonstrated on the angiogram (Fig. 17.7).

  Minimal anastomoses have also been identified between perforators of the brainstem (Kalimo et al. 1997). These connections and the corresponding flow, however, are minimal and do not play any role in developing a collateral circulation in case of an acute occlusion, but they could increase the flow and act as a collateral way when the occlusion is a long-lasting process.

  In this context, considering the patients in whom a flow-diverter stent has been used, the perforators can be saved by the flow passing through the strut of the stent, or in cases of occlusion of some perforators, these could be revascularized by the developing of a collateral circulation favored by the long-lasting occlusion process.
- Other more rare possibilities of collateral circulation are those between the choroidal arteries involving the AchA and the posteromedial and posterolateral choroidal arteries of the PCA and the connections between ICA and the vertebrobasilar sector through embryonic anastomoses (Sect. 2.3).

15.7.2 Collateral Circulation Between Extracranial and Intracranial Arteries

- Several branches of ECA are connected with the petrous-cavernous segments of ICA and can develop and enlarge in case of ICA occlusion. An important way is the connection of ECA with ICA through the ophthalmic artery.
- Potential large connections can develop between ECA, especially through branches of the APhA and occipital arteries and the VA.
- A particular very rare condition is the occlusion of the common carotid artery. In this case, a complex collateral circulation frequently develops, involving several arteries showing frequently the patency of the ICA (Mishkin and Schreiber 1974; Bradac and Oberson 1983). One way is that in which anastomoses develop between the VA or the cervical arteries and the ECA. This latter is retrograde injected down to the bifurcation, followed by an anterograde filling of the ICA. We also observed a case of anterograde filling of the ICA through anastomoses between VA and APhA, the latter arising as a variant from the ICA (Bradac and Oberson 1983; Pelz et al. 1987). Another collateral way in case of occlusion of the common carotid artery is that in which there is involvement of the circle of Willis. In this condition the ICA is retrograde filled down to the bifurcation through the contralateral ICA by the way of the AcomA or through the vertebrobasilar sector by the way of the PcomA.

– Connections between meningeal and transosseous temporal and occipital branches of ECA and meningeal branches of ICA and vertebrobasilar sector can develop. This commonly occurs in DAVFs. Meningeal branches of ECA can also be connected with pial arteries in some pathological conditions such as AVM and in Moyamoya disease.

15.7.3 The Vertebrobasilar Sector Deserves a Few More Considerations

An occlusion of one VA can be frequently well tolerated provided that the other VA is well developed. In this context, it is essential that the vascular territory of the PICA of the involved VA is sufficiently vascularized either by a retrograde injection of the occluded VA or by a large AICA or by a well-developed contralateral PICA extending also to the involved vascular territory. Also important is the sparing of ASA due to its bilateral origin or if unilateral arising from the nonoccluded VA. An important collateral circulation to the ASA can develop from the radiculomedullary branch arising from C3/C4 (Fig. 16.9). Finally, vertebral to vertebral artery anastomoses by the way of radicular branches and anastomoses with branches of the deep and ascending cervical arteries can also play a role in the revascularization of the occluded VA (Sect. 3.9). As far as it concerns the subclavian steal syndrome see Sect. 15.5.1.

In conclusion: the type of collateral circulation is strictly connected with the vascular territory involved. Its efficiency, however, depends on many factors, mainly on the rapidity of the occlusive process, distal embolization, anatomical variations, as well as the presence of comorbidity (cardiac and vascular). Furthermore, it should be take into account that for some territories (perforators), there is no collateral circulation.

15.8 General Considerations About Endovascular Treatment

- The introduction of thrombolysis has marked a big step forward in the treatment of this pathology. Positive results have been obtained using pharmacological drugs either intravenously (IV) or selectively injected in the occluded artery (Zeumer et al. 1982, 1993; Jansen et al. 1995; Von Kummer et al. 1995; Urbach et al. 1997; Qureshi et al. 2001, 2002; Arnold et al. 2002, 2003, 2004; Noser et al. 2005; Zaidat et al. 2005; Nogueira et al. 2008; Tauntopoulou et al. 2008; Ciccone et al. 2013). Progressively the selective endovascular treatment has changed passing from pharmacological to the mechanical thrombectomy (stent retriever and/or aspiration devices), sometimes preceded by IV application of thrombolytic agents, association called "bridging therapy."
- *Today, mechanical thrombectomy is considered superior to the IV and to the selective pharmacological thrombolysis when large vessels are involved (proximal-distal ICA; trunk of MCA; VA-BA). The devices used have become progressively more easily and safe to handle allowing in many cases a rapid recanalization with an evident improvement of the clinical results as reported* by many authors (Ringer et al. 2001; Song et al. 2002; Bergui et al. 2006; Eckert 2009; Choi et al. 2009; Kashiwagi et al. 2010, Roth et al. 2010; Castano et al. 2010; Moehlenbruch et al. 2012; Machi et al. 2012; Nogueira et al. 2012; Andersson et al. 2013; Davalos et al. 2012; Dorn et al. 2012c; Pereira et al. 2013; Kuntze-Soederquist et al. 2014; Kurre et al. 2014; Schwaiger et al. 2016) and confirmed in a large randomized study concerning the treatment of patients with acute stroke in the anterior circulation (Goyal et al. 2015; Berkhemer et al. 2015; Jovin et al. 2015).

Considering this group of patients, those with a favourable outcome i.e. without or only with a minimal disability after thrombectomy is now estimated between 50 and 60%.

Also improved positive results, can today be obtained in more critical conditions such distal ICA occlusion and in tandem occlusions with stenting of the extracranial ICA and thrombectomy of its intracranial segments. The rate of good outcome reported in this group of patients is less homogeneous varying from about 25 to 40% with improving of the positive results in the last years (Flint et al. 2007; Malik et al. 2011; Fesl et al. 2011; Mpotsaris et al. 2013; Cohen et al. 2013, 2015; Behme et al. 2015; Liebeskind et al. 2015; Maurer et al. 2015; Kappelhof et al. 2015; Bradac et al. 2017; Frahm et al. 2016).

Considering the cases involving the posterior circulation positive results can be obtained as reported by the majority of the authors in about 30% of the cases (Machi et al. 2012; Mordasini et al. 2012; Dorn et al. 2012c; Nagel et al. 2013; Gerber et al. 2017), with exceptionally good results reported by Roth et al. (2010) and Andersson et al. (2013) with almost 60% of the cases.

- *Many factors can influence negatively the final results*: among them there are the *severe clinical condition* from the onset, *the extent of the brain parenchyma definitely lost* demonstrated with CT perfusion and the *long interval* between the appearing of symptoms and the *achieved complete or partial recanalization. This basically should not be longer than 6 hours in the anterior circulation. A more longer interval is accepted in the posterior circulation*. The reopening of the vessel is an important step, but it is not a guarantee for a good clinical result. Indeed, there is a discrepancy between the rate of recanalization obtained today in about 70–80% of all the cases and the favourable clinical results as described above.
- An important role is played by the presence of an *efficient collateral circulation* which can partially protect the brain parenchyma in the interval between stroke and revascularization. In this context, an important factor is certainly the morphologic aspect of the *circle of Willis*. As described in Sects. 15.4.1.2 and 15.5.3, the same variations of the circle of Willis can act negatively or positively on the collateral circulation depending whether the occlusion is in anterior or posterior circulation. Another important form of collateral circulation is represented by the opening of *leptomeningeal anastomoses*. Its efficiency depends on many factors such the above described aspects of circle of Willis. Hypotension and anastomoses developing in a border zone located far from the occluded artery could also play a role in the given case. Furthermore this type of collateral way can be impaired by distal embolization which can reduce or annul the expected positive results obtained with the reopening of the occluded proximal artery (Bradac et al. 2014, 2017). Distal embolization can occur through emboli developing during the endovascular treatment or arising from the occluding thrombus immediately after the occlusion. More recently some authors (Pham and Bendszus 2016) have emphasized that also other factors can be involved in the failure of this kind of collateral circulation. Indeed, already in the 1960s some authors (Ames et al. 1968) have suggested that the failure of the collateral circulation could be due to the narrowing and occlusion of the microvasculature following the swelling of the endothelium and of the glial cell in the ischemic area. They called this phenomenon *no-reflow*. Other studies have shown that obstruction of the microcirculation can be due to the increased adhesion of white blood cells and platelets favoring the formation of thrombus (Okada et al. 1994; Choudri et al. 1998; Kleinschnitz et al. 2009). Other authors have suggested that

the pathological changes involving the microvasculature could be due to the association of thrombosis and inflammatory mechanisms, which have been called "thromboinflammation" (Nieswandt et al. 2011). In another study the role of hyperglycemia leading to pathological changes of the microvasculature has been emphasized (Van Seeters et al. 2016).

- This could explain the bad clinical result occurring in some patients in spite of the technically obtained good revascularization (Bang et al. 2011; Gratz et al. 2015). In this context as also reported by some authors (Nelles et al. 2014) a more accurate selection of the patients could be useful performing CT perfusion and CT angiography before treatment, aimed to identify large irreversible damaged area and the presence and extent of the collateral circulation.

Complications are another factor which can worse the prognosis. Among them there are dissections, occlusion, spasm of the treated artery, as well as distal embolization into new territories and hemorrhages occurring with a frequency which varies in the reports of different authors. It can be valued occurring in about 10% of the cases. Fortunately, the majority of these events are asymptomatic. In a certain number of patients, however, complications have a clinical relevance and so influence negatively the prognosis.

Symptomatic new ischemic lesions occur in a rate of 1.1–5.6% (Kurre et al. 2014, Behme et al. 2014; Berkhemer et al. 2015), and *symptomatic parenchymal hemorrhage* is reported in a rate of 1.5–10% of the cases (Castano et al. 2010; Pereira et al. 2013; Behme et al. 2014; Soize et al. 2014; Goyal et al. 2015; Behme et al. 2015; Berkhemer et al. 2015; Jovin et al. 2015; Maurer et al. 2015). Some authors reported an higher rate of hemorrhage in tandem and "carotid-T" occlusion (Fesl et al. 2011, Behme et al. 2014, 2015). Hemorrhage can be due to vessel injury or reperfusion of the infarcted area. The risk increases in relation to the extent of the area of ischemic brain and also to the time passing between the occlusion and recanalization (Kuntze-Soderquist et al. 2014; Nelles et al. 2014). The role of the associated I.V. fibrynolitic therapy has been discussed. The rate of hemorrhage is lower in patients with vertebrobasilar occlusions, probably due to the increased density of the white matter tracts.

More recently also the *presence of subarachnoid hemorrhage (SAH*), associated to the parenchymal but frequently also isolated, has been reported by several authors (Shi et al. 2010; Parrilla et al. 2012, Yoon et al. 2013; Yilmaz et al. 2014; Nikoubashman et al. 2014; Schwaiger et al. 2016). The pathogenesis of SAH is not completely clear. A vessel injury is a probable mechanism in many cases. Indeed it occurs more frequently where a mechanical thrombolysis is performed. Another pathogenesis could be the high concentration of contrast medium acting as a toxic element in the area already suffering of hypoperfusion. Both factors could favor the disruption of the blood brain barrier with leakage of blood sometimes associated with contrast medium (Nikoubashman et al. 2014). In the cases in which the finding is due only or predominantly to contrast medium, it rapidly disappears on CT controls made 24–48 h after treatment. It is worthwhile noticing that similar cases due to the toxicity of contrast medium in the absence of ischemia have been reported in patients who received an high amount of contrast during cardiovascular procedures (Sharp et al. 1999; Khan et al. 2014).

A particular aspect, as already described in Sects. 15.4.1, 15.4.2, 15.4.3, 15.4.4, 15.4.5, 15.5.2, 15.5.3, 15.5.4, and 15.5.5 *is the involvement in* the *ischemic stroke of the perforators*. These are *end arteries* and so their impairment in acute occlusion also for a short time, can lead to ischemia in their vascular territories. In addition should be note that gray matter tolerates hypoperfusion worse in comparison to the white matter.

While the infarcts in the vertebrobasilar sector are always more or less symptomatic, those involving the basal ganglia are often "asymptomatic" or only linked with mild neurological deficit.

- Another cause of ischemia, frequently presenting with TIAs or minimal stroke is that due to

microatheroma involving the intracranial arteries as described in Sects. 15.4.1, 15.4.2, 15.4.4, 15.5.2, 15.5.3, and 15.5.4. These lesions which can be symptomatic but also incidentally discovered are reported to have a bad prognosis (Thijs and Albers 2000; WASID 2003). Some of these lesions, such those located in the petrous-cavernous-supraclinoid segments of ICA, in the M1 segment and in the intracranial VA and BA, can today be treated, by endovascular approach, with a good morphological and clinical results (Phatouros et al. 2000; Berkefeld et al. 2003; Gupta et al. 2003; Bose et al. 2007; Turk et al. 2008; Bradac et al. 2008b; Qureschi et al. 2008; Berkefeld and Zanella 2009; Wang et al. 2009; Miao et al. 2011; Dorn et al. 2012a; Derdeyn et al. 2013, Wang et al. 2016b). The rate of complications, however, is still relatively high: hemorrhage due to vessel rupture or reperfusion of the acute ischemic lesion, and new ischemia can occur due to distal embolization or occlusion of the perforating branches from the struts crossing their origin or displacement of microatheroma material. Another unsolved problem is the *in-stent restenosis or thrombosis* (Kurre et al. 2010). This negative evolution involves all treated intracranial stenosis, but it is reported to be more frequent in the anterior circulation, especially in those lesions located in the intradural ICA and in young patients (Levy et al. 2007; Turk et al. 2008). There is not a clear explication for this. It has been suggested that the intradural ICA stenosis, in this group of patients represents a distinct pathology not linked to atherosclerosis, but to inflammatory diseases (Levy et al. 2007; Turk et al. 2008), which react differently to the endovascular treatment. *Taking these considerations into account, in the attempt to reduce complications and improve the clinical results, it seems to be appropriated as also recommended by several authors* (Chaturvedi and Caplan 2003; Kurre et al. 2010; Fiehler 2014; Reith et al. 2015) *to perform an accurate selection of patients, considering for endovascular treatment only symptomatic patients with severe stenosis not responsive to medical therapy, and not undertake the treatment in the acute phase of the stroke. Furthermore, it is thinkable that improvement of this treatment can be achieved by increasing experience of the operators and by the introduction of more appropriate devices.*

Spontaneous Dissection of Carotid and Vertebral Arteries

16

16.1 Introduction

Jentzer (1954) is the first author to have reported a case of spontaneous dissection of the carotid artery. Since then, more detailed studies have described this pathology (Bostrom and Liliequist 1967; Ehrenfeld and Wylie 1976; Fisher et al. 1978; Mokri et al. 1979; Anderson et al. 1980; Friedmann et al. 1980; Bradac et al. 1981a) which have helped to widen the understanding of the clinical and angiographic aspects of this disease. Spontaneous dissection is today a well-recognized pathology that is responsible for stroke in many cases. Its incidence is reported to be 2.5–3 cases of carotid dissection and 1–1.5 cases of vertebral dissection per 100,000 persons yearly (Schievink 2001; Menon and Norris 2008; Redekop 2008). Young and middle-aged patients are predominantly affected. Multiple lesions occur about 20% of the cases (Pelkonen et al. 2003; Bejot et al. 2014).

16.2 Pathology and Pathogenesis

The cause of dissection can be *traumatic* occurring in blunt trauma of the neck due to forced flexion-extension or rotation movements, sometimes associated with fractures of the cervical spine or the skull basis (Redekop 2008). In the majority of the cases the dissection is *spontaneous* whose pathogenesis is not completely clear. Underlying structural changes of the arterial wall associated with mechanical factors, are probably involved. Indeed, it is well known that dissection occurs frequently in patients with connective-tissue disorders such fibromuscular dysplasia (FMD), Ehlers-Danlos syndrome, Marfan syndrome, alpha-glucosidase deficiency, polycystic kidney disease, osteogenesis imperfecta, and lupus erythematous (Makos et al. 1977; Anderson et al. 1980; Mitsias and Levine 1994; Schievink et al. 1994a; Schievink 2001; North et al. 1995). Association with cystic medial necrosis has also been demonstrated in some cases (Schievink et al. 1994a). Dissections are reported to be more frequent in patients with migraine and in women using oral contraceptives (Mokri et al. 1986; D'Anglejan-Chatillon et al. 1989). A family history has also been reported (Shievink and Mokri 1995). Trauma, even minor as occurring in neck manipulation (Hufnagel et al. 1999; Nadgir et al. 2003) or associated with sport, sexual activity, lifting of heavy objects, or in forced vomiting and coughing, is present in the clinical history of some patients (Dittrich et al. 2007). In this context, the association of trauma, even minor, and raised blood alcohol as a cause of dissection, particularly in the vertebrobasilar sector, have been emphasized (Hiraiwa et al. 2005). Also the association with recent infection, especially of the upper respiratory tract has been reported (Guillon et al. 2003). Some authors (Konrad et al. 2003; Vila et al. 2003) have reported in cases of dissection a deficiency of alpha 1-antitrypsin. This is a proteinase that has a protective action on collagen

G.B. Bradac, *Applied Cerebral Angiography*, DOI 10.1007/978-3-319-57228-4_16

and elastin, which are important components of the connective tissue of the arterial wall. The same deficiency has been identified also in cases of FMD, which has an high tendency for dissection (Schievink et al. 1998). In many cases a specific etiologic cause is not found.

From the pathological point of view, the lesion is characterized by a hemorrhage within the layer of the media from which it can extend towards the intima or towards the adventitia. In the first case one speaks of an *subintimal* dissection leading commonly to a stenosis or occlusion of the artery, in the second case of a *subadventitial* dissection in which frequently a pseudoaneurysm develops. The hemorrhage is due to a tears of the intima allowing the blood to pass into the wall of the artery. Commonly the dissection can present only with a point of entrance, but sometimes there is an entry and an exit point leading to the formation of a pseudo-lumen. Both the true lumen and the pseudo-lumen can be patent. This latter can sometimes be predominant. Dissection can be due to a primary hemorrhage within the wall of the artery not associated to a rupture of the wall. In these cases the cause is thought to be due to rupture of the vasa vasorum.

In this context, there are interesting autoptic studies in patients with intracranial dissecting aneurysms involving the vertebrobasilar sector (Sasaki et al. 1991a; Mizutani et al. 2001, Endo et al. 1993). An anatomopathological study of dissecting aneurysm of the anterior cerebral artery has also been reported (Mizutani et al. 2001). The main remarkable finding was a disruption of the internal elastic lamina (IEL) associated with a different grade of disruption of the media. If the disruption of the media was minimal the hemorrhage was between the media and IEL. When the disruption involved largely the media the hemorrhage extended towards the adventitia. In a few cases, however, there was no connections between the lumen and the intramural hemorrhage indicating that the hemorrhage develop primary in the wall of the artery probably due to rupture of the vasa vasorum.

Vasa vasorum deserves some specific considerations. They are present in extracerebral arteries, but their presence in the intracranial sector has not been well-defined and has been controversial. In this context very useful have been the anatomical and immunohistochemical studies of some authors (Aydin 1998) who have demonstrated the presence of vasa vasorum in the first segments of intracranial ICA and VA, more rarely in the more distal branches. According to the studies of these authors, the frequency of vasa vasorum increases in atherosclerosis and other cerebral vasculopathies. It is then thinkable that vasa vasorum can develop in pathological changes involving the wall of the artery leading to intramural hemorrhage and dissection. The presence of new formed vessel in and around the wall have been demonstrated in pathological specimen in dissecting intracranial vertebral artery where the intramural hemorrhage had no connections with the lumen of the artery (Endo et al. 1993).

As far as it concerns the types of dissection, it should be considered that an important factor is the structure of the wall of the arteries which is different in the extracranial or intracranial sector. The wall of the extracranial carotid and vertebral arteries is composed of five layers (intima, internal elastic lamina, media, external elastic lamina, and adventitia). In the intracranial arteries, as it has already been described in Chap. 11 there is no external elastic lamina. This explain the more frequent extent of the hemorrhage towards the adventitia with the formation of pseudoaneurysm in dissection of intracranial arteries.

16.3 Location

- *Extracranial internal carotid artery* (*ICA*), 2–3 cm distal to the bifurcation is the most frequent site of dissection. This ends abruptly with rare exception, where the artery enters the base of the skull. *The extracranial vertebral artery* (VA) is the second frequent location. Any part of the VA can be involved, but the lesions involve more often

the distal segment of the artery, at the C1–C2, and at the atlas loop level, probably because this segment is more exposed to mechanical trauma (Chiras et al. 1985; Mokri et al. 1988).

- *Intracranial dissection is more rare. It involves typically the vertebrobasilar sector* usually affecting the first intracranial segment of the VA, sometimes as an extension of an extracranial dissection. The VA dissection differs from that of the extracranial ICA, which usually do not extend intracranially. Dissection of the basilar artery is less common; it can be primary or a secondary extension of a dissected VA. Progressively more attention has been given to this pathology which explains the increase of studies appeared in the literature in the last years (Alexander et al. 1979; Shimoji et al. 1984; Berger and Wilson 1984; Friedman and Drake 1984; Caplan et al. 1988a; Yamamura et al. 1990, 1999; Pozzati et al. 1995; Shin et al. 2000; Lacour et al. 2000; Manabe et al. 2000; Kurata et al. 2001; Anxionnat et al. 2003; Sugiu et al. 2005; Ramgren et al. 2005; Lee et al. 2006a; Zhao et al. 2007; Bhogal et al. 2015, 2016). Depending on the site of the dissection the cerebellar arteries can be indirectly involved. Selective dissection of these arteries can also occur (see Sect. 11.6.8). For dissecting aneurysms of the posterior cerebral artery and PcomA, see Sects. 11.6.5 and 11.6.2.4, respectively.
- *Intracranial dissection in the anterior circulation* occurs less frequently in comparison to the vertebrobasilar sector, but it is not so rare as commonly thought. The terminal ICA, M1, or A1 is the typical location. Dissections involving also the M2, A2, or more distal branches are increasingly reported (Ramsey and Mosquera 1948; Kunze and Schiefer 1971; Hochberg et al. 1975; Fisher et al. 1978; Sasaki et al. 1991b; Massoud et al. 1992; Bassetti et al. 1994; Nakatomi et al. 1997; Mizutani 1998; Mizutani et al. 2001; Kurino et al. 2002; Ohkuma et al. 2003; Lee JS et al. 2006a, b; Thines et al. 2006; Lv et al. 2009; Küker et al. 2012; Fukuma et al. 2015; Gao et al. 2016; Hensler et al. 2016).

16.4 Morphological Diagnostic Appearance

- *In the extracranial sector*, occlusion with a typical tapered appearance is frequent as well as an irregular stenosis, which extends for various lengths. Minor changes in the form of slight irregularities of the wall can occur. Demonstration of a double lumen or an intimal flap can be pathognomonic, but it is rare. Pseudosaccular aneurysms can also develop. Examples of dissection of the ICA are presented in Figs. 11.1, 16.1, 16.2, 16.3, 16.4, 16.5, 16.6, 16.7, and 17.5. Dissections of the VA are shown in Figs. 16.2, 16.8, 16.9, and 16.10.
- *Intracranial dissection* appears as occlusion, irregular stenosis (Figs. 16.9 and 16.15) or aneurysms (pseudoaneurysms) of different size which can be fusiform involving part or entire the lumeno of the artery, which can in some parts present saccular dilatation. Saccular aneurysm can also develop. They have frequently an ill-defined neck and changes in form of narrowing or dilatation are visible on the artery in the area adjacent to the aneurysm. They can grow and become very large (see also Sect. 11.8). Examples of dissecting aneurysms in the anterior circulation are presented in Figs. 5.10, 11.8a, b, 11.12b, 11.15, 11.17, and 16.17. Those in the posterior circulation are demonstrated in Figs. 11.9c, 11.24, 11.25, 11.26, 11.27, 11.29, 11.30, 16.11, 16.13, 16.14, and 16.16. *Not infrequently the arterial changes are minimal. Repeated examinations days or weeks later can show more conspicuous alterations* (Fig. 16.12a, b).

  CT and MRI demonstrate the ischemic lesions or the subarachnoid bleeding in case of ruptured dissecting aneurysm. Furthermore MR can show hyperintensity or dilatation of the involved artery. Eccentric signal void (corresponding to the residual lumen) surrounded by a semilunar hyperintensity (corresponding to the mural hematoma) can be evident (Fig. 16.5). This, however, may be visible only 1 or 2 days after the acute episode first on

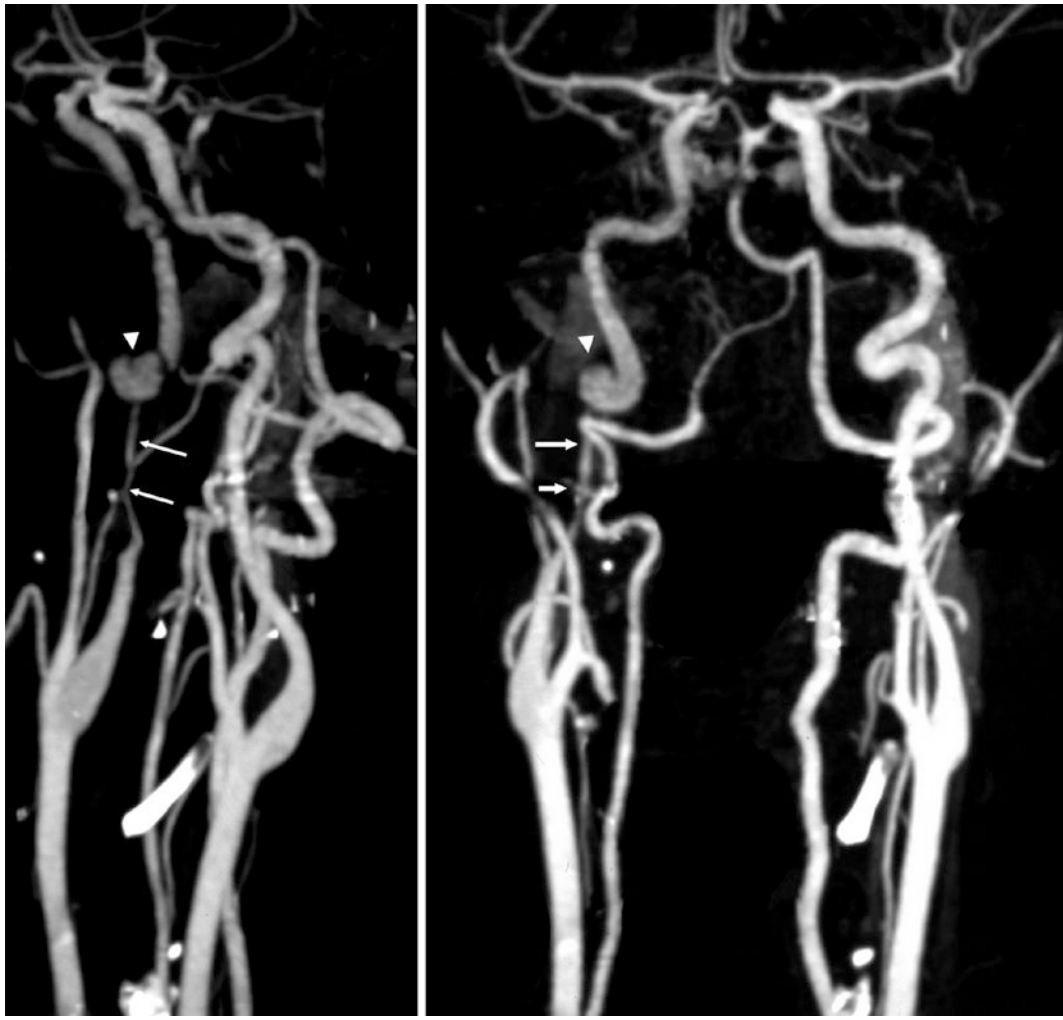

Fig. 16.1 CT angiography. Dissection of the right ICA, characterized by severe stenosis 2 cm distal to the bifurcation (*arrows*). A pseudoaneurysm is also present (*arrowhead*). On the CT study, there was a small infarct in the territory of the MCA, probably embolic

T1- and then on T2-weighted sequences (Iwama et al. 1990; Zuber et al. 1994; Hosoya et al. 1999; Vertinsky et al. 2008; Provenzale 2009).

MRI and CT angiography can replace conventional angiography in many cases. But the latter, owing to its precise morphological demonstration of the arteries, still remains the gold standard and it is to be used every time the diagnosis is not sufficiently clear or when a treatment (surgical or endovascular) is planned.

16.5 Clinical Relevance

- *Dissection most commonly occurs extracranially*, and it is responsible for 2% of all ischemic strokes and for about 20% of all strokes in patients under 45 years of age (Bogousslavsky et al. 1987; Schievink 2001; Redekop 2008). Some dissections may be accompanied only by cervical and facial pain (Buyle et al. 2001), which are always present and by Horner's syndrome as a result of a palsy of the sympathetic fibers sur-

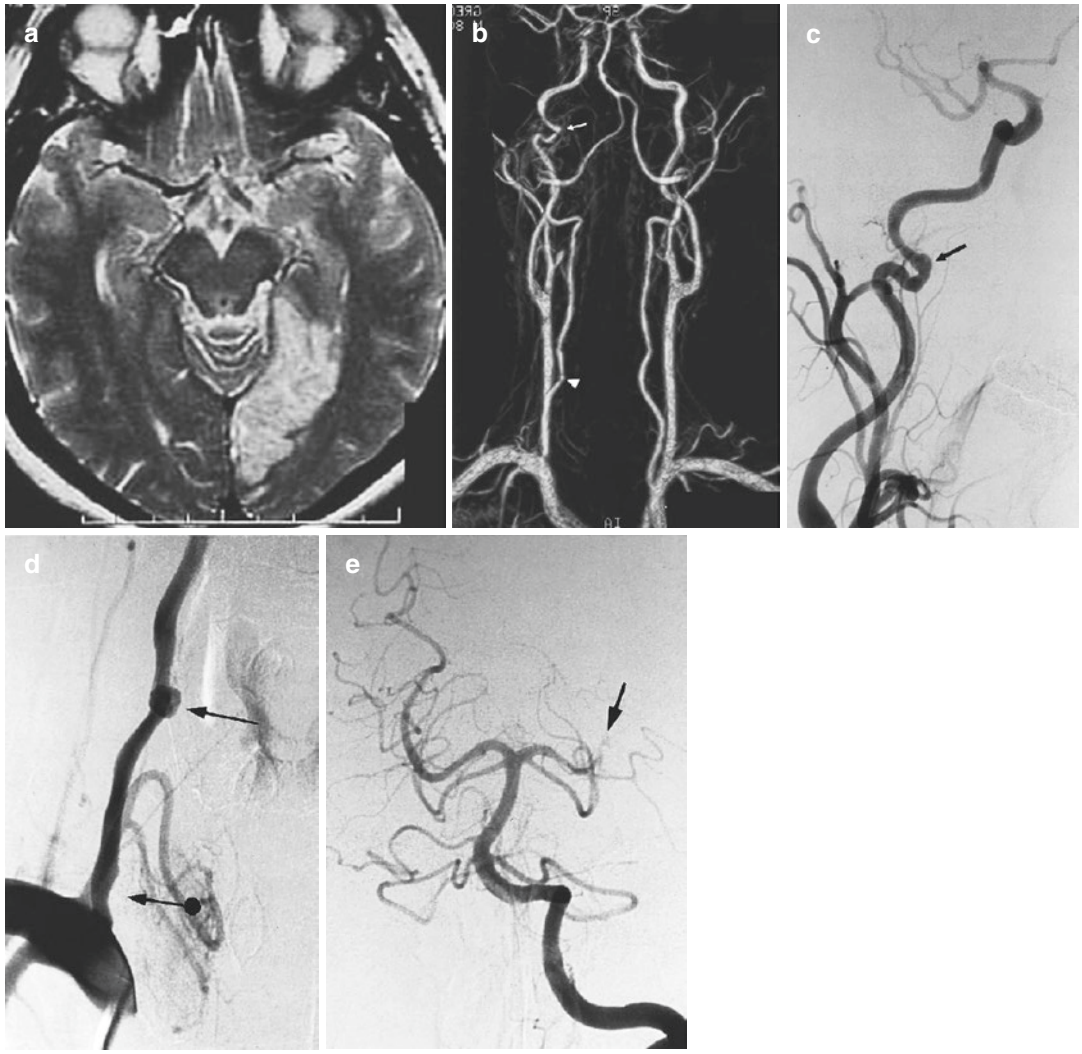

Fig. 16.2 Patient admitted with acute ischemia in the vascular territory of the left PCA. (**a**) MRI showing infarct in the left occipital region. (**b**) MR angiography. Irregularity of the right ICA (*arrow*). Doubtful finding on the right vertebral artery (*arrowhead*). (**c**) The angiogram of the right ICA confirmed the changes of the artery, suggesting dissection (*arrow*). (**d**) The right VA angiogram showed the stenosis of the artery at its origin (*arrow with dot*) and the rounded dissecting pseudo-aneurysm at the level of C6 (*arrow*). (**e**) Probably embolic occlusion of the left PCA (*arrow*)

rounding the dissected ICA. These minimal signs can elude an imprecise neurological examination.

Dissection can leads to ischemia, varying from TIAs to major strokes, due to hypoperfusion, intracranial embolization, or both, involving the anterior or posterior circulation, depending on the artery involved. Ischemia of the spinal cord can also occur in dissection of the VA (Weidauer et al. 1999; Crum et al. 2000) (Fig. 16.8).

An interesting aspect is palsy of the last four cranial nerves in various combination in dissection of the ICA (Bradac et al. 1981a, 1989, 2000; Maitland et al. 1983; Hommel et al. 1984; Lieschke et al. 1988; Nusbaum et al. 1998; Waespe et al. 1988; Vargas et al. 1992; Schievink et al. 1993; Mokri et al. 1996;

Note the adjacent course of the AphA. (**c**) Pseudoaneurysm (*arrow*). (**d**) Irregular fusiform dilatation (*arrows*). A flap (*arrow with dot*) is recognizable

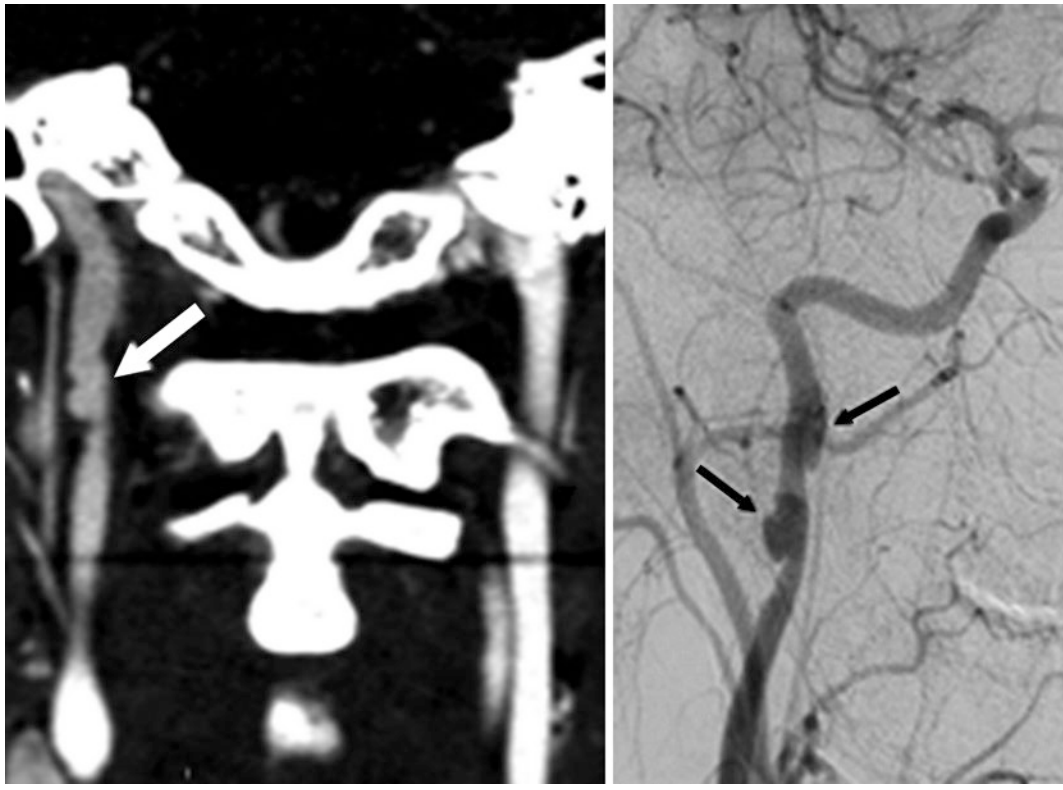

Fig. 16.4 ICA dissection. CT angiography and conventional angiography. The irregularity and the pseudoaneurysms (*arrows*) are better demonstrated on the angiogram

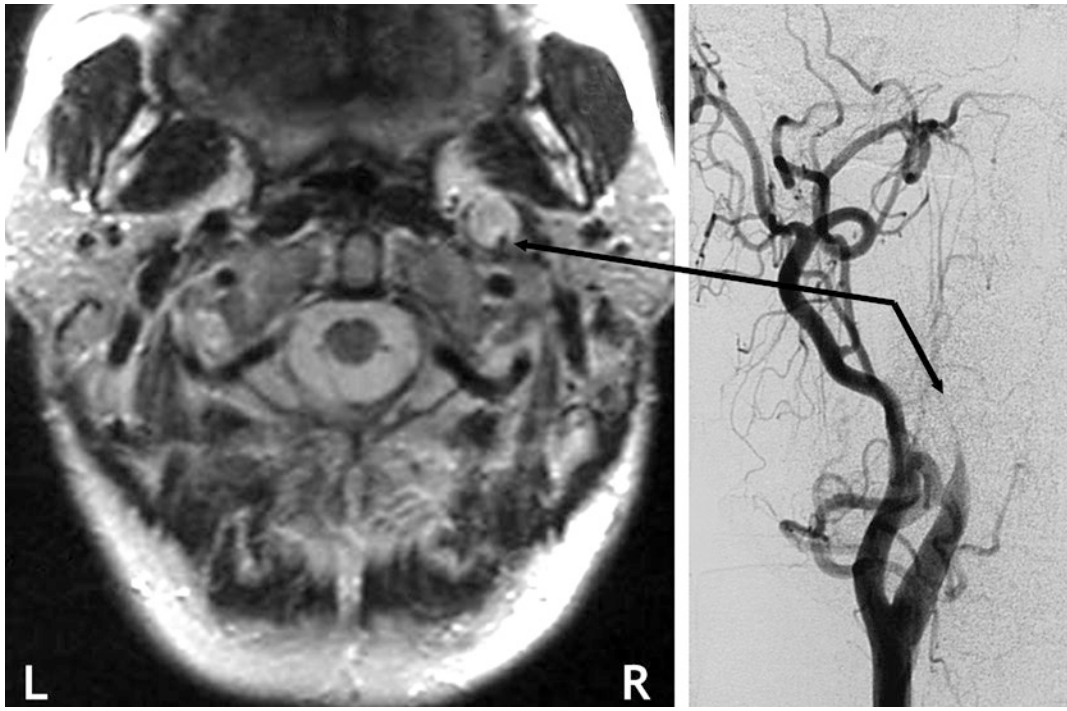

Fig. 16.5 Typical tapered occlusion in ICA dissection shown on the angiogram. On the MR examination the eccentric signal void and the surrounding hyper-intensity corresponding to the residual lumen and the mural hemorrhage respectively are well visible

Sturzenegger et al. 1995). Increased volume of the artery due to the intramural hematoma or the presence of pseudoaneurysm can lead to compression of the nerves. Another possibility which could be considered is the involvement of the ascending pharyngeal artery which runs parallel and adjacent to the ICA (Bradac et al. 1989, 2000). It is known that this artery supplies these nerves (Lasjaunias and Doyon 1978) and so its compression could lead to impairment in the supply of the nerves. The rare occurring palsy of the cranial nerves III, IV, and VI supplied by branches of the inferolateral trunk could be explained by involvement of these fine arteries due to minimal extension of the dissection to the cavernous portion of the ICA or due to hypoperfusion or distal embolization. Indeed, involvement of these nerves has been described in cases of ICA occlusion (Wilson et al. 1989; Kapoor et al. 1991).

- *Intracranially, dissection involves predominantly the vertebrobasilar sector*. The lesion can lead to *ischemia* in the cerebellum and/or brainstem with varying clinical symptoms frequently associated with abrupt cervicooccipital pain (Yoshimoto and Wakai 1997; Hosoya et al. 1999; Lee et al. 2006a). In many other cases, as increasingly reported in the literature dissection leads to a rupture of the artery and *to subarachnoid bleeding*. Some authors (Ro et al. 2009) in an histopathological study of dissection of intracranial VA resulted in fatal bleeding have demonstrated along with the ruptured dissection a few other partially or completely repaired dissections involving also the contralateral VA. According to these authors, this finding seems to demonstrate the existence of a specific vulnerability and tendency to dissections in certain patients.

Fig. 16.6 (**a**) Occlusion of the Left ICA due to traumatic dissection (*arrows*), without involvement of the intracranial circulation. Complete recanalization 4 weeks later. (**b–d**) Occlusion of the left ICA due to spontaneous dissection in a young patient presenting with stroke. (**b**) ICA angiogram. (**c**) It was not difficult to overcome the dissection with a microcatheter showing the patent distal ICA and occlusion of M2 branches of the MCA (*arrow*) which were reopened by aspiration. (**d**) The treatment was completed with stenting of the ICA. Good clinical outcome

Fig. 16.6 (continued)

- *Dissection even if more rare can occur also in the anterior circulation where it is progressively recognized as a cause of ischemia* (*Sato* et al. *2010; Nagamine* et al. *2014; Fukuma* et al. *2015*). *Subarachnoid bleeding can also develop* (*see also Chap. 11*). A little curious aspect in patients with dissecting aneurysm in the anterior circulation *presenting with ischemia is its association with a subarachnoid bleeding* (Ohkuma et al. 2003, Fukuma et al. 2015; Hensler et al. 2016). In these cases, the hemorrhage is localized commonly in the frontoparietal cortical area distally to the diagnosed dissection, in a territory different of the ischemia, suggesting that probably in these cases multiple dissections occur (Fukuma et al. 2015). This is indeed conceivable, considering, as described above, that multiple dissections have been demonstrated on pathological studies in some patients. These patients are reported to be younger in comparison to those with dissection in the vertebrobasilar sector and seem to be more frequent in Asiatic population (Yamaura et al. 1999; Kurino et al. 2002). Among other pathologies presenting with cortical hemispheric hemorrhage, the RCVS should be especially taken into consideration in the differential diagnosis in these cases (see also Sect. 17.6).

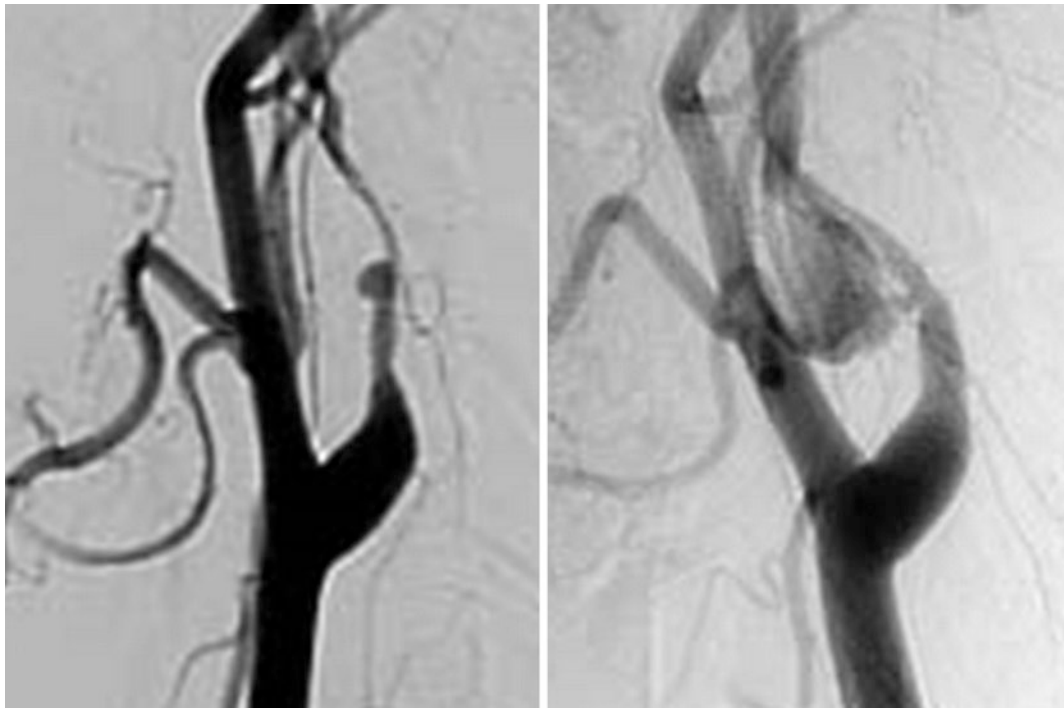

Fig. 16.7 Severe stenosis and pseudoaneurysm (*arrow*) in a case of ICA dissection. Enlargement of the aneurysm on the control angiogram 3 months later

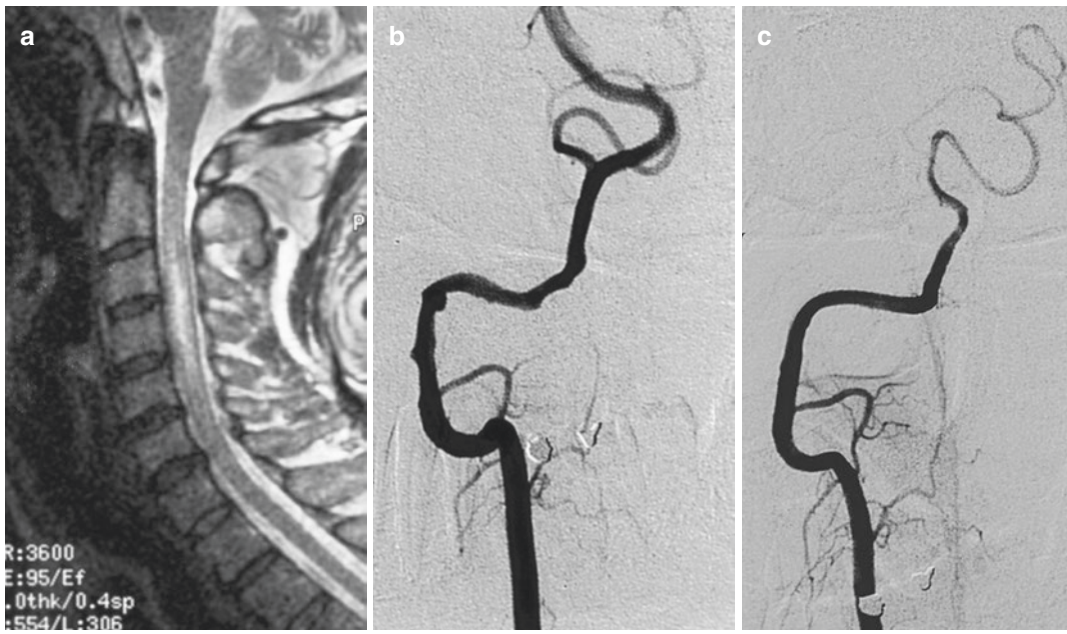

Fig. 16.8 Spinal cord ischemia in a young patient due to involvement of the anterior spinal artery following dissection of the right VA. (**a**) MRI, T2-weighted images showing the hyperintense lesion of the spinal cord. (**b**) Right VA angiogram showing the irregularity with small pseudoaneurysms of the distal extracranial VA with partial involving also of the intracranial segment. The left VA was normal. (**c**) Normalization of the right VA 4 months later. Clinical improvement

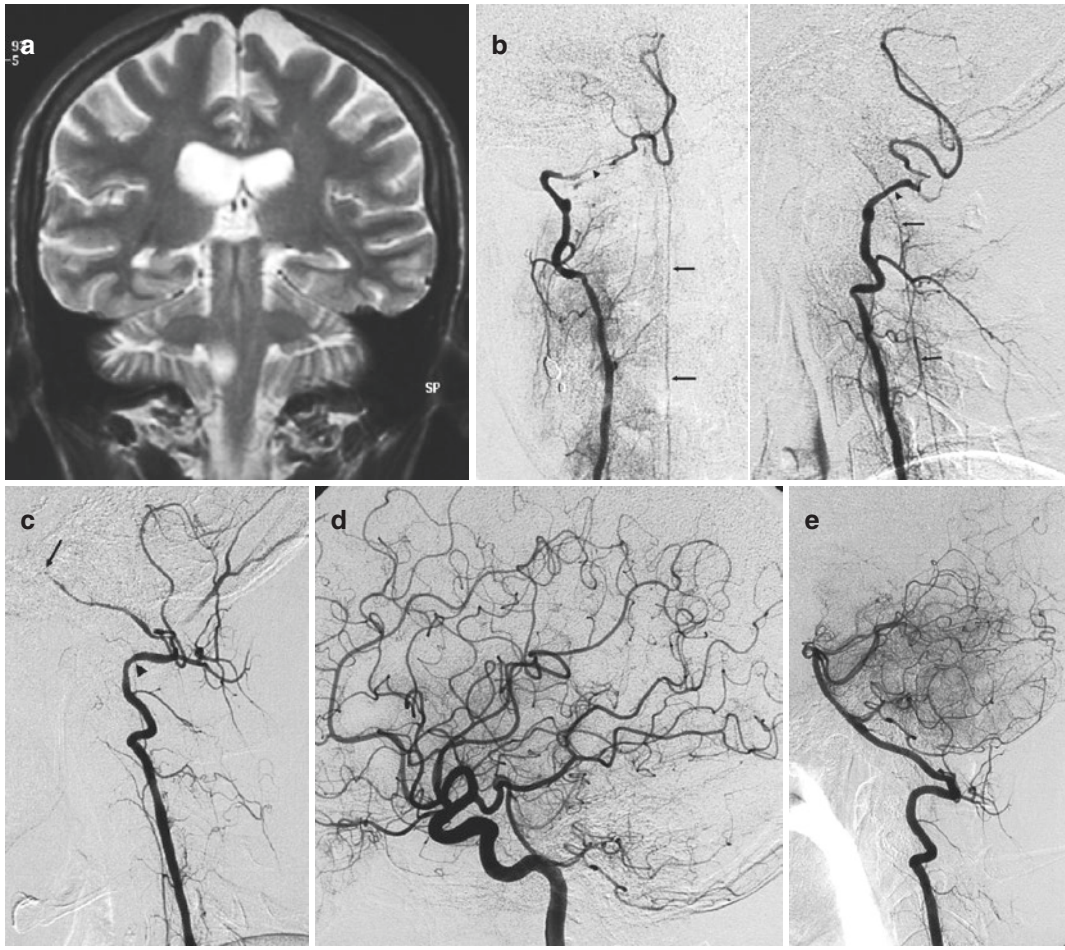

Fig. 16.9 Young patient with brainstem stroke due to dissection of both vertebral arteries (VAs) with involvement also of the basilar artery (BA). (**a**) MRI T2-weighted image showing a small lateral bulbar ischemia. (**b**) Angiogram of the right VA (AP and lateral view). Irregularity and narrowing of the distal VA (*arrowhead*). The VA ends in the PICA. Injection of the anterior spinal artery (*arrows*) through a radiculo-medullary artery. (**c**) Left VA angiogram. Narrowing of the distal VA (*arrowhead*) and BA which is distally occluded. (**d**) Carotid angiogram. Good collateral circulation through the circle of Willis, with retrograde filling of the BA. Medical therapy was performed. Clinical improvement of the patient who was symptom free 2 month later. (**e**) Normal control vertebral angiogram

- A few specific considerations should be made for the so-called *blood blister-like aneurysm* which has been reported to occur typically on the superior-anterior wall of the supraclinoid ICA, predominantly in women. With acquired experience similar aneurysm has been identified also in the ACA and MCA as well as in the vertebrobasilar sector (Park et al. 2009b; Peschillo et al. 2015). The pathogenesis of these lesions is not completely clear. They are probably a particular form of dissection (Ishikawa et al. 1997; Okuchi et al. 1999; Ogawa et al. 2000). Some other authors (Abe et al. 1998) have suggested that an important role is played by the atherosclerosis, where ulcerated plaques lead progressively to a focal defect in the artery wall which eventually is replaced by hematoma covered by fibrous tissue. In the acute phase the angiogram can be normal or only show an irregularity or a small bulge on the artery wall. Over subsequent days, the pattern commonly changes, with increasing of the bulge or forming a saccular aneurysm (Fig. 11.8c, d).

- The cause of dissection can also be *a traumatic lesion* of the artery. In patients with severe craniocerebral trauma, as well as in those with blunt neck injuries, or cervico-vertebral or basal skull fracture the neuroradiological investigation should be directed not only to exclude intracranial parenchymal and/intracranial vessels lesions but also to examine the extracranial cervical arteries showing sometimes unexpected dissections, as also reported by others (Biffl et al. 2000; Miller et al. 2001; Schneidereit et al. 2006; Redekop 2008).

16.6 Treatment

- *The treatment of extracranial dissection* is controversial, since an important aspect is normalization of the vessel lumen in the majority of the cases (Kasner et al. 1997; Schievink 2000, 2001; Djouhri et al. 2000; Touzé et al. 2001; Pelkonen et al. 2003). This is particularly true when stenosis is present (80–90% of the cases of Pelkonen et al. (2003), Wessels et al. (2008), and Rederkop (2008) showed normalization). Recanalization can also occur in a certain number of occlusion. In the report of the same authors (Pelkonen et al. 2003; Wessels et al. 2008; Redekop 2008) this latter occurred in 30–50% of the cases (Fig. 16.6). Pseudoaneurysms can thrombose, but commonly remain unchanged or enlarge (Fig. 16.7). The risk, however, that remaining irregularities of the wall as well as the persistence of pseudoaneurysm are the cause of stroke due to distal embolization is minimal.
  Taking this into consideration, in the acute phase, in asymptomatic patients or in those with mild neurological symptoms, conservative medical therapy, to avoid embolization is commonly preferred. Endovascular treatment may be performed later, if stenosis or pseudoaneurysm remains. There is, however, a group of patients in whom dissection leads to a major stroke, due to hypoperfusion or due to intracranial embolization (tandem lesions) or both. In these cases the efficiency of the medical therapy is limited (Engelter et al. 2012) and there is a need of a more aggressive approach.
  While in patients presenting with these clinical conditions due to atherosclerotic pathology, endovascular treatment is the undiscussed therapy of choice (see also Sect. 15.4.1.2) the indication of this treatment in patient presenting similar clinical conditions due to dissection, has not been clearly defined. Progressively, positive results of endovascular approach have appeared in many reports, describing this treatment in ICA dissections, showing the utility of this therapy (Ohta et al. 2011; Juszkat et al. 2015; Haussen et al. 2016; Kurre et al. 2016; Murias Quintana et al. 2016; Hoving et al. 2017). The same authors, reported however the not seldom re-occlusion of the artery, due to the formation of an intra-stent thrombus. This occurs more frequently than in similar patients treated for atherosclerotic pathology, indicating that the damage of the wall of the artery reacts differently in case of dissection.
  Depending on the pathological findings and on the presenting difficulties, the endovascular treatment can involve the extracranial dissection or the intracranial occlusion or both (Fig. 16.6b–d).
  The same endovascular approach can be applied in tandem lesions in the vertebrobasilar sector (Cohen et al. 2003). In these cases, frequently one of the VAs is normal and can be used to reach and to treat the intracranial occlusion. This avoids the risk to pass through the dissected VA, with the risk of further embolization. Examples are represented in Figs. 15.40, 16.2, and 16.10.
- *In cases of intracranial dissection with an angiographic pattern of stenosis or occlusion with ischemia,* considering the frequent spontaneous healing of the artery, as reported by some authors (Yoshimoto and Wakai 1997; Kurino et al. 2002) and also observed in our cases, the best treatment is probably a medical therapy (Figs. 16.8 and 16.9). However, it should be considered that the aspect of these lesion can change with formation of aneurysm which can modify the therapeutic approach.
- *In cases in which the intracranial dissection presents with SAH with clearly diagnosed aneurysm, the lesion should be treated rapidly*, since the risk of rebleeding is high especially

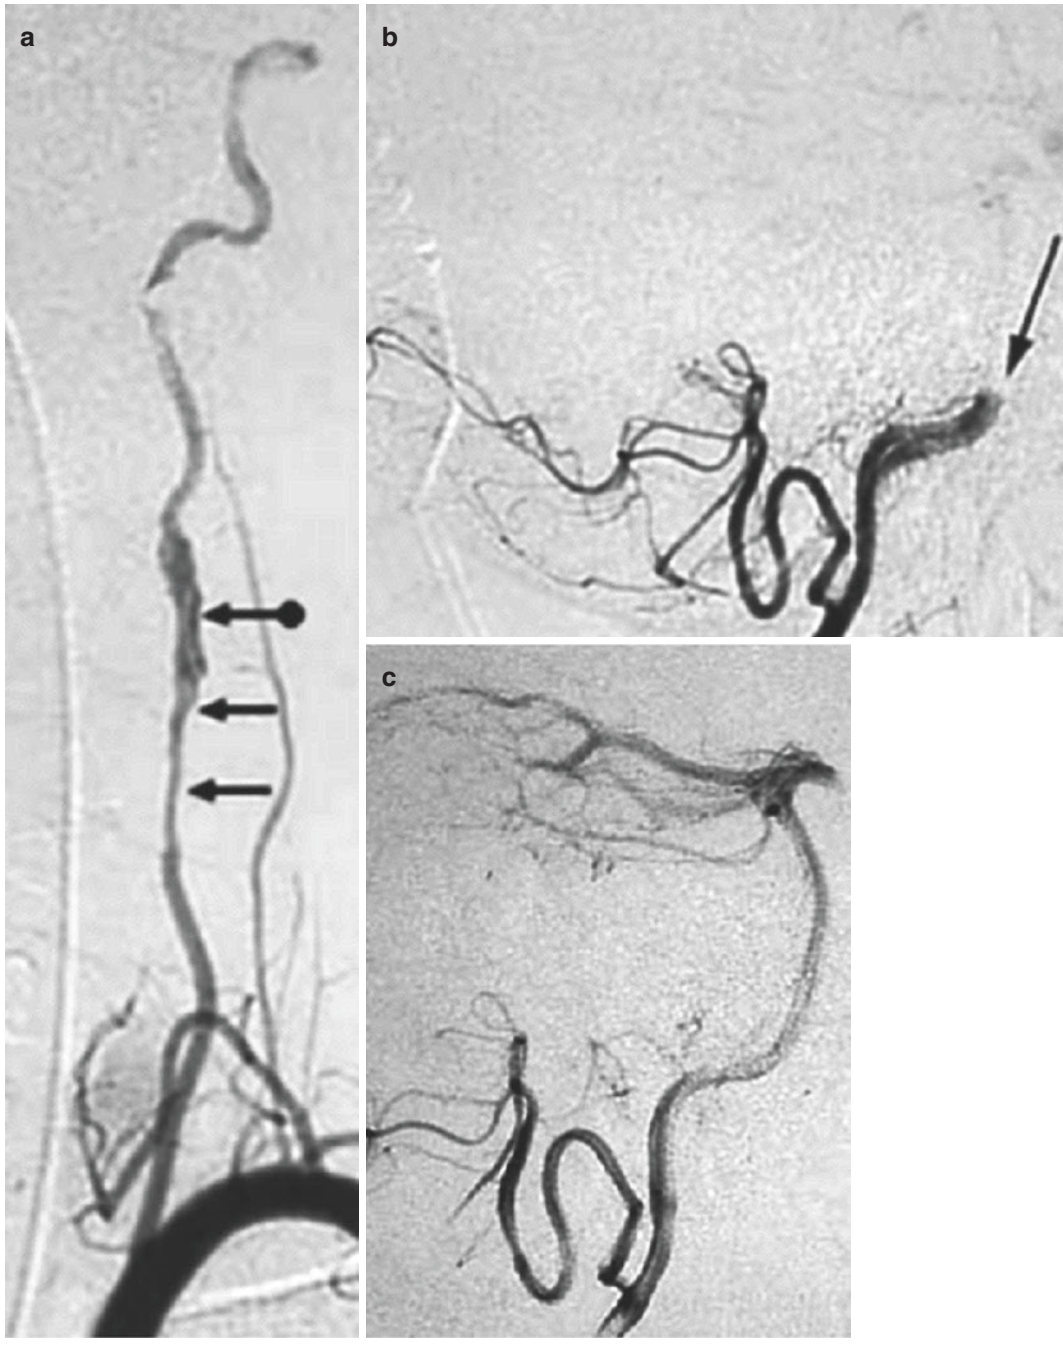

Fig. 16.10 Spontaneous dissection of the left vertebral artery in a very young patient presenting with clinical symptoms of brainstem involvement. (**a**) Left VA angiogram showing irregularity of the artery with stenosis (*arrow*) and dilatation. A double lumen is also recognizable (*arrow with dot*). (**b**) Occlusion probably embolic of the basilar artery (*arrow*). (**c**) A micro-catheter was advanced in the BA through the right VA, followed by pharmacological thrombolysis. Rapid reopening of the BA. Complete recovery of the patient within 2 months

in the first days. The risk of bleeding decreases progressively in the next weeks (Mizutani et al. 2001). Sometimes, however, the vascular changes are minimal on the first angiogram making a certain diagnosis very difficult. The dissection appears more evident in the following days, showing, sometimes very surprising change (Fig. 16.12). This evolution has been described typically in the so-called *blister-like aneurysms* commonly observed in the supraclinoid ICA. It is, however, conceivable as also reported by some authors that they can be develop also elsewhere. It can also occur, as reported by some authors (Mizutani 1998) that the angiographic study in patients with SAH does not show a pseudo-aneurysm, but stenosis or occlusion. The latter can evolve later forming an aneurysm (Hensler et al. 2016). Also spontaneous occlusion of the dissected artery followed by recanalization demonstrating the dissecting aneurysm has been reported (Matsumoto et al. 2008; Akiyama et al. 2012).

- The treatment can be surgical or endovascular. This latter is today commonly preferred. Depending on the site of the dissection, its morphological aspect, the pattern of the vascular anatomy, and the presenting clinical situation, occlusion of the aneurysm along with the parent artery or selective repair with stent and coils, flow-diverter stent, or stent-in-stent technique can be used (Sugiu et al. 2005; Ramgren et al. 2005; Henkes et al. 2006; Yang et al. 2007; Fiorella et al. 2009a; Fischer et al. 2012; Bhogal et al. 2015, 2016) (Figs. 11.12b, 16.11, 16.12, 16.13, 16.14, and 16.17). For examples of treatment of dissecting aneurysms involving distal branches see Figs. 5.10, 11.9c, 11.15, 11.17, 11.24, 11.25, 11.26, 11.27, and 16.16).
  A few extra observations should be made for the treatment of the *blister-like* aneurysms, which remain very critical lesions due to their morphological and structural aspects. Surgery (clipping, trapping, or arterial suturing) has been commonly used as treatment. Endovascular approach has been mainly characterized by occlusion of the aneurysm together with the ICA. This technique remains a good alternative approach as confirmed in a recent work (Kim et al. 2014). In the study, of these authors, in which 11 patients were considered, a good outcome was reported in about 70% of the cases. Improvement of the endovascular technique with the introduction of stent with coils and later of the flow-diverter stent has added new possibility of treatment. A few cases of treatment with flow-diverter has been reported (Kulcsar et al. 2010; Rasskazoff et al. 2010). In the last years, the number of cases has progressively increased. Cinar et al. (2013) reported their experience in the treatment of seven patients presenting with SAH due to "blister-like" aneurysms of distal ICA. One patient was treated with occlusion of ICA. In the other six a flow-diverter was used. Treatment was performed in the subacute phase (3, 4 weeks after the bleeding). The final result was a good clinical outcome with occlusion of the aneurysm in 70% of the cases. Chalouhi et al. (2014) reported the successful treatment of height "blister-like" aneurysms. Seven were located in the ICA and one in the BA. Among them five presented with SAH. In the patients with SAH the treatment was performed acutely (within 2 days) in two cases and in the subacute phase (2 weeks) in the other three patients, using a flow diverter with a final good outcome in all these patients. The treatment (surgical or endovascular) of these aneurysms has been described by Gonzales et al. (2014) in an extensive review of the literature to which the authors added their own positive experience with stent with coils and flow-diverter stents, showing the advantage of the endovascular treatment in comparison to the surgery. The necessity to associate the flow diverter to an antiplatelet therapy applied shortly before or during the treatment appears not to have negative consequences also in the acute phase of treatment. In conclusion, all these reports seem to show the great utility of the flow diverter, which appears to be the best promising therapy to be used at least as the first choice in the treatment of this very critical pathology.

In conclusion: In the diagnosis and treatment of dissections it should be taken into consideration that these are in the acute-subacute phase unstable lesions which can modify their morphological feature, showing not rarely very surprising vascular changes. In cases of an uncertain diagnosis, a close monitoring is mandatory. This can today be performed with angio-CT or angio-MR, followed by conventional angiography when necessary.

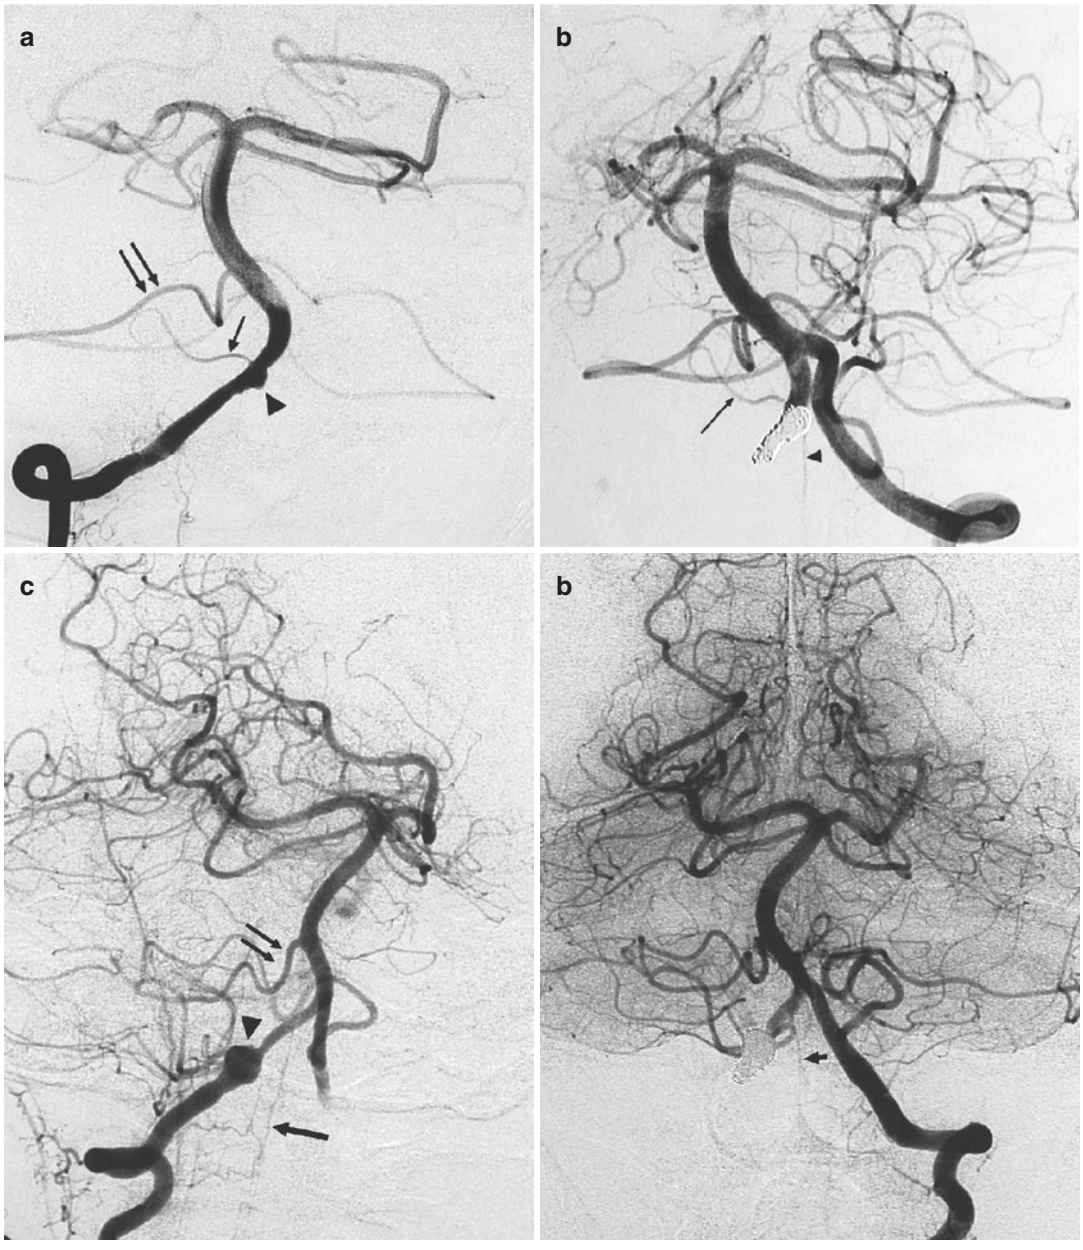

Fig. 16.11 Two examples (**a**, **b** and **c**, **d**) of dissecting aneurysms of the right VA presenting with SHA. (**a**) Right VA angiogram showing the irregular small fusiform aneurysm (*arrow head*) proximal to the origin of the small PICA (*small arrow*). There is a large AICA (*arrows*) supplying also the territory of the PICA. (**b**) Left VA angiogram after occlusion of with coils of the aneurysm and the VA. The right PICA was preserved (*arrow*) as well as the anterior spinal artery (*arrowhead*). The patient recovered well. (**c**) Another with a similar lesion and clinical presentation. On the right VA angiogram (oblique view) round dilatation of the VA (*arrowhead*) suggesting dissection. There is a large AICA (*double arrows*) supplying completely the vascular territory of the PICA. Anterior spinal artery (*arrow*). Well-developed PICA on the left. (**d**) Left VA angiogram after occlusion of the aneurysm and right VA with coils. Anterior spinal artery (*arrow*). Good recovery of the patient

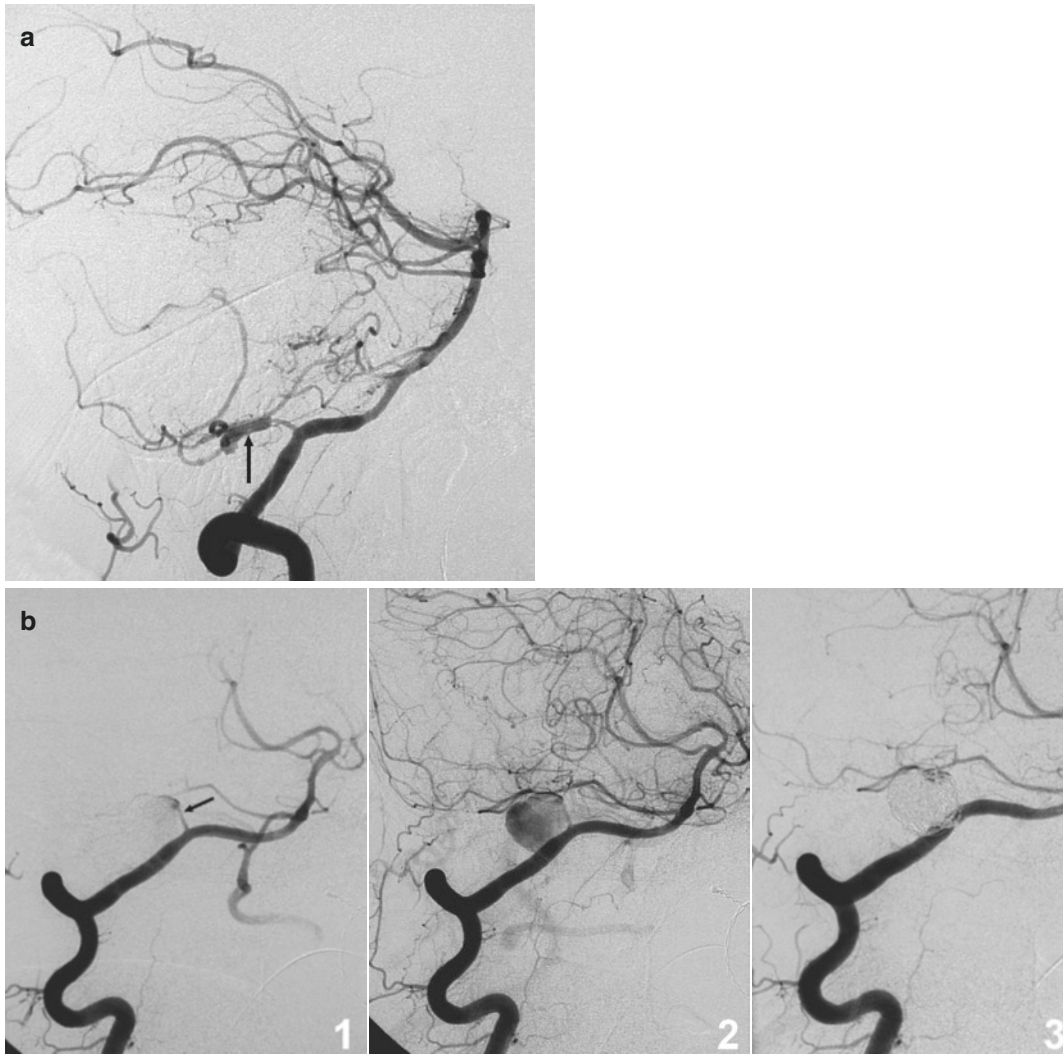

Fig. 16.12 Severe SAH in a young patient. (**a**) Right vertebral angiogram showing a fusiform dilatation suggesting a dissecting aneurysm (*arrow*) of the lateral bulbar segment of the PICA. The deep comatose patient was in very clinical critical condition. No treatment was performed. (**b**) There was a progressively slowly clinical improvement and a second angiogram 3 weeks later showed a tremendous enlargement of the aneurysm involving now completely the PICA up to its origin from the VA (*arrow*). Selective occlusion of the aneurysm with coils was performed (figure on the *right*)

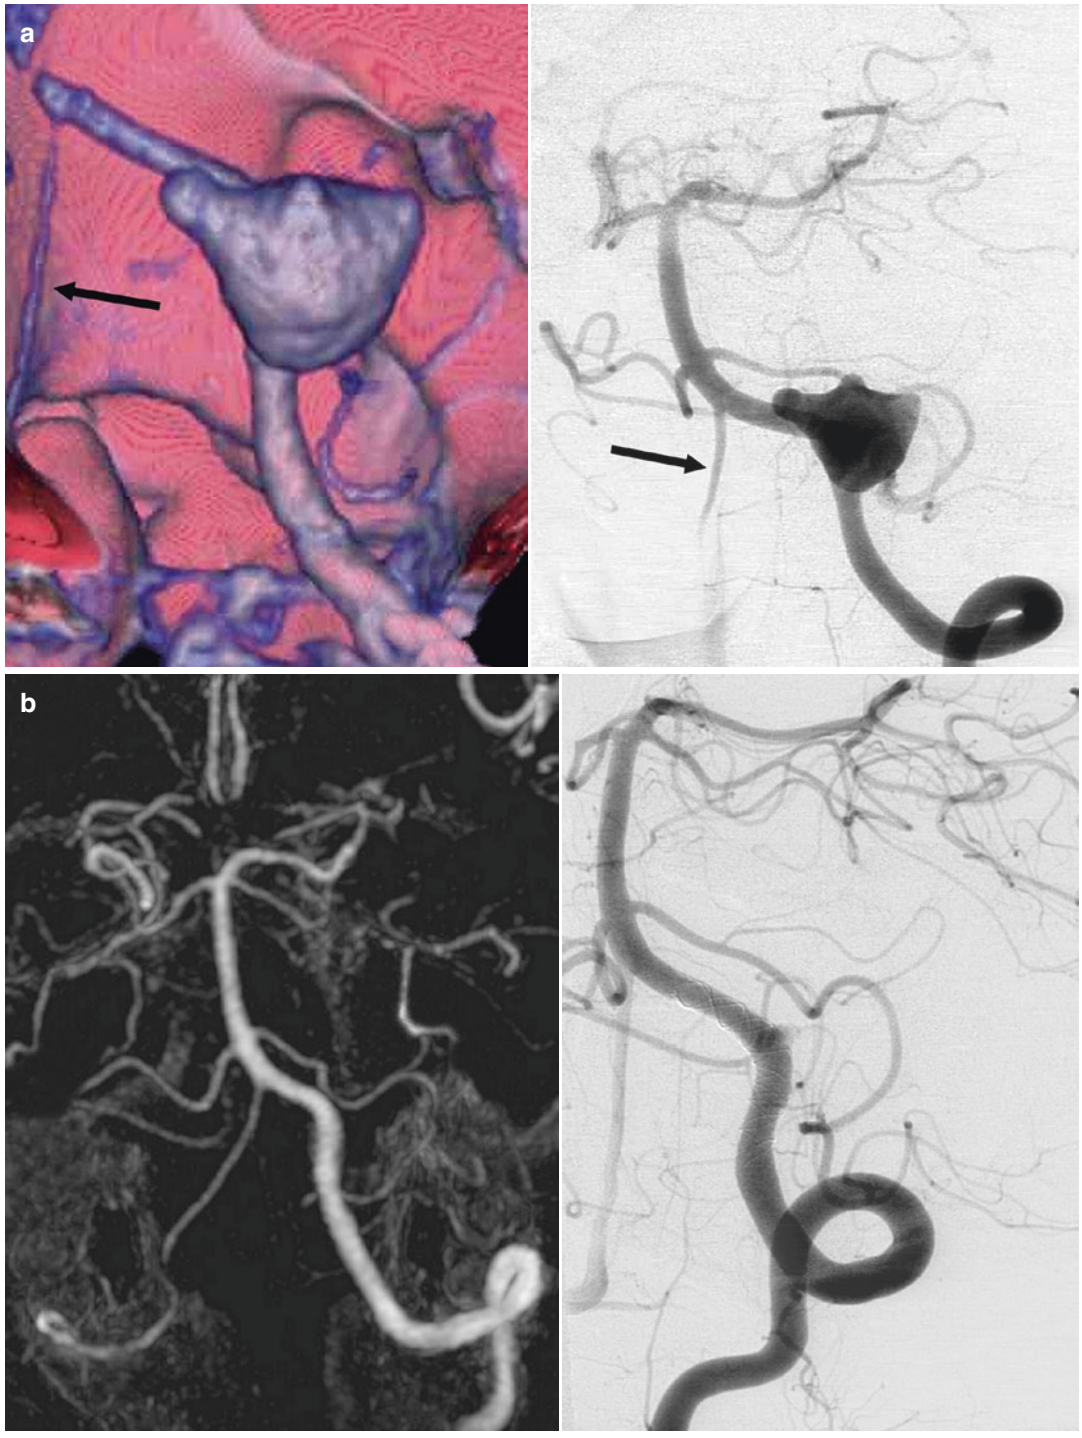

Fig. 16.13 Large dissecting aneurysm of the left VA incidentally discovered in a young patient with a Marfan syndrome. (**a**) CT angiography showing the aneurysm. There is no filling of the PICA. The right VA is hypoplastic (*arrow*). The conventional angiogram (*right* in the figure) shows that the absence of the PICA is compensated by a bilateral well-developed AICA. The patient was treated with a flow-diverter stent (Sylk). (**b**) MR angiography and left vertebral angiogram performed 1 year later. The aneurysm is no longer visible. Normalization of the vertebral artery. On the angiogram the stent is well visible

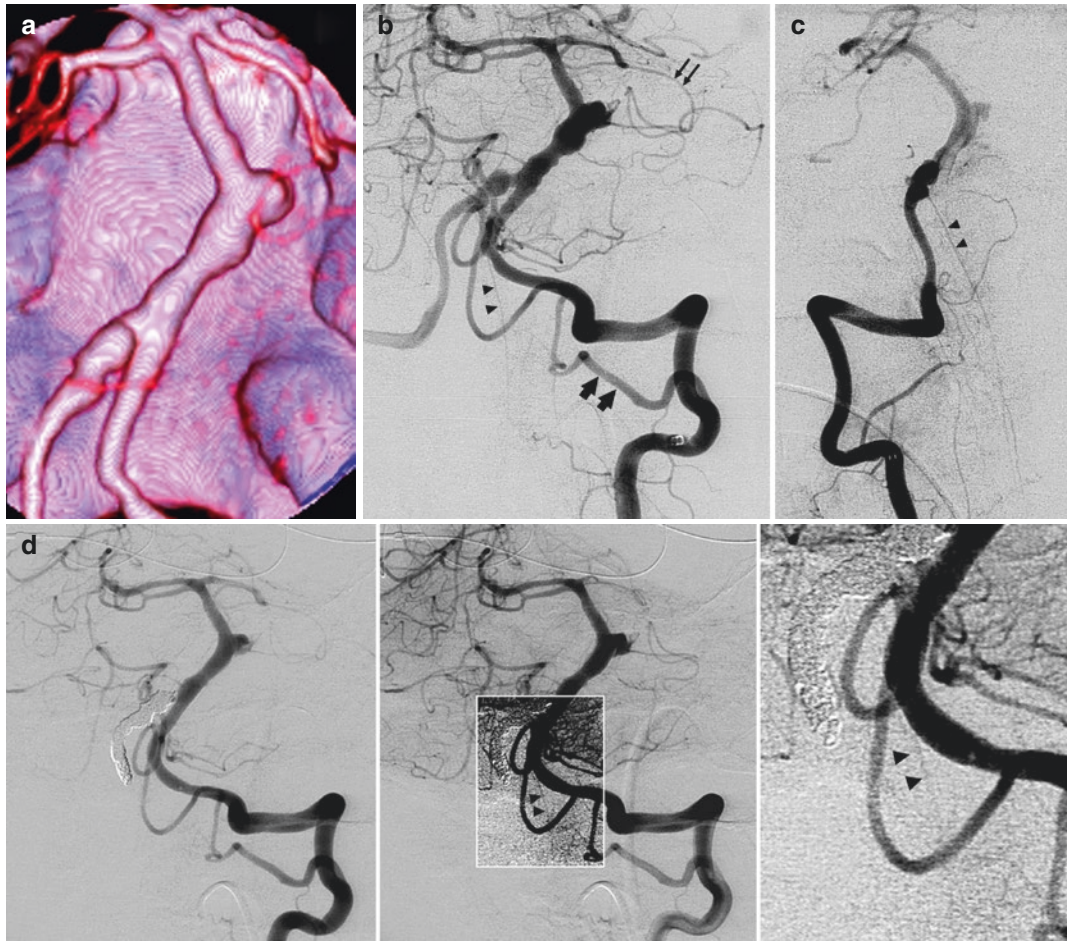

Fig. 16.14 Middle-aged black patient presenting with hemorrhage due dissecting aneurysm involving the distal right VA and proximal and middle BA. (**a**) CT angiography, showing the extensive dissection of the right distal VA and proximal and middle BA, with associated rounded saccular dilatation. (**b**) Left vertebral angiogram with a reflux in the smaller right VA. There is a very large left PICA (*arrows*) arising extracranially at the C1–C2 level supplying also the contralateral territory of the right PICA and probably also of the right AICA. The left SCA (*small arrows*) through its marginal branch supplies probably partially the territory of the left AICA also involved in the dissection. The origin of the ASA is not recognizable. It appears to be unilateral arising from the right VA (*arrowhead*). (**c**) The origin of the ASA from the right VA (*arrowhead*) seems to be confirmed on the angiogram of the right VA. On this angiogram two flow-diverter stents have already be positioned in the BA. *The unilateral right origin of the ASA was an unfavorable condition. However, considering the presence of a large left VA and Left PICA and the possibilities of anastomoses on the surface of the medulla (see also Sects. 6.2.1.1 and 15.7.3), the decision to occlude the right VA with coils was taken.* (**d**) On the left VA angiogram (early and late phases with magnification) performed immediately posttreatment shows improvement of the lumen of the BA and presence of the ASA. The patient tolerated well the treatment. He had deglutition troubles which improved gradually. (**e**) The MRI performed 10 days later showed a small ischemic lesion in the right lateral medulla and in the right splenium, the latter probably embolic. Small old lesion in the white matter. (**f**) MR angiography a month later showed a progressive morphological improvement of the BA. (**g**) Control angiogram 1 year later showed the normalization of the BA and of the left AICA. On the non-subtracted image the position of stents and coils is recognizable. Note the slight intima hyperplasia (*arrows*) which has incorporated the stent. The patient was clinically free of symptoms

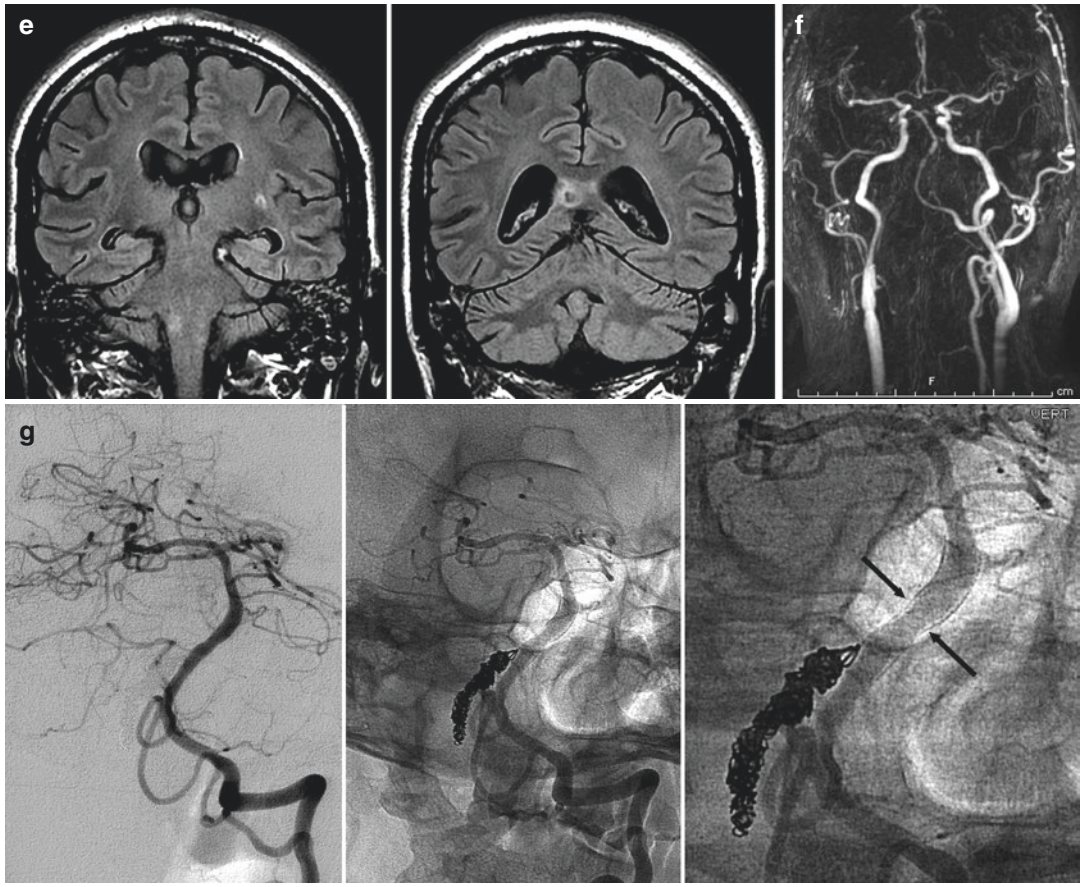

Fig. 16.14 (continued)

16.7 Dissection and Dissecting Aneurysms in Children

Dissection in childhood is relatively rare, accounting for about 7% of all dissections (Schievink et al. 1994b). As in adults, dissection in children can be *traumatic* or *spontaneous*. In children with extracranial dissection the pathogenesis is prevalently traumatic involving ICA or VA with a pattern similar to that described in adults. Instead, the intracranial dissection is predominantly spontaneous and is reported to be relatively more common than in adults (Schievink et al. 1994b; Fullerton et al. 2001). It typically involves the distal ICA and MCA appearing as stenosis or occlusion with a pattern not different to that occurring in other intracranial vasculopathies (Fig. 16.15) (see also Chap. 19), leading to ischemia. It is noteworthy that in cases of extracranial dissection the typical symptoms characterized by head and neck pain associated with the Horner syndrome is frequently absent and the clinical symptoms are due to the cerebral ischemia due to hypoperfusion or embolization (Fullerton et al. 2001; Rafay et al. 2006). The pathogenesis of the spontaneous dissections are pathological changes involving the wall of the arteries as described in Sect. 16.2.

Dissection can lead to the formation of pseudoaneurysms. Unlike in adults, in whom this kind of aneurysms are prevalently in the posterior circulation, in children they are also frequent in the anterior circulation (Lasjaunias et al. 2005).

Among the arteries typically involved in the anterior circulation, the most frequent are the terminal ICA and MCA, and in the posterior circulation the VA, BA, and PCA (Hochberg et al. 1975; Nass et al. 1982; Graber et al. 1992; Laughlin et al. 1997; Massimi et al. 2003; Vilela and Goulao 2006; Bradac et al. 2008a; Gandolfo 2012). Intracranially large pseudoaneurysms have frequently a mass effect on the surrounding parenchyma. They can cause distal embolization and depending on the site can involve the perforators (Figs. 16.16 and 16.17). Intracranial hemorrhage due to rupture of the aneurysm can occur, but it is less common than in the adults.

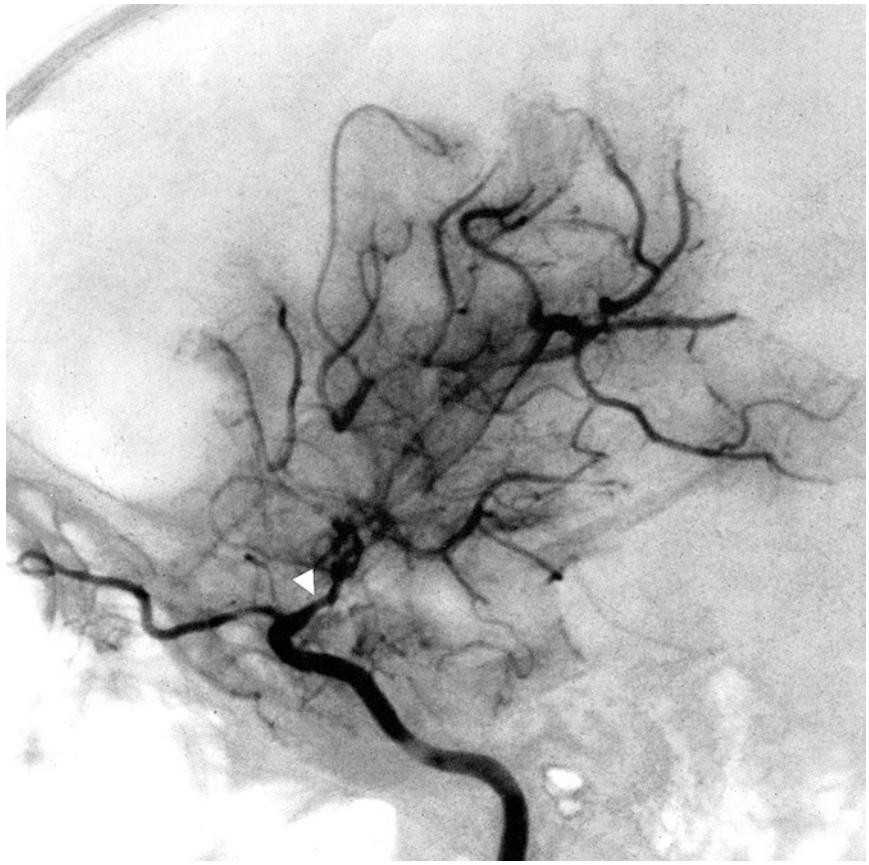

Fig. 16.15 Lateral carotid angiogram in a 5-year-old child with a sudden onset of hemiplegia and aphasia. Left lateral carotid angiogram. Narrowing of the terminal segment of the ICA (*arrowhead*). Irregularity and occlusion of many branches of the middle cerebral artery. A spontaneous dissection with distal embolization was suspected

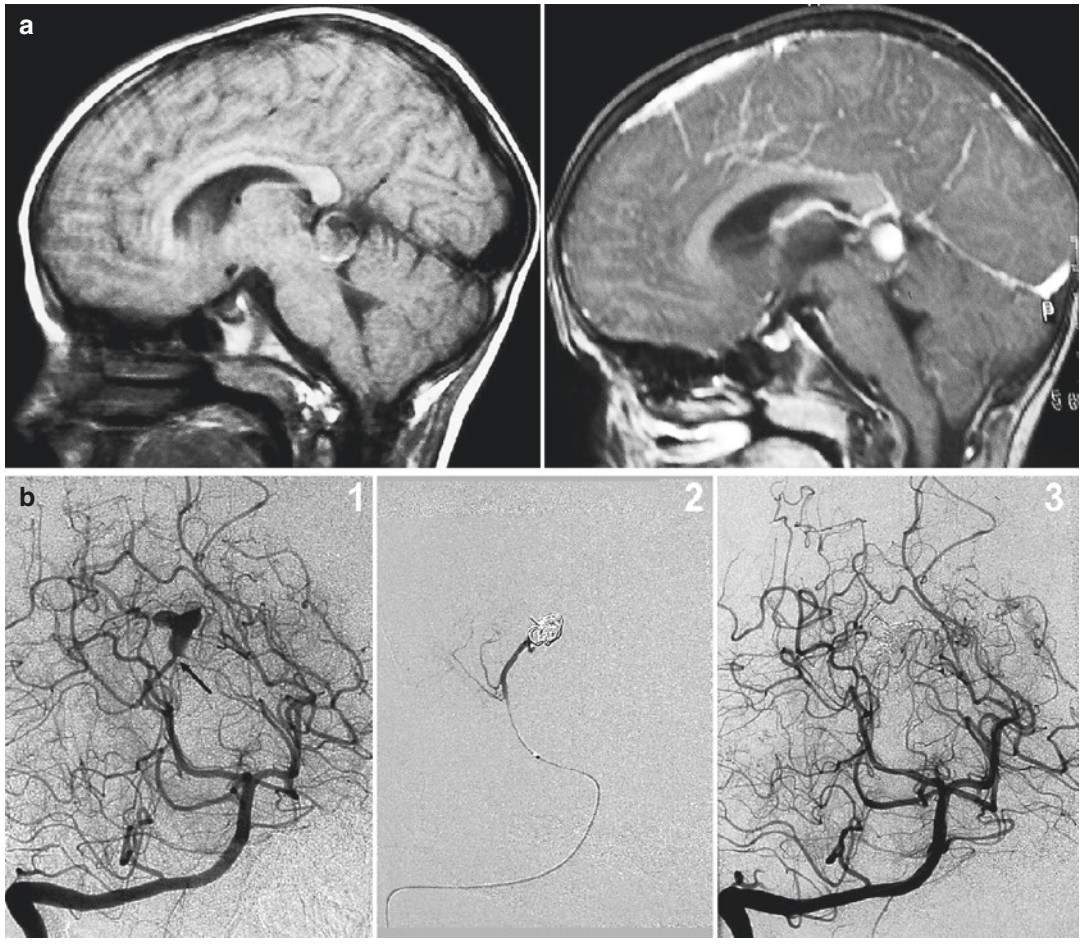

Fig. 16.16 Seven-year-old boy with a short clinical history of severe headache. (**a**) MRI T1-weighted sagittal images. A mass lesion, characterized by an inhomogeneous signal and an hyper-intense peripheral rim, corresponding probably to a large aneurysm with an intramural thrombus of different ages, is visible. After contrast medium enhancement of the patent part of the aneurysm is demonstrated. Compression of the aqueduct and midbrain. (**b**) The vertebral angiogram (1) shows an irregularly shaped aneurysm arising from a small branch of the P3–P4 segment of the right PCA. Focal stenotic segment proximal to the aneurysm (*arrow*). Selective catheterization of the aneurysm and its occlusion with coils (2). Final control angiogram (3). Full recovery of the patient

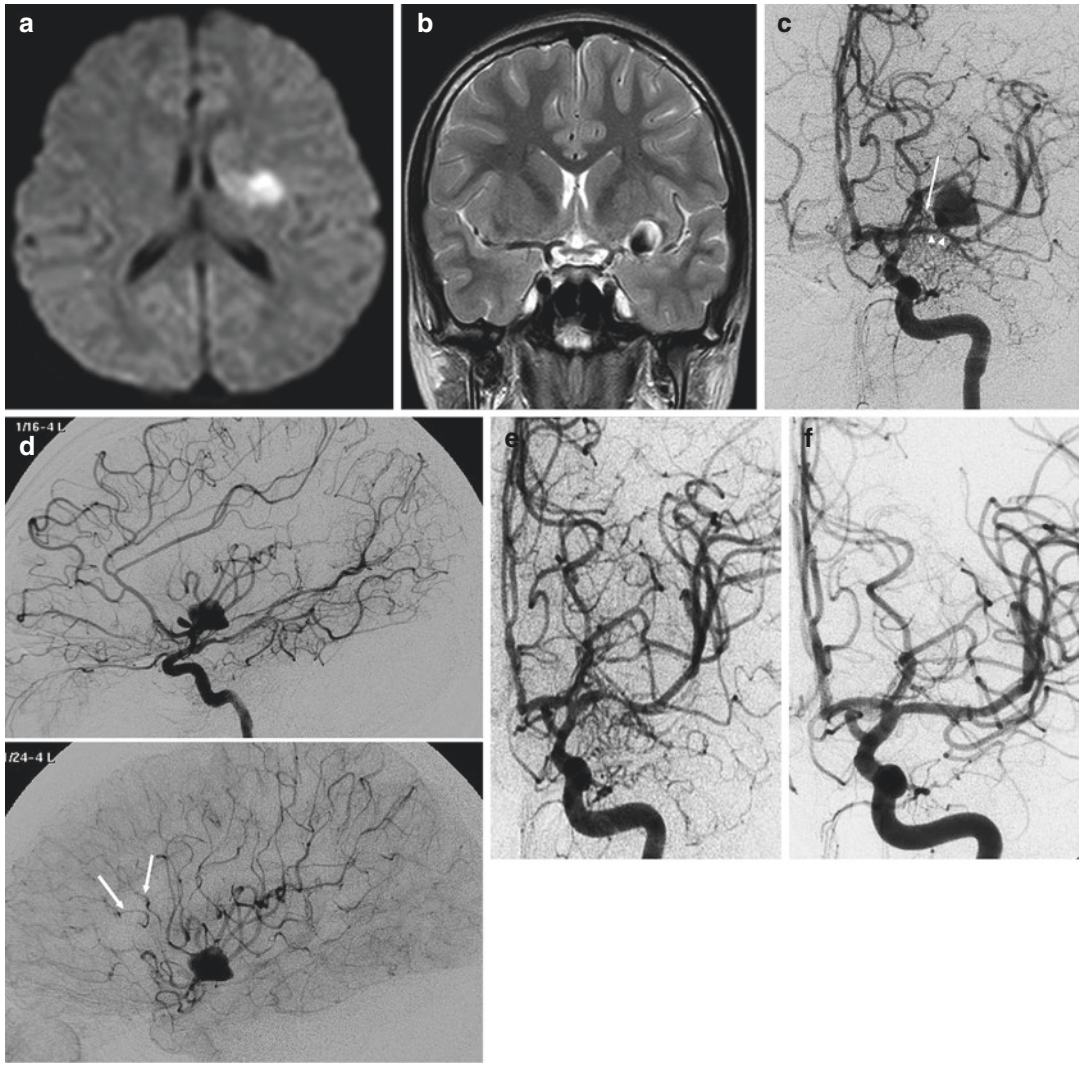

Fig. 16.17 Eight-year-old girl presenting with acute severe headache and right motor deficit. (**a**) MRI. Axial DWI showing ischemia in the vascular territory of the perforators of the left MCA. (**b**) MRI. Coronal T2 showing and aneurysm of the M1 segment of the left MCA. (**c**) Left carotid angiogram. AP view. Aneurysm in the more distal segment of the M1 which appears irregular and narrowed (*arrowhead*) suggesting dissection. Medial perforators are spared (*arrow*). (**d**) Carotid angiogram, lateral view. Early and later phases. Slowdown in the filling of the distal branches of MCA. Some of these (*arrows*) are probably occluded by emboli and retrograde injected through pial anastomoses with the ACA. A treatment with a flow-diverter stent (pipeline) was performed. (**e**) Immediate and a 6 months later control angiograms. Good recovery of the patient

Other Nonatherosclerotic Vasculopathies

17

17.1 Introduction

Nonatherosclerotic vasculopathies comprise a great variety of diseases, as listed in Table 17.1, that result from different etiologies; they include collagenopathies, immunological, hematological, and infection diseases, and other rarer pathologies that have in common the possibility of affecting the cerebral vessels, leading to ischemia and sometimes hemorrhage. Indeed cerebral

Table 17.1 Non-atherosclerotic vasculopathies

Primary angiitis of the CNS
Granulomatous vasculitis, affecting predominantly the precapillary arterioles, occasionally large vessels (such as ICA, PCA, MCA, ACA)
Small aneurysms have also been reported. Angiography frequently normal
Systemic vasculitis that can affect the CNS
Giant cell arteritis: granulomatous vasculitis involving predominantly superficial temporal ophthalmic arteries, occasionally extracranial ICA and VA
Takayasu arteritis: granulomatous vasculitis
Polyarteritis nodosa: necrotizing vasculitis; large intracranial vessels can be involved; aneurysm may be present
Wegener's granulomatosis: necrotizing vasculitis; can involve intracranial arteries with ischemia due to occlusion and hemorrhage due to rupture of arteries
Systemic diseases that can affect the CNS
Systemic lupus erythematosus
Behçet's disease: no signs of necrotizing or granulomatous vasculitis are found; frequently perivenular infiltrations are present; angiography often
Normal
Rheumatic disease
Sjogren's syndrome
Crohn's disease
Sarcoidosis
Hematological conditions
Sickle cell disease, polycythemia vera, Moschcowitz disease, platelet hyperaggregability, disseminated intravascular coagulation, antiphospholipid syndrome, deficiency of factors involved in coagulation (deficiency of proteins C and S, antithrombin III, factor V Leyden), homocystinuria
Vasculopathies not linked to inflammatory processes
Neurofibromatosis, intracranial vessel occlusion, possible intracranial aneurysm
Ehlers Danlos, Marfan syndrome (aneurysm, frequently dissecting, of the extra- and intracranial arteries; dissecting aneurysm of the intracavernous ICA with spontaneous cavernous fistulas)
Fibromuscular dysplasia
Scleroderma
Livedo reticularis (Sneddon's syndrome)
Moyamoya disease
Infection diseases
Bacterial, fungal, parasitic, viral (varicella zoster; herpes simplex; cytomegalovirus; HIV)
Others
Vasculopathies related to drugs, radiotherapy, intracranial tumors, trauma
Migraine stroke

G.B. Bradac, *Applied Cerebral Angiography*, DOI 10.1007/978-3-319-57228-4_17

arteries can be involved in many systemic angiitis or other generalized vasculopathies and can be selectively affected in some diseases such as the primary angiitis of the central nervous system (PACS), the Moyamoya diseases, and the reversible cerebral vasoconstriction syndrome (RCVS). In the majority of these diseases, the angiogram shows findings such as occlusion, irregular narrowing, alternating with dilatation, and sometimes aneurysms. These changes are not typical of one specific disease, but are common to all, independent of their basic pathology. Furthermore, in many cases where the involved vessel is in the precapillary-capillary sector, the angiogram can be normal, and so the diagnosis is made on clinical, laboratory findings and neuroradiological examinations of the brain parenchyma including CT and MR. In some cases brain biopsy is the essential final step.

It is beyond the scope of this book to treat each of these pathologies, since there is already a very rich literature about it. A few specific studies are here reported (Hayreh 1981; Tan et al. 1982; Collado et al. 1989; Beattie et al. 1995; Singleton et al. 1995; Govoni et al. 2001; Hoffman et al. 2002; Weygand and Goronzy 2003; Lucivero et al. 2004). Some angiographic examples are presented in Figs. 17.1, 17.2, and 17.3.

A few of these diseases will be described more in detail considering their clinical relevance and particular clinic-pathological aspects.

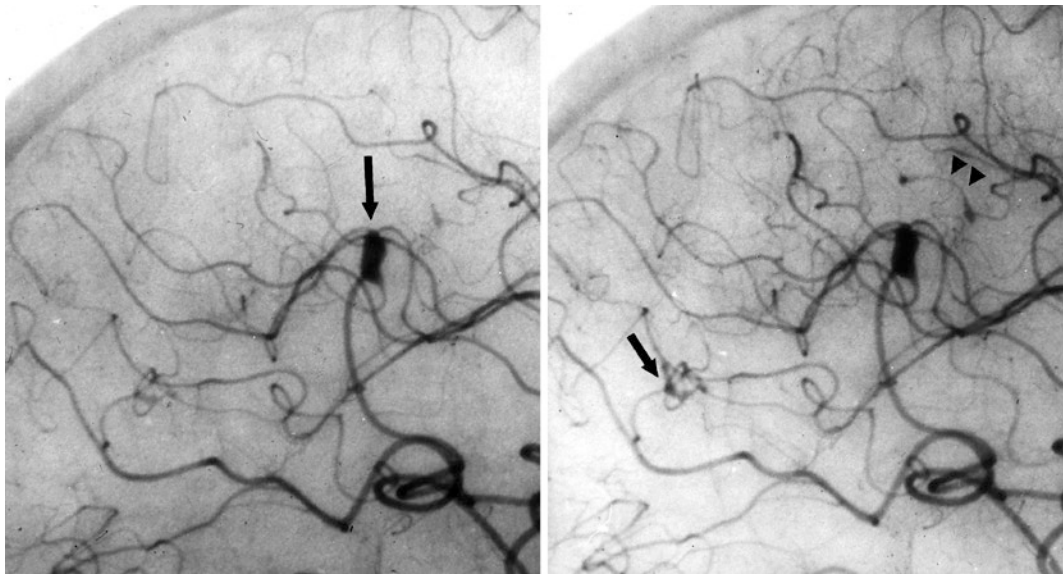

Fig. 17.1 Lateral carotid angiogram (detail with magnification) in a patient with polyarteritis nodosa. Early and later phases. Aneurysm dilatations (*arrow*) and stenotic changes (*arrowheads*) are present

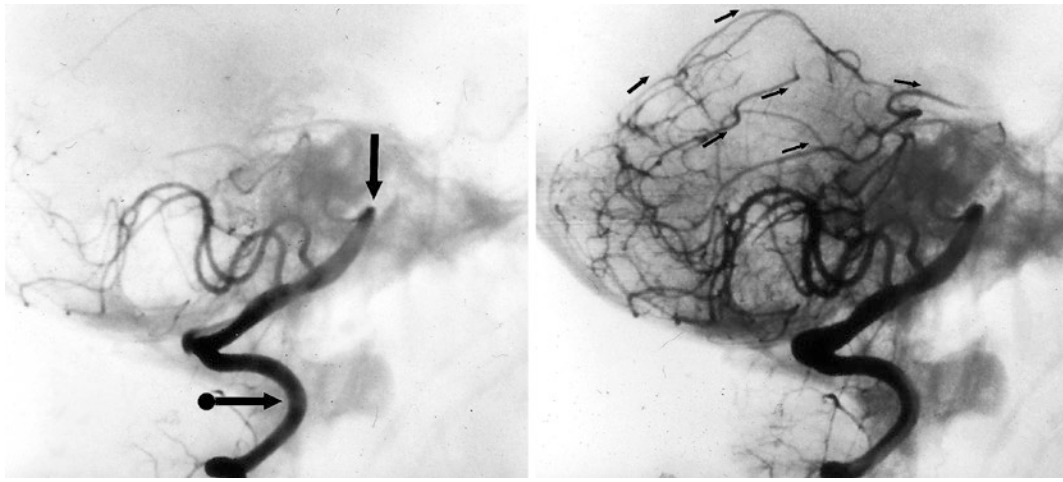

Fig. 17.2 A young boy with neurofibromatosis presenting with acute occlusion of the basilar artery. VA angiogram showing the occlusion (*arrow*). The rounded feature of the occlusion let think that this was probably preceded by a narrowing of the lumen due to pathological changing in the wall linked to the primary pathology. In the later phase, there is a retrograde injection of the SCA and AICA through opening of anastomoses with the PICA (*arrows*). There is a slight displacement of the vertebral artery at the C1–C2 owing to dysplasia of the cervical spine (*arrow with dot*)

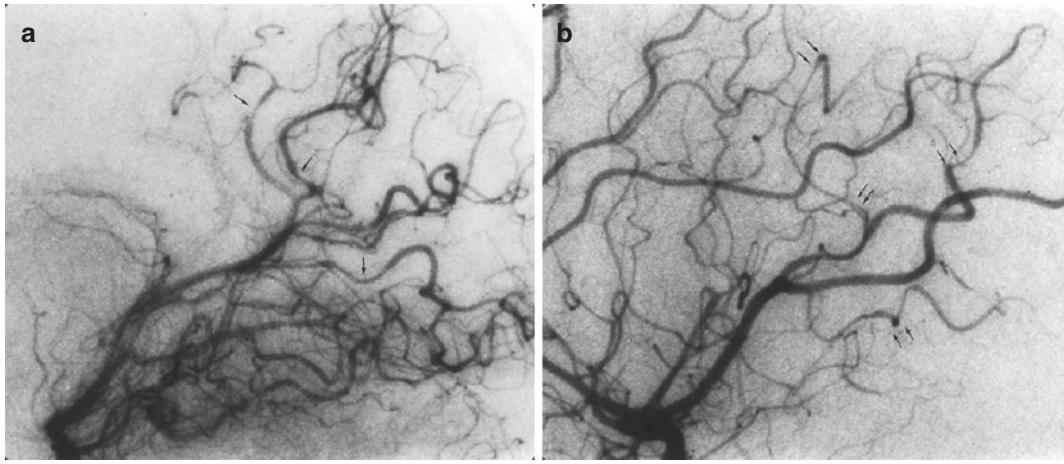

Fig. 17.3 Suspected primary angiitis in a young boy presenting with sudden onset of epileptic seizures and psychic impairment. Lateral VA (**a**) and (**b**) ICA angiograms. Irregularity and focal narrowings of several distal branches in the anterior and posterior circulations are visible (*arrows*)

17.2 Cerebrovascular Fibromuscular Dysplasia

Fibromuscular dysplasia (FMD) is a systemic vascular disease, characterized by nonatherosclerotic changes involving the wall of medium-small sized. All territories can be affected; among them, FMD is seen more frequently in the renal arteries, responsible very often for hypertension. Palubinskas and Rypley (1964) and Palubinskas and Newton (1965) were the first to report the angiographic aspects of this disease in the cephalic arteries. Numerous reports followed (Palubinskas et al. 1966; Andersen 1970; Wylie et al. 1966; Houser and Baker 1968; Bradac and Heymat 1970; Stanley et al. 1974; Manelfe et al. 1974; Osborn and Anderson 1977; Bradac and Oberson 1983), clearly distinguishing FMD from atherosclerotic and other nonatherosclerotic lesions and its possible relationship with stroke.

The true incidence of FMD is unknown. In some reports, it is cited up to 10% of angiographic studies (Chiras et al. 1985). It is more frequent in women, and it is rare in children (Andersen 1970).

17.2.1 Pathology and Etiopathogenesis

FMD is due to structural changes involving the medial layer, characterized by a fibrous proliferation and hyperplasia of the smooth muscle cells. More rarely also involvement of the intima and adventitia occur. These pathological changes lead to thickening and fibrosis of the layers involved. The precise etiopathogenesis has not identified yet. A deficiency of alpha1-antitrypsin has been reported (Schievink et al. 1998).

17.2.2 Diagnosis

The aspect of the arteries involved is typical, characterized on CT-MR angiography and conventional angiography by multifocal stenosis, sometimes severe, alternating with areas of mural dilatation, leading to the so-called *string-of-beads* appearance. Sometimes, it can present with tortuosity, pseudoaneurysm, and tubular stenosis. In the latter situation, the differential diagnosis with spontaneous dissection can be sometimes difficult. On control angiograms, the findings remain unchanged in FMD, while in dissection a normalization frequently occurs. The extracranial ICA in its midportion is the artery most often involved, frequently bilaterally, followed by the extracranial vertebral artery. Multiple vessels are commonly affected. A more rare atypical form, as already been described in the past, and which has gained a new attention more recently is that characterized by the presence at the ICA bifurcation of a small defect frequently thin called differently (septal fibromuscular dysplasia, septa, diaphragm, web and pseudovalvular fold or simply atypical FMD) (Ehrenfeld et al. 1967; Rainer et al. 1968; Houser et al. 1971; Gee et al. 1974; Lipchik et al. 1974; Osborn and Anderson 1977; So et al. 1979; Wirth et al. 1981; Kliever and Carroll 1991; Morgenlander and Goldstein 1991, Kubis et al. 1999; Joux et al. 2014; Boesen et al. 2017). Similar findings involving the distal extracranial VA (Lenk et al. 2014) and the common carotid artery (So et al. 1979) have been reported. It is important to think of FMD in this atypical form and location especially when this is present in young patients presenting with stroke. The defect can be very small and escape to the diagnosis with CT-MR angiography, requiring in these patients a conventional angiography. Differently from the majority of the authors Lenk et al. (2014) consider these changes as an independent entity and not a subtype of FMD.

Intracranial vessels may also be affected, even if it is relatively rare (Elias 1971; Frens et al. 1974; Tomasello et al. 1976; Saygi et al. 1990).

Examples are presented in Figs. 17.4a, b, 17.5, and 17.6.

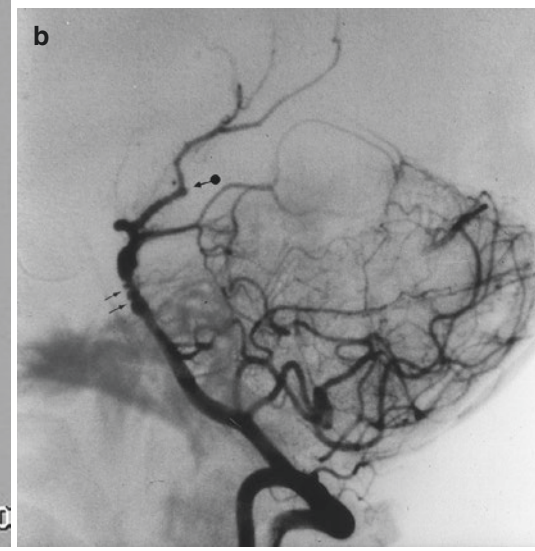

Fig. 17.4 (**a**) Typical "string of beads" appearance of the internal carotid artery (*arrow*). (**b**) "String-of-beads" appearance at the level of distal basilar artery (*arrows*) associated to a similar finding involving PCO. Occlusion of branches of the PCO (*arrow with dot*) and of the SCA probably embolic

FMD is frequently associated with cerebral aneurysms (Handa et al. 1970a; Hirsch and Roessmann 1975; Osborn and Anderson 1977; Paulson et al. 1978). Carotid-cavernous sinus and vertebral artery with peri-vertebral veins fistulas have also been reported (Geraud et al. 1973; Bradac et al. 1985; Hieshima et al. 1986).

17.2.3 Clinical Relevance

The extracranial changes of FMD can be an incidental discovery in patients examined for other pathologies. It can, however, be the cause of ischemic stroke owing to the formation of thromboembolic material at the site of the extracranial-intracranial lesions. The close relationship of FMD with dissection is well known. This can be in the extra or intracranial sector and be responsible of ischemia. Intracranial dissection can be the cause of hemorrhage (Küker et al. 2011). Association with intracranial berry aneurysms is frequent.

The treatment (medical, surgical endovascular) depends on the clinical symptoms and type of lesion.

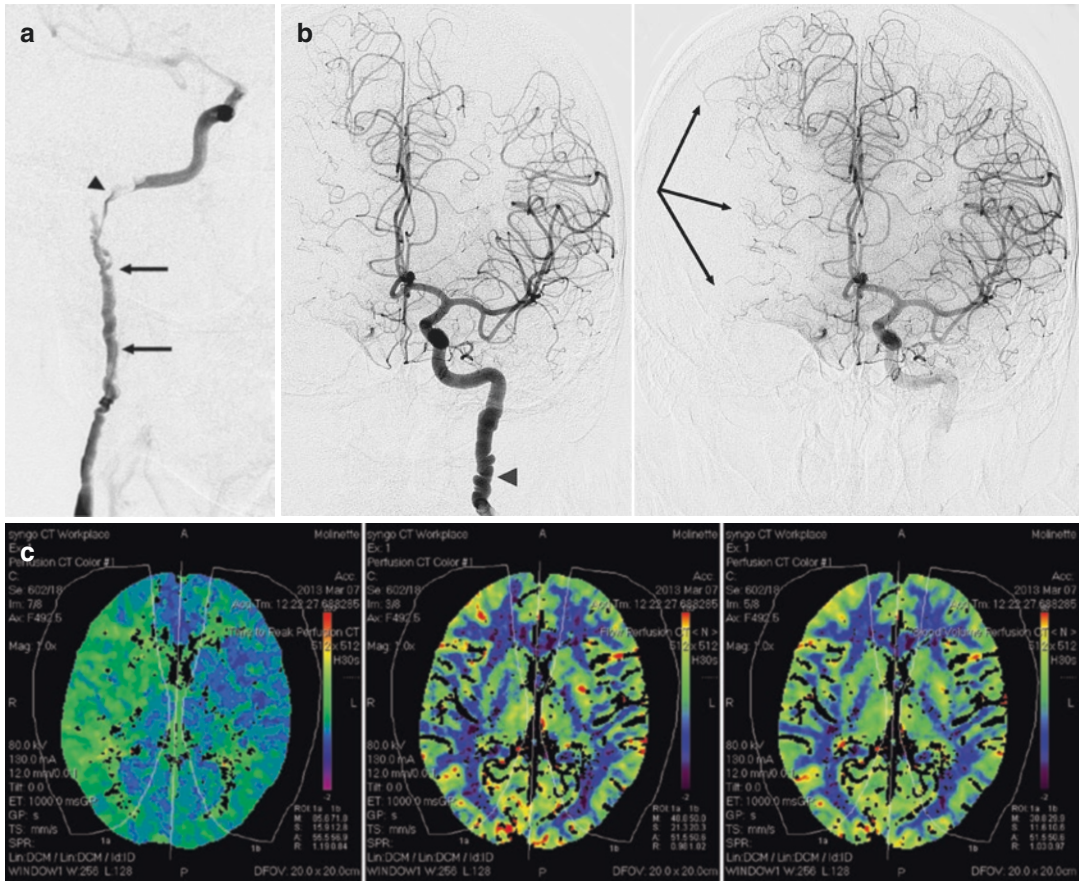

Fig. 17.5 (**a**–**c**) Middle-aged woman presenting with one episode of right amaurosis fugax. On the admission in the hospital, she was clinically normal. The CT angiography followed by a complete conventional angiographic study revealed a severe fibromuscular dysplasia with dissection of the right extracranial ICA. (**a**) Right ICA angiogram. Typical string-of-beads appearance (*arrows*). Dissection close to the skull base where probably an intraluminal thrombus is present (*arrowhead*). There is a slowdown of the intracranial circulation. The A1 is not recognizable. (**b**) Left ICA angiogram (early and later phases) showing similar changing of the extracranial ICA (*arrowhead*). There is aplasia of the right A1. Pial anastomoses from right ACA toward MCA (*arrows*). A rich collateral circulation through pial anastomoses between right PCA and right MCA was visible on the vertebral angiogram. There was aplasia of P1. A rich collateral circulation occurred also through the right ECA (see Fig. 3.13). (**c**) CT perfusion study showed, on the image on the *left*, a slight delay of the *time to peak* on the right hemisphere, but no changes of the *CBF* and *CBV* were demonstrated on the two images on the *right*. The patient underwent medical therapy

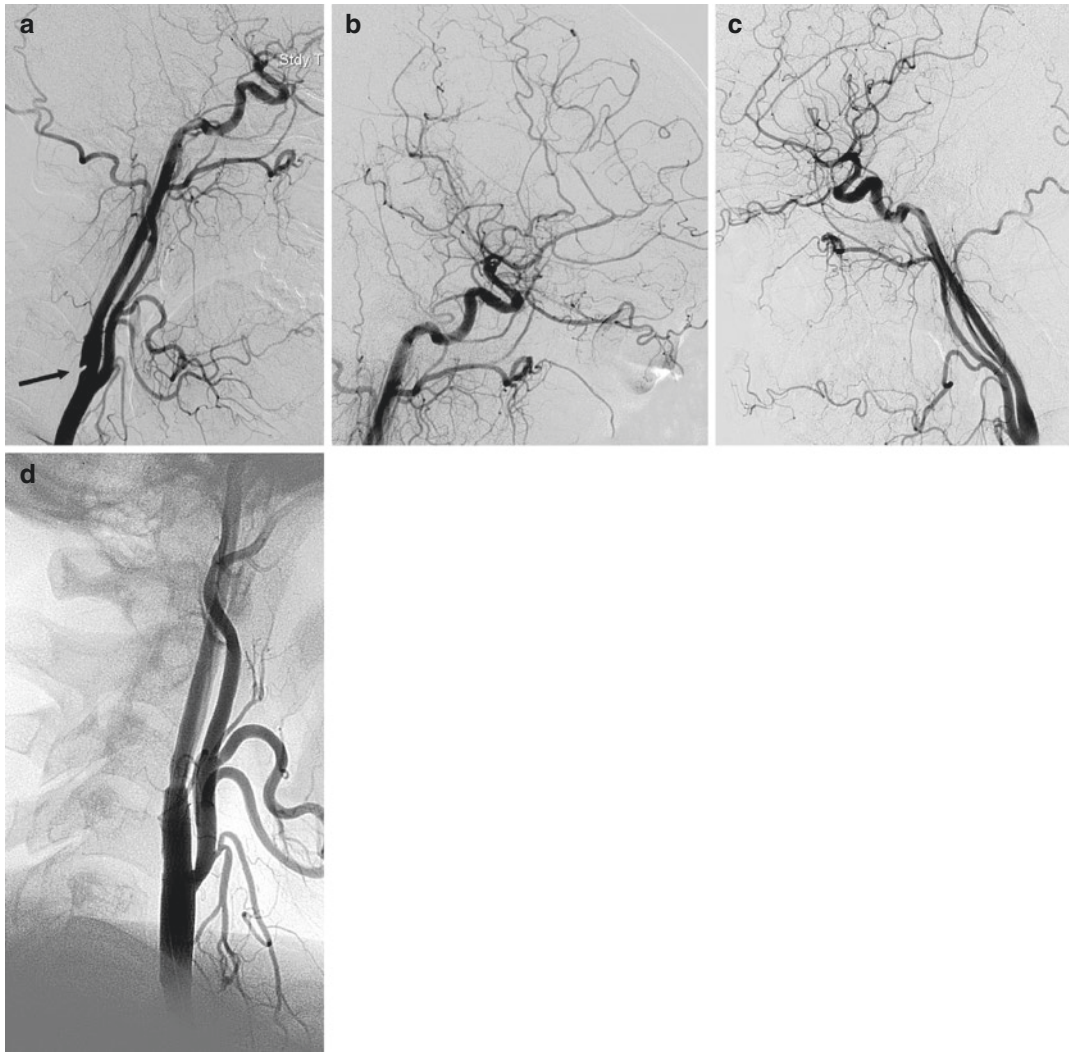

Fig. 17.6 Young man presenting with hypertension and acute left motor deficit. On CT small infarct in the vascular territory of the MCA was shown. A carotid and vertebral angiograms were performed. (**a**) Right carotid angiogram showing atypical defect on the extracranial right ICA, associated (**b**) with occlusion probably embolic of a few branches of the MCA. (**c**) The left carotid angiogram was normal as well as the VA angiogram. The diagnosis of atypical FMD was made. (**d**) Two weeks later after improvement of the deficit the right ICA lesion was treated with stent (courtesy of Prof. Bergui M and Dr. Stura G, Neuroradiology of Turin)

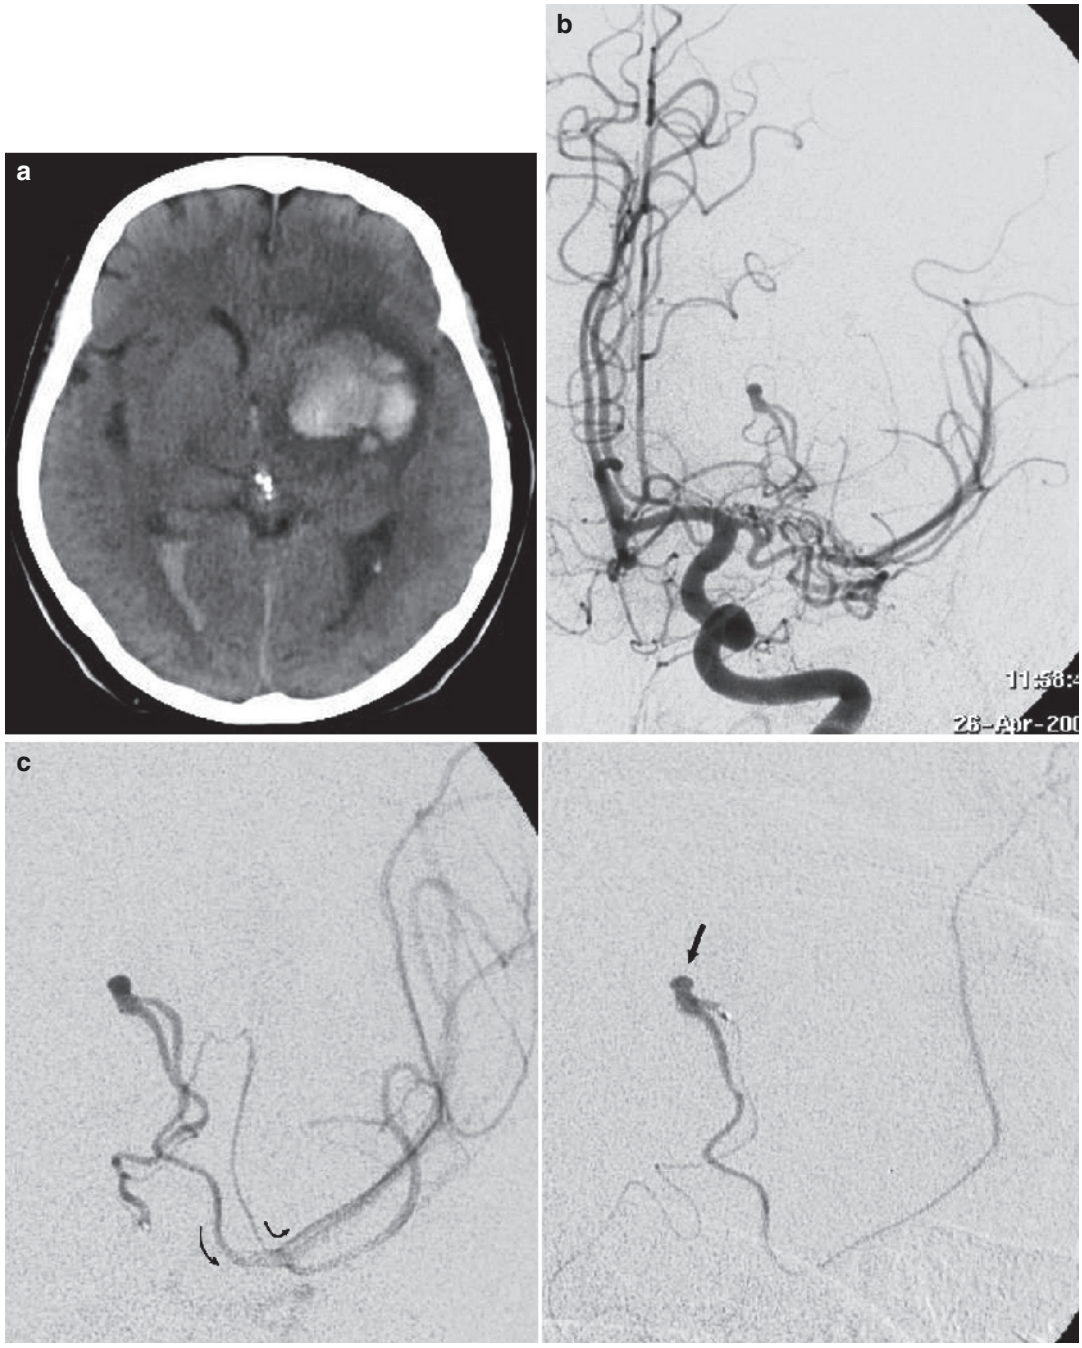

Fig. 17.7 Sixty-year-old woman presenting with sudden hemorrhage in the left basal ganglia. CT (**a**). Left carotid angiogram, AP view (**b**). Several changes are recognizable in the first segment of the middle cerebral artery (MCA). The M1 appears tortuous and very small, continuing to the normal M2 segment. There is also a well-developed network involving perforators with a pattern resembling that in Moyamoya disease. As demonstrated in the selective study (**c**), at least two perforators (*curved arrows*) anastomose to each other, contributing to revascularization of the M2 segments. On one of these perforators, a small aneurysm is recognizable (*arrow*), which was probably responsible for the hemorrhage. This was occluded with glue. Final control angiogram (**d**)

Fig. 17.7 (continued)

17.3 Moyamoya Disease

This is a chronic, progressive cerebrovascular disease, first described in Japanese patients by Takeuchi and Shimizu in 1957. Other Japanese reports followed (Kudo 1968; Nishimoto and Takeuchi 1968). The term Moyamoya, proposed by Suzuki and Takaku (1969), means *vague puff of smoke*. Despite the fact that the disease is more frequent in Japanese patients, later studies showed that it can occur also in non-Asians (Taveras 1969; Galligioni et al. 1971; Picard et al. 1974a, b; Huber 1979; Bradac and Oberson 1983; Masuda et al. 1993). Children and young patients are prevalently involved, but the disease may also be seen in older patients.

17.3.1 Pathology and Etiopathogenesis

Intimal thickening due to proliferation and migration of smooth muscle cells leads to progressive narrowing and final occlusion of the distal intracranial ICA with extension also to the M1 and A1. A rich network of vessels develops, involving perforators of the middle and anterior cerebral arteries as well as of the posterior communicating and anterior and posterior choroidal arteries. The significance of this network is not completely clear. Some authors (Taveras 1969; Crouzet et al. 1974; Picard et al. 1974a, b) have suggested that this is a kind of collateral circulation formed through anastomoses between the deep and superficial vascular territories. This interpretation is little intriguing since deep perforators are commonly thought to be end arteries with no connections neither to one another nor to the medullary arteries. Microangiographic studies, however (Kodama and Suzuki 1974; Umansky et al. 1985) (see also Sect. 15.7.1), have shown that a few anastomoses can be demonstrated between the single deep perforators and between these and the medullary arteries. It is therefore conceivable that in slowly occurring occlusive disease like Moyamoya, anastomoses develop. In Fig. 17.7 is shown a patient with an angiographic study with a pattern resembling a Moyamoya in which these anastomoses could be identified.

Basically, two phases of the disease can be recognized. The first is characterized by a progressive occlusion of the distal ICA and its branches at the circle of Willis with formation of the typical basal network involving the deep perforators. In second phase, the occlusion of the ICA is complete, and a leptomeningeal collateral circulation develops between the distal branches of the cerebral arteries and meningeal and transosseous branches of the external carotid artery and before complete occlusion of the ICA with meningeal branches arising from the ophthalmic artery (Fig. 17.8).

The posterior circulation, at least in the first phases of the disease, is not affected. It is, however, involved in the collateral circulation through the perforators arising from PcomA and P1 and through leptomenigeal anastomoses between PCA and ACA and MCA. Later, the P1 also is occluded, so that only branches of the external carotid artery are responsible for the intracranial circulation in the supratentorial sector.

The etiology of the disease is not known. Moyamoya disease can occur in different pathological conditions: vasculitis with or without an autoimmune mechanism, a postirradiation state, neurofibromatosis, hemoglobinophaties, and atherosclerosis. A genetic predisposition plays probably also an important role.

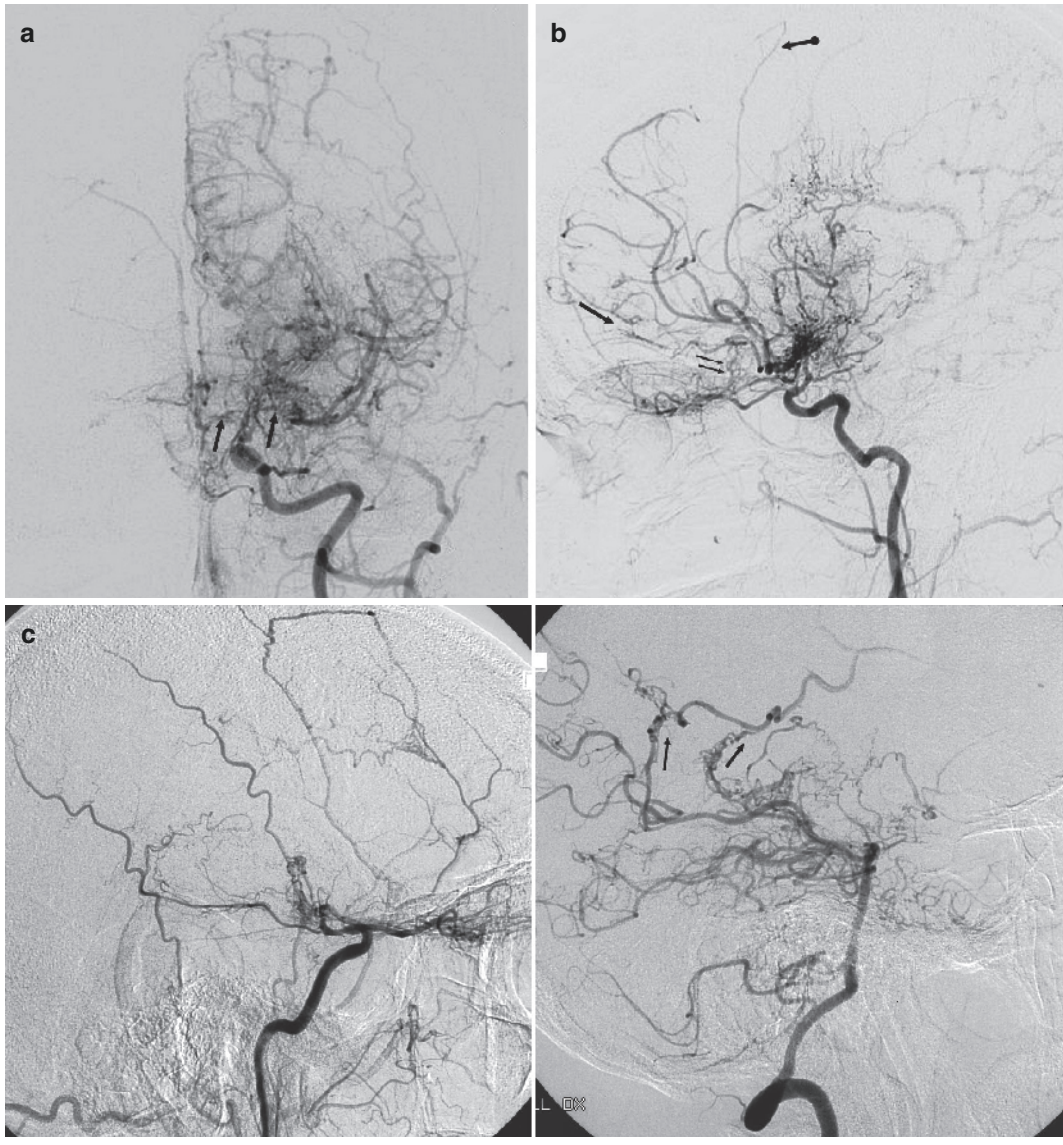

Fig. 17.8 Moyamoya disease in a young patient. (**a**) Common carotid angiogram, AP view. There is an irregular severe stenosis of the proximal M1 and A1 (*arrow*). Rich basal network involving perforators, acting probably as a collateral circulation toward the distal segments of the MCA and anterior cerebral artery (ACA). (**b**) On the lateral angiogram, there is the beginning of collateral flow toward the ACA through opening of an anastomosis from the anterior falx artery (*arrow*) and posterior ethmoidal arteries (*arrows*). There is also an initial collateral flow from the middle meningeal artery (MMA; *arrow with dot*). A partial filling of the distal pericallosal artery through anastomosis with the PCA is present. (**c**) Bilateral Moyamoya disease in another patient. Lateral carotid angiogram. Complete occlusion of the ACA and MCA. Persistence of a minimal basal network. Beginning of a collateral circulation toward the anterior circulation from the left PCA visible on the left carotid angiogram and from the right PCA (*arrow*) visible on the vertebral angiogram. Partial involvement also of the MMA, recognizable on the left carotid angiogram

17.3.2 Diagnosis and Clinical Relevance

Angiography is the essential method for identifying the disease. It has a progressive character, leading to ischemic stroke and hemorrhage. The latter is frequently due to small aneurysms present in the basal network (Figs. 17.7 and 17.8).

17.4 Takayasu's Arteritis

Takayasu's arteritis is a systemic granulomatous vasculitis that affects the aorta and its main branches. The pathological changes are characterized by inflammatory infiltration of the artery wall by lymphocytes, plasma cells, and presence of granulomas composed by giant cells. The pathological changes are similar to those found in giant cells arteritis, but the vessels involved are different and the affected patients in Takayasu's arteritis are younger. Children can also be involved (Al Abrawi et al. 2008).

Retinal ischemia and cerebral infarction are the typical symptoms. Hemorrhage due to a ruptured intracranial aneurysm can occurs. Hypertension due to involvement of the renal arteries and symptoms linked to aorta aneurysm are present. On the angiogram, occlusion or stenosis of the common carotid artery and vertebral artery at its origin are typical findings. A rich collateral circulation involving especially the ECA develop. An example is presented in Fig. 17.9.

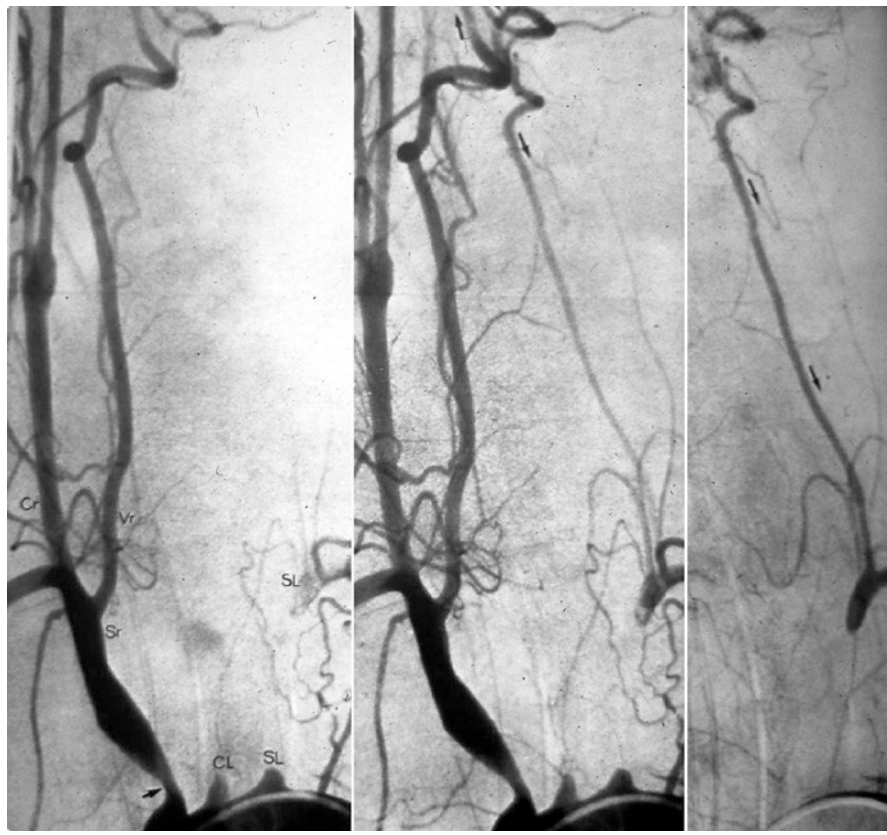

Fig. 17.9 Aortic arch angiogram in a patient with Takayasu's arteritis. Occlusion of the left subclavian (SL) and left common carotid artery (CL). Severe stenosis of the brachiocephalic trunk. In the late phases, retrograde injection of the left vertebral and left subclavian artery (*arrows*) from the right vertebrobasilar artery (subclavian steal syndrome)

17.5 Sneddon's Syndrome

This syndrome is characterized by pathological changes involving the cerebral vessels in patients by *Livedo reticularis* (Sneddon 1965). This is a cutaneous pathology characterized by a bluish reticulated aspect of the skin as a result of impaired superficial venous drainage. The pathogenesis is unknown. In some of these patients antiphospholipid antibodies have been demonstrated. The cerebral angiogram of these patients shows occlusions of the distal branches of the cerebral vessels, with a formation close to the occlusions of a typical network of capillaries and venules (Fig. 17.10). The clinical symptoms are characterized by several stroke which can lead in some patients to a progressive dementia.

Fig. 17.10 Lateral carotid angiogram in a patient with Sneddon's syndrome. Several areas with the typical capillary network associated with vessel occlusion are evident

17.6 Reversible Cerebral Vasoconstriction Syndrome (RCVS)

This is a very rare pathological condition characterized by a sudden onset of extreme intense headache, sometimes with agitation and confusion. CT can show a minimal SAH on the convexity of the cerebral hemispheres. More rarely infarct or intracerebral hemorrhage occur. On the angiogram, segmental narrowings of medium-sized arteries are visible. This angiographic finding is not different from that presented in vasculitis and spasm in cases of SAH. The syndrome is commonly benign, and all symptoms as well as the morphologic changes of the vessels disappear within weeks. It was described first in women during pregnancy and in the postpartum (Fisher 1971; Rascol et al. 1979). Later, it became evident that it can occur in several other conditions, among them in association with a sympathomimetic therapy using drugs such as ergot derivate or following use of drugs such as cocaine and amphetamine or also triggered by factors such as sexual and physical activity (Calabrese et al. 2007; Singhal et al. 2009). The diagnosis can present some difficulties. It is important to exclude a SAH due to a ruptured aneurysm. In this context it is useful to remember that some dissecting aneurysm in the anterior circulation can present with a pattern of minimal SHA involving the cerebral convexity similar to that visible in cases of RCVS (Kumar et al. 2010; Obusez et al. 2014; Fukuma et al. 2015) (see also intracranial dissection in Chap. 16). The absence of inflammation signs in labor examinations will help in the differential diagnosis with angiitis. Cases of amyloid angiopathy with bleeding localized on the cortical region have been also reported (Apoil et al. 2013). These

patients are older in comparison to those with RCVS. In the differential diagnosis also cerebral venous thrombosis should be considered. Indeed, as reported by some authors (Boukobza et al. 2016) thrombosis of cortical veins, alone or associated with sinus thrombosis, can present with cortical SAH. An example of RCVS is presented in Fig. 17.11.

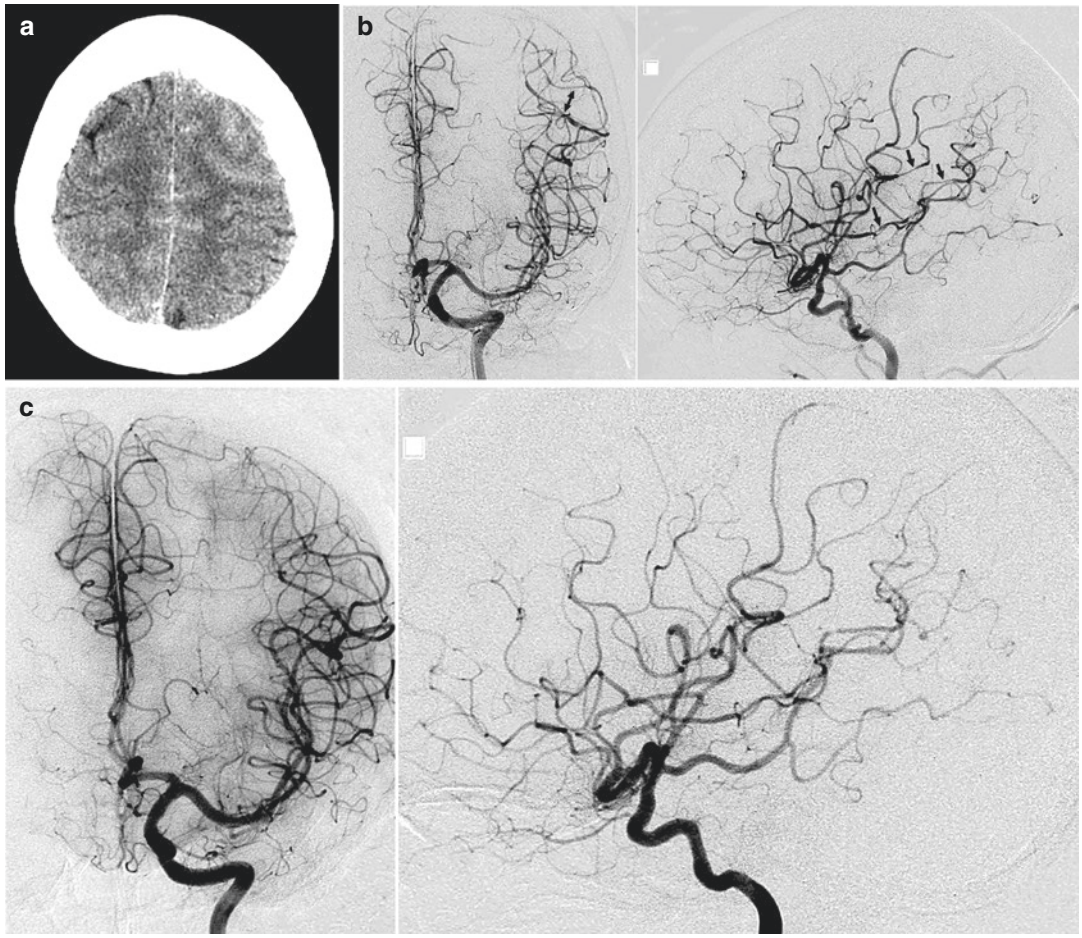

Fig. 17.11 (RCVS) Middle-aged woman with acute onset of severe headache followed by intense physical activity. (**a**) CT showed diffuse mild SAH. (**b**) left ICA angiogram AP and Lateral view. Irregularity and narrowing of several MCA branches are visible (*bidirectional* and *simple arrows*). Similar changes were visible on the contralateral ICA angiogram. The VA angiogram was normal. No vascular malformations were detected. The patient recovery completely and the control angiograms (**c**) two months later showed clear improvement of the morphological changes of the arteries

17.7 Primary Angiitis of the CNS (PACNS)

This is a rare angiitis involving selectively the cerebral arteries, which is increasingly recognized and diagnosed (Calabrese and Mallek 1988; Salvarani et al. 2007; Birnbaum and Hellmann 2009; Hajj-Ali and Calabrese 2009; Magnus et al. 2012; Taschner et al. 2013). No other arteries outside of the CNS are affected. All ages are involved including children and old patients. The disease can present with acute headache disorientation, and coma followed by death, or can have a slower indolent course with episodes of stroke, seizures, and multifocal neurological symptoms. The pathologic aspects are commonly that of a granulomatous infiltration of small, sometimes medium-sized arteries. Labor examinations show signs of inflammation. Small ischemic lesions, sometimes hemorrhages, in the vascular territories of deep perforators and medullary arteries are recognizable on MR images. Large infarcts are rare.

Useful for the diagnosis are T1-weighted images with contrast medium showing enhancement in the wall of the arteries suggesting inflammation (Küker 2007; Küker et al. 2008). As reported by some authors (Mineyko et al. 2013) the latter finding should be considered with caution since it can be observed also in normal conditions. Angiography is frequently normal. Pathological changes of the vessels can be identified when medium-sized arteries are involved (Fig. 17.3).

17.8 Autosomal Dominant Arteriopathy with Subcortical Infarct and Leukoencephalopathy (CADASIL)

The term CADASIL for this pathological condition has been proposed by Baudrimont et al. (1993). This is a rare inherited small vessel arteriopathy affecting 20/30-year-old patients. The disease is due to mutation of the NOTCH 3 gene on chromosome 19 (Joutel et al. 1996; Chabriat et al. 1996). Clinically the disease presents with migraine attacks and strokes leading progressively to cognitive deficit and dementia. On MR T2-weighted images, areas of hyperintensity are recognizable in the territories of deep perforators and medullary arteries, indicating ischemia. This finding is not different of that occurring in patients with severe small vessel disease due to arteriosclerosis (Sect. 15.4.5). However, differently from these, in CADASIL the lesions extend frequently and typically to the external capsule, to the anterior white matter of the temporal lobe, and sometimes to the corpus callosum (Chabriat et al. 2000; Van Den Boom et al. 2002) (Fig. 17.12). Angiography is normal.

Studies with the electron microscopy have shown the presence of granular osmiophilic material in the media of the arteries, where the muscles cells appear swollen and degenerated.

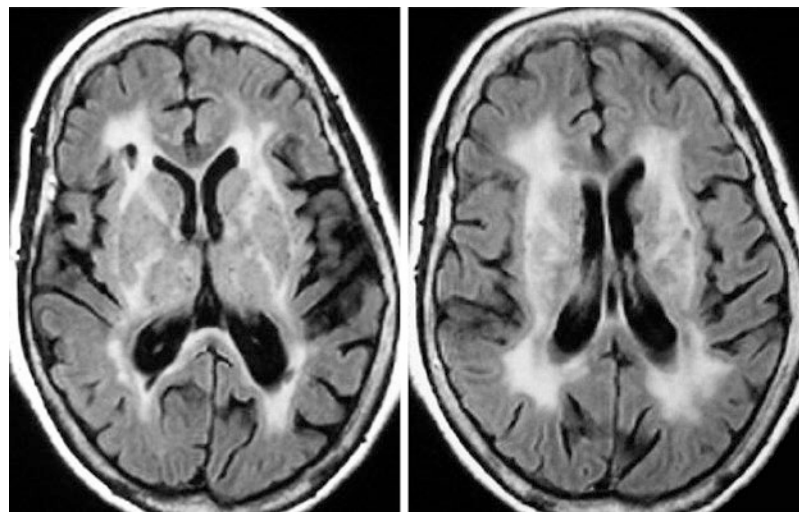

Fig. 17.12 40-year-old patient with episodes of stroke and progressive cognitive deficit. MR T2-Flair sequences. Diffuse changes involving the white matter and basal ganglia. The external capsule is also affected. The diagnosis of CADASIL was confirmed by biopsy and genetic studies

These changes can be associated with hyalinosis and fibrosis (Gutierrez et al. 1994; Zhang et al. 1994; Dong et al. 2012), leading progressively to occlusion of the arteries.

An interesting observation has been made by Ruchoux et al. (1994, 1995). These authors demonstrated that the changes present in the cerebral vessels could also be demonstrated in other organs, including spleen, liver, kidneys, muscles, and skin. Other authors (Schroder et al. 1995) identified the same pathological changes in the sural nerve. These studies showed the systemic character of the disease, allowing a more easy diagnosis with biopsy.

Similar diseases with, however, some different genetic and clinical features have also been described by other authors (Fukutake and Hirayama 1995).

17.9 Migraine and Stroke

Stroke occurring in migraine has been described in the past. MR studies in patients with migraine have shown the presence of microlesion in the white matter. However, it is not clear whether these are due to a previous infarcts or are simple micro-areas of gliosis due to other causes. Furthermore, various vascular disorders are present being responsible for the stroke in many migrainous patients: dissection, dysfunction of the venous drainage, Cadasil and the coexistence of other factors such as the use of oral contraceptives, cigarettes, and various other drugs (Diener and Kurth 2011). Today, there are many doubts whether migraine can lead to a stroke. Which are the possible intervening factors or possible mechanisms remains open to question and should be clarified with further studies.

Cardiac Diseases

18

There are many cardiac diseases responsible for cerebral ischemia, which is frequently the result of emboli in patients with cardiac dysrhythmia, myocardial infarction, atrial septal aneurysm, cardiac valves diseases, prosthetic valves, endocarditis of various origin, and congenital heart diseases. Paradoxical embolism through a *patent foramen ovale (PFO)* has become also a frequent explanation for embolism. It should, however, be remarked that the role played by the PFO in stroke remains a little controversial. Indeed, it should be considered that it can be detected in the general population with a frequency up to 25% (Lechat et al. 1988) and some authors have found no clear relationship between PFO and stroke (Kutty et al. 2009, 2012). Others have linked the possibility of stroke in cases of large PFO (Schuchlenz et al. 2000).

Cardiac abnormalities responsible for embolization have been identified in systemic lupus erythematosus and in primary antiphospholipid antibody syndrome. Another rare pathology is *myxoma*. This is a tumor that commonly originates in the left atrium in young to middle-aged patients. The emboli consist of myxomatous tissue that leads to parenchymal tumoral localization and vascular changes characterized by occlusion and aneurysmal dilatation (New et al. 1970; Roeltgen et al. 1981) (Fig. 18.1).

The commonest site of cardiac emboli is the anterior circulation, especially in the distal internal carotid artery and in the middle cerebral artery territory. The posterior circulation is less involved with a typical location being that of the top of the basilar artery (see Chap. 15). In this context it should be noticed, that the distribution of the emboli can be influenced by the presence of anomalies in the origin of the arteries from aortic arch, anomalies of the circle of Willis and persistence of embryonic arteries.

The incidence of cardio-embolism is reported to be 15–20% of all strokes (see also Chap. 15). It is frequent in young adults (Barnett 1974; Barnett et al. 1980; Bogousslavsky et al. 1988a; Kittner et al. 1991; Broderick et al. 1992). In case of small emboli, spontaneous thrombolysis and rapid recanalization can occur, so the angiography performed later appears normal. In other cases, occlusion is visible and a cardiogenic brain embolism can be clearly suspected when there is a *specific cardiac pathology, no atherosclerotic changes or other pathologies of carotid or vertebral arteries are present*, *more than one vascular territory,* is involved, or the stroke has occurred in *patients younger than 45 years of age*, where atherosclerotic changes of the extra-intracranial arteries are less frequent than in the elderly. In some cases the cardiac embolism can be only suspected, but not

G.B. Bradac, *Applied Cerebral Angiography*, DOI 10.1007/978-3-319-57228-4_18

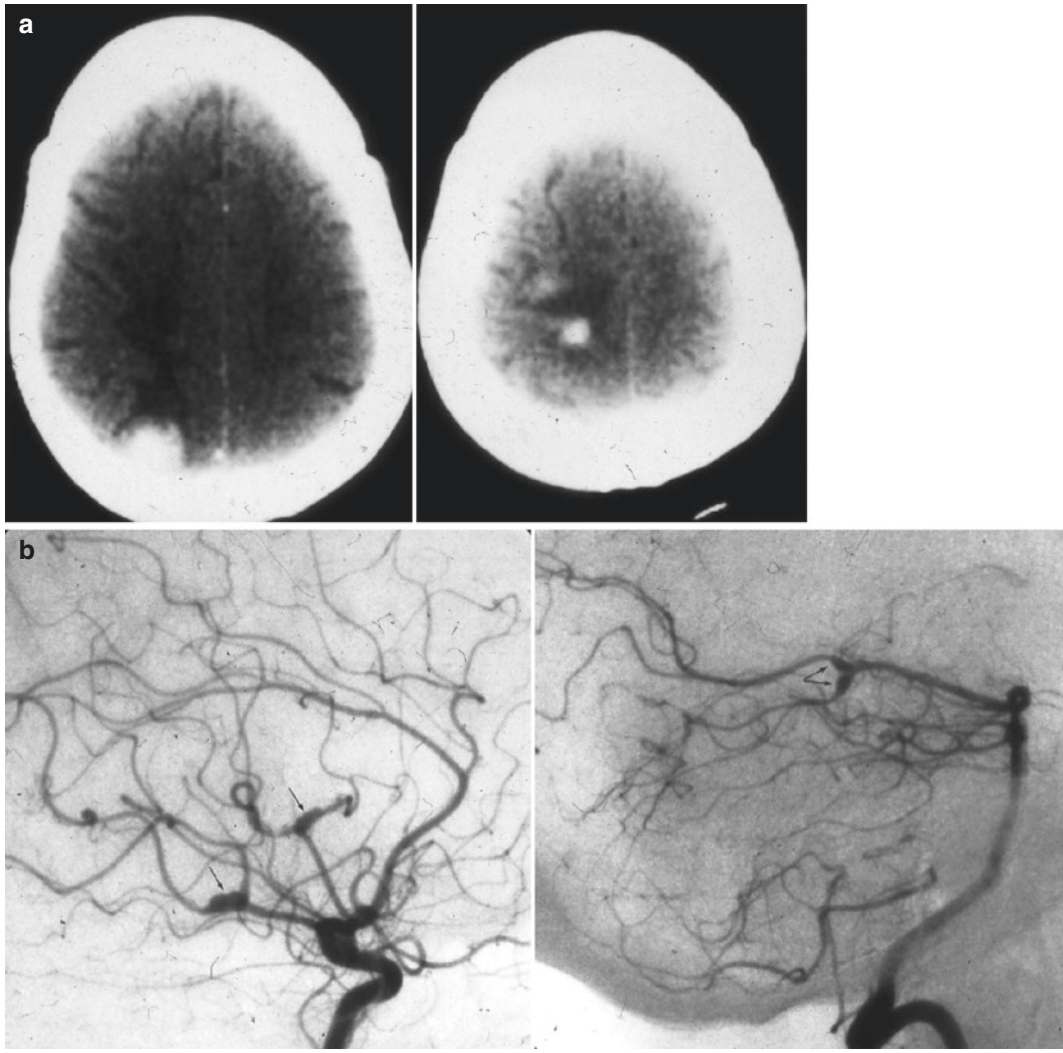

Fig. 18.1 Cerebral embolization in a patient with cardiac myxoma. (**a**) CT showing parenchymal localization of tumor emboli. (**b**) Carotid and vertebral angiogram disclosing aneurysmal dilatation due to tumoral infiltration of the vessel wall (*arrows*)

confirmed. In other cases, it can be difficult to establish whether the stroke has a cardiogenic origin or it is due to atherosclerotic changes of the extra-intracranial arteries when both pathologies are present in the given patient. (In addition to Figs.18.1, 18.2, 18.3, 18.4, and 18.5 see also Sects. 15.4.1, 15.4.2, 15.5.2, 15.5.3, 15.5.4, and 15.5.5).

Cerebral infarcts due to cardiac embolism are commonly superficial. However, even if they are more rare, small lacunar infarcts in the deep structures can occur. These are thought to be due to microemboli especially in patients with atrial fibrillation and they are diagnosed progressively more often in the elderly considering that this cardiac pathology increases with the age (Kempster et al. 1988; Arboix et al. 2000) (See also Sects. 15.4.5 and 15.5.4).

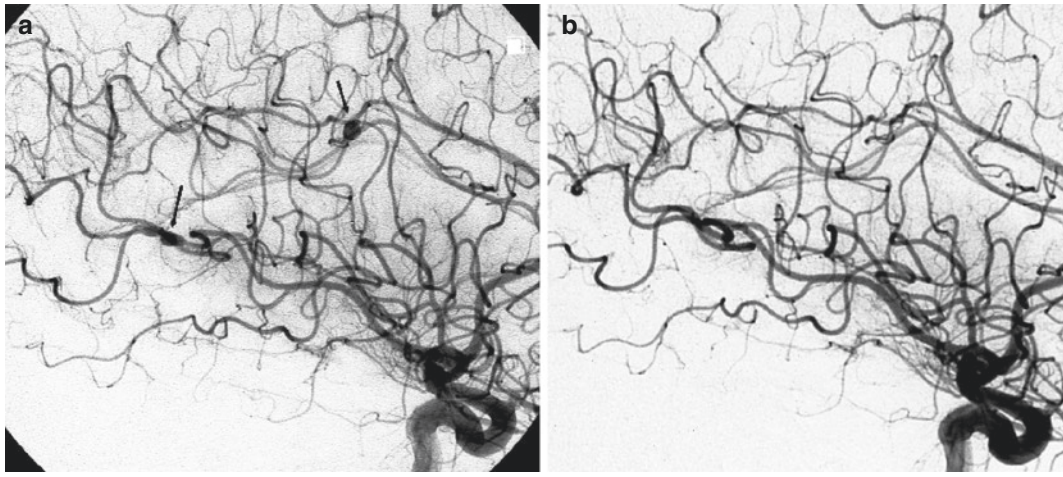

Fig. 18.2 Mycotic aneurysm in a patient with bacterial endocarditis. (**a**) Lateral carotid angiogram showing the aneurysm involving branches of the MCA and ACA (*arrows*). (**b**) Control angiogram 2 months later after intensive antibiotic therapy, showing the disappearance of the aneurysms

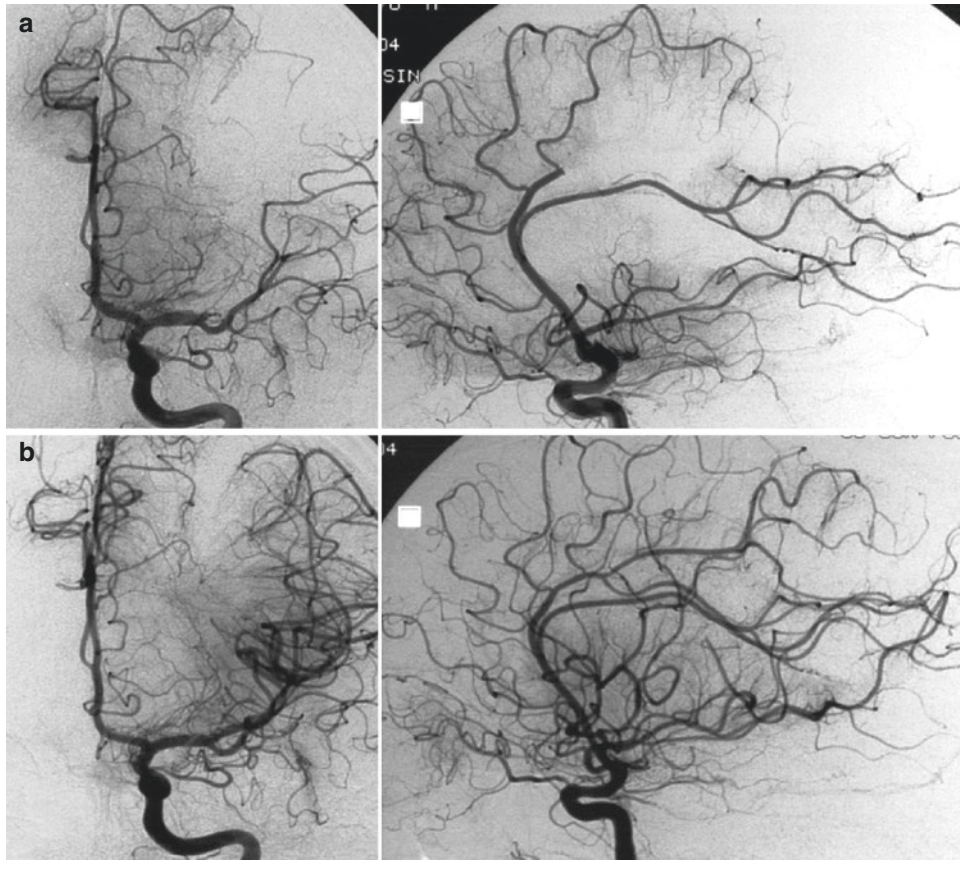

Fig. 18.3 Acute multiple occlusions involving branches of the MCA and ACA in a middle-aged woman presenting with right hemiplegia and partial aphasia. (**a**) Left carotid angiogram. AP and lateral views showing the occlusions. (**b**) Selective pharmacological thrombolysis, with a quick reopening of the occlusions. There was a rapid clinical improvement. A cardiac pathology was suspected. However, no cardiac disease was found

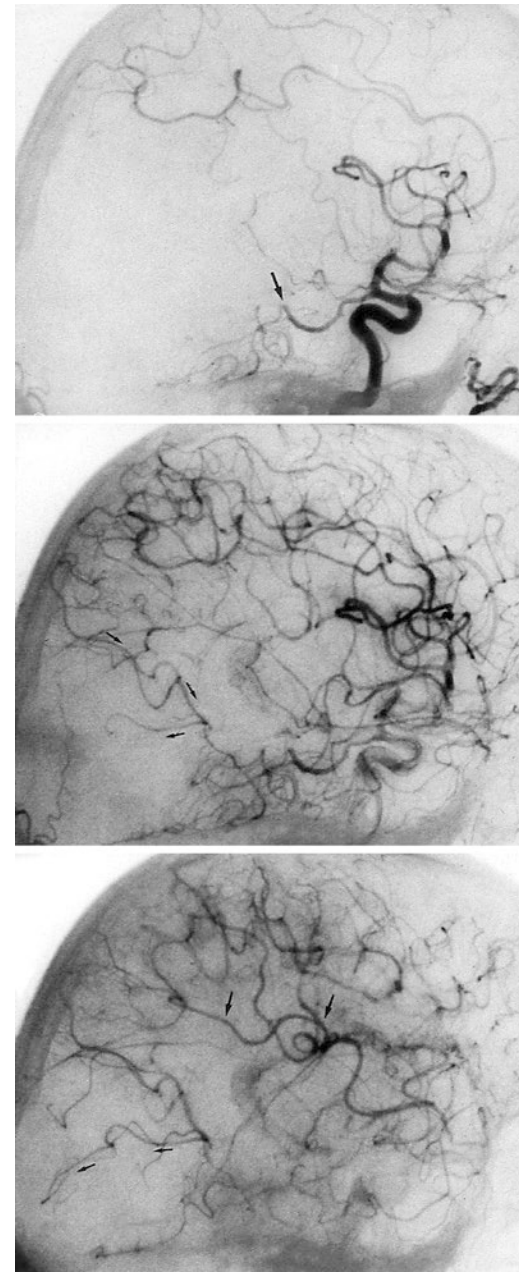

Fig. 18.4 Cardiac embolization in an old patient involving several branches of the MCA and fetal PCA (*arrow*). Partial retrograde filling of the occluded branches (*arrows*) through opening of anastomoses with the ACA. Compare this figure with Figs. 15.15 and 15.16

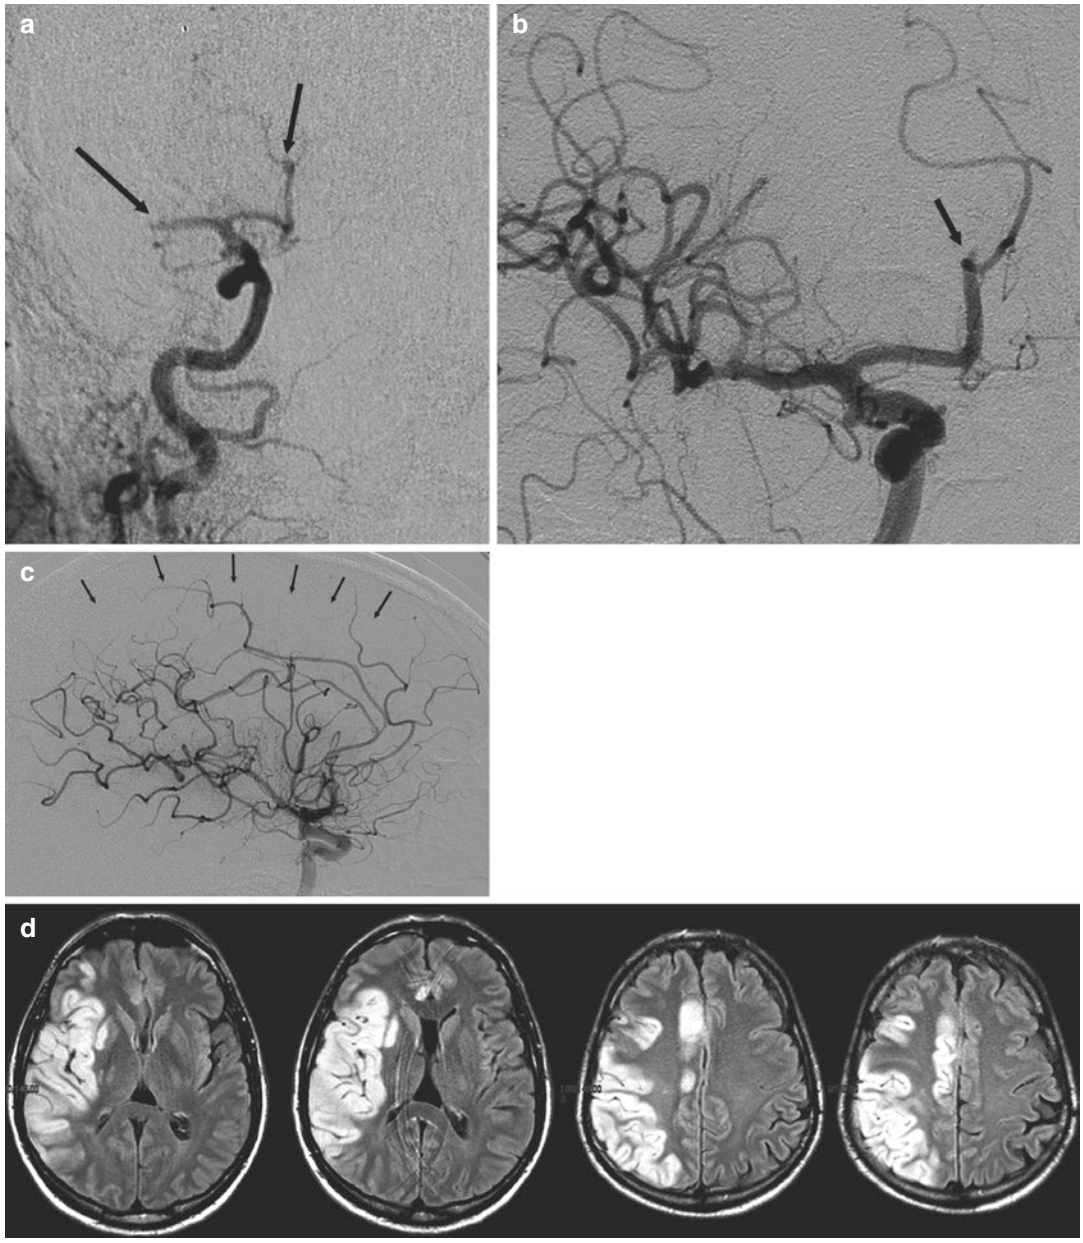

Fig. 18.5 Acute occlusion, probably cardioembolic, of proximal right MCA and more distal ACA in a middle-aged patient. (**a**) Angiogram of the right carotid artery showing the occlusions (*arrows*). (**b**) Rapid recanalization with mechanical thrombolysis (solitaire) of the M1 with apparently good filling of the distal branches of MCA. An attempt to open the occlusion of the distal pericallosal artery (*arrow*) was also performed. (**c**) final lateral carotid angiogram showing persistent occlusion of a few distal branches of ACA and MCA (*arrowheads*). (**d**) CT performed 24 h later showed ischemic lesions, which were better defined with MR 4 days later. The ischemia involved largely the distal vascular territory of the MCA, with partial involvement of the basal ganglia (pallidum). There was ischemia in the distal territory of the ACA. The extensive ischemia in spite of the rapid proximal reopening of the occluded arteries can be explained by impairment of the leptomeningeal collateral circulation due to many factors, among them a distal embolization and the unfavorable contemporaneous occlusion of the MCA and ACA (see also text 15.8). The left hemiplegic patient recovered slowly. After intensive physiotherapy he was able to walk with some difficulties 6 months later

Arterial Occlusive Diseases in Children

19

Ischemia in children deserves some specific considerations. It is not as rare as it is commonly thought (Barnes et al. 2004; Amlie-Lefond et al. 2008, 2009) with a frequency reported to be 2–6/100,000 children per year. Unlike in adults, it is rarely linked to factors related to atherosclerosis. Instead, it is associated with a variety of pathological processes, including cardiac diseases and other non-atherosclerotic arteriopathies which are listed in Table 17.1 (Chap. 17). In some cases, a precise etiology can be identified; in many others, however, it may only be suspected or remain unknown (Barnes et al. 2004; Jones et al. 2010).

Among the most frequent causes are infections, especially of the upper respiratory tract. Arteritis due to a previous varicella zoster infection can occur (Sebire et al. 1999; Barnes et al. 2004; Lauthier et al. 2005; Miravet et al. 2007; Jones et al. 2010).

Primary cerebral angiitis (PACNS) has been emphasized by some authors (Elbers and Benseler 2008; Hajj-Ali and Calabrese 2009) (see also Sect. 17.7). An example is presented in Fig. 17.3.

Stroke occurs frequently in sickle cell disease (Jones et al. 2010). This is due to the altered red blood cells causing an endothelia damage leading to an intimal hyperplasia and a progressive narrowing of the lumen of the artery. Among the intracranial vessels, the supraclinoid internal carotid artery is the most frequently involved. Furthermore, MR studies (Pegelow et al. 2002; Stem et al. 2003) in children with sickle cell disease have shown with a high frequency asymptomatic microischemic lesions in the white matter of the cerebral hemispheres indicating an involvement also of the superficial perforators.

Many pathological conditions altering the blood coagulation (see Table 17.1) can be the cause of stroke in adults. The same can occur, even if more rarely, in childhood. In the study of Barnes and Deveber (2006), prothrombotic abnormalities (elevated lipoprotein, protein C deficiency, factor V Leiden mutation, antiphospholipid antibodies) were identified in 25–50% of children presenting with stroke.

Another pathology which can be associated with occlusion of the cerebral vessels is the neurofibromatosis type 1. The pathogenesis is unclear. It has been suggested that the loss of the neurofibromin, a special protein, would favor the proliferation of the smooth muscle cells leading to occlusion of the artery (Rea et al. 2009). Since it can be asymptomatic, at least in the first phases of the pathological process, it can escape the diagnosis. Rea et al. (2009) recommend in all these patients to perform MR angiography to study the cerebral vessels. An example is presented in Fig. 17.2.

Moyamoya disease is another pathology of the cerebral vessels involving frequently children (see Sect. 17.3).

Among other pathologies, spontaneous dissection is another increasingly recognized cause of stroke in children (Schievink et al. 1994a;

G.B. Bradac, *Applied Cerebral Angiography*, DOI 10.1007/978-3-319-57228-4_19

Fullerton et al. 2001; Rafay et al. 2006) (see Sect. 16.7 for dissection in children).

As far as it concerns the diagnosis, in addition to the CT/MR examination for the identification of the ischemia, CT/MR angiography can be frequently sufficient to show the lesions of the vessels in the form of occlusion, stenosis, or in some case of dissection also the presence of pseudoaneurysm. For a more detailed diagnosis, angiography remains the examination of choice.

Cerebral Venous Thrombosis 20

A venous thrombosis involving the SSS linked to an infectious disease has been described, in an autoptic study, about 200 years ago in 1825 by Ribes. Since then, a progressive improvement in diagnostic methods, in particular angiography (Huhn 1957, 1962; Krayenbühl 1961, 1967; Vines and Davis 1971) and later CT, MRI, and MR angiography, has made it possible to better identify this pathology. The true incidence of cerebral venous thrombosis (CVT), however, remains unknown, even if there is no doubt that it is more frequent than had previously been thought (Krayenbühl 1967; Bousser et al. 1985; Ameri and Bousser 1992; Einhäupl and Masuhr 1994; Bousser and Russell 1997; Linn and Brueckmann 2010).

20.1 Etiopathogenesis

A frequent cause is infection, either due to intracranial extension of infectious diseases involving the skin or bone cavities of the craniofacial area or in cases of general bacterial septicemia or viral infection, especially due to HIV and cytomegalovirus (CMV). In young women, CVT can occur during pregnancy, in puerperium, and due to use of oral contraceptives. Other causes are pathologies of the red blood cells, such as thrombophilia, polycythemia, sickle cell disease, leukemia, and lymphoma and many coagulation disorders, such as protein C and S deficiency and disseminated intravascular coagulation. CVT is also frequent in patients with Behçet's disease, systemic lupus erythematosus, and in patients with severe dehydration and cardiac failure. Another rare cause, described by a few authors (Savoiardo et al. 2006; Katoaka et al. 2007; Richard et al. 2007; Bousser and Ferro 2007; Schievink and Maya 2008; Yoon et al. 2011; Qin et al. 2012), is that occurring in patients with spontaneous intracranial hypotension. It has been suggested that, in these patients, the fall of volume and pressure of cerebrospinal fluid (CSF) is compensated by a dilatation of the sinuses commonly the SSS or the TS which reduces the flow velocity of the blood in the sinuses. This, associated with a decreased absorption of CSF in the sinuses due to the loss of CSF, results in an increased blood viscosity, favoring the thrombosis. Other causes of CVT are cranial trauma and neurosurgical intervention. Finally, intracranial tumors, specially meningiomas, can involve the adjacent sinus and cause thrombosis. As far as it concerns sinus thrombosis in patients with DAVfs, see Chap. 13.

It should be taken into consideration that in many cases—up to 35%—the cause remains unknown (Milandre et al. 1988; Ameri and Bousser 1992; Cantu and Barinagarrementeria 1993; Einhäupl and Masuhr 1994).

20.2 Location

The superior sagittal sinus (SSS) is the venous channel most commonly involved, followed by the transverse sinus. Both are frequently affected together (Ameri and Bousser 1992; Cantu and

G.B. Bradac, *Applied Cerebral Angiography*, DOI 10.1007/978-3-319-57228-4_20

Barinagarrementeria 1993; Tsai et al. 1995; Linn and Brükmann 2010). The thrombosis can be limited to the sinus and the clinical presentation may frequently be characterized by symptoms owing to the intracranial hypertension, such as headache and visual disturbances. Cortical vein tributaries of the thrombosed sinus can be secondarily involved as a result of retrograde propagation of the thrombus, leading to ischemia. Many anastomoses are present in the venous system which can act as a venous collateral circulation, in case of isolated sinus thrombosis. This collateral, however, can be impaired in cases of thrombosis of the sinuses involving also of the cerebral veins (Bergui et al. 1999; Bradac and Bergui 2001).

Isolated cortical veins thrombosis may also occur. This has been thought to be very rare (Ameri and Bousser 1992; Einhäupl and Masuhr 1994). Through improvement in MRI technique and progressive awareness of this pathology, cases have been increasingly reported (Sagduyu et al. 2006; Boukobza et al. 2009; Albayram et al. 2009; Linn and Brükmann 2010).

Thrombosis of the deep venous system, involving the straight sinus and the vein of Galen, with retrograde extension to the internal cerebral and basal veins, is another usually severe condition that is, fortunately, less common. In these situations, transcerebral anastomoses via connections between the superficial and deep medullary veins as described in Sect. 9.1.2.1 can act as an important collateral circulation (Bergui et al. 1999; Bradac and Bergui 2001). Another important aspect which can play a role in the location of the ischemia are the variations of the drainage of the SSS and SS as described in Sects. 9.3.1, 9.3.3, and 9.3.5.

Cavernous sinus thrombosis is another frequent localization leading to a typical cavernous sinus syndrome. The lesion can extend to the superior-inferior petrosal sinuses. Involvement of the intracavernous internal carotid artery due to arteritis, especially in the infectious form of thrombosis can lead to stenosis/occlusion of the artery (Segall et al. 1982). Indeed the cavernous sinus thrombosis is commonly due to infectious processes involving the skin of the facial area, nose, paranasal sinuses, orbita, teeth, and middle ear.

20.3 Diagnosis

CT and MRI allow the detection of changes to the brain parenchyma in the form of hemorrhagic and/or nonhemorrhagic infarcts, uni- or bilateral, single or multiple, with various locations depending on the site and extension of the thrombosis. Hemorrhagic ischemia can be easily diagnosed on CT studies, presenting as hyperdense area. White matter hypodensity on CT and hyperintensity on T2-weighted images on MR, which indicate edema preceding the venous infarct, is also a finding which can suggest venous thrombosis.

On CT, an abnormal hyperdensity can be recognized at the level of the torcular herophili, SSS and TS. This is difficult to differentiate in the majority of cases from the normally slight hyperdensity of these structures. Though it is not always present, a more reliable indicator is the so-called empty sign, which is visible after contrast injection, and it is due to opacification of the sinus wall contrasting with the low density of the thrombus in the lumen (Buonanno et al. 1978; Kingsley et al. 1978). MRI can be a very useful alternative method (Bousser and Ferro 2007). In the acute phase, it shows the hypointensity and isointensity of the thrombus in the involved sinus and occasionally in the cortical or deep veins, respectively, on T2- and T1-weighted images. After 3–7 days, the clot becomes progressively hyperintense on both T1 and T2 sequences. In this context, the high diagnostic value of the T2*-weighted gradient echo in identifying also isolated cortical vein thrombosis has been emphasized by many authors. On these sequences the thrombotic vessel is characterized by hypointensity which is already present in the acute phase and persist for several months differently from the changes of signal of T1 and T2 images (Fellner et al. 2005; Urban and Müller-Forrell 2005; Boukobza et al. 2009; Linn and Brükmann 2010).

Finally, in cases of suspected venous thrombosis, MRI angiography should be performed. In doubtful cases or whenever a more specific diagnosis is required, conventional angiography remains the essential diagnostic method. A rapid and precise diagnosis is important since anticoagulant therapy can improve the prognosis in many of these patients (Villringer et al. 1994; Einhäupl et al. 2006).

As far as the differential diagnosis with arachnoid granulations and brain herniations protruding in the sinuses see Sect. 9.3.

Examples of venous thrombosis are shown in Figs. 20.1, 20.2, 20.3, 20.4, and 20.5.

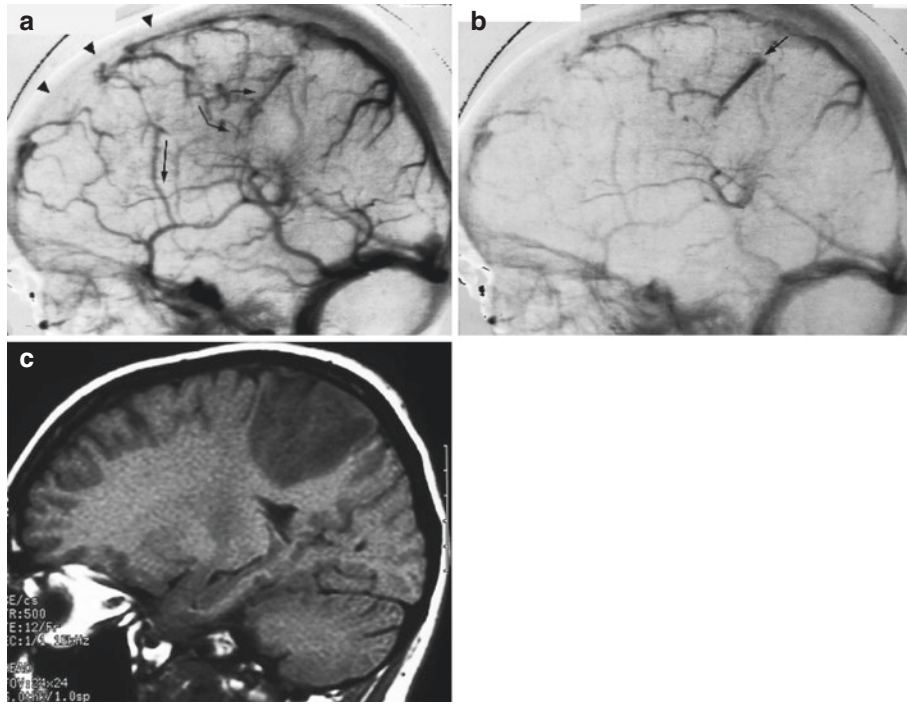

Fig. 20.1 Thrombosis of the anterior and middle segments of the superior sagittal sinus (SSS). (**a**) Carotid angiogram, lateral view, venous phase. Occlusion of the SSS (*arrowheads*). Rerouting of the venous drainage through cortical veins toward the parietal and temporal area (*arrows*). Later phase (**b**). Distal occlusion of the cortical veins (*arrow*) probably explaining the parietal ischemia, visible on MRI (**c**)

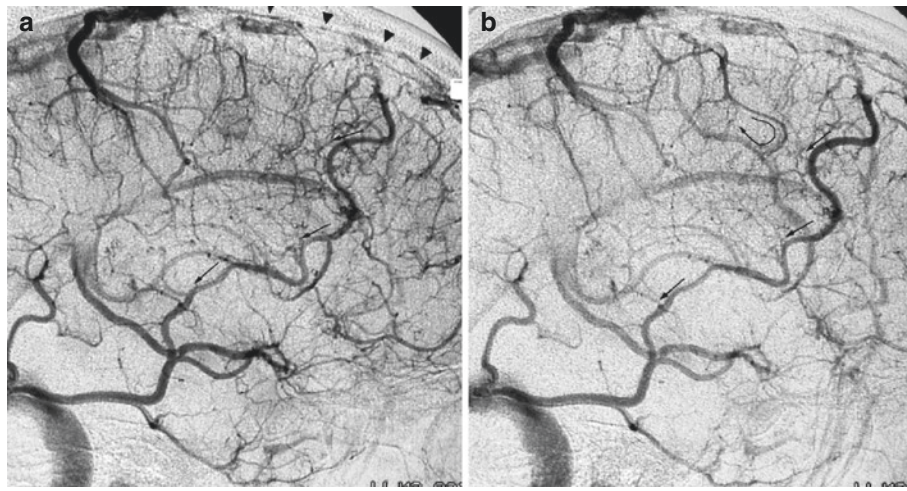

Fig. 20.2 ICA angiogram, lateral view, venous phase. (**a**) Thrombosis of the anterior and middle segments of the SSS (*arrowheads*) involving also the distal segment of the draining cortical veins. (**b**) Later phase. Rerouting of the venous drainage through a large vein of Trolard into the vein of Labbé (*arrows*), partial reorganized venous drainage in the parietal area (*curved arrow*) toward the patent segment of the SSS

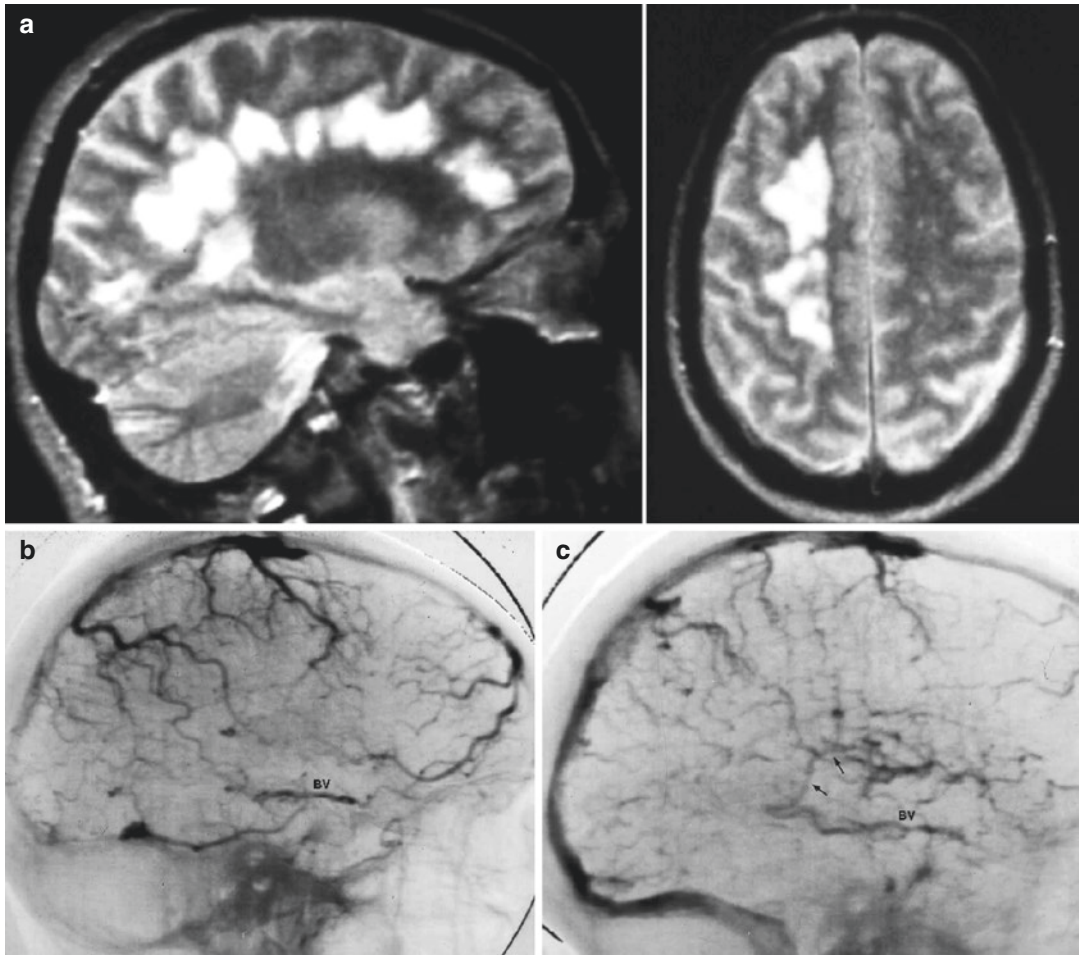

Fig. 20.3 Venous thrombosis involving the deep venous system. (**a**) MRI, sagittal and axial views, T2-weighted images showing changes corresponding to venous ischemia involving predominantly the white matter of the right hemisphere. (**b**) Right and (**c**) left carotid angiograms, venous phase. The vein of Galen and straight sinus are not injected. On the right, only the proximal part of the basal vein (BV) is recognizable, filled through its anterior tributaries. On the left, in addition to the basal vein reaching the proximal part of the vein of Galen, there is filling of the internal cerebral vein (*arrows*). It is conceivable that a collateral circulation involving the subependymal and medullary veins toward the cortical veins has developed, explaining the absence of ischemia in the left hemisphere

Catheterization of TS and/or SSS followed by injection of thrombolytic agents has been proposed in those cases in which the anticoagulant therapy fails to improve the clinical condition of the patient (Hocker et al. 2008; Sujith et al. 2008; Gala et al. 2013).

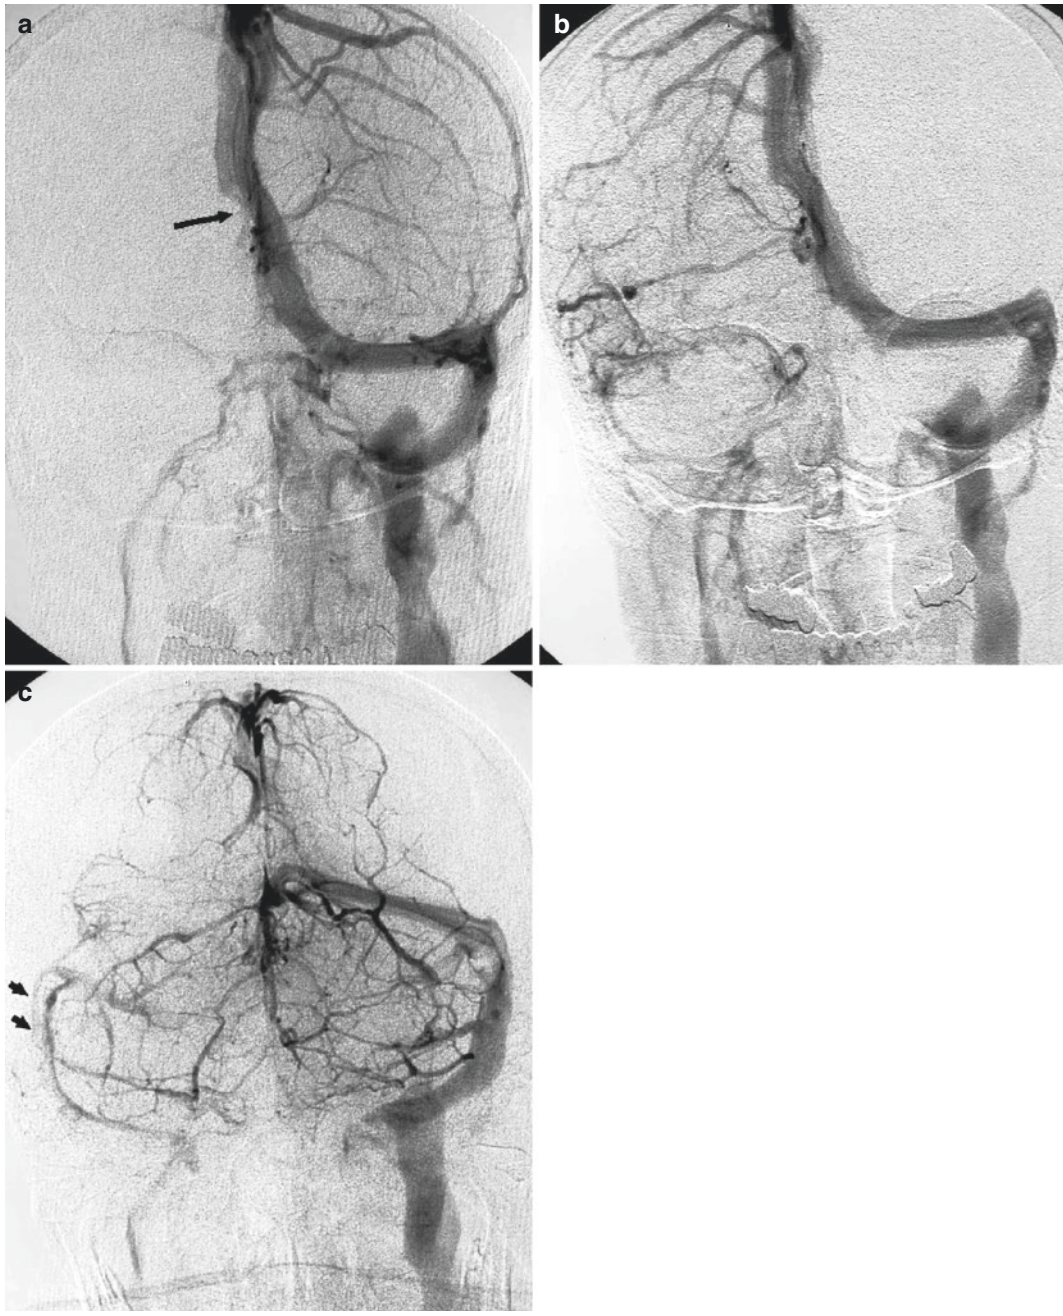

Fig. 20.4 Venous thrombosis involving the distal portion of the right segment of the duplicated SSS extending to the transverse sinus (TS). Old female patient with headache. The MRI study disclosed hyperintensity on T1-weighted images of the right TS. Angiography confirmed the suspected diagnosis of sinus thrombosis. (**a**, **b**) Left and right carotid angiogram, venous phase. There is no opacification of the distal right segment of the SSS (*arrow*) and right TS. Both internal cerebral veins are recognizable. They drain into the vein of Galen, continuing to the straight sinus well visible on the lateral angiogram (not demonstrated) entering the left TS. (**c**) Vertebral angiogram. The minimal laminar injection of the right TS (*arrows*) allows identification of the thrombus

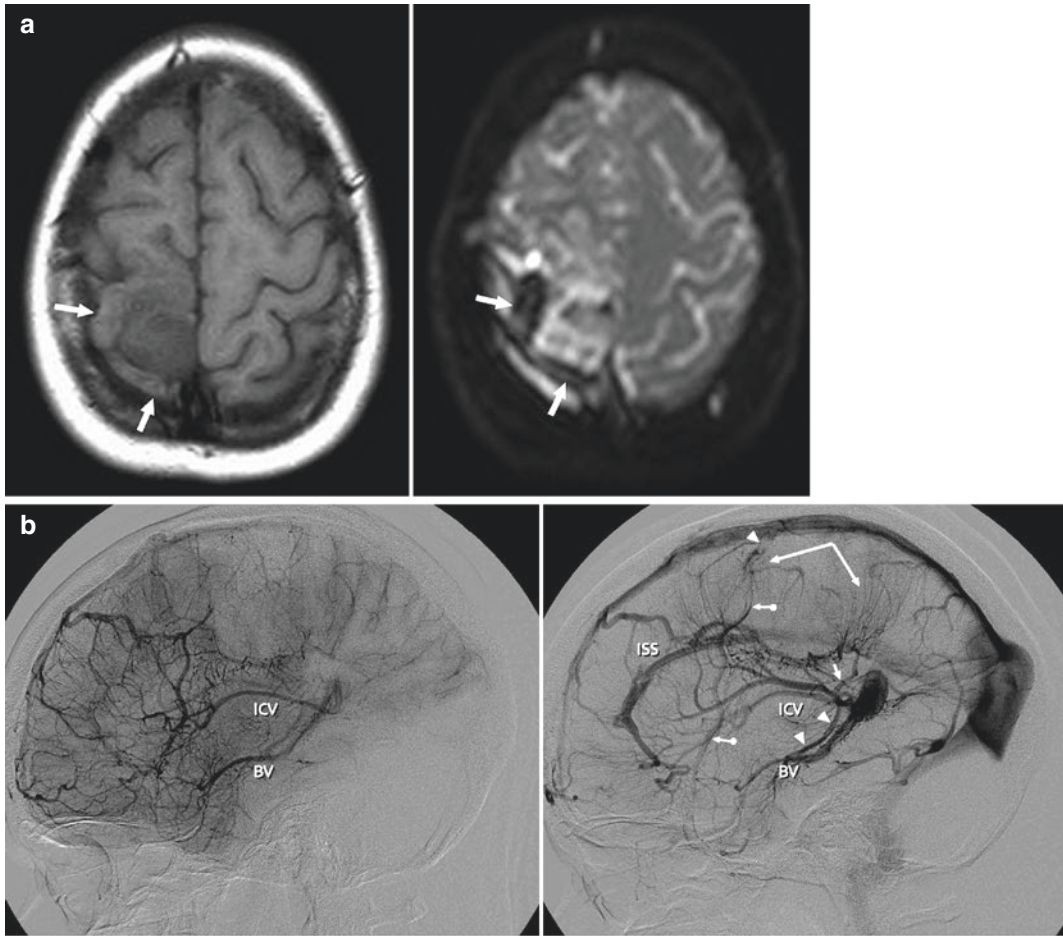

Fig. 20.5 Ischemia due to venous thrombosis occurring in a middle-aged patient with a congenital complex anomaly of the venous system. (**a**) MR performed a few days later. A large parietal vein is occluded by a thrombus appearing slightly hyperintense on the T1 image (*arrow*). The same is partially hypointense (*arrow*) on the T2* gradient-echo image. Ischemia in the surrounding area is present. (**b**) Lateral right ICA angiogram. Early and late phases. In the early phase, the venous drainage in the frontal area is recognizable occurring in the SSS, in the internal cerebral vein (ICV), and basal vein (BV). In the later phase appears the venous drainage in the parietal area, where the superficial veins are poorly filled. There is an anterior parietal vein occluded near the SSS (*arrowhead*) corresponding to that visible on the MR. Its drainage is diverted toward the SMCV (*arrow with dot*). The dilated medullary veins (*arrow with angle*) converge to dilated subependymal veins (*medial atrial*: *arrow*; *inferior ventricular*: *coupled arrowheads*) ending in the ICV and BV, respectively. The distal BV close to the Galen is dilated. The drainage continues in the straight sinus to which converges a dilated ISS. (**c**) AP view of the right ICA angiogram. Early and late phases. Aplasia of the right TS. Occlusion of the parietal vein (*arrowhead*). The dilated medullary veins converge to the medial atrial vein (*arrow*) and the basal vein (BV). (**d**) AP view of the left ICA confirming the aplasia of the right TS, absent also on the VA angiogram. Greatly dilated left TS

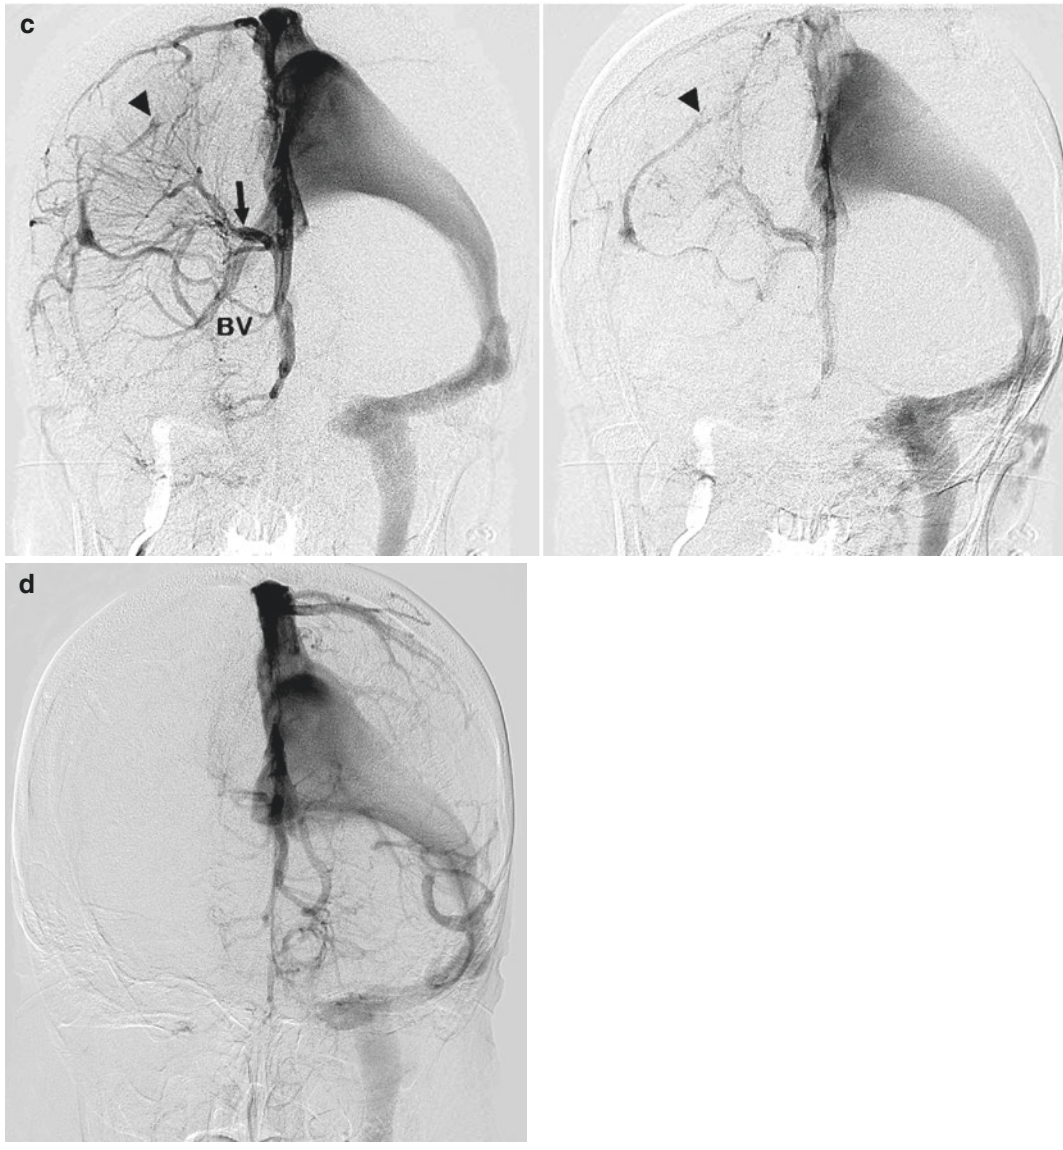

Fig. 20.5 (continued)

Association of Venous Sinus and IJV Stenosis and Some Clinical Pathological Conditions

21

The relationship between Idiopathic Intracranial Hypertension (IIH) and stenosis of the transverse sinus has already been described in the past (Johnston et al. 2002; Farb et al. 2003). Venous sinus stenting, as a possible method of therapy, has also been reported (Higgins et al. 2002; Tsumoto et al. 2003) and proposed again, recently, by Aguilar - Perez et al. 2017. This last author have treated with stenting 51 patients with IIH reporting in improvement or resolution of headache or papilledema in about 80% of the cases. This is certainly an interesting study which needs, however, further confirmation. More recently, the association of bilateral stenosis of transverse sinus and migraine has been emphasized by some authors (Bono et al. 2006; De Simone et al. 2012; Fofi et al. 2012). Other authors (Donnet et al. 2013) have reported a study in patients with a special type of headache provoked by several triggering factors such as cough, physical exertion, and sexual activity, well known as *a primary cough, exertional, and sexual activity headache* (Headache Classification 2004). In many of these patients examined with MR and MR venography, stenosis of TS, and/or IJV was detected. The authors discussed the possibility that headache could be due to a preexistent asymptomatic idiopathic intracranial hypertension which could be increased by cough or physical or sexual activity favored by the preexistent venous abnormalities.

The recognition of these venous abnormalities in the above-described pathological conditions is certainly an interesting aspect. Their causative effect, however, is still controversial and needs further studies for confirmation. In this context, the efficiency of a collateral outflow involving the condylar veins, the anterior epidural venous plexus, and the vertebral artery venous plexus should be examined (see also Sect. 9.3.8).

In another recent study some authors (Malekzadehlashkariani et al. 2016) in patients with idiopathic intracranial hypertension have demonstrated the presence of brain herniations within arachnoid granulations, and have discussed the possibility that these could lead to flow impairment in the sinus responsible of the clinical syndrome. However, it is not completely clear whether the brain herniations are the cause or the result of the intracranial hypertension or a simple incidental discovery. Indeed, it should be considered that brain herniations can be found in patients examined for different clinical reasons. Among them there are cases with secondary intracranial hypertension due to intracranial tumors, but also patients with nonspecific symptoms such headache, vertigo, cognitive disorders, epileptic seizures, and vascular pathologies, which raises doubts, at least in the majority of the cases, about the real clinical relevance of the herniations (see also Sect. 9.3).

We only mention here that similar venous abnormalities including stenosis or brain herniations have been described in patients with multiple sclerosis. Today, however, there is no scientific confirmation that these are responsible in the development of the disease.

Cerebral Hemorrhage

22

The cerebral hemorrhage can have different patterns involving the cerebral parenchyma, the ventricular system, or the subarachnoid space in varying combinations and at different locations. The presence of bleeding can be diagnosed using CT or MR. More difficult is the diagnosis of its pathogenesis. In many cases, the angiography can clearly show the cause of the hemorrhage, but in other cases it does not. As we have described previously (Chaps. 11, 12, 13, and 16) in cases of bleeding due to aneurysm, AVM, and DAVF, the malformation can easily be diagnosed with angiography. Angiography can also show the venous thrombosis responsible of the hemorrhagic ischemia. Hemorrhages occur in many cases of arteriopathies and arteritis described in Chap. 17. To this group belong also hemorrhages due to drug abuse such as sympathomimetic drugs, heroin, cocaine, LSD, as well as those linked to alcohol abuse. In all these cases the angiography shows nonspecific changes of the vessels characterized by narrowing, dilatations, and sometimes aneurysms involving commonly medium-sized arteries. The angiography, however, fails to demonstrate some vascular malformations such as the cavernous angioma and the telangiectasia. In spite of this the angiogram can be useful, excluding the presence of other vascular malformations such as an AVM. Also in some cases of SAH, the suspected aneurysm cannot be demonstrated. This uncommon condition has been discussed in Sect. 11.11.

Furthermore, there are other pathological conditions in which the cause of bleeding cannot be demonstrated on the angiogram. The most frequent in this group is the hemorrhage occurring in hypertensive commonly old patients reported to be more frequent in the Asian population. It involves typically the putamen and thalamus; more rarely the hemorrhage is lobar or located in the pons or cerebellum. In the latter the hemorrhage is commonly in the hemisphere and more rarely is located in the vermis. Depending on the site, the ventricular system or the subarachnoid space can be secondarily involved. Typically it is a monophase bleeding as opposed to rebleeding in case of aneurysm, AVM, or amyloid angiopathy. The etiopathogenesis has been thought to be the rupture of microaneurysms of deep or superficial perforators. Some authors, however (Challa et al. 1992) failed to demonstrate aneurysms on histological studies, interpreting the bleeding as due to the extensive atherosclerotic changes (lipohyalinosis) in the wall of the arteries, similar to that responsible of lacunar infarct (Sect. 15.4.5). Indeed, in these patients, the association of lacunar infarcts and old microhemorrhage is not rare, indicating probably that this specific pathology of the arteries can be the cause either of ischemia or of hemorrhage (see also Sects. 15.4.5 and 15.5.4). In elderly, hypertensive patients with typical location of the hemorrhage, the angiography is commonly not indicated.

G.B. Bradac, *Applied Cerebral Angiography*, DOI 10.1007/978-3-319-57228-4_22

A second less frequent cause is the cerebral amyloid angiopathy responsible of lobar hemorrhages in the elderly. The hemorrhages are frequently multiple, occurring typically in the posterior regions (parieto-occipital and temporo-occipital) (Massaro et al. 1991). The superficial location explains the frequent extension of the bleeding to the subarachnoid space. A few cases presenting only with a minimal subarachnoid bleeding involving the cerebral convexity have been reported (Apoil et al. 2013). The angiopathy is characterized by the deposition of amyloid material in the wall of the arteries, followed by destruction of the smooth muscle, dilatation of the artery, and formation of microaneurysms. The lobar location indicates an involvement of the superficial medullary arteries. In these patients, but also in some healthy old persons, small foci suggesting the presence of old and new microhemorrhages in the superficial white matter can be demonstrated on MRI studies using T2 gradient-echo or SWI sequences (Roobs et al. 1999; Greenberg et al. 1999, 2004). In these patients angiography is commonly not performed.

The risk of hemorrhage due to anticoagulant therapy usually in old cardiovascular patients is known. In these patients also subdural hematomas following minimal craniocerebral trauma can develop.

Finally, hemorrhage can be the first clinical manifestation of intracranial tumors linked to the rich vascularization and the presence of pathological altered vessels. Commonly this occurs in malignant primary or secondary lesions such as glioblastoma or metastasis of choriocarcinoma, melanoma, thyroid, renal, and lung carcinomas. Sometimes, also benign tumors such as meningiomas can present with bleeding (Bradac et al. 1990).

Vascular Pathology Involving the Intraorbital Vessels

23

The anatomical situation of the ophthalmic artery and ophthalmic veins and their connections with arterial and venous channels of the intracranial and craniofacial areas explain the frequent involvement of the ophthalmic artery and ophthalmic veins in vascular malformations located outside of the orbit.

In this chapter we summarize all these pathological conditions already presented in detail in the corresponding chapters. In addition we describe some specific pure intraorbital vascular malformations.

As far as it concerns the ophthalmic artery and its branches, they can be involved in DAVFs especially of the frontobasal area (Sect. 13.7) and in brain AVM such as in the Wyburn-Mason syndrome (Sect. 12.7.4), and can contribute to the supply of AVM of the craniofacial region (Sect. 3.9.1 and Fig. 3.19). Pure intraorbital AVMs are rare (Smoker et al. 2008). An example is presented in Fig. 23.5. Angiography is essential in the diagnosis of this pathology, and it is also useful in the differential diagnosis of other richly vascularized orbital tumors such as hemangiopericytoma, hemangioblastoma, and meningioma.

The most frequent and typical aneurysm involving the ophthalmic artery is the carotid-ophthalmic arising at the origin of the ophthalmic artery from ICA or close to it (Sect. 11.6.2.3). More distally located aneurysms are very rare. They can originate from the intracranial portion of the artery close to the optic canal (Yanaka et al. 2002) or be more distally intraorbitally located (Meyerson and Lazar 1971; Day 1990; Ogawa et al. 1992; Kikuchi and Kowada 1994; Ernemann et al. 2002; Dehdashi et al. 2002). Cases of fusiform, probably dissecting aneurysms extending through the optic canal, have also been described (Piche et al. 2005; Choi et al. 2008). Visual disturbances and SAH in cases of rupture of the intracranial segment are the typical symptoms.

The ophthalmic veins can be involved as a venous drainage in DAVFs involving directly or indirectly the cavernous and paracavernous sinuses (Sects. 13.7 and 13.8) and in direct carotid-cavernous sinus fistulae (Chap. 14). Craniofacial AVMs can drain in the ophthalmic veins.

A specific intraorbital malformation is the so-called orbital varix. This is characterized by a single dilated venous channel or by a network of small veins all draining commonly, but not always in the SOV (Smoker et al. 2008). It can intermittently fill and collapse leading to an acute temporary exophthalmos. The latter occurs in particular conditions such as lowering the head or following a cough or exertion activities. Hemorrhage and thrombosis can occur (Mafee 2003). The malformation can be associated with other intracranial venous anomalies. CT and/or MR without and with contrast medium in supine and prone positions or associated with Valsalva maneuver or jugular vein compression can clarify the diagnosis (Figs. 23.1 and 23.2). Commonly, the carotid angiogram fails to demonstrate the

G.B. Bradac, *Applied Cerebral Angiography*, DOI 10.1007/978-3-319-57228-4_23

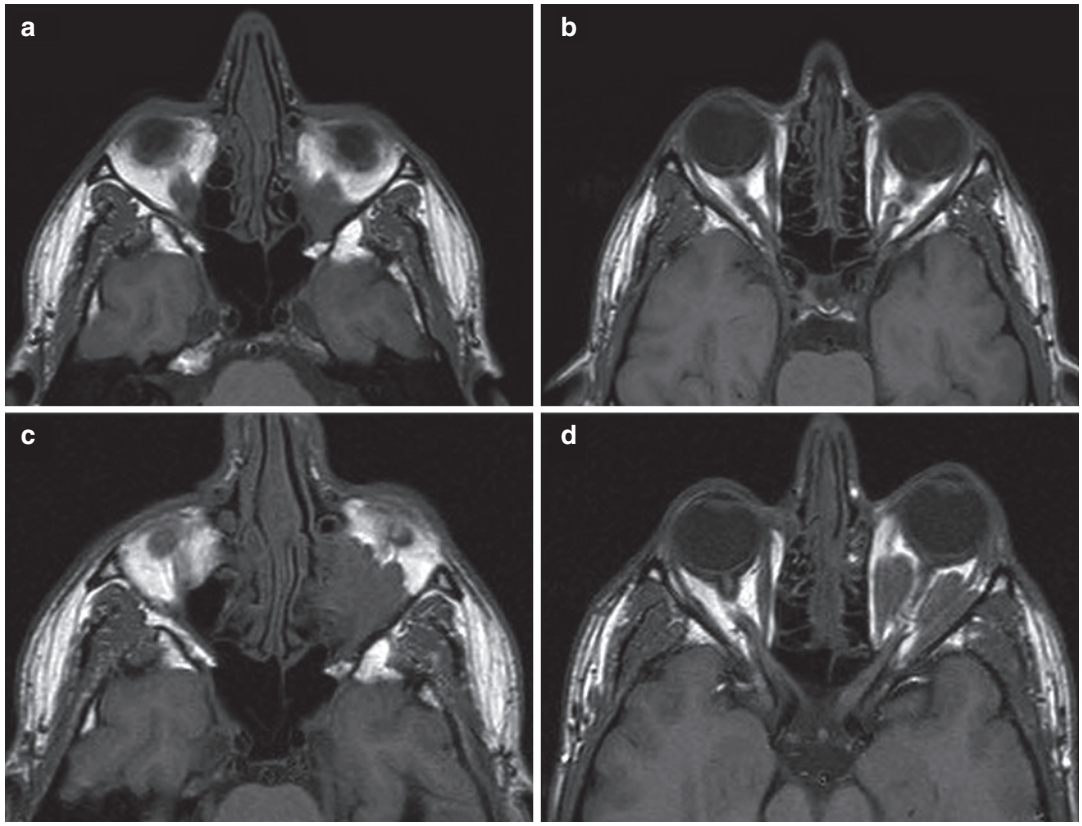

Fig. 23.1 Orbital varix. MR T1-weighted images. (**a**, **b**) Supine position. (**a**) Image near the floor of the orbita. (**b**) Image more cranial, at the level of the optic nerve. (**c**, **d**) Prone position. (**c**) Image near the floor of the orbita. (**d**) Image at the level of the optic nerve. The varix is already partially recognizable in the supine position. It becomes very large in the prone position

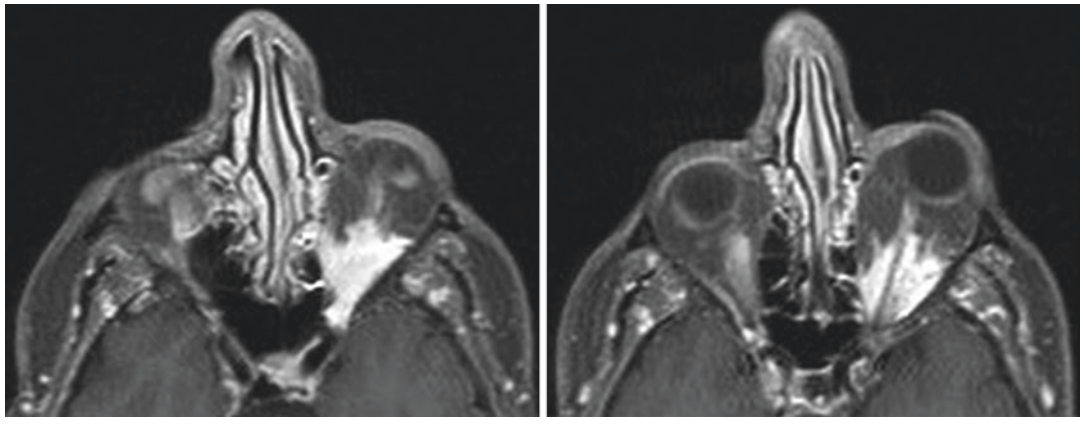

Fig. 23.2 Same patient as in Fig. 23.2. Enhancement of the varix after contrast medium in the prone position

malformation, which is sometimes visible when large connections with the intracranial venous system are present. Furthermore, the angiogram can show the presence of other associated intracranial venous malformations (Figs. 23.3 and 23.4).

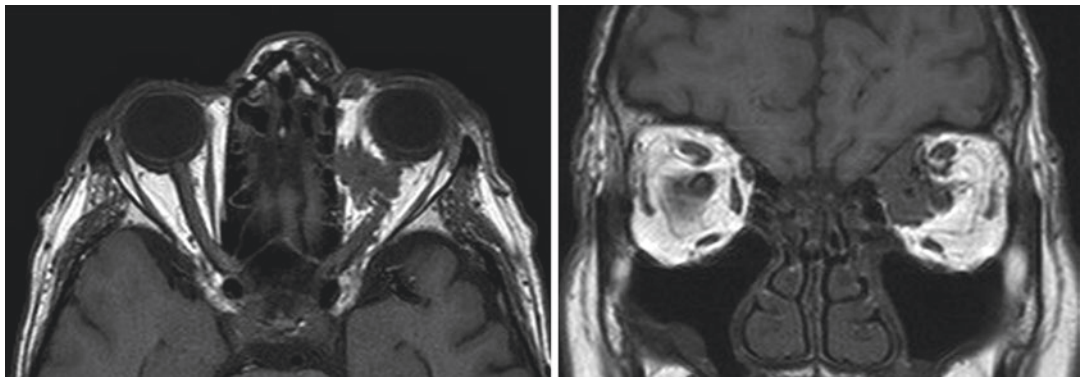

Fig. 23.3 Another case of orbital varix recognizable on MR T1-weighted images in the supine position. Axial and coronal studies. The medially located, predominantly intraconal lesion compresses the optic nerve

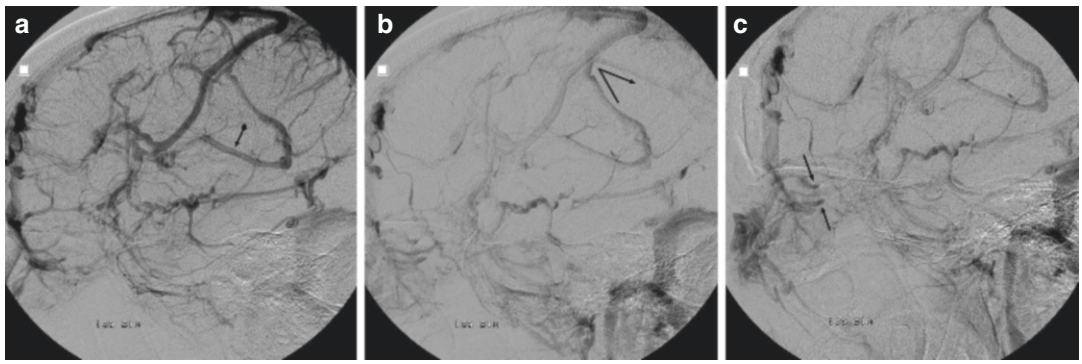

Fig. 23.4 Same patient of Fig. 23.3. Carotid angiogram, early and later phases (**a**, **b**). Complex intracranial venous anomaly. Several veins are dilated and a small varix is present. The straight sinus is absent. The enlarged internal cerebral vein (*arrow with dot*) drains into the Galen vein and further in an anomalous sinus, probably the falcine sinus (*arrow with angle*). Repeated angiogram to better study the orbita (**c**). The intraorbital dilated veins, partially filled, are recognizable (*arrows*). There are connections with the superior sagittal sinus. The varix drains in a large extraorbital pouch continuing in the facial vein (courtesy of Dr. Gozzoli and Dr. Boghi, Neuroradiology, Cuneo)

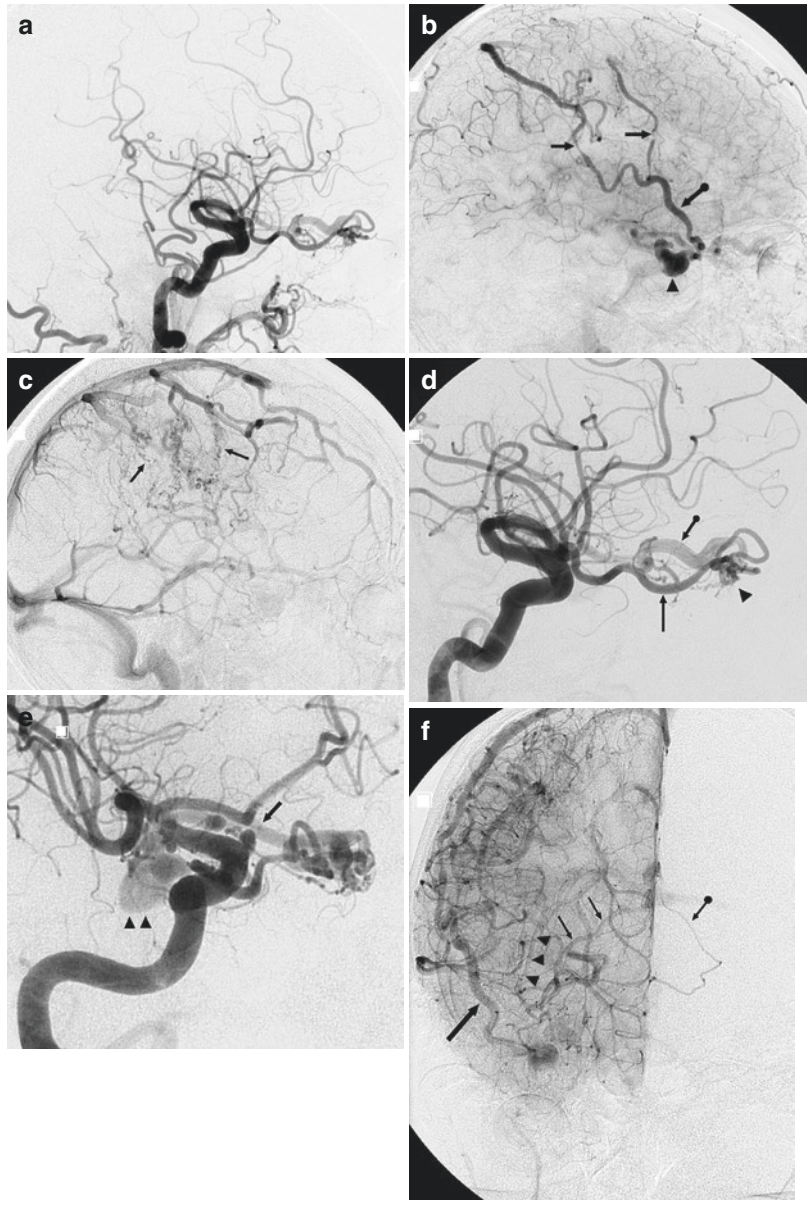

Fig. 23.5 Middle-aged man examined for acute transient left hemiparesis. The angiographic study showed an intraorbital arteriovenous angioma having an anomalous intracranial venous drainage. (**a**) Carotid angiogram. There is a dilated ophthalmic artery supplying a small AVM located in the anterior part of the orbita, draining in a dilated superior ophthalmic vein. (**b**, **c**) ICA angiogram, late phases. (**b**) The ophthalmic vein having passed the superior orbital fissure, is not connected with the cavernous sinus, instead it continues in a tortuous intracranial venous channel, ending in a temporo-basal venous pouch (*arrowhead*). This continues in the superficial middle cerebral vein (SMCV, *arrow with dot*) which drains further in parietal cortical veins ending in the SSS. Where the distal segment of the SMCV is connected with the parietal veins a narrowing is present (*arrows*). Partial thrombosis? (**c**) Appearing of a venous network indicating the venous congestion in the parietal area (*arrows*). (**d**) Lateral carotid angiogram. Magnification. Ophthalmic artery (*arrow*), small Nidus (*arrowhead*). Ophthalmic vein (*arrow with dot*). (**e**) Oblique view showing the dilated ophthalmic vein (*arrow*), reaching the temporo-basal venous pouch (*arrowhead*). (**f**) AP view, later phase, showing that in addition to the superficial middle cerebral vein (*arrow*), there is involvement of the deep middle cerebral veins (*arrowheads*) which are connected with the right basal vein (*arrows*). There is also a minimal injection of the left basal vein (*arrow with dot*). The patient recovered completely and 2 months later the AVM was occluded with glue after selective endovascular catheterization of the ophthalmic artery

sphenopalatine A., 46, 282
vidian (pterygoid A.), 45, 46
lingual artery, 36
occipital artery
anomalous origin, 40
branches, 40, 41
in DAVF, 249–257, 269–272, 275, 278, 289
in paraganglioma, 58
transosseous branches in DAVF, 253, 256
posterior auricular A., 41
superficial temporal A.
collateral circulation in ICA occlusion, 46
transverse facial A., 41, 47, 62
superior thyroid artery, 35, 36

F
Fibromuscular dysplasia (FMD)
and aneurysm, 168, 397
in dissection, 371, 398
and fistula, 297, 397
Flow-dependent (related) aneurysms, 221

H
Herophili (torcular), 129, 149, 151
Hyoid A., 19
Hypophyseal arteries, 15, 20
and aneurysms, 172

I
Infarcts
hemodynamic, territorial, lacunar, 304, 305
Inferolateral trunk (ILT), 15
in angiofibroma, 55
in DAVF, 265, 269, 271
Internal carotid artery (ICA)
aberrant course, 33

aplasia of ICA, 26
cavernous segment, 15
cervical segment, 11–13
clinoid segment, 13, 15
embryonic connection between ICA/vertebrobasilar, 28–33
lacerum segment, 13
petrous segment, 13–14
supraclinoid segment, 15
Intraorbital vessels, vascular pathology involving, 429–432

L
Leptomeningeal (pial) anastomosis, 365
Limbic arch in Galen vein malformation, 239
Lipohyalinosis, 305, 340, 358
Luxury perfusion syndrome, 364

M
Mandibular A., 13, 14
in angiofibroma, 55
connections with pterigo-vaginal A. and Vidian A., 13, 14, 63
Maxillary artery (primitive), 26
Medullary arteries, 77, 82, 91, 120, 125, 358, 365
Meningeal arteries
of ACA, 71
accessory meningeal A., 43
anterior artery of falx, 18
falx cerebelli A., 96
middle meningeal artery (MMA), 42
origin from ICA, 20
of PCA, 116
petrosquamous A., 42
posterior meningeal A., 97
recurrent meningeal A., 18
of SCA, 108
Meningohypophyseal trunk (MHT), 15–16
in angiofibroma, 55
in DAVF, 269, 271, 274
Middle cerebral artery (MCA)
accessory middle cerebral A., 89–91
aneurysms of perforators, 85, 400
dissecting aneurysm, 392
distal aneurysms, 186, 188
fenestration/duplication of M1, 89
microatheroma, 334
perforators of M1, 82
Migraine and stroke, 407
Moyamoya disease, 401
haemorrhage in Moyamoya, 403
pathology, pathogenesis, 401–402

N
Neurofibromatosis, 393, 395, 415

O
Occlusive diseases in children, 415–16
Odontoid arch, 39, 64, 96, 97
Ophthalmic A. (OA)
anomalous origin of OA, 16, 20, 22, 75
in DAVF, 282
embryogenesis, 19–20
ethmoidal arteries, 18
in meningioma, 61
Ophthalmic vein (superior-inferior), 158
carotid–cavernous fistulas, 297
in DAVF, 258–262, 293–296
embryogenesis, 163
Orbital varix, 429–431

P
PHACE, 52
Pituitary gland vascular supply, 20
Polyarteritis nodosa, 393, 394
Posterior cerebral artery (PCA)
aneurysms of PCA, 175
calcarine, parieto-occipital temporal A., 118
collicular A., 116
fetal, 1, 21, 115
microatheroma, 362
posterior medial/lateral choroidal A., 116–117
posterior thalamoperforating A., 116
relationship with AchA, 23–25
splenial A., 118
thalamogeniculate A., 117
Posterior communicating A. (PcomA)
aneurysms of, 175
anterior thalamoperforating A., 115
origin from ophthalmic A., 21
Posterior inferior cerebellar A. (PICA)
aneurysms, 189
dissecting aneurysms, 189
in occlusive disease, 358
perforators for medulla, 99–100
relationship with AICA segments, 100, 104
Primary angiitis of the CNS (PACNS), 406

R
Rektorzik venous plexus, 156
Rendu-Osler syndrome, 53, 237
Rete mirabile, 26, 28
Reversible cerebral vasoconstriction syndrome (RCVS), 404–5

S
Sinuses (venous)
cavernous sinus (CS), 157
and bridging veins with pontine veins, 157

Sinuses (venous) (*cont.*)
in carotid–cavernous fistula, 297
in DAVF, 255–263
falcine sinus, 130–151
in Galen vein malformation, 240
inferior petrosal sinus (IPS), 153–157
inferior petro-occipital sinus (inferior occipito-petrosal sinus) IOPV, 153–157
inferior sagittal sinus, 151
occipital sinus, marginal sinus, 152
in Galen vein malformation, 240
paracavernous sinus (PCS), 132, 154, 157
primary head sinus, 129
primary marginal sinus, 129
primitive tentorial sinus, 129
pro-otic sinus, 129
sigmoid sinus (SiSs), 153
spheno-parietal sinus, 157
straight sinus (SS), 129, 151
in Galen vein malformation, 240
superior ophthalmic vein (SOV), 158
superior petrosal sinus (SpS), 153
superior sagittal sinus (SSS), 149
transverse sinus (TS), 152
isolated transverse sinus in DAVF, 247
Sneddon's syndrome, 404
Stapedial artery (StA), 19
Stylomastoid A., 40
Subclavian steal syndrome, 342–343
Superior cerebellar A. (SCA), 105
duplicated, 107–108
marginal A., 106
meningeal A., 108 (*see also* Meningeal arteries)
origin from P1, 101, 105
perforators for midbrain, 108

T

Takayasu's arteritis, 403
Tympanic arteries
anterior tympanic (IMA), 41, 58
caroticotympanic artery (ICA), 13–14, 20, 33, 64
inferior tympanic (AphA), 38, 43, 60
posterior tympanic (stylomastoid A.), 40
superior tympanic (MMA), 42

V

Vascular malformations
arteriovenous malformations
aneurysms and AVM, 221–225
AV fistula, 226
AVM in children, 208, 209, 226
AVM treatment, 231, 232
cerebral proliferative angiopathy, 228–229
eloquent areas, 232
feeders, 209
flow-related aneurysms, 221
intranidal aneurysms, 221
nidus, 228–230
pathogenesis, 207–208
perinidal changes, 231
pseudoaneurysms, 218, 224
venous drainage of AVM, 226–228
venous pouch, 226
capillary malformations (telangiectasias), 233, 235
cavernous malformations (cavernomas), 232–233
in cavernous sinus, 233
familiarity, 232–233
pathology, 232
developmental venous anomaly (DVA), 235–237
Klippel–Trenaunay–Weber syndrome, 238
Rendu–Osler syndrome, 237
Sturge–Weber syndrome, 237
transition form of AVM (mixed AVM), 236–237
vein of Galen dilatation, 240, 244
vein of Galen malformation239–244
Vascular pathology, involving intraorbital vessels, 429–432
Veins
anterior cardinal vein, 129
anterior condylar confluence (ACC), 153–155
anterior, lateral, posterior condylar veins, 155–156
atrial veins, 135
basal vein, 136–138
basal vein and tributaries, 136–137
basal vein and variants, 137
basal vein in carotido-cavernous fistula, 297
basal vein in DAVF of tentorium and torcular, 269–281
basal vein in DAVS of CS, 263
choroidal veins, 136
deep cervical vein, 164, 302
deep middle cerebral vein (DMCV), 136–137, 154–155
diploic vein, 165
embryogenesis (veins), 129–130
emissary veins, 164–165
external jugular vein (EJV), 164
facial vein, 163
in fistula of VA, 302
Galen vein, 142
infratentorial cerebral veins
anterior medullary (AM) vein, 143
anterior pontomesencephalic vein (APM), 143
brachial veins, 145
cerebellar veins, 148
lateral medullo-pontine vein, 144
lateral mesencephalic vein, 145
peduncular vein, 143
petrosal vein, 148
posterior mesencephalic vein, 137–138
precentral vein (PC), 143
Vermian veins (superior-inferior), 143–145
internal cerebral vein (ICA), 136
internal jugular vein (IJV), 165
medullary veins, 134
occipital vein, 164
posterior auricular vein, 164
primitive maxillary vein, 163

prosencephalic vein, 129, 240
pterygoid venous plexus, 132, 154, 155, 157
retromandibular vein, 164
striate veins, 135–136
subependymal veins, 134–135
superficial middle cerebral vein (SMCV), 129, 132, 154, 157
superficial temporal vein, 164
thalamic veins, 136
uncal vein, 137, 154, 155
vein of corpus callosum, 132, 133
vein of Labbè, 132
vein of Trolard, 131
Venous sinus stenosis and headache, 425
Venous thrombosis
etiopathogenesis, 417
thrombosis of cortical vein, 418
thrombosis of deep venous system, 418
Vertebral artery (VA)
aneurysms of VA, 189
dissection of VA
extracranial, 372, 373
intracranial, 373
and spinal cord ischemia, 380
embryogenesis, 2–5
extracranial branches, 95, 96
falx cerebelli and posterior meningeal arteries, 96, 97
intracranial branches, 98–100
occlusive disease
intracranial microatheroma of VA, 346
occlusion, 342
perforators of VA, 98
posterior spinal artery (PSA), 100
unilateral origin of ASA, 100
variants of VA
anomalous origin, 110
duplication, 108
fenestration, 110
Vertebral artery (venous plexus), 153–156
Vertebral venous (anterior internal plexus), 156
Virchow–Robin spaces, 77

W
Willis (circle of), 4, 5, 364
variants, 365
Wyburn–Mason syndrome, 238
